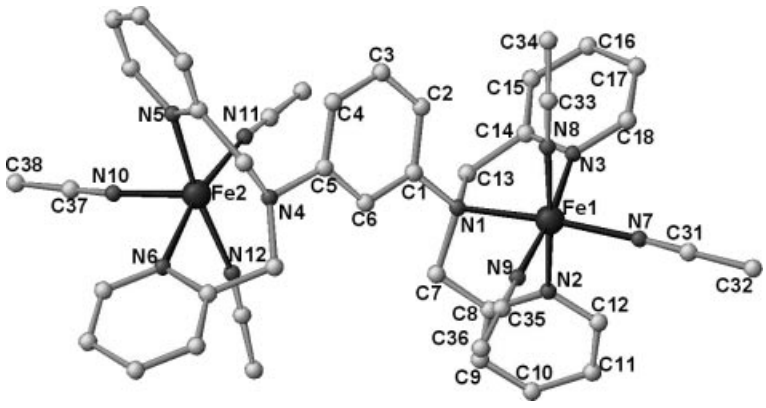

Figure 4. Molecular structure of the cation of $[Fe_2(1,3\text{-tpbd})(CH_3CN)_6](ClO_4)_4 \cdot 2CH_3CN \cdot 0.5H_2O$ (**1**); hydrogen atoms and solvent molecules are omitted for clarity.

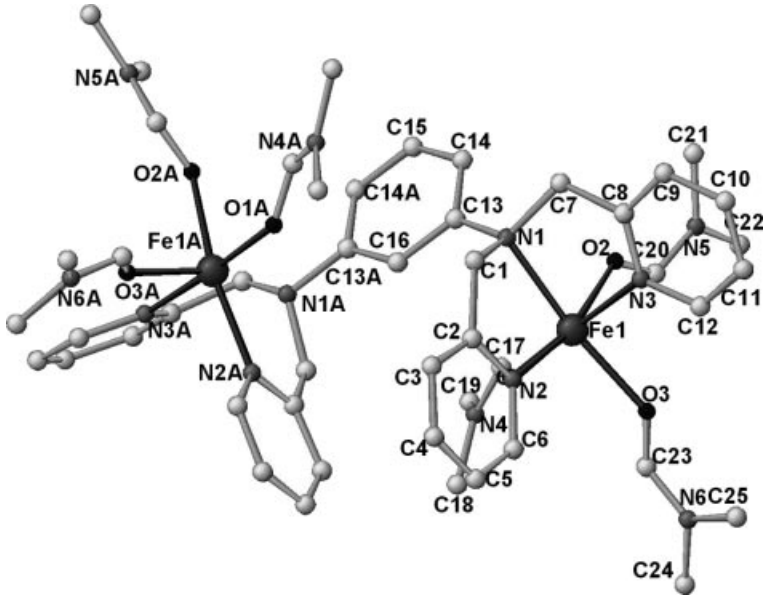

Figure 5. Molecular structure of the cation of $[Fe_2(1,3\text{-tpbd})(DMF)_6](ClO_4)_4$ (**2**); hydrogen atoms are omitted for clarity.

those found in **1**. The Fe–$O_{DMF}$ distances [2.075(2) to 2.112(2) Å] and the average *cis*-coordinated angles [O–Fe–O 92.58°] indicate that the DMF molecules are strongly coordinated to the iron(II) center. The Fe···Fe separation of 6.962 Å is shorter than in **1**, probably a consequence of the stronger π···π interaction (ca. 3.596 Å) between the two pyridine rings (C2–C3–C4–C5–C6–N2 and C2A–C3A–C4A–C5A–C6A–N2A) each from a different tridentate end of the 1,3-tpbd molecule.

Both iron(II) complexes were found to only react slowly with dioxygen, however much faster with hydrogen peroxide. Preliminary kinetic studies of both oxidation reactions indicated complex reaction mechanisms that could not be elucidated. Most likely this is a consequence that 1,3-tpbd is not an innocent ligand and is also involved in the oxidation reactions (see below). Furthermore, efforts to isolate reaction products from these oxidations, such as the according iron(III) complexes described above, were unsuccessful. In contrast with 1,4-tpbd as a ligand only polymeric iron(II) complexes were obtained.[19] With *N*,*N*-bis(2-pyridylmethyl)-aniline (phdpa), the half ligand system of 1,3-tpbd, a 2:1 ligand/metal ion ratio was observed, however, no crystal structures were reported.[20]

**Nickel Complexes:** Reacting $[Ni(DMF)_6](ClO_4)_2$ with 1,3-tpbd under anaerobic conditions in a glove box led to the nickel(II) analogue of **2**, $[Ni_2(1,3\text{-tpbd})(DMF)_6](ClO_4)_4$ (**3**). Crystals suitable for X-ray crystallography were grown and isolated. Compound **3** crystallizes with nearly identical cell parameters as **2** (Table 2), but the structure of **3** is much better described in the monoclinic space group *C*2 (**3**) than *C*2/*c* (**2**). Accordingly, the systematic absences for the glide plane in *C*2/*c* for **3** are not observed, whereas for **2** these systematic absence conditions are fulfilled absolutely so that the structure of **2** is described correctly in *C*2/*c*. However, a description of the structure of **3** in *C*2/*c* is possible but leads to a significant increase of the $R_1$ value from 10 to 16%. Therefore; even if it can be assumed from the cell parameters that **2** and **3** are isostructural, the crystal structure of **3** here is presented in the lower symmetric space group *C*2. A Figure of the molecular structure of the cation of **3** as

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

well as crystal structure data and refinement parameters, bond lengths and angles are presented in the Supporting Information.

The asymmetric unit of complex **3** comprises two crystallographically independent "half" cation units and four $ClO_4^-$ anions, of which three are disordered. The full contents of the unit cell is generated by applying symmetry operations to the asymmetric unit cell. As the structure of **3** is very similar to that of **2** and the calculations might be performed as well in the centrosymmetric space group *C*2/*c* the final absolute structure parameter is relatively high. The two crystallographically independent $[Ni_2(1,3\text{-tpbd})(DMF)_6]^{2+}$ cations of **3** differ only marginally with regard to their bond lengths and angles.

**Zinc Complexes:** In investigating redox-active metal complexes of iron and copper it is useful to study in comparison complexes with nonredox active centers such as zinc. Copper(II) ions can be substituted by zinc(II) ions and additionally show quite similar coordination behavior. Such zinc(II) complexes themselves can show interesting reaction properties, for example they can be used to hydrolyze diribonucleoside monophosphate diesters.[29] However, in contrast to our expectations the synthesis of a zinc(II) complex of 1,3-tpbd turned out to be more difficult than the synthesis of the according copper(II) complexes. Mixing zinc(II) perchlorate and 1,3-tpbd in alcoholic solution, immediately led to white gelatinous-like precipitates that could not be (re)crystallized. Only after a large number of experiments (applying different conditions), we obtained crystals of the zinc(II) complex $[Zn_2(1,3\text{-tpbd})(CH_3CN)_2(SO_3CF_3)_2(H_2O)](SO_3CF_3)_2$ (**4**) with triflate as a counter anion. The molecular structure of the cation of **4** in Figure 6 shows an unsymmetric di-zinc unit, both ions linked by the *m*-phenylenediamine group and a triflate ion giving an intramolecular Zn···Zn distance of 6.007(1) Å, which is much shorter than in those complexes that are only bridged by 1,3-tpbd. However, it is close to the Cu···Cu distance [5.873(1) Å] in the analogous complex $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3](ClO_4)$ with an additional perchlorate- in-

stead of the triflate-bridge (crystal structure data and refinement parameters, selected bond lengths and angles are presented in Table 3 and Table 1).[1]

The coordination geometry around Zn1 is best described as distorted octahedral. The equatorial plane around the zinc(II) center is occupied by three N-donor atoms of the meridional capping ligand 1,3-tpbd (N1, N2 and N3). Apical positions are occupied by O12 of the bridging triflate anion and O1 of a water molecule. The nature of the ligands around Zn2 differs from Zn1 in that a terminal triflate, instead of a water molecule, occupies one of the apical coordination sites. The $N_{pyridine}$–Zn–$N_{pyridine}$ bond angles of 156.1(2)° and 152.3(2)° in **4** are smaller than $N_{pyridine}$–Cu–$N_{pyridine}$ in $[Cu_2(1,3\text{-tpbd})(H_2O)_2](ClO_4)_4\cdot 4H_2O$ [164.5(2)°] apparently owing to the bigger steric hindrance of the triflate ion. Accordingly, both distances of Zn–$N_{pyridine}$ in the range of 2.021(5)–2.046(5) Å and Zn–$N_{amine}$ at 2.350(5) and 2.346(4) Å are longer than those in $[Cu_2(1,3\text{-tpbd})(H_2O)_2](ClO_4)_4\cdot 4H_2O$ [av. Cu–$N_{pyridine}$ 1.969(5) Å; Cu–$N_{amine}$ 2.089(5) Å]. This also applies for the distance of the acetonitrile substituent [Zn–$N_{C\equiv N}$ av. 2.091(5) Å] instead of water [Cu–$O_w$ 1.985(5) Å] at the fourth equatorial site. A triflate anion bridges the two zinc(II) centers via O11 and O12 [Zn1–O12 2.242(4) Å and Zn2–O11 2.122(4) Å]. The structure is "capped" at the apical positions by a water molecule [Zn1–O1 2.243(5) Å] for Zn1 and by a terminal triflate anion [Zn2–O21 2.578(4) Å]. To the best of our knowledge there is only one further example of a crystal structure containing a bridging triflate anion linking two zinc(II) ions found in the Cambridge Crystallographic Database.[30] Efforts to obtain crystals of the (1,3-tpbd)copper(II) triflate analogue failed so far. Furthermore, using 1,4-tpbd as a ligand only a mononuclear zinc complex, $[ZnCl_2(1,4\text{-tpbd})]$, was obtained and its crystal structure has been reported.[19]

In contrast to the according copper(II) complexes, complex **4** is diamagnetic and can be studied in solution by $^1H$ NMR spectroscopy. Four types of pyridine proton resonances are found in the range 7.4–8.6 ppm (see Exp. Sect.). These four proton resonances represent four symmetry equivalent sets of the pyridine protons found in the complex. Two triplets and two doublets are formed by the splitting of each pyridine proton by its adjacent proton(s). The splitting scheme is depicted in Figure 7. $H_a$ is split into a doublet by $H_b$ ($J$ = 5 Hz), and $H_d$ is split into a doublet by $H_c$ ($J$ = 8 Hz). Proton $H_a$ is assigned to the downfield doublet, and $H_d$ as the upfield doublet. $H_b$ is split by both $H_a$ ($J$ = 6 Hz) and $H_c$ ($J$ = 7 Hz) to form a triplet, and $H_c$ is split by both $H_b$ ($J$ = 7 Hz) and $H_d$ ($J$ = 8 Hz) to form a triplet. $H_c$ is assigned to the downfield triplet, and $H_b$ is assigned to the upfield triplet. The assignments of $H_c$ and $H_b$ are based on greater stabilisation of electron withdrawal in the *para* position, compared to the *meta* position, and previous assignments of pyridine protons in related compounds.[31]

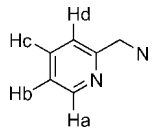

Figure 7. NMR assignment in complex **1**, **2** and **4**.

**Heterodinuclear Zinc(II) and Copper(II) Complexes:** After achieving the synthesis of a zinc(II) complex as well as the previously reported copper(I) and copper(II) complexes with the ligand 1,3-tpbd, it was obvious that we should try to prepare a heterodinuclear zinc(II) copper(II) complex as a model complex for the enzyme superoxide dismutase (CuZnSOD).[32–38] However, mixing stoichiometric amounts of 1,3-tpbd together with zinc(II) and copper(II) chloride did not lead to the isolation of pure $[CuZn(1,3\text{-tpbd})Cl_4]$, but instead to a mixture of the three dinuclear complexes: $[Zn_2(1,3\text{-tpbd})Cl_4]$ (**5**), $[Cu_2(1,3\text{-tpbd})Cl_4]$ (**6**) and $[CuZn(1,3\text{-tpbd})Cl_4]$ (**7**). Structural characterization of all three complexes was achieved by picking individual crystals (that were different in color) from the reaction mixture. The molecular structure of **5** is shown in Figure 8 and that of **7** in Figure 9 (crystal structure data and refinement parameters, bond lengths and angles are presented in Table 3 and Table 1).

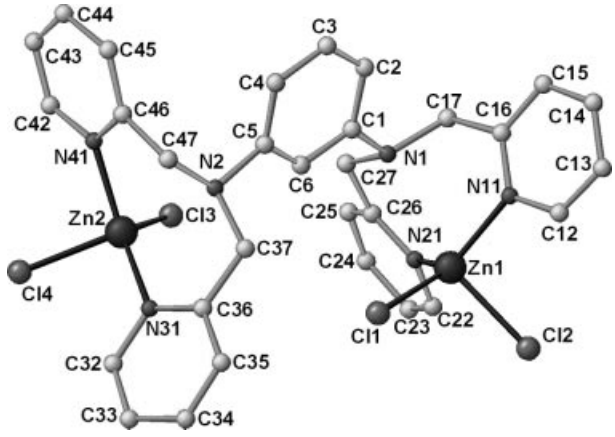

Figure 8. Molecular structure of $[Zn_2(1,3\text{-tpbd})Cl_4]$ (**5**); hydrogen atoms are omitted for clarity.

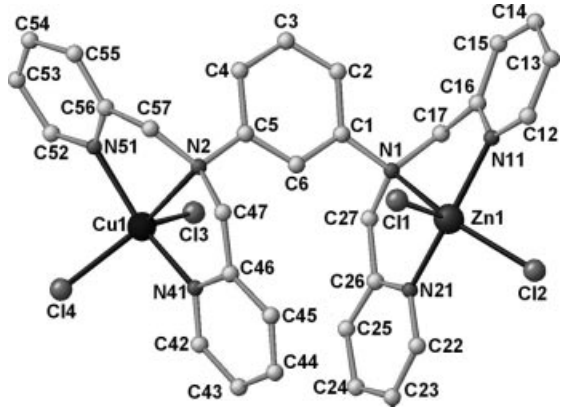

Figure 9. Molecular Structure of $[CuZn(1,3\text{-tpbd})Cl_4]$ (**7**); hydrogen atoms are omitted for clarity.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The crystal structure of $[Cu_2(1,3\text{-tpbd})Cl_4]$ (**6**) has been obtained previously in a different study and crystallographic details will be published elsewhere.[13] Due to the fact that here X-ray crystallography measurements do not allow the differentiation between zinc and copper ions, the presence of the different metal ions was further confirmed by photon-induced X-ray emission spectroscopy of the crystals of **5**, **6** and **7**.

The metal ions are linked through the 1,3-phenylenediamine group leading to an intramolecular Zn···Zn distance of 6.925 Å for **5** and Cu···Zn separation of 6.849 Å for **7**, both of them shorter than the Cu···Cu distance of 7.434 Å for **6**. In **5**, the zinc(II) ions are pentacoordinate by three nitrogen atoms of the 1,3-tpbd ligand and two chloride ions, with the following distances: Zn1–Cl1 2.248(2), Zn1–Cl2 2.305(2), average Zn1–$N_{pyridine}$ 2.050(6) and Zn1–$N_{amine}$ 2.646(2) Å. Considering such weak $N_{amine}$ ligation to zinc(II) ions, the coordination geometry around Zn1 and Zn2 can be described as distorted trigonal bipyramidal. The axial positions of the coordination sphere around Zn1 are occupied by N1 and Cl2 and the equatorial plane of the $ZnN_3Cl_2$ unit comprises N11, N22 and Cl1 with Zn1 lying out of the basal plane by 0.2956 Å. Compared to the mononuclear zinc(II) 1,4-tpbd complex with Zn–$N_{pyridine}$ average distance 2.14(1) Å and Zn–$N_{amine}$ 2.26(1) Å, where the Zn–$N_{pyridine}$ distance is significantly longer and the Zn–$N_{amine}$ distance is significantly shorter than in **5**.[19] In **7**, both coordination geometries around the copper(II) and zinc(II) centers are close to trigonal bipyramidal with N41 and N51 occupying the axial positions around Cu1 and N11 and N21 occupying the axial positions of Zn1. Similar to complex **5**, the three nitrogen atoms of one tridendate end of the 1,3-tpbd ligand and the metal center to which they are coordinated are almost coplanar, with Cu–$N_{pyridine}$ average distance 2.054(2) and Cu–$N_{amine}$ 2.499(2) Å, Zn–$N_{pyridine}$ average distance 2.034(2) and Zn–$N_{amine}$ 2.370(2) Å. The Cu–Cl distances are very close to each other [2.279(3) and 2.284(3) Å], likewise for the Zn–Cl bonds [2.307(4) and 2.333(3) Å]. The Zn–$N_{pyridine}$ and Cu–$N_{pyridine}$ distances are in accordance to those determined for related mononuclear analogues, in contrast the Zn–$N_{amine}$ and Cu–$N_{amine}$ distances in the mononuclear complexes of 2.142(2) Å and 2.207(6) Å are significantly shorter.[39,40] However, these complexes are complexes with a different ligand to metal cation ratio (one metal ion and two coordinated bispicolylamine ligands) at the amine nitrogen atom and the hydrogen atom is not substituted by an organic group.

**"Zinc-Ion-Assisted" Formation of a Dinuclear Copper Complex:** During our efforts to prepare model complexes for CuZnSOD described above, we observed a very surprising reaction behavior when stoichiometric mixtures of copper(II) and zinc(II) perchlorate salts were mixed with 1,3-tpbd. Instead of obtaining the heterodinuclear complex, we isolated a new dinuclear copper(II) complex, $[Cu_2(1,3\text{-tpbd})_2(H_2O)_2](ClO_4)_4$ (**8**), in which two copper(II) ions had reacted with two 1,3-tpbd ligand units. The molecular structure of the cation of complex **8** is shown in Figure 10 (crystal structure data and refinement parameters, bond lengths and angles are presented in Table 3 and Table 1).

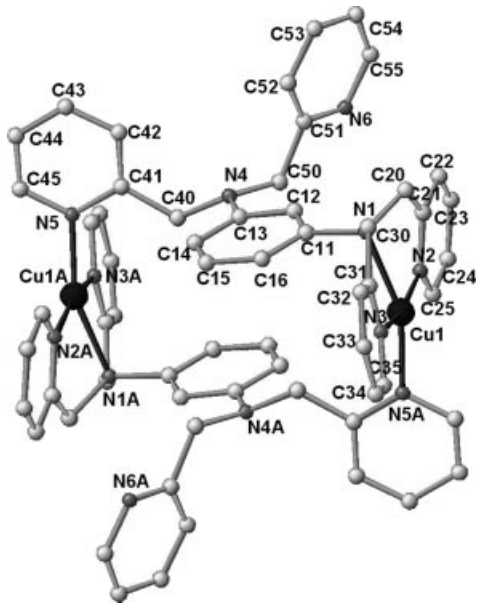

Figure 10. Molecular structure of the cation of $[Cu_2(1,3\text{-tpbd})_2(H_2O)_2](ClO_4)_4$ (**8**); water molecules and hydrogen atoms are omitted for clarity.

Complex **8** is a so called "dimetallocyclophane" and it is interesting to compare its structure with the dinuclear complex, $[Cu_2L'_2(H_2O)_2](ClO_4)_4{\cdot}2H_2O$, obtained previously from an impurity that was formed during the synthesis of 1,3-tpbd.[1] The "impurity" L′ is a derivative of the 1,3-tpbd ligand, missing one pyridyl "arm" (derived from incomplete formation of 1,3-tpbd during synthesis). A schematic presentation of the complex with the "impurity" as ligand in comparison with **8** is shown in Figure 11.

Complex **8** likewise crystallizes with an inversion center located in the middle of the "dimetallocyclophane" core. However, the metal coordination sphere is quite different to that of $[Cu_2L'_2(H_2O)_2](ClO_4)_4{\cdot}2H_2O$. The copper(II) ions in **8** exhibit a "4+1" square-based pyramidal geometry with three nitrogen atoms (N1, N2 and N3) from one tridentate end of 1,3-tpbd in the meridional form, and the pyridine (N5A) from the symmetry-related ligand completing the basal plane, while a water molecule (O1) occupies the apical site. In **8** the tertiary amine (N4A) from the symmetry-related ligand is not bound to the copper(II) center with a long distance of 4.472 Å, while the corresponding nitrogen (N2) as a secondary amine is coordinated to the copper(II) center with a bond length of 2.071(2) Å in the corresponding $[Cu_2L'_2(H_2O)_2](ClO_4)_4{\cdot}2H_2O$ complex.

The two pyridyl "arms" from the same tertiary amine are *trans* to one another [N2–Cu1–N3 164.8(2)°], [Cu1–N2 1.986(3), Cu1–N3 1.976(3) Å]. However, the corresponding two pyridyl nitrogen atoms in $[Cu_2L'_2(H_2O)_2](ClO_4)_4{\cdot}2H_2O$ are *cis*-coordinated to copper(II) with a N11–Cu1–N12 angle of 86.2(5)°. In complex **8**, all the Cu–$N_{pyridine}$ lengths are in general slightly shorter than the *trans* Cu–$N1_{amine}$ [2.074(3) Å]. The steric influence of the non-coordinated

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

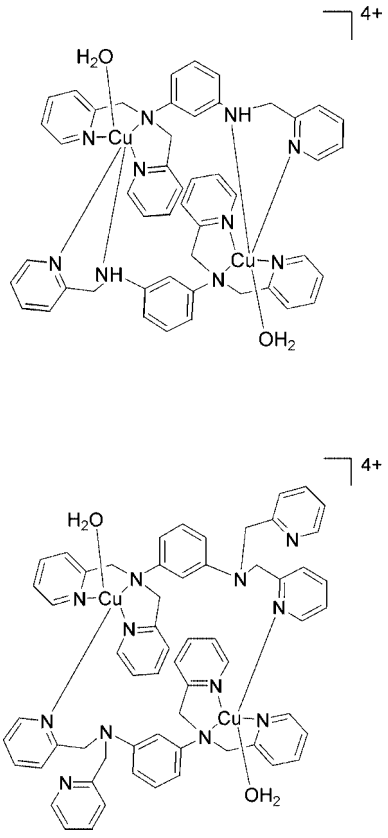

Figure 11. Schematic representation of the complex with the "impurity"L′ as ligand (top) in comparison to **8** (bottom).

pyridine ring results in the different coordination geometry and an intramolecular distance of Cu···Cu [8.820(1) Å] which is 1.3 Å longer than that of $[Cu_2L'_2(H_2O)_2](ClO_4)_4 \cdot 2H_2O$.

The finding that **8** forms despite the presence of zinc(II) ions is extremely surprising due to the results described above that zinc(II) can substitute copper(II) ions perfectly well in complexes of the ligand 1,3-tpbd. Furthermore, **8** can also be prepared if only a small amount (e.g. 5%) of zinc(II) ions are present. This result clearly suggests that zinc(II) ions should not be necessarily present and that it should be possible to synthesize **8** by mixing copper(II) perchlorate and 1,3-tpbd in a one to one stoichiometric ratio (Figure 12) because the reaction in a stoichiometric ratio of one (1,3-tpbd) to two $Cu(ClO_4)_2$ affords the dinuclear copper(II) complex $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3](ClO_4)$ that has been structurally characterized previously.[1]

However, in contrast a series of experiments showed that **8** cannot be prepared under aerobic conditions without the presence of zinc(II) ions. For example a mixture of 1,3-tpbd and one equivalent of copper(II) perchlorate in methanol/$H_2O$, acetonitrile or DMF exposed to air caused the effect that the green solutions rapidly started to turn to a deep-red color within a day.

Such a phenomenon has precedence with other related *m*-phenylendiamine derivatives where radical reactions were observed during oxidation reactions.[41–43] A possible mechanism (shown in Figure 13) can be postulated according to these previous findings (most likely an oxygen atom

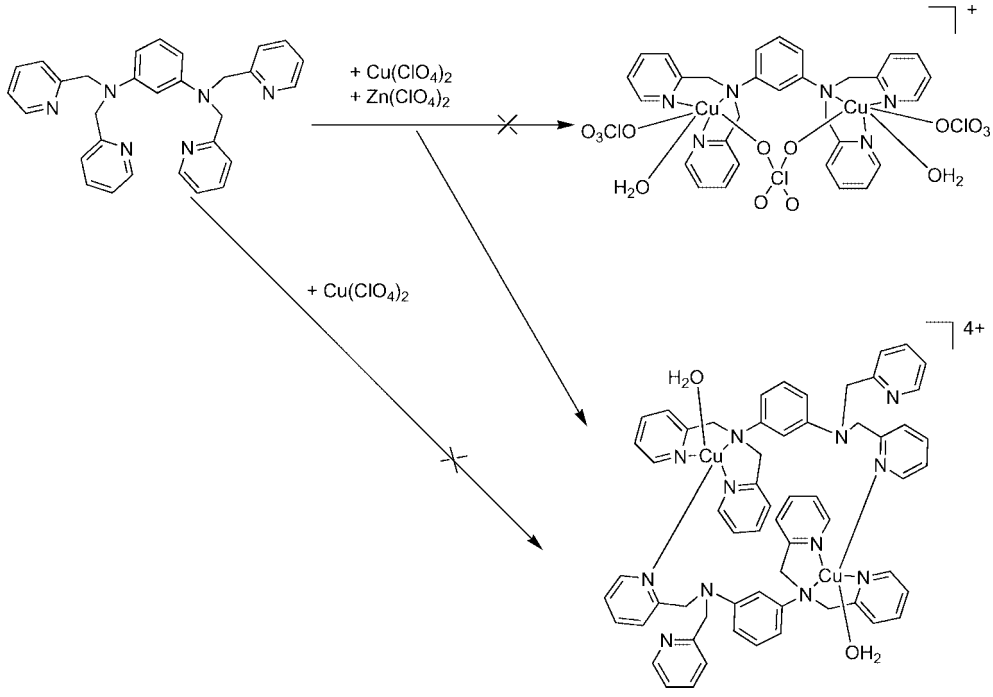

Figure 12. Scheme of reactions observed during the "zinc-assisted" formation of **8**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

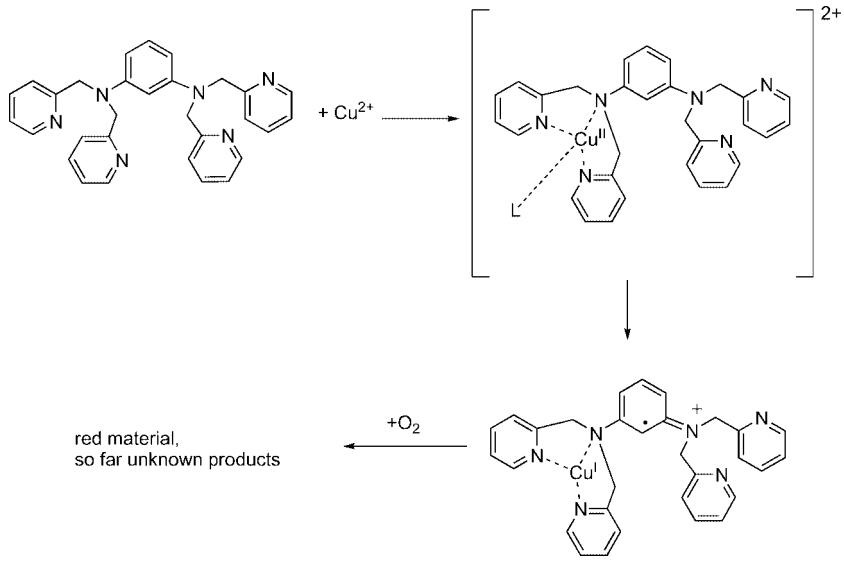

Figure 13. Possible reaction scheme for the formation of an oxidation product of 1,3-tpbd.

reacts with the benzene ring of the 1,3-tpbd ligand).[42] Unfortunately, all our efforts to identify this "red" material in order to ascertain whether 1,3-tpbd has been modified have been unsuccessful (only oily dark red reaction mixture products could be obtained so far).

However, this part of the postulated mechanism of ligand oxidation could readily explain the zinc(II) assisted crystallization of **8**. If enough copper(II) ions are present the formation of the radical intermediate shown in Figure 13 will be suppressed because both coordination sites are blocked with the copper(II) ions and dinuclear copper(II) complexes such as $[Cu_2(1,3\text{-tpbd})(H_2O)_2(ClO_4)_3]$-$ClO_4$ can be easily prepared.

If nonredox-active zinc(II) ions are present they will (as outlined above) coordinate to 1,3-tpbd as well. Most likely – and not for an obvious reason – they seem to prefer coordination only to one of the ligand sites as observed previously with the 1,4-tpbd derivative as ligand (see above), where even the crystal structure of this 1:1 complex was reported.[19] Then, the other coordination site will be filled with a copper(II) ion and in a consecutive reaction the zinc(II) ion will now be substituted by a copper(II) ion already coordinated to another 1,3-tpbd ligand molecule. Thus the zinc(II) ion will be liberated and can again interact with a different 1,3-tpbd ligand molecule [which would also explain why stoichiometric amounts of zinc(II) ions are not necessary]. Once complex **8** is formed, radical oxidations are again suppressed, and therefore allow the facile synthesis and isolation of complex **8**.

In our efforts to get a better understanding of the assumed ligand-oxidation processes we also reinvestigated the oxidation of the dinuclear 1,3-tpbd copper(I) complex with dioxygen described previously.[1] In the past this reaction has been studied in methanol, a solvent less suitable for stabilizing reactive intermediates such as copper "dioxygen adduct" complexes.[1] In our current experiments using more suitable solvents such as acetone we observed spectral changes that indicate the formation of a peroxido copper complex (even at ambient temperature), however, so far all efforts to isolate or to characterize this species in a pure form were unsuccessful.

As a complimentary means to obtain insights into the structure and energetics of possible dioxygen adduct complexes we performed quantum chemical calculations at the B3LYP/TZVP level of density functional theory. We optimized the structures of three isomers, i.e. the ($\eta^2$:$\eta^2$)-peroxido, the bis-μ-oxido, and the *trans*-($\eta^1$:$\eta^1$)-peroxido species. These calculations corroborate the interpretation of a side-on-bound ($\eta^2$:$\eta^2$)-peroxido species as the most stable complex formed. According to the quantum chemical results, the bis-μ-oxido species is 3.2 kcal/mol less stable, followed by the *trans*-peroxido species, which is 12.1 kcal/mol less stable than the side-on-bound peroxido isomer. Key parameters of the optimized structures are shown in Figure 14.

So far our efforts to isolate and characterize the final oxidation product(s) have been unsuccessful. A possible product that could arise from an intramolecular ligand hydroxylation similar to oxidation reactions observed previously for related systems[11] would lead to a phenol ligand shown in Figure 1 (R = H). Therefore we synthesized a derivative of this ligand (R = $CH_3$) from 2,6-diamino-*p*-cresol dihydrochloride[44] and 2-chloromethylpyridine hydrochloride. The copper(II) complex was obtained easily when copper(II) perchlorate was mixed with the ligand and crystals suitable for crystallographic characterization could be isolated. The crystal structure of $[Cu_2(2,6\text{-tpcd})(H_2O)(Cl)]$-$(ClO_4)_2 \cdot 2H_2O$ (**9**) is shown in Figure 15 (crystal structure data and refinement parameters, bond lengths and angles are presented in Table 3 and Table 1). The coordinated chloride ion is a consequence of the usage of the protonated ligand (isolation as the hydrochloride salt). The H atoms of water solvent molecules were derived from a difference Fou-

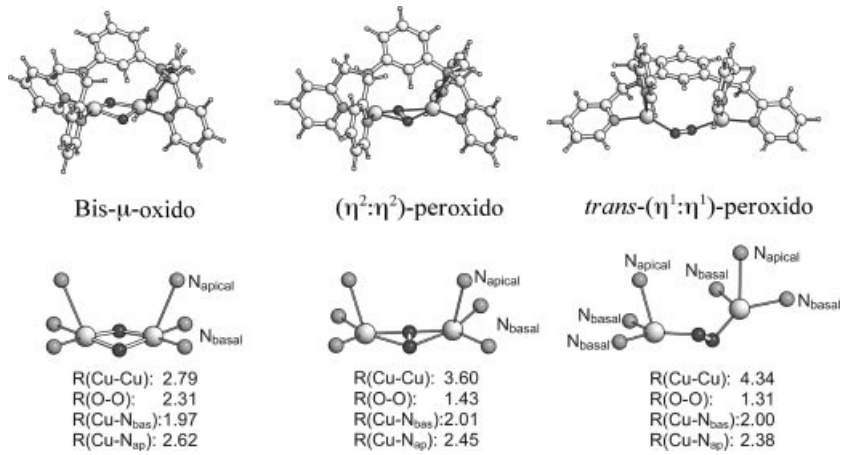

Figure 14. Calculated structures of the dioxygen copper adduct complex of 1,3-tpbd.

rier map and isotropically refined. **9** crystallizes with one coordinated and two additional water solvent molecules per unit.

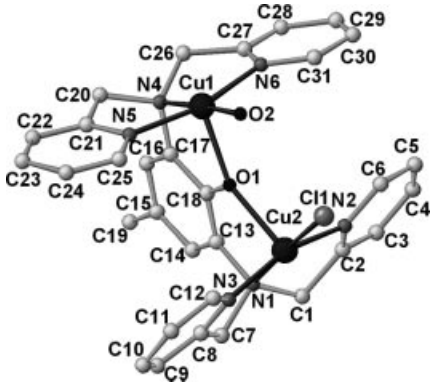

Figure 15. Molecular structure of the cation of $[Cu_2(2,6\text{-tpcd})(H_2O)(Cl)](ClO_4)_2$ (**9**).

In **9** both copper(II) ions are "4+1" coordinated forming a distorted square-pyramidal geometry. The basal plane consists of two pyridine nitrogen atoms (N2 and N3), the amine nitrogen N1 and the chloride anion Cl1 while the apical plane consists of the phenol oxygen atom O1. The distance between both copper(II) ions is 4.027 Å. Interestingly the distance Cu1–O1 with 2.153(1) Å is slightly longer than the corresponding distance Cu2–O1 [2.106(2) Å].

Parallel to our work, Karlin and co-workers investigated the reactivity of a dinuclear copper(I) complex with a nearly identical ligand (PD′OH) (Figure 1, R = *tert*-butyl). Besides selective DNA interactions of this complex[15] they furthermore reported in that regard a very interesting hydroxylation reaction of nitriles to aldehyde and cyanide during oxidation. A hydroperoxido complex has been postulated as reactive species in these reactions.[16]

## Conclusions

1,3-tpbd is a versatile ligand that can be used successfully to coordinate two metal ions in close proximity. While the nickel complex shows normal coordination behavior, redox active metal centers such as iron or copper ions demonstrate that 1,3-tpbd is a non-innocent ligand. Interestingly 1,3-tpbd does not coordinate iron(III) ions, instead protonation of the ligand is preferred. Oxidations of iron(II) complexes or copper(I) complexes of 1,3-tpbd led to reaction product mixtures that could not be characterized so far. Theoretical calculations support the formation of a dinuclear side-on peroxido copper complex during the reaction of the copper(I) complex with dioxygen. Intramolecular ligand hydroxylation might occur during the oxidation reaction, however, could not be proved experimentally. The possible reaction product, a phenolate-bridged derivative of the 1,3-tpbd complex could be synthesized in an independent way. Most interestingly is the reaction if only one equivalent of copper(II) salt is reacted with one equivalent of 1,3-tbpd. Under aerobic conditions a red product was formed after a short while, suggesting ligand oxidation. However, this reaction could be suppressed completely in the presence of zinc ions. Here $[Cu_2(1,3\text{-tpbd})_2(H_2O)_2](ClO_4)_4$ a so called "dimetallocyclophane" formed.

## Experimental Section

**General Remarks:** All chemicals were purchased from commercial sources and used as received.

***CAUTION!*** *The perchlorate salts used in this study are potentially explosive and should be handled with care.*

**Physical Measurements:** Elemental analyses were carried out with a Carlo Erba 1106 using a Mettler Toledo UMX-2. NMR spectra were recorded with a 400 MHz Bruker-Aspect 2000/3000. IR spectra were recorded with a Bruker Optics IFS25.

**Ligand Synthesis:** The ligand *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)-benzene-1,3-diamine (1,3-tpbd) was synthesized according to litera-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ture procedures.[1] Slow evaporation of a methanol solution of 1,3-tpbd in a glove box afforded single crystals suitable for X-ray diffraction studies.

**2,6-Bis[bis(2-pyridylmethyl)amino]-*p*-cresol (2,6-tpcd):** A solution of sodium hydroxide (4.18 g, 0.1050 mol) in water (30 mL) was added dropwise with stirring to a mixture of 2,6-diamino-*p*-cresole·2HCl[44] (2 g, 0.0095 mol) and 2-(chloromethyl)pyridine hydrochloride (7.82 g, 0.0475 mol) in 5 mL $H_2O$ under inert conditions. The crude product was recrystallized several times from acetone and 0.5 g (0.001 mol) 10.5% 2,6-tpcd were obtained. $^1$H NMR ($CDCl_3$/TMS, 400 MHz): $\delta$ = 8.48 (m, 4 H, pyr-$H_a$), 7.48 (m, 4 H, pyr-$H_c$), 7.45 (m, 8 H, pyr-$H_b$/$H_d$), 7.39 (s, 2 H, Ar-H), 4.75 (s, 8 H, –$CH_2$–), 2.15 (s, 3 H, -$CH_3$) ppm.

**$[H_4(1,3\text{-tpbd})_2](ClO_4)_4\cdot(CH_3CN)_3$:** A solution of iron(III) perchlorate hydrate (141.7 mg, 0.4 mmol) in water (3 mL) was added to a solution of 1,3-tpbd (95.2 mg, 0.2 mmol) in $CH_3OH$ (7 mL). The reaction mixture (a brown suspension) was stirred for 1 h at room temperature and filtered. The precipitate was dissolved in $CH_3CN$ (5 mL) and allowed to stand at room temperature for 2 d affording yellow block-shaped crystals suitable for X-ray diffraction analysis. $C_{66}H_{69}Cl_4N_{15}O_{16}$(1470.16): calcd. C 53.92, H 4.73, N 14.29; found C 53.78, H 4.94, N 14.51.

**$[H_4(1,3\text{-tpbd})_2](SO_3CF_3)_4$:** The complex was obtained in a similar way as for the perchlorate salt described above, however, for this compound no analytical data were collected. The crystal structure and data are reported in the Supporting Information.

**Synthesis of Complexes**

**$[Fe_2(1,3\text{-tpbd})(CH_3CN)_6](ClO_4)_4\cdot(CH_3CN)_2\cdot(H_2O)_{0.5}$ (1) and $[Fe_2(1,3\text{-tpbd})(DMF)_6](ClO_4)_4$ (2):** Complexes **1** and **2** were synthesized by the same procedure in a glove box differing only by the different solvents used. $Fe(ClO_4)_2\cdot H_2O$ (101.9 mg; 0.4 mmol) and 1,3-tpbd (95.2 mg, 0.2 mmol) were dissolved in 10 mL of $CH_3CN$ or DMF. The resulting clear, light-brown solution was stirred for 30 min at room temperature followed by vapor diffusion with diethyl ether (20 mL) at –11 °C. Nearly colorless square crystals of **1** and light yellow plate crystals of **2** suitable for X-ray diffraction analysis were grown after three weeks. Yield: 161 mg (0.12 mmol, 61%) for **1** and 159 mg (0.11 mmol, 56%) for **2**. $C_{46}H_{53}Cl_4Fe_2N_{14}O_{16.50}$ (1319.52) (**1**): calcd. C 41.87, H 4.05, N 14.86; found C 41.74, H 3.99, N 14.69. $C_{24}H_{35}Cl_2FeN_6O_{11}$ (710.33)(**2**): calcd. C 40.58, H 4.97, N 11.83; found C 40.65, H 4.84, N 11.87. $^1$H NMR ($CD_3CN$, 400 MHz): for **1**: $\delta$ = 9.78 (d, $J_{HH}$ = 1.9 Hz, 4 H, pyr-$H_a$), 8.97 (t, $^3J_{HH}$ = 7.7 Hz, 4 H, pyr-$H_c$), 8.55 (t, $^3J_{HH}$ = 5.5 Hz, 4 H, pyr-$H_b$), 8.49 (d, $J_{HH}$ = 7.4 Hz, 4 H, pyr-$H_d$), 8.07 (t, $^3J_{HH}$ = 14.6 Hz, 1 H, Ar-H), 7.32 (s, 1 H, Ar-H), 7.26 (dd, $J_{HH}$ = 6.99 Hz, 2 H, Ar-H), 6.00 (s, 8 H, –$CH_2$–) ppm; ($CD_3CN$, 400 MHz) for **2**: $\delta$ = 8.40 (d, 4 H, pyr-Ha), 8.00 (s, 1 H, DMF-H), 7.59 (t, 4 H, pyr-Hc), 7.05–7.16 (t/d, 8 H, pyr-Hb/–Hd), 6.70 (t, 1 H, Ar-H), 5.85–5.97 (s/d, 3 H, Ar-H), 4.61 (s, 8 H, –$CH_2$–), 2.71–2.87 (s, 36 H, DMF-$CH_3$) ppm.

**$[Ni_2(1,3\text{-tpbd})(DMF)_6](ClO_4)_4$ (3):** Similar to the above procedure for **1** and **2**, this complex was synthesized by adding a solution of $[Ni(DMF)_6](ClO_4)_2$[45] in DMF to a solution of 1,3-tpbd in DMF under the inert conditions of a glove box. Crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of diethyl ether into the solution. $C_{48}H_{70}Cl_4N_{12}Ni_2O_{22}$ (1426.38): calcd. C 40.42, H 4.95, N 11.78; found C 39.77, H 4.48, N 11.60. UV/Vis (DMF): $\lambda_{max}$ = 612, 774, 937 nm. The crystal structure and data are reported in the Supporting Information.

**$[Zn_2(1,3\text{-tpbd})(CH_3CN)_2(SO_3CF_3)_2(H_2O)](SO_3CF_3)_2$ (4):** Zinc triflate (154 mg, 0.42 mmol) was added to a solution of 1,3-tpbd (100 mg, 0.21 mmol) in acetonitrile under an inert atmosphere. The solution was allowed to stir at room temperature for a further 2 h. The solvent was removed in vacuo and dichloromethane (5 mL) was added to the residual oil. Diethyl ether (20 mL) was added until the solution was slightly turbid. The vessel was placed in the freezer compartment of a fridge and within 3 d, large transparent blocks of 4 formed. IR (Nujol mull): $\tilde{\nu}$ 3631 (w), 3629 (w), 3627 (w), 3549 (w), 3434 (w), 3245 (m), 3120 (m), 2972 (s), 2948 (s), 2885 (s), 2845 (s), 2726 (m), 2676 (m), 2416 (w), 2394 (w), 2317 (m), 2288 (m), 2211 (w), 2038 (w), 1923 (w), 1610 (m), 1582 (m), 1456 (s), 1376 (s), 1287 (s), 1246 (s), 1167 (s), 1105 (m), 1031 (s), 957 (m), 901 (m), 850 (m), 817 (m), 774 (m), 726 (m), 696 (m), 634 (m), 574 (m), 544 (m), 517 (m), 472 (w) cm$^{-1}$. $^1$H NMR ($CD_3CN$, 300 MHz): $\delta$ = 8.60 (d, $^3J_{HH}$ = 4.9 Hz, 4 H, pyr-$H_a$), 8.10 (t, $^3J_{HH}$ = 7.5 Hz, 4 H, pyr-$H_c$), 7.63 (t, $J_{HH}$ = 6.0 Hz, 4 H, pyr-Hb), 7.44 (d, $^3J_{HH}$ = 7.9 Hz, 4 H, pyr-$H_d$), 6.90 (t, $^3J_{HH}$ = 8.3 Hz, 1 H, Ar-H), 6.33 (dd, $^3J_{HH}$ = 1.9 Hz, 1 H, 8.7 Hz, Ar-H), 5.96 (s, 1 H, Ar-H), 4.60 (s, 8 H, –$CH_2$–).

**$[Zn_2(1,3\text{-tpbd})Cl_4]\cdot H_2O$ (5), $[Cu_2(1,3\text{-tpbd})Cl_4]$ (6), $[CuZn(1,3\text{-tpbd})Cl_4]$ (7):** Slow evaporation of an aqueous methanolic solution of a stoichiometric mixture of $ZnCl_2$, $CuCl_2$ and 1,3-tpbd led to a mixture of yellow and two different green-colored crystals suitable for X-ray diffraction analysis.

**$[Cu_2(1,3\text{-tpbd})_2(H_2O)_2]\cdot(ClO_4)_4\cdot 2H_2O$ (8):** A methanolic suspension of 1,3-tpbd (95.2 mg, 0.2 mmol) was added to an aqueous methanol solution of $Cu(ClO_4)_2\cdot 6H_2O$ (64.1 mg, 0.2 mmol) and $Zn(ClO_4)_2\cdot 6H_2O$ (74.4 mg, 0.2 mmol). The mixture was stirred for 2 h, filtered and allowed to slowly evaporate at room temperature. Large green blocks formed within 48 h. A single-crystal X-ray diffraction analysis was performed and the structure of the green crystals was determined to be $[Cu_2(1,3\text{-tpbd})(OH_2)_2](ClO_4)_4$. That no zinc ions were present at all was further confirmed by photon-induced X-ray emission.

**$[Cu_2(2,6\text{-tpcd})(H_2O)(Cl)](ClO_4)_2\cdot 2H_2O$ (9):** A suspension of 2,6-tpcd (100 mg, 0.2 mmol) in 5 mL methanol was added to a solution of $Cu(ClO_4)_2\cdot 6\ H_2O$ (148.2 mg, 0.4 mmol) in 5 mL $H_2O$. The mixture was stirred for 30 min at room temperature and allowed to slowly evaporate at room temperature. Within two days small green needles of **9** suitable for X-ray diffraction analysis were formed.

**Computational Methods:** Density functional calculations have been performed employing the B3LYP functional[46–49] as implemented in the Turbomole program.[50–52] The TZVP basis set has been employed for all atoms.[53] Solvent effects have partially been included in these calculations employing the COSMO continuum solvent model (dielectric constant for acetone at room temperature: $\varepsilon$ = 36.64).[54]

**X-ray Crystallographic Studies:** X-ray crystallographic data for 1,3-tpbd were collected with a STOE IPDS-diffractometer at 193 K equipped with a low-temperature system (Karlsruher Glastechnisches Werk). Cell parameters were refined by using up to 5000 reflections. A sphere of data (210 frames) was collected with the $\varphi$ oscillation mode (0.9° frame width; Irradiation times/frame: 7 min.) No absorption corrections were applied. The structures were solved by direct methods in SHELXS97, and refined by using full-matrix least-squares in SHELXL97.[55] The hydrogen atoms were positioned geometrically and all non-hydrogen atoms were refined anisotropically, if not mentioned otherwise. All following data were corrected for Lorentz and polarization effects. Intensity data of **1** were collected with a Bruker-Nonius KappaCCD diffractometer, intensity data for **4** and **8** were collected with a Siemens P4 four circle diffractometer. Absorption effects were corrected either by semi-empirical methods based on multiple scans (**1**)[56] or on the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

basis of Psi-scans.[57] The structures were solved by direct methods; full-matrix least-squares refinement was carried out on $F^2$ using SHELXTL NT 6.12.[58] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were geometrically positioned except for the hydrogen atoms of the water molecules or aqua ligands the positions of which were derived from a difference Fourier synthesis; their isotropic displacement parameters were tied to those of their corresponding carrier atoms by a factor of 1.2 or 1.5. One of the perchlorate anions of **1** is disordered; two preferred orientations were refined resulting in occupancy factors of 50.1(6) and 49.9(6) %. In **8** both of the two independent perchlorate anions are subjected to disorder. Two preferred orientations refined led to occupancy factors of 72(2) and 28(2)% around Cl1 and 61(2) and 39(2) % around Cl2, respectively.

Intensity data of protonated tpbd, **2**, **3** and **9** were collected with a Siemens SMART CCD 1000 diffractometer by the $\omega$-scan technique collecting a full sphere of data with irradiation times of 10 to 20 s per frame and $\Delta\omega$ ranges between 0.3° and 0.45°. The collected reflections were corrected for absorption effects.[56] All structures were solved by direct methods and refined by least-squares techniques using the SHELX97 programme package.[55] The hydrogen atoms were positioned geometrically and all non-hydrogen atoms were refined anisotropically, if not mentioned otherwise. Further data collection parameters are summarised in Tables 2, 3 and in the Supporting Information.

Intensity data of of **5** and **7** were collected with a Nonius MACH3 diffractometer. Cell parameters were obtained and refined from 25 reflections. Absorption corrections (psi-scans) were applied. The space groups were determined from systematic absences and subsequent least-squares refinement. The structures were solved by direct methods. The parameters were refined with all data by full-matrix-least-squares on $F^2$ using SHELXL-97.[55] Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were fixed in idealized positions using a riding model. Scattering factors were taken from the literature.[59] Figures of the molecular structures were obtained using Winray.[61]

CCDC-610594 (for 1,3-tpbd), -610424 (for $[1,3\text{-tpbdH}_2](ClO_4)_2$), -615270 (for **1**), -610425 (for **2**), -610426 (for $[1,3\text{-tpbdH}_2](CF_3SO_3)_2$), -610427 (for **3**), -615271 (for **4**), -611033 (for **5**), -611034 (for **7**), -615272 (for **8**) and -610428 (for **9**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Crystallographic data and selected bond lenghts and angles of $[H_2]1,3\text{-tpbd}](SO_3CF_3)_2$ and **3**.

# Thermal Behavior of Tetrahydropyran-Intercalated $VOPO_4$: Structural and Dynamics Study

**Klára Melánová,[a] Ludvík Beneš,*[a] Vítězslav Zima,[a] Eva Černošková,[a] Jiří Brus,[b] Martina Urbanová,[b] Miroslava Trchová,[b] and Jiří Dybal[b]**

**Keywords:** Intercalations / NMR spectroscopy / IR spectroscopy / Thermal behavior / Quantum chemical calculations

The thermal behavior of tetrahydropyran-(THP-)intercalated $VOPO_4$ was probed by an extensive combination of experimental methods (XRD, DSC, FTIR, solid-state NMR) and quantum chemical calculations. Two temperature-induced transitions were detected and all polymorphs exhibit a high degree of molecular order and tight packing of THP in $VOPO_4$. The first reversible thermal transition at around 100 °C was attributed to boat/chair conformation changes of the THP molecules. Most probably, a low-temperature boat conformation of the guest molecules present in the interlayer space of $VOPO_4$ changes to a high-temperature chair conformation. This rearrangement of the THP molecules was confirmed by variable-temperature $^{13}C$ CP/MAS NMR spectroscopy. Quantum chemical calculations using a B3LYP functional and 6-31G(d) basis set also support this idea. The second change at around 140 °C is probably caused by a weakening of the donor–acceptor bond between the oxygen molecule of THP and the vanadium atom of the host and the formation of a disorder in packing of the THP molecules.

## Introduction

Vanadyl phosphate belongs to phosphates with a layered structure. The layers are formed of a tetragonal grid in which atoms of vanadium and phosphorus alternate. The atoms of vanadium and phosphorus are connected by oxygen atoms ($O_{host}$) of the phosphate groups.[1,2]

Thus, every vanadium atom is surrounded by four equatorial oxygen atoms. In addition, two oxygen atoms are bonded to the vanadium atoms forming a $VO_6$ octahedron. One of these two vanadium–oxygen bonds is shorter indicating the presence of a V=O bond, while the other is much longer and can be ascribed to the coordination of the oxygen atom from the V=O group of an adjacent $(VOPO_4)_\infty$ layer. The interlayer interactions are therefore accomplished by V=O···V bonds in anhydrous $VOPO_4$. In the vanadyl phosphate intercalates, the sixth position in the $VO_6$ octahedron is complemented by a donor atom of a guest molecule, which is then in a *trans* position to the oxygen atom of the V=O bond. Vanadyl phosphate forms a number of intercalation compounds with molecular guests having Lewis base character, among others also with ether oxygen as a donor atom.[3] Recently, tetrahydrofuran,[4,5] tetrahydropyran (THP),[5] 1,4-dioxane, 1,3,5-trioxane, and 18-crown-6[6] were intercalated into vanadyl phosphate. It is presumed that the guests are coordinated to the vanadium atoms of the host layer through the free electron pairs of the donor O atoms of the guests. These intercalates are generally very stable in air and the guest molecules are released at relatively high temperatures (for example the tetrahydrofuran intercalate decomposes at about 160 °C[5]). This indicates that the host–guest interaction is very strong.

Recently, we studied the thermal behavior of tetrahydropyran-intercalated $VOPO_4$. This intercalate was prepared by replacing 1-propanol in the $VOPO_4{\cdot}2C_3H_7OH$ intercalate with the THP. The lattice parameters of the tetragonal structure are $a$ = 6.201(2) Å and $c$ = 12.014(2) Å and the intercalate contains one THP molecule per formula unit. The probable arrangement of the THP molecules in the host interlayer space is derived from molecular simulations with the Cerius[2] 4.5 programme. The molecular simulations showed a bilayer arrangement of the THP molecules in the interlayer space, in which the guest layers are slightly overlapping.[5]

The thermal behavior of THP intercalated vanadyl phosphate was monitored by powder X-ray diffraction and TG-DTA. The basal spacing slightly increases up to 85 °C. At this temperature, a new phase with the basal spacing 12.8 Å appears. This effect is fully reversible during cooling. Another weak increase of the basal spacing up to 122 °C is followed by a significant increase of the basal spacing between 122–140 °C, which is accompanied by a broadening of the (00*l*) diffraction lines. At higher temperatures, the intensity of the (00*l*) diffraction lines decreases due to slow

decomposition of the intercalate. The *a* parameter of the tetragonal lattice does not change up to 158 °C. The color of the intercalate does not change up to 122 °C at which point it changes to yellow-green. This indicates gradual reduction of vanadium(V).

As follows from the TG measurement, thermal decomposition of the intercalate starts at 140 °C, and THP is slowly released up to 600 °C. There are two endothermic effects on the DTA curve which occur at the temperatures (78 and 126 °C) when the step changes of the basal spacing are observed. No weight loss accompanies these effects. The exothermic effects at higher temperatures are probably due to the combustion of the released compounds.

The question is, what is the reason for the reversible effects that occur in the temperature range 60–130 °C and how these effects are connected to the presumed changes in the arrangement of the guest molecules in the interlayer space of the host. For this purpose, we utilized solid-state NMR spectroscopy together with other methods. Structural changes occurring in the investigated materials, in our case in the intercalated systems, can be easily inferred from the chemical shifts obtained by solid-state NMR spectroscopy. Besides, many NMR parameters are highly sensitive to the internal dynamics of molecular systems and for instance motional amplitudes of molecular segments can be directly extracted from the precise measurements of the site-specific motionally averaged one-bond dipolar couplings.

This paper reports the results of a DSC, IR, and NMR study of the thermal behavior of the THP intercalate. We focused also on the description of the basic structural motifs and motional states of the intercalated molecules of THP within the interlayer space of $VOPO_4$. For this task we used the analysis of the $^{13}C$ CP/MAS NMR spectra and the measurements of the $^{1}H$-$^{13}C$ and $^{1}H$-$^{31}P$ dipolar coupling constants. Furthermore, the conformational changes and the rearrangement of THP molecules that occur as the temperature is gradually elevated were probed by a variable-temperature measurement of the $^{13}C$ CP/MAS NMR spectra.

## Results and Discussion

The THP intercalate was prepared according to two methods: stirring at room temperature and refluxing. Both methods provide samples with the same composition $VOPO_4{\cdot}C_5H_{10}O$ but with slightly different basal spacings. The sample prepared at room temperature has a basal spacing of 12.02 Å and its lattice parameters are the same as those of the intercalate described in the previous paper.[5] The sample prepared by refluxing has a slightly higher basal spacing of 12.11 Å. Both samples were heated to 115 °C and then cooled to room temperature. After the thermal treatment, the basal spacing of the sample prepared at room temperature shifts from 12.02 to 12.11 Å (see Figure 1a). On the other hand, the diffractograms of the sample prepared by refluxing are practically the same before and after the thermal treatment and its thermal XRD behavior seems to be fully reversible (Figure 1b). Therefore, all other investigations were done with this sample.

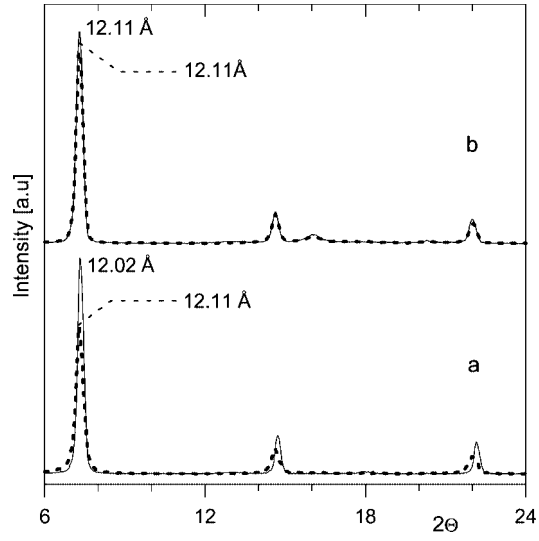

Figure 1. Comparison of the diffractograms measured before (solid line) and after (dashed line) thermal treatment for the THP intercalate prepared at room temperature (a) and by refluxing (b).

### DSC Measurements

Figure 2 shows the DSC curves for the intercalate. Three cycles of heating and cooling were carried out (curves 1–6). The first heating curve (dashed line 1) shows an endothermic peak at 98 °C with a shoulder at 102 °C. The second and third heating curves (3 and 5) are identical and differ

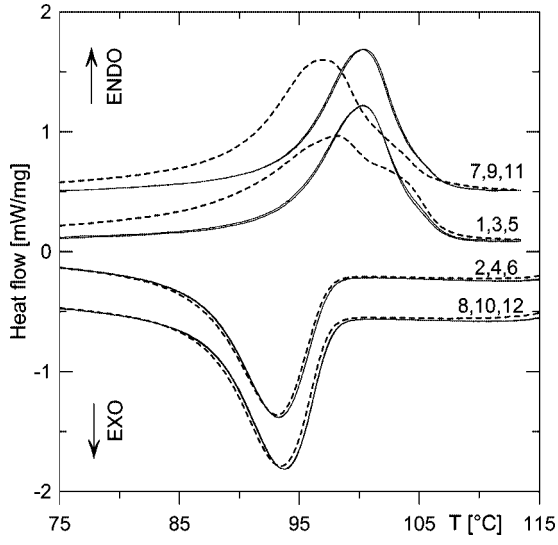

Figure 2. DSC curves of the intercalate prepared by refluxing. The curves are numbered as they were measured. The measurements 7–12 were repeated after 5 d with the same samples as measurements 1–6. The first cycles of heating (1 and 7) and cooling (2 and 8) are marked with dashed lines.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

from the first heating curve. They have only one endothermic peak at 100.5 °C. All three cooling curves (2, 4, and 6) are nearly the same.

After 5 d, another three heating and cooling cycles were carried out with the same sample. The first heating curve in this series (dashed line 7) is similar to the first heating of the fresh sample. There is an endothermic peak at 97 °C but the shoulder at 102 °C is less marked. It indicates some slow relaxation at room temperature. The next two heating curves (9 and 11) and all cooling curves (8, 10, and 12) are practically the same and do not differ from those of the fresh sample.

### FTIR Spectroscopy

The phase transitions in $VOPO_4 \cdot C_5H_{10}O$ intercalate demonstrated by DSC analysis have been tested by FTIR spectroscopy. The FTIR spectra of the intercalate $VOPO_4 \cdot C_5H_{10}O$ during heating from 25 to 120 °C and of pure THP are shown in Figures 3 and 4.

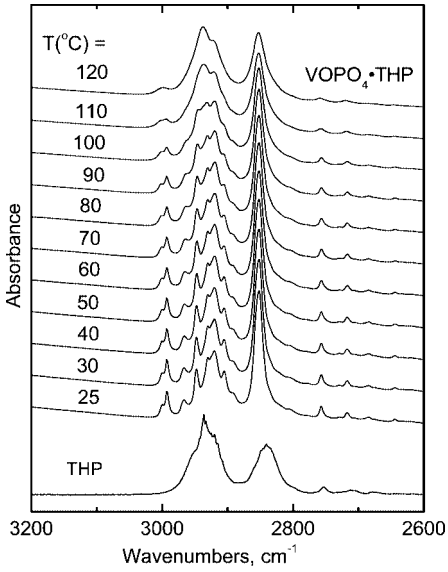

Figure 3. FTIR spectra of the intercalate $VOPO_4$ with THP in KBr pellets during heating from 25–120 °C and ATR FTIR spectrum of pure THP in the region from 3200 to 2600 $cm^{-1}$.

The infrared spectrum of the $VOPO_4 \cdot C_5H_{10}O$ intercalate at ambient temperature exhibits pronounced peaks which correspond to the THP vibrations. The intercalation of THP into vanadyl phosphate has been characterized by IR and Raman spectroscopy.[5] The band at 996 $cm^{-1}$ in the infrared spectrum of $VOPO_4 \cdot C_5H_{10}O$ has been assigned to the symmetric $\nu(PO_4)$ stretching vibration which is infrared-active due to the distortion of the phosphate tetrahedron in the intercalate. The shoulder at 1001 $cm^{-1}$ is most probably the V=O stretching band of the vanadyl group. Its position corresponds to the coordination of the oxygen atom of THP to the other axial position of the $VO_6$ octahedron. The band at 1149 $cm^{-1}$ in the infrared spectrum of the intercalate with THP is the asymmetric $\nu(PO_4)$ stretching vibration of the phosphate tetrahedron. The position of the main spectral bands of the host structure differs only slightly from those of anhydrous vanadyl phosphate or its hydrated form.[7] This confirms that the structure of the original $VOPO_4$ layers remains unchanged after the intercalation reaction.

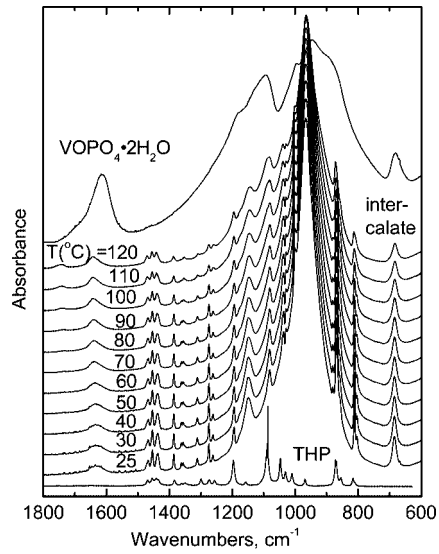

Figure 4. FTIR spectra of $VOPO_4 \cdot H_2O$ and of the intercalate $VOPO_4$ with THP in KBr pellets during heating from 25 to 120 °C and ATR FTIR spectrum of pure THP in the region from 1800 to 600 $cm^{-1}$.

The position, shape, and intensity of bands in the 3100–2700 $cm^{-1}$ region (see Figure 3) of the spectrum of the intercalate differs from those in the spectrum of pure THP.[8,9] Some changes of the $CH_2$ stretching vibrations have been observed when going from the liquid state to the intercalated form of THP. During the fixation of the intercalated molecules in the interlayer space, the asymmetric $CH_2$ stretching vibrations at 2936 and 2840 $cm^{-1}$ split into several bands and a new doublet shifted to 3002 and 2993 $cm^{-1}$ appears in the infrared spectrum of the intercalated THP (see Figure 3). Going from the liquid to the intercalated state of THP a change of the scissoring (several bands from 1380 to 1470 $cm^{-1}$), wagging (at about 1350 $cm^{-1}$), twisting (at about 1250 $cm^{-1}$), and rocking (at about 1150 $cm^{-1}$) vibrations of the $CH_2$ group have been observed in the infrared spectrum of the intercalate (see Figure 4).[8,9] The band of the asymmetric C–O–C ring vibrations at about 1090 $cm^{-1}$ is overlapped by $PO_4$ vibrations of vanadyl phosphate in the infrared spectrum. The position of the deformation ring vibration is shifted from 817 to 813 $cm^{-1}$ in the infrared spectrum. The peak of the deformation ring vibration at 872 $cm^{-1}$ of THP is shifted to 870 $cm^{-1}$ with a shoulder at 881 $cm^{-1}$.

The infrared spectra of the $VOPO_4$ intercalate with THP present some reversible changes during heating to 120 °C and cooling back to 25 °C. In the region 3100–2700 $cm^{-1}$, the asymmetric $CH_2$ stretching vibration, which is split into

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

several bands at ambient temperature, passes to two bands at 2936 and 2840 $cm^{-1}$ and the doublet at 3002 and 2993 $cm^{-1}$ passes to one band at 3001 $cm^{-1}$ during heating at about 110 °C. This transition occurs at 90 °C during cooling (see Figure 3). At the same temperatures we observe the reversible changes in the region from 1500 to 1100 $cm^{-1}$ of the scissoring, wagging, and twisting vibrations of $CH_2$ groups and in the region from 1000 to 800 $cm^{-1}$ of the ring deformation vibration (see Figure 4). The observed changes might be explained by the existence of two different conformations of the intercalated THP molecules. Basically, a six-membered ring of THP can adopt one of the two most common conformations: boat and chair. At ambient temperature, the attractive forces between the host layers compel the guest molecules to adopt the boat conformation, which is spatially less demanding. The corresponding low-temperature intercalate has therefore a lower basal spacing. On heating, the attractive forces between layers become less important and the THP molecule can adopt the energetically most favorable conformation, the chair conformation. The high-temperature chair conformation requires more space which results in a higher basal spacing of the intercalate at elevated temperature. This idea is strongly supported by the quantum mechanical calculations presented below.

## NMR Spectroscopy

### *Local Structure and Segmental Dynamics*

The standard $^{13}C$ CP/MAS NMR spectrum of the intercalate (Figure 5a) clearly reflects that the THP molecules intercalated between the layers of vanadyl phosphate are regularly arranged. This is indicated by relatively narrow and symmetric signals with a linewidth of about 0.59, 0.55, and 0.45 ppm for signals C1, C2, and C3, respectively. As these linewidths are almost comparable with the linewidths of $CH_2$ signals of highly crystalline substances measured under the same conditions (e.g. glycine: 0.42 ppm), this feature reflects a high degree of organization and packing of the THP molecules. The other possible explanation, a narrowing of the signals due to the fast rotation or fast ring interconversion of the THP molecules in the interlayer space, can be excluded. As reflected by the determined heteronuclear one-bond $^1H$-$^{13}C$ dipolar splitting $\nu_{CH}$ = 12.2–11.8 kHz (Figure 6), the THP molecules in the basic state at room temperature are fairly immobilized. This follows from the comparison with the expected rigid limit value of $\nu_{CH}$, found to be 12.3 kHz based on a model compound measurement (crystalline glycine).

Motional averaging of the dipolar splitting expressed by an order parameter[10]

$$S = \nu_{CH}/\nu_{CH,rig} = \nu_{CH}/12.3\ \text{kHz}$$

is a measure of the equilibrium distribution of orientations of the bond vector in a molecular reference frame. Assuming segmental motion to be axially symmetric and small in amplitude ($\langle \sin\theta \rangle \approx \langle \theta \rangle$), the order parameter can be converted to a root mean square (*r.m.s.*) angular fluctuation of the bond vector according to the following definition:[10,11]

$$S = 1 - {}^3/_2\langle\theta^2\rangle$$

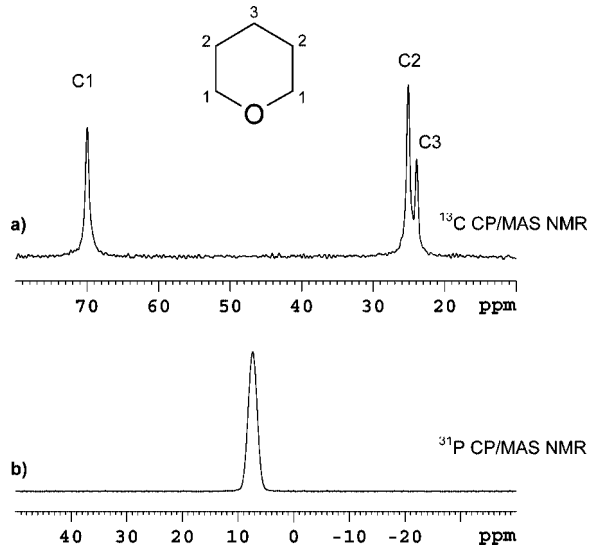

Figure 5. $^{13}C$ CP/MAS NMR spectrum (a) and $^{31}P$ CP/MAS NMR spectrum (b) of $VOPO_4$ with THP.

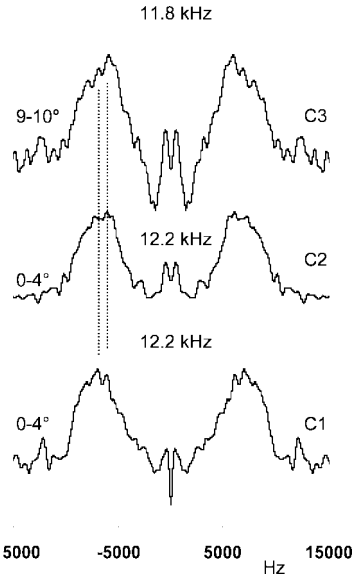

Figure 6. $^{13}C\{^1H\}$ NMR dipolar spectra of $CH_2$ units of the intercalated THP molecules measured at room temperature. The splitting in kHz ($\Delta\nu$) reflecting the motionally averaged dipolar coupling constant ($D_{CH}$) is shown between the maxima and calculated *r.m.s.* amplitudes at the left side of each spectrum.

In the case of the THP molecules intercalated in $VOPO_4$ the order parameter *S* ranges from 0.995 to 0.959. Applying the above-mentioned simplest but still physically realistic model, the determined motional amplitudes of the most rigid carbon atoms C1 and C2 of the THP molecule are about 0–4°. The motional amplitude of the most mobile segment C3 corresponds to a fluctuation angle of about 9–10°. This definitely confirms very low flexibility of THP

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

molecules at room temperature and therefore existence in one preferred conformation. The observed motional restrictions are probably induced by strong interaction with $VOPO_4$ layers.

The character of this intermolecular binding can be deduced from the $^{13}C$ NMR chemical shift. At room temperature the chemical shifts for the resonance peaks of THP trapped in as-synthesized vanadyl phosphate are significantly different from those of THP in the liquid state. It can be seen that the chemical shifts of the carbon atom connected to the oxygen atom in THP (C1), move to low field ($\delta$ = 69.9 ppm) in the $VOPO_4$ intercalate in comparison with $\delta$ = 68.4 ppm in the liquid state. Oppositely, the signals of C2 are significantly moved to high field ($\delta$ = 25.1 ppm), while the position of the signal of the C3 atom is almost unchanged ($\delta$ = 23.9 ppm). In the liquid state the carbon atoms C2 and C3 resonate at $\delta$ = 26.9 and 23.8 ppm. This phenomenon is caused by the nature of the interaction between the oxygen atom of THP and vanadyl phosphate. THP is a polar molecule in which the electronegativity of the oxygen atom is larger than that of the carbon atoms. As the oxygen atom of THP approaches the V atom, part of the electrons on the oxygen atom move to the vanadium atom, leaving the C1 atom with less negative charge. The deshielding effect causes the chemical shift to move to lower field, leading to a larger value of the chemical shift. Consequently, due to the inductive effects, electron density increases around the C2 atoms leading to a higher shielding of the nuclear spins and corresponding lower values of the chemical shifts. As the observed changes in the chemical shift are relatively large, +1.5 and –1.8 ppm for C1 and C2, respectively, the interaction between THP and the vanadyl phosphate framework must be strong.

A tight contact between the THP molecules and the $VOPO_4$ framework is further evidenced by a $^{31}P$ CP/MAS NMR experiment in which the nuclear polarization is transferred from hydrogen atoms of THP to spatially close phosphorus atoms (their distance must not exceed 6 Å). As this experiment can be easily performed (Figure 5b) and the obtained result is quite identical with the $^{31}P$ MAS NMR spectrum measured with a direct excitation of the $^{31}P$ magnetization (not shown here) the THP molecules must be regularly arranged over the whole sample and must be in close contact with all phosphorus atoms.

Average short distances between the hydrogen and phosphorus atoms were estimated from the measurement of $^{31}P$-$^{1}H$ dipolar profiles employing a recently developed and applied two-dimensional Lee–Goldburg cross-polarization experiment.[12,13] The obtained dipolar spectrum (Figure 7) probably corresponds to two superimposed dipolar doublets reflecting a superposition of two independent contributions. The most probable short-range $^{1}H$-$^{31}P$ pairs are reflected by the main splitting of the dipolar spectrum which is about 210 Hz. This corresponds to the average interatomic distance of 5.1 Å. The outer low-intensive doublet with the dipolar splitting of 460 Hz may reflect the shortest $^{1}H$-$^{31}P$ pairs, the interatomic distance of which is about 4.0 Å. The reliability of the applied analysis of the $^{1}H$-$^{31}P$ dipolar spectrum was confirmed by the measurement and subsequent simulation of the $^{1}H$-$^{31}P$ dipolar profiles for a four-spin system of $CaHPO_4$ for which the neutron-diffraction crystal structure is well known.[14]

### *Variable-Temperature $^{13}C$ CP/MAS NMR Spectroscopy*

Variable-temperature NMR experiments offer an interesting prospect to probe a temperature-induced rearrangement occurring in the investigated intercalated system. Gen-

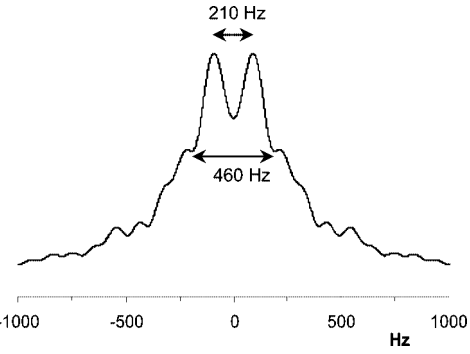

Figure 7. $^{31}P\{^{1}H\}$ dipolar spectrum of $VOPO_4$·THP intercalate measured at room temperature. The splitting in Hz ($\Delta\nu$) is shown between the maxima.

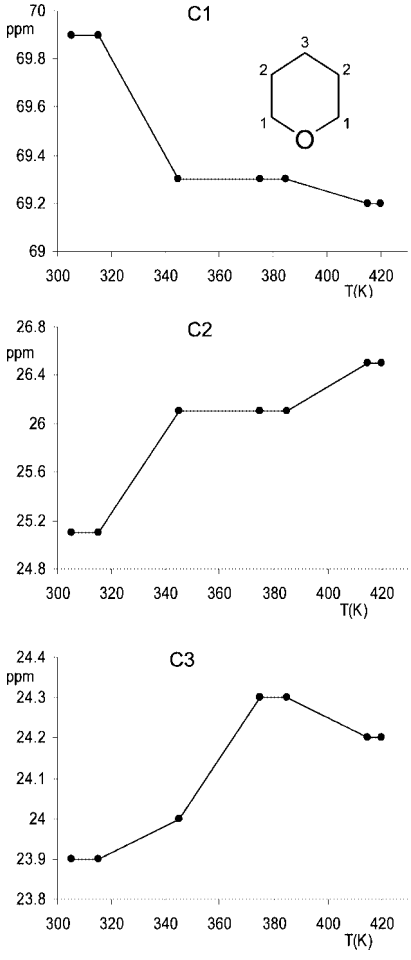

Figure 8. Temperature dependence of the $^{13}C$ NMR chemical shift of $VOPO_4$ with THP.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

erally, an increase in temperature may help to overcome energy barriers and a reconstitution of the molecules – transition to another "polymorphic" form – can take place. Such changes can be simply monitored by two basic NMR parameters: chemical shift and linewidth of the $^{13}C$ NMR signals.

In our particular case the temperature dependence of the $^{13}C$ NMR chemical shifts (Figure 8) clearly revealed two conformation transitions. Both these transitions are not quite instant and rather occur in more or less broad temperature ranges. The first one occurs in the temperature range 70–85 °C and it is accompanied by a rearrangement of the THP molecules. This statement follows from three observed phenomena: (i) the $^{13}C$ NMR shifts of the C1 and C2 carbons signals substantially moved; (ii) the linewidth of all signals after the transition is significantly narrowed; and finally, (iii) in the temperature range of the phase transition it is almost impossible to record the $^{13}C$ NMR spectra.

The impossibility to detect the $^{13}C$ NMR spectra indicates that the molecules of THP are involved in the dynamic exchange process. The molecular motion, however, is neither very fast nor isotropic, because the $^{13}C$ MAS NMR spectrum measured with direct excitation provides only broad and unresolved signals. That is why this transformation could be attributed to the local conformation transition, for example boat/chair, which – at this temperature range – is reversible. At higher temperatures (95–130 °C) after the first transition, the molecules of THP are again stabilized and rearranged with a significantly higher degree of self-assembling. This is reflected by a high efficiency of the cross-polarization and very narrow signals with a linewidth of 0.48–0.38 ppm (Figure 9). The second transition occurring at about 130 °C is not so dramatic. We observe only slight changes in the $^{13}C$ NMR shift and slight broadening of the corresponding signals indicating increased disorder in packing of the THP molecules. The changes in the chemical shifts observed with increasing temperature further indicate a tendency of the molecules of THP to reach a relatively "free" state without the strong interaction with the $VOPO_4$ framework. Each transition is probably connected to a weakening of the intermolecular interactions between the THP molecules and vanadyl phosphate structure units.

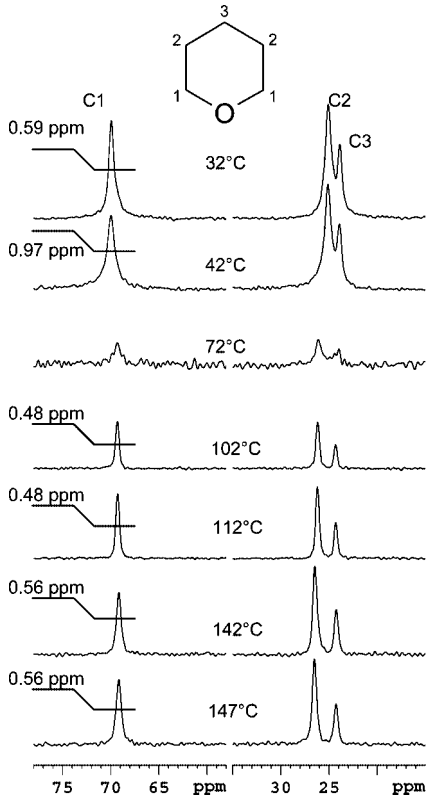

Figure 9. Variable-temperature $^{13}C$ CP/MAS NMR spectra of $VOPO_4$ with THP.

## Quantum Chemical Calculations

The character of the bonding between the guest molecules and the host layer in the THP intercalate was investigated by the methods of quantum chemical calculations. Figure 10 shows a DFT-optimized structure of the molecular segment representing local interactions of vanadyl phosphate with THP, using a B3LYP functional and 6-31G(d) basis set. In order to keep the overall planar structure of the segment during full geometry optimizations and to make the electronic structure in the segment close to the conditions appearing in the intercalates, an oxygen atom was inserted between two neighboring $PO_4$ groups and terminal oxygen atoms were substituted by OH groups.[15] The

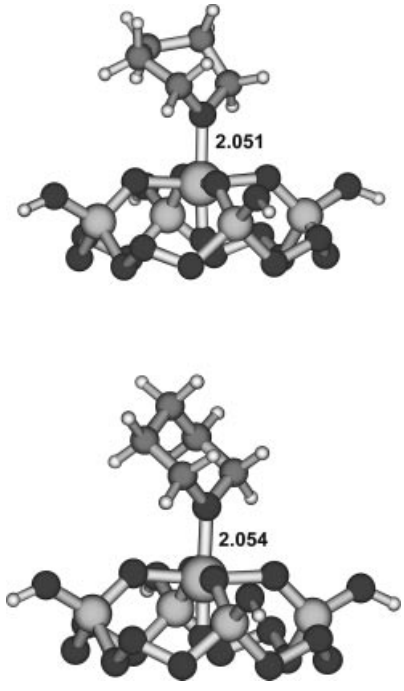

Figure 10. Optimized B3LYP/6-31G(d) structures of the molecular segment modeling the vanadyl phosphate–THP interaction with THP in boat and chair conformations.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

total charge of the model compound was set to +3. It was found that all geometry optimizations with various starting orientations of THP with respect to the vanadyl group lead to the structures displayed in Figure 10, with the boat and chair conformations of THP. The structure with the chair conformation is energetically more favored by 4.9 kcal/mol.

## Conclusions

In summary, the following conclusions can be made:

(i) The donor-acceptor bond between the oxygen atom of THP and the vanadium atom of $VOPO_4$ has been confirmed by both IR and NMR spectroscopy. This bond loosens with increasing temperature.

(ii) The phase transition observed by the DSC and powder XRD methods is accompanied with changes in the infrared spectrum of the intercalate.

(iii) The existence of two phases (with the phase transition in the temperature region 80–120 °C) could be explained by the fact that the six-membered ring of THP forms two conformations: chair and boat. The chair conformation is energetically more favorable, as follows from the quantum chemical calculations, but is sterically more demanding. Thus, its existence can be presumed at higher temperature, when there is more space between the layers of the host as indicated by higher basal spacing observed for the high-temperature phase. The boat conformation, on the other hand, can be arranged in the interlayer space in such a way that the distance between layers is lower. Therefore, this boat conformation can be present in the low-temperature phase, where it is favored by steric conditions.

(iv) The second transition/change at around 140 °C is most probably caused by weakening of the donor–acceptor bond $O_{THP}$–V and formation of a disorder in packing of the THP molecules. These phenomena are followed by a slow decomposition of the intercalate.

## Experimental Section

**Sample Preparation:** The THP intercalate was prepared either by stirring a suspension of $VOPO_4{\cdot}2C_3H_7OH$ in THP at room temperature overnight or by refluxing a suspension of $VOPO_4{\cdot}2C_3H_7OH$ in THP for 1 h. The products were filtered off and dried under nitrogen at room temperature.

**XRD:** The powder data were obtained with a D8 Advance diffractometer (Bruker AXE, Germany) using Cu-$K_\alpha$ radiation with a secondary graphite monochromator. The diffraction angles were measured from 7 to 80° ($2\theta$). The temperature measurements from 25 to 200 °C were carried out on the heated corundum plate with a thermocouple. Each diffractogram was measured at constant temperature and each cycle of heating and measuring lasted about 60 min.

**DSC Measurements:** DSC experiments were performed with a Mettler DSC 12E instrument. The instrument was previously calibrated with indium, tin, and lead standards. A crystalline powder sample of about 1 mg was placed in an aluminum pan and measured with a heating and cooling rate of 5 K min$^{-1}$ in the range from 40 to 115 °C.

**Infrared Measurements:** The structural and optical properties of the samples were checked using Fourier transform infrared (FTIR) spectroscopy. Infrared measurements were performed with a Bruker IFS 55 EQUINOX FTIR spectrometer with a DLATGS detector. All spectra in the range 400–4000 cm$^{-1}$ with 2 cm$^{-1}$ spectral resolution were obtained from compressed KBr pellets in which the $VOPO_4{\cdot}$THP powders were evenly dispersed. Two hundred scans were used to record each FTIR spectrum. A variable-temperature-controlled cell (Specac Ltd.) in the range from 0 to +250 °C with solid holders was used for temperature-dependent measurements. The spectrum of the corresponding liquid THP was measured by the ATR technique on a ZnSe crystal. The spectra were corrected for the content of $H_2O$ and $CO_2$ in the optical path.

**Solid-State NMR Spectroscopy:** Standard one-dimensional (1D) experiments with cross-polarization (CP) and with direct excitation as well as two-dimensional (2D) recoupling experiments were performed with a Bruker Avance 500 NMR spectrometer (Karlsruhe, Germany, 2003) with a 4-mm $ZrO_2$ rotor. Magic-angle spinning (MAS) speed was 10–12 kHz, the nutation frequency of the $B_1(^{13}C)$ and $B_1(^{31}P)$ field was 62.5 kHz, and the repetition delay was 4 s. To detect site-specific $^1H$-$^{13}C$ and $^1H$-$^{31}P$ dipolar spectra, 2D PILGRIM (Phase Inverted LG Recoupling under MAS) experiments[12] were applied. Incremented off-resonance LG-CP with a 22.6 μs increment was used as a dipolar evolution period. The intensity of the $B_1(^1H)$ field for cross-polarization was $\omega_1/2\pi$ = 62.5 kHz and Hartman–Hahn matching conditions at the +1 spinning side-band were optimized experimentally. TPPM (two-pulse phase-modulated) decoupling was applied during the detection periods. The phase modulation angle was 15°, and the flip-pulse length was 4.7 μs. The applied nutation frequency of the $B_1(^1H)$ field was $\omega_1/2\pi$ = 89.3 kHz. The $^{13}C$ scale was calibrated with glycine as the external standard ($\delta$ = 176.03 ppm: low-field carbonyl signal). The $^{31}P$ scale was calibrated with $CaHPO_4$ ($\delta$ = –0.6 ppm). Taking into account frictional heating of the samples during fast rotation[16] precise temperature calibration was performed before variable-temperature experiments.

**Method of Calculation:** Quantum chemical calculations were carried out at the ab initio level of theory employing the Gaussian 98[17] program package. Local interactions and structures in the intercalates of vanadyl phosphate with THP were studied at a DFT level using a B3LYP functional with a 6-31G(d) basis set.

# Reactivity and X-ray Structural Studies in Ligand Substitution of [Cp/(Ind)Ru(dppf)Cl] – Epimerisation in [Cp/(Ind)Ru(Josiphos)Cl] {Cp = $\eta^5$-$C_5H_5$, Ind = $\eta^5$-$C_7H_9$, dppf = 1,1′-Bis(diphenylphosphanyl)ferrocene, Josiphos = (*R*)-(–)-1-[(*S*)-2-(Diphenylphosphanyl)ferrocenyl]ethyldicyclohexylphosphane}

**Sin Yee Ng,[a] Guihua Fang,[a] Weng Kee Leong,*[a] Lai Yoong Goh,*[a] and Marc V. Garland[b]**

**Keywords:** Indenyl / Ruthenium / dppf / Josiphos / Epimerisation / Phosphanes

Ligand substitution of [(Ind)Ru($PPh_3$)$_2$Cl] (**1**) led to the isolation of [(Ind)Ru($PPh_3$){$Ph_2P(CH_2)_2C_9H_7$}Cl] (**2**), [(Ind)Ru(dppf)Cl] (**3**) and [(Ind)Ru{$(Ph_2PCH_2)_3CMe$}]$PF_6$ ([**4**]$PF_6$), and diastereoisomers [(*R*)- and (*S*)-(Ind)Ru(Josiphos)Cl] [(*R*)-**5** and (*S*)-**5**], where (*R*)-(*S*)-Josiphos is the ferrocene-based chiral diphosphane ligand (*R*)-(–)-1-[(*S*)-2-(diphenylphosphanyl)ferrocenyl] ethyldicyclohexylphosphane. The Cp analogues of **5**, viz. (*R*)-**6** and (*S*)-**6**, were also obtained from [CpRu($PPh_3$)$_2$Cl] (**1a**). Josiphos-dependent epimerisation was observed, with conversion of the (*S*) isomer to the (*R*) isomer in both cases. Chloride abstraction of **3** with $NaPF_6$ in $CH_3CN$ and $NaN_3$ in EtOH gave [(Ind)Ru(dppf)($CH_3CN$)]$PF_6$ ([**7**]$PF_6$) and [(Ind)Ru(dppf)($N_3$)] (**8**), respectively. The azido ligand in **8** underwent [3+2] dipolar cycloaddition with dimethyl acetylenedicarboxylate to give a *N*-bound bis(methoxycarbonyl)-1,2,3-triazolato complex, **9**. X-ray crystal structures of the new complexes, except (*R*)-**5**, (*S*)-**5** and (*S*)-**6**, have been determined.

## Introduction

The chemistry of phosphane organometallic complexes has been well established in the last four decades,[1] interest being fuelled by their roles in medicinal and catalytic applications.[2] In particular, [CpRu($PPh_3$)$_2$Cl] (**1a**), first synthesised in 1969 by Gilbert and Wilkinson,[3] has attracted much attention. A rich chemistry has unfolded, based on the facile substitution of the $PPh_3$ ligand by two-electron donors, as well as the ready displacement of the chlorido ligand by both anionic and neutral ligands.[4] Its well-defined CpRu($PPh_3$)$_2$ moiety is an attractive auxiliary that can be used for the attachment of organic groups in studies of their steric and electronic effects on the chemical[4a] and catalytic[5] reactivity of the complex. More recently, the role of metallophosphane ligands, for example, of the symmetrical and unsymmetrical ferrocenyl type, in catalysis of organic reactions is increasingly being studied, as the ligands become more readily available.[6]

The marked effect of the capping ligand on reactivity of the complex came to light with the synthesis of [(Ind)Ru($PPh_3$)$_2$Cl] (**1**) (Ind = $\eta^5$-$C_9H_7$) some 16 years after that of its Cp analogue, **1a**.[7] The enhanced reactivity, commonly known as the "indenyl effect", was found to be largely brought about by ring slippage.[8] The combined effect of capping ligand and phosphane ligand variant would therefore be of interest. We note that research in recent years on (Ind)Ru chemistry has been focused on vinylidene and allenylidene complexes by the group of Gimeno,[8,9] and nitrogen-containing ligands, for example, amines, nitriles, *N*,*N*′-donor Schiff bases and azine ligands, by Kollipara and co-workers.[10] In this work, we have investigated the reactivity of **1** with the ferrocenyl diphosphane ligands 1,1′-bis(diphenylphosphanyl)ferrocene (dppf) and chiral ferrocenyl diphosphane ligand {(*R*)-(*S*)-Josiphos} and with the tripod ligand {$(Ph_2CH_2)_3CMe$}, and the reactivity of [(Ind)Ru(dppf)Cl] (**3**) towards N-containing ligands.

## Results and Discussion

### Phosphane Substitution

#### *Synthesis of [(Ind)Ru($PPh_3$){$Ph_2P(CH_2)_2C_9H_7$}Cl] (2), [(Ind)Ru(dppf)Cl] (3) and [(Ind)Ru(tripod)]$PF_6$ ([4]$PF_6$)*

As in [CpRu($PPh_3$)$_2$Cl] (**1a**), the substitution lability of $PPh_3$ in [(Ind)Ru($PPh_3$)$_2$Cl] (**1**) has provided an easy entry to various [(Ind)Ru] complexes. For instance, [(Ind)Ru(diphos)Cl] had been synthesised from a reaction of [(Ind)-

$Ru(PPh_3)_2Cl$] by substitution with the desired diphos in refluxing toluene.[7] Adopting the reported procedure for the synthesis of (Ind)Ru(dppe)Cl [dppe = 1,2-bis(diphenylphosphanyl)ethane],[11] phosphane substitution of **1** at elevated temperature in toluene gave air- and moisture-stable red solids of the monophosphane-substituted complex [(Ind)-$Ru\{Ph_2P(CH_2)_2C_9H_7\}(PPh_3)Cl$] (**2**), containing the (1-indenylethyl)diphenylphosphane ligand **LH** (Scheme 1a), the diphosphane-substituted complex [(Ind)Ru(dppf)Cl] (**3**) with dppf (Scheme 1b), and a totally substituted complex [(Ind)-$Ru(Ph_2PCH_2)_3Me]PF_6$ ([**4**]$PF_6$) with the tripodal triphos ligand $(Ph_2PCH_2)_3CMe$ (Scheme 1c), in high yields.

It is anticipated that phosphane substitution of **1** will be facilitated by the release of steric stress in the coordination sphere by dissociation of one or both of the bulky $PPh_3$ ligands. This is very likely the driving force in the formation of **2**, as the ligand **LH** is less bulky than $PPh_3$. In the cases of **3** and [**4**]$PF_6$, the reactions are additionally assisted by the chelating effect of the incoming di- and triphosphane ligand, respectively.

The $^1H$ NMR spectrum of **2** shows four multiplets in the range $\delta$ = 1.79–3.52, assigned to the four inequivalent methylene protons of **LH**. The $CH_2$ protons of the five-membered ring of **LH** resonate at $\delta$ = 2.93, while the olefinic proton resonates at a higher field at $\delta$ = 6.5. On the other hand, the protons $H^{1-3}$ (see Experimental Section for numbering scheme) of the $\eta^5$-coordinated Ind ligand resonate at $\delta$ = 4.95–5.00 and $\delta$ = 5.78 ppm. The $^{31}P$ NMR spectrum shows two doublets at $\delta$ = 46.5 and $\delta$ = 50.0 with $^2J_{PP}$ = 42.9 Hz due to the coupling of the two inequivalent phosphorus atoms.

The $^1H$ NMR spectrum of **3** shows an ABCD pattern for the proton signals of the ferrocene rings at $\delta$ = 3.66, 3.83, 3.90 and 4.20, suggesting an eclipsed conformation for the chelating dppf ligand in **3**;[12] this was supported by the X-ray single-crystal diffraction analysis. The Cp proton signals of the $\eta^5$-indenyl ligand appear at $\delta$ = 4.66 ($H^1$) and 5.57 ($H^{2,3}$). The latter resonance is 1.67 ppm downfield shifted from that in the bis($PPh_3$) analogue, owing to relief from the shielding effect caused by the ring current of the Ph ring of $PPh_3$ on $H^2$ and $H^3$ in **1**.[13]

The $^1H$ NMR spectrum of [**4**]$PF_6$ shows a multiplet at $\delta \approx 1.5$ and a broad singlet at $\delta \approx 2.39$, assigned to the methyl and methylene groups of the tripod ligand, indicating the fluxionality of these groups in solution. However, a sharp singlet at $\delta$ = 39.9 in the $^{31}P$ NMR spectrum indicates an equivalent chemical environment for the three coordinated phosphorus atoms of tripod. The proton resonances of $H^1$ and $H^{2,3}$ of the indenyl ligand appear at $\delta$ = 5.51 and 5.57 ppm, while $H^{4-7}$ appear as two characteristic four-line multiplets at $\delta$ = 7.31–7.34 and $\delta$ = 7.43–7.47, respectively.

The molecular structures of **2**, **3** and [**4**]$^+$ have been determined by single-crystal X-ray crystallographic studies; their ORTEP diagrams are shown in Figures 1, 2 and 3, respectively, and selected bond parameters are compared with those of CpRu(dppf)Cl[14] in Table 1.

The molecular structures of **2** and **3** show Ru hexacoordinated to Ind, a Cl atom and two phosphorus atoms, that is, from $PPh_3$ and $C_9H_7(CH_2)_2PPh_2$ in **2** and from chelating dppf in **3**. The molecular structure of [**4**]$^+$ consists of a mononuclear cation [($\eta^5$-Ind)Ru(tripod)]$^+$ and $PF_6^-$ anion, to-

gether with two solvent molecules of dichloromethane, one of which is disordered.

A general, yet prominent structural feature of $\eta^5$-indenyl complexes is the distortion from $\eta^5$- to $\eta^3$-coordination, equivalent to an allyl-ene bonding description for the $C_5$ ring. Such a distortion is found in **2**, **3** and [**4**]$^+$, as evident from the values of their slip distortions ($\Delta$) and hinge angles (HA), which fall in the range of small or moderate distortion towards a $\eta^3$ binding mode.[15] The slightly larger distortion in **3** (longer $\Delta$) is probably a result of the stronger $\sigma$-donor capability of dppf.[8] The unusually large fold angle (FA) in [**4**]$^+$ likely arises from the steric congestion created by the phenyl rings of the tripod ligand, which causes the benzenoid ring of the indenyl ligand to twist upwards,

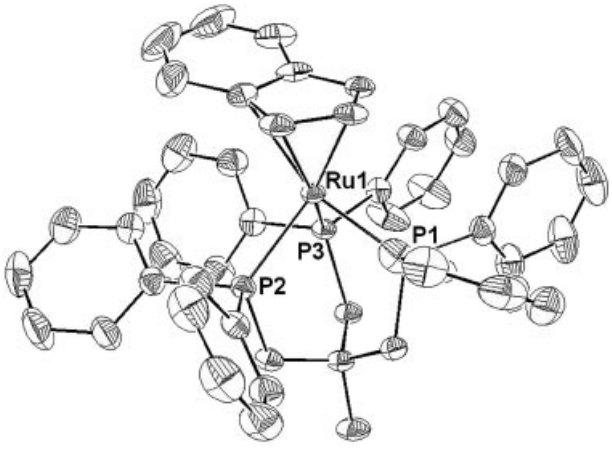

Figure 3. ORTEP diagram of [**4**]$^+$. Thermal ellipsoids are drawn to 50% probability level. Hydrogen atoms are omitted for clarity.

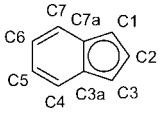
Table 1. Selected bond parameters of complexes **2**, **3**, [**4**]$^+$ and [CpRu(dppf)Cl].



| Complexes | **2** | **3** | [**4**]$^+$ | [CpRu(dppf)Cl][14] |
|---|---|---|---|---|
| $\Delta$ [Å][a] | 0.182(5) | 0.193(4) | 0.182(5) | – |
| Hinge angle (HA) [°][a] | 7.43 | 7.69 | 7.71 | – |
| Fold angle (FA) [°][a] | 11.22 | 11.02 | 15.62 | – |

[a] Slip-fold parameters as defined in ref.[15]. [b] C* = centroid of the five-membered ring, C1, C2, C3, C3a and C7a.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

thereby increasing the FA. This steric congestion is also reflected in the significantly longer C*–Ru1 bond length.

The "ene" character of the "dangling" ethylindene substituent of **LH** in **2** was indicated by the short C3–C11 bond length [1.329(7) Å], of C–C double bond character.[16] The C–C bond lengths of the benzenoid ring have an average of 1.382 Å, consistent with aromaticity of the ring.[16]

The metric data for the structures of **2**, **3** and [**4**]$^+$ are significantly different from those of CpRu(dppf)Cl.[14] While the Ru1–P bond lengths in the latter complex are almost identical, the two Ru1–P bond lengths in each of **2**, **3** and [**4**]$^+$ differ substantially, by 0.04–0.07 Å, probably because of the steric repulsion between the benzenoid ring of the indenyl ligand and the phenyl rings bonded to P2, which are situated directly below the benzenoid ring. The Cp rings of dppf in **3** are almost eclipsed (synperiplanar), with a torsional angle ($\tau$) of 4.3°, and the rings are tilted at an angle of 6.3°. The P1–Ru1–P2 angle of 98.22° is larger than those in **2** and [**4**]$^+$, undoubtedly because of the expanse of the dppf ligand. However, the value, like that of the Cp analogue (95.05°), falls in the range 91.6–102.2° reported for Ru(dppf) complexes.[17]

### *Synthesis of [(CpIInd)Ru(Josiphos)Cl]*

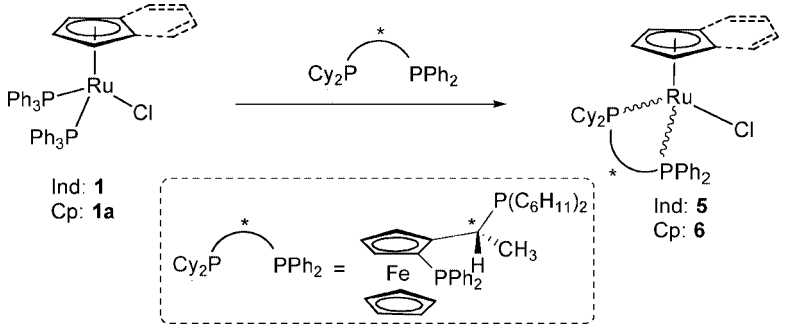
Phosphane substitution of **1** or **1a** by the ferrocene-based chiral diphosphane ligand (*R*)-(–)-1-[(*S*)-2-(diphenylphosphanyl)ferrocenyl]ethyldicyclohexylphosphane {(*R*)-(*S*)-Josiphos} can likewise be achieved at an elevated temperature (Scheme 2). Because of the inequivalence of the two phosphorus atoms in (*R*)-(*S*)-Josiphos and the pseudotetrahedral geometry of **1** and **1a**, a pair of diastereomers is formed, as displacement of $PPh_3$ by chiral Josiphos generates a chiral ruthenium centre.

It was found that an 8-h reflux generated a 1:1:3:2 equilibrium mixture of **1**, free Josiphos, (*R*)-**5** and (*S*)-**5** diastereomers. Prolonged reaction time did not lead to completion, but gave instead a decomposition product with a $^{31}P$ NMR resonance at $\delta$ = 24.9 ppm. Pure (*R*)-**5** can be isolated by liquid chromatography of the mixture, with 'loss' of the (*S*)-**5** isomer. Purification by fractional crystallisation was rendered impossible by the similar solubility of **1** and **5**.

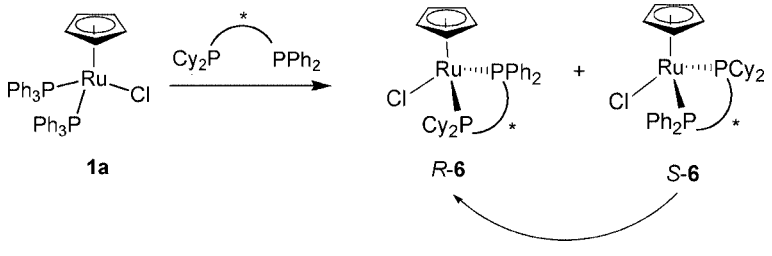
A similar reaction of **1a** with (*R*)-(*S*)-Josiphos (1:1) for 1.5 h gave a 1.5:1 molar mixture of (*R*)- and (*S*)-[CpRu(Josiphos)Cl] (**6**) diastereomers. Further heating caused epimerisation of (*S*)-**6** to (*R*)-**6**, with complete conversion in 8 h, indicating that (*S*)-**6** is the kinetic product, while (*R*)-**6** is the thermodynamically more stable isomer (Scheme 3). The simultaneous appearance of two new sets of doublets in the $^{31}P$ NMR spectrum, corresponding to (*R*)-**6** and (*S*)-**6**, respectively, indicated that the chelation of Josiphos was a concerted process. This was unlike the stepwise process observed in the analogous displacement reactions of **1a** by other chiral diphosphanes.[18]

Pure (*R*)-**6** can be isolated by either liquid chromatography or by fractional crystallisation. Isolation of pure (*S*)-**6** was in vain, owing to epimerisation to (*R*)-**6**, despite attempts to slow down the process by the presence of a free ligand (see rate studies below); the process was found to be accelerated on a silica-gel column.

The configuration at the metal centre of **5** was determined by matching the coupling constants of the pair of doublets observed in the $^{31}P$ NMR spectrum to those of **6** [structurally determined (*R*)-**6** possesses $\delta$ = 37.5 and 67.2 ppm ($^2J_{PP}$ = 53.4 Hz) and (*S*)-**6**: $\delta$ = 49.3 and 68.1 ppm ($^2J_{PP}$ = 49.6 Hz)]. Based on these, the resonances for the diastereoisomers of **5** were assigned as follows: a pair of



Scheme 2.



Scheme 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

doublets at $\delta$ = 36.0 and 77.3 ppm ($^2J_{PP}$ = 53.4 Hz) for (*R*)-**5**, and $\delta$ = 60.5 and 68.4 ppm ($^2J_{PP}$ = 49.6 Hz) for (*S*)-**5**. In the $^1$H NMR spectra of (*R*)-**5** and (*R*)-**6**, the cyclohexyl protons resonate as broad signals in the range $\delta$ = 0.6–2.7; the Me resonance sits on top of one of the broad signals. The Cp protons of Josiphos in (*R*)-**5** and (*R*)-**6** resonate in the range $\delta$ = 3.68–4.30. Protons signals at $\delta$ = 5.34 ($H^1$) and 5.73 ($H^{2,3}$) are assignable to protons of $\eta^5$-Ind in (*R*)-**5**. In (*R*)-**6**, the protons of $\eta^5$-CpRu are observed at $\delta$ = 4.49 ppm.

The NMR spectroscopic data of (*S*) isomers of **5** and **6** were obtained from spectra of their diastereoisomeric mixtures by eliminating the resonances assigned to their (*R*) isomers and the starting materials. The $^{31}$P resonances of both (*S*)-**5** and (*S*)-**6** can be easily identified, as they are very well resolved. However, their $^1$H resonances overlapped extensively with those of the corresponding (*R*) isomer, with the exception of the singlets at $\delta$ = 3.56 in (*S*)-**5** and 3.89 in (*S*)-**6**, which belong to the protons of the Cp ring of Josiphos.

The X-ray crystal structure of (*R*)-**6** was obtained. A view of the molecule is shown in Figure 4, together with selected bond parameters. The cyclopentadienyl ring is slightly distorted, with a hinge angle of 2.22° and $\Delta$ of 0.037 Å. The bond lengths of Ru1–P, Ru1–Cl1 and average Ru1–C (of Cp ring) are comparable to those of (*S*)-{RuCl(Cp)[(*R*)-dppp]}.[19] The longer Ru1–P2 compared to Ru1–P1 is also observed in the crystal structure of *trans*-$RuCl_2${(*R*)-(*S*)-Josiphos}$(py)_2$.[20]

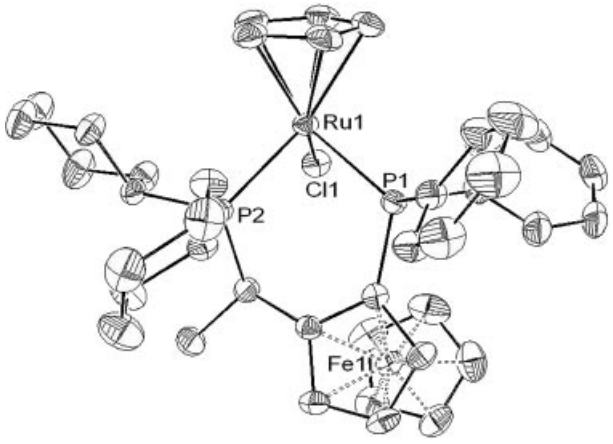


Figure 4. ORTEP diagram of (*R*)-**6**. Thermal ellipsoids are drawn to 50% probability level. Hydrogen atoms are omitted for clarity. Selected bond parameters: $\Delta$ = 0.037(4) Å; HA = 2.22°; C*–Ru1 1.858(4) Å; Ru1–P1 2.2804(11) Å; Ru1–P2 2.3115(11) Å; Ru1–Cl1 2.4525(11) Å; P1–Ru1–P2 90.22(4)°; P1–Ru1–Cl1 89.22(4)°; P2–Ru1–Cl1 90.41(4)°.

### Epimerisation of 6

As both complexes **5** and **6** undergo $S \rightarrow R$ epimerisation, it would be desirable to investigate their configurational stability and racemisation processes, as these processes often determine the potential of chiral-at-metal complexes in homogeneous catalysis. Complex **6** was chosen to be investigated rather than **5**, as the latter is thermally unstable.

$^1$H and $^{31}$P NMR spectral observations of the reaction of **1a** with Josiphos showed that the rate of epimerisation was markedly dependent on the concentration of free Josiphos in the reaction mixture. Thus, three experiments were carried out keeping Josiphos concentration [**J**] at 10 mM, and varying the molar ratio of **1a** to Josiphos. The results are given in Figure 5. In all three experiments, (*R*)-**6** and (*S*)-**6** were formed in about 1.2:1 ratio in the first 10 min of the reactions. Subsequently, the ratio of (*R*)-**6** to (*S*)-**6** increased rapidly in reactions **A** and **B**, as epimerisation proceeded at approximately similar rates, reaching a ratio of about 3 in 30 min, followed by a sharp increase to 118 at 90 min (reaction **A**), and 83.5 at 100 min (reaction **B**). It was observed that Josiphos was totally consumed at 30 min in reaction **A**, but was slowly consumed in reaction **B** to a negligible amount at about 50 min. In reaction **C**, using a 0.5 molar excess of Josiphos, epimerisation was observed to be extremely sluggish: the (*R*)-**6**/(*S*)-**6** ratio remained at about 1.5 up to 135 min, followed by a slow increase to about 10 in 500 min. This dramatic inhibition of epimerisation would suggest a dissociative type of mechanism, but the role of free Josiphos is currently still unclear to us. This case, involving a bidentate biphosphane, would not be expected to exactly parallel that for phosphane substitution in indenyl and $CpRu(PPh_3)_2$ complexes, for which a dissociative mechanism had been proposed by Gimeno on the basis of rate retardation by added $PPh_3$.[11] Nonetheless, the inhibitory effect of free Josiphos provides a useful way to control the rate of epimerisation.

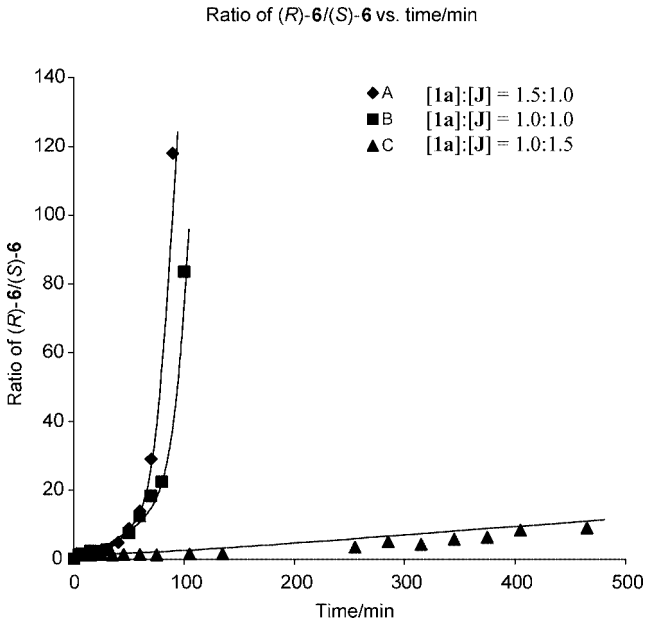

Figure 5. A plot of the ratio of (*R*)-**6**/(*S*)-**6** vs. time for the reaction of **1a** with Josiphos (**J**); [**J**] = 10 mM.

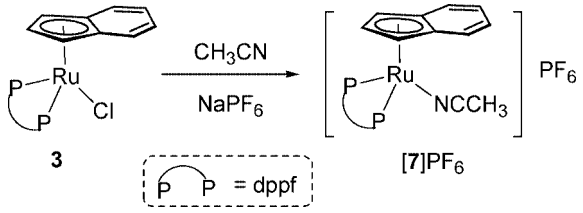
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Complex (*R*)-**6** was observed to exhibit configurational stability in solution indefinitely, even at elevated temperature. As configurational stability is an asset for catalyst performance to give high enantioselectivity, (*R*)-**6** has good catalytic potential, especially for transfer hydrogenation of ketones, as was found for chiral-at-metal organoruthenium complexes.[21] Catalytic investigations of (*R*)-**6** are currently in progress in our laboratory.

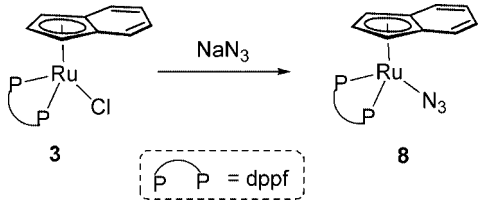
### Chloro Lability of [(Ind)Ru(dppf)Cl] (3)

As in the case of **1** and **1a**, chloro substitution of **3** provides a convenient pathway to new derivatives. It was found that chloride abstraction with $NaPF_6$ occurred readily in $CH_3CN$ under reflux, giving the yellow acetonitrile solvento complex $[(Ind)Ru(dppf)(CH_3CN)]PF_6$ ([**7**]$PF_6$) (Scheme 4). This compound was fully characterised spectroscopically (see Experimental Section). The Cp protons of dppf display an ABCD pattern, similar to that in **3**.



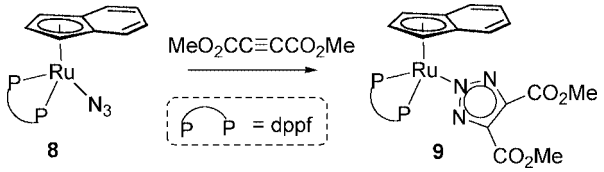
Scheme 4.

Treatment of **3** with $NaN_3$ in ethanol at reflux for 4 h afforded an 85% yield of **8** (Scheme 5), the spectral characteristics of which are given in Experimental Section. Here again, the Cp protons show an ABCD pattern.



Scheme 5.

As at $Pt^{II}$[22] and $Pd^{II}$[23] centres, the azido ligand in **8** undergoes [3+2] dipolar cycloaddition reaction with dimethyl acetylenedicarboxylate, giving the N(2)-bound 4,5-bis(methoxycarbonyl)-1,2,3-triazolato complex **9** in 55% yield from an ambient temperature reaction (Scheme 6). Several cycloaddition reactions have been reported in half-sandwich ruthenium systems, like $[(Ind)Ru(LL)(N_3)]$, $[Cp^*Ru(LL)(N_3)]$ (LL = dppm, dppe)[10f] and $[CpRu(dppe)(N_3)]$.[24] This is a useful synthetic route to some heterocycles, but it should be noted that the viability of the method may be dependent on the substituents on the acetylenic carbons, as we found that the reaction of **8** with $(CN)_2C{\equiv}C(CN)_2$ or $HC{\equiv}C(CO_2Me)$ led to dissociation of the indenyl ligand and did not yield any isolable product.



Scheme 6.

The ORTEP diagrams for the molecular structures of **8** and **9** are shown in Figures 6 and 7, respectively.

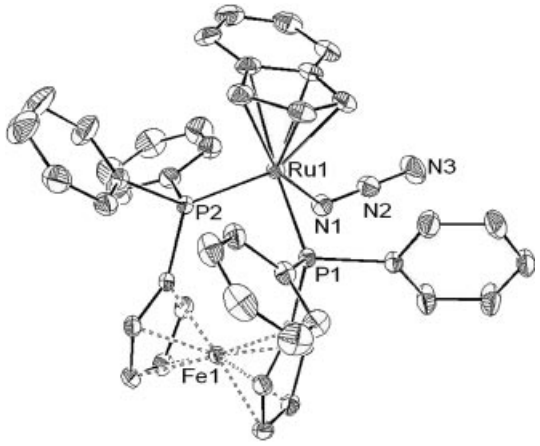


Figure 6. ORTEP diagram of **8**. Thermal ellipsoids are drawn to 50% probability level. Hydrogen atoms are omitted for clarity. Selected bond parameters: Δ = 0.163 Å; HA = 6.85°; FA = 8.70°; C*–Ru1 1.892 Å; Ru1–P1 2.2559(5) Å; Ru1–P 22.3251(6) Å; Ru–N1 2.1355(18) Å; N1–N2 1.192(3) Å; N2–N3 1.156(3) Å; P1–Ru1–P2 97.744(19)°; P1 Ru1–N1 84.42(5)°; P2–Ru1–N1 92.14(5)°; Ru1–N1–N2 117.96(15)°; N3–N2–N1 176.6(2)°.

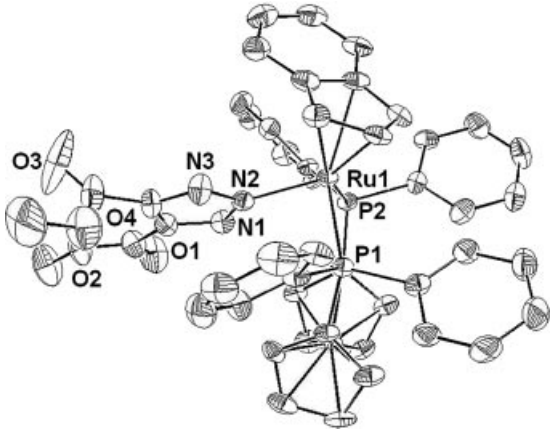

Figure 7. ORTEP diagram of **9**. Thermal ellipsoids are drawn to 50% probability level. Hydrogen atoms are omitted for clarity.

The slip-fold parameters of **8** fall in the normal range for $\eta^5$-coordination.[15] The Cp rings of the dppf ligand adopt a more stable synclinal staggered conformation, with tor-

sional angle 39.09°. The Ru1–N1 bond length of 2.1355(18) Å falls within the range of reported values for azido Ru complexes.[25] The coordinated terminal azido ligand is almost linear, the N3–N2–N1 angle being 176.6°.

In **9**, Ru is coordinated to two phosphorus atoms of the dppf ligand, heterocycle $N_3C_2(CO_2Me)_2$ through N(2) and an $\eta^5$-indenyl ligand. The coordination geometry of **9** is effectively similar to those of its Ind/Cp analogues containing dppe.[10f,24] The only noticeable difference lies in the irregularity of the pentagonal heterocyclic ring in **9**. This undoubtedly is caused by the steric demands of the bulky dppf ligand. It is seen in the structure of **9** that the heterocycle is hemmed in by the phenyl rings of dppf; moreover, N3, being nearer to the benzenoid ring of the indenyl ligand, suffers from additional steric encumbrance, hence the shortened N2–N3 bond length.

Selected metric data of **9**, including the slip-fold distortion parameters, are listed in Table 2, which also gives the metric data of its Ind/Cp dppe analogues for comparison. While these analogues possess very similar bond parameters, these differ appreciably from those of **9**, especially the bond angles. These significant differences are no doubt a consequence of the bulkiness of the dppf ligand.

## Conclusions

(Ind)Ru($PPh_3$)$_2$Cl has been prepared and mono-, di- and trisubstitution derivatives have been obtained with the monophosphane ligand **LH**, dppf and triphos, respectively. (*R*) and (*S*) diastereomers have been obtained with Josiphos, but only the thermodynamically stable (*R*) isomer could be isolated pure. A similar result was obtained with CpRu($PPh_3$)$_2$Cl. A rate study by $^1$H NMR spectroscopy showed Josiphos-dependent epimerisation of CpRu(Josiphos)Cl. Chloro substitution of (Ind)Ru(dppf)Cl with $CH_3CN$ and $N_3^-$ appears to indicate that this process is as facile as in the well-studied complex CpRu($PPh_3$)$_2$Cl. The [3+2] dipolar cycloaddition of the azido ligand provides an additional example for this uncommon occurrence at Ru.

## Experimental Section

**General:** All reactions were carried out using conventional Schlenk techniques under inert nitrogen or under argon in an M. Braun Labmaster 130 Inert Gas System. NMR spectra were measured on a Bruker 300 FT NMR spectrometer; for $^1$H and $^{31}$P spectra, chemical shifts were referenced to residual H-signals of the deuterated

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solvents $C_6D_6$, $CD_3CN$. IR spectra in KBr pellets were measured in the range 4000–400 $cm^{-1}$ with a BioRad FTS-165 FTIR instrument. Mass spectra were run on a Finnigan Mat 95XL-T (FAB) or a Finnigan-MAT LCQ (ESI) spectrometer. Elemental analyses were performed by the microanalytical laboratory in-house. [(Ind)-$Ru(PPh_3)_2Cl$] (**1**)[7] and $C_9H_7(CH_2)_2PPh_2$[26] were prepared by the published methods. All other chemicals were obtained commercially and used without any further purification. All solvents were dried with sodium/benzophenone and distilled before use. Celite (Fluka AG), silica gel (Merck Kieselgel 60, 230–400 Mesh) were dried at 140 °C overnight before chromatographic use. Conventional numbering of indenyl protons is shown in Figure 8.

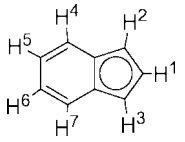

Figure 8. Numbering of indenyl protons.

**Synthesis of [(Ind)Ru(PPh$_3$){Ph$_2$P(CH$_2$)$_2$C$_9$H$_7$}Cl] (2):** $C_9H_7(CH_2)_2$-$PPh_2$ (35 mg, 0.11 mmol) was added to a red solution of **1** (70 mg, 0.09 mmol) in toluene (10 mL). The mixture was heated at 80 °C for 4 h. The resultant red solution was concentrated to about 1 mL and eluted through a silica gel column (2 × 2 cm) prepared in *n*-hexane with toluene/diethyl ether (10:1). From the red eluate, red microcrystals of [(Ind)Ru($PPh_3$){$Ph_2P(CH_2)_2C_9H_7$}Cl] (**2**) (57 mg, 75% yield) were obtained upon recrystallisation from THF/hexane. X-ray diffraction-quality crystals were obtained from a concentrated ether solution with hexane layering after 2 d at –30 °C.

**Data for 2:** $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 1.73–1.90 (br. m, 1 H, C*H*$_2$), 2.18–2.30 (br. m, 1 H, C*H*$_2$), 2.93 (s, 2 H, C*H*$_2$ on IndH), 3.15 (s, 1 H, C*H*$_2$), 3.40–3.52 (m, 1 H, C*H*$_2$), 4.95–5.00 (m, 2 H, H$^{2,3}$), 5.78 (s, 1 H, H$^1$), 6.57–6.60 (d-like m, 1 H, IndH), 6.79–6.81, 6.84–6.94, 6.98–7.13, 7.19–7.22 (each m, total 29 H, H$^{4–7}$and Ph), 7.65–7.68 (d-like m, 1 H, Ph), 8.25 (t-like m, 2 H, Ph) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 46.5, 50.0 [each d, $^2J_{PP}$ = 42.9 Hz, $PPh_3$ and IndH$(CH_2)_2$-$PPh_2$] ppm. FAB$^+$-MS: *m*/*z* (%) = 842 [M]$^+$, 808 [M – Cl]$^+$, 691 [M – Ind]$^+$, 581 [M – $PPh_3$]$^+$, 545 [M – $PPh_3$ – Cl]$^+$, 479 [M – IndH$(CH_2)_2PPh_2$ – Cl]$^+$, 429 [M – Ind – $PPh_3$ – Cl]$^+$. $C_{50}H_{43}ClP_2Ru$ (842.35): calcd. C 71.3, H 5.2; found C 71.6, H 5.3.

**Synthesis of [(Ind)Ru(dppf)Cl] (3):** 1,1′-Bis(diphenylphosphanyl)ferrocene (dppf) (0.76 g, 1.37 mmol) was added to a red solution of **1** (1 g, 1.29 mmol) in toluene (15 mL) and the mixture refluxed for 2 h. Red air- and moisture-stable crystalline solids, [(Ind)Ru(dppf)-Cl] **3**, precipitated out from the solution and were filtered (0.62 g, 60% yield). The supernatant was concentrated to about 5 mL. Addition of hexane (about 2 mL) gave a second crop after 2 h at 0 °C (0.27 g, 26% yield). In solution, the red compound of **3** decomposed in air within a day to a brown species. X-ray diffraction-quality crystals were obtained from a saturated solution of **3** in $C_6D_6$ after a day at room temperature.

**Data for 3:** $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 3.66, 3.83, 3.90 and 4.20 (each s, 2 H, $C_5H_4$), 4.66 (t, $^3J_{HH}$ = 2.5 Hz, 1 H, H$^1$), 5.57 (s, 2 H, H$^{2,3}$), 7.01–7.13 and 7.47–7.58 (m, 24 H, H$^{4–7}$ and Ph) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 51.9 (s, dppf) ppm. FAB$^+$-MS: *m*/*z* (5) = 806 [M]$^+$, 771 [M – Cl]$^+$, 655 [M – Cl – Ind]$^+$. $C_{43}H_{35}ClFeP_2Ru$ (806.05): calcd. C 64.1, H 4.4; found C 64.3, H 4.1.

**Synthesis of [(Ind)Ru(tripod)]PF$_6$ ([4]PF$_6$):** $NaPF_6$ (20 mg, 0.12 mmol) and tripod (40 mg, 0.06 mmol) were added to a red solution of **1** (50 mg, 0.06 mmol) in toluene/THF (5:1, 12 mL). The mixture was refluxed for 4 h, during which the colour of the mixture changed from red to yellow. The resultant yellow suspension was filtered through Celite. The filtrate was concentrated to about 5 mL. Addition of ether (2 mL) gave yellow microcrystals, [(Ind)-Ru(tripod)]$PF_6$ ([**4**]$PF_6$), after 1 d at –30 °C (51 mg, 83% yield). X-ray diffraction-quality crystals were obtained from a saturated solution of [**4**]$PF_6$ in $CH_2Cl_2$ with ether layering after 2 d at –30 °C.

**Data for [4]PF$_6$:** $^1$H NMR (300 MHz, $CD_3CN$): $\delta$ = 1.56–1.57 (m, 3 H, Me), 2.39 (br. s, 6 H, $CH_2$), 5.51 (d, $^3J_{HH}$ = 2.5 Hz, 2 H, H$^{2,3}$), 5.70 (t, $^3J_{HH}$ = 2.5 Hz, 1 H, H$^1$), 6.78–6.82 (br. s, 12 H, Ph), 7.04 (t, $^3J_{HH}$ = 7.4 Hz, 12 H, Ph), 7.22 (t, $^3J_{HH}$ = 7.4 Hz, 6 H, Ph), 7.31–7.34 and 7.43–7.47 (each m, 2 H, H$^{4–7}$) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 39.9 (s, tripod), –142.9 (septet, $PF_6$) ppm. IR (KBr): $\tilde{\nu}$ = 058 (w), 2923 (w), 2868 (w), 1482 (w), 1434 (m), 1092 (m), 839 [vs. ($PF_6$)], 744 (m), 697 (s), 557 [m ($PF_6$)], 517 (s) $cm^{-1}$. FAB$^+$-MS: *m*/*z* (%) = 841 [M]$^+$. FAB$^–$-MS: *m*/*z* (%) = 145 [$PF_6$]$^–$. $C_{50}H_{46}F_6P_4Ru$ (985.86): calcd. C 60.9, H 4.7; found C 60.5, H 5.2.

**Synthesis of [(Ind)Ru{(*R*)-(*S*)-Josiphos}Cl] (5):** (*R*)-(–)-1-[(*S*)-2-(Diphenylphosphanyl)ferrocenyl]ethyldicyclohexylphosphane {(*R*)-(*S*)-Josiphos} (23 mg, 0.04 mmol) was added to a red solution of **1** (30 mg, 0.04 mmol) in toluene (5 mL) and the mixture was refluxed. The reaction was monitored using $^{31}$P NMR spectroscopy. Refluxing was ceased when the ratio of starting materials and product remained constant (about 8 h). The solution was concentrated to about 2 mL and loaded onto a silica gel column (2 × 8 cm) prepared in *n*-hexane. Elution gave three fractions: (i) a yellow eluate in hexane/diethyl ether (1:1, about 4 mL), which recovered free (*R*)-(*S*)-Josiphos (2 mg, 9% recovery); (ii) an orange-red solution in hexane/diethyl ether (1:1, about 15 mL), which yielded [(*R*)-(Ind)-Ru{(*R*)-(*S*)-Josiphos}Cl] [(*R*)-**5**] (12 mg, 37% yield) as orange solids; and (iii) a red solution in THF (about 3 mL), which recovered unreacted **1** (2 mg, 7% recovery).

**Data for (*R*)-5:** $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 0.87–1.10 (br. m, 6 H, Cy), 1.24–1.56 (br. m) with 1.47 (dd, sitting on top of br. m, $^3J_{HH}$ = 7.41, $^2J_{HP}$ = 9.9 Hz, total 11 H, Cy and Me), 1.63–1.68 (br. m, 1 H, Cy), 1.76–1.85 (br. m, 2 H, Cy), 1.94–1.98 (br. m, 2 H, Cy), 2.18–2.32, 2.37–2.50 and 2.60–2.68 (each br. m, 1 H, Cy), 3.68 (s, 5 H, Cp), 4.06 (t-linked m, 1 H, Cp), 4.19 and 4.23 (each br. s, 1 H, Cp), 5.22–5.29 [m, 1 H, C*H*MeP(Cy)$_2$], 5.34 (s, 1 H, H$^1$), 5.73 (s, 2 H, H$^{2,3}$), 6.89–6.94, 6.99–7.08, 7.11–7.16, 7.24–7.30, 7.44–7.49, 7.52–7.59 and 7.75–7.78 (each m, total 14 H, H$^{4–7}$ and Ph) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 36.0 (d, $^2J_{PP}$ = 53.4 Hz, Josiphos), 77.3 (d, $^2J_{PP}$ = 53.4 Hz, Josiphos) ppm. FAB$^+$-MS: *m*/*z* (%) = 846 [M]$^+$, 812 [M – Cl]$^+$. $C_{45}H_{51}ClFeP_2Ru$ (846.20): calcd. C 63.9, H 6.1; found C 63.9, H 6.3.

**Synthesis of [CpRu{(*R*)-(*S*)-Josiphos}Cl] (6):** (*R*)-(*S*)-Josiphos (18 mg, 0.03 mmol) was added to a yellow solution of **1a** (30 mg, 0.04 mmol) in toluene (5 mL) and the mixture was refluxed for 8 h. The solvent was removed in vacuo and the residue extracted using ether (3 × 2 mL).

**Purification Method (i):** The ether extract was concentrated to about 1 mL and loaded onto a silica gel column (2 × 4 cm) prepared in *n*-hexane. Elution gave two fractions: (i) a yellow eluate in hexane/diethyl ether (5:1, about 20 mL), which yielded [(*R*)-CpRu{(*R*)-(*S*)-Josiphos}Cl] [(*R*)-**6**] (28 mg, 85% yield) as orange microcrystals; and (ii) a yellow solution in hexane/diethyl ether (1:1, about 3 mL), which gave unreacted **1a** (6 mg, 20% recovery).

**Purification Method (ii):** The ether extract was concentrated to about 1 mL and hexane was added (about 2 mL). Orange solids of **1a** were recovered after 1 d at –30 °C, and removed by filtration (5 mg, 16% recovery). The mother liquor was concentrated to about 1 mL and hexane was added (about 4 mL). Orange yellow

solids of (*R*)-**6** were obtained after 1 d at –30 °C (15 mg, 46% yield). Subsequently, four additional crops of (*R*)-**6** were obtained, each about 3 mg (total 11 mg, 34% yield). X-ray diffraction-quality crystals were obtained from a concentrated ether solution with hexane layering after a day at –30 °C.

**Data for (*R*)-6:** $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 0.61–0.77 (br. m, 2 H, Cy), 1.29–1.55 (br. m) with 1.52 (dd, sitting on top of br. m, $^3J_{HH}$ = 7.41, $^2J_{HP}$ = 9.06 Hz, total 13 H, Cy and Me), 1.65–1.92 (br. m, 6 H, Cy), 2.09–2.18 and 2.41–2.46 (each br. m, 2 H, Cy), 3.79 (s, 5 H, Cp), 4.11 (t, $^3J_{HH}$ = 2.49 Hz, 1 H, Cp), 4.27 and 4.30 (each br. s, 1 H, Cp), 4.49 (s, 5 H, $\eta^5$-*Cp*Ru), 5.23–5.34 [m, 1 H, C*H*MeP(Cy)$_2$], 6.85–6.90 and 7.20–7.23 (each m, 1 H, Ph), 6.93–6.97, 7.01–7.06 and 7.31–7.36 (each m, 2 H, Ph), 8.71 (br. s, 2 H, Ph) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 37.5 (d, $^2J_{PP}$ = 53.4 Hz, Josiphos), 67.2 (d, $^2J_{PP}$ = 53.4 Hz, Josiphos) ppm. FAB$^+$-MS: *m*/*z* (%) = 846 [M]$^+$, 812 [M – Cl]$^+$. $C_{41}H_{49}ClFeP_2Ru\cdot(CH_3CH_2)_2O$ (870.26): calcd. C 62.1, H 6.8; found C 62.2, H 6.8.

**Epimerisation Kinetics:** Complex **1a** [2.4 mg, 3.3 mmol (reaction **A**); 3.6 mg, 5 mmol (reaction **B**); 5.4 mg, 7.5 mmol (reaction **C**)] and (*R*)-(*S*)-Josiphos (3.0 mg, 5.0 mmol) were added to three different NMR tubes in three different ratios, that is, 1:1.5, 1:1 and 1.5:1. [D$_8$]toluene (0.5 mL) was added into each NMR tube. The initial $^1$H and $^{31}$P NMR spectrum of each reaction mixture was measured, and then at intervals during the reaction at 100 °C. The concentration of each component in the reaction mixtures was obtained from the integration of the Cp protons of the Josiphos [$\delta$ = 3.71 in (*R*)-**6** and $\delta$ = 3.89 in (*S*)-**6**], using as internal standard the residual 0.1% H-signal of 99.9% [D$_8$]toluene.

**Synthesis of [(Ind)Ru(dppf)(CH$_3$CN)]PF$_6$ ([7]PF$_6$):** $NaPF_6$ (16 mg, 0.09 mmol) was added to a red suspension of **3** (50 mg, 0.06 mmol) in $CH_3CN$ (10 mL) and the mixture was refluxed. The colour of the suspension changed slowly from red to yellow in 4 h. The suspension was filtered and the filtrate was evacuated to dryness. The residue was redissolved in THF (about 4 mL) and hexane (about 2 mL) was added. Yellow crystals of [(Ind)Ru(dppf)(CH$_3$CN)]PF$_6$ ([7]PF$_6$) (55 mg, 93% yield) were obtained after 1 d at –30 °C.

**Data for [7]PF$_6$:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 2.15 (s, 3 H, C*H*$_3$CN), 4.22, 4.33 and 4.35 (each s, 2 H, $C_5H_4$), 4.44 (br. s, 3 H, $C_5H_4$ and H$^1$), 4.60 (d, $^3J_{HH}$ = 2.5 Hz, 2 H, H$^{2,3}$), 6.63–6.66 and 7.18–7.21 (each 4-line m, 2 H, H$^{4–7}$), 6.82–6.88, 7.28–7.33, 7.40–7.52 (m, 20 H, Ph) ppm. $^{31}$P{$^1$H} NMR: $\delta$ = 50.7 (s, dppf), –144.1 (septet, $PF_6$) ppm. IR (KBr): $\tilde{\nu}$ = 055 (w), 2974 (w), 2057 (w), 2276 [w (CN)], 1481 (m), 1435 (m), 1158 (m), 1092 (m), 840 [vs. ($PF_6$)], 749 (s), 699 (s), 557 [s ($PF_6$)], 514 (m) cm$^{-1}$. FAB$^+$-MS: *m*/*z* (%) = 812 [M]$^+$, 771 [M – $CH_3CN$]$^+$, 655 [M – $CH_3CN$ – $C_9H_7$]$^+$. FAB$^-$-MS: *m*/*z* (%) = 145 [$PF_6$]$^-$. $C_{45}H_{38}F_6FeNP_3Ru\cdot$½$CH_3CN$ (977.16): calcd. C 56.5, H 4.0, N 2.2; found C 56.0, H 3.9, N 2.1.

**Synthesis of [(Ind)Ru(dppf)N$_3$] (8):** $NaN_3$ (20 mg, 0.3 mmol) was added to a red suspension of **3** (50 mg, 0.06 mmol) in EtOH (10 mL) and the mixture was refluxed for 4 h. The solvent was removed in vacuo and the red residue extracted using $CH_2Cl_2$ (2 × 4 mL). The extract was concentrated to about 3 mL and hexane (about 10 mL) was added. After being kept overnight at –30 °C, red crystals of [(Ind)Ru(dppf)N$_3$] **8** (43 mg, 85% yield) were obtained. X-ray diffraction-quality crystals were obtained from a saturated solution in $CH_2Cl_2$ with hexane layering after 2 d at –30 °C.

**Data for 8:** $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 3.79, 4.05, 4.21 and 4.29 (each s, 2 H, $C_5H_4$), 4.58 (s, 1 H, H$^1$), 4.79 (s, 2 H, H$^{2,3}$), 7.09–7.12, 7.14–7.23, 7.26–7.29, 7.39–7.44, 7.47–7.52 (each m, total 24

H, H$^{4-7}$ and Ph) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 52.5 (s, dppf) ppm. IR (KBr): $\tilde{\nu}$ = 053 (w), 2025 [vs. ($N_3$)], 1433 (w), 1159 (w), 1091 (w), 1034 (w), 745 (m), 697 (m), 513 (m) cm$^{-1}$. FAB$^+$-MS: *m*/*z* (%) = 785 [M – $N_2$]$^+$, 771 [M – $N_3$]$^+$, 670 [M – Ind – $N_2$]$^+$, 655 [M – Ind – $N_3$]$^+$. $C_{43}H_{35}FeN_3P_2Ru$ (812.62): calcd. C 63.6, H 4.3, N 5.2; found C 63.5, H 4.8, N 5.2.

**Synthesis of [(Ind)Ru(dppf){$N_3C_2(CO_2Me)_2$}] (9):** Dimethyl acetylenedicarboxylate (38 μL, 0.31 mmol) was added into a red solution of **8** (50 mg, 0.06 mmol) in $CH_2Cl_2$ (10 mL) and the reaction mixture was stirred at room temperature for 24 h. The colour of the solution slowly changed from red to orange-red. The solution was concentrated to about 2 mL and hexane (8 mL) was added. Yellow crystals [(Ind)Ru(dppf){$N_3C_2(CO_2Me)_2$}] **9** (33 mg, 55% yield) were obtained after 18 h at –10 °C. X-ray diffraction-quality crystals were obtained from a saturated solution in $CH_2Cl_2$ with ether layering after 1 week at 4 °C.

**Data for 9:** $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 3.52 (s, 6 H, Me), 3.76, 4.10, 4.31 and 4.34 (each s, 2 H, $C_5H_4$), 4.78 (s, 1 H, H$^1$), 5.35 (s, 2 H, H$^{2,3}$), 6.86–6.90 (m, 2 H, H$^{4-7}$), 6.96–6.97, 7.16–7.43, 7.72–7.78 (each m, total 22 H, H$^{4-7}$ and Ph) ppm. $^{31}P\{^1H\}$ NMR: $\delta$ = 56.8 (s, dppf) ppm. IR (KBr): $\tilde{\nu}$ = 057 (w), 2945 (w), 1736 [vs. (C=O)], 1434 [m (N=N)], 1292 [m (C–O)], 1165 (m), 1087 (s), 772 (m), 697 (m), 508 (m) cm$^{-1}$. FAB$^+$-MS: *m*/*z* 955 [M]$^+$, 771 [M – $N_3C_2(CO_2Me)_2$]$^+$. $C_{49}H_{41}FeN_3O_4P_2Ru$ (954.73): calcd. C 61.6, H 4.3, N 4.4; found C 61.7, H 3.8, N 4.4.

**Crystal Structure Determinations:** Crystals were mounted on quartz fibres. X-ray data were collected on a Bruker AXS APEX system, using Mo-$K_\alpha$ radiation, with the SMART suite of programs.[27] Data were processed and corrected for Lorentz and polarisation effects with SAINT,[28] and for absorption effects with SADABS.[29] Structural solution and refinement were carried out with the SHELXTL suite of programs.[30] Crystal and structure refinement data are summarised in Tables 3 and 4. The structures were solved by direct methods or Patterson maps to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. All non-hydrogen atoms were generally given anisotropic displacement parameters in the final model.

CCDC-616431 to -616436 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# (Indenyl)ruthenium Complexes Containing 1,1′-Bis(diphenylphosphanyl)-ferrocene (dppf) and Thiolato Ligands: Synthesis, X-ray Structure Analysis, Electrochemistry and Magnetic Studies

**Sin Yee Ng,[a] Weng Kee Leong,*[a] Lai Yoong Goh,*[a] and Richard D. Webster[b]**

**Keywords:** (Indenyl)ruthenium / Thiolates / dppf / Cyclic voltammetry / ESR / Ruthenium

The reaction of [(Ind)Ru(dppf)Cl] (Ind = $\eta^5$-$C_9H_7$) (**2**) with RSNa {R = Me, Et, Ph, $Ph_2P(CH_2)_2$} proceeds in MeOH to give [(Ind)Ru(dppf)(SR)] {R = Me (**3**), Et (**4**), Ph (**5**), $Ph_2P(CH_2)_2$ (**7**)}, as well as [(Ind)Ru(dppf)H] (**6**), in all cases except for R = Ph. This R-dependence of the product mixture was rationalised on a $RS^-$/MeOH ↔ $MeO^-$/RSH equilibrium involving the interaction of thiolate ($RS^-$) with MeOH, and the relative nucleophilicities of $RS^-$ versus $MeO^-$; **6** arose from β-H elimination from an OMe derivative. Cyclic voltammetric measurements on **2**, **3**, **4** and **5**, as well as the Cp ($\eta^5$-$C_5H_5$) and Cp* ($\eta^5$-$C_5Me_5$) analogues of **2**, indicated that the formal oxidation potentials for [LRu(dppf)Cl] complexes {L = Ind (**2**), Cp (**2A**) and Cp* (**2B**)} occurred in the order Cp* < Ind < Cp, correlating with the more electron-donating groups lowering the oxidation potentials. EPR experiments performed on the one-electron oxidised forms of **3** and **5** indicated paramagnetic compounds with *g* values close to 2, while the two-electron oxidised forms of **3** and **5** were diamagnetic. All the complexes were characterised spectroscopically, and **5** and **6** also crystallographically.

## Introduction

The development of the chemistry of indenyl complexes of ruthenium(II) could be considered to date from the high-yield synthesis of [(Ind)Ru($PPh_3$)$_2$Cl] (Ind = $\eta^5$-$C_9H_7$) (**1**),[1] which superseded [(Ind)Ru(CO)$_2$]$_2$, a low-yield compound,[2] as the common source material for the synthesis of (indenyl)ruthenium complexes. A recently improved synthesis of [(Ind)Ru(COD)Cl][3] has provided yet another alternative starting material. The initial interest in the indenyl ligand stems from its resemblance to $\eta^5$-cyclopentadienyl Cp/Cp* ligands, the 'pillar' ligands of transition-metal organometallic chemistry; subsequent interest was heightened by the observation of the so-called indenyl effect, an enhancement of reactivity of the complex brought about by facile ring slippage from $\eta^5$ to $\eta^3$ involving aromatisation of the benzene ring.[4]

In the last decade Gimeno's group have carried out intensive studies, with emphasis on reactivity, including catalytic aspects, particularly of vinylidene and allenylidene derivatives of ruthenium half-sandwich complexes.[5] Prior to these, there had been limited reports from various groups on studies of indenyl complexes of Fe, followed by those of the Group 6, 7 and 9 metals.[6] Recently reports of a few (indenyl)Ru complexes carrying N-containing ligands have emerged,[7] but to date there is only one report of examples carrying S-donor ligands, viz. EtS and EtMeS.[8]

In recent work, we have performed a comparative study of the reactivity of [($\eta^6$-$C_6Me_6$)Ru(dppf)Cl] and [CpRu(dppf)Cl] (**2A**) with various nucleophiles, including S donor ligands.[9] It is therefore of interest to include the indenyl analogue of these in the comparison. This paper describes the reactions of [(Ind)Ru(dppf)Cl] (**2**) with simple alkyl/aryl monothiolates, $RS^-$ (R = Me, Et and Ph), to compare with reported analogous reactions of [(Ind)Ru($PPh_3$)$_2$-Cl] (**1**) with EtSNa,[8] and the comparative electrochemistry studies of [LRu(dppf)Cl] {L = Ind (**2**), Cp (**2A**) and Cp* (**2B**)} and [LRu(L′$_2$)Cl] (L = Ind, Cp and Cp*; L′$_2$ = dppm, dppe and dppf).

## Results and Discussion

[(Ind)Ru(dppf)Cl] (**2**) was synthesised from phosphane substitution of [(Ind)Ru($PPh_3$)$_2$Cl] (**1**), following a published procedure for the Cp analogue.[1]

### Chloro Substitution

#### *(a) Reaction of 2 with RSNa [R = Me (3), Et (4), Ph (5)] and Solvent Dependence*

The reaction of **2** with an excess of RSNa in alcoholic solvent (MeOH or EtOH) at room temperature gave

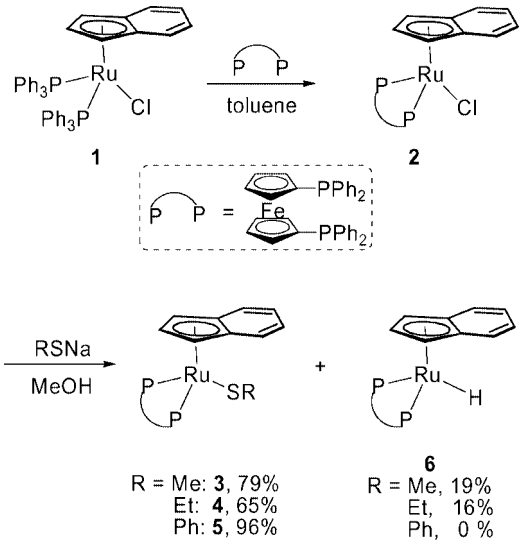
[(Ind)Ru(dppf)(SR)] in R-dependent yields. (NOTE: with 1 equiv. of RSNa, the reaction at r.t. did not reach completion even after 18 h.) In the cases of R = Me and Et, a hydride complex, [(Ind)Ru(dppf)H] (**6**), was also isolated in about 20% yield (Scheme 1).



Scheme 1.

The latter complex was not anticipated, as hydride formation was not reported in the preparation of [(Ind)-$Ru(PPh_3)_2(SEt)$] from the reaction in refluxing THF of [(Ind)$Ru(PPh_3)_2Cl$] (**1**) with NaSEt,[8] or in similar syntheses of [$CpRu(PPh_3)_2(SR)$] (R = 1-$C_3H_7$, $CHMe_2$ and 4-$C_6H_4Me$).[10] Very recently, Gimeno and co-workers obtained mono- and diphosphane analogues of **6** from the reaction of [(Ind)Ru(P-P)Cl] {P-P = diphosphanes (dppm, dppe) or bis($PR_3$)} with an excess of MeONa in MeOH.[11] The formation of metal hydrides from alkoxide precursors by β-hydrogen elimination is a well-established phenomenon.[12,13] Invoking the role of alkoxide in this reaction involving the use of thiolates in MeOH will require the participation of an equilibrium represented by Equation (1).

$$RS^- + MeOH \overset{K}{\rightleftharpoons} MeO^- + RSH \quad (1)$$

In such a situation the competition of nucleophiles $RS^-$ and $MeO^-$ in displacement of X from [(Ind)Ru(dppf)X] (X = Cl or MeOH) comes into play. This will depend on their relative nucleophilicities ($RS^- > MeO^-$), as well as the preponderance of one species over the other, a direct consequence of the equilibrium constant *K*. This is in agreement with the order of $pK_a$'s in MeOH of the thiols as follows: MeSH (14.3)[14] ≤ EtSH (14.4)[15] > PhSH (10.9).[16] Thus, under similar concentrations of reactants, [$MeO^-$] in equilibrium (2) from $PhS^-$ will be about two orders of magnitude lower than that from $RS^-$ (S = Me or Et). This is in agreement with the observed absence of metal hydride formation for the R = Ph case. When both $RS^-$ (R = Me and Et) and $MeO^-$ are present, the higher nucleophilicity of the former anions qualitatively accounts for the preponderance of metal thiolate over metal hydride products.

This postulation is in agreement with our observation that the reaction of **2** with MeSNa *will not proceed in THF*, despite refluxing for 2 h, but went to completion within 15 min at 65 °C upon addition of 1/5 volume of MeOH. We similarly carried out, on an NMR scale, Hidai's reaction of **1**, using MeSNa, and found that in refluxing THF, [(Ind)-$Ru(PPh_3)_2(SMe)$] was the only product, while in refluxing MeOH, the hydride species [(Ind)$Ru(PPh_3)_2H$] was also formed [$^1$H NMR ($C_6D_6$): $\delta$ = –15.39 (t, $^2J_{HP}$ = 33.8 Hz) vs. lit. values in $CDCl_3$: $\delta$ = –15.40 (t, $^2J_{HP}$ = 31.6 Hz)[1]]. This indicates that nucleophilic substitution of $Cl^-$ with $MeS^-$ in THF is feasible in **1** but not in **2**, suggestive of the presence of a stronger Ru–Cl bond, which necessitates assistance from MeOH for cleavage. It is likely that **2**, like [$CpRu(PPh_3)_2Cl$] (**1A**), the Cp analogue of **1**, shows appreciable ionic behaviour in MeOH, as shown in Equation (2).

$$[CpRu(PPh_3)_2Cl] + MeOH \rightleftharpoons [CpRu(PPh_3)_2(MeOH)]^+ + Cl^- \quad (2)$$

Indeed, the MeOH complex had been isolated as the $BPh_4^-$ salt,[17] and nucleophilic displacement of chloride in **1A** by nitriles, tertiary phosphanes or phosphites has been shown to proceed by displacement of the weakly bound MeOH.[18] Such a dissociative tendency of the Ru–Cl bond will facilitate the dissociative pathways found to operate in substitution reactions of both Cp and indenyl complexes of Ru.[19] Incidentally, we have noted that the majority of reported reactions of (Ind)Ru complexes have been carried out in MeOH. In this present system, we have also observed, in a small-scale NMR tube reaction, that the solvent derivative of **2**, [(Ind)Ru(dppf)($CH_3CN$)]$PF_6$ (**2S**), reacted with MeSNa in THF at r.t. to give **3** as the sole product. In fact, Stone and co-workers had established that increasing donor ability of phosphane ligands strengthens the Ru–Cl bond sufficiently that displacement of chloride in [$CpRu(L)_2Cl$] (L = phosphane) cannot be effected.[20] Hence the observed stronger Ru–Cl bond in **2** versus its Cp analogue **2A** and versus its bis($PPh_3$) analogue **1** [here dppf vs. $(PPh_3)_2$] is in agreement with the recent finding that the indenyl ligand is more electron-donating than Cp towards Ru,[13] as is also confirmed by CV measurements in this study (see cyclic voltammetric and EPR measurements section).

Complex **5** crystallises with one $CH_2Cl_2$ and 0.5 MeOH in the orthorhombic *Fdd*2 space group, while **6** crystallises in the monoclinic $P2_1/n$ space group. Their molecular structures are very similar to those of their respective Cp analogues,[9b,21] and are illustrated in the ORTEP diagrams shown in Figures 1 and 2. The metal centres are coordinated to $\eta^5$-Ind, $\eta^2$-dppf and $\eta^1$-thiophenolate/hydrido ligands. Selected bond parameters are compared with those of the Cp analogues in Table 1.

The Ru–S distances in **5** and its Cp analogue are comparable and longer than in other examples of Ru–S(thiolate) bonds [2.30 Å (av.)].[23] The Cp rings of dppf in **5** are almost eclipsed (*syn* periplanar) to each other, with a torsional angle ($\tau$) of 2.1°. The phenyl ring on thiophenolate is almost parallel to the phenyl ring on P1, while the phenyl ring of

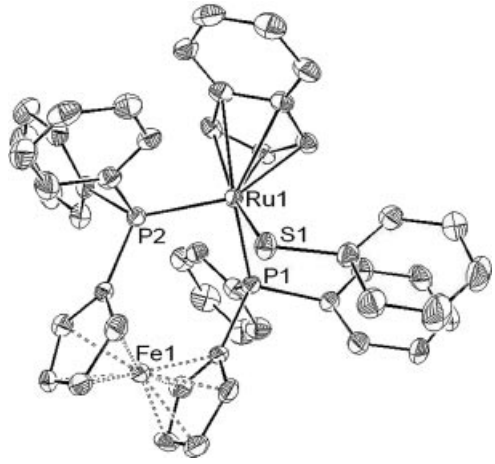

Figure 1. ORTEP diagram of **5**. Thermal ellipsoids are drawn to 50% probability level. Hydrogen atoms are omitted for clarity.

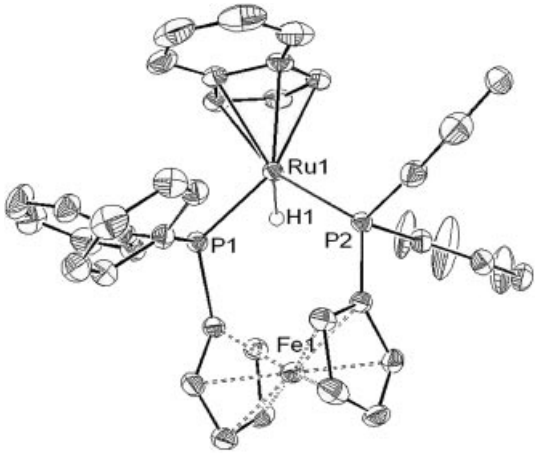

Figure 2. ORTEP diagram of **6**. Thermal ellipsoids are drawn to 50% probability level. Except for the metal hydride atom H1, all other hydrogen atoms are omitted for clarity.

thiophenolate in the Cp analogue points away from the phenyl rings on dppf. This is probably because of the steric bulk of the indenyl ligand, which restricts the orientation of the thiophenolate ligand in **5**.

The hydride ligand in **6** is located in the electron density map and refined with a Ru–H bond length of 1.499(6) Å and P–Ru–H angles of 80.19(2)° and 85.28(2)°. Compared to the eclipsed conformation in **5**, the Cp rings of the dppf in **6** adopt a more stable *syn* clinal (gauche) configuration. This is facilitated because the smaller terminal hydride relieves the steric stress around the Ru centre, enabling the dppf ligand to orientate to the lower-energy *syn* clinal configuration with a torsional angle ($\tau$) of 39.67°. The benzenoid ring of the indenyl ligand was predicted to arrange itself *trans* to the hydride, the higher *trans*-influence ligand,[4d] as shown in Figure 3.

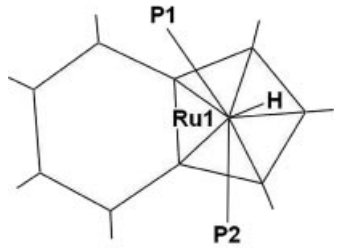

Figure 3. Top view of **6**.

### *(b) Reaction of 2 with the Mixed-Donor Ligand $^{-}S(CH_2)_2PPh_2$*

The reaction in MeOH of **2** with $Ph_2P(CH_2)_2S^-$, a 'hybrid' ligand with two coordinating sites, resulted in a mixture of [(Ind)Ru($\eta^2$-dppf){$\kappa^1$*S*-S$(CH_2)_2PPh_2$}] (**7**) and **6** in 54% and 15% yields respectively (Scheme 2), indicating an equilibrium between $Ph_2P(CH_2)_2S^-$ and $Ph_2P(CH_2)_2SH$ in MeOH. This reaction cannot be effected in THF at r.t. or at reflux, as previously observed. The amount of **6** isolated suggested that the p$K_a$ of $Ph_2P(CH_2)_2SH$ is similar to that of EtSH (see Scheme 1).

The $^1$H NMR and $^{31}$P NMR spectra of **7** indicate that the Ru centre is coordinated to $\eta^5$-Ind, $\eta^2$-dppf and $\kappa^1$*S*-2-(diphenylphosphanyl)ethylthiolate [$Ph_2P(CH_2)_2S^-$]; the coordinated phosphorus atoms of dppf resonate at $\delta$ = 56.1, while the low-field $^{31}$P signal ($\delta$ = –14.8 ppm) of the hybrid ligand pertains to a noncoordinating $PPh_2$ entity, in agreement with the higher nucleophilicity of thiolato sulfur, and hence its better coordinative capability to the Ru$^{II}$ centre when compared to phosphane P. The mixed-donor ligand

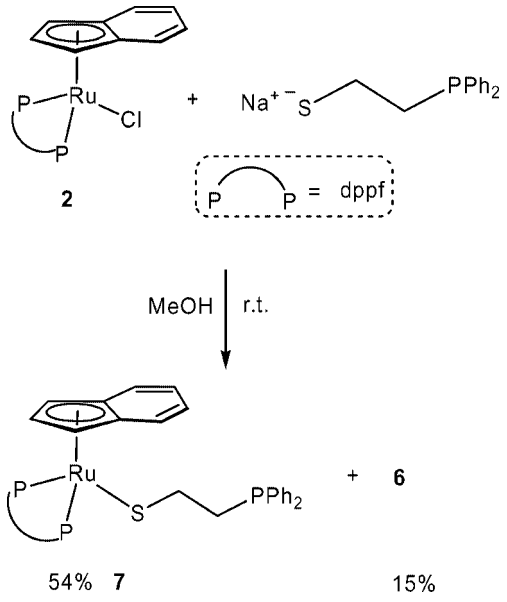

Scheme 2.

displaced neither the indenyl ligand nor dppf, indicating the stronger chelating effect of the dppf ligand versus $Ph_2P(CH_2)_2S^-$.

### Cyclic Voltammetric and EPR Measurements

Cyclic voltammograms obtained at a GC electrode in 0.5 mM solutions of **3**, **4**, **5**, **2**, **2A** and **2B** in $CH_2Cl_2$ at 233 K are shown in Figure 4. On the CV timescale, complexes **3**, **4** and **5** displayed chemically reversible oxidation processes at low temperatures, although at room temperature the third (most-positive) oxidation processes were only partially chemically reversible, suggesting chemical instability of the triply oxidised species. The expression "chemical reversibility", when used in connection with cyclic voltammetry experiments, relates to the ratio of the oxidative ($i_p^{ox}$) to reductive peak currents ($i_p^{red}$). The $i_p^{ox}/i_p^{red}$ ratio approaches unity for a fully chemically reversible process.

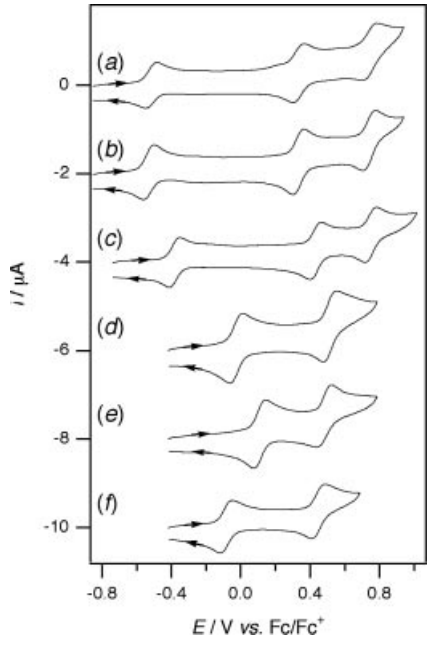

Figure 4. Cyclic voltammograms performed at a 1-mm diameter planar GC electrode in $CH_2Cl_2$ (0.25 M $Bu_4NPF_6$) at 233 K at a scan rate of 100 mV s$^{-1}$ for 0.5 mM (a) **3**, (b) **4** (c) **5**, (d) **2**, (e) **2A** and (f) **2B**. CVs in (b), (c), (d), (e) and (f) are offset by –2, –4, –6, –8 and –10 µA respectively.

Complexes **2**, **2A** and **2B** displayed two chemically reversible oxidation processes, except for **2A**, where the second more positive process was only partially chemically reversible at a scan rate of 100 mV s$^{-1}$ (suggesting instability of the more highly oxidised state). At scan rates >100 mV s$^{-1}$, the $i_p^{ox}/i_p^{red}$ ratio for the second process of **2A** became closer to one. Complexes **3**, **4** and **5** also displayed one chemically irreversible reduction process at about –2.5 V versus $Fc/Fc^+$ (data not shown), with a similar current magnitude to the first oxidation process (indicating that the same number of electrons were transferred).

Table 2 lists the reversible oxidation potentials ($E^r_{1/2}$) that were calculated from CV data under conditions where the $i_p^{ox}/i_p^{red}$ ratios were equal to unity and using the relationship (3)

$$E^r_{1/2} = (E_p^{ox} + E_p^{red})/2 \quad (3)$$

where $E_p^{ox}$ and $E_p^{red}$ are the anodic and cathodic peak potentials, respectively. In situations where no reverse peak was observed, only the peak potential is given. Voltammetric data from reports on several other related compounds are also given in Table 2. The $\Delta E$ values for several of the literature compounds are very large (>>100 mV), indicating complicated electrochemical behaviour, and suggesting that the reported $E^r_{1/2}$ values do not correspond closely to the formal potentials.

In most instances where the $E_p^{ox}$ and $E_p^{red}$ peak separation ($\Delta E$) could be measured, the values obtained were close to that expected for a one-electron transfer (Table 2). There were some variations detected in the peak current intensities for equivalent concentrations of different compounds (Figure 4), but this is likely to be due to differences in diffusion coefficients, as the peak currents appear to approximately inversely correlate with the size of the molecules. Coulometry measurements made during exhaustive controlled potential electrolysis (CPE) experiments at 233 K for the first oxidation process of **3** and **5**, at applied potentials 100 mV more positive than the $E^r_{1/2}$ values, confirmed the transfer of one electron per molecule, see Equation (4) in the Exp. Sect. The one-electron oxidised species were stable for at least 2–3 h at 233 K in $CH_2Cl_2$ and could be reversibly reduced back to their starting materials. The electrolysis experiments were performed at low temperatures to ensure increased stability of the oxidised compounds (compared to at ambient temperatures).

Free dppf is oxidised at about +200 mV more positive than ferrocene.[24] The product of this one-electron oxidation is not as stable as the $Fc/Fc^+$ system and moderate scan rates of around 3 V s$^{-1}$ are needed to obtain $i_p^{ox}/i_p^{red}$ ratios equal to unity.[24] When dppf is coordinated to other

[a] All potentials are relative to the $Fc/Fc^+$ redox couple. Data from literature reports[13,27] that were vs. SCE have been converted to vs. $Fc/Fc^+$ by adding 0.46 V (corrections for differences in temperature have not been made). [b] $E_p^{ox}$ = oxidative peak potential. [c] $E_p^{red}$ = reductive peak potential. [d] $E^r_{1/2} = (E_p^{ox} + E_p^{red})/2$. [e] $\Delta E = |E_p^{ox} - E_p^{red}|$.

metal ions through the phosphorus atoms, the oxidation potential increases to about +0.5 V versus $Fc/Fc^+$ and the stability of the oxidised dppf is substantially improved so that $i_p^{ox}/i_p^{red}$ ratios equal to unity are obtained at slow scan rates of 100 mV s$^{-1}$ (similar to $Fc/Fc^+$).[24,25] In the light of these previous observations,[24,25] we conclude that the oxidation process that occurs at +0.32–0.51 V versus $Fc/Fc^+$ in the CV's of **3**, **4**, **5**, **2**, **2A** and **2B** (i.e., the second process) is likely to be associated with the one-electron oxidation of [dppf] to $[dppf]^+$. Therefore, the first oxidation process observed in the CV's in Figure 4 is associated with the formal oxidation of $Ru^{2+}$ to $Ru^{3+}$ (although it is likely some electron delocalisation occurs). The conclusion that the first process is associated with localised oxidation of the Ru centre is consistent with a similar first oxidation potential for **3**, **4** and **5** (ca. –0.45 V vs. $Fc/Fc^+$) and for **2**, **2A** and **2B** (ca. 0 V vs. $Fc/Fc^+$) (Figure 4), as the potential is likely to be most sensitive to the substituents coordinated directly to the ruthenium. The third oxidation process for **3**, **4** and **5** is possibly again centred on the ruthenium ion, as an $Ru^{3+}$-to-$Ru^{4+}$ redox transformation is to be expected (although the exact location of the oxidation process is difficult to determine from CV experiments). Complexes **2**, **2A** and **2B** may also be further oxidised, but at a more positive potential than **3**, **4** and **5** (additional oxidation processes were not detected within the solvent/electrolyte potential window).

The $E^r_{1/2}$ values of the complexes (Table 2) indicate ease of oxidation of the complexes as follows: for [LRuCl(dppf)] complexes (L = Ind, Cp and Cp*), Cp* < Ind < Cp, in agreement with the decreasing electron-donor capability of the corresponding ligands. Similar trends have been observed for the dppe, dppm, $(PPh_3)_2$ and $(PMe_2Ph)_2$ analogues.[13,27] The data also show [(Ind)RuCl(dppf)SMe] (**3**) is more easily oxidised than its Ph analogue **5**, in agreement with decrease of electron density at the metal centre in **5**, caused by delocalisation into the Ph ring.

EPR experiments were performed at 10 K on frozen samples of $\mathbf{3}^+$ and $\mathbf{5}^+$ that were produced by electrochemically oxidising the starting materials by one electron at a constant potential at 233 K (Figure 5). The spectrum obtained for $\mathbf{5}^+$ showed additional hyperfine structure, suggesting that the unpaired electron was partially delocalised, possibly on the Ph group bonded to the S. Complex $\mathbf{3}^+$ did not display hyperfine structure, possibly because the unpaired electron was less able to be accommodated about the methyl group bonded to the sulfur. Interaction of the unpaired electron with the $^{31}P$ atoms ($I$ = ½, 100% abundance) is also possible, as has been observed in diastereomeric [($\eta^6$-arene)$Ru^{III}$(P-As)Cl] complexes in which the ruthenium atom is a chiral stereocentre.[26] EPR spectra of $\mathbf{3}^+$ or $\mathbf{5}^+$ were not detected at room temperature, indicting that the unpaired electron was mainly localised on the metal ion,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rather than on the organic ligands. The further one-electron oxidation of $\mathbf{3}^+$ and $\mathbf{5}^+$ at 233 K (two electrons overall) produced compounds that did not give an EPR signal at 10 K and above, either because they were diamagnetic or were paramagnetic with rapid relaxation times. Complex $\mathbf{4}^+$ was not examined by EPR spectroscopy because the cyclic voltammetry experiments indicated that its electrochemical behaviour was essentially identical to $\mathbf{3}^+$ (Figure 4).

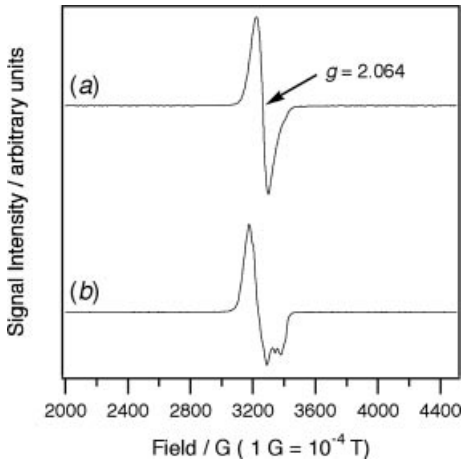

Figure 5. Continuous wave X-band EPR spectra obtained at 10 K with microwave frequency of 9.44 GHz and microwave power of 0.2 mW after the exhaustive electrochemical one-electron oxidation of (a) **3** to $\mathbf{3}^+$ and (b) **5** to $\mathbf{5}^+$ at –0.2 V vs. $Fc/Fc^+$ in $CH_2Cl_2$ (with 0.25 M $Bu_4NPF_6$) at 233 K.

Cyclic voltammograms of [(Ind)Ru(dppf)H] **6** obtained in $CH_2Cl_2$ solutions at 233 K at a GC electrode are displayed in Figure 6. The compound displayed two chemically reversible (or quasireversible) oxidation processes at about –0.3 and –0.1 V versus $Fc/Fc^+$. The second oxidation process had smaller peak currents than the first process, which may be caused by interactions between the oxidised compound and the electrode surface. On a Pt electrode, only one drawn out oxidation process was detected between –0.2 and 0.2 V, indicating that the oxidation processes were strongly influenced by the nature of the electrode surface. The cyclic voltammetry significantly changed from that shown in Figure 6 as the temperature was raised,

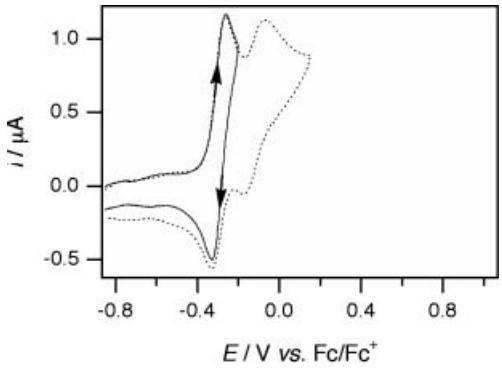

Figure 6. Cyclic voltammograms recorded at 100 $mV s^{-1}$ of a 1.2 mM $CH_2Cl_2$ solution of **6** with 0.5 M $Bu_4NPF_6$ at a 1-mm planar GC electrode at 233 K.

because of instability of oxidised **6** in $CH_2Cl_2$. At 293 K, only one chemically irreversible oxidation process was detected at about +0.6 V versus $Fc/Fc^+$.

[(Ind)Ru(dppf)H] (**6**) was approximately 0.3 V easier to oxidise than the corresponding Cl complex, [(Ind)Ru(dppf)-Cl] (**2**) (Table 2), which is a similar trend seen for other $\eta^5$ organometallic compounds containing the dppf ligand and Cl or H.[28]

## Conclusions

Chloro substitution of [(Ind)Ru(dppf)Cl] (**2**) with thiolates ($RS^-$) in MeOH was found to yield both thiolato derivatives and a hydrido complex, [(Ind)Ru(dppf)H] (**6**), the yield of which is both solvent- and R-dependent. From observations that the reaction could not proceed in the absence of MeOH, it was rationalised that **6** was formed by β-H elimination from ligated $MeO^-$, the latter being formed in equilibrium amounts by an interaction between $RS^-$ and MeOH. The product mixture therefore reflected the relative nucleophilicity of $RS^-$ and $MeO^-$. Voltammetry experiments indicated that the formal oxidation potentials for [LRu(dppf)Cl] compounds (L = Ind, Cp and Cp*) occurred in the order Cp* < Ind < Cp, with a 200 mV difference between the Cp* and Cp compounds. For [(Ind)Ru(L′)Cl] compounds {L′ = dppm, dppe, dppf, $(PPh_3)_2$}, the formal potentials decreased in the order dppm < dppe/dppf < $(PPh_3)_2$, although the total difference in oxidation potential spanning all the different diphosphanes [(Ind)Ru(L′)Cl] was a relatively small 60 mV. EPR experiments on $\mathbf{3}^+$ and $\mathbf{5}^+$ at 10 K indicated that the monocations were paramagnetic and the dications were EPR silent.

## Experimental Section

**General:** All reactions were carried out using conventional Schlenk techniques under inert nitrogen or argon in an M. Braun Labmaster 130 Inert Gas System.

NMR spectra were measured with a Bruker 300 FT NMR spectrometer; for $^1H$ and $^{31}P$ spectra, chemical shifts were referenced to residual solvent in the deuterio-solvents. IR spectra in KBr pellets were measured in the range 4000–400 $cm^{-1}$ by means of a BioRad FTS-165 FTIR instrument. Mass spectra were run on a Finnigan Mat 95XL-T (FAB) or a Finnigan-MAT LCQ (ESI) spectrometer. Elemental analyses were performed by the microanalytical laboratory in-house.

[(Ind)Ru($PPh_3$)$_2$Cl] (**1**)[1] and $Ph_2P(CH_2)_2SH$[29] were prepared by published methods. [(Ind)Ru(dppf)Cl] (**2**) was synthesised from phosphane substitution of **1**, while [(Ind)Ru(dppf)($CH_3CN$)]$PF_6$ (**2S**) was derived from **2** by reaction with $NaPF_6$ in refluxing $CH_3CN$.[30] All other chemicals were obtained commercially and used without any further purification. All solvents were dried with sodium/benzophenone and distilled before use. Celite (Fluka AG) and silica gel (Merck Kieselgel 60, 230–400 mesh) were dried at 140 °C overnight before chromatographic use.

**Electrochemical Studies:** Voltammetric experiments were conducted with a computer-controlled Eco Chemie µAutolab III potentiostat. Solutions of electrogenerated compounds for the EPR experiments

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were prepared in a divided controlled potential electrolysis cell separated with a porosity no. 5 (1.0–1.7 μm) sintered glass frit. The working and auxiliary electrodes were identically sized Pt mesh plates symmetrically arranged with respect to each other. A silver wire reference electrode (isolated by a salt bridge containing 0.5 M $Bu_4NPF_6$ in $CH_3CN$) was positioned to within 2 mm of the surface of the working electrode. The electrolysis cell was jacketed in a glass sleeve and cooled to 233 K (for improved stability of the oxidised compounds) using a Lauda RL6 variable temperature methanol-circulating bath. The volumes of both the working and auxiliary electrode compartments were approximately 20 mL each. The number of electrons transferred during the bulk oxidation process was calculated from Equation (4)

$$N = Q/nF \quad (4)$$

where $N$ is the number of mols of the starting compound, $Q$ is the charge (coulombs), $n$ is the number of electrons and $F$ is the Faraday constant (96485 C mol$^{-1}$). The electrolysed solutions were transferred under vacuum into cylindrical 3-mm (id) EPR tubes that were immediately frozen in liquid $N_2$. EPR spectra were recorded with a Bruker ESP 300e spectrometer in a $TE_{102}$ cavity at 10 K using liquid He cooling.

**Synthesis of [(Ind)Ru(dppf)(SR)] {R = Me (3), Et (4), Ph (5)}:** RSNa {0.25 mmol: R = Me, 17 mg; R = Et [freshly prepared in situ from EtSH (19 μL) and MeONa obtained from 6 mg Na in 2 mL MeOH]; R = Ph, 33 mg} was added to a red suspension of [(Ind)-Ru(dppf)Cl] (**2**) (50 mg, 0.062 mmol) in MeOH (5 mL) and the mixture was stirred, whereupon the colour of the suspension changed immediately to green. After stirring at r.t. for 18 h, the solvent was removed in vacuo and the residue was extracted using toluene (2 × 5 mL). The extract was concentrated to about 2 mL and then loaded onto a silica gel column (2 × 5 cm) prepared in *n*-hexane. Elution gave two fractions: (i) a yellow eluate in toluene (about 8 mL), which yielded [(Ind)Ru(dppf)H] (**6**) (for the reaction in which R = Me, 9 mg, 19% yield; R = Et, 8 mg, 16% yield); (ii) a green eluate in toluene/THF (20:1, about 10 mL), which yielded [(Ind)Ru(dppf)(SR)] {R = Me (**3**), 40 mg, 79% yield; R = Et (**4**), 33.5 mg, 65% yield; R = Ph (**5**), 52 mg, 96% yield}; (iii) an orange-red eluate in THF (3 mL), which gave **2** in trace amounts.

Compound **3** was also formed from the reaction of [(Ind)-Ru(dppf)($CH_3CN$)]$PF_6$ (**2S**) with MeSNa as follows: MeSNa (2 mg, 0.029 mmol) was added to a yellow solution of **2S** (5 mg, 0.005 mmol) in THF (2 mL) and the mixture was stirred at r.t. The colour of the mixture slowly changed from yellow to green in 4 h. The $^1$H and $^{31}$P NMR spectra of an aliquot of the product mixture showed the sole presence of **3**.

**Data for 3:** $^1$H NMR ($C_6D_6$): $\delta$ = 1.96 (s, 3 H, SMe), 3.36, 3.89, 3.92 and 4.06 (each s, 2 H, $C_5H_4$), 5.29 (s, 1 H, Ind), 5.60 (s, 2 H, Ind), 7.04–7.58 (m, 24 H, Ind and Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 56.0 (s, dppf) ppm. FAB$^+$-MS: *m*/*z* (%) = 818 [M]$^+$, 771 [M – SMe]$^+$, 655 [M – SMe – Ind]$^+$. $C_{44}H_{38}FeP_2RuS$ (817.70): calcd. C 64.6, H 4.7, S 3.9; found C 64.7, H 4.8, S 3.9.

(*Note:* The proton resonances of the five-membered ring of Ind in this complex, as in others in this work, appear as singlets, although couplings are anticipated, most probably because these are too small to be resolved using the 300-MHz instrument.)

**Data for 4:** $^1$H NMR ($C_6D_6$): $\delta$ = 1.62 (t, $^3J_{HH}$ = 7.4 Hz, 3 H, $SCH_2CH_3$), 2.16 (q, $^3J_{HH}$ = 7.4 Hz, 2 H, $SCH_2CH_3$), 3.63, 3.89, 3.94 and 4.06 (each s, 2 H, $C_5H_4$), 5.27 (s, 1 H, Ind), 5.70 (s, 2 H, Ind), 7.04–7.57 (m, 24 H, Ind and Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 56.1 (s, dppf) ppm. FAB$^+$-MS: *m*/*z* (%) = 832 [M]$^+$, 771 [M – SEt]$^+$, 655 [M – SEt – Ind]$^+$. $C_{45}H_{40}FeP_2RuS$ (831.73): calcd. C 65.0, H 4.9, S 3.9; found C 65.5, H 5.1, S 3.4.

**Data for 5:** $^1$H NMR ($C_6D_6$): $\delta$ = 3.62, 3.79, 3.88 and 4.06 (each s, 2 H, $C_5H_4$), 5.25 (s, 1 H, Ind), 5.64 (s, 2 H, Ind), 6.38–6.40, 6.94–6.97 (each 4-line m, 2 H, Ind), 7.04–7.58 (m, 20 H, Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 54.9 (s, dppf) ppm. FAB$^+$-MS: *m*/*z* (%) = 880 [M]$^+$, 771 [M – SPh]$^+$, 655 [M – SPh–Ind]$^+$. $C_{49}H_{40}FeP_2RuS$ (879.77): calcd. C 66.9, H 4.6, S 3.6; found C 67.3, H 4.8, S 4.1.

**Small-Scale Reactions of 1 with MeSNa in MeOH and THF – Effect of Solvent:** MeSNa (2 mg, 0.029 mmol) was added to a red solution or suspension of **1** (5 mg, 0.006 mmol) in the selected solvent (1 mL), and the mixture was refluxed. After the reaction, the product mixture was evacuated to dryness and the respective residues extracted with toluene, for examination by $^1$H and $^{31}$P NMR spectroscopy.

(i) In MeOH: A reflux for 1 h produced a suspension of dark green solids in a faint yellow supernatant. The spectra indicated the product was a mixture of [(Ind)Ru($PPh_3$)$_2$(SMe)] (**3P**) and the hydride species [(Ind)Ru($PPh_3$)$_2$H] [$^1$H NMR ($C_6D_6$): $\delta$ = –15.39 ppm (t, $^2J_{HP}$ = 33.8 Hz), cf. lit. values in $CDCl_3$: $\delta$ = –15.40 ppm (t, $^2J_{HP}$ = 31.6 Hz)[1]] in the ratio of 1:1.

(ii) In THF: The solution changed slowly to dark green during reflux (2 h). The spectra indicated that [(Ind)Ru($PPh_3$)$_2$(SMe)] (**3P**) was the sole product.

**Data for 3P:** $^1$H NMR ($C_6D_6$): $\delta$ = 2.23 (s, 3 H, SMe), 4.30 (s, 2 H, Ind), 5.22 (s, 1 H, Ind), 6.88–7.47 (m, 34 H, Ind and Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 50.2 (s, $PPh_3$) ppm.

**Reaction of 2 with MeONa (in THF/MeOH):** Complex **2** (10 mg, 0.012 mmol) as a red solid was added to a suspension of dry MeONa [freshly prepared from Na (6 mg, 0.26 mmol) in MeOH (4 mL)] in THF (5 mL), and the slurry stirred at r.t. The $^1$H and $^{31}$P NMR spectra in $C_6D_6$ of aliquots of the reaction mixture at 2 h, and after reflux for an additional 4 h, revealed that the reaction did not proceed. MeOH (1 mL) was then added into the mixture and stirring continued at r.t. A slow colour change from orange-red to yellow occurred within 1 h. The $^1$H and $^{31}$P NMR spectra of an aliquot in $C_6D_6$ showed the formation of **6** as the sole product.

**Data for 6:** $^1$H NMR ($C_6D_6$): $\delta$ = –15.4 (t, $^2J_{HP}$ = 33 Hz, 1 H), 3.77 (s, 4 H, $C_5H_4$), 4.13 and 4.27 (each s, 2 H, $C_5H_4$), 4.34 (s, 2 H, Ind), 5.75 (s, 1 H, Ind), 6.28–6.31, 6.80–6.83 (each 4-line m, 2 H, Ind), 7.12–7.19, 7.28–7.33 and 8.03–8.08 (each m, total 20 H, Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 62.9 (s, dppf) ppm. ESI$^+$-MS: *m*/*z* (%) = 772 [M + H]$^+$. $C_{43}H_{36}FeP_2Ru$ (771.61): calcd. C 66.9, H 4.7; found C 66.9, H 4.5.

**Synthesis of [(Ind)Ru(dppf){S($CH_2$)$_2$$PPh_2$}] (7):** $Ph_2P(CH_2)_2SH$ (54 μL, 0.25 mmol) was added into excess NaH in THF (5 mL) and the suspension was stirred at r.t. overnight. The suspension was filtered through Celite into a red suspension of **2** (50 mg, 0.06 mmol) in MeOH (10 mL). The reaction mixture was stirred at r.t. for 18 h. A slow colour change from red suspension to dark green solution was observed. The solvent was removed in vacuo, and the residue extracted with toluene (2 × 5 mL). The toluene extract was concentrated to about 1 mL and loaded onto a silica gel column (2 × 10 cm) prepared in *n*-hexane. Elution gave two fractions: (i) a yellow eluate in toluene (about 4 mL), which gave **6** (7 mg, 15% yield); and (ii) a dark green eluate in toluene/diethyl ether (1:1, about 10 mL), which yielded [(Ind)Ru(dppf){S($CH_2$)$_2$-$PPh_2$}] (**7**) (34 mg, 54% yield).

**Data for 7:** $^1$H NMR ($C_6D_6$): $\delta$ = 2.31–2.39 and 2.75–2.80 (each m, 2 H, $CH_2$), 3.64, 3.88, 3.92 and 4.06 (each s, 2 H, $C_5H_4$), 5.18

**Crystal Structure Determinations:** Crystals were mounted on quartz fibres. X-ray data were collected on a Bruker AXS APEX system, using Mo-$K_\alpha$ radiation, with the SMART suite of programs.[31] Data were processed and corrected for Lorentz and polarisation effects with SAINT,[32] and for absorption effects with SADABS.[33] Structural solution and refinement were carried out with the SHELXTL suite of programs.[34] Crystal and structure refinement data are summarised in Table 3. The structures were solved by direct methods or Patterson maps to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. All non-hydrogen atoms were generally given anisotropic displacement parameters in the final model.

Two solvent molecules were found for **5**: a dichloromethane and a half-molecule of methanol. The latter was refined with a common isotropic thermal parameter each for the O and C atoms, and the C–O bond length was restrained at 1.45(2) Å.

CCDC-621607 (for **5**·$CH_2Cl_2$·0.5MeOH) and -621608 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis, Structures and Comparison of Neutral Complexes Formed by 2-(2′-Pyridyl)indole and $d^6$ Transition Metals

**Bernd Neumann,[a] Christoph Krinninger,[a] and Ingo-Peter Lorenz*[a]**

**Keywords:** Metallacycles / N ligands / Rhenium / Ruthenium / Rhodium / Iridium

2-(2′-Pyridyl)indole acts as an N,N-bidentate ligand when deprotonated and forms (1-amido-4-imine)metallacycles with $Re^{I}$, $Ru^{II}$, $Rh^{III}$ and $Ir^{III}$. The crystal structures of 2-(2′-pyridyl)indole and the complexes $[Re(C_{13}H_9N_2)(CO)_2(PPh_3)_2]$, $[Ru(C_{13}H_9N_2)(\eta^6\text{-}C_6Me_6)Cl]$, $[Rh(C_{13}H_9N_2)(\eta^5\text{-}C_5Me_5)Cl]$ and $[Ir(C_{13}H_9N_2)(\eta^5\text{-}C_5Me_5)Cl]$ are presented and their spectra discussed. This provides a foundation for the increased use of this ligand, which is a prototype of a monoanionic, bidentate N,N-chelating ligand. The introduction of negatively charged N,N-bidentate ligands can increase the possibility of synthesising complexes tailored to catalysis and other applications.

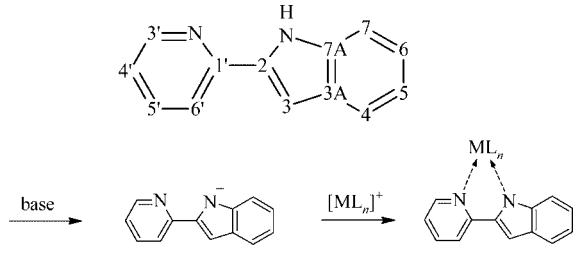
## Introduction

Chelating ligands play an important role both in classical coordination chemistry and in modern organometallic chemistry. Both symmetrical and asymmetrical chelates with the same type of donor atoms or asymmetrical ones with different donor atoms have been reported, and the formation of five-membered metallacycles has been found to be preferred due to the increased stability of the resulting complexes. A 1,4-relationship of the donor atoms allows complexation of a broad range of metal ions in tetrahedral, octahedral and square-planar geometries. This can be achieved by minor changes in the ligand's geometry. Asymmetric chelation with two identical donor atoms occurs in two different types. First, the backbone bridge of the chelating ligand can induce asymmetry, as is observed with the axially chiral BINAP and related ligands.[1] Second, the two donor atoms can be electronically different, with one being assigned a negative charge or coordinating with $sp^2$ or $sp^3$ free electron pairs. Among the N,N-bidentate ligands, two types of symmetrical ligands have found widespread use, namely neutral diamine ligands such as ethylenediamine (en) and neutral diimine ligands like bipyridine (bpy) or 1,10-phenanthroline (phen). However, nonsymmetric anionic bidentate ligands have so far been much less investigated even though ligands of this type should be useful for several reasons. Firstly, they can be used to adjust the overall charge of the complex, which allows high formal oxidation states of the central atom to remain stable within such complexes. Secondly, they may facilitate proton channelling in or out of the complex centre, with the overall complex remaining mostly intact. Most catalytic cycles known in homogeneous catalysis involve the formation and modification of metal hydrides and protons. Both substrate movement towards and away from the complex as isomerisation occurs within a catalytic cycle will be affected by a proton acceptor. Thirdly, a bidentate ligand allows the former process to take place without cleavage of the ligand from the complex as an anionic ligand is more likely to tolerate an intermediate protonated stage than a neutral ligand. We selected 2-(2′-pyridyl)indole (Hpyind) as the first ligand to be examined within a series of noble metal complexes. After deprotonation, Hpyind is capable of acting as a 1,4-chelate, with one of the nitrogen donor atoms being an imine and the other being an amido function (Scheme 1). Further N,N- and N,P-chelating ligands will be presented and discussed in future publications.



Scheme 1. General numbering (except crystal structures) and reaction scheme.

Hpyind is a well-known molecule that has been investigated in several recent publications. Indeed, complexes with pyind-like structures included in a larger molecule were described[2,3] even before the first detailed study on the behav-

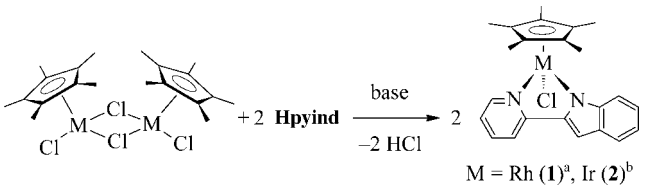
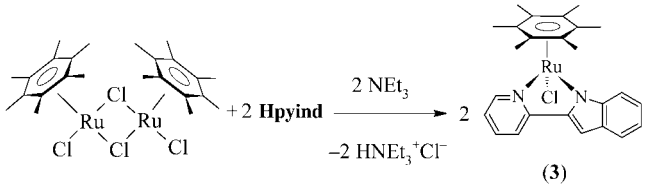
iour of Hpyind itself as a ligand was presented by Thummel et al.[4] Since the first isolated and structurally characterised pyind complex[5] with $Rh^I$ was described, some other related complexes have been reported.[6–9] Recent work has concerned not only pyind complexes as catalysts in hydroarylation[10] and the Heck reaction,[11] but also its use in optical devices.[12–16] It has also been used in an organometallic mimic for the protein kinase staurosporin.[17–21] The authors of the latter complex pointed out the "solely structural role" of an inert ruthenium complex in the biological activity of this pyind derivative, and they achieved enhanced activity and selectivity of the biologically active centre by modifying the distant ruthenium's ligand sphere. The promising idea of using such inert complexes within organic molecules is new[21] and supports the application of specially tailored chelate ligands such as Hpyind. In detail, such an anionic pyind-type ligand can form stable complexes with highly charged central atoms better than similar neutral ligands. It also leaves more space for varying the coligands at the metal centre than most neutral and anionic polydentate ligands and can easily be modified at several positions. We have therefore investigated the reactivity of rhenium(I), ruthenium(II), rhodium(III) and iridium(III) precursor complexes towards Hpyind in the presence of an appropriate base.

## Results and Discussion

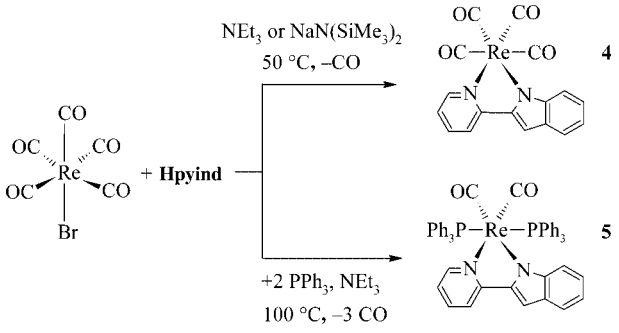
In the synthesis of the complexes reported here, we first use a strong amide base or potassium hydride for the deprotonation of Hpyind in a nonprotic solvent to which we then add the precursor complex. The synthetic strategy shown in Scheme 2 for the rhodium complex **1** works well, although the stoichiometry of the amide has to be strictly controlled as some side-reactions may occur when excess base is present. We further established that even weak bases such as triethylamine are capable of quantitatively abstracting the proton of Hpyind when it is acidified by pre-coordination of the precursor complex to the pyridine ring (Scheme 3). The resulting triethylammonium halide is easily precipitated from toluene or separated from the product by extraction into a small amount of ethanol. Only one product was obtained in the reactions of $Ru^{II}$, $Rh^{III}$ and $Ir^{III}$, whereas the $Re^I$ complex **5** required purification by flash chromatography in a dry and oxygen-free environment. We were unable to obtain an analytically pure sample of complex **4** from the reaction of $[Re(CO)_5Br]$ with Hpyind and $NaN(SiMe_3)_2$ or $NEt_3$. The result of this reaction is summarised in Scheme 4. Complex **4**, which contains an $Re(CO)_4$ moiety, is likely to be less stable than **5**, which is stabilised by the bulky axial $PPh_3$ groups. The IR spectrum of **4** supports a pseudo-$C_{2v}$ symmetry and shows four ν(C=O) absorptions at 2015, 1936, 1912 and 1891 $cm^{-1}$. Upon evaporation of toluene, or in a more polar solvent like acetone, only two frequencies are observed [2011 and 1892 $cm^{-1}$ (br.)], thus suggesting a *fac*-$Re(CO)_3$ species. The DEI mass spectrum shows only an $[Re(CO)_3(pyind)]^+$ fragment as the highest peak.



Scheme 2. Formation of rhodium and iridium complexes **1** and **2**; [a] toluene, $NaN(SiMe_3)_2$, 60 °C; [b] $CH_2Cl_2$, $NEt_3$, 25 °C.



Scheme 3. Synthesis of ruthenium complex **3**.



Scheme 4. Formation of complexes **4** and **5**.

The isolated complexes **1**–**3** are stable under argon at room temperature. However, some decomposition can be observed in moist air after several days. Solutions of these complexes in dichloromethane are stable for days, whereas the addition of methanol or moisture leads to the appearance of several new signals in the NMR spectra and decomposition. Complex **5** is somewhat more sensitive, and its decomposition is indicated by the formation of an intense green colour after a few seconds when the complex is exposed to moist air. All of the complexes show a high thermal stability, which makes them suitable for direct mass spectrometry.

The $^1H$ NMR spectrum of Hpyind has been described in the literature[4] but we have found some minor errors in the previous assignment concerning $H^{3'}$, $H^{4'}$, $H^4$ and $H^{6'}$. We therefore conducted H,H-COSY and HMQC measurements for both Hpyind and complex **1** in order to better understand the effect of complexation. These 2D NMR spectra of Hpyind and **1** are given as Supporting Information. Upon complexation, the NH signal of Hpyind disappears completely, the signals of $H^5$ and $H^6$ are shifted upfield by about 0.2 ppm, while those of $H^{5'}$, $H^{6'}$ and $H^7$ remain largely unaffected in complexes **1**–**3**. The signal of $H^3$ is affected only in the iridium complex **2**, where it is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

shifted upfield by 0.1 ppm. Complex **5** shows a different picture due to the lower metal oxidation state, because the phosphane ligands are more electron-donating and the protons of pyind are affected by the phenyl groups of $PPh_3$ (ring current). The signals of the pyridine ring protons are shifted upfield by about 1.1 ppm on average, thereby indicating a highly electron-enriched aromatic system. All complexes give nearly identical peaks for the C–H carbon atoms in the $^{13}C$ NMR spectra, with $C^7$, which shows a 5 ppm downfield shift, being the only significantly shifted signal. The four quaternary carbon signals are shifted downfield, by about 7 ppm for $C^{1'}$, about 10 ppm for $C^2$ and $C^{7A}$ and about 3 ppm for $C^{3A}$, in all complexes. This effect is well known for metallacycle carbon atoms but somewhat surprising for the other ones. To conclude, the main effect of complexation is observed at the benzene ring of the indole moiety, and no major change is expected in the pyridylpyrrole moiety.

The mass spectra show no unexpected behaviour and are easily interpreted as a result of the metal and halide isotope distribution. The main fragmentation pattern is given by splitting off the ligands one after another.

The IR spectra of the complexes show a common strong band at around 1610 $cm^{-1}$ for ν(C=N) and lack the indole ν(NH) band of Hpyind at 3450 $cm^{-1}$. The two carbonyl bands of complex **5** indicate the sole presence of the *cis* conformation in solution, as was also observed in the crystal structure of **5**. They appear at very low energy ($\tilde{\nu}$ = 1905, 1823 $cm^{-1}$), in the range of terminal carbonyl ligands. Similar low frequencies have been reported for anionic complex radicals of rhenium(I).[22]

The electronic spectra of Hpyind have been discussed previously.[23–25] On complexation, the absorption maximum at 325 nm in Hpyind[4] shows a bathochromic shift of 40–65 nm. Table 1 shows this effect to be affected by the metal's charge and that it is stronger for complexes containing fifth-row metals than those with fourth-row metals.

Table 1. UV absorption data for pyind complexes in $CH_2Cl_2$.

| | $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}$ $cm^{-1}$]) | $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}$ $cm^{-1}$]) | $\lambda_{max}$ [nm] ($\varepsilon$ [$M^{-1}$ $cm^{-1}$]) |
|---|---|---|---|
| **1** | 363 (15890) | 314 (9000) | 260 (16680) |

| **3** | 374 (11670) | 331 (9860) | 248 (14760) |
| **5** | 367 (11335) | 323 (11430) | |

As several structure-related questions about Hpyind have been discussed in the literature, we were surprised to find that the crystal structure was unknown. In these studies, bridging methylene chains have been attached to restrain the nitrogen atoms in a *cis* conformation,[4] and tautomeric forms upon *N*-methylation have been studied.[26] After recrystallisation from chloroform/hexane we obtained colourless single crystals of Hpyind. An ORTEP plot of the molecular structure is displayed in Figure 1, which shows that Hpyind exists in a *cis* conformation in the solid state. The indole and pyridyl moieties are somewhat twisted by about 14°, as shown by the dihedral angle N(1)–C(1)–C(9)–N(2) given in Table 2. Within the crystal, two Hpyind molecules form a dimeric unit where the planes of the two Hpyind molecules form an angle of 110.8°. They are connected by two hydrogen bonds, where H(1) is refined freely between N(1) of one molecule and N(2) of the other molecule with an almost ideal N(1)–H(1)–N(2) angle of 170(2)° and an N(1)–N(2) distance of 2.988(3) Å, which indicates a strong interaction. The luminescent beryllium complex of pyind reported by Liu et al.[16] shows a similar structure. In order to compare the changes in the pyind moiety on complexation, some interatomic distances have been summarised in Table 3. In all our complexes the pyind ligand becomes planar, with the previously mentioned dihedral angle reduced to almost zero. This is accompanied by a significant shortening of the C(1)–C(9) bond. Together with these two carbon atoms, the two nitrogen donor atoms and

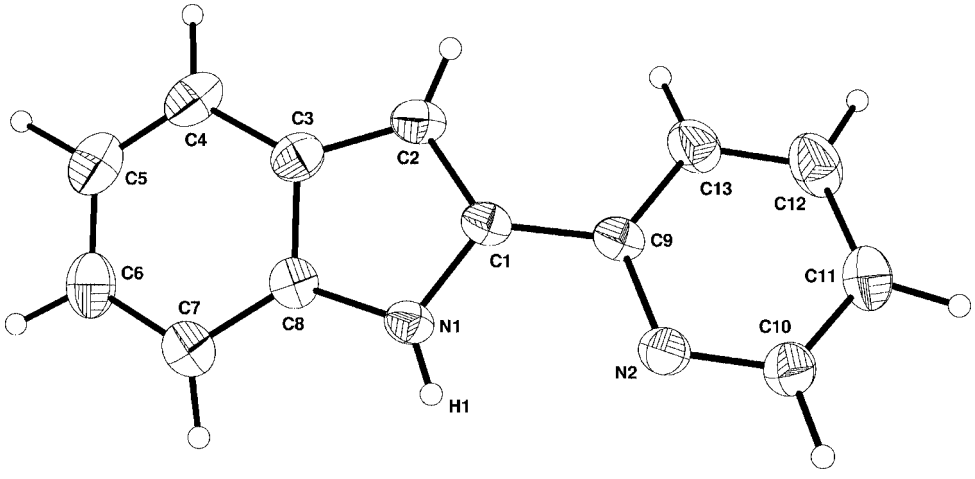

Figure 1. ORTEP plot (25% probability) of Hpyind. The numbering displayed is used in the discussion of all crystal structures for the pyind moiety.

Table 2. Selected angles [°] and dihedral angles [°].

| | Hpyind | 1 | 2 | 3 | 5 |
|---|---|---|---|---|---|
| Cl(1)–M(1)–N(1) | | 88.55(6) | 86.69(10) | 87.72(9) | |
| Cl(1)–M(1)–N(2) | | 87.45(5) | 85.62(10) | 88.70(9) | |
| N(1)–M(1)–N(2) | | 76.79(8) | 76.12(14) | 76.08(12) | 74.73(9) |
| M(1)–N(1)–C(1) | | 116.6(3) | 116.07(16) | 114.3(3) | 116.20(19) |
| M(1)–N(2)–C(9) | | 117.1(3) | 115.47(16) | 115.3(3) | 116.49(19) |
| N(1)–C(1)–C(9) | 121.28(17) | 115.9(2) | 115.4(4) | 114.9(3) | 117.6(2) |
| N(2)–C(9)–C(1) | 117.18(17) | 115.0(2) | 114.1(4) | 113.8(3) | 114.9(2) |
| N(1)–C(1)–C(9)–N(2) | –13.8(3) | –3.7(3) | 3.3(5) | –4.1(5) | –2.0(4) |

the metal atom form a coplanar five-membered metallacycle. The pyind ligand has quite a small bite angle of 74–77°, which makes it a nonideal ligand for large atoms. As it fits well into the octahedral coordination geometry of $d^6$ complexes, this deficiency seems to be compensated for by its charge transfer to the metal centre.

Table 3. Selected interatomic distances [Å].

| | Hpyind | 1 | 2 | 3 | 5 |
|---|---|---|---|---|---|
| M(1)–N(1) | | 2.073(2) | 2.050(3) | 2.082(3) | 2.153(2) |
| M(1)–N(2) | | 2.1343(19) | 2.103(3) | 2.108(3) | 2.202(2) |
| M(1)–Cl(1) | | 2.3987(8) | 2.3860(12) | 2.4142(10) | |
| N(1)–C(1) | 1.372(3) | 1.375(3) | 1.378(5) | 1.382(4) | 1.382(4) |
| C(1)–C(9) | 1.458(3) | 1.440(4) | 1.421(6) | 1.446(6) | 1.427(4) |
| C(9)–N(2) | 1.342(3) | 1.355(3) | 1.342(5) | 1.366(5) | 1.368(4) |

The $Rh^{III}$ complex **1** (Figure 2) and the $Ir^{III}$ complex **2** (Figure 3) are very similar, as would be expected, but some differences should be emphasised. The C(9)–N(2) distance increases in all complexes relative to the noncoordinated Hpyind ligand, but it remains unchanged in complex **2**. This is in agreement with the shorter metal–ligand contacts and the shorter C(1)–C(9) distance observed. As the $Rh^{III}$ centre in complex **1** should be smaller than $Ru^{II}$ in complex **3** (Figure 4), the latter would be expected to show larger metal–ligand distances. This is true for the slightly larger N(1)–Ru(1) distance, although the N(2)–Ru(1) distance is shortened by 0.05 Å. On the contrary, the shorter distances in complex **2** along with the shorter distances in the metallacycle mean that the ruthenium metallacycle of **3** has larger intraligand distances than found in **1**.

When complex **5** (Figure 5) is considered, the different co-ligand situation in this complex compared to the other complexes has to be taken in account. The two axial phosphane ligands show virtually identical Re–P distances of

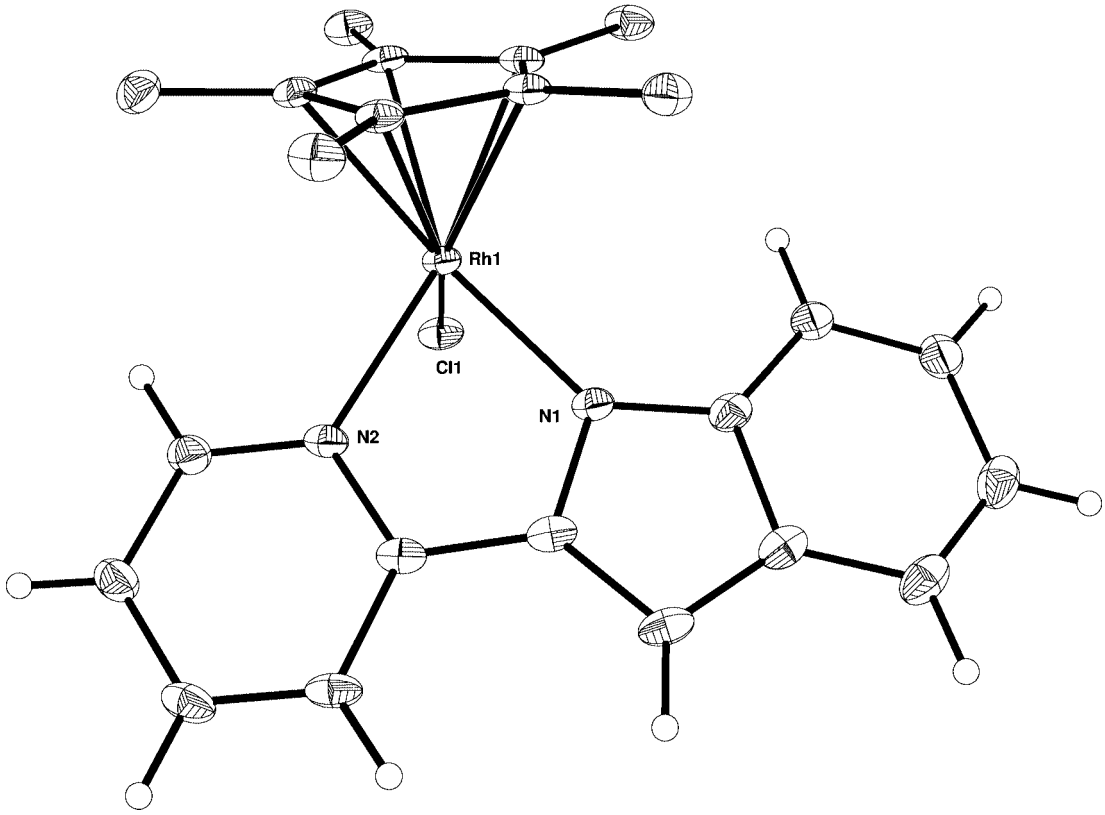

Figure 2. Molecular structure of rhodium complex **1** (25% probability). The methyl protons of $C_5Me_5$ are omitted for clarity.

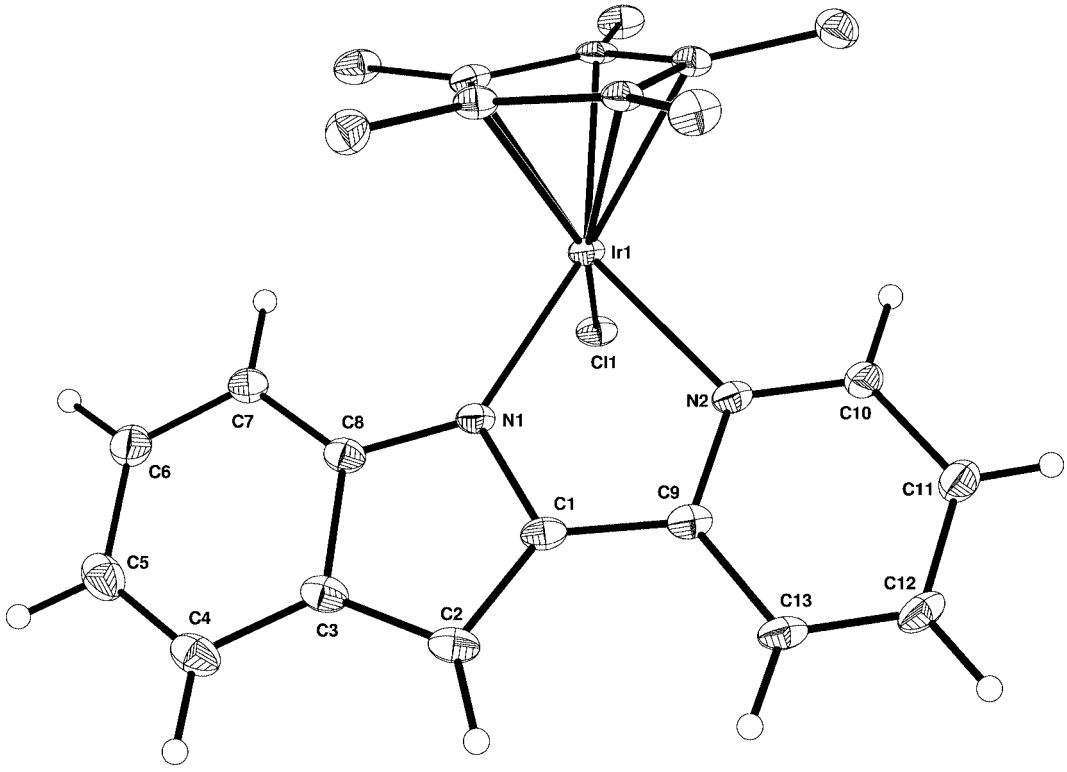

Figure 3. Molecular structure of complex **2** (25% probability). The methyl protons of $C_5Me_5$ are omitted.

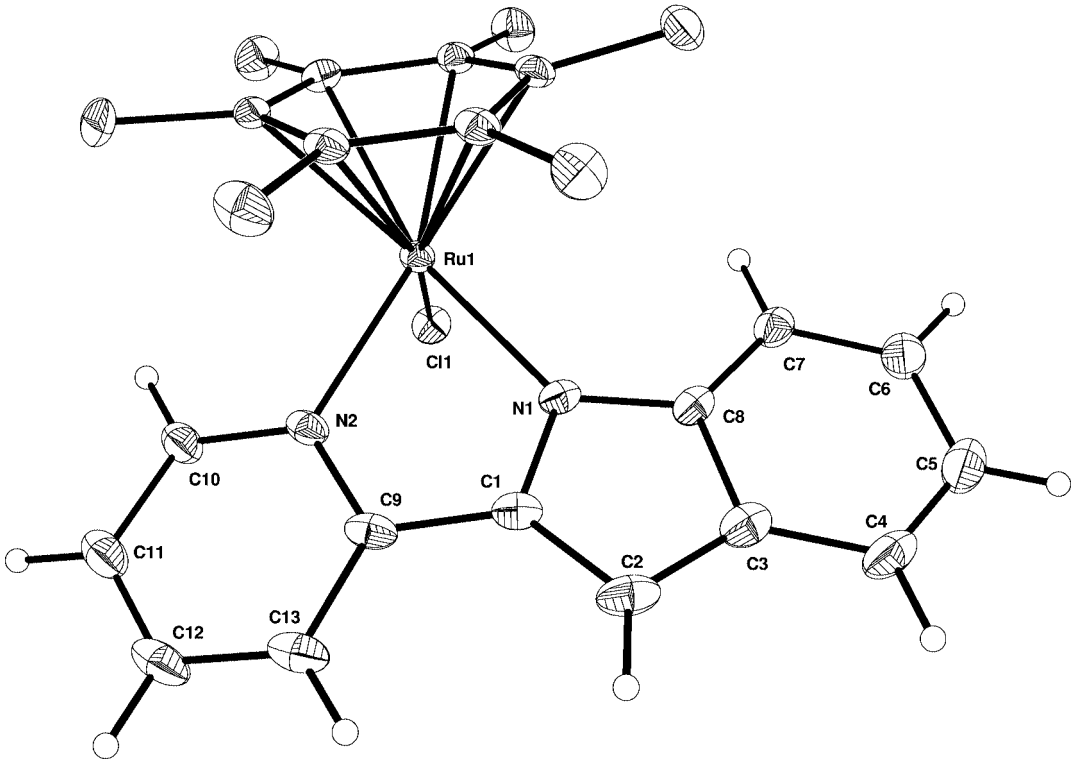

Figure 4. ORTEP plot of complex **3** (25% probability). The 18 disordered protons of the hexamethylbenzene moiety are omitted and a solvent molecule of $CH_2Cl_2$ is not included in the diagram.

2.4273(9) and 2.4324(9) Å, respectively, and all of the P–C distances of the phenyl groups lie between 1.832(3) and 1.837(3) Å. Two linear carbonyl ligands, which can act as both σ-donors and π-acceptors, are found in the *trans* positions with respect to the nitrogen donors. The very low C=O valence vibration energy observed suggests these car-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bonyl groups absorb a considerable amount of electron density. The low-valent rhenium(I) centre is larger than the optimum size for a chelating pyind ligand. Both of the Re–N distances are 0.10 Å longer than in the iridium complex **2**. However, the ligand shows both a shortened C(1)–C(9) bond, as was observed in compound **2**, as well as longer C=N bonds, as in **3**.

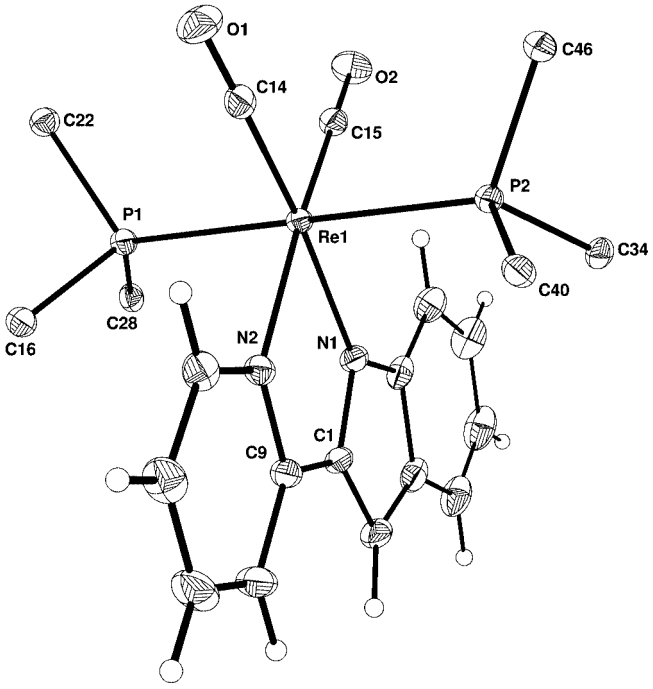

Figure 5. ORTEP plot of the rhenium compound **5** (25% probability). Only the terminal carbon atoms of both axial triphenylphosphane ligands are displayed. One disordered molecule of toluene is omitted.

## Conclusion

We have synthesised a series of novel transition metal complexes with the bidentate amido–imine ligand 2-(2′-pyridyl)indole. This is the first study to compare the properties that arise when different central atoms are used to form amido–imine complexes. Work on related anionic bidentate ligands, such as further modified amido–imine ligands and amido–phosphane ligands, is currently in progress. In addition, complexes containing different oxidation states for the central atoms, especially d$^8$ systems such as Rh$^{I}$, Ir$^{I}$ and Pd$^{II}$, will also be investigated. Investigations into the catalytic activity and optimisation of these complexes to improve certain catalytic processes are also underway.

## Experimental Section

**General:** All reactions were carried out under argon using standard Schlenk and vacuum-line techniques. Solvents were purified by standard procedures; dichloromethane was distilled from calcium hydride. The complexes $[RhCl_2Cp^*]_2$,[27] $[IrCl_2Cp^*]_2$,[27] $[Ru(CO)_2ClCp^*]$,[28] $[Ru(C_6Me_6)Cl_2]_2$[29] and $[Re(CO)_5Br]$[30] and Hpyind[4] were prepared and purified according to literature procedures. NMR spectra were measured with a Jeol Eclipse 270, Jeol Eclipse 400 or Jeol EX 400 spectrometer; the chemical shifts are given relative to external standards (TMS and 85% $H_3PO_4$). Mass spectra were recorded with a Jeol MStation JMS 700. IR spectra were recorded from KBr pellets or solutions in an NaCl cell using a Perkin–Elmer Spectrum One FT-IR spectrometer. UV/Vis spectra were measured in glass cuvettes with a Perkin–Elmer Lambda 16 spectrometer. The melting points, obtained with a Büchi 510 apparatus, are uncorrected. Elemental analysis was performed by the Microanalytical Laboratory of the Department of Chemistry and Biochemistry, LMU, using a Hereaus Elementar Vario El apparatus.

**2-(2′-Pyridyl)indol (Hpyind):** This compound was prepared according to the procedure reported by Thummel[4] and recrystallised from chloroform/hexanes. The following NMR assignments differ slightly from the literature. The 2D NMR spectra are given as Supporting Information. $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 9.79 (s, 1 H, NH), 8.57 (ddd, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 1.6, $^5J_{H,H}$ = 1.0 Hz, 1 H, H$^{3'}$), 7.82 (dt, $^3J_{H,H}$ = 8.0, $^{4,5}J_{H,H}$ = 1.0 Hz, H$^{6'}$), 7.73 (td, $^3J_{H,H}$ = 8.0, $^4J_{H,H}$ = 1.6 Hz, H$^{5'}$), 7.62 (dd, $^3J_{H,H}$ = 8.0, $^4J_{H,H}$ = 1.0 Hz, H$^4$), 7.38 (dd, $^3J_{H,H}$ = 8.0, $^4J_{H,H}$ = 1.0 Hz, H$^7$), 7.18 (td, $^3J_{H,H}$ = 8.0, $^4J_{H,H}$ = 1.0 Hz, 1 H, H$^6$), 7.18 (ddd, $^3J_{H,H}$ = 8.0, $^3J_{H,H}$ = 5.2, $^4J_{H,H}$ = 1.0 Hz, H$^{4'}$), 7.08 (td, $^3J_{H,H}$ = 8.0, $^4J_{H,H}$ = 1.0 Hz, 1 H, H$^5$), 7.02 (dd, $^4J_{H,H}$ = 2.0, $^5J_{H,H}$ = 1.0 Hz, 1 H, H$^3$) ppm. $^{13}$C NMR (100.62 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 150.3 (C$^{1'}$), 149.2 (C$^{3'}$), 136.9 (C$^2$), 136.7 (C$^{5'}$), 136.6 (C$^{7A}$), 129.2 (C$^{3A}$), 123.1 (C$^6$), 122.1 (C$^{4'}$), 121.1 (C$^4$), 120.1 (C$^5$), 119.9 (C$^{6'}$), 111.4 (C$^7$), 100.3 (C$^3$) ppm.

**Chlorido(η$^5$-pentamethylcyclopentadienido)[2-(2′-pyridyl)indolido-*N*,*N*′]rhodium(III) (1):** A 1 M solution of $NaN(SiMe_3)_2$ (280 μL, 0.28 mmol) was added to a solution of Hpyind (54 mg, 0.28 mmol) in toluene (10 mL). The mixture was stirred for 15 min and a solution of $[Rh_2Cl_4Cp^*_2]$ (85 mg, 0.14 mmol) in toluene (20 mL) was added dropwise. The red solution became darker and was stirred at 60 °C; after 10 min, an orange precipitate had formed. After 60 min, precipitation was complete and complex **1** was filtered, washed with cold toluene and dried in vacuo (115 mg, 0.25 mmol, 89%). $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 8.54 (br. d, $^3J_{H,H}$ = 5.7 Hz, 1 H, H$^{3'}$), 7.76 (ddd, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.7, $^4J_{H,H}$ = 0.8 Hz, 1 H, H$^{6'}$), 7.71 (ddd, $^3J_{H,H}$ = 8.1, $^3J_{H,H}$ = 7.0, $^4J_{H,H}$ = 1.5 Hz, 1 H, H$^{5'}$), 7.57 (dt, $^3J_{H,H}$ = 7.9, $^4J_{H,H}$ = 1.1 Hz, 1 H, H$^4$), 7.39 (dq, $^3J_{H,H}$ = 8.2, $^{4,5}J_{H,H}$ = 1.0 Hz, 1 H, H$^7$), 7.14 (ddd, $^3J_{H,H}$ = 7.0, $^3J_{H,H}$ = 5.7, $^4J_{H,H}$ = 1.7 Hz, 1 H, H$^{4'}$), 7.04 (ddd, $^3J_{H,H}$ = 8.2, $^3J_{H,H}$ = 6.8, $^4J_{H,H}$ = 1.1 Hz, 1 H, H$^6$), 7.00 (d, $^4J_{H,Rh}$ = 1.1 Hz, 1 H, H$^3$), 6.88 (ddd, $^3J_{H,H}$ = 7.9, $^3J_{H,H}$ = 6.8, $^4J_{H,H}$ = 1.0 Hz, 1 H, H$^5$), 1.62 (s, 15 H, Cp*) ppm. $^{13}$C NMR (100.52 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 157.4 (C$^{1'}$), 150.3 (C$^{3'}$), 145.8 (C$^2$), 144.9 (C$^{7A}$), 137.8 (C$^{5'}$), 132.5 (C$^{3A}$), 121.8 (C$^4$), 121.6 (C$^{4'}$), 120.9 (C$^6$), 119.8 (C$^{6'}$), 117.7 (C$^5$), 115.3 (C$^7$), 101.2 (C$^3$), 94.6 (d, $^1J_{C,Rh}$ = 7.7 Hz, Cp*), 9.4 (s, Cp*) ppm. DEI-MS (70 eV): *m*/*z* (%) = 466 (10) [M$^+$], 431 (100) [M$^+$ – Cl], 237 (17) [RhCp* – H], 235 (15) [RhCp* – 3 H], 194 (13) [pyind]. IR (KBr) $\tilde{\nu}$ = 3047 (w), 2984 (w), 2914 (w), 1607 (s), 1536 (s), 1449 (s), 1350 (m), 1310 (m), 1271 (w), 1199 (w), 1156 (m), 1119 (w), 1019 (m), 763 (s), 753 (m) cm$^{-1}$; ($CH_2Cl_2$) $\tilde{\nu}$ = 3049 (m), 2978 (w), 2918 (w), 1608 (s), 1537 (s), 1453 (s), 1361 (m), 1350 (m), 1312 (m), 1262 (m), 1200 (w), 1154 (m), 1141 (w), 1118 (w), 1077 (w), 1023 (m), 963 (w) cm$^{-1}$. **Chlorido(η$^5$-pentamethylcyclopentadienido)[2-(2′-pyridyl)indolido-*N*,*N*′]iridium(III) (2):** Hpyind (59 mg, 0.3 mmol) and [$Ir_2Cl_4Cp^*_2$] (120 mg, 0.15 mmol) were dissolved in $CH_2Cl_2$ (5 mL) and $NEt_3$ (42 μL, 0.4 mmol) was added. After stirring at room temp. for 48 h, the solvent was evaporated. The yellow residue was stirred with EtOH (3 × 5 mL) to remove $HNEt_3Cl$ and the slightly yellow solution was discarded after centrifugation. Drying in vacuo yielded **2** (135 mg, 0.24 mmol, 81%). $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 8.55 (d, $^3J_{H,H}$ = 5.8 Hz, 1 H, H$^{3'}$), 7.81 (d, $^3J_{H,H}$ = 8.2 Hz, 1 H, H$^{6'}$), 7.70 (t, $^3J_{H,H}$ = 8.1 Hz, 1 H, H$^{5'}$), 7.54 (d, $^3J_{H,H}$ = 8.0 Hz, 1 H, H$^4$), 7.37 (d, $^3J_{H,H}$ = 8.4 Hz, 1 H, H$^7$), 7.09 (dd, $^3J_{H,H}$ = 6.5, $^3J_{H,H}$ = 5.8 Hz, 1 H, H$^{4'}$), 7.01 (dd, $^3J_{H,H}$ = 8.4, $^3J_{H,H}$ = 6.8 Hz, 1 H, H$^6$), 6.91 (s, 1 H, H$^3$), 6.90 (dd, $^3J_{H,H}$ = 7.8, $^3J_{H,H}$ = 6.8 Hz, 1 H, H$^5$), 1.66 (s, 15 H, Cp*) ppm. $^{13}$C NMR (100.52 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 158.1 (C$^{1'}$), 150.4 (C$^{3'}$), 145.3 (C$^2$), 144.9 (C$^{7A}$), 138.1 (C$^{5'}$), 131.5 (C$^{3A}$), 122.1 (*C*$^4$ and C$^{4'}$), 121.7 (C$^6$), 119.6 (C$^{6'}$), 118.1 (C$^5$), 115.2 (C$^7$), 101.8 (C$^3$), 86.8 (Cp*), 9.6 (Cp*) ppm. DEI-MS: *m*/*z* (%) = 556 (65) [M$^+$], 521 (100) [M$^+$ – Cl], 363 (20) [IrCp*Cl], 323 (17) [Ir(C$_7$H$_{11}$)Cl]. IR (KBr) $\tilde{\nu}$ = 3052 (w), 2986 (w), 1609 (s), 1541 (s), 1491 (w), 1447 (s), 1371 (w), 1349 (m), 1311 (m), 1266 (w), 1203 (w), 1155 (m), 1122 (m), 1082 (w), 1022 (m), 965 (w), 769 (s), 753 (s), 517 (w), 443 (w), 376 (w) cm$^{-1}$; ($CH_2Cl_2$) $\tilde{\nu}$ = 3047 (w), 2978 (w), 2921 (w), 1612 (s), 1453 (s), 1450 (s), 1381 (w), 1360 (w), 1359 (m), 1314 (m), 1202 (w), 1155 (w), 1120 (w), 1080 (w), 1030 (m) cm$^{-1}$. UV/Vis ($CH_2Cl_2$, 25 °C): $\lambda$ ($\varepsilon$) = 377 (14620), 326 (10800), 260 (15240), 226 (24740 M$^{-1}$ cm$^{-1}$) nm. $C_{23}H_{24}ClIrN_2$ (556.12): calcd. C 49.67, H 4.35, N 5.04; found C 49.43, H 4.15, N 4.90. M.p. 305–307 °C (dec.). Single crystals suitable for X-ray structure analysis were obtained by diffusion of pentane into a solution of **2** in $CH_2Cl_2$.

**Chlorido(hexamethylbenzene)[2-(2′-pyridyl)indolido-*N*,*N*′]-ruthenium(II) (3):** Hpyind (78 mg, 0.4 mmol) and [$Ru_2Cl_4(C_6Me_6)_2$] (134 mg, 0.2 mmol) were dissolved in $CH_2Cl_2$ (10 mL) and $NEt_3$ (30 μL, 0.4 mmol) was added. After stirring at room temp. for 24 h, the NMR spectrum indicated quantitative reaction. The solution was concentrated in vacuo and the residue was stirred with a small amount of EtOH (2 × 3 mL) to remove $HNEt_3Cl$. The EtOH solution was discarded after centrifugation from the insoluble residue, which was dried to give **3** as a yellow to orange powder (153 mg, 0.31 mmol, 78%). $^1$H NMR (270 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 8.49 (ddd, $^3J_{H,H}$ = 5.8, $^4J_{H,H}$ = 1.4, $^5J_{H,H}$ = 1.0 Hz, 1 H, H$^{3'}$), 7.65 (ddd, $^3J_{H,H}$ = 8.2, $^4J_{H,H}$ = 2.4, $^5J_{H,H}$ = 1.0 Hz, 1 H, H$^{6'}$), 7.62 (ddd, $^3J_{H,H}$ = 8.2, $^3J_{H,H}$ = 6.5, $^4J_{H,H}$ = 1.4 Hz, 1 H, H$^{5'}$), 7.53 (dt, $^3J_{H,H}$ = 8.1, $^4J_{H,H}$ = 1.0 Hz, 1 H, H$^4$), 7.30 (dq, $^3J_{H,H}$ = 8.4, $^{4,5}J_{H,H}$ = 1.0 Hz, 1 H, H$^7$), 7.06 (td, $^3J_{H,H}$ = 6.5, $^3J_{H,H}$ = 5.8, $^4J_{H,H}$ = 2.4 Hz, 1 H, H$^{4'}$), 7.00 (ddd, $^3J_{H,H}$ = 8.4, $^3J_{H,H}$ = 6.8, $^4J_{H,H}$ = 1.4 Hz, 1 H, H$^6$), 6.94 (d, $^4J_{H,H}$ = 0.8 Hz 1 H, H$^3$), 6.87 (ddd, $^3J_{H,H}$ = 7.8, $^3J_{H,H}$ = 6.8, $^4J_{H,H}$ = 1.1 Hz, 1 H, H$^5$), 1.98 (s, 18 H, C$_6$Me$_6$) ppm. $^{13}$C NMR (67.9 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 157.5 (C$^{1'}$), 151.9 (C$^{3'}$), 146.6 (C$^2$), 144.3 (C$^{7A}$), 137.0 (C$^{5'}$), 132.3 (C$^{3A}$), 121.6 (C$^4$), 120.7 (C$^{4'}$), 120.1 (C$^6$), 118.9 (C$^{6'}$), 117.6 (C$^5$), 116.0 (C$^7$), 101.2 (C$^3$), 93.1 (C$_6$Me$_6$), 15.8 (C$_6$Me$_6$) ppm. FAB-MS: *m*/*z* (%) = 493 (25) [MH$^+$], 492 (28) [M$^+$], 457 (100) [M$^+$ – Cl]. IR (KBr) $\tilde{\nu}$ = 3039 (w), 1605 (s), 1532 (s), 1446 (s), 1383 (w), 1360 (w), 1347 (m), 1309 (s), 1261 (m), 1226 (w), 1150 (w), 1115 (w), 1071 (m), 1036 (m), 1020 (m), 782 (m), 769 (m), 748 (m), 517 (w), 456 (w), 373 (w) cm$^{-1}$; ($CH_2Cl_2$) $\tilde{\nu}$ = 3052 (m), 2977 (w), 2923 (w), 1608 (s), 1534 (s), 1447 (s), 1386 (w), 1361 (w), 1348 (m), 1312 (m), 1199 (w), 1153 (w), 1118 (w), 1075 (w), 1021 (m), 960 (w), 895 (w) cm$^{-1}$. UV/Vis ($CH_2Cl_2$, 25 °C): $\lambda$ ($\varepsilon$) = 374 (11670), 331 (9860), 248 (14760), 229 (20135 M$^{-1}$ cm$^{-1}$) nm. $C_{25}H_{27}ClN_2Ru$ (492.02): calcd. C 61.03, H 5.53, N 5.69; found C 58.30, H 5.58, N 5.34. M.p. >320 °C. Single crystals suitable for X-ray structure analysis were obtained by diffusion of pentane into a solution of **3** in $CH_2Cl_2$. They contain one molecule of $CH_2Cl_2$ per formula unit.

**Tetracarbonyl[2-(2′-pyridyl)indolido-*N*,*N*′]rhenium(I) (4):** Hpyind (97 mg, 0.5 mmol) was dissolved in toluene (10 mL) and a solution of [$Re(CO)_5Cl$] (181 mg, 0.5 mmol) in toluene (10 mL) was added. A 0.1 M solution of $NaN(SiMe_3)_2$ in toluene (5.0 mL) or $NEt_3$ (75 μL, 0.5 mmol) was then added and the mixture stirred at 50 °C. Concentration of the solution after 16 h yielded a blue-green solid that dissolved readily in acetone or $CH_2Cl_2$. All our attempts to crystallise the substance by diffusion of a non-polar solvent into a solution of **4** or by cooling were not successful. NMR signals in the aromatic region are broad and could not be unambiguously interpreted. DEI-MS (70 eV): *m*/*z* (%) = 464 (89) [M$^+$ – CO], 436 (50) [M$^+$ – 2 CO], 408 (53) [M$^+$ – 3 CO], 380 (100) [Re(pyind)], 353 (25) [Re(pyind) – HCN]. IR (toluene) $\tilde{\nu}$ = 2015 (vs), 1936 (m), 1912 (vs), 1891 (vs) cm$^{-1}$; (acetone) $\tilde{\nu}$ = 2011 (vs), 1892 (vs) cm$^{-1}$; (toluene, from $NEt_3$ run) $\tilde{\nu}$ = 2010 (vs), 1891 (vs) cm$^{-1}$. Further details of the characterisation are not available.

**Dicarbonyl[2-(2′-pyridyl)indolido-*N*,*N*′]bis(triphenylphosphane)-rhenium(I) (5):** Hpyind (39 mg, 0.2 mmol), [$Re(CO)_5Br$] (81 mg, 0.2 mmol), $PPh_3$ (106 mg, 0.4 mmol) and $NEt_3$ (31 μL, 0.22 mmol) were dissolved in toluene (5 mL) and stirred in a sealed Schlenk tube at 100 °C for 48 h. The hot yellow-brown solution was separated from the colourless precipitate ($HNEt_3Cl$). The IR spectrum shows several carbonyl bands, thereby indicating that a mixture of species is present. The solution was cooled to –32 °C overnight and a yellow precipitate formed. This was separated (80 mg, 42%) from the solution and purified using a short chromatography column [$SiO_2$ 60, 70–230 mesh, 250 mL (!) $CH_2Cl_2$]. An air- and moisture-free environment must be maintained during the entire workup process as the crude product easily decomposes to form an intensely green oil, whereas the final pure product is considerably more stable. Drying yielded **5** as a yellow solid (70.2 mg, 73 μmol, 37%). $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 7.64–7.66 (m, 1 H, H$^4$), 7.46 (br. d, $^3J_{H,H}$ = 5.2 Hz, H$^{3'}$), 7.15 (dd, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.2 Hz, 1 H, H$^7$), 7.12 (ddd, $^3J_{H,H}$ = 8.0, $^3J_{H,H}$ = 7.2, $^4J_{H,H}$ = 1.2 Hz, H$^6$), 7.08–7.11 (m, 18 H, $PPh_3$), 6.99–7.01 (m, 12 H, $PPh_3$), 6.97–6.98 (m, 1 H, H$^5$), 6.85 (d, $^4J_{H,H}$ = 1.0 Hz, H$^3$), 6.63 (dd, $^3J_{H,H}$ = 6.0, $^3J_{H,H}$ = 5.2 Hz, 1 H, H$^{4'}$), 6.63 (d, $^3J_{H,H}$ = 7.4 Hz, 1 H, H$^{6'}$), 6.00 (ddd, $^3J_{H,H}$ = 7.4, $^3J_{H,H}$ = 6.0, $^4J_{H,H}$ = 1.6 Hz, 1 H, H$^{5'}$) ppm. $^{13}$C NMR (100.63 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 156.9 (C$^{1'}$), 151.6 (C$^{3'}$), 147.8 (C$^2$), 145.9 (C$^{7A}$), 135.3 (C$^{5'}$), 133.5 (t, $J_{C,P}$ = 5.3 Hz, $PPh_3$), 132.2 (C$^{3A}$), 129.1 ($PPh_3$), 127.7 (t, $J_{C,P}$ = 4.3 Hz, $PPh_3$), 120.49 (C$^4$), 120.47 (C$^{4'}$), 120.0 (C$^6$), 118.6 (C$^{6'}$), 117.8 (C$^5$), 117.1 (C$^7$), 101.4 (C$^3$) ppm. $^{31}$P NMR (162.00 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 21.05 ppm. DEI-MS (70 eV): *m*/*z* (%) = 960 (7) [M$^+$], 698 (5) [M$^+$ – $PPh_3$], 642 (9) [Re($PPh_3$)(pyind)], 262 (100) [$PPh_3$], 183 (45) [$PPh_2$]. IR (KBr) $\tilde{\nu}$ = 1905 (vs), 1823 (vs), 1609 (m), 1533 (m), 1481 (m), 1455 (w), 1444 (m), 1432 (s), 1367 (w), 1349 (w), 1318 (w), 1263 (w), 1153 (w), 1091 (m), 741 (s), 694 (s), 613 (w), 518 (s), 413 (w) cm$^{-1}$. UV/Vis ($CH_2Cl_2$, 25 °C) $\lambda$ ($\varepsilon$) = 367 (11335), 323 (11430 M$^{-1}$ cm$^{-1}$) nm. $C_{51}H_{39}N_2O_2P_2Re$ (960.02): calcd. C 63.81, H 4.09, N 2.92; found C 59.19, H 3.86, N 2.56. M.p. 211–214 °C (dec.). Single crystals suitable for X-ray structure determination were obtained from the initial toluene solution after separating the $HNEt_3Cl$ and cooling from 100 °C to room temp. within 10 h. The yellow, block-shaped crystals contain one molecule of toluene per formula unit.

**X-ray Crystallography:** X-ray crystallographic data (Table 4) were collected with a Nonius Kappa CCD and with an Oxford Diffraction Xcalibur S, both using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Structures were solved by direct methods with

# Merocyanine-Like Chromophores as Ligands for Catalytic Active Metals of Group VIII

**Jörg Blumhoff,[a] Rainer Beckert,*[a] Dirk Walther,[b] Sven Rau,[b] Manfred Rudolph,[b] Helmar Görls,[b] and Winfried Plass[b]**

**Keywords:** N ligands / Chromophores / Palladium / Nickel / Electrochemistry

Nickel and palladium complexes that contain merocyanine-like 4*H*-imidazoles as ligands have been synthesized in good yields. The complexes were characterized by elemental analyses, mass spectrometry, $^1$H NMR, $^{13}$C NMR spectroscopy and in the solid state by single crystal diffraction analyses. The new palladium complexes of type **4** can be regarded as new functional dyes as well as deeply coloured and redox active metallacycles that display catalytic activity. In contrast to parent compounds **2**, the palladacycles of type **4** show two well-separated reductions that are fully reversible. The values of semiquinone formation constants of derivatives **4** (between $10^{11}$ and $10^{12}$) are only somewhat lower than those reported for similar boracycles.

## Introduction

Nitrogen-containing ligands based on oxalic amidines **1** have recently attracted increasing interest.[1–3] These bifunctional amidines can act as diamide or diamidinate ligands after deprotonation and the ligands can be easily modified in their electronic and steric effects by variation of the substituents on the nitrogen atoms. Moreover, they can adopt several possible coordination modes in their metal complexes. During the last decade we focussed our interests on the development of new cyclic versions of oxalic amidines. Thus, amidines without hydrogen in the α-position, such as benzamidines, can easily be cyclized with bis(imidoyl chlorides) derived from oxalic acid in order to yield 4*H*-imidazoles **2** (Figure 1).[4] A new class of chromophores/fluorophores was developed employing these diazafulvene imines.[5,6] In addition, the 4*H*-imidazoles **2** are reversible two-electron redox systems which have been optimized to powerful electron-accepting derivatives in the form of boratetraazapentalenes.[7] Their radical anions are characterized by an unusual thermodynamic stability as can be seen from semiquinone formation constants $K_{SEM}$ in the magnitude of $10^{15}$.

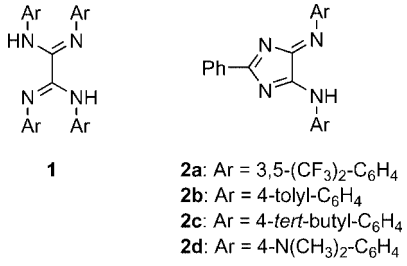

Figure 1. Oxalic amidines **1** and their cyclic versions 4*H*-imidazoles **2**.

The 4*H*-imidazoles **2** can therefore be regarded as multifunctional molecules in which the properties can easily be tuned by variation of the aryl substituents. Compared with derivatives of type **1**, they possess the same substructure which may serve as a donor site for metal complexation.

Because of the fact that open-chained oxalic amidines **1** have been successfully applied as ligands for cross-coupling methods,[8] their cyclic versions "cycloamidines" 4*H*-imidazoles **2**, should also be promising candidates. Zinc complexes of 4*H*-imidazoles have previously been reported.[9] Attempts to deprotonate derivatives **2** by lithium hydride[10] yielded unusual lithium complexes that surprisingly contain one molecule of water in their first complexation sphere.

Apart from porphyrins, phthalocyanines and related systems metal complexes in which the ligand is identical with an efficient chromophore are quite rare. Our aim was therefore to combine the redox active chromophore of 4*H*-imidazoles **2** with the catalytic activity of selected d-metals.

## Results and Discussion

### Synthesis and Characterization

First we attempted to synthesize $Ni^{II}$ complexes starting from nickel$^{II}$-$(acac)_2$. This diketonato complex even reacts at room temperature with **2a**, the red solution changing to a deep purple. In order to complete the reaction, the mixture has to be heated under reflux for approx. 4 h (monitoring by TLC). It is remarkable that the complex formation takes place without addition of bases; most likely the acetylacetonato moiety functioned as a base for the deprotonation of the NH function. The X-ray structural analysis obtained from a single crystal of complex **3a** revealed a molecular structure as illustrated in Figure 2.

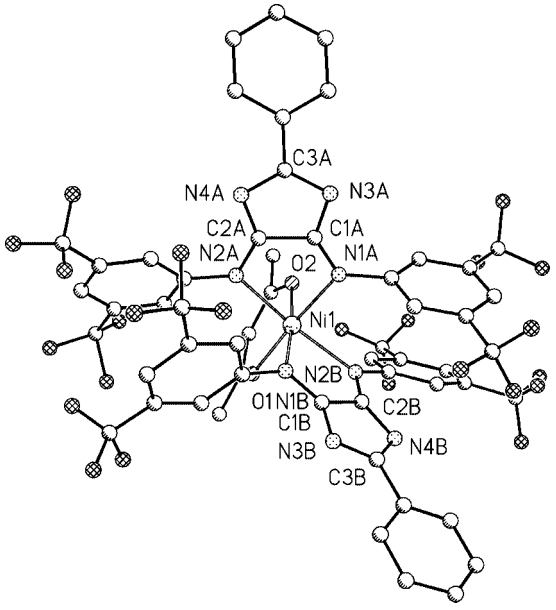

Figure 2. Molecular structure of complex **3a** (H atoms have been omitted for clarity). Selected bond lengths [Å]: Ni1–N1A 2.100(4), Ni1–N2A 2.197(4), Ni1–N1B 2.072(4), Ni1–N2B 2.201(4), Ni1–O1 2.009(3), Ni1–O2 2.042(3).

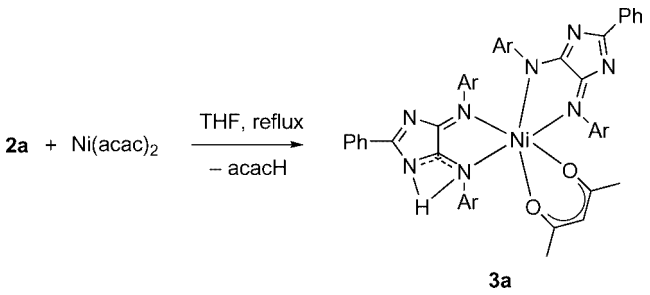
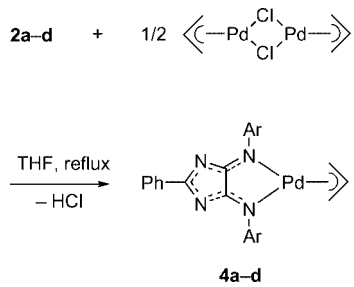
In the new chelate complex **3a** (Scheme 1) two 4*H*-imidazoles coordinate the nickel$^{II}$ centre, whereby the two remaining coordination sites are occupied by an acetylacetonato ligand. While one 4*H*-imidazole is coordinated in the deprotonated form, the other is bound as a neutral ligand. This fact could be verified by determining the Ni–N distances of the coordinating nitrogen atoms. This molecule is in agreement with the stoichiometry of the reaction. The octahedral nickel centre in **3a** exhibits paramagnetism and therefore, no NMR-data could be obtained. Characterization of complex **3a** via mass spectroscopy confirmed the results of the X-ray analysis. A high-resolution mass spectrum verified the chemical composition of compound **3a** ($C_{55}H_{30}F_{24}N_8NiO_2$). In addition, the complex **3a** shows a characteristic fragmentation due to the split-up of the ligands.



Scheme 1. Synthesis of complex **3a**.

Because of the fact that palladium plays a vital role as a catalytically active metal in cross-coupling methods, further investigations were directed towards the synthesis of analogous Pd complexes. As a starting metal complex, the easily accessible allyl palladium(II) chloride dimer was applied. Because of its tendency to dissociate in solution into two coordinative unsaturated fragments, it enables easy complexation of other ligands at the palladium(II) centre. Furthermore, the allyl palladium-fragment preferably forms complexes with an almost square-planar geometry showing diamagnetism that allows a detailed structural elucidation by NMR spectroscopy.

Even at room temperature the complex formation is visible by a colour change from red to purple. After heating under reflux conditions, for 2–4 h, chromatographic purification allowed the isolation of new complexes of type **4**. Elemental analysis, NMR spectroscopic data and MS data confirmed the composition of a 1:1 complex in **4a**. According to Scheme 2, the dimeric palladium species reacted with one molecule of the ligands **2a**–**d** to yield palladacycles **4a**–**d**. A high symmetry of the molecule was indicated by the $^1$H NMR spectrum of **4a**, which showed only five signals for the aromatic H-atoms in addition to the characteristic coupling pattern of the allyl substructure. Moreover, the $^{13}$C-NMR spectra confirm the symmetry of the molecule by a single set of signals. The signal for C-atom C4 is, compared to the ligand ($\delta$ = 190 ppm), shifted to a lower field in complex **4a** ($\delta$ = 199 ppm). This down-field shift is comparable to that in the corresponding boratetraazapentalenes,[7] thus indicating the change from the merocyanine to the cyanine chromophore.



Scheme 2. Synthesis of complexes **4a**–**d**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

A single-crystal X-ray structure analysis of **4a** allowed an unambiguous assignment of these compounds, as shown in Figure 3. According to our presumptions, one 4*H*-imidazole is coordinated at the palladium(II) centre. Being a second ligand, the allyl-anion is $\eta^3$-bonded and causes square-planar coordination geometry in view to the palladium(II) centre and shows $C_2$ symmetry. In analogy to the synthesis of the bis(3,5-trifluoromethyl) derivative **4a**, complexes of 4*H*-imidazoles could be prepared that possess electron-donating substituents. The various aryl substituents have no significant influence on the complexation ability of the corresponding 4*H*-imidazole. Interestingly, all new synthesized Pd complexes of type **4** show high stabilities as solids as well as in solution. They can be handled under normal atmospheric conditions and tolerate slightly acidic and basic conditions. In comparison with the 4*H*-imidazoles the UV/Vis maxima of the palladium complexes are shifted to higher wavelengths (**2a**: $\lambda_{max}$ = 460, 515 nm; **4a**: $\lambda_{max}$ = 549, 590 nm) as shown in Figure 4. Furthermore, complex **4a** shows a weak fluorescence at 623 nm (THF).

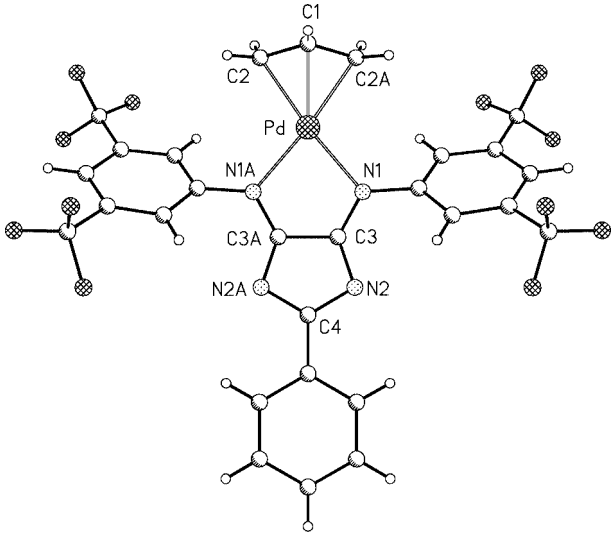


Figure 3. Molecular structure of complex **4a**. Selected bond lengths [Å]: Pd–N1 2.128(4), Pd–N1A 2.128(4), Pd–C2 2.120(5), Pd–C2A 2.120(5), Pd–C1 2.109(9).

## Electrochemical Measurements of Complexes 4

The electrochemical reduction of the palladacycles **4** occurs in two one-electron steps. A typical series of cyclic square-wave voltammograms measured with square-wave frequencies from 25 to 800 Hz is shown in Figure 5. The half-wave potentials extracted from these measurements are summarized in Table 1.

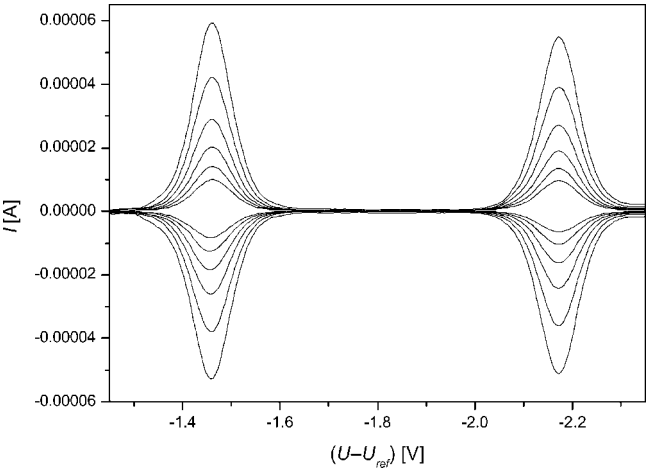

Figure 5. Cyclic square-wave voltammograms of the reduction of 1.5 mM of **4b** in DMF/tetrabutylammonium hexafluorophosphate at a mercury drop electrode using square-wave frequencies of 800, 400, 200, 100, 50 and 25 Hz. $U_{ref}$ is the potential of the ferrocenium/ferrocene couple in the same electrolyte.

Table 1. Half-wave potentials and semiquinone formation constants of complexes **4a**–**c**.

| Complex | $U_1^{1/2}$ | $U_2^{1/2}$ | $K_{sem}$ |
|---|---|---|---|
| **4b** | –1.460 V | –2.175 V | $1.26 \cdot 10^{12}$ |
| **4a** | –1.015 V | –1.670 V | $1.26 \cdot 10^{11}$ |
| **4c** | –1.455 V | –2.175 V | $1.58 \cdot 10^{12}$ |

If only the first reduction process is measured (by reversing the potential scan before the second reduction takes place), the experimental curves agree very well with those simulated for a fast (fully reversible) charge-transfer process followed by a slow first-order decomposition reaction. This means, as far as the charge transfer steps are concerned, a deviation from Nernstian behaviour cannot be detected up to square-wave frequencies of approx. 1000 Hz. However, the one-fold reduced species is chemically not fully stable in the solvent system. A second, (much faster) follow-up reaction is induced upon scanning over a potential range including the second reduction step. Interestingly, this follow-up reaction has a much larger effect on the re-oxidation wave associated with the second charge transfer reaction. The ratio between cathodic and anodic peak current remains close to 1 for the first charge transfer step even when using relatively low square-wave frequencies such as shown in Figure 6 ($f$ = 25 Hz). In the case of **4b** an almost perfect agreement between experimental and simulated curves was obtained on the basis of the reaction shown in Scheme 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

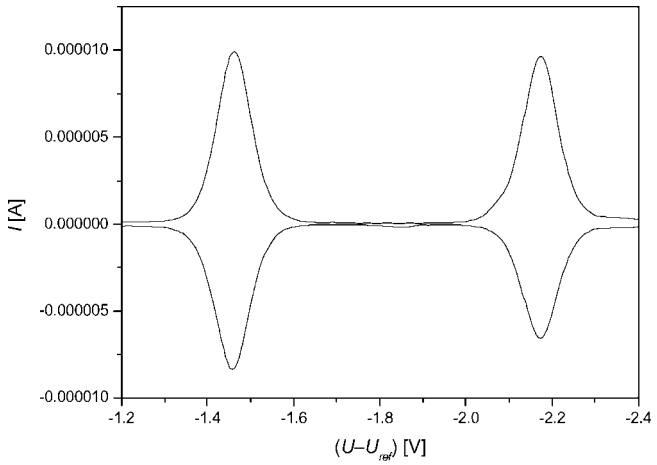

Figure 6. Cyclic square-wave voltammogram of the reduction of 1.5 mM of **4b** in DMF/tetrabutylammonium hexafluorophosphate at a mercury drop electrode using a square-wave frequency of 25 Hz. $U_{ref}$ is the potential of the ferrocenium/ferrocene couple in the same electrolyte.

$$O + e \rightleftarrows R_1 \quad \left(U_1^{1/2} = -1.46V, k_s^\circ \geq 1cm/s\right)$$

$$R_1 \longrightarrow P_1 \quad \left(k \approx 0.03s^{-1}\right)$$

$$R_1 + e \rightleftarrows R_2 \quad \left(U_2^{1/2} = -2.175V, k_s^\circ \geq 0.15cm/s\right)$$

$$R_2 \longrightarrow P_2 \quad \left(k \approx 0.65s^{-1}\right)$$

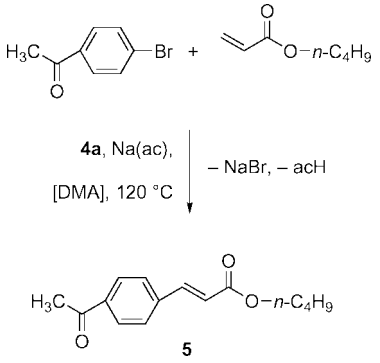
$$P_2 \longrightarrow R_1 \quad \left(k \approx 0.8s^{-1}\right)$$

Scheme 3. Reaction scheme for an almost perfect agreement between experimental and simulated curves.

We assume that the twofold reduced species reacts to give an intermediate from which the onefold reduced species is formed in a subsequent reaction; the data determined for **4c** are virtually identical. In the case of **4a**, the first reduction process is accompanied by a pre-wave. Since the latter could not be reproduced by digital simulation, only the half-wave potentials are reported in Table 1.

The lack of success of the Sonogashira and Suzuki reactions with these cross-conjugated heterocycles can now be explained due to the fact that the 4*H*-imidazoles act as very efficient chelating ligands for palladium. This means that required catalytic amounts of palladium were immobilized immediately by complexation and consequently no catalytic activity was observed. However, the palladacycles themselves are able to catalyze other types of cross-coupling reactions as shown by the Heck reaction.

In an initial experiment we used the substrates 4-bromoacetophenone and acrylic acid *n*-butylester in dimethylacetamide as the solvent at 120 °C, yielding the 4-substituted cinnamic acidester **5** (Scheme 4) to evaluate the catalytic activity of palladium complex **4a**. This complex belongs to the very rare group of Pd-catalysts with *N*,*N*-chelate ligands that are active in this C–C-coupling method. After 2 h of heating under reflux, 60% of the substrate was converted into cinnamic derivative **5**. Prolonged reaction times led to a nearly quantitative conversion.



Scheme 4. The Heck coupling as a model reaction for the determination of the catalytic activity of **4a**.

On the basis of these experimental findings the subject of further research will be the synthesis of homo- and heterobimetallic complexes of 4*H*-imidazoles and studies directed to the electronic communication between both metal centres. Applications of molecular architectures similar to those described above could prove to be light-driven reactions and catalyses.

## Experimental Section

**General Comments:** All reactions were monitored by TLC, carried out on 0.25-mm Merck TLC aluminium sheets (aluminium oxide 150 $F_{254}$ neutral) using UV light. $^1$H and $^{13}$C NMR spectra were recorded with a Bruker DRX 400 (400 MHz) or a Bruker AC 250 (250 MHz) spectrometer. UV/Vis spectra were recorded with a Perkin–Elmer Lambda 19 spectrophotometer. MS spectra were taken from measurements on a Finnigan MAT SAQ 710 mass spectrometer. Elemental analyses were carried out in-house with an automatic analyzer LECO CHNS 932.

**Synthesis of the Nickel(II) Complex 3a:** In a 100-mL one-necked round flask, equipped with a magnetic stirrer, **2a** (1 mmol) was dissolved in THF (50 mL). Then, bis(acetylacetonato)nickel(II) (1 mmol) dissolved in THF (10 mL) was added dropwise at room temperature. A darkening of the reaction mixture indicated a fast complexation reaction. The reaction mixture was heated to completion under reflux for 3–5 h. HRMS of **3a**: $C_{55}H_{31}F_{24}N_8NiO_2$: $M$ = 1349.15401113 g mol$^{-1}$ (calculated), $M$ = 1349.15494000 g mol$^{-1}$ (found).

**Synthesis of the Palladium(II) Complexes 4a–d:** In a 100-mL one-necked round flask, equipped with a magnetic stirrer, 1 mmol of the corresponding 4*H*-imidazole **2a** was dissolved in THF (50 mL). Then, allylpalladium(II) chloride dimer (0.5 mmol) dissolved in THF (10 mL) was added dropwise at room temperature. The reaction mixture was heated to completion under reflux for 3–5 h and the progress of the reaction was monitored by TLC. For complex **4a**, the solvent was removed in vacuo and the residue was suspended in acetone. The resulting precipitate was filtered off and dried in vacuo. The complexes **4b–d** were purified by column chromatography (alumina, activity V, toluene).

**Complex 4a:** Yield: 587 mg (79%). $^1$H NMR ($CD_2Cl_2$, 250 MHz): $\delta$ = 8.34 (m, 2 H, aryl-H), 8.16 (s, 4 H, aryl-H), 7.59 (m, 3 H, aryl-

H), 7.45 (m, 2 H, aryl-H), 5.50 (m, 1 H, allyl C-H), 3.55 (d, $J$ = 7.5 Hz, 2 H, allyl $CH_2$), 3.03 (d, $J$ = 12.5 Hz, 2 H, allyl $CH_2$) ppm. $^{13}C$ NMR ($CD_2Cl_2$, 100 MHz): $\delta$ = 199.0, 178.8, 149.1, 134.9, 132.3, 131.5 [q, $^2J$(C,F) = 33.2 Hz], 130.9, 128.6, 125.8, 123.3 [q, $^1J$(C,F) = 272.7 Hz], 119.2, 116.1, 62.3 ppm. FAB-MS (NBA): $m/z$ (%) = 743 $[M]^+$, 702 $[M - allyl]^+$, 597 $[M - allyl - Pd + H]^+$. UV/Vis (THF): $\lambda_{max}$ (lg$\varepsilon$) = 549 (4.0), 590 nm (4.0). $C_{28}H_{16}F_{12}N_4Pd$ (742.86): calcd. C 45.27, H 2.17, N 7.54; found C 45.25, H 2.16, N 7.45.

**Complex 4b:** Yield: 274 mg (55%). $^1H$ NMR ($CD_2Cl_2$, 250 MHz): $\delta$ = 8.33 (m, 2 H, aryl-H), 7.51 (m, 7 H, aryl-H), 7.21 (m, 4 H, aryl-H), 5.63 (m, 1 H, allyl-CH), 3.62 (d, $J$ = 6.9 Hz, 2 H, allyl-$CH_2$), 3.16 (d, $J$ = 12.4 Hz, 2 H, allyl-$CH_2$), 2.40 (s, 6 H, $CH_3$) ppm. Micro-ESI-MS (methanol): $m/z$ (%) = 499 $[M + H]^+$. UV/Vis (THF): $\lambda_{max}$ (lg$\varepsilon$) = 560 (4.0), 600 nm (4.0). $C_{26}H_{24}N_4Pd$ (498.92): calcd. C 62.59, H 4.85, N 11.23; found C 62.55, H 4.80, N 11.31.

**Complex 4c:** Yield: 291 mg (50%). $^1H$ NMR ($CD_2Cl_2$, 250 MHz): $\delta$ = 8.35 (m, 2 H, aryl-H), 7.57 (m, 5 H, aryl-H), 7.43 (m, 6 H, aryl-H), 5.60 (m, 1 H, allyl-CH), 3.64 (d, $J$ = 6.9 Hz, 2 H, allyl-$CH_2$), 3.15 (d, $J$ = 12.4 Hz, 2 H, allyl-$CH_2$), 1.38 (s, 18 H, $CH_3$) ppm. Micro-ESI-MS (methanol): $m/z$ (%) = 582 $[M + H]^+$. UV/Vis (THF): $\lambda_{max}$ (lg$\varepsilon$) = 563 (4.1), 604 nm (4.1). $C_{32}H_{36}N_4Pd$ (583.08): calcd. C 65.92, H 6.22, N 9.61; found C 65.90, H 6.18, N 9.55.

**Complex 4d:** Yield: 362 mg (65%). $^1H$ NMR ($CD_2Cl_2$, 250 MHz): $\delta$ = 8.22 (m, 2 H, aryl-H), 7.61 (m, 4 H, aryl-H), 7.39 (m, 3 H, aryl-H), 6.64 (m, 4 H, aryl-H), 5.53 (m, 1 H, allyl-CH), 3.56 (d, $J$ = 6.9 Hz, 2 H, allyl-$CH_2$), 3.09 (d, $J$ = 12.4 Hz, 2 H, allyl-$CH_2$), 2.91 [s, 12 H, $N(CH_3)_2$] ppm. Micro-ESI-MS (methanol): $m/z$ (%) = 556 $[M]^+$. UV/Vis (THF): $\lambda_{max}$ = 630, 673 nm. $C_{28}H_{30}N_6Pd$ (557.01): calcd. C 60.38, H 5.43, N 15.09; found C 60.40, H 5.48, N 15.05.

**Heck Reaction Catalyzed by Complex 4a:** In a typical experiment, 4-bromoacetophenone (6.25 mmol) and anhydrous sodium acetate (7 mmol) were placed in a 25-mL two-necked flask equipped with a stirring bar, reflux condenser and septum. The flask was degassed under vacuum and purged with argon to ensure an inert reaction atmosphere. Then, *N*,*N*-dimethylacetamide (10 mL) as the solvent and *n*-butyl acrylate (0.5 g) were added through the septum. The reaction mixture was thoroughly stirred and heated to the appropriate reaction temperature at which it was held for 5 min followed by treatment with the catalyst solution containing complex **4a** (1.25 μmol in 0.5 mL of THF). After the appropriate time intervals samples (0.5 mL) of the reaction mixture were hydrolyzed with 2 M HCl (0.5 mL) and extracted with $CH_2Cl_2$ (0.5 mL). The organic phase was dried with $K_2CO_3$ and stored at –21 °C until GC analysis for determination of the yield.

**Crystal Structure Determination**: The intensity data for the compounds were collected with a Nonius KappaCCD diffractometer, using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz and polarization effects, but not for absorption.[11,12] The structures were solved by direct methods (SHELXS[13]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELXL-97[14]). The hydrogen atoms of the structures were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[14] XP (Siemens Analytical X-ray Instruments, Inc.) was used for structure representations.

**Crystal Data for 3a:**[15] $2C_{55}H_{31}F_{24}N_8NiO_2 \cdot C_{50}H_{82}Ni_8O_{30} \cdot 3CH_2Cl_2 \cdot H_2O$, $M$r = 4649.27 g mol$^{-1}$, red-brown prism, size 0.05 × 0.05 × 0.04 mm, monoclinic, space group $P2_1/c$, $a$ = 15.8755(2), $b$ = 20.4987(3), $c$ = 32.8158(4) Å, $\beta$ = 101.482(1)°, $V$ = 10465.4(2) Å$^3$, $T$ = –90 °C, $Z$ = 2, $\rho_{calcd.}$ = 1.475 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 10.77 cm$^{-1}$, $F$(000) = 4714, 60125 reflections in $h$(–18/20), $k$(–26/26), $l$(–42/36), measured in the range 1.18° ≤ $\Theta$ ≤ 27.47°, completeness $\Theta_{max}$ = 99.3%, 23821 independent reflections, $R_{int}$ = 0.030, 18727 reflections with $F_o > 4\sigma(F_o)$, 1272 parameters, 0 restraints, $R_{1obs}$ = 0.087, $wR_{2obs}$ = 0.271, $R_{1all}$ = 0.111, $wR_{2all}$ = 0.289, GOOF = 2.184, largest difference peak and hole: 3.707/–1.610 e Å$^{-3}$.

**Crystal Data for 4a:**[15] $C_{28}H_{16}F_{12}N_4OPd \cdot H_2O$, $M$r = 759.86 g mol$^{-1}$, red-brown prism, size 0.04 × 0.04 × 0.03 mm, monoclinic, space group $C2/m$, $a$ = 18.7198(8), $b$ = 18.9056(8), $c$ = 9.8808(2) Å, $\beta$ = 120.749(2)°, $V$ = 3005.29(19) Å$^3$, $T$ = –90 °C, $Z$ = 4, $\rho_{calcd.}$ = 1.679 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 7.22 cm$^{-1}$, $F$(000) = 1500, 10750 reflections in $h$(–24/24), $k$(–22/24), $l$(–12/12), measured in the range 1.66° ≤ $\Theta$ ≤ 27.50°, completeness $\Theta_{max}$ = 99.4%, 3540 independent reflections, $R_{int}$ = 0.039, 2996 reflections with $F_o > 4\sigma(F_o)$, 226 parameters, 0 restraints, $R_{1obs}$ = 0.064, $wR_{2obs}$ = 0.186, $R_{1all}$ = 0.077, $wR_{2all}$ = 0.203, GOOF = 1.055, largest difference peak and hole: 2.860/–0.943 e Å$^{-3}$.

**Cyclovoltammetric Instrumentation and Procedures:** Cyclic square-wave voltammetry was conducted with the 3-electrode technique using a home-built computer-controlled instrument based on the PCI 6110 data acquisition board (National Instruments). The experiments were performed in DMF containing 0.25-M tetrabutylammonium hexafluorophosphate (Merck, Darmstadt) under a blanket of solvent-saturated argon. The DMF was purified by stirring with NaH, distilled under reduced pressure and stored over molsieves 4A under argon.

The Ohmic resistance that had to be compensated was determined by measuring the impedance of the system at potentials where the Faradayic current was negligibly small. Background correction was accomplished by subtracting the current curves of the blank electrolyte (containing the same concentration of supporting electrolyte) from the experimental curves.

Working electrode: hanging mercury drop ($m_{Hg-drop}$ = 3.95–4.00 mg) produced by the CGME instrument (Bioanalytical Systems Inc., West Lafayette, USA). A platinum wire served as the counter electrode. Internal reference electrode: Ag/AgCl electrode in acetonitrile containing 0.25 M tetrabutylammonium chloride. However, for convenience all potentials reported in this paper refer to the ferrocenium/ferrocene couple. The latter was measured at the end of each experiment using a 1.5-mm Pt disk electrode. The evaluation of the experiments was accomplished by subjecting the experimental voltammograms to a nonlinear regression procedure using the freely available DigiElch software (htpp://www.DigiElch.de).

# A Novel Amphiphilic $Re^{I}$ Complex with Bis(fullerene)-Substituted Bipyridine Ligands: Synthesis, Electrochemistry, and Langmuir Film

**Hwi Deuk Lee,[a] Sang Keun Oh,[a] Chan Soo Choi,[b] and Kwang-Yol Kay*[a]**

**Keywords:** Rhenium / Fullerenes / Bipyridines / Cyclic voltammetry / Langmuir films

An amphiphilic fullerene ($C_{60}$) derivative with a (bipyridine)-tricarbonylrhenium(I) chloride polar head group has been prepared. Electrochemical studies indicate that some ground state electronic interactions between the fullerene subunit and the metal complexed moiety are present in $Re^{I}$ complex **1**. The Langmuir film of this compound has been characterized by its surface pressure versus molecular area isotherm and Brewster angle microscopy (BAM) observations.

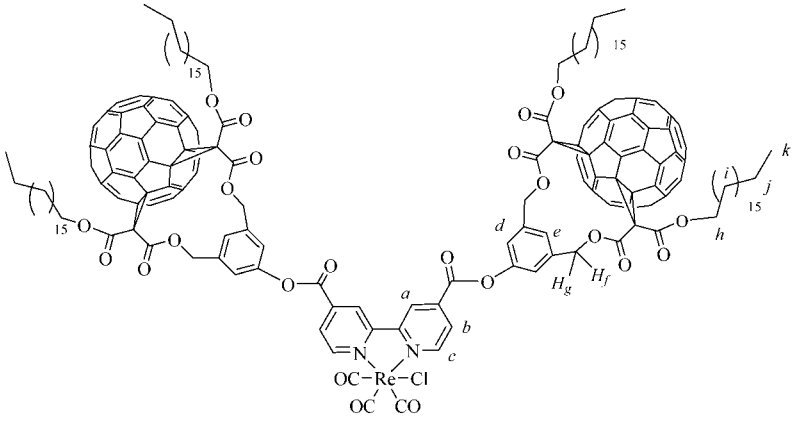
## Introduction

The fullerene ($C_{60}$) is an attractive functional group for a large number of multicomponent molecular architectures with photoinduced electron transfer processes[1] because of its electro- and photophysical properties. Fullerene is especially attractive because it can efficiently induce a rapid charge separation accompanied by a slow charge recombination.[2] Various donors such as porphyrin,[1f,3] TTFs,[4] ferrocene,[5] pyrene,[6] carbazol,[7] oligothiophenes,[8] *N*,*N*′-dialkylaniline,[9] carotenoid,[10] and phthalocyanine[11] have mainly been attached to fullerene ($C_{60}$) to investigate energy- and electron-transfer interactions. Recently, further efforts have been made to produce long-lived and high-energy intramolecular charge separated states, which can be exploited for practical applications such as solar energy conversion.[12] Among these, hybrid systems combining the fullerene with coordination compounds of metal ions such as $Ru^{II}$,[13] $Re^{I}$,[13e] and $Cu^{I}$[1g,14] are interesting because the long-lived metal-to-ligand charge transfer (MLCT) excited state of such complexes has a marked reducing character and is capable of initiating photoinduced electron transfer to the fullerene subunit. In fact, the photoelectrochemical (PEC) devices prepared from fullerene-substituted tris(2,2′-bipyridine)ruthenium(II) derivatives have shown the possibility for a controlled fabrication of the molecular level devices with high energy conversion efficiencies.[15]



**1**

However, only one multicomponent system of such an array with a $Re^{I}$ complex[13e] has been reported to date. In this hybrid system, one fullerene and $Re^{I}$ complex are connected by a long, flexible alkyl linker and have mutual inter-

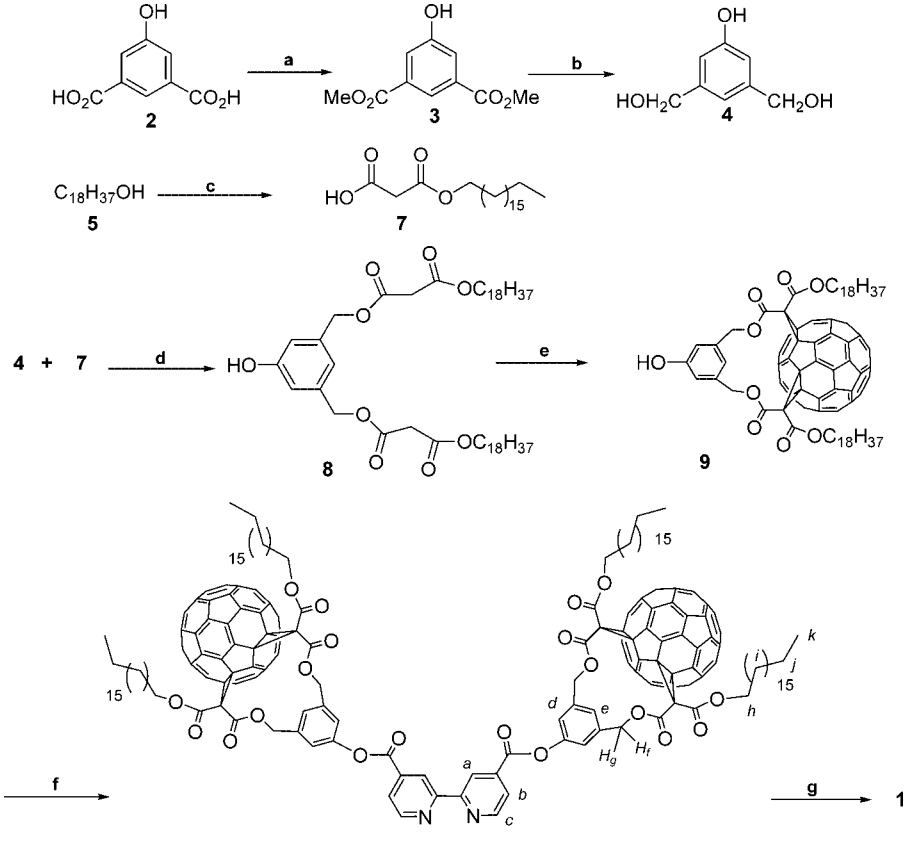
actions through spatial arrangement of the two components. Also, no $Re^{I}$ complex with more than one fullerene substituent has been reported until now, to the best of our knowledge. On the other hand, studies on Langmuir and Langmuir–Blodgett films from amphiphilic fullerene derivatives have already been reported by Diederich, Nierengarten and others.[16] However, only a limited number of the Langmuir films from fullerene–metal conjugates, such as monofullerene–ruthenium(II) coordination compound has been reported so far.[13g] In line with these aspects, we report herein the first synthesis of $Re^{I}$ coordination compound **1** that possesses a bis(fullerene)-substituted bipyridine ligand, which has short and relatively rigid linkages between fullerene and the $Re^{I}$ complex. Furthermore, we also report its electrochemical properties and Langmuir films.

## Results and Discussion

The synthetic route leading to the bis(fullerene)-substituted 2,2′-bipyridine ligand used for the preparation of rhenium(I) complex **1** is depicted in Scheme 1. Commercially available 5-hydroxyisophthalic acid (**2**) was esterified to give diester **3** (93% yield), and subsequent reduction of **3** with LAH produced 3,5-bis(hydroxymethyl)phenol (**4**) in a yield of 85%. Octadecanol (**5**) reacted with meldrum's acid (**6**) to afford malonic acid monooctadecyl ester (**7**) in 89% yield. Esterification of **4** with monoester **7** of malonic acid in the presence of *N*,*N*′-dicyclohexylcarbodiimide (DCC) yielded bis(malonate) **8** (73% yield). The functionalization of $C_{60}$ was based on the highly regioselective Diederich reaction,[17] which led to macrocyclic bis adducts of $C_{60}$ through macrocyclization of the carbon sphere with the bis(malonate) derivatives in a double Bingel addition.[18] Treatment of $C_{60}$ with **8**, iodine, and 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in toluene at room temperature afforded mono adduct **9**[11b] in 28% yield. The reaction of mono adduct **9** with 2,2′-bipyridine-4,4′-dicarbonyl dichloride (**10**)[19] which was prepared by oxidation of 4,4′-dimethyl-2,2′-bipyridine with $K_2Cr_2O_7$ and subsequent conversion of the diacid to diacyl dichloride **10**, went smoothly in the presence of triethylamine to produce bis adduct **11**[20] in 83% yield. Finally, fullerene-functionalized ligand **11** reacted with pentacarbonylrhenium(I) chloride in toluene to afford complex **1**[20] in 92% yield.

To compare the electrochemical and photochemical properties of ligand **11** and its $Re^{I}$ complex **1**, model compounds **12**[20] and **13**[20] that lack fullerene moieties were synthesized in an analogous method (Scheme 2).



Scheme 1. Synthesis of ligand **11** and complex **1**: a) MeOH, $H_2SO_4$, reflux, 24 h, 93%; b) $LiAlH_4$, THF, reflux, 48 h, 85%; c) Meldrum's acid (**6**), 110–120 °C, 2 h, 89%; d) DCC, DMAP, HOBT, THF, room temp., 12 h, 73%; e) $C_{60}$, $I_2$, DBU, room temp., 24 h, 28%; f) **10**, $Et_3N$, $CHCl_3$, room temp., 12 h, 83%; g) $Re(CO)_5Cl$, toluene, 80 °C, 12 h, 92%;.

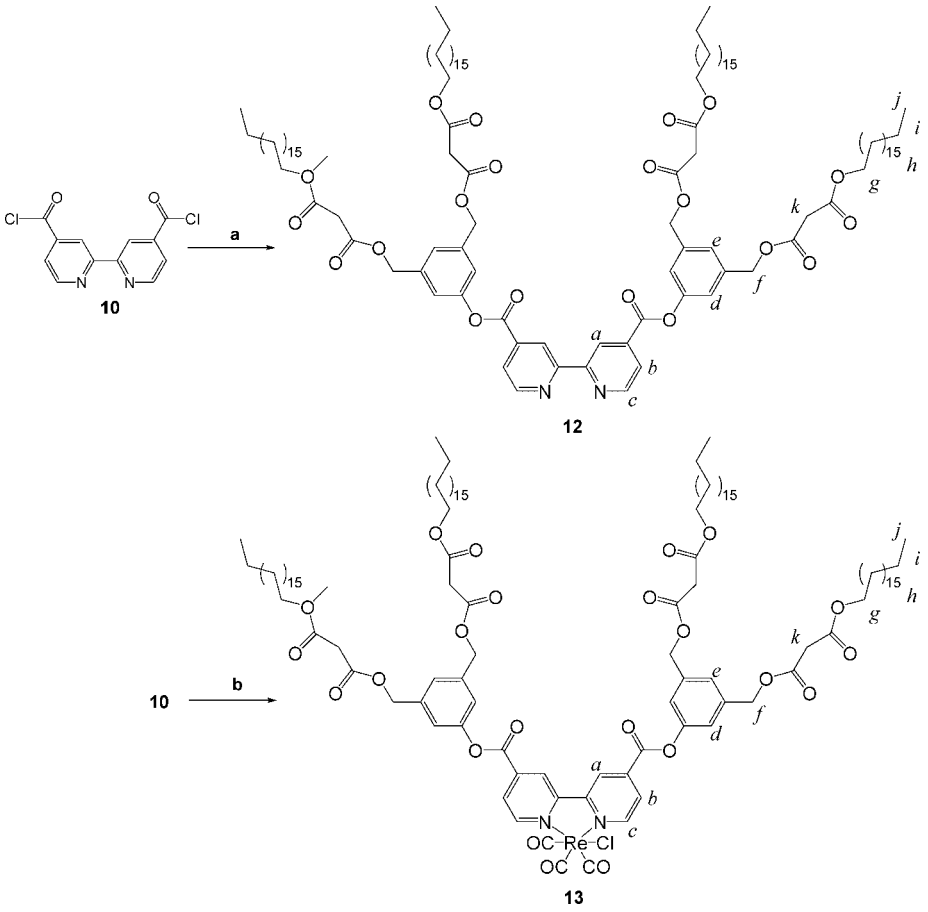

Scheme 2. Synthesis of model compounds **12** and **13**: a) **8**, $Et_3N$, $CHCl_3$, room temp., 12 h, 29%; b) $Re(CO)_5Cl$, EtOH, reflux, 12 h, 86%.

The structure and purity of the new compounds were confirmed by $^1H$ NMR and IR spectroscopy, MALDI-TOF mass spectrometry, and elemental analysis.[20] The $^1H$ NMR spectra of **11** and **1** show the characteristic features of the 1,3-phenylenebis(methylene)-tethered fullerene *cis*-2 bis adduct substituent.[11b,13g] In **11** and **1**, a set of AB quartets are clearly observed for the benzylic $CH_2$ groups ($H_f$ and $H_g$) and an $AX_2$ system is revealed for the aromatic protons ($H_d$ and $H_e$) of the 1,3,5-trisubstituted bridging phenyl ring. The spectra are also characterized by three sets of aromatic signals in a typical pattern for a 4,4′-disubstituted 2,2′-bipyridine ($H_a$, $H_b$, and $H_c$). Thus, the $^1H$-NMR spectrum of complex **1** is consistent with the proposed structure. Detailed assignments of the peaks in **11** and **1** are given and compared with model compounds **12** and **13**.[20]

The structure of **1** was also confirmed by mass spectrometry. The MALDI-TOF MS of **1** is characterized by a singly charged peak at $m/z$ = 3574.81, which can be assigned to **1** after loss of one chlorine atom.

The electrochemical properties of rhenium(I) complex **1** and ligand **11** were investigated and compared with those of model compounds **12** and **13** by cyclic voltammetry (CV) together with differential pulse voltammetry (DPV) in tetrahydrofuran (THF) with tetrabutylammonium tetrafluoroborate ($TBABF_4$) as a supporting electrolyte (Table 1). In the negative potential region, complex **1** shows nine reduction processes. As shown by comparison with corresponding ligand **11**, which lacks rhenium moiety, complex **1** showed five waves (–0.21, –0.69, –1.29, –1.62, and –2.11 V), which correspond to $C_{60}$-centered reductions. These reduction waves are regularly spaced around 500 mV. The first three fullerene-centered reduction waves of triad compound **1** are shifted about 30 mV more cathodically with respect to those (–0.19, –0.66, and –1.25 V) of the corresponding fullerene model compound, ligand **11**. This indicates that the LUMO energy levels of the ground state of the fullerene moiety are elevated by $Re^I$ complexation. However, Armaroli et al.[13e] reported that the first two fullerene-centered reductions of a $C_{60}$–$Re^I$ dyad showed opposite shifts. They suggested that this observation could be a consequence of a small electronic interaction due to spatial proximity for the two chromophores (more facile fullerene reduction) in $C_{60}$–$Re^I$. The triad of the present work seems to have adopted an extended conformation through rigid linkers between fullerene and the $Re^I$ complex, which prevents spatial interactions among the chromophores. So, our electrochemical results suggest that the electron donation from $Re^I$ to fullerene chromophores mainly occurs through the bonds. We have to mention that Armaroli et al.[13e] used a fullerene model compound without a bipyridine ligand, which does not provide a background for the representation of only a difference in $Re^I$. Thus, it is difficult to directly

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compare their results with the results of the present work. Therefore, the present work only provides more convincing results to explain the electron donating effects of $Re^{I}$. The additional waves at –1.00 and –1.48 V that originated from the bipyridine–malonate domain also shifted negatively compared with those of ligand **11** (–0.98, –1.43 V). This indicates that the complexation of rhenium to the bipyridine ligand can influence this negative shift. However, the corresponding waves of model compound **13** (–0.97, –1.47 V) showed a relatively large positive shift by the complexation of rhenium of corresponding ligand **12** (–1.22, –1.57 V). The redox processes of ligand **11** were found to have also shifted positively from those of ligand **12**. These results indicate that the electron-withdrawing $C_{60}$ group strongly affects the characteristics of ligand **11**. In model compounds **12** and **13** there are oxidation processes at the redox potentials of 0.81 V ($\Delta E_p$ = 100 mV) and 0.77 V ($\Delta E_p$ = 110 mV), respectively (not shown in Table 1). This may be caused by a redox reaction of the aromatic ester group. Interestingly, the negative potential shift of compound **13** shows that the oxidation of this group is easier, probably because of an electron donating function of rhenium. On the other hand, the additional waves $E_2$ and $E_8$ in Table 1 seem to originate from the metal center because only the compounds with rhenium metal show these waves.

Table 1. Electrochemical properties of **1**, **11**, **12**, and **13**.[a]

[a] Cyclic voltammetric measurements: glassy carbon disk working electrode (3 mm in diameter), Pt wire counter electrode, and silver wire pseudoreference electrode ($Ag/Ag^+$) were used. The electrolyte contained degassed THF, 0.1 M $Bu_4NBF_4$ and $3 \times 10^{-4}$ M synthesized compounds. The scan rate was 100 mV/s. Values for $E_{1/2}$ (in V) as $(E_{pa} + E_{pc})/2$ and $\Delta E_p$ (in mV) are given in parentheses. DPV technique was also used to confirm redox potentials, and the results were in good agreement with CV technique within the first decimal point. (i) denotes irreversible. The experiments were performed at ambient temperature and pressure.

The UV/Vis spectrum of **1** in a $CHCl_3$ solution shows the characteristic absorption features of the fullerene units as well as the diagnostic MLCT band of the 2,2′-bipyridine rhenium(I) complex at 380 nm. Interestingly, preliminary luminescence measurements of **1** in $CHCl_3$ solution ($\lambda_{exc}$ = 292 and 380 nm) show strong quenching of the emission by introducing the fullerene moieties in **1**, which indicates the occurrence of intramolecular photoinduced processes. Detailed photophysical studies are currently under investigation and will be reported in due time.

Langmuir films of compound **1** have been characterized by their surface pressure versus molecular area (π/A) isotherms and Brewster angle microscopy (BAM) observation.[21] Figure 1 shows a surface pressure/area isotherm (π-A isotherm) of compound **1** on a water surface. Under continuous compression, the surface pressure started to increase steeply around 200 $Å^2$/molecule and the Langmuir film collapsed around $\pi_c \approx 50$ mN/m. The results suggest that compound **1** forms very stable monolayers on the water surface because of the balance between the hydrophobicity of the fullerene surrounded by two long alkyl chains and the hydrophilicity of the bipyridine $Re^{I}$ complex. Good reversible behavior in the successive compression/expansion cycles (data not shown) is also consistent with the amphiphilic structure of compound **1**, where aggregation of fullerenes is largely prevented by the long alkyl chains. These results are in a good agreement with the previous findings on a related amphiphilic fullerene derivative with ruthenium(II).[13g] The occupied surface area obtained by extrapolation of the steeply rising portion of the π-A isotherm to zero pressure is 166 $Å^2$/molecule, which is very close to the molecular area estimated by molecular modeling of compound **1**. A Brewster angle microscope was used to monitor the structural change of the Langmuir films during compression. The insets of Figure 1 show the BAM images of the Langmuir films at 200, 300, and 500 $Å^2$/molecule. The images clearly show that the domain size (brighter regions in the images) becomes larger as the surface pressure is increased, and a homogeneous monolayer is formed below 200 $Å^2$/molecule.

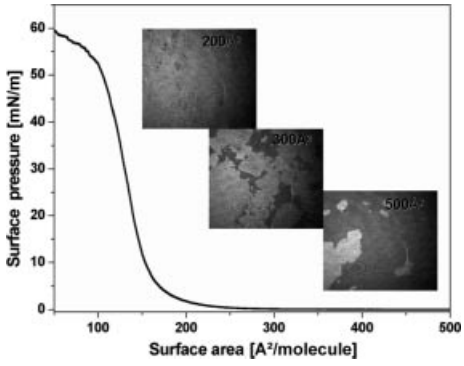

Figure 1. π-A isotherm recorded during compression of the monolayer of compound **1**. The insets are the BAM images of the Langmuir films at 200, 300, and 500 $Å^2$/molecule.

## Conclusions

We have synthesized a new $Re^{I}$ complex with bis(fullerene)-substituted bipyridine ligands, which is a suitable amphiphilic derivative for the preparation of stable Langmuir films. Electrochemical properties of this compound have also shown that some ground state electronic interactions between the fullerene subunit and the metal complexed moiety are present in this complex. We are currently investi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gating the physical properties of Langmuir–Blodgett films of this molecule and attempting to apply their behavior in PEC cells for solar energy conversion.

# A Surprising Reaction of Trimethylphosphane with the Unsaturated Diruthenium Complex $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$: Synthesis and Molecular Structure of the Cations $[(\eta^6\text{-}C_6Me_6)Ru_2(PMe_3)_3(\mu_2\text{-}H)_3]^+$ and $[(\eta^6\text{-}C_6Me_6)_2Ru_2(PMe_3)_2(\mu_2\text{-}H)(H)_2]^+$

**Mathieu J.-L. Tschan,[a] Frédéric Chérioux,[b] Bruno Therrien,[a] and Georg Süss-Fink*[a]**

**Keywords:** Ruthenium complexes / Arene complexes / Phosphane ligands / Hydrido ligands

Whereas aromatic or aliphatic phosphanes undergo cleavage of the P–C bond in the reaction with $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ to give phosphido-bridged diruthenium cations of the type $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PR_2)(\mu_2\text{-}H)_2]^+$, trimethylphosphane surprisingly yields the substitution product $[(\eta^6\text{-}C_6Me_6)Ru_2(PMe_3)_3(\mu_2\text{-}H)_3]^+$ (**1**), as well as the racemic intermediate $[(\eta^6\text{-}C_6Me_6)_2Ru_2(PMe_3)_2(\mu_2\text{-}H)(H)_2]^+$ (**2**), in the form of the tetrafluoroborate salts. In complex **2**, the hydrido ligands are fluxional in solution, as shown by variable-temperature $^1H$ NMR spectroscopy. Cation **1** reacts with *p*-bromothiophenol to give the complex $[(\eta^6\text{-}C_6Me_6)_2Ru_2(PMe_3)_3\{\mu_2\text{-}(p\text{-}Br\text{-}C_6H_4)\text{-}S\}(\mu_2\text{-}H)_2]^+$ (**3**), isolated as the tetrafluoroborate salt.

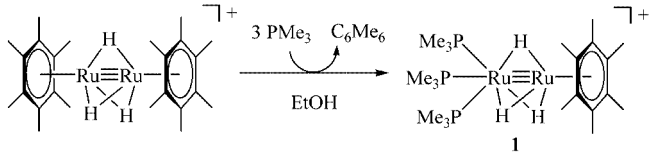
## Introduction

Tertiary phosphanes are without any doubt among the most important ligand systems used in organometallic chemistry or in molecular catalysis.[1] The cleavage of the carbon–phosphorus bond has been observed in numerous cases, essentially by reacting metal carbonyl complexes with aromatic phosphanes.[2] Recently, we found that trisubstituted (aliphatic or aromatic) phosphanes, $PR_3$, undergo facile P–C bond cleavage with the unsaturated complex $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ to give the phosphido-bridged complexes $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PR_2)(\mu_2\text{-}H)_2]^+$.[3] In the reaction of triphenylphosphane with $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ to give $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)_2]^+$, we were able to isolate an intermediary complex containing a bridging phenyl ligand, $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PPh_2)(\mu_2\text{-}Ph)(\mu_2\text{-}H)]^+$, and to perform a single-crystal X-ray structure analysis of the tetrafluoroborate salt. In the reaction of trialkylphosphanes with $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ to give $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PR_2)(\mu_2\text{-}H)_2]^+$ (R = *n*Oct, *n*Bu), we were able to show that the reaction produces the corresponding olefins (*n*-octene or *n*-butene) and not the expected alkanes. This suggests that the P–C bond cleavage in trialkylphosphanes at the diruthenium centre occurs by β-H elimination from the alkyl group. In order to confirm this hypothesis, we decided to study the reaction of $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ with trimethylphosphane, in which β-H elimination is impossible.

## Results and Discussion

The reaction of $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ with $PMe_3$ indeed does not yield the expected complex $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PMe_2)(\mu_2\text{-}H)_2]^+$, but surprisingly leads to the formation of the cation $[(\eta^6\text{-}C_6Me_6)Ru_2(PMe_3)_3(\mu_2\text{-}H)_3]^+$ (**1**), in which one of the two hexamethylbenzene ligands has been replaced by three trimethylphosphane ligands. Cation **1** is obtained in 28% yield and it can be isolated as the tetrafluoroborate salt (Scheme 1). The substitution of an $\eta^6$-arene ligand at a ruthenium atom by three phosphane ligands has been observed so far for benzene,[4] toluene[5] and *p*-cymene[6] ligands, but never for the strongly bound $\eta^6\text{-}C_6Me_6$ ligand.



Scheme 1. Synthesis of **1**.

The single-crystal X-ray structure analysis of [**1**][$BF_4$], crystallised by slow diffusion of diethyl ether in a concentrated acetone solution of [**1**][$BF_4$], reveals for cation **1** the presence of three bridging hydrido ligands coordinated to

the two ruthenium atoms, one ruthenium atom being coordinated to an $\eta^6$-$C_6Me_6$ ligand and the other one to three $PMe_3$ ligands. The molecular structure of cation **1** is shown in Figure 1.

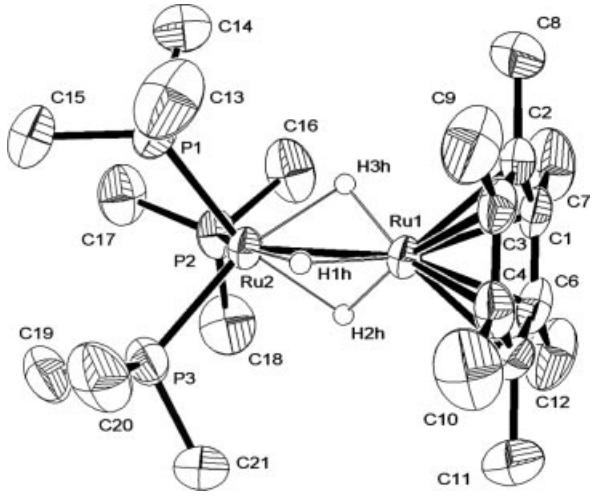

Figure 1. Molecular structure of cation **1** (ORTEP drawing of **1** at the 50% probability level with hydrogen atoms and tetrafluoroborate anion omitted for clarity).

The Ru–Ru distance [2.4934(6) Å] is within the range of a ruthenium–ruthenium triple bond.[7] The replacement of a hexamethylbenzene ligand by three $PMe_3$ ligands does not significantly affect the geometrical parameters of the $Ru_2(\mu_2\text{-}H)_3$ backbone as compared to $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$.[7b] The three independent Ru–P lengths (ca. 2.258 Å) are comparable to those found in $[Ru_2(PMe_3)_6(\mu_2\text{-}H)_3]^+$.[8] In the $^1$H NMR spectrum the nine methyl protons give rise to a broad signal, each carbon atom of the three equivalent $PMe_3$ ligands can be differentiated in the $^{13}$C NMR spectrum (i.e. $\delta$ = 24.59, 24.69 and 24.79 ppm). This is probably due to the steric hindrance of the methyl groups (see Figure 2) and suggests a restricted rotation of the three $PMe_3$ ligands, which gives rise to three independent signals in the $^{13}$C NMR spectrum.

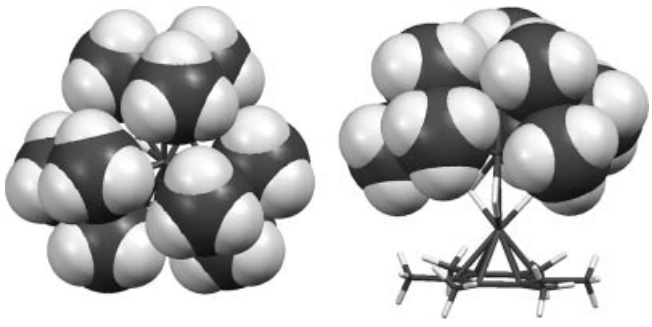

Figure 2. Mixed van der Waals and capped sticks representation of **1** with hydrogen atoms.

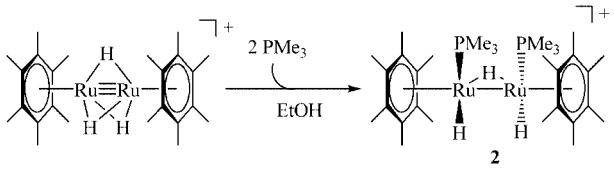
The molar ratio of $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ and $PMe_3$ in the synthesis of **1** is critical: Although the stoichiometry of the reaction requires 3 equiv. of $PMe_3$ (see Scheme 1), the reaction must be carried out with an excess of $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3][BF_4]$.

The best yield (28%) is obtained with 2.5 equiv. of $PMe_3$, 3 equiv. or more leads to decomposition. In order to shine light on this strange observation, we carried out the reaction of $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ with 2 equiv. of $PMe_3$ in ethanol at room temperature. In this case, the reaction quantitatively gives the cation $[(\eta^6\text{-}C_6Me_6)_2Ru_2(PMe_3)_2(\mu_2\text{-}H)(H)_2]^+$ (**2**), in which both hexamethylbenzene are still present (Scheme 2). Cation **2** can be considered as an intermediate in the formation of cation **1** (see below), and its conversion with $PMe_3$ into **1** is accompanied by the formation of mononuclear complexes, mainly $[(\eta^6\text{-}C_6Me_6)\text{-}Ru(PMe_3)_2H]^+$.[9] This explains why any local excess of trimethylphosphane has to be avoided for the synthesis of **1**.



Scheme 2. Synthesis of **2**.

The single-crystal X-ray structure analysis of [**2**][$BF_4$], crystallised by slow diffusion of diethyl ether in a concentrated acetone solution of [**2**][$BF_4$], reveals for cation **2** only one hydrido bridge, each ruthenium atom being coordinated also to a terminal hydride, an $\eta^6$-$C_6Me_6$ ligand and a $PMe_3$ ligand. The molecular structure of cation **2** is shown in Figure 3.

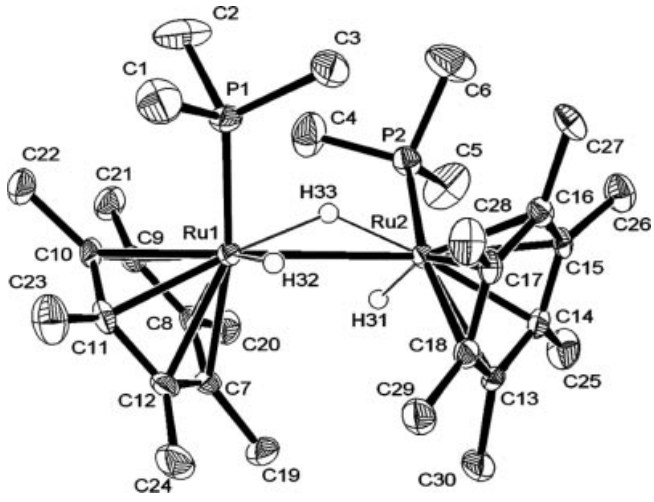


Figure 3. Molecular structure of cation **2** (ORTEP drawing of **2** at the 50% probability level with hydrogen atoms and tetrafluoroborate anions omitted for clarity).

The two $C_6Me_6$ arene ligands are not parallel to each other, and the angle between the $C_6Me_6$ planes is 56.6(2)°. Accordingly, to reduce the steric hindrance, the phosphorus atoms adopt a staggered conformation, the P1–Ru1–Ru2–P2 torsion angle being 67.79° (Figure 3). Interestingly, in **2**, the Ru–Ru distance [3.2230(8) Å] is very long. As the electron count of 34 e suggests a formal metal–metal single bond, this would be the longest Ru–Ru bond observed in a dinuclear complex. In the absence of DFT calculations,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

however, the question of metal–metal bonding interaction remains a debatable point.

At room temperature, no hydride resonances can be observed in the $^1$H NMR spectrum of [**2**][$BF_4$], which suggests a fluxional behaviour of the hydrido ligands. This is confirmed by variable-temperature NMR experiments down to –40 °C (Figure 4). At 0 °C, two badly-defined signals centred at $\delta$ = –13.00 and –25.25 ppm appear, which sharpen at –40 °C, to give a doublet of doublets at $\delta$ = –13.10 ppm [dd, $^2J_{(H,H)}$ = 7.6 Hz, $^2J_{(H,P)}$ = 51.8 Hz, 2 H], which corresponds to the two terminal hydrides, and a triplet of triplets at –25.24 ppm [tt, $^2J_{(H,H)}$ = 7.6 Hz, $^2J_{(H,P)}$ = 23.4 Hz, 1 H], which is assigned to the bridging hydride in the $^1$H NMR spectra.

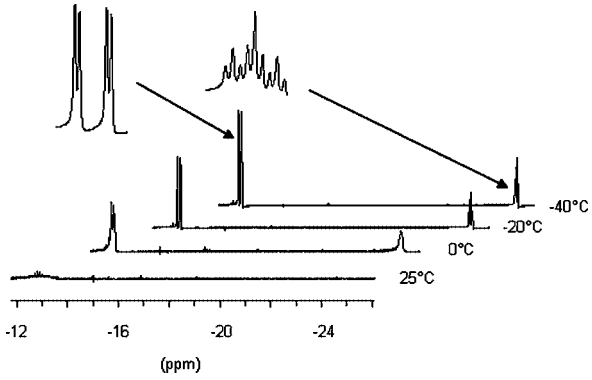

Figure 4. Variable $^1$H NMR temperature for [**2**][$BF_4$] in [$D_6$]acetone.

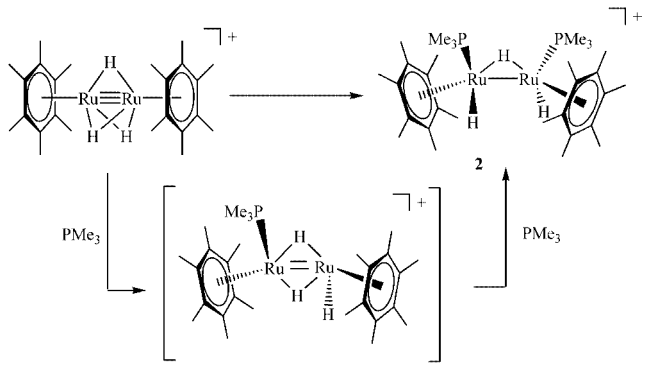
The two ruthenium atoms in **2** are stereogenic, the crystal structure analysis of [**2**][$BF_4$] reveals a racemic mixture of the (*R*,*R*) and the (*S*,*S*) enantiomers, the *meso* (*R*,*S*) isomer being absent. This observation shows that the addition of the trimethylphosphane ligands to [($\eta^6$-$C_6Me_6$)$_2$Ru$_2$($\mu_2$-H)$_3$]$^+$ occurs diastereospecifically.

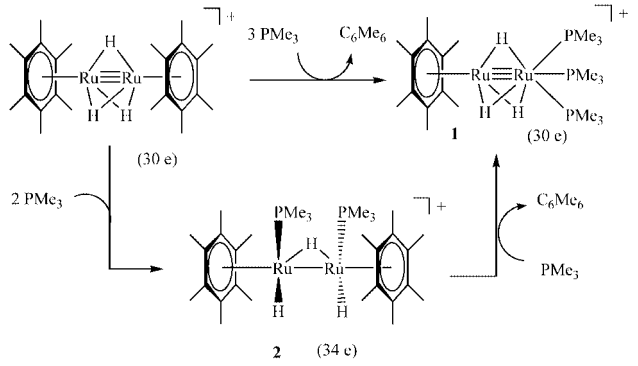
This can be explained by step-wise attack of the two $PMe_3$ molecules: In the first step, one $PMe_3$ molecule coordinates to one ruthenium atom, which forces the two hexamethylbenzene ligands to adopt a tilted geometry in the *trans* configuration with respect to each other, and pushes one of the three hydrido ligands from a bridging into a terminal position at the second ruthenium atom, in an *anti* configuration with respect to the $PMe_3$ ligand. In the second step, the next $PMe_3$ molecule enters the complex coordinating to the second ruthenium atom, *trans* with respect to the $\eta^6$-$C_6Me_6$ ligand, which pushes a second hydrido ligand from a bridging into a terminal position. As the coordination of the first trimethylphosphane ligand does not favour the (*R*) or (*S*) enantiomers, the racemic mixture is obtained (Scheme 3). Alternatively, an intermediate containing a bridging trimethylphosphane ligand may be considered.[10]

At 80 °C in the presence of $PMe_3$ (0.1 equiv.), cation **2** converts into cation **1** with liberation of one equivalent of hexamethylbenzene (10% yield), which suggests **2** to be an intermediate in the reaction between [($\eta^6$-$C_6Me_6$)$_2$Ru$_2$($\mu_2$-H)$_3$]$^+$ and $PMe_3$ to give **1** (Scheme 4). However, no evidence



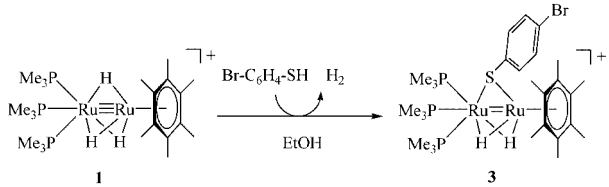
Scheme 3. Mechanistic proposal for the diastereospecific addition of two $PMe_3$ ligands to [($\eta^6$-$C_6Me_6$)$_2$Ru$_2$($\mu_2$-H)$_3$]$^+$.

for the direct transfer of one $PMe_3$ ligand from one ruthenium atom to the other one in **2** to give **1**, could be obtained.



Scheme 4. Mechanistic hypothesis for the synthesis of **1**.

In order to study the reactivity of unsaturated complex **1** (30 e), we reacted **1** with *p*-bromothiophenol given that the parent cation [($\eta^6$-$C_6Me_6$)$_2$Ru$_2$($\mu_2$-H)$_3$]$^+$ (30 e) reacts with *p*-bromothiophenol to give [($\eta^6$-$C_6Me_6$)$_2$Ru$_2${$\mu_2$-(*p*-Br-$C_6H_4$)-S}($\mu_2$-H)$_2$]$^+$ and [($\eta^6$-$C_6Me_6$)$_2$Ru$_2${$\mu_2$-(*p*-Br-$C_6H_4$)-S}$_2$($\mu_2$-H)]$^+$.[11] Indeed, complex **1** reacts in refluxing ethanol with *p*-bromothiophenol to give, with elimination of molecular hydrogen, the thiolato-bridged derivative [($\eta^6$-$C_6Me_6$)Ru$_2$($PMe_3$)$_3${$\mu_2$-(*p*-Br-$C_6H_4$)-S}($\mu_2$-H)$_2$]$^+$ (**3**), isolated as the tetrafluoroborate salt (Scheme 5) in 45% yield. Unlike the reaction of [($\eta^6$-$C_6Me_6$)$_2$Ru$_2$($\mu_2$-H)$_3$]$^+$ with *p*-bromothiophenol, analogous complex **1** gives only the monosubstituted product even with a large excess (10 equiv.) of *p*-bromothiophenol, probably for steric reasons.



Scheme 5. Synthesis of **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The two hydrido ligands in **3** are not equivalent due to the tetrahedral geometry of the sulfur atom, which gives rise to two signals in the hydride region ($\delta$ = –14.29 and –15.48 ppm) in the $^1$H NMR spectrum.

## Conclusions

In conclusion, we studied the reactivity of the unsaturated cation $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ toward trimethylphosphane, which shows that even the strongly bound $\eta^6$-$C_6Me_6$ ligand can be replaced by three trimethylphosphane ligands in $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ to give $[(\eta^6\text{-}C_6Me_6)\text{-}Ru_2(PMe_3)_3(\mu_2\text{-}H)_3]^+$ (**1**). A possible intermediate $[(\eta^6\text{-}C_6Me_6)_2Ru_2(PMe_3)_2(\mu_2\text{-}H)(H)_2]^+$ (**2**), obtained as a racemic mixture of both (*R*,*R*) and (*S*,*S*) enantiomers, has been isolated by reacting $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ and trimethylphosphane at room temperature.

## Experimental Section

**General Remarks:** All manipulations were carried out in an inert atmosphere of nitrogen by using standard Schlenk techniques. All solvents were degassed with nitrogen prior to use. Silica gel (type G) used for preparative thin-layer chromatography was purchased from Macherey–Nagel GmbH. Trimethylphosphane solution (1 M) in thf was purchased from Aldrich. The dinuclear trihydrido complex $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3][BF_4]$ was synthesised by a previously described method.[12] Deuterated NMR solvents were purchased from Cambridge Isotope Laboratories, Inc. NMR spectra were recorded with a Bruker 400 MHz spectrometer and ESI mass spectra were recorded at the University of Fribourg by Prof. Titus Jenny. Microanalyses were carried out by the Laboratory of Pharmaceutical Chemistry, University of Geneva.

**Synthesis of $[(\eta^6\text{-}C_6Me_6)Ru_2(PMe_3)_3(\mu_2\text{-}H)_3][BF_4]$ ([1][BF$_4$]):** In a pressure Schlenk tube, $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3][BF_4]$ (100 mg, 0.16 mmol) was dissolved in ethanol (20 mL, puriss.) and a solution of trimethylphosphane (1 M) in thf (0.4 mmol, 0.4 mL) was then added. The resulting solution, which turned red after a few minutes, was stirred at 80 °C for 18 h. The reaction mixture was then cooled to room temperature, and the solvent was evaporated under reduce pressure. The resulting orange-red solid was purified by preparative thin-layer chromatography on silica (acetone/dichloromethane, 1:10). The pure product was extracted with acetone from the main orange band and evaporation of the solvent gave [**1**][BF$_4$]. Yield: 30 mg, 0.044 mmol (28%). $^1$H NMR (400 MHz, [D$_6$]acetone, 25 °C): $\delta$ = –13.24 (q, $^2J_{(H,P)}$ = 4.5 Hz, hydride), 1.51 [br., 27 H, P(C$H_3$)$_3$], 2.46 [s, 18 H, $C_6$(C$H_3$)$_6$] ppm. $^{13}$C{$^{31}$P, $^1$H} NMR (100 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 18.05 [$C_6$(*C*H$_3$)$_6$], 24.59 [P(*C*H$_3$)$_3$], 24.79 [P(*C*H$_3$)$_3$], 24.89 [P(*C*H$_3$)$_3$], 93.53 [$C_6$(CH$_3$)$_6$] ppm. $^{31}$P{$^1$H} NMR (160 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 18.69 (s) ppm. MS (ESI): *m*/*z* = 597 [M + H]$^+$. $C_{21}H_{48}BF_4P_3Ru_2$ (682.47): calcd. C 36.95, H 7.08; found C 36.88, H 7.02.

**Synthesis of $[(\eta^6\text{-}C_6Me_6)_2Ru_2(PMe_3)_2(\mu_2\text{-}H)(H)_2][BF_4]$ ([2][BF$_4$]):** In a pressure Schlenk tube, $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3][BF_4]$ (100 mg, 0.16 mmol) was dissolved in ethanol (20 mL, puriss) and a solution of trimethylphosphane (1 M) in thf (0.33 mmol, 0.33 mL) was added. The resulting solution, which turns red after a few minutes, was stirred at room temperature for 18 h. The solvent was evaporated to dryness under reduced pressure. The red solid was washed with diethyl ether (3 × 60 mL), dissolved in acetone, and filtered through celite under an inert atmosphere by using a Mülheim apparatus. The solvent was then evaporated to dryness to give quantitatively [**2**][BF$_4$] (115 mg, 0.15 mmol). $^1$H NMR (400 MHz, [D$_6$]-acetone, –40 °C): $\delta$ = –25.24 (tt, $^2J_{(H,H)}$ = 7.6 Hz, $^2J_{(H,P)}$ = 23.4 Hz, 1 H, hydride), –13.10 (dd, $^2J_{(H,H)}$ = 7.6 Hz, $^2J_{(H,P)}$ = 51.8 Hz, 2 H, hydride), 1.40 [d, $^2J_{(H,P)}$ = 9.16 Hz, 18 H, P(C$H_3$)$_3$], 2.28 [s, 36 H, $C_6$(C$H_3$)$_6$] ppm. $^{13}$C{$^{31}$P, $^1$H} NMR (100 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 18.14 [$C_6$(*C*H$_3$)$_6$], 23.45 [d, $^1J_{(P\text{-}C)}$ = 32 Hz, P(*C*H$_3$)$_3$], 99.26 [$C_6$(CH$_3$)$_6$] ppm. $^{31}$P{$^1$H} NMR (160 MHz, [D$_6$]-acetone, 25 °C): $\delta$ = 8.61 (s) ppm. MS (ESI): *m*/*z* = 681 [M]$^+$ (and decomposition signals). $C_{30}H_{57}BF_4P_2Ru_2$ (768.66): calcd. C 46.87, H 7.47; found C 46.94, H 7.39.

**Conversion of 2 into 1:** In a pressure Schlenk tube, $[(\eta^6\text{-}C_6Me_6)_2\text{-}Ru_2(\mu_2\text{-}H)_3][BF_4]$ (100 mg, 0.16 mmol) was dissolved in ethanol (20 mL, puriss.) and a solution of trimethylphosphane (1 M) in thf (0.34 mmol, 0.34 mL) was added. The resulting red solution was stirred at room temperature for 18 h. The solution containing [**2**][BF$_4$] was heated at 80 °C for 8 h, and the solvent was then evaporated to dryness under reduce pressure. The resulting orange-red solid was purified by preparative thin-layer chromatography on silica (acetone/dichloromethane, 1:10). The product was extracted with acetone from the main orange band and evaporation of the solvent gave [**1**][BF$_4$]. Yield: 11 mg, 0.016 mmol (10%).

**Synthesis of $[(\eta^6\text{-}C_6Me_6)Ru_2(PMe_3)_3\{\mu_2\text{-}(p\text{-}Br\text{-}C_6H_4)\text{-}S\}(\mu_2\text{-}H)_2]\text{-}[BF_4]$ ([3][BF$_4$]):** $[(\eta^6\text{-}C_6Me_6)Ru_2(PMe_3)_3(\mu_2\text{-}H)_3][BF_4]$ (30 mg, 0.044 mmol) and *para*-bromothiophenol (26.6 mg, 0.14 mmol) were dissolved in ethanol (25 mL, puriss.), and the red solution was heated at reflux for 18 h. After cooling to room temperature, the solvent was evaporated to dryness, and the red solid was washed with diethyl ether (3 × 40 mL). The red solid was purified by preparative thin-layer chromatography on silica (acetone/dichloromethane, 1:10). The product was extracted with acetone from the main orange fraction and evaporation of the solvent gave the pure product. Yield: 18 mg, 0.02 mmol (45%). $^1$H NMR (400 MHz, [D$_6$] acetone, 25 °C): $\delta$ = –15.48 (m, 1 H, hydride), –14.29 (m, 1 H, hydride), 1.14 [d, $^2J_{(H,P)}$ = 9.0 Hz, 9 H, P(C$H_3$)$_3$], 1.47 [d, $^2J_{(H,P)}$ = 9.4 Hz, 9 H, P(C$H_3$)$_3$], 1.69 [d, $^2J_{(H,P)}$ = 8.7 Hz, 9 H, P(C$H_3$)$_3$], 2.22 [s, 18 H, $C_6$(C$H_3$)$_6$], 7.48 (br., 4 H, *H*-Ar) ppm. $^{13}$C{$^{31}$P, $^1$H} NMR (100 MHz, [D$_6$] acetone, 25 °C): $\delta$ = 17.75 [$C_6$(*C*H$_3$)$_6$], 21.64 [P(*C*H$_3$)$_3$], 21.92 [P(*C*H$_3$)$_3$], 22.01 [P(*C*H$_3$)$_3$], 22.31 [P(*C*H$_3$)$_3$], 24.03 [P(*C*H$_3$)$_3$], 24.32 [P(*C*H$_3$)$_3$], 94.97 [$C_6$(CH$_3$)$_6$], 121.53 (*C*-Br), 132.67 (*C*-Ar), 133.11 (*C*-Ar), 146.25 (*C*-S) ppm. $^{31}$P{$^1$H} NMR (160 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 10.89 (dd, $^2J_{(H,P)}$ = 28 Hz, $^2J_{(H,P)}$ = 32 Hz), 12.68 (dd, $^2J_{(H,P)}$ = 32 Hz, $^2J_{(H,P)}$ = 43 Hz), 16.40 (dd, $^2J_{(H,P)}$ = 30 Hz, $^2J_{(H,P)}$ = 44 Hz) ppm. MS (ESI) *m*/*z* = 783 [M + H]$^+$. $C_{27}H_{51}BBrF_4P_3Ru_2S$ (869.53): calcd. C 37.29, H 5.91; found C 37.34, H 5.94.

**X-ray Crystallography:** Crystals of [**1**][BF$_4$] and [**2**][BF$_4$] were mounted on a Stoe Image Plate Diffraction System equipped with a φ circle goniometer by using Mo-$K_\alpha$ graphite monochromated radiation ($\lambda$ = 0.71073 Å) with φ range 0–200°, increment of 1.0 and 1.5°, respectively, 2$\theta$ range from 2.0–26°, $D_{max}/D_{min}$ = 12.45/0.81 Å. The two structures were solved by direct methods by using the program SHELXS-97.[13] Refinement and all further calculations were carried out by using SHELXL-97.[14] The H-atoms were included in calculated positions and treated as riding atoms with the use of the SHELXL default parameters. The non-H atoms were refined anisotropically by using weighted full-matrix least-square on $F^2$. Crystallographic details are summarised in Table 1. Figure 1 and Figure 3 (ORTEP[15] drawing) show the labelling scheme for [**1**][BF$_4$] and [**2**][BF$_4$]. Figure 3 is drawn with MERCURY.[16]

# Mechanistic Analysis of Nucleophilic Substrates Oxidation by Functional Models of Vanadium-Dependent Haloperoxidases: A Density Functional Theory Study

**Curtis J. Schneider,[a] Giuseppe Zampella,[b] Claudio Greco,[b] Vincent L. Pecoraro,*[a,c] and Luca De Gioia*[b]**

**Keywords:** Peroxido ligands / Tripodal ligands / Oxidation / Vanadium / Density functional calculations

Density functional theory has been used to investigate the structural, electronic, and reactivity properties of an established functional model for vanadium-dependent haloperoxidases, K[VO($O_2$)Hheida] (Hheida$^{2-}$ = 2,2′-[(2-hydroxyethyl)imino]diacetate). Possible solution species were determined on the basis of potential exogenous donors present under the conditions necessary for reactivity. The energetically favored solution-state species is a 1:1 complex of Hheida and vanadium with a coordinated hydroxyethyl donor *trans* to the vanadium–oxido bond which is in agreement with the reported solid-state structure for K[VO($O_2$)Hheida]. Transition states of the oxidation reaction were located for four substrates: chloride, bromide, iodide, and dimethyl sulfide. The role of protonation and its effects on reactivity were examined for each substrate. Protonation of the peroxido moiety leads to a significant drop in the activation barrier for oxidation. In contrast no transition states could be located for an oxido-transfer process involving the oxido ligand. Barriers of activation calculated for halide oxidation were similar, providing support to the hypothesis that the p$K_a$ of the halide in acetonitrile is responsible for the decrease in reactivity between $I^-$, $Br^-$, and $Cl^-$. The results presented herein provide a mechanistic correlation between a functional model and the enzyme, making K[VO($O_2$)Hheida] a "complete" functional model for vanadium-dependent haloperoxidase.

## Introduction

Vanadium complexes have been used in a number of oxidative transformations[1] relevant to organic synthesis, including but not limited to alcohol oxidation, halide oxidation, and sulfoxidation. Of these reactions, the oxidation of achiral sulfides to chiral sulfoxides[1–4] has sparked the most attention in recent years because of the potential applications of chiral sulfoxides.[5] Peroxido-vanadium complexes are capable of the single oxidation of organic sulfides to sulfoxides with little double oxidation product (sulfone).[1,6,7] A number of catalysts have been presented in the literature[3,8–11] to be competent with respect to sulfide oxidation and in some cases to be stereoselective. To date the best peroxido vanadium-based catalyst is K[VO($O_2$)Hheida], showing the highest rates of sulfide oxidation of any reported catalyst for bromide and organic sulfide oxidation. The mechanism of both halide and sulfide oxidation with this complex have been extensively studied. Thus, the K[VO($O_2$)Hheida] serves as an effective functional mimic for the vanadium-dependent haloperoxidase class of enzyme and is an excellent catalyst in its own right.

Vanadium-dependent haloperoxidases (VHPO) are metalloenzymes containing a mononuclear vanadium(V) cofactor[12] that catalyze the oxidation of halides in the presence of hydrogen peroxide. The oxidized species (HOX, $X_3^-$, or $X_2$) subsequently adds to organic molecules, yielding halogenated marine products.[13] The first example of this vanadoenzyme class was a bromoperoxidase isolated from the marine algae *Ascophyllum nodosum*.[14] The enzyme nomenclature is based upon the most electronegative halide that the enzyme is capable of oxidizing. VHPO's can also catalyze the stereospecific two-electron oxidation of organic sulfides to chiral sulfoxides.[15] The importance of a protonation of the active site for reactivity is suggested by the catalytically relevant p$K_a$ of 5.9[16] for a vanadium bromoperoxidase. A number of X-ray crystal structures are now available for VHPO,[17–20] including peroxide-bound and unbound forms of a vanadium chloroperoxidase from the fungus *Curvularia inaequalis*.[19] The vanadate co-factor is covalently coordinated to an enzyme-bound histidine. The coordination geometry is trigonal bipyramidal, with an oxygen atom in the axial position *trans* to N atom of histidine, three other oxygen atoms complete the coordination sphere. The peroxide-bound form is best described as having a distorted tetragonal geometry when treating the per-

oxido ligand as a single donor ligand. The coordination sphere is completed by an imidazole nitrogen donor, one oxido, and one hydroxido oxygen atoms.

Recently, computational methods have been employed to examine the resting and catalytically active states for simple models of the enzyme[21–26] active site. The limitations of X-ray crystallography left some ambiguity as to the protonation state of the vanadate co-factor in the resting and peroxido-bound forms. Density functional theory was used to explore the energetic consequences of protonation of a quantum chemical (QC) model for the vanadate co-factor with fixed nearby donor residues.[25] The results of this study indicate the resting state to contain a *cis*-dioxido vanadium(V) species with one axial hydroxido group, an equatorial hydroxido, with an imidazole completing the first coordination sphere. Recent QM/MM calculations have indicated another isoenergetic potential resting state configuration that is stabilized by long range electrostatic interactions, and which contains three oxido moiety plus an axial water.[22,23] $^{51}V$ solid state NMR spectroscopy was used in conjunction with DFT methods to examine the resting state configuration of vanadium chloroperoxidase; these studies confirm the resting state structure proposed in the aforementioned DFT and QM/MM studies.[21]

A number of mechanisms have been proposed for these enzyme based on small molecule mimics, including $KVO(O_2)$Hheida, which generally invoke oxido-transfer catalysis. It has been shown that protonation of the peroxido moiety is essential for reactivity. Thus, in the catalytically active form there exists on the vanadium a terminal oxido and a protonated and unprotonated peroxido oxygen atoms. The question that then arises is which of these oxygen atoms is transferred to the substrate.[27] Colpas et al. proposed that the transferred oxygen originated from the hydroperoxido moiety; however, these authors could not identify whether the protonated or unprotonated oxygen was involved. Computational methods have been employed to differentiate these two possibilities in QC models of VHPO.[26] These studies indicate that oxido-transfer proceeded through the unprotonated peroxido atom through an $S_N2$-like process and that protonation of the peroxide ligand significantly lowered the barrier of activation for both halide and sulfide oxidation. These computational studies are in full agreement with reported catalytic abilities of the enzyme system.[16]

As previously mentioned, considerable effort has been expended to clarify the enzymatic mechanism, relatively little attention has been focused on the understanding the mechanism of the original catalysts described by Colpas and co-workers. These complexes are not only important for further our understanding of VHPO's, but in their own right as useful catalysts in organic synthesis. These vanadium tripodal amine complexes are the most effective sulfoxidation catalysts reported in the literature.[6,27] Mechanistic studies have shown the maximal rate of substrate oxidation occurs when one equivalent of proton with respect to vanadium is present. A red shift in the peroxido-vanadium charge-transfer band indicates the direct protonation of the vanadium complex. $V^{51}$ NMR showed a single resonance with a chemical shift and a linewidth consistent with a single mono-peroxido oxidovanadium(V) species under the reaction conditions; however, this does not rule out rapidly interconverting isoenergetic species. These observations were incorporated into a mechanistic proposal that was developed on the basis of the previously proposed halide oxidation mechanism, involving a hydroperoxido vanadium species undergoing an oxido transfer reaction with organic sulfides[6] (Figure 1). Despite these extensive mechanistic studies solution speciation under the reported reaction conditions, the site of catalyst protonation, the role of the protonated peroxido moiety in oxidative catalysis and the geometry of the transition state, still require further scrutiny.

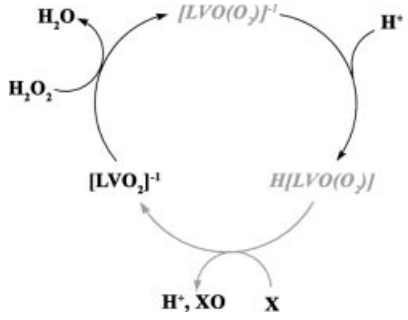

Figure 1. Diagram of the proposed mechanism for oxidation of a nucleophilic substrate by tripodal amino complexes of vanadium(V). X = $Br^-$, $I^-$, or $R_2S$. Steps highlighted in grey are the focus of this study.

Density functional theory has been used to address questions regarding reactivity and spectroscopic properties of transition-metal systems related to biology[28] and catalysis.[29] Balcells et al. reported computational studies of a truncated QC models for vanadium(V)-containing Schiff base complexes[30] and its ability to oxidize organic disulfides in the presence of hydrogen peroxide. This study was later expanded to determine the factors controlling the stereoselectivity of disulfide oxidation using QM/MM methods[31] on sterically hindered Schiff bases often employed in vanadium catalysis literature.[7,9–11,32] Balcells et. al demonstrated the characteristics of an $S_N2$-like transition state, where oxido-transfer occurs from the unprotonated oxygen of the peroxido moiety to organic sulfides. Although the coordination environment of the Schiff base complex is significantly different from the enzyme system, it does bear some similarities (side-bound peroxido, similar transition state) and lends support to a peroxido atom transfer to the substrate. Schiff base vanadium(V) complexes have been shown to be functional mimics for VHPO based on their ability to oxidize bromide and organic sulfide,[9,11,32] but kinetic analysis and, therefore, detailed mechanistic studies are not possible due to bromination of the ligand system.[33]

$K(VO(O_2)$Hheida) has been studied extensively with respect to both bromide[27] and sulfide[6] oxidation, despite these synthetic results mechanistic questions relevant to future catalyst design based on these systems (i.e. protonation state of the catalytically active species and transition-state

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

geometries). We present herein a detailed computational investigation of this catalyst. Treating the entire complex quantum mechanically, we provide a better understanding of the mechanism for substrate oxidation allowing more efficient catalyst design and providing a mechanistic correlation between these functional mimics and VHPO's.

## Results

### Quantum Chemical System

The X-ray coordinates for K[VO($O_2$)Hheida][34] were used as a starting point to set up a quantum chemical model of this system. Waters of crystallization were removed, as was the potassium ion. Under the reaction conditions used by Colpas et al., there are two equivalents of 18-crown-6 which chelate the potassium ion in acetonitrile, limiting the potential interactions of the cation with the vanadium complex during the catalytic cycle. The resulting energy-minimized geometry of [VO($O_2$)Hheida]$^{-1}$ (**1**), depicted in Figure 2 is nearly identical to the bond lengths reported in the crystal structure (Table 1).

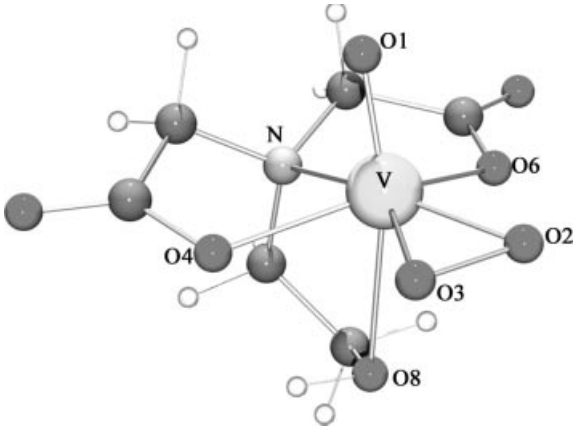

Figure 2. Ball-and-stick representation of geometry optimized **1**.

Table 1. Bond lengths [Å] of [VO($O_2$)Hheida]$^{-1}$.

| | X-ray structure | Optimized **1** |
|---|---|---|
| V–O1 | 1.60 | 1.62 |
| V–O2 | 1.87 | 1.85 |
| V–O3 | 1.86 | 1.85 |
| V–O4 | 2.05 | 2.10 |
| V–O6 | 2.04 | 2.05 |
| V–O8 | 2.24 | 2.45 |
| V–N1 | 2.19 | 2.28 |
| O3–O2 | 1.43 | 1.44 |

### Protonation and Solution Speciation

Before exploring the oxidative chemistry of **1**, a better understanding of the solution-state speciation for this pre-catalytic species is necessary. The crystal structure of K[VO($O_2$)Hheida] shows a disordered hydroxyethyl arm due to two ring conformation of a five-membered chelate ring. The interconversion between these two states is rapid compared to the rate of oxidation, therefore, the left- and right-hand sides of **1** are treated as equivalent for optimizations involving an Hheida$^{-2}$ ligand. The weakest coordinating and therefore most labile donor atom is the oxygen associated with the hydroxyethyl arm of Hheida$^{2-}$. Geometry-optimized structures were obtained initially both with a coordinated hydroxy oxygen atom and a completely dissociated hydroxy group. The former being the more stable of the two by 1.3 kcal/mol. Given the two potential pre-catalytic isomers, a coordinated hydroxy and the uncoordinated hydroxy group and the presence of sigma donor ligands under the reaction conditions (water, acetonitrile, and substrate), a vacant coordination site is not likely. As there is no experimental evidence supporting coordination of substrate molecules in VHPO or in the small molecule models, substrate coordination was ruled out as possibility. A comparison of the energetic differences between the van der Waals complex of the exogenous donors, water and acetonitrile, with the coordinated exogenous donor in place of the hydroxy group was made. These comparisons were made using the most stable protonated species to reduce the electronic repulsion created by the approach of a sigma donor to an anionic vanadium species. The results of this comparison are presented later.

Five potential sites of protonation were identified on the basis of the areas of highest electron density for **1**: oxido (**0c**), peroxido left (**0b**), peroxido right (**0a**), carboxylate oxygen (**0d**), and the carbonyl oxygen (**0e**) (Figure 3). Only one of the carboxylate donors was protonated due to the previously mentioned conformational isomerism. Protonation of the peroxido can occur in four possible locations as illustrated in part b of Figure 3. The most stable optimized structures involved protonation of the peroxido ligand **0a** or **0b**. The four possible orientations of the proton around

the peroxido ligand were isoenergetic when ring conformations were taken into account. There is significant contraction of the vanadium hydroxy bond (V–O8) upon protonation of the complex in **0a**, **0b**, or **0c**, a decrease of 0.1 Å for **0a** and **0b**, and 0.2 Å for **0c.**

The most stable optimized geometry, **0a**, was used to determine whether exogenous ligands can bind *trans* to the oxido moiety. Three exogenous donors were tested in place of hydroxy coordination to the vanadium center: water, acetonitrile, and bromide. In all cases, a van der Waals complex of the exogenous donor and **0a** is more stable than coordination of the respective donor in place of the hydroxy. In the case of water coordination to **0a**, (Figure 3, parts c, d), hydroxy coordination to vanadium over water was favored by 4.0 kcal/mol. A coordinatively unsaturated species, dissociation of the hydroxy group with no *trans* donor, was less favored by 4.6 kcal/mol.

### Halide Transition States

Transition states corresponding to the nucleophilic attack of halide ions ($Cl^-$, $Br^-$, $I^-$) on the peroxido ligand of the vanadium atom were located for both **1** and **0a**. Due to the anionic character of both the halide and **1**, starting materials were calculated on the basis of two infinitely separated species, as any attempt to minimize a van der Waals complex resulted in the two ions rapidly diverging. The transition-state geometry found for **1** with all three halides (**1_cl**, **1_br**, **1_i**) are nearly identical, therefore, a representative case will be presented for the oxidation of bromide. The transition state for bromide oxidation is characterized by a linear halide peroxido bond angle (173°), where the dihedral angle between the peroxido ligand and the vanadium–oxido is 100° (Figure 4). The rest of the vanadium coordination sphere is significantly perturbed in comparison to **1**, there is a dramatic lengthening of all bonds in the first coordination sphere, in the case of **1_br** the carboxylate donors have bond lengths of 2.27 Å whereas the carboxylate-vanadium distances in **1** are 2.04 Å. Additionally the tertiary nitrogen bond lengthened by 0.3 Å in relation to **1** (Table 2). The computed barrier of activation, $\Delta G^{\ddagger}$, for bromide oxidation is 38.1 kcal/mol.

Table 2. Bond lengths [Å] of the transition states for bromide oxidation.

| | 1 | 1_br | 0a_br |
|---|---|---|---|
| V–O1 | 1.62 | 1.64 | 1.62 |
| V–O2 | 1.85 | 1.71 | 2.05 |
| V–O3 | 1.86 | 1.90 | 1.90 |
| V–O4 | 2.10 | 2.27 | 2.02 |
| V–O6 | 2.05 | 2.27 | 1.99 |
| V–O8 | 2.45 | 2.48 | 2.30 |
| V–N1 | 2.28 | 2.50 | 2.29 |
| O3–O2 | 1.44 | 1.87 | 1.69 |
| O3–Br | – | 2.27 | 2.38 |

Protonation of **1** at the most stable site (**0a**) yields an earlier transition state (**0a_br**), in which the Br–O bond is only partially formed with a nearly complete O–OH bond in the peroxido moiety, with a significantly lower barrier of activation (21.1 kcal/mol). The bromide–peroxido oxygen bond lengths is longer by 0.11 Å than **1_br**, with a comparably shorter peroxide bond length. The Br–O3–O2 bond angle is 163.4° while the dihedral angle between the peroxido ligand and the vanadium–oxido is 123.8°. Transitions states were only located in the protonated case where a hydrogen bond formed between the halide and the hydroxy ligand. No transition states related to halide oxidation could be located for attack of the substrate on the protonated peroxido ligand. This is true for all anionic halide transition states (**0a_cl**, **0a_br**, **and 0a_i**), where the corresponding barriers to activation are 23.0 kcal/mol for $Cl^-$ and 19.0 kcal/mol for $I^-$.

To explore the reactivity of **0a_x** further, a coordinatively unsaturated geometry was used as the starting point, in which a halide can weakly coordinate to vanadium(V) center. Bromide was used as the substrate and positioned to weakly coordinate to the vanadium center. **0a_br2** is characterized by a distortion of the dihedral angle V–O1–O2–O3 (149°) allowing a weak interaction of the bromide with vanadium 3.03 Å. A reasonable reactant structure could be located with bromide coordinating to the vanadium, and the computed barrier of activation is 8.6 kcal/mol. The barrier is significantly lower in energy because the coordination of bromine to an coordinatively unsaturated vanadium complex (**0a_br2**) is 10 kcal/mol higher energy than the corresponding hydrogen-bonded starting materials (**0a_br**).

Table 3. Comparison of relevant bond lengths and $\Delta E_{scf}$ [kcal/mol] for transition states associated with halide oxidation.

| | **1** | **1a_cl** | **1a_br** | **1a_i** | **0a** | **0a_cl** | **0a_br** | **0a_i** | **0a_br2** |
|---|---|---|---|---|---|---|---|---|---|
| O3–X | – | 2.17 Å | 2.27 Å | 2.39 Å | – | 2.29 Å | 2.38 Å | 2.55 Å | 2.48 Å |
| O3–O2 | 1.44 Å | 1.85 Å | 1.87 Å | 1.90 Å | 1.46 Å | 1.77 Å | 1.69 Å | 1.69 Å | 1.70 Å |
| V–O1–O2–O3 | 98.5° | 100.3° | 100.0° | 100.0° | 103.7° | 124.5° | 123.7° | 121.8° | 149.0° |
| $\Delta E_{scf}^{\ddagger}$ [kcal/mol] | – | 39.2 | 38.1 | 36.0 | – | 23.0 | 21.1 | 19.0 | 20.05 |

The geometries and respective energy differences between starting materials and transition states for all located halide transition states are presented in Table 3. No transition states could be located corresponding to attack of the halide on the oxido ligand of **1**, **0a**, or **0c**.

### Sulfide Transition States

The effects of protonation on the barrier of activation were also explored for the oxidation of dimethyl sulfide. Transition states calculated for dimethyl sulfide oxidation are less distorted from the energy minimized structures of **1** or the appropriate protonated species **0(a**,**b)** than the corresponding halide transition state. Figure 5 shows two representative transition states located for sulfide oxidation by anionic and neutral vanadium species.

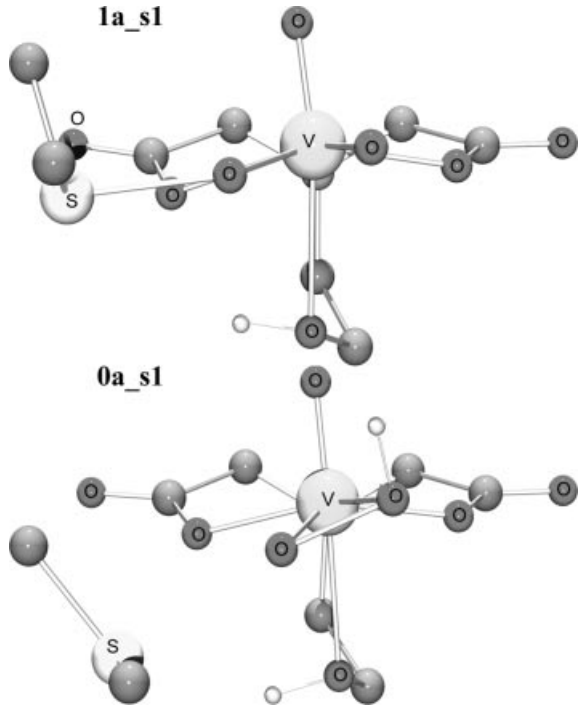

Figure 5. Ball-and-stick representation of an anionic (top) and neutral (bottom) transition state located for dimethyl sulfide oxidation.

The transition-state geometry **1_s** is characterized by a nearly linear S–O2–O3 bonding angle, identical to that identified for the case of halide oxidation. Due to the asymmetry associated with upper and lower halves of **1**, multiple transition states with slightly different energies could be located, the only difference being related to relative orientation of the methyl groups of dimethyl sulfide. Approach of dimethyl sulfide to the left or right hand side of **1** yielded nearly isoenergetic transition states, with a barrier of activation of 18.3 kcal/mol. Starting materials were minimized from each located transition state generating a van der Waals complex of dimethyl sulfide and **1**.

Transition states were located for the protonated complexes **0a_s** and **0b_s**. As was the case for **1**, multiple rotational isomers could be located and are related to orientation of the methyl groups on the substrate. The neutral transition states located for dimethyl sulfide oxidation are less distorted than **0a_X**, with dihedral angles approx. V–O1–O2–O3 111.8° and a S–O3–O2 of 166.6° where the sulfide attacks the unprotonated peroxido oxygen. To calculate the barrier of activation, van der Waals complexes of dimethyl sulfide and the appropriately protonated vanadium species were optimized. The lowest energy starting material complex located contained a hydrogen bond forms between dimethyl sulfide and the hydroxy group of the complex the barrier of activation for the oxidation reaction is 9.4 kcal/mol. The barrier of activation drops significantly (by 9 kcal/mol), when the peroxido moiety is protonated, leading to four isoenergetic transition coordinates differing in the approach of sulfide to the neutral vanadium complex and orientation of the sulfide. No transition states could be located related to attack of the sulfide on the unprotonated oxido group (**0c**) or attack of the sulfide on the protonated peroxido oxygen.

## Discussion

Although many model complexes[27,32,33,35,36] have been presented in the literature, the pre-catalytic species K[VO($O_2$)Hheida][34] isolated by Colpas and co-workers is the most thoroughly investigated system. Detailed mechanistic studies have shown the importance of protonation of the complex with respect to halide[27] and sulfide oxidation.[6] These studies established K[VO($O_2$)Hheida] as a functional mimic of the vanadium-dependent haloperoxidases and as an excellent catalyst for organic transformations. We have undertaken a thorough computational investigation of the mechanism for halide and sulfide oxidation, specifically with respect to the effects of protonation of the complex on the activation barrier for these processes in order to develop future asymmetric oxidation catalysts based on the $H_3$heida architecture.

Starting coordinates are taken from the crystallographically characterized pre-catalyst, we optimized chemically reasonable solution state species. The crystal structure of K[VO($O_2$)Hheida] shows a hydroxy group *trans* to the ox-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ido, with tertiary nitrogen *trans* to the peroxido moiety, a typical binding mode for oxidovanadium(V) peroxido complexes with tripodal amino ligands. The experimental conditions have been taken into account when setting up the QM investigation, both regarding solvent polarizing power, and to explore the possibility of binding by exogenous donor ligand to vanadium. Potassium is chelated by 18-C-6 allowing K[VO($O_2$)Hheida] to be solubilized in acetonitrile. On the basis of this condition, the quantum chemical model, **1**, excluded potassium in all geometry optimizations. The weakest donor group in **1** is the hydroxy group *trans* to the oxido. As there is no ligand field stabilization energy for a vanadium(V) complex, a coordinatively unsaturated species is potentially feasible. Geometry optimization was performed on an anionic complex in which the hydroxy group was completely dissociated from the complex, the resulting optimized structure is 1.3 kcal/mol higher in energy when enthalpic and entropic corrections are taken into account. Under the reaction conditions a number of exogenous donors are present in at least equimolar quantities with respect to the vanadium complex, making a coordinately unsaturated species less likely.

Before examining the energetic preference for exogenous donors, we explored the energetics of monoprotonated **1**. The potential proton acceptors in the complex are all of the oxygen atoms associated with the ligand, this generates five potential sites of protonation. Protonation of the peroxido ligand is the most energetically favored, there is a slight difference between protonation of O3 and O2 this effect is negligible when chelate ring conformations of the hydroxyethyl arm of **1** are taken into account. Protonation of the peroxido (**0a** and **0b**) is favored by 3 kcal/mol over protonation of the oxido ligand (**0c**), while protonation of either carboxylate oxygen generates a species 6 kcal/mol higher in energy.

Using the energetically favored protonation states of the complex, two optimizations were performed for exogenous donors, one in which a van der Waals complex of the donor was made with a coordinated hydroxy species **0a**, and one with the exogenous donors coordinated in place of the hydroxy. For all the exogenous donors tested (water, acetonitrile, and bromide), the van der Waals complex was more stable by 2, 7, and 15 kcal/mol, respectively. Thus a coordinated hydroxy species is likely to be the dominate solution species present. Previously $^{51}$V NMR has been used to explore the number of vanadium species present under the reaction conditions, suggesting only one species is present or there is an exchange process faster than the $^{51}$V NMR timescale. All factors considered, the loss of entropy is higher in the cases of exogenous donor molecules. Since the enthalpic contribution is roughly similar when considering exogenous and endogenous ligands (on binding to V) a larger gain in the entropy is expected when a water, bromide, or other exogenous ligand dissociates, compared to an endogenous ligand.

Using the most stable unprotonated (**1**) and protonated species (**0a**) as a starting point, transition-state searches were performed for chloride, bromide and iodide. Transition state located for **1** showed a significant lengthening of all ligand bonds to the vanadium, due to the increased electron density of the complex in the transition state. All bond lengths are still within a weak bonding distance. The transition state corresponded to the $S_N2$-like attack on the peroxido ligand of the vanadium complex as determined by examining the single negative vibrational eigenvalue. No transition state could be located for bromide attack on the vanadium–oxido bond. The energy of **1** and the appropriate halide at infinite separation were used as starting materials, as any attempt to generate a van der Waals complex resulted in a rapid divergence of the two anions. The resulting energies of activation were 39, 38, and 36 kcal/mol for chloride, bromide, and iodide, respectively.

Upon protonation of the complex, a pre-reaction adduct is formed, in which a hydrogen bond between the halide ion and the complex is present and, most importantly, the barriers of activation decreased dramatically. The resulting monoanionic transition states are $S_N2$-like with the nearly linear V–O3–O2H bond angle and have strongly distorted V–O1–O3–O2 dihedral angle. The hydrogen bond is maintained in all anionic halide transition states, and no transition states could be located for complexes in which this hydrogen bond was not present. Due to the large electron density surrounding the carboxylate donors of **0a**, it is necessary to stabilize the negative charge of the halide in this early transition state. Under the experimental reaction conditions this stabilization could be accomplished by the presence of hydrogen-bond donors (water or hydrogen peroxide) or cations (tetraethylammonium or potassium).

Zampella et al. located transition states for the oxidation of bromide using quantum chemical models of the active site of a VHPO.[26] Their results showed that nucleophilic attack of the halide on the unprotonated oxygen of a hydroperoxido species had the lowest barrier of activation. Transition states were located for the peroxido vanadium adduct; protonation of the peroxido moiety yielded a significantly more stable transition geometry resulting in a lower barrier of activation. The hydroperoxido transition state occurred significantly earlier with respect to halide–oxygen formation than the peroxido transition state. The transition states located for bromide oxidation by **1** and **0a** show the same trend with respect to the halide–oxygen bond formation. The resulting transition state **0a_br** shows a longer halide–oxygen bond than **1_br**, indicating an earlier transition state. Additionally, there is dramatic decrease in the barrier of activation from **1_br** to **0a_br** (Table 3); this observed decrease in the barrier of activation is likely an oversimplification of experimental barrier because of the interaction between two anionic species (vanadium complex and the halide) in the case of **1_br**. Indeed, under reaction conditions it may be possible to carry out this reaction by offsetting the negative charge with strongly associated cations or hydrogen-bond donors. These results now correlate the mechanism of halide oxidation for the best reported functional model for VHPO, K[VO($O_2$)Hheida], with the proposed mechanism for halide oxidation by the enzyme. The importance of offsetting the negative charge on the anionic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

halide is observed in the case of **0a_br** transition state, where a hydrogen bond forms between the bromide and the hydroxy group of the ligand resulting in a distorted dihedral angle for the peroxido moiety with respect to the vanadium–oxido bond. This is further supported by the location of a nearly isoenergetic reaction pathway, in which the bromide weakly coordinates to coordinatively unsaturated vanadium species **0a_br2**.

Given that VClPO is capable of oxidizing chloride, bromide and iodide, and K[VO($O_2$)Hheida] has been shown to be competent with respect to only bromide and iodide oxidation, we chose to explore the differences in barrier of activation for the oxidation of the aforementioned halides. Reactivity studies demonstrate the protonated K[VO($O_2$)-Hheida] is capable of oxidizing bromide and iodide, but not chloride. Two possible factors could contribute to this inability to oxidize chloride: 1. The reduction potential of the chloride is sufficiently high to prevent oxidation, 2. The active protonated form of the complex can not be generated in presence of chloride. The latter hypothesis was presented by Colpas et al. to explain this reactivity.[27] Slebodnick et al. demonstrated the ability of a tripodal amino complex to oxidize chloride when a mixture of acetonitrile (94%) and water (6%) was used as the solvent system.[37] Because chloride oxidation is not observed in either pure solvent it appears that in a mixture of the two solvents the basicity of the peroxido vanadium species increases with respect to chloride, allowing the catalytically active protonated species to be formed. On the basis of the transition-state energies presented herein, there is not a large difference in the energies of activation for each of the halides, therefore, differences in the reactivity can not be explained solely on the differences in reduction potentials of the oxidized halides. As protonation of the complex generates an early transition state, in which formation of the halide–oxygen bond is very weak, there is less contribution of halide orbital character in the transition state leading to smaller differences in the barrier of activation for halide oxidation (Table 3). These energies of activation presented here provide further support for this hypothesis.

To complete the functional correlation between the quantum-chemical models of the enzyme system and functional models for the enzyme, we examined the effects of protonation of the complex on organic sulfide oxidation. In the case of halide oxidation, the effects of protonation on the reaction barriers are masked to some degree by a highly charged dianionic transition state in the case of **1_x**, although this does represent the experimental conditions quite well, considering the chelation of potassium ions by 18-crown-6 preventing strong ion pair formation.

The organic sulfide oxidation system does not suffer from this highly charged transition state, resulting in a better understanding on the effects of protonation of the peroxido with respect to the barrier of activation for oxidation. Dimethyl sulfide was used as the organic sulfide to explore a number of transition-state geometries for both anionic and neutral catalytic species. The anionic transition states located were similar to those located for halide oxidation, a nearly linear S–O–O bond angle (175°) with V–O–O–O dihedral angle of 101°. The S–O bond length at the transition state was 2.08 Å indicating a high degree of sulfide–oxygen bonding character. These geometric parameters were conserved across the four anionic transition states located, two transitions for nucleophilic attack of DMS on the left- and right-hand side of the complex with two rotational isomers of DMS per side. Protonation of the peroxido moiety of **1** yielded lower energy transitions states (**0a_s**, **0b_s**), again exhibiting a lower degree of sulfur–oxygen bond formation leading to an earlier transition state identical to the trend observed for halide oxidation. The decrease in the barrier of activation of 8 kcal/mol is consistent with the dramatic increase in the rate of sulfide oxidation by K[VO($O_2$)Hheida] upon protonation. As the transition states located for the anionic catalytic species (**1_s1**, **1_s2**, etc.) are monoanionic, there is an overestimation of the barrier of activation for this pathway, though this overestimation is less dominant that it was in the case of the dianionic halide transition states. The anionic catalytic species may still present a viable reaction path in the presence of strong hydrogen bonding or ionic effects that could stabilize the transition state. This being said, the energy differences between the **1_s** and **0a_s** or **0b_s** are significant enough to consider the latter to be the dominant catalytic pathway.

The results presented above provide a direct correlation between the proposed transition-state geometries for VHPO's with the best known functional mimic for the same enzymes, making K[VO($O_2$)Hheida] a complete functional model for vanadium-dependent bromoperoxidases. As was the case for the enzyme studies, protonation of the peroxido moiety leads an early transition state and a dramatic decrease in the barrier of activation for substrate oxidation (substrate = halide or sulfide). Typical features of the transition states from enzyme model system are maintained (i.e. nearly linear O–O–S angle, similar bonding distances). Additionally, we provide support to the reactivity hypothesis presented by Colpas et al. describing the halide oxidation ability of K[VO($O_2$)Hheida]. The early transition states generated by protonation of the complex lead to small differences in the barrier of activation for halide oxidation; in contrast to the large difference in reduction potential for chloride, bromide, and iodide.

A comparison of van der Waals reactants adducts obtained with the hydrido-peroxido species of enzyme and synthetic models show that in both cases the substrate has a suitable spatial orientation to react with the hydroperoxido moiety. In particular, in the enzyme models, the atom of the substrate which undergoes oxidation (S, Br, I, Cl) is weakly coordinated to the vacant coordination position of vanadium and the interaction with vanadium place the substrate in the proper spatial orientation to act as attacking group in the $S_N2$ reaction.[26] In the synthetic model, the role of vanadium in positioning the substrate is played by the hydroxido ligand coordinated to the metal. In fact, the structure of the pre-reaction adducts obtained with the hydroperoxido form of the synthetic complex show that the atom of the substrate that will undergo oxidation is involved in a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

hydrogen bond with the hydroxido group. Formation of this hydrogen bond positions the substrate in the proper location to act as a nucleophile in the $S_N2$ reaction. Therefore, in both cases (enzyme and synthetic models) the vanadium complex plays a role in properly positioning the substrate in the transiently formed pre-reaction adduct.

The calculated barriers to activation for K[VO($O_2$)-Hheida], in the case of both bromide and sulfide oxidation, are slightly higher than that calculated for the enzyme system (Table 4). The differences in the barriers of activations between the enzyme and synthetic model systems can be explained by the polarization of the peroxido bond and the torsional angle of the peroxido ligand in the transition state. The hydroperoxido moiety is more activated in the enzyme model, in particular, the O–O bond is longer (1.467 enzyme model vs. 1.458 Å synthetic model) and the peroxido bond is more polarized ($Dq$ = 0.12 enzyme model vs. 0.02 synthetic model). Additionally, in the transition states computed for the synthetic model, the hydroperoxido group is slightly tilted (see Figure 5 above) due to simultaneous formation of the hydrogen bond with the hydroxido group and $S_N2$-type oxido transfer reaction. The tilting of the hydroperoxido group in the transition state is possibly another factor responsible for increasing the energy of the transition state thereby increasing the barrier to activation.

Table 4. Comparison of computed $\Delta G^{\ddagger}$ for thioether (DMS) and bromide (Br) oxidation using the enzyme and synthetic models (energies in kcal/mol). All energy values are obtained as difference between TS energies and Van der Waals reactant adducts.

| | Enzyme model | Synthetic model |
|---|---|---|
| DMS | 2.9 | 9.4 |
| $Br^-$ | 3.7 | 21.1 |

These results demonstrate the importance of protons in catalytic process. Many vanadium catalysts have been presented in the literature for a variety of oxidations: alcohol oxidations,[38] olefin epoxidation,[1,39–41] sulfide oxidation,[6,7,9,11,41] and phosphane oxidation.[1,8] Many of these processes use in-situ-derived catalytic systems from vanadium starting materials, vanadyl sulfate and vanadyl acetylacetonate being the most common, with a variety of ligands. The reported rates and turnover numbers for sulfide oxidation are significantly lower than those presented for K[VO($O_2$)Hheida], despite the similarities in coordination environments and terminal oxidant (hydrogen peroxide). The difference between other systems and the Hheida system is often the protonation of the peroxido ligand; which as shown herein decrease the barrier of activation and has experimentally been shown to increase the rate of reaction. To design better oxidation catalysts using vanadium, care should be taken to limit potential competitive protonation states. Additionally, steric bulk and H-bond acceptors should be added in such a way as to encourage selective protonation of one side of peroxido ligand thereby limiting the potential orientations a pro-chiral can adopt in the linear $S_N2$ type transition state. The computational results contained herein make it possible to design ligand sets capable of stereoselective oxidations using non-redox active $d^0$ metal–peroxido coordination complexes rationally.

## Conclusions

Our group has shown K[VO($O_2$)Hheida] to be an effective functional model and biomimetic catalyst for thioether and halide oxidation. Density functional theory was used to explore the chemically feasible pre-catalytic species, protonation states, and transition-state geometries. We have shown that coordination of the hydroxyethyl arm of Hheida is energetically favored over coordination of an exogenous donor such as acetonitrile or water. All chemically reasonable protonation states were examined on the basis of the precatalytic species. These results showed that protonation of the peroxido moiety is favored over protonation of Hheida or the oxido ligand. Transition states were located for thioether and halide oxidations (halide = $I^-$, $Br^-$, and $Cl^-$), all transition states were $S_N2$-like, with a nearly linear substrate–peroxido oxygen bond angles. Protonation of the peroxido moiety dramatically reduces the barrier to activation for both thioether and halides; however barriers are insensitive to the identity of the halide. This further supports the hypothesis that the inability of K[VO(OOH)-Hheida] to oxidize chloride is the result of the increasing basicity of the substrate, which leads to deprotonation of the catalytically active hydroperoxido species. These results provide the necessary information regarding the transition-state geometry and the importance of protons in the catalytic cycle to develop the class of catalysts based upon K[VO(OOH)Hheida] for asymmetric oxidations.

## Experimental Section

DFT geometry optimization of molecular structures were performed using the BP86 functional[42] and an all-electron triple-ζ basis set with polarization functions on all atoms (TZVP).[43] Calculations were carried out using the Turbomole suite of programs[44] in conjunction with the resolution of identity technique.[45,46]

Optimizations of the transition-state structures were performed using a procedure based on a pseudo Newton–Raphson method. Initial starting structures of a guessed transition state were optimized by constraining the distances related to the reaction coordinate, specifically the peroxido O–O and the substrate X–O or S–O (where X = $I^-$, $Br^-$, $Cl^-$ S = sulfur of dimethyl sulfide) interatomic distances. The initial Hessian matrix was calculated at the classical level, whereas the BP86-RI/TZVP was used to compute the Hessian matrix of the minimum energy structures. Full vibrational analysis of the stationary points were carried out to ensure the presence of one eigenmode featuring an imaginary frequency corresponding to the reaction coordinate. This point was then used as a starting point for the transition-state searches, which were conducted using an eigenvector-following strategy.

Transition states are labeled on the basis of the number negative charges present on vanadium complex (–1 or **0**), site of protonation (Figure 6, a), and the substrate. In the case of dimethyl sulfide transition states a number has been assigned to the rotational confor-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mation of the methyl groups, **P** indicating a methyl group parallel to the vanadium peroxido group or **A** indicating an antiparallel methyl group (Figure 6, b). A transition state corresponding to protonation of the left-side peroxido oxygen atom with dimethyl sulfide in a parallel methyl group orientation would be **0a_sP**, while the anionic transition state for bromide oxidation would be **1_br**.

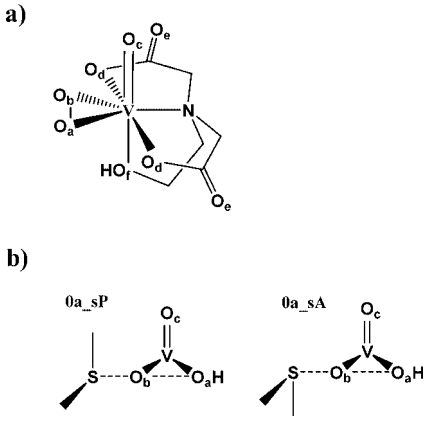

Figure 6. Illustration of the nomenclature adopted for this manuscript.

Full vibrational analysis has been carried out to characterize each stationary point. The effects of solvation were evaluated with the solvent continuous model approach COSMO[47,48] as implemented in the Turbomole suite. The polarizable continuum medium is expected to mimic the effects of a pure solvent environment to this purpose the dielectric constant for acetonitrile ($\varepsilon$ = 36.64) was used as previous studies[6,27] have employed it as the solvent to explore the reactivity of monoperoxido oxidovanadium complexes. Corrections have been computed to estimate $\Delta G$ from $\Delta E$, by calculating roto-vibrational partition function of the different molecular species.

# ZnO Nanoparticles From a Metal-Organic Framework Containing $Zn^{II}$ Metallacycles

**Harjyoti Thakuria,[a] Ballav Moni Borah,[a] and Gopal Das*[a]**

**Keywords:** Metallacycles / Tripodal ligands / Hydrogen bonds / Metal-organic frameworks / Nanoparticles

Nitrilotriacetic acid ($H_3NTA$) reacts in the solid phase with zinc hydroxide (1:1) to form a 3D ladder-like metal-organic framework that forms wurtzite ZnO nanoparticles when heated above 600 °C. Complex **1** contains a 1D zig-zag water chain. A mixed coordination network **2** is formed with excess $Zn^{II}$ hydroxide, which, on decomposition at about 500 °C, forms microwires of ZnO.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

In the past decade, the design and synthesis of functional molecule analogues by the self-assembly of metal-connecting points and organic linkers under controlled reaction conditions has attracted a great deal of attention among the inorganic, materials, and supramolecular chemistry communities.[1] As a result of these concerted efforts, the studies on the syntheses of metal-organic frameworks (MOFs) have undergone tremendous development by virtue of their attractive topologies and potential application in areas such as magnetism, non-linear optics, electrical conductivity, host–guest chemistry, gas storage, nonlinear optics, ion-exchange, and catalysis.[2,3]

The development of metal complexes that assemble into predictable supramolecular structures in the crystal is of great interest because of their potential in designing new materials with desirable optical and magnetic properties.[4] Nitrilotriacetate ($H_3NTA$) is a multidentate $C_3$-symmetric tripodal ligand that has been attracting much attention.[5] The self-complementary character of this ligand controls its assembly into aggregates by intermolecular hydrogen bonds and its threefold symmetry is maintained upon complexation.

The physical properties such as electric conductivity and magnetic, optical, and mechanical characteristics of nanosized metal oxide particles are known to be substantially different from those of bulk materials. The preparation methods of metal oxide nanoparticles have been extensively studied to precisely control the morphology at the nanometer scale. ZnO is one of the most important oxide materials for such wide ranging industrial applications as transparent conductors, UV-protection films, and chemical sensors.[6] Synthetic routes that have been employed to prepare ZnO nanoparticles include a liquid-phase method, vapor deposition, and a precursor process.[7]

Here we report the solid-phase synthesis of $Zn^{II}$-containing metallacycles using simple yet versatile acid-base chemistry with the $C_3$-symmetric tripodal ligand nitrilotriacetic acid ($H_3NTA$) in a 1:1 ratio. The resulting complex **1** forms a ladder-like 3D polymeric metal-organic framework (MOF). The macrocyclic pores host a zig-zag 1D infinite chain of lattice water. Complex **1** forms wurtzite ZnO nanoparticles when heated above 600 °C. A mixed coordination network **2** is formed with excess $Zn^{II}$ hydroxide, which, on decomposition at around 500 °C, forms microwires of ZnO.

## Results and Discussion

### Synthesis and Characterization

Complex **1** was synthesized by a simple acid-base reaction in the solid phase. A mixture of nitrilotriacetic acid (1 mmol, 0.191 g) and anhydrous freshly prepared zinc hydroxide (1 mmol, 0.099 g) was ground thoroughly with a pestle in an open mortar at room temperature under air. The mixture was ground for 5 min until the mixture turned into a slurry. X-ray quality single crystals of Zn complex **1** were grown from water within a day at room temperature in quantitative yield. Complex **2** was synthesized following the same procedure as **1**, only the metal to ligand ratio was different (3:2).

### $[(HNTA)(H_2O)_3Zn^{II}]\cdot H_2O$ (1)

The molecular structure of complex **1** consists of a $Zn^{II}$ ion, partially deprotonated NTA, and water molecules (Fig-

ure 1). The X-ray structure determination shows that compound **1** contains hexacoordinate $Zn^{II}$ with a distorted octahedral geometry. The angular distortion around Zn from the octahedral geometry is significant. The N(1)–Zn–O angles deviate considerably from 90° and range between 78.22(7)° and 100.02(8)° while the N(1)–Zn–O(7) angle is only 162.19(11)°. The metal ion is bonded to two carboxylates from the ligand, each of which donates a single O atom. The third coordination site is occupied by the tertiary amine bridgehead N-atom of the ligand, while the remaining coordination sites of the octahedral geometry are occupied with water molecules. The resulting coordination polymer looks like an array of zinc-containing metallomacrocycles (see Supporting Information). The Zn–O(carboxylate) and Zn–N bond lengths are 2.068(3), 2.074(2), and 2.222(2) Å, respectively, in good agreement with other $Zn^{II}$ carboxylate complexes.[8] The Zn–O(water) bond lengths are 2.0671(17), 2.107(3), and 2.105(3) Å, and are also similar to other Zn–$OH_2$ bond lengths reported in the literature.[9] The bond lengths and bond angles are found to be within normal statistical errors.[8]

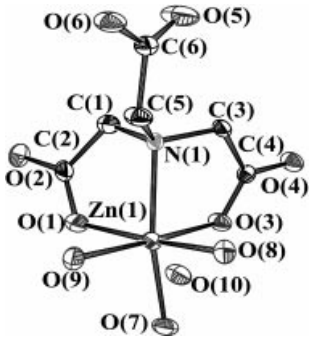

Figure 1. An ORTEP view of complex **1**.

Figure 2 shows an illustration of the 3D assembly of an infinite ladder framework. The rails of the ladder are made of almost linear, seven-atom units consisting of intermolecularly hydrogen bonded O(4)–C(4)–O(3)–Zn(1)–O(1)–C(2)–O(2) groups of NTA. The rungs of the ladder are made of an O atom of the axial water molecule. The distance between the rails of the ladder is 7.652 Å (distance between two adjacent Zn atoms forming the rail) and the two adjacent ladders are separated by 11.218 Å (distance between two Zn atoms of neighboring rails). However, the separation between the rungs of the ladder is 5.093 Å (forming the rail distance between two axial water oxygen atoms). Adjacent rails of the ladders are interconnected by intermolecular hydrogen bonds (Figure 2).

A crystal water molecule (O10) forms strong hydrogen bonds with neighboring metal-coordinated water molecules as well as with the coordinated O atom of the carboxylic acid group. Each of the crystal water molecules is hydrogen bonded to the four neighboring molecules in an almost tetrahedral arrangement (see Supporting Information). The hydrogen bonding between the crystal water molecules is comparatively weak in nature and forms a 1D zig-zag infinite water chain along the *b* axis (Figure 3), which is one

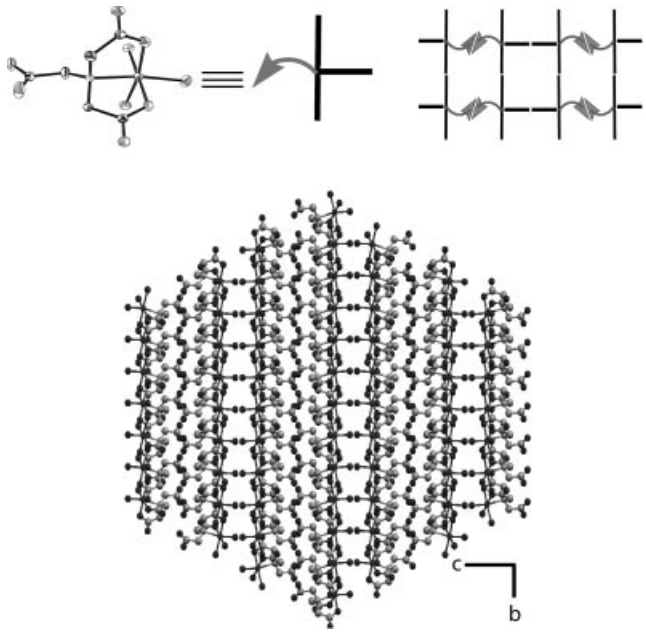

Figure 2. An infinite ladder framework along the *a* axis of **1**.

of the probable proton wire structures found in biological systems.[10] A zig-zag motif of a water chain has also been reported for nonbiological system.[11]

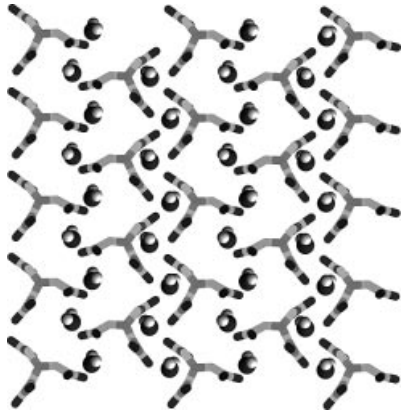

Figure 3. Perspective view of the zig-zag water chain in the crystal lattice of complex **1**.

The uncoordinated carboxylic acid group of NTA forms strong intramolecular hydrogen bonds with the neighboring O atom of the coordinated carboxylate group [O4···H4 1.793(5), O4–O6 2.604(7) Å and O6–H4–O4 170.23°]. O4 is acting as a H-bond acceptor and O6 as a H-bond donor and they act together like a clip (see Supporting Information), which eventually helps to form the 3D hydrogen-bonded MOF. Here, both water–MOF and water–water interactions are important for the stability of the overall polymeric structure.

The interaction between the MOF and the water chain is moderate, as thermogravimetric analysis of complex **1** under $N_2$ shows a 22.67% weight loss at around 100 °C, which corresponds to the loss of four water molecules (calculated 22.08%). Among the three carboxylic acid groups present

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the ligand, two are coordinated to the metal ion as carboxylate. TG analysis shows the sequential removal of one $CO_2$ molecule from the uncoordinated carboxylic acid group and two $CO_2$ molecules from the two coordinated carboxylate groups in the ranges 260–330 °C (loss of 17.24%; calcd. 17.32%) and 330–420 °C (loss of 41.66%; calcd. 41.79%) respectively, which is in good agreement with the X-ray crystal structure. Complete decomposition is achieved at about 600 °C. The DSC plot shows an endothermic peak at 100 °C due to the loss of water molecules. It also shows two exothermic peaks at 310 and 370 °C due to the decomposition of the carboxylic acid groups.

The FT-IR spectrum of complex **1** shows a broad band centered at 3300 $cm^{-1}$ due to the presence of water molecules; this vanishes when the compound is heated under vacuum (0.1 mm) at 150 °C for 6 h. Two types of carboxylic acid groups are present in complex **1**: uncoordinated, unionized and coordinated, ionized. The FT-IR spectrum clearly shows the presence of uncoordinated, unionized COOH at 1740 $cm^{-1}$ and coordinated, ionized $COO^-$ at 1590 $cm^{-1}$; these values agree well with those in the literature (see Supporting Information).[12] The $^1H$ NMR spectrum shows a broad singlet in $D_2O$ at $\delta$ = 3.49 ppm ($NCH_2COOH$), which proves the dynamic complexation and decomplexation behavior of the third carboxylic acid group at room temperature in solution.

The powder X-ray diffraction patterns of **1** show significant changes in the peak positions as well as intensities before and after water removal (Figure 4), which match well with the simulated pattern.

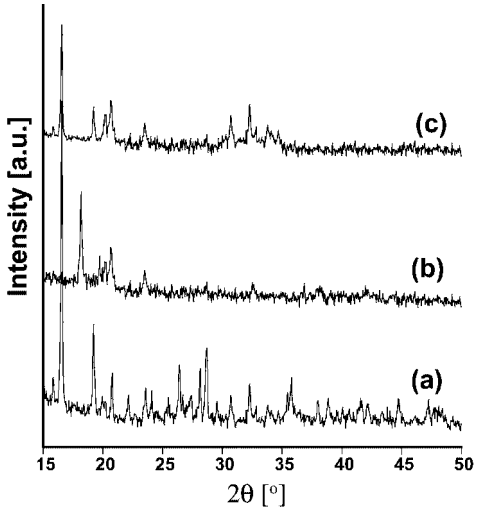

Figure 4. The powder XRD pattern of complex **1** before water removal (a), after water removal (b), and after re-hydration (c).

Thermal decomposition of complex **1** at 700 °C for 6 h in a muffle furnace forms wafers of ZnO with lengths ranging from 0.2 to 1.2 mm. The average size of these wafers remains unchanged with longer reaction time, up to 14 h. SEM images taken of several batches of samples showed that the entire wafer is formed from a uniform and densely packed array of ZnO nanoparticles (Figure 5). The nanoparticles' crystallinity was analyzed by powder X-ray diffraction techniques. The diffraction peaks (Figure 6) can be indexed as the wurtzite structure of ZnO (JCPDS 36-1451), thereby indicating that the zinc NTA complex has been thermally decomposed into ZnO.[13] The X-ray diffraction pattern shows an enhanced (101) peak resulting from the linear orientation of the nanoparticles. A typical synthesis yields particles with diameters ranging between 10 and 60 nm.

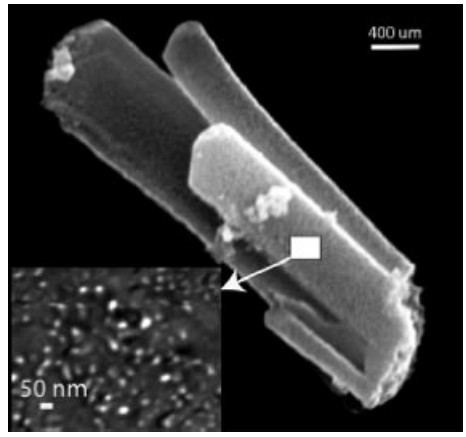

Figure 5. SEM micrographs of microwafers made of ZnO nanoparticles.

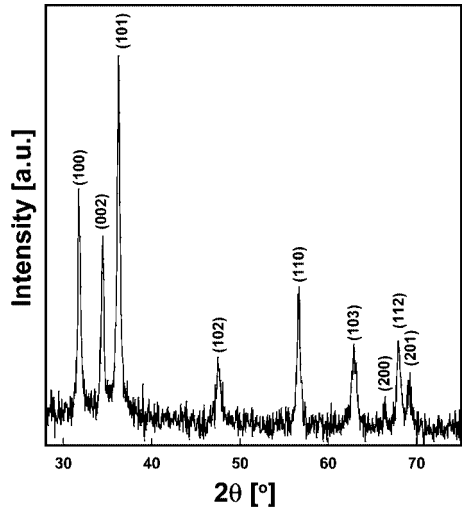

Figure 6. Powder XRD pattern of ZnO (wurtzite) nanoparticles.

### $[(H_2O)_6Zn][(NTA)_2Zn_2]\cdot 2H_2O$ (2)

The dimeric Zn nitrilotriacetato complex **2** is formed in the presence of an excess of zinc hydroxide. The asymmetric unit contains the hexaaquazinc(II) cation, the dimeric Zn-NTA complex anion, and crystal water. There are three symmetry-independent Zn sites in the structure. The first two of them (Zn1 and Zn2) are distorted octahedral with five carboxyl oxygens and one amine nitrogen making up the coordination environment. The other zinc cation, Zn3, is coordinated to six water molecules. Zn1 and Zn2 are bridged together by the carboxylic O3, O4, O11, and O12

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

atoms to form an infinite metal-organic framework. Among these four oxygen atoms, O3 and O11 form very rare μ-oxo carboxylato type bridges where each carboxylate ligand is bonded to three metal centers. Atom O3 forms a stronger bond with Zn2 [Zn(1)–O(3) 2.365(2), Zn(2)–O(3) 1.947(2) Å] while O11 forms a stronger bond with Zn1 [Zn(1)–O(11) 1.948(2) and Zn(2)–O(11) 2.351(2) Å]. Atom O3 occupies the axial position of Zn1 but the equatorial position of Zn2, whereas O11 occupies the axial position of Zn2 and the equatorial position of Zn1. The remaining four carboxylic oxygen atoms (O2, O6, O8, and O10) are not coordinated to the metal cation but form strong hydrogen bonds with the water molecules coordinated to the Zn3 cation. The carboxylic acid of one arm of each NTA unit is coordinated to the three zinc centers simultaneously along the crystallographic *ab* plane, which results in the formation of a complicated 3D polymeric rectangular network (Figures 7 and 8). The other two arms of each NTA unit form extensive hydrogen bonds with water molecules along the crystallographic *bc* plane. The overall 3D network is built up with the help of water of hydration (O19 and O20). The crystal water molecule O19 acts as a double hydrogen-bond donor as well as acceptor, while O20 acts as a single hydrogen-bond donor and acceptor. Both of these water molecules are strongly hydrogen bonded to the carboxylate as well as another coordinated water molecule. Unlike the mononuclear Zn-NTA complex **1**, there is no direct hydrogen bond between two crystal water molecules, which, in turn, prevents the formation of any water network in the solid-state structure. Two of the alternate rectangular void spaces in the 2D rectangular network are filled with these water molecules. Alternating Zn-aqua and Zn-NTA moieties form this 2D network.

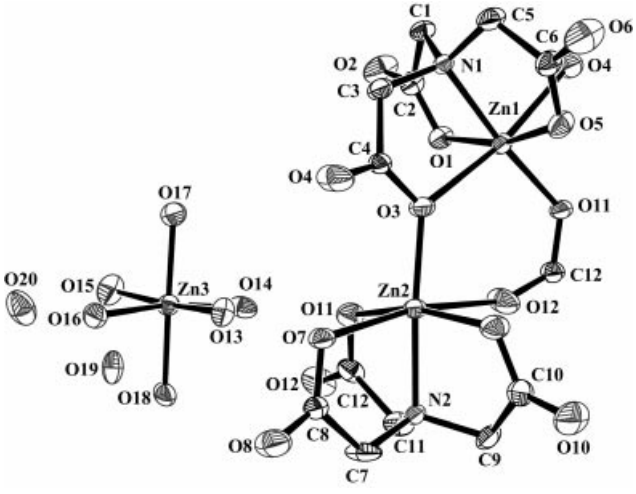

Figure 7. An ORTEP view of the Zn-NTA complex **2**.

Thermogravimetric analysis of complex **2** under $N_2$ shows a 21.08% weight loss between 30 and 100 °C corresponding to the loss of eight water molecules (calcd. 20.09%). All six coordinated carboxylic acid groups are removed between 100 and 240 °C with a weight loss of 47.08% (calcd. 46.11%), which is in good agreement with the X-ray crystal structure. Complete decomposition is achieved at about 480 °C and shows the formation of ZnO as the decomposed product. The DSC plot shows an endothermic peak at 75 °C due to the loss of water molecules. It also shows two exothermic peaks at 200 and 340 °C due to the decarboxylation and complete decomposition, respectively.

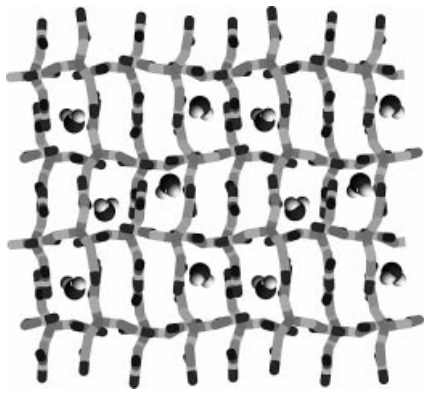

Figure 8. An infinite rectangular network along the *ab* plane of **2**.

The FT-IR spectrum of complex **2** shows a broad band centered at 3500 $cm^{-1}$ due to the presence of water molecules, which also vanishes when heated, as for complex **1**. Unlike complex **1**, however, it contains only coordinated, ionized types of carboxylic acid groups, which absorb at 1620 $cm^{-1}$.[12]

Complex **2** decomposes above 500 °C to form microwires of ZnO with lengths ranging from 200 nm to 8 μm. The average size and shape of these fibers does not change with temperature and reaction time. The powder X-ray diffraction pattern of these microwires also confirms the presence of the wurtzite structure of ZnO (Figure 9).

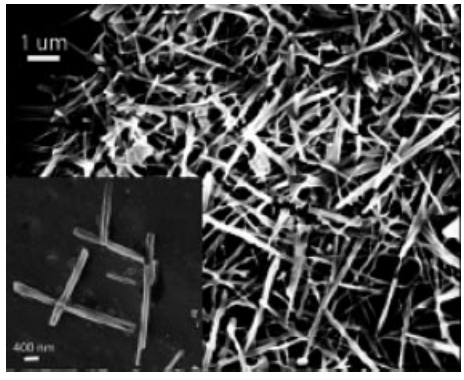

Figure 9. SEM micrographs of ZnO microwires.

## Conclusions

We have been able to synthesize two different metal-organic frameworks in the solid state by changing the metal to ligand ratio. An infinite array of metallacycles forms an interesting ladder and rectangular net like structures. The mononuclear complex **1** contains a 1D zig-zag infinite water

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chain. The stability of the water chain is derived from strong H-bonding interactions with the carboxylate group and the metal-bound water molecules. The binuclear complex **2** contains a very rare μ-oxo carboxylato bridge, where one carboxylate ligand binds to three metal centers simultaneously. Several other combinations of metal and ligand to synthesize MOFs of interest in solvent-free methods are currently under investigation in our laboratory. We have also demonstrated a precursor synthesis of ZnO nanoparticles and microwires with a wurtzite structure. The crystal lattice deposition temperatures for ZnO are very high because of the formation of extensive coordination networks of these supramolecular complexes. The technique demonstrated here can be extended to the synthesis of a wide range of nanomaterials having similar structures. These studies are currently underway in our laboratory.

## Experimental Section

**Materials and Methods:** Reagents were purchased from commercial sources and, unless otherwise stated, were used as received. Nitrilotriacetic acid was purchased from Sigma–Aldrich Co. and used without further purification. The IR spectra were recorded with a Perkin–Elmer Spectrum One FT-IR Spectrometer as KBr disks in the range 4000–400 $cm^{-1}$. The thermogravimetric analyses (TGA) of the compounds were performed with an SDTA 851e TGA thermal analyzer (Mettler Toledo) with a heating rate of 2 °C $min^{-1}$ under $N_2$ with 5–10 mg of sample per run. Scanning electron micrograph (SEM) images were obtained with a LEO-1430 VP electron microscope on samples glued onto an aluminum stub and gold sputtered. Powder XRD data were recorded with a Seifert powder X-ray diffractometer (XRD, 3003TT) with Cu-$K_\alpha$ source ($\lambda$ = 1.54 Å) on a glass surface for an air-dried sample.

**X-ray Crystallography:** Colorless single crystals of **1** and **2** were grown by slow evaporation of an aqueous solution of the complexes at room temperature. The X-ray diffraction data were collected at room temp. with a Bruker three-circle diffractometer (Bruker Nonius SMART APEX-II) equipped with CCD area detectors, and using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) from a 60-W microfocus Siemens Microsource with glass polycapillary optics. The SMART[14] software was used for data acquisition and the SAINT[14] software for data extraction. The structures were solved by direct methods and refined by full-matrix least-squares against $F^2$. Absorption corrections were done using SADABS. Structures were solved and refined using SHELX 97.[15] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located from the difference Fourier maps and refined.

**Compound 1:** $C_6H_{15}NO_{10}Zn$, $M$ = 326.58, orthorhombic, $a$ = 12.2958(10), $b$ = 6.6129(10), $c$ = 27.846(2) Å, $V$ = 2262.4(4) $Å^3$, space group $Pbca$, $Z$ = 8, $T$ = 298(2) K, $\mu$ (Mo-$K_\alpha$) = 2.288 $mm^{-1}$, $F(000)$ = 1170, GOF = 1.103; final $R$ indices: $R_1$ = 0.0213 [$I > 2\sigma(I)$], $wR_2$ = 0.0610; $R$ indices (all data): $R_1$ = 0.0224, $wR_2$ = 0.0604.

**Compound 2:** $C_{12}H_{28}N_2O_{20}Zn_3$, $M$ = 716.53, orthorhombic, $a$ = 12.7369(10), $b$ = 11.3290(10), $c$ = 16.4424(14) Å, $V$ = 2372.6(3) $Å^3$, space group $Pna2_1$, $Z$ = 4, $T$ = 298(2) K, $\mu$ (Mo-$K_\alpha$) = 3.120 $mm^{-1}$, $F(000)$ = 1272, GOF = 0.931; final $R$ indices: $R_1$ = 0.0282 [$I > 2\sigma(I)$], $wR_2$ = 0.0980; $R$ indices (all data): $R_1$ = 0.0291, $wR_2$ = 0.0997.

CCDC-280983 (for **1**) and -612885 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): The TGA-DSC curves, FT-IR spectra, powder XRD patterns, and selected figures.

## Acknowledgments

Financial support from the Council of Scientific and Industrial Research (CSIR) of India to GD and HT [grant no. 01(1948)/04/EMR-II] is gratefully acknowledged. We thank the Central Instrument Facility, Center for Nanotechnology and Department of Chemistry IIT Guwahati for SEM, powder XRD, and single-crystal XRD measurements.

# Ligand Effects on the Chemical Activity of Copper(I) Complexes: Outer- and Inner-Sphere Oxidation of $Cu^{I}L$

**Ariela Burg,*[a] Eric Maimon,[b,c] Haim Cohen,[b,d] and Dan Meyerstein*[b,d]**

**Keywords:** Copper / Electron self exchange rate constant / Outer-sphere mechanism / Inner-sphere mechanism

The effect of the ligands acetonitrile (AN), fumaric acid ($H_2$fum) and 2,5,8,11-tetramethyl-2,5,8,11-tetraazadodecane ($L^1$) on the kinetics of oxidation of $Cu^{I}$ complexes by $[(cyclam)Ni^{III}(SO_4)_2]^-$ and $[(NH_3)_5Co^{III}Cl]^{2+}$ in aqueous solutions via an outer- and inner-sphere mechanism, respectively, has been studied. The effects of the ligands on the electron self-exchange rate constants have also been evaluated. All ligands studied stabilize $Cu^{I}$ in aqueous solution but affect the redox potential of the $Cu^{II/I}L$ couple differently. The ligands decrease the rate of the redox reactions and the electron self-exchange rate constants. The results indicate that acetonitrile and alkenes should not be used as solvents for $[Cu^{I}L]^{+}$-catalyzed processes that involve redox steps. On the other hand, the results also suggest that $[Cu^{I}L^{1}]^{+}$ should be a good catalyst for such processes.

## Introduction

Copper complexes are used as catalysts for a variety of important redox processes[1–18] such as the Ullmann reaction and are present in various enzymes. As $Cu^{+}_{aq}$ is not stable due to its disproportionation to $Cu^{2+}_{aq}$ and $Cu^{0}$,[19] and as the solubility product of $Cu_2O$ in neutral and alkaline solutions is very low,[20] ligands are required in order to stabilize it. The electron transfer in these processes involves an unusually large change in the coordination geometry: $Cu^{II}$ complexes generally exist as Jahn–Teller distorted octahedra (though other configurations are known), while $Cu^{I}$ complexes are usually four-coordinate tetrahedral or linear species. These large changes in the complex geometry during redox processes are expected to slow them down, therefore the choice of ligands has a major effect on the rates of catalytic processes involving copper complexes.

In general, redox processes proceed by one of two mechanisms: outer sphere or inner sphere. It therefore seemed of interest to study the effect of different types of ligands on the kinetics of oxidation of $[Cu^{I}L^{i}]^{+}$ complexes by an outer sphere and an inner sphere oxidizing agent. For this purpose, the following reactions were studied:

$$[(cyclam)Ni^{III}(SO_4)_2]^- + [Cu^{I}L]^{+} \xrightarrow{k_1} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + [Cu^{II}L]^{2+} \quad (1)$$

$$[(NH_3)_5Co^{III}Cl]^{2+} + [Cu^{I}L]^{+} \xrightarrow{k_2} \text{Products} \quad (2)$$

as $[(cyclam)Ni^{III}(SO_4)_2]^-$ and $[(NH_3)_5Co^{III}Cl]^{2+}$ are known to be an outer-sphere and an inner-sphere oxidant, respectively.[21–23]

In the present study the effect of several ligands that are used, or have been recommended for use, in catalytic processes on the electron self-exchange rate of the $Cu^{II/I}L$ couple has been studied. The ligands chosen affect the redox potential of the $Cu^{II/I}_{aq}$ couple differently — two of them shift it anodically and the other cathodically. They bind to $Cu^{I}$ and $Cu^{II}$ ions in different modes. The first ligand, acetonitrile (AN), which is used as a solvent in many industrial synthetic processes catalyzed by copper(I),[24–26] is a σ donor and a π acceptor in its complexes with $Cu^{I}$ and is not a ligand of $Cu^{II}$ in aqueous solutions at acetonitrile concentrations below 1 M. The second ligand is fumaric acid (fum). Many polymerization processes and other synthetic processes catalyzed by $Cu^{I}$ complexes involve alkenes as substrates,[27,28] and it has been suggested that in order to decrease pollution these reactions should be carried out using the neat alkenes without any solvent.[28] However, alkenes form relatively stable π complexes with $Cu^{I}$,[9,29–31] therefore it is of interest to study the effect of an alkene on the kinetics of the reaction. Fumaric acid was chosen as a model for this study as it is known to bind to copper ions via its π system[29–33]). 2,5,8,11-Tetramethyl-2,5,8,11-tetra-

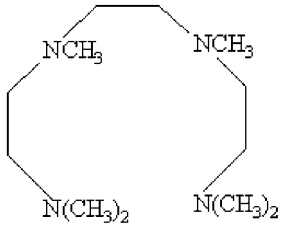

Figure 1. $L^1$ = 2,5,8,11-tetramethyl-2,5,8,11-tetraazadodecane.

azadodecane ($L^1$; Figure 1) shifts the redox potential of the $Cu^{II/I}{}_{aq}$ couple cathodically.[9,29,30,34–37] However, it shifts equilibrium (3) to the left:

$$2Cu^{+}{}_{aq} \leftrightarrows Cu^{2+}{}_{aq} + Cu^{0}\ K_3{}^{[19]} = 1 \times 10^6\ \text{M}^{-1} \quad (3)$$

this stems from

$$2Cu^{I}L_n \leftrightarrows Cu^{II}L_m + Cu^{0} + (2n - m)L\ K_4 \quad (4)$$

where $K_4 = ([Cu^{II}L_m][L]^{2n-m})/[Cu^{I}L_n]^2 = (K^{II}[Cu^{2+}{}_{aq}][L]^m\text{-}[L]^{2n-m})/(K^{I}[Cu^{+}{}_{aq}][L]^n)^2 = K^{II}[Cu^{2+}{}_{aq}]/(K^{I})^2[2Cu^{+}{}_{aq}]^2 = 10^6K^{II}/(K^{I})^2$, and $K^{II}$ and $K^{I}$ are $[Cu^{II}L_m]/([Cu^{2+}{}_{aq}][L]^m)$ and $[Cu^{I}L_n]/([Cu^{+}{}_{aq}][L]^n)$, respectively.

Equilibrium (4) will be shifted to the left if $(K^{I})^2 > K^{II}$, whereas the redox potential of the $Cu^{II}L_m/Cu^{I}L_n$ couple is shifted cathodically if $K^{II} > K^{I}$. Thus, the addition of ligands for which both of these criteria are fulfilled to a mixture of $Cu^{2+}{}_{aq}$ and $Cu^0$ should improve the catalytic properties of this mixture as they stabilize $Cu^{I}$ and increase its reducing power. With regards to this property, $L^1$ is special.

Each of the ligands chosen for this study affects the redox potential of the copper complex differently (Table 1) as each has a different effect on the geometric structure and the electronic configuration of the copper complex. Thus, $[Cu^{I}AN]^+$, $[Cu^{I}(AN)_2]^+$, and $[Cu^{I}(fum)]$ complexes are probably linear, whereas the $(Cu^{I}L^1)^+$ complex is tetrahedral, therefore it was expected that each of them would affect the rate constant of the redox reactions differently. Awareness of the effect of the ligands on the rate constants of outer- and inner-sphere reactions is essential for the design of good copper catalysts.

Table 1. The rate constants for reactions (1) and (2).

| $[Cu^{I}L]^+$ | $E^0$ [V][a] | $k_1$ [$M^{-1}s^{-1}$] | $k_{-11}$ [$M^{-1}s^{-1}$] | $k_2$ [$M^{-1}s^{-1}$] |
|---|---|---|---|---|
| $Cu^{+}{}_{aq}$ | 0.15 | $3.0\times10^4$ | $2.7\times10^{-4}$ | $5.4\times10^4$ |
| $[Cu^{I}fum]^+$ | 0.38[29] | $\leq3.0\times10^1$ | $\leq3.0\times10^{-7}$ | $1.0\times10^2$ |
| $[Cu^{I}AN]^+$ | 0.35[38–41] | $\approx8.5\times10^2$ | $\approx9.7\times10^{-5}$ | $2.2\times10^2$ |
| $[Cu^{I}(AN)_2]^+$ | 0.41[38–41] | $\approx5.0\times10^1$ | $\approx2.2\times10^{-6}$ | 9.3 |
| $[Cu^{I}L^1]^+$ | 0.08[35] | $2.3\times10^4$ | $1.4\times10^{-5}$ | $2.4\times10^4$ |

## Results

$[(cyclam)Ni^{III}(SO_4)_2]^-$ and $[(NH_3)_5Co^{III}Cl]^{2+}$ in excess were used as reagents, each one separately, with $Cu^{I}L$ (L = AN, fum, $L^1$). We decided to study systems with an excess of these complexes due to the possibility of some dioxygen leakage, which means that the $[Cu^{I}L]^+$ concentration is less accurate (the reactions with $L^1$ and fum were also studied with $[Cu^{I}L]^+$ in excess — the rate constants are the same). The observed rate constants depend linearly on the $[(cyclam)Ni^{III}(SO_4)_2]^-$ and $[(NH_3)_5Co^{III}Cl]^{2+}$ concentrations (see, for example, Figure 2). The slope of these lines equals the rate constant of the reaction under the experimental conditions. The rate constants thus obtained for all the complexes studied are summarized in Table 1.

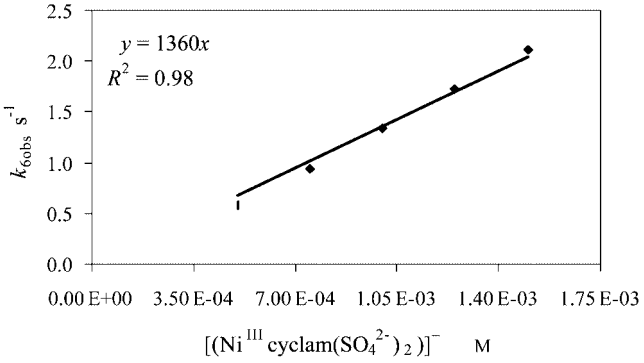

Figure 2. Dependence of $k_6$obs on $[(cyclam)Ni^{III}(SO_4)_2]^-$. The experiments were performed in solutions containing $2.0\times10^{-4}$ M $[Cu^{I}]_T$, $2.5\times10^{-3}$ M fum, $\mu$ = 0.30 M, He-saturated at pH 3.0. As $[(cyclam)Ni^{III}(SO_4)_2]^-$ is stable in the absence of $[Cu^{I}L]^+$, the slope was calculated assuming that the line passes through the origin.

### Derivation of $k(Cu^{+}{}_{aq})$, the Rate Constant of Reactions (5) and (9)

$$[(cyclam)Ni^{III}(SO_4)_2]^- + Cu^{+}{}_{aq} \xrightarrow{k(Cu^{+}{}_{aq})} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + Cu^{2+}{}_{aq} \quad (5)$$

The effect of fum concentration on the rate of reaction (6) was measured by changing its concentration $[(0.25\text{–}1.13)\times10^{-2}$ M].

$$[(cyclam)Ni^{III}(SO_4)_2]^- + [Cu^{I}L]^+ \xrightarrow{k_6} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + [Cu^{II}L]^{2+} \quad (6)$$

$[Cu^{I}]_T = [Cu^{I}L] = [[Cu^{I}(H_2fum)]^+ + [Cu^{I}(Hfum)] + Cu^{+}{}_{aq}]$ (It should be noted that at pH 3.0 the equilibrium reaction $HO_2CCH{=}CHCO_2H \rightleftarrows HO_2CCH{=}CHCO_2^- + H^+$; $pK_{a1}$ = 2.9[29] dictates that about 50% of the two species exist in the solution. The $pK_a$ of fumarate bound to $Cu^{I}$ is similar.[29])

$$[(cyclam)Ni^{III}(SO_4)_2]^- + [Cu^{I}(H_2fum)]^+/Cu^{I}(Hfum) \xrightarrow{k_7} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + [Cu^{II}(H_2fum)]^{2+}/[Cu^{II}(Hfum)]^+ \quad (7)$$

The rate law for reaction (6) is $-d[Ni^{III}]/dt = k_6[Cu^{I}]_T[Ni^{III}]$. As $[Cu^{I}]_T << [Ni^{III}]$, this rate law can be rewritten as $-d[Ni^{III}]/dt = k_{6obs}[Cu^{I}]_T$, where $k_{6obs} = k_6[Ni^{III}]$.

The rate constants $k_{6obs}$ at each fum concentration depend linearly on the $[(cyclam)Ni^{III}(SO_4)_2]^-$ concentration (Figure 2). The dependence of $k_6$ on fum concentration is plotted in Figure 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

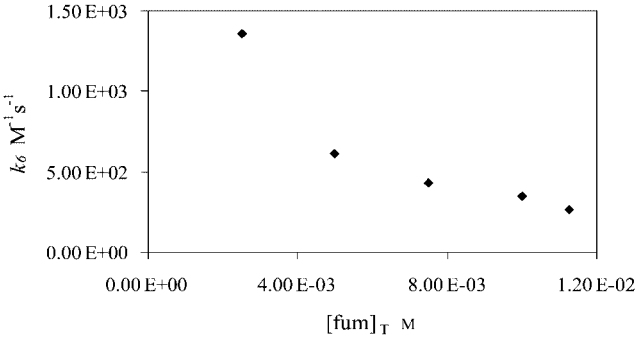

Figure 3. $k_6$ as a function of fumaric acid concentration. The experiments were carried out at $[Cu^I]_T = 2.0 \times 10^{-4}$ M, $\mu = 0.30$ M, pH 3.0; the solutions were He-saturated.

It was decided to assume, as a first approximation, that the contribution of $[Cu^I(fumH_2)]^+$ and $[Cu^I(fumH)]$ species to the rate is negligible, i.e. $k_7 = 0$ and reaction (5) is the only reaction which contributes to $k_6$. Therefore, the rate law can be written $-d[Ni^{III}]/dt = k_5[Cu^+_{aq}][Ni^{III}]$.

From the equilibrium constant of reaction (8):

$$Cu^+_{aq} + fumH_2/fumH^- \leftrightarrows [Cu^I(fumH_2)]^+/[Cu^I(fumH)]; \quad K_8 \text{ (at pH 3.0)}^{[29]} = 8.70 \times 10^3 \text{ M}^{-1} \quad (8)$$

$[Cu^+_{aq}]$ can be expressed as

$K_8 = [Cu^IL]/([Cu^+_{aq}][L])$

$[Cu^+_{aq}] = [(Cu^IL)]/(K_8[L]) = ([Cu^I]_T - [Cu^+_{aq}])/K_8[L]$

$[Cu^+_{aq}] = [Cu^I]_T/(K_8[L] + 1)$

Therefore, under these assumptions, $-d[Ni^{III}]/dt = k_5[Cu^I]_T/(K_8[L] + 1)[Ni^{III}]$.

Plotting $k_6$ (at different fum concentrations) as a function of $1/(K_8[L] + 1)$ (Figure 4) yields a straight line with a slope which equals $k_5$. Thus, the rate constant of reaction (5), $k_5$, is found to be $(3.0 \pm 0.3) \times 10^4$ M$^{-1}$ s$^{-1}$.

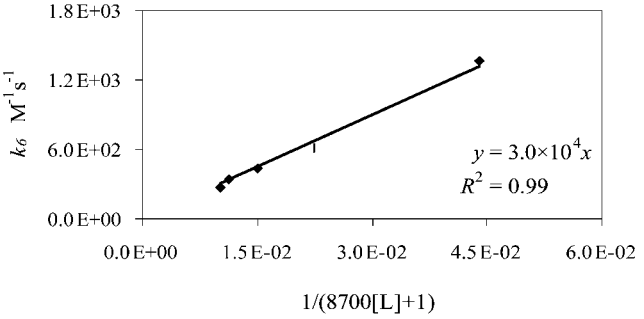

Figure 4. $k_6$ as a function of 1/(8700[fum] + 1). The experiments were carried out at $[Cu^I]_T = 2.0 \times 10^{-4}$ M, $\mu = 0.30$ M, pH 3.0; the solutions were He-saturated.

From the fact that no intercept is obtained in Figure 4 one can calculate that $k_7 \leq 30$ M$^{-1}$ s$^{-1}$ (this is the upper limit of the rate constant assuming that the error of the experiments is ±10%).

The rates of reactions (9) and (10) were studied using an analogous approach.

$$[(NH_3)_5Co^{III}Cl]^{2+} + Cu^+_{aq} \xrightarrow{k_9} \text{products} \quad (9)$$

$$[(NH_3)_5Co^{III}Cl]^{2+} + [Cu^I(fumH_2)]^+/[Cu^I(fumH)] \xrightarrow{k_{10}} \text{products} \quad (10)$$

The results yield $k_9 = (5.4 \pm 0.5) \times 10^4$ M$^{-1}$ s$^{-1}$. This rate constant is in good agreement with an earlier study.[23] The intercept in Figure 5 gives a value for $k_{10}$ of $\leq 100$ M$^{-1}$ s$^{-1}$.

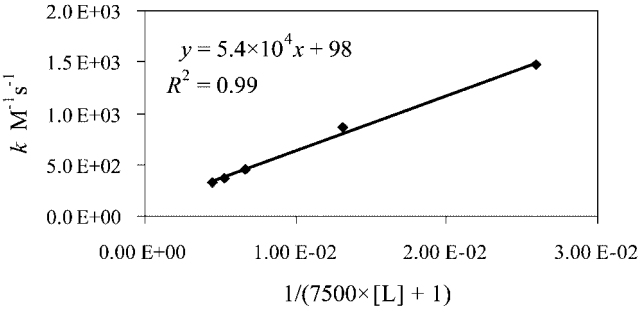

Figure 5. $k$ as a function of 1/(7500[L] + 1), for the reduction of $[(NH_3)_5Co^{III}Cl]^{2+}$ by $Cu^I$ in the presence of fumarate. The experiments were carried out at $[Cu^I]_T = 4.0 \times 10^{-4}$ M, $\mu = 0.20$ M, pH 2.0; the solutions were saturated with He. $k$ = the rate constant observed at each fumaric acid concentration.

### Oxidation of $[Cu^I(AN)_n]^+$

The apparent rate constants of reaction (11) were measured at different acetonitrile concentrations. The results are summed up in Table 2.

$$[(cyclam)Ni^{III}(SO_4)_2]^- + [Cu^I(AN)_n]^+ \xrightarrow{k_{11}} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + [Cu^{II}(AN)_n]^{2+} \quad (11)$$

The results show that $k_{11}$ decreases with an increase in acetonitrile concentration (Figure 6). Under the experimental conditions used here four $Cu^I$ complexes are present in the solution,[38–41] namely $Cu^+_{aq}$, $[Cu^I(AN)]^+$, $[Cu^I(AN)_2]^+$, and $[Cu^I(AN)_3]^+$. Therefore, it is reasonable to assume that the dependence of $k_{11}$ on acetonitrile concentration stems from the relative concentrations of these complexes in the solutions and the rate constants of reactions (5), (12), (13), and (14).

$$[(cyclam)Ni^{III}(SO_4)_2]^- + [Cu^I(AN)]^+ \xrightarrow{k_{12}} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + [Cu^{II}(AN)]^{2+} \quad (12)$$

$$[(cyclam)Ni^{III}(SO_4)_2]^- + [Cu^I(AN)_2]^+ \xrightarrow{k_{13}} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + [Cu^{II}(AN)_2]^{2+} \quad (13)$$

$$[(cyclam)Ni^{III}(SO_4)_2]^- + [Cu^I(AN)_3]^+ \xrightarrow{k_{14}} [(cyclam)Ni^{II}(SO_4)_2]^{2-} + [Cu^{II}(AN)_3]^{2+} \quad (14)$$

The stability constants of the different $[Cu^I(AN)_n]^+$ complexes are known, although their accuracy is not very high, as can be seen from the different values given by different authors.[38–42] The results in Table 2 suggest that (1) the observed rate constants approach a limiting value at high acetonitrile concentration, i.e. the observed reaction is not due

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2. The observed rate constants for reaction (11).

| AN [M] | $[Cu^{+}_{aq}]$ [M] | $[[CuAN]^{+}]$ [M] | $[[Cu(AN)_2]]^{+}$ [M] | $[[Cu(AN)_3]^{+}]$ [M] | $k_{11}$ [$M^{-1}s^{-1}$] | $k_{11}$ calculated [$M^{-1}s^{-1}$] |
|---|---|---|---|---|---|---|

| 0.14 | $2.5\times10^{-7}$ | $6.7\times10^{-5}$ | $1.15\times10^{-4}$ | $1.8\times10^{-5}$ | 420 | 370 |
| 0.17 | $1.9\times10^{-7}$ | $5.9\times10^{-5}$ | $1.19\times10^{-4}$ | $2.2\times10^{-5}$ | 390 | 330 |
| 0.19 | $1.5\times10^{-7}$ | $5.3\times10^{-5}$ | $1.20\times10^{-4}$ | $2.5\times10^{-5}$ | 220 | 290 |
| 0.24 | $9.6\times10^{-8}$ | $4.3\times10^{-5}$ | $1.24\times10^{-4}$ | $3.2\times10^{-5}$ | 125 | 240 |
| 0.29 | $6.7\times10^{-8}$ | $3.6\times10^{-5}$ | $1.25\times10^{-4}$ | $3.9\times10^{-5}$ | 120 | 200 |
| 0.38 | $3.7\times10^{-8}$ | $2.7\times10^{-5}$ | $1.22\times10^{-4}$ | $5.1\times10^{-5}$ | 95 | 160 |
| 0.67 | $1.1\times10^{-8}$ | $1.4\times10^{-5}$ | $1.08\times10^{-4}$ | $7.9\times10^{-5}$ | 88 | 90 |

The $[Cu^{I}(AN)_n]^{+}$ concentrations were calculated from the stability constant of the following reactions:

$Cu^{+}_{aq} + AN \leftrightarrows [Cu^{I}AN]^{+}$ $K$[42] = $1.9\times10^{3}$ $M^{-1}$

$Cu^{+}_{aq} + 2AN \leftrightarrows [Cu^{I}(AN)_2]^{+}$ $\beta_2$[42] = $2.2\times10^{4}$ $M^{-2}$

$Cu^{+}_{aq} + 3AN \leftrightarrows [Cu^{I}(AN)_3]^{+}$ $\beta_3$[42] = $2.4\times10^{5}$ $M^{-3}$

by the following equations:

$[Cu^{I}]_T = 2.0\times10^{-4}\ M = [Cu^{+}_{aq}](1 + K_1[AN] + \beta_2[AN]^2 + \beta_3[AN]^3)$

$[[Cu^{I}AN]^{+}] = [Cu^{+}_{aq}]\times\beta_1\times[AN]$

$[[Cu^{I}(AN)_2]^{+}] = [Cu^{+}_{aq}]\times\beta_2\times[AN]^2$

$[[Cu^{I}(AN)_3]^{+}] = [Cu^{+}_{aq}]\times\beta_3\times[AN]^3$

This set of equilibria constants was chosen as they were measured at similar ionic strengths to those used in this study. The use of the stability constants reported by Jordan et al.[41] does not affect the derived rate constants considerably.

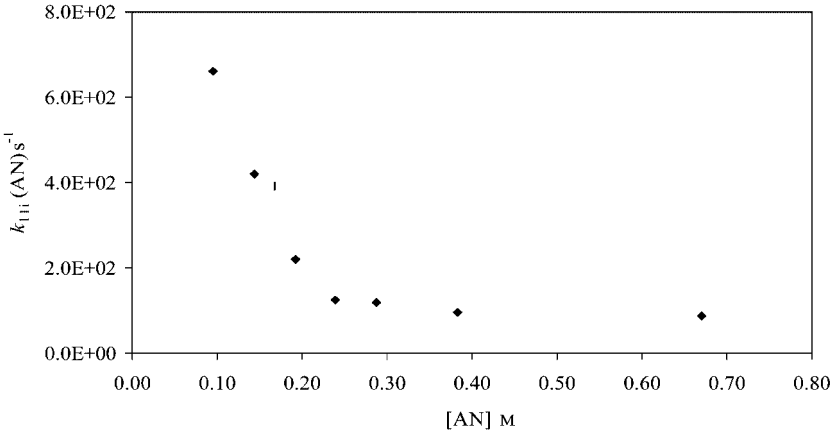

Figure 6. $k_{11}$ as a function of acetonitrile concentration. The experiments were carried out at $[Cu^{I}]_T = 2.0\times10^{-4}$ M, $\mu$ = 0.30 M, pH 3.0; the solutions were He-saturated.

only to reaction (5) and (2) the observed rates at high acetonitrile concentration seem to be independent of $[Cu^{I}(AN)_3]^{2+}$, i.e. one can assume that $k_{14}$ is negligible. Following these assumptions, and with $k_5$ determined above, $k_{12}$ and $k_{13}$ were calculated by repetitive approximations. The deviations of the calculated rate constants from the experimental ones are probably due mainly to the uncertainties in $K([Cu^{I}(AN)]^{+})$, $K([Cu^{I}(AN)_2]^{+})$ and $K([Cu^{I}(AN)_3]^{+})$.

The rate constants of reactions (15), (16), and (17) were evaluated analogously.

$$[(NH_3)_5Co^{III}Cl]^{2+} + [Cu^{I}(AN)]^{+} \xrightarrow{k_{15}} \text{products} \quad (15)$$

$$[(NH_3)_5Co^{III}Cl]^{2+} + [Cu^{I}(AN)_2]^{+} \xrightarrow{k_{16}} \text{products} \quad (16)$$

$$[(NH_3)_5Co^{III}Cl]^{2+} + [Cu^{I}(AN)_3]^{+} \xrightarrow{k_{17}} \text{products} \quad (17)$$

The rate constants are summed up in Table 3.

### Evaluation of the Self-Exchange Rate Constants, $k'_{11}$, of Reaction (18) for the Complexes Studied

According to the Marcus theory,[43–46] for reactions proceeding by the outer-sphere mechanism, $k'_{12}$, the rate constant of the cross reaction, reaction (1), depends on three parameters: the equilibrium constant of the cross reaction ($K_{12}$) and the electron self-exchange rate constants $k'_{11}$ [reaction (18)] and $k'_{22}$ (the electron self-exchange rate con-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stant for the $[(cyclam)Ni^{III/II}(SO_4)_2]^{-/2-}$ couple). The equilibria constants $K_{12}$ are known from the redox potentials of the different complexes. Some of them were calculated from the known stability constants of the different complexes using the Nernst equation,[29,35,37,41] and $k'_{22}$ was measured by the following procedure: the rate of the reaction of ascorbate ($HA^-$) with $[(cyclam)Ni^{III}(SO_4)_2]^-$ at pH 4.9 was measured [reaction (19)].

$$[Cu^{I}L]^+ + [*Cu^{II}L]^{2+} \rightarrow [Cu^{II}L]^{2+} + [*Cu^{I}L]^+ \quad (18)$$

$$HA^- + [(cyclam)Ni^{III}(SO_4)_2]^- \rightarrow HA^{\cdot} + [(cyclam)Ni^{II}(SO_4)_2]^{2-};\ k_{19} = 2.7\times10^4\ M^{-1}s^{-1} \quad (19)$$

The electron self-exchange rate constant for the ascorbate couple is known.[47] From these values, a value of $k'_{22} = 1.1\times10^3\ M^{-1}s^{-1}$ for $[(cyclam)Ni^{III}(SO_4)_2]^-$ at $\mu = 0.30$ M is obtained. Using these data and the measured rate constants for reaction (1) (neglecting the electrostatic work term, which is small for reactions of relatively large ions with small charges in solutions with a relatively high ionic strength) the self-exchange rate constants, $k'_{11}$, of the $Cu^{II}L/Cu^{I}L$ couples, reaction (18), were calculated by applying the Marcus cross relation. These results are summed up in Table 1.

The results obtained for the self exchange of $Cu^{2+/+}_{aq}$ [reaction (20)] are in very good agreement with those of Davies et al.,[48] who obtained $k'_{11} = 2.0\times10^{-4}\ M^{-1}s^{-1}$.

$$Cu_{aq}^{+} + *Cu_{aq}^{2+} \overset{k'_{11}}{\rightarrow} Cu_{aq}^{+} + *Cu_{aq}^{2+} \quad (20)$$

This observation suggests that the value used for $k'_{22}$ and the experimental approach used are adequate, although the value reported by Sisley and Jordan,[49] $k'_{11} = 5\times10^{-7}\ M^{-1}s^{-1}$, is considerably lower. Recently,[40] the electron self-exchange of $[Cu^{II/I}(AN)_n]^+$ ($n$ = 3 or 4) was reported to be around $5\times10^{-9}\ M^{-1}s^{-1}$ in solutions containing 50–97.5% AN. The authors state that "the various $Cu^{II}$ solvates have similar self-exchange constants", although this is clearly not the case for $[Cu^{I}(AN)]^+$ and $[Cu^{I}(AN)_2]^+$ measured in the present study, which shows that $k'_{11}$ decreases with an increase in $n$. The value reported for $n$ = 3–4 is orders of magnitude smaller than that for $n$ = 2, and this observation is in agreement with the assumption that $k_{14}$ is very small and can be neglected.

It is of interest to note that all the ligands studied by us lower the self-exchange rate constant relative to that of $Cu^{2+/+}_{aq}$. This observation is not general,[50] and the self-exchange rate constants of copper enzymes are about ten orders of magnitude higher.[51–53]

## Discussion

The three ligands chosen for this study slow down the rates of reduction of both $[(cyclam)Ni^{III}(SO_4)_2]^-$, an outer-sphere oxidant, and $[(NH_3)_5Co^{III}Cl]^{2+}$, an inner-sphere oxidant, although this is clearly not a general observation as $L^1$ accelerates the rate of reduction of $NO_2^-$ by $Cu^{I}$.[18] The effect of $L^1$, which shifts the redox potential of the $Cu^{2+/+}_{aq}$ couple cathodically,[34–36] on the rate constants is considerably smaller than would be expected.

It is of interest to note that AN and $H_2$fum not only shift the redox potential of the $Cu^{2+/+}_{aq}$ couple anodically but also considerably decrease the rate of the electron self-exchange reaction [reaction (18)]. The combination of the effect of these ligands on the redox potential and on the electron self-exchange rate constants suggests that their complexes are poor catalysts for $Cu^{I}$-catalyzed processes that involve a redox process. Thus, it is concluded that acetonitrile and alkenes should not be used as solvents for such processes. On the other hand, the electron self-exchange rate of the $[Cu^{II/I}L^1]^{2+/+}$ couple is only slightly lower than that of the $Cu^{2+/+}_{aq}$ couple and $L^1$ shifts the redox potential of the $Cu^{II/I}$ couple cathodically. The contribution of these effects explains the observation that $[Cu^{I}L^1]^+$ is a very good catalyst[54] for $Cu^{I}$-catalyzed processes.

## Experimental Section

**Materials:** $CuSO_4$, $Cu^0$, acetonitrile (AN), fumaric acid ($H_2$fum), $L^1$, sodium perchlorate, and perchloric acid were ordered from Aldrich. $[(cyclam)Ni^{III}(SO_4)_2]H$[55] and $[(NH_3)_5Co^{III}Cl](ClO_4)_2$[23] were synthesized according to literature procedures. All solutions were prepared from A.R. grade chemicals and from deionized water further purified by passing through a Milli Q Millipore setup (final resistivity > 10 MΩ cm$^{-1}$).

Solutions of the $[Cu^{I}L]^+$ complexes were prepared by a comproportionation process [reaction (4)]. The solutions' color changed after several hours from blue (indicating $[Cu^{II}L]^{2+}$ complexes) to colorless (indicating $[Cu^{I}L]^+$ complexes). Solid copper metal was added to deaerated solutions containing $CuSO_4$ and an excess of L.

Reaction (1) was studied at $\mu = 0.30$ M, maintained by the addition of $Na_2SO_4$ in order to stabilize $[(cyclam)Ni^{III}(SO_4)_2]^-$. The stability constant of $[(cyclam)Ni^{III}(SO_4)_2]^-$ is $K = [[(cyclam)Ni^{III}(SO_4)_2]^-]/[[(cyclam)Ni^{III}(H_2O)_2]^{3+}[SO_4^{2-}]^2] = 5\times10^6\ M^{-2}$,[56,57] therefore a high concentration of $SO_4^{2-}$ is essential. Solutions of $[(cyclam)Ni^{III}(SO_4)_2]^-$ were prepared by literature procedures.[56,58] Reaction (2) was studied at $\mu = 0.20$ M. The reactions were carried out at the appropriate pH, i.e. that at which the ligands bind to the copper ion. The experiments with AN and $H_n$fum ($n$ = 0–2) as ligands were carried out at pH 3.0. The experiments with $L^1$ were carried out at pH 6, where $L^1$ also acts as a buffer. Table 3 sums up the p$K$'s of the ligands and the binding constants of $[Cu^{I}L]^+$. All $[Cu^{I}L]^+$, $[(cyclam)Ni^{III}(SO_4)_2]^-$, and $[(NH_3)_5Co^{III}Cl]^{2+}$ complexes were handled under strictly anaerobic conditions, using the syringe technique. All experiments were carried out at room temperature (22 °C). Blank experiments demonstrated, as expected, that the different $[Cu^{II}L]^{2+}$ complexes do not react with $[(cyclam)Ni^{III}(SO_4)_2]^-$ or $[(NH_3)_5Co^{III}Cl]^{2+}$.

**Kinetic Measurements:** Stopped-flow experiments were carried out using an SX.18 Applied PhotoPhysics stopped flow machine that enables kinetic measurements of reactions with half lifetimes above 2 ms. A 05-109 Spectra Kinetics Monochromator, which enables measurements in the range 200–700 nm, was used. The optical path was 10 mm.

The absorbance was followed as a function of time at the appropriate absorption bands of the complexes. The disappearance of [(cy-

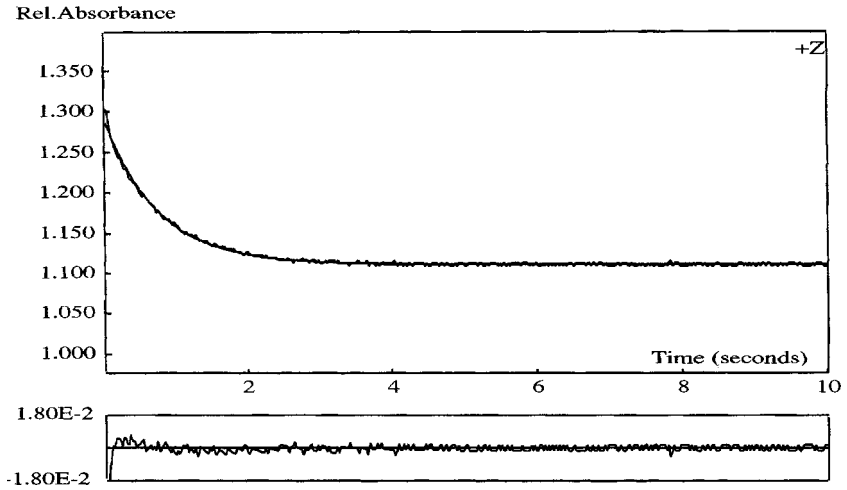

Figure 7. Dependence of $[(cyclam)Ni^{III}(SO_4)_2]^-$ concentration on time. The experiments were carried out at $[Cu^{I}]_T = 2.0 \times 10^{-4}$ M, $2.5 \times 10^{-3}$ M fum, $\mu = 0.30$ M, pH 3.0; the solutions were He-saturated.

clam)$Ni^{III}(SO_4)_2]^-$ and $[(NH_3)_5Co^{III}Cl]^{2+}$ was followed at 435 and 530 nm, respectively (Figure 7). The formation of $[Cu^{II}L]^{2+}$ was followed at $\lambda > 600$ nm. Each kinetic run was repeated at least five times using at least two independently prepared stock solutions. The error limit of the measured rates is $\leq 10\%$.

The Δ(absorbance) observed was always in agreement with expectations based on $[Cu^{I}L]^+$ and $\varepsilon[Ni^{III}L(SO_4)_2]^-$ and $\varepsilon[(NH_3)_5Co^{III}Cl]^{2+}$.

## Acknowledgments

This study was supported, in part, by a grant from the Budgeting and Planning Committee of The Council of Higher Education. D. M. wishes to express his thanks to Irene Evens for her ongoing interest and support.

# Dinuclear Metallocenes with a Modulated Biphenylene Bridge for Olefin Polymerization

**Seong Kyun Kim,[a] Hwa Kyu Kim,[a] Min Hyung Lee,[a][‡] Seung Woong Yoon,[a] Yonggyu Han,[a] Sungjin Park,[a] Junseong Lee,[a] and Youngkyu Do*[a]**

**Keywords:** Homogeneous catalysis / Metallocenes / Olefins / Polymerization / Titanium / Zirconium

Dinuclear group 4 metallocene catalysts linked by a biphenylene or 1,2-diphenylethylene bridge, namely [4,4′-$(C_5Me_4)_2$-$(C_6H_4)_2$][$CpZrCl_2$]$_2$ (**2a**), [*p*-$(C_5Me_4)C_6H_4CH_2$]$_2$[$CpZrCl_2$]$_2$ (**2b**), [*p*-(3,4-$Me_2C_5H_2$)$C_6H_4CH_2$]$_2$[$CpZrCl_2$]$_2$ (**2c**), [$(C_5Me_4)_2$-$(C_6H_4)_2$][$TiCl_3$]$_2$ (**3a**), [*p*-$(C_5Me_4)C_6H_4CH_2$]$_2$[$TiCl_3$]$_2$ (**3b**), and [*p*-(3,4-$Me_2C_5H_2$)$C_6H_4CH_2$]$_2$[$TiCl_3$]$_2$ (**3c**), have been prepared and the crystal structures of **2b** and **3b** determined by X-ray diffraction methods. The crystal structures reveal that these complexes consist of two equivalent metal units inverted with respect to the center of the bridge. All the complexes were tested for the polymerization of ethylene and styrene in the presence of methylaluminoxane (MAO), and direct comparisons of their catalytic properties with those of the corresponding mononuclear analogues [$(PhC_5Me_4)$-$CpZrCl_2$] (**4a**), [(*p*-$TolC_5Me_4$)$CpZrCl_2$] (**4b**), [(1-*p*-Tol-3,4-$Me_2C_5H_2$)$CpZrCl_2$] (**4c**), [$(PhC_5Me_4)TiCl_3$] (**5a**), [(*p*-$TolC_5Me_4$)$TiCl_3$] (**5b**), and [(1-*p*-Tol-3,4-$Me_2C_5H_2$)$TiCl_3$] (**5c**) were performed. The dinuclear zirconocenes show a high activity in ethylene polymerization comparable with those of the corresponding mononuclear catalysts and give an increased molecular weight of polyethylene. The dinuclear half-sandwich titanocenes exhibit similar or slightly lower activity and molecular weight in styrene polymerization compared with their mononuclear analogues.

## Introduction

Single-site catalytic systems for olefin polymerization based on group 4 metal complexes have become well established during the last two decades and have provided various opportunities to tailor the polymer properties, especially molecular weight, molecular weight distribution, and stereochemistry, as well as high catalytic activity.[1–6] The fruits of these endeavors are the various kinds of catalyst systems that are now being used in practical applications. Syndiotactic polystyrene (sPS) from half-sandwich metallocene catalysts and linear low-density polyethylene (LLDPE) from constrained-geometry catalysts are typical products available commercially from single-site catalyst systems. Most of these catalyst systems, however, involve mononuclear complexes, as dinuclear systems that consist of two active centers linked within the same molecule have become a focus of attention only since the first report by Mülhaupt et al.[7] on a phenylene-bridged dinuclear zirconocene system for propylene polymerization. Initial efforts made by several groups have shown that these catalyst systems are effective in olefin polymerization[8–11] but they have still remained much less defined in terms of structural aspects, class of catalysts, and kinds of polymerization they can perform in comparison with the well-known mononuclear systems.

Recently, it has been found that dinuclear systems are able to show interesting catalytic behaviors that are different from those of mononuclear systems. Systematic polymerization studies by Noh et al. using polysiloxane- and polymethylene-bridged dinuclear complexes have demonstrated that the catalytic activity[12,13] and co-monomer incorporation ratio[14–16] are strongly correlated with both the nature and the length of the bridging group employed. Marks et al. have revealed that dinuclear constrained-geometry catalysts connected by ethylene and/or methylene bridges exhibit unique polymerization behaviors such as high α-olefin incorporation,[17,18] high activity in styrene polymerization,[19] and branched or significantly increased molecular weights in ethylene polymerization[18,20–22] mainly due to the cooperative interactions between two active centers. Alt et al. have also reported asymmetric dinuclear zirconocenes that are capable of producing polyethylene with a bimodal molecular weight distribution.[23,24]

Although it has been suggested from the foregoing studies that the catalytic properties of dinuclear complexes can be strongly affected by the nature of the bridging group and possible cooperative metal–metal interactions, very few studies on the variation of the bridging group have been

performed. Flexible alkylene groups still constitute the majority of bridges,[7–26] therefore it is of great value to examine the electronic and/or steric effects of the bridging group that play an important role in governing the catalytic properties of dinuclear complexes and thereby rationalize the cooperative reactivity of dinuclear catalysts. In this regard, our group recently reported the well-defined dinuclear group 4 metal complexes [4,4′-$(C_5Me_4)_2(C_6H_4)_2$][$CpZrCl_2$]$_2$ (**2a**) and [4,4′-$(C_5Me_4)_2(C_6H_4)_2$][$TiCl_3$]$_2$ (**3a**), which are linked by a rigid biphenylene bridge, and the direct comparison of their catalytic properties with those of the corresponding mononuclear analogues in ethylene and styrene polymerization.[27] We observed an increase of both molecular weight of polymer and catalytic activity, irrespective of the co-catalyst employed, especially in ethylene polymerization.

In the present report, which includes a further investigation of the polymerization behavior of the biphenylene-bridged system, we aim to endow the existing biphenylene group with flexibility that could provide additional metal–metal interactions and at the same time to keep each metal center highly active by minimizing the steric hindrance between the two active centers. To this end, we have developed novel dinuclear group 4 catalysts containing bis(cyclopentadienido) ligands bound to a rigid but flexible 1,2-diphenylethylene bridge. A complete set of comparative polymerization studies in olefin polymerization with the corresponding mononuclear catalysts is also reported.

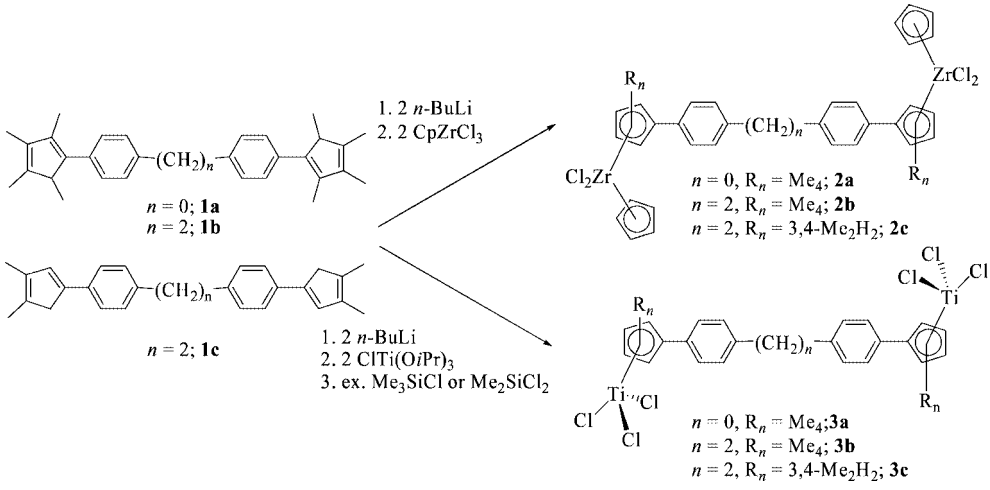
## Results and Discussion

### Complexes Synthesis and Characterization

Two new ligands (**1b** and **1c**) were synthesized by a procedure analogous to that for ligand **1a** reported in our previous communication.[27] These ligands are poorly soluble in common organic solvents but are more soluble than **1a**, thus reflecting their flexible nature. The zirconium complexes **2b** and **2c** were prepared in a straightforward manner by the direct transmetalation of dilithium salts of the ligands with two equivalents of [$CpZrCl_3$] in thf. Complexes **2b** and **2c** have much better solubility then **1a** in hydrocarbon solvents, which could be an important advantage when the immobilization of the catalysts is considered for industrial applications. Reaction of the dilithium salt of the ligands with two equivalents of $ClTi(OiPr)_3$ in thf, followed by in situ chlorination with an excess of $Me_3SiCl$ or $Me_2SiCl_2$ in $CH_2Cl_2$, also afforded the final titanium trichloride complexes **3b** and **3c** (Scheme 1). Complex **3c** is less soluble in $CHCl_3$ and $CH_2Cl_2$ than **3a** and **3b**, which suggests that the sterically less congested nature of **3c** allows the retention of planarity between the phenyl and cyclopentadienido rings in the ligand backbone. Two singlets for the methyl proton resonance in the $^1H$ NMR spectra of **2a**, **2b** and **3a**, **3b**, and one singlet methyl resonance for **2c** and **3c** indicate that the two metal units in these dinuclear complexes are in an identical chemical environment in solution.

### X-ray Crystallographic Structures of 2b and 3b

The molecular structures of **2b** and **3b** are depicted in Figure 1 and selected interatomic distances and angles are listed in Table 1. The zirconium complex **2b** crystallizes in the space group *C*2/*c* with only one half of the molecule in the asymmetric unit. Interestingly, the diphenylethylene bridge adopts a *gauche* conformation in which the molecule has a $C_2$-symmetric axis perpendicular to the C(16)–C(16′) bond. Thus, two [Cp′$CpZrCl_2$] (Cp′ = $C_5Me_4Ph$) fragments are perfectly inverted along the rotation axis, which indicates that complex **2b** consists of two equivalent units in the solid state. The detailed structural analysis indicates that the bonding geometry around the zirconium center, such as the Cl(1)–Zr–Cl(2) and Cg(1)–Zr–Cg(2) bond angles and Zr–Cl and Zr–Cg bond lengths shown in Table 1, are in a similar range to those of mononuclear, unbridged zirconocene complexes.[28–30] The dihedral angle of 41.28(18)° between the $C_5Me_4$ ring [Cp(1)] and the adjacent phenylene ring [Ph(1)] is closer to that of the phenyl-substituted mo-



Scheme 1.

nonuclear zirconocene **4a** (47.2°)[31] than that observed in the biphenylene-bridged **2a** [63.6(2)°],[27] which suggests that flexible nature of the bridging group makes the steric environment of each metallocene unit of **2b** similar to that of the mononuclear **4a**.

Table 1. Selected bond lengths [Å] and angles [°] for **2b** and **3b**.

| Compound | **2a** (M = Zr)[a] | **2b** (M = Zr) | **3b** (M = Ti) |
|---|---|---|---|
| Cl(1)–M–Cl(2) | 96.5(0) | 97.07(3) | 103.57(11) |
| Cg(1)–M–Cg(2)[b] | 129.8 | 130.98 | – |
| Cp′(1)–Ph(1)[c] | 63.6(2) | 41.28(18) | 62.6(3) |
| M–Cl(1) | 2.429(1) | 2.4337(11) | 2.242(4) |
| M–Cl(2) | 2.440(1) | 2.467(10) | 2.245(4) |
| M–Cl(3) | – | – | 2.240(4) |
| M–Cg(1) | 2.224(1) | 2.2231(15) | 2.026(4) |
| M–Cg(2) | 2.199(2) | 2.213(2) | – |

[a] Data taken from ref.[27] [b] Cg(1) and Cg(2) are the centroids of the $C_5Me_4$ (C1–C5) and Cp (C21–C25) rings, respectively. [c] Cp′(1) is the plane of $C_5Me_4$ (C1–C5) and Ph(1) the plane of $C_6H_4$ (C10–C15).

The titanium complex **3b** crystallizes in the space group *C*2/*c* and contains half of each of two independent molecules in the asymmetric unit. Similarly to **2a** and **3a**, two $Cp'TiCl_3$ ($Cp' = C_5Me_4Ph$) fragments are also perfectly inverted with respect to the C(16)–C(16′) bond axis, thus indicating that complex **3b** consists of two equivalent units in the solid state. According to the solid-state structure, **3b** adopts an *anti* conformation of the diphenylethylene bridge. The bond angles and distances around titanium are also similar to those for mononuclear complexes but, interestingly, the dihedral angle between the $C_5Me_4$ ring [Cp(1)] and the adjacent phenylene ring [Ph(1)] is much larger [62.6(3)°] than those of the corresponding dinuclear zirconocene **2b** [41.28(18)°] and $[(C_6H_4C_5Me_4)TiCl_2]_2(\mu\text{-}O)$ (50.4°).[32]

### Ethylene Polymerization

Ethylene polymerizations with the dinuclear zirconocene complexes **2a**–**c** were carried out in toluene solution under 1 bar of ethylene. To compare their catalytic properties with those of the corresponding mononuclear catalysts, polymerizations with **4a**–**c** were also performed under identical conditions (Table 2). All the catalysts show high activities that are in a range similar to that of the corresponding mononuclear complexes **4a**–**c** at all reaction temperatures. The polyethylenes produced by the dinuclear zirconocenes also show a narrow molecular weight distribution ($M_w/M_n$) similar to that of polyethylenes obtained with the mononuclear complexes, which suggests that the two zirconium centers in the dinuclear complexes behave as independent single active sites, as expected from the crystal structures and NMR spectra. In particular, biphenylene-bridged **2a** shows higher activity than mononuclear **4a** at high temperature, while diphenylethylene-bridged **2b** and **2c** show lower activity than mononuclear **4b** and **4c** at the low- and high-temperature limits. Thus, an enhanced thermal stability of the active species is seen only for biphenylene-bridged **2a** among the three dinuclear systems. Moreover, the activity of **2a** is higher than that of **2b** at all temperatures, while the corresponding mononuclear analogues **4a** and **4b** exhibit a similar activity. In addition, in the case of the flexible diphenylethylene-bridged systems, a higher activity was observed for di-

| 25 | $Cp_2ZrCl_2$ (2.0) | 50 | 0.571 | 8.57 | 235 | 2.92 | 134.7 |

[a] Conditions: *P*(ethylene): 1 bar; solvent: 50 mL of toluene; $t_p$: 2.0 min; MAO: s-MAO; [Al]/[Zr]: 1000. [b] Activity: kg of PE per mol of Zr per hour per bar.

methyl-substituted **2c** than for tetramethyl-substituted **2b**, which implies that the steric effect of the ligand strongly influences the activity. These results may indicate that the lower steric hindrance and the possible electronic stabilization caused by the rigid and conjugative nature of the biphenylene bridge in **2a** lead to the higher activity.

Thus, it can be suggested that the biphenylene group acts as a much more effective bridge in terms of catalytic activity. Noh et al. have pointed out that the more electron releasing and the longer the bridge, the higher the activity of the dinuclear zirconium complexes compared with that of the mononuclear catalyst in ethylene polymerization.[13] In our case, the rigidity, coupled with the appropriate length of the bridging unit, provides favorable electronic stabilization and steric effects and thus likely plays an important role in governing catalytic activity when compared with the flexible diphenylethylene-bridged systems.

The characteristic most noteworthy of mention is the molecular weight of the polyethylene: the polyethylenes produced by **2a**–**c** have a higher molecular weight than those of **4a**–**c**, especially at temperatures below 50 °C, while at high temperature (>70 °C), the values are similar to those of the mononuclear analogues. Between two diphenylethylene-bridged systems, the more electron-releasing **2b** gives higher molecular weights than **2c** at all temperatures, as expected. However, in contrast to the trend in activity, the molecular weight given by **2b** is greater than the biphenylene-bridged **2a** under identical conditions. Note that the ratio of molecular weights between **2b** and **4b** is about 2.0 while that between **2a** and **4a** is about 1.5 (Figure 2). This result can be mainly explained by steric reasons, as for the activity. Due to the flexible nature of the bridge, the two metal centers in **2b** can exert mutual steric hindrance by being located in proximal positions despite the partial relief of such an interaction due to the presence of an additional phenylene linkage. This increased steric hindrance towards the growing polymer chains presumably leads to a reduced rate of chain-transfer reactions.[33] This assumption also appears to be valid for the higher molecular weight produced by **2b** and **2c** in comparison to mononuclear **4b** and **4c**, respectively.

### Styrene Polymerization

From the polymerization results in Table 3, it can be seen that dinuclear half-sandwich titanocenes behave as highly active, single-site catalysts for styrene polymerization, and the syndiotactic index (SI) and melting temperature ($T_m$) of the polystyrenes suggest that the syndiospecific stereocontrol is also well maintained. For a given Cp ligand, a biphenylene bridge appears to form a more efficient dinuclear catalytic system than a diphenylethylene bridge, as judged from the polymerization behavior of **3a** and **3b** at all temperatures (note the higher activity of biphenylene-bridged **3a** than diphenylethylene-bridged **3b** and the retention of the high activity of **3a** even at 90 °C). For a given bridging ligand, the sterically less congested dimethyl-substituted Cp ligand fragment affords a catalytically more active system than the tetramethyl-substituted Cp ligand fragment, as exemplified by **3b** and **3c**. A similar effect of the Cp ligand on the catalytic system has been observed with **5c** and **5b** and other reported mononuclear catalyst systems.[34–36]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

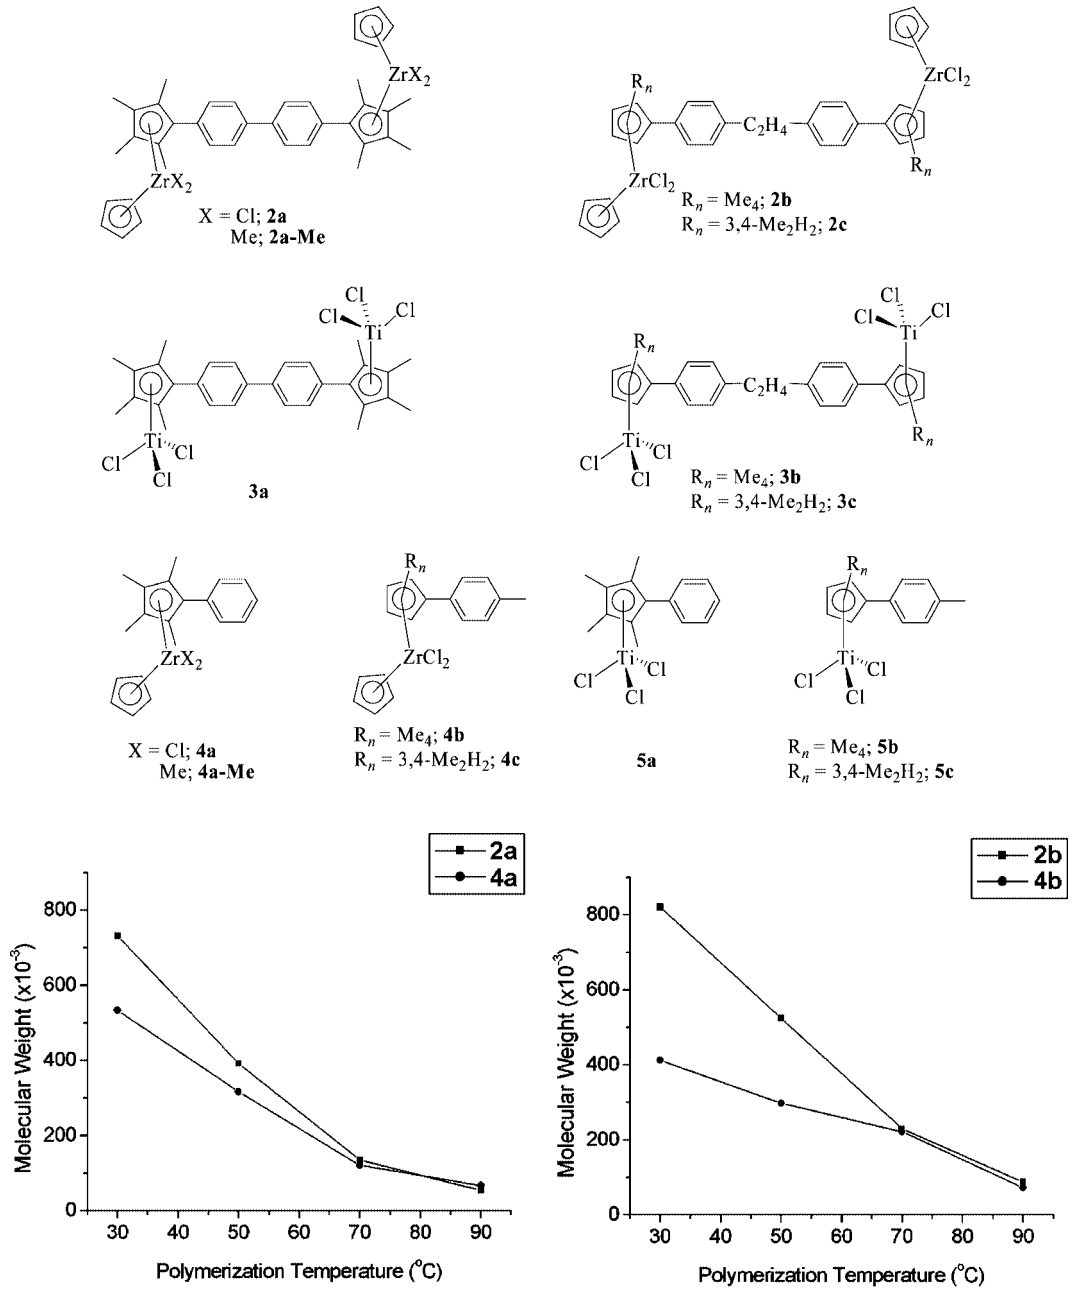

Figure 2. Molecular weight difference between the polymers obtained with **2a** and **4a** (left) and **2b** and **4b** (right).

The activities of the dinuclear complexes are slightly lower than those of the corresponding mononuclear systems. The extent of the activity decrease is more significant in **3b** and **3c**, which have a flexible diphenylethylene bridge, than in **3a**, which has a rigid biphenylene bridge, thereby indicating the effect of the steric influence on the catalytic activity in styrene polymerization.[37] Rausch et al. have also reported that ethylene-bridged dinuclear indenyltitanium trichloride shows much lower activity than the corresponding mononuclear compound in spite of similar syndioselectivity of these two complexes.[38] This result may imply that the bridge flexibility in **3b** and **3c** makes the two polymer chains growing at the two active centers exert a steric influence on each other which slows down the rate of chain propagation.[39]

The polystyrenes produced by dinuclear **3a**–**c** have a lower molecular weight than those of the corresponding mononuclear **5a**–**c** at all reaction temperatures. This can be explained in terms of the steric effect of the ligand, which means that β-H elimination becomes preferred to propagation as the steric hindrance between the polymer chain and ligand in half-sandwich metallocenes increases.[39] However, in contrast to the activity trend, the molecular weights of the polymers formed by the dinuclear systems are in the order **3a** > **3b** > **3c**, which is similar to the order of the mononuclear systems (**5a** ≈ **5b** > **5c**). The low molecular

| 19 | $Cp^*TiCl_3$ | 50 | 0.963 | 288.9 | 310 | 1.90 | 266 | 96 |

[a] Conditions: solvent: 50 mL of toluene; [Al]/[Ti]: 1000; styrene: 5.0 mL; $t_p$: 20 min; MAO: s-MAO. [b] Activity: kg of PS per mol of Ti per hour. [c] Syndiotacticity determined from the amount of polymer insoluble in 2-butanone.

weight obtained with both the most active complexes (**3c** and **5c**) appears to be mainly ascribed to the lower electron-donating effect of the dimethyl-substituted ligand. The molecular weight trend **3a** > **3b** can be considered to be a manifestation of the reduced steric effects in **3a** compared to **3b**.

## Conclusions

The biphenylene- and diphenylethylene-bridged dinuclear zirconocenes [4,4′-$(C_5Me_4)_2(C_6H_4)_2$][$CpZrCl_2]_2$ (**2a**), [*p*-$(C_5Me_4)C_6H_4CH_2]_2$[$CpZrCl_2]_2$ (**2b**), and [*p*-(3,4-$Me_2C_5H_2)C_6H_4CH_2]_2$[$CpZrCl_2]_2$ (**2c**) consistently provide high molecular weight polymers and have a high catalyst activity in ethylene polymerization, although there are some differences, including both structural and polymerization properties, between rigid and flexible bridged dinuclear complexes in terms of activity and molecular weight trends. In contrast, the corresponding dinuclear half-sandwich titanocenes [$(C_5Me_4)_2(C_6H_4)_2$][$TiCl_3]_2$ (**3a**), [*p*-$(C_5Me_4)$-$C_6H_4CH_2]_2$[$TiCl_3]_2$ (**3b**), and [*p*-(3,4-$Me_2C_5H_2)C_6H_4CH_2]_2$-[$TiCl_3]_2$ (**3c**) do not show any enhanced polymerization properties in styrene polymerization compared to their mononuclear analogues. Indeed, they show a significant decrease in the molecular weight of the polymer produced and a slight decrease of catalytic activity. These results appear to be due to the cooperative participation of the electronic effect of the two cationic metal centers through the biphenylene or diphenylethylene bridge and/or the steric effects between them.

## Experimental Section

**General:** Tetrahydrofuran, toluene, *n*-hexane, and *n*-pentane were distilled from Na-K alloy, $Et_2O$ from Na-benzophenone ketyl, and $CH_2Cl_2$ from $CaH_2$. All solvents were stored over activated molecular sieves (5 Å). All other chemicals were used without any further purification. 3,4-Dimethylcyclopent-2-enone,[40] 4,4′-$(C_6H_4)_2$-$(C_5Me_4H)_2$ (**1a**),[27] ($p$-$BrC_6H_4CH_2)_2$,[41] [4,4′-$(C_5Me_4)_2(C_6H_4)_2$]-[$CpZrCl_2]_2$ (**2a**),[27] [4,4′-$(C_5Me_4)_2(C_6H_4)_2$][$TiCl_3]_2$ (**3a**),[27] [$(PhC_5Me_4)CpZrCl_2$] (**4a**),[31] [(*p*-tolyl$C_5Me_4)CpZrCl_2$] (**4b**),[31] 1-tolyl-3,4-$Me_2C_5H_3$,[7] [(1-tolyl-3,4-$Me_2C_5H_2)CpZrCl_2$] (**4c**),[7] [$(PhC_5Me_4)TiCl_3$] (**5a**),[42] and [(*p*-tolyl$C_5Me_4)TiCl_3$] (**5b**)[43] were prepared according to literature procedures. Methylaluminoxane (MAO) was used as a solid (s-MAO). This was obtained by complete evaporation of the solvent and residual $AlMe_3$ from a toluene solution of PMAO (Witco, EUROCEN 30T) and a toluene solution of PMAO (Witco, EUROCEN 10T). Polymerization-grade ethylene monomer from Honam Petrochemical Corporation was used after purification by passing through Labclear™ and Oxiclear™ filters. Styrene monomer purchased from Aldrich was used after purification by passing through an alumina column. $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker Spectropin 400 spectrometer at ambient temperature. All chemical shifts are reported in $\delta$ units with reference to the residual peaks of $CDCl_3$ for proton ($\delta$ = 7.24 ppm) and carbon ($\delta$ = 77.0 ppm). Elemental analyses were carried out with an EA 1110-FISONS (CE Instruments) at KAIST.

**Synthesis of [*p*-$(C_5Me_4H)C_6H_4CH_2]_2$ (1b):** A solution of (*p*-$BrC_6H_4CH_2)_2$ (3.40 g, 10 mmol) in 50 mL of diethyl ether was treated with 2.2 equiv. of *n*BuLi (8.8 mL) at 0 °C and the reaction mixture was stirred at this temperature for 1 h. The slow formation of a white precipitate was observed and the reaction mixture was then warmed to room temperature and stirred for a further 2 h. The colorless solution was then decanted off and 30 mL of thf was added to the resulting dilithium salt. Subsequently, two equivalents of 2,3,4,5-tetramethylcyclopent-2-enone (2.76 g) in 20 mL of thf was added slowly through a cannula at –78 °C. The reaction mixture was slowly warmed to room temperature and stirred overnight. The resulting light orange solution was treated with 30 mL of a saturated aqueous solution of $NH_4Cl$. The organic portion was separated and the aqueous layer was further extracted with diethyl ether (50 mL). The combined organic portions were dried with anhydrous $MgSO_4$, filtered, and the solvents evaporated to dryness to afford a colorless oily product. The crude product was redissolved in $CH_2Cl_2$ (30 mL) and a catalytic amount of solid *p*-TsOH (0.1 g)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was added to the solution at room temperature. A yellow solid was immediately formed, and the stirring was continued for a further hour. The volume of the resulting reaction mixture was reduced to 10%, and 30 mL of *n*-hexane was poured into the flask in order to precipitate the product and dissolve the unreacted materials. The large amount of yellow solid obtained was filtered through a glass frit and washed successively with ethanol (30 mL), diethyl ether (30 mL), and *n*-pentane (30 mL). Drying in vacuo afforded 2.83 g of **1b** in 67% yield. $^1$H NMR (400.13 MHz, $CDCl_3$): $\delta$ = 7.18 (m, 8 H), 3.17 (q, 2 H), 2.93 (m, 4 H), 2.02 (s, 6 H), 1.91 (s, 6 H), 1.85 (s, 6 H), 0.95 (d, 6 H) ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): $\delta$ = 142.7, 140.4, 139.0, 136.7, 135.0, 134.8, 128.4, 128.1, 50.1, 37.6, 14.9, 12.7, 11.9, 11.1 ppm. EIMS: *m*/*z* 422 (85) [$M^+$], 408 (9) [$M^+ - CH_2$], 225 (15) [$M^+ - C_6H_4C_5Me_4H$], 211 (100) [$M^+/2$]. $C_{32}H_{38}$ (422.64): calcd. C 90.94, H 9.06; found C 90.33, H 9.44.

**Synthesis of [*p*-(3,4-$Me_2C_5H_3$)$C_6H_4CH_2$]$_2$ (1c):** An identical procedure to that for the synthesis of **1b** was employed with 3,4-dimethylcyclopent-2-enone (2.18 g) instead of 2,3,4,5-tetramethylcyclopent-2-enone. This afforded 2.31 g of an ivory solid (**1c**) in 63% yield. $^1$H NMR (400.13 MHz, $CDCl_3$): $\delta$ = 7.35 (d, 4 H), 7.09 (d, 4 H), 6.60 (s, 2 H), 3.24 (s, 4 H), 2.86 (s, 4 H), 1.96 (s, 6 H), 1.87 (s, 6 H) ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): $\delta$ = 142.4, 139.7, 135.5, 135.4, 134.2, 131.0, 128.6, 124.5, 45.3, 37.6, 13.4, 12.6 ppm. EIMS: *m*/*z* 366 (76) [$M^+$], 183 (100) [$M^+/2$], 167 (61) [$M^+/2 - CH_3$]. $C_{28}H_{30}$ (366.54): calcd. C 91.75, H 8.25; found C 91.23, H 8.52.

**Synthesis of [{[*p*-($C_5Me_4$)$C_6H_4CH_2$][$CpZrCl_2$]}$_2$] (2b):** A slurry of **1b** (0.422 g, 1.00 mmol) in 20 mL of thf was treated with two equivalents of *n*BuLi (0.8 mL) at –78 °C. The reaction mixture was warmed to room temperature and stirred for 4 h. Two equivalents of [$CpZrCl_3$] (2.0 mmol, 0.525 g) dissolved in 10 mL of thf was added to the resulting yellow suspension through a cannula at –78 °C. The reaction mixture was then warmed to room temperature and stirred for 24 h. The golden-yellow solution formed was then evaporated to dryness and extracted with 30 mL of toluene. The mixture was filtered through a Celite pad, and the light-yellow filtrate was evaporated to dryness. The crude product was washed twice with 10 mL of a mixture of *n*-hexane and diethyl ether (2:1, v/v). Drying in vacuo afforded spectroscopically pure **2b** as a light-yellow solid (0.639 g, 73%). Recrystallization of a concentrated $CH_2Cl_2$ solution of **2b** layered with *n*-hexane at room temperature afforded light golden colored, single crystals suitable for an X-ray diffraction study. $^1$H NMR (400.13 MHz, $CDCl_3$): $\delta$ = 7.19 (d, 4 H), 7.05 (d, 4 H), 6.13 (s, 10 H), 2.99 (s, 4 H), 2.21 (s, 12 H), 2.04 (s, 12 H) ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): $\delta$ = 140.5, 131.6, 129.7, 128.5, 126.5, 126.1, 124.2, 116.7, 37.3, 14.0, 12.3 ppm. $C_{42}H_{46}Cl_4Zr_2$ (875.07): calcd. C 57.65, H 5.30; found C 56.64, H 5.72.

**Synthesis of [{[*p*-(3,4-$Me_2C_5H_2$)$C_6H_4CH_2$][$CpZrCl_2$]}$_2$] (2c):** An identical procedure to that used for the synthesis of **2b** was employed with the ligand **1c** (0.366 g, 1.00 mmol) to afford **2c** as a light-yellow solid (0.573 g, 70%). $^1$H NMR (400.13 MHz, $CDCl_3$): $\delta$ = 7.36 (d, 4 H), 7.12 (d, 4 H), 6.49 (s, 4 H), 6.11 (s, 10 H), 2.86 (s, 4 H), 2.15 (s, 12 H) ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): $\delta$ = 140.8, 131.4, 129.4, 128.7, 125.1, 122.6, 116.5, 114.0, 37.3, 13.8 ppm. $C_{38}H_{38}Cl_4Zr_2$ (818.97): calcd. C 55.73, H 4.68; found C 55.74, H 4.87.

**Synthesis of [*p*-($C_5Me_4$)$C_6H_4CH_2$]$_2$[$TiCl_3$]$_2$ (3b):** A slurry of **1b** (0.422 g, 1.00 mmol) in 20 mL of thf was treated with two equivalents of *n*BuLi (0.8 mL) at –78 °C. The reaction mixture was warmed to room temperature and stirred for 4 h to give a yellow suspension. Two equivalents of [$ClTi(OiPr)_3$] (2.0 mmol, 0.521 g) dissolved in 10 mL of thf was added to the reaction mixture through a cannula at –78 °C. The resulting reaction mixture was then warmed to room temperature and stirred for 24 h. The golden-yellow solution formed was evaporated to dryness and extracted with 30 mL of $CH_2Cl_2$. The mixture was subsequently treated with an excess amount of $Me_3SiCl$ (3 to 4 equiv.) at 0 °C. After warming to room temperature, the reaction mixture was further stirred overnight. During the course of the reaction, the slow formation of a red precipitate was observed. The resulting red mixture was evaporated, and the shiny red product was washed twice with 20 mL of a mixture of *n*-hexane and $CH_2Cl_2$ (4:1, v/v). Drying in vacuo afforded 0.445 g of scarlet microcrystals of **3b** in 61% yield. Recrystallization of a concentrated $CH_2Cl_2$ solution of **3b** layered with *n*-hexane at room temperature afforded red single crystals suitable for an X-ray diffraction study. $^1$H NMR (400.13 MHz, $CDCl_3$): $\delta$ = 7.24 (m, 8 H), 2.99 (s, 4 H), 2.46 (s, 12 H), 2.41 (s, 12 H) ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): $\delta$ = 142.9, 142.0, 138.7, 136.1, 130.8, 130.3, 128.4, 37.3, 15.5, 14.6 ppm. $C_{32}H_{36}Cl_6Ti_2$ (729.08): calcd. C 52.72, H 4.98; found C 52.65, H 5.44.

**Synthesis of [{[*p*-(3,4-$Me_2C_5H_2$)$C_6H_4CH_2$][$TiCl_3$]}$_2$] (3c):** A similar procedure to that used for the synthesis of **3b** was employed with the ligand **1c** (0.366 g, 1.00 mmol), but with an excess of $Me_2SiCl_2$ instead of $Me_3SiCl$, to afford **3c** as a dark-red solid (0.451 g, 67%). $^1$H NMR (400.13 MHz, $CDC_{l3}$): $\delta$ = 7.57 (d, 4 H), 7.17 (s, 4 H), 7.10 (d, 4 H), 2.93 (s, 4 H), 2.47 (s, 12 H) ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): $\delta$ = 143.3, 140.6, 139.3, 130.8, 129.2, 126.1, 119.1, 37.4, 16.0 ppm. $C_{28}H_{28}Cl_6Ti_2$ (672.97): calcd. C 49.97, H 4.19; found C 49.60, H 5.02.

**Synthesis of [(1-*p*-tolyl-3,4-$Me_2C_5H_2$)$TiCl_3$] (5c):** A similar procedure to that used for the synthesis of **3b** was employed with 1-tolyl-3,4-$Me_2C_5H_3$ (0.366 g, 1.00 mmol), but with an excess of $Me_2SiCl_2$ instead of $Me_3SiCl$, to afford **6c** as dark red microcrystals (0.432 g, 64% yield). $^1$H NMR (400.13 MHz, $CDCl_3$): $\delta$ = 7.61 (d, 2 H), 7.22 (d, 2 H), 7.18 (s, 2 H), 2.47 (s, 6 H), 2.37 (s, 3 H) ppm. $^{13}C\{^1H\}$ NMR (100.62 MHz, $CDCl_3$): $\delta$ = 140.8, 140.4, 139.2, 130.2, 129.6, 126.0, 119.0, 21.4, 15.9 ppm. $C_{14}H_{15}Cl_3Ti$ (337.49): calcd. C 49.82, H 4.48; found C 49.42, H 4.61.

**Ethylene Polymerization:** Freshly distilled toluene (48 mL) was placed in a degassed 250-mL glass reactor charged with a pre-weighed amount of s-MAO (Al/Zr = 1000) and the temperature was adjusted using an external bath. The flask was then filled with ethylene monomer at 1 bar with vigorous stirring after degassing with the monomer several times. Polymerization was started by addition of a toluene solution of catalyst (2.0 mL, 2.0 μmol of Zr). After 2 min, all the reactions were quenched by addition of an acidified ethanol solution (10% HCl in EtOH) and the resulting polyethylene was precipitated by the addition of 200 mL of ethanol. After stirring for 1 to 2 h, the polyethylenes were filtered off, washed with ethanol several times, and dried under vacuum to a constant weight at 80 °C.

**Styrene Polymerization:** Freshly distilled toluene (48 mL) and styrene (5.0 mL) were successively added to a degassed, 250-mL glass reactor charged with a pre-weighed amount of s-MAO (Al/Ti = 1000) with vigorous stirring. The temperature was adjusted using an external bath. Polymerization was started by addition of a toluene solution of catalyst (2.0 mL, 10.0 μmol of Ti). After 20 min, all the reactions were quenched by addition of an acidified ethanol solution (10% HCl in EtOH) and the resulting polystyrene was further precipitated by addition of 200 mL of ethanol. After stirring for 1 to 2 h, polystyrenes were filtered off, washed with ethanol several times, and dried under vacuum to a constant weight at

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

80 °C. The crude polymer was extracted with refluxing 2-butanone for 12 h, and the insoluble fraction was filtered and dried under vacuum overnight at 80 °C in order to determine the syndiotactic polystyrene portion.

**Polymer Analysis:** The molecular weight ($M_w$) and molecular weight distribution ($M_w/M_n$) of polypropylenes were determined by GPC (Polymer Laboratories PL-GPC 220) in 1,2,4-trichlorobenzene using standard polystyrenes as a reference. The melting temperatures ($T_m$) of polypropylenes were measured by DSC (TA Instrument, 2910 MDSC).

**X-ray Structure Determination:** X-ray diffraction measurements were performed with a Bruker AXS diffractometer with a CCD area detector, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 293 K. A hemisphere of data was collected using ω scans. The frame data sets were processed using the SAINT and XPREP processing package. An empirical absorption correction was applied to each data set with the program SADABS. All the intensity data were corrected for Lorentz and polarization effects. The structure was solved by direct methods and refined by full-matrix least-squares methods using the SHELXTL program package with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were placed at their geometrically calculated positions and refined as riding on the corresponding carbon atoms with isotropic thermal parameters. For **2b**, final refinement based on the reflections with $I > 2\sigma(I)$ converged at $R1$ = 0.0348, $wR2$ = 0.0851, GOF = 0.963, and for **3b**, $R1$ = 0.0506, $wR2$ = 0.1156 and GOF = 0.845 (Table 4).[44]

Table 4. X-ray crystallographic data.

| Compound | **2b** | **3b** |
|---|---|---|
| Formula | $C_{42}H_{46}Cl_4Zr_2$ | $C_{32}H_{36}Cl_6Ti_2$ |
| Formula weight | 875.07 | 729.08 |
| Crystal system; space group | monoclinic; *C*2/*c* | monoclinic; *C*2/*c* |
| *a* [Å] | 21.509(5) | 36.11(6) |
| *b* [Å] | 16.944(4) | 6.625(11) |
| *c* [Å] | 12.933(3) | 15.33(2) |
| $\alpha, \beta, \gamma$ [°] | 90, 124.370(4), 90 | 90, 94.59(9), 90 |
| *V* [Å$^3$] | 3890.5(16) | 3656(10) |
| *Z* | 4 | 8 |
| $D_{calcd.}$ [g cm$^{-3}$] | 1.494 | 1.325 |
| *F*(000) | 1784 | 1496 |
| *T* [K] | 293 | 293 |
| $\mu$ (Mo-$K_\alpha$) [mm$^{-1}$] | 0.839 | 0.895 |
| $\theta$ range [°] | 1.66–28.37 | 1.13–27.97 |
| No. of unique/observed $[I > 2\sigma(I)]$ reflections | 4499/12111 | 4059/10577 |
| No. of parameters refined | 221 | 193 |
| $R1$, $wR2$[a] | 0.0348, 0.0851 | 0.0506, 0.1156 |
| GOF | 1.045 | 0.845 |
| Min./max. electron density [e Å$^{-3}$] | –0.692/0.302 | –0.360/0.313 |

[a] $R1 = \sum||F_o| - |F_c||/\sum|F_o|$; $wR2 = [\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]]^{1/2}$.

# Linear and Rectangular Trinuclear Phthalocyanines

Sergey G. Makarov,[a,b] Olga N. Suvorova,[b] Christian Litwinski,[c] Eugeny A. Ermilov,[c] Beate Röder,[c] Olga Tsaryova,[a] Thomas Dülcks,[a] and Dieter Wöhrle*[a]

**Keywords:** Phthalocyanines / NIR absorption / UV/Vis spectroscopy / Semiempirical calculations / Fused-ring systems

Isomeric linear and rectangular trinuclear metal-free and zinc(II) phthalocyanine complexes connected by common annulated benzene rings have been synthesized by the mixed cyclotetramerization of a 1,2,4,5-tetracyanobenzene derivative and 4,5-bis(2,6-dimethylphenoxy)phthalonitrile. Their electronic-absorption and fluorescence spectra have been studied in comparison with the corresponding mono- and dinuclear phthalocyanines. For the zinc complexes, the molecular orbitals and electronic spectra have been calculated semi-empirically. The trinuclear phthalocyanines exhibit absorptions up to 940 nm with extinction coefficients up to about 700000 $M^{-1}cm^{-1}$, which shows the extension of the π-electron system.

## Introduction

Conjugated porphyrin oligomers are the subject of significant interest due to their potential uses as molecular wires, materials for optical limiting, and other advanced technologies.[1] Accordingly, many compounds have been synthesized and studied in recent years. However, much less is known[2] about such systems based on phthalocyanines (Pcs) − the most common porphyrin analogues. Pcs have many applications, such as in dyes and pigments,[3a] catalysts and photocatalysts,[3b–3d] photoconductors in laser printers,[3e] and photosensitizers in photodynamic therapy.[3f] They are also of significant interest as potential molecular conductors and semiconductors,[4a] electrochromic[4b,4c] and non-linear optical[4d,4e] materials, components of organic photovoltaic cells,[4f] and light-emitting diodes.[4g] The high overall stability and exceptional electronic properties of Pcs are responsible for most of their actual and potential applications. The synthesis of conjugated oligomers as a way of modifying the electronic structure of phthalocyanines by increasing the dimensions of the conjugated π-electron system is of substantial interest for the design of new functional materials.

Changes in the electronic structure of Pcs are well indicated by their electronic absorption spectra. Most Pcs in solution have a sharp intense absorption band (Q band) in the red spectral region ($\lambda_{max} \approx 680$ nm). The extension of the Pc π-conjugated system causes a bathochromic shift and, depending on the resulting symmetry, splitting of the Q band. To understand these spectral changes MO calculations, which are normally in good agreement with experimental data, are often performed.

One possible way to extend the Pc π-system is annulation of further benzene rings at the periphery of the molecule, which leads to naphthalocyanines (Ncs), anthracocyanines (Acs),[5a] and different unsymmetrical analogues such as phthalonaphthalocyanines.[5b,5c] Unsymmetrical annulation gives more flexibility when it comes to tuning the electronic properties. However, this approach also leads to decreased stability.[5a,5b] The other possibility is the construction of conjugated Pc oligomers. Some dimers of Pcs and their close analogues have been described[2] but only a very few conjugated trimers are known: a diacetylene-bridged "Pc triangle", a benzo-annulated SubPc trimer, and only one conjugated benzo-annulated Pc trimer (described by us).[2a,2b,2g–2i,2l] It has been shown that the strongest known interaction between Pc units is probably achieved if they are connected through a common annulated benzene ring.[2b] It is interesting to point out that further annulation of a Pc ring to a dimer of this type will lead to isomeric linear and rectangular trimers with different symmetries and electronic properties. In our previous work,[2b] a substituted metal-free dimer and a linear metal-free trimer were prepared and their photophysical properties were described. To the best of our knowledge, a rectangular trimer of this type has not yet been reported and neither have metal-containing linear and rectangular trimers. In this work, we describe the preparation and basic photophysical properties of linear and rectangular metal-free and zinc Pc trimers in comparison

with their mono- and dinuclear analogues. For the zinc complexes, molecular orbitals and electronic spectra have been calculated semi-empirically.

## Results and Discussion

The metal-free linear trinuclear phthalocyanine $H_6$**5** was described in our previous work.[2b] It was isolated in 0.2% yield from the Pc mixture obtained by co-cyclotetramerization of the tetracyanobenzene derivative **1** and the substituted phthalonitrile **2**. Bulky 2,6-dimethylphenoxy groups in the phthalonitrile derivative **2** were selected to avoid or reduce aggregation of the corresponding Pcs. Compared to Pcs prepared from a mono-substituted phthalonitrile, a Pc synthesized from **2** exists as single isomer, which allows easier isolation and better characterization. The corresponding rectangular metal-free trimer was not isolated but was detected from a peak at around 900 nm in the UV/Vis/NIR spectrum of the reaction mixture.[2b] In the present work more careful gradient elution from a silica gel column with a toluene/hexane mixture, followed by column chromatography of all mixed fractions, allowed us to isolate both $H_6$**5** and $H_6$**6** in yields of 0.9 and 1.7%, respectively. Their zinc complexes were prepared by the usual metalation with zinc acetate in toluene/dmf (Scheme 1).

All compounds prepared in this work are stable in air and to light in solution as well as in the solid state. They are soluble in aromatic solvents, thf and halogenated hydrocarbons. Linear trinuclear Pcs, especially $Zn_3$**5**, have significantly lower solubility and higher aggregation tendency than the other Pcs described previously and here.[2b] This becomes significant in toluene (concentration dependence of the extinction coefficient, broad bands at around 850 and 1000 nm) at concentrations higher than $10^{-6}$ M. This tendency is not so pronounced in chloroform for $H_6$**5** or in thf for both $H_6$**5** and $Zn_3$**5**. Generally, zinc complexes $Zn_2$**4**–$Zn_3$**6** tend to aggregate more strongly than the corresponding free ligands.

The electrospray ionization (ESI) method was used for mass-spectrometric characterization of the prepared compounds. This method is widely employed for high-molecular-weight ($M > 1000$) compounds such as biomacromolecules,[6a] supramolecular systems,[6b] fullerenes[6c,6e] etc. It is known that ESI is sensitive only to ions already present in the solution or compounds that easily ionize through acid/base (Brønsted or Lewis) or redox chemistry.[6c,6d] To enhance the sensitivity to compounds that are more difficult to ionize, different reagents that convert the substrate into an ionic form (oxidants,[6c] salts,[6b,6d,6e] even in combination with chemical derivatization of analyte[6b,6d]) are used. In the present work, we found that the use of pyridine as a basic co-solvent for $H_6$**6**, or a small amount of sodium cyanide ($\approx 10^{-4}$ M) for $Zn_3$**5** and $Zn_3$**6**, facilitates their ionization to produce [$M^{2-}$ – 2H] and [$M^{2-}$ + 2CN], respectively. Pyridine is expected to deprotonate pyrrole fragments and cyanide coordinate to Zn. An interesting example of using

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NaCN in ESI MS is the analysis of higher fullerenes.[6e] In this case the nucleophilic addition of cyanide to fullerene is responsible for ionization. In summary, the molecular ions of the annulated dinuclear and trinuclear Pcs were clearly identified by the ESI MS method, although it was not possible to distinguish by mass spectrometric means between the isomeric trinuclear linear **5** and rectangular **6**.

The difference between linear and rectangular trinuclear Pcs can be clearly seen in their $^1$H NMR spectra, where Pc ring currents help to resolve the spectra of di- and trinuclear Pcs by deshielding the protons of the neighboring Pc fragments.[2b] The $^1$H NMR spectrum of $H_6$**5** has been described previously.[2b] The spectrum of $H_6$**6** (Figure 1) is more complicated due to its lower symmetry. The signals of the methyl protons are only partially resolved,[7a] in contrast to the clearly resolved group of four singlets in the case of the linear $H_6$**5**. In the aromatic region of the spectrum, two signals of (two types of) protons of the bridging benzene rings appear at $\delta$ = 11.46 and 11.25 ppm, and two groups of signals of the other Pc aromatic protons (eight types, resolved only partially) at $\delta$ = 8.99–9.08 and 8.17–8.37 ppm. In the case of $H_6$**5** there are only five types of Pc ring protons that give separate singlets. The aromatic protons of the substituents show a broad signal at $\delta$ = 7.32–7.54 ppm. In the rectangular trimer, one pair of substituents get very close to each other and, in one of the possible conformations, their tails can be located over the neighboring benzene rings of the remote Pc fragments. The doublet at $\delta$ = 6.96 ppm and the triplet at $\delta$ = 6.63 ppm in the spectrum of $H_6$**6**, which disappear upon increasing temperature, can be assigned to the aromatic protons of these substituents. Zinc complexes $Zn_3$**5** and $Zn_3$**6** show similar spectra to the corresponding free ligands except for the two signals of the pyrrole protons near $\delta$ = 0 ppm (1:2 ratio), which belong to central and peripheral Pc rings, respectively.

The UV/Vis/NIR absorption spectra of **3**–**6** (M = Zn) are shown in Figure 2. The values for the most intense bands are given in Table 1. The spectrum of $H_6$**6** is very similar to that of $Zn_3$**6** [for **3**–**5** (M = 2 H) see ref.[2b]]. The spectral changes on going from Zn**3** to $Zn_2$**4** and further to $Zn_3$**5** are similar to the changes reported[2b] for their metal-free analogues, namely a strong red shift of the Q band [166 nm (2900 cm$^{-1}$) from Zn**3** to $Zn_2$**4** and 102 nm (1300 cm$^{-1}$) from $Zn_2$**4** to $Zn_3$**5**], and an increase of its ex-

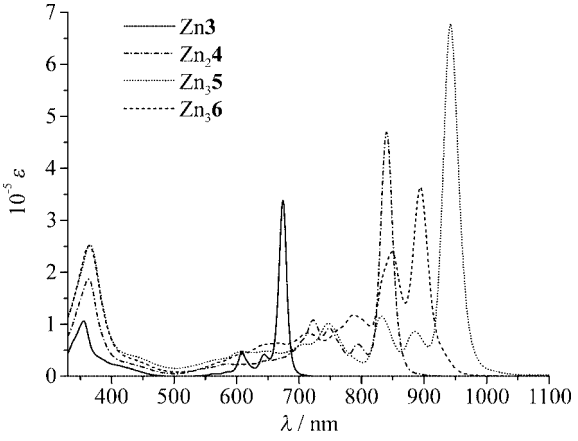

Figure 2. Electronic absorption spectra of **3**–**6** (M = Zn) in thf.

Table 1. Main electronic absorption bands of **3**–**6** (M = Zn).

| | Q band | | B band | |
|---|---|---|---|---|
| | $\lambda$ [nm] (cm$^{-1}$) | $\varepsilon$ [M$^{-1}$ cm$^{-1}$] | $\lambda$ [nm] (cm$^{-1}$) | $\varepsilon$ [M$^{-1}$ cm$^{-1}$] |
| Zn**3** | 674 (14800) | 338000 | 355 (28200) | 106000 |
| $Zn_2$**4** | 840 (11900) | 470000 | 363 (27500) | 187000 |
| $Zn_3$**5** | 942 (10600) | 680000 | 365 (27800) | 253000 |
| $Zn_3$**6** | 894 (11200) | 364000 | 364 (27500) | 251000 |
| | 849 (11800) | 239000 | | |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tinction coefficient. The spectrum of $Zn_3$**6** is more complex. The Q band appears between those of $Zn_2$**4** and $Zn_3$**5**, thus indicating that the rectangular annulation of the third Pc ring has less effect on the frontier orbitals than the linear one. In contrast to $D_{2h}$-symmetric $Zn_2$**4** and $Zn_3$**5**, the Q band of $C_{2v}$-symmetric[8] $Zn_3$**6** is split into two sub-bands of similar intensity; its maximal extinction coefficient is lower than that of $Zn_3$**5**. The Soret band position is not significantly influenced by π-system extension, which indicates only a weak perturbation of the higher excited singlet state. The intensity of the Soret band increases with molecular size − the intensity ratios for Zn**3**/$Zn_2$**4**/$Zn_3$**5**/$Zn_3$**6** are 1:1.76:2.38:2.36, i.e. not proportional to the number of Pc rings but more likely to the number of benzene rings (ratios 1:1.75:2.50:2.50).

For better understanding of the observed spectral changes semi-empirical MO calculations (ZINDO/s method) were carried out for the unsubstituted analogues Zn**3a**–$Zn_3$**6a** of Zn**3**–$Zn_3$**6**, respectively. The initial geometries were constructed from the crystal structure of the unsubstituted ZnPc (Zn**3a**)[9] by making the molecules perfectly planar and adopting $D_{4h}$ (Zn**3a**), $D_{2h}$ ($Zn_2$**4a** and $Zn_3$**5a**), or $C_{2v}$ symmetry ($Zn_3$**6a**), as described for dinuclear Pc.[2f] The distance between the closest hydrogen atoms located at the first and the third Pc ring of $Zn_3$**6a** is only 2.8 Å, which means that bulky substituents at these positions in **6** have to escape each other (see discussion of NMR spectra), perhaps also distorting the Pc rings. This more sterically hindered and less symmetrical structure could be the reason for the much higher solubility of **6** compared to **5**. The calculated spectra are shown in Figure 3 and the partial orbital diagrams in Figure 4. The results obtained for Zn**3a** and $Zn_2$**4a** are similar to data reported previously.[2c,2e,2f] The shapes of the theoretical spectra are in good agreement with the experimental ones, although the transition energies are underestimated by around 10% for the Q bands of $Zn_2$**4**–$Zn_3$**6**. The splitting of the Q band for $Zn_3$**6** is predicted. Also, the higher-energy transitions at around 700 nm calculated for $Zn_2$**4**–$Zn_3$**6** can be seen in their spectra as broad bands of low intensity. The observed strong Q band changes can be explained by considering a simplified orbital model (Figure 4). The Pc Q band is essentially a HOMO–LUMO transition. A series of two HOMOs and four LUMOs of **4a** can be described as a linear combination of frontier orbitals of two mononuclear Pc molecules.[2f] The splitting of the corresponding energy levels reduces the HOMO–LUMO gap, and this effect increases with addition of the third Pc ring. Whereas the HOMO splitting pattern is similar for $Zn_3$**5a** and $Zn_3$**6a**, the LUMO splitting is different: it is stronger for $Zn_3$**5a**, and in the case of $Zn_3$**6a** two lowest unoccupied levels have very similar energy values, which is responsible for the Q band splitting. This is very similar to the observed difference between opposite and adjacent annulation of benzene rings at the Pc:[5b,5c] the splitting of the LUMO (and, as a consequence, of the Q band) in the latter case is much weaker. This can be explained by the orthogonality of the Pc LUMOs ($E_{gx}$ and $E_{gy}$). In the case of rectangular (adjacent) annulation they interact with the orbitals of annulated fragments (Pc or benzene rings) almost independently, which results in a rather small splitting. This is in contrast to linear (opposite) annulation along the $x$ axis, where the $E_{gx}$ LUMO interacts

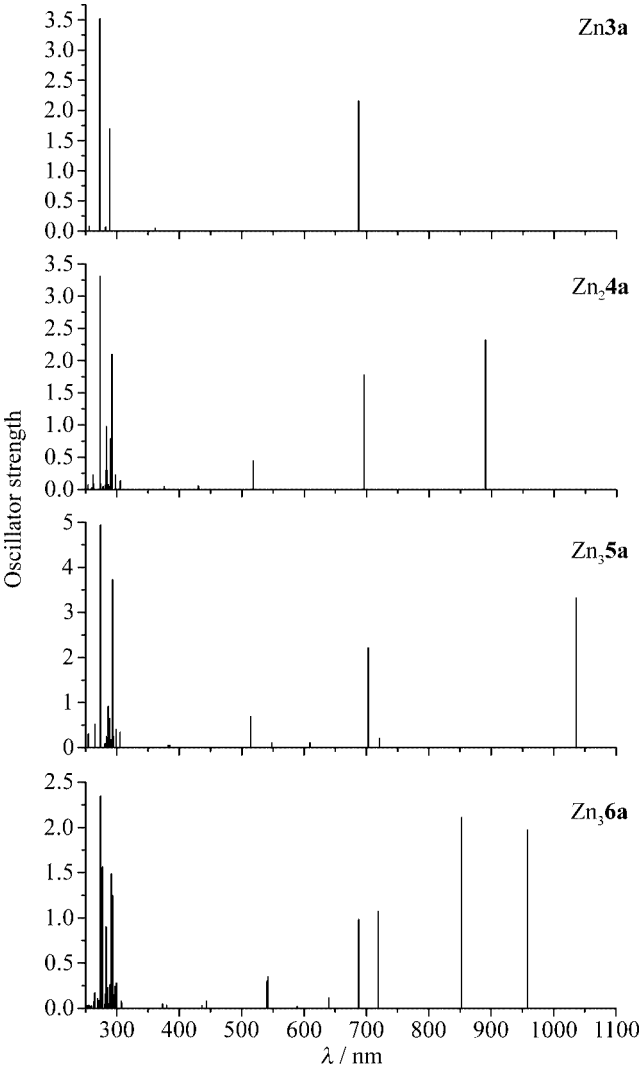

Figure 3. Calculated electronic spectra (ZINDO/s method) for unsubstituted analogues **3a**–**6a** (M = Zn) of **3**–**6** (M = Zn).

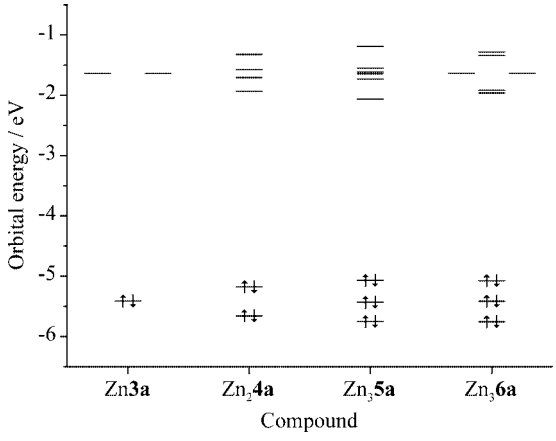

Figure 4. Partial orbital diagrams of **3a**–**6a** (M = Zn).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

strongly with both fragments, resulting in strong red shift of the *x*-polarized Q sub-band. Since the Pc HOMO ($A_{1u}$) is symmetric relative to all four $C_2$ axes within the plane, its interaction with the orbitals of additional Pc or benzene rings, which results in splitting or destabilization[5b] of the corresponding energy levels, is similar for both types of annulation. Each trimer has one occupied and two unoccupied orbitals with energies very similar to the HOMO and LUMOs of Zn**3a**. These "unperturbed" orbitals are located on peripheral Pc rings.

The fluorescence spectra of compounds **3**–**6** (M = Zn) in thf are shown in Figure 5. The maximum of the fluorescence spectrum of the mononuclear Pc Zn**3** ($\lambda_{max}$ = 687 nm) shifts to 846 nm for the dinuclear Pc $Zn_2$**4**, 902 nm for the rectangular trimer $Zn_3$**6**, and to 948 nm for the linear trimer $Zn_3$**5** (Table 2). The fluorescence quantum yield ($\Phi_{fl}$) of the mononuclear Pc Zn**3** is 0.28, that of the dinuclear Pc $Zn_2$**4** is 0.08, and those for the linear ($Zn_3$**5**) and rectangular ($Zn_3$**6**) trinuclear Pcs less than 0.03 (Table 2). The fluorescence lifetime ($\tau_{fl}$) of Zn**3** is 3.05 ns, whereas it is 0.68 ns for $Zn_2$**4**, 0.35 ns for $Zn_3$**5**, and 0.56 ns for $Zn_3$**6**. The values of the fluorescence quantum yield of the dinuclear and trinuclear ZnPcs are reduced compared with that of the mononuclear Pc. This reduction is in agreement with a decrease of the fluorescence lifetime. The decrease of the HOMO–LUMO gap and a more extended vibrational level structure of larger molecules, which increase the probability of nonradiative decay, are the reasons for this effect.[2b,2f,2j,10] Compared to the values for $H_2$**3** reported in our previous publication,[2b] the fluorescence lifetime and fluorescence quantum yield of Zn**3** are strongly reduced due to the heavy-atom effect, which is usual for Pcs with a closed-shell central metal.[10] Due to the strongly increased probability of nonradiative deactivation of the first excited singlet state of **4** and **5**, the difference between the fluorescence lifetime and quantum yield for metal-free and Zn di- and trinuclear Pcs becomes negligible.[11]

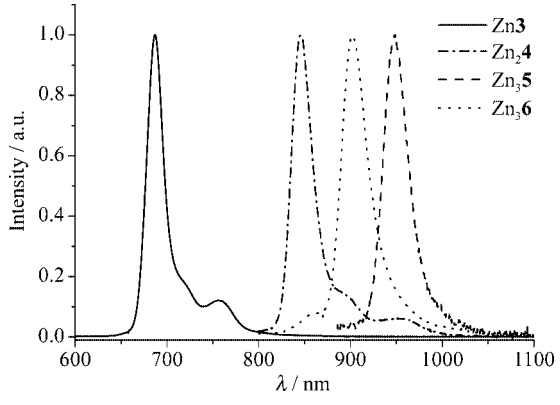

Figure 5. Fluorescence spectra (uncorrected) of **3**–**6** (M = Zn) in thf.

Table 2. Photophysical properties of **3**–**6** (M = Zn) in thf.

| | Fluorescence max. $\lambda$ [nm] ($cm^{-1}$) | $\Phi_{fl}$ | $\tau_{fl}$ [ns] |
|---|---|---|---|
| Zn**3** | 687 (14550) | 0.28 | 3.05 |
| $Zn_2$**4** | 846 (11800) | 0.08 | 0.68 |
| $Zn_3$**5** | 948 (10550) | <0.03 | 0.35 |
| $Zn_3$**6** | 902 (11100) | <0.03 | 0.56 |

## Conclusions

Isomeric linear and rectangular trinuclear phthalocyanines connected through common annulated benzene rings have been obtained by the mixed condensation of a tetracyanobenzene derivative and 4,5-bis(2,6-dimethylphenoxy)-phthalonitrile together with mono- and dinuclear Pcs. The different annulated Pcs could be separated by column chromatography. Metal-free rectangular and zinc linear and rectangular trinuclear Pcs of this type have been prepared for the first time. The annulated zinc complexes show intense ($\varepsilon = 2\times10^5$–$7\times10^5$ $M^{-1}cm^{-1}$) NIR absorption bands at $\lambda \approx 950$ nm for the linear and $\lambda \approx 850$ and 900 nm for the rectangular trimer, whereas the dinuclear Pc absorbs at $\lambda \approx 850$ nm. This clearly reflects the extension of the π-electron system. An exceptionally long wavelength shift and decreasing HOMO–LUMO gap is also observed for triply linked fused porphyrins due to conjugation over the whole planar π-system.[1b,1e,1f] Compared to the linear trimer, the less symmetrical rectangular one shows a more complex spectrum with a splitting of the lowest energy absorption band. The observed spectral changes are in good agreement with semi-empirical MO calculations (ZINDO/s method). The difference between the orbitals and spectra of linear and rectangular trinuclear Pcs is analogous to that in opposite and adjacent dibenzo-annulated Pc analogues.[5b,5c] The fluorescence quantum yields and lifetimes decrease with increasing molecular size. The rectangular trimer $Zn_3$**6** has a longer fluorescence lifetime than the linear $Zn_3$**5**. Work is now in progress to study the electronic properties of these trinuclear Pcs in more detail.

## Experimental Section

**Measurements:** Electronic absorption spectra were recorded with a Perkin–Elmer Lambda 2 spectrophotometer, IR spectra with a Perkin–Elmer Spectrum 1000 FT-IR spectrometer, NMR spectra with a Bruker Avance DPX 200 (200 MHz), and ESI mass spectra with a Bruker Esquire LC mass spectrometer. The experimental setups for steady-state and time-resolved fluorescence measurements have been described previously.[2b] The excitation source for the time-resolved measurements was a pulsed frequency doubled linear polarized Nd:$VO_4$ laser (Cougar, Time Bandwidth Products) with a wavelength of 532 nm, a pulse width of 12 ps, and a repetition rate of 60 MHz. The steady-state fluorescence spectra of **3**–**6** were recorded at an excitation wavelength of 360 nm.

Molecular Orbital Calculations were performed using the ZINDO/s method within the HyperChem R 5.02[12] software program. The σ–σ and π–π overlap weighing factors were 1.267 and 0.585, respectively. The electronic spectra were calculated using the configuration interaction method including all singly excited configurations with excitation energies up to 8 eV, as described previously.[2c] The initial geometries were constructed from the X-ray crystal structure

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the unsubstituted PcZn[9] by making the molecules perfectly planar and adopting $D_{4h}$ (Zn**3a**), $D_{2h}$ ($Zn_2$**4a** and $Zn_3$**5a**), or $C_{2v}$ symmetry ($Zn_3$**6a**), as described previously for $Zn_2$**4a**.[2f]

**Materials:** Zinc acetate dihydrate (Fluka) purchased in the highest available grade was used without further purification. The solvents (Fluka, analytical reagent grade) were dried, distilled, and stored under nitrogen. Merck silica gel 60 (40–63 μm) was used for chromatographic separations. The compounds Zn**3** and $Zn_2$**4** were prepared as described previously.[2l]

The phthalocyanines **3**–**6** (M = 2 H) were prepared by the mixed condensation procedure described by us previously.[2b] After demetalation of the obtained mixture of MgPcs with trifluoroacetic acid, the resulting mixture of metal-free Pcs was chromatographed on silica gel eluting with toluene/hexane and *very slowly* reducing the hexane content from 15 to 5 vol.-%. The eluate content was analyzed by UV/Vis/NIR spectroscopy, the fractions containing peaks at about 900 and 950 nm were collected, and the ones with almost identical spectra were mixed and re-chromatographed to obtain two fractions whose spectra did not change during elution from the column. The solvents were then evaporated under reduced pressure. Compound $H_6$**5** (less soluble) was recrystallized from toluene and $H_6$**6** re-precipitated from toluene with hexane; both were then dried under vacuum ($10^{-2}$ mbar) at 60 °C.

**$H_6$5:** Dark-green powder; yield: 8.5 mg (0.9%). $^1$H NMR: identical to previous data.[2b] UV/Vis (thf): $\lambda_{max}$ ($\varepsilon$) = 944 (400000), 890 (89000), 836 (100000), 754 (85000), 660 (sh, 45000), 608 (41000), 418 (sh, 72000), 356 nm (215000 $M^{-1}cm^{-1}$).[13] MS (ESI, $CH_2Cl_2$/dmf, 1:10, negative mode): *m*/*z* 1652.5 [$M^{2-}$ – H].

**$H_6$6:** Dark-green powder; yield: 16 mg (1.7%). $^1$H NMR (200 MHz, $CDCl_3$, 25 °C, TMS):[7a] $\delta$ = 11.46 (s, 2 H), 11.25 (s, 2 H), 9.08 (s, 2 H), 9.02 (s, 2 H), 8.99 (s, 2 H), 8.37 (s, 2 H), 8.35 (s, 2 H), 8.27 (s, 2 H), 8.17 (br., 4 H), 7.32–7.54 (br. m, 42 H), 6.96 (d, $J_{H,H}$ = 7.6 Hz, 4 H), 6.63 (t, $J_{H,H}$ = 7.6 Hz, 2 H), 2.36–2.72 (m, 96 H), 0.73 (br. s, 2 H), 0.10 (br. s, 4 H) ppm. UV/Vis (thf): $\lambda_{max}$ ($\varepsilon$) = 907 (288000), 860 (209000), 810 (118000) 773 (sh, 102000), 729 (107000), 668 (sh, 66000), 420 (sh, 84000), 357 nm (232000 $M^{-1}cm^{-1}$). MS (ESI, pyridine/dmf, 1:10, negative mode): *m*/*z* 1652 [$M^{2-}$ – 2 H].

**Compound $Zn_3$5:** $H_6$**5** (5.1 mg, 1.5 μmol) was suspended in toluene (2 mL) by sonication. A solution of zinc acetate dihydrate (30 mg, 0.14 mmol) in dmf (1 mL) was then added and the resulting mixture was refluxed for 15 h. The cooled mixture was diluted with methanol (10 mL) and the precipitate was collected by centrifugation, washed with methanol, vacuum-dried, dissolved in toluene containing 8 vol.-% of diethyl ether, and chromatographed on silica gel eluting with toluene/diethyl ether (approx. 10 vol.-% of diethyl ether). The solvents were then evaporated under reduced pressure and the compound was recrystallized from toluene and vacuum-dried ($10^{-2}$ mbar, 60 °C) to obtain a black powder. Yield: 2.3 mg (42%). $^1$H NMR (200 MHz, $C_6D_6$, 65 °C, TMS):[7b] $\delta$ = 11.71 (s, 4 H), 9.82 (s, 4 H), 8.68 (br., 8 H), 7.25–7.49 (br. m, 48 H), 2.73 (s, 24 H), 2.64 (s, 24 H), 2.40 (s, 24 H), 2.28 (s, 24 H) ppm. UV/Vis (thf): $\lambda_{max}$ ($\varepsilon$) = 942 (680000), 885 (86000), 832 (115000), 746 (102000), 709 (sh, 62000), 648 (48000), 607 (48000), 365 nm (253000 $M^{-1}cm^{-1}$). MS (ESI, dmf + NaCN, negative mode): *m*/*z* 1772 [$M^{2-}$ + 2CN].

**Compound $Zn_3$6:** Similarly, a mixture of $H_6$**6** (10.9 mg, 3.3 μmol) in toluene (2 mL) was treated with zinc acetate dihydrate (44 mg, 0.20 mmol) in dmf (1 mL). The crude product was chromatographed on silica gel eluting with toluene/diethyl ether (approx. 9 vol.-% of diethyl ether), re-precipitated from toluene with hexane, and vacuum-dried ($10^{-2}$ mbar, 60 °C) to obtain $Zn_3$**6** as a dark-green powder. Yield: 5.1 mg (44%). $^1$H NMR (200 MHz, $C_6D_6$, 60 °C, TMS):[7a] $\delta$ = 11.91 (s, 2 H), 11.81 (s, 2 H), 9.77 (s, 2 H), 9.74 (s, 2 H), 9.55 (s, 2 H), 8.71 (br., 10 H), 7.24–7.52 (m, 48 H), 2.25–2.80 (m, 96 H) ppm. UV/Vis (thf): $\lambda_{max}$ ($\varepsilon$) = 894 (364000), 849 (239000), 787 (118000), 715 (83000), 664 (sh, 64000), 364 nm (251000 $M^{-1}cm^{-1}$). MS (ESI, dmf + NaCN, negative mode): *m*/*z* 1772 [$M^{2-}$ + 2CN].

# Synthesis, Structure and Reactivity of Trimethylsilyl-Substituted Phosphametallocenes

**Rebekka Loschen,[a] Christoph Loschen,[a][‡] and Walter Frank,[a][‡‡] and Christian Ganter*[a]**

*Dedicated to Prof. Dr. Gerhard E. Herberich on the occasion of his 70th birthday*

**Keywords:** Metallocenes / P ligands / Silicon / Phosphaferrocenes / Conformation analysis

New sterically crowded phosphaferrocene and -ruthenocene derivatives were synthesized via the 2,5-bis(trimethylsilyl)-phospholide anion **5**. Their reactivity with regard to the exchange of the $Me_3Si$ groups for other functional groups was examined. X-ray structures were determined for the mono- (**6**) and the 1,1′-diphosphaferrocene (**8**). The activation barrier for ring–ring rotation in **8** was determined by NMR spectroscopy and supported by DFT calculations. Attempts to prepare 2,5-difunctional phosphaferrocenes through electrophilic substitutions were unsuccessful, but yielded en route a new bidentate P,P ligand (**3**) and its $Mo(CO)_4$ complex, which were both characterized by X-ray diffraction.

## Introduction

Phosphametallocenes are interesting compounds that show remarkable equivalence with their carbocyclic analogues regarding some of the physical and chemical properties but also show markedly different behaviour with regard to other properties. The Fe containing phosphaferrocenes are by far the most intensively studied phosphametallocenes, which were discovered in 1977 and still continue to be of interest.[1] In particular, the use of phosphaferrocene building blocks for the construction of multidentate, chiral chelate ligands has brought about a renewed interest within the last decade.[2] The chemical reactivity of phosphaferrocenes in view of synthetically useful transformations is restricted to electrophilic aromatic substitutions, which provide access to derivatives with one additional functional group attached to the phosphole ring, thereby rendering the phosphaferrocene a planar-chiral moiety. In this paper we report our attempts to prepare phosphaferrocene and phospharuthenocene derivatives with two functional groups at the 2,5-position of the phosphole ring. Related compounds were prepared earlier by converting suitable phosphole precursors into the respective phosphametallocenes[3] and this strategy was successfully employed in this work. The sought-after 2,5-difunctionalized phosphaferrocenes are synthetically interesting compounds and may be used for the assembly of extended structures like macrocycles containing several individual phosphaferrocene units. Such compounds would significantly expand the class of known macrocyclic ligands, which mainly consist of oxygen, sulfur or nitrogen containing derivatives.[4] In contrast, much less is known about phosphorus containing macrocycles although the first example was prepared as early as 1975.[5,6] While the O, N and S containing compounds feature strong σ-donor properties, the P derivatives are of special interest because they may exhibit a more or less pronounced π-acceptor character, depending on the nature of the phosphorus subunit. For example, a macrocycle comprising four phosphinine rings with strong acceptor properties[7] has been reported by Mathey et al.[8] This ligand formed stable complexes with low-valent transition-metal fragments of $Rh^I$, $Ir^I$, $Au^I$ and $Au^0$.[8a,9] Phosphaferrocenes also feature $sp^2$-hybridized P atoms with a significant π-acceptor capacity[1] and have been used recently as building blocks for the construction of bi- and oligodentate chiral chelate ligands. In view of their potential use for the assembly of macrocycles we decided to elaborate on the synthesis of 2,5-disubstituted phosphaferrocenes.

## Results and Discussion

A potential retrosynthetic fragmentation of a phosphaferrocene containing macrocycle is presented in Scheme 1. Disconnection leads to 2,5-disubstituted phosphaferrocene derivatives with suitable functional groups. Thus, a 2,5-diformyl or diacyl derivative, or compounds derived thereof, appear to be attractive synthetic targets.

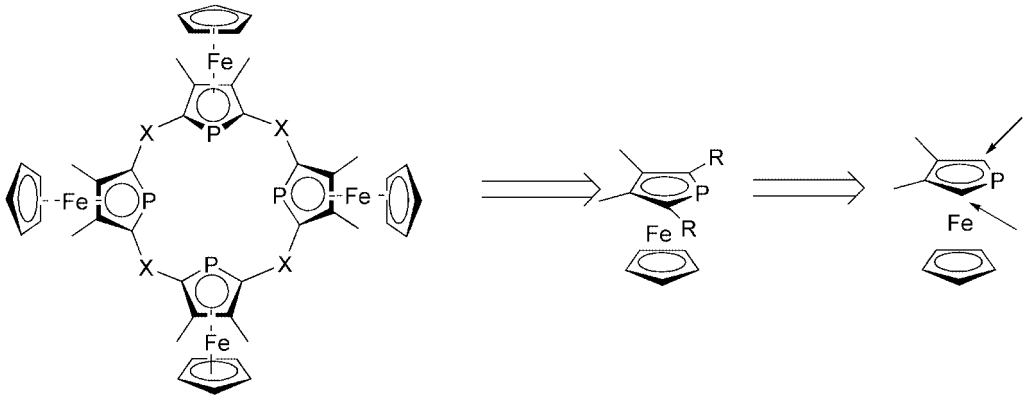
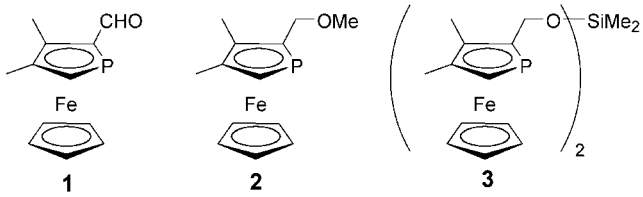


Scheme 1.

**Modification of an Existent Phosphaferrocene**

In contrast to ferrocene, which can be deprotonated and treated with a great variety of electrophiles, this protocol is not applicable to phosphaferrocenes,[10] thus preventing an easy and general access to functionalized derivatives. As mentioned above, electrophilic substitution is the only reported method for the introduction of a substituent into the phosphole ring of a given phosphaferrocene unit. For example, the electrophilic formylation,[11] acylation[12] and carboxylation[13] of 3,4-dimethylphosphaferrocene under Friedel–Crafts or Vilsmeyer conditions have been reported to occur selectively on the phosphole ring giving the monofunctionalized products with the additional substituent at the 2-position in good yield, thereby rendering the phosphaferrocene a planar-chiral moiety. The deactivating nature of the formyl, acyl and carboxylic ester functional groups prevents the formation of disubstituted derivatives. We thought that transformation of these functional groups into less deactivating or even activating ones might overcome this situation and allow the introduction of a second functional group via electrophilic substitution. Therefore, we prepared the ether derivatives **2** and **3** in good yield after initial reduction of the aldehyde **1** to the corresponding alcohol (Scheme 2).



Scheme 2.

The spectroscopic characterization revealed that compound **3** was obtained as a *rac*/*meso* mixture in the ratio of 2:1 because of the racemic nature of the starting aldehyde **1**. The *rac* isomer of **3** could be characterized by an X-ray diffraction analysis. It crystallizes in the triclinic space group $P\bar{1}$ with both enantiomers in the asymmetric unit ($Z$ = 4). The geometrical data for the two independent molecules are identical within experimental precision and values are reported for one molecule only. Bond lengths and angles fall in the range typically observed for phosphaferrocene derivatives. The suitability of the dinuclear phosphaferrocene **3** to act as a bidentate-P,P ligand was demonstrated by the formation of the complex **3**·Mo(CO)$_4$. Again, the X-ray structure of the complex containing the *rac*-ligand could be determined and the two structures are depicted in Figure 1 and Figure 2, relevant geometrical data are compiled in Table 1 and Table 2. The Mo complex lacks any molecular symmetry in the solid state (point group $C_1$), but features effective $C_2$ symmetry in solution leading to a singlet resonance for the two phosphorus atoms in the $^{31}$P NMR spectrum. A Similar behaviour has been observed before for other Mo(CO)$_4$ complexes with $C_2$-symmetric bisphosphaferrocenes.[14,15] The deviations of the central MoL$_6$ core from regular octahedral symmetry in terms of bond angles are rather small since the P,P ligand is highly flexible because of the extended backbone. The Mo–P and Mo–CO distances are in agreement with values observed for related complexes with phosphaferrocene or other π-acidic P-ligands.[16] The changes of intra-ligand geometrical parameters upon coordination are small but typical and mainly

Unfortunately, all attempts to introduce a second functional group into the derivatives **2** and **3** by electrophilic formylation or acylation have met with failure. Furthermore, the dinuclear derivative 1,1′-bis[(3,4-dimethylphosphaferrocene-2-yl)methyl]ferrocene[15] could also neither be formylated nor acylated.

### *2,5-Disubstituted Phosphaferrocenes from Preformed Phospholes*

Because of the unsuccessful attempts described in the preceding paragraph a different synthetic approach was envisaged. An alternative access to 2,5-disubstituted phosphaferrocenes is the synthesis of a suitable 2,5-disubstituted phospholide anion in a first step and subsequent coordination to a CpFe source. For this purpose we chose the well-known zirconocene-mediated coupling of alkynes: with 1-trimethylsilylpropyne as a coupling partner, the zirconacyclopentadiene with the $Me_3Si$ groups in α-positions is formed regioselectively in high yield and can be converted into the corresponding bromophosphole (**4**) by treatment with $PBr_3$ (Scheme 3).[17,18]

Reduction of bromophosphole (**4**) by elemental lithium proceeds straightforwardly to the corresponding phospholide anion **5**, the conversion can easily be monitored by $^{31}P$ NMR spectroscopy [$\delta$ = 141 (**5**), 78 ppm (**4**)]. Subsequent coordination of anion **5** to suitable Cp-metal fragments gave access to new TMS-substituted phosphametallocenes (Scheme 4): 2,5-bis(trimethylsilyl)-3,4-dimethylphosphaferrocene (**6**), the analogous ruthenocene (**7**) and 2,2′,5,5′-tetrakis(trimethylsilyl)-3,3′,4,4′-tetramethyl-1,1′-diphosphaferrocene (**8**), which has been synthesized before but was only characterized by $^1H$ NMR spectroscopy.[19]

### *2,5-Bis(trimethylsilyl)-3,4-dimethylphosphaferrocene (6)*

In order to prepare 2,5-bis(silyl)monophosphaferrocene derivatives the phospholide anion **5** was treated with different iron precursors. While the reaction with [(mesitylene)$FeCp^+$]$PF_6$ was unsuccessful, treatment with $[Cp^*FeCl]_n$ (Scheme 3) – prepared in situ from Cp*Li and $FeCl_2$ in THF according to the literature[2g] – proceeded straightforwardly to produce the Cp*-phosphaferrocene **6** in 55% yield as red crystals after crystallization from MeOH, which was completely characterized by NMR spectroscopy, mass spectroscopy, elemental analysis and X-ray diffraction. An

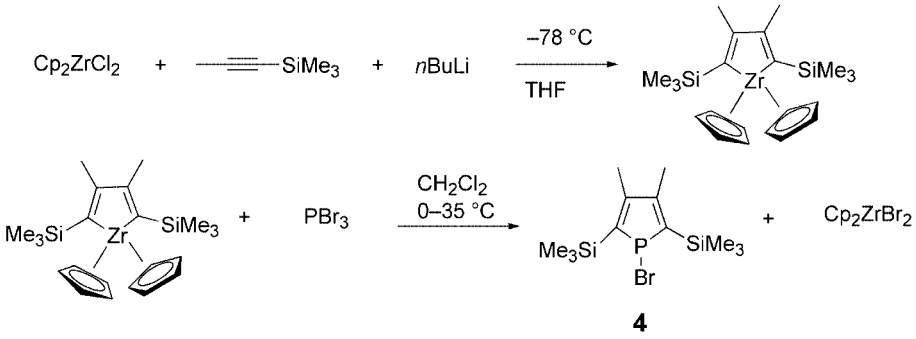
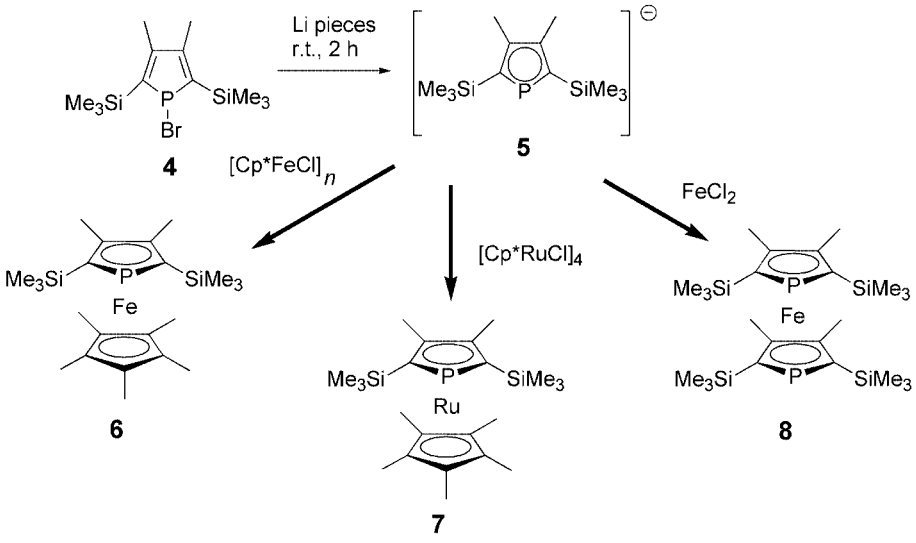


Scheme 3.



Scheme 4.

ORTEP plot of the molecular structure of **6** is depicted in Figure 3, relevant geometrical data can be found in Table 3. Complex **6** features a typical sandwich-type structure with an almost planar phospholyl ring parallel to the Cp* ring. The distances between the Fe atom and the phospholyl centroid Ct1 (1.668 Å) and the Cp* centroid Ct2 (1.690 Å), respectively, are very similar. As is usually observed in phosphametallocene complexes, the C1–P1–C4 angle (91.4°) is close to 90°, the mean P–C distances are 1.790 Å and the C–C bonds in the phospholyl ring are very similar. The steric bulk of the $SiMe_3$ groups becomes apparent from the angles Fe–Ct1–Si (95.7°, 96.8°), which exceed the ideal value of 90°, while the deviation for the β-Me groups is significantly smaller (90.9°, 91.1°). In conclusion, the structural parameters of the parent compound differ only very slightly from those observed for the related phosphaferrocene and ruthenocene ([Cp*M{(2,5-$t$Bu$_2$)$C_4H_2P$}], M = Fe,[20] Ru[21]) with $t$Bu groups in place of the $Me_3Si$ groups. A closely related molecule with alkynyldimethylsilyl substituents was obtained by Mathey et al. via [CpFe($\eta^6$-$C_9H_{12}$)][$PF_6$].[18]

groups for other functional groups, although the small polarity of the C–Si bond limits the reaction bandwidth.[22] For example, the conversion of an *i*$Pr_3$Si group attached to a phosphametallocene into a trifluoroacetyl group has recently been reported[23] and the bis(trifluoroacetyl) derivative derived from **6** would be of high synthetic value. However, upon treatment of complex **6** with trifluoroacetic anhydride and $BF_3$·$OEt_2$ only one TMS group is substituted, the other one is protodesilylated by the acid formed during the reaction.

An even simpler approach to 2,5-difunctionalized phosphaferrocenes with substituents suitable for further transformation might involve the preparation of 2,5-diacyl- or dicarboxylic ester derivatives. Although the syntheses of the appropriate phospholide anions with two acyl or ester groups have been elaborated by Mathey et al.,[24] we were unsuccessful in transforming these functional phospholide anions into the respective Fe or Ru sandwich complexes.

### *2,5-Bis(trimethylsilyl)-3,4-dimethylphospharuthenocene (7)*

Phospharuthenocenes are much less investigated than phosphaferrocenes. The first example, [Cp*Ru{(2,5-*t*$Bu_2$)-$C_4$P}], was prepared by Carmichael et al. in 1994[21] and some mixed Ru/Fe tripledecker[25] complexes were reported later. Meanwhile, a couple of additional derivatives with bulky groups in 2,5-positions like naphthyl,[26] triisoproplylsilyl,[23] cyclohexyl or menthyl[27] could be prepared as well. To prevent $\eta^1$-P-coordination in the complexation reaction, the phosphole has to bear either bulky substituents at the α-position or, as was found out later, an electron-withdrawing group.[28] Once the phosphole is coordinated to ruthenium, the α-substituents can be transformed into other sterically less demanding functional groups. Treatment of anion **5** with $[Cp^*RuCl]_4$ afforded the new 2,5-bis(trimethylsilyl)ruthenocene (**7**) (Scheme 4) as a brown solid after chromatographic workup. Interestingly, the $^{31}$P resonance of complex **7** ($\delta$ = 0.95 ppm) is drastically shifted to lower field as compared to the 2,5-*t*$Bu_2$ analogue ($\delta$ = –63.0 ppm).[21]

In analogy to **6** the reactivity of **7** towards electrophilic desilylation was tested in a trifluoroacylation reaction. However, the only product isolated from this reaction was the protodesilylated complex, as was evident from the appearance of a doublet in the $^1$H NMR spectrum due to the α protons.

### *2,2′,5,5′-Tetrakis(trimethylsilyl)-3,3′,4,4′-tetramethyl-1,1′-diphosphaferrocene (8)*

This compound has been synthesized before, but was only poorly characterized.[19] We found that treatment of anion **5** with anhydrous $FeCl_2$ in THF at low temperature provides ready access to complex **8**, which was completely characterized by NMR and mass spectroscopy, elemental analysis and X-ray diffraction. An ORTEP view of the molecular structure is given in Figure 4 and selected geometrical data are given in Table 3. The compound crystallizes in the orthorhombic space group *Pnna* with the Fe atom sitting on a crystallographic twofold axis ($Z$ = 4). Bond lengths and angles are within the range of values usually observed for 1,1′-diphosphaferrocenes in general and compare well in particular with the closely related molecules [{2,5-($SiMe_2CCMe$)$_2$-3,4-$Me_2$-$C_4P$}$_2$Fe] (**A**)[18] and [{2,5-$Cy_2$-$C_4H_2P$}$_2$Fe] (**B**).[27] Again, as observed for compound **6**, the deviation of the Fe–Ct–Si angles from 90° (95.0 and 97.6°) is more pronounced than that for the β-Me groups (91.1 and 91.5°), reflecting the increased steric bulk of the silyl groups. The most interesting feature of the structure is the conformation of the two phospholyl rings with a P–Ct–Ct′–P′ torsion angle of $\alpha$ = 85.4°, which means that the P atom of one ring is roughly eclipsing the α-C atom of the other (P/$C_\alpha$-conformation). Several conformations are conceivable for 1,1′-diphosphaferrocenes:[29] the limiting high-symmetry conformations $C_{2v}$ and $C_{2h}$, with the P atoms in a *syn* ($\alpha$ = 0°) or *anti* ($\alpha$ = 180°) arrangement, respectively, and two $C_2$-symmetric conformations in which the P atoms are superposed either with the α carbon (P/$C_\alpha$, $\alpha$ = 90–100°) or with the β carbon of the other ring (P/$C_\beta$, $\alpha$ = 140–145°). Indeed, examples for all of these conformations have been observed in the solid state and the question of which conformation is preferred has been addressed on various levels of theory. Both extended Hückel[30] and Fenske–Hall[31] calculations indicated that the $C_{2h}$-symmetric conformation has the highest relative energy for the unsubstituted derivative, lying some 10 kcal/mol above a $C_2$-symmetric arrangement with $\alpha > 100°$. However, for substituted derivatives the substitution pattern may also influence the relative stability of conformers by the avoidance of sterically unfavourable interactions of the substituents. For example, for the 3,3′,4,4′-tetramethyl derivative the P/$C_\beta$ conformation is found in the solid state in accordance with theory,[11] minimizing the steric interference of the Me groups. For 2,2′,5,5′-tetraphenyl-1,1′-diphosphaferrocene, however, an exceptional P,P-*syn* conformation is found ($\alpha$ = 0°), which is stabilized presumably by additional π–π interactions between the two pairs of parallel phenyl rings.[29] This contradicts nicely with the structure of the 2,2′,5,5′-tetracyclohexyl derivative, for which a P,P-*anti* arrangement has been identified.[27] However, this conformation seems to be the exception rather than the rule, because many other 1,1′-diphosphaferrocenes with sterically demanding groups in the 2,5 positions show the P/$C_\alpha$ conformation as observed for complex **8**. Examples include the alkynylsilyl derivative **A**,[18] the 2,5-*t*$Bu_2$-diphosphametallocenes with Sn and Pb,[32] the Sb analogue of **8**[17b] and the parent 1,1′,3,3′-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tetrakis(trimethylsilyl)ferrocene.[33] DFT calculations on a B3LYP level were performed for complex **8** and exhibited a P/$C_\alpha$ minimum energy conformation with a torsion angle of $\alpha \approx 86°$. The highest relative energy (11.6 kcal/mol) was identified for the $C_{2v}$ symmetric conformation ($\alpha = 0°$).

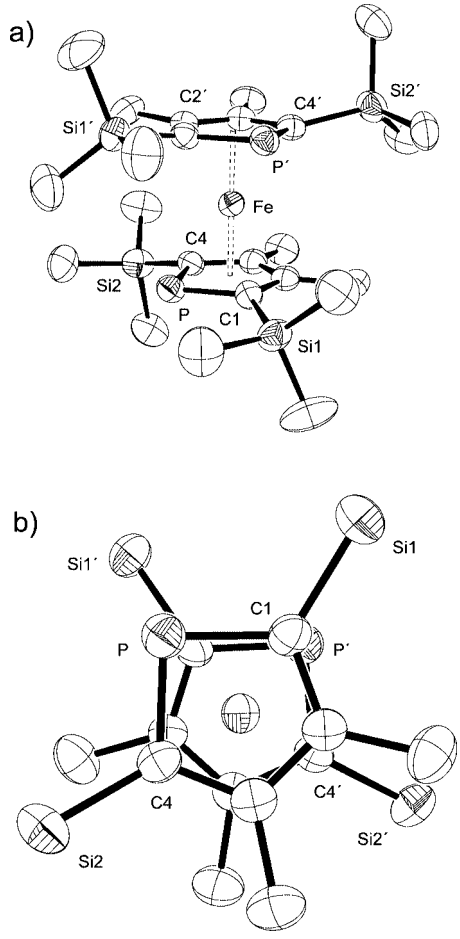

Figure 4. Two views of the molecular structure of complex **8**.

*Solution Dynamics of **8***

The proton NMR spectrum of **8** at room temperature shows two singlets corresponding to the methyl and to the TMS groups in a ratio 6:18. Obviously, ring rotation at ambient temperature is fast on the NMR time-scale. On cooling a sample in [$D_8$]toluene coalescence was observed (500 MHz) at ca. –5 °C for the $SiMe_3$ signals ($\Delta\nu = 125$ Hz) and at –20 °C for the β-Me signals ($\Delta\nu = 34$ Hz). At –50 °C the signals were clearly separated. The value of $12.6 \pm 0.3$ kcal/mol for the rotational barrier calculated from these data is in agreement with the value determined by Al-Taweel[19] and lies well within the range of 10–14 kcal/mol observed for other ferrocenes and diphosphaferrocenes with bulky substituents (Table 4) and fits nicely with the value obtained from the DFT calculations of 11.6 kcal/mol. No substantial differences between ferrocenes and diphosphaferrocenes are recognizable.

Table 4. Activation barriers ($\Delta G^{\ddagger}$) for ring rotation in 1,1′-diphosphaferrocenes and ferrocenes with bulky substituents.

Treatment of **8** with DMSO/KOtBu[34] in order to examine the reactivity of the complex towards desilylation resulted in decomposition of the starting material and no product could be isolated.

## Experimental Section

**DFT Calculations:** In order to determine the rotational barrier B3LYP[35] single point energies with Ahlrichs TZVP basis set[36] on top of BP86[37] geometries, optimized with a SVP basis set[38] have been carried out, as implemented in the program package Turbomole.[39] For the BP86 calculations the resolution of the identity (RI) approach has been used to fit the density within the Coulomb potential with an auxiliary basis set.[40] The phosphaferrocene backbone has been kept frozen at different torsional orientations of the two rings whereas the remainder of the molecule has been relaxed to its equilibrium geometry. The minimum structure has been characterized by calculating the Hessian matrix.

Reactions were carried out under an atmosphere of dry nitrogen by means of conventional Schlenk techniques. Solvents were dried and purified by standard methods. Alumina was heated at 220 °C for 12 h, cooled to room temp. under high vacuum, deactivated with 5% water and stored under nitrogen. NMR spectra were recorded with a Bruker Avance DRX 500 ($^1$H NMR, 500 MHz; $^{31}$P{$^1$H} NMR, 202 MHz; $^{13}$C{$^1$H} NMR, 126 MHz) and a Bruker Avance DRX 200 spectrometer ($^1$H NMR, 200 MHz; $^{31}$P{$^1$H} NMR, 81 MHz). $^1$H NMR spectra are referenced to the residual solvent signal and $^{31}$P NMR spectra to external $H_3PO_4$ (85%). Mass spectra were recorded with a Varian MAT 311A spectrometer (EI, 70 eV electron energy). 2,5-Bis(trimethylsilyl)-3,4-dimethyl-1,1-bis(cyclopentadienyl)zirconacyclopentadiene,[17] **4**,[18] [Cp*FeCl]$_n$,[2g] 2-Hydroxymethyl-3,4-dimethyl-1-phosphaferrocene[11] and [Cp*RuCl]$_4$[41] were prepared according to the literature.

**Synthesis of 2:** A suspension of NaH (60 wt.-% in mineral oil, 0.21 g, 5.25 mmol) in THF was added dropwise to a mixture of 2-hydroxymethyl-3,4-dimethyl-1-phosphaferrocene (1.01 g, 3.86 mmol) and methyliodide (2.4 mL, 38.6 mmol) in THF at –55 °C. The mixture was slowly warmed to room temp. while stirring overnight and was subsequently heated to reflux for 30 min. After cooling to room temp. water (10 mL) was added and the product was extracted with dichloromethane. The organic phase was dried with $Na_2SO_4$, filtered and the solvent was removed under high vacuum. Column chromatography on alumina (hexane/ether, 5:1) gave pure

**2** as an orange oil (1.003 g, 95%). $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 2.215, 2.222 (s, 6 H, 3,4-$CH_3$), 3.35 (s, 3 H, O-$CH_3$), 3.78 (d, $^2J_{CP}$ = 35.89 Hz, 1 H, α-H), 4.12 (s, 5 H, Cp), 3.86–4.24 (m, 2 H, $CH_2$) ppm. $^{13}$C NMR (126 MHz, $CDCl_3$): $\delta$ = 13.48 and 16.86 (s, 3,4-$CH_3$), 57.78 (s, $OCH_3$), 71.02 (d, $^2J_{CP}$ = 21.80 Hz, $CH_2$), 71.85 (s, Cp), 76.92 (d, $^1J_{CP}$ = 58.13 Hz, α-CH), 92.69 (d, $^1J_{CP}$ = 55.71 Hz, α-C), 94.20 (d, $^2J_{CP}$ = 4.84 Hz, β-C), 96.75 (d, $^2J_{CP}$ = 7.26 Hz, β-C) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $CDCl_3$): $\delta$ = –73.24 (s) ppm. $C_{13}H_{17}FePO$ (276.10), EI-MS: *m*/*z* = 276 ($M^+$), 246 ($M^+$ – 2 $CH_3$), 231 ($M^+$ – $CH_2OMe$). Calcd. C 56.55, H 6.21; found C 56.57, H 6.30.

**Synthesis of 3:** Triethylamine (328 μL, 2.36 mmol) was added to a solution of 2-hydroxymethyl-3,4-dimethyl-1-phosphaferrocene (620 mg, 2.36 mmol) in THF (20 mL) at room temp. Dichlorodimethylsilane (143 μL, 1.18 mmol) was added slowly via syringe and the mixture was refluxed for 3 h. After cooling to room temp. water was added and the product extracted with diethyl ether and dried with $Na_2SO_4$. Filtration and removal of the solvent under high vacuum gave the *rac*/*meso* mixture of **3** in a 2:1 ratio as an analytically pure orange oil (411 mg, 0,71 mmol, 60%). Cooling an ether solution gave the pure *rac* isomer as orange crystals suitable for X-ray diffraction. $^1$H NMR (200 MHz, $CDCl_3$); *rac*/*meso* mixture: $\delta$ = 0.115 (s, 3 H, $SiCH_3$), 0.122 (s, 3 H, $SiCH_3$), 2.173, 2.183, 2.193, 2.205 (4s, 12 H, $CCH_3$), 3.75 (d(br), $^1J_{HP}$ = 35.89 Hz, 2 H, α-H), 4.114, 4.121 (2s, 10 H, Cp), 4.155–4.365 (m, 4 H, $CH_2$-O) ppm; *rac* isomer: $\delta$ = 0.121 (s, 6 H, $SiCH_3$), 2.173 (s, 6 H, $CCH_3$), 2.184 (s, 6 H, $CCH_3$), 3.75 (d, 2 H, α-H, $^2J_{HP}$ = 35.89 Hz), 4.120 (s, 10 H, Cp), 4.26 (m, 4 H, $CH_2$-O) ppm. $^{13}$C NMR (125 MHz, $CDCl_3$); *rac*/*meso* mixture: $\delta$ = –2.53 (br. s, $SiCH_3$), –0.597 (br. s, $SiCH_3$), 13.54 (s, $CH_3$), 16.92 (s, $CH_3$), 61.18 (d, $^2J_{CP}$ = 24.2 Hz, $CH_2$), 71.81 (s, Cp), 71.83 (s, Cp), 76.70 (d, $^1J_{CP}$ = 58.1 Hz, α-CH), 76.58 (d, $^1J_{CP}$ = 58.1 Hz, α-CH) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$, 81 MHz): $\delta$ = –74.18 (*rac*); –74.34 (*meso*) ppm. EI-MS (80 eV, 150 °C), *m*/*z* = 580 ($M^+$), 515 ($M^+$ – Cp), 262 (PFc – $CH_2O^+$), 245 ($PFcCH_2^+$), 179 ($PFcCH_2^+$-Cp), 124 (179 – Fe). $C_{26}H_{34}Fe_2O_2P_2Si$ (580.28): calcd. C 53.82, H 5.91; found C 53.00, H 5.83. The too small value for C is probably due to the formation of some SiC, which is rather frequently encountered.

**Synthesis of [(*rac*-3)·Mo(CO)$_4$]:** A solution of [(nbd)Mo(CO)$_4$] (65 mg, 0.217 mmol) in THF was added to a solution of *rac*-**3** (126 mg, 0.217 mmol) in THF, the mixture was stirred at room temp. for 30 min and subsequently refluxed for two hours. The solvent was removed under high vacuum and the residue was recrystallized from ether. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 0.06 (s, 6 H, $SiCH_3$), 2.20, 2.21 (s, 6 H, $CH_3$), 3.84 (d, 2 H, $^2J_{HP}$ = 32.12 Hz, α-H), 4.21 (s, 10 H, Cp), 4.19 (m, 4 H, $CH_2$) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $CDCl_3$): –22,74 (s) ppm. IR ($CDCl_3$): 2029 (mst), 1935 (st), shoulders at 1920 and 1900 cm$^{-1}$. $C_{30}H_{34}Fe_2MoO_6P_2Si$ (788.20): calcd. C 45.71, H 4.35; found C 45.49, H 4.50.

**Synthesis of 6:** Freshly cut lithium pieces (excess) were added to a solution of bromophosphole (**4**) (400 mg, 1.19 mmol) in THF at room temp. After complete conversion of the phosphole to the phospholide anion (monitored by $^{31}$P NMR, **5**: 141 ppm, ca. 3 h) the solution was transferred by cannula to a freshly prepared solution of $[Cp^*FeCl]_n$ at 0 °C and the mixture was stirred overnight at room temp. and refluxed for 1 h. Water was added and the product was extracted with diethyl ether. The organic phase was dried with $Na_2SO_4$, filtered and the solvent was removed under high vacuum. The crude product was purified by column chromatography over alumina (hexane). Recrystallization from methanol yielded bright red crystals (ca. 290 mg, 55%) contaminated with trace amounts of decamethylferrocene. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 0.20 (d, $^4J_{HP}$ = 0.75 Hz, 18 H, $SiMe_3$), 1.81 (s, 15 H, Cp*), 2.03 (s, 6 H, $CH_3$) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $CDCl_3$): $\delta$ = –8.18 ppm (s). $C_{22}H_{39}FePSi_2$ (446): calcd. C 59.17, H 8.80; found C 58.99, H 8.88. EI-MS: *m*/*z* = 446 ($M^+$), 374 ($M^+$ – TMS + H), 326 (374 – $SiMe_2$).

**Synthesis of 7:** A solution of phospholide (**5**) was prepared as described above from bromophosphole (**4**) (111 mg, 0.33 mmol). $[Cp^*RuCl]_4$ (90 mg, 0.083 mmol) was suspended in THF and added to the phospholide solution at –78 °C. The reaction mixture turned from red to brown and was warmed to room temp. while stirring overnight. The solvent was removed under high vacuum and the crude product was purified by column chromatography over alumina (hexane/ether = 5:1). Compound **7** (120 mg, 36%) was obtained as a brown powder after the removal of the solvent in vacuo. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 0.20 (d, $^4J_{HP}$ = 0.75 Hz, 18 H, $SiMe_3$), 1.87, (s, 15 H, Cp*), 1.93 (s, 6 H, 3,4-$CH_3$) ppm. $^{13}$C NMR (126 MHz, $CDCl_3$): $\delta$ = 1.6 (d, $^3J_{CP}$ = 5.5 Hz, $SiMe_3$), 11.6 (s, Cp*-$CH_3$), 13.8 (d, $^3J_{CP}$ = 1.8 Hz, 3,4-$CH_3$), 87.4 (s, Cp*-C), 88.6 (d, $^1J_{CP}$ = 79.7 Hz, α-C), 100.1 (d, $^2J_{CP}$ = 4.6 Hz, β-C) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $CDCl_3$): $\delta$ = 0.95 (s) ppm. EI-MS ($C_{22}H_{39}PRuSi_2$, 491.77): *m*/*z* = 492 ($M^+$), 477 ($M^+$ – $CH_3$), 419 ($M^+$ – $SiMe_3$). Calcd. C 53.73, H 7.99; found C 54.01, H 8.15.

**Synthesis of 8:** A solution of phospholide (**5**) was prepared as described above from bromophosphole (**4**) (0.51 g, 1.52 mmol). Anhydrous $FeCl_2$ (0.096 g, 0,76 mmol) was added to the phospholide solution at –78 °C. The solution was stirred overnight and warmed to room temp. The solvent was removed under high vacuum and the crude product purified by chromatography over alumina (hexane). Recrystallization from methanol yielded **8** (0.150 g, 35%) as red crystals suitable for X-ray diffraction. $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 0.27 (s, 36 H, $SiMe_3$), 2.08 (s, 12 H, 3,4-$CH_3$) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $CDCl_3$): $\delta$ = –26.13 (s) ppm. $^{13}$C NMR (126 MHz, 298 K, $CDCl_3$): $\delta$ = 1.80, 1.82, 1.84, 1.86 (s, $SiMe_3$), 16.5 (br. s, 3,4-$CH_3$), 103.8 (d, $^2J_{CP}$ = 4.6 Hz, β-C) ppm. EI-MS ($C_{24}H_{48}FeP_2Si_4$, 566.78): *m*/*z* = 566 ($M^+$), 494 ($M^+$ – H – $SiMe_3$) 405 ($M^+$ – H – $SiMe_3$ – $CH_3$). Calcd. C 50.86, H 8.54; found C 51.02, H 8.50.

**X-ray Crystallographic Study:** Crystals of compounds **3**, **3**·Mo(CO)$_4$, **6** and **8** suitable for X-ray studies were investigated with a Stoe IPDS using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 291 K. In the cases of **3**·Mo(CO)$_4$ and **6** a space group type of $P2_1/n$ and in the case of **8** the space group *Pnna* were uniquely determined. In the case of **3** the symmetry of the diffraction pattern was compatible with space group types $P1$ and $P\bar{1}$. The latter proved to be the correct one after structure refinement. Lorentz polarization corrections were applied to all the intensity data. In the case of **3**·Mo(CO)$_4$ and **8** absorption corrections using symmetry equivalent reflections and a face-indexed Gaussian integration procedure, respectively, were applied. The structures were solved by direct methods[42] and the positions of all but the H atoms of the pentamethylcyclopentadienyl group of **6** were found via $\Delta F$ syntheses. Refinements[43] by full-matrix least-squares calculations on $F^2$ converged to the indicators given in Table 5. Anisotropic displacement parameters were refined for all atoms heavier than hydrogen. Idealized bond lengths and angles were used for the $CH_3$, $CH_2$ and CH groups; the riding model was applied for their H atoms. In addition, the H atoms of the $CH_3$ groups were allowed to rotate around the neighbouring C–C bonds. The isotropic displacement parameters of the H atoms were kept equal to 120% of the equivalent isotropic displacement parameters of the parent "aromatic" or secondary carbon atom and equal to 150% of the parent primary carbon atom, respectively. A summary of

# Synthesis of the η²-1-Phosphaallene Complexes [(η⁵-$C_5H_5$)(CO)(NO)W{η²-$R^1P$=C=C($R^2$)H}] ($R^1$ = *t*Bu, Cy; $R^2$ = Ph, H) from [(η⁵-$C_5H_5$)(CO)(NO)-W=C=C($R^2$)H] ($R^2$ = Ph, H) and Inversely Polarized Phosphaalkenes $R^1P$=C($NMe_2$)$_2$ ($R^1$ = *t*Bu, Cy), and Their Structure

**Lothar Weber,*[a] Gabriel Noveski,[a] Thomas Braun,[a] Hans-Georg Stammler,[a] and Beate Neumann[a]**

**Keywords:** Vinylidene complexes / Phosphaallene complexes / Phosphaalkenes / Tungsten

The reaction of the vinylidene complex [(η⁵-$C_5H_5$)(CO)(NO)-W=C=C(H)Ph] (**9**) with the phosphaalkenes RP=C($NMe_2$)$_2$ (**1a**: R = *t*Bu; **1c**: R = *c*-$C_6H_{11}$) affords the novel η²-1-phosphaallene complexes [η²-{RP=C=C(H)Ph}W(CO)(NO)(η⁵-$C_5H_5$)] (**14**: R = *t*Bu; **15**: R = *c*-$C_6H_{11}$) in addition to the carbene complex [(η⁵-$C_5H_5$)(CO)(NO)W=C($NMe_2$)C(Ph)=C(H)-$NMe_2$] (**16**). Similarly, treatment of [(η⁵-$C_5H_5$)(CO)(NO)-W=C=$CH_2$] (**12**) with the phosphaalkenes gives rise to the formation of [η²-{RP=C=$CH_2$}W(CO)(NO)(η⁵-$C_5H_5$)] (**17**: R = *t*Bu; **18**: R = *c*-$C_6H_{11}$). The novel compounds **14**, **15**, **17**, and **18** were characterized by elemental analysis and by spectroscopy (IR, $^1$H, $^{13}$C NMR, MS). Moreover, the molecular structures of **14** and **16** were determined by X-ray diffraction analyses.

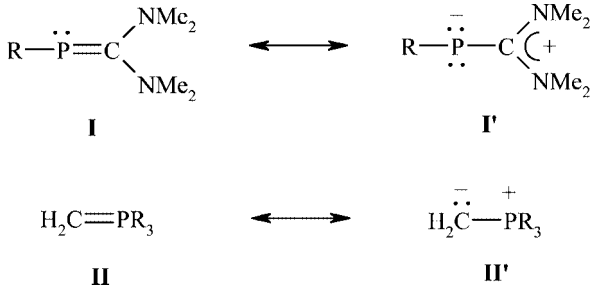
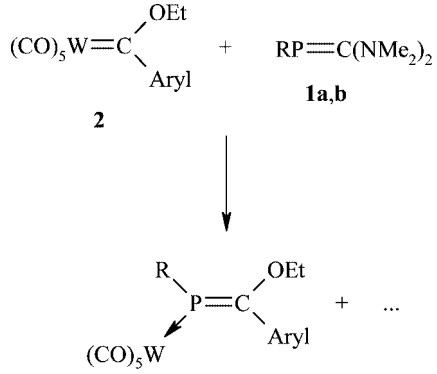
## Introduction

Inversely polarized phosphaalkenes (**I**) with an electron-distribution $P^{\delta-}C^{\delta+}$ about the P=C double bond may be described by two canonical formulae (**I** and **I′**).[1] This situation mirrors the bonding in phosphorus ylides **II** (Scheme 1).[2]



Scheme 1. Mesomeric structures of inversely polarized phosphaalkenes (**I**) and phosphorus ylides (**II**).

The chemical behavior of both classes of compounds (e.g. protonation, alkylation, complexation) can be rationalized by considering the zwitterionic structures **I′** and **II′**. Phosphorus ylides are nucleophilic transfer reagents of alkylidene groups to electrophilic functionalities (e.g. Wittig reaction). The combination of phosphorus ylides and aryl(alkoxy)carbene complexes affords enol ethers.[3] Recently, we discovered that the inversely polarized phosphaalkenes RP=C($NMe_2$)$_2$ [R = *t*Bu (**1a**), $Me_3Si$ (**1b**)] react with aryl(alkoxy)carbene complexes to yield novel phosphaalkene complexes by a formal transfer of the phosphinidene unit to the carbene ligand (Scheme 2).[4]



**3** (R = *t*Bu; Aryl = 2-$MeOC_6H_4$)
**4** ($Me_3Si$; 2-$MeOC_6H_4$)
**5** ($Me_3Si$; 2-$MeC_6H_4$)

Scheme 2. Reaction of Fischer carbene complexes with inversely polarized phosphaalkenes.

We have since described the smooth transfer of phosphinidine units from phosphaalkenes **1a** (R = *t*Bu) and **1c** (R = Cy) to the electrophilic ligand in the phosphavinylidene complexes **6** and **7** to produce the first η³-1,2-diphosphaallyl complexes (Scheme 3).[5] Similar transformations have been effected with inversely polarized arsaalkenes.[6]

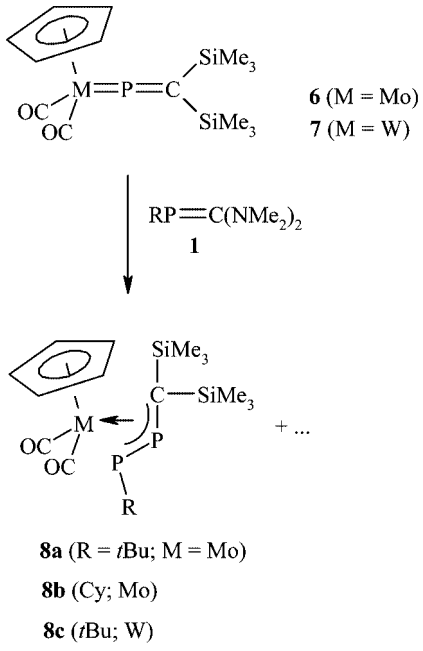
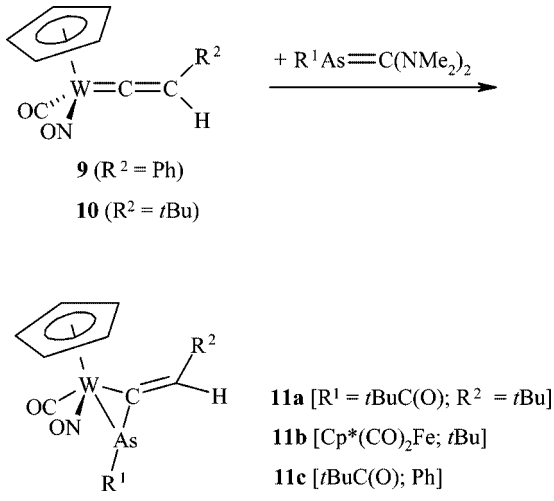


Scheme 3. Formation of 1,2-diphosphaallyl complexes **8a**–**c**.

The obvious next step was to extend our studies on the nucleophilic transfer of phosphinidenes from inversely polarized phosphaalkenes to the electrophilic ligand of vinylidene complexes. This extension seemed particularly promising in light of the previous synthesis of $\eta^2$-1-arsaallene complexes **11a**–**c** from vinylidene complexes **9** and **10** and arsaalkenes (Scheme 4).[7]

Moreover, Ipaktschi et al. have succeeded in the transformation of vinylidene complex **12** into $\eta^2$-allene complexes **13a**–**c** by treating them with diazomethane and ethyl diazoacetate (Scheme 5).[8] In this contribution we present our results on the smooth phosphinidene transfer from phosphaalkenes **1a** and **1c** to the vinylidene ligands of complexes **9** and **12**.

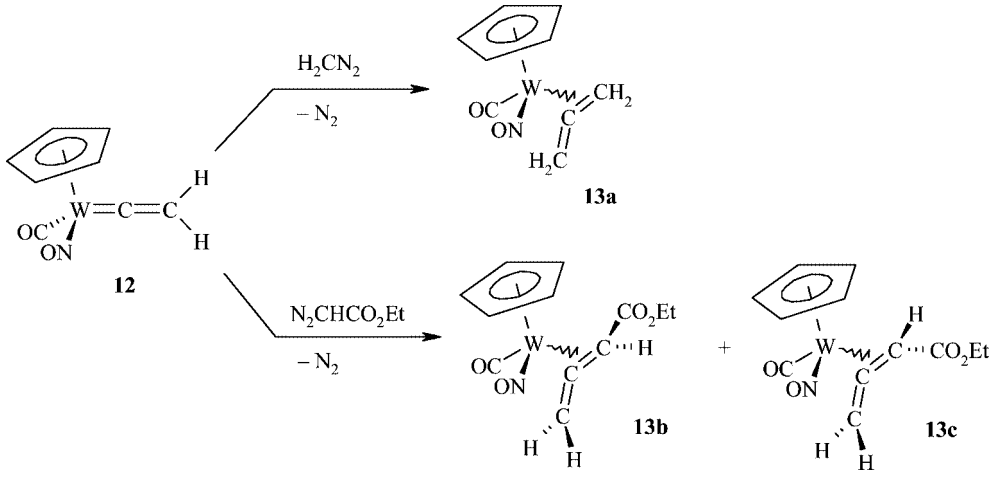


Scheme 4. Synthesis of $\eta^2$-1-arsaallene complexes **11a**–**c**.

## Results and Discussion

Treatment of [Cp(CO)(NO)W=C=C(H)Ph] (**9**)[9] with half a molar equivalent of phosphaalkenes $RP=C(NMe_2)_2$ (**1a**: R = *t*Bu;[4a] **1c**: R = Cy[5]) in tetrahydrofuran (**1a**) or diethyl ether (**1c**) in the range 0 to 20 °C afforded the crystalline $\eta^2$-1-phosphaallene complexes **14** (20% yield) and **15** (19% yield), respectively. Purification of the products was effected by column chromatography on Florisil with hexane as an eluent (Scheme 6).

Red, crystalline carbene complex **16** was formed as a by-product in these reactions. During this process it appears that the nucleophilic carbene $C(NMe_2)_2$ is released and attacks a second equivalent of **9**. In keeping with this, if the precursors are employed in a 1:1 molar ratio half of the phosphaalkene remains unaffected. Carbene complex **16** can be eluted from the column with diethyl ether. However, only impure samples were obtained by this method. In a more efficient protocol, the phosphaallene complex **15** was extracted from the solid, red reaction residue with a diethyl ether/pentane mixture and the remaining orange residue



Scheme 5. Synthesis of $\eta^2$-allene complexes **13a**–**c** from **12** and diazoalkanes.

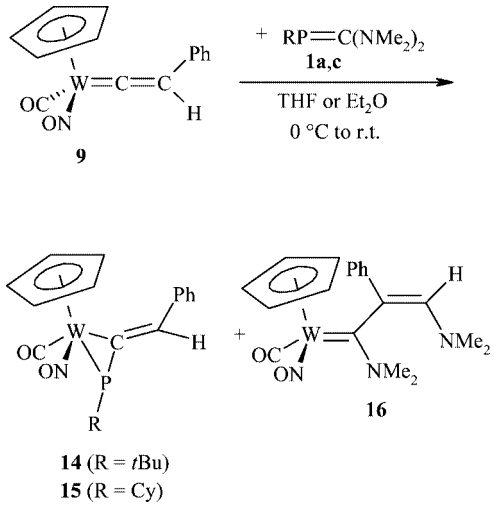
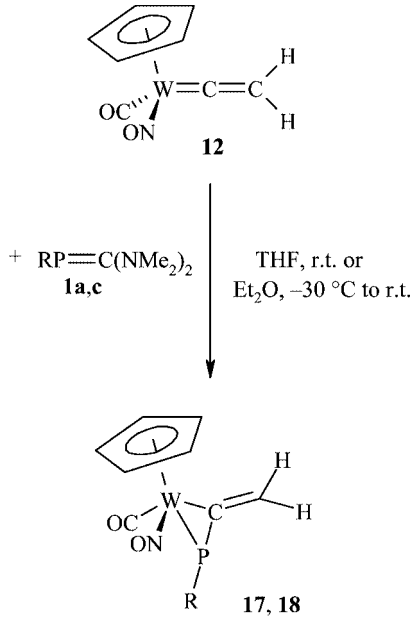


Scheme 6. Formation of the 1-phosphaallene complexes **14** and **15** and carbene complex **16**.

was dissolved in a dichloromethane/pentane mixture (3:1). Storage of the filtered solution at 4 °C afforded red crystalline **16**. The air- and moisture-sensitive complexes **14** and **15** are well soluble in saturated hydrocarbon, ethereal, and aromatic solvents. Complex **16** has been generated previously by the treatment of **9** with $[Cp^*(CO)_2FeAs{=}C(NMe_2)_2]$ in 69% yield,[7] and characterized by means of spectroscopy and elemental analyses. Similarly, yellow crystalline **17** resulted from the reaction of phosphaalkene **1a** and vinylidene complex **12**[10] in a molar ratio of 1:2 in thf at 20 °C (Scheme 7). The synthesis of **18** from **12** and **1c** was accomplished in diethyl ether at –30 °C.



Scheme 7. Preparation of the 1-phosphaallene complexes **17** and **18**.

Doublets at $\delta$ = 8.66 ($^3J_{P,H}$ = 8.2 Hz) and 8.77 ppm ($^3J_{P,H}$ = 8.8 Hz) in the $^1$H NMR spectra of **14** and **15**, respectively, can be assigned to the proton of the exocyclic methylene group. In precursor **9** this proton gives rise to singlets at significantly higher field ($\delta$ = 6.54 and 6.59 ppm; ratio 4:5).[9] In the unsupported phosphaallene Mes*P=C=C(Ph)H a doublet at $\delta$ = 6.67 ($^3J_{P,H}$ = 27 Hz) accounts for this proton.[11] The singlets at $\delta$ = 5.81 and 5.84 ppm (ratio 5:4) for the $C_5H_5$ protons in **9** are markedly deshielded [$\delta$ = 4.76 (**14**), 4.79 ppm (**15**)], which is taken as an indication of the improved donor character of the $\eta^2$-phosphaallene over the vinylidene ligand in **9**. The resonances at $\delta$ = 344.64, 209.2 (210.6), and 130.95 (131.3) ppm in the $^{13}C\{^1H\}$ NMR spectrum of **9** are assigned to $C_\alpha$, the carbonyl ligands, and $C_\beta$ in the two isomers, respectively. The $C_\alpha$ atom in the $\eta^2$-phosphaallene complexes **14** and **15** is strongly shielded [**14**: $\delta$ = 166.5 ppm (d, $^1J_{P,C}$ = 97.7 Hz); **15**: $\delta$ = 167.6 ppm (d, $^1J_{P,C}$ = 94.9 Hz)], whereas the $C_\beta$ atom is slightly deshielded in **14** [$\delta$ = 142.2 ppm (d, $^2J_{P,C}$ = 6.9 Hz)] and **15** [$\delta$ = 142.2 ppm (d, $^2J_{P,C}$ = 7.4 Hz)]. The $C_\alpha$ and $C_\beta$ resonances in free phosphaallene Mes*P=C=C(Ph)H are observed as doublets at $\delta$ = 239.3 (d, $^1J_{P,C}$ = 25 Hz) and $\delta$ = 112.9 (d, $^2J_{P,C}$ = 10 Hz) ppm.[11] The carbonyl ligands in complexes **14** and **15** give rise to doublets at $\delta$ = 218.7 ($^2J_{P,C}$ = 16.1 Hz) and 218.8 ppm ($^2J_{P,C}$ = 17.3 Hz). The shift to high field of about 8 ppm in comparison to **9** [$\delta$(CO) = 209.2 (210.6) ppm] is easily explained by the more pronounced donor capacity of the organophosphorus ligand. Pronounced bathochromic shifts of the CO and NO stretching frequencies of **14** and **15** relative to those of **9** additionally support the NMR findings. In the $^{31}P\{^1H\}$ NMR spectra of **14** and **15** singlet resonances appear at $\delta$ = –130.0 and –158.0 ppm, in the characteristic region for three-membered, phosphorus-containing rings.[12] A similar situation is encountered for the phosphaalkene complexes **17** and **18**. In the $^{31}$P NMR spectra the phosphorus atoms of the three-membered rings give rise to singlets at $\delta$ = –124.0 and –153.6 ppm, respectively. Two doublets at $\delta$ = 6.48 ($^3J_{P,H}$ = 19.5 Hz) and 7.18 ppm ($^3J_{P,H}$ = 6.9 Hz) in the $^1$H NMR spectrum of **17** and at $\delta$ = 6.46 ($^3J_{P,H}$ = 20.7 Hz) and 7.41 ppm ($^3J_{P,H}$ = 6.9 Hz) account for the magnetically different protons of the terminal methylene unit of **18**. Singlets in the $^{13}$C NMR spectrum of the complexes at $\delta$ = 126.0 and 125.9 ppm account for the $^{13}$C nuclei of these groups. The carbon atom $C_\alpha$ is observed as a doublet at $\delta$ = 169.3 ($^1J_{P,C}$ = 94.8 Hz) in **17** and at $\delta$ = 172.5 ppm ($^1J_{P,C}$ = 93.6 Hz) in **18**.

### X-ray Structural Investigations

Single crystals of **14** suitable for X-ray diffraction analysis were grown from hexane at 4 °C. The analysis (Figure 1) shows a molecule with a distorted piano-stool geometry [P(1)–W(1)–C(1) 72.3(1)°, C(1)–W(1)–N(1) 91.3(2)°, N(1)–W(1)–C(2) 91.8(1)°], with nearly linear carbonyl and nitrosyl ligands [W(1)–C(1)–O(1) 178.8(4)°, W(1)–N(1)–O(2) 174.4(3)].

The most interesting part of the molecule is the 1-phosphaallene ligand, which is unsymmetrically linked to the metal atom in an $\eta^2$-fashion by the W(1)–P(1) [2.568(1) Å] and W(1)–C(2) [2.175(4) Å] bonds. The latter bond is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

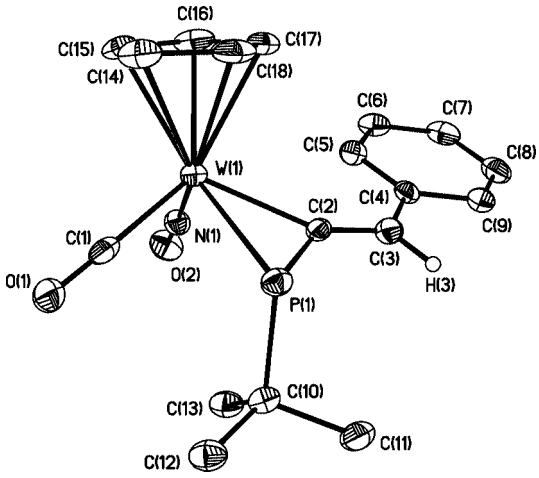


Figure 1. Molecular structure of **14** in the crystal. Selected bond lengths [Å] and angles [°]: W(1)–C(1) 2.007(4), W(1)–N(1) 1.801(3), W(1)–C(2) 2.175(4), W(1)–P(1) 2.568(1), W(1)–C(14–18) 2.335(4) – 2.382(4), P(1)–C(2) 1.742(4), P(1)–C(10) 1.904(4), C(2)–C(3) 1.353(6), C(3)–C(4) 1.468(5); W(1)–C(1)–O(1) 178.8(4), W(1)–N(1)–O(2) 174.4(3), W(1)–C(2)–P(1) 81.1(2), W(1)–C(2)–C(3) 142.2(3), C(2)–W(1)–P(1) 42.1(1), C(2)–W(1)–N(1) 91.8(1), N(1)–W(1)–C(1) 91.3(2), C(1)–W(1)–P(1) 72.3(1), W(1)–P(1)–C(10) 115.1(1), W(1)–P(1)–C(2) 56.8(1), P(1)–C(2)–C(3) 136.7(3), C(10)–P(1)–C(2) 105.3(2).

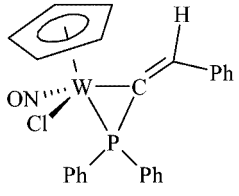
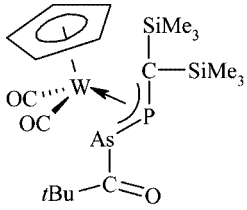
significantly shorter than the W(1)–C distances of the [$C_5H_5W$] part of the molecule [2.335(4)–2.382(4) Å]. The W(1)–C(2) bond length is comparable to that in complex **19** [2.178(7) Å],[13] but much smaller than in the ($\eta^3$-2-phospha-1-arsaallyl)tungsten complex **20** [2.439(2) Å].[6]



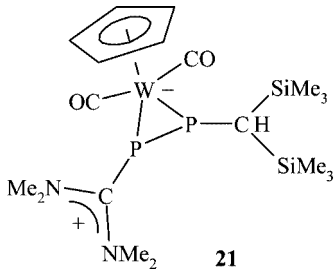
**19**



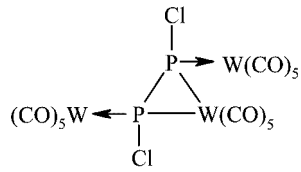
**20**

Thus, the situation of a π complex involving the W atom and the P=C double bond is not reflected satisfactorily by the structural data of **14**. Moreover, inspection of the W=C bond lengths in a series of carbene–tungsten complexes [1.859(4)–2.23(2) Å][14] reveals some degree of WC multiple bonding in our new complex. A similar observation was made in the molecular structure of **11b**.[7] The W(1)–P(1) separation [2.568(1) Å] markedly exceeds the WP bond length in **19** [2.434(2) Å] and may be compared with the endocyclic WP bond lengths in complexes **21** [2.5352(7) and 2.5695(7) Å][5] or **22** [2.573(4) and 2.582(4) Å].[15]

The endocyclic P(1)–C(2) bond length [1.742(4) Å] may be regarded as being a π-coordinated multiple bond. Generally, unsupported P=C bonds in acyclic phosphaalkenes range from 1.65–1.72 Å,[16] and a value of 1.63 Å has been reported for the P=C distance in the 1-phosphaallene Mes*P=C=$CPh_2$.[17] The carbon-carbon double bond C(2)–C(3) [1.353(6) Å] is lengthened with respect to that in Mes*P=C=$CPh_2$ (1.31 Å),[17] and the P(1)–C(2)–C(3) angle



**21**



**22**

of 136.7(3)° is strongly compressed when compared with that in the free 1-phosphaallene (167°). Carbon atoms C(3) and C(4) are located in the plane defined by the atoms W(1), P(1), and C(2), and atom P(1) is roughly placed in a *trans* disposition to the nitrosyl ligand whereas C(2) and the carbonyl group are *trans* oriented.

Wine-red, single crystals of carbene complex **16** were grown by slow diffusion of pentane into a $CH_2Cl_2$ solution during a period of seven days. The analysis (Figure 2) reveals a molecule with a distorted, three-legged piano-stool geometry [N(1)–W(1)–C(6) 91.6(1)°, N(1)–W(1)–C(7) 101.1(1)°, C(6)–W(1)–C(7) 80.7(1)°] with nearly linear carbonyl and nitrosyl ligands [W(1)–C(6)–O(2) 176.5(2)°, W(1)–N(1)–O(1) 173.7(2)°]

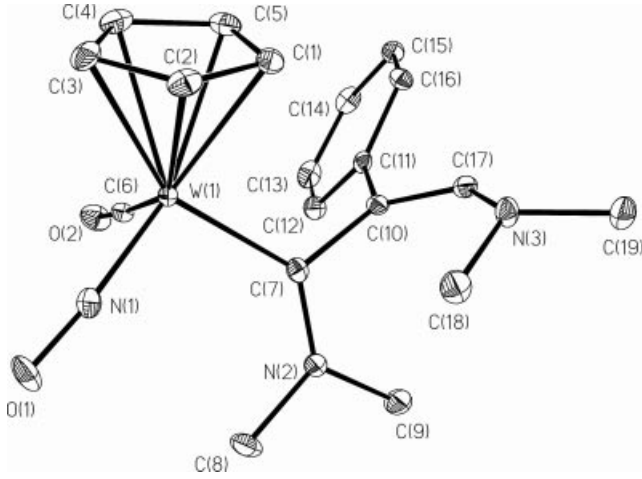


Figure 2. Molecular structure of **16** in the crystal. Selected bond lengths [Å] and angles [°]: W(1)–N(1) 1.802(2), W(1)–C(6) 1.979(2), W(1)–C(7) 2.126(2), W(1)–C(1–5) 2.373(2) – 2.407(2), N(2)–C(7) 1.339(3), N(2)–C(8) 1.478(3), N(2)–C(9) 1.481(3), C(7)–C(10) 1.516(3), C(10)–C(11) 1.491(3), C(10)–C(17) 1.369(3), N(3)–C(17) 1.383(3), N(3)–C(18) 1.437(3), N(3)–C(19) 1.467(3); N(1)–W(1)–C(6) 91.6(1), N(1)–W(1)–C(7) 101.1(1), C(6)–W(1)–C(7) 86.7(1), W(1)–C(7)–N(2) 130.4(2), W(1)–C(7)–C(10) 115.6(1), N(2)–C(7)–C(10) 114.0(2), C(7)–C(10)–C(17) 124.3(1), C(7)–C(10)–C(11) 117.8(2), C(11)–C(10)–C(17) 117.8(2), C(10)–C(17)–N(3) 132.3(2), C(17)–N(3)–C(18) 123.0(2), C(17)–N(3)–C(19) 116.5(2), C(18)–N(3)–C(19) 113.6(2).

The third leg is a dimethylamino vinylcarbene ligand which is attached to the metal by the W(1)–C(7) double bond [2.126(2) Å]. The plane defined by the atoms C(7), C(8), C(9), C(10), and N(2) is nearly coplanar with the vector W(1)–N(1) (torsion angle 7.5°). The contact N(2)–C(7) of 1.339(3) Å represents multiple bonding. An accepted average value for a $C_{sp^2}$–$N_{sp^2}$ single bond amounts to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.41 Å.[18] Within the β-aminoalkenyl substituents the C(7)–C(17) bond [1.516(3) Å] has a bond order of unity. The C(10)–C(17) double bond of 1.369(3) Å is lengthened by conjugation with the lone pair at the slightly pyramidalized N(3) atom (sum of angles: 353.1°). As a consequence, the N(3)–C(17) distance [1.383(3) Å] is a shortened single bond. The plane defined by the atoms N(3), C(17), C(10), C(11), and C(7) is oriented nearly orthogonally to the plane of the carbene moiety.

## Conclusions

The previously observed transition-metal-induced cleavage of inversely polarized phosphaalkenes to give $\eta^3$-1,2-diphosphaallyl complexes[5] has been extended to the smooth generation of $\eta^2$-1-phosphaallene complexes **14**, **15**, **17**, and **18**. This reaction underlines the ability of phosphaalkenes to act as convenient sources for phosphanediyl (phosphinidene) units under mild conditions.

## Experimental Section

**General:** All experiments were performed under dry, oxygen-free dinitrogen using standard Schlenk techniques. Solvents were carefully dried with the appropriate drying agent and freshly distilled under $N_2$ before use. The following compounds were prepared according to literature procedures: [Cp(CO)(NO)W=C=C(H)Ph] (**9**),[9] [Cp(CO)(NO)W=C=$CH_2$] (**12**),[10] *t*BuP=C($NMe_2$)$_2$ (**1a**),[4a] CyP=C($NMe_2$)$_2$ (**1c**).[5] IR spectra were recorded with a Bruker FT-IR VECTOR 22 spectrometer. $^1$H, $^{13}$C, and $^{31}$P NMR spectra were recorded at room temperature with a Bruker AM Avance DRX 500 instrument ($^1$H: 500.13, $^{13}$C: 125.75, $^{31}$P: 202.46 MHz). References: $SiMe_4$ ($^1$H, $^{13}$C) and 85% $H_3PO_4$ ($^{31}$P). MS: Bruker Esquire Ion Trap mass spectrometer. Florisil was purchased from Merck.

**[Cp(CO)(NO)W{$\eta^2$-*t*BuP=C=CHPh}] (14):** A solution of phosphaalkene **1a** (0.16 g, 0.83 mmol) in thf was added dropwise at 0 °C to a well stirred solution of complex **9** (0.61 g, 1.5 mmol) in thf (15 mL). Stirring was continued at 0 °C for 1 h. The solution was then warmed up to ambient temp. and stirred for another 2.5 h at room temp. The solvents were removed in vacuo to afford a red solid residue. The latter was suspended in hexane (150 mL) and filtered through a pad of Florisil (*l* = 1.5 cm, *d* = 2 cm). A yellow zone was eluted with hexane (4 × 30 mL). Concentration of the elute to about 15 mL and storage at 4 °C for 14 h led to the separation of product **14** as big yellow crystals. (Yield: 0.15 g, 20%). IR (KBr): $\tilde{\nu}$ = 1972 s (CO), 1630 s (NO) cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 1.29 (d, $^3J_{P,H}$ = 13.2 Hz, 9 H, *t*Bu), 4.76 (s, 5 H, Cp), 7.12 (t, $^3J_{H,H}$ = 7.5 Hz, 1 H, *p*-H-Ph), 7.26 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, *m*-H-Ph), 7.70 (d, $J_{H,H}$ = 6.9 Hz, 2 H, *o*-H-Ph), 8.66 [d, $^3J_{P,H}$ = 8.2 Hz, 1 H, =C(*H*)Ph] ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$): $\delta$ = 30.4 [d, $^2J_{P,C}$ = 16.1 Hz, C(*C*H$_3$)$_3$], 35.5 [d, $^1J_{P,C}$ = 47.1 Hz, *C*(CH$_3$)$_3$], 96.7 (s, $C_5H_5$), 127.3 (s, Ph), 128.1 (s, Ph), 128.5 (s, Ph), 139.9 (d, $^3J$ = 5.7 Hz, *i*-C-Ph), 142.2 (d, $^2J_{P,C}$ = 6.9 Hz, P–C=*C*), 166.5 (d, $^2J_{P,C}$ = 97.7 Hz, P=*C*), 218.7 (d, $^2J_{P,C}$ = 16.1 Hz, CO) ppm. $^{31}$P{$^1$H} NMR $\delta$ = –130.0 ppm. EI-MS: *m*/*z* 498 [M + H$^+$]. $C_{18}H_{20}NO_2PW$ (497.17): calcd. C 43.49, H 4.05, N 2.82; found C 43.51, H 4.14, N 2.86.

Compound **16** with low purity may be extracted from the column with neat diethyl ether. The preparation of analytically pure **16** in an acceptable yield requires a slightly modified protocol. Thus, a solution of **1a** (0.33 g, 1.75 mmol) in thf (15 mL) was added dropwise to chilled solution of complex **9** (1.45 g, 3.54 mmol) in thf (15 mL). After stirring the reaction mixture for 2.5 h at room temp., solvents and other volatile components were removed in vacuo. The red solid residue was triturated with 32 mL of a diethyl ether/pentane mixture, and then the liquid phase was decanted. The solid was washed with pentane (6 × 10 mL) and dried at $10^{-6}$ bar. The orange solid was dissolved in a dichloromethane/pentane mixture (3:1), filtered, and the filtrate was stored at +4 °C. Carbene complex **16** separated as red crystals (0.65 g, 36% yield). The spectroscopic data were identical with a sample obtained previously by another method.

**[Cp(CO)(NO)W{$\eta^2$-CyP=C=CHPh}] (15):** A solution of phosphaalkene **1c** (0.24 g, 1.12 mmol) in diethyl ether (30 mL) was slowly added to a chilled solution (0 °C) of complex **9** (0.83 g, 2.03 mmol) in diethyl ether (30 mL). Stirring at 0 °C was continued for 2.5 h before the mixture was warmed to room temp. It was then evaporated to dryness and the orange-red solid residue was suspended in hexane (125 mL). It was filtered through a pad of Florisil (*l* = 1.5 cm, *d* = 2 cm). A yellow zone was eluted with hexane (4 × 30 mL). The elute was concentrated to about 15 mL and stored for 12 h at 4 °C to afford 0.20 g (19%) of orange-yellow crystalline **15**. IR (KBr): $\tilde{\nu}$ = 1990 s (CO), 1625 s (NO) cm$^{-1}$. $^1$H NMR ($C_6D_6$): $\delta$ = 0.88–2.29 (br., 11 H, $C_6H_{11}$), 4.79 (s, 5 H, Cp), 7.11 (t, $^3J_{H,H}$ = 7.2 Hz, 1 H, *p*-H-Ph), 7.24 (t, $^3J_{H,H}$ = 7.5 Hz, 2 H, *m*-H-Ph), 7.71 (d, $^3J_{H,H}$ = 7.5 Hz, 2 H, *o*-H-Ph), 8.77 [d, $^3J_{P,H}$ = 8.8 Hz, =C(*H*)Ph] ppm. $^{13}$C{$^1$H} NMR ($C_6D_6$): $\delta$ = 96.7 (s, $C_5H_5$), 127.3 (s, Ph), 128.1 (s, Ph), 128.5 (s, Ph), 140.1 (d, $^3J_{P,C}$ = 6.2 Hz, *i*-C-Ph), 142.2 (d, $^3J_{P,C}$ = 7.4 Hz, P=C=*C*), 167.6 (d, $^1J_{P,C}$ = 94.9 Hz, P=C), 218.8 (d, $^2J_{P,C}$ = 17.3 Hz, CO) ppm. $^{31}$P{$^1$H} NMR $\delta$ = –158.0 (s) ppm. EI-MS: *m*/*z* 524.2 [M + H$^+$], 496.2 [M – CO + H$^+$]. $C_{20}H_{22}NO_2PW$ (523.21): calcd. C 45.91, H 4.24, N 2.68; found C 46.04, H 4.27, N 2.67.

**[Cp(CO)(NO)W{$\eta^2$-*t*BuP=C=$CH_2$}] (17):** A solution of phosphaalkene **1a** (0.11 g, 0.58 mmol) in thf (5 mL) was added dropwise at ambient temp. to a solution of complex **12** (0.37 g, 1.11 mmol) in thf (10 mL). Stirring was continued for 2.5 h before the reaction mixture was evaporated to dryness. The yellow solid residue was chromatographed on a small column charged with Florisil (*l* = 4 cm, *d* = 2 cm). A yellow zone was eluted with hexane/diethyl ether (30:2). The elute was concentrated to 15 mL and stored at 4 °C for 18 h to give **17** as yellow crystals (0.14 g, 30% yield). IR (KBr): $\tilde{\nu}$ = 1979 s (CO), 1618 s (NO) cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 1.11 (d, $^3J_{P,H}$ = 13.2 Hz, 9 H, *t*Bu), 5.63 (s, 5 H, Cp), 6.48 (d, $^3J_{P,H}$ = 19.5 Hz, 1 H, =$CH_2$), 7.18 (d, $^3J_{P,H}$ = 6.9 Hz, 1 H, =$CH_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 30.2 [d, $^2J_{P,C}$ = 16.2 Hz, C(*C*H$_3$)$_3$], 34.4 [d, $^1J_{P,C}$ = 42.8 Hz, *C*(CH$_3$)$_3$], 96.8 (s, Cp), 126.0 (s, P=C=*C*), 169.3 (d, $^1J_{P,C}$ = 94.8 Hz, P=*C*=C), 217.3 (d, $^2J_{P,C}$ = 12.7 Hz, CO) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = –124.0 ppm. EI-MS: *m*/*z* 422.1 [M + H$^+$]. $C_{12}H_{16}NO_2PW$ (421.08): calcd. C 34.23, H 3.83, N 3.33; found C 33.51, H 3.87, N 3.30.

**[Cp(CO)(NO)W{$\eta^2$-CyP=C=$CH_2$}] (18):** A solution of phosphaalkene **1c** (0.22 g, 1.04 mmol) in diethyl ether (25 mL) was added dropwise to a chilled solution (–30 °C) of complex **12** (0.62 g, 1.86 mmol) in diethyl ether (30 mL). Stirring was continued at –30 °C for 1 h, and then at room temp. for another 2.5 h. The mixture was evaporated to dryness. The red solid residue was suspended in pentane (150 mL) and filtered through a pad of Florisil (*l* = 1.5 cm, *d* = 2 cm). A yellow zone was eluted with a diethyl ether/pentane mixture (1:3). The elute was concentrated to 20 mL and stored at 4 °C for 14 h, whereby product **18** separated as yellow crystals (0.10 g, 12%). IR (KBr): $\tilde{\nu}$ = 1973 s (CO), 1618 s (NO)

**X-ray Crystallography:**[19] Crystallographic data were collected with a Nonius KappaCCD diffractometer with Mo-$K_\alpha$ radiation (graphite monochromator, $\lambda$ = 0.71073 Å) at 100 K. The crystallographic programs used for structure solution and refinement were SHELXS-97 and SHELXL-97. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ of all unique reflections with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were included at calculated positions with $U$(H) = 1.2 $U_{eq}$ for $CH_2$ groups and $U$(H) = 1.5 $U_{eq}$ for $CH_3$ groups. The largest difference peaks for **14** are located near W(1) (0.82 and 0.89 Å). Other crystal data for both compounds are listed in Table 1.

# The Hydrothermal Synthesis of Transition Metal Complex Templated Octamolybdates

**Katikaneani Pavani,[a] Samuel E. Lofland,[b] Kandalam V. Ramanujachary,[c] and Arunachalam Ramanan*[a]**

**Keywords:** Solvothermal synthesis / Molybdenum / Supramolecular chemistry / Organic–inorganic hybrid composites

The hydrothermal reaction of an aqueous ammonium heptamolybdate solution with cobalt or copper metal salts in the presence of imidazole (imi) or pyrazole (pz) in the temperature range 120–180 °C and at autogenous pressure yields four fully oxidized metal-complex-templated octamolybdates, namely $[\{Cu^{I}(imi)_2\}_4(imi)_2Mo_8O_{26}]\cdot 4H_2O$ (**1**), $(Himi)_2[\{Cu^{II}(imi)_2\}_2Mo_8O_{27}]$ (**2**), $[\{Co^{II}(pz)_4\}_2(pz)_2Mo_8O_{26}]$ (**3**), and $[\{Cu^{II}(pz)_4\}_2Mo_8O_{26}]\cdot 2H_2O$ (**4**). The single-phase nature of the solids was established by single-crystal and powder X-ray diffraction, thermal analysis, and spectroscopic techniques. Compounds **1**, **3**, and **4** are neutral composite solids – **1** is a discrete molecular unit while **3** and **4** are 2D sheets. Compound **2** consists of anionic chains with imidazolium counter cations. The influence of the metal complex and temperature of the hydrothermal reaction on the formation of the different hybrid solids built of octamolybdate clusters is discussed. We also provide plausible mechanisms for the self-assembly of the crystals in terms of supramolecular organization between metal complexes and soluble molybdenum precursors in the initial stages of the reaction. The magnetic properties of **2**, **3**, and **4** confirm the presence of Cu and Co in the divalent state with no appreciable long-range order down to 5 K, whereas **1** is diamagnetic.

## Introduction

Polyoxomolybdate (POM) cluster anions are ideal nanobuilding blocks to assemble giant molecular crystals exhibiting compositional variation and structural diversity.[1,2] A contemporary interest in this area is to employ organic components or metal complexes to dictate the formation of novel organic–inorganic hybrid composites as these show promising applications in the areas of catalysis, magnetism, photochemistry, sensors, and energy storage.[3–6] A large number of POM-based solids have been self-assembled from aqueous solution in the presence of organic molecules as structure directors.[7–9] In particular, the role of organic diamines in the formation of discrete POM clusters to three-dimensional networks of molybdenum oxide based materials has been investigated extensively.[10–12] It is well established that solids crystallized from aqueous molybdate solution under either ambient or hydrothermal conditions in the presence of organic diamines are predominantly based on organic–inorganic hybrid salts. These may be salts between organic ammonium cations and discrete POM anions or composite solids with extended POM anions incorporated with organic cations.[13,14] If an additional transition metal ion is present, the metal complex formed in situ can either occur as the counter cation or derivatise the POM anion, or they can also be part of the extended network linking POM cluster anions.[15–17] In selected cases, the organic ammonium ions can take part in unusual hydrogen bonding and/or π-π interactions, which, in turn, can direct the crystal packing.[18] In an attempt to rationalize the reactivity pattern in the formation of these solids under hydrothermal conditions, we have been systematically analyzing the chemistry involved in controlling the reaction and hence the structure of molybdates, even though hydrothermal reactions are commonly termed as "black box" in nature. Apart from pH, molybdenum's ability to coordinate with aromatic diamines to form either pillared or composite solids is also important.[19] Another issue is the nature of the complex formed between the organic amine and the transition metal ion and its stability under hydrothermal conditions. Frequently, some of these organic amines can reduce transition metals under hydrothermal conditions and hence can lead to a different metal complex in situ. In addition, the temperature of crystallization is important. Apart from these, nonbonding interactions taking place between molybdate cluster anions and organic groups along with water molecules will influence the crystal structure packing. In our earlier work,[20] we have shown how a weak

ligand such as 2-aminopyridine ($pK_a \approx 6.9$) affects the hydrolysis and condensation reactions taking place in aqueous molybdate solution containing first-row transition metal ions.

Acidification of aqueous molybdate solution in the presence of organic cations yields a variety of POM cluster anions with varying numbers of molybdenum atoms. Among them, the octamolybdate anion **A** (Figure 1, left) with the composition $[Mo_8O_{26}]$ is predominant.[21–23] This cluster anion exhibits different isomeric structures; the cluster can occur either as discrete entities (zero-dimensional) or act as building blocks for 1D chains, 2D sheets, or 3D frameworks.[24–26] Another octamolybdate cluster, **B**, which has a different composition $[Mo_8O_{28}]$ (Figure 1, right), is observed in a few solids although in only one example does it exist as a discrete cluster.[27] While $Mo_8O_{26}$ is rarely protonated,[28,29] the cluster anion $Mo_8O_{28}$ is possibly protonated in aqueous solution and hence has a strong tendency to become derivatized or condensed under suitable conditions.[30–32] In this paper, we explore the reaction conditions necessary to form the octamolybdate cluster anion as a versatile inorganic building block for the construction of new hybrid molybdates in the presence of imidazole and its isomer pyrazole as templates. We also discuss the formation of **1**–**4** in terms of ideas recently proposed by Ramanan and Whittingham[33] for the formation of metal organic polymers and later extended to explain the formation of copper coordination polymers based on molybdates crystallized under hydrothermal conditions.[34]

## Results and Discussion

The hydrothermal reaction of copper and cobalt salts in the presence of imidazole (imi) or pyrazole (pz) at different temperatures leads to different products. Powder and single crystal XRD, TGA, and FTIR analysis were employed to establish the crystal structure, phase purity, and composition. Scheme 1 summarizes the optimal reaction conditions employed to obtain monophasic solids.

### Crystal Structure of 1

The crystal structure of $[\{Cu^{I}(imi)_2\}_4(imi)_2Mo_8O_{26}]\cdot 4H_2O$ (**1**) shows the presence of a discrete octamolybdate cluster (type **B**) derivatized by two imidazole moieties and

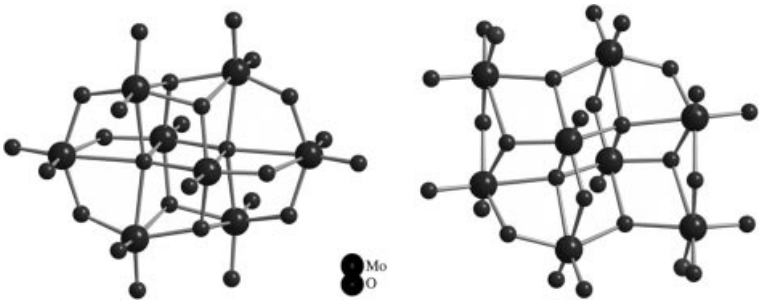

Figure 1. A view of (a) the β-octamolybdate anion $[Mo_8O_{26}]$ (type **A**) and (b) the octamolybdate anion $[Mo_8O_{28}]$ (type **B**).

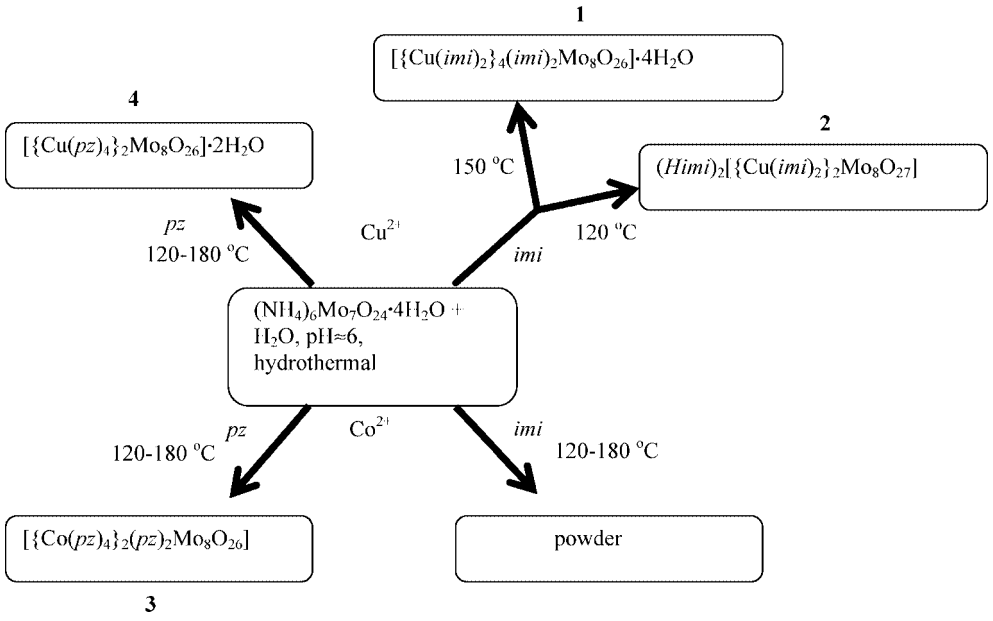

Scheme 1. Experimental details.

four tricoordinate copper imidazole complexes (Figure 2). An inversion center occurs in the center of the cluster anion. Each molybdenum atom in the $\{Mo_8O_{26}N_2\}^{4-}$ cluster anion has a distorted octahedral environment with six oxygen atoms. The thirteen asymmetric oxygen atoms in this cluster anion fall into four groups: seven are terminal, three are doubly bridging, two are triply bridging, and one is a quadruply bridging ligand. The copper(I) imidazole complex has two imidazole ligands and the third coordination is to the terminal oxygen of the cluster anion. In all the examples reported in the literature, derivatization of the cluster anion with an organic moiety (e.g. acetate or formate groups) appears to take place only on the molybdenum containing three terminal oxygens.[35,36] An interesting feature of this structure is that copper occurs in the +1 oxidation state and is tricoordinate. The supramolecular assemblies based on the derivatized octamolybdate unit $[\{Cu^{I}(imi)_2\}_4(imi)_2Mo_8O_{26}]$ are further connected to each other through strong H-bonding interactions of the type N–H···O (see Figure S1 in the Supporting Information). Apart from these, C–H···π interactions with an angle of 123.17° also dominate the crystal packing (Figure 3). Such copper(I) tricoordination is seen in the literature for β- and γ-octamolybdate cluster anions.[37–39] Complex **1** appears to be similar to one reported in the literature even though we have prepared it under different reaction conditions.[40]

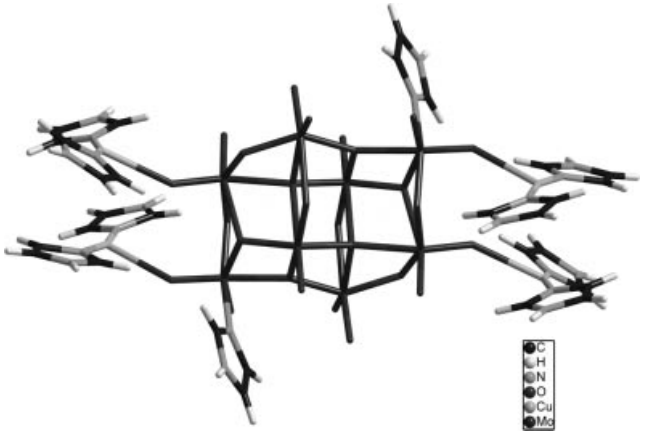

Figure 2. Crystal structure of the discrete octamolybdate **B** in **1** derivatized by two imidazole groups and four tricoordinate copper imidazole complexes.

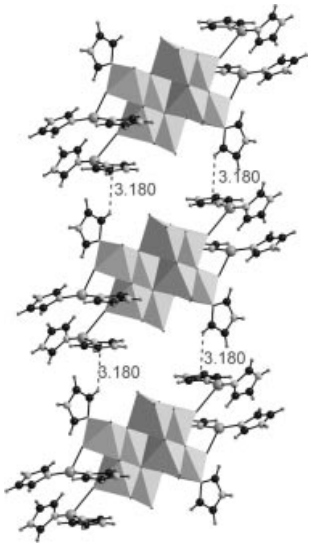

Figure 3. C–H···π interactions (Å, dotted lines) dominating the packing of the unit cell in **1**.

## Crystal Structure of 2

The crystal structure of $(Himi)_2[\{Cu^{II}(imi)_2\}_2Mo_8O_{27}]$ (**2**) consists of imidazolium cations and infinite $\{Mo_8O_{27}\}_\infty$ chains connected to square-pyramidal copper complexes (Figure 4). The $\{Mo_8O_{27}\}_\infty$ chain propagates along the *a*-axis and is surrounded by six others (see Figure S2 in the Supporting Information). The inter-chain regions are filled with imidazolium cations that participate extensively in strong hydrogen bonding with the cluster oxygens. An interesting feature observed in the crystal structure is the strong π···π interaction between the imidazole groups coordinated to the copper atoms of two adjacent chains (Figure 5). The Mo–O distances are significantly different due to their multiple bonding character and range from 1.687(3) to 2.504

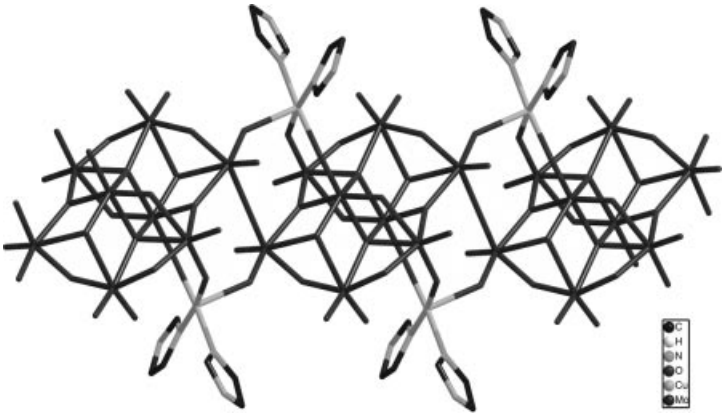

Figure 4. Anionic molybdenum oxide chains $\{Mo_8O_{27}\}^{6-}$ built from the octamolybdate clusters of type **B** sharing corners and also coordinated to square-pyramidal copper complexes in **2**.

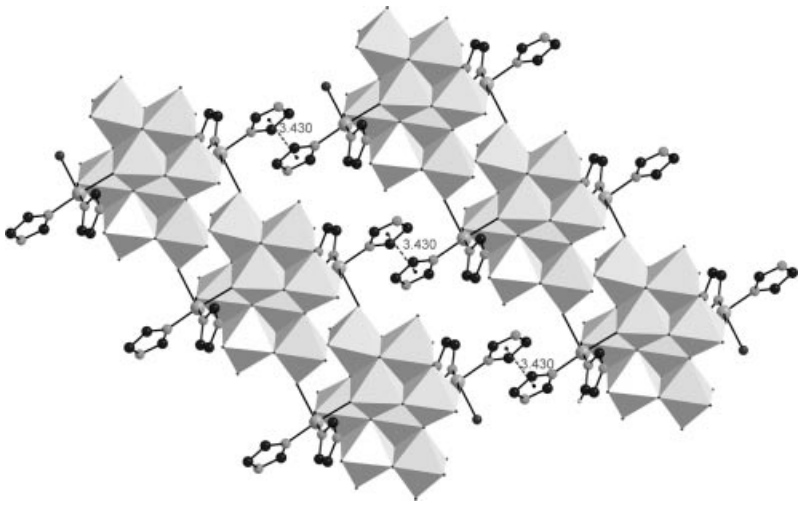

Figure 5. Strong π···π interactions (Å, dotted lines) between copper-coordinated imidazole groups of two adjacent chains in **2**.

(3) Å; the Cu–O distances range from 2.134 to 2.315 Å. A sixth Cu–O distance is 2.705 Å. The octamolybdate chains found in **2** are similar to those of $(NH_4)_6Mo_8O_{27}\cdot 4H_2O$[41] and $(C_4H_{12}N_2)_3Mo_8O_{27}$,[42] which are built from type **B** clusters, but with different counter cations such as ammonium or protonated amines. A similar metal coordination to the molybdate chain has been found previously in the case of rare-earth metals like samarium[43] and europium.[44] However, this is the first example of a transition metal organic complex coordinating with the chain. The structure is also special as the same organic group occurs as the counter cation as well as a coordinating unit during self-assembly.

### Crystal Structure of 3

The single-crystal analysis of $[\{Co^{II}(pz)_4\}_2(pz)_2Mo_8O_{26}]$ (**3**) shows the presence of octamolybdate (type **B**) derivatized by two pyrazole moieties and covalently bonded to the four cobalt pyrazole square-planar complexes (see Figure S3 in the Supporting Information). Each cobalt complex in this structure is covalently linked to two octamolybdate cores by a singly bridging oxo ligand. The $Co^{II}$ sites exhibit octahedral geometry $\{CoN_4O_2\}$ in such a way that each cobalt ion is coordinated to four nitrogen donors of pyrazole in the basal plane and two bridging oxo groups of the octamolybdate clusters at the apical position, thereby forming the 2D network shown in Figure 6. Linkage of cobalt complexes through molybdate clusters has rarely been reported in the literature, and this is the first example where a cobalt complex is covalently linking the derivatized octamolybdate. There are two other examples where cobalt complexes are linked to the β-octamolybdate cluster anion $[Mo_8O_{26}]$ (type **A** in Figure 1a).[24] This structure is a unique example where the derivatized $[Mo_8O_{28}]^{[8]-}$ is covalently linked to metal complexes to extend it into a 2D network.

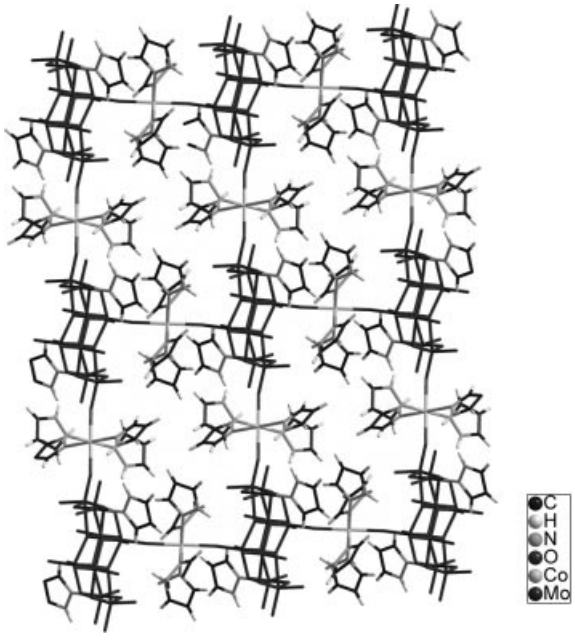

Figure 6. Pyrazole-derivatized octamolybdate cluster **B** linked through square-planar cobalt pyrazole complexes forming 2D sheets in **3**.

### Crystal Structure of 4

Solid $[\{Cu^{II}(pz)_4\}_2Mo_8O_{26}]\cdot 2H_2O$ (**4**) contains β-octamolybdate clusters (type **A**) that are covalently linked to four square-planar $\{Cu(pz)_4\}^{2+}$ complexes to form 2D sheets with isolated water molecules (Figure 7). The $\{Mo_8O_{26}\}^{4-}$ cluster unit is identical to the well-documented β form, with eight edge-sharing $MoO_6$ octahedra where all molybdenum atoms are in the +6 oxidation state. Each copper complex in this structure is covalently linked to two octamolybdate cores by a singly bridging oxo ligand (see Figure S4 in the Supporting Information). The $Cu^{II}$ sites exhibit an octahedral geometry $\{CuN_4O_2\}$ such that each copper center is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coordinated to four nitrogen donors of pyrazole in the basal plane and two bridging oxo groups of the octamolybdate clusters at the apical positions, thus extending it into a 2D network. A number of structures where octamolybdate clusters are covalently bonded to $\{M(ligand)\}^{n+}$ complexes have been described previously,[24–26] although the framework in **4** is unique. There are a few other solids based on β-octamolybdate clusters covalently linked through copper. In $[\{Cu(2,2'\text{-bipy})_2\}_2Mo_8O_{26}]$,[45] the β-octamolybdate cluster is linked to two square-pyramidal copper bipyridyl complexes and occurs as a supramolecular entity. In $[\{Cu_2(C_8H_6N_2)_2(C_7H_6N_2)\}_2Mo_8O_{26}]$,[46] the copper complex with two bidentate ligands links β-octamolybdate clusters into 1D chains. On the other hand, in $[\{Cu(o\text{-phen})_2\}_2Mo_8O_{26}]$ and $[\{Cu(en)_2\}_2Mo_8O_{26}]$, octamolybdate clusters are reported to adopt the α and γ forms, respectively.[47]

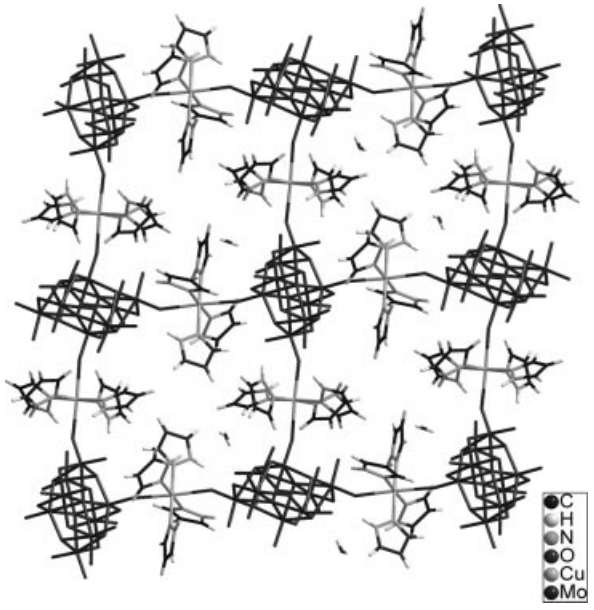

Figure 7. The 2D network observed in **4** involving the linkage of the octamolybdate anion $[Mo_8O_{26}]$ (type **A**) to square-planar copper pyrazole complexes.

### Chemistry of Formation of Hybrid Solids Based on Octamolybdate Anions

The cobalt or copper salts and the amines used as templates in this work were employed under identical reaction conditions (in terms of molybdate precursor, concentration, volume of the solution, molar ratios of the reacting species) to examine the nature of the molybdates formed. The selected amines act as good complexing agents and are stable under hydrothermal conditions. In addition, they have similar $pK_b$ values and therefore do not affect the pH of the reaction medium considerably. We also varied the tempera-

ture (and indirectly the autogenous pressure) to understand its effect on the nature of the products formed. When the heptamolybdate cluster anion is dissolved in aqueous solution in the presence of an organic diamine (pz or imi) and a cobalt or copper salt, a number of cluster anions, including $[Mo_8O_{26}]^{4-}$ (**A**) or $[H_xMo_8O_{28}]^{-(8-x)}$ (**B**), self-assemble due to hydrolysis and condensation of neutral and/or anionic molybdenum precursors, the assembly of which depends on the pH, ionic strength, and polarity of the medium. An examination of the literature shows that **A** is the dominant cluster found in several solids crystallized from acidified aqueous molybdate solution. However, in the majority of these solids **A** occurs as a discrete unit, whereas **B** occurs as a discrete protonated cluster in only one example[27] as it invariably gets derivatized by the organic group or condensed to form a 1D chain through three kinds of linkages, i.e. sharing edges, corners and pair –M–O–M– bridges,[20] or links through metal complexes to form 2D sheets (see Figure S5 in the Supporting Information). This is probably due to the large negative charge present on the anion **B**. Crystallization of **1**–**3** as well our previous report suggests that cluster **B** can also act as a building block to form multidimensional structures under favorable conditions. One can interpret the formation of **1**–**3** based on the complexing strength of the ligand and their lability with hydroxy groups in aqueous solution. In our earlier work, we also observed that in the presence of a better leaving group, such as 2-aminopyridine, cobalt yielded a heptamolybdate while copper yielded Lindgrenite-type copper molybdate as both cobalt and copper complex weakly with 2-aminopyridine.[20] In the presence of imi, copper forms a bis complex by *cis* addition. This prefers to derivatize cluster **B** and form the supramolecular assembly in **1** (Figure 2). In contrast, the reaction in the presence of pz leads to the formation of the square-planar complex $\{Cu(pz)_4\}^{2+}$, which crystallizes with the counter anion **A** to yield the solid **4**. On the other hand, the reaction of imi with cobalt yields only a powder that could not be structurally characterized. Reaction of cobalt with pz forms the complex $\{Co(pz)_4\}^{2+}$, which coordinates with **B** and crystallizes as **3**. We also note that the heteroatom of the organic moiety plays two roles: it provides a coordination linkage and acts as a charge compensator if necessary. The temperature does not affect the product if the metal complexes formed are stable in the presence of the organic amine (**3** and **4**). Imidazole is a better reducing agent than pyrazole, and hence $[Cu(H_2O)_4(imi)_2]^{2+}$ is readily reduced at higher temperature to form $[Cu(H_2O)(imi)_2]^{+}$, which derivatises **B** to form **1**.

Ramanan and Whittingham[33] have recently postulated a hypothetical mechanism for the formation of metal organic polymers from soluble molecular species. Pavani et al. have extended this approach to rationalize the formation of cop-

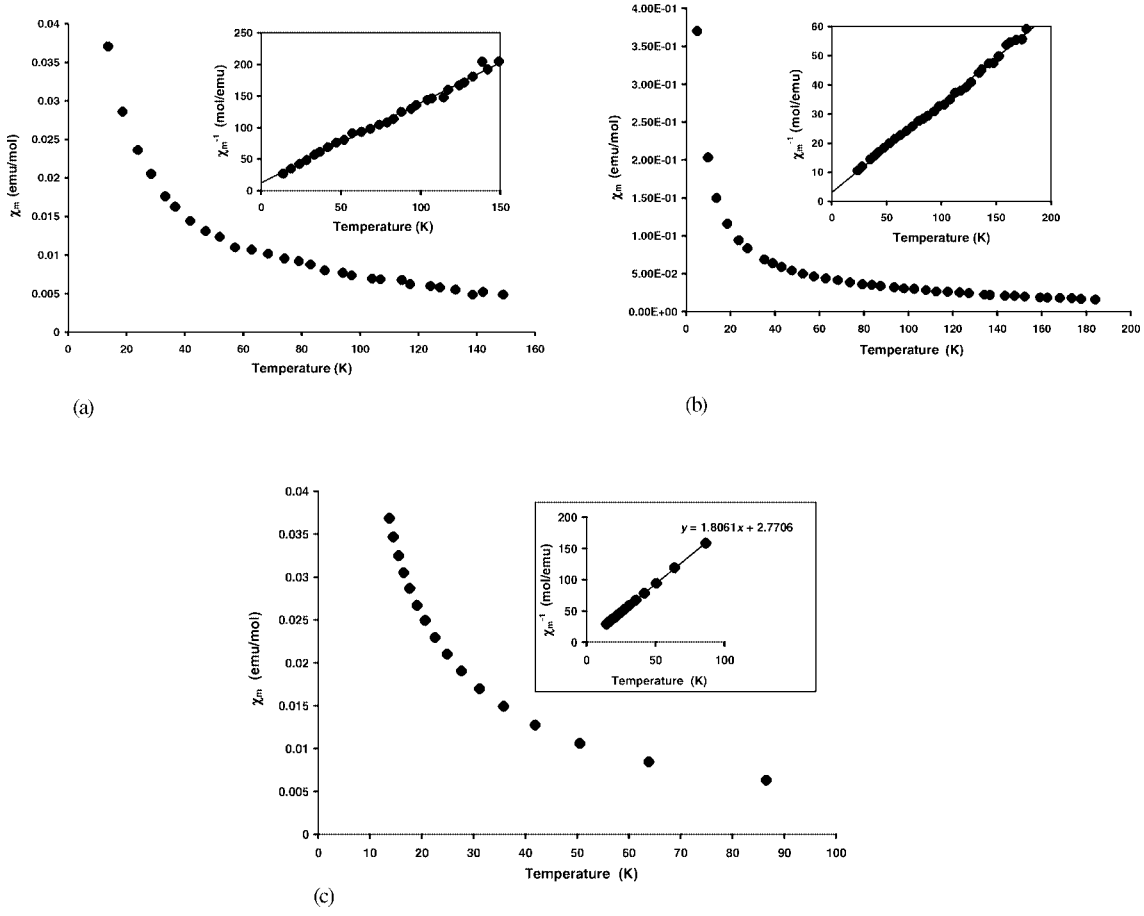

Figure 8. $\chi_m$ and $\chi_m^{-1}$ (insets) vs. *T* plots for (a) **2**, (b) **3**, and (c) **4**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

per coordination polymers based on molybdates under hydrothermal conditions.[34] Here, we have employed a similar strategy to understand the self-assembly of octamolybdate complexes that incorporate a copper/cobalt amine complex and/or the amine. Scheme 2 shows the proposed formation of the two cluster anions **A** and **B** from the condensation (dehydration) of monomeric molybdenum precursors. While **A** is built from two precursors, one neutral and another anionic, **B** forms from three types of molybdenum precursors. The formation of hybrid salts based on **A** can be visualized in terms of supramolecular aggregation of ion pairs formed between a molybdenum anionic precursor and organic cation along with a neutral molybdenum precursor. The presence of a large negative charge on **B** makes it unstable and the supramolecular aggregation is redefined to yield extended molybdate chains through edge-shared, pairs of vertex-shared, or vertex-shared clusters with K, $NH_4$, 2-ampy, picolinium, hexylammonium, etc. cations (as shown in Scheme S1 in the Supporting Information). However, when the solutions contain metal amine complexes and uncomplexed amines different supramolecular assemblies occur. In Scheme 3 we have proposed a plausible model to account for the formation of **1**–**4**.

### Magnetic Properties

The presence of $Cu^{II}(d^9)$ in **2**, **4** and $Cu^{II}(d^7)$ in **3** prompted us to carry out a magnetic study of these materials. The vast structural diversity of polyoxomolybdates and their ability to incorporate a large number of 3d metal cations opens synthetic routes to new magnetic molecules in which a diamagnetic molybdate framework acts as an efficient mediator of magnetic superexchange. The thermal variations of $\chi_m$ and $\chi_m^{-1}$ in the temperature range 5–160 K for **2**, **3**, and **4** are shown in Figure 8. The molar magnetic susceptibility was corrected for the diamagnetic corrections of the core electrons of the ions and functional groups. The linear portions of the plots were fitted to the Curie–Weiss relation given below, where $\theta$ is the Weiss constant and $C$ is the Curie constant. The Weiss constants are –10, –10, and –1.5 K for **2**, **3**, and **4** respectively.

$$\chi_m = C/(T - \theta)$$

The negative values of the Weiss constant indicate that the precursor exchange interactions are dominantly antiferromagnetic, although no long-range ordering was observed down to 5 K in these samples. As already mentioned, the structures consist of copper complexes that are well separated by the diamagnetic octamolybdate cluster units $\{Mo_8O_{28}\}^{8-}$ and $\{Mo_8O_{26}\}^{4-}$. The exchange correlations can be attributed to the superexchange couplings between the copper(II) or cobalt(II) ions. The effective magnetic moments calculated for **2**, **3**, and **4** are 2.51, 5.10, and 2.22, respectively, per formula unit and are consistent with divalent copper and cobalt ions.

## Conclusions

In conclusion, our results suggest that hybrid molybdates can be crystallized in the presence of cobalt or copper pyrazole (or imidazole) complexes as templates. A pH value of about 6 is crucial for the formation of octamolybdate anion as well as for the stability of the metal complex. At this stage, predicting the exact nature of the metal complex and the type of octamolybdate anion (**A** or **B**) formed in a particular solid is difficult to rationalize. Reduction of the copper complex under hydrothermal conditions is apparent. However, it is almost impossible to determine beforehand whether a metal complex or organic moiety will act as a counter cation or derivatize the anion during crystallization. In this context, our proposal of hypothetical mechanisms for the occurrence of various hybrid crystals not only underlines the role of molecular recognition but also simplifies the crystal structure in terms of molecular bricks. The present work demonstrates how condensation of $[Mo_8O_{28}]$ cluster anions into 1D chains or 2D sheets is facilitated by hydrothermal conditions. We strongly believe that recognition of such molecular building blocks will allow us to rationalize the synthetic protocols to be employed for the design of such solids.

## Experimental Section

**Materials and Methods:** All the starting materials were reagent grade and were used as purchased. The IR spectra were recorded with a Nicolet 5DX spectrophotometer with pressed KBr pellets. TG analyses were carried out with a Perkin–Elmer TGA7 and DTA7 system on well ground samples under flowing nitrogen with a heating rate of 10 °C min$^{-1}$. Room-temperature X-ray powder diffraction data were collected with a Bruker D8 Advance diffractometer using Ni-filtered Cu-$K_\alpha$ radiation. Data were collected with a step size of 0.02° and a count time of 2 s per step over the range $2° < 2\theta < 60°$. The susceptibility measurements as a function of temperature were performed with a SQUID magnetometer. Diamagnetic corrections were estimated from Pascal's constants.

**Synthesis:** A mixture of $(NH_4)_6Mo_7O_{24}{\cdot}4H_2O$ (0.7724 g, 0.625 mmol), $CuCl_2{\cdot}2H_2O$ (0.8524 g, 5 mmol), imidazole (imi; 0.5106 g, 7.5 mmol) and water (18 mL) was sealed in a Teflon-lined stainless-steel reactor and heated at various temperatures between 120 and 180 °C for three days. After the reaction, the system was slowly cooled down to room temperature. To rationalize the effect of the organic component as well as the metal ion, reactions with similar molar compositions were also carried out with pyrazole (pz) instead of imidazole and cobalt chloride instead of copper chloride. The reaction mixtures containing copper chloride and imidazole yielded two phases **1** (68% yield based on Mo) and **2** (71% yield based on Mo) at 150 and 120 °C, respectively, but the reaction between copper and pyrazole yielded **4** (84% yield based on Mo) at all temperatures between 120 and 180 °C. While the reaction mixture containing pyrazole and cobalt salt yielded **3** (87% yield based on Mo), the reaction between imidazole and cobalt resulted in a powder that could not be structurally characterized due to lack of suitable single crystals.

**Crystallographic Studies:** Single-crystal diffraction studies were carried out with a Bruker AXS SMART Apex CCD diffractometer

fitted with a Mo-$K_\alpha$ (0.71073 Å) radiation source at 28 °C for **1**–**4**. The software SADABS was used for absorption correction and SHELXTL for space group and structure determination and refinements.[48,49] The molybdenum atoms were located first and then remaining atoms were deduced from subsequent difference Fourier syntheses. The hydrogen atoms were located using geometrical constraints. All the atoms except H were refined anisotropically. The least-squares refinement cycles on $F^2$ were performed until the model converged. Experimental conditions and crystal data are provided in Tables 1 and 2, respectively.

CCDC-284102 (for **1**), -284101 (for **2**), -284103 (for **3**) and -269635 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Vibrational Spectroscopy:** In the IR spectrum of **1**, the peaks at 933, 890, 845, and 651 $cm^{-1}$ are attributed to the $\nu(Mo\text{-}O_t)$ and $\nu(Mo\text{-}O_b)$ vibrational modes of the $[Mo_8O_{28}]^{8-}$ anion. Features at 3132, 2946, 1630, 1540, 1504, 1435, 1326, 1257, and 1181 $cm^{-1}$ are characteristic absorptions of copper-coordinated imidazoles. The broad band at around 3371 $cm^{-1}$ can be ascribed to the absorption of lattice water molecules. The IR spectra of **2** and **3** are similar to **1** expect that the peak at 3371 $cm^{-1}$ is absent in the former, thus showing that there are no water molecules. The IR spectrum of **4** shows characteristic peaks at 945, 910, 849, 710, 666, and 551 $cm^{-1}$ due to β-octamolybdate; the bands at 3132, 2946, 1630, 1540, 1504, 1435, 1326, 1257, and 1181 $cm^{-1}$ are characteristic of copper-coordinated pyrazoles.

**Thermal Stability of 1–4:** The thermal dehydrations of **1**–**4** are quite different (Figure 9). All samples show a weight loss in multiple steps. For **1**, the loss of water molecules and free organic molecules and the decomposition of metal complexes occur in multiple steps. This observation clearly reflects the strength of hydrogen-bonding and other weak interactions noticed in the single crystal structure of the solids and was further confirmed by powder XRD and FTIR studies. The first two steps correspond to the loss of four water molecules and one organic group. The third and fourth steps correspond to degradation of the assembly. In **2**, the first step corresponds to the loss of two imidazole groups (≈ 200 °C) and the second step corresponds to the collapse of the structure with the loss of remaining organic groups. Complex **3** loses its organic groups in three steps. In the case of **4**, the loss of organic and water molecules was observed in the range 100–450 °C. In all cases the phase purity of the samples was further established by simulating powder X-ray diffraction patterns on the basis of the single-crystal structure data.

**Supporting Information** (see also the footnote on the first page of this article): Figures S1–S5 show additional figures for **1**–**4**, Figures S6–S9 show simulated and experimental powder X-ray diffraction patterns for **1**–**4**, and bond lengths and bond angles for **1**–**4** are given in Tables S10–S13.

## Acknowledgments

K. P. thanks the Council of Scientific and Industrial Research, Government of India (CSIR) for a research fellowship and A. R. acknowledges the Department of Science and Technology, Government of India (DST), for financial support. We thank Dr. N. G. Ramesh for helpful discussion. A. R. also thanks the DST for funding a powder X-ray diffractometer under IRHPA and a Smart Apex CCD single-crystal X-ray diffractometer under FIST to the Department of Chemistry at IIT, Delhi. A. R. thanks Professor M. S. Whittingham for his support and encouragement during his sabbatical leave. S. E. # Niobium Oxide Mesophases Obtained by Self-Assembly of an Aqueous Soluble Niobium Complex Precursor and Organic Templates

**Marcos A. Bizeto[a] and Vera R. L. Constantino*[a]**

**Keywords:** Niobium / Mesophases / Organic–inorganic hybrid composites / Template synthesis / Sol–gel synthesis

In this paper the use of triammonium trioxalato(oxido)-niobate $\{(NH_4)_3[NbO(C_2O_4)_3]\}$ as an inorganic precursor to assemble organized hybrid niobium oxide mesophases using *n*-octylamine (OCT) and cetyltrimethylammonium (CTA) bromide as structure-directing agents is described for the first time. The niobium complex is water-soluble and its hydrolysis at controlled pH and in the presence of organic templates leads to the formation of hybrid mesophases. A lamellar mesophase is produced by a neutral route based on the interaction of hydrolyzed units with the octylamine micelles. On the other hand, a hexagonal (*p*6*m*) mesophase is obtained when hydrolyzed species interact with CTA micelles through a charge-matching route (ionic route). This is the first time that such an ionic route has been described for the production of organized niobium oxide hybrids.

## Introduction

Organic–inorganic hybrid materials obtained by soft chemistry routes are the basis for the production of hierarchical inorganic structures that are of great interest in scientific and industrial areas. The molding of an inorganic structure around templates constituted of micellar aggregates produces organized mesophases that are precursors of periodic porous materials. Upon template removal, the mesophase can be transformed into an inorganic structure full of voids with regular shapes and sizes that are useful for applications in some industrial and technological fields, such as catalysis, separations, sensing, and others.[1] The approach to tailor-made porous structures started with Mobil corporation researchers, who created a family of mesoporous silicas called M41S.[2] These materials are obtained by controlling the hydrolysis of an inorganic precursor, generally silicon alkoxides such as tetraethylorthosilicate, around surfactant micelles. Since the discovery of mesoporous silicas, much effort has been devoted to the development of new mesoporous systems based on non-silicate materials. A great deal of work has concentrated on the synthesis of transition metal mesoporous oxides due to the possibility of these metal centers participating in chemical reactions. However, these materials are difficult to synthesize due to their tendency to crystallize and undergo chemical reactions that lead to mesostructure collapse.[3] The critical step of the process is the mesostructure formation as it is necessary to provide experimental conditions where the interaction between the inorganic species and organic template is established at the interface and is strong enough to promote the self-assembly of the moieties. There are different ways for these interactions to occur. The simplest one happens when the inorganic and organic moieties have opposite charges under the synthesis condition,[4] known as the "ionic route". The interaction can also take place by H-bonding or dipolar forces − the "neutral route".[5] A third possibility is exclusive for some transition metals where interaction can occur by coordination of a structure-directing agent to the metal center, leading to the so-called "ligand-assisted crystal templating".[6] One of the first successful examples of a stable mesoporous structure based on a transition metal oxide was mesoporous niobium oxide.[6] Ordered porous niobium oxide phases have been obtained by synthetic procedures where inorganic precursors, such as niobium alkoxides or chlorides, are used together with neutral structure-directing agents based on alkylamines or non-ionic surfactant micelles.[6,7] Mesoporous niobium oxides present interesting properties that can be used in many technological applications. The confinement of species into their pores, such as fullerides,[8] metallocenes,[9] or biomolecules,[10] produces materials with interesting electronic, magnetic, catalytic, and sensing properties. Taking these properties into account, the development of simple synthetic routes employing cheap and easy to handle reactants is an important issue to be resolved. The inorganic precursors normally used for this purpose are expensive, not easy to synthesize, and require controlled humidity conditions to be manipulated.

The niobium compound $(NH_4)_3[NbO(C_2O_4)_3]\cdot 3H_2O$ (Figure 1) has some interesting chemical properties that are useful not only for the assembly of mesoporous solid pre-

cursors (mesophases) but also in sol–gel-like soft-chemical routes. First of all triammonium trioxalato(oxido)niobate is water-soluble and stable in acid solution. Secondly, the niobium oxalate moiety has a negative charge and labile water molecules in the niobium coordination sphere when the aqueous equilibrium with the two oxalato ligands is considered.[11] These properties make this compound suitable for self-assembly with organic species by coordination and electrostatic interactions. The third and most important point is that triammonium trioxalato(oxido)niobate can be synthesized directly from niobium oxide by simple chemical procedures,[12,13] which means that the starting material can be easily recycled. Considering the possible interaction modes of trioxalato(oxido)niobate with organic moieties, in this paper we describe the use of a cationic surfactant and a long carbon chain amine as structure-directing agents for the generation of niobium oxide mesophases that might be further converted into mesoporous phases by template removal. A previous attempt at using a water-soluble niobium precursor derived from niobium pentoxide was not successful in a similar process.[6b]

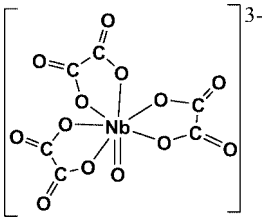

Figure 1. Chemical structure of $[NbO(C_2O_4)_3]^{3-}$.

## Results and Discussion

Triammonium trioxalato(oxido)niobate is soluble in water and is in equilibrium[11] with dioxalate species in solution, according to the chemical equation below.

$$[NbO(C_2O_4)_3]^{3-} + 2\ H_2O \rightleftharpoons [NbO(C_2O_4)_2(H_2O)_2]^{-} + C_2O_4^{2-}$$

Both species in equilibrium have a heptacoordinate niobium atom.[14] The initial pH of an aqueous solution of the compound is very acid due to partial hydrolysis of the compound. Upon increasing the pH to near 4 with a hydroxide solution, the niobium oxalate hydrolysis reaction is favored and leads to the formation of a hydrated amorphous niobium oxide bulk phase.[11] Figure 2 shows the typical sodium hydroxide titration curve of an aqueous triammonium trioxalato(oxido)niobate solution. According to this curve, trioxalato(oxido)niobate hydrolysis occurs in the pH range 4.2–5.8. Thus, it is possible to modulate the interaction of the oxide phase with structure-directing agents by controlling the hydrolysis process by adjusting the amount of base added.

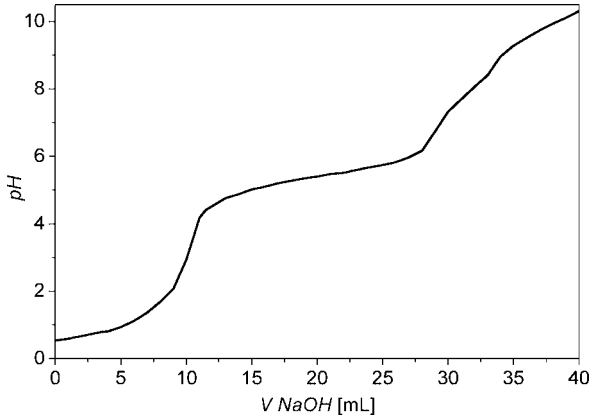

Figure 2. Titration curve of an aqueous solution of triammonium trioxalato(oxido)niobate (0.2 M) with a 3 M NaOH solution.

The crystal structure of triammonium trioxalato(oxido)-niobate belongs to the triclinic crystal system with the niobium atom heptacoordinate in a pentagonal-bipyramidal arrangement.[13] The high crystallinity of the solid can be seen in the powder XRD pattern shown in Figure 3. The solid isolated at a pH of around 5.5 is amorphous (Figure 3), while the solid isolated at higher pH (excess of base) is crystalline with a diffraction pattern very different from the pristine material (Figure 3). It is possible to produce an organized mesophase characterized by an amorphous inorganic framework with a regular repetition of voids filled with template micelles by performing the hydrolysis in the presence of a structure-directing agent. This synthetic approach was tested using cetyltrimethylammonium (CTA) bromide and *n*-octylamine (OCT) as structure-directing agents.

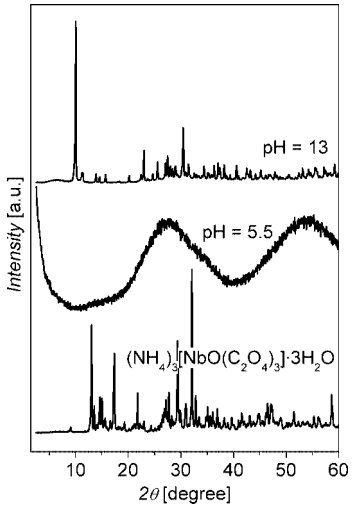

Figure 3. XRD patterns of triammonium trioxalato(oxido)niobate and its hydrolysis products isolated at different pH values.

CTA is a common template used in the synthesis of mesoporous silica, such as MCM-41, by a charge-matching ionic route. However, for niobium oxide hybrid mesostructures, only neutral routes with non-ionic surfactants have been performed until now. As can be seen in Figure 4, hy-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

drolysis of the trioxalato(oxido)niobate in the presence of the CTA template produces a hexagonally packed mesostructure. The XRD pattern of this phase shows reflection peaks at low angles related to the long-range order of the assembled hybrid material (Figure 4). Two types of hexagonal phases are known for silica-based systems: 2D hexagonal *p6m* (MCM-41) and 3D $P6_3/mmc$ (SBA).[15] The diffraction peak distances in Figure 4 are in a ratio close to 1:3, which can be attributed to a *p6m* hexagonal phase. The diffraction pattern also indicates that the assembled hybrid structure is not highly ordered. Hexagonal phases with regular parallel channels filled with the template provide intense diffraction patterns with many peak orders.[16] In the case of the synthesized CTA/niobium oxide phase, however, only two diffraction peaks are observed in the low-angle region, which suggests a non-fully parallel channel architecture. According to the diffraction data, the most organized mesophases are generated when an Nb/CTA molar ratio of 1:1 is used. The $d_{100}$ distance related to the first-order peak of the hexagonal mesophases has a mean value of 42.5 Å, while the mean $d_{110}$ value is 23.3 Å.

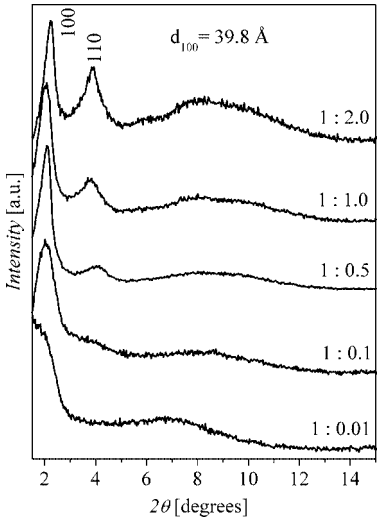

Figure 4. XRD patterns of the as-synthesized niobium oxide mesophase with CTA template at different Nb/CTA molar ratios.

The partial disorder of the porous architecture was confirmed by TEM (Figure 5). In the micrograph shown in Figure 5a, it is possible to observe that pores (elongation aligned parallel to the observer's view) are irregularly distributed along the material, like a wormhole pattern. In Figure 5b, the pores' elongation is parallel to the grid plane and some domains with well-ordered porous organization can be observed.

In the neutral-route synthesis the CTA template was replaced by *n*-octylamine (OCT), which resulted in a mesophase with a lamellar arrangement for Nb/OCT molar ratios above 1:0.5 (Figure 6). As can be seen from the XRD patterns in Figure 6, the distances of the diffraction peaks have a ratio of 1:2:3, which corresponds to a lamellar mesophase ($d_{001} \approx 24.5$, $d_{002} \approx 12.1$, and $d_{003} \approx 8.2$ Å). The TEM micrographs (Figure 7) also reveal a well-organized lamellar mesophase.

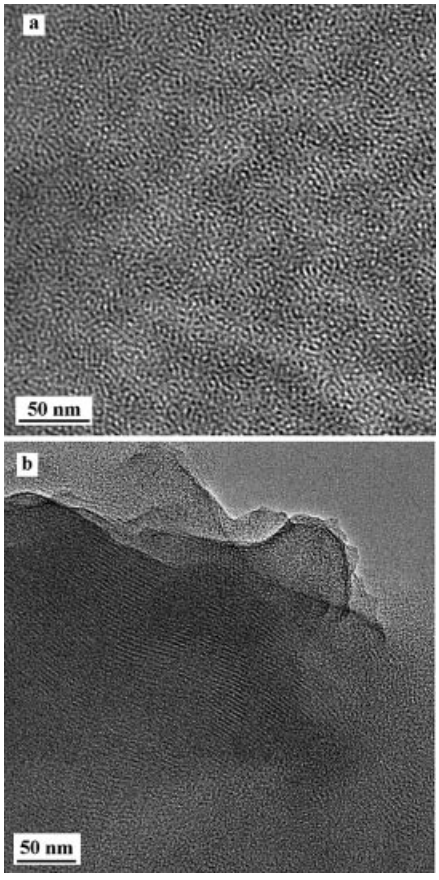

Figure 5. TEM images of the as-synthesized niobium oxide mesostructure (Nb/CTA molar ratio of 1:1): (a) porous elongation parallel to the view; (b) porous elongation perpendicular to the view.

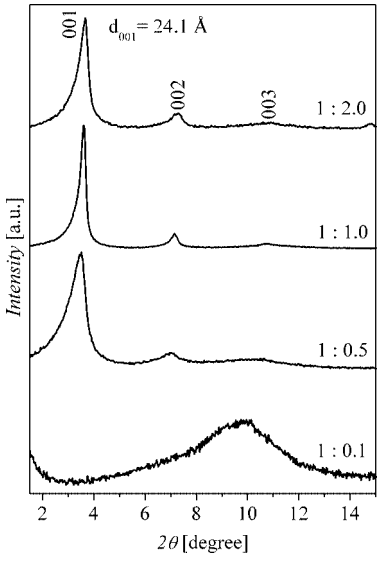

Figure 6. XRD patterns of the as-synthesized niobium oxide mesophase with *n*-octylamine as template at different Nb/OCT molar ratios.

To generate a mesoporous niobium oxide it is necessary to remove the template from the material to produce empty voids with regular shape and size along the mesostructure.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

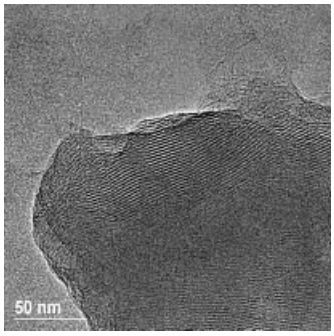

Figure 7. TEM image of the as-synthesized niobium oxide mesostructure (Nb/OCT molar ratio of 1:1).

This procedure is not possible in lamellar mesophases since the mesoporous phase is not stable after template removal due to the absence of species that keep the inorganic slabs apart. The collapse of lamellar mesostructures has already been observed in niobium oxide[6b] and silica MCM-50[17] phases.

The first attempt at CTA removal was made by solvent extraction, but due to the strong interaction between inorganic and organic moieties in the charge-matching mechanism of mesophase formation this solvent-template extraction was not an efficient process. Therefore, calcination of the hexagonal mesophase was performed based on thermogravimetric data obtained in air. According to thermogravimetric analysis (not shown), the complete removal of CTA occurs above 600 °C. The thermal stability of the generated mesoporous phase is closely related to the Tammann temperature of the respective oxide structure, which for $Nb_2O_5$ is 892 K (ca. 620 °C).[18] In the vicinity of the Tammann temperature the mobility of the atoms in the oxide structure increases significantly, thereby favoring the mesostructure collapse. Thus, the temperature requirement for complete template elimination is close to the Tammann temperature of niobium oxide, which makes calcination an unsuitable process for template removal in this case. In fact, when the mesophase calcination was performed at 600 °C we observed mesostructure collapse and production of an orthorhombic crystalline niobium oxide phase. The amorphous niobium oxide phase turns into a crystalline T-phase[12b] at around 500–600 °C, and this process could be the reason for the mesostructure collapse since the bridging Nb–O–Nb bond angles might change with crystallization. Other methods described in the literature[6b] for template removal by calcination also promoted the mesostructure collapse. In the charge-matching mechanism of mesophase formation, removal of the template leaves behind an unbalanced charge in the inorganic framework that contributes to the structure instability.[5] Considering this feature, the CTA removal was performed by combining a process of solvent extraction and ion exchange by using a mixture of ethanol and HCl, but also without success. Template extraction from the hexagonal mesophase was only possible when the ethanol/HCl solution was replaced by an ethanol solution of a large organic cationic species such as tetrabutylammonium (TBA) hydroxide. The organic cation provides the structural charge neutralization but, due to its large size, the porous voids are still occluded, thereby producing a material with low porosity, as confirmed by the desorption/adsorption isotherm experiments (not shown). Further calcination of the TBA-exchanged phase also promoted the mesostructure collapse.

In light of these results, an investigation of the causes of the low thermal stability of the hexagonal mesostructure was performed using vibrational Raman spectroscopy to determine the condensation degree of the inorganic framework. Intense bands between 900 and 1000 $cm^{-1}$ are attributed to terminal Nb=O stretching modes, with the respective bending modes in the region 200–400 $cm^{-1}$.[11,19] The range between 500 and 700 $cm^{-1}$ is dominated by Nb–O–Nb stretching modes of corner- or edge-shared octahedral $NbO_6$ units.[11,19] The presence of bands in this region indicates the condensation degree of the octahedral units that constitute the mesophase inorganic framework. Figure 8 shows the Raman spectra recorded for the mesophases. For comparison purposes, we have included the spectrum of $HNb_2O_5$, which is a thermodynamically stable niobium oxide crystalline phase.[12] Figure 8a presents the spectral region dominated by Nb–O vibrations. Thus, comparing the Raman spectra of the mesophases with that of $HNb_2O_5$ (Figure 8a) it is possible to determine a low condensation degree of the inorganic framework in mesophases due to the absence of strong bands in the region 500–700 $cm^{-1}$.

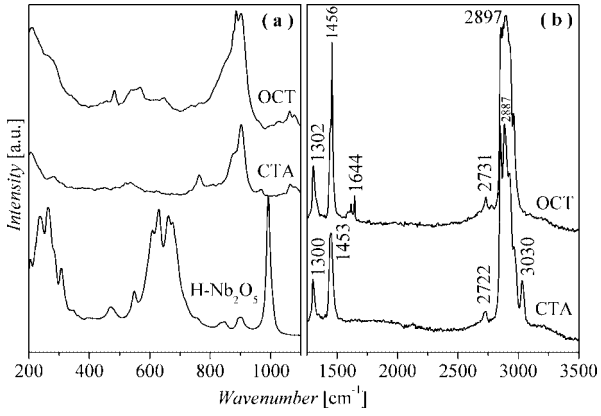

Figure 8. Raman spectra of niobium oxide mesophases (Nb/template molar ratio of 1:1) compared to $HNb_2O_5$: (a) region dominated by Nb–O vibrations; (b) vibrational region of organic templates.

The spectral region dominated by vibrational bands related to the organic moieties (1200–3500 $cm^{-1}$) is shown in Figure 8b, where it is possible to observe intense vibrational bands around 2900 $cm^{-1}$ attributed to the ν(C–H) vibrational modes of the template's carbon chains. Figure 8b also shows vibrational bands in the region 1200–1500 $cm^{-1}$ attributed to the oxalate $\nu_a$(C=O), $\nu_s$(C–O) and δ(O–C=O) modes,[20] thus indicating that the hydrolysis process of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

inorganic precursor is not complete. This could be one of the factors that affect the mesostructure stability. So, modifications of experimental procedures are necessary to achieve a better condensation of skeletal inorganic units and also to ensure complete trioxalato(oxido)niobate hydrolysis.

Some information about the local structure of poorly crystalline solids can be obtained by X-ray absorption techniques. Figure 9 shows the X-ray absorption near-niobium *K*-edge (XANES) spectra of the *n*-octylamine niobium oxide mesophase, the starting triammonium trioxalato(oxido)niobate, and the crystalline $HNb_2O_5$ phase. The absorption edge outline is mainly related to the element oxidation state but some local structural information can be obtained by simple comparison with XANES spectra of compounds whose structures are already known. The intensity of the pre-edge peak at the low-energy side of the spectra is related to the coordination site distortions around Nb.[21] This pre-edge peak is low in intensity for an octahedral geometry.[22] Some authors assume that it is related to the presence of Nb=O bonds and its absence is related to the presence of tetrahedral $NbO_4$ units.[23] Extended niobium oxides are mainly constituted of joined distorted $NbO_5$ and $NbO_6$ octahedral units. As determined by Raman spectroscopy, the synthesized niobium mesophases have bands in the region attributed to Nb=O bonds. The beyond-edge peaks shown in Figure 9 indicate that niobium in the $Nb_2O_5$ mesophase has neighboring atoms in an arrangement similar to niobium in $HNb_2O_5$, which is expected by the hydrolysis of trioxalato(oxido)niobate and condensation of the generated hexacoordinate niobium octahedral centers. As previously mentioned, the starting triammonium trioxalato(oxido)niobate has heptacoordinate niobium centers in a pentagonal-bipyramidal arrangement.[13]

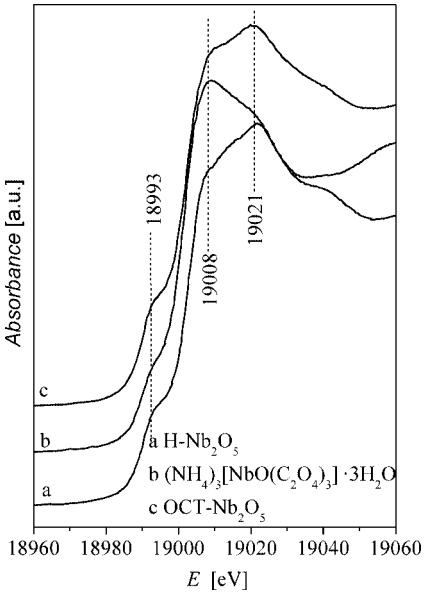

Figure 9. Niobium *K*-edge XANES spectra of (a) $HNb_2O_5$, (b) triammonium trioxalato(oxido)niobate, and (c) the OCT/$Nb_2O_5$ mesophase (Nb/OCT molar ratio of 1:1).

Other ways to achieve a better consolidation of the inorganic framework are under investigation. One of the synthetic changes tried comprises the use of a nonionic surfactant based on copolymers such as Brij56 (Aldrich). According to the literature,[5] nonionic routes produce mesostructures with thicker walls with a better thermal stability and easy template removal. When using Brij56 as structure-directing agent and triammonium trioxalato(oxido)niobate as inorganic precursor (Nb/Brij56 molar ratio of 1:0.5), the interaction at the interface of the inorganic and organic domains is very weak and no organized mesophase is produced, as shown in Figure 10 and also confirmed by X-ray diffractometry (not shown). The as-synthesized mesophase is even less stable than the mesophases described above since it crystallizes under the electron beam while registering the micrograph (TEM micrograph with higher magnification not shown). Maybe an organized mesophase with Brij56 as template can be obtained under experimental conditions (solvent/template/Nb molar ratios, pH, and temperature) distinct to those reported here.

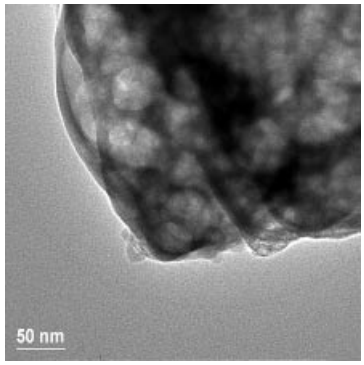

Figure 10. TEM image of the as-synthesized niobium oxide mesostructure using Brij56 as template (Nb/Brij56 molar ratio of 1:0.5).

Other synthetic modifications are still under investigation, such as the use of hydrothermal conditions, slow addition of the hydroxide to pH = 5.5, with constant monitoring of the pH, the use of other sources of base, such $NH_4OH$ and tetraethylammonium hydroxide, and templates, pre-hydrolysis of the trioxalato(oxido)niobate before mixing with the template, and thermal treatment of the mesophase under an inert gas before template removal. All the products generated by these synthetic modifications are now being characterized.

## Conclusions

In conclusion, this paper shows that it is possible to use triammonium trioxalato(oxido)niobate as an inorganic precursor to synthesize niobium oxide mesostructures by means of a neutral or an ionic route. The advantage of using this niobium compound instead of metal alkoxides or chloride precursors is related to its low cost, stability in water, easy manipulation, and possibility of recycling. Triammonium trioxalato(oxido)niobate can interact with neutral and cationic templates to produce organized mesophases under

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

controlled pH conditions. To obtain mesoporous niobium oxides from the synthesized mesophases, further studies are necessary to define experimental conditions that promote a better condensation and consolidation of the skeletal inorganic units, since attempts at template removal by calcination or solvent extraction lead to the collapse of the mesostructure.

## Experimental Section

In a typical synthesis, 12.0 g of triammonium trioxalato(oxido)-niobate, $(NH_4)_3[NbO(C_2O_4)_3]\cdot 3H_2O$ (CBMM; Companhia Brasileira de Metalurgia e Mineração) was dissolved in 200 mL of deionized water. The template [CTAB (Aldrich) or OCT (Merck)] was dissolved in 100 mL of a 3 M aqueous NaOH solution. The Nb/template molar ratios were varied from 1:0.1 to 1:2 to determine the influence of this parameter on mesophase formation. The solution of niobium complex was poured into the template solution (NaOH/Nb molar ratio of 4:1) and constantly stirred at room temperature for 48 h and at 80 °C for another 24 h to promote the decomposition of any remaining oxalate anion. After this period, the solid was filtered off, washed with water, and dried at 120 °C for 5 h. The obtained solids were characterized by X-ray diffractometry (XRD), transmission electron microscopy (TEM), Raman spectroscopy, and XANES. The standard $HNb_2O_5$ was obtained by treating a sample of $Nb_2O_5$ at 1200 °C for 2 h and its structure was confirmed by X-ray diffractometry.

X-ray diffraction patterns of the powdered samples were recorded with a Rigaku diffractometer model Miniflex using Cu-$K_\alpha$ radiation (1.541 Å, 30 kV and 15 mA), a step of 0.03°, and Ni filter. TEM images were recorded with a 300 kV JEM-3010 ARP microscope (1.7 Å point resolution) at the LME/LNLS (Laboratory of Electron Microscopy of the Brazilian Synchrotron Light National Laboratory, Campinas, Brazil). Samples were prepared by dispersing solids in ethanol in an ultrasonic bath followed by deposition on a carbon-coated Cu microgrid. Raman spectra were recorded with a Renishaw Raman Microscope model 3000, fitted with an Olympus metallurgical microscope (BH2-UMA) and a CCD camera (Wright, 600 × 400 pixels), with laser excitation line at 632.8 nm of an He-Ne laser (Spectra Physics, model 127). The XANES measurements at room temperature were performed at the XAFS beam line of Brazilian Synchrotron Light Laboratory (ring energy of 1.37 GeV and a beam current of about 175 mA). The monochromator was an Si(220) crystal and the recorded energy steps were 0.5 eV for the 18980–19060 eV XANES region in fluorescence mode. All energy values in the Nb *K*-edge spectra were calibrated against niobium metal.

## Acknowledgments

The authors acknowledge the Brazilian agencies FAPESP (Fundação de Amparo à Pesquisa do Estado de São Paulo) and CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico) for financial support and fellowships. We are thankful to LNLS for recording the HRTEM images and XANES spectra (projects TEM-2173 and D04B-XAFS1 4337/05). We are also grateful to the Companhia Brasileira de Metalurgia e Mineração (CBMM) for the triammonium trioxalato(oxido)niobate sample and the Laboratório de Espectroscopia Molecular (IQ-USP) for recording the Raman spectra.

# Synthesis and Characterisation of Metal Isobutylsilsesquioxanes and Their Role as Inorganic–Organic Nanoadditives for Enhancing Polymer Thermal Stability

**Fabio Carniato,[a] Enrico Boccaleri,*[a] Leonardo Marchese,[a] Alberto Fina,[b] Daniela Tabuani,[b] and Giovanni Camino[b]**

*Dedicated to the memory of Roberto Piazza*[†]

**Keywords:** Silsesquioxanes / Titanium / Vanadium / Polymers / Nanocomposites

Metal isobutylsilsesquioxanes (M-POSS) with $Ti^{IV}$ and $V^{V}$ metal centres have been prepared by direct corner-capping of trisilanolisobutyl-POSS (**1**). The synthetic procedure has been followed in solution by FTIR spectroscopy and samples have been characterised by $^{29}Si\{^{1}H\}$ NMR, FTIR, FT-Raman and UV/Vis spectroscopy in order to study the structure and the chemical properties of the transition metal centres incorporated in the synthesised compounds. The corner-capping reaction basically lead to tetrahedrally coordinated metal centres inserted in the siliceous cage. The hybrid inorganic–organic nature of these compounds and the possibility of dispersing catalytically active metal centres in a highly efficient way within organic matrices have been investigated by dispersing the title compounds at 3 wt.-% in a polypropylene matrix by melt blending, which leads to nanocomposite materials. A study of the thermal degradation of polypropylene, trisilanolisobutyl-POSS and metal-isobutyl-POSS composites shows a significantly enhanced thermal stability under oxidative conditions only when metal-containing silsequioxanes are dispersed, along with an extended formation of condensed polyaromatic compounds (charring products). This evidence is consistent with a possible catalytic effect favouring oxidative dehydrogenation of the polymeric organic chains occurring in the condensed phase under combustion conditions, and highlights a possible promising use of M-POSS as fire-retardant additives for polymers.

## Introduction

Polyhedral oligomeric silsesquioxanes (POSS) are a class of condensed, three-dimensional oligomeric organosilica compounds with cage frameworks having different degrees of symmetry. These materials are present in most of the up-to-date research topics in the field of advanced materials development as they combine a nanodimensional, well-defined geometry (given by their molecular nature) with the structural and chemical properties of both inorganic siliceous materials and organic molecules. The stoichiometry of these compounds shows each silicon atom bonded to one-and-a-half oxygens (sesqui-) and to a hydrocarbon (-ane), which leads to ($RSiO_{1.5}$) units.[1–3] Besides fully condensed polyhedral silsesquioxanes, which are essentially centred on cubic $R_8Si_8O_{12}$ molecules, open-corner POSS compounds with incompletely condensed silanol groups [with general formula $R_7Si_7O_9(OH)_3$], which can generally be obtained by direct synthesis from specific chlorosilanes[1–5] or by cleavage of completely condensed POSS,[6–7] are far more interesting due to the possibility of further functionalisation both with specific organosilanes and with heteroelements. In particular, these compounds (Figure 1) are suitable for reaction with a variety of transition metal complexes (in the form of alkoxides or chlorides) to form completely condensed metal-silsesquioxanes (M-POSS).[8–12] These metal-containing cage structures have proved to be promising both as homogeneous catalysts and as precursors for highly efficient metal-based heterogeneous catalysts.[13–16]

Since a wide variety of organic groups can be bound to the silicon, the inorganic cage can also show a tunable chemical affinity towards several organic solvents and also for polymeric matrices. Thus, these inorganic–organic hybrid molecular materials may be made chemically compatible towards polymers and become suitable for preparing nanocomposites. The use of cubic silsesquioxanes in the

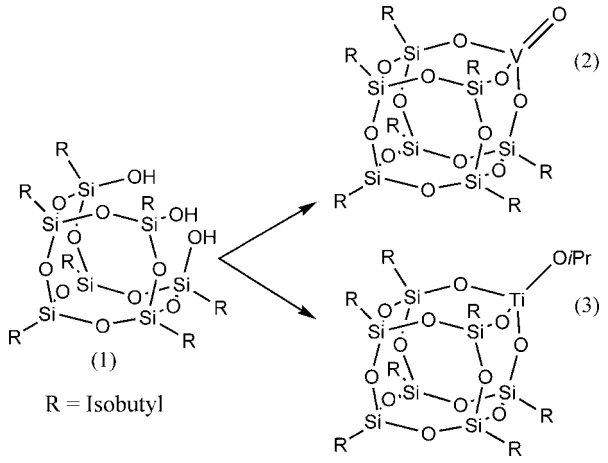

Figure 1. Trisilanolisobutyl-POSS (**1**), V-isobutyl-POSS (V-POSS; **2**) and Ti-isobutyl-POSS (Ti-POSS; 3); dimeric forms (see Figure 3 for instance) can also be present.

preparation of polymer nanocomposites has resulted in physicochemical properties that are significantly different to those of the parent polymer.[17–20] For this reason, the ability to disperse homogeneous metal-containing silsesquioxanes in polymeric matrices can lead to the distribution of well-exposed, coordinatively defined metallic centres within the organic matrix which, by acting as condensed-phase catalytic centres, can further modify the chemical behaviour of polymers, in particular at high temperatures (i.e. combustion conditions). In particular, M-POSS can deliver important flame retarding properties as they are able to activate, for instance, oxidative dehydrogenation reactions, thus reducing polymer ablation by the formation of carbonaceous and ceramic layers (given by the silica cage) on the polymer surface. Fina et al., for example, have recently shown that Al- and Zn-isobutyl-POSS are catalytic promoters of the formation of charring products during thermal oxidation of polypropylene.[21,22] Hence, interesting results can be expected when catalytically active transition metals are inserted in the siliceous cage and dispersed.

Some papers in the literature show the use of metal oxide species as additives for polymeric matrices different from polypropylene.[23] In particular, composites containing $TiO_2$ particles dispersed in poly(methyl methacrylate) or polystyrene have been investigated.[24–26] When reported, the presence of this inorganic filler showed interesting effects on the thermal stability of composites (for instance in the study of oxidative thermal degradation with TGA), giving a temperature shift on oxidative thermal degradation of about 50 °C for PMMA with 5–20 wt.-% of $TiO_2$. However, the net amount of transition metal inserted and the type of dispersion and interfacial interactions occurring with the polymer are extremely different and hard to relate to the selected M-POSS. Furthermore, as reported previously,[17–20] the introduction of silsesquioxane nanostructures can also modify other properties of the polymeric materials (i.e. mechanical behaviour).

This work focuses on the synthesis of V and Ti isobutyl-silsesquioxanes by corner-capping reactions.[27–29] The synthetic conditions for the insertion of $[(n\text{PrO})_3\text{VO}]$ and $[\text{Ti}(\text{O}i\text{Pr})_4]$ within the cage of isobutyl-POSS have been optimised (solvent, temperature and reaction time) and followed by FTIR spectroscopy. The products have been thoroughly characterised by $^{29}\text{Si}\{^1\text{H}\}$ NMR, FTIR, FT-Raman and UV/Vis spectroscopy. The materials obtained, together with the unmodified parent silsesquioxane, have been blended with polypropylene (to the best of our knowledge, the preparation of these composites is reported here for the first time) and the composites have been characterised by thermogravimetric analysis (TGA) under nitrogen and air in order to investigate the role of the dispersed metal during thermal and thermo-oxidative degradation.

## Results and Discussion

The occurrence of the corner-capping reaction of the open cage silsesquioxane was observed in the $^{29}\text{Si}\{^1\text{H}\}$ NMR spectra. The products were diluted with the appropriate deuterated solvents at about 5 wt.-% concentration. For example, sample **1** (Figure 2, A) gave a $^{29}\text{Si}\{^1\text{H}\}$ NMR spectrum (in $C_6D_6$ at 25 °C) that contains three distinct multiplet signals at $\delta$ = –58, –66.5 and –68 ppm in a 3:1:3 ratio. After functionalisation with a metal centre [part B of Figure 2, shows the $^{29}\text{Si}\{^1\text{H}\}$ NMR spectrum of V-isobutyl-POSS], the changes in the NMR spectrum are clear. Thus, the signal at $\delta$ = –58 ppm due to Si–OH is substituted by a

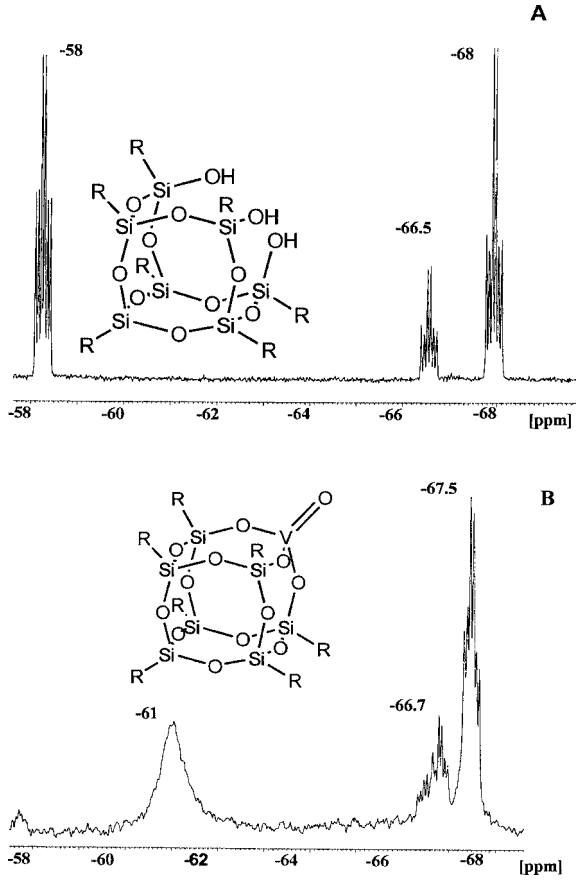

Figure 2. $^{29}\text{Si}\{^1\text{H}\}$NMR spectra of **1** (A) and **2** (B).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

broader signal at $\delta$ = –61 ppm in the V-containing silsesquioxane and, as expected, the fine structure of the multiplet signal disappears due to the presence of dipolar interactions with the $^{51}V$ nucleus. This result strongly supports the introduction of a tricoordinate vanadyl group into the cage corner of the trisilanolisobutyl-POSS, and that this is the main product. Moreover, these signals are typical of a monomeric structure of V-isobutyl-POSS, although possible changes of solution concentration and temperature can favour a dimer structure in equilibrium with the monomeric one.[28]

The Si–OH signal is also absent in the $^{29}Si\{^1H\}$ NMR spectrum of the titanium derivative **3**, thus suggesting that the corner-capping reaction is also successful for this compound. However, the spectrum shows a complex multiplet centred at around $\delta$ = –66.5 ppm, which was attributed to the presence of an equilibrium between dimeric and monomeric Ti-isobutyl-POSS molecules (Figure 3). This assignment was suggested by the fact that similar results have been reported for Ti-cyclohexyl-POSS.[27]

In order to evaluate the reaction evolution, and to optimise the synthesis time of V-isobutyl-POSS, the process was followed by IR spectroscopy (Figure 4A) in the liquid phase by collecting small amounts of the reaction medium. The IR spectra collected at increasing reaction time show a rapid disappearance of the broad absorption in the 3400–3100 $cm^{-1}$ range that is attributable to the O–H stretching of H-bonded silanols of the POSS cage. The maximum of this absorption could not be detected due to overlap with the C–H stretching modes of the aromatic ring of the solvent. However, it is very clear that this absorption disappears almost completely within five minutes.

The reaction times are longer for the synthesis of Ti-isobutyl-POSS, and 90 minutes are necessary to the complete corner-capping reaction of partially condensed isobutyl-POSS (Figure 4B).

The IR spectra of M-POSS in KBr pellets (Figure 5) show a clear similarity to that of the parent open-cage POSS in the fingerprint region (1500 and 1000 $cm^{-1}$), where the stretching and bending modes of the isobutyl chains and of the cage framework [$\nu_{as}$(Si–O–Si) around 1100 $cm^{-1}$] absorb. However, only the parent trisilanolisobutyl-POSS

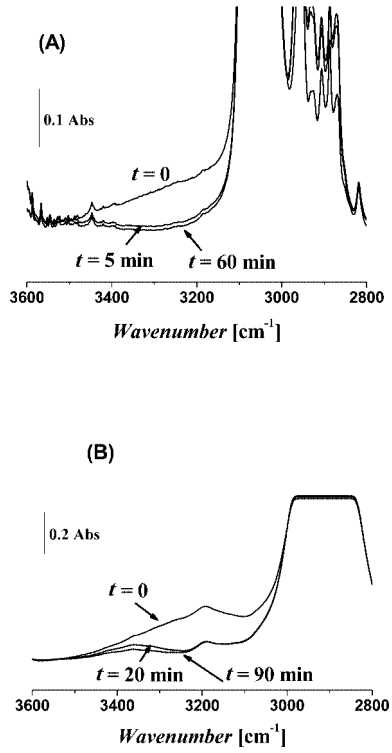

Figure 4. (A) IR spectra of the reaction mixture (in $C_6H_6$ solution) for the preparation of V-isobutyl-POSS; (B) IR spectra of the reaction mixture (in *n*-hexane solution) for the preparation of Ti-isobutyl-POSS.

(**1**) shows a clear band at 890 $cm^{-1}$ (Figure 5, curve 1) due to the bending mode of the Si–O–H groups, which is replaced by bands at 910 and 920 $cm^{-1}$ in the case of V- and Ti-POSS respectively (Figure 5, curves 2 and 3). These absorptions, which appear with the disappearance of the Si–OH bending mode[27] of **1**, can be assigned to $\nu_{as}$(Si–O–V)[30] and $\nu_{as}$(Si–O–Ti),[31] respectively.

Raman spectroscopy (Figure 6) confirmed that the vanadyl group is present in V-POSS. In fact, a sharp new peak at 1020 $cm^{-1}$, due to the V=O stretching vibration, is found in the Raman spectrum of V-POSS. The remaining part of the spectrum is almost unchanged with respect to the parent trisilanolisobutyl-POSS **1**. The NMR, FTIR and Ra-

man spectra therefore provide clear evidence that silanol groups are complexed with Ti or V metal centres leading to the closure of the isobutyl-POSS polyhedral cage.

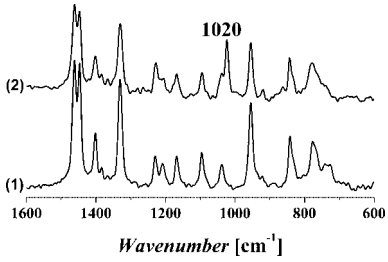

Figure 6. Raman spectra of **1** and **2**.

Diffuse-reflectance UV/Vis spectroscopy was used to monitor the oxidation states of the metals in **2** and **3**. Two bands at 250 and 300 nm are found in the spectrum of V-isobutyl-POSS (Figure 7, dotted line). These bands are assigned to low-energy charge-transfer (CT) transitions associated with framework vanadium species in a tetrahedral coordination environment.[32] In particular, the absorption at 250 nm is correlated to an electron-transfer transition between the bridging oxygens and the metal centre, while the band at 300 nm is an n → π* transition due to the terminal V=O bond.

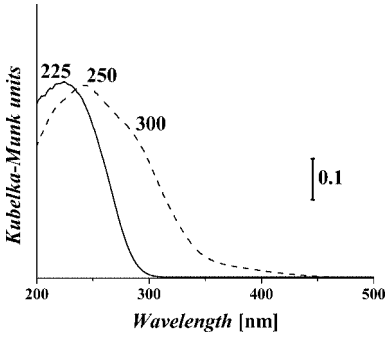

Figure 7. Diffuse reflectance UV/Vis spectra of **2** (dotted line) and **3** (solid line) mixed with anhydrous $BaSO_4$.

The vanadium centre within this material is sensitive to the presence of water, undergoing expansion of its coordination number in the presence of humidity. This was proved by recording the UV/Vis spectrum of V-isobutyl-POSS mixed with hydrated KBr. The band at 400 nm confirms a change of coordination of the metal centre, which passes from tetrahedral to fivefold coordination. It should be noted, however, that under these conditions the formation of oxide aggregation by-products is not observed. On the basis of these observations, the M-POSS complexes were stored under nitrogen in order to prevent any interaction with water.

The diffuse-reflectance UV/Vis spectrum of Ti-isobutyl-POSS (Figure 7, solid line) is characterised by a broad band at 225 nm, which is typical of tetrahedrally coordinated $Ti^{IV}$, as reported in the literature for similar samples[33] and mesoporous titanosilicates.[34]

## Polypropylene/M-POSS Nanocomposites: Thermogravimetric Analysis

Thermogravimetry is a well-established technique for the assessment of the ability of nanoadditives to favour the activation of degradation pathways suitable to protect the polymeric matrix and delay its weight loss upon heating.[35–37] In particular, the comparative analysis of the thermal behaviour of pure polymer and nanocomposite under inert or oxidative conditions is straightforward. On the other hand, these materials may activate catalytic reactions in the condensed phase due to the presence of peculiar surface and interfacial properties, such as surface acidity or redox catalytic sites, when in contact with oxygen at a given temperature. In particular, besides oxidative phenomena (which lead to the formation of small volatile molecules or CO, $CO_2$ and water), oxidative dehydrogenation reactions (ODH), which can be responsible for the formation of carbonaceous products, may occur. Moreover, the inorganic fillers can provide a physical protection to the polymeric matrix by limiting the oxygen diffusion, and thus the oxidation processes, by the formation of thermally stable siliceous or carbosiliceous surface layers (physical effect).

Due to the high affinity of isobutyl-POSS for polypropylene,[38] the prepared M-isobutyl-POSS complexes were dispersed in a polypropylene matrix by melt blending to give inorganic–organic nanocomposite materials. During the preparation of composite materials in a microextruder, the extrusion process was performed in the absence of humidity at 190 °C in order to avoid possible interactions between the metal centres and the water molecules. On the basis of the results of the NMR spectra collected on solutions (discussed above) in which the concentration of M-isobutyl-POSS is higher than in the composites, assuming a similar efficient dispersion of the nanofiller within the polymeric organic matrix, it can reasonably be expected that a large amount of M-POSS within PP exists as the monomeric species. The polymer was also blended with open cage trisilanolisobutyl-POSS (i.e. without metals in the siliceous cages), following the same procedure, for comparison. This proved to be helpful to discriminate the physical and chemical role of the dispersed nanofillers (e.g. the role of metal centres in promoting ODH reactions).

TGA measurements run under nitrogen showed that the maximum decomposition rate of pure polypropylene (Fig-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 8, curve A) occurs at about 454 °C (see the weight loss derivative curves, DTG, in the bottom panel). The addition of trisilanolisobutyl-POSS (Figure 8, B) and Ti-isobutyl-POSS (Figure 8, D) does not significantly change the thermal behaviour of the polypropylene, whereas in the presence of V-isobutyl-POSS (Figure 8, C) the degradation occurs at slightly higher temperature (464 °C).

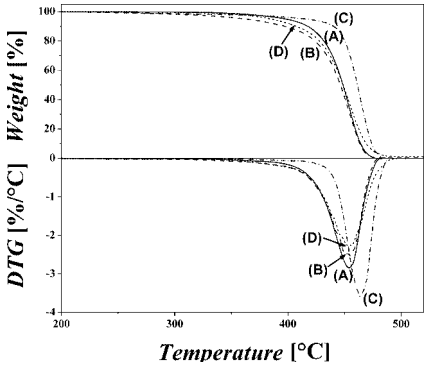

Figure 8. TGA measurements (10 °C min$^{-1}$) under nitrogen (the derivative curves, DTG, are shown in the bottom panel) for PP (A), PP-trisilanolisobutyl-POSS (3 wt.-%; B), PP-V-isobutyl-POSS (3 wt.-%; C) and PP-Ti-isobutyl-POSS (3 wt.-%; D).

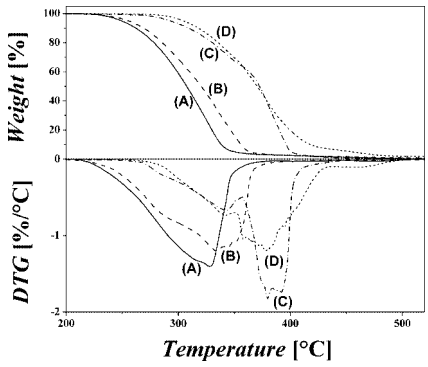

Figure 9. TGA measurements (10 °C min$^{-1}$) under air (the derivative curves, DTG, are shown in the bottom panel) for PP (A), PP-trisilanolisobutyl-POSS (3 wt.-%; B), PP-V-isobutyl-POSS (3 wt.-%; C) and PP-Ti-isobutyl-POSS (3 wt.-%; D).

Table 1. Comparison of the degradation processes of PP, PP-trisilanolisobutyl-POSS and PP-M-isobutyl-POSS composites from TGA data under oxidative conditions.

| | $T_{onset}$ [°C] | $T_{max}$ [°C] | Residue at 400 °C |
|---|---|---|---|
| Polypropylene (PP) | 247 | 327 | 2.5% |
| PP-trisilanolisobutyl-POSS | 255 | 335 | 2.5% |
| PP-V-isobutyl-POSS | 290 | 390 | 6% |
| PP-Ti-isobutyl-POSS | 303 | 375 | 20% |

On the other hand, large modifications of the thermal degradation behaviour were observed with both Ti- and V-isobutyl-POSS when heating the composites in air (Figure 9). In an oxidative atmosphere, the thermal oxidation of pure polypropylene occurs with maximum rate (measured from the DTG curve) at 327 °C (Figure 9, A) and the presence of trisilanolisobutyl-POSS (Figure 9, B) has only a limited effect, shifting the maximum weight loss rate to 335 °C. The effect of the presence of V-isobutyl-POSS (Figure 9, C) and Ti-isobutyl-POSS (Figure 9, D) is well evident from curves C and D in Figure 9, where a significant shift of the whole thermal oxidation process towards higher temperature can be observed. In detail, the degradation onset temperature (calculated when the decomposition reaches 5% of weight loss) for composites with M-isobutyl-POSS, reported in Table 1, are shifted to 290 and 303 °C, respectively, an increase of 43 and 56 °C with respect to pure polypropylene (onset temperature: 247 °C). The temperatures of maximum decomposition rate (by DTG profiles), which were found to be 327 °C for the pristine PP matrix, 390 °C for the PP-Ti-isobutyl-POSS composite and 375 °C for the PP-V-isobutyl-POSS composite, further confirmed this evidence. This effect can be attributed to the presence of Ti and V catalytic centres, which are active in ODH reactions and promote the formation of thermally stable char products. This is demonstrated by the presence of a meaningful amount of degradation products, which are oxidised only at temperatures higher than 400 °C. Indeed, while the residues of polypropylene and the PP-trisilanolisobutyl-POSS composite oxidised above 400 °C are very low, a far greater amount (about 20 wt.-%) can be detected with M-isobutyl-POSS (in particular Ti-isobutyl-POSS; Table 1).

Further evidence for the role of M-POSS on the oxidative thermal degradation of the polymeric matrix can be found by monitoring the weight loss under isothermal conditions in air (Figure 10). When setting the temperature to the beginning of the degradation of the pure matrix (i.e. 250 °C), neat PP and trisilanolisobutyl-POSS showed a very similar behaviour, with a rapid degradation that led to a residue of around 10 wt.-% in only 50 min (Figure 10, curves A and B). On the contrary, polypropylene composites containing both V- and Ti-isobutyl-POSS showed a massive formation of thermally stable products. After 250 min, in fact, residues of 28 and 42 wt.-% were found for V-isobutyl-POSS (Figure 10, C) and Ti-isobutyl-POSS (Figure 10, D), respectively. These results can be explained by the presence of catalytically active metal centres dispersed within the polymeric matrix, which result in the formation of thermally stable charring products, and suggest that the phenomenon is sensitive to the chemical nature of the metal centres.

The μ-ATR-IR spectroscopic data of composites containing Ti- and V-isobutyl-POSS were recorded on the residues at 250 °C. As shown in Figure 11, the presence of a band at 1600 cm$^{-1}$ suggests that the metal-containing nanofillers activate the early formation of unsaturated moieties as degradation products of the polypropylene matrix in the presence of oxygen. The bands observed at 1770 and 1710 cm$^{-1}$ can be attributed to the formation of oxidised species (i.e. γ-lactones and ketones).[39] The formation of extended conjugated unsaturated regions, which is favoured by the catalytic role of the metal centres, could be responsible for the stabilization of the thermal behaviour of the polymer, in agreement with the thermogravimetric analysis.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

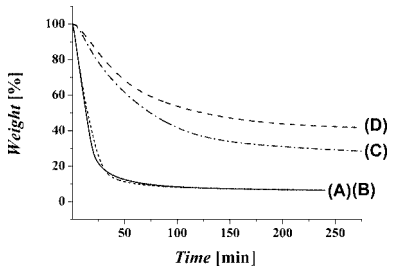

Figure 10. TGA measurements under isothermal conditions (250 °C) in air for PP (3 wt.-%; A), PP-trisilanolisobutyl-POSS (3 wt.-%; dotted line, B), PP-V-isobutyl-POSS (3 wt.-%; C) and PP-Ti-isobutyl-POSS (3 wt.-%; D).

Further studies on the mechanism acting within the M-POSS polypropylene composites carried out with several spectroscopic techniques highlight and confirm the solid-state catalytic activity of the nanofillers within the polymeric matrix.[40]

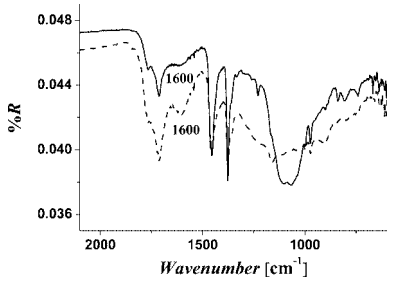

Figure 11. μ-ATR-IR spectra of the residues obtained at 250 °C under air flow for PP-Ti-isobutyl-POSS (solid line) and PP-V-isobutyl-POSS (dashed line).

When polypropylene is blended with Ti-POSS, the stabilisation effect on the polymer is more effective. These results are far more remarkable when the extremely low amount of metal dispersed in the material is considered (less than 0.2 wt.-%).

## Conclusions

This article focuses on the synthesis of V- and Ti-functionalised cubic silsesquioxanes, which are reported for the first time with an isobutyl substituent on the cage corners. A detailed characterisation during the synthetic procedure has highlighted that the reaction times are very short with respect to the results published on POSS with different organic substituents. Besides solution $^{29}Si\{^1H\}$ NMR, FTIR spectroscopy is a sensitive probe for the monitoring of the corner-capping reaction and the characterisation of the products, while Raman spectroscopy can often provide complementary information about the nature of the transition metal centres inserted into the cage. The coordination state of the metallic centres has been investigated by diffuse reflectance UV/Vis spectroscopy.

Due to their chemical affinity, these compounds have been used as additives (3 wt.-%) in polypropylene by melt blending to give nanocomposite materials. The thermal degradation of these materials under an inert or oxidative atmosphere was followed by thermogravimetric analysis. Whilst metal-free additives (i.e. trisilanolisobutyl-POSS) have limited effects on the degradation pathway of the polymeric matrix, Ti-POSS and V-POSS shift the oxidative degradation significantly to higher temperature (around 70–80 °C). Moreover, under isothermal conditions, while neat polypropylene and metal-free PP-POSS composites degrade rapidly at 250 °C in air (leaving less than 10% of residue after 50 min), in the presence of V- and Ti-POSS the degradation is significantly slower and leads to large amounts of residues: 28% and 42% respectively after 250 min. This suggests that metal-bearing nanofillers can operate chemically on the polymeric matrix degradation pathway, thereby inducing significant modifications to the high temperature oxidative processes. In particular, oxidative dehydrogenation reactions, which lead to thermally stable charring products, are seemingly favoured in this case.

A more detailed multi-technique investigation, which is currently in progress, is needed to highlight the chemical reactivity induced by the presence of M-POSS and the related evolution of the species that are formed within the polymeric matrix.

## Experimental Section

**Materials:** Trisilanolisobutyl-POSS (**1**) from Hybrid Plastics Company was used as precursor for the preparation of M-isobutyl-POSS by a corner-capping reactions. The preparation was performed under inert conditions (nitrogen). All solvents, freshly opened, were used without further purification.

**V-Isobutyl-POSS (2):** An equimolar solution of $[(n\mathrm{PrO})_3\mathrm{VO}]$ (98%, Sigma Aldrich) and trisilanolisobutyl-POSS was prepared by adding a 2-mL solution of $[(n\mathrm{PrO})_3\mathrm{VO}]$ (288 μL, $1.27\times10^{-3}$ mol) in benzene to a solution of **1** (1.00 g, $1.27\times10^{-3}$ mol) in 20 mL of benzene under vigorous stirring. As found by IR spectroscopy, trisilanolisobutyl-POSS was almost completely transformed within a few minutes; however, the mixture was stirred for 1.5 h to complete the reaction. Filtration through a fine sintered glass funnel, and solvent removal in vacuo, led to the isolation of 900 mg of V-isobutyl-POSS as a white amorphous foam.

**Ti-Isobutyl-POSS (3):** $[\mathrm{Ti}(O\mathit{i}\mathrm{Pr})_4]$ (375 μL, $1.27\times10^{-3}$ mol; 97%, Sigma Aldrich) was added with vigorous stirring to a solution of **1** (1.00 g, $1.27\times10^{-3}$ mol) in 160 mL of *n*-hexane. The reaction solution was carefully purged with nitrogen to prevent the rapid hydrolysis of $[\mathrm{Ti}(O\mathit{i}\mathrm{Pr})_4]$. After addition, the temperature was raised to 60 °C and the mixture stirred for 90 min. In this case, FTIR spectroscopy showed that the transformation of trisilanolisobutyl-POSS was almost complete within 1.5 h. Subsequently, the solvent was evaporated until a white powder (900 mg) was obtained.

Both complexes were stored under nitrogen in order to prevent any interaction with water.

Melt blending of M-isobutyl-POSS in a polypropylene matrix (3 wt%) was performed using a Basell Moplen HP501L Polypropylene Homopolymer (density: 0.9 $g\,cm^{-3}$). The melt flow rate (MFR) (230 °C/2.16 kg) was 6.0 g/10 min. The mixing was performed using a Haake twin screw microextruder at 190 °C for 10 min. The extruder was driven at 100 rpm.

**Characterisation:** $^{29}Si\{^1H\}$ NMR spectra of the samples dissolved in $C_6D_6$ (concentration: 0.1 M) at room temperature were recorded

with a Jeol Eclipse Plus spectrometer equipped with an 8-T magnet.

Infrared (IR) spectra of solid samples in KBr pellets were recorded in the range 4000–400 $cm^{-1}$ at 4-$cm^{-1}$ resolution with a Bruker Equinox 55 spectrometer.

ATR spectra of the samples were recorded in the range 4000–500 $cm^{-1}$ at 4-$cm^{-1}$ resolution with a Perkin–Elmer Spectrum GX FTIR SystemMultiscope FTIR Microscope.

Raman spectra were recorded in the range 4000–50 $cm^{-1}$ at 4-$cm^{-1}$ resolution (500 scans) with a RFS 100 Bruker FT-Raman spectrometer equipped with a 1064-nm wavelength excitation laser. The laser power was set at 100 mW.

UV/Vis spectra were recorded in the range 190–750 nm with a Perkin–Elmer Lambda 900 spectrometer equipped with a diffuse reflectance sphere attachment (DR-UV/Vis). The samples were dispersed in anhydrous $BaSO_4$ (10 wt.-%).

Thermogravimetric analyses (TGA) of composite materials (M-isobutyl-POSS dispersed in polypropylene) were performed in air or nitrogen (60 mL $min^{-1}$) with a Q500 TA Instruments thermobalance, heating from 50 to 600 °C at 10 °C $min^{-1}$ or under isothermal conditions, with 10-mg samples.

## Acknowledgments

The authors thanks Dr. Nadia Tzankova Dintcheva of the University of Palermo for blending M-POSS in PP. The authors are grateful to the European Commission for financial support by means of the Specific Targeted Research or Innovation Project (STRP) project "Nanofire" (proposal no. 505637-1) in the context of the 6th Framework Programme. Financial support by the Ministero per l'Università e la Ricerca Scientifica (MIUR) through a PRIN 2002 project is gratefully acknowledged.

# Structural Trends in Alkaline Earth and Rare Earth Metal 3,5-Diisopropylpyrazolates

**Julia Hitzbleck,[a,b] Glen B. Deacon,[b] and Karin Ruhlandt-Senge*[a,b]**

**Keywords:** Alkaline earth metals / Lanthanoids / N ligands / Coordination modes

A series of 3,5-diisopropylpyrazolates of magnesium, calcium, and strontium in addition to a divalent europium analog continues our investigation on the differences and similarities between the alkaline earth and divalent rare earth metal elements. The alkane elimination reaction between dibutylmagnesium and excess 3,5-diisopropylpyrazole (*i*Pr$_2$pzH) in toluene afforded the dinuclear magnesium pyrazolate [{Mg(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)}$_2$] (**1**). [{Ca(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$] (**2**) and [{Eu(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$] (**3**) were obtained as the product of redox-transmetallation/ligand-exchange reactions between an excess of the corresponding metal, 2 equiv. of *i*Pr$_2$pzH, and Hg(C$_6$F$_5$)$_2$ in toluene. This reaction with Sr metal led to the isolation of a unique byproduct, [Hg$_3$(*i*Pr$_2$pz)$_4$(C$_6$F$_5$)$_2$] (**4**). High-temperature direct metallation of barium with *i*Pr$_2$pzH afforded [{Ba(*i*Pr$_2$pz)$_2$(py)$_3$}$_2$] (**5**) upon treatment of the hydrocarbon-insoluble homoleptic [{Ba(*i*Pr$_2$pz)$_2$}$_n$] with pyridine (py). X-ray crystal structure analyses revealed dinuclear structures for compounds **1**–**3** and **5** with μ-η$^n$:η$^m$ bridging pyrazolato ligands, including the new μ-η$^1$:η$^5$ linkage, and further stabilization of **1**–**3** by intramolecular hydrogen bonding between the terminal pyrazole donor and terminal **1** or bridging pyrazolato ligands in **2** and **3**. The trinuclear **4** displays the first example of a complex with an *open*, triangular Hg$_3$ unit. It has μ-η$^1$:η$^1$ bridging pyrazolato ligands and terminal pentafluorophenyl groups.

## Introduction

The coordination chemistry of the pyrazolate ligand system has been a point of interest for quite some time, and the recognized array of binding modes keeps increasing as this work continues.[1] Many of the pyrazolato complexes reported in the literature to date involve transition metals,[1b,1d,2] followed by a much smaller number of lanthanoid pyrazolates.[3] Nevertheless, triggered by the potential use of this ligand system for chemical vapor deposition (CVD) precursor materials,[3i,4] the pyrazolate series was extended to the more electropositive alkaline earth metals in recent years.[4c,5] Despite the numerous coordination modes reported (e.g. *C*- or *N*-η$^1$, η$^2$, η$^5$, μ-η$^n$:η$^m$)[3,5,6] and the close structural similarities with the analogous lanthanoid pyrazolates, suitable group 2 CVD precursor materials have not been obtained as of yet, because of the thermal instability of the compounds.[5] Hence the custom design of such materials still requires a more in-depth understanding of the coordination chemistry of alkaline earth metals and the resulting structure–reactivity relationship of their compounds.

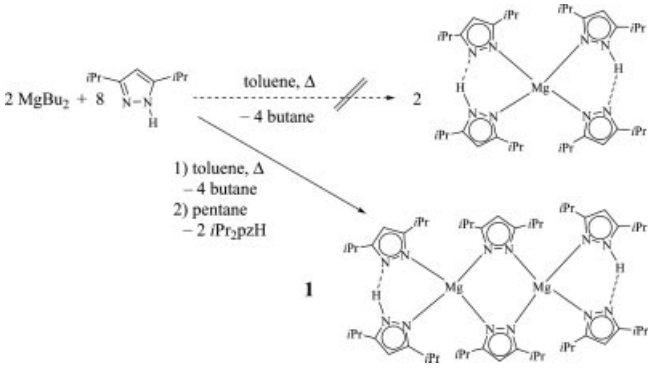
Considerable effort in our laboratories has shed light on the chemistry of alkaline earth and rare earth metal pyrazolates, and we recently reported on several metal-based syntheses of alkaline earth 3,5-diphenyl- and 3,5-dimethylpyrazolates Ph$_2$pz and Me$_2$pz.[5c] Structural analysis revealed the expected similar coordination modes to the previously reported rare earth metal pyrazolates[3e,3k,3m,6f] and identical structures for metals with similar ionic radii (e.g. Ca$^{2+}$/Yb$^{2+}$; Sr$^{2+}$/Sm$^{2+}$/Eu$^{2+}$).[7] Alternatively, where the Yb$^{2+}$ complexes have not been crystallized,[3j] a prediction can be made from the structure of the Ca complex and vice versa.[5c,5d,5f] Furthermore, we could show that, in the absence of suitable donor solvents, or if ideal steric saturation cannot be achieved by co-solvent coordination, formation of oligonuclear species is observed.[5d,5f] While the sterically demanding alkaline earth metal diphenylpyrazolates [M(Ph$_2$pz)$_2$(thf)$_4$] (M = Ca, Sr, Ba) form exclusively mononuclear complexes in the presence of thf,[5c] the corresponding di-*tert*-butylpyrazolates [{M(*t*Bu$_2$pz)$_2$(thf)$_n$}$_2$] crystallize as dinuclear species with an array of μ-η$^2$:η$^n$-bridging pyrazolato modes.[5f] An even greater variety of coordination modes is observed in the products of high-temperature metallation, affording linear, homoleptic alkaline earth metal 3,5-di-*tert*-butylpyrazolates [{M(*t*Bu$_2$pz)$_2$}$_n$] (M = Ca, Sr, Ba; *n* = 3, 4, 6 respectively).[5d] Where the corresponding pyrazoles are coligands,[3l,3m] hydrogen bonding also plays a major role in determining the structures of alkaline earth metal derivatives.[5b,5c,8] The coordination of a neutral li-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gand is also an important design element of potential CVD precursor molecules.[3i,8] Deposition experiments have shown that the addition of the free ligand to the vapor frequently results in increased complex stability,[8] and we recently reported on enhanced vapor transport of complexes containing free pyrazole as a donor.[5f] Nevertheless, the effect of ligand bulk on the synthesis of alkaline earth metal pyrazolates as well as on their structures is incompletely understood. We now report a study of the synthesis and structures of alkaline earth and a rare earth metal 3,5-diisopropylpyrazolates. *i*Pr$_2$pz has steric bulk intermediate between the Ph$_2$pz and Me$_2$pz ligands, further assisting an understanding of this important class of complexes. Particular features are the influence of the thermal stability of the ligand in high-temperature syntheses, and the effect of hydrogen bonding as well as π-Ar–M pyrazolate coordination on the geometry of the resulting structures.

## Results and Discussion

The commercial availability of a variety of magnesium alkyls offers a straightforward and clean synthetic route to magnesium amides.[5b,9] Hence the magnesium pyrazolate [{Mg(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)}$_2$] (**1**) (Figure 1) was prepared by alkane elimination from dibutylmagnesium in toluene in the presence of four equivalents of 3,5-diisopropylpyrazole (Scheme 1). Despite excess pyrazole (sixfold also examined), dimerization and coordination of only one pyrazole group per metal center is observed. This contrasts with the report on monomeric [Mg(*t*Bu$_2$pz)$_2$(*t*Bu$_2$pzH)$_2$], in which two equivalents of free pyrazole coordinate to the metal center.[5b]

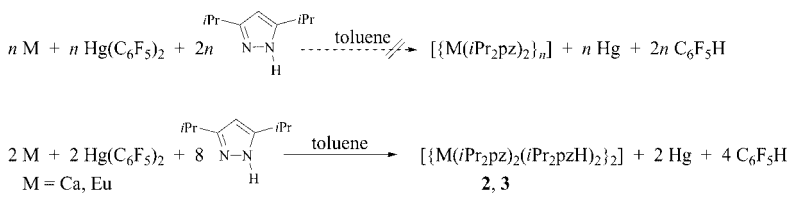


Scheme 1.

For the heavier congeners, metal dialkyls or "heavy Grignard" reagents are less accessible because of their inherent higher reactivity. Even though dibenzyl complexes of the heavier group 2 metals have been reported,[10] their synthesis is quite involved, making these reagents less competitive starting materials for our target compounds. To expand the synthetic schemes on hand for the alkaline earth metals, we recently reported on metal-based routes to heavy group 2 pyrazolates, circumventing problems encountered in salt metathesis.[5a] One of these, redox-transmetallation/ligand-exchange, has now been employed to prepare [{Ca(*i*Pr$_2$pz)$_2$-(*i*Pr$_2$pzH)$_2$}$_2$] (**2**) and [{Eu(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$] (**3**) (Figure 2 and Figure 3). However, the redox-transmetallation/ligand-exchange reaction of excess metal, *i*Pr$_2$pzH and Hg(C$_6$F$_5$)$_2$ (mol ratio 2:1) in toluene (M = Ca, Eu) did not go to completion to yield [{M(*i*Pr$_2$pz)$_2$}$_n$]. Instead, only 50% conversion of the organomercurial and the pyrazole was observed under these conditions, leading to the isolation of complexes **2** and **3** in good yields with respect to the pyrazole used (Scheme 2). Redox-transmetallation/ligand-exchange syntheses are normally carried out in polar solvents (S), giving [Ln(L)$_n$S$_m$] complexes,[3e,3g,3j,3l,5c,11] but use of a nonpolar solvent such as toluene enabled the preparation of homoleptic compounds, as demonstrated with [La(Odpp)$_3$] (Odpp = 2,6-diphenylphenolate).[12]

The phenomenon of an incomplete reaction due to the preferred formation of a "free-ligand" stabilized species is a recurring feature of group 2 pyrazolates syntheses.[5b,5c] In a similar fashion, the transamination reaction between alkaline earth metal bis[bis(trimethylsilylamido)] complexes [M{N(SiMe$_3$)$_2$}$_2$(thf)$_2$] (M = Ca, Sr, Ba) and Me$_2$pzH in thf yielded monomeric Me$_2$pz analogs [M(Me$_2$pz)$_2$(Me$_2$pzH)$_4$], instead of the expected Lewis base donor adducts [M(Me$_2$pz)$_2$(thf)$_n$].[5c] The formation of pyrazole adducts is a likely consequence of the stabilizing effect of hydrogen bonding (vide infra) between the anionic ligand and the free pyrazole, in addition to the strong donor properties of the latter, as also observed for compounds **1**–**3**. The energy gain through such a hydrogen bonding stabilization prevents the complete ligand-exchange reaction since all pyrazole is consumed when 50% of the mercurial is converted.

Surprisingly, the same reaction with either strontium or ytterbium metal repeatedly did not afford analogs of **2** and **3** (Scheme 3), even though this route has been successful with Ca and Sr in combination with thf or dme and 3,5-diphenylpyrazole,[5c] or with Yb, 3,5-diphenylpyrazole and HgPh$_2$.[3j,13] The redox-transmetallation/ligand-exchange reaction at room temperature led repeatedly to the recovery



Scheme 2.

of unreacted metal, $i$Pr$_2$pzH, and Hg(C$_6$F$_5$)$_2$. The use of more forcing conditions in refluxing toluene initiated the ligand rearrangement between the already formed strontium pyrazolate and remaining mercurial to form a unique heteroleptic trinuclear organomercurial [Hg$_3$($i$Pr$_2$pz)$_4$(C$_6$F$_5$)$_2$] (**4**) (Figure 5).

$$Sr + Hg(C_6F_5)_2 + 2\ i\mathrm{Pr}_2\mathrm{pzH} \longrightarrow Sr(i\mathrm{Pr}_2\mathrm{pz})_2 + Hg + 2\ C_6F_5H$$

$$2\ Sr(i\mathrm{Pr}_2\mathrm{pz})_2 + 3\ Hg(C_6F_5)_2 \longrightarrow [Hg_3(i\mathrm{Pr}_2\mathrm{pz})_4(C_6F_5)_2] + 2\ Sr(C_6F_5)_2$$

Scheme 3.

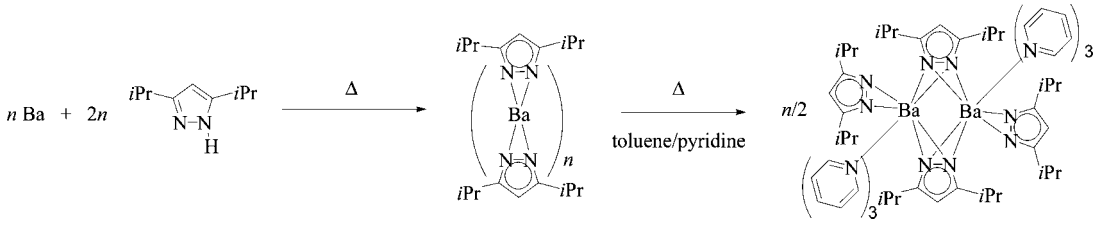
In the presence of unreacted bis(pentafluorophenyl)mercury, a rearrangement reaction can occur, leading to preferential crystallization of the novel complex **4**. Bis(pentafluorophenyl)mercury is normally resistant to protolysis[14] and in particular does not react with 3,5-diphenylpyrazole.[15] The Sr(C$_6$F$_5$)$_2$ from the rearrangement may undergo protolysis to Sr($i$Pr$_2$pz)$_2$ or decompose to SrF$_2$ by C–F activation.

A third synthetic route involving direct metallation at elevated temperatures (Scheme 4) was attempted for the synthesis of homoleptic 3,5-diisopropylpyrazolato complexes [{M($i$Pr$_2$pz)$_2$}$_n$] (M = Ca, Sr, Ba). Contrasting the straightforward syntheses of the corresponding 3,5-di-*tert*-butylpyrazolates [{M($t$Bu$_2$pz)$_2$}$_n$] (M = Ca, Sr, Ba),[5d] 3,5-diisopropylpyrazole failed to react with calcium and strontium under elevated-temperature conditions, suggesting a slightly less acidic character for $i$Pr$_2$pzH than for $t$Bu$_2$pzH. The addition of a drop of elemental mercury to the reaction mixture for surface amalgamation of the metal has been proven to be useful in combination with the slightly less reactive rare earth metals (e.g.[3h,3k–m]). In contrast, for the group 2 metals, direct metallation reactions under such conditions proceeded without the addition of mercury in other pyrazole systems (Ph$_2$pzH, $t$Bu$_2$pzH).[5c,d,f] Nevertheless, with $i$Pr$_2$pzH even mercury addition did not result in the desired reaction, and only ligand decomposition was observed in the reaction of Ca and Sr upon increasing temperature. Only for the most reactive alkaline earth metal barium metallation occurred, as indicated by the slowly solidifying reaction mixture. In contrast to the 3,5-di-*tert*-butylpyrazolates, the homoleptic species could not be sublimed in the Carius tube. Several extractions with hot toluene were also unsuccessful, thus indicating an oligo- or polynuclear structure comparable to [{Ba($t$Bu$_2$pz)$_2$}$_6$].[5d] Extraction of the crude material with pyridine afforded the toluene-soluble dinuclear [{Ba($i$Pr$_2$pz)$_2$(py)$_3$}$_2$] (**5**).

All compounds were analyzed by spectroscopic methods (IR; NMR except for **3**); **1**, **2**, and **5** show the expected signals corresponding to the pyrazole/pyrazolato ligands (**1**, **2**), or the pyridine donor and pyrazolato ligand in **5** in the $^1$H and $^{13}$C NMR spectra of the respective compounds. Variable temperature NMR studies indicated the fluxional behavior of complexes **1** and **2** in solution, forfeiting the differentiation between bridging and terminal pyrazolato or pyrazole [CH(pzH) and CH(pz)] ligands even at low temperature (–60 °C). This is in contrast to the homoleptic 3,5-di-*tert*-butylpyrazolate [{M($t$Bu$_2$pz)$_2$}$_n$] (M = Ca, Sr, Ba) analogs where a clear separation of the pyrazolate CH signals has been observed upon cooling, and they correspond to the different types of terminal and bridging pyrazolato ligands in the multinuclear species.[5d] Compound **4** reveals the characteristic signals of the pentafluorophenyl group, with $^3J_{(Hg,F)}$ appropriate for a mono(pentafluorophenyl)-mercury compound.[16]

The solid-state structures of the 3,5-diisopropylpyrazolate compounds **1**–**5** were determined by single-crystal X-ray crystallography; perspective views of **1**–**5** are shown in Figures 1–5. Compounds **1**–**3** are all dinuclear; **1** contains one pyrazole per metal center, while the larger metals satisfy their coordination sphere with two pyrazole donors in **2** and **3**, or three pyridine donors in **5**. Crystal data are given in Table 5, and selected bond lengths and angles are summarized in Tables 1–4.

The metal centers in the dinuclear compounds [{M($i$Pr$_2$pz)$_2$($i$Pr$_2$pzH)$_n$}$_2$] ($n$ = 1, M = Mg **1**; $n$ = 2, M = Ca **2**, Eu **3**, Figure 1) are further stabilized by intramolecular hydrogen bonding involving the acidic proton of the pyrazole donor and the lone pair on the pyridine-like nitrogen of the η$^1$-bonded pyrazolates. In contrast to the heavier analogs **2** and **3**, but in accordance with the dinuclear magnesium *tert*-butylpyrazolates [{Mg($t$Bu$_2$pz)$_2$}$_2$] and [{Mg($t$Bu$_2$pz)$_2$(thf)}$_2$],[4c] the bridging ligands in **1** bind fairly symmetrically in a μ-η$^1$:η$^1$-fashion and are slightly twisted out of plane (Mg1, Mg2, pz3, pz4) to reduce steric interactions of the pendant isopropyl groups with the terminal ligands. This results in a distorted tetrahedral coordination environment for magnesium [maximum deviation from the ideal tetrahedral angle 9.7(1)°]. Surprisingly, the terminal Mg–N bonds for the σ-η$^1$-pyrazolates [Mg–N



Scheme 4.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.077(2)–2.088(2) Å] are slightly elongated as compared with the bridging ligands [Mg–N 2.053(2)–2.061(2) Å]. In addition, there is no marked difference in Mg–N bond length (within experimental error) between the terminal anionic ligand pz2 and the neutral donor pzH1 [Δ(Mg–N) 0.003(4) Å]. Pz2 and pzH1 display short hydrogen-bonding contacts between H12 and N22 [1.56(5) Å; N12–H12–N22 155.66°]. Even though the corresponding pz5 and donor pzH6 on Mg2 show slightly larger differences [Δ(Mg–N) 0.011(4) Å], the hydrogen-bonding contacts are very similar [H62···N52 1.58(4) Å, N62–H62–N52 154.76°].

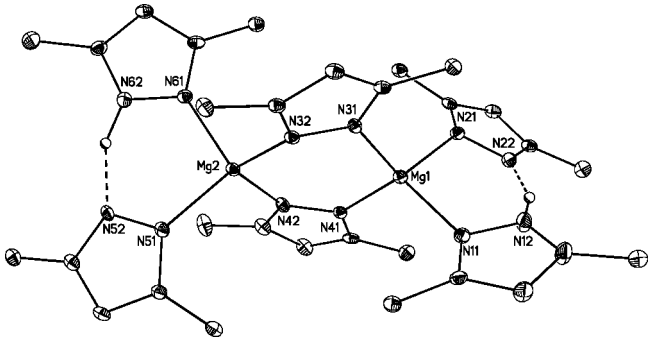


Figure 1. X-ray crystal structure of [{Mg(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)}$_2$] (**1**); the isopropyl groups and hydrogen atoms have been removed for clarity, except for those involved in hydrogen bonding.

A dinuclear structural motif identical to **1** has been reported for the zinc dimethylpyrazolate complex [{Zn(Me$_2$pz)$_2$(Me$_2$pzH)$_2$}$_2$], with a pseudotetrahedral geometry around the zinc atoms [N–Zn–N 99.6(2)° –113.8(2)°].[2a] Analogous to the magnesium complex **1**, the metal centers are bridged by two μ-η$^1$:η$^1$-Me$_2$pz ligands, but with significantly shorter bridging bond lengths [Zn–N 1.991(3) Å] than the terminal ligand [Zn–N 2.025(3) Å]. The zinc atoms are capped by a Me$_2$pz/Me$_2$pzH pair, which is linked together by hydrogen bonding [N1–H1···N2 141°; H1···N2 1.77 Å], where the position of the hydrogen atom is disordered over two possible sites (Table 1).

The effect of metal size on the pyrazolato binding mode is nicely demonstrated in the heavier analogs **2** and **3**. Here, the larger size of calcium and europium (Ca$^{2+}$ = 1.14 Å, Eu$^{2+}$ = 1.31 Å, Mg$^{2+}$ = 0.860 Å; CN = 6)[7] requires the coordination of two equivalents of pyrazole to afford the dinuclear structures [{Ca(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$] (**2**, Figure 2) and [{Eu(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$] (**3**, Figure 3). The larger metals also display a more pronounced side-on coordination of the pyrazolate ring, as well as a π-bonding interaction of the europium metal centers with the aromatic core of the ligand, leading to an increased torsion angle between the N–N ligand moiety and the metal–metal axis (N1–N2–M1–M2 18° **1**, 55° **2**, 80° **3**). The same trend has been reported previously for the structures of [{M(*t*Bu$_2$pz)$_2$(thf)}$_2$] (M = Ca/Yb; Sr/Eu)[3e,5f] and [{M(*t*Bu$_2$pz)}$_n$] (M = Ca, *n* = 3; M = Sr/Eu, *n* = 4), where a more extended π-coordination of the bridging pyrazolato ligand is observed upon increasing metal size (Ca/Yb to Sr/Eu (μ-η$^2$:η$^2$ Ca/Yb, μ-η$^5$:η$^2$ Sr/Eu) in the former complexes, or an overall increase in metal–ligand contact sites in the latter compounds [Ση$^n$ = 8 (Ca2), 9 (Ca1,3); Ση$^n$ = 12 (Sr1), 9 (Sr2)].[3e,3k,5d,5f]

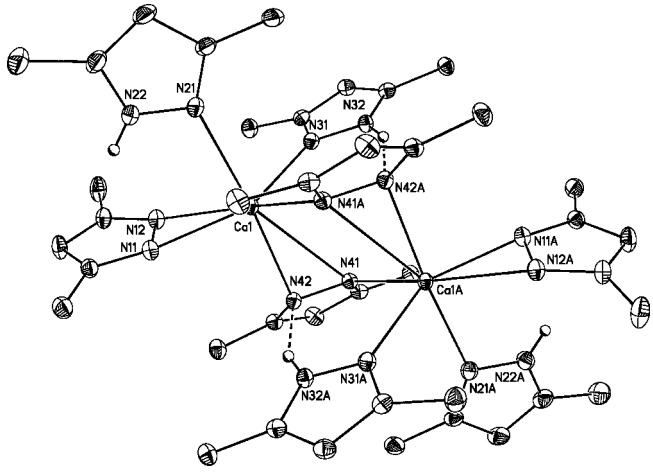

Figure 2. X-ray crystal structure of [{Ca(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$] (**2**); the isopropyl groups and hydrogen atoms have been removed for clarity, except for those involved in hydrogen bonding.

The additional donor in **2** and **3**, in comparison to **1**, also leads to binding modes of μ-η$^2$:η$^1$-pyrazolato ligands in **2** and new μ-η$^5$:η$^1$-pyrazolato ligands in **3** further stabilized by hydrogen bonding between the pyrazole donor and the bridging ligand [N32–H···N42# 2.138(3) Å, 147.88° **2**, 2.012(5) Å, 151.20° **3**] but *not* between the terminal *i*Pr$_2$pz and *i*Pr$_2$pzH ligands. To better indicate this novel type of bridging coordination of the pyrazolato ligand, the coordination mode could also be expressed as μ$_3$-η$^1$(H):η$^2$(Ca):η$^1$(Ca) in **2** and μ$_3$-η$^1$(H):η$^5$(Eu):η$^1$(Eu) in **3**. This arrangement prevents the second pyrazolate nitrogen from bridging the metal centers [M1–N42# closest contact 3.292(1) Å **2**, 3.471(4) Å **3**, cf. M–N$_{br}$ 2.405(2)–3.003(2) Å **2**, 2.684(4)–2.794(4) Å **3**] and results in rather unsymmetrical M–N bond lengths induced by the twisting of the bridging pyrazolato ligand. The hydrogen bonding of pzH3 to the bridging pyrazolato ligand pz4 leads to closer M–N(pzH3) contacts relative to those of the second pyrazole

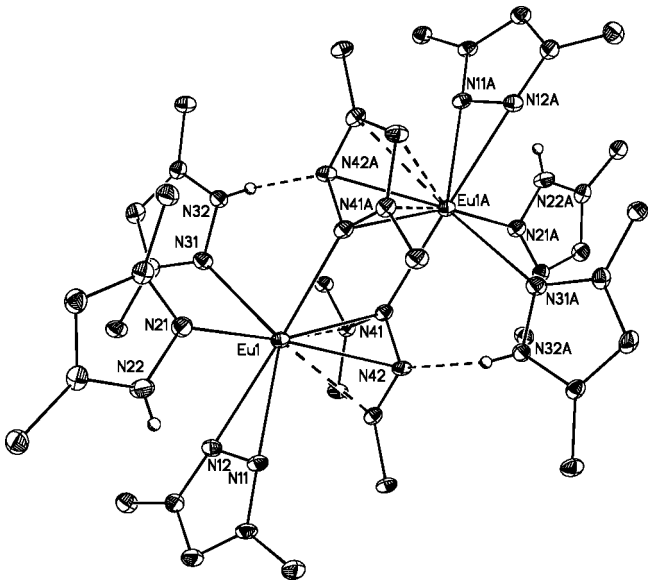

Figure 3. X-ray crystal structure of [{Eu($i$Pr$_2$pz)$_2$($i$Pr$_2$pzH)$_2$}$_2$] (**3**); the isopropyl groups and hydrogen atoms have been removed for clarity, except for those involved in hydrogen bonding.

donor pzH2, which also binds to the metal by means of its pyridine-like nitrogen [2.567(2) Å **2**, 2.693(4) Å **3**; cf. pzH3 2.455(2) Å **2**, 2.659(4) Å **3**] in an almost perpendicular orientation to the σ-bonded pyrazolate pz1 [dihedral angle 88.9(1)° **2**, 82.9(1)° **3**], thereby preventing further hydrogen-bonding contacts. Hence the novel type of bridging coordination of the pyrazolato ligand, μ-$\eta^2$:$\eta^1$ in **2** and μ-$\eta^5$:$\eta^1$ in **3**, is enforced by hydrogen bonding as one pz(N) is unable to further bridge the metal centers. A related structural feature of hydrogen-bonded, enforced $\eta^1$-pyrazolato coordination has been observed previously in [Nd($\eta^2$-Me$_2$pz)$_2$($\eta^1$-Me$_2$pz)(Me$_2$pzH)$_2$(py)].[31] The Eu–C43,45 distances in **3** are comparable with π-Eu–C bonds in [{Eu($t$Bu$_2$pz)$_2$}$_4$],[3k] which is consistent with the proposal of $\eta^5$-bonding, whereas the longer Ca–C distances for the smaller divalent metal are nonbonding (Table 2).

The coordination environment of the metal (formal coordination numbers 7 for **2**, and 8 for **3**) can be described in a simplified manner as a distorted trigonal bipyramid by considering the bonding through the center of the N–N bond for the σ-bonded pyrazolato ligand pz1 to be justified by the small bite angle [pz1 33.89(6)° **2**, 31.5(1)° **3**] and through the centroid (cen) of the N–N bond (**2**) or pyrazolate core (**3**) of the bridging ligand pz4. The pz4 ($\eta^2$ **2**, $\eta^5$ **3**) and N21 occupy the axial positions (169.4° **2**, 174.1° **3**), whereas the angle between N31–M–N41A (92.9° **2**, 87.6° **3**) in the equatorial plane is smaller than the others [cen(N11,12)–M–N31, cen(N11,12)–M–N41A 128.7°, 135.6° **2**, 113.7°, 151.1° **3**] because of hydrogen bonding.

The heteroleptic complex [{Ba($i$Pr$_2$pz)$_2$(py)$_3$}$_2$] (**5**, Figure 4) is a centrosymmetric dinuclear compound having nine-coordinate barium centers bridged by two chelating μ-$\eta^2$:$\eta^2$-pyrazolato ligands. Due to steric interactions with the third donor, the terminal $\eta^2$-pyrazolato ligands coordinate rather unsymmetrically to the metal [Ba–N 2.739(4) Å, 2.838(4) Å]. In contrast, the chelating, bridging ligand binds more symmetrically [Ba–N 2.806(4) Å, 2.884(4) Å; Ba–N# 2.991(4) Å, 3.060(4) Å], and the pyrazolate core is slightly inclined by 9.7(5)° towards Ba1 from an ideal perpendicular μ-$\eta^2$:$\eta^2$-bridging mode. This ligand inclination only provides very weak π-interactions between Ba1 and

C23, 25 [3.464(4) Å, 3.499(4) Å], contrasting the strong π-coordination observed in the absence of additional donors in the related complex [{Ba(*t*Bu$_2$pz)$_2$}$_6$] [Ba–C 3.10(1)–3.39(1) Å].[5d] The overall coordination sphere around the metal in **5** can be described as distorted octahedral with three pyridine donors and the N–N centroid (Ncen) of the bridging pyrazolato ligand in the equatorial plane [angles between neighboring ligands N31, N41, N51, Ncen(21,22), N31 94.1°, 82.0°, 90.9°, 97.1° respectively], whereas the axial positions are occupied by the terminal and the symmetry-generated bridging pyrazolato ligands [Ncen(21A,22A)–Ba–Ncen(11,12) 164.2°]. The Ba–N distances of the neutral pyridine donors range from 2.856(4) Å to 2.959(4) Å and thus lie between the bond lengths for the bridging pyrazolato ligand [2.806(4) Å–3.060(4) Å], though they are significantly longer than those for the terminal pyrazolato ligand [2.739(4) Å, 2.838(4) Å], as anticipated for a neutral donor (Table 3).

#1 indicates symmetry generated atoms: 2–*x*, 2–*y*, 1–*z*.

The difference in steric demand of *i*Pr$_2$pz compared with that of the *t*Bu$_2$pz ligand is apparent in the monomeric structure of the magnesium complex [Mg(*t*Bu$_2$pz)$_2$-(*t*Bu$_2$pzH)$_2$] [H···N 2.745(2) Å, N–H···N 153(3)°],[5b] which, despite the common metal, shows more similarity to the heavier monomeric dimethylpyrazolato analogs [M(Me$_2$pz)$_2$-(Me$_2$pzH)$_4$] (M = Ca, Sr) with hydrogen bonding between the terminal η$^1$-pyrazolato ligands and pyrazole donors [H···N 2.01(2) Å, N–H···N 156(2)° for Ca].[5c] The preferential formation of the present dinuclear, hydrogen-bonded complexes can be explained by the additional stabilization provided by the bridging of the metal centers, as the average bond length in **1** is shorter than in the monomeric [Mg(*t*Bu$_2$pz)$_2$(*t*Bu$_2$pzH)$_2$] whereas the overall metal coordination number is the same.[5b] The dinuclear formulation enables the formation of stronger/shorter hydrogen bonds. As the formation of **1** was also observed with an excess of *i*Pr$_2$pzH, targeting the formation of a monomeric [Mg(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$], the role of secondary interactions in coordination compounds must play a crucial role, a fact also observed in lanthanoid pyrazolate Nd(η$^2$-Me$_2$pz)$_2$-(η$^1$-Me$_2$pz)(Me$_2$pzH)$_2$(py)].[3l] For the larger analogs the dimerization leads to an increase in coordination number (**2** CN = 7, **3** CN = 8; cf. CN = 6 in [M(Me$_2$pz)$_2$(Me$_2$pzH)$_4$] M = Ca, Sr),[5c] while the average bond lengths are comparable despite the difference in coordination number.

In the structure of [Hg$_3$(*i*Pr$_2$pz)$_4$(C$_6$F$_5$)$_2$] (**4**, Figure 5), an open triangle of mercury atoms (Hg···Hg···Hg 55.66–67.22°) displays Hg1,2 as well as Hg2,3 [Hg···Hg 3.6395(6) Å, 3.7026(6) Å] each linked by two μ-η$^1$:η$^1$-3,5-diisopropylpyrazolato ligands, one nearly in the Hg$_3$ plane [Hg1,3, pz5 7.2(5)°; Hg2,3, pz3 26.9(5)°] and the other above or below the plane [Hg1,2, pz4 65.9(2)°; Hg2,3, pz2 77.0(3)°]. Both Hg1 and Hg3 have terminal C$_6$F$_5$ groups, and they form the open edge of the Hg$_3$ triangle [Hg···Hg 4.0644(7) Å]. It could be considered that the structure arises from the coordination of a [Hg(*i*Pr$_2$pz)$_4$]$^{2-}$ moiety to two [Hg-(C$_6$F$_5$)]$^+$ ions.

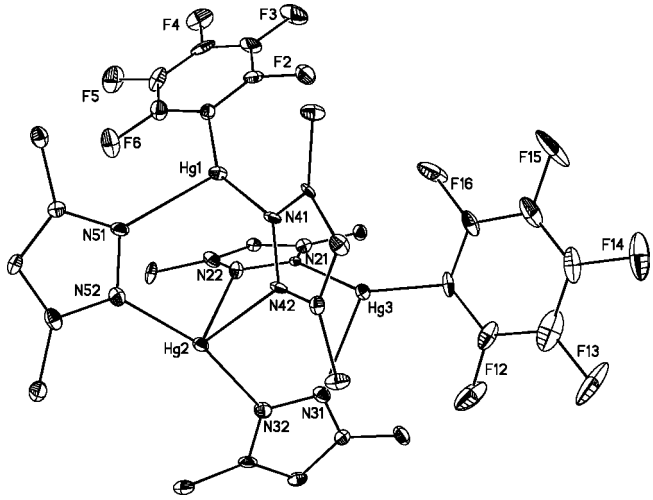

Figure 5. The crystal structure of [Hg$_3$(*i*Pr$_2$pz)$_4$(C$_6$F$_5$)$_2$] (**4**); the isopropyl groups and hydrogen atoms have been omitted for clarity.

Each terminal mercury atom, Hg1,3, is strongly bonded to a carbon and a nitrogen donor atom [Hg–C(N) ≈ 2.10 Å] and a further, more distant, nitrogen atom [Hg–N ≈ 2.43 Å]. Even the larger Hg–N bonds are well within the sum of the van der Waals radii of mercury (1.73 Å,[17] which is a conservative value, see also 1.9–2.0 Å,[17,18] or 2.1–2.2 Å[19]) and nitrogen (1.60 Å[20]). The geometry deviates considerably from the expected T-shape[21] (where the strongly bound ligands are linear) towards trigonal (angles ≈ 154°, 116°, 90°). Although coordination of the more distant nitrogen causes considerable bending of C1,11–Hg1,3–N41,21, any effect on the Hg–C distances [2.09(1) Å, 2.08(1) Å] is marginal, as they are near the Hg–C bond lengths observed in the homoleptic organomercurial Hg(C$_6$F$_5$)$_2$ [Hg–C 2.047(6)–2.052(6) Å][22] in the trinuclear [{Hg(C$_6$F$_4$)}$_3$]·(C$_6$H$_6$) [Hg–C 2.058(8) Å][23] or in the T-shaped three-coordinate [Hg(C$_6$F$_4$OH-*p*)$_2$(OH$_2$)] [Hg–C 2.047(7), 2.058(7) Å].[21b] Both the short and longer Hg–N distances are close to the values (ca. 2.15 Å, ca. 2.5 Å from X-ray powder diffraction data) for pseudo-polymeric mercuric pyrazolate.[24] By contrast with Hg1,3, Hg2 is four-coordinate with two short Hg–N bonds in a *transoid* arrangement [N32–Hg2–N52 163.5(4)°] and with two more distant nitrogen donors each nearly perpendicular to the N32–Hg2–N52 vector, resulting in overall sawhorse geometry. This is as expected for two strong and two weak donors

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bound to mercury,[21a,22,23] though distorted square planar geometry has also been observed.[21b,25] Both short and long Hg–N bond lengths compare favorably to those observed at Hg1,3 (Table 4).

The structural motif of trinuclear mercury complexes has been reported for a number of compounds,[26] although many structures contain mixed-valent or fractional valence species,[27] as seen in a series of $[\{Hg[P(Ph_2)CH_2P(Ph_2)]\}_3][A]_n$ with a range of different counterions (A = $CH_3SO_3$, $CF_3SO_3$, $PF_6$, $SiF_6$, $CF_3CO_2$),[27a] leaving the (*ortho*-phenylene)mercury derivatives $[\{Hg(C_6F_4)\}_3]$ and $[\{Hg(C_6H_4)\}_3]$ as the most closely related species.[23,26] However, these display closed $Hg_3$ unit, whereas **4** is open. Another difference of such compounds from **4** is the planar metal/ligand arrangement, favoring π-stacking with a variety of arenes (benzene, toluene, naphthalene, etc.).[23,26k] In the heteroleptic complex **4**, the trinuclear metal center is shielded by two pyrazolato ligands above and below the plane. In addition, the steric bulk provided by the isopropyl substituents prevents any potential stabilizing arene–Hg interactions.

## Conclusions

The increasing metal size in the 3,5-diisopropylpyrazolates **1**–**3** and **5** leads to a stepwise increase in coordination number [Mg 4, Ca 7, Eu 8, Ba 9], in addition to changes in the bridging ligand orientation from the exobidentate pyrazolato ligands in the magnesium complex **1**, via the already tilted, hydrogen-bonded μ-$\eta^1$:$\eta^2$-bridging pyrazolato ligands in the heavier metal analog **2** and μ-$\eta^1$:$\eta^5$ in **3**, to the almost perpendicular μ-$\eta^2$:$\eta^2$-bridging ligand and three pyridine donors in the barium complex **5**. These compounds display further examples of the amazing variety of binding modes of the pyrazolato ligand system and illustrate the unique role of secondary interactions in the stabilization of labile or highly reactive compounds. Intramolecular hydrogen bonding in pyrazolato complexes has previously only been reported between terminal ligands,[2a,4c,5b] enforcing an $\eta^1$-coordination over the otherwise preferred terminal $\eta^2$-chelation. The interaction with the μ-$\eta^1$:$\eta^n$ bridging ligands is a new structural feature and implies that minor steric effects or the potential of additional stabilization via hydrogen bonding of the ligand/donor can significantly influence the overall complex geometry. It is interesting to note that compounds **1**–**3** form preferentially over analogs of the oligonuclear $[M(t\mathrm{Bu}_2\mathrm{pz})_2]_n$ (M = Ca, Sr, Ba; $n$ = 3–6),[5d] as rationalized by the decreased steric demand of the $i\mathrm{Pr}_2$pz ligand and hence insufficient shielding of the metal centers. A polynuclear formulation for $[Ba(i\mathrm{Pr}_2\mathrm{pz})_2]_x$ provides an explanation for its hydrocarbon insolubility and the need for additional donors as in **5** to induce solubility and enable crystallization.

## Experimental Section

**General Remarks:** All preparations were carried out under an atmosphere of purified nitrogen. Pentane and toluene were predried with sodium, distilled under nitrogen from sodium/benzophenone, and stored in Schlenk flasks fitted with Teflon taps, or freshly distilled from sodium/potassium alloy and degassed in three freeze-pump-thaw cycles; pyridine was distilled from $CaH_2$ under nitrogen and stored in Schlenk flasks fitted with Teflon taps. 3,5-Diisopropylpyrazole, dibutylmagnesium (1.0 M solution in heptane), calcium, strontium, ytterbium, and europium metals were obtained commercially (+99.9% distilled ingots; europium ingots stored under oil); $Hg(C_6F_5)_2$ was prepared by a literature method.[28] IR data (4000–650 $cm^{-1}$) were obtained for Nujol or mineral oil mulls sandwiched between NaCl plates with a Perkin–Elmer 1600 or Perkin–Elmer Paragon FTIR spectrometer. $^1$H and $^{13}$C NMR spectra were recorded with Bruker Avance spectrometers (300 MHz; 25 °C) in [$D_6$]benzene and the chemical shifts referenced to the residual solvent signals. Melting points of air-sensitive compounds were obtained in capillaries sealed under nitrogen and are uncorrected.

**Synthesis of Compounds 1–5**

**$[\{Mg(i\mathrm{Pr}_2\mathrm{pz})_2(i\mathrm{Pr}_2\mathrm{pzH})\}_2]$ (1):** 3,5-Diisopropylpyrazole (0.63 g, 4.0 mmol) was dissolved in toluene (30 mL), dibutylmagnesium (1.0 M in heptane; 1.0 mL, 1.0 mmol) was added with a syringe, and the reaction mixture was heated at reflux for 2 h. Filtration, removal of the solvent, and recrystallization from hot pentane yielded very thin, colorless plates of **1** at room temperature (0.40 g, 84%). M.p. 76–79 °C. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.22 [s, 72 H, CH(C$H_3$)$_2$], 3.02–2.87 [m, 12 H, C$H$(CH$_3$)$_2$], 5.86 [s, 2 H, C4-H(pzH)], 5.88 [s, 2 H, C4-H($pz_{ter}$)], 5.99 [s, 2 H, C4-H($pz_{br}$)], 11.02 [br. s, 2 H, (pz)NH] ppm. $^{13}$C NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 23.3 [pzH, CH(*C*H$_3$)$_2$], 24.7 [pz, CH(*C*H$_3$)$_2$], 27.6 [pzH, *C*H(CH$_3$)$_2$], 28.7 [pz, *C*H(CH$_3$)$_2$], 97.3 [*C*H(pzH)], 97.6 [*C*H($pz_{ter}$)], 98.6 [*C*H($pz_{br}$)], 159.0 [*ipso*-*C*(pzH)], 165.0 [*ipso*-*C*(pz)] ppm. IR (Nujol): $\tilde{\nu}$ = 3307 (w), 3166 (m), 3087 (m), 1867 (m), 1728 (w), 1674 (w), 1575 (m), 1522 (s), 1504 (s), 1467 (s), 1422 (m), 1360 (m), 1302 (s), 1263 (s), 1176 (m), 1102 (s), 959 (w), 922 (m), 866 (s), 786 (s), 725 (m), 700 (m), 665 (m) $cm^{-1}$.

Attempted preparation of $[Mg(i\mathrm{Pr}_2\mathrm{pz})_2(i\mathrm{Pr}_2\mathrm{pzH})_4]$ by reaction of 3,5-diisopropylpyrazole (0.95 g, 6.0 mmol) and dibutylmagnesium (1.0 M in heptane; 1.0 mL, 1.0 mmol) in toluene (30 mL) led to the cocrystallization of thin plates of **1** and thin needles of $i\mathrm{Pr}_2$pzH.

**$[\{Ca(i\mathrm{Pr}_2\mathrm{pz})_2(i\mathrm{Pr}_2\mathrm{pzH})_2\}_2]$ (2):** Calcium metal in pieces (0.20 g, 5.0 mmol), bis(pentafluorophenyl)mercury (0.54 g, 1.0 mmol), and 3,5-diisopropylpyrazole (0.31 g, 2.0 mmol) were stirred in toluene (40 mL) for two days. Filtration, reduction of the solvent volume (20 mL), and cooling to –20 °C yielded colorless rods of **2** (0.29 g, 89% on pyrazole). M.p. 116–120 °C. $^1$H NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 1.21 [bd, 96 H, CH(C$H_3$)$_2$], 3.03 [br. s, 16 H, C*H*(CH$_3$)$_2$], 5.92 [s, 8 H, C4-H(pz)], 11.86 (b, 4 H, N-H) ppm. $^{13}$C

NMR (300 MHz, $C_6D_6$, 25 °C): $\delta$ = 24.0 [$CH(CH_3)_2$], 28.2 [$CH(CH_3)_2$], 97.8 [*C*H(pz)], 157.8 [*ipso*-C(pz)] ppm. IR (Nujol): $\tilde{\nu}$ = 3338 (m), 3167 (m), 3100 (w), 1638 (m), 1612 (w), 1561 (m), 1510 (s), 1460 (s), 1416 (m), 1303 (m), 1293 (m), 1276 (m), 1251 (m), 1176 (m), 1134 (s), 1070 (s), 1050 (m), 1011 (m), 991 (m), 966 (s), 892 (w), 878 (w), 805 (m), 782 (m), 726 (m), 692 (w), 669 (w) $cm^{-1}$.

**[{Eu(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$] (3):** Europium metal in pieces (0.76 g, 5.0 mmol), bis(pentafluorophenyl)mercury (0.54 g, 1.0 mmol), and 3,5-diisopropylpyrazole (0.31 g, 2.0 mmol) were stirred in toluene (40 mL) for two days. Filtration, reduction of the solvent volume (20 mL), and cooling to –20 °C yielded dark yellow rods of **3** (0.37 g, 96% on pyrazole). M.p. 88 °C. IR (Nujol): $\tilde{\nu}$ = 3329 (m), 3088 (m), 1930 (w), 1860 (w), 1819 (w), 1763 (w), 1713 (w), 1638 (m), 1556 (m), 1506 (s), 1464 (s), 1373 (s), 1275 (m), 1178 (m), 1135 (m), 1069 (s), 1019 (m), 967 (s), 805 (m), 721 (m) $cm^{-1}$.

**[Hg$_3$(*i*Pr$_2$pz)$_4$(C$_6$F$_5$)$_2$] (4):** Strontium metal in pieces (0.44 g, 5.0 mmol), bis(pentafluorophenyl)mercury (0.27 g, 0.5 mmol), 3,5-diisopropylpyrazole (0.32 g, 2.0 mmol) were heated at reflux in toluene (30 mL) for 48 h. Filtration and reduction of the solvent volume (20 mL) led to the isolation of very small, colorless plates after several days at room temperature. Yield 0.09 g (18% on mercury). M.p. 76–82 °C (melted), >110 °C (clear). IR (Nujol): $\tilde{\nu}$ = 3180 (m), 3097 (m), 1634 (m), 1573 (m), 1506 (s), 1362 (s), 1300 (m), 1263 (m), 1177 (m), 1128 (m), 1097 (s), 1076 (s), 1044 (s), 1010 (s), 963 (s), 874 (w), 792 (s), 718 (s) $cm^{-1}$. $^1$H NMR (300 MHz, [D$_6$]benzene, 25 °C): $\delta$ = 5.89 [s, 4 H, C4-H(pz)], 2.83 [m, 8 H, $CH(CH_3)_2$], 1.18 [d, 48 H, $CH(CH_3)_2$] ppm. $^{13}$C NMR: $\delta$ = 129.8 [*ipso*-*C*(pz)*i*Pr], 98.1 [*C*H(pz)], 28.6 [$CH(CH_3)_2$], 24.0 [$C(CH_3)_2$] ppm; $C_6F_5$ undetected. $^{19}$F NMR: $\delta$ = –115.8 (td, $^3J_{(F\text{-}F)}$ = 20 Hz, $^3J_{(Hg\text{-}F)}$ = 502 Hz, 4 F, F2,6), –155.3 (t, $^3J_{(F\text{-}F)}$ = 20 Hz, 2 F, F4), –161.9 (t, $^3J_{(F\text{-}F)}$ = 20 Hz, 4 F, F3,5) ppm.

**[{Ba(*i*Pr$_2$pz)$_2$(py)$_3$}$_2$] (5):** Barium metal in pieces (0.65 g, 5 mmol) and 3,5-diisopropylpyrazole (0.31 g, 2 mmol) were heated to 170 °C for 5 d in a sealed and evacuated (approx. $1 \times 10^{-3}$ Torr) Carius tube until the contents of the tube solidified. Extraction of the crude product [{Ba(*i*Pr$_2$pz)$_2$}$_n$] with a mixture of toluene (30 mL) and pyridine (15 mL) led to the isolation of colorless plates upon cooling to –20 °C. Yield 0.26 g (56%). M.p. 63–65 °C, 115 °C (solidifies again), >235 °C (decomposition). IR (Nujol): $\tilde{\nu}$ = 3178 (m), 3101 (m), 1858 (w), 1574 (s), 1502 (s), 1405 (s), 1360 (s), 1304 (s), 1261 (s), 1218 (w), 1177 (s), 1129 (sh), 1105 (s), 1047 (w), 994 (s), 882 (m), 846 (m), 725 (s), 747 (w), 699 (s), 682 (sh), 673 (w) $cm^{-1}$. $^1$H NMR (300 MHz, [D$_6$]benzene, 25 °C): $\delta$ = 8.48 [td, $^3J_{(H,H)}$ = 3.0 Hz, 6 H, *o*-H(py)], 6.98 [tt, $^3J_{(H,H)}$ = 8.0 Hz, 3 H, *p*-H(py)], 6.66 [tt, $^3J_{(H,H)}$ = 4.0 Hz, 6 H, *m*-H(py)], 5.97 (s, 4 H, H4-pz), 3.02 [sept, 8 H, $CH(CH_3)_2$], 1.26 [d, 48 H, $CH(CH_3)_2$] (partially desolvated) ppm. $^{13}$C NMR: $\delta$ = 157.2 [*ipso*-*C*(pz)-*i*Pr], 150.6 [*o*-*C*(py)], 135.7 [*p*-*C*(py)], 123.9 [*m*-*C*(py)], 98.1 [*C*H(pz)], 28.3 [$CH(CH_3)_2$], 24.0 [$CH(CH_3)_2$] ppm.

**Attempted Preparation of [{Yb(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$]:** Ytterbium metal in pieces (0.88 g, 5.0 mmol), bis(pentafluorophenyl)mercury (0.54 g, 1.0 mmol), and 3,5-diisopropylpyrazole (0.31 g, 2.0 mmol) were stirred in toluene (40 mL) for two days. Filtration, reduction of the solvent volume (20 mL), and cooling to –20 °C led to the subsequent recovery of 3,5-diisopropylpyrazole and bis(pentafluorophenyl)mercury toluene solvate.

**Attempted Preparation of [{Sr(*i*Pr$_2$pz)$_2$(*i*Pr$_2$pzH)$_2$}$_2$]:** Strontium metal in pieces (0.44 g, 5.0 mmol), bis(pentafluorophenyl)mercury (0.54 g, 1.0 mmol), and 3,5-diisopropylpyrazole (0.31 g, 2.0 mmol) were stirred in toluene (40 mL) for two days. Filtration, reduction of the solvent volume (20 mL), and cooling to –20 °C led to recovery of 3,5-diisopropylpyrazole and bis(pentafluorophenyl)mercury. Changing the ligand/mercurial stoichiometry to a ratio of 4:1 and heating the reaction mixture at reflux led to the isolation of **4**.

**X-ray Crystallography:** For compounds **1**–**5** a hemisphere of low temperature data was collected (monochromatic Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) by using a Bruker AXS SMART system, complete with 3-circle goniometer and APEX-CCD detector, for **1** and **4** and an Enraf–Nonius CCD area-detector instrument for **2**, **3**, **5** (Table 5). A total of $N$ unique reflections ($N_o$ [$I > 2\sigma(I)$] "observed") were used in least-squares refinement [anisotropic $U$ for non-hydrogen atoms, ($x$, $y$, $z$, $U_{iso}$)$_H$ constrained] after structure solution by Direct Methods as included in the XSEED or SHELXTL-Plus program package.[29] Absorption corrections were performed with the programs SADABS (**1**, **4**) and maXus (**2**, **3**,

**5**).[30] All carbon-bound hydrogen atoms were placed geometrically and refined, including free rotation about C–C bonds for methyl groups with $U_{iso}$ constrained at 1.2 for non-methyl groups, and 1.5 for methyl groups times $U_{eq}$ of the carrier C atom. The pyrazole N–H hydrogen atoms were located in the respective difference Fourier maps and refined isotropically.

CCDC-283035 to -283037 (for **1**–**3**), -608636 (for **4**), -299836 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We gratefully acknowledge support from the Monash University Small Grant Scheme, the Australian Research Council, and the National Science Foundation [Grants CHE-0108098 (including a supplement) and CHE-0505863], enabling the collaboration between Monash University and Syracuse University. Purchase of the X-ray diffraction equipment at Syracuse was made possible with grants from the National Science Foundation (Grants CHE-9527858 and CHE-0234912), Syracuse University, and the W. M. Keck Foundation.

# The Interplay between Yttrium and Barium or Copper Trifluoroacetates and *N*-Methyldiethanolamine: Synthesis of a Heterometallic $Y_3Cu$ Trifluoroacetate Complex and a Homometallic Ba-TFA 1D Polymer

**Shashank Mishra,*[a] Jianyong Zhang,[a] Liliane G. Hubert-Pfalzgraf,[a][†] Dominique Luneau,[b] and Erwann Jeanneau[b]**

**Keywords:** Heterometallic complexes / Yttrium / Copper / Barium / N,O ligands

The reactions between $[Y(TFA)_3(H_2O)_3]$ and either $[Cu(TFA)_2(MeOH)]$ or $[Ba(TFA)_2]_\infty$ in the presence of excess *N*-methyldiethanolamine ($mdeaH_2$) have been investigated in relation with their use as precursors for high Tc superconductors. They afford the heterometallic $Y_3Cu$ complex $[CuY_3(\mu_3\text{-}OH)(\mu\text{-}\eta^3\text{:}\eta^1\text{-}mdeaH)_3(\mu_3\text{-}\eta^3\text{:}\eta^1\text{:}\eta^1\text{-}mdeaH)_2(\eta^2\text{-}TFA)(\mu,\eta^2\text{-}TFA)_2](TFA)_2(H_2O)$ (**1**) and the homometallic Ba-TFA 1D polymer $[Ba_3(\eta^3\text{-}mdeaH_2)_2(\mu\text{-}\eta^3\text{:}\eta^1\text{-}mdeaH_2)_2(\eta^1\text{-}TFA)_2(\eta^2\text{-}TFA)_2(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^1\text{-}TFA)_2]_{1\infty}$ (**2**), respectively, in high yield. These compounds were characterised by X-ray diffraction and FT-IR, ESR (for **1**) and NMR (for **2**) spectroscopy. Single-crystal X-ray diffraction studies show the versatile bonding modes of the trifluoroacetate and *N*-methyldiethanolamine ligands, with the former acting not only as a terminal ($\eta^1$ and $\eta^2$) or bridging-chelating ($\mu,\eta^2$ and $\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^1$) ligand but also as a counterion, whereas the latter, either protonated or partially deprotonated, binds the metal centres in a chelating ($\eta^3$) or bridging-chelating ($\mu,\eta^3\text{:}\eta^1$ and $\mu_3\text{-}\eta^3\text{:}\eta^1\text{:}\eta^1$) manner. The triangular $Y_3$ unit [3.480(6)–3.550(6) Å] in the cation of **1** consists of one nine-coordinate and two eight-coordinate Y atoms, the former of which are quite scarce in alkoxide chemistry. The unique feature of the 1D polymeric structure of **2** is the secondary F···cation bond, which has not been observed so far for TFA ligands. In addition, it is the only example where the Ba atom is linked to monodentate, bidentate and bridging trifluoroacetate ligands simultaneously.

## Introduction

Fluorinated carboxylates, especially fluoroacetates, are the most common precursors for the elaboration of high Tc superconductor coatings.[1] For barium, their preferential decomposition into $BaF_2$ represents a means to avoid the formation of highly stable barium carbonate, which is detrimental to the superconducting properties. Mixed-metal species are a means to provide homogeneity at a molecular level in order to modify the reactivity pattern and solubility.[2] Various amino alcohols, such as 2,6-bis[(dimethylamino)methyl]-4-methylphenol (bdmmpH) and 1,3-bis(dimethylamino)propan-2-ol (bdmapH), have been shown to stabilize lanthanide–copper and alkaline-earth metal–copper heterometallic complexes with trifluoroacetate (TFA) ancillary ligands.[3] Compounds of different nuclearity, such as $[LaCu(TFA)_3(bdmmp)(bdmmpH)(OH)]_2$,[4] $LaCu_2(TFA)_4(bdmap)_3$,[5] $[LnCu(bdmapH)_2(hfacac)_2(TFA)L]$ [Ln = Y, Pr; hfacac = hexafluoroacetylactonate; L = 2-methyl-2,4,6-tris(trifluoromethyl)-1,3-dioxane-4,6-diolato],[6] $[LnCu_2(hfacac)(hfacacH)(bdmap)_3(OAc)(TFA)]$ (Ln = Pr, Nd),[6,7] $[Cu_3(bdmap)_3(TFA)_2]_2[Y_2(bdmap)_2(TFA)_6]$,[8] $[MCu(TFA)_2(bdmap)_2(H_2O)]_x$ (M = Ca, $x$ = 1; M = Sr, $x$ = 2),[9] $[Sr_2Cu_4(TFA)_4(bdmap)_6(OH)_2]$,[9] $[SrCu_2(TFA)_3(bdmap)_3]$[10] and $[BaCu_4(bdmap)_4(2\text{-}PyO)_4(TFA)_2]$,[11] have been isolated. To the best of our knowledge, no amino alcohol has been shown to bridge yttrium and barium (or a lanthanide and an alkaline-earth metal) so far. Further studies are desirable to have a better understanding of the reactivity of these TFA species and to access heterometallic complexes with the right stoichiometry for the formation of $YBa_2Cu_3O_{7-x}$ films.

We have been interested in the design and synthesis of new homo- and heterometallic TFA derivatives related to high Tc superconductors.[12–14] The 1D coordination polymer $[Ba_3Cu_2(\mu,\eta^2\text{-}TFA)_6(\mu,\eta^2\text{-}dmea)_4(MeOH)_2\cdot 2MeOH]_{1\infty}$ was recently reported by our lab from the reaction between copper powder and $[Ba(TFA)_2]_\infty$ in methanol under air and in the presence of *N*-dimethylethanolamine (dmeaH).[12] The use of *N*-methyldiethanolamine ($mdeaH_2$) instead of dmeaH led to co-crystallisation of $[Ba(\eta^1\text{-}TFA)_2(mdeaH_2)_2]$ and $[Cu(mdeaH)_2]$.[12] In continuation, we now wish to report the reactions between Y and Cu or Ba trifluoroacetates in the presence of *N*-methyldiethanolamine. These reactions afford the heterometallic, tetranuclear complex $[CuY_3(\mu_3\text{-}OH)(\mu\text{-}\eta^3\text{:}\eta^1\text{-}mdeaH)_3(\mu_3\text{-}\eta^3\text{:}\eta^1\text{:}\eta^1\text{-}mdeaH)_2$-

($\eta^2$-TFA)($\mu$,$\eta^2$-TFA)$_2$](TFA)$_2$($H_2O$) (**1**) and the homometallic Ba TFA 1D polymer [$Ba_3$($\eta^3$-mdea$H_2$)$_2$($\mu$-$\eta^2$:$\eta^1$:$\eta^1$-mdea$H_2$)$_2$($\eta^1$-TFA)$_2$($\eta^2$-TFA)$_2$($\mu_3$-$\eta^2$:$\eta^2$:$\eta^1$-TFA)$_2$]$_{1\infty}$ (**2**), respectively, which were characterised by X-ray diffraction and FT-IR, X-band ESR (for **1**) and NMR (for **2**) spectroscopy.

## Results and Discussion

### Reactions between TFA Derivatives

The reaction between [Y(TFA)$_3$($H_2O$)$_3$] and [Cu(TFA)$_2$-(MeOH)] in the presence of mdea$H_2$ afforded the heterometallic $CuY_3$ complex **1**. The reaction in the right stoichiometry improved the yield of the product [Equation (1)].

$$[Cu(TFA)_2(MeOH)] + 3\,[Y(TFA)_3(H_2O)_3] + 5\ mdeaH_2 \xrightarrow{thf} \underset{\mathbf{1}}{[CuY_3(\mu_3\text{-}OH)(mdeaH)_5(\eta^2\text{-}TFA)(\mu,\eta^2\text{-}TFA)_2](TFA)_2(H_2O)} + 6\ TFAH + 7\ H_2O \quad (1)$$

In contrast, no heterometallic Y-Ba species was obtained by treating [Y(TFA)$_3$($H_2O$)$_3$] with [Ba(TFA)$_2$]$_\infty$, even in the presence of excess mdea$H_2$. Instead, the 1D barium coordination polymer **2** was isolated and no yttrium derivative could be crystallised out. Complex **2**, which can also be obtained by treating [Ba(TFA)$_2$]$_\infty$ with 4/3 mol of mdea$H_2$ in thf, is different from the previously reported Ba TFA derivatives with mdea$H_2$ as ligand, namely the neutral complex [Ba(TFA)$_2$(mdea$H_2$)$_2$] (**3**)[12] or the ionic complex [Ba(mdea$H_2$)$_3$](TFA)$_2$ (**4**; Scheme 1).[13]

Heterometallic Y(Ln)-Ba derivatives are quite scarce when compared to heterometallic Y(Ln)-Cu[4–8,15] or Ba-Cu[16] derivatives and are limited to compounds where the connection between the metals is ensured by classical[17] or fluorinated[18] alkoxides or siloxides.[19] Lanthanide–alkaline-earth metal heterometallic derivatives stabilized by hydroxyquinoline or aminocarboxylic acids are also known.[20]

### Spectroscopic Characterisation

The FT-IR spectra of **1** and **2** show the presence of alcohol functionalities [$\nu$(OH) absorptions at 3413 and 3330 for **1** and 3313 cm$^{-1}$ for **2**] as well as trifluoroacetate groups in the metal coordination sphere. The $\nu_{as}(CO_2)$ absorption at high frequency (1698 cm$^{-1}$) suggests the presence of ionic TFA ligands, whereas that at 1660 cm$^{-1}$ indicates a chelating-bridging TFA in **1**. The overlap of the $\nu_{as}(CO_2)$ absorptions due to the presence of different TFA ligands (monodentate, bidentate and bridging) in **2** results in a strong broad absorption centred at 1680 cm$^{-1}$. Strong C–F and C–O absorption bands in the 1120–1210 cm$^{-1}$ range also characterise the spectra of **1** and **2**. Three characteristic absorptions for TFA derivatives are found in the 850–720 cm$^{-1}$ region.[12–14] The low-frequency absorptions at 632–404 cm$^{-1}$ are due to the $\nu$(M–O) and $\nu$(M–N) vibrations.[12–14] The $^1$H NMR spectrum of **2** indicates the presence of protonated *N*-methyldiethanolamine ligands in at least two different environments. It exhibits a broad peak at $\delta$ = 5.30 ppm, two triplets ($J$ = 6.0 Hz) at $\delta$ = 3.85 and 3.75 ppm, two broad peaks at $\delta$ = 2.82 and 2.53 ppm and a singlet at $\delta$ = 1.86 ppm due to OH, $OCH_2$, $NCH_2$ and NMe groups, respectively. The X-band ESR spectrum of polycrystalline **1** at room temperature exhibits a well-resolved hyperfine structure ($A_\parallel$ = 47 G) due to interaction of the unpaired electron with the nuclear spin ($I$ = 3/2) of both $^{63}$Cu and $^{65}$Cu (Figure 1). It reveals that the Cu$^{II}$ centre is indeed axial ($2.0 < g_\perp < g_\parallel$) with a $d_{x^2-y^2}$ ground state. The

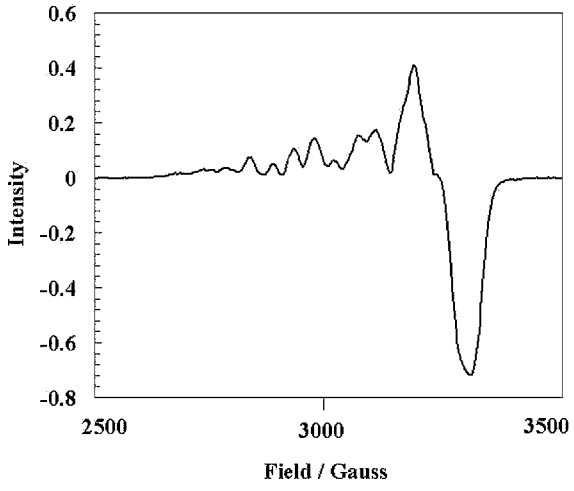

Figure 1. Room-temperature ESR spectrum of **1**.

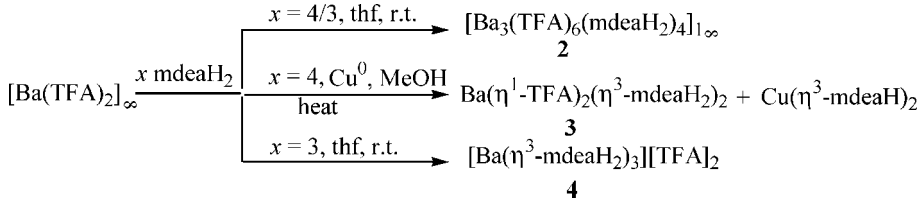

Scheme 1. Reactions of [Ba(TFA)$_2$]$_\infty$ with mdea$H_2$ with different stoichiometries and conditions.

values of the spin Hamiltonian parameters, $g_{\perp}$ = 2.047 and $g_{\parallel}$ = 2.281, are typical for a tetragonally distorted octahedral $Cu^{II}$ ion.[21]

### Molecular Structures of $[CuY_3(\mu_3\text{-}OH)(\mu\text{-}\eta^3\text{:}\eta^1\text{-}mdeaH)_3(\mu_3\text{-}\eta^3\text{:}\eta^1\text{:}\eta^1\text{-}mdeaH)_2(\eta^2\text{-}TFA)(\mu,\eta^2\text{-}TFA)_2](TFA)_2(H_2O)$ (1) and $[Ba_3(\eta^3\text{-}mdeaH_2)_2(\mu\text{-}\eta^3\text{:}\eta^1\text{-}mdeaH_2)_2(\eta^1\text{-}TFA)_2(\eta^2\text{-}TFA)_2(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^1\text{-}TFA)_2]_{1\infty}$ (2)

A single-crystal X-ray diffraction study of $[CuY_3(\mu_3\text{-}OH)(\mu\text{-}\eta^3\text{:}\eta^1\text{-}mdeaH)_3(\mu_3\text{-}\eta^3\text{:}\eta^1\text{:}\eta^1\text{-}mdeaH)_2(\eta^2\text{-}TFA)(\mu,\eta^2\text{-}TFA)_2](TFA)_2(H_2O)$ (**1**) revealed that it is an ionic complex (Figure 2, Table 1). All five amino alcohols are only partially deprotonated to afford mdeaH ligands. These are of two types, which act either in a doubly or triply bridging-chelating manner. The cationic species can be described as a regular triangular $Y_3$ unit [3.4805(6)–3.5503(6) Å] capped by oxygen atoms O10 and O6 of the mdeaH ligands. The Y atoms are eight-coordinate for Y1 and Y3 and nine-coordinate for Y2. Nine-coordinate yttrium atoms are rare in alkoxide chemistry, although they have been observed with poly(amino alkoxides).[22] The connection between yttrium atoms Y1, Y2 and the copper atom is achieved through oxygen atom O1M3, which is actually a hydroxide ligand, with a tetrahedral configuration, as well as by the oxygen atoms of two $\mu,\eta^2$-trifluoroacetates and one deprotonated oxygen of an *N*-methylethanolaminate ligand. The third trifluoroacetate ligand is linked in a chelating manner to Y2. The six-coordinate copper atom has an $O_5N$ environment where the Cu–O1 [2.549(4) Å] and Cu–O13 [2.453(4) Å] bond lengths are longer than the other Cu–O bond lengths (1.948 Å av.) as a combined result of the coordination with an alcohol functionality and a Jahn–Teller distortion.[23] The Cu–N1 bond length [2.028(4) Å] is in good agreement with those found in other copper complexes with N-heterocyclic ligands.[23] The Y–O bond lengths vary from 2.245(3)

to 2.520(3) Å, the order of variation being Y–O(μ,η²-mdeaH) < Y–O($\mu_3$-OH) ≈ Y–O($\mu_3$,η³-mdeaH) ≈ Y–O(η¹-mdeaH) ≈ Y–O(μ,η²-TFA) < Y–O(η²-TFA). The transannular Y–N bond lengths are longer (av. 2.615 Å) but are comparable to those reported for $[Y_2Cu_6(bdmap)_8(TFA)_{10}]$.[8] The distance between one TFA counteranion (O41) and the oxygen of the $\mu_3$-hydroxo group O1M3···O41 is 2.802(6) Å, which suggests hydrogen bonding. The $\mu_3$-OH must originate from the coordinated water of $[Y(TFA)_3(H_2O)_3]$ since **1** was obtained by treating $[Y(TFA)_3(H_2O)_3]$ with $[Cu(TFA)_2(MeOH)]$ and $mdeaH_2$ in anhydrous thf. This further confirms that the yttrium starting material is easily hydrolysed to form trinuclear $Y_3$ units.[14]

The structure of **2** is that of a homometallic Ba 1D coordination polymer of formula $[Ba_3(\eta^3\text{-}mdeaH_2)_2(\mu\text{-}\eta^3{:}\eta^1\text{-}mdeaH_2)_2(\eta^1\text{-}TFA)_2(\eta^2\text{-}TFA)_2(\mu_3\text{-}\eta^2{:}\eta^2{:}\eta^1\text{-}TFA)_2]_{1\infty}$. It contains two types of barium atoms, namely Ba1 and Ba2, which are present in a 2:1 ratio and form a zig-zag chain (Figures 3, 4 and 5). Selected bond lengths and angles are collected in Table 2. Polymer **2** can be seen formally as the association between $[Ba_2(\eta^3\text{-}mdeaH_2)_2(\mu\text{-}\eta^3{:}\eta^1\text{-}mdeaH_2)_2(\mu,\eta^2{:}\eta^1\text{-}TFA)_2]^{2+}$ and $[Ba(\eta^2\text{-}TFA)_2(\eta^1\text{-}TFA)_2]^{2-}$ units through one oxygen and one fluorine atom [Ba2···F = 3.010(3) Å] of μ,η²:η¹-TFA ligands, which overall act as unique triply bridging TFA ligands bonded in two different chelating manners [η²(O,O) and η²(O,F); Figures 3 and 4). The triply bridging $\mu_3$-η¹:η²:η¹ coordination mode is known for TFA (Scheme 2) for a Ba[24] and few other complexes,[25] but no secondary F···cation bond has been reported so far. Such metal–fluorine interactions appear to be a common feature for compounds of large elements such as alkaline-earth metals or lanthanides with fluorinated alkoxides or β-diketonates,[26] but are reported here for the first time with TFA.

Two types of amino alcohols coordinating to Ba1 are not deprotonated: one $mdeaH_2$ acts in a tridentate mode and

[a] Symmetry codes: (i) $2 - x, y, {}^{1}/_{2} - z$; (ii) ${}^{3}/_{2} - x, {}^{1}/_{2} - y, - z$.

the other one acts as a bridging ligand with one OH as well as a tridentate ligand. The coordination number of 10 around each Ba1 is achieved by two $\eta^3$-mdeaH$_2$ ligands, one $\eta^2$-TFA [actually the triply bridging one bonded in an $\eta^2$(O,O) manner], one $\eta^1$-mdeaH$_2$ (bridging) and an $\eta^1$-TFA (actually the triply bridging one bonded in a μ-O manner). Two $\eta^1$-TFA, two $\eta^2$-TFA and two triply bridging TFA ligands bonded in an $\eta^2$(O,F) manner provide a coordination number of 10 around Ba2 as well. The Ba1···Ba1# distance is 4.115(9) Å, whereas the Ba1···Ba2 ones are longer [5.292(1) Å]. The Ba–O(μ-mdeaH$_2$) bond lengths [2.906(4)–2.929(4) Å] are longer than the terminal Ba–OH [2.721(4)–2.769(4) Å] one (Table 2). The Ba1–O(TFA) bond lengths vary from 2.779(4) to 3.064(4) Å. The transannular Ba–N coordination bond lengths [3.001(6)–3.034(5) Å] are comparable with those reported in [Ba($\eta^1$-TFA)$_2$-(mdeaH$_2$)$_2$].[12] The Ba2 atom bears two monodentate and two bidentate trifluoroacetate ligands. The Ba2–O($\eta^1$-TFA) bond length [2.668(4) Å] is shorter than those for bidentate TFA [2.833(4)–2.863(5) Å] and bridging TFA [2.795(3)]. Compound **2** is the only example thus far where Ba is linked to both mono- and bidentate as well as bridging trifluoroacetate ligands.

The structure of **2** shows the versatility of the reactions between [Ba(TFA)$_2$]$_\infty$ and *N*-methyldiethanolamine (mdeaH$_2$) since it is the third Ba-TFA-mdeaH$_2$ derivative (Scheme 1). The two other derivatives have recently been reported by us.[12,13] The eight-coordinate Ba centre in [Ba($\eta^1$-TFA)$_2$(mdeaH$_2$)$_2$] (**3**) bears two monodentate dangling trifluoroacetate and two *N*-methyldiethanolamine ligands,[12] whereas ionic [Ba(mdeaH$_2$)$_3$][TFA]$_2$ (**4**) has a nine-coordinate $Ba^{2+}$ cation surrounded by three tridentate *N*-methyldiethanolamines, with two trifluoroacetate ligands acting as counterions.[13] No Ba···F short interactions are found in the solid. Strict control of the stoichiometry is required for access to a specific Ba-TFA adduct with the neutral mdeaH$_2$ ligand. The absence of deprotonation of amino alcohols in Ba-TFA adducts, probably due to the large radius of $Ba^{2+}$ cation, precludes the formation of Y-Ba heterometallic complexes. In contrast, the reaction between Y and Cu TFA derivatives proceeds with partial deprotonation of amino alcohols and removal of some TFA as TFAH to form heterometallic compounds.

## Experimental Section

All reactions were carried out under argon by using standard Schlenk-tube and vacuum-line techniques. Solvents were purified by standard methods. Trifluoroacetic acid (TFAH) was stored over molecular sieves. [Ba(TFA)$_2$], [Cu(TFA)$_2$(MeOH)][12,13] and [Y(TFA)$_3$(H$_2$O)$_3$][14] were prepared as reported previously. Analytical data were obtained from the Service Central d′Analyses du CNRS. FT-IR spectra were recorded as Nujol mulls with a Perkin–Elmer Paragon 500 spectrometer. NMR spectra were recorded with a Bruker AC-300 spectrometer. The ESR spectrum (X-band, 9.4 GHz) was obtained at room temp. for the powder with a Bruker spectrometer (microwave power of 10 mW, modulation frequency of 100 kHz). Diphenylpicrylhydrazyl (DPPH) was used as an internal reference ($g$ = 2.0036).

**Synthesis of [CuY$_3$(μ$_3$-OH)(mdeaH)$_5$($\eta^2$-TFA)(μ,$\eta^2$-TFA)$_2$](TFA)$_2$(H$_2$O) (1):** MeN(C$_2$H$_4$OH)$_2$ (0.5 mL, excess) was added dropwise to a greenish blue solution of [Cu(TFA)$_2$(MeOH)] (0.276 g, 0.85 mmol) and [Y(TFA)$_3$(H$_2$O)$_3$] (0.408 g, 0.85 mmol) in thf (20 mL). The colour of the solution changed to blue in a few minutes. After stirring overnight, blue crystals were obtained by layering the medium with Et$_2$O (0.29 g, 67% based on Y). The reaction in the right stoichiometry {[Cu(TFA)$_2$(MeOH)] (0.095 g, 0.26 mmol), [Y(TFA)$_3$(H$_2$O)$_3$] (0.381 g, 0.73 mmol), MeN(C$_2$H$_4$OH)$_2$ (0.5 mL, excess)} improved the yield of the product (0.31 g, 78%). $C_{35}H_{62}CuF_{15}N_5O_{22}Y_3$ (1520.1): calcd. C 27.65, H 4.11, N 4.61; found C 27.35, H 4.09, N 4.57. IR (nujol): $\tilde{\nu}$ = 3413 cm$^{-1}$ w, 3330 m [ν(OH)]; 1698 s, 1660 m [$\nu_{as}$(CO$_2$)], 1462 s [$\nu_s$(CO$_2$)], 1213 s, 1195 s, 1139 s [ν(C–F)], 844 w, 800 m, 723 m, 632 w, 615 w, 597 w, 588 w, 557 w, 541 w, 521 w, 459 m.

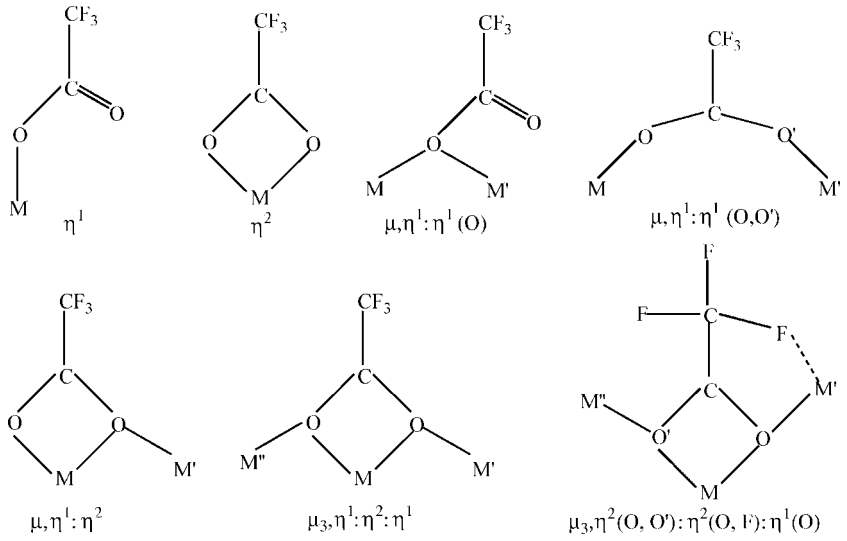

Scheme 2. Various bonding modes observed in TFA complexes.

**$[Ba_3(\eta^3\text{-mdeaH}_2)_2(\mu\text{-}\eta^3\text{:}\eta^1\text{-mdeaH}_2)_2(\eta^1\text{-TFA})_2(\eta^2\text{-TFA})_2(\mu_3\text{-}\eta^2\text{:}\eta^2\text{:}\eta^1\text{-TFA})_2]_{1\infty}$ (2):** $MeN(CH_2CH_2OH)_2$ (0.5 mL, excess) was added to a solution of $[Y(TFA)_3(H_2O)_3]$ (0.88 g, 1.83 mmol) and $[Ba(TFA)_2]$ (0.67 g, 1.84 mmol) in thf (20 mL) and the medium was stirred overnight. Colourless needles (0.81 g, 84% based on Ba) were obtained at room temp. by concentration (3 mL). Anal: found (calcd.) for $C_{32}H_{52}Ba_3F_{18}N_4O_{20}$ (1566.76): calcd. C 24.50, H 3.31, N 3.57; found C 24.39, H 3.27, N 3.56. IR (nujol): $\tilde{\nu}$ = 3313 $cm^{-1}$ br [ν(OH)], 1670 s [$\nu_{as}(CO_2)$], 1461 s [$\nu_s(CO_2)$], 1194 s, 1130 s [ν(C–F)], 836 s, 787 s, 763 m, 714 s, 598 m, 512 m, 404 m. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 5.30 (br., 8 H, OH), 3.85, 3.75 (t, $J$ = 6.0 Hz, 16 H, $OCH_2$), 2.82, 2.53 (br., 16 H, $NCH_2$), 1.86 ppm (s, 12 H, NMe). Compounds **1** and **2** are soluble in thf but insoluble in toluene, *n*-hexane and diethyl ether. Unlike **2**, which is moderately soluble in chloroform and dichloromethane, **1** is completely insoluble in these solvents.

**Crystallography:** Suitable crystals of **1** were obtained by layering its thf solution with $Et_2O$ whereas a concentrated thf solution of **2** gave crystals at room temp. suitable for X-ray crystallography. X-ray single-crystal diffraction data were collected with a Nonius Kappa CCD diffractometer ($\lambda$ = 0.71073 Å) using the COLLECT software (Nonius BV, 1997–2000) and processed with the DENZO reduction software.[27] The structure of **1** was solved and refined on $F^2$ using SHELXTL[28] whereas **2** was solved with the SIR97 program[29] and refined with CRYSTALS.[30] All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in the final refinement in calculated positions with isotropic thermal parameters. Crystal data for $C_{35}H_{62}CuF_{15}N_5O_{22}Y_3$ (**1**): $M_w$ = 1520.17, $T$ = 163(2) K, triclinic, $P\bar{1}$, $a$ = 12.646(2), $b$ = 15.100(3), $c$ = 15.793(3) Å, $\alpha$ = 104.134(1)°, $\beta$ = 90.185(1)°, $\gamma$ = 96.564(1)°, $V$ = 2903.68(9) $Å^3$, $Z$ = 2, $\mu$(Mo-$K_\alpha$) = 3.451 $mm^{-1}$, reflections collected 24438, independent reflections 13214 [$R$(int) = 0.043], data/restraints/parameters 13214/0/766, $R$ [$F^2 > 2\sigma(F^2)$] = 0.055, $wR$ ($F^2$) = 0.150, $R$ (all data) = 0.078, $wR$ (all data) = 0.168, GOF = 1.17, residual electron density: –0.996 and 1.424 e $Å^{-3}$.

$C_{32}H_{52}Ba_3F_{18}N_4O_{20}$ (**2**): $M_w$ = 1566.76, $T$ = 150(2) K, monoclinic, $C2/c$, $a$ = 17.008(5), $b$ = 18.376(5), $c$ = 17.659(5) Å, $\beta$ = 92.436(5), $V$ = 5514(3) $Å^3$, $Z$ = 4, $\mu$(Mo-$K_\alpha$) = 2.25 $mm^{-1}$, reflections collected 8528, independent reflections 8324 [$R$(int) = 0.069], data/restraints/parameters 5887/6/348, $R$ [$F^2 > 2\sigma(F^2)$] = 0.056, $wR(F^2)$ = 0.060, $R$ (all) = 0.087, $wR$ (all data) = 0.076, GOF 1.08, residual electron density: –1.01 and 1.57 e $Å^{-3}$.

CCDC-244549 (for **1**) and -296883 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Hierarchical, Lithium-Templated Assembly of Helicate-Type Complexes: How Versatile Is This Reaction?

**Markus Albrecht,*[a] Marcel Fiege,[a] Miriam Baumert,[a] Marita de Groot,[a] Roland Fröhlich,[b] Luca Russo,[c] and Kari Rissanen[c]**

**Keywords:** Dinuclear complexes / Helicates / Hierarchical assembly / Chelate ligands / N,O ligands

Catechol ligands that bear carbonyl functions such as esters or aldehydes in the 3-position (**1a**–**c**-$H_2$) form triple-stranded, helicate-type complexes $[Li_3(\mathbf{1a}–\mathbf{c})_6Ti_2]^-$ with titanium(IV) and the corresponding double-stranded compounds $[Li_2(\mathbf{1a}–\mathbf{c})_4B_2]$ with boron(III) in hierarchical, lithium-templated processes. The related 8-hydroxyquinoline ligands **2a**,**b**-H can be used for the formation of similar complexes $[Li_3(\mathbf{2a},\mathbf{b})_6M_2]^+$ with cobalt(II), nickel(II), or zinc(II). A prerequisite for the formation of the lithium-bridged dimers is a negative charge of the mononuclear complexes, which are able to electrostatically attract the lithium cations and thus compensate the repulsion between the cations.

## Introduction

Hierarchical processes are frequently observed in the formation of natural and non-natural aggregates.[1–7] The build-up of viruses or proteins, for example, depends on the specific interplay of binding interactions of different strength.[8]

Recently, we described the hierarchical assembly of dinuclear, helicate-type coordination compounds[9–15] that possess three lithium cations bridging mononuclear building blocks. Here, in a first "recognition event", mononuclear catechol complexes are formed that bear carbonyl units in the 3-position of the ligands. These provide a second binding site (Figure 1) that is ideal for the coordination of lithium cations that form three bridging units between two mononuclear moieties in a second "recognition event".[16–26]

Coordination compounds of this type have been found for derivatives of 3-carbonyl-substituted catechols (carbonyl = aldehyde, ketone, ester) with titanium(IV) and gallium(III) ions. The resulting dinuclear, helicate-type dimers $[Li_3\{(ligand)_6M_2\}]^{n-}$ (M = Ti, $n$ = 1; M = Ga, $n$ = 3), are in equilibrium with the monomeric complex units. This equilibrium has been thoroughly investigated by NMR spectroscopic and ESI FT-ICR MS methods.[16]

In addition, a related equilibrium was found for monomeric and dimeric catecholate complexes with molybdenum(VI) centers. Here, only two catechols bind to each of the metal centers as the remaining coordination site is blocked by two *cis* arranged oxo units. In case of the dimer, the dioxomolybdenum units take part in the bridging of the three lithium cations.[27]

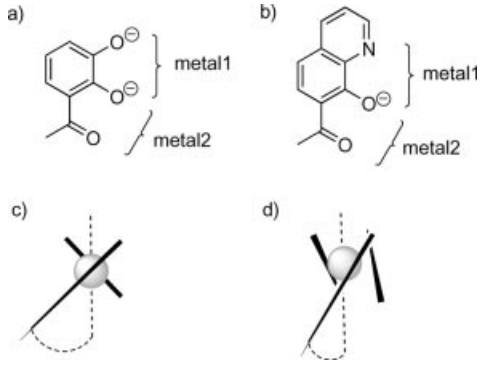

Figure 1. Representation of the two metal binding sites in carbonyl-substituted catecholate (a) and related 8-quinolinate ligands (b) and schematic representations of the relative orientation of chelating ligands in tetrahedral bis-ligand (c) or octahedral tris-ligand complexes (d).

At first sight the hierarchical assembly of helicates seems to be limited to very special examples. However, in this manuscript we report some new compounds to show that the formation of such helicate-type complexes is more general and is not limited to triple-stranded systems or catechol ligands. We also show that the dimerization depends strongly on the electrostatic attraction between negatively charged metal complexes and lithium cations.

## Results and Discussion

### General Considerations

In our recent studies on the hierarchical, lithium-templated assembly of dinuclear, helicate-type complexes, 3-carbonyl-substituted catechol derivatives were used as ligands (see Figure 1, a).[16,27] Compounds of this type provide two binding sites for metal ions: a first metal can be bound to the catecholate unit, while a second metal ion might coordinate to the chelating unit formed by the internal catecholate oxygen atom and the carbonyl oxygen. A tilt angle of 90° between the two chelating units seems to be appropriate in order to allow the formation of the dimeric, lithium-bridged compounds.

A similar geometry to that of the catechol derivatives can be found for 7-carbonyl-substituted 8-hydroxyquinolines (Figure 1, b). Although this ligand has different electronic features compared to the catecholates, it should be able to coordinate two different metal ions and form hierarchically assembled heteronuclear coordination compounds.

Another problem that will be addressed in this study is the formation of double-stranded vs. triple-stranded lithium-bridged dinuclear complexes. Double-stranded coordination compounds are formed if metal cations are introduced that prefer a tetrahedral coordination geometry, while the corresponding triple-stranded systems are formed with octahedral metal centers. Due to the different tilt angles of the projection of the ligand planes on the main axis of the complex unit (see Figure 1c,d), one kind of ligand can form both double- and triple-stranded compounds if the spacer with the lithium cations possesses some flexibility.

In earlier studies we have shown that, due to the donor strength of the carbonyl unit, ester-substituted ligands are the most appropriate to obtain a monomer–dimer equilibrium of lithium-bridged complexes, with the dimer being the dominant species.[16] Therefore we now mainly discuss complexes with the ester-substituted ligands **1a**,**b**-$H_2$ and **2a**,**b**-H. In addition, we have used 2,3-dihydroxybenzaldehyde (**1c**-$H_2$) for comparison studies (Figure 2).

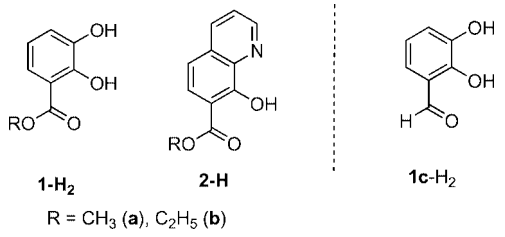

Figure 2. Ester-substituted catechol (**1a**,**b**-$H_2$) and 8-hydroxyquinoline ligands (**2a**,**b**-H) and 2,3-dihydroxybenzaldehyde (**1c**-$H_2$).

### Triple- and Double-Stranded, Helicate-Type Complexes Based on Catecholate Ligands

Recently we described a series of X-ray structures of dinuclear titanium(IV) complexes of carbonyl-substituted catecholate ligands with aldehyde, ketone, or ester sidechains.[16,28,29]

A representation of the dimers Li[$Li_3${(**1a**–**c**)$_3$Ti}$_2$] is shown in Figure 3. The side view of the complex shows the two pseudo-octahedral titanium(IV) centers and the bridging tetrahedral lithium cations binding to the carbonyl and to the internal catecholate oxygens.

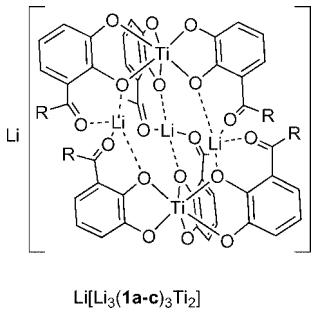

Figure 3. Schematic representation of the dimers Li[$Li_3${(**1a**–**c**)$_3$-Ti}$_2$].

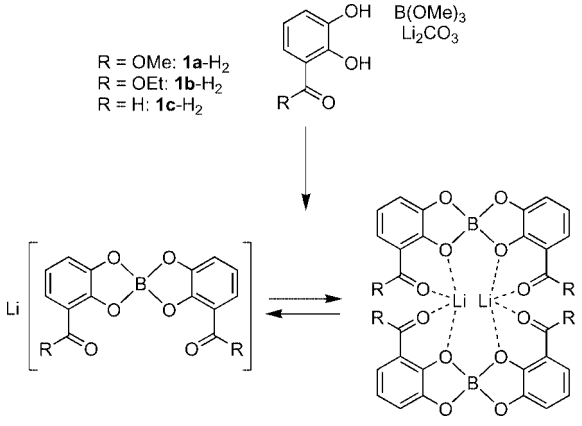
In order to obtain a double-stranded system, we substituted the titanium(IV) ions by boron(III). This ion can only bind two catecholates to form a pseudo-tetrahedral coordination compound. Two of the carbonyl-substituted mononuclear units [(ligand)$_2$B]$^-$ should be able to form a double lithium-bridged dinuclear complex. We performed the reaction of the catechol ligands **1a**–**c** with boric acid in the presence of lithium carbonate.[30] The complexes are still contaminated with free ligand in most cases, and pure material can only be obtained in minor amounts by crystallization (Scheme 1).



Scheme 1.

Well resolved NMR spectra of "Li[(**1a**–**c**)$_2$B]" can be obtained in deuterated chloroform. For example, only one set of signals can be observed for the complex of the aldehyde derivative **1c** in this solvent at $\delta$ = 9.08 (s, 1 H), 7.01 (dd, $J$ = 7.7, 1.1 Hz, 1 H), 6.82 (t, $J$ = 7.7 Hz, 1 H) and 6.67 ppm (dd, $J$ = 7.7, 1.1 Hz, 1 H). The high-field shift of the signal of the aldehyde proton to $\delta$ = 9.08 ppm seems to be indicative of a dimeric structure for this complex.[16] In this case the aldehyde proton of one complex unit is located in the anisotropic region of the aromatic moieties of the second.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

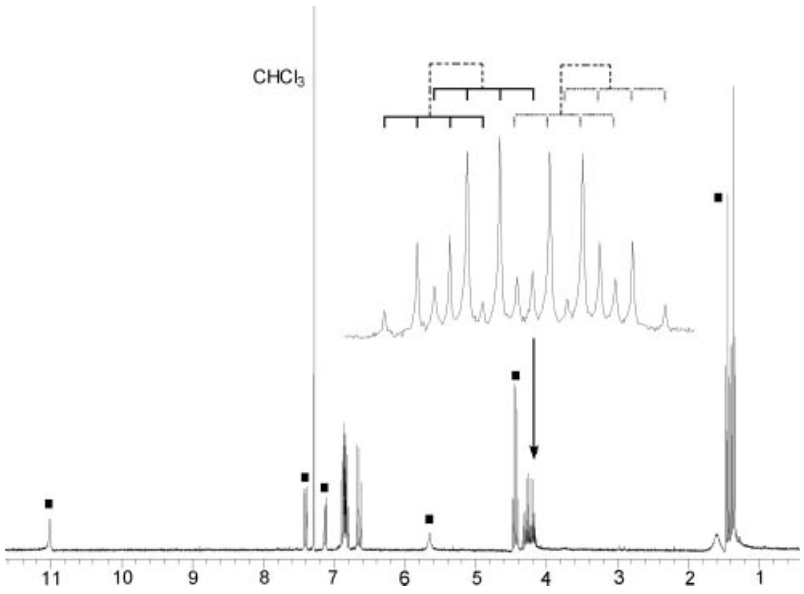


Figure 4. $^1$H NMR spectrum of "Li[(**1b**)$_2$B]" in deuterated chloroform showing the signals of the complex and the free ligand **1b**-H$_2$ (■). The inset shows the doublet of quartets of the diastereotopic methylene protons in the complex.

Figure 4 shows the $^1$H NMR spectrum of "Li[(**1b**)$_2$B]" in deuterated chloroform as a representative example. Signals of the free ligand can be observed together with the resonances of the complex. The aromatic protons are observed in the region $\delta$ = 6.6–6.9 ppm as multiplets. The most informative resonances can be observed for the ethyl group. The methyl signal is detected as a triplet ($J$ = 7.2 Hz) at $\delta$ = 1.37 ppm, while the methylene protons are diastereotopic and appear as two doublets of quartets at $\delta$ = 4.19 and 4.28 ppm ($J_{gem}$ = 10.8 Hz). The high-field shifts of the protons of the ethyl ester indicate that a dimeric complex should be present, although no final decision can be made based on the NMR spectra.

The dimeric species [Li$_2${(**1a**–**c**)$_2$B}$_2$] possess no charge and therefore cannot be detected directly by mass spectrometry. However, we were able to detect characteristic fragments by ESI MS. Peaks of the complexes with ligand **1a** are observed in the negative detection mode at *m*/*z* 343 [(**1a**)$_2$B]$^-$ and 693 [Li{(**1a**)$_2$B}$_2$]$^-$; [K{(**1a**)$_2$B}$_2$]$^-$ is found at *m*/*z* 725 as an impurity. The positive ESI mass spectrum shows a peak for [Li$_3${(**1b**)$_2$B}$_2$]$^+$ at *m*/*z* 763. Fortunately, we were able to obtain X-ray quality crystals of dimeric [Li$_2${(**1a**)$_2$B}$_2$] from chloroform.

The dimer crystallizes in the space group *Cc*, with a noncrystallographic twofold axis perpendicular to the plane formed by the four centers (Li and B). This results in two nonequivalent catecholate ligands, which is in contrast to the high-symmetry spectrum that is observed by NMR spectroscopy. Two of the ligands in the crystal are orientated more or less parallel to the B–B axis, while the others are severely tilted with respect to this axis (Figure 5). This unsymmetrical orientation of the ligands is probably due to the tendency to reduce strain at the bridging lithium cations. The boron and lithium cations adopt a distorted tetrahedral coordination geometry, with B–B, Li–Li, and Li–B separations of 4.456, 4.255, and 3.158–3.187 Å, respectively.

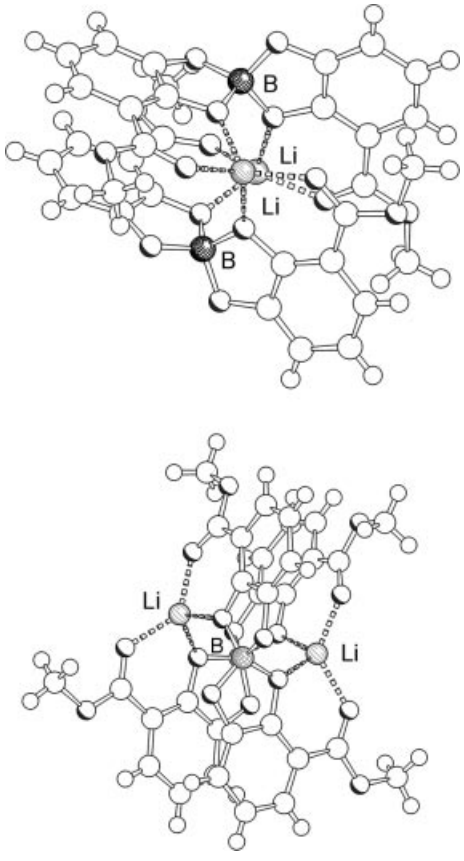

Figure 5. Views of the solid-state structure of dimeric [Li$_2${(**1a**)$_2$B}$_2$] down the Li–Li (top) and down the B–B axis (bottom).

The catecholate complexes with boron show a green or blue fluorescence in chloroform solution. Thus, upon excitation at $\lambda$ = 265 or 363 nm the aldehyde Li[(**1c**)$_2$B] shows an emission maximum at $\lambda$ = 476 nm. The corresponding

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methyl ester shows emission at $\lambda$ = 393 nm when excited either at $\lambda$ = 248 or 326 nm.

### Triple-Stranded Complexes Based on 8-Hydroxyquinolinate Ligands

8-Hydroxyquinoline and catechol are sterically similar chelating units for metal ions[31] as a five-membered heterocycle is formed upon coordination of the metal. However, their electronic features are severely different. In the deprotonated form, catecholate possesses a charge of 2– while 8-hydroxyquinolinate is a mono anion (see Figure 1). In order to test the versatility of the lithium-templated dimerization of complex units, we decided to substitute the catecholate moiety by 8-hydroxyquinolinate.

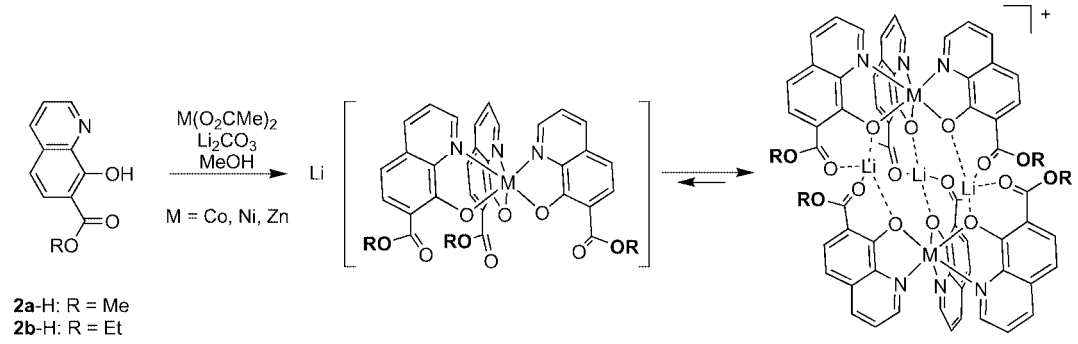
The methyl and ethyl esters **2a**-H and **2b**-H were prepared by simple sulfuric acid catalyzed esterification of 8-hydroxyquinoline-7-carboxylic acid in the corresponding alcohol as solvent.[32]

In initial experiments, coordination studies of ligands **2a/b**-H were performed with aluminium(III) and gallium(III) salts. Elemental analysis of the resulting complexes showed a 3:1 ligand-to-metal ratio. NMR spectroscopy revealed complicated spectra with broad signals, probably due to a *syn*/*anti* isomerization. However, the positive-ion ESI mass spectra showed the formation of the complexes [(**2a**,**b**)$_3$Ga/Al]. Cationic species can be observed at *m*/*z* 656 [(**2a**)$_3$AlNa]$^+$, 676 [(**2b**)$_3$AlH]$^+$, 676 [(**2a**)$_3$GaH]$^+$, and 718 [(**2b**)$_3$GaH]$^+$.[33]

Addition of lithium perchlorate to solutions of [(**2a**,**b**)$_3$Ga/Al] in [D$_4$]MeOH does not alter the NMR spectra, and the ESI mass spectra do not show the formation of "{Li$_3$[(**2a**,**b**)$_3$Ga/Al]$_2$}$^{3+}$" dimers. The neutral complex units are obviously not good binders for the lithium cations due to a lack of the electrostatic attraction that it is present in the corresponding compounds of titanium(IV) or gallium(III) with catecholate ligands.

In order to introduce negative charge at the complexes, we switched to cobalt(II), nickel(II), and zinc(II) ions as metal centers (Scheme 2).

The reaction of cobalt(II), nickel(II), or zinc(II) acetate with ligands **2a**,**b**-H in methanol in the presence of lithium carbonate leads, after work-up, to coordination compounds



Scheme 2.

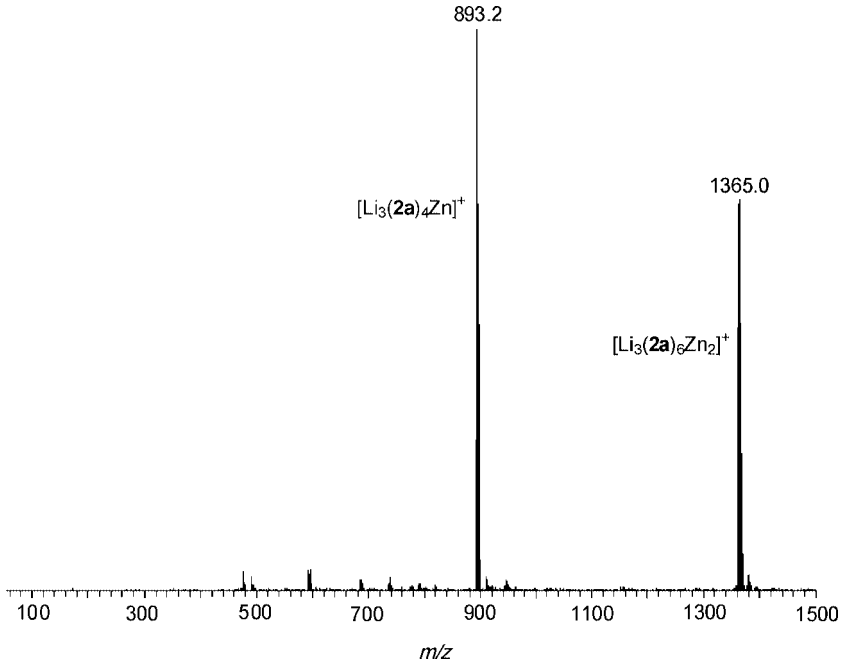


Figure 6. ESI mass spectrum of [Li$_3$(**2**)$_6$Zn$_2$][OAc] in methanol/chloroform.

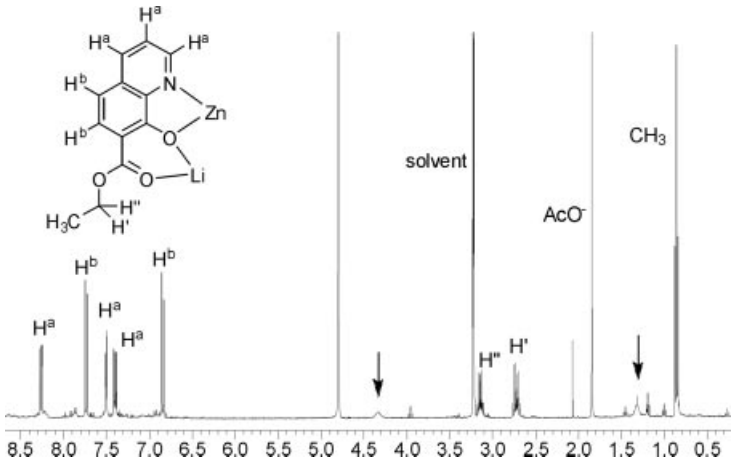

Figure 7. $^1$H NMR spectrum of $[Li_3(\mathbf{3b})_6Zn_2][O_2CCH_3]$ in $[D_4]$MeOH. The signals of the dimeric complex are assigned. The broad signalsarked with arrows are probably due to monomeric complexes.

that show peaks for the dimeric species $[Li_3(\mathbf{2})_6M_2]^+$ (M = Co, Ni, Zn) at *m/z* 1365 $[Li_3(\mathbf{2a})_6Zn_2]^+$, 1449 $[Li_3(\mathbf{2b})_6Zn_2]^+$, 1349 $[Li_3(\mathbf{2a})_6Ni_2]^+$, 1433 $[Li_3(\mathbf{2b})_6Ni_2]^+$, and 1351 $[Li_3(\mathbf{2a})_6Co_2]^+$ in the positive-ion ESI mass spectra. All signals possess the expected isotopic patterns. The spectrum of the zinc(II) complex with ligand **2a** is shown in Figure 6.

A monomeric complex with three ligands is observed only for $[Li_2(\mathbf{2b})_3Ni]^+$ (*m/z* 720). The dominating fragmentation is the formation of different mononuclear species. Mononuclear transition metal complexes with four ligands and three lithium cations can be detected in the gas phase at *m/z* 893 $[Li_3(\mathbf{2a})_4Zn]^+$, 949 $[Li_3(\mathbf{2b})_4Zn]^+$, 887 $[Li_3(\mathbf{2a})_4Ni]^+$, 943 $[Li_3(\mathbf{2b})_4Ni]^+$, and 889 $[Li_3(\mathbf{2a})_4Co]^+$. This shows an unsymmetrical decomposition of the dimer under these ionization conditions with loss of the neutral mononuclear $[(\mathbf{2a},\mathbf{b})_2Zn/Ni/Co]$.[16]

The diamagnetic zinc(II) complexes can be studied by NMR spectroscopy. The spectrum of "Li$[(\mathbf{2b})_3Zn]$" in $[D_4]$-MeOH is shown in Figure 7 as a representative example.

The dinuclear zinc(II) complex $[Li_3(\mathbf{3b})_6Zn_2][O_2CCH_3]$ is observed as the dominant species. The signals of the three pyridine protons $H^a$ appear at $\delta$ = 8.26 (dd, $J$ = 8.2, 1.7 Hz), 7.50 (dd, $J$ = 4.2, 1.7 Hz), and 7.39 ppm (dd, $J$ = 8.2, 4.2 Hz) while the doublets ($J$ = 9.5 Hz) of the phenolic unit $H^b$ are detected at $\delta$ = 7.73 and 6.82 ppm. The terminal $CH_3$ group of the ethyl ester is found as a triplet ($J$ = 7.1 Hz) at $\delta$ = 0.86 ppm. The methylene group results in two doublets of quartets at $\delta$ = 2.72 and 3.14 ppm, with a geminal coupling constant 11.0 Hz. The high-field shift and the diastereotopicity of those two signals show that the dimeric complex is present, as (1) in the dimeric complex the ethyl groups of one complex unit are located close to the aromatic system of the second. This leads to an anisotropic shift to low field. This effect is also observed for the resonance of the methyl group. (2) In the dimeric complex the stereochemistry at the complex units is fixed so no fast racemization between the Λ and Δ isomers takes place. In the monomers this isomerization as well as a *syn–anti* isomerization should proceed much more rapidly. According to this, broad signals at $\delta$ = 4.33 and 1.31 ppm (marked by an arrow in Figure 7) can be tentatively assigned to the ethyl groups of a highly dynamic mononuclear complex.

We were able to obtain X-ray quality crystals of $[Li_3(\mathbf{2b})_6Ni_2][HSO_4]\cdot Et_2O$ from ethanol/diethyl ether. The structure of the $[Li_3(\mathbf{2b})_6Ni_2]^+$ cation is depicted in Figure 8.[34] This compound is built up from two pseudo-octahedral nickel(II) complexes $[(\mathbf{2b})_3Ni]^-$ with the quinolinate ligands **2b** orientated in a *syn* fashion. This enables the binding of three lithium cations to the phenolate carbonyl

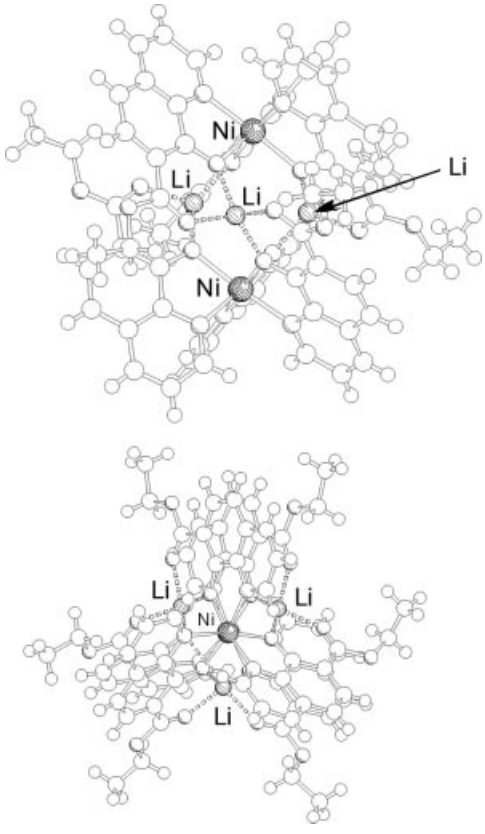

Figure 8. Views of the solid-state structure of the cation $[Li_3\{(\mathbf{2b})_3Ni\}_2]$ down the Li–Li (top) and down the Ni–Ni axis (bottom).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chelate of each of the two units and formation of the triply bridged dimer, with nickel–nickel separations of 5.276 Å. The three lithium cations form a triangle with distances of 3.607, 3.804, and 3.825 Å, respectively. The alkali metal ions are located 3.374–3.462 Å away from the transition metals.

The structure of the hydroxyquinoline complex $[Li_3(\mathbf{2b})_6Ni_2]^+$ is very similar to those observed for titanium(IV) catechol derivatives like $[Li_3\{(\mathbf{1b})_3Ti\}_2]^-$.

## Conclusions

We have studied the versatility of the lithium-templated hierarchical assembly of dinuclear, helicate-type complexes. As described earlier, titanium(IV) catecholate complexes that bear carbonyl substituents in the 3-position of the ligand are able to form triple-stranded dimers in the presence of lithium cations.[16] Substitution of the titanium(IV) centers by boron results in the formation of the analogous double-stranded complexes, which, although they are labile and are often obtained in a mixture with free ligand, can be readily characterized.

Furthermore, this approach to oligonuclear complexes is not restricted to catecholate ligands as 8-hydroxyquinolines with a carbonyl in the 7-position can form related compounds with late transition metals. With aluminum(III) or gallium(III) ions neutral 8-hydroxyquinolinate complexes are obtained, which do not show a tendency to lithium-mediated dimerization. This indicates that the electrostatic attraction between anionic complex units and lithium cations is an essential driving force in the dimerization process.

We have a broad set of different kinds of ligands and different metal centers available for future studies. We will investigate whether we can use "combinatorial" approaches to obtain specific heterodinuclear complexes and we will functionalize the periphery of the complexes in order to tune their properties.

## Experimental Section

NMR spectra were recorded with a Varian Mercury 300 or Inova 400 spectrometer. FT-IR spectra were recorded with a Bruker IFS spectrometer. Mass spectra were recorded with a Thermo Deca XP mass spectrometer. Elemental analyses were obtained with a Heraeus CHN-O-Rapid analyser. Fluorescence measurements were performed on a Perkin–Elmer LS-50B spectrofluorimeter.

**$Li[Li_3(\mathbf{1a–c})_6Ti_2]$:** The titanium(IV) complexes were prepared as described earlier.[16]

**General Procedure for the Preparation of Boron Complexes:** Catechol **1a**–**c**-$H_2$ (2 equiv.), boric acid (1 equiv.), and lithium carbonate (1 equiv.) were dissolved in methanol (10 mL) and the solution stirred overnight. The solvent was then removed and the residue was recrystallized from chloroform and dried in vacuo. Attempts to purify the compounds over Sephadex LH20 did not result in pure material.

**$Li_2[B_2(\mathbf{1a})_4]$:** Yield: 40 mg (42%). $^1$H NMR ($CDCl_3$, 400 MHz): $\delta$ = 6.77 (m, 8 H), 6.57 (t, $J$ = 8.0 Hz, 4 H), 3.71 ppm (s, 12 H). IR (KBr): $\tilde{\nu}$ = 3460, 2361, 2340, 1678, 1469, 1322, 1262, 1227, 1143, 1107, 1031, 744 cm$^{-1}$. Negative ESI MS (dmf, MeOH): $m/z$ 693 $[LiB_2(\mathbf{1a})_4]^-$, 343 $[B(\mathbf{1a})_2]^-$. Fluorescence data: ($CHCl_3$): $\lambda_{ex}$ (nm) = 248, 326; $\lambda_{em}$ (nm) = 395. $C_{32}H_{24}B_2Li_2O_{16}\cdot 4H_2O$ (772.10): calcd. C 49.77, H 4.18; found C 49.98, H 4.69. A single crystal of the product was selected and mounted on a cryo-loop for single-crystal X-ray data collection on a Bruker–Nonius KAPPACCD diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å), an APEXII area detector, and an Oxford Cryostream cryogenic device (data collected at 173 K). Structure solution was performed with SHELXS-97,[35] with subsequent refinement on $F^2$ by full-matrix least-squares (SHELXL-97[35]). Hydrogen atoms were calculated at their idealized positions and refined with a riding model (isotropic displacement parameters 1.2- or 1.5-times C anisotropic displacement parameters). Multiscan absorption correction was applied to the data (SADABS[12]). Crystal system: monoclinic; space group: $Cc$; $a$ = 9.2853(19), $b$ = 23.783(5), $c$ = 14.844(3) Å, $\beta$ = 106.70(3)°; cell volume: 3139.7(11) Å$^3$; $Z$ = 4; calculated density: 1.481 g cm$^{-3}$; absorption coefficient: 0.117 mm$^{-1}$; $F$(000) = 1440; crystal color: colorless; size: 0.40 × 0.20 × 0.10 mm$^3$; reflections for cell refinement: 1005 ($\theta$ range 2.5 to 27.5°); data collection method: &phis; and $\omega$ scans; $\theta$ range for data collection: 3.4 to 27.4°; index ranges: $-11 \le h \le 11$, $0 \le k \le 30$, $0 \le l \le 19$; completeness to $\theta$ = 27.4°: 97.2%; reflections collected: 3470; independent reflections: 3470 ($R_{int}$ = 0.0654, before merging); reflections with $F^2 > 2\sigma$: 2416; absorption correction: semi-empirical from equivalents; Min. and max. transmission: 0.9546 and 0.9884; structure solution: direct methods; full-matrix least-squares on $F^2$; weighting parameters: $a$ = 0.0449, $b$ = 0.1095; data/restraints/parameters: 3470/2/470; final $R$ indices [$F^2 > 2\sigma$] $R_1$ = 0.0632, $wR_2$ = 0.1064; $R$ indices (all data) $R_1$ = 0.1141, $wR_2$ = 0.1293; goodness-of-fit on $F^2$: 1.190; absolute structure parameter: 1.0(14); extinction coefficient: 0.0020(4); largest and mean shift/su: 0.001 and 0.000; largest diff. peak and hole: 0.23 and –0.28 e Å$^{-3}$.

**$Li_2[B_2(\mathbf{1b})_4]$:** Yield: 39 mg (38%). $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 6.85 (m, 8 H), 6.64 (t, $J$ = 7.2 Hz, 4 H), 4.19 (qd, $J$ = 7.2, 10.8 Hz, 4 H), 4.28 (qd, $J$ = 7.2, 10.8 Hz, 4 H), 1.36 ppm (t, $J$ = 7.2 Hz, 12 H). IR (KBr): $\tilde{\nu}$ = 3474, 2983, 2361, 2369, 1675, 1468, 1372, 1263, 1222, 1102, 1033, 885, 742 cm$^{-1}$. Positive ESI MS ($CHCl_3$, MeOH): $m/z$ 763 $[Li_3B_2(\mathbf{1b})_4]^+$, 385 $[Li_2B(\mathbf{1b})_2]^+$. Fluorescence data: ($CHCl_3$): $\lambda_{ex}$ (nm) = 255, 328; $\lambda_{em}$ (nm) = 395. $C_{36}H_{32}B_2Li_2O_{16}\cdot 7H_2O$ (882.25): calcd. C 49.01, H 5.25; found C 48.86, H 5.46.

**$Li_2[B_2(\mathbf{1c})_4]$:** Yield: 57 mg (54%). $^1$H NMR ($CDCl_3$, 400 MHz): $\delta$ = 9.08 (s, 1 H), 7.00 (dd, $J$ = 7.6, 1.1 Hz, 1 H), 6.83 (t, $J$ = 7.6 Hz, 1 H), 6.67 ppm (dd, $J$ = 7.6, 1.1 Hz, 1 H). IR (KBr): $\tilde{\nu}$ = 3854, 3744, 3420, 2361, 2340, 1661, 1621, 1585, 1467, 1403, 1266, 1214, 1086, 880, 737, 680 cm$^{-1}$. Negative ESI MS (dmf, MeOH): $m/z$ 573 $[LiB_2(\mathbf{1c})_4]^-$, 283 $[B(\mathbf{1c})_2]^-$. Fluorescence data: ($CHCl_3$): $\lambda_{ex}$ (nm) = 265, 363; $\lambda_{em}$ (nm) = 471. $C_{28}H_{16}B_2Li_2O_{12}$ (579.93): calcd. C 57.99, H 2.78; found C 58.21, H 3.26.

**General Procedure for the Preparation of Aluminum(III) and Gallium(III) Complexes of the 8-Hydroxyquinoline Ligands 2a,b-H:** 8-Hydroxyquinoline derivative **2a**-H or **2b**-H (3 equiv.) and gallium nitrate or aluminum trichloride (1 equiv.) were dissolved in methanol or ethanol and stirred overnight. The solvent was then removed under reduced pressure to obtain solid materials in close to quantitative yields.

**$[(\mathbf{2a})_3Al]$:** Yield: 59.1 mg (92%). $^1$H NMR (400 MHz, $CD_3OD$): $\delta$ = 3.96 (s, 3 H), 7.34 (d, $J$ = 8.8 Hz, 1 H), 7.60 (dd, $J$ = 4.2, 8.3 Hz, 1 H), 7.86 (d, $J$ = 8.8 Hz, 1 H), 8.26 (dd, $J$ = 1.1, 8.3 Hz, 1 H), 8.80 ppm (dd, $J$ = 1.1, 4.2 Hz, 1 H). Positive ESI MS: $m/z$ 656

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[Na(\mathbf{2a})_3Al]^+$. IR (KBr): $\tilde{\nu}$ = 3431, 3056, 2990, 2948, 2843, 1702, 1629, 1605, 1572, 1501, 1459, 1397, 1317, 1291, 1247, 1195, 1123, 1055, 1009, 984, 916, 882, 789, 757, 667, 621, 575, 474, 458 $cm^{-1}$. $C_{33}H_{24}AlN_3O_9 \cdot 1.5\,H_2O \cdot 1.5\,CH_3OH$ (708.64): calcd. C 58.48, H 4.69, N 5.93; found C 58.56, H 4.73, N 5.93.

**$[(\mathbf{2b})_3Al]$:** Yield: 52.2 mg (98%). $^1H$ NMR (400 MHz, $CD_3OD$): Due to the presence of different isomers only an uninformative spectrum with broad signals is obtained. Positive ESI MS: *m/z* 676 $[H(\mathbf{2b})_3Al]^+$. IR (KBr): $\tilde{\nu}$ = 3791, 3447, 3066, 2980, 2931, 2901, 1707, 1603, 1572, 1501, 1458, 1399, 1311, 1292, 1244, 1197, 1112, 1055, 1024, 948, 884, 833, 755, 666, 622, 573, 529, 492 $cm^{-1}$. $C_{36}H_{30}AlN_3O_9 \cdot H_2O$ (693.65): calcd. C 62.34, H 4.65, N 6.06; found C 62.35, H 4.98, N 5.97.

**$[(\mathbf{2a})_3Ga]$:** Yield: 56.7 mg (97%). $^1H$ NMR (400 MHz, $CD_3OD$): $\delta$ = 3.59 (s, 3 H), 7.23 (d, $J$ = 8.8 Hz, 1 H), 7.45 (d, $J$ = 8.8 Hz, 1 H), 7.61 (d, $J$ = 8.2 Hz, 1 H), 7.63 (d, $J$ = 8.2 Hz, 1 H), 7.95 ppm (d, $J$ = 8.8 Hz, 1 H). Positive ESI MS: *m/z* 676 $[H(\mathbf{2a})_3Ga]H^+$. IR (KBr): $\tilde{\nu}$ = 3898, 3854, 3744, 3694, 3674, 3620, 3589, 3565, 3437, 2948, 2360, 2339, 1842, 1700, 1652, 1564, 1504, 1456, 1391, 1317, 1293, 1243, 1197, 1117, 1058, 1005, 884, 834, 748, 666, 610, 561, 509 $cm^{-1}$. $C_{33}H_{24}GaN_3O_9 \cdot 2\,H_2O$ (712.32): calcd. C 55.64, H 3.96, N 5.90; found C 55.69, H 3.99, N 6.01.

**$[(\mathbf{2b})_3Ga]$:** Yield: 49.1 mg (89%). $^1H$ NMR (400 MHz, $CD_3OD$): Due to the presence of different isomers only an uninformative spectrum with broad signals was obtained. Positive ESI MS: *m/z* 718 $[H(\mathbf{2b})_3Ga]^+$. IR (KBr): $\tilde{\nu}$ = 3511, 3408, 3063, 2979, 2934, 2901, 1711, 1603, 1569, 1500, 1452, 1395, 1311, 1291, 1243, 1196, 1119, 1054, 1022, 948, 833, 788, 747, 665, 607, 563, 521 $cm^{-1}$. No correct elemental analysis was obtained.

**General Procedure for the Preparation of Cobalt(II), Nickel(II), and Zinc(II) Complexes of the 8-Hydroxyquinoline Ligands 2a,b-H:** 8-Hydroxyquinoline derivative **2a**-H or **2b**-H (3 equiv.), lithium carbonate, and cobalt(II), nickel(II) or zinc(II) acetate (1 equiv.) were dissolved in methanol or ethanol and stirred overnight. The solvent was removed under reduced pressure to obtain solid materials in close to quantitative yields.

**$[Li_3(\mathbf{2a})_6Co_2][O_2CCH_3]$:** Yield: 24 mg (97%) as crude product. IR (KBr): $\tilde{\nu}$ = 3448, 2952, 1680, 1600, 1562, 1500, 1449, 1404, 1384, 1307, 1245, 1198, 1117, 1008, 833, 797, 752, 671, 616, 536, 462 $cm^{-1}$. Positive ESI MS: *m/z* 1351 $[Li_3(\mathbf{2a})_6Co_2]^+$. No correct elemental analysis was obtained, probably due to the exchange of acetate by other anions.

**$[Li_3(\mathbf{2a})_6Ni_2][O_2CCH_3]$:** Yield: 56.9 mg (98%). Positive ESI MS: *m/z* 1349 $[Li_3(\mathbf{2a})_6Ni_2]^+$. IR (KBr): $\tilde{\nu}$ = 3411, 3049, 2999, 2949, 1680, 1601, 1556, 1500, 1447, 1403, 1308, 1246, 1193, 1152, 1116, 1051, 1006, 883, 829, 788, 746, 669, 611, 536, 472 $cm^{-1}$. $C_{66}H_{48}Li_3N_6Ni_2O_{18} \cdot OCOCH_3 \cdot 2\,CH_3OH$ (1474.5): calcd. C 57.02, H 4.03, N 5.70; found C 57.36, H 4.26, N 5.93.

**$[Li_3(\mathbf{2b})_6Ni_2][HSO_4]$:** The complex was prepared using **2b**-H·$H_2SO_4$ as ligand. Yield: 55.8 mg (95%). Positive ESI MS: *m/z* 1432.9 $[Li_3(\mathbf{2b})_6Ni_2]^+$. IR (KBr): $\tilde{\nu}$ = 3425, 3056, 2979, 2932, 1677, 1599, 1557, 1500, 1450, 1406, 1361, 1305, 1244, 1191, 1157, 1115, 1026, 950, 828, 785, 744, 667, 616, 538, 493, 458 $cm^{-1}$. $C_{72}H_{60}Li_3N_6Ni_2O_{18} \cdot HSO_4 \cdot C_2H_5OH$ (1578.66): calcd. C 56.30, H 4.28, N 5.32; found C 56.54, H 4.47, N 5.21.

**X-ray Crystal Structure Analysis for $[Li_3(\mathbf{2b})_6Ni_2][HSO_4]$:** Formula: $[C_{72}H_{60}Li_3N_6Ni_2O_{18}][HSO_4] \cdot C_4H_{10}O$; $M$ = 1606.69; yellow crystal, 0.20 × 0.15 × 0.06 $mm^3$; $a$ = 12.763(1), $b$ = 16.435(1), $c$ = 18.420(1) Å, $\alpha$ = 83.93(1)°, $\beta$ = 78.12(1)°, $\gamma$ = 87.00(1)°; $V$ = 3758.0(4) $Å^3$; $\rho_{calc}$ = 1.420 $g\,cm^{-3}$; $\mu$ = 0.610 $mm^{-1}$; empirical absorption correction (0.888 ≤ $\theta$ ≤ 0.964); $Z$ = 2, triclinic, space group $P\bar{1}$ (no. 2); $\lambda$ = 0.71073 Å; $T$ = 198 K; $\omega$ and $\varphi$ scans, 24802 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sin$\theta$)/$\lambda$] = 0.54 $Å^{-1}$; 9777 independent ($R_{int}$ = 0.078) and 6454 observed reflections [$I \geq 2\sigma(I)$]; 1008 refined parameters, $R$ = 0.078, $wR_2$ = 0.231, max. residual electron density 2.51 (–0.82) e $Å^{-3}$ in the region of the disordered anion, which was refined with geometrical and thermal constraints; hydrogen atoms were calculated and refined as riding. The data set was collected with a Nonius KappaCCD diffractometer equipped with a rotating anode generator. Programs used: data collection: COLLECT (Nonius B.V., 1998); data reduction: Denzo-SMN;[36] absorption correction: SORTAV;[37,38] structure solution: SHELXS-97;[39] structure refinement: SHELXL-97 (G. M. Sheldrick, University of Göttingen, 1997); graphics: SCHAKAL (E. Keller, University of Freiburg, 1997).

**$[Li_3(\mathbf{2a})_6Zn_2][O_2CCH_3]$:** Yield: 56.1 mg (96%). $^1H$ NMR (400 MHz, $CD_3OD$): $\delta$ = 1.79 (s, 3 H), 2.64 (s, 3 H), 6.86 (d, $J$ = 9.0 Hz, 1 H), 7.40 (dd, $J$ = 3.9, 8.2 Hz, 1 H), 7.50 (dd, $J$ = 1.2, 3.9 Hz, 1 H), 7.69 (d, $J$ = 9.0 Hz, 1 H), 8.26 ppm (dd, $J$ = 1.2, 8.2 Hz, 1 H). positive ESI MS: *m/z* 1365.4 $[Li_3(\mathbf{3a})_6Zn_2]^+$. IR (KBr): $\tilde{\nu}$ = 3986, 3946, 3661, 3428, 3053, 2949, 1682, 1601, 1557, 1500, 1449, 1405, 1308, 1248, 1194, 1153, 1116, 1056, 1008, 908, 827, 788, 743, 701, 670, 616, 543, 479 $cm^{-1}$. $C_{66}H_{48}Li_3N_6O_{18}Zn_2 \cdot OCOCH_3 \cdot 3\,H_2O \cdot 3\,CH_3OH$ (1573.9): calcd. C 54.18, H 4.42, N 5.34; found C 54.10, H 4.33, N 5.48.

**$[Li_3(\mathbf{2b})_6Zn_2][O_2CCH_3]$:** Yield: 56.5 mg (98%). $^1H$ NMR (400 MHz, $CD_3OD$): $\delta$ = 0.86 (t, $J$ = 7.1 Hz, 3 H), 1.84 (s, 3 H), 2.72 (dd, $J$ = 3.5, 7.1 Hz, 1 H), 3.14 (dd, $J$ = 3.5, 7.1 Hz, 1 H), 6.84 (d, $J$ = 8.8 Hz, 1 H), 7.40 (dd, $J$ = 4.7, 8.2 Hz, 1 H), 7.50 (dd, $J$ = 1.4, 4.7 Hz, 1 H), 7.73 (d, $J$ = 8.8 Hz, 1 H), 8.26 ppm (d, $J$ = 1.4, 8.2 Hz, 1 H). # Solid-Phase Synthesis of Chiral Modular Ferrocene-Based Peptides

Katja Heinze,*[a] Ute Wild,[a] and Manuela Beckmann[a]

**Keywords:** Conformation analysis / Hydrogen bonds / Metallocenes / Molecular modelling / Solid-phase synthesis

Ferrocene-containing tripeptides with one to two ferrocene building blocks were prepared by solid-phase peptide synthesis (SPPS) using Fmoc-protected 1′-aminoferrocene-1-carboxylic acid (Fca). The conformations of the tripeptides were analysed by spectroscopic and theoretical methods. The immobilised ferrocene compounds can be reversibly oxidised on-bead to positively charged peptides and were analysed for anion-binding affinities by a solid-phase binding assay.

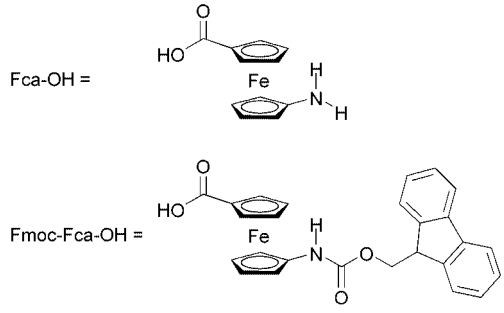
## Introduction

In contrast to organic-based receptors[1] with carboxylate binding sites, which are either charged (e.g. guanidinium or pyridinium ions[2]) or uncharged (e.g. pyrroles, amides or diketopiperazines[3]), suitably substituted ferrocene derivatives create the possibility to switch between the neutral ferrocene (low-affinity state) and charged ferricinium (high-affinity state) simply by applying an external voltage or by chemically induced redox reactions (redox control of molecular recognition[4]). Application of the reverse concept for cation binding to a ferrocene derivative has been recently demonstrated.[5]

With this idea in mind we set out to prepare chemically diverse chiral ferrocene-based two-armed receptors preferably in a combinatorial fashion using state-of-the-art solid-phase peptide synthesis methods (SPPS). For this application we have recently prepared a SPPS-compatible ferrocene building block, namely the fluorenylmethoxycarbonyl-protected 1,1′-ferrocene amino acid Fmoc-Fca-OH (Scheme 1).[6]

Peptides incorporating the artificial amino acid Fca have been previously synthesised by Metzler-Nolte, Kraatz, Rapić and by us using solution-phase methods.[7,8] Fca derivatives have been employed as transition-state analogues for formation of catalytic antibodies.[9] Simple neutral ferrocene-containing amides were shown to bind anions with moderate affinity while the charged ferricinium counterparts bind anions much more strongly because of additional electrostatic interactions between host and guest.[10,11] Fca derivatives bind chloride anions in an induced fit binding process.[11]



Scheme 1.

## Results and Discussion

### Solid-Phase Synthesis of Ferrocene-Containing Peptides

Here we report a general and modular synthetic approach to peptides containing ferrocene in the backbone compatible with standard SPPS based on the Fmoc-protection strategy.[12] As solid support/linker TentaGel-Wang resins turned out to be superior to polystyrene/divinyl benzene-Wang resins both for SPPS and on-bead reactions. After Fmoc removal from the TentaGel support using piperidine, Fmoc-Fca-OH is preactivated with DIC/HOBt and coupled to the free amine (Scheme 2, DIC = 1,3-diisopropylcarbodiimide, HOBt = 1-hydroxybenzotriazole). Because of the orange colour of the immobilised ferrocene, a Kaiser test for free amines proved impossible. Capping of unreacted amino groups was done using $Ac_2O$/pyridine (see Experimental Section).

Fmoc deprotection of the immobilised ferrocene occurs under standard conditions, as does DIC/HOBt-promoted coupling with an *N*-acetylated L-α-amino acid. Cleavage of the resulting tripeptide from the support with trifluoroacetic acid (TFA) gives tripeptides **1**–**3**. Attaching Ac-Fca-OH[6] instead of an α-amino acid yields the diferrocene peptide **4**. After chromatographic workup the orange peptides

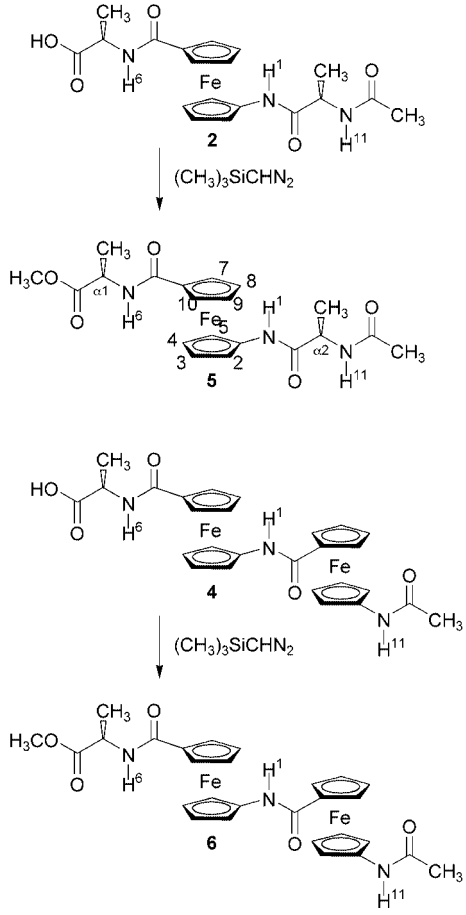

Scheme 3.

**1**–**4** were characterised by spectroscopic and mass spectrometric techniques. The data fully prove the composition and sequence of the peptides.

### Conformational Analysis of Ferrocene-Containing Peptides

Negative ion ESI mass spectra of **1**–**4** display, in addition to the $[M - H]^-$ peaks, signals corresponding to $[2M - H]^-$ consistent with the formation of carboxylic acid dimers in solution.[13] The dimer motif is also the most stable arrangement in the solid state as the signal for the $C{=}O_{acid}$ stretching vibration is found at 1725 $cm^{-1}$.[6]

To allow a detailed conformational analysis, the acid groups of **2** and **4** were methylated with (trimethylsilyl)diazomethane, giving esters **5** and **6** (Scheme 3). This increases the solubility of the tripeptides and eliminates the interference of the OH group. The IR spectra of **5** and **6** in $CH_2Cl_2$ indicate free and hydrogen-bonded NH groups (**5**: $\tilde{\nu}_{NH}$ = 3439, 3353, 3323 $cm^{-1}$; **6**: $\tilde{\nu}_{NH}$ = 3432, 3373, 3291 $cm^{-1}$) as well as hydrogen-bonded $CO_{ester}$ groups for **5** but not for **6** (**5**: $\tilde{\nu}_{CO}$ = 1727 $cm^{-1}$; **6**: $\tilde{\nu}_{CO}$ = 1741 $cm^{-1}$).

For ester **5** the chemical shifts of the amide protons $H^1$ and $H^6$ in $CD_2Cl_2$ ($\delta$ = 9.19, 7.95; for atom numbering see Scheme 3 and Figure 3) show that these two protons engage in (intramolecular) hydrogen bonds while $H^{11}$ ($\delta$ = 7.08 ppm) does not. This is also supported by the finding that $H^6$ exchanges more slowly against deuterium than $H^{11}$, with half-lives of $\tau_{1/2}(H^6)$ = 6.8 min and $\tau_{1/2}(H^{11})$ = 5.6 min in $CD_2Cl_2/D_2O$. In addition the chemical shift of proton $H^{11}$ is significantly different in the hydrogen-bond-forming solvent [D$_6$]DMSO as compared to the shift in $CD_2Cl_2$ [$\Delta\delta(H^{11}$, [D$_6$]DMSO, $CD_2Cl_2$) = 1.05] while $H^1$ and $H^6$ form hydrogen bonds in both solvents [$\Delta\delta(H^1$, [D$_6$]DMSO, $CD_2Cl_2$) = 0.08; $\Delta\delta(H^6$, [D$_6$]DMSO, $CD_2Cl_2$) = 0.08].[7]

However, $H^{11}$ forms an intermolecular hydrogen bond in concentrated $CD_2Cl_2$ solution [$\delta(H^{11})$ = 7.08 in concentrated solution; $\delta(H^{11})$ = 6.39 in diluted solution], at lower temperature, as the proton resonance is strongly temperature-dependent [$\Delta\delta(H^{11})$ = –24 ppb $K^{-1}$ in concentrated $CD_2Cl_2$ solution and $\Delta\delta(H^{11})$ = –27 ppb $K^{-1}$ in diluted $CD_2Cl_2$ solution; Figure 1], as well as in the solid state ($\tilde{\nu}_{NH}$ = 3316 $cm^{-1}$).

NOE contacts *between* the two ferrocene substituents of **5** are observed in $CD_2Cl_2$ but not in [D$_6$]DMSO, namely cross-peaks between $H^6$–$H^1$ and $H^6$–$H^{\alpha 2}$ (Figure 2). Thus the NMR and IR data of **5** suggest a conformation with two intramolecular hydrogen bonds $H^1\cdots O^4$ and $H^6\cdots O^1$ between the two substituents – a pattern similar to that found in the crystalline state of the tetrapeptide Boc-Ala-Fca-Ala-Ala-OMe.[7] The hydrogen bond between $H^1$ and $O^4$ is also found in short dipeptides of the type Ac-Fca-AA-OMe (AA = L-Val, L-Ile).[8] DFT calculations (B3LYP, LANL2DZ) additionally indicate this (*P*)-helical conformation with two

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

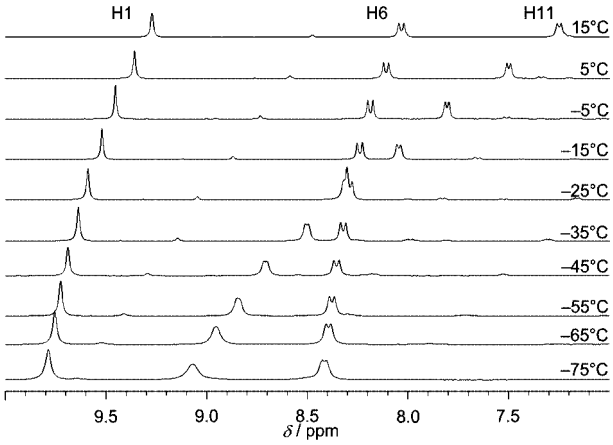

Figure 1. VT $^1$H NMR spectra of **5** in concentrated $CD_2Cl_2$ solution.

intramolecular hydrogen bonds to be the global minimum of seven hydrogen-bonded conformations of **2** (Figure 3). Other folded conformations for **1**–**3** with one to three intramolecular hydrogen bonds are calculated higher in energy by 6–39 kJ mol$^{-1}$ (see Supporting Information).

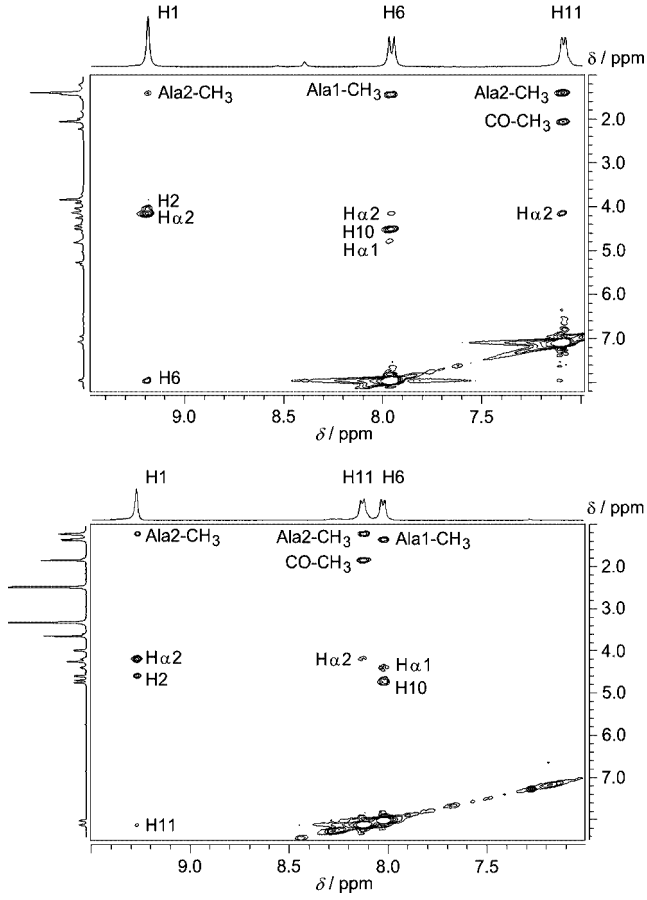

Figure 2. NOESY spectra of **5** in $CD_2Cl_2$ (top) and in [$D_6$]DMSO (bottom).

The observed vicinal coupling constants $^3J(H^6\text{-}H^{\alpha1})$ = 7.7 Hz and $^3J(H^{11}\text{-}H^{\alpha2})$ = 6.0 Hz in $CD_2Cl_2$ and the derived torsion angles[14] C–N–C$^{\alpha1}$–C = –86° and C–N–C$^{\alpha2}$–C = –76° fit well to the DFT calculated angles C–N–C$^{\alpha1}$–C = –90° and C–N–C$^{\alpha2}$–C = –73° of the preferred conformer. In THF similar vicinal coupling constants are observed [$^3J(H^6\text{-}H^{\alpha1})$ = 7.5 Hz and $^3J(H^{11}\text{-}H^{\alpha2})$ = 5.4 Hz] while in [$D_6$]DMSO the folded structure is completely disrupted [$^3J(H^6\text{-}H^{\alpha1})$ = 6.9 Hz and $^3J(H^{11}\text{-}H^{\alpha2})$ = 6.7 Hz]. These findings support the assumption that even the TentaGel immobilised peptides in THF retain this preferred conformation.

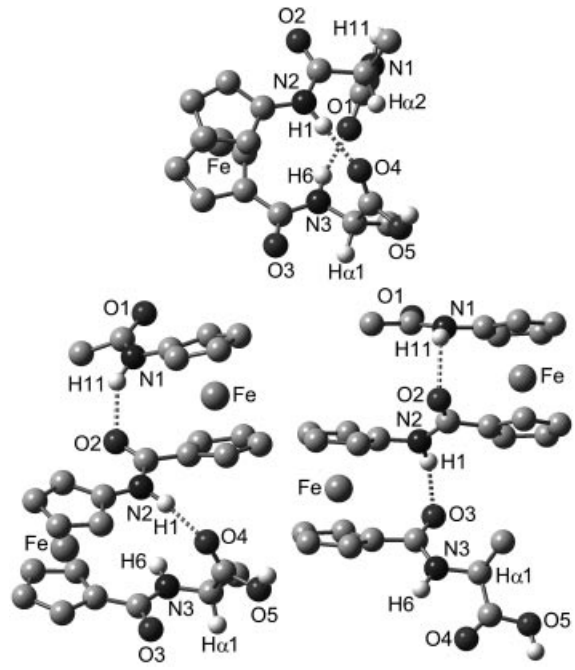

Figure 3. DFT calculated minimum conformations of **2** (top) and **4** (bottom) (Cp and methyl H atoms omitted).

For diferrocene **4** several different conformations were calculated with similar energy (Figure 3, Supporting Information). This is also supported by NMR and IR spectroscopy of ester **6**. The amide proton H$^1$ engages prevalently in hydrogen bonds ($\delta$ = 8.54; $\Delta\delta$ = –10.5 ppb K$^{-1}$; $\tau_{1/2}$ = 26 min) as compared to H$^{11}$ ($\delta$ = 7.61; $\Delta\delta$ = –13.7 ppb K$^{-1}$; $\tau_{1/2}$ = 5.8 min). However, even H$^6$ participates in hydrogen bonding ($\delta$ = 7.10; $\Delta\delta$ = –14.5 ppb K$^{-1}$). The finding that all amide protons form hydrogen bonds can only be accomplished by an ensemble of conformations in solution (two of the low-energy conformations of **4** are shown in Figure 3).

### Electrochemistry of Ferrocene-Containing Peptides

Monoferrocenes **1**–**3** are reversibly oxidised to the corresponding ferricinium cations around 500 mV versus SCE in $CH_3CN$ almost independently of the α-amino acids employed, while diferrocene **6** displays two oxidation waves at 470 and 590 mV versus SCE (Figure 4). The difference in the redox potentials of **6** ($\Delta E_{1/2}$ = 590 – 470 = 120 mV) is significantly smaller than that observed for Fc-NHCO-Fc-NHAc with differently substituted ferrocene moieties ($\Delta E_{1/2}$ = 305 mV[6]). The similarly substituted ferrocene

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

units in **6** (in contrast to Fc-NHCO-Fc-NHAc) allow estimation of the comproportionation constant for the monocation $\mathbf{6}^+$ as $K_C = 107$, which characterises $\mathbf{6}^+$ as a class II mixed-valent species with moderate delocalisation of the electron hole.

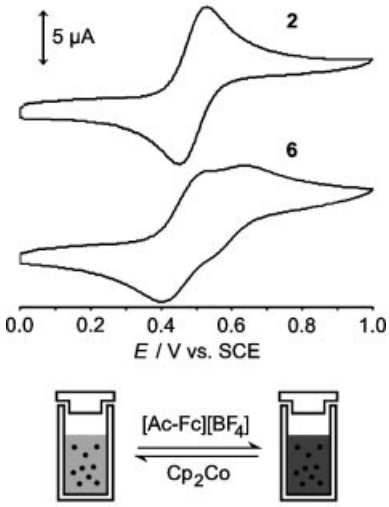

Figure 4. Cyclic voltammograms of tripeptides **2** and **6** (top) and chemical on-bead oxidation/reduction of ferrocene-containing tripeptide **2** (bottom).

To test binding affinities of neutral and charged peptides directly on-resin, it is necessary to chemically oxidise the peptides on the solid support. On-bead oxidation is performed by adding soluble [Ac-Fc][$BF_4$] ($E_{1/2}$ = 730 mV vs. SCE in $CH_2Cl_2$[15]) in $CH_2Cl_2$ solution to the immobilised tripeptide. Progress of the oxidation reaction is monitored UV/Vis-spectrophotometrically as the 633 nm absorption band of $[Ac\text{-}Fc]^+$ disappears while the 449 nm band of Ac-Fc increases (Figure 5, top). The reaction is finished within minutes. EPR spectroscopy[16] confirms the formation of the immobilised ferricinium cation as the typical axial pattern with $g_{\|} = 4.30$ and $g_{\perp} = 1.99$ is observed.[17]

Chemical reversibility is checked on-bead by re-reduction to the neutral peptides employing $CoCp_2$ as reductant and UV/Vis-spectrophotometric monitoring (disappearance of the 512 nm band of $CoCp_2$ and development of the 400 nm absorption band of $[CoCp_2]^+$). Reduction requires hours to be completed, probably because of the hydrophobic character of $CoCp_2$ and the hydrophilic nature of the Tentagel resin employed (Figure 5, bottom).

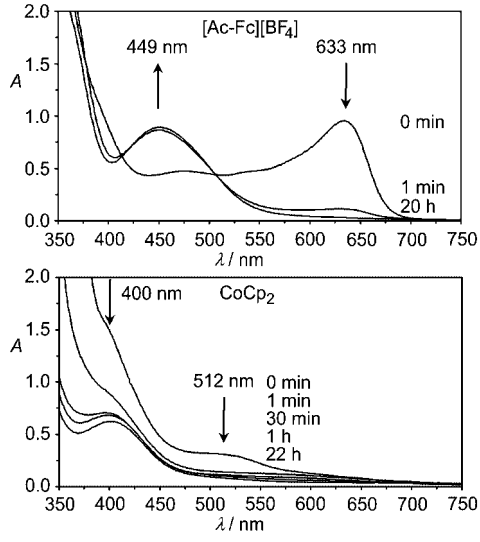

Figure 5. UV/Vis spectra during oxidation of immobilised **2** with [AcFc][$BF_4$] and during reduction of immobilised $\mathbf{2}^+$ with $CoCp_2$.

## Preliminary Solution and On-Bead Binding Studies

The conformation analysis suggests that binding of a guest to Fca peptides should occur by an induced fit process rather than being governed by the static lock and key concept.[11] ESI mass spectra of **5** and an equimolar mixture of five *N*-acetylated α-amino acids (Ac-Gly, Ac-Ala, Ac-Val, Ac-Ile, Ac-Phe; **5**: Ac-NH-CHR-COOH, 10:1) in $CH_3CN$ provide a first hint that Fca peptides bind these guests as carboxylates (*m*/*z* = 559.3, 573.3, 601.2, 615.3 and 649.4 for [**5** + Ac-Gly – H]$^+$, [**5** + Ac-Ala – H]$^+$, [**5** + Ac-Val – H]$^+$, [**5** + Ac-Ile – H]$^+$ and [**5** + Ac-Phe – H]$^+$, respectively; Figure 6; the peak at *m*/*z* = 556.3 corresponds to [**5** + TFA – H]$^+$ with TFA present in the mass spectrometer).

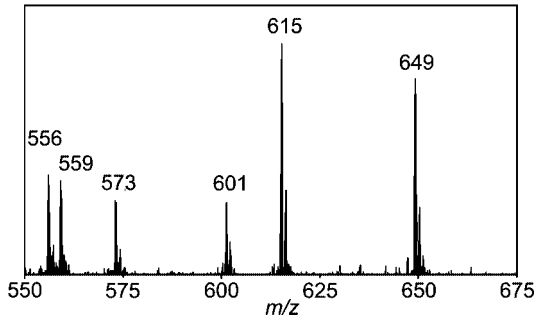

Figure 6. Partial ESI (neg.) mass spectrum of **5** and a mixture of five *N*-acetylated α-amino acids.

On-bead analysis[18] of immobilised peptide **2** using the chromophoric substrates pyrene-$(CH_2)_3$-COOH/$P_1t$Bu [$\lambda_{max}$ = 344 nm (60000 $M^{-1}cm^{-1}$) in THF] and coumarin-3-COOH/$P_1t$Bu[19] [$\lambda_{max}$ = 315 nm (12000 $M^{-1}cm^{-1}$) in THF] allowed determination of binding affinities by absorption spectroscopy. Equilibrium is reached after about 10 h in both cases according to spectroscopic measurements (Figure 7). Binding constants $K_a$ were calculated with the assumption of a 1:1 receptor substrate complex by Equation (1).

$$K_a = [RS]/\{([R]_0 - [RS])([S]_0 - [RS])\} \quad (1)$$

where [RS] is the concentration of receptor/substrate complex at equilibrium, $[R]_0$ is the initial receptor concentration and $[S]_0$ is the initial substrate concentration.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

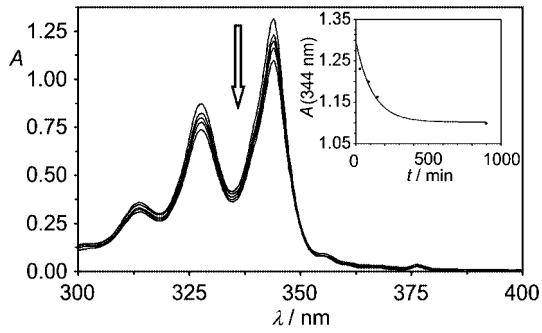

Figure 7. UV/Vis absorption spectra during reaction of immobilised **2** with pyrene-$(CH_2)_3$-COOH/$P_1t$Bu in THF (the inset shows the corresponding $t$ vs. $A$ plot).

Tripeptide **2** binds the coumarin derivative significantly stronger than the pyrene derivative [$K_a$(coumarin) = 670 $M^{-1}$, $K_a$(pyrene) = 200 $M^{-1}$]. This is probably due to the presence of additional hydrogen acceptors (oxygen atoms) in the coumarin dye as compared to the pyrene dye, which complements the three NH groups of peptide **2** (three-point binding vs. two-point-binding). A detailed analysis of the binding modes of different (chiral) substrates to ferrocene peptides as well as to charged ferricinium peptides is currently in progress. For the latter investigation, redox-stable chromophoric substrates have to be used as the coumarin and pyrene dyes employed in this study undergo chemical degradation when reacted with immobilised $\mathbf{2}^+$.

## Conclusions

The development of SPPS for ferrocene amino acids, conformational analyses of the peptides, on-bead oxidation procedures and on-bead binding assays paves the way for devising selective redox-controlled receptor and transporter systems, which, by synthetic design, are amenable to parallel solid-phase peptide synthesis and on-bead oxidation and screening assays.

## Experimental Section

Unless noted otherwise, all manipulations were carried out under argon by means of standard Schlenk techniques. All solvents were dried by standard methods and distilled under argon prior to use. All other reagents were used as received from commercial sources.

NMR: Bruker Avance DPX 200 at 200.15 MHz and Varian Unity Plus 400 at 399.89 MHz ($^1$H); chemical shifts ($\delta$) in ppm with respect to residual solvent peaks as internal standard: $CD_2Cl_2$ ($^1$H: $\delta$ = 5.32; $^{13}$C: $\delta$ = 53.5 ppm), [$D_8$]THF ($^1$H: $\delta$ = 1.73, 3.58; $^{13}$C: $\delta$ = 25.5, 67.7), [$D_6$]DMSO ($^1$H: $\delta$ = 2.49 ppm). IR spectra were recorded with a BioRad Excalibur FTS 3000 spectrometer using $CaF_2$ cells in $CH_2Cl_2$ and as CsI disks. Cyclic voltammetry was performed using a glassy carbon electrode, a platinum electrode and a SCE electrode, $10^{-3}$ M in 0.1 M $n$Bu$_4$NPF$_6$/$CH_2Cl_2$; potentials are given relative to that of SCE. ESI mass spectra were recorded with a Finnigan TSQ 700 spectrometer. EPR spectra were recorded with a Bruker ELEXSYS E500 spectrometer (X-band). UV/Vis spectra were recorded with a Perkin–Elmer Lambda 19, 0.2-cm cells (Hellma, suprasil). Melting points were determined with a Gallenkamp capillary melting point apparatus MFB 595 010 and are uncorrected.

**Computational Method:** Density functional calculations were carried out with the Gaussian03/DFT[20] series of programs. The B3LYP formulation of density functional theory was used employing the LanL2DZ basis set.[20] This functional/basis set combination has been successfully applied previously to investigate the conformational preference of substituted ferrocenes.[6,8,11,21,22] All points were characterised as minima ($N_{imag}$ = 0) by frequency analysis.

**Solid-Phase Peptide Synthesis of 1–4**

TentaGel-Wang-AA$^1$-Fmoc [1 g; AA$^1$ = Gly (**1**), Ala (**2**, **4**), Phe (**3**); 0.17–0.24 mmol g$^{-1}$] was deprotected with 20% piperidine in $CH_2Cl_2$/DMF (9:1). The loading was determined spectrophotometrically at 290 nm. The resin was washed with DMF (2×), $CH_2Cl_2$ (1×), DMF (1×) and $CH_2Cl_2$ (2×). Fmoc-Fca-OH (1.5 equiv.) was activated by using DIC (1.8 equiv.) and HOBt (1.8 equiv.) in $CH_2Cl_2$/DMF (1:1) for 10 min and added to the resin. The resin was shaken for 12 h, washed with DMF (2×), $CH_2Cl_2$ (1×), DMF (1×) and $CH_2Cl_2$ (2×) treated with acetic anhydride/pyridine (10:1) for 30 min and washed with DMF (2×), $CH_2Cl_2$ (1×), DMF (1×) and $CH_2Cl_2$ (2×). Fmoc was removed with 20% piperidine in $CH_2Cl_2$/DMF (9:1). Ac-AA$^2$-OH [1.5 equiv.; AA$^2$ = Ala (**1**, **2**), Phe (**3**), Fca (**4**)] activated with HOBt (1.8 equiv.) and DIC (1.8 equiv.) in $CH_2Cl_2$/DMF (1:1) for 10 min was added and the resin shaken for 12 h. After washing with DMF (2×), $CH_2Cl_2$ (1×), DMF (1×) and $CH_2Cl_2$ (2×) the tripeptide was cleaved from the resin with 50% TFA in dichloromethane (1 h) and purified on silica gel (EtOAc/MeOH or EtOAc/THF) to give an orange powder.

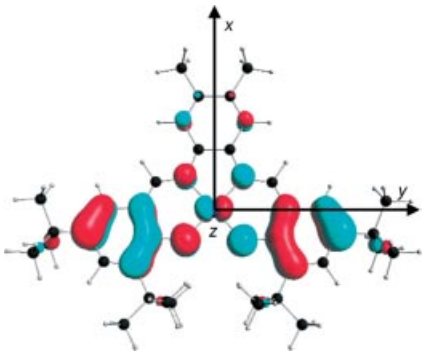
## SHORT COMMUNICATIONS

### Monoradical Complexes

**L. Benisvy, R. Kannappan, Y.-F. Song, S. Milikisyants, M. Huber, I. Mutikainen, U. Turpeinen, P. Gamez, L. Bernasconi, E. J. Baerends, F. Hartl, J. Reedijk*** ..... **637–642**

A Square-Planar Nickel(II) Monoradical Complex with a Bis(salicylidene)diamine Ligand

**Keywords:** Phenoxyl radicals / Nickel(II) complexes / Redox chemistry / Spectroelectrochemistry / EPR spectroscopy / Density functional calculations



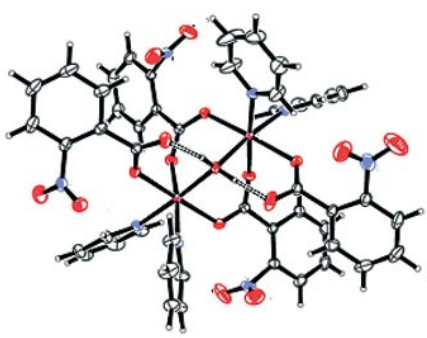
The square complex [Ni($^{Me}$L)] (**1**$^{Me}$) [$^{Me}$L = the dianionic phenolato form of *N*,*N*′-bis(3,5-di-*tert*-butylsalicylidene)-4,5-dimethyl-1,2-phenylenediamine ($^{Me}$LH$_2$)] has been synthesised and characterised. Electrochemical one-electron oxidation of **1**$^{Me}$ produces thermally stable (**1**$^{Me}$)$^+$ [10–295 K]. UV/Vis and EPR spectroscopy, supported by DFT calculations, indicate that (**1**$^{Me}$)$^+$ is best described as a Ni$^{II}$ monoradical complex and does NOT exist in a Ni$^{III}$ ground state, in contrast to its demethylated counterpart [Ni($^{H}$L)]$^+$ (**1**$^{H}$)$^+$ below 170 K.

### Polymorphism

**A. Karmakar, R. J. Sarma, J. B. Baruah*** ..... **643–647**

Polymorphism in an Aqua-Bridged, Dinuclear 2-Nitrobenzoate Complex of Cobalt(II)

**Keywords:** Dinuclear cobalt complexes / Aqua-bridged complexes / Polymorphism / Conformers



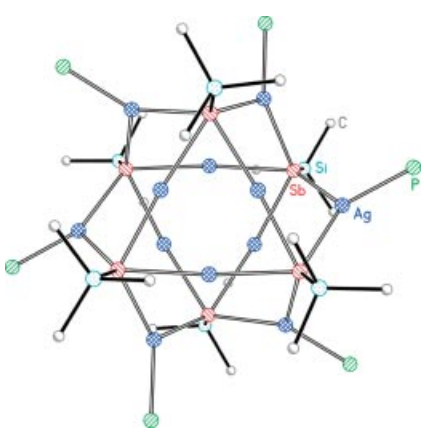
Three polymorphs of a dinuclear, aqua-bridged cobalt complex [$Co_2$(μ-$OH_2$)-($C_5H_5N$)$_4$(μ-$O_2CC_6H_4$-2-$NO_2$)$_2$($O_2CC_6H_4$-2-$NO_2$)$_2$] are structurally characterised. Selective crystallisation of the polymorphs is achieved by controlling the reaction conditions and the crystallisation processes. Reaction of cobalt(II) acetate tetrahydrate with 2-nitrobenzoic acid followed by treatment with excess pyridine leads to the mononuclear complex [$Co(H_2O)_2(C_5H_5N)_2$-($O_2CC_6H_4$-2-$NO_2$)$_2$].

### Antimony Anions

**D. Fenske,* A. Rothenberger, S. Wieber** ..... **648–651**

Synthesis and Characterization of the First Silver Complexes with Antimony Anions

**Keywords:** Silver / Antimony / Clusters



The synthesis and characterization of the silver antimony complexes [$Ag_{12}${Sb-($SiMe_3$)}$_6$($Pi Pr_3$)$_6$] (**1**), [$Ag_4(Sb_4Ph_4)_2$-($Pi Pr_3$)$_4$] (**2**) and [$Ag_4(Sb_6Ph_6)_2$($Pn Bu_3$)$_4$] (**3**) is reported.

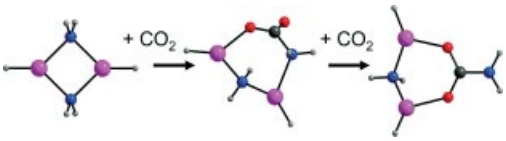
## $CO_2$ Fixation

**H.-J. Himmel* ..... 675–683**

$CO_2$ Fixation by Alkylzinc Amides: A Quantum Chemical Study Motivated by Recent Experimental Results

**Keywords:** $CO_2$ fixation / Zinc / Reaction mechanisms / Quantum chemical calculations



The mechanism of $CO_2$ fixation by monomeric as well as dimeric alkylzinc amides was studied by quantum chemical calculations. The results of this work help us in the understanding of $CO_2$ fixation by synthesized alkylzinc amides and also shed light on enzymatic reactivity.

## Metal-Organic Polymers

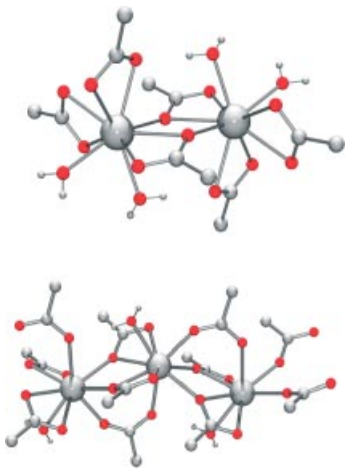
The Effect of Hydrothermal and Non-Hydrothermal Synthesis on the Formation of Holmium(III) Succinate Hydrate Frameworks

**Keywords:** Lanthanides / Hydrothermal synthesis / Hybrid frameworks / Coordination polymers



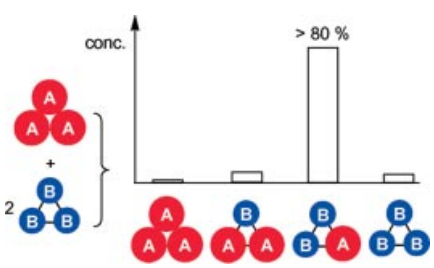
Holmium(III) succinates $[Ho_2(C_4H_4O_4)_3(H_2O)_4]\cdot 6H_2O$ (**1**) and $[Ho_2(C_4H_4O_4)_3(H_2O)_2]\cdot H_2O$ (**2**) have been synthesized under ambient and hydrothermal conditions, respectively. Single-crystal XRD shows that **1** is a 2D hybrid polymer and **2** presents a 3D architecture showing that hydrothermal conditions favor increasing dimensionality. They were characterized by FTIR and Raman spectroscopy, thermal analysis and magnetic measurements.

## Supramolecular Chemistry

**Z. Grote, R. Scopelliti, K. Severin* ..... 694–700**

Controlled Formation of Mixed-Metal Macrocycles Using Dynamic Exchange Processes and Steric Constraints

**Keywords:** Dynamic combinatorial chemistry / Metallamacrocycle / Organometallic complex / Rhodium / Ruthenium



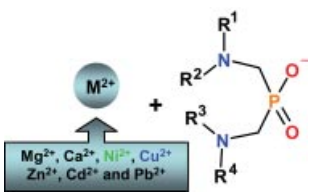
Size matters: Steric interactions in combination with dynamic exchange processes can be used to generate mixed-metal macrocycles in high yield. This is demonstrated by the controlled formation of organometallic macrocycles containing different (π-ligand)M fragments (M = Rh, Ru).

## Phosphinic Acid Derivatives

**G. Tircsó,* A. Bényei, R. Király, I. Lázár, R. Pál, E. Brücher ..... 701–713**

Complexation Properties of the Di-, Tri-, and Tetraacetate Derivatives of Bis(aminomethyl) Acid

**Keywords:** Phosphinic acid derivatives / Divalent metal ions / Synthesis / Protonation constants / Stability constants



Acetate derivatives of bis(aminomethyl)-phosphinic acid are synthesized and the stability of the complexes formed with these diamino-di-, -tri-, and -tetracarboxylates involving some endogenous ($Mg^{2+}$, $Ca^{2+}$, $Cu^{2+}$, $Zn^{2+}$) and toxic ($Ni^{2+}$, $Pb^{2+}$, and $Cd^{2+}$) doubly charged metal ions, are reported. The structure of the ligand $L^3$ (tricarboxylate) and the $Cu^{2+}$ complex of $L^1$ are studied in the solid state.

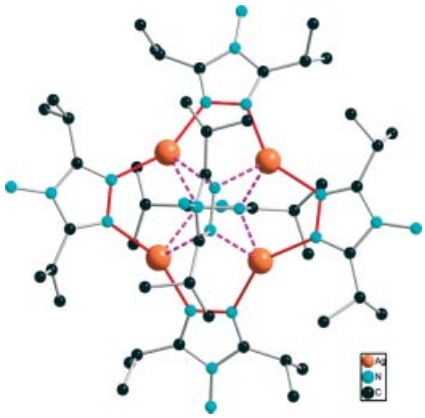
## Anion-Dependent Structural Diversity



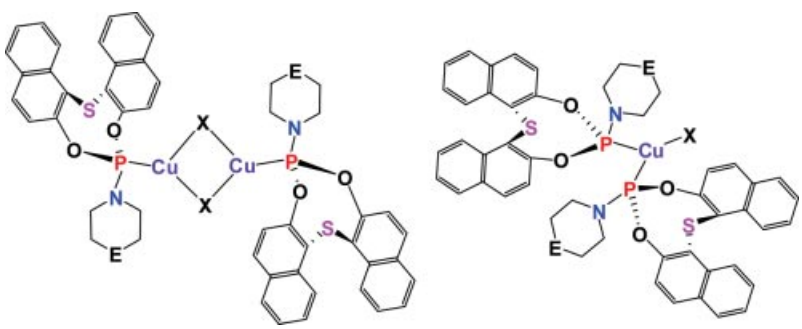
Reactions of silver(I) salts with 4-amino-3,5-diisopropyl-1,2,4-triazole (L) yield, based on the anion used, dinuclear, triangular or cyclic tetranuclear complexes. Shown here is the tetranuclear cation $[Ag_4L_6]^{4+}$, anions (not shown) are $BF_4^-$.

**G. Yang,* Y.-L. Wang, J.-P. Li, Y. Zhu, S.-M. Wang, H.-W. Hou, Y.-T. Fan, S. W. Ng ..... 714–719**

Anion-Dependent Structural Diversity in Silver(I) Complexes of 4-Amino-3,5-diisopropyl-1,2,4-triazole

**Keywords:** Silver / Triazole / Anions

## Thioether Aminophosphonite Complexes



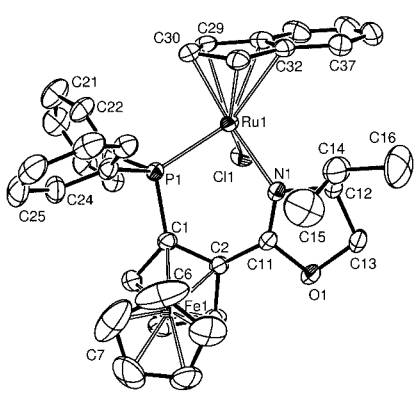
The reactivity of thioether aminophosphonites (L) with group 11 metal derivatives is described. A series of three-coordinate monomeric and dimeric complexes with or without the sulfur coordination are reported. Halogen exchange is observed between [LAuCl] and CuI to form [LAuI] and CuCl.

**B. Punji, J. T. Mague, M. S. Balakrishna* ..... 720–731**

Group 11 Metal Complexes of the Mesocyclic Thioether Aminophosphonites $[-OC_{10}H_6(\mu\text{-}S)C_{10}H_6O-]PNC_4H_8E$ (E = O, NMe)

**Keywords:** Thioether-aminophosphonites / P,S ligands / Copper / Gold

## Half-Sandwich Ruthenium(II) Complexes



Chiral-at-metal indenyl- and areneruthenium(II) complexes containing the chiral ligand (4*S*)-2-[($S_P$)-2-(diphenylphosphanyl)ferrocenyl]-4-(methylethyl)oxazoline (FcPN) have been synthesised diastereoselectively. The reported complexes include those containing alkynyl, allenylidene, and Fischer-type carbene ligands. The absolute configuration of the ruthenium atoms in representative complexes has been determined by X-ray analyses.

**A. García-Fernández, J. Gimeno, E. Lastra,* C. A. Madrigal, C. Graiff, A. Tiripicchio ..... 732–741**

Half-Sandwich $\eta^5$-Indenyl- and $\eta^6$-Areneruthenium(II) Complexes Bearing the Chiral Ligand (4*S*)-2-[($S_p$)-2-(Diphenylphosphanyl)-ferrocenyl]-4-(methylethyl)oxazoline (FcPN)

**Keywords:** N,P ligands / Phosphanes / Indenyl complexes / Arene complexes / Ruthenium

# A Square-Planar Nickel(II) Monoradical Complex with a Bis(salicylidene)-diamine Ligand

**Laurent Benisvy,[a] Ramu Kannappan,[a] Yu-Fei Song,[a] Sergey Milikisyants,[b] Martina Huber,[b] Ilpo Mutikainen,[c] Urho Turpeinen,[c] Patrick Gamez,[a] Leonardo Bernasconi,[d] Evert Jan Baerends,[d] František Hartl,[e] and Jan Reedijk*[a]**

**Keywords:** Phenoxyl radicals / Nickel(II) complexes / Redox chemistry / Spectroelectrochemistry / EPR spectroscopy / Density functional calculations

The new square-planar $Ni^{II}$–$N_2O_2$ complex [Ni($^{Me}$L)] (**1**$^{Me}$), where $^{Me}$L stands for the dianionic phenolato form of *N*,*N*′-bis(3,5-di-*tert*-butyl-salicylidene)-4,5-dimethyl-1,2-phenylenediamine ($^{Me}LH_2$), has been synthesised and fully characterised. X-ray crystallography was also used for the characterisation. The electrochemical one-electron oxidation of **1**$^{Me}$ produces the thermally stable (within the temperature range 10–295 K) cationic species (**1**$^{Me}$)$^+$. The UV/Vis and X-band EPR experimental data, supported by DFT calculations, indicate that (**1**$^{Me}$)$^+$ is best described as a $Ni^{II}$ monoradical complex and, thus, does NOT exist in a $Ni^{III}$ ground state, in contrast to its demethylated counterpart [Ni($^{H}$L)]$^+$ (**1**$^{H}$)$^+$ below 170 K.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

There has been much current interest in the nature and properties of d-transition-metal complexes in which one or more of the ligands are present in a radical state.[1] This interest has been stimulated by the observation and study of so-called "radical enzymes" in nature,[2] as illustrated by galactose oxidase (GO) that uses, in its active form, a phenoxyl radical directly bound to a $Cu^{II}$ centre to perform two-electron oxidation reactions.[3] Further, metal complexes bearing radical-type ligands may exhibit novel physical properties. In some cases, valence tautomerism [$M^{n+1}$–$^-$OPh] ↔ [$M^{n+}$–$^{\cdot}$OPh] occurs, which is of relevance for the construction of molecular switches.[4] For these reasons, a thorough understanding of the factors governing the locus of the oxidation (metal versus ligand) is of importance.

Consequently, various suitably protected phenol-containing ligands were designed and successfully applied to stabilise a phenoxyl radical state when coordinated to a transition metal.[1a] With nickel, various $Ni^{III}$ species have been characterised.[5] Recently, De Castro et al. investigated bis(salicylidene)diamine-type ligands at $Ni^{II}$ centres. Oxidation of the complexes in various polar solvents ($S_Y$) yielded the corresponding octahedral $Ni^{III}$ species [$Ni^{III}$(L)$(S_Y)_2$]$^+$.[5i–5n] At the same time, two research groups have independently reported that one-electron oxidation of the square-planar complexes [$Ni^{II}$($^{R}$L)] {$^{R}$L = a dianionic Schiff-base ligand with a cyclohexylene-1,2-diamine backbone ($^{Cy}$L*)[6] and a phenylene-1,2-diamine ($^{H}$L) backbone[7]} (see structure below) produces, in dichloromethane, a $Ni^{III}$ complex [$Ni^{III}$($^{R}$L)]$^+$ at sufficiently low temperature and a $Ni^{II}$ radical complex [$M^{II}$($^{R}$L$^{\cdot}$)]$^+$ ($^{R}$L$^{\cdot}$ = phenoxyl radical anion of $^{R}$L) above 190 K. These interesting results have been interpreted in terms of temperature-dependent tautomerism.[6,7]

Herein we report the synthesis and characterisation of the analogous dimethylated complex [Ni($^{Me}$L)] (**1**$^{Me}$) ($^{Me}$L contains the 4,5-dimethylphenylene-1,2-diamine backbone) and its one-electron oxidised product [Ni($^{Me}$L)]$^+$. Surprisingly, experimental EPR spectroscopic and UV/Vis spectroelectrochemical data reveal that the oxidised species does NOT exist in a $Ni^{III}$ ground state in the studied low-temperature range, in contrast to its counterparts [Ni($^{H}$L)]$^+$ and [Ni($^{Cy}$L)]$^+$.[6,7] Instead, it can be best formulated as a $Ni^{II}$ monoradical complex [$Ni^{II}$($^{Me}$L$^{\cdot}$)]$^+$. DFT calculations support this assignment, pointing to the negligible effect of the methyl groups when the electronic structures of [Ni($^{H}$L)]$^+$ and [Ni($^{Me}$L)]$^+$ are compared.

The tetradentate ligand *N*,*N*′-bis(3,5-di-*tert*-butyl-salicylidene)-4,5-dimethylphenylene-1,2-diimine ($^{Me}LH_2$) was synthesised by the condensation of 4,5-dimethylphenylene-1,2-diamine with 3,5-di-*tert*-butyl-salicylaldehyde, as previously reported.[8] The reaction of $^{Me}LH_2$ with $Ni(ClO_4)_2{\cdot}6H_2O$ (1:1) in methanol leads to the formation of red, needlelike crystals of [Ni($^{Me}$L)] ($\mathbf{1}^{Me}$) in 77% yield. The molecular structure of $\mathbf{1}^{Me}$ (Figure 1), determined by X-ray crystallography at 173 K, reveals a $Ni^{II}$ centre with a square-planar $N_2O_2$ coordination sphere defined by the two imine nitrogen atoms [N(30), N(40)] and the two phenolate oxygen atoms [O(10), O(20)] of $^{Me}$L. As expected, the structure and molecular dimensions of $\mathbf{1}^{Me}$ are almost identical to those of $\mathbf{1}^{H}$ (see Table S1).[7] Thus, the Ni–O and Ni–N bond lengths [1.853(3)–1.861(2) Å] are short. The mean deviation from the least-squares plane defined by Ni(1), O(10), O(20), N(30) and N(40) is 0.11 Å, with a dihedral angle of 9.6° between the O(10)–Ni(1)–N(30) and O(20)–Ni(1)–N(40) planes.

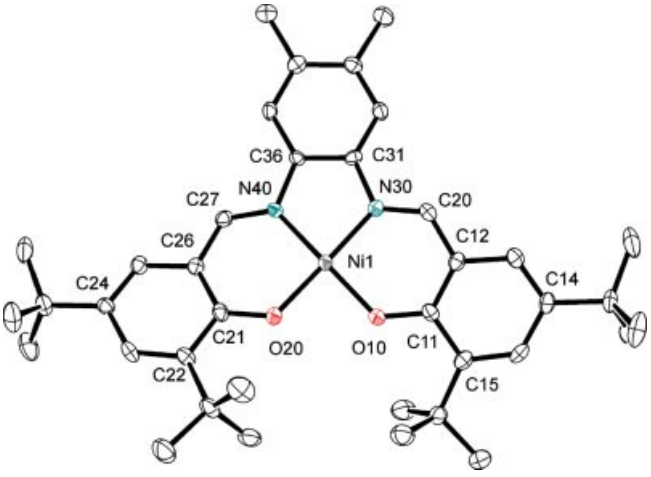

Figure 1. ORTEP representation of [Ni($L^{Me}$)] ($\mathbf{1}^{Me}$) shown with 50% thermal ellipsoids, as determined at 173 K. The hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°] for **1**: Ni(1)–O(10), 1.856(2); Ni(1)–O(20), 1.861(2); Ni(1)–N(30), 1.856(3); Ni(1)–N(40), 1.853(3); C(11)–O(10), 1.327(4); C(21)–O(20), 1.327(4); C(27)–N(40), 1.321(4); C(36)–N(40), 1.428(4); C(31)–N(30), 1.421(4); C(17)–N(30), 1.318(4) Å. O(10)–Ni(1)–N(40), 173.03(11); O(10)–Ni(1)–N(30), 94.07(11); N(40)–Ni(1)–N(30), 85.63(12); O(10)–Ni(1)–O(20), 86.86(9); N(40)–Ni(1)–O(20), 94.25(11); N(30)–Ni(1)–O(20), 173.37(11)°.

Complex $\mathbf{1}^{Me}$ exhibits no EPR signal, neither in the solid state nor in $CH_2Cl_2$ solution, at room temperature or at 77 K. This result indicates that $\mathbf{1}^{Me}$ is diamagnetic ($S = 0$), as expected for a low-spin $d^8$ square-planar $Ni^{II}$ complex. In $CDCl_3$ solution, $\mathbf{1}^{Me}$ exhibits a well-defined $^1$H NMR spectrum with resonances between 0 and 10 ppm, which also confirms its diamagnetic nature. Similar to that of complex $\mathbf{1}^{H}$,[7] the UV/Vis spectrum of $\mathbf{1}^{Me}$ in $CH_2Cl_2$ (Figure 2) displays an absorption band at $\lambda_{max}$ = 385 nm ($\varepsilon_{max}$ = 29800 $M^{-1}cm^{-1}$) due to a $\pi\rightarrow\pi^*$ intraligand transition. Another intense absorption band at 499 nm ($\varepsilon_{max}$ = 8900 $M^{-1}cm^{-1}$) and a shoulder at 475 nm ($\varepsilon$ = 6700 $M^{-1}cm^{-1}$) are assigned to a phenolate→$Ni^{II}$ charge transfer. A weak shoulder at about 600 nm ($\varepsilon < 200\ M^{-1}cm^{-1}$) may correspond to a largely metal-centred (MC) transition. These spectroscopic observations suggest that the square-planar $Ni^{II}$–$N_2O_2$ coordination sphere is retained in $CH_2Cl_2$ solution.

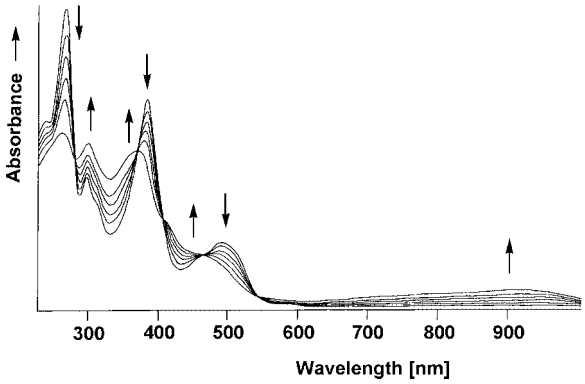

Figure 2. UV/Vis spectroelectrochemistry for the first oxidation of $\mathbf{1}^{Me}$ in $CH_2Cl_2$ containing $[NBu^n_4][ClO_4]$ (0.3 M) at 293 K.

The cyclic voltammogram (CV) of complex $\mathbf{1}^{Me}$ in dichloromethane ($v$ = 100 mV/s, $T$ = 293 K) exhibits two reversible ($I_{p,c}/I_{p,a}$ = 1) one-electron anodic processes at $E_{1/2}$ = +0.49 V ($\Delta E_p$ = 80 mV) and 0.78 V ($\Delta E_p$ = 110 mV) vs. $Fc/Fc^+$ ($\Delta E_p$ = 80 mV) used as an internal standard (see Figure S1). These oxidation processes are associated with the formation of $(\mathbf{1}^{Me})^+$ and $(\mathbf{1}^{Me})^{2+}$, respectively. The larger peak-to-peak separation for the second anodic step producing $(\mathbf{1}^{Me})^{2+}$ indicates a slower electron transfer, most likely associated with a change in the molecular structure of the dicationic product. This difference between the anodic steps became more apparent on the longer time scale of the spectroelectrochemical experiments (see below). Interestingly, the $E_{1/2}$ values determined for $\mathbf{1}^{Me}$ are lower than those observed for $\mathbf{1}^{H}$ by 90 and 20 mV for the first and second couple, respectively,[7] and reveal a stabilisation effect of the methyl groups at the phenyl-diene backbone on the oxidised species.

Corresponding UV/Vis spectroelectrochemical experiments with $\mathbf{1}^{Me}$ in the anodic region were performed in dichloromethane at 293 K (Figure 2) and 233 K, with almost identical results. The one-electron-oxidised species

$(\mathbf{1}^{Me})^+$ remains fully stable at both temperatures, as revealed by the completely reversible thin-layer cyclic voltammetric response (with a small $\Delta E_p$ value of about 20 mV, which is comparable to that of the $Fc/Fc^+$ couple) recorded in the course of the anodic and reverse cathodic scans. In the UV/Vis spectral region, the conversion of $\mathbf{1}^{Me}$ to $(\mathbf{1}^{Me})^+$ at room temperature is accompanied by the disappearance of the absorption bands of the parent complex (see Experimental Section) and the growth of new intense bands of the cationic product at $\lambda_{max}$ ($\varepsilon_{max}$, $M^{-1}\,cm^{-1}$) = 300 (23 200), 374 (22 400), 411 (sh., better resolved at 233 K) and 468 nm(7300); in addition, a broad absorption band of lower intensity appears at a low energy, with poorly resolved maxima at $\lambda_{max}$ ($\varepsilon_{max}$, $M^{-1}\,cm^{-1}$) = 810 (2100) and 920 nm (2500). The reversibilty of the first anodic step is reflected by the presence of isosbestic points at 280, 375, 405, 466 and 543 nm (Figure 2) and the full recovery of the initial UV/Vis spectrum of $\mathbf{1}^{Me}$ after "back reduction" of $(\mathbf{1}^{Me})^+$. It is important to note that absorption bands at ca. 400 nm ($\varepsilon_{max}$ ca. 10 000 $M^{-1}\,cm^{-1}$) are typically found for phenoxyl radical complexes and have been attributed to a $\pi\rightarrow\pi^*$ electronic transition of the phenoxyl ligand.[1a,9] The broad low-energy bands may have their origin in an electron transfer to the phenoxyl singly occupied molecular orbital (SOMO) from lower-lying occupied levels.[10] Thus, one-electron-oxidised $(\mathbf{1}^{Me})^+$ shows the spectroscopic signature of a phenoxyl radical complex, which suggests that the oxidation of $\mathbf{1}^{Me}$ to $(\mathbf{1}^{Me})^+$ is predominantly ligand-centred.

The second anodic step, i.e. the oxidation of $(\mathbf{1}^{Me})^+$ to $(\mathbf{1}^{Me})^{2+}$, is characterised by a large separation between the anodic and reverse cathodic peaks of the couple observed in the thin-layer cyclic voltammogram exceeding 500 mV at 233 K. This result points to a significant difference between the ultimate molecular structures of $(\mathbf{1}^{Me})^+$ and $(\mathbf{1}^{Me})^{2+}$. The electronic absorption spectrum of $(\mathbf{1}^{Me})^{2+}$ (not shown) exhibits a very intense band at 300 nm with a shoulder at 325 nm, two less intense bands of similar intensities at 420 and 455 nm and a weak band at 558 nm. The absorption maximum at 820 nm disappeared and the broad, low-energy absorption band shifted more to the NIR region relative to $(\mathbf{1}^{Me})^+$ (Figure 2). These absorption features indicate the presence of the coordinated phenoxyl radical chromophore also in the dicationic product $(\mathbf{1}^{Me})^{2+}$. The subsequent oxidation of $(\mathbf{1}^{Me})^+$ is presumably localised more at the nickel(II) centre, causing changes in the coordination sphere, which may explain the electrochemically irreversible nature of the second anodic step. However, detailed investigation of this process is beyond the scope of this work. Back reduction of $(\mathbf{1}^{Me})^{2+}$ resulted in the smooth recovery of $(\mathbf{1}^{Me})^+$, thereby excluding any decomposition or irreversible structural change induced by the second anodic reaction.

The X-band EPR spectra of $(\mathbf{1}^{Me})^+$ − generated electrochemically (Figure 3) by bulk electrolysis in $CH_2Cl_2$ (see Experimental Section) − were recorded in the temperature range 10–240 K. Above the freezing point of $CH_2Cl_2$ (170–190 K), the EPR spectrum exhibits a single unresolved isotropic signal centred at $g_{iso}$ = 2.04 with a peak-to-peak line width of ca. 100 G. This spectrum resembles those obtained for $[Ni(^{H}L)]^{+}$[7] and $[Ni(^{Cy}L)]^{+}$[6] at T > 190 K. The $g_{av}$ values for the latter spectra (2.03–2.04) are much lower than those expected for a $Ni^{III}$ species ($g_{av}$ values ranging from 2.13 to 2.17),[5] but higher than $g$ factors reported for free[11] or Zn-coordinated[7,10] phenoxyl radicals (2.004–2.005), which are typically close to the free electron value ($g_e$ = 2.0023).[10b] At temperatures below the freezing point of $CH_2Cl_2$ (10–170 K), the EPR spectrum of $(\mathbf{1}^{Me})^+$ displays a rhombic signal with $g_{11}$ = 2.00, $g_{22}$ = 2.02, $g_{33}$ (broad) = 2.10 and a $g_{av}$ value of 2.04 (obtained from numerical calculation of the average over the whole spectrum). The values $g_{11}$ = 2.00 and $g_{22}$ = 2.02 were obtained directly from the spectrum, and $g_{33}$ was calculated from $g_z = 3g_{av} - g_x - g_y$. Thus, the $g_{av}$ value in frozen $CH_2Cl_2$ is identical to that obtained above 190 K in fluid solution. This observation is in sharp contrast with the EPR spectra recorded for $[Ni(^{H}L)]^+$ and $[Ni(^{Cy}L)]^+$ at $T < 170$ K, which exhibit an axial signal with $g_\perp > g_\parallel$ and $g_{av}$ of 2.17 and 2.18, respectively.[6,7] The latter spectra are typically observed as a result of a $(d_{z^2})^1$ ground state, which, to the best of our knowledge, can only be achieved for six-coordinate tetragonally elongated nickel(III) compounds,[5] as predicted by the theory.[12]

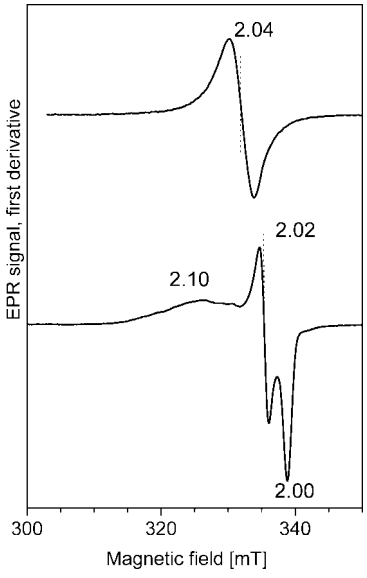

Figure 3. X-band EPR spectrum of electrochemically generated$(\mathbf{1}^{Me})^+$ recorded in frozen $CH_2Cl_2$ at 30 K (bottom) and at 255 K (top). The numbers indicate the $g$ values (see text).

Thus, the experimental data obtained for $(\mathbf{1}^{Me})^+$ indicate that the electronic structure of the complex remains unchanged in the 10–240 K temperature range. In frozen $CH_2Cl_2$, the anisotropy becomes resolved. The anisotropy of $(\mathbf{1}^{Me})^+$ and the low $g_{av}$ value are consistent with a $Ni^{II}$ radical complex; the metal centre has a partial $Ni^{III}$ character (vide infra) with a $(dp)^1$ configuration (dp = $d_{xy}$, $d_{xz}$ or $d_{yz}$) in a square-planar coordination environment. Such interpretation agrees well with the rhombic or axial EPR

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectra obtained for $Ni^{II}$–$(N_2O_2)^{\cdot}$ complexes bearing oxamato ($g_{\|} = 2.040 > g_{\perp} = 2.005$;[13] $g_{av} = 2.028$), salicylamidato ($g = 2.09, 2.03, 1.95$; $g_{av} = 2.023$)[7] or semiquinonato ($g_x = 2.0098, 2.0384, 2.1097$; $g_{av} = 2.019$)[14] radical ligands.

DFT calculations were performed with all core states explicitly included, and exchange-correlation effects were treated at the BP86[15a,15b] level of theory. Geometry optimisation, frontier orbitals and EPR parameters were calculated for both parent ($\mathbf{1}^{Me}$) and oxidised compound $(\mathbf{1}^{Me})^+$, and similar treatments were applied for $\mathbf{1}^{H}$ and $(\mathbf{1}^{H})^+$ for comparison. The calculated structural parameters for geometry optimised $\mathbf{1}^{Me}$ and $\mathbf{1}^{H}$ have been found to agree appreciably with the corresponding data obtained by X-ray crystallography: bond lengths are reproduced within ±0.02 Å and bond angles within ±0.2° (Table S1). The calculated *g*-tensor parameters for $(\mathbf{1}^{Me})^+$ are $g_{xx} = 2.1341$, $g_{yy} = 2.0027$, $g_{zz} = 1.9822$. The *z* axis is perpendicular to the plane of the molecule and the *x* axis is the $C_2$ axis of the system along the plane of the molecule, as indicated in Figure 4. The result is in good agreement (within 0.03) with the experimental data. In particular, the anisotropy in the *g* values has been well reproduced, with the two *g* values close to $g_e$ separated by ca. 0.02 ($g_{yy} - g_{zz}$) and $g_{xx} > g_{yy}$, $g_{zz}$. We thus tentatively assign the principal *g*-tensor orientations as $g_{11}(2.00) = g_{zz}$, $g_{22}(2.02) = g_{yy}$ and $g_{33}(2.10) = g_{xx}$. This finding supports the validity of the theoretical model and rules out unambiguously a $(d_{z^2})^1$ low-spin $Ni^{III}$ ground state, as had been proposed for $(\mathbf{1}^{H})^+$[7] and $(\mathbf{1}^{Cy})^+$.[6] The calculated singly occupied molecular orbital (SOMO) and the corresponding unpaired spin density distribution of $(\mathbf{1}^{Me})^+$ were also analysed. The SOMO is mainly delocalised on both phenoxy rings, with appreciable contributions of the nickel $d_{xz}$ (6.49%) and $d_{yz}$ (6.33%) orbitals (Figure 4). Consequently, ca. 75% of the unpaired spin is located on the ligand and 25% on the nickel centre. For each phenoxy ring, the typical phenoxy radical pattern with an alternating spin density distribution was obtained; a significant amount of positive spin population at the O (0.115), $C_{ortho}$ (0.08 and 0.06) and $C_{para}$ (0.11) atoms (Figure S2 and Table S2) accounts for ca. 72% of the total spin density. Hence, the calculations agree well with the experimental findings, and $(\mathbf{1}^{Me})^+$ is best described as a nickel(II) complex with a phenoxyl-type radical ligand. In addition, the DFT calculation on $(\mathbf{1}^{H})^+$ shows that the calculated bond parameters of the complex, the nature of the SOMO and the anisotropy in the *g* tensor (calculated *g* values are $g_{zz} = 1.97771$, $g_{yy} = 2.0027$, $g_{xx} = 2.1329$) are essentially identical to the corresponding parameters obtained for $(\mathbf{1}^{Me})^+$. This result is consistent with the calculated absence of spin density on the methyl groups in $(\mathbf{1}^{Me})^+$ and rules out any significant electronic effect of the methyl groups that can explain the EPR discrepancies between $(\mathbf{1}^{Me})^+$ and $(\mathbf{1}^{H})^+$ in frozen $CH_2Cl_2$. Moreover, in the case of $(\mathbf{1}^{H})^+$, the EPR data in MeOH remain essentially unchanged relative to those obtained in $CH_2Cl_2$, which suggest a six-coordinate species.[7] Such a coordination environment may have been achieved by either axial coordination of remnant water molecules or intermolecular interactions that may have been prevented by the presence of the methyl groups in the case of $(\mathbf{1}^{Me})^+$.

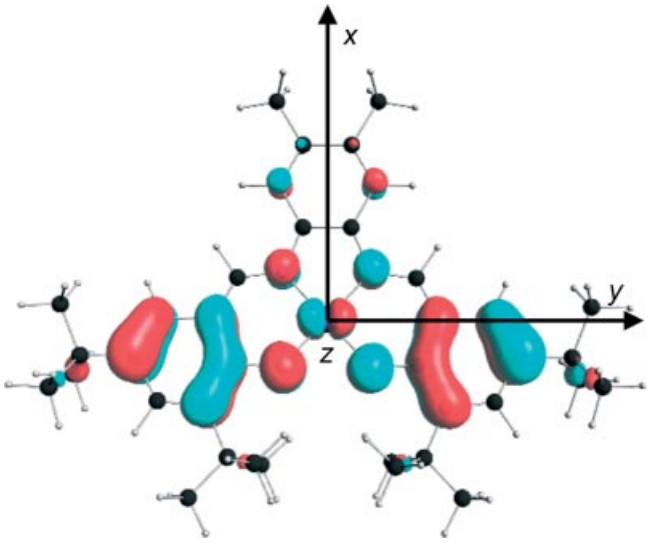

Figure 4. Calculated SOMO for geometry-optimised $(\mathbf{1}^{Me})^+$.

## Conclusions

In this communication, we have demonstrated that the one-electron oxidation of the diamagnetic $S = 0$, $d^8$, low-spin $Ni^{II}$ square-planar compound $[Ni^{II}(^{Me}L)]$ occurs largely on the Schiff-base ligand, yielding $[Ni^{II}(^{Me}L^{\cdot})]^+$. The latter cation is the first example of a thermally stable (within the temperature range 10–295 K) $Ni^{II}$ phenoxyl radical complex. The EPR discrepancies observed (below 170 K) for the reported related complexes $[Ni^{III}(^{H}L)]^+$ and $[Ni^{III}(^{Cy}L)]^+$ cannot be explained by electronic effects. Rather, they may be the result of axial coordination by water (present as impurities) and/or intermolecular interactions, which allow the stabilisation of a six-coordinate $Ni^{III}$ complex. Apparently, this coordination is not stable at higher temperatures and leads to a *g* value in liquid solution that is close to the $g_{av}$ value observed in the present study. Several new bis(salicylidene)diaminenickel(II) complexes with various substituents on the phenylene backbone are being synthesised in order to shed more light on the factors that govern the "spectroscopic" oxidation states of their one-electron oxidation product.

## Experimental Section

**Synthesis of [Ni($^{Me}$L)] ($\mathbf{1}^{Me}$) and Characterisation by NMR Spectroscopy, MS and Elemental Analysis:** $H_2L$ (0.568 g, 0.001 mol) in $CHCl_3$ (25 mL) was added to a solution of nickel(II) perchlorate hexahydrate (0.365 g, 0.001 mol) in methanol (10 mL), and the resulting red solution was stirred for 2 h at room temperature. Slow evaporation of the solvent yielded red, needle-shaped crystals within one day, which were isolated, washed with diethyl ether and dried in air. The crystals appeared to be suitable for X-ray structural determination. Yield: 0.46 g (77%). $C_{38}H_{50}N_2NiO_2$ (625.51): calcd. C 72.97, H 8.06, N 4.48; found C 73.04, H 7.71, N 4.40.

ES(+)-MS: $m/z$ = 624.36 [$M^+$]. IR (neat solid): $\nu$(C=N): 1616 $cm^{-1}$. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon_{max}$, $M^{-1}cm^{-1}$) = 268 (42 400), 299 (18 300), 312 (sh.), 385 (29 800), 475 (sh.), 499 (8 900) nm. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.14 (s, 2 H, H–C=N), 7.44 (s, 2 H, $H_{PhN_2}$), 7.39 (d, $^4J$ = 2.7 Hz, 2 H, $H_{PhO}$), 7.09 (d, $^4J$ = 2.7 Hz, 2 H, $H_{PhO}$), 2.30 (s, 6 H, $CH_3$), 1.46 [s, 18 H, $C(CH_3)_3$], 1.30 [s, 18 H, $C(CH_3)_3$] ppm. All measurements were performed on locally available standard instruments.

**Electrochemistry:** Each experiment was performed under dinitrogen using dry, distilled and degassed $CH_2Cl_2$. The cyclic voltammogram of the studied compound $\mathbf{1}^{Me}$ ($10^{-3}$ M) in $CH_2Cl_2$ containing [$NBu^n_4$][$ClO_4$] ($4\times10^{-1}$ M) as the background electrolyte was recorded at room temperature with a glassy carbon working electrode, a Pt plate auxiliary electrode and a Ag/AgCl reference electrode. The electrode potentials are referenced against the $Fc/Fc^+$ couple that was used as the internal standard. The oxidised species $(\mathbf{1}^{Me})^+$ was generated by controlled potential electrolysis (CPE) performed on $\mathbf{1}^{Me}$ ($10^{-3}$ M) at 263 K in a $CH_2Cl_2$ solution containing [$NBu^n_4$][$ClO_4$] ($4\times10^{-1}$ M) as the background electrolyte. The electrolytic cell consisted of a Pt gauze basket working electrode, a Pt gauze auxiliary electrode and a Ag/AgCl reference electrode. Both CV and CPE measurements were performed by using an Autolab PGSTAT20 potentiostat.

**UV/Vis Spectroelectrochemistry:** UV/Vis spectroelectrochemical experiments at low temperatures were performed with a cryostatted optically transparent thin-layer electrochemical (OTTLE) cell equipped with $CaF_2$ windows and a Pt minigrid working electrode (32 wires per cm).[16a] The electrolysis at room temperature was conducted with another home-made demountable OTTLE cell.[16b] The concentrations of the solutions were typically $3\times10^{-1}$ M in the supporting electrolyte ([$NBu^n_4$][$ClO_4$]) and $10^{-3}$ M in the analyte. The working electrode potential of the spectroelectrochemical cells was controlled with a PA4 potentiostat (EKOM, Polná, Czech Republic). A thin-layer cyclic voltammogram was recorded during the course of each spectroelectrochemical experiment. The electronic absorption spectra were obtained with a HP 8453 diode array spectrophotometer.

**EPR Spectroscopy:** X-band (9.48 GHz) cw-EPR spectra were recorded by using a ELEXSYS E680 (Bruker, BioSpin, Rheinstetten) spectrometer with a TE102 resonator. Sample solutions of electrochemically generated $(\mathbf{1}^{Me})^+$ (vide ultra) were rapidly transferred under exclusion of dioxygen into an X-band quartz tube (4-mm inner diameter), which was immediately frozen and stored in liquid nitrogen. The measurements were performed at temperatures from 10 to 240 K using an Oxford ESR 900H cryostat. The microwave power supplied to the resonator was varied in the range 0.2–2 mW; a 100-kHz magnetic field modulation with a peak-to-peak amplitude of 0.5 mT was used.

**DFT Calculations:** The calculations were performed with the Amsterdam Density Functional (ADF 2005) program system.[15c,15d] A Slater-type orbital basis set of triple zeta quality for the valence orbitals was used, augmented with a polarization function, cf. the standard TZP basis.[15e] Calculations were performed on isolated molecules, without inclusion of solvent molecules.[15f]

**X-ray Crystallographic Study of $\mathbf{1}^{Me}$:** Crystal data: $C_{38}H_{50}N_2NiO_2$, red, needle, $F_w$ = 625.51, triclinic, space group $P\bar{1}$, $a$ = 9.2500(10) Å, $b$ = 14.865(2) Å, $c$ = 14.951(2) Å, $\alpha$ = 119.220(10)°, $\beta$ = 101.650(10)°, $\gamma$ = 92.310(10)°, $V$ = 1733.9(4) $Å^3$, $d$ = 1.198 $g\,cm^{-3}$, $Z$ = 2, $T$ = 173(2) K, $F(000)$ = 627, $\mu$(Mo-$K_\alpha$) = 0.593 $mm^{-1}$. A transparent, red, needlelike single crystal of $0.25\times0.05\times0.05$ mm was mounted on a Lindemann glass capillary and transferred into the cold nitrogen stream of a Nonius KappaCCD diffractometer on a rotating anode (Mo-$K_\alpha$ radiation, graphite monochromator, $\lambda$ = 0.71073 Å). 27617 independent reflections (7944 unique; $R_{int}$ = 0.117) were collected. The intensity data were corrected for Lorentz and polarisation effects and for absorption. The structure was solved by direct methods. The programs COLLECT[17a] SHELXS-97[17b] and SHELXL-97[17c] were used for data reduction, structure solution and structure refinement, respectively. The final agreement factors are $R_1$ = 0.0657 for 4241 data with $F > 4\sigma(F)$ and $R_1$ = 0.1554, $wR_2$ = 0.1433 for 7944 data. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed at idealised positions and allowed to ride on the connecting atom. CCDC-622859 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Cyclic voltammogram of $\mathbf{1}^{Me}$, in $CH_2Cl_2$, containing [$NBu^n_4$][$ClO_4$] (0.4 M), plot of the distribution of the non-zero spin populations, calculated bond lengths [Å] and angles [°] for the optimised structure of $\mathbf{1}^{Me}$ and $\mathbf{1}^{H}$, list of individual atomic electron spin density calculated for $(\mathbf{1}^{Me})^+$.

# Polymorphism in an Aqua-Bridged, Dinuclear 2-Nitrobenzoate Complex of Cobalt(II)

**Anirban Karmakar,[a] Rupam J. Sarma,[a] and Jubaraj B. Baruah*[a]**

**Keywords:** Dinuclear cobalt complexes / Aqua-bridged complexes / Polymorphism / Conformers

Three polymorphs of a dinuclear, aqua-bridged cobalt complex with the composition $[Co_2(\mu\text{-}OH_2)(C_5H_5N)_4(\mu\text{-}O_2CC_6H_4\text{-}2\text{-}NO_2)_2(O_2CC_6H_4\text{-}2\text{-}NO_2)_2]$ are identified and the crystal structures are determined by X-ray crystallography. Selective crystallisation of the polymorphs can be achieved by controlling the reaction conditions as well as the crystallisation processes. The reaction of cobalt(II) acetate tetrahydrate with 2-nitrobenzoic acid followed by treatment with excess pyridine leads to a mononuclear complex with the composition $[Co(H_2O)_2(C_5H_5N)_2(O_2CC_6H_4\text{-}2\text{-}NO_2)_2]$.

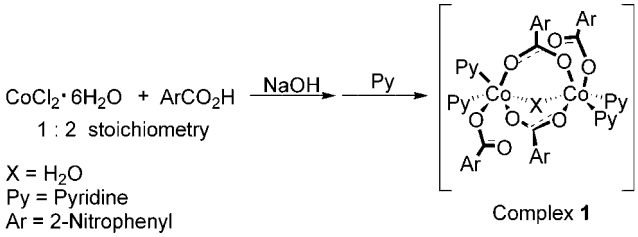
## Introduction

Polymorphism of a molecule (or compound) may be related to the ability of it having different crystalline phases. The crystallisation process leading to a polymorph is generally sensitive to variation in the conditions of temperature, pressure and/or the manner in which the crystals are obtained.[1] Polymorphism in organic crystals,[2] including crystals of pharmaceutically active compounds,[3] is an active area of research, which is driven by the rationale that such a study would provide insight/understanding into the kinetic and thermodynamic factors that govern nucleation and crystal growth. Subsequently, this may enable us to gain control of the crystallisation process, and in particular, the production/exclusion of the specific polymorph. Studies have shown that interconversion between polymorphs is possible through the mechanochemical processing of solid compounds[4] or through the mixing of several components in the solid phase.[5] Consequently, aspects related to the synthesis, structure and polymorphism in metal coordination complexes is emerging as an active field of research.[6] In this communication, we report three polymorphs of an aqua–bridged, dinuclear cobalt(II) complex **1** and describe their synthetic and structural aspects. From a structural perspective, such aqua-bridged dinuclear cobalt(II) complexes may be regarded as synthetic mimics of the active sites of certain metalloenzymes[7] such as leucine aminopeptidase as they contain a dinuclear cobalt core that has an aqua as well as a carboxylate group as bridged ligands, along with monodentate nitrogen-containing ligands at two ends. This makes their study quite relevant. While the complex itself [having the same coordination environment about the two cobalt(II) ions] may be synthesised by grinding the solid reactants followed by solution processing or by solution processing alone, the polymorphs may be identified from differences in the relative orientation of the 2-nitrobenzoate groups that are coordinated to the cobalt(II) ions in the complex. A similar phenomenon is known for organic compounds,[8] but is less known for coordination complexes of cobalt(II) carboxylate compounds.[9a]

## Results and Discussion

We have found that the reaction of cobalt(II) chloride hexahydrate with 2-nitrobenzoic acid, sodium hydroxide and pyridine in methanol gives complex **1** [Equation (1)], which crystallises as pink rods in the triclinic space group $P\bar{1}$ (polymorph **I**).



(1)

In this complex, each cobalt(II) ion is coordinated to a monodentate benzoate molecule and two pyridine molecules; the six-coordinate octahedral geometry is completed by two bridging 2-nitrobenzoate groups and a bridging aqua ligand. The monodentate 2-nitrobenzoate molecule is intramolecularly hydrogen bonded to the bridging aqua group {O(17)–H···O(14) [2.578(2) Å, 167(3)°] and O(17)–

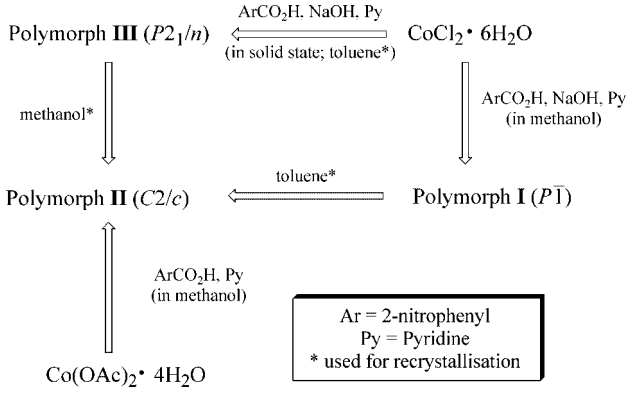
H···O(2) [2.508(3) Å, 177(4)°]}. The corresponding Co(1)–O(17) and Co(2)–O(17) bond lengths are found to be 2.1255(15) and 2.1278(15) Å, respectively, while the Co(1)–O(17)–Co(2) bond angle is 114.55(7)°. Moreover, weak intramolecular C(6)–H···O(3) [3.255(4) Å, 158°], C(6)–H···O(1) [3.103(3) Å, 124°], C(10)–H···O(10) [3.104(4) Å, 125°], C(10)–H···O(12) [3.281(5) Å, 150°] and C(17)–H···O(5) [2.722(3) Å, 101°] interactions are also observed in this polymorph. These interactions stabilise the *out-out* orientation of the nitro groups of 2-nitrobenzoate ligand relative to the Co(1)–O(17)–Co(2) fragment in the complex. These molecules have a self-assembled structure in the lattice through weak C(14)–H···O(12) [3.429(4) Å, 158°] and C(2)–H···O(7) [3.279(5) Å, 139°] interactions, and the corresponding packing diagram is shown in Figure 2a. We have also found two other polymorphs of this compound, and the synthesis of these polymorphs is highly dependent on the reaction conditions, as illustrated in Scheme 1. The crystal structures of all the three polymorphs were determined and are shown in Figure 1.



Scheme 1.

Complex **1** was also prepared by reaction of cobalt(II) acetate tetrahydrate with 2-nitrobenzoic acid and pyridine in methanol. However, this complex crystallises, from methanol, as pink plates in the monoclinic *C*2/*c* space group (polymorph **II**). In polymorph **II**, each cobalt(II) ion is coordinated to a monodentate 2-nitrobenzoate molecule and two pyridine molecules; two bridged 2-nitrobenzoate groups and the aqua bridge complete the six-coordinate octahedral geometry. The crystal structure of **II** shows that the complex is stabilised [such that the Co(1)···Co(1′) distance is 3.616(3) Å] by intramolecular hydrogen bonding between the monodentate 2-nitrobenzoate and bridging aqua groups {O(9)–H···O(2) [2.582(16) Å, 157°]}. The corresponding Co(1)···O(9) distance is 2.142(9) Å, while the Co(1)–O(9)–Co(1′) bond angle is 115.11(8)°. The packing structure of **II** is shown in Figure 2b, wherein the molecules are held in the lattice through weak intermolecular C3–H···O2 [3.229(3) Å, 156°] and C4–H···O4 [3.292 Å, 127°] interactions. In polymorph **II**, the nitro groups of each carboxylate ligand projects inwards and they therefore may be described as having *in-in* orientations.

Reaction of cobalt(II) chloride hexahydrate, 2-nitrobenzoic acid and sodium hydroxide in the solid state followed by addition of pyridine (in a 1:2:2 stoichiometry) also gave the dinuclear cobalt(II) complex **1**. This complex is soluble in toluene and could subsequently be crystallised as pink plates in the $P2_1/n$ space group (polymorph **III**). The packing diagram of this polymorph is given in Figure 2c.

It is noteworthy that in polymorph **I**, each of the nitro groups adopts an *out-out* orientation in the dinuclear cobalt(II) complex. On the other hand, polymorph **III** can be identified by two of the 2-nitrobenzoate groups adopting an *out-out* orientation and two adopting an *out-in* orientation relative to the Co–O–Co fragment. The corresponding powder XRD patterns of the polymorphs were recorded and compared with the calculated patterns, which substantiated our observation of distinct crystalline phases. Surprisingly, recrystallisation of polymorph **I** from methanol gave pink "square" plates, and structural analysis led to the identification of polymorph **II** (monoclinic *C*2/*c*). Similarly, recrystallisation experiments of polymorph **III** from toluene also gave pink "square" plates in the *C*2/*c* space group. Subsequently, we performed powder XRD analysis of the samples (see Supporting Information), which confirmed the

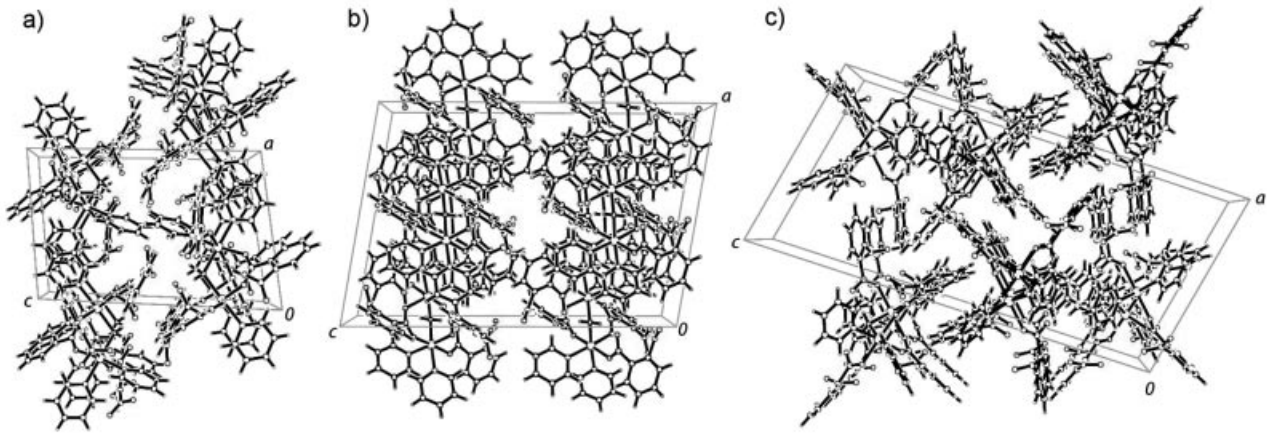

Figure 2. Packing structures of complex **1**: a) polymorph **I**, (b) polymorph **II** and (c) polymorph **III**.

conversion of both polymorphs **I** and **III** into **II**, as illustrated in Scheme 1.

A close inspection of the bond lengths (Table 1) in the three polymorphs of complex **1** shows that the coordination environment around each cobalt(II) ions is similar; the cobalt(II) ions are coordinated to a monodentate benzoate group and two N-donor pyridine ligands. The two cobalt(II) ions are bridged by two 2-nitrobenzoate ligands and an aqua group that is intramolecularly hydrogen bonded to the carboxyl group of the monodentate 2-nitrobenzoate.

[a] X = (2-nitrobenzoate); Y, Y′ = μ-(2-nitrobenzoate). [b] $-x$, $y$, $-z+1/2$.

Each of the polymorphs (**I**–**III**) described above obtained from complex **1** shows broad signals centred at 3407 $cm^{-1}$ (O–H stretching) in their solid-state FTIR spectra. This apparently corresponds to the presence of intramolecular hydrogen-bonding interactions involving the 2-nitrobenzoate group and the bridging aqua ligand. Solid-state FTIR spectra of polymorphs **II** and **III** exhibit similar absorptions in the carbonyl C=O (1531 and 1635 $cm^{-1}$, respectively) and nitro N–O stretching regions (1364 and 1395 $cm^{-1}$, respectively). While the corresponding C=O absorptions of polymorph **I** are similar to those of **II** and **III**, the N–O stretching bands appear as a broad absorption at 1390 $cm^{-1}$ with a shoulder at about 1356 $cm^{-1}$.

In order to study the influence of the solvent on the crystallisation process, we performed the reaction of the cobalt(II) salts with 2-nitrobenzoic acid and sodium hydroxide in the presence of excess pyridine rather than by using the stoichiometric amount. In each case, two concomitant complexes were obtained both by solid-state synthesis and by solution processing. One of the complexes, which was obtained as orange prisms, turned out to be the mononuclear cobalt(II) complex **IV**, as depicted in Figure 3. The other complex was found to be the dinuclear complex **1** that crystallises as pink rods in the $P\bar{1}$ space group.

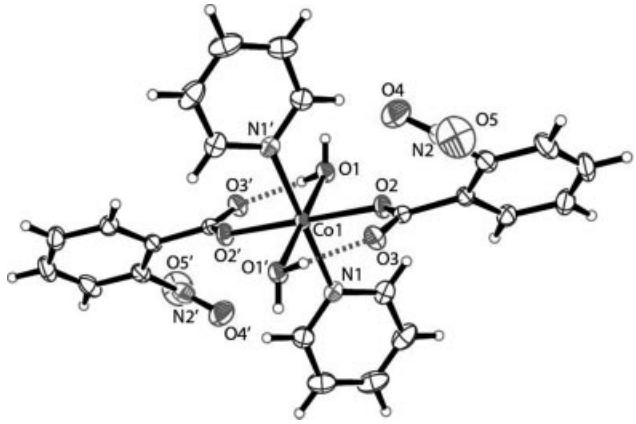

Figure 3. Structure of the mononuclear complex **IV**.

The mononuclear complex **IV** is formed preferentially during the reaction of cobalt(II) sulfate heptahydrate with 2-nitrobenzoic acid in the presence of sodium hydroxide and excess pyridine in methanol. Similarly, reactions of cobalt(II) chloride with 2-nitrobenzoic acid and sodium hydroxide in excess pyridine led to mononuclear complex **IV**, which suggests that the role of anion in the synthesis through the solution route is not prominent. However, the formation of polymorph **I** from the reaction of cobalt chloride with 2-nitrobenzoic acid in the presence of sodium hydroxide and pyridine and the formation of polymorph **II** directly from the reaction of cobalt(II) acetate with 2-nitrobenzoic acid and pyridine clearly indicates that the reaction conditions and the crystallisation procedures can influence

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the formation and isolation of crystal(s) of the complexes with different orientations of the nitro groups. The polymorphs **I**–**III** isolated in this study are three conformers of several possible conformers that can be envisaged by imagining the dimeric core as a rigid unit and by fixing the 2-nitrophenyl groups in different orientations at two ends of the rigid unit – similar to those for cubane-type organic molecules with different orientations of nitro groups.[8b]

In conclusion, we have shown that depending on the method of synthesis and crystallisation, three distinct polymorphs (**I**–**III**) of an aqua–bridged, dinuclear 2-nitrobenzoate cobalt(II) complex **1** may be obtained. In this case, the formation of polymorphs originates from the orientations of the nitro group in the 2-nitrobenzoate units in the complex. The formation of the polymorphs is controlled by three factors: (a) the synthetic route (solid- or solution phase), (b) the solvent of crystallisation and (c) the stoichiometry of the auxiliary ligand pyridine.

## Experimental Section

X-ray crystallographic data were collected at 296 K with a Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) by using a Bruker Nonius SMART CCD diffractometer equipped with a graphite monochromator. The SMART software was used for data collection, for indexing the reflections and for determining the unit cell parameters; the collected data were integrated by using the SAINT software. The structures were solved by direct methods and refined by full-matrix least-squares calculations ($F^2$) by using the SHELXTL-97 software. All non-H atoms were refined in the anisotropic approximation against $F^2$ for all reflections. All H atoms, except those attached to O atoms, were placed at their calculated positions and refined in the isotropic approximation; those attached to heteroatoms were located in the difference Fourier maps and refined with isotropic displacement coefficients. Crystal data for the cobalt complexes is given in Table 2. CCDC-619774, CCDC-619773, CCDC-608665 and CCDC-620812 (for compounds **I**–**IV**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Polymorphs I:** 2-Nitrobenzoic acid (0.34 g, 2 mmol) was dissolved in methanol (10 mL) and sodium hydroxide (0.081 g, 2 mmol) was added to it. The mixture was stirred vigorously for 5 min, and cobalt(II) chloride hexahydrate (0.238 g, 1 mmol) was then added. The reaction mixture became pink, and subsequently pyridine (0.158 g, 2 mmol) was added. The solution was filtered, and the pink filtrate was kept at room temperature. Pink, rodlike crystals were obtained after 3 d, which were then collected and dried in air. Yield 44% (based on Co).

**Synthesis of Polymorph II:** 2-Nitrobenzoic acid (0.34 g, 2 mmol) was added to a solution of cobalt acetate tetrahydrate (0.249 g, 1 mmol) in methanol (20 mL), and the mixture was stirred overnight. To this solution, pyridine (0.158 g, 2 mmol) was added, and the mixture stirred for 10 min. On standing for 2 d, square–shaped, pink crystals were obtained from the reaction mixture. Yield 41% (based on Co).

**Synthesis of Polymorph III:** 2-Nitrobenzoic acid (0.34 g, 2 mmol), sodium hydroxide (0.081 g, 2 mmol) and $CoCl_2{\cdot}6H_2O$ (0.238 g, 1 mmol) was finely ground with a mortar and pestle and heated at 100 °C for 15 min – the pink colour turns to blue. The reaction mixture was cooled to room temperature and transferred into a

round-bottomed flask, and toluene (20 mL) was added to it. The heterogeneous mixture was stirred at room temperature for 5 min followed by the addition of pyridine (0.158 g, 2 mmol). The blue supernatant liquid turned pink. The residue was filtered off, and the pink filtrate was left undisturbed. Pink crystals were collected after 3 d and dried in air. Yield: 34% (based on Co). IR (KBr): $\tilde{\nu}$ = 3412 (b), 3076 (ms), 1636 (s), 1603 (ms), 1531 (s), 1447 (ms), 1395 (s), 1218 (ms), 1154 (ms), 1040 (ms), 821 (s), 735 (s), 700 (s) $cm^{-1}$. Magnetic moment: 6.56 BM at 25 °C. UV/Vis: $\lambda_{max}$ ($\varepsilon$, $M^{-1} cm^{-1}$) = 521 nm (39.23).

**Synthesis of IV:** 2-Nitrobenzoic acid (0.34 g, 2 mmol) was dissolved in methanol (20 mL), and to this solution, sodium hydroxide (0.08 g, 2 mmol) was added. After 10 min of stirring, cobalt(II) sulfate heptahydrate (0.281 g, 1 mmol) was added to the solution, and the heterogeneous mixture was stirred for 30 min. To this heterogeneous mass, pyridine (0.15 g, 2 mmol) was added, and the mixture stirred for 10 min. The residue was filtered and discarded. Orange crystals were collected after 4 d from the filtrate. The crystals were collected and dried in air. Yield: 51% (based on Co). $\mu_{eff}$ = 3.952 BM at 25 °C. IR (KBr): $\tilde{\nu}$ = 3414 (wb), 3064 (w), 1604 (m), 1582 (s), 1555 (s), 1526 (s), 1484 (m), 1448 (s), 1400 (s), 1356 (s), 1303 (w), 1069 (w), 1041 (w), 911 (wb), 818 (s), 759 (w), 738 (s), 695 (s) $cm^{-1}$. UV/Vis (methanol): $\lambda_{max}$ ($\varepsilon$, $M^{-1} cm^{-1}$)= 515 nm (6.7).

**Supporting Information** (see footnote on the first page of this article): The X-ray powder diffraction pattern of polymorphs **I**–**III** and the solid-state FTIR spectra of the polymorphs **I**–**III** are given.

# Synthesis and Characterization of the First Silver Complexes with Antimony Anions

**Dieter Fenske,*[a] Alexander Rothenberger,[a,b] and Stephan Wieber[b]**

*Dedicated to Joachim Strähle on the occasion of his 70th birthday*

**Keywords:** Silver / Antimony / Clusters

The synthesis and characterization of the silver antimony complexes $[Ag_{12}\{Sb(SiMe_3)\}_6(PiPr_3)_6]$ (**1**), $[Ag_4(Sb_4Ph_4)_2(PiPr_3)_4]$ (**2**) and $[Ag_4(Sb_6Ph_6)_2(PnBu_3)_4]$ (3) is reported.

## Introduction

In 1989 Cowley et al. had synthesized the first copper complex containing an antimony anion by the metathesis reaction of a $Cu^I$ salt with lithium dimesitylantimonide.[1] More recent developments in the area of complexes containing antimony anions represent the discovery of a new class of compounds with unstoichiometric mixtures of Cu and Sb atoms and a range of novel group 13 metal complexes.[2,3] The synthesis of complexes e.g., $[Cu_{40}Sb_{12}(PMe_3)_{20}]$ and $[Cu_{45}Sb_{16}(PEt_2Me)_{16}]$, was achieved by reactions of silylated stibanes with phosphane complexes of $Cu^I$ salts. For the heavier coinage metals, only very few complexes with stibanes as ligands are known and a common feature of them is the interaction of the coinage metal (Ag or Au) with the lone pair of a neutral trisubstituted stibane.[4]

In contrast to antimony, several examples for arsenic anions bridging silver or gold centres are known.[5] The silver arsinidene cluster $[Ag_{14}(AsPh)_6Cl_2(PEt_3)_8]$ or the isostructural complexes $[Ag_4(As_4Ph_4)_2(PEt_3)_4]$ and $[Au_4(As_4Ph_4)_2(PnPr_3)_4]$ can be obtained by the reaction of coinage metal salts with $PhAs(SiMe_3)_2$ in the presence of tertiary phosphanes.[6] This prompted us to attempt the synthesis of silver and gold complexes containing antimony anions. In the following first results of mixed-metal Ag/Sb complexes are described.

## Results and Discussion

The reactions of silver nitrate with stibanes produced the silver antimony compounds $[Ag_{12}\{Sb(SiMe_3)\}_6(PiPr_3)_6]$ (**1**), $[Ag_4(Sb_4Ph_4)_2(PiPr_3)_4]$ (**2**) and $[Ag_4(Sb_6Ph_6)_2(PnBu_3)_4]$ (**3**) (Scheme 1).

$$AgNO_3 + Sb(SiMe_3)_3 \xrightarrow{PiPr_3} [Ag_{12}(SbSiMe_3)_6(PiPr_3)_6]\ (\mathbf{1})$$

$$AgNO_3 + PhSb(SiMe_3)_2 \xrightarrow{PiPr_3} [Ag_4(Sb_4Ph_4)_2(PiPr_3)_4]\ (\mathbf{2})$$

$$AgNO_3 + PhSb(SiMe_3)_2 \xrightarrow{PnBu_3} [Ag_4(Sb_6Ph_6)_2(PnBu_3)_4]\ (\mathbf{3})$$

Scheme 1. Synthesis of the Ag/Sb complexes **1**, **2** and **3**.

The complex **1** crystallizes from diethyl ether as orange blocks in the trigonal space group $P\bar{3}$ with three molecules in the unit cell. It can be described by a distorted triangular antiprism of antimony atoms in which every edge is capped by a silver atom (Ag1) (Figure 1). The other six silver atoms (Ag2) are coordinated by phosphane ligands.

On each Sb atom a trimethylsilyl group is retained. The Sb–Si bond length of 2.527(1) Å is in the range of commonly observed Sb–Si bond lengths.[2] The Sb–Ag distances in **1** are also similar to reported average Ag–Sb distances of 2.72 Å in 75 compounds with most of them of the general type $[R_3Sb–AgX]$ (R = organic group, X = anion).[7,8] The stability of the cluster compounds increased when $PhSb(SiMe_3)_2$ was used as antimony source. By the reaction of $AgNO_3$ with $PhSb(SiMe_3)_2$ and four equivalents of $PiPr_3$ in diethyl ether the cluster compound $[Ag_4(Sb_4Ph_4)_2(PiPr_3)_4]$ (**2**) is obtained as red crystals together with colourless blocks of the silver phosphane complex $[Ag(NO_3)(PiPr_3)_2]$ (Table 1) and $[PhSb]_6$.[9] **2** crystallizes in the triclinic space group $P\bar{1}$ with one molecule in the unit cell and

two lattice-bound ether molecules (Figure 2). The molecular structure of **2** is isostructural to the structure of $[Ag_4(As_4Ph_4)_2(PEt_3)_4]$ in the solid state.[6]

The structure of **2** can be described as a centrosymmetric dimer of a $[(PhSb)_4]^{2-}$ anion and two Ag-phosphane units. Each $[(PhSb)_4]^{2-}$ anion chelates Ag(1,1A) by terminal Sb atoms. Ag(2) is coordinated by Sb atoms of different anions. The longest Ag–Sb bond in **2**, which is observed between Sb(3) and Ag(1A), corresponds to distances commonly observed between neutral stibanes and $Ag^I$ centres.[4a,4b] These interactions are slightly longer than bonds between silver and terminal antimony atoms. The coordination sphere of the four silver atoms is completed by additional P*i*Pr$_3$ ligands. The formation of the $[(PhSb)_4]^{2-}$ anion in **2** is intriguing, and it is currently assumed that **2** represents an intermediate of the $Ag^I$-induced oxidation of $PhSb(SiMe_3)_2$ to *cyclo*-$[PhSb]_6$. The Sb–Sb distances are in the range of reported Sb–Sb bond lengths of about 2.8 Å.[9]

The use of the phosphane P*n*Bu$_3$ instead of P*i*Pr$_3$ leads to the cluster compound [Ag$_4$(Sb$_6$Ph$_6$)$_2$(P*n*Bu$_3$)$_4$] (**3**). Compound **3** crystallizes in the triclinic space group $P\bar{1}$ with two molecules in the unit cell (Figure 3).

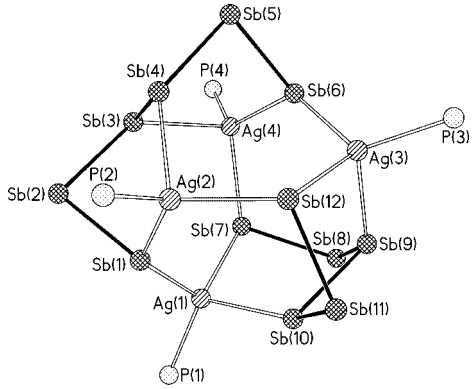

Figure 3. Molecular structure of **3** in the crystal (without organic substituents). Selected bond lengths [Å] and angles [°]: Sb(1)–Ag(2) 2.7462(11), Sb(1)–Ag(1) 2.7635(10), Sb(3)–Ag(4) 2.9944(10), Sb(4)–Ag(2) 2.9331(12), Sb(6)–Ag(4) 2.7433(10), Sb(6)–Ag(3) 2.7853(11), Sb(7)–Ag(1) 2.7248(11), Sb(7)–Ag(4) 2.7620(12), Sb(1)–Sb(2) 2.8012(10), Sb(2)–Sb(3) 2.8234(10), Sb(3)–Sb(4) 2.8446(10), Sb(4)–Sb(5) 2.8197(10), Sb(5)–Sb(6) 2.7868(10), Sb(7)–Sb(8) 2.7946(9), Sb(8)–Sb(9) 2.8161(10), Sb(9)–Sb(10) 2.8359(11), Sb(9)–Ag(3) 2.9445(11), Sb(10)–Sb(11) 2.8354(10), Sb(10)–Ag(1) 2.9237(11), Sb(11)–Sb(12) 2.8035(11), Sb(12)–Ag(2) 2.7631(10), Sb(12)–Ag(3) 2.7666(11), Ag–P 2.459(3)–2.481(3), Sb–Sb–Sb 88.06(3)–92.95(3).

The molecular structure of **3** consists like **2** of two *oligo*-[(PhSb)$_6$]$^{2-}$ anions and four Ag atoms. Compound **3**, however, represents, in comparison to **2**, an intermediate where the [PhSb]$_6$ chain is preformed at metal centres and "ready to cyclize" to *cyclo*-[PhSb]$_6$, which is formed in all the investigated reactions between Ag$^{I}$ salts and PhSb(SiMe$_3$)$_2$. The almost tetrahedral arrangement of the four Ag atoms in **3** is favoured by the sterically demanding anions over the centrosymmetric arrangement in the solid-state structure of **2** or other possibilities. Each of the [(PhSb)$_6$]$^{2-}$ anions in **3** chelates two Ag atoms forming five-membered rings as observed in **2** and all Ag atoms are coordinated by Sb atoms of both dianions. Bond lengths between silver atoms and inner antimony atoms in **3** are ca. 0.2 Å longer than distances Ag–Sb(terminal).

## Conclusions

In this contribution the first examples of silver complexes containing antimony anions are reported. A common feature of the compounds is their thermal instability and rather difficult syntheses. Currently, attempts are made to optimise the reactions towards a selective formation of a particular complex in high yield in order to allow subsequent investigations of physical properties.

## Experimental Section

**General Remarks:** All operations were carried out under purified nitrogen. Hexane and diethyl ether were dried with LiAlH$_4$ and freshly distilled. AgNO$_3$ and P*n*Bu$_3$ were purchased from Sigma–Aldrich. P*n*Bu$_3$ was distilled prior use. P*i*Pr$_3$, PhSb(SiMe$_3$)$_2$ and Sb(SiMe$_3$)$_3$ were prepared according to published procedures.[10]

**1:** AgNO$_3$ (0.18 g, 1.06 mmol) was dissolved in Et$_2$O (15 mL) and P*i*Pr$_3$ (0.79 mL, 4.2 mmol) by briefly heating to reflux. The clear, colourless solution was cooled to –78 °C and Sb(SiMe$_3$)$_3$ (1.467 mL, 0.66 mmol, 0.45 mol/L in hexane) was added. The brown reaction mixture was stored at –78 °C for four days. Sensitive red crystals of **1** could be isolated for crystallographic measurements.

**2:** AgNO$_3$ (0.18 g, 1.06 mmol) was dissolved in Et$_2$O (15 mL) and P*i*Pr$_3$ (0.79 mL, 4.2 mmol) by briefly heating to reflux. The clear, colorless solution was cooled to –78 °C and PhSb(SiMe$_3$)$_2$ (0.27 mL) was added. The brown reaction mixture was stored at –78 °C for one day. Then it was warmed up to –40 °C. After one week red crystals of **2** besides colourless crystals of the silver phosphane complex could be isolated for crystallographic measurements.

**3:** AgNO$_3$ (0.18 g, 1.06 mmol) was dissolved in Et$_2$O (15 mL) and P*i*Pr$_3$ (0.79 mL, 4.2 mmol) by briefly heating to reflux. The clear, colorless solution was cooled to –78 °C and PhSb(SiMe$_3$)$_2$ (0.27 mL) was added. The brown reaction mixture was stored at –78 °C for one day. Then it was warmed up to –8 °C. After three weeks red crystals of **3** could be isolated for crystallographic measurements.

Due to thermal instability of **1**–**3** (slow decomposition even at –80 °C) characterization was restricted to X-ray crystallography.

**X-ray Crystallographic Study:** Data were collected with a STOE IPDS II diffractometer by using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ (all data) using the SHELXTL programme package (Table 1).[11] Hydrogen atoms were placed in calculated positions, non-hydrogen atoms were assigned anisotropic thermal parameters. Disordered components were refined with isotropic thermal parameters.

CCDC-627012 to -627014 and CCDC-627632 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Square-Planar Noble Metal Iodate $[M(IO_3)_4]^{n-}$ ($M = Pd^{II}$, $Au^{III}$; $n = 2, 1$) Anions and Their Ability to Form Polar and Centrosymmetric Architectures

**Jie Ling[a] and Thomas E. Albrecht-Schmitt*[a]**

**Keywords:** Gold / Palladium / Iodate / Oxo ligands

$K^+$ salts of the square-planar noble metal iodate $[M(IO_3)_4]^{n-}$ ($M = Pd^{II}$, $Au^{III}$; $n = 2, 1$) anions have been prepared under mild hydrothermal conditions, and the structures elucidated to demonstrate that while both are highly polar anions, polar and centrosymmetric extended architectures can form using these building units.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Iodate compounds have been the subject of intense interest because of their propensity for adopting noncentrosymmetric structures that are often polar,[1–8] a feature that is aptly illustrated by $A[MoO_3(IO_3)]$ (A = Rb, Cs),[9] $A[(VO)_2(IO_3)_3O_2]$ (A = $NH_4$, Rb, Cs),[10] and $NaYI_4O_{12}$.[11] This structural attribute can be exploited in the development of new nonlinear optical, pyroelectric, piezoelectric, and ferroelectric materials, with the first property being the most heavily investigated. Structure–property relationships in early d-block and f-block iodates are becoming well-developed.[1–11] However, noble metal iodates are virtually unknown.[12]

Renewed interest in noble metal oxoanion compounds has led to the discovery of a plethora of remarkable solids including $AuSO_4$, which contains a $Au^{II}$–$Au^{II}$ dimer,[13] and polar $Au_2(SeO_3)_2(SeO_4)$, which is constructed from square-planar $Au^{III}$ and both selenite and selenate anions.[14] Despite repeated attempts over the past eight years, gold iodates have remained elusive for several reasons. First, common anions employed in gold reactions such as chloride and nitrate can interfere with the formation of these compounds. Second, iodate and periodate do not react appreciably with elemental gold, even under acidic compounds. Finally, as with many iodates, gold iodates are quite insoluble under normal conditions precluding simple crystallization techniques.

## Results and Discussion

The solution to the synthesis of a gold iodate proved to be the use of a strongly oxidizing mixed-anion system. In this case the reaction of elemental gold with concentrated selenic acid and $KIO_4$ under mild hydrothermal conditions results in the formation of $K[Au(IO_3)_4]$. As is shown in Figure 1, single crystals of $K[Au(IO_3)_4]$ grow directly off of the surface of the gold metal and ultimately passivate the surface. We speculate that selenic acid dissolves small quantities of the gold metal to yield a halo of $Au^{III}$ that rapidly reacts with iodate to yield $K[Au(IO_3)_4]$ crystals. The in situ generation of iodate by the reduction of periodate by water is a critical feature of this reaction, because it allows for the slow introduction of the key reactant that controls solubility.[9,10,15]

Figure 1. A photograph showing yellow crystals of $K[Au(IO_3)_4]$ that have grown directly on the surface of elemental gold under hydrothermal conditions. Crystals typically have maximum dimensions of several millimeters.

The structure of $K[Au(IO_3)_4]$ is quite unusual in that it crystallizes in the lowest symmetry space group $P1$. The origin of the asymmetry becomes obvious by viewing the $[Au(IO_3)_4]^{1-}$ anion shown in Figure 2, and the packing of these anions in Figure 3. The $[Au(IO_3)_4]^{1-}$ anions contain square-planar $Au^{III}$ bound by four monodentate iodate

anions. As can be viewed in Figure 2, all of the iodate anions in the $[Au(IO_3)_4]^{1-}$ anions are aligned on one side of the $AuO_4$ square plane. Hence, these anions are highly polar, and pack in the lattice with identical orientation yielding a polar structure consistent with the space group. The Au–O bond lengths range from 1.981(9) Å to 1.987(9) Å, and are normal.[16] We have surveyed 28 high-resolution iodate crystal structures to arrive at a value of 1.792(5) Å for terminal I–O bonds. The terminal I–O bonds in the $[Au(IO_3)_4]^{1-}$ anions are normal in this respect. In contrast, I–O bond lengths for bridging or $\mu_2$-O bonds from 32 different structures, show an average distance 1.831(5) Å. The bridging I–O bond lengths strain the normal limits and average 1.882(9) Å. The bridging I–O bond lengths are of a length expected for protonated moieties, suggesting polarization in the Au–O–I bonds. There are several other $Au^{III}$ compounds with monodentate oxoanions that share features in common with the bonding found in $K[Au(IO_3)_4]$; these compounds include $K[Au(NO_3)_4]$,[17] $(H_5O_2)[Au(NO_3)_4]\cdot H_2O$,[18] and $(ClO_2)[Au(ClO_4)_4]$.[19] In all three examples significant lengthening of the bridging E–O (E = N, Cl) bonds is observed.

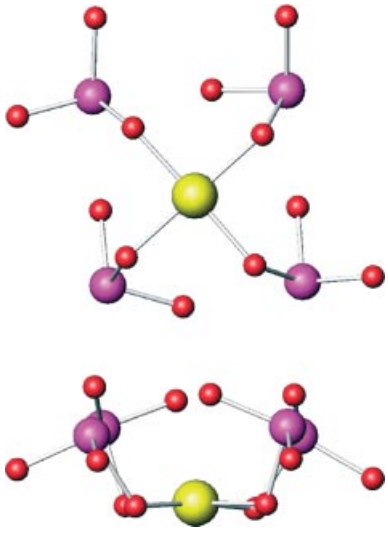

Figure 2. Two views of the $[Au(IO_3)_4]^{1-}$ anion in the structure of $K[Au(IO_3)_4]$. Gold is shown in yellow, iodine in magenta, and oxygen in red.

Short contacts on the order of 2.5 to 2.8 Å between the oxygen atom from one iodate anion and the iodine atom of a neighboring iodate play a critical role in the structures of iodate compounds and minerals.[20] The importance of iodate···iodate interactions in the structure of $K[Au(IO_3)_4]$ can not be underestimated. We have previously shown that these interactions can lead to alignment of the lone pair of electrons on the iodate anions in $Na_2[UO_2(IO_3)_4(H_2O)]$.[21] This also occurs in the structure of $K[Au(IO_3)_4]$ where there are numerous intermolecular iodate···iodate interactions. These interactions stitch what appears to be a molecular structure into a complex polar network.

The IR vibrational spectrum of $K[Au(IO_3)_4]$ shows four weak bands at 519, 514, 503 and 499 $cm^{-1}$ that are attributed to vibrations within the $[AuO_4]$ unit.[22,23] Iodate stretching vibrations ($\nu_1$ and $\nu_3$) are found at 822, 803, 778, 765, 741, and 664 $cm^{-1}$.[24–26] The Raman spectrum shows a broad peak centered at 508 $cm^{-1}$ that coincides well with the IR features. In addition, there is a broad envelope for the various iodate modes with discernible vibrational modes at 860, 821, 773, and 741 $cm^{-1}$.

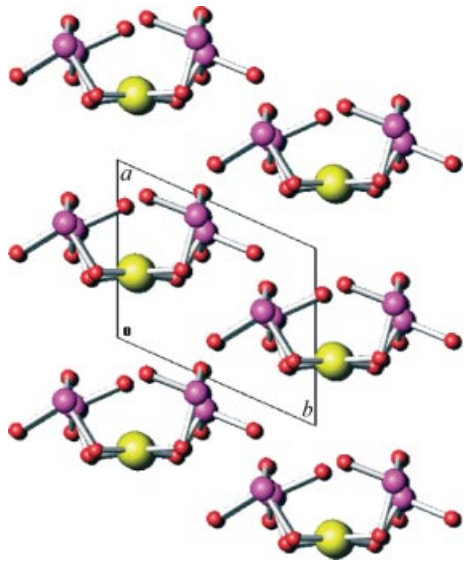

Figure 3. A view down the *c* axis of the structure of $KAu(IO_3)_4$ showing the polar stacking of the $[Au(IO_3)_4]^{1-}$ anions. $K^+$ cations have been omitted for clarity. Gold is shown in yellow, iodine in magenta, and oxygen in red.

The thermal behavior of $K[Au(IO_3)_4]$ was addressed using differential scanning calorimetry (DSC), and shows that it is stable to 375 °C. Two sharp endotherms are then observed at 387 and 518 °C, which are ascribed to the decomposition of $K[Au(IO_3)_4]$ to elemental gold and thermal disproportionation of iodate, respectively. The first endotherm is immediately followed by an exothermic event, again consistent with the formation of elemental gold, which can be visually observed in the sample containers at the end of the thermal analysis.

In contrast to the difficulties in synthesizing $K[Au(IO_3)_4]$, the synthesis of its $Pd^{II}$ analog, $K_{2.5}[Pd(IO_3)_4]\cdot H_{0.5}IO_3$, proved to be quite straightforward as it can be prepared from the reaction of $Pd(NO_3)_2\cdot 2H_2O$ with $KIO_4$ under mild hydrothermal conditions. Again the in situ reduction of $IO_4^-$ to $IO_3^-$ is utilized. The complexation of $Pd^{II}$ by four iodate anions yields $[Pd(IO_3)_4]^{2-}$ anions. Unlike the $[Au(IO_3)_4]^{1-}$ anion, in which the bridging I–O bonds are slightly polarized with an average bond length of 1.882(9) Å, all I–O bond lengths in the $[Pd(IO_3)_4]^{2-}$ anions are within the range of 1.790(4) to 1.865(5) Å, and no excessive lengthening of the bridging I–O bonds are observed. The $[Pd(IO_3)_4]^{2-}$ anions are similar to $[Au(IO_3)_4]^{1-}$ in that all of the four iodate anions in the $[Pd(IO_3)_4]^{2-}$ anions are aligned on one side of the $PdO_4$ square plane, as is shown in Figure 4. However, individual anions are related through inversion centers, and it crystallizes in the centrosymmetric space group *C*2/*m* (Figure 5).

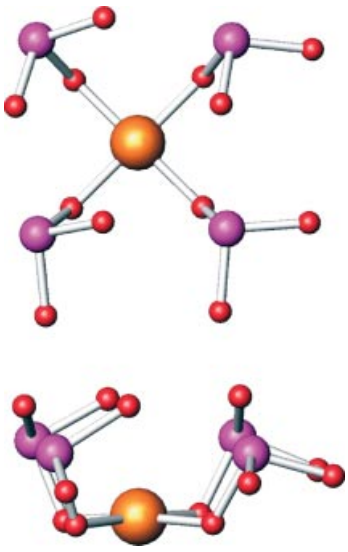

Figure 4. Two depictions of the $[Pd(IO_3)_4]^{2-}$ anion in the structure of $K_{2.5}Pd(IO_3)_4{\cdot}H_{0.5}IO_3$. Palladium is shown in orange, iodine in magenta, and oxygen in red.

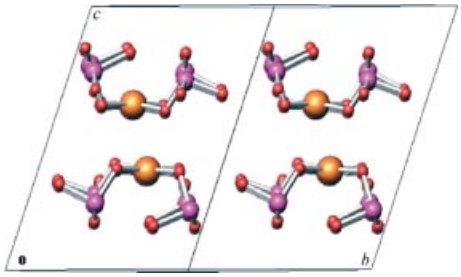

Figure 5. An illustration of the centrosymmetric packing of the $[Pd(IO_3)_4]^{2-}$ anions in $K_{2.5}Pd(IO_3)_4{\cdot}H_{0.5}IO_3$. $K^+$ cations and iodate/iodic acid units have been omitted for clarity. Palladium is shown in orange, iodine in magenta, and oxygen in red.

The critical feature of the vibrational spectrum of $K_{2.5}[Pd(IO_3)_4]{\cdot}H_{0.5}IO_3$ is the presence of a I–OH stretch at 1180 $cm^{-1}$, confirming the protonation of the co-crystallized iodate moiety.[27] In addition, a low frequency band at 495 $cm^{-1}$ is observed that might be attributable to a stretch mode of Pd–O. A set of weak bands centered at 560 $cm^{-1}$ can potentially be assigned to distortions of the $[PdO_4]$ square plane.[28,29] Iodate stretching vibrations ($\nu_1$ and $\nu_3$) are found at 797, 782, 728, 696, 673 and 659 $cm^{-1}$.

## Conclusions

In conclusion, we have demonstrated that two new noble metal iodates can be prepared under mild hydrothermal conditions by using in situ reduction of periodate to iodate. These compounds are the first members a new family of noble metal iodate compounds containing square-planar metal ions. The importance of these compounds lies in their ability to form polar structures that will allow for the development of new nonlinear optical, pyroelectric, piezoelectric, and ferroelectric materials.

## Experimental Section

**$K[Au(IO_3)_4]$:** Prepared by loading gold (70 mg, 0.355 mmol), $KIO_4$ (300 mg, 1.304 mmol), 0.2 mL concentrated $H_2SeO_4$ solution, and 0.05 mL of distilled and filtered water (Millipore) in 23 mL PTFE-lined autoclave. The autoclave was heated at 200 °C for 4 d, and slowly cooled to 9 °C/h to 22 °C. The product consisted of yellow crystals of $K[Au(IO_3)_4]$ that had grown on the surface of unreacted gold metal, and a bright yellow solution, that was converted into a yellow precipitate of $Au_2(SeO_3)_3$ when water was added. Yield for $K[Au(IO_3)_4]$: 50 mg (15% based on Au). EDX analysis provided a K/Au/I ratio of 1:1:4.

**$K_{2.5}[Pd(IO_3)_4]{\cdot}H_{0.5}IO_3$:** Prepared by loading $Pd(NO_3)_2{\cdot}2H_2O$ (105.8 mg, 0.397 mmol), $KIO_4$ (284.2 mg, 1.236 mmol), and 0.5 mL distilled and filtered water (Millipore) in 23 mL PTFE-lined autoclave. The autoclave was heated at 200 °C for 3 d, and slowly cooled to 9 °C/h to 22 °C. The product consisted of dark orange plates of $K_{2.5}[Pd(IO_3)_4]{\cdot}H_{0.5}IO_3$ and unreacted $Pd(NO_3)_2{\cdot}2H_2O$. Yield for $K_{2.5}[Pd(IO_3)_4]{\cdot}H_{0.5}IO_3$: 54 mg (12% based on Pd). EDX analysis provided a K/Pd/I ratio of 2.3:1:5.1.

**X-ray Structural Analyses**

**$K[Au(IO_3)_4]$ (1):** Yellow block, crystal dimensions $0.084 \times 0.048 \times 0.046$ mm, triclinic, $P\bar{1}$, $Z = 1$, $a = 5.6484(5)$, $b = 7.1935(7)$, $c = 8.1377(8)$ Å, $\alpha = 105.264(2)°$, $\beta = 93.585(2)°$, $\gamma = 111.840(2)°$, $V = 291.30(5)$ $Å^3$ ($T = 193$ K), $\mu = 236.39$ $cm^{-1}$, $R_1 = 0.0289$, $wR_2 = 0.0762$.

**$K_{2.5}[Pd(IO_3)_4]{\cdot}H_{0.5}IO_3$ (2):** Dark orange plate, crystal dimensions $0.055 \times 0.020 \times 0.012$ mm, monoclinic, $C2/m$, $Z = 4$, $a = 11.3270(13)$, $b = 11.8246(14)$, $c = 12.9665(15)$ Å, $\beta = 114.417(2)°$ $V = 1581.4(3)$ $Å^3$ ($T = 193$ K), $\mu = 116.67$ $cm^{-1}$, $R_1 = 0.0277$, $wR_2 = 0.0635$. Bruker APEX CCD diffractometer: $\theta_{max} = 56.58°$ (for **1**) and 56.62° (for **2**), Mo-$K_\alpha$, $\lambda = 0.71073$ Å, 0.3° $\omega$ scans, 2796 (for **1**) and 7413 (for **2**) reflections measured, 2440 (**1**) and 2007 (**2**) independent reflections all of which were included in the refinement. The data were corrected for Lorentz polarization effects and for absorption (numerical and SADABS), solutions were solved by direct methods, anisotropic refinement on all heavy atoms of $F^2$ by full-matrix least-squares, 164 (**1**) and 125 (**2**) parameters. # Synthesis and Oxidation of Vanadyl Complexes Containing Bispidine Ligands

**Peter Comba,*[a] Shigemasa Kuwata,[a] Gerald Linti,[a] Máté Tarnai,[a] and Hubert Wadepohl[a]**

**Keywords:** Peroxido complexes / Superoxido complexes / Rigid ligand / Bispidine

The reaction of 3-methyl-9-oxo-7-picolyl-2,4-di(2-pyridyl)-3,7-diazabicyclo[3.3.1]nonane-1,5-dicarboxylate ($L^2$) with vanadyl sulfate in methanol yields the purple complex $[V^{IV}{=}O(L^{2'})](ClO_4)_2$, where $L^2$ is hydrated to the corresponding 9-diol $L^{2'}$. The crystal structure of $[V^{IV}{=}O(L^{2'})](ClO_4)_2$ has a saturated coordination sphere with a long bond to the tertiary amine N7 *trans* to the oxido group (2.36 Å). Oxidation of $[V^{IV}{=}O(L^{2'})](ClO_4)_2$ with an excess of aqueous hydrogen peroxide yields the orange complex $[V^{V}{=}O(O_2)(L^{2'})]ClO_4$. This can be further oxidized with $Ce^{4+}$ in MeCN at –40 °C to the unstable vanadium(V)-oxidosuperoxido complex $[V^{V}{=}O(O_2)(L^{2'})]^{2+}$, as shown by EPR spectroscopy. The X-ray crystal structure of $[V^{V}{=}O(O_2)(L^{2'})]ClO_4$ shows that the N7-pendant pyridine donor is dissociated and the V–N7 bond is elongated (2.56 Å). The O–O distance of the side-on bound peroxide in $[V^{V}{=}O(O_2)(L^{2'})]ClO_4$ is unexpectedly short (1.28 Å) and is therefore in the range which is typical for a superoxido group. However, the IR spectrum of $[V^{V}{=}O(O_2)(L^{2'})]ClO_4$ shows $^{18}O$ isotope shifts, which support the assignment as a peroxido complex, and this is also supported by EPR and UV/Vis spectroscopic analysis. The short O–O bond is attributed to a static disorder rather than to libration of the "non-rigid" peroxido group.

## Introduction

Oxidation states up to +5 are accessible for vanadium, and in the high valent vanadium(IV) ($d^1$, vanadyl) and vanadium(V) ($d^0$, vanadate) forms the hard metal centers form stable oxido complexes. There is a considerable interest and activity in developing vanadium complexes as models for a variety of metalloenzymes, specifically for the mononuclear haloperoxidases, which catalyze the peroxide-dependent halogenation of organic substrates.[1,2] Vanadium(V) oxido-peroxido complexes have also been found to be catalytically active in the oxidation of organic substrates (e.g., epoxidation of alkenes and hydroxylation of alkanes and aromatic compounds).[3,4] In addition, mononuclear vanadyl(IV) and peroxidovanadium(V) complexes are known to have insulin-mimetic properties.[5,6]

Three pentadentate bispidine-based ligands with tertiary amine, pyridine, and phenolate donors have been used for the isolation and characterization of oxido- and peroxidovanadium(IV) and -vanadium(V) complexes (see Scheme 1). Upon complexation, the 9-keto group of the ligands is hydrated to the corresponding 9-diol, and in methanolic solution the hemiacetal structure (9-hydroxy-9-methoxy) can be formed; the hydrated diol ligands are denoted as $L^{1'}$, $L^{2'}$, and $L^{3'}$, respectively. Bispidine ligands are relatively soft and therefore prefer relatively large metal ions,[7] which means that they are not optimal for vanadium(IV/V) chemistry and quite rigorous methods have to be used for their preparation. Several methods have been reported for the preparation of vanadyl complexes;[8] of special interest are those for the synthesis of complexes with similar amine/pyridine-based ligands.[9]

We report here the synthesis and properties of vanadium complexes of the three ligands shown in Scheme 1. Specifically, we have been interested in the structural and spectroscopic properties of the oxidovanadium(V) peroxide complex and the possibility of oxidizing it to the corresponding superoxide complex. Possible applications in the area of oxidation catalysis are briefly discussed on the basis of preliminary test reactions.

## Results and Discussion

### Synthesis and Structure of the Vanadyl Complexes

The vanadyl complexes with the pentadentate ligands $L^2$ and $L^3$ were prepared from vanadyl sulfate. These complexes are easily obtained from hot methanolic or acetonitrile ($L^3$) solutions (with addition of one equivalent of triethylamine to deprotonate the phenolic group donor). The complexes were purified by ion-exchange chromatography. Attempts to use vanadium(III) salts (chloride, acetylacetonate) did not produce any of the desired products. Interestingly, the method found to be successful for the pentadentate ligands did not succeed for the tetradentate ligand $L^1$. Treatment of $L^1$ with an ethanolic solution of [VO(OEt)$_3$] produced a deep-green solution after refluxing overnight, from which a dark green solid precipitated after several days in the refrigerator (4 °C). Characterization of the product confirmed the formation of the vanadyl complex of $L^1$ ([V=O($L^{1'}$)(OH$_2$)]$^{2+}$).

A plot of the molecular structure of [$V^{IV}$=O($L^{2'}$)](ClO$_4$)$_2$·H$_2$O, as determined by X-ray crystal structure analysis, is shown in Figure 1; the structural data are presented in Table 1. Only one of the two independent complex ions is discussed because they do not differ much in their structural parameters. The vanadyl ion coordinates to $L^{2'}$ in a distorted octahedral geometry. The vanadium center lies almost in the plane defined by Npy1, Npy2, and N3. The distance between vanadium and this plane is 0.074 Å, although the two pyridyl rings are twisted by 14.0° and 13.5° with respect to this plane. The length of the V=O bond (1.59 Å) is consistent with values found for other vanadyl complexes.[10] The V–N7 bond length (2.36 Å) is rather long for a $V^{IV}$–$N_{amine}$ bond, whereas that of V–N3 (2.10 Å) is as expected.[11] The average $V^{IV}$–N bond length (2.15 Å) is ideal for the $L^2$ bispidine ligand cavity, which means that almost no strain is induced in the ligand by the vanadyl center.[7] Long bonds to N7 are quite common in bispidine coordination chemistry,[12–14] probably due to the bispidine-ligand-enforced angular distortion of the N7–V–O axis and, to a lesser extent, to π-bonding involving the two in-plane pyridine donors.[15] Long bonds in vanadyl complexes *trans* to the yl oxygen donor are also common, therefore the bispidine ligands $L^2$ and $L^3$, which enforce the yl oxygen group *trans* to N7, have a high complementarity with respect to the vanadyl fragment and form stable vanadyl complexes.

### Spectroscopy of the Vanadyl Complexes

The IR spectra for all complexes, as expected, have no Bohlmann band (ca. 2600 $cm^{-1}$), which typically appears for the metal-free bispidine ligand (interaction between the lone pairs of the tertiary amine nitrogen donors); this is usually missing when a metal is coordinated.[16] The vibrational band at 986 $cm^{-1}$ in the spectrum of $[V^{IV}{=}O(L^{2'})](ClO_4)_2$ is assigned to the V=O stretching mode, and this is consistent with known five- and six-coordinate vanadyl complexes, where $\nu_{V=O}$ appears around 980 $cm^{-1}$ and 950 $cm^{-1}$, respectively.[17,18] As expected from the structural data (see above) $[V^{IV}{=}O(L^{2'})](ClO_4)_2$, due to the long V–N7 distance, has a V=O stretching mode similar to that expected for a five-coordinate vanadyl complex.

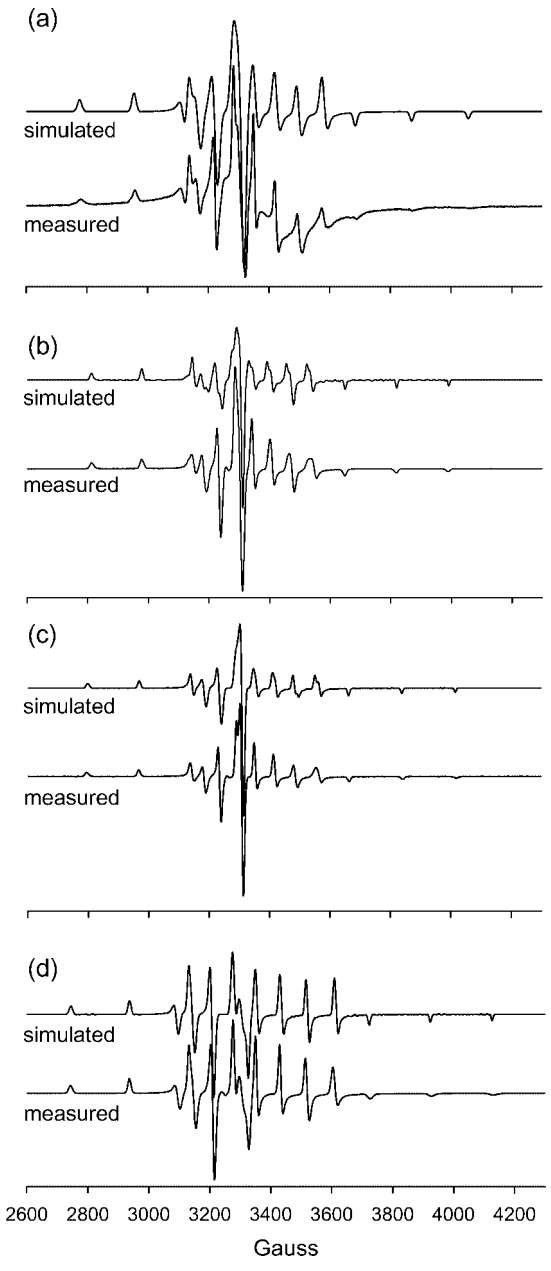

Figure 2. Experimental and simulated EPR spectra of $[V{=}O(L^{1'})]^{2+}$ (a), $[V{=}O(L^{2'})]^{2+}$ (b), $[V{=}O(L^{3'})]^{+}$ (c), and $[V{=}O(OH_2)_5]^{2+}$ (d) (dmf/$H_2O$, 2:1, 125 K, X-band).

The three d–d transitions expected for a distorted octahedral $d^1$ system are observed in the UV/Vis spectrum of $[V^{IV}{=}O(L^{2'})](ClO_4)_2$. The highest energy transition, which appears as a shoulder of the high intensity charge-transfer band at 363 nm, is assigned to the $d_{xy} \rightarrow d_{z^2}$ transition. Two weaker transitions at 514 and 695 nm are assigned to $d_{xy} \rightarrow d_{x^2-y^2}$ and $d_{xy} \rightarrow d_{xz,yz}$, respectively. A moderate ligand field in the expected range ($D_q$ = 1950 $cm^{-1}$) emerges [$D_q(VOSO_4{\cdot}H_2O)$ = 1600 $cm^{-1}$] from this.[19,20] For $[V^{IV}{=}O(L^{3'})]^{+}$, only one dd transition is observed at 571 nm. The others are probably not resolved due to the strong charge-transfer transition at 386 nm, and this supports the coordination of the phenolate donor group.

The EPR spectra of the three bispidine vanadyl compounds and of the vanadyl aqua ion are shown in Figure 2. The spin-Hamiltonian parameters, obtained by spectral simulation,[21] are given in Table 2. The spectra are typical for $d^1$ vanadyl systems with a $d_{xy}$ ground state and a compressed tetragonal geometry.[22–24] The trend of the *g*- and *A*-tensor parameters (in particular of the *z* components) with decreasing values along the series $L^2 > L^3 > L^1 > (H_2O)_5$ depends on the type of chromophore ($N_aO_b$, $a + b = 5$), and is consistent with the expected level of delocalization of the unpaired electron to the donor groups, with the softer N donors leading to more covalent interactions than the harder O donors.

### Oxidation of the Vanadium(IV) Bispidine Complexes

The oxidation of a methanolic solution of $[V^{IV}{=}O(L^{2'})]^{2+}$ with a large excess of 30% aqueous $H_2O_2$ was studied by time-dependent UV/Vis/NIR spectroscopy. The series of spectra (see Figure 3) show a gradual decrease of the d–d transitions of the vanadyl complex (695 nm) and the appearance of a more intense single band at 429 nm (the color of the solution changes from light purple to orange). These changes indicate that metal-centered oxidation occurs. The reaction shows two isosbestic points at 390 and 547 nm and a pseudo-first-order behavior. The rate

of disappearance of the d–d band at 700 nm and increase of the charge-transfer band at 430 nm leads to a reaction rate, $k_{obs}$, of $1.02 \times 10^{-3}$ s$^{-1}$. The product formed was purified by ion-exchange chromatography and characterized as a oxidovanadium(V) peroxide complex. The transition at 430 nm is assigned to a peroxide-to-vanadium charge-transfer transition. This is in the range typical for oxidovanadium(V) peroxide complexes.[8,30]

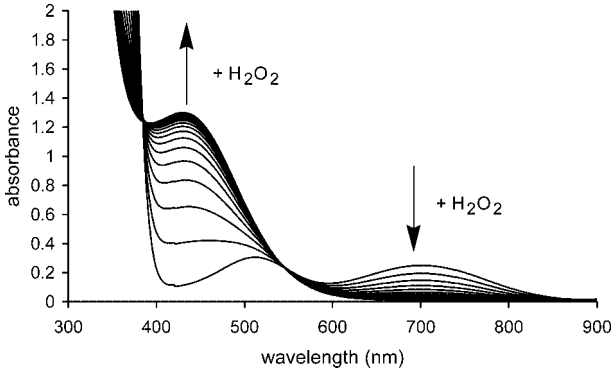

Figure 3. Time-dependent UV/Vis NIR spectra of the oxidation of $[VO(L^{2'})]^{2+}$ (11 mM MeOH) at 25 °C by $H_2O_2$ (170 equiv. of 30% aqueous solution) recorded at 5 min time intervals.

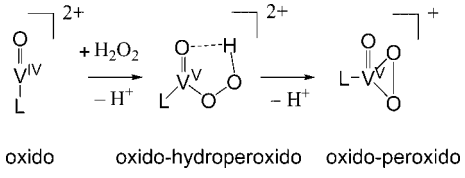
The CT band at 430 nm formed during oxidation is shifted to 456 nm in a much slower process (approx. one day). This is assigned to a rearrangement of an initially formed oxidohydroperoxido intermediate, which produces the oxidovanadium(V) peroxide complex (see Scheme 2).[4] This intramolecular rearrangement is expected to be a slow process because it involves ligand substitution at the vanadium(V) center. No intermediates were detected by EPR spectroscopy, which indicates that the first, relatively fast process is probably the oxidation of the $V^{IV}$=O complex and that no vanadyl peroxide intermediates can be trapped.



Scheme 2.

The oxidation products were analyzed with various oxidant concentrations, in a number of different solvents, and after quenching the reactions after various time intervals. Maximum yields of the vanadium(V) product were obtained with rather large amounts of $H_2O_2$ as oxidant (170 equiv.) and when the reaction was quenched after 2 h. When these reaction mixtures were left for two days, ESI mass spectrometry indicated that the orange product had completely decomposed (yellow solution). Aprotic solvents seem to lead to more side products than protic solvents, and the highest yields were obtained in MeOH and MeCN. This is not unexpected since vanadyl/$H_2O_2$ systems are known to produce OH radicals[25] and the yields of the vanadium(V) product seem to correlate with the ability of the solvent to quench these radicals.

Three transitions are found in the low energy part of the IR spectrum, at 890, 932, and 962 cm$^{-1}$. Based on published data, the absorption at 962 cm$^{-1}$ can be attributed to the V=O stretching vibration. The other two are tentatively assigned to O–O modes. To confirm this assignment, an $^{18}$O-labeling study was performed with $H_2{}^{18}O_2$ as oxidant (see Figure 4). In the IR spectrum of the $[V^{V}=O(^{18}O_2)(L^{2'})]^{+}$ complex, the transitions originally seen at 932 and 890 cm$^{-1}$ are shifted to 887 and 850 cm$^{-1}$, respectively. These experimental isotope shifts are close to those expected theoretically. Similar isotope shifts are also observed in the nitrate salt of the complex.

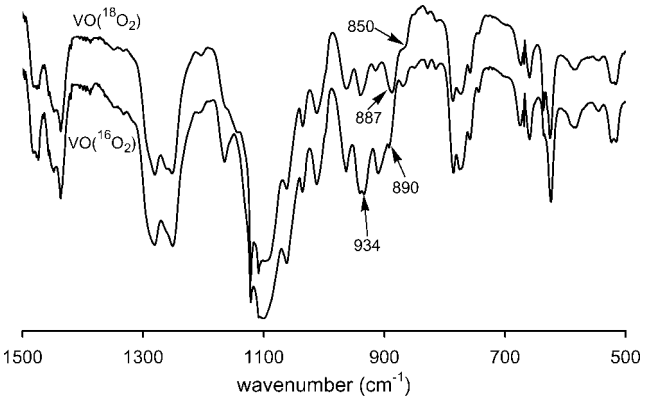


Figure 4. FT-IR spectra (KBr pellet) of $[V=O(O_2)(L^{2'})]^{+}$; top: synthesis with $H_2{}^{18}O_2$; bottom: synthesis with $H_2{}^{16}O_2$.

Single crystals of $[V^{V}=O(O_2)(L^{2'})]ClO_4 \cdot H_2O$ suitable for an X-ray structure determination were obtained by slow evaporation of the solvent (water/acetonitrile, 1:10). The resulting orange crystals are stable in air for several days. The structure of the cation $[V^{V}=O(O_2)(L^{2'})]^{+}$ is shown in Figure 1; selected geometric parameters are given in Table 1. The V–Npy1 and V–Npy2 distances are similar to the values determined for the corresponding vanadyl complex (see Table 1). The V–N3 distance is somewhat longer than in the vanadium(IV) complex and this may be due to the peroxido group, which leads to five in-plane donor atoms attached to the vanadium(V) center. This also leads to a smaller Npy1–V–Npy2 angle in the oxidovanadium(V) peroxide complex. The structure shows that the side-on coordination of the peroxido group requires the dissociation of the third pyridine group Npy3. As a result, there is a marked elongation of the V–N7 bond (2.56 vs. 2.36 Å) and, as a consequence, the distance between the two tertiary amino nitrogen donors increases from 2.84 to 2.91 Å. This value is very similar to that in the metal-free ligand $L^1$ (N3···N7 = 2.901 Å) and indicates that the oxidation of the vanadium center and the coordination of the peroxido group are assisted by the rigid bispidine ligand structure. The V=O distance, as expected, is rather insensitive to the oxidation state and coordination environment of vanadium.[10]

The description of the complex as an oxidovanadium(V) peroxide species is not unambiguous − it might alternatively be assigned as an oxidovanadium(IV) superoxide complex. There is a linear correlation between the O–O

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

stretching frequency and the bond length in this type of complexes:[26] peroxido complexes generally have O–O distances of 1.4–1.5 Å and O–O stretching frequencies of 1050–1200 $cm^{-1}$.[26] Therefore, judging from the apparent bond length in the crystal [1.281(5) Å] the assignment should rather be $[V^{IV}{=}O(O_2)(L^{2'})]^+$ (superoxide), while the IR spectra (see above) indicate that $[V^{V}{=}O(O_2)(L^{2'})]^+$ (peroxide) is the correct formulation. Close inspection of the crystal structure reveals much larger atomic displacement parameter (ADPs) for O1 and O2 than for the other oxygen, nitrogen, and carbon atoms. In addition, there is a systematic deviation of the shapes of the "thermal" envelopes for O1 and O2 from spherical (Figure 5). Normally, such effects can be attributed to thermally induced libration of "non-rigid groups".[27] Such libration leads to a systematic shortening of the apparent bond lengths between the affected atoms. This effect has indeed been observed in some $\eta^2$-$O_2$ metal complexes.[26] In the present case, the Hirshfeld Δ parameters indicate a highly correlated displacement of the $O_2$ moiety relative to the rest of the molecule. However, the diffraction data were collected at low temperature (100 K), which should greatly diminish the amplitude of librational motion. Indeed, attempts to model the effects by libration around the obvious axis joining V and the mid-point between O1 and O2 were unsuccessful. Dynamic effects (i.e. thermal motion) cannot be ruled out completely, but the ADPs also reflect static displacements of the atoms in many individual unit cells from their macroscopic space-averaged positions. We therefore tentatively assign the high ADPs of O1 and O2 to static disorder effects and do not see any particular significance in the apparently short oxygen–oxygen bond. In addition to the infrared spectroscopic data discussed above, there are no low intensity dd transitions in the 600–1000 nm range in the UV/Vis spectrum. Furthermore, the charge-transfer transition at 456 nm is in the area expected for vanadium(V) peroxide compounds.

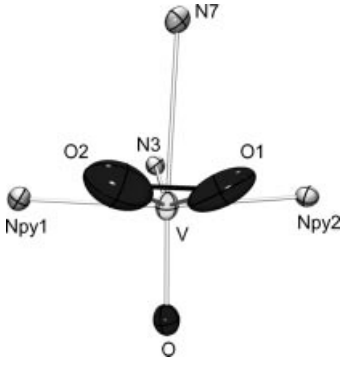

Figure 5. Displacement ellipsoids (50%) for the $N_4OVO_2$ core of the complex cation $[V{=}O(O_2)(L^{2'})]^+$.

It should be possible to oxidize oxidovanadium(V) peroxide complexes to the corresponding superoxido compounds.[28,29] Various oxidants were investigated ($Co^{3+}$, $KO_2$, $Ce^{4+}$), but only the preliminary experiments with $Ce^{4+}$ were partially successful. Thus, addition of one equivalent of $Ce^{4+}$ at –40 °C to an orange solution of $[V{=}O(O_2)$-$(L^{2'})]^+$ leads to a pale-yellow solution. Both $Ce^{3+}$ and oxidovanadium(V) superoxide complexes are expected to be yellowish. Addition of $H_2O_2$ to this solution brings the orange color back. The EPR spectrum of the yellow solution shows a signal for $Ce^{3+}$. No other signals were observed after five minutes at 230 K. When the sample is left for a longer time at 230 K (10 min, see Figure 6) additional signals appeared, which were assigned to a $VO^{2+}$ complex. These increase in intensity with longer reaction times whereas the intensity of the $Ce^{3+}$ signal does not change. We tentatively interpret these observations as being due to the oxidation of $[V^{V}{=}O(O_2)(L^{2'})]^+$ (peroxide) to $[V^{V}{=}O(O_2)(L^{2'})]^{2+}$ (superoxide) and assume that the EPR signal of the superoxide is hidden under the $Ce^{3+}$ signal. The vanadyl spectrum is a result of the decomposition of the metastable vanadium(V) superoxide complex to a vanadyl complex and dioxygen.

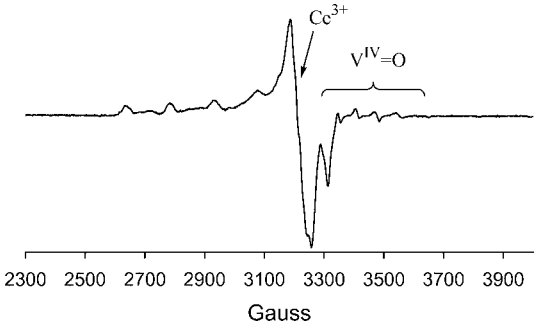

Figure 6. EPR spectrum of $[V^{V}{=}O(O_2)(L^{3'})]$ + 1 equiv. of $Ce^{4+}$ (reaction for 10 min at 230 K; spectrum recorded at 100 K) in MeCN/dmf (1:2).

## Reactivity

The vanadium(V) complexes were used for a number of catalytic oxidation test reactions (see Experimental Section). These include the bromination of phenol red (haloperoxidase test reaction)[30] and the oxidation of cyclohexene (epoxidation, hydroxylation).[4] There was no activity in the haloperoxidase test reaction and for cyclohexene oxidation the vanadium(V) complexes were also inactive. However, vanadyl complexes are also known to be able to oxidize olefins in the presence of $H_2O_2$.[31,32] Indeed, $[V^{IV}{=}O(L^{2'})]^{2+}$ has been shown to be able to oxidize cyclohexane but with a very low activity [0.7 mM catalyst, 7 mM $H_2O_2$, TON (cyclohexen-1-ol) = 0.1, TON (cyclohexen-1-one) = 0.3]. The vanadyl cations are believed to form hydroxyl radicals with $H_2O_2$,[25] and the allylic products probably emerge from these. The larger fraction of ketone product probably results from subsequent oxidation of the alcohol. The allylic products are likely to be, at least partially, the result of an autoxidation process involving dioxygen from air.[33] A possible reason for the low activity of the $[V^{IV}{=}O(L^{2'})]^{2+}/H_2O_2$ and $[V^{V}{=}O(O_2)(L^{2'})]^{+}/H_2O_2$ oxidation catalysis system is the saturated coordination sphere. A vacant coordination site has been proposed as

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

an active intermediate for the epoxidation process.[22] This might then explain the observed selectivity for allylic products.

## Experimental Section

**General:** The ligands $L^1$,[34] $L^2$,[35] and $L^3$ [35] were synthesized according to known procedures.

$H_2{}^{18}O_2$ (90% $^{18}O$ enriched, 2% solution in $H_2{}^{16}O$) was obtained from ICON services, USA. Commercially available chemicals were used without further purification.

UV/Vis spectra were recorded with a V-570 Jasco instrument. $^1H$ and $^{13}C$ NMR spectra at 200.13 and 50.54 MHz, respectively, were recorded with a Bruker AS 200 spectrometer in $CDCl_3$, [$D_6$]-DMSO, or $D_2O$ using TMS as an internal standard. Elemental analyses were obtained by the microanalytical laboratory of the chemical institutes of the University of Heidelberg. Mass spectra were measured with a Finnigan 8400 mass spectrometer. EPR spectra were recorded with a Bruker Elexsys E500 spectrometer at 110 K. Spectral parameters were determined by simulation using the program XSophe.[21] GC analyses were performed on a Varian 3900 gas chromatograph instrument equipped with a flame ionization detector, using a capillary column of Phenomenes Zebron ZB-1701 (length: 30 m; internal diameter: 0.25 mm). Temperature program: after 1 min, heating at a rate of 15 °C min$^{-1}$ from 40 to 130 °C; after 11 min at this temperature, heating at a rate of 49 °C min$^{-1}$ to 250 °C.

**Crystal Structure Determination:** Intensity data were collected with a STOE IPDS I or a Bruker AXS Smart1000 CCD diffractometer, and corrected for absorption and other effects.[36] Crystal data are compiled in Table 3. The structures were solved by direct methods and refined by full-matrix least-squares based on $F^2$. All non-hydrogen atoms were given anisotropic displacement parameters. Hydrogen atoms (except those of the solvent water molecule) were input in calculated positions. The calculations were performed using the programs SHELXS-86,[37,38] SHELXL-97.[39] Analysis of thermal motion was carried out with the program THMA11.[40]

CCDC-615579 ($[V^{IV}{=}O(L^{2'})](ClO_4)_2{\cdot}H_2O$) and -615580 ($[V^{V}{=}O(O_2)(L^{2'})]ClO_4{\cdot}H_2O$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**$[V^{IV}{=}O(L^{1'})](ClO_4)_2$:** $V_2O_5$ (608 mg, 3.34 mmol) was added to MeOH (150 mL) and the resulting yellow suspension was refluxed overnight. Unreacted solid $V_2O_5$ was removed from the green suspension obtained by filtration, and a solution of $L^1$ (2.485 g, 5.67 mmol) in EtOH (100 mL) was added to the hot solution containing the $VO(OEt)_3$ product (0.5157 g, 5.67 mmol, 84.8%). The yellowish/greenish mixture was refluxed for 20 h, then $NaClO_4$ (1.593 g, 11.34 mmol) was added, and the solution was left at 4 °C overnight. The precipitate which formed was removed by filtration, washed with small portions of cold EtOH, and dried in vacuo. Yield: 260 mg (0.37 mmol, 7%). ESI-MS (MeOH): *m/z* 521.3 $[V^{IV}{=}O(L^1)(OH)]^+$, 539.3 $[V^{IV}{=}O(L^{1\prime})(OH)]^+$, 553.3 $[V^{IV}{=}O(L^1)(OH)(MeOH)]^+$. $C_{23}H_{26}Cl_2N_4O_{14}V$ (704.34): calcd. C 39.22, H 3.72, N 7.96; found C 39.30, H 4.07, N 8.30. IR (KBr): $\tilde{\nu}$ = 3436 br. s, 3078 w (CH), 2974 ($CH_2$), 1734 (C=O), 1604 m, 1474 m, 1444 m, 1270 m, 1090 ($ClO_4$), 964 m, 780 m, 624 m. UV (MeOH): $\lambda$ ($\varepsilon$) = 370 nm (910 M$^{-1}$ cm$^{-1}$), 470 (350, sh), 590 (190), 680 (190).

**$[V^{IV}{=}O(L^{2'})](ClO_4)_2{\cdot}H_2O$:** $L^2$ (1.00 g, 1.94 mmol) was dissolved in MeOH (30 mL) and a solution of $VOSO_4{\cdot}H_2O$ (0.49 g, 1.94 mmol)

Table 3. Crystal data for $[V^{IV}{=}O(L^{2'})](ClO_4)_2{\cdot}H_2O$ and $[V^{V}{=}O(O_2)(L^{2'})]ClO_4{\cdot}H_2O$.

in MeOH (5 mL) was added. After refluxing for 1 h, the purple solution was evaporated to dryness and the product was separated on a CM Sephadex C-25 ion-exchange column with 0.1 M $NaClO_4$ as eluent. After partial solvent removal from the eluted purple band the product precipitated and was filtered and dried in vacuo. Yield: 0.81 g (0.99 mmol, 51%). ESI-MS (MeOH): *m/z* 291.5 $[V^{IV}{=}O\text{-}(L^2)]^{2+}$, 300.4 $[V^{IV}{=}O\ (L^{2'})]^{2+}$. $C_{28}H_{35}Cl_2N_5O_{17}V$ (835.42): calcd. C 40.25, H 4.22, N 8.38; found C 40.65, H 4.11, N 8.43. IR (KBr): $\tilde{\nu}$ = 3484 br. s, 3092 w, 2956 w, 1728 vs (C=O), 1608 s, 1479 m, 1437 w, 1286 s, 1281 w, 1253 w, 1205 w, 1098 vs, 1086 w, 986 w, 774 m, 658 w, 624 s, 538 w. CV (MeCN): $E$ = –1.10 V (quasi rev.), –0.24 V (irrev.), 1.60 V (irrev.). UV (MeOH): $\lambda$ ($\varepsilon$) = 254 nm (591 $M^{-1}cm^{-1}$), 363 (sh, 290), 514 (30), 695 (29)

**$[V^{IV}{=}O(L^{2'})](BF_4)_2{\cdot}H_2O$:** The reaction was performed in a similar fashion to that of $[V^{IV}{=}O(L^{2'})](ClO_4)_2{\cdot}H_2O$ but with 0.1 M $NaBF_4$ as eluent. Yield: 34%. ESI-MS: *m/z* 291.5 $[V^{IV}{=}O(L^2)]^{2+}$, 300.4 $[V^{IV}{=}O(L^{2'})]^{2+}$, 599.4 $[V^{IV}{=}O(L^2)(OH)]^{+}$. $C_{28}H_{35}B_2F_8N_5O_9V$ (810.13): calcd. C 41.50, H 4.35, N 8.65; found C 41.37, H 4.44, N 8.57. UV (MeOH): $\lambda$ ($\varepsilon$) = 363 nm (290 $M^{-1}cm^{-1}$), 514 (30), 695 (29). IR (KBr): $\tilde{\nu}$ = 3432 br. s, 3112 w, 2962 w, 1732 s, 1608 m, 1482 m, 1438 s, 1284 s, 1258 s, 1060 vs, 776 m, 658 m.

**$[V^{IV}{=}O(L^{3'})]Cl{\cdot}Et_3NHCl{\cdot}1.5H_2O$:** A solution of $VOSO_4$ (239 mg, 0.942 mmol) in MeCN (40 mL) was added to a MeCN solution (50 mL) of $L^3$ (500 mg, 0.942 mmol), followed by triethylamine (131.1 µL, 0.942 mmol). The reaction mixture was refluxed for 1 h, whereupon the color of the solution turned deep green. After the solution had cooled down, water (200 mL) was added and the mixture was transferred to a CM Sephadex C-25 ion-exchange column. The blue band eluted with 0.1 M NaCl was collected. Yield: 513 mg (0.63 mmol, 67%). ESI-MS (MeOH): *m/z* 596.4 $[VO(L^3H_{-1})]^{+}$, 614.4 $[VO(L^{3'}H_{-1})]^{+}$, 628.4 $[VO(L^3H_{-1})(MeOH)]^{+}$. $C_{35}H_{50}Cl_2N_5O_{9.5}V$ (814.65): calcd. C 51.60, H 6.18, Cl 8.71, N 8.60; found C 51.47, H 5.97, Cl 8.83, N 8.79. UV (MeOH): $\lambda$ ($\varepsilon$) = 386 nm (305 $M^{-1}cm^{-1}$), 571 (65), 766 (15, sh). IR (KBr): $\tilde{\nu}$ = 3422 br. s, 3070 w, 2980 w, 2950 w, 2676 m, 2624 m, 2498 w, 1734 vs (C=O), 1606 s, 1482 s, 1458 s, 1274 vs, 1100 vs, 974 s, 770 m, 622 m.

**$[V^{V}{=}O(O_2)(L^{2'})]ClO_4{\cdot}H_2O$:** 30% hydrogen peroxide (300 µL, 10 equiv.) was added to $[V^{IV}{=}O(L^{2'})](ClO_4)_2{\cdot}H_2O$ (0.25 g, 0.30 mmol) in MeOH (30 mL). After stirring at room temp. for 2 h, the formed orange product was purified on a CM Sephadex C-25 ion-exchange column. The orange band was collected by eluting with 0.1 M $NaClO_4$. After partial solvent removal, the precipitated orange solid was collected, washed with water, and dried in vacuo. Yield: 0.43 g (0.14 mmol, 47%). ESI-MS: *m/z* 632.3 $[VO(O_2)\text{-}(L^{2'})]^{+}$. $C_{28}H_{33}ClN_5O_{14}V$ (749.96): calcd. C 44.84, H 4.44, N 9.34; found C 44.59, H 4.55, N 9.20. $^1$H NMR ([D$_6$]DMSO): $\delta$ = 7.23–9.92 (m, 12 H, Ar-H), 5.59 (s, 2 H, N-C*H*), 3.81 (s. 2 H, N-C$H_2$), 3.69 (s, 6 H, O-C$H_3$), 3.57 (s, 3 H, N-C$H_3$), 2.65 (d, 2 H, C$H_2$), 1.95 ppm (d, 2 H, C$H_2$). UV (MeOH): $\lambda$ ($\varepsilon$) = 456 nm (137 $M^{-1}cm^{-1}$). IR (KBr): $\tilde{\nu}$ = 3378 s, 2952 w, 1734 vs, 1608 s, 1475 m, 1450 w, 1436 w, 1286 s, 1250 s, 1164 w, 1098 s, 1061 w, 1035 w, 1012 w, 963 w, 932 w, 890 w, 785 w, 771 w, 675 w, 623 m, 523 m.

**$[V^{V}{=}O(O_2)(L^{2'})NO_3{\cdot}H_2O]$:** The reaction was performed in a similar fashion to that of $[V^{V}{=}O(O_2)(L^{2'})]ClO_4{\cdot}H_2O$ but with 0.1 M $NaNO_3$ as eluent. ESI-MS(+): *m/z* 614.3 $[VO_3(L^2)]^{+}$, 632.4 $[VO_3(L^{2'})]^{+}$, 646.4 $[VO_3(L^2)(MeOH)]^{+}$; ESI-MS(–): *m/z* 738.2 $[VO_3(L^2)(NO_3)_2]^{-}$, 756.2 $[VO_3(L^{2'})(NO_3)_2]^{-}$, 770.2 $[VO_3(L^2)(NO_3)_2\text{-}(MeOH)]^{-}$. $C_{28}H_{33}N_6O_{13}V$ (712.51): calcd. C 47.20, H 4.67, N 11.80; found C 47.02, H 4.56, N 12.62. UV (MeOH): $\lambda$ ($\varepsilon$) = 450 nm (350 $M^{-1}cm^{-1}$, sh). IR (KBr): $\tilde{\nu}$ = 3430 br. s, 3070 w, 2956 m, 1730 vs, 1606 s, 1480 m, 1436 m, 1384 s, 1278 m, 1250 m, 1204 w, 1158 m, 1106 m, 1060 s, 1032 m, 1006 w, 961 s, 937 m, 923 w, 830 w, 788 m, 674 m, 657 m, 585 m, 527 w.

**$[V^{V}{=}O(^{18}O_2)(L^{2'})]ClO_4{\cdot}H_2O$:** The reaction was performed in a similar fashion to that of $[V^{V}{=}O(O_2)(L^{2'})]ClO_4{\cdot}H_2O$ but with 2% $H_2{}^{18}O_2$ as oxidant. IR (KBr): $\tilde{\nu}$ = 3422 br. s, 3120 w, 2958 w, 2852 w, 1734 vs, 1608 m, 1482 m, 1436 m, 1282 s, 1252 s, 1098 vs, 1036 sh, 1012 m, 964 m, 936 w, 914 w, 886 m, 786 m, 772 m, 624 s.

**$[V^{V}{=}O(O_2)(L^{3'}H_{-1})]Cl{\cdot}Et_3NHCl{\cdot}3.5H_2O$:** A 30% (w/w) $H_2O_2$ solution (3.09 mL, 116 equiv.) was added to a solution of $[V^{IV}{=}O(L^{3'}H_{-1})]Cl{\cdot}Et_3NHCl{\cdot}1.5H_2O$ (211 mg, 0.259 mmol) in MeOH (40 mL). The reaction mixture was stirred for one week at room temp., whereupon the color turned orange. After dilution with water the mixture was transferred to a CM Sephadex C-25 ion-exchange column, and the main orange band was collected with 0.1 M NaCl as eluent. Yield: 64 mg (0.049 mmol, 19%). ESI-MS: *m/z* 629.3 $[V^{V}{=}O(O_2)(L^3H_{-1})]^{+}$, 647.4 $[V^{V}{=}O(O_2)(L^{3'}H_{-1})]^{+}$, 661.3 $[V^{V}{=}O(O_2)(L^3H_{-1})(MeOH)]^{+}$. $C_{53}H_{103}Cl_5N_8O_{13.5}V$ (1296.7): calcd. C 49.09, H 8.00, Cl 13.67, N 8.64; found C 49.09, H 7.35, Cl 13.67, N 8.66. IR (KBr): $\tilde{\nu}$ = 3430 br. s, 2977 w, 2942 w, 2678 m, 2623 w, 2604 w, 2495 m, 1734 m, 1607 m, 1473 m, 1442 m, 1279 br m, 1261 br m, 1106 w, 1036 w, 959 w. UV (MeOH): $\lambda$ ($\varepsilon$) = 431 nm (240 $M^{-1}cm^{-1}$).

**$[V^{V}{=}O(^{18}O_2)(L^{2'})]NO_3{\cdot}H_2O$:** The reaction was performed in a similar fashion to that of $[V^{V}{=}O(O_2)(L^{2'})]NO_3{\cdot}H_2O$ but with 2% $H_2{}^{18}O_2$ as oxidant. IR (KBr): $\tilde{\nu}$ = 3420 br. s, 3080 br. m, 2952 m, 2852 w, 1732 s, 1608 m, 1480 w, 1436 m, 1384 vs, 1278 s, 1250 s, 1162 m, 1106 m, 1060 s, 1034 m, 1012 w, 962 m, 938 m, 886 s, 786 m sh, 776 sh, 758 m, 674 m, 658 m, 584 m, 517 m

**Catalysis Test Reactions**

**Haloperoxidase Test:** Bromination of the organic dye Phenol Red was carried out under conditions reported in the literature.[30]

**Cyclohexene Oxidation:** An $H_2O_2$ solution (0.3 mL; prepared by mixing 60 µL of 35% $H_2O_2$ and 10 mL of dry acetonitrile) was injected over 30 min with a syringe pump to a mixture of 2.1 µmol of vanadium complex and 2.1 mmol of cyclohexene in 2.7 mL of dry acetonitrile. After a given reaction time 1 mL of 6.8 mM naphthalene in acetonitrile was added as internal standard. The mixture was passed through a silica column, washed with ethyl acetate, and the eluate was directly analyzed by GC.[41]

# Alkyl Abstraction from a Trialkylyttrium Complex $[YR_3(thf)_2]$ ($R = CH_2SiMe_3$) Using a Group-13 Element Lewis Acid $ER_3$ (E = B, Al, Ga, In) – Structural Characterisation of the Ion Pair $[YR_2(thf)_4]^+[GaR_4]^-$ and of $ER_3$ (E = B, Al, Ga)

**Mathias U. Kramer,[a] Dominique Robert,[a] Yumiko Nakajima,[a] Ulli Englert,[a] Thomas P. Spaniol,[a] and Jun Okuda*[a]**

**Keywords:** Yttrium / Lewis acids / Alkyl abstraction / Group-13 elements / Cationic complexes

The alkyl abstraction reaction of $[YR_3(thf)_2]$ ($R = CH_2SiMe_3$) with group-13 trialkyl complexes $[(ER_3)_n]$ (E = B, Ga, In: $n$ = 1; E = Al: $n$ = 2) forming cationic yttrium species $[YR_2(thf)_4]^+[ER_4]^-$ (E = Al, Ga, In) shows a strong dependence on the Lewis acidic metal centre E and on the solvent basicity. Whilst the boron compound does not react with $[YR_3(thf)_2]$, the heavier homologues form the ion pairs $[YR_2(thf)_4]^+[ER_4]^-$ (E = Al, Ga, In) which dissociate to give the neutral compounds in apolar solvents such as benzene. Single-crystal structure analysis of the gallate $[YR_2(thf)_4]^+[GaR_4]^-$ shows the presence of an ion pair with *cis*-arranged alkyl ligands in the octahedral yttrium cation and a tetrahedral gallate anion. Group-13 trialkyl compounds $[(ER_3)_n]$ (E = B, Al, Ga), all liquids at room temperature, and $[Li(12\text{-crown-}4)_2]^+[AlR_4]^-$ were characterised by single-crystal X-ray diffraction and NMR spectroscopy.

## Introduction

There has recently been an increasing interest in cationic alkyl complexes of rare-earth metals, due to their enhanced electrophilicity and application in homogeneous catalysis, most prominently in α-olefin polymerisation catalysis.[1] One way to generate and isolate the cationic species is to irreversibly react neutral trialkyl complexes $[LnR_3(L)_n]$ with a weak Brønsted acid such as $[NEt_3H][BPh_4]$ or a strong Lewis acid such as $[Ph_3C][B(C_6F_5)_4]$. Another way is an alkyl abstraction with neutral Lewis acids, in particular group-13 organometallic compounds such as $[B(C_6X_5)_3]$ (X = H, F). The resulting ion pairs are either charge-separated or consist of contact ion pairs, such as $[ScMe_2(Me_3\text{-}TACN)(\mu\text{-}Me)B(C_6F_5)_3]$, (TACN = 1,4,7-triazacyclononane) prepared from $[ScMe_3(Me_3\text{-}TACN)]$ and $[B(C_6F_5)_3]$ in thf.[2] In the context of studying homogeneous ethylene polymerisation catalysis by $[Y(CH_2SiMe_3)_3(thf)_2]$/$[PhNMe_2H][B(C_6F_5)_4]$/$[AlR_3]$ we isolated a charge-separated ion pair $[Y(CH_2SiMe_3)_2(thf)_4]^+[Al(CH_2SiMe_3)_4]^-$ (**1a**) from the reaction of $[Y(CH_2SiMe_3)_3(thf)_2]$ and $[Al(CH_2SiMe_3)_3(thf)]$ that underwent further protonolysis to afford the dication $[Y(CH_2SiMe_3)(thf)_5]^+[B(C_6F_5)_4]^-{}_2$.[3,4] We report here a solvent dependent reversible equilibrium between ionic **1a** and its neutral precursors $[Y(CH_2SiMe_3)_3(thf)_2]$ and $[Al(CH_2SiMe_3)_3(thf)]$ and an extension of this alkyl abstraction reaction to the use of homologous group-13 trialkyl compounds $[\{E(CH_2SiMe_3)_3\}_n]$ (E = B, **3**, $n$ = 1; E = Al, **4**, $n$ = 2; E = Ga, **5**, $n$ = 1; E = In, **6**, $n$ = 1). In addition, we present the crystal structures of the group-13 trialkyl complexes **3**–**5**.[5]

## Results and Discussion

### Cationic Yttrium Complexes

Encouraged by the facile formation of **1a** by reaction of the trialkyl compound $[Y(CH_2SiMe_3)_3(thf)_2]$ with a stoichiometric amount of the trialkylaluminium **4** in thf,[3,4] attempts were made to synthesise yttrium cationic complexes bearing the analogous borate, gallate and indate anions, $[B(CH_2SiMe_3)_4]^-$, $[Ga(CH_2SiMe_3)_4]^-$, and $[In(CH_2SiMe_3)_4]^-$ respectively. It was found, however, that whilst the reaction proceeds at ambient temperature for the gallium and indium species **5** and **6** in thf, no reaction was observed with the borane **3** in $[D_8]$thf or $[D_5]$bromobenzene at elevated temperatures up to 60 °C. The lack of reactivity of **3** is not only due to insufficient Lewis acidity of the boron atom in **3**, as $[B(CH_2SiMe_3)_4]^-$ is a known species with a variety of cations,[6] but it appears that the neutral boron compound is not sufficiently electrophilic to abstract an alkyl group from the yttrium centre. A possible explanation is the formation of a very stable adduct with thf, as is the case in the alkyl abstraction from $[Y(CH_2SiMe_3)_3(thf)_2]$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

using $[B(C_6F_5)_3]$, where heating of the reaction mixture was necessary for the abstraction to proceed.[4] The low reactivity of **3** towards Lewis bases compared to the remaining group-13 species is also illustrated in its negligible water sensitivity, whereas **4**–**6** all react with water.[5] The formation of alkyl gallates and indates $[Y(CH_2SiMe_3)_2(thf)_4]^+$-$[E(CH_2SiMe_3)_4]^-$ (E = Ga, **1b**; In, **1c**) as charge-separated ion pairs in thf solutions (vide infra) represents the first cationic rare-earth metal alkyl complexes with these anions (Table 1). Previously only neutral complexes with bridging alkyl groups bound to gallium were reported.[7]

[a] For **1b** only one of the two crystallographically independent ion pairs chosen.

Based on the results from X-ray crystallographic and NMR spectroscopic analysis in $[D_8]$thf, complex **1a** was described previously as a charge-separated ion pair.[3,4] When measured in less donating solvents, such as $[D_6]$benzene, $[D_8]$toluene and $[D_5]$bromobenzene, the previously isolated complex **1a** dissociates to form $[Y(CH_2SiMe_3)_3(thf)_2]$ and $[Al(CH_2SiMe_3)_3(thf)]$ (Scheme 1). The NMR spectra are exact superpositions of the spectra of the corresponding neutral species.[8] A notable feature for the $AlCH_2$ signal in the $^1H$ NMR spectra ($[D_8]$thf) is that the signal in $[Al(CH_2SiMe_3)_3(thf)]$ is a singlet, whilst the corresponding resonance in the anion $[Al(CH_2SiMe_3)_4]^-$ is a distorted sextet due to coupling to quadrupolar aluminium ($I$ = 5/2) that collapses to a singlet in the $^1H\{^{27}Al\}$ decoupled spectrum (Figure 1). Correspondingly, the $^{27}Al$ NMR shows a nonet at $\delta$ = 150.9 ppm with $^2J_{Al,H}$ = 9.0 Hz. The same NMR spectroscopic features are found for the lithium salts containing the anion $[Al(CH_2SiMe_3)_4]^-$ (vide infra), confirming the ion separation in thf solution.

Addition of one equivalent of 12-crown-4 to a $[D_6]$benzene solution of **1a** results in complete ionisation of the neutral species to form the previously reported ion pair $[Y(CH_2SiMe_3)_2(12\text{-crown-}4)(thf)]^+[Al(CH_2SiMe_3)_4]^-$ (**2a**).[4] Similarly, upon addition of $[D_8]$thf to the $[D_6]$benzene solution of the neutral compounds, dissociation occurs, depending on the solvent mixture and temperature. An investigation of **1a** in a range of $[D_6]$benzene/$[D_8]$thf mixtures (composition range 40–60 mol-% of $[D_8]$thf) and at different temperatures was therefore conducted. However, even inside this reduced range, an exact quantification of equilibrium constants $K = c([Y(CH_2SiMe_3)_2(thf)_4][Al(CH_2SiMe_3)_4])/c([Y(CH_2SiMe_3)_3(thf)_2])\cdot c([Al(CH_2SiMe_3)_3(thf)])$ for the equilibrium depicted in Scheme 1 remained difficult due to peak overlapping in the $^1H$ NMR spectra. An increase in the amount of $[D_8]$thf leads to an increase in the dissociation constant $K$. Using a 60:40 mixture $[D_8]$thf/$[D_6]$benzene, variable-temperature NMR measurements were conducted at 25 °C, 35 °C, and 45 °C. Using the van't Hoff equation $d(\ln K)/dT = \Delta_r H°/RT^2$, the standard enthalpy change for the ionisation $\Delta_r H°$ is estimated as about –70 kJ mol$^{-1}$ at 308 K. The exchange equilibrium is slow on the NMR timescale, as coupling patterns of the neutral and cationic yttrium species are observed.

Similarly to the aluminate **1a**, both gallate **1b** and indate **1c** form charge-separated complexes in thf solutions. The signals in their NMR spectra belonging to the $[Y(CH_2SiMe_3)_2(thf)_4]^+$ cation are identical to those reported for the aluminate **1a** and similar to those of compounds containing other anions (Table 2), indicating that the anions are only weakly coordinating in the $[D_8]$thf solutions.[9] Probably due to the quadrupolar nature of Ga ($I$ = 3/2) and In ($I$ = 9/2), the $^1H$ NMR signals assigned to the $ECH_2$ (E = Ga, In) protons are very broad (Figure 2). The corresponding signal for the indate **1c** in the $^{13}C$ NMR spectrum is not detected, as was previously noted for the $^{13}C$ signals of $BCH_2$ in similar complexes containing the $[B(C_6X_5)_3(CH_2SiMe_3)]^-$ (X = H, F) anions.[4]

|---|---|---|---|
| $[Ga(CH_2SiMe_3)_4]$ | –0.68 | 3.0 | this work |
| $[In(CH_2SiMe_3)_4]$ | –0.68 | 3.3 | this work |
| $[Al(CH_2SiMe_3)_4]$ | –0.68 | 3.2 | this work |
| $[B(C_6F_5)_4]$ | –0.69 | 3.2 | [4] |
| $[BPh_4]$ | –0.77 | 3.3 | [4] |
| $[B(C_6F_5)_3(CH_2SiMe_3)]$ | –0.70 | 2.9 | [4] |
| $[BPh_3(CH_2SiMe_3)]$ | –0.80 | 3.2 | [4] |

When NMR spectra of **1b** and **1c** are measured in $[D_6]$benzene, $[D_8]$toluene, and $[D_5]$bromobenzene, it is found that on the NMR timescale all $CH_2$ protons and all $SiMe_3$ protons are equivalent in these solvents. The peaks in the $^1$H NMR spectra appear broad, and lack any coupling pattern to yttrium. It is therefore postulated that the molecules are fluxional and exchange alkyl groups intermolecularly (due to the lack of coupling) fast on the NMR timescale. Spectra of **1b** in $[D_8]$thf and $[D_6]$benzene are shown in Figure 2. This situation is similar to that found in compounds of the type $MR_2{\cdot}ZnR_2$ (M = Sr or Ba; R = $CH_2SiMe_3$).[10] NMR spectroscopic analysis of these compounds showed that all alkyl groups are chemically and magnetically equivalent on the NMR timescale and an equilibrium between neutral alkyl complexes, "ate" complexes, contact ion pairs and solvent separated ions was proposed in the literature.[10–12]

A further example for solvent dependence of the structures and for intra-/intermolecular exchange was reported for $[La(\eta^5\text{-}C_5Me_5)\{CH(SiMe_3)_2\}BPh_4]$, where the tetraphenylborate anion is coordinating to the lanthanum centre in aromatic solvents. In constrast to the case of **1b** and **1c**, irreversible charge separation is achieved by solvation to give $[La(\eta^5\text{-}C_5Me_5)\{CH(SiMe_3)_2\}(thf)_3][BPh_4]$ in thf.[13]

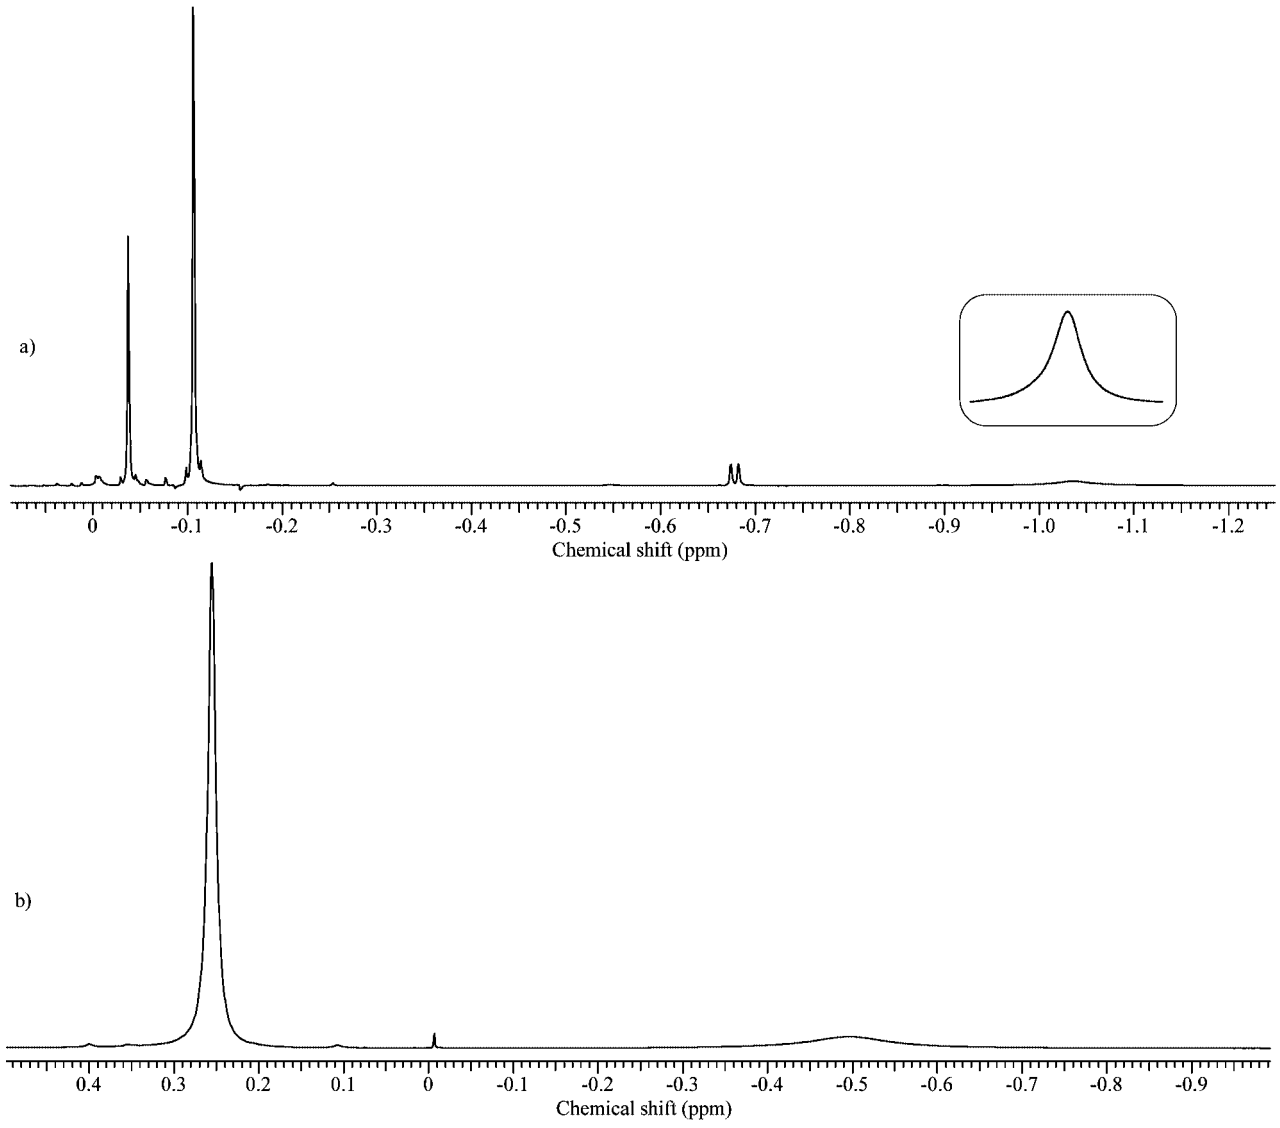

Figure 2. $^1$H NMR spectra at 25 °C of $[Y(CH_2SiMe_3)_2(thf)_4][Ga(CH_2SiMe_3)_4]$ (**1b**) in a) $[D_8]$thf and b) in $C_6D_6$.

Upon addition of one equivalent of 12-crown-4 to $[D_6]$-benzene solutions of **1b** and **1c** the molecules separate into the charge-separated ion pairs $[Y(CH_2SiMe_3)_2(12\text{-crown-4})(thf)]^+[E(CH_2SiMe_3)_4]^-$ (E = Ga, **2b**; In, **2c**), as was observed for **1a**. The peaks arising from the cationic yttrium species are similar in all three cases, implying only weakly coordinating anions.

Single crystals of the gallate **1b** suitable for X-ray analysis were grown by slowly cooling a thf/pentane solution to –30 °C. The unit cell contains two sets of independent ion pairs, each expressing slightly distorted tetrahedral geometry around the gallium atom and distorted octahedral geometry around the yttrium centre (Figure 3). Whilst the cationic fragments express a similar octahedral geometry with *cis*-arranged alkyl groups to that observed in $[Y(CH_2SiMe_3)_2(thf)_4]^+[Al(CH_2SiMe_3)_4]^-$ (**1a**),[3] the anionic fragments are slightly more distorted from perfect tetrahedral geometry than their aluminate counterparts, with C–Ga–C angles ranging from 107.98(13)° to 111.02(11)°, compared to C–Al–C bond angles only ranging from 108.9(2)° to 109.8(3)° (vide infra).

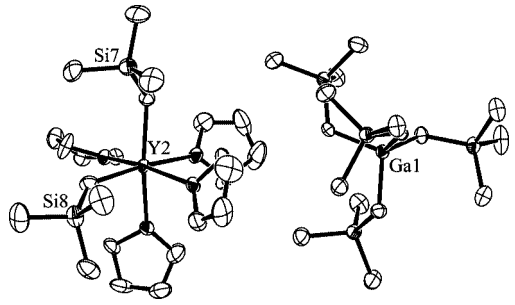

Figure 3. ORTEP representation of one ion pair of $[Y(CH_2SiMe_3)_2(thf)_4]^+[Ga(CH_2SiMe_3)_4]^-$ (**1b**). Displacement ellipsoids drawn at the 50% probability level, hydrogen atoms omitted for clarity.

The Y–C bond lengths range from 2.375(3) Å to 2.400(3) Å and thus lie within the range of distances reported in the literature for cationic and neutral (trimethylsilymethyl)yttrium complexes as are the Y–O distances [2.324(2) Å to 2.478(2) Å].[4] The Ga–C distances found in the two anions range from 2.031(3) Å to 2.058(3) Å (mean 2.042 Å) and are very similar to those found for the sterically less demanding benzyl ligand in $[Mg_3Br_{2.4}Cl_{1.6}(OEt_2)_6][Ga(CH_2Ph)_4]_2$·0.5 toluene (2.039 Å mean),[14] the terminal trimethylsilylmethyl ligand in $[Li(dioxane)_{1.5}][Ga(CH_2SiMe_3)_4]$ (2.025 Å mean),[15] and the bulky fluorenyl ligand in $[Li(DME)_3][Ga(C_{13}H_9)_4]$ (2.062 Å mean).[16] Compared to the parent molecule **5** the bonds have increased in length by about 5%.

### Structure of Tris(trimethylsilylmethyl) Group-13 Metal Complexes

To compare the Lewis acidity of the group-13 complexes we have carried out structural comparison of the (trimethylsilylmethyl)boron, -aluminium and -gallium compounds **3**–**5**. As expected, only the aluminium compound turned out to be dinuclear (Table 3).

Table 3. Selected bond lengths [Å] and bond angles [°] for **3**, **4** and **5**.

#### *Tris(trimethylsilylmethyl)boron*

As expected, the crystal structure of tris(trimethylsilylmethyl)boron (**3**), Figure 4, revealed discrete molecules, structurally similar to $BEt_3$ with respect to the arrangement of the ligands around the central atom.[17] The three B–C–Si angles [117.04° on average, ranging from 114.27(14)° to 119.73(15)°] deviate from the ideal tetrahedral angle 109.47° at the carbon, which was already observed in other tris(alkyl) boron compounds (cf. $BEt_3$: B–C–C average: 118.9°,[17] or B*t*Bu$_3$: B–C–C 120.6(2)°[18]). In these compounds, hyperconjugation was invoked to justify these abnormally large values. In **3** however, it is more likely that the important steric bulk of the trimethylsilyl groups dictates their orientation, rather than hyperconjugation. Indeed, the B–C–Si angles of the two groups pointing towards each other [B–C1–Si1 117.13(13)° and B–C3–Si3 119.73(15)°] are found to be larger than the corresponding angle in the third alkyl group [B–C2–Si2 114.27(14)°].

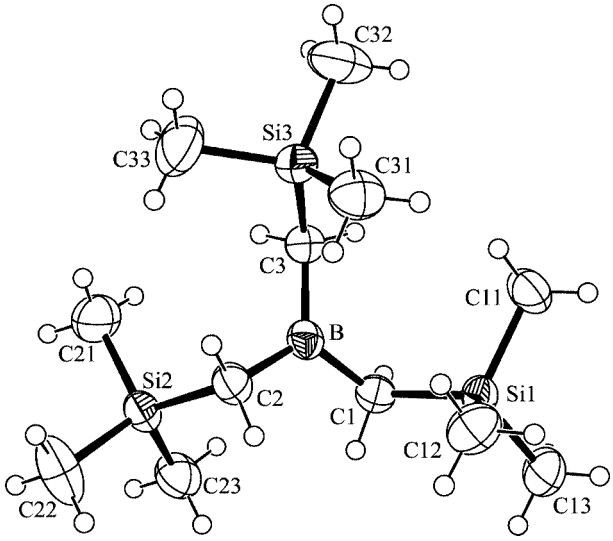

Figure 4. ORTEP representation of the molecular structure of $[B(CH_2SiMe_3)_3]$ (**3**). Displacement ellipsoids of non-H atoms drawn at the 50% probability level.

The B–C bond lengths [1.568 Å mean, ranging from 1.563(3) Å to 1.573(3) Å] do not present any particular deviation from the values typically observed in homoleptic boron compounds. The same was observed for the C–B–C angles, the planar geometry around the boron centre being almost perfect ($\Sigma_{C-B-C}$ = 359.95°).

#### *Tris(trimethylsilylmethyl)aluminium*

As many other homoleptic (e.g. $[(AlMe_3)_2]$,[19] $[(AlPh_3)_2]$,[20] $[\{Al(cyclo\text{-}Pr)_3\}_2]$,[21] $[\{Al(C_6H_4\text{-}2\text{-}Me)_3\}_2]$[22]) and mixed-alkyl (e.g. $[\{AlMe_2(\mu\text{-}Ph)\}_2]$,[23] $[\{Al\textit{i}Bu_2(\mu\text{-}C{=}C\textit{t}Bu)\}_2]$[24]) aluminium species, $[\{Al(CH_2SiMe_3)_3\}_2]$ (**4**), Figure 5, was found to adopt a dimeric structure. The molecule shows crystallographic inversion symmetry and exhibits in addition two non-equivalent C–Al bonds for each bridging carbon in the solid state. Only few organoaluminium compounds have so far been reported to exhibit such unsymmetrical bridges (e.g. $[\{AlPh_2(\mu\text{-}C{\equiv}CPh)\}_2]$,[25] or $[\{AlMe_2(\mu\text{-}C{\equiv}CMe)\}_2]$[26]). Until now, to the best of our knowledge, no homoleptic dimeric trialkylaluminium compound featuring non-equivalent bridges has been reported. Thus **4** appears to be the first example for this coordination mode in the solid state. These findings are in agreement with a previous report that **4** is only partially dimerised in benzene solution based on cryoscopic measurements.[27]

Due to steric bulk of the $CH_2SiMe_3$ groups, the Al–Al distance observed in $[\{Al(CH_2SiMe_3)_3\}_2]$ of 2.8328(13) Å is amongst the longest reported. As a consequence, the Al–C1–Al′ bridge angle of 80.55(7)° is also slightly larger than usually observed (Table 4). Only heteroleptic aluminium de-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

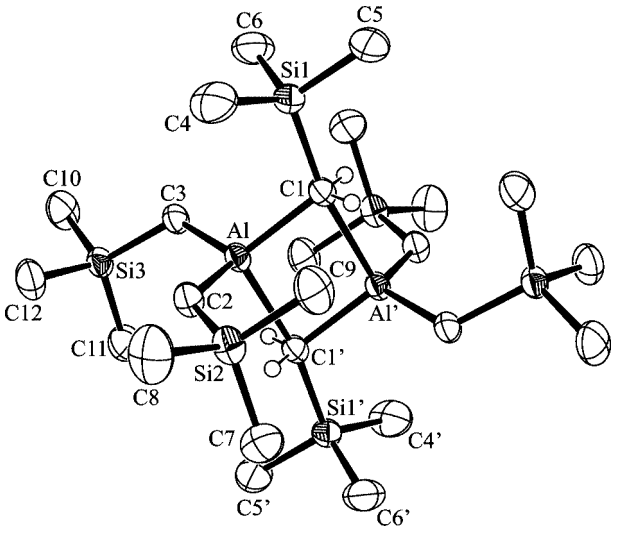

Figure 5. ORTEP representation of the molecular structure of $[\{Al(CH_2SiMe_3)_3\}_2]$ (**4**). Displacement ellipsoids of non-H atoms drawn at the 50% probability level; only hydrogen atoms bonded to bridging carbons shown.

rivatives bearing rigid bridging groups like $[\{AlPh_2(\mu\text{-}C{\equiv}CPh)\}_2]$ (Al–$C_b$–Al 91.73°)[25] or $[\{AlMe_2(\mu\text{-}C{\equiv}CMe)\}_2]$ [Al–$C_b$–Al 92.0(1)°],[26] or bulky bridging groups, like $[\{Al(C_6H_4\text{-}2\text{-}Me)_3\}_2]$ [Al–$C_b$–Al 81.9(1)°],[22] display larger bridge angles.

Table 4. Al–Al bond lengths [Å] and Al–$C_b$–Al angles [°] for dimeric organoaluminium compounds.

| Compound | Al–Al [Å] | Al–$C_b$–Al [°] | Ref. |
|---|---|---|---|
| $[\{Al(CH_2SiMe_3)_3\}_2]$ | 2.8328(13) | 80.55(7) | this work |
| $[(AlMe_3)_2]$ | 2.700(10) | 78.0(3) | [19] |
| $[\{AlMe_2(\mu\text{-}Ph)\}_2]$ | 2.690(4) | 77.8(2) | [23] |
| $[(AlPh_3)_2]$ | 2.702(2) | 76.5(2) | [20] |
| $[\{Al(C_6H_4\text{-}2\text{-}Me)_3\}_2]$ | 2.817(2) | 81.9(1) | [22] |
| $[\{Al(cyclo\text{-}Pr)_3\}_2]$[a] | 2.618(3)/2.607(3) | 78.2(3)/77.9(2) | [21] |

[a] First value determined at 22 °C, second at –67 °C.

In **4** the $SiMe_3$ fragment of the bridging ligands is oriented away from the second aluminium centre [Al–$C_b$–Si1 109.10(10)° and Al′–$C_b$–Si1 167.57(12)°]. The two protons and the trimethylsilyl group bonded to the bridging carbons are in a staggered conformation with the silicon being located 0.2539(8) Å outside of the plane defined by Al, $C_b$, Al′ and $C_b$′. The sum of the C–Al–C angles around the aluminium ($\Sigma_{C-Al-C}$ = 343.34°) represents a non-negligible deviation from planarity, with the aluminium situated 0.4748 Å above the C1–C2–C3 plane. The bonds to the terminal alkyl groups [Al–C2 and Al–C3 1.958(2) Å] were found to be in the typical range for this type of compound. The Al–C bond of the bridging ligand [Al–C1 2.031(2) Å] shows considerable elongation; the second bridging contact [Al–C1′ 2.336(2) Å] is the longest ever reported in such a dimer. $[(AlPh_3)_2]$ is the only other known compound with bridging contacts of that magnitude [Al–$C_b$ 2.180(5) and Al–$C_b$′ 2.184(5) Å].[20]

### *Tris(trimethylsilylmethyl)gallium*

$[Ga(CH_2SiMe_3)_3]$ (**5**), Figure 6, crystallises with four equivalent monomeric molecules per unit cell. Unlike in $[GaEt_3]$,[28] in which the three ethyl groups adopt a propeller-like configuration (in only three of the four independent molecules of the unit cell however), the $CH_2SiMe_3$ groups in **5** adopt a structure resembling that of **3**. Two alkyl groups occupy the same side of the molecule, and display enlarged Ga–C–Si angles [116.60(19)° and 118.24(19)°] whilst the third one lies on the opposite side and is more bent towards the gallium centre [Ga–C2–Si2 114.82(19)°]. With an average value of 116.55°, the Ga–C–Si angles express the same deviation from the expected value as does the boron homologue (117.04° mean). In **5** hyperconjugation again has smaller influence on the molecular geometry than the steric requirements of the ligands. The Ga–C bond lengths [1.959 Å mean, ranging from 1.952(4) Å to 1.971(3) Å] fall within the range of already reported values, as well as the C–Si bonds. The three groups define a perfectly planar skeleton around the gallium ($\Sigma_{C-Ga-C}$ = 359.99°).

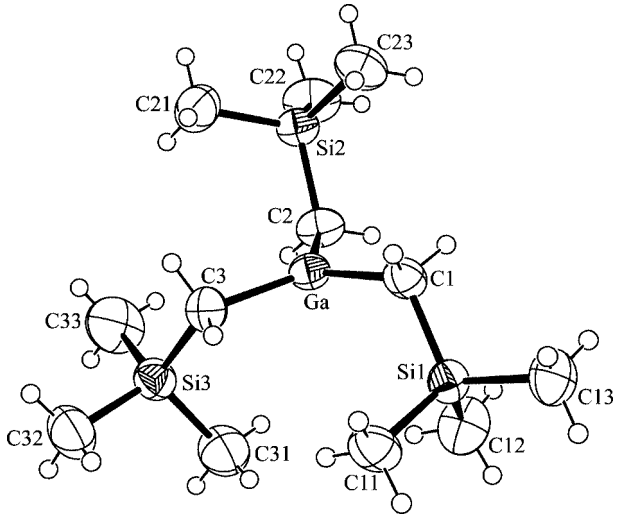

Figure 6. ORTEP representation of the molecular structure of $[Ga(CH_2SiMe_3)_3]$ (**5**). Displacement ellipsoids drawn at the 50% probability level.

That $[Ga(CH_2SiMe_3)_3]$ is monomeric is of no great surprise, since other structurally characterised trialkylgallium compounds which do not contain ligand-based electron pairs tend to be monomeric. $[GaEt_3]$ exhibits short intermolecular contacts in the solid-state structure, and $[GaMe_3]$ shows a tetrameric arrangement of the molecules in the lattice, the interactions in both compounds being however very weak.[28] Dimeric gallium compounds require electron-donating bridging ligands, such as $[\{GaMe_2(\mu\text{-}C{\equiv}CMe)\}_2]$,[29] $[\{Ga(CH{=}CH_2)_3\}_2]$,[30] $[\{GaMe_2(\mu\text{-}C{\equiv}CPh)\}_2]$,[31] $[\{Ga(CH_2Ph)_2Br\}_2]$ or $[\{Ga(CH_2Ph)_2(NHtBu)\}_2]$.[32] The solid-state structure of a TMEDA adduct of $[Ga(CH_2SiMe_3)_3]$, $[\{Ga(CH_2SiMe_3)_3\}_2]\cdot Me_2NCH_2CH_2NMe_2$[33] shows slightly elongated Ga–C bonds (by 1.6% on average) compared to the parent mole-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cule $[Ga(CH_2SiMe_3)_3]$, but no significant influence of the TMEDA coordination could be seen in the length of the C–Si bonds.

### Lithium Tetrakis(trimethylsilylmethyl)aluminates

To compare with the structure of the ion pair $[Y(CH_2SiMe_3)_2(thf)_4]^+[Al(CH_2SiMe_3)_4]^-$ (**1a**), solvent separated lithium derivatives of the $[Al(CH_2SiMe_3)_4]^-$ anion were prepared.[3] Upon addition of two equivalents of TMEDA or 12-crown-4 to $[Li]^+[Al(CH_2SiMe_3)_4]^-$ (**7a**),[34] obtained by reaction of $[\{Al(CH_2SiMe_3)_3\}_2]$ with $LiCH_2SiMe_3$, the corresponding adducts $[Li(TMEDA)_2]^+[Al(CH_2SiMe_3)_4]^-$ (**7b**) and $[Li(12\text{-crown-}4)_2]^+[Al(CH_2SiMe_3)_4]^-$ (**7c**) were isolated. Crystals of **7c** were obtained from cooling a saturated thf solution. The geometry around the aluminium centre is further shifted towards a regular tetrahedral arrangement compared to that in the neutral parent $[\{Al(CH_2SiMe_3)_3\}_2]$ (Figure 7). Thus, the three C–Al–C angles of the alkyl groups composing the "base" of the tetrahedron display very close values [106.43(6)°, 107.32(6)° and 107.58(6)°] whilst the fourth alkyl group (involving C18) forms together with the three other ligands angles of 110.02(6)°, 110.35(6)° and 114.80(6)°. All four Al–C bonds are almost equal (2.028 Å on average).

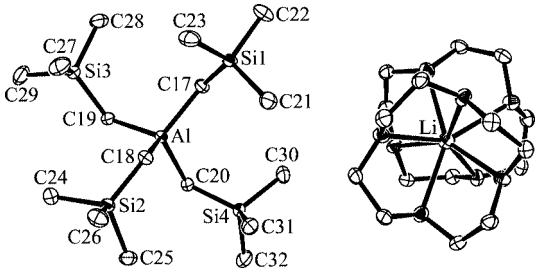

Figure 7. ORTEP representation of the molecular structure of $[Li(12\text{-crown-}4)_2]^+[Al(CH_2SiMe_3)_4]^-$ (**7c**). Displacement ellipsoids drawn at the 50% probability level, hydrogen atoms omitted for clarity.

The anionic part of $[Y(CH_2SiMe_3)_2(thf)_4]^+[Al(CH_2SiMe_3)_4]^-$ (**1a**)[3] displays a geometry much closer to a regular tetrahedral arrangement. The three alkyl groups defining the base of the structure show C–Al–C angles of 109.7(2)°, 109.7(2)° and 109.8(3)°. Angles of 109.19° in average ($\sigma$ = 0.2°) are measured between the fourth group and each of the three others. The aluminate anion in complex **1a** seems to be less influenced by the presence of the counter cation, and therefore adopts a perfectly tetrahedral geometry. Similar Al–C bond lengths and Al–C–Si angles were measured in **1a** (2.033 Å mean, cf. 2.029 Å in **7c**; 122.20° mean, cf. 124.17° in **7c**).

## Conclusions

The Lewis acid induced alkyl transfer reaction of the prototypical rare earth metal alkyl complex $[Y(CH_2SiMe_3)_3(thf)_2]$ with group-13 metal compounds $[\{E(CH_2SiMe_3)_3\}_n]$ proceeds to give an ion pair $[Y(CH_2SiMe_3)_2(thf)_4]^+[E(CH_2SiMe_3)_4]^-$ for E = Al, Ga and In in thf solution. In the presence of aromatic hydrocarbons, however, recombination to form the neutral precursors $[Y(CH_2SiMe_3)_3(thf)_2]$ and $[E(CH_2SiMe_3)_3(thf)]$ occurs. The small boron compound $[B(CH_2SiMe_3)_3]$ failed to react with $[Y(CH_2SiMe_3)_3(thf)_2]$ for kinetic reasons as well as for reduced Lewis acidity. The present results may be relevant to the reversible chain transfer reaction between rare earth metal alkyl catalyst and cocatalyst such as aluminium and zinc alkyl during olefin polymerisation.[1,3,4,35]

## Experimental Section

**General:** All operations were performed under an inert atmosphere of argon using standard Schlenk-line or glovebox techniques. Thf and pentane were distilled from sodium benzophenone ketyl and sodium benzophenone ketyl triglyme, respectively. Deuterated thf and benzene were dried with sodium, distilled and degassed prior to use; deuterated dichloromethane was dried with $CaH_2$, then distilled and degassed. Anhydrous $AlBr_3$, $GaCl_3$, $InCl_3$, $YCl_3$, and $BF_3{\cdot}OEt_2$ (STREM) were used as received. $LiCH_2SiMe_3$[36] and $[Y(CH_2SiMe_3)_3(thf)_2]$[37] were prepared according to literature procedure. All other chemicals were commercially available and used after appropriate purification. NMR spectra were recorded at room temperature on a Bruker DRX 400 spectrometer ($^1H$ 400.1 MHz, $^{13}C$ 100.6 MHz) or on a Varian Unity 500 spectrometer ($^1H$ 499.6 MHz, $^{13}C$ 125.6 MHz, $^{11}B$ 160.3 MHz, $^7Li$ 194.2 MHz, $^{27}Al$ 130.2 MHz) unless otherwise stated. All chemical shifts are given in ppm. Chemical shifts for $^1H$ and $^{13}C$ NMR spectra were referenced internally using the residual solvent resonances and reported relative to $SiMe_4$. $^{11}B$ NMR spectra were referenced externally to a saturated solution of $NaBH_4$ in $D_2O$. $^7Li$ NMR spectra were referenced externally to a 1 mol $L^{-1}$ solution of LiCl in $D_2O$. $^{27}Al$ NMR spectra were referenced externally to a 1.5 mol $L^{-1}$ solution of $Al(NO_3)_3$ in $D_2O$.

**$[Y(CH_2SiMe_3)_2(thf)_4][Al(CH_2SiMe_3)_4]$ (1a):** The compound was prepared according to the literature procedure.[3,4] $^1H$ NMR (200 MHz; [D$_8$]thf): $\delta$ = –1.22 (sextet, $AlCH_2$, $^2J_{Al,H}$ = 9.0 Hz, 8 H), –0.68 (d, $^2J_{Y,H}$ = 3.2 Hz, 4 H, $YCH_2$), –0.11 [s, 36 H, $AlCH_2Si(CH_3)_3$], 0.03 [s, 18 H, $YCH_2Si(CH_3)_3$], 1.77 (16 H, β-$CH_2$, thf), 3.62 (16 H, α-$CH_2$, thf) ppm. $^{27}Al$ NMR (130 MHz; [D$_8$]thf): $\delta$ = 150.9 (nonet, $^2J_{Al,H}$ = 9.0 Hz) ppm. $^1H$ NMR (400 MHz; $C_6D_6$): $\delta$ = –0.81 (s, 6 H, $AlCH_2$), –0.69 (d, $^2J_{Y,H}$ = 2.8 Hz, 6 H, $YCH_2$), 0.28 [s, 27 H, $AlCH_2Si(CH_3)_3$], 0.29 [s, 27 H, $YCH_2Si(CH_3)_3$], 1.27 (16 H, β-$CH_2$, thf), 3.72 (16 H, α-$CH_2$, thf) ppm. $^{13}C\{^1H\}$ NMR (100 MHz; $C_6D_6$): $\delta$ = –0.67 ($AlCH_2$), 3.30 [$AlCH_2Si(CH_3)_3$], 4.58 [$YCH_2Si(CH_3)_3$], 25.14 (β-$CH_2$, thf), 33.70 (d, $^1J_{Y,C}$ = 35.5 Hz, $YCH_2$), 69.99 (α-$CH_2$, thf) ppm.

**$[Y(CH_2SiMe_3)_2(thf)_4][Ga(CH_2SiMe_3)_4]$ (1b):** To a solution of $[Y(CH_2SiMe_3)_3(thf)_2]$ (974 mg, 1.969 mmol) in thf (5 mL), $[Ga(CH_2SiMe_3)_3]$ (653 mg, 1.969 mmol) in thf (5 mL) was added dropwise whilst stirring. Upon complete addition, the reaction mixture was stirred for further 10 min and all volatiles were subsequently removed under reduced pressure to yield a colourless solid, which was washed with pentane and dried under vacuum to yield **1b** as a colourless solid (1650 mg, 86%). Single crystals suitable for X-ray diffraction analysis could be obtained by slow cooling of a saturated thf/pentane solution of **1b**. $^1H$ NMR (400 MHz; [D$_8$]thf): $\delta$ = –1.04 (br. s, 8 H, $GaCH_2$), –0.68 (d, $^2J_{Y,H}$ = 3.0 Hz, 4 H, $YCH_2$), –0.11 [s, 36 H, $GaCH_2Si(CH_3)_3$], –0.04 [s, 18 H, $YCH_2$-

$Si(CH_3)_3$], 1.77 (16 H, β-$CH_2$, thf), 3.62 (16 H, α-$CH_2$, thf) ppm. $^{13}C$ NMR (100 MHz; [$D_8$]thf): $\delta$ = 2.67 ($GaCH_2$), 4.02 [$GaCH_2Si(CH_3)_3$], 4.07 [$YCH_2Si(CH_3)_3$], 26.31 (β-$CH_2$, thf), 37.47 (d, $^1J_{Y,C}$ = 41.6 Hz, $YCH_2$), 68.21 (α-$CH_2$, thf) ppm. $^1H$ NMR (400 MHz; $C_6D_6$): $\delta$ = –0.49 (br. s, 12 H, $GaCH_2$ and $YCH_2$), 0.26 [br. s, 54 H, $YCH_2Si(CH_3)_3$ and $GaCH_2Si(CH_3)_3$], 1.31 (16 H, β-$CH_2$, thf), 3.70 (16 H, α-$CH_2$, thf) ppm. $^{13}C\{^1H\}$ NMR (100 MHz; $C_6D_6$): $\delta$ = 3.64 [br., $GaCH_2Si(CH_3)_3$ and $YCH_2Si(CH_3)_3$], 25.24 (β-$CH_2$, thf), 33.82 (v br, $GaCH_2$ and $YCH_2$), 69.56 (α-$CH_2$, thf) ppm. $C_{40}H_{98}GaO_4Si_6Y$ (970.36): calcd. C 49.51, H 10.17; found C 48.61, H 10.43%.

**[Y(CH$_2$SiMe$_3$)$_2$(thf)$_4$][In(CH$_2$SiMe$_3$)$_4$] (1c):** To a solution of [$Y(CH_2SiMe_3)_3(thf)_2$] (487 mg, 0.984 mmol) in thf (5 mL), [$In(CH_2SiMe_3)_3$] (371 mg, 0.984 mmol) in thf (5 mL) was added dropwise whilst stirring. Upon complete addition, the reaction mixture was stirred for a further 10 min and volatiles were subsequently removed under reduced pressure to yield an oily solid, which was washed with pentane and dried under vacuum to yield **1c** as a colourless solid (823 mg, 82.4%). $^1H$ NMR (400 MHz; [$D_8$]-thf): $\delta$ = –1.07 (br. s, 8 H, $InCH_2$), –0.68 (d, $^2J_{Y,H}$ = 3.3 Hz, 4 H, $YCH_2$), –0.10 [s, 36 H, $InCH_2Si(CH_3)_3$], –0.04 [s, 18 H, $YCH_2Si(CH_3)_3$], 1.77 (16 H, β-$CH_2$, thf), 3.62 (16 H, α-$CH_2$, thf) ppm. $^{13}C$ NMR (100 MHz; [$D_8$]thf): $\delta$ = 4.02 [$InCH_2Si(CH_3)_3$], 4.06 [$YCH_2Si(CH_3)_3$], 26.31 (β-$CH_2$, thf), 37.47 (d, $^1J_{Y,C}$ = 42.5 Hz, $YCH_2$), 68.20 (β-$CH_2$, thf), the signal for the $InCH_2$ carbons was not detected ppm. $^1H$ NMR (400 MHz; $C_6D_6$): $\delta$ = –0.48 (br. s, 12 H, In$CH_2$ and Y$CH_2$), 0.28 [br. s, 54 H, $InCH_2Si(CH_3)_3$ and $YCH_2Si(CH_3)_3$], 1.34 (16 H, β-$CH_2$, thf) 3.65 (16 H, α-$CH_2$, thf) ppm. $^{13}C\{^1H\}$ NMR (100 MHz; $C_6D_6$): $\delta$ = 3.79 [br., $InCH_2Si(CH_3)_3$ and $YCH_2Si(CH_3)_3$], 25.38 (β-$CH_2$, thf), 69.12 (β-$CH_2$, thf) ppm. the signals for the $InCH_2$/$YCH_2$ carbons were not detected. $C_{40}H_{98}InO_4Si_6Y$ (1015.45): calcd. C 47.31, H 9.72; found C 46.28, H 9.94%.

**NMR-Tube Synthesis of [Y(CH$_2$SiMe$_3$)$_2$(12-crown-4)(thf)][Al(CH$_2$SiMe$_3$)$_4$] (2a):** To a solution of [$Y(CH_2SiMe_3)_2(thf)_4$][$Al(CH_2SiMe_3)_4$] (20 mg, 21.6 μmol) in $C_6D_6$, neat 12-crown-4 (3.5 μL, 21.6 μmol) was added and the reaction mixture was shaken. $^1H$ NMR (400 MHz; $C_6D_6$): $\delta$ = –0.68 (d, $^2J_{Y,H}$ = 3.0 Hz, 4 H, $YCH_2$), –0.62 (br. s, 8 H, $AlCH_2$), 0.23 [s, 18 H, $YCH_2Si(CH_3)_3$], 0.50 [s, 36 H, $AlCH_2Si(CH_3)_3$], 1.42 (16 H, β-$CH_2$, thf), 3.36 (br. s, 16 H, $CH_2$, 12-crown-4), 3.58 (16 H, α-$CH_2$, thf) ppm. $^{13}C\{^1H\}$ NMR (100 MHz; $C_6D_6$): $\delta$ = 3.30 ($AlCH_2$), 4.30 [$YCH_2Si(CH_3)_3$], 4.83 [$AlCH_2Si(CH_3)_3$], 25.68 (β-$CH_2$, thf), 36.73 (d, $^1J_{Y,C}$ = 40.7 Hz, $YCH_2$), 68.00 (br., $CH_2$, 12-crown-4), 68.37 (α-$CH_2$, thf) ppm.

**[Y(CH$_2$SiMe$_3$)$_2$(12-crown-4)(thf)][Ga(CH$_2$SiMe$_3$)$_4$] (2b):** To a solution of [$Y(CH_2SiMe_3)_3(thf)_2$] (200 mg, 0.38 mmol) in thf (2 mL) were successively added [$Ga(CH_2SiMe_3)_3$] (131 mg, 0.38 mmol) in thf (1 mL) and neat 12-crown-4 (70 mg, 0.38 mmol). The resulting clear solution was stirred for five minutes, after which the volatiles were removed under vacuum. Washing with pentane (2 × 10 mL) and drying afforded **2b** as a white powder (315 mg, 89%). $^1H$ NMR (400 MHz; $C_6D_6$): $\delta$ = –0.68 (d, $^2J_{Y,H}$ = 3.1 Hz, 4 H, $YCH_2$), –0.43 (s, 8 H, $GaCH_2$), 0.22 [s, 18 H, $YCH_2Si(CH_3)_3$], 0.49 [s, 36 H, $GaCH_2Si(CH_3)_3$], 1.44 (4 H, β-$CH_2$, thf), 3.17 and 3.43 (2 × 8 H, m, $CH_2$, 12-crown-4), 3.59 (4 H, α-$CH_2$, thf) ppm. $^{13}C\{^1H\}$ NMR (100 MHz; $C_6D_6$): $\delta$ = 2.5–3.8 (br. m, $GaCH_2$), 4.32 [$YCH_2Si(CH_3)_3$], 4.65 [$GaCH_2Si(CH_3)_3$], 25.64 (β-$CH_2$, thf), 36.85 (d, $^1J_{Y,C}$ = 41.6 Hz, $YCH_2$), 67.58 (12-crown-4), 68.61 (α-$CH_2$, thf) ppm. $C_{36}H_{90}GaO_5Si_6Y$ (930.25): calcd. C 46.48, H 9.75; found C 45.83, H 9.43%.

**[Y(CH$_2$SiMe$_3$)$_2$(12-crown-4)(thf)][In(CH$_2$SiMe$_3$)$_4$] (2c):** Following the procedure described for **2b**, [$Y(CH_2SiMe_3)_3(thf)_2$] (200 mg, 0.38 mmol) in thf (2 mL) was treated with [$In(CH_2SiMe_3)_3$] (131 mg, 0.38 mmol) in thf (1 mL) and neat 12-crown-4 (70 mg, 0.38 mmol). Identical work-up afforded **2c** as a white powder (333 mg, 90%). $^1H$ NMR (400 MHz; $C_6D_6$): $\delta$ = –0.68 (d, $^2J_{Y,H}$ = 3.2 Hz, 4 H, $YCH_2$), –0.47 (br. s, 8 H, $InCH_2$), 0.22 [s, 18 H, $YCH_2Si(CH_3)_3$], 0.48 [s, 36 H, $InCH_2Si(CH_3)_3$], 1.44 (4 H, β-$CH_2$, thf), 3.17 and 3.41 (m, 2 × 8 H, $CH_2$, 12-crown-4), 3.59 (4 H, α-$CH_2$, thf) ppm. $^{13}C\{^1H\}$ NMR (100 MHz; $C_6D_6$): $\delta$ = 4.30 [$YCH_2Si(CH_3)_3$], 4.60 [$InCH_2Si(CH_3)_3$], 25.66 (β-$CH_2$, thf), 36.79 (d, $^1J_{Y,C}$ = 41.6 Hz, $YCH_2$), 67.57 (12-crown-4), 68.53 (α-$CH_2$, thf) ppm. the signal for the $InCH_2$ carbons was not detected. $C_{36}H_{90}InO_5Si_6Y$ (975.35): calcd. C 44.33, H 9.30; found C 43.78, H 9.15%.

**[B(CH$_2$SiMe$_3$)$_3$] (3):** This compound was synthesised according to the procedure described in the literature[5a] and isolated as a colourless liquid (9745 mg, 74.5%), m.p. –32 °C. $^1H$ NMR (500 MHz; $C_6D_6$): $\delta$ = 0.12 [s, 27 H, $Si(CH_3)_3$], 0.93 (s, 6 H, $BCH_2$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $C_6D_6$): $\delta$ = 0.02 [$Si(CH_3)_3$], 23.80 ($BCH_2$) ppm. $^{11}B$ NMR (160 MHz, $C_6D_6$): $\delta$ = 78.8 ppm.

**[{Al(CH$_2$SiMe$_3$)$_3$}$_2$] (4):** The product was synthesised according to the procedure described in literature[5b] and isolated as a colourless liquid (6490 mg, 75.0%), m.p. –18 °C. $^1H$ NMR (500 MHz; $C_6D_6$): $\delta$ = –0.54 (s, 6 H, $AlCH_2$), 0.00 [s, 27 H, $Si(CH_3)_3$] ppm. $^{13}C\{^1H\}$ NMR (125 MHz; $C_6D_6$): $\delta$ = 0.27 [$Si(CH_3)_3$], 2.65 ($AlCH_2$) ppm. $^{27}Al$ NMR (130 MHz; $C_6D_6$): $\delta$ = 290.3 ppm.

**[Ga(CH$_2$SiMe$_3$)$_3$] (5):** The product was synthesised according to the published procedure[5c] and isolated as a colourless liquid (2575 mg, 65.2%), m.p. –42 °C. $^1H$ NMR (400 MHz. $CD_2Cl_2$): $\delta$ = 0.06 [s, 27 H, $Si(CH_3)_3$], 0.08 (s, 6 H, $GaCH_2$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz. $CD_2Cl_2$): $\delta$ = 2.4 [$Si(CH_3)_3$], 12.5 ($GaCH_2$) ppm.

**[In(CH$_2$SiMe$_3$)$_3$] (6):** The product was synthesised according to the published procedure[5d] and isolated as a colourless liquid (4701 mg, 55.2%), m.p. –45 °C. $^1H$ NMR (400 MHz. $CD_2Cl_2$): $\delta$ = –0.06 (s, 6 H, $InCH_2$), 0.03 [s, 27 H, $Si(CH_3)_3$] ppm. $^{13}C\{^1H\}$ NMR (100 MHz. $CD_2Cl_2$): $\delta$ = 2.47 [$Si(CH_3)_3$], 10.79 ($InCH_2$) ppm.

**[Li][Al(CH$_2$SiMe$_3$)$_4$] (7a):** The procedure described in the literature[34] for the synthesis of **4** was slightly modified: In the glovebox, $Al(CH_2SiMe_3)_3$ (289 mg, 1 mmol) was dissolved in pentane (3 mL); $Li(CH_2SiMe_3)$ (94 mg, 1 mmol) in pentane (3 mL) was added dropwise at room temperature. A colourless precipitate formed immediately and the suspension was stirred for 1 h. Filtration, washing with pentane (2 × 5 mL) and drying in vacuo afforded **4** (328 mg, 86%) as a colourless powder. $^1H$ NMR (500 MHz; [$D_8$]thf): $\delta$ = –1.22 (br. m, 8 H, $AlCH_2$), –0.11 [s, 36 H, $Si(CH_3)_3$] ppm. $^{13}C\{^1H\}$ NMR (100 MHz; [$D_8$]thf): $\delta$ = 1.51 (sextet, $^1J_{Al,C}$ = 60 Hz, $CH_2$), 3.78 [s, $Si(CH_3)_3$] ppm. $^{27}Al$ NMR (130 MHz; [$D_8$]thf): $\delta$ = 150.1 (nonet, $^2J_{Al,H}$ = 9.0 Hz) ppm. $^7Li$ NMR (194 MHz, [$D_8$]thf): $\delta$ = –0.54 ppm.

**[Li(tmeda)$_2$][Al(CH$_2$SiMe$_3$)$_4$] (7b):** In the glovebox, neat tmeda (191 mg, 1.65 mmol) was added at once to a solution of **4** (315 mg, 0.82 mmol) in thf (3 mL), and the resulting clear solution stirred overnight. After all volatiles were removed in vacuo, the residue was washed three times with 5 mL of pentane, and dried in vacuo. The product was isolated as a colourless powder (255 mg, 51%). $^1H$ NMR (500 MHz, [$D_8$]thf): $\delta$ = –1.22 (br. m, 8 H, $AlCH_2$), –0.10 [s, 36 H, $Si(CH_3)_3$], 2.15 [s, 24 H, $(CH_3)_2N$], 2.31 (s, 8 H, $NCH_2CH_2N$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, [$D_8$]thf): $\delta$ = 2.00 (sextet, $^1J_{Al,C}$ = 60 Hz, $AlCH_2$), 4.23 [s, $Si(CH_3)_3$], 46.2 [$(CH_3)_2N$], 58.9 ($NCH_2CH_2N$) ppm. $^{27}Al$ NMR (130 MHz, [$D_8$]thf): $\delta$ = 150.2 (nonet, $^2J_{Al,H}$ = 9.0 Hz) ppm. $^7Li$ NMR (194 MHz, [$D_8$]thf): $\delta$ = –0.53 ppm. $C_{28}H_{76}AlLiN_4Si_4$ (615.20): calcd. C 54.67, H 12.45, N 9.11; found C 55.00, H 12.94, N 9.78%.

**[Li(12-crown-4)$_2$][Al(CH$_2$SiMe$_3$)$_4$] (7c):** Following the same protocol as for **7b**, this compound was obtained by addition of two equivalents of neat 12-crown-4 (290 mg, 1.65 mmol) to a solution of **4** (315 mg, 0.82 mmol) in thf (3 mL). After work-up, the product was isolated as a colourless powder (320 mg, 53%). A saturated thf solution was cooled down to –40 °C to afford crystals suitable for X-ray diffraction. $^1$H NMR (500 MHz, [D$_8$]thf): $\delta$ = –1.22 (br. m, 8 H, AlCH$_2$), –0.10 [s, 36 H, Si(CH$_3$)$_3$], 3.68 (s, 32 H, 12-crown-4) ppm. $^{13}$C{$^1$H} NMR (125 MHz, [D$_8$]thf): $\delta$ = 2.00 (sextet, $^1J_{Al,C}$ = 60 Hz, AlCH$_2$), 4.23 [s, Si(CH$_3$)$_3$], 70.2 (12-crown-4) ppm. $^{27}$Al NMR (130 MHz, [D$_8$]thf): $\delta$ = 150.2 (nonet, $^2J_{Al,H}$ = 9.0 Hz) ppm. $^7$Li NMR (194 MHz, [D$_8$]thf): $\delta$ = –0.21 ppm. $C_{32}H_{76}AlLiO_8Si_4$ (735.22): calcd. C 52.28, H 10.42; found C 52.54, H 10.44%.

**X-ray Diffraction:** Data collections were performed with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Single crystals of **3**, **4**, and **5** were directly grown on a NONIUS CAD4 diffractometer. Capillaries containing ca. 2 μL of **3**, **4**, and **5** were exposed in appropriate geometry ($\chi$ = 90°) to a cold stream of $N_2$; the samples completely solidified. The temperature of the gas stream was gradually increased to the melting point, retaining only a small fraction of solid in the tip of the capillary. Slow cooling resulted in a crystalline sample. The procedure was repeated until single crystals of satisfactory quality were obtained; their diffraction pattern was directly registered on the CAD4 diffractometer. The structures of **3** and **5** are closely related and probably isomorphous. Intensity data for **1b** and **7c** were collected on a Bruker CCD D8 goniometer equipped with a SMART APEX CCD detector. Data were processed using SAINT and SADABS to yield the reflection data file.[38] Subsequent calculations were carried out using the SHELXS and SHELXL programs.[39] Analytical scattering factors for neutral atoms were used throughout the analysis.[40] The hydrogen atoms attached to the bridging carbon atom in **4** were freely refined; all other H atoms were included at calculated positions. Crystal data, parameters of data collection and convergence results for the diffraction experiments are compiled in Table 5.

CCDC-621523 (for **1b**), -620839 (for **3**), -620838 (for **4**), -620840 (for **5**), -620841 (for **7c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# $CO_2$ Fixation by Alkylzinc Amides: A Quantum Chemical Study Motivated by Recent Experimental Results

**Hans-Jörg Himmel*[a]**

**Keywords:** $CO_2$ fixation / Zinc / Reaction mechanisms / Quantum chemical calculations

Herein the insertion of $CO_2$ into the Zn–N bond of alkylzinc amides of the general formula $RZnNR'_2$ (R = H, $CH_3$, $CF_3$, R′ = $CH_3$, *i*Pr, H, F, $C_6H_5$) is discussed on the basis of quantum chemical calculations. Several possible reaction pathways were considered, starting from monomeric as well as dimeric alkylzinc amides. Special consideration is given to the influence of the electronic properties of the amido group on the reaction energy. The mechanisms were studied in detail starting with the model compounds $HZnNH_2$ and $H_3CZnN(CH_3)_2$ as well as the dimer $[HZnNH_2]_2$. The reaction of monomeric compounds with $CO_2$ first leads to an intermediate featuring a Zn–N–C–O four-membered ring. This first step requires an activation energy $\Delta G$ of ca. 60 kJ·mol$^{-1}$ and turns out to be the rate-determining step. In the second step, which requires a much smaller activation energy, the carbamate product is formed. Reactions of dimeric alkylzinc amides are subject to a significantly higher activation barrier (with a $\Delta G$ value of 103 kJ·mol$^{-1}$), with a four-membered ring as the transition-state structure. The activation energy is slightly higher than the energy required for decomposition of the dimer into two monomers, and therefore it is plausible that the alkylzinc amides react as monomers with $CO_2$. The calculations for the dimer reaction again gave evidence for the formation of an intermediate exhibiting in this case a six-membered ring. The barrier to formation of the carbamate from this intermediate is very small. The results of this work contribute to the knowledge of $CO_2$ fixation by alkylzinc amides and might shed some light on enzymatic reactivity.

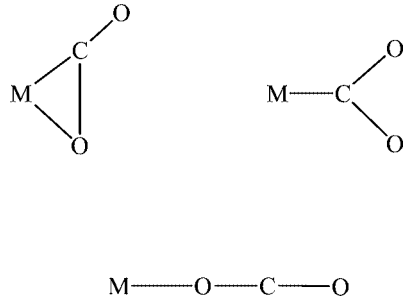
## Introduction

The reduction of $CO_2$ emission, a gas that besides others is responsible for global warming, is continuing to be an extremely important issue, especially since no real alternatives to fossil fuels[1] have yet been discovered. Therefore, there is a great demand for methods to either reduce $CO_2$ production or for suitable materials that help to reduce the release of the produced $CO_2$ into the air (and ideally turn $CO_2$ into something useful at the same time). There are now numerous examples of transition-metal complexes that can bind $CO_2$.[2] In the case of mononuclear complexes three coordination modes can be realized (see Scheme 1). The first authenticated example for the $\eta^1$-OCO binding mode was discovered only very recently,[3] although it seems to play an important role in enzymes. In this example a linear $CO_2$ unit is bound to a trivalent uranium atom in the center of a sterically crowded complex. The unusual coordination mode most likely results from the restricted space that the ligand shell offers to the incoming $CO_2$.



Scheme 1.

Several main-group element compounds are also known to react with $CO_2$. Very recently it was claimed that the reaction of $Mg[N(SiMe_3)_2]_2$ with $AlR_3$ (R = Me or Et) and $CO_2$ in THF affords aluminium–magnesium complexes with linearly bridging $CO_2$ units, viz. $[\{R_2Al(\mu\text{-}NSiMe_3)(\mu\text{-}OSiMe_3)Mg(thf)_2(\mu\text{-}O_2C)\}_3]$.[4] However, this result was questioned by a later analysis,[5] according to which the compound exhibits bridging $NCO^-$ ligands instead of the isoelectronic neutral $CO_2$ ligands. Zn compounds, especially pyrazolylborate zinc hydroxides,[6] dinuclear complexes that should mimic the reactive center of enzymes,[7] and zinc amides (see below), were also the focus of recent research, particularly because of their biological relevance.

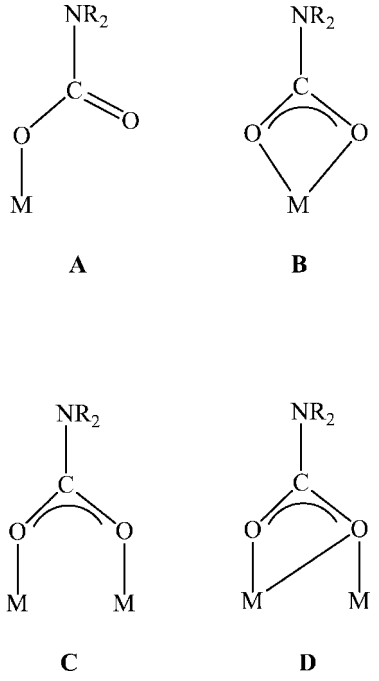
Several amides of main group elements (such as Li or Mg) have been shown to react with $CO_2$ to give carbamate molecules. Generally four bonding modes can be realized (see Scheme 2).[8] The enzyme rubisco (ribulose-1,5-biphosphate-carboxylase/oxygenase) features a $Mg^{2+}$ ion in the center to which a monodentate carbamato ligand is bound (thus realizing bonding mode **A**).[9,10] Bonding mode **C** is realized, for example, in the enzymes urease and phosphotriesterase in which a carbamato ligand (formed from a lysine) bridges two nickel (urease) or zinc (phosphotriesterase) ions.[10,11] The first example for bonding mode **B** was found only very recently in the unsymmetrical dinuclear compound $[Mg_2(O_2CNCy_2)_4(HMPA)]$, where Cy = cyclohexyl and HMPA = hexamethylphoshoramide.[12] There are several synthetic routes to carbamates, one of which is a direct reaction of amides with $CO_2$.[2] It was shown that chiral carbamates can be synthesized from the reaction between chiral lithium amides and $CO_2$.[13] The mechanism for these reactions was recently analyzed on the basis of quantum chemical (B3LYP) calculations.[14]



Scheme 2.

The reactions between alkylzinc amides of the formula $RZnNEt_2$ (R = Me, Et) and $CO_2$ were reported to first give the tetramer $[R_2Zn_4O_2C(NEt_2)_6]$,[15] which reacts with an excess of $ZnMe_2$ to give the compound $[Zn_4Me_4(O_2CNEt_2)_4]$ featuring an approximately tetrahedral arrangement of the four Zn atoms.[16] Very recently it was shown that $CO_2$ inserts into the metal–nitrogen bond of $H_3CZnNR_2$ (R = *i*Pr, *i*Bu or piperidinyl) to give tetrameric cage compounds of the formula $[H_3CZnO_2CNR_2]_4$,[17] which seem to contradict previously obtained results. Interestingly, addition of pyridine achieves a breakage of the tetramer into two dimeric units. In light of all these findings a theoretical analysis of the reaction pathways is highly desirable.

## Results and Discussion

The discussion is divided into two sections. In the first one it is assumed that the alkylzinc amide reacts as a monomer with $CO_2$, although of course the majority of alkylzinc amides are generally expected to be dimeric or even trimeric. However, monomeric alkylzinc amides containing sterically demanding alkyl groups are known, e.g. $(Me_3Si)_3CZnN(H)Si(iPr_3)$.[18] It is assumed that the reaction first leads to a monomeric zinc carbamate, which oligomerizes afterwards. In the second section $CO_2$ fixation by dimeric alkylzinc amides is discussed.

### 1. Reactions Starting from Monomeric Alkylzinc Amides

Although monomeric alkylzinc amides can only be isolated in the case of sterically demanding alkyl groups, they could in other cases exist in solution (in small quantities) in equilibrium with the dimeric form.[19] The general consensus in the case of mononuclear transition-metal complexes is that electrophilic attack at the amide nitrogen by the carbon atom of $CO_2$ initiates reaction. However, the role of the metal has not yet been accessed in sufficient depth. In the case of *fac*-$(CO)_3$(dppe)MnOR derivatives featuring an alkoxide or aryloxide (OR) group in place of an amide a four-membered transition state has been postulated.[20] In this transition state, the C atom of the $CO_2$ group interacts with the O atom of the OR group, and one of the O atoms of $CO_2$ interacts with the metal center. This suggestion might imply that the metal–oxygen interaction is already established at an early stage of the reaction. One of the objectives of the following discussion is therefore to analyze the role of the metal–oxygen bond during the reactions of alkylzinc amides with $CO_2$. However, other questions concerning the mechanism arise. In the case of insertion of $CO_2$ into the metal–nitrogen bond of the transition-metal complex $(Ph)(PCy_3)_2PtNH_2$[21] it was claimed, on the basis of spectroscopic (IR, NMR) evidence, that in benzene a nitrogen-bonded carbamate is first formed. This species was reported to rearrange readily when dissolved in dichloromethane to the more stable oxygen-bonded carbamate. Thus the calculations in this paper also have to answer the question whether or not the nitrogen-bonded carbamate represents an intermediate in the course of the reaction with alkylzinc amides.

The analysis starts with the simplest possible model compound, cf. $HZnNH_2$. Two different initial orientations of the $CO_2$ molecule were considered. In the first one the O–C–O axis is oriented perpendicular to the H–Zn–N plane ("vertical" approach). The $CO_2$ axis at the start of the reaction has roughly the same relative orientation as in the product. The symmetry is constrained to $C_{2v}$ throughout the approach of the $CO_2$ toward the alkylzinc amide. Figure 1 displays the energy as calculated using BP/TZVPP relative to that of the two separated reactants ($HZnNH_2$ and $CO_2$) versus the Zn–N–C angle. The $CO_2$ molecule already occurs at large values of the reaction coordinate, slightly attracted by the lone pair at the N atom. For a Zn–N–C

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

angle of 112.2°, a minimum is reached at a relative energy of not more than –8 kJ·mol$^{-1}$ (according to BP/TZVPP). The N···C separation at this point amounts to 295.7 pm. The C–O distances (117.2 pm) are almost identical to those in free $CO_2$ (117.1 pm according to our BP/TZVPP calculations, exp. value: 116.32 pm). The Zn–N distance measures 183.7 pm and is also only very slightly elongated relative to the distance in free $HZnNH_2$ (183.1 pm). If the molecule is restricted to $C_{2v}$ symmetry the energy again increases for smaller values of the reaction coordinate, and no binding interaction between the O atoms and the Zn atom is established. The interaction energy between the amido group and the $CO_2$ under these conditions is thus only –8 kJ·mol$^{-1}$, a value too weak to bring about reaction. This is a first result underlining the importance of an early formation of a metal–oxygen interaction for any further reaction to occur.

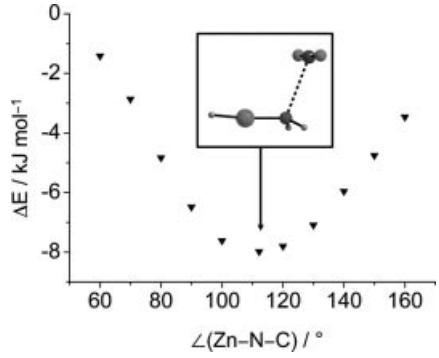


Figure 1. Energy versus the Zn–N–C angle and relative to the separated reactants for the "vertical" approach of the $CO_2$ molecule toward monomeric $HZnNH_2$ as calculated with BP/TZVPP. The inlet shows the structure of the minimum.

The second possibility is that at an early stage of the reaction the three atoms of the $CO_2$ molecule are located roughly in the same plane as the H, Zn, and N atoms of the alkylzinc amide ("parallel" approach). Of course, in this case the symmetry has to change somewhere along the reaction coordinate and therefore all calculations were carried out in $C_1$ symmetry.[22] Figure 2 shows the relative energy calculated versus the N–C distance. Again a shallow minimum ($\Delta E$ of ca. 8 kJ·mol$^{-1}$ without ZPE corrections) occurs at large N–C distances (centered at 280 pm). However, after the system has passed a first transition state (with $\Delta E$ being +7 without and +18 kJ·mol$^{-1}$ with ZPE corrections, and $\Delta G$ being +59 kJ·mol$^{-1}$) it reaches a local minimum that is bound with respect to the reactants by –19 kJ·mol$^{-1}$ without and –8 kJ·mol$^{-1}$ with ZPE corrections. At +33 kJ·mol$^{-1}$ the $\Delta G$ value is still positive at this point. This local minimum features a four-membered [ZnNCO] ring and is characterized by the following bond lengths (in pm, for BP/TZVPP): 155.1 (N–C), 102.4 (N–H), 120.8/129.6 (C–O), 151.7 (Zn–H), 196.1 (Zn–O), and 252.7 (Zn–N). The C–O bond as part of the four-membered ring is significantly elongated (129.6 pm) to a value that falls in between the typical regions for CO single (ca. 142 pm) and double bonds. At 132.0° the O–C–O bond angle is already quite small. A significant Zn–O interaction is already established and, together with a larger C–N interaction, is responsible for the decrease in energy. The Zn–N distance at this point is substantially elongated with respect to that in free $HZnNH_2$ (183.1 pm). However, the formation of new bonds can more than compensate the decrease of the Zn–N bond strength. For N–C distances shorter than 155.1 pm, the relative energy first slightly rises until, at ca. 145 pm, a second transition state is reached. The energy at this transition state is not more than 6 kJ·mol$^{-1}$ higher than that of the preceding local minimum. Relative to the reactants the energy at this point amounts to –13 without and –1 kJ·mol$^{-1}$ with ZPE corrections, and $\Delta G$ is +40 kJ·mol$^{-1}$. Finally, at an N–C distance of 135.5 pm, the carbamate product is reached, which adopts the structure type **B** (see Scheme 2). The energy of the carbamate is by –79 or –67 kJ·mol$^{-1}$ (without or with ZPE corrections, respectively) lower than that of the two separated reactants. $\Delta G$ for the complete reaction is –26 kJ·mol$^{-1}$. The Zn–H, Zn–O, C–O, and N–H distances were calculated to be 151.8, 204.6, 128.9, and 101.0 pm, respectively. The Zn···N separation now amounts to 236.2 pm and the O–C–O angle measures 119.9°. This compares to an O–C–O angle of 119.63(16)° in the compound $[Mg_2(O_2CNCy_2)_4(HMPA)]$ (see Introduction), the only known example of mode **B** in Mg chemistry.[12]

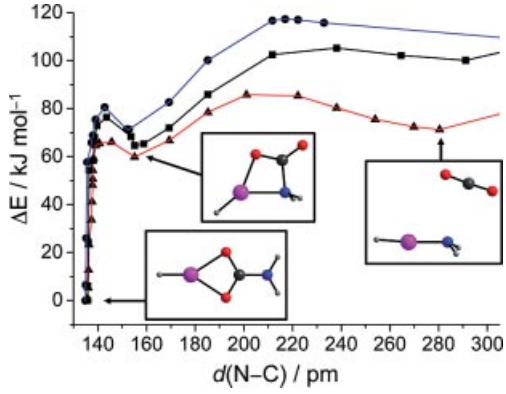

Figure 2. Energy relative to the carbamate product versus the N–C distance as calculated for the reaction of $CO_2$ with $HZnNH_2$ (BP/TZVPP calculation, red line), $H_3CZnN(CH_3)_2$ (BP/TZVPP calculation, black line) and $H_3CZnN(CH_3)_2$ (B3LYP/TZVPP calculation, blue line).

There is no evidence for the formation of a nitrogen-bonded carbamate as an intermediate in the course of the reaction. Nevertheless, we have calculated the geometry and energy of such a species. Its energy turned out to be 12 kJ·mol$^{-1}$ according to BP/SVP and 7 kJ·mol$^{-1}$ according to BP/TZVPP higher than that of the intermediate four-membered ring that is formed during the reaction. This value is higher than the barrier to carbamate formation (second TS, see Table 1) and it is not likely that interaction with the solvent (toluene) leads to a significant stabilization. Therefore any engagement of the nitrogen-bonded carbamate in the reaction can be ruled out. Figure 3 summarizes the reaction pathway.[23]

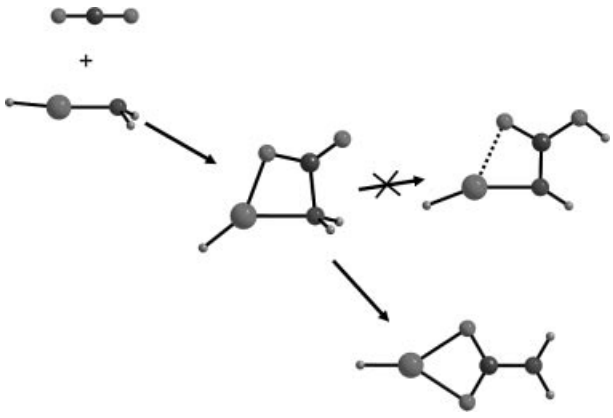

Figure 3. Pathway calculated for the reaction between $HZnNH_2$ with $CO_2$ leading to the carbamate $HZnO_2CNH_2$.

The calculations were repeated with the more realistic model compound methylzinc dimethylamide, $H_3CZnN(CH_3)_2$. For this molecule the effect of changing the method from the pure DFT method BP to the hybrid method B3LYP, which generally gives more accurate energies, was also analyzed. The energy curves resulting from these calculations are included in Figure 2. It can be seen that the reaction mechanism is qualitatively and in some important details also quantitatively similar to that obtained for $HZnNH_2$. Again, a $\Delta G$ barrier of ca. 60 kJ·mol$^{-1}$ leads from the separated reactants to the intermediate, which is, however, this time more strongly bound ($\Delta E$ = –40 kJ·mol$^{-1}$, instead of –19 kJ·mol$^{-1}$ in the case of $HZnNH_2$). A small barrier separates this intermediate from the carbamate product, which is now bound by $\Delta E$ = –105 kJ·mol$^{-1}$ (instead of –79 kJ·mol$^{-1}$ in the case of $HZnNH_2$). The values calculated for the relative energies with and without zero-point energy corrections, and for the standard Gibbs energy are summarized in Table 1. BP and B3LYP give similar relative energies.

Table 2 summarizes the energy changes calculated for reactions of several different monomeric model alkylzinc amides with $CO_2$ to give monomeric carbamates. All carbamates prefer structure type **B** (see Scheme 2). Facile oligomerization reactions of the monomeric carbamates should therefore be responsible for the fact that this mode is so seldom realized (see Introduction). On the other hand, the hypothesis that the electron density donated by the two oxygen atoms is so great that the highly strained four-membered ring of **B** generally cannot form[24] can be ruled out. It can be seen that the reaction energy is very sensitive to variations of the amide group (see Figure 4). Thus the reaction energy increases in the order $NF_2 < N(Ph)_2 < N(H)Ph < NH_2 < N(iPr)_2$, a trend that can easily be explained by the increasing basicity. On the other hand, the reaction energy is not significantly different for $HZnNH_2$, $CH_3ZnNH_2$, and $CF_3ZnNH_2$ indicating that the energies are less sensitive to alterations on the alkyl side. Table 3 compares the Zn–N distances in the initial alkylzinc amides and the Zn–O distances in the carbamate products with the reaction energy. In general large Zn–N distances of the alk-

ylzinc amide reactant lead to large Zn–O distances in the carbamate product and consequently smaller values of the absolute reaction energies.

### *Oligomerization of Monomeric Carbamates*

The final step in our model reaction pathway is oligomerization of the monomeric carbamates. Tetramers seem to represent the preferred end products. Figure 5 visualizes the oligomerization process for the simplest model reactant $HZnNH_2$ leading first to dimers and finally to tetramers. Dimerization of two carbamate monomers is associated with an energy change of –116 (BP/SVP) or –76 kJ·mol$^{-1}$ (BP/TZVPP). The zero-point corrected energy change and the $\Delta G$ value for this process are –71 and –19 kJ·mol$^{-1}$, respectively (BP/TZVPP). The dimer is unsymmetrical ($C_1$ symmetry) and features C–O, Zn–H, Zn–O, and C–N bond lengths of 127.8–128.7, 153.0, 197.5–199.3, and 136.2 pm, respectively. The O–Zn–O and O–C–O bond angles measure 99.8° and 124.3/125.0°. Further dimerization of these dimers to give tetramers is even more exothermic [reaction energies of –162 (BP/SVP) or –103 kJ·mol$^{-1}$ (BP/TZVPP) and $\Delta G$ = –36 kJ·mol$^{-1}$ (BP/TZVPP)]. To test the accuracy of our calculations we have also calculated the structure of

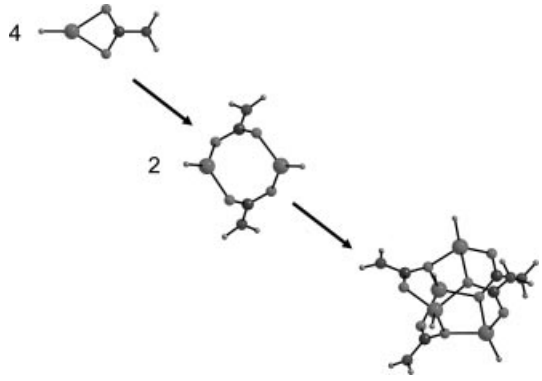

Figure 5. Pathway leading to the $[HZnO_2CNH_2]_4$ tetramer starting with a $HZnNH_2$ monomer.

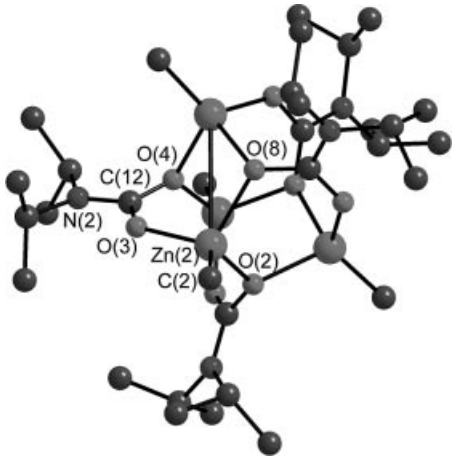

Figure 6. Experimentally determined structure of the $[MeZnO_2CN(iPr)_2]_4$ tetramer (see ref.[14]). H atoms are omitted for the sake of clarity.

$[H_3CZnO_2CN(iPr)_2]_4$ (only with BP/SVP because of computational restrictions) and compared it to the experimentally observed one. Figure 6 shows the structure of $[CH_3ZnO_2CN(iPr)_2]_4$ from the literature[17] and Table 4 compares the experimentally obtained dimensions with the corresponding calculated ones for $[MeZnO_2CN(iPr)_2]_4$ and $[HZnO_2CNH_2]_4$. The labeling of the atoms as shown in Figure 6 and Table 4 is taken from ref.[17] It can be seen that the general level of agreement between the calculated and experimentally observed dimensions is already good with BP/SVP.

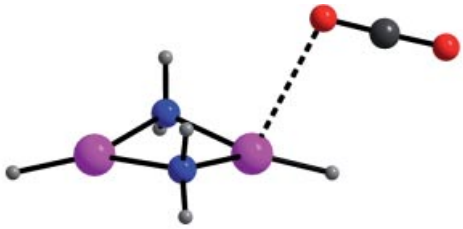
### 2. Reactions Starting from Dimeric Alkylzinc Amides

There are numerous examples of authenticated dimeric alkylzinc amides. However, their structural analysis using X-ray diffraction is limited. Just to name two of them, the crystal structures of dimeric methylzinc and ethylzinc triisopropylsilylamide have recently been reported.[25] Dimerization of the model compound $HZnNH_2$ to give cyclic $[HZnNH_2]_2$ is associated with an energy change of –189 kJ·mol$^{-1}$ according to BP/SVP and –133 kJ·mol$^{-1}$ according to BP/TZVPP calculations. In addition to DFT calculations using the BP functional ab initio (MP2) calculations were performed in this special case to test the accuracy of our calculated methods. MP2/TZVPP calculations gave a dimerization energy of –157 kJ·mol$^{-1}$. Thus the energies calculated with DFT methods are relatively close to those calculated with MP2. The standard Gibbs energy change for dimerization, $\Delta G°$, was calculated to be –75 kJ·mol$^{-1}$ according to BP/TZVPP and –99 kJ·mol$^{-1}$ according to MP2/TZVPP. The Zn–H, Zn–N, and N–H distances in the dimer amount to 154.6, 204.6, and 102.3 pm, respectively, and the N–Zn–N and Zn–N–Zn bond angles were calculated to be 86.9° and 93.1°, respectively. In the case of $[MeZnN(iPr)_2]_2$, an example for which crystal structures are available,[28] the Zn–N distances, and N–Zn–N and Zn–N–Zn bond angles were experimentally determined to be 201.5–204.0 pm, 89.8–90.0°, and 90.1–90.2°, respec-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tively. Thus the experimental values are in good agreement with the ones calculated for the model dimer $[HZnNH_2]_2$.



Structure of the complex $[(HZnNH_2)_2(CO_2)]$

$CO_2$ first forms only a weakly bound complex with $[HZnNH_2]_2$. The binding energy amounts to no more than –11 kJ·mol$^{-1}$ according to BP/SVP and –5 kJ·mol$^{-1}$ according to BP/TZVPP. In this complex, the Zn atom interacts with one of the O atoms of $CO_2$, the distance being ca. 298 pm. The N and C atoms are separated by ca. 460 pm. As anticipated, the dimer does not allow any attractive N···C interaction to be established (all valence orbitals on the N atoms are engaged in bonding with the H and Zn atoms of the $[HZnNH_2]_2$ unit). A vibrational analysis (at the BP/SVP level) confirmed that this complex defines a minimum on the potential energy surface.

Part a of Figure 7 displays the relative energy versus the separation between the carbon atom of the $CO_2$ molecule and one of the N atoms. It can be seen that the energy first increases (extremely sharply between 240 and 232 pm) until a transition state is reached at 232.8 pm. The sharp increase coincides with a large increase in the Zn–N bond length into which $CO_2$ first inserts (from 208.9 pm at an N···C distance of 238.1 pm to 285.5 pm for an N···C distance of 232.8 pm). The transition state energy is 51 kJ·mol$^{-1}$ higher than the sum of the energies of the separated reactants. $\Delta G$ at this point amounts to +103 kJ·mol$^{-1}$ (see Table 5) The barrier is caused by the weakening of the strong Zn–N bonds, which cannot be compensated by the newly formed C–N and O–Zn interactions. The transition state is further characterized by Zn···O and N···C distances of 228.9 and 232.9 pm, respectively. The C–O distances measure 120.1 and 117.6 pm. Thus one of the C–O distances is already significantly elongated with respect to the distance in free $CO_2$ (117.1 pm). We therefore conclude that the reaction of the dimeric alkylzinc amide is subjected to a significantly higher barrier than that starting from the monomer. It is also higher than that calculated for the reaction between dimeric lithium amides and $CO_2$ (a Gibbs free energy barrier of +41 kJ·mol$^{-1}$ was obtained in this work).[14] In the case of the lithium amides, the Li–N distance seems to be insignificantly elongated at the transition state.

For smaller distances the energy decreases again, but not steadily, until the carbamate is formed. A local minimum is reached at 148.6 pm exhibiting a relative energy of –19 kJ·mol$^{-1}$ ($\Delta G$ = +33 kJ·mol$^{-1}$) and featuring a six-membered [ZnNZnNCO] ring. A vibrational analysis confirms that it is a real minimum (no imaginary frequencies occurred). The Zn–N–C angle at this point amounts to 105.9°. If we introduce the atom numbers N1, N2, Zn1, Zn2, O1, and O2, with Zn1 being bound to O1 and N1, and Zn2 being bound to N1 and N2, the bond lengths (in pm) are as follows: 203.7 (Zn1–N1), 197.2 (Zn2–N1), 218.2 (Zn2–N2), 148.6 (N2–C), 129.0 (C–O1), 122.3 (C–O2), 198.2 (O1–Zn1). The Zn1···N2 separation amounts to 351.7 pm. The changes in the C–N distance between the structure of this local minimum (148.6 pm) and the carbamate product (136.9 pm) are relatively small. In fact toward the end of the reaction the C–N distance remains almost unchanged although the energy still decreases. Therefore for this stage of the reaction, the C–N distance is not the optimal choice for the reaction coordinate and the Zn–N–C bond angle was taken instead. The corresponding energy curve is displayed in Figure 7b. It can be seen that the barrier separating the intermediate from the heterodimer $[H_2Zn(NH_2)(O_2CNH_2)]$ amounts to no more than 1.3 kJ·mol$^{-1}$. The overall reaction to give the heterodimer product is associated with an energy change of –102 kJ·mol$^{-1}$ according to BP/SVP and –75 kJ·mol$^{-1}$ according to BP/TZVPP. $\Delta G$ for the overall reaction is –24 kJ·mol$^{-1}$ (BP/TZVPP). The nonplanar product is char-

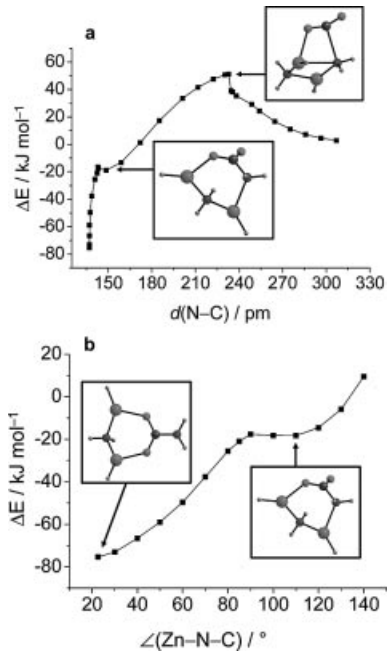


Figure 7. (a) Energy versus the N–C separation and relative to the separated reactants for the reaction of the $[HZnNH_2]_2$ dimer with $CO_2$. (b) Energy versus the Zn–N–C angle and relative to the separated reactants for the reaction of the $[HZnNH_2]_2$ dimer with $CO_2$.

Table 5. Energy, $\Delta E$, zero-point energy corrected energy, $\Delta E_{ZPE}$, and $\Delta G$ (at 298 K, 1 bar), all in kJ·mol$^{-1}$, relative to the reactants for the reaction between $[HZnNH_2]_2$ and $CO_2$ as calculated with BP/TZVPP.

| | $\Delta E$ | $\Delta E_{ZPE}$ | $\Delta G$ |
|---|---|---|---|
| First TS[a] | +51 | +65 | +103 |
| Intermediate | –19 | –5 | +34 |
| Second TS[a] | –18 | –4 | +35 |
| Product | –75 | –63 | –24 |

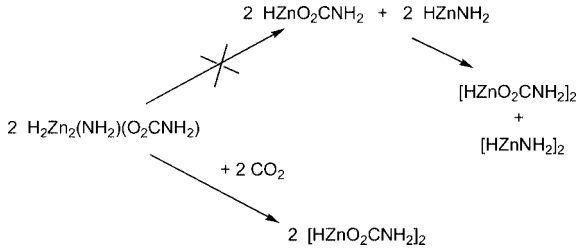
acterized by the following distances (in pm) and angles: 128.1 (C–O), 200.2 (Zn–O), 200.0 (Zn–N), 136.9 (C–N), 127.2° (O–C–O), and 106.5° (Zn–N–Zn). In summary, the rate-determining step again turns out to be the formation of the intermediate, which is opposed by a barrier $\Delta G$ of +103 kJ·mol$^{-1}$.



### *Further Reaction with $CO_2$ and Oligomerization*

Two possible routes lead from the heterodimer $H_2Zn_2(O_2CNH_2)(NH_2)$ to the homodimer $[HZnO_2CNH_2]_2$. The first one includes dissociation of $H_2Zn_2(O_2CNH_2)(NH_2)$ to give monomeric $HZnO_2CNH_2$ and $HZnNH_2$, which afterwards dimerize to $[HZnO_2CNH_2]_2$ and $[ZnNH_2]_2$, respectively. The energy needed to form the monomers is, however, 176 (BP/SVP) or 129 kJ·mol$^{-1}$ (BP/TZVPP). The subsequent dimerization is, of course, exothermic, but the overall formation of $[HZnO_2CNH_2]_2$ and $[ZnNH_2]_2$ is still endothermic (see Table 6). The second possibility is that $[HZnO_2CNH_2]_2$ is formed by the reaction between $H_2Zn_2(O_2CNH_2)(NH_2)$ and a second $CO_2$ molecule. This reaction is calculated to be exothermic [reaction energy of –55 (BP/SVP) or –26 kJ·mol$^{-1}$ (BP/TZVPP)], and therefore this most likely represents the preferred path. It is worth mentioning that our calculations show that the fixation of the first $CO_2$ molecule (reaction energy of –75 kJ·mol$^{-1}$ according to BP/TZVPP) is significantly more exothermic than the fixation of the second one (reaction energy of only –26 kJ·mol$^{-1}$). While $\Delta G$ for the fixation of the first $CO_2$ is negative (–24 kJ·mol$^{-1}$), it is positive (+34 kJ·mol$^{-1}$) for the fixation of the second one. It has been shown that in enzymes the presence of a carbamato ligand is important for $CO_2$ fixation. Carbamate formation preorganizes the active center e.g. of the $Mg^{2+}$ complex in the center of the enzyme rubisco. The carbamato ligand adopts in this special case an end-on monodentate rather than a bidentate coordination mode, which is different from our model compounds. Figure 8 shows the reaction pathway leading first to $[H_2Zn_2(NH_2)(O_2CNH_2)]$ and then to $[HZnO_2CNH_2]_2$. This molecule dimerizes finally to the tetramer as shown in Figure 5. This dimerization is accompanied by an energy change of –103 kJ·mol$^{-1}$. $\Delta G$ for this process is –36 kJ·mol$^{-1}$.

Table 6. Reaction energies (in kJ·mol$^{-1}$) as calculated with BP/SVP and BP/TZVPP for reactions involving the $[HZnNH_2]_2$ dimer.

| Reaction | BP/SVP | BP/TZVPP |
|---|---|---|
| 2 $HZnNH_2 \rightarrow [HZn(\mu\text{-}NH_2)]_2$ | –189 | –133 |
| $[HZn(\mu\text{-}NH_2)]_2 + CO_2 \rightarrow$ $H_2Zn_2(O_2CNH_2)(NH_2)$ | –102 | –75 |
| $H_2Zn_2(O_2CNH_2)(NH_2) + CO_2 \rightarrow$ $[HZn(O_2CNH_2)]_2$ | –55 | –26 |

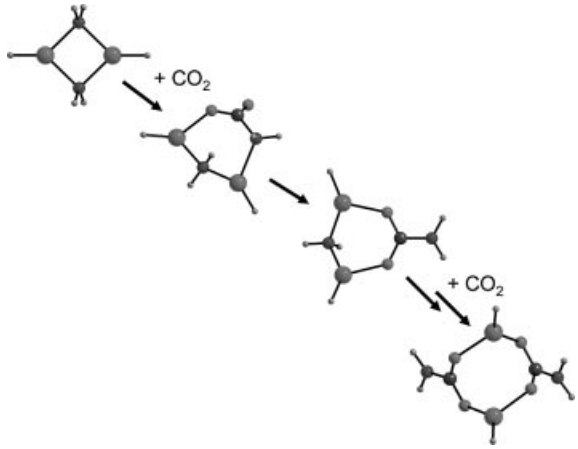

Figure 8. Pathway from $[HZnNH_2]_2$ and $CO_2$ leading to the $[HZnO_2CNH_2]_2$ homodimer that later dimerizes as shown in Figure 5.

## Conclusions

Quantum chemical calculations were used to obtain detailed insight into $CO_2$ fixation by monomeric as well as dimeric alkylzinc amides. The reaction of monomeric alkylzinc amides first leads to an intermediate featuring a four-membered [ZnNCO] ring. The activation energy $\Delta G$ of this first, rate-determining step is around +60 kJ·mol$^{-1}$. From this local minimum on the potential energy surface the system has to pass a much smaller barrier to proceed to the monomeric carbamate product. Dimerization and tetramerization of the monomeric carbamates follow (both exhibiting negative $\Delta G$ values). Any engagement of an N-bonded carbamato species during the reaction can be ruled out. $CO_2$ fixation by several different alkylzinc amide molecules bearing the overall formula RZnNR′R′′ was then compared. The reaction energies were found to be highly sensitive to changes in the electronic properties of the amido group, while modifications on the alkyl (R) side bear almost no influence.

The calculations indicate that the reaction of dimeric alkylzinc amides with $CO_2$ is opposed by a larger barrier ($\Delta G$ value more than +100 kJ·mol$^{-1}$). In this case the transition state features a four-membered [ZnNCO] ring. A six-membered ring then follows as a local minimum on the potential energy curve. The barrier separating this intermediate from the product is again very small. Surprisingly, the calculations indicate that the barrier for $CO_2$ fixation by dimeric alkylzinc amides is higher than the negative dimerization energy of the monomeric alkylzinc amide. It is also higher than the barrier for $CO_2$ fixation by monomeric alkylzinc

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

amide (ca. 60 kJ·mol$^{-1}$). Therefore, although dimeric alkylzinc amides are preferred over monomers, reaction with $CO_2$ could very well predominantly occur from the monomeric state.

## Computational Details

Calculations were carried out with the aid of the TURBOMOLE program package.[26] Pure DFT calculations relied on the BP method (BP is the short notation for Becke–Perdew and is a nonlocal DFT method employing the Becke exchange and Perdew correlation functionals). In addition the hybrid-method B3LYP (DFT using Becke exchange functional and Lee–Yang–Parr correlation functional, as well as Hartree–Fock exchange)[27] was used in the mechanistic studies since this method generally leads to more accurate energies.

It has been shown in the case of quantum chemical studies on $CO_2$ fixation by lithium amides[14] that the choice of basis set is important and that large basis sets (ideally including polarization functions) are necessary. Therefore for all our calculations we have used not only an SVP (split-valence, polarized), but also a TZVPP (triple-zeta valence, doubly-polarized) basis set.[28] It turned out that the reaction energies as calculated with the SVP basis set are in some cases different from those calculated with the TZVPP basis set.

It should be mentioned that for the mechanistic studies it is assumed, as in almost all mechanistic studies of this kind, that the reaction can be divided into several steps, e.g. the dimeric alkylzinc amide reacts in the first step with one equivalent of $CO_2$ and afterwards in a second step with another equivalent of $CO_2$. Of course it is plausible that the reaction with a second $CO_2$ already occurs before completion of the reaction with the first one, and this should indeed happen if it leads to lower energies. However, it is almost impossible to consider all reaction pathways. The "step-by-step" hypothesis thus leads to an upper limit for the true reaction barrier.

In the mechanistic studies a vibrational analysis was carried out at each point to make sure that the approach of the two reactants occurs along a low-energy path. The relative energies, zero-point corrected energies, and the Gibbs energies of all the important points along the reaction path are included in the discussion (see also Tables 1 and 5). Solvent effects were not considered. The solvent used in most of the synthetic work is toluene. The interaction between toluene and the two reactants is expected to be small. In addition, the accurate description of interactions of this kind, which involve the π system of toluene, is extremely difficult and requires highly sophisticated and practically unusable methods to model the complete reaction mechanism.

[22] The start and end geometries exhibit both $C_{2v}$ symmetry, but the mirror plane changes.
[23] Calculations were also carried out for $CO_2$ fixation by the analogue magnesium model compound $HMgNH_2$ to obtain information on the effect that variation of the metal atom brings about. This reaction was shown to follow the same pattern as that of the Zn compound. The "vertical" approach again leads to a small minimum, which this time adopts a Mg–N–C angle of 109.8° and an energy relative to the sum of the energies of the separated reactants of –25 (BP/SVP) or –6 kJ·mol$^{-1}$ (BP/TZVPP). The interatomic distances (Mg–N 191.6, C–O 117.3, C···N 302.3 pm) and the O–C–O angle (176.1°) again indicate that the geometries of the two reactants are only slightly influenced by this adduct formation. The intermediate featuring a four-membered Mg–N–C–O ring formed in the course of the "parallel" approach now exhibits a relative energy of –127 (BP/SVP) or –79 kJ·mol$^{-1}$ (BP/TZVPP). It is reached at a Zn–N–C angle of 84.5°. The Mg–N, N–C, and C–O distances are 215.2, 157.4, and 128.8/120.9 pm, respectively, and the O–C–O bond angle measures 132.9°. With –198 (BP/SVP) or –153 kJ·mol$^{-1}$ (BP/TZVPP) the overall reaction energy for carbamate formation is almost twice as large as that for the Zn compound.

# The Effect of Hydrothermal and Non-Hydrothermal Synthesis on the Formation of Holmium(III) Succinate Hydrate Frameworks

**Maria C. Bernini,[a] Elena V. Brusau,[a] Griselda E. Narda,*[a] Gustavo E. Echeverria,[b,c] C. Gustavo Pozzi,[b] Graciela Punte,[b] and Christian W. Lehmann[d]**

**Keywords:** Lanthanides / Hydrothermal synthesis / Hybrid frameworks / Coordination polymers

Two novel hydrated holmium(III) succinates with formula $[Ho_2(C_4H_4O_4)_3(H_2O)_4]\cdot 6H_2O$ (**1**) and $[Ho_2(C_4H_4O_4)_3(H_2O)_2]\cdot H_2O$ (**2**) have been synthesized from aqueous solution under ambient and hydrothermal conditions, respectively. Single-crystal X-ray diffraction shows that $Ho^{III}$ is nine-coordinate in both compounds even though their structures are markedly different, the main distinctive features being the $[H_2O]/[C_4H_4O_4^{2-}]$ ratio in the coordination sphere, the conformation and coordination ability of the succinate ions, and the resulting framework dimensionality. Compound **1** is a 2D hybrid polymer and its crystal structure is unprecedented for rare-earth succinates. It consists of centrosymmetric dimers of edge-sharing $HoO_7(H_2O)_2$ polyhedra linked by succinate ions in the [100] and [101] directions. Hydrogen-bonded hydration water molecules connect layers to give three-dimensional stability. Compound **2** is built up from infinite chains of $HoO_8(H_2O)$ polyhedra linked by succinates that result in a 3D architecture. This structure shows that hydrothermal conditions favor an increase in the overall dimensionality of these hybrids, in agreement with theoretical considerations. The compounds were characterized by FTIR and Raman spectroscopy, thermal analysis, and variable-temperature magnetic susceptibility measurements and the results are discussed in connection with the structural findings. The effect of the dimensionality on the thermal stability of both structures after removal of the hydration water molecules is also analyzed.

## Introduction

The last few years have witnessed a great effort dedicated to the investigation, design, and prediction of open hybrid organic/inorganic frameworks with metal cations and multifunctional anions as structural agents.[1–8] Such molecular-based porous materials have potential utility in catalysis, optics, gas separation/storage, and host–guest chemistry.[9–14]

The observed wide use of dicarboxylates to build open framework systems is due to the versatility of these anions' interactions. Their different coordination modes with metals, many of which can coexist, and their ability to act as hydrogen-bond acceptors and donors make them capable of generating supramolecular assemblies and account for their multifunctionality. The synthesis of specific rare-earth dicarboxylates allows us to expand the range of applications of this kind of compounds by constructing smart materials with attractive optical or magnetic properties, depending on the nature of the metal ion.[15–17]

One important limitation for the practical application of hybrid materials is their thermal stability, although this can be considerably improved by the formation of extended metal–oxygen–metal arrays.[13] In the case of lanthanide dicarboxylates, the combination of lanthanide ions with a high coordination number and relatively flexible ligands, like aliphatic dicarboxylates, is expected to prevent collapse of the structure upon removal of guest molecules as well as interpenetration of networks, which obstructs the pores.

A large variety of coordination polymers have been synthesized by crystallization under mild conditions, and hydrothermal techniques allow the variety of structural types to be considerably extended. Although the synthesis conditions are known to play an important role in the framework dimensionality and hydration grade, the way in which all the variables influence the framework development is not yet clear. According to the literature, hydrothermal conditions are more suitable for preparing 3D solids with extended M–O–M networks, which favors better thermal stability since they enhance metal–ligand interactions rather

than metal–water coordination.[18,19] According to Férey et al.,[20] although helping the formation of M–O–M networks, hydrothermal conditions preclude the assistance of computer simulations in the rational design of this kind of compounds as hydrothermal conditions modify the nature of the species in solution.

Lanthanide succinates have been examined by various authors and several compounds have been reported in the literature, especially $[Ln_2(C_4H_4O_4)_3(H_2O)_2]$ (Ln = Ce,[21] Eu,[22] Gd[23] and Er;[24] type 1), $[Ln_2(C_4H_4O_4)_3(H_2O)_2]\cdot H_2O$ (Ln = Y, La,[14] Pr,[25] Sm,[21,25] Gd[23] and Tb;[22] type 2), and $[Lu_2(C_4H_4O_4)_3(H_2O)_4]\cdot 4H_2O$[26] (type 3). All of these have been obtained by hydrothermal synthesis or under high-temperature conditions and are 3D hybrid frameworks with channels that can host hydrogen-bonded hydration water molecules. Structural analyses have indicated that type-1 compounds, which crystallize in the triclinic system (space group $P\bar{1}$) and do not host hydration waters, present a framework with important structural similarities with type-2 compounds, which crystallize in the monoclinic $C2/c$ space group. Both structural types include infinite 1D inorganic networks (running along a crystallographic axis) that are built up from edge-sharing $LnO_8(H_2O)$ polyhedra interconnected by succinate dianions, with channels parallel to the chains. On the other hand, the lutetium succinate structure (type 3) consists of isolated, irregular $LuO_6(H_2O)_2$ polyhedra linked by organic moieties to form a three-dimensional framework.

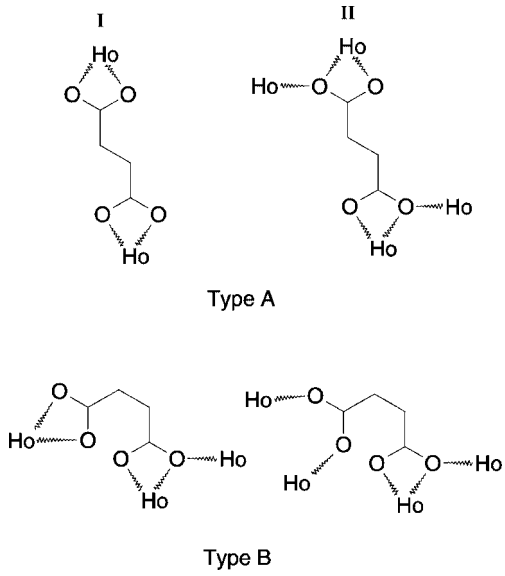
To better understand the factors that influence the way of binding and the formation and stability of polymeric structures with different dimensionalities in hybrid systems we decided to explore the self-assembly of $Ho^{III}$ and succinate ligands under ambient and hydrothermal conditions. Two novel dicarboxylate complexes, formulated as $[Ho_2(C_4H_4O_4)_3(H_2O)_4]\cdot 6H_2O$ (**1**) and $[Ho_2(C_4H_4O_4)_3(H_2O)_2]\cdot H_2O$ (**2**), were obtained and their thermal stability was studied. Their characterization by single-crystal X-ray diffraction, thermal and magnetic measurements, and FTIR and Raman spectroscopy are presented here. It is worth noting that the crystal structure of compound **1**, which was obtained under mild conditions, has not been observed previously and therefore it is the first lanthanide succinate with a 2D open structure.

## Results and Discussion

### Crystal Structures

Compound **1** crystallizes in the triclinic space group $P\bar{1}$ with $Z = 2$, although its structure is different from type 1 described above. Compound **2** crystallizes in the monoclinic space group $C2/c$ and is isostructural with all the $Ln^{III}$ succinates that crystallize in the type-2 structure mentioned above (see Experimental Section).

There are two crystallographically independent anions in compound **1**. One (A) is located on an inversion center such that the anion has a perfect *trans* conformation (torsion angle: 180°) with a distance between the α and ω carbon atoms of 3.902(7) Å and the other anion (B) adopts a *gauche* conformation, with a torsion angle of –60.4(5)° and a distance between the α and ω carbon atoms of 2.999(7) Å. Both oxygens of both carboxylates of anion A are bound in a chelating mode, while although both O atoms of both carboxylates in anion B bind in a chelating mode, one oxygen atom of one of the carboxylates also acts in a bridging mode (see Scheme 1).



Scheme 1.

The $Ho^{III}$ cations are coordinated by nine oxygen atoms, seven of them belonging to four succinate anions and the others to the two crystallographically inequivalent water molecules (Figure 1 and Table 1). The $HoO_7(H_2O)_2$ coordination polyhedra can be described as a monocapped square antiprism. Edge-sharing polyhedra, related by an inversion

center, form centrosymmetric dimers (see Figure 2) where the Ho$^{III}$ cations are connected by two chelating bridging carboxylates, with the chelating plane (CP) departing 17.5(2)° from the bridging plane (BP; see Table 1 for plane labeling). These dimers are further strengthened by a hydrogen bond (HB) interaction involving the coordinated water W1 and the carboxylate oxygen O3 (see Table 2). The Ho···Ho distance within the dimer is 4.0579(2) Å. The distances between Ho$^{III}$ and the coordinated succinate oxygen atoms range between 2.348(3) and 2.532(3) Å; these extreme values correspond to the bridging oxygen atoms O1 and O1$^{ii}$ [O1–Ho–O1$^{ii}$ angle: 112.4(1)°; ii: 1 – *x*, 1 – *y*, –*z*]. The overall structure can therefore be described as consisting of 2D organic–inorganic polymeric layers, as shown in Figure 3.

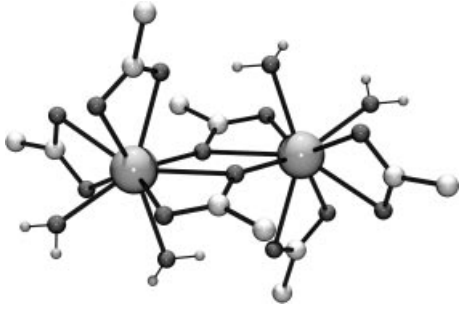

Figure 2. Perspective diagram showing the Ho$^{III}$ and succinate ion connections in the dimer together with the bridging and chelating planes. For reasons of clarity only the relevant succinate fragments are shown. The Ho$^{III}$ ions (bulky spheres) are medium color, while the carbon and oxygen atoms are light and dark gray, respectively.

Within a layer the dimers are connected by succinates A along [100] and succinates B along [101]. The connection along [100] is further stabilized by a HB between W1 and the succinate oxygen O5 (see Table 2). The hydration water molecules (W3, W4, and W5) are located between the 2D

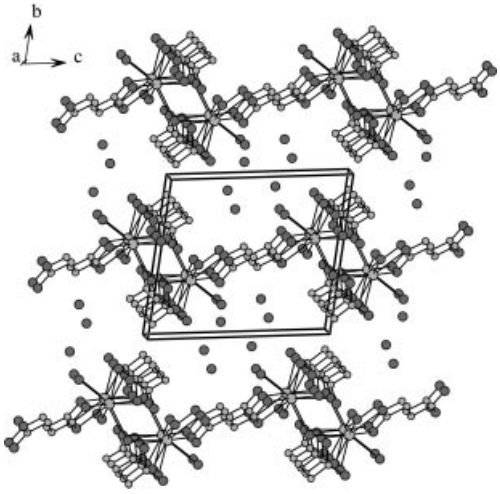

Figure 3. Projection of the framework along the *a* direction of **1**.

organic–inorganic polymeric layers. Hydration waters are connected by HBs to form six-membered clusters, which are located around the inversion centers at (0,0,1/2) and equivalent positions. The coordinated water W2 links clusters through two HBs, thus generating hydrogen-bonded chains of hydration water clusters running in the [100] direction. Hydration waters are further hydrogen bonded to succinate anions, providing in this way the connection between the layers and the stabilization of the three-dimensional arrangement. In spite of the differences in coordination number and coordination modes, we have observed a similar 2D structure in diaquasuccinatocadmium(II).[27,28]

There are also two crystallographically independent anions in compound **2**. One (A) is also located on an inversion center (perfect *trans* conformation) with a distance between the α and ω carbon atoms of 3.838(12) Å and the other (B) adopts a *gauche* conformation with a torsion angle of –73.1(8)° and a distance between the α and ω carbon atoms of 3.21(1) Å. Different to **1**, both carboxylates belonging to anion A in compound **2** coordinate the cations through a chelating and a bridging mode, while one carboxylate of anion B coordinates the cation through a chelating and a bridging mode and the two O atoms of the other carboxylate are only involved in a bridging interaction (see Scheme 1). The $Ho^{III}$ cations in this compound are also coordinated to nine oxygen atoms, in this case adopting a tricapped trigonal prismatic geometry. In this structure just one oxygen of the coordination polyhedra belongs to a water molecule, with the other eight belong to six different carboxylate groups (see Figure 4 and Table 1). Neighboring $Ho^{III}$ cations are connected by two chelating bridging carboxylates and by an additional bidentate carboxylate, which is oriented with the O–C–O plane almost perpendicular to the corresponding BP [the angle is 87.0(9)°; see Figure 5]. This connectivity, different from that observed in **1**, is extended by the twofold screw axis parallel to the *b* axis to build infinite chains where all $Ho^{III}$ ions are at the same distance [4.007(1) Å]. In spite of this, bridging Ho–O–Ho geometries within adjacent polyhedra are different within three esd's. The bridging Ho–O distances are 2.391(5) and 2.388(4) Å [2.497(5) and 2.428(5) Å] and the Ho–O–Ho angle is 112.6(2)° [110.1(2)°; see Table 1]. The chains are connected by anions of type A running perpendicular to the (101) planes and by anions of type B situated along the [101] direction. Adjacent chains along *a* are 8.920(5) and 11.002(5) Å apart and those along *b* 6.016(7) and 7.894(6) Å apart. This arrangement helps the development of an open-framework with two set of channels of different cross-section size [28.8(5) and 20.8(5) $Å^2$], both of which run parallel to the $HoO_2$ chains with the hydration waters located in the largest channel, as can be seen in Figure 6. The hydration waters are linked to the framework by hydrogen bonds (see Table 2). They interact as donors with coordination waters and as H-acceptors from type-B succinate anions.

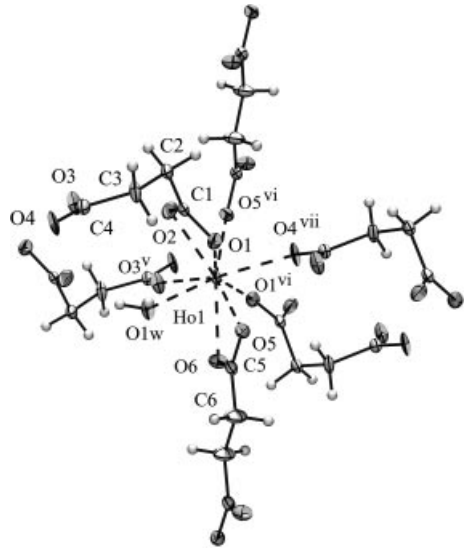

Figure 4. ORTEP-III view of the coordination polyhedron of $Ho^{III}$ in **2** showing the atom-labeling scheme. Displacement ellipsoids are drawn at 50% probability. See footnote to Table 2 for symmetry codes.

Figure 5. Perspective diagram showing the $Ho^{III}$ and succinate ion connections along the chain together with the bridging and chelating planes. Similar to Figure 2, the relevant succinate fragments and gray shades are used.

Taking into account the synthesis conditions that give rise to each structure, it can be inferred that the presence of a higher number of coordination waters, the smaller Ho–OW distances, and the less rich coordination modes of the dicarboxylate anions in **1** are favored by the milder conditions of the solution. This synthesis path leads to the devel-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

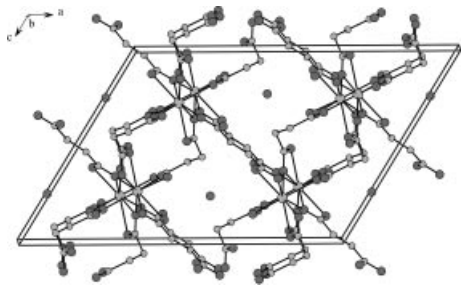

Figure 6. Projection of the framework along the *b* direction of **2**.

opment of 2D organic–inorganic polymeric layers whose hydrophilic surfaces are linked by the hydration waters. On the other hand, the hydrothermal conditions used for the synthesis of **2** help to prevent the presence of a high number of coordination waters and enhance carboxylate coordination, thereby facilitating the formation of infinite Ho–O–Ho networks (see Figure 5) and a 3D framework structure. A comparison of the densities reported in Table 3 shows that they increase with the temperature employed during the synthesis. This correlates with the increasing dimensionality and is in accordance with the results reported in the literature for other metal dicarboxylates.[18,19,29]

### Vibrational Spectra

Figure 7 shows the FTIR and Raman spectra of both compounds. IR and Raman frequencies values for compound **2** are reported in parentheses below. The interpretation of the IR and Raman spectra is performed by considering the internal vibrations of water molecules, carboxylates, and methylene groups and their comparison with those observed in succinic acid and other related compounds. According to structural data, both structures are centrosymmetric ($P\bar{1}$ and $C2/c$) and no coincidences between IR and Raman frequencies (or at least only a few) can be expected, in agreement with the mutual exclusion rule.

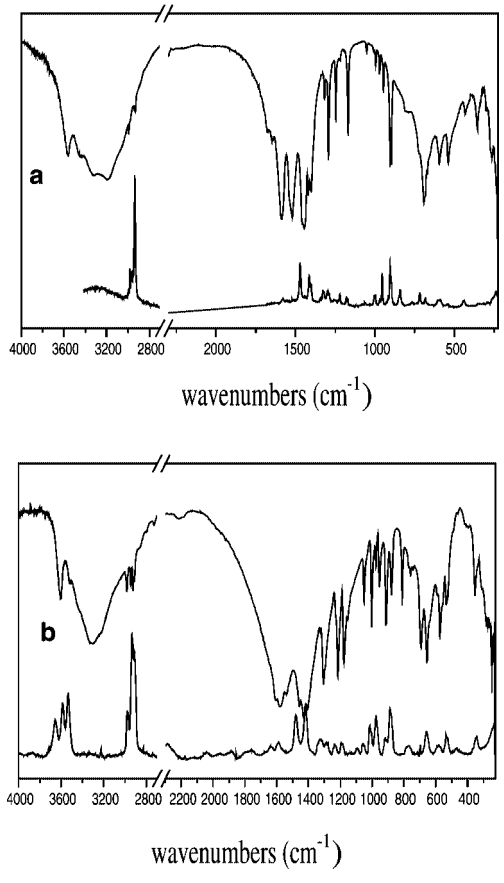

Figure 7. FTIR (top) and Raman (bottom) spectra of a) **1** and b) **2**.

### *Water Modes*

The assignment of these modes, particularly the librational ones, was performed by comparing the spectra of partially and completely dehydrated samples, which were obtained by using a variable-temperature IR cell (the thermal diagrams were taken into account; see Figure 8).

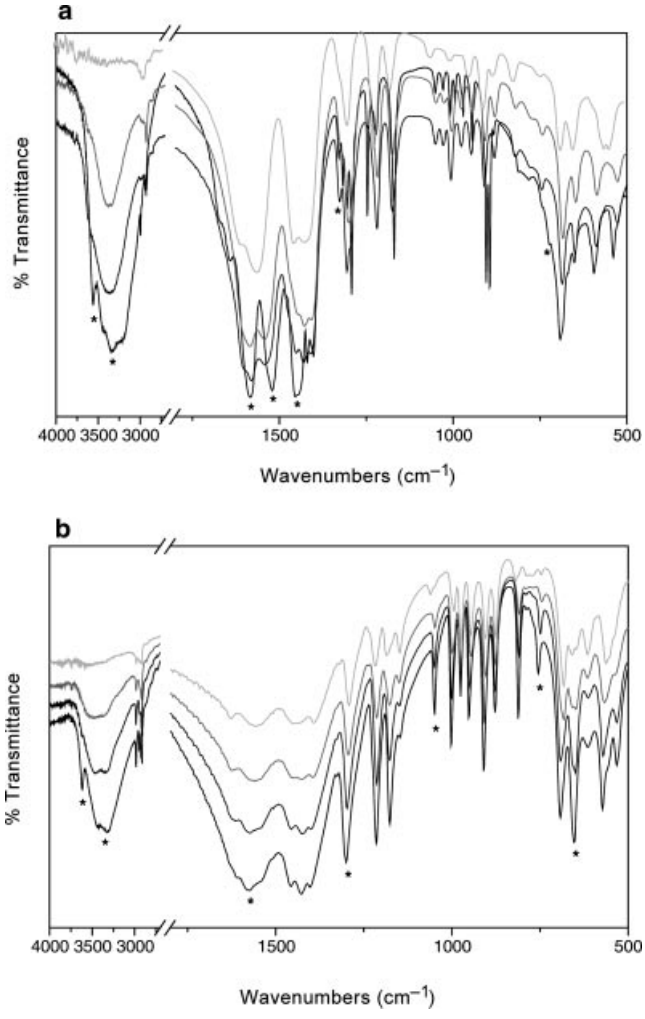

Figure 8. FTIR spectra recorded as a function of temperature during the dehydration of a) **1** and b) **2**. The most notable changes are indicated with asterisks.

The ν(OH) absorption can be identified in the FTIR spectrum of compound **1** as one broad, markedly asymmetric band that involves several components. This fact is consistent with the structural data, where four different kinds

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of water molecules are seen to be present. The components centered at 3560 and 3460 $cm^{-1}$ (3560, 3520, and 3445 $cm^{-1}$ for **2**) are mainly associated with hydration water since they disappear after partial dehydration; on the contrary, those centered at 3330 and 3175 $cm^{-1}$ (3315 and 3210 $cm^{-1}$ for **2**), which are absent upon complete dehydration, can be attributed to the remaining coordinated water.

The two low-intensity bands located at 1675 and 1645 $cm^{-1}$ are associated with the bending mode; the former is related to those water molecules that are eliminated first during thermal treatment since it is absent in the spectra of partially dehydrated samples.

### *OCO Group Modes*

Both carboxylate stretching modes are present in the FTIR spectra as broad, asymmetric bands with various components included. The splitting of these modes can be explained in terms of the different types of interactions between the carboxylate groups and the $Ho^{III}$ cations found in the crystals of both compounds (see Scheme 1). Two bands at 1585 and 1520 $cm^{-1}$ (1610, 1580, and 1540 $cm^{-1}$) are assigned to $\nu_{as}$(OCO), with the bands at 1330, 1315, and 1305 $cm^{-1}$ (1300 $cm^{-1}$) being associated with the corresponding symmetric mode. Splitting of the OCO stretching modes is not observed in the IR spectra of metal succinates where a unique binding mode for carboxylate groups has been reported.[28,30] No evidence for a carbonyl absorption is present, in agreement with the observed C–O distances (see Table 1).

### Thermal Analysis

TGA curves and thermodiffractograms up to complete dehydration for compounds **1** and **2** are shown in Figures 9 and 10, respectively. The temperature values were selected with reference to TG and *d*TG data; experimental $\Delta m$ percentages and temperature values for compound **2** are presented in parentheses. The differences between the $\Delta m$ percentages found for both compounds and the calculated ones do not exceed 1%. Dehydration proceeds in two stages at 68 °C (55 °C) and 115 °C (176 °C), as expected from the structural data. The first weight loss of 12.5% (1.93%) is related to loss of hydration water whereas the second mass decay of 8% (4.97%) corresponds to the elimination of coordinated water molecules. Differential water removal has also been observed in other type-2 lanthanide succinates, such as the La and Gd ones, whereas in those of Y, Pr, Sm, and Tb hydration and coordinated water molecules are lost in a single step.

A comparison of the dehydration events in **1** and **2** highlights noticeable differences. The continuous loss of weight between 40 and 87 °C for compound **1** accounts for the different interactions of the clustered hydration water molecules, and a rather narrow range of temperatures separates it from the next dehydration step. On the contrary, compound **2** exhibits an extended plateau of stability in the range 60–150 °C after hydration water elimination. These differences in the thermal behaviors of **1** and **2** can be explained as a consequence of the hydrogen bonds inside the framework and the interactions with the water molecules in the channels. These results show that the hydration water in **2** is looser than in other type-2 compounds such as that of

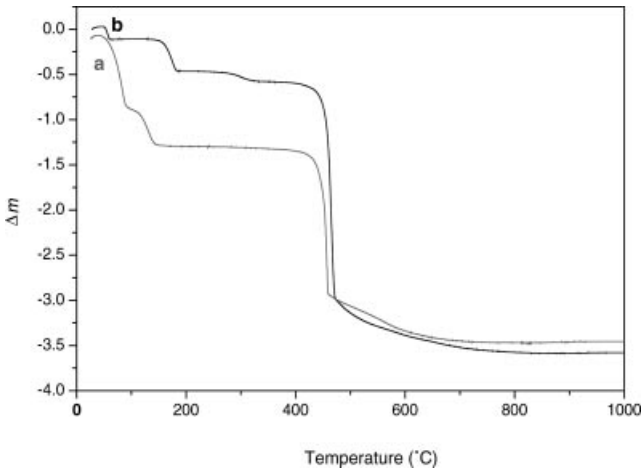

Figure 9. TG curves of **1** and **2**.

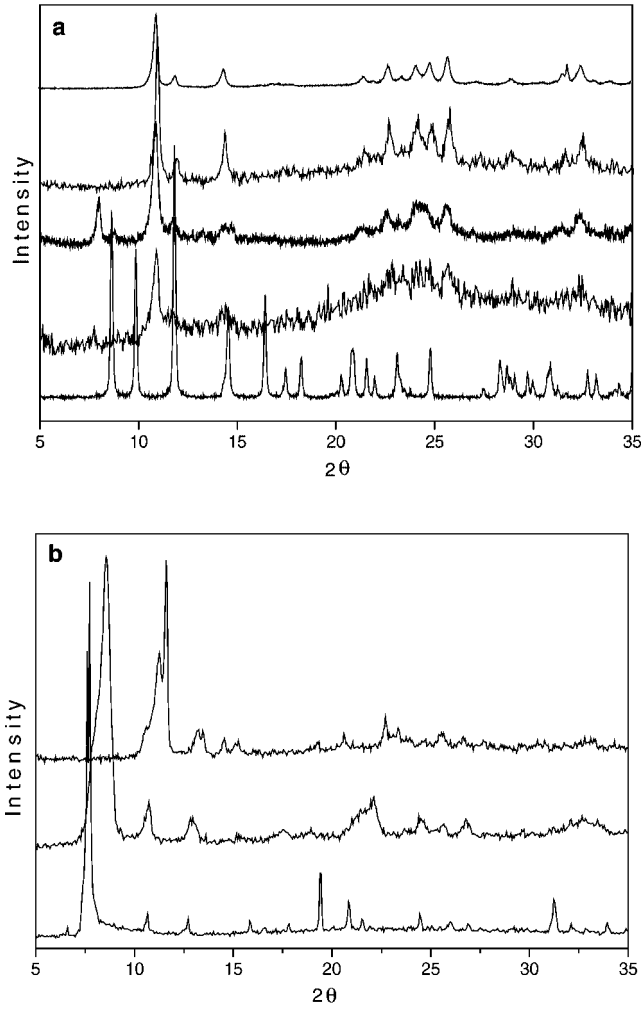

Figure 10. XRD patterns as a function of temperature of a) **1** and b) **2** thermolyzed to dehydration.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Sm^{III}$, where the DTA curve only shows one peak at 214 °C due to loss of both hydration and coordinated waters, or $Gd^{III}$, where lattice and coordinated water molecules are lost in the 200–240 °C and 270–325 °C ranges, respectively.

Dehydration of compounds **1** and **2** was also followed by variable-temperature FTIR spectroscopy (Figure 8). The broad band assigned to the ν(OH) stretching gradually decreases in intensity until its complete disappearance at higher temperature. The OCO stretching bands are strongly affected by dehydration of compound **1** due to the progressive degradation of the H-bond network. Thermally induced changes in these modes are less significant for compound **2**, where a shift to lower frequencies is observed in the main component of the $\nu_{as}$(OCO) and in the corresponding $\nu_s$(OCO) band. The spectra recorded at the highest temperature for both compounds do not display the librational modes of water molecules below 1100 $cm^{-1}$.

The removal of hydration water molecules in **1** leads to an amorphous phase that recrystallizes on further heating and remains stable, with increasing crystallinity, up to succinate ion decomposition, as has been observed for other 2D metallic dicarboxylates (see Figure 10a).[27,30] An extremely weak endothermic DSC signal at 165 °C is related to this transition (see Supporting Information). The X-ray powder diffraction pattern of the new crystalline phase, corresponding to the anhydrous compound, was indexed in the monoclinic space group *P*2/*m* (no. 10), using the TREOR program,[31] with the following cell parameters: $a$ = 19.378(5), $b$ = 8.157(4), $c$ = 4.236(1) Å, and $\beta$ = 92.22(1)°. Taking into account the structural features of compound **1** (described above), it is reasonable to expect that removal of hydration water implies loss of crystallinity.

Compound **2** essentially retains its crystalline structure when the first water molecule is lost, with the decrease in the XRPD intensity being the most outstanding difference between patterns corresponding to different temperature treatments (see Figure 10b).

The thermal evolution of both compounds presents a final event at 442 °C for **1** (460 °C for **2**) which is associated with succinate ion decomposition to give cubic holmium oxide as the final product; this is stable up to 1000 °C (PDF card 43-1018). A change in the slope of the TG trace around 500 °C suggests the formation of an intermediate product. A carbonated phase, which further decomposes to the oxide, appears upon heating to 500 °C and its identification was performed by FTIR spectroscopy, which exhibits characteristic bands at 1390 and 860 $cm^{-1}$.[32]

## Magnetic Measurements

The magnetic behavior of **1** and **2** is shown in Figure 11, where the real component of the AC magnetic susceptibility ($\chi'$) and the product $\chi'T$ are plotted against temperature. In both cases, at temperatures below 100 K, the $\chi'T$ curve departs from a Curie–Weiss law. The Curie constant, $C$, and Curie temperature, $\theta$, were determined from a linear fit of the inverse of $\chi'^{-1}$ in the range of temperatures where the Curie–Weiss law stands. This fit yields the values $C$ = 14.27(7) and 13.49(3) $cm^3\,K\,mol^{-1}$ and $\theta$ = –2.5(5) and –3.6(6) K for **1** and **2**, respectively. The negative value of the Curie temperature and the temperature dependence of $\chi'T$ indicate that an antiferromagnetic ordering is reached at lower temperatures. The effective magnetic moments ($\mu_{eff}$) calculated from the Curie constants are 10.68(1) $\mu_B$ for **1** and 10.37(1) $\mu_B$ for **2**, both of which are very close to the effective magnetic moment of the free $Ho^{III}$ cation (10.6 $\mu_B$). The observed lower $\mu_{eff}$ value in **2** might be a consequence of the higher delocalization of the $Ho^{III}$ electrons in this compound due to the higher number of oxy-

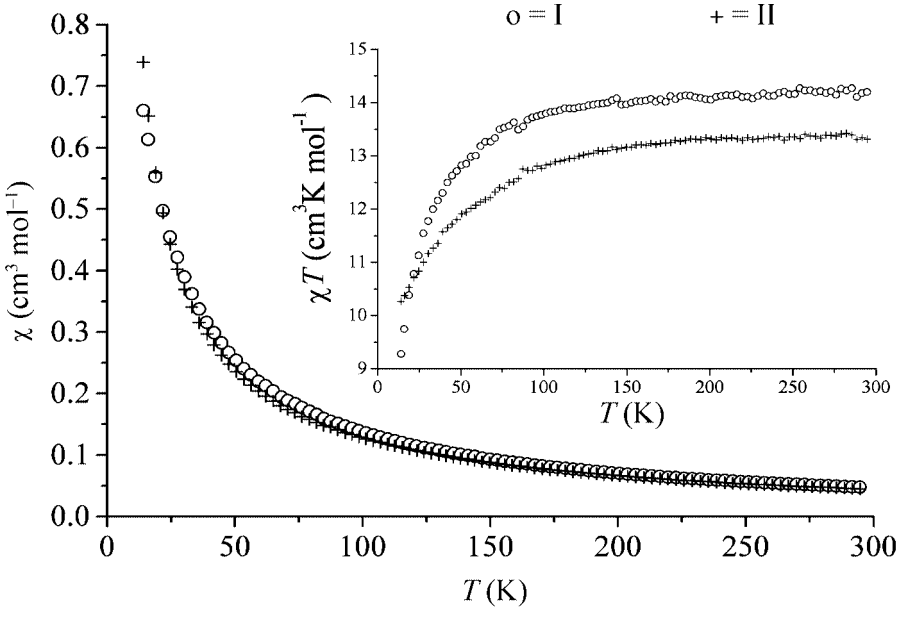

Figure 11. Thermal dependence of $\chi'$ for **1** and **2**. The inset shows the $\chi'T$ curves, which display the Curie–Weiss antiferromagnetic behavior of both compounds.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gens belonging to succinate anions in the coordination sphere.

At low temperatures, where the $\chi' T$ curves deviate from the Curie–Weiss law, the calculated $\mu_{eff}$ values at 14 K are 8.62(4) $\mu_B$ for **1** and 9.06(1) $\mu_B$ for **2**. A deviation of the magnetic behavior from a Curie–Weiss law and a decrease of the $\chi' T$ product with temperature have been observed in other $Ho^{III}$ carboxylates[33] and have been mainly ascribed to crystal field effects, which induce a depopulation of the rare-earth cation Stark components at low temperatures.

## Conclusions

Two $Ho^{III}$ succinate coordination polymers, namely $[Ho_2(C_4H_4O_4)_3(H_2O)_4]\cdot 6H_2O$ (**1**) and $[Ho_2(C_4H_4O_4)_3(H_2O)_2]\cdot H_2O$ (**2**), have been prepared and characterized employing mild and hydrothermal conditions, respectively. $Ho^{III}$ is nine-coordinate in both compounds. The structure of **1** consists of 2D organic–inorganic polymeric layers where coordination polyhedra form dimers that are connected by hydrogen-bonded hydration waters. In **2**, neighboring $Ho^{III}$ ions build infinite Ho–O–Ho chains linked by *trans* and *gauche* succinates. Chain formation supports the development of a hybrid open framework with two set of channels of different size, the largest of which contains the hydration waters. Thus, the multidentate character of the succinate ions in this compound, together with the substitution of a water ligand by an oxygen of the OCO groups, favors the formation of infinite M–O–M networks and plays an important role in the inorganic condensation. This also allows us to explain the observed difference in the magnetic results as being due to the presence of a dissimilar number of oxygens belonging to the succinate anions in the coordination sphere.

A crystalline anhydrous phase is obtained upon heating **1** after water removal, while the partially dehydrated compound obtained upon heating **2** shows a plateau of thermal stability, which indicates the potential capability of the dehydrated form of **2** to act as a stable open-framework material with empty channels.

All the above results show the effect of the synthesis conditions on the dimensionality and thermal stability of the metal-organic polymers and reinforce the necessity of the hydrothermal method for the formation of inorganic networks and open channels. However, other parameters, at present under study, need to be looked at to understand the relationship between synthesis temperature and the structure and properties of the products.

## Experimental Section

**Synthesis:** Reagents of analytical grade were used in the synthesis of compounds **1** and **2** according to the following procedures.

**$[Ho_2(C_4H_4O_4)_3(H_2O)_4]\cdot 6H_2O$ (1):** $HoCl_3\cdot 6H_2O$ (2 mmol) was dissolved in distilled water (100 mL) and then added to an aqueous solution containing succinic acid (3 mmol, 100 mL) whilst stirring; the resulting pH was raised to 4.5 by NaOH addition. The solution was then left to evaporate slowly at room temperature. A large number of pale-orange, needle-shaped single crystals (70% yield) suitable for a crystallographic study were obtained after several days. These were filtered, washed with distilled water, and dried at room temperature. $C_6H_{16}HoO_{11}$ (429.12): calcd. C 16.39, H 3.81; found C 16.78, H 3.73.

**$[Ho_2(C_4H_4O_4)_3(H_2O)_2]\cdot H_2O$ (2):** A solution prepared as described above (50 mL) was allowed to react under autogenous pressure for 3 d at 180 °C. Pale-orange, prismatic single crystals (58% yield) suitable for a crystallographic study were obtained. These were filtered, washed with distilled water, and dried at room temperature. $C_6H_{10}HoO_{7.5}$ (367.07): calcd. C 19.71, H 2.58; found C 19.63, H 2.45.

**X-ray Powder Diffraction (XRPD):** X-ray powder diagrams were obtained with a Rigaku D-MAX-IIIC diffractometer using Cu-$K_\alpha$ radiation (Ni filter) and NaCl and quartz as external calibration standards.

**Single-Crystal Structure Determination:** Single-crystal X-ray data for compound **1** were collected using a KappaCCD area detector diffractometer equipped with a Bruker AXS FR591 rotating anode. Data collection and determination of the unit cell parameters were performed with the Nonius collect software package, while integration of the data frames and scaling of the intensities were performed using the DENZO suite of programs.[34] Room temperature data did not provide a flat difference-Fourier synthesis map, proba-

Table 3. Crystal data, structure determination, and refinement summary for $[Ho_2(C_4H_4O_4)_3(H_2O)_4]\cdot 6H_2O$ (**1**) and $[Ho_2(C_4H_4O_4)_3(H_2O)_2]\cdot H_2O$ (**2**).

bly due to thermal smearing induced by motion of the hydration waters. The crystal was therefore cooled down to 100 K in a stream of cold nitrogen gas using a Cryostream cooler from Oxford Cryosystems. Data collected at that temperature were used for structure refinement. Data for compound **2** were collected on an automatic four-circle CAD-4 diffractometer at ambient temperature (293 K). CAD-4 software was used for data collection and cell refinement.[35] The program XCAD4[36] was employed for data reduction. Both structures were solved by direct methods using SHELXS-86[37] and refined by full-matrix least-squares based on $F^2$ using SHELXL-93.[38] The succinate hydrogen atoms in both structures were located from a difference-Fourier synthesis, while the program CALC-OH[39] was employed to calculate the position of the hydrogen atoms of water. Further refinements were performed with the hydrogen atoms riding on bound atoms. The structural analyses were performed with PLATON[40] and PARST.[41] The molecular graphics were produced with ORTEP[42] and POV-Ray.[43] Crystal data and details of data collection and structure refinement are given in Table 3. Selected interatomic distances and bond, torsion, and dihedral angles are listed in Table 1. Table 2 lists the H-bonds' geometry.

CCDC-618378 and -618379 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Infrared and Raman Spectroscopy:** FTIR spectra were recorded with a Nicolet Protégé 460 spectrometer in the 4000–225 $cm^{-1}$ range with 32 scans, using the KBr pellet technique; spectral resolution was 4 $cm^{-1}$. Raman spectra were recorded with a Raman Jobin–Yvon T64000 equipped with a CCD and an Ar laser operating at 514.5 nm.

**Thermal Analysis:** TG curves and DSC measurements were recorded with a Shimadzu TGA-50H thermal analyzer apparatus and a Shimadzu DSC-60 apparatus under flowing oxygen at 50 mL $min^{-1}$ at a heating rate of 10 °C $min^{-1}$. Appropriate combinations of X-ray powder diffraction and FTIR spectroscopy were used for further characterization of the pyrolysis products.

**Magnetic Measurements:** Magnetic measurements were carried out in the range 14–330 K with a LakeShore 7130 AC Susceptometer with an alternating field of 1 Oe and 825 Hz.

**Supporting Information** (see footnote on the first page of this article): DSC diagram of compound **1** to support the thermal analysis.

**Keywords:** Dynamic combinatorial chemistry / Metallamacrocycle / Organometallic complex / Rhodium / Ruthenium

The exchange reaction of the trinuclear macrocycles $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**) and $[(cymene)Ru(C_5H_3NO_2)]_3$ (**BBB**) has been studied. It was found that the equilibration proceeds in two steps and that the final mixture is completely dominated by the mixed-metal macrocycles $[\{(C_6H_3iPr_3)Ru\}_2\{(cymene)Ru\}(C_5H_3NO_2)_3]$ (**AAB**) and $[\{(C_6H_3iPr_3)Ru\}\{(cymene)Ru\}_2(C_5H_3NO_2)_3]$ (**ABB**). The results are rationalized by assuming unfavorable steric interactions between adjacent $(C_6H_3iPr_3)Ru$ fragments. It is shown that interactions of this kind can be used to bias scrambling processes in such a way that mixed-metal macrocycles are obtained in over 80% yield. The structures of $[\{(C_6Me_6)Ru\}\{(C_6H_6)Ru\}_2(C_5H_3NO_2)_3]$ and $[(Cp^*Rh)\{(C_6H_6)Ru\}_2(C_5H_3NO_2)_3]$ have been determined by single-crystal X-ray analysis.

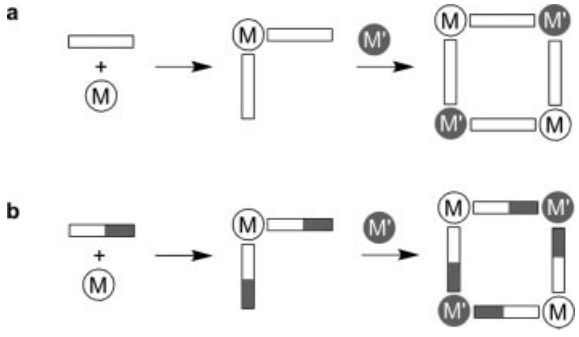
## Introduction

Transition metal-based self-assembly processes have been used extensively to build macrocyclic compounds with diverse structures and functionalities.[1] In the majority of these cases, metal complexes M with available coordination sites were combined with bridging ligands L to give symmetrical macrocycles of the type $M_nL_n$. These reactions are typically performed in a single step under thermodynamic control. Macrocycles containing two different metal fragments M and M′, however, are generally constructed in a two-step procedure.[2,3] For mixed-metal squares and rectangles, this is illustrated in Scheme 1. In a first step, a ditopic ligand is coordinated to a metal M. The resulting complex $ML_2$ is then reacted with a metal M′ to give the tetranuclear complex $M_2M'_2L_4$. Usually, the preformed metal complex $ML_2$ is kinetically inert under the reaction conditions employed in the second step (Scheme 1, a).[2] This avoids scrambling reactions, which would lead to mixtures of assemblies with variable M-M′ content and position. Alternatively, the formation of mixed-metal assemblies can be favored by the utilization of ligands having two distinct donor sites, each of which with a pronounced selectivity for the respective metal fragment M or M′, respectively (Scheme 1, b).[3] Additional specificity can be achieved by template effects. For the latter case, one-step syntheses of heterometallic macrocycles under thermodynamic control have been reported.[4]



Scheme 1. Stepwise synthesis of tetranuclear macrocycles containing two different metal fragments M and M′.

Over the last few years, we have reported in a number of publications the synthesis and host–guest chemistry of trinuclear metallamacrocycles comprised of (arene)$Ru^{II}$ or (cyclopentadienyl)$M^{III}$ (M = Rh, Ir) complexes and bridging 2,3-dihydroxypyridine ligands.[5] These complexes represent organometallic analogues of 12-crown-3 and show an outstanding affinity for lithium ions, even in aqueous solutions.[6] During the course of our studies we observed that in polar solvents, these metallacrown complexes undergo exchange reactions. This was used to create dynamic combinatorial libraries[7] of macrocycles and to investigate the adaptive behavior of such mixtures.[8] In the following we show that steric interactions can be used to guide the scrambling process in such a fashion that a defined mixed-metal macrocycle can be obtained in synthetically interesting yields.

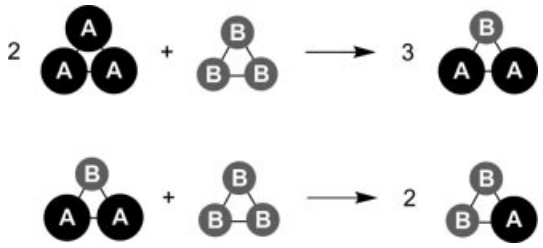
## Results and Discussion

In a first experiment, we investigated the scrambling reaction of the two trimeric (arene)Ru complexes $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**) and $[(cymene)Ru(C_5H_3NO_2)]_3$ (**BBB**) (Scheme 2). The complexes were mixed in a 1:1 ratio in $CD_3OD$, with an initial concentration of 5.0 mM each. To accelerate the exchange process, the solution was gently heated to 40 °C. The reaction was followed by $^1H$ NMR spectroscopy and the time course is shown in Figure 1.



Scheme 2. The equilibration of $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**) and $[(cymene)Ru(C_5H_3NO_2)]_3$ (**BBB**) proceeds in two steps. First, the sterically encumbered **AAA** is converted into **AAB**. This is followed by a second, much slower transformation, in which **ABB** is formed.

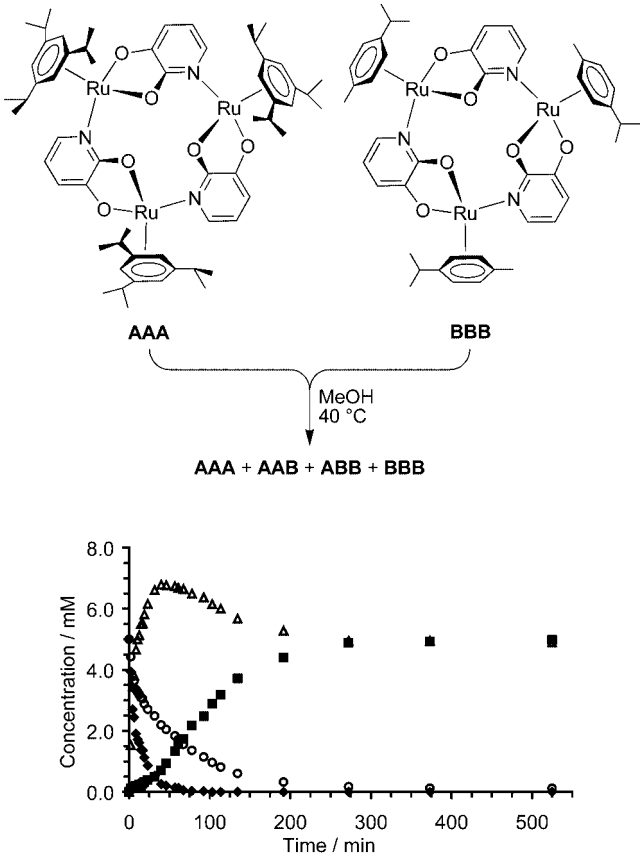


Figure 1. Time course of the reaction between $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**; ♦) and $[(cymene)Ru(C_5H_3NO_2)]_3$ (**BBB**, ○) to give the mixed-metal macrocycles **AAB** (Δ) and **ABB** (■) as determined by $^1H$ NMR spectroscopy. The reaction was performed in $CD_3OD$ at 40 °C with initial concentrations of [**AAA**] = [**BBB**] = 5.0 mM.

The beginning of the reaction was marked by a fast decrease of **AAA** and a rapid increase of **AAB**. The formation of **ABB** was almost negligible in the first 15 min. During this period, the decrease of **AAA** was almost twice as fast as the decrease of **BBB**. After 40 min, a turning point was reached. The concentration of **AAB** was at its maximum and represented 68% of the total trimer concentration. Subsequently, a decrease of **AAB** and a concomitant increase of **ABB** were observed. Accordingly, the concentration-time profile of **ABB** shows a sigmoidal form. After six hours, the mixture was at equilibrium and only the two mixed complexes **AAB** and **ABB** were present in significant amounts.

For equally stable macrocycles, a statistical mixture of **AAA/AAB/ABB/BBB** = 1:3:3:1 would be expected. At first glance, the complete dominance of **AAB** and **ABB** after equilibration might suggest a preferential stabilization of the mixed complexes with respect to the homotrimers **AAA** and **BBB** (situation a, Figure 2). But there is another explanation for such a distribution: the B-rich species **ABB** and **BBB** are stabilized and the homotrimer **AAA** is significantly destabilized (situation b, Figure 2). For $\Delta\Delta G1 = \Delta\Delta G2 = 1/2\ \Delta\Delta G3$, the two situations result in the same equilibrium distribution with equal amounts of heterotrimers being the dominant species in solution. It is interesting to note that for the situation described in Figure 2 (b), the concentration of the stable homotrimer **BBB** is as low as that of the disfavored **AAA**. A more detailed discussion of this phenomenon can be found in a recent theoretical study.[9]

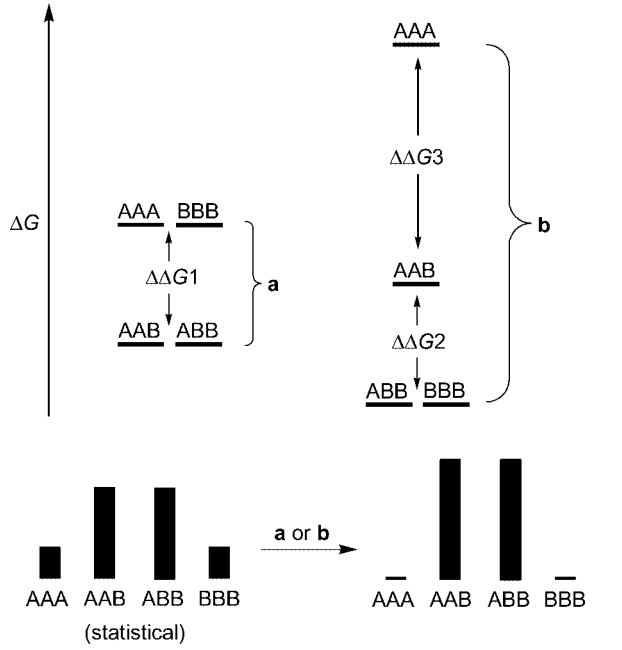

Figure 2. For equally stable trimers **AAA**, **AAB**, **ABB**, and **BBB**, a statistical 1:3:3:1 distribution is expected. The energetic situations shown in **a** and **b** both result in selective formation of the mixed trimers **AAB** and **ABB**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

An energy distribution similar to what is described in Figure 2 (b) is more likely to account for the dynamic mixture described above. Complex $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**) has three sterically demanding triisopropylbenzene ligands. The π-ligands approach each other and destabilize the aggregate. For the mixed trimer **AAB**, only one unfavorable A···A interaction is found, whereas the aggregates **ABB** and **BBB** display no intramolecular A···A contacts at all. The kinetic data support this picture. The sterically encumbered trimer **AAA** rapidly reacts with the smaller cymene complex **BBB** to give **AAB**. This first reaction is followed by a second, much slower reaction, in which **AAB** is converted into **ABB** (Scheme 2). It should be noted that the sequential formation of first **AAB** and then **ABB** excludes a simple bimolecular reaction mechanism in which two trimers **AAA** and **BBB** exchange fragments.

An interesting consequence from an asymmetric free energy distribution is the possibility to bias the equilibration process in favor of a certain species. For a dynamic mixture of equally stable trimers **AAA**, **AAB**, **ABB**, and **BBB**, the relative concentration of the mixed trimer **ABB** after equilibration can be increased from 37.5% to a maximum theoretical value of 44.3% by using two equivalents of **BBB** and only one equivalent of **AAA**. For a system such as the one described in Figure 2 (b), the maximum relative concentration of a mixed trimer after equilibration can be much higher.

To demonstrate this point, we have investigated the scrambling reaction of $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**) and $[(C_6H_6)Ru(C_5H_3NO_2)]_3$ (**CCC**) (Figure 3). The small benzene complex **CCC** was chosen to further accentuate the difference between the π-ligands. This time, the complexes were mixed in a 1:2 ratio with initial concentrations of [**AAA**] = 2.0 mM and [**CCC**] = 4.1 mM. The time course of the reaction is shown in Figure 3. The beginning of the equilibration process was again marked by the fast formation of the mixed complex **AAC** comprised of two large $(C_6H_3iPr_3)Ru$ moieties and the simultaneous rapid decrease of **AAA**. After 26 min, more than 95% of the initial amount of complex **AAA** was converted and the concentration of **AAC** reached its maximum. Then, its concentration decreased in favor of **ACC**. The equilibrium was reached after 10 h, after which the heterotrimer **ACC** completely dominated the mixture (83 ± 2%). Only minor amounts of **AAC** (7 ± 2%) and **CCC** (10 ± 2%) were found in the solution.

The results described above suggest that equilibration processes with 2:1 stoichiometries of complexes having significantly different π-ligands can be used for the controlled formation of mixed-metal macrocycles in preparative amounts. The following results show that this is indeed the case. Solutions containing two equivalents of the small benzene complex $[(C_6H_6)Ru(C_5H_3NO_2)]_3$ (**CCC**) and one equivalent of the trimers $[(C_6Me_6)Ru(C_5H_3NO_2)]_3$ (**DDD**) or $[Cp^*Rh(C_5H_3NO_2)]_3$ (**EEE**), both of which have sterically demanding π-ligands, were tempered in $CD_3OD$ at 45 °C overnight. Similar to what was found in experiments with **AAA**, the mixed-metal complexes **DCC** and **ECC** were

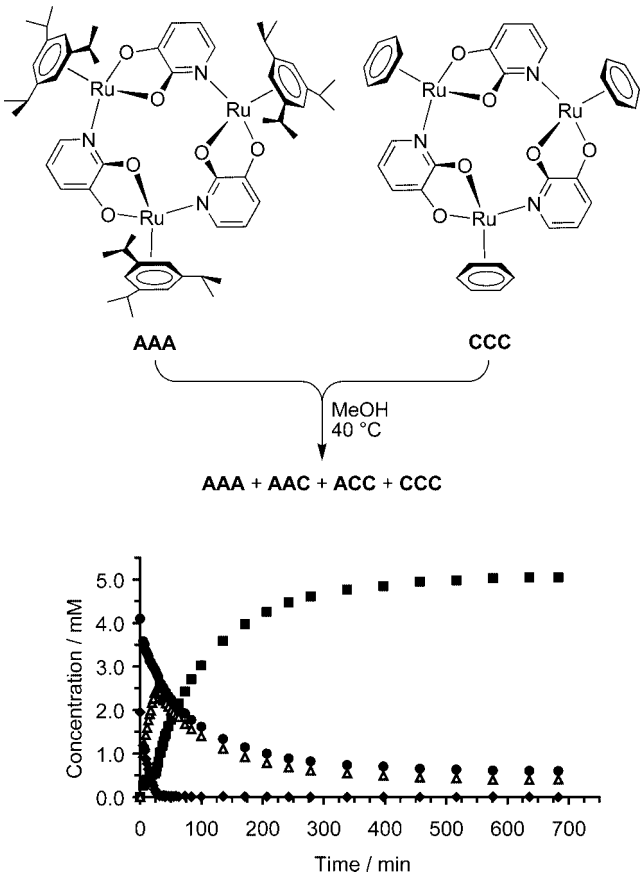

Figure 3. Time course of the reaction between $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**; ♦) and $[(C_6H_6)Ru(C_5H_3NO_2)]_3$ (**CCC**, ●) to give the mixed-metal macrocycles **AAC** (Δ) and **ACC** (■) as determined by $^1H$ NMR spectroscopy. The reaction was performed in $CD_3OD$ at 40 °C with initial concentrations of [**AAA**] = 4.1 mM and [**CCC**] = 2.0 mM.

formed almost exclusively (>80%) as evidenced by $^1H$ NMR spectroscopy.

The complexes **ACC**, **DCC**, and **ECC** can not only be obtained by scrambling of preformed homotrimers but also directly from appropriate amounts of the respective building blocks. Thus, when two equivalents of the dimer $[(C_6H_6)RuCl_2]_2$,[10] one equivalent of $[(C_6H_3iPr_3)RuCl_2]_2$, $[(C_6Me_6)RuCl_2]_2$, or $[Cp^*RhCl_2]_2$ and six equivalents of the 2,3-dihydroxypyridine ligand were reacted in methanol in the presence of $Cs_2CO_3$, the products **ACC**, **DCC**, and **ECC** could be isolated with yields of ca. 60% and in good purity. It was also possible to obtain mixed-metal trimers with two large metal fragments and one small fragment. This was corroborated by the synthesis of complex **AAC** using two equivalents of $[(C_6H_3iPr_3)RuCl_2]_2$ and one equivalent of $[(C_6H_6)RuCl_2]_2$. It should be noted that exchange processes were found to be significantly slower in less polar solvents such as benzene and chloroform as compared to methanol. This allowed the characterization of the mixed-metal trimers in pure form.

The $^1H$ NMR spectroscopic data of all three products were in agreement with the anticipated structure: three sets of signals were observed for aromatic protons of the bridging pyridonate ligands and two singlets were found for the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chemically distinct benzene π-ligands. The complexes **DCC** and **ECC** were also characterized by a single-crystal X-ray analysis (Figure 4, Figure 5, and Figure 6).

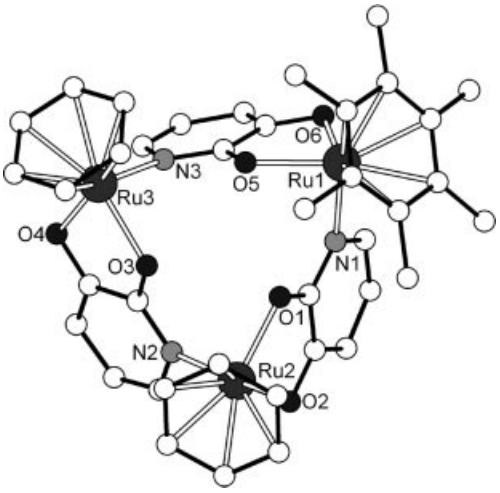

Figure 4. Ball-and-stick representation of the molecular structure of **DCC** in the crystal. The hydrogen atoms and the solvent molecules ($2CHCl_3$) are omitted for clarity. Selected bond lengths [Å]: Ru1–N1 2.130(6), Ru1–O5 2.086(4), Ru1–O6 2.065(5), Ru2–O1 2.060(5), Ru2–O2 2.069(5), Ru2–N2 2.118(6), Ru3–O3 2.069(5), Ru3–O4 2.073(5), Ru3–N3 2.139(6).

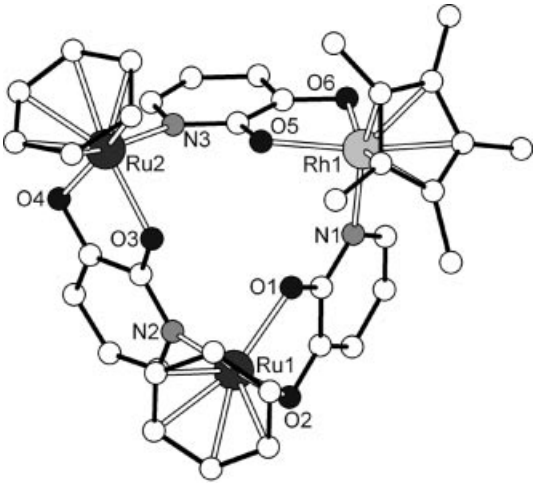

Figure 5. Ball-and-stick representation of the molecular structure of **ECC** in the crystal. The hydrogen atoms and the solvent molecules ($H_2O$, MeOH, $C_6H_5CH_3$) are omitted for clarity. Selected bond lengths [Å]: Rh1–O5 2.080(7), Rh1–O6 2.088(8), Rh1–N1 2.122(9), Ru1–O2 2.067(6), Ru1–O1 2.078(7), Ru1–N2 2.106(8), Ru2–O3 2.072(6), Ru2–O4 2.076(7), Ru2–N3 2.104(9).

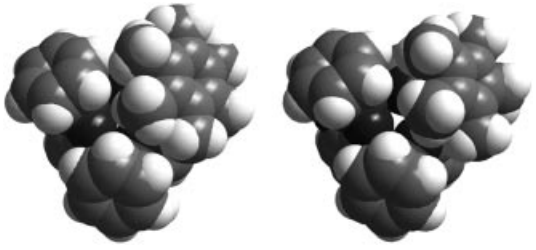

Figure 6. Space filling representation of the molecular structure of **DCC** (left) and **ECC** (right) in the crystal. The solvent molecules have been omitted for clarity.

The bond lengths and angles found for the macrocyclic core of **DCC** and **ECC** are comparable to what has been observed for the corresponding homotrimeric complexes.[5] Additional structural anisotropy due to the presence of different half-sandwich complexes was not observed. Indirect evidence for the reduced steric strain of the mixed-metal macrocycles **DCC** and **ECC** is the fact that their average metal–metal distances (**DCC**: 5.26 Å; **ECC**: 5.26 Å) are shorter than what has been observed for the homotrimers **DDD** (5.46 Å) and **EEE** (5.35 Å).[5g] The importance of the size of the π-ligand for the stability of the trimeric aggregates is also evident from the space filling representations of **DCC** and **ECC** (Figure 6).

## Conclusions

The synthesis of metallamacrocycles containing two different metal fragments M and M′ is mostly performed in two or more steps under kinetic control. We have shown that steric interactions can be used to bias dynamic exchange processes in such a way that mixed-metal macrocycles are obtained in over 80% yield under thermodynamic control. The results are conceptually related to work on *mixed-ligand* metallamacrocycles and cages. Navarro and Romero et al. have shown that scrambling of symmetrical (en)$Pd^{II}$-based macrocycles with bridging 4,7-phenanthroline and 2-pyrimidinolate ligands can lead to the dominant formation of a single product given that appropriate stoichiometries are employed;[11] and Fujita et al. and James et al. have used steric interactions between ligands to achieve the quantitative formation of macrocycles and coordination cages containing two different heterocyclic ligands.[12,13] It should be noted that rather small differences in free energy of the various aggregates can be sufficient to bias dynamic mixtures of metallamacrocycles (or cages) towards the formation of a defined product. For the system described in Figure 2 (b), for example, a difference of $\Delta\Delta G2 = 1/2\ \Delta\Delta G3 = 3.0\ kcal\,mol^{-1}$ results in an increase of the relative concentration of mixed product **ABB** from 44.3% (statistical) to 91.6% (for $[\mathbf{AAA}]_{initial} = 1/2\ [\mathbf{BBB}]_{initial}$).[14] In view of the fact that asymmetric metallamacrocycles may display interesting functional differences (host–guest chemistry etc.) when compared to their symmetrical $M_nL_n$ counterparts, the strategy discussed above should be regarded as an attractive alternative to step-wise synthetic procedures.

## Experimental Section

**General:** All reactions were performed under dry dinitrogen. The complexes $[(C_6H_3iPr_3)Ru(C_5H_3NO_2)]_3$ (**AAA**),[8c] [(cymene)-$Ru(C_5H_3NO_2)]_3$ (**BBB**),[5h] $[(C_6H_6)Ru(C_5H_3NO_2)]_3$ (**CCC**),[5g] $[(C_6Me_6)Ru(C_5H_3NO_2)]_3$ (**DDD**),[5g] $[Cp^*Rh(C_5H_3NO_2)]_3$ (**EEE**),[5g] $[(C_6H_3iPr_3)RuCl_2]_2$,[15] $[(C_6Me_6)RuCl_2]_2$,[16] $[Cp^*RhCl_2]_2$[17] and $[(C_6H_6)RuCl_2]_2$[18] were prepared according to literature procedures. 2,3-Dihydroxypyridine (95%) was purchased from Fluka and $Cs_2CO_3$ (99.9%) was purchased from Aldrich. The $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker Advance DPX

400 spectrometer with the residual protonated solvent as internal standard. All spectra were recorded at room temperature.

**Synthesis of Complex [{($C_6H_3iPr_3$)Ru}{($C_6H_6$)Ru}$_2$($C_5H_3NO_2$)$_3$] (ACC):** A suspension of [($C_6H_3iPr_3$)$RuCl_2$]$_2$ (75 mg, 0.10 mmol), [($C_6H_6$)$RuCl_2$]$_2$ (110 mg, 0.22 mmol), 2,3-dihydroxypyridine (69 mg, 0.60 mmol), and $Cs_2CO_3$ (489 mg, 1.50 mmol) in degassed MeOH (25 mL) was stirred overnight at 45 °C. After evaporation of the solvent under reduced pressure, the product was extracted with $CH_2Cl_2$ (30 mL). A small amount of precipitate was observed after addition of hexane (60 mL), which was removed by filtration. The clear solution was concentrated to 15 mL and the resulting precipitate was filtered off and dried in vacuo. The mixed trimer was obtained as an orange powder in 60% yield (126 mg, 0.12 mmol) and 96% purity. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.40 [d, $^3J$ = 7 Hz, 9 H, CH(C$H_3$)$_2$], 1.44 [d, $^3J$ = 7 Hz, 9 H, CH(C$H_3$)$_2$], 2.81 [sept, br, $^3J$ = 7 Hz, 3 H, C$H$(C$H_3$)$_2$], 4.97 (s, 3 H, $C_6H_3iPr_3$), 5.44 (s, 6 H, $C_6H_6$), 5.45 (s, 6 H, $C_6H_6$), 5.62–5.69 (m, 3 H, pyridone), 6.08 (dd, $^3J$ = 7 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.12 (dd, $^3J$ = 7 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.16 (dd, $^3J$ = 7 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.60 (dd, $^3J$ = 6 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.63 (dd, $^3J$ = 6 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.67 (dd, $^3J$ = 6 Hz, $^4J$ = 1 Hz, 1 H, pyridone) ppm. $^{13}$C NMR (101 MHz, $CDCl_3$): $\delta$ = 22.60, 23.28 ($CH_3$), 31.51 (CH), 71.09 ($C_6H_3iPr_3$), 81.60, 81.66 ($C_6H_6$), 107.10 ($C_6H_3iPr_3$), 109.99, 110.24, 110.30, 114.82, 115.09, 115.33, 132.11, 132.81, 133.11, 156.05, 156.28, 157.43, 171.06, 171.07, 171.62 (pyridone) ppm. $C_{42}H_{45}N_3O_6Ru_3\cdot 2CH_3OH$ (1055.12): calcd. C 50.09, H 5.06, N 3.98; found C 49.84, H 4.89, N 4.08.

**Synthesis of Complex [{($C_6Me_6$)Ru}{($C_6H_6$)Ru}$_2$($C_5H_3NO_2$)$_3$] (DCC):** A suspension of [($C_6Me_6$)$RuCl_2$]$_2$ (67 mg, 0.10 mmol), [($C_6H_6$)$RuCl_2$]$_2$ (110 mg, 0.22 mmol), 2,3-dihydroxypyridine (69 mg, 0.60 mmol), and $Cs_2CO_3$ (489 mg, 1.50 mmol) in degassed MeOH (25 mL) was stirred overnight at 45 °C. After evaporation of the solvent under reduced pressure, the product was extracted with $CH_2Cl_2$ (30 mL). A small amount of precipitate was observed after addition of hexane (60 mL), which was removed by filtration. The clear solution was concentrated to 15 mL and the resulting precipitate was filtered off and dried in vacuo. The mixed trimer was obtained as an orange powder in 50% yield (113 mg, 0.10 mmol) and 92% purity. The complex was crystallized from $CHCl_3$/pentane. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 2.16 (s, 18 H, $C_6Me_6$), 5.46 (s, 6 H, $C_6H_6$), 5.48 (s, 6 H, $C_6H_6$), 5.60 (dd, $^3J$ = 7 Hz, $^3J$ = 6 Hz, 1 H, pyridone), 5.67 (t, $^3J$ = 7 Hz, 1 H, pyridone), 5.71 (dd, $^3J$ = 7 Hz, $^3J$ = 6 Hz, 1 H, pyridone), 6.03 (dd, $^3J$ = 7 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.16 (dd, $^3J$ = 7 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.17 (dd, $^3J$ = 7 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.47 (dd, $^3J$ = 6 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.60 (dd, $^3J$ = 6 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.60 (dd, $^3J$ = 6 Hz, $^4J$ = 2 Hz, 1 H, pyridone) ppm. $^{13}$C NMR (101 MHz, $CDCl_3$): $\delta$ = 15.71 ($CH_3$), 81.47, 81.62 ($C_6H_6$), 89.11 ($C_6Me_6$), 109.51, 110.14, 110.53, 113.38, 114.73, 115.05, 131.36, 132.23, 132.21, 156.10, 156.13, 158.39, 170.28, 171.19, 171.76 (pyridone) ppm. $C_{39}H_{39}N_3O_6Ru_3\cdot 2CH_2Cl_2$ (1118.82): calcd. C 44.01, H 3.87, N 3.76; found C 44.27, H 4.53, N 3.95.

**Synthesis of Complex [{Cp*Rh}{($C_6H_6$)Ru}$_2$($C_5H_3NO_2$)$_3$] (ECC):** A suspension of [Cp*$RhCl_2$]$_2$ (62 mg, 0.10 mmol), [($C_6H_6$)$RuCl_2$]$_2$ (150 mg, 0.30 mmol), 2,3-dihydroxypyridine (69 mg, 0.60 mmol), and $Cs_2CO_3$ (489 mg, 1.50 mmol) in degassed MeOH (25 mL) was stirred overnight at 45 °C. After evaporation of the solvent under reduced pressure, the product was extracted with $CH_2Cl_2$ (30 mL). A small amount of precipitate was observed after addition of hexane (60 mL), which was removed by filtration. The clear solution was concentrated to 15 mL and the resulting precipitate was filtered off and dried in vacuo. The mixed trimer was obtained as brown-red powder in 59% yield (114 mg, 0.12 mmol) and 83% purity. The complex was crystallized from toluene/pentane. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.77 (s, 18 H, Cp*), 5.45 (s, 6 H, $C_6H_6$), 5.46 (s, 6 H, $C_6H_6$), 5.65 (t, $^3J$ = 7 Hz, 1 H, pyridone), 5.69 (t, $^3J$ = 7 Hz, 1 H, pyridone), 5.79 (t, $^3J$ = 7 Hz, 1 H, pyridone), 6.10 (dd, $^3J$ = 7 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.19 (dd, $^3J$ = 7 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.23 (dd, $^3J$ = 7 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.62 (dd, $^3J$ = 6 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.64 (dd, $^3J$ = 6 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.73 (dd, $^3J$ = 6 Hz, $^4J$ = 1 Hz, 1 H, pyridone) ppm. $^{13}$C NMR (101 MHz, $CDCl_3$): $\delta$ = 14.26 ($CH_3$), 81.57, 81.77 ($C_6H_6$), 90.32 (d, $^1J$(C,Rh) = 8 Hz, C, Cp*), 109.72, 110.24, 110.96, 113.99, 115.12, 115.21, 131.76, 131.84, 132.38, 156.25, 156.63, 157.93, 169.95, 171.22, 171.88 (pyridone) ppm. $C_{37}H_{36}N_3O_6RhRu_2\cdot CH_3OH\cdot H_2O$ (973.80): calcd. C 46.87, H 4.35, N 4.32; found C 46.57, H 4.59, N 4.29.

**Synthesis of Complex [{($C_6H_3iPr_3$)Ru}$_2$(benzene)Ru}($C_5H_3NO_2$)$_3$] (AAC):** A suspension of [($C_6H_3iPr_3$)$RuCl_2$]$_2$ (151 mg, 0.20 mmol), [($C_6H_6$)$RuCl_2$]$_2$ (50 mg, 0.1 mmol), 2,3-dihydroxypyridine (69 mg, 0.60 mmol), and $Cs_2CO_3$ (489 mg, 1.50 mmol) in degassed MeOH (25 mL) was stirred overnight at 45 °C. After evaporation of the solvent under reduced pressure, the product was extracted with $CH_2Cl_2$ (30 mL). After addition of hexane (60 mL), the solution was concentrated to 15 mL and the resulting precipitate filtered off and dried in vacuo. The mixed trimer was obtained as a brown powder in 45% yield (100 mg, 0.09 mmol) and 90% purity. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 1.16 [d, $^3J$ = 7 Hz, 9 H, CH(C$H_3$)$_2$], 1.33 [d, $^3J$ = 7 Hz, 9 H, CH(C$H_3$)$_2$], 1.38 [d, $^3J$ = 7 Hz, 9 H, CH(C$H_3$)$_2$], 1.52 [d, $^3J$ = 7 Hz, 9 H, CH(C$H_3$)$_2$], 2.81 [sept, $^3J$ = 7 Hz, 3 H, C$H$(C$H_3$)$_2$], 3.22 [sept, $^3J$ = 7 Hz, 3 H, C$H$(C$H_3$)$_2$], 4.86 (s, 3 H, $C_6H_3iPr_3$), 4.90 (s, 3 H, $C_6H_3iPr_3$), 5.39 (s, 6 H, $C_6H_6$), 5.56 (t, $^3J$ = 7 Hz, 1 H, pyridone), 5.61 (t, $^3J$ = 7 Hz, 1 H, pyridone), 5.65 (t, $^3J$ = 7 Hz, 1 H, pyridone), 6.01 (dd, $^3J$ = 7 Hz, $^4J$ = 1 Hz, 1 H, pyridone), 6.03 (dd, $^3J$ = 7 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.12 (dd, $^3J$ = 7 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.57 (dd, $^3J$ = 6 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.63 (dd, $^3J$ = 6 Hz, $^4J$ = 2 Hz, 1 H, pyridone), 6.64 (dd, $^3J$ = 6 Hz, $^4J$ = 1 Hz, 1 H, pyridone) ppm. $^{13}$C NMR (1010 MHz, $CDCl_3$): $\delta$ = 21.48, 22.42, 22.73, 24.19 ($CH_3$), 30.85, 31.64 (CH), 69.27, 69.87 ($C_6H_3$), 81.41 ($C_6H_6$), 107.96, 108.25 ($C_6H_3$), 109.55, 109.63, 110.14, 113.75, 114.12, 114.84, 132.03, 132.92, 133.09, 156.02, 156.64, 157.65, 171.02, 171.47, 171.29 (pyridone) ppm. $C_{51}H_{63}N_3O_6Ru_3\cdot 2CH_2Cl_2$ (1287.13): calcd. C 49.46, H 5.25, N 3.26; found C 49.07, H 5.41, N 3.61.

**X-ray Crystallography:** Details for the crystals and their structure refinement are listed in Table 1 whereas some relevant geometrical parameters are included in the picture captions. Data collection was performed at 140(2) K by means of a Mar345 imaging plate detector. Data reduction was carried out with CrysAlis RED, release 1.7.0.[19] Absorption correction has been applied to both data sets. Structure solution and refinement were performed with the SHELXTL software package, release 5.1.[20] The structures were refined using the full-matrix least-squares on $F^2$ with all non-H atoms anisotropically defined except the toluene molecule of complex **ECC**, which has been retained as isotropic with a fixed geometry. H atoms were placed in calculated positions using the riding model.

CCDC-617057 and -617058 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Complexation Properties of the Di-, Tri-, and Tetraacetate Derivatives of Bis(aminomethyl)phosphinic Acid

Gyula Tircsó,*[a][‡] Attila Bényei,[b] Róbert Király,[a] István Lázár,[a] Róbert Pál,[a] and Ernő Brücher*[a]

**Keywords:** Phosphinic acid derivatives / Divalent metal ions / Synthesis / Protonation constants / Stability constants

Four ligands, which can be considered as di- [both symmetric ($L^1$) and asymmetric ($L^2$)], tri- ($L^3$), and tetraacetate ($L^4$) derivatives of bis(aminomethyl)phosphinic acid ($L^0$) have been synthesized and their complexation equilibria involving $Mg^{2+}$, $Ca^{2+}$, $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, and $Pb^{2+}$ have been studied by pH potentiometry. The first two protonation constants of the ligands are lower than those of the analogous diaminopolycarboxylates due to the electron-withdrawing effect of the phosphinate group. The asymmetric ligands $L^2$ and $L^3$ and their complexes are protonated first at the primary ($NH_2$) and secondary (NH) amine groups, respectively. The ligands $L^0$, $L^1$, $L^2$, and $L^3$ form the species ML, MLH, $ML_2$, and $ML_2H$ whereas heptadentate $L^4$ forms very stable ML complexes, protonated (MLH and $MLH_2$) species and, unlike the other ligands, it also forms dinuclear $M_2L$ complexes. The stability constants of the complexes of $L^0$, $L^1$, $L^2$, and $L^3$ are generally lower, while those of the $L^4$ are similar or higher, than those of the analogous diaminocarboxylate derivatives. The phosphinate group is not directly coordinated to the metal ions but may contribute to the stability by increasing the electrostatic interaction, which is significant for the complexes of $L^4$. The $^1H$ NMR spectra of complexes $ZnL^2$, $ZnL^3$, and $ZnL^4$ show an AB multiplet pattern for the protons of the iminodiacetate moiety of the ligands, which indicates the long half-life of the $Zn^{2+}$–N bond and the rigid structure of this segment of the complexes. The solid-state structure of the ligand $[H_5L^3]Cl$ and complex $K[CuL^1]\cdot H_2O$ have been determined by X-ray diffraction techniques. The arrangement of the ligand $L^1$ is square planar around $Cu^{2+}$ with two nitrogen and carboxylate oxygen donor atoms, although the axial proximity of a carboxylate and a phosphinate oxygen atom in two neighboring molecules results in a distorted octahedral coordination.

## Introduction

Due to their biological importance there has been a growing interest in recent years in the coordination chemistry of ligands containing phosphinate functional groups.[1] The charge of the phosphinate group, $PO_2^-$, is minus one, similar to that of the carboxylate, and thus the complexation properties of aminoalkylphosphinate ligands are similar to those of aminocarboxylates in many respects. However, as phosphinate groups are less basic than carboxylates, the stability constants of the complexes formed with aminoalkylphosphinates are lower than those of aminocarboxylates.[2–8]

The successful use of some tri- and tetraacetate derivatives of cyclen in medical diagnosis and therapy has drawn attention to the tetramethylenephosphinates of cyclen, and a number of cyclen derivatives have been synthesized with different phosphinate functional groups. The $Gd^{3+}$ complexes of these ligands have been proposed as contrast enhancing agents in magnetic resonance imaging.[9–15] Since the methylenephosphinate groups [$CH_2P(R)O_2^-$, where R is H, alkyl, or aryl] in these cyclen derivatives are attached to the ring nitrogens, the phosphinate groups are in terminal position, similar to open-chain ligands. However, in contrast to the carboxylate and phosphonate groups, phosphinate groups may also occupy an "in-chain" position and some multidentate aminocarboxylate ligands that contain $PO_2^-$ groups as linkers have attracted considerable interest in recent years.[16–26] Phosphinic acid peptides are specific inhibitors of peptide hydrolytic enzymes (e.g. Zn metalloproteinases and aspartic acid proteinases) because the non-hydrolyzable $>PO_2^-$ moiety resembles the transition state of the hydrolyzable peptides.[18,19]

The complexation properties of bis(aminomethyl)phosphinic acid and some of its derivatives have already been investigated. Complex formation between the ligands bis(aminomethyl)-, bis(*N*-methylsarcozinato)-, bis(*N*-methyl-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

prolinato)-, and bis(*N*-methyliminodiacetato)phosphinate and some divalent metal ($Co^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, $Pb^{2+}$) and lanthanide(III) ($Ln^{3+}$) ions has been studied in solution by pH potentiometry and $^1H$ NMR and EPR spectroscopy.[20–24] Although the coordination of the phosphinate group to $M^{2+}$ ions has been detected in some cases, it is more important in the formation of complexes with $Ln^{3+}$ ions.[21,22] The $PO_2^-$ group has also been incorporated into macrocyclic rings. Eight- and fourteen-membered functionalized bis(aminomethyl)phosphinate macrocycles have recently been synthesized by Aime et al. and Song et al., respectively.[25,26] The stability constant of the $Gd^{3+}$ complex formed with the eight-membered diphosphinate ligand was found to be relatively high ($\log K_{GdL} = 17.6$).[25] The fourteen-membered ligand does not form highly stable complexes.[26]

The ligand $HL^0$ (Scheme 1) was first synthesized by Maier and somewhat later by Natchev.[27,28] More recently, Kubiček et al. have published a new procedure for the synthesis of $HL^0$ and they also studied its $Co^{II}$, $Ni^{II}$, $Cu^{II}$, and $Zn^{II}$ complexes in solution and in the solid state.[24] The ligand $H_3L^1$ was also prepared by Maier but its complexation was studied only with $Ni^{II}$.[29] The same author prepared the ligand $H_5L^4$ from the reaction of iminodiacetic acid ($H_2$imda) and paraformaldehyde in the presence of hypophosphorus acid.[30] Similar conditions were used previously in our laboratory by Varga to obtain some bis(aminomethyl)phosphinic acid derivatives from various imino(di)acids.[20] The experimental conditions were found to have a great influence on these reactions. Thus, high concentrations of the reactants at reflux temperature led to the formation of a number of by-products and purification of the final products was difficult.[20]

Scheme 1. Structure of the ligands synthesized and investigated in this work.

One of our goals was to find a procedure which would allow the large-scale preparation of bis(aminomethyl)phosphinic acid derivatives from readily available, inexpensive starting materials without expensive instrumental purification methods. Similarly, the bis(aminomethyl)phosphinic acid itself can be considered as a building block for the synthesis of macrocycles containing linker phosphinate group(s) when the macrocycle itself has a negative charge. By dividing the Mannich-type synthesis into two consecutive steps we have successfully synthesized the ligands $H_3L^1$, $H_3L^2$, and $H_3L^3$ (Scheme 1). These compounds can be regarded as fragments of the edta analog $H_5L^4$, which was reported earlier.[21,22] In the present study, the stability constants of the complexes formed between some endogenous ($Mg^{2+}$, $Ca^{2+}$, $Cu^{2+}$, and $Zn^{2+}$) and toxic ($Ni^{2+}$, $Cd^{2+}$, and $Pb^{2+}$) divalent metal ions and bis(aminomethyl)phosphinic acid derivatives are examined by pH potentiometry. The structures of the ligand $[H_5L^3]Cl$ and the complex $K[CuL^1]\cdot H_2O$ have been determined in the solid state by X-ray diffraction methods and the $Zn^{2+}$ complexes studied by $^1H$ and $^{31}P$ NMR spectroscopy in solution.

## Results and Discussion

### Synthesis of the Ligands

Synthesis of the symmetric bis(aminomethyl)phosphinic acid derivatives was achieved in a multi-step reaction starting from *N*,*N*-dibenzylamine according to Scheme 2. The monohydrochloride of the intermediate **1** was obtained in high yields by a Mannich reaction in 6 M HCl. The debenzylation of this key intermediate by catalytic hydrogenolysis can be carried out in different ways depending on the solvent selected. Using acetic acid/water as a solvent in the presence of EtOH with slight heating to achieve complete dissolution of the starting material the bis(aminomethyl)-phosphinic acid hydrochloride **2** could be prepared in very high yields. Another advantage of this synthesis is that it does not use expensive materials or instrumentation and can be scaled up easily. The debenzylation of **1** in MeOH in the presence of formic acid was found to be controlled by solubility and the hydrochloride salt of the selectively protected bis(benzylaminomethyl)phosphinic acid **3** crystallized out quantitatively from the reaction mixture during the reduction process. An analytical sample of **3** was obtained by recrystallization of crude **3** from hot water. Compound **3** proved to be a valuable intermediate for the synthesis of new carboxy- or phosphonomethyl derivatives of bis(aminomethyl)phosphinic acid. Alkylation of **3** with bromoacetic acid in the presence of NaOH afforded the trisodium salt of **4**. The monohydrochloride salt of the free acid was prepared by crystallizing **4** from fairly acidic solutions ($pH < 2$). Debenzylation of **4** in a water/acetic acid mixture afforded compound **5** ($H_3L^1$).

The synthesis of the asymmetric bis(aminomethyl)phosphinic acid derivatives **7**–**10** is presented in Scheme 3. They are all new compounds that have not been published previously. The intermediate **6** was obtained from the reaction of iminodicarboxylic acid with paraformaldehyde in a Mannich-type reaction in ethanol in the presence of excess hypophosphorus acid, which also acts as an acid catalyst. In this particular case (when $H_2$imda was used as starting material), the reaction was found to be solubility controlled and at the end of the reaction the product crystallized out from the reaction mixture. The remaining P–H bond in the molecule can be reacted further in a second Mannich-type reaction in 6 M HCl to replace the H with another aminomethyl

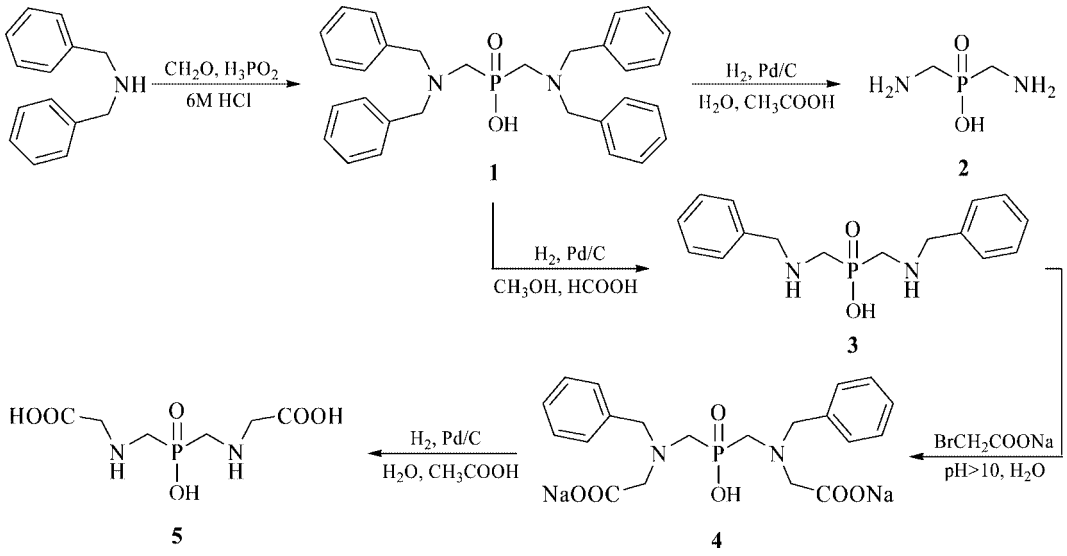

Scheme 2. Synthesis of the symmetric bis(aminomethyl)phosphinic acid derivatives studied in this work.

segment. This process allowed us to synthesize hitherto unknown asymmetric bis(aminomethyl)phosphinic acid derivatives (Scheme 3). The best yields for this reaction were obtained when short reaction times (about 1.5 h) were used as the number of by-products in the reaction mixture increased with an increase of the reaction time while the amount of desired products (**7** and **9**) decreased. When longer reaction times (up to 6 h) were used the reaction mixtures yielded compounds **4** and $H_5L^4$, respectively, after the workup and separation procedure. The formation of these compounds is evidence that the phosphorus–carbon bond [$CH_2P(O)(OH)H$] is not stable under Mannich conditions and *trans*-aminomethylation occurs. The debenzylation of **7** and **9** to **8** ($H_4L^3$) and **10** ($H_3L^2$), respectively, was achieved by catalytic hydrogenation under similar conditions to those described for compound **2**.

### X-ray Crystal Structure of $[H_5L^3]Cl$ and $K[CuL^1]\cdot H_2O$

The structures of $[H_5L^3]Cl$ and $K[CuL^1]\cdot H_2O$ were established by single-crystal X-ray diffraction studies (see Figures 1 and 2, Tables 1 and 2, and the Supporting Information). The most important feature of the structure of the protonated ligand of $[H_5L^3]Cl$ is the extensive H-bonding network (Table S1) and the related disordered position of the chloride ions (see below). The compound crystallizes in the noncentrosymmetric space group $Pn2_1a$ (no. 33). It is important to note that the position of the carboxylate hydrogen atoms as well as the protons at the nitrogen atoms could be found in the difference electron density maps of both structures. However, these hydrogen atoms were placed in geometric positions in the final refinement cycle. The C–O bond length data (Table 3) of $[H_5L^3]Cl$ show C3–O4, C6–O6, and C8–O8 bond lengths of 1.298(10), 1.316(9), and 1.310(10) Å, respectively, which also indicate the sites of protonation. Besides the electronic and steric factors of the phosphinate moiety, the higher values of the P–C bond lengths compared to C–C bonds as well as the slightly different bond angles are another tool for the fine tuning of the ligand that could be important in applications. For example, the water exchange rate and thereby the relaxivity of $Gd^{III}$ complexes formed with poly(amino)carboxylates depends on the steric crowding in the complex.[31] In our case, the significant difference between the P1–C1 and P1–C4 distances [1.803(7) and 1.821(8) Å, respectively] also shows the electronic and steric effects of the mono- and bis(diacatate) arms on the N1 and N2 nitrogen atoms, respectively as these bond lengths are the same in the analogous symmetric bis(aminomethyl)phosphinate hydrochloride structure.[24]

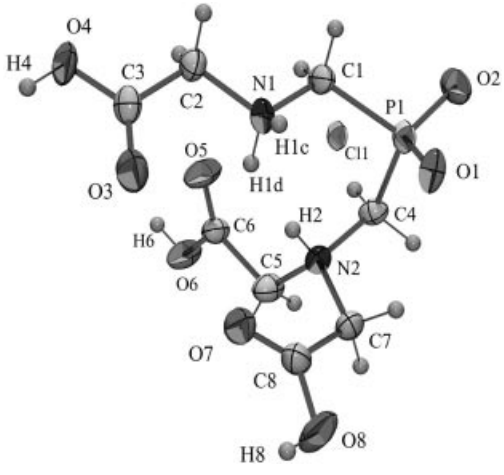

Figure 1. ORTEP view of the asymmetric unit in the structure of $[H_5L^3]Cl$ with thermal ellipsoids at the 50% probability level, with atom-numbering scheme.

The packing of $[H_5L^3]Cl$ is shown in Figure S1 and the data of the H-bonding network are listed in Table S1 (see Supporting Information). The high max/min atomic displacement parameter ratio of the chloride ions in the structure of $[H_5L^3]Cl$ can be explained by the fact that the chloride ion is not fixed in the lattice but loosely occupies a polar channel. Strong N–H···Cl hydrogen bonds fix the anion in the analogous layered structure of bis(aminomethyl)phosphinate hydrochloride, although the long range Cl–Cl distances are similar in the two structures (approx. 3.96 Å). In our case, however, the three strong hydrogen bonds with the participation of carboxylate donors and P1–O1 or P1–O2 as acceptors as well as the steric restraints prevent the formation of N–H···Cl hydrogen bonds (Table S1).

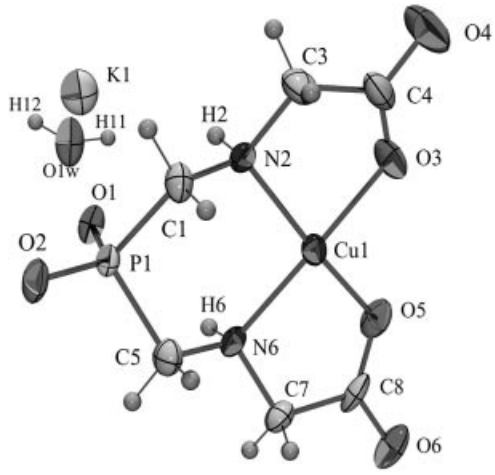

Figure 2. ORTEP view of the asymmetric unit in the structure of $K[CuL^1]\cdot H_2O$ with thermal ellipsoids at the 50% probability level, with atom-numbering scheme.

$K[CuL^1]\cdot H_2O$ crystallizes in the trigonal centrosymmetric space group $R\bar{3}$ (no. 148). The configuration of the nitrogen atoms N2 and N6 is mixed, and the complex exists as a racemate with equal amounts of (*R*,*S*) and (*S*,*R*) enantiomers present in the lattice. Selected bond lengths and angles are summarized in Table 2. The coordination of the $Cu^{2+}$ in $K[CuL^1]\cdot H_2O$ is best described as elongated distorted octahedral. N2, N6, O3, and O5 form the basal square-planar coordination and the copper is positioned out of this plane by 0.211 Å. The carboxylate oxygen atom $O5^{i}$ and phosphinate oxygen atom $O2^{ii}$ of symmetry-related molecules (i: $-x, -y, -z$; ii: $y + 1/3, -x + y + 2/3, -z + 2/3$) are coordinated in the axial positions with Cu–O distances of 2.945 and 2.249 Å, respectively. In this way, two O5 atoms serve as bridging ligands that hold together two copper complexes with a Cu–Cu distance of 3.827 Å and give rise to a supramolecular polymer structure. This bridging role of O5 also supports an octahedral rather than a square-pyramidal coordination. The coordination of O2 of the next complex in the lattice can be attributed to the electron-withdrawing properties of the phosphinate group as well as the increase in the length of the side arm due to the P–C bonds.

The hydrogen-bond data are summarized in the Supporting Information (Table S2). In this web, the H2 and H6 participate in bifurcating hydrogen bonds while O1 is a bifurcating acceptor. However, the N2–H2···O1 hydrogen bond has an unfavorable angle of 107°.

Tetradentate ligands analogous to 1,3-propanediamine-*N*,*N*′-diacetate can form square-pyramidal copper(II) complexes.[32] However, a search in the Cambridge Structural Database (version 5.27, November 2005; update May 2006) revealed that octahedral coordination may also occur in similar compounds.[33] This is especially important in the case of a $Cu^{II}$ complex containing a small, sterically undemanding ligand such as in (3-hydroxy-1,5-diazacycloheptane-*N*,*N*′-diacetato)copper(II), where the coordination is N2O4.[34] Here, the hydroxyl oxygen and a water molecule complete the octahedral coordination with Cu–O distances of 2.456 and 2.564 Å, respectively. The deposited data do not contain hydrogen atoms, which may indicate some ambiguity, but similar octahedral coordination has also been observed in another case where an axial water molecule and another axial carboxylate oxygen complete the coordination sphere of the copper ion with Cu–O distances of 2.275 and 2.780 Å, respectively.[35]

The coordination of potassium is also octahedral, with carboxylate, phosphinate, and water oxygen atoms ($O6^{i}$, $O6^{iii}$, O4, O1, O1w, and $O1w^{iv}$; i: $-x, -y, -z$; iii: $x - y + 1/3, -x + 2/3, -z + 2/3$; iv: $-y + 2/3, x - y + 1/3, z + 1/3$) with K···O distances in the range o2.65–3.01 Å. O6 and O1w serve as bridges between the potassium ions and the K···K distance is 4.046 Å. Altogether, the complicated supramolecular structure of $K[CuL^1]\cdot H_2O$ is stabilized by interpenetrating ionic and coordination interactions as well as a strong hydrogen bond network. In the polymer there are hexagonal channels with a diameter of approximately 8.5 Å (Figure S2, Supporting Information), which are filled with disordered water molecules.

**Protonation Constants and Protonation Sites of the Ligands**

The protonation equilibria of the ligands, $L^0$, $L^1$, $L^2$, $L^3$, and $L^4$ were studied by pH-potentiometry and $^1H$ (in some cases $^{31}P$) NMR spectroscopy (Figures S3–S7 in the Supporting Information). The titrations were performed in the pH range of about 1.8–11.5 in the presence of 1.0 M $Me_4NCl$. The protonation constants, defined as $K_i^H = [H_iL]/[H_{i-1}L][H^+]$, were also determined in 1.0 M $KNO_3$ since the complexation with $Cd^{2+}$ and $Pb^{2+}$ was studied in $KNO_3$ solution in order to avoid the formation of chloro complexes. For the calculation of the protonation constants of the ligands, the number of data points was between 160 and 250. The $\log K_i^H$ values obtained are presented in Table 3, where the standard deviations are shown in parentheses. The protonation constants of the ligands $L^0$ and $L^4$, which have been determined previously (Table 3),[22–24] are comparable with the ones obtained in this work when the different experimental conditions are taken into account.

As was expected, we found by $^1H$ (and $^{31}P$) NMR studies that the most basic donor atoms in all derivatives of $L^0$ are the two nitrogens, which are protonated first (Figures S4 and S5).[21,22,24] The protonation of these nitrogens is followed by protonation of the carboxylates, while the strongly acidic phosphinate group is protonated only in strongly acidic solution.[22,24] The protonation constants of $L^0$ are lower than those of 1,3-diaminopropane ($\log K_1^H = 10.52$ and $\log K_2^H = 8.74$), in which the two nitrogen donors are also separated from each other by three atoms. The behavior of the derivatives of $L^0$ is similar. The first two protonation constants of $L^4$ (Table 3) are significantly lower than those of 1,3-diaminopropane-*N*,*N*′,*N*′′,*N*′′′-tetraacetic acid (10.41 and 8.02).[36] Similarly, the $\log K_1^H$ and $\log K_2^H$ values of $L^1$ are lower than the first two protonation constants of ethylenediamine-*N*,*N*′-diacetic acid ($L^6$; 9.69 and 6.72).[36] The lower basicity of the nitrogen atoms of the phosphinate ligands is probably due to the electron-withdrawing effect of the phosphinate group.

Table 3. Protonation constants of the ligands $L^0$, $L^1$, $L^2$, $L^3$, and $L^4$ (25 °C).

A comparison of the data in Table 3 reveals that the difference between the protonation constants $\log K_1^H$ and $\log K_2^H$ is lower for the symmetric ligands $L^0$, $L^1$, and $L^4$ than for asymmetric $L^2$ and $L^3$, which show a larger difference in the basicity of the nitrogen atoms. Parallel with this finding, the question arises regarding the protonation order of the nitrogens in the asymmetric ligands $L^2$ and $L^3$. The protonation scheme of $L^2$ and $L^3$ was determined by $^1$H NMR titrations in the pH range of about 1–12. The $^1$H NMR titration curves of ligands $L^2$ and $L^3$ are shown in Figures 3 and 4, respectively. In Figure 3, the chemical shift of the -C$H_2$NH$_2$ methylene protons (the center of the doublet) increases with a decrease of pH from about 12 to 8.5, while the signals of both the phosphinate and acetate methylene protons [-C$H_2$N(C$H_2$COO$^-$)$_2$] are practically not shifted. This finding indicates that the first proton is attached to the $NH_2$ group of $L^2$. In the pH range of about 4 to 7 the signals of both the phosphinate and acetate methylene protons [-C$H_2$N(C$H_2$COO$^-$)$_2$] are strongly shifted to higher frequencies due to the protonation of the imda nitrogen. A further decrease of pH below about 3 results in a shift of the signal of the acetate methylene protons to higher frequencies, which indicates the protonation of the carboxylate groups.

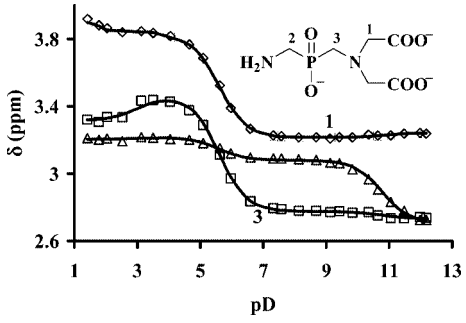

Figure 3. $^1$H NMR titration curves of ligand $L^2$ ($C_L$ = 0.05 M, 25 °C) showing the change in the chemical shifts of the protons indicated in the figure.

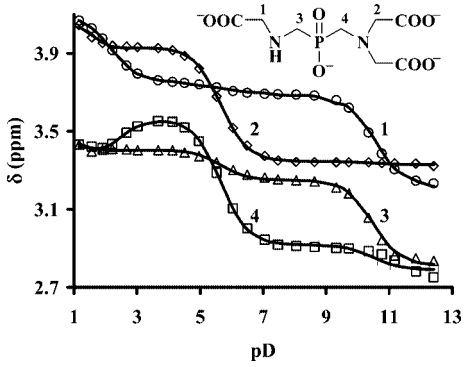

Figure 4. $^1$H NMR titration curves of ligand $L^3$ ($C_L$ = 0.05 M, 25 °C) showing the change in the chemical shifts of the protons indicated in the figure.

In Figure 4, a decrease of the pH from about 12 to 8 leads to a significant change in the chemical shifts of the glycinate and phosphinate methylene protons (-C$H_2$NHC$H_2$COOH), which indicates the protonation of the glycinate nitrogen of $L^3$. In the pH range 4–7 a strong change can be observed in the chemical shifts of the imda and phosphinate methylene protons, which shows that the second proton is attached to the nitrogen of the imda group. At a pH of around 3.5 the signal of the glycinate methylene protons starts to move to higher frequencies due to the protonation of the glycinate carboxylate.

The protonation constants $\log K_1^H$ determined in $KNO_3$ solution are generally lower than those obtained in $Me_4NCl$ solution, and the $\log K_1^H$ value of $L^4$ determined in NaCl solution is even lower. These results indicate that at higher pH values the ligands form very poorly stable complexes with $K^+$ and somewhat more stable complexes with $Na^+$ ions.

### Stability Constants of the Complexes

To characterize the complexation properties of $L^0$, $L^1$, $L^2$, $L^3$, and $L^4$ the formation equilibria between these ligands and the metal ions $Mg^{2+}$, $Ca^{2+}$, $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, and $Pb^{2+}$ were studied by pH potentiometry. The titrations were performed at three or four different metal-to-ligand concentration ratios. The number of data points for the calculations were usually between 250 and 500. Some typical titration curves are presented in Figure 5, which shows the formation of complexes with $L^1$. The equilibrium models used for the calculation of the stability constants were selected on the basis of the properties of the metal ions and the ligands by taking into consideration the quality and number of the donor atoms. The results of the EPR study of the $Cu^{2+}$ complexes with $L^0$, $L^1$, and $L^4$ were also used to assume the species formed in these systems.[23] For characterizing the solution equilibria, the formation of the following complexes was considered: $MLH_2$, MLH, ML, M(OH)L, $ML_2H$, $ML_2$, and $M_2L$. The stability constants that describe the equilibria were defined as follows (the charges of the species have been omitted for simplicity):

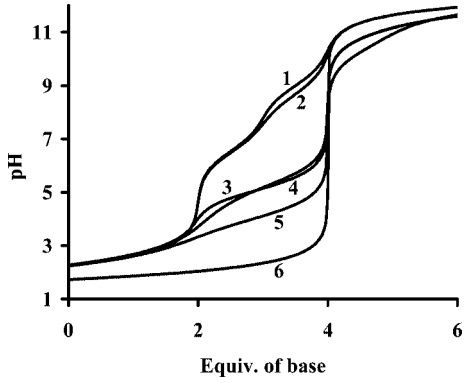

Figure 5. Titration curves of a $5 \times 10^{-3}$ M solution of $L^1$ in the absence of metal ions (1) and in the presence of one equivalent of $Ca^{2+}$ (2), $Pb^{2+}$ (3), $Cd^{2+}$ (4), $Zn^{2+}$ (5), and $Cu^{2+}$ (6).

$$K_{ML} = \frac{[ML]}{[M][L]} \quad ; \quad K_{ML}{}^{H} = \frac{[MLH]}{[ML][H]}$$

$$K_{MLH}{}^{H} = \frac{[MLH_2]}{[MLH][H]} \quad ; \quad K_{M(OH)L} = \frac{[M(OH)L][H]}{[ML]}$$

$$K_{ML_2} = \frac{[ML_2]}{[ML][L]} \quad ; \quad K_{ML_2}{}^{H} = \frac{[ML_2H]}{[ML_2][H]}$$

$$K_{M_2L} = \frac{[M_2L]}{[ML][M]}$$

The equilibrium constants $\beta_{pqr} = [M_pH_qL_r]/[M]^p[H]^q[L]^r$ were calculated with the program PSEQUAD.[37] Tables 4, 5, 6, and 7 present the stepwise stability constants related to the formation of ML, $ML_2$ and $M_2L$ complexes as calculated from the $\beta_{pqr}$ values. We also calculated the protonation constants of the complexes, $K_{ML}{}^{H}$, $K_{MHL}{}^{H}$, and $K_{ML_2}{}^{H}$ because these values give some information about the site of protonation (nitrogen or carboxylate oxygen). By fitting the titration data to the assumed equilibrium model we obtained the equilibrium constants $\beta_{pqr}$ and also the standard deviation values (given in parentheses in Tables 4–7).

Table 4. Stability constants of the complexes formed between $L^0$ and $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$ (25 °C, 1.0 M $Me_4NCl$), $Cd^{2+}$, and $Pb^{2+}$ (25 °C, 1.0 M $KNO_3$).

[a] $I$ = 0.1 M $KNO_3$.[24] [b] $I$ = 1.0 M $Me_4NCl$.[23]

### *Complexes of L⁰*

The formation of complexes between the $L^0$ and $Mg^{2+}$ or $Ca^{2+}$ could not be detected by pH potentiometry up to a pH of around 10. This is probably due to the fact that the nitrogens of the two $NH_2$ groups do not coordinate to $Mg^{2+}$ or $Ca^{2+}$ and the binding of the phosphinate oxygen is very weak. The titration curves obtained in the presence of $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, and $Pb^{2+}$ can be interpreted by assuming the formation of complexes ML and $ML_2$ and the protonated species MLH and $ML_2H$. The possible formation of hydroxo complexes was taken into consideration when calculating the stability constants by using the equilibrium constants known for the species $M(OH)^+$.[38] The stability constants of the complexes of $Ni^{2+}$, $Cu^{2+}$, and $Zn^{2+}$ determined by Kubiček et al. and in our laboratory are similar (Table 4). The $\log K_{ML}$ and $\log K_{ML_2}$ values are lower than those of the complexes formed with 1,3-diaminopropane ($L^5$). The stability constants ($\log K$) of the species ML, $ML_2$, and $ML_3$ formed, for example, between $Ni^{2+}$ and $Cd^{2+}$ and $L^5$ are 6.47, 4.43, and 1.2 and 4.50, 2.70, and 0.8, respectively.[36] The lower stabilities of the complexes of $L^0$ indicate that the phosphinate group does not play a role in the complexation. It is more probable that $L^0$ is coordinated to the two N donor atoms to form a six-membered chelate ring.[24] However, the ligand $L^5$ forms $ML_3$ species and the absence of the formation of 1:3 complexes with $L^0$ shows that some weak interaction may exist between the metal ion and the phosphinate group and the steric requirement of the $L^0$ is larger than that of $L^5$, which hinders the coordination of a third $L^0$ ligand.

The $K_{ML}{}^{H}$ and $K_{ML_2}{}^{H}$ protonation constants of the complexes are relatively large (Table 4), which suggests that the protonation occurs at one of the two $NH_2$ groups while the ligand $L^0$ is coordinated only through its other $NH_2$ group. The negatively charged phosphinate group may contribute to the stability of the protonated complex.

### *Complexes of L¹ and L²*

The ligands $L^1$ and $L^2$ possess two amine nitrogens, two carboxylate oxygens, and one phosphinate oxygen as donor atoms. The structure of $L^1$ and the asymmetric $L^2$ resemble the structure of ethylenediamine-*N*,*N*′-diacetate ($L^6$) and ethylenediamine-*N*,*N*-diacetate ($L^7$), with the difference that the latter do not contain a phosphinate moiety. For comparison, therefore, the diacetate derivatives of 1,3-diaminopropane would be more suitable, but unfortunately these ligands have not been studied to date. The titration data obtained for $L^1$ in the presence of $Mg^{2+}$, $Ca^{2+}$, $Ni^{2+}$, and $Cu^{2+}$ can be interpreted by assuming the formation of the species ML only, while $Zn^{2+}$, $Cd^{2+}$, and $Pb^{2+}$ form hydroxo complexes M(OH)L and very weak $ML_2$ complexes as well at a pH above 9. The stability constants are shown in Table 5. Ligand $L^1$ has been prepared earlier and the stability constant of its $Ni^{2+}$ complex, $\log K_{NiL}$ = 12.24, agrees well with the value found by us (Table 5).[17] The stability constants of the ML complexes formed with $L^1$ are somewhat lower than those formed with $L^6$ (the $\log K_{ML}$ values for the complexes of $L^6$ formed with $Mg^{2+}$, $Ni^{2+}$, $Zn^{2+}$, and $Cd^{2+}$ are 3.95, 13.65, 11.22, and 8.99, respectively).[36] The lower $\log K_{ML}$ values of the complexes can be interpreted as being due to the lower protonation constants of the ligand $L^1$ (the protonation constants for $L^6$ are 9.69, 6.72, 2.37, and 1.66).[36] Considering these findings, it is surprising that the stability constant $\log K_{ML}$ of the $Cu^{2+}$ complex of $L^1$ is higher than that of $CuL^6$ ($\log K_{CuL}$ = 16.2).[36] This unexpected result can not be interpreted by assuming participation of the phosphinate group in the complexation. It is more likely that the formation of two five-membered ($>NCH_2COO^-$) and a six-membered ($>NCH_2PO_2-CH_2N<$) chelate ring around the $Cu^{2+}$ ion leads to a more stable square-planar arrangement than the coordination of $L^6$, which involves the formation of three five-membered chelate rings. Similar results are known for the formation

[a] Ref.[23] [b] The stability constants of $ML_2$ complexes formed with $L^1$ are as follows: $\log K_{ZnL_2}$ = 1.94 (0.06), $\log K_{CdL_2}$ = 2.47 (0.05), $\log K_{PbL_2}$ = 2.95 (0.04). [c] The studies with $Cd^{2+}$ and $Pb^{2+}$ were performed in 1.0 M $KNO_3$.

of $Cu^{2+}$ complexes with *N*,*N*′-bis(2-aminoethyl)dimethylenediamine ($\log K_{CuL}$ = 23.9) and triethylenetetramine ($\log K_{CuL}$ = 20.1).[36]

The structure and donor atoms of ligand $L^1$ and those of bis(*N*-methylsarcosinato)phosphinic acid, which was synthesized previously in our laboratory, are similar, although the stability constants of the complexes formed with $L^1$ are higher.[20,21] This difference is probably a result of the steric hindrance caused by the two methyl groups attached to the nitrogen donor atoms of the bis(*N*-methylsarcosinato)phosphinate ligand.

The titration data obtained for $L^2$ in the presence of the metal ions were interpreted by assuming the formation of the species ML, MLH, $ML_2$, and M(OH)L. The stability constants of ML complexes are generally higher than those of the complexes of $L^1$. The only exception is complex $CuL^2$, which exhibits much lower stability than $CuL^1$. This difference in the behavior of $Cu^{2+}$ complexes is understandable if we take into account the propensity $Cu^{2+}$ to form square-planar complexes. The other metal ions studied prefer octahedral (or some other) geometry. Due to its linear structure, $L^1$ forms a high stability square-planar complex with $Cu^{2+}$. The ligand $L^2$ can not occupy four coordination sites in one plane if the phosphinate is not involved in complexation. For metal ions other than $Cu^{2+}$, the coordination of the two nitrogen and two carboxylate oxygen donor atoms of $L^2$ is possible at four apices of an octahedron, which results in relatively high $\log K_{ML}$ values. The fourth coordination site of $CuL^2$ in the equatorial position is probably occupied by a water molecule as, in contrast to $CuL^1$, $CuL^2$ starts to hydrolyze at about pH 8.

All the metal ions except $Cu^{2+}$ and $Zn^{2+}$ form $ML_2$ complexes with $L^2$. The $\log K_{ML_2}$ values are much lower than those for ligand $L^7$ (the $\log K_{ML_2}$ values for the $ML_2$ complexes of $Ni^{2+}$ and $Cd^{2+}$ are 5.91 and 6.01, respectively).[36] The low $\log K_{ML_2}$ values indicate that the first ligand probably coordinates in the equatorial plane and hinders the coordination of the second ligand. As a result, the second ligand is coordinated through only two donor atoms for steric reasons.

### *Complexes of $L^3$ and $L^4$*

Ligands $L^3$ and $L^4$ are structurally similar. While the symmetric $L^4$ possesses two nitrogen, four carboxylate, and one phosphinate oxygen donor atoms, the asymmetric $L^3$ contains only three carboxylate groups. Because of its heptadentate nature, $L^4$ does not form $ML_2$ complexes, and the $ML_2$ species formed with hexadentate $L^3$ have very low stability ($Cu^{2+}$ does not even form such a complex). The $L^3$ ligands in the $ML_2$ complexes are probably coordinated through their imda groups and the coordination of two imda groups is more favorable than formation of the ML complex.

The titration data obtained for the ligand $L^3$ in the presence of metal ions can be interpreted by the formation of the complexes MLH, ML, M(OH)L, $ML_2$, and $ML_2H$. The calculated stability constants are presented in Table 6. The $\log K_{ML}$ values are significantly lower than those of the hexadentate edta (ethylenediamine-*N*,*N*,*N*′,*N*′-tetraacetate). The only exception is $CuL^3$, whose stability constant is similar to that of $Cu(edta)^{2-}$ ($\log K_{CuL}$ = 18.80).[36]

The $\log K_{ML}$ values of the complexes $CuL^3$ and $CuL^1$ are practically identical, which suggests that $L^3$ is coordinated to $Cu^{2+}$ through two nitrogen and two carboxylate oxygen donor atoms and that the third carboxylate (and phosphinate) group does not participate in the complexation. The protonation constant of the complex $CuL^3$ is very low, which indicates protonation of the free carboxylate. The protonation constants of the other complexes of $L^3$ are higher (particularly those of $MgL^3$ and $CaL^3$) as in these species the nitrogen atom of the glycinate is most likely protonated.

In an earlier study of complexes of the ligand $L^4$ with some divalent metal ions the formation of ML and MLH species was assumed.[21] The results of a recent, more detailed pH potentiometric titration study were interpreted by the formation of ML, MLH, $MLH_2$, and $M_2L$ species. The number of data points used for the calculations, which were obtained at three or four metal-to-ligand ratios, are given in parenthesis for the respective metals as follows: $Mg^{2+}$ (338), $Ca^{2+}$ (355), $Ni^{2+}$ (347), $Cu^{2+}$ (665), $Zn^{2+}$ (513), $Cd^{2+}$ (476), and $Pb^{2+}$ (493). The calculated stability constants as well as the data reported for the analogous propylenediamine-*N*,*N*,*N*′,*N*′-tetraacetate ($L^8$) are shown in Table 7. We have also determined the protonation constants of $L^8$ and found that at 25 °C in 1.0 M KCl the $\log K_i^H$ values are 10.50 (0.03), 8.17 (0.04), 2.78 (0.05), and 1.96 (0.05). These $\log K_i^H$ values are significantly higher than those of $L^4$

[a] Propylenediamine-*N*,*N*,*N*′,*N*′-tetraacetate.[36] [b] Ref.[23] [c] The studies with $Cd^{2+}$ and $Pb^{2+}$ were performed in 1.0 M $KNO_3$.

(Table 3). In spite of the lower protonation constants, the stability constants of the complexes of $L^4$ are very similar or higher than those of $L^8$. The phosphinate oxygen is not coordinated directly to the metal ion and the high stability constants probably result from the higher negative charge of the ligand and the two coordinated imda groups, which pull the phosphinate closer to the metal ion. However, the complexes of smaller and larger metal ions ($Ni^{2+}$, $Cu^{2+}$, and $Zn^{2+}$ vs. $Cd^{2+}$and $Pb^{2+}$) behave differently, which is particularly evident when the stability constants are compared with those of the edta complexes. The $\log K_{ML}$ values for the edta complexes of $Zn^{2+}$ and $Pb^{2+}$ are 16.50 and 18.04, respectively, while ligand $L^4$ shows an unexpectedly high selectivity for $Zn^{2+}$ over $Pb^{2+}$ ($\log K_{ML}$ values of 15.94 and 11.29, respectively; Table 7). These results can be interpreted according to Hancock, who found that larger metal ions prefer five-membered chelate rings while smaller metal ions form high stability complexes with both five- and six-membered chelate rings.[39] In the dinuclear complexes formed with $L^4$ both metal ions are attached to an iminodiacetate group of the ligand, as was found for the $Cu^{2+}$ complexes by EPR spectroscopy.[23] The formation of dinuclear complexes was also unambiguously detected by pH potentiometry. Typical titration curves obtained in the presence of one and two equivalents of $Pb^{2+}$ are shown in Figure 6. Because of the strong competition between protons and $Pb^{2+}$ in the presence of one extra equivalent of $Pb^{2+}$, the buffer region observed at a 1:1 metal-to-ligand ratio disappears completely, which indicates the formation of dinuclear species in solution. The $K_{ML}^{H}$ protonation constants imply the protonation of the acetate group in the complexes of $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, and $Cd^{2+}$ while the protonation is more probable at a nitrogen in the complexes of $Mg^{2+}$, $Ca^{2+}$, and $Pb^{2+}$.

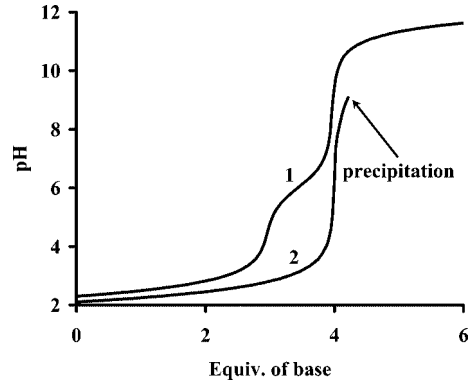

Figure 6. Titration curves of $5 \times 10^{-3}$ M solutions of $L^4$ in the presence of one (1) and two equivalents (2) of $Pb^{2+}$ ions ($I$ = 1.0 M $KNO_3$, $T$ = 25 °C).

## $^1$H NMR Spectra of the $Zn^{2+}$ Complexes

The formation of complexes between $Zn^{2+}$ and the ligands $L^1$, $L^2$, $L^3$, and $L^4$ results in a significant change in the $^1$H NMR spectra. The doublet signals of the phosphinate ($-[CH_2]_2PO_2^-$) methylene protons are shifted slightly to low field but their multiplicity does not change. The shift of the signals of the methylene protons is due to the inductive effect of the $Zn^{2+}$ ion. Upon formation of $ZnL^1$ the signal of the glycinate methylene protons is shifted to $\delta$ = 3.48 ppm but is not split. With a decrease of temperature from 50 °C to close to 0 °C the signals broaden significantly, however an AB multiplet pattern could not be observed even at this temperatures (Figure S8). Similarly, the signal of the glycinate methylene protons for $ZnL^3$ is not split by the formation of the complex and it appears at about $\delta$ = 3.30 ppm (pH 7.05) as a broad signal (Figure 8). The shift of the signals for the acetate methylene protons

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the iminodiacetate groups are usually larger and often appear in the form of AB multiplets (Figures 7 and 8). The formation of an AB multiplet indicates the inequivalence of the acetate methylene protons of the imda group, which is the result of the relatively long lifetime of the $Zn^{2+}$–N bond on the NMR timescale.[40] The chemical shifts of the non-equivalent A and B protons of $ZnL^2$ at pH 7.02 (Figure 7) are $\delta$ = 3.62 and 3.23 ppm, respectively. The exceptionally large H–C–H geminal coupling constant between these protons ($^2J_{H,H}$ = 17.3 Hz) suggests a dihedral angle of about 180° for the coordinated acetate arms (positions of the $CH_2$ H atoms towards the $p_z$ orbital of the carbon atom of $COO^-$).[41] The signals of the phosphinate methylene protons give a "pseudo-triplet" consisting of two overlapping doublets centered at $\delta$ = 2.99 and 2.96 ppm ($^2J_{P,H}$ = 8.6 and $^2J_{P,H}$ = 11.5 Hz). Since these signals are doublets due to coupling with phosphorus, the value of the geminal coupling constants for the $CH_2$ protons ($^2J_{H,H}$) can not be determined from the spectra (the values appear to be less than 0.8 Hz), which indicates a very weak interaction between the phosphinate oxygen and $Zn^{2+}$ in these complexes (presumably of an electrostatic nature). Figure 8 shows the $^1H$ NMR spectrum of $ZnL^3$ recorded at pH 7.05. The AB multiplet pattern of the iminodiacetate methylene protons appears at $\delta$ = 3.57 and 3.19 ppm (the geminal coupling constant is $^2J_{H,H}$ = 17.3 Hz), and the broad singlet at $\delta$ = 3.30 ppm is due to the glycinate methylene protons, while the doublets of the phosphinate methylene protons are centered at $\delta$ = 2.95 and 2.93 ppm ($^2J_{P,H}$ = 12.6 and $^2J_{P,H}$ = 13.3 Hz). For $ZnL^4$ the imda methylene protons appear as an AB multiplet ($^2J_{H,H}$ = 17.5 Hz), which shows the rigid structure of the complex (Figure S9). These carboxymethyl groups may occupy equivalent positions on the coordination polyhedron around $Zn^{2+}$. In summary, we can state that in complexes $ZnL^2$, $ZnL^3$, and $ZnL^4$ the $Zn^{2+}$–N bond of the coordinated imda fragment has a long lifetime while the $Zn^{2+}$–N bonds formed by the coordination of the $-NHCH_2COO^-$ group in $ZnL^1$ and $ZnL^3$ and the $-CH_2NH_2$ group in $ZnL^2$ appear to be more labile. These findings demonstrate that the lifetime of the $Zn^{2+}$–N bond is long on the NMR timescale as the coordination of the two carboxylate groups keeps the N atom in the vicinity of the $Zn^{2+}$ ion.

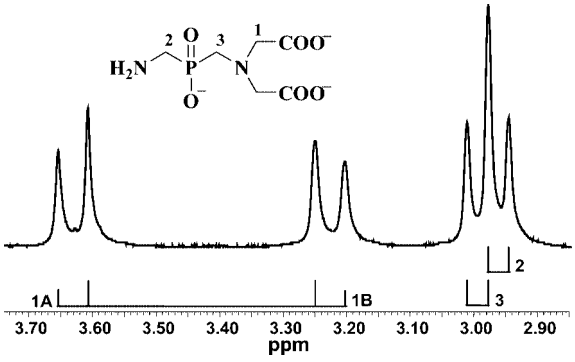

Figure 7. $^1H$ NMR spectrum of a 0.05 M $ZnL^2$ solution at 25 °C (pH 7.02).

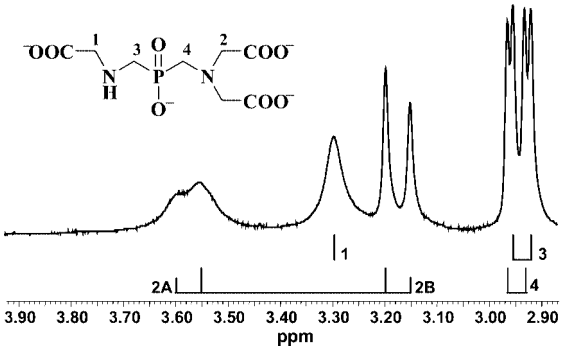

Figure 8. $^1H$ NMR spectrum of a 0.05 M $ZnL^3$ solution at 25 °C (pH 7.05).

## Conclusions

A new synthetic method has been developed that starts from inexpensive materials and gives reasonable yields of bis(aminomethyl)phosphinic acid as well as its derivatives containing the phosphinate group in a linker position. In addition, two consecutive Mannich reactions afford asymmetric bis(aminomethyl)phosphinic acids. These procedures can easily be scaled up and do not require inert atmosphere techniques. This synthetic method will likely be applicable to the synthesis of macrocyclic ligands that incorporate a bis(aminomethyl)phosphinic acid moiety in the macrocycle.

The basicities of the nitrogen atoms of the symmetric and asymmetric diacetate ($L^1$ and $L^2$) and tri- ($L^3$) and tetraacetate ($L^4$) derivatives of bis(aminomethyl)phosphinic acid ($L^0$) are lower than those of the analogous diaminopolycarboxylates mainly due to the electron-withdrawing effect of the phosphinate group. For a given ligand, the basicity of the nitrogen atoms decreases in the order primary > secondary > tertiary.

The stability constant of complexes formed between $L^0$, $L^1$, $L^2$, $L^3$, and $L^4$ and the metal ions $Mg^{2+}$, $Ca^{2+}$, $Ni^{2+}$, $Cu^{2+}$, $Zn^{2+}$, $Cd^{2+}$, and $Pb^{2+}$ increase with an increasing number of carboxylate groups of the ligands. The complexes formed with ligands $L^0$, $L^1$, $L^2$, and $L^3$ generally have lower stability constants than those of the analogous diaminopolycarboxylates, which indicates the unimportant role of the phosphinate group in the complexation. On the other hand, the presence of the phosphinate group has a significant effect on the complexation properties of $L^4$. In spite of the lower basicities of the two nitrogen atoms of $L^4$, it forms complexes of similar or higher stability with the smaller metal ions than the analogous 1,3-diaminopropane-*N*,*N*,*N*′,*N*′′-tetraacetate ($L^8$). $L^4$ also shows an unusually high selectivity for $Zn^{2+}$ over $Pb^{2+}$, unlike edta or $L^8$. Its stability constants are higher probably because of the higher charge of the ligand, and there is a strong electrostatic interaction between the phosphinate and the metal ion due to the coordination of both imda groups. Furthermore, $L^4$ shows a strong propensity for the formation of dinuclear $M_2L$ complexes, which indicates that in the presence of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phosphinate group the two imda groups behave more independently than in the case of edta or L[8].

Of the two diacetate derivatives the asymmetric $L^2$ forms complexes of higher stability with the metal ions that prefer octahedral coordination. However, the metal ions that prefer square-planar coordination, like $Cu^{2+}$, form more stable complexes with the symmetric ligand $L^1$. The equatorial coordination of $L^1$ to $Cu^{2+}$ has been confirmed by X-ray crystallography in the solid state for $K[CuL^1]\cdot H_2O$, which has a polymer structure with hexagonal channels.

The ligands $L^2$ and $L^3$ form ML and $ML_2$ complexes but the stability constants of the $ML_2$ species are relatively low, probably due to the larger steric requirement of the phosphinate-containing ligands.

In the $^1H$ NMR spectra of the complexes of $Zn^{2+}$ formed with $L^1$, $L^2$, $L^3$, and $L^4$ the acetate methylene protons of the coordinated imda groups appear as an AB multiplet, thus indicating the long lifetime of the $Zn^{2+}$–N bond on the NMR timescale, while the signal of the glycinate methylene protons is a singlet.

## Experimental Section

**Synthesis of the Ligands:** All reagents and solvents used in this paper were commercially available and used without further purification, unless noted otherwise. The synthesis of ligands $L^0$, $L^1$, $L^2$, and $L^3$ is outlined in Schemes 1 and 2. Ligand $L^4$ was prepared following a previously published procedure.[20] A detailed description of the synthetic procedures for compounds **1**–**10** is included in the Supporting Information (SI). The purity of the ligands was controlled by multinuclear ($^1H$, $^{13}C$, and $^{31}P$) NMR spectroscopy; the spectra obtained together with the results of pH potentiometric studies indicated the suitable purity of the ligands (higher than 99%).

**X-ray Diffraction Studies:** Large crystals of approx. 1 cm × 5 mm × 3 mm were obtained from saturated solution after the purification of $L^3$. Equivalent amounts (0.3 mmol) of $H_3L^1$ and $CuCl_2$ stock solutions were mixed and the pH of the mixture was increased to about pH 7.5 by addition of KOH solution. The solution was evaporated to dryness and a weighed amount (0.1 mmol) of the dried complex was redissolved in doubly distilled water (0.5 mL) and placed into a narrow tube. Anhydrous ethanol was carefully layered on the aqueous phase and the tube was placed in a refrigerator at around 4 °C. Navy blue crystals suitable for X-ray crystallography grew in three weeks.

X-ray quality crystals of $[H_5L^3]Cl$ and $K[CuL^1]\cdot H_2O$ were mounted on a glass fiber using epoxy resin. Data were collected at 293(1) K with an Enraf Nonius MACH3 diffractometer using monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) in the $\omega$–$2\theta$ mode. The absorption correction was made using psi scans. The structure was solved by direct methods with the SIR-92 software and refined on $F^2$ by full-matrix least-squares methods with the program SHELX-97.[42,43] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included using a riding model. Some of the water hydrogen atoms were found in the difference electron density map while others were placed in calculated positions for strong hydrogen bonds. For the final refinement the O–H bond lengths were restrained at 0.85 Å but otherwise the coordinates of O–H hydrogen atoms were refined. Publication material was prepared with the WINGX-97 suite.[44] Some other details of data collection and structure determination are shown in Table 8.

[a] $R = \Sigma|F_o - F_c|/\Sigma F_o$. [b] $R_w = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$, where $w = 1/[\sigma^2\{F_o^2 = +(aP)^2 + bP\}]$, $P = (F_o^2 + F_c^2)/3$; $a$ and $b$ are given in the Supporting Information.

CCDC-616444 (for $[H_5L^3]Cl$) and -616445 (for $K[CuL^1]\cdot H_2O$) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Materials and Preparation of Solutions:** Stock solutions of $MgCl_2$, $CaCl_2$, $NiCl_2$, $CuCl_2$, $ZnCl_2$, $Cd(NO_3)_2$, $Pb(NO_3)_2$, $Me_4NOH$, and KOH were prepared with the highest analytical grade reagents. The concentrations of the metal-ion solutions were determined by complexometric titration with standardized $Na_2H_2edta$ solution using eriochrome black T, murexide or xylenol orange indicator. Aqueous solutions of the ligands were prepared by weight and the concentrations were determined by pH potentiometric titrations.

**Equilibrium Studies:** The protonation constants of the ligands and stability constants of complexes were determined by pH potentiometric titration in vessels thermostatted at 25 °C. The ionic strength of the solutions was kept constant at 1.0 M $Me_4NCl$ or, in the case of $Cd^{2+}$ and $Pb^{2+}$, at 1.0 M $KNO_3$. Titration experiments were performed at two to four different metal-to-ligand ratios (1:1, 1:2, 1:3, and 2:1) by varying the ligand concentration in the range 0.0025–0.006 M. The titrations were performed with a Radiometer pHM 85 pH-meter equipped with pHG 211 glass and REF 201 Ag/AgCl electrodes and a Radiometer ABU 80 autoburette. The

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

samples (in general 15 mL) were stirred and argon was bubbled through the solutions. KH-phthalate (pH = 4.005) and borax (pH = 9.180) buffers were used to calibrate the pH meter. The $H^+$ ion concentration was obtained from the measured pH data by the method suggested by Irving et al. A 0.01 M HCl solution was titrated in 1.0 M $Me_4NCl$ (or 1.0 M $KNO_3$) with the $Me_4NOH$ (or KOH) solution used for the titrations.[45] The difference between the calculated and measured pH values was used to obtain the $H^+$ ion concentrations from the pH values measured in the titration experiments.[45] The ionic product of water ($pK_w$) was also calculated from the data obtained in the titration of the 0.01 M HCl solution. The $pK_w$ values obtained in 1.0 M $Me_4NCl$ and 1.0 M $KNO_3$ are 13.99 and 13.88, respectively. The protonation constants of the ligands and stability constants of the complexes were calculated from the titration data with the computer program PSEQUAD.[37]

**NMR Measurements:** The solutions of complexes were prepared by mixing equivalent amounts of the ligands and $ZnCl_2$ solutions. After evaporation of the $H_2O$ the solid material was dissolved in $D_2O$. The pD of the solutions was monitored by the addition of KOD or DCl (Cambridge Isotope Laboratories, Inc.) solutions and the readings were corrected for the deuterium isotope effect using the relationship pH = 0.4 + pD. Both one- and two-dimensional NMR spectra were recorded on a Bruker Avance DRX-360 spectrometer operating at 360.0 and at 90.5 MHz for $^1H$ and $^{13}C$, respectively. A Bruker DRX-500 spectrometer equipped with a Eurotherm variable temperature unit (±0.1 K), which was calibrated by the methanol method,[46] was used for variable-temperature measurements. Two-dimensional $^1H$-$^1H$ correlation spectra (COSY-45, DQF-COSY, NOESY, EXSY) were recorded using standard pulse sequences in direct mode with a 5-mm QNP probehead. $^{13}C$ NMR spectra were recorded in *J*-modulated or inverse gated decoupling mode. Data processing was performed with the Bruker WinNMR software package.

**Supporting Information** (see footnote on the first page of this article): Description of the synthetic procedures for compounds **1**–**10**; H-bond network in $[H_5L^3]Cl$ (Figure S1); data of the H-bond network in $[H_5L]Cl$ (Table S1); the H-bond network and long-range packing in $K[CuL^1]\cdot H_2O$ (Figure S2); the H-bond network in $K[CuL^1]\cdot H_2O$ (Table S2); $^1H$ and $^{31}P$ NMR titration curves for the ligands $L^0$, $L^1$, and $L^4$ (Figures S3–S7); temperature dependence of the $^1H$ NMR spectra of $ZnL^1$ (Figure S8); $^1H$-$^1H$ COSY spectrum of $ZnL^4$ (Figure S9).

# Anion-Dependent Structural Diversity in Silver(I) Complexes of 4-Amino-3,5-diisopropyl-1,2,4-triazole

Guang Yang,*[a] Ying-Li Wang,[a] Jin-Peng Li,[a] Yu Zhu,[a] Shao-Min Wang,[a] Hong-Wei Hou,[a] Yao-Ting Fan,[a] and Seik Weng Ng[b]

**Keywords:** Silver / Triazole / Anions

Reactions of silver salts with 4-amino-3,5-diisopropyl-1,2,4-triazole (L) afford dinuclear complex $[Ag_2L_2(NO_3)_2(CH_3CN)]$, triangular complex $[Ag_3L_3](CF_3SO_3)_3$, and cyclic tetranuclear complexes $[Ag_4L_6](BF_4)_4$ and $[Ag_4L_6](ClO_4)_4$. On the basis of the X-ray analyses, anions are found to play an important role in determining the structures. Through coordination/noncoordination, anions can impart their influence on the coordination geometry of Ag atoms and the angles of N–Ag–N, which seems to be the main factor controlling the nuclearity of the reaction products in this system. $^1$H NMR and MS measurements suggest that these complexes probably retain their structural integrities in $CH_3CN$ solution.

## Introduction

With the coordination complexes of metals, the anions serve more than merely balancing the charges of a cationic species;[1–8] anions impart their influence on the structure of a given supramolecular system through coordinative bonding to metal ions or through weak interaction with organic ligands. Leob et al. reported that a molecular square, rectangle and an infinite helical chain have been obtained by the reaction of 4-(2-pyridyl)pyrimidine with various silver salts and the degree of aggregation is dependent on the anion used.[2] Dunbar et al. found that reaction of 3,6-di(2-pyridyl)-1,2,4,5-tetrazine with first-row transition metals could yield a molecular square and a pentagon with one anion accommodated in the cavities of the polygons. In this case, anions function as templates through anion-π interactions.[3] It seems promising that one can, to some extent, control or tune the structures of some supramolecules by simply changing anions. Obviously, before the use of anions can become a powerful tool for synthetic chemists in the construction of supramolecules, more work is needed towards understanding the mechanism of anion action.

Recent years have seen a rapidly increasing interest in the structures and properties of metal complexes of 1,2,4-triazole and its derivatives.[9] 1,2,4-Triazole is believed to unite the coordination geometries of both pyrazoles and imidazoles, and exhibit versatile coordination modes upon ligation to metals. 4-Amino-3,5-diisopropyl-1,2,4-triazole (4-$NH_2$-3,5-*i*$Pr_2$-tz) has been known for some time,[10] however, so far only few of its metal complexes have appeared in the literature to the best of our knowledge.[11] On the other hand, the less-crowded analogues with methyl or ethyl groups in place of the isopropyl groups are common ligands that furnish a large number of adducts with metal salts.[9] We report herewith the syntheses and crystal structures of four $Ag^I$-4-$NH_2$-3,5-*i*$Pr_2$-tz complexes; the structural outcomes of these adducts appear to be dependent on the nature of anions used.

## Results and Discussion

### Structure of $[Ag_2(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_2(NO_3)_2(CH_3CN)]$ (1)

The product of stoichiometric quantities of $AgNO_3$ and 4-$NH_2$-3,5-*i*$Pr_2$-tz is the dinuclear complex **1**; the two Ag atoms are four-coordinate in different environments (Figure 1). The Ag(1) atom is coordinated by two triazole N atoms, two O atoms from the chelating nitrate, while the Ag(2) atom is coordinated by two triazole N atoms, one N atom of acetonitrile, and one O atom from the monodentate nitrate; each triazole bridges two Ag atoms (Scheme 1, a). The distance between Ag(1) and Ag(2) is 3.2867(5) Å, less than the sum of the van der Waals radii for the Ag atoms (3.44 Å). Complex **1** features a $(Ag–N–N–)_2$ ring having a boat conformation with the two Ag atoms forming the ring tips. Such a six-membered ring is also observed in other (triazole)silver complexes, e.g. $[Ag_2(\mu_2\text{-}tzH)_2(NO_3)_2]$[15] and $[Ag_2(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}Me_2\text{-}tz)_2(CF_3COO)_2]$[16] (tzH = 1,2,4-triazole; 4-$NH_2$-3,5-$Me_2$-tz = 4-amino-3,5-dimethyl-1,2,4-triazole). A number of dinuclear pyrazolato complexes also have this feature.[17,18]

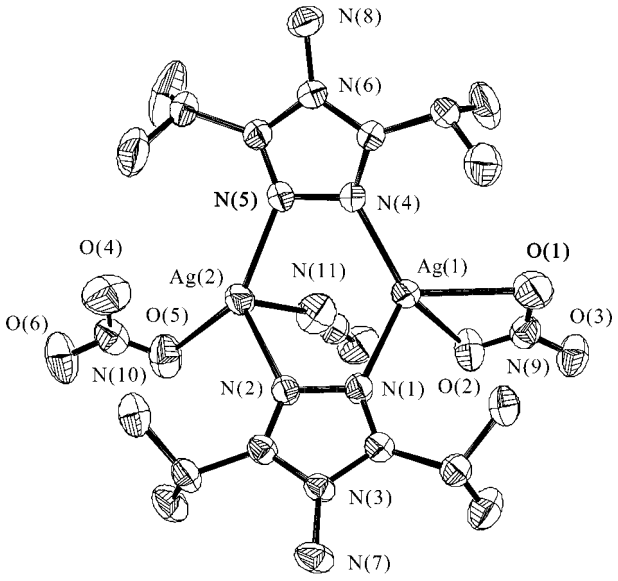

Figure 1. ORTEP diagram (at 35% probability) of the X-ray structure of $[Ag_2(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i\text{Pr}_2\text{-}tz)_2(NO_3)_2(CH_3CN)]$ (**1**). Selected distances [Å] and angles [°]: Ag(1)···Ag(2) 3.2867(5), Ag(1)–N(1) 2.282(3), Ag(1)–N(4) 2.213(3), Ag(1)–O(1) 2.567(4), Ag(1)–O(2) 2.471(3), Ag(2)–N(2) 2.325(3), Ag(2)–N(5) 2.275(3), Ag(2)–N(11) 2.526(5), Ag(2)–O(5) 2.507(4), N(1)–Ag(1)–N4 110.56(11), N(2)–Ag(2)–N(5) 109.88(11), N(2)–N(1)–Ag(1) 113.4(2), N(1)–N(2)–Ag(2) 115.0(2), N(5)–N(4)–Ag(1) 116.6(2), N(4)–N(5)–Ag(2) 113.0(2).

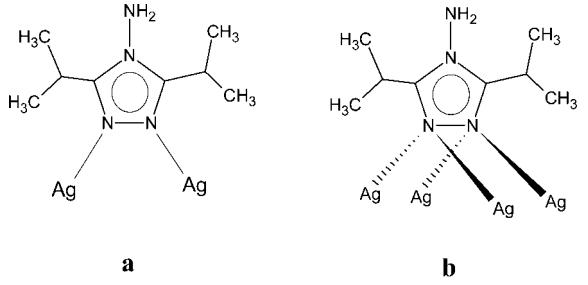

Scheme 1.

From the structure of **1**, we can see that nitrates participate in the distorted four-coordinate environment around the Ag atoms, the N–Ag–N angles of ca. 110° are critical for the formation of the six-membered ring. For a given system like this one containing silver(I) and an *exo*-bidentate ligand, other cyclic products or 1D complexes might be formed,[19] depending on the angles of N–Ag–N. It is thus possible to obtain other products by using weaker coordinating or noncoordinating anions, which would have an influence on the coordination geometry of Ag atoms and the angles of N–Ag–N.

### Structure of $[Ag_3(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i\text{Pr}_2\text{-}tz)_3](CF_3SO_3)_3$ (2)

Trifluoromethylsulfonates are weaker coordinating anions than nitrates owing to the electron-withdrawing $CF_3^-$ entity. In the $AgCF_3SO_3$ adduct, **2**, the $(Ag–N–N–)_n$ ring is a nine-membered, triangular-shaped ring. The Ag atoms are two-coordinate in a linear geometry, and the triazoles act as *exo*-bidentate bridging ligands (see parts a in Figure 2 and Scheme 1). The $(Ag–N–N–)_3$ ring is roughly planar, the mean deviation from the plane defined by three Ag atoms and six triazole N atoms being 0.0853 Å.

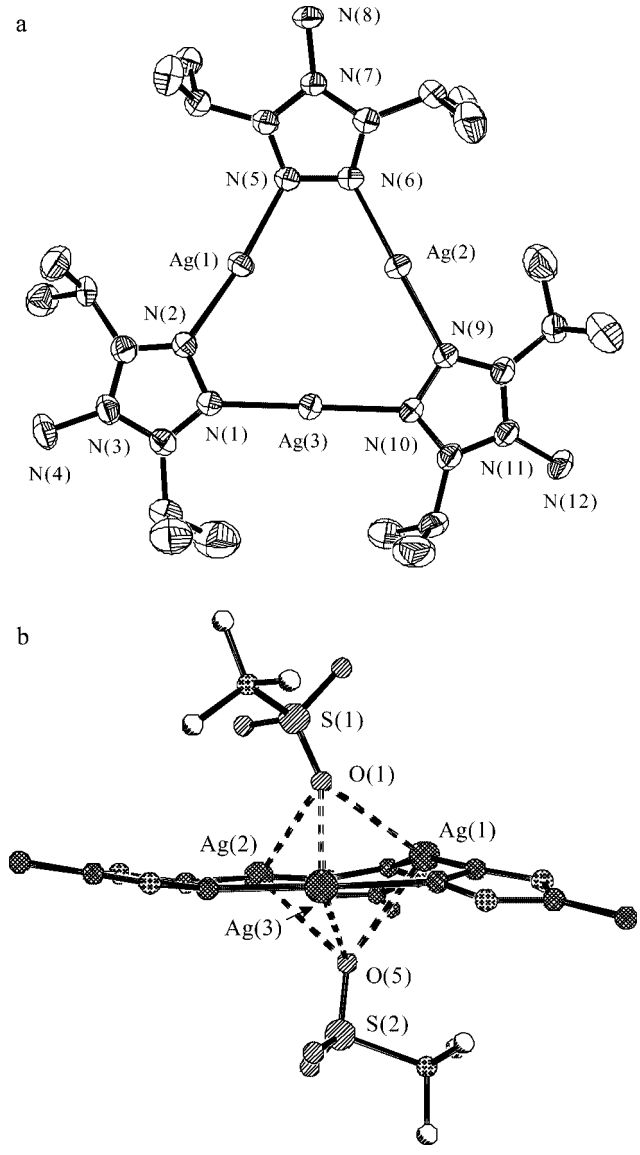

Figure 2. (a) ORTEP diagram (at 35% probability) of the X-ray structure of the cationic triangular $[Ag_3(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i\text{Pr}_2\text{-}tz)_3]^{3+}$ in **2**. (b) An edge-on-view with the two closest anions of $CF_3SO_3^-$. Selected distances [Å] and angles [°]: Ag(1)···Ag(2) 3.4316(9), Ag(1)···Ag(3) 3.4579(8), Ag(2)···Ag(3) 3.5573(8), Ag(1)–N(2) 2.132(3), Ag(1)–N(5) 2.129(3), Ag(2)–N(6) 2.159(3), Ag(2)–N(9) 2.168(3), Ag(3)–N(1) 2.165(3), Ag(3)–N(10) 2.168(3), N(5)–Ag(1)–N(2) 165.36(14), N(6)–Ag(2)–N(9) 176.02(14), N(1)–Ag(3)–N(10) 178.72(14), N(1)–N(2)–Ag(1) 121.5(2), N(6)–N(5)–Ag(1) 119.4(2), N(5)–N(6)–Ag(2) 117.8(2), N(10)–N(9)–Ag(2) 119.6(2), N(2)–N(1)–Ag(3) 116.3(2), N(9)–N(10)–Ag(3) 120.4(2).

Two of the three $CF_3SO_3^-$ anions are located on each side of the $(Ag–N–N–)_3$ ring with one O atom pointing to the centre of the triangle defined by three Ag atoms; contacts are O(1)···Ag(1) 2.668 Å, O(1)···Ag(2) 2.711 Å, O(1)···Ag(3) 2.742 Å, $O(5^i)$···Ag(1) 2.696 Å, $O(5^i)$···Ag(2)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.736 Å, O(5$^{i}$)···Ag(3) 2.684 Å (symmetry code: *i*: –*x*, –*y* + 1, –*z* + 1) (Figure 2, b). Interestingly, while the above-mentioned two weakly coordinated $CF_3SO_3^-$ anions are in full occupancy in the X-ray structure, the third one, which has no contacts with Ag atoms, is disordered and has been refined as two parts with an occupancy factor of 0.5 each. Since the structure motif of the 1D chain may compete with the triangle when the angular units of ca. 60° (the triazole ligand) are combined with the ditopic linear units (the two-coordinate $Ag^I$ atoms),[19] the triangular arrangement observed in **2** is possibly the result of the pre-organization of the Ag atoms and triazoles through weak Ag···O interactions.

A number of neutral triangular silver-pyazolates have been known for a long time,[20] however, a triangular silver-triazole compound has not been reported; on the other hand several $Pd^{II}$, $Cu^{II}$-triazole compounds do adopt this triangular motif.[21]

### Structures of $[Ag_4(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_6](ClO_4)_4\cdot H_2O$ (3) and $[Ag_4(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_6](BF_4)_4$ (4)

Since two different anions ($NO_3^-$ and $CF_3SO_3^-$) give two different structures of silver complexes of 4-$NH_2$-3,5-*i*$Pr_2$-tz, the possibility exists that other structural arrangements may be discovered in this system when other anions with different shapes and different coordinating abilities are used. Perchlorate and tetrafluoroborate anions have been proven to be weaker or noncoordinate ligands for silver(I), therefore $AgClO_4$ and $AgBF_4$ were used in the reaction with 4-$NH_2$-3,5-*i*$Pr_2$-tz. X-ray analyses demonstrate that the resulting two new compounds **3** and **4** are structurally similar, however, different from **1** and **2**. They are tetranuclear compounds with the formula $Ag_4L_6X_4$, featuring a (Ag–N–N–)$_4$ ring (L = 4-$NH_2$-3,5-*i*$Pr_2$-tz; X = $ClO_4^-$, $BF_4^-$). Figure 3 shows the structure of compound **3**. In both complexes the four Ag atoms are approximately coplanar defining a rhombus with Ag–Ag distances in the range of 3.374(1)–3.444(1) Å in **3** and 3.303(1)–3.477(1) Å in **4**, Ag–Ag–Ag angles of 88.02(2)–88.77(2)° in **3** and 86.93(2)–93.00(2)° in **4**. The $Ag_4$ rhombus in **3** is actually a little butterfly-distorted while that in **4** is almost planar, as indicated by the mean deviations of Ag atoms from the best-fit $Ag_4$ planes being 0.2823 Å (for **3**) and 0.0460 Å (for **4**). For both, the four bridging triazole ligands alternate above and below the $Ag_4$-plane forming a (Ag–N–N–)$_4$ ring of roughly $S_4$ symmetry (Scheme 1, a). The best-fit planes of the opposite triazoles form dihedral angles of 46.0, 54.0° and 30.5, 53.9° for **3** and **4**, respectively. A similar (Ag–N–N–)$_4$ ring is observed in the pyrazole complex $[Ag(\mu_2\text{-}3,5\text{-}t Bu_2pz)]_4$,[22] however, the rings in **3** and **4** are flatter than that in $[Ag(\mu_2\text{-}3,5\text{-}t Bu_2pz)]_4$. Additionally, two triazole ligands are placed nearly orthogonally on each side of the $Ag_4$ plane with the Ag···N contacts falling in the range of 2.513(5)–2.845(5) Å (for **3**) and 2.428(5)–2.859(5) Å (for **4**). These values are much longer than the Ag–N distances of the (Ag–N–N–)$_4$ rings, thus these two triazoles are only weakly bound to Ag atoms in an uncommon $\eta^2,\eta^2,\mu_4$ fashion (Scheme 1, b).

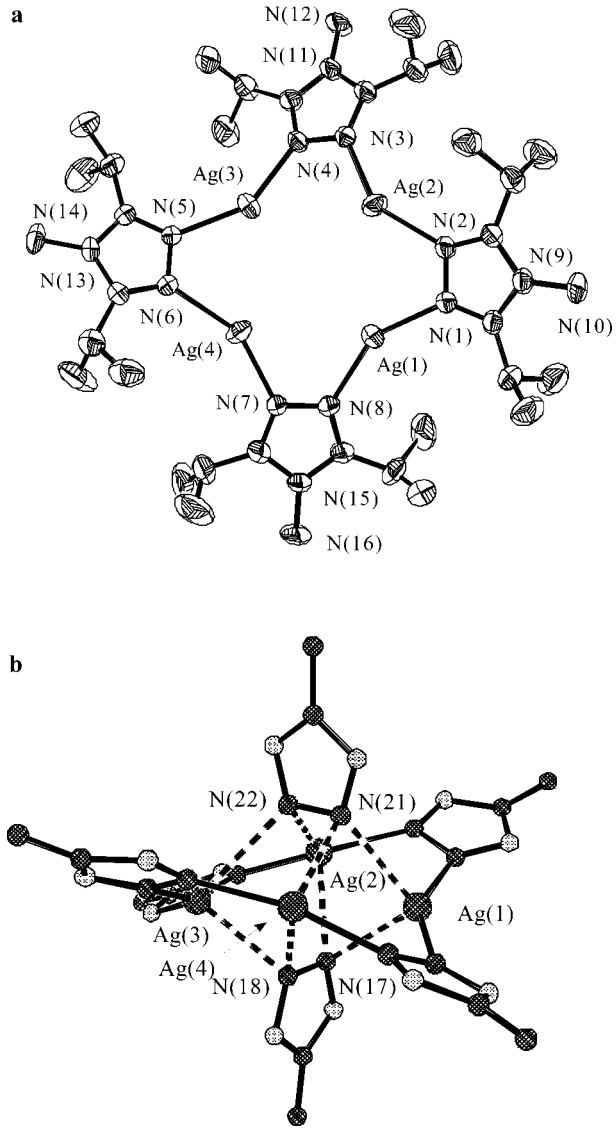

Figure 3. (a) ORTEP diagram (at 35% probability) of the X-ray structure of the cationic tetranuclear ring $[Ag_4(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_4]^{4+}$ in **3**. (b) A side view of $[Ag_4(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_6]^{4+}$ in **3** showing two weakly bound triazoles (the isopropyl groups are omitted for clarity). Selected distances [Å] and angles [°]: Ag(1)···Ag(2) 3.3754(9), Ag(3)···Ag(4) 3.3743(9), Ag(2)···Ag(3) 3.4436(9), Ag(1)···Ag(4) 3.4399(9), Ag(1)–N(1) 2.220(5), Ag(1)–N(8) 2.240(5), Ag(2)–N(3) 2.206(5), Ag(2)–N(2) 2.238(5), Ag(3)–N(5) 2.190(5), Ag(3)–N(4) 2.204(5), Ag(4)–N(7) 2.186(5), Ag(4)–N(6) 2.198(5), Ag(1)···N(17) 2.570(5), Ag(1)···N(21) 2.626(5), Ag(2)···N(22) 2.513(5), Ag(2)···N(17) 2.678(5), Ag(3)···N(18) 2.555(5), Ag(3)···N(22) 2.845(5), Ag(4)···N(21) 2.621(5), Ag(4)···N(18) 2.768(5), N(1)–Ag(1)–N(8) 148.80(18), N(3)–Ag(2)–N(2) 147.04(18), N(5)–Ag(3)–N(4) 148.91(18), N(7)–Ag(4)–N(6) 149.99(18).

Considering all the close contacts, the coordinate geometry of Ag atoms is better described as highly distorted tetrahedral. The N–Ag–N angles in (Ag–N–N–)$_4$ rings fall in the range of 146.4(2)–157.6(2)°. These values are less than those in (Ag–N–N–)$_3$ (ca. 180°), but larger than those in (Ag–N–N–)$_2$ (ca. 110°), which might account for the formation of the (Ag–N–N–)$_4$ ring in **3** and **4**. Very recently, Ag-triazole complexes with the same formula of $Ag_4L_6X_4$ have

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

been reported by Cheng et al.[23] Interestingly, their complexes could be considered as two dinuclear units (similar to that in **1**), which are further connected via two additional $N^1$,$N^2$-bridged triazoles and therefore are structurally different from those we report in this paper.

Hydrogen bonds are found in the crystal structures of the four complexes. In complexes **1**, **2** and **4**, some of the amino groups of the triazole ligands serve as donors and the O atoms and/or F atoms of anions as acceptors for the hydrogen bonds. In **3**, only one amino group [N(24)] is found to form a hydrogen bond with the lattice water molecule [O(17)]; the water molecule is further H-bonded with two O atoms [O(2), O(13)] from two perchlorates. Therefore, this water molecule acts as both acceptor and donor in the hydrogen bonds presenting in **3**. The distances of N(24)···O(17), O(17)···O(2) and O(17)···O(13) are 2.846(13), 2.977(15) and 2.763(19) Å, respectively. The hydrogen bonds observed here, although relatively weaker, might contribute to the stabilisation and packing of the molecules in the crystals.

### Solution Study

Free 4-$NH_2$-3,5-*i*$Pr_2$-tz exhibits resonances of *i*Pr protons at $\delta$ = 3.15 [m, H-C(Me)$_2$] and 1.27 (d, Me) ppm in $CD_3CN$; complexes **1**–**4** show only one set of slightly downfield-shifted resonances for the corresponding *i*Pr protons at 3.28, 1.32 (**1**); 3.25, 1.32 (**2**); 3.22, 1.29 (**3**); 3.21, 1.29 ppm (**4**), respectively. The resonances are interpreted in terms of the triazoles binding to $Ag^I$ atoms in a symmetric fashion in $CD_3CN$ solution.

The ESI-MS spectrum of **1** in $CH_3CN$/MeOH exhibits peaks at *m*/*z* = 275, 316 and 443, with the appropriate isotopic distributions, that correspond to [Ag(4-$NH_2$-3,5-*i*$Pr_2$-tz)]$^+$, [Ag(4-$NH_2$-3,5-*i*$Pr_2$-tz)($CH_3CN$)]$^+$ and [Ag(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_2$]$^+$, respectively. No disilver species could be observed in this case. On the other hand, complex **2** exhibits peaks at *m*/*z* = 275, 316, 443, 699 and 1123 in its ESI MS spectrum in $CH_3CN$, which are assigned to [Ag(4-$NH_2$-3,5-*i*$Pr_2$-tz)]$^+$, [Ag(4-$NH_2$-3,5-*i*$Pr_2$-tz)($CH_3CN$)]$^+$, [Ag(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_2$]$^+$, [$Ag_2$(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_2$($CF_3SO_3$)]$^+$ and [$Ag_3$(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_3$($CF_3SO_3$)$_2$]$^+$, respectively (Figure 4). The presence of trisilver species in the ESI MS spectrum of **2**, together with the fact that there was only one set of proton resonances in its $^1$H NMR spectrum, implies that the complex of **2** retains the integrity of its triangular nature in $CH_3CN$ solution. Besides the peaks at *m*/*z* = 275, 316 and 443, the tetranuclear complex **3** also exhibits weak peaks at *m*/*z* = 649, 1023, and 1397 in $CH_3CN$, which could be assigned to [$Ag_2$(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_2$($ClO_4$)]$^+$, [$Ag_3$(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_3$($ClO_4$)$_2$]$^+$ and [$Ag_4$(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_4$($ClO_4$)$_3$]$^+$. The presence of $Ag_4L_4$ species instead of the crystallographically characterized $Ag_4L_6$ in the ESI MS spectrum of **3** indicates that two of the six triazoles are easily dissociated from the $Ag_4$ cluster under the conditions of MS measurement. This is in agreement with the crystal structure of **3**. However, since only one set of proton resonances is observed in the $^1$H NMR spectrum of **3**, we therefore propose that the complex **3** is a fluxional molecule. All the triazoles (the weakly bound and tightly bound ones) exchange their positions very quickly in $CH_3CN$ solution at room temperature.

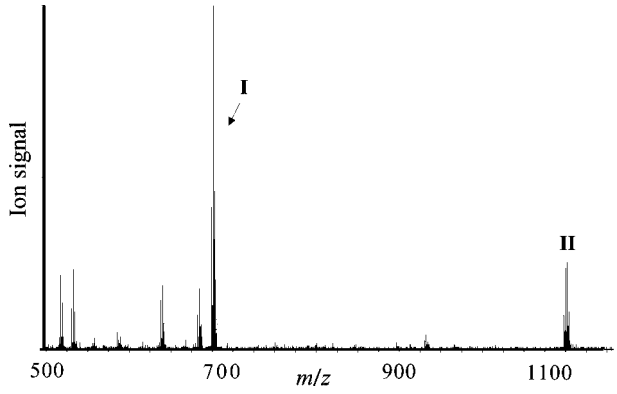

Figure 4. Electrospray mass spectrum of complex **2** in MeCN/MeOH. The ion signals displayed correspond to [$Ag_2$(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_2$($CF_3SO_3$)]$^+$ (**I**) at *m*/*z* = 699, and [$Ag_3$(4-$NH_2$-3,5-*i*$Pr_2$-tz)$_3$($CF_3SO_3$)$_2$]$^+$ (**II**) at *m*/*z* = 1123.

## Conclusion

In this paper, we describe an interesting case of anion-dependent structural diversity. We found the reaction of $Ag^I$ salts with 4-amino-3,5-diisopropyl-1,2,4-triazole produce complexes of different nuclearity, dependent on the anions employed. The role of the anions consists of determining the coordination geometry of the Ag-centres, namely the N–Ag–N angles in the (Ag–N–N–)$_n$ rings. Furthermore, we also found that 4-amino-3,5-diisopropyl-1,2,4-triazole acts as an *exo*-bidentate N-ligand in a somewhat similar way as pyrazolates, although the former is a neutral species.

## Experimental Section

4-Amino-3,5-diisopropyl-1,2,4-triazole was prepared according to literature methods.[10] Other reagents were commercially available and used as received.

The CHN microanalyses were carried out with an ELEMENTAR vario EL elemental analyser. IR spectra (KBr pellets) were recorded with a Niclolet Impact 420 FT-IR spectrometer. $^1$H NMR spectra were recorded with a Bruker DPX-400 spectrometer (400 MHz). Positive ESI mass spectra were recorded with a Waters Q-Tof micro mass spectrometer.

### Syntheses

**[$Ag_2$($\mu_2$-4-$NH_2$-3,5-*i*$Pr_2$-tz)$_2$($NO_3$)$_2$($CH_3CN$)] (1):** A solution of $AgNO_3$ (0.1 mmol, 17 mg) in MeCN (2 mL) was mixed with a 2-mL ethanol solution of 4-$NH_2$-3,5-*i*$Pr_2$-tz (0.1 mmol, 17 mg). The resulting mixture was allowed to evaporate for one week to yield colourless crystals of **1** (30 mg), suitable for X-ray work. Yield: 42%. IR (KBr): $\tilde{\nu}$ = 3222 (m) ($NH_2$), 2974 (m) (*i*Pr), 1645 (w), 1518 (w), 1383 (s) ($NO_3^-$), 1110 (w), 1041 (w) cm$^{-1}$. $^1$H NMR ($CD_3CN$): $\delta$ = 1.32 (d, 12 H, Me), 3.28 [m, 2 H, H-C(Me)$_2$] ppm.

$C_{18}H_{35}Ag_2N_{11}O_6$ (717.31): calcd. C 30.21, H 4.90, N 21.54; found C 29.53, H 4.86, N 21.58.

**$[Ag_3(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_3](CF_3SO_3)_3$ (2):** A 2-mL aqueous solution of $AgCF_3SO_3$ (0.1 mmol, 26 mg) was mixed with a 2-mL ethanol solution of 4-$NH_2$-3,5-$i$Pr$_2$-tz (0.1 mmol, 17 mg). The resulting mixture was allowed to evaporate for several days to yield colourless crystals of **2** (76 mg). Yield: 60%. IR (KBr): $\tilde{\nu}$ = 3233 (m), 3122 (m) ($NH_2$), 2976 (s), 2935 (w) ($i$Pr), 1625 (w), 1517 (m), 1460 (m), 1251 (s) ($CF_3$), 1172 (s), 1109 (w), 1045 (s), 653 (s), 579 (w), 522 (m) cm$^{-1}$. $^1$H NMR ($CD_3CN$): $\delta$ = 1.32 (d, 12 H, Me), 3.25 [m, 2 H, H-C(Me)$_2$] ppm. $C_{27}H_{48}Ag_3F_9N_{12}O_9S_3$ (1275.56): calcd. C 25.47, H 3.77, N 13.21; found C 25.44, H 3.73, N 13.23.

**$[Ag_4(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_6](ClO_4)_4\cdot H_2O$ (3):** This compound was prepared as **2** using $AgClO_4$ instead of $AgCF_3SO_3$. Yield: 55% (based on ligand). IR (KBr): $\tilde{\nu}$ = 3232 (m), 3121 (m) ($NH_2$), 2975 (m), 2935 (w) ($i$Pr), 1662 (w), 1517 (m), 1461 (w), 1385 (w), 1145 (s), 1089 (s) ($ClO_4^-$), 631 (m), 549 (w) cm$^{-1}$. $^1$H NMR ($CD_3CN$): $\delta$ = 1.29 (d, 12 H, Me), 3.22 [m, 2 H, H-C(Me)$_2$] ppm. $C_{48}H_{98}Ag_4Cl_4N_{24}O_{17}$ (1856.78): calcd. C 31.14, H 5.30, N 18.16; found C 31.11, H 5.38, N 18.11.

**$[Ag_4(\mu_2\text{-}4\text{-}NH_2\text{-}3,5\text{-}i Pr_2\text{-}tz)_6](BF_4)_4$ (4):** This compound was prepared as **2** using $AgBF_4$ instead of $AgCF_3SO_3$. Yield: 53% (based on ligand). IR (KBr): $\tilde{\nu}$ = 3235 (m), 3122 (m) ($NH_2$), 2976 (s), 2935 (w), 1660 (w), 1518 (m), 1462 (m), 1385 (w), 1077 (s) ($BF_4^-$), 527 (w) cm$^{-1}$. $^1$H NMR ($CD_3CN$): $\delta$ = 1.29 (d, 12 H, Me), 3.21 [m, 2 H, H-C(Me)$_2$] ppm. $C_{48}H_{96}Ag_4B_4F_{16}N_{24}$ (1788.21): calcd. C 32.29, H 5.38, N 18.83; found C 32.04, H 5.62, N 18.75.

**X-ray Crystallography:** Diffraction intensities were collected with a Bruker SMART Apex CCD diffractometer (for **1**), Rikagu RAXIS-RAPID imaging plate diffractometer (for **2**) and a Rikagu RAXIS IV imaging plate diffractometer (for **3** and **4**), with graphite-monochromated Mo-$K_\alpha$ radiation. The data collected by CCD diffractometer were processed by *SAINT*;[12] while those collected by Rikagu diffractometers were corrected by "multi-scan" absorption corrections.[13] The structures were solved by direct methods and refined by least-squares on $F^2$ using the SHELXL program.[14] All non-hydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms were treated as riding. For complexes **2** and **4**, some of the anions and isopropyl groups have been split into two parts with an occupancy factor of 0.5. The lower completeness and lower redundancy of the data for **3** and **4** are probably caused by (a) the poorer quality of crystals of **3** and **4**; (b) the aged detector of the diffractometer used for collection of the intensities. The crystal data for the complexes reported here are summarised in Table 1.

CCDC-620543 to -620546 (for **1**–**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Group 11 Metal Complexes of the Mesocyclic Thioether Aminophosphonites [-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-]$PNC_4H_8E$ (E = O, NMe)

**Benudhar Punji,[a] Joel T. Mague,[b] and Maravanji S. Balakrishna*[a]**

**Keywords:** Thioether-aminophosphonites / P,S ligands / Copper / Gold

Group 11 metal complexes of the mesocyclic thioether aminophosphonites [-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-]$PNC_4H_8E$ {**2a**: E = O; **2b**: E = NMe; IUPAC names: 4-(dinaphtho[2,1-*d*:1′,2′-*g*][1,3,6,2]dioxathiaphosphocin-4-yl)morpholine (**2a**), 1-(dinaphtho[2,1-*d*:1′,2′-*g*][1,3,6,2]dioxathiaphosphocin-4-yl)-4-methylpiperazine (**2b**)} are reported. Thioether aminophosphonites **2a** and **2b** react with CuX (X = Cl, Br, and I) in a 1:1 molar ratio to give the tricoordinate, dimeric complexes [{[{-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-}$PNC_4H_8E$-κ*P*]Cu(μ-X)}$_2$] (**4a**: E = O, X = Cl; **4b**: E = NMe, X = Cl; **5a**: E = O, X = Br; **5b**: E = NMe, X = Br; **6a**: E = O, X = I; **6b**: E = NMe, X = I), whereas with 2:1 molar ratios monomeric complexes of the type [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-]$PNC_4H_8O$-κ*P*}$_2$CuX] (**7a**: E = O, X = Cl; **7b**: E = NMe, X = Cl; **8a**: E = O, X = Br; **8b**: E = NMe, X = Br; **9a**: E = O, X = I; **9b**: E = NMe, X = I) are obtained in excellent yield. The P,S-chelated cationic complexes [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-]$PNC_4H_8E$-κ*P*,κ*S*}$_2$Cu]$BF_4$ (**10a**: E = O; **10b**: E = NMe) are obtained when **2a** and **2b** are treated with half an equivalent of [$(MeCN)_4$Cu]$BF_4$. Similarly, the silver complexes [{[{-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-}$PNC_4H_8E$-κ*P*,κ*S*]-Ag$CF_3SO_3$}$_2$] (**11a**: E = O: **11b**: E = NMe) and [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-]$PNC_4H_8E$-κ*P*,κ*S*}Ag($PPh_3$)]$CF_3SO_3$ (**12a**: E = O; **12b**: E = NMe) are synthesized by the treatment of thioether aminophosphonites **2a** and **2b** with AgOTf and [Ag($PPh_3$)][OTf], respectively. Reactions of **2a** and **2b** with [AuCl($SMe_2$)] produce the simple monomeric gold(I) complexes [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6O$-]$PNC_4H_8E$-κ*P*}AuCl] (**13a**: E = O; **13b**: E = NMe). The iodo derivatives [{[-$OC_{10}H_6$(μ-S)-$C_{10}H_6O$-]$PNC_4H_8E$-κ*P*}AuI] (**14a**: E = O; **14b**: E = NMe) are obtained by the halide-exchange reaction of **13a** and **13b** with CuI at room temperature. The structures of complexes **5a**, **7a**, **8a**, **13a**, **13b**, and **14a** are confirmed by single-crystal X-ray diffraction studies. In all of these complexes, the sulfur atom in the mesocyclic ring shows coordinative interaction towards the phosphorus atom, and in **5a**, **7a**, **8a**, and **14a** towards the metal center as well.

## Introduction

In recent years, complexes of mixed-donor ligands have been found to be more advantageous than those of ligands having only one type of donor atom because of their catalytic potential in various organic transformations.[1] In principle, those ligands containing donor atoms with different binding abilities are ideally suited to provide temporary coordinative saturation to the metal center via chelation until it is required to furnish an active site at the metal center prior to oxidative addition, an important step in homogeneous catalysis. Among various mixed-donor ligands of the type P,O,[2] P,N,[3] and P,S,[4] ligands combining phosphorus and sulfur centers are especially interesting. Both phosphorus and sulfur are excellent donor atoms for a wide range of metals while the low ionization energy of sulfur and the existence of several lone pairs of electrons (three in the case of a thiolate anion) offer the possibility of a rich sulfur-based chemistry of the complexes. Although, the coordination chemistry of P,S ligands with various transition metal derivatives has been well studied and some complexes have proved to be active catalysts,[5] P,S ligand chemistry with the group 11 metals is limited. Of the few complexes of mixed P,S donor ligands with group 11 metal derivatives that are known, some show excellent catalytic activity and offer interesting structural features (only P or both P and S coordination), and some bimetallic complexes show metallophilic interactions that can make them ideal candidates for luminescence studies.[6]

We recently reported the synthesis of the mesocyclic mixed P,S ligands **2a** and **2b**, which exhibit an interesting coordination behavior towards palladium and platinum derivatives that results in cationic, anionic (**3a**, **3b**), and neutral complexes (Scheme 1).[7] In all compounds, the sulfur atom present as part of an eight-membered thioether aminophosphonite ring system shows a coordinative interaction with phosphorus, which creates a pseudo trigonal bipyramidal (TBP) geometry at the phosphorus center. All the palladium complexes synthesized are promising catalysts for Suzuki cross-coupling reactions, with the anionic complexes **3a** and **3b** being particularly active (TONs of up to 92000). Since group 11 metal complexes of P,S ligands are

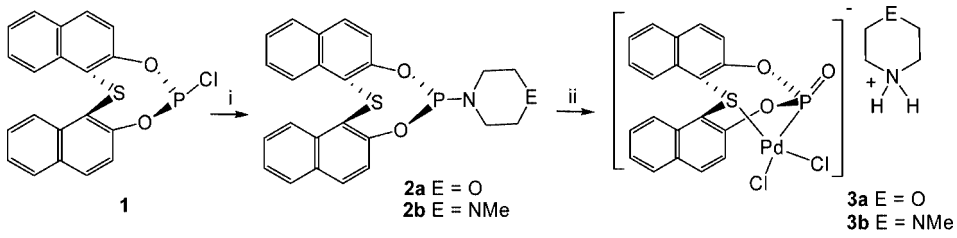


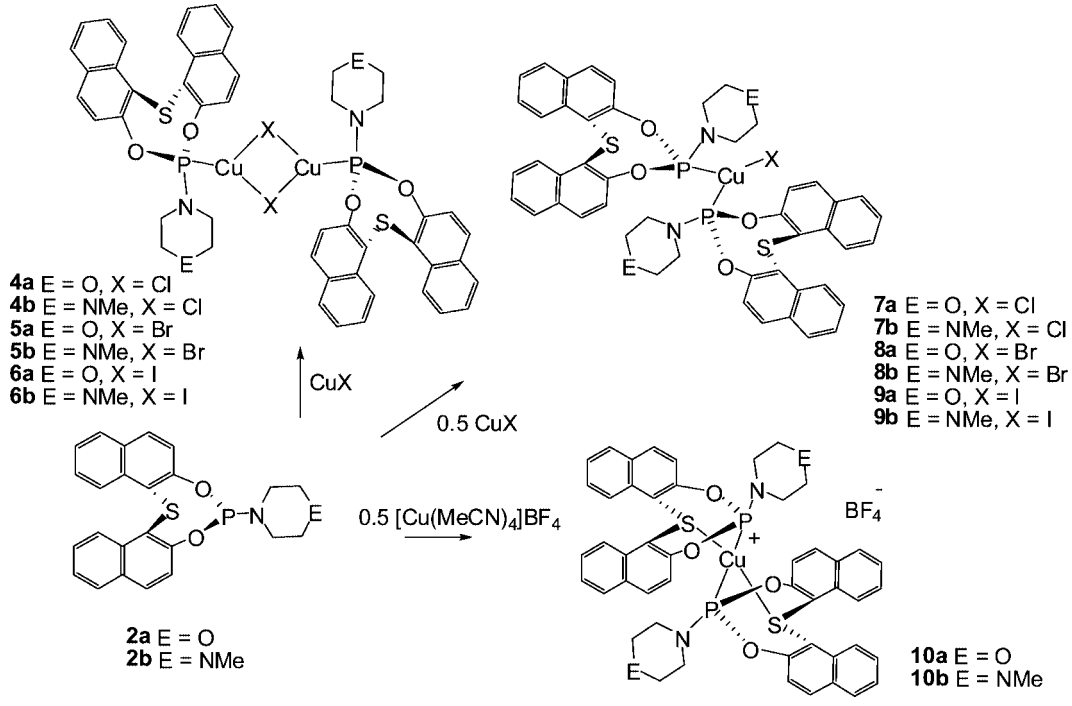
Scheme 1.

few in number, we sought to examine the reactivity of these thioether aminophosphonites with the group 11 metals. As part of our interest in organometallic chemistry[8] and catalytic investigations,[7,9] we report here on the reactivity of the mesocyclic thioether aminophosphonites **2a** and **2b** with group 11 metal centers as well as halide-exchange reactions of gold(I) complexes. X-ray structures of copper(I) (**5a**, **7a**, **8a**) and gold(I) (**13a**, **13b**, **14a**) complexes are also described.

## Results and Discussion

### Synthesis of Copper(I) Complexes

Treatment of thioether aminophosphonites **2a** and **2b** with one equivalent of CuX (X = Cl, Br, and I) in dichloromethane/acetonitrile mixtures leads to the formation of the halide-bridged dinuclear $Cu^{I}$ complexes [{[{-$OC_{10}H_6$(μ-S)-$C_{10}H_6O$-}$PNC_4H_8$E-κ*P*]Cu(μ-X)}$_2$] (**4a**: E = O, X = Cl; **4b**: E = NMe, X = Cl; **5a**: E = O, X = Br; **5b**: E = NMe, X = Br; **6a**: E = O, X = I; **6b**: E = NMe, X = I) in good yields, as shown in Scheme 2. Both the chloro derivatives (**4a** and **4b**) and iodo derivative **6b** precipitated from the reaction mixture as white insoluble solids, whereas the remaining complexes (**5a**, **5b**, and **6a**) crystallize from the mother liquor either at –25 °C or at room temperature. Most of the complexes (except for **4a** and **6b**) are soluble only in DMSO, which allows us to carry out spectroscopic studies. The $^{31}P$ NMR spectra of complexes **4b**, **5a**, **5b**, and **6a** show single resonances at $\delta$ = 114.4, 113.3, 110.5, and 110.4 ppm, respectively. In the $^{1}H$ NMR spectra of these complexes, two broad singlets are observed in the region $\delta$ = 2.49–3.71 ppm for the $CH_2$ protons of the morpholine and piperazine moieties. The mass spectrum of complex **5a** shows two peaks at *m*/*z* 576.0 and 496.0 for the ions corresponding to [$M^+$ – (**2a** + CuBr)] and [$M^+$ – (**2a** + $CuBr_2$)], respectively. Spectroscopic studies on complexes **4a** and **6b** could not be carried out because of their poor solubility in most organic solvents; however, their chemical compositions were established by elemental analysis. The molecular structure of complex **5a** was confirmed by a single-crystal X-ray diffraction study.



Scheme 2.

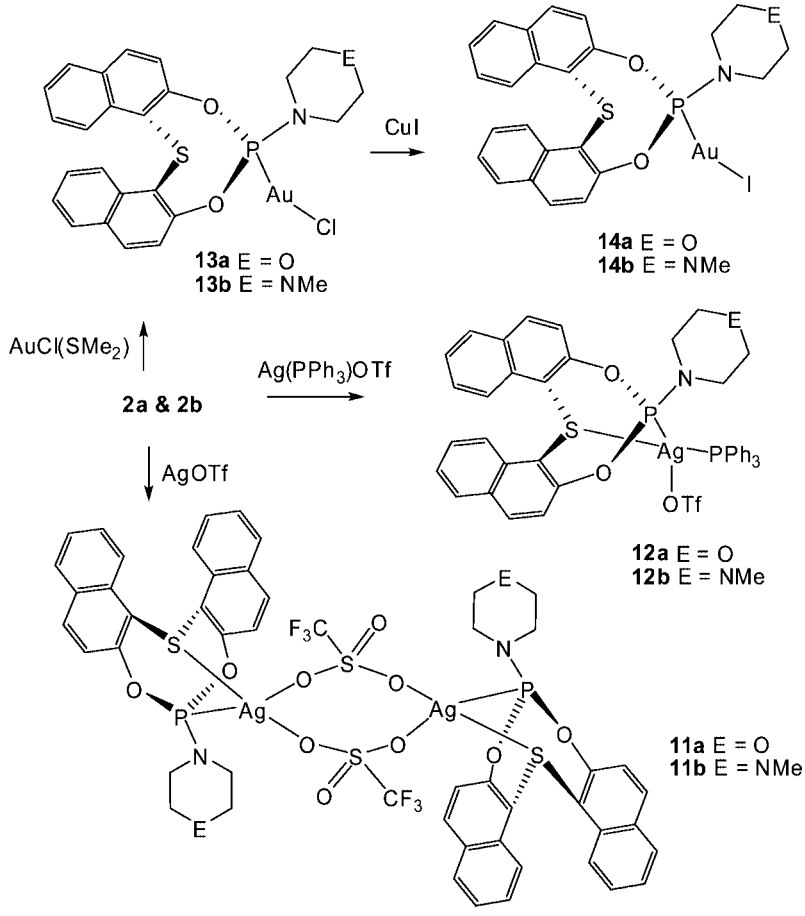
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The reactions of **2a** with CuX (X = Cl, Br, and I) in a 2:1 ratio in dichloromethane afford the tricoordinate mononuclear complexes [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6$O-]$PNC_4H_8$O-κ*P*}$_2$CuX] (**7a**: X = Cl; **8a**: X = Br; **9a**: X = I; Scheme 2). The $^{31}$P NMR spectra of complexes **7a**, **8a**, and **9a** show single resonances at $\delta$ = 115.8, 112.3, and 111.8 ppm, respectively. In the $^1$H NMR spectra of these complexes, two broad singlets are observed in the region $\delta$ = 3.29–3.66 ppm for the $CH_2$ protons of the morpholine moiety, although two distinct triplets ($\delta$ = 3.41 and 3.79 ppm) are observed for ligand **2a**. Similarly, the reactions of **2b** with half an equivalent of CuX (X = Cl, Br, and I) produce the mononuclear complexes [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6$O-]$PNC_4H_8NCH_3$-κ*P*}$_2$CuX] (**7b**: X = Cl; **8b**: X = Br; **9b**: X = I) in good yields The chloro and bromo derivatives precipitate during the course of reaction while the iodo derivative crystallizes from the mother liquor. The $^{31}$P NMR spectra of complexes **7b**, **8b**, and **9b** show single resonances at $\delta$ = 112.2, 113.4, and 116.9 ppm, respectively. Further support for the structural composition of these complexes comes from their $^1$H NMR spectra and elemental analyses, while single-crystal X-ray structure determinations established the structures of complexes **7a** and **8a**.

Surprisingly, ligands **2a** and **2b** in the above complexes (**4a**–**9b**) are monodentate with only phosphorus coordination and do not form chelate rings with the P and S centers despite these centers being in close proximity [P···S nonbonding distances in **2a** and **2b** are 3.089(1) and 3.040(1) Å, respectively].[7] However, the P,S-chelated cationic complexes [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6$O-]$PNC_4H_8$O-κ*P*,κ*S*}$_2$Cu]$BF_4$ (**10a**) and [{[-$OC_{10}H_6$(μ-S)$C_{10}H_6$O-]$PNC_4H_8NCH_3$-κ*P*,κ*S*}$_2$Cu]$BF_4$ (**10b**) are formed when ligands **2a** and **2b** are treated with half an equivalent of [Cu(MeCN)$_4$]$BF_4$, as shown in Scheme 2. Both these complexes are moderately stable in the solid state but decompose slowly in solution. The $^{31}$P NMR spectra of complexes **10a** and **10b** show single resonances at $\delta$ = 112.2 and 113.7 ppm, respectively. The mass spectrum of complex **10a** shows peaks at *m*/*z* 929.1 and 496.0 for the ions [$M^+$ – $BF_4$] and [$M^+$ – (**2a** + $BF_4$)], respectively. Similarly, for complex **10b** peaks are observed at *m*/*z* 955.2 and 509.1 for the ions [$M^+$ – $BF_4$] and [$M^+$ – (**2b** + $BF_4$)], respectively.

### Synthesis of Silver(I) Complexes

Treatment of thioether aminophosphonites **2a** and **2b** with one equivalent of AgOTf gives complexes with the composition [(**2a**)Ag(OTf)] (**11a**) and [(**2b**)Ag(OTf)] (**11b**), respectively. These complexes are highly light sensitive in solution, whereas they are moderately stable in the solid state. In the room-temperature $^{31}$P NMR spectrum of com-



Scheme 3.

plex **11b**, two broad resonances separated by about 594 Hz are observed centered at $\delta$ = 123.3 ppm, while one broad singlet is observed at $\delta$ = 118.8 ppm for complex **11a**. Previous $^{31}$P NMR studies of phosphane and phosphite complexes of $Ag^I$ salts involving both coordinating and noncoordinating anions[6d,10] have shown the existence of ligand dissociation and/or exchange processes at or below room temperature that lead to broad resonances due to the loss of the expected $^1J_{Ag,P}$ couplings. Typically, the low-temperature limiting spectra consist of two doublets for each group of chemically equivalent phosphorus nuclei due to coupling with both $^{109}$Ag and $^{107}$Ag. Unfortunately, due to the poor solubility and stability of **11a** and **11b**, low-temperature NMR studies could not be carried out, so that while with **11a** there is probably only one phosphorus environment, in the case of **11b** it is not clear whether there are two different phosphorus environments or simply one where the dynamic process occurring is sufficiently slow that an average $^1J_{Ag,P}$ coupling is observed. Structural studies of the silver complexes of another P,S ligand [Fc(PPh$_2$)(SPh)] show a preference for a four-coordinate tetrahedral geometry.[6d] Although only tentatively because of the limited data available, we suggest that complexes **11a** and **11b** contain a chelating P,S ligand and are either monomeric with a bidentate trifluoromethanesulfonate or dinuclear with bridging trifluoromethanesulfonate ligands. Similarly, the P,S chelated complexes [{[-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-]PNC$_4$H$_8$E-κ*P*,κ*S*}Ag(PPh$_3$)]CF$_3$SO$_3$ (**12a**: E = O; **12b**: E = NMe) can be synthesized by treatment of **2a** and **2b** with [Ag(PPh$_3$)][OTf] in a 1:1 molar ratio. The $^{31}$P NMR spectrum of complex **12a** shows two sets of broad doublets centered at $\delta$ = 123.9 and 9.7 ppm with $^1J_{Ag,P}$ coupling constants of about 512 and 394 Hz for coordinated **2a** and PPh$_3$, respectively. However, the $^{31}$P NMR spectrum of complex **12b** shows broad singlets at $\delta$ = 130.3 and 8.2 ppm for coordinated **2b** and PPh$_3$, respectively. In the mass spectra of complexes **12a** and **12b**, peaks are observed at *m*/*z* 803.1 and 816.9, respectively, for the ion [M$^+$ – CF$_3$SO$_3$]. By analogy with the complex [Ag(PPh$_3$){Fc(PPh$_2$)(SPh)}(OTf)],[6d] which contains a chelating P,S ligand and coordinated triflate, we propose that **12a** and **12b** are monomeric, four-coordinate species with chelating P,S ligands and monodentate trifluoromethanesulfonate. Further support for the composition of these complexes comes from their $^1$H NMR spectra and elemental analysis data (Scheme 3).

### Synthesis of Gold(I) Complexes

The reactions of thioether aminophosphonites **2a** and **2b** with [AuCl(SMe$_2$)] in dichloromethane afford the mononuclear P-coordinated complexes [{[-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-]PNC$_4$H$_8$E-κ*P*}AuCl] (**13a**: E = O; **13b**: E = NMe). Both complexes are white, crystalline solids and are light sensitive while in solution. Attempt to synthesize three-coordinate gold complexes akin to [(PPh$_3$)$_2$AuCl][11] were unsuccessful and resulted in the formation of complexes **13a** and **13b**. This may be due to the bulkiness of the ligand, with the closeness of the sulfur atom to the gold center (vide infra) preventing another ligand from approaching the gold center. The $^{31}$P NMR spectra of complexes **13a** and **13b** show single resonances at $\delta$ = 113.1 and 115.3 ppm, respectively. When these complexes are treated with CuI in dichloromethane at room temperature, they undergo halide exchange to form the iodo derivatives [{[-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-]PNC$_4$H$_8$E-κ*P*}AuI] (**14a**: E = O; **14b**: E = NMe). The $^{31}$P NMR spectra of complexes **14a** and **14b** show singlets at $\delta$ = 118.1 and 118.9 ppm, which are considerably deshielded compared to their chloro analogs. The molecular compositions of these complexes (**13a**,**b** and **14a**,**b**) were further confirmed by their $^1$H NMR spectra, elemental analysis data, and X-ray diffraction studies for complexes **13a**, **13b**, and **14a**. Other groups have also reported similar halogen-exchange reactions of gold complexes with KI at elevated temperature,[12] although halogen exchange of gold(I) complexes with CuI is not known in the literature.

### Crystals Structures of Complexes 5a, 7a, 8a, 13a, 13b, and 14a

Perspective views of the molecular structures of compounds **5a**, **7a**, **8a**, **13a**, **13b**, and **14a** with the atom-numbering schemes are shown in Figures 1, 2, 3, 4, 5, and 6, respectively. Selected bond lengths and bond angles for complexes **5a**, **7a**, and **8a** appear in Table 1, whereas those of complexes **13a**, **13b**, and **14a** are listed in Table 2. Crystal data and the details of the structure determinations are given in the Experimental Section.

In the molecular structure of complex **5a**, each of the copper centers is coordinated to one phosphorus center and two bromine atoms and exists as a centrosymmetric dimer. The morpholine rings adopt a chair conformation and the sulfur atoms connecting the naphthalene groups face towards the Cu$_2$Br$_2$ ring with a Cu···S separation of 3.0901(14) Å. As this is less than the sum of the van der Waals radii for copper and sulfur (3.20 Å),[13] there may be a weak Cu···S interaction. The backbones of two aminophosphonite ligands are in the staggered conformation, while the PCu(μ-Br)$_2$CuP unit is almost planar. Several trigonal planar dinuclear copper complexes of this type containing monophosphanes have been well characterized,[14] however those of aminophosphonites or phosphites are rare. The Cu–P bond length [2.171(1) Å] in complex **5a** is comparable with that in the tetrahedral copper complex of the monophosphite 4-nitro,2,6,7-trioxa-1-phosphabicyclo-[2.2.2]octane [Cu–P 2.1683(6) Å].[15] The Cu···Cu and Br···Br distances are 3.108 and 3.758 Å, respectively, indicating a possible weak Cu···Cu interaction. The core angles Cu–Br–Cu$_a$ [79.17(2)°] and Br–Cu–Br$_a$ [100.83(2)°] are significantly distorted from those of the above-mentioned monophosphite complex [Cu–Br–Cu$_a$ 75.183(12); Br–Cu–Br$_a$ 104.817(12)°].[15]

Interestingly, the sulfur atom also appears to show a weak coordinative interaction with phosphorus, as indi-

cated by the P···S distance [3.098(2) Å]. This P···S distance is comparable to that observed in our previous report[7] and that of others[16] (see Table 3). While considerably greater than the sum of the covalent radii for sulfur and phosphorus (2.12 Å),[17] this distance is less than the sum of van der Waals radii (3.65 Å)[13] for these two elements. This interaction leads to the structural displacement of phosphorus from pyramidal to a pseudo TBP. The degree to which the TBP is approached can be seen from the axial S–P–R angle and can be quantified by the procedure of Holmes and coworkers.[18] In this procedure, the degree of displacement from pyramidal toward TBP can be calculated by noting how far the P···S distance departs from the sum of the van der Waals radii (3.65 Å) toward the sum of the covalent radii (2.12 Å). For complex **5a** the %TBP displacement is calculated to be 36.1% (Table 3).

The molecular structures of the chloride (**7a**) and bromide (**8a**) complexes are isomorphous; they crystallize in the monoclinic space group $P2_1/n$. In both structures the copper centers are coordinated through two aminophosphonite ligands and a halide ion and exist as monomers. The geometries around the copper center are almost planar. The Cu–P bond lengths in complex **7a** [Cu–P1 2.2062, Cu–P2 2.1897(7) Å] and complex **8a** [Cu–P1 2.1884(6), Cu–P2 2.2063(5) Å] are almost identical. As seen in complex **5a**, the sulfur atoms in complexes **7a** and **8a** show coordinative interaction towards the phosphorus centers [**7a**: S1–P1 3.088(1), S2–P2 3.199(1) Å; **8a**: S1–P1 3.1918(8), S2–P2 3.0874(8) Å], which forces the phosphorus centers to as-

sume pseudo TBP geometries (Table 3). Although the sulfur atoms in both complexes are pointing towards the copper center, no sulfur to copper bonding interaction is observed as the Cu···S separations are 0.17–0.42 Å greater than the sum of the van der Waals radii. The P1–Cu–P2 bond angle in bromo derivative **8a** [130.20(2)°] is slightly greater than that of the chloro complex **7a** [128.61(3)°]. Structural data are available for a number of three-coordinate complexes of

For complexes **13a** and **13b** the unit cell contains two molecules arranged in an anti-parallel manner with no intermolecular gold–gold interaction [a common feature among linear mononuclear gold(I) complexes][12b] present (Au···Au 5.017 and 5.511 Å, respectively). The Au–Cl [2.2725(7) and 2.2786(5) Å] and Au–P bond lengths [2.2002(7) and 2.2038(5) Å] in complexes **13a** and **13b** are comparable with those observed for [(PhO)$_3$PAuCl] [Au–Cl 2.273(5), Au–P 2.192(5) Å][19a] as well as for [{2,4,6-*t*Bu$_3$C$_6$H$_2$P=C(Cl)PPh$_2$}AuCl] [Au–Cl 2.283(1), Au–P 2.229(1) Å].[19b] The S···Au separations observed in **13a** and **13b** are 3.4876(6) and 3.4508(5) Å, respectively, which are comparable to the sum of the van der Waals radii for gold and sulfur (3.46 Å).[13] There is thus only a minimal Au···S interaction at best. As with the previous complexes, the sulfur atoms in **13a** and **13b** show a coordinative interaction towards phosphorus, with S···P separations of 3.1820(8) (for **13a**) and 3.1673(7) Å (for **13b**), which are markedly shorter than the sum of the van der Waals radii for sulfur and phosphorus (3.65 Å).[13] The geometries around gold are not quite linear, with Cl–Au–P bond angles of 178.73(2)° and 176.67(2)°, respectively, for **13a** and **13b**. Again, these are comparable with that found in [(PhO)$_3$PAuCl] [Cl–Au–P 178.5(2)°].[19a]

The molecular structure of complex **14a** is shown in Figure 6. The unit cell contains two molecules that are somewhat more closely packed (Au···Au 4.285 Å) than is observed for the chloro derivative **13a**. The Au–P bond [2.2291(8) Å] is somewhat longer than that found in the chloro derivative **13a**, possibly reflecting the increased size and polarizability of iodine compared with chlorine. The sulfur shows weak interactions with the gold and phosphorus centers since the S···Au and S···P distances [3.2976(9) and 3.1566(13) Å, respectively] are less than the sum of the van der Waals radii (S···Au 3.46 and S···P 3.65 Å).[13] There is a C–H···I contact of 3.075 Å with a C17–H17–I angle of 139.82°. As this distance lies between the outer limits proposed by Steiner[20] and by Brammer et al.[21] for C–H···I hydrogen bonds, and as the C–H···I angle is rather small, this is a weak interaction at best. The coordination about the gold center is less linear, with an I–Au–P bond angle of 170.41(2)°.

## Conclusions

Group 11 metal complexes of thioether aminophosphonite ligands have been synthesized. The aminophosphonites **2a** and **2b**, which contain a hemilabile thioether functionality, show versatile coordination properties. By choosing appropriate metal reagents and reaction conditions both mono- and chelating bidentate modes of coordination can be achieved. With copper halides both the mononuclear and dinuclear trigonal planar complexes are obtained. In these complexes only phosphorus takes part in coordination, leaving the sulfur center uncoordinated. The uncoordinated sulfur atom is pointing towards the metal center in all complexes, and in some cases there is an interaction with the metal. Structurally characterized dinuclear trigonal-planar copper complexes of phosphites or aminophosphonites of the type **5a** are rare. Silver and cationic copper complexes (**10a** and **10b**) have also been synthesized where sulfur is also involved in coordination. Gold complexes of both the thioether aminophosphonite ligands undergo halide exchange with copper(I) iodide to form the iodide derivatives in quantitative yield at room temperature. Generally, the halogen-exchange reactions of platinum metal derivatives are carried out at high temperature using an excess of NaI or KI. In all the complexes, the sulfur atom present in the eight-membered mesocycle shows a tendency to coordinate to phosphorus. As a consequence, the tricoordinate geometry of phosphorus is displaced towards TBP.

## Experimental Section

**Reagents and Technique:** All experimental manipulations were carried out under an atmosphere of dry nitrogen or argon using Schlenk techniques. Solvents were dried and distilled prior to use by conventional methods. The thioether aminophosphonites (**2a** and **2b**) were prepared as reported previously.[7] The metal precursors CuX (X = Cl and Br),[22] [Cu(MeCN)$_4$]BF$_4$,[23] [AuCl(SMe$_2$)][24] and [Ag(OTf)PPh$_3$][25] were prepared according to the published procedures. The $^1$H and $^{31}$P{$^1$H} NMR spectra ($\delta$ in ppm) were obtained with a Varian VXR 300 or VRX 400 spectrometer operating at frequencies of 300 or 400 ($^1$H) and 121 or 162 MHz ($^{31}$P), respectively. The spectra were recorded for $CDCl_3$ (or [D$_6$]DMSO or [D$_6$]acetone) solutions with $CDCl_3$ (or [D$_6$]-DMSO or [D$_6$]acetone) as an internal lock; TMS and 85% $H_3PO_4$ were used as internal and external standards for $^1$H and $^{31}$P{$^1$H} NMR, respectively. Positive shifts lie downfield of the standard in all cases. IR spectra were recorded with a Nicolet Impact 400 FTIR instrument as KBr disks. Microanalyses were carried out with a Carlo–Erba Model 1106 elemental analyzer. Q-Tof Micromass experiments were carried out with a Waters Q-Tof micro (YA-105). Melting points of all compounds were determined with a Veego melting point apparatus and are uncorrected.

**Synthesis of [{[{-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-}PNC$_4$H$_8$O-κ*P*]Cu(μ-Cl)}$_2$] (4a):** A solution of **2a** (0.087 g, 0.202 mmol) in dichloromethane (10 mL) was added dropwise to a solution of CuCl (0.02 g, 0.202 mmol) in acetonitrile (4 mL) and the reaction mixture was stirred for 1 h. The white precipitate formed was filtered and dried under vacuum. Yield: 85% (0.091 g); m.p. 208 °C (dec.). C$_{48}$H$_{40}$Cl$_2$Cu$_2$N$_2$O$_6$P$_2$S$_2$ (1064.9): calcd. **Synthesis of [{[-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-]PNC$_4$H$_8$O-κ*P*}AuCl] (13a):** A solution of **2a** (0.051 g, 0.119 mmol) in $CH_2Cl_2$ (8 mL) was added dropwise to a dichloromethane (5 mL) solution of [AuCl(SMe$_2$)] (0.035 g, 0.119 mmol) and the reaction mixture was stirred for 3 h at room temperature. The solution was concentrated to 3 mL and layered with petroleum ether to give colorless crystals of **13a** on cooling to –25 °C. Yield: 90% (0.071 g); m.p. 178–180 °C (dec.). $C_{24}H_{20}AuClNO_3PS$ (665.88): calcd. C 43.29, H 3.03, N 2.10, S 4.82; found C 43.19, H 2.99, N 2.08, S 4.79. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 8.77 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, ArH), 7.63–7.87 (m, 6 H, ArH), 7.51 (t, $^3J_{H,H}$ = 7.2 Hz, 2 H, ArH), 7.24 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, ArH), 3.84 (t, $^3J_{H,H}$ = 4.8 Hz, 4 H, $CH_2$), 3.65 (t, $^3J_{H,H}$ = 5.2 Hz, 4 H, $CH_2$) ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz, $CDCl_3$): $\delta$ = 113.1 (s) ppm.

**Synthesis of [{[-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-]PNC$_4$H$_8$NCH$_3$-κ*P*}AuCl] (13b):** This was synthesized by a procedure similar to that for **13a** from **2b** (0.053 g, 0.119 mmol) and [AuCl(SMe$_2$)] (0.035 g, 0.119 mmol). Yield: 89% (0.072 g); m.p. 158 °C (dec.). $C_{25}H_{23}AuClN_2O_2PS$ (678.92): calcd. C 44.23, H 3.41, N 4.13, S 4.72; found C 44.18, H 3.37, N 4.09, S 4.69. $^1H$ NMR (400 MHz, [D$_6$]acetone): $\delta$ = 8.84 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, ArH), 8.08 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, ArH), 7.99 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, ArH), 7.52–7.76 (m, 4 H, ArH), 7.49 (d, $^3J_{H,H}$ = 7.6 Hz, 2 H, ArH), 3.72 (br. s, 4 H, $CH_2$), 2.91 (br. s, 4 H, $CH_2$), 2.37 (s, 3 H, $CH_3$) ppm. $^{31}P\{^1H\}$ NMR (121.4 MHz, [D$_6$]acetone): $\delta$ = 115.3 (s) ppm.

**Synthesis of [{[-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-]PNC$_4$H$_8$O-κ*P*}AuI] (14a):** A solution of CuI (0.014 g, 0.075 mmol) in acetonitrile (5 mL) was added dropwise to a solution of **13a** (0.05 g, 0.075 mmol) in dichloromethane (8 mL) and the reaction mixture was stirred for 3 h. The solution obtained was concentrated to 5 mL to give a crystalline product on cooling to –25 °C. Yield: 74% (0.042 g); m.p. 208–210 °C (dec.). $C_{24}H_{20}AuINO_3PS$ (757.33): calcd. C 38.06, H 2.66, N 1.85, S 4.23; found C 37.98, H 2.63, N 1.81, S 4.19. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 8.78 (d, $^3J_{H,H}$ = 8.0 Hz, 2 H, ArH), 7.43–7.81 (m, 8 H, ArH), 7.28 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, ArH), 3.85 (br. s, 4 H, $CH_2$), 3.68 (br. s, 4 H, $CH_2$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 118.1 (s) ppm.

**Synthesis of [{[-OC$_{10}$H$_6$(μ-S)C$_{10}$H$_6$O-]PNC$_4$H$_8$NCH$_3$-κ*P*}AuI] (14b):** This complex was synthesized by a procedure similar to that for **14a** from CuI (0.014 g, 0.075 mmol) and **13b** (0.051 g, 0.075 mmol). Yield: 69% (0.04 g); m.p. 192–194 °C (dec.). $C_{25}H_{23}AuIN_2O_2PS$ (770.37): calcd. C 38.98, H 3.01, N 3.64, S 4.16; found C 38.92, H 2.97, N 3.59, S 4.12. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 8.76 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, ArH), 7.80–7.85 (m, 4 H, ArH), 7.64 (t, $^3J_{H,H}$ = 7.6 Hz, 2 H, ArH), 7.48 (t, $^3J_{H,H}$ = 7.6 Hz, 2 H, ArH), 7.22 (d, $^3J_{H,H}$ = 8.8 Hz, 2 H, ArH), 3.67 (br. s, 4 H, $CH_2$), 2.55 (br. s, 4 H, $CH_2$), 2.39 (s, 3 H, $CH_3$) ppm. $^{31}P\{^1H\}$ NMR (162 MHz, $CDCl_3$): $\delta$ = 118.9 (s) ppm.

**X-ray Crystallography:** Crystals of **5a**, **7a**, **8a**, **13a**, **13b**, and **14a** were mounted in a Cryoloop™ with a drop of Paratone oil and placed in the cold nitrogen stream of the Kryoflex™ attachment of a Bruker APEX CCD diffractometer. A full sphere of data was collected using 606 scans in $\omega$ (0.3° per scan) at $\phi$ = 0, 120, and 240° (for **5a**, **7a**, and **14a**) or 400 scans in $\omega$ (0.5° per scan) at $\phi$ = 0, 90, and 180° plus 800 scans in $\phi$ (0.45° per scan) at $\omega$ = 0 and 210° (for **8a**, **13a**, and **13b**) using the SMART software package.[26] The raw data were reduced to $F^2$ values using the SAINT+ software[27] and global refinements of unit cell parameters using 4630–9050 reflections chosen from the full data sets were performed. Multiple measurements of equivalent reflections provided the basis for empirical absorption corrections as well as corrections for any crystal deterioration during the data collection (SADABS[28]). The structures were solved by direct methods (for **5a**, **7a**, **8a**, **13a**, and **13b**) or the position of the metal atoms was obtained from a sharpened Patterson function (for **14a**) and refined by full-matrix least-squares procedures using the SHELXTL program package.[29] Hydrogen atoms were placed in calculated positions and included as riding contributions with isotropic displacement parameters tied to those of the attached non-hydrogen atoms. Pertinent crystallographic data and other experimental details are summarized in Tables 4 and 5.

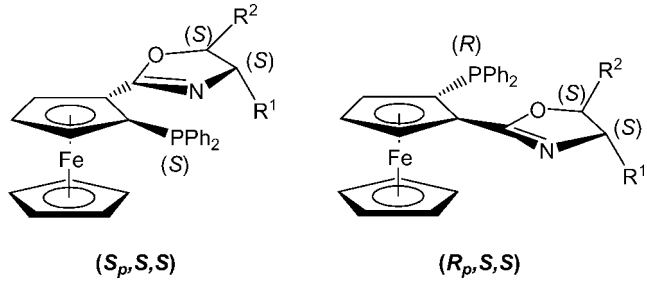
## Introduction

Metal-mediated asymmetric catalysis has emerged as a very valuable synthetic tool to obtain enantiomerically pure substances.[1] Chiral ferrocene-based ligands incorporating both planar and central chirality are especially attractive due to their potential use in asymmetric induction.[2] Phosphanylferrocenyloxazoline derivatives[3,4] (Scheme 1) belong to this class of ligands and show a remarkable versatility since the substituents in the oxazoline group allow the modulation of the stereogenic centre located close to the N donor atom. Hybrid hemilabile phosphorus–nitrogen ligands are also gaining increasing relevance in coordination and organometallic chemistry since they can reversibly create and/or occupy a vacant coordination site at the metal.[5] In particular, ruthenium complexes containing chiral phosphanylferrocenyloxazoline ligands have proven to be good catalysts in hydrogenation,[6] hydrosilylation,[7] and transfer hydrogenation[8,9] of ketones, imines and ketoximes. However, most of the active species are formed in situ and therefore their coordination chemistry has been scarcely studied.



($S_p$,*S*,*S*) ($R_p$,*S*,*S*)

Scheme 1.

The only isolated ruthenium(II) derivatives with FcPN ligands are either five-coordinate, such as [RuCl$_2${$\kappa^2$(*P*,*N*)-FcPN}(PPh$_3$)],[9] or octahedral complexes, such as [RuX$_2${$\kappa^2$(*P*,*N*)-FcPN}(PR$_3$)$_2$], [RuCl$_2${$\kappa^2$(*P*,*N*)-FcPN}-(dppm)], [RuCl$_2$(CO){$\kappa^2$(*P*,*N*)-FcPN}(L)] and [RuCl(CO)-{$\kappa^2$(*P*,*N*)-FcPN}(dppm)][PF$_6$] [dppm = bis(diphenylphosphanyl)methane].[10,11] It is interesting to note that no half-sandwich species have been described to date.

Following our interest in the chemistry of half-sandwich ruthenium(II) fragments and their use as promoters of catalytic[12] and stoichiometric C–C coupling reactions,[13] we report herein the diastereoselective synthesis of the first half-sandwich $\eta^5$-indenyl- and $\eta^6$-areneruthenium(II) complexes containing the chiral ligand FcPN (Scheme 2).

## Results and Discussion

### Synthesis of Indenyl Complexes

#### *Synthesis of [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(P,N)-FcPN}($PPh_3$)][$PF_6$] (1)*

The lability of the triphenylphosphane ligands in the complex [Ru($\eta^5$-$C_9H_7$)Cl($PPh_3$)$_2$] allows their ready exchange and the synthesis of a large series of mixed and chelating diphosphane complexes such as [Ru($\eta^5$-$C_9H_7$)-Cl($PPh_3$)L] and [Ru($\eta^5$-$C_9H_7$)Cl(L–L)].[14] Following this methodology, the reaction of [Ru($\eta^5$-$C_9H_7$)Cl($PPh_3$)$_2$] with FcPN in refluxing toluene does not lead, however, to the expected phosphane exchange. Rather, the cationic complex [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(*P*,*N*)-FcPN}($PPh_3$)][Cl] is formed. Subsequent treatment with $NaPF_6$ in methanol leads to the hexafluorophosphate salt [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(*P*,*N*)-FcPN}($PPh_3$)]-[$PF_6$] (**1**) in 81% yield, which was isolated as a red, air-stable solid (Scheme 3).

[Ru($\eta^5$-$C_9H_7$)Cl($PPh_3$)$_2$] —(i) FcPN, toluene, Δ; (ii) $NaPF_6$, MeOH→ [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(*P*,*N*)-FcPN}($PPh_3$)][$PF_6$]

**1**

Scheme 3.

Complex **1** is soluble in dichloromethane and thf and insoluble in diethyl ether and hexane. It was characterised by analytical and spectroscopic methods (see Experimental Section for details). The most remarkable spectroscopic features are: i) the IR spectrum (KBr) shows a strong absorption at 841 $cm^{-1}$ due to the $PF_6^-$ group, and ii) the $^{31}P\{^1H\}$ NMR spectrum displays two doublet resonances at $\delta$ = 34.7 and 58.8 ppm ($^2J_{P,P}$ = 36.5 Hz), as expected for an AB system arising from the presence of the inequivalent phosphorus nuclei.

#### *Synthesis of [Ru($\eta^5$-$C_9H_7$)Cl{$\kappa^2$(P,N)-FcPN}] (2)*

The neutral, chelating FcPN complex [Ru($\eta^5$-$C_9H_7$)-Cl{$\kappa^2$(*P*,*N*)-FcPN}] (**2**) was readily obtained by displacement of the labile COD ligand in [Ru($\eta^5$-$C_9H_7$)Cl-(COD)][12e] (COD = 1,5-cyclooctadiene) by treatment with one equivalent of FcPN in refluxing thf (Scheme 4). Complex **2** was isolated (95% yield) as an air-stable, red solid that is soluble in dichloromethane, thf and diethyl ether and insoluble in hexane. It was fully characterised by analytical and spectroscopic methods and X-ray crystallography, which confirmed the chelating coordination mode of FcPN. Slow diffusion of hexane into a solution of **2** in dichloromethane resulted in crystals suitable for X-ray diffraction studies. An ORTEP view of the molecule is shown in Figure 1; selected bond lengths are listed in the caption.

[Ru($\eta^5$-$C_9H_7$)Cl(COD)] —FcPN, THF, Δ→ [Ru($\eta^5$-$C_9H_7$)Cl{$\kappa^2$(*P*,*N*)-FcPN}]

**2**

Scheme 4.

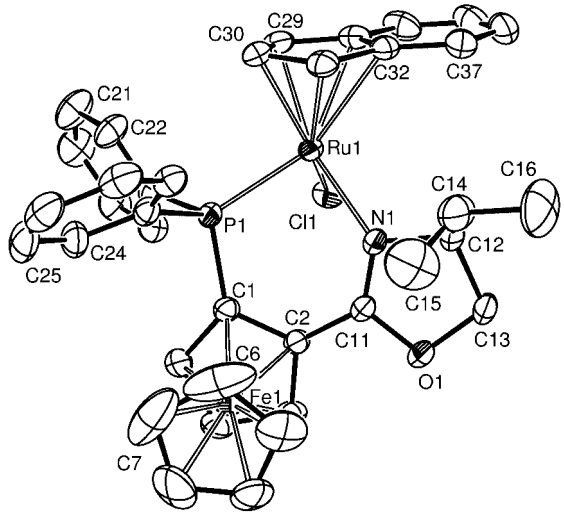

Figure 1. Molecular structure and atom-labelling scheme for complex **2**. Non-hydrogen atoms are represented by their 30% probability ellipsoids. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å]: Ru(1)–C* 1.884(4), Ru(1)–N(1) 2.137(2), Ru(1)–P(1) 2.228(1), Ru(1)–Cl(1) 2.434(1), N(1)–C(11) 1.284(3), P(1)–C(1) 1.813(3), C(1)–C(2) 1.444(4), C(2)–C(11) 1.444(4). Selected bond angles [°]: C*–Ru(1)–P(1) 126.27(6), C*–Ru(1)–N(1) 132.78(8), C*–Ru(1)–Cl(1) 120.73(6), N(1)–Ru(1)–P(1) 90.65(6), N(1)–Ru(1)–Cl(1) 83.56(6), P(1)–Ru(1)–Cl(1) 88.60(3), C(1)–P(1)–Ru(1) 112.94(9), N(1)–C(11)–C(2) 128.8(2), C(1)–C(2)–C(11) 125.8(2), C(2)–C(1)–P(1) 123.6(2). C* means the centroid of atoms C(29), C(30), C(31), C(32) and C(33).

The complex adopts a three-legged piano-stool structure with P and N atoms from the bidentate chelating FcPN ligand and the Cl atom as the legs. The Ru–N, Ru–P and

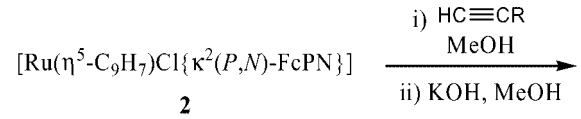
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Ru–Cl bond lengths are 2.137(2), 2.227(1) and 2.434(1) Å respectively. The ruthenium atom interacts in an $\eta^5$ fashion with the five-membered C29–C33 ring of the indenyl ligand, although in an asymmetric way as the Ru–C bond lengths range from 2.134(3) to 2.382(3) Å. The chelating six-membered ring shows an envelope conformation. The crystal structure of **2** indicates that only one diastereoisomer ($S_{Ru}$,*S*,$S_P$) is present in the crystal.

Although the crystallisation of complex **2** gives rise to the isolation of only one diastereoisomer, the $^1H$, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectra in $CD_2Cl_2$ (see Experimental Section) indicate the presence of two isomers. In particular, the $^{31}P\{^1H\}$ NMR spectrum shows two signals at $\delta$ = 63.8 and 60.7 ppm whose ratio is dependent on the solvent, thereby suggesting a potential epimerisation of the $S_{Ru}$,*S*,$S_P$ into the $R_{Ru}$,*S*,$S_P$ diastereoisomer, a behaviour that is typical for configurationally unstable chiral-at-metal complexes.[15] Chloride dissociation as well as the opening of the Ru–P–N chelate ring could promote this isomerisation. However, complex **2** behaves as a neutral species since its conductivity values in dichloromethane (4.2 $\Omega^{-1}cm^2mol^{-1}$) and acetone (1.5 $\Omega^{-1}cm^2mol^{-1}$) are rather low. Provided that no ring opening is observed for ruthenium complexes with the FcPN ligand,[10,11] we assume that two rotamers[16] arising from different favoured conformations of the indenyl ring[14] are formed in solution.

### *Synthesis of the Alkynyl Derivatives [Ru(η⁵-C₉H₇)-(C≡CR){κ²(P,N)-FcPN}] [R = Ph (3a), p-CH₃C₆H₄ (3b)]*

Reaction of complex **2** with HC≡CR and KOH in methanol affords the alkynyl complexes [Ru($\eta^5$-$C_9H_7$)-(C≡CR){$\kappa^2$(*P*,*N*)-FcPN}] [R = Ph (**3a**), *p*-$CH_3C_6H_4$ (**3b**)], which were isolated as air-stable brown solids [Yields: 79% (**3a**) and 69% (**3b**); Scheme 5].



[Ru($\eta^5$-$C_9H_7$)(C≡CR){$\kappa^2$(*P*,*N*)-FcPN}]

R = Ph (**3a**), *p*-$CH_3C_6H_4$ (**3b**)

Scheme 5.

Complexes **3a**,**b** are soluble in dichloromethane, thf and diethyl ether and insoluble in hexane. Both complexes were characterised analytically and spectroscopically (see the Experimental Section for details). In contrast to its chloride precursor **2**, all spectroscopic data are consistent with the presence of only one diastereoisomer. The following observations are of particular interest: i) the singlet resonances observed at $\delta$ = 69.3 (**3a**) and 68.4 ppm (**3b**) in the $^{31}P\{^1H\}$ NMR spectra remain unchanged within the range –90 to 20 °C, thus obviating the possibility of a dynamic process in solution; ii) the $^{13}C\{^1H\}$ NMR spectrum shows the expected resonances of the alkynyl groups (doublet signals for $C_\alpha$ [$\delta$ = 82.8 ppm ($J_{C,P}$ = 44.0 Hz) for **3a**; $\delta$ = 82.1 ppm ($J_{C,P}$ = 44.7 Hz) for **3b**] and singlets for $C_\beta$ [$\delta$ = 110.7 (**3a**) and 109.9 ppm (**3b**)]). In addition, the IR spectra (KBr) show the characteristic ν(C≡C) absorption at 2073 (**3a**) and 2074 $cm^{-1}$ (**3b**).

The absolute configuration of the ruthenium atom in these complexes was determined from an X-ray diffraction study of complex **3a**. Single crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of hexane into a solution of complex **3a** in dichloromethane. An ORTEP-type view of the complex is shown in Figure 2; selected bonding data are listed in the caption.

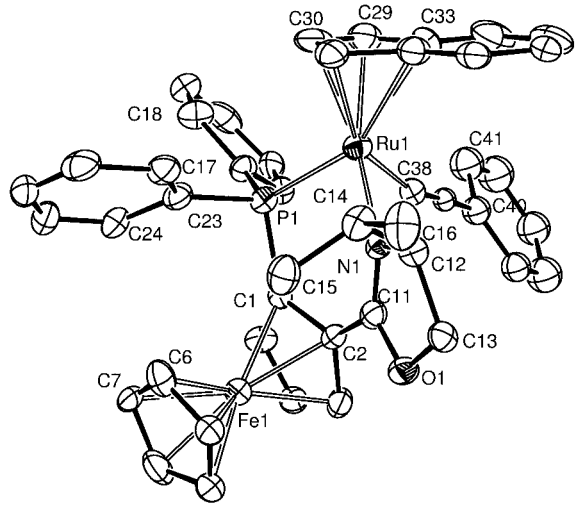


Figure 2. Molecular structure and atom-labelling scheme for complex **3a**. Non-hydrogen atoms are represented by their 10% probability ellipsoids. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å]: Ru(1)–C* 1.894(4), Ru(1)–N(1) 2.098(11), Ru(1)–P(1) 2.207(4), Ru(1)–C(38) 2.042(14), C(38)–C(39) 1.11(2) [1.27(3)], N(1)–C(11) 1.438(16), P(1)–C(1) 1.867(14), C(1)–C(2) 1.446(17), C(2)–C(11) 1.462(18). Selected bond angles [°]: C*–Ru(1)–P(1) 127.77(7), C*–Ru(1)–N(1) 132.33(5), C*–Ru(1)–C(38) 119.27(7), N(1)–Ru(1)–P(1) 89.6(3), N(1)–Ru(1)–C(38) 88.0(4), P(1)–Ru(1)–C(38) 84.6(4), C(1)–P(1)–Ru(1) 111.5(4), N(1)–C(11)–C(2) 124.8(14), C(1)–C(2)–C(11) 127.4(13), C(2)–C(1)–P(1) 120.5(11). C* means the centroid of atoms C(29), C(30), C(31), C(32) and C(33).

The complex is very similar to complex **2**. The Ru–N and Ru–P bond lengths are 2.098(11) and 2.207(4) Å, respectively, very similar to those found in **2**. The alkynyl ligand is disordered and is distributed over two positions with an equal occupancy factor. The two images have C38 as common atom [the Ru–C(38) bond length is 2.042(14) Å]. The Ru–C bond lengths involving the asymmetric $\eta^5$ interaction of the Ru atom with the five-membered ring of the indenyl ligand span from 2.10(2) to 2.34(2) Å. The stereochemistry around the ruthenium atom is $S_{Ru}$,*S*,$S_P$ and therefore no change occurs with respect to the precursor complex **2**.

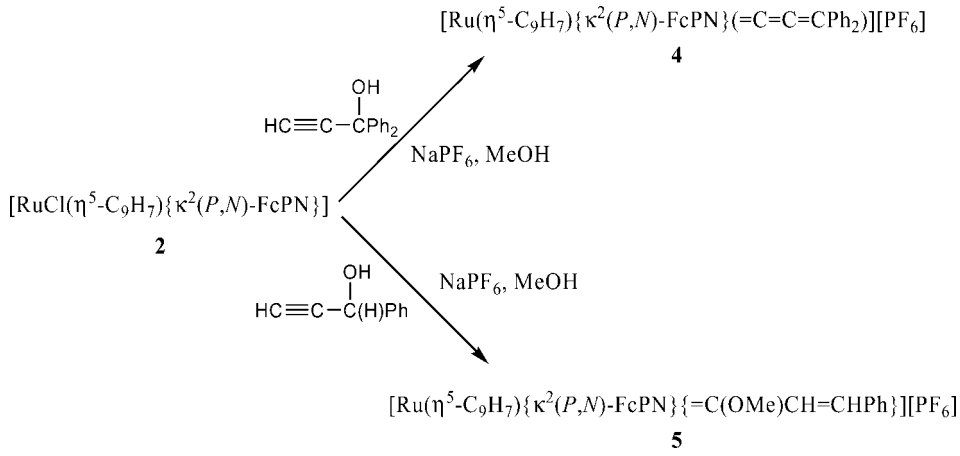


Scheme 6.

### *Synthesis of Allenylidene [Ru(η⁵-C₉H₇)[κ²(P,N)-FcPN](=C=C=CPh₂)][PF₆] (4) and Methoxycarbene [Ru(η⁵-C₉H₇){κ²(P,N)-FcPN}{=C(OMe)CH=CHPh}][PF₆] (5) Complexes*

The activation of terminal alkynes with ruthenium(II) complexes is the most direct route to cumulenylidene and related carbene complexes.[17] Following this methodology we explored the reactivity of [Ru($\eta^5$-$C_9H_7$)Cl{$\kappa^2$(*P*,*N*)-FcPN}] (**2**) towards propargylic alcohols. As expected, the reaction of equimolecular amounts of complex **2** and 1,1-diphenyl-2-propyn-1-ol in methanol in the presence of $NaPF_6$ yields the allenylidene derivative [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(*P*,*N*)-FcPN}(=C=C=$CPh_2$)][$PF_6$] (**4**), which was isolated as a purple-red solid in 65% yield after work-up (Scheme 6). However, the reaction with 1-phenyl-2-propyn-1-ol gives the alkenyl carbene [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(*P*,*N*)-FcPN}{=C(OMe)CH=CHPh}][$PF_6$] (**5**), which was isolated as a yellow solid in 73% yield after work-up (Scheme 6).

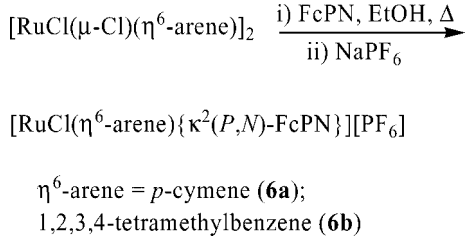
Complexes **4** and **5** are soluble in dichloromethane and thf and insoluble in diethyl ether and hexane. The elemental analysis and IR and NMR spectroscopic data are in accordance with the proposed formulations (see Experimental Section for details). The most representative spectroscopic data are as follows. The IR spectrum of complex **4** shows the ν(C=C=C) absorption at 1926 $cm^{-1}$ and the absorption corresponding to the $PF_6^-$ group at 841 $cm^{-1}$. Its $^{31}P\{^1H\}$ spectrum displays a singlet resonance at $\delta$ = 50.7 ppm and its $^{13}C\{^1H\}$ NMR spectrum shows a low-field signal for $C_\alpha$ [doublet at $\delta$ = 286.9 ppm ($J_{C,P}$ = 21.0 Hz)] and two broad singlet resonances at $\delta$ = 215.9 and 154.5 ppm for $C_\beta$ and $C_\gamma$, respectively. The IR spectrum of complex **5** shows the ν(Ru=C) absorption at 1955 $cm^{-1}$ and the ν(P–F) absorption at 841 $cm^{-1}$. The expected singlet in the $^{31}P\{^1H\}$ NMR spectra appears at $\delta$ = 57.4 ppm, and the $^1H$ NMR spectrum shows a singlet at $\delta$ = 3.75 ppm due to the methoxy group and two doublets at $\delta$ = 5.09 and 5.97 ppm ($J_{H,H}$ = 16.0 Hz) for the hydrogen atoms of the alkenyl group. The coupling constant for these doublets indicates a *trans* disposition. The $^{13}C\{^1H\}$NMR spectrum shows a low-field doublet at $\delta$ = 305.9 ppm ($J_{C,P}$ = 16.4 Hz) due to the $C_\alpha$ resonance.

The formation of **5** probably proceeds through the nucleophilic addition of one methanol molecule to the intermediate cationic allenylidene complex [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(*P*,*N*)-FcPN}(=C=C=CHPh)]$^+$.[17]

## Synthesis of $\eta^6$-Arene Complexes

### *Synthesis of [RuX(η⁶-arene){κ²(P,N)-FcPN}][PF₆] [arene = p-cymene, X = Cl (6a), H (7), N₃ (8); arene = 1,2,3,4-tetramethylbenzene, X = Cl (6b)]*

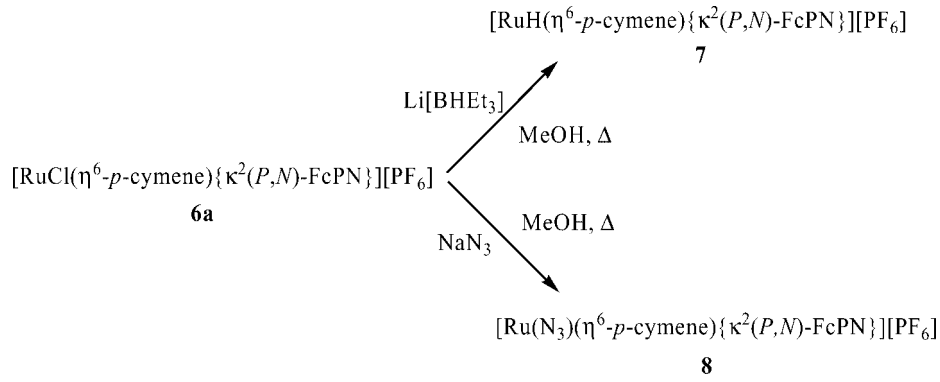
The reaction of two equivalents of FcPN with [RuCl(μ-Cl)($\eta^6$-arene)]$_2$ ($\eta^6$-arene = *p*-cymene, 1,2,3,4-tetramethylbenzene) in refluxing ethanol leads to the complexes [RuCl($\eta^6$-arene){$\kappa^2$(*P*,*N*)-FcPN}][Cl]. Subsequent chloride exchange with $NaPF_6$ gives the hexafluorophosphate salts [RuCl($\eta^6$-arene){$\kappa^2$(*P*,*N*)-FcPN}][$PF_6$] [$\eta^6$-arene = *p*-cymene (**6a**), 1,2,3,4-tetramethylbenzene (**6b**)], which were isolated as air-stable orange solids in yields of 89% (**6a**) and 86% (**6b**; Scheme 7).



Scheme 7.

Complex **6a** has been shown to be a good precursor of analogous derivatives by metathesis of the chloride ligand. Thus, the reaction with an excess of Li[$BHEt_3$] leads to the hydride derivative [RuH($\eta^6$-*p*-cymene){$\kappa^2$(*P*,*N*)-FcPN}][$PF_6$] (**7**), which was isolated as an air-stable green solid in 75% yield. Likewise, the treatment of **6a** with sodium azide in refluxing methanol gives [Ru($N_3$)($\eta^6$-*p*-cymene){$\kappa^2$(*P*,*N*)-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

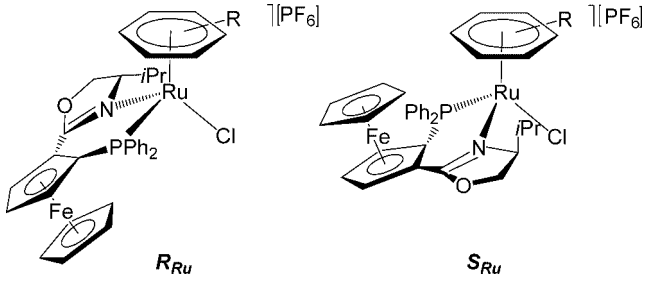


Scheme 8.

FcPN}][$PF_6$] (**8**), which was isolated as a brown solid in 71% yield (Scheme 8).

The analytical and spectroscopic data support these formulations (see Experimental Section for details). The syntheses are diastereoselective, as determined from the NMR spectra ($^1H$, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$). In particular, the $^{31}P\{^1H\}$ NMR spectra display only a singlet resonance at $\delta$ = 24.9 (**6a**) 26.5 (**6b**) 50.7 (**7**) and 23.1 ppm (**8**) at room temperature. The spectra of the complexes remain unchanged in the range –90 to 20 °C, thus indicating that, as for the analogous indenyl complex **1**, no dynamic processes take place in this temperature range. The most characteristic spectroscopic features are the ν(Ru–H) absorption at 1967 $cm^{-1}$ in the IR spectrum (KBr) and a high-field doublet for the hydride resonance at $\delta$ = –8.66 ($^2J_{H,P}$ = 43.7 Hz) in the $^1H$ NMR spectrum of complex **7**, and the ν(N=N=N) absorption at 2035 $cm^{-1}$in the IR spectrum (KBr) of complex **8**.

NOESY experiments performed on complex **6a** show cross-peaks between the $OCH_2$ and CHN protons of the oxazoline and the isopropyl group of the *p*-cymene ligand, thus indicating thier spatial proximity and suggesting that the stereochemistry around the metal is $R_{Ru}$ (see Scheme 9).



Scheme 9.

This stereochemistry was confirmed by an X-ray crystal diffraction study. Single crystals suitable for X-ray diffraction analysis were obtained by slow diffusion of hexane into a solution of complex **6a** in dichloromethane. Two crystallographically independent cations (A and B) and two $PF_6^-$ anions are present in the crystals of **6a**. The two independent complexes are very similar but differ in the coordination of the *p*-cymene: in the former the isopropyl substituent is almost eclipsed with respect to the Cl atom whereas in the latter the methyl substituent is almost eclipsed with the Cl atom. Practically, the *p*-cymene ligand is rotated by 180° in the two complexes. An ORTEP view of one of the two independent cationic complexes (B) is shown in Figure 3; selected bonding data for both complexes are listed in the caption.

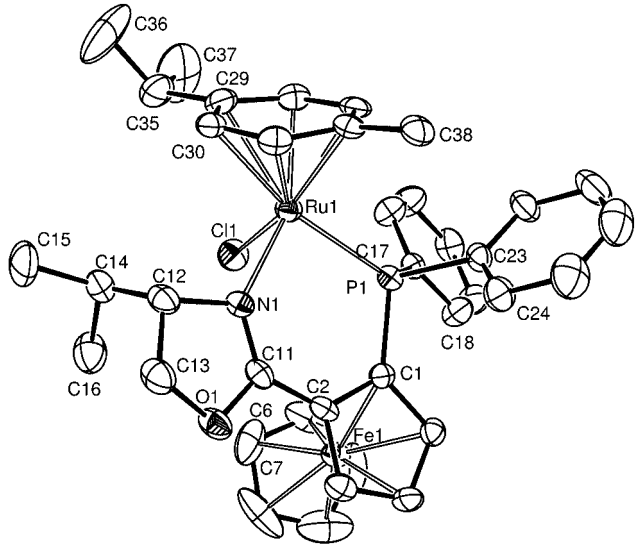


Figure 3. Molecular structure and atom-labelling scheme for complex **6a**. Non-hydrogen atoms are represented by their 30% probability ellipsoids. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å]: Ru(1)–C* 1.749(4) [1.744(5)], Ru(1)–N(1) 2.150(4) [2.122(3)], Ru(1)–P(1) 2.349(1) [2.347(1)], Ru(1)–Cl(1) 2.374(1) [2.390(1)], N(1)–C(11) 1.270(5) [1.283(5)], P(1)–C(1) 1.806(4) [1.824(5)], C(1)–C(2) 1.433(6) [1.427(6)], C(2)–C(11) 1.445(6) [1.443(6)]. Selected bond angles [°]: C*–Ru(1)–P(1) 127.66(6) [129.30(5)], C*–Ru(1)–N(1) 129.99(4) [126.22(4)], C*–Ru(1)–Cl(1) 122.58(8) [125.27(5)], N(1)–Ru(1)–P(1) 89.41(10) [91.54(11)], N(1)–Ru(1)–Cl(1) 84.23(10) [84.99(10)], P(1)–Ru(1)–Cl(1) 89.35(5) [85.68(4)], C(1)–P(1)–Ru(1) 114.27(15) [113.32(15)], N(1)–C(11)–C(2) 131.5(5) [129.0(5)], C(1)–C(2)–C(11) 127.3(4) [129.8(4)], C(2)–C(1)–P(1) 122.6(4) [122.9(4)]. C* means the centroid of atoms C(29), C(30), C(31), C(32), C(33), C(34). Data in square brackets refer to complex B.

As shown in Figure 3, the absolute configuration at the ruthenium atom ($R_{Ru}$) is the opposite to that found for the indenyl complexes **2** and **3a**. The Ru–N bond lengths [2.150(4) and 2.122(3) Å for cation B] do not differ significantly from those observed in **2** and **3a**, while the Ru–P

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ones are longer [2.349(1) and 2.347(1) Å]. The Ru–Cl bond lengths [2.374(1) and 2.390(1) Å] are slightly shorter than that found in **2** [2.434(1) Å]. The Ru–C bond lengths of the *p*-cymene ligand span from 2.180(5) to 2.321(4) Å.

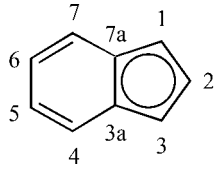
The stereochemistry $R_{Ru}$ found for complex **6a** can also be tentatively assigned to be the same for the chloride (**6b**), hydride (**7**) and azide (**8**) complexes.

## Conclusions

In summary, we have described the diastereoselective synthesis of new chiral-at-metal $\eta^5$ and $\eta^6$ half-sandwich ruthenium(II) complexes containing the chiral ligand (4*S*)-2-[($S_p$)-2-(diphenylphosphanyl)ferrocenyl]-4-(methylethyl)-oxazoline (FcPN). The absolute configuration of the ruthenium atoms has been determined by X-ray analyses of complexes **2**, **3a** and **6a**.

## Experimental Section

**General Procedures:** All manipulations were performed under an atmosphere of dry nitrogen using standard vacuum-line and Schlenk techniques. All reagents were obtained from commercial suppliers and used without further purification. Solvents were dried by standard methods and distilled under nitrogen before use. The compounds [Ru($\eta^5$-$C_9H_7$)Cl(COD)],[12e] [Ru($\eta^5$-$C_9H_7$)Cl($PPh_3$)],[18] [RuCl(μ-Cl)($\eta^6$-$C_{10}H_{14}$)]$_2$ [19] and (4*S*)-2-[($S_p$)-2-(diphenylphosphanyl)ferrocenyl]-4-(methylethyl)oxazoline (FcPN).[4] were prepared by previously reported methods. IR spectra were recorded with a Perkin–Elmer FT-IR Paragon 1000 spectrometer. The conductivities were measured at room temperature, for approximately $5 \times 10^{-4}$ M water solutions, with a Jenway PCM3 conductimeter. The C, H and N analyses were carried out with a Perkin–Elmer 240-B microanalyzer. NMR spectra were recorded with a Bruker AC300 or 300DPX instrument at 300 ($^1$H), 121.5 ($^{31}$P) or 75.4 MHz ($^{13}$C) using $SiMe_4$ or 85% $H_3PO_4$ as standards. DEPT experiments were carried out for all compounds. The following atom labels are used for the indenyl $^1$H and $^{13}$C{$^1$H} spectroscopic data. The label Ind-6 is used for the benzo ring.



**Synthesis of [Ru($\eta^5$-$C_9H_7$){$\kappa^2$(*P*,*N*)-FcPN}($PPh_3$)][$PF_6$] (1):** FcPN (859 mg, 1.8 mmol) was added to a solution of [Ru ($\eta^5$-$C_9H_7$)-Cl($PPh_3$)$_2$] (1320 mg, 1.7 mmol) in toluene (80 mL) and the reaction mixture was refluxed for 2.5 h. The solvents were removed under vacuum and the resulting solid was dissolved in methanol (65 mL). $NaPF_6$ (857 mg, 5.1 mmol) was added and the solution was stirred for 1 h at room temperature. The solvents were then removed under vacuum and the solid residue extracted with $CH_2Cl_2$. The solution was filtered through kieselguhr, concentrated under vacuum to a volume of about 5 mL, and diethyl ether (80 mL) was added. The solid was washed with diethyl ether ($2 \times 80$ mL) and dried under vacuum to afford complex **1** as an orange-red solid. Yield: 1.521 g (81%). Conductivity [$(CH_3)_2CO$, 20 °C]: 123 $\Omega^{-1}$ cm$^2$ mol$^{-1}$. FTIR (KBr): $\tilde{\nu}$ = 841 cm$^{-1}$ ($PF_6^-$). $^1$H NMR (300 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 7.77–7.05 (m, 28 H, Ph, Ind-6), 5.91 (m, 1 H, H-1 or H-3), 5.65 (d, $^3J_{H,H}$ = 8.3 Hz, 1 H, Ind-6), 5.32 (m, 1 H, H-1 or H-3), 4.94 (m, 1 H, $C_5H_3$), 4.68 (t, $^3J_{H,H}$ = 5.0 Hz, 1 H, $C_5H_3$), 4.66 (m, 1 H, $C_5H_3$), 4.34 (dd, $^2J_{H,H}$ = 1.9, $^3J_{H,H}$ = 8.7 Hz, 1 H, $OCH_2$), 3.64 (s, 5 H, $C_5H_5$), 3.60 (d, $^3J_{H,H}$ = 8.7 Hz, 1 H, $OCH_2$), 3.18 (m, 1 H, H-2), 3.03 (t, $^3J_{H,H}$ = 8.7 Hz, 1 H, CHN), 2.89 [sept d, $^3J_{H,H}$ = 2.6, $^3J_{H,H}$ = 7.0 Hz, 1 H, C*H*($CH_3$)$_2$], 1.28 (d, $^3J_{H,H}$ = 7.0 Hz, 3 H, $CH_3$), 1.26 (d, $^3J_{H,H}$ = 7.0 Hz, 3 H, $CH_3$) ppm. $^{13}$C NMR (75.4 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 170.8 (s, *C*$OCH_2$), 143.6–128.0 (Ph, Ind-6), 124.6 (s, Ind-6), 124.4 (s, Ind), 116.8 (d, $^2J_{C,P}$ = 3.8 Hz, C-3a or C-7a), 112.3 (m, C-3a or C-7a), 93.7 (s, C-2), 79.0 (d, $J_{C,P}$ = 39.4 Hz, $CPPh_2$), 75.7 (s, $C_5H_3$), 75.3 (s, $C_5H_3$), 74.5 (d, $^2J_{C,P}$ = 19.1 Hz, *C*$CPPh_2$), 73.2 (d, $^3J_{C,P}$ = 6.4 Hz, CHN), 72.9 (d, $^2J_{C,P}$ = 7.0 Hz, $C_5H_3$), 72.3 (s, $C_5H_5$), 68.4 (d, $^2J_{C,P}$ = 12.7 Hz, C-1 or C-3), 67.7 (s, $OCH_2$), 63.6 (s, C-1 or C-3), 29.2 [s, *C*H($CH_3$)$_2$], 19.5 (s, $CH_3$), 15.2 (s, $CH_3$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 58.8 (d, $^2J_{P,P}$ = 36.5 Hz), 34.7 (d, $^2J_{P,P}$ = 36.5 Hz) ppm. $C_{55}H_{50}F_6FeNOP_3Ru$ (1104.82): calcd. C 59.79, H 4.56, N 1.27; found C 59.42, H 4.48, N 1.27.

**Synthesis of [Ru($\eta^5$-$C_9H_7$)Cl{$\kappa^2$(*P*,*N*)-FcPN}] (2):** FcPN (1203 mg, 2.5 mmol) was added to a solution of [RuCl($\eta^5$-$C_9H_7$)(COD)] (900 mg, 2.5 mmol) in thf (90 mL) and the reaction mixture was refluxed for 7 h. The solvents were removed under vacuum to a volume of about 5 mL, and hexane (50 mL) was added. The solid was washed with hexane ($2 \times 50$ mL) and dried under vacuum to afford complex **2** as a red solid. Yield: 1.741 g (95%). $C_{37}H_{35}ClFeNOPRu$ (733.02): calcd. C 60.63, H 4.81, N 1.91; found C 60.47, H 4.72, N 1.83.

**Rotamer 2a:** $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 8.67–7.01 (m, 14 H, Ph, Ind-6), 5.07 (m, 1 H, H-1 or H-3), 4.87 (m, 1 H, H-1 or H-3), 4.49–4.38 (m, 3 H, CHN, $C_5H_3$), 4.32 (dd, $^2J_{H,H}$ = 4.1, $^3J_{H,H}$ = 8.7 Hz, 1 H, $OCH_2$), 4.10 (br. s, 1 H, $C_5H_3$), 4.04 (s, 5 H, $C_5H_5$), 3.74 (m, 1 H, $OCH_2$), 3.05 (m, 1 H, H-2), 2.37 [m, 1 H, C*H*($CH_3$)$_2$], 0.76 (d, $^3J_{H,H}$ = 6.4 Hz, 3 H, $CH_3$), 0.69 (d, $^3J_{H,H}$ = 6.9 Hz, 3 H, $CH_3$) ppm. $^{13}$C NMR (75.4 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 166.4 (s, *C*$OCH_2$), 145.6–124.6 (Ph, Ind-6), 121.1 (s, Ind-6), 117.4 (d, $^2J_{C,P}$ = 6.0 Hz, C-3a or C-7a), 111.6 4 (m, C-3a or C-7a), 85.7 (s, C-6), 77.7 (br. s, $C_5H_3$), 75.8 (d, $J_{C,P}$ = 37.0 Hz, $CPPh_2$), 75.0 (d, $^2J_{C,P}$ = 18.1 Hz, *C*$CPPh_2$), 73.8 (d, $^2J_{C,P}$ = 3.8 Hz, $C_5H_3$), 71.8 (s, $C_5H_5$), 71.6 (m, CHN), 71.0 (s, $C_5H_3$), 68.0 (s, $OCH_2$), 63.6 (s, C-1 or C-3), 50.8 (s, C-1 or C-3), 28.0 [s, *C*H($CH_3$)$_2$], 19.4 (s, $CH_3$), 15.8 (s, $CH_3$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 60.7 (s) ppm.

**Synthesis of [Ru($N_3$)($\eta^6$-*p*-cymene){$\kappa^2$(*P*,*N*)-FcPN}][$PF_6$] (8):** A solution of **6a** (449 mg, 0.5 mmol) and $NaN_3$ (49 mg, 0.75 mmol) in methanol (50 mL) was refluxed for 4 h. After cooling, the solvents were removed under vacuum and the solid residue extracted with $CH_2Cl_2$. The solution was filtered through kieselguhr, concentrated under vacuum to a volume of about 5 mL, and diethyl ether (70 mL) was added. The solid was washed with diethyl ether (2 × 70 mL) and dried under vacuum to afford complex **8** as a brown solid. Yield: 0.321 g (71%). Conductivity [$(CH_3)_2CO$, 20 °C]: 84 $\Omega^{-1}$ cm$^2$ mol$^{-1}$. FTIR (KBr): $\tilde{\nu}$ = 2035 ($N_3$), 841 ($PF_6^-$) cm$^{-1}$. $^1$H NMR (300 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 8.10 (m, 2 H, Ph), 7.70 (m, 3 H, Ph), 7.45 (m, 3 H, Ph), 7.03 (m, 2 H, Ph), 5.89 (d, $^3J_{H,H}$ = 6.0 Hz, 1 H, 1 H, CH), 5.81 (d, $^3J_{H,H}$ = 6.0 Hz, 1 H, 1 H, CH), 5.39 (br. s, 1 H, CH), 5.17 (br. s, 1 H, $C_5H_3$), 4.84 (br. s, 1 H, $C_5H_3$), 4.64 (m, 1 H, $OCH_2$), 4.57 (br. s, 1 H, $C_5H_3$), 4.45 (t, $^3J_{H,H}$ = 9.0 Hz, 1 H, CHN), 4.33 (m, 1 H, $OCH_2$), 4.12 (br. s, 1 H, CH), 3.98 (s, 5 H, $C_5H_5$), 2.70 [m, 1 H, C*H*$(CH_3)_2$], 2.38 [m, 1 H, C*H*$(CH_3)_2$], 2.32 (s, 3 H, $CH_3$), 1.17 (d, $^3J_{H,H}$ = 6.3 Hz, 3 H, $CH_3$), 1.11 (d, $^3J_{H,H}$ = 6.3 Hz, 3 H, $CH_3$), 1.02 (d, $^3J_{H,H}$ = 6.3 Hz, 3 H, $CH_3$), 0.67 (d, $^3J_{H,H}$ = 6.3 Hz, 3 H, $CH_3$) ppm. $^{13}$C NMR (75.4 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 171.3 (br. s, *C*$OCH_2$), 139.7–129.2 (Ph), 119.4 (s, *C*CH), 99.9 (m, CH), 99.2 (s, *C*CH), 94.3 (m, CH), 88.4 (br. s, CH), 85.4 (s, CH), 79.7 (s, $C_5H_3$), 76.4 (d, $^3J_{C,P}$ = 5.4 Hz, CHN), 75.2 (s, $C_5H_3$), 74.4 (d, $^2J_{C,P}$ = 7.2 Hz, $C_5H_3$), 72.5 (m, $C_5H_5$, *C*$CPPh_2$), 69.4 (d, $J_{C,P}$ = 33.2 Hz, $CPPh_2$), 68.4 (s, $OCH_2$), 31.0 [s, *C*H$(CH_3)_2$], 29.9 [s, *C*H$(CH_3)_2$], 24.4 (s, $CH_3$), 21.1 (s, $CH_3$), 19.9 (s, $CH_3$), 17.4 (s, $CH_3$), 14.0 (s, $CH_3$) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $CD_2Cl_2$, 20 °C): $\delta$ = 23.1 (s) ppm. $C_{38}H_{42}F_6FeN_4OP_2Ru$ (903.62): calcd. C 50.51, H 4.68, N 6.20; found C 49.9, H 4.75, N 6.24.

**X-ray Crystal Structure Determination of Complexes 2·$CH_2Cl_2$, 3a and 6a:** Data for **2**·$CH_2Cl_2$ and **6a** were collected at 293 K with a Bruker AXS SMART 1000 single-crystal diffractometer (Mo-$K_\alpha$ graphite-monochromated radiation, $\lambda$ = 0.71073 Å) equipped with an area detector,[20] while data for compound **3a** were collected at 293 K with a Philips PW1100 single-crystal diffractometer (Mo-$K_\alpha$ graphite-monochromated radiation, $\lambda$ = 0.71073 Å). Crystals of **3a** were of poor quality, so the collection of the reflections was limited to $\theta$ = 22°. Details of the X-ray data collections are reported in Table 1. The structures were solved by Patterson and direct methods with SHELXS-97 and refined against $F^2$ with SHELXL-97,[21] with anisotropic thermal parameters for all non-hydrogen atoms. The dichloromethane molecule in **2**·$CH_2Cl_2$ was found to be disordered over two positions with occupancy factors of 0.60 and 0.40 and refined isotropically. The C≡CPh moiety in **3a** was found to be disordered over two positions with occupancy factors of 0.5 and refined with geometrical restraints (idealised planar ring). Four fluorine atoms of the two independent $PF_6^-$ anions in **6a** were found to be disordered and distributed over two positions (occupancy factors of 0.7 and 0.3). The absolute configuration of the three structures was confirmed by refining the Flack parameter, which showed the enantiopure character of the crystal.

CCDC-608692 (for **2**), -608693 (for **3a**) and -608694 (for **6a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# A Series of Cadmium(II) Coordination Polymers Synthesized at different pH Values

Zhengang Guo,[a] Rong Cao,*[a] Xiaoju Li,[a] Daqiang Yuan,[a] Wenhua Bi,[a] Xiandong Zhu,[a] and Yafeng Li[a]

**Keywords:** Cadmium / Polymers / Self-assembly / Photoluminescence

A new family of cadmium(II) coordination polymers, $\{[Cd(Hbic)_2\cdot(H_2O)_2]\cdot 2H_2O\}_n$ (**1**), $[Cd(Hbic)_2]_n$ (**2**), $[Cd(Hbic)_2\cdot(H_2O)]_n$ (**3**), $H_2bic$ = 1H-benzimidazole-5-carboxylic acid, has been hydrothermally prepared by the assembly of $Cd^{II}$ with $H_2bic$. A change in the pH values resulted in a series of compounds with different compositions and dimensionalities. Formed at the lowest pH, compound **1** has a two-dimensional supramolecular structure, which contains 1D chains extended by hydrogen bonds. At a slightly higher pH, compound **2** is synthesized with a higher number of deprotonated carboxylate groups per cadmium atom. A further increase in the pH leads to 3D dinuclear compound **3** with yellow-green emitting fluorescence.

## Introduction

The rational design and synthesis of metal–organic frameworks (MOFs) has undergone tremendous development owing to their structural and functional motifs,[1] which include magnetism,[2] catalysis,[3] luminescence,[4] and gas sorption.[5] The utilization of organic aromatic moieties containing carboxylic and nitrogen donor groups, for example imidazolecarboxylate or pyridylcarboxylate groups, can result in many intriguing polymers.[6] To obtain designed and predictable frameworks with potential properties, the observation of coordination polymers constructed from organic ligands and metal ions through a self-assembly route has been explored intensively, but it is still a challenge to date. The aromatic organic ligands with carboxy groups and nitrogen donors, on one hand, have been extensively employed in the construction of inorganic/organic hybrid materials for thermal stability and, on the other hand, can result in structures with high dimensions because of the multifunctional coordination sites.[7] The structure chemistry of functional groups such as carboxylates and nitrogen-donor groups are sensitive to pH values and the protonation states of these ligands. The formation of novel coordination compounds markedly depends on the metal ions.[8]

In order to have a better understanding of the effects of the pH value on the aromatic nitrogen-donor ligands, the reaction system of $H_2bic$ ($H_2bic$ = 1H-benzimidazole-5-carboxylic acid) and $Cd(NO_3)_2\cdot 4H_2O$ was studied. As a hybrid ligand, $Hbic^-$ possesses two kinds of resonance structures (Scheme 1). The conformation of polymorphism is worthy to explore.[9] Furthermore, there are four potentially coordinating sites: two oxygen atoms of the carboxylate group and two nitrogen atoms of the imidazole ring. Two protons, one from the carboxylate and the other from the nitrogen donor, should play an important role in the process of assembly. Consequently, $H_2bic$ is a good candidate for the investigation of the relation between the pH value and the coordination geometry. The diverse geometries of different metal ions may play critical roles in the assembly of metal–organic frameworks with various structures. The choice of metal ions in the systems is very important.[10] In the present work, we have selected cadmium(II) as metal nodes because of the luminescent characteristics. Other factors of the system such as the temperature, the amount of distilled water, and the type of stainless steel reactor are kept critically constant. Herein, we report the syntheses and characterizations of a new family of cadmium(II) coordination polymers: compounds $\{[Cd(Hbic)_2\cdot(H_2O)_2]\cdot 2H_2O\}_n$ (**1**), $[Cd(Hbic)_2]_n$ (**2**), and $[Cd(Hbic)_2\cdot(H_2O)]_n$ (**3**), built from the aromatic nitrogen-donor ligands $H_2bic$ and $Cd(NO_3)_2\cdot 4H_2O$. The three compounds have been characterized by IR

spectra, elemental analysis, thermogravimetric analysis, and fluorescent spectroscopy, as well as single-crystal X-ray diffraction analysis.[11–12] Discussion of the subtleties is addressed below.

## Results and Discussions

### Syntheses

Our aim is to investigate the effects of the pH value on the coordination behavior of aromatic nitrogen-donor ligands and the structures of the compounds thus formed. $H_2$bic and $Cd(NO_3)_2{\cdot}4H_2O$ were selected as starting materials in our study. We first carried out the reaction at a pH value of 5.0, compound **1** with a 2D supramolecular assembly was obtained, in which the carboxylic proton was deprotonated and $Hbic^-$ adopted a single coordination mode (Figure S1, a). We raised the pH value to 6.5 and compound **2** with a $4^4$ rhombus network structure was obtained, in which $Hbic^-$ adopted two different coordination modes (Figure S1, b and c). If the pH value was raised to 7.2, compound **3** with a 3D architecture was isolated, in which $Hbic^-$ also adopted two different coordination modes (Figure S1, d and e). The results illustrate that the pH value plays a crucial role on the coordination mode of $Hbic^-$ and the structures of the products. To confirm this, the reaction was carried out at a pH value between 5.0 and 6.5, a mixture of compounds **1** and **2** was obtained. If the reaction was carried out at a pH value between 6.5 and 7.2, a mixture of **2** and **3** was obtained. However, our efforts to obtain a compound constructed from $bic^{2-}$, in which both nitrogen atoms of $H_2$bic were deprotonated, at high pH values was unsuccessful. Among the three compounds, only compound **1** has coordinated water molecules which formed at the lowest pH value. The higher the pH value, the more difficult it is for water molecules to coordinate to the metal ions.

### Structural Descriptions

#### *{[Cd(Hbic)$_2$·(H$_2$O)$_2$]·2H$_2$O}$_n$ (1)*

Structure determination shows that compound **1** crystallizes in the monoclinic space group $C_2/c$ and has a 1D chain architecture with guest water molecules. The coordination environment of the metal ion and the coordination mode of $Hbic^-$ are shown in Figure 1 and Figure S1, respectively. The $Cd^{II}$ ion is coordinated by two nitrogen atoms, two water molecules and two *syn* carboxylate oxygen atoms in a distorted octahedral environment. The bond lengths of Cd–N1, Cd–OW1, and Cd–O2B are 2.280(3), 2.325(4), and 2.338(3) Å, respectively, which are the typical distances of Cd–N and Cd–O bonds. Linked by two $Hbic^-$ ligands, these metal nodes are extended into 1D chains along the [010] direction (Figure 2, a). In addition, each guest water is hydrogen bonded to one coordinated water molecule [OW2–OW1A distance: 2.702 Å; symmetry code: A: $x + 1/2, -y + 1/2, z - 1/2$] and two monodentate carboxylate oxygen atoms: one from the same polymeric chain with the coordinated water molecule [OW2–O2 distance 2.751 Å; symmetry code: B: $-x + 1/2, y + 1/2, -z - 1/2$] and the other from a neighboring polymeric chain [OW2–O1 distance: 2.795 Å] (Figure 2, b). The hydrogen bonds lead the 1D

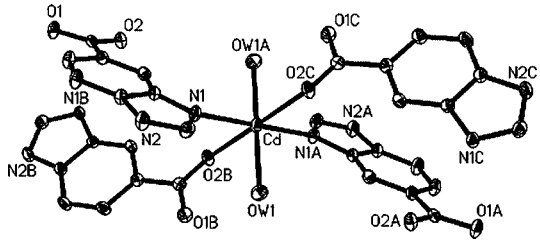

Figure 1. The coordination environment around $Cd^{II}$ in compound **1** with the thermal ellipsoids drawn at the 30% probability level. The guest water molecules are omitted for clarity. Symmetry codes: A: $-x, -y, -z$; B: $-x, y, -z-1/2$.

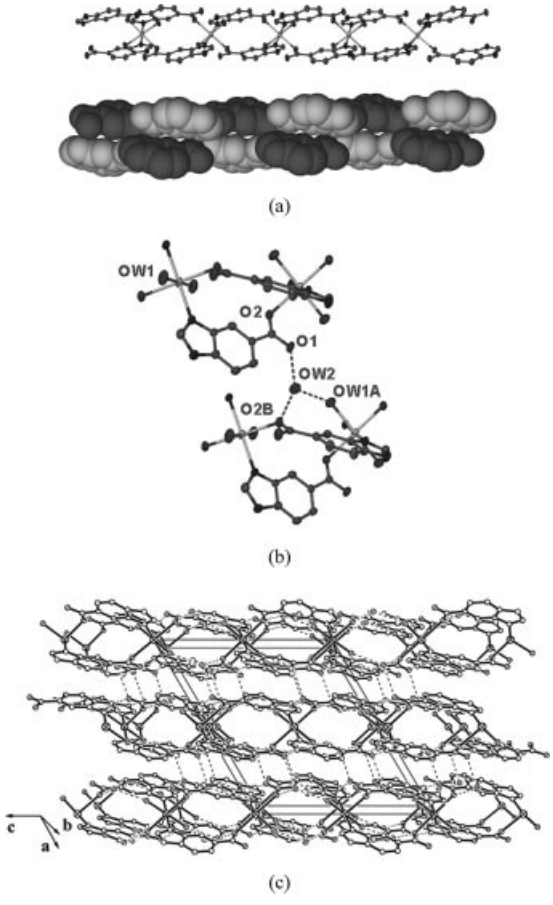

Figure 2. The 1D polymeric chain architecture in compound **1** (a). View of the supramolecular assembly along the [010] direction in compound **1** (b), the guest water molecules are omitted for clarity. Details of H-bond (dotted lines) for compounds **1** (c), hydrogen atoms are omitted for clarity, and thermal ellipsoids are drawn at the 50% probability level. Symmetry codes: A: $x+1/2, -y+1/2, z-1/2$; B: $-x+1/2, y+1/2, -z-1/2$.

chains to a supramolecular architecture (Figure 2, c).[13] Ping Liu and coworkers have synthesized a Co compound that is isostructural to compound **1**.[14]

### *[Cd(Hbic)$_2$]$_n$ (2)*

Single-crystal X-ray diffraction analysis reveals that compound **2** crystallizes in the orthorhombic space group *Pbcn* and is composed of a 2D coordination network. The asymmetric unit of compound **2** is shown in Figure 3, which contains one $Cd^{II}$ and two $Hbic^-$ ligands showing two different coordination modes (Figure S1). Similar to compound **1**, the central $Cd^{II}$ ions in **2** are six-coordinate in a distorted octahedral coordination geometry. The equatorial plane is defined by one nitrogen atom, a chelating carboxylate group, and one oxygen atom from another chelating carboxylate group. One nitrogen atom and one oxygen atom from the chelating carboxylate group occupy the axial positions of the octahedron with an O2–Cd–N1B bond angle of 146.96(10)°. The bond lengths of Cd–O1, Cd–O2, and Cd–N3 are 2.330(3), 2.335(3), and 2.278(3) Å, respectively, which are all within the normal ranges. The ligands link adjacent $Cd^{II}$ nodes into the formation of a $4^4$ rhombus network, which is different from other square-grid frameworks (Figure 4, a).[15] Furthermore, the distance between benzene rings is 3.585 Å, which indicates that there are weak face-to-face π–π stacking interactions between the neighboring layers (Figure 4, b and c).[16] We have reported a weak antiferromagnetic coordination polymer synthesized from $Ni(NO_3)_2{\cdot}6H_2O$ and $H_2bic$,[17] which is an allomer of **2**.

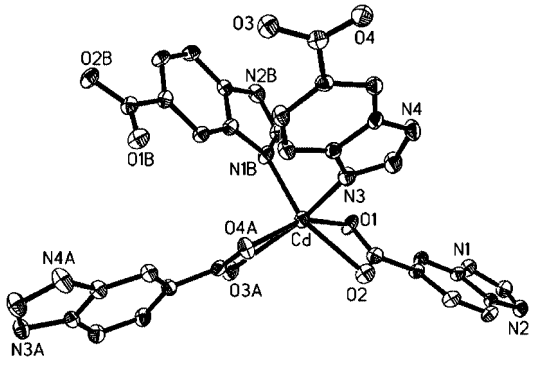

Figure 3. Perspective view of the asymmetric unit of compound **2** (30% probability ellipsoids). Symmetry codes: A: $x$, $-y$, $z-1/2$; B: $-x+3/2$, $y-1/2$, $z$.

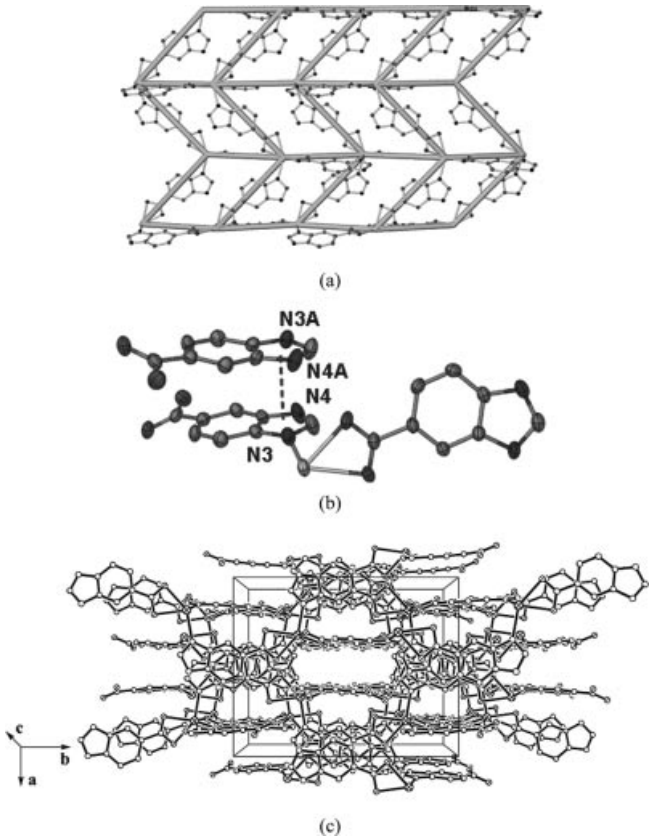

Figure 4. The $4^4$ rhombus network (a) along the [100] direction. Details of π–π stacking interactions (dotted lines) for compound **2** (b), hydrogen atoms are omitted for clarity, and the thermal ellipsoids are drawn at the 50% probability level. Symmetry code: A: $2-x$, $y$, $1/2-z$. Packing of the 2D framework of compound **2** (c) along the [001] direction.

### *[Cd(Hbic)$_2$·(H$_2$O)]$_n$ (3)*

The framework of compound **3** crystallizes in the monoclinic space group *P21/c* and has a 3D architecture with guest water molecules. The structure is built up of dinuclear units in which the cadmium atoms are joined by two oxygen atoms from the chelating/bridging carboxylate groups (Figure 5). Each cadmium atom is six-coordinate through two nitrogen atoms of $Hbic^-$ at apical positions and four oxygen atoms in the equatorial basal plane: one from monodentate carboxylate group and three from two chelating/bridging carboxylate groups (Cd–N, Cd–O). The coordination geometries for $Hbic^-$ are shown in Figure S1 and act as bridging and chelating/bridging ligands, respectively. With a head-to-head aggregation, four $Hbic^-$ ligands link $Cd^{II}$ centers into a $[Cd(Hbic^-)]_4$ ring, in which four metal ions and four ligands are approximately coplanar. On the basis of $Cd^{II}$ distances, the ring is $7.922 \times 10.259$ Å$^2$. In addition, every couple of neighboring $Cd^{II}$ ions is involved in another kind of building unit which consists of two metal joints and two oxygen atoms from chelating/bridging carboxylate groups. Two types of rings form the butterfly framework (Figure 6, a). Interestingly, each $[Cd(Hbic^-)]_4$ is surrounded by four other perpendicular $[Cd(Hbic^-)]_4$ rings through sharing $Cd^{II}$ joints, which may be due to the proper geometry of the metal ion. The 3D network can be classified as a $4^{28}$ topological-type based on eight connected nodes. As hydrogen bonding donors, the water molecules are involved in interactions with the nitrogen atoms and chelating carboxylate oxygen atoms to stabilize the framework furthermore [OW–N1, 2.825 Å; OW–O2A, 3.009 Å; symmetry code: A: $-x+1$, $-y+2$, $-z-1$].[13] Finally, the weak face-to-face π–π stacking interactions between adjacent $Hbic^-$ ligands (distance, 3.600 Å) stabilize the whole framework further (Figure 6, b and c).[16]

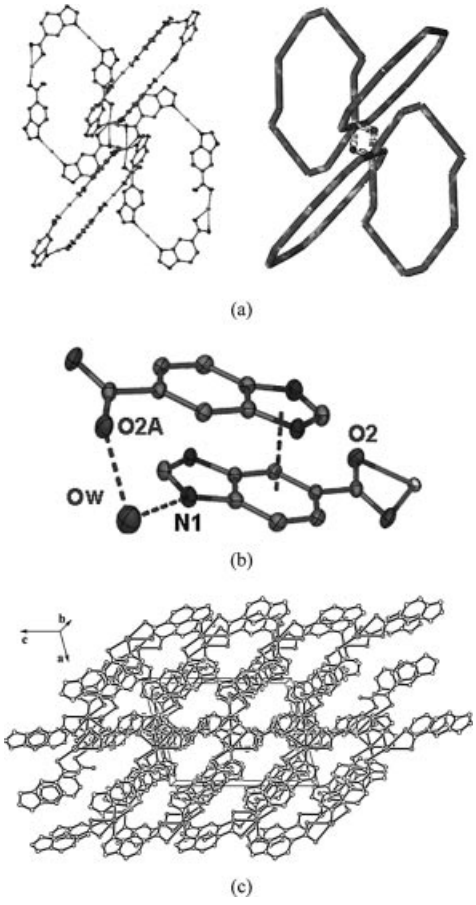

Figure 6. View of the butterfly framework generated from four $[Cd(Hbic^{-})]_4$ rings (a). Details of H-bond and π–π stacking interactions (dotted lines) for compound **3** (b), hydrogen atoms are omitted for clarity, and the thermal ellipsoids are drawn at the 50% probability level. Symmetry code: A: $-x+1$, $-y+2$, $-z-1$. Packing of the 3D framework of compound **3** along the [010] direction (c), the guest water molecules are omitted for clarity.

### Characterization of Vibrational Spectra

In the IR spectrum of compound **1**, a strong and broad peak at 3467 $cm^{-1}$ indicates the presence of water molecules. The antisymmetric and symmetric stretching vibrations of carboxylate group at 1530 $cm^{-1}$ and 1384 $cm^{-1}$, respectively, show that all $Hbic^{-}$ ligands adopt a monodentate coordination mode that is consist with the crystal structure. The IR spectrum of compound **2** shows typical chelating carboxylate antisymmetric and symmetric stretching bands at 1530 $cm^{-1}$ and 1417 $cm^{-1}$, respectively. The IR spectrum of compound **3** shows a broad peak at 3451 $cm^{-1}$ that also testifies to the existence of guest water molecules. The antisymmetric and symmetric stretching vibrations at 1532 $cm^{-1}$ and 1418 $cm^{-1}$, and at 1383 $cm^{-1}$, respectively, show that the carboxylate groups employ the chelating and monodentate coordination geometry.[18]

### Thermogravimetric Analysis

To access the thermal stability of the three compounds, thermogravimetric analyses were carried out with a NETZSCH STA 449C unit, at a heating rate of 10 °C/min under an air atmosphere. As shown in Figure S2, the TGA curve of compound **1** exhibits two significant weight losses. The first weight loss occurs between 81 °C and 185 °C, which can be attributed to the loss of guest water molecules. The observed weight loss of 6.79% is in good agreement with the calculated value (7.11%). From 304 °C to 631 °C, the weight loss of 65.74% suggests the decomposition of compound **1**. The residue weight (24.55%) is ascribed to CdO (calculated 25.34%). The TGA curve of compound **2** indicates only one weight loss stage. The weight loss of 70.2% covers a temperature range from 251 °C to 545 °C, which is possibly due to the collapse of compound **2**. The TGA curve of compound **3** indicates two obvious weight loss stages: 4.04% between 94 °C and 148 °C, and 66.02% between 296 °C and 647 °C. The former is in accordance with the loss of the guest water molecules (calculated 3.98%). The latter suggests the chemical decomposition of compound **3**. The residue weight (27.8%) is attributed to CdO (calculated 28.3%).

### Fluorescent Properties

At room temperature, the luminescent spectra of compounds **1**–**3** and the $H_2bic$ ligand in solid state are shown in Figure 7. The fluorescence spectrum of compound **1** is shown in Figure 7 and exhibits one emission maxima at 443 nm. The emission spectrum of compound **2**, shown in Figure 7 and redshifted relative to **1**, appears at 572 nm. Also shown in Figure 7, the emission spectrum of compound **3** is redshifted compared with those of compounds **1** and **2** to 576 nm. As previously reported, the emission of compound **1** may be attributed to σ-donation from the coordination environment of the $Cd^{II}$ centers, and may be assigned to a ligand-to-metal charge-transfer (LMCT).[19] To ascertain the adscription of the emission spectra, the photoluminescence of pure $H_2bic$ is measured with one emission maxima at 550 nm under the same conditions (Figure 7, ligand). We speculate that the maximum emis-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sions bands of compounds **2** and **3** may be caused by the intraligand π–π* transition. Owing to the yellow-green emissions of compounds **2** and **3**, the remarkable feature demonstrates that they may be potential candidates for yellow-green emitting fluorescent materials.[20]

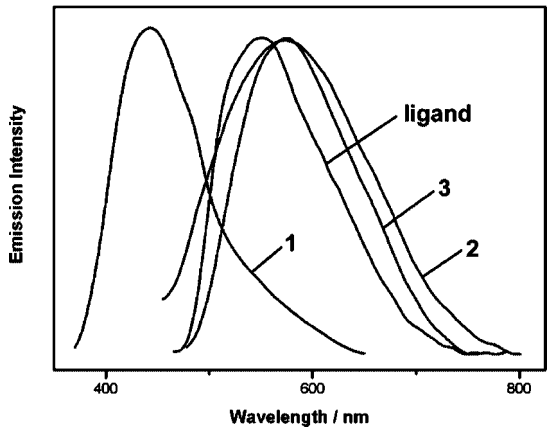

Figure 7. Solid-state emission spectra for compounds **1**–**3** and the $H_2$bic ligand at room temperature.

## Conclusions

A new family of compounds, $\{[Cd(Hbic)_2{\cdot}(H_2O)_2]{\cdot}2H_2O\}_n$ (**1**), $[Cd(Hbic)_2]_n$ (**2**), $[Cd(Hbic)_2{\cdot}(H_2O)]_n$ (**3**), has been synthesized hydrothermally and characterized during our investigation of the $Cd(NO_3)_2{\cdot}4H_2O$/$H_2$bic/NaOH reaction system. The pH values played an important role in the formation of these compounds. At 165 °C, the reaction at a pH value of 5.0 led to the formation of compound **1** with a 2D supramolecular assembly consisting of one-dimensional chains and hydrogen bonded water molecules. When the pH value was raised to 6.5, the reaction gave rise to the formation of compound **2** with a $4^4$ rhombus network structure. Further increase in the pH to a value of 7.2 led to the formation of compound **3** with a 3D architecture based on dinuclear cadmium units. With yellow-green emissions, compounds **2** and **3** may be good candidates for fluorescent materials.

## Experimental Section

**Materials and General Methods:** $H_2$bic = 1H-benzimidazole-5-carboxylic acid was purchased from Acros and used without further purification; all other reagents are commercially available and used as purchased. IR spectra as KBr pellets were recorded with a Magna 750 FTIR spectrophotometer. Elemental analysis of C, H, and N were determined by using a Perkin–Elmer 240C elemental analyzer. Fluorescence spectroscopy was performed with an Edinburgh Analytical instrument FLS920.

**Synthesis:** A mixture of $Cd(NO_3)_2{\cdot}4H_2O$ (0.25 mmol, 77.1 mg), $H_2$bic (0.25 mmol, 40.5 mg), NaOH (0–0.37 mmol, 0–14.8 mg), and distilled water (12 mL) was sealed in a 18 mL stainless steel vessel with a Teflon liner and heated at 165 °C for 72 h. After cooling at a rate of 3 °C/h to 25 °C, the crystals were obtained and washed with water and ethanol. Optimized syntheses of compounds **1**, **2**, and **3** are given below.

**Synthesis of $\{[Cd(Hbic)_2{\cdot}(H_2O)_2]{\cdot}2H_2O\}_n$ (1):** A mixture of $Cd(NO_3)_2{\cdot}4H_2O$ (0.25 mmol, 77.1 mg), $H_2$bic (0.25 mmol, 40.5 mg), and $H_2O$ (12 mL) was placed in a Teflon-lined stainless steel vessel then heated at 165 °C for 72 h. After cooling the reac-

**X-ray Crystallographic Studies:** Measurements of compounds **1**, **2**, and **3** were collected with a Rigaku CCD. The absorption corrections were performed with the procedure contained within the CrystalClear software package.[11] The structures were solved by direct methods with the SHELXL-97 program package.[12] All data were refined by full-matrix least-squares minimizations of $\sum(F_o - F_c)^2$ with anisotropic thermal parameters for all non-hydrogen atoms. The hydrogen atoms were generated geometrically (C–H 0.95 Å). The crystallographic data and structure determination summaries for compounds **1**, **2**, and **3** are listed in Table 1. Selected bond lengths and angles for the three compounds are listed in Table 2. CCDC-609811, CCDC-609812, and CCDC-609813 for compounds **1**, **2**, and **3**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): The coordination modes of $Hbic^-$ and TGA curves for compounds **1**–**3**.

# Metal Complexation of Calix[4]azacrown Derivatives – Evidence for Communication Between Upper and Lower Functionalised Rims

**Andrew D. Bond,[a] Bernadette S. Creaven,[b] Denis F. Donlon,[b,c] Tammy L. Gernon,[b,c] John McGinley,*[c] and Hans Toftlund[a]**

**Keywords:** Calix[4]arene / Macrocyclic ligands / Heterometallic compounds / Copper(II) / Manganese(II) / Ruthenium(II) / EPR spectroscopy

The coordination chemistry of calix[4]azacrowns obtained from the reaction of a diester calix[4]arene with diethylenetriamine provided unusual copper(II) and manganese(II) complexes in which calix[4]azacrown acts as a bidentate N,O-donor ligand, in some cases, but as a unidentate N-donor ligand, in other cases. The first example of a binuclear ruthenium(II)/manganese(II) complex, involving the calix[4]arene framework as the bridging ligand, is also reported. The calix[4]arene framework consists of a bipyridyl unit connected at the upper rim of the calix[4]arene, through an amide linkage, and an azacrown unit at the lower rim, also connected through amide groups.

## Introduction

Calix[4]arenes are versatile host molecules for supramolecular chemistry, which have been incorporated into numerous elaborate structures.[1] Double calix[4]arenes,[2] for example, have been constructed covalently through upper rim/upper rim linkage,[3] lower rim/lower rim linkage[4] or upper rim/lower rim linkage,[5] and also noncovalently through hydrogen bonding.[6] Incorporation of a crown ether into a rigid calix[4]arene creates a new type of supramolecular host, with interesting prospects for binding metal ions.[7] The family of calix[4]azacrowns combine calix[4]arenes with azaethylene chains attached to the phenolic oxygen atoms by acetamido groups, which serve both as covalent linking functions and as potential chelating

groups. The first calix[4]azacrowns of type **1** (Figure 1) were prepared by reaction of either a calix[4]arene dimethyl ester or calix[4]arene diacyl chloride derivative with the appropriate diamine and were shown by FAB-mass spectrometry to complex divalent ($Be^{2+}$, $Mg^{2+}$, $Ca^{2+}$, $Sr^{2+}$, $Ba^{2+}$) and trivalent ($Sc^{3+}$, $Y^{3+}$, $In^{3+}$, $Gd^{3+}$, $Bi^{3+}$) metal cations.[8]

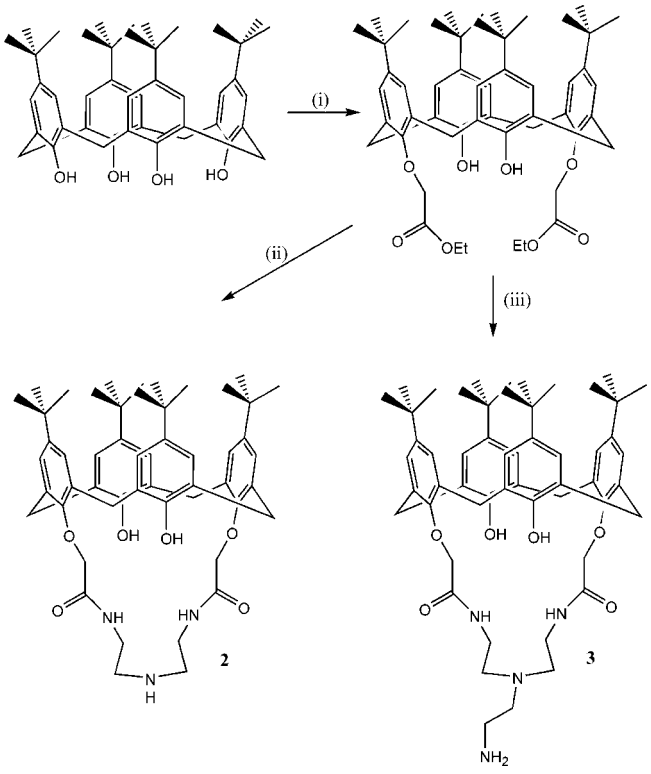
We have previously reported upper- and lower-rim functionalised calix[4]arenes, capable of binding transition-metal and alkali-metal salts, as well as ligands capable of attachment to calix[4]arenes.[9] One such calix[4]arene contained picolyl groups.[9c] In extending this theme, we targeted the design of calix[4]azacrowns and, in particular, the calix[4]arenes **2** and **3** which are capped by a diamide bridge at the 1,3-position on the lower rim.

Transition-metal ions which are covalently linked to each other through a ligand system are of interest and importance for a variety of purposes.[10–17] They can be used for studies into light-induced energy and electron transfer, as well as model systems for the development of supramolecular compounds which are capable of performing useful light induced processes such as photochemical devices. Indeed, the conversion of light energy into chemical energy is of current interest with particular focus on the development of efficient solar energy conversion schemes. To observe such transfer processes between the metal centres, they must be linked by a bridging ligand. These ligands have varied from chelating units linked by either flexible or rigid chains or by rod-like spacers.[14,18–21] More recently, the cage compound 1,12-dicarba-*closo*-dodecaborane, known as *p*-carborane, has been used as the linker molecule.[22] These linker or spacer molecules determine the spatial arrangement of the whole molecule while their chemical properties are important in influencing the spectroscopic and redox properties of the two metal centres as well as determining the rate of the electron/electron transfer process. We have focused our efforts on the construction of polynuclear complexes in which a photoactive and redox-active metal are linked by bridges based on a calix[4]arene derivative.[9a] Extensive functionalisation has been carried out at both the upper and lower rims of the calix[4]arene. A calix[4]arene, with appropriate functionalisation at both the wide and narrow rims, is capable of maintaining a well-defined distance between two metal centres positioned at each rim. By the simple modification of the synthesis of the functionalised calix[4]arene, this distance can be easily altered. To the best of our knowledge, there has been no report of a calix[4]arene derivative as a spacer molecule in energy/electron transfer reactions.

## Results and Discussion

### Lower-Rim Complexes

The method used for preparation of lower-rim functionalised calix[4]azacrown (**2**) is shown in Scheme 1. Base-promoted reaction of *p*-*tert*-butylcalix[4]arene with ethyl bromoacetate in acetonitrile produced the diester 5,11,17,23-tetra-*tert*-butyl-25,27-bis(ethoxycarbonylmethyloxy)calix[4]-arene (diester calix[4]arene),[9a,23] which was then stirred for 72 h with either diethylenetriamine or tris(2-aminoethyl)-amine in a methanol/toluene solvent mixture to give the cyclic amides **2** and **3** as white solids in good yield, similar to that described by Bitter et al.[24] The IR spectra of **2** and **3** exhibit a strong C=O signal at 1678 and 1681 $cm^{-1}$ respectively (compared to 1746 $cm^{-1}$ in the starting diester calix[4]arene), indicative of the amide functional group, together with a sharp N–H signal at 3372 and 3399 $cm^{-1}$, which is not present in the spectrum of the starting diester derivative. The $^1H$ NMR spectrum suggests that the calix-[4]arene molecules in **2** and **3** adopt a distorted cone conformation:[25] a pair of AB-type doublets is observed for the diastereotopic methylene protons at $\delta$ = 4.16 and 3.36 ppm in **2** and at $\delta$ = 4.17 and 3.39 ppm in **3**, respectively, compared to $\delta$ = 4.43 and 3.30 ppm for the corresponding signals in the starting diester calix[4]arene.



Scheme 1. Reagents and conditions: (i) $K_2CO_3$, ethyl bromoacetate, MeCN, reflux, 18 h; (ii) diethylenetriamine, MeOH, toluene, 48 h; (iii) tris(2-aminoethyl)amine, MeOH, toluene, 48 h.

$^1H$ NMR studies have previously indicated that macrocycles of this type show interesting binding properties;[7c,7d,26] for example, while the tetra(*p*-*tert*-butyl)calix-[4]azacrown **1** does not extract transition-metal ions, the corresponding 1,3-dimethoxy-*p*-*tert*-butylcalix[4]azacrown extracts $Cu^{2+}$ ions selectively with respect to $Co^{2+}$ and $Ni^{2+}$ ions.[7c,7d] Complexation behaviour of **2** towards alkaline-earth and transition-metal ions has been recently described[26] and the X-ray crystal structure of the complex with $Mg^{2+}$ revealed that the metal ion was not bound to any of the nitrogen atoms, but lay outside of the crown loop, forming a coordination polymer through metal–oxy-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

gen bonds to carbonyl O atoms from different calix[4]arene entities. Oueslati et al.[7d] found that metal extraction did not occur on attempted complexation of **2** with copper, nickel and cobalt picrates. Instead, crystals were formed in which a water molecule lies within the crown loop of **2** and picric acid accepts a hydrogen bond from this water molecule. In an effort to understand the binding, or lack thereof, of $Cu^{2+}$ to calix[4]azacrowns, we undertook complexation reactions of **2** and **3** with various copper(II) salts, as well as investigating the complexation behaviour of $MnCl_2$.

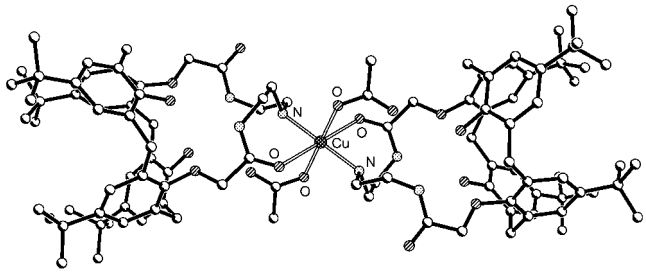


Figure 2. Molecular structure of **4** (H atoms omitted).

### Copper(II) Complexes

Complexation reactions of **2** and **3** were carried out in MeOH at reflux temperature, using copper(II) acetate hydrate, copper(II) chloride dihydrate and copper(II) perchlorate hexahydrate, respectively, in each case in a 1:1 ratio. Intense blue solutions were obtained in all cases and most of the solvent had to be removed under reduced pressure before precipitation occurred. For the reaction involving **2** with copper(II) acetate, a blue/green complex **4** was obtained, which was shown by X-ray diffraction to be $Cu(\mathbf{2})_2(CH_3CO_2)_2(MeOH)_2$ (Figure 2). The $Cu^{2+}$ ion is not complexed within the calix[4]azacrown, but instead is bound to two such units through interactions with the lone pairs on the NH of the crown ring and the C=O groups of the amide units. Thus, **2** acts as a bidentate N,O-donor ligand. The complex is centrosymmetric, and $Cu^{2+}$ adopts a typical [4+2] distorted octahedral geometry. The Cu–N and Cu–O(acetate) bond lengths are 2.052(4) and 1.957(3) Å, respectively, while the axial Cu–O=C distances are 2.715(3) Å. The monomeric nature of the copper acetate unit, in contrast to the bridging structures, usually associated with simple copper(II) acetate salts,[27] may be attributed to the steric bulk of the calix[4]azacrown ligand, which prevents further association. The coordinated amine group of **2** retains its proton, forming an N–H···O hydrogen bond to the unbound O atom of the acetate group. An O–H···O hydrogen bond is also formed from the phenolic OH group of **2** to the acetate group. In the solid state, MeOH molecules form O–H···O hydrogen bonds to the Cu-bound and unbound C=O groups of the amide bridge. The infrared spectrum of **4** shows two bands in the carbonyl region, as was expected from the X-ray crystal structure, at 1690 $cm^{-1}$, representative of an amide carbonyl bond, and also at 1578 $cm^{-1}$, representing the acetate carbonyl group. The reaction of **3** with copper(II) acetate also results in a green solid **5** which showed similar bands in the infrared spectrum, particularly in the carbonyl region at 1676 and 1555 $cm^{-1}$ suggesting that the acetate was binding to the copper in an analogous manner. A broad band at 3360 $cm^{-1}$ was also evident implying that the copper was bonding to **3** through the pendant amine. Elemental analysis on this compound also suggested a 1:2 metal/ligand complex as observed in **4**.

The complexation reactions of **2** and **3** with copper(II) perchlorate hexahydrate gave the green complexes **6** and **7**. Comparison of the IR spectrum of **6** and **7** with that of **4** reveals slight differences in the spectra. The differences suggest that the mode of complexation of the calixazacrown derivative is not determined solely by the metal ion (although this clearly will have some bearing), but is also influenced by the anion and its coordinating ability. The more strongly complexing acetate anion remains bound to $Cu^{2+}$ in **4**, while the weakly complexing perchlorate anions may be less likely to do so in **6** and **7**. Elemental analyses of both **6** and **7** suggest the presence of one perchlorate anions per $Cu^{2+}$ ion as well as the presence of only one calix[4]-azacrown unit, requiring that the ligands of **2** and **3** be neutral, possibly using the lone pairs on the nitrogen atoms in the ring to bind $Cu^{2+}$ internally in the calixazacrown loop. Furthermore, the metal complexes crystallise along with a molecule of methanol in both cases. To date, we have not been able to obtain suitable crystals of **6** or **7** to establish this conclusively.

For the complexation reaction of **2** with copper(II) chloride, a mixture of green **8** and blue **9** solids was obtained when the reaction was allowed to proceed for 120 min. On decreasing the reaction time to 20 min, the major product was **8**. The green material **8** has an IR spectrum similar to that of **4** (with the exception of the carbonyl stretching frequency due to the acetate group). This suggests that **8** comprises of copper(II) chloride bound between two calixazacrown ligands in a similar manner to the copper(II) acetate complex **4**. Since **8** is the major product obtained from the reaction after only a the short time period, complexation of copper(II) chloride by **2** appears to be the initial outcome. When the reaction proceeds for a longer time, the blue solid **9** is formed. Single crystals of **9** were obtained from the mother liquor after 90 min reaction, and single-crystal X-ray analysis[28] confirmed that cleavage of the amide bonds had occurred, resulting in the simple copper-diethylenetriamine complex shown in Figure 3. This complex can also be obtained by direct reaction of diethylenetriamine with copper(II) chloride dihydrate in a 1:1 ratio.[29] Cleavage of amide bonds by copper(II) chloride has been described previously.[30] On repeating the reaction, we were also able to obtain the calix[4]arene di-acid derivative[31] that is formed in the cleavage reaction. We have only observed the formation of **9** when the reaction mixture is heated for long periods of time. This suggests that the green complex **8** is relatively stable, and that it requires a considerable amount of energy before the cleavage reaction pro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ceeds. One probable mechanism for this process involves $Cu^{2+}$ moving from being externally coordinated (in the manner of **4**) to being internally coordinated, with this movement allowing the amide bonds to cleave.

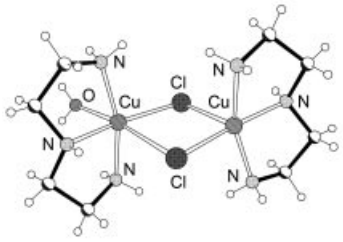

Figure 3. Molecular structure of the cleavage product **9**.

The complexation reaction of **3** with copper(II) chloride results only in a single green complex **10**. The infrared spectrum of this compound was very similar to that obtained for **8** which suggested that the copper was bonded to the free amine of the calix[4]azacrown. Microanalysis suggested the presence of only one chloride anion which would mean that the calix[4]azacrown was acting as a unidentate ligand through loss of a proton from the pendant amine group. The remaining coordination sites about the copper atom were occupied by water molecules. There was no evidence in this case of any cleavage reactions occurring or of two calix[4]azacrown units bonding to the copper atom.

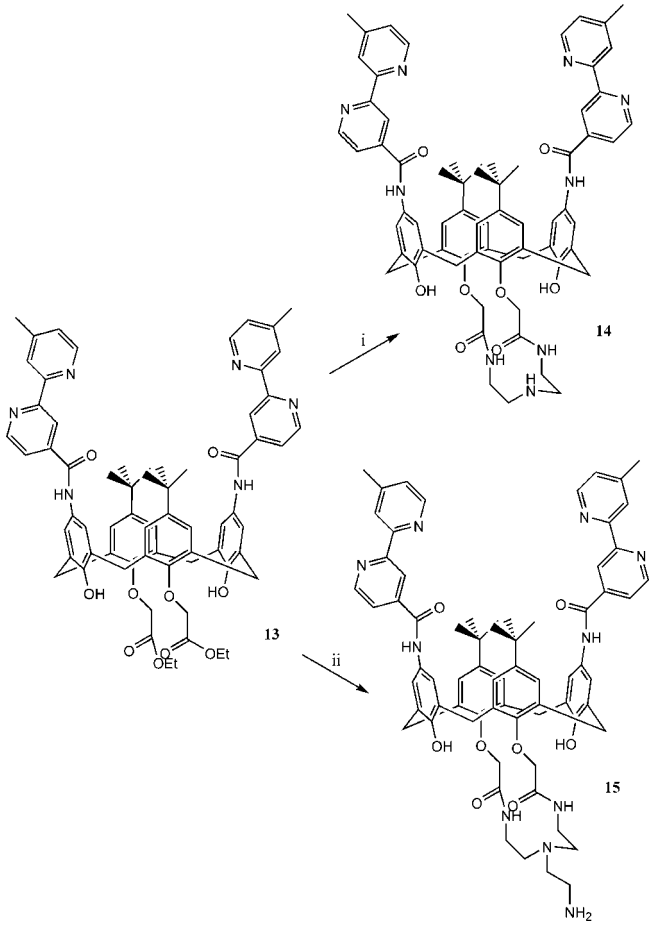
### Manganese(II) Complexes

As in the case of the copper complexations described above, the complexation reactions of **2** and **3** with manganese(II) chloride tetrahydrate were carried out in MeOH at reflux temperature, respectively, in each case in a 1:1 ratio. Brown solutions were obtained in both cases and most of the solvent had to be removed under reduced pressure before precipitation occurred. Compound **11** crystallises with a molecule of methanol present as solvent of crystallisation. Elemental analyses for **11** and **12** suggest the presence of only one chloride anion which would mean that the calix[4]azacrown **3**, in each case, was acting as a unidentate ligand through loss of a proton from the pendant amine group. The remaining coordination sites about the metal atom were occupied by water molecules.

The EPR spectra of the $Mn^{II}$ complexes without any functionalisation on the upper rim (**11**–**12**) were obtained as glasses in dimethylformamide (DMF) at 120 K. Both spectra were almost identical, showing jagged six-line spectra; the six-line spectrum in each case arising from the fact that $Mn^{II}$ has $I = 5/2$. These spectra indicate that the coordination of $Mn^{II}$ is very similar in each case. We believe that the manganese atom is bonded to the amine nitrogen of the azacrown ring, either NH or $NH_2$ depending on the calix[4]arene derivative **2** or **3**, similar to the bonding of the copper metal in the X-ray crystal structure of **4**. The remaining coordination sites around the manganese metal are occupied by water molecules. Elemental analyses and the infrared spectra of these complexes support this hypothesis.

### Ruthenium(II)/Manganese(II) Complexes

We have previously investigated the complexation of copper(I) to a pyridyl derivative of a calix[4]arene and were able to oxidise the metal centre while retaining complexation.[9c] Retention of this bonding is important, because if energy or electron transfer occurs from one rim to the other, then a change in the oxidation state of the metal at the lower rim must happen. Thus, it is essential that the metal–ligand bonding is retained at the lower rim. To achieve a scaffold capable of holding two different metals at different coordination sites, we have functionalised both the upper and lower rim of a calix[4]arene (Scheme 2); the synthesis of **13** has been reported previously.[9a]



Scheme 2. Reagents and conditions: (i) diethylenetriamine, MeOH, toluene, 48 h; (ii) tris(2-aminoethyl)amine, MeOH, toluene, 48 h.

The bis(bipy) diester calix[4]arene **13** was treated with 0.5 equiv. of either diethylenetriamine or tris(2-aminoethyl)-amine in methanol/toluene[24] to give the calix[4]azacrown derivatives **14** and **15**. The $Ru^{II}$ complexes **16** and **17** were prepared by reacting **14** or **15** with 1.1 equiv. of Ru(bipy)-$Cl_4$[32] in refluxing absolute ethanol and, on cooling, a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

brown solid precipitated in each case and recrystallised from chloroform. These solids were kept in the dark during the filtering and drying stages and were stored at room temperature in the dark. All efforts to obtain $^1$H NMR spectra of both **16** and **17** failed in all solvents, due to lack of solubility in the deuterated solvents. Elemental analyses for both products showed the presence of three molecules of chloroform. The $Ru^{II}/Mn^{II}$ complexes **18** and **19** were prepared by the reaction of the appropriate $Ru^{II}$ complexes **16** or **17** with manganese(II) chloride tetrahydrate in refluxing methanol. Elemental analyses for **18** and **19** suggest the presence of only one chloride anion which would mean that the calix[4]azacrowns **16** and **17**, in each case, were acting as a unidentate ligand through loss of a proton from the pendant amine group. The remaining coordination sites about the metal atom were occupied by water molecules. Furthermore, in both cases, two molecules of chloroform were also present as solvent of crystallisation, the chloroform being present from the washing of the solid to remove any unreacted calix[4]azacrown scaffold. Interestingly, the two metal centres are not directly connected through the same aromatic ring of the calix[4]arene. This is simply due to the synthetic path chosen. The first step in the functionalisation process is the etherification reaction at the lower rim, which has a dual role; firstly, it protects two of the phenol groups on the narrow rim while conferring cone conformation on the molecule, and secondly, it directs the functionalisation of the wide rim opposite the remaining free hydroxy groups of the narrow rim. It is this second function which does not allow a direct connection between both metal centres.

The EPR spectra of the complexes **18** and **19** were obtained as glasses in DMF at 120 K. Both spectra were almost identical. Some very small peaks for $Ru^{III}$ were observed, which was not unexpected as it was impossible to keep the sample under light-free conditions at all times during the preparation of the sample for the experiment. The very similar, jagged six-line spectra for **18** and **19** indicate that the coordination of $Mn^{II}$ is very similar in both complexes. We believe that, in both cases, the Mn atom is bonded to one nitrogen atom from the azacrown unit and that the remaining five coordination sites of the manganese are occupied by water molecules. These results are similar to those observed by Berg et al., where they had synthesised $[Ru(bipy)_3]^{2+}$ complexes covalently attached to bis(picolylamine) or tris(picolylamine) functional groups to which $Mn^{II}$ could be attached.[33]

The $Ru^{II}/Mn^{II}$ complexes **18** and **19** were partially oxidised to obtain the mixed valence $Ru^{III}/Mn^{II}$ complexes. The reactions were preformed using ammonium cerium(IV) nitrate as the oxidant in a 3:1 mixture of DMF and methanol, similar to that described by Ghirotti et al.[22] Dimethylformamide was one of the two solvents in which these compounds would dissolve, the other was methyl sulfoxide. The oxidation was monitored using EPR spectroscopy. On cooling the partially oxidised sample, no decrease in the signal intensity of the six-line region of the spectra, associated with the $Mn^{II}$ signals, was observed. There was, however, a substantial increase in the signals for a $Ru^{III}$ species, which indicated that the oxidation had occurred only at the $Ru^{II}$ sites. The samples were then warmed to 273 K and recooled to 120 K. This was to allow any energy or electron transfer to occur. On recording the spectra again, the spectra looked identical to the initial partially oxidised spectra. However, closer examination revealed that the intensity of both the $Mn^{II}$ and $Ru^{III}$ species had decreased by ca. 30%, indicating that either energy or electron transfer was occurring from the $Mn^{II}$ centre to the $Ru^{III}$ centre, with consequent oxidation of the $Mn^{II}$ to $Mn^{III}$, an EPR-silent species. Importantly, this suggests that the two metals are in communication with each other, despite the fact that there is no direct pathway between them, since they are not attached to the same benzene ring. More unprecedented was that the result could be observed using the relative slow EPR spectroscopy technique, instead of having to use transient spectroscopy with nanoseceond laser flash photolysis. This would indicate that the charge recombination reaction in this case is very slow, implying that the charge-separation between the metal species is close to an optimum distance.

## Conclusions

We have shown that binding of copper(II) and manganese(II) to calixazacrowns can be achieved, and that the particular mode of coordination appears to be influenced by the coordination ability of the associated anion. We have also synthesised mixed metal complexes with ruthenium(II) at the upper rim of our calix[4]arene scaffold and manganese(II) at the lower rim. Furthermore, initial EPR studies of these complexes indicate that the metals are able to communicate with each other, although they are not bound to the same aromatic ring of the calix[4]arene structure. We are currently examining the amide cleavage reaction in more detail and also looking at the coordination chemistry of other transition metals with **2** and **3**, as well as carrying out transient spectroscopy on the mixed metal species in an effort to understand the communication processes being undertaken.

## Experimental Section

$^1$H and $^{13}$C NMR ($\delta$ in ppm; $J$ in Hz) spectra were recorded with either a JEOL JNM-LA300 FT-NMR spectrometer or a Bruker Avance 300 MHz spectrometer using saturated $CDCl_3$ solutions with $Me_4Si$ reference, unless indicated otherwise, with resolutions of 0.18 Hz and 0.01 ppm, respectively. Infrared spectra ($cm^{-1}$) were recorded as KBr discs or liquid films between KBr plates with a Nicolet Impact 410 FT-IR. All UV/Vis spectra were recorded on a Shimadzu UV-160A spectrometer. Melting point analysis was carried out using a Stewart Scientific SMP 1 melting point apparatus and are uncorrected. The EPR spectra were recorded either at room temperature or in frozen glass at 120 K using a Bruker EMX spectrometer operating at the X-band. Microanalysis was carried out at the Microanalytical Laboratory of either University College, Dublin or the National University of Ireland Cork. Standard Schlenk techniques were used throughout. Starting materials were

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

commercially obtained and used without further purification. The synthesis of compounds 4-*tert*-butylcalix[4]arene,[34] 5,11,17,23-tetra-*tert*-butyl-25,27-diethoxycarbonylmethyloxycalix[4]arene,[9a,23] calix[4]azacrown **2**,[35] and 5,17-di-*tert*-butyl-11,23-bis[(4′-methyl-2,2′-bipyridin-4-yl)carbonylamino]-25,27-bis(ethoxycarbonylmethoxy)calix[4]arene (**13**)[9a] and $Ru^{II}(bipy)Cl_4$[32] have been described in the literature previously.

**Synthesis of Calix[4]azacrown 3:** A solution of diester calix[4]arene (2.0 g, 2.5 mmol) and tris(2-aminoethyl)amine (2.26 mL, 15.1 mmol) in a mixture of methanol (25 mL) and toluene (25 mL) was stirred at room temperature for 3 d. After this time, the solution was concentrated under reduced pressure. The solid residue was suspended in methanol and filtered to give a white solid.

**Calix[4]azacrown 3:** Yield 1.23 g (56.4%). $C_{54}H_{74}N_4O_6$ (875.19): calcd. C 74.10, H 8.52, N 6.40; found C 74.25, H 8.40, N 6.43; m.p. 262–264 °C. IR (KBr): $\tilde{\nu}_{max}$ = 3390 (NH), 1680 (amide C=O) $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.29 (br. t, 2 H, CON*H*$CH_2$), 7.12 (s, 4 H, Ar-*H*), 6.70 (s, 4 H, Ar-H), 6.33 (s, 2 H, OH), 4.48 (s, 4 H, $OCH_2CO$), 4.18 (d, $^1J$ = 13.0 Hz, 4 H, Ar-$CH_aH_b$-Ar), 3.52 (m, 6 H, $CH_2$), 3.39 (d, $^1J$ = 13.0 Hz, 4 H, Ar-C$H_aH_b$-Ar), 2.95 (m, 6 H, $CH_2$), 1.33 (s, 18 H, *t*Bu), 0.88 (s, 18 H, *t*Bu) ppm.

**General Synthesis of Copper(II) Complexes 4–10:** To a solution of the calix[4]azacrown (0.5 mmol) in chloroform (5 mL) was added the appropriate copper(II) salt (0.5 mmol) in methanol (5 mL) and the resulting blue solution was heated to reflux for 2 h. On cooling, the solution was allowed to stand and, after several days, either a powder or crystals appeared, which was collected by filtration and dried.

**4:** Blue solid, yield 0.39 g (84%). $C_{112}H_{160}CuN_6O_{20}$ (1974.04): calcd. C 68.14, H 8.17, N 4.26; found C 67.78, H 8.00, N 4.43; m.p. 179–180 °C. IR (KBr): $\tilde{\nu}_{max}$ = 3360 (NH), 1690 (amide C=O) $cm^{-1}$, 1578 ($COO_{asym}$) $cm^{-1}$, 1448 ($COO_{sym}$) $cm^{-1}$.

**5:** Green/blue solid, yield 0.42 g (88%). $C_{112}H_{154}CuN_6O_{16}$ (1932.01): calcd. C 69.62, H 8.03, N 5.80, found C 69.78, H 8.00, N 5.43; m.p. 179–180 °C. IR (KBR): $\tilde{\nu}_{max}$ = 3360 (NH), 1690 (amide C=O) $cm^{-1}$, 1578 ($COO_{asym}$) $cm^{-1}$, 1448 ($COO_{sym}$) $cm^{-1}$.

**6:** Green solid, yield 0.42 g (86%). $C_{53}H_{72}ClCuN_3O_{11}$ (1026.15): calcd. C 62.03, H, 7.07, N 4.09; found C 61.93, H 6.98, N 4.32; m.p. 200 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 3359 (NH), 1677 (amide C=O), 1109 ($ClO_4$) $cm^{-1}$, 625 ($ClO_4$) $cm^{-1}$.

**7:** Green solid, yield 0.41 g (78%). $C_{55}H_{77}ClCuN_4O_{11}$ (1069.22): calcd. C 61.78, H 7.22, N 5.24, found C 62.19, H 6.83, N 5.32; m.p. 212 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 3355 (NH) $cm^{-1}$, 1668 (amide C=O) $cm^{-1}$, 1110 ($ClO_4$) $cm^{-1}$, 625 ($ClO_4$) $cm^{-1}$.

**8:** Green solid, yield 0.38 g (85%). $C_{104}H_{138}Cl_2CuN_6O_{12}$ (1798.69): calcd. C 69.45, H 7.73, N 4.67; found C 69.68, H 7.36, N 5.01; m.p. 150 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 3340 (NH), 1678 (amide C=O) $cm^{-1}$.

**9:** Blue solid, yield 0.18 g (88%). $C_8H_{26}Cl_2Cu_2N_6O$ (420.33): calcd. C 22.86, H 6.23, N 19.99; found C 22.87, H 5.84, N 19.90; m.p. 160 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 3240 (NH) $cm^{-1}$.

**10:** Green solid, yield 0.24 g (80%). $C_{54}H_{84}ClCuN_4O_{11}$ (1064.26): calcd. C 60.94, H 7.96, N 5.26; found C 60.42, H 7.47, N 5.64; m.p. 160 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 3340 (NH, OH), 1681 (C=O amide) $cm^{-1}$.

**General Synthesis of Manganese(II) Complexes 11–12:** To a solution of the calix[4]azacrown (0.5 mmol) in chloroform (5 mL) was added manganese(II) chloride (0.5 mmol) in methanol (10 mL) and the resulting brown solution was stirred for 2 h. The solution was allowed to stand and, after several days, a brown powder precipitated, which was collected by filtration and dried.

**11:** Brown solid, yield 0.39 g (75%). $C_{53}H_{82}ClMnN_3O_{12}$ (1043.62): calcd. C 61.00, H 7.92, N 4.03; found C 61.19, H 8.15, N 4.48; m.p. 220 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 3343 (NH) $cm^{-1}$, 1680 (amide C=O) $cm^{-1}$.

**12:** Brown solid, yield 0.40 (76%). $C_{54}H_{83}ClMnN_4O_{11}$ (1054.65): calcd. C 61.50, H 7.93, N 5.31; found C 61.99, H 7.55, N 5.74; m.p. 220 °C (dec.). IR (KBr): $\tilde{\nu}_{max}$ = 3357 (NH) $cm^{-1}$, 1667 (amide C=O) $cm^{-1}$.

**Synthesis of Extended Calix[4]azacrown 14:** A solution of the bis(bipy) calix[4]arene **13** (0.4 mmol) and diethylenetriamine (1.6 mmol) in a mixture of methanol (20 mL) and toluene (20 mL) was stirred at room temperature for 5 d. After this time, the solution was concentrated under reduced pressure. The solid residue was dissolved in methanol, recrystallised and filtered to give a white solid.

**Calix[4]azacrown 14:** Yield 0.26 g (67%). $C_{68}H_{71}N_9O_8$ (1142.35): calcd. C 71.50, H 6.26, N 11.04; found C 71.39, H 6.04, N 11.09; m.p. 250 °C (dec.). IR: (KBr): $\tilde{\nu}_{max}$ = 3400 (NH, OH), 1671 (amide C=O) $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.89 (d, $^1J$ = 7.2 Hz, 2 H, 6-H), 8.78 (s, 2 H, 3-H), 8.59 (d, $^1J$ = 7.2 Hz, 2 H, 6′-H), 8.35 (s, 2 H, 3′-H), 8.20 (s, 2 H, OH), 8.05 (br. t, 2 H, CON*H*$CH_2$), 7.94 (d, $^1J$ = 7.2 Hz, 2 H, 5-H), 7.52 (s, 4 H, Ar-H), 7.23 (d, $^1J$ = 7.2 Hz, 2 H, 5′-H), 6.79 (s, 4 H, Ar-H), 6.28 (s, 1 H, NH), 4.47 (s, 4 H, $OCH_2CO$), 4.21 (d, $^1J$ = 14.0 Hz, 4 H, Ar-$CH_aH_b$-Ar), 3.55 (m, 4 H, $CH_2$), 3.47 (d, $^1J$ = 14.0 Hz, 4 H, Ar-C$H_aH_b$-Ar), 2.94 (m, 4 H, $CH_2$), 2.49 (s, 6 H, $CH_3$), 0.96 (s, 18 H, *t*Bu) ppm.

**Synthesis of Extended Calix[4]azacrown 15:** A solution of **13** (0.5 mmol) and diethylenetriamine (2.0 mmol) in a mixture of methanol (15 mL) and toluene (15 mL) was stirred at room temperature for 5 d. After this time, the solution was concentrated under reduced pressure. The solid residue was dissolved in methanol, recrystallised and filtered to give a white solid.

**Calix[4]azacrown 15:** Yield 0.21 g (44%); m.p. 200 °C (dec.). $C_{70}H_{76}N_{10}O_8$ (1185.42): calcd. C 70.92, H 6.46, N 11.82; found C 71.39, H 6.04, N 11.59. IR (KBr): $\tilde{\nu}_{max}$ = 3360 (NH, OH), 1666 (amide C=O) $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.85 (d, $^1J$ = 7.2 Hz, 2 H, 6-H), 8.80 (s, 2 H, 3-H), 8.55 (d, $^1J$ = 7.2 Hz, 2 H, 6′-H), 8.31 (s, 2 H, 3′-H), 8.13 (br. t, 2 H, CON*H*$CH_2$), 7.92 (d, $^1J$ = 7.2 Hz, 2 H, 5-H), 7.53 (s, 4 H, Ar-H), 7.30 (s, 2 H, OH), 7.18 (d, $^1J$ = 7.2 Hz, 2 H, 5′-H), 6.84 (s, 4 H, Ar-H), 4.52 (s, 4 H, O$CH_2$CO), 4.18 (d, $^1J$ = 14.0 Hz, 4 H, Ar-$CH_aH_b$-Ar), 3.53 (m, 6 H, $CH_2$), 3.46 (d, $^1J$ = 14.0 Hz, 4 H, Ar-C$H_aH_b$-Ar), 2.76 (m, 6 H, $CH_2$), 2.50 (s, 6 H, $CH_3$), 0.97 (s, 18 H, *t*Bu) ppm.

**General Synthesis of Ruthenium(II) Complexes 16 and 17:** To a solution of the calix[4]azacrown **14** or **15** (0.185 mmol) in absolute ethanol (20 mL) was added $Ru^{II}(bipy)Cl_4$ (0.37 mmol) in absolute ethanol (20 mL) and the resulting brown solution was heated to reflux for 3 h. On cooling, a brown precipitate resulted in each case. The precipitate was collected by filtration, dried and stored in the dark.

**16:** Red/brown solid, yield 0.32 g (83%). $C_{91}H_{90}Cl_{13}N_{13}O_8Ru_2$ (2156.8): calcd. C 50.68, H 4.21, N 8.44; found C 50.78, H 4.00, N 8.73; m.p. > 300 °C. IR (KBr): $\tilde{\nu}_{max}$ = 3385 (NH, OH), 1663 (amide C=O) $cm^{-1}$.

**17:** Red/brown solid, yield 0.30 g (76%). $C_{93}H_{95}Cl_{13}N_{14}O_8Ru_2$ (2180.8): calcd. C 50.78, H 4.32, N 8.91; found C 50.48, H 4.01, N 8.43; m.p. > 300 °C. IR (KBr): $\tilde{\nu}_{max}$ = 3385 (NH, OH), 1661 (amide C=O) $cm^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**General Synthesis of Ruthenium(II)/Manganese(II) Complexes 18 and 19:** To a solution of the ruthenium(II) calix[4]azacrown **16** or **17** (0.11 mmol) in methanol (10 mL) was added manganese(II) chloride tetrahydrate (0.11 mmol) in methanol (10 mL) and the resulting brown solution was stirred at room temperature for 2 h. During the course of the reaction, a dark brown solid precipitated in each case. The precipitate was collected by filtration, washed with $CHCl_3$, dried and stored in the dark.

**18:** Brown solid, yield (62%). $C_{90}H_{98}Cl_{11}MnN_{13}O_{13}Ru_2$: calcd. C 48.76, H 4.46, N 8.21; found C 48.21, H 4.39, N 8.72; m.p. > 300 °C: IR (KBr): $\tilde{\nu}_{max}$ = 3374 (NH, OH), 1662 (amide C=O) $cm^{-1}$.

**19:** Brown solid, yield 0.14 g (57%). $C_{92}H_{103}Cl_{11}MnN_{14}O_{13}Ru_2$ (2216.9): calcd. C 48.89, H 4.59, N 8.68; found C 49.19, H 4.63, N 9.17; m.p. > 300 °C. IR (KBr): $\tilde{\nu}_{max}$ = 3378 (NH, OH), 1660 (amide C=O) $cm^{-1}$.

**X-ray Crystallography:** Crystal data for **4**: $C_{112}H_{160}CuN_6O_{20}$, $M$ = 1974.00, monoclinic, $a$ = 12.2259(8) Å, $b$ = 24.0471(17) Å, $c$ = 19.5251(13) Å, $\beta$ = 101.262(3)°, $U$ = 5629.8(7) Å$^3$, $T$ = 180(2) K, space group $P2_1/n$, $Z$ = 2, $\mu$(Mo-$K_\alpha$) = 0.261 $mm^{-1}$. 66796 reflections measured, 9751 unique ($R_{int}$ = 0.0913) which were used in all calculations. The final $R_1$ = 0.0824, $wR_2$ (all data) = 0.2874, goodness-of-fit on $F^2$ = 1.09. Data were collected at 180(2) K with a Bruker Nonius X8 APEX II diffractometer,[36] and a multi-scan correction was applied.[37] The structures were refined against $F^2$ using all data.[38] Hydrogen atoms were placed at calculated positions and refined using a riding model.

CCDC-616020 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

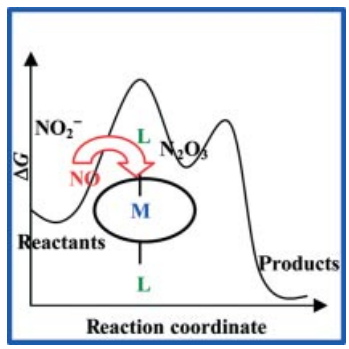
## MICROREVIEW

### NO Activation

**A. Franke, F. Roncaroli, R. van Eldik* ..... 773–798**

Mechanistic Studies on the Activation of NO by Iron and Cobalt Complexes

**Keywords:** Activation of NO / Reductive nitrosylation / Kinetics / Cytochrome P450 / Vitamin $B_{12}$ / Porphyrins / Chelates



The reactions of NO with selected Fe and Co chelates and porphyrins, as well as with cytochrome P450, vitamin $B_{12}$ and model complexes are reviewed. Throughout, the focus is on mechanistic details of the binding and release of NO from metal complexes and on the nature of the stable metal–NO complexes produced in solution.

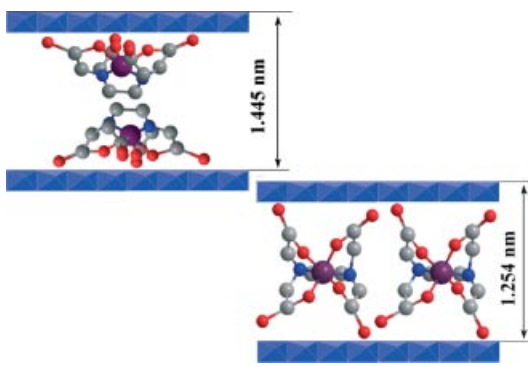
### Reorientation of Guests

**G. Q. Wu, L. Y. Wang*, L. Yang, J. J. Yang ..... 799–808**

Factors Affecting the Interlayer Arrangement of Transition Metal–Ethylenediaminetetraacetate Complexes Intercalated in Mg/Al Layered Double Hydroxides

**Keywords:** Layered compounds / Intercalation / Metal–edta complexes / Reorientation / Organic–inorganic hybrid composites



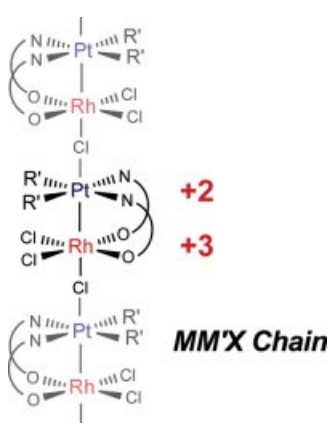
Guests on the Move: Transition metal–edta complex $\{[M(edta)]^{2-}\}$ intercalates of layered double hydroxide (LDH) were obtained by a hydrothermal synthesis method. The observed basal spacings of the LDH complexes, 1.445 nm in $Mg_2Al$–M(edta) LDH and 1.254 nm in $Mg_3Al$–M(edta) LDH, were ascribed to bilayer and monolayer arrangements of the incorporated $[M(edta)]^{2-}$, respectively. Heat treatment of the $Mg_2Al$–M(edta) LDH resulted in similar monolayer arrangements to that found in the $Mg_3Al$–M(edta) LDH. Rehydration of the calcined solids allows for the recovery of their original bilayer structures upon cooling to room temperature in air.

### 1D Metal Complexes

**K. Uemura, K. Yamasaki, K. Fukui, K. Matsumoto* ..... 809–815**

Synthesis, Crystal Structures, and Oxidation States of MM′X-Type Platinum–Rhodium Dinuclear Complexes Having Amidate Bridging Ligands

**Keywords:** Platinum / Rhodium / 1D Chains / Dinuclear complexes



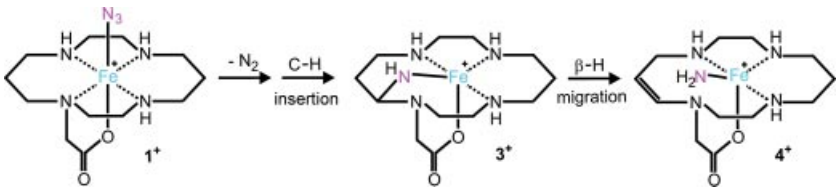
Two kinds of metal ions are bridged by amidate ligands to form Pt–Rh dinuclear complexes, which exist as pseudo 1D chains (MM′X chain), $[-Pt-Rh-Cl-]_n$, in the crystals. The dinuclear complexes have close metal–metal bond lengths with Pt(+2)–Rh(+3) formal oxidation states.

## Metal Azide → Nitrido Complex?

**D. Schröder,* H. Schwarz, N. Aliaga-Alcalde, F. Neese ..... 816–821**

Fragmentation of the (Cyclam-acetato)iron Azide Cation in the Gas Phase

**Keywords:** N ligands / Iron / Azides / Mass spectrometry



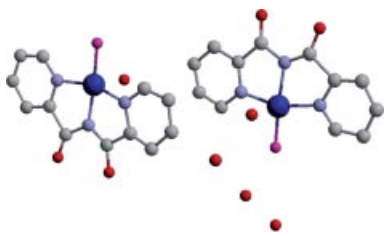
Collision-induced decomposition of the azido complex $\mathbf{1}^+$ in the gas phase to afford an iron(V) nitrido species appears to be followed by subsequent hydrogen rearrangements to afford isomers $\mathbf{3}^+$and $\mathbf{4}^+$.

## Chemical Nucleases

**J. Borrás,* G. Alzuet, M. González-Alvarez, J. L. García-Giménez, B. Macías, M. Liu-González ..... 822–834**

Efficient DNA Cleavage Induced by Copper(II) Complexes of Hydrolysis Derivatives of 2,4,6-Tri(2-pyridyl)-1,3,5-triazine in the Presence of Reducing Agents

**Keywords:** Copper triazine complexes / Oxidative DNA damage / ROS scavengers / Oxidation



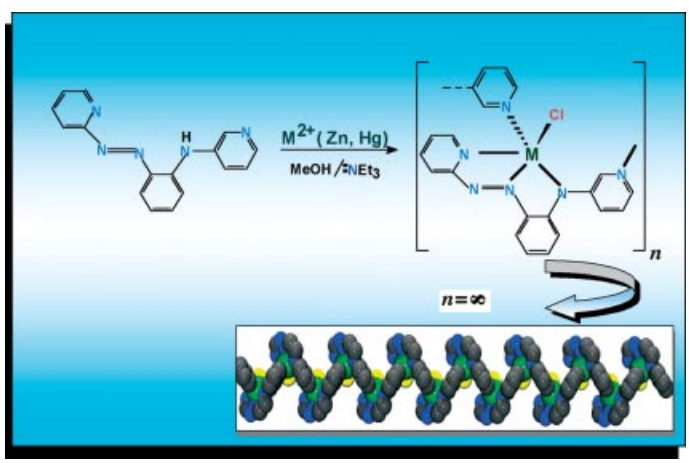
The complexes $[Cu(ptN_2)(OAc)]\cdot 3H_2O$ (**1**), $[Cu(ptO_2)(OAc)(H_2O)]\cdot H_2O$ (**2**), $[Cu(ptN_2)(for)]\cdot 3H_2O$ (**3**), $[Cu(ptO_2)(for)(H_2O)]$ (**4**), $[Cu(ptO_2)(benz)]\cdot H_2O$ (**5**), and $[Cu(ptO_2)F(H_2O)]_2\cdot 3H_2O$ (**6**) are obtained from the reaction of 2,4,6-tri(pyridyl)-1,3,5-triazine (ptz) and copper(II) salts in dmf/water (1:1) as a result of the hydrolysis of ptz. Efficient oxidative DNA cleavage by these compounds is observed in the presence of ascorbate and dioxygen.

## Coordination Polymers

**P. Banerjee, S. Kar, A. Bhaumik, G.-H. Lee, S.-M. Peng, S. Goswami* ..... 835–845**

Isolation and Characterization of $Zn^{II}$ and $Hg^{II}$ Coordination Polymers with a Designed Azo-Aromatic Ligand: Identification of Micrometer- and Nanometer-Sized Particles

**Keywords:** Coordination polymers / Azo-aromatic ligands / $d^{10}$ metal ions / X-ray structures / Nanostructures / Fluorescence



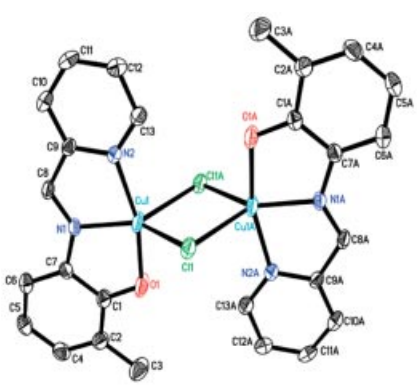
Isolation and characterization of one-dimensional, *zigzag*-chain, metal–organic framework of zinc ($Zn^{II}$) and mercury ($Hg^{II}$) with the bridging azo-aromatic ligand 2-[3-(pyridylamino)phenylazo]pyridine is described.

## Ferromagnetic Copper Complex

**S.-L. Ma, X.-X. Sun, S. Gao, C.-M. Qi,* H.-B. Huang, W.-X. Zhu ..... 846–851**

A New Chloro-Bridged $Cu^{II}$ Schiff Base Complex with Ferromagnetic Exchange Interaction

**Keywords:** Copper / Schiff bases / Dinuclear complex / Crystal structure / Magnetic properties



One μ-Cl-bridged dimer $[CuLCl]_2$ with distorted trigonal-bipyramidal geometry and ferromagnetic coupling is reported. A comparison for the magnetic coupling of $[CuLCl]_2$ with other $Cu(\mu\text{-}Cl)_2Cu$ compounds with square-pyramidal and trigonal-bipyramidal geometry is discussed.

# Mechanistic Studies on the Activation of NO by Iron and Cobalt Complexes

Alicja Franke,[a] Federico Roncaroli,[a,b] and Rudi van Eldik*[a]

**Keywords:** Activation of NO / Reductive nitrosylation / Kinetics / Cytochrome P450 / Vitamin $B_{12}$ / Porphyrins / Chelates

In this review, the reactions of nitric oxide with selected Fe and Co complexes of biological and environmental importance are reviewed. Fundamental chemical kinetics and mechanisms of reactions that lead to the formation and decay of nitrosyl complexes are illustrated and discussed on the basis of studies on $Fe^{II}$ chelates, $Fe^{II/III}$ pentacyano complexes, $Fe^{III}$ porphyrins, cytochrome P450 and model complexes, $Co^{II/III}$ porphyrins and vitamin $B_{12}$. Throughout the review, the focus is on mechanistic details of the binding of NO to and the release of NO from metal complexes and on the nature of the stable metal–NO complexes produced in solution. As will be seen for most of the presented reactions, the interaction of NO with the metal complex involves activation of the small NO molecule so that charge transfer occurs as a result of the formation of the metal–NO bond.

## 1. Introduction

In recent years, we developed an interest in the interaction of NO with complexes of Fe, Co and Ru, and in their mechanistic understanding. Since this was a new research area for us, we were confronted with many fundamental questions that forced us to make a critical evaluation of the

*Alicja Franke was born in Biecz, a small town in south-eastern Poland, in 1972. After completing her M.Sc. in 1996 from the Jagiellonian University, Krakow, she was awarded TEMPUS (1997) and DAAD (1998) Fellowships to perform research work at the University of Erlangen-Nürnberg, Germany, in the group of Prof. Rudi van Eldik. In 2001 she received her PhD in the kinetics and mechanism of nitric oxide donation and binding in model systems of biological relevance, under the supervision of Prof. Grazyna Stochel (Jagiellonian University). In 2002 she joined the research group of Prof. Rudi van Eldik as a post-doctoral fellow. She continues to work in Erlangen on the kinetics and mechanism of small-molecule activation by iron-heme centres, as well as on the activation of organic peracids by cytochrome P450 and model complexes in the "peroxide-shunt" catalytic cycle.*

*Federico Roncaroli was born in Buenos Aires, Argentina, in 1976. He graduated as a chemist in 2000 at the University of Buenos Aires. In 2001 he was awarded a doctoral fellowship from the Scientific Research Council of Argentina (CONICET) to perform research work at the University of Buenos Aires and at the University of Erlangen-Nürnberg, Germany. At the first institution, he studied the reactivity and spectroscopic properties of metal–nitrosyl complexes under the direction of Professor José Olabe, which allowed him to earn a PhD degree in 2004. At the second institution, under the supervision of Professor Rudi van Eldik, his work focused on the reactions of nitric oxide with biologically relevant complexes like vitamin $B_{12}$ and metal porphyrins, for which he was awarded a Dr. rer. nat. in 2005. His current interests are bioinorganic chemistry, homogeneous catalysis and activation of small molecules.*

*Rudi van Eldik was born in 1945 in Amsterdam and grew up in Johannesburg (South Africa). He received his chemistry education and Ph.D. at Potchefstroom University (SA), followed by post-doctoral work with Gordon M. Harris (SUNY at Buffalo, NY) and Hartwig Kelm (University of Frankfurt, Germany). After completing his habilitation in physical chemistry at the University of Frankfurt in 1982, he was appointed as Professor of Inorganic Chemistry at the private University of Witten/Herdecke in 1987. In 1994 he accepted his present position as Professor of Inorganic and Analytical Chemistry at the University of Erlangen-Nürnberg. His research interests cover the elucidation of inorganic, organometallic and bioinorganic reaction mechanisms, with special emphasis on the application of high-pressure thermodynamic and kinetic techniques. He is presently editor of Advances in Inorganic Chemistry and author of ca. 680 research papers and reviews in international journals (www.chemie.uni-erlangen.de/vaneldik). He has developed a promotional activity for chemistry and related experimental sciences in the form of chemistry edutainment over the past ten years (www.magic-chemistry-lecture.com).*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

existing literature data at that time. One aspect that was particularly disturbing was the fact that for many metal–NO complexes the exact oxidation state of both components was not stated and the Enemark and Feltham notation[1] was adopted in which the product is written as $\{M–NO\}^{(n+1)}$, where $n$ represents the number of d electrons of the metal ion [one is added ($n$ + 1) for the unpaired electron on the NO radical]. From a basic coordination chemistry viewpoint, this situation was not very satisfying since the oxidation state of the metal centre is very crucial for the understanding of its chemical behaviour and for analysing the extent to which the coordinated NO is 'activated' during the binding process. Another aspect that caused us to run into severe problems was the fact that in aqueous solutions of NO there are always unavoidable traces of nitrite that can totally inhibit or overrule the reaction with NO. Thus, we wondered whether it is really NO that reacts under the selected conditions, and if it is NO, what is the nature of the M–NO complex that is formed in terms of the formal-oxidation-state assignment. Along these lines, the first review of our work was entitled: 'To be or not to be NO in coordination chemistry? A mechanistic approach'.[2]

In this microreview, we focus on our most recent mechanistic studies dealing with the interaction of NO with complexes of $Fe^{II}$, $Fe^{III}$, $Co^{II}$ and $Co^{III}$, which also include the enzymes cytochrome P450 and vitamin $B_{12}$, as well as suitable model systems. The interaction will describe the reversible binding kinetics of NO, the characterization of the produced metal–nitrosyl complex, and provide information on subsequent reactions that lead to stable product species. The employed kinetic techniques (stopped-flow and laser flash photolysis at ambient and high pressure) allowed the extraction of the appropriate rate constants and activation parameters for the forward ("on") and back ("off") reactions for the reversible binding of NO and enabled us to discuss mechanisms underlying NO-substitution processes. In general, substitution reactions involving the displacement of a ligand coordinated to a metal centre by a free ligand in solution can be visualized as presented schematically in Figure 1.

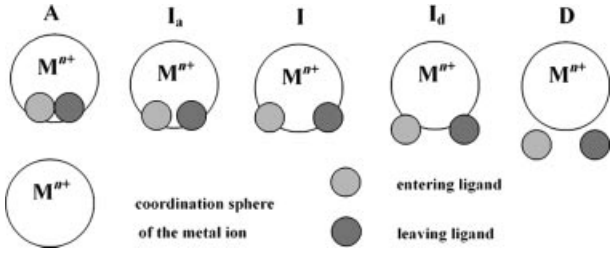

Figure 1. Schematic representation of the transition states of different substitution mechanisms.

If the activation parameters for the "on" and "off" reactions support an intermediate of higher and lower coordination number than in the reactant state, the mechanisms are of the limiting type denoted as associative (A) and dissociative (D), respectively. When the association and dissociation of the entering and leaving ligand, respectively, occur to an equal extent, then the mechanism can be described as an interchange (I) process. However, a "pure" interchange mechanism occurs very rarely and more often associative interchange ($I_a$) and dissociative interchange ($I_d$) mechanisms are observed in which the entering and leaving ligands are either firmly ($I_a$) or weakly ($I_d$) embedded in the coordination sphere of the metal ion.

## 2. Structure and Properties of Metal Nitrosyls

Binding of NO to a metal centre must result in the stabilisation of NO, a radical species in the ground state. Such stabilisation can be achieved by a shift of electron density to the metal centre or to the nitrosyl ligand and can formally be described as the formation of the nitrosyl cation ($NO^+$) or the nitroxyl anion ($NO^–$), respectively, as depicted by the mesomeric structures in reactions (1a) and (1b).

$$(L)M^{n+} + NO \rightleftharpoons (L)M^{n+}–NO \leftrightarrow (L)M^{(n-1)+}–NO^+;$$
linear M–N–O group (1a)

$$(L)M^{n+} + NO \rightleftharpoons (L)M^{n+}–NO \leftrightarrow (L)M^{(n+1)+}–NO^–;$$
bent M–N–O group (1b)

In reaction (1a), the $NO^+$ group is isoelectronic with CO, whereas in reaction (1b) the $NO^–$ group is isoelectronic with $O_2$. These two formal descriptions of the M–N–O bond are extreme and ideal, since metal–nitrosyl complexes usually show M–NO angles between 180° and 120°, and their electronic structures cannot be described as $M–NO^+$ or $M–NO^–$. Moreover, some complexes can be described as $(L)M^{n+}–NO^{\cdot}$, where the odd electron is *mainly* located on the metal. Nevertheless, in terms of the coordination chemistry at hand, it is in many cases useful to think in terms of formal oxidation states in order to understand the mechanistic behaviour of the complexes. A detailed account of the formal description of these limiting situations along with the description introduced by Enemark and Feltham have been published in an earlier account from our group.[2] The characterization of the produced metal–nitrosyl complexes has, in general, been done on the basis of EXAFS, XAS Fe-edge, resonance Raman, EPR and Mössbauer spectroscopic and magnetic circular dichroism data. Spin-crossover and spin-coupling phenomena account for the overall observed spin behaviour of the investigated complexes.

## 3. Interaction of NO with $Fe^{II}$ Chelate Complexes

Before we discuss the results of the interaction of NO with $Fe^{II}$ chelate complexes, we would like to refer to the interaction of NO with aquated $Fe^{II}$ in acidic medium, a classical text book example that forms part of the well-known brown-ring test for nitrate. A detailed kinetic and spectroscopic study[3] revealed that the overall reaction can be formulated as shown in reaction (2), where the product is formally an $Fe^{III}–NO^–$ species in which the high-spin $Fe^{III}$ ($S$ = 5/2) is antiferromagnetically coupled to the two un-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

paired electrons on $NO^-$ ($S = 1$) to result in the overall $S = 3/2$ spin state of the product.

$$[Fe^{II}(H_2O)_6]^{2+} + NO \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} [Fe^{III}(H_2O)_5(NO^-)]^{2+} + H_2O \quad (2)$$

The 'on' reaction is controlled by water exchange on $[Fe(H_2O)_6]^{2+}$ and follows an $I_d$ mechanism as can be clearly seen from the volume profile for this reaction reported in Figure 2.

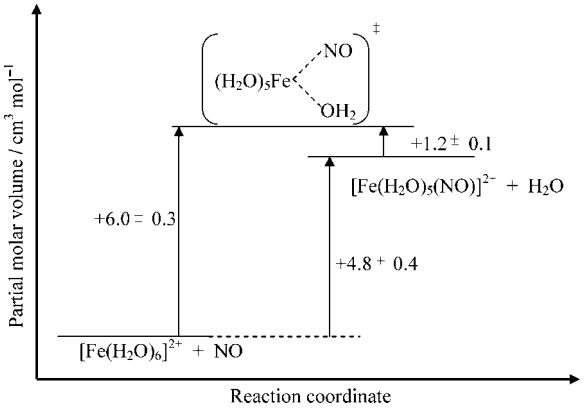

Figure 2. Volume profile for the binding of NO to aquated $Fe^{II}$ as given in reaction (2).[3]

The introduction of a chelate such as a polyaminocarboxylate labilizes the $Fe^{II}$ complex and significantly increases the water-exchange rate constant. The nitrosation of such complexes can be formulated as shown in reaction (3). Spectroscopic data suggested that the reaction product is formally $Fe^{III}$–$NO^-$.

$$[Fe^{II}L(H_2O)]^{2+} + NO \underset{k_{off}}{\overset{k_{on}}{\rightleftharpoons}} [Fe^{II}L(NO)]^{2+} + H_2O \quad (3)$$

A systematic study of the series of $Fe^{II}(L)$ complexes with different polyaminocarboxylate ligands indicated that their ability to reversibly bind NO is strongly affected by the selected chelating ligand. This influence is apparent from the large variation in the overall binding constant $K_{NO}$ ($= k_{on}/k_{off}$), which spans a wide range from ca. $1 \times 10^3$ to $2 \times 10^7$ $M^{-1}$ for the studied complexes (see Figure 3).[4] In addition, an interesting correlation was found between the stability of the $Fe^{III}(L)(NO^-)$ complexes and the oxygen sensitivity of the parent $Fe^{II}(L)$ complexes, in other words, their tendency to form $Fe^{III}(L)(O_2^-)$ species. From the comparison presented in Figure 3, it can, in general, be concluded that the higher the $K_{NO}$ value for a given metal–nitrosyl complex, the larger the oxygen sensitivity of the parent $Fe^{II}(L)$ complex. Clearly, an increasing inductive effect of the chelate ligand causes an increase in stability of the $Fe^{III}$–$NO^-$ bond and also an enhancement of the shift of electron density from iron to oxygen atom in the corresponding $Fe^{III}(L)(O_2^-)$ complex.

A quantitative basis for the observed trends in the stability of the $Fe^{III}(L)(NO^-)$ complexes was provided by kinetic and mechanistic studies on the binding and release of NO from selected $Fe^{II}(L)$ complexes. The complexes exhib-

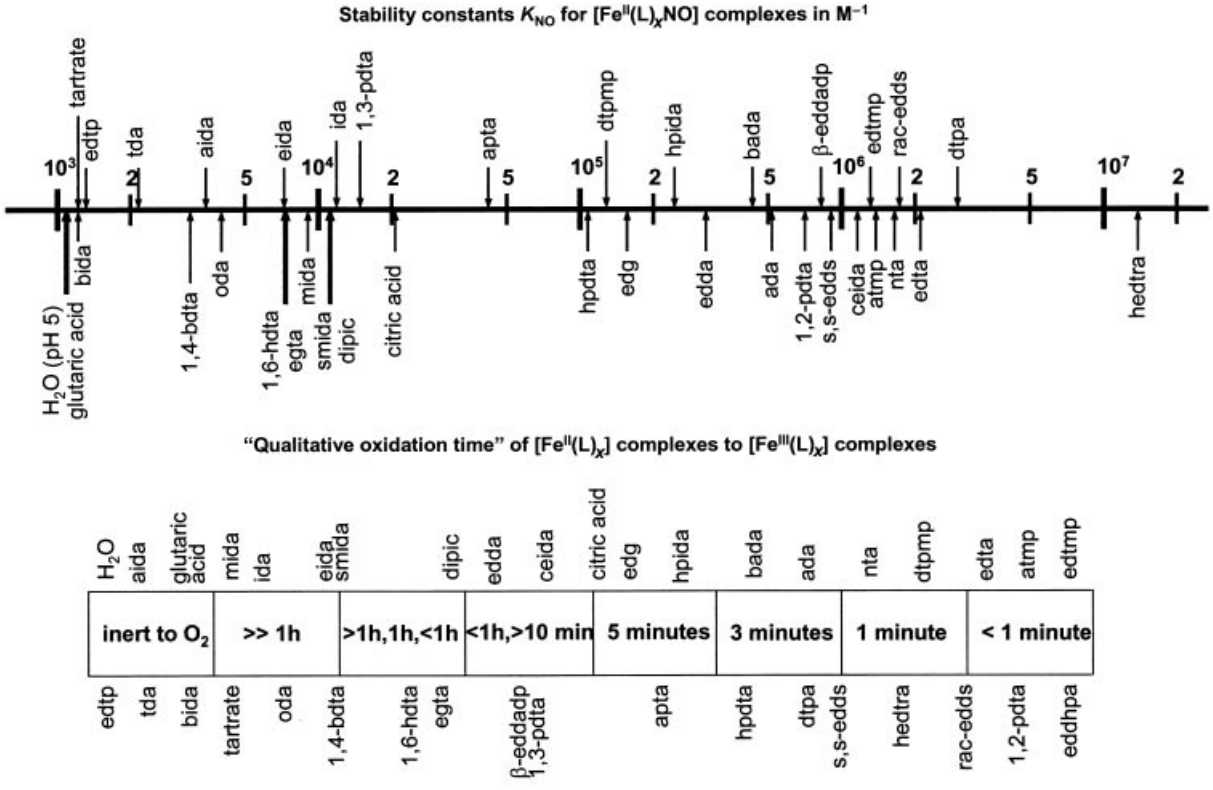

Figure 3. Correlation between $K_{NO}$ [defined by reaction (3)] and qualitative oxidation time of selected $Fe^{II}(L)$ complexes.[4]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ited quite different behaviour in their reactions with NO. The observed differences are particularly large in the case of the $Fe^{II}$(mida) and $Fe^{II}$(edta) complexes: the mida complex shows almost no oxygen sensitivity, exhibits a low binding affinity for NO and releases NO almost completely on passing an inert gas through the solution. In contrast, the edta complex is extremely oxygen sensitive, shows a very high binding affinity for NO and releases NO only slowly when treated with an inert gas.

More detailed insight into the mechanisms of the thermal reactions in which NO binds and dissociates from the iron centre in the studied $Fe^{II}$(L) systems comes from activation parameters for the "on" and "off" reactions, obtained from systematic studies of $k_{on}$ and $k_{off}$ as a function of temperature and pressure.[5] The positive volumes of activation found in most cases clearly indicate that the complex-formation reactions can be best described by a dissociative interchange ($I_d$) mechanism. The exception is the reaction of $Fe^{II}$(nta)$(H_2O)_2$ with NO, which exhibits a definite (Figure 4) negative volume of activation, suggesting that the reaction occurs through an associative interchange ($I_a$) mechanism. The difference in the mechanism of nitrosylation observed for the $Fe^{II}$(nta)$(H_2O)_2$ complex relative to the other studied complexes becomes clear from a comparison of the volume profiles for the edta and nta systems shown in Figure 4. Such a variation in the mechanism presumably reflects the fact that $Fe^{II}$(nta)$(H_2O)_2$ is a six-coordinate complex, whereas it is known that $Fe^{II}$(edta)$H_2O$ is seven-coordinate. This would mean that some complexes react according to an $I_d$ mechanism as a result of their seven-coordinate, 20-valence-electron character, whereas the six-coordinate nta complex reacts according to an $I_a$ mechanism because of its 18-valence-electron character. These results suggest that water-exchange reactions on the studied $Fe^{II}$(L) complexes presumably control the kinetics and mechanism of the NO binding.

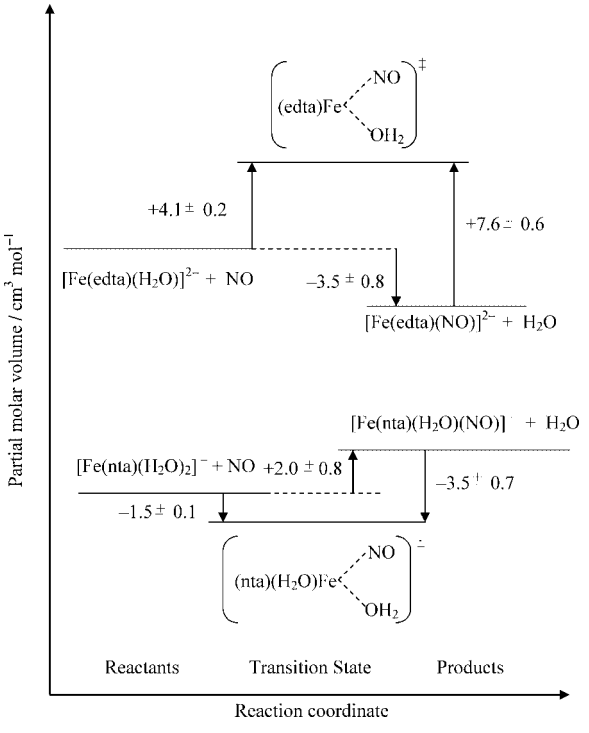

Figure 4. Volume profiles for the reversible binding of NO to $[Fe^{II}(edta)H_2O]^{2-}$ (top) and $[Fe^{II}(nta)(H_2O)_2]^{-}$ (bottom).[5]

## 4. Interaction of NO with Pentacyanoferrate(II)

Complex-formation and -dissociation reactions of the $[Fe^{II}(CN)_5(H_2O)]^{3-}$ complex have been extensively studied over the past decades for a good variety of ligands.[6,7] For this reason, this complex seemed to be an attractive choice for studying the reaction with NO and for comparing its binding, reactivity and coordination properties with other ligands; a comparison which, to the best of our knowledge, was missing or not addressed thoroughly enough in the literature. In this way, the investigated reaction is shown in reaction (4).

$$[Fe^{II}(CN)_5(H_2O)]^{3-} + NO \rightleftharpoons [Fe^{II}(CN)_5(NO^{\cdot})]^{3-} + H_2O;\ k_f,\ k_d \quad (4)$$

The product of reaction (4), the $[Fe^{II}(CN)_5(NO^{\cdot})]^{3-}$ complex, which can also be generated upon reduction of nitroprusside with several reducing agents or with different techniques (i.e. electrochemical, pulse radiolysis),[8,9] was characterized by different spectroscopic methods (UV/Vis, IR, EPR).[8,9] This compound was postulated to be responsible for the hypotensive effect of nitroprusside, i.e. $[Fe^{II}(CN)_5(NO^{+})]^{2-}$ is reduced in biological fluids to the $[Fe^{II}(CN)_5(NO^{\cdot})]^{3-}$ complex, which eventually releases NO.[10] This complex shows a *trans*-labilization effect which can be formulated as shown in reaction (5).

$$[Fe^{II}(CN)_5(NO^{\cdot})]^{3-} \rightleftharpoons [Fe^{I}(CN)_4(NO^{+})]^{2-} + CN^{-};\ k_5,\ k_{-5},\ K_5 \quad (5)$$

The parameters of reaction (5) were determined at 25 °C: $k_5 = 2.7 \times 10^2\ s^{-1}$, $k_{-5} = 4 \times 10^6\ M^{-1}\,s^{-1}$, $K_5 = 6.8 \times 10^{-5}$ M.[9] They indicate that the equilibrium is driven to the formation of the $[Fe^{II}(CN)_5(NO^{\cdot})]^{3-}$ species at high pH (>8) and in the presence of $CN^-$.

UV/Vis and EPR spectroscopic data at pH > 8 showed that the $[Fe^{II}(CN)_5(NO^{\cdot})]^{3-}$ complex is the product of reaction (4).[11] Between pH 4 and 8, the $[Fe(CN)_5(NO)]^{3-}$ complex could not be detected, which is in agreement with reaction (5).[12] However, a systematic study of the reaction between $[Fe^{II}(CN)_5(H_2O)]^{3-}$ and NO as a function of the pH allowed us to conclude that the reaction is controlled by the substitution of the coordinated water molecule by NO, i.e. the decay of the $[Fe(CN)_5(H_2O)]^{3-}$ complex was independent of the pH (4–10).[11]

From a systematic study as a function of the NO concentration, the complex-formation rate constant $k_f = 250 \pm 10\ M^{-1}\,s^{-1}$ (25.4 °C, $I$ = 0.1 M, pH = 7.0) was obtained. As shown in Table 1, this value is very close to the complex-formation rate constant for several neutral ligands. Experiments at different temperatures and pressures afforded the activation parameters $\Delta H^{\#} = 70 \pm 1\ kJ\,mol^{-1}$, $\Delta S^{\#} = +34 \pm 4\ J\,K^{-1}\,mol^{-1}$ and $\Delta V^{\#} = +17.4 \pm 0.3\ cm^3\,mol^{-1}$. In Table 1, the activation parameters are also compared with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the corresponding values for other ligands. Several mechanisms have been proposed to explain these complex-formation reactions (Scheme 1).

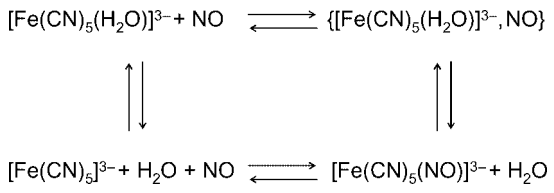
[a] For the reaction: $[Fe(CN)_5H_2O]^{3-} + L \rightarrow [Fe(CN)_5L]^{n-} + H_2O$, $T$ = 25.0 °C, with the exception of L = NO where $T$ = 25.4 °C. [b] $I$ = 1 M. [c] $I$ = 0.1 M. [d] $I$ = 0.5 M.



Scheme 1.

In the limiting dissociative mechanism (D), the reaction is controlled by the release of the water molecule, generating a pentacoordinate intermediate (left side of Scheme 1), followed by fast coordination of NO (bottom of Scheme 1).[13] The dissociative interchange mechanism ($I_d$) implies the rapid formation of a precursor complex between $[Fe(CN)_5(H_2O)]^{3-}$ and NO (top of Scheme 1), followed by the rate-determining ligand interchange between the first and the second coordination spheres of the precursor complex (right side of Scheme 1).[13] Finally, in a variation of the last mechanism ($D_{pc}$), the slow dissociation of the water molecule occurs within a precursor complex.[6] All of these mechanisms agree with the second-order behaviour of the rate law and with the dependence of $k_f$ on the charge of the coordinating ligand. The consistent rate constants found for the complex-formation reactions with different ligands of the same charge, and the significantly large and positive values for the activation entropies and volumes, suggest the operation of a D mechanism.[13] An additional argument presented in favour of the D mechanism is based on the principle of microscopic reversibility, since strong evidence, i.e. large activation volumes, supports the operation of a D mechanism in the complex-dissociation reaction ($k_d$). Moreover, the activation volumes in Table 1 range from +14 to +18 $cm^3\,mol^{-1}$.[14] These values are consistent with the theoretical activation volume calculated for the dissociation of a water molecule in an octahedral metal centre (+13.1 $cm^3\,mol^{-1}$).[15]

From the complex-formation rate constants, we conclude that NO behaves like a normal Lewis base. Since the complex-formation rate constant is controlled by the dissociation of water, it is not possible to obtain specific information on the coordination properties of NO, and no specific influence of the unpaired electron on NO is observed when it is compared with the coordination ability of diamagnetic ligands.

The $[Fe(CN)_5(NO)]^{3-}$ complex is the product of reaction (4), and we were able to generate it through the reaction between $[Fe(CN)_5(H_2O)]^{3-}$ and NO at pH > 8. The addition of $CN^-$ allowed us to prevent the formation of the $[Fe(CN)_4NO]^{2-}$ complex and its subsequent reactions.[12] In this way, it was possible to study the complex-dissociation reaction ($k_d$). The overall reaction of the former complex in the presence of $CN^-$ is shown in reaction (6).

$$[Fe(CN)_5(NO)]^{3-} + CN^- \rightleftharpoons [Fe(CN)_6]^{4-} + NO \quad (6)$$

During reaction (6), the characteristic bands of the reactant at 347 and 440 nm decayed according to a first order process. Only a shoulder at 320 nm, assignable to $[Fe(CN)_6]^{4-}$, remained. NO was detected by mass spectrometry and electrochemical techniques.[11] With excess cyanide, the observed rate constant is independent of the concentration of this ligand, and reaction (6) is controlled by the dissociation of NO, i.e. $k_d$. At pH 10 (25.0 °C, $I$ = 0.1 M), the observed rate constant was $(1.58 \pm 0.06) \times 10^{-5}\ s^{-1}$. The activation parameters were $\Delta H^{\#} = 106.4 \pm 0.8\ kJ\,mol^{-1}$, $\Delta S^{\#} = +20 \pm 2\ J\,K^{-1}mol^{-1}$ and $\Delta V^{\#} = +7.1 \pm 0.2\ cm^3\,mol^{-1}$. Table 2 summarizes the data for the complex-dissociation rate constants for similar complexes with different ligands that show different σ–π interactions with the metal centre. The activation enthalpies and entropies are consistent with those reported for the release of other ligands in the pentacyanoferrate(II) fragment. Although the activation volume for NO is significantly smaller than for other ligands, it is still indicative of a D mechanism. In Table 2, we can appreciate that $k_d$ for NO is significantly lower than for most ligands, comparable to that for the π-acceptor ligand DMSO, but faster than those for the strong π-acceptor ligands such as CO, $CN^-$ or $NO^+$ (the release of $NO^+$ is, in principle, undetectable in $M^{II}NO^+$ complexes).

In view of the presented value of $k_d$, we conclude that NO is not released from the $[Fe(CN)_5(NO)]^{3-}$ complex after biological reduction of nitroprusside. In vitro experiments showed that conditions favouring the release of $CN^-$ after reduction of nitroprusside are required to allow the release of NO.[12] Figure 5 shows the volume profile for reaction (4) constructed with the activation volumes determined for $k_f$ and $k_d$. Evidently, the partial molar volume of the transition state is much larger than that of the reactant and the product states, which is consistent with the proposal of a D mechanism. This mechanism is in agreement with that expected for a pentacyano fragment, where the σ-donor and π-acceptor properties of the ligands cause significant *trans*- and *cis* labilization of water or NO.[7]

Several volume profiles for the reversible binding of NO to different iron complexes have been recently reported,

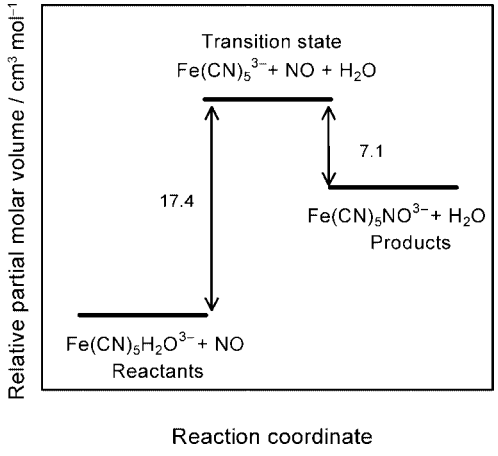

Figure 5. Volume profile for the overall reaction (4).

some of them support the operation of a D mechanism. Examples are the reaction of NO with metmyoglobin and some iron(III) porphyrin complexes. It is important to note that the volume profile shown in Figure 5 is the first reported for a reversible reaction with NO where no formal charge transfer occurs during the reaction, as is the case for the previously reported data.

## 5. Interaction of NO with Pentacyanoferrate(III)

The reaction between the $[Fe(CN)_5(H_2O)]^{2-}$ complex and NO produces quantitatively $[Fe(CN)_5NO]^{2-}$ (nitroprusside).[24] Thus, the overall reaction can be described by reaction (7) ($k_f$ and $k_d$ are redefined for this reaction).

$$[Fe^{III}(CN)_5(H_2O)]^{2-} + NO \rightleftharpoons [Fe^{II}(CN)_5(NO^+)]^{2-} + H_2O;\ k_f,\ k_d \quad (7)$$

Several attempts were made to determine $k_d$ by using trapping agents for the released NO, but they were unsuccessful, probably due to the slowness of the release reaction. When the $[Fe(CN)_5(H_2O)]^{2-}$ complex reacted with excess NO, the characteristic bands of the reactant at 394 and 340 nm decayed and a new band at 264 nm, assignable to nitroprusside, grew following a first-order behaviour. By working at different NO concentrations, $k_f$ was found to be $0.252\pm0.004$ M$^{-1}$ s$^{-1}$ (25.5 °C, $I$ = 0.1 M). From the pressure and temperature dependence of reaction (7), the activation parameters were obtained: $\Delta H^{\#} = 52\pm1$ kJ mol$^{-1}$, $\Delta S^{\#} = -82\pm4$ J K$^{-1}$ mol$^{-1}$ and $\Delta V^{\#} = -13.9\pm0.5$ cm$^3$ mol$^{-1}$.[24]

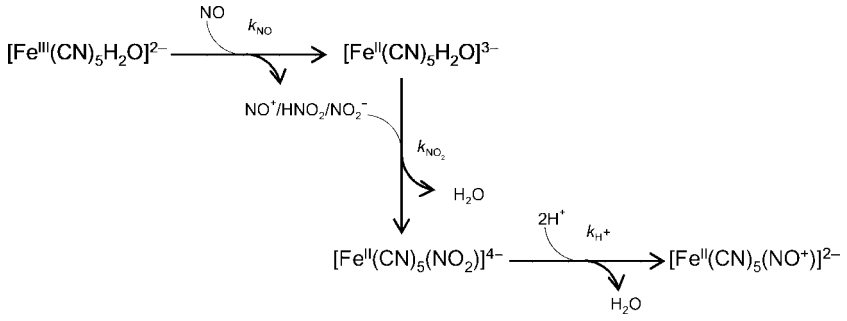
Although the coordination chemistry of the pentacyanoferrate(III) system has not been disclosed as deeply as for the $Fe^{II}$ analogue, there are studies with several other ligands that allow a comparison with our results for NO. In general, substitution reactions of this complex are slow reactions with second-order rate constants that range from $10^{-4}$ to $10^{-7}$ M$^{-1}$ s$^{-1}$.[21–23] The activation entropies and volumes for the substitution reaction with some nucleosides were studied. The values were in the range 5–120 J K$^{-1}$ mol$^{-1}$ and 3–6 cm$^3$ mol$^{-1}$, respectively.[23] These data were interpreted in terms of a dissociative interchange mechanism ($I_d$) and proposed to be generally valid for water-substitution reactions of $[Fe(CN)_5(H_2O)]^{2-}$. These slow reactions can be catalyzed by $Fe^{II}$ or other reducing species.[21,22]

In contrast, $k_f$ is several orders of magnitude faster than the typical values for substitution reactions of this complex. Moreover, the activation entropy and volume are negative.[24] On the basis of these discrepancies, we propose that reaction (7) is controlled by an electron-transfer reaction that produces the $[Fe^{II}(CN)_5(H_2O)]^{3-}$ complex, which in turn reacts with the ligands present in the medium generating nitroprusside (see Scheme 2).

The $[Fe^{II}(CN)_5(H_2O)]^{3-}$ complex was not detected as an intermediate; in fact no intermediates were observed during the reaction. This complex is labile; the rate of water exchange was estimated to be ca. 300 s$^{-1}$,[6] and this is consistent with the fact that the reported values of $k_{NO_2^-}$ (Scheme 2) are at least one order of magnitude faster than $k_{NO}$.[6,7] The rate constant $k_{H^+}$ is also reported to be very fast under the selected conditions.[25] According to this information, the reduction by NO must be rate determining in the overall reaction (7), and $k_f = k_{NO}$. Although NO reduction of the $[Fe(CN)_5(H_2O)]^{2-}$ complex through an outer-sphere reaction is very unfavourable,[24] the possibility of an inner-sphere path can explain why the reaction is still observable.[11] Kinetic studies on the reduction of the $[Fe(CN)_5(NO_2)]^{3-}$ and $[Fe(CN)_6]^{3-}$ complexes with ascorbic acid afforded very similar activation parameters to those obtained in our study, namely $\Delta S^{\#} = -119$ J K$^{-1}$ mol$^{-1}$ and $\Delta V^{\#} = -10$ cm$^3$ mol$^{-1}$ for the reaction of $[Fe(CN)_5(NO_2)]^{3-}$ to generate nitroprusside.[26]

Another possibility is that NO, which is in excess, reacts with the $[Fe(CN)_5(H_2O)]^{3-}$ complex (Scheme 2) to generate the $[Fe(CN)_5NO]^{3-}$ complex [reaction (4)]. The latter complex would be oxidized by the starting compound to nitroprusside, and the reaction would be autocatalytic.[11,24,27] Nevertheless, this intermediate was not detected. Moreover, experiments done in the presence of pyrazine (vide infra) showed that neutral ligands cannot compete effectively with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

$NO^+/HNO_2/NO_2^-$ present in the second coordination sphere, since concentrations as high as 50 mM were insufficient to convert all of the reactant into the pyrazine complex.[24] On the other hand, the yield of nitroprusside for the reaction between $[Fe(CN)_5H_2O]^{3-}$ and NO at pH 3–5 was quite low: 35–45%,[11] while the reaction with the $Fe^{III}$ complex under similar conditions generated nitroprusside quantitatively.[24] Finally, we would expect a quadratic NO concentration dependence for such an autocatalytic mechanism, according to Scheme 2 and Equation (8) (vide infra).

Reaction (7) was studied in the presence of other ligands (pyrazine and $SCN^-$) that could scavenge the $[Fe(CN)_5(H_2O)]^{3-}$ complex and give evidence of its presence during the reaction.[24] When $SCN^-$ was used, a first order decay of the bands characteristic of the $[Fe(CN)_5(H_2O)]^{2-}$ complex was accompanied by formation of the $[Fe^{III}(CN)_5SCN]^{3-}$ complex, which was evidenced by its typical absorption band at 598 nm. Working at constant NO concentration, the observed rate constant depended linearly on the $SCN^-$ concentration, with a slope of $2.3 \times 10^{-3}$ M$^{-1}$ s$^{-1}$. The intercept was $2.17 \times 10^{-4}$ s$^{-1}$, which is very similar to the value obtained in the absence of $SCN^-$, as expected. By using pyrazine instead of $SCN^-$, a very similar picture was obtained, and a first-order reaction with a linear dependence on the pyrazine concentration was also observed. It is important to note that such reactions in the absence of NO are orders of magnitude slower.[22] To explain these findings, we propose the mechanism depicted in Scheme 3, where pyrazine or $SCN^-$ compete with $NO^+$, $HNO_2$ or $NO_2^-$ to react with the $[Fe(CN)_5(H_2O)]^{3-}$ complex. The $Fe^{II}$ complexes thus produced are oxidized by the reactant to form the corresponding $Fe^{III}$ compounds.

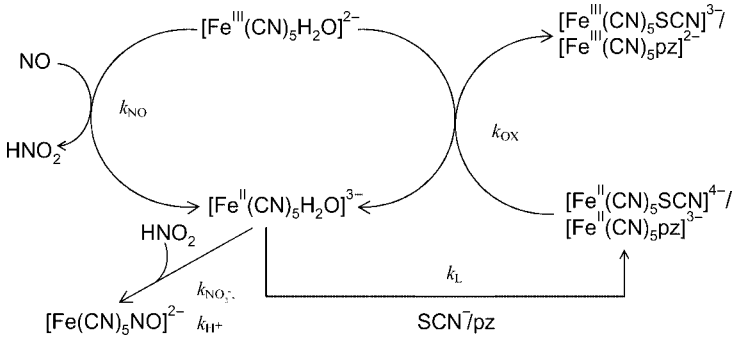
Assuming that the $Fe^{II}$ complexes are in steady state, Equation (8) was derived.[24]

$$k_{obs} = k_{NO}[NO]\left(1 + \frac{k_L[SCN^-/pz]}{k_{NO_2^-}[HNO_2]}\right) \quad (8)$$

The rate law predicts a linear dependence of $k_{obs}$ on the pyrazine and $SCN^-$ concentrations, as was observed, which provides evidence for the role of the $[Fe(CN)_5(H_2O)]^{3-}$ complex as an intermediate and strong support for the proposed mechanism.

To obtain additional information in favour of this proposal, the reaction of NO with other $[Fe^{III}(CN)_5L]$ complexes was studied. When L = pyridine, the corresponding $Fe^{II}$ complex was observed as an intermediate. Moreover, the $[Fe(CN)_5(NO_2)]^{3-}$ complex generates nitroprusside quantitatively when it reacts with NO at pH 5.[24]

The present reaction and the proposed mechanism were discussed in a recent review, and an alternative mechanism was proposed.[27] It involves the formation of a seven-coordinate intermediate between NO and the starting compound $[Fe^{II}(CN)_5(H_2O)(NO^+)]^{2-}$. This intermediate would lead to the formation of nitroprusside through the release of water or would lead to the formation of $[Fe(CN)_5(H_2O)]^{3-}$ through the release of $NO^+$. As we mentioned before, the $Fe^{II}$–$NO^+$ bond is very stable, and we find it rather unlikely that the $[Fe(CN)_5(H_2O)]^{3-}$ complex would be generated as an intermediate in this way. Alternatively, the formation of a related precursor between NO and the starting complex could be proposed, in which NO interacts with the



Scheme 3.

$CN^-$ ligands without changing the first coordination sphere of the Fe centre.[11] In this way, the reaction would proceed through an inner-sphere electron-transfer reaction, generating also the $[Fe(CN)_5(H_2O)]^{3-}$ complex. This mechanism would provide an explanation why neutral ligands like pyrazine cannot effectively compete with $HNO_2$. This mechanism does not change our conclusions and the main argument in favour of a prior reduction of the $Fe^{III}$ complex, in the absence of a change in the first coordination sphere, followed by coordination of $HNO_2/NO_2^-$ and final conversion into nitroprusside.

## 6. Reactions of NO with Iron(III) Porphyrin Complexes

In terms of biological activity, the most significant property of NO is its interactions with iron centres of hemoproteins. It has been suggested that many heme-based enzymes have their activity modulated by NO in vivo. Under bioregulatory conditions, two important target enzymes of NO action in biological systems such as mammalian guanylate cyclase[28] and fungal nitric oxide reductase[29] utilize the iron-heme-cofactors. NO–iron-porphyrin interactions have been shown to be responsible for the inhibition of certain hemoproteins that under physiological conditions bind/or activate dioxygen, including hemoglobin, myoglobin and the cytochrome P450 super family.[30] Moreover, NO binding to the iron-heme centre of a ferriheme salivary protein (nitrophorins) is considered to play an important role in vasodilating effects of blood sucking insects.[31] Since in vivo interactions of NO with iron centres of hemoproteins affect physiological and pathophysiological actions, numerous mechanistic and structural studies on NO binding to iron hemes and their biomimetic models have been undertaken.[32] However, because of the close interplay of many factors that govern the dynamics of NO binding to iron heme centres and of NO release from heme nitrosyls (e.g. oxidation state and spin state of the iron centre, type of the heme ring, number and identity of the axial ligands, interactions of the amino acid residues around the active site in the protein pocket, protein superstructure, accessibility of the iron heme centre to the NO ligand, polarity of the reaction media, etc.), the elucidation of the details of the molecular pathways followed during NO coordination to and dissociation from iron hemes is very difficult and far from complete.

Our own contribution to the understanding of the role of these factors involves in-depth mechanistic and kinetic investigations of the reversible NO binding to selected ferriheme proteins and model iron(III) porphyrins that can supplement other results from structural, kinetic and thermodynamic studies available to date on this topic. In contrast to the NO reactions with iron(II) centres, which are inconvenient to measure because of slow NO dissociation kinetics, the kinetic behaviour of the reactions with iron(III) centres enables the determination of both association and dissociation processes of NO under physiological conditions. In this context, we present an overview of some developments in the mechanistic chemistry involving reactions of selected iron(III) porphyrin complexes [hemoproteins and synthetic iron(III) porphyrin models] with NO, which gives an opportunity to gain insight into the mechanisms of formation and decay of nitrosyl hemoproteins in vivo.

In acidic aqueous solution, NO reversibly binds to six-coordinate, water-soluble iron(III) porphyrin complexes such as $(TPPS^{4-})Fe(H_2O)_2$, $(TMPS^{4-})Fe(H_2O)_2$ and $(TMPyP^{4+})Fe(H_2O)_2$, where TPPS = tetraphenylporphyrinato-4-sulfonate, TMPS = tetramesitylporphyrinato-4-sulfonate and TMPyP = tetra(4-*N*-methylpyridyl)porphyrin.[33,34] Coordination of NO to these hemoproteins induces a low-spin electronic configuration of the metal centre in the resulting nitrosyl derivative.[35] According to the Enemark and Feltham formalism,[1] the nitrosyl products of NO binding to iron(III) porphyrins are typically diamagnetic complexes (type $\{Fe–NO\}^6$) with a linear $Fe^{II}–NO^+$ unit, as has been demonstrated by $^{15}N$ NMR and IR spectroscopy.[36,37] In general, the kinetic behaviour of NO binding to the above-mentioned iron(III) porphyrins is described by the relatively high values for the association and dissociation rate constants (Table 3). The "on" rates for NO binding to these complexes are, however, about three orders of magnitude lower than those found for the iron(II) analogues.[33] In addition, the $(TMPyP^{4+})Fe(H_2O)_2$ complex with a 4+ charge on the porphyrin ring reacts with nitric oxide 25–100 slower than the other two systems, $\{(TPPS^{4-})Fe(H_2O)_2$ and $(TMPS^{4-})Fe(H_2O)_2\}$, in which the porphyrin carries a 4– charge. A close examination of the activation parameters, especially the activation volumes, determined for these reactions appears to be very helpful in understanding the kinetic trends observed in NO binding reactions for the studied iron(III) porphyrins.

The reactions of NO binding to $(TPPS^{4-})Fe(H_2O)_2$ and $(TMPS^{4-})Fe(H_2O)_2$ are described by large and positive values for the activation entropy and activation volume for both the "on" and "off" processes (Table 3), which are signatures for ligand substitution dominated by dissociation of a water molecule as depicted in Scheme 4 ("D" mechanism).[33]

Thus, in acidic medium the dynamics of the reversible binding of NO to the iron(III) centres of $(TPPS^{4-})Fe(H_2O)_2$ and $(TMPS^{4-})Fe(H_2O)_2$ seems to be mainly controlled by the lability of the metal centre. An analogous dissociatively activated mechanism was also proposed for NO release from the nitrosyl complexes of these iron(III) porphyrins. A dissociative mechanism requires that the exchange of the water molecule proceeds in a comparable way. Indeed, variable temperature/pressure NMR studies on the water-exchange kinetics of these iron(III) porphyrin diaqua species[38] very nicely confirmed that activation parameters found for the nitrosylation reaction of these two complexes are largely defined by a dissociative mechanism and the limiting step is the dissociation of the coordinated water molecule. On the basis of this mechanism, it can be explained why NO association reactions with iron(II) porphyrins are

several orders of magnitude faster than those with the iron(III) analogues. Since high-spin iron(II) porphyrins may be five-coordinate, NO binding to the metal centre can proceed without first displacing another ligand [for example a water molecule in the iron(III) porphyrin diaqua species]. Another important conclusion that can be drawn from these studies is that the free radical nature of NO appears to have only a minor (if any) influence on the NO substitution dynamics at the metal centres of iron(III) porphyrins, thus NO behaves as a typical Lewis base donor.

Another mechanistic scenario was observed for the NO interaction with the positively charged $(TMPyP^{4+})Fe(H_2O)_2$.[34] The much slower bond cleavage observed for this system [both NO association and dissociation rate constants are significantly lower than those for the iron(III) porphyrins carrying a 4– charge] must be closely related to the electrophilicity of the iron centre in the TMPyP complex. From the activation parameters found for this system (Table 3), it is clear that in this case the substitution of a coordinated water molecule by NO follows a dissociative interchange ($I_d$) mechanism. The changeover from a limiting dissociative substitution mechanism observed for the corresponding iron(III) TPPS and -TMPS complexes to an $I_d$ mechanism found in this case can be ascribed to the lower lability of the coordinated water molecule in the $(TMPyP^{4+})Fe(H_2O)_2$ complex. This finding appears to be in line with the trend observed for the rate constants and activation parameters measured for water-exchange reactions of these three complexes,[38] where the water-exchange reaction at the iron(III) centre of the positively charged porphyrin is much slower than for the other studied systems with a 4– charge on the porphyrin rings. It seems that in acidic medium, water-exchange processes control the rate and mechanism of the nitrosylation reactions of all three diaqua iron(III) porphyrins in which the labilization of the $Fe–OH_2$ bond is determined by the electron-donating/withdrawing properties of the substituted porphyrin, which in turn depend on the anionic/cationic nature of the substituents, respectively.

In order to better understand the influence of the porphyrin microenvironment in iron(III) porphyrin systems on the rate and mechanism of NO binding and release, as well as to establish the relationship between the structure of the prosthetic group and its reactivity toward NO in various hemoproteins in vivo, two new iron(III) porphyrin models, a highly negatively charged {$(P^{8-})Fe^{III}$ = [5⁴,10⁴,15⁴,20⁴-tetra-*tert*-butyl-5²,5⁶,15²,15⁶-tetrakis(2,2-biscarboxylatoethyl)-5,10,15,20-tetraphenylporphyrin]iron(III)} and a highly positively charged {$(P^{8+})Fe^{III}$ = [5,10,15,20-tetrakis(4′-*tert*-butyl-2′,6′-bis(4-*tert*-butylpyridine)phenyl)porphyrinato]iron(III)} water-soluble porphyrin, have been synthesized[39,40] (see Figure 6). A detailed kinetic and mechanistic description of the reversible binding of NO to these complexes in aqueous solution at low and high pH has been presented recently.[40,41]

In general, iron(III) porphyrins may occur as five- and six-coordinate complexes in which the iron atom can exist in three different spin states, the low-spin state ($S$ = 1/2, typically six-coordinate with short axial and equatorial bonds), high-spin state ($S$ = 5/2, often five-coordinate with elongated equatorial bonds and displacement of the iron atom out of the porphyrin plane) and intermediate-spin state ($S$ = 3/2 with short equatorial and elongated axial bonds). In addition, depending on the nature of the axial ligands and porphyrin-ring substituents, the spin state of

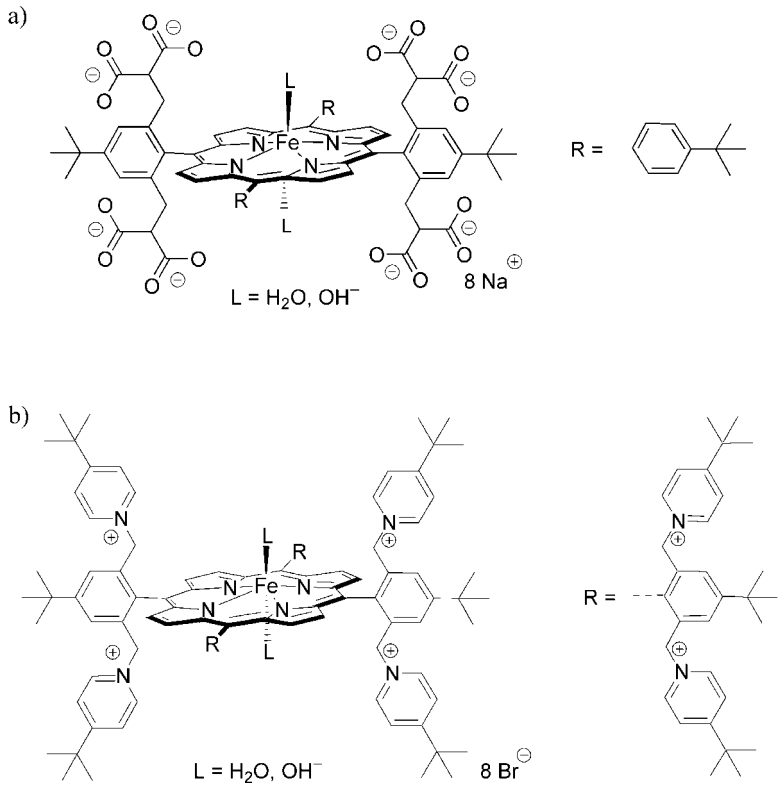

Figure 6. Structures of (a) a highly negatively charged $(P^{8-})Fe^{III}(L)_2$[40] and (b) a highly positively charged $(P^{8+})Fe^{III}(L)_2$[39] iron(III) porphyrin model.

the iron(III) in many iron(III) porphyrins can be described as admixed intermediate, in which varying ratios of $S = 5/2$ and $S = 3/2$ admixing were noted.[42] In this context, it was revealed that introduction of four flexible malonate substituents on the highly negatively charged porphyrin $(P^{8-})Fe^{III}(H_2O)_2$ (in buffered, aqueous solution at pH = 7) leads to significant electronic effects on the iron(III) centre, which are reflected by the relatively high contribution of the $S = 3/2$ spin state in the spin-admixed intermediate.[40] Moreover, these electronic effects together with the possible through-space interactions of negatively charged substituents with coordinated water resulted in an increase in the $pK_a$ value of the coordinated $H_2O$ to the highest value reported to date. With regard to the kinetic behaviour of $(P^{8-})Fe^{III}(H_2O)_2$ in its reaction with NO, a relatively high contribution of the $S = 3/2$ spin state in the spin-admixed state of this complex in comparison with those of other iron(III) porphyrins correlates very well with high NO coordination rates (see Table 3) and the high lability of coordinated water measured for this system.[40] A comparison of the rate and activation parameters for the binding and release of NO for $(P^{8-})Fe^{III}(H_2O)_2$ in aqueous solution at pH = 7 (Table 3) with those reported for other diaqua-ligated iron(III) porphyrin species leads to the conclusion that the reactivity of this complex toward NO is described by the same dissociative (D or $I_d$) mechanism, in which the NO association reaction is controlled by substitution of a water molecule. Similarly, the release of NO from the corresponding nitrosyl complex also follows a dissociative mechanism.

Markedly smaller (in absolute values) NO association and dissociation rate constants as well as activation parameters (especially activation volumes) were obtained for a highly positively charged water-soluble porphyrin, viz. $(P^{8+})Fe^{III}(H_2O)_2$ (Table 3) in which the $Fe^{III}$ centre is weakly spin-admixed with only a 10-% contribution of the intermediate $S = 3/2$ spin state.[41] NO coordination to the iron(III) centre of this highly positively charged porphyrin appears to follow an $I_d$ or even I mechanism (without a predominant a- or d-character). In a similar way, the substantially smaller value of the activation volume determined for NO release from the nitrosyl complex of $(P^{8+})Fe^{III}(H_2O)_2$ than the corresponding values reported for other porphyrin nitrosyls clearly implies a less dissociative mode for NO dissociation from the highly positively charged iron(III) porphyrin.

In summary, the results from the kinetic and mechanistic studies presented above for reversible NO binding to the water-soluble iron(III) diaqua-ligated porphyrins (Table 3) clearly demonstrate that the identity and charge of the substituents in the porphyrin periphery strongly affect the dynamics of both the binding and release of NO. These effects can be summarized as follows: (i) Electron-donating *meso* substituents on the porphyrin rings increase and electron-withdrawing groups decrease electron density on the iron(III) centres, which is reflected by an increase or a decrease in the contribution of the $S = 3/2$ spin state in the spin-admixed system, respectively. (ii) Electron density on the iron(III) centre influences the lability of the coordinated

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

water molecule. Thus, a porphyrin-induced increase in electron density on the iron(III) centre facilitates breakage of the Fe–$H_2O$ bond, whereas for porphyrins with electron-withdrawing *meso* substituents, this bond is more stabilized. (iii) As a result of (i) and (ii), the rate of NO binding to iron(III) diaqua-ligated porphyrins increases with increasing electron donation from the porphyrin *meso* substituents, which is also reflected by the change in the mechanism of NO coordination to the iron(III) centre from predominantly dissociative for the porphyrins with electron-donating *meso* substituents to interchange ($I_d$ or I) for the systems carrying electron-withdrawing *meso* substituents on the porphyrin rings. (iv) Electron-donating groups on the porphyrin rings destabilize, whereas electron-withdrawing substituents stabilize, the $Fe^{II}$–$NO^+$ bond in the nitrosyl complexes of (P)Fe($H_2O$)$_2$, which is illustrated by the variation in $k_{off}$ for the complexes studied. In general, NO dissociation from nitrosyl porphyrins is interpreted in terms of a dissociative mechanism. However, a decrease in the electron-donation from the porphyrin substituents was shown to result in a less dissociative mode for NO release from the corresponding nitrosyl complex.

The reactivity pattern presented above for the iron(III) diaqua-ligated porphyrins points to a crucial role of the lability of the coordinated water molecule in the dynamics of the reversible binding of NO to model iron(III) porphyrins. However, our recent systematic studies on the reactivity of various water-soluble (P)$Fe^{III}$ species towards NO revealed that interactions of NO with heme centres need not always be controlled by the lability/accessibility of the metal centre, but can be determined by electronic and structural factors such as reorganization of the spin density of the iron centre and the accompanying structural changes.[40,41,43]

It has been demonstrated that the rate and mechanism of nitrosylation of water-soluble iron(III) porphyrin complexes can be nicely tuned by the pH of the solution, which determines the nature and number of the axial ligands on the (P)$Fe^{III}$ species and thereby controls the coordination number, spin state and reactivity of the iron(III) centre toward NO.[43] In this context, kinetic and mechanistic investigations on the reactions of NO with monohydroxo-ligated forms of (P)$Fe^{III}$ [formed by deprotonation of coordinated water in (P)Fe($H_2O$)$_2$ at pH > p$K_a$] were performed for the first time.[40,41,43] In general, according to the known *trans*-labilizing effect of the hydroxo ligand, it can be expected that the presence of a more labile water molecule in the position *trans* to $OH^-$ [or even its absence as revealed for example in the ($TMPS^{4-}$)$Fe^{III}$ and ($P^{8-}$)$Fe^{III}$ species, which exist as five-coordinate monohydroxo complexes at high pH] should result in a significant increase in the NO binding rate constants relative to those measured for the corresponding iron(III) diaqua-ligated species. Surprisingly, NO rate constants and activation parameters determined for the monohydroxo forms of (P)$Fe^{III}$ appear to be significantly smaller than those found for the (P)Fe($H_2O$)$_2$ species, indicating that NO coordination to these complexes is no longer controlled by the lability or accessibility of the iron(III) centre. Obviously, this must involve a changeover

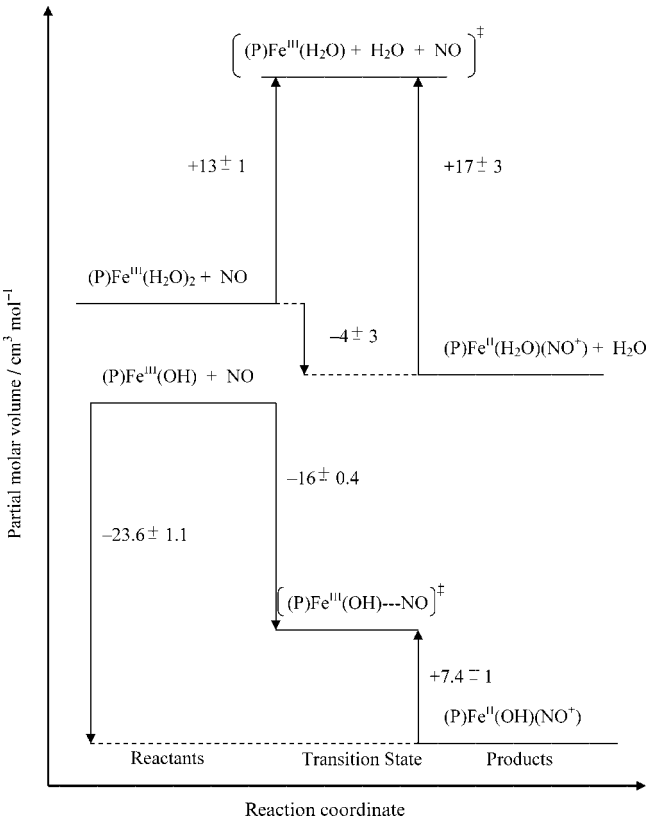

Figure 7. Volume profiles for reversible NO binding to ($TMPS^{4-}$)-$Fe^{III}(H_2O)_2$[33c] (top) and ($TMPS^{4-}$)$Fe^{III}$(OH) (bottom).[43]

in the mechanism of NO binding from dissociative in iron(III) diaqua-ligated species to associatively activated in the (P)$Fe^{III}$(OH) forms. This mechanistic difference can be nicely illustrated by a comparison of the volume profiles constructed for the reactions of reversible binding of NO to ($TMPS^{4-}$)$Fe^{III}(H_2O)_2$ and ($TMPS^{4-}$)$Fe^{III}$(OH), as depicted in Figure 7.

The associatively activated mechanism proposed for NO coordination to ($TMPS^{4-}$)$Fe^{III}$(OH) involves the diffusion-controlled formation of an encounter complex, {(P)-$Fe^{III}$(OH)‖NO}, and subsequent rate-determining $Fe^{II}$–$NO^+$ bond formation. A similar mechanism was proposed previously for NO binding to the high-spin iron(II) porphyrins[32b,33c] and to substrate-bound cytochrome P450.[44] The significantly slower (and therefore rate-limiting) $Fe^{II}$–$NO^+$ bond formation during NO coordination to monohydroxo iron(III) porphyrins than those observed for the nitrosylation reactions of (P)Fe($H_2O$)$_2$ species (in this case $Fe^{II}$–$NO^+$ bond formation is fast and a less energetically demanding process) can be ascribed to the difference in the spin reorganization of the iron(III) centre upon NO binding at low and high pH. Accordingly, the overall spin-state change accompanying the formation of low-spin ($TMPS^{4-}$)-$Fe^{II}(NO^+)$ from purely high-spin ($TMPS^{4-}$)$Fe^{III}$(OH) ($S$ = 5/2 → $S$ = 0) is larger than that occurring upon binding of NO to the spin-admixed, diaqua-ligated complex ($S$ = 5/2, 3/2 → $S$ = 0). This marked difference in the spin reorganiza-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion and the accompanying structural changes [in the purely high-spin $(TMPS^{4-})Fe^{III}(OH)$, the iron atom is displaced out of the porphyrin plane] can be responsible for the observed ca. 100-fold decrease in the NO rate constants at high pH and for the changeover in the mechanism of NO coordination to the complexes studied.

In addition to the effects associated with the lability/accessibility of the metal centre, the spin reorganization of the iron atom and the structural changes that were discussed above in detail, a number of other factors resulting from the presence of the protein coat, such as hydrogen-bonding interactions of the amino acid residues around the active site, polarity of the protein pocket, accessibility of the heme prosthetic group to the solvent, etc., should be considered in the interpretation of reactivity patterns observed for the reversible binding of NO to iron(III) centres of hemoproteins. Indeed, the results from mechanistic studies on the interactions of NO with native ferriheme proteins and comparison to those obtained for "free" iron(III) model porphyrins revealed the important role of the heme pocket in NO interactions with hemoproteins.[45,46] This can be illustrated by mechanistic studies on the reversible binding to metmyoglobin (metMb).[45] Like the iron(III) models $[(TPPS^{4-})Fe^{III}(H_2O)_2$ and $(TMPS^{4-})Fe^{III}(H_2O)_2]$, the iron(III) centre of metmyoglobin is six-coordinate and a water molecule occupies the site at which NO will coordinate. Activation parameters found for NO interaction with metMb (Table 3) clearly evidence the similar mechanistic behaviour of metmyoglobin and model iron(III) porphyrins at low pH, i.e. NO coordination to the iron(III) centre follows a dissociative mechanism controlled by the lability of the water molecule. However, close inspection of the activation volumes determined for these systems indicate that the value of $\Delta V^{\#}_{on}$ observed for the binding of NO to metMb is significantly larger than the corresponding values observed for "free" iron(III) porphyrins (see Figure 8) and therefore cannot reflect only the volume changes associated with dissociation of the water molecule from an octahedral complex (≈13 $cm^3 mol^{-1}$[47]) as was thought for the model complexes. This finding suggests that the protein may undergo some structural rearrangement upon release of coordinated water prior to the binding of NO, which can lead to a further increase in the size of the protein pocket in the transition state. This conclusion was confirmed by the results from XAFS structural studies on nitrosylated metMb.[48] The importance of the protein pocket in the interaction of NO with metmyoglobin can also be demonstrated by a comparison of the NO dissociation rate constants observed for the nitrosyl complexes of metMb and iron(III) porphyrin models $(TPPS^{4-})Fe^{III}(H_2O)_2$ and $(TMPS^{4-})Fe^{III}(H_2O)_2$ (Table 3). The much lower values of $k_{off}$ reported for the metMb/NO system than the corresponding values observed for porphyrin models can be interpreted in terms of the stabilization of the $Fe^{II}$–$NO^+$ moiety by hydrogen-bonding interactions with the residues of the amino acids in the protein pocket. Obviously, the NO molecule cannot be as effectively "caged" after coordination to the iron(III) centres of "free" porphyrin models.

The essential contribution of the protein architecture in the dynamics of reversible NO binding to heme proteins has also been revealed by flash photolysis studies of the analogous nitrosyl complex of ferrous myoglobin (Mb).[49] The existence of multiple geminate-type intermediates in the recombination pathway of Mb(NO) has been ascribed to the presence of the protein pocket from which NO released after the laser flash cannot escape significantly from the protein as recombination occurs much faster than dissociation of the {Mb, NO} geminate pair.

Another important example of protein influence on the kinetics of NO binding to heme centres in hemoproteins can be illustrated by the reaction of NO with ferric and ferrous cytochrome *c* (Cyt *c*) in which the protein limits access of NO molecules to the iron centre.[33a,50] Since the axial ligands in Cyt *c* are occupied by histidine and methionine residues in both oxidation states of the iron centre, coordination of NO must involve displacement of a relatively tightly bound axial ligand (methionine or histidine). As a result, NO binding rate constants observed for Cyt $c^{II}$

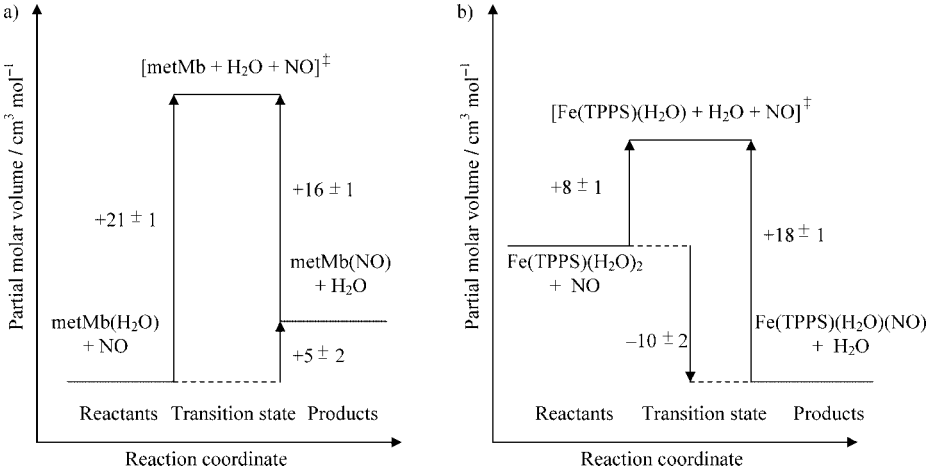

Figure 8. Comparison of the volume profiles constructed for the reversible binding of NO to (a) metmyoglobin[45] and (b) water-soluble $Fe^{III}(TPPS)(H_2O)_2$.[33]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and Cyt $c^{III}$ are unusually small relative to rate constants obtained for ferric and ferrous hemoproteins in which access to the metal centre for the entering NO ligand is not limited by the protein (or the coordination site is occupied by a very labile ligand such as a water molecule in metMb).

## 7. Reactions of NO with $P450_{cam}$ and Model Complexes

Since the nature of the anionic proximal ligand coordinated to the iron(III) centre plays a crucial role in controlling the properties and reactivity of hemoproteins in numerous catalytic processes,[51] the super-family of cytochromes P450 with its quite unusual thiolate ligation attracts particular attention with regard to the spin-state equilibria of the resting state, the redox potential of the iron(III) porphyrin and the electronic nature of the high-valent iron(IV) oxo species. In order to elucidate the mechanism of action of cytochrome P450 in vivo and to understand the essence of its biological function, it is very important to gain detailed mechanistic insight into binding of small molecules such as $O_2$, NO and CO to the catalytic site of this enzyme. Unlike carbon monoxide and dioxygen, NO can bind to both oxidation states of cytochrome P450; the nitrosyl complexes of the ferrous forms with their electronic structure and geometry resemble the physiologically important dioxygen complexes of P450 enzymes. Furthermore, several pieces of evidence revealed that cytochromes P450 might be primary targets for NO action in vivo.[52] Since the reactions of ferrous cytochromes P450 with small molecules have already been extensively investigated, we have focused our attention on the kinetics and mechanistic interpretation of the reversible binding of NO to ferric cytochrome $P450_{cam}$ (isolated from bacterium *Pseudomonas putida*) in the absence and presence of the substrate (1*R*-camphor).[44] The substrate-free ferric $P450_{cam}$ is a low-spin ($S$ = 1/2), six-coordinate complex with a water cluster bound at the distal site *trans* to the cysteine axial ligand in the proximal position. Upon binding of camphor to the active site, water molecules are expelled from the coordination sphere, which leads to the formation of a high-spin ($S$ = 5/2), five-coordinate iron-heme centre. Coordination of NO to the substrate-free or camphor-bound form of $P450_{cam}$ results in the formation of the relatively stable, six-coordinate nitrosyl complex. Earlier EPR[53] and resonance Raman[54] studies on the NO adduct of $P450_{cam}$ showed that the nitrosyl complex of $P450_{cam}$ is a low-spin complex (EPR silent) in which the Fe–NO group adopts a linear structure in the absence of substrate, but becomes slightly bent upon binding of camphor. However, subsequent crystallographic characterization of the Fe–N–O linkage in the $\{FeNO\}^6$ species (models and enzymes)[55] revealed that such systems can also display an axial NO bending feature coupled with tilting of the Fe–NO group. The tilting/bending mode of the axial NO ligand in nitrosyl complexes of iron(III) porphyrins was found to be intrinsic to species of the type $(Por)Fe^{III}(NO)X$, where X is a strong σ-donor ligand.[55a]

Binding of NO to the substrate-free $P450_{cam}$ was shown to exhibit biphasic kinetics, which can be interpreted in terms of an equilibrium between conformational substates in cytochrome P450 (which is the effect of different hydrogen-bonding networks between differently packed water molecules in the heme pocket).[44] The NO binding rate constants and activation parameters determined for both reaction steps (Table 4) are consistent with the operation of a limiting dissociative ligand-substitution mechanism, in which the lability of coordinated water dominates the reactivity of the iron(III) centre with NO.

It should be noted that a similar mechanism was proposed for NO binding to metMb and synthetic water-soluble $(P)Fe^{III}(H_2O)_2$ complexes. In agreement with the principle of microscopic reversibility, the activation parameters found for the release of NO from the nitrosyl complex of substrate-free $P450_{cam}$ also indicate a rate-limiting dissociative mechanism. The overall reaction volume determined for this system is close to zero and is very similar to that found for NO binding to metmyoglobin. The apparent larger value for $\Delta V^{\#}_{on}$ (which represents volume changes associated with a pathway in which a water molecule is dissociated) reported for the reaction between NO and substrate-free $P450_{cam}$ relative to that found for the metMb/NO system can be accounted for in terms of much higher structural rearrangement in the protein pocket of $P450_{cam}$ during dissociation of the water molecule that is additionally bound to the ordered water cluster. Formation of the five-coordinate transition-state $Fe^{III}$ complex is associated with a change in spin state from low-spin to high-spin, which is accompanied by a volume increase of between 12 and 15 $cm^3 mol^{-1}$ on the basis of literature data for such spin-state changes.

A different mechanistic scenario was observed for the reversible binding of NO to the camphor-bound form of cytochrome $P450_{cam}$.[44] As already mentioned, the substrate-bound $P450_{cam}$ is a five-coordinate, high-spin complex with no water molecule occupying the sixth coordination position of the iron(III) centre. The NO association rate constants determined for this complex appear to be significantly higher than those reported for the substrate-free $P450_{cam}$ (Table 4). Moreover, the presence of camphor markedly affects not only the NO binding rate constants but also NO release from the corresponding nitrosyl complex. The substantial negative values for the activation entropy and activation volume found for the "on" reaction (Table 4) clearly indicate that the mechanistic pathways for NO coordination to the iron(III) centres of the substrate-free and camphor-bound form of $P450_{cam}$ are completely different. Since the $Fe^{III}$-heme centre in substrate-bound $P450_{cam}$ is five-coordinate, formation of an Fe–NO bond does not require initial displacement of a water molecule, and therefore the ligation cannot be limited by the rate of $H_2O$ dissociation as was observed for the reaction with substrate-free $P450_{cam}$. These features are consistent with the associatively activated mechanism in which an encounter complex, $\{(P)Fe^{III}\|NO\}$, is formed prior to NO bond formation, as was also proposed for the reaction of NO with

ferroheme proteins[56] and their model complexes[32b,33c] or with the water-soluble monohydroxo iron(III) porphyrin models.[40,41,43] The value of the second-order rate constant for the binding of NO to camphor-bound $P450_{cam}$ is relatively small relative to the rate constants known for the diffusion-controlled reactions in water. This observation, along with the negative activation entropy and activation volume values, supports an activation-controlled reaction mechanism in which Fe–NO bond formation is the rate-determining step. In such a case, Fe–NO bond formation and the concomitant change in spin-state from high- ($S$ = 5/2) to low spin ($S$ = 0) should result in negative contributions to the activation entropy and activation volume. Notably, the large and positive values for the activation parameters found for the release of NO from the nitrosyl complex of camphor-bound $P450_{cam}$ are consistent with a reaction mechanism in which the iron–nitrosyl bond is broken. This process should formally involve charge transfer from iron(II) to the nitrosyl ligand (i.e. formal oxidation of $Fe^{II}$ to $Fe^{III}$) with concomitant solvational changes as a result of charge distribution. The difference in the mechanistic mode observed during NO coordination to the iron(III) centre of $P450_{cam}$ in the absence and presence of substrate can be illustrated nicely by comparison of volume profiles constructed on the basis of kinetic data determined for both reactions (see Figure 9a and Figure 10a). The importance of NO bond-formation/bond-breakage processes coupled to changes in the spin state of the iron(III) centre in camphor-bound $P450_{cam}$ is reflected by a drastic volume decrease on going from the reactant to the product states, whereas the overall reaction volume measured for the nitrosylation reaction of substrate-free $P450_{cam}$ is close to zero, indicating no overall spin-state change occurs during NO binding to the low-spin, six-coordinate $P450_{cam}$. Moreover, the transition states for these reactions differ significantly in terms of the contribution arising from Fe–NO bond formation. In the case of NO binding to $P450_{cam}$ in the presence of camphor, the transition state can be described as "early", i.e. close in nature to the reactant state, which indicates that only partial bond formation accounts for this position. Subsequently, bond formation is completed and accompanied by a change in spin state.

Comparison of the NO association and dissociation rate constants obtained for the reversible binding of NO to $P450_{cam}$ with those found for other iron(III) thiolate- and imidazole-ligated proteins, led to the conclusion that it is very problematic to quantify the real *trans* effect of proximal imidazole and thiolate coordination in such systems. Taking into account that iron(III) heme proteins with even the same thiolate ligation can display quite a wide range of NO binding and release rate constants, it is clear that apart from factors arising from the coordination mode and spin state of the iron(III) centre [i.e. the lability of the leaving group (or its absence) and the identity of the axial and porphyrin ligands], other effects associated with different protein architecture of the heme active sites and their accessibility to ligands should be considered in the dynamics of reactions of NO with metal centres of biological relevance. It seems very likely that nature uses the simultaneous interplay of all these factors to achieve a desired goal, viz. regulation (facilitation or slowing down) of the rates of NO binding or release processes, depending on the physiological requirements. For example, the binding of NO to ferric $P450_{cam}$ was found to be significantly faster in the presence of camphor than in its absence. As mentioned above, this feature can be ascribed to the vacant position in the coordination sphere of the camphor-bound cytochrome. However, considering the fact that the reactions of NO with five-coordinate ferrous hemoporphyrins are about three orders of magnitude larger than those for the six-coordinate ferric analogues, the effect of the vacant distal position of iron(III) in camphor-bound $P450_{cam}$ does not seem to be so large (the NO binding rate constant is only 10 times larger in the presence of camphor than in its absence). It is likely that in this case the effect of facilitation of NO binding as a result of the free coordination site is partially compensated by other opposite effects such as the greater rigidity of the active site (binding of camphor to $P450_{cam}$ causes the pro-

tein and the heme pocket to be more rigid and less compressible[57]) and/or the much larger reorganization of spin multiplicity upon NO binding to substrate-bound $P450_{cam}$ (from $S = 5/2$ to $S = 0$) than that observed for the substrate-free analogue (from $S = 1/2$ to $S = 0$).

In order to elucidate the extent to which NO binding to P450 enzymes is controlled by the metal–ligand system and the extent to which the protein heme environment can influence the dynamics of NO binding and release processes, our interest focused on mechanistic studies of NO binding to synthetic models relevant to P450 cytochrome enzymes that do not possess a protein coat. Although a number of sophisticated thiolate-ligated iron(III) porphyrins have been synthesized, most of them tend to be unstable under the employed experimental conditions, mainly because of the axial sulfur atom, which was found to be very sensitive to oxidation.[58] In this context, Higuchi and coworkers[59] prepared a stable, low-spin $Fe^{III}$-porphyrin alkanethiolate complex (SR complex, see complex **1** in Figure 11), in which the thiolate ligand is sterically protected by bulky pivaloyl groups. It was shown that the SR complex displays a reactivity that is similar to that of cytochrome P450 enzymes, and its bulky, protected axial thiolate ligand remains stable during the catalytic cycle.[60] Moreover, the first synthetic SR–NO complex was prepared and was characterized with the application of spectroscopic and electrochemical methods.[61] The study revealed that NO binds reversibly to the $Fe^{III}$ centre of SR (when an equivalent amount of NO was introduced into the reaction medium), and the resulting nitrosyl complex is diamagnetic (EPR silent) with $\nu$(N–O) and $\nu$(Fe–N) modes that are similar to those of natural heme-thiolate-containing enzymes.

These results motivated us to investigate the mechanistic aspects of the reversible binding of NO to the SR complex in coordinating (methanol) and non-coordinating (toluene) solvents.[62] During the course of the systematic kinetic studies involving concentration-, temperature- and pressure dependences, we revealed that the interaction of the SR complex with NO cannot be described as a simple reversible binding of NO to the iron(III) centre as was reported earlier for the $P450_{cam}$/NO system.[44] Even for a low excess of NO, a rather complex reactivity pattern with several reaction steps was clearly observed. Under the conditions of low NO concentrations, NO reversibly coordinates to the SR complex in methanol with a binding rate constant that is similar to that found for the related reaction with $P450_{cam}$

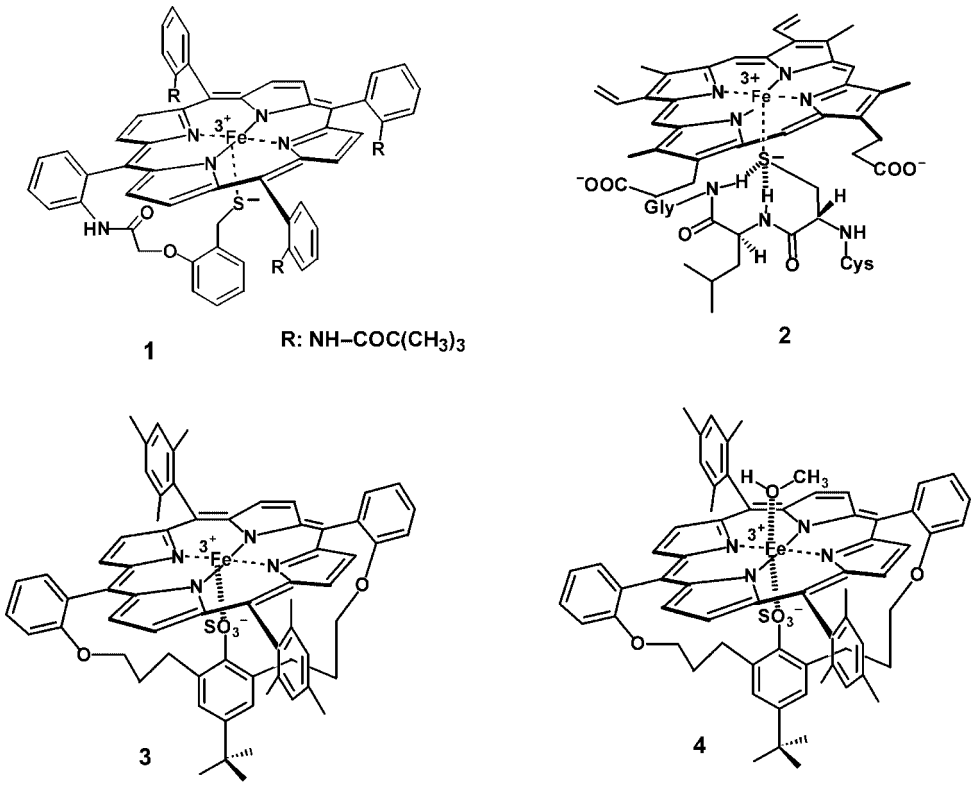

Figure 11. P450 enzyme models [**1** (SR complex),[59] **3**[65] and **4**[65]] and coordination sphere of $P450_{cam}$ (**2**).

(Table 4). The NO dissociation rate constant, although determined with a relatively large extrapolation error (because of subsequent reactions it was impossible to measure this value directly with the use of NO scavengers), is also of the same order of magnitude as that reported for the $P450_{cam}$/NO system.

The activation parameters determined for the formation of the SR–NO complex in methanol (Table 4) indicate a limiting dissociative mechanism that is dominated by dissociation of a coordinated methanol molecule. The value for the NO binding rate constant determined for this reaction in a non-coordinating solvent such as toluene is almost three orders of magnitude higher and clearly supports that the NO binding dynamics is, in this case, governed by the coordination mode of the iron(III) centre.

Under conditions of excess NO, the rapid formation of the SR–NO complex is followed by subsequent slower processes. The second observed reaction step can be accounted for in terms of direct attack of a second NO molecule at the sulfur atom of the thiolate ligand in the initially formed SR–NO complex. This leads to the formation of the five-coordinate $SR(Fe^{II})$ nitrosyl complex, which was characterized by EPR and IR spectroscopy. Although the thiolate ligand in SR is sterically protected by bulky groups, formation of the S-nitrosylated derivative under conditions of a large excess of NO does not seem unusual. It should be noted that a similar scenario was observed for the reactions between NO and the stable glutathionylcobalamin[63] and insect nitrophorins.[64] The following two slower reactions appeared to be strongly accelerated by a large excess of NO or by the presence of higher nitrogen oxides ($NO_x$) in the reaction medium. They can be accounted for in terms of the dynamic equilibria between higher nitrogen oxides and the reactive SR species, which results in the formation of a nitrosyl–nitrite complex of $SR(Fe^{II})$ as the final product.

In summary, although $P450_{cam}$ and the SR model display similar NO association and dissociation rate constants, their reactivity towards NO differs, leading to several $NO_x$-induced reaction steps in the latter case. The use of NO even in a large excess did not result in the nitrosylation of the proximal thiolate group of cytochrome $P450_{cam}$. This observation reflects very well the importance of the protein structure in the neighbourhood of the iron centre not only in controlling the coordination mode and spin state of the metal centre, but also in stabilizing thiolate coordination to the iron(III) heme centre. On the other hand, the multiple reaction steps observed for the SR/NO system can be regarded as a good model for the reactions occurring in vivo, where the dynamic equilibria involving iron(III) hemoproteins and redox-related $NO_x$ species present under aerobic physiological conditions can lead to the rather complex reactivity pattern in which $NO_x$ can act (i) as a ligand that coordinates to the metal centre, (ii) as a S-nitrosylation agent or (iii) as a nucleophile (catalyst), leading to the reductive nitrosylation of the iron(III) heme centres.

More suitable and inert towards oxidation and S-nitrosylation appears to be an enzyme mimic in which the thiolate group is replaced by a $RSO_3^-$ group (complex **3**, Figure 11).[65] DFT calculations[65d] revealed that introduction of the $RSO_3^-$ ligand significantly reduces the negative

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

charge localized on the oxygen atom that coordinates to the iron(III) centre. Therefore, such a system can better mimic the coordination sphere of several native P450 enzymes, in which electron donation from the sulfur atom is also reduced because of the presence of hydrogen bonding between the thiolate ligand and residues of the amino acids in the protein pocket (compare complex **2** and **3** in Figure 11). Moreover, preliminary UV/Vis[65f] and kinetic[66] experiments showed that upon treatment of complex **3** with peracid (peroxide shunt pathway), the oxoiron(IV) porphyrin π-cation radical is produced, which is regarded in the literature as a reactive intermediate responsible for the oxygen atom transfer to hydrocarbons in P450-catalyzed reactions.

To investigate the influence of the identity of the proximal and distal ligands on the dynamics of NO binding to the new synthetic model carrying the $RSO_3^-$ group in the axial position, we performed thermodynamic and kinetic studies on NO coordination to complexes **3** (in non-coordinating toluene) and **4** (in coordinating methanol).[67] In toluene, the five-coordinate, high-spin complex **3** reminiscent of the camphor-bound $P450_{cam}$ is formed, whereas in methanol the six-coordinate complex **4** (see Figure 11) is produced, which resembles the resting state of $P450_{cam}$. As can be seen from Table 4, model complex **3**, although having no protein pocket and possessing a $SO_3^-$ group as proximal ligand, displays a NO binding rate constant in a non-coordinating solvent that is similar to that measured for the NO association reaction of camphor-bound $P450_{cam}$. However, the rate constants for the NO release from the nitrosyl complexes of **3** and camphor-bound $P450_{cam}$ differ by almost four orders of magnitude; **3** has a significantly lower value for the NO binding constant at room temperature. However, the binding constant increases significantly as the temperature decreases. Activation parameters found for NO binding to complex **3** and to native camphor-bound $P450_{cam}$ support the same mechanism for both reactions; the mechanism is dominated by $Fe^{III}$–NO bond formation accompanied by a change in the iron(III) spin state (from $S = 5/2$ to $S = 0$). However, despite the similarity in the reaction volume and entropy, the volume profiles for NO binding to these complexes (Figure 9) differ substantially in terms of the position of the transition state, which can reflect different contributions arising from bond formation and change in spin state. In contrast to the volume profile constructed for the reaction between NO and camphor-bound $P450_{cam}$, reversible binding of NO to **3** is described by a "late" transition state for the association reaction and an "early" transition state for the dissociation reaction. This feature is in agreement with relatively slow "on" and fast "off" reactions and results in the much lower binding constant for NO coordination to **3** than to the native $P450_{cam}$.

When the reaction between NO and the model complex **3** was carried out in a coordinating solvent (methanol), a different mechanistic scenario was observed, indicating the importance of the spin state and the coordination mode of the iron(III) centre in the NO binding process.[67] In methanol, complex **4** is a six-coordinate, high-spin species. The presence of methanol coordinated to iron(III) slows down the binding of NO to **4** by about a factor of 10 relative to the binding of NO to **3**, which lacks the sixth ligand (Table 4). A similar substitution behaviour was noted for the reversible binding of NO to the substrate-free and camphor-bound forms of $P450_{cam}$.[44] However, the activation parameters determined for NO coordination to **4** (Table 4) indicate a different mechanism than that proposed for the reversible binding of NO to substrate-free $P450_{cam}$. Whereas NO binding to the resting form of $P450_{cam}$ is controlled by dissociation of a coordinated water molecule, the displacement of a methanol molecule in **4** follows an associative interchange process in which the volume collapse reflects $Fe^{III}$–NO bond formation with a concomitant change from a high-spin to low-spin state. As already mentioned, NO coordination to substrate-free $P450_{cam}$ does not involve a high-spin to low-spin rearrangement of the iron(III) centre.[44] These opposite effects are clearly seen by comparison of the volume profiles constructed for these two reactions (Figure 10).

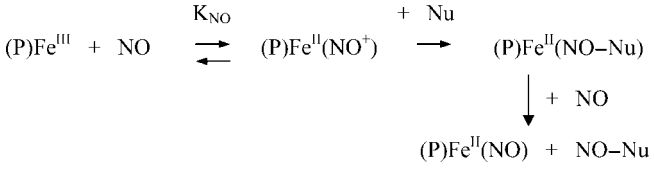
The NO binding constants determined for the enzyme models **3** and **4** are about four orders of magnitude smaller than those found for the native $P450_{cam}$/NO system, which can be explained in terms of the very effective NO dissociation from the nitrosyl complexes of **3** and **4**. Because of the exothermic nature of NO coordination to **3** and **4**, the NO binding constants for these complexes increase significantly with decreasing temperature. This is a general observation noted also for other model enzymes (for instance, the binding of dioxygen to hemocyanine and tyrosinase) where intermediate oxidant or substrate-bound species can be stabilized only at very low temperatures. This feature clearly evidences the important role of the enzyme pocket of $P450_{cam}$ in stabilizing the $NO^+$ state and in forming more stable nitrosyl complexes at ambient temperature relative to those observed for many protein free model complexes. Thus, although the ligand-substitution behaviour of synthetic iron(III) porphyrin complexes can to some extent be regulated by tuning the electronic nature of the porphyrin ring, by the identity and number of axial ligands and by selection of experimental conditions (coordinating/non-coordinating solvent, pH, temperature, etc.), comparison of the kinetic and thermodynamic data for the native iron(III)-thiolate hemoproteins with those obtained for protein-free enzyme models clearly highlights the unique features of the protein architecture in controlling the dynamics of NO binding to P450 cytochromes according to their physiological activity.

## 8. Reductive Nitrosylation Reactions of $Fe^{III}$ Porphyrin Complexes

As mentioned in earlier sections, the binding of NO to the iron(III) centres of hemoproteins and model systems results in the formation of nitrosyl products with a linear coordination mode of the Fe–NO bond and significant charge transfer from NO to the metal centre. This leads formally to the one-electron reduction of the $Fe^{III}$ centre

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and to the formation of a $(P)Fe^{II}(NO^+)$ complex with a coordinated nitrosyl ($NO^+$) ligand, which is isoelectronic to carbon monoxide. Clearly, $NO^+$ as an electrophilic ligand (much more electrophilic than free NO) may be susceptible to nucleophilic attack in aqueous and nonaqueous solution, which can result in the apparent instability of the nitrosyl complexes of iron(III) porphyrins relative to their analogous $(P)Fe^{II}(NO)$ species. Indeed, it has long been known that ferriheme proteins (methemoglobin and ferricytochrome *c*) undergo autoreduction when exposed to NO in aqueous solution.[68] Although many groups have systematically investigated NO reduction processes of various ferriheme proteins,[50,69] the mechanisms of these reactions are still far from completely understood. Hoshino et al.[70] reported detailed kinetic studies on the NO reductions of some ferriheme proteins in buffered solutions at various pH and proposed a plausible reaction sequence for the reductive nitrosylation of iron(III) centres. This involves attack of a nucleophile (Nu), viz. a water molecule or hydroxide ion as a general base, on the ferrous nitrosonium complex to produce a ferrous porphyrin species [which reacts very rapidly with excess NO to give (P)Fe(NO)] and the nitrosylated nucleophile as shown in Scheme 5.



Scheme 5.

This finding has motivated many researchers to study, in detail, the role of general base buffer and hydroxide ion catalysis on the reductive nitrosylation of many ferriheme proteins and iron(III) porphyrin models.[71,72] During the course of these studies, a very important discovery was made that the nitrite ion (present in the reaction medium as a reaction product or as an ubiquitous impurity in aqueous NO solutions) can also be regarded as a catalyst for this reaction.[72] In order to account for the catalytic effect of nitrite, two mechanistic proposals were made.[72] The first involves an inner-sphere pathway proceeding by nucleophilic attack of the nitrite ion on the electrophilic, coordinated $NO^+$ to produce the iron(II) complex of the $N_2O_3$ species ($Fe–N_2O_3$) as a key intermediate. Dissociation of this complex followed by subsequent fast reactions [i.e. hydrolysis of $N_2O_3$ to nitrous acid and very rapid nitrosylation of the iron(II) porphyrin complex] lead to the reaction products and regeneration of catalytic nitrite. Another possible mechanism is described by an outer-sphere electron-transfer process between the nitrite ion and the ferrous nitrosonium complex to give a nitrosyl iron(II) porphyrin and nitrogen dioxide. $NO_2$ would then react very rapidly with the excess NO to form $N_2O_3$, which further undergoes hydrolysis to nitrite. Notably, a common aspect of these two mechanisms is the formation of $N_2O_3$ as a reactive intermediate. In aqueous solution, it can very easily undergo hydrolysis to nitrous acid; however, in the hydrophobic protein pocket, $N_2O_3$ formed during reductive nitrosylation of ferriheme proteins can offer other possibilities, for example, as an important nitrosating agent for protein amines or thiols.

All these interesting results have inspired us to investigate the reactions of reductive nitrosylation of iron(III) porphyrin models in more detail. Our contribution in this area involves temperature and pressure studies on the reductive nitrosylation reactions following the binding of NO to $(TMPyP^{4+})Fe^{III}(H_2O)_2$ (at pH = 4)[34] and to the highly negatively $[(P^{8-})Fe^{III}]$ and highly positively $[(P^{8+})Fe^{III}]$ charged ferric porphyrins (at high and low pH).[73] Estimation of the activation parameters for the nitrite-catalyzed reductive nitrosylation of these iron(III) models enabled us to discuss the validity of the above-mentioned inner- and outer-sphere mechanisms proposed for the catalytic effect of the $NO_2^-$ ion, as well as allowed us to establish the role of the overall charge on the porphyrin ring and iron centre on the rate and mechanism of reductive nitrosylation reactions.

Nitrite concentration dependence studies of the reaction between the nitrosyl complex of $(TMPyP^{4+})Fe^{III}(H_2O)_2$ and $NO_2^-$ at pH = 4 revealed that positively charged $(TMPyP^{4+})Fe^{II}(H_2O)(NO^+)$ undergoes reductive nitrosylation (in the presence of added nitrite) significantly faster than that already reported for the negatively charged $(TPPS^{4-})Fe^{II}(H_2O)(NO^+)$ complex[72] (Table 5). Activation parameters determined for this reaction are significantly positive (Table 5), which can indicate the significant role of electrostriction effects as a result of charge neutralization during binding of $NO_2^-$ to coordinated $NO^+$. The substantial contribution of these effects on the rate of reductive nitrosylation processes can be better understood in terms of the more recent results from mechanistic studies on the nitrite-catalyzed reductive nitrosylation of $(P^{8-})Fe^{III}$ and $(P^{8+})Fe^{III}$ complexes.[73] It was shown that exposure of aqueous solutions of $(P^{8-})Fe^{III}(H_2O)_2$ at pH = 7 and of $(P^{8+})Fe^{III}(H_2O)_2$ at pH = 2 leads to rapid nitrosylation reactions to produce $(P^{8-})Fe^{II}(H_2O)(NO^+)$ and $(P^{8+})Fe^{II}(H_2O)(NO^+)$, respectively. The NO binding reaction is, in both cases, followed by the slower subsequent reductive nitrosylation reaction, which leads to the formation of five-coordinate nitrosyl adducts as the final products, $(P^{8-})Fe^{II}(NO)$ and $(P^{8+})Fe^{II}(NO)$, respectively. The NO concentration dependence of the observed rate constant for reductive nitrosylation of these complexes enabled the calculation of the first-order rate constants for the reduction reactions ($k_{red}$). It was revealed that the value of $k_{red}$ is almost two orders of magnitude larger for the reduction of the positively charged $(P^{8+})Fe^{II}(NO^+)$ species than for that of the negatively charged $(P^{8-})Fe^{II}(NO^+)$ porphyrin. This observation is in line with the results obtained earlier for the reductive nitrosylation of $(TPPS^{4-})Fe^{III}$ and $(TMPyP^{4+})Fe^{III}$[34,72] and can be explained in terms of the electrophilicity of the iron(III) centres in both complexes. The accelerated reductive nitrosylation observed for $(P^{8+})Fe^{II}(NO^+)$ can be ascribed to the higher electrophilicity of

the metal centre and of coordinated $NO^+$, which is the result of the presence of the positively charged electron-withdrawing *meso* substituents in the heme environment. Conversely, electron-donating groups in $(P^{8-})Fe^{II}(NO^+)$ seem to stabilize the nitrosyl complex by the increased electron density at the iron(II) centre and therefore slow down the reductive nitrosylation reaction. Similarly, the presence of the $OH^-$ group in the position *trans* to $NO^+$ in $(P^{8+})$-$Fe^{II}(OH)(NO^+)$ (at pH = 8) has been shown to reduce $k_{red}$ significantly for this complex, mainly because of the induced electron density (coming from the *trans* $OH^-$ ligand) on the nitrosyl ligand and the decrease in electrophilic character.[73]

Since the reductive nitrosylation reactions observed for the above systems can be catalyzed by nitrite ions present in the solution as a final reaction product, a detailed study of the nitrite-catalyzed reduction of $(P^{8-})Fe^{II}(NO^+)$ and $(P^{8+})Fe^{II}(NO^+)$ was performed.[73] The values of the reduction rate constant with nitrite ion as catalyst ($k_{nit}$) obtained for these complexes and related systems are summarized in Table 5.

During the course of these studies, it was revealed that the rates of reductive nitrosylation are sensitive to the nature of the reactant, viz. HONO or $NO_2^-$ [see for example the rate constants determined for the $(P^{8+})Fe(H_2O)_2$ complex at pH = 2 and 4, where nitrous acid exists mainly as HONO and $NO_2^-$, respectively], and to the protonated/deprotonated form of the coordinated water molecule [see rate constants determined for $(P^{8+})Fe(H_2O)_2$ and $(P^{8+})$-$Fe(OH)(H_2O)$ at pH = 4 and 8, respectively]. All these observations indicate that nitrite-catalyzed reductive nitrosylation of the complexes studied proceeds according to an inner-sphere mechanism described by direct nucleophilic attack of the $HONO/NO_2^-$ species on coordinated $NO^+$ to form the $Fe^{II}$–$N_2O_3$ complex, which subsequently dissociates $N_2O_3$ and rapidly binds NO (present in excess in solution) to form the final product $(P)Fe^{II}(NO)$. Such a mechanism is also strongly supported by the activation parameters determined for $k_{nit}$ (Table 5). Activation entropies and activation volumes for the nitrite-catalyzed reductive nitrosylation of cationic complexes are substantially positive, whereas those for the negatively charged porphyrin complexes are significantly negative. This correlates very well with the electrophilicity of coordinated $NO^+$, which in turn controls the contribution of changes in electrostriction that accompanies bond formation between the electrophilic nitrosonium ligand and the $HONO/NO_2^-$ species. For example, the electrophilicity of the $NO^+$ ligand in $(P^{8-})$-$Fe^{II}(H_2O)(NO^+)$ is not expected to be high because of the overall negative charge on the porphyrin ring, such that charge neutralization and decrease in the electrostriction during bond formation is relatively small in comparison to the intrinsic contributions arising from bond formation. This means that positive contributions to the activation entropy and activation volume arising from the decrease in electrostriction (accompanied by the release of solvent molecules) can only partially compensate the negative intrinsic contributions associated with bond formation, which finally leads to the substantially negative values of the activation parameters and relatively small value of $k_{nit}$. In contrast, bond formation between $HONO/NO_2^-$ and the highly electrophilic $NO^+$ in $(P^{8+})Fe^{II}(H_2O)(NO^+)$ (because of the additional positive charge on the heme environment) will result in more effective charge neutralization. Thus, in this case, the positive contributions arising from the significant decrease in electrostriction are expected to play a major role. This is reflected by the substantially positive values for the activation parameters and high $k_{nit}$ values found for this system. In summary, the observed trend in the $k_{nit}$ values for a series of $(P^n)Fe^{III}$ complexes [$(P^{8+})Fe^{III}$ > $(TMPyP^{4+})$-$Fe^{III}$ > $(TPPS^{4-})Fe^{III}$ > $(P^{8-})Fe^{III}$] along with the activation parameters determined for these systems strongly support the operation of an inner-sphere electron-transfer mechanism for the reductive nitrosylation reactions of iron(III) porphyrins, as opposed to an outer-sphere electron-transfer mechanism, which was proposed in recent reports.[71c,72]

## 9. Reductive Nitrosylation of Water-Soluble Cobalt Porphyrins

Vitamin $B_{12a}$, aquacobalamin [$Cbl(H_2O)$], was proposed to react with NO under biological conditions and to regulate its physiological functions in this way.[74] Experimental and theoretical work from our laboratory proved that $Cbl(H_2O)$ does not react with NO at pH 7.[75,76] Nevertheless, it was reported later that $Cbl(H_2O)$ reacts with NO at low pH, under conditions in which the dimethylbenzimidazole group is protonated and subsequently dechelates.[77] The final product of this reaction was not a $Co^{III}$–(NO) complex but $Co^{II}$–(NO), or better described as $Co^{III}$–$(NO^-)$. This complex is also obtained when reduced $Cbl(H_2O)$ reacts with NO;[78] in this way, the reaction is a reductive nitrosylation process. Co porphyrins react in a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

manner similar to that for Cbl($H_2O$) at low pH, generating $Co^{III}$–($NO^-$) complexes as final products.[33c,79] In this way, the reaction under study can be described by reaction (9).

$$Co^{III}(P) + 2\,NO \rightarrow\!\!\rightarrow Co^{III}(P)(NO^-) + NO_2^- \quad (9)$$

From titrations of the $[Co^{III}(TPPS)(H_2O)_2]^{3-}$ complex solution with NO, the stoichiometry of the consumption of NO was determined to be close to 2. Quantification of the $NO_2^-$ concentration at the end of the reaction allowed us to conclude that approximately 1 mol of $NO_2^-$ is produced per mol of complex, which gives strong support to the overall stoichiometry described by reaction (9).[80]

Three different Co-porphyrin complexes were studied [TPPS, TMPyP and TCPP = *meso*-tetra(4-carboxyphenyl)-porphyrin]; all of them react with NO and show, qualitatively, a very similar picture.[80] The reactivity difference correlates with the electron density on the metal centre. The reaction with NO proceeds through an apparently single first-order reaction; however, the isosbestic points are not clean, the observed rate constants are not reproducible and, in some cases, the kinetic traces had to be fitted to a two-exponential function. These findings suggest a more complex behaviour. For this reason the influence of $NO_2^-$/$HNO_2$ on the kinetics was studied in detail, since these species are typical and unavoidable impurities in aqueous NO solutions.[72c,75] The reactions of the three complexes under study were strongly pH dependent. At pH > 3, two reaction steps were clearly observed, whereas at pH < 3, a single reaction step was observed.

At pH < 3, in contrast to the behaviour at higher pH, formation of the final product is observed from the beginning of the reaction. The kinetic data show that the reaction is controlled by the reversible substitution of coordinated water to produce the $[Co^{III}(P)(NO)(H_2O)]$ complex, i.e. the product of the primary interaction between NO and the starting compound.[80] A weak EPR signal obtained at pH 1 with a $[Co(TPPS)(H_2O)_2]^{3-}$ sample saturated with NO gives some evidence for the presence of this intermediate.[80,81c] These complexes were obtained by electrochemical methods in organic solvents and characterized in situ,[81] since they are very unstable towards NO dissociation, to generate $[Co(P)(solvent)_2]$ complexes.[81b] We propose that the $[Co^{III}(P)(NO)(H_2O)]$ complex reacts with a second NO molecule to generate the dinitrosyl species $[Co^{III}(P)(NO)_2]$ (see left side of Scheme 6). This compound produces the final product through an inner-sphere electron-transfer reaction. These $[Co(P)(L)_2]$ compounds were observed for all the ligands studied, viz. $SCN^-$, $I^-$, pyridine.[82] Moreover, we observed the formation of $[Co(P)(NO_2^-)_2]$ complexes.[80] In all of these cases, the coordination of the second ligand molecule is faster than that of the first because of the increase in electron density on the metal centre, which is in agreement with the fact that coordination of the first NO molecule is the rate-determining step and with the observation of a single reaction step.

At pH > 3, two reactions were clearly observed when mixtures of NO and $NO_2^-$ were used. It was concluded that the first reaction is controlled by the competition between these two species to substitute one of the coordinated water molecules in the complex.[80] In this way, the expression of the observed rate constant for this reaction ($k_{1(obs)}$) can be written as in Equation (10) [see Figure 12].

$$k_{1(obs)} = k_{NO}[NO] + k_{NO_2^-}[NO_2^-] \quad (10)$$

The values of $k_{NO}$ obtained at pH 1 are in agreement with those obtained at higher pH in the presence of $NO_2^-$. This is also true for the values of $k_{NO_2^-}$ obtained in the absence and presence of NO (see Figure 12). The proposed rate law in Equation (10) is supported by the kinetic data and activation parameters obtained for the first reaction step at pH 5 and 1 and is in agreement with the data reported in the literature for the reaction of the same Co(P)

NO concentration dependence for the reaction with $[Co(TPPS)(H_2O)_2]^{3-}$ studied under different conditions: pH = 5.0 (0.01 M acetate buffer) or pH = 1.0 ($HClO_4$), $I$ = 0.1 M ($NaClO_4$), $T$ = 25.0 °C, $[Co(TPPS)(H_2O)_2^{3-}]$ = 1–5 × $10^{-6}$ M. Different values of $k_{obs}$ represent the spread in the measurements at a particular NO concentration (each data point is the average of 4 to 10 kinetic runs).

complexes with other ligands (see Table 6 and Table 7).[82] The first reaction step for the three complexes correlates with the electron density on the metal centre as was previously observed. The spectrum of the intermediate generated during the reaction was very similar to that of the $[Co(P)(NO_2^-)(H_2O)]$ complex; no final product, i.e. $[Co^{III}(P)(NO^-)]$, was produced and no EPR signals could be detected either. According to Equation (10), the $[Co(P)(NO_2^-)(H_2O)]$ and $[Co(P)(NO)(H_2O)]$ complexes should be the products of the first reaction, where $NO_2^-$ and NO compete. Nevertheless, only the first compound was detected. We propose that the second intermediate is unstable under these conditions, even more than at pH 1, and the presence of $NO_2^-$ leads to the decomposition of this intermediate thus releasing NO and generating $[Co(P)(NO_2^-)(H_2O)]$ (see central part of Scheme 6). This decomposition of the intermediate by $NO_2^-$ is prevented at low pH through protonation, where formation of the final product is observed from the beginning of the reaction.

The second reaction was observed at pH > 3. The observed rate constants for this reaction ($k_{2(obs)}$) are very similar to those observed for the reaction between the $[Co(P)(NO_2^-)(H_2O)]$ complexes and NO under similar conditions. On the other hand, they do not depend significantly on the $NO_2^-$ concentration, they depend linearly on the NO concentration (see Figure 12) and the activation parameters support a dissociative mechanism. The nature of this reaction is discussed elsewhere, and several possible mechanisms are considered, among them the oxo-transfer reaction.[80] We propose that the $[Co(P)(NO_2^-)(H_2O)]$ complex is, in the presence of NO, in equilibrium with small amounts of the $[Co(P)(NO_2^-)(NO)]$ intermediate (see lower part of Scheme 6). This last intermediate slowly decomposes through an inner-sphere electron-transfer reaction to generate the final product $[Co^{III}(P)(NO^-)]$ and $NO_2$. Thus, this reaction would be the rate-determining step for the second reaction. This proposal is consistent with the NO- and $NO_2^-$ concentration dependences, as well as with the activation parameters.

In the reductive nitrosylation of $Fe^{III}$ porphyrins, where general base catalysis was observed, it was proposed that the $[Fe^{III}(P)NO]$ complex is attacked by nucleophiles such as $NO_2^-$, different bases and even solvents to generate the $Fe^{II}(P)$ complex.[71,72] The latter complex reacts under diffusion-controlled conditions with NO to produce the final product. We do not have any evidence in favour of such catalysis in our system. If this was the case, we would expect different $NO_2^-$ concentration- and pH dependences. We believe that the reason why reductive nitrosylation of Co porphyrins is so different from that of the Fe analogues is the instability of the $[Co^{III}(P)(NO)(H_2O)]$ intermediate.[80,81] Although the electronic structure of this compound may have some contribution from the $[Co^{II}(P)(NO^+)(H_2O)]$

structure, its instability prevents any further reaction with nucleophiles. In fact, such reactions are quite slow and they are about $10^{-3}$ $s^{-1}$ for the reactions with solvent (water), acetate, etc.[71,72]

## 10. Reductive Nitrosylation of Aquacobalamin at Low pH

As mentioned in the previous section, aquacobalamin, [Cbl($H_2O$)], does not react with NO at pH 7,[75,76] nevertheless, it was reported that it can undergo reductive nitrosylation at low pH to generate a $Co^{III}$–$NO^-$ complex or Cbl($NO^-$)[77] in a manner similar to that of Co porphyrins.[79] As a natural extension of the kinetic and mechanistic studies on Co porphyrins,[80] the reductive nitrosylation of Cbl($H_2O$) at low pH was revisited.[83] Many similarities between Cbl($H_2O$) and the previously studied Co porphyrins, as well as some important differences, were found.

In the preliminary experiments, kinetic traces obtained during the reaction with NO were irreproducible, which shows, in many cases, a more complex behaviour than a simple first-order process. The influence of $HNO_2$ impurities was studied by using mixtures of NO and $HNO_2$. As previously found for Co porphyrins, two reaction steps were observed. The first reaction shows very small absorption changes and proceeds on the stop-flow timescale. The UV/Vis spectrum of the intermediate generated during the first reaction is very similar to that of the Cbl($NO_2^-$) complex generated for the same $HNO_2$ concentration. The observed rate constants obtained for this reaction ($k_{1(obs)}$) are independent of the NO concentration. On the other hand, they show a linear dependence on the $HNO_2$ concentration with a slope of $110 \pm 2$ $M^{-1}s^{-1}$ and an intercept of $(4.0 \pm 0.2) \times 10^{-2}$ $s^{-1}$. Very similar parameters were obtained if no NO (only $HNO_2$) is present in the medium, i.e. $106 \pm 5$ $M^{-1}s^{-1}$ and $3.3 \pm 0.6$ $s^{-1}$, respectively. In other words, NO does not react with Cbl($H_2O$) even at pH 1.[83]

The second reaction step shows the spectral changes reported in the literature for the reductive nitrosylation of Cbl($H_2O$) at low pH, and the Cbl($NO^-$) complex is produced as final product.[77] It was previously reported that this reaction was independent of the NO concentration.[77] We found, however, that the observed rate constant for this reaction ($k_{2(obs)}$) depends on the NO and $HNO_2$ concentrations, but the dependence on the concentration of each species is quite surprising and unexpected.[83] For example, when the $HNO_2$ concentration was kept constant, the $k_{2(obs)}$ values decreased with increasing NO concentration. As the yield of the reaction decreased as the NO concentration decreased, quantitative information was not obtained. On the other hand, when the NO concentration was kept constant, the $k_{2(obs)}$ values increased with increasing $HNO_2$ concentration, and a non-linear, quadratic dependence was observed (see Figure 13). The yield of the final product decreased also when the $HNO_2$ concentration increased, which is in agreement with the previous finding. The second reaction step is strongly pH dependent. As was previously reported, the reaction rate decreases with increasing pH, and the reaction is no longer observed at pH > 4.[77] The pH dependence correlates with the spectral changes observed for the Cbl($NO_2^-$) complex as a function of pH. From the UV/Vis data, the p$K_a$ of the protonated Cbl($NO_2^-$) complex is estimated to be close to 1.[83] In contrast, the p$K_a$ of protonated Cbl($H_2O$) is –2.5.[84] We propose that the dimethylbenzimidazole group is protonated at low pH and dissociates from the metal centre to leave a vacant site for the coordination of NO. The dissociation of this group after protonation is a fast reaction [ca. 0.3 $s^{-1}$ at pH 1 for the Cbl($NO_2^-$) complex].[83] In this way, the reactive species towards NO is not Cbl($H_2O$) but the Cbl($NO_2^-$) complex (see Scheme 7), since the concentration of the protonated form of Cbl($H_2O$) is extremely low at pH 1.

The effect of the $HNO_2$ concentration on $k_{2(obs)}$ and on the yield of the reaction revealed the possibility of a reaction between $HNO_2$ and the Cbl($NO^-$) complex, i.e. a *back reaction*. Interestingly, the observed rate constants for this last reaction ($k_{obs}$) do not differ significantly from $k_{2(obs)}$ obtained for identical $HNO_2$ and NO concentrations (see

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

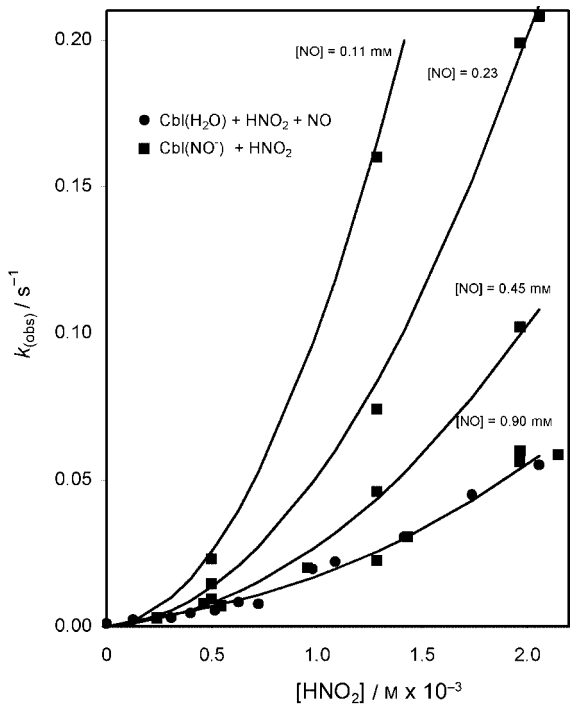

Figure 13. $[HNO_2]$ dependence of the observed rate constant for the second reaction step ($k_{2(obs)}$) and of the reaction between $Cbl(NO^-)$ and $HNO_2$ ($k_{obs}$). The solid line corresponds to the simulated data according to Equation (12), by using $K_{HNO_2}$ = 2800 $M^{-1}$ (fixed variable), $k_{NO} = 7 \pm 2$ $M^{-1} s^{-1}$ and $K = 0.6 \pm 0.2$. Experimental conditions: pH = 1.0, $I$ = 0.1 M ($HClO_4$), $T$ = 25.0 °C. $[Cbl(H_2O)]$ = 0.01–0.05 mM.

Figure 13).[83] Moreover, $k_{obs}$ values show a quadratic dependence on the $HNO_2$ concentration and decrease when the NO concentration increases. The product of the *back reaction* must be $Cbl(NO_2^-)$ in equilibrium with $Cbl(H_2O)$, since $HNO_2$ is in excess and no consecutive reactions are observed. In this way, the reductive nitrosylation is a reversible reaction and can be expressed by reaction (11).

$$Cbl(NO_2^-) + 2\,NO + H_2O \rightleftharpoons Cbl(NO^-) + 2\,HNO_2;\ K \qquad (11)$$

According to the kinetic data and the earlier work on Co porphyrins, the proposed mechanism for the reaction of $Cbl(H_2O)$ with NO at low pH is summarized in Scheme 7.

According to this mechanism and the assumptions described elsewhere,[83] Equation (12) can be derived, where $K_{HNO_2}$ is the equilibrium constant for the formation of the $Cbl(NO_2^-)$ complex, $K$ is the equilibrium constant for the reductive nitrosylation expressed in reaction (11) and $k_{NO}$ expresses the rate constant for the release of $NO_2^-$ from the $Cbl(NO_2^-)(NO)$ intermediate (see Scheme 7), which is the rate-determining step in the second reaction step.

$$k_{2(obs)} = \frac{K_{HNO_2}[HNO_2]}{1 + K_{HNO_2}[HNO_2]}\, k_{NO}[NO] + \frac{k_{NO}[HNO_2]^2}{K\,[NO]} \qquad (12)$$

Equation (12) can account for the dependence of $k_{2(obs)}$ for the reductive nitrosylation and of $k_{obs}$ for the *back reaction* on the NO and $HNO_2$ concentrations. Moreover, by fitting the experimental data with this equation, the values of $7 \pm 2$ $M^{-1} s^{-1}$ and $0.6 \pm 0.2$ were obtained for $k_{NO}$ and $K$, respectively. This latter parameter was confirmed by direct equilibrium measurements.[83] These measurements were also consistent with the stoichiometry expressed in reaction (11). In summary, the reductive nitrosylation is dominated by its *back reaction*, and this is the reason for its strange NO- and $HNO_2$ concentration dependences.

DFT calculations were performed on the present system.[83] Earlier studies concluded that $Cbl(H_2O)$ cannot interact with NO in aqueous solution.[76] The more recent work focused on the effect of the coordination of NO, $NO_2^-$, $H_2O$ and $OH^-$ on the lengthening of the Co–dimethylbenzimidazole bond.[83] On deprotonation of the coordinated water molecule in the $Cbl(H_2O)$ complex, significant lengthening of the Co–dimethylbenzimidazole bond occurs. A similar effect is observed upon coordination of $NO_2^-$. On the other hand, the Co–dimethylbenzimidazole bond length in the Cbl(NO) complex is similar to that in $Cbl(H_2O)$. In this way, lengthening of the Co–dimethylbenzimidazole bond in the $Cbl(NO_2^-)$ complex allows its protonation and dechelation at low pH. This is evidently not possible for the $Cbl(H_2O)$ and Cbl(NO) complexes.

In conclusion, we confirmed that $Cbl(H_2O)$ cannot react with NO even at low pH. We propose that the active species towards NO is $Cbl(NO_2^-)$ and not $Cbl(H_2O)$. A mechanism based on (and consistent with) previous work on Co porphyrins is proposed. This mechanism accounts for the NO- and $HNO_2$ concentration dependences of the observed rate constant for the reductive nitrosylation ($k_{2(obs)}$) as well as for the pH dependence. As we mentioned in the previous section, $Co^{III}$–(NO) complexes are very unstable compounds.[81] This is the main reason why the reductive nitrosylation in Co porphyrins is so different from that in the Fe analogues.[71,72] This instability of the $Co^{III}$–(NO) complexes determines why $Cbl(H_2O)$ does not react with NO as well.[76,83]

## 11. Conclusions and Future Outlook

The work summarized in this microreview has greatly assisted the mechanistic clarification of the interaction of NO with Fe and Co complexes and of the observed subsequent reactions. It forms an excellent basis for the clarification of observations in the literature that are of significant biological and environmental importance. In this process the application of volume-profile analysis has been extremely useful, especially in cases where the activation of NO is accompanied by changes in the spin state of the metal centre. Presently, we are extending this work to water-soluble model complexes of P450 that closely resemble the coordination environment of P450. Although NO is a radical, the presented work clearly shows that it behaves like any other nucleophile, with the exception that once it is bound to the metal centre there is a redistribution of charge density, which results in a formal redox reaction. Furthermore, the fundamental work involving the binding of NO to P450 and model complexes forms a basis for the understanding of the more complex reaction sequences observed during the activation of peroxides by such systems, a topic that is now being studied in more detail in our group.

## Acknowledgments

We gratefully acknowledge financial support from the National Research Council of Argentina (CONICET) and the Deutsche Forschungsgemeinschaft within SFB 583 on "Redox-Active Metal Complexes". We appreciate the productive collaboration with Norbert Jux (Institute for Organic Chemistry, University of Erlangen-Nürnberg).

# Factors Affecting the Interlayer Arrangement of Transition Metal–Ethylenediaminetetraacetate Complexes Intercalated in Mg/Al Layered Double Hydroxides

**Guoqing Wu,[a] Lianying Wang,*[a] Lan Yang,[a] and Junjiao Yang[a]**

**Keywords:** Layered compounds / Intercalation / Metal–edta complexes / Reorientation / Organic–inorganic hybrid composites

Transition metal (M)–ethylenediaminetetraacetate (edta) complexes {$[M(edta)]^{2-}$} have been intercalated in layered double hydroxides (LDHs) by a hydrothermal method using $MgAl–NO_3$ LDH as the precursor. The factors affecting the orientation of the incorporated $[M(edta)]^{2-}$ in the resulting well-ordered materials were investigated. Whilst varying the metal cation in the intercalated complex has no major influence on the orientation of the $[M(edta)]^{2-}$ (M = Co, Ni, Cu, Zn) anion in the interlayer galleries, there is a marked dependence on layer charge density. The observed basal spacings of 1.402–1.461 nm for $Mg_2Al$–M(edta) LDH and 1.254 nm for $Mg_3Al$–Zn(edta) LDH can be ascribed to bilayer and monolayer arrangements, respectively, of the $[M(edta)]^{2-}$ anion. When the Mg/Al ratio is varied in the range 2.2–2.7 the two guest arrangements coexist. The evolution of the interlayer arrangement of $[M(edta)]^{2-}$ in LDHs with increasing temperature was studied by variable-temperature in-situ XRD measurements, variable-temperature in-situ FT-IR, and combined thermogravimetric analysis and mass spectrometry (TGA-MS). In the case of $Mg_2Al$–M(edta) LDH, a metastable phase with a similar monolayer structure to that found in $Mg_3Al$–M(edta) LDH was detected by XRD in the range 140–300 °C. Cooling of the calcined solid to room temperature in air leads to the recovery of the original bilayer structure. The reversible nature of the structural transformation indicates that a reorientation of the guest $[M(edta)]^{2-}$ complex in the interlayer galleries occurs on heating, rather than a grafting process. Heat treatment of $Mg_3Al$–M(edta) LDH results only in a gradual contraction of the basal spacing associated with the loss of interlayer water without any reorientation of the guest $[M(edta)]^{2-}$ complex.

## Introduction

By virtue of their anion-exchange properties, layered double hydroxides (LDHs) have potential applications as catalysts or precursors to new catalytic materials, such as ion exchangers, adsorbents, or hosts for nanoscale reactions as well as in medicine.[1] LDHs can be represented by the general formula $[M^{II}_{1-x}M^{III}_{x}(OH)_2]^{x+}(A^{n-})_{x/n}\cdot yH_2O$. Their structure is based on the stacking of positively charged layers arising from the substitution of trivalent cations for part of the divalent cations in brucite-like layers, and exchangeable anions ($A^{n-}$) in hydrated interlayer galleries.

In recent years, great attention has been paid to the intercalation of metal complex anions in LDHs in an effort to develop new functional materials such as heterogeneous catalysts, photocatalytic materials, magnetic nanocomposites, and luminescent materials.[2–5] In particular, intercalation of metal–edta complexes into LDHs has been extensively studied due to the strong chelating ability of the edta ligand with almost any metal cation.[6–14] O'Hare et al.[6] have recently prepared LDHs containing such complexes, either directly by intercalation of the transition metal–edta complex or indirectly by forming the metal complex in situ in the interlayer galleries of Li–Al LDH pre-intercalated with edta. Tsyganok et al.[7] have studied the catalytic activity in dry reforming of methane of a material derived from LDH-intercalated $[Ni(edta)]^{2-}$ complexes. Lukashin et al.[3] have reported the magnetic properties of anisotropic metal nanoparticles prepared from an LDH containing an edta complex of $Fe^{III}$ or $Ni^{II}$. The synthesis and characterization of an $Mg_2Al$ LDH intercalated by luminescent $[Eu(edta)]^-$ complexes was recently reported.[8]

In general, the arrangement of interlayer guest anions can dramatically influence the physicochemical properties of LDH materials.[15–18] For example, in the case of poly(diacetylenecarboxylates) incorporated in LDHs, the possibility of having different arrangements of interlayer guests is responsible for the observed reversible thermal color changes.[18] In developing such functional materials it is important to be able to control the orientation of functional guest anions in the interlayer galleries in order to fully uti-

lize their anisotropic properties. An understanding of the factors controlling the interlayer arrangement is important if tailored applications in areas such as those mentioned above are to be found for LDHs containing $[M(edta)]^{2-}$ complexes, but no such study has been reported to date.

In addition, thermal treatment is a key step in the synthesis of LDH-derived catalysts. Despite numerous investigations of the structural evolution of LDHs with temperature the process of thermal decomposition of LDHs, in particular the origin of thermally metastable intermediate phases, is still a matter of debate. The possible role of grafting simple or complex anions to the slabs in the formation of the thermally metastable phase has been extensively discussed. Whilst a grafting phenomenon at low temperature has been reported for LDHs with both oxygen-containing and non-oxygen-containing anions,[19–24] other authors have suggested that the thermally metastable phase originates from a reorientation of the anions in the interlayer domains rather than from such a grafting process.[25–30]

In this work, we report the intercalation of transition metal complexes $[ZnY]^{2-}$, $[NiY]^{2-}$, $[CoY]^{2-}$, and $[CuY]^{2-}$ (where Y denotes $edta^{4-}$) into MgAl LDHs with different Mg/Al ratios, by a hydrothermal synthesis method. Our aim is to clarify the factors affecting the orientation of the complexes, particularly in the temperature interval 30–400 °C, in order to understand the evolution of the interlayer phase with temperature. Structural changes arising from thermal treatment are monitored by variable-temperature in-situ XRD, variable-temperature in-situ FT-IR, and combined thermogravimetric analysis and mass spectrometry (TGA-MS). Such information should enable a better understanding of the LDH–M(edta) structure and provide a framework for the synthesis of new functional materials.

## Results and Discussion

Three methods for the intercalation of the $[MY]^{2-}$ complex in LDH materials, namely ion exchange, coprecipitation, and reconstruction, have been described in the literature. In order to obtain a pure LDH phase containing the $[MY]^{2-}$ complex, a large (tenfold) excess of the $[MY]^{2-}$ complex has typically been employed.[3,7] If the amount of $[MY]^{2-}$ complex is low it has been reported that the materials suffer from poor crystallinity and the coexistence of more than one phase, which makes it impossible to study their structures in detail.[8,31] In an attempt to overcome this problem we chose to employ a hydrothermal synthesis using only a twofold excess of the $[MY]^{2-}$ complex.

### Effect of Varying the Metal Cation in the Complex Anion on Interlayer Orientation

Chemical analysis (see Table 1) confirms both that the nitrate anions in the LDH-2.0-$NO_3$ precursor have been completely exchanged by anionic edta complexes and that there is no contamination by co-intercalated carbonate ions. The composition of the LDH-2.0-$NO_3$ precursor (where 2.0 refers to the $Mg^{2+}/Al^{3+}$ molar ratio in the synthesis mixture) and intercalated materials are given in Table 1. The Mg/Al molar ratio in LDH-2.0-[MY] (M = Zn, Ni, Co, Cu) is essentially the same as that in the LDH-2.0-$NO_3$ precursor (2.04), which excludes the possibility of partial dissolution of the magnesium in the layers during the hydrothermal synthesis.

The XRD patterns of the LDH-2.0-$NO_3$ precursor and its exchanged products (LDH-2.0-[MY]) are shown in Figure 1. The patterns are typical of lamellar materials, with a basal reflection and associated harmonics at low angles $2\theta$ and weaker nonbasal reflections at higher angles. Intercalation of $[MY]^{2-}$ leads to an increase in basal spacing for all the exchanged LDHs and the values of the basal spacing in LDH-2.0-[MY] (M = Zn, Cu, Co) are rather similar, whilst that for LDH-2.0-[NiY] is slightly lower (see Table 1). This is indicative of a similar orientation of the $[MY]^{2-}$ anions within the interlayer galleries. No change is observed in the value of the unit cell parameter *a*, calculated from the posi-

Table 1. Chemical composition, cell parameter *a*, and basal spacing *d*(003) for the LDH materials.

tion of the $d(110)$ reflection near $2\theta = 60°$, suggesting that the average cation–cation distance in the layers of LDH-2.0-[MY] remains unaffected (Table 1). This is consistent with the result from chemical analysis. An inversion of the relative intensities between the (006) and (009) reflections in the XRD pattern of LDH-2.0-[MY] is observed relative to those in the LDH-2.0-$NO_3$ precursor. This phenomenon has been ascribed to the presence of atoms with large scattering power in the interlayer region.[2,25] This will be discussed in detail below. The observation that the Mg/Al ratio in the layers is not affected by the incorporation of the edta complexes and that the orientation of the anions within the interlayer galleries is essentially independent of the identity of the metal M may be attributed to the similar coordination mode and high stability constants of the metal–edta complexes.[32,33]

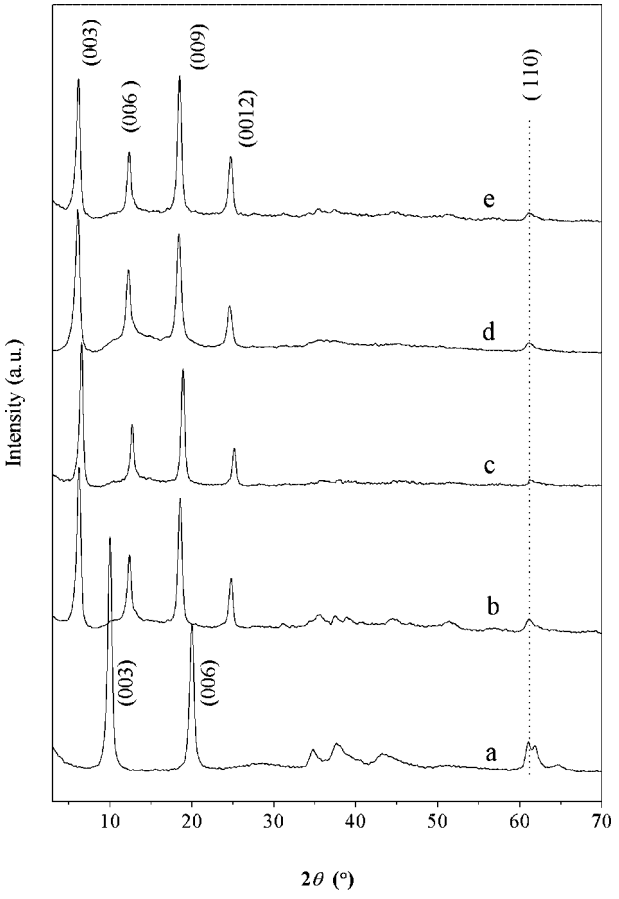

Figure 1. Powder XRD patterns of (a) LDH-2.0-$NO_3$, (b) LDH-2.0-[ZnY], (c) LDH-2.0-[NiY], (d) LDH-2.0-[CuY], and (e) LDH-2.0-[CoY].

The LDH materials were also characterized by FT-IR and selected spectra are shown in Figure 2. For the LDH nitrate precursor (Figure 2a), the intense and broad absorption band centered at 3445 $cm^{-1}$ corresponds to the stretching vibrations of the hydroxyl groups of both the layer hydroxide moieties and interlayer water molecules. The broadening of this band is due to hydrogen-bond formation.[34] The band close to 1640 $cm^{-1}$ corresponds to the deformation mode ($\delta H_2O$) of water molecules. The absorption peaks at 1384 and 839 $cm^{-1}$ are usually assigned to the $\nu_3$ and $\nu_2$ vibration modes, respectively, of $NO_3^-$ with $D_{3h}$ symmetry,[35] whilst bands around 447 and 675 $cm^{-1}$ are from Al–O and Mg–O lattice vibrations, respectively.[36]

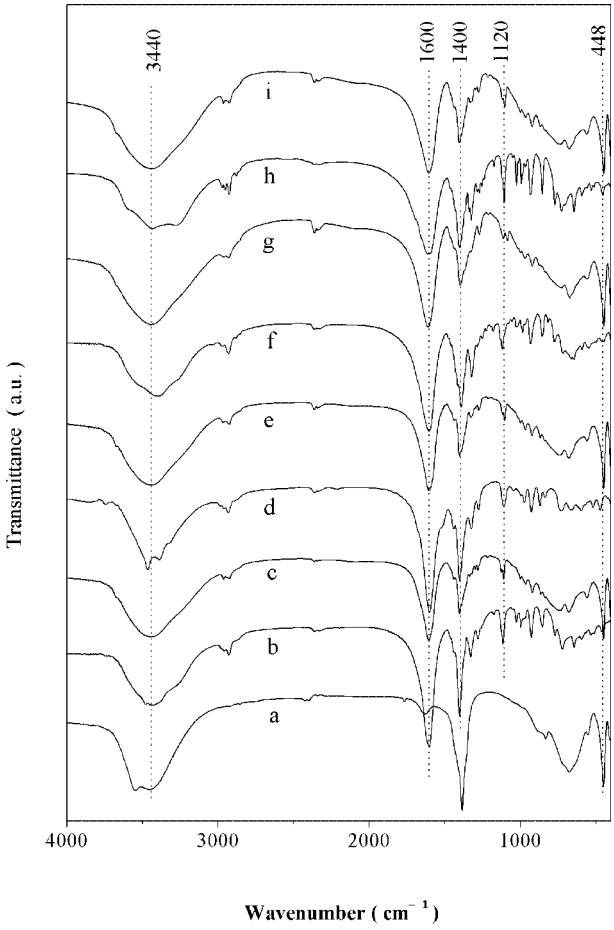

Figure 2. FT-IR spectra of (a) LDH–$NO_3$-2.0, (b) $Na_2$[ZnY], (c) LDH-2.0-[ZnY], (d) $Na_2$[NiY] (e) LDH-2.0-[NiY], (f) $Na_2$[CuY], (g) LDH-2.0-[CuY], (h) $Na_2$[CoY], and (i) LDH-2.0-[CoY].

After exchange of $Mg_2Al$–$NO_3$ LDH with $Na_2$[MY]·$3H_2O$ the $\nu_3$ vibration of $NO_3^-$ disappears, and the asymmetric $\nu_{as}$(COO) and symmetric $\nu_s$(COO) stretching modes of the carboxylate groups, at 1600 and 1400 $cm^{-1}$, respectively, appear (Figure 2c). The wavenumber difference $\Delta\nu = \nu_{as} - \nu_s$ gives information about the coordination environment of the carboxylate group.[37,38] The value of $\Delta\nu$ in both $Na_2$[MY]·$3H_2O$ and LDH-2.0-[MY] is greater than 200 $cm^{-1}$, indicating the presence of deprotonated carboxylate groups coordinated to the metal ion in a monodentate fashion.[37,38] Furthermore, the similar values of $\Delta\nu$ for LDH-2.0-[MY] and $Na_2$[MY]·$3H_2O$ suggest that the coordination mode of the carboxylate groups is unchanged after intercalation. The slight difference in the value of $\Delta\nu$ may be a reflection of the different intermolecular hydrogen-bonding environments experienced by the anion in the sodium salt and in the interlayer galleries of the LDH.[38–40] This result clearly confirms the presence of $[MY]^{2-}$ anions between the layers.

### Effect of Varying the Layer Charge Density on the Orientation of the Guest Anions

The layer charge density is often an important factor in determining the orientation of the guest anions in the interlayer galleries.[16,41] For further insight into the structure of the LDH-intercalated $[MY]^{2-}$ complexes samples of LDH-*X*-[ZnY] (with Mg/Al ratio in the synthesis mixture $X = 2.0$, 2.2, 2.5, 2.7, 3.0) were chosen. Elemental compositions of the resulting LDH-*X*-[ZnY] materials are given in Table 1. The Mg/Al molar ratios in LDH-*X*-[ZnY] are essentially the same as those in the corresponding LDH-*X*-$NO_3$ precursors (not shown in Table 1) which excludes the possibility of partial dissolution of the magnesium in the layers during the hydrothermal synthesis. Elemental analysis confirms that small amounts of $NO_3^-$ anion are co-intercalated with $[ZnY]^{2-}$ at high Mg/Al molar ratios, suggesting that intercalation of the bulky $[ZnY]^{2-}$ anion becomes less favorable as the layer-charge density decreases.[41,42]

The XRD results of LDH-*X*-[ZnY] (see Figure 3) show that there is not only a progressive decrease in the basal spacing for samples from 1.445 nm in LDH-2.0-[ZnY] (Figure 3a) to 1.254 nm in LDH-3.0-[ZnY] (Figure 3e) but also a significant variation in the relative intensities of the (00*l*) ($l$ = 3, 6, 9, 12) reflections with the Mg/Al mol ratio, suggesting different orientations of $[MY]^{2-}$ within the interlayer galleries. In general, when atoms with large scattering power are located at different positions along the *c* axis, the usual pattern of decreasing intensities of successive (00*l*) reflections with increasing *l* is not observed because of the fluctuations in the one-dimensional electron-density distribution along the *c* axis.[2,4,25,43–45] When the intensity of the (006) reflection is greater than that of (003), as is the case for LDH-3.0-[ZnY], it has been proposed that the heavy metal atom is located at the midpoint of the interlayer galleries.[2,4,25,44] In LDH-2.0-[ZnY], the intensity of the (009) reflection is greater than that of (006), suggesting that the alternate heavy metal centers are located above and below the midpoint of the interlayer galleries.[4,43,45]

When the Mg/Al molar ratio is increased to 2.2 no significant changes are observed (Figure 3b), suggesting there is only a single phase corresponding to a basal spacing of 1.445 nm. However, on further increasing the Mg/Al molar ratio, LDH-2.5-[ZnY] shows a complicated pattern of broad XRD reflections suggesting that two or more phases (Figure 3c), with different basal spacings, are present; the intensity of the third harmonic reflection (009) also decreases much more than that of the other (00*l*) reflections. These results indicate that some variation in the arrangement of the guest anions is associated with the decrease in layer-charge density. In the case of LDH-2.7-[ZnY] (see Figure 3d), the asymmetric (00*l*) reflections and the splitting of the (006) reflection are also consistent with the presence of at least two LDH phases. When the Mg/Al molar ratio is increased to 3.0, with the exception of a weak shoulder on the (006) reflection peak centered at $2\theta \approx 12°$, the reflections are characteristic of a single phase with a basal spacing of 1.254 nm. The elemental analysis results also

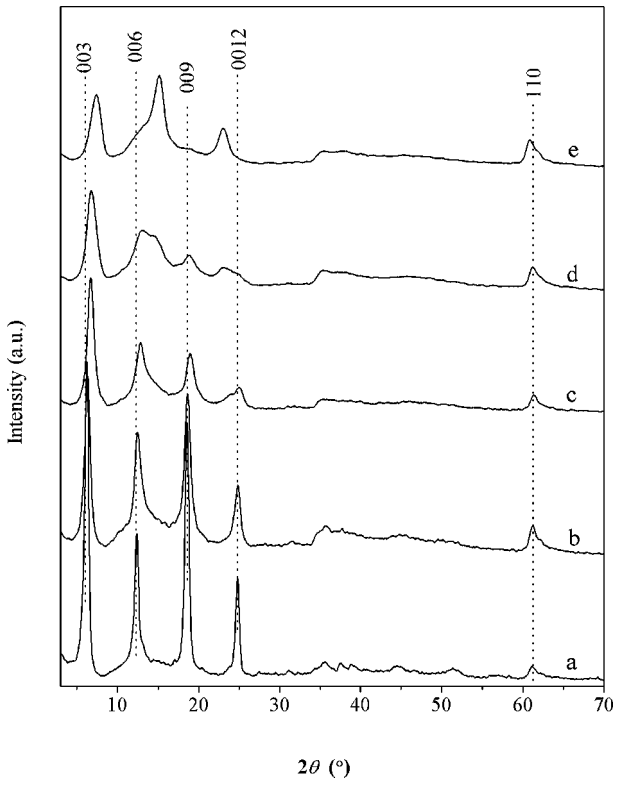

Figure 3. Powder XRD patterns of (a) LDH-2.0-[ZnY], (b) LDH-2.2-[ZnY], (c) LDH-2.5-[ZnY], (d) LDH-2.7-[ZnY], and (e) LDH-3.0-[ZnY].

show that LDH-3.0-[ZnY] in contrast to LDH-2.0-[ZnY] contains a significant amount of $NO_3^-$. This can perhaps also contribute to the asymmetric shape of the peaks in the XRD pattern of the former sample. The XRD data suggest that the phase LDH-2.0-[ZnY] involves the heavy metal centers located alternately above and below the midpoint of the interlayer galleries and the phase LDH-3.0-[ZnY] has the heavy metal centers located at the midpoint of the interlayer galleries. For intermediate Mg/Al molar ratios (2.2–2.7) the two LDH phases are both present; there is no evidence for a new phase with a third guest arrangement in LDH–[ZnY].

### Structural Model for LDH–MY

The observed basal spacings are 1.445 nm in LDH-2.0-[ZnY] and 1.254 nm in LDH-3.0-[ZnY], respectively. If the thickness of the LDH layer is taken as 0.48 nm,[46] the gallery heights are 0.97 nm and 0.77 nm, respectively. A gallery height of 0.97 nm is in close agreement with the maximal dimensions (0.90–1.00 nm) of the complex anion in salts such as $K_2[CuY]\cdot 3H_2O$, $Ca[NiY]\cdot 4H_2O$, and $Ca[Co(H_2O)Y]\cdot 4H_2O$ as determined by single-crystal XRD.[32,23] On this basis O'Hare et al.[6] proposed that the interlayer of $LiAl_2$–[MY] LDH consists of a monolayer of metal–edta complexes with the maximal dimension of each anion perpendicular to the hydroxide layers. This model, with the heavy

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metal atom located at the midpoint of the interlayer galleries, is not consistent with the observed inversion of the relative intensities between the (006) and (009) reflections in the LDH-2.0-[MY]. However, this indicates that the heavy metal atom is located at sites alternately above and below the midpoint of the interlayer galleries in LDH-2.0-[MY], as discussed above.

A gallery height of 0.97 nm in LDH-2.0-[ZnY] is, however, almost twice as long as the minimal dimensions (0.5 nm) of the complex anion in the above salts.[32,33] Therefore it is reasonable to assume that the interlayer galleries consist of a condensed bilayer of guest species with the minimal dimension of each anion perpendicular to the brucite-like layers in the LDH-2.0-[ZnY], as shown schematically in Figure 4a. In this model the four carboxylate groups of individual anions all interact with the same hydroxide layer, maximizing the interaction with the layers through both electrostatic attractions with the positive charge and hydrogen bonding with the layer hydroxyl groups. The inversion of the relative intensities between the (006) and (009) reflections in the XRD pattern of LDH-2.0-[ZnY] is consistent with this model of a bilayer arrangement of $[ZnY]^{2-}$ guests. In the bilayer orientation, the corresponding cross-sectional area occupied by each anion in the *ab* plane is in the range 0.81–1.00 $nm^2$ (see Figure 4a). The area per unit charge of the host lattice with an Mg/Al ratio of 2.0, calculated from the crystallographic data, is 0.25 $nm^2$.[16,47] Since the guests are orientated in a bilayer (as shown in Figure 4a), the area available per two divalent anions is approximately 1.0 $nm^2$ ($4 \times 0.25$ $nm^2$). It follows that in a bilayer of $[ZnY]^{2-}$ anions, the host layer charge can be balanced, although relatively close packing of guest anions in the *c* axis direction is required.

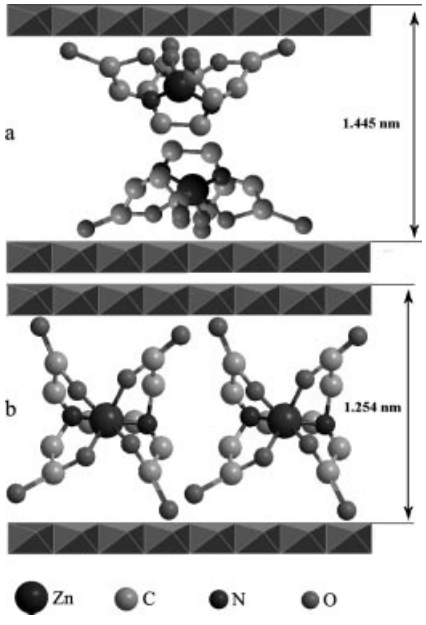

Figure 4. Schematic illustration of the structures of (a) LDH-2.0-[ZnY] and (b) LDH-3.0-[ZnY].

Taking into account the gallery height (0.77 nm) and the observed inversion of intensity between the first two (00*l*) peaks in LDH-3.0-[ZnY], we propose that in LDH-3.0-[ZnY] the metal–edta complexes form a monolayer of guest species with two carboxylate groups of individual anions attracted electrostatically to the upper hydroxide layer and the other two attracted to the lower one, as shown schematically in Figure 4b. This model also allows a favorable interaction between the four carboxylate groups of the guest and the host layers through both electrostatic attraction with the positively charged layers and hydrogen bonding with the layer hydroxyl groups. The height (0.77 nm) in LDH-3.0-[ZnY] probably arises from a monolayer assembly, with the maximal dimension of each anion tilted with respect to the hydroxide layers. Calculations show that the $[ZnY]^{2-}$ anion is capable of balancing the host layer charge of LDH-3.0-[ZnY] when arranged in a monolayer, since the cross-sectional area occupied by each anion in the *ab* plane is in the range 0.45–0.50 $nm^2$, whereas the area available per divalent anion is approximately 0.66 $nm^2$ ($2 \times 0.33$ $nm^2$).[16,47]

The above two guest arrangements maximize the interaction between the four carboxylate groups of the guest and the host layers and this is consistent with the absence of a new phase corresponding to a third guest arrangement at intermediate Mg/Al molar ratios. Other arrangements, such as two carboxylate groups of individual anions being fixed to upper and lower hydroxide layers and the other carboxylate groups extending into the interlayer galleries without any interaction with hydroxide layers, as proposed by O& apos;Hare et al., are less likely on energetic grounds.

The monolayer and bilayer orientation observed for the guest anions in the gallery have been reported in the literature.[4,43] Benzoate anions form bilayer-like structures[41] or monofilms of interdigitated species as found for methyl orange.[17] In all cases, the preferred orientation of the guest species is such as to permit the maximum interaction of the carboxylate groups with the layers through hydrogen bonding with the layer hydroxyl groups and, at the same time, the hydrophobic aromatic groups are located at the center of the galleries as far apart as possible from the hydrophilic layer hydroxyl groups.

### Reorientation of $[MY]^{2-}$ in the Interlayer Space under Thermal Treatment

The in situ variable-temperature powder X-ray diffraction patterns of LDH-2.0-[ZnY] and LDH-3.0-[ZnY] in the temperature range 30–900 °C in an ambient atmosphere are shown in Figures 5 and 6, respectively. The relationship between the *d*(003) basal spacings of LDH–[ZnY] and the temperature is shown in Figure 7. It can be observed that the basal reflections in both LDH-2.0-[ZnY] and LDH-3.0-[ZnY] move to a higher angle with increasing temperature indicating a contraction in the interlayer spacing. However, the magnitudes and evolution of the contraction observed on heating the two samples are very different (see Figure 7). A significant contraction in basal spacing (0.244 nm) is ob-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

served for LDH-2.0-[ZnY] over a very small temperature range, between 110 and 140 °C, with the basal spacing remaining nearly constant before and after the transition. In contrast, LDH-3.0-[ZnY] shows only a gradual small contraction (0.082 nm) on heating from room temperature up to 150 °C, which can be associated with loss of water. TGA-MS (see below) indicates that similar amounts of water are released over the temperature range 30–150 °C for both LDH-2.0-[ZnY] and LDH-3.0-[ZnY], suggesting that the much larger contraction observed for the former cannot be ascribed to the loss of interlayer water alone. Above 140 °C the basal spacing of LDH-2.0-[ZnY] (1.201 nm) is similar to that of LDH-3.0-[ZnY] at room temperature (1.254 nm). This suggests that a reorientation of the $[MY]^{2-}$ anions in the interlayer galleries, probably induced by the loss of the interlayer water, is the real origin of the significant contraction in LDH-2.0-[ZnY].

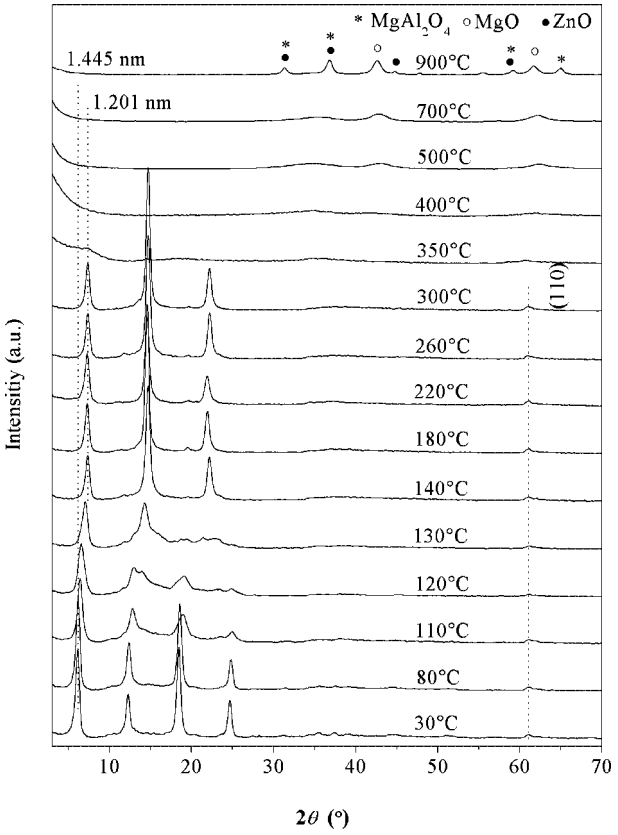

Figure 5. In-itu powder XRD patterns of LDH-2.0-[ZnY] over the temperature range 30–900 °C.

The occurrence of such a guest reorientation is confirmed by the significant variation in the relative intensities of the (00*l*) reflections in the XRD patterns of LDH-2.0-[ZnY] with increasing temperature. The inversion in intensity between the (006) peak and (009) peak in LDH-2.0-[ZnY] disappears on heating from 30 °C to 130 °C. Especially in the range 120–130 °C, the (00*l*) reflections broaden significantly and become asymmetric, which possibly corresponds to an unstable intermediate resulting from disorder in the arrangement of guests induced by loss of interlayer water from the hydrogen-bonded framework in the interlayer galleries. However, the intensity of the (006) reflections becomes significantly stronger between 140 and 300 °C and in addition a series of symmetric and strong (00*l*) reflections, with the pattern resembling that of LDH-3.0-[ZnY], emerge. Therefore it can be concluded that removal of interlayer water occurs upon heating, resulting in stronger electrostatic and hydrogen-bonding interactions between $[ZnY]^{2-}$ and LDH layer hydroxyl groups. This will

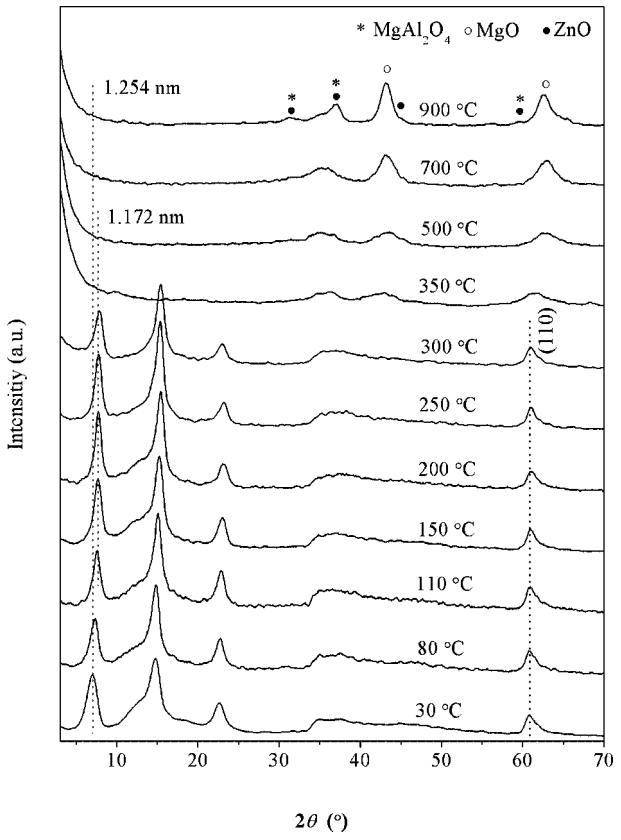

Figure 6. In-situ powder XRD patterns of LDH-3.0-[ZnY] over the temperature range 30–900 °C.

cause the bilayer $[ZnY]^{2-}$ to adopt a thermodynamically more stable monolayer orientation. Pillar reorientation at 140 °C, therefore, appears to be responsible for the observed gallery contraction of 0.244 nm for the LDH-2.0-[ZnY]. In the case of LDH-3.0-[ZnY], the relative intensities of the (00*l*) reflections are almost unchanged with increasing temperature, confirming that the orientation of $[ZnY]^{2-}$ in the interlayer galleries of LDH-3.0-[ZnY] does not vary with temperature. In addition, a weak shoulder on the (006) reflection peak centered at $2\theta \approx 12°$ in the pattern for LDH-3.0-[ZnY] gradually disappears with increasing temperature, indicating that the small amount of bilayer phase initially present is completely converted into the monolayer form.

The monolayer structure in LDH–[ZnY] is retained on heating up to 300 °C. On further heating above 300 °C, however, the absence of (00*l*) diffraction peaks corresponding to an LDH phase indicates that the layer structure is completely destroyed. This is consistent with TGA-MS data (see below), which suggest that dehydroxylation of the brucite-like layers along with anion decomposition occurs above 300 °C. At 400 °C, reflections characteristic of a cubic MgO-like phase begin to appear and at 900 °C reflections from an $MgAl_2O_4$ spinel phase and MgO are present, as is generally observed for calcined MgAl LDHs.[48] In addition, peaks that can be assigned to ZnO (JCPDS Card 01-1136), resulting from the decomposition of $[ZnY]^{2-}$, can be observed.

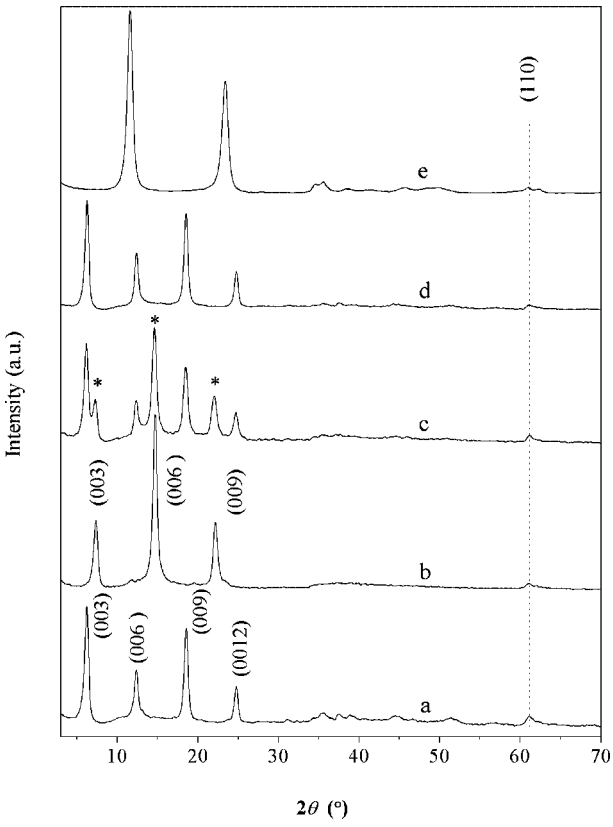

Figure 8. Powder XRD patterns of LDH-2.0-[ZnY] at (a) room temperature, (b) 140 °C, (c) room temperature (after cooling the sample from 140 °C in moist air for 20 min), (d) room temperature (after cooling the sample from 140 °C in moist air for 1 h), and (e) LDH–$CO_3$–[ZnY].

### A Reversible Structural Transformation

Although we have suggested above that the origin of the observed metastable phase is a reorientation of the $[MY]^{2-}$ anion in the interlayers, the possibility remains that it could be because of grafting of the anion to the hydroxyl layers as has been claimed by some authors for other anions in describing the formation of similar metastable phases associated with a significant interlayer contraction.[19–24] In order to provide further insight into the origin of the metastable phase, a sample of LDH-2.0-[ZnY] was heated to 140 °C and, after recording the powder XRD pattern at this temperature, subsequently cooled to room temperature over either 20 min or 1 h (in moist air), and the powder XRD patterns measured again (see Figure 8). The results show that the original phase and the metastable phase coexist when the sample is cooled in moist air for 20 min (Figure 8c), indicating that the structural transformation is reversible upon hydration. When the hydration reaction time is extended to 1 h the structural transformation is completely reversed as shown by the disappearance of peaks associated with the metastable phase (Figure 8d).

The recovery of the original phase on cooling demonstrates that heat treatment (up to 140 °C) does not result in covalent grafting of the anions to the hydroxyl layers. The absence of grafting is further confirmed by the observation that the $[MY]^{2-}$ anions in the metastable phase are readily exchanged with carbonate anions (Figure 8e). This would not be expected to be the case if the ions were actually grafted to the layers. The reversible structural transformation observed on heating and cooling is shown schematically in Figure 9.

To further study the evolution of the interlayer arrangement in this reversible transition the thermal behavior of LDH-2.0-[ZnY] was investigated by TGA, coupled with mass spectrometry. The TGA curves, as well as the analysis of the evolved decomposition products by mass spectrometry, are presented in Figure 10. Generally, four steps are observed in the thermal evolution of LDHs: desorption of physically adsorbed water, removal of the interlayer structural water, dehydroxylation of the brucite-like sheets, and the decomposition of the interlayer anions, although the first two steps may overlap in the low-temperature range. The thermal decomposition of LDH-2.0-[ZnY] is indeed characterized by three mass-loss steps. The first one from room temperature to 300 °C corresponds to the removal of surface adsorbed water and interlayer water molecules with their respective DTG peaks centered at 88 and 134 °C. The coupled mass spectrometry confirms this result since the ion current peak ($m/z$ = 18 $[H_2O^+]$) is assigned to the evolution of water. The temperature range of the loss of interlayer water is similar to that associated with the large contraction associated with guest reorientation (see Figure 5). This suggests that loss of water molecules may play an im-

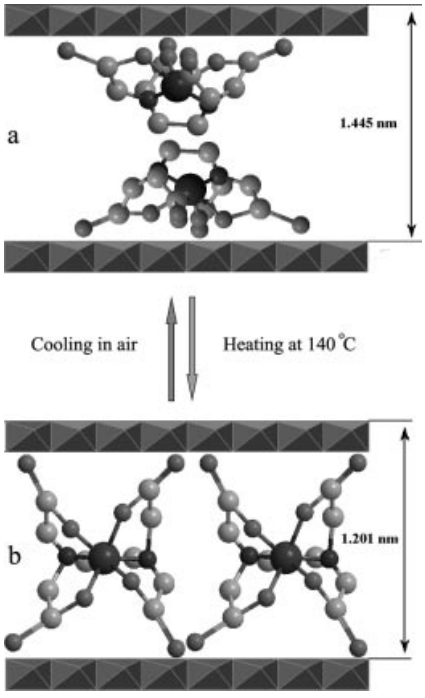

Figure 9. Schematic illustration of the reversible structural transformation of LDH-2.0-[ZnY] at (a) room temperature and (b) 140 °C.

portant role in initiating the reorientation. The sharp mass loss observed in the range 300–600 °C is due to the dehydroxylation of the brucite-like layers as well as combustion of the organic materials, with a corresponding sharp peak centered at 396 °C in the DTG curve (Figure 10a). This is confirmed by the mass spectrometry results (Figure 10b), which show strong $CO_2^+$, $NO^+$, and $H_2O^+$ ion currents over the entire decomposition range. The final gradual mass loss in the range 600–950 °C is a result of the oxidation of residual organic material as shown by the evolution of $CO_2$ alone in the MS trace. The thermal decomposition data is in good agreement with the in-situ HT-XRD data discussed above.

The in-situ FT-IR spectra of LDH-2.0-[ZnY] heated in the temperature range 30–550 °C are shown in Figure 11, and are also indicative of a reorientation taking place upon heating rather than a grafting process. On heating, the first change in the FT-IR spectra occurs between 30 and 150 °C. The band at 3444 $cm^{-1}$ moves to a higher frequency (3506 $cm^{-1}$) and its intensity decreases. This may be attributed to an increase in the force constant of the OH bond as a result of the loss of hydrogen bonding with interlayer

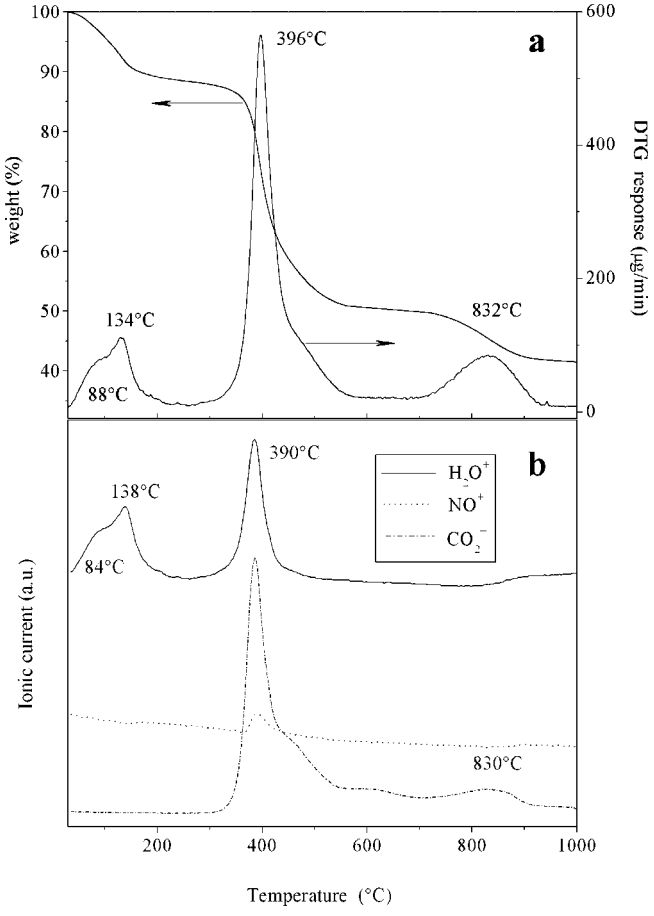

Figure 10. TGA curve (a) and coupled mass spectrometry trace (b) for LDH-2.0-[ZnY].

water. The asymmetric and symmetric stretching vibrations of the carboxylate group show slight shifts to higher frequency and lower frequency, respectively. As discussed above, the wavenumber difference $\Delta\nu = \nu_{as} - \nu_s$ gives information about the coordination environment of the carboxylate group. The value of $\Delta\nu$ shows only a marginal increase, from 202 $cm^{-1}$ at 30 °C to 210 $cm^{-1}$ at 150 °C, which suggests that the coordination environment of the carboxylate group remains nearly unaffected; this is consistent with the proposed reorientation of the $[ZnY]^{2-}$ anions on heating. If the carboxylate groups actually became covalently grafted to the hydroxyl layers a much more dramatic change in the value of $\Delta\nu$ would be expected.[23]

On heating from 320 to 550 °C there is a gradual decrease in the intensity of hydroxyl and carboxylate vibration bands, consistent with the dehydroxylation and decomposition processes observed by TGA-MS in this temperature range. The emergence of bands at 885 and 760 $cm^{-1}$ above 450 °C can be assigned to M–O vibrations in mixed oxide phases.

## Conclusions

Highly ordered MgAl LDHs intercalated by $[MY]^{2-}$ guest anions have successfully been prepared by a hydrothermal synthesis method. Charge matching between the $[MY]^{2-}$ anions and the LDH layers controls the gallery orientation of the $[MY]^{2-}$ anions. In the case of LDH-2.0-[MY], the interlayer separation for the fully hydrated material indicates that the guest species are arranged in a bilayer with the minimal dimension perpendicular to the host layers. In contrast, in LDH-3.0-[MY] the guest species are arranged in a monolayer with the maximal dimension tilted with respect to the host layers. Heating LDH-2.0-[MY] at 140 °C results in a reorientation of the $[MY]^{2-}$ complex in the interlayer giving a similar monolayer structure to that found in LDH-3.0-[MY]. The metastable monolayer phase is quite stable and the layered structure can still be identified by powder XRD after heat treatment at 300 °C. Rehydration of the calcined solids upon cooling to room temperature in air leads to the recovery of materials with the original values of the gallery heights. The reversible nature of the transformation is inconsistent with a grafting process and strongly supports a mechanism involving reorientation of the anion in the interlayer galleries. Calcination at 400 °C gives rise to a collapse of the layered structure and amorphous phases are formed. Further heat treatment of LDH-2.0-MY leads to a mixture of MgO, MO, and $MgAl_2O_4$ spinel phases above 750 °C.

## Experimental Section

### Synthesis

**Preparation of $Na_2[MY]\cdot xH_2O$:** The $Na_2[MY]\cdot xH_2O$ (M = Zn, Ni, Co, Cu; Y = $edta^{4-}$) complexes were prepared by mixing the appropriate molar equivalents of aqueous solutions of the corresponding metal nitrate, $Na_2C_{10}H_{14}N_2O_8\cdot 2H_2O$ ($Na_2H_2Y$), and $Na_2CO_3$, which is similar to the method described by Sawyer and Paulsen.[49] The resulting solution was adjusted to pH = 7.0 with dilute $HNO_3$ solution and warmed to boiling point. After concentration of the solution to one-third of the initial volume, absolute ethanol was added until a slight turbidity appeared. Finally, the solution was cooled in a refrigerator. The resulting crystalline material was filtered and recrystallized from a water/ethanol mixture. The recrystallized complexes were isolated by filtration and dried under air.

**Preparation of LDH–Nitrate Precursor:** MgAl–$NO_3$ LDH with different Mg/Al molar ratios (designated LDH-*X*-$NO_3$, where *X* = value of Mg/Al molar ratios in the mixed solution) were prepared by a coprecipitation method at controlled pH as described in the literature.[50] These preparations were carried out under constant nitrogen flow using freshly decarbonated, deionized water. Mixed solutions of $Mg(NO_3)_2$ and $Al(NO_3)_3$ with the required Mg/Al molar ratio, having total cation concentrations equal to 1 M, have been used at constant pH = 9.5. After precipitation, the suspension was aged at 100 °C for 8 h while stirring. The resulting white precipitate was collected by centrifugation, washed several times with carbonate-free deionized water, and dried in air at 50 °C for 24 h.

**Preparation of $[MY]^{2-}$-Intercalated MgAl LDH:** LDH-2.0-[MY] was obtained by anion exchange of the LDH-2.0-$NO_3$ precursors under hydrothermal conditions. As an example, the intercalation of the $[NiY]^{2-}$ anion into the LDH-2.0-$NO_3$ precursor is described. In the first step, a mixture of the LDH precursor (0.550 g, 0.002 mol) and $Na_2[NiY]\cdot 3H_2O$ (1.788 g, 0.004 mol) in a twofold molar excess over the anion exchange capacity was crushed in an agate mortar for 5 min and placed in an autoclave (22 $cm^3$) with distilled and decarbonated water (20 $cm^3$). The autoclave was then heated at 120 °C for 24 h developing an autogenous pressure. The powdered products were collected by centrifugation, washed three times with carbonate-free deionized water, and finally dried in air at 50 °C for 24 h. Other LDH-*X*-[ZnY] materials were obtained by the same procedure using the corresponding LDH-*X*-$NO_3$ precursors and $Na_2[ZnY]\cdot xH_2O$.

### Characterization

Elemental analyses for metals were performed by inductively coupled plasma (ICP) emission spectroscopy with a Shimadzu ICPS-7500 instrument using solutions prepared by dissolving the samples in dilute $HNO_3$. C, H, and N analyses were carried out using an Elementarvario elemental analysis instrument. The in-situ powder X-ray diffraction (in-situ XRD) data were recorded with a Shimadzu XRD-6000 powder diffractometer over the temperature range 30–900 °C in air, using Cu-$K_\alpha$ radiation ($\lambda$ = 0.154 nm) at 40 kV and 30 mA. The samples, as unoriented powders, were step-scanned in steps of 5°/min in the $2\theta$ range from 3 to 70° using a count time of 4 s per step. The rate of temperature increase was 10 °C/min with a holding time of 5 min before each measurement. The in situ Fourier transform infrared (in-situ FT-IR) spectra were recorded with a Nicolet 605XB FT-IR spectrometer in the range 4000–400 $cm^{-1}$ with 4 $cm^{-1}$ resolution under flowing $N_2$ (65 $cm^3$/min) with a heating rate of 5 °C/min in the range 25–450 °C. The KBr pellet technique, with a typical pellet containing ca. 1 wt% sample in KBr, was employed. Thermogravimetric analysis coupled to mass spectrometry was performed using a Perkin–Elmer Diamond TG apparatus linked to a ThermoStar mass spectrometer by a quartz capillary transfer line heated at 190 °C. The heating rate was 10 °C/min with an $N_2$ flow rate of 200 $cm^3$/min. The TG apparatus was at atmospheric pressure, and the mass spectrometer at a working pressure of $6\times10^{-6}$ Torr. The mass of sample used was 10 mg in each case.

# Synthesis, Crystal Structures, and Oxidation States of MM′X-Type Platinum–Rhodium Dinuclear Complexes Having Amidate Bridging Ligands

**Kazuhiro Uemura,[a][‡] Kana Yamasaki,[a] Kôichi Fukui,[a][‡‡] and Kazuko Matsumoto*[a][‡‡‡]**

**Keywords:** Platinum / Rhodium / 1D Chains / Dinuclear complexes

Six novel Pt–Rh dinuclear complexes (**1**–**6**), $[PtRh(PVM)_2(NH_3)_2Cl_3]\cdot 4H_2O$ (**1**, PVM = *t*BuCONH$^-$), $[PtRh(PVM)_2(en)Cl_3]\cdot 3H_2O$ (**2**, en = ethylenediamine), $[PtRh(PVM)_2(NH_2CH_3)_2Cl_3]\cdot 3H_2O$ (**3**), $[PtRh(PVM)_2(NH_2tBu)_2Cl_3]\cdot 3H_2O$ (**4**), $[PtRh(TCM)_2(NH_3)_2Cl_3]$ (**5**, TCM = $Cl_3CCONH^-$), and $[PtRh(BZM)_2(NH_3)_2Cl_3]\cdot H_2O$ (**6**, BZM = PhCONH$^-$), have been synthesized from Pt mononuclear complexes having nitrogen-coordinated amidate ligands with noncoordinated amidate oxygen atoms. X-ray analysis revealed that compounds **1** and **2** form zigzag one-dimensional chains in the form $[–Pt–Rh–Cl–]_n$. The oxidation states of the metal ions have been determined by X-ray photoelectron spectroscopy (XPS) and $^{195}$Pt NMR spectroscopic analysis, and are Pt(+2, $d^8$)···Rh(+3, $d^6$). In comparison with the Pt–Rh distances found in the literature, it has become apparent that the Pt–Rh dinuclear complexes have a dative Pt($d^8$)→Rh($d^6$) bond, where the Pt $d_{z^2}$ orbital is stabilized by the overlap with the $d_{z^2}$ orbital of the Rh atom.

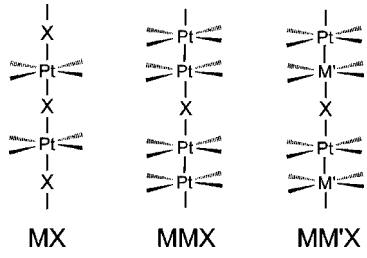
## Introduction

One-dimensional (1D) metal complexes have been one of the intriguing subjects for the last several decades owing to their unusual electrical properties that are based on a variety of possible metal oxidation states.[1] Most of the 1D chains are made up of Rh(+1/+2) and/or Pt(+2/+3) because partial oxidation or reduction of the $d_{z^2}$ orbital attributed to the $d^8 \leftrightarrow d^7$ redox change affords partially filled valence bands. Several 1D metal complexes comprising infinite –Pt–Pt– bonds[2] or –Rh–Rh– bonds[3] and halogen-bridged Pt (MX and MMX) chains[4,5] have been synthesized and investigated to present. MMX chains have mixed-valence states of the dinuclear units and adopt a variety of electronic structures represented by the four extreme valence-ordering states.[4] Control of the electronic structures by tailoring the ligands with subtle chemical modifications has been attempted with MMX chains.[4] However, control of the electronic structures by introduction of another metal (M′) to the MMX chains to make so-called MM′X chains has not been reported, to the best of our knowledge (Scheme 1). A series of MM′X chains is considered to be a new class of 1D metal complexes and is expected to have interesting electrical properties.



Scheme 1.

On the basis of the background above, we have tried to synthesize MM′X chains by starting with Pt mononuclear complexes with amidate ligands such as $[Pt(PVM)_2(NH_3)_2]\cdot 2H_2O$ (PVM = *t*BuCONH$^-$),[6] which can easily bind a second metal ion with the noncoordinated oxygen atoms in the amide moieties and afford various dinuclear and trinuclear Pt complexes (Scheme 2).[7] When M′ is one of the first transition metals (e.g. Co, Ni, Cu), trinuclear Pt–M′–Pt complexes are obtained because of their thermal stabilities and the ease of substitution of the ligands, even if the mixing ratio is 1:1 (Pt:M′).[6] Considering the undesired trimerization and the necessity of mixed valency for 1D chains, we selected Rh atoms as M′. Herein, we show the synthesis, crystallographic characterization, and determination of the formal metal oxidation states in Cl$^-$ ion bridged Pt–Rh dinuclear complexes.

## Results and Discussion

### Synthesis and Characterization

Mixing of $[Pt(PVM)_2(NH_3)_2]\cdot 2H_2O$[6] with $RhCl_3\cdot 3H_2O$ in MeOH provided a dinuclear Pt–Rh complex, $[PtRh(PVM)_2(NH_3)_2Cl_3]\cdot 4H_2O$ (**1**) (Scheme 3). The reaction was stoichiometrically complete within 3 d at 40 °C, where the solution color changed from dark red to dark brown. The dark brown MeOH solution was concentrated, and then excess KCl in $H_2O$ was added to yield the pure product, which was confirmed by $^1H$ NMR spectroscopic analysis. The $^1H$ NMR spectra of **1** shows a single peak at $\delta$ = 1.19 ppm for the *t*Bu moieties,[8] which is apparently shifted from the peak at $\delta$ = 1.10 ppm for the *t*Bu moieties in $[Pt(PVM)_2(NH_3)_2]\cdot 2H_2O$.[6a] Figure 1a shows the ESI-MS (positive) spectra of **1** by dilution in MeOH. The peak at *m*/*z* = 1241, attributed to the dinuclear complex, was observed and the simulated isotope pattern based on the dinuclear complex apparently coincides with the observed one.

Other Pt–Rh dinuclear complexes with various amidates (TCM = $Cl_3CCONH^-$, BZM = $PhCONH^-$) and coligands, $[PtRh(PVM)_2(en)Cl_3]\cdot 3H_2O$ (**2**), $[PtRh(PVM)_2(NH_2CH_3)_2Cl_3]\cdot 3H_2O$ (**3**), $[PtRh(PVM)_2(NH_2tBu)_2Cl_3]\cdot 3H_2O$ (**4**), $[PtRh(TCM)_2(NH_3)_2Cl_3]$ (**5**), and $[PtRh(BZM)_2(NH_3)_2Cl_3]\cdot H_2O$ (**6**), were also obtained in a similar manner from the Pt mononuclear complexes having the noncoordinated oxygen atoms in the amide moieties; *cis*-$[Pt(PVM)_2(en)]\cdot 4H_2O$, *cis*-$[Pt(PVM)_2(NH_2CH_3)_2]\cdot H_2O$, *cis*-$[Pt(PVM)_2(NH_2tBu)_2]$, *cis*-$[Pt(TCM)_2(NH_3)_2]$, and *cis*-$[Pt(BZM)_2(NH_3)_2]$.[9] As shown in Figure 1, the ESI-MS peaks attributed to each dinuclear complex (**2**–**6**) were observed.

### Crystal Structure of $[PtRh(PVM)_2(NH_3)_2Cl_3]\cdot 4H_2O$ (1)

Figure 2 shows the crystal structure of **1**, and Table 1 summarizes the selected bond lengths and angles for **1**. The single-crystal consists of Pt and Rh dinuclear complexes in which the two metal ions are doubly bridged by two PVM

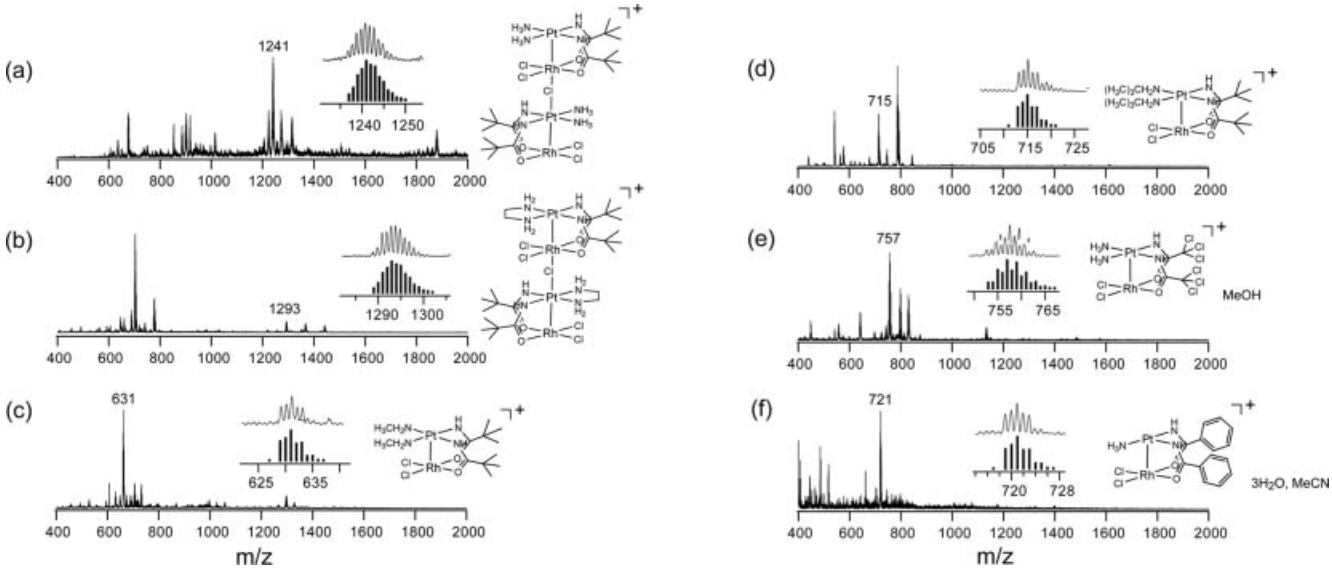

Figure 1. ESI-MS (positive) spectra for (a) **1**, (b) **2**, (c) **3**, (d) **4**, (e) **5**, and (f) **6**. Complexes **1**–**5** and **6** were measured by dilution in MeOH and MeOH/MeCN (v/v = 1:1), respectively.

ligands (Figure 2a). The asymmetric unit consists of Pt(1), Rh(1), Cl(1–3), one amine [N(1)], and one PVM [including O(1), O(2), N(2), and C(1)] ligand, with a crystallographic mirror along the *ab* plane [along the Pt(1)–Rh(1)–Cl(1) line]. The *cis* coordinated Cl(2)/Cl(3) and O(1)/O(2) atoms are in a disordered relationship with the 0.50/0.50 occupancy level, which means that two kinds of Rh(1) coordination planes, O(2)–O(1′)–Cl(2′)–Cl(3) and O(1)–O(2′)–Cl(3′)–Cl(2), are present in the crystal with a 50:50 ratio.

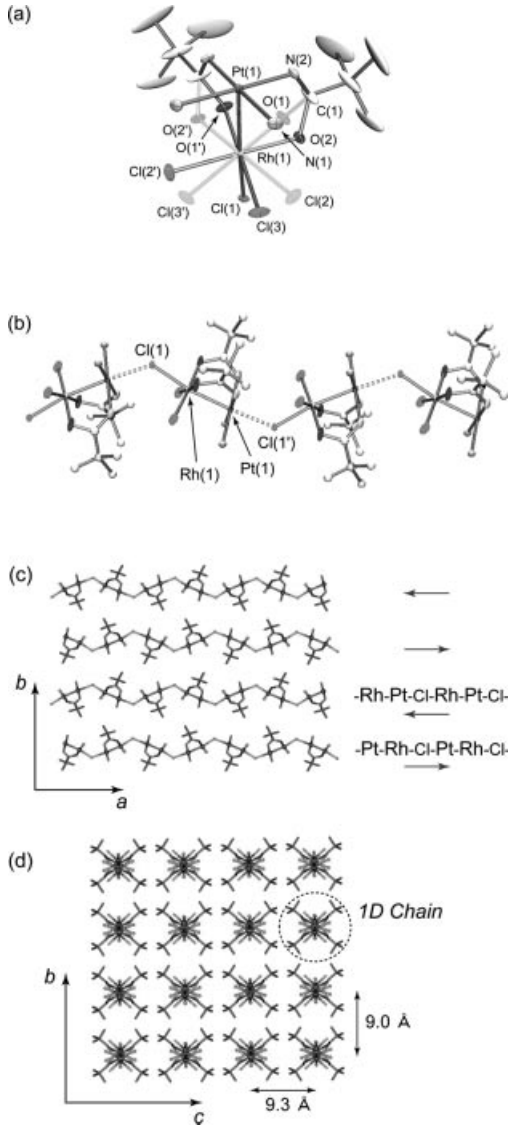

Figure 2. Crystal structure of $[PtRh(PVM)_2(NH_3)_2Cl_3]\cdot 4H_2O$ (**1**). (a) ORTEP drawing of **1** at the 30% probability level. Hydrogen atoms and water molecules are omitted for clarity. O(1) and O(2), and Cl(2) and Cl(3) atoms are in a disordered relationship. (b) Pseudo 1D chain where axially coordinated Cl(1) atoms bridge the dinuclear complexes. (c) Four pseudo 1D chains are aligned in parallel. Arrows indicate the chain directions. (d) Crystal packing diagram along the *a* axis. Water molecules are omitted for clarity.

Within the dimer, the Pt and Rh atoms are separated by 2.5704(7) Å (**1**). The Pt atom is *cis* coordinated with two amine ligands and two deprotonated nitrogen atoms of the PVM ligands. The Rh atom is coordinated by three $Cl^-$ ions, two *cis* in the equatorial plane and one axially coordinated to Rh with the distances Rh(1)–Cl(1) = 2.4127(18), Rh(1)–Cl(2) = 2.333(3), and Rh(1)–Cl(3) = 2.329(3) Å. The coordination planes of the two metals are slightly tilted by 11.9°.

Table 1. Selected distances [Å] and angles [°] for $[PtRh(PVM)_2(NH_3)_2Cl_3]\cdot 4H_2O$ (**1**).[a]

| | | | |

| Rh(1)–Cl(1)–Pt(1)[3] | 127.42(7) | | |

[a] Symmetry operators: (1) $x-1/2, -y+1/2, z$; (2) $x, y, -z$; (3) $x+1/2, -y+1/2, z$.

As shown in Figure 2b, the axially coordinated $Cl^-$ ion on the Rh atom contacts the neighboring Pt atom with a distance of 2.6328(17) Å and bridges two Pt–Rh dimers. As to the packing of the Pt–Rh dimers, infinite strands of the head–head dimers are formed to give chains with the expression $[–Pt–Rh–Cl–]_n$. All chains run along the *a* axis, where adjacent chains run in the opposite direction as shown in Figure 2c. The one-dimensional chains are not linear but zigzag; the bridging $Cl^-$ ions form the zigzag chains with the angle Rh(1)–Cl(1)–Pt(1′) = 127.42(7)°. All the chains run along the *a* axis without significant interaction between them (Figure 2d); the distances between the chain centers are about 9.0 and 9.3 Å.

### Crystal Structure of $[PtRh(PVM)_2(en)Cl_3]\cdot 3H_2O$ (2)

Figure 3 shows the crystal structure of **2**, and Table 2 summarizes the selected bond lengths and angles for **2**. Compound **2** contains two individual dinuclear complexes in the unit cell. The asymmetric unit consists of Cl(1), Rh(1), Pt(1), Cl(3), Rh(2), Pt(2), two amines, and two PVM ligands, with a crystallographic mirror along the *ac* plane [along the Cl(1)–Rh(1)–Pt(1)–Cl(3)–Rh(2)–Pt(2) line] (Figure 3a). The carbon atoms C(1)/C(2) and C(8)/C(9) in the en ligands are disordered with the 0.58/0.42 occupancy level. Similar to **1**, the Pt and Rh ions in the dinuclear complexes are doubly bridged by two PVM ligands. The Pt atom is *cis* coordinated by four N-donor ligands; one en and two PVM ligands. The Rh atom is coordinated by three $Cl^-$ ions, of which the axially coordinated $Cl^-$ ion bridges two Pt–Rh dimers (Figure 3b). The distances between Pt and Rh are 2.5796(19) and 2.5771(17) Å. The coordination planes of the two metals are slightly tilted by 11.8 and 13.8°.

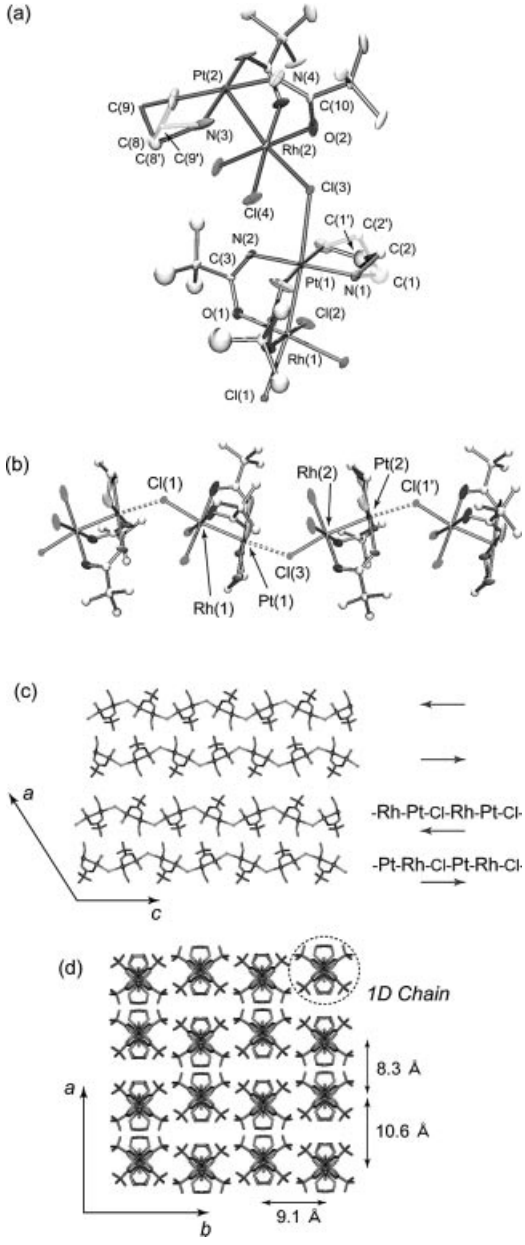

Figure 3. Crystal structure of $[PtRh(PVM)_2(en)Cl_3]\cdot 3H_2O$ (**2**). (a) ORTEP drawing of **2** at the 30% probability level. Hydrogen atoms and water molecules are omitted for clarity. C(1) and C(2), and C(8) and C(9) atoms are in a disordered relationship. (b) Pseudo 1D chain where axially coordinated Cl(1) and Cl (3) atoms bridge the dinuclear complexes. (c) Four pseudo 1D chains are aligned in parallel. Arrows indicate the chain directions. (d) Crystal packing diagram along the *c* axis. Water molecules are omitted for clarity.

As found in the packing structure of **2** (Figure 3c and Figure 3d), the pseudo 1D chain consists of the repetition of head–head dimers with the expression $[–Pt–Rh–Cl–]_n$, in a similar manner to **1**. The one-dimensional chains of **2** also zigzag, where the $Cl^–$ ions form bent bridges between the dimers with the angles of 128.08(18) and 129.26(19)°. The distances between Pt and axially contacted Cl atoms [Pt(1)···Cl(3) = 2.662(5), Pt(2)···Cl(1′) = 2.692(4) Å] in **2** are slightly longer than the corresponding one in **1**: Pt(1)···Cl(1′) = 2.6328(17) Å. As shown in Figure 3d, two

[a] Symmetry operators: (1) *x*, *y*, *z* + 1; (2) *x*, –*y* + 1, *z*; (3) *x*, *y*, *z*– 1.

parallel chains run in the opposite directions, $[–Pt–Rh–Cl–]_n$ and $[–Cl–Rh–Pt–]_n$, in close proximity of about 8.3 Å.

Both **1** and **2** give pseudo 1D infinite chains expressed as –MM′X–. A substantial number of halogen bridged chains have been thoroughly investigated to date, namely: (1) –MX– type chains,[5] (2) –MMX– type chains,[4] (3) the $Cl^–$-bridged platinum tan {= HH-$[Pt(2.5+)_4(NH_3)_8(\mu\text{-}C_4H_6NO)_4(Cl)]_n^{5n+}$, "platinum tan"[10] is the dark red amidate-bridged Pt tetranuclear complex containing the $Pt(2.5+)_4$ mixed valency} expressed as the $M_4X$-type chain.[11] In contrast, the present quasi 1D system is distinctly different from the previous systems on the ground that two kinds of metal ions are conjugated in the system (–MM′X– type chain).

## Determination of the Oxidation States

The X-ray analysis of **1** and **2** revealed that the three $Cl^–$ ions and two amidate ligands are coordinated in the dinuclear unit, which indicates that the total oxidation state of the Pt–Rh core is +5. Considering the general oxidation states of the Pt and Rh atoms, possible formal oxidation states of **1** and **2** are Pt(+3)–Rh(+2) and Pt(+2)–Rh(+3). In order to determine the oxidation state of the metal ions in the Pt–Rh dinuclear complexes, XPS and $^{195}Pt$ NMR measurements were carried out.

Figure 4 shows the Rh $3d_{5/2}$ and $3d_{3/2}$, and Pt $4f_{7/2}$ and $4f_{5/2}$ core level spectra for **1**–**6** at room temperature. In the $3d_{3/2}$ region of rhodium, Pt $4d_{5/2}$ signals also exist but are overlapped with the Rh signals. The Pt $4f_{7/2}$ binding energies were determined as 73.4 (**1**) and 73.3 (**2**), which are closer to that of the Pt(+2) complex $[Pt^{II}(en)_2(\alpha\text{-pyridonato})_2](NO_3)_2$ (72.6 eV) than that of the Pt(+3) complex $[Pt^{III}(NH_3)_4(\alpha\text{-pyrrolidonato})_2(NO_3)_2](NO_3)_2$ (75.0 eV).[12] On the other hand, the Rh $3d_{5/2}$ binding energies obtained

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are 309.4 (**1**) and 309.2 (**2**), which are close to the value of Rh(+3) in $RhCl_3 \cdot 3H_2O$ (310.0 eV).[13] As shown in Table 3, compounds **3**–**6** have binding energies similar to those of **1** and **2**.

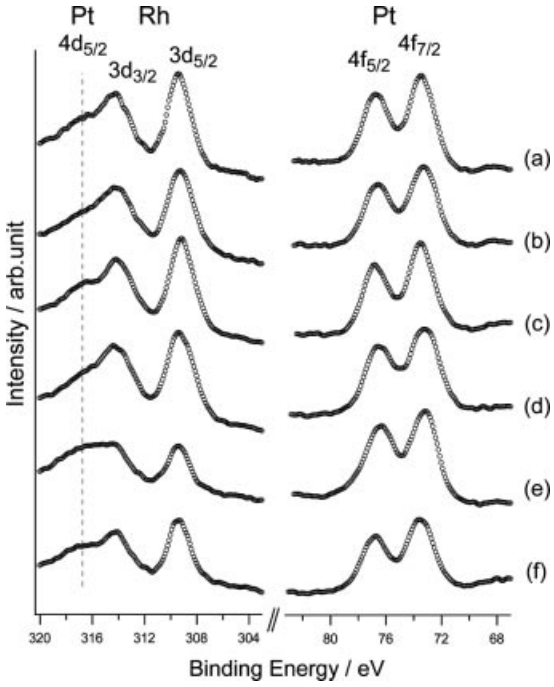

Figure 4. Rh $3d_{5/2}$ and $3d_{3/2}$ (left), Pt $4f_{7/2}$ and $4f_{5/2}$ (right) core levels of XPS for (a) **1**, (b) **2**, (c) **3**, (d) **4**, (e) **5**, and (f) **6**.

Table 3. Binding energy (eV) for 3d region of rhodium and 4f region of platinum in **1**–**6**.

| Complex | Rh $3d_{3/2}$ | Rh $3d_{5/2}$ | Pt $4f_{5/2}$ | Pt $4f_{7/2}$ |
|---|---|---|---|---|
| **1** | 314.2 | 309.4 | 76.7 | 73.4 |
| **2** | 314.1 | 309.2 | 76.5 | 73.3 |
| **3** | 314.2 | 309.1 | 76.8 | 73.5 |
| **4** | 314.4 | 309.4 | 76.6 | 73.2 |
| **5** | 314.2 | 309.4 | 76.3 | 73.1 |
| **6** | 314.1 | 309.3 | 76.7 | 73.6 |

Furthermore, the $^{195}Pt$ NMR chemical shifts obtained in MeOD by using an aqueous solution of $K_2[PtCl_6]$ as the external reference are –2452 (**1**), –2590 (**2**), –2365 (**3**), –2642 (**4**), and –2371 ppm (**5**), which are in the expected range for Pt(+2) complexes.[14,15] The broad line widths of the $^{195}Pt$ NMR signals are probably due to the interactions with $^{14}N$ nuclear spins. Compounds **4** and **5** did not show well-defined $^{195}Pt$ NMR signals in MeOD because of equilibrium mixing.[15] Interestingly, the $^{195}Pt$ chemical shifts for **1**–**5** are dispersed in a rather wide range (–2365 to –2642 ppm), which shows that there is a significant difference in the electronic states among them. Considering the results of XPS and $^{195}Pt$ NMR, we conclude that the formal oxidation state of the metal ions in **1**–**6** is Pt(+2, $d^8$)···Rh(+3, $d^6$).

### Comparison with Other Pt–Rh Dinuclear Complexes

Previously, we reported unique heterometal chains with mixed valence (so-called HMMs), $\{[PtRh(PVM)_2(NH_3)_2Cl_{2.5}]_2[Pt_2(PVM)_2(NH_3)_4]_2(PF_6)_6 \cdot 2MeOH \cdot 2H_2O\}_n$ (HMM-**1**), that comprised Pt–Rh and Pt–Pt dinuclear complexes possessing an unpaired electron over the octanuclear unit.[16] Compound **1** corresponds to a fragment of the octanuclear repetition unit in HMM-**1**. Because the HOMO is in the Pt–Rh dinuclear metal orbital part in HMM-**1**,[16] comparison between **1** and HMM-**1** is meaningful. As shown in Table 4, the Pt–Rh distances in **1** and **2** are slightly shorter than that of Pt(+3, $d^7$)···Rh(+2.5, $d^{6.5}$) in HMM-**1**.[16]

Table 4. Pt–Rh oxidation states and distances [Å].

| Compound | Oxidation states | Pt–Rh distance | Ref. |
|---|---|---|---|
| [a] | Pt(+2, $d^8$)···Rh(+1, $d^8$) | 3.043(1) | [17] |
| [b] | Pt(+2, $d^8$)···Rh(+1, $d^8$) | 3.079(2) | [18] |
| HMM-**1** | Pt(+3, $d^7$)···Rh(+2.5, $d^{6.5}$) | 2.5987(11) | [19] |
| **1** | Pt(+2, $d^8$)···Rh(+3, $d^6$) | 2.5704(7) | this work |
| **2** | Pt(+2, $d^8$)···Rh(+3, $d^6$) | 2.5796(19) | this work |

[a] = *trans*-Rh–(CO)Cl(μ-$Ph_2AsCH_2PPh_2)_2$-*cis*-$PtCl_2$. [b] = $[(NC)_2PtRh(CNtBu)_2(\mu\text{-dpm})_2](PF_6)$ [μ-dpm = bis(diphenylphosphanyl)methane].

In addition, the Pt–Rh distances in **1** and **2** are about 0.5 Å shorter than those reported in other Pt–Rh dinuclear complexes, *trans*-Rh–(CO)Cl(μ-$Ph_2AsCH_2PPh_2)_2$-*cis*-$PtCl_2$ (***a***)[17] and $[(NC)_2PtRh(CNtBu)_2(\mu\text{-dpm})_2](PF_6)$ (***b***, μ-dpm = bis(diphenylphosphanyl)methane),[18] where the formal oxidation states are Pt(+2, $d^8$)···Rh(+1, $d^8$). It has been shown that an occupied $d_{z^2}$ orbital in the $d^8$ transition metal ion with square-planar coordination geometry can act as a donor to other metal ions (M′) to form a dative Pt($d^8$)→M′ bond.[19] Considering the short Pt–Rh distances, compounds **1** and **2** are considered to have a dative Pt($d^8$)→Rh($d^6$) bond, where the Pt $d_{z^2}$ orbital is stabilized by the overlap with the $d_{z^2}$ orbital of Rh.

## Conclusions

The present study is focused on the synthesis and single-crystal X-ray analysis of novel Pt–Rh dinuclear complexes having a Pt–Rh bond doubly bridged by amidate ligands, and we have succeeded in obtaining six dinuclear complexes with various amidate and amine ligands. Compounds **1** and **2** are zigzag MM′X chains, and XPS and $^{195}Pt$ NMR spectroscopic measurements revealed that the dinuclear complexes have the formal oxidation state of Pt(+2, $d^8$)···Rh(+3, $d^6$). Apparently, there is no electronic interaction between the Pt–Rh dinuclear complex units bridged by $Cl^-$ ions in the zigzag chain. Because linear 1D chains constructed from Pt and a heterometal are expected to have unique physical properties, attempts to straighten the alignment of the Pt–Rh dinuclear complexes in the chain by modifying the axial ligand is currently in progress.

## Experimental Section

**Synthesis of $[PtRh(PVM)_2(NH_3)_2Cl_3] \cdot 4H_2O$ (1):** A MeOH solution (200 mL) of $[Pt(PVM)_2(NH_3)_2] \cdot 2H_2O$ (1 mmol, 0.47 g) was stirred

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with $RhCl_3 \cdot 3H_2O$ (1 mmol, 0.26 g) for 3 d at 40 °C. The resulting brown solution was concentrated to yield a brown solid. The brown solid was stirred with an aqueous solution (10 mL) of KCl (4.0 mmol, 0.30 g) to give the brown product. Yield: 0.28 g (39%). The product was recrystallized by diffusing excess KCl into the aqueous solution to give suitable single crystals. IR (KBr pellet): C=O stretching, $\tilde{\nu}$ = 1639 (m), 1574 (s) $cm^{-1}$. $C_{10}H_{34}Cl_3N_4O_6PtRh$ (711): calcd. C 16.90, H 4.82, N 7.88; found C 17.12, H 4.51, N 7.09.

**Synthesis of $[PtRh(PVM)_2(en)Cl_3] \cdot 3H_2O$ (2):** A MeOH solution (300 mL) of $[Pt(PVM)_2(en)] \cdot 4H_2O$ (1.5 mmol, 0.79 g) was stirred with $RhCl_3 \cdot 3H_2O$ (1.5 mmol, 0.395 g) for 2 d at 40 °C. The resulting brown solution was concentrated to yield a brown solid. The brown solid was stirred with an aqueous solution (10 mL) of KCl (4.0 mmol, 0.30 g) to give the dark green product. Yield: 0.29 g (27%). The product was recrystallized by diffusing excess KCl into the aqueous solution to give suitable single crystals. IR (KBr pellet): C=O stretching, $\tilde{\nu}$ = 1635 (m), 1574 (s) $cm^{-1}$. $C_{12}H_{34}Cl_3N_4O_5PtRh$ (719): calcd. C 20.05, H 4.77, N 7.79; found C 20.30, H 4.43, N 7.64.

**Synthesis of $[PtRh(PVM)_2(NH_2CH_3)_2Cl_3] \cdot 3H_2O$ (3):** A MeOH solution (136 mL) of $[Pt(PVM)_2(NH_2CH_3)_2] \cdot H_2O$ (0.68 mmol, 0.32 g) was stirred with $RhCl_3 \cdot 3H_2O$ (0.68 mmol, 0.18 g) for 2 d at 40 °C. The resulting dark violet solution was concentrated to yield a dark violet solid. The dark violet solid was stirred with an aqueous solution (6.5 mL) of KCl (6.7 mmol, 0.50 g) to give the brown product. Yield: 0.15 g (31%). IR (KBr pellet): C=O stretching, $\tilde{\nu}$ = 1645 (m), 1570 (s) $cm^{-1}$. $C_{12}H_{36}Cl_3N_4O_5PtRh$ (721): calcd. C 20.00, H 5.03, N 7.77; found C 20.40, H 4.50, N, 7.17.

**Synthesis of $[PtRh(PVM)_2(NH_2tBu)_2Cl_3] \cdot 3H_2O$ (4):** A MeOH solution (90 mL) of $[Pt(PVM)_2(NH_2tBu)_2]$ (0.45 mmol, 0.24 g) was stirred with $RhCl_3 \cdot 3H_2O$ (0.45 mmol, 0.12 g) for 2 d at 40 °C. The resulting brown solution was concentrated to yield a brown solid. The brown solid was stirred with an aqueous solution (5 mL) of KCl (1.3 mmol, 0.10 g) to give the brown product. Yield: 0.23 g (63%). IR (KBr pellet): C=O stretching, $\tilde{\nu}$ = 1647 (m), 1571 (s) $cm^{-1}$. $C_{18}H_{48}Cl_3N_4O_5PtRh$ (805): calcd. C 26.86, H 6.01, N, 6.96; found C 25.90, H 5.16, N 6.01.

**Synthesis of $[PtRh(TCM)_2(NH_3)_2Cl_3]$ (5):** A MeOH solution (150 mL) of $[Pt(TCM)_2(NH_3)_2]$ (0.75 mmol, 0.41 g) was stirred with $RhCl_3 \cdot 3H_2O$ (0.75 mmol, 0.20 g) for 3 d at 40 °C. The resulting brown solution was concentrated to yield a brown solid. The brown solid was stirred with an aqueous solution (4 mL) of NaCl (10.3 mmol, 0.60 g) to give the dark green product. Yield: 0.25 g (43%). IR (KBr pellet): C=O stretching, $\tilde{\nu}$ = 1716 (m), 1628 (s) $cm^{-1}$. $C_4H_8Cl_9N_4O_2PtRh$ (761): calcd. C 6.31, H 1.06, N, 7.36; found C 6.31, H 1.50, N 7.33.

**Synthesis of $[PtRh(BZM)_2(NH_3)_2Cl_3] \cdot H_2O$ (6):** A MeOH solution (120 mL) of $[Pt(BZM)_2(NH_3)_2]$ (0.6 mmol, 0.28 g) was stirred with $RhCl_3 \cdot 3H_2O$ (0.6 mmol, 0.16 g) for 3 d at 40 °C. The resulting brown solution was concentrated to yield a brown solid. The brown solid was stirred with an aqueous solution (4 mL) of KCl (9.3 mmol, 0.70 g) to give the brown product. Yield: 0.18 g (42%). IR (KBr pellet): C=O stretching, $\tilde{\nu}$ = 1597 (m), 1558 (s) $cm^{-1}$. $C_{14}H_{20}Cl_3N_4O_3PtRh$ (697): calcd. C 24.14, H 2.89, N 8.04; found C 24.38, H 2.91, N 7.48.

**X-ray Structure Determination for 1 and 2:** Measurements were carried out with a Bruker SMART APEX CCD diffractometer equipped with a normal focus Mo-target X-ray tube ($\lambda$ = 0.71073 Å) operated at 2000 W power (50 kV, 40 mA) and a CCD two-dimensional detector. A total of 1315 frames were collected with a scan width of 0.3° in $\omega$ with an exposure time of 20 (**1**) and 40 (**2**) s/frame. The frames were integrated with the SAINT software package with a narrow frame algorithm.[20] Absorption correction was applied by using SADABS.[21] All the structures were solved by direct methods with the subsequent difference Fourier syntheses and the refinement with the SHELXTL (version 5.1) software package.[22] For all compounds, the non-hydrogen atoms were refined anisotropically and all hydrogen atoms were placed in the ideal positions. In **1**, O(1) and O(2), Cl(2) and Cl(3) atoms were refined with disorder relationship. In **2**, C(1) and C(2), C(8) and C(9) atoms were refined with disorder relationship. In **2**, C(1), C(2), C(5)–(9), O(4) and O(6) were isotropically refined under rigid conditions (Table 5). CCDC-618494 (for **1**) and -618495 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 5. Crystal data and structure refinement for $[PtRh(PVM)_2(NH_3)_2Cl_3] \cdot 4H_2O$ (**1**) and $[PtRh(PVM)_2(en)Cl_3] \cdot 3H_2O$ (**2**).

# Fragmentation of the (Cyclam-acetato)iron Azide Cation in the Gas Phase

Detlef Schröder,*[a] Helmut Schwarz,[b] Núria Aliaga-Alcalde,[c] and Frank Neese[c]

**Keywords:** N ligands / Iron / Azides / Mass spectrometry

Mass spectrometry is used to investigate the fragmentation of the ligated azidoiron cation [(cyclam-acetato)Fe($N_3$)]$^+$, which is accessible in the gas phase by electrospray ionization of a solution of its hexafluorophosphate salt in methanol/water. Upon collisional activation, mass-selected [(cyclam-acetato)Fe($N_3$)]$^+$ undergoes competing loss of dinitrogen or $HN_3$ as the prevailing fragmentations. The former dissociation pathway is investigated in detail in order to determine whether or not the free, high-valent iron nitride [(cyclam-acetato)FeN]$^+$ is formed. The evidence obtained indeed supports the formation of the iron nitride species as an intermediate, although the long-lived ion sampled after mass selection may also have undergone further rearrangements.

## Introduction

High-valent iron species are of long-standing interest in coordination chemistry due to their occurrence as reaction intermediates in metalloenzyme reactions.[1] The field has gained significant momentum since the discovery of the first proven $Fe^{IV}$ intermediate in mononuclear nonheme iron enzymes[2] and the first crystal structure of an elusive $Fe^{IV}$-oxo species by Rohde et al.[3] More recently, it has proven possible to proceed beyond the oxidation state $Fe^{IV}$ and to obtain definitive spectroscopic evidence for genuine $Fe^{V}$[4,5] and even $Fe^{VI}$ species.[6,7] The high-valent iron sites in these compounds are stabilized in a distorted octahedral environment by an innocent framework provided by ligands designed on the basis of the cyclam motif together with an extremely basic axial nitrido ligand, which is generated in situ by photolysis of the corresponding iron azide precursors. For the time being these species can only be generated in an immobilized state in solids or frozen solutions, therefore their chemistry cannot yet be explored in detail. In this work we take a first step towards studying the reactivity of these elusive species by generating them in the gas phase. In addition to the interest from biological chemists, the chemistry of transition-metal nitride compounds is attracting ongoing attention due to their potential in organic synthesis, with the formation of C–N bonds being particularly important.[8–10] The evidence for metal nitride species is, however, often only circumstantial because of the intrinsically high reactivity of these species. Recently, the photolysis of solid [(cyclam-acetato)Fe($N_3$)][$PF_6$] ([**1**][$PF_6$]), was described to yield the [(cyclam-acetato)FeN]$^+$ cation **2**$^+$ according to Equation (1).[5]

[(cyclam-acetato)Fe($N_3$)][$PF_6$] → [(cyclam-acetato)FeN][$PF_6$] + $N_2$ (1)

Cation **2**$^+$ can be viewed as an example of a genuine and isolated nitridoiron cation and hence offers a possibility for the investigation of the gas-phase reactivity of these compounds. In this context, it has been demonstrated previously[11,12] that the bare imidoiron cation $FeNH^+$ provides an excellent model system for the examination of transition-metal-mediated imine transfer in the gas phase. The chemical behavior of $FeNH^+$ towards oxygen, water, hydrogen, various aliphatic hydrocarbons (including methane), benzene, and toluene reveals an intrinsically high reactivity of $FeNH^+$, even under thermal conditions. Thus, reactions are brought about which are otherwise difficult to realize, such as the direct amination of organic substrates (RH) according to Equation (2).

RH + ‹NH› → $RNH_2$ (2)

Compared to $FeNH^+$, much less is known about the gas-phase chemistry of the diatomic iron nitride FeN.[13] Given the availability of the precursor salt [**1**][$PF_6$], electrospray ionization (ESI) appeared to be a promising method to probe the occurrence of reaction (1) in the gas phase and to subsequently investigate the gas-phase reactivity of such a rare transition-metal nitrido complex.

## Results and Discussion

Under mild ionization conditions, ESI of [(cyclam-acetato)Fe($N_3$)][$PF_6$] dissolved in methanol/water provides an intense signal for the molecular cation [(cyclam-acetato)-Fe($N_3$)]$^+$ (**1**$^+$) at *m*/*z* 355 for the most abundant $^{56}$Fe isotope

with the expected isotope pattern.[14,15] Under increasingly harsher ionization conditions, $\mathbf{1}^+$ undergoes consecutive dissociations, and ESI under enforced conditions can hence be used to generate these fragment ions (see below).[16,17] CID of mass-selected [(cyclam-acetato)$Fe(N_3)]^+$ shows mass differences, $\Delta m$, of –28 and –43 as the major fragmentation pathway in the CID spectra over the whole range of collision energies studied (Figure 1). Phenomenological analysis of the energy behavior reveals an appearance energy of $1.0 \pm 0.2$ eV for the $\Delta m$ = –28 fragmentation and $1.9 \pm 0.4$ eV for the $\Delta m$ = –43 fragmentation. Accordingly, the fragmentation with $\Delta m$ = –28 is the lowest-energy dissociation pathway of $\mathbf{1}^+$.

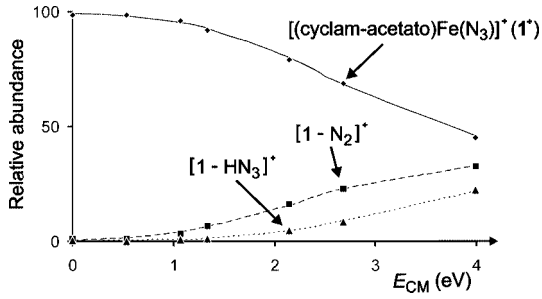

Figure 1. Collision-induced fragmentation of mass-selected [(cyclam-acetato)$Fe(N_3)]^+$ ($\mathbf{1}^+$) as a function of collision energy (center-of-mass frame). The lines connecting the experimental data points show the result of the fits using sigmoid functions (see Experimental Section).

Given the elemental composition of $\mathbf{1}^+$ ($C_{12}H_{25}N_7O_2Fe$), the mass difference of –43 can be associated with various combinations of neutral molecules lost. However, the presence of an azido group very much implies the expulsion of $HN_3$ according to reaction (3).

$$\underset{m/z\ 355}{[(\text{cyclam-acetato})Fe(N_3)]^-} \rightarrow \underset{m/z\ 312}{[(\text{cyclam-acetato} - H)Fe]^+} + HN_3 \quad (3)$$

$$\rightarrow \underset{m/z\ 327}{[(\text{cyclam-acetato})FeN]^+} + N_2 \quad (4)$$

The additional proton required for the formation of neutral $HN_3$ must come from the ligand backbone, most probably from one of the three NH groups. This view is supported by an analogous and moreover exclusive loss of $CH_3OH$ from the related species [(cyclam-acetato)-$Fe(OCH_3)]^+$, which is formed upon slow solvolysis of [**1**][$PF_6$] in methanol/water solution (half-life of about 5 days at ambient temperature). If the $\Delta m$ = –43 fragmentation were instead due to a facile degradation of the cyclam ligand itself (e.g. a loss of vinylamine), the same mass difference would also be expected for [(cyclam-acetato)-$Fe(OCH_3)]^+$; however, such a fragmentation is not observed even in traces. By the same line of reasoning, the $\Delta m$ = –28 fragmentation is attributed to the expulsion of a nitrogen molecule from the azido group, see reaction (4), which is in perfect analogy to the occurrence of reaction (1) in the condensed phase.[5] If this mass loss were instead due to a fragmentation of the cyclic ligand, it would also be expected to occur for the methoxido complex, for which it is not observed experimentally.

The key question which we will pursue in the following is the nature of the ionic fragment $[\mathbf{1} - N_2]^+$ formed in reaction (4) because it could either correspond to the elusive nitridoiron cation $\mathbf{2}^+$ or an isomeric product of a subsequent rearrangement (see below). While mass spectrometry alone cannot provide an unambiguous answer in this respect, analysis of the fragmentation pattern might provide insight into the isomeric structures conceivable from an experimental point of view.[18] Hence, the fragment ion $[\mathbf{1} - N_2]^+$ (*m*/*z* 327) formed in the ESI source under slightly enforced ESI conditions was mass-selected and subjected to CID.

Not unexpectedly, the fragmentation pattern of $[\mathbf{1} - N_2]^+$ is rather rich, and the most significant dissociation pathways are associated with mass differences of –16, –17, –30, –44, –61, –99, and –142. Most of these routes cannot be explained in a straightforward manner, although this is to be expected if $\mathbf{2}^+$ were indeed formed. Thus, $\Delta m$ = –16, for example, can correspond to either losses of neutral $CH_4$, $NH_2$, or O. Likewise, $\Delta m$ = –17 may account for expulsion of $NH_3$ or OH, and for $\Delta m$ = –30 neutral fragments like $C_2H_6$, $CH_2NH_2$, $CH_2O$, or even NO are conceivable. In the case of the larger mass differences, the options become increasingly more complex. Due to the manifold of fragments, the collision-energy dependence of the fragmentation behavior is also not analyzed in detail. Qualitatively, however, it can be noted that the fragments associated with $\Delta m$ = –17, –30, –44, and –99 already appear at lower collision energies (Figure 2, a), whereas those with $\Delta m$ = –16, –61, and –142 are more pronounced at elevated collision energies (Figure 2, b); the comparison indicates that the latter are either due to consecutive fragmentations or correspond to entropically favored, but energy-demanding, direct bond cleavages.[19]

In general, isotopic labeling would appear to be an ideal strategy for the identification of the various neutral losses. Selective isotope labeling of the ligand is, however, not easily applicable here because the precursor synthesis is not trivial and our major interest concerns the nature of the putative nitridoiron species rather than the degradation of the ligand backbone. Therefore, only three isotopic ions were considered. At first, the ion with *m*/*z* 325 was mass-selected as this can be attributed exclusively to the $^{54}Fe$ isotope of $[\mathbf{1} - N_2]^+$ and shows the same mass differences as listed above. Accordingly, none of the neutrals lost upon CID contain the iron atom of $[\mathbf{1} - N_2]^+$. Next, the precursor [**1**][$PF_6$] was dissolved in $D_2O$ and the solution was stored for 2 h at room temperature. In the resulting mass spectrum, the signal due to $\mathbf{1}^+$ is cleanly shifted three mass units higher, which is attributed to the exchange of all amino hydrogen atoms by deuterium, i.e. [*N*,*N*,*N*-$D_3$]-$\mathbf{1}^+$ (*m*/*z* 358). CID of mass-selected [*N*,*N*,*N*-$D_3$]-$\mathbf{1}^+$ yields the loss of $N_2$ ($\Delta m$ = –28) and $DN_3$ ($\Delta m$ = –44), as expected from the occurrence of reactions (3) and (4) for the unlabeled ion.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

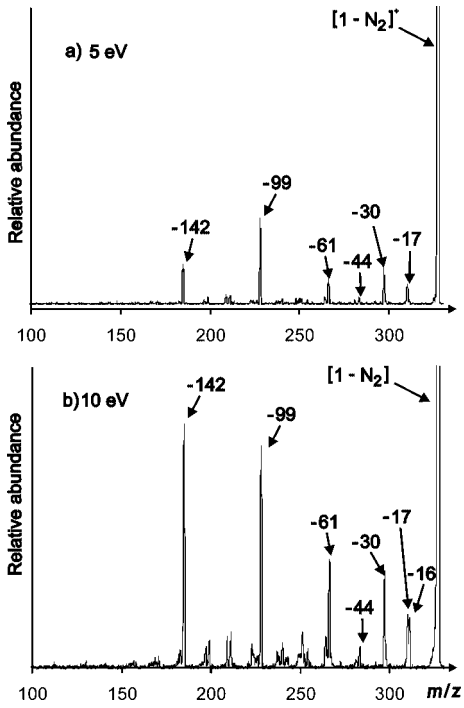

Figure 2. CID spectra of mass-selected $[\mathbf{1} - N_2]^+$ at a collision energy of a) 5 and b) 10 eV. In both spectra, the parent ion is 20-fold off-scale.

For the fragment ion $[\{N,N,N\text{-}D_3\}\text{-}\mathbf{1}^+ - N_2]^+$, mass differences of –17, –19, –30, –31, –32, –44, –63, –99, –100, –142, and –143 are observed (Table 1). Likewise, a sample of the precursor was investigated in which the azido ligand is $^{15}N_1$-labeled − terminally $^{15}N_1$-labeled azide was used in the preparative synthesis to afford a 1:1 mixture of [(cyclam-acetato)Fe($^{15}N^{14}N^{14}N$)]$^+$ and [(cyclam-acetato)-Fe($^{14}N^{14}N^{15}N$)]$^+$. CID of the mass selected ion $[^{15}N_1]$-$\mathbf{1}^+$ (*m*/*z* 356) shows a 1:1 ratio of $^{14}N_2$ and $^{14}N^{15}N$ losses ($\Delta m$ = –28 and – 29) as well as an expulsion of neutral $[^{15}N_1]$-$HN_3$ ($\Delta m$ = –44). Hence, the fragmentations of $\mathbf{1}^+$ exclusively involve the azido group, as already concluded above from the behavior of the methoxido complex [(cyclam-acetato)Fe($OCH_3$)]$^+$. Mass selection of $[\{^{15}N_1\}\text{-}\mathbf{1} - N_2]^+$ and subsequent CID lead to mass differences of –17, –18, –30, –44, –62, –100, and –143, thus indicating the participation of the labeled nitrogen atom in most of the neutral losses.

The following conclusions can be drawn from the mass shifts observed for the ions compared to the unlabeled species (Table 1): (i) The mass differences $\Delta m$ = –16 and –17 are most likely associated with loss of an amino radical and ammonia, respectively, with exclusive participation of the azido N-atom and incorporation of one H-atom from the hydrocarbon linkers while the other hydrogen(s) stem(s) from the amino groups; (ii) with the given elemental composition of $[\mathbf{1} - N_2]^+$, the mass difference $\Delta m$ = –30 can correspond to the formation of either $C_2H_6$, $[CH_4N]$, $CH_2O$, or NO. Based on the results for the deuterated compound, participation of the amino groups is obvious and hence implies loss of $[CH_4N]$ (e.g. an aminomethyl radical $CH_2NH_2$ or $CH_3NH$),[20] although a definitive assignment of the neutral fragment cannot be made; (iii) even though other options cannot be rigorously excluded, the labeling patterns as well as the known structure of $[\mathbf{1}][PF_6]$ imply that $\Delta m$ = –44 corresponds to decarboxylation, which is further supported by the fragment with $\Delta m$ = –61, whose genesis can be explained by combined losses of $CO_2$ and ammonia; (iv) $\Delta m$ = –99 and $\Delta m$ = –142 are assigned to fragmentations of the ligand backbone after initial decarboxylation, with only limited participation of the amino protons. It is noteworthy that the azido N-atom is incorporated in the neutral fragment lost; (v) investigation of the $^{54}$Fe isotope demonstrates that iron is not contained in any of the neutral fragments lost.

Some additional information can be derived by inspecting the CID spectra of some of the major fragment ions of $[\mathbf{1} - N_2]^+$ which are formed under more drastic ionization conditions. For example, the ion at *m*/*z* 310 formally corresponding to loss of ammonia from $[\mathbf{1} - N_2]^+$ shows a mass loss of –44 as the most abundant mass difference upon CID. Further, the relationship of $\Delta m$ = –99 and –142 as consecutive processes is supported by the observation of $\Delta m$ = –43 as a major fragmentation pathway in the CID spectrum of $[\mathbf{1} - N_2 - 99]^+$. Not all fragment ions of interest can be investigated by this approach, however, because of interfering isobaric ions formed in the course of ESI.

Combining the insights derived from the CID spectra together with the data of the isotopologs, a sequence for the successive fragmentation of $\mathbf{1}^+$ can be suggested (Scheme 1). While such a scenario is necessarily also based on several assumptions derived from chemical plausibility considerations, it can provide a consistent explanation for most of the fragmentations observed. Thus, in the first step, molecular nitrogen is lost from $\mathbf{1}^+$ to afford the elusive nitridoiron species $\mathbf{2}^+$. Next, this nitridoiron species is suggested to undergo an intramolecular insertion into one of the C–H bonds of the methylene groups in one of the $C_3$ bridges

Table 1. Mass differences[a] and relative abundances observed in the CID spectra of mass-selected $[\mathbf{1} - N_2]^+$ and some of its isotopologs at a collision energy of 10 eV.

| Precursor ion | *m*/*z* | Mass difference (abundance)[b] |
|---|---|---|
| $[\mathbf{1} - N_2]^+$ | 327 | –16 (20), –17 (25), –30 (40), –44 (8), –61 (45), –99 (90), –142 (100) |

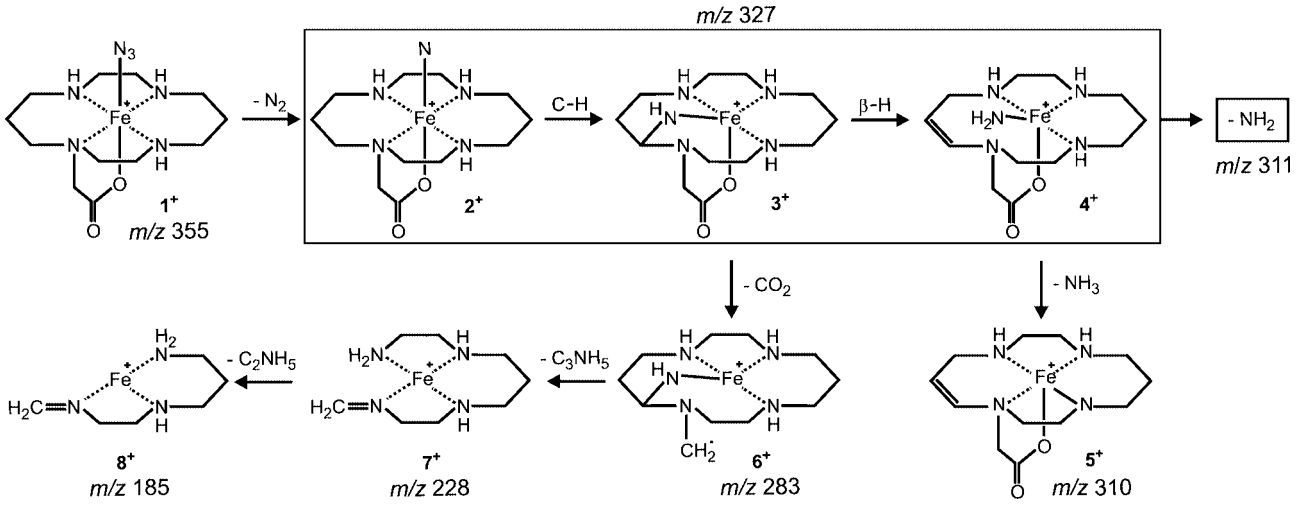

Scheme 1.

(here it is shown in the vicinity of the carboxymethyl substituent). The thus-formed insertion intermediate $\mathbf{3}^+$ can subsequently undergo β-hydrogen transfer to afford structure $\mathbf{4}^+$, from which either an $NH_2$ group can be lost directly at higher collision energies ($\Delta m$ = –16) or ammonia is released ($\mathbf{4}^+ \rightarrow \mathbf{5}^+$; $\Delta m$ = –17). As an alternative, decarboxylation of intermediate $\mathbf{3}^+$ is suggested to afford the aminoalkyl radical $\mathbf{6}^+$ ($\Delta m$ = –44), which then loses a $[C_3H_5N]$ unit in a rapid consecutive reaction to afford $\mathbf{7}^+$ ($\Delta m$ = –99); note that the latter process already has a related precedent in the mass spectra of $CH^+$ adducts of the cyclam ligand.[21] Eventual degradation of the neighboring $C_2$ bridge can then lead to $\mathbf{8}^+$ ($\Delta m$ = –142). Note, however, that we have deliberately not included the loss of $CH_2NH_2$ because the labeling patterns (particularly the lack of a mass shift upon $^{15}N$-labeling) preclude us from even proposing a speculative pathway.

The entire fragmentation sequence is thus fully in accordance with the formation of the genuine nitridoiron cation $\mathbf{2}^+$. Specifically, the suggested C–H bond insertions and the formations of $NH_2$ and $NH_3$ are indicative of the presence of a highly reactive intermediate which is capable of bond-activation processes such as the bare iron oxide cation $FeO^+$[22,23] or the iminoiron cation $FeNH^+$.[11,12] It is of crucial importance to note, however, that this chemical evidence very much supports the presence of structure $\mathbf{2}^+$ as an intermediate but does not prove that the long-lived $[\mathbf{1} - N_2]^+$ ion sampled in the MS/MS experiments described here still exhibits this particular structure. In fact, the experimental data reported so far are consistent with all isomeric structures $\mathbf{2}^+$–$\mathbf{4}^+$ suggested in Scheme 1 in that the reactions considered to be characteristic for the nitridoiron cation will also occur for the products of consecutive rearrangements.

In light of this, we finally attempted to probe the structure of $[\mathbf{1} - N_2]^+$ by investigating its ion/molecule reactions at thermal energy. To this end, mass-selected $[\mathbf{1} - N_2]^+$ was allowed to interact with butane, 1-butene, as well as deuterated methanol, where the order of the neutral reagents parallels the ease of bond-activation processes.[24,25] No reactions were observed at all with the two hydrocarbons, however, and with $CD_3OD$ only a very slow formation of the formal adduct $[\mathbf{1} - N_2 + CD_3OD]^+$ was observed. While again not providing unambiguous evidence, these preliminary reactivity studies suggest that long-lived $[\mathbf{1} - N_2]^+$ may indeed exist in an already rearranged structure such as $\mathbf{3}^+$ or $\mathbf{4}^+$. We would like to point out that this conclusion is all but trivial because it is quite often simply assumed that well-known reactions, such as the decomposition of an azide, lead to the species anticipated by analogies from other media. However, it needs to be tested in every instance that the particular structures are also maintained on a unimolecular level and are not altered by subsequent rearrangements. In the present case, for example, we do not have any reasonable doubt that the nitrido species $\mathbf{2}^+$ is formed as an intermediate – in fact it has been observed in frozen matrices[5] – but the experimental evidence obtained for the gaseous ion at least indicates that the long-lived ions bears a different connectivity.

## Conclusions

Electrospray mass spectrometry has been used to show that the decomposition of gaseous [(cyclam-acetato)Fe-$(N_3)$]$^+$ leads to the bare, high-valent $Fe^V$ nitride cation [(cyclam-acetato)FeN]$^+$, as already suggested for the condensed phase. Analysis of the fragmentation pattern implies, however, that this iron nitride species undergoes further rearrangements which mean that the long-lived ion might have a different structure. This question cannot be solved unambiguously with the mass spectrometric methods used here, and further studies of mass-selected [(cyclam-acetato)-FeN]$^+$ would hence be desirable in order to investigate

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

whether or not the cyclam-acetato ligand has indeed lost his "innocence", i.e. has undergone degradation processes due to the close vicinity of the free iron nitride unit. In this respect, the CID experiments reported here are not ideal for a distinction of isomeric structures,[18] and this question is perhaps best addressed by the appropriate spectroscopic experiments in the gas phase coupled with quantum chemical calculations; work along these lines is in progress in our laboratories.[26]

## Experimental Section

The experiments were performed using a VG BIO-Q mass spectrometer as described in detail elsewhere.[27] Briefly, the VG BIO-Q is a commercial instrument which consists of an electrospray ionization source combined with a tandem mass spectrometer of QHQ configuration (Q stands for quadrupole and H for hexapole). In the present experiments, millimolar solutions of [(cyclam-acetato)Fe($N_3$)][$PF_6$] in methanol/water (4:1) were introduced through a fused-silica capillary to the ESI source with a syringe pump (ca. 5 μL min$^{-1}$). Nitrogen was used as nebulizing and drying gas at a source temperature of about 80 °C. Maximal yields of the desired ions $\mathbf{1}^+$ and $\mathbf{2}^+$ (see below) were achieved by adjusting the cone voltage to about 30 and 60 V, respectively. For collision-induced dissociation (CID) at low collision energies, the ions of interest were mass-selected using Q1, interacted with xenon as a collision gas in the hexapole H under single-collision conditions (typically $2 \times 10^{-4}$ mbar) at variable collision energies ($E_{lab}$ = 0–20 eV), while scanning Q2 to monitor the ionic products. At $E_{lab}$ = 0 eV, no significant fragmentations of either mass-selected $\mathbf{1}^+$ or $\mathbf{2}^+$ were observed under these conditions. We note in passing that the sample examined contains some traces of potassium, which lowers the yield of Fe-containing cations in the ESI spectra somewhat but does not hinder the experiments.

As pointed out previously, the VG Bio-Q does not allow the direct extraction of quantitative threshold information from CID experiments due to several limitations of the commercial instrument.[27] For weakly bound ions,[28] for example, a non-negligible amount of ion decay is observed even at $E_{lab}$ = 0 eV, which is in part attributed to the presence of collision gas not only in the hexapole but also in the focusing regions between the mass analyzers. Note that this dissociation does not correspond to metastable ions because it does not occur in the absence of collision gas. To a first approximation, however, the energy dependence of the product distributions in the CID spectra can be modeled by a sigmoid function,[29] which allows the extraction of some semi-quantitative information about the energetics of the ions examined.[30] Nevertheless, the energy dependence of the CID fragments can be approximated by sigmoid functions of the type $I_i(E_{CM}) = \{BR_i/[1 + e^{(E_{1/2} - E_{CM})/b}]\}$ using a least-squares criterion; for the parent ion M, the relation is $I_M(E_{CM}) = \{1 - \Sigma(BR_i/[1 + e^{(E_{1/2,i} - E_{CM})/b}_i]\}$, where $BR_i$ is the branching ratio of a particular product ion ($\Sigma BR_i = 1$), $E_{1/2}$ is the energy at which the sigmoid function of ion intensities has reached half of its maximum, $E_{CM}$ is the collision energy in the center-of-mass frame [$E_{CM} = m_T/(m_T + m_I) \times E_{lab}$, where $m_T$ and $m_I$ stand for the masses of the collision gas and the ion, respectively], and $b$ describes the rise of the sigmoid curve. In consecutive dissociations, all secondary product ions were added to the intensity of the primary fragment. Further, non-negligible ion decay at $E_{lab}$ = 0 eV as well as some fraction of nonfragmenting parent ions at large collision energies were acknowledged by means of appropriate scaling and normalization procedures. This empirical, yet physically reasonable, approach is able to reproduce the measured ion yields quite well; note, however, that this simplified formalism does not explicitly include a treatment of competitive branching ratios at elevated energies. It is obvious, however, that the term $E_{1/2}$ used in the exponent corresponds neither to the intrinsic appearance energy of the fragmentation of interest nor to the thermochemical thresholds at 0 K. The phenomenological threshold energies given below were derived from linear extrapolations of the rise of the sigmoid curves at $E_{1/2}$ to the base line.

# Efficient DNA Cleavage Induced by Copper(II) Complexes of Hydrolysis Derivatives of 2,4,6-Tri(2-pyridyl)-1,3,5-triazine in the Presence of Reducing Agents

**Joaquín Borrás,*[a] Gloria Alzuet,[a] Marta González-Alvarez,[a] Jose L. García-Giménez,[a] Benigno Macías,[b] and Malva Liu-González[c]**

**Keywords:** Copper triazine complexes / Oxidative DNA damage / ROS scavengers / Oxidation

The reaction of 2,4,6-tri(pyridyl)-1,3,5-triazine (ptz) and copper(II) salts in dmf/water (1:1) results in the hydrolysis of ptz and formation of the anions bis(2-pyridylcarbonyl)amide ($ptO_2^-$) and bis(2-pyridylamine)amide ($ptN_2^-$), which are found in the complexes $[Cu(ptN_2)(OAc)]\cdot 3H_2O$ (**1**), $[Cu(ptO_2)(OAc)(H_2O)]\cdot H_2O$ (**2**), $[Cu(ptN_2)(for)]\cdot 3H_2O$ (**3**) (for = formate), $[Cu(ptO_2)(for)(H_2O)]$ (**4**), $[Cu(ptO_2)(benz)]\cdot H_2O$ (**5**) (benz = benzoate), and $[Cu(ptO_2)F(H_2O)]_2\cdot 3H_2O$ (**6**). This report includes the chemical and spectroscopic characterization of all these complexes along with the crystal structures of **4**–**6**. The coordination spheres of $Cu^{II}$ in **4** and **5** are best described as distorted tetragonal square pyramidal for the former and distorted square planar for the latter. The crystal structure of **6** shows the presence of two discrete monomeric $[Cu(ptO_2)F(H_2O)]$ entities in the crystallographic asymmetric unit in which both copper(II) ions have a distorted square-pyramidal coordination geometry. The binding of the complexes to DNA has been investigated with the aid of viscosity and thermal denaturation studies, both of which indicate that the interaction is probably due to the outer-sphere mechanism. The ability of the compounds to cleave DNA has also been tested. Efficient oxidative cleavage was observed in the presence of a mild reducing agent (ascorbate) and dioxygen. Mechanistic studies with reactive oxygen species (ROS) scavengers confirm that hydrogen peroxide, the hydroxyl radical, singlet oxygen-like species, and the superoxide anion are necessary diffusible intermediates in the scission process. A mechanism involving either the Fenton or the Haber–Weiss reaction plus the formation of copper oxene species is proposed for the DNA cleavage mediated by these compounds.

## Introduction

The interaction of reactive oxygen species (ROS) with DNA is of considerable interest because of the potential pathobiological significance of ROS-induced DNA damage. Such damage may be promutagenic and has been linked to the pathogenesis of human diseases such as cancer and aging.[1,2]

The transition metal ion catalyzed reduction of hydrogen peroxide has served as a useful model reaction for generating ROS. Reduction of $H_2O_2$ by copper ion produces highly reactive DNA-damaging species.[3] Copper ion induces significantly more DNA base damage in the presence of $H_2O_2$ than does ferrous ion, the other biologically relevant transition metal ion.[4,5] Moreover, copper is an important structural metal ion in chromatin,[6–8] which contains about one copper ion per kilobase.[6] For these reasons, there is an increased interest in the ability of copper ion to participate in DNA-damaging reactions in vivo.[8,9]

Kinetic,[9–11] inhibitor,[4,5,9] and sequence-context[12–15] studies have all suggested that DNA damage induced by copper ion in the presence of $H_2O_2$ occurs site-specifically at the sites of DNA-associated copper. However, the nature of the last DNA-oxidizing species produced by the interaction of the DNA-$Cu^I$ complex with $H_2O_2$ remains uncertain. Some investigators have suggested that the hydroxyl radical is the principal reactive intermediate,[9,16] while others have proposed less reactive intermediates such as an oxidocopper complex[11,14,15] or cupryl ion.[10] Regardless of the true nature of the reaction mechanism, exposure of DNA to copper has been reported to result in single- and double-strand breaks, modified bases, abasic sites, and DNA-protein crosslinks.[17,18]

2,4,6-Tri(2-pyridyl)-1,3,5-triazine (ptz; Scheme 1) is of current interest due to its utility as a spacer for designing multinuclear metal complexes. Compounds of this family of 2,4,6-triaryltriazines are usually stable against hydrolysis;

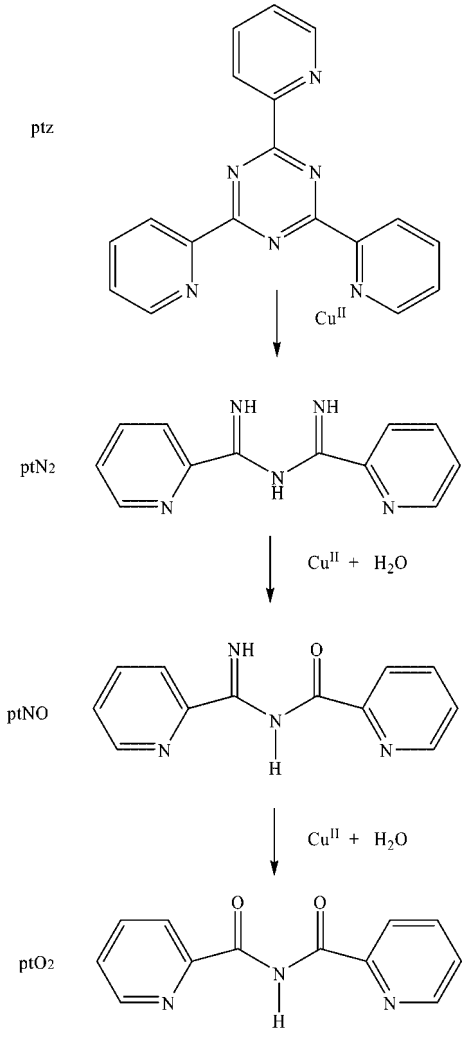
indeed, their hydrolysis requires the presence of a concentrated mineral acid and temperatures above 150 °C.[19] Lerner and Lippard[20,21] have found that ptz undergoes hydrolysis in the presence of $Cu^{II}$ in aqueous media. They have also reported the crystal structure of a copper(II) complex with a hydrolysis product of ptz. On the basis of the Cu–N bond lengths and angles of the carbonyl carbon atoms within the chelate ring, they suggested that the coordination of ptz induces an angular strain which allows a nucleophilic attack at the carbon atoms of the triazine ring by the solvent, which, in turn, results in the hydrolysis of ptz.[20,22] Kinetic and thermodynamic data have revealed that such a reaction probably occurs by nucleophilic attack at the triazine ring by $OH^-$ or $H_2O$.[23] However, a comparison of the structural and NMR spectroscopic data of rhodium and ruthenium complexes with ptz and a ptz derivative have led to the conclusion that a decrease in electron density at the carbon atoms of the triazine ring due to the electron-withdrawing effect (L→M) of the metal ion is a more predominant factor than angular strain in the metal-assisted hydrolysis of ptz.[24,25] Very recently, Li et al. have confirmed by a theoretical study that the hydrolysis of ptz is affected by the electron-withdrawing effect of the metal ions.[26]

The hydrolysis of ptz (Scheme 1) involves the formation of several intermediates containing either two imino nitrogens ($ptN_2^-$), one imino and one carbonyl ($ptNO^-$), and finally two carbonyl groups ($ptO_2^-$). The literature contains reports of metal complexes of the $ptO_2^-$ ligand, usually described as $bpca^-$, which is formed upon deprotonation of bis(2-pyridylcarbonyl)amine (Hbpca; Scheme 1). Mono-, di- (homo- and heteronuclear), and trinuclear complexes have been reported for various divalent and trivalent metal ions ($M^{II}$ = $Cu^{II}$, $Fe^{II}$, $Mn^{II}$, $Co^{II}$, $Ni^{II}$, and $Zn^{II}$; $M^{III}$ = $Fe^{III}$, $Rh^{III}$).[27–33] Among these, a ternary complex of copper(II) with one $bpca^-$ and another derivative formed during the hydrolysis process, namely 2-picolinamide, has been described.[28] The $ptO_2^-$ anion is obtained by means of a Cannizzaro-type reaction of pyridine-2-carboxaldehyde and NaNCO in the presence of copper metal ion.[34] Kawijara et al. have described the $ptN_2^-$ ligand,[35] which forms when ptz is mixed with copper(II) acetate at reflux in dry MeOH in the presence of $NaClO_4$. This ligand links the copper(II) ions to form a polymer chain.

In this paper we describe the crystal structures of copper(II) complexes with $ptO_2^-$ and other new copper complexes with $ptN_2^-$. The ptz and the ptz-derived ligands present a planar structure and can interact with the bases of DNA through stacking, which is one of the well-known conditions for interaction with DNA in order to give rise to ROS that then cleave the DNA. In this vein, Thorp et al.[36] have reported the DNA-cleavage activity of $Ru^{II}$-ptz complexes based on the formation of oxidoruthenium(IV). Our group has also published numerous papers about the nuclease activity of copper(II) complexes in the presence of reducing agents.[37–42] In this paper we assay the nuclease activity of the synthesized copper(II) complexes in the presence of reducing agents such as mercaptopropionic acid, ascorbic acid, and glutathione.



Scheme 1. Hydrolysis of 2,4,6-tri(2-pyridyl)-1,3,5-triazine.

## Results and Discussion

### Synthesis

The reaction of copper salts and ptz in dmf/$H_2O$ (4:1) resulted in the hydrolysis of ptz to $ptO_2^-$ or $ptN_2^-$ anions and afforded complexes of composition $[Cu(ptO_2)(X)(H_2O)]$, $[Cu(ptN_2)(X)]\cdot 3H_2O$ (X = acetate or formate), $[Cu(ptO_2)(benz)]\cdot H_2O$, and $[Cu(ptO_2)(F)(H_2O)]_2\cdot 3H_2O$.

### Crystal Structures

#### *[Cu(ptO$_2$)(for)(H$_2$O)] (4)*

Figure 1 shows an ORTEP view of the molecule with the atomic numbering scheme. Selected bond lengths and angles are listed in Table 1. The coordination sphere of copper(II) is best described as a distorted tetragonal square pyramid, as can be deduced from the $\tau$ value of 0.24.[43] The basal positions are occupied by the three nitrogen atoms of the $ptO_2^-$ ligand and one oxygen atom of the monodentate formate (for) anion. The apical site is occupied by the oxygen atom from the coordinated water molecule. The Cu–N

bond lengths, which range from 1.942(3) to 2.022(2) Å, are very similar to those found in other previously reported copper(II) complexes with $ptO_2^-$.[27] The Cu–$O_{for}$ and the Cu–$O_{water}$ bond lengths are 1.933(2) and 2.329(4) Å, respectively. The four basal atoms are quasi coplanar, and the copper ion is displaced 0.106 Å below the plane. The second oxygen of the formate group is located a long distance away from copper(II) [2.882(4) Å].

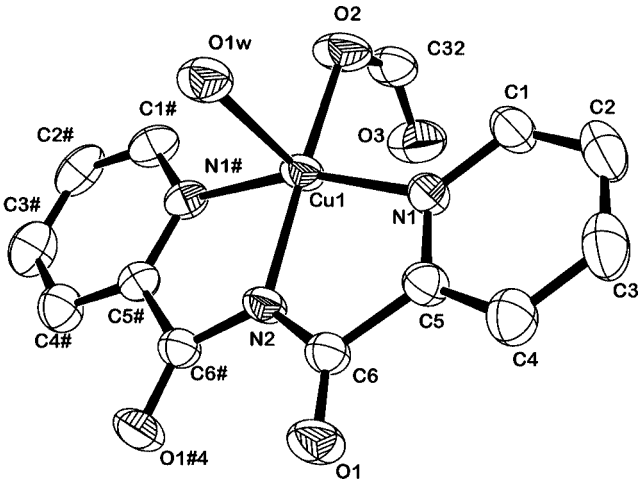

Figure 1. ORTEP drawing of [Cu($ptO_2$)(for)($H_2O$)] (**4**).

The crystal packing is stabilized by intermolecular hydrogen bonds. A moderate hydrogen bond is formed between O1W and O3 of the formate anion [O1W···O3 2.792(5) Å, O1W–H1A–O3 174.92(4.60)°]. In addition, O1W forms a moderately strong hydrogen bond with the carbonyl O1 [O1W···O1 2.944(3) Å, O1W–H1B–O1 137.56(6)°].[44]

### *[Cu($ptO_2$)(benz)]·$H_2O$ (5)*

An ORTEP view of the complex with the atom numbering scheme is shown in Figure 2. Selected bond lengths and angles are listed in Table 1. The geometry of the copper(II) ion can be described as distorted square planar. The coordination polyhedron is formed by a $ptO_2^-$, which functions as a tridentate ligand through the nitrogen atoms, and one carboxylate O atom from the benzoate (benz) ligand. The three Cu–N bond lengths, which are within the range 1.9268(13)–2.0007(16) Å, are similar to those of the complex described above and to those found for other copper(II) $ptO_2$ complexes.[27] The distortion of the square-planar geometry can be determined by the dihedral angle between the $CuN_2$ and CuNO planes. When the dihedral angle is 0° the geometry is planar while when the angle is 90° the stereochemistry is tetrahedral. In this complex, the dihedral angle value of 3.48(6)° indicates a very slightly distorted square planar configuration. A distorted square pyramid could be considered due to fact that the Cu–O4

distance is 2.690(2) Å. In this case, the carboxylate acts as a bidentate ligand, in contrast to that observed for $[Cu(ptO_2)(for)(H_2O)]$ (**4**) and for the previously reported complex $[Cu(ptO_2)(OAc)(H_2O)]\cdot H_2O$.[27] The four basal atoms deviate slightly from planarity, and the copper ion is displaced 0.037 Å below the plane.

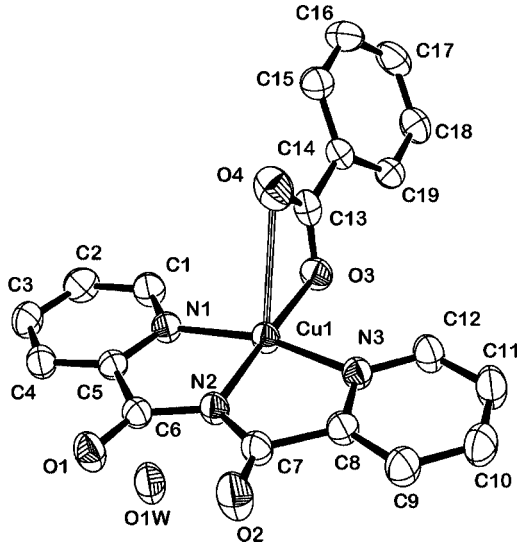

Figure 2. ORTEP drawing of $[Cu(ptO_2)(benz)]\cdot H_2O$ (**5**).

The molecule is stabilized by moderate and weak hydrogen bonds formed by O1W and two O carbonyl groups [O1W···O1 3.112(3) Å, O1W–H1A–O1 129.67(2.35)°; O1W···O2 2.858(2) Å, O1W–H1A–O2 150.18(2.45)°; O1W···O1 3.112(3) Å, O1W–H1B–O1 101.46(2.35)°].[44]

### *$[Cu(ptO_2)F(H_2O)]_2\cdot 3H_2O$ (6)*

Figure 3 displays the structure of complex $[Cu(ptO_2)F(H_2O)]_2\cdot 3H_2O$ with the labeling scheme. Selected interatomic distances and angles are listed in Table 1. The crystal structure shows the presence of two discrete monomeric $[Cu(ptO_2)F(H_2O)]$ entities and three lattice water molecules in the crystallographic asymmetric unit. Both copper(II) ions have a distorted square-pyramidal coordination geometry. The equatorial planes are defined by three nitrogen atoms of the $ptO_2^-$ ligand [Cu–N in the range 1.87(2)–2.02(2) Å for Cu(1) and 1.94(2)–2.03(3) Å for Cu(2)] and one fluoride anion [Cu(1)–F(1) 1.933(12), Cu(2)–F(2) 1.902(11) Å]. The apical position is occupied by the O atom of a water molecule [Cu(1)–O1 2.290(10), Cu(2)–O2 2.283(11) Å]. The equatorial plane displays a slight tetrahedral distortion as Cu(1) is displaced 0.1407 Å below the plane while Cu(2) lies 0.1559 Å above the plane. These two monomeric $[Cu(ptO_2)F(H_2O)]$ entities show different trigonality parameters ($\tau$). These different $\tau$ values − 0.24 for Cu(1) and 0.16 for Cu(2) − are due to crystal packing effects.

The $CuN_3F$ plane in each entity is coplanar to the $ptO_2^-$ ligand [angle between planes of 179.74° in Cu(1) and 178.63° in Cu(2)]. Moreover, both $[Cu(ptO_2)F(H_2O)]$ entities are also coplanar (the angle between the $Cu1N_3F$ and $Cu2N_3F$ planes is 178.70°).

The crystal structure is stabilized by many hydrogen-bonding interactions involving the fluoride anions (F1, F2), the oxygen atoms of the $ptO_2^-$ ligand (O2, O3), and the oxygen atoms of the water molecules (O1W, O2W, and O3W), some of which are of moderate strength.[44]

### Spectroscopic Properties

The IR spectra of $[Cu(ptN_2)(for)]\cdot 3H_2O$ (**3**; violet) and $[Cu(ptO_2)(for)(H_2O)]$ (**4**; blue) are significantly different (see Figure S1 in the Supporting Information). Thus, while the presence of a strong band at 1712 $cm^{-1}$, attributable to the ν(C=O) vibrations characteristic of the $ptO_2^-$ ligand,[27] is a significant feature in the IR spectrum of **4**, the IR spectrum of **3** does not show this band but rather shows a band

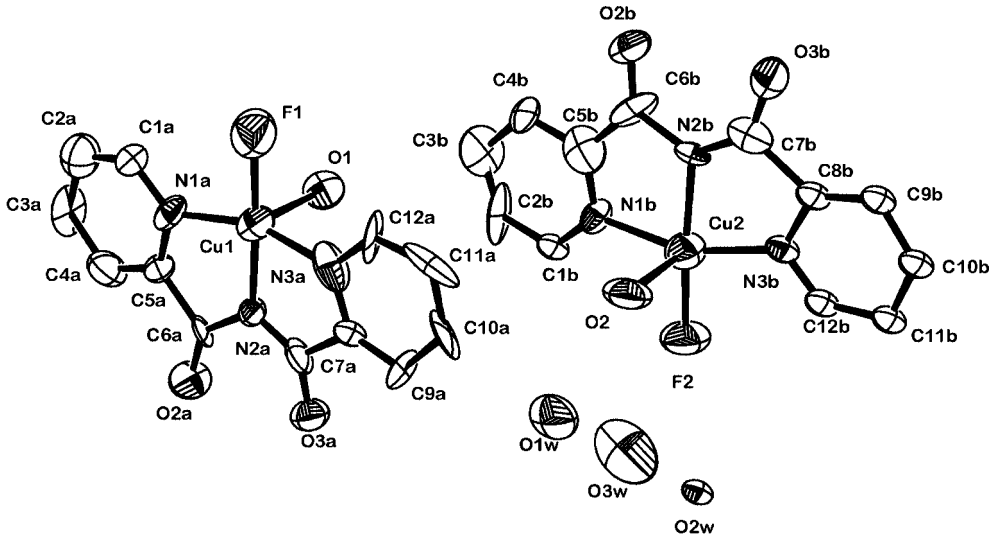

Figure 3. ORTEP drawing of $[Cu(ptO_2)F(H_2O)]_2\cdot 3H_2O$ (**6**).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

at 1666 $cm^{-1}$ due to the $\delta$(N–H) vibrations. Another domain in which noteworthy differences exist between the IR spectra of both complexes is that between 3500 and 3000 $cm^{-1}$. For example, in the spectrum of **4**, a strong band with two peaks is observed at 3500 and 3440 $cm^{-1}$, attributable to ν(O–H) vibrations of the water molecules, while in the IR spectrum of **3** two bands appear at 3300 and 3100 $cm^{-1}$. These can most likely be assigned to ν(N–H) and ν(O–H) vibrations of the lattice water molecules, respectively. Both spectra exhibit bands at 1600 and 1350 $cm^{-1}$ that correspond to the $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ vibrations of the formate group.

The interpretation of the IR spectrum of **4** is corroborated by the corresponding IR spectra of $[Cu(ptO_2)(benz)]\cdot H_2O$ (**5**) and $[Cu(ptO_2)F(H_2O)]_2\cdot 3H_2O$ (**6**), which both show the strong band at 1712 $cm^{-1}$ and the two peaks at 3500 and 3440 $cm^{-1}$. In contrast, the IR spectrum of $[Cu(ptN_2)(OAc)]\cdot 3H_2O$ (**1**) shows no bands at 3500, 3440, or 1712 $cm^{-1}$, but rather at 3300, 3100, and 1660 $cm^{-1}$, similar to those of $[Cu(ptN_2)(for)]\cdot 3H_2O$ (**3**). In the IR spectrum of **5**, the bands attributable to the $\nu_{as}(COO^-)$ and $\nu_s(COO^-)$ vibrations of the benzoate group appear at 1600 and 1350 $cm^{-1}$, respectively.

Differences between complexes **3** and **4** are also found in their reflectance spectra. Thus, while the spectrum of **4** shows an unresolved broad d–d band at about 637 nm, that of **3** presents the d–d transition at about 565 nm. The same pattern is observed for the d–d bands of **2** (620 nm) and **1** (565 nm). Complexes **5** and **6** show the d–d band at 582 and 627 nm, respectively. The position of the d–d maximum thus follows the order **5** < **2** < **6** < **4**. The order of the d–d maximum position for the three latter complexes is in good agreement with the extent of geometrical distortion defined by the $\tau$ parameter: 0.16 (**2**), 0.16 and 0.24 (**6**), and 0.24 (**4**). In addition to the d–d band, a shoulder appears at about 420 nm in complexes **2**, **4**, and **5**; this can be assigned to an LMCT band. While the spectrum for the complex **1** does not exhibit this band, that of **6** shows a very strong band at 400 nm that can be attributed to an F–Cu LMCT band.

As the complexes are soluble in $H_2O$, we also recorded their UV/Vis spectra in aqueous solution. The spectra of aqueous solutions of complexes **5**, **2**, and **4** show the same maxima at 646 nm ($\varepsilon$ = 45, 91, and 90 $M^{-1}cm^{-1}$, respectively), thus suggesting that all three compounds contain the same chromophore in solution. The shift of the d–d band position with respect to that in the diffuse reflectance spectra is probably a consequence of the coordination of water molecules and the dissociation of the carboxylate anions. Moreover, a weak LMCT band at about 400 nm, similar to that observed in the solid-state spectra, is present, which indicates the interaction between the metal ion and the $ptO_2^-$ anion. Finally, the UV/Vis spectrum of an aqueous solution of complex **1**, while showing a band at 590 nm ($\varepsilon$ = 49 $M^{-1}cm^{-1}$), shows none around 400 nm (see Figure S2 in the Supporting Information), thus confirming the results in the solid state.

## EPR Spectroscopy

The X- and Q-band spectra of polycrystalline samples of the complexes were recorded at room temperature. Powder samples of **2**, **4**, **5**, and **6** were prepared from the single crystals. The EPR parameters obtained by simulation with WINSimphonia[45] are given in Table 2. The Q-band EPR spectrum of **5** is the axial-only spectrum, with $g_\parallel > g_\perp$. This indicates a mainly copper(II) $d_{x^2-y^2}$ orbital ground state. The other Q-band EPR spectra are rhombic, with $g_x < g_y < g_z$ and $R$ values ranging from 0.07 to 0.38, which suggests that the unpaired electron is in the $d_{x^2-y^2}$ orbital. The pattern of the EPR spectra is in good agreement with the square-planar geometry of **5** and the square-pyramidal geometry of **4** and **6**. Interestingly, the better resolution of the Q-band spectra allowed us to deduce the rhombic nature of the EPR spectrum of **2**, which had been hypothesized to be axial in a previous paper.[27]

It is also interesting to note that the EPR spectra of the complexes with the $ptO_2^-$ ligands (**2** and **4**) are different from those of the complexes with the $ptN_2^-$ ligand (**1** and **3**; see Figure S3 in the Supporting Information).

## Mass Spectral Analysis

The FAB spectra of complexes **2**, **4**, **5**, and **6** show a major peak at *m*/*z* 289 that corresponds to the $[Cu(ptO_2)]^+$ fragment due to the dissociation of the carboxylate or $F^-$ anions. There are, however, other significant peaks in the spectra. The FAB spectrum of **2**, for example, shows peaks at *m*/*z* 349 and 307 attributable to the $[Cu(ptO_2)(OAc) + H]^+$ and $[Cu(ptO_2) + H_2O]^+$ fragments. The FAB mass spectrum of **6**, which is similar to that of **2**, shows a peak at *m*/*z* 309 that can be attributed to the $[Cu(ptO_2)F + H]^+$ fragment. The FAB spectrum of complex **4** displays a peak at *m*/*z* 335 that corresponds to the $[Cu(ptO_2)(for)H]^+$ entity. The FAB spectrum of **5** shows a peak at *m*/*z* 411 that is

Table 2. X- and Q-band EPR data for the complexes.

| Compound | Q-band | | | | X-band | | | |
|---|---|---|---|---|---|---|---|---|
| | $g_x$ | $g_y$ | $g_z$ | $R$ | $g_\parallel$ | $g_\perp$ | $g_\parallel$ | $g_\perp$ |
| $[Cu(ptN_2)(OAc)]\cdot 3H_2O$ (**1**) | 2.045 | 2.062 | 2.217 | 0.11 | | | 2.060 | 2.208 |
| $[Cu(ptO_2)(OAc)(H_2O)]\cdot H_2O$ (**2**) | 2.046 | 2.049 | 2.230 | 0.07 | | | 2.211 | 2.060 |

assigned to the $[Cu(ptO_2)(benz) + H]^+$ fragment. Interestingly, the mass spectrum of **1** presents a peak at *m*/*z* 305, which corresponds to the $[Cu(ptN_2) + H_2O]^+$ fragment. The presence of this peak agrees with the difference in mass between $ptO_2^-$ (226.06) and $ptN_2^-$ (224.09).

### Electrochemical Behavior

In the electroactivity domain of acetonitrile/$Bu_4NClO_4$, the cyclic voltammograms of complexes **2** and **5** have the same shape. A reduction peak is observed around –0.90 mV (vs. SCE) towards cathodic potentials; this can be attributed to the reduction of $Cu^{II}$ to $Cu^{I}$. The same $E_{cat}$ value for both complexes indicates that **2** and **5** give identical species in acetonitrile solution, probably the $[Cu(ptO_2)]^+$ entity, thus confirming the UV/Vis and FAB data. On the reverse scan, an anodic peak was found at about –0.2 mV. The voltammogram is clearly irreversible, probably because the $Cu^{I}$ species formed upon reduction of $Cu^{II}$ is unstable. The reduction peak at –0.90 mV relative to SCE corresponds to –0.68 mV relative to NHE. Such a value indicates a higher stabilization of the $Cu^{II}$ species with respect to those of $Cu^{I}$.

Attempts to determine the electrochemical behavior of the complexes in cacodylate buffer, the medium used in the biological studies, were unsuccessful because a solid precipitated in the electrolytic cell.

### DNA-Binding Interactions

The mode and propensity of binding of the complexes to calf-thymus DNA (CT-DNA) were studied with the aid of various techniques.

#### *Viscosity Measurements*

Viscosity measurements were carried out on CT-DNA by varying the concentration of the complexes. Hydrodynamic measurements that are sensitive to length changes are regarded as the least ambiguous and most critical tests of binding in solution. One classic intercalation model results in the lengthening of the DNA helix as the base-pairs are separated to accommodate the binding ligand, thus leading to the increase of DNA viscosity. In contrast, complexes that bind exclusively in DNA grooves by means of partial and/or nonclassical intercalation under the same conditions typically cause either a less pronounced change (positive or negative) of DNA solution viscosity or none at all.[46] The results obtained with our compounds reveal that the presence of complexes **3**, **5**, or **6** has no effect on the relative viscosity of CT-DNA. This indicates that the interaction of these complexes follows the general pattern of complexes that bind in DNA grooves by either a partial or nonclassical intercalation.

#### *Thermal Denaturation*

In order to obtain a better understanding of the interaction of the compounds, the binding of complexes **3**, **5**, and **6** to CT-DNA was studied by examining the thermal denaturation profile of DNA. The melting temperature ($T_m$) of CT-DNA upon addition of **3**, **5**, or **6** was found to be 75.7, 78.5, and 75.6 °C respectively. The complexes thus produce no increase in $T_m$ upon addition to DNA ($T_m$ = 76.6 °C in cacodylate buffer 0.1 M, NaCl 2 mM, pH 6.0). These results suggest that the complexes do not effect duplex stabilization through intercalation between the DNA base-pairs.

In summary, both viscosity and $T_m$ measurements indicate that the complexes do not intercalate between the DNA base-pairs. Most probably, the interaction of the complexes is mainly electrostatic through the phosphate backbone of the DNA since the compounds are present in solution as the positive $[Cu(ptO_2)]^+$ or $[Cu(ptN_2)]^+$ species.

### Nuclease Activity of Complexes and Mechanistic Investigations

#### *Oxidative DNA Cleavage Mediated by the Compounds*

The ability of complexes **1**–**6** to cleave DNA was investigated by means of gel electrophoresis with supercoiled pUC18 in 0.1 M cacodylate buffer (pH 6.0) and with ascorbate activation. Control experiments with $CuSO_4$ were also carried out under the same experimental conditions. The DNA cleavage activity of the complexes was assayed by the conversion of supercoiled DNA (SC, form I) to nicked circular (NC, form II) or linearized DNA (LC, form III). All the complexes were found to exhibit nuclease activity (Figure 4). At 6, 18, and 30 μM the compounds present the same cleavage pattern (lanes 2–4, parts a–f of Figure 4). The fact that the complexes exhibit similar nuclease activity is not surprising since they are dissociated in solution into $[Cu(ptO_2)]^+$ or $[Cu(ptN_2)]^+$. The $[Cu(ptO_2)]^+$ or $[Cu(ptN_2)]^+$ entities derived from the complexes must therefore be the active species that mediate DNA-strand scission since $CuSO_4$ at the highest concentration assayed is only able to produce a partial conversion of SC DNA into NC DNA (lane 6, Figure 4, g). Thus, the DNA cleavage activity of the compounds can be ascribed to the cooperative effect between $Cu^{II}$ and the $ptO_2^-$ or $ptN_2^-$ ligands.

Because certain copper(II) complexes are able to bring about hydrolytic cleavage of DNA, the possibility of a hydrolytic mechanism for the DNA damage mediated by these compounds must be taken into account. In order to clarify this point, the nuclease activity of complexes **1**–**6** was assayed without ascorbate activation. No DNA cleavage was observed, which indicates that a hydrolytic mechanism is not involved (lane 1, parts a–f of Figure 4).

The nuclease efficiency of a large number of $Cu^{II}$ complexes is known to depend on the reducing agent used for initiating the DNA cleavage. We thus tested the activity of **4** in the presence of various activators [ascorbate, hydrogen peroxide, 3-mercaptopropionic acid (MPA), and glutathione] at a 50-fold excess relative to the complex concentration. The results, shown in Figure 5 (A), indicate the following increasing order of efficiency: hydrogen peroxide < glutathione < MPA < ascorbate (cf. lanes 8, 10, 12, and 14 in Figure 5, A). By way of comparison, the same assays were

performed with $CuSO_4$. Lanes 3–6 (Figure 5, A) show that $CuSO_4$ at 30 μM is not an efficient chemical nuclease in the presence of these activating agents. Several authors have studied the influence of different reducing agents on the cleavage of DNA by copper(II) complexes.[47–50] Sigman et al.,[47] for example, examined the influence of the activating agent on the nuclease activity of a bis(*o*-phenanthroline)-copper(II) complex and deduced that ascorbic acid and 3-mercaptopropionic acid are the most efficient reducing agents. However, while these same authors found MPA to be superior to ascorbic acid because it produces less background cleavage, in our study ascorbic acid is clearly more efficient than MPA. Chiou et al.[48] have indicated that ascorbate is more effective in cleaving DNA than other reducing agents such as MPA and dithiothreitol even though the latter compounds possess higher reducing powers than ascorbate. The uniqueness of ascorbate as a reducer in the scission reaction may depend on its ability to generate hydrogen peroxide in the presence of oxygen and metal ions, whereas other reducing agents with a thiol group are known to produce superoxide, which rapidly undergoes dismutation in aqueous solution. Detmer et al.[49] have found that a combination of ascorbate and $H_2O_2$ is a more effective activating agent than ascorbate alone. In order to elucidate the influence of mixing ascorbate with $H_2O_2$, the cleavage process of **5** was studied with ascorbate/$H_2O_2$ (50×) or ascorbate (50× and 100×) as activators (Figure 5, B). No significant differences in DNA damage were found.

### *Mechanistic Studies*

The mechanism of pUC18 DNA cleavage by the compounds was studied using inhibiting reagents. The results for complexes **3** and **5** are shown in Figure 6. The involvement of ROS was investigated with standard hydroxyl radical scavengers (DMSO, *tert*-butyl alcohol, potassium iodide, and urea), singlet oxygen scavengers (azide and DABCO), superoxide radical scavengers (Tiron), and catalase. The groove binding preferences were tested in the presence of the minor groove binder distamycin and the major groove binder methyl green. The reduction of $Cu^{II}$ to $Cu^{I}$ during the cleavage process was evaluated with neocuproine, a ligand that chelates strongly to copper(I).

A strong inhibition of DNA cleavage mediated by **5** is observed upon addition of DMSO, *tert*-butyl alcohol, potassium iodide, or urea, thereby indicating that hydroxyl radical is involved in the cleavage process (lanes 4–7, Figure 6, A). The addition of sodium azide or DABCO (lanes 8 and 9, Figure 6, A) also decreases the cleavage efficiency, which indicates that either $^1O_2$ or a singlet-oxygen-like entity is one of the active oxygen intermediates responsible for the cleavage. The inhibitory activity of sodium azide can be ascribed to the affinity of the azide anion for transition metals.[51] Adding Tiron to the reaction mixture decreases the DNA damage slightly, which suggests that the superoxide anion is involved in the DNA scission (lane 10, Figure 6, A). Catalase also inhibits the nucleolytic process, which confirms that hydrogen peroxide is also necessary in the DNA strand scission (lane 14, Figure 6, A).

Treatment of pUC18 DNA with distamycin prior to the addition of **5** has no effect on the cleavage reaction mediated by the compound (lane 11, Figure 6, A). In contrast, prior treatment with methyl green attenuates the DNA strand scission (lane 12, Figure 6, A). It can thus be inferred from these results that **5** prefers major groove binding. Finally, neocuproine does not inhibit the DNA damage (lane 13, Figure 6, A). This is probably due to the strong redox stability of the $[Cu(ptO_2)]^+$ species, as was deduced from the electrochemical studies.

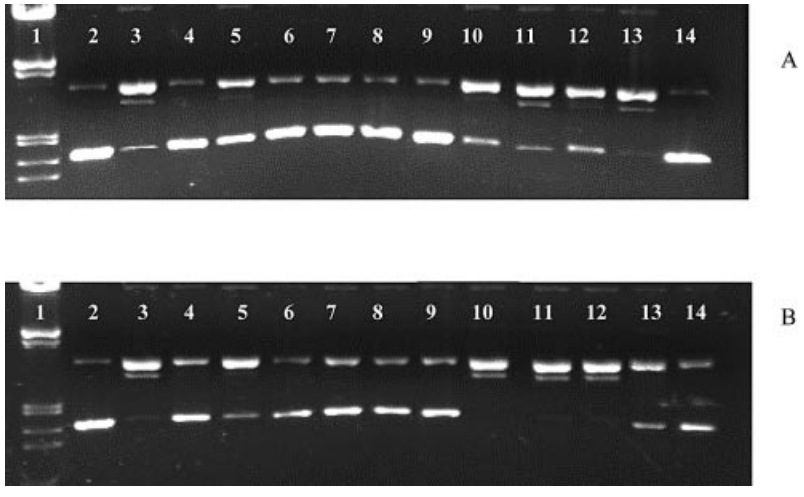

Figure 6. A) Agarose gel electrophoresis of pUC18 plasmid treated with 30 μM $[Cu(ptO_2)(benz)]\cdot H_2O$ (**5**) and 1.5 mM ascorbate/$H_2O_2$ in the presence of potential inhibitors. Incubation time: 1 h (37 °C). B) Agarose gel electrophoresis of pUC18 plasmid treated with 30 μM $[Cu(ptN_2)(for)]\cdot 3H_2O$ (**3**) and 1.5 mM ascorbate/$H_2O_2$ in the presence of potential inhibitors. Incubation time: 1 h (37 °C). Lane 1: λDNA/EcoRI + Hind III Marker; lane 2: supercoiled DNA; lane 3: complex without inhibitors; lane 4: complex + DMSO (1 M); lane 5: complex + *tert*-butyl alcohol (1 M); lane 6: complex + IK (0.4 M); lane 7: complex + urea (0.4 M); lane 8: complex + $NaN_3$(100 mM); lane 9: complex + DABCO (0.4 M); lane 10: complex + Tiron (10 mM); lane 11: complex + distamycin (8 μM); lane 12: complex + methyl green (2.5 μL of a 0.01 mg mL$^{-1}$ solution); lane 13: complex + neocuproine (75 μM); lane 14: complex + catalase (6.5 units).

The results for complex **3** (Figure 6, B) indicate that, as was the case for **5**, hydroxyl radical, $^1O_2$, and hydrogen peroxide are the active species responsible for the DNA damage (lanes 4–7, 8, 9, and 14, Figure 6, B). However, the cleavage scission process mediated by this compound is somewhat different from that of **5**. First of all, the superoxide anion does not seem to be involved in the DNA scission (lane 10, Figure 6, B). Also, since neocuproine attenuates the DNA cleavage in this case (lane 13, Figure 6, B), it seems likely that the reduction of $Cu^{II}$ to $Cu^{I}$ takes place, probably due to a lower stability of $[Cu(ptN_2)]^+$ with respect to that of $[Cu(ptO_2)]^+$. Moreover, in contrast to **5**, complex **3** does not show major or minor groove binding preferences (lanes 11 and 12, Figure 6, B).

The involvement of hydroxyl radicals was subjected to further studies. The hydroxyl release by **5** was studied by using 2-deoxy-D-ribose as a radical trap.[52] 2-Deoxy-D-ribose provides a chemically equivalent model for the oxidative target in DNA strand scission chemistry. The quantitation of 2-deoxy-D-ribose under sodium ascorbate/$H_2O_2$ activation conditions is displayed in Figure 7, where it can be seen that the calculated production of hydroxyl radicals increases to about 700 nM at 60 min.

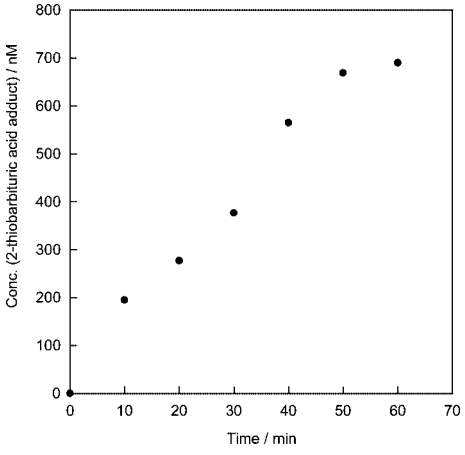

Figure 7. Production of hydroxyl radicals by $[Cu(ptO_2)(benz)]\cdot H_2O$ (**5**) as assayed by the 2-deoxy-D-ribose/2-thiobarbituric acid system.

In general, two mechanisms can be proposed for $Cu^{II}$ complexes that mediate oxidative DNA cleavage, one involving hydroxyl radicals and another involving metal-oxido species. Bocarsly et al.[49,50,53] have suggested that hydroxyl radicals are generated by a variety of chemical and physical processes. Transition-metal-mediated hydroxyl radical production is known to occur by a number of routes; two well-known pathways are the Fenton and the Haber–Weiss mechanism. In the Fenton mechanism, the metal acts as a catalyst for hydroxyl radical generation from hydrogen peroxide:

$$Cu^{II}L + ascH_2 \rightarrow Cu^{I}L + ascH^-$$

$$Cu^{I}L + H_2O_2 \rightarrow Cu^{II}L + OH^- + OH^{\cdot}$$

whereas the Haber–Weiss reaction involves the reaction between superoxide anion and hydrogen peroxide:

$$Cu^{I}L + O_2 \rightarrow Cu^{II}L + O_2^-$$

$$O_2^- + H_2O_2 \rightarrow O_2 + OH^- + OH^{\cdot}$$

On the other hand, Sigman has suggested that bis(*o*-phenanthroline)copper(II), the classic nuclease system, follows a different mechanistic pathway.[54] Thus, reduction of the copper to cuprous state leads to the generation of superoxide anion. The $O_2^-$ then dismutates to $H_2O_2$ and dioxygen and the hydrogen peroxide reacts with another equivalent of copper(I) to produce hydroxyl radical-like species, which may be bound to the metal. This species, which could be considered analogous to a metal-oxido species, is responsible for initiating DNA strand scission.[55]

Bocarsly et al. have compared their proposed mechanism with that of Cu-phenanthroline. They concluded that the differences between the two mechanisms are most likely related to the electronic differences between the ligands. Their mechanism is related to complexes with ligands that present σ character, while the mechanism proposed by Sigman is related to complexes with ligands that present π character (phen). Since the $ptO_2^-$ and the $ptN_2^-$ ligands in the title complexes present both σ and π character, both mechanisms can be proposed. This could explain why both hydroxyl radical scavengers and scavengers of singlet oxygen or singlet-oxygen-like species inhibit the DNA damage and strand breakage.

## Conclusions

Ternary copper(II) complexes with 2,4,6-tri(2-pyridyl)-1,3,5-triazine hydrolytic derivatives have been prepared and structurally characterized with the aid of X-ray crystallography. The binding of DNA has been studied with the aid of viscosity and $T_m$ measurements, which indicate that the complexes do not intercalate between the DNA base pairs. In contrast, an electrostatic interaction of the complexes with the phosphate backbone of the DNA can be deduced since the compounds are present in solution as the cationic $[Cu(ptO_2)]^+$ or $[Cu(ptN_2)]^+$ species. The complexes act as efficient chemical nucleases upon ascorbate activation. The participation of $H_2O_2$, hydroxyl radical, superoxide anion, and singlet-oxygen-like entities in the scission process mediated by the compounds suggests a mechanism pathway involving a Fenton or a Haber–Weiss reaction and copper(II)-oxene species.

## Experimental Section

**Materials and Physical Measurements:** Reagents and solvents were commercially available and used without further purification. pUC18 was purchased from Roche Diagnostics. Calf-thymus DNA (CT-DNA) was supplied by Sigma–Aldrich.

Elemental analyses (C,N,H) were performed with a Carlo–Erba AAS instrument. IR spectra (KBr disks) were recorded with a Mattson satellite FT-IR spectrometer in the range 4000–400 $cm^{-1}$. Diffuse reflectance spectra (nujol mulls) of the complexes were recorded with a Shimadzu UV-2101 PC spectrophotometer. UV/Vis

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectra of the complex solutions were recorded with an HP 8453 spectrophotometer. FAB mass spectra were obtained with a VG Autospec spectrometer with 3-nitrobenzyl alcohol as matrix. EPR spectra were recorded at the X- and Q-band frequencies at room temperature with a Bruker ELEXSYS spectrometer. Electrochemical measurements were performed with the aid of a Princeton Applied Research Model 273A potentiostat/galvanostat. Cyclic voltammograms were obtained for acetonitrile solutions of the complexes with [TBA][$ClO_4$] as the supporting electrolyte under argon. The electrochemical cell employed had a standard three-electrode configuration, with a platinum working electrode, a platinum wire counter electrode, and an Ag/AgCl reference electrode.

**[Cu(ptN$_2$)(OAc)]·3H$_2$O (1):** An aqueous solution of $Cu_2Ac_4{\cdot}2H_2O$ (10 mL; 200 mg, 1 mmol) was added with continuous stirring to 40 mL of a yellow dmf solution of ptz (312 mg, 1 mmol). A dark green solution was formed immediately; after 30 min it turned blue-green in color and overnight it became blue with a small amount of violet precipitate. The precipitate was isolated by filtration, washed, and dried until constant weight. Yield: 20%. $C_{14}H_{19}CuN_5O_5$: calcd. C 41.94, H 4.77, N 17.47; found C 41.15, H 4.59, N 17.76.

Slow evaporation of the filtrate yielded blue, needle-like crystals that correspond to [Cu(ptO$_2$)(OAc)(H$_2$O)]·H$_2$O (**2**), which has previously been reported as [Cu(bpca)(OAc)(H$_2$O)]·H$_2$O.[26]

**[Cu(ptN$_2$)(for)]·3H$_2$O (3) and [Cu(ptO$_2$)(for)(H$_2$O)] (4):** An aqueous solution of [Cu$_2$(for)$_4$]·4H$_2$O (10 mL; 225 mg, 1 mmol) was added to 40 mL of a yellow dmf solution of ptz (312 mg, 1 mmol). A dark green solution was formed immediately; after 30 min it turned blue-green in color and overnight it became blue with a small amount of violet precipitate. The precipitate was isolated by filtration, washed, and dried until constant weight. Yield: 16%. $C_{13}H_{16}CuN_5O_5$: calcd. C 42.43, H 3.92, N 18.20; found C 42.43, H 4.14, N 18.12.

Slow evaporation of the filtrate yielded blue, needle-like crystals that correspond to [Cu(ptO$_2$)(for)(H$_2$O)] (**4**). Yield: 47%. $C_{13}H_{11}CuN_3O_5$: calcd. C 44.26, H 3.14, N 11.47; found calcd. C 44.10, H 3.09, N 11.90.

**[Cu(ptO$_2$)(benz)]·H$_2$O (5):** This compound was obtained by a procedure similar to that described above, but with $Cu_2(benz)_4$ (611 mg, 1, mmol), which was obtained either by mixing copper(II) perchlorate with sodium benzoate or by electrochemical synthesis. Slow evaporation of the resulting blue solution gave rise to blue, needle-like crystals after four or five days. Yield: 65%. $C_{19}H_{15}CuN_3O_5$: calcd. C 53.21, H 3.52, N 9.75; found C 52.99, H 3.44, N 9.75.

**[Cu(ptO$_2$)F(H$_2$O)]·1.5H$_2$O (6):** The synthesis of this compound is similar to that described above, but with $CuF_2{\cdot}2H_2O$ (137 mg, 1 mmol). Blue crystals formed 4 or 5 days after its preparation. Yield: 22%. $C_{12}H_{13}CuFN_3O_{4.5}$: calcd. C 40.74, H 3.70, N 11.88; found C 41.50, H 3.38, N 12.03.

**X-ray Crystallography**

**[Cu(ptO$_2$)(for)(H$_2$O)] (4):** Greenish-blue crystal, size $0.2\times0.2\times0.2$ mm, orthorhombic, space group $A2_1am$ (determined from the systematic absences). Data collection was performed at 293 K with a Nonius Kappa-CCD single crystal diffractometer, with Mo-$K_\alpha$ radiation ($\lambda$ = 0.7173 Å). The crystal–detector distance was fixed at 45 mm, and a total of 148 images were collected by means of the oscillation method, with a scan angle per frame of 2° oscillation and a 10-s exposure time per image. Unit cell dimensions were determined from 895 reflections between $\theta$ = 2.91° and 27.49°. Unit cell parameters: $a$ = 6.575(5), $b$ = 13.462(5), $c$ = 15.516(5) Å, $V$ = 1373.4(12) Å$^3$, $Z$ = 4, $D_x$ = 1.701 mg m$^{-3}$, $\mu$ = 1.619 mm$^{-1}$. Multiple observations were averaged, $R_{merge}$ = 0.000, resulting in 1533 unique reflections of which 1390 were observed with $I > 2\sigma(I)$. Final mosaicity was 0.42. Data completeness was 99.4%. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in the difference Fourier map and located geometrically. The final cycle of full-matrix least-squares refinement based on 1533 reflections and 131 parameters converged to a final value of $R1$ [$F^2 > 2\sigma(F^2)$] = 0.0291, $wR2$ [$F^2 > 2\sigma(F^2)$] = 0.0732, $R1$ ($F^2$) = 0.0338, $wR2$ ($F^2$) = 0.0754. The final difference Fourier maps showed no peaks higher than 0.323 e Å$^{-3}$ at 1.56 Å from C32 and no troughs deeper than –0.513 e Å$^{-3}$ at 0.72 Å from Cu1.

**[Cu(ptO$_2$)(benz)]·H$_2$O (5):** Violet crystal, size $0.8\times0.16\times0.008$ mm, monoclinic, space group $P2_1/a$ (determined from the systematic absences). Data collection was performed at 293 K with a Nonius Kappa-CCD single crystal diffractometer, with Mo-$K_\alpha$ radiation ($\lambda$ = 0.7173 Å). The crystal–detector distance was fixed at 30.4 mm, and a total of 175 images were collected by means of the oscillation method, with a scan angle per frame of 1.7° oscillation and a 25-s exposure time per image. Unit cell dimensions were determined from 6088 reflections between $\theta$ = 0.998° and 33.142°. Unit cell parameters: $a$ = 10.359(5), $b$ = 10.295(5), $c$ = 16.555(5) Å, $\beta$ = 99.482(5)°, $V$ = 1741.4(13) Å$^3$, $Z$ = 4, $D_x$ = 1.636 mg m$^{-3}$, $\mu$ = 1.293 mm$^{-1}$. Multiple observations were averaged, $R_{merge}$ = 0.027, resulting in 6517 unique reflections of which 4279 were observed with $I > 2\sigma(I)$. Final mosaicity was 0.6. Data completeness was 98.5%. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in the difference Fourier map and located geometrically. The final cycle of full-matrix least-squares refinement based on 6517 reflections and 315 parameters converged to a final value of $R1$ [$F^2 > 2\sigma(F^2)$] = 0.0381, $wR2$ [$F^2 > 2\sigma(F^2)$] = 0.0887, $R1$ ($F^2$) = 0.0701, $wR2$ ($F^2$) = 0.0997. The final difference Fourier maps showed no peaks higher than 0.43 e Å$^{-3}$ at 0.71 Å from C5 and no troughs deeper than 0.56 e Å$^{-3}$ at 0.66 Å from Cu1.

**[Cu(ptO$_2$)F(H$_2$O)]$_2$·3H$_2$O (6):** Blue crystal, size $0.4\times0.25\times0.15$ mm, triclinic, space group $P\bar{1}$. Data collection was performed at 293 K with a Nonius Kappa2000 single crystal diffractometer, with Cu-$K_\alpha$ radiation ($\lambda$ = 1.54184 Å). The crystal–detector distance was fixed at 35 mm, and a total of 261 images were collected by means of the oscillation method, with a scan angle per frame of 2° oscillation and 2-s exposure time per image. Unit cell dimensions were determined from 1136 reflections between $\theta$ = 0.999° and 47.840°. Unit cell parameters: $a$ = 6.7680(4), $b$ = 10.2740(5), $c$ = 20.8690(10) Å, $\alpha$ = 98.635(2)°, $\beta$ = 90.641(2)°, $\gamma$ = 107.633(2)°, $V$ = 1364.78(12) Å$^3$, $Z$ = 2, $D_x$ = 1.722 mg m$^{-3}$, $\mu$ = 2.621 mm$^{-1}$. Multiple observations were averaged, $R_{merge}$ = 0.000, resulting in 1477 unique reflections of which 745 were observed with $I > 2\sigma(I)$. Final mosaicity was 0.65. Data completeness was 59.4%. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in the difference Fourier map and located geometrically. The final cycle of full-matrix least-squares refinement based on 1477 reflections and 407 parameters converged to a final value of $R1$ [$F^2 > 2\sigma(F)^2$] = 0.048, $wR2$ [$F^2 > 2\sigma(F^2)$] = 0.122, $R1$ ($F^2$) = 0.108, $wR2$ ($F^2$) = 0.162. The final difference Fourier maps showed no peaks higher than 0.36 e Å$^{-3}$ at 0.92 Å from H3B and no troughs deeper than –0.37 e Å$^{-3}$ at 0.31 Å from H2A.

Data collection for all complexes was performed with the program Collect.[56] Data reduction and cell refinement were performed with the programs HKL Denzo and Scalepack.[57] The crystal structure was solved by direct methods with the program SIR-97.[58] Aniso-

tropic least-squares refinement was carried out with SHELXL-97.[59] Geometrical calculations were made with PARST.[60] The crystallographic plots were made with ORTEP.[61] A summary of the crystallographic data of the complexes is given in Table 3.

CCDC-615303, -615304, and -615305 (for **4**–**6**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Viscosity Measurements:** Viscosity experiments were carried out with a Cannon 25 L97 viscometer immersed in a Julabo thermostatted water bath maintained at 25.0 ± 0.1 °C. Solutions of the complexes (1–10 μM) in cacodylate buffer (pH 6.0) were added to a calf-thymus DNA (50 μM base pairs) solution in cacodylate buffer. The flow times were measured with a digital stopwatch. The flow measurements were performed in triplicate. Data are presented as $(\eta/\eta_0)^{1/3}$ vs. the ratio of the concentration of complex and DNA, where $\eta$ is the viscosity of DNA in the presence of the complex and $\eta_0$ is the viscosity of DNA alone. Viscosity values were calculated from the observed flow time of a DNA-containing solution corrected for the flow time of buffer alone ($t_0$), $\eta = t - t_0$.

**Thermal Denaturation Experiments:** DNA-melting experiments were carried out by monitoring the absorbance (260 nm) of CT-DNA (100 μM base-pairs) at different temperatures in the absence and presence of the complexes in a 4:1 DNA/complex ratio. Measurements were performed with an Agilent 8453 UV/Vis spectrophotometer equipped with a Peltier temperature-controlled sample cell and driver (Agilent 89090A). The solution containing the ternary complex and CT-DNA in 0.1 M cacodylate buffer (2 mM NaCl, pH 6.0) was stirred continuously and heated with a rate of temperature increase of 1 °C min$^{-1}$. The temperature interval studied ranged from 25 to 90 °C.

**pUC18 DNA Cleavage:** A typical reaction with the complexes was undertaken by mixing 7 μL of 0.1 M cacodylate buffer (pH 6.0), 1 μL of pUC18 (0.25 μg μL$^{-1}$), 6 μL of a solution of the tested complex at increasing concentrations between 20 and 100 μM, and 6 μL of ascorbate (100-fold molar excess relative to the concentration of the complex) in cacodylate buffer. The mixtures were allowed to stand for 1 h at 37 °C, then 3 μL of a quench buffer solution consisting of 0.25% bromophenol blue, 0.25% xylene cyanole, and 30% glycerol was added. The solution was then subjected to electrophoresis on a 0.8% agarose gel in 0.5× TBE buffer (0.045 M tris, 0.045 M boric acid, and 1 mM EDTA) containing 2 μL per 100 mL of a solution of ethidium bromide (10 mg mL$^{-1}$) at 80 V for about 2 h. The gel was photographed on a capturing gel printer plus TDI.

To test for the presence of reactive oxygen species (ROS) generated during strand scission, various scavengers were added to the reaction mixtures. The scavengers used were Tiron (10 mM), DMSO (1 M), *tert*-butyl alcohol (1 M), potassium iodide (0.4 M), urea (0.4 M), sodium azide (100 mM), DABCO (0.4 M), and catalase (6.5 units). An assay in the presence of the minor groove binder distamycin (8 μM) and the major groove binder methyl green (2.5 μL of a 0.01 mg mL$^{-1}$ solution) was also performed. Neocuproine, a ligand that chelates strongly to copper(I), was tested at 75 μM. Samples were treated as described above.

**Hydroxyl Radical Assay by 2-Deoxy-D-ribose Degradation:** Hydroxyl radical production by the complexes was assayed by degradation of 2-deoxy-D-ribose followed by quantitation of the 2-thiobarbituric acid adduct.[62] A 100 μM solution of metal complex was treated at room temperature with 4 mM 2-deoxy-D-ribose with activation by 50 mM sodium ascorbate and $H_2O_2$. Reactions were performed in a 4 mL volume of 0.1 M cacodylate buffer (pH 6.0). Reaction solutions were quenched with EDTA (2.4 mM final concentration) and stored in ice for 5 min. Each aliquot was then treated with 2-thiobarbituric acid (1.1 mM final concentration) at 95 °C for 15 min. The chromophore concentration was measured from its fluorescence intensity at 553 nm (excitation at 532 nm). The fluorescence intensity was used due to its sensitivity and also to the fact that ascorbate by-products absorb in the visible region and therefore interfere with visible quantitation of the thiobarbituric adduct. Fluorescence intensity was converted to concentration with a standard fluorescence curve constructed from known concentrations of the chromophore, synthesized from malondialdehyde and 2-thiobarbituric acid.[63] Blank reactions lacking a cleavage agent were included in each run and the blank intensity was subtracted from each experimental point.

# Isolation and Characterization of $Zn^{II}$ and $Hg^{II}$ Coordination Polymers with a Designed Azo-Aromatic Ligand: Identification of Micrometer- and Nanometer-Sized Particles

**Priyabrata Banerjee,[a] Soumitra Kar,[b] Asim Bhaumik,[b] Gene-Hsiang Lee,[c] Shie-Ming Peng,[c] and Sreebrata Goswami*[a]**

**Keywords:** Coordination polymers / Azo-aromatic ligands / $d^{10}$ metal ions / X-ray structures / Nanostructures / Fluorescence

Controlled layering of the deprotonated methanolic solution of the azo-aromatic ligand $[L^3]^-$ ($HL^3$ = 2-[3-(pyridylamino)-phenylazo]pyridine) over the aqueous/methanolic solutions of metal chlorides $MCl_2$ (M = Zn, Hg) afforded nano- and micrometer-sized particles of the metal–organic polymeric complexes of $[HgCl(C_{16}H_{12}N_5)]_\infty$ (**1**) and $[ZnCl(C_{16}H_{18}N_5O_3)]_\infty$ (**2**). Time-dependent growth of the above particles is followed by the SEM and TEM analyses of the samples at different time intervals. The X-ray structure of the mercury polymer reveals that two infinite 1D, *zigzag* chains composed of $[HgCl(L^3)]_\infty$ units run along the *a* axis antiparalelly. The polynuclear Zn compound, in contrast, agglomerates fast to form hemispherical microcrystals with a diamondoid surface morphology, and no suitable X-ray quality crystal of this complex could be isolated. Powder XRD analyses of the samples as well as thermogravimetric analysis (TGA) are used for their characterization. Unusually, these metal–organic polymers of the reference $d^{10}$ metal ions are green and absorb in the low-energy region of the visible spectrum, 660–675 nm. Semiempirical calculations on a representative complex **1** suggest that the transitions in the complexes involve ligand orbitals. These also show multiple emissions in the blue-green region. The Zn complex, which is microporous, shows reversible adsorption/desorption of $N_2$ and $H_2$ gasses. The mercury polymer, on the other hand, shows poor adsorption ability.

## Introduction

Inorganic as well as organic polymeric substances have attracted intensive attention during the recent years primarily because of their potential applications as functional materials.[1] In the past decade, several organic and inorganic materials[2] have been synthesized and investigated. In contrast, examples[3,4] of nano- or micrometer-scale particles of metal–organic coordination polymers are limited. Thus, their preparation is challenging owing to their ability to tailor their physical and chemical properties through deliberate selection[5] of metal and multifunctional ligands. Various types of bridging ligands[6–8] have been used for the construction of coordination polymers. However, such examples containing azo-aromatic bridging ligands are uncommon primarily because of the lack of availability of suitable ligands.[8] Azo-aromatic compounds, with the exception of their use in dyestuff industry, have extensively been studied in recent years owing to their novel optical[9] and redox properties. Low-lying vacant π*(azo) orbitals in metal–azo-aromatic compounds are responsible for low-energy transitions and the colour of the compounds. During recent years we have been working on the coordination chemistry of a new class of azo-aromatic ligands [HL]. Three different ligands $HL^1$, $HL^2$ and $HL^3$ have been isolated[10–12] following regioselective *ortho* fusion of suitable aromatic amines. The deprotonated ligand $[L^1]^-$ binds in a bischelating fashion to produce monometallic complexes, the other two ligands, $[L^2]^-$ and $[L^3]^-$, each containing an additional pyridyl donor, serve as bridges between two or more metal centres. Moreover, the coordination mode of the deprotonated ligand $[L^3]^-$ is different from that of its positional isomer $[L^2]^-$ and is found to be suitable[13] for the construction of one-dimensional polymeric material,[14,15] particularly with coordinately unsaturated metal ions.

The primary concern of this paper is to report our results on the isolation of one-dimensional $Hg^{II}$ and $Zn^{II}$ coordination polymers with the bridging ligand $[L^3]^-$. Unusually, the polymeric $d^{10}$ metal complexes are intensely coloured and absorb in the low-energy region of the visible spectrum.

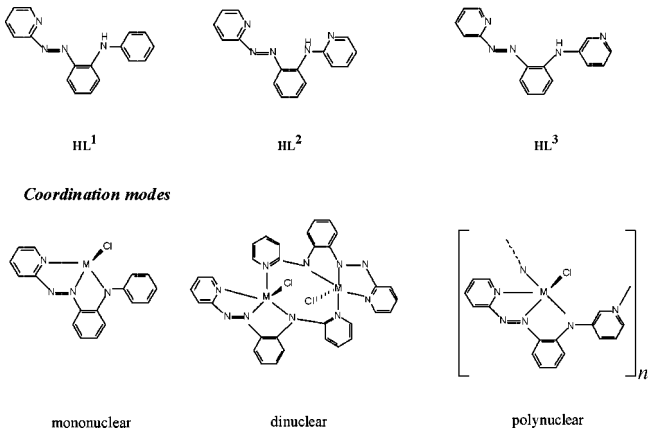
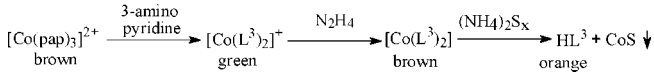
These polymers form different-sized particles (micrometer to nanometer) at different time intervals under identical experimental conditions. Their growth processes have been followed by FESEM, TEM, HRTEM, XRPD, EDS and single-crystal X-ray data analysis of the frameworks.



## Results and Discussion

The ligand $HL^3$ has been synthesized by regioselective C–N bond fusion of 3-aminopyridine to cobalt(II)-coordinated 2-(phenylazo)pyridine following the reaction strategy developed by us[10a] (Scheme 1).



Scheme 1.

The green cobalt complex $[Co(L^3)_2]ClO_4$ was purified on a preparative TLC (silica gel) plate by using a chloroform/toluene (1:1) solvent mixture as eluent and was characterized spectroscopically. Its $^1H$ NMR spectrum is submitted as Figure S1 Supporting Information. Reduction of the cationic cobalt complex by dilute $N_2H_4$ followed by removal of $[Co]^{2+}$ as CoS led to the isolation of the ligand $[HL^3]$ in moderate yield. The pure ligand was obtained as a yellow crystalline solid, whose ESI-MS spectrum shows an intense peak at $m/z$ = 276 amu assigned to the $[H_2L^3]^+$ ion (Figure S2, Supporting Information). The $^1H$ and $^{13}C$ NMR spectra of the ligand $[HL^3]$ (Figures S3 and S4, Supporting Information) corroborate fully with its formulation. The deprotonated ligand $[L^3]^-$ (generated in situ by addition of $NEt_3$) reacts spontaneously with the methanolic/aqueous solutions of $MCl_2$ (M = Zn, Hg) at room temperature. The dark green compounds, thus produced, are rapidly precipitated. However, by controlled layering of the deprotonated ligand solution over the solutions of metal salts, we could achieve the synthesis of stable particles of the reference metal–organic polymers. It may be noted here that the salt $CdCl_2$ failed to produce any stable compound under identical experimental conditions. Chemical compositions of the polymers were established on the basis of their elemental analyses. Both are pentacoordinate and have identical repeating units $[MCl(L^3)]$. Notably, the morphology and the growth process of the mercury polymer are totally different from those of the zinc analogue. The growth processes of the two products are detailed separately.

### Hg–$L^3$ Polymer

For the evaluation of the crystalline mercury coordination polymer, the synthetic reactions were carried out in

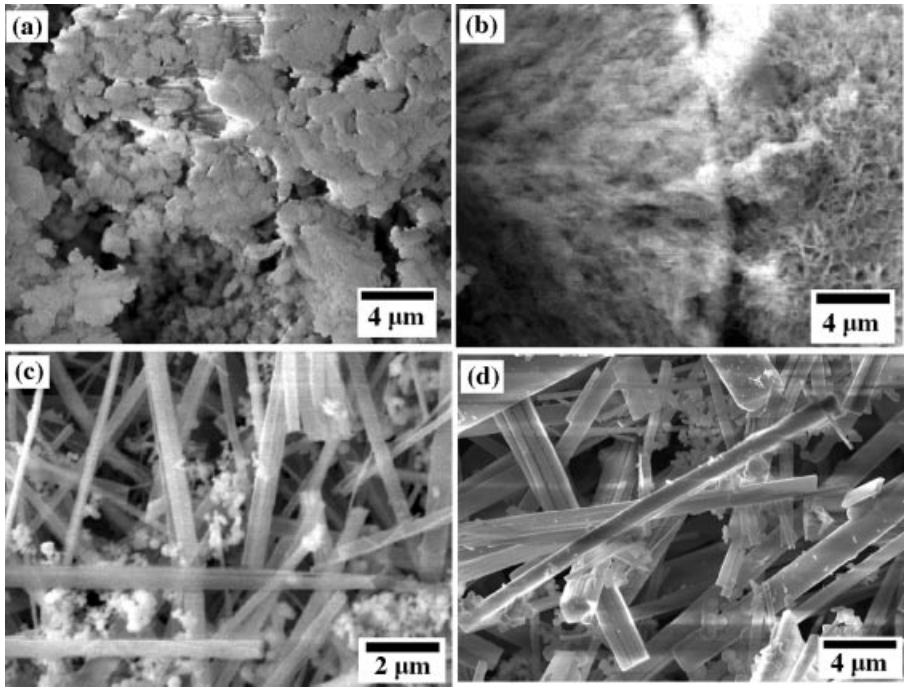


Figure 1. FESEM images of the $[HgClL^3]_\infty$ polymer at different time intervals: (a) 5 h, (b) 36 h, (c) 5 d, (d) 10 d.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

five sealed glass tubes (A–E) under the same experimental conditions but with varying reaction times. A deprotonated methanolic solution of the ligand was layered over an aqueous solution of mercuric chloride and left undisturbed for diffusion (see Experimental Section). Figure 1a–d shows the SEM images of the as-synthesized products. It reveals the following features: (i) The product obtained from the tube A (after 5 h) is amorphous (Figure 1a); (ii) The SEM image (Figure 1b) of the second sample (tube B, after 36 h) reveals fine wirelike morphology; (iii) The SEM shown in Figure 1c is obtained from the third sample (tube C, after 5 d) and indicates the formation of nano-ribbonlike morphology. The width of these ribbons varies from a few nm to 500 nm, and their lengths lie within a few tens of micrometers. The facets of these ribbons are not well defined, which is an indication of their poor crystallinity; (iv) Interestingly, the fourth sample (tube D, after 10 d) is composed of well-defined microribbons (Figure 1d); and (v) X-ray-quality single crystals are obtained from tube E after 3 weeks and their X-ray structures are analyzed (vide infra).

For understanding the growth mechanism, we also investigated these samples by transmission electron microscopy (TEM). The first product is a featureless amorphous spherical compound, and the second is wirelike. The fourth sample (tube D) is quite thick for TEM measurement, and the electron beam failed to penetrate through it. Fairly interesting micrographs are obtained from the third sample (tube C). Figure 2a shows the TEM image of a single ribbonlike morphology. Closer observation of the image reveals the presence of large quantities of spherical particles embedded within the structure. Figure 2b shows the magnified TEM image of a ribbon, which indicates the presence of a large number of dark, spherical nanoparticles. The TEM image in Figure 2d reveals the presence of a large number of spherical nanoparticles of the polynuclear mercury sample **1** with diameters that vary between 10 and 30 nm. Some grain agglomeration is also observed in this image and is indicated by arrows. It is also interesting to note, from the TEM images, the layered nature of the agglomerated particles, which can perhaps explain the reason for the rapid increase in the dimension of the products. Thus, on the basis of the SEM and TEM observations we can conclude that the crystalline metal–organic framework (MOF) is produced in four steps. The first step is the formation of amorphous nucleation centres, followed by formation of the one-dimensional amorphous framework; the amorphous nature is also evident from its featureless powder XRD pattern (Figure S5, samples of Figure 1a and b). The nanocrystalline particles act as the nucleation sites (thus formed within the amorphous network), absorb more reactants from the solution and agglomerate with each other to grow in one-dimension to form fine wire- or ribbonlike products. In the final step these products crystallize to yield large whiskerlike single crystals. This is as expected since the amorphous products are high-energy systems[16] and have a natural tendency to minimize their energy by crystallization. Larger single-crystalline products are achieved if the reaction is allowed to take place for 3 weeks or more.

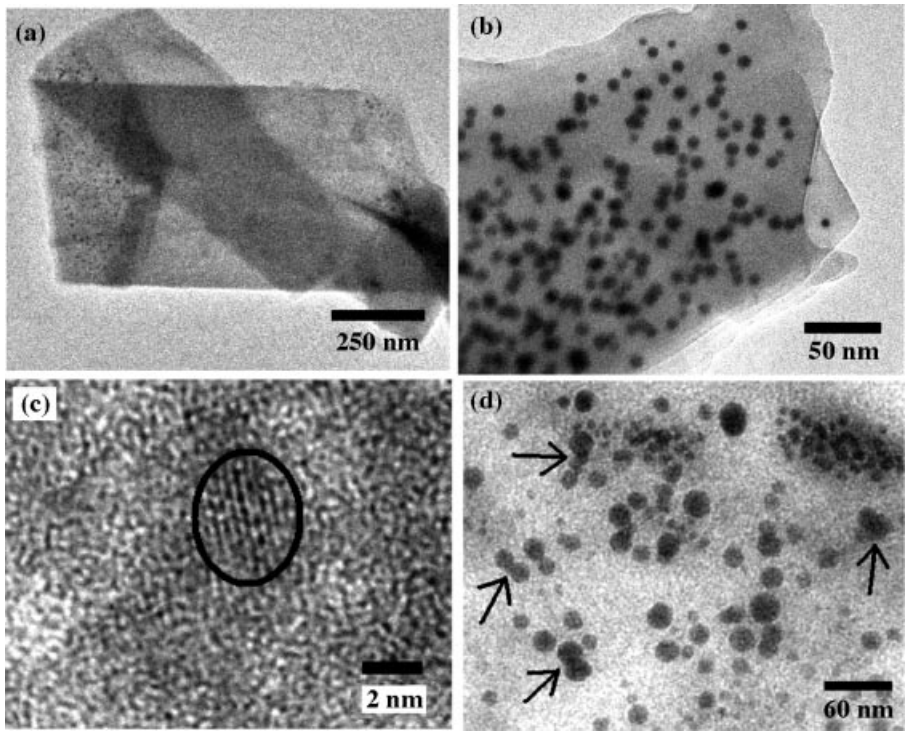

Figure 2. (a) TEM image of the single ribbonlike products of $[HgClL^3]_\infty$. (b) Zoomed TEM image showing spherical nanoparticles of Hg containing MOF. (c) Representative zoomed HRTEM image of a single metal–ligand nanoparticle. (d) Arrows indicating the agglomeration of the particles.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

We examined the XRPD pattern for all the samples obtained from the aforementioned five tubes (A–E). The sample from tube A exhibits a featureless XRPD pattern, which implies that it is amorphous. However, experimental XRPD patterns of the samples from the three tubes (B–D) are similar and consistent with the simulated pattern derived from the single-crystal (tube E). Thus, we conclude that the bulk sample has the same structure as that of the single crystal. The experimental powder diffraction pattern of a representative sample (tube C), along with the simulated pattern, are shown in Figure 3 for comparison. Furthermore, microelemental analyses of the above mercury samples reveal that they have an identical composition, [HgCl($L^3$)], which was further supported by energy dispersive spectroscopy (EDS) (Figures S6 and S7).

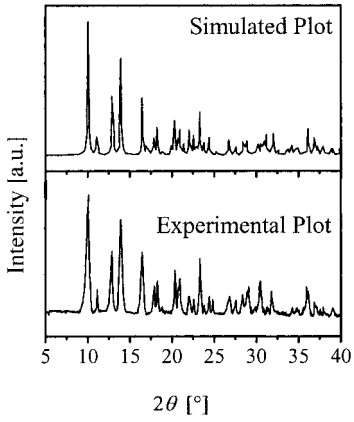

Figure 3. Experimental and simulated XRPD patterns of the as-synthesized mercury polymer $[HgClL^3]_\infty$.

### Zn–$L^3$ Polymer

The results obtained in this case were notably different from that of its mercury analogue. Here, two types of micrometer-sized particles are identified. The SEM image of the products obtained after 1 d reaction time shows the formation of large numbers of nanorods bundled together (Figure 4a). With time, these particles grow in one direction, and the basal region crystals penetrate through each other and agglomerate to form large microcrystals. As these particles grow on the tube walls they cannot form spheres, instead hemispherical particles are isolated (Figure 4b). The SEM image of a hemispherical single unit (after 6 d) is shown in Figure 4c, and a further magnified image of it is displayed in Figure 4d. This reveals that the individual basic units with pyramidal tips interpenetrate[16] to form the hemispherical particles. Figure 4e shows the broken basal region of a hemispherical crystal that indicates agglomeration[17] of closely packed individual units. No suitable single crystal of this sample could be isolated in this case, possibly because of fast agglomeration, although the powder diffraction pattern indicates a crystalline nature (Figure 5). The Zn samples are too thick for TEM measurements; however, high resolution transmission electron microscopy

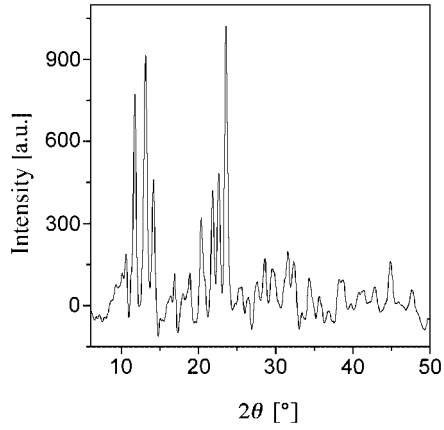

Figure 5. XRPD pattern of the polycrystalline polymer $[ZnClL^3{\cdot}3H_2O]_\infty$.

(HRTEM) on the crushed sample reveals that these particles are crystalline with a highly ordered arrangement of the micropores (Figure 6). Microelemental analyses on the Zn samples indicate that their compositions are similar to those of the mercury analogues, with the exception that the Zn polymer contains three $H_2O$ molecules of crystallization per formula weight ($[ZnCl(L^3)]\cdot 3H_2O$) of the repetitive building unit (TG analysis, vide infra). Energy dispersive spectra of these samples (Figures S8a and S8b) also corroborate the above formulation.

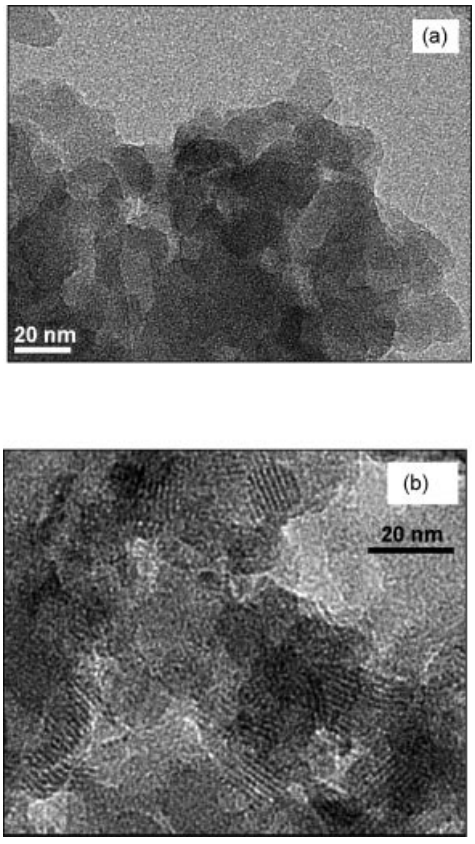

Figure 6. HRTEM images of the as-synthesized $[ZnClL^3\cdot 3H_2O]_\infty$ polymer: (a) low magnification, (b) high magnification.

### Crystal Structure of $[HgCl(L^3)]_\infty$ (1)

The three-dimensional structure of the mercury complex (sample obtained from tube E) was determined by single-crystal X-ray diffraction. In this structure, two 1D infinite polymeric chains made of $[HgCl(L^3)]_\infty$ units run antiparalelly along the *a* axis.[18] As shown in Figure 7, each mercury atom in this molecule is in a pentacoordinated $N_4Cl$ environment, and the geometry around each $Hg^{II}$ ion may be described as distorted square pyramidal[19] with a $\tau$ value of 0.21. In this context, we note that higher-coordination-number (>4) complexes of divalent mercury[20] are scarce in the literature. In the molecule **1**, Hg(1) sits above the plane formed by the three coordinating nitrogen atoms, N(1), N(3) and N(4), by 0.0464(1) Å; this pattern is repeated throughout the polymeric chain. The bending of the ligand and its coordination at the Hg centre result in *zigzag* chains that adopt a saw-tooth-like structure (Figure 8a). The two independent polymeric chains are closely packed/locked through metal–pi interactions[21a] along with face-to-face π–π ring interactions.[21b] Notably, the metal–pi interactions predominate over the π–π interactions. For example, the perpendicular distance between the centroids of the two interacting polymeric chains lies between 3.44 and 3.45 Å, whereas the distance between the Hg metal and centroid (Cg) lies in the range 3.37–3.41 Å. Selected bond lengths and angles, and the crystallographic data for the crystal $[HgCl(L^3)]_\infty$ are collected in Table 1 and Table 2, respectively. The secondary interactions in this structure (Figure 8b) work together to bring the two consecutive chains close together (Table 3 and Table 4). Notably, the closest distances between the two mercury atoms (both inter- and intramolecular) are quite long: intramolecular Hg(1)···Hg(1a) and Hg(2)···Hg(2a) distances are 6.243 Å and 6.307 Å, respectively, which are appreciably longer than the sum of the van der Waals radii[12c,22] between two consecutive mercury atoms (3.50 Å). The distance between two mercury atoms to complete one pitch [irrespective of Hg(1) or Hg(2)] is 10.145 Å. The Hg–π and π–π interactions are depicted in Figure 8b. For comparison, we wish to note that the ligand $HL^2$ reacts with $HgCl_2$ to produce the soluble dinuclear mercury(II) blue complex, in which the two $[L^2]^-$ ligands bridge the two mercury centres.[12c]

### Spectral Properties

Infrared spectra of the two polymeric complexes $[MClL^3]_\infty$ (M = Hg, Zn) are almost identical, and $\tilde{\nu}_{C=N}$ and $\tilde{\nu}_{N=N}$ appear[12] in the range 1585–1600 $cm^{-1}$ and 1305–1325 $cm^{-1}$, respectively. These complexes also show characteristic $\tilde{\nu}_{M-Cl}$ bands that appear[12] near 275 $cm^{-1}$. Both complexes are insoluble in common organic solvents, and their UV/Vis spectra in the solid state were studied. The lowest-energy transition in free $[L^3]^-$ (460 nm) is redshifted considerably by ca. 200 nm in the corresponding metal complexes. Whereas the mercury complex shows a broad transition at 660 nm, its zinc analogue absorbs at 675 nm. Notably, examples of $d^{10}$ metal ion complexes that absorb in such a low-energy part of the visible region are uncommon.[12] In order to gain some insight into the nature of the orbitals involved in electronic transitions of the above complexes, semiempirical EHMO calculations on the representative mercury complex $[HgClL^3]_\infty$ was performed with the program CACAO[23] created by Mealli and Proserpio. The calculations were made on the basis of atomic coordinates obtained from the single-crystal X-ray data analysis of compound **1**. The results reveal that HOMO–1, HOMO, LUMO and LUMO+1 all are essentially ligand orbitals with (>90% ligand contribution, see Figure S9). Thus the lowest-energy transitions in the present polymeric complexes are ascribed to electronic transitions within the ligand orbitals (π–π*). Modification of the properties of the ligand orbitals in the present examples is due to increased

planarity of the ligand and also to extensive charge delocalization along the ligand backbone. A similar type of finding was reported recently on the $Zn^{II}$ and $Cd^{II}$ complexes[24,25] of heterocyclic ligands. In such systems, heteroatoms decrease the π and π* orbital energies considerably, and as a result, the HOMO and LUMO lack contribution from the metal atoms. In addition, multiple electronic transitions are

also noted in the high-energy region. Spectral data of **1** and **2** are presented in the Experimental Section, and the spectra are shown in Figure 9.

The emission properties of the complexes were studied in the solid state at room temperature. The emission spectra are found to be dependent on the excitation wavelength. For example, the mercury complex **1** shows a relatively weak emission band at 690 nm upon excitation at 640 nm. Interestingly, multiple blue-green emission bands with maxima at 420, 450 and 485 nm are observed upon excitation at 335 nm, whereas emission bands with maxima at 425 nm and 460 nm are observed upon excitation with the very short wavelength of 235 nm. Multiple emission bands were reported[26] previously in other $d^{10}$ metal complexes. A similar behaviour in the emission spectrum of the corresponding zinc complex is also observed. The emission spectra of the mercury MOF are displayed in Figure 10, whereas the

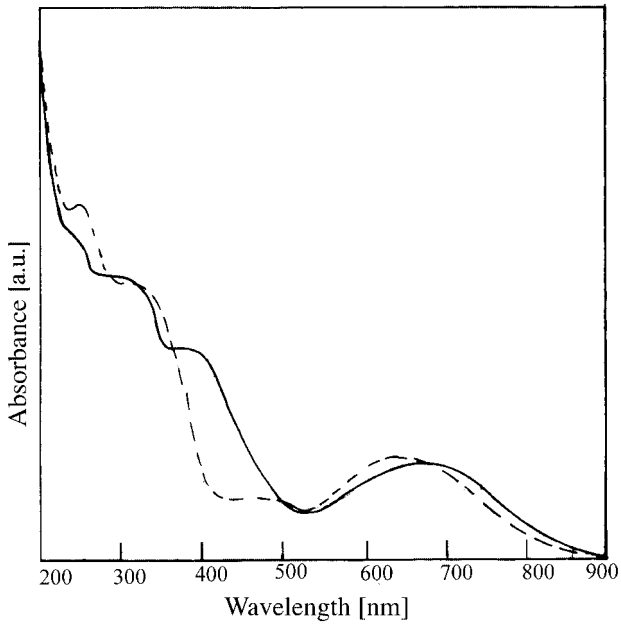

Figure 9. An overlay of UV/Vis spectra for the two MOFs in the solid state: (i) $[HgClL^3]_\infty$ (----), (ii) $[ZnClL^3 \cdot 3H_2O]_\infty$ (−).

emission spectra of its Zn analogue have been submitted as Supporting Information (Figure S10). It should be noted that the ligand [$HL^3$] shows very weak luminescence in the solid state upon excitation at 255 and 335 nm. The photophysical properties of complexes **1** and **2** are unique in the sense that no other reported compound of this and similar azo-aromatic ligands exhibit detectable luminescence. The luminescence properties in these examples thus may be attributed to the[27–28] polymeric nature of the complexes. This imparts rigidity in the ligand framework and thus reduces energy loss through a nonradiative relaxation pathway. In this context, it should be noted that blue-green luminescent coordination complexes have been studied intensively because of their possible applications in material science.[29]

## Sorption Properties

The presence of peaks at low $2\theta$ range in the XRPD pattern of the above polymers suggest that the possible ordering of the building units of these functional materials[30] is similar to that of microporous[31] systems. Whereas the Zn complex indeed shows the moderate ability of adsorption of small molecules like $N_2$ and $H_2$, its $Hg^{II}$ analogue shows poor adsorption ability.

The $N_2$ sorption experiment on the Zn polymer **2** at 77 K suggests a type I isotherm at low $P/P_0$ ratio of $N_2$ that corresponds to the presence of micropores with a BET surface area of 214 m$^2$ g$^{-1}$. Pore size distribution of the sample, obtained by using Horvath–Kawazoe method,[32] is shown in Figure 11. Two broad maxima can be seen at 9.2 and 14.1 Å in the micropore region.The average pore diameter of 9.2 Å can be explained from the low-range $2\theta$ peaks in the powder XRD pattern (Figure 5). The pore diameter of this sample

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

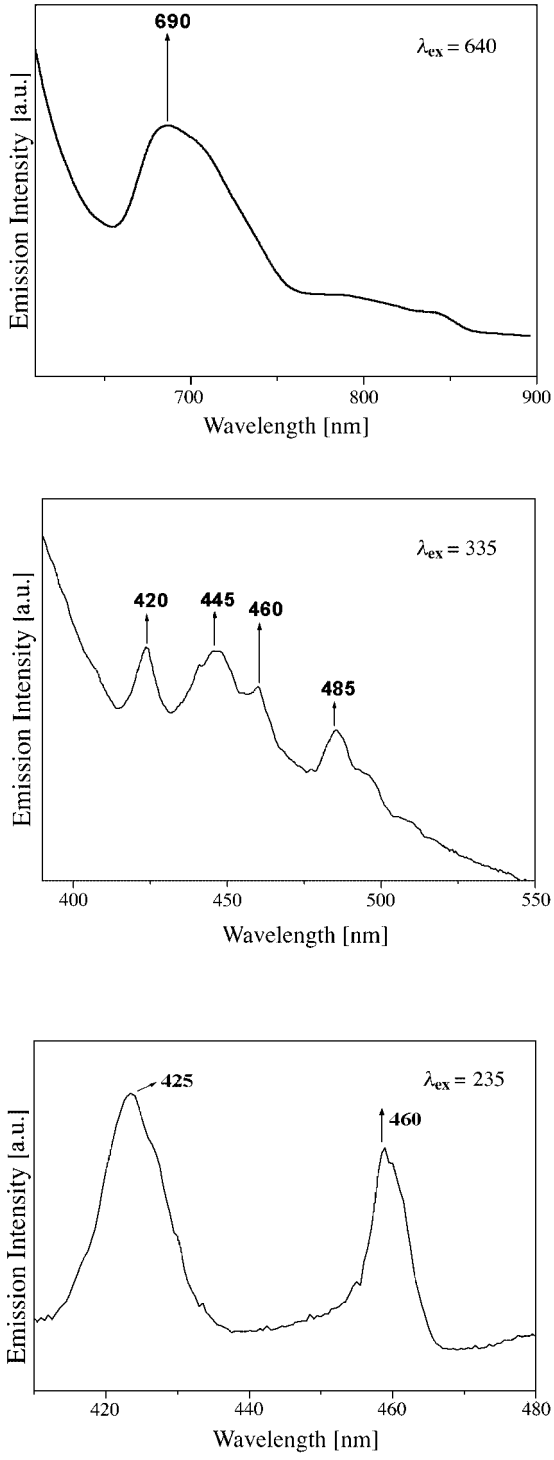

Figure 10. Multiple emission spectra for $[HgClL^3]_\infty$ at different excitation wavelengths.

estimated from the TEM analysis (vide supra) [Figure 6] agrees well with the $N_2$ sorption data. The presence of the peak at a pore diameter of 14.1 Å may be attributed to the large micropores generated at the interparticle cages. We have also carried out $H_2$ sorption on the reference Zn polymer. The $H_2$ adsorption/desorption isotherm at 77 K is shown in Figure 12. The nature of the isotherms suggests complete reversible adsorption and desorption for $H_2$, and a steady increment in the uptake of $H_2$ with increasing pressure.

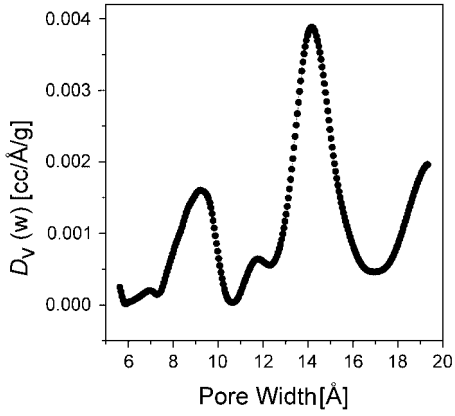

Figure 11. Pore size distribution curve for $[ZnClL^3{\cdot}3H_2O]_\infty$.

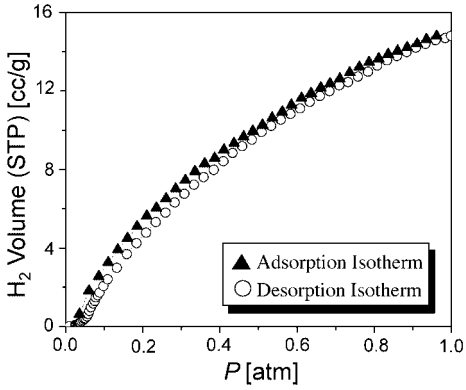

Figure 12. Isotherms for the adsorption and desorption of $H_2$ gas for $[ZnClL^3{\cdot}3H_2O]_\infty$.

The observed BET surface area of the mercury polymer is small, 13.5 $m^2g^{-1}$, and is quite low relative to that of the zinc sample. This indicates that nitrogen gas adsorption occurs primarily at the external surface of the mercury polymer and that the adsorbate nitrogen molecule cannot freely diffuse into the internal channels of this solid, as observed for other microporous solids.[33]

Thermogravimetric (TGA) analyses of samples **1** and **2** were performed to estimate the stability of the complexes at elevated temperatures. Figure S11 in the Supporting Information shows the TGA curves for samples **1** and **2**. The mercury sample **1** is stable only up to 97 °C. A continuous weight loss (>35%) followed by another massive weight loss of (> 50%) are noted in the temperature range 100–225 °C and 225–375 °C, respectively. The weight loss in the temperature range 100–225 °C may be attributed to the loss of the ligand, 2-(phenylazo)pyridine. In comparison, the Zn polymer **2** shows a slow weight loss of 7.2% in the range 25–275 °C, which is attributed to the loss of adsorbed water. Between 275 °C and 325 °C, there are multiple stages of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

weight loss, which amount to 14.4%, presumably due to the loss of water present from the large micropore region. A weight loss of 11.1% in the range 325–370 °C and of 14.0% in the range 370–500 °C, as a result of the collapse of the metal–ligand framework, is observed. We wish to note here that the Zn–$L^3$ framework remains intact up to 325 °C, as evidenced by their near identical XRPD pattern; above this temperature, the network collapses.

## Conclusions

In this work we have described the isolation and characterization of a polymeric network of $Zn^{II}$ and $Hg^{II}$ with a designed azo-aromatic ligand. The gradual growth of the particles of the polymeric materials has been followed by successive product isolation at different time intervals. Unusually, the polymers are blue-green, have five-coordinate metal centres and display emission in the blue-green region of the visible spectrum. The Zn polymer is microporous and its sorption isotherm is reversible. Our work in the area of designing multifunctional azo-aromatic bridging ligands continues.

## Experimental Section

**Materials:** The starting complex $[Co(pap)_3](ClO_4)_2$ was prepared by a reported procedure.[34] The salts $ZnCl_2$ and $HgCl_2$ were obtained from Merck India Limited and Qualigens, respectively. 3-Aminopyridine was obtained from S.D. Fine-chemical Limited. Solvents and chemicals used for synthesis were of analytical grade.

**Physical Measurements:** A JASCO V-570 Spectrophotometer was used to record electronic spectra. The IR spectra were recorded with a Perkin–Elmer 783 spectrophotometer. $^1H$ NMR spectra were measured in $CDCl_3$ with a Bruker Avance DPX 300 spectrometer, and $SiMe_4$ (TMS) was used as the internal standard. A Perkin–Elmer 240C elemental analyzer was used to collect microanalytical data (C, H and N). The compositional analyses were evaluated by energy dispersive spectroscopy (EDS). Microstructures of the nano forms were studied by scanning electron microscopy (SEM, Hitachi S-3200), transmission electron microscopy (TEM) and high resolution transmission electron microscopy (HRTEM, JEOL JEM 2010 TEM at an accelerating voltage of 200 kV). Solid state emission spectra were recorded at room temperature at different excitation wavelengths with a Perkin–Elmer LS 55 Luminescence Spectrometer. ESI mass spectra were recorded on a micromass Q-TOF mass spectrometer (serial no. YA-263). Powder XRD data were recorded on a Seifert 3000P diffractometer, on which small- and wide-angle goniometers were mounted, at 40 kV and 20 mA by using Cu-$K_\alpha$ radiation ($\lambda$ = 1.5406 Å) with a scan speed of 2° $min^{-1}$. Sorption isotherm studies were performed by using a Quantachrome AUTOSORB 1C-TCD sorption instrument at 77 K. Prior to gas adsorption measurements, samples were degassed for 2 h at 100 °C for **1** and at 120 °C for **2** to remove all guest molecules. Thermogravimetric (TGA) analyses for the representative samples were conducted at a scan rate of 5.00 °C $min^{-1}$ by using a Perkin–Elmer DIAMOND TG/DTA thermogravimeter. Melting points were determined with the help of a capillary fitting Mel. Temp. II (Laboratory Devices Inc., USA) apparatus.

**Synthesis of Compounds**

**$HL^3$ Synthesis:** Two steps were involved: (i) *ortho*-amination on $[Co(pap)_3]^{2+}$ followed by (ii) ligand isolation from the cobalt complex.

**Isolation of $[Co(L^3)_2]ClO_4$ from $[Co(pap)_3](ClO_4)_2$:** A mixture of $[Co(pap)_3](ClO_4)_2$ (0.2 g, 0.25 mmol) and 3-aminopyridine (0.1 g, 1.06 mmol) was heated on a steam bath for 7 h. The initial brown colour gradually became intense green. The crude product, which contained mainly the compound $[Co(L^3)_2]ClO_4$, was further purified on a preparative TLC plate (silica gel) with a acetonitrile/chloroform mixture (1:4) as eluent. A yellowish band of unreacted 3-aminopyridine moved first, followed by a major green band of the cobalt compound $[Co(L^3)_2]ClO_4$. The major green band was collected and was thoroughly washed with diethyl ether. Crystalline pure green $[Co(L^3)_2]ClO_4$ was obtained from a dichloromethane/hexane mixture. Yield: 0.125 g, 70%. ESI-MS: $m/z$ = 607.15 [M – $ClO_4^-$]. $C_{32}H_{24}ClCoN_{10}O_4$ (706.93): calcd. C 54.36, H 3.42, N 19.81; found C 54.40, H 3.40, N, 19.75. IR (KBr): $\tilde{\nu}$ = 1600 (s) [C=N], 1325 (vs) [N=N], 1085 (s), 620 (s) [$ClO_4^-$] $cm^{-1}$. UV/Vis (in dichloromethane, $\lambda_{max}$): 315, 400, 720, 790, 880 nm.

**Isolation of [3-(2-Pyridylamino)phenyl]azopyridine ($HL^3$) from $[Co(L^3)_2]ClO_4$:** The cobalt complex $[Co(L^3)_2]ClO_4$ (0.15 g, 0.21 mmol) was dissolved in ethanol (30 mL), and hydrazine hydrate (5 mL) and yellow ammonium sulfide (5 mL) were added. The mixture was then stirred for 30 min at room temperature. The resulting orange-yellow solution was evaporated to dryness, and the product was extracted with dichloromethane and loaded on a preparative TLC plate (silica gel) for purification. An orange-yellow band was eluted with a toluene/chloroform mixture (2:1), which on evaporation yielded orange crystals of $HL^3$. Yield: 0.075 g, 65%. M.p. 98 °C. ESI-MS: $m/z$ = 276.10. p$K_a$ = 8.7±0.1. $C_{16}H_{13}N_5$ (275.28): calcd. C 69.81, H 4.75, N 25.44; found. C 69.75, H 4.80, N 25.40. IR (KBr): $\tilde{\nu}$ = 1585 (s) [C=N], 1315 (vs) [N=N) $cm^{-1}$. UV/Vis (solid, $\lambda_{max}$): 255, 335, 460 nm.

**Polynuclear Mercury(II) Complex $[HgClL^3]_\infty$ (1):** In a long neck crystal tube, an aqueous solution (5 mL) containing $HgCl_2$ (100 mg, 0.365 mmol), water (2 mL) and a methanolic solution of a mixture of $HL^3$ (100 mg, 0.365 mmol) and of $NEt_3$ (2 drops) were layered gradually in the above order. In between the water and methanol solvent layer, a green ring formed almost immediately. The tube was stoppered and left undisturbed at room temperature. Slow diffusion between the two solutions afforded dark green crystals of complex **1** after 3 weeks. Yield: 0.130 g, 70%. $C_{16}H_{12}ClHgN_5$ (510.32): calcd. C 37.66, H 2.37, N 13.72; found C 37.65, H 2.39, N 13.67. IR (KBr): $\tilde{\nu}$ = 1590 (s) [C=N], 1300 (vs) [N=N] $cm^{-1}$. UV/Vis (solid, $\lambda_{max}$): 245, 345, 500, 660 nm.

The growth process of the mercury particles was followed by carrying out the synthetic reaction in five sealed tubes (A–E) by using an identical reaction mixture as stated above but by varying the reaction time. The samples were collected after 5 h, 36 h, 5 d, 10 d and 21 d.

**Polynuclear Zinc(II) Complex $[ZnClL^3 \cdot 3H_2O]_\infty$ (2):** In a long neck crystal tube, the deprotonated methanolic ligand solution of $[L^3]^-$ (100 mg, 0.365 mmol) was layered over a methanolic solution of $ZnCl_2$ (50 mg, 0.365 mmol). The tube was stoppered and left undisturbed at room temperature. A dark polycrystalline complex of the zinc polymer was isolated from the tube after 6 d. Yield: 0.125 g, 80%. $C_{16}H_{18}ClN_5O_3Zn$ (429.16): calcd. C 44.77, H 4.22, N 16.31; found C 44.70, H 4.22, N 16.26. IR (KBr): $\tilde{\nu}$ = 1595 (s) [C=N], 1310 (vs) [N=N], 3440 (s) [$H_2O$] $cm^{-1}$. UV/Vis (solid, $\lambda_{max}$): 255, 335, 380, 675 nm.

**X-ray Crystallography:** Crystallographic data for compound **1** is collected in Table 2. Specific details are given below.

**$[HgClL^3]_\infty$ (1):** Suitable X-ray quality crystals ($0.20 \times 0.10 \times 0.02$ mm) of $[HgClL^3]_\infty$ (**1**) were obtained by layering an aqueous solution of $HgCl_2$ over an aqueous solution of the deprotonated ligand $[L^3]^-$ in a crystal tube, as described above. Suitable crystals were obtained after 3 weeks from the tube. X-ray data were collected on a Bruker SMART diffractometer equipped with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and were corrected for Lorentz-polarisation effects. A total of 29113 reflections were collected, of which 7341 were unique ($R_{int}$ = 0.0990) and were used in subsequent analysis. The structure was solved by employing the SHELXS-97 program package[35a,35b] and refined by full-matrix least-squares based on $F^2$ (SHELXL-97).[35c] Crystallographic graphics were obtained by using the programs ORTEP[36] and PLATON.[37] CCDC-621241 (for **1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): ESI-MS spectrum of ligand $[H_2L^3]^+$, $^1$H- and $^{13}$C NMR spectra for $HL^3$ and $[Co(L^3)_2]^+$, powder X-ray diffraction analysis for amorphous complex **1**, photoluminescence spectra for complex **2**, energy dispersive spectra for complexes **1** and **2**, semiempirical EHMO calculation of complex **1**, and TGA curve for complexes **1** and **2** are available.

## Acknowledgments

the type $[M(L^3)_2]^{n+}$, where the 3-pyridyl nitrogen atom of the ligand remains[15] uncoordinated. There are strong indications that suggest that these complexes might be useful building blocks for the construction of heterometallic systems.

# A New Chloro-Bridged $Cu^{II}$ Schiff Base Complex with Ferromagnetic Exchange Interaction

**Shu-Lan Ma,[a] Xu-Xia Sun,[a] Song Gao,[b] Chuan-Min Qi,*[a] Hai-Bo Huang,[a] and Wen-Xiang Zhu[a]**

**Keywords:** Copper / Schiff bases / Dinuclear complex / Crystal structure / Magnetic properties

The synthesis and characterization of the μ-Cl-bridged dinuclear complex $[CuLCl]_2$ with the new Schiff-base ligand HL, 2-methyl-6-[(pyridine-2-ylmethylene)amino]phenol, is reported. The structural study shows the complex has the unusual distorted trigonal-bipyramidal geometry. Variable temperature susceptibility measurements in the range of 2.0–300 K reveal a novel ferromagnetic coupling, $2J = 1.52\ cm^{-1}$. A comparison for the magnetic coupling of $[CuLCl]_2$ with other reported $Cu(\mu\text{-}Cl)_2Cu$ compounds with square-pyramidal or trigonal-bipyramidal geometry is discussed in detail. The complex may provide useful information for the magneto-structural correlations of these compounds.

## Introduction

Recently, chemists as well as physicists have concentrated their efforts on the study of multinuclear molecular-based magnetic materials so as to understand the magnetic interactions between the paramagnetic metal ions and the bridging ligands to develop the magneto-structural correlations enabling the design of interesting magnetic materials.[1] The exchange coupling between the spins of unpaired electrons on metal atoms in polynuclear compounds is termed ferro- or antiferromagnetism, depending upon whether the individual spins in the ground state show a parallel or antiparallel alignment. The construction of molecular-based magnetic materials with ferromagnetic ordering is a major challenge. The relative simplicity of dinuclear systems has permitted the proposal of some magneto-structural correlations that are very useful for predicting magnetic properties of new compounds.

A good degree of success has been accomplished in correlating structure and magnetic properties for dihydroxo-bridged dinuclear copper complexes,[2] but no unique magneto-structural correlation has been found for dichloro-bridged dinuclear copper complexes. Different magnetic behavior has been found in these systems and great difficulties remain in establishing a magneto-structural correlation due to the much larger structural variety.[3] Further investigations into the magneto-structural correlation of dichloro-bridged $Cu^{II}$ dimers seem necessary.

We synthesize the tridentate Schiff-base ligand HL {2-methyl-6-[(pyridine-2-ylmethylene)amino]phenol} containing one pyridine ring and one phenolic ring, from which the dichloro-bridged copper dimer $[CuLCl]_2$ is obtained. The complex provides unique trigonal-bipyramidal geometry and exhibits unusual ferromagnetic interaction.

## Results and Discussion

### UV Spectra

The UV-visible spectroscopic data for the ligand and the complex were studied in MeOH. HL exhibits three maxima centered at 289, 361, and 442 nm while $[CuLCl]_2$ shows three maxima at 281, 357, and 506 nm. The absorption bands at 200–400 nm in $[CuLCl]_2$ may correspond to the ligand-centered π-π* transitions, and the band at 506 nm may correspond to the ligand-to-metal charge transfer transition. The shifts and the new absorptions may account for the coordination.

### Description of Structure

The crystal structure of $[CuLCl]_2$ is shown in Figure 1. Selected bond lengths and bond angles are listed in Table 1. Besides $Cl^-$ bridges, the coordination sites of $Cu^{II}$ are the $N_{imine}$, $N_{py}$, and the deprotonated phenolate oxygen $O_{pheno}$ from the Schiff-base ligand. The distortion parameter $\tau$[4] of 0.448 (near to 0.50) in $[CuLCl]_2$ indicates that the geometry may be described as either a distorted square-pyramid

(SP) or a trigonal-bipyramid (TBP), which resembles other dimers ($\tau$ is 0.487, 0.485, and 0.455, respectively).[3b,5] In the TBP geometry for $[CuLCl]_2$, the apical sites are occupied by O1 and N2, with Cl1, Cl1A, and N1 making up the equatorial plane. The $Cu^{II}$ ion sits 0.043 Å apart from the plane, and the apical O1 and N2 are located –1.954 and 1.955 Å on either side. If the geometry is viewed as a SP, the axial ligand is Cl1A and the basal ones consist of N1, N2, O1, and Cl1, with $Cu^{II}$ sitting 0.455 Å from the plane. The bond angles for two idealized five-coordinate geometries are listed in Table 1. The distortion from ideal TBP geometry is observed in equatorial bond angles of 90.77, 132.34, and 136.77°, showing deviation from ideal 120° angles. The distortion from an ideal SP is much more obvious in the angles of 136.77° for N1–Cu1–Cl1 and 132.34° for N1–Cu1–Cl1A, showing significant deviation from the ideal angles of 180 and 90°, respectively. So this system is much more readily described as a distorted TBP. The bridging $Cu_2Cl_2$ unit is constrained to be planar by the presence of the crystallographic center. The Cu–Cl–Cu angle of 89.23° is slightly shorter than the average 89.40° and the Cu–Cu distance of 3.424 Å is in agreement with the average value for 188 chloro-bridged copper(II) dimers (3.499 Å) in CSD. The two Cu–Cl bridging distances of 2.444 and 2.430 Å fall into the range between 2.309 Å (short)[6] and 2.554 Å (long)[7] for five-coordinate copper(II) complexes.

## Magnetic Properties

Variable temperature magnetic susceptibility on $[CuLCl]_2$ was measured in the range 2.0–300 K (Figure 2). At room temperature $\chi_m T$ is 0.88 $cm^3 mol^{-1} K$, which is slightly higher than the expected value 0.75 $cm^3 mol^{-1}$ K for two uncoupled spin-only $Cu^{II}$ ions ($S = 1/2$, $g = 2$). Upon cooling from room temperature, $\chi_m T$ increases very smoothly increasing continuously below 20 K, and reaching a value of 0.99 $cm^3 mol^{-1}$ K near to 2.0 K. The $\chi_m^{-1}$ vs. $T$ plot is essentially linear, and least-squares fitting of the data to the Curie–Weiss law gave $C = 0.88$ $cm^3 mol^{-1}$ K and $\theta = +0.52$ K. The increase of $\chi_m T$ upon cooling, and the small positive Weiss constant indicates that there exists a weak but unquestionably ferromagnetic coupling between two $Cu^{II}$ ions. The magnetization measured at 2.00 K increases with the field, and reaches 2.02 $N\beta$ per $Cu_2$ at 50 kOe, slightly higher than the expected saturation value of 2 $N\beta$ for two spin-only $Cu^{II}$ ions with $S = 1/2$, $g = 2.0$. The expression of the molar susceptibility $\chi_m$ is presented by the following Bleaney–Bowers equation:

$$\chi_m = 2Ng^2\beta^2/kT\cdot[3 + \exp(-2J/kT)]^{-1}$$

The best fitting for the experiment data leads to the parameters $g = 2.17$ and $2J = 1.52$ $cm^{-1}$. The agreement factor $R$, defined as $\Sigma(\chi_m T_{obs} - \chi_m T_{calc})^2/\Sigma(\chi_m T_{obs})^2$, is equal to $4.26\cdot10^{-4}$. The solid line in Figure 2 corresponds to the best theoretical fit.

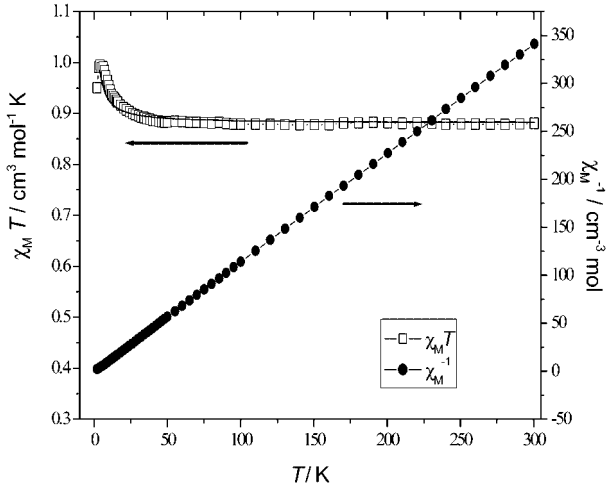

Figure 2. The plot of temperature dependence of $\chi_m^{-1}$ (●) and $\chi_m T$ (□) of complex $[CuLCl]_2$ measured at 1000 Oe. The solid line represents the best fit of the experimental data as discussed in the text.

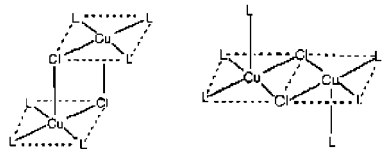
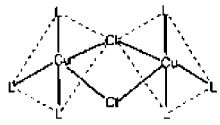
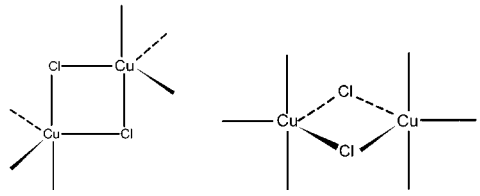
The sign and magnitude of the coupling constant $2J$ for pentacoordinate $Cu(\mu\text{-}Cl)_2Cu$ dimers depend mainly on the Cu–Cl–Cu bridging angle $\varphi$, the Cu–Cl distance, the nature of the terminal ligands, and the distortions of the coordination geometry.[8] The SP geometry for these dimers is the usual one, but a distortion toward TBP can exist. Three different SP geometries have been experimentally characterized: square pyramids sharing a base-to-apex edge with parallel basal planes (SP I), square pyramids sharing a basal edge with coplanar basal planes (SP II), and square pyramids that also share a base-to-apex edge, but with perpendicular basal planes (SP III). For the less common TBP geometry, two types are formed: TBP I is formed by sharing an edge joining the axial and equatorial chloride atoms (axial-equatorial dimer) while TBP II is formed by sharing an edge joining two equatorial chloride ligands (equatorial-equatorial dimer). For reason of contrast, the SP I,[3c,9] SP II,[10] SP III[3d] compounds with ferromagnetic coupling, and the TBP I[3a,3b,5,11] and TBP II[12] compounds known so far with ferromagnetic or antiferromagnetic coupling, are listed in Table 2. The SP I compounds usually show small ferromagnetic[3c,9] or antiferromagnetic coupling constants,[13] and those of SP II show antiferromagnetic behavior when halide ions are present in the terminal ligands[14] and ferromagnetic behavior in the presence of N-donors.[10] The only SP III compound known so far presents ferromagnetic coupling ($2J$ = +85.88 $cm^{-1}$).[3d] The TBP I compounds usually exhibit antiferromagnetic behavior[3a,3b,5b,11] while TBP II compounds (only two examples) often show ferromagnetic behavior.[12]







The values of Cu–Cl–Cu angle $\varphi$ in TBP I complexes are always obtuse and as shown in Table 2 (structures **10**–**15**) are close to 95° (from 94.8 to 97.9°). While the $\varphi$ values in TBP II geometries are always lower than 90°, and for the two compounds **16** and **17** they are in the range 81.8–89.3°.[12] The $2J$ obtained from the TBP complexes in

Table 2 including our present $[CuLCl]_2$ are consistent with the 90° angle rule[15] that the coupling is ferromagnetic for the $\varphi$ value near to 90° and antiferromagnetic for that diverging from 90°. The $\varphi$ values of 89.3 and 89.1° in **16** and **17**[12] and 89.23° in the present work are fairly close to 90°, and that induces their ferromagnetic coupling ($2J > 0$). TBP I compounds **12**–**15** have $\varphi$ values with a larger divergence from 90°, and hence antiferromagnetic interactions occur ($2J < 0$). Because the ferromagnetic coupling may increase when the Cu–Cl bridging distance decreases,[8b] the stronger ferromagnetic interaction in **11** may be thanks to its shorter Cu–Cl bridging bonds (2.330 Å) though with a large $\varphi$ value (94.9°). Another compound, $[(terpy)CuCl]_2[PF_6]_2$, has a $\varphi$ value near to 90° (89.9°)[13a] but shows antiferromagnetic coupling ($2J = -2.32$ cm$^{-1}$). The longer Cu–Cl bridging distance of 2.72 Å and the SP geometry may induce its antiferromagnetic behavior.

The bridge angle can determine the sign of the exchange-coupling constant, and the bond length in the superexchange pathway may inflect the magnitude of $2J$. Hatfield and co-workers have proposed an empirical correlation between $2J$ and the $\varphi/R_0$ ratio in $Cu(\mu\text{-}Cl)_2Cu$ complexes,[3b,16] where $R_0$ is the (longer) axial Cu–Cl bridging distance in the SP geometry while representing the equatorial distance in the TBP geometry.[3b] They found that for a value of $\varphi/R_0$ lower than 32.6 or higher than 34.8 [°/Å] the exchange interaction is antiferromagnetic and for values falling between these limits the interactions are ferromagnetic. Their analysis was predominantly for the SP I and TBP I systems involving the axial-equatorial dimers.[3b] From Table 2 we can see that most of the compounds with SP I and TBP I geometries are consistent with this correlation. The structures of TBP II complexes **16** and **17** are complicated by the presence of two crystallographically independent dimers in **16** and two nonequivalent Cu–Cl–Cu bridges in **17**, so we can only use the mean $\varphi/R_0$ ratios (33.77 for **16** and 33.90 for **17**). According to the mean $\varphi/R_0$ ratios, their magnetic coupling also fits the prediction of the correlation between $2J$ and $\varphi/R_0$. Our present complex $[CuLCl]_2$ has a relative simple and sterling structure and has an $\varphi/R_0$ value of 36.50, and it shows ferromagnetic coupling, which does not fit the trend of Hatfield's analysis. This may result from its unique geometry distortion. We can not substantiate the magneto-structural correlation due to the very sparse number of examples of this kind of TBP II complexes.

The unpaired spin should lie predominantly in the $d_{x^2-y^2}$ orbital in the SP geometry, and in the $d_{z^2}$ orbital in the TBP geometry.[3b,12c,17] But for the axial-equatorial SP I and TBP I dimers, this distinction is unnecessary, since they are interconvertible by a single angular deformation. Thus, they may be viewed as belonging to the same structural type and their magnetic properties can be compared directly as in the correlation between $2J$ and $\varphi/R_0$ by Hatfield.[3b] This statement is restricted to SP I and TBP I complexes, since the deformation would not transform SP I to the equatorial-equatorial TBP II dimer. An extended Hückel molecular orbital calculation for the TBP II compound **17** revealed that its occupied molecular orbitals were located mainly in the $d_{z^2}$ orbitals.[12c] Therefore, the relative orientation of the metallic part of the magnetic orbitals of our present complex may be represented as depicted in Figure 3. The distortion from SP to TBP induced a change in the $d_{Cu}$ metal orbital from $d_{x^2-y^2}$ to $d_{z^2}$, and an effective overlap occurs between two Cu centers, leading to the increase of the ferromagnetic contribution for $[CuLCl]_2$.[3a,8a,13a]

Another interesting structural feature for $[CuLCl]_2$ is that its $Cu_2Cl_2$ bridging unit is nearly a square (the two Cu–Cl bridging bonds are 2.444 and 2.430 Å, and the Cu–Cl–Cu′ and Cl–Cu–Cl′ angles are 89.23 and 90.77°, respectively), which is not observed in other known $Cu(\mu\text{-}Cl)_2Cu$ complexes. There are three complexes containing near Cu–Cl bridging bonds: $[KCuCl_3]_2$ (2.314, 2.322 Å),[18] $[(iPrNH_3)(CuCl_3)]_2$ (2.301, 2.315 Å),[14b] and $[CuCl(hpba_3)]_2$ (2.306, 2.316 Å).[10] But they all adopt the SP II geometries, have bridging angles diverging considerably from 90° (95.9, 95.4, and 94.51°), and exhibit divergent magnetic interaction ($2J$ = –38.23, –19.46, and +33.7 cm$^{-1}$, respectively). When $2J$ values of these complexes were plotted against $\varphi$, the points fell nearly in a straight line of slope –48.6 [cm$^{-1}$/°] and passed through $2J = 0$ at 95.1°.[8a,10] $[CuLCl]_2$ is not placed close to the line, which may be due to its unique TBP geometry.

Many chloro-bridged $Cu^{II}$ dimers use $Cl^-$ as terminal ligands, and a change from antiferromagnetic to ferromag-

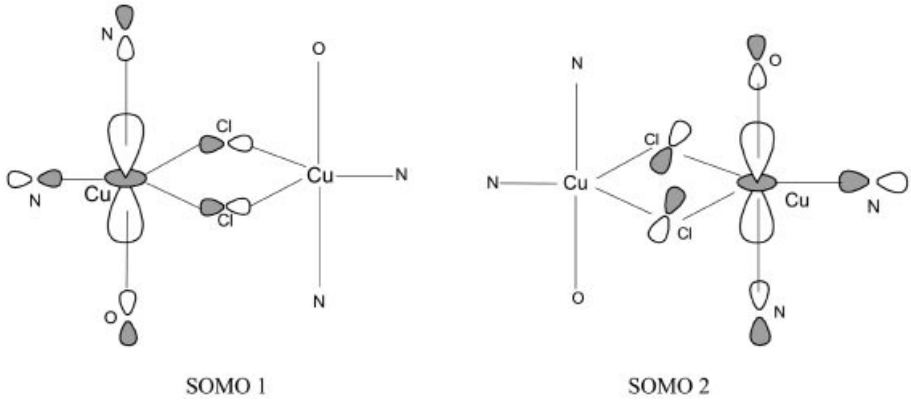

Figure 3. The two SOMOs of the complex $[CuLCl]_2$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

netic behavior may occur when $Cl^-$ is substituted by a N donor.[8b] Our present complex $[CuLCl]_2$ and **2**[3c] are two unique cases containing phenolate oxygen donors. The deprotonation of the phenolate group can provide one anion and cut down the number of $Cl^-$ anions thus featuring the unprecedented magnetic behavior.

$[CuLCl]_2$ represents a very rare example of the unique equatorial-equatorial TBP geometry. Its interesting structure and the novel ferromagnetic behavior might provide useful information for the magneto-structural correlations for this TBP system in the future. With continued research efforts designed to improve theoretical models and to obtain a greater number of experimental examples, the nature of the relationship between the structural properties and the exchange-coupling constant for TBP systems can be refined.

## Conclusions

In summary, we have prepared and characterized a novel equatorial–equatorial trigonal bipyramidal copper dimer with ferromagnetic exchange interaction. The complex has a Cu–Cl–Cu bridging angle close to 90° and two shorter and near Cu–Cl bridging bonds, and the deprotonation of the phenolate group can reduce the number of $Cl^-$ anions. The distortion from SP to TBP geometry may cause an effective overlap between two Cu centers. All these features of the complex may thus increase its ferromagnetic behavior.

## Experimental Section

**General Remarks:** All commercially available chemicals were of analytical grade and were used as received. C, H, and N were determined with an Elementar vario EL elemental analyzer. UV/Vis spectra were measured with a GBC Cintra 10e UV/Vis spectrophotometer in MeOH solution. The IR spectra were recorded with a Nicolet-AVATAR 360 FT-IR spectrometer using KBr pellets in the 4000–400 $cm^{-1}$ regions. $^1H$ NMR spectra were recorded with a Varian 500 Bruker spectrometer in DMSO. Variable-temperature magnetic susceptibility data for the crystalline sample were obtained in an external field of 1000 G on an Oxford Maglab 2000 system magnetometer in the 2–300 K temperature range. The susceptibilities were corrected for diamagnetism with Pascal's constants for all the constituent atoms.

**Synthesis of HL:** A mixture of pyridine-2-carbaldehyde (0.107 g, 1 mmol) and 2-amino-6-methylphenol (0.123 g, 1 mmol) was refluxed in anhydrous ethanolic solution (20 mL) for 2 h. After the solvent was removed, *n*-hexane was added (20 mL) and the mixture was refluxed for another 0.5 h. The reaction mixture was filtered and left to stand at room temperature and then brown crystals were obtained from the filtrate after 15 min. Yield: 0.172 g, 81%. M. p. 95–96 °C. $C_{13}H_{12}N_2O$ ($M_r$ = 212.10): calcd. C 73.56, H 5.70, N 13.20; found C 73.57, H 5.92, N 13.22. $^1H$ NMR (500 MHz, DMSO): $\delta$ = 8.76 (s, 1 H, phenol-OH), 8.74 (s, 1 H, imide-H), 8.70 (d, $J$ = 4.2 Hz, 1 H, pyridine-H), 8.58 (d, $J$ = 7.9 Hz, 1 H, pyridine-H), 7.96 (t, $J$ = 7.6 Hz, 1 H, pyridine-H), 7.50 (t, $J$ = 6.3 Hz, 1 H, pyridine-H), 7.28 (d, $J$ = 7.9 Hz, 1 H, Ar-H), 7.08 (d, $J$ = 7.3 Hz, 1 H, Ar-H), 6.78 (t, $J$ = 7.7 Hz, 1 H, Ar-H), 2.22 (s, 3 H, $-CH_3$) ppm. IR (KBr pellet): $\tilde{\nu}$ = 3402, 3061, 2918, 1627, 1600, 1582, 1566, 1476, 1433, 1344, 1235, 1205, 1163, 1079, 1013, 944, 834, 783, 742, 733, 598 $cm^{-1}$. UV/Vis ($\lambda_{max}$, MeOH): 289, 361, 442 nm.

**Synthesis of Complex $[CuLCl]_2$:** To a 10-mL $CH_2Cl_2$–$CH_3OH$ (1:1) yellow solution of HL (0.011 g, 0.05 mmol), a 5-mL $CH_3OH$ solution of $CuCl_2{\cdot}2H_2O$ (0.008 g, 0.05 mmol) was added dropwise with continuous stirring, and then the mixture was refluxed for 1 h. The reaction mixture was filtered and left to stand at room temperature. On slow evaporation of the solution for several days, the deep red crystals of $[CuLCl]_2$ suitable for X-ray analysis were collected. $C_{13}H_{11}ClCuN_2O$ ($M_r$ = 310.23): calcd. C 50.33, H 3.55, N 9.02; found C 50.43, H 3.45, N 9.27. IR (KBr pellet): $\tilde{\nu}$ = 3410, 3056, 3002, 1605, 1593, 1543, 1477, 1449, 1423, 1359, 1276, 1247, 1205, 1157, 1075, 922, 848, 782, 746 $cm^{-1}$. UV/Vis ($\lambda_{max}$, MeOH): 281, 357, 506 nm.

**X-ray Crystallographic Study:** The crystal with dimensions $0.30 \times 0.22 \times 0.10$ mm was selected for X-ray diffraction experiments. The measurements were performed with a Bruker SMART 1000 CCD diffractometer at room temperature (293 K) with graphite monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Semi-empirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ using the SHELXS-97 and SHELXL-97 programs.[19] All non-hydrogen atoms were refined with anisotropic displacement parameters and the hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinements. A summary of the crystallographic data and details of the structure refinements are listed in Table 3. CCDC-285069 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 3. Crystal data and structure refinement details for complex $[CuLCl]_2$.

| Empirical formula | $C_{26}H_{22}Cl_2Cu_2N_4O_2$ |

# The Active Intermediates of Non-Heme-Iron-Based Systems for Catalytic Alkene Epoxidation with $H_2O_2/CH_3COOH$

**Eduard A. Duban,[a] Konstantin P. Bryliakov,[a] and Evgenii P. Talsi*[a]**

**Keywords:** Oxidoiron(IV) complexes / Acylperoxido complexes / EPR spectroscopy / Paramagnetic NMR spectroscopy / Intermediates / Oxidation

Iron complexes with aminopyridine ligands $[Fe^{II}(BPMEN)(CH_3CN)_2](ClO_4)_2$ (**1**) [BPMEN = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)-1,2-diaminoethane] and $[Fe^{II}(TPA)(CH_3CN)_2](ClO_4)_2$ (**2**) [TPA = tris(2-pyridylmethyl)amine] are rare examples of iron-based catalysts for selective olefin epoxidation with $H_2O_2/CH_3COOH$ combination. Using $^{1,2}H$ NMR and EPR spectroscopy, it was shown that the active species of the catalytic systems **1**/$H_2O_2/CH_3COOH$ and **2**/$H_2O_2/CH_3COOH$ are mononuclear iron(IV)-oxido complexes $[(BPMEN)Fe^{IV}{=}O(S)]^{2+}$ and $[(TPA)Fe^{IV}{=}O(S)]^{2+}$, respectively (S = solvent molecule). These intermediates are formed via decomposition of the corresponding acylperoxido complexes $[(L)Fe^{III}(O_3CCH_3)]^{2+}$ (L = BPMEN or TPA). The acylperoxido complex $[(BPMEN)Fe^{III}(O_3CCD_3)]^{2+}$ was identified in the catalytic system **1**/$H_2O_2/CD_3COOD$ by $^2H$ NMR spectroscopy. The improved epoxidation activity and selectivity of the catalytic systems **1**/$H_2O_2/CH_3COOH$ and **2**/$H_2O_2/CH_3COOH$, with respect to **1**/$H_2O_2$ and **2**/$H_2O_2$, is caused by the effective formation of intermediates $[(L)Fe^{IV}{=}O(S)]^{2+}$ via decomposition of the acylperoxido complexes $[(L)Fe^{III}(O_3CCH_3)]^{2+}$.

## Introduction

Iron complexes with aminopyridine ligands are known to efficiently catalyze selective olefin oxidation using $H_2O_2$ or $CH_3CO_3H$ as terminal oxidants.[1–13] $[Fe^{II}(BPMEN)(CH_3CN)_2](ClO_4)_2$ (**1**) [BPMEN = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-pyridylmethyl)-1,2-diaminoethane] and $[Fe^{II}(TPA)(CH_3CN)_2](ClO_4)_2$ (**2**) [TPA = tris(2-pyridylmethyl)amine] (Figure 1) represent the catalysts investigated thus far in the most detail.[1–3,10] Interestingly, the epoxidation of olefins by $H_2O_2$ catalyzed by **1** and **2** was improved by the addition of acetic acid,[2] and the in situ formation of peroxyacetic acid was later inferred in these systems.[4] The iron(IV)-oxido species $[LFe^{IV}{=}O(S)]^{2+}$ (L = BPMEN or TPA, S = solvent molecule) are considered as possible reactive intermediates of the catalytic systems **1**/$H_2O_2/CH_3COOH$ and **2**/$H_2O_2/CH_3COOH$. This postulate was derived from nearly identical product distribution obtained for olefin oxidations catalyzed by **1** and **2** with $CH_3CO_3H$ and $H_2O_2/CH_3OOH$ as oxidants.[12] However, whereas the $[(TPA)Fe^{IV}{=}O(S)]^{2+}$ intermediate active towards cyclooctene was trapped in the catalytic system **2**/$CH_3CO_3H$,[14] such type of species have never been detected in **2**/$H_2O_2/CH_3COOH$ and **1**/$H_2O_2/CH_3COOH$ combinations. Thus, the experimental proof is required for the proposed key role of an $Fe^{IV}{=}O$ oxidant in **1**/$H_2O_2/CH_3COOH$ and **2**/$H_2O_2/CH_3COOH$ systems.

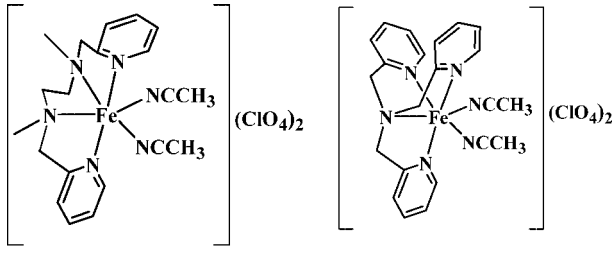

Figure 1. Structures of complexes **1** and **2**.

For **1**/$H_2O_2$ and **2**/$H_2O_2$ catalytic systems, the nature of active intermediates is even less clear. The low-spin ferric hydroperoxo species $[LFe^{III}(OOH)(S)]^{2+}$ were identified in **1**/$H_2O_2$[6] and **2**/$H_2O_2$.[15,16] Later, it was proposed that $[(TPA)Fe^{III}(OOH)(S)]^{2+}$ by itself is a sluggish oxidant but could be a precursor of more reactive species (e.g. $[(TPA)Fe^{IV}{=}O(S)]^{2+}$).[17] However, mononuclear $[LFe^{IV}{=}O(S)]^{2+}$ intermediates have never been detected in **1**/$H_2O_2$ and **2**/$H_2O_2$ systems.

In this work, we report $^{1,2}H$ NMR and EPR detection and reactivity studies of $[LFe^{IV}{=}O(S)]^{2+}$ and other intermediates formed in the catalytic systems **1**/$CH_3CO_3H$, **2**/$CH_3CO_3H$, **1**/$H_2O_2/CH_3COOH$, **2**/$H_2O_2/CH_3COOH$, and **1**/$H_2O_2$.

## Results and Discussion

### Catalytic Systems 1/$CH_3CO_3H$ and 1/$H_2O_2$/$CH_3COOH$

The $^1H$ NMR spectrum recorded 10 min after onset of the reaction of **1** with 2 equiv. of $CH_3CO_3H$ at –50 °C in a 1:1 $CD_2Cl_2/CD_3CN$ mixture displays broad peaks of $Fe^{III}$–O–$Fe^{III}$ dimers and additional sharp peaks (marked by points) of the new complex **3** (Figure 2, a). Most of the $^1H$ NMR peaks of **3** possess negative $^1H$ NMR chemical shifts, whereas mononuclear high-spin ferrous complex **1** and dinuclear $Fe^{III}$–O–$Fe^{III}$ species with BPMEN ligands exhibit mainly the $^1H$ NMR peaks with positive chemical shifts.[6,18] Such unusual negative $^1H$ NMR chemical shifts were previously observed for X-ray characterized low-spin mononuclear complex $[(N_4Py)Fe^{IV}=O]^{2+}$, where $N_4Py$ is the pentadentate ligand *N*,*N*′-bis(2-pyridylmethyl)-*N*-bis(2-pyridyl)methylamine.[19] Thus, complex **3** could be assigned to a mononuclear $Fe^{IV}$=O complex. In agreement with this assumption, complex **3** could also be obtained upon reaction of **1** with 1 equiv. of iodosylbenzene at –50 °C in a 1:1 $CD_2Cl_2/CD_3CN$ mixture (Figure 2, b). The reaction of a ferrous precursor with iodosylbenzene is the commonest method for the generation of $Fe^{IV}$=O species.[14] By analogy with X-ray characterized complex $[(TMC)Fe^{IV}=O(CH_3CN)]^{2+}$ (TMS is tetradentate ligand tetramethylcyclam, cyclam = 1,4,8,11-tetraazacyclotetradecene),[20] the following structure could be proposed for **3**: $[(BPMEN)Fe^{IV}=O(CH_3CN)]^{2+}$. A molecule of solvent ($CH_3CN$) occupies the sixth coordination site of **3**.

$[(BPMEN)Fe^{IV}=O(CH_3CN)]^{2+}$ **3**

$[(BPMEN)Fe^{III}(O_3CCH_3)]^{2+}$ **4**

$[(BPMEN)Fe^{III}–O–Fe^{IV}=O(BPMEN)(S)]^{3+}$ **5**

$[(TPA)Fe^{IV}=O(S)]^{2+}$ **6**

$[(OH)(BPMEN)Fe^{III}–O–Fe^{III}(BPMEN)(H_2O)](ClO_4)_3$ **7**

$[(BPMEN)Fe^{III}(OOH)]^{2+}$ **8**

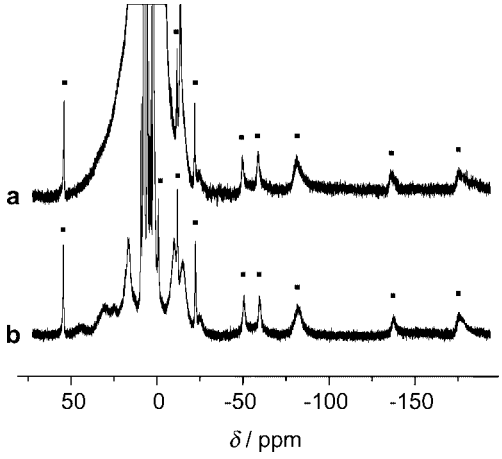

Figure 2. $^1H$ NMR spectra (–50 °C) of **1**/$CH_3CO_3H$ (a) and **1**/PhIO (b) systems recorded 10 min after mixing the reagents at –50 °C in a 1:1 $CD_2Cl_2/CD_3CN$ mixture ([**1**] = [PhIO] = 0.05 M, [$CH_3CO_3H$] = 0.1 M). Points denote peaks of **3**.

The number of the $^1H$ NMR peaks of **3** corresponds to the number of chemically nonequivalent protons of the BPMEN ligand.[21] The intensities of the $^1H$ NMR peaks of **3** correspond to the conversion of up to 30% of **1** into **3**. Complex **3** is stable in a 1:1 $CD_2Cl_2/CD_3CN$ mixture at –50 °C and decays at higher temperatures (the half-life time $\tau_{1/2}$ is 15 min at –10 °C). After the addition of 5 equiv. of cyclohexene to the solution containing **3** at –50 °C, the latter disappears within several minutes. This decay is accompanied by the rise of the $^1H$ NMR peaks of the 1,2-epoxycyclohexane. Thus, complex **3** is the key intermediate of epoxidation by the catalytic system **1**/$CH_3CO_3H$.

The same complex **3** was observed by $^1H$ NMR upon addition of $H_2O_2$ into the **1**/$CH_3COOH$ system ([**1**] = [$H_2O_2$] = [$CH_3COOH$] = 0.05 M, 1:1 $CD_2Cl_2/CD_3CN$ mixture, –50 °C). The concentration of **3** was close to that for the **1**/$CH_3O_3H$ system ([**1**] = [$CH_3CO_3H$] = 0.05 M, 1:1 $CD_2Cl_2/CD_3CN$ mixture, –50 °C). Thus, mononuclear ironoxido complex $[(BPMEN)Fe^{IV}=O(S)]^{2+}$ (**3**) is the active species of cyclohexene epoxidation by the catalytic systems **1**/$CH_3CO_3H$ and **1**/$H_2O_2$/$CH_3COOH$.

Apparently, it is the ferric acylperoxido complex $[(BPMEN)Fe^{III}(O_3CCH_3)]^{2+}$ (**4**) that is the precursor of **3**. We have undertaken the search for **4** by $^2H$ NMR using deuterated peroxo acetic acid ($CD_3CO_3H$). The $^2H$ NMR spectrum recorded 10 min after the addition of 1.5 equiv. of $CD_3CO_3H$ to **1** in a 1:1 $CH_2Cl_2/CH_3CN$ mixture at –50 °C exhibits a broad peak at $\delta$ = 102.7 ppm (the half height width $\Delta\nu_{1/2}$ = 230 Hz) (Figure 3). The same peak was observed after the addition of 1 equiv. of $H_2O_2$ to the sample containing **1** and 1 equiv. of $CD_3COOD$ in a 1:1 $CH_2Cl_2/CH_3CN$ mixture at –50 °C ([**1**] = 0.05 M). This peak disappeared upon warming ($\tau_{1/2}$ = 10 min at –30 °C). For the high-spin complex $(TPP)Fe^{III}–O–O–CD_2–CD_3$ (TPP = dianion of tetra-*p*-tolylporphyrin), a $CD_2$ peak was observed at $\delta$ = 180 ppm, and a $CD_3$- peak at 4 ppm.[22] On the basis of these data, the resonance at $\delta$ = 102.7 ppm could be assigned to the $OOCCD_3$ or $O_3CCD_3$ moiety bound to high-spin $Fe^{III}$. To rule out the assignment of the observed peak to the $OOCCD_3$ moiety, $CD_3COOD$ was added to the solution containing **1** at –50 °C. In this case, no $^2H$ NMR peaks near 100 ppm were observed. Thus, the $^2H$ NMR resonance at $\delta$ = 102.7 ppm belongs to the $O_3CCD_3$ moiety of the high-spin ferric acylperoxido complex **4**. The maximum

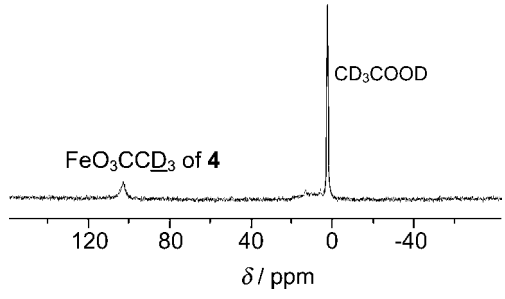

Figure 3. The $^2H$ NMR spectrum (–50 °C) of the system **1**/$CD_3CO_3D$ recorded 10 min after mixing the reagents at –50 °C in a 1:1 $CH_2Cl_2/CH_3CN$ mixture ([**1**] = 0.05 M, [$CD_3CO_3H$] = 0.075 M).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

concentration of **4** was about 10% of the initial concentration of **1**.

The high-spin mononuclear ferric complex **4** should display an EPR signal at $g = 4.23$.[23,24] EPR spectra recorded in various moments of time after onset of the reaction of **1** with 2 equiv. of $CH_3CO_3H$ at –60 °C in a 2:1 $CH_2Cl_2$/$CH_3CN$ mixture show: (1) a signal at $g = 4.23$ (peak-to-peak width $\Delta H = 260$ G), (2) an axially anisotropic signal ($g_1 = g_2 = 2.42$, $g_3 = 2.67$), and (3) a very broad signal at $g \approx 2$ ($\Delta H = 1200$ G) (Figure 4, a and b). The signal at $g = 4.23$ ($\Delta H = 260$ G) was gone upon warming to room temperature, and another weaker and sharper signal ($\Delta H = 70$ G) with the same $g$-factor was observed. The latter signal persists after storing at room temperature for hours and thus belongs to a stable mononuclear high-spin ferric species. The broad signal near $g = 2$ disappeared upon warming (Figure 4, c).

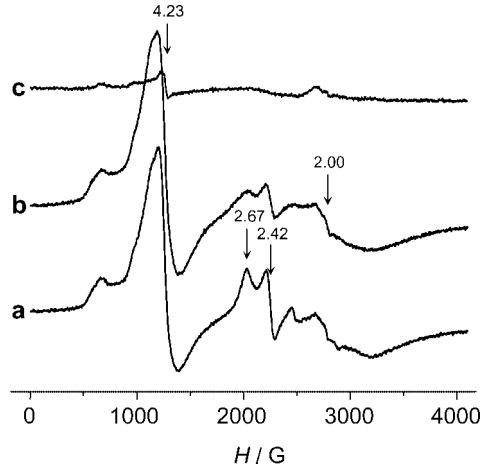

Figure 4. X-band EPR spectra (–196 °C) recorded 1 min (a) and 10 min (b) after mixing **1** and $CH_3CO_3H$ at –60 °C in a 2:1 $CH_2Cl_2$/$CH_3CN$ mixture. Sample (b) after warming to room temperature (c). ([**1**] = 0.05 M, [$CH_3CO_3H$] = 0.1 M).

It is tempting to assign the observed signal at $g = 4.23$ (Figure 4, a and b) to acylperoxido complex **4**. However, another high-spin ferric species (e.g., high-spin hydroxido complex [(BPMEN)$Fe^{III}$(OH)]$^{2+}$) could have an EPR signal in the same range. At present, it is difficult to determine the contribution of **4** to the observed signal at $g = 4.23$. The origin of a very broad signal near $g = 2$ (Figure 4, a and b) is also unclear.

The axial spectrum ($g_1 = g_2 = 2.42$, $g_3 = 2.67$) (Figure 4, a and b) belongs to the very unstable complex **5** ($\tau_{1/2}$ = 10 min at –60 °C). The same signal could be observed in the catalytic system **1**/$H_2O_2$ along with the rhombic spectra of the low-spin ferric hydroperoxido complexes [(BPMEN)-$Fe^{III}$(OOH)S]$^{2+}$ (see below).

EPR spectra of the low-spin ferric complexes (heme and non-heme) show a rhombic pattern ($g_x \neq g_y \neq g_z$) with $g$-values in the range ca. 1–4 (one of the $g$-values is less than $g_e = 2.0024$)[10,23–26] These spectra differ markedly from that of **5** ($g_1 = g_2 = 2.42$, $g_3 = 2.67$). The EPR spectra of high-spin ferric complexes with TPA- and BPMEN-type ligands display an EPR signal at $g_{eff} = 4.23$.[10,23–26] Therefore, complex **5** is not the low-spin, nor the high-spin ferric complex. EPR spectra of binuclear $Fe^{III}Fe^{II}$ moieties reported for some enzymes (methane monooxygenase, ribonucleotide reductase, Rieske-type dioxygenase, etc) and model compounds exhibit resonances in the range $g_1 = 1.93$–$2.01$, $g_2 = 1.85$–$1.92$, $g_3 = 1.64$–$1.80$,[24,25] and again are very different from that of **5**. Complexes with $Fe^{III}$–O–$Fe^{III}$, $Fe^{IV}$=O, and $Fe^{IV}$–O–$Fe^{IV}$ fragments are EPR silent.[13,14,24,27] Thus, it is reasonable to assume that **5** is a binuclear $Fe^{III}Fe^{IV}$ complex. Recently, Wieghardt et al. have identified iron species formed upon photooxidation of *trans*-[(cyclam)$Fe(N_3)_2$]$ClO_4$ in acetonitrile solution by Mössbauer and EPR spectroscopy. The major photolysis product in liquid solution at room temperature was nitrido-bridged binuclear ($Fe^{III}$, $Fe^{IV}$) complex with localized antiferromagnetically coupled $Fe^{III}$ ($S = 3/2$) and low-spin $Fe^{IV}$ ($S = 1$) units, the total spin being $S = 1/2$.[28] The EPR spectrum of this (μ-nitrido) diiron complex ($g$-values of 2.04, 2.06, and 2.20) resembles that of complex **5**. Both the spectra display almost axial symmetry and for both spectra all the $g$-values are larger than $g_e$. Thus, complex **5** can be tentatively assigned to a mixed-valence $Fe^{III}Fe^{IV}$ complex. The formation of $Fe^{III}$–O–$Fe^{III}$ binuclear complexes is highly characteristic for the catalytic systems studied.[18,29] Therefore, the existence of binuclear intermediates [(BPMEN)$Fe^{III}$–O–$Fe^{IV}$=O(BPMEN)(S)]$^{3+}$ (**5**) along with mononuclear species [(BPMEN)$Fe^{IV}$=O(S)]$^{2+}$(**3**) seems to be rather probable. The attempts to obtain additional spectroscopic evidences in favor of the proposed structure of **5** were unsuccessful due to the low concentration of **5** with respect to the concentrations of the other iron species present in the sample.

Intermediate **5** ($\tau_{1/2}$ = 10 min at –60 °C) is far less stable than **3** ($\tau_{1/2}$ = 15 min at –10 °C). As was mentioned, in the presence of cyclohexene, the decay of **3** at –50 °C is accompanied by the rise of concentration of the 1,2-epoxycyclohexane. Thus, despite the fact that intermediate **5** could also react with cycloxehene (see below), intermediate **3** is the active species of cyclohexene epoxidation by the catalytic systems **1**/$CH_3CO_3H$ and **1**/$H_2O_2$/$CH_3COOH$.

### Catalytic Systems 2/$CH_3CO_3H$ and 2/$H_2O_2$/$CH_3COOH$

By analogy with BPMEN-based systems, it is natural to assume that the active species of **2**/$CH_3CO_3H$ and **2**/$H_2O_2$/$CH_3COOH$ systems is the oxidoiron(IV) complex [(TPA)-$Fe^{IV}$=O(S)]$^{2+}$ (**6**). In full agreement with this assumption, peaks of **6** (marked by points) were observed in the $^1H$ NMR spectra of **2**/$H_2O_2$/$CH_3COOH$ and **2**/$CH_3CO_3H$ in 1:1 $CD_2Cl_2$/$CD_3CN$ at –50 °C (Figure 5). The remaining paramagnetically shifted signals belong to binuclear $Fe^{III}$–O–$Fe^{III}$ species.[29] Complex **6** is unstable ($\tau_{1/2}$ = 10 min at –10 °C). The most characteristic and easily assignable peaks of **6** belong to β,β′-protons of the picolinic rings [1:1 $CDCl_3$/$CD_2Cl_2$, –50 °C, $\delta$ = 58.8 (2 H), 49.8 (1 H), –24.9 (2 H), and –28.7 (1 H)]. The ratio between the four observed peaks (2:1:2:1) corresponds to two equivalent and one

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

unique picolinic rings of a coordinated TPA ligand. The observed pattern of β,β′-protons of **6** resembles that for X-ray characterized complex $[(N_4Py)Fe^{IV}=O]^{2+}$ [$\delta$ = 44.4 (2 H), 30.05 (2 H), –11.2 (2 H), –17.8 (2 H)].[19] The assignment of the other signals of **6** is more complicated and is still not completed, as in the case of $[(N_4Py)Fe^{IV}=O]^{2+}$. Complex **6** is stable at –50 °C and rapidly (within several minutes) disappears at this temperature in the presence of 5 equiv. of cyclohexene. The decay of **6** was accompanied by the rise of the $^1$H NMR peaks of 1,2-epoxycyclohexane. Fresh portions of $CH_3CO_3H$ or $H_2O_2/CH_3COOH$ restore the concentration of **6**. Apparently, it is the oxidoiron intermediate $[(TPA)Fe^{IV}=O(S)]^{2+}$ (**6**) that is the active species of the catalytic systems **2**/$H_2O_2$/$CH_3COOH$ and **2**/$CH_3CO_3H$. An intermediate similar to intermediate **5** in the BPMEN-based system was not detected in the TPA-based analogue.

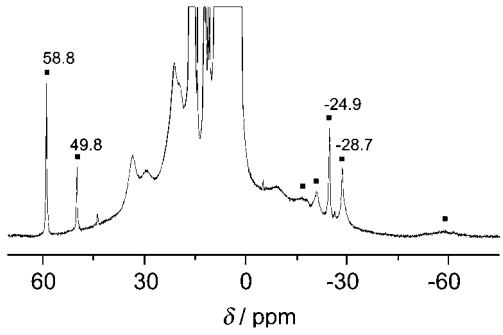

Figure 5. The $^1$H NMR spectrum (–50 °C) of the **2**/$H_2O_2$/$CH_3COOH$ system recorded 10 min after addition of $H_2O_2$ to **2**/$CH_3OOH$ in a 1:1 $CD_2Cl_2/CD_3CN$ mixture at –50 °C ([**2**] = [$CH_3COOH$] = 0.05 M, [$H_2O_2$] = 0.1 M). Points denote peaks of **6**.

### Catalytic System 1/$H_2O_2$

The $^1$H NMR spectrum of **1** in $CD_3CN$ at high temperature corresponds to a paramagnetic high-spin ferrous complex. Complex **1** decreases its spin state with decreasing temperature and displays the $^1$H NMR spectrum characteristic of diamagnetic low-spin ferrous species at –40 °C.[8,30] The addition of 2 equiv. of $H_2O_2$ to the 0.03 M solution of **1** in $CD_3CN$ at 20 °C gives rise to immediate conversion of the major part of **1** into a new complex with a $^1$H NMR spectrum very similar to that reported for binuclear complex $[(OH)(BPMEN)Fe^{III}–O–Fe^{III}(BPMEN)(H_2O)](ClO_4)_3$ (**7**).[18] Thus, the predominant iron-containing species in the **1**/$H_2O_2$ system is μ-oxo diferric complex **7**. To identify unstable intermediates, the reaction between **1** and $H_2O_2$ was studied at low temperatures.

Figure 6 shows the EPR spectrum recorded 1 min after onset of the reaction between **1** and 1.5 equiv. of $H_2O_2$ in a 2:1 $CH_2Cl_2/CH_3CN$ mixture at –60 °C. It is seen that besides the characteristic signals of the low-spin ferric hydroperoxo intermediates $[(BPMEN)Fe^{III}(OOH)(CH_3CN)]^{2+}$ (**8**-$CH_3CN$) ($g_1$ = 2.218, $g_2$ = 2.178, $g_3$ = 1.967) and $[(BPMEN)Fe^{III}(OOH)(H_2O)]^{2+}$ (**8**-$H_2O$) ($g_1$ = 2.195, $g_2$ = 2.128, $g_3$ = 1.970),[6] the axially symmetric signal of complex **5** ($g_1$ = $g_2$ = 2.42 and $g_3$ = 2.67) is observed. In the presence of 8 equiv. of cyclohexene, the decay of **5** at –60 °C increases at least by a factor of 5, whereas the rate of **8**-$CH_3CN$ and **8**-$H_2O$ decomposition remains unchanged (Figure 7 and Figure 8). These data are in agreement with

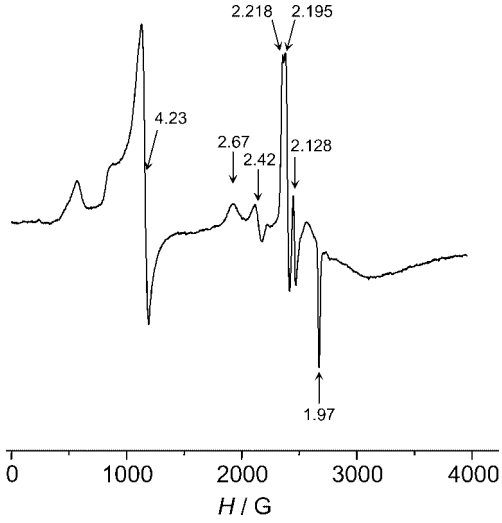

Figure 6. X-band EPR spectrum (–196 °C) recorded 1 min after mixing **1** and 1.5 equiv. of $H_2O_2$ at –60 °C in a 2:1 $CH_2Cl_2/CH_3CN$ mixture. ([**1**] = 0.05 M).

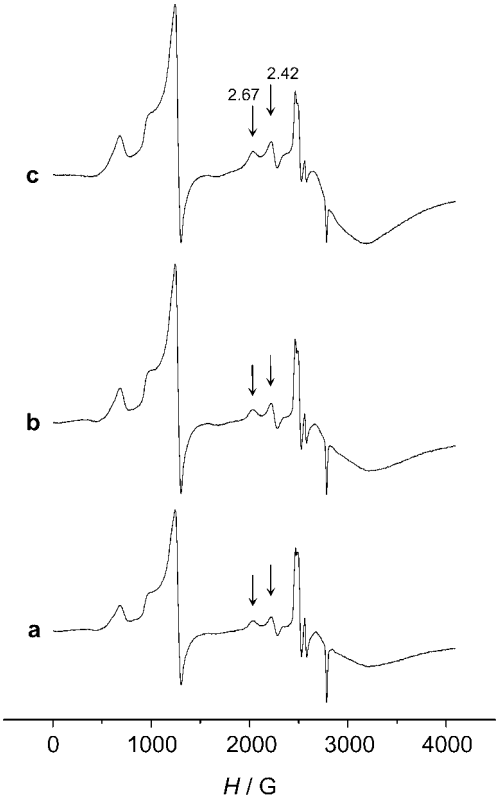

Figure 7. EPR spectra recorded 2 min (a), 5 min (b), and 7 min (c) after onset of reaction of **1** with 1.5 equiv. of $H_2O_2$ in a 2:1 $CH_2Cl_2/CH_3CN$ mixture at –60 °C.([**1**] = 0.05 M). Arrows denote signals of **5**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

our assumption that **5** contains the active $Fe^{IV}$=O moiety. The concentration of intermediates **5** and **8** does not exceed 5% of the concentration of **1**.

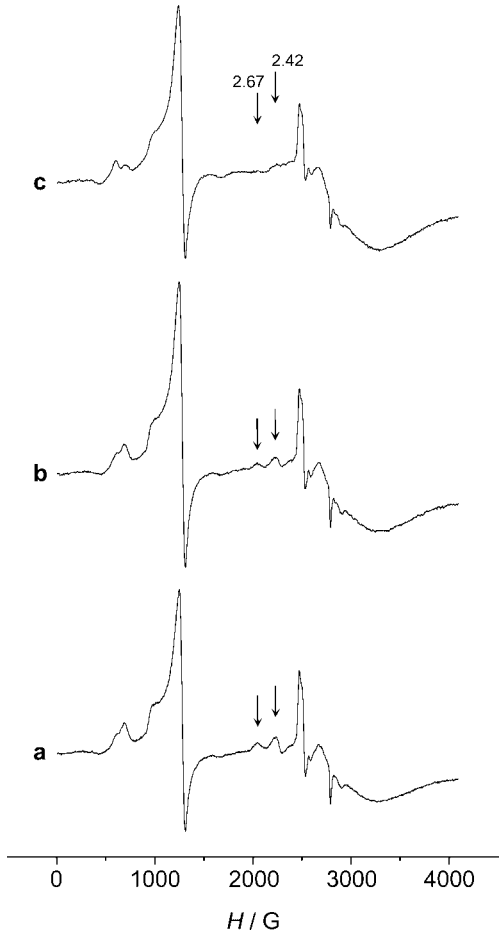

Figure 8. EPR spectra recorded 2 min (a), 3 min (b), and 6 min (c) after onset of reaction of **1** with 1.5 equiv. of $H_2O_2$ in a 2:1 $CH_2Cl_2$/$CH_3CN$ mixture containing cyclohexene at –60 °C ([**1**] = 0.05 M, [$C_6H_{10}$] = 0.4 M). Arrows denote signals of **5**.

In contrast to the **1**/$CH_3CO_3H$ and **1**/$H_2O_2$/$CH_3COOH$ catalytic systems, the mononuclear iron(IV) oxido intermediate **3** was not detected in the catalytic system **1**/$H_2O_2$. The only observable intermediate sensitive to the presence of substrate is complex **5** with the proposed structure [(BPMEN)$Fe^{III}$–O–$Fe^{IV}$=O(BPMEN)(S)]$^{3+}$. Thus, different intermediates operate in the catalytic systems **1**/$H_2O_2$ and **1**/$H_2O_2$/$CH_3COOH$. This result agrees with differing activities and selectivities of the catalytic systems **1**/$H_2O_2$ and **1**/$H_2O_2$/$CH_3COOH$ in epoxidation of olefins.[2,4,12] However, the actual role of intermediate **5** in epoxidation with **1**/$H_2O_2$ is far from being established. Very recently, it has been shown that binuclear iron(III)-BPMEN complexes are less active in epoxidation with $H_2O_2$ than mononuclear complex **1** under the same conditions.[31] This result argues against the involvement of a binuclear intermediate in the **1**/$H_2O_2$ system. On the other hand, the diiron complex with dinucleating, covalently linked TPA derivatives confirms the high reactivity of oxo-bridged diiron(III) species in olefin epoxidation.[32] Further studies are needed to elucidate the active species of the **1**/$H_2O_2$ and **2**/$H_2O_2$ catalytic systems.

Fortunately, for the most active and selective epoxidizing systems **1**/$H_2O_2$/$CH_3COOH$ and **2**/$H_2O_2$/$CH_3COOH$, the situation is more definite. On the basis of the results of our study, the active species of these catalytic systems are mononuclear $Fe^{IV}$ species [(L)$Fe^{IV}$=O(S)]$^{2+}$. The improved epoxidation activity and selectivity of the catalytic systems **1**/$H_2O_2$/$CH_3COOH$ and **2**/$H_2O_2$/$CH_3COOH$, with respect to **1**/$H_2O_2$ and **2**/$H_2O_2$, is caused by the effective formation of intermediates [(L)$Fe^{IV}$=O(S)]$^{2+}$ via decomposition of the acylperoxido complexes [(L)$Fe^{III}$($O_3CCH_3$)]$^{2+}$.

## Experimental Section

Acetonitrile, [$D_3$]acetonitrile, dichloromethane, [$D_2$]dichloromethane, [$D_4$]acetic acid, 2-picolyl chloride hydrochloride, and *N*,*N*′-dimethyl-1,2-ethanediamine were purchased from Aldrich and used without additional purification. Hydrogen peroxide (95 %) was obtained by concentration of commercial 30% $H_2O_2$ under reduced pressure. The concentrated $H_2O_2$ diluted ten times by a 1:1 $CH_2Cl_2$/$CH_3CN$ mixture was used for the preparation of samples. $CH_3CO_3H$ (or $CD_3CO_3D$) was prepared by mixing equivalent amounts of 95% $H_2O_2$ and $CH_3CO_3H$ (or $CD_3COOD$) in the presence of 1% $H_2SO_4$, and stirring the mixture overnight. [(TPA)$Fe^{II}$($CH_3CN$)$_2$]($ClO_4$)$_2$ and [(BPMEN)$Fe^{II}$($CH_3CN$)$_2$]($ClO_4$)$_2$ were synthesized following a method previously described[3,24] and satisfactorily characterized by $^1$H NMR spectroscopy. To start the reaction, 1.5–2 equiv. of $CH_3CO_3H$ or $H_2O_2$ was added to 0.5 mL of a 0.05 M solution of **1** or **2** in $CH_2Cl_2$/$CH_3CN$ or $CH_2Cl_2$/$CH_3CN$/$CH_3COOH$ mixtures at –60 to –50 °C directly in quartz EPR or glass NMR tubes ($d$ = 5 mm). For kinetic EPR studies, solutions containing unstable intermediates were placed in a thermostat at an appropriate temperature directly in an EPR tube. To stop the reaction, the tube was immersed in liquid nitrogen, followed by registration of the EPR spectrum at –196 °C. For kinetic NMR studies, $^1$H or $^2$H NMR spectra of intermediates were recorded at selected temperatures. If necessary, the appropriate amounts of cyclohexene were added to the reaction solutions. For evaluation of the concentration of **3** by $^1$H NMR, the integral intensity of the N–$CH_3$ peak of **3** was compared with the integral intensity of the residual peak of $CD_2HCN$ in $CD_3CN$. The concentration of residual $CD_2HCN$ in $CD_3CN$ was preliminarily determined by $^1$H NMR spectroscopy. For this goal the specified amount of $CHCl_3$ was added to $CD_3CN$. For evaluation of the concentration of **4**, the integral intensity of its $CD_3CO_3$ peak was compared with that of $CD_3COOD$.

EPR spectra (–196 °C) were recorded at 9.2–9.3 GHz with a Bruker ER-200D spectrometer. Measurements were made in a quartz Dewar vessel filled with liquid nitrogen. EPR signals near $g$ = 2 were quantified by double integration with copper(II) chloride as a standard at –196 °C. $^{1,2}$H NMR spectra were recorded at 400.13 and 61.425 MHz in 5-mm glass sample tubes, on a Bruker Avance 400 MHz NMR spectrometer. The following operating conditions were used for $^1$H NMR measurements: spectral width 125 kHz, spectrum accumulation frequency 10 Hz; number of scans 5000–10000; 45° pulse at 5 μs. The $^1$H and $^2$H chemical shifts were referenced to the residual peak of the solvent (C*H*$D_2$CN, and C*D*$H_2$CN, $\delta$ = 1.96 ppm). The typical operating conditions used for $^2$H NMR measurements were as follows: sweep width 125 kHz; spectrum accumulation frequency 2.5 Hz; number of transients 5000–10000; 45° pulse at 10 μs.

# Synthesis of Tin(II) Phosphate Open Frameworks Using Isomers of 1,2-Diaminocyclohexane as Template

Xuejun Yuan,[a,b] Yi-Zhi Li,[b] Yan Xu,[b] Xiaozeng You,*[b] and Robert J. Linhardt*[a]

**Keywords:** Tin(II) phosphate / Open framework / Templated hydrothermal synthesis / Leaching

A novel layered framework of tin(II) phosphate, $[Sn_4(PO_4)_3(OH)]^{2-}\cdot[trans\text{-}1,2\text{-}C_6H_{10}(NH_3)_2]^{2+}$, has been synthesized under hydrothermal conditions with tin(II) oxalate, phosphoric acid and a mixture of *trans*- and *cis*-1,2-diaminocyclohexane (1,2-DACH). The compound crystallizes in the monoclinic space group $P2_1/n$ (No. 14). The channels of the *trans*-1,2-DACH are occluded by hydrogen bonding in the doubly protonated form, which is leached out from the framework. Reaction using only *tran*-DACH gives the same compound. For comparison, when *cis*-DACH is used as template under the same conditions instead of the mixture of *trans* and *cis* isomers, the neutral inorganic phosphate framework $(Sn_3O)_2(Sn_2O)_2(PO_4)_4$ is formed. It crystallizes in the triclinic space group $P\bar{1}$ (No. 2). These results suggest that *trans*-1,2-DACH is selectively occluded in the framework $[Sn_4(PO_4)_3(OH)]^{2-}\cdot[trans\text{-}1,2\text{-}C_6H_{10}(NH_3)_2]^{2+}$.

## Introduction

During the past decade, preparation of open-framework metal phosphates has attracted much attention because of their potential applications, which take advantage of microporosity, thermal stability, appropriate acidity and their sturdiness with regard to solvent.[1] The use of structure-directing agents (SDA) or template agents in the synthesis of new solids exhibiting open-framework structures has gained prominence. It is now well established that for the synthesis of such new micro- and mesoporous materials, an organic template can be used to steer the process of crystallization to form open architectures.[2] An organic moiety is normally accommodated within the cavities or between neighboring sheets. In many cases, template can be removed by post-synthesis treatment such as calcination or chemical extraction (i.e. leaching).[3]

Open-framework tin(II) phosphate compounds can be synthesized with the aid of organic amines.[4] The building units in these compounds are commonly trigonal-pyramidal $SnO_3$, and/or square-pyramidal $SnO_4$ and tetrahedral $PO_4$ groups linked by sharing their vertices to form frameworks with channels and or cages.[5] The tin atoms are coordinated with oxygen atoms which occupy the vertex of pyramid, whereas the lone pair presumably occupies the fourth vertex of a polyhedron formed by oxygen atoms and the lone pair itself around the $Sn^{II}$ atom.[6] A single organic amine quite often affords several open framework phosphates with different structures.[7] The amine might act as a structure-directing agent or merely fill the available voids and stabilize the structure through hydrogen bonding and or other interactions.[8] Because the amine generally is protonated in reactions, it also helps in charge compensation of the inorganic framework. Recently, it has been suggested the formation of the amine phosphates may act as intermediates in the formation of the metal phosphates.[8,9]

We attempted to synthesize tin(II) phosphate framework under hydrothermal conditions using a mixture of *trans*- and *cis*-1,2-diaminocyclohexane(1,2-DACH), or only *trans*-1,2-DACH, or only *cis*-1,2-DACH as template. Interestingly, two tin(II) phosphate frameworks with unique structure characteristics, $[Sn_4(PO_4)_3(OH)]^{2-}\cdot[trans\text{-}1,2\text{-}C_6H_{10}(NH_3)_2]^{2+}$ (**1**) and $(Sn_3O)_2(Sn_2O)(PO_4)_4$ (**2**), were obtained. Here, we present the syntheses and structural determinations of them. In addition, the separation of the organic amine isomers of **1** is also described.

## Results and Discussion

### Synthesis

Dispersion of $SnC_2O_4$ in aqueous phosphoric acid followed by the addition of a mixture of *trans*- and *cis*-1,2-DACH and heating under pressure at 443 K affords colorless schistose single crystals of **1**. A reaction using only *trans*-1,2-DACH under the same conditions also gives compound **1**. Synthesis utilizing only *cis*-1,2-DACH affords colorless prismatic crystals of **2**.

### Characterization

Inductively coupled plasma (ICP) analysis indicates that **1** contains 53.0 wt.-% Sn and 10.5 wt.-% P, in good agreement with the formula based on crystal-structure determination (calcd. 53.3 wt.-% Sn, 10.4 wt.-% P). This gives rise to an Sn/P ratio of 4:3. The elemental analysis showed that the C, H and N contents are 8.12, 1.70 and 3.16 wt.-% (calcd. 8.08 wt.-% C, 1.68 wt.-% H, 3.14 wt.-% N), respectively, corresponding to an empirical molar ratio of C/H/N = 6:17:2. These analysis results indicated that the solid sample of **1** was a pure phase.

The ICP analysis indicated that **2** contained 73.5 wt.-% Sn and 7.8 wt.-% P, in accordance with formula based on the single crystal structure analysis (calcd. 72.8 wt.-% Sn and 7.6 wt.-% P). The elemental analysis showed that it contained no C, H or N. These analytic results indicated that the solid sample of **2** was also a pure phase.

The FTIR spectrum of **1** was assigned as follows: The bands observed at 3505–3250 $cm^{-1}$ were attributed to H-bonded N–H groups. The band at 2920 $cm^{-1}$ was attributed to the $\delta_{C-H}$ vibration of 1,2-DACH. The bands 1109 and 965 $cm^{-1}$ were assigned as the asymmetric stretching vibration of $PO_4$ units. Absorptions at 624, 536 and 486 $cm^{-1}$ were due to bending vibration of $PO_4$ groups. The bands at 1624, 1559, 1540, 1446 and 1377 $cm^{-1}$ were attributed to $\delta_{N-H}$, $\nu_{C-H}$, $\nu_{C-C}$ and $\nu_{C-N}$ vibrations of the doubly protonated 1,2-DACH cation occluded in the framework. The FTIR of **2** showed vibrations corresponding to the $PO_4$ unit at 1065, 1009, 600, 553 and 442 $cm^{-1}$.

Thermogravimetric analysis (TGA) curve showed that the weight loss of **1** occurring between 310 °C and 400 °C is 13.6%, and was related to the loss of absorbed water and the decomposition of the occluded amine (calcd. 12.8%). Differential thermal analysis (DTA) curve afforded a single broad endothermic peak at approximately 345 °C, corresponding to this decomposition. Similar analysis of **2** showed only a small mass loss (ca. 1.0%) at < 200 °C, due to the loss of absorbed water.

### Description of the Structures

Detailed crystallographic data are listed in Table 1. and the selected bond lengths and angles are given in Table 2. The asymmetric unit of **1** is shown in Figure 1, (a). The structure of **1** shows the tin atom in a three-coordinate environment with respect to oxygen. The trigonal-pyramidal $SnO_3$ is alternatively linked to tetrahedral $PO_4$ units through bridging oxygen atoms. Of the eleven bridging oxygen atoms in the asymmetric unit, ten are bridged to a tin atom and a phosphorus atom. The remaining oxygen atom

bonds two tin atoms. From the Fourier map, we note that the oxygen atom forming the Sn–O–Sn units is protonated. Bond valence sum calculations performed on the framework confirm the presence of the proton on the oxygen involved in forming the Sn–O(H)–Sn linkages.[10] Bonding involved two tin atoms and a hydroxy group has been previously reported.[5,11]

Table 2. Selected bond lengths [Å] and angles [°] for $[Sn_4(PO_4)_3(OH)]^{2-}\cdot[trans\text{-}1,2\text{-}C_6H_{10}(NH_3)_2]^{2+}$ (**1**).[a]

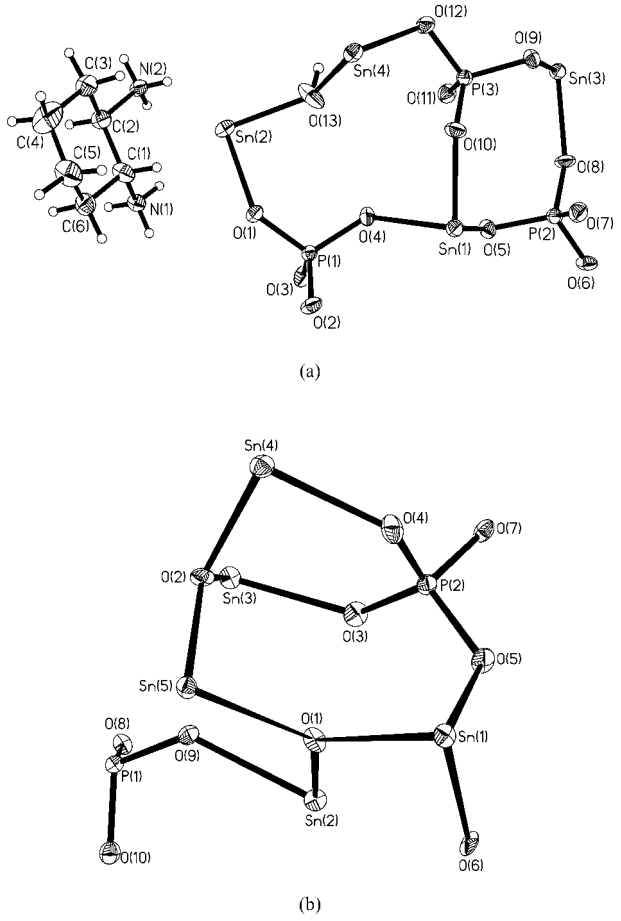

Figure 1. (a) ORTEP view of $[Sn_4(PO_4)_3(OH)]^{2-}\cdot[trans\text{-}1,2\text{-}C_6H_{10}(NH_3)_2]^{2+}$ structure showing the atom-labeling Scheme (30% thermal ellipsoids), with arbitrary radius of hydrogen atom. (b) ORTEP drawing of $(Sn_3O)_2(Sn_2O)(PO_4)_4$ structure showing the atom-labeling scheme (30% thermal ellipsoids).

There are two different phosphorus sites in the asymmetric unit of **1**. Of the three independent phosphorus atoms, P(1) atom is four-coordinate with respect to bridging oxygen (average P–O bond length 1.537 Å and average O–P–O bond angles 109.5°). P(2) and P(3) atoms are coordinated with three bridging oxygens and a double-bonded oxygen, respectively. The P(2)–O(7) distance of 1.520(4) Å and the P(3)–O(11) distance of 1.518(3) Å arise from the formal P=O double bond. The terminal P=O groups in $H_3PO_4\cdot0.5H_2O$, are generally between 1.485 and 1.495 Å in length.[12] The O–P–O bond angles are in the range 103.88–114.1° (av. 108.7°). The largest bond angle is observed for bonds involving the P=O linkage [114.1(1)° for P(2) and 113.7(2)° for P(3)], including the multiple-bond nature of P=O bonds. Each tin atom is triply coordinated to oxygen, resulting in average Sn–O bond length of 2.145 Å and average Sn–O bond angle of 86.93°. These values are in good agreement with other tin(II) phosphate open-framework structures.[5–7,13]

The connectivity of the $PO_4$ and $SnO_3$ units in **1** results in an anionic layer with the stoichiometry $[Sn_4(PO_4)_3(OH)]^{2-}$, which propagates along the *a*-axis. The structure is constructed entirely from a unit of double 5-rings.[14] Two 5-rings are joined each other through common edge of Sn–O–Sn to form the unit of two 5-rings. The units build up of zigzag chains through phosphorus bridges. These chains are related to one another by a center of inversion, and are linked in double-connected manner through oxygen bridges. The connection forms corrugated sheets along the *a* direction, resulting in 4-rings and 8-rings (Figure 2, a). The hydrogen atoms of the protonated *trans*-1,2-DACH molecules interact strongly with the framework oxygen atoms, espe-

The bridging hydroxy groups in the framework are not involved in forming hydrogen bonds. The multipoint hydrogen-bonding interactions between amino groups and framework sheets cause the layers to bend. Presumably the two amino groups in *trans* configuration provide better access for hydrogen bond formation, compared to the *cis*-diamine. Thus, it afforded a more stable open-framework structure. This might be attributable to selective intercalation of *trans*-DACH with the exclusion of *cis*-DACH in compound **1**. This selectivity was confirmed by leaching experiments. The liquid residue obtained contained 98.9% *trans* diamine. The adjacent layers then are packed one over the other translated by approximately a one-half cell unit along the *c*-axis through the van der Waals interaction between tin atom and oxygen atom located in neighboring sheets (the distance between Sn and O is about 3.0 Å). This stacking leads to the formation of pseudo 18-ring channels along the *a*-axis (Figure 2, b). If van der Waals radii are taken into account, the width of 18-ring 1D channel is 1.62 nm × 1.26 nm (longest O–O distances and shortest O–O distances). The lone pair borne by the tin atom manifests itself in the lattice by creating open space in the channel. Repulsion between lone pairs associated with next tin atoms makes a small position shift between adjacent layers. At the same time, 8-ring channels are formed along the [011] direction.

An ORTEP representation of **2** is shown in part b of Figure 1 and the selected bond lengths and angles are given in Table 4. The tin atoms afford two different coordination environments with oxygen in this structure; the triply coordinated trigonal-pyramidal $SnO_3$ and the tetra-coordinated truncated square-pyramidal $SnO_4$. The $SnO_3$, $SnO_4$ and $PO_4$ moieties are vertex-linked forming the 3D neutral framework. The structure is dominated by a number of $Sn_2O_2$ 4-rings, resulting in a higher Sn/P ratio (2.5), in con-

Table 4. Selected bond lengths [Å] and angles [°] for $(Sn_3O)_2(Sn_2O)(PO_4)_4$ (**2**).[a]

trast to those reported previously.[5–7,13] The triply-coordinated oxygen atoms do not create a situation where P–O–P bonding occurs, in accordance with Loewenstein rule.[15] Of the five independent Sn atoms in the asymmetric unit, Sn(1), Sn(2), Sn(3) and Sn(5) are triply-coordinated with respect to oxygen and the remaining Sn(4) atom is tetra-coordinated. The Sn($x$)–O ($x$ = 1, 2, 3, 5) bond lengths are in the range 2.088–2.406 Å (av. 2.336 Å), and the O–Sn($x$)–O ($x$ = 1, 2, 3, 5) bond angle are in the range 74.8–94.6° (av. 85.2°); The Sn(4)–O distances are in the range of 2.154–2.525 Å (av. 2.336 Å), and O–Sn(4)–O bond angles are in the range 71.0–141.3° (av. 89.9°). The longest Sn–O distance (2.525 Å) in the present structure as well as the largest O–Sn–O bond angle (141.3°) are associated with the tetra-coordinated Sn(4). P(1) and P(2) are both tetra-coordinate with respect to bridging oxygen with average P–O bond length of 1.577 Å and average O–P–O bond angle of 109.4°. These values are in agreement with those reported earlier.[5–7,13]

In the neutral framework structure **2**, the trigonal-pyramidal $SnO_3$, square-pyramidal $SnO_4$ and tetrahedral $PO_4$ units are linked through bridging oxygen atoms. The second building unit (SBU) is a cage that is composed of eight Sn atoms and two P atoms (Figure 3, a). These cages are linked through 4-rings (2P + 2Sn) in three different ways (Figure 3, b), i.e. connections between an oxygen atom of the cage and a phosphorus atom of the 4-ring, or between a tin atom of the cage and a phosphorus atom of the 4-ring through bridging oxygen atom, or between an oxygen atom of the cage, and a tin atom of the 4-ring. A 4-ring is connected with six cages. Each phosphorus atom of the 4-ring is linked with two cages, while each tin atom linked only with one cage. These cages are related to each other by a center of inversion diagonally in the 4-ring. In contrast, each cage is connected with six 4-rings, four of them through phosphorus atom of the 4-ring and the rest two through a tin atom of the 4-ring. These connections result in formation of 3D framework with sequences of helical 6-ring and elliptical 12-ring channels in the b-direction (Figure 3, b). A 6-ring consists of three phosphorus and three tin atoms, and 12-membered ring consists of four phosphorus and eight tin atoms. The maximal width of the channel is 9.37 Å (P–P distance, not including van der Waals radii). However, the minimal width is merely 0.5 Å (Sn–Sn distance, not including van der Waals radii). Since the lone pair borne by tin atom occupies the channels, access by any molecule is prohibited. Experiments of $N_2$ adsorption and desorption also verify this conclusion affording an adsorbed volume is only 4.29 $cm^3 g^{-1}$ at pressure of 790 Torr.

The framework density (FD) for **1** and **2** are 13.8 and 22.35 T-atoms (T = Sn, P) per $nm^3$, respectively. Compound **2** shows dense packing morphology compared to other framework materials (FD < 20).[14,16]

In conclusion, although a mixture of isomers of 1,2-DACH was used in the synthesis, only the *trans* species were as templates occluded in **1** as confirmed through leaching experiments. The *trans* isomer has two chiral centers, corresponding to 1*S*,2*S* and 1*R*,2*R* enantiomers. Four [*trans*-1,2-

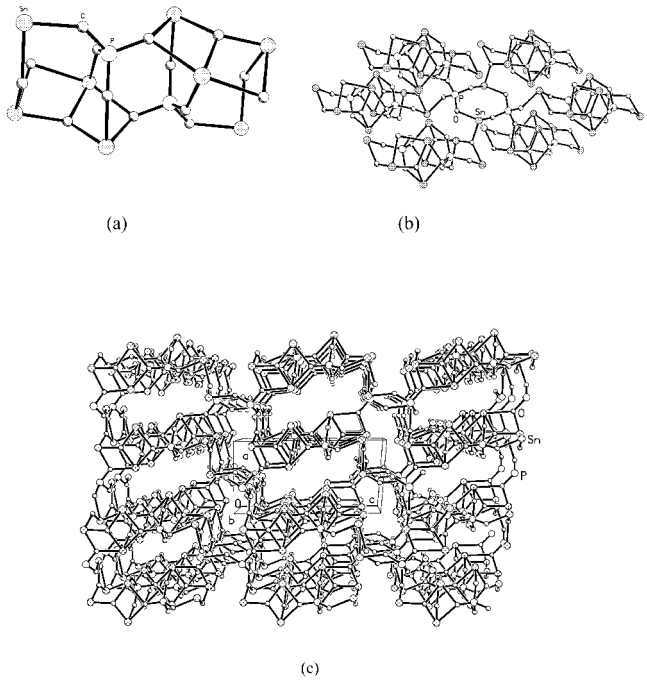

Figure 3. (a) Cage as a SUB for structure of compound **2**, $(Sn_3O)_2(Sn_2O)(PO_4)_4$. (b) The connections of cages with (2P + 2Sn) 4-ring. (c) The structure of $(Sn_3O)_2(Sn_2O)(PO_4)_4$ viewed along the *b*-axis, showing sequences of helical 6-rings and elliptical 12-rings channels in the same direction.

$C_6H_{10}(NH_3)_2]^{2+}$ cations are found in a unit cell and the nearest neighboring cations are symmetry related by a $2_1$-screw axis (Figure 2, b). The cation site is occupied by mirror plane related diastereoisomer with an occupancy factor of 50%. When only *cis* isomer was used as template in the synthesis of **2**, no template molecule is occluded in the inorganic framework (Figure 3, c). Only a *trans* orientation of the two amino groups provides the appropriate hydrogen bonding interaction to result in complex formation. This may afford some interesting insight in terms of role that templates play in hydrothermal synthesis.

## Experimental Section

**Synthesis:** All chemicals used were of analytical grade. Hydrothermal synthesis of **1** is described here. $SnC_2O_4$ (1.187 g, 5.74 mmol) was dispersed in 10 mL of water and 0.60 mL of 85 wt.-% aqueous $H_3PO_4$ was added to the mixture under continuous stirring. A mixture of *trans*- and *cis*-1,2-DACH (1.23 mL, 10 mmol) was added. The reaction mixture was stirred until it was homogeneous and the pH value was 7.4. The mixture ($SnC_2O_4$/1.5 $H_3PO_4$/1.8 DACH/58 $H_2O$) was transferred into a 23 mL Teflon™-lined stainless steel autoclave and heated at 443 K for 10 d under autogenous pressure. The pH value of the solution was 6.7. The solid product (in about 70% yield based on the Sn source) consisting of colorless schistose single crystals **1** was recovered by filtration, washed thoroughly with distilled water, and dried at room temperature. Compound **1** was also afforded with an approximate 60% yield when *trans*-1,2-DACH was used under the conditions. The pH values of the solution before and after reaction were 7.4 and 6.6, respectively. Colorless prismatic crystals of **2** were obtained hydrothermally using only

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*cis*-1,2-DACH as template under the same reaction conditions to those for **1**. The pH value of solution was 7.5 and the yield was about 58%.

**Initial Characterization:** The element analysis of the product was performed with a Foss Heraeus CHN-O-RAPID elemental analyzer, and the ICP analysis was performed with a Jarell-Ash 1100+2000 ICP instrument. The IR spectra were recorded with a Bruker 410 FT-IR spectrometer using KBr pellets. TGA and DTA were conducted with V1.1B TA thermogravimetric analyzer under nitrogen in the range between 25 and 600 °C, with a heating rate of 10 °C min$^{-1}$. Assays of isomeric residue in leaching experiment were carried out with a Varain-5000 high-performance chromatograph with fixed-wavelength UV absorbance detector set at 254 nm under ambient temperatures, on a 150 mm × 4.6 mm reversed-phase Eclipse XDB-C8 LC Column (Agilent Technologies Corp., USA) with an eluting mobile phase consisting of acetonitrile/0.05% phosphoric acid (45:55).

**Single-Crystal X-ray Diffraction:** A plate-like crystal of approximate dimensions 0.30 × 0.30 × 0.20 mm for **1** was mounted on a glass fiber on a Siemens Smart-CCD diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation. A hemisphere of intensity data was collected at 291(2) K in the $2\theta$ range 3.54–55.00°. A total of 4354 reflection was collected, of which 4075 were considered to be observed with $I > 2\sigma(I)$. Data processing was accomplished with SAINT processing program.[17] The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ using SHELX97.[18] Each carbon attached to an amino group is disordered with a SOF (site occupation factor) of 0.5. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed geometrically and allowed to ride on the atoms to which they were attached with fixed isotropic thermal parameters by program.

CCDC-165851 contains the supplementary crystallographic data of **1** for this paper. These data can be obtained free of charge from Cambridge Crystallographic Data Center at www.ccdc.cam.ac.uk/data_request/cif.

A prismatic crystal with dimension of 0.3 × 0.2 × 0.2 mm for **2** was mounted on a glass fiber. Data were collected on FR590 CAD-4 diffractometer (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) at 293(2) K in the range $3.18 < 2\theta < 49.6°$ using the $\omega$ scan technique. A total of 1990 reflections were collected of which 1709 with $I > 2\sigma(I)$ were used. An empirical absorption correction was applied. The structure was solved by direct methods and refined using SHELX97 programs.[18] All atoms were refined anisotropically. Pertinent experimental details for the structure determination are listed in Table 1.

Further details of the crystal-structure investigation may be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany (http://www.fiz-karlsruhe.de), on quoting the depository number CSD-412358.

**Leaching Experiment:** Compound **1** (4.46 g, 5 mmol) was added to 50 mL of 0.2 N NaAc solution in THF. The mixture was continuously stirred under reflux for 10 h and cooled to room temperature. The solids were filtered off, washed with THF. Then 20 mL of 20% NaOH aqueous solution was added to the filtrate to liberate 1,2-DACH from the acetate salt. The mixture was continuously extracted with 40 mL of benzene for 5 h. The benzene extract was evaporated under vacuum, leaving a liquid residue (about 0.25 g, yield 44.0% based on the empirical formula of **1**). The liquid residue consisted of 98.9% *trans*-1,2-DACH and 1.1% *cis*-1,2-DACH.[19] After leaching, the crystal structure was lost and the resulting amorphous solid showed a different powder diffraction pattern from that of compound **1**.

(Agilent Technologies Corp., USA) with an eluting mobile phase consisting of acetonitrile/0.05% phosphoric acid (45:55). Eluents were aspirated prior to use. At a flow-rate of 1.0 mL/min column equilibration with the mobile phase was achieved in approximately 30 min. The retention times are 8.6 min, 10.4 min, 11.9 min for *trans*-(1*S*,2*S*)-DACH, *cis*-1,2-DACH and *trans*-(1*R*,2*R*)-DACH, respectively. Samples preparation: 0.2 mL of 0.4% acetonitrile solution of 2,3,4,6-tetra-*O*-acetyl-D-glucopyranosyl isothiocyanate was added to 0.1 mL of 0.025% acetonitrile solution of 1,2-DACH. Ten minutes later, 0.1 mL of 0.2% acetonitrile solution of ethanolamine was added to the given mixture. And three minutes later, 2.0 mL of 0.05% phosphoric acid was added to dilute the above solution.

# Preparation, Structure and Reactivity of Polynuclear Gold(I) Phosphanyl Alkanethiolates

**Antonella Battisti,[a] Oliver Bellina,[a] Pietro Diversi,*[a] Serena Losi,[b] Fabio Marchetti,[a] and Piero Zanello[b]**

**Keywords:** Gold(I) complexes / Tertiary phosphane complexes / Thiolates / Aurophilicity / Redox behaviour

The homoleptic gold(I) thiolates of formula $[Au(SR)]_n$ (R = $CMe_3$, $CH_2CMe_3$, $CH_2CHMe_2$, $CPh_3$) have been converted into their phosphane derivatives of general formula [Au(SR)(L)] (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$) and $[Au_2(SR)_2(dppe)]$ [dppe = 1,2-bis(diphenylphosphanyl)ethane], which have been characterized by elemental analysis, mass spectrometry, $^1H$ and $^{31}P$ NMR spectroscopy and cyclic voltammetry. Complexes $[Au(SCMe_3)(PMePh_2)]$ (**1c**), $[Au_2(SCMe_3)_2(dppe)]$ (**1e**) and $[Au(SCH_2CMe_3)(PPh_3)]$ (**3d**) have been characterized in the solid state by X-ray diffraction: no aurophilic interactions have been found. The electrochemical behaviour of these phosphane thiolato derivatives shows two irreversible oxidation processes, the first of which involves 0.5 electrons per Au–SR. Chemical oxidation by $[FeCp_2]BF_4$ produces disulfide and cationic gold(I) complexes of formula $[Au_2(SR)(L)_2][BF_4]$ and $[Au_2(SR)(dppe)][BF_4]$, characterized by elemental analysis, mass spectrometry and $^1H$ and $^{31}P$ NMR spectroscopy. All the complexes are presumably dimeric in the solid state as shown in the case of $[Au_4(SCMe_3)_2(dppe)_2][BF_4]_2$ (**5e**) and $[Au_4(SCH_2CMe_3)_2(PMe_3)_4][BF_4]_2$ (**7a**), which have been fully characterized by X-ray diffraction. The aurophilic interactions form a structure of four gold atoms with pairs of atoms bonded by bridging thiolato ligands, which are arranged in an almost perfect square in the case of **7a** and in an unprecedented zigzag sequence in the case of **5e**. Complex **4a** reacts with $HSCMe_3$ under basic conditions to give $[Au(SCMe_3)(PMe_3)]$ and with LiX (X = Me, $CH_2CMe_3$) to give a 1:1 mixture of $[AuX(PMe_3)]$ and $[Au(SCMe_3)(PMe_3)]$.

## Introduction

Research on gold(I) thiolate complexes has produced numerous reports over the past few decades, because of their various practical applications such as, i.a., in gilding technology,[1] in the treatment of rheumatoid arthritis and in cancer chemotherapy.[2] In fact some phosphane gold(I) thiolates are the active principles of Auranofin and other antiarthritic products,[3] whose therapeutic activity seems to be correlated to their oxidation products in vivo. In particular Bruce et al., by thoroughly investigating the oxidation of such thiolato-phosphane derivatives, have been able to show that the final products are cationic gold clusters stabilized in the solid state by aurophilic interactions.[3]

In spite of many literature reports on the synthesis and properties of gold thiolates,[4] complexes containing simple aliphatic groups have been limited to some scattered scientific reports[4a–4c,4g,4h] and some information deriving from patents.[5] So far attention has mostly been dedicated to the few homoleptic thiolates, which are soluble in organic solvents,[4k] and to the phosphane-thiolato derivatives carrying biologically interesting substrates.[3d]

In this paper we describe the synthesis, the characterization and the redox behaviour of a series of gold(I) thiolate complexes derived from simple sterically demanding alkanethiols, where the alkyl group is the *tert*-butyl, *sec*-butyl and neopentyl group. We have also studied triphenylmethanethiol derivatives for comparison purposes. We have prepared homoleptic, neutral derivatives with phosphanes, and the corresponding cationic products prepared according to the Bruce oxidative procedure[3] as a strategy for building gold–gold interactions in the solid state. We report also the structural characterization and a preliminary investigation on the reactivity of these polynuclear cations.

## Results and Discussion

### Syntheses

The homoleptic thiolates $[Au(SR)]_n$ (R = $CMe_3$, $CH_2CHMe_2$, $CH_2CMe_3$, $CPh_3$) have been prepared following essentially two literature methods: addition of an excess

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(3:1) of the thiol to a solution of aqueous tetrachloroauric acid, or alternatively the use of bis(2-hydroxyethyl) sulfide as the auxiliary reducing agent before adding the thiol.[4c] The two methods give similar yields (almost quantitative), but the latter was preferred in the case of the neopentanethiolate, owing to the necessity of saving the starting thiol. In this case care must be used in controlling the temperature to avoid the formation of metallic gold. The thiolates have good stability either in the air or in the light and are generally insoluble at room temperature in the most common organic solvents, apart from the neopentanethiolate that is slightly soluble in benzene and dichloromethane after it has been kept for a while at 40–45 °C. Owing to their insolubility the complexes were characterized only by elemental analysis. They react easily with stoichiometric amounts of the appropriate phosphane to yield the corresponding gold(I) phosphane thiolates of formula [Au(SR)(L)] (R = *tert*-butyl, L = $PMe_3$ **1a**, $PMe_2Ph$ **1b**, $PMePh_2$ **1c**, $PPh_3$ **1d**; R = isobutyl, L = $PMe_3$ **2a**, $PMe_2Ph$ **2b**, $PMePh_2$ **2c**, $PPh_3$ **2d**; R = neopentyl, L = $PMe_3$ **3a**, $PMe_2Ph$ **3b**, $PMePh_2$ **3c**, $PPh_3$ **3d**; R = trityl, L = $PMe_3$ **4a**, $PMe_2Ph$ **4b**, $PMePh_2$ **4c**, $PPh_3$ **4d**).[4e,4h,4i] As far as we know, only [Au($SCMe_3$)($PPh_3$)] (**1d**) and [Au($SCH_2CHMe_2$)($PPh_3$)] (**2d**) have already been reported in the literature, **1d** having been prepared by the reaction of [AuCl($PPh_3$)] with [Pb($SCMe_3$)$_2$][4c] and **2d** by the reaction of [AuCl($PPh_3$)] with the thiol in the presence of a base.[4a]

The reactions were carried out in benzene at room temperature, the yields varying from 80 to 95%. The compounds are crystalline colourless solids, stable in the air and humidity, soluble in aromatic and chlorinated solvents and insoluble in aliphatic hydrocarbons.

The gold(I) dppe thiolates [$Au_2$($SR$)$_2$(dppe)] (R = $CMe_3$ **1e**; $CH_2CHMe_2$ **2e**; $CH_2CMe_3$ **3e**), have been prepared in the same way by using a phosphane/Au = 1/2 molar ratio. All the compounds have been characterized by elemental analysis and NMR spectroscopy.

Well-formed crystals suitable for X-ray determination have been obtained for [Au($SCMe_3$)($PMePh_2$)] (**1c**), [$Au_2$($SCMe_3$)$_2$(dppe)] (**1e**) and [Au($SCH_2CMe_3$)($PPh_3$)] (**3d**) by crystallization from toluene at low temperature. None of these complexes show the presence of aurophilic interactions. The molecular structure of **1c** is shown in Figure 1, the most relevant distances and angles are also listed in Table 1. The gold atom shows the expected linear coordination and Au–S and Au–P distances are very similar to those observed in many other structurally characterized gold(I) phosphanyl-thiolate complexes that are reported in the literature,[6] and closely correspond to those reported for other gold(I) methyldiphenylphosphane derivatives.[6c]

Figure 2 shows the centrosymmetric structure of compound **1e** whose geometrical parameters around the gold atom are listed in Table 1. The observed conformation of the dppe ligand is a normal feature in almost all the gold(I) diphosphanyl-thiolate complexes studied hitherto,[7] apart from the cases with bidentate thiolate ligands, which result in cyclic complexes.[8]

Finally, the most relevant distances and angles of **3d** (the molecular structure is shown in Figure S1 in the Supporting Information) are listed in Table 1. The gold coordination is very similar to that found in **1e** and **3d** and corresponds very closely to that which has been found in the neutral phosphanyl-thiolato complexes of gold(I) with triphenylphosphane.[7f,9]

### Oxidation of Gold Thiolates

In spite of the widespread use in several decomposition techniques and some applications in galvanic processes, the electrochemistry of gold complexes was until recently rather poorly explored. A review summarizes the results of the redox behaviour of gold and silver compounds.[11] In particular the Bruce group has found that gold phosphane thiolates undergo two irreversible oxidation processes, that, in agreement to theoretical studies, were assigned as sulfur- and gold-centred, respectively.[3] Chemical complications following oxidation have been elucidated by studying the reaction with ferrocenium tetrafluoroborate.[3] The oxidation process ultimately gives disulfide and a cationic cluster that in the solid state appears to be constituted by a dicationic tetragold system with gold–gold distances that are in the range of typical distances for aurophilic interactions.[3,10] Such reactivity has been observed in a variety of phosphane and diphosphane gold thiolates, and in particular in the case of those derivatives that are the active principles of Auranofin and of other antiarthritic drugs.[3]

The present study is aimed at elucidating the behaviour of our systems towards both electrochemical and chemical oxidation and exploiting the Bruce reaction in order to build up polynuclear structures, and possibly to understand how the structure and the geometry depend on the nature of the ligands.

### Electrochemical Studies

As representatively shown in Figure 3, which refers to [Au(SCH$_2$CMe$_3$)(PMe$_3$)], the gold thiolates with monophosphanes undergo two oxidation processes, both having features of chemical irreversibility.[12] Indeed, also limited to the first oxidation (peak **A**), it lacks the directly associated return peak even at high scan rates (2.0 V s$^{-1}$), thus indicating that the oxidized product undergoes rapid chemical complications.

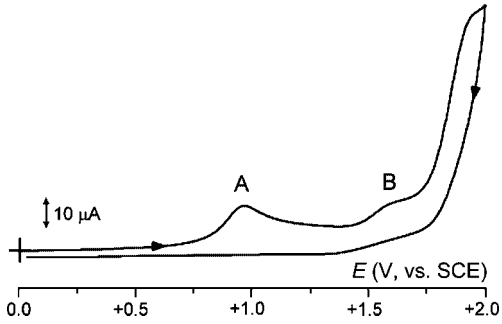

Figure 3. Cyclic voltammogram recorded at a platinum electrode in $CH_2Cl_2$ solution containing [Au(SCH$_2$CMe$_3$)(PMe$_3$)] ($1.8 \times 10^{-3}$ mol dm$^{-3}$) and [NBu$_4$][PF$_6$] (0.2 mol dm$^{-3}$). Scan rate: 0.2 V s$^{-1}$.

In agreement with the literature,[3] exhaustive oxidation that corresponds to the first oxidation ($E_w$ = +1.2 V) consumes ca. half an electron per molecule, confirming that the ligand centred[9] first process is coupled to fast chemical reactions. Because of the partial overlapping of the solvent discharge no attempts to identify the product arising from the second gold-centred process have been carried out (the standard reduction potential of the couple Au$^{I}$/Au$^{0}$ in water is +1.69 V).

Table 2 consists of the electrode potentials from the first oxidation of all the compounds studied: An attempt to account for the influence of the electronic effects from the different substituents present in the phosphane or the thiolate groups[12] on the location of the oxidation processes (Table S1 in the Supporting Information) suggests that the main contribution would arise from the inductive effects of the substituents of the phosphane moieties. In fact, they display the highest correlation coefficients, whereas the contribution of the thiolate substituents greatly departs from linearity. However, it has been considered that, given the irreversibility of the electron removals, the potentials for the first oxidation might have a thermodynamic meaning only under the assumption that the kinetics of the coupled chemical complications proceed with similar rates.[13]

In fact, as in the case of the mononuclear complexes, exhaustive oxidation at the first anodic process consumes half an electron per gold atom, which means one electron per molecule. The peak potentials for the first oxidation of the dinuclear derivatives are reported in Table 2.

Since in the mononuclear derivatives the SCMe$_3$ group seems to be a more efficient electron donor than the

Table 2. Peak potentials (V vs. SCE) for the first oxidation process exhibited by the present mono- and digold thiolates in $CH_2Cl_2$ solution.

| Complex | $E_p$[a] | Complex | $E_p$[a] | Complex | $E_p$[a] |
|---|---|---|---|---|---|
| [Au(SCMe$_3$)(PMe$_3$)] (**1a**) | +0.97 | [Au(SCH$_2$CHMe$_2$)(PMe$_3$)] (**2a**) | +0.97 | [Au(SCPh$_3$)(PMe$_3$)] (**4a**) | +0.91 |
| [Au(SCMe$_3$)($^{m}$e2Ph)] (**1b**) | +0.95 | [Au(SCH$_2$CHMe$_2$)(PPh$_3$)] (**2d**) | +1.09 | [Au(SCPh$_3$)(PMe$_2$Ph)] (**4b**) | +0.96 |
| [Au(SCMe$_3$)(PMePh$_2$)] (**1c**) | +1.03 | [Au(SCH$_2$CMe$_3$)(PMe$_3$)] (**3a**) | +1.00 | [Au(SCPh$_3$)(PMePh$_2$)] (**4c**) | +1.04 |
| [Au(SCMe$_3$)(PPh$_3$)] (**1d**) | +1.04 | [Au(SCH$_2$CMe$_3$)(PPh$_3$)] (**3d**) | +1.22 | [Au(SCPh$_3$)(PPh$_3$)] (**4d**) | +1.07 |
| [Au$_2$(SCMe$_3$)$_2$(dppe)] (**1e**) | +0.90 | | | | |
| [Au$_2$(SCH$_2$CHMe$_2$)$_2$(dppe)] (**2e**) | +1.10 | | | | |
| [Au$_2$(SCH$_2$CMe$_3$)$_2$(dppe)] (**3e**) | +0.75 | | | | |

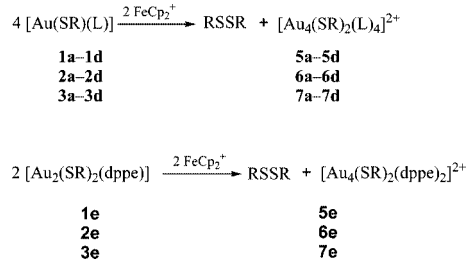
[a] Measured at 0.2 V s$^{-1}$. In turn the dinuclear derivatives exhibit a voltammetric profile qualitatively similar to those of the mononuclear complexes {the cyclic voltammetric behaviour of [Au$_2$(SCH$_2$CMe$_3$)$_2$(dppe)] (**3e**) is illustrated in Figure S2 in the Supporting Information}.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$SCH_2CMe_3$ ligand, it is puzzling that $[Au_2(SCMe_3)_2(dppe)]$ is oxidized less easily than $[Au_2(SCH_2CMe_3)_2(dppe)]$, unless a different relative arrangement of the thiolato groups in the complexes with dppe might be operative.

### Chemical Oxidation

Following previous reaction conditions,[3] the phosphane gold thiolates **1**–**3** have been reacted with $[FeCp_2][BF_4]$ (Scheme 1). In all cases (apart from the thiolates **4**, which react giving uncharacterized products) the reaction proceeds by consuming one mol of ferrocenium salt per two mol of gold thiolate moiety, as shown by colour changes at the equivalence point (the persistence of the green colour of the ferrocenium ion indicates that the reaction is complete).



Scheme 1.

The solid residue, after evaporation of the solvent, is washed with diethyl ether in order to extract ferrocene and the disulfide (RSSR) (the oxidation product of the thiolato ligand), which were identified by NMR spectroscopy. The residue was crystallized from dichloromethane/hexane to give grey to pale yellow crystals of **5**–**7**, which are stable in the air and insoluble in aliphatic and aromatic hydrocarbons, and fairly soluble in acetone and dichloromethane. All the products present satisfactory elemental analyses and have been characterized by NMR spectroscopy and mass spectrometry. On the basis of the relative 2:1 ratio of the $^1H$ NMR signals from the phosphane and the thiolato groups we have attributed a general formula $[Au_2(SR)(L)_2][BF_4]$. Actually, for similar compounds, the literature reports[3] structures in the solid state that generally result from the aggregation of the monocations in dimers of the formula $[Au_4(SR)_2(phosphane)_4][BF_4]_2$, where the tetranuclear arrangement of the gold atoms is due to aurophilic interactions.

Well-formed crystals suitable for structural determination have been obtained in the case of **5e** and **7a** by crystallization from dichloromethane/hexane or dichloromethane/diethyl ether solutions.

The structure of the tetranuclear cation $[Au_4(SCH_2CMe_3)_2(PMe_3)_4]^{2+}$ is sketched in Figure 4 and the most significant bond lengths and angles are listed in Table 3. The four gold atoms make a square ring by means of four aurophilic interactions. Such an arrangement is very frequent in phosphanyl-thiolato complexes of gold(I), notably with the trimethylphosphane.[6e,14] The cation belongs to the point group 2/*m* ($C_{2h}$), possessing the inversion centre in the middle of the square of the four gold atoms, the twofold axis lying in the gold plane in the middle between the atoms Au and Au′ and the mirror perpendicular to the axis passing through the S and C(1) atoms. It is a common feature of the gold derivatives with this framework that the PSP plane makes a dihedral angle with the $Au_4$ plane acute from the side of the sulfur atom. Our cation conforms to this feature showing a torsion angle Au′–Au–Au′′–S of 85.2°. The methyl groups of the phosphanes do not comply with the high symmetry of the molecule, resulting in a statistical disorder between two limit conformations almost equally populated and corresponding to different torsion angles Au′–Au–P–C(5). For the sake of simplicity, only the A conformation of the methyl groups, as marked by the labels, has been drawn in the figure because of its slightly higher frequency.
