by calcination at temperatures higher than 600 °C. (3) Crystallization of the metal oxide can be readily achieved under the confinement of the mesostructure of carbon. In practice, we used the mesoporous carbon hollow spheres of interconnected mesostructure as a solid *exo* template to prepare the porous metal oxide hollow spheres.[22] Figure 6 shows the representative TEM and SEM images of the $ZrO_2$, $Al_2O_3$, $TiO_2$, and $Fe_2O_3$ hollow spheres prepared by impregnating mesoporous carbon hollow spheres with acidic ethanolic solutions of $Zr(OAc)_4$, $Al(NO_3)_3$, $Ti(OBu)_4$, and $Fe(NO_3)_3$ salts, respectively, and calcination at 600 °C in air. These images clearly demonstrate that the metal oxide hollow spheres can be easily obtained from a typical impregnation process by using mesoporous carbon hollow spheres as a solid template. In addition to preserving the hollow-sphere morphology, the HR-TEM image reveals that the shell of the metal oxide hollow spheres is composed of many nanocrystals (ca. 5–30 nm, insets of Figure 6). In combination with the high-angle XRD patterns of the metal oxide hollow spheres, all broad XRD peaks can be assigned undisputedly to the $\gamma$-$Al_2O_3$, *anatase*-$TiO_2$, $\alpha$-$Fe_2O_3$, and $ZrO_2$ nanoparticles. According to these results, we proposed a possible mechanism for the formation of the mesoporous metal oxide hollow spheres. In the first stage, the precursors of the metal oxides can be incorporated into the interconnected nanopores of the mesoporous carbon shell. Upon heat treatment, the precursors thermally decompose, and the nanoparticles derived therefrom grow larger and crystallize. In the presence of thermally stable carbon, the crystalline dimension is confined to the nanoscale. Because the nanocrystals interlink with each other and form continuous and stable frameworks, the hollow-sphere morphology is fully replicated even after the removal of the carbon template by further high temperature heat treatment. These metal oxide hollow spheres have a high surface area (100–150 $m^2 g^{-1}$), large pore size (8.0–12.0 nm), and a large volume (0.25–0.35 $cm^3 g^{-1}$; Supporting Information, Figure S4, Table S1). In addition to $ZrO_2$, $\gamma$-$Al_2O_3$, *anatase*-$TiO_2$, and $\alpha$-$Fe_2O_3$ mesoporous hollow spheres,[23–27] other metal oxide hollow spheres (e.g. MgO and $CeO_2$; Supporting Information, Figure S5) were also produced by using the mesoporous carbon hollow spheres as a solid template. Moreover, to obtain magnetic nanoparticles containing mesoporous carbon hollow spheres, the $Fe(NO_3)_3$ impregnated mesoporous carbon was heated to 900 °C under a $N_2$ atmosphere instead. Figure 6F shows that the Fe nanoparticles are embedded within the mesoporous carbon shell or in the interior of the hollow spheres. The magnetic nanoparticles containing mesoporous carbon hollow spheres demonstrate the magnetic properties (Supporting Information, Figure S6).

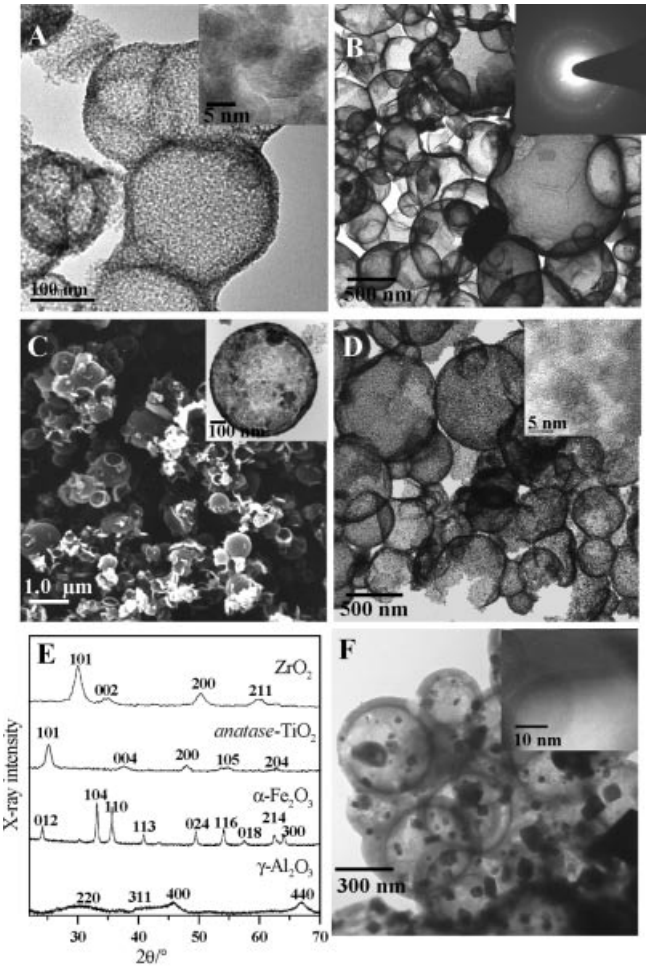

Figure 6. TEM and SEM images and XRD patterns of the mesoporous metal oxide hollow spheres prepared by using mesoporous carbon hollow spheres as hard templates. (A) $ZrO_2$; (B) $\gamma$-$Al_2O_3$; (C) $\alpha$-$Fe_2O_3$; (D) *anatase*-$TiO_2$, (E) XRD patterns; (F) The Fe nanoparticle containing mesoporous carbon hollow spheres obtained from pyrolysis of a $Fe(NO_3)_3$ impregnated mesoporous carbon hollow spheres at 700 °C under an atmosphere of $N_2$. Insets are the HR-TEM and electron-diffraction images of the metal oxides and iron nanoparticles.

## Conclusions

In brief, we have described a new method to conveniently synthesize PF–PEO/silica hollow spheres. The synergistic PF–PEO/silica hybrid composite can be transferred to mesoporous carbon and mesoporous silica hollow spheres as required. This synthetic method for the preparation of hollow spheres with different diameters involves the simple mixing of well-defined precursors and changing the components and pH value of the mixture; thus scale-up of the hollow spheres is readily accomplished. The phase-separation approach can be extended to different polymer blends and nonsilica metal oxides. With good control of assembling kinetics, one can judiciously select other polymer blends to manufacture hollow mesoporous spheres with high flexibility in their compositions. In addition, the use of stable mesoporous carbon hollow spheres is an alternative for the preparation of metal oxides hollow spheres of high crystallinity and magnetic mesoporous carbon hollow spheres. These hollow spheres of high composition-flexibility have potential to be applied as a catalyst, absorbent, sensor, magnetically separable carrier, microcapsule, supercapacitor, and as an aid in drug-delivery and fuel cells.

## Experimental Section

**Typical Synthesis of Mesoporous Carbon and Silica Hollow Spheres:** The PEO (Acrös) (2.0 g) and PF (0.5–3.0 g; PF2180, phenol/aldehyde, 0.8–0.9; MW ca. 96000; Chung-Chun Plastic, Taiwan) polymers were dissolved in a mixture of ethanol (20.0 g) and water (5–15 g) to form a clear solution. Then, the PF–PEO blend solution was poured quickly into an acidified sodium silicate solution aqueous solution (pH ≈ 5.0–6.0) at 40 °C, which was prepared by adjusting the pH value of a mixture of sodium silicate (27 wt.-% $SiO_2$, 8.0 g, Aldrich) and water (300.0 g) to 4.0–7.0 and aging for 3–10 min. A light-yellowed precipitate formed within a few seconds. Filtration, washing, and drying at 100 °C gave the PF–PEO/silica hollow spheres. The mesoporous carbon hollow spheres with mesoporous shells were gained after a pyrolysis at 1000 °C under a $N_2$ atmosphere for 2 h and silica removal by 6 wt.-% HF etching. Alternatively, to obtain the hollow silica spheres with a mesoporous shell, the PF–PEO/silica hollow spheres were kept static in a polypropylene bottle at 100 °C for 1 d and calcined at 580 °C for 6 h to remove the organic template.

**Synthesis of Metal Oxides Hollow Sphere:** A proper amount of metal oxide precursor (metal/carbon ≈ 1:50 in mol) was dissolved in an acidic ethanolic solution (95 wt.-% ethanol, 20.0 g, conc. $HNO_3$, 1.0 g). The $Zr(OAc)_4$, $Al(NO_3)_3$, $Ti(OBu)_4$, and $Fe(NO_3)_3$ were used as the precursors to the $ZrO_2$, $\gamma$-$Al_2O_3$, *anatase*-$TiO_2$, and $\alpha$-$Fe_2O_3$ hollow spheres, respectively. Then, the ethanolic solution was combined with the mesoporous carbon hollow sphere sample (0.4 g). After stirring for 1 d under ambient conditions and dried at 60 °C to evaporate the solvent, the dried metal oxide precursor impregnated mesoporous carbon was obtained. Calcination at 600 °C for 8 h to remove the mesoporous carbon template gave the metal oxides hollow spheres.

**Characterization:** $N_2$ adsorption–desorption isotherms were obtained at 77 K with a Micromeritics ASAP 2010 apparatus. Before analysis, the sample was degassed at 120 °C for about 6 h at $10^{-3}$ Torr. The pore size distribution was obtained from the analysis of the adsorption branch by using the BJH (Barrett–Joyner–Halenda) method. Scanning electron microscopy (SEM) and transmission electron microscopy (TEM) images were obtained with an S-800 (Hitachi) operated at an acceleration voltage of 20 keV and an H-7500 (Hitachi) operated at 100 keV, respectively. The organic content in the mesoporous silicas and the porous carbon thermostability were measured by thermogravimetric analysis (TGA). TGA tests were conducted with a TA Q-50 thermogravimetric system. In a typical experiment, ca. 10 mg of the sample was heated to 700–800 °C at 10 °C $min^{-1}$ in air. Raman spectra were obtained with a Dilor XY Raman spectrum, using an Ar laser with an excitation wavelength of 514.5 nm.

**Supporting Information** (see footnote on the first page of this article): TGA curve of the mesoporous carbon hollow spheres, $N_2$ adsorption–desorption isotherm of the PF–PEO*n* polymer blend-templated mesoporous carbon hollow spheres, SEM images of the different PF–PEO*n* polymer blend templated mesoporous silica hollow spheres, $N_2$ adsorption–desorption isotherms of the different mesoporous metal oxides hollow spheres, TEM images of mesoporous MgO and $CeO_2$ hollow spheres, photograph showing magnetic Fe@mesoporous carbon hollow sphere, and table of the precursors and properties of the metal oxides and Fe@carbon hollow spheres.

# Structurally Characterized Erbium Alkoxides for Use as an Amphoteric Dopant in PErZT Ceramic Thin Film and Nanoparticles

**Timothy J. Boyle,*[a] Leigh Anna M. Ottley,[a] Luke N. Brewer,[b] Jennifer Sigman,[b] Paul G. Clem,[b] and Jacob J. Richardson[c]**

**Keywords:** Ceramics / Perovskites / Nanomaterials / Lanthanide alkoxides / PZT

A family of erbium alkoxides [$Er(OR)_3$] was prepared from the reaction of $Er[N(SiMe_3)_2]_3$ with a series of alcohols (HOR) in selected solvents and crystallographically characterized as: $[Er(\mu\text{-Onep})_2(Onep)]_4$, (**1**), $[Er_4(\mu_4\text{-O})(\mu_3\text{-Onep})(\mu\text{-Onep})_5(Onep)_4(py)_3]$ (**3**), $Er_3(\mu_3\text{-O}t\text{Bu})_2(\mu\text{-O}t\text{Bu})_3(O t\text{Bu})_4(HO t\text{Bu})_2$ (**4**), $Er_3(\mu_3\text{-O})(\mu\text{-O}t\text{Bu})_4(O t\text{Bu})_3(py)_3$ (**7**), $Er(dmp)_3(solv)_3$ [solv = thf (**9**), py (**10**)], $[Er(\eta\text{-dip})(dip)_2]_2$ (**11**), $Er(dip)_3(thf)_2$ (**12**), $[Er(\mu\text{-OH})(dbp)_2(thf)]_2$ (**15**), $Er(dbp)_3(py)_2$ (**16**), $[Er(\mu\text{-tps})(tps)_2]_2$ (**17**), $Er(tps)_3(solv)_3$ [solv = thf (**18**) and (py) (**19**)] where Onep = neopentoxide ($OCH_2CMe_3$), O*t*Bu = *tert*-butoxide ($OCMe_3$), dmp = 2,6-dimethylphenoxide [$OC_6H_3(Me)_2$-2,6], dip = 2,6-diisopropylphenoxide [$OC_6H_3(CHMe_2)_2$-2,6], dbp = 2,6-di-*tert*-butylphenoxide [$OC_6H_3(CMe_3)_2$-2,6], tps = triphenylsiloxide [$OSi(C_6H_5)_3$], tol = toluene, thf = tetrahydrofuran, and py = pyridine. The structures observed and data collected for the Er family of compounds are, in general, consistent with those reported previously for the Dy congeners over the range of solvated mono-, di-, tri-, and tetranuclear species. Representative members of the $Er(OR)_3$ precursors were used for the production of a PErZT precursor solution, which was subsequently used to generate thin films and nanoparticles. Further, these select Er precursors were used to generate $Er_2O_3$ nanoparticles. The full characterization of this family of compounds is reported along with the results of the materials investigations.

## Introduction

The perovskite phase of lead zirconium titanate (PZT) has found utility in a wide range of applications including ferroelectric nonvolatile random access memories, sports equipment, window tinting, sensors, smart cards, and numerous other electronic applications.[1–6] However, PZT ceramic materials demonstrate rapid fatigue when cycled on standard platinized silica (Pt/Si) supports. Recently, we reported on the "aliovalent cation effect" (ACE) where the PZT thin films fatigue properties were improved through selective doping with lanthanide (Ln) cations that could occupy either the A or B site.[7,8] In particular, the Dy-doped PZT films (PDyZT) were found to possess high remanent polarization ($P_r$), high dielectric constant ($\varepsilon'$), and reduced fatigue when cycled on Pt/Si wafers.[7,8] Due to the void of acceptable dysprosium alkoxide [$Dy(OR)_3$] precursors (see Table 1), it was necessary to synthesize and characterize a series of systematically varied $Dy(OR)_3$ compounds (21 new compounds) to determine the optimal Dy-dopant precursor.[8] From this novel family of compounds, the 2,6-diisopropylphenoxide (dip) derivative yielded the highest quality PDyZT films with impressive fatigue resistance. In an effort to further explore this phenomenon we were interested in determining where the edges of the ACE stopped. Fortunately, the Ln series possesses a systematic change in the +3 Ln cations, which allows for a controlled probing of the ACE phenomenon in PZT ceramic thin films. However, for the smaller lanthanides, there are surprisingly few structurally characterized alkoxides available in the literature.[9–11]

Therefore, to further develop this neglected area and identify new sol-gel precursors, we undertook the synthesis and characterization of a systematically varied family of $Er(OR)_3$ in a variety of solvents. These compounds were isolated following Equation (1), where the alcohol (H-OR) ranged from H-Onep = neopentyl alcohol ($H\text{-}OCH_2CMe_3$), H-O*t*Bu = *tert*-butyl alcohol ($H\text{-}OCMe_3$), H-dmp = 2,6-dimethylphenol [$H\text{-}OC_6H_3(Me)_2$-2,6], H-dip = 2,6-diisopropylphenol [$H\text{-}OC_6H_3(CHMe_2)_2$-2,6], H-dbp = 2,6-di-*tert*-butylphenol [$H\text{-}OC_6H_3(CMe_3)_2$-2,6], H-tps = triphenylsilanol [$H\text{-}OSi(C_6H_5)_3$] using a variety of solvents: tol = toluene, thf = tetrahydrofuran, and py = pyridine. The general matrix used in this study led to the synthesis of compounds **1**–**19** and is shown in Table 1 along with a comparison to the $Dy(OR)_3$ compounds that were previously

isolated.[8] From this matrix, the following $Er(OR)_3$ compounds were crystallographically characterized as: $[Er(\mu\text{-Onep})_2(Onep)]_4$ (**1**), $[Er_4(\mu_4\text{-O})(\mu_3\text{-Onep})(\mu\text{-Onep})_5(Onep)_4(py)_3]$ (**3**), $Er_3(\mu_3\text{-O}t\text{Bu})_2(\mu\text{-O}t\text{Bu})_3(O t\text{Bu})_4(HO t\text{Bu})_2$ (**4**), $Er_3(\mu_3\text{-O})(\mu\text{-O}t\text{Bu})_4(O t\text{Bu})_3(py)_3$ (**7**), $Er(dmp)_3(solv)_3$ [solv = thf (**9**), py (**10**)], $[Er(\eta\text{-dip})(dip)_2]_2$ (**11**), $Er(dip)_3(thf)_2$ (**12**), $[Er(\mu\text{-OH})(dbp)_2(thf)]_2$ (**15**), $Er(dbp)_3(py)_2$ (**16**), $[Er(\mu\text{-tps})(tps)_2]_2$ (**17**), $Er(tps)_3(thf)_3$ (**18**), $Er(tps)_3(py)_3$ (**19**). The synthesis and full characterization of these compounds are discussed. Suitable crystals were not isolated for compounds **2** (Onep/thf), **5** (O*t*Bu/tol), **6** (O*t*Bu/thf), **8** (dmp/tol), **13** (dip/py), **14** (dbp/tol) and additional discussion of these compounds will not be pursued since their structures were not unequivocally established.

$$Er[N(SiMe_3)_2]_3 + 3\ H\text{-}OR' \rightarrow Er(OR')_3 + 3\ H\text{-}N(SiMe_3)_2 \quad (1)$$

Representative species from this novel family of compounds were used to explore their utility for the production of ceramic materials. The ACE for PErZT thin films was probed using **11** as the dopant precursor due to the similarity with the Dy counterpart (Table 1).[7,8] Further, since new properties were expected on the nanoscale, attempts were made to generate $Er_2O_3$ and PErZT nanoceramics. With this wide variety of structurally varied species, it was possible to further explore the "precursor structure argument" (PSA)[12–16] for nanoparticle morphology predictions. A solution route to nanoparticles of $Er_2O_3$ was discovered using **1** and **11**. Full details of the synthesis, characterization, and subsequent properties of these precursors and materials are presented.

## Results and Discussion

A systematically varied series of $Er(OR)_3$ was required in order to initiate the material evaluation of Er ceramics with controlled properties. A search of the literature reveals only two $Er(OR)_3$ had been previously crystallographically characterized including $Er_5(\mu_5\text{-O})(\mu_3\text{-O}i\text{Pr})_4(\mu\text{-O}i\text{Pr})_4(O i\text{Pr})_5$[10,11] and $Er(dip)_3(thf)_2$.[9] The remainder of alkoxy-like species possess other metals,[17–21] halides,[22] or polyfunctional ligands[23] which prevents use for generation of high quality ceramic oxide materials due to the potential cross cation, anion, and/or residual ligand contamination. Due to the lack of available $Er(OR)_3$ compounds, it was necessary to synthesize a series of precursors to determine the optimal species. A study of a matrix of sterically varied precursors in different solvents was undertaken (see Table 1). For this report, only those compounds that were crystallographically characterized will be discussed.

### Synthesis

On the basis of our previous experience with the problems associated with the ammoniacal route, we elected to use the amide/alcohol metathesis route that proved beneficial for the Dy system.[8] The $Er(NR_2)_3$, where $NR_2 = N(SiMe_3)_2$, was synthesized according to established routes involving the metathesis reaction between $ErCl_3$ and 3 equiv. of $KNR_2$ in thf.[8,24–29] The resultant powder isolated from the metathesis route was sublimed and crystallized to ensure pure starting material. It is of note that purification of the $Er(NR_2)_3$ is critical to the successful isolation of crystalline material. Once isolated, this precursor was treated with a variety of alcohols as shown in Equation (1) (Table 1).

The majority of samples remained clear after stirring for 12 h; however, those that formed a precipitate, typically the more sterically demanding ligands, were warmed slightly to redissolve the powder. Crystals were either isolated by slow evaporation or rotary evaporation of the volatile portion of the reaction mixture followed by cooling the reaction mixture to –35 °C, if necessary.

FTIR data of the resultant powders revealed no amide stretches and, for the majority of samples no –OH stretches, which implies complete substitution had occurred between the amide and the alcohol. Two exceptions to this were the spectra noted for compound **4** and **15**, which showed broad IR stretches around 3000 $cm^{-1}$ associated with the bound H-O*t*Bu and the -OH, respectively. In general, elemental analyses were found to be consistent with the single-crystal X-ray structures isolated (vide infra) for these compounds. Those that were off slightly from expected values were solvated species and the high volatility of the bound solvent often causes significant problems in obtaining accurate analyses.[8,30] Due to the paramagnetic nature of the Er metal center, we were unable to get meaningful NMR spectroscopic data either in solution or solid-state. Therefore, single-crystal X-ray diffraction studies were undertaken to assist in elucidating the identity of the final products isolated.

### Crystal Structures

As mentioned only two structures of $Er(OR)_3$ have previously been reported.[9–11] Obviously, no general trends can

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be discerned from this limited set of precursors but comparisons to literature compounds will be made when appropriate. Figures 1, 2, 3, and 4 are the structure plots of representative crystal structures for this family of compounds. The various compounds are discussed below in order of the ligand increasing steric bulk of the ligand.

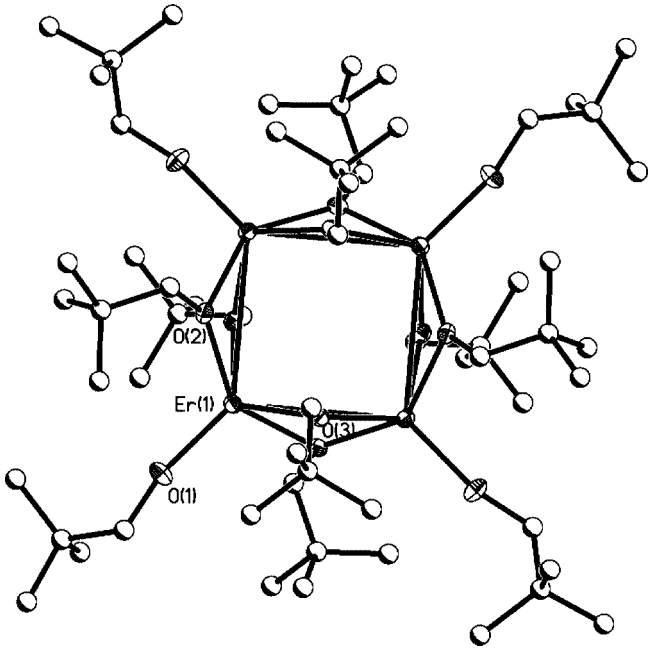

Figure 1. Structure plot of **1**. Thermal ellipsoids of heavy atoms are drawn at the 30% level and carbon atoms are shown as stick and ball for clarity. Selected bond lengths [Å]: Er(1)–O(1) 2.033(5); Er(1)–O(2) 2.241(6); Er(1)–O(3) 2.244(6). Selected bond angles [°]: O(1)–Er(1)–O(3) 122.8(3); O(1)–Er(1)–O(2) 112.9(3); O(3)–Er(1)–O(2) 72.7(2); O(1)–Er(1)–O(3) 118.3(3); O(2)–Er(1)–O(3) 89.5(3); O(1)–Er(1)–O(2) 105.8(3); O(3)–Er(1)–O(2) 86.9(2); O(3)–Er(1)–O(2) 71.7(2).

Using the more sterically demanding Onep ligand reduced the nuclearity and prevented the formation of an oxo ligand as noted for the smaller O*i*Pr derivative $Er_5(\mu_5\text{-}O)(\mu_3\text{-}OiPr)_4(\mu\text{-}OiPr)_4(OiPr)_5$.[10,11] The resultant species, identified as $[Er(\mu\text{-}Onep)_2(Onep)]_4$ (**1**), is consistent with the other Ln- and Group 3 neopentoxide species (Figure 1)[31] wherein, each of the four trigonal bipyramidal (TBP) Er metal centers possess two μ-Onep and one Onep ligand. Attempts to isolate this compound using the Lewis basic solvents thf (**2**) did not lead to X-ray quality crystals; however, from py the tetramer observed in **1** was reduced to a trinuclear species surprisingly forming an oxo species, $[Er(\mu_3\text{-}O)(\mu\text{-}Onep)_6(Onep)_4(py)_3]$ (**3**). The source of the oxo species is not known as of yet and typically not observed for the Onep derivatives, unless esterification mechanisms from side reactions with carboxylic acids occur but may be due to adventitious water in the solvent.[30–32]

Increasing the steric bulk to the O*t*Bu groups, led to crystallization of the trinuclear **4** which had additional HO*t*Bu bound to it, as shown in Figure 2. Previously, we isolated a Ce/O*t*Bu tetramer[30] that did not possess any

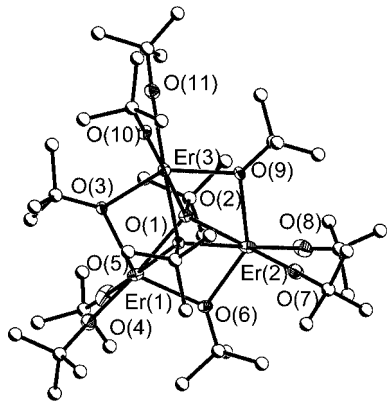

Figure 2. Structure plot of **4**. Thermal ellipsoids of heavy atoms are drawn at the 30% level and carbon atoms are shown as stick and ball for clarity. Selected bond lengths [Å]: Er(1)–O(1) 2.305(3); Er(1)–O(2) 2.371(3); Er(1)–O(3) 2.269(3); Er(1)–O(4) 2.525(4); Er(1)–O(5) 2.067(3); Er(1)–O(6) 2.250(3). Selected bond angles [°]: O(5)–Er(1)–O(6) 106.17(13); O(5)–Er(1)–O(3) 104.93(13); O(6)–Er(1)–O(3) 143.78(12); O(5)–Er(1)–O(1) 109.45(13); O(6)–Er(1)–O(1) 76.35(12); O(3)–Er(1)–O(1) 76.16(12); O(5)–Er(1)–O(2) 177.71(13); O(6)–Er(1)–O(2) 74.47(12); O(3)–Er(1)–O(2) 73.78(12); O(1)–Er(1)–O(2) 68.48(11); O(5)–Er(1)–O(4) 74.73(14); O(6)–Er(1)–O(4) 101.31(13); O(3)–Er(1)–O(4) 104.40(12); O(1)–Er(1)–O(4) 175.59(12); O(2)–Er(1)–O(4) 107.37(12).

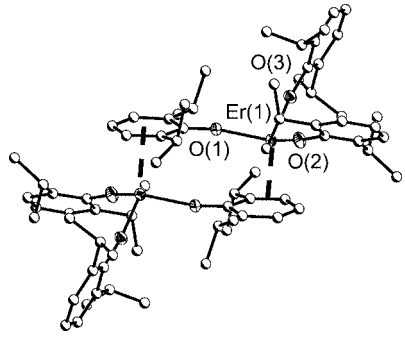

Figure 3. Structure plot of **11**. Thermal ellipsoids of heavy atoms are drawn at the 30% level and carbon atoms are shown as stick and ball for clarity. Selected bond lengths [Å]: Er(1)–O(1) 2.096(18); Er(1)–O(3) 2.069(17); Er(1)–O(2) 2.095(18); Er(1)-ring 2.81 Å. Selected bond angles [°]: O(2)–Er(1)–O(1) 109.3(7); O(2)–Er(1)–O(3) 102.5(7); O(3)–Er(1)–O(1) 106.3(7); O(1)–Er(1)–ring 108.1(9); O(2)–Er(1)–ring 83.9(9); O(3)–Er(1)–ring 140.6(8).

Lewis basic solvents (i.e., thf, py, or HO*t*Bu) however, the Er corollary could not be isolated without bound solvents as noted for the pyridine adduct, $Er_3(\mu_3\text{-}O)(\mu\text{-}OtBu)_4(OtBu)_3(py)_3$ (**7**). Again, the py adduct appears to produce the oxo which argues for water present in the py; however, numerous structures using the same solvent did not yield the oxide, so the origin of the oxo is still unproven. This complex is similar to **4** and other trinuclear species where the terminal ligands are now replaced by these stronger.

Aryl oxides are often used to control nuclearity because the steric bulk around the metal center can be easily altered.[8,12,13,30,33–36] We routinely use the most sterically demanding di-*ortho*-substituted phenoxide ligands to induce as large an effect as possible. The resulting products are again discussed in increasing steric demand (dmp, dip,

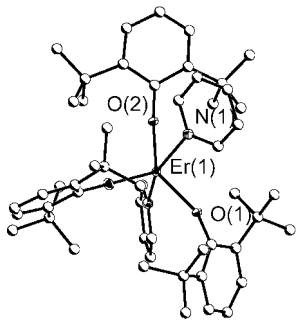

Figure 4. Structure plot of **16**. Thermal ellipsoids of heavy atoms are drawn at the 30% level and carbon atoms are shown as stick and ball for clarity. Selected bond lengths [Å]: Er(1)–O(2) 2.095(4); Er(1)–O(1) 2.161(3); Er(1)–O(1A) 2.161(3); Er(1)–N(1) 2.469(4); Er(1)–N(1A) 2.469(4). Selected bond angles [°]: O(2)–Er(1)–O(1) 112.54(8); O(2)–Er(1)–O(1A) 112.54(8); O(1)–Er(1)–O(1A) 134.92(16); O(2)–Er(1)–N(1) 101.96(9); O(1)–Er(1)–N(1) 81.96(12); O(1)–Er(1)–N(1A) 88.91(13); O(2)–Er(1)–N(1A) 101.96(9); O(1A)–Er(1)–N(1A) 88.91(13); O(1A)–Er(1)–N(1) 88.96(12); N(1)–Er(1)–N(1A) 156.08(18).

dbp). For the dmp derivative, large clear crystals were easily isolated from toluene but the diffraction was poor and an acceptable structure solution could not be garnered for **8**. Therefore, we employed the Lewis basic solvents to assist in growing acceptable crystals. For both thf and py, mononuclear species with three solvents to form an octahedral geometry were isolated as $Er(dmp)_3(solv)_3$ [solv = thf (**9**) and py (**10**)].

Increasing the steric bulk of the *ortho* substituent to isopropyl groups led to the isolation of **11** (Figure 3). The η-interaction noted for **11** is the same as previously noted for the La,[37] Nd,[9] and Dy[8] systems. Again, the η-interaction was easily disrupted using Lewis basic solvents forming the trigonal bipyramidal (TBP) monomeric species **12** for the thf adduct.

Using the most sterically demanding dbp ligand, crystals of the unsolvated species **14** could not be isolated in high quality; however, in the presence of a Lewis base, two very different species were characterized. Out of thf, a dinuclear thf adduct was isolated as **15**. Surprisingly, the dinuclear species possesses a μ-OH group which was not identified for the Dy series[8] but have been reported for other lanthanides species including, $[(\mu\text{-OH})Yb(OAr)_2(thf)]_2$ (OAr = dbp,[38] dbp-But-4,[38,39]) and $[(\mu\text{-OH})Sm(dbp\text{-Me-}4)_2(OPPh_3)]_2$.[40] Increasing the Lewis basicity of the solvent to py led to the TBP monomer **16** (Figure 4). It is most likely not due to adventitious water in the solvent or it would have been observed in the Dy system.[8]

Siloxide ligands offer the potential for the production of Si-containing materials and slightly different ligand properties both sterically and electronically. Therefore, we added the tps ligand into our structural investigation. The tps derivatives isolated for the Er system are consistent with the $Dy(tps)_3$ structure[8] wherein a dinuclear complex was isolated from tol (**17**) with μ-tps and terminal tps in standard edge-shared tetrahedral-bound metal centers. Subsequent monomers were isolated from Lewis basic solvents as **18** and **19**, for thf and py. The bulky tps ligands allow for tetrahedral (Td) arrangements for the metal centers of **17** and octahedral (Oh) geometries for **18** and **19** through the binding of three solvent molecules.

In general, the structures noted for the Er system were consistent with the $Dy(OR)_3$ precursors previously reported;[8] however, **15** does prove that unaccounted variations are possible, and probable. Surprisingly, a number of compounds could not be successfully isolated for the Er system that were easily isolated for the Dy system.[8] Subtle effects that dictate crystal growth are at play and require further investigations.

## Materials

With these compounds successfully characterized, a sufficient number and variety of species were available for systematic materials structure–property investigations. Two systems were investigated: Er-doped PZT (or PErZT) thin films for electronic properties and nanomaterials of $Er_2O_3$ and PErZT.

### *Film Characteristics*

The precursor solutions of $Pb_{0.98}(Er)_{0.04}(Zr_{0.3}Ti_{0.7})_{0.98}O_3$ [PErZT(4/30/70)] and $Pb_{0.98}(Er)_{0.04}(Zr_{0.52}Ti_{0.48})_{0.98}O_3$ [PErZT(4/52/48)] were prepared as described in the experimental section. Selection of the Er dopant on the B site of the perovskite is based on previous studies and a dopant concentration of 4% Er was selected to maximize the possible effects of the dopant without creating unwanted secondary phases. Dektak profilometer film thickness measurements were 150–180 nm after the deposition of 4 layers. X-ray diffraction patterns and hysteresis loops are shown in Figure 5, a–d. Both films were found to be polycrystalline, single-phase perovskite films (Figure 5, b and d) with an enhanced (111) orientation, attributed to the templating effects of the $Pt(111)/Ti/SiO_2/Si$ substrates. The PErZT(4/30/70) films also showed a more pronounced (100) peak than PErZT(4/52/48) films. This is consistent with the room temperature tetragonal structure of a PZT(30/70) film compared to the room temperature morphotropic structure of a PZT(52/48) film. The previously reported PZT(30/70) films isolated under identical conditions used for the PErZT films, had narrow and square loops with reasonable properties: spontaneous polarization ($P_r$) = 24 μC/cm$^2$, coercive field ($E_c$) = 93 kV/cm$^2$, a dielectric constant ($\varepsilon'$) = 396, and $\tan\delta$ = 0.007 (10 kHz, 100 mV). For the PDyZT(4/30/70) films, comparable values were obtained: $P_r$ = 26 μC/cm$^2$, $E_c$ = 126 kV/cm, $\varepsilon'$ = 343, and $\tan\delta$ = 0.009 (10 kHz, 100 mV).[8]

After top-electrodes were sputter-deposited, the ferroelectric properties were discerned for PErZT films. Hysteresis loops for the PErZT(4/30/70) and PErZT(4/52/48) films are shown in Figure 5a and Figure 5c, respectively. In agreement with the Dy-doped films, the PErZT(4/30/70) films displayed a $P_r$ = 30 μC/cm$^2$, $E_c$ = 171 kV, $\varepsilon'$ = 366 and $\tan\delta$ = 0.03. For the PErZT(4/52/48) films slightly lower ferroelectric property values were obtained, with a $P_r$ =

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

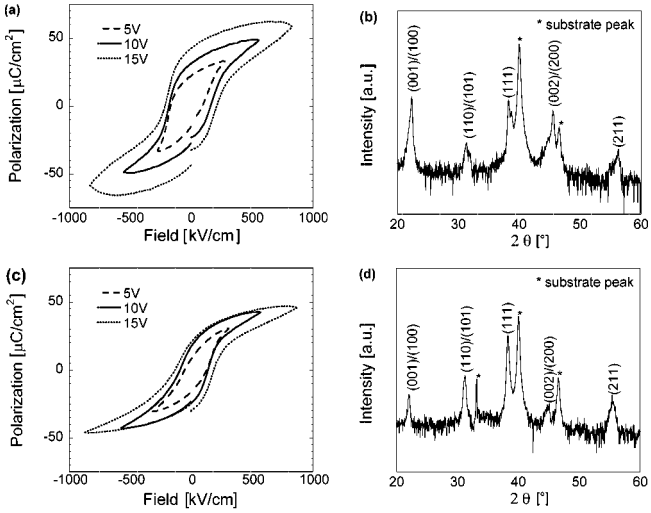

Figure 5. Characterization of PErZT(4/30/70): (a) hysteresis loop, (b) XRD; and characterization of PErZT (4/52/48): (c) hysteresis loop, (d) XRD.

20 μC/cm$^2$ and an $E_c$ = 137 kV; however, the dielectric properties improved: $\varepsilon'$ = 564 and tan $\delta$ = 0.01. The higher $P_r$ observed in the PErZT(4/30/70) is attributed to the room temperature tetragonal composition of this film while the higher $\varepsilon'$ observed in the PErZT(4/52/48) is attributed to the film's room temperature morphotropic boundary composition. Unfortunately, the fatigue testing for the Er-doped films did not show the significant improvement noted for the Dy doping.[7,8] However, this sets a lower limit for the ACE phenomenon and the slightly larger Y and Ho cations are now under investigation.

### *Nanoparticles*

With this family of well-characterized compounds in hand, it was decided to investigate their utility as precursors for nanomaterials. Nanoparticles are of interest due to the novel properties expected for materials on this size scale. In the literature, 5 to 30 nm sized erbium(III) oxide nanocrystals dispersed in titania have been previously isolated by employing $Er(NO_3)_3$ in an inverse microemulsion process followed by a heat treatment at 600 °C.[41,42] The resulting materials were identified as $Er_2O_3$ by powder XRD and photoluminescent measurements.[41,42] Recently, a solution route using decomposition of lanthanide acetylacetonate in oleic acid, oleylamine, and octadecene at 310 °C yielded $Er_2O_3$ nanoparticles.[43] We are interested in controlling the properties of nano-$Er_2O_3$ for electrooptic applications. Therefore, we undertook two different approaches to generate nanoparticles that were more amenable to large-scale syntheses: (a) solution precipitation and (b) solvothermal using our novel representative $Er(OR)_3$ precursors **1** and **11**. Both of the processing routes are greatly simplified in comparison to the microemulsion route,[41,42] are amenable to large scale synthesis, and require significantly lower processing temperatures than the Ln-acac route.[43] The results for solution precipitation of **1** and **11** are presented, followed by the results of the solvothermal routes.

### *Solution Precipitation*

The reaction pathway for both of the alkoxides appeared to follow identical pathways, wherein the pale pink solution of the precursor immediately formed a white precipitate upon injection into the refluxing solution. The subsequent isolation also proceeded in an identical manner. Therefore, all of the observed differences in the generated manner can only be attributed to the variations in pendant hydrocarbon chain of the alkoxide ligand.

For **1**, the resulting powder was found to be made of 7–8 nm highly crystalline $Er_2O_3$ (see Figure 6) particles, as found by TEM imaging, the observed SAED pattern, and only Er and O observed in the EDS spectrum (Cu is background from the grid). The PXRD spectrum was fairly broad but consistent with $Er_2O_3$ nanoparticles of 1.7 nm, based on the Scherrer equation calculations. In comparison, using **11** (Figure 7) 3–4 nm nanoparticles of $Er_2O_3$ were formed as characterized by TEM and EDS analyses with a noted decrease in crystallinity by SAED. For select grains, HRTEM images clearly show the lattice fringes of $Er_2O_3$. The PXRD was broad peaks consistent with $Er_2O_3$ wherein calculations indicated nanoparticles of 1.9 nm were formed.

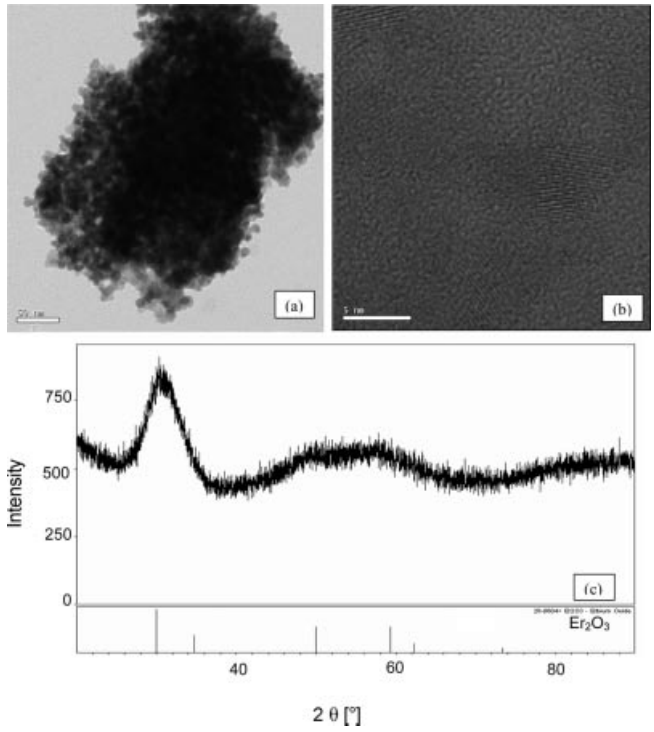

Figure 6. TEM images of $Er_2O_3$ generated from **1** using the solution precipitation route: (a) TEM image (50 nm scale bar), (b) HRTEM (5 nm scale bar), and (c) PXRD.

The difference in the observed particle sizes between the TEM and XRD measurements may be due to several factors in the X-ray diffraction measurement. Particle size affects the PXRD pattern by broadening the peak. Several

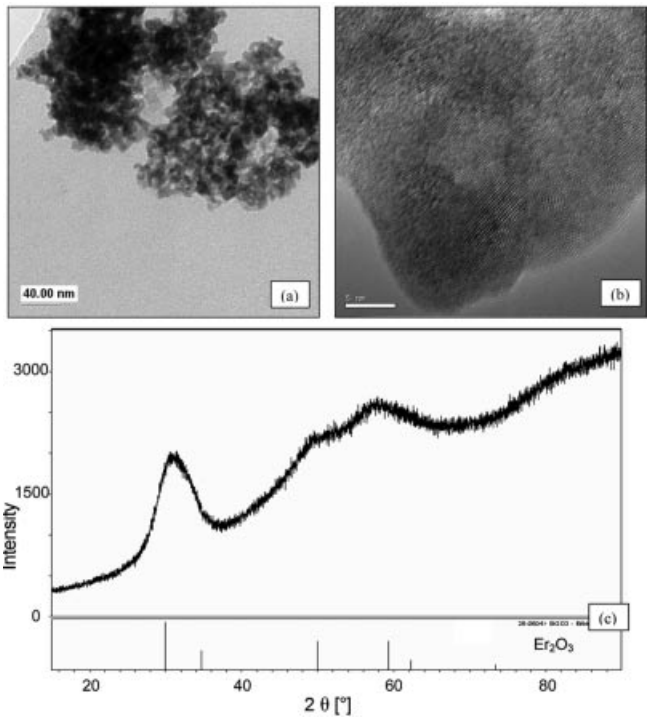

Figure 7. TEM images of $Er_2O_3$ generated from **11** using the solution precipitation route: (a) TEM image (40 nm scale bar), (b) HRTEM (5 nm scale bar), and (c) PXRD.

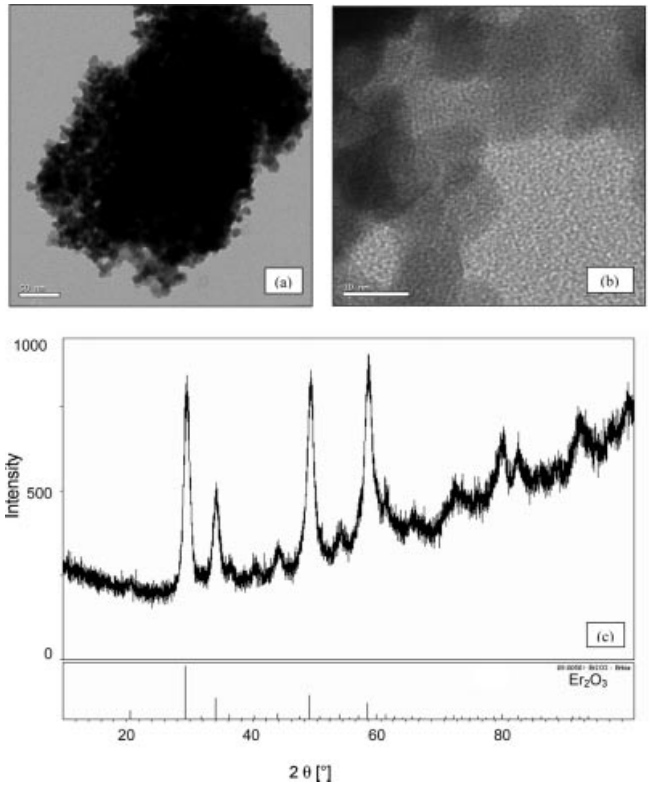

Figure 8. Nanoparticles from Parr bomb using **1**: (a) TEM image (50 nm scale bar), (b) HRTEM(10 nm scale bar), and (c) PXRD.

factors contribute to this peak broadening, including instrument line broadening, reduction in particle size, variation in particle composition, and microstrain. Of these possible effects, variation in particle composition and some instrument line broadening may account for the systematic underestimation of the particle size from the PXRD measurement. Despite this difference, the PXRD measurement of particle size is useful for efficient measurement of many samples and for particle size measurement on materials with strong agglomeration.

In general, from this study the formation of crystalline $Er_2O_3$ was more easily achieved with **1** than **11**. Upon introduction of a Lewis base, both compounds alter their original structure forming a trinuclear solvated species for **1** (as evidenced by **4**, and **7**) and a solvated monomer for **11** (**9**, **10**, **12**, **16**, **18**, and **19**). Using the PSA, the size of the resultant nanoparticles could be reasoned; however, the morphologies did not follow any trends. The faster and more uniform the nanoparticles form, the longer they will have to crystallize under the conditions we used. The particle precursor for **1** is more likely to have a larger nucleation seed in comparison to that of monomeric **11**. Thus, **1** yields higher quality nanoparticles as determined by the nature of the solvated structure.

### *Solvothermal Synthesis*

Under solvothermal conditions, a Parr digestion bomb of the same solution was investigated to determine processing variations for the same compounds. For **1**, spheroidal nanoparticles of $Er_2O_3$ were isolated ranging from 10–

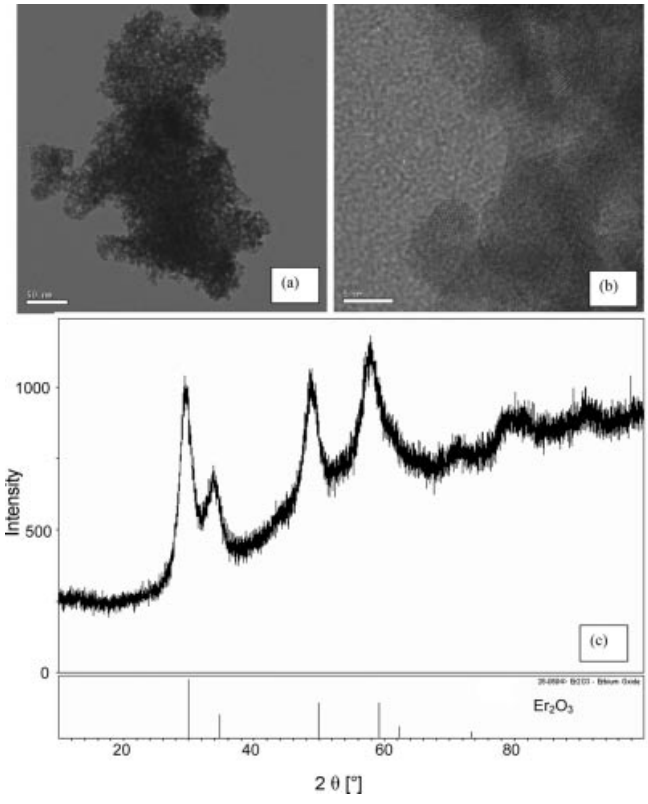

Figure 9. Nanoparticles from Parr bomb using **11**: (a) TEM image (50 nm scale bar), (b) HRTEM (5 nm scale bar), and (c) PXRD.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

15 nm in size verified by EDS and PXRD (Figure 8). Surprisingly, the PXRD pattern was much sharper with calculated sizes of 7.0 nm. For **11**, more spherical shaped nanoparticles were isolated in the same approximate size range of 10–15 nm (Figure 9). The particles were more uniform in morphology and size in comparison to **1** but the particles appear less crystalline by PXRD pattern; however, HRTEM reveals the crystalline lattice planes. The broad peaks of PXRD pattern were calculated to generate particles of 3.7 nm. The TEM images and those calculated from the XRD pattern have a significant difference again the issues discussed previous (vide infra) may account for this variance.

In general, the structures of the precursors do not appear to play as large a role in determining the morphology of the final Ln-based nanomaterials isolated as noted for transition metals.[12–16] However, there are significant differences based on the structural considerations of **1** vs. **11**. The crystallinity of the final material appears to be higher with the bomb preparative routes vs. the solution precipitation methods.

### *PErZT Nanoparticles*

Due to the success with the simple Er system, it was of interest to determine if more complex nanoparticles could be generated from the same solution under similar conditions. Attempts to generate PErZT nanomaterials were undertaken using the same precursor thin film solution with **1** as the dopant and the process for preparing nano-$Er_2O_3$ as discussed above. The solution precipitation route yielded large nanoparticles on the order of 30 nm in size (Figure 10). EDS indicates each of the cations is present; however, the PXRD pattern shows only $ErTiO_3$ is present as a crystalline material. The absent Pb and Zr cations are probably phase separated as amorphous $PbZrO_3$, which requires significantly higher temperatures to crystallize. Alternatively, the solvothermal route led to the isolation of particles on the size of 5–10 nm (Figure 11) with each of the cations present in the EDS. Interestingly, highly crystalline particles (HRTEM with *d* spacing ca. 3.0 Å) were observed in the $PbTiO_3$ structure that is consistent with PZT (3.1 Å). Further work to improve the uniformity and consistency of the multication nanomaterial in order to explore the properties of these electroceramic materials is underway.

## Conclusions

We have synthesized and fully characterized a family of $Er(OR)_3$ from the reaction of $Er[N(SiMe_3)_2]_3$ and a variety of commercially available alcohols that systematically varied in steric bulk. The isolated compounds are structurally similar to the $Dy(OR)_3$ species[8] isolated previously with nuclearity ranging from mono- (**9**, **12**, **16**, **18**, **19**), to bis- (**11**, **15**, **17**), to tri- (**6**) to tetranuclear (**1**) species. From this set of $Er(OR)_3$ compounds **11** was used to generate PErZT. The ferroelectric properties were consistent with the Dy doped PZT; however, the fatigue properties were not improved as noted for the Dy species.[7,8] Additional work to elucidate the ACE demarcation line is in progress with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

other large Ln cations. Nanoparticles of $Er_2O_3$ were successfully synthesized and isolated; however, the more complex ternary PErZT yielded mixed size particles of various compositions.

## Experimental Section

All compounds described below were handled with rigorous exclusion of air and water using standard Schlenk line and glove box techniques. All solvents were stored under argon and used as received (Aldrich) in sure seal bottles, including hexanes (hex), tol, thf, and py. The following chemicals were used as received (Aldrich): $ErCl_3$, $KN(SiMe_3)_2$ ($KNR_2$), H-Onep, H-O*t*Bu, H-dmp, H-dip, H-dbp, H-tps, $[Zr(OiPr)_4(HOiPr)]_2$. $Ti(OiPr)_4$ was distilled immediately prior to use and stored under and inert atmosphere. $Er(NR_2)_3$ was synthesized from the reaction of $ErCl_3$ and three equivalents of $LiNR_2$ in thf and purified by sublimation and subsequent crystallization from hexanes.[8] FT-IR data were obtained on a Bruker Vector 22 Instrument using KBr pellets under an atmosphere of flowing nitrogen. Elemental analysis was performed on a Perkin–Elmer 2400 CHN-S/O Elemental Analyzer.

**General Synthesis:** The appropriate HOR was added by a pipette to a stirring mixture of $Er(NR_2)_3$ that was dissolved in desired solvent. After 12 h, if a precipitate formed, the solution was warmed until the precipitate redissolved. After cooling to room temperature, the volatile material was allowed to slowly evaporated or the volume of the reaction was drastically reduced via rotary evaporation. The reaction was then set aside or cooled to –35 °C, if necessary until crystals formed.

**General X-ray Crystal Structure Information:** [44] Crystals were mounted onto a glass fiber from a pool of Fluorolube™ and immediately placed in a cold $N_2$ vapor stream, with a Bruker AXS diffractometer equipped with a SMART 1000 CCD detector using graphite-monochromatized Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å). Lattice determination and data collection were carried out using SMART Version 5.054 software. Data reduction was performed using SAINTPLUS Version 6.01 software and corrected for absorption using the SADABS program within the SAINT software package.

Structures were solved by direct methods that yielded the heavy atoms, along with a number of the lighter atoms or by using the PATTERSON method, which yielded the heavy atoms. Subsequent Fourier syntheses yielded the remaining light-atom positions. The hydrogen atoms were fixed in positions of ideal geometry and refined using SHELXS software. The final refinement of each compound included anisotropic thermal parameters for all non-hydrogen atoms. It is of note that crystal structures of $M(OR)_x$ often contain disorder within the atoms of the ligand chain causing higher than normal final correlations.[24–29]

Data collection parameters for **1**–**19** are given in Table 2. Specific issues associated with individual structures are discussed below. Fully refined structures of **3** and **7** could not be obtained due to significant disorder in the Onep and O*t*Bu ligands, respectively; however, the connectivity of both compounds were unequivocally established and are in agreement with the $Dy(OR)_3$ structures reported. Structure **11** had significant disorder in the isopropoxide ligands that resulted in oblong thermal ellipsoids and a slightly higher $R_1$ value; however, the overall structure observed is in agreement with $[Dy(\eta\text{-dip})(dip)_2]_2$ in both unit cell and connectivity. For **17**, it was necessary to squeeze disorder electron density of 317.1 $A^3$ which is in agreement with ca. 1 tol molecule. Noncentrosymmetric settings were chosen for **1**, **7**, **12**, and **18** even though a mirror plane appears to exist for these molecules. By further investigation of these species, disruption in the symmetry due to nonrigid ligands, such as Onep (**1** and **7**) or disorder in coordinating solvent thf (**12** and **18**) ultimately requires refinement in noncentrosymmetric settings.

CCDC-641110 to -641120 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Film Production:** Standard spin-coat deposition routes[45] were used to generate the PErZT thin films with a brief description of the preparation and processing described below. The PZT (30/70 or 48/52) films were produced following the established "basic route to PZT" (BRP) route,[45,46] in which $Pb(OAc)_2{\cdot}(HOAc)$ (Aldrich, 95%) dissolved in pyridine (py) was added to a mixture of $Ti(O\textit{i}Pr)_4$ and $[Zr(O\textit{i}Pr)_4(HO\textit{i}Pr)]_2$ dissolved in tol to form the PZT precursor mixture. The appropriate $Er(OR)_3$ precursor was dissolved in py and then added to the PZT mixture to form the ca. 0.4 M PErZT precursor solution.

Multilayered films of the desired composition were spin-coat deposited, in air, onto Pt(1700 Å)/Ti(300 Å) coated, thermally oxidized $SiO_2$/Si substrates using a photoresist spinner (3000 rpm for 30 s). After each deposition, the films were heated on a hot plate (300 °C for ca. 5 min) and cooled to room temperature before the deposition of the next layer. After the final layer received the 300 °C treatment (for this study 2–4 layers were used), the film was crystallized in a tube furnace at 650 °C for 30 min in air. X-ray diffraction (XRD) was used to confirm the phase purity and orientation of the final films.

**Ferroelectric Testing:** To measure the electrical properties of the films, gold top electrodes (ca. 250 × 250 μm) were sputter-deposited onto the films using a shadow mask to create a parallel-plate capacitor geometry. Capacitor top electrode areas were individually measured with a calibrated optical microscope and film thicknesses were measured using a Dektak profilometer. The low-field dielectric properties were measured at 10 kHz (100 mV p–p) using an HP 4284A impedance analyzer (Palo Alto, CA). The ferroelectric properties of the PLnZT films were measured using an RT66A ferroelectric tester from Radiant Technologies (Albuquerque, NM). Accelerated ferroelectric fatigue tests were performed using a 1-MHz bipolar square wave pulse, with the applied electric field normalized to ca. 700 kV/cm.

**Nanoparticle Synthesis:** Nanoparticles of $Er_2O_3$ were formed following one of two methods using **1** or **11** which were chosen as representative members of the alkyl- and aryloxide derivatives, respectively. The BRP method was also used to generate the PErZT precursor solution for the multication nanoparticles.

Two general routes were explored to synthesize nanoparticles: (a) solution precipitation and (b) solvothermal routes. (a) *Solution Precipitation*. The first route used a mixture of 1-methyl imidazole and water (MeIm/$H_2O$) having a 14.5/0.5 mL ratio. This solution was placed in a two-neck round bottom equipped with a reflux condenser and a septum. Under flowing argon, the MeIm/$H_2O$ solution was brought to reflux conditions (ca. 200 °C) and the desired precursor dissolved in tol was injected via syringe. A white precipitate formed immediately and the mixture was stirred for 30 min at 197 °C then cooled to room temperature. The as prepared particles were collected by centrifugation and rinsed with ethanol and then calcined in a tube furnace under flowing argon at 600 °C for 1 h. (b) *Solvothermal*. The second route used was a 45 mL Parr Acid Digestion Bomb. In the glove box, the desired precursors were dissolved in ca. 15 mL of benzyl alcohol (BzOH) and the clear solutions were transferred to the Teflon™ liners and placed in the bomb. The bomb was taken out of the glove box and the reaction was heated to 200 °C for 48 h. The white precipitate was collected by centrifugation and rinsed with ethanol.

The resulting nanopowders were slurried in tol followed by placing a drop of the solution onto a holey-carbon copper grid and allowing it to air dry. Upon complete drying for the samples were then examined with a transmission electron microscope (TEM) Philips CM30 with acceleration voltage of 300 KeV to obtain images, as well as selected area electron diffraction (SAED) data when necessary. Elemental composition information was obtained with a Noran energy dispersive X-ray detector (EDX) using system 6 software. In addition, the powder was characterized using a PANalytical powder diffractometer using Cu-$K_\alpha$ radiation with step size 0.0167 degree, with 53.340 seconds dwelling time.

# Nickel Complexes Bearing 2-(Benzimidazol-2-yl)-1,10-phenanthrolines: Synthesis, Characterization and Their Catalytic Behavior Toward Ethylene Oligomerization

**Min Zhang,[a] Shu Zhang,[a] Peng Hao,[a] Suyun Jie,[a] Wen-Hua Sun,*[a] Peizhou Li,[b] and Xiaoming Lu[b]**

**Keywords:** Nickel / Tridentate complexes / Phenanthrolines / Ethylene oligomerization / Oligomerization

A series of 2-(benzimidazol-2-yl)-1,10-phenanthrolines and their nickel(II) complexes were synthesized and characterized by elemental and spectroscopic analysis along with single-crystal X-ray crystallography. X-ray diffraction analysis revealed that complexes **1a** and **6a** have a six-coordinate distorted octahedral geometry due to the coordination of solvent molecules, whereas **3a** is a centrosymmetric dimer in the solid state and **5b** displays a five-coordinate distorted trigonal-bipyramidal geometry. Upon activation with diethylaluminum chloride ($Et_2AlCl$), high catalytic activity up to $1.27 \times 10^7$ g·mol$^{-1}$(Ni)·h$^{-1}$ and high selectivity for 1-butene (90.5%) could be achieved. A higher activity up to $3.95 \times 10^7$ g·mol$^{-1}$(Ni)·h$^{-1}$ was observed in the **7a**/$Et_2AlCl$ system with addition of 20 equiv. of $PPh_3$ as an auxiliary ligand. Reaction conditions and the ligand environment significantly influenced the catalytic properties of the complexes.

## Introduction

Ethylene oligomerization is a major industrial process, and developing new catalysts for ethylene oligomerization is of academic and industrial interest for the synthesis of α-olefins, which are feedstocks for the preparation of detergents, plasticizers, and fine chemicals, as well as comonomers for the production of linear low-density polyethylene (LLDPE).[1] One of the major industrial processes in ethylene oligomerization, named the SHOP process, employs nickel complexes as catalysts.[2] Over the past decades, considerable research effort has been devoted to the design of new nickel complexes as catalysts for olefin reactivity.[3,4] A large number of nickel complexes have been described as active species in ethylene oligomerization. However, limited examples among them could selectively produce α-olefins, because of their fast β-hydrogen elimination and chain immigration.[5] Therefore, the current challenges of nickel complexes in ethylene oligomerization are to find suitable catalysts for better α-olefin selectivity and to improve their catalytic activities. The fundamental research in designing novel homogeneous catalysts will rely on synthesizing ligands possessing environmental coordination to metal atoms that is favorable to the formation of suitable active species. In addition to the P^O chelating nickel complexes used in the SHOP process,[2,6] there are numerous nickel catalysts being investigated with bidentate ligands, such as N^O,[7,8] P^N,[9,10] and N^N,[3,11–13] and tridentate ligands, such as N^N^O,[14] N^P^N,[15] P^N^P,[16] P^N^N,[13d,16] and N^N^N,[17,18] as well as organometallic compounds.[15a]

Considering N^N^N tridentate nickel complexes as catalysts for ethylene oligomerization, several models with high activities have been developed in our group by using 2-imino-1,10-phenanthrolines (**A**),[18b] 2-(2-benzimidazole)-6-iminopyridine (**B**) ligands,[19] and 6-imino-2-quinoxalinylpyridines.[20] Inspired by these model catalysts, our strategy for ethylene activation is to synthesize 2-(benzimidazol-2-yl)-1,10-phenanthrolines and their metal complexes (Scheme 1). A new synthetic methodology for 2-(benzimidazol-2-yl)-1,10-phenanthrolines has been developed, and a further coordination reaction with nickel halides produced their nickel complexes with dichlorides or dibromides. By

tuning the bulkiness and electronic effects of their substituents ($R^1$ and $R^2$), these nickel complexes are investigated for ethylene oligomerization, including their catalytic activities and the oligomers produced.

In the presence of $Et_2AlCl$, these nickel complexes show good catalytic activity towards ethylene oligomerization, especially with high selectivity of ethylene dimerization to 1-butene. In addition, the introduction of $PPh_3$ as an auxiliary ligand in the catalytic system greatly enhances the activity of the nickel complexes. Herein, we report the synthesis and characterization of 2-(benzimidazol-2-yl)-1,10-phenanthrolines and their nickel complexes; moreover, ethylene oligomerization of these nickel complexes is investigated in detail, along with the influence of reaction conditions and ligand environment.

## Results and Discussion

### Synthesis and Characterization of Ligands L1–L10 and Complexes 1a–10a, 1b–10b

The original organic compound 2-(1*H*-benzimidazol-2-yl)-9-methyl-1,10-phenanthroline (**L1**) is not yet reported in the literature. According to our previous work and the literature,[19,21] **L1** was synthesized by the reaction of 2,9-dimethyl-1,10-phenanthroline and *o*-phenylenediamine with sulfur as an oxidant. Another original compound, 2-(1*H*-benzimidazol-2-yl)-1,10-phenanthroline (**L6**), was synthesized by the condensation reaction of *o*-phenylenediamine with 1,10-phenanthroline-2-carboxylic acid in the presence of polyphosphoric acid (ppa) under microwave radiation.[22] The modified literature procedure was employed for the preparation of ligands **L2**–**L5** and **L7**–**L10** through the *N*-alkylation of **L1** and **L6** (Scheme 2).[19,23] All the synthesized compounds were well characterized and confirmed by elemental analysis, and $^1H$ and $^{13}C$ NMR, and IR spectroscopy. Their nickel complexes **1a**–**10a** and **1b**–**10b** were obtained in high yields by the equimolar reaction of the corresponding ligand and $NiCl_2·6H_2O$ or $(dme)NiBr_2$. These complexes were characterized by IR spectroscopy, elemental analysis, and single-crystal X-ray diffraction techniques (Figures 1–5). Some elemental data showed incorporation of solvent molecules because the samples were prepared by recrystallization. To understand their real structures, ligand **L7** and complexes **1a**, **3a**, **6a**, and **5b** were analyzed by single-crystal X-ray diffraction.

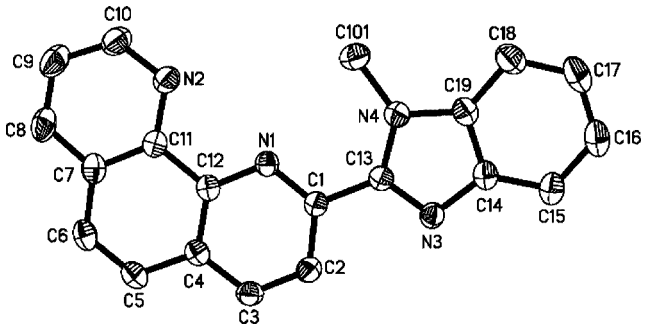

Figure 1. ORTEP drawing of ligand **L7** with thermal ellipsoids at the 30% probability level. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: N3–C13 1.3204(2), N3–C14 1.3822(2), N4–C13 1.3746(2), N4–C19 1.3863(2); N3–C13–N4 113.00(1), C13–N3–C14 105.13(1), C13–N4–C19 106.10(1).

Single crystals of ligand **L7** suitable for X-ray diffraction analysis were obtained by slow concentration of its ethyl acetate solution at room temperature. In the structure of ligand **L7** (Figure 1), the dihedral angle between the phenanthrolinyl plane and the benzimidazole plane is 7.6°, which indicates all the atoms of the ligand are almost coplanar. The N3–C13 bond [1.3204(2) Å] is longer than the typical imino C=N bond. The methyl group on the imidazole nitrogen atom stretches to the inner side of the phenanthroline ring because of the flexibility of the C1–C13 single bond.

Single crystals of complexes **1a**, **3a**, and **6a** suitable for X-ray diffraction analysis were individually grown by slow layering diffusion of diethyl ether into their methanol solutions. However, single crystals of **5b** were grown from its

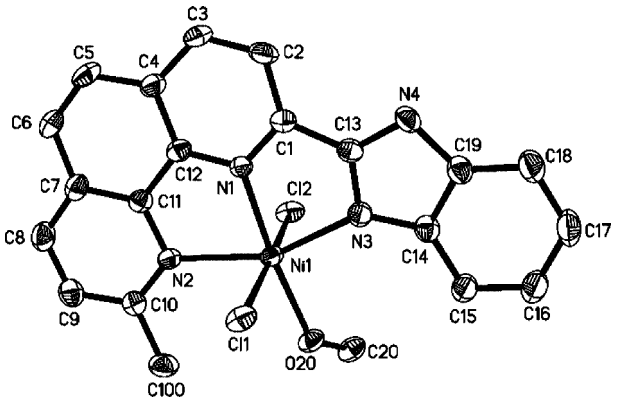

Figure 2. ORTEP drawing of complex **1a** with thermal ellipsoids at the 30% probability level. Hydrogen atoms have been omitted for clarity.

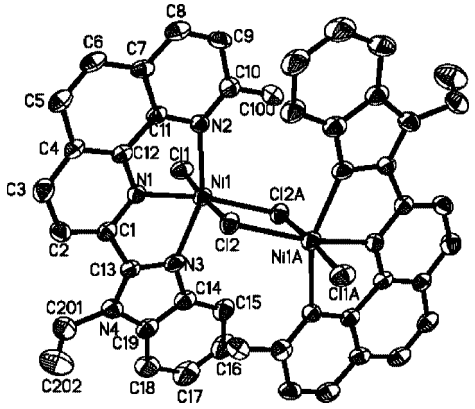

Figure 3. ORTEP drawing of complex **3a** with thermal ellipsoids at the 30% probability level. Hydrogen atoms and one molecule of $H_2O$ have been omitted for clarity.

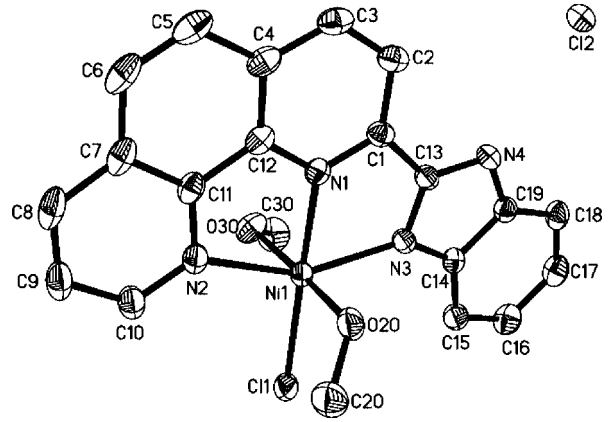

Figure 4. ORTEP drawing of complex **6a** with thermal ellipsoids at the 30% probability level. Hydrogen atoms have been omitted for clarity.

acetonitrile solution layered with diethyl ether. Their structures are depicted in Figures 2–5, and selected bond lengths and angles are collected in Table 1.

In the structure of **1a** (Figure 2), the coordination geometry around the nickel center can be described as a distorted octahedron because of the coordination of the solvent. The

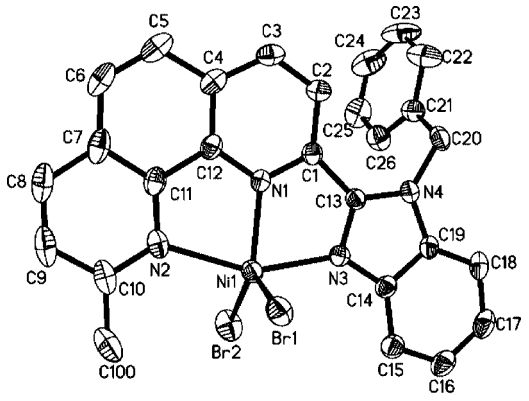

Figure 5. ORTEP drawing of complex **5b** with thermal ellipsoids at the 30% probability level. Hydrogen atoms have been omitted for clarity.

nickel center is coordinated to N1, N2 (1,10-phenanthroline), and N3 (benzimidazole), forming two fused five-membered rings with acute Ni–N angles: 77.85(1)° (N1–Ni1–N2) and 76.88(1)° (N1–Ni1–N3). The Ni1 atom deviates by 0.1149 Å from the coordinated plane. The dihedral angle between the phenanthrolinyl plane and the benzimidazole plane decreases to 5.8°, which is smaller than that of **L7** (7.6°). The bond lengths of Ni–N and Ni–Cl are significantly different: the Ni1–N1 bond [2.006(4) Å] is shorter than Ni1–N2 [2.208(4) Å] and Ni1–N3 [2.158(4) Å]; the Ni1–Cl2 bond [2.4460(2) Å] is longer than Ni1–Cl1 [2.3823(2) Å].

The structure of **3a** shows a centrosymmetric dinuclear nickel center (Figure 3) in a slightly distorted octahedral geometry. Each nickel atom is coordinated by three nitrogen atoms of the ligand, one terminal chlorine atom (Cl1), and two bridged chlorine atoms (Cl2 and Cl2A). The Ni1 atom deviates by 0.0785 Å from the plane of Cl1–N1–Cl2 and 0.0488 Å from the coordination plane (N1–N2–N3). The coordination plane incorporating N1, N2, and N3 is nearly perpendicular to the Ni1–Ni1A–Cl2–Cl2A plane, with a dihedral angle of 87.9°. The intramolecular distance of Ni···Ni is 3.658 Å, which is shorter than that in other dinuclear nickel complexes.[8c,12a] The dihedral angle between the phenanthrolinyl plane and the benzimidazole plane in **3a** ($R^2$ = Et) is 7.9°, which is wider than that in **1a** ($R^2$ = H) (5.8°). The bond lengths of Ni–N and Ni–Cl in **3a** are also different: the Ni1–N2 bond [2.202(3) Å] is longer than Ni1–N1 [2.006(3) Å] and Ni1–N3 [2.129(3) Å]; the bridged Ni1–Cl2 bond [2.5200(1) Å] is longer than Ni1–Cl1 [2.3846(1) Å].

As previously reported,[17a,18b] crystals of N^N^N tridentate nickel complexes contain not only five-coordinate species (**5b**), which are often observed in similar nickel complexes, but also six-coordinate ones, which can be realized through either the formation of dimers with bridged halogen atoms (**3a**) or the coordination of an additional solvent molecule to the metal atom (**1a**). Complex **6a** demonstrates another way of realizing the distorted octahedral coordination geometry of the Ni center (Figure 4). The six-coordinate structure of **6a** is similar to that of complexes **1a** and

**3a**. However, one chlorine atom (Cl2) is replaced by one methanol molecule and acts as a counterion relatively far from the nickel atom Ni1, with an Ni1···Cl2 distance of 6.892 Å. The nickel atom and the mutually *trans*-disposed oxygen atoms are almost in the same line, with an angle of 174.85° (O20–Ni1–O30). Also, the nickel atom, N1, and Cl1 are almost in the same line, with an angle of 177.77 ° (N1–Ni1–Cl1). The Ni atom deviates slightly from the coordination plane, by 0.0459 Å. The dihedral angle between the phenanthrolinyl plane and the benzimidazole plane in **6a** is 7.5°, which is wider than that in **1a** (5.8°).

In the structure of **5b** (Figure 5), the coordination geometry of the nickel center can be best described as distorted trigonal-bipyramidal; the phenanthroline nitrogen atom (N1) and the two bromine atoms (Br1 and Br2) form the equatorial plane. The nickel atom slightly deviates from the plane, by 0.0347 Å, and equatorial angles range between 103.33(8)° and 127.54(8)°. The two axial Ni–N bonds subtend an angle of 154.55(1)°. This equatorial plane is essentially perpendicular to the phenanthrolinyl plane, with a dihedral angle of 90.1°. The sterically bulky benzyl group ($R^2$) is nearly perpendicular to the phenanthrolinyl plane, with a dihedral angle of 76.8°. It is notable that different $R^2$ substituents in the ligands have some influence on the Ni1–N3 bond length, and the Ni1–N3 bond of complex **5b** [2.094(3) Å] is shorter than those of complex **1a** [2.158(4) Å] and complex **3a** [2.129(3) Å]. The Ni1–N1 (phenanthroline) bond is shorter by about 0.1 Å than the Ni1–N3 (benzimidazole) (2.0943 Å) bond and by 0.187 Å than the Ni1–N2 (phenanthroline) (2.1813 Å) bond, which is similar to the (2-imino-1,10-phenanthrolinyl)nickel complexes.[18b] The two Ni–Br bond lengths show a slight difference between Ni1–Br2 [2.3969(8) Å] and Ni1–Br1 [2.4217(7) Å].

### Catalytic Properties of Complexes 1a–10a and 1b–10b for Ethylene Oligomerization

Ethylene oligomerization catalyzed by these nickel complexes using different cocatalysts has been systematically investigated. Treatment of complexes **6a** and **5b** with MAO, MMAO, $Et_3Al$, or $Et_2AlCl$ in toluene generates active ethylene oligomerization catalysts. The results are summarized in Table 2. In each case, the reaction produced a mixture of $C_4$ and $C_6$ components. $Et_2AlCl$ was found to be the most effective cocatalyst, which was similar to our previous N^N^N nickel system.[18b] Meanwhile, $Et_2AlCl$ generally led to slightly higher selectivities for 1-butene (Entries 4 and 8, Table 2).

In the presence of $Et_2AlCl$, complexes **6a** and **5b** were typically investigated for further optimization by varying the Al/Ni molar ratio, ethylene pressure, reaction temperature, and reaction time. The detailed results are shown in Table 3.

For the nickel chloride complex **6a**, the highest activity [$1.27 \times 10^7$ g·mol$^{-1}$(Ni)·h$^{-1}$] was observed at an Al/Ni ratio of 300 (Entry 2, Table 3), and greater loading of $Et_2AlCl$ (500–1000 equiv.) led to lower activities (Entries 3–5, Table 3). For the nickel bromide complex **5b**, the enhancement of the Al/Ni molar ratio from 200 to 800 resulted in an increase of catalytic activity (Entries 14–17, Table 3). With an Al/Ni molar ratio of 800, the catalytic activity of **5b** peaked at $4.00 \times 10^6$ g·mol$^{-1}$(Ni)·h$^{-1}$ (Entry 17, Table 3). A further increase of the Al/Ni molar ratio resulted in decreased oligomerization activity (Entry 18, Table 3). The α-$C_4$ selectivity was also affected by the Al/Ni molar ratio. When the Al/Ni molar ratio was enhanced from 200 to 1000, α-$C_4$ selectivity for both **6a** and **5b** monotonously and

[a] General conditions: 5 μmol of complex; 100 mL of toluene; $Et_2AlCl$ as cocatalyst. [b] $10^6$ g·mol$^{-1}$(Ni)·h$^{-1}$. [c] Determined by GC.

gradually decreased. However, the varied amounts of cocatalyst had no apparent influence on the proportion of the $C_4$ component in the oligomers produced.

As is apparent, the ethylene concentration significantly affects the catalytic behaviors of the complexes. When the ethylene pressure increased from 10 atm to 30 atm, the ethylene oligomerization activity increased sharply for both **6a** and **5b**. In addition, the α-$C_4$ selectivity also increased slightly (Entries 2, 9, 10 and Entries 17, 22, 23, Table 3). Elevating the reaction temperature of the **6a**/$Et_2AlCl$ and **5b**/$Et_2AlCl$ systems from 20 °C to 80 °C resulted in a sharp decrease of activity and α-$C_4$ selectivity, which may be attributed to the decomposition of the active catalytic sites and lower ethylene concentration at higher temperature (Entries 2, 6–8 and Entries 17, 19–21, Table 3).

The catalyst lifetime is a significant factor in industrial considerations. The oligomerization activities and selectivities for 1-butene were monitored at different time intervals in the ethylene oligomerization promoted by **6a**/$Et_2AlCl$ and **5b**/$Et_2AlCl$ systems. A slight decrease in activity was determined over a period of 20 min to 1 h for complex **6a**, indicating a rather long catalyst lifetime. Meanwhile, the α-$C_4$ selectivity decreased slightly with prolonged reaction time. This observation may be attributed to the isomerization reaction of the produced 1-butene catalyzed by the nickel complex.[9c,17b,24] However, for complex **5b**, the catalytic species showed almost no activity after 20 min.

The results of ethylene oligomerization with all the nickel complexes as precatalysts are collected in Table 4. It can be observed that the ligand environment has considerable ef-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fects on the catalytic behaviors, such as activity and α-$C_4$ selectivity. The introduction of a methyl group on the 9-position of the phenanthroline ring led to a dramatic decrease in oligomerization activity and a slight increase in α-$C_4$ selectivity. This could be demonstrated by comparing complexes **1a**–**5a** ($R^1$ = Me) with **6a**–**10a** ($R^1$ = H). As shown in Table 4, complexes **6a**–**10a** (Entries 6–10, Table 4) displayed higher activities and lower α-$C_4$ selectivities than their analogues **1a**–**5a** (Entries 1–5, Table 4). The same trend was also observed for the nickel dibromide complexes **1b**–**10b** (compare Entries 16–20 with Entries 11–15, Table 4).

The incorporation of an alkyl group on the nitrogen atom of the benzimidazole ligand in the complex led to a decrease in oligomerization activity and α-$C_4$ selectivity. Complexes **1a** and **1b** or **6a** and **6b** containing the N–H group showed much higher activities than their *N*-alkylated analogues (compare Entry 1 with Entries 2–5, Entry 11 with Entries 12–15, Entry 6 with Entries 7–10, and Entry 16 with Entries 17–20, Table 4). Tentatively, these results suggest that N–H functionality is essential for high activity and selectivity with this ligand system, which could be caused by their deprotonation to give anionic amide ligands when activated by $Et_2AlCl$. The anionic amide ligands could be free or form N–Al species (anion–cation pair) to increase their catalytic activity. This observation is consistent with a previous report, although the mechanism is not clear.[22a,25] Different alkyl groups such as methyl, ethyl, isopropyl, and benzyl groups had no obvious influence on α-$C_4$ selectivity. Meanwhile, the steric bulk effects of these groups on oligomerization activities are not very regular, which could be attributed to the longer distance between the alkyl group and the metal center.

The effect of the coordinated halide X (X = Cl or Br) on the ethylene reactivity seems to be rather small. With the exception of complexes **6a** and **6b**, each nickel bromide complex showed slightly higher activity than the corresponding chloride ones, which may be attributed to the better solubility in toluene for the bromide complexes.

Previous studies on nickel catalysts have demonstrated that incorporating $PPh_3$ into the catalytic system can lead to higher activity and longer lifetime. Meanwhile, the potential catalytic intermediates incorporating $PPh_3$ were observed and the relationship between the amounts of $PPh_3$ and the catalytic activity was explored.[8c,12e,18b] Complexes **2a**, **6a**, **7a**, and **1b** were selected to further study the effect of $PPh_3$ on the α-$C_4$ selectivity. The detailed results are summarized in Table 5. In the presence of 20 equiv. of $PPh_3$,

[a] General conditions: 5 μmol of complex; $Et_2AlCl$ as cocatalyst and Al/Ni = 300; 20 equiv. of $PPh_3$ and 100 mL of toluene; $T$ = 20 °C, 30 atm of $C_2H_4$, 20 min. [b] $10^7$ g·mol$^{-1}$(Ni)·h$^{-1}$. [c] Determined by GC.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the activities of all investigated complexes are much higher [up to $10^7$ g·mol$^{-1}$(Ni)·h$^{-1}$] than those of catalytic systems without $PPh_3$. For complex **7a**, a more than 10 times higher activity was achieved, reaching $3.95 \times 10^7$ g·mol$^{-1}$(Ni)·h$^{-1}$ (Entry 7 in Table 4 vs. Entry 3 in Table 5). The plausible role of $PPh_3$ is that of association and dissociation with the nickel core to activate and protect the active sites. However, it is noteworthy that analysis of the products shows that the selectivities for 1-butene are much lower (≤26.7%). Further studies to understand the effects of the auxiliary ligand on the ethylene oligomerization are in progress.

## Conclusions

A series of nickel catalysts ligated by 2-(benzimidazol-2-yl)-1,10-phenanthroline derivatives have been found to possess several characteristics that make them attractive catalysts for ethylene oligomerization. On treatment with $Et_2AlCl$, these complexes oligomerize ethylene to dimers and trimers with high activities and α-olefin selectivities. Further experimental results illustrate their sensitivity toward different ligand environments, reaction temperatures, and ethylene pressures. Complexes **1a**–**5a** and **1b**–**5b**, with a methyl group on the 9-position of the phenanthrolinyl ring ($R^1$ = Me), showed lower activities but higher selectivities for α-olefins than complexes **6a**–**10a** and **6b**–**10b** ($R^1$ = H). The incorporation of an alkyl group ($R^2$) on the nitrogen atom of the benzimidazole led to a decrease in oligomerization activity and selectivity for 1-butene (complexes **1a**, **1b**, **6a**, and **6b**). In general, higher ethylene pressure and lower temperature resulted in higher activities and α-olefin selectivities of the catalysts. Additionally, in the presence of 20 equiv. of $PPh_3$, the activities of all investigated complexes increased dramatically with lower selectivities for 1-butene.

## Experimental Section

**General Procedure:** All air- or moisture-sensitive manipulations were carried out under nitrogen using standard Schlenk techniques. Melting points were determined with a digital electrothermal apparatus without calibration. IR spectra were obtained with a Perkin–Elmer FTIR 2000 spectrophotometer by using KBr disks in the range of 4000–400 cm$^{-1}$. NMR spectra were recorded with a Bruker DMX-300 or Bruker ARX 400 spectrometer with TMS as the internal standard. Elemental analyses were performed with a Flash EA 1112 microanalyzer. GC was performed with a VARIAN CP-3800 gas chromatograph equipped with a flame ionization detector and a 30-m (0.2 mm i.d., 0.25 μm film thickness) CP-Sil 5 CB column. Toluene was refluxed in the presence of sodium/benzophenone and distilled under nitrogen prior to use. The polymerization-grade ethylene was supplied by Beijing Yansan Petrochemical Co. $Et_2AlCl$ (1.90 M) solution in toluene and triethylaluminum (diluted to 2 M in toluene for usage) were purchased from Acros Chemicals, while methylaluminoxane (MAO, 1.46 M in toluene) and modified methylaluminoxane (MMAO, 1.93 M in heptane, 3A) were purchased from Akzo Nobel Corp. All other commercial chemicals were used without further purification.

**Synthesis of Ligands:** New synthetic procedures were developed to prepare the original organic compounds, 2-(1*H*-benzimidazol-2-yl)-9-methyl-1,10-phenanthroline (**L1**) and 2-(1*H*-benzimidazol-2-yl)-1,10-phenanthroline (**L6**). The *N*-alkylation of **L1** and **L6** was subjected to different modified conditions to synthesize their derivatives, **L2**–**L5** and **L7**–**L10**, individually.

**2-(1*H*-Benzimidazol-2-yl)-9-methyl-1,10-phenanthroline (L1):** A mixture of 2,9-dimethyl-1,10-phenanthroline ($2C_{14}H_{12}N_2 \cdot H_2O$) (1.00 g, 4.80 mmol), *o*-phenylenediamine (0.58 g, 5.36 mmol), and sulfur (3.00 g, 11.70 mmol) was heated and kept at 170 °C for 8 h. After the mixture had cooled to room temperature, 200 mL of methanol was added to extract the product, and the precipitated solid was filtered off. The filtrate was concentrated and the residual brown oil was purified by column chromatography (silica gel, chloroform/ethyl acetate/methanol as elute, v/v/v = 20:20:1) to give an ivory-white powder (0.60 g) in 42% yield. M.p. 138–140 °C. IR (KBr disk): $\tilde{\nu}$ = 3419, 3051, 2950, 1620, 1590, 1466, 1435, 1337, 1189, 1065, 889, 768, 743 cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 13.60 (s, 1 H, NH), 8.58 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.18 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.06 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 7.82 (d, $^1J$ = 6.0 Hz, 1 H, Phen), 7.66 (s, 2 H, Phen), 7.49 (d, $^1J$ = 6.0 Hz, 1 H, benzimidazole), 7.36 (d, $^1J$ = 8.4 Hz, 1 H, benzimidazole), 7.24 (dd, $^1J$ = 6.0 Hz, 2 H, benzimidazole), 2.80 (s, 3 H, $CH_3$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 157.9, 151.9, 150.6, 147.2, 143.7, 143.5, 135.8, 135.6, 127.7, 126.0, 125.5, 124.5, 123.0, 119.8, 111.9, 23.5 ppm. $C_{20}H_{14}N_4$ (310.35): calcd. C 77.06, H 4.39, N 18.55; found C 77.40, H 4.55, N 18.05.

**9-Methyl-2-(1-methyl-1*H*-benzimidazol-2-yl)-1,10-phenanthroline (L2):** $K_2CO_3$ (0.50 g, 3.62 mmol) was added to a solution of **L1** (0.25 g, 0.80 mmol) in acetonitrile (50 mL). After the mixture was refluxed for 12 h, iodomethane (0.07 mL, 1.12 mmol) was added and the mixture was stirred at room temperature for 24 h. After filtration and concentartion, an orange oil was obtained; thereafter it was dissolved in $CHCl_3$ (50 mL) and washed with water (50 mL × 3). The organic phase was separated, dried with anhydrous $MgSO_4$, and the solvents were evaporated. The residue was purified by column chromatography (silica gel, triethylamine/petroleum ether as elute, v/v = 2:1) to give a white powder (0.12 g) in 46% yield. M.p. 170–172 °C. IR (KBr disk): $\tilde{\nu}$ = 2919, 1614, 1588, 1438, 1414, 1326, 1258, 1096, 855, 728 cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 8.77 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.38 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.17 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 7.89 (d, $^1J$ = 8.0 Hz, 1 H, Phen), 7.83 (d, $^1J$ = 8.8 Hz, 1 H, Phen), 7.79 (d, $^1J$ = 8.8 Hz, 1 H, Phen), 7.55 (t, $^1J$ = 7.2 Hz, 2 H, benzimidazole), 7.40 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 7.35 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 4.78 (s, 3 H, $CH_3$), 2.94 (s, 3 H, $CH_3$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 159.5, 150.4, 150.1, 145.7, 145.0, 142.8, 137.8, 136.7, 136.3, 127.2, 127.0, 125.3, 123.7, 123.4, 122.7, 120.2, 110.2, 33.2, 26.0 ppm. $C_{21}H_{16}N_4$ (324.38): calcd. C 77.45, H 5.23, N 17.32; found C 77.76, H 4.97, N 17.27.

**2-(1-Ethyl-1*H*-benzimidazol-2-yl)-9-methyl-1,10-phenanthroline (L3):** Ligands **L3**–**L5** and **L7**–**L10** were prepared using a similar method to that for **L2**. Iodoethane (0.09 mL, 1.12 mmol) reacted with deprotonated **L1** at 60 °C for 12 h. **L3** was obtained as a pink solid in 60% yield after purification by column chromatography (silica gel, triethylamine as elute). M.p. 128–130 °C. IR (KBr disk): $\tilde{\nu}$ = 2962, 1615, 1588, 1488, 1416, 1329, 1264, 1097, 849, 731 cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 8.75 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.37 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.16 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 7.90 (d, $^1J$ = 8.0 Hz, 1 H, Phen), 7.83 (d, $^1J$ = 8.8 Hz, 1 H, Phen), 7.79 (d, $^1J$ = 8.8 Hz, 1 H, Phen), 7.55 (t, $^1J$ = 7.2 Hz, 2 H, benzimidazole), 7.39 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 7.34 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 5.34 (q, $^1J$ = 7.2 Hz, 2 H, $CH_2CH_3$), 2.92 (s, 3 H, $CH_3$), 1.77 (t, $^1J$ = 7.2 Hz, 3 H, $CH_2CH_3$) ppm. $^{13}$C

NMR (75 MHz, $CDCl_3$): $\delta$ = 159.5, 150.2, 150.0, 145.9, 145.3, 143.1, 136.8, 136.6, 136.1, 128.4, 127.2, 127.0, 125.3, 123.6, 123.3, 122.6, 120.3, 110.3, 41.4, 25.8, 15.8 ppm. $C_{22}H_{18}N_4$ (338.41): calcd. C 77.81, H 5.66, N 16.53; found C 78.08, H 5.36, N 16.56.

**2-(1-Isopropyl-1*H*-benzimidazol-2-yl)-9-methyl-1,10-phenanthroline (L4):** 2-Iodopropane (0.11 mL, 1.12 mmol) reacted with deprotonated **L1** and was refluxed for 12 h. **L4** was obtained as yellow crystals in 43% yield by column chromatography (silica gel, triethylamine as elute). M.p. 130–132 °C. IR (KBr disk): $\tilde{\nu}$ = 2967, 1617, 1588, 1493, 1419, 1404, 1387, 1132, 855, 740 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.63 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.36 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.12 (d, $^1J$ = 8.1 Hz, 1 H, Phen), 7.91 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 7.78–7.75 (m, 3 H, 2 H-Phen, 1 H-benzimidazole), 7.51 (d, $^1J$ = 8.4 Hz, 1 H, benzimidazole), 7.33 (m, 2 H, benzimidazole), 6.67 (sept, $^1J$ = 6.6 Hz, 1 H, C*H*$(CH_3)_2$), 2.90 (s, 3 H, C*H*$_3$), 1.90 (d, $^1J$ = 6.6 Hz, 6 H, CH(C*H*$_3)_2$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 158.6, 145.0, 149.5, 144.9, 144.1, 142.8, 135.9, 135.3, 134.3, 127.4, 126.4, 126.1, 124.4, 123.2, 122.8, 122.1, 121.4, 119.8, 112.3, 48.7, 25.0, 20.9 ppm. $C_{23}H_{20}N_4$ (352.43): calcd. C 77.98, H 6.03, N 15.99; found C 78.38, H 5.72, N 15.90.

**2-(1-Benzyl-1*H*-benzimidazol-2-yl)-9-methyl-1,10-phenanthroline (L5):** Benzyl bromide (0.13 mL, 1.12 mmol) reacted with deprotonated **L1** and was refluxed for 12 h. **L5** was obtained by column chromatography (silica gel, triethylamine as elute) as an ivory-white powder in 55% yield. M.p. 122–124 °C. IR (KBr disk): $\tilde{\nu}$ = 3038, 3004, 1616, 1587, 1495, 1442, 1414, 1329, 864, 740, 720 $cm^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 8.77 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.36 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.17 (d, $^1J$ = 8.0 Hz, 1 H, Phen), 7.94 (dd, $^1J$ = 6.0 Hz, 1 H, Phen), 7.80 (dd, $^1J$ = 8.4 Hz, 2 H, Phen), 7.55 (d, $^1J$ = 8.0 Hz, 2 H, benzimidazole), 7.37 (dd, $^1J$ = 6.0 Hz, 2 H, benzimidazole), 7.31 (d, $^1J$ = 6.0 Hz, 2 H, Ph), 7.13 (m, 3 H, Ph), 6.90 (s, 2 H, C*H*$_2$), 2.89 (s, 3 H, C*H*$_3$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 163.6, 158.5, 149.1, 145.2, 143.9, 143.6, 143.2, 142.0, 137.2, 136.4, 135.7, 135.2, 127.4, 126.2, 124.3, 122.7, 122.3, 121.9, 119.4, 110.0, 48.1, 24.8 ppm. $C_{27}H_{20}N_4$ (400.47): calcd. C 80.53, H 5.23, N 14.24; found C 80.98, H 5.03, N 13.99.

**2-(1*H*-Benzimidazol-2-yl)-1,10-phenanthroline (L6):** A mixture of 1,10-phenanthroline-2-carboxylic acid (1.12 g, 5.00 mmol), *o*-phenylenediamine (0.58 g, 5.40 mmol), and polyphosphoric acid (ppa) (7.00 g) was irradiated in a microwave oven (450 W) three times, for 2 min each time. The heated reaction mixture was poured into ice-cold water (300 mL), and the pH was adjusted to 9 by the addition of $NaHCO_3$. The precipitated solid was filtered off. After purification of the solid by column chromatography (silica gel, ethyl acetate/methanol as elute, v/v = 1:1), **L6** was obtained as white crystals (0.36 g) in 26% yield. M.p. 126–128 °C. IR (KBr disk): $\tilde{\nu}$ = 3399, 3059, 1619, 1587, 1502, 1431, 1315, 1275, 856, 740 $cm^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 13.43 (s, 1 H, NH), 9.06 (dd, $^1J$ = 4.4 Hz, 1 H, Phen), 8.74 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.35 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.24 (dd, $^1J$ = 8.0 Hz, 1 H, Phen), 7.88 (t, $^1J$ = 6.4 Hz, 1 H, benzimidazole), 7.82 (dd, $^1J$ = 8.8 Hz, 2 H, Phen), 7.64 (dd, $^1J$ = 8.0 Hz, 1 H, Phen), 7.57 (m, 1 H, benzimidazole), 7.30 (m, 2 H, benzimidazole) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 151.3, 149.0, 148.4, 145.2, 144.8, 144.2, 136.6, 136.5, 134.7, 128.8, 128.5, 126.4, 123.6, 123.0, 122.0, 120.9, 119.6, 111.6 ppm. $C_{19}H_{12}N_4$ (296.33): calcd. C 77.38, H 3.83, N 18.79; found C 77.01, H 4.08, N 18.91.

**2-(1-Methyl-1*H*-benzimidazol-2-yl)-1,10-phenanthroline (L7): L7** was obtained as a white powder in 51% yield by column chromatography (silica gel, triethylamine as elute). M.p. 186–188 °C. IR (KBr disk): $\tilde{\nu}$ = 2936, 1617, 1590, 1496, 1463, 1439, 1414, 1259, 1100, 855, 736 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 9.23 (d, $^1J$ = 3.9 Hz, 1 H, Phen), 8.77 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.42 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.31 (d, $^1J$ = 8.0 Hz, 1 H, Phen), 7.92–7.88 (m, 3 H, 2 H-Phen, 1 H-benzimidazole), 7.70 (dd, $^1J$ = 7.8 Hz, 1 H, Phen), 7.55 (d, $^1J$ = 7.4 Hz, 1 H, benzimidazole), 7.41 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 7.36 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 4.72 (s, 3 H, $CH_3$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 149.4, 149.2, 145.1, 144.3, 144.0, 141.6, 138.0, 136.4, 135.6, 134.9, 127.9, 126.1, 125.2, 122.7, 122.4, 122.0, 121.5, 119.0, 109.0, 29.7 ppm. $C_{20}H_{14}N_4$ (310.35): calcd. C 77.18, H 4.88, N 17.94; found C 77.40, H 4.55, N 18.05.

**2-(1-Ethyl-1*H*-benzimidazol-2-yl)-1,10-phenanthroline (L8): L8** was obtained as a pale yellow powder in 62% yield by column chromatography (silica gel, triethylamine as elute). M.p. 156–158 °C. IR (KBr disk): $\tilde{\nu}$ = 3038, 2961, 1614, 1588, 1555, 1461, 1418, 1379, 1328, 1290, 1105, 845, 734 $cm^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 9.22 (d, $^1J$ = 4.0 Hz, 1 H, Phen), 8.76 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.42 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.30 (d, $^1J$ = 8.0 Hz, 1 H, Phen), 7.91 (d, $^1J$ = 7.6 Hz, 1 H, benzimidazole), 7.88 (s, 2 H, Phen), 7.68 (dd, $^1J$ = 8.0 Hz, 1 H, Phen), 7.57 (d, $^1J$ = 8.0 Hz, 1 H, benzimidazole), 7.40 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 7.36 (t, $^1J$ = 7.2 Hz, 1 H, benzimidazole), 5.38 (q, $^1J$ = 7.2 Hz, 2 H, C*H*$_2$CH$_3$), 1.61 (t, $^1J$ = 7.2 Hz, 3 H, CH$_2$C*H*$_3$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 149.3, 149.1, 148.7, 145.3, 144.2, 141.8, 137.5, 135.4, 134.7, 127.8, 126.1, 125.1, 122.4, 122.3, 121.9, 121.3, 119.0, 109.0, 39.8, 14.3 ppm. $C_{21}H_{16}N_4$ (324.38): calcd. C 77.48, H 4.78, N 17.64; found C 77.76, H 4.97, N 17.27.

**2-(1-Isopropyl-1*H*-benzimidazol-2-yl)-1,10-phenanthroline (L9): L9** was obtained as a brown powder in 32% yield through column chromatography (silica gel, triethylamine as elute). M.p. 130–132 °C. IR (KBr disk): $\tilde{\nu}$ = 2973, 1617, 1586, 1495, 1457, 1422, 1336, 1282, 1254, 1136, 862, 744 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 9.18 (d, $^1J$ = 3.3 Hz, 1 H, Phen), 8.60 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.41 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.27 (d, $^1J$ = 8.0 Hz, 1 H, Phen), 7.90 (d, $^1J$ = 5.4 Hz, 1 H, benzimidazole), 7.86 (s, 2 H, Phen), 7.76 (d, $^1J$ = 6.0 Hz, 1 H, benzimidazole), 7.65 (dd, $^1J$ = 7.2 Hz, 1 H, Phen), 7.32 (m, 2 H, benzimidazole), 6.45 [sept, $^1J$ = 6.9 Hz, 1 H, C*H*$(CH_3)_2$], 1.86 [d, 6 H, CH(C*H*$_3)_2$] ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 149.7, 149.5, 149.4, 145.2, 144.1, 142.5, 135.6, 134.7, 133.8, 127.8, 127.0, 126.2, 125.1, 123.2, 122.0, 121.7, 121.0, 119.5, 111.9, 48.2, 20.5 ppm. $C_{22}H_{18}N_4$ (338.41): calcd. C 78.44, H 4.93, N 16.63; found C 78.08, H 5.36, N 16.56.

**2-(1-Benzyl-1*H*-benzimidazol-2-yl)-1,10-phenanthroline (L10): L10** was obtained as a brown powder in 47% yield by column chromatography (silica gel, triethylamine as elute). M.p. 108–110 °C. IR (KBr disk): $\tilde{\nu}$ = 2928, 1605, 1588, 1496, 1434, 1351, 1259, 1163, 1078, 857, 735 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 9.13 (d, $^1J$ = 3.2 Hz, 1 H, Phen), 8.65 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.27 (d, $^1J$ = 8.4 Hz, 1 H, Phen), 8.18 (d, $^1J$ = 7.2 Hz, 1 H, Phen), 7.84 (t, $^1J$ = 6.0 Hz, 1 H, benzimidazole), 7.74 (s, 2 H, Phen), 7.58 (dd, $^1J$ = 8.0 Hz, 1 H, Phen), 7.47 (t, $^1J$ = 6.0 Hz, 1 H, benzimidazole), 7.28 (t, $^1J$ = 3.2 Hz, 2 H, benzimidazole), 7.22 (s, 1 H, Phen), 7.12 (d, $^1J$ = 3.2 Hz, 2 H, Ph), 6.99 (m, 3 H, Ph), 6.71 (s, 2 H, C*H*$_2$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 149.4, 149.2, 148.9, 145.3, 141.9, 137.0, 136.2, 135.7, 134.9, 128.0, 127.3, 126.3, 126.1, 125.2, 122.9, 122.6, 122.1, 121.8, 119.3, 109.8, 47.9 ppm. $C_{26}H_{18}N_4$ (386.45): calcd. C 81.13, H 4.82, N 14.05; found C 80.81, H 4.69, N 14.50.

**Syntheses of Nickel Complexes 1a–10a and 1b–10b:** Complexes **1a**–**10a** were prepared according to the following procedure. The corresponding ligand and 1 equiv. of $NiCl_2 \cdot 6H_2O$ were individually dissolved in ethanol and mixed together. The reaction mixture was stirred at room temperature for 8 h. The resulting precipitate was

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

filtered, washed with diethyl ether, and dried in a vacuum. Instead of $NiCl_2·6H_2O$ in the same synthetic procedure, a stoichiometric amount of (dme)$NiBr_2$ and the corresponding ligand in $CH_2Cl_2$ were stirred under nitrogen to form the nickel bromide complexes **1b**–**10b**.

**Characterization Data of Nickel Dichloride Complexes 1a–10a. 1a**: Green powder in 87% yield. IR (KBr disk): $\tilde{\nu}$ = 3254, 1624, 1588, 1504, 1429, 1321, 863, 747 $cm^{-1}$. $C_{20}H_{14}Cl_2N_4Ni·H_2O$ (457.97): calcd. C 52.19, H 3.17, N 12.66; found C 52.45, H 3.52, N 12.23. **2a**: Green powder in 82% yield. IR (KBr disk): $\tilde{\nu}$ = 1622, 1589, 1504, 1486, 1464, 862, 745 $cm^{-1}$. $C_{21}H_{16}Cl_2N_4Ni$ (453.98): calcd. C 55.14, H 3.07, N 12.55; found C 55.56, H 3.55, N 12.34. **3a**: Green powder in 86% yield. IR (KBr disk): $\tilde{\nu}$ = 3333, 1621, 1585, 1491, 1441, 1334, 862, 746 $cm^{-1}$. $C_{22}H_{18}Cl_2N_4Ni$ (468.00): calcd. C 56.14, H 3.47, N 11.65; found C 56.46, H 3.88, N 11.97. **4a**: Green powder in 91% yield. IR (KBr disk): $\tilde{\nu}$ = 3371, 2973, 1622, 1586, 1517, 1446, 1334, 1161, 865, 747 $cm^{-1}$. $C_{23}H_{20}Cl_2N_4Ni$ (482.03): calcd. C 57.62, H 4.46, N 11.33; found C 57.31, H 4.18, N 11.62. **5a**: Green powder in 90% yield. IR (KBr disk): $\tilde{\nu}$ = 3056, 1619, 1586, 1522, 1481, 1447, 1426, 1334, 857, 746 $cm^{-1}$. $C_{27}H_{20}N_4NiCl_2$ (530.07): calcd. C 61.04, H 3.57, N 10.65; found C 61.18, H 3.80, N 10.57. **6a**: Green powder in 84% yield. IR (KBr disk): $\tilde{\nu}$ = 3273, 3046, 1614, 1581, 1512, 1446, 1321, 859, 742, 706 $cm^{-1}$. $C_{19}H_{12}Cl_2N_4Ni$ (425.92): calcd. C 53.13, H 2.51, N 13.50; found C 53.58, H 2.84, N 13.15. **7a**: Green powder in 88% yield. IR (KBr disk): $\tilde{\nu}$ = 3273, 1621, 1577, 1530, 1510, 1460, 1418, 1335, 854, 743, 706 $cm^{-1}$. $C_{20}H_{14}Cl_2N_4Ni$ (439.95): calcd. C 54.11, H 3.59, N 12.47; found C 54.60, H 3.21, N 12.73. **8a**: Green powder in 85% yield. IR (KBr disk): $\tilde{\nu}$ = 3340, 1621, 1607, 1579, 1526, 1482, 1442, 1334, 853, 745 $cm^{-1}$. $C_{21}H_{16}Cl_2N_4Ni$ (453.98): calcd. **X-ray Crystallography:** Single-crystal X-ray diffraction studies for complex **1a** were carried out on a Rigaku RAXIS Rapid IP diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Intensity data for crystals of ligand **L7** and complexes **3a**, **6a**, and **5b** were collected with a Bruker SMART 1000 CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Cell parameters were obtained by global refinement of the positions of all collected reflections. Intensities were corrected for Lorentz and polarization effects and empirical absorption. The structures were solved by direct methods and refined by full-matrix least squares of $F^2$. All non-hydrogen atoms were refined anisotropically. Structure solution and refinement were performed using the SHELXL-97 package.[26] Crystal data and processing parameters are summarized in Table 6. CCDC-643354 (for **L7**), -643355 (for **1a**), -643356 (for **3a**), -643357 (for **6a**), and -643358 (for **5b**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**General Procedure for Ethylene Oligomerization:** A 250-mL stainless steel autoclave equipped with a mechanical stirrer and a temperature controller was heated in vacuo at 80 °C for 2 h. It was cooled to the required reaction temperature under ethylene, and charged with toluene, the desired amount of cocatalyst, and toluene solution of catalytic precursor; the total volume was 100 mL. The reactor was sealed and pressurized to the desired ethylene pressure, and the ethylene pressure was maintained with feeding of ethylene. After the reaction was carried out for the required period, the pressure was released. A small amount of the reaction solution was collected, the reaction in this small sample was terminated by the addition of 5% aqueous hydrogen chloride, and the organic layer was analyzed by gas chromatography (GC) for determining the composition and mass distribution of oligomers obtained.

# Synthetic, X-ray Diffraction, Electrochemical, and Density Functional Theoretical Studies of (Indenyl)ruthenium Complexes Containing Dithiolate Ligands

**Sin Yee Ng,[a] Jialin Tan,[a] Wai Yip Fan,[a] Weng Kee Leong,[a] Lai Yoong Goh,*[a] and Richard D. Webster[b]**

**Keywords:** Ruthenium complexes / Dithiolates / Cyclic voltammetry / Density functional calculations

Halide substitution of the complexes [(Ind)Ru($L_2$)X] {Ind = $\eta^5$-$C_9H_7$. **1**: ($L_2$) = dppf [1,1′-bis(diphenylphosphanyl)ferrocene], X = Cl; **2**: ($L_2$) = dppm [1,1′-bis(diphenylphosphanyl)methane], X = Cl; and **18**: ($L_2$) = $(CO)_2$, X = I} with the 1,1-dithiolates $^-S_2CNR_2$ (dialkyl dithiocarbamates for R = Me, Et, and $C_5H_{10}$), $^-S_2COR$ (alkyl xanthates for R = Et and *i*Pr), and $^-S_2PR_2$ (dithiophosphinates for R = Et and Ph) showed that the lability of the indenyl ligand is influenced by the nature of both the coligand and the incoming dithiolate, as well as the solvent. In addition to dithiolate derivatives, the reactions also produced the hydride species [(Ind)Ru(diphos)H] in solvent- and stoichiometry-dependent yields. The observed dependence of lability of Ind on ($L_2$) follows the order, dppf < dppm ≈ $(CO)_2$, in agreement with the electron-donor capability of $L_2$, as well as the estimation of lowest activation energy for the $\eta^5 \rightarrow \eta^3$ ring slippage process in the series of complexes [(Ind)Ru$(L)_2(S_2COMe)$] (L = $PMeH_2$, $PH_3$, CO) for L = CO. The computational study also indicated an indenyl lability order for dithiolate substitution (dithiocarbamate > xanthate), in agreement with experimental findings. The dissociation of the indenyl ligand in chloro substitution of **1** by $^-S_2CNEt_2$ was found to be exhaustive in a polar solvent like MeOH, but only partial in $CH_2Cl_2$. Cyclic voltammetry experiments indicated that [(Ind)Ru(dppf)($\eta^1$-$S_2COiPr$)] (**10**) and [(Ind)Ru(dppf)($\eta^1$-$S_2PPh_2$)] (**13**) can be oxidized in one-electron chemical irreversible or chemical reversible processes, respectively (at a scan rate of 100 mV/s), at about 0 V versus $Fc/Fc^+$. Complex **13** underwent additional one-electron oxidation processes at +0.5 and +0.8 V versus $Fc/Fc^+$. The new complexes have all been characterized spectroscopically, and some (four containing the indenyl ligand and three of the non-indenyl type) by X-ray diffraction as well.

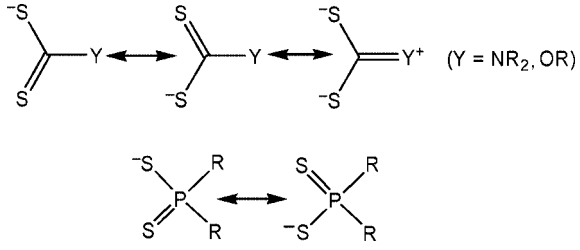
## Introduction

1,1-Dithiolate compounds represent a class of versatile ligands, owing to the occurrence of resonance phenomena, which result in electron delocalization, as depicted in Scheme 1. Their coordination chemistry with the transition metals commands much interest, on account of the rich diversity of the complexes and their numerous and potential applications in industry and agriculture.[1]

Our work on some of these ligands was directed at their reactivity in the coordination environment of $CpCr(CO)_n$ ($n$ = 2 or 3),[2] (HMB)Ru(dppf), and CpRu(dppf) (Cp = $\eta^5$-$C_5H_5$ and HMB = $\eta^6$-$C_6Me_6$).[3] A logical and interesting follow-up of these studies on Ru would be a corresponding reactivity study of the indenyl (Ind) analogue, as Ind can potentially assume bonding modes involving $\eta^5$-Cp or by



Scheme 1.

ring slippage to $\eta^3$ or $\eta^6$-$C_9H_7$.[4] Such an investigation is also timely, as there is intense interest in reactivity aspects of (Ind)Ru complexes, especially from catalytic perspectives;[5] and the bulk of the literature on (Ind)Ru complexes deals with examples containing phosphanes as coligands, with only two such complexes carrying S-donor ligands, viz. SEt and SEtMe.[6] Moreover, the outcome of the study will provide a useful comparison to our completed study of (Ind)Ru(dppf)Cl (**1**) with simple alkyl/aryl monothiolates, $SR^-$ (R = Me, Et, and Ph).[7] This paper will describe the results of reactions of **1**, its dppm analogue **2**, and (Ind)-$Ru(CO)_2I$ **18** with dialkyl dithiocarbamate, alkyl xanthate, and bis(alkyl/aryl)dithiophosphinate, together with X-ray

structural and electrochemical data of some of the new complexes, and a computational estimation of the energies involved in $\eta^5 \rightarrow \eta^3$ ring slippage of the indenyl ligand in selected molecules.

## Results and Discussion

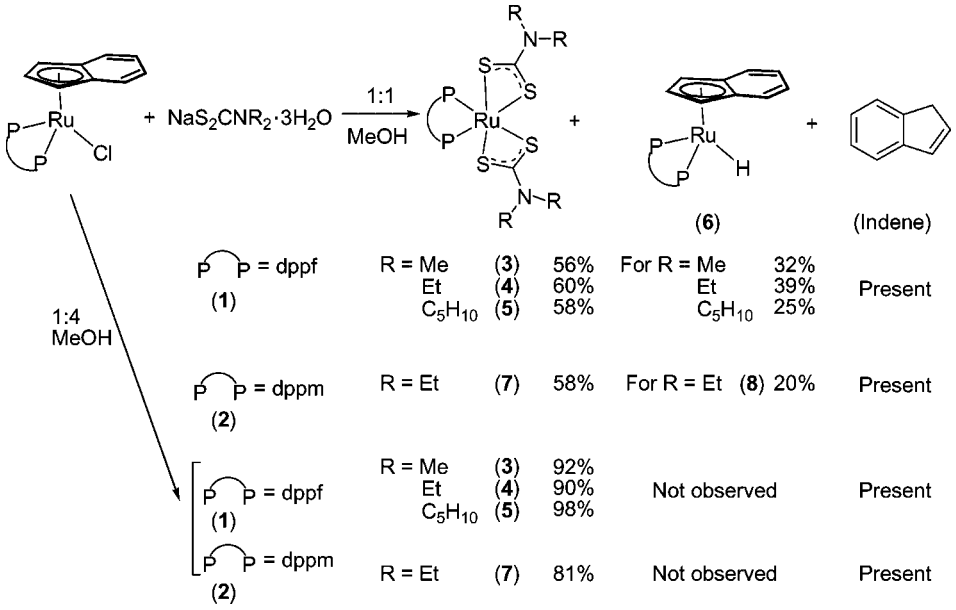
### Reactions of [(Ind)Ru($L_2$)Cl] ($L_2$ = dppf, dppm)

#### *Reaction with Dialkyl Dithiocarbamates*

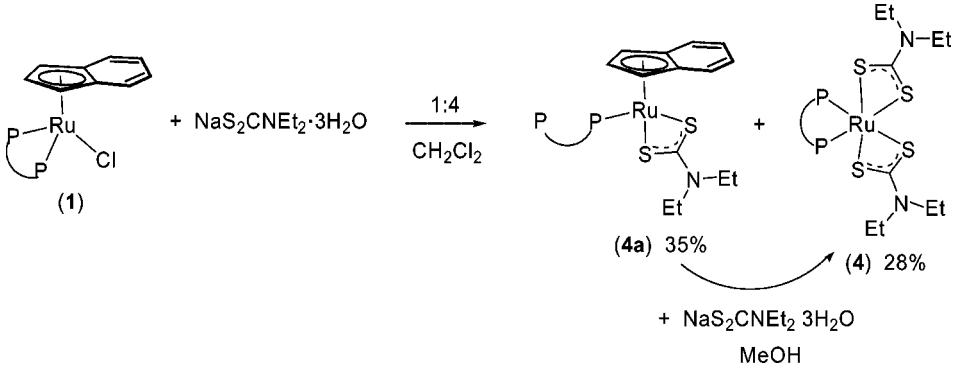
Complex [(Ind)Ru(dppf)Cl] (**1**) and its dppm analogue [(Ind)Ru(dppm)Cl] (**2**) were reacted with $NaS_2CNR_2$. The product mixture from the reaction of **1** in MeOH is both stoichiometry- and time-dependent. Thus the addition of 1 mol-equiv. of $^-S_2CNR_2$ to **1** gives complexes [Ru($\eta^2$-dppf)($\eta^2$-$S_2CNR_2$)$_2$] [R = Me (**3**), Et (**4**), $C_5H_{10}$ (**5**)], together with the hydride, [(Ind)Ru(dppf)H] **6**, which was not observed with the use of excess $^-S_2CNR_2$ (Scheme 2). The release of indene in all cases is consistent with the formation of the non-indenyl complexes **3**–**5**. In the reaction of **1** with 1 mol-equiv. of $^-S_2CNEt_2$, $^{31}$P NMR spectroscopy showed that the reaction mixture contained species **1** ($\delta$ = 51.7 ppm), **6** ($\delta$ = 62.8 ppm), **4** ($\delta$ = 47.1 ppm), and [(Ind)-Ru($\eta^1$-dppf)($\eta^2$-$S_2CNEt_2$)] **4a** ($\delta$ = –17.7 and 57.3), in an approximate 2:3:7:1 molar proportion after 4 h at room temperature, but finally only complexes **4** and **6** in 3:2 molar ratio after 16 h. A repeat of the reaction in $CH_2Cl_2$ using **1** and $NaS_2CNEt_2$ in 1:4 molar proportion yielded a final 1:1 molar mixture of **4** and **4a**, which was isolated in 35% yield. It was further demonstrated that the reaction of **4a** with $NaS_2CNEt_2$ in MeOH yielded **4** (Scheme 3).

The structure of **4a** was determined by X-ray diffraction analysis. This is consistent with its NMR spectroscopic data, which indicated the presence of $\eta^5$-Ind and $\eta^2$-$S_2CNEt_2$ ligands in the proton spectrum, and $\eta^1$-dppf in the $^{31}$P spectrum ($\delta$ = –17.7 and 57.3, with the upfield signal associated with the uncoordinated phosphorus atom).

The progression of **1** to **4** via **4a** indicates the weaker thermodynamic stability of bidentate dppf versus $^-S_2CNEt_2$, which in excess will also displace the indenyl ligand, accompanied by rechelation of the monodentate dppf ligand in **4a** to achieve the favored hexacoordination at



Scheme 2.



Scheme 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Ru^{II}$. We had previously isolated complex **4** in 80% yield by displacement of triphenylphosphane in $Ru(\eta^2\text{-}S_2CNEt_2)_2(PPh_3)_2$ with dppf and have observed mono- and bidentate exchange behavior of the dithiocarbamate ligand in solution.[8]

The formation of **6** points to the role of methoxide arising from an equilibrium, as discussed before for $SR^-$ (R = Me, Et):[7]

$$^-S_2CNR_2 + MeOH \overset{K}{\rightleftharpoons} {}^-OMe + HS_2CNR_2$$

It is significant that **6** was not detected when excess $^-S_2CNR_2$ was used. Although it is probable that it was formed but underwent a facile $H^-$ and $^-S_2CNEt_2$ exchange, as found in the reactions of $CpRu(PPh_3)_2H$ with the halide and SCN anions,[9] this probability was ruled out experimentally in this case, as **6** did not react at all with excess $NaS_2CNR_2$, indicating that **6** was not the intermediate leading to **4**. As the formation of **4** requires 2 mole equiv. of $^-S_2CNEt_2$ to **1**, such a stoichiometric reaction was carried out in MeOH, in an attempt to further investigate the reaction pathways. A yellow precipitate, identified as **4**, was obtained, while the reaction of the filtrate with a new batch of **1** for 18 h at room temp. generated **6**, indicative of the presence of $^-OMe$ in the filtrate. This indirectly demonstrated that MeOH was the proton source for the conversion of the indenyl moiety to indene.

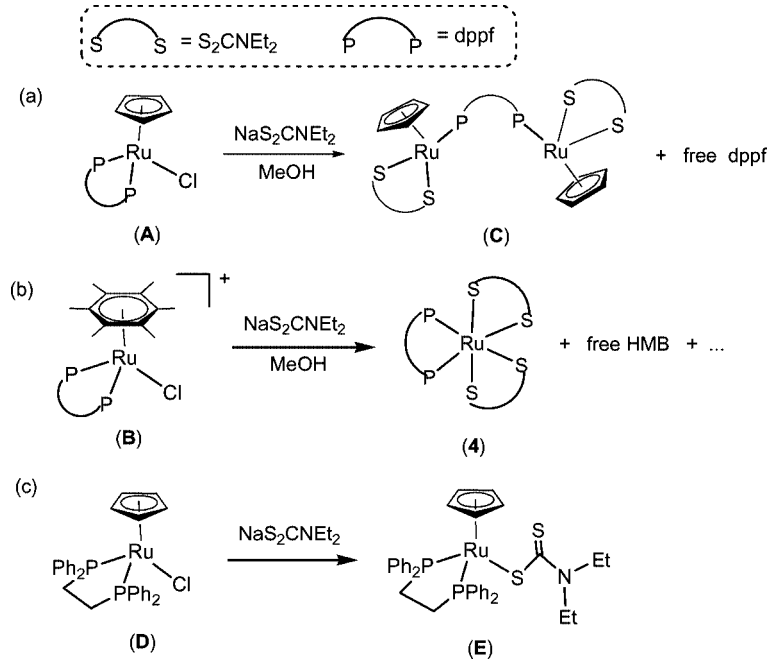
A comparative study was carried out on the reactivity of [(Ind)Ru(dppm)Cl] (**2**), the dppm analogue of **1**, towards the nucleophile $^-S_2CNR_2$. As shown in Scheme 2, similar observations were found in MeOH solvent, giving **7** (a compound similar to **4**) and **8** (a hydride similar to **6**);[10] the latter was not formed when the nucleophile was used in excess. However, the dppm equivalent of **4a**, that is, [(Ind)-$Ru(\eta^1\text{-dppm})(\eta^2\text{-}S_2CNEt_2)$], was not observed, probably because of thermodynamic instability, though complexes with monodentate dppm are known.[11]

Our previous studies showed that the outcome of the reactions of LRu(dppf)Cl [L = Cp (**A**), HMB (**B**)] with $^-S_2CNEt_2$ were very different. For L = Cp, a dinuclear complex $[CpRu(S_2CNEt_2)_2]_2(\mu\text{-dppf})$ (**C**) was formed, and for L = arene, $^-S_2CNEt_2$ displaced the arene ligand, as it displaced the indenyl ligand in complex **1**, as discussed above (see Scheme 4, a,b[3a]). In comparison, the analogous reaction of [CpRu(dppe)Cl] (**D**) was reported to give the mononuclear complex $[CpRu(dppe)(\eta^1\text{-}S_2CNEt_2)]$ (**E**) (Scheme 4, c).[12]

### *Reaction with Alkyl Xanthates*

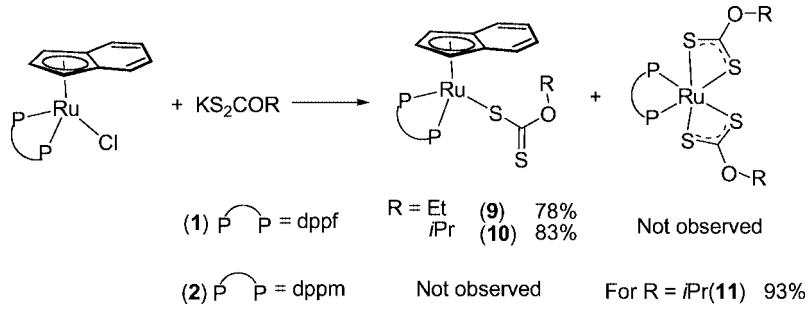
The reaction of **1** with $KS_2COR$ (R = Et, *i*Pr) in MeOH at room temp. or in refluxing $CH_2Cl_2$ yielded $[(Ind)Ru(\eta^2\text{-dppf})(\eta^1\text{-}S_2COR)]$ in high yield [R = Et (**9**), 78% yield; R = *i*Pr (**10**), 83% yield]. On the other hand, the reaction of **2** with $KS_2CO$*i*Pr in MeOH gave only a non-indenyl complex $[Ru(\eta^2\text{-dppm})(\eta^2\text{-}S_2CO$*i*$Pr)_2]$ (**11**) (Scheme 5). There was no sign of the formation of any (Ind)Ru complex, neither $[(Ind)Ru(\eta^2\text{-dppm})(\eta^1\text{-}S_2COR)]$ nor $[(Ind)Ru(\eta^1\text{-dppm})(\eta^2\text{-}S_2COR)]$, indicative of thermodynamic instability of such indenyl compounds in MeOH. A change of solvent to $CH_2Cl_2$ was attempted; however, unlike in the case with $^-S_2CNR_2$, there was no reaction at all, even after prolonged heating.

The $^1H$ NMR spectra of **9** and **10** showed the presence of $\eta^5$-Ind [$\delta(H^2)$ 5.16–5.17, $\delta(H^{1,3})$ 5.43–5.51]. Bidentate coordination of dppf is evident from its single $^{31}P$ resonance in both **9** ($\delta$ = 54.9 ppm) and **10** ($\delta$ = 54.8 ppm). Monodentate coordination of the xanthate ligand was supported by X-ray diffraction analysis.

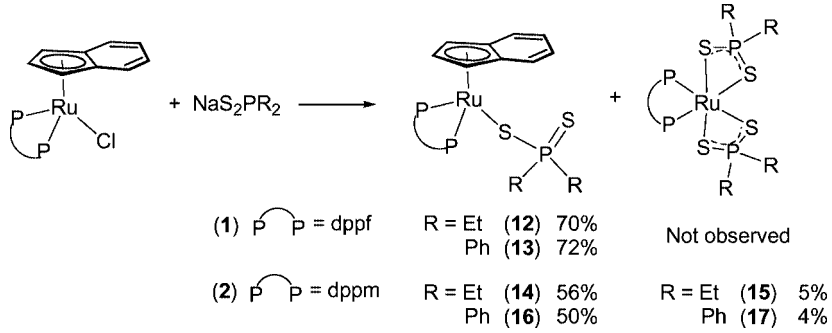


Scheme 4.[3a]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 5.



Scheme 6.

Complex **11** was formulated, based on its spectroscopic data. Its $^1$H NMR spectrum showed the absence of a $\eta^5$-Ind ligand and its $^{31}$P NMR spectrum showed a singlet at $\delta = 4.1$, assignable to chelating dppm. The FAB$^+$-mass spectrum showed the molecular ion peak at *m*/*z* 756, consistent with the presence of the non-indenyl six-coordinate complex.

### *Reaction with Dialkyl/Aryl Dithiophosphinates*

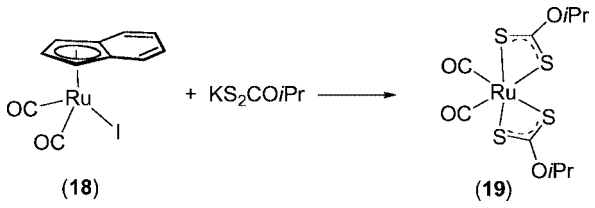
The reactions of **1** with $NaS_2PR_2$ gave high yields of [(Ind)Ru(dppf)($\eta^1$-$S_2PR_2$)] [R = Et (**12**), R = Ph (**13**)] (Scheme 6). The similar reaction of the dppm complex **2** gave the dppm analogues of **12** and **13**, viz. [(Ind)Ru(dppm)($\eta^1$-$S_2PR_2$)] [R = Et (**14**), 56%; and R = Ph (**16**), 50%], the lower yields probably arising from degradation to the non-indenyl compounds, [Ru(dppm)($\eta^2$-$S_2PR_2$)$_2$] [R = Et (**15**) and R = Ph (**17**)], which were isolated in 4–5% yields.

The $^1$H NMR spectra of **12**–**14** and **16** showed $\eta^5$-Ind bonding to the Ru center, $\delta$(H$^2$) 4.84–5.15 and $\delta$(H$^{1,3}$) 5.34–6.12. In their $^{31}$P NMR spectra, the chelating diphosphanes are seen as doublets (in the range $\delta = 53.1$–$54.8$ for $\eta^2$-dppf in **12** and **13**, and at $\delta = 12.5$–$12.6$ for $\eta^2$-dppm in **14** and **16**), while the monodentate dithiophosphinate ligand is seen as a triplet in the range $\delta = 84.9$–$87.9$ for $S_2PEt_2$ and $\delta = 70.9$–$71.1$ for $S_2PPh_2$.

The multiplet nature of these resonances is indicative of coupling between the two ligands in each of these complexes. However, for some unclear reason, such coupling is not evident in the $^{31}$P NMR spectra of the non-indenyl complexes **15** and **17**, both of which show a singlet for the dithiophosphinate ligand at $\delta = 88.0$–$105.6$, as well as for dppm at $\delta = 4.0$–$5.1$.

### Reactions of [(Ind)Ru(CO)$_2$I] (18) with $NaS_2CNEt_2$ and $KS_2CO$*i*Pr with or without Mediation by Trimethylamine *N*-Oxide

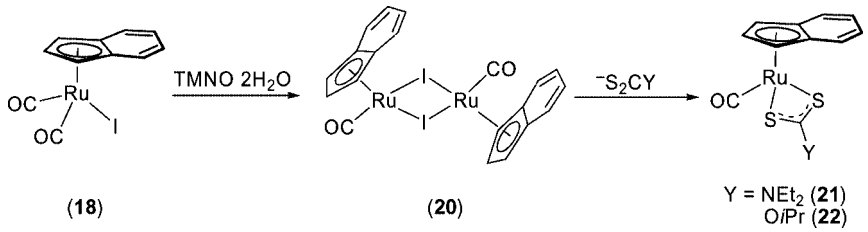
The reaction of **18** with $^-S_2CO$*i*Pr in MeOH gave, within 30 min, free indene and the six-coordinate Ru complex, [Ru($\eta^2$-$S_2CO$*i*Pr)$_2$(CO)$_2$] (**19**) (Scheme 7). It is apparent that the strong propensity of $^-S_2CO$*i*Pr towards chelation facilitated the dissociation of the weaker indenyl ligand rather than the CO ligands. Liberation of free indene was likewise observed in the reactions of **18** with thiolates, for example, $^-$SMe or $^-S_2CNC_6H_4$.[13]



Scheme 7.

An attempt was made to hamper the dissociation of the indenyl ligand by generating a vacant site for coordination of the incoming bidentate thiolate. This was done by prior removal of CO ligands in **18** with trimethylamine *N*-oxide dihydrate, TMNO·2H$_2$O. It was found that decarbonylation of **18** resulted in a dark brown solution, from which a red

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 8.

solid of $[(Ind)Ru(CO)(\mu\text{-}I)]_2$ (**20**) (70%) was obtained, undoubtedly from facile dimerization of the coordinatively unsaturated [(Ind)Ru(CO)I] species.

Complex **20** was characterized, based on its $^1H$ NMR spectrum, which showed $\eta^5$-Ind resonances at $\delta$ = 4.26 ($H^{1,3}$), 4.37 ($H^2$), and 6.54–7.59 ($H^{5-8}$), its $ESI^+$-mass spectrum, which gave the molecular ion peak at *m*/*z* 742.5 and an isotopic fragmentation pattern indicative of a $Ru_2$ moiety, and its IR spectrum, which showed a terminal CO stretch at 1925 $cm^{-1}$, in addition to an X-ray diffraction analysis.

The dark brown solution of **20** in $CH_3CN$ reacted slowly with $^-S_2CNEt_2$ or $^-S_2CO$*i*Pr giving dirty green and dirty yellow solutions, respectively, from which (Ind)Ru(CO){$\eta^2$-(S–S)} [S–S = $S_2CNEt_2$ (**21**, 55%), $S_2CO$*i*Pr (**22**, 81%)] was isolated (Scheme 8).

The infrared spectra of **21** and **22** in THF showed a new CO stretching frequency at 2031 and 2041 $cm^{-1}$, respectively. The presence of the $\eta^5$-Ind ligand was again indicated by the $^1H$ NMR signals at $\delta$ = 4.77–4.85 ($H^2$), 5.07–5.16 ($H^{1,3}$), and 6.83–7.16 ($H^{5-8}$). The molecular ions were observed at *m*/*z* 393 and 380, respectively. The structure of **21** has been determined by single-crystal X-ray diffraction analysis.

## Crystallographic Studies

The molecular structure of **4a** is illustrated in the ORTEP diagram (Figure 1, with selected bond parameters), which shows Ru coordinated to $\eta^5$-Ind, $\eta^2$-$S_2CNEt_2$, and $\eta^1$-dppf ligands. The Cp rings of dppf are almost eclipsed (anticlinal) to each other, with a torsional angle ($\tau$) of 136.58°. The slip-fold parameters of the indenyl ligand (see Table 1) suggest undistorted $\eta^5$-coordination,[14] with the benzenoid ring "flipped" towards the Ru center, probably a consequence of the relief in steric congestion around the metal center, which undoubtedly is the underlying cause for the dppf ligand to adopt a rare $\eta^1$-coordination mode, the first such case (as far as we are aware) in a structurally characterized mononuclear complex. Likewise steric demands have caused the pendant $PPh_2$ group to point away from the [(Ind)Ru($S_2CNEt_2$)] fragment. The extensive electron delocalization in the $S_2CNEt_2$ ligand can be observed in the bond lengths of S1–C10, S2–C10, and C10–N1, the values of which lie between those of a single and a double bond (C–S 1.81 Å; C=S 1.61 Å; C–N 1.47 Å; C=N 1.27 Å).[15]

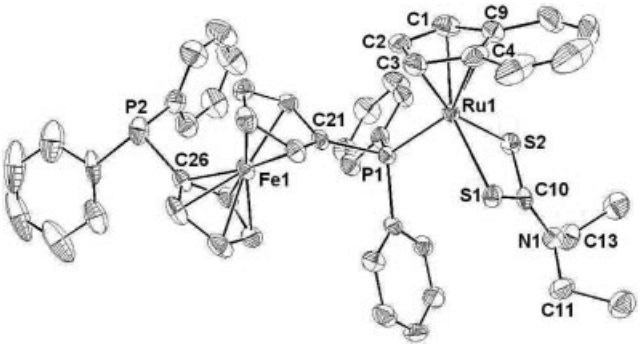


Figure 1. ORTEP diagram of **4a**. Thermal ellipsoids are drawn to 50% probability level. Hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–C* 1.873, Ru1–C1 2.180(5), Ru1–C2 2.159(5), Ru1–C3 2.185(5), Ru1–C4 2.309(5), Ru1–C9 2.302(5), Ru1–P1 2.2392(13), Ru1–S1 2.4068(13), Ru1–S2 2.3826(14), S1–C10 1.699(5), S2–C10 1.718(5), C10–N1 1.337(6), P1–C21 1.825(5), P2–C26 1.810(6), S1–Ru1–S2 71.85(4), S1–Ru1–P1 93.73(5), S2–Ru1–P1 88.04(5), S1–C10–S2 110.7(3), S1–C10–N1 126.3(4), S2–C10–N1 122.9(4), C10–N1–C11 121.1(4), C10–N1–C13 119.7(4), Ru1–P1–C21 111.90(16).

Table 1. Comparison of slip-fold parameters[a] of the ($\eta^5$-Ind)Ru complexes.

| Complex | Δ [Å] | HA [°] | FA [°] |
|---|---|---|---|
| [(Ind)Ru($DTC_{Et}$)($\eta^1$-dppf)] **4a** | 0.123 | 4.68 | 3.53 |
| [(Ind)Ru(dppf)($\eta^1$-$S_2COEt$)] **9** | 0.152 | 6.23 | 9.21 |
| [(Ind)Ru(dppf)($\eta^1$-$S_2PEt_2$)] **12** | 0.203 | 7.52 | 12.91 |
| [(Ind)Ru(dppm)($\eta^1$-$S_2PPh_2$)] **16** | 0.128 | 6.38 | 4.96 |
| $[(Ind)Ru(CO)I]_2$ **20** | 0.162, 0.185 | 6.32, 5.87 | 3.96, 4.18 |
| [(Ind)Ru(CO)($DTC_{Et}$)] **21** | 0.165 | 6.81 | 4.83 |
| [(Ind)Ru(CO)I{$P(CH_2Ph)_3$}] **F**[17] | 0.10 | 3.32 | 5.59 |
| $[(Ind)RuH(PPh_3)_2]$ **G**[5a] | 0.154 | 5.1 | 8.4 |

[a] Δ is the difference in the average bond lengths of the metal to the ring junction carbons, i.e., C4, C9, and of the metal to adjacent carbon atoms of the five-membered ring, i.e., C1, C3. HA is the angle between the planes defined by [C1,C2,C3] and [C1,C3,C4,C9]. FA is the angle between the planes defined by [C1,C2,C3] and [C4,C5,C6,C7,C8,C9][14] (see Figure 9 for atom numbering).

The asymmetric unit of complex **9** contains one ruthenium complex and two dichloromethane solvent molecules. The Ru center is coordinated to $\eta^5$-Ind, $\eta^2$-dppf, and a monodentate xanthate ligand. The Ru centers in **12** and **16** are similarly coordinated with a monodentate dithiophosphinate ligand. The ORTEP diagrams of complexes **9**, **12**, and **16** are shown in Figures 2, 3, and 4.

The $\eta^5$-indenyl ligands in **9** and **16** do not show noticeable distortion, while that of **12** is slightly distorted[14] (see Table 1). The fold angle of complex **16** indicates that the benzenoid ring of the indenyl ligand bends towards the ruthenium center rather than away as observed in **9** and **12**. This presumably is due to the coordination of a less sterically demanding dppm compared to dppf. Another interesting feature in the structures of complexes **9**, **12**, and **16** is the orientation of the monodentate dithiolate ligand. The noncoordinating S atom of the xanthate ligand in **9** is oriented away from the indenyl ligand, whereas those of the dithiophosphinate ligands in **12** and **16** are pointing towards the indenyl ligands, as shown in their stereo views. This probably arises from steric repulsion between the two

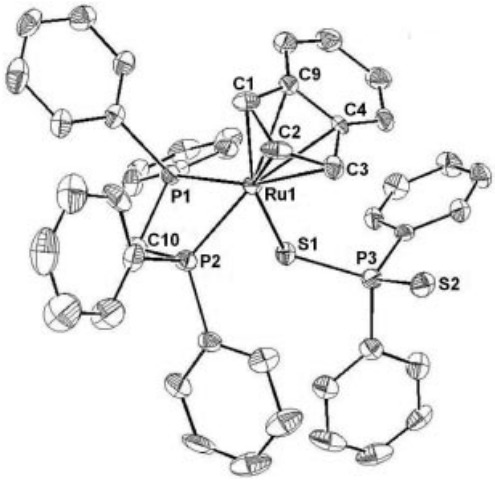

Figure 4. ORTEP diagram of **16**. Thermal ellipsoids are drawn to 50% probability level. Hydrogen atoms are omitted for clarity. R groups in dithiophosphinate ligands and the indenyl ligands.

The six-coordinate complexes **7**, **11**, and **17** have also been characterized by X-ray diffraction analysis. Their molecular structures were found to be similar to those of known analogues, such as $[Ru(dppf)(S_2CNEt_2)_2]$[8] and $[Ru(L)(L')(S_2Z)_2]$ (L = CO, L = $PEt_3$, Z = $CNMe_2$, COEt, L = L′ = $PMe_2Ph$, Z = $PEt_2$)[16] (see electronic supporting information).

The molecular structure of the di-iodo-bridged complex **20** is shown in the ORTEP diagram (Figure 5). The structure exhibits crystallographic mirror symmetry, with the

mirror plane passing through the two Ru centers, the two CO ligands and the center of the two $\eta^5$-Ind ligands through C12 and C22. As in $[(Ind)Ru(CO)_2]_2$, the structure possesses two *trans* CO ligands and two *trans* [(Ind)-Ru(CO)] fragments, but unlike it, there is no interaction between Ru1 and Ru2 (4.014 Å).

The ORTEP diagram for the molecular structure of **21** is depicted in Figure 6, together with selected bond parameters. The structure shows a three-legged piano-stool configuration at $Ru^{II}$, being coordinated to $\eta^5$-Ind, $\eta^2$-$S_2CNEt_2$, and one CO ligand. The slip-fold parameters for **21** are in agreement with $\eta^5$-coordination of Ind.[14] As in the structure of **4a**, the metric data show that there is extensive electron delocalization in the $S_2CNEt_2$ ligand.

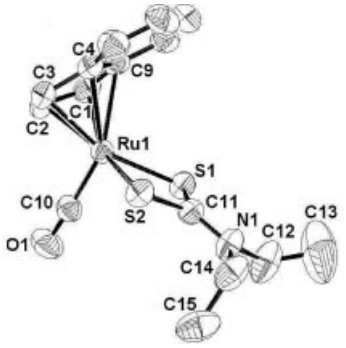

Figure 6. ORTEP drawing of $(Ind)Ru(CO)(S_2CNEt_2)$ **21** with 50% probability thermal ellipsoids. H atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Ru1–C* 1.910, Ru1–C1 2.210(4), Ru1–C2 2.174(4), Ru1–C3 2.191(4), Ru1–C4 2.358(4), Ru1–C9 2.372(4), Ru1–S1 2.4035(10), Ru1–S2 2.3930(10), S1–C11 1.712(4), S2–C11 1.724(4), C11–N1 1.320(5), Ru1–C10 1.807(4), S1–Ru1–S2 72.22(3), S1–C11–S2 110.7(2).

An examination of slip-fold parameters of the indenyl complexes in this study and two other reported examples (Table 1) shows that complexes **4a**, **16**, **20**, and **21** possess FA values smaller than their HA values. This observation is unusual for $\eta^5$-indenyl complexes. The probable cause is the lack of a bulky ligand directly below the benzenoid ring of the Ind ligand in these complexes, unlike the structural feature found in **9**, **12**, **F**, and **G**. In these four latter phosphane complexes, the steric repulsion between the indenyl and bulky phosphane ligands forces the benzenoid ring to "flip" away from the Ru center, hence resulting in greater FA values.

### Lability of the Indenyl Ligand

The foregoing results indicate that the lability of the indenyl ligand is influenced by the incoming 1,1-dithiolate and the coligands, according to the following trends: (i) dithiolates: $^-S_2CNR_2 > {}^-S_2COR > {}^-S_2PR_2$, (ii) coligands: CO ≈ dppm > dppf. Trend (i) can be readily rationalized, based on e-density considerations of the S donor atoms. The observation of monodenticity of the $S_2PR_2$ moiety in the high-yield indenyl complexes, **12**–**14** and **16**, is significant. In this dithiolate series, the S atoms in $^-S_2PR_2$ possess the most *localized* and hence highest electron density, whereas those in $^-S_2CNR_2$ possess the *lowest* electron density because of extensive electron delocalization. Hence the increased tendency of the latter towards chelation. In the absence of a vacant site or an easily displaceable ligand, chelation of a ligand will inevitably enforce dissociation of the indenyl ligand. For rationalizing trend (ii), we note that the benzenoid ring of the indenyl ligand can be considered as an electron-withdrawing group,[18] hence an electron-rich Ru center is required for strong interaction with $\eta^5$-Ind through its fused $C_5H_3$ ring, a situation provided by strong donor coligands like dppf, while labilization of the indenyl ligand will be assisted by the presence of a strong π-acceptor coligand, like CO.

The application of density functional theory has provided an understanding of the effect of different ligands on the energetics of $\eta^5 \rightarrow \eta^3$ ring slippage of the indenyl ligand and hence on its dissociation tendency. In a recent study, Veiros et al. demonstrated that the effect of the nature of the coligands on the strength of the indenyl–metal bond plays an important role in the energetics of $\eta^5$ versus $\eta^3$ indenyl–molybdenum complexes.[19] Because of the constraints on computational time, we have selected the complexes $[(Ind)Ru(L)_2(S_2COMe)]$ (**H1**: L = $PMeH_2$, **H2**: L = $PH_3$, **H3**: L = CO), containing small phosphane ligands such as $PH_3$ and $PH_2Me$, rather than the larger diphos ligands (dppm or dppf), as the model compounds for study. In this series, complex **H1** contains the strongest σ-donor ligand, followed by **H2**, with **H3** possessing the strongest π-acceptor ligand. The dissociation of the indenyl ligand by $\eta^5 \rightarrow \eta^3 \rightarrow \eta^1$ has been considered and the results are presented in Figure 7.

It was found that $\eta^5 \rightarrow \eta^3$ indenyl ring slippage in complexes **H1** and **H2** possesses comparable activation energy (67 and 70 kJ/mol, respectively), with the process in **H1** being slightly more endothermic (7.4 kJ/mol). However, a remarkable difference was observed in the case of the strong π-acceptor CO in complex **H3**. Not only is the activation energy of the slippage almost half that for both **H1** and **H2** (33 kJ/mol), but the $\eta^3$-Ind coordination mode is more favorable, with the $\eta^5 \rightarrow \eta^3$ ring slippage process being exothermic (–13 kJ/mol). This is consistent with the expectation that stronger σ-donor ligands enhance the interaction between electron-rich Ru and the $\eta^5$-Ind ligand and vice versa. Therefore, as the dithiolate ligand tends to chelate to the electron-deficient Ru, the weak interaction of the $\eta^5$-Ind ligand and the Ru center would have facilitated the ease of $\eta^5 \rightarrow \eta^3$ slippage, and the combined effect would be the dissociation of the indenyl ligand.

A comparison between the effect of xanthate and dithiocarbamate ligands on indenyl ring slippage has also been made using the $PH_3$-containing complex **H4** as the model compound. As shown in Figure 1, the formation of the $\eta^3$-Ind isomer of the dithiocarbamate complex **H4** is a much more exothermic process. Unfortunately the transition state for this process could not be located, though it is not uncommon for activation energies of highly exothermic processes to be much lower or even close to zero, thus causing the transition state to assume a structure similar to that of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

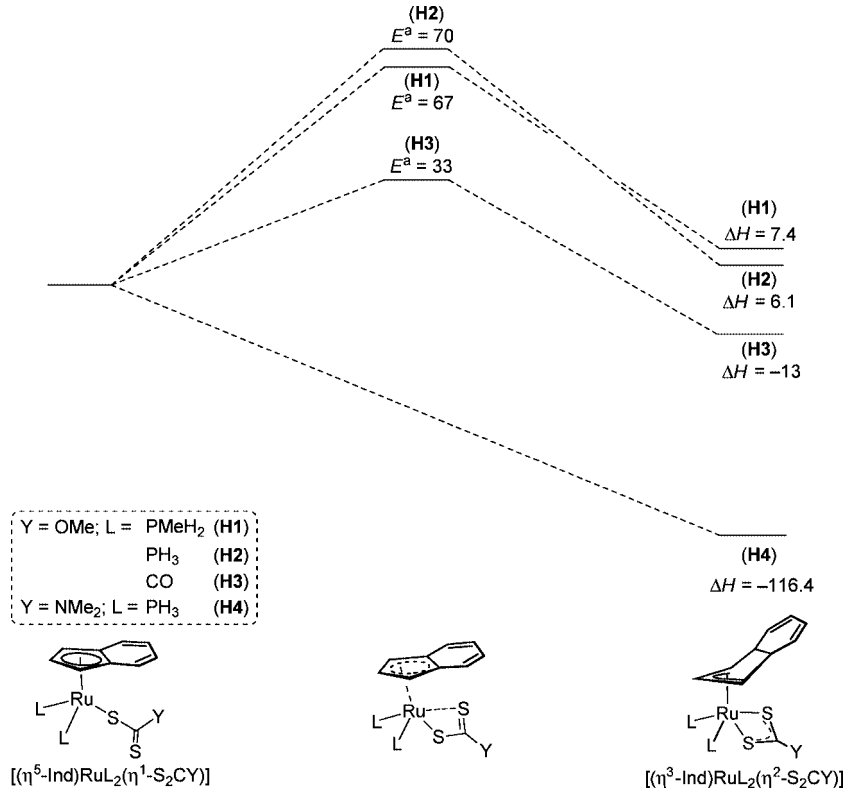

Figure 7. Energy diagram of ring slippage from $\eta^5 \rightarrow \eta^3$ ($E^a$ is activation energy in kJ/mol).

the reactant. This may have caused difficulty in optimizing the transition-state structure using computational methods. Nevertheless the calculations indicated that $^-S_2CNR_2$ exerts a stronger effect than xanthate in causing indenyl ring slippage, in good agreement with the trend observed in the experimental data.

## Electrochemical Studies

Cyclic voltammograms performed at a GC electrode in 0.5 mM solutions of **10** and **13** in $CH_2Cl_2$ at 233 K are shown in Figure 8. Complex **10** displayed one chemically irreversible oxidation process at about 0 V versus $Fc/Fc^+$. The expression "chemical reversibility" when used in connection with cyclic voltammetry experiments relates to the ratio of the oxidative ($i_p^{ox}$) to reductive peak currents ($i_p^{red}$). The $i_p^{ox}/i_p^{red}$ ratio approaches unity for a fully chemically reversible process. Complex **13** showed three oxidation processes, although the two most positive processes displayed small reverse peaks when the scan direction was reversed, suggesting instability of the highly oxidized states. Increasing the scan rate up to 5 V/s did not improve the chemical reversibility of the processes shown in Figure 8. Table 2 lists the reversible oxidation potentials ($E^r_{1/2}$) that were calculated from CV data under conditions where the $i_p^{ox}/i_p^{red}$ ratio was equal to unity and using the relationship [Equation (1)]

$$E^r_{1/2} = (E_p^{ox} + E_p^{red})/2 \quad (1)$$

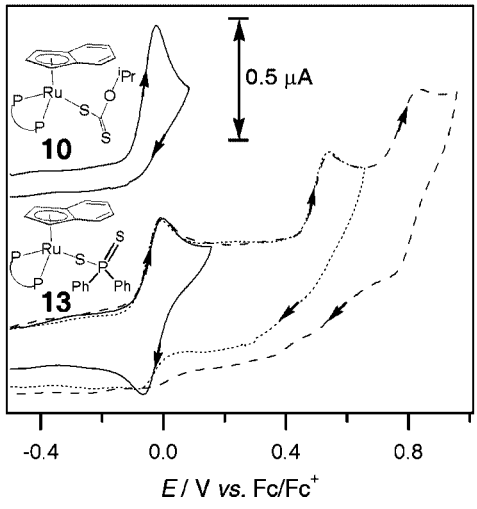

Figure 8. Cyclic voltammograms performed at a 1-mm diameter planar GC electrode in $CH_2Cl_2$ (0.25 M $Bu_4NPF_6$) at 233 K at a scan rate of 100 mV/s for 0.5 mM **10** and **13**.

where $E_p^{ox}$ and $E_p^{red}$ are the anodic and cathodic peak potentials respectively. In situations where small reverse peaks were observed, only the forward (oxidative) peak potentials are given.

The peak current intensities were similar to those obtained under identical conditions for the one-electron oxidation of **1**, [(Ind)Ru(dppf)(SMe)], [(Ind)Ru(dppf)(SPh)],[7]

Table 2. Cyclic voltammetric data obtained at a scan rate of 100 mV/s at a 1-mm diameter glassy carbon electrode at 233 K in $CH_2Cl_2$ with 0.25 M $Bu_4NPF_6$ as the supporting electrolyte.

| Compound | Oxidation process[a] | | | |
|---|---|---|---|---|
| | $E_p^{ox}$ [V][b] | $E_p^{red}$ [V][c] | $E^r_{1/2}$ [V][d] | $\Delta E$ [mV][e] |
| **10** | –0.023 | | | |
| **13** | –0.004 | –0.068 | –0.04 | 64 |
| | +0.540 | | | |
| | +0.830 | | | |

[a] All potentials in Table 2 are relative to the ferrocene/ferrocenium redox couple. [b] $E_p^{ox}$ is the oxidative peak potential. [c] $E_p^{red}$ is the reductive peak potential. [d] $E^r_{1/2} = (E_p^{red} + E_p^{ox})/2$. [e] $\Delta E = |E_p^{ox} - E_p^{red}|$.

**I**, and [Cp*Ru(dppf)Cl] (**VI**), indicating that **10** and **13** were also oxidized by one electron. However, **1**, [(Ind)Ru(dppf)(SMe)], [(Ind)Ru(dppf)(SPh)], **I**, and **VI** showed two or three one-electron chemically reversible oxidation processes, whilst cyclic voltammograms performed on solutions of **10** and **13** indicated that their oxidized states were relatively unstable even at low temperatures (Figure 8).[7]

Based on previous studies, it is thought that the initial oxidation process in Figure 8 for **10** and **13** is associated with $Ru^{II}$ being oxidized to $Ru^{III}$ (rather than oxidation in the region of dppf), as this process is very sensitive to the substituent (S or Ind) coordinated to the Ru. It is thought that the second process in the CV of **13** is associated with oxidation in the region of dppf, as the potential is close to that observed in other dppf-containing complexes,[7] while the third oxidation process is associated with further oxidation of the Ru ion. This would explain why the third oxidation process shows more chemical reversibility than the second process, if the individual regions (Ru and Fe) are not electronically communicating, then it is possible that the individual oxidation processes are semi-independent of one another (i.e., the first and third are associated with oxidation of the Ru ion, whilst the second process involves oxidation in the vicinity of dppf).

Both compounds displayed one chemically irreversible reduction process at very negative potentials (about –2.5 V vs. $Fc/Fc^+$), with a similar current magnitude to the first oxidation process (indicating that the same number of electrons were transferred). It is not possible to conclude whether the chemical instability of the reduced compounds is because of increased chemical reactivity due to the very high reduction potentials, or due to an $\eta^5 \rightarrow \eta^3$ ring slippage mechanism following reduction.

## Conclusions

The lability of the Ind ligand in halide substitution of [(Ind)Ru($L_2$)Cl] [$L_2$ = dppf, dppm or $(CO)_2$] with 1,1′-dithiolates is dependent on several variables: (i) the nature of the coligand $L_2$, which follows a lability order: dppf < dppm ≈ CO, in agreement with the electron donor capability of $L_2$ and calculated energetics for $\eta^5 \rightarrow \eta^3$ ring slippage in related (Ind)Ru complexes, (ii) the incoming dithiolates, which results in ease of indenyl ligand dissociation at (Ind)Ru(dppf) as follows: dithiocarbamates > xanthates > dithiophosphinates, in agreement with DFT calculations, and (iii) the solvent medium, as illustrated in complete dissociation of Ind from (Ind)Ru(dppf) in dithiocarbamate substitution in the highly polar solvent MeOH relative to partial dissociation in $CH_2Cl_2$. In the case of the (Ind)-$Ru(CO)_2$ substrate, dissociation of Ind could be averted by chemically assisted decarbonylation of the complex before reaction with 1,1-dithiolate ligands. The hydride species [(Ind)Ru(diphos)H], formed in solvent- and stoichiometry-dependent yields in the (diphos) systems, presumably arose from the presence of $OMe^-$ in MeOH, as previously observed.[7] Cyclic voltammetry experiments indicate that the (Ind)Ru(dppf) derivatives containing $\eta^1$-$S_2CO$*i*Pr and $\eta^1$-$S_2PPh_2$ can be oxidized in one-electron chemical irreversible and reversible processes, respectively, at a scan rate of 100 mV/s at about 0 V versus $Fc/Fc^+$.

## Experimental Section

**General:** All reactions were carried out using conventional Schlenk techniques under inert nitrogen or under argon in an M. Braun Labmaster 130 Inert Gas System. NMR spectra were measured on a Bruker 300 FT NMR spectrometer, $^1H$ chemical shifts were referenced to residual solvent in the deuterio-solvents, $C_6D_6$ or $CD_3CN$, and $^{31}P$ chemical shifts were referenced to external $H_3PO_4$. IR spectra in KBr pellets were measured in the range 4000–400 $cm^{-1}$ by means of a BioRad FTS-165 FTIR instrument. Mass spectra were run on a Finnigan Mat 95XL-T (FAB) or a Finnigan-MAT LCQ (ESI) spectrometer. Voltammetric experiments were conducted with a computer-controlled Eco Chemie μAutolab III potentiostat. The electrochemical cell was jacketed in a glass sleeve and cooled to 233 K using a Lauda RL6 variable-temperature methanol-circulating bath. Elemental analyses were performed by the microanalytical laboratory in-house. [(Ind)Ru(dppf)Cl] (**1**),[20] [(Ind)Ru(dppm)Cl] (**2**),[21] and [(Ind)Ru$(CO)_2$I] (**18**)[22] were prepared by published methods. All other chemicals were obtained commercially and used without any further purification. All solvents were dried with sodium/benzophenone and distilled before use. Celite (Fluka AG) and silica gel (Merck Kieselgel 60, 230–400 Mesh) were dried at 140 °C overnight before chromatographic use.

Conventional numbering of indenyl protons shown in Figure 9 is followed in the assignment of NMR signals.

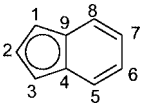

Figure 9. Atom labeling of the indenyl ligand.

### (I) Reactions of (Ind)Ru(diphosphane) Complexes

### (a) Reactions with Dialkyl Dithiocarbamates

(i) Reactions of [(Ind)Ru(dppf)Cl] (**1**) with $NaS_2CNR_2$ were carried out at stoichiometries of 1:1 and 1:4. A typical reaction for each stoichiometry is described for R = Et, as follows:

**1:$S_2CNR_2$ (1:1):** $NaS_2CNEt_2 \cdot 3H_2O$ (10 mg, 0.04 mmol) was added to a suspension of **1** (35 mg, 0.04 mmol) in MeOH (5 mL) and the mixture was stirred at room temp. for 18 h. The color of the suspen-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sion slowly changed from red to yellow. The suspension was filtered and the residue was extracted using toluene (2 × 5 mL). The filtrate was examined by GC/MS, which showed indene. The extract was concentrated to about 2 mL and loaded onto a silica gel column (2 × 5 cm) prepared in n-hexane. Elution gave two fractions: (i) a yellow eluate in toluene (8 mL), which yielded [(Ind)Ru(dppf)H] (**6**) (13 mg, 39% yield) (for the reaction in which R = Me, 11 mg, 32% yield, R = $C_5H_{10}$, 8 mg, 25% yield), (ii) a yellow eluate in toluene/THF (1:1, 10 mL), which yielded [Ru($\eta^2$-dppf)($\eta^2$-$S_2CNEt_2$)$_2$] **4** (25 mg, 60% yield). Similar reactions gave **3** (R = Me), 22 mg, 56% yield, and **5** (R = $C_5H_{10}$), 25 mg, 58% yield. Analytical pure samples of complexes **3**–**5** were obtained by recrystallization from THF/hexane (1:5).

**1:$S_2CNR_2$ (1:4). Reaction in MeOH:** $NaS_2CNEt_2 \cdot 3H_2O$ (40 mg, 0.16 mmol) was added to a suspension of **1** (35 mg, 0.04 mmol) in MeOH (5 mL) and the mixture was stirred at room temp. for 18 h. The color of the suspension slowly changed from red to yellow. The solvent was removed in vacuo and the residue was extracted with toluene (2 × 5 mL). The extract was concentrated to about 2 mL, addition of hexane (2 mL) at –30 °C for 1 d gave yellow crystals of **4** (37 mg, 90% yield). Similar reactions gave **3** (R = Me), 36 mg, 92% yield, and **5** (R = $C_5H_{10}$), 41 mg, 98% yield.

**Reaction in $CH_2Cl_2$:** $NaS_2CNEt_2 \cdot 3H_2O$ (60 mg, 0.24 mmol) was added to a solution of **1** (50 mg, 0.06 mmol) in $CH_2Cl_2$ (10 mL) and the mixture was refluxed for 4 h. The solution was evacuated to dryness and the residue extracted with diethyl ether (2 × 3 mL). The extract was concentrated to about 3 mL and kept at –30 °C, after 2 d, yellow microcrystals of **4** (16 mg, 28% yield) were collected. Addition of hexane (about 0.5 mL) to the mother liquor led to the isolation of red microcrystals of [(Ind)Ru($\eta^1$-dppf)($\eta^2$-$S_2CNEt_2$)] (**4a**) (20 mg, 36% yield) after two more days at –30 °C.

A small-scale reaction was carried out at stoichiometry 1:2, using **1** (5 mg, 6.2 μmol) and $NaS_2CNEt_2 \cdot 3H_2O$ (3 mg, 12 μmol) in MeOH (2 mL) and the red suspension was stirred at room temp. for 18 h. The resultant yellow suspension was filtered to give yellow solids, **4** (5 mg, 85% yield), and pale yellow filtrate. The $^1$H and $^{31}$P NMR spectra of the yellow solids (in $C_6D_6$) showed **4** as the sole product. A new batch of **1** (5 mg, 6.2 μmol) was added to the filtrate and the red suspension was stirred for another 18 h. The resultant yellow suspension was filtered and the yellow solids, **6** (4 mg, 84% yield) were obtained. The $^1$H and $^{31}$P NMR spectra of the yellow solids in $C_6D_6$ indicate the sole presence of **6**.

**Data for 3:** $^1$H NMR ($C_6D_6$): $\delta$ = 2.41 and 2.43 [each s, 3 H, $S_2CN(CH_3)_2$], 3.94, 4.04, 4.62 and 4.69 (each s, 2 H, $C_5H_4$), 7.03–7.11, 7.21–7.25, 7.95 and 8.20–8.25 (m, 20 H, Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 47.9 (s, dppf) ppm. IR (KBr): $\tilde{\nu}$ = 3053 (w), 2922 (w), 2855 (w), 1509 [m, SC(S)], 1432 [m, SC(S)], 1386 [s, SC(S)], 1262 [m, SC(S)], 1146 (m), 1086 (m), 1028 (m), 811 (w), 746 (w), 697 (m), 548 (w), 521 (w) cm$^{-1}$. **Data for 4a:** $^1$H NMR ($C_6D_6$): $\delta$ = 0.61 [t, $^3J_{HH}$ = 7.4 Hz, 6 H, $S_2CN(CH_2CH_3)_2$], 2.81 and 3.04 [each m, $^3J_{HH}$ = 7.4 Hz, 2 H, $S_2CN(CH_2CH_3)_2$], 4.11 and 4.33 (each s, 2 H, $C_5H_4$), 4.19 (s, 4 H, $C_5H_4$), 4.56 (t, $^3J_{HH}$ = 2.5 Hz, 1 H, H$^2$), 4.89 (d, $^3J_{HH}$ = 2.5 Hz, 2 H, H$^{1,3}$), 7.04–7.16, 7.37–7.40, 7.42–7.48 and 7.75–7.81 (each m, total 24 H, H$^{5-8}$ and Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 57.3 and –17.7 (each s, dppf) ppm. IR (KBr): $\tilde{\nu}$ = 3050 (w), 2972 (w), 2929 (w), 1484 [s, SC(S)], 1431 [vs, SC(S)], 1380 (w), 1324 (w), 1270 [m, SC(S)], 1215 (w), 1159 (m), 1092 (m), 1030 (m), 830 (w), 743 (m), 696 (vs), 543 (m), 517 (m) cm$^{-1}$. FAB$^+$-MS: *m*/*z* (%) = 804 [M – Ind]$^+$. $C_{48}H_{45}FeNP_2RuS_2$ (918.87): calcd. C 62.7, H 4.9, N 1.5, S 7.0, found C 62.6, H 5.2, N 1.3, S 6.9.

**Data for 5:** $^1$H NMR ($C_6D_6$): $\delta$ = 0.95 (br. s, 12 H, $S_2CNC_5H_{10}$), 3.02, 3.63 (each br. s, 4 H, $S_2CNC_5H_{10}$), 3.95, 4.05, 4.62 and 4.71 (each s, 2 H, $C_5H_4$), 7.00–7.23, 7.69–7.72, 8.03–8.05 and 8.19–8.24 (each m, total 20 H, Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 47.6 (s, dppf) ppm. IR (KBr): $\tilde{\nu}$ = 3048 (w), 2931 (m), 2853 (m), 1479 [s, SC(S)], 1433 [s, SC(S)], 1233 [s, SC(S)], 1129 (m), 1086 (m), 995 (m), 885 (w), 850 (w), 811 (w), 743 (m), 695 (s), 546 (m), 518 (m) cm$^{-1}$. FAB$^+$-MS: *m*/*z* (%) = 976 [M]$^+$, 816 [M – $S_2CNC_5H_{10}$]$^+$. $C_{46}H_{48}FeN_2P_2RuS_4$ (976.01): calcd. C 56.6, H 5.0, N 2.9, S 13.1, found C 56.5, H 5.0, N 2.7, S 12.9.

(ii) Reactions of [(Ind)Ru(dppm)Cl] **2** with $NaS_2CNEt_2$ were carried out at stoichiometries of 1:1 and 1:4.

**2:$S_2CNR_2$ (1:1):** $NaS_2CNEt_2 \cdot 3H_2O$ (10 mg, 0.04 mmol) was treated with **2** (20 mg, 0.04 mmol) in MeOH (5 mL). A similar workup as described above for the dppf analogue yielded [Ru(dppm)($\eta^2$-$S_2CNEt_2$)$_2$] (**7**) (18 mg, 58% yield) and [(Ind)Ru(dppm)H] (**8**) (5 mg, 20% yield), identified by its published proton NMR spectroscopic data, notably $\delta$(H) –14.21 (s) in $C_6D_6$ versus the lit. value of –14.12 (s) in $CD_2Cl_2$.[10]

**Using 2:$S_2CNR_2$ (1:4):** A similar reaction as described above for **1** was carried out, using $NaS_2CNEt_2 \cdot 3H_2O$ (20 mg, 0.08 mmol) and [(Ind)Ru(dppm)Cl] (**2**) (10 mg, 0.02 mmol) in MeOH (5 mL) and the mixture was stirred for 4 h. Similar workup procedures gave yellow crystals of [Ru(dppm)($\eta^2$-$S_2CNEt_2$)$_2$] (**7**) (10 mg, 81% yield).

**Data for 7:** $^1$H NMR ($C_6D_6$): $\delta$ = 0.63–0.68 and 0.86–0.91 (each t-like m, 6 H, $CH_3$), 2.85–3.02 (m, 2 H, $CH_2CH_3$), 3.15–3.28 (m, 2 H, $CH_2CH_3$), 3.43–3.62 (m, 4 H, $CH_2CH_3$), 4.73 (t, $^2J_{HP}$ = 9.9 Hz, 2 H, $CH_2$ of d), 6.98–7.16 (m, 14 H, Ph), 7.54–7.58 (m, 3 H, Ph), 7.93–7.95 (m, 3 H, Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 3.7 (s, dppm) ppm. IR (KBr): $\tilde{\nu}$ = 3050 (w), 2974 (w), 2929 (w), 2871 (w), 1483 [s, SC(S)], 1426 [s, SC(S)], 1303 (w), 1268 [s, SC(S)], 1214 (m), 1142 (m), 1091 (m), 997 (w), 911 (w), 848 (w), 698 (s), 535 (m) cm$^{-1}$. FAB$^+$-MS: *m*/*z* (%) 782 [M]$^+$, 634 [M – $S_2CNEt_2$]$^+$. $C_{35}H_{42}N_2P_2RuS_4$ (782.00): calcd. C 53.8, H 5.4, N 3.6, S 16.4, found C 53.8, H 5.5, N 3.7, S 16.2.

**(b) Reactions with Alkyl Xanthates**

(i) $KS_2COR$ (0.07 mmol, R = Et, 11 mg, R = *i*Pr, 12 mg) was added into a solution of **1** (15 mg, 0.02 mmol) in $CH_2Cl_2$ (10 mL) and the mixture was refluxed. The reaction was not accompanied by any color change, hence it was monitored by $^1$H and $^{31}$P NMR spectroscopy. After the reaction was complete (about 4 h), the solution was evacuated to dryness. The solid residue was extracted with toluene (2 × 2 mL) and the concentrated extract recrystallized from 1:2 THF/hexane at –30 °C. Red microcrystals of [(Ind)Ru(dppf)($\eta^1$-$S_2COR$)] [R = Et (**9**), 13 mg, 78% yield, R = *i*Pr (**10**), 14 mg, 83% yield] were obtained after one day.

**Data for 9:** $^1$H NMR ($C_6D_6$): $\delta$ = 1.06 (t, $^3J_{HH}$ = 7.4 Hz, 3 H, $S_2COCH_2CH_3$), 3.55, 3.81, 3.98 and 4.34 (each s, 2 H, $C_5H_4$), 4.41 (q, $^3J_{HH}$ = 7.4 Hz, 2 H, $S_2COCH_2CH_3$), 5.16 (s, 1 H, H$^2$), 5.43 (s, 2 H, H$^{1,3}$), 6.98–7.14, 7.26–7.30 and 7.43–7.48 (each m, total 24 H, H$^{5-8}$ and Ph) ppm. $^{31}$P{$^1$H} NMR ($C_6D_6$): $\delta$ = 54.9 (s, dppf) ppm. IR (KBr): $\tilde{\nu}$ = 3050 (w), 2978 (w), 1478 (w), 1432 (w), 1382 (w), 1165 [s, (CO)], 1105 [s, (CS)], 1030 [vs, (CS)], 858 w, 819 w, 792 w, 744 m, 697 s, 631 w, 513 m. FAB$^+$-MS: *m*/*z* (%) = 892 [M]$^+$, 777 [M – Ind]$^+$, 655 [M – Ind – $S_2COEt$]$^+$. $C_{46}H_{40}FeOP_2RuS_2$ (891.80): calcd. C 62.0, H 4.5, S 7.2, found C 61.6, H 4.8, S 7.5.

**Data for 10:** $^1$H NMR ($C_6D_6$): $\delta$ = 1.25 [d, $^3J_{HH}$ = 5.76 Hz, 6 H, $S_2COCH(CH_3)_2$], 3.55, 3.84, 3.98 and 4.46 (each s, 2 H, $C_5H_4$),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

5.17 (s, 1 H, $H^2$), 5.51 (s, 2 H, $H^{1,3}$), 5.67 [sept, $J$ = 6.6 Hz, 1 H, $S_2COCH(CH_3)_2$] 7.00–7.47 (m, 24 H, $H^{5-8}$ and Ph) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 54.8 (s, dppf) ppm. IR (KBr): $\tilde{\nu}$ = 3047 (w), 2963 (w), 2923 (w), 1940 (w), 1478 (w), 1433 (w), 1382 (w), 1261 [m, (CO)], 1187 (w), 1089 [s, SC(S)], 1015 [s, SC(S)], 803 (s), 743 (m), 695 (s), 631 (w), 507 (m) $cm^{-1}$. $FAB^+$-MS: $m/z$ (%) = 906 $[M]^+$, 791 $[M - Ind]^+$, 771 $[M - S_2CO{i}Pr]^+$, 655 $[M - Ind - S_2CO{i}Pr]^+$. $C_{47}H_{42}FeOP_2RuS_2$ (905.83): calcd. C 62.3, H 4.7, S 7.0, found C 61.9, H 4.8, S 6.6.

(ii) $KS_2CO{i}Pr$ (23 mg, 0.13 mmol) was added to a solution of **2** (20 mg, 0.03 mmol) in MeOH (5 mL) and the solution was stirred at room temp. for 18 h. The color of the solution changed slowly from red to yellow in the course of reaction. The yellow product solution was evacuated to dryness and the residue extracted with toluene (2 × 2 mL). Addition of hexane (about 4 mL) into the concentrated extract (about 2 mL) at –30 °C for 1 d gave [Ru(dppm)($\eta^2$-$S_2CO{i}Pr$)$_2$] (**11**) (27 mg, 93% yield) as yellow microcrystals.

**Data for 11:** $^1H$ NMR ($C_6D_6$): $\delta$ = 0.87–0.89 and 0.95–0.97 (each d-like m, 6 H, $CH_3$), 4.67 (t, $^2J_{HP}$ = 9.9 Hz, 2 H, $CH_2$ of d), 5.34 [sept, $^3J_{HH}$ = 6.6 Hz, 2 H, $CH(CH_3)_2$], 6.95–7.02 (m, 7 H, Ph), 7.08–7.16 (m, 5 H, Ph), 7.38–7.45 (m, 4 H, Ph), 7.81–7.89 (m, 4 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 4.1 (s, dppm) ppm. IR (KBr): $\tilde{\nu}$ = 3049 (w), 2976 (w), 2930 (w), 1481 (w), 1432 (m), 1371 (w), 1231 [vs, (CO)], 1093 [vs, SC(S)], 1033 [s, SC(S)], 905 m, 723 s, 696 s, 538 m, 509 s. $FAB^+$-MS: $m/z$ (%) = 756 $[M]^+$. $C_{33}H_{36}O_2P_2RuS_4$ (755.92): calcd. C 52.4, H 4.8, S 17.0, found C 52.4, H 4.8, S 17.0.

**(c) Reactions with Dithiophosphinates**

(i) $NaS_2PR_2$ (0.04 mmol, R = Et, 7 mg, R = Ph, 11 mg) was added to a suspension of **1** (10 mg, 0.01 mmol) in MeOH and the mixture was stirred at room temp. for 18 h. The resultant red solution was evacuated to dryness and the residue extracted with toluene (2 × 3 mL). The extract was concentrated to about 2 mL and loaded on a silica gel column (1.5 × 2.0 cm). Elution with 2:1 hexane/diethyl ether (3–5 mL) and subsequent workup gave red crystals of [(Ind)Ru(dppf)($\eta^1$-$S_2PR_2$)] (R = Et (**12**), 8 mg, 70% yield, R = Ph (**13**), 9 mg, 72% yield).

**Data for 12:** $^1H$ NMR ($C_6D_6$): $\delta$ = 1.18–1.30 [m, 6 H, $S_2P(CH_2CH_3)_2$], 1.90–2.12 [m, 4 H, $S_2P(CH_2CH_3)_2$], 3.70, 3.81, 4.20 and 5.15 (each s, 2 H, $C_5H_4$), 4.84 (s, 1 H, $H^2$), 5.70 (s, 2 H, $H^{1,3}$), 6.90–6.93 and 7.58–7.61 (each 4-line m, $^3J_{HH}$ = 3.3 Hz, 2 H, $H^{5-8}$), 7.11–7.68 (m, 20 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 54.8 (d, $^3J_{PP}$ = 16 Hz, dppf), 87.5 (t, $^3J_{PP}$ = 16 Hz, $S_2PEt_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3054 (w), 2966 (w), 2924 (w), 2868 (w), 1479 (w), 1433 (m), 1325 (w), 1157 (w), 1090 (m), 1030 (m), 821 (m), 746 [s, (PS)], 695 (PS), 594 [w, (PS)], 632 (m), 511 (s) $cm^{-1}$. $FAB^+$-MS: $m/z$ (%) = 924 $[M]^+$, 809 $[M - Ind]^+$, 771 $[M - S_2PEt_2]^+$, 655 $[M - Ind - S_2PEt_2]^+$. $C_{47}H_{45}FeP_3RuS_2$ (923.833): calcd. C 61.1, H 4.9, found C 61.4, H 4.7.

**Data for 13:** $^1H$ NMR ($C_6D_6$): $\delta$ = 3.60, 3.79, 4.05 and 5.20 (each s, 2 H, $C_5H_4$), 5.10 (s, 1 H, $H^2$), 5.34 (s, 2 H, $H^{1,3}$), 6.61–6.64 and 7.35–7.39 (each 4-line m, 2 H, $H^{5-8}$), 7.05–7.19, 7.26–7.33 and 7.45–7.51 (each m, total 26 H, Ph), 8.43–8.50 (4-line m, 4 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 53.1 (d, $^3J_{PP}$ = 15 Hz, dppf), 71.1 (t, $^3J_{PP}$ = 15 Hz, $S_2PPh_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3052 (w), 2922 (w), 2854 (w), 1650 (w), 1477 (w), 1433 (m), 1158 (w), 1089 (m), 1033 (w), 821 (w), 745 [m, (PS)], 698 [s, (PS)], 649 [m, (PS)], 512 (m) $cm^{-1}$. $FAB^+$-MS: $m/z$ (%) = 1020 $[M]^+$, 905 $[M - Ind]^+$, 771 $[M - S_2PPh_2]^+$, 655 $[M - Ind - S_2PPh_2]^+$. $C_{55}H_{45}FeP_3RuS_2$ (1019.91): calcd. C 64.8, H 4.5, S 6.3, found C 64.8, H 4.4, S 5.8.

(ii) $NaS_2PR_2$ (0.31 mmol, R = Et, 55 mg, R = Ph, 85 mg) was added to a suspension of **2** (50 mg, 0.08 mmol) in MeOH and the red mixture was stirred at room temp. for 18 h. The red product solution was evacuated to dryness and the residue extracted with toluene (2 × 3 mL). The extract was concentrated to about 2 mL and loaded on a silica gel column (1.5 × 2.0 cm). Elution gave three fractions: (i) a yellow eluate in ether/hexane (1:2, about 4 mL), which yielded [Ru(dppm)($\eta^1$-$S_2PR_2$)$_2$] (R = Et (**15**), 3 mg, 5% yield, R = Ph (**17**), 3 mg, 4% yield), (ii) a red eluate in ether:hexane (2:1, 4–8 mL), which yielded [(Ind)Ru(dppm)($\eta^1$-$S_2PR_2$)] (R = Et (**14**), 16 mg, 56% yield, R = Ph (**16**), 33 mg, 50% yield), (iii) an orange-yellow eluate in THF (3 mL), which gave **2** in trace amounts.

**Data for 14:** $^1H$ NMR ($C_6D_6$): $\delta$ = 1.07 and 1.11 [each t, $^3J_{HH}$ = 7.4 Hz, 3 H, $S_2P(CH_2CH_3)_2$], 1.46–1.57 [m, 4 H, $S_2P(CH_2CH_3)_2$], 4.04–4.16 and 4.43–4.54 [each m, 1 H, $CH_2(PPh_2)_2$], 5.15 (t, $^3J_{HH}$ = 2.5 Hz, 1 H, $H^2$), 6.12 (d, $^3J_{HH}$ = 2.5 Hz, 2 H, $H^{1,3}$), 6.89–7.12, 7.23–7.29, 7.37–7.43 and 7.78–7.81 (each m, total 24 H, $H^{5-8}$ and Ph) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 12.5 (d, $^3J_{PP}$ = 19 Hz, d), 84.9 (t, $^3J_{PP}$ = 19 Hz, $S_2PEt_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3052 (w), 2967 (w), 2927 (w), 1433 (m), 1324 (w), 1093 (m), 1027 (w), 730 [s, (PS)], 697 [vs, (PS)], 596 (m, (PS)], 534 m, 510 m. $FAB^+$-MS: $m/z$ (%) = 791 $[M - Ind + S_2PEt_2]^+$, 639 $[M - Ind]^+$, 601 $[M - S_2PEt_2]^+$. $C_{38}H_{39}P_3RuS_2$ (753.84): calcd. C 60.5, H 5.2, S 8.5, found C 60.6, H 5.3, S 8.3.

**Data for 15:** $^1H$ NMR ($C_6D_6$): $\delta$ = 0.45–0.57 [m, 6 H, $S_2P(CH_2CH_3)_2$], 0.87–1.02 [m, 4 H, $S_2P(CH_2CH_3)_2$], 1.14–1.25 [m, 6 H, $S_2P(CH_2CH_3)_2$], 2.18–2.45 [m, 4 H, $S_2P(CH_2CH_3)_2$], 4.78–4.85 [m, 2 H, $CH_2(PPh_2)_2$], 6.91–7.34 and 8.10–8.16 (each m, total 20 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($C_6D_6$): $\delta$ = 5.1 (s, d), 105.6 (s, $S_2PEt_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3049 (w), 2967 (w), 2929 (w), 2874 (w), 1433 (m), 1096 (m), 1036 (w), 723 [s, (PS)], 699 [vs, (PS)], 674, 603 [w, (PS)], 541 (m), 510 (m) $cm^{-1}$. $FAB^+$-MS: $m/z$ (%) = 791 $[M]^+$, 639 $[M - S_2PEt_2]^+$. $C_{33}H_{42}P_4RuS_4$ (791.92): calcd. **(II) Reactions of (Ind)Ru(carbonyl) Complexes**

**(a) Reaction with Isopropyl Xanthate:** A solution of [(Ind)Ru(CO)$_2$I] (**18**) (50 mg, 0.13 mmol) and $KS_2CO{i}Pr$ (45 mg, 0.26 mmol) in $CH_3OH$ (15 mL) was stirred for 30 min at ambient temperature. The red solution slowly turned orange-yellow. Solvent was removed under vacuo and extracted with toluene (about 20 mL) to afford orange-red solids of [Ru(CO)$_2$($\eta^2$-$S_2CO{i}Pr$)$_2$] (**19**) (24 mg, 50% yield).

**Data for 19:** $^1H$ NMR ($C_6D_6$): $\delta$ = 0.85 (m, 6 H, $CH_3$), 5.15 (sept, $^3J_{HH}$ = 6.1 Hz, 1 H, $CH$) ppm. $^{13}C$ NMR ($C_6D_6$): $\delta$ = 21.8 ($CH_3$),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

78.0 (O-*C*H), 195.3 (S*C*O), 230.0 (*C*O) ppm. IR (THF): $\tilde{\nu}_{CO}$ = 2047 s, 1986 (s) $cm^{-1}$ (literature[23] values 2052 s, 1990 s in $C_6H_{12}$). $FAB^+$-MS: 429.3 $[M + H]^+$.

**(b) Reaction with Trimethylamine *N*-Oxide (TMNO):** A solution of **18** (20.0 mg, 0.05 mmol) and TMNO·$2H_2O$ (12.0 mg, 0.11 mmol) in $CH_3CN$ (10 mL) was stirred for 1 h at ambient temperature. The resulting dark brown solution was adsorbed onto Celite (150 mg). Solvent was removed under vacuo and the Celite mixture was loaded onto a silica gel column (5 × cm) prepared in *n*-hexane. Elution with toluene gave an orange-red solution (about 40 mL), which, upon removal of solvent to dryness, afforded a red solid of $[(Ind)Ru(CO)I]_2$ (**20**) (13 mg, 70% yield).

In a repeated reaction of the same scale, the resulting brown solution was evacuated to dryness. The residue was dissolved in $C_6D_6$ and filtered. The reddish brown filtrate was allowed to evaporate at room temperature. Analytical pure red microcrystals of **20** were obtained after 2 d (10 mg, 54% yield).

**Data for 20:** $^1H$ NMR ($C_6D_6$): $\delta$ = 4.26 (d, $^3J_{HH}$ = 2.5 Hz, 4 H, $H^{1,3}$), 4.37 (t, $^3J_{HH}$ = 2.5 Hz, 2 H, $H^2$), 6.54 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, $H^{5-8}$), 6.77 (t, $^3J_{HH}$ = 8.1 Hz, 2 H, $H^{5-8}$), 6.90 (t, $^3J_{HH}$ = 7.9 Hz, 2 H, $H^{5-8}$), 7.59 (d, $^3J_{HH}$ = 8.2 Hz, 2 H, $H^{5-8}$) ppm. IR (KBr): $\tilde{\nu}_{CO}$ = 1925 (s) $cm^{-1}$. $ESI^+$-MS: 742.5 $[M]^+$. $C_{20}H_{14}I_2O_2Ru_2 \cdot 0.35C_6D_6$ (771.67): calcd. C 34.4, H 1.8, found C 34.8, H 2.3.

**(c) Reaction with Diethyl Dithiocarbamate in the Presence of TMNO:** A solution of **18** (30.0 mg, 0.08 mmol) and TMNO·$2H_2O$ (17.0 mg, 0.15 mmol) in $CH_3CN$ (15 mL) was stirred for 30 min at ambient temperature. The resulting dark brown solution was transferred via a cannula into a flask containing $NaS_2CNEt_2 \cdot 3H_2O$ (17.0 mg, 0.80 mmol) and the mixture was stirred for 1 h, giving a dirty green solution. This was concentrated to about 10 mL and adsorbed onto Celite (200 mg). Solvent was removed under vacuo and the Celite mixture was loaded onto a silica gel column (5 × 2 cm) prepared in *n*-hexane. Elution gave a yellow eluate in toluene (about 25 mL), which, upon removal of solvent, afforded a yellow solid of $(Ind)Ru(CO)(\eta^2\text{-}S_2CNEt_2)$ (**21**) (16 mg, 55% yield).

**Data for 21:** $^1H$ NMR ($C_6D_6$): $\delta$ = 0.61 (t, $^3J_{HH}$ = 7.1 Hz, 6 H, N-$CH_2CH_3$), 2.94 (q, $^3J_{HH}$ = 7.1 Hz, 4 H, N-$CH_2$), 4.85 (t, $^3J_{HH}$ = 2.6 Hz, 1 H, $H^2$), 5.16 (d, $^3J_{HH}$ = 2.6 Hz, 2 H, $H^{1,3}$), 6.91–6.96 (4-line m, 2 H, $H^{5-8}$), 7.12–7.16 (m, 2 H, $H^{5-8}$) ppm. $^{13}C$ NMR ($C_6D_6$): $\delta$ = 11.7 ($CH_3$), 43.1 (N–$CH_2$), 64.6 ($C^{1,3}$), 85.8 ($C^2$), 113.1 ($C^{4,9}$), 124.4, 126.3 ($C^{5,8}$ and $C^{6,7}$), 201.5 (S*C*N), 215.3 (*C*O) ppm. IR (THF): $\tilde{\nu}_{CO}$ = 1931 (s) $cm^{-1}$. $FAB^+$-MS: 393.0 $[M]^+$, 364.9 [M – CO]$^+$. $C_{15}H_{17}NORuS_2$ (392.5): calcd. C 45.9, H 4.4, N 3.6, S 16.3, found C 45.8, H 4.2, N 3.2, S 16.0.

**(d) Reaction with Isopropyl Xanthate in the Presence of TMNO:** A similar reaction using $KS_2CO$*i*Pr (14.0 mg, 0.08 mmol) to replace $NaS_2CNEt_2 \cdot 3H_2O$ resulted in a brownish yellow solution. A similar chromatographic workup gave a yellow solution in toluene (about 25 mL), which, upon removal of solvent, afforded an orange oil. Recrystallization of the orange oil in hexane gave yellow crystals of $(Ind)Ru(CO)(\eta^2\text{-}S_2CO$*i*$Pr)$ (**22**) (23.0 mg, 81% yield).

**Data of 22:** $^1H$ NMR ($C_6D_6$): $\delta$ = 0.80 (d, $^3J_{HH}$ = 6.2 Hz, 6 H,$CH_3$), 4.77 (t, $^3J_{HH}$ = 2.6 Hz, 1 H, $H^2$), 5.00 (sept, $^3J_{HH}$ = 6.2 Hz, 1 H, O-C*H*), 5.07 (d, $^3J_{HH}$ = 2.6 Hz, 2 H, $H^{1,3}$), 6.83–6.87 (4-line m, 2 H, $H^{5-8}$), 6.95–6.98 (4-line m, 2 H, $H^{5-8}$) ppm. $^{13}C$ NMR ($CD_2Cl_2$): $\delta$ = 21.4 ($CH_3$), 65.1 ($C^{1,3}$), 76.8 (O-*C*H), 85.8 ($C^2$), 111.6 ($C^{4,9}$), 124.8, 127.4 ($C^{5,8}$ and $C^{6,7}$), 199.4 (S*C*O), 231.9 (*C*O) ppm. IR (THF): $\tilde{\nu}_{CO}$ = 2041 (s) $cm^{-1}$. EI-MS: 380.1 $[M]^+$, 352.0 [M – CO]$^+$, 217.0 [M – CO–$S_2COC_3H_7$]$^+$. HR-$FAB^+$-MS for $C_{14}H_{14}O_2RuS_2$ $[M]^+$: *m*/*z* (%) = 379.9563 (found), 379.9473 (calcd.), for $C_{13}H_{14}ORuS_2$ [M – CO]$^+$: *m*/*z* (%) = 351.9599 (found), 351.9524 (calcd.). $C_{14}H_{14}O_2RuS_2$ (379.46): calcd. C 44.3, H 3.7, S 16.9, found C 44.7, H 3.7, S 16.8.

**Crystal Structure Determinations:** X-ray diffraction-quality crystals were obtained at –30 °C from solvent mixtures as follows: **7**, **9**, **11**, **16**, and **17** from $CH_2Cl_2$/hexane, **4a** from $CH_2Cl_2$/ether and **12** from THF/hexane, while those of **20** and **21** were obtained at room temperature from $C_6D_6$ and $CH_3CN/C_6D_6$, respectively. Crystals were mounted on quartz fibers. X-ray data were collected on a Bruker AXS APEX system, using Mo-$K_\alpha$ radiation, with the SMART suite of programs.[24] Data were processed and corrected for Lorentz and polarization effects with SAINT,[25] and for absorption effects with SADABS.[26] Structural solution and refinement were carried out with the SHELXTL suite of programs.[27] Crystal and structure refinement data are summarized in Table 3. The structures were solved by direct methods or Patterson maps to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. All non-hydrogen atoms were generally given anisotropic displacement parameters in the final model.

The crystal of **4a** contains one and a half $Et_2O$ solvent molecules. The half solvent molecule was disordered over two sites related by an inversion center, appropriate restraints on the molecular geometry were applied.

The crystal of **11** contained two half $CH_2Cl_2$ solvent molecules, both at special position and both disordered, while the crystal of **17** contained three $CH_2Cl_2$ solvent molecules. Two $CH_2Cl_2$ solvent molecules were also found and refined for **7** and **9**. The latter also contained a half molecule of hexane, which was modeled as disordered over two sites of equal occupancies, a common thermal parameter each for the $CH_2$ and $CH_3$ carbon atoms were assigned, with appropriate restraints on the bond lengths. The molecule of **7** exhibited disorder of the $NEt_2$ fragment over two alternative sites, the occupancies were allowed to refine and summed to unity, giving an approximate 65:35 ratio. The thermal parameters for the corresponding atoms were restrained to be the same, as were the bond lengths.

For complex **12**, two half molecules of THF were found. These were modeled with a common thermal parameter each for the O and C atoms, and with appropriate restraints on the bond lengths. The molecule of **12** exhibited disorder, which was modeled with two alternative sites for the Ru atom and the $PEt_2$ fragment. The occupancies were initially refined in an all-isotropic model and then fixed at 0.9 and 0.1 for the two sites, respectively, in the final model. Appropriate restraints similar to those described for the solvent molecule above were also applied. The molecular structure of **20** exhibits crystallographic mirror symmetry, with the mirror plane passing through the two Ru atoms and bisecting the $Ru_2S_2$ plane.

CCDC-626123 to -626131 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computation:** The initial geometries of the ruthenium complexes used for the calculations were based on some of the X-ray crystal structures obtained. The structures of the reactants, products, and transition state were fully optimized at the B3LYP density functional theory together with LANL2DZ basis sets. Harmonic frequencies were calculated at the optimized geometries to characterize stationary points as equilibrium structures, with all real frequencies, or transition states with one imaginary frequency, and to evaluate zero-point energy (ZPE) corrections. For all cases in which transition states have been found, these states were verified by following the path traced by the reaction coordinate, which was the

# Preparation of $Cu_2O$ Hollow Nanospheres under Reflux Conditions

**Muquan Yang,[a] Yingwei Zhang,[a] Guangsheng Pang,*[a] and Shouhua Feng[a]**

**Keywords:** Cuprous oxide / Nanospheres / Reflux conditions

Cuprous oxide hollow nanospheres were prepared by heating a solution of copper acetate and hydrazine as a reductant in 2-propanol at reflux. The size distribution of the nanospheres is mainly in the range 100–200 nm. The products were characterized by X-ray diffraction, UV/Vis diffuse reflectance spectroscopy, SEM, and TEM. The results indicated that the $Cu_2O$ hollow nanospheres aggregated from small nanoparticles with an average size of ca. 6.6 nm. The UV/Vis diffuse reflectance spectrum indicated that the optical absorption edge of the hollow $Cu_2O$ nanospheres is redshifted relative to their solid counterparts. The influence of the reaction conditions, such as reaction temperature, reaction time, and the amount of water, on the formation of the nanospheres as well as their morphology were studied.

## Introduction

In recent years, controlled architectures and the fabrication of hollow inorganic micro- and nanostructures have attracted extensive research interests owing to their unique thermal, electrical, optical, and surface properties.[1–8] Materials with hollow interiors have potential applications in many fields, such as catalyst, adsorbent, drug delivery, photonic crystals, optical imaging, low dielectric constant materials, and acoustic insulation etc. Cuprous oxide is an important *p*-type semiconductor with a direct bandgap of 2.17 eV. Owing to its unique optical property, $Cu_2O$ has potential applications in the catalytic oxidation of CO to $CO_2$,[9] photocatalytic degradation of organic pollutants, and decomposition of water into $H_2$ and $O_2$ under visible light.[10]

Various methods have been reported for the preparation of $Cu_2O$ with various morphologies and hollow structures, such as nanowire,[11] octahedral nanocages,[12] hollow cubes, and spheres.[13–16] There have been two main preparative routes for the synthesis of the hollow structure. In the template method, raw materials or target precursors are adsorbed onto the template surface and subsequently the template is removed by calcination or dissolution with solvent.[1] Another preparative strategy concerns physical phenomena such as "Ostwald ripening"[13,14,17] and the "Kirkendall effect".[2] Cetyltrimethylammonium (CTAB)[15] and gelatin[16] are used to prepare $Cu_2O$ hollow nanospheres by the template-assisted method. Here, we describe a facile template-free and surfactant-free route for the formation of hollow $Cu_2O$ nanospheres by heating a solution of copper acetate and hydrazine as the reductant in 2-propanol at reflux.

## Results and Discussion

Figure 1(a) shows the SEM image of the $Cu_2O$ nanospheres prepared by heating a solution of copper acetate and hydrazine in 2-propanol at reflux. The hollow feature of the nanospheres can be confirmed from TEM by observing that the light interior in contrast to the dark periphery as shown in the inset of Figure 1(a). The TEM image shows that the nanospheres are aggregated by small nanoparticles,

and the thickness of the hollow sphere shell is estimated to be ca. 20 nm for the nanosphere with a diameter of 210 nm as shown in the inset of Figure 1(a). The size distribution of the $Cu_2O$ nanospheres is mainly in the scale of 100–200 nm as shown in Figure 1(c).

Temperature is a crucial factor in the formation of the hollow structure. The boiling point of 2-propanol is 81.5 °C, and $Cu_2O$ nanospheres can also be prepared at lower temperature. Although spherical morphology was observed in the products prepared at 20 °C, as shown in Figure 1(b), a longer reaction time of 90 min was necessary and only solid nanospheres were observed by TEM from the inset of Figure 1(b). The diameter of these solid nanospheres varies from 100 to 500 nm, and is mainly concentrated in the region 200–400 nm as shown in Figure 1(c). As the temperature was increased to 50 °C, the size distribution of the spheres narrowed, but still only solid nanospheres were observed. As the temperature was increased to 70 °C, hollow nanospheres were observed to coexist with the solid nanospheres. Figure 2 shows that all of the nanospheres prepared at 81 °C were hollow.

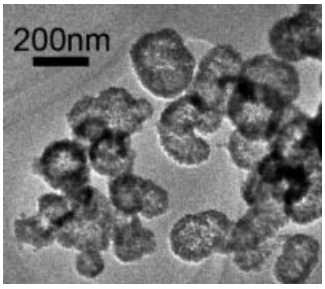

Figure 2. TEM image of $Cu_2O$ hollow nanospheres prepared at 81 °C.

Figure 3 shows the XRD patterns of the samples prepared at 20, 50, 70, and 81 °C. All the diffraction peaks can be indexed to cubic $Cu_2O$ (JCPDS card No. 05–0667). The average particle size of the primary particles that agglomerated into nanospheres was estimated from the line broadening of the XRD peak (111) by using the Scherrer equation ($D_{hkl} = k\lambda/\beta_{hkl}\cos\theta$). The results indicate that the average size of the primary particles decreased slightly from 9.6 to 7.9 nm, and then to 6.6 nm within the same reaction time of 10 min when the preparation temperature was increased from 50 to 70 °C, and then 81 °C.

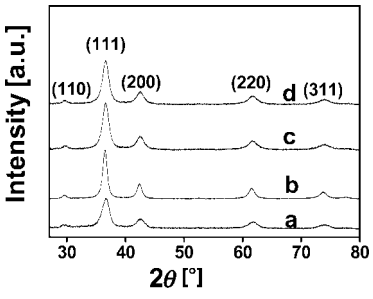

Figure 3. XRD patterns of the cubic $Cu_2O$ samples prepared at different temperatures: (a) 20 °C, (b) 50 °C, (c) 70 °C, and (d) 81 °C.

Reaction time had an influence on the morphology of the nanospheres as well as the average size of the primary particles. Figure 4 show the SEM images of the $Cu_2O$ hollow spheres prepared by heating for 20, 30, and 120 min at 81 °C in 2-propanol. In Figure 4(a), the $Cu_2O$ hollow spheres that were prepared in 20 min have smooth surfaces that are similar to the products prepared after 10 min. The spherical diameter distribution is concentrated in the range 100–300 nm as shown in Figure 4(d). When the reaction time was increased to 30 min, the surfaces of the products were relatively rough as shown in Figure 4(b), and the spherical diameter distribution was then concentrated in the region from 200 to 400 nm as shown in Figure 4(d). When the reaction time was increased to 120 min, irregular spheres with large sizes and rough surfaces were observed in Figure 4(c), and many broken particles were spread around. There was no change in the size of the primary particles when the reaction time was less than 20 min. The average size of the primary particles increased from 6.6 to 9.3 nm when the reaction time was increased from 20 to 30 min, according to the XRD line broadening.

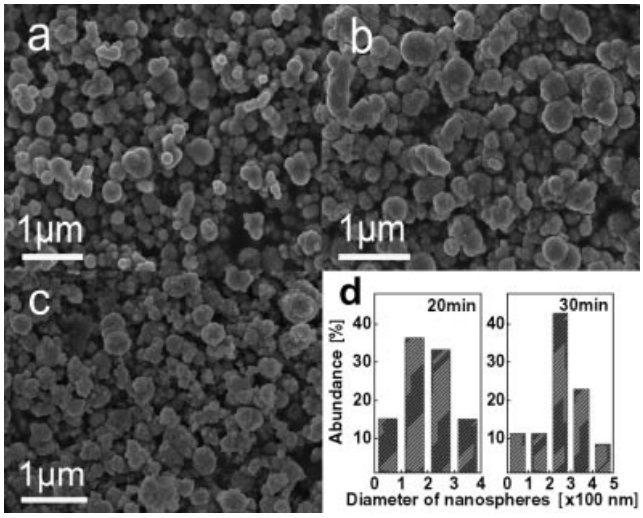

Figure 4. SEM images of hollow $Cu_2O$ nanospheres prepared at 81 °C after (a) 20 min, (b) 30 min, and (c) 2 h. (d) The size distribution of the $Cu_2O$ nanospheres.

There is a small amount of water that exists in the reaction system owing to the hydrazine aqueous solution. Although the products maintain their spherical morphology when additional water is introduced, the size of the nanospheres as well as the primary particles changed significantly. Figure 5(a) and (b) show the products prepared by adding 10 mL and 20 mL of water, respectively. The majority of the products are still hollow spheres as shown in the inset of Figure 5(a), but they have relatively small hollow interiors relative to the nanospheres that were prepared without additional water. As shown in Figure 5(c), the size distribution of the nanospheres prepared with an additional 10 mL of water is in the range 100–700 nm and is mainly concentrated around 300–400 nm. When 20 mL of water were added, we found that the size distribution of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nanospheres changed to 200–800 nm and was basically concentrated around 600–700 nm. This change indicates that the size of the spheres increases by adding more water. According to the XRD line broadening, the average size of the primary particles increased to ca. 15.4 nm and ca. 14.7 nm for the samples with the additional 10 mL and 20 mL of water.

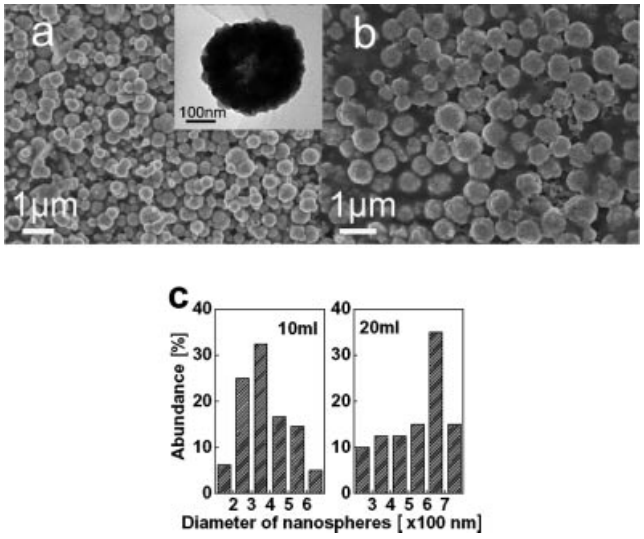

Figure 5. SEM images of hollow $Cu_2O$ nanospheres prepared with (a) 10 mL and (b) 20 mL of additional water. The inset of (a) shows a TEM image of a hollow sphere. (c) The size distribution of $Cu_2O$ nanospheres prepared with 10 mL and 20 mL of additional water.

Figure 6 shows the UV/Vis diffuse reflectance spectrum of $Cu_2O$ nanospheres that were prepared at 20, 50, 70, and 81 °C. The bandgaps of $Cu_2O$ were estimated according to the absorption edge position as shown in Figure 6 by intercepting the two linearly extrapolated lines. It is observed that the optical absorption edge of the $Cu_2O$ hollow nanospheres prepared at 81 °C occurs at about 616 nm, corresponding to a bandgap energy of 2.01 eV. The optical absorption edge of the $Cu_2O$ solid nanospheres prepared at 20 °C is at about 600 nm, corresponding to a bandgap energy of 2.07 eV. It is worth noting that the hollow nanospheres exhibit similar features in the DRS spectra (Figure 6a and b) whereas there are significant differences with that of solid nanospheres (Figure 6c and d). Relative to the solid nanospheres, the optical absorption edge of hollow the $Cu_2O$ nanospheres is redshifted. It is well known that the optical absorption would be altered considerably by the morphology and crystallinity of the nanospheres. The average particle size of the primary particles that were agglomerated into hollow and solid nanospheres is in the range of 6–10 nm, according to the XRD line broadening. The size distributions of hollow and solid nanospheres are all basically in the region of 100 to 400 nm. Hence, we speculate that the enhanced optical absorption of the nanospheres results from their hollow structure. The surface structure and adsorbed species on the surface have an influence on the optical absorption. The inner and outer surfaces of the hollow nanospheres may be different, which will result in a redshift.

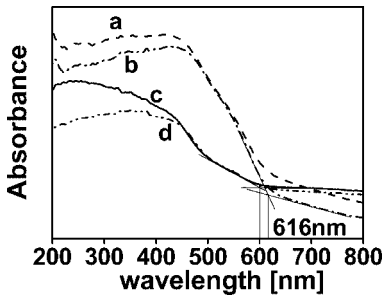

Figure 6. UV/Vis diffuse reflectance spectra of $Cu_2O$ nanospheres prepared at different reaction temperatures: (a) 81 °C, (b) 70 °C, (c) 50 °C, and (d) 20 °C.

## Conclusions

A facile template-free and surfactant-free route was developed for the preparation of hollow $Cu_2O$ nanospheres. Cuprous oxide hollow nanospheres with diameters of ca. 100–200 nm were successfully prepared by heating a solution of $Cu(OAc)_2 \cdot H_2O$ and hydrazine as a reductant in 2-propanol at reflux. The nanospheres were aggregated from small primary particles with an average size of 6–10 nm. Temperature is a critical factor in the formation of the hollow nanospheres, and hollow spheres come into being only when the temperature is close to the boiling point of the solvent. Both the reaction time and the amount of water have an influence on the formation of the $Cu_2O$ hollow structures as well as the morphology and the size of the primary particles. The UV/Vis diffuse reflectance spectrum indicated that the hollow structure enhanced the absorption of visible light relative to their solid counterpart.

## Experimental Section

All reagents (A.R) were from the Beijing Chemical Reagent Corporation and used without further purification. In a typical synthesis procedure, $Cu(OAc)_2 \cdot H_2O$ (2.0 g) was added to 2-propanol (100 mL) in a three-necked flask whilst stirring. The solution was heated at reflux (81 °C) for 20 min. and then a hydrazine (2.5 mL, 1 mol $L^{-1}$) solution was added dropwise. The resulting deep green mixture was stirred for another 10 min, and a reddish brown suspension came into being. The solid product was separated from the solution by centrifugation, washed with absolute ethanol, and dried in air.

The X-ray powder diffraction (XRD) patterns of the products were collected with a Rigaku D/MAX 2500/PC X-ray diffractometer with graphite-filtered Cu-$K_\alpha$ radiation at 40 kV and 200 mA with a scan rate of 1° $min^{-1}$. The morphologies were observed by SEM with a JSM-6700F electron microscope and TEM with a JSM-3010 electron microscope. UV/Vis diffuse reflectance spectra of the products were measured with a UV/Vis spectrometer Lambda 20.

# Crystal Structure and Surface Photovoltage Properties of $Mn^{II}$ Coordination Supramolecules

Li-Ping Sun,[a] Shu-Yun Niu,*[a] Jing Jin,[a] and Li Zhang[a]

**Keywords:** Manganese / Hydrogen bonds / Surface photovoltage spectroscopy

Three $Mn^{II}$ coordination supramolecular complexes $[Mn(pdc)(H_2O)]_n$ **1**, $\{[Mn(pdc)(phen)(H_2O)]\cdot 3H_2O\}_n$ **2**, and $\{[Mn(cyan)_2(H_2O)_4]\cdot 2HCl\cdot 2(Hcyan)\}$ **3** ($H_2pdc$ = pyridine-2,3-dicarboxylic acid, Hcyan = cyanuric acid, phen = 1,10-phenanthroline) were hydrothermally synthesized and their structures determined by single-crystal X-ray diffraction. The pdc group in complex **1** bridges the $Mn^{II}$ ions to form an infinite 3D structure. In complex **2**, the $Mn^{II}$ ion is bridged to a 1D infinite chain by pdc groups and the chain is further connected to a 2D structure by hydrogen bonds. The 3D structure of complex **3** is formed by hydrogen bonds and O···Cl weak interactions. Surface photovoltage spectroscopy (SPS) of complexes **1**–**3** indicate that they all possess positive SPV response in the range of 300–800 nm and show *p*-type semiconductor characteristic. The intensities of the SPV responses are obviously different, and this can mainly be attributed to the differences in their structures. Field-induced surface photovoltage spectroscopy (FISPS) of complexes **1**–**3** confirms their *p*-type semiconductor characteristic.

## Introduction

In recent years, the most attractive areas of research in the fields of crystal engineering and supramolecular chemistry have been aimed at creating a wide range of purpose materials with specific structures and useful properties, such as electronic, magnetic, optical, and catalytic properties.[1,2] In inorganic coordination polymers, the choice of metal–ligand combination is the main factor controlling both the supramolecular topology and dimensionality, but other factors such as hydrogen-bonding, $\pi\rightarrow\pi^*$ interactions, and metal–metal interactions can also greatly influence the crystal structure and its dimensionality.[3,4] Owing to the particularity and variety of electronic configurations possible for manganese ions, manganese coordination complexes have attracted great attention in the domain of coordination chemistry all along, though the research of $Mn^{n+}$ coordination complexes have gone across hundreds of years. Manganese complexes play an important role in some biological redox systems owing to the various oxidation states of the manganese ion;[5,6] the water oxidizing complex of photosystem II [PS (II)] involves manganese ions in various combinations of oxidation states, including $Mn^{II}$, $Mn^{III}$, and $Mn^{IV}$.[7,8] It is well-known that the electronic arrangement of the six-coordinate $Mn^{II}$ ($d^5$) ion can take the high-spin (HS) and low-spin (LS) states depending on the different ligand field. The spin conversion between HS and LS probably accompanies magnetic behaviors. When $Mn^{II}$ ion takes HS, there are more unpaired electrons, which easily leads to the behavior of paramagnetism, antiferromagnetism, and ferromagnetism.[9,10] When the $Mn^{II}$ ion takes LS, various transitions will occur, which makes the corresponding complexes appear to have photoelectric and optical properties. In addition, $Mn^{II}$ complexes coordinated by a carboxylic group have some potential application in human pharmaceuticals.[11] At present, research on the properties of $Mn^{II}$ coordination complexes is mainly focused on magnetism.[12–14] Research into photoelectric properties is mainly involved in the coordination complexes which depend on phthalocyanine and porphyrin as ligands. There are few reports on the photoelectric properties of coordination polymers.[15–17] Surface photovoltage spectroscopy (SPS) is an effective technique that can be used to investigate the photophysics of the excited states and the surface charge behavior of the sample. This technique provides information about the properties of the sample surface layer (several atomic layers), and it has a very high sensitivity. The sensitivity of this method is about $10^8$ $q\,cm^{-2}$, or about one elementary charge per $10^7$ surface atoms, which exceeds that of conventional spectroscopy such as XPS and Auger spectroscopy by many orders of magnitude. Moreover, the SPV method is a contactless and nondestructive technique. This technique has been used to investigate the photoelectric processes such as charge transfer and photocatalysis.[18,19] On the basis of the principle of SPS, Wang and coworkers developed a field-induced surface photovoltage spectroscopy (FISPS) technique,[20,21] which can demon-

strate the photoelectric properties of semiconductors under the effect of an external electric field. In this paper we report the synthesis, structure, and properties of three $Mn^{II}$ coordination supramolecules. Meanwhile we discuss the influence of the different structures on the photoelectric properties.

## Results and Discussion

### $[Mn(pdc)(H_2O)]_n$ (1)

Single-crystal X-ray diffraction analysis reveals that complex **1** possesses a 3D infinite structure and its building unit is [Mn(pdc)($H_2O$)] (Figure 1a). The $Mn^{II}$ ion is six-coordinate with an $NO_5$ donor set in the distorted octahedron environment. One O atom and one N atom are from the same pdc group, the other four O atoms are from three different pdc ligands and one coordinated water molecule (Figure 1b). The equatorial plane is defined by the O1, O2, O3, and O5 atoms with the O4 and N1 atoms occupying the apical positions. The bond lengths of Mn–O range from 2.1464(16) to 2.2436(18) Å and the bond length of Mn–N is 2.287(2) Å. In the crystal, the pdc group plays a bridging role. The two β-carboxylic O atoms (O2, O3) bridge equivalent $Mn^{II}$ ions and the $Mn^{II}$ ion is connected to a 1D infinite chain along the *a* axis. Along the *c* axis, the two α-carboxylic O atoms (O1, O5) separately coordinate to two equivalent $Mn^{II}$ ions. The $Mn^{II}$ ions are also connected to a 1D infinite structure. Then, complex **1** is connected to a regular 2D structure in the *ac* plane (Figure 2). Moreover, along the *b* axis, the α-carboxylic O atom (O1) together with the pyridine N atom chelate to one $Mn^{II}$ ion, the β-carboxylic O atom (O2) coordinates to the other equivalent $Mn^{II}$ ion, then the $Mn^{II}$ ions are also linked to a 1D infinite chain. It can be seen that the *ab* plane is also a regular 2D web structure (Figure 3). Complex **1** is therefore webbed to a 3D infinite structure (Figure 4).

### {[Mn(pdc) (phen)($H_2O$)]·3$H_2O$}$_n$ (2)

Single-crystal X-ray diffraction analysis reveals that complex **2** possesses a 2D infinite structure and its building unit is {[Mn(pdc)(phen)($H_2O$)]·3$H_2O$}. The $Mn^{II}$ ion is six-coordinate by the $N_3O_3$ donor (N1, N2, N3, O1, O3, and O4) set in a distorted octahedron. The equatorial plane is defined by the N1 and N2 atoms from one phen molecule and the O3 and O4 atoms from two different pdc groups. The O1 and N3 atoms are separated from the coordinated water molecules and the pdc group occupies the apical position. The bond lengths of Mn–N range from 2.2718(16) to 2.3149(15) Å and the bond lengths of Mn–O are from 2.0963(13) to 2.1710(3) Å. The pdc group plays a bridging role: its two carboxylic groups adopt a monodentate coordination mode, one together with the pyridine N atom coordinates to one $Mn^{II}$ ion, the other coordinates to a second equivalent $Mn^{II}$ ion. Then, the $Mn^{II}$ ions are linked to a 1D infinite chain along the *b* axis (Figure 5). Two 1D infinite chains are connected to a 1D double chain through the hydrogen bond [O1–H···O2, 2.835(2) Å], which from the coordinated water molecule and uncoordinated carboxylic O atom (Figure 6). Between the different 1D double chains, there are two styles of O–H···O hydrogen bonds. They are the interactions between the lattice water molecules and the uncoordinated carboxylic O atoms [O6–H···O5, 2.854(3) Å, O7–H···O5, 2.833(3) Å] as well as lattice water molecules [O6–H···O8, 2.758(3) Å, O8–H···O7, 2.794(3) Å]. These hydrogen bonds link the multi 1D double chains to form an infinite structure along the *a* axis. Therefore, complex **2** is linked to a 2D irregular structure by hydrogen bonds (Figure 7).

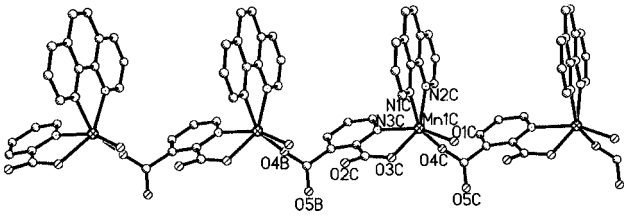

Figure 5. The 1D chain structure of complex **2**.

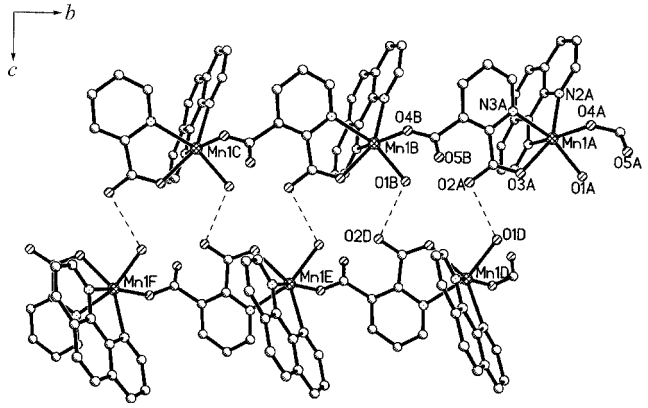

Figure 6. The 1D double chain structure of complex **2**. Dotted lines are hydrogen bonds.

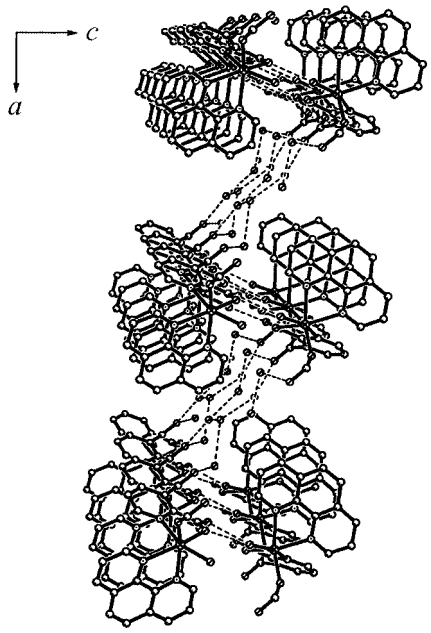

Figure 7. The 2D structure of complex **2**. Dotted lines are hydrogen bonds.

### {[Mn(cyan)$_2$($H_2O$)$_4$]·2HCl·2(Hcyan)} (3)

Complex **3** is a mononuclear coordination complex. The $Mn^{II}$ ion is six-coordinate with an $N_2O_4$ donor set in the better octahedron environment (Figure 8). Four O atoms (O6, O6A, O3, and O3A) are from four different coordinated water molecules and they comprise the equatorial plane. The bond lengths of Mn1–O3 and Mn1–O6 are 2.228(4) and 2.238(3) Å, respectively. The O6–Mn1–O6A and O3–Mn1–O3A bond angles are all 180°. The O3–Mn1–O6 and O3A–Mn1–O6 bond angles are 95.32(14)° and 84.68(14)°, respectively. The two N atoms (N1, N1A) are from two different cyan groups and they occupy the apical positions of the octahedron. The Mn1–N bond length of 2.261(4) Å and N1–Mn1–N1A bond angles of 180° means that the coordination environment of $Mn^{II}$ ion is a better octahedron. The free chloride ion is from the $MnCl_2$ reagent. The hydrogen ion comes from the coordinated Hcyan group. The N atom of the Hcyan group coordinates to the $Mn^{II}$ ion, simultaneously, the N–H bond breaks, the corresponding hydrogen ion dissociates itself from the N–H

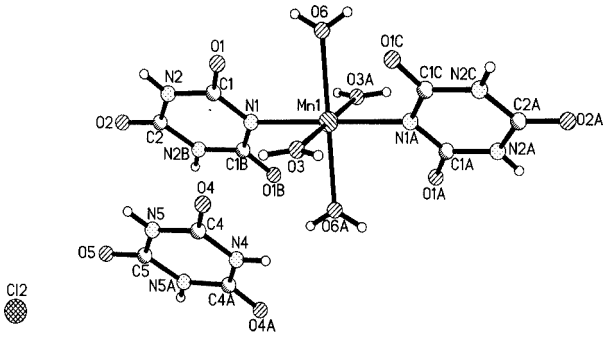

Figure 8. The molecule structure of complex **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bond to the solution and they exactly take on the action of balancing the charge. In the crystal, there are two styles of O–H···O and O–H···N hydrogen bonds. The former is from one coordinated water molecule and a carbonyl O atom of the free Hcyan, [O3–H···O4, 2.771(3) Å], the latter is from the other coordinated water molecule and the N atom of the free Hcyan group [O6–H···N4, 2.920(4) Å]. The two styles of intermolecular hydrogen bonds link the molecule to form an infinite 1D structure along the *c* axis. In addition, there are two kinds of O···Cl weak interactions between the chlorine ion and the carbonyl O atom of the coordinated cyan group (O2···Cl, 2.867 Å) as well as the carbonyl O atom of the free Hcyan group (O5···Cl, 2.893 Å). The O···Cl weak interactions also link the molecule to form a 1D infinite structure along the *b* axis. So complex **3** is linked to a 2D regular structure at the *bc* plane (Figure 9). Moreover, the weak interactions between the free chlorine ions and the coordinated water molecules (O6···Cl, 2.949 Å; O3···Cl, 2.819 Å) as well as the carbonyl O atom of the coordinated cyan group (O1···Cl, 2.906 Å) link complex **3** to form a 1D infinite structure along the *a* axis. When projecting along the *c* axis, the *ab* plane is also a regular 2D layer (Figure 10). So complex **3** is connected to a 3D structure by hydrogen bonds and a O···Cl weak interaction (Figure 11).

### SPS of Complexes 1–3

The emergence of the surface photovoltage (SPV) response band indicate that when the surface of the solid sample is illuminated, the electron-hole pairs separate under a built-in field, resulting in a change in the surface potential barrier, which produces the photoelectric behavior. The detected signal by SPS is equivalent to the change in the surface potential barrier on illumination ($\delta V_s$), which is given by the equation: $\delta V_s = V_s' - V_s^o$, where $V_s'$ and $V_s^o$ are the surface potential barriers before and after illumination, respectively. As far as band-to-band transitions are concerned, a positive response in SPV ($\delta V_s > 0$) means that the sample is characterized as a *p*-type semiconductor, whereas a negative response means that the sample is an *n*-type semiconductor. The magnitude of the surface potential barrier depends on the numbers of surface net charge. Figures 12, 13, and 14 show the SPS spectra of complexes **1**–**3**, respectively. They all appear as positive SPV response bands between 300 and 800 nm. Thereinto, the signal detected by SPS at 300–500 nm is a wide peak. The signal is actually the result of overlap of several SPV response bands. To make the assignment of each SPV response band clear, we separated them by the Origin 7.0 program. Then, complexes **1** and **3** present two positive SPV responses and complex **2** appears as three positive SPV responses in the range 300–800 nm, which indicates that they all possess *p*-type semiconductor characteristics. In complex **1**, the response at $\lambda_{max}$ = 349 nm is attributed to the $\pi \rightarrow \pi^*$ transition of the ligands and the response at $\lambda_{max}$ = 403 nm is assigned to the LMCT (from ligand-to-metal charge transfer) transition. At 600–800 nm, some very weak and splitting peaks appear, this phenomenon is associated with the weak crystal-field coordination environment of the $Mn^{II}$ ion. In the six-coordinate atoms of the $Mn^{II}$ ion, there are one N atom and five O atoms. The four O atoms are from four carboxylic groups and one O atom is from one coordination water molecule. According to the spectra chemical series (–COO $<$ $H_2O$ $<$ N complexes), the $Mn^{II}$ ion ($d^5$) in complex **1** can be regarded as lying among the weak crystal field. So the $d \rightarrow d^*$ transition is forbidden. However, the microenvi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ronment of the $Mn^{II}$ ion is not a strict octahedron, and there still appears to be weak splitting SPV response bands at 600–800 nm.

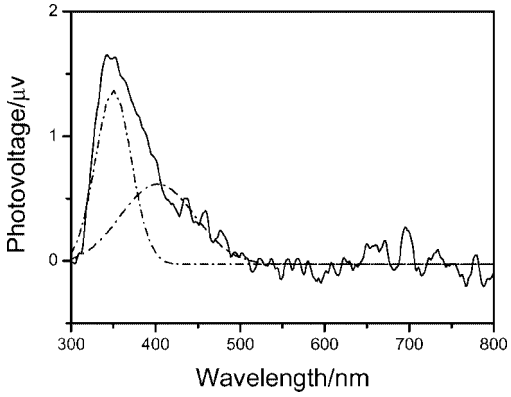

Figure 12. The SPS of complex **1**. Dotted lines are treated peak.

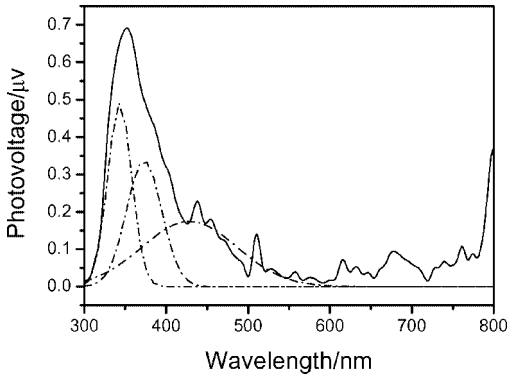

Figure 13. The SPS of complex **2**. Dotted lines are treated peak.

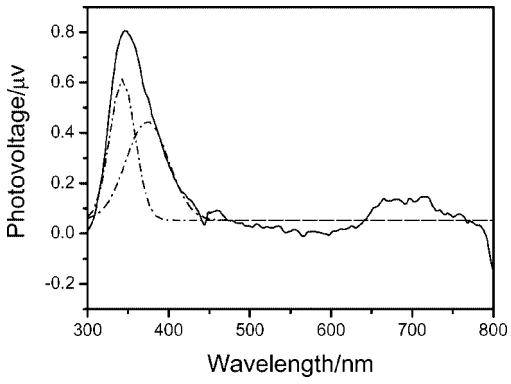

Figure 14. The SPS of complex **3**. Dotted lines are treated peak.

In complex **2**, there are three SPV responses in the range 300–800 nm. The SPV response at $\lambda_{max}$ = 349 nm is assigned to the π→π* transition of the ligand and the response at $\lambda_{max}$ = 370 nm is attributed to the LMCT transition. The response at $\lambda_{max}$ = 429 nm can be assigned to the d→d* transition ($^2T_2 \rightarrow {}^2A_2,{}^2T_2$) of the $Mn^{II}$ ion. In contrast with complex **1**, complex **2** has another SPV response band ($\lambda_{max}$ = 429 nm) that is caused by a d→d* transition, and the energy of this SPV band is very high. This can be attributed to the crystal field of the $Mn^{II}$ ion in complex **2**, which is different than that in complex **1**. The coordination atoms for the $Mn^{II}$ ion in complex **2** are three N atoms and three O atoms. So it can be regarded that the crystal field of the $Mn^{II}$ ion in complex **2** is stronger than that of in complex **1**; the d→d* transition $^2T_2 \rightarrow {}^2A_2,{}^2T_2$ can take place. The $^2T_2 \rightarrow {}^4T_1$ transition is forbidden. So only one SPV response band ($\lambda_{max}$ = 429 nm) is caused by a d→d* ($^2T_2 \rightarrow {}^2A_2,{}^2T_2$) transition. The weak and splitting SPV response band at 600–800 nm is attributed to the forbidden d→d* transition ($^2T_2 \rightarrow {}^4T_1$), owing to the microenvironment of the $Mn^{II}$ ion not being a strict octahedron.

In complex **3**, there are two positive SPV responses at 300–800 nm. The response at $\lambda_{max}$ = 340 nm is attributed to the π→π* transition of the ligand, and the response at $\lambda_{max}$ = 376 nm is assigned to the LMCT transition. Analogous with complex **1**, in the coordinated atoms with the $Mn^{II}$ ion, there are two N atoms from two cyan groups and four O atoms from four coordinated water molecules. The $Mn^{II}$ ion can be regarded as lying among a weak crystal field. The d→d* transition is forbidden. The microenvironment of the $Mn^{II}$ ion is not a strict octahedron and a weak SPV response band at 600–800 nm appears.

Comparing the SPV responses of complexes **1**–**3** at 300–500 nm (Figure 15), it can be seen that the SPV intensity of complex **1** is larger than that of complexes **2** and **3**. The differences in their intensities are maybe mainly due to the differences in their structures. Complex **1** is a 3D infinite coordination polymer. In the crystal, the 3D structure is completely formed by the coordination bonds and it can supply more transmission passages for the electrons and holes. That means that more electrons diffuse to the surface, which leads to an increase in the SPV intensity. Moreover, the 2D plane made from the *ab* and *bc* planes in complex **1** is a regular structure, and it is very favorable for the transmission of electrons and holes. Although complex **2** possesses a 2D infinite structure, the 2D structure is an irregular space structure. The irregular space structure in transferring electrons and holes is smaller than the regular structure. So the SPV intensity of complex **2** is lower than that of complex **1**. Complex **3** is a mononuclear complex and the molecule is further connected to a 3D structure by hydrogen bonds and weak interactions. Hydrogen bonds belong to the class of weak bonds and they are not as capable

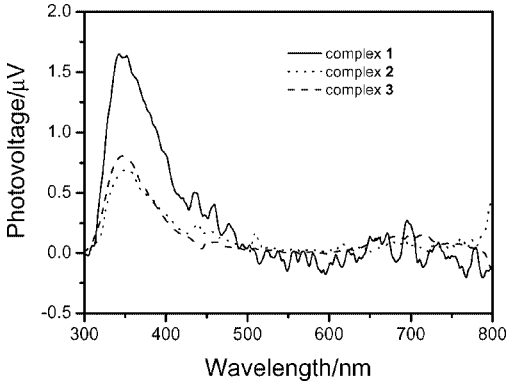

Figure 15. The contrastive SPS diagram of complexes **1**–**3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in transferring electrons and holes as coordination bonds. So the SPV intensity of complex **3** is lower than that in complex **1**. Meanwhile, the 2D structure of the *ab* and *bc* planes in complex **3** are all regular structures, which benefits to the transmission of electrons and holes. Thereby, the SPV intensity of complex **3** and complex **2** is nearly the same.

### FISPS of Complexes 1–3

FISPS can determine the direction of the built-in field and the mobile direction of photogeneration carriers. If we apply a positive electric field (the illuminated surface is positive) vertically to the *p*-type semiconductor surface, whose direction is the same as the direction of the built-in field, the separation efficiency of the photogeneration carriers are increased and the intensity of the SPV response increases in the original direction. If a negative electric field, whose direction is opposite to that of the built-in field, is applied, the separation efficiency of the photogenerated carriers reduces and the intensity of the SPV response is weakened, even in the reverse direction. In contrast to *p*-type semiconductors, the SPV response intensity of the *n*-type semiconductors increase as a negative field is applied and reduces as a positive electric field is applied. The FISPSs of complexes **1**–**3** are given in Figures 16, 17, and 18. The SPV responses in the range 300–800 nm in all three complexes increase linearly with a positive electric field, which shows that the direction of the positive electric field is consistent with the built-in field. This enhances the separation efficiency of the photoexcited electron-hole pairs and results in an increase in the surface potential; thus, the fact that complexes **1**–**3** have *p*-type semiconductor characteristics is confirmed. Otherwise, in complexes **1** and **2**, when adding a DC +2 V, some new SPV responses are produced: $\lambda_{max}$ = 442, 490 nm for complex **1** and $\lambda_{max}$ = 388, 454 nm and $\lambda_{max}$ = 700 nm for complex **2**. These new SPV response bands may be attributed to the forbidden spectroscopic term transition because the external positive electric field provides more impetus for electronic transitions, which makes the forbidden transitions take place.

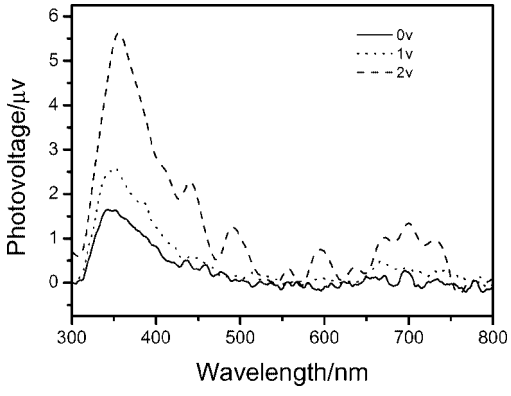

Figure 16. The FISPS of complex **1**. The intensities of the SPV response increase linearly with the external positive electric field.

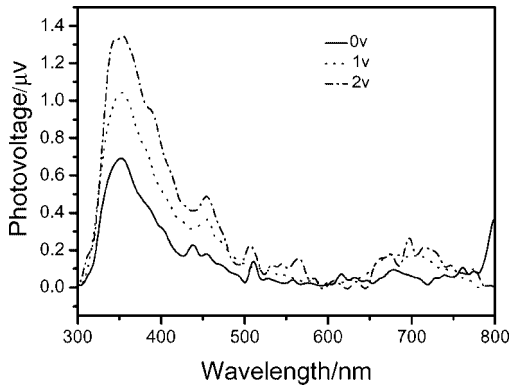

Figure 17. The FISPS of complex **2**. The intensities of the SPV response increase linearly with the external positive electric field.

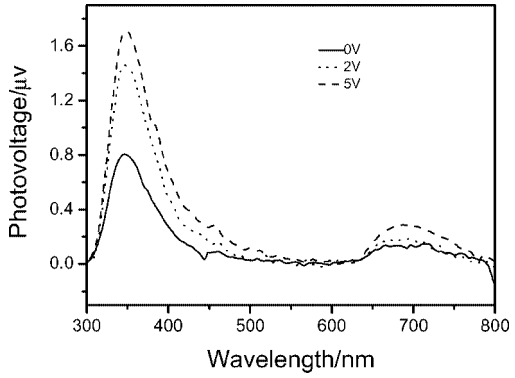

Figure 18. The FISPS of complex **3**. The intensities of the SPV response increase linearly with the external positive electric field.

## Conclusion

In this paper, three $Mn^{II}$ coordination supramolecules were synthesized by a hydrothermal method. Complex **1** possesses a 3D infinite structure. Complex **2** contains a 1D coordination chain, and the chains are further connected to a 2D infinite structure by hydrogen bonds. The 3D structure of complex **3** is completely formed by hydrogen bonds and weak interactions. The SPS of complexes **1**–**3** indicate that they all show positive SPV responses in the range 300–800 nm and all show *p*-type semiconductor characteristics. The intensities of the SPV response band at 300–500 nm in complex **1** is obviously stronger than that in complexes **2** and **3**. The differences in the intensities are attributed to the differences in their structures. The 3D structure of complex **1** is connected completely by coordination bonds and the *ab* and *bc* planes are all of regular structure. This structure style is very beneficial to the transferring of electrons and holes. Meanwhile, the microenvironment (crystal field) of the $Mn^{II}$ ion in the complexes has a certain effect on the SPV responses, especially the d→d* transition response. Due to the crystal field, complex **2** shows a stronger response than complexes **1** and **3**, and the SPV response from the d→d* transitions are obviously different. Moreover, the FISPS confirm the *p*-type semiconductor characteristic of complexes **1**–**3**.

## Experimental Section

**Materials and Methods:** All the reagents are A.R grade. IR spectra were recorded in the range 220–4000 $cm^{-1}$ with a JASCO FT/IR 480 spectrophotometer using KBr pellets. The elemental compositions of the complexes were determined with a PE-240C Analyzer and a PLASAM-SPEC-II instrument. The SPS and FISPS instrument was made by ourselves. Monochromatic light was obtained by passing light from a 500W xenon lamp through a double-prism monochromator. The slit width of the entrance and exit was 3 mm. A lock-in amplifier, synchronized with a light chopper, was employed to amplify the photovoltage signal. The range of modulating frequency is from 20 to 70 Hz. The spectral resolution is 1 nm. The samples were rubbed to power and were pressed between two slices of ITO glass during the SPS and FISPS measurements. The construction of the photovoltaic cell is an ITO/sample/ITO sandwich structure.[22] It was ensured that the light penetrating depth was much less than the powder layer thickness. All the measurements were performed under atmospheric pressure and at ambient temperature.

**$[Mn(pdc)(H_2O)]_n$ (1):** A solution of $MnCl_2{\cdot}4H_2O$ (0.10 g, 0.5 mmol) in water (10 mL) was added to the solution of $H_2pdc$(0.08 g,0.5 mmol) and NaOH (0.04 g,1 mmol) in water (10 mL); the solution was colorless. Then, this solution was transferred into a Teflon-lined stainless steel vessel, and the vessel was sealed and heated to 150 °C for 5 d. The mixture was cooled to room temp., and pink crystals of complex **1** were collected. $C_7H_5MnNO_5$ (238.06): calcd. C 35.31, H 2.12, N 5.89, Mn 23.08; found C 35.55, H 2.34, N 5.97, Mn 22.93. IR(KBr): $\tilde{\nu}$ = 3440, 3354

**X-ray Crystallographic Data:** Crystallographic data for complexes **1**–**3** were collected with a Smart 1000 APEX II CCD diffractometer using graphite monochromated Mo-$K_\alpha$ radiation. ($\lambda$ = 0.71073 Å) at 293 K. All data were corrected for L-P factor and empirical absorption. The structures were solved by direct methods and refined by full-matrix least-squares calculations on $F^2$ using the SHELXTL 97 program. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were found by mixed methods. The crystal data and structure refinement of complexes **1**–**3** are summarized in Table 1. Selected bond lengths and bond angles of complexes **1**–**3** are listed in Table 2.

CCDC-634132 (for **1**), -634133 (for **2**), and -634134 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Two correlated structure figures of complexes **1** and **2**, IR spectra of complexes **1**–**3**, principle of the SPS, analysis of the transition assignment, and equipment of the SPV technique.

# Stereospecific Synthesis, Structural Characterisation and Resolution of 2-Phospha[3]ferrocenophane Derivatives – a New Chiral Scaffold

**Nicolas Fleury-Brégeot,[a] Armen Panossian,[a] Angèle Chiaroni,[a] and Angela Marinetti*[a]**

**Keywords:** Phosphane ligands / Ferrocenophane / Chiral resolution / Palladium

The first 2-phospha[3]ferrocenophanes containing stereogenic carbon atoms in the three-atom bridge have been synthesised from phenylphosphane by stereospecific ring-closing phosphanation reactions. Either α-substituted 1,1′-bis-(hydroxymethyl)ferrocenes or the corresponding 2-oxa-[3]ferrocenophanes have been used as diastereomerically pure starting materials. The resolution of 1,2,3-triphenyl-[2]phosphaferrocenophane has been achieved by chromatographic separation of the diastereomeric adducts of a chiral cyclopalladate complex. The X-ray crystal structures of two 2-phospha[3]ferrocenophane-borane complexes are also reported.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

The emergence of monodentate, bulky, electron-rich phosphanes is a recent, noteworthy issue in the field of organometallic catalysis. Tris(*tert*-butyl)phosphane, biphenyl-(di-*tert*-butyl)- and dicyclohexylphosphane are prototypical compounds of this class. By showing their great potential in palladium-promoted coupling reactions,[1] the pioneering work of Nishiyama, Fu and Buchwald stimulated the active search for new catalytic applications[2] as well as for new ligand structures. Among others, the synthesis and use of ferrocenyl-based phosphanes have been considered, which combine the steric bulk of the organometallic moiety with the electron-donating properties of alkyl and/or ferrocenyl phosphorus substituents.[3] Representative examples are given in Figure 1.

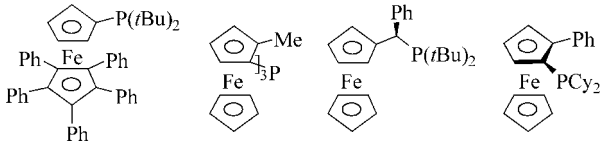

Figure 1. Ferrocenylphosphanes.

An especially attractive and favourable feature of ferrocenylphosphanes for routine bench use is their higher resistance to air oxidation with respect to other ligands with similar bulk and electron-donating ability. This is the basis of, for instance, the impressive development of ferrocenyl-based phosphanes in enantioselective catalysis,[4] and it motivates new studies in these series.

In this context, our purpose is to expand the field of monodentate, electron-rich ferrocenylphosphanes, and especially that of chiral species, to include unprecedented or neglected scaffolds. In most known ferrocenyl phosphanes, a phosphorus function and the cyclopentadienyl ring are either directly bonded or separated by a one-carbon spacer (representative examples of monodentate derivatives are shown in Figure 1). In only a few cases have two[3d,5,6] or three[3c] ferrocene moieties been connected to the same phosphorus atom, and ferrocenophane frameworks bearing phosphorus functions in a carbon-tethering chain are especially uncommon. Thus, ferrocenophane moieties of this series have been selected in this work as target compounds.

It may be interesting to recall here that, among phosphorus-containing ferrocenophanes, 1-phospha[1]ferrocenophanes are moderately stable compounds that have been extensively studied mainly as precursors for high-molecular-weight poly(ferrocenes) by thermal or photochemical ring-opening polymerisation.[7] Similarly, incorporation of phosphorus in the two-atom chain of [2]ferrocenophanes has been used to generate strained starting materials for the synthesis of polymeric materials.[8] On the other hand, three- to five-atom tethers are known to afford stable phosphorus derivatives. Thus, for instance, the synthesis and coordinating properties of a 3-phospha[5]ferrocenophane have been reported.[9] Concerning phosphorus-containing [3]ferrocenophanes, most known compounds have three heteroatom bridges. These include 1,3-distanna-,[10] 1,3-dithia-[11] and 1,3-diaza-2-phospha[3]ferrocenophanes.[12] The first [3]ferrocenophanes where phosphorus is included in a

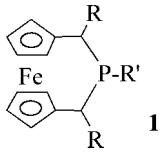
carbon tether have only recently been isolated from the reaction of 6,6′-dimethylfulvene with, successively, the dilithiated phosphanes $PhPLi_2$ or $CyPLi_2$, and $FeCl_2$ (Scheme 1).[13]

## Results and Discussion

### Synthesis and Characterisation of 2-Phospha[3]ferrocenophanes

As far as we know, no chiral, enantiomerically pure phosphaferrocenophanes where either phosphorus or phosphorus-containing chains link the two cyclopentadienyl rings are known to date.[14] Thus, in this work, 2-phospha-[3]ferrocenophane derivatives of the general formula **1** (Figure 2), including optically pure compounds, have been targeted as new bulky, rigid and electron-rich phosphanes for use in organometallic catalysis.



**1**

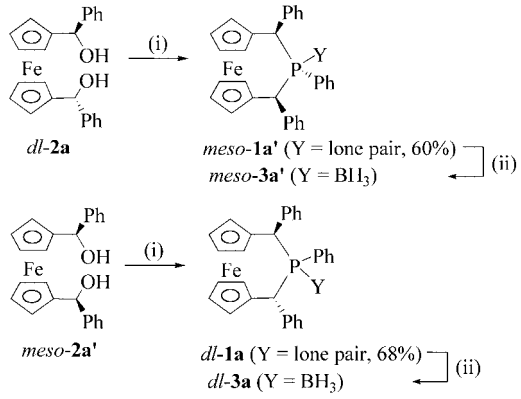
Figure 2. 2-Phospha[3]ferrocenophane derivatives **1**.

A key prerequisite for the synthesis of chiral derivatives is establishing reliable, stereospecific synthetic approaches to the [3]ferrocenophane scaffold; then convenient resolution procedures must be defined. The synthetic approach to 2-phospha[3]ferrocenophane shown in Scheme 1 is unlikely to be applied to the stereoselective synthesis of the targeted phospha[3]ferrocenophanes **1**, given that mixtures of all possible stereoisomers of **1** are expected to form as a result of such a procedure. Thus, alternative approaches that start from preformed, suitably substituted ferrocenes have been considered in this work. Known methods for the formation of P–C bonds from ferrocenylmethyl derivatives have been tested and adapted to the synthesis of the ferrocenophane derivatives **1**.

Since the pioneering work of Kumada and Hayashi, ferrocenylmethyl acetates or the corresponding ammonium salts have been routinely used for the synthesis of (ferrocenylmethyl)phosphanes through reactions with secondary phosphanes.[15] Starting from α-substituted derivatives, these highly stereospecific reactions take place with retention of the carbon configuration, because of the high configurational stability of the intermediate carbocation.

Although the use of primary phosphanes in such reactions has scarcely been reported,[6,16] the method might provide stereospecific access to 2-phospha[3]ferrocenophanes starting from 1,1′-bis(α-acetoxymethyl)ferrocenes. In preliminary experiments, however, the reaction of 1,1′-bis(α-acetoxybenzyl)ferrocene with phenylphosphane in usual experimental conditions (room temp. in acetic acid) afforded only trace amounts of the expected compounds, together with supposedly polymeric, insoluble material. We thus turned our attention to alternative starting materials and found that suitable reactants and conditions for the stereospecific synthesis of **1** must be selected for each of the targeted phosphanes. Especially, the availability of diastereomerically pure starting materials is a key prerequisite for these reactions.

For R = Ph, high-yield, stereospecific synthesis of **1a** and **1a′** has been performed from the *meso* and *dl* diols **2a′** and **2a** respectively, by their reactions with $PhPH_2$ in acetic acid (Scheme 2).



Reagents and conditions: (i) $PhPH_2$, 1 equiv., AcOH, 0°C to r.t. (ii) excess $BH_3$·THF

Scheme 2.

Diol **2a** can be obtained easily, albeit in an expensive and redundant way, by CBS reduction[17] of the corresponding diketone, 1,1′-dibenzoylferrocene. Alternatively,[18–20] diol **2a** can be obtained from the 1:1 mixture of the *meso* and *dl* diols produced by $NaBH_4$ reduction of 1,1′-dibenzoylferrocene, by repeated crystallisations from ethyl acetate/hexane. The *meso* diol **2a′** was obtained by fractional crystallisation of the *meso*/*dl* (2:1) diastereomeric mixture, which is produced when the same diketone is reduced with $LiAlH_4$ in ether.

The stereochemical course of the reactions of diols **2** with phenylphosphane (Scheme 2) follows the expected pattern: retention of the carbon configuration takes place in the first, intermolecular nucleophilic substitution step, while the intramolecular ring-closing reaction necessarily induces inversion of the carbon configuration. In both steps an iron-stabilised carbocation is formed after departure of the leaving group;[21] however, the entering nucleophiles approach the carbocation once from the face opposite the iron atom and once from the "iron face". Consequently, the *dl* diol **2a** affords the *meso* derivative, *anti*,*anti*-1,3-diphenyl-2-phospha[3]ferrocenophane **1a′**, while the *meso* diol **2a′** selectively affords the *dl* isomer **1a**.

The cyclisation reaction is best performed by adding phenylphosphane to an ice-cooled suspension of diols **2** in acetic acid and then warming the mixture to room temperature. Prolonged stirring of the diol in acetic acid should be avoided, in order to prevent epimerisation.

The [3]ferrocenophanes **1** are air-stable in the solid state and oxidise slowly in solution. These compounds, as well as the corresponding borane complexes **3**, have been fully

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

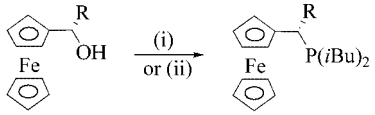
characterised. The crystal structure of the *dl* isomer **3a** has been determined by X-ray diffraction studies (see below). Phosphane **1a**′ and corresponding borane **3a**′ have been assigned as the *anti*,*anti* isomers, based on the small $^2J_{H-P}$ coupling (6.0 Hz) observed for the *CH*Ph protons in the $^1$H NMR spectrum of **1a**′.[22] This isomer is expected to be the thermodynamically favoured one.

The use of ferrocenylmethyl alcohols as precursors for phosphanes has been rather infrequently reported,[3d,16,23] the alcohols usually being converted into acetates before their reaction with phosphorus nucleophiles. Thus, having ascertained the high stereoselectivity of the reaction between diols **2a** and phenylphosphane in acetic acid, we wondered if the method could also be applied to the stereoselective synthesis of simpler phosphanes, directly from enantiomerically enriched alcohols. As a representative example, the commercially available diisobutylphosphane has been reacted with (*S*)-α-ferrocenylpentan-1-ol **4a**[24] and (*S*)-α-(ferrocenyl)benzyl alcohol **4b**.[25] In both cases the targeted phosphane could be obtained stereoselectively when suitable experimental conditions were applied.

The (α-ferrocenyl-1-pentyl)diisobutylphosphane **5a** is formed with total retention of the carbon configuration when diisobutylphosphane is added to a solution of (*S*)-**4a** in acetic acid at room temperature. However, in the same conditions, the substitution reaction on the α-(ferrocenyl)-benzyl alcohol (*S*)-**4b** induces partial racemisation of the carbon centre. Racemisation can be avoided by immediately adding the phosphane to an ice-cooled suspension of the chiral alcohol **4b** in acetic acid. This procedure avoids prolonged contact of alcohol **4b** with the acidic medium and thus allows a stereospecific substitution reaction to take place with the phosphane.

These results corroborate previous data showing lack of stereochemical control in the substitution reaction between **4b** and imidazoles in acidic medium and almost total retention of the carbon configuration in the analogous substitution on α-ferrocenylethanol at room temperature.[26] On the other hand, however, a stereospecific reaction has been reported by Hu to take place between **4b** and phenylphosphane in acetic acid at room temperature.[3d]

Taken together, the results shown in Scheme 3 and literature data afford additional evidence that the stereochemical course of the substitution reactions on the α-substituted(ferrocenyl) alcohols **4** and most particularly on α-aryl-



(*S*)-**4a** R = Bu (*ee* = 98%)
(*S*)-**4b** R = Ph (*ee* = 94%)
(*S*)-**4b** R = Ph (*ee* = 96%)

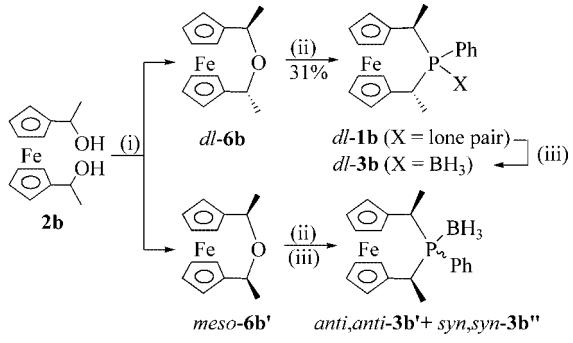
**5a** R = Bu, 90% yield, *ee* = 98%[(i)]
**5b** R = Ph, 65% yield, *ee* = 49%[(i)]
**5b** R = Ph, 86% yield, *ee* = 96%[(ii)]

Reagents and conditions: (i) slow addition of $i$Bu$_2$PH (1 equiv.) to a solution of **4** in AcOH, at r.t. (ii) rapid addition of $i$Bu$_2$PH (1 equiv.) to an ice-cooled suspension of **4** in AcOH.

Scheme 3.

substituted species depends on the nature of the entering nucleophile and/or on the precise experimental procedure, racemisation of the starting alcohol possibly being a competitive side reaction. Experimental conditions can be found where the substitution reaction overcomes the racemisation process induced by the acidic medium and the chiral alcohols **4** can be conveniently converted into the corresponding phosphanes by using nucleophilic phosphorus reagents.

Returning to our main aim, that is, the stereospecific synthesis of 2-phospha[3]ferrocenophanes, we next considered synthetic approaches to phosphanes **1b** (R = Me). In this case, the question arises of the availability of suitable, diastereomerically pure starting materials.[27] It is well known that the diastereomeric mixture of the 1,1′-bis(α-hydroxyethyl)ferrocenes **2b/2b**′ obtained by reduction of 1,1′-diacetylferrocene cannot be separated either by chromatography or by crystallisation. On the other hand, according to Yamakawa and Hisatome,[18] the corresponding diastereomeric 2-oxa[3]ferrocenophanes **6b/6b**′ are easily separable by column chromatography. The cyclic ethers **6**[28] have thus been selected as starting materials for the synthesis of phosphanes **1b**, which have been isolated as their borane complexes **3b**, according to the method shown in Scheme 4.



Reagents and conditions: (i) $HCl_{aq}$, column chromatography on silica gel. (ii) $PhPH_2$, $BF_3{\cdot}Et_2O$, $CH_2Cl_2$. (iii) $BH_3{\cdot}THF$

Scheme 4.

Treatment of diol **2b** (1:1 isomeric mixture) with aqueous HCl induces the ring-closure reaction and quantitatively affords the diastereomeric ethers **6**, which are easily separated by column chromatography on silica gel with hexane/ethyl acetate (9:1) as the eluent. The *meso*-**6b**′ isomer was eluted first ($R_f$ = 0.47), followed by the *dl* isomer **6b** ($R_f$ = 0.35).[29]

For the direct conversion of the cyclic ethers **6** into phosphanes, we envisioned a reaction with phenylphosphane in the presence of acid catalysts. Addition of the acid catalyst to the bridging oxygen atom is expected to generate a ferrocene-stabilised carbocation,[30] which should then react with the nucleophilic phosphane to afford a phosphonium salt intermediate. A second, intramolecular, acid-catalysed, nucleophilic substitution between the corresponding phosphane and the residual hydroxy function should then lead to the expected phospha[3]ferrocenophane **1b**. The use of both Brønsted and Lewis acid catalysts ($HBF_4$, $CF_3CO_2H$,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$BF_3{\cdot}Et_2O$, $SnCl_4$) has been considered. Boron trifluoride proved to be the best catalyst, affording the desired 2-phospha[3]ferrocenophanes **1b** in about 30% yield. The final phosphane–borane complexes are easily purified by column chromatography, given that the only side-products formed in the reaction are insoluble and probably polymeric.

The substitution reaction takes place with total stereoselectivity with respect to the carbon configuration, through a conceivably double inversion process. A single diastereoisomer is obtained from the *dl* ether **6b**, while a mixture of the *anti*,*anti* and *syn*,*syn* isomers **3b′** and **3b′′** respectively are formed from *meso*-**6b′**.

### X-ray Crystal Structures of the Borane Complexes of 2-Phospha[3]ferrocenophane

As compounds **1** and **3** are the first known, stereochemically defined, phosphorus-bridged ferrocenophanes, the molecular structure of one of them, the *dl*-triphenyl-substituted derivative **3a**, has been investigated by X-ray diffraction studies. Suitable single crystals of **3a** were obtained by slow crystallisation from ethyl acetate/hexane. The ORTEP drawing is presented in Figure 3.

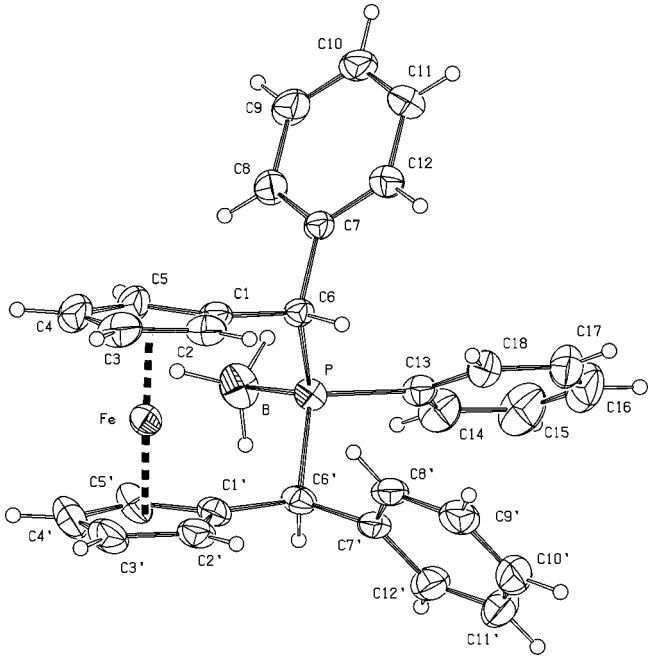


Figure 3. ORTEP drawing of *dl*-**3a**. Displacement ellipsoids are shown at the 30% probability level.

For comparison purposes, the carbon-unsubstituted *P*-phenylferrocenophane **3c** has been prepared from the corresponding oxa[3]ferrocenophane[31] and phenylphosphane (see Experimental Section) and structurally characterised (Figure 4). Comparative bond lengths and angles for compounds **3a** and **3c** are given in Table 1, together with relevant values for compound **I** from ref.[13]

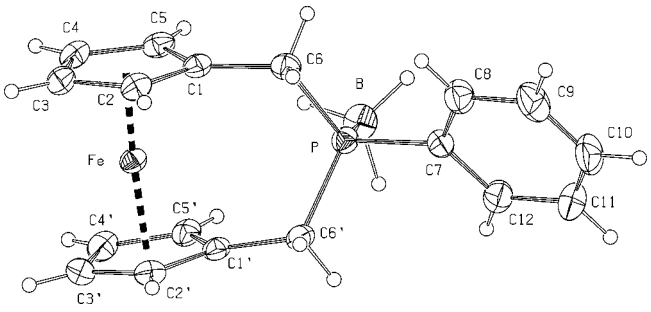

Figure 4. ORTEP view of the 2-phenyl-2-phospha[3]ferrocenophane borane complex **3c**. Displacement ellipsoids are shown at the 30% probability level.

Table 1. Selected bond lengths [Å] and angles [°] for **3a**, **3c** and **I** (see Scheme 1).

| | *dl*-**3a** | **3c** | **I**[13] |
|---|---|---|---|
| P–C6 | 1.855(2) | 1.826(3) | 1.899(2) |
| P–C6′ | 1.878(2) | 1.826(3) | 1.900(2) |
| P–C13 or P–C7 | 1.813(3) | 1.813(3) | 1.844(2) |
| P–B | 1.910(3) | 1.929(4) | |
| C1–C6 | 1.510(3) | 1.512(3) | 1.516(3) |
| C1′–C6′ | 1.515(3) | 1.508(3) | 1.516(3) |
| Fe–C1 | 2.025(2) | 2.024(3) | 2.034(2) |
| Fe–C1′ | 2.016(2) | 2.023(2) | 2.045(2) |
| C6–P–C6′ | 108.28(9) | 105.28(13) | 109.16(9) |
| B–P–C13 or C7 | 110.20(14) | 110.57(16) | |
| C7–C6–P | 110.72(14) | | 118.5(2) |
| C7′–C6′–P | 113.37(14) | | 104.8(2) |

The crystal structures of **3a** and **3c** display roughly the same preferred arrangement and geometrical features as other 2-phospha[3]ferrocenophane derivatives.[13,32]

The Cp rings of **3** and, consequently, the C1–C6 and C1′–C6′ bonds are almost perfectly eclipsed in a synperiplanar conformation. The ferrocenophane scaffold therefore shows a symmetry plane including the iron and phosphorus atoms. This symmetry plane will be lost in **3a** because of the presence of the stereogenic α-carbon atoms. The mean values for the Fe–C distances are identical in the two complexes at 2.035 Å.

In **3a**, the plane of the phenyl ring bonded to C6 forms a dihedral angle of 74.8° with the Cp ring (pseudoaxial position), while the phenyl bonded to C6′ has a dihedral angle of 40.6° with the Cp plane (pseudoequatorial position). The phenyl substituent on phosphorus occupies an *anti* position with respect to the ferrocenyl moiety, which should minimise steric repulsions.

In both phosphane–borane complexes **3**, the cyclopentadienyl rings are slightly tilted toward each other, with dihedral angles of 4.8° and 5.6° for **3a** and **3c** respectively. Moreover, the angles around the phosphorus atom are very close to the expected tetrahedral value (109.5°). This suggests a very low degree of ring strain induced by the three-atom tether.

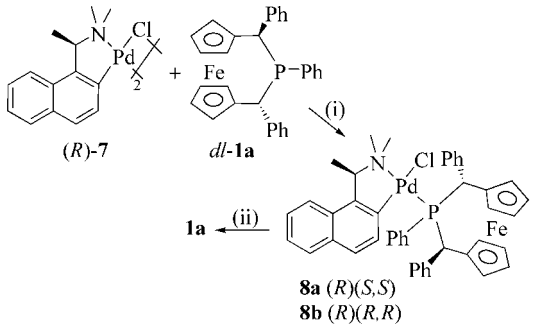
### Resolution of *dl*-1,2,3-Triphenyl-2-phospha[3]ferrocenophane

The final aim of our work is to set up the 2-phospha[3]ferrocenophane unit as a new structural motif for the de-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sign of chiral ligands. Thus, within these first and preliminary studies, the last step has been the search for a suitable resolution procedure for the representative phosphane **1a**. For this resolution process we envisioned the use of *ortho*-palladate derivatives of optically active amines whose versatility as resolving agents for Lewis bases has been largely demonstrated.[33] The choice of the chiral amine auxiliary proved crucial. Attempts to separate diastereomeric palladium complexes derived from either α-methylbenzylamine, *N*,*N*-dimethyl-α-methylbenzylamine or 1-(α-naphthyl)ethylamine were unsuccessful, however better results were obtained with the (*R*)-configured cyclopalladate complex **7**.[34]

The (*R*)-configured cyclopalladate complex **7** was treated with the racemic 1,2,3-triphenyl-2-phospha[3]ferrocenophane *dl*-**1a** to afford a 1:1 mixture of the mononuclear diastereomeric complexes **8a** and **8b** by displacement of the chloride bridge (Scheme 5). Separation of the mixture proved to be straightforward: column chromatography on silica gel with a heptane/ethyl acetate (8:2) mixture as the eluent afforded **8a** and **8b** separately ($R_f$ = 0.5 and 0.3 respectively in heptane/ethyl acetate, 6:4). An X-ray crystal structure of **8a** allowed assignment of the relative configuration of the phospha[3]ferrocene ligand with respect to the known (*R*) configuration of the amine fragment. In complex **8a** the 1,2,3-triphenyl-2-phospha[3]ferrocenophane has an (*S*,*S*) configuration (Figure 5).



Reagents and conditions: (i) acetone, r.t., 2h, chromatographic separation of the diastereomeric complexes **8**; (ii) dppe, $CH_2Cl_2$, r.t., 3h

Scheme 5.

Compared to the X-ray structures of compounds **3a** and **3c**, the special feature of the ferrocenophane moiety in **8a** is the synclinal staggered conformation of the cyclopentadienyl rings. The dihedral angle between the Cp rings is 11.7°, that is, slightly larger than in the corresponding borane complex **3c**. This distorted conformation may result from steric constraints in the hindered palladium complex.

Decomplexation of phosphane **1a** from **8** was performed according to the standard method, by reaction with the chelating diphosphane dppe, in dichloromethane, followed by separation on a short silica column. The optically active (*S*,*S*)-1,2,3-triphenyl-2-phospha[3]ferrocenophane **1a** obtained from **8a** gave $[a]_D$ = +392 (*c* = 0.2, $CHCl_3$).

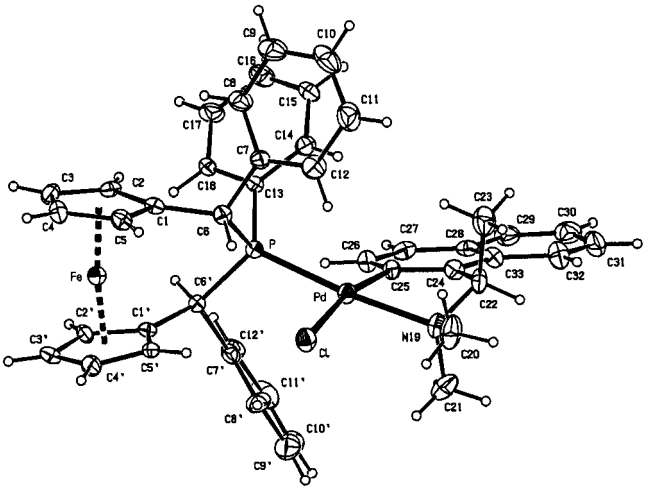


Figure 5. ORTEP view of the cyclopalladate complex **8a**. Displacement ellipsoids are shown at the 30% probability level.

## Conclusions

This work demonstrates an unprecedented synthetic approach to the 2-phospha[3]ferrocenophane scaffold, which allows the stereospecific synthesis of α,α′-disubstituted derivatives. Moreover, optical resolution of the 2-phospha[3]-ferrocenophane **1a**, which contains stereogenic carbon atoms in the three-atom bridge, has been performed. These preliminary studies open the way to the development of a new family of phosphorus ligands based on the 2-phospha[3]ferrocenophane unit as a new chiral cyclic scaffold.

## Experimental Section

NMR spectra were recorded with Bruker Avance 300 or Avance 500 spectrometers in $CDCl_3$ solutions. Chemical shifts are reported in ppm with reference to the residual solvent peak ($CHCl_3$) for $^1H$ and $^{13}C$. Mass spectra were run on LCT Waters-Micromass (Electrospray) or on a MALDI-TOF Perseptive Biosystem Voyager DE-STR (HRMS). $[a]_D$ values were recorded with a Jasco P-1010 polarimeter at 20 °C. All reactions were carried out under argon.

**General Procedure for the Synthesis of the 1,2,3-Triphenyl-2-phospha[3]ferrocenophanes 1a,1a′ and Their Borane Complexes 3a,3a′:** The known 1,1′-bis(hydroxybenzyl)ferrocenes **2a** and **2a′** were obtained according to literature methods.[18,19] NMR spectra are in good agreement with those reported previously.[17c,19] $^1H$ NMR ($CDCl_3$), *dl*-**2a**: δ = 4.17 (s, 2 H), 4.23 (s, 2 H), 4.28 (s, 2 H), 4.29 (2 H, OH), 4.46 (s, 2 H), 5.55 (s, 2 H, CHPh), 7.2–7.3 (10 H, Ph); *meso* **2a′**: δ = 4.12 (s, 2 H), 4.21 (s, 2 H), 4.25 (s, 2 H), 4.29 (2 H, OH), 4.33 (s, 2 H), 5.54 (s, 2 H, CHPh), 7.2–7.4 (10 H, Ph) ppm.

A Schlenk tube was charged with acetic acid (6 mL) and ice-cooled under argon for about 10 min. The 1,1′-bis(hydroxybenzyl)ferrocene **2** (0.2 g, 0.5 mmol) was added at once, followed by addition of phenylphosphane (60 μL, 0.6 mmol). The mixture was warmed slowly to room temperature while stirring for about 1 h. The solvent was removed under vacuum. In order to remove the residual solvents, degassed $CH_2Cl_2$ was added and removed again under vacuum to afford an orange solid. Starting from the *meso* isomer **2a′**, $^1H$ NMR of the crude mixture shows formation of *dl*-**1a** as the single diastereomer of the final product. Starting from *dl*-**2a**,

the thermodynamically favoured *anti*,*anti* isomer **1a′** has been obtained as the major product. Phosphanes **1a** and **1a′** have been purified by column chromatography under argon.

To obtain the borane complexes **3a** or **3a′**, the crude product isolated from the reaction above after removal of acetic acid was dissolved in THF. An excess of $BH_3$·THF adduct (1.6 mL, 1 M solution in THF) was added at room temperature. After evaporation of the solvent, the final product was purified by column chromatography.

***anti*,*syn*-1,2,3-Triphenyl-2-phospha[3]ferrocenophane (1a):** Complex **1a** was purified by column chromatography on silica gel with hexane/ethyl acetate (90:10) as the eluent ($R_f$ = 0.5). It was obtained as an orange solid in 68% yield (160 mg). $^1$H NMR ($CDCl_3$): $\delta$ = 4.00 (d, $J_{H,P}$ = 12.5 Hz, 1 H, CHPh), 4.09 (d, $J_{H,P}$ = 5.0 Hz, 1 H, CHPh), 4.13 (m, 1 H, Cp), 4.14 (m, 1 H, Cp), 4.15 (m, 1 H, Cp), 4.18 (m, 1 H, Cp), 4.22 (m, 1 H, Cp), 4.29 (m, 1 H, Cp), 4.34 (m, 1 H, Cp), 4.41 (m, 1 H, Cp), 6.80 (t, 2 H), 6.95 (4 H), 7.06 (4 H), 7.21 (3 H), 7.39 (d, $J$ = 7.5 Hz, 2 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 35.9 (d, $^1J_{P,C}$ = 18.6 Hz, PCH), 44.8 (d, $^1J_{P,C}$ = 24.0 Hz, PCH), 68.1 ($CH_{Cp}$), 68.3 ($CH_{Cp}$), 68.5 (d, $J_{P,C}$ = 6.3 Hz, $CH_{Cp}$), 68.8 ($CH_{Cp}$), 69.1 ($CH_{Cp}$), 69.5 (d, $J_{P,C}$ = 9.2 Hz, $CH_{Cp}$), 69.7 ($CH_{Cp}$), 70.4 (d, $J_{P,C}$ = 4.2 Hz, $CH_{Cp}$), 85.5 (d, $^1J_{P,C}$ = 7.4 Hz, $C_{Cp}$), 87.3 (d, $^1J_{P,C}$ = 15.5 Hz, $C_{Cp}$), 126.0, 126.1, 127.2, 127.3, 127.6, 128.3, 128.6, 128.7, 128.8, 133.2, 133.3, 134.5 (d, $^1J_{P,C}$ = 20.5 Hz, $C_{Ph}$), 137.5 (d, $^2J_{P,C}$ = 6.6 Hz, $C_{Ph}$), 141.4 (d, $^2J_{P,C}$ = 14.4 Hz, $C_{Ph}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 26 ppm. MS (MALDI): *m*/*z* (%) = 472.1 (100) [M]. HRMS: calcd. for $C_{30}H_{26}FeP$ [M + H] 473.1099; found 473.1122.

**Borane Complex of *anti*,*syn*-1,2,3-Triphenyl-2-phospha[3]ferrocenophane (3a):** Column chromatography was performed with hexane/ethyl acetate, 80:20 ($R_f$ = 0.4) to afford **3a** as a yellow-orange solid. $^1$H NMR ($CDCl_3$): $\delta$ = 4.19 (m, 1 H, Cp), 4.21 (d, $J_{H,P}$ = 4.7 Hz, 1 H, CHPh), 4.24 (m, 1 H, Cp), 4.28 (m, 1 H, Cp), 4.34 (m, 1 H, Cp), 4.37 (m, 2 H, Cp), 4.46 (d, $J_{H,P}$ = 18.3 Hz, 1 H, CHPh), 5.19 (m, 2 H, Cp), 6.9–7.2 (13 H, Ph), 7.50 (2 H, Ph) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 34.0 (d, $^1J_{P,C}$ = 27.3 Hz, PCH), 46.7 (d, $^1J_{P,C}$ = 26.3 Hz, PCH), 68.3 ($CH_{Cp}$), 68.4 ($CH_{Cp}$), 70.4 ($CH_{Cp}$), 70.5 ($CH_{Cp}$), 70.7 ($CH_{Cp}$), 71.0 ($CH_{Cp}$), 71.1 ($CH_{Cp}$), 81.7 ($C_{Cp}$), 83.8 ($C_{Cp}$), 127.1, 127.4, 127.5, 128.1, 129.6, 130.0, 130.1, 130.4, 132.3, 132.4 ($CH_{Ph}$), 136.6 ($C_{Ph}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 55 ppm. HRMS (MALDI): calcd. for $C_{30}H_{25}FeP$ [M – $BH_3$] 472.1043; found 472.1031.

***anti*,*anti*-1,2,3-Triphenyl-2-phospha[3]ferrocenophane (1a′):** Complex **1a** was purified by column chromatography on silica gel with hexane/ethyl acetate (90:10) as the eluent ($R_f$ = 0.5). It was obtained in 60% yield (70 mg, starting from 0.25 mmol of **2a**) as an orange solid. $^1$H NMR ($CDCl_3$): $\delta$ = 4.05 (d, $J_{H,P}$ = 6.0 Hz, 2 H, CHPh), 4.08 (m, 2 H, Cp), 4.26 (m, 2 H, Cp), 4.33 (m, 2 H, Cp), 4.88 (m, 2 H, Cp), 6.9 (t, 2 H), 7.0–7.1 (6 H), 7.2 (4 H), 7.2–7.3 (4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 48.7 (d, $^1J_{P,C}$ = 15.8 Hz, PCH), 67.8, 68.7 (d, $J_{P,C}$ = 7.2 Hz, Cp), 69.8, 70.2 (d, $J_{P,C}$ = 3.9 Hz, Cp), 86.8 (d, $^1J_{P,C}$ = 12.8 Hz, $C_{Cp}$), 125.9, 127.6, 127.7, 128.1, 128.2, 129.0, 133.0, 133.3 ($CH_{Ph}$), 135.9 (d, $^1J_{C,P}$ = 16.0 Hz, $PC_{Ph}$), 141.5 (d, $^2J_{C,P}$ = 11.4 Hz, $C_{Ph}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 21 ppm.

**Borane Complex of *anti*,*anti*-1,2,3-Triphenyl-2-phospha[3]ferrocenophane (3a′):** Column chromatography was performed with hexane/ethyl acetate (80:20) ($R_f$ = 0.4) to afford 150 mg of **3a′** (63% yield) as a yellow-orange solid. $^1$H NMR ($CDCl_3$): $\delta$ = 4.08 (m, 2 H, Cp), 4.19 (d, $J_{H,P}$ = 17.7 Hz, 2 H, CHPh), 4.20 (m, 2 H, Cp), 4.29 (m, 2 H, Cp), 5.17 (m, 2 H, Cp), 6.9–7.0 (6 H, Ph), 7.1 (4 H, Ph), 7.1–7.33 (3 H, Ph), 7.55 (t, 2 H, Ph) ppm. $^{13}$C NMR (selected data, $CDCl_3$): $\delta$ = 45.8 (d, $^1J_{P,C}$ = 29.1 Hz, PCH), 68.6 ($CH_{Cp}$), 70.9 ($CH_{Cp}$), 71.1 ($CH_{Cp}$), 71.2 ($CH_{Cp}$), 83.1 ($C_{Cp}$), 126.8, 126.9, 127.6, 128.1, 128.2, 129.7, 129.8, 131.1, 132.4, 132.5 ($CH_{Ph}$), 136.5 ($C_{Ph}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 51 ppm. MS (MALDI): *m*/*z* (%) = 472.1 (100) [M – $BH_3$].

**(*S*)-1-Ferrocenylpentan-1-ol (4a):**[24] A solution of borane–dimethyl sulfide complex (1.0 mL, 10 mmol) in anhydrous THF (about 10 mL) was prepared under argon. A fifth of this solution (2.2 mL) was added to a solution of (*R*)-2-methyl-CBS-oxazaborolidine in toluene (1 M, 3.0 mL, 3.0 mmol) under argon. The remaining $BH_3$–$Me_2S$ solution and a solution of pentanoylferrocene (2.70 g, 10.0 mmol) in THF (10 mL) under argon were added simultaneously to this mixture at 0 °C. The addition was carried out over about 60 min. The mixture was stirred for another 60 min at 0 °C, then quenched by dropwise addition of methanol (2 mL) and satd. aqueous $NH_4Cl$ (8 mL). The aqueous layer was extracted with diethyl ether. The organic phases were combined, washed with water and brine, and dried with magnesium sulfate. Purification by column chromatography (eluent: heptane/ethyl acetate, 5:1) gave (*S*)-1-ferrocenylpentan-1-ol as an amber-orange oil. Yield: 2.51 g (92%). $^1$H NMR ($CDCl_3$): $\delta$ = 0.92 (t, $J_{H,H}$ = 7.0 Hz, 3 H, Me), 1.3–1.5 (m, 4 H, $CH_2$), 1.6–1.7 (m, 2 H, $CH_2$), 1.94 (d, $^3J_{H,H}$ = 3.5 Hz, 1 H, OH), 4.2 (m, 3 H, $CH_{Cp}$), 4.23 (s, 5 H, Cp), 4.27 (1 H, $CH_{Cp}$), 4.33 (m, 1 H, CHOH) ppm. HPLC [Chiralpak AD; *n*-hexane/isopropyl alcohol, 98:2, 1 mL/min; $t_R$/min = 17.2 (*R*), 23.7 (*S*)]: *ee* = 98%. $[\alpha]_D$ = +45 ($c$ = 1, $CHCl_3$).

**(*S*)-(α-Ferrocenylpentyl)diisobutylphosphane (5a):** Diisobutylphosphane (4 mL) in hexane (10 wt.-% solution, about 1.8 mmol) was added to a degassed solution of (*S*)-1-ferrocenylpentan-1-ol (275 mg, 1.0 mmol) in degassed acetic acid (10 mL) under argon. The mixture was stirred overnight under argon at room temperature. The solvent and the remaining diisobutylphosphane were evaporated under vacuum. The residue was purified by chromatography on a short silica gel column, under argon. Elution with heptane/ethyl acetate (5:1) gave (*S*)-(1-ferrocenylpentyl)diisobutylphosphane as an amber-coloured oil. Yield: 360 mg (90%). $^{31}$P NMR ($CDCl_3$): $\delta$ = –28 ppm. HRMS: calcd. for $C_{23}H_{38}FeP$ [M + H] 401.2041; found 401.2061. $[\alpha]_D$ = –39 ($c$ = 0.1, $CHCl_3$); *ee* = 98%. NMR characterisation has been performed on the corresponding borane complex, **5a**·$BH_3$: $^1$H NMR ($CDCl_3$): $\delta$ = 0.92 (d, $^3J$ = 6.6 Hz, 3 H, Me), 0.95 (d, $^3J$ = 6.6 Hz, 3 H, Me), 1.03 (t, 3 H, Me), 1.04 (d, $^3J$ = 6.9 Hz, 6 H, Me), 1.2–1.7 (7 H, $CH_2$, CH), 1.8–2.1 (5 H, $CH_2$, CH), 2.50 (ddd, $J$ = 8.1, $J$ = 6.6, $J$ = 4.5 Hz, 1 H, CHP), 3.97 (1 H, $CH_{Cp}$), 4.08 (1 H, $CH_{Cp}$), 4.19 (s, 5 H, Cp), 4.2 (2 H, $CH_{Cp}$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 14.0 (Me), 23.0 ($CH_2$), 24.0, 24.3, 24.6 (d, $J_{P,C}$ = 2.0 Hz), 24.7 (d, $J_{P,C}$ = 1.0 Hz), 25.1 (d, $J_{P,C}$ = 7.5 Hz), 25.3 (d, $J_{P,C}$ = 7.8 Hz), 31.1 (d, $^1J_{P,C}$ = 30.1 Hz, $PCH_2$), 31.4 (d, $J_{P,C}$ = 3.5 Hz, $CH_2$), 32.7 (d, $^1J_{P,C}$ = 30.3 Hz, $PCH_2$), 33.1 (d, $J_{P,C}$ = 3.5 Hz, $CH_2$), 36.0 (d, $^1J_{P,C}$ = 26.9 Hz, PCH), 66.9 ($CH_{Cp}$), 67.2 ($CH_{Cp}$), 67.9 ($CH_{Cp}$), 68.7 ($CH_{Cp}$), 69.0 (Cp), 88.7 (d, $J_{P,C}$ = 4.1 Hz, $C_{Cp}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 23 ppm. $[\alpha]_D$ = –35 ($c$ = 0.1, $CHCl_3$). The enantiomeric excess of **5a** was determined by HPLC analysis of the corresponding oxide, which was prepared as follows: (*S*)-(1-ferrocenylpentyl)diisobutylphosphane (100 mg, 0.25 mmol) was dissolved in acetone (about 2 mL), and hydrogen peroxide (35 wt.-% solution in water) was added. The mixture was stirred overnight at room temp. After addition of water, the aqueous phase was extracted with dichloromethane. The organic layer was washed with brine, dried with magnesium sulfate and concentrated to give (*S*)-(1-ferrocenylpentyl)diisobutylphosphane oxide as a red-brown oil. $^1$H NMR ($CDCl_3$): $\delta$ = 0.98–1.07 (15 H, Me), 1.3–2.1 (12 H, $CH_2$, CH), 2.71 (ddd, $J$ = 16.2, $J$ = 6.6, $J$ = 4.5 Hz, 1 H, CHP), 4.01 (1 H, $CH_{Cp}$), 4.16 (2 H, $CH_{Cp}$), 4.17 (s, 5 H, Cp), 4.22 (1 H, $CH_{Cp}$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 14.0

(Me), 23.3 ($CH_2$), 23.5 (d, $J_{P,C}$ = 3.5 Hz), 23.6 (d, $J_{P,C}$ = 3.6 Hz), 24.5–25.0 (5 C), 30.1 ($CH_2$), 32.7 (d, $J$ = 3.2 Hz, $CH_2$), 34.5 (d, $J$ = 61.7 Hz, $PCH_2$), 36.1 (d, $J$ = 61.8 Hz, $PCH_2$), 40.4 (d, $J$ = 58.1 Hz, PCH), 66.9 ($CH_{Cp}$), 67.3 ($CH_{Cp}$), 67.7 ($CH_{Cp}$), 68.2 ($CH_{Cp}$), 68.8 (Cp), 88.3 ($C_{Cp}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 49 ppm. HPLC (Chiralcel OD; *n*-hexane/2-propanol, 98:2, 1 mL/min) $t_R$/min = 10.0 (*R*), 11.3 (*S*).

**(*S*)-(α-Ferrocenylbenzyl)diisobutylphosphane (5b):** (a) Phosphane **5b** was first prepared by following the same procedure used for the synthesis of **5a**. Starting from (*S*)-ferrocenylbenzyl alcohol **4b**[17a,30] (290 mg, 1.0 mmol, 94% *ee*), phosphane **5b** was obtained as a pale orange solid after chromatography (silica gel, heptane/ethyl acetate, 9:1). Yield 270 mg (65%); *ee* = 49%. (b) The same phosphane **5b** was then prepared as follows: (*S*)-ferrocenylbenzyl alcohol **4b** (1 mmol, 96% *ee*) was added to ice-cooled acetic acid (10 mL) under argon, and diisobutylphosphane was added immediately to the yellow suspension without waiting for the alcohol to be dissolved. The mixture was warmed slowly to room temperature. After overnight stirring, workup was performed as described above for **5a**. Phosphane **5b** was obtained in 86% yield (360 mg); *ee* = 96%. $^1$H NMR ($CDCl_3$): $\delta$ = 0.77 (d, $^3J$ = 6.5 Hz, 3 H, Me), 0.83 (d, $^3J$ = 6.5 Hz, 3 H, Me), 0.85 (d, $^3J$ = 6.5 Hz, 3 H, Me), 0.92 (d, $^3J$ = 6.5 Hz, 3 H, Me), 1.1 (m, 3 H), 1.3 (m, 2 H), 1.38 (m, $J$ = 6.5 Hz, 1 H, CHMe), 3.39 (d, $^1J_{H-P}$ = 5.0 Hz, CHP), 3.78 (s, 5 H, Cp), 4.08 (1 H, $CH_{Cp}$), 4.12 (1 H, $CH_{Cp}$), 4.14 (1 H, $CH_{Cp}$), 4.18 (1 H, $CH_{Cp}$), 7.2–7.4 (5 H, Ph) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 23.8 (d, $^3J_{P,C}$ = 9.0 Hz, Me), 24.0 (d, $^3J_{P,C}$ = 9.2 Hz, Me), 24.2 (Me), 24.3 (Me), 26.18, 26.28, 26.38, 26.48 (*CH*Me), 38.7 (d, $^1J_{P,C}$ = 17.5 Hz, $PCH_2$), 38.8 (d, $^1J_{P,C}$ = 17.5 Hz, $PCH_2$), 48.3 (d, $^1J_{P,C}$ = 15.6 Hz, PCH), 66.2 ($CH_{Cp}$), 67.3 (d, $J_{C,P}$ = 5.2 Hz, $CH_{Cp}$), 68.1 ($CH_{Cp}$), 68.4 (Cp), 69.4 ($CH_{Cp}$), 91.2 (d, $^2J_{C,P}$ = 14.9 Hz, $C_{Cp}$), 126.1, 127.9, 129.0, 129.1 ($CH_{Ph}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = –14 ppm. HRMS: calcd. for $C_{25}H_{34}FeP$ [M + H] 421.1748; found 421.1738. The enantiomeric excess of the phosphane was determined by HPLC analysis of the corresponding oxide, which was prepared as described above. $^1$H NMR ($CDCl_3$): $\delta$ = 0.88 (d, $^3J$ = 6.5 Hz, 3 H, Me), 0.90 (d, $^3J$ = 7.0 Hz, 3 H, Me), 0.93 (d, $^3J$ = 6.5 Hz, 3 H, Me), 0.99 (d, $^3J$ = 6.5 Hz, 3 H, Me), 1.3–1.5 (4 H), 1.8–1.9 (2 H, *CH*Me$_2$), 3.75 (d, $^1J_{H-P}$ = 12.5 Hz, CHP), 3.79 (s, 5 H, Cp), 4.15 (1 H, $CH_{Cp}$), 4.18 (1 H, $CH_{Cp}$), 4.31 (1 H, $CH_{Cp}$), 4.35 (1 H, $CH_{Cp}$), 7.34 (1 H, Ph), 7.43 (2 H, Ph), 7.54 (2 H, Ph) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 23.7 (dd, 2 × *CH*Me), 24.4 (Me), 24.5 (Me), 24.9 (dd, 2 × Me), 36.5 (d, $^1J_{P,C}$ = 62.0 Hz, $PCH_2$), 36.6 (d, $^1J_{P,C}$ = 61.2 Hz, $PCH_2$), 49.9 (d, $^1J_{P,C}$ = 56.1 Hz, PCH), 66.9 ($CH_{Cp}$), 68.3 (d, $J_{C,P}$ = 2.2 Hz, $CH_{Cp}$), 68.5 (Cp), 68.6 ($CH_{Cp}$), 70.0 (d, $J_{C,P}$ = 2.1 Hz, $CH_{Cp}$), 85.6 ($C_{Cp}$), 127.2 (d, $J_{C,P}$ = 1.6 Hz, $CH_{Ph}$), 128.3, 128.4, 129.7, 129.8 ($CH_{Ph}$), 138.5 (d, $J_{C,P}$ = 3.3 Hz, $C_{Ph}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 45 ppm. HPLC (Chiralpak AD column, *n*-hexane/2-propanol, 93:7, 1 mL/min) $t_R$/min = 8.3 (*S*), 13.9 (*R*).

### Syntheses of the Borane Complexes of 1,3-Dimethyl-2-phenyl-2-phospha[3]ferrocenophane (6b, 6b′ and 3b)

**(a) 1,3-Dimethyl-2-oxa[3]ferrocenophanes, 6b,b′:**[28] 1,1′-Bis(acetyl)ferrocene (3.0 g, 11 mmol) was reduced with $NaBH_4$ in methanol. After hydrolysis and extraction in ether, the ether solution of crude 1,1′-bis(α-hydroxyethyl)ferrocene was acidified with aqueous HCl (1 N). After 1 h of stirring at room temperature, the organic layer was separated, dried with $MgSO_4$ and the final product was submitted to column chromatography. Elution with hexane/ethyl acetate (9:1) afforded 1.2 g (41% yield) of *meso*-**6b′** ($R_f$ = 0.47), followed by 1.1 g (38% yield) of *dl*-**6b** ($R_f$ = 0.35). *meso*-**6b′**: $^1$H NMR ($CDCl_3$): $\delta$ = 1.54 (d, $^3J_{H,H}$ = 6.5 Hz, 6 H, Me), 3.84 (q, $^3J_{H,H}$ = 6.5 Hz, 2 H, C*H*Me), 4.05 (m, 2 H), 4.17 (m, 2 H), 4.27 (m, 4 H) ppm. HRMS: calcd. for $C_{14}H_{16}FeO$ 256.0551; found 256.0531. *dl*-**6b**: $^1$H NMR ($CDCl_3$): $\delta$ = 1.48 (d, $^3J_{H,H}$ = 7.0 Hz, 6 H, Me), 4.12 (m, 4 H), 4.22 (m, 2 H), 4.24 (m, 2 H), 4.34 (q, $^3J_{H,H}$ = 7.0 Hz, 2 H, C*H*Me) ppm. HRMS: calcd. for $C_{14}H_{16}FeO$ 256.0551; found 256.0523.

**(b) 3b:** A solution of $BF_3$·$Et_2O$ (0.28 mL, 2 mmol) in $CH_2Cl_2$ (5 mL) was added to a solution containing 1,3-dimethyl-2-oxa[3]-ferrocenophane (250 mg, 0.98 mmol) and phenylphosphane (0.12 mL, 1.1 mmol) in dichloromethane (20 mL) at room temperature. After two hours of stirring, an excess of $BH_3$·THF was added (2 mL, 1 M solution). The mixture was hydrolysed with water. The organic layer was dried with $MgSO_4$. After evaporation of the solvents, the crude product was purified by chromatography on silica gel with hexane/ethyl acetate (8:2) as the eluent. The borane complex **3b** was purified by column chromatography.

**Borane Complex of *anti*,*syn*-1,3-Dimethyl-2-phenyl-2-phospha[3]ferrocenophane (3b):** Complex **3b** was obtained in 31% yield (105 mg) as a yellow solid after column chromatography with hexane/ethyl acetate (9:1) as the eluent ($R_f$ = 0.5). $^1$H NMR ($CDCl_3$): $\delta$ = 1.15 (dd, $^3J$ = 12.5, $^3J$ = 7.5 Hz, 3 H, Me), 1.45 (dd, $^3J$ = 15.5, $^3J$ = 7.0 Hz, 3 H, Me), 2.83 (qd, $^3J$ = 7.5, $^2J_{H-P}$ = 3.0 Hz, 1 H, C*H*Me), 3.16 (dq, $^2J_{H-P}$ = 16.5, $^3J$ = 7.0 Hz, 1 H, C*H*Me), 4.04 (m, 1 H, $CH_{Cp}$), 4.11 (m, 1 H, $CH_{Cp}$), 4.14 (m, 1 H, $CH_{Cp}$), 4.16 (m, 1 H, $CH_{Cp}$), 4.23 (m, 1 H, $CH_{Cp}$), 4.25 (m, 1 H, $CH_{Cp}$), 4.72 (m, 1 H, $CH_{Cp}$), 4.87 (m, 1 H, $CH_{Cp}$), 7.54 (3 H, Ph), 7.87 (2 H, Ph) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 14.1 (d, $^2J_{P,C}$ = 6.9 Hz, Me), 16.8 (d, $^2J_{P,C}$ = 7.0 Hz, Me), 19.2 (d, $^1J_{P,C}$ = 32.4 Hz, *CH*Me), 29.4 (d, $^1J_{P,C}$ = 32.0 Hz, *CH*Me), 67.2 ($CH_{Cp}$), 67.6 ($CH_{Cp}$), 67.8 (d, $J_{P,C}$ = 4.1 Hz, $CH_{Cp}$), 69.8 (d, $J_{P,C}$ = 6.1 Hz, $CH_{Cp}$), 70.1 ($CH_{Cp}$), 70.2 ($CH_{Cp}$), 70.5 ($CH_{Cp}$), 71.6 ($CH_{Cp}$), 84.1 ($C_{Cp}$), 84.4 ($C_{Cp}$), 128.6, 127.8 ($CH_{Ph}$), 129.6 (d, $^1J_{C,P}$ = 43.3 Hz, $C_{Ph}$), 130.9 (d, $J_{C,P}$ = 2.2 Hz, $CH_{Ph}$), 132.1 ($CH_{Ph}$), 132.2 ($CH_{Ph}$) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 57 ppm. HRMS: calcd. for $C_{20}H_{21}FeP$ [M – $BH_3$] 348.0730; found 348.0741.

**Borane Complexes of *syn*,*syn*- and *anti*,*anti*-1,3-Dimethyl-2-phenyl-2-phospha[3]ferrocenophane (3b′ and 3b′′):** The diastereomeric mixture of *anti*,*anti* and *syn*,*syn* isomers of the 1,3-dimethyl-2-phenyl-2-phospha[3]ferrocenophane borane complexes **3b′** and **3b′′** was characterised by mass spectrometry and $^1$H NMR spectroscopy. ESI-MS: *m*/*z* (%) = 348 (100) [M]. A sample of pure *syn*,*syn*-**3b′′** was obtained by chromatography. *syn*,*syn*-**3b′′**: $^1$H NMR ($CDCl_3$): $\delta$ = 1.37 (dd, $^3J$ = 15.9, $^3J$ = 7.5 Hz, 6 H, Me), 2.92 (dq, $^2J_{H-P} \approx {}^3J_{H,H}$ = 7.5 Hz, 2 H, C*H*Me), 4.12 (m, 2 H, $CH_{Cp}$), 4.17 (m, 4 H, $CH_{Cp}$), 4.23 (m, 2 H, $CH_{Cp}$), 7.5 (3 H, Ph), 8.2 (2 H, Ph) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 17.7 (Me), 30.0 (d, $^1J_{P,C}$ = 32.9 Hz, *CH*Me), 67.6 ($CH_{Cp}$), 68.5 ($CH_{Cp}$), 69.9 ($CH_{Cp}$), 71.5 (d, $J$ = 5.2 Hz, $CH_{Cp}$), 88.7 ($C_{Cp}$), 128.5, 131.4, 134.7 ($CH_{Ph}$) ppm. *anti*,*anti*-**3b′** was characterised from the mixture of isomers: $^1$H NMR ($CDCl_3$): $\delta$ = 1.19 (dd, $^3J_{H-P}$ = 15.5, $^3J$ = 7.0 Hz, 6 H, Me), 2.85 (dq, $^2J_{H-P}$ = 16.5, $^3J_{H,H}$ = 7.0 Hz, 2 H, C*H*Me), 4.07 (m, 2 H, $CH_{Cp}$), 4.12 (m, 2 H, $CH_{Cp}$), 4.21 (m, 2 H, $CH_{Cp}$), 4.72 (m, 2 H, $CH_{Cp}$), 7.5 (3 H, Ph), 7.9 (2 H, Ph) ppm.

**Synthesis of the Borane Complex of 2-Phenyl-2-phospha[3]ferrocenophane (3c):** (a) 2-Oxa[3]ferrocenophane.[35] A solution of 1,1′-bis-(hydroxymethyl)ferrocene (107 mg, 0.43 mmol) in HCl (1 M)/ether (1:1, 12 mL) was stirred vigorously for 6 h. The layers were separated and the organic layer dried with $MgSO_4$, filtered and concentrated in vacuo. The crude product was purified by flash chromatography (hexane/ethyl acetate, 8:2) to yield 81 mg (82%) of the desired compound as an orange solid. $^1$H NMR ($CDCl_3$): $\delta$ = 3.92 (s, 4 H, $CH_2$), 4.17–4.19 ($CH_{Cp}$, 8 H, $A_2B_2$) ppm. $^{13}$C NMR

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

($CDCl_3$): $\delta$ = 64.6 ($OCH_2$), 69.9 ($CH_{Cp}$), 70.1 ($CH_{Cp}$), 83.2 ($C_{Cp}$) ppm.

(b) The same experimental procedure as for the synthesis of **3b** was applied, starting from 2-oxa[3]ferrocenophane. Compound **3c** was obtained in 17% yield as a yellow-orange solid. $^1H$ NMR ($CDCl_3$): $\delta$ = 2.55 (t, $J_{H,P} = J_{H,H}$ = 15.0 Hz, 2 H, $CH_2$), 2.65 (d, $J_{H,H}$ = 14.0 Hz, 2 H, $CH_2$), 4.02 (s, 2 H, $CH_{Cp}$), 4.11 (s, 2 H, $CH_{Cp}$), 4.22 (s, 2 H, $CH_{Cp}$), 4.61 (s, 2 H, $CH_{Cp}$), 7.56 (3 H, Ph), 7.91 (2 H, Ph) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 22.5 (d, $^1J_{P,C}$ = 34.6 Hz, $PCH_2$), 68.0 ($CH_{Cp}$), 69.8 ($CH_{Cp}$), 70.8 (d, $J_{P,C}$ = 5.1 Hz, $CH_{Cp}$), 71.6 ($CH_{Cp}$), 78.5 (d, $^2J_{P,C}$ = 4.6 Hz, $C_{Cp}$), 128.9, 129.0 ($CH_{Ph}$), 130.3 (d, $^1J_{C,P}$ = 48.8 Hz, CPh), 131.3, 131.4 ($CH_{Ph}$) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 46 ppm. HRMS (MALDI): calcd. for $C_{18}H_{17}PFe$ [M – $BH_3$] 320.0417; found 320.0412.

**Resolution of *dl*-1,2,3-Triphenyl-2-phospha[3]ferrocenophane (1a):** Complex **7** was obtained from the corresponding amine[36] and palladium(II) chloride, as described in the literature.[37] *anti*,*syn*-1,2,3-Triphenyl-2-phospha[3]ferrocenophane **1a** (100 mg, 0.21 mmol) and complex **7** (72 mg, 0.11 mmol) were dissolved in acetone (10 mL) under argon and the mixture was stirred at room temperature for 2 h. After evaporation of the solvent, the crude product was obtained as a diastereomeric mixture, which was separated by column chromatography on silica gel with a heptane/ethyl acetate (8:2) mixture as the eluent.

Complex **8a** was eluted first ($R_f$ = 0.5 in heptane/ethyl acetate, 6:4, 35 mg, 40% yield): $^1H$ NMR ($CDCl_3$): $\delta$ = 1.96 (d, $^3J_{H,H}$ = 6.5 Hz, 3 H, CH*Me*), 2.44 (s, 3 H, NMe), 3.08 (d, $J$ = 3.5 Hz, 3 H, NMe), 4.1–4.2 (4 H, Cp, N*CH*Me), 4.35 (1 H, Cp), 4.44 (2 H, Cp), 4.48 (1 H, Cp), 5.42 (d, $^1J_{H\text{-}P}$ = 15.0 Hz, 1 H, CHPh), 5.62 (dd, 1 H, Naph), 5.92 (1 H, Cp), 6.48 (d, $^3J$ = 7.0 Hz, 1 H, Naph), 6.91 (t, $J$ = 8.5 Hz, 1 H), 7.0–7.5 (Ar), 7.54 (d, $J$ = 8.5 Hz, 1 H), 8.16 (d, $J$ = 7.0 Hz, 2 H) ppm. $^{13}C$ NMR (selected data, $CDCl_3$): $\delta$ = 21.8 (CH*Me*), 43.4 (d, $^1J_{P,C}$ = 10.9 Hz, PCH), 46.2 (d, $^1J_{P,C}$ = 12.1 Hz, PCH), 48.0 (NMe), 50.3 (NMe), 67.3, 68.1, 68.3, 69.5, 70.5, 70.6, 70.7, 71.8, 72.1 (Cp, N*CH*Me), 84.0 (d, $^1J_{P,C}$ = 9.2 Hz, $C_{Cp}$), 86.2 ($C_{Cp}$), 121–129 (Ar), 137.4 [C-3′ (Naph)], 141.2, 145.9, 150.0 (C) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 80.4 ppm. MS (MALDI): *m*/*z* (%) = 776 (100) [M – Cl]. HRMS (MALDI): calcd. for $C_{44}H_{41}FeNPPd$ 776.1361; found 776.1359. $[a]_D$ = +281 ($c$ = 0.2, $CHCl_3$).

Complex **8b** was then eluted with $R_f$ = 0.3 in heptane/ethyl acetate (6:4). $^1H$ NMR ($CDCl_3$): $\delta$ = 2.19 (d, $^3J_{H,H}$ = 6.5 Hz, 3 H, CH*Me*), 2.73 (s, 3 H, NMe), 3.13 (d, $J$ = 3.5 Hz, 3 H, NMe), 4.18, 4.21, 4.23, 4.28, (Cp), 4.31 (m, N*CH*Me), 4.35, 4.39 (Cp), 4.77 (d, $^1J_{H-P}$ = 17.0 Hz, 1 H, CHPh), 5.47 (1 H, Cp), 5.65 (dd, $^3J_{H,H}$ = 8.5 Hz, $^4J_{H,P}$ = 5.0 Hz, 1 H, Naph), 6.02 (1 H, Cp), 6.12 (d, $^3J$ = 8.5 Hz, 1 H, Naph), 6.33 (d, $^1J_{H-P}$ = 6.5 Hz, 1 H, CHPh), 6.65 (2H), 6.88 (t, $J$ = 7.5 Hz, 1 H), 7.0–7.5 (Ar), 7.67 (d, $J$ = 8.5 Hz, 1 H), 7.84 (2H). $^{13}C$ NMR (selected data, $CDCl_3$): $\delta$ = 22.4 (CH*Me*), 37.7 (d, $^1J_{P,C}$ = 15.1 Hz, PCH), 46.6 (d, $^1J_{P,C}$ = 17.3 Hz, PCH), 48.7 (NMe), 50.9 (NMe), 69.0, 69.2, 69.3, 69.6, 70.1, 70.3, 70.7, 71.5, 73.5 (Cp, N*CH*Me), 82.1 ($C_{Cp}$), 83.9 ($C_{Cp}$), 123–131 (Ar), 136.2 (CH), 136.3 (CH), 137.2, 138.1, 147.0, 148.0 (C) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 75.8 ppm. $[a]_D$ = –160 ($c$ = 0.2, $CHCl_3$).

Complex **8a** (32 mg, 0.04 mmol) was treated with 1,2-bis(diphenylphosphanyl)ethane (15 mg) in $CH_2Cl_2$ (2 mL) at room temperature for 3 h. After evaporation, phosphane **1a** was isolated by filtration through a short silica gel column with heptane/ethyl acetate (8:2) as the eluent ($R_f$ = 0.6). $[a]_D$ = +392 ($c$ = 0.2, $CHCl_3$).

**X-ray Crystal Structure Analyses:** For the three structures, intensity data were measured with a Nonius Kappa-CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation, in $\phi$- and $\omega$-scans, up to $\theta$ = 27.5° for compounds **3a** and **3c**, and only to 22° for **8c**. The structures were solved by direct methods with the program SHELXS86[38] and refined by full-matrix least-squares, on the basis of unique $F^2$, with the program SHELXL97.[39] The hydrogen atoms were located on difference Fourier maps and fitted at theoretical positions [$d$(C–H) = 0.93 or 0.98 Å], except those fixed to the B atom, which were refined. They were assigned an isotropic displacement parameter equivalent to 1.12 times that of the bonded atom.

**Crystallographic Data for Compound 3a:** A small brown-yellow prismatic crystal of 0.55 × 0.45 × 0.45 mm, cut from a larger one, was used. Empirical formula $C_{30}H_{28}BFeP$, $M$ = 486.15, $T$ = 293 K. Monoclinic system, centrosymmetric space group $P2_1/n$. The unit cell of parameters $a$ = 7.401(4), $b$ = 29.868(15), $c$ = 11.186(6) Å, $\beta$ = 93.75(2)°, $V$ = 2467 Å$^3$ contains four molecules ($Z$ = 4); $d_{calcd}$ = 1.309 g cm$^{-3}$, $F$(000) = 1016, $\mu$ = 0.692 mm$^{-1}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å. A total of 9485 data were collected, giving 6901 monoclinic reflections, of which 4806 were unique.[40] Refinement of 307 parameters on $F^2$ led to $R_1(F)$ = 0.0382 calculated with the 3942 observed reflections having $I \geq 2\sigma(I)$ and to $wR_2(F^2)$ = 0.0946 considering all 4806 unique reflections. Goodness of fit = 1.050. The residual density was found to be between –0.36 and 0.29 e Å$^{-3}$.

**Crystallographic Data for Compound 3c:** A yellow prismatic crystal of 0.25 × 0.10 × 0.10 mm was used. Empirical formula $C_{18}H_{20}BFeP$, $M$ = 333.97, $T$ = 293 K. Monoclinic system, centrosymmetric space group $P2_1/a$. The unit cell of parameters $a$ = 10.891(4), $b$ = 7.472(4), $c$ = 19.160(6) Å, $\beta$ = 94.47(2)°, $V$ = 1554 Å$^3$ contains four molecules ($Z$ = 4); $d_{calcd}$ = 1.427 g cm$^{-3}$, $F$(000) = 696, $\mu$ = 1.062 mm$^{-1}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å. A total of 14535 data were collected, giving 6478 monoclinic reflections, of which 3530 were unique. Refinement of 199 parameters on $F^2$ led to $R_1(F)$ = 0.0401 calculated with the 2292 observed reflections having $I \geq 2\sigma(I)$ and to $wR_2(F^2)$ = 0.0956 considering all 3530 unique reflections. Goodness of fit = 1.044. The residual density was found to be between –0.47 and 0.42 e Å$^{-3}$.

**Crystallographic Data for Compound 8a:** From very small crystals, a small orange needle of 0.20 × 0.05 × 0.012 mm was chosen. Empirical formula $C_{44}H_{41}ClFeNPPd{\cdot}C_7H_8$, $M$ = 904.58, $T$ = 293 K. Tetragonal system, chiral space group $I4_1$. The unit cell of parameters $a$ = $b$ = 27.112(7), $c$ = 11.592(5) Å, $V$ = 8521 Å$^3$ contains eight molecules ($Z$ = 8); $d_{calcd}$ = 1.410 g cm$^{-3}$, $F$(000) = 3891, $\mu$ = 0.90 mm$^{-1}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å. A total of 26093 reflections were collected, giving 5070 unique tetragonal reflections. In addition, a toluene molecule of crystallisation solvent was found per molecule. The absolute configuration was calculated from the anomalous dispersion effects in diffraction measurements. Refinement of 510 parameters on $F^2$ led to $R_1(F)$ = 0.0440 calculated with the 3891 observed reflections having $I \geq 2\sigma(I)$ and to $wR_2(F^2)$ = 0.0768 considering all 5070 unique reflections. Goodness of fit = 1.032. The residual density was found to be between –0.28 and 0.25 e Å$^{-3}$.

CCDC-636890 (for **3a**), -636891 (for **3c**) and -636892 (for **8a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.cccd.cam.ac.uk/data_request/cif.

# Facile Synthesis and Photoluminescence of Europium Ion Doped $LaF_3$ Nanodisks

**Ling Zhu,[a,b] Jian Meng,[a] and Xueqiang Cao*[a]**

**Keywords:** Materials science / Crystal growth / Rare earths / Fluorescence

$LaF_3$:$Eu^{3+}$ (5.0 mol-% $Eu^{3+}$) nanodisks with perfect crystallinity were successfully synthesized by a simple method. The synthesis was carried out in an aqueous solution at room temperature without the use of templates or organic additives. The mechanism of formation of the nanodisks was explored, and the fluoride source ($KBF_4$) is believed to play a key role in controlling the morphology of the final product. Furthermore, the size of the disk can be simply moderated by varying the concentration of the initial reactants. The room-temperature photoluminescence of $LaF_3$:$Eu^{3+}$ with different morphologies and sizes were also investigated, and the results indicate that the emission intensity of the product is strongly affected by their size, shape, and other factors.

## Introduction

Inorganic materials with controllable morphologies and sizes have attracted increasing attention because of their unique morphology- and size-dependent chemical and physical properties.[1–5] To date, a number of synthetic approaches including laser ablation, templating direction, electrochemical deposition, thermolysis of complex precursors in solution phase, and solvothermal/hydrothermal treatments have been developed to control the morphologies of materials.[6–11] However, the reported conventional methods suffer from the requirement of a template, high temperatures, special conditions, or tedious procedures, and therefore, facile and template-free methods are highly desired. Because of the significant advantages, such as the ease of control, low temperature, low cost, and easy scale-up, the stirring method is a powerful and practical route to prepare a great deal of inorganic materials with uniform and unique morphologies. Recently, great progress was made in the synthesis of nanodisks. Wu et al. reported the preparation of monodispersive silver nanodisks by thermolysis of the layered silver thiolate precursor.[12] Zhang et al. successfully synthesized ultrathin $WO_3$ nanodisks by using a wet chemical route with polyethylene glycol (PEG) as the surface modulator.[13] Korgel et al. developed the solvent-free thermolysis of a copper alkylthiolate molecular precursor to prepare $Cu_2S$ nanodisks.[14] Iron oxide nanodisks can also be obtained through the nonhydrolytic, surfactant-mediated thermal reaction of iron pentacarbonyl and an oxidizer.[15] The growth of $Cd(OH)_2$ nanodisks by a hydrothermal route was reported by Zhang et al.[16]

The study of rare-earth fluorides is currently an active research field in modern materials chemistry as these compounds have potential applications in optics, optoelectronics, biological labeling, catalysis fields, etc.[17–21] Rare-earth fluoride crystals with various morphologies have been prepared by different synthetic techniques, for example, fullerene-like $LnF_3$ (Ln = La, Pr, Nd, Sm, and Y),[22,23] bundle-like, rod-like, hexagonal and triangular $YF_3$ nanocrystals,[24–26] monodisperse $LaF_3$ triangular nanoplates,[27] and $EuF_3$ nanocrystals with different crystalline phases and morphologies.[28,29] Wang et al. reported a hydrothermal method for the growth of $LaF_3$ nanodisks using $KF{\cdot}2H_2O$ as the fluoride source, and then the self-assembly of these nanodisks into the plate-built cylinders through oriented aggregation.[30] However, it is still a challenge to develop a more simple method to prepare $LaF_3$:$Eu^{3+}$ with the controlled morphology under mild reaction conditions. Herein, we report a facile and fast solution-based method for the synthesis of singly crystalline $LaF_3$:$Eu^{3+}$ nanodisks without the use of templates or organic additives, and further investigate their microstructure and luminescence properties.

## Results and Discussion

### Structure and Morphology of the Product

The crystal structure of the $LaF_3$:$Eu^{3+}$ sample was characterized by XRD. As shown in Figure 1, all the peaks can be readily indexed to a hexagonal structure of $LaF_3$ [space

group $P\bar{3}c1$ (No. 165)] with lattice constants of $a$ = 7.187 Å and $c$ = 7.350 Å (JCPDS No. 32–0483). No impurities were observed in the XRD pattern. The strong and sharp diffraction peaks indicate that the product crystallizes well.

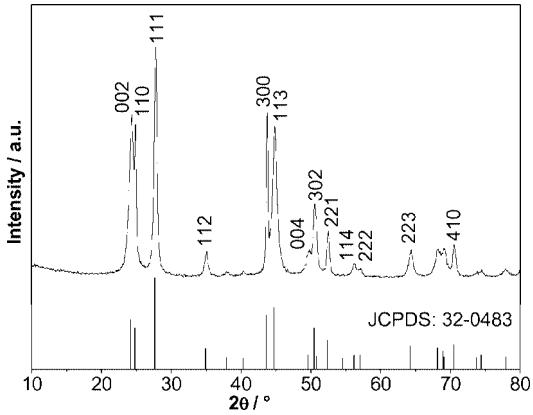

Figure 1. XRD pattern of the $LaF_3$:$Eu^{3+}$ nanodisks.

The morphology and microstructure detail of the as-synthesized sample was investigated by SEM, TEM, HRTEM, and SAED observation. The SEM image with a low magnification (Figure 2a) reveals that the $LaF_3$:$Eu^{3+}$ product is entirely comprised of disks with a uniform size and round shape. The average diameter of the disks is about 500 nm, as can be seen from the SEM with a high magnification (Figure 2b), and this is confirmed by the TEM images (Figure 2c). The thickness of the disk is about 20 nm, as observed from those disks that are perpendicular to the silicon substrate in the SEM image (Figure 2b). Furthermore, Figure 2b shows that the surfaces of the $LaF_3$:$Eu^{3+}$ nanodisks are extremely smooth. The clear lattice fringes in the HRTEM image (Figure 2d) confirm the high crystallinity of the $LaF_3$:$Eu^{3+}$ nanocrystals. The SAED image (Figure 2e) of a disk shows the regular diffraction spots and confirms that the $LaF_3$:$Eu^{3+}$ nanodisks are singly crystalline. Furthermore, the diffraction observation indicates that <1120> is the growth direction for developing the hexagonal crystals, and the $LaF_3$:$Eu^{3+}$ nanodisks are dominated by {0001} facets. These results indicate that $LaF_3$:$Eu^{3+}$ nanodisks with uniform morphology and size can be obtained by this simple and mild method, and the productivity of the product is as high as 81%.

It is well-known that lanthanum fluoride has a small solubility product constant ($K_{sp}$ = $2.0 \times 10^{-19}$ at 25 °C),[31] implying that upon direct mixing, $La^{3+}$ and $F^-$ would immediately react to form the precipitate of lanthanum fluoride. For this rapid reaction it is thus difficult to control the morphology and size of the product. Figure 3 show the TEM images of the $LaF_3$:$Eu^{3+}$ samples that were synthesized by using either NaF or $NH_4F$ as the fluoride source, and the other preparation conditions are identical to those of the disk-like product. It can be seen that the $LaF_3$:$Eu^{3+}$ samples are composed of irregular nanoparticles with serious agglomeration (Figure 3). Moreover, the SAED images of these two samples reveal that the $LaF_3$:$Eu^{3+}$ nanoparticles are polycrystalline in nature (insets of Figure 3). In the case

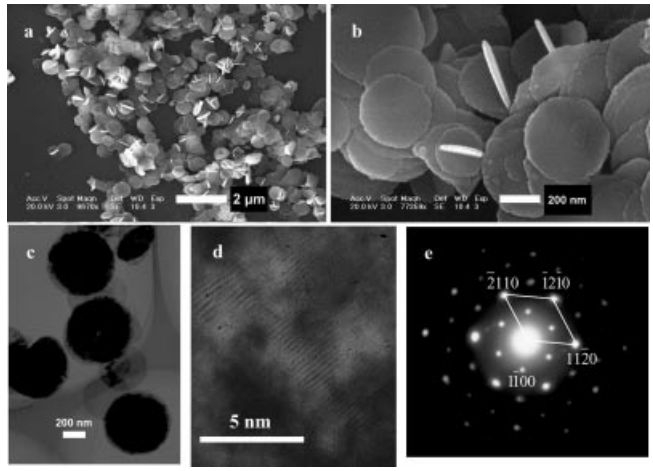

Figure 2. SEM images of the $LaF_3$:$Eu^{3+}$ nanodisks with different magnification (a, b), TEM (c), HRTEM (d), and SAED (e) images of the $LaF_3$:$Eu^{3+}$ nanodisks.

of NaF and $NH_4F$, a white precipitate appeared immediately after the lanthanum nitrate solution was mixed with sodium or ammonium fluoride, which indicated that the nucleation had taken place rapidly. These results indicate that in the current case, the rapid reaction process is not suitable to prepare $LaF_3$:$Eu^{3+}$ with controlled morphology and size. Therefore, to solve these problems, a slow reaction process was adopted. It is interesting to observe that the experimental phenomena and the morphology of the final product are different when $KBF_4$ is used as the fluoride source. When $KBF_4$ was used, the reaction solution became turbid after 40 min, and the uniform nanodisks were formed. In an aqueous solution, $KBF_4$ was slowly hydrolyzed to produce $F^-$ anions; these $F^-$ anions reacted with $Ln^{3+}$ cations (Ln = La, Eu) to form the lanthanum fluoride as described by Equations (1) and (2).

$$BF_4^- + 3H_2O \leftrightarrow H_3BO_3 + 3HF + F^- \quad (1)$$

$$Ln^{3+} + 3F^- \rightarrow LnF_3\downarrow \quad (2)$$

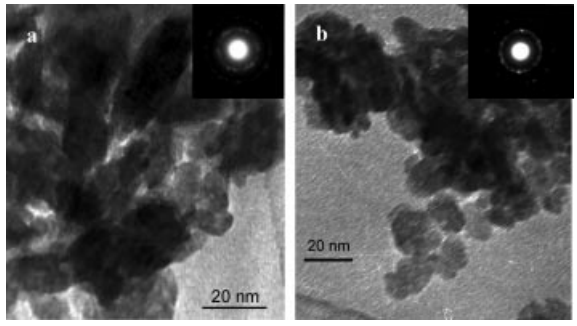

Figure 3. TEM (a) and SAED (inset a) images of the $LaF_3$:$Eu^{3+}$ nanocrystal from NaF and the TEM (b) and SAED (inset b) images of the $LaF_3$:$Eu^{3+}$ nanocrystal from $NH_4F$.

The equilibrium constant of the hydrolysis reaction [Equation (1)] is very small ($K^0$ = $6.41 \times 10^{-12}$ at 25 °C)[32], which is helpful to keep the concentration of $F^-$ ions in the reaction solution at a low level, and consequently, this leads

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to slow crystallization of the product. The slow crystallization process can be further confirmed by the experimental observation that the reaction solution became turbid after stirring for 40 min, and the pH value of the aqueous solution gradually increased from approximately 5.0 at the beginning of the reaction to 1.5 when the reaction was complete. From the above observation, it is believed that the slow reaction process is a key factor for the synthesis of the singly crystalline $LaF_3:Eu^{3+}$ nanodisks with uniform morphology and size. Mann et al. reported the synthesis of Prussian blue nanoparticles and nanocrystal superlattices by the slow photoreduction of $[Fe(C_2O_4)_3]^{3-}$ to $Fe^{2+}$ in the presence of $[Fe(CN)_6]^{3-}$ in reverse microemulsion.[33] Hu et al. synthesized perfect α-$Fe_2O_3$ fractal dendrites by the slow decomposition and hydrolysis of $K_3Fe(CN)_6$ under hydrothermal conditions.[34] Therefore, it can be reasonably inferred that a slow reaction process is very useful to control the morphology and size of the materials, especially for those with small $K_{sp}$ values.

A crystal growth process consists of the nucleation and the growth, which are affected by the intrinsic crystal structure and the external conditions such as the kinetic energy barrier, temperature, time, and capping molecules, etc. Generally speaking, for materials with a hexagonal structure, the anisotropic growth along the *c* axis is available to form the 1D nanostructures, as the {001} planes (which are perpendicular to the *c* axis) exhibit significantly different surface energies relative to the {100} and {110} crystal planes. However, in the current case, only nanoparticles were obtained when NaF or $NH_4F$ was used as the fluoride source and 2D nanodisks were obtained if $KBF_4$ was used as the fluoride source, indicating that $KBF_4$ plays a critical role in the formation of 2D nanodisks of the $LaF_3:Eu^{3+}$ crystals. $BO_3^{3-}$ ions are produced during the hydrolysis of $KBF_4$ in aqueous solution as shown in Equation (1), and their appearance has been proven by other groups.[35] It is quite possible that these anions, such as $BF_4^-$, $NO_3^-$, and $BO_3^{3-}$, are adsorbed on the (0001) plane of the crystal seed, which slow down the crystal growth along the <0001> orientation. Accordingly, the intrinsically anisotropic growth of $LaF_3$ along the <0001> direction is substantially suppressed, and the 2D disk-like $LaF_3$ is formed. It is well-documented that adsorbed ions can change the growth kinetics and the surface energies of different crystal faces, which can ultimately lead to anisotropic growth of low-symmetry nanostructures, such as the nanodisk, the nanoplate, the nanorod, and the nanowire.[36–39] For example, Liu et al. used a seed growth procedure to obtain a complex hexagonal ZnO nanostructure with capping of the citric acid, which adsorbs preferably on the (001) surface of ZnO and slows down the crystal growth along the *c* axis.[40] Xia et al. observed that the polyvinylpyrrolidone capping agent interacted more strongly with the silver atoms on the {100} facets than those on the {111} facets, and the growth of silver could be directed into a highly anisotropic mode to form uniform nanowires.[41] Accordingly, in this work, $KBF_4$ is believed to play a key role in the formation of $LaF_3:Eu^{3+}$ nanodisks in the adopted reaction system. Therefore, through the above analysis, it is proposed that there are two key factors that allow $LaF_3:Eu^{3+}$ nanocrystals with the 2D disk-like morphology to be obtained. One is the slow reaction process, and the other is the selective absorption of anions ($BF_4^-$, $NO_3^-$, $BO_3^{3-}$) specifically on the crystal faces of the crystal seed. However, the mechanism of formation of the $LaF_3:Eu^{3+}$ nanodisks is not fully understood. Further theoretical and experimental work is required to understand the exact nature of the mechanism of growth.

Further experiments indicated that the size of the synthesized $LaF_3:Eu^{3+}$ disk depends strongly on the concentration of the initial reagents. At the fixed molar ratio of 3:1 for $KBF_4$:La(Eu)$(NO_3)_3$, the size of the product decreased from 500 to 100 nm with an increase in the initial concentration of the reactant. Figure 4a shows a typical SEM image of a $LaF_3:Eu^{3+}$ sample that was prepared from an aqueous solution in which the concentrations of La(Eu)$(NO_3)_3$ and $KBF_4$ were 0.04 and 0.12 M, respectively. The average size of the disk is 300 nm. A further increase in the concentration of La(Eu)$(NO_3)_3$ to 0.08 M and that of $KBF_4$ to 0.24 M caused the average size of the disk to be reduced to 100 nm, as illustrated in Figure 4b. Moreover, it is obvious that the surface of the nanodisk becomes coarse with an increase in the concentration of the initial reagents. The above experiments indicate that the size of the $LaF_3:Eu^{3+}$ disks could be tuned by simply changing the concentrations of the precursors.

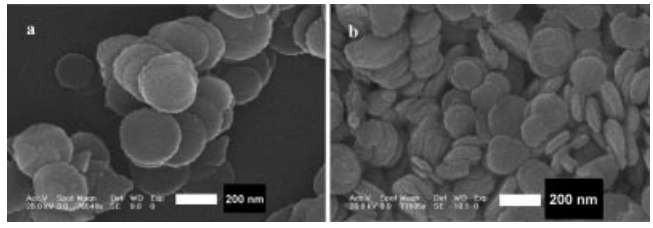

Figure 4. SEM image (a) of the $LaF_3:Eu^{3+}$ nanocrystal with La(Eu)$(NO_3)_3$ and $KBF_4$ concentrations of 0.04 and 0.12 M, respectively, and the SEM image (b) of the $LaF_3:Eu^{3+}$ nanocrystal with La(Eu)$(NO_3)_3$ and $KBF_4$ concentrations of 0.08 and 0.24 M, respectively.

### Photoluminescent (PL) Properties

Figure 5 shows the room-temperature emission spectra of $LaF_3:Eu^{3+}$ nanodisks and nanoparticles that were prepared from different fluoride sources. Both samples were measured under identical conditions with an excitation wavelength of $\lambda_{ex}$ = 399 nm. In the emission spectra, the characteristic emission peaks of $Eu^{3+}$ in the wavelength range from 520 to 720 nm were observed, corresponding to the transitions from the excited $^5D_1$ and $^5D_0$ levels to $^7F_J$ ($J$ = 0–4) levels, with the magnetic dipole $^5D_0 \rightarrow {}^7F_1$ allowed transition (589 nm) being the most prominent emission line.[42] The relative intensities of the emission peaks were similar to those reported earlier,[19] indicating that the $Eu^{3+}$ ion is located in the $La^{3+}$ crystal site with $C_2$ symmetry,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

which is the same as that of the bulk $LaF_3$ crystals.[43] For the C2 site, the electric and magnetic dipole transitions are allowed. Therefore, both the $^5D_0 \rightarrow {}^7F_1$ and the $^5D_0 \rightarrow {}^7F_2$ transitions of $Eu^{3+}$ can be observed in the $LaF_3$:$Eu^{3+}$ nanocrystals. Although the emission positions of the major peaks of these two samples are identical, the emission intensity of the disk-like $LaF_3$:$Eu^{3+}$ product is significantly higher than that of the particle-like product. It is well-documented that the grain size, morphology, crystal structure, dimension, and surface modification of the luminescent material all influence its photoluminescent properties.[44–46] Owing to a large surface area to volume ratio, an important source of luminescence quenching in small particles is the surface where the coordination of the atom differs from that in the bulk and the site where different chemical species can be adsorbed. Because the samples were prepared in aqueous solution, the surface of the nanocrystals can be covered with hydroxy species such as lanthanum or europium hydroxides, fluorine ions, or adsorbed water molecules. Different sizes and shapes result in different combinations between the surface and the adsorbed species so as to produce different quenching abilities of the emissions of the $Eu^{3+}$ ions; therefore, the differences in the PL intensities of the samples may be attributed to the different abilities of the adsorbed species on the surface to quench the emissions from the $Eu^{3+}$ ions. The luminescence intensity of the disk-like nanocrystals is obviously stronger than that of the particle-like nanocrystals, which may be due to the factor that the nanostructure can prevent the adsorbed species on the surface from quenching the emission from the $Eu^{3+}$ ions. We also assume that the particle-like crystals would possess more defects due to the fast growth of the crystal. Some of these defects may act as the nonradiative recombination centers, and they may be responsible for the decrease in the luminescence intensity as observed in the particle-like product.

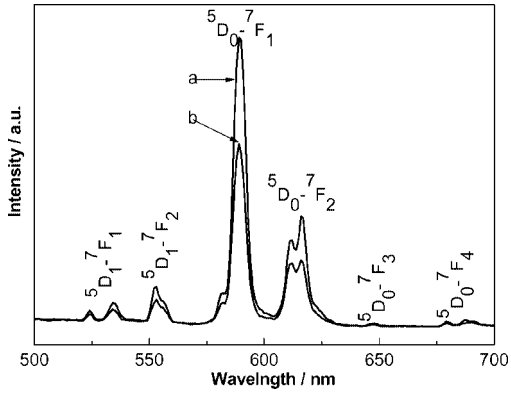

Figure 5. Emission spectra of the nanodisks (a) and nanoparticles (b) of $LaF_3$:$Eu^{3+}$ nanocrystals.

The emission spectra of $LaF_3$:$Eu^{3+}$ disks with different sizes under excitation at 399 nm were also investigated. From Figure 6 it can be seen that the emission intensity of the $LaF_3$:$Eu^{3+}$ phosphors basically increase with an increase in the size of the disks. It is well-known that a large particle size is helpful for improving the PL intensity of phosphors.[47,48] A more extensive investigation of the differences in the luminescent properties of the products with different morphologies, crystal structures, sizes, and dimensions will be further investigated in our future work.

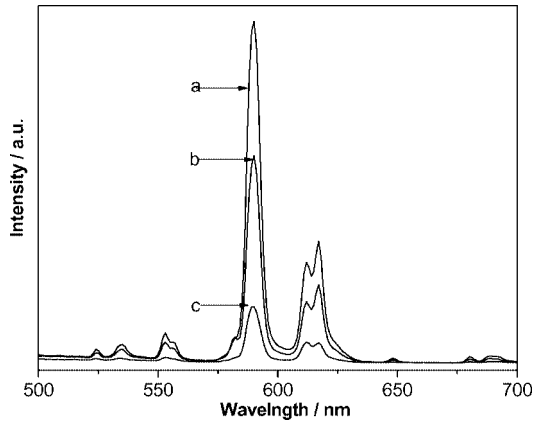

Figure 6. Emission spectra of the $LaF_3$:$Eu^{3+}$ disks with different size: 500 nm (a), 300 nm (b), and 100 nm (c).

## Conclusions

We utilized a mild and facile synthetic route to prepare $LaF_3$:$Eu^{3+}$ nanodisks from an aqueous solution of $(La,Eu)(NO_3)_3$ and $KBF_4$ without the use of templates or organic additives. The size of the $LaF_3$:$Eu^{3+}$ nanodisks can be tuned by simply controlling the concentration of the precursors. The mechanism of formation of the disk-like structures was investigated, and the fluoride source ($KBF_4$) clearly contributes to the creation of such a structure. Room-temperature photoluminescence of the $LaF_3$:$Eu^{3+}$ samples with different morphologies and sizes were also investigated, and the results reveal that all of these samples showed similar features but different luminescence intensities.

## Experimental Section

**General:** All the reagents used were of analytical grade, including $La_2O_3$ and $Eu_2O_3$ (Shanghai Chemical Reagent), $KBF_4$, NaF, and $NH_4F$ (Beijin Chemical Reagent), and used as received without further purification.

**Typical Synthesis:** Appropriate amounts of $La_2O_3$ and $Eu_2O_3$ (La:Eu = 95:5, in molar ratio) were first dissolved in nitric acid (10%) and then mixed with a $KBF_4$ solution in a 150-mL plastic flask to give a final concentration of 20 mM of $La(Eu)(NO_3)_3$ and 60 mM of $KBF_4$. The total volume of the solution was 100 mL. The resulted solution was stirred at ambient temperature for 3 h. A white precipitate was centrifuged and then washed with distilled water and absolute ethanol in sequence. The final product was dried under vacuum at 60 °C for 12 h.

**Crystal Structure Determination:** X-ray powder diffraction (XRD) was performed with a Rigaku D/MAX-2500 diffractometer with Cu-$K_\alpha$ radiation ($\lambda$ = 0.15406 nm) and a scanning rate of 5 °$min^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Scanning electron micrographs (SEM) were taken with a XL30 field-emission scanning electron microscope. Transmission electron micrographs (TEM), high-resolution transmission electron micrographs (HRTEM), and the selected area electron diffraction (SAED) were taken with a JEOL-JEM-2010, operating at 200 kV (JEOL, Japan). Samples for TEM were prepared by dropping a diluted suspension of the sample powders onto a standard carbon-coated (20–30 nm) Formvar film on a copper grid (230 mesh). Photoluminescence (PL) spectra were recorded with a Hitachi F-4500 spectrophotometer equipped with a 150 W xenon lamp as the excitation source. All the measurements were performed at room temperature.

# Self-Assembly of Silver(I) Coordination Polymers from AgX (X = $BF_4^-$, $ClO_4^-$, $CF_3COO^-$, and $SO_3CF_3^-$) and a Rigid Bent 3,6-Dicyano-9-phenylcarbazole Ligand: The Templating Effect of Anions

**Kai-Ju Wei,[a] Jia Ni,[b] Jian Gao,[a] Yangzhong Liu,*[a] and Qing-Liang Liu*[a]**

**Keywords:** Silver / N ligands / Supramolecular chemistry / Luminescence / Coordination polymers / Metal-organic frameworks

One rigid bent bridging ligand with highly planar π-conjugated spacers, 3,6-dicyano-9-phenylcarbazole (dcphcz), was designed and synthesized. The coordination reactions of dcphcz with a series of $Ag^I$ salts with different counterions has been investigated. Four coordination polymers were obtained by solution reactions and characterized by IR, elemental analysis, and single-crystal X-ray diffraction. The solid-state structures of $\{[Ag(dcphcz)]BF_4\}_n$ (**1**) and $\{[Ag(dcphcz)]ClO_4\}_n$ (**2**), exhibit similar 1D "zigzag" patterns. The complex $\{[Ag(dcphcz)][Ag_2(dcphcz)(H_2O)_2](SO_3CF_3)_3 \cdot C_6H_6 \cdot (H_2O)_2\}_n$ (**3**) includes two different one-dimensional (1D) chain units: one forms double-layer two-dimensional (2D) metal–organic frameworks (MOFs) through intermolecular Ag–O–Ag bridging interactions, the other features double-layer 2D supramolecular networks through C–H···O hydrogen-bonding interactions. The complex $[Ag_2(dcphcz)(CF_3COO)_2]_n$ (**4**) features a bundle of novel nanotubular structures, which contain silver chains formed by carboxylate spacers. Furthermore, all these complexes are connected by face-to-face π···π stacking interactions between carbazolyl planes, affording a series of three-dimensional (3D) architectures with different structural geometries. The structural diversities of these complexes demonstrated that counteranions and bridging ligands play essential roles in the construction of supramolecular frameworks. In addition, the luminescence properties of the free ligand dcphcz and complexes **1**–**4** were investigated.

## Introduction

The design and synthesis of metal–organic coordination polymers have attracted intensive attention not only because of their novel topologies and intriguing structural diversity,[1] such as nanotubes[2] and various metal–organic frameworks (MOFs),[3] but also because of their unique chemical and physical properties and their potential applications as optoelectronic, magnetic, and porous materials.[4] In fact, the ultimate aim of supramolecular and coordination chemistry is to control the structure of the target products and investigate the relationship between the structures and physicochemical properties. Generally, the topology of a coordination polymer generated from the self-assembly of metals and ligands can be controlled by ingenious design of the organic ligand,[5] selection of proper metal ions and counterion,[6] solvent system,[7] pH value of solution,[8] and the molar ratio of the reagents.[9] On top of these factors, a bridging ligand as a "*building block*" is a pivotal point in manipulating the network structures. Because of configuration, coordination activity, and relative orientation of the donor groups, the organic spacers take important roles in determining the structure and geometry of the polymers. Rigid linear ligands have already been extensively studied[3n,10] for designing polymers; however, bent ligands still remain a challenge in self-assembly due to their unpredictable coordination geometry.

It is well recognized that the carbazole moiety not only possesses highly planar π-conjugated systems, but also can be easily functionalized at its 3-, 6-, or 9-positions and covalently linked to other functional moieties.[11] Furthermore, the thermal stability of organic compounds can be greatly improved upon incorporation of a carbazole moiety in the core structure.[12] Therefore, thermally stable molecules possessing dual functions, light-emitting and hole-transporting, should be achieved by using carbazole as the central core. Currently, compounds with highly π-conjugated systems are of great interest due to their various applications in chemical sensors, molecular optical and electronic devices.[13]

Herein, we report the design and synthesis of a new organic molecule with large angular and highly planar π-con-

jugated spacers based on carbazole, 3,6-dicyano-9-phenylcarbazole (dcphcz). In most cases, the conformation of coordination polymers from bent bidentate ligands are hardly predictable because of the variation of coordination geometry, such as *cis*, *trans*, or intermediary.[7,14] On the other hand, these variations also provide more chances for designing novel polymeric patterns. The ligand dcphcz does not have a conformational diversity owing to the particular structure of carbazole as the central core, neglecting the rotationality of the terminal phenyl ring of dcphcz. The coordination reactions of dcphcz and the $Ag^I$ ion with different counterions were investigated aiming at expanding dcphcz units through the "soft" $Ag^I$ metal ion and exploring the templating effects of counterions in the self-assembly process. It has been reported[6b,6c,10c,15] that the –CN functional group on the aromatic ring serves as a good candidate for coordination bonding in the self-assembly of Ag-supramolecular architectures. With a $d^{10}$ electronic configuration, the $Ag^I$ ion often has irregular coordination geometries and shows a strong tendency to display versatile coordinations. Thus, the $Ag^I$ ion is much more accommodating towards ligands and is expected to form polymer structures more readily than other $d^{10}$ metal ions. At the same time, the ancillary ligation by different counterions, such as $NO_3^-$, $BF_4^-$, $ClO_4^-$, $SO_3CF_3^-$, $CF_3COO^-$, $PF_6^-$, and $SbF_6^-$, may cause a significant structural change of the polymer.[6,10c,14,15] With different polymeric motifs, four new Ag-containing coordination polymers, $\{[Ag(dcphcz)]BF_4\}_n$ (**1**), $\{[Ag(dcphcz)]ClO_4\}_n$ (**2**), $\{[Ag(dcphcz)][Ag_2(dcphcz)(H_2O)_2](SO_3CF_3)_3{\cdot}C_6H_6{\cdot}(H_2O)_2\}_n$ (**3**), and $[Ag_2(dcphcz)(CF_3COO)_2]_n$ (**4**), were synthesized based on ligand 3,6-dicyano-9-phenylcarbazole and their luminescence properties were characterized in this work.

## Results and Discussion

### Synthesis and Characterization

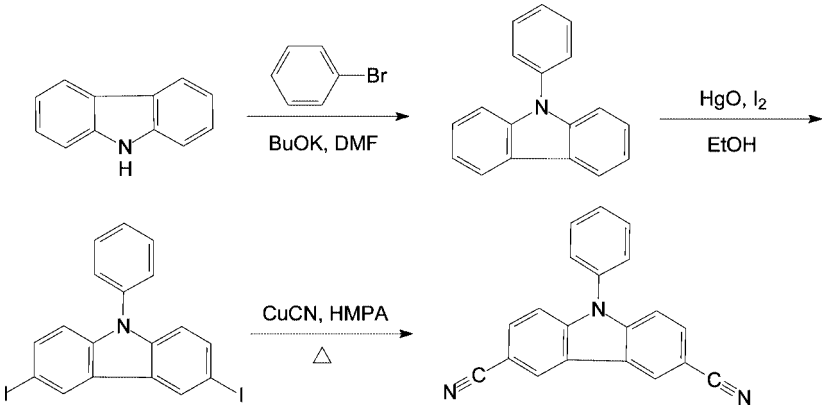
3,6-Dicyano-9-phenylcarbazole (dcphcz) was synthesized in high yield by using the modified Ullmann condensation procedure depicted in Scheme 1, where 3,6-diiodo-9-phenylcarbazole reacts with CuCN in the presence of an HMPA catalyst. The dcphcz is very soluble in common organic solvents, such as $CH_2Cl_2$, $CHCl_3$, THF, benzene, toluene, and $CH_3CN$. The slow diffusion of a $CH_2Cl_2$ solution of dcphcz into a benzene solution of AgX (X = $BF_4^-$, $ClO_4^-$, $SO_3CF_3^-$, and $CF_3COO^-$) afforded a 3:2 ratio of $Ag^I$ salt/dcphcz ligand adduct for $SO_3CF_3^-$ and 1:1 adducts for $BF_4^-$, $ClO_4^-$, and $CF_3COO^-$, which may result from the subtle templating effects of the counterions. It was observed that the products do not depend on the ligand/metal ratio; however, increasing the metal/ligand ratio resulted in somewhat higher yields and better crystal qualities. Complexes **1**–**4** are stable in air at room temperature only for a short time. All these complexes are insoluble in $CH_2Cl_2$, $CHCl_3$, THF, benzene, and $CH_3CN$, but moderately soluble in MeOH, and soluble in DMF.

The structures of the ligand dcphcz and complexes **1**–**4** were determined by IR and elemental analysis. The IR spectrum of ligand dcphcz and complexes **1**–**4** show a –CN absorption band at 2219, 2251, 2251, 2220, and 2219 $cm^{-1}$, respectively. The rigid bidentate or tridentate ligands containing benzonitrile groups, such as 4,4′-dicyanobiphenyl,[15n] 2,5-bis{3-[(4-cyanophenyl)ethynyl]phenyl}-1,3,4-oxadiazole,[7] 1,3,5-tris[(4-cyanophenyl)ethynyl]benzene,[15n] and 1,3,5-tris{4-[(4-cyanophenyl)ethynyl]phenyl}benzene,[15k] have shown excellent bridging action to construct porous frameworks and supramolecular polymers. However, to the best of our knowledge, no supramolecular architectures based on carbazole-containing nitrile groups have been reported.

### Crystal Structures

#### *Structural Analysis of Ligand dcphcz*

The structure of dcphcz was further confirmed by single-crystal X-ray diffraction, as shown in Figure 1. The central carbazolyl group is nearly planar (with a dihedral angle of 2.9° between the two benzonitrile groups). The terminal (–CN) N···N separation is 9.631 Å, which is close to that of 1,2-bis(4-pyridyl)ethyne (9.685 Å).[16] The terminal phenyl ring is not coplanar with the carbazolyl group, as indicated by the dihedral angle of 59.5° between the terminal phenyl



Scheme 1. Preparation of the ligand dcphcz.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plane and the five-membered ring of the carbazolyl group. Evidently, the nonplanarity of the ligand is caused by the steric hindrance between C–H groups in two phenyl rings.

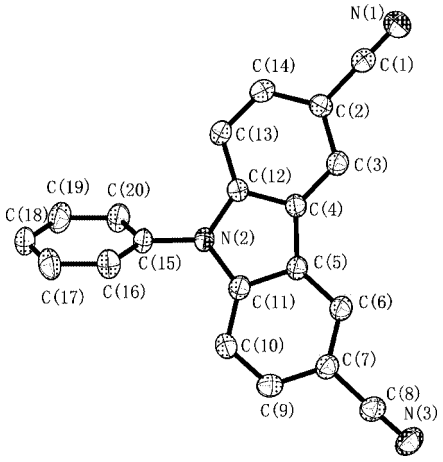


Figure 1. ORTEP diagram showing the structure of dcphcz with 30% thermal ellipsoid probability and the atom-labeling scheme. Hydrogen atoms have been omitted for clarity in this and the following figures.

Figure 2 shows several intermolecular noncovalent interactions in the dcphcz crystal that extends the packing in the solid-state structure. There are two kinds of C–H···N hydrogen-bond interactions between the –CN groups and carbazolyl groups on adjacent molecules of dcphcz, which results in the formation of 1D double chains. The distances of N(1)···H(9) and N(3)···H(3) (2.620 and 2.75 Å, respectively) are significantly shorter than the sum of the van der Waals radii for nitrogen and hydrogen (ca. 1.2 Å for H, and 1.70 Å for N).[17] The other intermolecular interaction, face-to-face π···π stacking between terminal phenyl rings, constructs 2D networks from the 1D chain (Figure 2). At the same time, the C(3)-containing phenyl ring is involved in a moderately strong[18] face-to-face π-stacking interaction with its symmetry-related equivalent, with an interplane distance of 3.47 Å. Thus, the dual interactions of π-stacking and H-bonding extend the 2D networks into 3D architectures.

### *Structural Analysis of {[Ag(dcphcz)]$BF_4$}$_n$ (1) and {[Ag(dcphcz)]$ClO_4$}$_n$ (2)*

Crystallization of dcphcz with $AgBF_4$ in a dichloromethane/benzene mixed solvent afforded **1** as an infinite 1D chain structure. As shown in Figure 3a, single-crystal analysis reveals, that there is only one $Ag^I$ center in complex **1**. Each $Ag^I$ ion is coordinated by two nitrogen atoms from two different dcphcz ligands and two fluorine atoms from the $BF_4^-$ anion. The bond lengths of Ag(1)–N(1) and Ag(1)–N(3) are 2.116 and 2.119 Å, respectively. The Ag(1)–F(1) and Ag(1)–F(2) bonds (2.654 and 2.910 Å) are significantly shorter than the sum of the van der Waals radii for Ag and F (3.19 Å),[17] which indicates the coordination between $Ag^I$ and anion $BF_4^-$.

As shown in Figure 4a, the intrapolymer chain Ag···Ag distance is 13.378 Å. Furthermore, the 1D polymeric chain of **1** is linked into a 2D double-layer network through interpolymer C–H···F hydrogen-bonding interactions (Figure 5). The hydrogen-bonding system involves F(3) of the coordinated $BF_4^-$ counterion and H(7) and H(13) on the dcphcz ligand of the neighboring chain. The F(1)···H(7) and F(1)···H(13) contacts are 2.398 and 2.563 Å, respectively. The corresponding C(7)–H(7)···F(1) and C(13)–H(13)···F(1) angles are 158.36° and 155.18°, respectively.

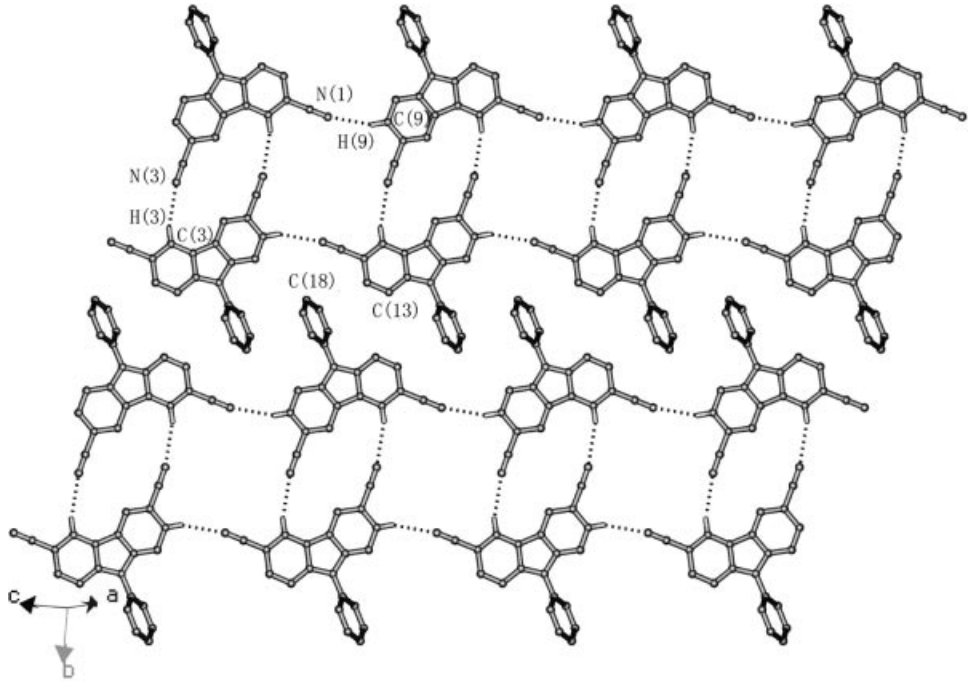

Figure 2. 2D network of dcphcz, showing the π-stacking interactions between the phenyl rings and weak C–H···N hydrogen-bond interactions.

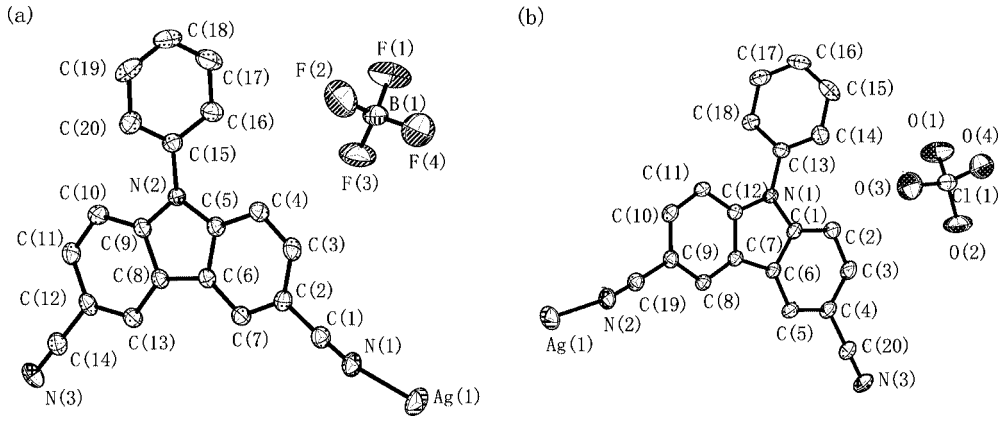

Figure 3. ORTEP diagram showing the structures of **1** (a) and **2** (b), respectively, with 30% thermal ellipsoid probability and the atom-labeling scheme.

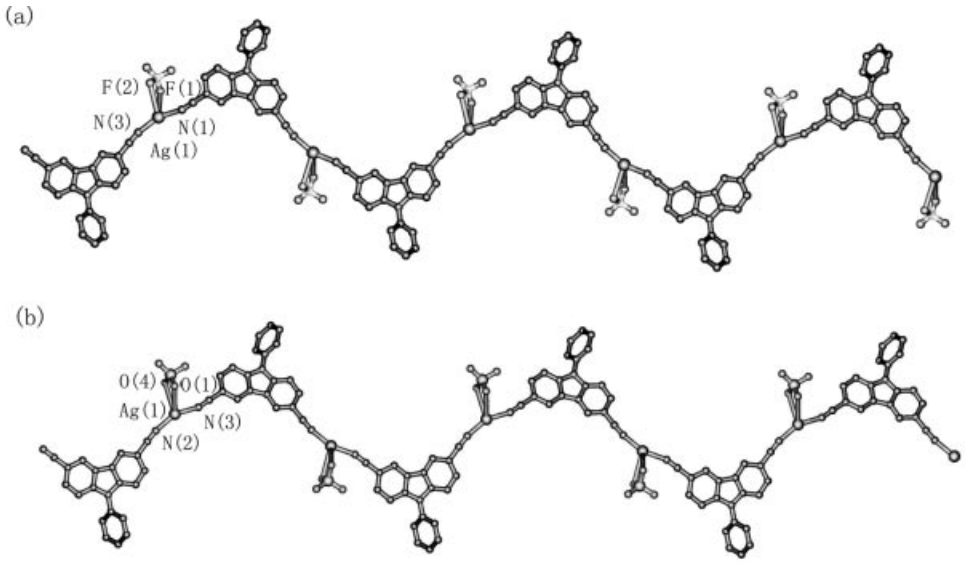

Figure 4. View of one-dimensional "zigzag" chain of **1** (a) and **2** (b).

The existence of weak C–H···X (X = F, Cl, Br, I, O, S, and N) hydrogen-bonding interactions are observed in many compounds and the structural importance is well established.[11b,11c,15d–15j,19] These weak hydrogen bonds often contribute significantly to the alignment of the supramolecular structures in the crystalline state. In complex **1**, the $BF_4^-$ anion contributes to the packing of the complex by coordinating the $Ag^I$ center in one chain and hydrogen-bonding to the F atoms in the neighboring chain. These 2D double-layer networks stack in the *ac* plane through π···π interactions between the lateral carbazolyl planes with an interplane distance of 3.391 Å. Of course, there is also a face-to-face π···π stacking in 2D double-layer networks with an interplane distance of 3.357 Å. Undoubtedly, these π-stacking interactions serve as important driving forces to cross-link the 2D double-layer networks into a 3D architecture. Some examples have shown that the organic ligands involved in the nucleation process use both coordination and π···π interactions to construct the framework.[6b,20]

The other 1D zigzag chain **2** was obtained in a similar way to **1** by using $AgClO_4$ in place of $AgBF_4$. The two complexes have very similar coordination features with two dcphcz chelating ligands (Figure 3b and Figure 4b), while the $ClO_4^-$ anion takes the place of $BF_4^-$ with two coordinating O atoms. The Ag–N bond lengths are close to those in complex **1**, whereas the two Ag–O bonds are somewhat longer (2.636 and 2.847 Å) than Ag–F and within the typical Ag–O bond lengths as reported previously.[11c] The N(1)–Ag(1)–N(3) bond angle (154.02°) and the intrapolymer Ag···Ag distance (13.257 Å) are similar to those in complex **1**. Obviously, the structural similarity of **1** and **2** is generated by the similar nature of the anions ($BF_4^-$ and $ClO_4^-$).

Recently, Ag-supramolecular complexes have been reported[6,10c,14,15,21] based on bent organic ligands with pyridyl, cyano, aminophenyl, and acetylenylphenyl groups as the terminal coordination sites. However, these bent organic ligands exhibit potentially diverse conformations on coordi-

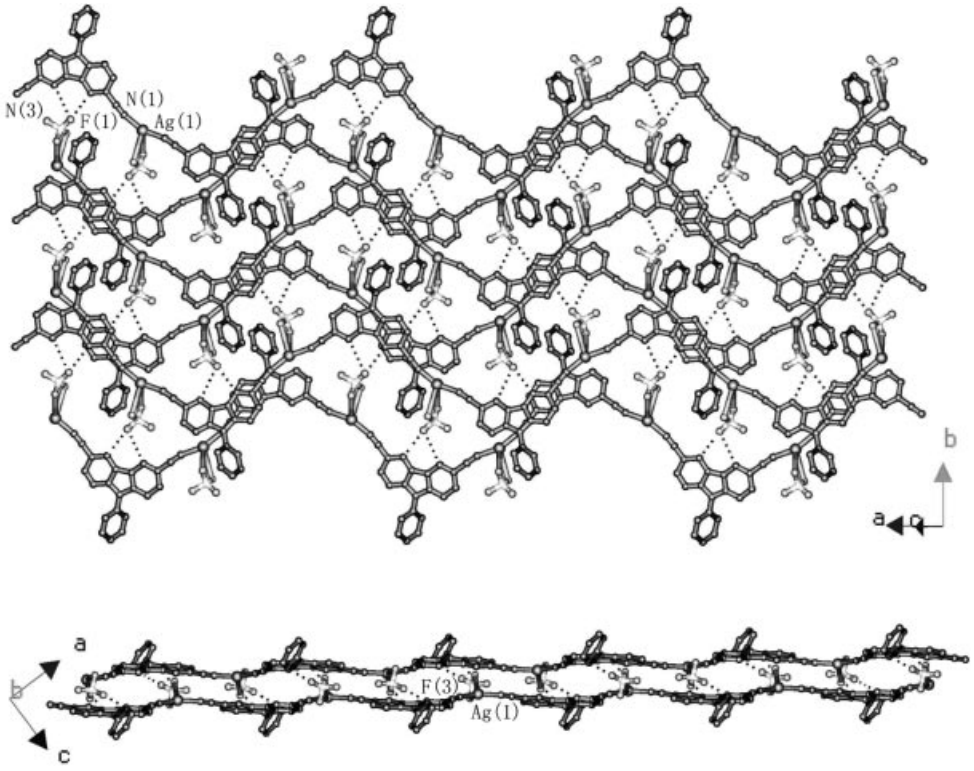

Figure 5. Top (top) and side (bottom) views of two-dimensional double-layer supramolecular networks of **1** stacked together through multiple C–H···F hydrogen-bonding interactions and face-to-face π···π stacking interactions ($d_{\pi-\pi}$ = 3.357 Å).

nation; while dcphcz has a conformation suitable for coordinating to metal centers retaining the bending geometry, making it easy to control and predict the structure and geometry of the resulting polymers.

Similar to complex **1**, a double-layer architecture is formed through multiple C–H···O hydrogen bonding [O(2)···H(5) 2.594 Å, C(5)–H(5)···O(2) 155.75°; O(2)···H(8) 2.395 Å, C(8)–H(8)···O(2) 159.68°]. The parallel carbazole rings from adjacent chains are paired to furnish face-to-face π···π stacking with an interplane distance of 3.349 Å, which extends the 2D network into 3D supramolecular architectures along the *ac* plane.

### *Structural Analysis of {[Ag(dcphcz)][$Ag_2$(dcphcz)-($H_2O$)$_2$]($SO_3CF_3$)$_3$·$C_6H_6$·($H_2O$)$_2$}$_n$ (3)*

Bright yellow single crystals of **3** were obtained by slow diffusion of a benzene solution of $AgSO_3CF_3$ into a $CH_2Cl_2$ solution of dcphcz. Single-crystal analysis reveals that there are three independent $Ag^I$ centers in **3**. The ligand dcphcz has a similar coordination mode in this complex relative to **1** and **2**, however, the different property of the anion alters the molecular architectures in **3**. Atoms Ag(1) and Ag(2) expand the dcphcz units into two independent zigzag chains a and b, respectively, whereas atom Ag(3) is locked in the chain b through a peculiar Ag–C interaction to the phenyl ring (Figure 6). The Ag–N bond lengths in the two chains are all within the range typical for Ag–N bond lengths,[15] though it is slightly longer in chain a [Ag(1)–N(3) 2.134 Å; Ag(1)–N(4) 2.148 Å] than in chain b [Ag(2)–N(1) 2.098 Å; Ag(2)–N(2) 2.119 Å]. The Ag(1) center in chain a also weakly coordinates to an anionic oxygen atom [Ag(1)–O(2) 2.803 Å], and a water oxygen atom [Ag(1)–O(11) 2.738 Å], showing tetrahedral coordination geometry with an N(3)–Ag(1)–N(4) bond angle of 174.4°. While Ag(2) in the chain b center only weakly coordinates to an anionic oxygen atom [Ag(2)–O(9) 2.660 Å], showing T-shaped coordination geometry with an N(1)–Ag(2)–N(2) bond angle of 166.3°. Although these Ag–O distances are relatively long, they are all significantly shorter than the sum of the van der Waals radii for silver and oxygen (3.24 Å).[17] The intrapolymer Ag···Ag distances are 12.559 and 12.308 Å for chains a and b, respectively, which are shorter than those of complexes **1** and **2**. Interestingly, a solvent benzene molecule is located in chain b through weak Ag···C interactions with the nearest Ag···C distance of 2.959 Å.

Sitting on the flank of chain a, Ag(3) has a coordination environment different to those of atoms Ag(1) and Ag(2). In addition to the coordination of two water molecules, Ag(3) has a strong interaction with a terminal phenyl ring from chain a. The Ag(3) atom sits above the phenyl rings and slightly off the center, resulting in a shortest Ag–$C_{benzene}$ distance of Ag(3)–C(17) (2.523 Å) which is still within the normal range for Ag–C bond lengths (2.47–2.76 Å), while the remaining Ag–C distances [Ag(3)···C(16) 2.852 Å; Ag(3)···C(18) 2.889 Å] are beyond the limits commonly observed in $Ag^I$-aromatic complexes.[14,15f–15j,22] Thus, it is concluded that the benzene ring coordinates to the Ag(3) ion with an $\eta^1$-bonding mode. The $\eta^1$-type interaction between the $Ag^I$ ion with a phenyl ring has already been observed in many complexes,[14,15j] although it is less

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

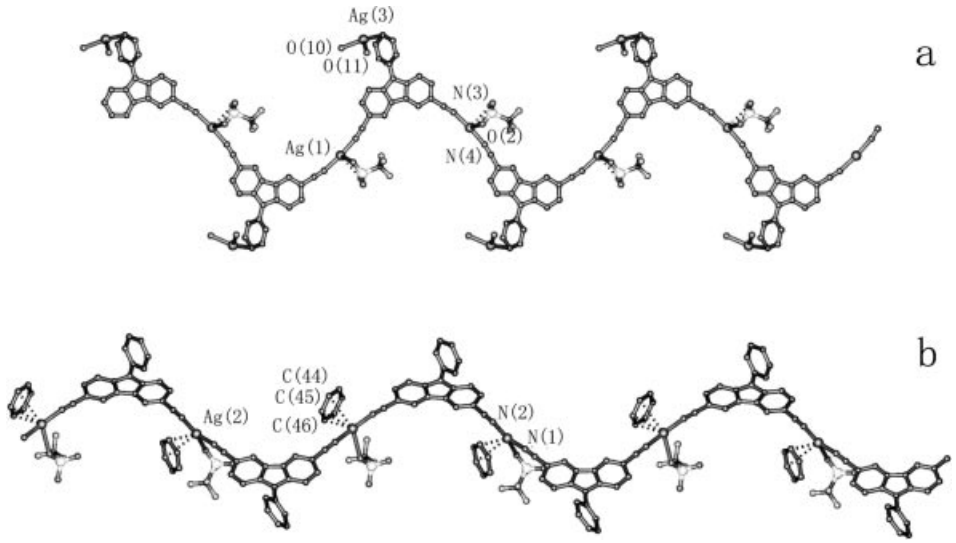

Figure 6. Views of the "zigzag" chains a (top) and b (bottom) in complex **3**.

common than the $\eta^2$-type interaction in which the metal ion interacts with one edge of the phenyl ring.

As shown in Figure 7, the packing style of **3** from chains a and b is different from **1** and **2**. Chains a extend along the crystallographic *b* axis and generate a 2D double-layer metal–organic framework containing irregular channels through Ag–(μ-$O_{water}$)–Ag and Ag–(μ-$SO_3CF_3$)–Ag bridging and face-to-face π···π stacking with an interplane distance of 3.552 Å. Chains b link together into a 2D double-layer supramolecular network through interpolymer C–H···O interactions [O(7)···H(30) 2.436 Å, C(30)–H(30)–O(7) 138.23°; O(9)···H(34) 2.656 Å, C(34)–H(34)–O(9) 125.35°] and face-to-face π···π stacking between adjacent b chains with an interplane distance of 3.485 Å (Figure 8). Consequently, chains a and b stack in an ...*ABC*... sequence along the *a* axis in complex **3**. The parallel carbazole rings from adjacent chains a and b are also paired to furnish π···π stacking with a centroid–centroid distance of 3.879 Å and a dihedral angle of 8.4°, which extend two 2D networks into a 3D architecture along the *ac* plane (Figure 9). In ad-

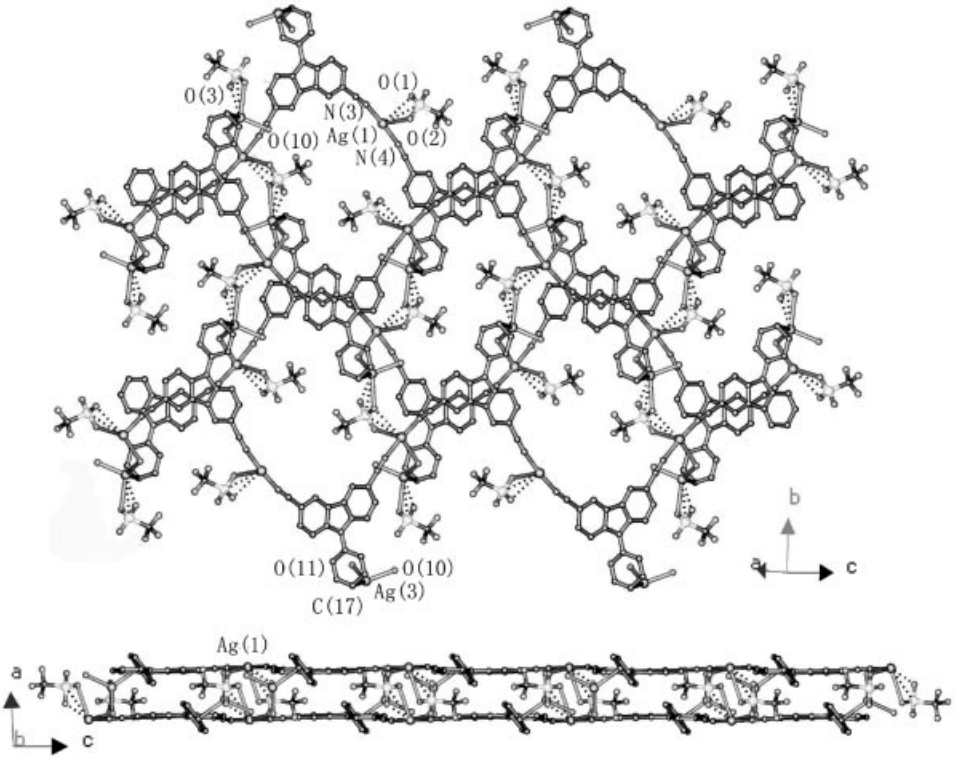

Figure 7. Top (top) and side (bottom) views of 2D double-layer metal–organic frameworks (MOFs) of chain a stacked together through μ-O and μ-$SO_3CF_3$ bridging and face-to-face π···π stacking interactions ($d_{\pi-\pi}$ = 3.552 Å).

dition, the chains a and b are also linked through interpolymer O···H hydrogen-bonding interactions. The O(8)···H(10A) distance of 1.945 Å and the O(8)···H(10A)–O(10) angle of 162.67° indicate a very strong hydrogen-bonding interaction. To the best of our knowledge, it is the first example that independent 2D + 1D polymers coexist in one crystal without mutual interpenetration. The shortest interchain Ag(1)···Ag(2) separation is 3.593 Å between chains a and b, which is slightly longer than the sum of the van der Waals radii of two silver atoms, 3.44 Å. It can be concluded from the architecture of the three complexes that the counterions (polar $SO_3CF_3^-$ vs. nonpolar $ClO_4^-$ and $BF_4^-$) play a key role in determining the polymeric structures of complex **3**.

### *Structural Analysis of [Ag$_2$(dcphcz)(CF$_3$COO)$_2$]$_n$ (4)*

In order to further investigate the effect of the counterion on the long-range order of the $Ag^I$-dcphcz coordination polymer, the more strongly coordinating $CF_3CO_2^-$ anion was used instead of the weakly coordinating $BF_4^-$, $ClO_4^-$, and $SO_3CF_3^-$ anions. Yellowish crystals of **4** were obtained.

Single-crystal X-ray analysis of **4** reveals a novel two-dimensional nanotube from two different crystallographic silver(I) centers. As shown in Figure 10, each Ag(1) center is coordinated by two nitrogen atoms of –CN groups and two oxygen atoms from two different $CO_2CF_3^-$ anions, resulting in a severely distorted tetrahedral environment, with the angles around the Ag(1) center ranging from 98.1 to 150.05°. The Ag(1)–N(1) and Ag(1)–O(1) bond lengths are 2.371 and 2.263 Å, respectively, while the coordination sphere around each Ag(2) center is composed of four oxygen atoms from four $CO_2CF_3^-$ anions with two different Ag–O distances (2.235 and 2.570 Å). Thus, the final coordination geometry around the Ag(2) center is irregular with bond angles ranging from 75.30 to 163.84°. The Ag(1) and

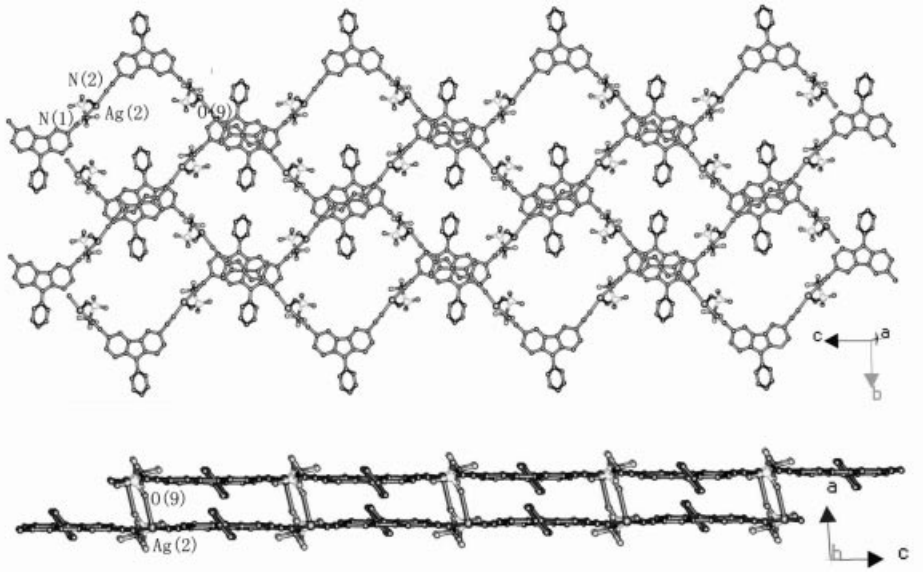

Figure 8. Top (top) and side (bottom) views of two-dimensional double-layer supramolecular networks of chain b stacked together through multiple C–H···O hydrogen-bonding interactions and face-to-face π···π stacking interactions ($d_{\pi-\pi}$ = 3.485 Å).

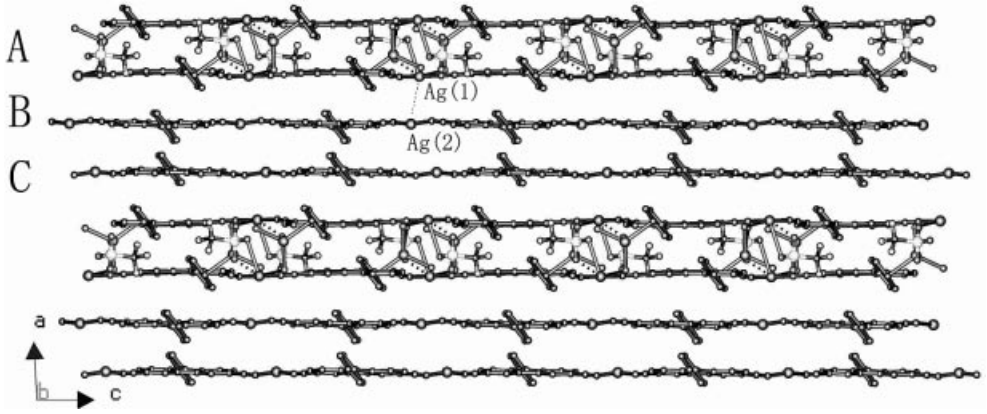

Figure 9. View of the packed structure (parallel to *ac* plane) in complex **3**, showing *...ABC...* packing sequence of chains a and b in the crystal lattice. Some of the $SO_3CF_3^-$ anions, water, and benzene molecules have been omitted for clarity in this figure.

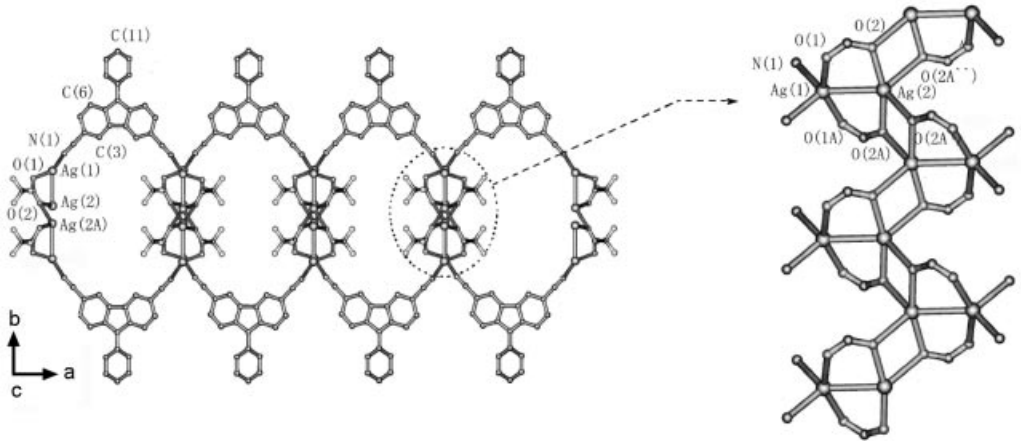

Figure 10. Perspective view of **4**, showing a one-dimensional macrocycle-containing chain.

Ag(2) atoms are bridged by two carboxyl groups with an Ag–Ag distance of 2.992 Å, which is slightly longer than for metallic silver (ranging from 2.803 to 2.987 Å) and shorter than for other reported ligand-unsupported Ag–Ag distances (ranging from 3.011 to 3.655 Å).[14,23] To form the nanotube, each carboxyl group of $CF_3CO_2^-$ connects to three Ag atoms through its two oxygen atoms: one oxygen atom bridges two Ag atoms, while another oxygen atom attaches to the third Ag atom. Therefore, $CF_3CO_2^-$ acts as a $\mu_2$-bridge and links two Ag(2) units, resulting in linear distorted ladder-like Ag chains. The ligand dcphcz is therefore bridged by Ag(1) atoms, producing a condensed nanotubular structure with dimensions of about $12 \times 13$ Å. The adjacent nanotubes are in line through multiple Ag–$O_{carbonyl}$ bonding (Figure 11). Of course, the whole structure can also be regarded as parallel Ag chains linked by dcphcz spacers.

Analogously, adjacent 2D architectures containing 1D open channels along the *c* axis direction stack in the *ab* plane through noncovalent face-to-face π···π interactions between the carbazolyl planes of dcphcz ligands with an interplane distance of 3.355 Å for **4**. However, the open channels are fully filled with the terminal phenyl group of dcphcz from adjacent 2D units. These noncovalent interactions serve again as important driving forces for cross-linking the 2D structure into a 3D architecture.

The different polymeric motifs from the four complexes indicate that the counteranions and bridging ligands are two crucial factors in designing the structure and geometry of the self-assemblies. The properties of the bridging ligands, such as π-conjugated spacers and relative orientation of the donor groups, take important roles in controlling the structural topologies of their metal–organic supramolecular architectures. In this system, the coordination conformation of dcphcz is special because of the conformational irrotationality around the central five-membered ring of the carbazolyl group. Thus, the architecture of the complexes depends greatly on the counterions. Furthermore, π···π stacking between carbazole rings is the basis of the 3D architectures in the complexes **1**–**4**.

### Thermogravimetric Analysis

Thermogravimetric analysis of compound **3** was performed by heating the complex from 20 to 600 °C under $N_2$. The TGA curve for complex **3** showed that the first major weight loss of the lattice benzene occurred between 40 and 100 °C by 5.10% weight (calcd. 7.38%), which indicates that benzene molecules could easily escape from the crystal lattice of **3**. As shown in Figure S14, further thermogravimetric data shows the second major weight loss of the four water molecules between 110 and 145 °C by 4.11% weight (calcd. 4.78%).

### Luminescent Properties

For potential applications as luminescent materials,[24] fluorescence properties have been investigated in metal–organic coordination polymers. Because of their ability to affect the emission wavelength of organic materials, syntheses of inorganic–organic coordination polymers have employed the ingenious design of conjugated organic ligands and judicious choice of proper metal centers in order to obtain new types of luminescent materials,[25] especially for $d^{10}$ metal systems[13c,13d,26] and highly conjugated ligand-containing complexes.[11,13c,27] We have explored the luminescent properties of 3,6-bis(2,2′-dipyridylamino)-9-phenylcarbazole and its $Ag^I$ coordination polymer.[11c] The results indicated that the emission color of organic spacers ddpapcz was remarkably affected by Ag coordination compounds. Herein, the luminescent properties of 3,6-dicyano-9-phenylcarbazole and its metal complexes **1**–**4** were investigated.

The UV/Vis spectra of ligand dcphcz and complexes **1**–**4** display two intense absorption bands from π→π* electronic transitions (from 230 to 290 nm), which originate from the carbazolyl groups (Figure S15). No difference in emission colors has been observed between free ligand and complexes in methanol, which has a broad fluorescent emission band (from 340 to 420 m), with $\lambda_{max}$ = 367 nm (Figure S16). This probably implies that the polymeric complexes disaggregate in methanol solution. The dissociation of Ag-supramolecules in solvent has been reported in many other samples.[11c,14]

Despite the similarity of emission bands in solution, the emission bands of five compounds in the solid state are significantly different (Figure S17). A very strong emission of the free ligand dcphcz with a wavelength from 375 to 575 nm ($\lambda_{max}$ = 404 nm) upon excitation at 330 nm is observed, which has a redshift relative to the solution state. This can be explained by the extensive π···π stacking in the solid state, which is between the carbazolyl planes of one dcphcz and the neighboring molecules with an interplane distance of 3.47 Å. This π···π stacking lowers the excited energy of dcphcz in the solid state and causes the redshift of emission energy relative to the solution, in which the carbazolyl stacking could not exist.

Blue/green luminescence is observed with the coordination to the silver center. In the solid state, complexes **1**–**3** show broad emission bands at 499 (**1**), 515 (**2**), and 492 nm (**3**), respectively, upon 330 nm excitation, whereas **4** has also a very broad emission band (bandwidth at half-height = 110 nm) with $\lambda_{max}$ = 425 nm, which is in the blue region and yields visible blue luminescence. Thus, complex **4** may have potential applications as a luminescent material in organic light-emitting devices. Generally, the intraligand fluorescence emission wavelength is determined by the energy gap between π and π* molecular orbitals of the free ligand, which is related to the extent of π conjugation in the system.[28] Since the emission peak positions of complex **4** almost corresponded to that of the ligand dcphcz, they should be due to neither ligand-to-metal nor metal-to-ligand charge transfer and can be ascribed to the intraligand π-π* charge transfer of dcphcz. All these complexes exhibited relatively weak emissions, which may be a result of the heavy-atom effect of silver.[29]

It is clear that significantly different emission in **1**–**4** is due to the variation of anions and coordination environments, because photoluminescence behaviors closely associate with the local environments around metal ions.[20a,30] In **1** and **2**, the anions $BF_4^-$ and $ClO_4^-$ are similar in nature and also display similar weak coordination to $Ag^I$. Complex **3** has two 1D chain units, which are similar to those in **1** and **2**, and the anion $CF_3SO_3^-$ also weakly coordinates to $Ag^I$ although it has properties different from those of $BF_4^-$ and $ClO_4^-$. In contrast, each $Ag^I$ ion in complex **4** is strongly coordinated by O atoms of $CF_3CO_2^-$ and provides a coordination geometry different from those of **1**–**3**.

## Conclusions

Four $Ag^I$-dcphcz coordination polymers with one-, two-, and three-dimensional supramolecular structures have been successfully prepared by the reaction of dcphcz and $Ag^I$ salts with different counterions in solution. The roles of the counteranions in determining the molecular structures of the coordination polymers have been exhibited. The nature of the anions is the underlying reason behind the differences in the structures of this series of $Ag^I$ complexes. In complexes **1** and **2**, the weakly coordinated $BF_4^-$ and $ClO_4^-$ anions not only act as the counteranions to balance the charge but have a spatial templating effect in building up the coordination frameworks. For **3** and **4**, the bulkier $CF_3SO_3^-$ and $CF_3CO_2^-$ anions possess stronger coordination ability than $BF_4^-$ and $ClO_4^-$ and serve as linkages to bridge the 1D chains to 2D MOFs with Ag–O contacts. Moreover, the coordinated $CF_3SO_3^-$ and $CF_3CO_2^-$ ions also possess weak interactions with ligand units, probably act as templates for the formation of the network, and consequently maintain the structural stability. In addition, for the $Ag^I$-dcphcz system in this work, the conformation of dcphcz does not depend on the counterion and solvent system used in the formation of the complexes.

The self-assembly of the bent organic ligands with highly planar π-conjugated spacers provides a new approach for building metal–organic frameworks consisting of a 1D open

channel. We are also intrigued by the question whether the variation of the terminal group of dicyanocarbazole will lead to MOF assemblies with open channels by introducing small groups to the 9-position of the carbazole on coordination. Further work is currently ongoing in this laboratory.

## Experimental Section

**Materials and Methods:** All starting chemicals were of reagent-grade quality, obtained from commercial sources and used without further purification. Bromobenzene was freshly distilled. Benzene was freshly distilled from sodium/benzophenone; dichloromethane was dried and distilled from $P_2O_5$ under nitrogen; dmf was dried and distilled from $MgSO_4$. $^1H$ NMR spectra were recorded with a Bruker 300 Ultrashield spectrometer operating at 300 MHz. The FT-IR spectra were recorded in the region 400–4000 $cm^{-1}$ with a Bruker EQUINOX 55 VECTOR22 spectrophotometer and the samples were prepared using KBr pellets. Elemental analyses were carried out with an Elmentar Vario EL-III analyzer. Fluorescence measurements were carried out with a JOBIN YVON Analytical Instrument FLUOROLOG-3-TAU at room temperature. Thermogravimetric analyses (TGA) were performed with a TGA-50H thermoanalyzer under $N_2$ (in the temperature range 20–600 °C) at a heating rate of 10 °C/min. 9-Phenylcarbazole and 3,6-diiodo-9-phenylcarbazole were synthesized according to procedures reported earlier.[11c,31]

***Caution!*** One of the crystallization procedures involves $AgClO_4$, which is a strong oxidizer.

**Synthesis of 3,6-Dicyano-9-phenylcarbazole (dcphcz):** A mixture of 3,6-diiodo-9-phenylcarbazole (0.99 g, 0.002 mol) and CuCN powder (0.448 g, 0.005 mol) in HMPA (10 mL) was stirred under the protection of dry nitrogen at 160 °C for 6 h. The reaction mixture was cooled to ambient temperature, poured into aqueous $NaHCO_3$ (10%) and extracted with dichloromethane. The aqueous phase was discarded, the organic layer was washed with distilled water to neutral pH, dried with $MgSO_4$ and concentrated in vacuo. The residue was filtered to give the desired compound as a primrose solid. Yield: 0.55 g, 93%. IR (KBr): $\tilde{\nu}$ = 2219 (vs), 1631 (m), 1595 (s), 1502 (s), 1480 (s), 1455 (m) 1369 (m), 1292 (s), 1243 (s), 1185 (m) $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.48 (d, 2 H), 7.75–7.71 (d, 4 H), 7.68–7.60 (d, 1 H), 7.49–7.52 (d, 2 H), 7.42–7.44 (d, 2 H) ppm.

**Synthesis of $\{[Ag(dcphcz)]BF_4\}_n$ (1):** Upon a solution of dcphcz (0.0586 g, 0.2 mmol) in 5 mL of dichloromethane was successively layered a solution of $AgBF_4$ (0.0390 g, 0.2 mmol) in benzene (4 mL). The vial was covered with aluminum foil and the solvents were allowed to diffuse slowly. Bright yellow crystals suitable for X-ray structure analysis were obtained several days later. Yield: 0.0517 g, 53%. IR (KBr): $\tilde{\nu}$ = 2251 (vs), 1631 (m), 1591 (s), 1492 (s), 1362 (m), 1294 (s), 1244 (s), 1187 (m), 1063 (vs), 821 (m) $cm^{-1}$. $C_{20}H_{11}AgBN_3F_4$ (488.00): calcd. C 49.23, H 2.273, N 8.611; found C 49.31, H 2.274, N 8.620.

**Synthesis of $\{[Ag(dcphcz)]ClO_4\}_n$ (2):** Upon a solution of dcphcz (0.0586 g, 0.2 mmol) in 5 mL of dichloromethane was successively layered a solution of $AgClO_4$ (0.0414 g, 0.2 mmol) in benzene (5 mL). The vial was covered with aluminum foil and the solvents were allowed to diffuse slowly. Bright yellow crystals suitable for X-ray structure analysis were obtained several days later. Yield: 0.0651 g, 65%. IR (KBr): $\tilde{\nu}$ = 2251 (vs), 1628 (m), 1592 (s), 1501 (s), 1479 (s), 1367 (m), 1295 (s), 1245 (vs), 1188 (m), 1092 (vs) $cm^{-1}$. $C_{20}H_{11}AgClN_3O_4$ (500.6): calcd. C 47.98, H 2.215, N 8.393; found C 48.09, H 2.209, N 8.401.

**Synthesis of $\{[Ag(dcphcz)][Ag_2(dcphcz)(H_2O)_2](SO_3CF_3)_3 \cdot C_6H_6 \cdot (H_2O)_2\}_n$ (3):** Upon a solution of dcphcz (0.0586 g, 0.2 mmol) in 5 mL of dichloromethane was successively layered a solution of $AgSO_3CF_3$ (0.0514 g, 0.2 mmol) in benzene (5 mL). The vial was covered with aluminum foil and the solvents were allowed to diffuse slowly. Bright yellow single crystals suitable for X-ray structure analysis were obtained several days later. Yield: 0.0573 g, 57%. IR (KBr): $\tilde{\nu}$ = 2220 (vs), 1632 (m), 1596 (s), 1503 (s), 1481 (s), 1456 (m) 1369 (m), 1245 (vs), 1176 (vs), 1034 (vs) $cm^{-1}$. $C_{49}H_{36}Ag_3F_9N_6O_{13}S_3$ (1507.6): calcd. C 39.04, H 2.407, N 5.574; found C 39.01, H 2.402, N 5.583.

**Synthesis of $[Ag_2(dcphcz)(CF_3COO)_2]_n$ (4):** Upon a solution of dcphcz (0.0586 g, 0.2 mmol) in 4 mL of dichloromethane was successively layered a solution of $CF_3COOAg$ (0.0442 g, 0.2 mmol) in benzene (5 mL). The vial was covered with aluminum foil and the solvents were allowed to diffuse slowly. Bright yellow single crystals suitable for X-ray structure analysis were obtained several days later. Yield: 0.0471 g, 64%. IR (KBr): $\tilde{\nu}$ = 2219 (vs), 1682 (vs), 1595 (m), 1501 (m), 1480 (m), 1292 (m), 1209 (vs), 1132 (vs) $cm^{-1}$.

$C_{24}H_{11}Ag_2F_6N_3O_4$ (735.1): calcd. C 39.21, H 1.509, N 5.716; found C 39.22, H 1.509, N 5.721.

**X-ray Crystallography:** X-ray diffraction data were collected with a Bruker-AXS SMART CCD area detector diffractometer at 293 K using ω-rotation scans with a scan width of 0.3° and Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods and refined with the full-matrix least-squares technique using SHELXTL.[32] Anisotropic thermal parameters were applied to all non-hydrogen atoms. All of the hydrogen atoms in these structures are located from the differential electron density map and constrained to the ideal positions in the refinement procedure. The crystallographic calculations were conducted using the SHELXL-97 program. Crystal data and experimental details for the crystals of the ligand dcphcz and complexes **1**–**4** are summarized in Tables 1 and 2. CCDC-286976, -608217, -286975, -286973, and -286974 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): TGA, UV/Vis absorption spectra, emission spectra in MeOH solution and solid state.

# Synthesis and Coordination Behavior of Symmetrical Tetraamine Phosphinic Acids

**Vojtěch Kubíček,*[a] Ivan Řehoř,[a] Jana Havlíčková,[a] Jan Kotek,[a] Ivana Císařová,[a] Petr Hermann,[a] and Ivan Lukeš[a]**

**Keywords:** Aminophosphinates / Complexes / Stability constants / Potentiometry

Two new tetraamine ligands, bis[*N*-(2-aminoethyl)aminomethyl]phosphinic acid ($Hen_2p$) and bis[*N*-(3-aminopropyl)-aminomethyl]phosphinic acid ($Hpn_2p$), were synthesized from the corresponding diaminoalkanes and bis(chloromethyl)phosphinic acid. Their acid–base properties and complexation with $Cu^{2+}$, $Ni^{2+}$, and $Zn^{2+}$ ions were studied by potentiometric titrations. Different chain lengths of the ligands result in significantly different coordination abilities. The five-membered chelate ring of $Hen_2p$ leads to a higher stability of its complexes. In comparison with tetraamines having the same number of the bridging atoms separating the amino groups, the presence of the phosphinic acid moiety decreases the basicity of the amine groups, and consequently, the stability of their complexes. Several solid-state structures were determined by X-ray diffraction analysis. Four nitrogen atoms coordinate the $Cu^{2+}$ or $Zn^{2+}$ ion in a square-planar fashion, whereas the phosphinic acid group is not coordinated or acts as a bridging unit between neighboring metal ions. The unexpectedly high stability of the $Ni^{2+}/Hpn_2p$ complex can be explained by the possible presence of a tetramer in solution as was found in the solid state.

## Introduction

The phosphinic acid group is derived from phosphoric acid by replacement of two –OH groups with hydrogen, alkyl, or aryl groups (Figure 1). In comparison with phosphonates (where only one –OH group is replaced), phosphinic acid derivatives are less studied because their synthesis is more complicated. Derivatives of phosphonic and phosphinic acids substituted in the α-position with an amino group have been intensively studied over the last 25 years as inhibitors of various enzymes.[1] Tetrahedral phosphinic (or phosphonic) acid groups mimic a transition state that is present during the hydrolysis of peptides and block efficiently the active sites of hydrolytic enzymes. Hydrolytic enzymes such as, for example, peptidases often contain a metal ion in the active site, and the inhibiting aminophosphinic acid binds the metal ion. Therefore, complexation properties of the phosphorous acid analogs have been studied in solution as well in the solid state.[2,3] Some of these compounds are produced commercially in a large scale as herbicides (Glyphosate, Bialaphos, etc.).[4]

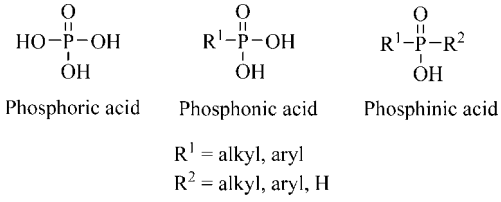

Figure 1. Phosphoric acid and its organophosphorus analogues.

Usually, an introduction of acidic fragments into a chelating molecule results in a higher stability of the complexes and decreases the overall charge of the complex formed in comparison with those of the corresponding amine. Phosphonic or phosphinic acid groups represent an alternative for the generally used carboxyl group. Relative to the carboxylate function, the presence of the phosphinic acid group decreases the basicity of the nearest amino group as well as the stability of the complexes as a result of the electron-withdrawing effect of the phosphorus atom. In the case of phosphonic acid derivatives, the doubly negative charge of the phosphonate overcompensates this disadvantage, leading to higher dissociation and, consequently, stability constants. Dissociation constants of the nitrogen atoms and stabilities of the complexes of these related ligands then follow the order: aminophosphinates < aminocarboxylates < aminophosphonates.[2,3] On the other hand, the higher acidity of the phosphonic and phosphinic acid groups causes the complexation to start at a lower pH. The lower stability

of the phosphinate complexes can by compensated by their structural flexibility. Whereas the carboxylic and phosphonic acid groups are the terminal ones, the phosphinic acid group allows the attachment of another molecule fragment and the formation of more complicated structures and bifunctional ligands. Studies of phosphinic acid analogs of common amino acids in solution are not very frequent and confirm the above general considerations.[5–9] In addition, the solution properties depend on the kind of substituent bound to the phosphorus atom for simple aminophosphinic acids[8] as well as for their dipeptides.[10] In the complexes in the solid state, the amino group can be protonated and the metal ion is bound only by the phosphinate oxygen atom(s)[9,11–15] or the phosphinic amino acids can behave as chelating ligands bound through amino and phosphinate groups.[8,9,16,17] In addition, the phosphinate moiety serves as a bridge between two metal ions, often forming characteristic eight-membered M–(O–P–O)$_2$–M metallacycles.[8,11,13–15]

During the last decades, aminoalkylphosphinic acid groups have been used as building blocks in the design of polydentate ligands.[2,18] These compounds, usually based on acyclic[19–22] or macrocyclic[23–29] polyamine skeletons, have been studied as ligands for binding of "hard" metal ions, e.g. lanthanide(III) ions. The introduction of the methylphosphinic acid group(s) into DTPA or DOTA skeletons has led to an interesting alteration of properties of complexes of such ligands which are studied as possible contrast agents in magnetic resonance imaging,[30–37] for utilization in nuclear medicine,[38] or for luminescence imaging.[39]

Surprisingly, complexation abilities of compounds bearing two aminoalkyl substituents on one phosphorus atom have been only sparingly investigated. There are only several studies dealing with the solution[9,40–42] or solid-state[9,41,42] studies of this class of ligands. To obtain more information about the ligands, we decided to synthesize and investigate two new symmetrical polyaminophosphinic acid ligands, bis[*N*-(2-aminoethyl)aminomethyl]phosphinic acid (Hen$_2$p) and bis[*N*-(3-aminopropyl)aminomethyl]phosphinic acid (Hpn$_2$p) (Figure 2). Their acid–base and complexation properties were studied by using potentiometric titrations and UV/Vis spectroscopy. The solid-state structures of several complexes were determined by X-ray diffraction. As ligands containing the phosphinic acid group inside a macrocyclic skeleton have been previously prepared,[43] these open-chain ligands can serve for comparison of the properties of the corresponding cyclic and acyclic ligands.

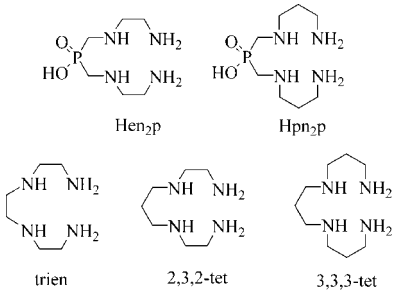

Figure 2. Ligands discussed.

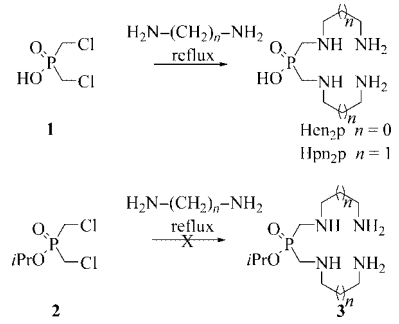
## Results and Discussion

### Synthesis

The ligands Hen$_2$p and Hpn$_2$p were prepared by reaction of bis(chloromethyl)phosphinic acid (**1**) with 1,2-diaminoethane or 1,3-diaminopropane. Nucleophilic substitution of the chlorine atoms proceeds in almost quantitative yield. The formation of polymers was reduced by using a 100-fold excess of the diaminoalkane. After purification on ion-exchange resins, both ligands were isolated as their trihydrobromides; they slowly lost hydrobromic acid on storage or heating.

Neither the two ligands nor their salts are soluble in common organic solvents. For future synthetic purposes, solubility in organic solvents would be useful. Therefore, we tried to prepare an esterified form **3** by the reaction of isopropyl bis(chloromethyl)phosphinate (**2**) with the diaminoalkanes (Scheme 1). All these attempts failed, as the deesterification (by alkylation of the diaminoalkane with the isopropyl group) proceeded much faster than the substitution of chlorine atoms, and, at reflux temperature, both ligands were formed in the nonesterified form. When the reaction mixture was stirred at ambient temperature, the only product formed was bis(chloromethyl)phosphinic acid (**1**) as a result of the deesterification.



Scheme 1. Synthesis of the ligands.

### Acid–Base Properties

Both ligands, Hen$_2$p and Hpn$_2$p, contain five groups that can be protonated. The last two dissociations occur in strongly alkaline solution. The protonation constants, corresponding to proton loss from the terminal (primary) amino groups, are similar to those found in the corresponding tetraazaalkanes (Table 1). Whereas these two deprotonations are almost independent, the other two dissociations are strongly affected by the number of atoms separating the secondary amino groups from already protonated primary amino groups. The presence of propylene bridges results in a higher basicity of the secondary amino groups. In the case

[a] trien = triethylenetetraamine (1,4,7,10-tetraazadecane). [b] 2,3,2-tet = 1,4,8,11-tetraazaundecane. [c] 3,3,3-tet = 1,5,9,13-tetraazatridecane).

of ligands $Hen_2p$ and $Hpn_2p$, these two dissociation constants were found to be 1–2 orders of magnitude lower than those found for 2,3,2-tet and 3,3,3-tet. This decrease in basicity is typical for amino groups in the α-position to the phosphinate moiety.[2,3,9] Protonation of the phosphinate group occurs at very low pH (<1). The values of the dissociation constants of the fully protonated species are below the limit of the potentiometric method, and it was therefore not possible to calculate these constants.

## Complexation Properties

To simplify the following text we use a three-digit code for describing the complexes. The first digit represents the number (stoichiometric coefficient) of protons, the second one is the number of ligand molecules, and the third one is the number of metal ions. The negative value of the first digit represents a hydroxido complex. In general, complex $[H_hL_lM_m]$ is represented by [hlm], and its overall stability constant is $\beta_{hlm}$. Charges of the complexes are omitted.

Complexation properties of the ligands $Hen_2p$ and $Hpn_2p$ towards $Cu^{2+}$, $Ni^{2+}$, and $Zn^{2+}$ ions were studied by potentiometric titrations. The results are listed in Table 2. Some of the constants were not calculated. This is probably due to a simultaneous protonation of two sites and/or a very low abundance of the corresponding species (<10%).

Table 2. Overall stability constants ($\log\beta_{hml}$) of the complexes.

### *Ligand $Hen_2p$*

In equimolar solutions, complexation of the $Cu^{2+}$ and $Ni^{2+}$ ions starts with formation of the monoprotonated

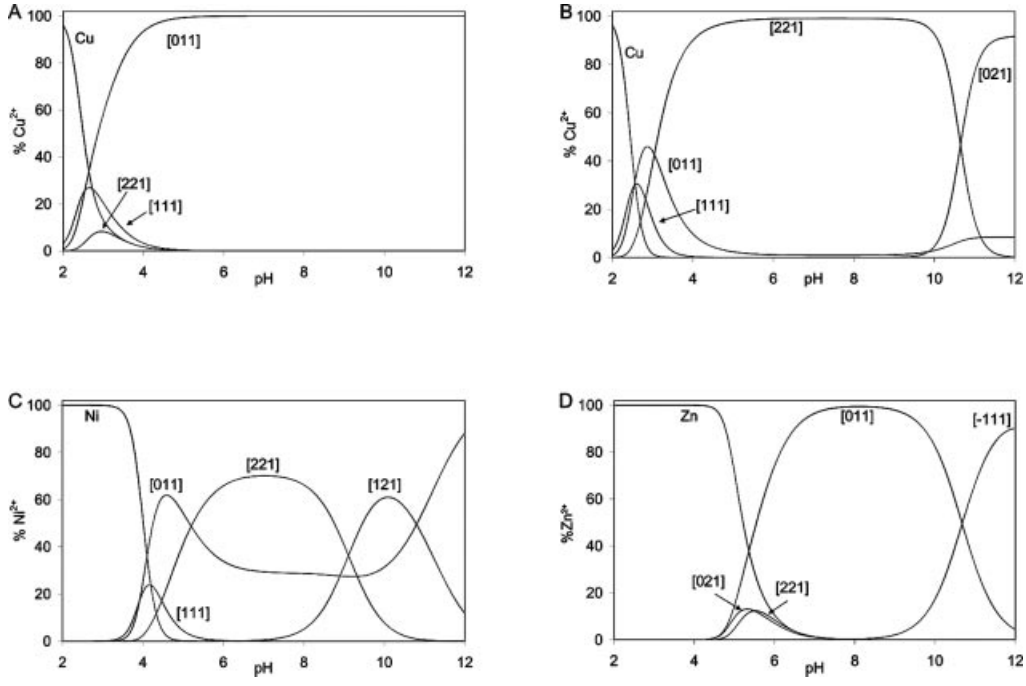

Figure 3. Distribution diagrams. (A) $Cu^{2+}/Hen_2p$ 1:1; (B) $Cu^{2+}/Hen_2p$ 1:2; (C) $Ni^{2+}/Hen_2p$ 1:2; (D) $Zn^{2+}/Hen_2p$ 1:1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[111] complex at pH ≈ 2 for $Cu^{2+}$ (Figure 3A) and pH ≈ 3 for $Ni^{2+}$. The protonated complex does not exhibit a high abundance (<30%), and its deprotonation to the [011] species occurs with low p$K_A$ (p$K_{Cu}$ = 2.5, p$K_{Ni}$ = 3.9). The nonprotonated complex [011] is the only species present in the neutral and alkaline regions. Complexation of the $Zn^{2+}$ ion proceeds differently. The protonated complex [111] was not observed. Complexation starts at pH ≈ 4.5 with the formation of the [011] complex. At pH > 8, the hydroxido [–111] complexes are formed and become the main species present in the solution under the strongly alkaline conditions (Figure 3D).

In the presence of excess ligand (1:2 $M^{2+}$/L ratio), [221] complexes were formed in the neutral region (abundance >90% for $Cu^{2+}$, ca. 70% for $Ni^{2+}$, ca. 40% for $Zn^{2+}$; Figure 3B, C). Deprotonation results in the formation of [021] complexes ($Cu^{2+}$, $Zn^{2+}$) at pH ≈ 10–11 or a [121] complex ($Ni^{2+}$) at pH ≈ 9. In the presence of excess metal (2:1 $M^{2+}$/L ratio), the $M^{2+}$ hydroxides precipitated in all systems. Distributions in all systems are given in the Supporting Information (Figure S1).

### *Ligand $Hpn_2p$*

A successful fitting of titrations of all three studied systems containing the ligand $Hpn_2p$ required inclusion of the complexes with M/L ratios 1:1, 1:2, and 2:1 in various degrees of protonation (Figure 4). The complexation process starts at slightly higher pH (about 0.5 units) than that for $Hen_2p$. Complexation of $Cu^{2+}$ and $Ni^{2+}$ ions exhibits a preference for formation of the [011] complex, which is the main species present in equimolar solution (Figure 4A, B). In the presence of excess ligand, the complexes with 1:2 $M^{2+}$/L stoichiometry are formed only in the case of $Cu^{2+}$ ion in alkaline solutions (pH > 9). In the case of $Ni^{2+}$, complex [011] remains the major species in the whole alkaline region (Figure 4C). In the presence of excess $Cu^{2+}$ ions, the dinuclear [012] complex becomes dominant with an abundance of ca. 90% (at pH ≈ 6). For $Ni^{2+}$, the abundance of the [012] complex does not reach more than 30%. The $Zn^{2+}$/$Hpn_2p$ system involves a mixture of several complexes with comparable abundances in equimolar solution and with ligand in excess. In the presence of excess $Zn^{2+}$ ions, the dinuclear [–112] hydroxido complex becomes a major species. The unusually high abundance of this complex in equimolar solution (ca. 50% at pH ≈ 8) indicates a strong preference for this species (Figure 4D), where $OH^-$ probably forms a bridge between two metal ions. A similar motif of two hydroxide-bridged zinc(II) ions was observed in several types of metalloenzymes[45] and artificial catalytic centers[46] playing a role in hydrolytic processes. Distributions in all systems are given in the Supporting Information (Figure S2).

Results of the potentiometric study show that both studied ligands exhibit similar trends of coordination behavior to that of related linear tetraamines (Table 3). Stability constants of complexes of the tetraamine ligands with divalent metals increase in the order 3,3,3-tet < trien < 2,3,2-tet as a result of steric properties of the ligand. The least stable complexes are formed by 3,3,3-tet as all chelate rings in the complexes are six-membered, which is in general less convenient relative to trien and 2,3,2-tet, which form five-membered chelate rings.[47] The flexibility of the propylene bridge in 2,3,2-tet allows the formation of complexes having ideal square geometry, whereas the shorter ethylene bridge of trien is not ideal for this equatorial coordination. The lower basicity of $Hen_2p$ and $Hpn_2p$ in comparison with those of 2,3,2-tet and 3,3,3-tet (ligands having the same

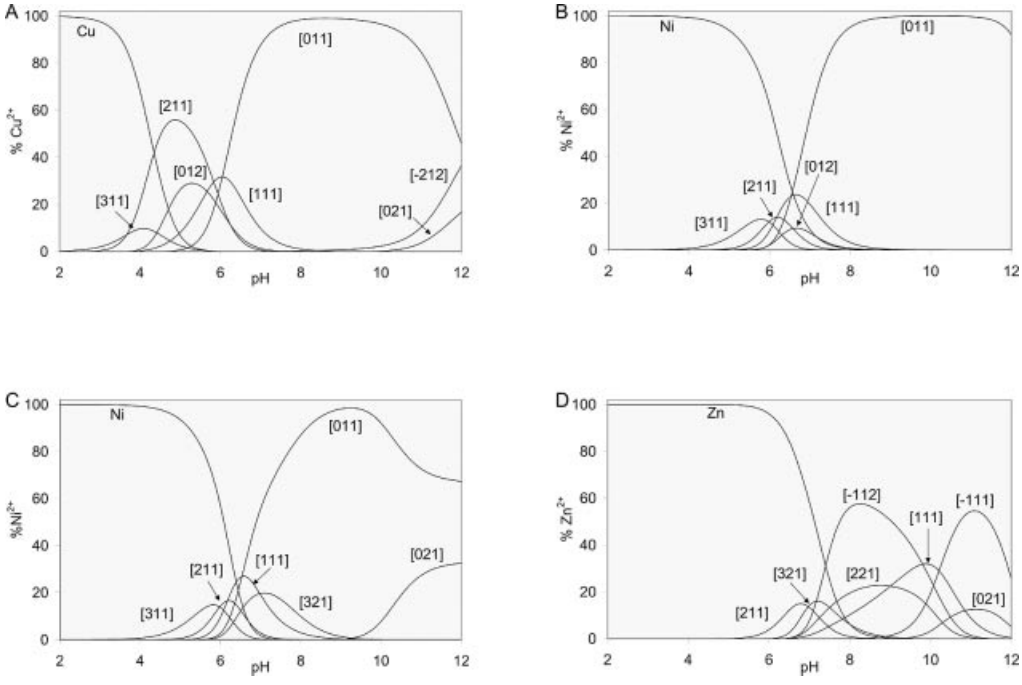

Figure 4. Distribution diagrams. (A) $Cu^{2+}$/$Hpn_2p$ 1:1; (B) $Ni^{2+}$/$Hpn_2p$ 1:1; (C) $Ni^{2+}$/$Hpn_2p$ 1:2; (D) $Zn^{2+}$/$Hpn_2p$ 1:1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

number of bridging atoms between amino groups) results in the decrease of the stability constants of the [011] complexes, which are 1–3 units lower than those reported for the corresponding tetraamines. The only exception is the $Ni^{2+}$/$Hpn_2p$ system, whose [011] complex exhibits a slightly higher stability than that of 3,3,3-tet. This can be explained by a possible formation of the cyclic tetrameric complex [044], which was identified in the solid state (see further). As this complex shows very similar potentiometric behavior to the [011] complex, the presence of the [044] complex cannot be confirmed by potentiometry, mainly because of the rather complex chemical model of the system. The possible presence of the tetramer in the solution is supported by the similarity of the UV/Vis spectra in the solution ($Ni^{2+}$/$Hpn_2p$ 1:1, pH = 10, 100% abundance of [011] species according to the distribution diagram, see Figure 4B) and in the solid state (complex [044], see crystallographic part). The UV/Vis spectra are shown in Figure 5 (maxima in the solution at 364, 581, and 947 nm; maxima in the solid state at 366, 587, and 970 nm).

Table 3. Comparison of stability constants $\log\beta_{011}$ of complexes found for $Hen_2p$ and $Hpn_2p$ with those reported for linear tetraamines.[44]

| Ion | $Hen_2p$ | $Hpn_2p$ | trien[a] | 2,3,2-tet[b] | 3,3,3-tet[c] |
|---|---|---|---|---|---|
| $Cu^{2+}$ | 21.63 | 15.94 | 20.2 | 23.9 | 17.3 |
| $Ni^{2+}$ | 15.68 | 11.34 | 14.4 | 16.4 | 10.65 |
| $Zn^{2+}$ | 12.04 | 8.22 | 12.1 | 12.8 | 9.41 |

[a] trien = triethylenetetraamine (1,4,7,10-tetraazadecane). [b] 2,3,2-tet = 1,4,8,11-tetraazaundecane. [c] 3,3,3-tet = 1,5,9,13-tetraazatridecane.

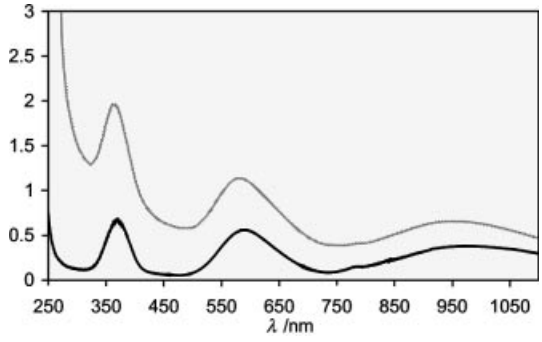

Figure 5. Comparison of the UV/Vis spectra of the $[Ni_4(pn_2p)_4]^{4+}$ complex in solution (dashed line) and in the solid state (solid line). The *y* axis shows absorbance units for solution and Kubelka–Munk units for the solid state.

Comparison of the $Hen_2p$ and $Hpn_2p$ systems can nicely document the different selectivity of these ligands. The higher stability of $Hen_2p$ complexes and the simpler models for the $M^{2+}$/$Hen_2p$ systems (4–5 species, strong preference for [011] complexes) indicate that the stereochemical properties of this ligand are much more suitable for the complexation of the studied divalent metal ions than those of the ligand $Hpn_2p$ (7–9 species in each system).

## Crystallography

The crystal structures of three salts of the $H_4en_2p$ cation, two $Hen_2p$ and two $Hpn_2p$ complexes were determined by X-ray diffraction. In contrast to the simplest bis(aminomethyl)phosphinic acid,[9] the phosphinic acid groups of the studied ligands are not coordinated in acid solution, and the ligand behaves only as an organic base. In the presence of a bulky anion, e.g. tetrachlorocuprate(II), the simple salts crystallize. In neutral and alkaline solutions, both ligands behave in a similar manner as the corresponding tetraamines; four nitrogen atoms of one ligand molecule are coordinated in equatorial positions around the transition-metal ion. In the solid state, the phosphinic acid group is mostly coordinated to another metal center and plays the role of the bridging unit. In simple systems [ligand, metal(II) chloride, hydrochloric acid, sodium hydroxide], crystallization experiments were not successful – oily and glassy products were formed. Single crystals were obtained after bulky anions (perchlorate, hexafluorophosphate) and ammonium cations (forming a hydrogen-bond network) were added and the pH was adjusted to the value of the maximum abundance of the species in solution (according to the distribution diagrams). In addition, in most cases, only several single crystals, which decomposed on standing in air, were obtained. Therefore, microanalytical data are not provided (the rest of the solution formed only oils).

### *Ligand Salt Structures (4, 5, 6)*

In all three structures, all four amino groups are protonated, and the phosphinic acid group is deprotonated. The distances between the phosphorus atom and the two oxygen atoms in the structure of $(H_4en_2p)Cl_3$ (**4**) are the same (1.49 Å), which indicates full delocalization of the phosphinate negative charge. The two side arms of the ligand are almost planar. Both compounds $(H_4en_2p)[CuCl_4]Cl$ (**5**) and $(H_4en_2p)[ZnCl_4]Cl$ (**6**) are almost isostructural. All amino groups are protonated, whereas the phosphinic acid group is deprotonated. In contrast to the structure of **4**, the ligand side-arms are not arranged in one plane. Torsion angles around the phosphorus atom (C–P–C–N) are 73–75° (for **4**), 155–158° (for **5**), and 160° (for **6**). The torsion angles about the P–C–N–C bonds are antiperiplanar (170–180°). Other bonds in the chain are in the synclinal conformation (torsion angles of 61–82°) probably because of the presence of the hydrogen-bond network between the protonated amino groups and the anions. The coordination sphere of both tetrachloroanions is a distorted tetrahedron. The structure of the $(H_4en_2p)^{3+}$ cation in $(H_4en_2p)Cl_3$ (Figure S3), the independent unit found in the crystal structure of $(H_4en_2p)[CuCl_4]Cl$ (Figure S4), and selected geometric parameters (Table S1) are given in the Supporting Information.

### *$Na_2(NH_4)_4[Cu(en_2p)]_4Br_4(PF_6)_6\cdot H_2O$ (7)*

The structural unit has a plane of symmetry. The structurally independent part consists of four halves of the complex molecules. Their central atoms ($Cu^{1a}$, $Cu^{1b}$, $Cu^{1c}$, and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Cu^{1d}$) are situated in a plane. Three complex units (with central ions $Cu^{1a}$, $Cu^{1b}$, and $Cu^{1c}$) are coordinated to one $Na^+$ cation ($Na^1$) through phosphinate oxygen atoms. The fourth complex forms a coordination bridge between $Cu^{1b}$ and $Cu^{1c\#}$ (of the neighboring crystal unit) through the two bromide anions $Br^2$ and $Br^3$. In all complexes, amino groups occupy equatorial positions, and the $N_4Cu$ plains are perpendicular to the crystallographic plane of symmetry. The $Cu^{2+}$ ions $Cu^{1a}$ and $Cu^{1b}$ have an octahedral coordination sphere with one bromide anion ($Br^1$ or $Br^2$) and one phosphinate oxygen atom ($O^{61b}$ or $O^{61c}$ coming from ligand molecules coordinated to the neighboring $Cu^{2+}$ ions) in axial positions. The coordination sphere of $Cu^{1c}$ is square-pyramidal with bromide anion $Br^{3\#}$ in the axial position. $Cu^{1d}$ has an octahedral coordination sphere with two bromide anions ($Br^2$ and $Br^3$) in the axial position. Part of the crystal structure of complex **7** is shown in Figure 6. Cocrystallized water molecules as well as ammonia cations fill the empty cavities of the structure, forming a system of hydrogen bonds. The remaining spaces in the coordination sphere of the $Na^+$ ion are occupied by fluorine atoms of the hexafluorophosphate anion, phosphinate oxygen atoms $O^{61a}$, $O^{61d}$, $O^{62d}$, and the bromide ion $Br^4$. Selected geometric parameters are given in the Supporting Information (Table S2).

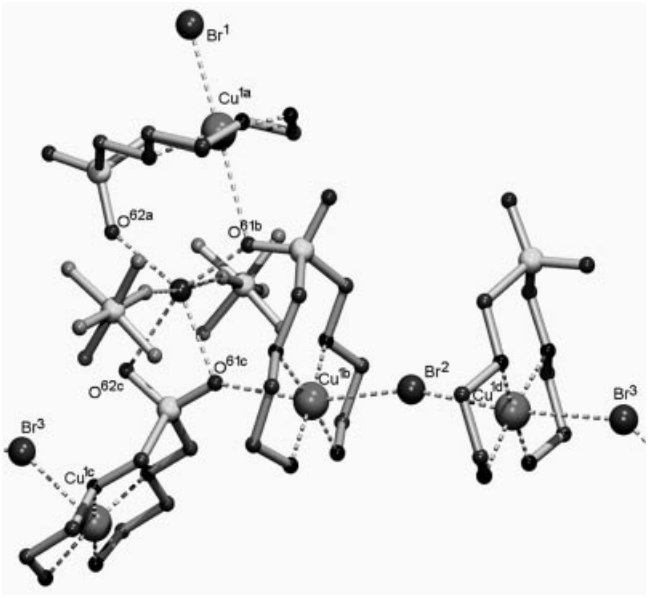

Figure 6. Complex framework found in the crystal structure of $Na_2(NH_4)_4[Cu(en_2p)]_4Br_4(PF_6)_6{\cdot}H_2O$ (**7**).

### *$Na_{3/2}(NH_4)_2[Zn(en_2p)]_3Br_{5/2}(PF_6)_4{\cdot}3H_2O$ (8)*

The structural unit has a plane of symmetry. Three halves of complex molecules form an independent part. Three central atoms ($Zn^{1a}$, $Zn^{1b}$, and $Zn^{1c}$) form three vertexes of the virtual square at the center of which is the $Na^+$ ion $Na^1$. The $N_4Zn$ planes in all complexes are perpendicular to the plane of symmetry. The first complex ($Zn^{1a}$) shows tetragonal pyramidal geometry. The axial position is occupied by the bromide anion $Br^{1a}$. The distance to another bromide anion $Br^1$ is too long (3.22 Å) to expect there to be a direct coordination bond in the remaining axial position. $Zn^{1b}$ has octahedral geometry. The axial positions are occupied by the phosphinate oxygen atom $O^{61a}$ and bromide anion $Br^2$. The bromide anion $Br^2$ plays the role of bridging ligand and it is coordinated to the atom $Zn^{1b\#}$ from the neighboring trimeric unit. The third complex molecule whose central atom is $Zn^{1c}$ has tetragonal pyramidal geometry with the phosphinate oxygen atom $O^{61b}$ in the axial position. Similarly to the first complex molecule, there

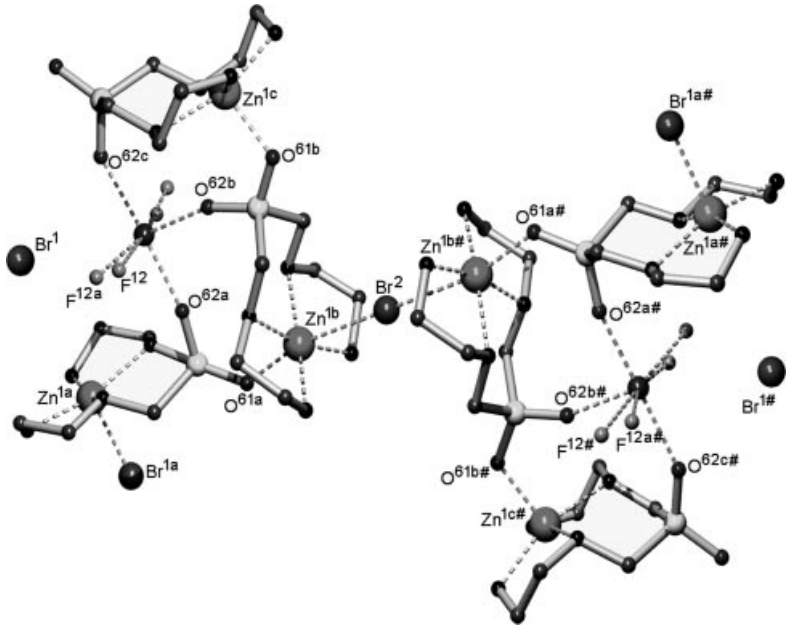

Figure 7. Complex framework found in the crystal structure of $Na_{3/2}(NH_4)_2[Zn(en_2p)]_3Br_{5/2}(PF_6)_4{\cdot}3H_2O$ (**8**). Two structural units are displayed. Fluorine atoms coordinated to the $Na^+$ ion belong to the hexafluorophosphate anions.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

is a bromide anion ($Br^{1\#}$) in the direction of the second axial position, but too far from the metal center to be assigned as directly coordinated (3.23 Å). The square-pyramidal coordination sphere of the $Na^+$ ion $Na^1$ is occupied by three phosphinate oxygen atoms ($O^{62a}$, $O^{62b}$, and $O^{62c}$) and two fluorine atoms coming from hexafluorophosphate anions. Other $PF_6^-$, $NH_4^+$, and $Br^-$ ions are bound into the structure by a framework of hydrogen bonds. The framework of the complex molecules found in the crystal structure of **8** is shown in Figure 7. Selected geometric parameters are given in the Supporting Information (Table S3).

### *$Na_2[Cu(pn_2p)]_4Br_2(ClO_4)_4\cdot 3H_2O$ (9)*

The structural unit has again a plane of symmetry. Four halves of the complexes (with central atoms $Cu^{1a}$, $Cu^{1b}$, $Cu^{1c}$, and $Cu^{1d}$) form an independent unit. The copper atoms are located in the corners of the virtual square at whose center is the $Na^1$ atom. The motif of four nitrogen atoms in the equatorial plane of the complexes is similar with that found in the previous structures; ligand equatorial planes are perpendicular to the crystallographic plane of symmetry. The coordination spheres of $Cu^{1a}$ and $Cu^{1b}$ have tetragonal pyramidal geometry, where the axial position is occupied by a phosphinate oxygen atom ($O^{71b}$ and $O^{71c}$, respectively) coming from the neighboring complex. The octahedral coordination sphere of the $Cu^{1c}$ atom is completed in the axial positions with the bromide anion $Br^{1c}$ and the disordered phosphinate oxygen atom $O^{71d}$ coming again from the neighboring complex unit. The trimethylene bridge of the ligand exhibits disorder into two positions. The last complex unit $Cu^{1d}$ has square-pyramidal geometry whose axial position is occupied by the oxygen atom of a water molecule, $O^{1d}$. The octahedral coordination sphere of the $Na^1$ consists of four oxygen atoms from four phosphinate groups in the equatorial plane ($O^{72a}$, $O^{72b}$, $O^{72c}$, and $O^{72d}$). Oxygen atoms coming from perchlorate anions occupy the axial positions. Cocrystallized water molecules and bromide anions are fixed in the structure by the hydrogen-bond network. The complex framework found in the crystal structure of $Na_2[Cu(pn_2p)]_4Br_2(ClO_4)_4\cdot 3H_2O$ (**9**) is shown in Figure 8. Selected geometric parameters are given in the Supporting Information (Table S4).

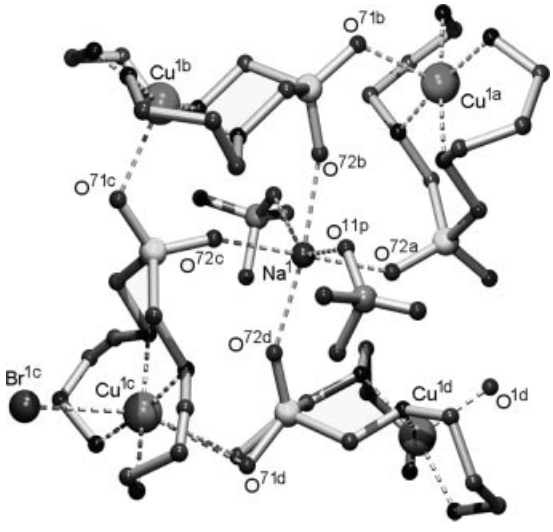

Figure 8. Complex framework found in the crystal structure of $Na_2[Cu(pn_2p)]_4Br_2(ClO_4)_4\cdot 3H_2O$ (**9**).

### *$[Ni_4(pn_2p)_4](ClO_4)_4\cdot 7H_2O$ (10)*

In comparison with the previous complexes, the structure of this coplex is exceptional, as a structural unit is formed by an isolated $[Ni_4L_4]$ tetramer. The $Ni^{2+}$ ions are connected by four ligand molecules to a supramolecular crown. Two nitrogen atoms of a propylenediamine fragment and one oxygen atom of a deprotonated phosphinate are coordinated to the metal ion in the meridional configuration. The second propylenediamine fragment and the second phosphinate oxygen atom are coordinated in the same way to the neighboring metal ion. The planes of those two groups of donor atoms are almost perpendicular. The remaining three positions around the metal ion are occupied by another ligand molecule. The $Ni^{2+}$ ions can be viewed as the vertexes of an intermediate shape between a square and a tetrahedron, as their mutual position shows almost perfect $D_{2v}$ symmetry with dihedral angles just between an ideal square and an ideal tetrahedron (Table 4; dihedral angles in the ideal tetrahedron are 70.5°, in square-planar geometry, the four angles are equal to 0°, and the remaining two are 180°). The positive charge is compensated for by four per-

Table 4. Dihedral angles [°] of the flattened tetrahedron formed by $Ni^{2+}$ ions found in the structure of the $[Ni_4(pn_2p)_4]^{4+}$ cation.

| Edge of the polyhedron | Angle /° | Square /° | Tetrahedron /° |
|---|---|---|---|
| Ni1···Ni2 | 51.9 | 0 | 70.5 |
| Ni1···Ni3 | 103.4 | 180 | 70.5 |
| Ni1···Ni4 | 52.0 | 0 | 70.5 |

chlorate anions, which are connected to water molecules by hydrogen bonds and ligand amino groups. The structure of the $[Ni_4(pn_2p)_4]^{4+}$ complex cation is presented in Figure 9, and selected geometric parameters are given in the Supporting Information (Table S5).

## Conclusions

Two new symmetrical tetraazaphosphinic acids, bis[*N*-(2-aminoethyl)aminomethyl]phosphinic acid ($Hen_2p$) and bis[*N*-(3-aminopropyl)aminomethyl]phosphinic acid ($Hpn_2p$), were prepared by reaction of bis(chloromethyl)phosphinic acid with excess 1,2-diaminoethane or 1,3-diaminopropane. Their protonation constants and the stability constants of their complexes with $Cu^{2+}$, $Ni^{2+}$, and $Zn^{2+}$ ions were determined by potentiometry. The presence of the electron-withdrawing phosphinic acid group decreases the basicity of the amino groups in the α-position in comparison with the linear tetraamines. The lower basicity results in the lower stability of the complexes with the divalent metal ions studied relative to that of the linear tetraamines containing the same number of bridging atoms between the amine groups. Chemical models for $M^{2+}/Hen_2p$ systems are simpler than those of systems containing $Hpn_2p$, with a high preference for complexes with a M/L ratio of 1:1 as a result of the better stereochemical properties and the higher selectivity of $Hen_2p$. In single crystals of the complexes obtained from neutral and alkaline solutions, all nitrogen atoms show equatorial coordination, whereas the phosphinic acid group is coordinated to the neighboring metal center. A different motif was found in the structure of the $[Ni_4(pn_2p)_4](ClO_4)_4{\cdot}7H_2O$, where four $Ni^{2+}$ ions and four ligand molecules form a cyclic supramolecular crown.

## Experimental Section

**Materials:** Commercially available chemicals had synthetic purity and were used as received. Bis(chloromethyl)phosphinic acid (**1**) and isopropyl bis(chloromethyl)phosphinate (**2**) were prepared according to the reported procedures.[48,49] Elemental analyses were performed in the Institute of Macromolecular Chemistry (Academy of Sciences of the Czech Republic, Prague).

**NMR Spectroscopy:** $^1H$ (400.0 MHz), $^{13}C$ (100.6 MHz) and $^{31}P$ (161.9 MHz) NMR spectra were recorded with a Varian $^{UNITY}$PLUS-400 spectrometer in 5 mm sample tubes. NMR experiments were performed at 298 K. For the measurements in $D_2O$, *tert*-butyl alcohol was used as an internal standard, the methyl signal being referenced to 1.2 ppm ($^1H$) and 31.2 ppm ($^{13}C$). For the measurements in $CDCl_3$, tetramethylsilane was used as an internal standard; the methyl signal was referenced to 0.0 ppm ($^1H$). The $^{31}P$ chemical shifts were measured with respect to 1% $H_3PO_4$ in $D_2O$ as an external standard (substitution method).

**Mass Spectrometry:** Mass spectra were recorded by using a Bruker Esquire 3000 spectrometer equipped with an electrospray ion source and an ion trap. All measurements were carried out in the positive-ion mode.

**General Procedure for Ligands $Hen_2p$ and $Hpn_2p$:** Bis(chloromethyl)phosphinic acid (**1**) (5.0 g, 30 mmol) was dissolved in diaminoalkane (3.0 mol). The solution was refluxed for 24 h. After removal of excess diaminoalkane in a rotary evaporator, the resulting oil was purified on a strong anion exchange resin (Dowex 1×8, 100–200 mesh, $OH^-$-form, elution with $H_2O$ followed with 20% aq. HCl) and a strong cation exchange resin (Dowex 50×4, 100–200 mesh, $H^+$-form, elution with $H_2O$ followed with 5% aq. $NH_3$). After evaporation of the volatiles, the resulting oily products were dissolved in 30% HBr (20 mL) and treated with charcoal. After filtration, the volatiles were removed in a rotary evaporator, the residue was dissolved in water (5 mL), and the resulting solution was slowly dropped into anhydrous EtOH (800 mL) with vigorous stirring. After 3 h, the precipitate was filtered, washed with EtOH, and dried with $P_2O_5$ under reduced pressure.

**Bis[*N*-(2-aminoethyl)aminomethyl]phosphinic Acid Trihydrobromide, $(H_4en_2p)Br_3$:** Yield 9.8 g (72%). $C_6H_{22}Br_3N_4O_2P$ (452.95): calcd. C 15.91, H 4.90, Br 52.92, N 12.37; found C 16.02, H 4.86, Br 48.55, N 11.47. $^1H$ NMR ($D_2O$): $\delta$ = 3.34 (m, 8 H, $NH_2$–C$H_2$–C$H_2$–NH), 3.44 (m, 4 H, C$H_2$–P) ppm. $^{31}P$ NMR ($D_2O$): $\delta$ = 19.0 (p, $^2J_{PH}$ = 9.7 Hz) ppm. $^{13}C\{^1H\}$ NMR ($D_2O$): $\delta$ = 37.9 (s, $NH_2$–C$H_2$), 48.5 (d, $^3J_{CP}$ = 21.8 Hz, NH–C$H_2$–$CH_2$), 49.2 (d, $^1J_{CP}$ = 103.2 Hz, C$H_2$–P) ppm. MS: calculated for [M + $Na^+$] 233.2; found 233.6.

**Bis[*N*-(3-aminopropyl)aminomethyl]phosphinic Acid Trihydrobromide, $(H_4pn_2p)Br_3$:** Yield 10.0 g (69%). $C_8H_{26}Br_3N_4O_2P$ (481.00): calcd. C 19.98, H 5.45, N 11.65, Br 49.84; found C 20.35, H 5.44, N 11.11, Br 47.76. $^1H$ NMR ($D_2O$): $\delta$ = 2.03 (m, 4 H, $CH_2$–C$H_2$–$CH_2$), 3.02 (t, $^3J_{HH}$ = 8.0 Hz, 4 H, $NH_2$–C$H_2$–$CH_2$), 3.17 (t, $^3J_{HH}$ = 8.0 Hz, 4 H, NH–C$H_2$–$CH_2$), 3.26 (d, $^2J_{PH}$ = 10.0 Hz, 4 H, NH–C$H_2$–P) ppm. $^{31}P$ NMR ($D_2O$): $\delta$ = 19.7 (p, $^2J_{PH}$ = 9.9 Hz) ppm. $^{13}C\{^1H\}$ NMR ($D_2O$): $\delta$ = 25.2 (s, $CH_2$–C$H_2$–$CH_2$), 38.1 (s, $NH_2$–C$H_2$), 47.7 (d, $^1J_{CP}$ = 101.9 Hz, C$H_2$–P), 48.1 (s, NH–C$H_2$–$CH_2$) ppm. MS: calculated for [M + $Na^+$] 261.3; found 261.5.

**Preparation of Single Crystals for X-ray Analysis**

**$(H_4en_2p)Cl_3$ (4):** $(H_4en_2p)Br_3$ (0.10 g, 0.31 mmol) was evaporated with HCl (10 mL, 6 M). The resulting oil was dissolved in HCl (2 mL, 6 M). Colorless single crystals were prepared by slow vapor diffusion of EtOH into the solution.

**$(H_4en_2p)[CuCl_4]Cl$ (5):** $(H_4en_2p)Br_3$ (0.1 g, 0.31 mmol) and $CuCl_2{\cdot}2H_2O$ (0.053 g, 0.31 mmol) were dissolved in HCl (2 mL, 12 M). Volatiles were removed in a rotary evaporator, and the resulting oil was dissolved in $H_2O$ (5 mL). Yellow single crystals of the product were obtained in 1 h.

**$(H_4en_2p)[ZnCl_4]Cl$ (6):** $(H_4en_2p)Br_3$ (0.10 g, 0.31 mmol) and $ZnCl_2$ (0.043 g, 0.31 mmol) were dissolved in HCl (2 mL, 12 M). Volatiles were removed in a rotary evaporator, and the resulting oil was dissolved in $H_2O$ (5 mL). Colorless single crystals were obtained by slow evaporation over a week.

**$Na_2(NH_4)_4[Cu(en_2p)]_4Br_4(PF_6)_6{\cdot}H_2O$ (7):** $(H_4en_2p)Br_3$ (0.048 g, 0.11 mmol) and $CuCl_2{\cdot}2H_2O$ (0.018 g, 0.11 mmol) were dissolved in water (0.75 mL). The pH of the solution was increased to 8.5 by using NaOH (5% aq.), and a concentrated solution of $NH_4PF_6$ in EtOH (0.5 mL) was added. Blue single crystals were obtained by slow evaporation over two weeks.

**$Na_{3/2}(NH_4)_2[Zn(en_2p)]_3Br_{5/2}(PF_6)_4{\cdot}3H_2O$ (8):** $(H_4en_2p)Br_3$ (0.048 g, 0.11 mmol) and $ZnCl_2$ (0.015 g, 0.11 mmol) were dissolved in water (0.75 mL). The pH of the solution was increased to 8.0 by using NaOH (5% aq.), and a concentrated solution of $NH_4PF_6$ in EtOH (0.5 mL) was added. Colorless single crystals were obtained by slow evaporation over a week.

**$Na_2[Cu(pn_2p)]_4Br_2(ClO_4)_4{\cdot}3H_2O$ (9):** $(H_4pn_2p)Br_3$ (0.055 g, 0.11 mmol) and $CuCl_2{\cdot}2H_2O$ (0.019 g, 0.11 mmol) were dissolved

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in water (0.75 mL). The pH of the solution was increased to 8.5 by using NaOH (5% aq.), and a concentrated solution of $NaClO_4$ in EtOH (0.5 mL) was added. Blue single crystals were obtained by slow evaporation over a week.

**$[Ni_4(pn_2p)_4](ClO_4)_4·7H_2O$ (10):** $(H_4pn_2p)Br_3$ (0.055 g, 0.11 mmol) and $NiCl_2·6H_2O$ (0.026 g, 0.11 mmol) were dissolved in water (0.75 mL). The pH of the solution was increased to 9.0 by using NaOH (5% aq.), and a concentrated solution of $NaClO_4$ in EtOH (0.5 mL) was added. Light blue single crystals were obtained from the mixture that was kept in a closed vial for a week.

**Crystal Structure Determination:** The selected crystals were mounted on glass fibers in random orientation by using silicone grease. Diffraction data were collected by using graphite-monochromated Mo-$K_\alpha$ radiation with an Enraf–Nonius KappaCCD diffractometer at 150(1) K [Cryostream Cooler (Oxford Cryosystems)] and analyzed with the HKL DENZO program package (ref.[50]). Cell parameters were determined from all data with the same program package.[50] The structure was solved by direct methods and refined by full-matrix least-squares techniques (SIR92,[51] SHELXL97[52]). The scattering factors used for neutral atoms were included in the SHELXL97 program. In the structures of $(H_4en_2p)Cl_3$ (**4**), $(H_4en_2p)[CuCl_4]Cl$ (**5**), and $(H_4en_2p)[ZnCl_4]Cl$ (**6**), all non-hydrogen atoms were refined anisotropically. The hydrogen atoms were localized in the difference map of electronic density and refined isotropically. In the structure of $Na_2(NH_4)_4[Cu(en_2p)]_4Br_4(PF_6)_6·H_2O$ (**7**), all non-hydrogen atoms of the complex units were refined anisotropically. The hydrogen atoms were placed in theoretical (C–H, N–H of amino groups) or original (O–H, N–H of ammonia cations) positions and treated by using a riding model with thermal parameters $U_{eq}(H) = 1.2U_{eq}(X)$. All copper(II) ions, phosphinate phosphorus and oxygen atoms, and bromide and sodium ions occupy the special positions (lying in the plane of symmetry). Two of the hexafluorophosphate anions were disordered. One was treated in two staggered positions (having axial fluorine atoms nondisordered, and equatorial ones with ca. 80:20 occupancies). All fluorine atoms of the second disordered hexafluorophosphate were refined in two positions in ca. 80:20 occupancies. More occupied fluorine atoms were refined anisotropically, less occupied atoms were refined isotropically. In the structure of $Na_{3/2}(NH_4)_2[Zn(en_2p)]_3Br_{5/2}(PF_6)_4·3H_2O$ (**8**), all non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in theoretical (C–H, N–H of amino groups) or original (O–H, N–H of ammonia cations) positions and treated by using a riding model with thermal parameters $U_{eq}(H) = 1.2U_{eq}(X)$. All zinc(II) ions, phosphinate phosphorus and oxygen atoms, and bromide and sodium ions occupy special positions (lying in the plane of symmetry). Both hexafluorophosphate anions were disordered, and all their fluorine atoms were refined in two positions with occupancies of ca. 60:40 and ca. 50:50, respectively. To obtain reliable thermal parameters, one bromide and one sodium(I) ion were treated as half-occupied. In the structure of $Na_2[Cu(pn_2p)]_4Br_2(ClO_4)_4·3H_2O$ (**9**), all non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in theoretical positions and treated by using a riding model with thermal parameters $U_{eq}(H) = 1.2U_{eq}(X)$. All copper(II) ions, phosphinate phosphorus and oxygen atoms, and bromide and sodium ions occupy special positions (lying in the plane of symmetry). Perchlorate oxygen atoms were disordered; the anion was found to be staggered in two positions with occupancies of ca. 70:30 (one oxygen atom was not disordered, the remaining three were disordered). The propylene backbone of one ligand molecule was refined in two positions with ca. 50:50 occupancies. Water oxygen atoms were treated as half-occupied to obtain reasonable thermal factors. In the structure of $[Ni_4(pn_2p)_4](ClO_4)_4·7H_2O$ (**10**), all non-hydrogen atoms were refined anisotropically. The hydrogen atoms belonging to the ligand molecules were localized in the difference map of electronic density and refined isotropically. Three perchlorate anions were disordered, and their oxygen atoms were refined with ca. 70:40–60:40 occupancies. Some water oxygen atoms were treated as half-occupied to obtain reliable thermal factors; hydrogen atoms belonging to cocrystallized water molecules were not found. Relatively high electronic maxima peaks

and holes in the structures of the compounds (**4**)–(**10**) are associated mainly with disordered hexafluorophosphate (or perchlorate) anions, as they are located in close proximity to phosphorus (or chlorine) atoms, respectively. Table 5 and Table 6 give the pertinent crystallographic data.

CCDC-627266 (**4**), -627267 (**5**), -627268 (**6**), -627269 (**7**), -627270 (**8**), -627271 (**9**), and -627272 (**10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Potentiometric Titrations:** The methodology of the potentiometric titrations and processing of the experimental data were similar to those previously reported.[9] Titrations were carried out in a vessel thermostatted at 25 ± 0.1 °C, at ionic strength $I$ ($KNO_3$) = 0.1 mol dm$^{-3}$. Ligand-to-metal ratios were 1:1, 1:2, and 2:1. Titrations were carried out at least four times, each titration yielding about 40 data points. The water ion product, p$K_w$ = 13.78, and stability constants of $M^{2+}$/$OH^-$ systems were taken from ref.[53] The protonation constants $\beta_n$ calculated are concentration constants and are defined by $\beta_n = [H_nL]/([H]^n \times [L])$ (p$K_1$ = log$\beta_1$; p$K_n$ = log$\beta_n$ – log$\beta_{n-1}$); the stability constant are defined by $\beta_{pqr} = [M_pH_qL_r]/[M]^p \times [H]^q \times [L]^r$. The constants (with standard deviations) were calculated with the program OPIUM.[54] Throughout the paper, pH means –log[$H^+$]. As hydrobromides of the ligands slowly lose HBr upon standing, the stock solutions for potentiometry were prepared from freshly isolated materials. The ligand and the proton concentrations in the stock solution determined together with the calculation of the protonation constants, is in perfect agreement with a 1:3 ligand/HBr stoichiometry. In all systems, equilibrium was established quickly (< 20 s) at all data points.

**UV/Vis Spectroscopy:** Solution spectra were recorded with a Cary 1E (Varian) spectrometer in the 200–1100-nm range at room temperature. $NiCl_2 \cdot 6H_2O$ and ligand $(H_4pn_2p)Br_3$ (one equivalent) were dissolved in water, and the pH of the sample was adjusted with dilute KOH solution to a value of ca. 10, where the maximum abundance of the $[ML]^+$ species occurs according to the distribution diagram. Reflection spectra of the microcrystalline sample diluted with $BaSO_4$ were recorded with a Lambda 19 (Perkin–Elmer) spectrometer by using an integration sphere in the 200–1100-nm range at room temperature.

**Supporting Information** (see footnote on the first page of this article): Distribution diagrams of all studied systems are shown in Figures S1 and S2. Geometric parameters of coordination polyhedrons in the crystal structures are listed in Tables S1–S5. Colored structures and ORTEP representations of compounds **4**–**10** are shown in Figures S3 to S8.

# Hydrothermal Syntheses and Characterizations of Three Coordination Polymers Based on Mixed Organic Ligands

Guo-Ping Yang,[a] Yao-Yu Wang,*[a] Lu-Fang Ma,[a,b] Jian-Qiang Liu,[a] Ya-Pan Wu,[a] Wei-Ping Wu,[a] and Qi-Zhen Shi[a]

**Keywords:** Copper / Manganese / Coordination polymers / Hydrogen bonds

Three new coordination polymers, namely $\{[Cu_2(bptc)(4,4'\text{-bpy})(H_2O)_2]\cdot 2H_2O\}_n$ (**1**), $\{Cu_2(bptc)(bpe)(H_2O)_6\}_n$ (**2**), and $\{[Mn(H_2bptc)(H_2O)_4]\cdot 2bpe\}_n$ (**3**) [$H_4$bptc = 3,3′,4,4′-biphenyltetracarboxylic acid, 4,4′-bpy = 4,4′-bipyridine, bpe = *trans*-1,2-bis(4-pyridyl)ethene], were rationally designed and hydrothermally synthesized at different pH values. Their structures were determined by X-ray diffraction on single crystals. Compound **1** exhibits a 3D network with 1D open channels that contain free solvent water molecules, and two kinds of chiral, helical, hydrogen-bonded chains exist in the neighboring holes. Both compounds **2** and **3** show a 3D supramolecular network that is connected through hydrogen bonds. Compound **2** also shows weak Cu···O semicoordinated interactions that are based on 1D chains. Importantly, bptc reveals three different coordination modes in these compounds: the four carboxylic groups combine with metal ions by bis(monodentate) and bis(chelate) fashions in **1**, whereas only two carboxylic groups are bis(monodentate) in **2** and **3**, respectively, and the 4,4′-carboxylic groups are protonated in **3**. The elemental analysis, IR spectra, UV/Vis spectra, and TG analysis for compounds **1**, **2**, and **3** are discussed. Additionally, the XRPD is also studied for compound **1**.

## Introduction

The design and construction of metal–organic coordination polymers is of current interest in the fields of supramolecular chemistry and crystal engineering.[1] Major reasons for this interest stem from their intriguing variety of topologies and structural diversity,[2] such as helixes[3]and diamondoid nets[4] and because of their potential applications as functional materials,[5] such as heterogeneous catalysis,[6] molecular recognition,[7] magnetism,[8] gas storage,[9] ion exchange,[10] nonlinear optics,[11] and electrical conductivity.[12] In order to build these molecular architectures, polycarboxylates are often employed as bridging ligands to construct coordination polymers owing to their versatile coordination modes and high structural stability.[13] These polymeric solids can be essentially regarded as a class of metal polycarboxylate salts. Hence, the structures of the resulting compounds are influenced by the degree of deprotonation, the coordination modes and capabilities, the size and shape of the polycarboxylic acids, as well as by the coordination spheres of the metal centers. Thus, it is possible to synthesize polymeric frameworks with interesting topologies through the appropriate choice of ligand, tailoring, and manipulation of the reaction conditions, including pH, temperature, stoichiometry, and the addition of templates or structure-directing agents. For resolving the poor solubility of reactants and products, the hydrothermal reaction technique offers a powerful synthetic route to prepare polymeric solids with better crystallinity[14] than traditional solution techniques such as evaporation, diffusion, and cooling etc. In most cases, water is not only a solvent but also acts as a competing ligand in these hydrothermal reactions. This phenomenon is observed in many coordination polymers that are constructed from polycarboxylate ligands where the water molecules usually act as terminal or bridging ligands in the coordination sphere of the metal; thus, the variety of the assembled structural topologies of the polymers increases.

According to the above strategy, 3,3′,4,4′-biphenyltetracarboxylic acid ($H_4$bptc, Scheme S1, Supporting Information), which has eight potential donor oxygen atoms, is undoubtedly a better choice as the ligand for the construction of novel metal–organic coordination polymers owing to its quadruple carboxylic dentate arms. However, to the best of our knowledge, polymers containing bptc have been scarcely studied so far.[15] With the aim to understand the coordination chemistry of bptc and to prepare new materials with interesting structures and excellent physical properties, we recently started to research this kind of coordination polymer. We also notice that the introduction of N-containing auxiliary ligands, such as 4,4′-bipyridine (4,4′-

bpy) and *trans*-1,2-bis(4-pyridyl)ethene (bpe), into the {M-bptc}(M = transition metal) system may lead to the structural evolution of these metal–organic compounds and their structural motifs may ultimately be fine-tuned. Herein, we report three interesting coordination polymers with mixed organic ligands, $\{[Cu_2(bptc)(4,4'\text{-bpy})(H_2O)_2]\cdot 2H_2O\}_n$ (**1**), $\{Cu_2(bptc)(bpe)(H_2O)_6\}_n$ (**2**), and $\{[Mn(H_2bptc)(H_2O)_4]\cdot 2bpe\}_n$ (**3**). Our results demonstrate that bptc adopts various coordination modes in the three compounds (Scheme S2, Supporting Information). Interestingly, two kinds of hydrogen-bonded-directed chiral helices exist in 1D open channels of compound **1**.

## Results and Discussion

### General Synthesis

Because the mixing of metal salts and carboxylate solutions usually resulted in precipitation in traditional aqueous reactions, which makes the growth of crystals difficult, the hydrothermal method was adopted in these reactions. The use of hydrothermal conditions causes a reaction to shift from the kinetic to the thermodynamic domain. By performing parallel experiments, it was found that the pH values of the reaction solutions play an important role in the isolation of the three compounds, as is the case for some other metal polycarboxylate coordination polymers reported.[15b,16] The three compounds were prepared at different pH values: compound **1** at pH 6, compound **2** at pH 7, and compound **3** at pH 4. If the pH values of the reactions were lower or higher than those listed in the Experimental Section, no products could be obtained. Besides the pH, a suitable steric geometry of the reactants is also very important for the fabrication of the resulting coordination architectures. As described in the Experimental Section, although the synthetic conditions are very similar, only a small difference in the steric demands of the reactants, for example between 4,4′-bpy and bpe, results in the different coordination architectures of compounds **1** and **2**. However, we found that the above reactions were not sensitive to the reaction temperature. If the reaction temperature was set 10 °C above or below 145 °C, the intended crystals still formed.

### Description of the Structures

#### *$\{[Cu_2(bptc)(4,4'\text{-bpy})(H_2O)_2]\cdot 2H_2O\}_n$ (1)*

Single-crystal X-ray structural analysis showed that compound **1** crystallizes in the monoclinic space group $P2_1/c$, with two copper(II) atoms, one hexadentate bptc ligand, one 4,4′-bpy ligand, two coordinated waters, and two lattice water molecules in each crystallographic unit (Figure 1). Each copper atom has a distorted square-pyramidal environment (tetragonality parameter $\tau = 0.55$)[17] and binds equatorially to three oxygen atoms (O1, O3A and O4A) of two different bptc ligands and one nitrogen atom (N1) of 4,4′-bpy; a water molecule ($O_w5$) coordinates in the apical position. The equatorial plane of the copper atom is tetrahedrally distorted (maximum atomic deviation 0.046 Å), with the metal atom displaced by 0.207 Å from the best mean plane toward the apical ligand.

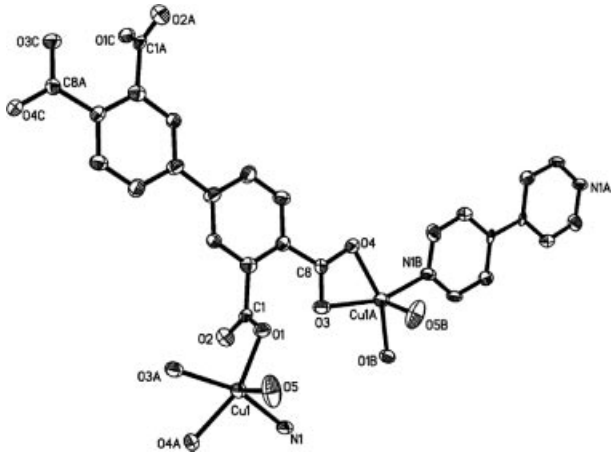

Figure 1. ORTEP representation (30% thermal probability ellipsoids) of the crystal structure of compound **1**. Hydrogen atoms and the lattice waters are omitted for clarity.

Compound **1** exhibits an extended 3D framework involving 1D open channels when viewed along the crystallographic *c* axis (Figure 2). The approximate dimensions of these channels are $15.55 \times 8.81$ Å (calculated from the distance of the neighboring $Cu^{II}$ atoms),[18] which are large enough to encapsulate guest solvent water molecules. When viewed along the crystallographic *b* axis, the bptc and 4,4′-bpy ligands alternate one by one in each layer to form huge "infinite sandwiches"[19] (Figure S1, Supporting Information). The planes of the pyridyl rings and phenyl rings are offset between the adjacent layers with a face-to-face separation with a center-to-center distance of 3.844 Å and a dihedral angle of 8.43°. To the best of our knowledge, compound **1** represents the first example of a perfect molecular network building upon ligands bptc and 4,4′-bpy with copper in which the four carboxylate groups of bptc take part in coordination: the two carboxylate groups (3,3′-$COO^-$) adopt bis(monodentate) coordination with two different copper ions, the other carboxylate groups (4,4′-$COO^-$) are bis(chelated) with two dissimilar copper cations, and the 4,4′-bpy ligands are coordinatively bridged with them.

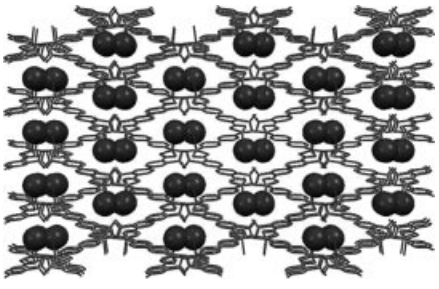

Figure 2. A perspective view of the 3D network of compound **1** containing 1D open channels encapsulating water molecules.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Multiple hydrogen bonds are known to cooperatively exert a dramatic influence on the control of molecular self-assembly in chemical and biological systems,[13b,20] and some examples of hydrogen-bonded helices have been reported.[21] The most fascinating structural feature of compound **1** is that chiral, helical, hydrogen-bonded (lengths and angles are listed in Table S1, Supporting Information) chains also exist in 1D open channels. Interestingly, when viewed along the crystallographic *a* axis, we found that the hydrogen-bonded chains, which are composed of coordinated water molecules (O5), carboxylate oxygen atoms (O2), and lattice water molecules (O6), show two different kinds of chiral helices (one is left-handed and the other is right-handed) in the neighboring holes (Figure 3) and that the winding axes are parallel to the *c* axis. The two parallel helices exist concurrently, and they are enchased in 1D channels by hydrogen bonds. So far, the examples that have two kinds of helices are still few.[3e,21c,22] Obviously, these strong hydrogen bonds undoubtedly steer the rotational direction of the helix.[23] It is worth noting that the use of hydrogen bonds as a steering force is becoming a very important strategy in crystal engineering.[24] To date, studies on this aspect are unprecedented with respect to the bptc ligand. Additionally, the O6 atom donates a hydrogen bond towards carboxyl oxygen atom O1 [$O_w6\cdots O_{COO}1$ = 2.903(2) Å] that is situated on the bptc ligand of the host framework. This additional interaction has an important effect on the stability of the 1D chiral, helical, hydrogen-bonded chains.

Figure 3. The right-handed (a) and left-handed (b) chiral helical hydrogen-bonded chains in the neighboring holes of compound **1** containing free solvent water molecules (light gray balls, O6), coordinated waters (dark gray balls, O5), and uncoordinated oxygen atoms (black balls,O2).

### *{Cu$_2$(bptc)(bpe)(H$_2$O)$_6$}$_n$ (2)*

The crystal structure of compound **2** consists of a neutral 1D zigzag chain based on alternating bptc and bpe ligands and crystallizes in the $P\bar{1}$ space group. As shown in Figure 4, in each asymmetry unit, compound **2** is composed of two copper(II) atoms, one bis(monodentate) bptc ligand, one bpe ligand, and six coordinated water molecules. The coordinated sphere of each copper atom is a distorted trigonal bipyramid with three water molecules in the equatorial plane, and a carboxylate oxygen atom (4,4′-COO$^-$) of bptc and a nitrogen atom of bpe occupy the apical positions.

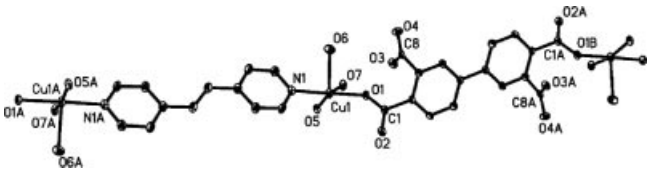

Figure 4. View of the 1D zigzag coordination polymer with alternating bptc and bpe ligands in compound **2** (30% thermal probability ellipsoids).

However, the copper atoms have a weak equatorial connection to semicoordinated centrosymmetrically related water molecules [Cu1···O5 = 2.896(4) Å, symmetry code: $1 - x,1 - y,1 - z$], resulting in a 5 + 1 coordination sphere for the copper atom (Figure 5). The equatorial plane of the copper atom has a moderate tetrahedral distortion (maximum atomic deviation 0.074 Å), the copper atom is displaced by only 0.073 Å from this plane towards the nitrogen atom. The dihedral angles between the equatorial plane and the planes of bptc and bpe are 87.62 and 73.18°, respectively. Furthermore, two pyridyl rings of bpe are parallel with each other at the distance of 0.528 Å.

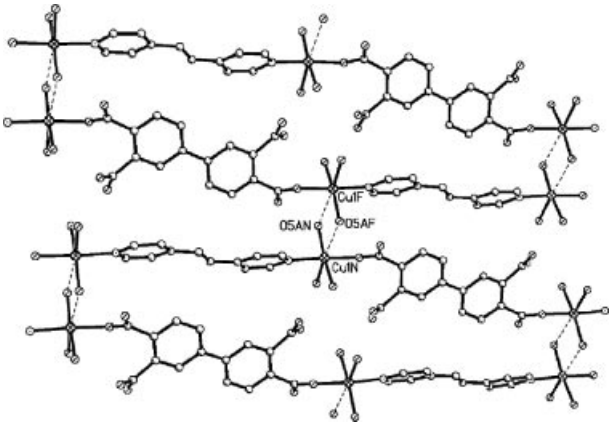

Figure 5. The 2D layer of compound **2** by Cu···O$_w$ semicoordination and hydrogen bonds. Hydrogen bonds are deleted for clarity.

The shortest intermolecular metal···metal distance is Cu1F···Cu1N and measures 3.862 Å. It occurs between the pairs of 1D staggered chains (···ABAB··· fashion) that are connected through the semicoordination mentioned above and simultaneously the chains form a 2D network that including interlocking of hydrogen bonds. In other reported papers,[25] we found that only the lower dimensional architectures (1D chains or dimers) existed by weak Cu···O interactions. Because compound **2** possesses multiuncoordinated carboxylate oxygen atoms and coordinated water molecules, hydrogen bonds connect the 2D layers into a 3D supramolecular framework.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *{[Mn(H$_2$bptc)(H$_2$O)$_4$]·2bpe}$_n$ (3)*

Compounds **3** and **2** have the same space group, $P\bar{1}$. The crystal structure of compound **3** also contains a neutral 1D chain, but here the chain is only based on bptc and the bpe ligands just exist as free solvent molecules in it. At the same time, different from **2**, two pyridyl rings of the bpe ligand are not parallel and have a dihedral angle of 2.72°. The manganese atoms are 4 + 2 six-coordinate in a slightly distorted octahedral coordination environment with four water molecules located in the equatorial plane and the two oxygen atoms (3,3′-COO) from the bptc ligand occupy the apical positions, as depicted in Figure 6. The best equatorial plane is defined by the O1, O2, O1A, and O2A atoms, which are perfectly planar (no deviation in the four atoms) and the manganese atom lies in this plane.

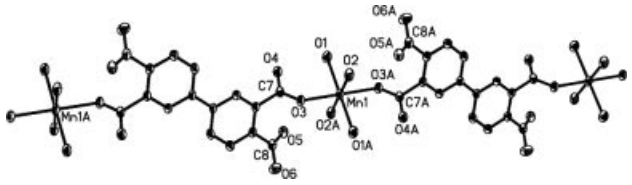

Figure 6. View of the coordination environment of $Mn^{II}$ in compound **3**. Hydrogen atoms and free bpe ligands are deleted for clarity.

According to the results of X-ray diffraction, there are two uncoordinated carboxylate groups of the bptc ligand that are protonated in compound **3**. This is dissimilar from compound **2** where two carboxylate groups do not take part in coordination even though they are deprotonated. The neighboring 1D chains are connected through hydrogen bonds between the coordinated water molecules and the oxygen atoms of the carboxylate groups [$O_w1\cdots O_{COO}6$ = 2.751(5) Å] (Figure S2, Supporting Information). The resulting wavelike 2D network contains almost rhombic holes in which the Mn···Mn distance through the bptc is 14.584 Å, whereas the distance through the water oxygen atoms of the bptc bridge is 7.970 Å, and there are no solvent molecules in the rhombic holes. The bpe ligands act as pillars, as in the case of the 4,4′-bpy ligand,[26] and link the 2D layers together to form a 3D network by using hydrogen-bonding recognition [$O_w2\cdots N1$ = 2.809(5) Å and $O_{COO}6\cdots N2$ = 2.560(4) Å] (Figure 7) as in compound **2**.

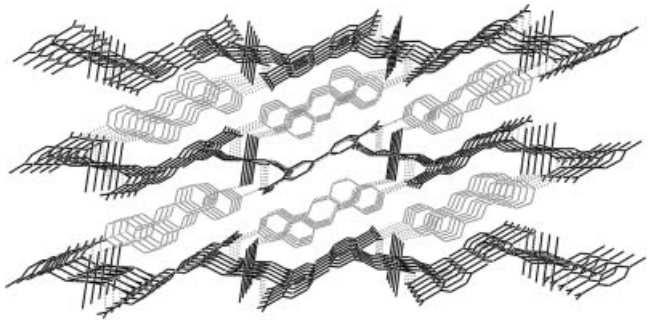

Figure 7. The 3D network of compound **3** constructed from 2D layers with bpe ligands as the pillars. The bpe ligands are represented in grey.

### Spectroscopic Characterization, Thermal Gravimetric Analysis, and XRPD Measurement

The IR spectra of the three compounds were performed as KBr pellets in the range 4000–400 cm$^{-1}$.These compounds show the characteristic bands of the carboxylate groups in the usual region[27] at 1630–1550 cm$^{-1}$ for the asymmetric vibration and at 1410–1360 cm$^{-1}$ for the symmetric, and the value $\Delta[\nu_{as}(COO^-) - \nu_s(COO^-)] > 200$ cm$^{-1}$ for the three compounds reveals that the carboxylate group is coordinated in a monodentate fashion,[28] which is consistent with the results of the X-ray analysis. Also observed were the bands for the 4,4′-bpy ligand at 1593, 1571, and 1494 cm$^{-1}$ for **1**, the bands of the bpe ligand at 1551 cm$^{-1}$ for **2** and 1574 cm$^{-1}$, 1506 cm$^{-1}$ for **3**. The splitting of $\nu_{as}(COO^-)$ in **1** confirms that the carboxylate groups have a variety of coordination fashions. These proposals are in accordance with the crystal structures. The UV/Vis spectra of the three compounds were recorded in *N*,*N*-dimethylformamide at room temperature and are characterized by several spectral regions (Figures S3, S4, and S5, Supporting Information). The maximum absorption band at 276 nm for the bptc ligand is ligand-centered (LC) due to π–π* transitions. The peaks at 286, 289, and 288 nm for compounds **1**, **2**, and **3**, respectively, are due to d–d transitions and the low-energy bands at 283, 299, and 298 nm, respectively, are assigned to metal-to-ligand charge-transfer transitions (MLCT).[29] This slight shift in absorption bands of the compounds relative to that of the bptc ligand is caused by the effect of metal-to-ligand charge-transfer transitions.

To examine the thermal stability of the three compounds, thermal gravimetric analyses (TGA) were carried out between 50–800 °C. As shown in Figure 8, for **1** a total weight loss of 11.58% occurred over the temperature range 67–158 °C, corresponding to the loss of four water molecules (calcd. 10.57%). When the temperature was increased to ca. 268 °C, the product began to lose the bptc and 4,4′-bpy ligands. Finally, the remaining weight of 19.10% corresponds to the percentage (calcd. 20.99%) of Cu and O components, indicating that the final product is $Cu_2O$. The TGA traces of **2** and **3** are much like that observed for **1**: compound **2** loses six water molecules between 74 and 171 °C (observed 15.61%, calcd. 14.54%), and compound

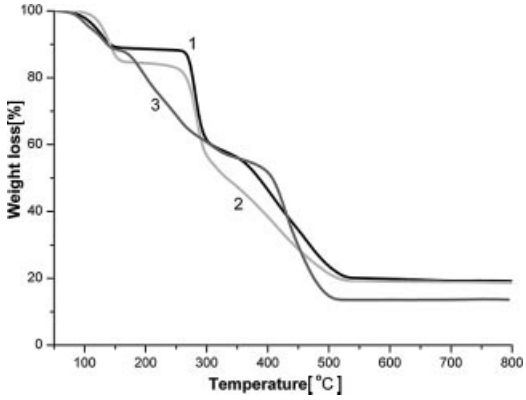

Figure 8. The TG curves of compounds **1**, **2**, and **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**3** loses two bpe ligands and four water molecules between 79 and 384 °C (observed 46.27%, calcd. 46.90%), respectively. The remaining weight of 18.71% (calcd. 19.24%) for **2** (observed 13.33%, calcd. 12.55% for **3**) indicates that the final product is $Cu_2O$ ($MnO_3$). Additionally, to confirm the phase-pure and the stable framework of compound **1**, the original sample and dehydrated sample were characterized by X-ray powder diffraction (XRPD) at room temperature. The pattern that was simulated from the single-crystal X-ray data of compound **1** was in good agreement with those that were observed, thus compound **1** was obtained as a single phase. For compound **1**, after heating at 85 °C for 3 h, the guest water molecules were removed (the evacuated frameworks are defined as **1′**). The XRPD pattern of **1′** is similar to compound **1**, although minor differences can be seen in the positions, intensities, and widths of some peaks (Figure S6, Supporting Information), which indicates that the framework of compound **1** is retained after the removal of the guest molecules.

## Conclusions

As described above, we successfully designed and synthesized three coordination polymers constructed from bptc and N-containing auxiliary ligands (4,4′-bpy, bpe) at different pH values. Comparing the structure of compounds **1**, **2**, and **3**, it was found that the different coordination modes of the bptc ligand may have a significant effect on the formation and dimension of the resulting structures. The successful preparation of three compounds provides a valuable approach for the construction of many other coordination polymers with different dimensional structures by the introduction of another kind of organic ligand. More significantly, compound **1** contains 1D open channels that contain free water molecules and chiral hydrogen bonded helices exist.

## Experimental Section

**Materials:** All chemicals purchased were of reagent grade and used without further purification. The bptc ligand was obtained by hydrolyzing 4,4′-biphthalic anhydride that is bought from Alfa Aesar. All syntheses were carried out in 25-mL Teflon-lined autoclaves under autogenous pressure. The reaction vessels were filled to approximately 60% volume capacity. Distilled water was used in all reactions.

**$\{[Cu_2(bptc)(4,4'\text{-bpy})(H_2O)_2]\cdot 2H_2O\}_n$ (1):** A mixture of $Cu(NO_3)_2\cdot 8H_2O$ (332 mg, 1.0 mmol), $H_4$bptc (165 mg, 0.5 mmol), 4,4′-bpy (78 mg, 0.5 mmol), and water (15 mL) was adjusted to pH 6 with a 1 M NaOH solution and then heated at 145 °C for 4 d. Well-shaped blue block crystals were obtained when the mixture was cooled to room temp. at 10 °C h$^{-1}$. Yield: 61.3%. IR (KBr): $\tilde{\nu}$ = 3472 (s), 3215 (m), 1613 (s), 1593 (s), 1571 (m), 1494 (m), 1423 (s), 1384 (s), 1221 (m), 1166 (w), 1096 (w), 1071 (m), 873 (s), 846 (s), 822 (s), 649 (m), 568 (m), 552 (w), 460 (w) cm$^{-1}$.$C_{26}H_{22}Cu_2N_2O_{12}$ (681.55): calcd. C 45.82, H 3.25, N 4.11; found C 45.69, H 3.22, N 4.20.

**$\{Cu_2(bptc)(bpe)(H_2O)_6\}_n$ (2):** A mixture of $Cu(OAc)_2\cdot H_2O$ (200 mg, 1.0 mmol), $H_4$bptc (165 mg, 0.5 mmol), bpe (91 mg, 0.5 mmol), and water (15 mL) was adjusted to pH 7 with a 1 M NaOH solution and then heated at 145 °C for 4 d. Blue-green crystals were obtained when the mixture was cooled to room temp. at 10 °C h$^{-1}$. Yield: 65.8%. IR (KBr): $\tilde{\nu}$ = 3397 (s), 3155 (m), 2921 (m), 1608 (s), 1551 (s), 1483 (m), 1370 (s), 1294 (m), 1159 (w), 1097 (w), 978 (m), 891 (w), 838 (m), 790 (m), 697 (w), 662 (m), 552 (m), 470 (m) cm$^{-1}$. $C_{28}H_{28}Cu_2N_2O_{14}$ (743.60): calcd. C 45.22, H 3.80, N 3.77; found C 45.35, H 3.62, N 3.64.

**$\{[Mn(H_2bptc)(H_2O)_4]\cdot 2bpe\}_n$ (3):** A mixture of $Mn(OAc)_2\cdot 4H_2O$ (123 mg, 0.5 mmol), $H_4$bptc (165 mg, 0.5 mmol), bpe (182 mg, 1.0 mmol), and water (15 mL) was adjusted to pH 4 with a 1 M NaOH solution and then heated at 145 °C for 4 d. Pale yellow crystals were obtained when the mixture was cooled to room temp. at 10 °C h$^{-1}$. Yield: 53.1%. IR (KBr): $\tilde{\nu}$ = 3333 (s), 3085 (m), 2225 (w), 1940 (w), 1626 (m), 1574 (s), 1506 (m), 1480 (m), 1403 (s), 1360 (m), 1250 (w), 1184 (w), 1094 (m), 944 (m), 899 (m), 868 (w), 793 (s), 694 (m), 636 (m), 544 (w), 450 (w) cm$^{-1}$. $C_{40}H_{36}MnN_4O_{12}$ (819.67): calcd. C 62.82, H 4.74, N 7.33; found C 62.73, H 4.89, N 7.21.

**Physical Measurements:** Elemental analyses (C, H, and N) were determined with a PE 2400 Elemental analyzer. Infrared spectra of KBr pellets were recorded with a BRUKER EQUINOX-55 spectrometer in the range of 4000–400 cm$^{-1}$. Thermal analyses were performed with a NETZSCH STA 449C microanalyzer with a heating rate of 10 °C min$^{-1}$ under a nitrogen atmosphere. Electronic spectra were recorded with a Cary 300 Bio UV/Vis spectrophotometer in the range 270–450 nm at ambient temperature. The XRPD pattern was recorded with a Pigaku D/Max 3III diffractometer.

**Crystal Data Collection and Refinement:** Diffraction experiments for **1**, **2**, and **3** were carried out with Mo-$K_\alpha$ radiation by using a BRUKER SMART APEX-CCD diffractometer at 291(2) (for **1**, **2**) and 296(2) (for **3**) K. A summary of the crystallographic data and structure refinement details are given in Table 1, and selected bond

[a] Symmetry codes: $x$, $-y + 3/2$, $z + 1/2$. [b] Symmetry codes: $-x$, $1 - y$, $2 - z$.

lengths and angles are listed in Table 2. Both structures were solved by direct methods and refined with the full-matrix least-squares technique on $F^2$ by using SHELXS-97[30] and SHELXL-97.[31] All non-hydrogen atoms were refined anisotropically. The water H atoms were located in a different Fourier map and refined with restrained O–H bond lengths [0.82(2) Å] in **1**. CCDC-634976 (for **1**), -634977 (for **2**), and -634978 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Coordination modes of the bptc ligand, table of hydrogen bond lengths and angles, UV/Vis spectra for the three compounds, XRPD pattern for compound **1**, and additional plots of the structures.

# Liquid Crystal Imidazolium Salts: Towards Materials for Catalysis and Molecular Electronics

Jean-Moïse Suisse,[a] Laurent Douce,*[a] Stéphane Bellemin-Laponnaz,[b] Aline Maisse-François,[b] Richard Welter,[b] Yasuo Miyake,[c,d] and Yo Shimizu[c]

**Keywords:** Liquid crystals / Imidazolium ions / Pd–carbenes / Homogenous catalysis / Conducting materials

1,3-Bis(4-alkyloxyphenyl)-3*H*-imidazol-1-ium trifluoromethanesulfonates, alkyl = $CH_3(CH_2)_{n-1}$, $n$ = 8, 10, 12, 14 and 16, can be derived from the analogous 4-alkyloxyphenylamines. These imidazolium salts exhibit a lamellar liquid-crystal mesophase between 99 °C and 191 °C. The smectic-A phase was fully characterised by polarising optical microscopy, differential scanning calorimetry and X-ray diffraction. We report also the synthesis, lamellar crystal structure and catalytic activity of the $Pd^{II}$ complex of the (deprotonated) carbene form of one of these salts. In addition, we measured the charged carrier mobilities in the mesophase.

## Introduction

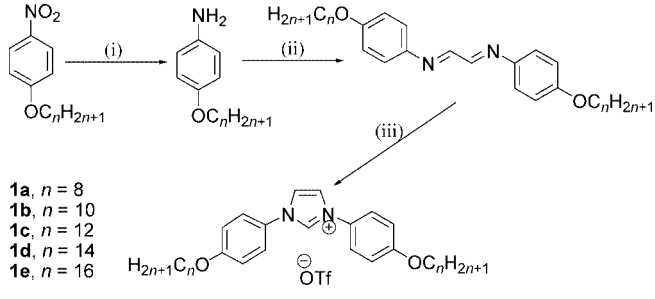
Extensive studies of ionic liquids have revealed their many useful properties such as their extremely low volatility, high thermal stability, nonflammability, high chemical stability, high ionic conductivity and wide electrochemical window.[1] Such salts are extremely versatile in that changes in both the cation and its counteranion can be used to tune their properties, which for imidazolium salts in particular includes their mesomorphism.[2] The merging of imidazolium ionic liquids and liquid-crystal chemistry has indeed begun to lead to a new range of materials[1d,3] with applications in, for example, dye-sensitised solar cells,[4] electron transport systems[3b] and nanoparticle electrosynthesis.[5] Variation of the imidazolium N-substituents is a facile means of creating this range. Of additional interest is the fact that the salts can be readily deprotonated to give, formally, N-heterocyclic carbenes that are excellent ligands for transition-metal-based catalysts.[6]

Herein, we wish to report the synthesis of imidazolium liquid crystals as well as the synthesis and catalytic activity of a $Pd^{II}$ carbene complex derived from a mesomorphic imidazolium species.

## Results and Discussion

### Synthesis

Compounds **1a**–**e** were obtained − as described previously for **1c**[7] − in a two-step procedure from aniline derivatives (Scheme 1). Condensation of the aniline derivatives with glyoxal followed by treatment with chloromethyl pivalate in the presence of 1 equiv. of silver triflate gave corresponding imidazolium salts **1a**–**e** in good yields, all of which were unequivocally characterised by $^1H$ and $^{13}C\{^1H\}$ NMR, UV and FTIR spectroscopy, as well as elemental analysis.



Scheme 1. Reagents and conditions: (i) hydrazine/C; (ii) glyoxal, ethanol, reflux; (iii) AgOTf, chloromethyl pivalate, $CH_2Cl_2$, 48 h reflux under inert atmosphere.

### Mesomorphic Properties

The mesomorphic behaviour and phase-transition temperatures were characterised by polarising optical microscopy (POM), differential scanning calorimetry (DSC) and X-ray diffractometry (XRD). The phase-transition temperatures and their corresponding enthalpy changes for compounds **1a**–**e** are compiled in Table 1, whereas typical results are displayed in Figure 1.

Table 1. Phase-transition temperatures (°C) and corresponding enthalpies $\Delta H$ (J/mmol) were determined from the first heating; abbreviations: Cr = crystalline phase, LC = smectic-A phase, I = isotropic phase.

| Compound | $T$ [°C] Cr → LC | $T$ [°C] LC → I |
|---|---|---|
| **1a** | 120.0 (48.51) | 126.0 (3.09) |
| **1b** | 116.0 (57.55) | 158.0 (3.78) |
| **1c** | 117.0 (80.03) | 175.7 (4.60) |
| **1d** | 118.3 (71.91) | 183.9 (3.87) |
| **1e** | 113.4 (108.44) | 191.1 (3.46) |

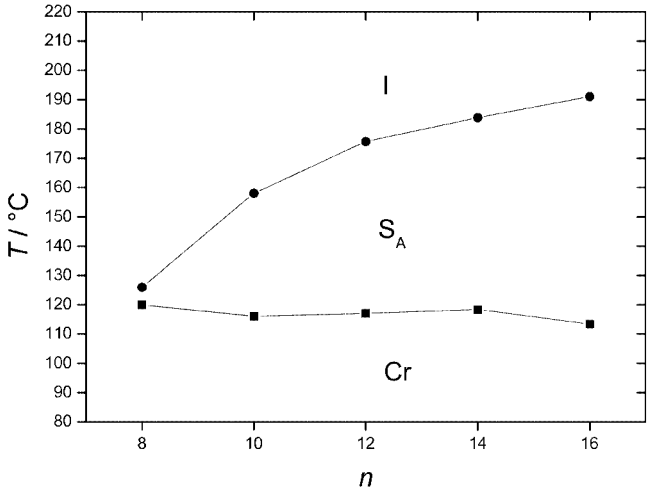

Figure 1. Phase diagram of compounds **1a**–**e** (I: isotropic liquid; $S_A$: smectic-A phase; Cr: crystalline phase).

The high stability of the compounds was demonstrated by the absence of significant perturbation of the DSC patterns following several heating–cooling cycles. The peak occurring at the lowest temperature (see Table 1 and Figure 1) corresponds to the melting of the crystal into a smectic-A phase. Determined by random motions of the paraffinic moiety, this peak involves an important enthalpy change that increases linearly with the number of carbon atoms of the tails (see Figure 2, ■).

The corresponding slope (7.2 ± 0.9) KJ/mol gives a value of the melting enthalpy of the methylene groups of (258 ± 32) J/g, comparable to that found for the complete melting of linear paraffins (289 J/g)[8] or for the transition of crystalline mesogens into a smectic phase (272[9a] and 238[9b] J/g).

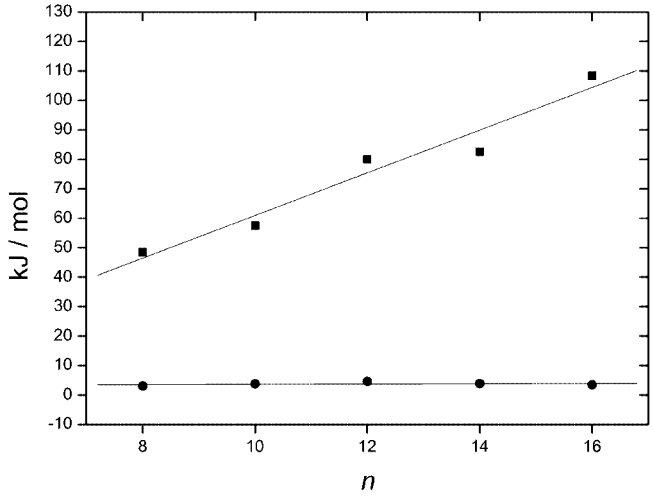

Figure 2. Phase transition enthalpies as a function of the number of carbon atoms in the alkyl chains; ■, Cr–$S_A$; ●, $S_A$–I.

The peak corresponding to the transition from the smectic-A phase to the isotropic liquid, related to the disordering of the aromatic cores of the molecules, involves an enthalpy that is independent of the length of the molecules, as expected and observed (see Figure 2, ●).

The liquid-crystalline phase was also confirmed by optical microscopy. The optical textures observed during slow cooling from isotropic melt showed the emergence of a smectic-A phase (see Figure 3a–b, initial appearance of rods turning into wide, fan-like, focal-conic textures).

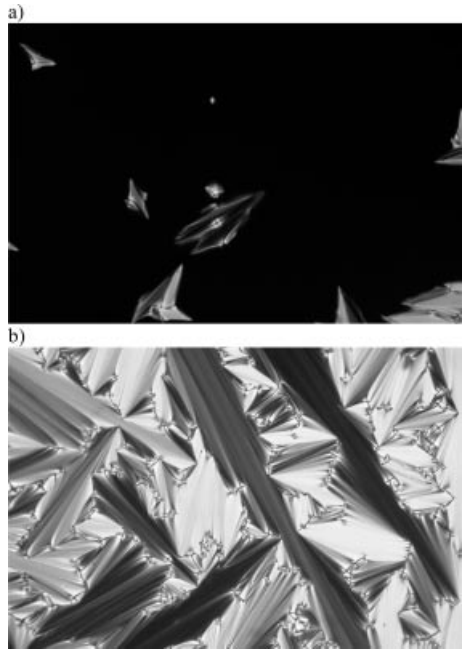

Figure 3. a) Polarising optical microscope image observed upon slow cooling of the isotropic melt clearly show the emergence of Batônnets with positive units. b) Typical smectic-A phase obtained from **1c** between 117 and 175 °C.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

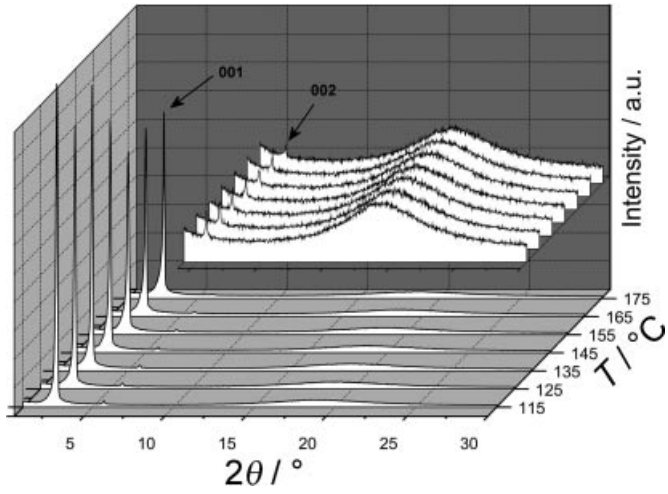

Figure 4. X-ray diffraction pattern of the smectic-A phase of **1c** at different temperatures. For clarity the intensities of the peak 002 and the broad band at Bragg angles $2\theta \geq 5°$ have been magnified.

The smectic-A arrangement is definitively established by the presence of two sharp, equidistant reflections (ratio 1:2) in the small angle region, related to smectic layering, and a broad band in the wide angle region, related both to the disordered conformation of the alkyl chains and the liquid-like lateral correlations of the aromatic core within the layers (Figure 4).

This mesophase was also evident in the XRD patterns, allowing determination of the *d*-spacing values for the smectic-A phase as shown in Figure 5. It is important to note that the smectic period increases in a linear manner with the molecular size.

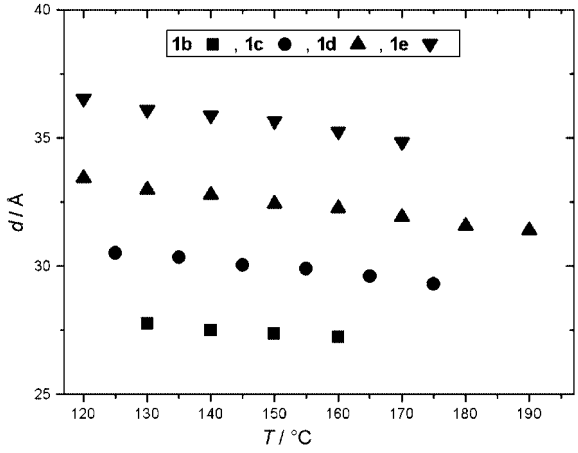

Figure 5. Variation of the smectic period of **1a**–**e** in the smectic-A state as a function of the number of carbon atoms in the alkyl chains and at different temperatures.

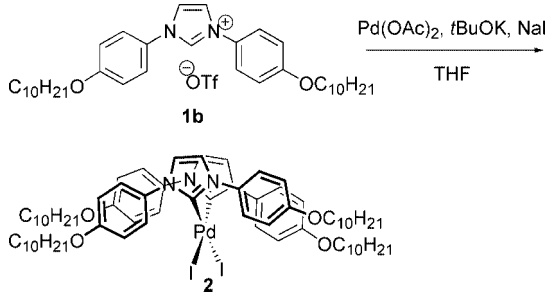
## Palladium(II) Carbene Complex

Transformation of imidazolium salts **1a**–**e** into N-heterocyclic carbene complexes was of interest in regard to possible applications in catalysis. Thus, palladium(II) complex **2** was obtain by deprotonation of imidazolium **1b** in the presence of the palladium salt precursor $Pd(OAc)_2$, KO*t*Bu (1 equiv.) and NaI (4 equiv.) (Scheme 2).[10] The formulation of complex **2** was confirmed by elemental analysis. The presence of a carbene centre was established by the observation of a signal at $\delta$ = 167.0 ppm in the $^{13}C$ NMR spectra, which was assigned to the 2C-imidazol-2-ylidene carbon nucleus, and by the absence of the resonance for the 2H-imidazolium proton in the $^{1}H$ NMR spectra. The details of the molecular structure of palladium carbene complex **2** in the solid state were established by a single-crystal X-ray diffraction study. The molecular unit present in the crystal is shown in Figure 6.



Scheme 2. Conditions: 12 h at room temp.

As shown in Figure 6, the $Pd^{II}$ centre is bound to two carbene ligands with a *cis* coordination geometry. The metal has a square-planar coordination sphere [C1–Pd–C36, 89.8(1)°; I–Pd–I, 92.42(4)°], with the heterocyclic rings near-perpendicular to the coordination plane and to one another.

The Pd–I [2.6788(3) and 2.6620(8) Å] and Pd–C bond lengths [2.009(3) and 2.000(4) Å] are similar to those in related complexes.[11] The *cis* geometry is probably favoured by a combination of steric and electronic factors involving the Pd centre as well as π–π interactions between the phenyl groups of the two heterocyclic ligands[12] [centroid distances of 3.54(2) and 3.66(2) Å for C20–C25/C55–C60 and C4–C9/C39–C44, respectively, labelled *x* in Figure 7). This in-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

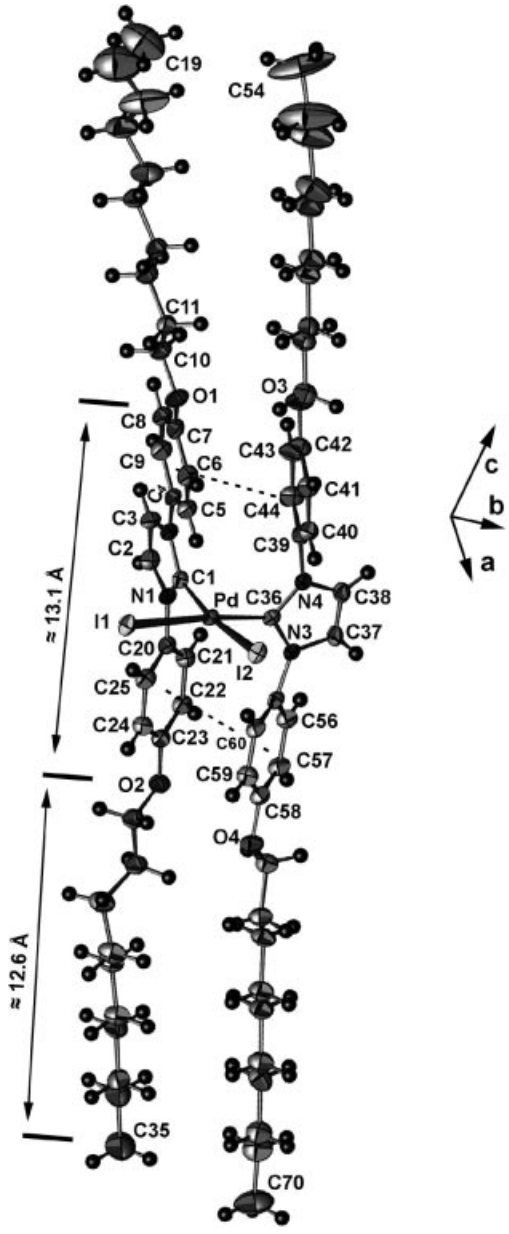


Figure 6. ORTEP view of the crystal structure asymmetric unit of complex **2** with partial labelling scheme. Thermal ellipsoids enclose 50% of the electronic density. Dashed lines indicate the intramolecular phenyl–phenyl π–π interactions.

teraction may also account for the orientation of the phenyl rings towards the heterocyclic carbene. The length of the rigid part of the molecule is around 13.1 Å, whereas the length of the alkoxy chain is around 12.6 Å (see Figure 6).

No classical hydrogen bonds were detected in this crystal structure. Nevertheless, careful analysis of the intermolecular approaches provided evidence for three nonclassical hydrogen bonds involving the iodine and carbon atoms of both the phenyl and heterocyclic rings.

These presumably weak hydrogen contacts[13] are listed in Table 2. The crystal packing can be interpreted in terms of a combination of CH–π and π–π interactions.[13] The intermolecular π–π interactions (labelled *y* in Figure 7) occurring between the heterocycles force them to be strictly parallel. Another π–π weak interaction is detected between both C36–N3–C37–C38–N4 rings of two adjacent molecules along the *b* axis [with a centroid distance of 3.90(2) Å].

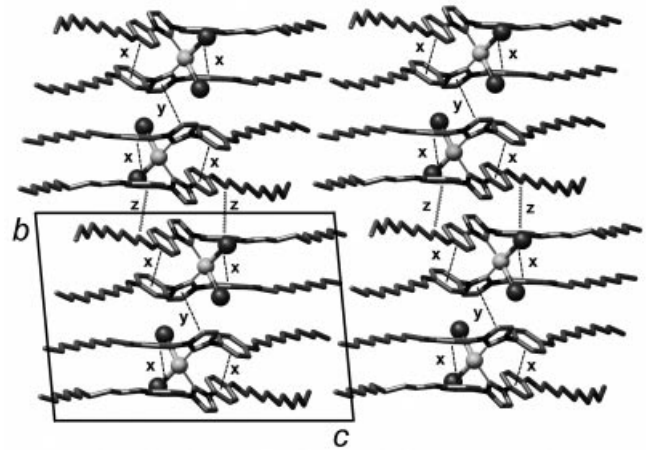

Figure 7. Solid-state packing diagram of complex **2** in projection on the (*b*,*c*) plane. The π–π and CH–π interactions are labelled with *x* (intramolecular π–π), *y* (intermolecular π–π) and *z* (intermolecular CH–π).

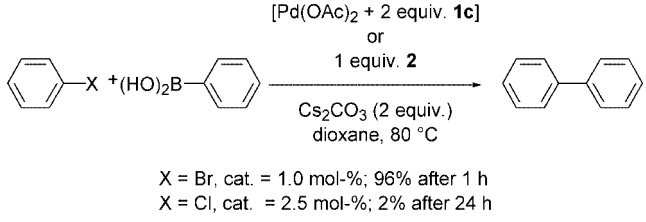
Table 2. Weak hydrogen interactions with iodine atoms.

| C–H···I | $d_{C–H}$ [Å] | $d_{H–I}$ [Å] | $d_{C–I}$ [Å] | C–H–I angle [°] |
|---|---|---|---|---|
| C25–H25···I1 | 0.95 | 2.99 | 3.8954 | 159 |
| C37–H37···I2 | 0.95 | 3.02 | 3.8384 | 146 |
| C60–H60···I2 | 0.95 | 2.93 | 3.8223 | 156 |

Finally, the CH–π interactions (C10–H10B···phenyl group and C11–H11A···phenyl group; labelled *z* in Figure 7) probably explain the form of the array along the crystallographic *b* axis.

## Catalysis Behaviour

Cross-coupling reactions represent an extremely versatile tool in organic synthesis. In order to explore the potential of our imidazolium salts as a source of N-heterocyclic carbene ligands for palladium-catalysed cross-coupling reactions, we decided to investigate the Suzuki–Miyaura reaction with imidazolium **1b** (Scheme 3).[14] Optimised conditions were used for the Suzuki–Miyaura cross-coupling: $Pd(OAc)_2$/imidazolium salt (2 equiv.), $Cs_2CO_3$ as base and dioxane as solvent (80 °C).[15]



Scheme 3. Suzuki–Miyaura reaction.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The coupling of bromobenzene and phenylboronic acid proceeds quite rapidly in high yields with a catalyst loading of 1.0 mol-% (96% GC yield after 1 h). However, we were not able to observe catalysis for the coupling of chlorobenzene and phenylboronic acid even with a higher catalyst loading (2.5 mol-%). Similar results were obtained by using palladium complex **2**. It is known that steric factors dictate the catalytic activity since bulky N-substituents in the imidazolium salt are required to get good catalytic activity. The presence of the alkoxy chain in the *para* position of the *N*-aryl imidazolylidene does not change the efficiency of the ligand in the cross-coupling. Therefore, imidazolium **1b** with two $C_{10}H_{21}$ alkyl tails acts as a ligand with the same reactivity as 1,3-bis(4-methylphenyl)imidazolylidene.[15]

### Mobility of Charged Carriers in the Mesophase

The carrier mobility measurements were carried out for the smectic-A phase of **1b** by using the time-of-flight (TOF) technique (Figure 8). As preliminary data, the mobility for the positive electrode illumination was estimated to be in the order of $10^{-4}$ $cm^2/Vs$, which is comparable to those of nematic liquid crystals ($10^{-4}$–$10^{-6}$ $cm^2/Vs$)[16] and the lower ordered smectic liquid crystals.[17–19]

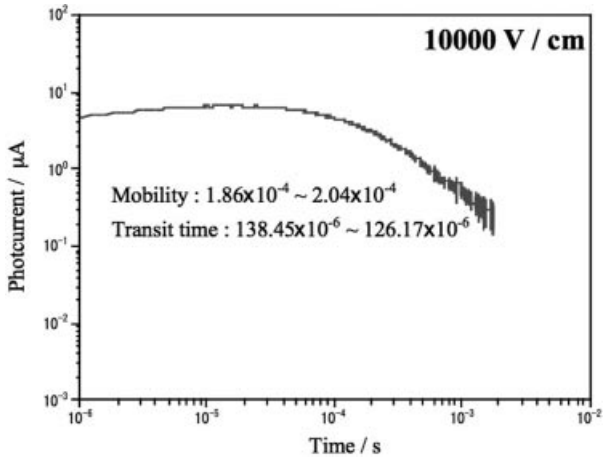


Figure 8. Typical decay curve of the transient photocurrent observed in the TOF measurements (bias: 10000 V/cm). The mesophase is smectic-A phase (131 °C) and the compound was not uniformly aligned in the cell gap (2.56 μm-thick).

This mobility is in a region where both electronic and ionic transports of charged carriers should be considered. It might indicate that both ionic transport and electronic hopping could be realised in the liquid-crystalline phase of this compound, though the reality of carriers is unknown for this mobility.

## Conclusions

We report the full characterisation of new mesomorphic compounds based on an imidazolium unit with different alkyls tails. We investigated the ability of the conjugate base of the cation to form carbene complexes with palladium(II). Preliminary measurements of the charged carrier mobility in the mesophase suggest electronic as well as ionic transports. To evaluate the influence of the supramolecular architecture on catalysis or palladium-catalysed reactions, we are now investigating the ability of this palladium(II) carbene complex to be dissolved in an ionic liquid crystal.

## Experimental Section

**Synthesis:** All commercially available chemicals were used without further purification. Dichloromethane (DCM) was carefully dried and distilled prior to use. Full details of the salt and $Pd^{II}$ complex syntheses will be given elsewhere, though all bisimines were obtained as indicated in Figure 1.[7] The new compounds were characterised by NMR spectroscopy and elemental analyses. With appropriate variations of the alkoxyphenyl diimine starting material (Figure 1), all imidazolium triflates were prepared by the method described below for octyloxy species **1a**.

**1,3-Bis(4-octyloxyphenyl)-3*H*-imidazol-1-ium Trifluoromethanesulfonate (1a):** To a mixture of the octyloxy bisimine (0.521 g, 1.12 mmol) and AgOTf (0.317 g, 1.23 mmol) was added dry $CH_2Cl_2$ (25 mL) and then chloromethyl pivalate (305 μL, 2.103 mmol). The mixture was stirred in the dark at 50 °C, under an argon atmosphere, for 20 h. The solution was cooled to room temp., the mixture was filtered through Celite, the solvent was evaporated and the crude product was purified by silica gel column chromatography ($CH_2Cl_2$ then $CH_2Cl_2$/MeOH, 95:5). The compound was subsequently crystallised from dichloromethane by the addition of hexane. The imidazolium triflate deposited as colourless crystals. (0.413 g, 59%). $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 9.64 (t, $^4J$ = 1.23 Hz, N–CH–N imidazolium), 7.67 (d, $^4J$ = 1.60 Hz, 2 H, N–CH–CH–N imidazolium), 7.65 (m, $^3J$ = 9.0 Hz, 2 H, aromatic, AA′ system), 7.04 (m, $^3J$ = 9.0 Hz, 2 H, aromatic, BB′ system), 3.90 (t, $^3J$ = 6.60 Hz, 2 H, $CH_2$–O), 1.80 (m, 2 H, $CH_2$–$CH_2$–O), 1.44 (m, 2 H, $CH_2$–$CH_2$–$CH_2$–O), 1.32 (br. s, 16 H, aliphatic), 0.90 (t, $^3J$ = 7.0 Hz, 3 H, $CH_3$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, 20 °C): $\delta$ = 14.04 (–$CH_3$), 22.61, 25.91, 29.03 29.17, 29.29, 31.76, 68.59 (O–$CH_2$), 115.90, 120.63 (q, $J$ = 320 Hz, $CF_3$) 121.98, 123.39, 124.82, 126.88, 132.35, 160.58 ppm. IR (KBr pellet): $\tilde{\nu}$ = 3141 and 3102 (C–H aromatic), 2918 and 2852 (C–H aliphatic), 1555 and 1513 (C=N imidazolium), 1266 ($OTf^-$) $cm^{-1}$. $\lambda$ ($\varepsilon$) = 277 (16375) nm. $C_{32}H_{45}F_3N_2O_5S$ (626.77): calcd. **Palladium–Carbene Complex 2:** Compound **1b** (250.0 mg, 0.367 mmol), $Pd(OAc)_2$ (41.2 mg, 0.183 mmol) and NaI (55.0 mg, 0.367 mmol) were suspended in THF (15 mL). *t*BuOK (41.1 mg, 0.367 mmol) was added to the suspension under an atmosphere of nitrogen. The resulting solution was stirred for 1.5 d at 40 °C. After evaporation of the solvent, the residue was extracted with dichloromethane/water. After drying the DCM layer over $Na_2SO_4$ and evaporating it to dryness, the orange solid was purified by flash column chromatography ($SiO_2$, $CH_2Cl_2$/pentane). Yield: 116 mg, 44%. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.51 (d, $J$ = 8.9 Hz, 4 H), 6.96 (s, 2 H), 6.75 (d, $J$ = 8.9 Hz, 4 H), 4.05 (t, $J$ = 6.6 Hz, 4 H), 1.86 (m, 4 H), 1.53–1.26 (m, 28 H), 0.89 (t, $J$ = 6.7 Hz, 6 H) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 167.0 ($C_{carbene}$), 158.5 ($C_q$), 133.0 ($C_q$), 127.8 (CH), 123.8 (CH), 114.5 (CH), 68.2, 31.9, 29.7, 29.6, 29.5, 29.4, 29.3, 26.2, 22.7, 14.1 ($CH_3$) ppm. $C_{71}H_{105}I_2N_3O_4Pd$ (1424.84): calcd. C 59.0, H 7.3, N 3.9; found C 58.95, H 7.45, N 3.80.

**General Procedure for the Suzuki-Type Coupling Reactions:** Palladium acetate (1–2.5 mol-%), imidazolium salt (2–5 mol-%), $Cs_2CO_3$ (652 mg, 2 mmol) and phenylboronic acid (183 mg, 1.5 mmol) were added to a small Schlenk tube under an atmosphere of nitrogen. Dioxane (3 mL) and the aryl halide (1 mmol) were then added, and the mixture was heated in an oil bath at 80 °C. At the conclusion of the reaction, the reaction mixture was cooled and analysed by GC–MS.

**Carrier Mobility Measurements:** The charge carrier mobility in the mesophase was measured by TOF (time-of-flight) measurement apparatus equipped with a polarising microscope and a hot stage. The light source was a pulsed nitrogen gas laser (Nippon Laser, $\lambda$ = 337 nm, 0.8 ns). The cells consisting of ITO- and $TiO_2$-coated glasses for an asymmetric structure of sandwich-type cells were mounted on the hot stage and electric bias was applied by a stabilised DC power supply. The resulting photocurrent was detected with a digital oscilloscope with a homemade preamplifier.

**X-ray Crystallography:** The selected crystal was mounted on a Nonius Kappa-CCD area detector diffractometer (Mo-$K_\alpha$, $\lambda$ = 0.71073 Å). The complete conditions of data collection (Denzo software) and structure refinements are given below. The cell parameters were determined from reflections taken from one set of ten frames (1.0° steps in phi angle), each at 20 s exposure. The structures were solved by direct methods (SHELXS97) and refined against $F^2$ using the SHELXL97 software. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated according to stereochemistry and refined by using a riding model in SHELXL97.[20] CCDC-628899 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Colourless single crystal; crystal dimension: $0.10 \times 0.08 \times 0.05$ mm$^3$. $C_{70}H_{104}I_2N_4O_4Pd$, $M$ = 1425.77 g/mol; Triclinic; space group $P\bar{1}$; $a$ = 10.7060(1) Å; $b$ = 15.8080(2) Å; $c$ = 21.6950(3) Å; $Z$ = 2; $D_{calcd.}$ = 1.354 g/cm; $\mu$ (Mo-$K_\alpha$) = 1.195 mm$^{-1}$; a total of 20389 reflections; $1.34° < \theta < 30.06°$, 1842 independent reflections with 12376 having $I > 2\sigma(I)$; 730 parameters; Final results: $R_1$ = 0.0460; $wR_2$ = 0.1287, *Goof* = 0.996, maximum residual electronic density = 1.887 e/Å$^3$.

## Acknowledgments

We are especially grateful to D. Guillon and J. Harrowfield for the critical evaluation of this manuscript, we also thank A. De Cian for the X-ray diffraction studies. # Rarely Decorated Rutile Frameworks Built from Triangular Organic Spacers and Distorted Octahedral $Co_3$ Building Blocks

Feng Luo,[a] Yun-xia Che,[a] and Ji-min Zheng*[a]

**Keywords:** Solvothermal syntheses / Rutile / Cobalt / Polymers

Under mild temperatures, the self-assembly of $CoCl_2$ and $H_3BTC$ in a solution of dmso generates a guest-free metal–organic polymer, namely $Co_3(BTC)_2(\mu_1\text{-dmso})_2(\mu_2\text{-dmso})_2$(**1**: dmso = dimethylsulfoxide, $H_3BTC$ = 1,3,5-benzenetricarboxylic acid). In **1**, the $Co^{II}$ ions show the six-coordinate octahedral geometry completed by the $BTC^{3-}$ ions and the dmso oxygen atoms; remarkably, the coordinated dmso ligands not only act as terminal ligands to complete the octahedral geometry of the $Co^{II}$ ions, but also play an important role in bridging $Co^{II}$ ions together to give the $Co_3$ secondary building units (SBUs). From a topological viewpoint, this novel polymer is classified to be the decorated (3,6)-connected rutile net with the $(4.6^2)_2(4^2.6^{10}.8^3)$ topology, where $BTC^{3-}$ ligands and $Co_3$ SBUs are viewed to be the 3- and 6-connected nodes, respectively. In addition, the magnetic properties of **1** are explored by using a linear trinuclear cobalt mode, thus leading to $g = 2.41$, $J = -34.92$ cm$^{-1}$, TIP = $340 \times 10^{-6}$ cm$^3$ mol$^{-1}$, $\theta = -6$ K (a $\theta$ parameter was included to take into account intertrinuclear interactions).

## Introduction

The design and synthesis of metal-organic frameworks (MOFs) is now of great interest owing to the potential applications and unusual topologies of these new materials.[1] Although this relatively new field of chemistry is aimed at the discovery and synthesis of new materials for practical applications with an emphasis on their functional aspects, it would be difficult to achieve true advancements without an understanding of the structural aspects of these materials at the molecular or atomic levels; however, recent remarkable research results and reviews on framework topologies and other geometrical characteristics of network solids reflect this importance.[2] It seems that for the majority of 3D metal–organic framework topologies, we can find the well-known prototypes in metallic or binary inorganic solids. For example, diamond or diamond-related nets that are composed of tetrahedral nodes are the most common, and they allow the highest interpenetration. A primitive cubic (**pcu**) net/or α-Po net, based on octahedral nodes is also frequently observed and shows the relatively lower two- or threefold interpenetration.[2a,3] Other 3D structures have recently been reported to have the following topologies: boracite, $CdSO_4$, $CaB_6$, feldspar, NbO, perovskite, $Pt_3O_4$, PtS, pyrite, quartz, rutile (**rtl**), sodalite, $SrSi_2$, and tungsten bronze.[4] Among the most important and frequently encountered mixed connectivity types, the rutile form of $TiO_2$ is an important (3,6)-connected net structure. To construct such a net, it appears that assembling triangular building blocks with octahedral building blocks will realize it. In this regard, several compounds with expanded (increased spacing between vertices in a network) **rtl** nets were constructed, most of which are interpenetrating structures constructed with cyano ligands.[5] By contrast, the decorated (replacement of a vertex in a net by a group of vertices) **rtl** nets are less developed. To the best of our knowledge, there are only four interpenetrating decorated and one noninterpenetrating such species.[3b,6] Hence, further investigation into the self-assembly of MOFs characterized by the noninterpenetrating decorated **rtl** nets is needed.

Very recently, most of the significant MOFs were prepared by solvothermal syntheses in $CH_3OH$, $C_2H_5OH$, and $CH_3CN$ solutions, but especially in DMF solution.[7] However, the solvothermal synthesis of MOFs in dmso solution is unexplored. Herein, we report such a reaction, and the resulting elegant MOF presents as the second noninterpenetrating decorated **rtl** net.

## Results and Discussion

The as-synthesized samples are air-stable and insoluble in water and common organic solvents, such as $CH_3OH$, $C_2H_5OH$, $CH_3CN$, and DMF. Incidentally, dmso decomposes at high temperature and emits a terrible odor; hence, we must be careful to obtain crystal samples from the reaction vessel.

### Crystal Structure and Network Topology

Single-crystal X-ray structural analysis revealed that **1** crystallizes in the monoclinic system, space group $P2(1)/c$.

There are two crystallographically independent cobalt ions in this structure. The local coordination geometry for the six-coordinate Co1 center is close to an octahedron coordinated by four $BTC^{3-}$ oxygen atoms and two dmso oxygen atoms. Co2 located at an inverse center is also surrounded by four $BTC^{3-}$ oxygen atoms and two dmso oxygen atoms to give the $CoO_6$ octahedral geometry. The $Co–O_{dmso}$ bond lengths vary from 2.097 to 2.243 Å, which are comparable to the $Co–O_{carboxylate}$ bond lengths in the range of 2.034–2.228 Å, and both of them are comparable with those observed in other Co–BTC compounds;[13] thus, the distortion parameter of the $CoO_6$ octahedra is $8.8 \times 10^{-4}$ for Co1 and $2.2 \times 10^{-3}$ for Co2.[8] As for each $BTC^{3-}$ ligand, it shows a pentadentate-coordinated mode with one carboxyl group chelated to the Co1 ion and two carboxyl groups bridging Co1 with Co2.

The Co1, Co2, and symmetry-related Co1′ ions are combined together by the *syn-syn* carboxyl groups of the $BTC^{3-}$ ligands and $\mu_2$-dmso bridges thus leading to the linear $Co_3$ SBU of corner-sharing octahedra (Figure 1). The intratrinuclear Co1–Co2 distance is 3.562 Å, and the $Co1–O_{dmso}–Co2$ angle is 109.04°. Furthermore, each SBU connects six $BTC^{3-}$ ligands in six directions (Figure 2), whereas each $BTC^{3-}$ ligand ligates three SBUs (Figure 3); consequentially, such a connectivity pattern is repeated infinitely to construct the infinite (3, 6)-connected net (Figure 4). For perspicuous representation, the $Co_3$ SBUs are represented by distorted octahedral nodes, as each carboxyl group is more-or-less offset from the phenyl plane and not all the vertices of each octahedral $Co_3$ SBU are symmetrically equivalent, whereas the $BTC^{3-}$ ligands are described as triangular units.

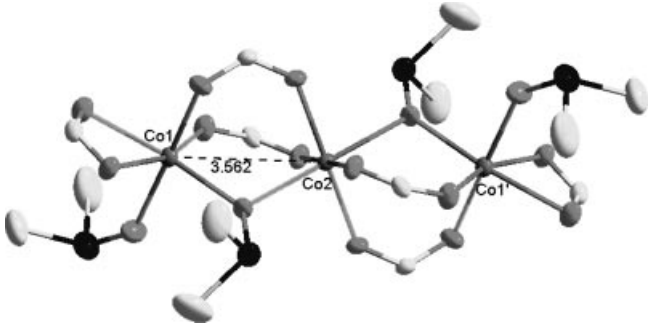

Figure 1. Schematic description of the $Co_3$ SBU and its coordinated environment: C is light grey, S is black, and O is dark grey. The atoms are drawn at the 50% probability level.

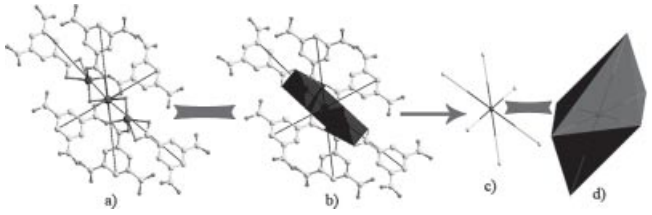

Figure 2. a) Ball-and-stick mode of the six-connected $Co_3$ SBU; b) polyhedral illustration of the $Co_3$ core; c) the simplified node-to-node fashion of the six-connected SBU; d) polyhedral illustration of the distorted octahedral SBU.

Hence, the framework should be viewed as a noninterpenetrating decorated **rtl** net with the $(4.6^2)_2(4^2.6^{10}.8^3)$ topology, where six-connected $Co_3$ SBUs and three-connected $BTC^{3-}$ units correspond to the Ti atoms and the O atoms in the **rtl** net structure, respectively.

Figure 3. a) Ball-and-stick mode of the three-connected $BTC^{3-}$ unit; b) polyhedral illustration of the $Co_3$ core; c) the simplified node-to-node fashion of the triangle $BTC^{3-}$ node.

Figure 4. View of the noninterpenetrating decorated rutile net with the $(4.6^2)_2(4^2.6^{10}.8^3)$ topology and constructed from distorted octahedral $Co_3$ SBUs and triangle $BTC^{3-}$ units.

Carefully checking the reported decorated **rtl** nets, we find that most of them are built from octahedral $M_2$ (M = metal ion) SBUs and triangular organic units. Obviously, the present one contains the biggest octahedral SBUs ($Co_3$).

## Magnetic Properties

The $\chi_M T$ product of crystal samples of **1** was measured in the temperature range 2–300 K with applied magnetic fields of 500 Oe (Figure 5). At room temp., the $\chi_M T$ value of 6.37 $cm^3 K mol^{-1}$ is slightly higher than that of three high-spin $Co^{II}$ ion (5.63 $cm^3 mol^{-1} K$, $S = 3/2$, $g = 2.0$) as a magnetically noninteracting center owing to orbital contribution from the octahedral high-spin $Co^{II}$ ions. Upon cooling from room temp., the $\chi_M T$ product linearly decreases to 2.30 $cm^3 K mol^{-1}$ at 10 K, which is due to the spin-orbit coupling effects of the high-spin octahedral $Co^{II}$ ions with an orbital degenerate $^4T_1$ ground term and the antiferromagnetic exchange coupling between $Co^{II}$ ions. The $\chi_M T$ values then sharply decrease to 1.19 $cm^3 K mol^{-1}$ at 2 K as a result of the ZFS (zero field splitting) and/or other fac-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tors, such as intertrinuclear interactions. In the $1/\chi_M$ versus $T$ plot, above 75 K, the plot is exactly a straight line well-fitted by the Curie–Weiss law [$\chi_M = C/(T - \theta)$], with $C$ = 8.3 $cm^3 mol^{-1} K$ and $\theta$ = –83.0 K. This is consistent with three $S$ = 3/2 $Co^{II}$ ions with moderate antiferromagnetic coupling to yield an average $g$ value of 2.4. This large Weiss constant indicates a dominated antiferromagnetic coupling between the $Co^{II}$ ions.

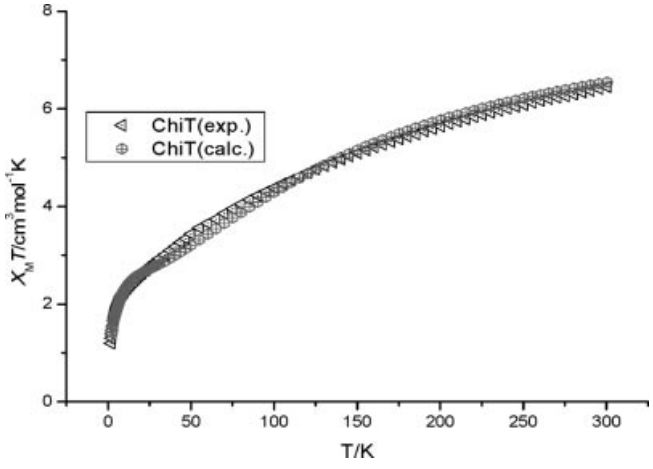

Figure 5. The plot of $\chi_M T$ vs. $T$: open triangle is the experimental curve and the crossed circle is the simulated curve.

As mentioned above, in this linear $Co_3$ unit, Co1 and Co1′ are symmetrical, and the closest distance of Co1–Co1′ is 7.124 Å; hence, we chose a "one $J$" mode to analyze the experimental magnetic data.[9] A least-squares fit to the data leads to $g$ = 2.41, $J$ = –34.92 $cm^{-1}$, TIP = $340 \times 10^{-6}$ $cm^3 mol^{-1}$, $\rho$ = 0.09 $cm^3 mol^{-1} K$, and $\theta$ = –6 K: $J$ is the magnetic coupling parameter between Co1–Co2 and Co1′–Co2, $g$ is the Zeeman factor, TIP is the temperature-independent paramagnetism, $\rho$ is the paramagnetic impurity, and $\theta$ is the intertrinuclear interactions. It is not surprising to find important TIP contributions and such a strong Zeeman factor. Indeed, the combined influences of the local distortion of the coordination sphere around the $Co^{II}$ ion and the spin-orbit coupling are known to produce this set of local parameters.[10]

Relative to the pyridazine-bridging Co3 compounds,[11] the preset compound bridged by $\mu_2$-O atoms displays the obviously bigger antiferromagnetic interactions, but comparable with the cobalt(II)–hydroxy compounds.[12]

### TGA Research of 1

The TG research (30–800 °C) of **1** shows that at 30–300 °C, there is no weight loss, which is consist with the structure of **1**, and polymer **1** then starts to perform the process of chemical decomposition (Figure 6). The remains may be $Co_2O_3$ (calcd. 28%; found 30%).

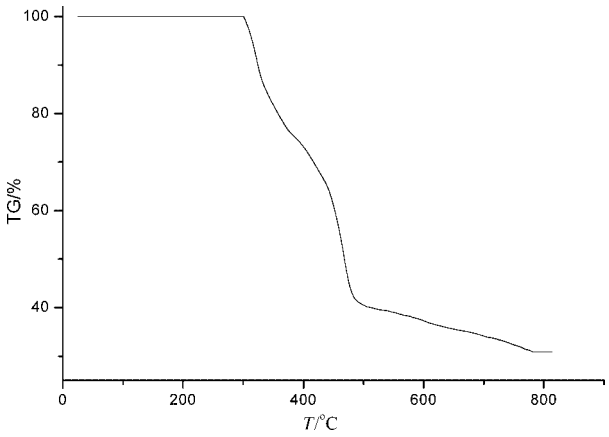

Figure 6. The TG plot of **1** (to our surprise, we found that the TG plot is straight until 300 °C; maybe, the former treatment such as heating to avoid the absorbed water molecules and $N_2$ protection are the main reason.

## Conclusions

Through this original research, we initiated the solvothermal synthesis of MOFs in dmso solution. The resulting MOF, defined as a noninterpenetrating decorated rutile net with the $(4.6^2)_2(4^2.6^{10}.8^3)$ topology, is built from distorted octahedral $Co_3$ SBUs and triangular $BTC^{3-}$ units. To the best of knowledge, this distorted octahedral $Co_3$ SBU is the biggest relative to those ($M_2$ SBU) observed in other similar instances. In addition, it should be highlighted that the dmso molecules in polymer **1** display two different ligand coordination modes: terminal and $\mu_2$-bridging; however, this phenomenon has never been observed in the literature. Thus, this study will largely enrich the field of MOFs and further understand the coordinated behavior of $H_3BTC$ ligands, especially the dmso molecules.

## Experimental Section

**Materials and Instrumentation:** All reagents were bought from commercial sources and used without further purification. Elemental analysis was carried out with an Elementar Vario ELIII microanalyzer. Magnetic measurements were carried out with a Quantum

Design (SQUID) magnetometer MPMS-XL-5. Thermal gravimetric analysis was completed with a NETZSCH TG 209 instrument.

**Preparation of 1:** A mixture of $CoCl_2 \cdot 6H_2O/H_3BTC$ (1:0.8) in a solution of dmso (10 mL) was placed in a Teflon reactor (23 mL) and heated at 160 °C for 3 d. The mixture was then cooled to room temp. at 5 °C $h^{-1}$. Purple crystals were obtained in 75% yield based on Co. $C_{26}H_{30}Co_3O_{16}S_4$ (903.53): calcd. C 34.56, H 3.35; found C 34.52, H 3.26.

**X-ray Crystallographic Studies:** Intensity data were collected with a rigaku r-axis rapid IP area detector with Mo-$K_\alpha$ monochromated radiation ($\lambda$ = 0.71073 Å) at room temp. Empirical absorption correction was applied. The structures of these polymers were solved by direct method and refined by full-matrix least-squares on $F^2$ by using the SHELXL-97 software. All of the non-hydrogen atoms were refined anisotropically. The organic hydrogen atoms were generated geometrically and refined with isotropic temperature factors. Crystal data and structure refinement for these polymers are summarized in Table 1. Selected bond lengths and angels are listed in Table 2. CCDC-638904 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

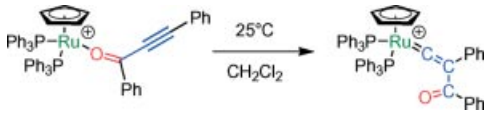
$\eta^1$-Vinylidene Formation from Internal Alkynones by C–C Bond Migration

**Keywords:** Ruthenium / Alkynes / Isomerization / Vinylidene bond activation / Unsaturated complexes



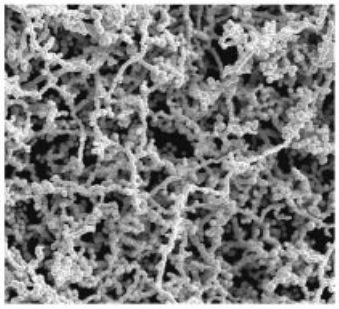
The formal 16-electron $[CpRu(PPh_3)_2]^+$ fragment was shown to react with three nonterminal acetylenic ketones to form $\eta^1$-vinylidene complexes. These reactions involve C–C bond activation and apparently proceed through $\eta^1$-ketone intermediates.

### Chain-Like CoNi Alloys

**L.-P. Zhu, H.-M. Xiao, S.-Y. Fu* ..... 3947–3951**

Surfactant-Assisted Synthesis and Characterization of Novel Chain-Like CoNi Alloy Assemblies

**Keywords:** Alloy / Assemblies / Hydrothermal method / Ferromagnetism / Coercivity



Novel chain-like CoNi alloy assemblies with a length of up to 6–7 μm were successfully prepared by a surfactant-assisted hydrothermal synthetic route. The results show that chain-like CoNi alloy assemblies composed of well-aligned CoNi alloy submicrospheres have a diameter of about 400–500 nm. Magnetic hysteresis measurements revealed that the chain-like CoNi alloy assemblies display ferromagnetic behavior.

### Hexamolybdates

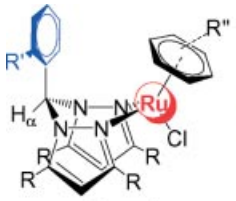
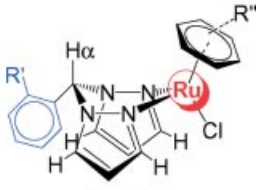
## (Arene)ruthenium(II) Complexes



Isomer A



Isomer B

A new and safer method for the synthesis of differently substituted bis(pyrazolyl)-methane ligands has been developed. Arene–Ru derivatives containing these ligands were obtained. The relative stability of isomers A and B has been analysed. The activity in transfer hydrogenation of benzophenone has been studied. Better results are obtained with ligands that contain methylated pyrazoles.

## $Zn^{II}$-cyclen-pyridine Complexes

Binary and ternary systems containing $Zn^{2+}$, cyclen and/or pyridine derivatives (picolinic, nicotinic and dipicolinic acids and nicotinamide) were investigated in solution and in the solid state, and the stability of the ternary complexes was determined.

## Metathesis Polymerization

Several $Ru^{II}$–N-heterocyclic carbene complexes were investigated for their use as pre-catalysts for the ring-opening metathesis polymerization of enantiomerically pure *exo* and *endo* norbornene derivatives. Differences in reactivity between the *exo* and *endo* derivatives were elucidated by quantum chemical calculations. These revealed different potential reaction pathways.

# Conversion of $CO_2$ into Formate by Homogeneously Catalyzed Hydrogenation in Water: Tuning Catalytic Activity and Water Solubility through the Acid–Base Equilibrium of the Ligand

**Yuichiro Himeda*[a]**

**Keywords:** Carbon dioxide fixation / Catalyst tuning / Ligand design / Substituent effects / Catalyst recycling

This Microreview focuses on the recently developed hydrogenation of $CO_2$ and hydrogen carbonate catalyzed by half-sandwich complexes with 4,4′-dihydroxy-2,2′-bipyridine (dhbp) and 4,7-dihydroxy-1,10-phenanthroline (dhpt). An unprecedented high catalytic activity and reusability of the catalyst without waste generation were achieved by automatic tuning of the catalytic activity and water solubility of the catalyst through the acid–base equilibrium of the catalyst ligand. The oxyanion generated from the phenol hydroxy group played significant roles in the electronic effect and polarity. The catalyst design concept and the excellent properties of the ligands are expected to have significantly broader implications for the design of new homogeneous catalysts.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

The conversion of $CO_2$ into useful organic products still remains an intriguing and challenging subject.[1–6] In nature, an enormous amount of $CO_2$ is transformed into carbohydrate in metal centers of enzymatic systems in an aqueous environment. However, the industrial application of $CO_2$ as a source of $C_1$ instead of carbon monoxide and phosgene is limited: a recent topic of interest is polycarbonate production by using $CO_2$ as a starting material.[7] From an academic viewpoint, the activation of inert $CO_2$ has attracted considerable interest. Many attempts to convert $CO_2$ by using transition-metal catalysts have focused on the photochemical[8–13] and electrochemical[14–16] reduction of $CO_2$. In addition, there have been significant advances in the homogeneously catalyzed hydrogenation of $CO_2$ in the last decade, although the primary products are limited, in general, to formic acid and its derivatives (Table 1).

The homogeneous hydrogenation of $CO_2$ to formic acid was first reported by Inoue et al. in 1976.[17] They used phosphane complexes of group 8, 9, and 10 metals, including Wilkinson's catalyst, in benzene in the presence of water and base. Recently, Ezhova and co-workers studied the hydrogenation by Wilkinson's catalyst in detail.[18] They reported that the rhodium catalysts required phosphane ligands for the hydrogenation of $CO_2$, whereas the complex with bipyridine as a ligand was inactive.

In 1994, Noyori and co-workers reported that the use of supercritical carbon dioxide ($scCO_2$) greatly improved the catalytic efficiency of $Ru^{II}$–phosphane complexes in the presence of amine.[19,20] They obtained TOFs (Please see the list of abbreviations at the end.) up to 95000 $h^{-1}$ at 19 MPa by the use of pentafluorophenol as the additive.[21] The good results are explained by the characteristic properties of $scCO_2$, such as its extremely high miscibility with $H_2$ and its good mass-transfer capability. However, a $scCO_2$-soluble catalyst and a relatively high pressure are required.

| K[RuCl(edta-H)] | $H_2O$ | – | 0.3/1.7 | 40 | 0.5 | | 250 | [24] |
| $RhCl(tppts)_3$ | $H_2O$ | $NHMe_2$ | 2/2 | 81 | 0.5 | | 7260 | [22] |
| | | | 2/2 | r.t. | 12 | 3439 | | [23] |
| $[RuCl_2(tppms)_2]_2$ | $H_2O$ | $NaHCO_3$ | 6/3.5 | 80 | 0.03 | 320 | 9600 | [29] |
| | | | 0.2/0.8 | 50 | 1 | | 50 | [29] |
| $RuCl_2(pta)$ | $H_2O$ | $NaHCO_3$ | 6/– | 80 | | | 807[a] | [31] |

[a] The initial TOF was calculated by nonlinear least-squares fitting of the experimental data obtained from the initial part of the reaction.

Leitner and co-workers reported that the water-soluble analogue of Wilkinson's catalyst, $[RhCl(tppts)_3]$ (Ligand abbreviations are in lowercase letters according to IUPAC recommendations; they may be in capital letters in some of the articles cited in this review.), serves as an effective catalyst in water.[22,23] In aqueous systems, an amine additive is required, and the final concentration of formic acid never exceeds that of the added amine. Moreover, the problem of separating the base from the reaction medium still exists. Khan and co-workers reported that $[RuCl(edta-H)]^+$ catalyzed the hydrogenation of $CO_2$ in pure water.[24] Although the initial rate of the reaction was relatively high (TOF of 250 $h^{-1}$), the decomposition of formic acid and formaldehyde as a reverse reaction occurred readily. Joo and Katho performed extensive studies on the hydrogenation of $CO_2$ and hydrogen carbonate in amine-free aqueous solutions. The use of rhodium and ruthenium complexes with widely used water-soluble phosphane ligands (i.e., tppms, tppts, and pta) were investigated in detail.[25–32] The rate of hydrogenation strongly depends on the central metal, the phosphane ligand, and the pH of the reaction solution. A high TOF of 9600 $h^{-1}$ was obtained by using $[RuCl_2(tppms)_2]_2$ at 9.5 MPa and 80 °C. More interestingly, in the hydrogenation of $CaCO_3$, the final formate concentration reached 143% (the calculation is based on the amount of added base). It was revealed that the hydrogenation proceeds in the absence of base. Their detailed kinetic, mechanistic, and theoretical investigations[25] provided useful information on the hydrogenation of $CO_2$ and hydrogen carbonate in water.

According to excellent reviews encompassing the literature until 2003,[5,33–35] almost all the active catalysts for the hydrogenation of $CO_2$ to formic acid are rhodium- and ruthenium-based complexes with phosphane ligands. On the other hand, there are a few, less active examples of other metals (e.g., Ir,[17] Pd,[36] and Ni[37]) and ligands (e.g., edta-H,[24] 6,6′-dichloro-2,2′-bipyridine[38]). Although an aqueous-phase catalyst might not be expected to be active on the basis of mass-transfer rates, a number of active catalysts were found from aqueous systems. On the other hand, an active catalyst promotes the decomposition of formic acid as a reverse process.[27,39] Therefore, the yield of formate is strongly dependent on the equilibrium between formic acid and $CO_2$. Furthermore, recovery and reusability of catalyst are serious concerns from the viewpoint of process cost, because highly active catalysts are restricted to the complexes of precious metals.[37] Several attempts have been made by Baiker and Ikariya to achieve reusability by immobilizing the catalyst for dmf synthesis under $scCO_2$.[40–44]

This Microreview focuses on aqueous catalysts containing rhodium, ruthenium, and, in particular, iridium with 4,4′-dihydroxy-2,2′-bipyridine (dhbp) and 4,7-dihydroxy-1,10-phenanthroline (dhpt) as ligands. In addition, catalyst recycling as well as improvement in catalytic efficiency is considered. For a more sophisticated process, the catalytic activity and water solubility of the metal complexes are controlled through the acid–base equilibrium of the catalyst ligand.

## The Use of Water as a Solvent

Water is innocuous, abundant, and cheap. Furthermore, in the hydrogenation of $CO_2$ and hydrogen carbonate into formic acid and formate, water serves not only as a bulk solvent but also as a participant. The solvation effect of water can significantly influence the thermodynamics of the reaction. Although the hydrogenation of $CO_2$ into formic acid [Equation (1)] in the gas phase is endergonic ($\Delta G°_{298}$ = +33 kJ mol$^{-1}$), the reaction in the aqueous phase is exergonic ($\Delta G°_{298}$ = –4 kJ mol$^{-1}$).[22] Similarly, on the basis of theoretical calculation, the hydrogenation of a hydrogen carbonate into formate in water [Equation (2)] is exergonic.[25] Thus, water is believed to be an ideal reaction medium for the hydrogenation of $CO_2$ and hydrogen carbonate.

$$CO_2 + H_2 \rightleftharpoons HCO_2H \quad (1)$$

$$HCO_3^- + H_2 \rightleftharpoons HCO_2^- + H_2O \quad (2)$$

The equilibriums of both $CO_2$ and formic acid in water must be considered [Equations (3) and (4)].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$$CO_2 + H_2O \rightleftharpoons H_2CO_3 \overset{pK_1 = 6.35}{\rightleftharpoons} HCO_3^- + H^+ \overset{pK_2 = 10.33}{\rightleftharpoons} CO_3^{2-} + 2H^+ \quad (3)$$

$$HCO_2H \overset{pK_a = 3.6}{\rightleftharpoons} HCO_2^- + H^+ \quad (4)$$

$CO_2$ reaches an equilibrium with hydrogen carbonate and carbonate, and this is strongly dependent on pH, temperature, and $CO_2$ pressure.[45,46] It is believed that, in acidic conditions, hydrogenation converts $CO_2$ into formic acid [Equation (1)], whereas in alkaline conditions, it converts hydrogen carbonate into formate [Equation (2)]. The presence of the base makes the hydrogenation of $CO_2$ more favorable.[33,39] Thus, the hydrogenation usually fails or provides only a small yield in the absence of a base, because the decomposition of formic acid as a reverse reaction might occur easily under acidic conditions. Joo reported an interesting result: the generation of formate exceeds the amount of added base, in other words, the product mixture contains formic acid, and the reaction solution changes from a basic solution into an acidic one.[27]

On the other hand, the catalysis in water requires the development of water-soluble ligands. Thus far, imparting water solubility to complexes for aqueous catalysis can be achieved by the introduction of charged or polar substituents such as acidic (-$SO_3H$, -$CO_2H$) and basic (-$NR_2$) functionalities into the ligands.[47,48] Although various phosphane ligands (e.g., tppms, tppts, and pta) have been the subject of considerable research in the area of aqueous catalysts, other types of water-soluble ligands have hardly been investigated.

## Background

Numerous studies have investigated half-sandwich bipyridine complexes $[(C_nR_n)M(ppy)X]^{k+}$ [ppy = 2,2′-bipyridine or 1,10-phenanthroline; R = H, Me, and alkyl; X = halogen, $H_2O$; M = Rh, Ir ($n$ = 5); M = Ru ($n$ = 6)], which are isoelectronic complexes of each other, because of their interesting properties.[49–55] In particular, the transfer hydrogenation of NAD catalyzed by rhodium complexes in water by using a formate as the hydrogen donor was extensively investigated by Steckhan et al.[56–60] The reaction of rhodium complexes with a formate provides the corresponding hydrido complex $[Cp^*RhH(bpy)]^+$ through a β-elimination reaction to produce $CO_2$. Direct hydride transfer from the hydrido complex to a ketone results in low yields under neutral conditions.[60] However, we found that transfer hydrogenation is strongly dependent on the pH value, and the yields were significantly improved under acidic formate conditions.[61,62] In addition, the decomposition of formic acid to $CO_2$ and $H_2$ (i.e., the reverse reaction of the hydrogenation of $CO_2$) catalyzed by $[Cp^*Rh(bpy)Cl]Cl$ proceeded smoothly with a TOF of 238 $h^{-1}$ at 40 °C.[63]

Caix and co-workers reported that rhodium and iridium complexes $[Cp^*MCl(bpy)]^+$ (M = Rh, Ir) serve as electrocatalysts for the reduction of $CO_2$ to formate in an aqueous organic medium.[16,64] It has been observed that the electrochemical reduction involves the formation of hydrido complexes $[Cp^*MH(bpy)]^+$, followed by the insertion of $CO_2$ into the metal–hydrogen bond.

Previous studies by us and others prompted us to investigate the hydrogenation of $CO_2$ or hydrogen carbonate by using the half-sandwich bipyridine complexes in water. Table 2 shows the results of the hydrogenation of $CO_2$ or hydrogen carbonate; the reaction proceeded in aqueous solution without the use of amine additives.[65] Interestingly, the hydrogenation proceeded under neutral and acidic conditions (entries 2 and 3), although these conditions are less suitable for activity than basic conditions. However, the decomposition of the formate as a reverse reaction occurred easily after pressure release, particularly in acidic solutions. It is noteworthy that the iridium complexes showed a catalytic activity similar to those of the rhodium and ruthenium complexes (entry 4). However, the catalytic activities of the half-sandwich bipyridine complexes were far from satisfactory.

Table 2. Hydrogenation catalyzed by half-sandwich bipyridine complexes in aqueous solution.[a]

| Entry | Complex | Solution | TON |
|---|---|---|---|
| 1 | $[Cp^*Rh(bpy)Cl]Cl$ | 1 M KOH aq. | 216 |
| 2 | $[Cp^*Rh(bpy)Cl]Cl$ | 1 M $NaH_2PO_4$ aq. | 76 |
| 3 | $[Cp^*Rh(bpy)Cl]Cl$ | $H_2O$ | 31 |
| 4 | $[Cp^*Ir(bpy)Cl]Cl$ | 1 M KOH aq. | 105 |
| 5 | $[(C_6Me_6)Ru(bpy)Cl]Cl$ | 1 M KOH aq. | 68[b] |

[a] The reaction was carried out by using a catalyst (0.1 mM) at 4 MPa ($CO_2/H_2$ = 1:1) and 80 °C for 20 h. [b] The catalyst concentration was 0.2 mM.

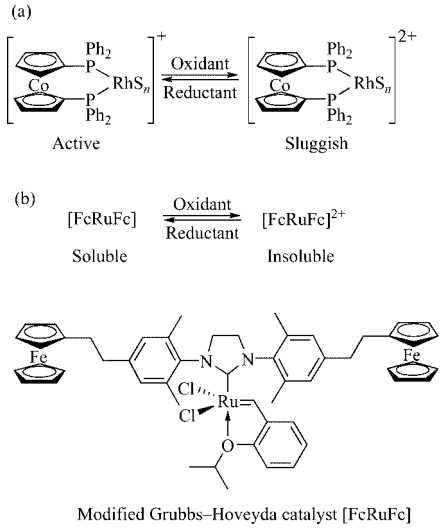
Sakaki's theoretical studies[66] and Jessop's experimental results[67] had the important implication that electron-donating ligands would improve the catalytic efficiency. The electronic substituent effect in a bipyridine ligand, in which the coordinated nitrogen atoms are incorporated in the aromatic ring, may have a stronger influence on the central metal atom than that in a triphenylphosphane ligand. In order to improve the catalytic activity and recover the catalyst, we designed a novel catalyst based on bipyridine complexes.

## Catalyst Design

Recently, extensive efforts have been undertaken to optimize an entire chemical process consisting of reaction and separation steps in order to minimize economical and environmental costs.[68–70] Control or switching of catalyst properties (e.g., reactivity and solubility) is one of the strategies employed for this purpose.[71] The pioneering reports of Wrighton demonstrated that catalytic activity can be electrochemically controlled by changing the oxidation state of the redox-active ligand by addition of stoichiometric amounts of simple redox reagents (Scheme 1a).[72,73] In the

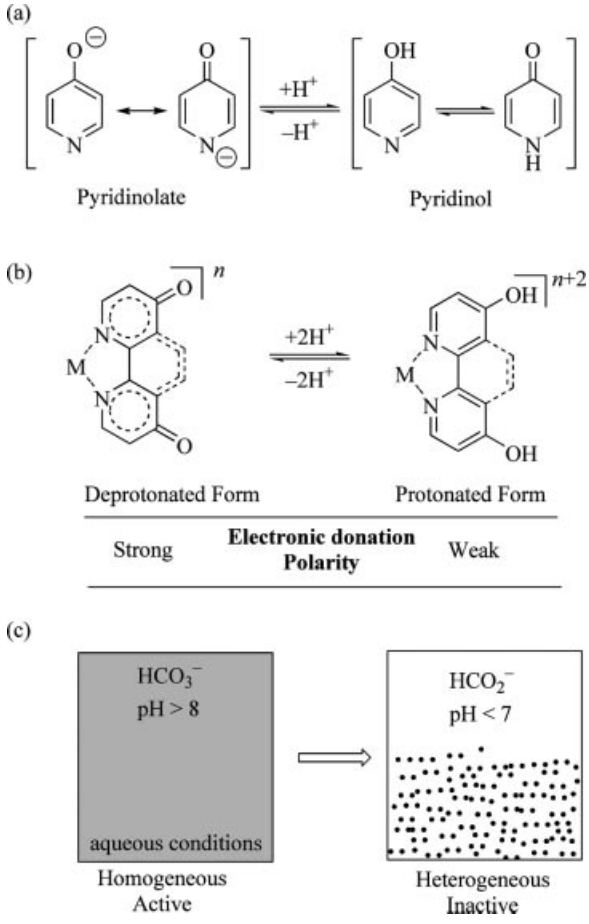
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

hydrogenation of cyclohexene, the reduced form of the diphosphanylcobaltocene-stabilized rhodium complex is approximately 16 times faster than its oxidized form. On the other hand, there are many reports of the use of an amphiphilic ligand for controlling the solubility of the complexes by varying the pH of the system.[74] For example, catalyst recycling was achieved by addition of acid or base to the solution after the reaction, followed by extraction or filtration.[75,76] Recently, the interesting work of Sussner demonstrated the recycling of the Grubbs–Hoveyda catalyst with two ferrocene moieties by using the redox-switching concept (Scheme 1b).[77] However, the simultaneous and effective control of two or more functions of a catalyst has never been demonstrated.



Scheme 1. Control of catalytic properties by switching of the redox-active ligand: (a) Electrochemical control of catalytic activity.[72] (b) Control of solubility for recyclability of catalyst.[77]

We focused our attention on catalyst tuning through the acid–base equilibrium between pyridinol and pyridinolate (Scheme 2). The interconversion leads to simultaneous changes in both electronic and polar properties, which are attributed to the difference between the hydroxy group in pyridinol and the oxyanion in pyridinolate (Scheme 2a). In comparison with the acid–base equilibrium of carboxylic acid and sulfonic acid, the interconversion of the phenol hydroxy group causes a drastic change in the electronic status on the benzene ring through the resonance structure. From the Hammett constant,[78] a substantial difference in the electronic effects of the oxyanion ($\sigma_p^+ = -2.30$) and the hydroxy group ($\sigma_p^+ = -0.91$) can be observed. Thus, the control of the electronic effect through the acid–base equilibrium of catalyst ligands provides a desirable reactivity of the catalyst, i.e., activation in the reaction step and deactivation in the separation step in order to prevent the reverse reaction. In addition, it should be noted that the $\sigma_p^+$ value of the oxyanion is much lower than those of the amine and alkoxy groups, which are widely used electron-donating substituents. On the other hand, it is known that the dipole moment of pyridone is much greater than that of pyridinol.[79,80] Accordingly, when pyridinol is used as a part of a complex ligand, the interconversion will provide an excellent opportunity for controlling the electronic effect and polarity of a catalyst by varying only the pH (Scheme 2b).



Scheme 2. Catalyst design for catalyst tuning: (a) Acid–base equilibrium between pyridinol and pyridinolate. (b) Interconversion between the deprotonated and protonated forms. (c) Catalyst state at the beginning and at the end of the hydrogenation of hydrogen carbonate in water.

It is noteworthy that our catalyst design based on the acid–base equilibrium of catalyst ligands is closely correlated with the change in the pH of the reaction solution during the hydrogenation of hydrogen carbonate. In other words, as the reaction proceeds, the reaction solution changes from basic to acidic. Therefore, it is expected that the catalyst may spontaneously transform from the homogeneous and active deprotonated form at the beginning of the reaction into the heterogeneous and inactive protonated form at the end (Scheme 2c). Our system has the advantages of heterogeneous catalysis (i.e., the simplicity of catalyst separation) and biocatalysis (i.e., aqueous reaction and pH dependence) as well as those of homogeneous catalysis (i.e., high catalytic performance).

This paper reviews catalysis with complexes of the 4,4′-dihydroxy-2,2′-bipyridine (dhbp: $H_2L^1$) and 4,7-dihydroxy-1,10-phenanthroline (dhpt: $H_2L^2$) ligands that succeeded in the activation and reusability of the catalyst for the hydro-

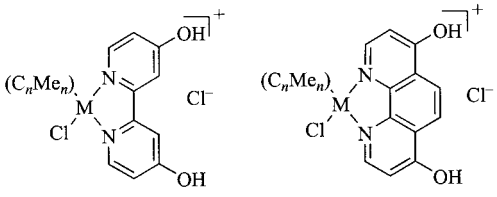
genation of $CO_2$ and hydrogen carbonate in water. In addition, our studies on catalyst tuning through the acid–base equilibrium of the catalyst ligand can be expected to provide valuable insights into the development of homogeneous catalysts.

## Properties of dhbp and dhpt Complexes

The most significant feature of dhbp and dhpt is that they have two acidic phenol hydroxy groups. While both ligands are soluble in an alkaline aqueous solution, dhpt is insoluble in water and common organic solvents except dmf and dmso. Hence, half-sandwich dhbp complexes $[(C_nMe_n)M(H_2L^1)Cl]Cl$ **1**–**3** [M = Rh, Ir ($n$ = 5), M = Ru ($n$ = 6)] were prepared from $[(C_nMe_n)MCl_2]_2$ in water or alcohol, but dhpt complexes $[(C_nMe_n)M(H_2L^2)Cl]Cl$ **4**–**6** were prepared in dmf.



**1:** M = Rh ($n$ = 5)
**2:** M = Ir ($n$ = 5)
**3:** M = Ru ($n$ = 6)

**4:** M = Rh ($n$ = 5)
**5:** M = Ir ($n$ = 5)
**6:** M = Ru ($n$ = 6)

The $^1H$ and $^{13}C$ NMR spectra of aqua complex $[Cp^*Ir(H_2O)(H_2L^1)]^{2+}$ (**7**) were strongly dependent on the pH of the environment (Table 3).[81] The substantial shifts are attributed not only to the transformation from the aqua ligand to the hydroxido ligand,[82] but also to the deprotonation of the hydroxy groups (Scheme 3).[83] The downfield shift in the $^{13}C$ NMR signal for the carbon atoms attached to oxygen strongly suggests the generation of the oxyanion. On the other hand, the complex with 3,3′-dihydroxy-2,2′-bipyridine (**8**) allows the formation of an intramolecular O–H–O hydrogen bond.[84]

Table 3. $^1H$ and $^{13}C$ NMR spectroscopic data for iridium complexes in $D_2O$ (chemical shifts in ppm).

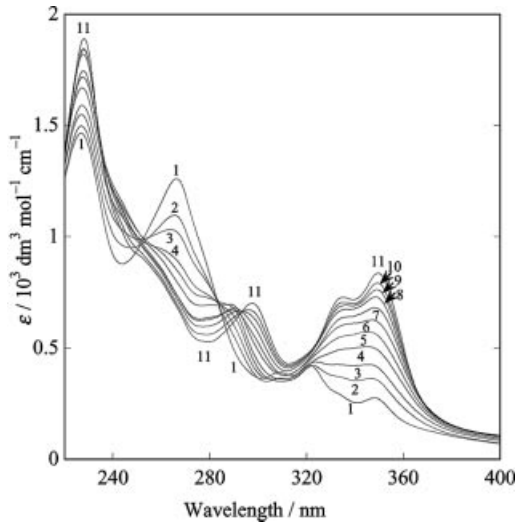

Figure 1. Absorption spectra of rhodium complex **4** (50 μM) in an aqueous solution containing 2.5% methanol at pH values of 1.9–2.3 (1), 3.3 (2), 3.6 (3), 4.0 (4), 4.2 (5), 4.5 (6), 4.8 (7), 4.9 (8), 5.2 (9), 5.5 (10), and 5.6–9.0 (11).

The electronic spectra of ruthenium dhpt complexes $[Ru(dhpt)(ppy)_2]^{2+}$ were studied in detail.[83,85,86] As a result of an acid–base equilibrium of the phenol hydroxy group in dhpt, the absorption spectra of the complexes are dependent on the pH of the environment. Similarly, in half-sandwich complexes **1**–**6**, spectral changes were observed with variations in the pH. Representative absorption spectra of rhodium dhpt complex **4** as a function of pH are shown in Figure 1. Plots of percent change in optical density against pH for iridium and ruthenium complexes are shown in Figure 2. Although the complexes have two acidic protons, only one inflection point is observed in the plots. The values of the overall dissociation constant $pK_a$ estimated from the pH at the inflection point are given in Table 4.[83] The result indicates that the dhpt complexes were obviously more acidic than the dhbp complexes, and the iridium complexes were slightly acidic relative to other complexes.

The structural features of ruthenium complex **3** obtained by single-crystal X-ray crystallographic analysis are similar to those of its 4,4′-dimethoxy-2,2′-bipyridine and bipyridine analogs (Figure 3).[87,88]

The water solubilities of chlorido complexes **1**–**6** are pH dependent: chlorido complexes are highly soluble in basic solution but poorly soluble under acidic and neutral conditions (Scheme 4). When an alkaline solution of deprotonated complexes **1**–**6** was acidified, it precipitated as the protonated complexes. However, the complexes remained par-

[a] Observed p$K_a$ is twice the pH at the inflection point in the curve.

tially in the mother liquor as a result of the generation of aqua complexes by the aquation of the chlorido complexes. It is highly probable that the dhpt complexes could be recovered more efficiently than the dhbp complexes. On the other hand, aqua complex **7** is water soluble. However, when HCl was added to a solution of **7**, chlorido complex **2** precipitated as a result of the anation of the aqua complex. This result shows that anation is preferable to aquation in half-sandwich bipyridine complexes.[53,89]

The pH-dependent solubility of the complexes in formate solutions was investigated.[90] An alkaline solution of the complex was added to the formate solution at various pH values. After the resulting solution was allowed to stand overnight, the metal concentrations of the filtrates were measured by ICP-MAS. Figure 4 shows the iridium concentrations of **2** and **5** at various pH values. In both of the complexes, the solubility decreased sharply below pH 8. In particular, the concentration of dhpt complex **5** was as low as 0.12 ppm in the pH range 4.5 to 5.5, which is almost one seventh that of the dhbp complex **2** (0.80 ppm at pH 7.4). Since it is known that half-sandwich bipyridine complexes form hydrido complexes under certain conditions in a formate solution,[61] the recovered solids may be mixtures of hydrido complexes, which consist of monoprotonated and fully protonated complexes. On the other hand, at pH 3.5 and below, the solubility of both the complexes increased; this was probably due to the generation of aqua complexes.[91,92] In the rhodium and ruthenium complexes, precipitation was not observed under these conditions, probably because of the instability of the hydrido complexes.

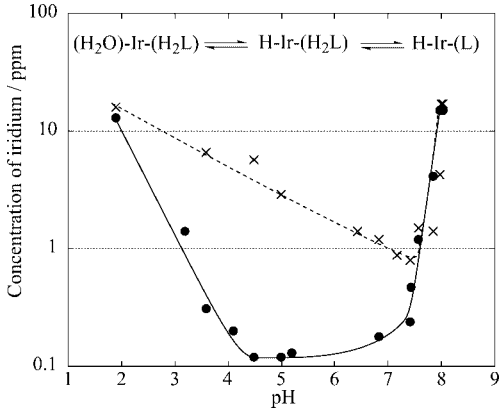

Figure 4. Iridium concentration in an aqueous formate solution (1 M) of **2** (crosses/dotted line) and **5** (filled circles/solid line). Ir = Cp*Ir, $H_2L$ = dhbp($H_2L^1$), dhpt($H_2L^2$).

## Electronic Effect on Catalytic Activity

Numerous studies have established a dependence of both stoichiometric and catalytic activity on electronic substituent effects in the range from the electron-withdrawing nitro group to the electron-donating amine groups.[93–95] The substituent effects on the electrochemical properties of the half-sandwich bipyridine rhodium and iridium complexes have been investigated.[59,96] Sakaki[66] and Jessop[67] suggested that electron-donating ligands would improve the catalytic efficiency for the hydrogenation of $CO_2$. On the other hand, a high catalytic activity might promote the reverse reaction after the release of pressure.[27,39] Such a conflicting requirement can be satisfied by controlling the electronic properties of the catalyst ligand (i.e., the catalytic activity) through the acid–base equilibrium of pyridinol.

The electronic substituent effect on the hydrogenation of hydrogen carbonate was investigated by using a series of iridium complexes [Cp*Ir(4,4′-$X_2$-2,2′-bpy)Cl]Cl [X = H, $CO_2H$, Me, OMe, OH(**2**)].[90,97,98] The time courses of formate generation are shown in Figure 5. The catalytic activities of the iridium complexes are strongly dependent on the substituent on the bipyridine ligand. The correlation between the substituent and the initial TOF can be explained on the basis of Hammett's rule. Note that the deprotonation of the phenol hydroxy group and the carboxyl group occurs under basic reaction conditions. Thus, the $\sigma_p^+$ value for the hydroxy complex is –2.30 and that for the carboxylic acid complex is –0.02, and they correspond to the oxyanion (-$O^-$) and carboxylato (-$CO_2^-$) values, respectively.[78] The Hammett plots of the initial TOF vs. the $\sigma_p^+$ value of X in [Cp*Ir(4,4′-$X_2$-2,2′-bpy)Cl]Cl at 4 MPa and 1 MPa and 80 °C are shown in Figure 6. Both plots have high correlation coefficients, and the reaction constants ($\rho$) are very similar. The electronic trend is in agreement with Sakaki's theoretical prediction[66] and Jessop's experimental results[67] for the catalytic hydrogenation of $CO_2$. The large $\sigma_p^+$ value of –2.30 and the $\rho$ value of –1.3 resulted in a remarkably high initial TOF for **2**, which was ca. 100 times greater than that of a methoxy complex (X = OMe) and over 1000 times greater than that of an unsubstituted complex (X = H). Similarly, a similar reactivity trend (H < OMe < OH) was observed for the series of disubstituted phenanthroline complexes.[63] This was the first example of a strong electronic oxyanion effect on catalytic activity in the field of complex catalysts.

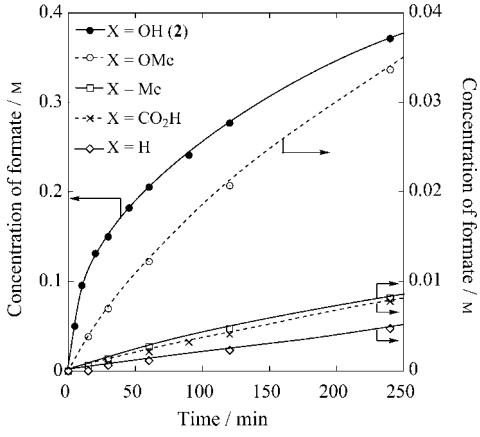

Figure 5. Time course of formate concentration during the hydrogenation of hydrogen carbonate catalyzed by [Cp*Ir(4,4′-$X_2$-2,2′-bpy)Cl]Cl (0.2 mM) at 4 MPa ($H_2$:$CO_2$ = 1:1) and 80 °C in an aqueous KOH solution (1 M).

Surprisingly, no significant activation was observed in *meta*-substituted analogue **8**, although one negative charge existed on the ligand.[63] One possible explanation is that the resonance structures of 3-hydroxypyridine cannot increase the π-electron density on the nitrogen atoms. This hypothesis is consistent with the data reported for the nucleophilicity of the nitrogen atom in the 3- and 4-hydroxypyridine anions.[99]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

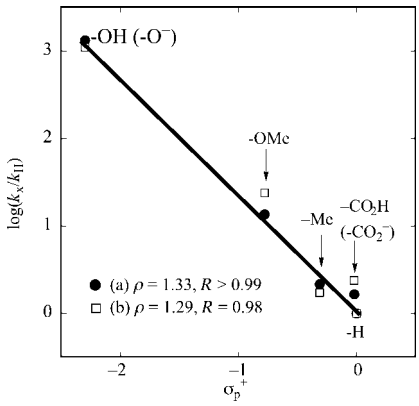

Figure 6. Hammett plot of initial TOF (= $k$) vs. the $\sigma_p^+$ value of substituent (X) in [Cp*Ir(4,4′-$X_2$-2,2′-bpy)Cl]Cl. The reaction was carried out with the catalyst (0.02–0.2 mM) at 80 °C in an aqueous KOH solution (1 M) at (a) 4 MPa and (b) 1 MPa.

Table 5 summarizes the results for the iridium complexes with dhbp, **2**, and dhpt, **5**, under various conditions. The catalysts were relatively stable at a high temperature. Unprecedented high activities [TOF = 42000 $h^{-1}$ (entry 3) and TON = 222000 (entry 11)] were obtained at 6 MPa and 120 °C in a highly diluted solution of the catalyst (<2 μM). As compared with $[RuCl_2(tppms)_2]_2$ under the same conditions (TOF = 30–50 $h^{-1}$ at 1 MPa and 50 °C),[29] **2** showed a far superior catalytic activity [TON = 740 after 1 h (entry 5)].[81] Furthermore, the hydrogenation of hydrogen carbonate proceeded at ambient pressure and 60 °C (entries 6 and 9) and even at 30 °C (entry 10). The results show that the corresponding hydrido complexes can be easily generated at ambient pressure, because the color of the solution changed immediately from pale yellow into deep yellow when $H_2$ was admitted. To the best of our knowledge, there is only one other report on homogeneously catalyzed hydrogenation of $CO_2$ that occurs at ambient pressure at room temperature (TON = 3 per day).[22]

Activation by the introduction of the hydroxy group into the bipyridine ligand as a catalyst ligand were also observed in ruthenium and rhodium complexes (Table 6).[63] In the (arene)ruthenium complexes $[(C_6Me_6)Ru(L)Cl]Cl$, the TONs for complexes with dhbp, **3**, and dhpt, **6**, were ca. 60 times greater than those of the unsubstituted ones. The detailed results under various conditions are summarized in Table 7. The ruthenium complexes yielded higher concentrations of formate relative to the iridium complexes, although their TOF and TON values were moderate (entries 2–5). The formate concentrations increased steadily with increasing pressure from 1.08 M at 2 MPa to 1.54 M at 6 MPa (entries 3–5). The TOFs increased with an increase in the

reaction temperature from 60 to 120 °C without a decrease in the product yield (Figure 7). However, at ambient pressure, only a small amount of formate was generated (TOF = 1.8 at 60 °C).

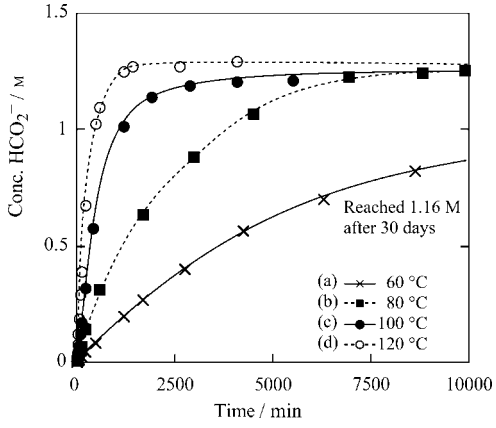

Figure 7. Time course of formate concentration during the hydrogenation of hydrogen carbonate catalyzed by ruthenium complex **6** (0.1 mM) at 4 MPa ($H_2/CO_2$ = 1:1) and (a) 60 °C, (b) 80 °C, (c) 100 °C, and (d) 120 °C in aqueous KOH solution (2 M).

Among rhodium complexes [Cp*Rh(L)Cl]Cl, the TOFs of the unsubstituted ones were the highest among those of all unsubstituted complexes. However, the TOFs for rhodium complexes **1** and **4** were ordinary, and the rates of increase against the unsubstituted complexes were moderate (8–10 times). In addition, the final concentrations of the formate were lower than those of the other metal complexes, probably because of the instability of the catalyst.[61]

The catalytic efficiencies (i.e., TOF, TON, and the concentration of formate) were strongly affected by the central metals. The effects of the metal in complexes with phosphane ligands were also reported.[17,31,32] Interestingly, in the series of the catalysts, the iridium complexes were superior to the rhodium and ruthenium complexes, which have so far dominated in the hydrogenation of $CO_2$. On the other hand, the difference between the effects of the dhbp and dhpt ligands on the catalytic efficiency is relatively small.

Interestingly, no significant decomposition of formate, which is sometimes a problem in the hydrogenation of $CO_2$ and hydrogen carbonate after pressure release, was observed.[39] This suggests that the catalyst activity decreases considerably at the end of the reaction, since it is highly probably that by the acidification of the reaction solution, the catalyst changes from the active deprotonated form into the sluggish protonated form, in which its activity might be lower relative to that of the methoxy analogue.

In this manner, the results demonstrated the usefulness of the concept of catalyst tuning through the acid–base equilibrium of dhbp and dhpt as a catalyst ligand for the hydrogenation of hydrogen carbonate. In other words, the catalyst in the deprotonated form showed an enormously high activity that can be attributed to the strong electron-donating ability of the oxyanion group. On the other hand, the decrease in the activity by the transformation from the deprotonated form into the protonated form restrained the reverse reaction at end of the reaction.

## Catalyst Recycling

Homogeneous catalysis generally has many advantages with respect to the reaction step; however, there are considerable difficulties involved in the separation of a catalyst from the product and/or solvent as compared with heterogeneous catalysis. There have been numerous attempts to recycle catalysts by using multiphase[100–105] and immobilized[106–111] catalysts; however, these often reduce the mixing efficiency between catalyst and substrate. Recently, in order to keep homogeneity in a reaction step, significant attention has been given to stimuli-responsive catalysts such as redox-switchable,[77] magnetic-,[112] temperature-,[113] and pH-responsive,[75] and self-assembly-supported[114] catalysts.[115] However, many concerns (e.g., reduced activity and selectivity, catalyst leaching, waste generation, and use of environmentally suspected solvents) still remain. In particular, a sophisticated design generally results in increasingly expensive complexes.

Reusability of the catalyst was achieved by tuning its water solubility through the acid–base equilibrium of the ligand.[116] In the hydrogenation of hydrogen carbonate in water, it is noteworthy that the reaction solution changes from basic to acidic during the course of the reaction, because the hydrogenation of a basic hydrogen carbonate yields a formate and then formic acid after the consumption of the added base.[27] Thus, it is expected that the catalyst may spontaneously transform from the water-soluble deprotonated form at the beginning of the reaction into the poorly water-soluble protonated form at the end. In particular, iridium–dhpt complex **5** will become favorable for catalyst recycling because of its water insolubility between pH 4 and 7 (Figure 4).

The hydrogenation of hydrogen carbonate catalyzed by **5** was strongly affected by the concentration of KOH, i.e., the pH of the solution. Figure 8 shows the time course of the

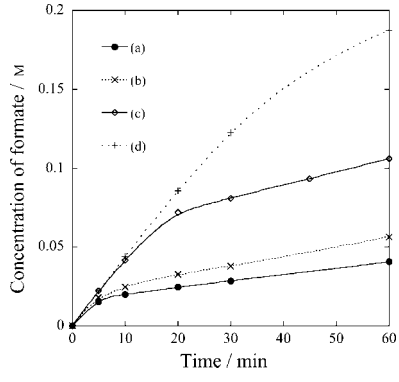

Figure 8. Time course of formate concentration during the hydrogenation of hydrogen carbonate with **5** (0.05 mM) at 6 MPa ($CO_2$/$H_2$ = 1:1) and 60 °C in (a) 0.1-M, (b) 0.2-M, (c) 0.5-M, and (d) 1.0-M aqueous KOH solution.

[a] The reaction was carried out by using **5** (0.05 mM) at 6 MPa ($CO_2/H_2$ = 1:1) and 60 °C. [b] The iridium concentration was measured by ICP-MS analysis.

formate concentration in a KOH solution (0.1–1.0 M). At the beginning of the reaction, the maximum TOFs (ca. 5000 $h^{-1}$) were observed in all the reactions. However, in 0.1- and 0.2-M KOH solutions, the reaction rates decreased drastically after 5 min. In a 1.0-M KOH solution, the rate was steady till 30 min, and it then decreased gradually. The results reveal that **5** exhibited high activity at the beginning of the reaction (i.e., basic conditions), in which **5** might exist in a homogeneous and activated deprotonated form.

On the other hand, prolongation of the reaction time to 72 h in 0.5-M KOH solution did not lead to complete consumption of the added base (Table 8). In other words, the reaction medium was not neutralized (pH = 7.5). Although most of the catalyst precursor was precipitated spontaneously and recovered by filtration of the obtained suspension, 0.61 ppm iridium remained in the filtrate. By using 0.2-M solutions, the added base was consumed completely, and the solution was neutralized. Hence, the remaining iridium decreased to 0.19 ppm. In particular, in 0.1-M KOH solutions, the concentration of the generated formate (0.105 M) exceeded that of the added base to give a weakly acidic suspension (pH = 5.5). The catalyst precursor was separated by filtration. As expected, the colorless filtrate was found to contain only 0.11 ppm iridium, which was 1.2% of the loaded catalyst. The value for iridium leaching was consistent with its solubility in the formate solution, as shown in Figure 4. Furthermore, the concentration of the filtrate and drying under vacuum at 100 °C resulted in pure potassium formate (>98% pure). These results imply the possibility of catalyst recycling in the conversion of $CO_2$ into formate without waste generation.

Subsequently, **5** was recycled in a batchwise cycle (Table 9). The above-mentioned recovered catalyst precursor was dissolved in a 0.1 M degassed aqueous KOH solution, from which 93% iridium was recovered [the loss of iridium was due to the sampling for assay (2%) and handling losses]. While all the four cycles could be performed without a significant loss of the catalytic activity, leaching increased and recovery decreased with an increase in the recycling of the catalyst. However, thermal degradation was observed. It appears that thermal stress and exposure to air lead to an increase in catalyst leaching.

The solubility behavior of **5** during the course of the reaction was visually observed by using a glass reactor. Complex **5** (0.05 mM) was completely soluble in the KOH solution with pressurized $CO_2$. When the reactor was recharged with 3 MPa of $H_2/CO_2$ (1:1) at 60 °C, the pale yellow solution immediately turned to orange, which might indicate the formation of a hydrido complex.[117] After 30 min, a yellow

Table 9. Batchwise recycling of **5** for the conversion of $CO_2$.[a]

| Cycle | Loaded [Ir] /ppm | Recovery efficiency/% | Leaching [Ir][b] /ppm | Final conc. of formate/M |
|---|---|---|---|---|
| 1 | 9.0 | – | 0.11 | 0.105 |
| 2 | 8.4 | 93 | 0.22 | 0.104 |
| 3 | 7.7 | 92 | 0.42 | 0.103 |
| 4 | 7.0 | 91 | 0.61 | 0.103 |

[a] The reaction was carried out at 6 MPa ($CO_2/H_2$ = 1:1) and 60 °C in aqueous KOH solution (0.1 M). No hydrogen carbonate was detected in all the four cycles. [b] The iridium concentration was measures by ICP-MS analysis.

precipitate was formed. After a further 2.5 h, the resulting suspension was filtered to give a clear pale yellow filtrate and yellow precipitate. The filtrate (pH = 7.9) was found to contain 0.05 M of the formate (50% conversion) and 1.0 ppm iridium (ca. 10% of the loaded iridium). The precipitate was readily converted to a deprotonated form by the addition of an aqueous base. Figure 9 shows the photographs of the reaction solution, in which ten times catalyst concentration (0.5 mM) was used for clarity. The pale yellow solution (Figure 9a) at the beginning of the reaction turned into a yellow suspension (Figure 9b) at the end of the reaction. By filtration of the suspension, a colorless solution (Figure 9c) was obtained.

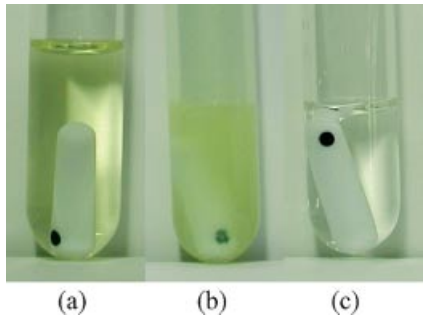

Figure 9. Photographs of the reaction solution (a) before reaction, (b) after reaction, and (c) after filtration. The reaction was carried out with **5** (0.5 mM) in an aqueous KOH solution (0.1 M) at 6 MPa ($CO_2/H_2$ = 1:1) and 60 °C for 15 h.

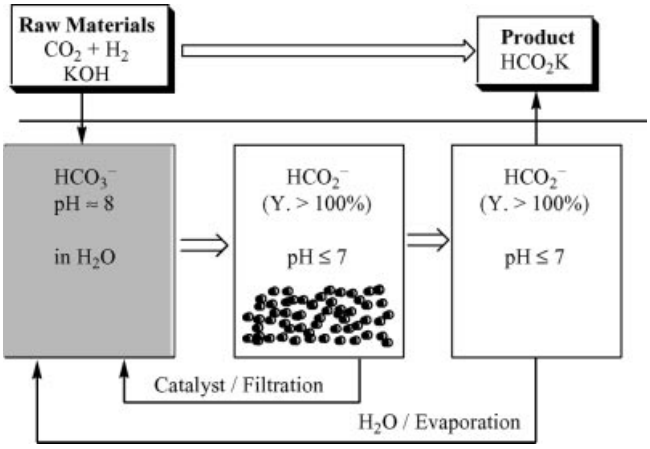
In this manner, the reusability of **5** was achieved by self-precipitation without a significant loss of catalytic activity. It is interesting to note that the three components (i.e., catalyst, product, and solvent) can be easily separated by using conventional filtration and evaporation without waste generation (Scheme 5). This catalytic system is characterized by interconversion between an active and homogeneous deprotonated form at the beginning of the reaction and an inac-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tive and heterogeneous protonated form at the end of the reaction, which is achieved through the acid–base equilibrium of the ligand; the catalyst is easily recovered, and the reverse reaction is suppressed in this system.

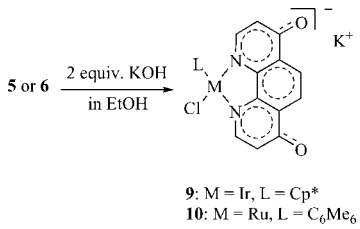


Scheme 5. Recycling system for the conversion of $CO_2/H_2$ and KOH into $HCO_2K$ with **5** in water.

## Mechanistic and Kinetic Studies

The mechanisms of the hydrogenation of hydrogen carbonate catalyzed by ruthenium and rhodium complexes with water-soluble phosphane ligands have been studied extensively by Joo and Katho.[26–32] Recently, a theoretical investigation with the density functional theory was reported.[25] Although these studies increased their mechanistic understanding, the pH-dependent catalysts with dhbp and dhpt ligands in our system are distinct from water-soluble phosphane complexes.

Deprotonated dhpt complexes [Cp*Ir($L^2$)Cl]K (**9**) and [($C_6Me_6$)Ru($L^2$)Cl]K (**10**) were isolated from an alkaline ethanol solution by the addition of ethyl ether (Scheme 6). Similar to the dhbp complex **7**, significant shifts of the deprotonated forms **9** and **10** were observed in the $^1H$ and $^{13}C$ NMR spectra in [$D_6$]dmso relative to those of the protonated forms **5** and **6**, respectively.[63] The $^1H$ NMR spectrum of **9** in $D_2O$ was nearly identical to that of **5** in KOD/$D_2O$ (i.e., the deprotonated form of **5**).



Scheme 6. Preparation of deprotonated complexes **9** and **10**.

The properties of the hydrido complexes [($C_nR_n$)-MH(ppy)]$^+$ [M = Rh, Ir ($n$ = 5), M = Ru ($n$ = 6)] are dependent on the central metal (M). Hydrido(iridium) complexes with bipyridine and phenanthroline were prepared by a reaction with $NaBH_3CN$ or a formate and were isolated.[92,118,119] The hydrido(iridium) complexes appear to be relatively stable.[55,117] Hydrido complexes [Cp*IrH-($L^1$)]$^-$ (**11**) and [Cp*IrH($L^2$)]$^-$ (**12**) were quantitatively generated under $H_2$ pressure. In comparison with the hydrido complexes with unsubstituted and methoxy-substituted bipyridine, significant upfield shifts of the aromatic protons in **11** and **12** were observed due to the oxyanion (Table 10). Hydrido(ruthenium) complex [($C_6Me_6$)RuH(bpy)]$^+$ was isolated by Ogo.[91] Under $H_2$ pressure, hydrido complexes [($C_6Me_6$)RuH($L^1$)]$^-$ (**13**) and [($C_6Me_6$)RuH($L^2$)]$^-$ (**14**) were generated as a mixture of the corresponding deprotonated forms, whose ratios depended on the $H_2$ pressure. However, the hydrido(rhodium) complex has never been isolated. Indeed, the corresponding hydrido complexes from **1** and **4** were not detected spectroscopically.

The reaction of the hydrido(iridium) complexes with $KHCO_3$ in aqueous solution led to the production of formate in an atmosphere of $H_2$. However, no formate was generated in the reaction with $K_2CO_3$. In the hydrogenation catalyzed by **2**, there was no induction period in the solution saturated by $CO_2$ prior to the reaction (Figure 10).[81] Conversely, an induction period was observed in the solution saturated by $H_2$ prior to the reaction. This indicates that the overall rate of the generation of hydrido complexes from **2** and the subsequent reaction with hydrogen carbonate was extremely rapid, when compared with the rate of hydration of $CO_2$ in aqueous KOH solution.

Scheme 7 shows the proposed pathway for the generation of hydrido complexes, which is marked by the acid–base equilibrium of dhbp and dhpt. The protonated form (**PX**: X = Cl) as the catalyst precursor was transformed into the deprotonated form (**DX**) in an alkaline solution. The reaction of **DX** with $H_2$ yielded the deprotonated hydrido complex (**DH**), which probably is the actual catalyst. The strong electron-donating ability of oxyanion on **DH** will play a significant role in the activation of the hydrido complexes. The generation of **DH** is strongly dependent on the central metal (M): under $H_2$ pressure, the iridium hydrido complexes are formed quantitatively, but the ruthenium complexes attain equilibrium between **DH** and **DX**. It is likely that the hydride-formation step is one of the factors that affect the catalyst activity of the hydrogenation of hydrogen carbonate. This hypothesis is consistent with the mechanistic investigation of Ogo: the rate-determining step for the hydrogenation of $CO_2$ in an acidic solution by using the methoxy ruthenium analog [($C_6Me_6$)Ru($Me_2L^1$)($H_2O$)]$^{2+}$ is the formation of a hydrido complex, whereas it is the reaction of the hydrido complex with $CO_2$ in the methoxy iridium analog [Cp*Ir($Me_2L^1$)($H_2O$)]$^{2+}$.[82]

The actual substrate could be established as hydrogen carbonate under basic conditions and as $CO_2$ under acidic conditions (Scheme 8).[33] It is known that $CO_2$ readily gets inserted into the metal–hydrogen bond to give a formato complex in nonaqueous media.[66,120–123] Similarly, the formato complex is believed to be generated by the insertion of $CO_2$ into the metal–hydrogen bond in an acidic aqueous solution and a water/amine mixture.[22,82] Indeed, the for-

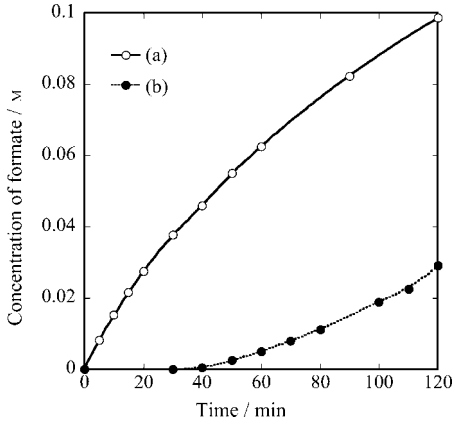

Figure 10. Time course of formate concentration during the hydrogenation of hydrogen carbonate catalyzed by **2** (20 μM) at 1 MPa ($CO_2/H_2$ = 1:1) and 80 °C after the reaction solution was saturated by (a) $CO_2$ and (b) $H_2$.[81]

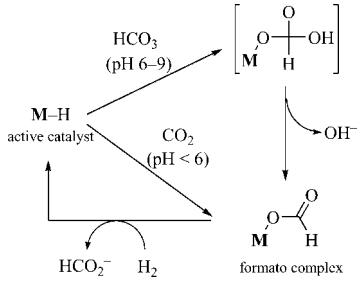
mato(ruthenium) complex was isolated in aqueous formate solution.[87] In contrast, the key intermediate has not been observed experimentally in the basic aqueous solution. However, it is assumed that the hydrogen carbonate is inserted into the metal–hydrogen bond, after which a formato intermediate is generated with the accompanying release of a hydroxide ion.[29,31]



Scheme 8. Suggested pathway for the hydrogenation steps of $HCO_3^-/CO_2$ in water.

During the course of the reaction, the acidification due to formate generation might cause the deprotonated form (**D**) to transform into the monoprotonated (**N**) or fully protonated form (**P**). Hence, this results in less catalytic activity and prevention of the decomposition of the formate as a reverse reaction. In particular, iridium–dhpt complexes,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

whose solubility is negligible under weak acidic formate conditions, can be recovered almost quantitatively at the end of the reaction. Further studies are required to clarify the interesting catalytic system for the conversion of $CO_2$ in detail.

## Summary and Outlook

The $CO_2$ conversion system that uses the half-sandwich complexes with dhbp and dhpt has significant features (high efficiency, catalyst recycling by self-precipitation, easy isolation of product, waste-free process, aqueous reaction, and prevention of reverse reaction); further, the system overcomes almost all of the problems occurring in the homogeneously catalyzed hydrogenation of $CO_2$ into formate. It should be noted that over a 1000-fold increase in catalytic activity was achieved as a result of the strong electron-donating ability of the oxyanion on the catalyst ligand. In addition, the three components (i.e., catalyst, product, and solvent) could be easily separated by conventional filtration and evaporation without waste generation. Our next goal will be the conversion of $CO_2$ into products other than formate (e.g., methanol or oxalic acid) by the homogeneously catalyzed hydrogenation of $CO_2$.

More importantly, the tuning of the catalyst through the acid–base equilibrium of dhbp or dhpt as a catalyst ligand offers a novel tool for the simultaneous control of the activity and water solubility of complex catalysts. It was shown that the properties of iridium complexes were strongly dependent on the pH of the aqueous solution. These significant features are attributed to the electronic effect and polarity of the oxyanion generated from the phenol hydroxy group. Consequently, the system combines the advantages of homogeneous catalysis (i.e., high catalytic performance) with those of heterogeneous catalysis (i.e., simplicity of catalyst separation) and biocatalysis (aqueous reaction and pH dependence). The control of catalyst properties through the acid–base equilibrium between pyridinol and pyridinolato as a ligand has not been explored previously in catalyst systems. For these features to appear, only the introduction of a hydroxy group into the pyridine and subsequent pH control are required. This catalyst design concept is expected to have significantly broader implications for the design of new homogeneous catalysts (e.g., strong electronic effect and water-soluble ligand). The idea of catalyst tuning will become increasingly important and will be an extremely challenging field of study.

**Abbreviations**: dhbp, 4,4′-dihydroxy-2,2′-bipyridine; dhpt, 4,7-dihydroxy-1,10-phenanthroline; edta-H, protonated ethylenediaminetetraacetic acid; pta, 1,3,5-triaza-7-phosphaadamantane; TON, turnover number (mole product per mol catalyst); TOF, turnover frequency (TON per hour); tppms, sodium 3-(diphenylphosphanyl)benzenesulfonate; tppts, triphenylphosphane-3,3′,3′′-trisulfonic acid trisodium salt.

## Acknowledgments

The author thanks Dr Nobuko Onozawa–Komatsuzaki, Dr Hideki Sugihara, and Dr Kazuyuki Kasuga at AIST for their many helpful suggestions and discussions related to this work.

# $\eta^1$-Vinylidene Formation from Internal Alkynones by C–C Bond Migration

Michael J. Shaw,*[a] Steven W. Bryant,[a] and Nigam Rath[b]

**Keywords:** Ruthenium / Alkynes / Isomerization / Vinylidene bond activation / Unsaturated complexes

The $[\mu^2\text{-}N_2\{CpRu(PPh_3)_2\}_2]^{2+}$ ($\mathbf{1}^{2+}$) dication is a source of the formal 16-electron $[CpRu(PPh_3)_2]^+$ fragment, and it reacts with internal alkynes such as 1,3-diphenylpropynone, 4-phenyl-3-butyn-2-one, and 3-cyclopropyl-1-phenylpropynone to yield $\eta^1$-vinylidene complexes $\mathbf{2a}^+$–$\mathbf{2c}^+$ by C–C bond activation. In the case of 1,3-diphenylpropynone, the $\eta^1$-ketone complex $[CpRu(PPh_3)_2\{PhC(\eta^1\text{-}O)C{\equiv}CPh\}]^+$ ($\mathbf{3a}^+$) was isolated as its $PF_6^-$ salt, and it is apparently an intermediate in the formation of the vinylidene complex. Complexes $\mathbf{2a}^+$–$\mathbf{2c}^+$ were characterized as their $BAr^F{}_4^-$ [ArF = 3,5-bis(trifluoromethyl)phenyl] salts by NMR and IR spectroscopic methods, ESI-MS, and EA. The single crystal X-ray diffraction structure of $\mathbf{2a}BAr^F{}_4$ is presented. These reactions represent the first examples where an internal alkyne undergoes C–C bond migration to form an $\eta^1$-vinylidene complex.

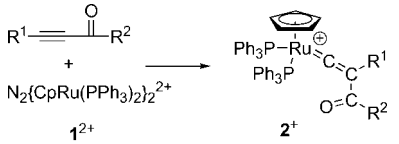
## Introduction

Terminal vinylidene complexes have an established role in the catalytic and stoichiometric transformation of alkynes into elaborated structures.[1] The isomerization of alkyne ligands to vinylidenes has been examined in detail by experimental[2] and theoretical techniques[3] and this reaction continues to generate interest.[4] A net 1,2-H atom shift is common,[5] but the migration of other functional groups is limited to $-SiMe_3$, –SR, and –I,[1,6] which means that further reactions are necessary to produce disubstituted vinylidenes. In only one case has C–C bond activation been observed in an alkyne-to-vinylidene conversion,[7] although C–C bond migration in vinylidene-to-alkyne isomerization has been reported.[8] This communication details the formation of terminal vinylidene complexes through C–C bond activation of acetylenic ketones by electrophilic cations derived from $[CpRu(PPh_3)_2Cl]$, a well-known starting material for the formation of vinylidene ligands from terminal alkynes.[9]

## Results and Discussion

Halide abstraction of $Cl^-$ by silver salts from $[CpRu(L)_2Cl]$ (L = phosphane) results in the formation of unsaturated cationic complexes that absorb $N_2$ even from high-purity argon.[10a] Thus, a solution that behaves as "$[CpRu(PPh_3)_2]PF_6$" can be prepared in situ from $[CpRu(PPh_3)_2Cl]$ and $AgPF_6$ in $CH_2Cl_2$, but the actual metal species has proved difficult to isolate and characterize, a circumstance previously described for several related unsaturated metal complexes.[10] A tractable material that serves as a synthon for the "$[CpRu(PPh_3)_2]^+$" unit is $[\mu^2\text{-}N_2\{CpRu(PPh_3)_2\}_2](BAr^F{}_4)_2$ [$\mathbf{1}(BAr^F{}_4)_2$, $Ar^F$ = 3,5-bis(trifluoromethyl)phenyl]. The addition of 1,3-diphenylpropynone, 4-phenyl-3-butyn-2-one, or 3-cyclopropyl-1-phenylpropynone to $CH_2Cl_2$ or $CDCl_3$ solutions of $\mathbf{1}(BAr^F{}_4)_2$ immediately and cleanly yield the $\eta^1$-vinylidene complexes $\mathbf{2a}BAr^F{}_4$–$\mathbf{2c}BAr^F{}_4$, respectively (Scheme 1).



**2a**$^+$: $R^1$ = Ph; $R^2$ = Ph
**2b**$^+$: $R^1$ = Ph; $R^2$ = Me
**2c**$^+$: $R^1$ = cyclopropyl; $R^2$ = Ph

Scheme 1. Formation of vinylidene complexes from acetylenic ketones.

The single-crystal X-ray diffraction study (Figure 1)[11] of $\mathbf{2a}BAr^F{}_4$ reveals the vinylidene cation $\mathbf{2a}^+$ and clearly shows that an unexpected C–C bond migration has taken place. This rearrangement represents an unprecedented rearrangement for an internal alkyne in a monometallic compound.

The structure of $\mathbf{2a}^+$ is comparable to similar structures of $[CpRu(L)_2(vinylidene)]^+$ cations (L = phosphane) with a Ru=C bond length of 1.818(4) Å, a C=C bond length of 1.335(5) Å, and P–Ru–C bond angles of 94.65(11)° and 98.30(3)°.[12] This structure clearly establishes that C–C bond migration occurs, which transforms 1,3-diphenylpro-

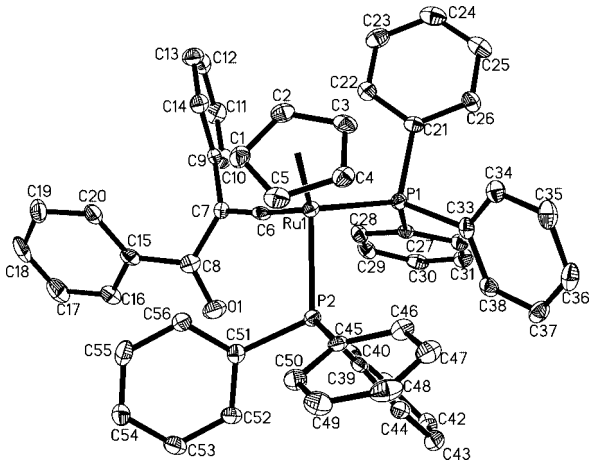

Figure 1. Projection view of complex $\mathbf{2a}^+$ with 50% thermal ellipsoids. The counterion and H atoms are omitted for clarity.

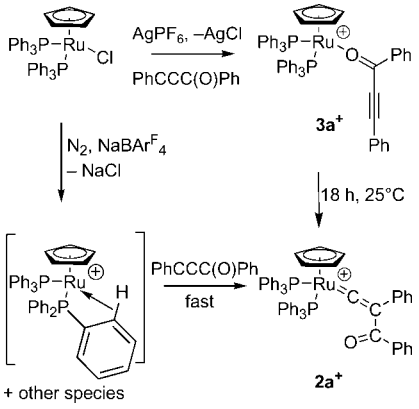
pynone into the 2-phenyl-2-benzoylvinylidene ligand. Cation $\mathbf{2a}^+$ is close in size to the $BAr^F{}_4^-$ anion (Supporting Information, Figure S1), a factor that often aids in the crystallization process. The solubility of the $BAr^F{}_4^-$ salts in $CDCl_3$ and $Et_2O$ is higher than the corresponding $PF_6^-$ salts, which tend to form oily masses rather than X-ray quality crystals.

Complexes $\mathbf{2a}^+$–$\mathbf{2c}^+$ were spectroscopically characterized by $^1H$, $^{13}C$, $^{31}P$, and $^{19}F$ NMR spectroscopy, IR spectroscopy, and ESI-MS as their $BAr^F{}_4^-$ salts. For example, the NMR spectra of $\mathbf{2a}BAr^F{}_4$ show the expected features such as a single resonance due to the $C_5H_5$ group in the $^1H$ and $^{13}C$ NMR spectra, and a single resonance due to the two equivalent phosphane ligands and the $BAr^F{}_4^-$ anion, respectively, in the $^{31}P$ and $^{19}F$ NMR spectra. Of note is the resonance at $\delta$ = 349.53 ppm in the $^{13}C$ NMR spectrum, which is due to the vinylidene carbon atom attached directly to the Ru atom.[13] Similarly, terminal vinylidenes $\mathbf{2b}BAr^F{}_4$ and $\mathbf{2c}BAr^F{}_4$ show diagnostic peaks in the $^{13}C$ NMR spectra at 351.91 and 353.29 ppm, respectively (see Supporting Information). For $\mathbf{2a}BAr^F{}_4$, a feature in the IR spectrum at 1658 $cm^{-1}$ is attributed to the vinylidene stretching vibration,[12b] but this vibration also appears to couple with the ketone stretching frequency that should occur in a similar position. The ESI-MS spectrum of $\mathbf{2a}BAr^F{}_4$ reveals the $P^+$ peak at 897 *m*/*z* with the expected pattern of Ru-isotope peaks.

The nature of the "$[CpRu(PPh_3)_2]^+$" cation in these reactions is an important factor. Solid samples of $\mathbf{1}(BAr^F{}_4)_2$ can be prepared by treating $[CpRu(PPh_3)_2Cl]$ with $NaBAr^F{}_4$ in $CH_2Cl_2$ under an argon atmosphere, followed by filtration of the mixture to remove NaCl and recrystallization (see Supporting Information). The Raman spectra of solid samples of $\mathbf{1}(BAr^F{}_4)_2$ show a peak at 2062 $cm^{-1}$, which is due to the bridging $N_2$ ligand.[10a,14] Exposure of this material in solution to nitrogen gas results in a band at 2192 $cm^{-1}$ in the KBr-pellet IR spectrum of the resulting solid as a result of the formation of a terminal $N_2$ ligand.[10a,14] However, exposure to excess $N_2$ appears to have no effect on the reactions of isolated $\mathbf{1}(BAr^F{}_4)_2$ with alkynones. Additionally, a $CH_2Cl_2$ signal ($\delta$ =5.32 ppm) is observed in the $^1H$ NMR spectrum of samples of $\mathbf{1}(BAr^F{}_4)_2$, so this solid is formulated as $\mathbf{1}(BAr^F{}_4)_2{\cdot}CH_2Cl_2$, which is consistent with the microanalytical data. As yet, X-ray quality crystals of this material are not available.

In $CDCl_3$ solution, $\mathbf{1}(BAr^F{}_4)_2$ appears to change into two species. As expected, there is no evidence of interaction between the noncoordinating $BAr^F{}_4^-$ anion and cation $\mathbf{1}^{2+}$ in the $^{19}F$ NMR spectrum. The $^1H$ NMR spectra of $\mathbf{1}(BAr^F{}_4)_2$ in $CDCl_3$ reveal two broad resonances at 4.53 and 5.16 ppm attributable to $C_5H_5$ protons, which indicates that the bulk of the ruthenium complex exists in two forms. There are also broad $^1H$ NMR signals at 7.01 and 10.11 ppm assigned to the *ortho* hydrogen atoms of the $PPh_3$ ligands. The $^1H$ NMR signal at 10.11 ppm disappears upon addition of alkynone with a corresponding increase in the usual Ph region of the spectrum. We suggest that the 10.11 ppm signal indicates that some of the ruthenium complex converts to a monometallic species agostically stabilized in solution by *ortho* C–H interactions as depicted in Scheme 2. Crystallographically characterized examples of related complexes with and without agostic interactions are known.[15] It is unlikely that this second cation exists as a true 16-electron species, as such compounds are known to have intense blue color.[14]



Scheme 2. The reaction of 1,3-diphenylpropynone with $\mathbf{1}BAr^F{}_4$ and in-situ-generated $\mathbf{1}PF_6$.

The reaction conditions play a considerable role in this alkyne-to-vinylidene conversion. Solutions of $\mathbf{1}(BAr^F{}_4)_2$ under an atmosphere of argon react immediately with 1,3-diphenylpropynone to form $\mathbf{2a}BAr^F{}_4$. Solutions of "$CpRu(PPh_3)_2PF_6$" generated in situ under an atmosphere of $N_2$ react over several hours to yield a mixture of products, in which $\mathbf{2a}PF_6$ can be observed spectroscopically by IR and $^1H$ NMR spectroscopy. Under these conditions an additional isomer of $\mathbf{2a}PF_6$ can be isolated (Scheme 2). The $\eta^1$-ketone complex $\mathbf{3a}PF_6$ can be isolated as a red-brown powder by fractional crystallization at –30 °C. Compound $\mathbf{3a}PF_6$ was characterized by NMR and IR spectroscopic methods and ESI-MS. These data establish that cation $\mathbf{3a}^+$ is an isomer of $\mathbf{2a}^+$. The definitive evidence for the $\eta^1$-ketone structure of $\mathbf{3a}PF_6$ comes from its IR spectrum

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

where an alkyne band at 2202 $cm^{-1}$ is almost unchanged from that of 1,3-diphenylpropynone (2207 $cm^{-1}$), whereas the ketone band moves to 1524 $cm^{-1}$, a shift of 116 $cm^{-1}$ lower than that of the free ligand.[16] The $^{13}C$ NMR spectra support this assignment with alkyne C atoms observable in their usual range, and the carbonyl C atom resonates at almost the same chemical shift as in the free ligand.[16]

It thus appears that the presence of ligands that coordinate more strongly than $BAr^F_4^-$ (such as $PF_6^-$) is a factor that can slow the formation of the vinylidene cation. $CH_2Cl_2$ solutions of "$[CpRu(PPh_3)_2]PF_6$" generated in situ by halide abstraction and then exposed to $N_2$ slowly develop IR bands at 2181 $cm^{-1}$, which are due to terminal $N_2$ ligands, as previously observed for similar Ru species.[14] The addition of 1,3-diphenylpropynone to such solutions (Scheme 2) immediately induces a change in the burgundy of **3a**$PF_6$. Over a period of hours, the color reverts to orange-brown. Progress monitored by FTIR spectroscopy indicates the immediate conversion of some "$[CpRu(PPh_3)_2]PF_6$" into **3a**$PF_6$, as evidenced by the appearance of a strong IR band at 1532 $cm^{-1}$. However, the alkyne band and the bound ketone band are very slowly consumed, whereas features due to vinylidene complex **2a**$PF_6$ increase in intensity (see Supporting Information). No features due to an η²-alkyne complex are observed in the region 1800–2000 $cm^{-1}$. From these results is it clear that the ketone complex **3a**$PF_6$ slowly isomerizes in $CH_2Cl_2$ to form the vinylidene complex **2a**$PF_6$.

An η²-alkyne intermediate cannot be ruled out at present. The conversion of η¹-ketone to η²-alkyne complexes was previously observed and is facile.[17] Calculations on $[Cp(PMe_3)_2(\eta^2\text{-}HC{\equiv}CR)]^+$ (R = H, $CH_3$) complexes show that initial slippage of the Ru atom from the alkyne triple bond to the terminal C–H bond is a necessary step in the isomerization process.[4d] It is likely that activation of the C(O)R group occurs in these reactions by a similar interaction of the Ru atom with the C–C bond that links the alkyne to the C=O unit. Ph group migration is unlikely because the addition of diphenylacetylene to **1**$BAr^F_4$ yields no vinylidene (monitored by NMR spectroscopy) and at least one related η²-PhC≡CPh complex was crystallographically characterized.[18] In the formation of the cyclopropyl complex **2c**$BAr^F_4$, no sign of ring-opening occurs during isomerization. If the cyclopropyl ring migrates, then migration must occur without a significant amount of positive charge or unpaired electron density build up on the migrating group, as these factors would encourage ring opening. Detailed calculations on this reaction pathway are currently underway.

## Conclusions

This report describes the reaction of an internal alkyne with a commonly encountered $d^6$-Ru complex cation that results in C–C bond migration to form a vinylidene complex. This migration represents a new path to disubstituted terminal vinylidene complexes, which are currently of intense theoretical and applied interest, and it may represent a general method for the activation of internal alkynes found in acetylenic ketones. Further theoretical and experimental studies are underway to establish a pathway for the activation of the acetylenic ketone ligand.

## Experimental Section

All manipulations were carried out under an atmosphere of prepurified nitrogen or argon. All solvents were distilled from appropriate drying agents (e.g. $CaH_2$ or K) and freeze–pump–thaw degassed before use.

**Preparation of 2a$BAr^F_4$:** Under an atmosphere of dry argon, $[CpRu(PPh_3)_2Cl]$ (1.40 g, 1.93 mmol) was mixed with $AgPF_6$ (0.487 g, 1.78 mmol) in $CH_2Cl_2$ (50 mL). The solution was stirred for 30 min and then 1,3-diphenylpropynone (0.45 g, 2.18 mmol) was added. The mixture was stirred in the dark for 5 d whereupon it was filtered, concentrated, and cooled to –30 °C. After 2 d, white crystals of AgCl had formed, and the solution was transferred to another vessel, further concentrated, and cooled again to –30 °C. This procedure was repeated until no more white precipitate formed, and then a crude solid (1.30 g) was precipitated from the solution by the addition of $Et_2O$ (50 mL). Half of the crude solid (0.62 g) was dissolved in $CH_2Cl_2$ (2.0 mL) to which $NaBAr^F_4$ (0.61 g, 0.69 mmol) was added. The solution was stirred for 30 min, filtered, and $Et_2O$ (10 mL) was added. The solution was concentrated under reduced pressure and cooled to –30 °C overnight whereupon **2a**$BAr^F_4$ precipitated from the solution as bright-orange crystals that were suitable for x-ray diffraction studies. Further concentration of the mother liquor resulted in four more crops of **2a**$BAr^F_4$ {0.521 g total, estimate 15% yield based on original $[CpRu(PPh_3)_2Cl]$}. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 5.12 (s, $C_5H_5$), 6.80–7.78 (m, aromatic) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$, 25 °C): $\delta$ = 349.53 (s, Ru=*C*=C), 188.57 (s, *C*=O), 95.29 (s, $C_5H_5$), 82.00 (s, Ru=C=*C*) ppm. $^{31}P$ NMR (121.46 MHz, $CDCl_3$, 25 °C): $\delta$ = 40.48 (s) ppm. IR (KBr): $\tilde{\nu}$ = 1657, 1557, 1439, 1360, 1281, 1128 $cm^{-1}$. ESI-MS: *m*/*z* = 987 $[P - BAr^F_4^-]^+$. $[C_{88}H_{57}BF_{24}OP_2Ru]$ (1760.21): calcd. C 60.05, H 3.26; found C 60.07, H 3.28.

**Preparation of 3a$PF_6$:** $[CpRuCl(PPh_3)_2]$ (0.38 g, 0.50 mmol), $CH_2Cl_2$ (20 mL), and $AgPF_6$ (0.13 g, 0.50 mmol) were placed in a 100-mL Schlenk tube. The mixture was stirred under inert conditions, and a voluminous white precipitate formed. The mixture was stirred for 30 min and 1,3-diphenylpropynone (0.11 g, 0.50 mmol) was then added. The mixture was stirred overnight in the dark and then filtered through a 1-cm layer of Celite supported on a medium porous glass frit. Toluene (2 mL) was then added to induce crystallization, and the mixture was concentrated under reduced pressure. The solution was cooled overnight to –30 °C, and a small amount of solid was isolated. Three small crops of solid were obtained first, all between ca. 2 and 5 mg, which corresponded to impure AgCl and **1**$PF_6$. After these crops were obtained, the solution began to form a separate layer of oil. The oil was concentrated under reduced pressure and $Et_2O$ was added (10 mL), and the solution was stirred overnight. The resulting powder of **3**$PF_6$ (0.22 g, 42%) was isolated by filtration, rinsed with $Et_2O$, and dried under vacuum. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 6.9–7.6 (40 H, Ph), 5.22 (5 H, $C_5H_5$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 189.0 (*C*=O), 98 ($C_5H_5$) ppm. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2207 [ν(C≡C)], 1524 [ν(C=O)] $cm^{-1}$. FAB-MS: *m*/*z* = 897.1 $[P]^+$, 690.9 $[P - dpp]^+$, 634.8 $[P - PPh_3]^+$. $C_{56}H_{45}OF_6P_3Ru$ (1041.95): C 64.55, H 4.35; found C 64.44, H 4.27.

**IR Spectroscopic Monitoring of the Reaction of $[CpRu(PPh_3)_2]PF_6$ with 1,3-Diphenylpropynone:** Under an atmosphere of dry argon, $[CpRu(PPh_3)_2Cl]$ (0.40 g, 0.96 mmol) was mixed with $AgPF_6$ (0.24 g, 0.96 mmol) in $CH_2Cl_2$ (50 mL). The solution was stirred for 30 min, and a portion (7.0 mL) of the mixture was then transferred by syringe into a cell equipped with a fiber optic FTIR probe. Two spectra were recorded that showed a flat baseline and a peak at 2181 $cm^{-1}$ [ν(N≡N)] and then 1,3-diphenylpropynone (0.14 g, 0.67 mmol) was added. Thirty spectra were recorded over 20 min: the spectra contained peaks at 2197 and 1532 $cm^{-1}$ that decreased in intensity and at 1658, 1596, 1580, and 1558 $cm^{-1}$ that increased in intensity; a strong peak at 1641 $cm^{-1}$ decreased slightly in intensity; and an isosbestic point at 1528 $cm^{-1}$. These spectra are plotted in Figure S2 (Supporting Information). A KBr-pellet IR spectrum of **2**$BAr^F{}_4$ is plotted in Figure S3.

**Supporting Information** (see footnote on the first page of this article): Experimental procedures and characterization data for the three vinylidene cations **2**$BAr^F{}_4$, crystal structure of **2**$BAr^F{}_4$, and IR spectra.

# Surfactant-Assisted Synthesis and Characterization of Novel Chain-Like CoNi Alloy Assemblies

**Lu-Ping Zhu,[a,b] Hong-Mei Xiao,[a,b] and Shao-Yun Fu*[a]**

**Keywords:** Alloy / Assemblies / Hydrothermal method / Ferromagnetism / Coercivity

Novel chain-like CoNi alloy assemblies with a length of up to 6–7 μm were successfully prepared by a surfactant-assisted hydrothermal synthetic route at 100 °C for 2 h. The individual submicrospheres built from smaller CoNi nanoparticles had a diameter of about 400–500 nm. These microspheres were then integrated to form the novel chain-like CoNi alloy assemblies. The effects of synthetic parameters such as surfactant and solvent on the formation and morphology of CoNi samples were investigated. The experimental results showed that $N_2H_4{\cdot}H_2O$ and $CTA^+$ play important roles in the formation of the novel chain-like CoNi alloy assemblies. Based on the structural information provided by X-ray powder diffraction, scanning electron microscopy, transmission electron microscopy, selected-area electron diffraction and energy-dispersive X-ray analysis, a growth mechanism was tentatively proposed for the formation of chain-like CoNi alloy assemblies. Magnetic hysteresis measurement revealed that the chain-like CoNi alloy assemblies display ferromagnetic behavior with a saturation magnetization of 96.15 emu/g and a coercivity of 144.75 Oe at room temperature.

## Introduction

Transition metal nanoparticles, especially those of Fe, Co and Ni, are considered to be very important for technological applications, such as electronic, optical and mechanic devices, magnetism, catalysis, superconductors and ferrofluids etc.[1–5] It is claimed by Ung et al.[6] that, as far as magnetic storage is concerned, very high storage density requires high magnetic anisotropy to overcome thermal effects and to prevent superparamagnetic behavior. Several kinds of magnetic anisotropy can be considered to meet this requirement, including (a) shape anisotropy of elongated magnetic particles, such as rods and wires;[7] (b) magnetocrystalline anisotropy (for example: CoPt, FePt, CuNi, $FeNi_3$, etc.);[8–12] and (c) exchange anisotropy of ferromagnetic/antiferromagnetic core-shell particles.[13]

As important transition metal alloys, CoNi alloys have been widely used for decoration, corrosion resistance and magnetic recording devices, etc.[14–17] Therefore, much effort has been made in preparation of CoNi alloys. Micro- and nanosized CoNi alloy particles were prepared by electrochemical reduction,[18–20] thermal decomposition of organometallic precursors,[21] sol-gel routes,[22] polyols of metal salts[23] and leaching technology.[24] Nanosized amorphous CoNi alloy powders were also obtained by sonochemical decomposition methods.[25] Using the cationic water-in-oil (W/O) microemulsion of water/butanol/cetyltrimethyl bromide (CTAB)/*n*-octane, Zheng and co-workers synthesized CoNi needle-like alloys of different compositions with aspect ratios of 10–20.[26] Zhang and co-workers fabricated CoNi nanowires within nanochannel alumina (NCA) templates.[27] The magnetic behavior of the nanowires showed strong temperature dependence. Furthermore, Ung et al. synthesized CoNi nanowires by heterogeneous nucleation in liquid polyol.[6] In our previous work, we reported the synthesis of submicro-sized spherical ferromagnetic CoNi alloy particles by a polyol process assisted by solvothermal treatment.[28] However, chain-like CoNi alloy assemblies have received much less attention, although they are (i) members of the family of one-dimensional structural materials, which are likely to play a critical role in the improvement of the efficiencies of various devices based on single particles or their composites and (ii) are of considerable interest in fundamental research since they provide a direct bridge between nanometer-scale objects and the macroscale world.[29]

Herein, we report the preparation of high-density chain-like CoNi assemblies by a surfactant-assisted hydrothermal method and characterize the size, structure and composition of the resultant particles by transmission electron microscopy, selected-area electron diffraction, scanning electron microscopy, energy-dispersive X-ray analysis and X-ray powder diffraction.

## Results and Discussion

The phase and purity of the as-prepared product formed at 100 °C for 2 h was determined by X-ray diffraction (XRD), as shown in Figure 1 for $2\theta$ angle values of 20–80°. The feature peaks of the as-prepared arise at $2\theta$ = 44.44, 51.72 and 76.32°, which match the (111), (200) and (220) characteristics of a face-centered cubic (fcc) structure, respectively. No characteristic peaks due to the impurities of $NiCl_2$, $CoCl_2$ or NaCl were detected, indicating that the as-obtained product was pure. In addition, there were no observable peaks in the XRD spectra corresponding to those of pure cobalt and nickel. If the homogeneous solid solution of CoNi were not formed, XRD peaks of pure Co or Ni should be observed simultaneously in the spectrum. These facts confirm that Co and Ni formed an alloy, rather than separate grains.

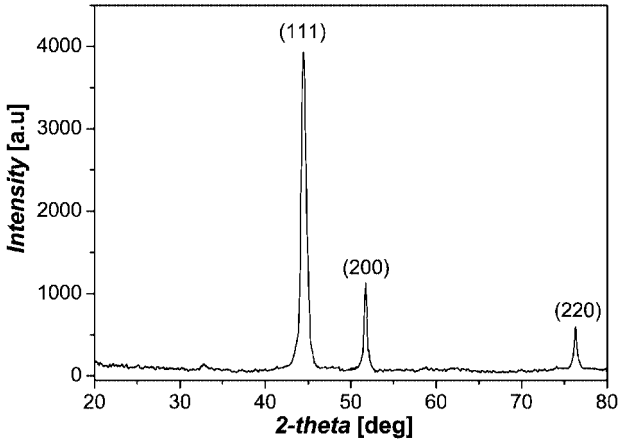

Figure 1. XRD pattern of the as-prepared sample obtained at 100 °C for 2 h.

Figure 2(a)–(c) shows SEM images of the as-synthesized product formed at 100 °C for 2 h. Figure 2(a) is the overall morphology of the sample, which indicates that the obtained product consists of large-scale chain-like assemblies. The magnified SEM image as shown in Figure 2(b) clearly displays that all of the CoNi chains are in the size range of 400–500 nm and in close contact with each other, forming branched, necklace-like chains with lengths of 6–7 μm. A close observation, as shown in Figure 2(c), reveals that the surface of the individual CoNi alloy submicroparticle is quite rough, and it presents a fine hierarchical nanostructure. On the basis of the above results, we conclude that the rough surfaces of these submicrospheres in the chain-like CoNi alloy assemblies are formed by attachment of nanoparticles, which may be related to the natural property and the presence of a surfactant. The morphology of the as-synthesized product was further determined by TEM as shown in Figure 2(d), which is consistent with that observed by SEM. The corresponding electron-diffraction pattern, displaying considerably sharp ring-like features of the selected area of the sample [Figure 2(e)], indicates that the as-obtained product is polycrystalline. The as-prepared alloy compositions were determined by EDX analysis under $N_2$. Figure 2(f) shows EDX spectra taken from the as-prepared products. The only detectable elements by EDX are cobalt and nickel, and the corresponding elemental analysis reveals that the atomic ratio of Co/Ni in the alloys is up to 1.0 which is very close to the designed composition, and hence the reduction reaction should be rather complete.

To investigate the influence of the surfactant on the formation feature of chain-like CoNi alloy assemblies, a synthetic experiment without CTAB was carried out. No chain-like materials that appeared in the experiment with the surfactant were observed [Figure 3(a)]. In addition, in the presence of CTAC, a similar result [Figure 3(b)] was obtained as in the presence of CTAB. These suggested that $CTA^+$ is a prerequisite to form the chain-like CoNi alloy assemblies. Other synthetic parameters were also examined. It was found that by introducing glycol into the present

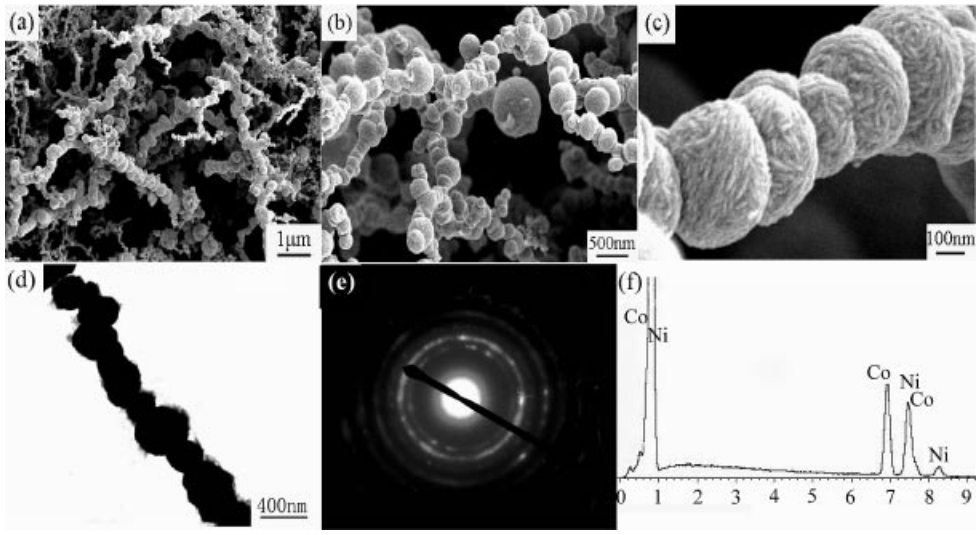

Figure 2. (a), (b), (c) SEM images at different magnifications of the as-prepared product. (d) TEM image, (e) the corresponding SAED pattern, (f) EDX spectrum of the as-prepared sample.

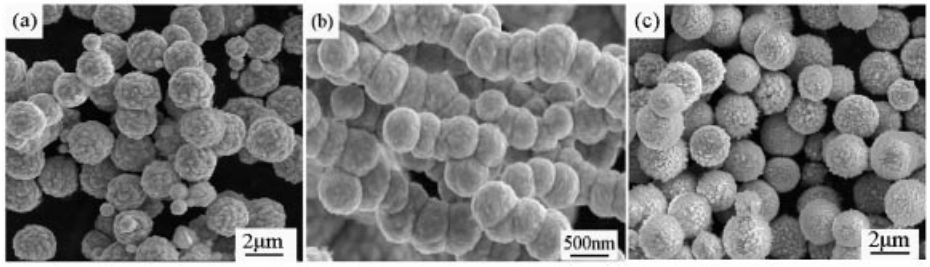

Figure 3. SEM images of the as-prepared product. (a) CoNi microspheres in the absence of surfactant. (b) CoNi submicrospheres in the presence of CTAC. (c) CoNi microspheres in the present system, with a water/polyol ratio of 1:2 (v/v).

system with a water/polyol ratio of 1:2 (v/v), CoNi microspheres rather than chain-like assemblies were obtained [Figure 3(c)]. Furthermore, the temperature rise did not show any additional effect on the morphology of the final products.

Regarding the mechanism for the growth of highly branched CoNi chain-like assemblies, we believe that both $N_2H_4{\cdot}H_2O$ and $CTA^+$ play important roles. In the experiment, hydrazine hydrate and sodium hydroxide were chosen as the reductant and buffer agent, respectively. The cobalt and nickel salts were reduced by hydrazine hydrate in concentrated basic media. The solution was blue before being reduced and afterwards became colorless. The reactions can be expressed as Equations (1) and (2).

$$2\ Ni^{2+} + N_2H_4 + 4\ OH^- \rightarrow 2\ Ni + N_2\uparrow + 4\ H_2O \quad (1)$$

$$2\ Co^{2+} + N_2H_4 + 4\ OH^- \rightarrow 2\ Co + N_2\uparrow + 4\ H_2O \quad (2)$$

Metallic cobalt and nickel give an intermetallic phase Equation (3).

$$Ni + Co \rightarrow CoNi \quad (3)$$

During the course of the reaction, the reduction of cobalt and nickel ions is effectively achieved by $N_2H_4$, which is a potent reducing agent in alkali solution.[12] A possible formation mechanism of chain-like CoNi alloy assemblies is proposed, as shown in Figure 4. Initially, cobalt(II) and nickel(II) ions react with hydroxy ions in the solution to form an intermediate phase consisting of cobalt and nickel hydroxide. Then, the redissolution of the intermediate solid phase takes place and the reduction of $Co^{II}$ and $Ni^{II}$ occurs according to Equations (1) and (2) and primary nuclei [Figure 4(a)] are formed in the presence of CTAB [see Equation (3)]. With the increase of the reaction time, presumably, the small CoNi primary nuclei diffuse and aggregate to form larger CoNi submicrospheres with a hierarchical nanostructure [Figure 4(b)] due to the magnetic dipole–dipole interaction[30] and effects of the $CTA^+$ templates. The larger CoNi submicrospheres are then assembled into chain-like assembles with multiple branches [Figure 4(e)] because of the stronger anisotropic magnetic forces.[31] This process is possible only when the magnetization of the particle does not fluctuate during the time of magnetic interaction in the suspension.[30] On the basis of the proposed mechanism for the growth of 1D nanostructure under the confinement of a capping reagent,[32,33] the surfactants CTAB or CTAC were necessary in the present procedure for the synthesis of chain-like CoNi alloy assemblies. It is assumed that the surfactants CTAB or CTAC play roles in at least two aspects. CTAB or CTAC are cationic surfactants, which can form $CTA^+$ in the solution. On the one hand, the surfactant could act as a template, which forms a $CH_3–CH_2–CH_2–N$ chain-like structure;[34,35] on the other hand, it could form a shell surrounding the particles to prevent them from aggregating to larger particles during the reduction process of the intermediate solid phase. Though

cobalt and nickel are easily oxidized, some possible oxides such as CoO, $Co_2O_3$ or NiO were not observed from the phase analysis by XRD. This might be due to the fact that the reaction was carried out at appropriate pH, temperature and hydrazine concentration and created under inert $N_2$ which does not favor cobalt and nickel oxidation.

The magnetic hysteresis measurement of the CoNi alloy was carried out at room temperature in an applied magnetic field sweeping from –10 to 10 kOe. Figure 5 shows magnetic hysteresis curves of the as-synthesized samples carried out at room temperature. The hysteresis loop of CoNi alloy samples reveals a ferromagnetic behaviour with a saturation magnetization ($M_s$) of 96.15 emu/g and a coercivity ($H_c$) of 144.75 Oe. Compared with the spherical CoNi alloy powders with a similar size of 200–500 nm in diameter in our previous work,[28] the coercivity increased from 108.23 to 144.75 Oe; on the other hand, the saturation magnetization decreased from 123.21 to 96.15 emu/g. It is well known that the size, structure and shapes of magnetic particles have effects on the magnetic properties of the products. The shape of the $M/H$ curve, or the shape of the hysteresis loop, may be strongly affected not only by the specific particle surface area but also by the magnetic anisotropy.[36] The magnetic anisotropy includes magnetocrystalline anisotropy, shape anisotropy, stress anisotropy, induced anisotropy and exchange anisotropy.[36] Cullity has given an expression for the magnetostatic energy $E_{ms}$ of the magnetic materials in the shape of a prolate spheroid with semimajor axis $c$ and semiminor axes of equal length a as in Equation (4),[36] where $M$ is the level of magnetization of an applied field, $\theta$ is the angle of the applied field to $c$, $N_a$ and $N_c$ are demagnetizing coefficients along $a$ and $c$, respectively.

$$E_{ms} = 1/2M^2N_c + 1/2(N_a - N_c)M^2\sin^2\theta \quad (4)$$

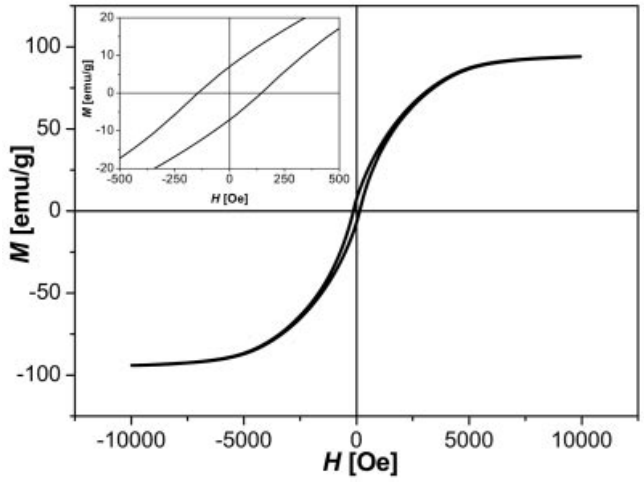

Figure 5. Hysteresis loop for the sample at room temperature.

The shape-anisotropy constant $K_s$ is given by Equation (5).

$$K_s = 1/2(N_a - N_c)M^2 \quad (5)$$

As Equation (5) shows, the strength of the shape anisotropy depends on the axial ratio $c/a$ of the specimen. Symmetrically shaped nanoparticles, such as spheres, do not have any net shape anisotropy. However, the synthesized representative chain-like CoNi alloy assemblies with an aspect ratio of about 15 on average would have shape anisotropy, which should increase the coercivity. So, the different coercivity may be attributed to the shape anisotropy of chain-like CoNi alloy assemblies, which prevent them from magnetizing in directions other than along their easy magnetic axes,[37] hence leading to the different saturation magnetization and coercivity.

## Conclusions

Novel chain-like CoNi alloy assemblies have been successfully prepared by the surfactant-assisted hydrothermal method. XRD, SEM, EDX, TEM, SAED, and VSM analyses have been employed for the characterization of the as-synthesized chain-like CoNi alloy assemblies. The results showed that $CTA^+$ plays an important role in the formation of chain-like CoNi alloy assemblies. The hysteresis loop of CoNi alloy samples revealed ferromagnetic behaviors with a saturation magnetization of 96.15 emu/g and a coercivity of 144.75 Oe at room temperature. A possible formation mechanism of the as-synthesized chain-like assemblies was proposed.

## Experimental Section

All reagents were of analytical grade from Beijing Chemical Reagent Ltd. and used without further purification. In a typical experiment, 0.50 g of $CoCl_2{\cdot}6H_2O$, 0.50 g of $NiCl_2{\cdot}6H_2O$, and 1 g of cetyltrimethylamonium bromide (CTAB) were dissolved in 30 mL of deionized water, and the mixture was strongly stirred for 5 min; then ultrasound sonication was applied for 30 min to ensure that all the reagents were dispersed homogeneously in the solution. Afterwards, a certain amount of a hydrazine hydrate ($N_2H_4{\cdot}H_2O$) solution in sodium hydroxide (NaOH) was added dropwise to the mixture whilst stirring. The obtained blue latex was then transferred into a 50 mL Teflon-lined stainless steel autoclave, sealed and maintained at 100 °C for 2 h after strongly stirring for 10 min. After being cooled to room temperature, the precipitates were collected and washed with deionized water and ethanol for several times. Finally, the precipitates were dried in vacuo at 40 °C for 12 h. The phase purity of the products was examined by X-ray powder diffraction (XRD) using a Rigaku D/max 2500 diffractometer at a voltage of 40 kV and a current of 200 mA with Cu-$K_\alpha$ radiation ($\lambda$ = 1.5406 Å), employing a scanning rate of 0.02°/s in the $2\theta$ range from 10 to 80°. Scanning electron microscopy (SEM) images and energy-dispersive X-ray (EDX) analysis were obtained using a HITACHI S-4300 microscope. Transmission electron microscopy (TEM) images and the corresponding selected-area electron-diffraction (SAED) pattern were taken with a HITACHI-600 transmission electron microscope at an accelerating voltage of 200 kV. Magnetic measurements for the samples were carried out at room temperature using a vibrating sample magnetometer (VSM, Lakeshore 7307, USA) with a maximum magnetic field of 10 kOe.

# Unprecedented Rearrangement of Molybdenum(VI) Oxide to ($\mu_2$-Oxido)-bis[dioxidomolybdenum(VI)] Hexamolybdate

**María R. Pedrosa,*[a] Rafael Aguado,[a] Virginia Díez,[a] Jaime Escribano,[a] Roberto Sanz,[a] and Francisco J. Arnáiz*[a]**

**Keywords:** Molybdenum / Hexamolybdates / O ligands / Polyoxometalates

$MoO_2(acac)_2$ reacts with water, amides, sulfoxides, and phosphane oxides in aqueous methanol, under mild conditions, to afford a new family of molybdates of composition $[Mo_2O_5L_6][Mo_6O_{19}]$ (L = $H_2O$, dimethylformamide, dimethylacetamide, dimethyl sulfoxide, dibutyl sulfoxide, tributylphosphane oxide, triphenylphosphane oxide, hexamethylphosphoramide). The crystal and molecular structures of the two first structurally characterized ($\mu_2$-oxido)bis[dioxidomolybdenum(VI)] hexamolybdates were established by X-ray diffraction analysis.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

Polymolybdates have played a significant role in molybdenum chemistry for more than a century. The contemporary interest in these compounds arises from their compositional range and structural versatility, as well as important optical, magnetic, catalytic, and medicinal properties.[1] The formation of a particular polymolybdate depends on the nature of the cation and the reaction conditions.[2] Hexamolybdates, despite their low relevance in aqueous media, are an important class of polyoxometalates because of the high symmetry of the anion and their concomitant capability to form interesting derivatives.[3]

Here we report the easy formation of several ($\mu_2$-oxido)-bis[dioxidomolybdenum(VI)] hexamolybdates of composition $[Mo_2O_5L_6][Mo_6O_{19}]$ [L = $H_2O$ (**1**), dimethylformamide (dmf) (**2**), dimethylacetamide (dma) (**3**), dimethyl sulfoxide (dmso) (**4**), dibutyl sulfoxide (dbso) (**5**), tributylphosphane oxide ($OPBu_3$) (**6**), triphenylphosphane oxide ($OPPh_3$) (**7**), hexamethylphosphoramide (hmpa) (**8**)], as well as the crystal and molecular structure of the dmso and $OPBu_3$ derivatives, **4** and **6**, respectively. To the best of our knowledge, these compounds are the first hexamolybdates with dioxidomolybdenum(VI) cations reported to date, and **6** is the first to crystallize in a noncentrosymmetric polar crystal class. These compounds are of high potential interest since: (1) the possibility of functionalization of both anion[4] and cation through substitution of the terminal oxido groups opens up the way to new materials with unexplored properties, (2) the expected different capability of anion and cation to work as oxido transfer catalysts may enable selective transformations, and (3) the ionic nature of the compounds and the tuning of the cation by coordinated ligands expand the options to work in a wide range of conditions.

As part of an ongoing study on the reactivity of $MoO_2(acac)_2$ (acac = acetylacetonate), it was soon evident that the diketonate hydrolyzes rapid and completely in aqueous methanol to yield a white solid for which molybdenum analysis and weight difference after heating were consistent with a composition very close to $MoO_3 \cdot 0.75H_2O$. We propose the formulation **1** for this compound because the IR spectrum showed the characteristic pattern of dioxidomolybdenum compounds, along with bands that strongly support the presence of the hexamolybdate anion,[5] and the $^1H$ NMR spectrum in [$D_4$]methanol only showed the presence of water.

To further elucidate the nature of this product we performed several reactions of $MoO_2(acac)_2$ in methanol in the presence of various O-donor ligands that are either able to stabilize oxidomolybdenum(VI) hydrates as previously reported[6] or to replace water from the coordination sphere of molybdenum.[7] In this manner we were able to isolate in high yield compounds **2**–**8**.

We also studied the reactivity of a suspension of freshly precipitated $MoO_3 \cdot nH_2O$ in methanol with the same ligands. In all cases partial formation of the corresponding $[Mo_2O_5L_6][Mo_6O_{19}]$ compounds was observed; the best result was obtained with the most basic ligand, hmpa.

According to these observations, the hydrolysis of $MoO_2(acac)_2$ in aqueous methanol leads to a hydrated molybdenum(VI) oxide that rearranges to the metastable $[Mo_2O_5(H_2O)_6][Mo_6O_{19}]$, which in turn reacts with strong O-donor ligands, such as amides, sulfoxides, and phosphane oxides, through replacement of coordinated water while respecting the preformed $[Mo_2O_5]$ and $[Mo_6O_{19}]$ cores.

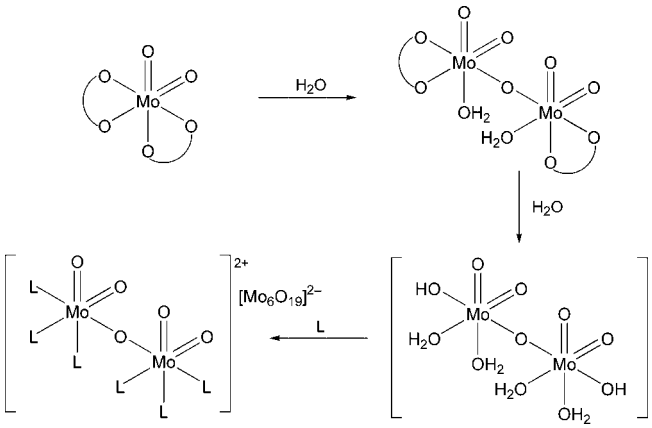
This process can be rationalized by assuming that the mentioned hydrolysis proceeds through a sequence of reactions as shown in Scheme 1, in which the formation of dinuclear species must play a relevant role, as evidenced by the easy formation of $Mo_2O_5(H_2O)_2(acac)_2$, which was recently characterized,[8] and the persistence of $[Mo_2O_5L_6]^{2+}$ cations in all compounds isolated.



Scheme 1. Suggested stepwise formation of $[Mo_2O_5L_6][Mo_6O_{19}]$.

Condensation and deprotonation of the dinuclear species $Mo_2O_5(H_2O)_4(OH)_2$ may lead to the formation of the $[Mo_6O_{19}]^{2-}$ anion, which could coexist for a while with the hydrated dinuclear cation $[Mo_2O_5(H_2O)_6]^{2+}$, which in turn is formed by protonation. According to this, when water is replaced by strong coordinating ligands $[Mo_2O_5L_6][Mo_6O_{19}]$ (**2**–**8**) were formed.

Compounds **1**–**8** were fully characterized by elemental analysis, and IR and $^1H$ NMR spectroscopy. The molecular structures of **4** and **6** were also confirmed by single-crystal X-ray diffraction,[9] and their dinuclear cations are shown in Figures 1 and 2, respectively.

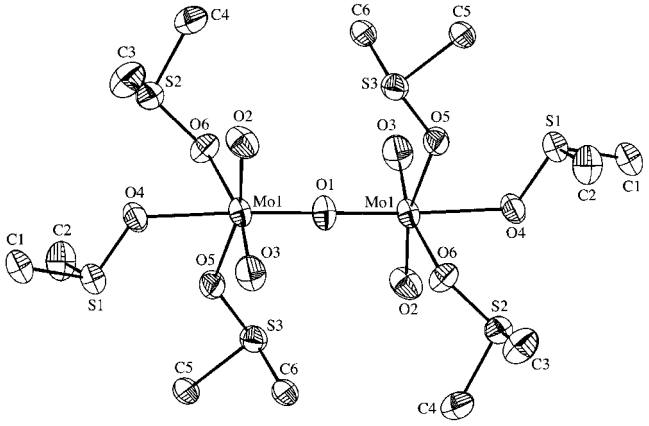


Figure 1. Crystal structure and atom-labeling scheme for $[Mo_2O_5(dmso)_6]^{2+}$ with thermal ellipsoids at the 50% probability level. The minor disorder component and hydrogen atoms are omitted for clarity.

Well-characterized compounds with the dication $[Mo_2O_5]^{2+}$ are rare, and to the best of our knowledge they are limited to $[Mo_2O_5L_2]^{2+}$ (L = *N*,*N*′,*N*′′-trimethyl-1,4,7-triazacyclononane, *N*,*N*′,*N*′′-tri-*tert*-butyl-1,4,7-triazacyclononane)[10–12] and $[Mo_2O_5L_6]^{2+}$ (L = $OPPh_3$).[13] For the cations from **4** and **6**, the Mo–O(t) and Mo–O($\mu_2$) bond lengths are similar to those reported for related cat-

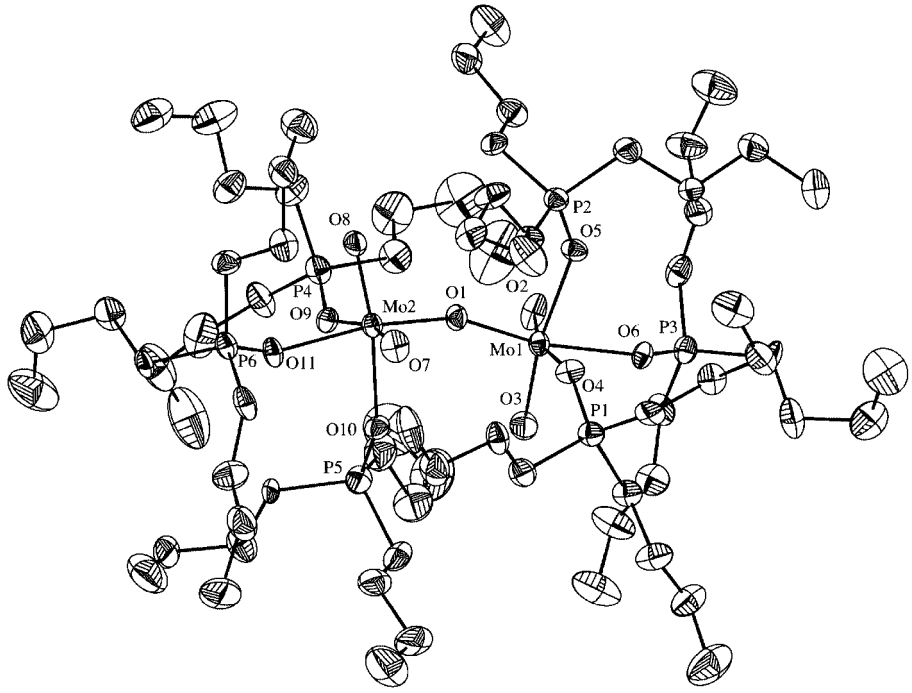

Figure 2. Crystal structure and atom-labeling scheme for $[Mo_2O_5(OPBu_3)_6]^{2+}$ with thermal ellipsoids at the 50% probability level. The minor disorder component and hydrogen atoms are omitted for clarity.

ions.[10–13] The cation from **4** has an inversion center at the oxygen bridge, which is analogous to cations reported in the literature; however, the angle Mo–O–Mo for the cation from **6** is 158.8(3)°, and this species is the first example of this type of cation that does not possess an inversion center.

The polyoxidoanion $[Mo_6O_{19}]^{2-}$ in **4** and **6** displays the well-known Lindqvist structure. The anion from **4** is highly symmetric, whereas that from **6** can be described as a distorted octahedron.

Whereas **4** crystallizes in the space group $P2_1/c$, quite common among the hexamolybdates previously reported, **6** crystallizes in the more interesting space group $P2(1)$. To the best of our knowledge, this is the first hexamolybdate in an acentric space group that falls in a noncentrosymmetric polar crystal class.[14] This kind of material possesses all four of the noncentrosymmetric symmetry-dependent properties,[15] specifically enantiomorphism, optical activity, pyroelectricity, and piezoelectricity.

The catalytic activity of compounds **1**–**8** for oxido transfer processes from several oxygen sources to $PPh_3$ was been measured and compared with that of the prototypical $[Bu_4N]_2[Mo_6O_{19}]$. It is noteworthy that full oxidation of $PPh_3$ to $OPPh_3$ could be achieved under mild conditions with these compounds when oxygen was used as the oxidant, whereas $[Bu_4N]_2[Mo_6O_{19}]$ proved to be inactive in the same conditions.

In summary, we have developed a simple reaction route to prepare ($\mu_2$-oxido)bis[dioxidomolybdenum(VI)] hexamolybdates from $MoO_2(acac)_2$. This easy procedure allows the reactions to be carried out in high yields under mild conditions. We have structurally characterized the two first members of this new family of hexamolybdates; one of them is the first hexamolybdate in a noncentrosymmetric polar crystal class. All these compounds show catalytic activity in oxidation processes with molecular oxygen as the oxidant. Further studies are currently being carried out in our laboratory.

# Mesoporous Carbon Prepared from Carbohydrate as Hard Template for Hierarchical Zeolites

**Kake Zhu,[a] Kresten Egeblad,[a] and Claus Hviid Christensen*[a]**

**Keywords:** Zeolite / Templating / Hierarchical materials / Sucrose / Porosity

A mesoporous carbon prepared from sucrose was successfully employed as a hard template to produce hierarchical silicalite-1, thus providing a very simple and inexpensive route to desirable zeolite catalysts from widely available raw materials. The porous carbon was prepared by hydrothermal treatment of a mixture of sucrose and ammonia followed by carbonization of the mixture in $N_2$ at high temperatures. The porous carbon produced by this method was subsequently applied as a hard template in the synthesis of mesoporous silicalite-1 and removed by combustion after synthesis. X-ray diffraction (XRD), scanning electron microscopy (SEM), transmission electron microscopy (TEM), selected-area electron diffraction (SAD), thermal gravimetry (TG), differential scanning calorimetry (DSC), $N_2$ physisorption measurements, Hg porosimetry and CHN elemental analysis techniques were applied to investigate the porous carbon template as well as the mesoporous zeolite single-crystal material.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Zeolites constitute an important class of crystalline microporous solids due to their widespread application in adsorption, separation and catalysis. Their importance stems from their unique pore structures, which make them highly selective to adsorbed molecules for separation purposes, or towards product molecules in catalysis. Moreover, they exhibit good thermal and hydrothermal stabilities during heterogeneous catalytic reactions.[1,2] However, the pore sizes of zeolites or zeolite-type materials, which are smaller than 1.5 nm, often restrict their applications due to diffusion limitations.[3]

Many strategies have been developed to overcome this problem, e.g. synthesizing larger-pore zeolite structures[4] and mesoporous molecular sieves,[5] reducing the size of the individual zeolite crystals,[6] subjecting the prepared zeolite to post-treatments like dealumination[7] and desilication,[8] as well as various hard template routes, where the template is removed after synthesis.[9] Naturally, pores created by post synthesis chemical treatments are highly dependant on the composition and structure of the original material, and a zeolite material consisting of nanosized crystals causes problems with handling during its applications. On the other hand, hard-template methods produce mesoporous zeolites with controlled porosity independent of their composition and structure, and have thus provided a general approach to solve this problem. So far, carbon blacks,[10] multiwalled carbon nanotubes,[11] carbon nanofibers,[12] carbon mesoporous molecular sieves,[13] carbon aerogels,[14–15] polymer aerogels,[16] and very recently mesoscale cationic polymers[17] have been utilized to fabricate zeolite materials which have a hierarchical pore system of intracrystalline mesopores interconnected with the conventional micropores.

Recently, mesoporous carbons have found application as hard templates for the production of very porous metal oxides such as $Al_2O_3$[18] and MgO.[19] Furthermore, also binary metal oxides like $MgAl_2O_4$ have been successfully prepared by this strategy.[20] More importantly, mesoporous carbons can also be employed to cast hierarchical-porous zeolites with tailored mesoporosities.[14–16] Mesoporous carbons are conventionally prepared by carbonization of a carbon precursor on a mesoporous silica template such as MCM-48,[21] SBA-15,[22] or amorphous silica,[23,24] which is subsequently removed by dissolving it in either HF or NaOH. Another category of mesoporous carbons are the carbon aerogels, which are prepared by pyrolysis of resorcinol/formaldehyde aerogels in an inert gas at high temperatures.[25–27] These methods are very costly and/or tedious. Preparation of an aerogel, for instance, entails supercritical fluid treatments making it both expensive and complex in preparation. In this paper, we report a simple and convenient way to prepare a mesoporous carbon template and its application in the synthesis of mesoporous silicalite-1. Contrary to the previously reported methods that typically rely on the availability of special and often expensive mesoporous carbons obtained from only a few suppliers, the present method only involves chemicals that are widely

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

available. The starting materials used here, sucrose and ammonia, are very inexpensive in comparison with aerogel precursors, and no sacrificial silica is needed. As carbon blacks are normally 100 times more expensive than sucrose, the outstanding features of the reported method are its simplicity, convenience and inexpensiveness.

## Results and Discussion

### Mesoporous Carbon Template

After hydrothermal treatment of a mixture of sucrose and ammonia for 2 d, a brown solid was obtained. $N_2$ physisorption measurements of this brown solid showed that it has a surface area of 34 $m^2/g$. In Figure 1 is shown a photographic image of the brown solid. It can be seen, that the brown solid retains the shape of the Teflon beaker in which it was produced and this allows for formation of larger zeolite objects though controlled templating.

Figure 1. Photographic image of the brown solid obtained after hydrothermal treatment of a mixture of sucrose and ammonia in a Teflon beaker. The porous carbon maintains the shape of the beaker.

From the TG and DSC measurements of the brown solid, shown in Figure 2, it can be seen that a major weight loss occurs between 400 and 500 °C. This is due to dehydration of the sucrose during decomposition. Above 500 °C, several endothermic peaks appear in the DSC profile. These are due to carbonization of the decomposed sucrose, since carbonization is an endothermic process. Hydrothermal treatment of the sucrose and ammonia mixture is necessary to obtain a porous carbon, because heating of sucrose directly causes melting and more complex decomposition, which results in non-porous carbon after thermal decomposition.

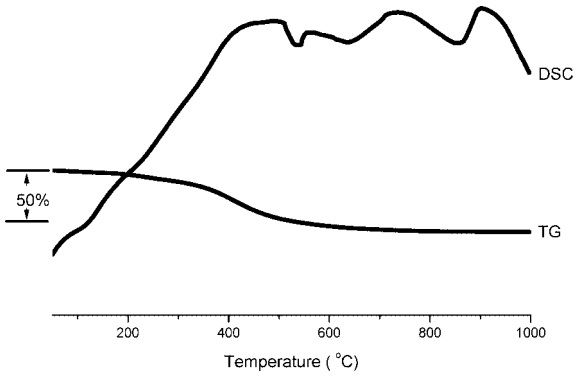

Figure 2. TG and DSC profiles of the solid obtained after hydrothermal treatment of a mixture of sucrose and ammonia.

Thermal decomposition of the brown solid at 850 °C in $N_2$ resulted in a porous black solid. This solid contained (by weight) 86.5% C, 1.17% N and 1.25% H, as examined by CHN elemental analysis. Thus, even after carbonization, minor amounts of nitrogen and hydrogen are present in the carbonaceous material. The remaining mass of the sample is most likely oxygen, which is not detected by this technique. Oxygen could easily be present in the carbonaceous material in the form of hydroxy groups.

$N_2$ adsorption and desorption isotherms of the porous black solid are shown in Figure 3. It can be seen that the isotherm contains a hysteresis loop which starts at a relative pressure of 0.8 and then rises dramatically with increasing pressure. According to the IUPAC classification of physisorption isotherms, isotherms featuring this type of hysteresis loops are classified as type IV isotherms, and are characteristic of mesoporous materials. From Figure 3 it is also evident, that the pore size distribution of the porous carbon is quite broad beginning at 10 nm and ending at more than 100 nm. Since the BET surface area of the carbon material presented here is only 416 $m^2/g$ (further results from the physisorption analyses are listed in Table 1), the material is not superior to the known carbon aerogels, which possess surface areas above 1000 $m^2/g$ and narrow pore size distributions.[27]

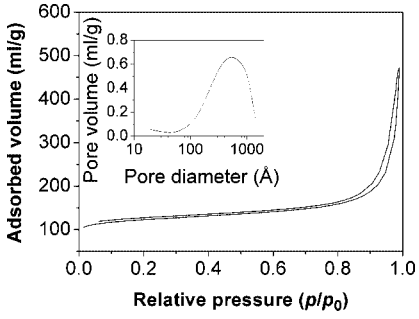

Figure 3. Nitrogen adsorption/desorption isotherms of the porous carbon obtained by carbonizing sucrose. The inset shows the pore size distribution obtained from the desorption branch of the isotherm using the BJH method.

Table 1. Surface area and porosity analyses of the mesoporous carbon template and the mesoporous silicalite-1 material obtained from it.[a]

| | $S_{BET}$ [$m^2$/g] | Micropore vol. [$cm^3$/g] | Meso- + macropore vol. [$cm^3$/g] | Mesopore size [nm] |
|---|---|---|---|---|
| Carbon | 416 | 0.13 | 0.60 | ca. 53 |
| Meso silicalite-1 | 403 | 0.09 | 0.37 | ca. 31 |

[a] The micropore volume is estimated from a *t* plot (DeBoer) and total pore volumes were calculated based on volume adsorbed at a relative pressure of $p/p_o = 0.99$, volumes of mesoporosity and macroporosity are calculated accordingly.[15]

However, given that the mesoporous carbon prepared in this way works well as a template in the synthesis of hierarchical zeolites, as will be shown later, the specific porosity properties of the material are not important.

### Mesoporous Silicalite-1

After crystallization of a zeolite gel mixture adsorbed on the porous carbon and subsequent calcination of the crude product in air, a white powder was obtained. The XRD pattern obtained for this powder is shown in Figure 4: the material contains exclusively highly crystalline MFI-structured material, since no peaks from other crystalline materials are observed in the pattern and there is no amorphous background. Thus, the prepared sample is a phase-pure silicalite-1 material. The peaks in the XRD diagram shown in Figure 4 are broader than the peaks observed in XRD patterns of conventional microporous ZSM-5 samples (also of MFI framework structure). This appears to be a general phenomenon in all XRD patterns of mesoporous zeolites produced by carbon templating. Even though the overall crystal sizes are similar in conventional and mesoporous samples, the XRD line width of the mesoporous samples always shows significant broadening. Thus, it is not possible to differentiate between nanosized and mesoporous zeolite samples from XRD analyses alone. However, the line broadening is still indicative of the porous carbon functioning as a chemically inert hard template during the crystallization of the zeolite.

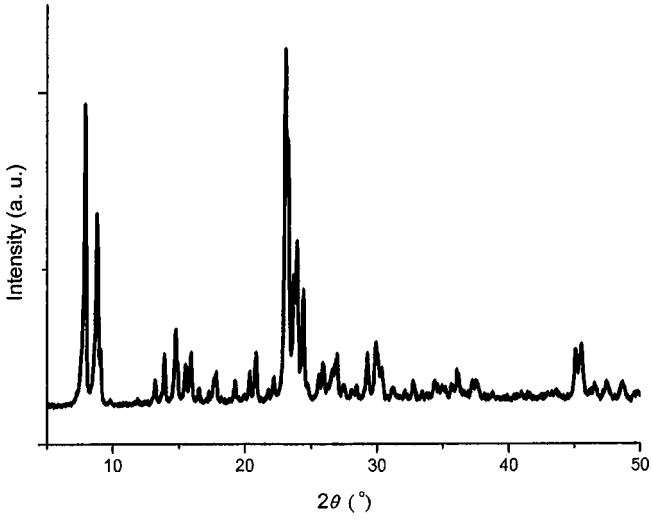

Figure 4. XRD pattern of the prepared silicalite-1 material.

In Figure 5 is shown the nitrogen physisorption isotherms of the mesoporous silicalite-1 material. It can be seen, that the isotherms contain two hysteresis loops, one at relative pressure below 0.4 and one starting at relative pressure 0.9. The hysteresis loop at a low relative pressure is commonly observed for microporous silicalite-1 and results from a phase transformation of dinitrogen inside the micropores of the pure silica MFI structure.[9] The hysteresis loop starting at a relative pressure of 0.9 is a type IV isotherm, which indicates that the material contains mesoporosity. Besides a micropore volume of 0.09 mL/g, the material contains an additional pore volume of 0.37 mL/g, attributable to mesopores and macropores. This is calculated from the total volume of $N_2$ adsorbed by the material at a relative pressure of $P/P_o = 0.99$. The pore size distribution of the mesoporous silicalite-1 is relatively narrow and centered at 31 nm, which is comparable to mesoporous zeolites prepared from other carbon templates.[10,14–16] The findings from nitrogen physisorption are completely verified by Hg intrusion data, which also reveal that some larger macropores, which cannot be seen efficiently by physisorption, are present. They are attributed to intercrystal voids in the material. The similarity of the physisorption data and the Hg porosimetry data confirms what has been found before: the pore system of the zeolite consists of an interconnected and homogeneously distributed system of intracrystalline mesopores that completely penetrate the crystals. Thus, since the newly developed procedure presented here clearly produces a hierarchical microporous/mesoporous material, which exhibits porosity similar to that of mesoporous silicalite-1 materials prepared using carbon blacks[10] and carbon aerogels as templates,[14–16] it is preferable when considering the complex nature of the carbon aerogel preparation and its high cost.

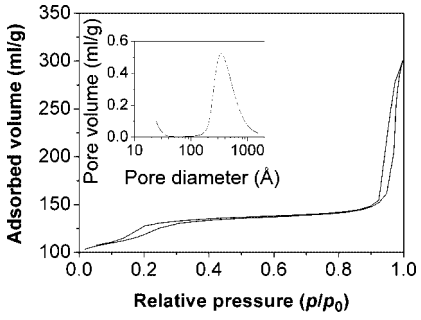

Figure 5. Nitrogen adsorption/desorption isotherms of the mesoporous zeolite silicalite-1 material after combustion of the carbon and organic templates. The inset shows the pore-size distribution obtained from the desorption branch of the isotherm using the BJH method.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

A comparison of the pore-size distributions of the porous carbon and the silicalite-1 material (Figures 3 and 5) clearly points out that a mesoporous zeolite with a relatively narrow pore size distribution can be produced from a porous carbon having a much more broad pore size distribution. This suggests that the mesoporous silicalite-1 crystals start to grow inside the pores of the carbon matrix and during crystallization gradually encapsulate the carbon. Thus, since the porosity of the zeolite is a negative replica of the carbon template, the specific pore size distribution of this template is less important. This tendency has also been observed for mesoporous zeolites templated from different carbon blacks, since not all carbon blacks are able to efficiently produce mesoporous zeolites.[12] In this light, the route to mesoporous zeolites presented here is superior to carbon-black-based methods because, using the method reported here, it is not possible to alter the porosity of the carbon matrix by pushing aside the carbon particles during zeolite growth.

Figure 6 shows the results of SEM analyses of the prepared mesoporous silicalite-1 after combustion of the carbon and organic templates. Figure 6a shows a low-magnification SEM image of the prepared material: the sample contains only impressively homogeneously sized single crystals, which can be seen all over the sample. From the higher resolution images, shown in Figure 6b–d, it can easily be seen that the single crystals are all sponge-like in appearance, which is a characteristic feature of mesoporous zeolites. Moreover, the coffin-like morphology exhibited by the mesoporous single crystals is typical of MFI-structured crystals. Furthermore, this mesoporous silicalite-1 material is quite similar to the one reported by Jacobsen using commercially available carbon black as hard template,[10] and it is different from carbon-aerogel-templated mesoporous silicalite-1 which contains a mixture of nanosized crystals and larger mesoporous monocrystals.[14] However, in the carbon-aerogel-templated systems the zeolite properties can be influenced by the crystallizations conditions.[14–16] This can probably be ascribed to different crystallization kinetics in the various carbon matrix materials. Thus, zeolite crystallization in the confined space of the carbons leads to nanosized crystals instead of the mesoporous crystals obtained when the zeolite encapsulates the carbon particles. From the SEM analyses of the prepared zeolite material it is concluded that the present sample contains exclusively mesoporous silicalite-1 single crystals. Here, we only show the use of a specific carbon produced by carbohydrate decomposition. However, it can be envisaged that a wide range of different carbons can be produced with this approach, and that could lead to possibilities for tuning the zeolite mesopore size just as it is possible with different carbon black materials.

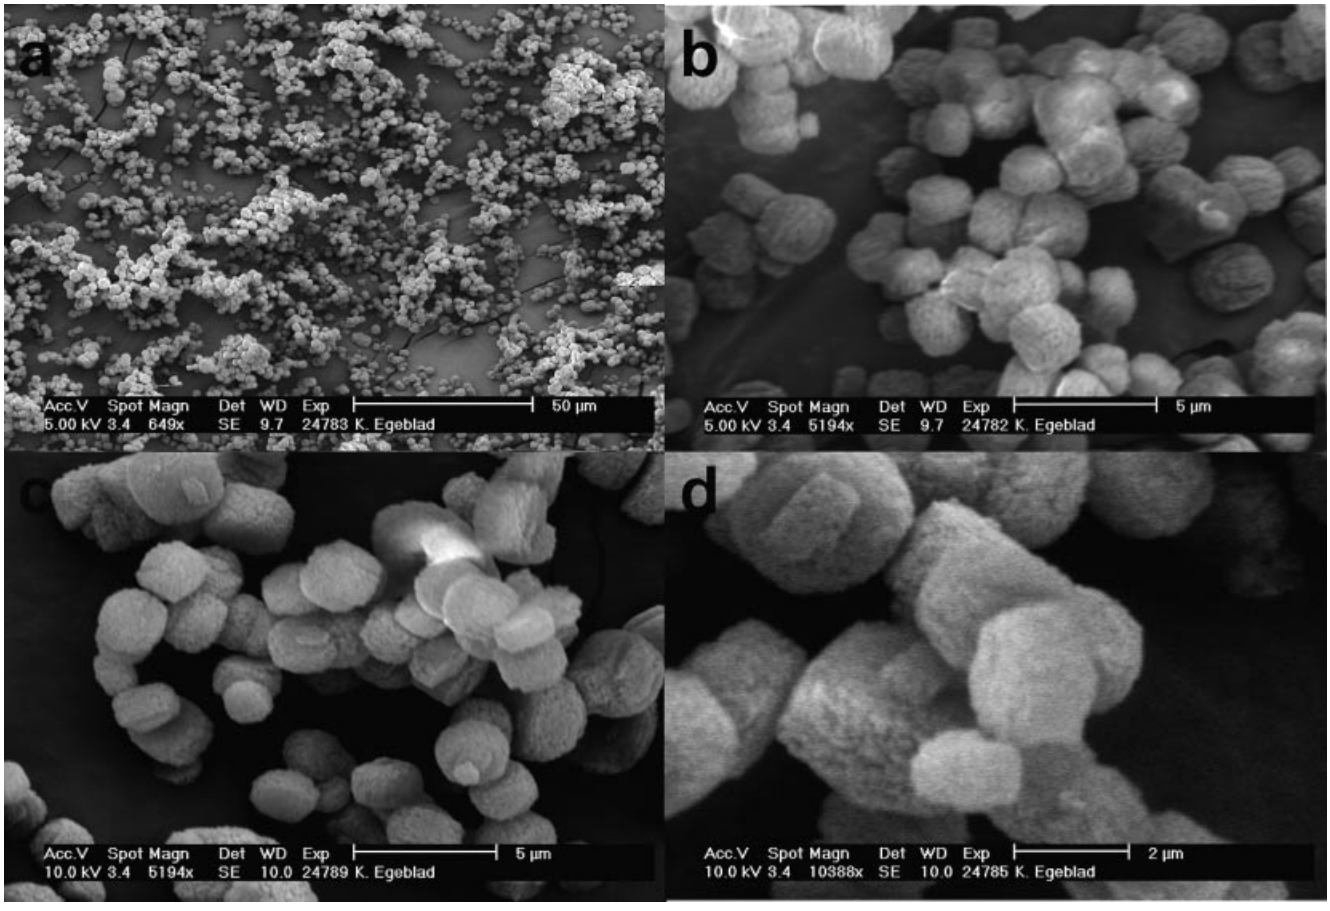

Figure 6. SEM images of the mesoporous silicalite-1 single crystals at different magnifications.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

From the TEM images of the prepared mesoporous silicalite-1 material shown in Figure 7 it is evident, that the material does indeed consist of mesoporous single crystals as the sponge-like coffin shape is readily identifiable in these images. The close-up TEM image shown in Figure 7b along with the SAD pattern shown in its inset unambiguously confirms the single-crystalline nature of the materials.

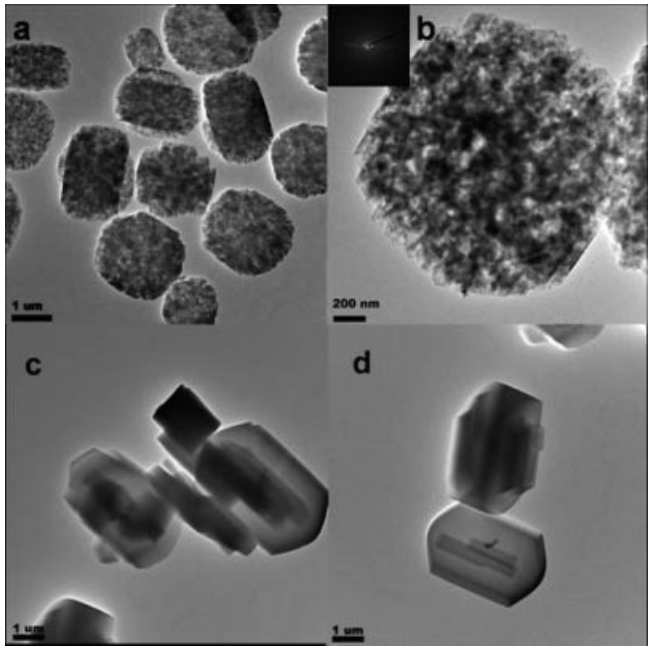

Figure 7. TEM images of the mesoporous silicalite-1 single crystals. The inset in (b) shows the SAD pattern of the area marked by a circle in the image, c) and d) show images of analogously prepared zeolite without the carbon template.

## Conclusions

Mesoporous zeolite single crystals of MFI structure were synthesized from cheap and readily available starting materials using a newly developed and very simple procedure in which an in-situ prepared mesoporous carbon is used as a mesopore template during synthesis and subsequently removed by combustion. XRD, SEM, TEM, SAD and $N_2$ physisorption measurements of the prepared zeolite material showed that the material contained exclusively mesoporous silicalite-1 single crystals, which are very similar to those obtained using much more expensive carbon black as the mesopore template. $N_2$ physisorption measurements of the carbon template showed that this material was in fact mesoporous, although not as porous as carbon aerogels. However, since the carbon template can obviously be used for the synthesis of mesoporous zeolite single crystals, the specific porosity of the carbon template is perhaps not so important. Nevertheless, understanding the mechanisms leading to the mesoporous carbon as well as its specific role in templating mesoporous zeolites might lead to mesoporous zeolites with even better properties. In all, the simple procedure presented here, combined with the comparatively cheap carbon matrix, make this method attractive for the synthesis of other zeolite or zeolite-type structures or perhaps even other oxide materials.

## Experimental Section

Hierarchical microporous/mesoporous silicalite-1 single crystals were obtained after combustion of a zeolite/carbon composite material, prepared by first producing a mesoporous carbon template material onto which the necessary zeolite gel components were impregnated and subjected to hydrothermal conditions.

The porous carbon template was prepared by dissolving 13.1 g of sucrose (98%, Aldrich) in a mixture of 9.6 mL of EtOH (absolute), 7.5 mL of $H_2O$ (deionized) and 1.0 mL of ammonia (25 wt.-%, Fluka) whilst stirring at 50 °C for 1.5 h. The material was transferred to a Teflon beaker and hydrothermally treated at 180 °C for 2 d, producing a brown solid which retained the shape of the beaker. The brown solid was crushed in a mortar and transferred to a horizontal tube furnace and heated to 850 °C in a flow of $N_2$ for 5 h to afford a porous black carbonaceous solid.

Mesoporous silicalite-1 single crystals were prepared by sequentially impregnating the necessary zeolite gel components onto the porous black carbonaceous solid. First, a mixture of 3.4 g of TPAOH (tetrapropylammonium hydroxide, 40 wt.-%, Aldrich) and 2.0 mL of EtOH was impregnated onto 2.5 g of porous black solid and the mixture was dried in air under ambient conditions overnight. Then, the material was impregnated with 3.0 mL of TEOS (tetraethyl orthosilicate, 98%, Aldrich) which was allowed to hydrolyze in air for 1 d. After aging, the material was transferred to a Teflon beaker which was placed inside a Teflon-lined autoclave with 10.0 mL of $H_2O$ added outside the beaker. The autoclave was hydrothermally treated at 180 °C for 3 d before the carbon and organic templates were removed by combustion at 550 °C for 24 h.

XRD was performed with a Philips PW 3710 X-ray diffractometer using Cu-$K_\alpha$ radiation ($\lambda$ = 0.154 nm) in the $2\theta$ range between 5 and 50° at a scanning speed of 0.6°/min.

Nitrogen adsorption/desorption isotherms were collected at liquid-nitrogen temperature (–196 °C) with a Micromeritics ASAP 2020. All samples were outgassed under vacuum at 200 °C overnight prior to measurement. The total surface area was calculated according to the BET method. Mesopore volumes were determined by the BJH method from the desorption branch of the isotherms, while micropore volumes and external surface areas were determined by using a *t*-plot analysis.

Hg porosimetry was measured by intrusion using a Quantachrome equipment.

SEM was performed with a Philips XL20 FEG. The calcined zeolite samples were placed on a carbon film and Pt was evaporated onto the sample for approximately 20 min to achieve sufficient conductivity.

TEM was performed with a JEM 2000FX using an accelerating voltage of 300 kV. SAD was used to obtain electron diffraction patterns from individual grains of powder. A few mg of the powdered samples were suspended in 2 mL of ethanol, and the suspension was sonicated for 1 h. Then, the suspension was allowed to settle for 15 min, before a drop was taken and dispersed on a 300 mesh copper grid coated with holey carbon film.

TG and DSC were conducted with NETZSCH STA 409 PC/PG equipment with a ramp of 20 °C/min under a nitrogen flow of 20 mL/min.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

CHN elemental analysis was performed with a CE Instruments FLASH 1112 Series EA.

# (Arene)ruthenium(II) Complexes Containing Substituted Bis(pyrazolyl)methane Ligands – Catalytic Behaviour in Transfer Hydrogenation of Ketones

**M. Carmen Carrión,[a] Félix A. Jalón,[a] Blanca R. Manzano,*[a] Ana M. Rodríguez,[b] Francisco Sepúlveda,[a] and Miguel Maestro[c]**

*Dedicated to the memory of Prof. S. Trofimenko*

**Keywords:** Ruthenium / Arene ligands / Homogeneous catalysis / Bis(pyrazolyl)methane / Transfer hydrogenation / X-ray structure determination

A new and safer methodology has been developed for the synthesis of bis(pyrazol-1-yl)methane ligands (NN). Several ligands containing different phenyl groups on the central carbon atom have been obtained. Ruthenium derivatives of the type [Ru(arene)Cl(NN)]$BPh_4$ (arene = benzene, *p*-cymene) have been synthesised using these ligands. One or two isomers that differ regarding the axial or equatorial disposition of the phenyl group on the metallacycle have been obtained. Their formation is rationalised by considering steric effects. The structures of five derivatives were determined by X-ray diffraction. In four complexes the phenyl substituent is in the axial disposition of the metallacycle and in one case in the equatorial orientation. The dihedral angle formed by the planes of the two pyrazole rings is always bigger for the complexes containing unsubstituted pyrazolyl heterocycles. The behaviour of the new derivatives in the transfer hydrogenation of benzophenone in the presence of KOH was studied. The benzene derivatives showed higher activity than the *p*-cymene complexes. A marked and positive effect of the methyl groups on the pyrazolyl rings was observed. The effect of the substituents on the benzyl carbon atom was also important. It has been observed that the benzophenone hydrogenation was possible without the addition of complexes. The effect of the KOH concentration was evaluated and a concentration that leads to negligible conversion in a base-only process was chosen.

## Introduction

(Arene)ruthenium(II) complexes constitute an important group of derivatives that have applications in numerous catalytic processes. Although some ruthenium derivatives containing poly(pyrazolyl)borate[1] or poly(pyrazolyl)methane[2] ligands have been reported, arene complexes with these groups[3] are extremely scarce. One of the catalytic applications of arene–ruthenium derivatives is in the transfer hydrogenation of ketones. This process gives high yields and enantiomeric excesses with some ketones and has the advantage over the traditional use of $H_2$ pressure of greater operational simplicity.[4] Different Ru–arene systems have been described for this process including PP, NN, NO and NPN ligands.[5] In this context, one of the most important breakthroughs was discovered by Noyori and involves the use of "$Ru^{II}$(arene)" precursors with chiral amino alcohols or diamines[6] in processes that lead to excellent activities and enantioselectivities. Because of the participation of the ligand in the catalytic reaction, Noyori has proposed the term bifunctional metal-ligand catalysis for this kind of process. He performed theoretical calculations concerning the mechanism and the origin of enantioselectivity.[7] Other groups have also developed systems based on Ru–arene fragments with amino alcohols,[8] amino amide[9] or amino carboxylate[10] ligands. Interesting papers concerning mechanisms have also appeared.[11] Besides the metal ligand bifunctional mechanism, other mechanisms involving monohydride or dihydride species have been proposed. Although not involving arene derivatives, it is worth noting that recently Baratta et al.[12] designed a new type of $Ru^{II}$ catalyst, containing the ligand 2-(aminomethyl)pyridine or its derivatives, that was active in the transfer hydrogenation of acetophenone, using NaOH as cocatalyst with TOF up to $4.0 \times 10^5$ $h^{-1}$.

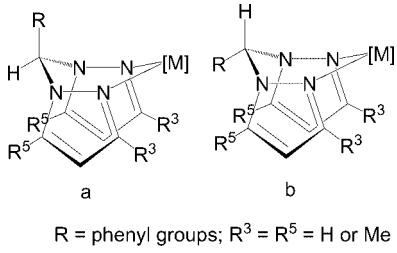
In recent years we have worked with a series of bis(pyrazolyl)methane derivatives.[2a,13] These compounds offer the possibility of modulating the steric and electronic properties by introducing substituents in the pyrazole rings and at the central carbon atom. We used ligands that contained differently substituted phenyl rings and pyrazole (pz) or 3,5-dimethylpyrazole (pz*) heterocycles attached to the central carbon atom. We have also explored the coordination chemistry of these ligands, mainly with palladium fragments.[13] An endobidentate coordination with the formation of metallacycles with a boat conformation has always been found. Interestingly, in all cases the phenyl substituent occupies the axial position in this metallacycle (see Scheme 1a). This is probably due to the steric hindrance that these groups would cause if they were in an equatorial position with respect to the pyrazole rings (Scheme 1b) and also the absence of other interactions in the axial position because of the square-planar environment of the metal centre. We found that with substituted pyrazolyl rings, the bite angle and the dihedral angle formed by the planes NPdN/$N_4$ were smaller and this influenced the dynamic behaviour of some derivatives.[13c] These data were rationalised by means of theoretical calculations.[14] Bis(pyrazolyl)methane complexes in which the substituent (pyrazole or thienyl) on the central CH group is situated in an equatorial position correspond to octahedral derivatives of ruthenium(II)[15] or platinum(IV).[16] In both cases, the pyrazolyl rings were unsubstituted.



Scheme 1.

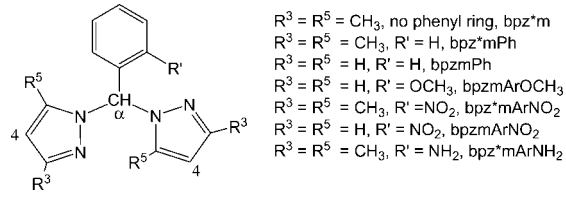
In the work described here we decided to synthesise a series of bis(pyrazolyl)methane ligands in which the central carbon atom bears phenyl rings that have different functional substituents such as $OCH_3$, $NO_2$ or $NH_2$. One objective was to find a method of synthesis that avoided the use of toxic phosgene. The purpose was also the synthesis of new arene (benzene, *p*-cymene) ruthenium derivatives that contain these ligands. Ultimately, we were interested in evaluating the stereochemistry of these complexes and, in particular, the preference for an equatorial or axial disposition of the phenyl ring and the relationship of this fact with the substitution on the pyrazolyl groups and the steric requirements of the arene. An open question concerned whether the change in the type of pyrazole present would also force the same type of distortions found in the related palladium chemistry.

Taking into account that Ru–arene complexes with poly(pyrazolyl)methane ligands have never been studied in hydrogenation transfer of ketones, another goal was the use of the new complexes as precatalysts in these processes using 2-propanol as the solvent and reducing agent. Preliminary tests will be presented. The NN ligands are clearly different to those used by Noyori because of the absence of NH groups as donor centres. In any case, it was of interest to evaluate the effect of the functional groups on the benzyl carbon atom outside the coordination centre including the $NH_2$ fragment.

## Results and Discussion

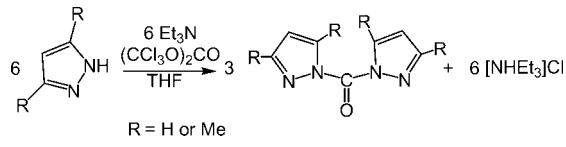
### Synthesis of the Ligands and Complexes

The ligands used in this work and their abbreviations are summarised in Scheme 2.



Scheme 2.

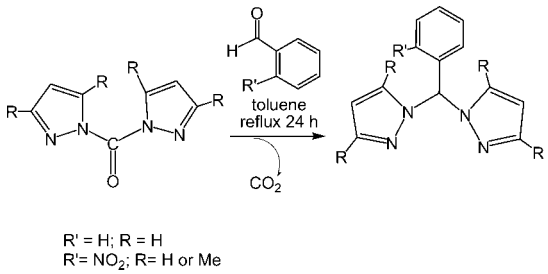
The ligands bpz*mPh,[17] bpzmPhOCH$_3$[13c] and bpz*m[18] have been described previously. The ligands bpz*mArNO$_2$, bpzmArNO$_2$ and bpz*mArNH$_2$ are described in this work for the first time. Until now, the intermediate bis(pyrazol-1-yl)ketone that is necessary for the preparation of these types of ligand, was synthesised by the reaction of pyrazole (substituted or not) and phosgene. In this work we tried to develop a greener method that could avoid the use of this highly toxic gas. The alternative that we have found is the use of the solid triphosgene. Thus, the synthesis of the ligands bpzmPh, bpz*mArNO$_2$ and bpzmArNO$_2$ was carried out in the following way. Firstly, the bis(pyrazol-1-yl)ketone species were obtained through the reaction of the corresponding pyrazole with triphosgene in the presence of triethylamine (Scheme 3).



Scheme 3.

The resulting ketone subsequently reacted with the corresponding aldehyde in toluene under reflux for 24 h (Scheme 4).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4.

The ligand bpz*mArNH$_2$ was obtained by hydrogenation of bpz*mArNO$_2$ using a Pd/C catalyst.

The Ru$^{II}$–arene (arene = benzene, *p*-cymene) complexes used in this work were obtained by treating the corresponding Ru$^{II}$ starting material, the nature of which depends on the arene, with the desired ligand in MeOH with the addition of Na[BPh$_4$] at the end of the reaction [see Equations (1) and (2)].

$$[RuCl_2(benzene)(CH_3CN)] + NN \xrightarrow{NaBPh_4} [RuCl(benzene)(NN)]BPh_4 + NaCl + CH_3CN \quad (1)$$

NN = bpz*m, **1**; bpz*mPh, **3**; bpzmPh, **5**; bpzmArOCH$_3$, **7**; bpz*mArNO$_2$, **9**; bpzmArNO$_2$, **11**; bpz*mArNH$_2$, **13**.

$$1/2\ [RuCl_2(p\text{-cymene})]_2 + NN \xrightarrow{NaBPh_4} [RuCl(p\text{-cymene})(NN)]BPh_4 + NaCl \quad (2)$$

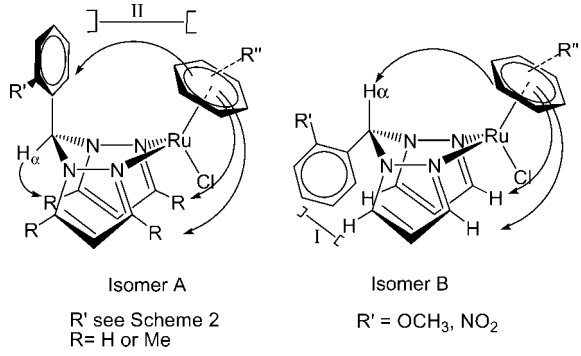
NN = bpz*m, **2**; bpz*mPh, **4**; bpzmPh, **6**; bpzmArOCH$_3$, **8**; bpz*mArNO$_2$, **10**; bpzmArNO$_2$, **12**; bpz*mArNH$_2$, **14**.

In cases where the nitrogenated ligands contained methylated pyrazolyl groups, only one isomer was obtained for the corresponding ruthenium complexes. A different situation was found when the ligand contained unsubstituted pyrazoles. Apart from the complexes containing bpzmPh, where only one isomer was found, the other derivatives exist as a mixture of two isomers (A and B). The relative ratios of these isomers, determined by NMR before recrystallisation, are shown, where applicable, in the Experimental Section.

The new complexes were characterised by elemental analysis as well as IR, $^1$H and $^{13}$C NMR spectroscopy and, in some cases, by X-ray diffraction. The bands corresponding to the stretching vibrations of the NO$_2$ and NH$_2$ groups were observed in the IR spectra (see Exp. Sect.).

## NMR Study

A careful NMR analysis of the new ligands and complexes was carried out. The assignment of the resonances was possible with the help of $^1$H,$^1$H-COSY, NOESY and *g*-HMQC spectra (in some cases also with *g*-HMBC) and by considering the values of coupling constants. The $^1$H NMR spectroscopic data are gathered in Table S1 of the Supporting Information. Coordination of the nitrogenated ligand to the [RuCl(arene)]$^+$ fragment results in shifts that, in some cases, were greater than 1 ppm towards higher frequencies for the pyrazolyl ring proton resonances. The same trend was observed for the $^{13}$C NMR resonances in cases where the appropriate data for direct comparison are available. This effect was attributed in general to the electron donation of the ligand to the metal cation (the effect of other groups in the molecule on specific protons will be detailed below). The increased electron deficiency of the heterocyclic rings also leads to an increase in the $^1$H,$^1$H coupling constants.[19] The assignment of structures to the complexes was done mainly by means of the NOESY spectra. The two possible structures are shown in Scheme 5. These compounds differ in the axial or equatorial orientation of the phenyl ring in the metallacycle. The arrows represent the most important NOEs observed. The disposition of the arene ring bonded to Ru and the chloride proposed in the scheme is thought to be the only possible situation for steric reasons. In the complexes obtained with methylated ligands and the isomers labelled A for the nonmethylated ones, an NOE is always observed between H$_\alpha$ and H$^5$ (or Me$^5$) of the pyrazolyl groups. In some cases, an NOE is also observed between resonances of the arene groups and the H atom of the phenyl group *ortho* to the benzyl carbon atom. These data indicate that in these complexes the phenyl ring is situated in an axial position. The structures in which the phenyl ring is in an equatorial disposition are assigned to isomers B. In fact, in complex **12B** an NOE was observed between H$_\alpha$ and the proton H$^3$ of the *p*-cymene ring. Although it does not provide structural information, a noticeable NOE is frequently observed in both types of isomer between the H$^3$ or Me$^3$ pyrazole resonances and signals from the arenes. This must be a consequence of the large dihedral angle NRuN/N$_4$ in the metallacycle having the boat conformation (see X-ray structures described below).



Scheme 5. Isomers A and B for the arene–Ru$^{II}$ derivatives. The most important NOEs are indicated with arrows. The steric interactions used to rationalise the isomer ratio are indicated by the roman numerals I and II. R′′ means that the arene ring is benzene or *p*-cymene.

Concerning the $^1$H NMR chemical shifts of the resonances of the two isomers, it is expected that the resonances of the H$^5$ pyrazole protons or even those of the arene rings would be affected by the position of the phenyl groups. In

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fact, the $H^5$ (pz) protons for isomers A appear in the range 8.23–8.50 ppm and those of isomers B in the range 7.69–7.80 ppm. When the phenyl groups are in an equatorial position, it is clear that these $H^5$ protons are more shielded. This must be due to the effect of the current anisotropy of the aromatic rings. A similar effect is observed for the aromatic resonances of the arenes. For example, the benzene signals of isomers A are in the region 4.90–5.75 ppm whereas isomers B give rise to signals in the range 6.24–6.27 ppm. This observation implies that, although the phenyl rings will rotate around the C(*ipso*)–$C_\alpha$ bond, the preferred orientation for the A isomers is that in which the ring forms an angle of approximately 90° with the $H_\alpha$–$C_\alpha$–C(*ipso*) plane. This orientation also leads to an upfield shift of the phenyl resonances of the protons situated *ortho* to $C_\alpha$, a situation due to the anisotropy effect of the pyrazole rings. These resonances could serve as a way of identifying the structure of a specific isomer. In the case of the $^{13}C\{^1H\}$ NMR resonances, a clear difference is also observed in the $C^5$ pyrazole signals, similar to that observed in the $^1H$ NMR spectra. For example, a higher chemical shift (difference of about 3–4 ppm) is observed for isomer A than isomer B.

The formation of a single isomer or a mixture of isomers, and even the ratio of isomers, can be rationalised on the basis of steric effects alone. Steric hindrance between the arene rings and the pyrazolyl groups exists in both isomers and probably will not influence their ratio (see Scheme 5). Steric hindrance I will be important in isomers B while steric hindrance II will be operating in isomers A. When the pyrazolyl groups are methylated, interaction I must predominate to induce the unique formation of complexes of type A. For the case of nonmethylated pyrazolyl groups, interaction I will be less important and both interactions may be competitive. In fact, both isomers are formed (see isomer ratio of complexes **7**, **8**, **11** and **12**; complexes **5** and **6** with bpzmPh constitute an exception, see Exp. Sect.), albeit in a ratio that depends on the nature of the arene. For the benzene complexes, isomers of type A are dominant, while for the bulkier *p*-cymene the ratio is nearly 1. In conclusion, in benzene derivatives interaction I is dominant while for the *p*-cymene complexes both interactions must be comparable. In the case of complexes with the ligand bpzmPh where the phenyl group does not have a functional group, it seems that interaction of type II is not very significant and only isomers of type A are formed.

It is interesting to compare these data with those found in square-planar palladium complexes,[13] in which the phenyl ring is always situated in an axial position, even for methylallyl derivatives.[13a,13b] The reason must be that in these types of derivatives the geometry of the metal centre means that interactions of type II do not exist or are not important.

In the case of complex **8** we obtained a crystallised sample that was enriched in isomer B and we monitored the evolution of this sample at 50 °C in a $[D_6]$acetone solution. Figure 1 reflects the changes that were observed with time. The initial ratio **8B/8A** of 77:23 changed to 55:45 after 90 min, which constitutes a clear indication that interconversion between isomers is possible. There is no signal coalescence or broadening of the resonances. Consequently, the energy of the process is high enough not to be observable by coalescence methods. This process cannot take place through a boat-to-boat interconversion of the metallacycle, because, although the axial or equatorial position of the phenyl rings will change with this process, it would not lead to the other isomer but to a species that we consider unstable for steric reasons (see Scheme 6). A possible way of isomer interconversion is through a partial decoordination of the nitrogenated ligand.

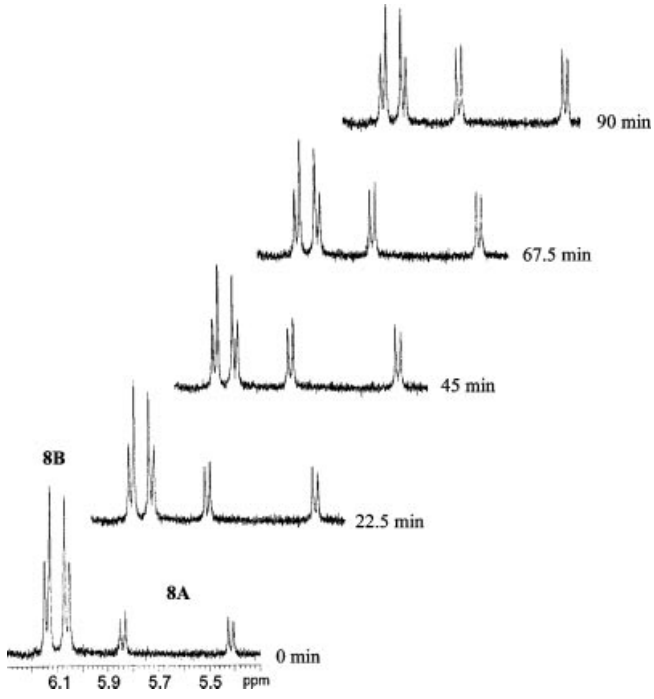


Figure 1. $^1H$ NMR monitoring of the evolution of a **8A/8B** mixture with time.

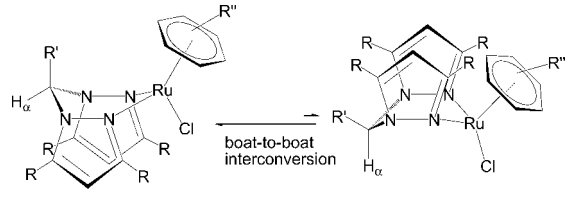

Scheme 6.

## X-ray Structure Determinations

The molecular structures of complexes **7A**·$0.5C_2H_4Cl_2$, **8B**, **9**, **10**·$0.5C_2H_4Cl_2$ and **12A** were determined by X-ray diffraction analysis. The crystallographic data are gathered in Table 1 and the most important bond lengths and angles, including some dihedral angles, are given in Table 2. The corresponding ORTEP drawings are shown in Figures 2, 3, 4, 5 and 6. In the case of **10**, two independent molecules exist in the asymmetric unit. The data for both are very

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

similar and only those of one molecule are given, in Table 2. All complexes have a half-sandwich structure consisting of the coordinated arene, a chloride and the bidentate nitrogenated ligand. In complexes **7**, **9**, **10** and **12** the phenyl group has an axial disposition on the metallacycle having the boat conformation. However, in the case of **8** we were fortunate to crystallise isomer B, in which this group is in an equatorial disposition. The distances between the Ru centre and the coordinated atoms are in the expected range. The average Ru–C distances are slightly longer for the *p*-cymene derivatives than for those containing benzene. The Ru–N distances are shorter for the nonmethylated pyrazolyl rings. The bite angle is in the range 83.4–85.5°. The values of the dihedral angles $NRuN/N_4$, which are listed in Table 2, are in the range 151–169°. In contrast to the palladium derivatives, there is no relationship in these ruthenium complexes between the bite angle or the stated dihedral angle and the nature of the substituent on the pyrazolyl rings. However, it is clear that the dihedral angle formed by the planes of the two pyrazole rings is always bigger for the complexes containing unsubstituted pyrazolyl heterocycles. We propose that this effect is due to steric hindrance be-

tween the methyl groups of the pyrazoles and the arene groups. When the angle between the pyrazoles decreases, this interaction may be reduced. This is clearly reflected in the structure drawing and the space-filling representations in Figure 7.

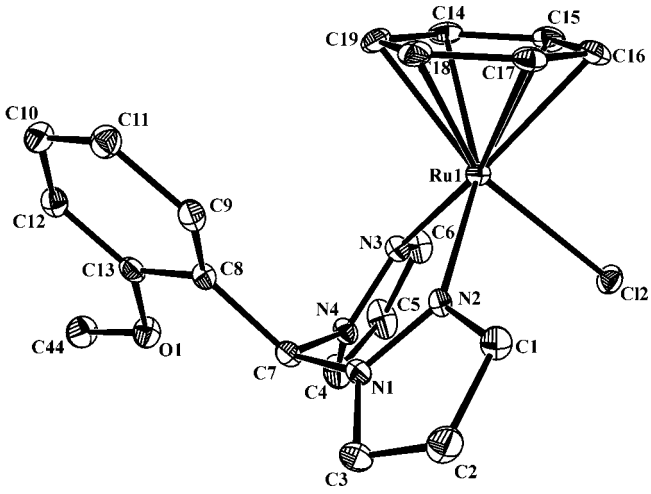

Figure 2. ORTEP view of the cation of complex **7A**·0.5$C_2H_4Cl_2$. Displacement ellipsoids are drawn at the 30% probability level. Hydrogen atoms have been omitted for clarity.

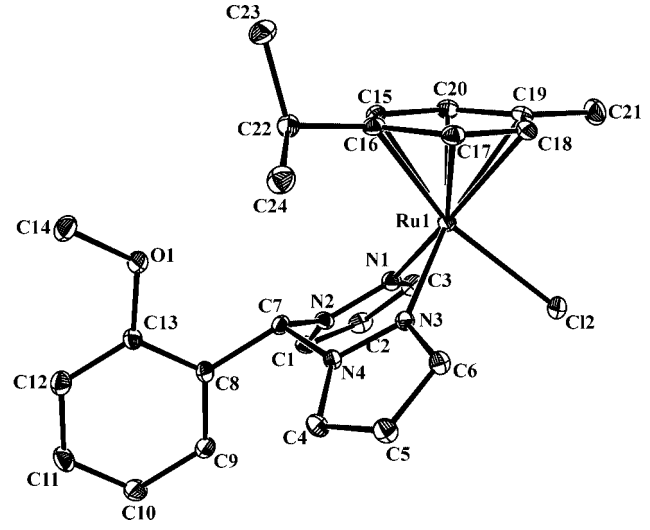

Figure 3. ORTEP view of the cation of complex **8B**. Displacement ellipsoids are drawn at the 30% probability level. Hydrogen atoms have been omitted for clarity.

The orientation of the phenyl ring with respect to the plane formed by the atoms $H_\alpha$–$C_\alpha$–C(*ipso*) is mainly dependent on the axial or equatorial disposition of this ring. When it is axial, the dihedral angle is very close to 90° (in the case of **7A** it is smaller: 56.12°), while for **8B** (where the group is equatorial) the value is only 10.79°.

The methoxy group is approximately in the plane of the phenyl ring. However, it is worth noting the orientation of the $NO_2$ plane with respect to the corresponding phenyl ring. Unexpectedly, these planes are not parallel, and the values for the dihedral angle are in the range 65–68° for the methylated complexes and 54.4° for the nonmethylated

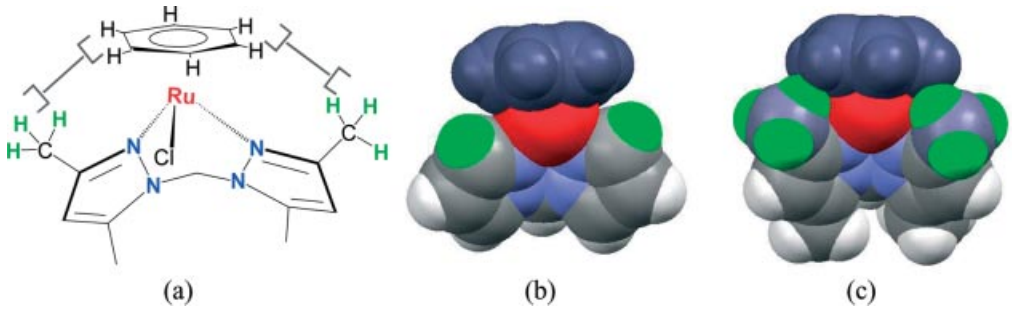

Figure 7. (a) Drawing scheme showing the steric interaction between the pyrazole $Me^3$ groups and the CH bonds of the coordinated benzene that influences the pz–pz interplanar angle (the same is applicable to the *p*-cymene derivatives). (b and c) Comparison of such interactions in a space-fill drawing of the X-ray structures of complexes **7** and **9** respectively (Cl ligands and benzyl groups on the $C_\alpha$ atom have been omitted for clarity).

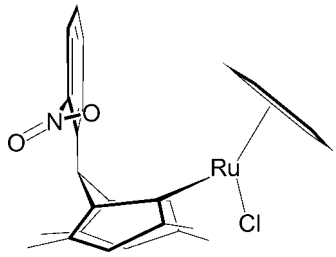
system. A closer inspection of the structure provides a plausible explanation for this observation. If the $NO_2$ plane was parallel to the phenyl ring, one of the oxygen atoms (with a negative charge density) would be situated very close to the π electron density of one pyrazole ring, and the aim of the torsion is probably to prevent this repulsive interaction. On the other hand, another orientation of the phenyl ring to minimise this problem would involve greater steric hindrance, because the phenyl ring would be too close to the arene that is bonded to the ruthenium centre (see Scheme 7).



Scheme 7.

As far as the orientation of the *p*-cymene ring in complexes **8B**, **10** and **12A** is concerned, there are two situations that are clearly different. In the case of complexes **10** and **12A**, where the phenyl ring has an axial orientation, the disposition of the *p*-cymene is such that the steric hindrance with this ring is reduced. The orientation in the case of **8B**, where the anisole ring is in an equatorial position, is clearly different and the isopropyl group is oriented towards the methoxy group. Closer inspection of the structure of **8B** reveals the existence of a hydrogen bond between the C–H fragment of the isopropyl group and the oxygen atom of the methoxy group. The C···O distance is 3.427 Å and the angle C–H–O is 142°. These data allow us to conclude that this hydrogen bond is weak.[20]

## Hydrogen Transfer Catalytic Tests

Preliminary tests were done concerning the behaviour of some of the new derivatives in catalytic transfer hydrogenation reactions of benzophenone using 2-propanol as the reducing agent and solvent in the presence of KOH as the base [Equation (3)]:

$$PhCOPh + iPrOH \rightarrow PhCHOHPh + Me_2CO \quad (3)$$

Conversion was not observed at room temperature. For example, on using complex **7** there was no conversion after 36 h (see Exp. Sect. for conditions). Consequently, the boiling point of the solvent (85 °C) was used as the temperature in all the experiments. Initially we performed catalytic tests with complexes **1** and **3** with a substrate/KOH/complex ratio of 1000:100:1. Only moderate yields of the alcohol were obtained after 24 h of reaction (28% for **1** and 15% for **3**). We decided to evaluate the influence of the base concentration and we increased the number of equivalents of KOH without changing other factors. We performed tests with 250, 500 and 1000 of KOH per mole of complex and a steady increase in the TOF number and yield was observed. At this point it is necessary to consider the possibility of a high effect of the base that could obscure the catalytic effect of the complex. Processes of hydrogenation have been described with molecular hydrogen of benzophenone with a base (mainly *tert*-butoxide) in the absence of a catalyst, but using very drastic conditions (about 200 °C, >100 bar $H_2$).[21] Regarding transfer hydrogenation, a conversion of 60% of acetophenone to the corresponding alcohol in boiling 2-propanol with NaOH 0.5 M[22] in 4 h and very low activity in 0.02 M KOH solutions has been reported.[23] Our highest concentration was 0.2 M. In any case, we decided to perform an analysis of the base-only reaction at different KOH concentrations. We found that KOH is able to catalyse the benzophenone hydrogenation with 2-propanol at 85 °C. When the alcohol yield is represented against different KOH concentrations, a straight line with positive slope (% yield = 0.91894 + 306.60015[KOH]; $R$ = 0.99421) is obtained. The results are reflected in Table 3. In Figure 8 a representation of conversion against time is reflected for two experiments without a catalyst (KOH 0.008 M and 0.2 M) and another two experiments with KOH 0.2 M in the presence of complexes **3** or **13** (substrate/KOH/complex ratio of 1000:1000:1). It is clear that when working with KOH concentrations of 0.2 M the effect of our complexes is very

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

small and other conditions must be chosen. We think that these studies must be taken into account before performing reactions of transfer hydrogenation in the presence of KOH.

Table 3. Transfer hydrogenation of benzophenone with KOH without Ru complexes.[a]

| [KOH] [mol·L$^{-1}$] | Mol KOH [500 mol substrate] | Yield [b] [%] |
|---|---|---|
| 0.004 | 10 | 0 |
| 0.006 | 15 | 2 |
| 0.008 | 20 | 3 |
| 0.016 | 40 | 7 |
| 0.04 | 100 | 10 |
| 0.1 | 250 | 36 |
| 0.2 | 500 | 68 |
| 0.3 | 750 | 88 |

[a] Conditions: 2 mmol of benzophenone, 10 mL of *i*PrOH, reflux (82 °C). [b] Yield of diphenylmethanol after 13 h.

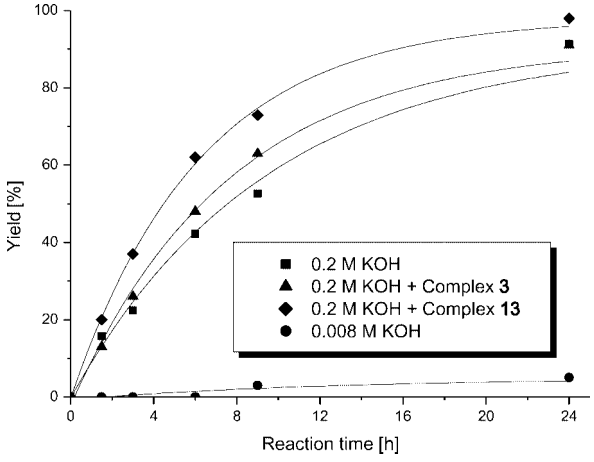


Figure 8. Yield of diphenylmethanol against time for the hydrogenation of benzophenone. Conditions: 2 mmol of benzophenone, 10 mL of *i*-PrOH, reflux (82 °C), 0.004 mmol precatalyst (when applicable).

Considering these results we decided to study the behaviour of our different derivatives with a base concentration of 0.008 M and a substrate/KOH/complex ratio of 500:20:1. The yields and the turnover frequencies evaluated at 20% conversion ($TOF_{20}$) are reflected in Table 4. The conversion for the TOF number was chosen in order to minimise the influence on the rate of decreases in substrate concentration and increases in product concentration. Several clear conclusions can be drawn from the analysis of the results. (i) Better behaviour of the benzene derivatives (those with an odd number) against *p*-cymene complexes (even number) is observed (in some cases the differences are not large). (ii) The introduction of methyl substituents on the pyrazole rings has a dramatic and positive effect (compare runs 4/6, 5/7, 11/13 and 12/14). For example, in the case of complexes **4** and **6**, the improvement is from 10 to 82% in the product yield (see Figure 9 to observe both effects). (iii) The introduction of a phenyl group at the benzyl carbon atom (compare runs 2/4 and 3/5) also increases the activity of the system. (iv) When the existence of functional groups on this ring is considered, a negative effect of the $NH_2$ (runs 4/15 and 5/16) or $NO_2$ groups (runs 4/11 and 5/12 for methylated pyrazoles and runs 6/13 and 7/14 for nonmethylated pyrazoles) is observed. However, a large increase in the activity is observed when the $OCH_3$ group is introduced on the phenyl ring (runs 6/8 and 7/10). In all the experiments samples were taken at 1.5, 3, 6, 9 and 24 h (see Supporting Information for the corresponding data).

Table 4. Transfer hydrogenation of benzophenone with Ru precatalysts.[a]

[a] Conditions: 2 mmol of benzophenone, 0.004 mmol precatalyst, 10 mL of *i*PrOH, reflux (82 °C), 0.008 M in KOH, substrate/KOH/complex ratio of 500:20:1. [b] Catalyst turnover frequency at 20% conversion. [c] Yield of diphenylmethanol at 24 h of reaction. [d] No precatalyst was added. [e] 300 equiv. of Hg was added.

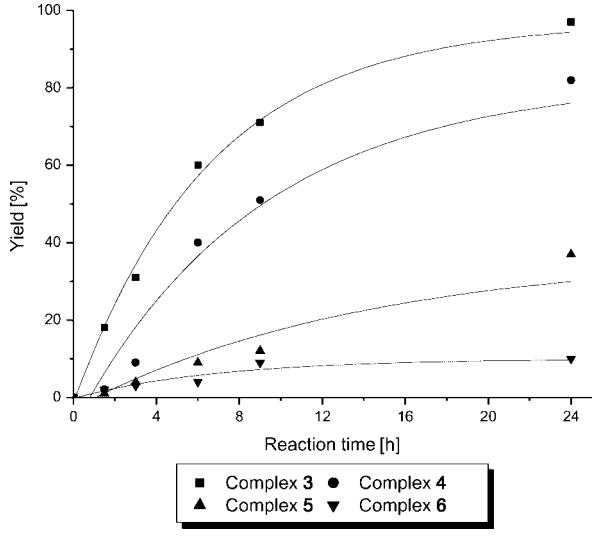

Figure 9. Yield of diphenylmethanol against time for the hydrogenation of benzophenone. Conditions: 2 mmol of benzophenone, 0.004 mmol precatalyst, 10 mL of *i*PrOH, reflux (82 °C), 0.008 M in KOH, substrate/KOH/complex ratio of 500:20:1.

We subjected complex **7** to the mercury drop test during the hydrogenation of benzophenone. Several authors[24] found that the addition of excess metallic mercury (with respect to the metal complex) to the reaction mixture led to the amalgamation of the surface of a heterogeneous metal particle, thus poisoning it, but did not affect a homogeneous catalyst. When we added 300 equiv. of Hg(0) to the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

reaction mixture at $t = 0$ min, the catalytic system only suffered a slight decrease in activity (compare runs 8/9), indicating the existence of a homogeneous system.

We also carried out a catalytic test with complex **7** (0.004 mmol), analysing samples at short times of 5, 10, 15, 30, 45 and 60 min. No induction period was observed. We also subjected complex **7** to a pretreatment of one hour, during which the precatalyst was heated at reflux in the presence of the base (base:**7** = 20:1) prior to the addition of the substrate (2 mmol), and the outcome of the reaction was the same as that without this treatment.

The precatalysts are not active in the hydrogenation of styrene. Thus, they exhibit selectivity towards the ketone unsaturation.

According to previous mechanistic proposals,[11a–11e] and considering the formulae and type of ligand present in our derivatives, the most plausible mechanism is that involving a monohydride intermediate generated after β elimination from an isopropoxide complex. In principle, the vacant coordination site necessary for the ketone coordination could be generated by partial decoordination of the nitrogenated ligand or by slippage of the arene moiety. Our study of the isomer interconversion and the fact that the methylated ligands that exhibit longer Ru–N distances have much higher activity point to the former possibility. Transfer of the hydride and reaction with 2-propanol will yield the dibenzyl alcohol.

More studies concerning the catalytic behaviour of these complexes are in progress. We will study complexes with the bpz*PhOCH$_3$ ligand that predictably will give better results than those reported in Table 4 and we will also consider the possibility of obtaining ligands that have pyrazoles containing more bulky substituents. Other parameters such as the introduction of other functional groups on the phenyl ring and the use of asymmetric ligands will also be analysed.

## Conclusions

New bis(pyrazol-1-yl)methane ligands containing different substituents on the central carbon atom have been synthesised using a new and safer methodology. Ru derivatives of the type [Ru(arene)Cl(NN)]BPh$_4$ (arene = benzene, *p*-cymene) have been synthesised from these ligands. The formation of two isomers is possible depending on the axial or equatorial disposition of the substituent on this carbon. The formation of only one isomer (axial) or a mixture of two (including their ratio) can be rationalised in terms of steric repulsions (effect of the methyl groups on the pyrazolyl rings or of the arene). A full NMR analysis was performed and a clear effect of the type of isomer on the chemical shifts of certain resonances was found. The structures of five derivatives were determined by X-ray diffraction. In four complexes the benzyl substituent is in the axial disposition and in one case in the equatorial disposition. A relationship between the dihedral angle formed by the planes of the two pyrazole rings and the substituent on these rings was found. The behaviour of the new derivatives in the transfer hydrogenation of benzophenone in the presence of KOH was studied. The influence of the arene, the functional group on the phenyl ring and the substitution on the pyrazole ring has been evaluated. A marked positive effect of the methyl groups on the pyrazole rings and of the methoxy group on the phenyl ring has been found. The hydrogenation of benzophenone without the addition of a complex in the presence of KOH is possible and the effect of the base concentration has been analysed.

## Experimental Section

**General:** All manipulations were carried out under dry oxygen-free nitrogen using standard Schlenk techniques. Solvents were distilled from the appropriate drying agents and degassed before use. Elemental analyses were performed with a Thermo Quest FlashEA 1112 microanalyser. IR spectra were recorded as KBr pellets or Nujol solutions with a Perkin–Elmer PE 883 IR spectrometer and on a Shimadzu IRPrestige-21 IR spectrometer equipped with a Pike Technologies ATR. $^1$H and $^{13}$C{$^1$H} NMR spectra were recorded with a Varian Unity 500 spectrometer. Chemical shifts (ppm) are relative to TMS ($^1$H, $^{13}$C NMR). $^1$H-$^1$H COSY spectra: standard pulse sequence with an acquisition time of 0.214 s, pulse width 10 ms, relaxation delay 1 s, number of scans 16, number of increments 512. For $^1$H-$^{13}$C *g*-HMBC and *g*-HMQC spectra the standard VARIAN pulse sequences were used (VNMR 6.1 C software). The spectra were acquired using 7996-Hz ($^1$H) and 25133.5-Hz ($^{13}$C) widths; 16 transients of 2048 data points were collected for each of the 256 increments. NOESY spectra were acquired using 8000-Hz width; 16 transients of 2048 data points were collected for each of the 256 increments; pulse time of 1 s and mixing time of 1 s. *o*-, *m*- and *p*- stand for *ortho*, *meta* and *para*. s, d, t and p stand for singlet, doublet, triplet and apparent for the NMR resonances. Unless otherwise stated, the $^{13}$C{$^1$H} NMR signals are singlets. The ligands bpz*m[18] and bpzmArOCH$_3$[13c] were prepared according to the methods described in the literature. For the preparation of the ligands bpzmPh and bpz*mPh[17] the ketone bpz*CO was synthesised as described below.

**bpz*CO:** 3,5-Dimethylpyrazole (1.5 g, 15.6 mmol) was dissolved in thf (20 mL) and NEt$_3$ (2.13 mL) was added afterwards. Triphosgene, Cl$_3$COCOOCCl$_3$ (772 mg, 2.60 mmol), was dissolved in thf (20 mL) and the resulting solution was added as quickly as possible to the initial one. After 16 h of stirring at room temperature, the white solid formed was filtered off and washed twice with thf. The thf fractions were combined and the solvent evaporated. The yellowish oil obtained was washed with pentane and a white solid was formed. The solid was recrystallised from toluene/hexane obtaining white crystals. Yield 1.4 g (80%).

**bpzCO:** The method was similar to that used for bpz*CO. Amounts were as follows: pyrazole (1 g, 15.6 mmol), NEt$_3$ (2.13 mL) and triphosgene (772 mg, 2.60 mmol). bpzCO was obtained as a white solid. Yield 948.6 mg (75%).

**bpz*mArNO$_2$:** bpz*CO (500 mg, 2.29 mmol) and 2-nitrobenzaldehyde (346 mg, 2.29 mmol) were mixed in toluene (25 mL). After refluxing for 24 h, the yellowish solution was evaporated and the residue was washed with pentane (3 × 10 mL), obtaining a white solid of bpz*mArNO$_2$. Yield 506.7 mg (68%). $^1$H NMR (500 MHz, CDCl$_3$, 298 K): $\delta$ = 2.08 (s, 6 H, Me$^5$-Pz), 2.15 (s, 6 H, Me$^3$-Pz), 5.89 (s, 2 H, H$^4$-Pz), 6.60 (d, $J$ = 7.7 Hz, 1 H, H$^3$-ArNO$_2$), 7.53 (td, $J$ = 7.7, 1.5 Hz, 1 H, H$^5$-ArNO$_2$), 7.57 (td, $J$ = 7.7, 1.5 Hz, 1 H, H$^4$-ArNO$_2$), 8.04 (dd, $J$ = 7.7, 1.5 Hz, 1 H, H$^6$-ArNO$_2$), 8.22

(s, 1 H, $H_\alpha$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 298 K): $\delta$ = 11.16 (2 C, $Me^5$-Pz), 13.97 (2 C, $Me^3$-Pz), 71.57 (1 C, $C_\alpha$), 107.22 (2 C, $C^4$-Pz), 122.25 (1 C, $C^6$-$ArNO_2$), 128.80 (1 C, $C^3$-$ArNO_2$), 129.78 (1 C, $C^5$-$ArNO_2$), 131.90 (1 C, $C^2$-$ArNO_2$), 133.86 (1 C, $C^4$-$ArNO_2$), 141.17 (2 C, $C^5$-Pz), 148.27 (1 C, $C^1$-$ArNO_2$), 148.76 (2 C, $C^3$-Pz) ppm. IR (KBr): $\tilde{\nu}$ = 1563 (CN); 1528, 1360, 1317 (NO) $cm^{-1}$.

**bpzmArNO$_2$:** The method was similar to that used for bpz*mArNO$_2$. Amounts were as follows: bpzCO (300 mg, 1.85 mmol) and 2-nitrobenzaldehyde (280 mg, 1.85 mmol). Yield 382.3 mg (62%). $^1H$ NMR (500 MHz, $CDCl_3$, 298 K): $\delta$ = 6.38 (pt, $J$ = 2.1 Hz, 2 H, $H^4$-Pz), 6.71 (dd, $J$ = 7.3, 1.7 Hz, 1 H, $H^3$-$ArNO_2$), 7.52 (d, $J$ = 2.2 Hz, 2 H, $H^5$-Pz), 7.57 (td, $J$ = 7.6, 1.7 Hz, 1 H, $H^5$-$ArNO_2$), 7.62 (td, $J$ = 7.6, 1.7 Hz, 1 H, $H^4$-$ArNO_2$), 7.63 (d, $J$ = 1.7 Hz, 2 H, $H^3$-Pz), 8.11 (dd, $J$ = 7.6, 1.9 Hz, 1 H, $H^6$-Ar $NO_2$), 8.52 (s, 1 H, $H_\alpha$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 298 K): $\delta$ = 74.42 (1 C, $C_\alpha$), 107.42 (2 C, $C^4$-Pz), 125.64 (1 C, $C^6$-$ArNO_2$), 129.40 (1 C, $C^3$-$ArNO_2$), 130.58 (1 C, $C^5$-$ArNO_2$), 130.92 (2 C, $C^5$-Pz), 131.79 (1 C, $C_2$-$ArNO_2$), 134.10 (1 C, $C^4$-$ArNO_2$), 141.44 (2 C, $C^3$-Pz), 147.52 (1 C, $C^1$-$ArNO_2$) ppm. IR (KBr): $\tilde{\nu}$ = 1580 (CN); 1526, 1350, 1312 (NO) $cm^{-1}$.

**bpz*mArNH$_2$:** bpz*mArNO$_2$ (745.1 mg, 2.29 mmol) was solved in toluene (30 mL) in a Fischer-Porter tube. A suspension of Pd/C (10%) catalyst (200 mg) in toluene (10 mL) was added to the initial solution. When the system was under dry oxygen-free nitrogen, hydrogen was introduced under pressure (about 3 kg·$cm^{-2}$). After 5.5 h of reaction at room temperature, the suspension was filtered off in a column filled with Kieselguhr. The solution was evaporated, obtaining a bright yellow oil, which was left under vacuum overnight, and a pale yellow solid was obtained. After recrystallisation in toluene/pentane, colourless crystals were obtained. Yield: 491.8 mg (90%). $^1H$ NMR (500 MHz, $CDCl_3$, 298 K): $\delta$ = 2.14 (s, 6 H, $Me^5$-Pz), 2.22 (s, 6 H, $Me^3$-Pz), 3.51 (br. s, 2 H, $NH_2$), 5.87 (s, 2 H, $H^4$-Pz), 6.42 (d, $J$ = 7.8 Hz, 1 H, $H^3$-$ArNH_2$), 6.65 (d, $J$ = 7.3 Hz, 1 H, $H^6$-$ArNH_2$), 6.68 (t, $J$ = 7.6 Hz, 1 H, $H^4$-$ArNH_2$), 7.13 (t, $J$ = 7.1 Hz, 1 H, $H^5$-$ArNH_2$), 7.40 (s, 1 H, $H_\alpha$) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 298 K): $\delta$ = 11.93 (2 C, $Me^5$-Pz), 14.08 (2 C, $Me^3$-Pz), 72.58 (1 C, $C_\alpha$), 107.19 (2 C, $C^4$-Pz), 116.48 (1 C, $C^6$-$ArNH_2$), 118.63 (1 C, $C^4$-$ArNH_2$), 121.53 (1 C, $C^2$-$ArNH_2$), 127.64 (1 C, $C^3$-$ArNH_2$), 129.88 (1 C, $C^5$-$ArNH_2$), 141.43 (2 C, $C^5$-Pz), 144.49 (1 C, $C^1$-$ArNH_2$), 148.96 (2 C, $C^3$-Pz) ppm. IR (KBr): $\tilde{\nu}$ = 3395, 3312 ($NH_2$); 1554 (CN) $cm^{-1}$.

**[RuCl(benzene)(bpz*m)][BPh$_4$] (1):** [$RuCl_2(C_6H_6)(CH_3CN)$] (93 mg, 0.32 mmol) and bpz*m (65.4 mg, 0.32 mmol) were mixed in MeOH (10 mL). After stirring for 12 h, a solution of $NaBPh_4$ (200 mg, 0.6 mmol) in MeOH (10 mL) was added to the initial orange solution, changing the colour to yellow. After 30 min, the solution was partially evaporated up to 5 mL and the solid obtained was filtered off. The light yellow solid was washed once with MeOH. The product was recrystallised from 1,2-dichloroethane/hexane. Yield 210.2 mg (89%). $C_{41}H_{42}BClN_4Ru{\cdot}C_2H_4Cl_2$ (837.11): calcd. C 61.70, H 5.54, N 6.69; found C 61.41, H 5.41, N 6.94. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 298 K): $\delta$ = 11.38 (2 C, $Me^5$-Pz), 15.76 (2 C, $Me^3$-Pz), 55.67 (1 C, $C_\alpha$), 85.46 (6 C, *C*-benzene), 109.35 (2 C, $C^4$-Pz), 122.11 [4 C, $C_p$-Ph($BPh_4$)], 125.81 [8 C, $C_m$-Ph($BPh_4$)], 136.19 [8 C, $C_o$-Ph($BPh_4$)], 142.99 (2 C, $C^5$-Pz), 156.28 (2 C, $C^3$-Pz), 164.31 [q, $J_{C-^{11}B}$ = 49.4 Hz, 4 C, $C_{ipso}$-Ph($BPh_4$)] ppm. IR: $\tilde{\nu}$ = 1558 (CN) $cm^{-1}$.

**[RuCl(*p*-cymene)(bpz*m)][BPh$_4$] (2):** [$RuCl_2$(*p*-cymene)]$_2$ (128 mg, 0.21 mmol) and bpz*m (85.8 mg, 0.42 mmol) were stirred in MeOH (10 mL) for 12 h. Afterwards, a solution of MeOH (10 mL) with $NaBPh_4$ (200 mg, 0.6 mmol) was added to the initial reddish solution, obtaining a yellow suspension. The solution was partially evaporated up to 5 mL and the solid obtained was filtered off. The yellow solid was washed once with MeOH. The product was recrystallised from 1,2-dichloroethane/hexane. Yield 293.5 mg (88%). $C_{45}H_{50}BClN_4Ru{\cdot}C_2H_4Cl_2$ (893.22): calcd. C 63.20, H 6.09, N 6.27; found C 63.51, H 6.06, N 6.37. $^{13}C\{^1H\}$ NMR (125 MHz, $CDCl_3$, 298 K): $\delta$ = 11.64 (2 C, $Me^3$-Pz), 16.02 (2 C, $Me^5$-Pz), 18.72 (1 C, Me-Tol), 22.77 (2 C, Me-*i*Pr), 31.87 (1 C, *C*H-*i*Pr), 56.01 (1 C, $C_\alpha$), 81.71 (2 C, $CH^{2/2'}$-*p*-cym), 84.86 (2 C, $CH^{3/3'}$-*p*-cym), 99.74 (1 C, $C^4$-*p*-cym), 107.38 (1 C, $C^1$-*p*-cym), 109.75 (2 C, $C^4$-Pz), 122.29 [4 C, $C_p$-Ph($BPh_4$)], 125.96 [8 C, $C_m$-Ph($BPh_4$)], 136.52 [8 C, $C_o$-Ph($BPh_4$)], 143.32 (2 C, $C^5$-Pz), 156.86 (2 C, $C^3$-Pz), 164.32 [q, $J_{C-^{11}B}$ = 49.4 Hz, 4 C, $C_{ipso}$-Ph($BPh_4$)] ppm. IR: $\tilde{\nu}$ = 1560 (CN) $cm^{-1}$.

**[RuCl(benzene)(bpz*mPh)][BPh$_4$] (3):** The method was similar to that used for complex **1**. Amounts were as follows: [$RuCl_2(C_6H_6)(CH_3CN)$] (93 mg, 0.32 mmol) and bpz*m (89.7 mg, 0.32 mmol). Complex **3** was obtained as a yellowish solid. The product was recrystallised from 1,2-dichloroethane/hexane. Yield 221.5 mg (85%). $C_{47}H_{46}BClN_4ORu{\cdot}0.5C_2H_4Cl_2$ (863.73): calcd. IR (Nujol): $\tilde{\nu}$ = 1562 (CN), 3467 ($NH_2$) $cm^{-1}$.

**Hydrogen-Transfer Catalysis:** A typical procedure for the catalytic hydrogen-transfer reaction is as follows. A mixture of benzophenone (368.1 mg, 2 mmol), KOH (10 mL, 0.008 M in *i*PrOH) and the catalyst (0.004 mmol) was heated to reflux under nitrogen. At the desired reaction times, aliquots were extracted from the reaction vessel, obtaining the yields by $^1H$ NMR spectroscopy.

**X-ray Crystallography:** A summary of crystal data collection and refinement parameters for all compounds is given in Table 1. The single crystals for **7A**·$0.5C_2H_4Cl_2$ and **8B** were mounted on a glass fibre and transferred to a Bruker X8 APPEX II CCD-based diffractometer equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å). Data were integrated using the SAINT[25] program and an absorption correction was performed with the program SADABS.[26] The software package SHELXTL version 6.12[27] was used for space group determination, structure solution and refinement by full-matrix least-squares methods based on $F^2$. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were placed using a "riding model" and included in the refinement at calculated positions.

Prismatic crystals of complexes **9**, **10**·$0.5C_2H_4Cl_2$ and **12A** were selected and mounted on a Bruker SMART-CCD area diffractometer. Intensities were collected with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Lorentz polarisation and absorption corrections were made.[26] The structures were solved by direct methods, using the SHELXS computer program[28] and refined by full-matrix least-squares method with the SHELX97 computer program.[28] All hydrogen atoms were computed and refined using a riding model.

CCDC-631606 to -631610 contain the supplementary crystallographic data for complexes **7A**·$0.5C_2H_4Cl_2$, **8B**, **9**, **10**·$0.5C_2H_4Cl_2$ and **12A**. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Tables S1 and S2 contain the $^1H$ NMR spectroscopic data and the results of the catalytic tests at different times, respectively.

## Acknowledgments

Financial support from the Junta de Castilla-La Mancha-FEDER Funds (PBI-05-003) and the Spanish DGES/MCyT (CTQ2005-01430/BQU) is acknowledged.

# Ternary Complexes of Zinc(II), Cyclen and Pyridinecarboxylic Acids

**Zuzana Vargová,*[a] Jan Kotek,[b] Jakub Rudovský,[b] Jan Plutnar,[b] Robert Gyepes,[b] Petr Hermann,[b] Katarina Györyová,[a] and Ivan Lukeš*[b]**

**Keywords:** Cyclen complexes / N ligands / Stability constants / Zinc

Binary and ternary systems containing $Zn^{2+}$, cyclen and/or pyridinecarboxylic acids and amides [picolinic ($HL^1$), nicotinic ($HL^2$) and dipicolinic ($H_2L^3$) acids and nicotinamide ($L^4$)] have been investigated in solution and in the solid state. Dissociation and stability constants for the ligands and binary systems, respectively, are in accordance with literature results. Both picolinic and dipicolinic acids form stable ternary complexes with the $[Zn(cyclen)]^{2+}$ species; a weak interaction is observed for nicotinic acid and nicotinamide. The formation of ternary complexes stabilizes the products of protonation at the cyclen nitrogen atom, and these protonated complexes are found even up to pH = 7. The structures of the complexes in solution correlate well with those found in the solid state and by molecular modelling calculations. The solid-state structures of several complexes are determined. The zinc atom in the $[Zn(cyclen)(NO_3)]^+$ complex is bound in an $N_4O$ tetragonal-pyramidal environment. The nicotinic acid anion forms a bridge in the $[\{Zn(cyclen)\}_2(\mu\text{-}L^2\text{-}N,O)]^{3+}$ cation, and both $[Zn(cyclen)]^{2+}$ units exhibit tetragonal-pyramidal arrangements. An unusual coordination mode is found in the $[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O{:}N,O')]^{3+}$ cation, where the picolinic acid anion also bridges two $[Zn(cyclen)]^{2+}$ units but is coordinated monodentately through one oxygen atom to one unit ($N_4O$ tetragonal pyramid) and chelates through the other pyridine nitrogen and carboxylate oxygen atoms. Nicotinamide in the $[Zn(cyclen)(L^4\text{-}N)]^{2+}$ cation is bound to the $[Zn(cyclen)]^{2+}$ unit through the pyridine nitrogen atom in the axial position of the tetragonal pyramid. This is the first fully quantitative assessment of $Zn^{2+}$-cyclen-ligand ternary systems, and the results, namely the presence of protonated cyclen in the ternary species even at high pH, are relevant for evaluation of the $[Zn(cyclen)]^{2+}$ unit as a model complex for zinc-containing enzymes.

## Introduction

Zinc is an essential element for all forms of life and plays a critical role in various functions, both structural and catalytic, in proteins and enzymes.[1] Typically, the metal ion is coordinatively saturated by four donor atoms from amino acid side-chains of the protein when playing a structural role. On the other hand, if the functional catalytic role is examined, the ion in the active site is mostly three- or four-coordinate or, less commonly, the coordination number can also reach four, five and rarely even six, although this is always accompanied by coordination of labile ligands.[2] There are two basic mechanisms by which zinc(II) exerts its catalytic function. The first is exemplified by carbonic anhydrase (CA) and involves delivery of a metal-bound hydroxido nucleophile, which can exist at pH values where the concentration of free hydroxide ion is extremely low. The second takes advantage of the strong Lewis acid character of zinc(II) to polarize a susceptible bond for substitution,[3] and thus zinc(II) appears to be the most abundant metal centre present in phosphatases and nucleases.[4] In addition, the zinc enzymes remain a central issue in the area of molecular recognition.[5] For example, CA recognizes not only its normal substrates ($CO_2$ and $HCO_3^-$) but also substrates such as phosphoric esters, carboxylic esters, aldehydes and binds halide anions, $SCN^-$, acetate, sulfonamides, carboxamides, phenol, imidazole and alcohols as inhibitors. Up-to-date information regarding zinc(II) functions in biological systems has been collated recently.[6]

An important contribution to the detailed understanding of the catalytic activity and molecular recognition of the enzyme has been made by experimental investigations with suitable model systems. Several ligands, usually with three or four nitrogen donor atoms, have been used to mimic the rigid and stable coordination centre of the active zinc(II) part of an enzyme. Various azacycles, especially 1,4,7,10-tetraazacyclododecane (cyclen) and its derivatives, have been used to model the protein environment of carbonic anhydrase,[7,8] phosphatases,[9–11] β-lactamase,[12] flavoenzymes[13] or NADH models.[14] A flavin-$[Zn(cyclen)]^{2+}$ complex has also been used as a catalyst for the photooxidation

of methoxybenzyl alcohol.[15] Cyclen ligands modified with other functionalities in the pendant arms, such as sulfonamides, carboxamides, phenols, alcohols or phosphoric esters, are also commonly used in these studies.[5]

There are only a few examples in the literature in which interactions or reactions of an unmodified $[Zn(cyclen)]^{2+}$ complex with another molecule have been studied. In addition to the examples of carbonic anhydrase mentioned above,[7,8] this complex has also been used to investigate the interaction and hydrolysis behaviour of phosphate esters[9,16] and has been found to catalyze the hydrolysis of *N*-benzylpenicillin.[17]

Most of the papers dealing with models based on $[Zn(cyclen)]^{2+}$ complexes are oriented towards the molecular recognition of nucleobases. These biomimetic studies, which have been summarised recently,[18,19] show that the $[Zn(cyclen)]^{2+}$ complex can be used as a novel receptor for imide-containing nucleobases such as thymine (T) and uracil (U) in aqueous solution and at physiological pH. Coordination of a nucleobase through a $Zn^{2+}$–N ("imide") bond is enforced by interaction of the "urea" carbonyl groups with the hydrogen atoms of the ring NH groups in the complementary positions. The dissociation constants, $K_d$, determined for ternary complexes of zinc(II), substituted cyclen and T or U are of the order of 10 μM, and for analogous systems containing bis($[Zn(cyclen)]^{2+}$) or tris($[Zn(cyclen)]^{2+}$) complexes (mononuclear complex units linked covalently through *p*-xylene or mesitylene spacers) with corresponding di- and trinucleotides (TpTp or TpTpTp) are even in a nanomolar range. In addition, bis- or tris($[Zn(cyclen)]^{2+}$) complexes connected through an imidazole group[20] and the formation of assembled three-dimensional supramolecules have also been studied.[21–25] Recently, a polymer containing $[Zn(cyclen)]^{2+}$ units was synthesised and investigated as a creatine receptor.[26]

As mentioned above, in contrast to the large number of papers dealing with modified cyclen complexes, only a few works have focused on the complexation and formation of ternary cyclen complexes,[7,8] which would be crucial for modelling the complexation at the active centre of the enzymes. Thus, in this paper we report a detailed investigation of the formation of ternary complexes of $[Zn(cyclen)]^{2+}$ and picolinic ($HL^1$), nicotinic ($HL^2$), and dipicolinic ($H_2L^3$) acids or nicotinamide ($L^4$) as the approaching ligands. This series helps to explain the complexing properties of the $[Zn(cyclen)]^{2+}$ species towards aromatic heterocycles and/or carboxylate coordination, their preference, and possible interactions of non-coordinated groups with the cyclen skeleton.

## Results and Discussion

### Preparation of the Complexes $[Zn(cyclen)(NO_3)]ClO_4$, $[\{Zn(cyclen)\}_2(\mu\text{-}L^2\text{-}N,O)](ClO_4)_3$, $[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O:N,O')](ClO_4)_3\cdot H_2O$, $[Zn(cyclen)(L^4\text{-}N)](ClO_4)_2$ and Their X-ray Crystal Structures

To assess the coordination modes in the ternary complexes formed with $Zn^{2+}$, cyclen and pyridinecarboxylic acids or nicotinamide in solution we tried to prepare single crystals suitable for X-ray analysis by slow evaporation of the solvent from mixed solutions of $Zn^{2+}$, cyclen and the corresponding pyridine-based ligand in an equimolar ratio at a concentration of about 0.1–0.2 M at various pH values. We succeeded in several cases, and the crystal structures of four crystalline materials were determined. The bond lengths found in the coordination spheres of the zinc(II) complexes and the deviations from planarity observed for the cyclen nitrogen atoms are given in Table 1. Further bond lengths and angles are listed in Table S1 (see Supporting Information).

Table 1. Selected bond lengths [Å] found in the crystal structures.

First, we obtained a single crystal of the parent $Zn^{2+}$-cyclen complex. $[Zn(cyclen)(NO_3)]ClO_4$ contains a five-coordinate $Zn^{2+}$ ion (Figure 1) with four nitrogen atoms of the macrocycle and one oxygen atom of nitrate ion coordinated to the metal centre to form a slightly distorted tetragonal pyramid ($\tau$ = 0.097; this parameter should be 1.000 for an ideal trigonal bipyramid and 0.000 for an ideal tetragonal pyramid[27]). The zinc atom is placed above the plane containing the four nitrogen atoms of cyclen (0.750 Å). All four five-membered chelate rings of cyclen have the same conformation (δδδδ in the independent unit), as is usual in similar complexes. The bond lengths and angles around the $Zn^{2+}$ ion (Tables 1 and S1) are as expected.

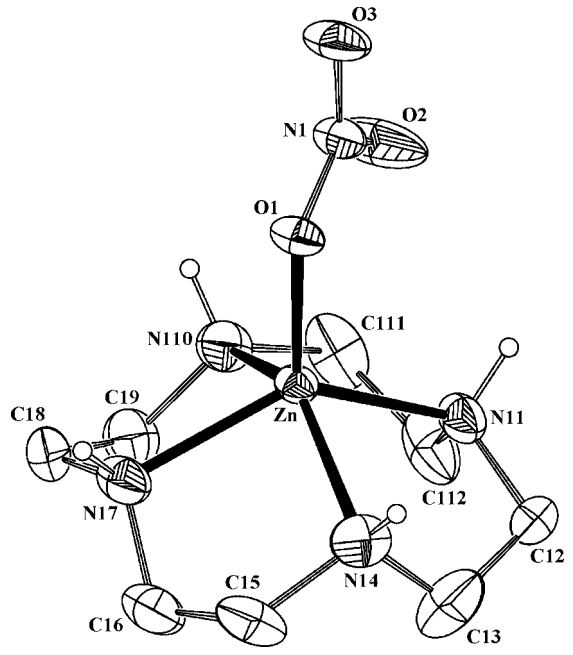

Figure 1. ORTEP drawing of the $[Zn(cyclen)(NO_3)]^+$ cation found in the structure of $[Zn(cyclen)(NO_3)](ClO_4)$. Hydrogen atoms bound to carbon atoms have been omitted for clarity.

$[\{Zn(cyclen)\}_2(\mu\text{-}L^2\text{-}N,O)](ClO_4)_3$ contains two $[Zn(cyclen)]^{2+}$ complex subunits bridged by nicotinate (Figure 2). All five-membered chelate rings of both cyclen ligands show the same conformation (λλλλ for both subunits in the independent unit). The fifth coordination sites are occupied by a pyridine nitrogen atom (N1–Zn1) and a carboxylate oxygen atom (O1–Zn2) to form slightly distorted tetragonal pyramids [the $\tau$ values for the coordination polyhedrons $Zn1(N_5)$ and $Zn2(N_4O)$ are 0.015 and 0.002, respectively]. The planar pyridine ring of the nicotinate anion is perpendicular to the cyclen plane formed by N11, N14, N17 and N110. The distances of Zn1 and Zn2 from the tetragonal basal planes formed by the nitrogen atoms of cyclen are 0.793 and 0.781 Å, respectively; these values are slightly longer than that observed in $[Zn(cyclen)(NO_3)]ClO_4$. The apical Zn1–N1 and Zn2–O1 bond lengths (2.026 and 1.924 Å, respectively) are shorter than the average Zn–N length (2.135 Å) in the basal plane of the cyclen units. Nevertheless, the bond lengths fall into the expected range for such complexes (Tables 1 and S1).[28]

$[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O{:}N,O')](ClO_4)_3{\cdot}H_2O$ also contains two independent zinc atoms with two different coordination geometries, namely a distorted tetragonal bipyramid $[Zn1(N_5O)$ coordination sphere] and a slightly distorted tetragonal pyramid [$Zn2(N_4O)$ coordination sphere with a $\tau$ value of 0.002; Figure 3]. The distance of Zn2 from the tetragonal basal plane formed by the nitrogen atoms of the cyclen ring (0.790 Å) is very close to that found in the previous structure; the picolinate oxygen atom O2 is coordinated in the apical position. The central Zn1 atom is surrounded by four nitrogen atoms of cyclen, and the coordination sphere is completed by *cis* coordination of the picolinate nitrogen atom N1 and oxygen atom O1. The atoms form an axially elongated tetragonal bipyramid, with the

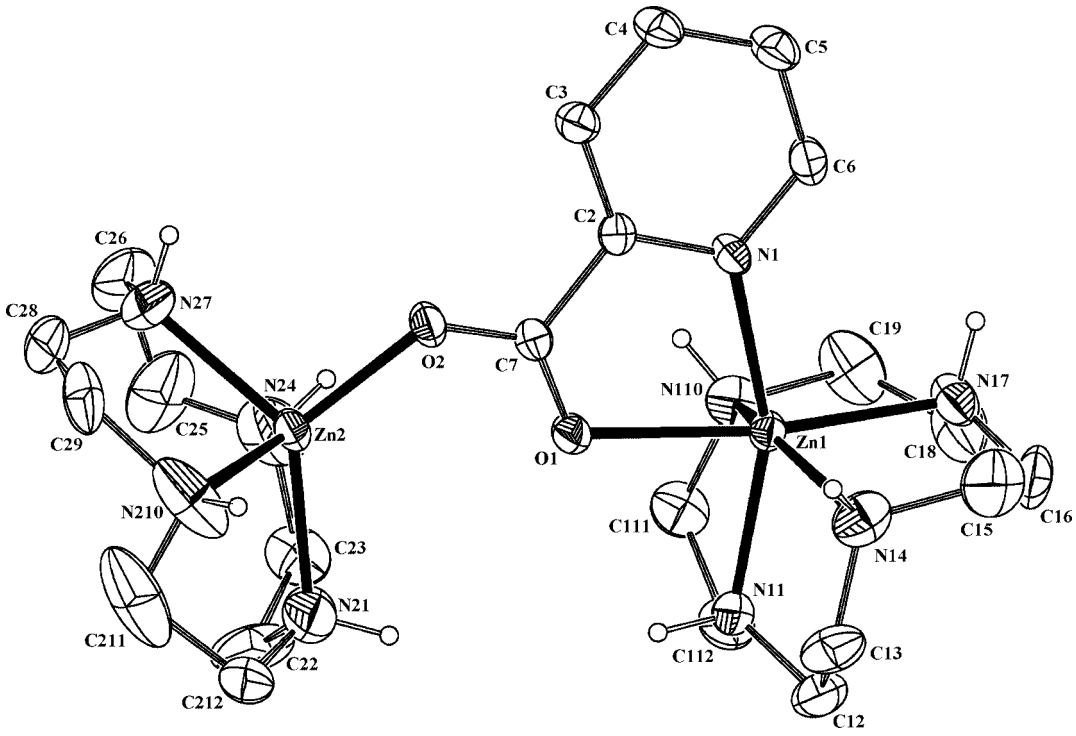

Figure 3. ORTEP drawing of the $[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O{:}N,O')]^{3+}$ cation found in the structure of $[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O{:}N,O')](ClO_4)_3\cdot H_2O$. Hydrogen atoms bound to carbon atoms have been omitted for clarity.

equatorial plane formed by three cyclen nitrogen atoms N11, N17 and N110 together with O1 from picolinate. However, the bond angles show large deviations from the corresponding ideal values. The coordination spheres of the Zn1 and Zn2 atoms contain different conformations of the cyclen. In the Zn2 sphere a λ conformation is observed for all four five-membered chelate rings formed due to coordination of the nitrogen atoms, whereas the nitrogen atoms of cyclen coordinated to Zn1 do not form a plane as in the other structures and the chelate rings adopt δλδλ conformations (see Figure S2 in the Supporting Information). Selected geometric parameters for this complex are listed in Table 1.

$[Zn(cyclen)(L^4\text{-}N)](ClO_4)_2$ contains monomeric units with a five-coordinate zinc atom (Figure 4). Four nitrogen atoms of the macrocycle and the nitrogen atom of nicotinamide are coordinated to the zinc atom in an approximately tetragonal-pyramidal sphere ($\tau = 0.017$). All four five-membered chelate rings of cyclen have the same conformation (λλλλ in the independent unit). Four cyclen nitrogen atoms N11, N14, N17 and N110 form a plane with a similar distance to the zinc atom as found in the previous structures (0.794 Å). The pyridine ring of nicotinamide is perpendicular to this plane. Selected geometric parameters are listed in Tables 1 and S1.

Two structural motifs are observed in the compounds studied. Thus, if the approaching ligand is monodentately coordinated to the $[Zn(cyclen)]^{2+}$ unit, the central $Zn^{2+}$ ion is placed above the plane formed by the four nitrogen atoms of cyclen and the conformation of all four five-membered chelate rings is the same, either all-δ or all-λ. The distance

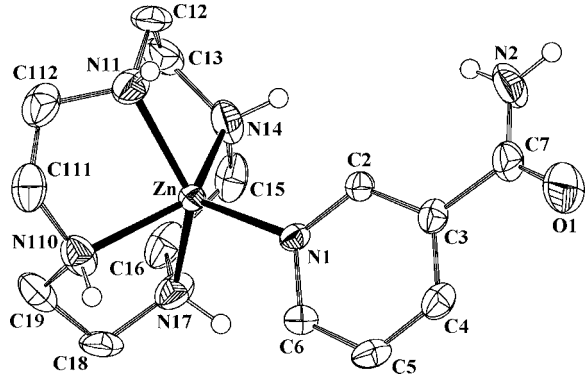

Figure 4. ORTEP drawing of the $[Zn(cyclen)(L^4\text{-}N)]^{2+}$ cation found in the structure of $[Zn(cyclen)(L^4\text{-}N)](ClO_4)_2$. Hydrogen atoms bound to carbon atoms have been omitted for clarity.

from the $N_4$ plane is 0.75 Å for $[Zn(cyclen)(NO_3)]ClO_4$ and about 0.79 Å for the ternary complexes, which means that it falls into the range 0.75–0.80 Å found in the CCDC[28,29] for $Zn^{2+}$ complexes of cyclen derivatives with no coordinated pendant. If the pendant group of cyclen is coordinated, however, the $N_4$–Zn distance is usually longer. Formation of an $N_4$ plane containing the cyclen nitrogen atoms has also been observed in structures with higher coordination numbers, such as in the $Zn^{2+}$ complexes with *N*,*N*′,*N*′′,*N*′′′-tetrakis(carbamoylmethyl)cyclen (dotam),[30] which has a coordination number of six, or with *N*,*N*′,*N*′′-tris(pyrazol-1-ylmethyl)cyclen,[31] which has a coordination number of seven. When the approaching ligand is bidentately coordinated to form a chelate, as found in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O{:}N,O')](ClO_4)_3\cdot H_2O$ (the coordination number of $Zn^{2+}$ is six), this results in a different δλδλ conformation of cyclen. This conformation is relatively rare among $Zn^{2+}$-cyclen complexes and is found, for example, in $[Zn(H_2dota)]$ ($H_4dota$ = 1,4,7,10-tetraazacyclododecane-1,4,7,10-tetraacetic acid)[32] and $[Zn(cyclen\text{-}R\text{-}O)(H_2O)]^{2+}$ (R = $CH_2COC_6H_4Br$-4).[33]

Pyridinecarboxylic acids also show a tendency to bridge the $[Zn(cyclen)]^{2+}$ units in dinuclear complexes. A similar bridging motif through another ligand has also been found for carbonate,[34] phosphate[35] and imidazole.[20] Crystallisation of the bridged dinuclear complexes from equimolar solutions is surprising but is probably due to their lower solubility due to the relatively hydrophobic surrounding sphere formed by the cyclen ligands.

## Potentiometric Study

To prevent misunderstandings and to clarify the following text, both the protonation and stability constants are concentration constants and are defined by the general term:

$$\beta_{pqrs} = [H_p(cyclen)_q(L^n)_rZn_s]/[H]^p \times [cyclen]^q \times [L^n]^r \times [Zn]^s$$

This definition will be used for proton-ligand speciation and for all binary systems ($Zn^{2+}$-cyclen and $Zn^{2+}$-$H_xL^n$) as well as for the ternary systems. The relevant stoichiometric coefficient for the missing component is taken to be zero. In this formalism, each species can be represented by the four-digit code *pqrs*; for example, the $[Zn(cyclen)]^{2+}$ complex can be viewed as 0101, and $[Zn(Hcyclen)(HL^1)]^{2+}$ as 2111. The charges are omitted from the general formulae for the sake of clarity.

### *Protonation Constants of $HL^1$, $HL^2$, $H_2L^3$ and $L^4$ and Their Stability Constants with $Zn^{2+}$ Ions*

Although the protonation constants of pyridinecarboxylic acids and nicotinamide have already been reported and summarised,[36] we determined them under our experimental conditions (25 °C and $I$ = 0.1 M $KNO_3$) by potentiometric titration. All values are listed in Table 2 together with the literature data for comparison. The $\log\beta_{1010}$ values correspond to the protonation of nitrogen atoms of the pyridine ring and the difference $\log\beta_{2010} - \log\beta_{1010}$ to the dissociation ($\log K_A$) of a proton from the carboxylic group.[36] In addition to the published protonation/dissociation constants, we were able to determine the $\log\beta_{3010}$ value for dipicolinic acid associated with protonation of the second carboxylate group.

The pyridine derivatives form complexes with a $Zn^{2+}$/$H_xL^n$ molar ratio of 1:1 and 1:2 in the presence of $Zn^{2+}$; $HL^1$ also forms a complex with a 1:3 ratio. The species determined for each system together with their stability constants and literature values are listed in Table 2; representative distribution diagrams are shown in Figure S3 (see the Supporting Information). It is clear that there are no significant differences between our data and the literature data for the systems with picolinic and dipicolinic acids.[36] The slight differences found for the 1:2 and 1:3 ratios are probably caused by variants in ionic strength and electrolyte. In addition, these values are a little higher than those expected for these ratios from the values determined for the 1:1 (or 1:2) species, although they still lie in the expected range of 3σ variance. The formation of a zinc(II) hydroxide precipitate was observed at pH > 8.0 in both systems. Both picolinic and dipicolinic acids form chelates through the nitrogen atom and the carboxylate group (see below) in the pH range 2–7, which means that these complexes are more stable than those found for nicotinic acid and nicotinamide. Nicotinic acid forms very weak complexes with a low abundance in aqueous solution, and in acid solution the main species seems to be $[Zn(HL^2)]^{2+}$, probably with a protonated pyridine nitrogen atom and coordinated through the carboxylate group and, in the neutral region, $[Zn(L^2)]^+$ species with a coordinated nitrogen atom. The abundance of these species is only about 20% (Figure S3). The uppermost estimate of $\log\beta_{0011}$ for the $[Zn(L^4)]^{2+}$ complex is one, which corresponds to the value found in the literature.[36]

### *Protonation Constants of Cyclen and Stability Constants of Its $Zn^{2+}$ Complexes*

The protonation constants of cyclen are given in Table 3. From the best fits of our experimental data, it appears that

binding of the third and fourth protons to the cyclen molecule occurs simultaneously. However, the value of $\log\beta_{4100} - \log\beta_{2100}$ (2.34) corresponds well with the sum of the $pK_A$ values (1.4 + 0.7 = 2.1) reported in the literature.[36] The out-of-cell method had to be used for potentiometric titrations of the $Zn^{2+}$-cyclen system due to the slow rate of the complex formation. The dominant species is $[Zn(cyclen)(H_2O)]^{2+}$, whose deprotonation starts at pH > 6.0, and the hydroxido complex $[Zn(cyclen)(OH)]^{+}$ is the main species in solution at pH = 8. The determined stability constants together with the literature values are also listed in Table 3 and the distribution diagram is shown in Figure S4 (see the Supporting Information).

### *Stability Constants in Ternary Systems*

The potentiometric titrations were performed by the out-of-cell method, as described in the Experimental Section. The determined stability constants are listed in Table 4 and the calculated distribution diagrams are shown in Figure 5A–C (except for the nicotinamide system, where the very low complex stabilities result in a very low abundance of the complex species). The distribution diagrams indicate the presence of binary $[Zn(L^n)]$ and $[Zn(cyclen)]^{2+}$ species. The abundance of the binary $[Zn(L^n)]$ species corresponds to their stability constant values, which are higher for the chelating ligands (picolinic and dipicolinic acids) than for nicotinic acid. The distribution of $Zn^{2+}$ between the binary and ternary species is evident from Figure 5D–F. The total abundance of ternary $[H_{0-2}(cyclen)(L^n)Zn]$ complexes in the systems with picolinic and dipicolinic acids increases with pH up to 70% in the neutral region as the abundance of the binary species decreases. The total abundance of $[H_{0-2}(cyclen)(L^2)Zn]$ in the nicotinic acid system is only 30%. The distributions in the binary systems are also included in Figure 5D–F for comparison. The nicotinamide system is different, and only the values of stability constants for the monoprotonated and non-protonated complexes were estimated here. Its value is close to the lower limit of the used method, so the interaction between $[Zn(cyclen)(H_2O)]^{2+}$ and nicotinamide is very weak, if any.

Formation of the 2111, 1111 and 0111 ternary complexes was observed in the systems with picolinic, dipicolinic and nicotinic acids. The acidic and basic groups of both ligands offer several possible protonation schemes and their corresponding dissociation constants. Comparison of the $pK_A$ values determined for the ternary systems with those found for the acids indicates the following scheme: formation of the diprotonated 2111 species starts at pH ≈ 2. These species deprotonate to the 1111 species with a $pK_A(2111)$ of about 3.5. These values are higher than the $pK_A$ values of carboxylic acid groups but lower than those corresponding to the pyridine nitrogen atoms. The proton is released from the pyridine nitrogen atom of the diprotonated 2111 species, and the dissociation constants decrease (compared with the free ligands), probably due to simultaneous coordination to $Zn^{2+}$. However, $pK_A(1111)$ is even higher than $pK_A$ of the protonated nitrogen atom of the pyridine ligands themselves (5–7), and thus this proton should be released from the cyclen amino group. The monoprotonated species can therefore be viewed as $[Zn(Hcyclen)(L^n)]$ and the diprotonated species as $[Zn(Hcyclen)(HL^n)]$; other microspecies with protonated carboxylic and pyridine functions could also be present.

The stability constants of the $[Zn(Hcyclen)(HL^n)]$, $[Zn(Hcyclen)(L^n)]$ and $[Zn(cyclen)(L^n)]$ species decrease in the order dipicolinic > picolinic > nicotinic acids (Table 4), in agreement with the stability constants of the binary systems (Table 2). The contribution of the acids to the stability of the ternary complexes {expressed as the equilibrium constant for the reaction $[Zn(cyclen)]^{2+} + (L^n)^{x-} \rightleftharpoons [Zn(cyclen)(L^n)]^{(2-x)+}$; $\log\beta_{0111} - \log\beta_{0101}$} is obviously lower than that of the $[Zn(L^n)]$ species for picolinic and dipicolinic acids. As these constants have a similar value to that corresponding to the formation of the $[Zn(cyclen)(imidazole)]^{2+}$ species ($\log K$ = 3.0),[37] which contains the more basic imidazole as a co-ligand, an extra stabilisation due to formation of the chelate ring should be assumed. These values are low (at the limit of potentiometry) in the case of nicotinic acid and nicotinamide and are therefore roughly comparable (see Table 4).

A structural motif in which the pyridinecarboxylic acid bridges two $[Zn(cyclen)]^{2+}$ subunits is observed in the complexes isolated in the solid state. All attempts to include a species of the $[\{Zn(cyclen)\}_2L^n]$ type into the chemical model to fit the potentiometric data failed. Thus, the presence of these species in solution is expected to be negligible; they crystallise in preference because of their low solubility.

### $^1$H NMR Study

To confirm the complexation behaviour suggested in the potentiometric section above, we monitored the changes in the $^1$H NMR spectra of a cyclen solution and its mixtures with $Zn^{2+}$. In the NMR spectra of cyclen itself, one peak of the $CH_2$ groups changes its position from $\delta$ = 3.03 ppm at pH = 1.9 to $\delta$ = 2.98 (pH = 9.0) and 2.66 ppm (pH = 12.2). The observed changes with pH correspond to the determined protonation constants.

A peak with a chemical shift close to that of free cyclen is observed for the system with $Zn^{2+}$ at pH ≈ 2, therefore no complexation is expected (Figure 6A). At pH > 2.55, a set of peaks attributable to the $[Zn(cyclen)(H_2O)]^{2+}$ species, namely two multiplets at $\delta$ = 2.65–2.87 ppm ($CH_2$ groups) and a broad singlet at $\delta$ = 3.67 ppm (NH groups), appear in addition to the signal for free cyclen. One can therefore conclude that the complex formed is rigid and that free and complexed ligand do not mutually exchange on the NMR timescale. The signal attributed to free cyclen disappears at pH > 5.0, which corresponds to full complexation of $Zn^{2+}$. The NMR spectra also indicate deprotonation of the coordinated water. The formation of the $[Zn(cyclen)(OH)]^{+}$ hydroxido complex does not influence the multiplets of the $CH_2$ groups, although the position of the signal corresponding to the NH proton is shifted from $\delta \approx 3.6$ ppm at pH = 6.99 to $\delta \approx 3.3$ ppm at pH = 8.97. The changes ob-

served in the NMR spectra correspond well to the speciation determined by potentiometry.

The changes in the cyclen region of the $^1$H NMR spectra of the ternary complexes as the pH is varied are also shown in Figure 6B for the system with picolinic acid. The trends in the spectra of the other ternary systems are similar. As is the case with the binary $[Zn(cyclen)]^{2+}$ species, the multiplets found close to $\delta$ = 2.8 ppm for all ternary systems can be assigned to deprotonated species of the type [Zn(cyclen)($L^n$)]. On the other hand, a singlet close to $\delta$ = 3 ppm is found in the ternary systems and is present even up to pH ≈ 6 for picolinic acid and 7 for dipicolinic acid; its position is slightly shifted at pH ≈ 5 from $\delta$ = 3.02 (free cyclen) to 2.95 ppm. Distribution diagrams B and E in Figure 6 show that about 80% of cyclen should be taken up in the complexes and that the protonated species [Zn(Hcyclen)($HL^n$)] and [Zn(Hcyclen)($L^n$)] should also be present at this pH along with the [Zn(cyclen)($L^n$)] species mentioned above. In contrast to [Zn(cyclen)($L^n$)], however, these protonated species are not likely to be rigid. Thus, the signal

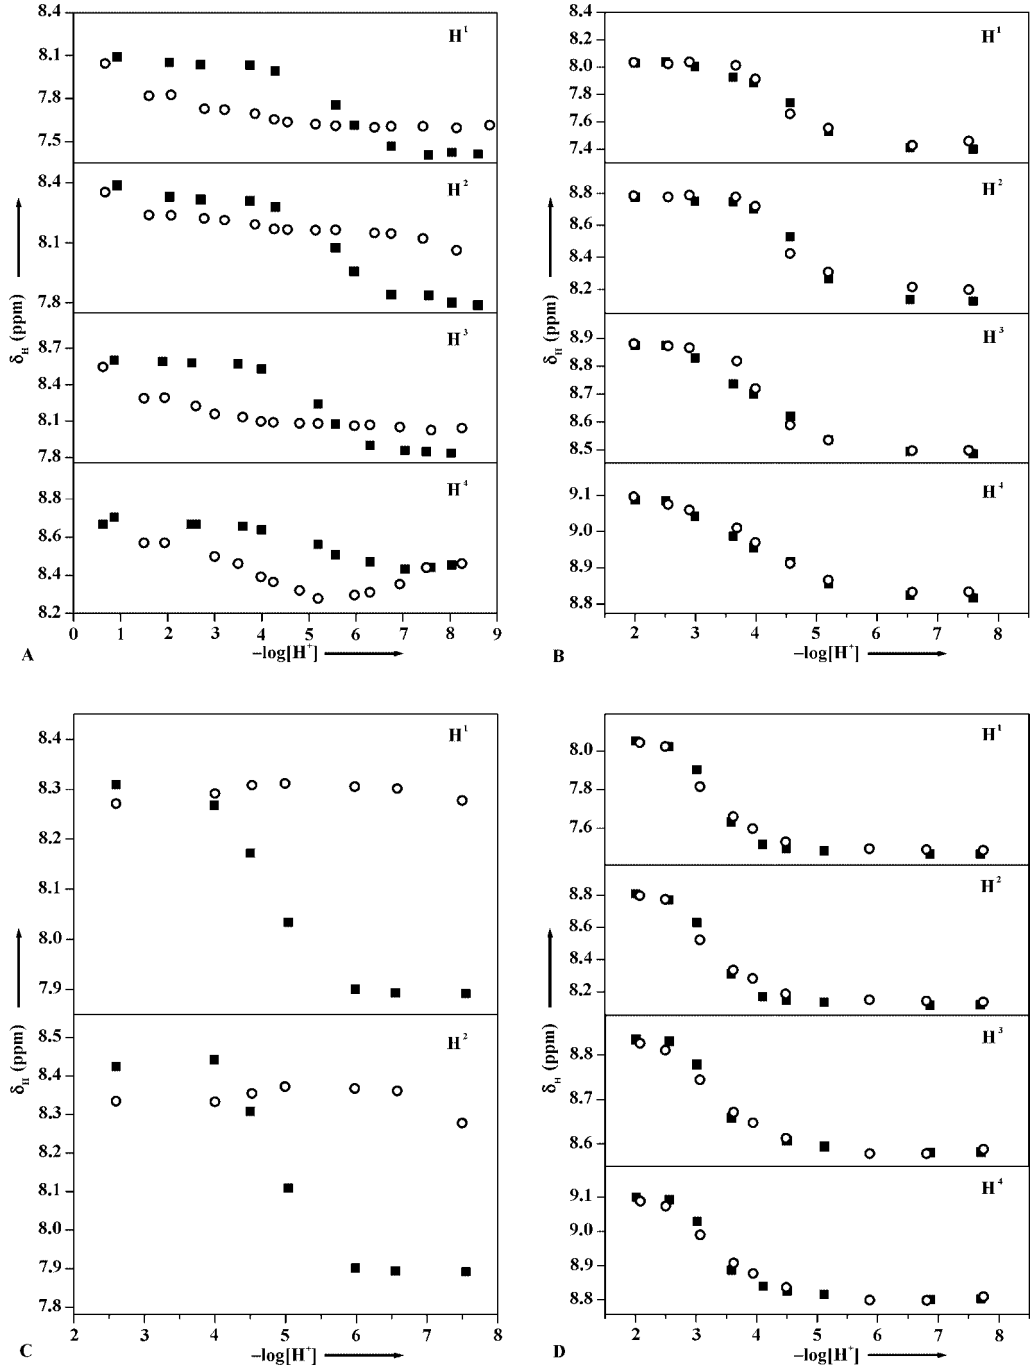

Figure 8. Comparison of $^1$H NMR chemical shifts of $HL^1$ (A), $HL^2$ (B), $H_2L^3$ (C) and $L^4$ (D) as a function of –log[$H^+$] for the free ligands (filled squares) and for the ligands in the ternary mixtures with $[Zn(cyclen)]^{2+}$ (open circles; see Figure 9 for assignment).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

at $\delta$ = 2.95 ppm can be attributed to free cyclen and the protonated ternary [Zn(Hcyclen)(HL$^n$)] and [Zn(Hcyclen)(L$^n$)] complexes in fast chemical exchange. This assignment corresponds with the integration of the $^1$H NMR signals, as the relative intensities of the singlet at $\delta \approx$ 2.95 ppm {suggested for species protonated at the cyclen amino groups, such as free cyclen and [Zn(Hcyclen)(HL$^n$)] and [Zn(Hcyclen)(L$^n$)] complexes} and the signals of the deprotonated ternary complex {[Zn(cyclen)(L$^n$)], multiplets at $\delta \approx$ 2.8 ppm} nicely correlate with the speciation suggested by potentiometry (Figure 7). The signal at $\delta$ = 2.95 ppm also appears in the spectrum after addition of picolinic acid to a solution of [Zn(cyclen)]$^{2+}$ at pH ≈ 6.

The formation of ternary complexes with pyridine ligands bound in the axial position is also evident from a small but distinct change of the position of the amine proton signal at $\delta \approx$ 3.5 ppm. Unlike to the binary Zn$^{2+}$-cyclen system, where $\delta_H$(NH) starts to change with the formation of the hydroxido complex (at pH > 7), in the ternary systems the amine proton signal (Figure 6) moves from pH ≈ 4 due to formation of the deprotonated ternary species (Figure 7). The chemical shift of the amine protons seems to be sensitive to the replacement of the water molecule in the axial position with a hydroxide anion and/or a pyridine ligand.

The changes in the aromatic region of the $^1$H NMR spectra of both Zn$^{2+}$-cyclen-H$_x$L$^n$ systems and free ligands H$_x$L$^n$ as the pH changes are plotted in Figure 8. Assignment of the protons is shown in Figure 9. It is clear from the plots of the free acids that distinct breaks of the chemical shifts correspond to deprotonation of the pyridine nitrogen atom. The estimated p$K_A$ values for this reaction correspond to those determined from potentiometry (see Table 2). Deprotonation of the carboxylic groups causes only small changes of the spectra.

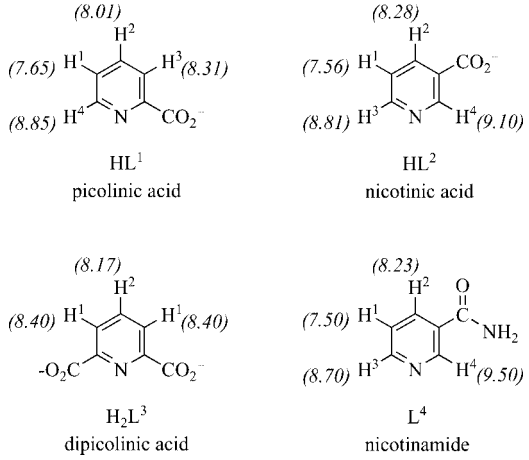

Figure 9. Assignment of the aromatic hydrogen atoms of HL$^1$, HL$^2$, H$_2$L$^3$ and L$^4$; $^1$H NMR chemical shifts for the protons (in ppm) in the free ligands are given in parentheses.

The plots of signals of the free ligands and the ligands in the ternary systems with nicotinic acid and nicotinamide are quite similar. This similarity indicates that deprotonation of the nitrogen atom is not significantly influenced by complexation and therefore that the interactions of both the ligands with [Zn(cyclen)]$^{2+}$ and in the acid region with free Zn$^{2+}$ are weak.

A different situation results from an analogous comparison of the systems with picolinic or dipicolinic acids. The chemical-shift changes of of free picolinic acid and its ternary system point to two deprotonation steps and simultaneous coordination: one in the pH range 1–2 and the other at pH = 3–5. The observed shapes of the $\delta_H$ vs. pH plots indicate that picolinic acid coordinates in the acid region through the carboxylic group whereas in the pH region 3–5 it forms a chelate through the carboxylate group and the nitrogen atom. This is especially evident from the signal of the H$^4$ proton, which is strongly influenced by the deprotonation of the pyridine nitrogen atom. In this case, the change in the signal position of the free acid and the ligand in the ternary system in the acid region is significant. For dipicolinic acid, the $\delta_H$ vs. pH plot indicates a similarity in the region of pH = 2–4 and, as above, the shape also points to the formation of a chelate. Thus, in both systems Zn$^{2+}$ is hexacoordinate in the [Zn(cyclen)(L$^n$)] species due to the bidentate coordination of the pyridinecarboxylic acids and tetradentate coordination of cyclen.

## Molecular Modelling

The minimal total energies, $E_{min}$, of both protonated and non-protonated [Zn(Hcyclen)(L$^n$)] and [Zn(cyclen)(L$^n$)] species were calculated to estimate an alternative Zn$^{2+}$ coordination by nitrogen or oxygen atoms and also to compare the energies of the protonated and non-protonated ternary complexes (see Table 5). As we concluded from the NMR results, monodentate coordination is found for nicotinic acid and nicotinamide and chelate formation for picolinic and dipicolinic acids. These coordination modes were therefore considered. The coordination sphere was completed with a molecule of water to give a coordination number of five where necessary.

Table 5. Minimised energies calculated for the ternary complexes.

| Species | $E_{min}$ [kJ mol$^{-1}$] Coordination of (L$^n$)$^{x-}$ through | | |
|---|---|---|---|
| | pyridine | oxygen | chelate |

| [Zn(cyclen)(L$^3$)] | | | 58.0 |
| [Zn(Hcyclen)(L$^3$)]$^{+}$ | | | 53.8 |

The $E_{min}$ values found for [Zn(Hcyclen)(H$_2$O)(L$^2$)]$^{2+}$ and [Zn(Hcyclen)(H$_2$O)(L$^4$)]$^{3+}$ are higher than those of [Zn(cyclen)(L$^2$)]$^{+}$ and [Zn(cyclen)(L$^4$)]$^{2+}$. As expected, species with fully coordinated cyclen are more stable than those in which one nitrogen atom is protonated (and non-coordi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nated). Both protonated species prefer to coordinate through the carbonyl oxygen atom rather than through the pyridine nitrogen atom. On the other hand, the $E_{min}$ values of the $[Zn(cyclen)(L^2)]^+$ and $[Zn(cyclen)(L^4)]^{2+}$ are virtually the same for both coordination modes, therefore an equilibrium between interactions through nitrogen and oxygen atoms is assumed in these species. The species $[Zn(Hcyclen)(H_2O)(L^2)]^{2+}$ and $[Zn(Hcyclen)(H_2O)(L^4)]^{3+}$ are present in acid solution (pH ≈ 3–4). There are no significant differences in the chemical shifts of the aromatic proton signals between the free ligands and the ligands in the ternary mixtures in this region, which indicates only a weak interaction between $[Zn(cyclen)]^{2+}$ and $HL^2$ or $L^4$.

As mentioned above, the formation of chelates for both $(L^1)^-$ and $(L^3)^{2-}$ is assumed in both protonated ($[Zn(Hcyclen)(L^1)]^{2+}$ and $[Zn(Hcyclen)(L^3)]^+$) and deprotonated ($[Zn(cyclen)(L^1)]^+$ and $[Zn(cyclen)(L^3)]$) species, and these types were included in our treatment. In contrast to the systems with nicotinic acid and nicotinamide, the values of $E_{min}$ in systems containing picolinic and dipicolinic acids are lower for the protonated complexes than for the deprotonated species. This corresponds to NMR titrations in which the presence of the protonated species was confirmed even at pH ≈ 7.

These results support the potentiometric conclusions, which suggest that the formation of an additional chelate in the $[Zn(cyclen)]^{2+}$ moiety destabilizes the tetradentate coordination of cyclen. Thus, the $Zn^{2+}$ complexes with coordination number six seem to be less stable than those with coordination number five.

In addition, we searched for intramolecular hydrogen bonds between the cyclen amino group and the carboxylate groups of the coordinated acids similar to those found in the $Zn^{2+}$-cyclen-thymine system.[38] The only interaction found was in the $[Zn(cyclen)(L^3)]$ species, with an estimated $H_{amine}\cdots O_{carboxylate}$ distance of around 2.16 Å (which corresponds to a weak hydrogen bond).

## Conclusions

The central $Zn^{2+}$ ion in the $[Zn(cyclen)(L^n)]$ complexes of nicotinic acid or nicotinamide is pentacoordinate in the solid state. This corresponds to the known structural motif of analogous complexes containing the $[Zn(cyclen)]^{2+}$ fragment. Picolinic acid forms a $[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O{:}N,O')]^{3+}$ cation in the solid state, where one zinc atom is pentacoordinate and the other hexacoordinate. A hexacoordinate motif has not yet been observed for the $[Zn(cyclen)]^{2+}$ fragment and is present in only a few complexes with *N*-substituted cyclen derivatives.

The NMR results in solution indicate that $Zn^{2+}$ is also hexacoordinate in the $[Zn(cyclen)(L^n)]$ species with picolinic and dipicolinic acids, and protonated $[Zn(Hcyclen)(HL^n)]$ and $[Zn(Hcyclen)(L^n)]$ species have also been identified. The cyclen ligand in these species should be protonated and only tridentate coordination is assumed from a comparison of $pK_A$ values; the coordination number of the central ion should therefore be five. Unfortunately, all attempts to prepare crystals of the protonated species to confirm this hypothesis failed.

The difference between the stability constants of $[Zn(cyclen)]^{2+}$ and $[Zn(L^{1,3})]$ is 9–10 orders of magnitude and between $[Zn(cyclen)]^{2+}$ and $[Zn(L^2)]^+$ 13 orders of magnitude (Tables 2 and 3). When comparing the stability constants of the binary systems, it is surprising that coordination of $H_xL^n$ to $[Zn(cyclen)]^{2+}$ causes the protonation of cyclen in the $[Zn(Hcyclen)(HL^n)]$ and $[Zn(Hcyclen)(L^n)]$ species even though the $[Zn(Hcyclen)]^+$ ion has not been identified in the binary system. This comparison suggests the preference for a coordination number of five in $Zn^{2+}$ complexes. This corresponds to Hancock's conclusion based on a comparison of the binding properties of $[Zn(cyclen)]^{2+}$ and [Zn(1,5,9-triazacyclododecane)]$^{2+}$ complexes.[39] The structures of the known zinc enzymes[6] also indicate the preference of $Zn^{2+}$ to form only three coordination bonds when anchored in the catalytic site of proteins. From this point of view, the [Zn(1,5,9-triazacyclododecane)]$^{2+}$ complex would be more convenient for modelling the zinc enzymes. On the other hand, the observed protonation of the $[Zn(cyclen)]^{2+}$ fragment could be utilized to model hydrolases in which one basic site is required. In addition, the affinity of $[Zn(cyclen)]^{2+}$ for picolinic and dipicolinic acids indicates potential inhibition properties of their derivatives for zinc enzymes. Generally, the possibility of protonating cyclen in its $Zn^{2+}$ complexes should be taken into account when considering the $[Zn(cyclen)]^{2+}$ fragment as a model for the above enzymes.

## Experimental Section

**General:** The pyridine derivatives were purchased from Fluka and recrystallised from water before use. Cyclen was obtained from Strem and purified by vacuum sublimation for potentiometric measurements. Elemental analyses were performed at the Department of Organic Chemistry, P. J. Šafárik University, Košice. The zinc content was determined by complexometric titration with $Na_2H_2$edta after sample mineralisation. The water used in physicochemical measurements was purified using the Milli-Q System (Millipore). $Zn(ClO_4)_2\cdot 6H_2O$ and $Zn(NO_3)_2\cdot 6H_2O$ (Lachema) were recrystallised from slightly acidified water. The other chemicals were of analytical purity.

### Preparation of the Zinc(II) Complexes

**$[Zn(cyclen)(NO_3)]ClO_4$:** A solution of cyclen (345 mg, 2.00 mmol) in water (20 mL) was acidified with dilute $HNO_3$ [378 mg of concentrated acid (6.00 mmol) in 20 mL of water]. An aqueous solution (20 mL) of zinc perchlorate hexahydrate (745 mg, 2.00 mmol) was then added, and the pH was adjusted with 1 M NaOH to 5.9. The mixture was allowed to stand for 24 h and then an equal volume of ethanol was added. Colourless crystals were obtained after a few days. Yield: 0.55 g (69%). $C_8H_{20}ClN_5O_7Zn$ (399.11): calcd. C 24.07, H 5.05, N 17.55, Zn 16.38; found C 20.38, H 4.42, N 13.52, Zn 17.85.

**$[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}N{:}O,O')](ClO_4)_3\cdot H_2O$:** Zinc perchlorate hexahydrate (172 mg, 0.462 mmol) in water (5 mL) was slowly added to an aqueous solution (5 mL) of cyclen (80 mg, 0.462 mmol). After standing for 24 h, an equimolar amount of picolinic acid (58 mg,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.462 mmol) in water (5 mL) was added, and, after a further 2 h, the pH was adjusted with 1 M NaOH to 5.6. The solution was left to stand in air for 24 h, then acetone (10 mL) was added, and colourless crystals were obtained after a few days. Yield: 0.14 g (66%). $C_{22}H_{46}Cl_3N_9O_{15}Zn_2$ (913.78): calcd. C 29.50, H 4.95, N 14.07, Zn 14.60; found C 29.14, H 4.78, N 12.95, Zn 13.75.

**[{Zn(cyclen)}$_2$(μ-L$^2$-*N*,*O*)](ClO$_4$)$_3$:** Zinc perchlorate hexahydrate (86 mg, 0.232 mmol) in water (3 mL) was slowly added to an aqueous solution (7 mL) of cyclen (40 mg, 0.232 mmol). After standing for 24 h, an equimolar amount of nicotinic acid (29 mg, 0.232 mmol) in water (10 mL) was added, and the solution was left to stand at room temperature (pH = 4.3). Colourless and transparent crystals were obtained after several days. Yield: 0.065 g (63%). $C_{22}H_{44}Cl_3N_9O_{14}Zn_2$ (895.76): calcd. C 29.50, H 4.95, N 14.07, Zn 14.60; found C 29.49, H 4.51, N 12.99, Zn 15.75.

**[Zn(cyclen)(L$^4$-*O*)](ClO$_4$)$_2$:** Zinc perchlorate hexahydrate (172 mg, 0.462 mmol) in water (5 mL) was slowly added to an aqueous solution (5 mL) of cyclen (80 mg, 0.462 mmol). After standing for 24 h, an equimolar amount of nicotinamide (56 mg, 0.462 mmol) in water (5 mL) was added. After another 2 h, once the pH of the solution had stabilized at 5.9, acetone (10 mL) was added. The colourless product crystallised over several days. Yield: 0.19 g (74%). $C_{14}H_{26}Cl_2N_6O_9Zn$ (558.68): calcd. C 30.10, H 4.69, N 15.04 Zn 11.70; found C 29.90, H 4.39, N 14.33, Zn 10.93.

**X-ray Crystallography:** Colourless prismatic crystals of the complexes selected from the bulk before filtration were used for data collection. Unit cell determination and data collection were carried out with a Nonius KappaCCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71070 Å). The phase problem was solved with SIR-97[40] and structure refinement was carried out by the full-matrix least-squares method on $F^2$ using the SHELXL-97[41] program. All non-hydrogen atoms were refined anisotropically. Experimental crystallographic parameters of all complexes are listed in Table 6. CCDC-633924 for [Zn(cyclen)(NO$_3$)]ClO$_4$, -633926 for [{Zn(cyclen)}$_2$(μ-L$^1$-*O:N,O′*)](ClO$_4$)$_3$·H$_2$O, -634730 for [{Zn(cyclen)}$_2$(μ-L$^2$-*N*,*O*)](ClO$_4$)$_3$ and -633925 for [Zn(cyclen)(L$^4$-*O*)](ClO$_4$)$_2$ contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**$^1$H NMR Titrations:** $^1$H NMR spectra were recorded with a Varian–Unity Inova 400 spectrometer. Samples were prepared in $H_2O$ and the spectra recorded relative to a $D_2O$ insert containing 0.5% *t*BuOH ($\delta$ = 1.25 ppm) as reference and lock. Four FIDs were accumulated for each spectrum using a standard-transmitter water-presaturated pulse sequence. The initial volume of solutions for each titration point was 0.7 mL. In the titration experiments, solutions contained aliquots of Zn(NO$_3$)$_2$·6H$_2$O, cyclen and an appropriate ligand. The initial concentration of individual species was 0.1 M for the ternary Zn$^{2+}$-cyclen-HL$^{1,2}$ and Zn$^{2+}$-cyclen-HL$^4$ mixtures and 0.05 M for the Zn$^{2+}$-cyclen-H$_2$L$^3$ system. The required pH values of the solutions were attained by adding aqueous 0.1 M NaOH or 0.1 M HNO$_3$ solutions.

**Potentiometric Titrations:** Stock solutions of pyridine derivatives were prepared by dissolving solid samples in deionised water. Their concentrations were calculated from the weight of samples and agreed well with those found in calculations of protonation constants of the ligands. The cyclen stock solution (approx. 0.02 M) was prepared by dissolving the solid in deionised water followed by addition of a standardised HNO$_3$ solution (final concentration of acid in the stock solution of cyclen was 0.06 M); the exact concentration of cyclen was calculated together with the determination of protonation constants. The preparation of standard solutions, titrations and calculation were performed as published previously.[42] Potentiometric measurements were carried out with a PHM 84 pH-meter, ABU 80 autoburette and a GK 2401 B combination electrode (Radiometer) in a glass vessel (10 mL) thermostatted at 25.0 ± 0.1 °C at an ionic strength $I$(KNO$_3$) of 0.1 M. An inert atmosphere was ensured by a constant flow of argon saturated with the solvent vapour. For determination of the protonation constants, the concentration of ligands was 0.004 M and the initial volume was 5 mL. In the case of Zn$^{2+}$ complexes with HL$^1$, HL$^2$, H$_2$L$^3$ and L$^4$, the volume of the initial solution was also 5 mL and the ligand concentration ranged from 0.002 to 0.004 M. The Zn$^{2+}$/ligand ratio was 2:1, 1:1, 1:2 and 1:4, with [Zn$^{2+}$] = 0.001–0.004 M. At least three parallel titrations were carried out for each ratio; each titration consisted of 40–50 points. The total dataset consisted of approximately 500 data points per given Zn-H$_x$L$^n$ system. Equilibration was slow for the Zn$^{2+}$-cyclen and ternary mixtures; therefore the out-of-cell method was used. Around 4 h was required to attain equilibrium in the binary Zn$^{2+}$-cyclen system. For the ter-

nary systems, the $Zn^{2+}$-cyclen complex was formed first (overnight equilibration), then a solution of the second ligand was added along with an appropriate amount of hydroxide solution. The final reaction mixture was left to stand for at least 15 h for equilibration. The molar ratios used were 1:1 for $Zn^{2+}$-cyclen and 1:1:1 for the ternary systems, with concentrations of the components in the range 0.003–0.004 M. The initial volume of the solution (before addition of the hydroxide solution) for each titration point was 1 mL. The titrations were performed at least in duplicate with 25 points per titration. A typical dataset consisted of around 70 data points for each system. Precise calibration of the electrode was carried out by titration of 0.03 M $HNO_3$ with 0.2 M KOH in the range $-\log[H^+] = 1.8–12.0$, with the pH-meter yielding $E$ values. The relation between $E$ and $-\log[H^+]$ is expressed by Equation (1) where the term $E_0$ contains the standard potentials of the electrodes used and the contribution of inert ions to the liquid-junction potential. $S$ corresponds to the Nernstian slope, the value of which should be close to the theoretical value, and $j_1 \times [H^+]$ and $j_2 \times [OH^-] = j_2 \times K_w/[H^+]$ are contributions of the $H^+$ and $OH^-$ ions, respectively, to the liquid-junction potential. The $pK_w$ value was 13.78 [Equation (1)].

$$E = E_0 - S \times (-\log[H^+]) + j_1 \times [H^+] + j_2 \times K_w/[H^+] \quad (1)$$

It is clear that $j_1$ and $j_2$ cause deviation from a linear dependence between $E$ and $-\log[H^+]$ only in strongly acid and strongly alkaline solutions. The protonation and stability constants were calculated with the OPIUM software package.[43]

**Molecular Modelling Calculations:** The calculations were carried out with a Pentium® IV 2.0 GHz PC using Hyperchem Pro™ version 7.04.[44] The Conformational Search module was used to find the lowest energy conformation of the coordinated cyclen, analyzing the systems in 1000 cycles. The energy of the systems in vacuo was minimised using molecular mechanics employing the MM+ force field and the Polak–Ribiere (conjugate gradient) algorithm, ending at an energy gradient of 0.01 kJ mol$^{-1}$. The geometry was optimised without any constraints by allowing all atoms, bonds and dihedral angles to change simultaneously.

**Supporting Information** (see footnote on the first page of this article): Colour versions of Figures 5 and 7; selected geometric parameters found in the studied crystal structures; arrangement of the chelate rings in the $[\{Zn(cyclen)\}_2(\mu\text{-}L^1\text{-}O{:}N,O')]^{3+}$ cation; distribution of the complex species formed in the $Zn^{2+}$-$H_xL^n$ systems as a function of $-\log[H^+]$; distribution of the complex species formed in the $Zn^{2+}$-cyclen system as a function of $-\log[H^+]$.

# Novel Ruthenium(II) N-Heterocyclic Carbene Complexes as Catalyst Precursors for the Ring-Opening Metathesis Polymerization (ROMP) of Enantiomerically Pure Monomers: X-ray Structures, Reactivity, and Quantum Chemical Considerations

**Michael R. Buchmeiser,*[a,b] Dongren Wang,[a] Yan Zhang,[a] Sergej Naumov,[a] and Klaus Wurst[c]**

**Keywords:** Carbene ligands / Ruthenium / ROMP / Quantum chemistry

Four chiral, enantiomerically pure monomers, *exo*,*exo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine ethyl ester (*exo*-**1**), *endo*,*endo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine ethyl ester (*endo*-**1**), *exo*,*exo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine-*tert*-butylamide (*exo*-**2**), and *endo*,*endo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine-*tert*-butylamide (*endo*-**2**), were subjected to ring-opening metathesis polymerization (ROMP) with $Ru(CF_3CO_2)_2(IMesH_2)$(*p*-cymene) (**3**), $Ru(CF_3CO_2)_2$(IMes)(*p*-cymene) (**4**), $RuCl_2$(IMes)(*p*-cymene) (**5**), $Ru(PCy_3)(CF_3CO_2)_2$(*p*-cymene) (**6**), $Ru(CF_3CO_2)_2$(*p*-cymene)·$CF_3COOAgPCy_3$(**6a**),$Ru(CF_3CO_2)_2(PPh_3)$(*p*-cymene) (**7**), $Ru(CF_3CO_2)_2$(IMes)$(PhNC)_3$ (**8**), and $Ru(CF_3CO_2)_2(IMesH_2)(PhNC)_3$ (**9**) (IMes = 1,3-dimesitylimidazol-2-ylidene, $IMesH_2$ = 1,4-dimesityl-4,5-diyhdroimidazolin-2-ylidene, $PCy_3$ = tricyclohexylphosphane). X-ray structures of precatalysts **3** and **6**–**9** are presented. Compounds **3** and **4** displayed significant ROMP activity, allowing for the controlled, yet nonliving synthesis of the corresponding polymers with polydispersity indices (PDIs) in the range of 1.17–2.14. In all cases the *exo* isomers of compounds **1** and **2** were polymerized by preference. While poly(*endo*-**1**) was formed in an all-*trans* form, poly(*exo*-**1**) and poly(*exo*-**2**) were produced in their *cis*/*trans* forms with a *cis* content of around 40%. Calculations carried out at the B3LYP/LACVP* level suggest two possible mechanisms for the increased reactivity of the 2,3-$R_2$-*exo*,*exo* isomers of norborn-5-ene-2,3-dicarbimido derivatives resulting in the formation of the ROMP-active $Ru^{IV}$ alkylidene.

## Introduction

The first reports on the activity of ruthenium(II) complexes in ring-opening metathesis polymerization (ROMP) were published some 15 years ago[1] and may certainly be regarded as the basis for the development of well-defined ruthenium(IV)–alkylidene complexes.[1,2] In 1997, Hafner et al. reported on the photo- and thermal activation of $Ru^{II}$ and $Os^{II}$ arene complexes of the general formula $MCl_2(PR_3)$(*p*-cymene) (M = Ru, Os) in the polymerization of norborn-2-ene.[3] Thermal initiation of the ROMP of norborn-2-ene was also observed by Lindner et al. for Ru(arene)H[P–O] complexes.[4] Noels et al. showed that complexes of the general formula $RuCl_2(PCy_3)$(arene) can be activated by treatment with diazo compounds to form ROMP-active Grubbs-type catalysts.[5] $RuCl_2$(IMes)(*p*-cymene) (**5**) (IMes = 1,3-dimesitylimidazol-2-ylidene) was first reported by Nolan et al., who showed that this complex was capable of performing ring-closing metathesis (RCM) reactions.[6] Later, Dixneuf et al. reported on the in situ formation of **5** and $RuCl_2(IMesH_2)$(*p*-cymene) ($IMesH_2$ = 1,4-dimesityl-4,5-diyhdroimidazolin-2-ylidene) and their use in RCM, enyne metathesis reactions,[7–10] and later in ROMP.[11] Noels et al. suggested the use of **5**, $RuCl_2(IMesH_2)$(*p*-cymene), and derivatives thereof as photoinitiators that can be activated by visible light.[12,13] However, in view of their inherent activity even *in the absence of light*,[14] they appear less suitable for these applications. As a matter of fact, calculations at the B3LYP/LACVP* level indicate a dissociation energy $E_{diss}$ of only 8.7 kcal/mol for the dissociation of the *p*-cymene ligand in $RuCl_2(IMesH_2)$(*p*-cymene).

In an ongoing project we are interested in the synthesis of novel latent metathesis catalysts[15,16] that may be converted into the active species in the presence of a monomer either thermally or by the action of (UV) light.[14] Key properties of such compounds are high thermal stability of

the precatalyst at least up to 45 °C and prolonged storability of ready-to-use monomer–precatalyst mixtures up to this temperature. Vice versa, either by the action of UV light or by thermal treatment, the precatalyst should, together with the monomer, form the active species to initiate ROMP. Despite selected reports on such systems,[3,17–20] these suffer from drawbacks such as thermal or visible light activation and significant metathesis activity *at room temperature and below*. In view of the pronounced changes in reactivity observed for bis(trifluoroacetate)-derived Grubbs and Grubbs–Hoveyda systems,[21–27] we were interested to what extent the replacement of the chlorine groups by trifluoroacetate groups would have influence on the ROMP activity of the resulting precatalysts. Instead of using norborn-2-ene, which is polymerized to some extent by virtually any metathesis catalyst, we focused on more complex molecules. On the basis of previous reports on the superiority of *exo* isomers in ROMP,[1] we prepared enantiomerically pure *exo* and *endo* isomers of two monomers, *exo*,*exo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine ethyl ester (*exo*-**1**), *endo*,*endo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine ethyl ester (*endo*-**1**), *exo*,*exo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine-*tert*-butylamide (*exo*-**2**), *endo*,*endo*-*N*,*N*-(norborn-5-ene-2,3-dicarbimido)-L-valine-*tert*-butylamide (*endo*-**2**) and investigated their polymerization using $Ru(CF_3CO_2)_2(IMesH_2)$(*p*-cymene) (**3**), $Ru(CF_3CO_2)_2$(IMes)(*p*-cymene) (**4**), $RuCl_2$(IMes)(*p*-cymene) (**5**), $Ru(PCy_3)(CF_3CO_2)_2$(*p*-cymene) (**6**), $Ru(CF_3CO_2)_2$(*p*-cymene)·$CF_3COOAgPCy_3$ (**6a**), $Ru(CF_3CO_2)_2(PPh_3)$(*p*-cymene) (**7**), $Ru(CF_3CO_2)_2$(IMes)$(PhNC)_3$ (**8**), and $Ru(CF_3CO_2)_2(IMesH_2)(PhNC)_3$ (**9**) (IMes = 1,3-dimesitylimidazol-2-ylidene, $IMesH_2$ = 1,3-dimesityl-4,5-diyhdroimidazolin-2-ylidene, $PCy_3$ = tricyclohexylphosphane). In addition, the structure of the final polymers was investigated. Finally, we performed theoretical calculations at the B3LYP/LACVP* level and propose a model that explains the superior reactivity of *exo* isomers compared to their *endo* analogues in ROMP.

## Results and Discussion

### Synthesis of Monomers and Catalyst Precursors

The synthesis of the *endo* monomers *endo*-**1** and *endo*-**2**,[28] the $CF_3COO$-derived precatalysts **3**, **4**, **8**, and **9**,[14] as well as of precatalyst **5**,[6] is described elsewhere. Monomer *exo*-**1** was prepared by esterification of *exo*,*exo*-(norborn-5-ene-2,3-dicarbimido)-L-valine with ethanol. Monomer *exo*-**2** was synthesized by reaction of L-valine-*exo*,*exo*-*N*,*N*-(norborn-2-ene-5,6-dicarbimide) with dicyclohexyldicarbodiimide (DCC) followed by the reaction of *tert*-butylamine. All structures are shown in Figure 1. In addition to the data already reported, the X-ray structures of compounds **3**, **6a**, **7**, **8**, and **9** are presented here. Thus, compound **3** crystallizes in the triclinic space group $P\bar{1}$ with $a$ = 11.3770(4) Å, $b$ = 12.1632(5) Å, $c$ = 14.5978(6) Å, $\alpha$ = 104.636(2)°, $\beta$ = 96.217(2)°, $\gamma$ = 113.276(2)°, $Z$ = 2. The distance Ru(1)–C(11) is 2.109(2) Å; the complex exists in a distorted octahedral form (Figure 2).

Precatalyst **6** was prepared from $[RuCl_2(p\text{-cymene})]_2$ by reaction with 2 equiv. of $PCy_3$ followed by reaction with 2 equiv. of $CF_3COOAg$. The compound crystallizes as the $CF_3COOAg{\cdot}PCy_3$ adduct **6a** in the triclinic space group $P\bar{1}$ with $a$ = 10.2007(4) Å, $b$ = 13.8886(4) Å, $c$ = 14.9130(6) Å, $\alpha$ = 107.497(2)°, $\beta$ = 94.569(2)°, $\gamma$ = 95.552(2)°, $Z$ = 2. The complex again exists with a distorted octahedral coordination for the Ru and a distorted tetrahedral coordination for the Ag center (Figure 3).

In a similar manner, precatalyst **7** was prepared from $[RuCl_2(p\text{-cymene})]_2$ by reaction with 2 equiv. of $PPh_3$ fol-

lowed by reaction with 2 equiv. of $CF_3COOAg$. Compound **7** crystallized in the monoclinic space group $C2/c$ with $a$ = 27.0985(3) Å, $b$ = 14.4321(4) Å, $c$ = 20.3053.(5) Å, $\alpha = \gamma$ = 90°, $\beta$ = 109.654(2)°, $Z$ = 8 (Figure 4).

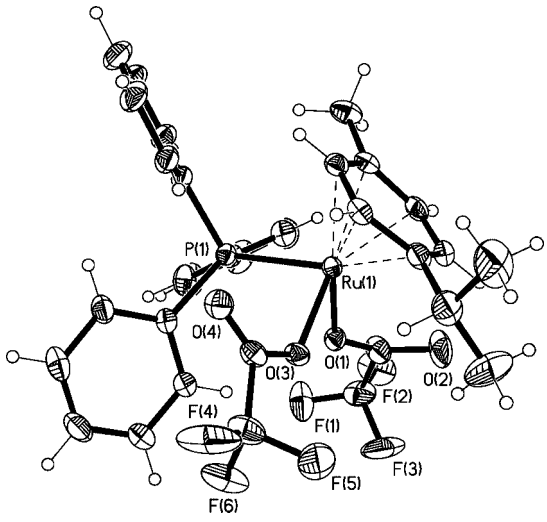

Figure 4. X-ray structure of **7**. Selected bond lengths [Å] and angles [°]: Ru(1)–O(3) 2.093(2), Ru(1)–O(1) 2.107(2), Ru(1)–C(6) 2.169(2), Ru(1)–C(5) 2.179(2), Ru(1)–C(3) 2.189(2), Ru(1)–C(2) 2.230(3), Ru(1)–C(4) 2.240(2), Ru(1)–C(1) 2.265(3), Ru(1)–P(1) 2.3654(7); O(3)–Ru(1)–O(1) 78.89(7), O(3)–Ru(1)–P(1) 89.59(5), O(1)–Ru(1)–P(1) 79.71(5).

Again, the complex exists with a distorted octahedral coordination of the Ru core. Compound **8** was prepared by reaction of **4** with excess phenylisonitrile.[14] It crystallizes in the orthorhombic space group $P2_12_12_1$ with $a$ = 10.8932(2) Å, $b$ = 16.4398(4) Å, $c$ = 26.9136(7) Å, $\alpha = \beta = \gamma$ = 90°, $Z$ = 4 (Figure 5). The Ru center again shows a slightly distorted octahedral coordination sphere with all angles close to 90 and 180°, respectively. One of the three phenylisonitrile ligands is arranged in a position *trans* to

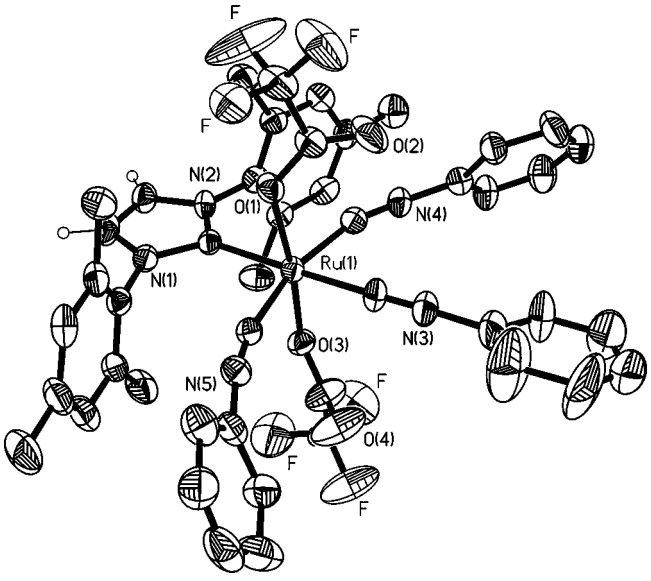

Figure 5. X-ray structure of **8**. Selected bond lengths [Å] and angles [°]: Ru(1)–C(27) 1.968(6), Ru(1)–C(20) 1.980(7), Ru(1)–C(34) 1.986(7), Ru(1)–O(3) 2.091(4), Ru(1)–O(1) 2.096(4), Ru(1)–C(1) 2.112(5); C(20)–Ru(1)–C(34) 164.9(2), O(3)–Ru(1)–O(1) 172.1(2), C(27)–Ru(1)–C(1) 178.5(2), Ru(1)–C(20)–N(3) 166.1(5), Ru(1)–C(27)–N(4) 177.2(6), Ru(1)–C(34)–N(5) 162.3(5).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the N-heterocyclic carbene ligand. The two trifluoroacetate ligands are *trans* to each other.

Because of its structural similarity to **8**, compound **9** again crystallizes in the orthorhombic space group $P2_12_12_1$ with $a$ = 10.8403(2) Å, $b$ = 16.5038(3) Å, $c$ = 27.1075(4) Å, $\alpha = \beta = \gamma = 90°$, $Z$ = 4 (Figure 6). The arrangement of the two phenylisonitrile and trifluoroacetate ligands is identical to that in **8**.

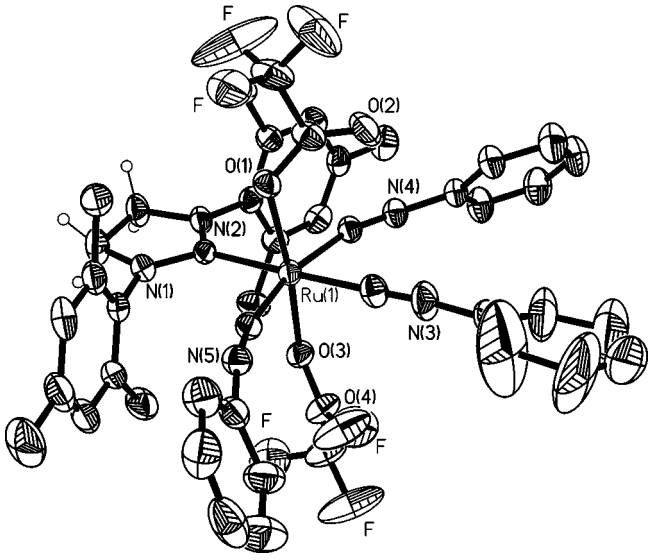

Figure 6. X-ray structure of **9**. Selected bond lengths [Å] and angles [°]: Ru(1)–C(27) 1.967(5), Ru(1)–C(20) 1.986(5), Ru(1)–C(34) 1.986(5), Ru(1)–O(3) 2.096(3), Ru(1)–O(1) 2.102(3), Ru(1)–C(1) 2.123(4), C(20)–Ru(1)–C(34) 164.4(2); O(3)–Ru(1)–O(1) 172.6(1), C(27)–Ru(1)–C(1) 178.5(2), Ru(1)–C(20)–N(3) 166.1(4), Ru(1)–C(27)–N(4) 178.4(5), Ru(1)–C(34)–N(5) 161.8(4).

## Reactivity in ROMP

All precatalysts, **3**–**9**, were investigated for their activity in ROMP using the monomers *exo*-**1**, *endo*-**1**, *exo*-**2**, and *endo*-**2**. In all cases, only precatalysts **3** and **4** were found to possess significant polymerization activity. Poly(*endo*-**1**) was prepared by the action of both precatalysts **3** and **4** (Table 1, entries 1–13) in the molecular weight range of 25000–160000 g/mol and polydispersity indices (PDIs) in the range of 1.17–1.54. A graph of the number of equivalents of the monomer with respect to the precatalyst ($N$) versus $M_n$ illustrates these results (Figure 7).

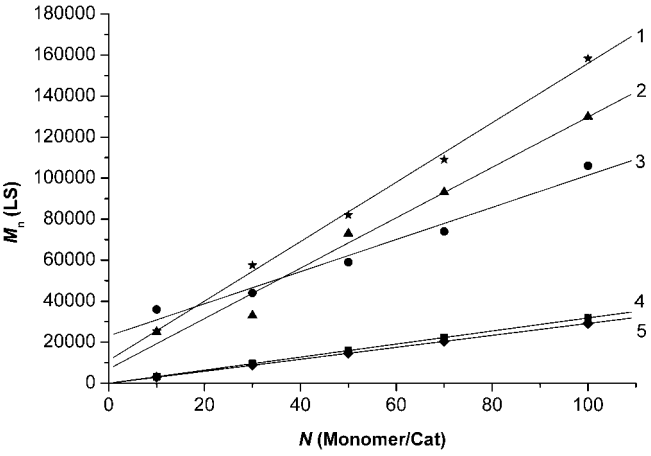

Figure 7. Plot of $M_n$ vs. number of monomer equivalents ($N$). 1: precatalyst **3** with *endo*-**1**; 2: precatalyst **4** with *exo*-**2**; 3: precatalyst **3** with *exo*-**2**; 4: calculated values for monomer **2**; 5: calculated values for monomer **1**.

As can be deduced therefrom, polymerization proceeds in a *controlled* manner, that is, the values of $M_n$ increase linearly with increasing $N$. The stepwise synthesis of poly-(*endo*-**1**)$_{100}$ (Table 1, entry 13) yields a polymer similar to the one prepared in a one-step procedure (Table 1, entry 9), however with higher PDI. This suggests that the polymerization does not proceed in a truly living[29] manner. The fact that the values for $M_n$ as determined by light scattering

are much higher than the calculated ones also suggests a nonquantitative initiation of the precatalysts. Not unexpectedly, addition of pyridine (Table 1, entry 11) reduces the molecular weight of the polymer.

It is worth noting that **3** is far more reactive than **4**, as illustrated by the comparably low yields (≤43%) obtained with the latter. The lower activity of **4** in comparison to **3** may be rationalized by the fact that precatalyst **3** is believed

to form a 1,3-dimesityl-3,4-dihydroimidazolin-2-ylidene-based propagating species. These types of initiators have been reported to be far more active than the corresponding 1,3-dimesitylimidazol-2-ylidene-derived ones.[30] An important finding is the fact that the parent complex **5** is virtually inactive in the ROMP of *exo*-**1**, *endo*-**1**, *exo*-**2**, and *endo*-**2**. Thus, the exchange of both chlorine ligands by trifluoroacetates appears to be a necessary prerequisite for the formation of an active precatalyst. Similar behavior has been observed in the Ru–alkylidene-initiated cyclopolymerization of 1,6-heptadiynes, where substitution of both chlorines of the Grubbs-[24] and Grubbs–Hoveyda-type initiators[21–23,31] by trifluoroacetate groups was necessary to generate polymerization-active systems. Precatalysts **6** and **6a**, as well as **7**, apparently decompose upon heating the polymerization mixture prior to any initiation. Finally, both precatalysts **8** and **9** are composed upon heating in the presence of any monomer. We tentatively assign this finding to an imine-type metathesis-type reaction[32,33] of dissociated phenylisonitrile with any in situ formed Ru–alkylidene complex resulting in cleavage of the Ru moiety from the polymer chain.

Polymerization results similar to those obtained for *endo*-**1** were observed for *exo*-**1**. Again, precatalyst **3** turned out to be more reactive than **4**. The values for $M_n$ of poly(*exo*-**1**) as determined by LS (Table 1, entries 19 and 20) were significantly lower than those for poly(*endo*-**1**) (Table 1, entries 8 and 10), indicative of a higher initiation efficiency of the precatalyst for the *exo* monomer. Such higher reactivity of *exo* isomers versus Grubbs-type initiators was also reported by other groups.[34] In contrast to *endo*-**1**, polymerization of *endo*-**2** with either **3** or **4** resulted only in oligomeric or insoluble products that were isolated in low yields, typically <20% (Table 2, entries 1–7).

However, *exo*-**2** may be polymerized by both precatalysts **3** and **4** in a controlled way (Table 2, entries 8–17). PDIs were in the range of 1.69–2.05 for precatalyst **4** and 1.25–1.56 for precatalyst **3**. An illustration is given in Figure 8.

## Polymer Structure

The structure of poly(*endo*-**1**) prepared by the action of either **3** or **4** was identical to the one published previously.[35] An atactic, all-*trans* structure was assigned to this polymer. In contrast to poly(*endo*-**1**), poly(*exo*-**1**) and poly(*exo*-**2**), whether prepared by the action of **3** or **4**, showed a *cis* content of roughly 40%, as evidenced by signals in the $^1$H NMR at $\delta$ = 5.44 ppm and in the $^{13}$C NMR spectrum around $\delta$ = 132 ppm and 52 ppm, respectively. For NMR assignment of signals, see refs.[36–38]

## Theoretical Considerations

Quantum chemical calculations were carried out to shed some light on the possible mechanism of the formation of ROMP-active Ru–alkylidene complexes and to provide an explanation for the different reactivity of the *exo* and *endo* forms of *N*,*N*-(norborn-5-ene-2,3-dicarbimide)-L-valine ethyl ester (NB-R1) and *N*,*N*-(norborn-5-ene-2,3-dicarbimide)-L-valine-*tert*-butylamide (NB-R2). For these calculations, the catalyst $RuCl_2(IMesH_2)$(*p*-cymene) was chosen as a model compound. Calculations revealed that the *exo* forms of both monomers studied are only insignificantly more stable (<2 kcal/mol) than the corresponding *endo* forms. Additionally, there is no essential effect of the substituent R {H, $CH_3$, 2-propyl, $CH[CH(CH_3)_2]COOEt$, $CH[CH(CH_3)_2]CONH$-*t*Bu} and conformation (*exo* vs. *endo*) on the Mulliken atomic charges and electron density at the C=C double bond of monomers. Thus, the calculated Mulliken atomic charges at the C atoms forming the double bond are –0.106/–0.104 and –0.119/–0.118 for the *exo* and *endo* forms, respectively (R = $CH_3$/R = H). Additionally, the calculated relative energies of the different Ru–alkylidene complexes for NB-R1 {R = $CH[CH(CH_3)_2]COOEt$} differ only slightly (<1 kcal/mol) from those calculated for R = H and $CH_3$. Therefore, a simplified form of the monomers with R = H, which is not too time-consuming in frequency analysis, was used for further calculations.

After dissociation of the *p*-cymene ligand ($\Delta U_{tot}$ = 6.2 kcal/mol), the formation of the corresponding Ru–alkylidene complexes was calculated. In the case of the *exo*-form, four possible stable structures for the catalyst–monomer complexes (*exo*-**IIIa**, *exo*-**IIIb**, *exo*-**IIIc**, and *exo*-**IIId**) (Figure 8) were optimized, with *exo*-**IIIa** with C7 in proximity to the Ru center being the most stable one.

Complexes *exo*-**IIIa** and *exo*-**IIIb** are characterized by monomer C=C double bonds orthogonal to the Ru–NHC bond. In contrast, the C=C double bond in *exo*-**IIIc** and *exo*-**IIId** (Figure 8) is almost parallel to the Ru–NHC bond. The calculated relative stabilities of different structures are given in Table 3.

All four *exo*-monomer–Ru complexes are stable ($\Delta U_{tot}$ is negative) and their possible transformations were further analyzed (Scheme 1).

Similar to the *exo* form, two stable catalyst–*endo*-monomer complexes with the C=C double bond of the monomer orthogonal to the Ru–NHC bond (*endo*-**IIIa** and *endo*-**IIIb**, Figure 8) were identified, *endo*-**IIIa** with C7 in proximity to the Ru center being the most stable one (Scheme 2). In addition, two structures, that is, *endo*-**IIIc** and *endo*-**IIId** with the C=C double bond of the monomer almost parallel to the Ru–NHC bond, are stable. Because of a strong steric interaction with the norborn-2-ene moiety, the Cl atom is *trans* to the N-heterocyclic carbene in *endo*-**IIId**. The calculated relative stabilities of the Ru–*endo*-monomer complexes (Table 3) indicate that formation of the structures *endo*-**IIIa**, *endo*-**IIIb**, *endo*-**IIIc**, and *endo*-**IIId** is exothermic ($\Delta U_{tot}$ is negative) and their possible transformations were therefore further analyzed (Scheme 2). In addition, it could be argued that the existence of an additional interaction between Ru and the N atom of the monomer in the case of the *endo* form (structure *endo*-**IIIb**, Figure 8, Ru–N = 0.2407 nm) may prevent further transformation. Here the question arose whether an additional interaction between the Ru and the N atoms of the monomer calculated for the cut-down

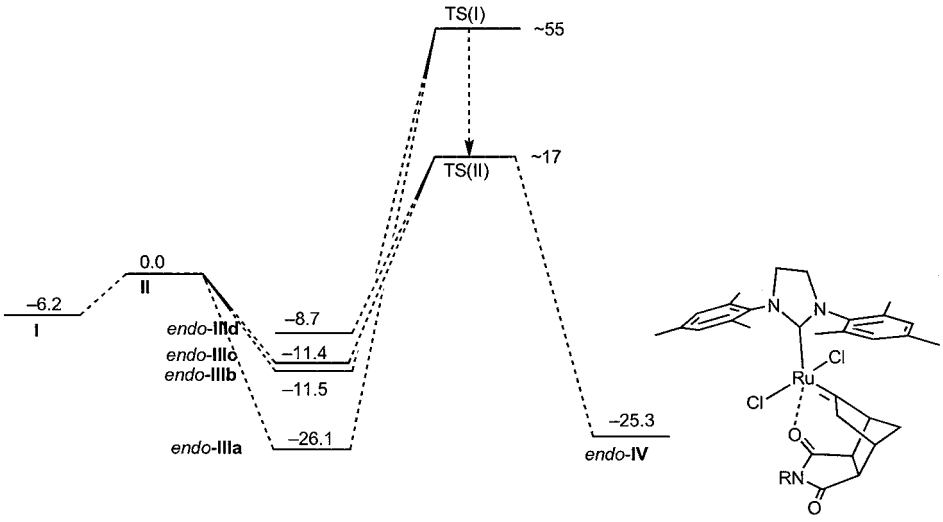
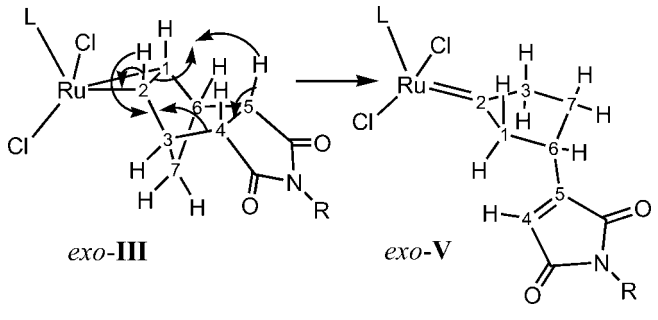


Scheme 2. Energy diagram and possible reaction pathways calculated at the B3LYP/LACVP* level for the reaction of an *endo* isomer with $RuCl_2(IMesH_2)$(*p*-cymene). Transition-state energies TS(I) and TS(II) are estimated for a simplified structure of the NHC (Supporting Information).

model *N*-R-norborn-5-ene-2,3-dicarboximide (R = H, $CH_3$) existed also for the actual monomers {R = $CH[CH(CH_3)_2]$-COOEt, $CH[CH(CH_3)_2]$CONH-*t*Bu} or whether other steric effects would dominate. To shed light on this point, calculations were carried out on the unrestricted monomers NB-R1 and NB-R2. As a matter of fact, these not only confirmed that this extra interaction exists, but revealed that the oxygen atom from the 2,3-dicarbimide group interacts very strongly with the Ru atom, thus forming an additional O–Ru bond. In due consequence, these two additional N–Ru and O–Ru interactions should aggravate any further transformation of *endo*-**IIIb** and thus further explain the reduced reactivity of the *endo*-monomer. The calculated *endo*-**IIIb** structures for NB-R1 and NB-R2 are given in Figure S2 in the Supporting Information.

To form the ROMP-active Ru–alkylidene complexes, the following mechanism may be proposed: one H atom from the C1=C2 double bond shifts from C1 to C2 followed by formation of the Ru–alkylidene complex, leading to structures *exo*-**IV** or *endo*-**IV** (Schemes 2 and 3).



Scheme 3. Proposed reaction cascade for the formation of a ROMP-active $Ru^{IV}$ alkylidene (structure *exo*-**5**).

Though structures *exo*-**IV** and *endo*-**IV** are energetically possible, the intramolecular C1 → C2 H-shift proceeds with a high activation barrier and should therefore be analyzed. However, in contrast to stable structures, the optimization of transition states for such large molecules is comparably complicated. So, we were forced to use simplified molecular structures for the estimation of the barrier for possible models of intramolecular H-shifts. Thus, in the search of the transition state for the H-shift from C1 to C2 of the double bond we started from the corresponding *exo* and *endo* monomers (i.e., *exo*- and *endo*-*N*-R-norborn-5-ene-2,3-dicarboximide, respectively; R = H, $CH_3$) *not* bonded to the Ru moiety. We found no effect of the substituents R on the nitrogen of the monomer on the structure and activation energy for the H-shift from C1 to C2. The calculated activation energy was very high (73 kcal/mol, 70 kcal/mol with Zero Point Energy correction). Transition structures of the monomer obtained that way were used as initial transition structures for the modeling of the different Ru–monomer complexes. A simplified catalyst structure with N–H instead of *N*-mesityl substituents was used.

Starting from the stable structures *exo*-**3a** and *exo*-**3b** (Scheme S1, Supporting Information), the transition structures [TS(I)] for the H-shift from C1 to C2 could be localized. The activation energy (given in Table 3) was again, as in the case of the nonbonded monomer, comparably high (up to 73 kcal/mol). However, when the H-shift from C1 to C2 was in conjunction with a concomitant formation of a Ru–alkylidene complex [TS(II)], the activation energy was essentially reduced, to 41 kcal/mol and 33 kcal/mol for *exo*-**3a** and *exo*-**3b**, respectively. Starting from the stable structures *exo*-**3c** and *exo*-**3d** (Scheme S1, Supporting Information), the transition structures [TS(I)] could not be localized and transformed directly into the corresponding sec-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ond transition structures [TS(II)]. This is a consequence of the geometries of TS(II), which have the alkylidene parallel to the Ru–NHC bond and do not need any additional rotation of the ruthenacyclopropane ring as is the case in *exo*-**3a** and *exo*-**3b**. Vice versa, the ruthenacyclopropane rings in *exo*-**3c** and *exo*-**3d** also already occupy a parallel orientation with respect to the Ru–NHC bond. The analysis of the TS(II) structures showed that in the case of the *exo* form only two structures of the TS(II) with very small differences in energy (<1 kcal/mol) exist. Here, the *exo*-**3a** structure is identical to *exo*-**3c** and *exo*-**3b** is identical to *exo*-**3d** (Supporting Information).

Starting from the stable structure *endo*-**3a** (Scheme S2, Supporting Information), the transition structure [TS(I)] for the H-shift from C1 to C2 could be localized with a very high activation energy (74 kcal/mol). In case the H-shift occurs concomitantly to a rotation of the ruthenacyclobutane, formation of a Ru–alkylidene complex occurs, and the activation energy is again essentially reduced to 46 kcal/mol [TS(II)] (Scheme S2, Supporting Information). TS(I) could not be localized for *endo*-**3b**, *endo*-**3c**, and *endo*-**3d** and transformed directly into the second transition structure [TS(II)]. Again, the TS(II) of *endo*-**3a** is identical to that of *endo*-**3c**. Formation of the TS(II) of *endo*-**3b**, being identical to that of *endo*-**3d**, was calculated to be slightly more favorable (about 2 kcal/mol) than the TS(II) of *endo*-**3a** and *endo*-**3c**.

Activation energies for the intramolecular C1 → C2 H-shift were calculated for the simplified structure of the NHC ligand with N–H instead of *N*-mesityl groups. These were further used for the analysis of the possible transformations of the Ru–alkylidene complexes (Table 3). However, it should be noted that the calculated activation energies for the 1,2-H-shift for the simplified form of the monomer (R = H) should be used on a qualitative rather than on a quantitative base. From the analysis of the data summarized in Table 3 it can be seen that the formation of TS(II) is particularly favorable (18 kcal/mol) in case the reaction proceeds via the *exo*-**IIId** structure.

From the analysis of the formation of the ROMP-active structures *exo*-**IV** and *endo*-**IV** through $C_1 \rightarrow C_2$ H-shift (Schemes 1 and 2) follows: (i) the ROMP-active structure *exo*-**IV** can be built starting from all four stable structures *exo*-**IIIa**, *exo*-**IIIb**, *exo*-**IIIc**, and *exo*-**IIId**; its formation is energetically favorable ($\Delta U_{tot}$ = –26.0 kcal/mol, –18.2 kcal/mol, –13.1 kcal/mol, and –3.3 kcal/mol, respectively); (ii) the transformation starting from the less stable complex *exo*-**IIId** occurs with lower activation energy (only 18 kcal/mol) than from the most stable structure *exo*-**IIIa**, indicating a low-energy pathway; (iii) the formation of *endo*-**IV** by the low-energy pathway starting from the less stable structure *endo*-**IIIc** occurs with activation energy 31 kcal/mol, which is 13 kcal/mol higher than that for the pathway starting from *exo*-**IIId**. Moreover, the structure *endo*-**IIIb** seems to be inactive because of additional Ru–N bonding. Finally, the structure *endo*-**IV** must be further expected to be virtually ROMP-inactive because of the formation of an additional Ru–O bond (Scheme 2, bond length = 0.240 nm). All these findings may be indicative of a lower activity of the *endo* forms of the monomers investigated in comparison to the corresponding *exo* forms.

An additional, alternative *activation mechanism* for the formation of Ru–alkylidene complexes necessary for ROMP may explain the different reactivity of the *exo* and *endo* forms of **1** and **2**. While there is no essential difference between the *exo* and *endo* forms of monomers in the electronic parameters, such as charge and electron density at the double bond, there is a deciding contrast in geometry. As can be seen in Figure 9, there is a significant difference in the distances between the C1 atom of the double bond and the H5 atom at the *exo* or *endo* position (0.269 nm and 0.367 nm, for *exo* or *endo* respectively).

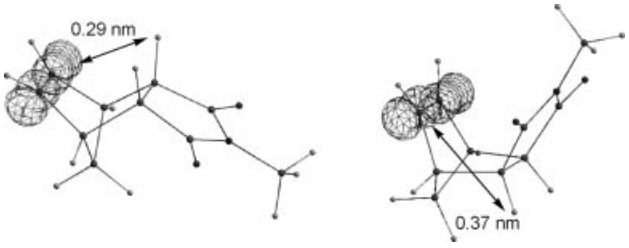


Figure 9. Distances between C1/C2 atoms of the double bond (the $p_z$ orbitals) and the H atoms at C4/C5 in the *exo* and *endo* forms.

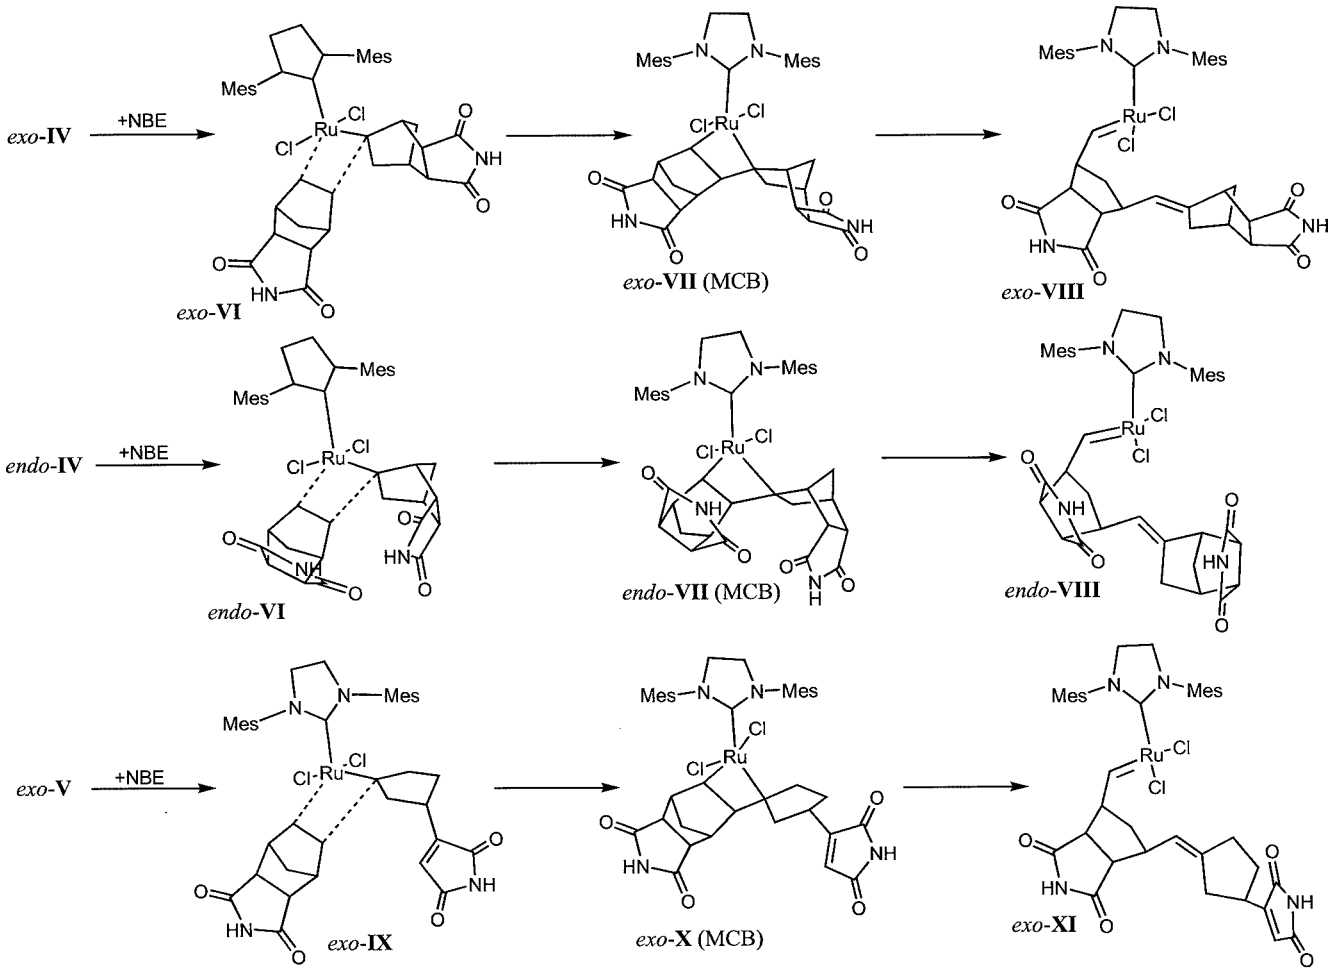
Consequently, the positively charged H atom in the *exo* position interacts strongly with the $p_z$ orbital on the negatively polarized C1, thus facilitating the intramolecular C5 → C1 (or C4 → C2) H-shift to the double bond. As geometry optimization reveals, the weakening of the C3–C4 bond could be followed by ring opening, concomitant intramolecular H-shift from C2 to C1, and formation of a Ru=C double bond. All these intramolecular transformations can apparently occur concomitantly (Scheme 3) with low activation energies leading to the structure *exo*-**V**. However, such transformation is impossible in the case of the *endo* form. For this reaction pathway, the starting complexes *exo*-**IIIb** and especially *exo*-**IIId** appear to be more favorable than complexes *exo*-**IIIa** and *exo*-**IIIc** for two reasons. First, as a consequence of the interaction between the double bond and the Ru center, the geometry on C1 and C2 is no longer planar (there is some admixture of $sp^3$ hybridization), thus leading to the deformation of $p_z$ electron density from the C atoms in the direction of the H atom at C4 and C5, respectively. This facilitates the interaction with the H atom and consequently the H-shift. This also explains the stability of the monomer in the absence of any catalyst. Second, as revealed by calculations, complexes *exo*-**IIIb** and *exo*-**IIId** are also energetically favorable for transformation into the activated catalyst *exo*-**V** ($\Delta G_{tot}$ = –0.8 kcal/mol and $\Delta G_{tot}$ = –16.35 kcal/mol respectively).

It should be emphasized that so far the discussed mechanism through the possible H-shift from C4 to C2 is only *qualitative* because of computational restrictions in the search for transition structures that operate through a concerted transformation (H-shifts and ring opening). However, such transformations are expected to occur easily be-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4. Most stable structures of Ru–alkylidene complexes (B3LYP/LACVP*).

cause of a favorable geometry for the H-shift in the *exo*-**IIIb** and *exo*-**IIId** complexes and the better interaction of the proton with the $p_z$ electrons of the double bond.

The mechanism discussed so far for the formation of Ru–alkylidene complexes (structures *exo*-**IV**, *exo*-**V**, and *endo*-**IV**) necessary for ROMP clearly shows the difference between the *exo* and *endo* forms. However, it might be of interest to identify the rate-determining step of the overall polymerization reaction. To understand differences in reactivities of the *exo* and *endo* forms, further insertion reactions of a second norborn-2-ene monomer into *exo*-**IV**, *exo*-**V**, and *endo*-**IV** were calculated. The calculated structures are shown in Scheme 4.

It was found that both active complexes *exo*-**IV** and *endo*-**IV** form stable π complexes (structures *exo*-**VI** and *endo*-**VI**) with stabilization energies of 2.6 kcal/mol and 0.6 kcal/mol respectively. The active complex *exo*-**V** can form a stable π complex (*exo*-**IX**) with norborn-2-ene (stabilization energy 3.1 kcal/mol) too. However, the next steps, that is, the conversion of the π complex into the corresponding metallacyclobutane (MCB) structures *exo*-**VII** (MCB), *exo*-**X** (MCB), and *endo*-**VII** (MCB) (Scheme 4) followed by ring opening (structures *exo*-**VIII**, *exo*-**XI**, and *endo*-**VIII**), proceed energetically differently for the *exo* and *endo* forms. Thus, though the ring-opening reaction is energetically favorable in all three cases, the formation of the MCB structure is very different for *exo* and *endo* forms. In the cases of *exo*-**IV** and *exo*-**V**, stable structures of the MCB were calculated with reaction enthalpies around –1.0 kcal/mol and –2.5 kcal/mol for *exo*-**VII** (MCB) and *exo*-**X** (MCB) respectively. On the contrary, *endo*-**VII** (MCB) is only a transition structure requiring an activation energy for MCB formation of about 17 kcal/mol. Such different behavior of the *endo* form is apparently caused by a strong steric interaction of the Cl ligand with the substituents at the *N*-imido group. In due consequence, the large activation energy for the MCB formation in the case of the *endo* form may be the rate-determining step of the overall polymerization reaction. A comprehensive study on the different reactivity of various *exo*- and *endo*-norborn-5-ene-2,3-dicarbimides is now in progress.

## Conclusions

A series of novel $Ru^{II}$-derived precatalysts have been investigated for their polymerization behavior in the ROMP of *exo*- and *endo*-norborn-5-ene-2,3-dicarbimides. Our in-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vestigations revealed that precatalysts containing an N-heterocyclic carbene ligand, two trifluoroacetate groups, and one labile ligand are best suited for the thermal initiation of ROMP. The *exo* isomer was preferentially polymerized in both cases. Quantum chemical calculations propose possible mechanisms for the formation of ROMP-active structures, which could also explain the experimental findings of the better reactivity of the *exo* form. Additionally, the different activation energies for MCB formation of the *exo* and *endo* forms may be the rate-determining step of the overall polymerization reaction. Further work will focus on the construction of suitable labile ligands that allow for a *quantitative initiation* of the precatalysts.

## Experimental Section

All manipulations were performed under nitrogen in a glovebox (MBraun LabMaster 130) or by standard Schlenk techniques. Purchased starting materials were used without any further purification. Dichloroethane was distilled from calcium hydride under nitrogen. Tetrahydrofuran (THF), pentane, diethyl ether, toluene, and dichloromethane were dried by an MBraun solvent purification system (SPS). NMR spectroscopic data were obtained at 250.13 MHz for proton and 62.90 MHz for carbon in the indicated solvent at 25 °C on a Bruker Spectrospin 250 and are listed in parts per million downfield from tetramethylsilane for proton and carbon. IR spectra were recorded with a Bruker Vector 22 using ATR technology. Molecular weights and polydispersity indices (PDIs) of the polymers were determined by GPC at 30 °C on Polymer laboratories columns (PLgel 10 μm MIXED-B, 7.5 × 300 mm) in THF at 25 °C using a Waters Autosampler, a Waters 484 UV spectrometer detector (254 nm), an Optilab Rex refractive index detector (Wyatt), and a MiniDawn light-scattering detector (Wyatt). Synthesis and structural data of compounds *endo*-**1** and *endo*-**2**,[28] **3**, **4**, **9**, **10**,[14] and **5**[6] have been reported elsewhere. Values for *dn*/*dc* for *endo*-**1**, *exo*-**1**, and *exo*-**2** were 0.119, 0.126, and 0.116, respectively.

***exo*,*exo*-*N*,*N*-(Norborn-5-ene-2,3-dicarbimido)-L-valine Ethyl Ester (*exo*-1):** *exo*,*exo*-*N*,*N*-(Norborn-5-ene-2,3-dicarbimido)-L-valine (575 mg, 2.18 mmol) and *p*-toluenesulfonic acid (17 mg, 0.08 mmol) were dissolved in dry ethanol and refluxed for 8 h. The ethanol was evaporated and the residue was dissolved in diethyl ether. The ether solution was subject to flash chromatography over silica gel 60 (diethyl ether/pentane, 5:1). Recrystallization gave *exo*-**1** as white needles in 35% yield (220 mg). IR (ATR): $\tilde{\nu}$ = 2975 (w), 1739 (m), 1693 (s), 1526 (m), 1380 (s), 1352 (m), 1281 (w), 1186 (s), 1097 (m), 1050 (m), 1018 (m), 969 (m), 892 (m), 825 (m), 771 (m), 724 (w), 673 (m) cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 6.30 (s, 2 H), 4.34 (d, $^1J$ = 8.1 Hz, 1 H), 4.25–4.08 (m, 2 H), 3.31 (br. s, 2 H), 2.78–2.57 (m, 3 H), 1.53 (m, 2 H), 1.20 (t, $^2J$ = 7.17 Hz, 3 H, $CH_3$), 1.10 (d, $^2J$ = 6.67 Hz, 3 H, $CH_3$), 0.84 (d, $^2J$ = 6.84 Hz, 3 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 177.4, 177.26, 168.3, 137.9, 61.37, 57.7, 47.8, 47.3, 45.6, 45.37, 42.8, 27.9, 22.3, 21.03, 19.34, 14.01 ppm. MS: calcd. for $C_{16}H_{21}NO_4$ $[M^{\cdot}]^+$ 291.15; found 291.

***exo*,*exo*-*N*,*N*-(Norborn-5-ene-2,3-dicarbimido)-L-valine-*tert*-butylamide (*exo*-2):** Dicyclohexyldicarbodiimide (DCC, 1.96 g, 0.95 mmol) was added to L-valine-*exo*,*exo*-*N*,*N*-(norborn-2-ene-5,6-dicarbimide) (5.0 g, 1.9 mmol) dissolved in acetonitrile. Soon after addition of DCC, dicyclohexylurea (DCU) precipitated, and the reaction mixture was stirred for a further 6 h. DCU was filtered off, *tert*-butylamine (2.0 mL, 1.9 mmol) was added to the filtrate, and the reaction mixture was stirred for 12 h. Finally, the ammonium salt was filtered off. Acetonitrile was evaporated under reduced pressure until an oily residue remained, which was dissolved in diethyl ether. The ether solution was subsequently washed with 0.1 M hydrochloric acid and saturated aqueous sodium hydrogen carbonate and finally dried with sodium sulfate. The solution was concentrated, and about the same amount of pentane was added. Crystallization was performed at –18 °C. Yield: 2.6 g (43%). IR (ATR-mode): $\tilde{\nu}$ = 3353 (m), 2965 (w), 2929 (m), 2864 (m), 1690 (s), 1523 (m), 1454 (m), 1376 (s), 1352 (s), 1212 (w), 1182 (s), 1044 (m), 927 (m), 891 (m), 858 (m), 823 (m), 777 (m), 720 (w) cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 6.63 (br. s, 1 H, NH), 6.11 (m, 2 H), 3.94 (d, $^2J$ = 11.54 Hz, 1 H, CH), 3.42 (br., 2 H), 3.29 (m, 2 H), 2.60 (m, 1 H), 1.74 (d, $^1J$ = 8.8 Hz, 1 H), 1.54 (d, $^1J$ = 8.9 Hz, 1 H), 1.30 (s, 9 H, *t*Bu), 0.98 (d, $^2J$ = 6.67 Hz, 3 H, $CH_3$), 0.75 (d, $^2J$ = 6.52 Hz, 3 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 178.31, 177.83, 167.50, 134.89, 134.6, 65.03, 52.35, 51.03, 45.58, 45.41, 45.12, 28.53, 26.50, 19.54 ppm. MS: calcd. for $C_{18}H_{26}N_2O_3$ $[M^{\cdot}]^+$ 318.19; found 276 $[M^{\cdot} - H_3C{-}CH{=}CH_2]^+$.

**[Ru(CF$_3$CO$_2$)($p$-cymene)PCy$_3$] (6):** $[RuCl_2(p\text{-cymene})]_2$[39] was treated with 2 equiv. of $PCy_3$ and $[RuCl_2(p\text{-cymene})PCy_3]$ was obtained in 90% yield according to ref.[5]. $^1$H NMR ($CDCl_3$): $\delta$ = 5.58 (br. s, 4 H, ArH), 2.83 [pent, $^2J$ = 6.9 Hz, 1 H, $CH(CH_3)_2$], 2.42 (q, $J$ = 22.3, 11.4 Hz, 3 H, cyclohexyl), 2.14 (s, 3 H, $CH_3$), 2.09 (br., 6 H, cyclohexyl), 1.88–1.66 (m, 9 H, cyclohexyl), 1.30 [d, $^2J$ = 7.0 Hz, 6 H, $CH(CH_3)_2$], 1.56–1.10 (m, 15 H, cyclohexyl) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 106.7, 94.2, 88.2 ($J_{^{31}P-^{13}C}$ = 3.8 Hz), 83.7 ($J_{^{31}P-^{13}C}$ = 4.9 Hz), 35.7 ($J_{^{31}P-^{13}C}$ = 17.9 Hz, cyclohexyl), 30.4 (s, cyclohexyl), 29.5 ($J_{^{31}P-^{13}C}$ = 2.1 Hz, cyclohexyl), 27.4 ($J_{^{31}P-^{13}C}$ = 9.8 Hz, cyclohexyl), 26.3 $[CH(CH_3)_2]$, 22.3 $[CH(CH_3)_2]$, 17.7 ($CH_3$) ppm.

$[RuCl_2(p\text{-cymene})PCy_3]$ (114 mg, 0.20 mmol) was dissolved in THF and added to a solution of silver trifluoroacetate (97.2 mg, 0.44 mmol) in THF, both cooled to –36 °C. After mixing, the solution was stirred for another 4 h, allowing it to reach room temperature. During that time a white precipitate of AgCl formed. The mixture was filtered through celite and the THF was removed in vacuo. Methylene chloride was added to dissolve the residue and the solution was again concentrated in vacuo. Diethyl ether and *n*-pentane were successfully layered over the red, saturated solution. Yield: 82%. FTIR (ATR mode): $\tilde{\nu}$ = 2934, 2853, 2052, 1701, 1448, 1396, 1187, 1126, 1006, 837, 784, 725, 672 cm$^{-1}$. $^1$H NMR ($CDCl_3$): $\delta$ = 6.14 (d, $^2J$ = 5.9 Hz, 2 H, ArH), 6.14 (d, $^2J$ = 6.1 Hz, 2 H, ArH), 2.60 [pent, $^2J$ = 6.9 Hz, 1 H, $CH(CH_3)_2$], 2.25 (q, $J$ = 11.9 Hz, 3 H, cyclohexyl), 2.07 (s, 3 H, $CH_3$), 1.98–1.69 (m, 15 H, cyclohexyl), 1.56–1.22 (m, 15 H, cyclohexyl), 1.18 [d, $^2J$ = 6.9 Hz, 6 H, $CH(CH_3)_2$] ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 163.0 [dq, $^2J_{^{19}F-^{13}C}$ = 36.3, 2.5 Hz, CO], 114.6 (q, $^1J_{^{19}F-^{13}C}$ = 291.1 Hz, $CF_3$), 107.2, 94.8, 84.2 ($J_{^{31}P-^{13}C}$ = 3.0 Hz), 81.8 ($J_{^{31}P-^{13}C}$ = 3.9 Hz), 35.6 ($J_{^{31}P-^{13}C}$ = 17.0 Hz, cyclohexyl), 31.5 (cyclohexyl), 29.3 ($J_{^{31}P-^{13}C}$ = 2.2 Hz, cyclohexyl), 27.7 ($J_{^{31}P-^{13}C}$ = 9.9 Hz, cyclohexyl), 26.4 $[CH(CH_3)_2]$, 22.5 $[CH(CH_3)_2]$, 18.8 ($CH_3$) ppm. $C_{32}H_{47}F_6O_4PRu$ (742.22): calcd. C 51.82, H 6.39; found C 51.87, H 6.50. Crystals of compound **6** were obtained in the form of its $CF_3COOAg$ adduct (**6a**).

**[Ru(CF$_3$CO$_2$)$_2$($p$-cymene)PPh$_3$] (7):** $[RuCl_2(p\text{-cymene})]_2$ was treated with $PPh_3$ (2 equiv.) according to the literature to give $[RuCl_2(p\text{-cymene})PPh_3]$ in 98% yield.[33] $^1$H NMR ($CDCl_3$): $\delta$ = 7.87–7.79 (m, 6 H, Ph), 7.40–7.32 (m, 9 H, Ph), 5.24 (d, $^2J$ = 6.2 Hz, 2 H, ArH), 4.98 (dd, $^2J$ = 6.2, 1.2 Hz, 2 H, ArH), 2.85 [pent, $^2J$ = 6.2 Hz, 1 H, $CH(CH_3)_2$], 1.86 (s, 3 H, $CH_3$), 1.09 [d, $^2J$ = 6.2 Hz, 6 H, $CH(CH_3)_2$] ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 134.3 ($^2J_{^{31}P-^{13}C}$ = 9.4 Hz, Ph), 133.7 ($^1J_{^{31}P-^{13}C}$ = 45.7 Hz, Ph), 130.2 ($^4J_{^{31}P-^{13}C}$ = 2.2 Hz, Ph),

127.9 ($^3J_{^{31}P-^{13}C}$ = 9.9 Hz, Ph), 111.2 ($^2J_{^{31}P-^{13}C}$ = 3.3 Hz, *p*-Cym), 95.9 (*p*-Cym), 89.0 ($^2J_{^{31}P-^{13}C}$ = 3.3 Hz, *p*-Cym), 87.1 ($^2J_{^{31}P-^{13}C}$ = 3.3 Hz, *p*-Cym), 30.2, 21.8, 17.7 (mesityl) ppm.

[$RuCl_2$(*p*-cymene)$PPh_3$] (56.8 mg, 0.10 mmol) was dissolved in THF and added to a solution of silver trifluoroacetate (44.2 mg, 0.20 mmol) in THF, both cooled to –36 °C. After mixing, the solution was stirred for another 4 h, allowing it to reach room temperature. During that time a white precipitate of AgCl formed. The mixture was filtered through celite and the THF was removed in vacuo. Methylene chloride was added to dissolve the residue and the solution was again concentrated in vacuo. Diethyl ether and *n*-pentane were successfully layered over the red, saturated solution. Red crystals formed at –36 °C. Yield: 62.2 mg, 86%. FTIR: $\tilde{\nu}$ = 3057, 1679, 1436, 1405, 1183, 1139, 1095, 845, 788, 750, 694, 620 $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.51–7.43 (m, 9 H, Ph), 7.40–7.34 (m, 6 H, Ph), 6.26 (d, $^2J$ = 5.1 Hz, 2 H, ArH), 4.98 (d, $^2J$ = 5.1 Hz, 2 H, ArH), 2.58 [pent, $^2J$ = 6.9 Hz, 1 H, $CH(CH_3)_2$], 1.68 (s, 3 H, $CH_3$), 1.26 (d, $^2J$ = 6.9 Hz, 6 H, $CH_3$) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 163.6 (dq, $^2J_{^{19}F-^{13}C}$ = 36.6, 1.8 Hz, CO), 134.4 ($^2J_{^{31}P-^{13}C}$ = 10.4 Hz, Ph), 130.9 ($^4J_{^{31}P-^{13}C}$ = 2.3 Hz, Ph), 129.5 ($^1J_{^{31}P-^{13}C}$ = 47.2 Hz, Ph), 128.4 ($^3J_{^{31}P-^{13}C}$ = 10.4 Hz, Ph), 114.8 (q, $^1J_{^{19}F-^{13}C}$ = 291.1 Hz, $CF_3$), 115.2 ($^2J_{^{31}P-^{13}C}$ = 8.4 Hz, *p*-Cym), 95.7 (*p*-Cym), 86.6, 86.5 ($^2J_{^{31}P-^{13}C}$ = 3.4 Hz, *p*-Cym), 82.8 (*p*-Cym), 31.4 [$CH(CH_3)_2$], 21.8, 18.1 ($CH_3$) ppm.

**Typical Procedure for ROMP:** Polymerizations were performed under argon. A solution of the corresponding initiator (5 mg) in $ClCH_2CH_2Cl$ (1 mL) was added to a solution of the monomer in $ClCH_2CH_2Cl$ (3 mL). The mixture was stirred at 70 °C for 8 h, then concentrated to about 1 mL, then the polymer was precipitated by dropwise addition of the solution to 30 mL of acidic methanol. The product was then filtered and dried in vacuo to give an off-white to light yellow powder.

**Poly(*exo*-1) Prepared by the Action of 3:** $M_n$ = 88000 g/mol; $M_w$ = 209000 g/mol; PDI = 2.36. IR (ATR): $\tilde{\nu}$ = 2964, 1740, 1702, 1456, 1375, 1269, 1182, 1129, 1025, 968, 812, 650 $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 5.76 (br. s), 5.44 (br. s), 4.28–4.16 (m, 3 H), 3.04 (m, 3 H), 2.62 (m, 2 H), 2.15 (m, 1 H), 1.62 (m, 1 H), 1.23 (t, $^2J$ = 7.1 Hz, 3 H), 1.10 (d, $^2J$ = 6.5 Hz, 3 H), 0.83 (d, $^2J$ = 6.7 Hz, 3 H) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 177.6, 168.3, 132 (unresolved m), 131.6, 61.3, 57.5, 52.0 (unresolved), 50.6, 45.9, 41.8, 27.7, 21.2, 19.3, 14.1 ppm. NMR spectra of poly(*exo*-**1**) prepared by the action of **4** ($M_n$ = 130200 g/mol; $M_w$ = 225800 g/mol; PDI = 1.73) were identical.

**Poly(*endo*-1) Prepared by the Action of 3:** $M_n$ = 158300 g/mol; $M_w$ = 218900 g/mol; PDI = 1.38. IR (ATR): $\tilde{\nu}$ = 2967, 1739, 1700 (s), 1461, 1380, 1274, 1188, 1133, 1028, 969, 922, 821, 715, 661 $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 5.65 (br. m, 2 H), 4.33 (m, 1 H), 4.14 (m, 2 H), 3.24 (br. s, 3 H), 2.93 (br. s, 1 H), 2.58 (br. s, 1 H), 1.86 (br. s, 1 H), 1.35–1.22 (m, 4 H), 1.08 (br. s, 3 H), 0.79 (br. s, 3 H) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 176.1, 175.3, 168.3, 129.3, 61.4, 57.7, 48.4, 45.5, 40.3, 37.3 (br), 27.5, 21.2, 19.4, 14.1 ppm. NMR spectra of poly(*endo*-**1**) prepared by the action of **4** ($M_n$ = 90900 g/mol; $M_w$ = 125600 g/mol; PDI = 1.39) were identical.

**Poly(*exo*-2) Prepared by the Action of 3:** $M_n$ = 106000 g/mol; $M_w$ = 158000 g/mol; PDI = 1.49. IR (ATR): $\tilde{\nu}$ = 2963, 1772, 1697, 1536, 1455, 1360, 1183, 1131, 967, 650 $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.75 (br. s), 5.75–5.48 (m), 4.05 (m, 1 H), 3.02 (br. s, 3 H), 2.68 (br. s, 2 H), 2.15 (br. s, 1 H), 1.62 (m, 1 H), 1.31 (s, 9 H), 1.03 (d, $^2J$ = 6.24 Hz, 3 H), 0.79 (d, $^2J$ = 6.18 Hz, 3 H) ppm. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 178.4, 167.4, 132 (unresolved m), 131.6, 64.8, 51.2 (unresolved), 50.4, 46.2, 41.8, 28.5, 26.7, 19.6, 19.3 ppm. NMR spectra of poly(*exo*-**2**) prepared by the action of **4** ($M_n$ = 130000 g/mol; $M_w$ = 218500 g/mol; PDI = 1.68) were identical.

**Computational Methods:** Density Functional Theory (DFT) calculations were carried out using Becke's three-parameter functional (B3)[40,41] in combination with the Lee, Yang, and Parr (LYP) correlation functional[42] with the LACVP* basis set (Jaguar, version 6.5 program[43]). The LACVP* basis set uses the standard 6-31G* basis set for light elements and the LAC pseudopotential[44] for the Ru atom. The molecular geometries and energies of all calculated structures were obtained at the same B3LYP/LACVP* level of theory. The B3LYP/LACVP* method has already been successfully used in many studies.[45–48] To prove the ability of this method, the calculated molecular structure of precatalyst **3** was compared with its X-ray structure.

The calculated parameters of structure **3** were in good agreement with those of the X-ray structure (given in Supporting Information Figure S1 and Table S1). Frequency analysis was used throughout for identification of the stationary points, which is especially important for the search of the transition states, and to obtain thermochemistry parameters such as zero point energy ($E_{ZP}$), entropy ($S$), total internal energy ($U_{tot}$), total enthalpy ($H_{tot}$), and total Gibbs free energy ($G_{tot}$) at 298 K. The relative stability of the different structures was calculated as a balance of both $U_{tot}$ and $G_{tot}$ relative to those of the intermediary $RuCl_2$(IMes$H_2$) complex (structure II in Scheme 1).

**X-ray Measurement and Structure Determination of 3, 6a, and 7–9:** Data collection was performed with a Nonius Kappa CCD equipped with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and a nominal crystal-to-area detector distance of 36 mm. Intensities were integrated using DENZO and scaled with SCALEPACK.[49] Several scans in $\phi$ and $\omega$ directions were made to increase the number of redundant reflections, which were averaged in the refinement cycles. This procedure replaces in a good approximation an empirical absorption correction. The structures were solved with direct methods SHELXS86 and refined against $F^2$ SHELXL97.[50] The function minimized was $\Sigma[w(F_o^2 - F_c^2)^2]$ with the weight defined as $w^{-1} = [\sigma^2(F_o^2) + (xP)^2 + yP]$ and $P = (F_o^2 + 2F_c^2)/3$. All non-hydrogen atoms were refined with anisotropic displacement parameters. Positions of hydrogen atoms were calculated using a riding model. Compound **3**: Triclinic space group $P\bar{1}$ (no. 2), $a$ = 11.3770(4) Å, $b$ = 12.1632(5) Å, $c$ = 14.5978(6) Å, $\alpha$ = 104.636(2)°, $\beta$ = 96.217(2)°, $\gamma$ = 113.276(2)°, $V$ = 1745.50(12) Å$^3$, $Z$ = 2, $\rho_{calcd}$ = 1.461 g/cm$^3$, $T$ = 233 K, $\mu$ = 0.521 mm$^{-1}$, orange prism, 6121 reflections > 2$\sigma(I)$, $R_1$ = 0.0350, and $\omega R_2$ = 0.0804. Compound **6a**: Triclinic space group $P\bar{1}$, $a$ = 10.2007(4) Å, $b$ = 13.8886(4) Å, $c$ = 14.9130(6) Å, $\alpha$ = 107.497(2)° $\beta$ = 94.569(2)° $\gamma$ = 95.552(2)°, $V$ = 1992.37(13) Å$^3$, $Z$ = 2, $\rho_{calcd}$ = 1.605 g/cm$^3$, $T$ = 233 K, $\mu$ = 0.993 mm$^{-1}$, orange prism, 6844 reflections > 2$\sigma(I)$, $R_1$ = 0.0282, and $\omega R^2$ = 0.0648. Compound **7**: Monoclinic space group $C2/c$ (no. 15), $a$ = 27.0985(3) Å, $b$ = 14.4321(4) Å, $c$ = 20.3053(5) Å, $\beta$ = 109.654(2)°, $V$ = 7478.5(3) Å$^3$, $Z$ = 8, $\rho_{calcd}$ = 1.413 g/cm$^3$, $T$ = 233 K, $\mu$ = 0.528 mm$^{-1}$, orange prism, 5820 reflections > 2$\sigma(I)$, $R_1$ = 0.0348, and $\omega R^2$ = 0.0784. Compound **8**: Orthorhombic space group $P2_12_12_1$ (no. 19), $a$ = 10.8932(2) Å, $b$ = 16.4398(4) Å, $c$ = 26.9136(7) Å, $\alpha = \beta = \gamma$ = 90°, $V$ = 4819.74(19) Å$^3$, $Z$ = 4, $\rho_{calcd}$ = 1.414 g/cm$^3$, $T$ = 233 K, $\mu$ = 0.506 mm$^{-1}$, colorless prism, 6183 reflections > 2$\sigma(I)$, $R_1$ = 0.0548, and $\omega R_2$ = 0.1203. Compound **9**: Orthorhombic space group $P2_12_12_1$, $a$ = 10.8403(2) Å, $b$ = 16.5038(3) Å, $c$ = 27.1075(4) Å, $\alpha = \beta = \gamma$ = 90°, $V$ = 4849.70(14) Å$^3$, $Z$ = 4, $\rho_{calcd}$ = 1.408 g/cm$^3$, $T$ = 233 K, $\mu$ = 0.503 mm$^{-1}$, colorless prism, 7510 reflections > 2$\sigma(I)$, $R_1$ = 0.0461, and $\omega R_2$ = 0.1181.

# Tetranuclear (Phosphane)(thiolato)gold(I) Complexes: Synthesis, Characterization and Photoluminescent Properties

**Eduardo J. Fernández,*[a] Antonio Laguna,*[b] José M. López-de-Luzuriaga,[a] Miguel Monge,[a] Manuel Montiel,[a] M. Elena Olmos,[a] Raquel C. Puelles,[a] and Eva Sánchez-Forcada[a]**

*Dedicated to Professor Vicente Gotor on the occasion of his 60th birthday*

**Keywords:** Phosphanes / Thiolates / Gold / Luminescence / Aurophilicity

The reactions of the tetraphosphane donor ligand $(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2$ with the gold precursors [AuCl(tht)] or [Au($C_6F_5$)(tht)] (tht = tetrahydrothiophene) leads to complexes $[Au_4R_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ [R = Cl (**1**) or $C_6F_5$ (**2**)]. Further substitution of the chlorine atoms in **1** by the corresponding 4-substituted benzenethiolates gives rise to the tetranuclear (phosphane)(thiolato)gold(I) complexes $[Au_4(S\text{-}C_6H_4\text{-}X)_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ [X = F (**3**), MeO (**4**), Me (**5**) and $NO_2$ (**6**)]. Complexes **2** and **4** were characterized by X-ray diffraction studies showing Au···Au interactions in the case of complex **4**. Complexes **3**–**6** display intense emissions in the solid state at 77 K with lifetimes in the microsecond range. The observed phosphorescent emissions are attributed to metal-to-ligand charge-transfer transitions. Nevertheless, the influence in the emission energies of gold–gold interactions or the contribution of the substituent in the 4-position of the benzenethiolate ring to the excited state cannot be neglected.

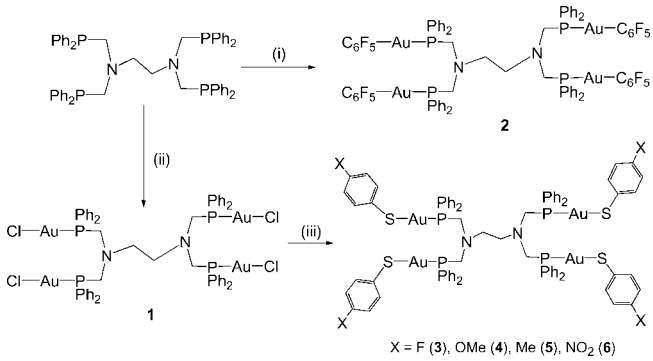
## Introduction

Polynuclear gold(I) complexes have attracted much interest in the last years mainly due to their intriguing structural dispositions, their rich photoluminescent properties[1] or even their potential applications in different fields as pharmaceutics, optical sensors, chemosensing, etc. In this sense, much of the interest has been generated by the clinical use of the mononuclear (phosphane)(thiolato)gold complex Auranofin,[2] employed in the treatment of reumathoid arthritis. Also, these types of complexes can be used as optical sensors for volatile organic compounds (VOCs) as shown by Eisenberg and coworkers[3] or as specific sensors for several cations as reported by Yam et al.[4]

(Thiolato)gold(I) complexes containing multidentate phosphane ligands can be considered an important class of polynuclear compounds, as the presence of several P–Au–S structural units in their structures permits the formation of aurophilic interactions. These interactions, which are comparable in strength with hydrogen bonding, are recognized as a structural motif that governs the amazing molecular and supramolecular arrangements found in the solid state for many types of gold(I) compounds.[5] Moreover, several (phosphane)(thiolato)gold(I) compounds also display very interesting photoluminescent properties over a wide range of the visible spectrum (400–700 nm), and the observed emissions are usually attributed to ligand-to-metal charge-transfer (LMCT) excited states that can be perturbed by the presence of the above-mentioned $Au^I\cdots Au^I$ interactions.[6]

In spite of several literature reports[7] on the synthesis of (phosphane)(thiolato)gold(I) complexes, the quest for high nuclearity compounds is often pursued through the use of



Scheme 1. Synthesis of complexes **1**–**6**. (i) [Au($C_6F_5$)(tht)]; (ii) [AuCl(tht)]; (iii) NaOMe, SH–$C_6H_4$–X (X = F, OMe, Me or $NO_2$).

bi- or tridentate phosphorus donor ligands. We focused a part of our outgoing research on the synthesis of high nuclearity gold(I) complexes through the reaction of the appropriate gold(I) precursors with the tetradentate P donor ligand $(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2$[8] that permits the synthesis of tetranuclear (phosphane)(thiolato)gold(I) compounds (Scheme 1).

In this paper we report the synthesis of tetranuclear (phosphane)(thiolato)gold(I) compounds that are brightly luminescent in the solid state at 77 K. We analyzed the mechanism responsible for the luminescence in this type of complex by taking into account the presence of intramolecular aurophilic interactions or the electronic influence of the substituent in the 4-position of the benzenethiolato ligands bonded to gold.

## Results and Discussion

### Synthesis and Characterization

The tetranuclear gold(I) compounds $[Au_4R_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ [R = Cl (**1**) or $C_6F_5$ (**2**)] were prepared by the reaction of 4 equiv. of the corresponding [AuCl(tht)] or $[Au(C_6F_5)(tht)]$ (tht = tetrahydrothiophene) precursors and 1 equiv. of the tetradentate phosphane ligand $(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2$ (Scheme 1) in quantitative yields by displacement of the labile tht ligand as crystalline white solids. All analytical and spectroscopic data are in agreement with the proposed stoichiometries. Their $^{31}P\{^1H\}$ NMR spectra display a singlet at 17.7 (**1**) or 24.7 ppm (**2**), which shows a large shift downfield upon coordination of the four Cl–Au or $C_6F_5$–Au units to the tetraphosphane ligand (–28.5 ppm). The $^{19}F$ NMR spectrum of complex **2** shows the expected pattern of the $C_6F_5$ groups bonded to $Au^I$ with three signals at –115.4, –157.7 and –161.8 ppm, which correspond to the fluorine atoms in the *ortho*, *para* and *meta* positions, respectively. Both complexes show the corresponding signals of the different methylene groups that are present in the phosphane ligand in their $^1H$ NMR spectra, and they are also shifted downfield relative to those of the free ligand. Their IR spectra show absorptions arising from the Au–Cl or Au–$C_6F_5$ groups that appear at 326 or at 1504, 954 and 792 $cm^{-1}$.

The reaction of complex **1** with different 4-substituted benzenethiols affords the corresponding compounds $[Au_4(S–C_6H_4\text{-}X)_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ [X = F (**3**), MeO (**4**), Me (**5**) and $NO_2$ (**6**)] as stable crystalline solids. The thiolato ligands are prepared in situ by the reaction of the benzenethiols with an excess amount of sodium methoxide. The analytical and spectroscopic properties are in accordance with the proposed formulations. Their $^{31}P\{^1H\}$ NMR spectra show very similar shifts for the corresponding singlets as a result of the similar chemical and magnetic environments around the P atoms at 23.5, 23.4, 23.5 and 23.5 ppm for complexes **3**–**6**, respectively. In all cases, their IR spectra display the characteristic absorptions due to $\nu$(C–S) at 1103, 857 (for **3**), 1101, 867 (for **4**), 1101, 867 (for **5**) and 1103, 857 $cm^{-1}$(for **6**).

### X-ray Structural Determination of Derivatives 2 and 4

Single crystals suitable for X-ray diffraction studies were obtained by layering diethyl ether or hexane into a solution of the complex in dichloromethane (for **2**) or toluene (for **4**). Both **2** and **4** crystallize in the $P\bar{1}$ space group of the triclinic system with one molecule of the complex and one half of a molecule of diethyl ether (for **2**) or one molecule of toluene (for **4**) in the unit cell. Both structures consists of tetranuclear molecules in which each phosphorus atom of the tetradentate phosphane binds a (pentafluorophenyl)-gold(I) unit or a (thiolato)gold(I) unit for **2** and **4**, respectively (Figures 1 and 2), with Au–P distances of 2.2725(14) and 2.2799(14) Å for **2** and 2.260(2) and 2.267(2) Å for **4**, which compare well to those found in other related (pentafluorophenyl)-[9] or (benzenethiolato)(phosphane)-gold(I)[6a,10,12] complexes. The gold(I) centres complete their usual lineal environment with the coordination of a carbon atom of the anionic ligand $C_6F_5$ or a sulfur atom of S–$C_6H_4$–OMe for **2** or **4**, respectively. The Au–C bonds

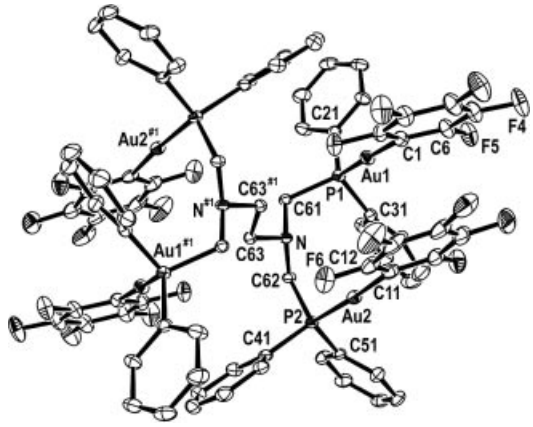

Figure 1. Molecular structure of complex **2**. Selected bond lengths [Å] and angles [°]: Au1–C1 2.049(6), Au2–C11 2.051(6), Au1–P1 2.2725(14), Au2–P2 2.2799(14), C1–Au1–P1 174.74(15), C11–Au2–P2 175.81(16).

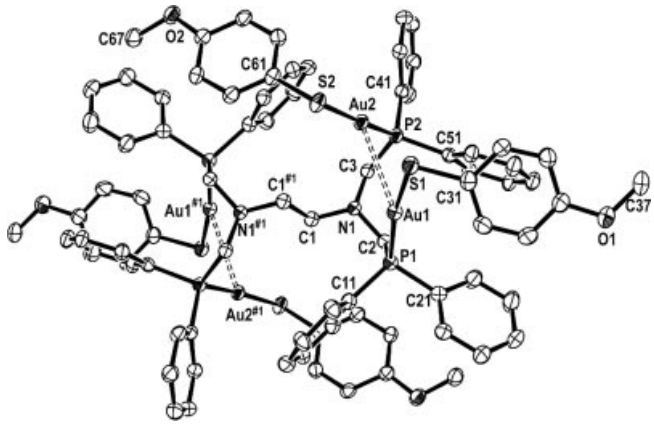

Figure 2. Molecular structure of complex **4**. Selected bond lengths [Å] and angles [°]: Au1–S1 2.318(2), Au2–S2 2.313(2), Au1–P1 2.260(2), Au2–P2 2.267(2), Au1–Au2 3.1485(4), S1–Au1–P1 169.13(8), S2–Au2–P2 173.13(7).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in **2**, of 2.049(6) and 2.051(6) Å, show typical values for pentafluorophenylphosphane gold(I) complexes,[9] whereas the Au–S bond lengths in **4** [2.318(2) and 2.313(2) Å] are slightly longer than the values found in a great number of (benzenethiolato)(phosphane)gold(I) complexes, but they are nearly identical to those observed in some derivatives containing the fragment Ph–S–Au–P.[6a,10a,10b,11] The main difference between these two structures is that whereas in **4** the metals associate into pairs through weak intramolecular Au···Au interactions of 3.1485(4) Å, the same disposition is not found in the case of complex **2**, in which the shortest Au–Au distance is 4.264 Å. The Au–Au distance in **4** is shorter than that in the related (diphosphane)(thiolato)-gold(I) complexes $[Au_2(S–B15C5)_2(dcmp)]$ [dcmp = bis(dicyclohexylphosphanyl)methane, S–B15C5 = 4′-mercaptobenzo-15-crown-5] [3.2556(8) Å] or $[Au_2(dcmp)(S–B18C6)_2]$ (S–B18C6 = 4′-mercaptobenzo-18-crown-6) [3.284(1) Å],[12] but it is longer than that in $[Au_2(m\text{-tc})_2\{Ph_2P(o\text{-}C_6H_4)O(o\text{-}C_6H_4)\ PPh_2\}]$ (tc = thiocresol) [3.0065(15) Å],[13] $[Au_2(S–C_6H_4NH_2\text{-}2)_2(dppm)]$ [3.1346(4) Å][6b] or $[Au_2(S–C_6H_4\text{-}CONH_2\text{-}2)_2(dppp)]$ [dppp = bis(diphenylphosphanyl)propane] [2.9997(7) Å].[10a]

### Photophysical Studies

The four phosphane–sulfide complexes display luminescence under UV light at 77 K, but they are not luminescent at room temperature or in solution. Thus, by excitation at 375 nm (complexes **3**–**5**) or 475 nm (complex **6**), emissions at 497, 508, 510 or 625 nm, respectively, are observed. The large Stokes shifts observed (>6500 for **3**, 6900 for **4**, 7000 for **5** and 5000 for **6**) implies that there is a large distortion in the excited state relative to the ground state, which is consistent with a charge transfer transition. In fact, in luminescent complexes containing S(thiolato)–Au–P(phosphane) units, the emissions are assigned to metal-to-ligand charge transfer (MLCT) transitions and, therefore, we propose a similar origin.[6] Nevertheless, the presence of phenyl groups in the ligands raises an alternative assignment, because emission bands near 500 nm in phenylphosphane metal complexes have previously been reported. These have their origin in π–π* transitions,[14] although this possibility appears remote as the chloro- and pentafluorophenylgold(I) derivatives **1** and **2**, which contain the same diphenylphosphane ligand, do not show luminescence neither in the solid state at different temperatures nor in solution.

The four complexes have long lifetimes in the microsecond range with values of 28.7 and 107.5 ($R^2$ = 0.997) for **3**, 32.4 ($R^2$ = 0.991) for **4**, 30.1 ($R^2$ = 0.991) for **5** and 399.7 μs ($R^2$ = 0.994) for **6**, suggesting that the excited states are of triplet parentage and, therefore, consistent with phosphorescent emissions (Figure 3).

As regards the position of the emission bands, previous studies in thiolate–phosphane–gold complexes carried out originally by Bruce et al.[15] and Fackler et al.[6a] point out two main factors that are responsible for the luminescent behaviour: electron-withdrawing groups on the thiolato ligands and the presence or absence of gold–gold interactions in the complexes. Electron-withdrawing groups on the thiolato ligand stabilize the sulfur orbital, which makes the ligand more difficult to oxidize and shifts the emissions to higher energies. By contrast, from these studies it was also concluded that the "gold–gold interaction is not a necessary condition for luminescence",[15] but "in some circumstances shift the emission maxima to lower energies".[6a] In our case, only the methoxy derivative was structurally characterized, and the metal–metal distance is 3.15 Å. As the emission band of the methyl derivative appears at similar energy and the electron withdrawing capability is similar for both groups, it is likely that this complex will display a similar gold–gold interaction. Nevertheless, when a fluorine atom is the substituent on the thiolato ligand its much higher electron-withdrawing ability only slightly shifts the emission band to higher energy; this can be attributed to a decreased effectiveness of this ability in the *para* position. Finally, the nitro derivative displays the longest wavelength emission in spite of its large electron-withdrawing ability. By taking into account that it is also placed in the *para* position where this effect is diminished, it is likely that the nitro group importantly contributes to the excited state or that this derivative presents a very short gold–gold interaction in the solid state.

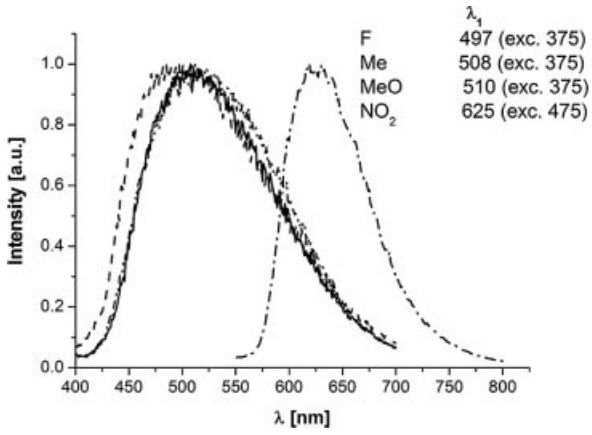

Figure 3. Emission spectra of complexes **3**–**6**.

## Conclusions

We report here the synthesis and characterization of new tetranuclear (phosphane)(thiolato)gold(I), in which a tetradentate phosphane with an ethylenediamine core and 4-substituted benzenethiols are employed as ligands. The X-ray structure of the precursor gold(I) complex with pentafluorophenyl groups bonded to gold does not show aurophilic interactions; meanwhile the corresponding (benzenethiolato)(phosphane)gold(I) complex **4** displays two $Au^I\cdots Au^I$ interactions leading to two pairs of P–Au–S units.

From the photophysical measurements it was shown that these (benzenethiolato)(phosphane)gold(I) tetranuclear derivatives display intense luminescence in the solid state at 77 K with lifetimes in the microsecond range. Both the pres-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ence of aurophilic interactions as well as the electron-withdrawing ability of the substituents in the 4-position of the benzenethiolato ligands were studied. It seems plausible that the electron-withdrawing abilities of the substituents in 4-position of the benzenethiolato ligand do not play a key role as it is not possible to correlate it with the emission energies. The results obtained could be more likely related to the presence of aurophilic interactions in the complexes, although the possibility of a contribution of the substituents to the excited state cannot be neglected.

## Experimental Section

**General:** The compounds [AuCl(tht)],[16] [Au($C_6F_5$)(tht)][17] and $(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2$[8] were synthesized by standard literature procedures. The starting materials $Ph_2PH$, *p*-formaldehyde and $NH_2CH_2CH_2NH_2$ were purchased from Sigma–Aldrich and used as received without further purification.

**Instrumentation:** Infrared spectra were recorded in the 4000–200 $cm^{-1}$ range with a Perkin–Elmer FTIR Spectrum 1000 spectrophotometer by using Nujol mulls between polyethylene sheets. C, H and N analyses were carried out with a C.E. Instrument EA-1110 CHNS-O microanalyzer. Mass spectra were recorded with a MICROFLEX MALDI-TOF spectrometer by using dithranol (DIT) as matrix. $^1H$, $^{19}F$ and $^{31}P\{^1H\}$ NMR spectra were recorded with a Bruker ARX 300 in $CDCl_3$. Chemical shifts are quoted relative to $SiMe_4$ ($^1H$ external), $CFCl_3$ ($^{19}F$ external) and $H_3PO_4$ (85%) ($^{31}P$ external), respectively. Excitation and emission spectra as well as lifetime measurements were recorded with a Jobin–Yvon Horiba Fluorolog 3–22 Tau-3 spectrofluorimeter.

**$[Au_4Cl_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ (1):** To a dichloromethane solution (20 mL) of [AuCl(tht)] (0.20 g, 0.624 mmol) in dichloromethane (20 mL) was added $(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2$ (0.13 g, 0.145 mmol). After 30 min of stirring at room temp., the solvent was evaporated to ca. 5 mL. The addition of *n*-hexane (20 mL) led to the precipitation of compound **1** as a white solid. Yield: 83%. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.80–7.20 (m, 40 H, aromatic protons), 3.87 (s, 8 H, P-$CH_2$-N), 2.60 (s, 4 H, N-$CH_2CH_2$-N) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = 17.7 (s, $PPh_2$) ppm. IR: $\tilde{\nu}$ = 1573 $\nu$(C–N), 327 $\nu$(Au–Cl) $cm^{-1}$. MS (MALDI+): *m/z* (%) = 1747.1 (100) $[M - Cl]^+$. $C_{54}H_{52}Au_4Cl_4N_2P_4$ (1782.57): calcd. C 36.38, H 2.94, N 1.57; found C 36.52, H 2.97, N 1.59.

**$[Au_4(C_6F_5)_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ (2):** To a dichloromethane solution (20 mL) of [Au$C_6F_5$(tht)] (0.15 g, 0.332 mmol) in dichloromethane (20 mL) was added $(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2$ (0.071 g, 0.083 mmol). After 30 min of stirring at room temp., the solvent was evaporated to ca. 5 mL. The addition of *n*-hexane (20 mL) led to the precipitation of compound **2** as a white solid. Yield: 75%. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.70–7.20 [m, 40 H, aromatic protons], 3.70 (s, 8 H, P-$CH_2$-N), 3.02 (s, 4 H, N-$CH_2CH_2$-N) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = 24.7 (s, $PPh_2$) ppm. $^{19}F$ NMR (283 MHz, $CDCl_3$): $\delta$ = –115.36 (m, 8 F, $F_{ortho}$), –157.71 (t, $^3J_{Fp\text{-}Fm}$ = 19 Hz, 4 F, $F_{para}$), –161.82 (m, 8 F, $F_{meta}$) ppm. IR: $\tilde{\nu}$ = 1586 $\nu$(C–N), 1504, 954, 792 $\nu$(Au–$C_6F_5$) $cm^{-1}$. MS (MALDI+): *m/z* (%) = 1777.9 (100) $[M - Au(C_6F_5)_2]^+$. $C_{78}H_{52}Au_4F_{20}N_2P_4$ (2308.99): calcd. C 40.57, H 2.27, N 1.21; found C 40.96, H 2.38, N 1.25.

**General Procedure for the Preparation of $[Au_4(S\text{-}C_6H_4\text{-}X)_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ [X = F (3), MeO (4), Me (5) and $NO_2$ (6)]:** To a dichloromethane solution (20 mL) of the benzenethiol (0.337 mmol) was added an excess amount of NaOMe (0.073 g, 1.34 mmol). After 15 min of stirring, complex $[Au_4Cl_4\{(Ph_2PCH_2)_2NCH_2CH_2N(CH_2PPh_2)_2\}]$ **1** was added (0.15 g, 0.084 mmol). The reaction mixture was stirred for 2 h, generating a white solid (NaCl) that was separated by filtration. The filtrate was evaporated to ca. 5 mL, and the addition of diethyl ether (20 mL) led to the precipitation of the compounds.

**3:** From 4-fluorobenzenethiol (0.043 g). Yield: 45%, white solid. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.70–7.20 (m, 40 H, Ph rings), 6.77 (m, 8 H, 3-H and 5-H in S-$C_6H_4$-F), 3.83 (s, 8 H, $PCH_2N$), 2.61 (s, 4 H, $NCH_2CH_2N$) ppm.$^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = 23.5 (s) ppm. $^{19}F$ NMR (283 MHz, $CDCl_3$): $\delta$ = –120.70 (s, 4 F) ppm. IR: $\tilde{\nu}$ = 1584 $\nu$(C–N), 1103, 857 $\nu$(C–S) $cm^{-1}$. MS (MALDI+): *m/z* (%) = 2022 (1.5) $[M - (S\text{-}C_6F_4\text{-}F)]^+$, 1698 (17) $[M - Au(S\text{-}C_6H_4\text{-}F)_2]^+$. $C_{78}H_{68}Au_4F_4N_2P_4S_4$ (2149.41): calcd. **Crystallography:** The crystals were mounted in inert oil on glass fibres and transferred to the cold gas stream of a Nonius Kappa CCD diffractometer equipped with an Oxford Instruments low-temperature attachment. Data were collected by monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Scan type $\omega$ and $\phi$. Absorption corrections: numerical (based on multiple scans). The structures were solved by direct methods and refined on $F^2$ by using the program SHELXL-97.[18] All non-hydrogen atoms were anisotropically refined with the exception of the solvent (diethyl ether) molecule in **2**. Hydrogen atoms were included using a mixed model. CCDC-647628 to -647629 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# An Approach to the Synthesis of Silicon Carbide Nanowires by Simple Thermal Evaporation of Ferrocene onto Silicon Wafers

**Jun-Jie Niu*[a] and Jian-Nong Wang[a]**

**Keywords:** Silicon / Carbides / Thermal evaporation / Ferrocene / Nanowires

Scales of silicon carbide nanowires (SiC-NWs) with high quality were synthesized by direct thermal evaporation of ferrocene onto silicon wafers at high temperature. Ferrocene decomposed into iron and carbon, which was subsequently treated with silicon to form SiC-NWs at high temperature. The SiC-NWs possess small diameters of ≈ 20 nm and lengths of several μms. Furthermore, the samples show a uniform morphology, crystalline structure, and a very thin oxide layer. The main crystal direction of [111] was confirmed by high-resolution field-emission-transmission electron microscopy (HR-FETEM). The Raman scattering spectra showed two peaks at ≈ 796 (TO) and ≈ 980 $cm^{-1}$ (LO) with varying intensity ratios at different positions. The band line fluctuation was contributed to the Raman selection rules. With reference to the experimental results, we suggested a tentative growth model according to the vapor–liquid–solid (VLS) mechanism. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Silicon carbide presents wide applications in many harsh conditions such as high temperature and high frequency due to the high mechanical strength, high chemical stability, low induced activity, and so forth.[1] Many high-performance silicon carbide based devices are now commercially available, including metal semiconductor field-effect transistors and Schottky rectifiers. One-dimensional nanomaterials deserve special attention, as they are expected to play a crucial role as building blocks of future molecular electronic applications.[2–4] Silicon carbide nanowires (SiC-NWs), possessing a special geometrical and wide band-gap semiconductor structure, show the considerable advantage of a high electrical conductance and excellent mechanical stability, which makes them extremely interesting in many electrical and mechanical fields. Much effort has been focused in the miniaturization of electronic devices by using SiC-NWs in the last decade.[5–7] It was demonstrated that the SiC-NWs displayed excellent field emission and optical properties due to their remarkable structural and chemical stabilities.[6,8–10] Furthermore, SiC-NWs also exhibit good mechanical features in reinforcing the strength of ceramic–matrix composite.[11–12]

A number of existing techniques can be used for the synthesis of SiC-NWs, including carbon nanotube confined reactions,[5,13–16] carbothermal reduction,[17–21] metal-assisted vapor–liquid–solid (VLS) growth,[8,22–25] etc. Among them, a process based upon the carbon nanotube (CNTs) solid–vapor reaction with volatile oxides and/or halide species, was reported.[5] By using the floating catalyst ferrocene with the $SiCl_4$–$C_6H_6$–$H_2$–Ar system, SiC nanorods with sizes of ≈ 100 nm were obtained.[23] If the ferrocene on the silicon wafer was reacted at 600 °C with an ultrahigh vacuum (UHV) system, SiC nanodots will be formed.[24] Lee and coworkers have synthesized crystalline β-SiC-NWs with diameters of 10–30 nm by hot filament chemical vapor deposition (HFCVD), and these nanowires possessed good field-emitting properties.[22,26] Yang et al. proposed the synthesis of SiC-NWs by the thermal decomposition of a polymeric precursor with a thickness ranging from 80 to 200 nm.[27] Needle SiC-NWs were successfully prepared by thermal evaporation of SiC powder and iron powder at a high temperature of 1700 °C.[28] Moreover, Deng et al. found that single crystalline SiC-NWs could be grown directly on the surface of bulk SiC ceramic substrates in a catalyst-assisted thermal heating process.[29] However, most of the synthetic methods involved complex processes and manipulations. Furthermore, the as-produced SiC-NWs were usually over 30 nm in size and a contained a thick oxide layer. It is desirable to fabricate crystalline SiC-NWs with small diameters that are free of oxide layers by a simple process. Furthermore, the Raman scattering spectra of SiC-NWs are seldom studied and need to be further investigated.

Herein we report an alternative approach in which scales of high-quality SiC-NWs were synthesized by the simple thermal evaporation of ferrocene onto silicon wafers. Iron as a catalyst and carbon pyrrolyzed by ferrocene at high temperatures deposited on the surface of silicon wafers and reacted with silicon to generate SiC-NWs. The as-formed

SiC-NWs with small diameters of ≈ 20 nm and lengths of several μms show a well-crystalline structure, uniform size distribution, and thin oxide layer. Furthermore, the crystal direction of [111] is clearly observed. Two peaks at ≈ 796 (TO) and ≈ 980 $cm^{-1}$ (LO) in the Raman scattering spectra show varying intensity ratios at different positions. The intensity fluctuation is attributed to the Raman selection rules. Finally, we suggest a possible growth model that is related to the vapor–liquid–solid (VLS) mechanism.

## Results and Discussion

Figure 1 displays the FESEM image of scales of SiC-NWs with diameters of ≈ 20 nm and lengths of several μms. Relatively straight SiC-NWs with uniform size distributions and smooth surfaces can be clearly observed from the enlarged image in Figure 1b. It also can be seen that the surface of the SiC-NWs is clean and free of impurities. Shown in Figure 1c is an interesting FESEM image of as-grown SiC-NWs sticking to the silicon wafer. As can be seen from the figure, the homogeneous SiC-NWs closely contact to the surface of the silicon wafer, indicating a different growth procedure relative to Figure 1a and b. The possible chemical composition of the sample was analyzed through the EDS data recorded from several pure nanowires (Figure 1d). The presence of peaks demonstrates that the nanowires are composed of silicon, carbon, and small amount of oxygen. The quantitative element analysis shows a Si/C ratio of 1:1, which corresponds well to the standard SiC (1:1) and thus confirms the composition of the SiC nanowires. The small quantity of oxygen may come from the resident oxide layer or the adsorbed oxygen in the air. The Fe peak was not detected because of the weak concentration. Shown in Figure 2 are the TEM images of several SiC-NWs with mean diameters of ≈ 20 nm and lengths of 2–3 μms. It is clear that the SiC-NWs are structurally uniform and dislocation free. We estimated the diameter distribution of the SiC-NWs by calculating hundreds of nanowires from the TEM images. As can be seen from Figure 4b, the majority of SiC-NWs show a concentrated diameter arrangement of ≈ 20 nm. Some of the SiC-NWs have sizes that are less than 10 nm and very few are over 25 nm. The high-magnification TEM image in Figure 2b more clearly shows a smooth morphology and homogeneous size distribution of the SiC-NWs. Moreover, the SiC-NWs are of high quality with free of defects such as stacking faults. The selected area electric diffraction (SAED) pattern corresponding to the SiC-NWs indicates a crystalline structure (Figure 2a inset). The (111) face that is confirmed in the figure suggests a main growth direction of [111] because of the lowest energy theory. Otherwise, the fluctuant brightness of black and white in the TEM image synchronously indicates a crystalline nature. The lattice structure of the SiC-NWs can be viewed in the HR-FETEM image (Figure 3). As can be seen from Figure 3, the regular interplanar spacing of 0.25 nm shows good agreement with SiC growth along the [111] direction, indicating a single-crystalline structure. Otherwise, it is observed that the lattice fringes are parallel to the nanowire axes, which indicates a [220] growth direction. It can also be observed that the surfaces

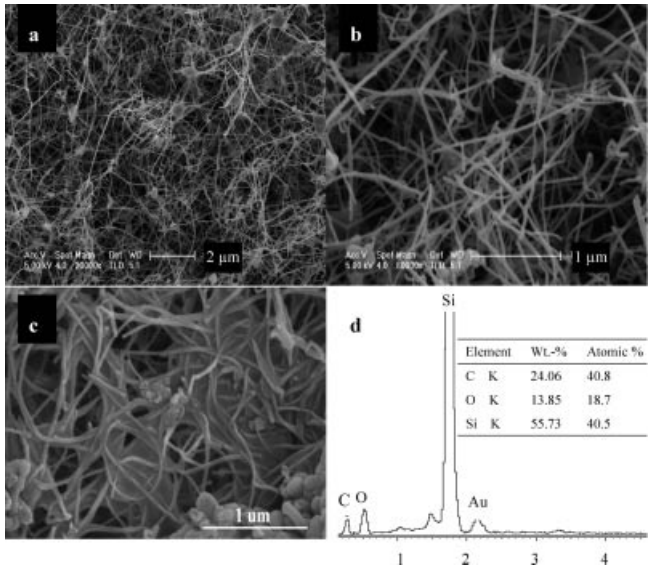

Figure 1. (a) The low-magnification, (b) high-magnification, and (c) special-structure FESEM images of the SiC-NWs with mean diameters of ≈ 20 nm and lengths of several μms. (d) The EDS spectrum and quantitative elemental analysis recorded from the pure SiC-NWs. The weak Au and unmarked peaks come from sample preparation during the FESEM measurements.

of the SiC-NWs are smooth and clean and possess only a very thin oxide layer of less than 1 nm. As a result, the SiC-NWs are structurally uniform, singly crystalline, and have only a thin oxide layer.

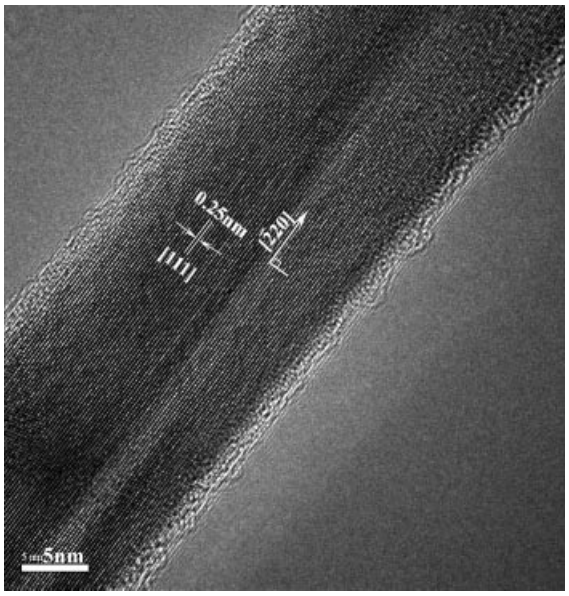

Figure 3. HR-FETEM image of a SiC-NW with the lattice orientation of [111].

Shown in Figure 4a is the XRD data of the sample, which is used for analyzing the crystalline structure. As can be seen from the pattern, the peaks of (111), (200), (220), (311), and (222) are completely consistent to the standard face-centered cubic (fcc) cell of SiC with the lattice constant of $a$ = 0.4349 nm (JCPDS card No. 73–1665). The strong intensity and narrow width of the lines also indicate an excellent crystal structure, which is also shown in the HR-FETEM image. Except for the peaks of SiC, several peaks of $Si_2N_2O$ with a low intensity are synchronously observed. These reflection lines are believed to be derived from weak nitrification and oxidation during the procedure.

Figure 5A displays the Raman scattering spectrum of a typical SiC-NW sample at room temperature. There is a prominent band line at ≈ 796 $cm^{-1}$ and a low intensity line at ≈ 980 $cm^{-1}$; these two lines correspond well to the band lines of a zincblende structure of bulk SiC. Furthermore, these bands normally result from the first-order phonon frequencies of the transverse optical (TO) and longitudinal optical (LO) modes, respectively.[30] Between these two lines, the lines at 729 and 887 $cm^{-1}$ can also be distinguished. These two peaks may be attributable to special SiC-NWs Raman-active modes or to impurities. As can be seen from the figure, the symmetry and narrow width of the lines indicate a crystalline nature of the high-quality SiC-NWs. The lines in this Raman spectrum are consistent with those reported for SiC nanorods or nanowires,[25,31] but they are different to those of bulk materials or films of SiC.[32–33]

It is known that the LO band line is usually higher than the TO band line near the zone center in bulk SiC.[34] However, in this Raman scattering spectrum, the TO band

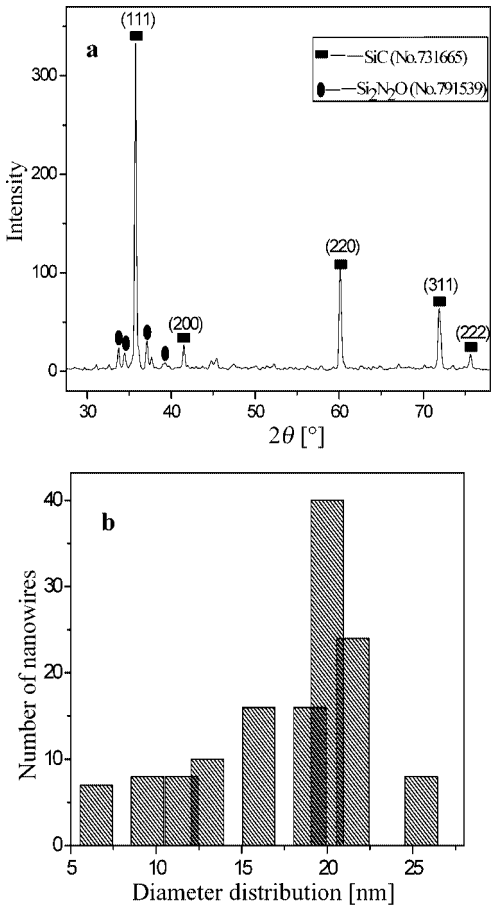

Figure 4. (a) XRD pattern of the SiC-NW sample. (b) Diameter distribution of the SiC-NWs.

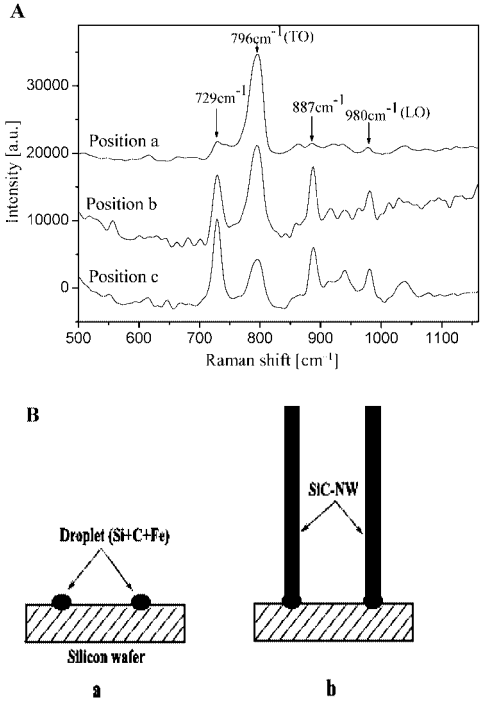

Figure 5. (A) Raman scattering spectra of the SiC-NWs with different positions. (B) Schematic illustration of the SiC-NWs growth model.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

shows a stronger intensity than the LO band (Figure 5A). As depicted in the figure, the SiC-NWs sample exhibits a fluxional intensity ratio of the various band lines when it was irradiated at different positions. The intensity of the TO band at ≈ 796 $cm^{-1}$ continually decreases whereas the LO band at ≈ 980 $cm^{-1}$ increases when the radiation is moved from position a to c. These phenomena may be explained by the Raman selection rules. During the Raman measurements, the radiated SiC-NWs were randomly arranged and had no unique predominant crystalline direction, although the [111] will be the major orientation of growth. Therefore, the polarization of the incident and scattered wave vectors such as the (011) face, which is perpendicular to the quasi-backscattering geometry face (100), was not strictly obeyed.[21,31] Consequently, the TO and LO band lines in the Raman spectrum of our sample were not completely forbidden or allowed but showed a varying intensity ratio with different positions.

The growth of SiC-NWs with a metal catalyst normally results from the VLS mechanism. In the current process, ferrocene was used to serve as the iron catalyst and a source of carbon whereas the silicon wafer was used as a silicon source and the substrate. Here we propose a possible growth model corresponding to the VLS mechanism. During the process, ferrocene [$(C_5H_5)_2Fe$] will favorably be pyrolyzed into iron and carbon at high temperature. The decomposed Fe and C atoms will then be deposited onto the surface of the silicon wafer to form an alloy droplet with Si atoms along the VLS mechanism (Figure 5B, a). Once the Si and C atoms reach supersaturation, the excess atoms will precipitate out from the nuclear (alloy droplet) and grow up to a SiC-NW (Figure 5B, b). In theory, it is also possible for the catalyst to serve as an anchor on the tip of the nanowire. During this step, the one-dimensional SiC-NW structure usually grows along the direction of [111] because of the lowest-energy principle. Here one case should be mentioned; a small quantity of silicon may be oxidized to $SiO_2$ or SiO. The produced silicon oxide will simultaneously react with the deposited carbon and form the structure of SiC-NW. Furthermore, some silicon or generated silicon oxide will possibly be nitrified by nitrogen gas at high temperature (as shown in Figure 4a). It is noted that the as-formed SiC-NWs are not easy to be nitrified because of their high stability in the present experiments. It is believed that if another inert gas, such as argon, was used, the nitrification will not happen. During the current process, the C, Si, and catalytic Fe sources are supplied simultaneously by ferrocene and the silicon substrate, which obviously simplifies the synthesis process. Thus, a useful technique for synthesizing scales of crystalline SiC-NWs is suggested.

## Conclusions

Scales of high-quality crystalline silicon carbide nanowires with small diameters of ≈ 20 nm and lengths of several μms were synthesized by direct thermal evaporation of ferrocene onto a silicon wafer at high temperature. The samples possessed a uniform size, crystalline structure, and a thin oxide layer. The HR-FETEM image showed a main single-crystal direction of [111]. The Raman scattering spectra of the sample showed varying intensity ratios at different positions, which is attributed to the Raman selection rules. Finally, a tentative growth model according to the vapor–liquid–solid (VLS) mechanism was suggested. The simple synthetic process presented here suggests a useful route for the fabrication of crystalline SiC-NWs with high quantity.

## Experimental Section

**General Procedure:** A ceramic boat containing pieces of silicon wafers (n-type Si (100) with a resistivity of about 4.1 Ωcm) and an amount of ferrocene powder was placed on a silicon surface and put in the center of a high-temperature chemical-vapor-deposition furnace. The furnace was heated to 1550 °C at a rate of 10 °C/min. A nitrogen gas flow was initiated at a rate of 70 mL/min at the beginning. After heating for ca. 2 h, the samples were taken out for the next measurements. The morphology and lattice structure of the samples were checked by field emission scanning electric microscopy (FESEM, FEI Sirion) and high-resolution field emission transmission electron microscopy (HR-FETEM, JEM 2010F). The possible chemical composition was investigated by using energy-dispersive X-ray spectroscopy (EDS) attached to the FESEM. The crystalline structure was measured by X-ray diffraction using Cu-$K_\alpha$ radiation (XRD, D8 DISCOVER, Bruker). Raman scattering spectra were measured with a Raman microscope (Renishaw inVia plus) with a 514.5 nm laser as the excitation source at room temperature.

## Acknowledgments

This work was supported by the Shanghai-Applied Materials Research and Development Fund (No. 06SA06) and Youth Teacher Fund of Shanghai Jiao Tong University (A2306B). We would like to thank the Instrumental Analysis Center of Shanghai Jiao Tong University for their great help in obtaining the measurements.

# Phosphaalkenes $R^1C(O)–P=C(NMe_2)_2$ ($R^1$=Ph, 4-Et$C_6H_4$): Versatile Reagents for 1,3-Dipolar Cycloadditions to Phosphenium Complexes $[Cp(CO)_2M = PPh_2]$ (M = Mo, W)

**Lothar Weber,*[a] Gabriel Noveski,[a] Stefan Uthmann,[a] Hans-Georg Stammler,[a] and Beate Neumann[a]**

**Keywords:** Phosphaalkenes / Phosphenium Complexes / Molybdenum / Tungsten

Reaction of $[Cp(CO)_2M = PPh_2]$ [where M = Mo (**2a**), W (**2b**)] with an excess of the phosphaalkenes arylC(O)P=C$(NMe_2)_2$ [where aryl = Ph (**3**), 4-Et$C_6H_4$ (**5**)] afforded the metallophosphaalkenes $[Cp(CO)_2M^a–P=C(aryl)–O–P^bPh_2(M^a–P^b)]$ [where M = Mo, aryl = Ph (**4a**); M = W, aryl = Ph (**4b**); M = Mo, aryl = 4-Et$C_6H_4$ (**6a**); M = W, aryl = 4-Et$C_6H_4$ (**6b**)] as orange crystals. Compounds **4a**,**b** and **6a**,**b** were characterized by means of spectroscopy (IR, $^1$H, $^{13}$C and $^{31}$P NMR spectroscopy and MS). Moreover, the molecular structures of **3**, **4a**, and **6b** were determined by X-ray diffraction analysis.

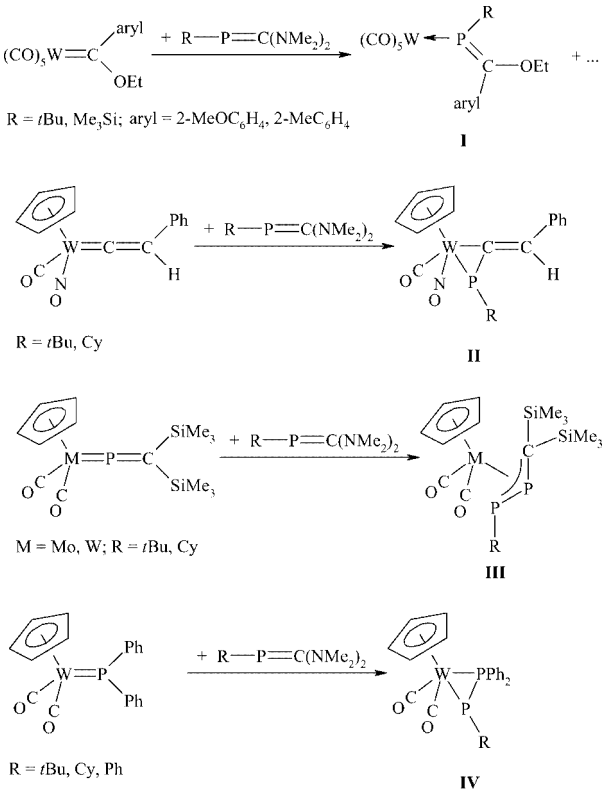
## Introduction

During the course of our studies on phosphaalkenes R–P=C$(NMe_2)_2$ (R = *t*Bu, Cy, Ph), we observed a facile metal-assisted cleavage of the PC multiple bond and the formal transfer of phosphanediyls (RP) on suitable complexes with electrophilic ligands.[1] Thus, reaction with selected Fischer carbene complexes gave rise to the formation of coordination compounds **I** with novel $\eta^1$-phosphaalkene ligands,[2] whereas treatment with vinylidene complexes resulted in the formation of $\eta^2$(P,C)-phosphaallene complexes **II**.[3] $\eta^3$-1,2-Diphosphaallyl complexes **III** were obtained from the combination of phosphaalkenes and phosphavinylidene complexes.[4] Only recently we disclosed the generation of $\eta^2$-diphosphanyl complexes **IV** by reacting phosphaalkenes and phosphenium complexes[5] (Scheme 1).

## Results and Discussion

The purpose of this work was to study the reactivity of the *P*-benzoylphosphaalkenes PhC(O)P=C$(NMe_2)_2$ (**3**)[6] and 4-Et$C_6H_4$C(O)P=C$(NMe_2)_2$ (**5**) with the phosphenium complexes $[Cp(CO)_2M = PPh_2]$ (**2a**: M = Mo; **2b**: W). The latter were generated in situ by the dehydrochlorination of the functionalized phosphane complexes $[Cp(CO)_2ClMP(H)Ph_2]$[7] (**1a**: M = Mo; **1b**: W) with diazabicycloundecene (DBU). Phosphaalkene **5** was synthesized as a yellow powder in 81% yield from 4-ethylbenzoylchloride and $Me_3SiP=C(NMe_2)_2$[8] (Scheme 2).



Scheme 1. Phosphanediyl-transfer from phosphaalkenes onto selected organometallic electrophiles.

Treatment of freshly prepared complexes **2a**,**b** with an excess of the phosphaalkenes in toluene solution over a temperature range of –30 to 20 °C afforded orange crystalline metallophosphaalkenes **4a**,**b** and **6a**,**b** in modest yields (Scheme 3).

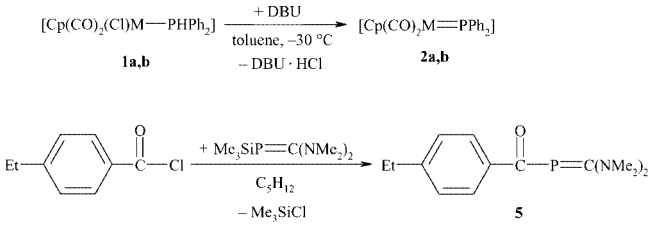
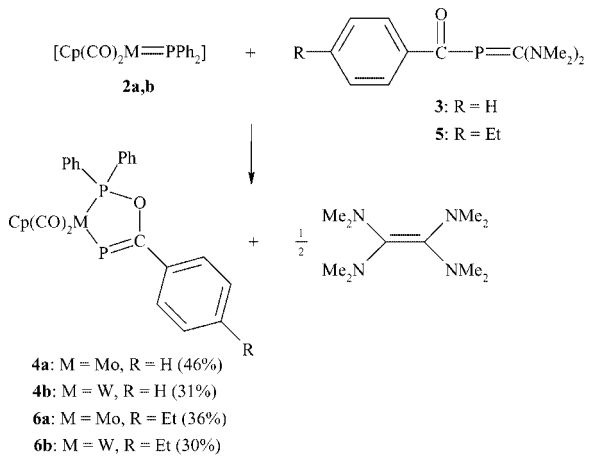


Scheme 2. Preparation of **2a**,**b** and **5**.



Scheme 3. Synthesis of metallophosphaalkenes **4a**,**b** and **6a**,**b**.

Isolation of the products was effected by column chromatography on Florisil with mixtures of pentane/diethylether as the eluents. Subsequent crystallization furnished analytically pure compounds.

The $^{31}P\{^1H\}$ NMR spectra of **4a** and **6a** show two doublets. The tetracoordinate P atoms give rise to signals at $\delta$ = 199.9 and 198.7 ppm, whereas the dicoordinate P atoms are observed at markedly lower field [**4a**: 235.5 (d); **6a**: 225.9 (d)] with PP coupling constants of 21.8 and 20.7 Hz, respectively. As expected, the corresponding doublets in tungsten complex **4b** and **6b** are more shielded and appear at $\delta$ = 170.7 (d, $PPh_2$) and 170.1 (d, $PPh_2$) ppm and $\delta$ = 209.4 (d, P=C) and 199.9 (d, P=C) with PP coupling constants of 21.8 and 22.5 Hz. Only tetracoordinate P atoms of **4b** and **6b** exhibit $^{183}W$ satellites with $^1J_{WP}$ = 329.3 and 330.4 Hz.

In the $^{13}C\{^1H\}$ NMR spectra of the products, the carbon atoms of the P=C bonds give rise to doublets of doublets in the typical low field region [**4a**: $\delta$ = 193.6 ppm ($^1J_{PC}$ = 85.6 Hz, $^2J_{PC}$ = 17.8 Hz); **4b**: $\delta$ = 192.9 ppm ($^1J_{PC}$ = 82.9 Hz, $^2J_{PC}$ = 18.2 Hz); **6a**: $\delta$ = 194.1 ppm ($^1J_{PC}$ = 86.2 Hz, $^2J_{PC}$ = 17.5 Hz); **6b**: $\delta$ = 193.4 ppm ($^1J_{PC}$ = 82.8 Hz, $^2J_{PC}$ = 18.4 Hz)]. The $^{13}C\{^1H\}$ NMR spectra of **4a**,**b** and **6a**,**b** show in the region of the carbonyl carbon atoms two markedly separated resonances at $\delta$ = 223.9 (s; **4b**, **6b**) and $\delta$ = 231.5 (d, $^2J_{PC}$ = 17.5 Hz; **4b**), 231.8 (d, $^2J_{PC}$ = 18.4 Hz; **6b**) and in the molybdenum compounds at $\delta$ = 234.3 (d, $^2J_{PC}$ = 12.7 Hz), 241.3 (d, $^2J_{PC}$ = 26.4 Hz) and at 234.3 (d, $^2J_{PC}$ = 12.1 Hz), 241.5 (d, $^2J_{PC}$ = 25.6 Hz) for **4a** and **6a**, respectively. We assign the resonances at higher field to the carbonyl group in the *trans* disposition of the $PPh_2$ unit. In keeping with the increased donor capability of the phosphaalkenyl group, the resonance of the carbonyl ligand in its *trans* disposition is attributed to the more deshielded signal. The $[M(CO)_2]$ group gives rise to two intense bands in the IR spectra at $\tilde{\nu}$ = 1935–1943 and 1864–1881 $cm^{-1}$, which are due to the symmetric and asymmetric CO stretching vibrations. Interestingly, the novel bidentate chelating ligand exhibits a decreased donor capacity relative to the $\eta^2$-diphosphanido ligand in complexes of the type $[Cp(CO)_2MPR^1–PR^2R^3]$, **IV** ($\tilde{\nu}$ = 1918–1933; 1837–1849 $cm^{-1}$).[5] The carbonyl vibration of the aryl group in precursor **4** was observed at $\tilde{\nu}$ = 1535 $cm^{-1}$, and does not show up in the products any longer, which means that it was involved in a cycloaddition process.

## X-ray Structural Investigations

Single crystals of phosphaalkene **2** suitable for X-ray diffraction studies were grown from *n*-pentane at –30 °C. The analysis (Figure 1, Table 1) shows a benzoyl-stabilized carbenium phosphanide, in which the planar carbenium center C(8) (sum of angles is 359.6°) displays multiple bonding to planarly configured nitrogen atoms [N(1)–C(8) = 1.344(2) Å, N(2)–C(8) = 1.356(2) Å].

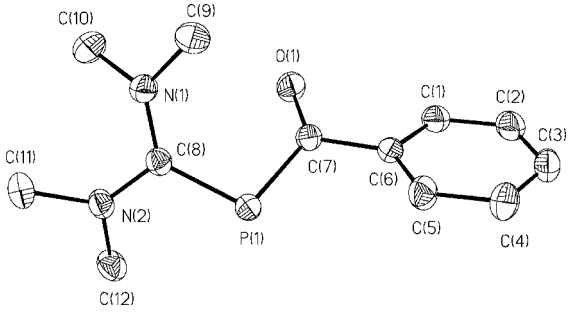


Figure 1. Molecular crystal structure of **2**. Selected bond lengths [Å] and angles [°]: P(1)–C(8) 1.800(1), P(1)–C(7) 1.806(1), O(1)–C(7) 1.240(2), N(1)–C(8) 1.344(2), N(1)–C(9) 1.462(2), N(1)–C(10) 1.468(2), N(2)–C(8) 1.356(2), N(2)–C(11) 1.461(2), N(2)–C(12) 1.457(2), C(6)–C(7) 1.511(2). C(8)–P(1)–C(7) 101.34(6), C(8)–N(1)–C(9) 123.0(1), C(8)–N(1)–C(10) 122.5(1), C(9)–N(1)–C(10) 113.4(1), C(8)–N(2)–C(11) 122.9(1), C(8)–N(2)–C(12) 123.3(1), C(11)–N(2)–C(12) 113.8(1), N(1)–C(8)–N(2) 116.8(1), N(1)–C(8)–P(1) 124.6(1), N(2)–C(8)–P(1) 118.2(1), P(1)–C(7)–O(1) 127.0(1), O(1)–C(7)–C(6) 118.0(1), C(6)–C(7)–P(1) 115.0(1).

The former P=C bond of the precursor [cf. $HP=C(NMe_2)_2$; *d*(P=C) = 1.740(1) Å] is markedly lengthened to 1.800(1) Å. A bond length of 1.806(1) Å is found between the phosphorus atom and the carbon atom of the carbonyl group in **2**, which compares well with the other PC bond of the molecule. Both bonds are best regarded as single bonds. The bonds between the phosphorus atom and the carbon atoms of both carbonyl groups in bis(pivaloyl)-phenylphosphane $[tBuC(O)]_2PPh$, however, are much longer [1.893(4) and 1.922(5) Å].[9] The CO double bond in **2** [1.240(1) Å] is slightly elongated relative to the CO bonds in $[tBuC(O)]_2PPh$ [1.201(6) and 1.217(6) Å]. The backbone of the compound defined by the atoms N(2), C(8), P(1), C(7), and C(6) deviates severely from a plane, as indicated

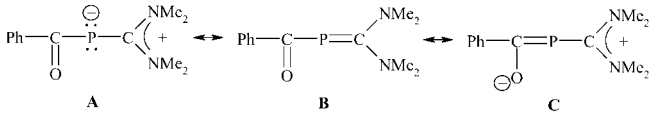
by the torsion angles O(1)–C(7)–P(1)–C(8) (–16.2°) and C(6)–C(7)–P(1)–C(8) (167.3°) and an interplanar angle of 40.5° between the plane defined by the atoms N(1),N(2), C(8) and P(1), C(7), C(8). From the X-ray structural data it can be concluded that compound **2** is best described by the zwitterionic limiting formula **A** and not by **B** or **C** (Scheme 4).



Scheme 4. Canonical formulae for phosphaalkene **3**.

Single crystals of **4a** suitable for X-ray diffraction analysis were grown from *n*-pentane at +4 °C. The analysis (Figure 2, Table 1) displays a molecule with a distorted four-legged piano-stool geometry [C(6)–Mo(1)–C(7) 78.79(7)°, C(6)–Mo(1)–P(2) 72.86(5)°, C(7)–Mo(1)–P(1) 80.57(5)°, P(1)–Mo(1)–P(2) 70.86(1)°] with two nearly linear carbonyl ligands [Mo(1)–C(6)–O(1) 177.9(2), Mo(1)–C(7)–O(2) 177.8(2)°]. The remaining two legs are represented by a 1,4,2-diphosphaoxabuten-3-yl ligand, which is chelating the metal atom through bonds Mo(1)–P(1) [2.3754(4) Å] and Mo(1)–P(2) [2.5602(5) Å]. The latter bond length compares well to the Mo–P distance in the metallophosphaalkene [$Cp(CO)_3Mo$–P=$C(SiMe_3)_2$] [2.568(1) Å].[10] The bond length between the metal atom and the tetracoordinated phosphorus atom of 2.3754(4) Å is slightly longer than the Mo–P contact in [$Cp(CO)_2Mo^a$–$PMe_2$–$C^b(SiMe_3)_2$(*Mo*$^a$–*C*$^b$)] [2.348(2) Å].[11]

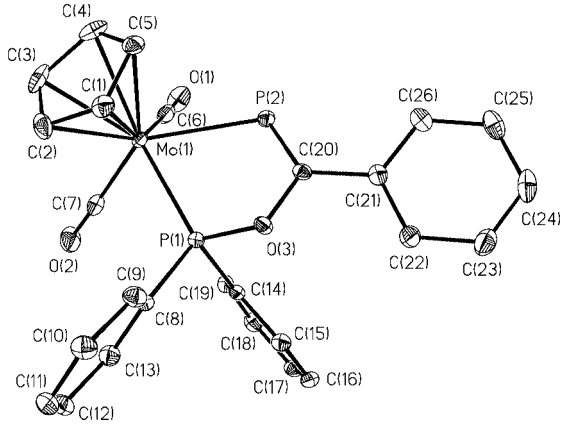


Figure 2. Molecular crystal structure of **4a**. Selected bond lengths [Å] and angles [°]: Mo(1)–C(6) 1.974(2), Mo(1)–C(7) 1.971(2), Mo(1)–P(1) 2.3754(4), Mo(1)–P(2) 2.5602(5), P(2)–C(20) 1.707(2), C(20)–O(3) 1.402(2), C(20)–C(21) 1.472(2), P(1)–O(3) 1.666(1), P(1)–C(8) 1.819(2), P(1)–C(14) 1.830(2); C(6)–Mo(1)–C(7) 78.8(1), C(6)–Mo(1)–P(2) 72.9(1), C(7)–Mo(1)–P(1) 80.6(1), P(1)–Mo(1)–P(2) 70.86(1), Mo(1)–P(1)–O(3) 112.51(4), P(1)–O(3)–C(20) 107.5(1), O(3)–C(20)–P(2) 121.7(1), Mo(1)–P(2)–C(20) 105.3(1), O(3)–C(20)–C(21) 112.7(1), P(2)–C(20)–C(21) 125.3(1), Mo(1)–C(6)–O(1) 177.9(2), Mo(1)–C(7)–O(2) 177.8(2)°.

Repulsion between the lone pair of electrons at P(2) and the electron-rich Mo atom may be responsible for the increased bond length relative to the Mo(1)–P(1) distance. This novel chelating ligand features the double bond P(2)–C(20) [1.707(2) Å], which compares well to the PC separation in the ferriophosphaalkene [$Cp(CO)_2Fe$–P=C-($OSiMe_3$)*t*Bu] [1.701(4) Å],[12] but it is markedly longer than that in the molybdophosphaalkene [$Cp(CO)_3Mo$–

P=C(SiMe$_3$)$_2$] [1.665(3) Å]. The contact P(1)–O(3) [1.666(1) Å] is shorter than the sum of the covalent radii (1.76 Å) but still reflects a bond order of unity.[13] Bond C(20)–O(3), which in precursor **2** exists as a carbonyl group with a bond length of 1.240(2) Å, is lengthened to a single bond of length 1.402(2) Å. The metalloheterocycle is slightly puckered (sum of endocyclic angles 517.9°).

Single crystals of **6b** were grown from *n*-pentane/diethyl ether at + 4 °C (Figure 3). Like **3a**, this complex has the geometry of a four-legged piano stool [C(6)–W(1)–C(7) 79.1(1), C(6)–W(1)–P(2) 72.9(1), C(7)–W(1)–C(7) 79.9(1), P(1)–W(1)–P(2) 72.77(2)°]. A 1,4,2-diphosphaoxabuten-3-yl ligand chelates the tungsten atom through bonds W(1)–P(1) [2.3632(5) Å] and W(1)–P(2) [2.5556(5) Å]. The former bond length is slightly shorter than the coordinative W–P bond in **7** [2.432(2) Å][7] or **8** [2.434(2) Å].[14]

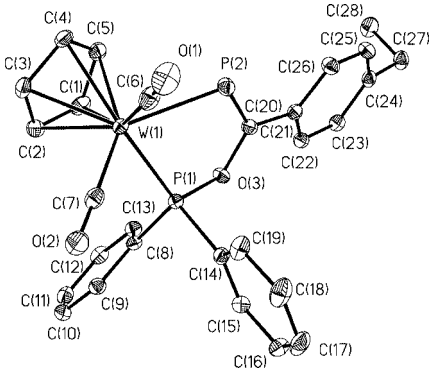

Figure 3. Molecular crystal structure of **6b**. Selected bond lengths [Å] and angles [°]: W(1)–C(6) 1.980(2), W(1)–C(7) 1.966(2), W(1)–P(1) 2.3632(5), W(1)–P(2) 2.5556(5), P(2)–C(20) 1.700(2), C(20)–O(3) 1.402(2), C(20)–C(21) 1.468(2), P(1)–C(8) 1.824(2), P(1)–C(14) 1.827(2); C(6)–W(1)–C(7) 79.1(1), C(6)–W(1)–P(2) 74.0(1), C(6)–W(1)–P(1) 116.2(1), C(7)–W(1)–P(1) 79.9(1), C(7)–W(1)–P(2) 127.1(1), P(1)–W(1)–P(2) 72.77(2), W(1)–P(1)–O(3) 113.64(4), P(1)–O(3)–C(20) 111.2(1), O(3)–C(20)–P(2) 121.7(1), W(1)–P(2)–C(20) 105.3(1), O(3)–C(20)–C(21) 112.0(1), P(2)–C(20)–C(21) 126.1(1), W(1)–C(6)–O(1) 177.4(2), W(1)–C(7)–O(2) 178.8(2).

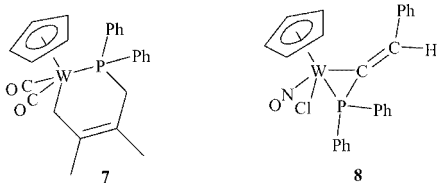
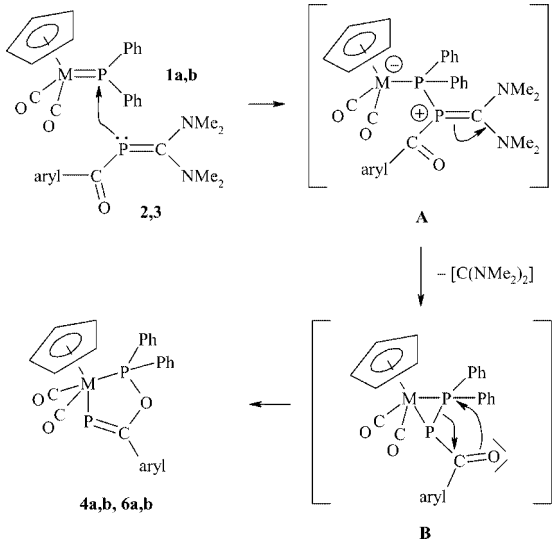


Bonding parameters within the chelating ligand of **6b** are close to those in **4a** and merit no particular discussion at this point. The five-membered metalloheterocycle of **6b** is more flattened (sum of endocyclic angles 529.6°) relative to that of **4a** (517.9°).

### Mechanisms

It is conceivable that the path towards the formation of complexes **4a**, **4b**, **6a**, and **6b** begins with nucleophilic attack of phosphaalkenes **2**,**3** by its electron-abundant phosphorus atom at the phosphenium center of **1a**,**b**, which affords zwitterion **A**. Release of a carbene unit and metal–phosphorus bond formation then affords intermediate **B**. Finally, ring enlargement leads to the final products; however, intermediates **A** and **B** were not detected by $^{31}$P NMR spectroscopic monitoring of the reaction (Scheme 5).



Scheme 5. Proposed mechanism for the synthesis of **4a**,**b** and **6a**,**b**.

## Conclusions

Transition-metal-induced cleavage of inversely polarized phosphaalkenes with concomitant transfer of the phosphanediyl unit on carbene- or phosphenium ligands to give $\eta^1$-phosphaalkene[2] and $\eta^2$-diphosphanido complexes[5] have previously been described. Here the smooth generation of complexes **4a**,**b** and **6a** featuring the chelating 1,4,2-diphosphaoxabutene-3-yl ligand underlines the ability of phosphaalkenes to act as convenient sources for phosphanediyl units under mild conditions.

## Experimental Section

**General:** All experiments were performed under a dry, oxygen-free nitrogen atmosphere by using standard Schlenk techniques. Solvents were carefully dried with an appropriate drying agent and freshly distilled under an atmosphere of $N_2$ before use. The following compounds were prepared according to literature procedures: [Cp(CO)$_2$ClMo–PHPh$_2$] (**1a**),[7] [Cp(CO)$_2$ClW–PHPh$_2$] (**1b**),[7] PhC(O)P=C(NMe$_2$)$_2$ (**3**),[6] and Me$_3$SiP=C(NMe$_2$)$_2$.[8] Diazabicycloundecene (DBU), 4-Et$C_6H_4$C(O)Cl, and Florisil (0.150–0.250 mm) were purchased commercially. IR spectra were recorded with a Bruker FTIR VECTOR 22 spectrometer. $^1$H-, $^{13}$C-, and $^{31}$P NMR spectra were recorded at room temp. with a Bruker AM Avance DRX 500 instrument. References: SiMe$_4$ ($^1$H, $^{13}$C) and 85% $H_3PO_4$ ($^{31}$P). MS was conducted with a Bruker Esquire Ion trap mass spectrometer autospec, sector field.

**4-Et$C_6H_4$C(O)P=C(NMe$_2$)$_2$ (5):** A solution of Me$_3$SiP=C(SiMe$_3$)$_2$ (0.25 g, 1.20 mmol) in *n*-pentane (20 mL) was added dropwise at –30 °C to the solution of 4-Et$C_6H_4$C(O)Cl (0.20 g, 1.20 mmol) in *n*-pentane(20 mL), whereby a yellow precipitate formed. Stirring was continued at –30 °C for 1 h. The cold slurry was filtered, and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the filtercake was washed with cold *n*-pentane (3 × 20 mL, –30 °C). The filtercake was dried at $10^{-3}$ bar to afford **5** as a bright yellow powder (yield: 0.26 g, 81%). $^1$H NMR (500.13 MHz, $C_6D_6$): $\delta$ = 0.99 (t, $^3J_{HH}$ = 7.5 Hz, 3 H, $CH_2CH_3$), 2.36 (q, $^3J_{HH}$ = 7.5 Hz, 2 H, $CH_2CH_3$), 2.59 (s, 12 H, $NCH_3$), 7.05 (m, 2 H, *m*-H-Ph), 8.54 (m, 2 H, *o*-H-Ph) ppm. $^{13}$C{$^1$H} NMR (125.75 MHz, $C_6D_6$): $\delta$ = 15.7 (s, $CH_2CH_3$), 29.0 (s, $CH_2CH_3$), 42.8 (d, $^3J_{PC}$ = 4.6 Hz, $NCH_3$), 126.9 (s, Ph), 127.0 (s, Ph), 142.9 (d, $^2J_{PC}$ = 48.3 Hz, *i*-C-Ph), 147.1 (s, *p*-C-Ph), 200.2 (d, $^1J_{PC}$ = 78.2 Hz, P=*C*), 215.4 (d, $^1J_{PC}$ = 78.2 Hz, PC=O) ppm. $^{31}$P{$^1$H} NMR (202.46 MHz, $C_6D_6$): $\delta$ = 30.8 (s) ppm. IR (KBr): $\tilde{\nu}$ = 1535 [s (CO)] cm$^{-1}$. MS (EI): *m*/*z* = 264 [M]$^+$, 133 [4 – $EtC_6H_4CO$]$^+$, 131 [P=C$(NMe_2)_2$]$^+$, 105 [4 – $EtC_6H_4$]$^+$. $C_{14}H_{21}N_2OP$ (264.30): calcd. C 63.62, H 8.01, N 10.60; found C 63.13, H 8.15, N 10.60.

**[Cp(CO)$_2$Mo$^a$–P=C(Ph)O–P$^b$Ph$_2$(*Mo$^a$–P$^b$*)] (4a):** A solution of [Cp(CO)$_2$ClMoPHPh$_2$] (**1a**; 0.80 g, 1.82 mmol) in toluene (40 mL) was added dropwise to a chilled solution (–30 °C) of PhC(O)-P=C$(NMe_2)_2$ (**3**; 1.29 g, 5.46 mmol) and DBU (0.42 g, 2.76 mmol) in toluene (30 mL). After 2 h, the addition was complete, and stirring at –30 °C was continued for 1 h. The mixture was then warmed to room temp. and stirred overnight. Solvent and volatile components were removed in vacuo. To the residue was added Florisil (3 g) and toluene (15 mL), and the slurry was evaporated to dryness. The remaining powder was brought on a column filled with Florisil and pentane (*l* = 5 cm, *d* = 2 cm). First the column was developed with pentane/diethyl ether (30:1) to separate a yellow zone. This zone was eluted with pentane/diethyl ether (30:5, ca. 250 mL). Concentration of the elute to ca. 120 mL and storage for 12 h at –30 °C furnished product **4a** as orange crystals (yield: 0.45 g, 46%). $^1$H NMR (500.13 MHz, $C_6D_6$): $\delta$ = 4.56 (s, 5 H, Cp), 6.80–7.08 (m, 9 H, Ph), 7.64 (m, 2 H, Ph), 7.81 (m, 2 H, Ph), 8.23 (m, 2 H, Ph) ppm. $^{13}$C{$^1$H} NMR (125.75 MHz, $C_6D_6$): $\delta$ = 93.0 (s, $C_5H_5$), 125.4, 125.5, 127.9, 128.1, 128.3, 128.4, 128.5, 128.6, 128.7, 129.8, 129.9, 130.3, 131.7, 132.4, 132.5, 137.9 (s, Ph), 138.2 (m, Ph), 141.7, 142.1 (s, Ph), 193.6 (dd, $^1J_{PC}$ = 85.6 Hz, $^2J_{PC}$ = 17.8 Hz, P=C), 234.3 (d, $^2J_{PC}$ = 12.7 Hz, CO), 241.3 (d, $^2J_{PC}$ = 26.4 Hz, CO) ppm. $^{31}$P{$^1$H} NMR (202.46 MHz, $C_6D_6$): $\delta$ = 199.3 (d, $^2J_{PP}$ = 21.8 Hz, $PPh_2$), 235.5 (d, $^2J_{PP}$ = 21.8 Hz, P=C) ppm. IR (KBr): $\tilde{\nu}$ = 1943 [s (CO)], 1874 [s (CO)] cm$^{-1}$. MS (EI): *m*/*z* = 540 [M]$^+$, 484 [M – 2 CO]$^+$. $C_{26}H_{20}MoO_3P_2$ (538.32): calcd. C 58.01, H 3.74; found C 57.20, H 3.42.

**[Cp(CO)$_2$W$^a$–P=C(Ph)O–P$^b$Ph$_2$(*W$^a$–P$^b$*)] (4b):** A solution of [Cp-(CO)$_2$ClWPHPh$_2$] (**1b**; 0.86 g, 1.63 mmol) in toluene (40 mL) was added dropwise (2 h) to a cold solution (–10 °C) of PhC(O)-P=C$(NMe_2)_2$ (**3**; 0.39 g, 1.63 mmol) and DBU (0.42 g, 2.76 mmol) in toluene (20 mL). The mixture was warmed to ambient temperature and stirred for 12 h. Volatile components were removed in vacuo, and the oily residue was combined with Florisil (2 g) and toluene and then chromatographed on Florisil as described above. A yellow zone was eluted with pentane/diethyl ether (3:2, ca. 300 mL). The elute was concentrated, and the residue was crystallized from toluene/pentane (1:1, 20 mL) at –30 °C over 24 h. The product separated as orange crystals (yield: 0.31 g, 31%). $^1$H NMR (500.13 MHz, $C_6D_6$): $\delta$ = 4.55 (s, 5 H, Cp), 6.82 (m, 1 H, Ph), 6.89 (m, 2 H, Ph), 6.99–7.11 (m, 6 H, Ph), 7.64 (m, 2 H, Ph), 7.81 (m, 2, Ph), 8.24 (m, 2 H, Ph) ppm. $^{13}$C{$^1$H} NMR (125.75 MHz, $C_6D_6$): $\delta$ = 91.6 (s, $C_5H_5$), 125.6, 125.8, 130.0, 130.1, 130.4, 131.8, 132.9, 133.0 (s, Ph), 192.9 (dd, $^1J_{PC}$ = 82.9 Hz, $^2J_{PC}$ = 18.2 Hz, P=C), 223.9 (s, CO), 231.5 (d, $^2J_{PC}$ = 17.5 Hz, CO) ppm. $^{31}$P{$^1$H} NMR (202.46 MHz, $C_6D_6$): $\delta$ = 170.7 (d, $J_{PP}$ = 21.8 Hz, $^1J_{WP}$ = 329.3 Hz, $PPh_2$), 209.4 (d, $^2J_{PP}$ = 21.8 Hz, P=C) ppm. IR (KBr): $\tilde{\nu}$ = 1935 [s (CO)], 1864 [s (CO)] cm$^{-1}$. MS (EI): *m*/*z* = 626 [M]$^+$, 570 [M – CO]$^+$. $C_{26}H_{20}O_3P_2W$ (626.22): calcd. C 49.87, H 3.22; found C 48.97, H 3.10.

**[Cp(CO)$_2$Mo$^a$–P=C(4-Et-C$_6$H$_4$)O–P$^b$Ph$_2$(*Mo$^a$–P$^b$*)] (6a):** As described above, solutions of [Cp(CO)$_2$ClMoPHPh$_2$] (**1a**; 0.68 g, 1.55 mmol) in toluene (30 mL), 4-$EtC_6H_4C$(O)P=C$(NMe_2)_2$ (**5**; 0.41 g, 1.55 mmol), and DBU (0.36 g, 2.33 mmol) in toluene (20 mL) were combined at –30 °C. Stirring was continued for 1 h at –30 °C and 12 h at 20 °C. The solvent and the volatile components were removed in vacuo, and the residue was chromatographed on Florisil. A yellow zone was eluted with a pentane/diethyl ether (10:3, ca. 350 mL). The elute was concentrated to ca. 50 mL and stored at –30 °C for 12 h. Product **6a** separated as orange crystals (yield: 0.32 g, 36%). $^1$H NMR (500.13 MHz, $C_6D_6$): $\delta$ = 0.98 (t, $^3J_{HH}$ = 7.5 Hz, 3 H, $CH_2CH_3$), 2.31 (q, $^3J_{HH}$ = 7.5 Hz, 2 H, $CH_2CH_3$), 4.59 (s, 5 H, Cp), 6.84 (m, 1 H, Ph), 6.89–6.91 (m, 4 H, Ph), 7.05–7.11 (m, 4 H, Ph), 7.66 (m, 2 H, Ph), 7.84 (m, 2 H, Ph), 8.19 (m, 2 H, Ph) ppm. $^{13}$C{$^1$H} NMR (125.75 MHz, $C_6D_6$): $\delta$ = 15.6 (s, $CH_2CH_3$), 28.9 (s, $CH_2CH_3$), 93.0 (s, $C_5H_5$), 125.6, 125.8, 128.3, 128.4, 128.7, 128.8, 129.9, 130.1, 131.7, 132.5, 132.6 (s, Ph), 194.1 (dd, $^1J_{PC}$ = 86.2 Hz, $^2J_{PC}$ = 17.5 Hz, P=C), 234.3 (d, $^2J_{PC}$ = 12.1 Hz, CO), 241.5 (d, $^2J_{PC}$ = 25.6 Hz, CO) ppm. $^{31}$P{$^1$H} NMR (202.46 MHz, $C_6D_6$): $\delta$ = 198.7 (d, $^2J_{PP}$ = 20.7 Hz, $PPh_2$), 225.9 (d, $^2J_{PP}$ = 20.7 Hz, P=C) ppm. IR (KBr): $\tilde{\nu}$ = 1942 [s (CO)], 1881 [s (CO)] cm$^{-1}$. MS (EI): *m*/*z* = 568 [M]$^+$, 540 [M – CO]$^+$, 512 [M – 2 CO]$^+$. $C_{28}H_{24}MoO_3P_2$ (566.38): calcd. C 59.38, H 4.27; found C 59.50, H 4.24.

**[Cp(CO)$_2$W$^a$–P=C(4-Et-C$_6$H$_4$)O–P$^b$Ph$_2$(*W$^a$–P$^b$*)] (6b):** As described above, a solution of [Cp(CO)$_2$ClWPHPh$_2$] (**1b**; 0.91 g, 1.73 mmol) in toluene (40 mL) was combined with a mixture of 4-$EtC_6H_4C$-(O)P=C$(NMe_2)_2$ (**5**; 0.47 g, 1.78 mmol) and DBU (0.36 g, 2.33 mmol) in chilled toluene (20 mL, –10 °C). After stirring at room temp. for 14 h, the mixture was evaporated to dryness, and the residue was chromatographed on Florisil. A yellow zone was eluted with pentane/diethyl ether (10:3, 250 mL; then 2:1, 200 mL). The elute was concentrated to ca. 120 mL and stored at –30 °C for 24 h, whereby product **6b** separated as yellow crystals (yield: 0.34 g, 30%). $^1$H NMR (500.13 MHz, $C_6D_6$): $\delta$ = 0.98 (t, $^3J_{HH}$ = 7.5 Hz, 3 H, $CH_2CH_3$), 2.31 (q, $^3J_{HH}$ = 7.5 Hz, 2 H, $CH_2CH_3$), 4.58 (s, 5 H, Cp), 6.83 (m, 1 H, Ph), 6.91 (m, 4 H, Ph), 7.03–7.11 (m, 3 H, Ph), 7.68 (m, 2 H, Ph), 7.84 (m, 2 H, Ph), 8.23 (m, 2 H, Ph) ppm. $^{13}$C{$^1$H} NMR (125.75 MHz, $C_6D_6$): $\delta$ = 15.6 (s, $CH_2CH_3$), 28.9 (s, $CH_2CH_3$), 91.6 (s, $C_5H_5$), 125.8, 125.9, 127.9, 128.3, 128.4, 128.6, 128.7, 130.1, 130.2, 130.4, 131.7, 132.9, 133.1, 135.7, 135.9, 136.0, 137.6, 138.0, 141.4, 141.8, 144.9, 145.0 (s, Ph), 193.4 (dd, $^1J_{PC}$ = 82.8 Hz, $^2J_{PC}$ = 18.4 Hz, P=C), 223.9 (br., CO), 231.8 (d, $^2J_{PC}$ = 18.4 Hz, CO) ppm. $^{31}$P{$^1$H} NMR (202.46 MHz, $C_6D_6$): $\delta$ = 170.1 (d, $J_{PP}$ = 22.5 Hz, $J_{PW}$ = 330.4 Hz, $PPh_2$), 199.9 (d, $J_{PP}$ = 22.5 Hz, P=C) ppm. IR (KBr): $\tilde{\nu}$ = 1935 [s (CO)], 1870 [s (CO)] cm$^{-1}$. MS (EI): *m*/*z* = 654 [M]$^+$, 626 [M – CO]$^+$, 598 [M – 2 CO]$^+$. $C_{28}H_{24}O_3P_2W$ (654.28): calcd. C 51.40, H 3.69; found C 51.47, H 3.51.

**X-ray Crystallography**: Crystallographic data for **3** was collected with a Siemens P3 diffractometer with Mo-$K_\alpha$ at 173 K, data for **4a** and **6b** were collected with a Nonius Kappa CCD diffractometer with Mo-$K_\alpha$ (graphite monochromator, $\lambda$ = 0.71073 Å) at 100 K. Crystallographic programs used for the structure solution and refinement were from SHELX-97.[15] The structures were solved by direct methods and refined by using full-matrix least-squares on $F^2$ of all unique reflections with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms for **3** were refined isotropically, for **4a** and **6b** they were included at calculated positions with $U$(H) = 1.2 $U_{eq}$ for $CH_2$ groups, $U$(H) = 1.5 $U_{eq}$ for $CH_3$ groups. Crystal data of the compounds are listed in Table 1.[16]

# Controlled Chemical Reduction of Uranyl Salts into $UX_4(MeCN)_4$ (X = Cl, Br, I) with $Me_3SiX$ Reagents

**Jean-Claude Berthet,*[a] Gérald Siffredi,[a] Pierre Thuéry,[a] and Michel Ephritikhine*[a]**

**Keywords:** Uranyl salts / Reduction / Silanes / Uranium

$UO_2I_2(thf)_3$ or $UO_2(OTf)_2$ are easily reduced by $Me_3SiX$ (X = Cl, Br, I) in acetonitrile into the tetravalent $UX_4(MeCN)_4$ complexes, which are useful precursors in uranium chemistry.

## Introduction

A variety of methods have been designed for the preparation of the uranium tetrahalides $UX_4$ (X = Cl, Br, I) and their Lewis base adducts, which are ordinary and convenient precursors for the synthesis of a large range of uranium derivatives.[1] Most of the usual procedures are based on the treatment of solid $UO_2$ or $UO_3$ with gaseous $X_2$ or HX at high temperature, or with halogenated liquid reagents under reflux conditions, which releases very toxic side-on gases.[1] In an attempt to avoid the thermal decomposition of $UI_4$, the synthesis of $UI_4(PhCN)_4$ was performed by the oxidation of uranium turnings with iodine in benzonitrile,[2] but a similar reaction in acetonitrile failed to produce pure $UI_4(MeCN)_4$,[2,3] which was conveniently obtained by metathesis of $UCl_4$ in acetonitrile by using excess $Me_3SiI$.[4] The $Me_3SiX$ molecules are versatile reagents that have found numerous applications in organic and inorganic syntheses.[5] In addition to being very efficient in metathesis reactions of d- and f-transition-metal halides,[4–6] they are also capable of inducing redox transformations.[5] Thus, $UF_6$ was reduced into $UF_5$ or $UF_4$ with $Me_3SiCl$;[7] $RuCl_3$ reacted with $Me_3SiI$ to give the $Ru^{II}$ compound $[Ru(MeCN)_6][I_4]$,[5] and $CrCl_2$ was oxidized with $Me_3SiI$ into the $Cr^{III}$ iodide $[CrI_2(MeCN)_4][CrI_4(MeCN)_2]$.[5] However, it seems surprising, in view of the strength of the Si–O bond, that the $Me_3SiX$ reagents have seldom been considered for the deoxygenation of metal oxides and their conversion into the corresponding halides.[8]

Activation of the reputedly inert U=O bond of the uranyl ion $[UO_2]^{2+}$ and the controlled reduction of this species represent a particularly active field of research that attracts much attention for both its fundamental aspects and applications.[9] Although the photosensitivity of the $[UO_2]^{2+}$ ion to UV light is a well-documented feature, leading generally to insoluble $UO_2$ or rare $U^{IV}$ coordination complexes,[10] chemical reduction of uranyl salts into interesting derivatives remains a challenging goal. Such transformations have mostly been observed serendipitously,[11,12] and it is only recently that some smooth and controlled reactions of the $[UO_2]^{2+}$ ion proved successful, revealing new aspects of uranyl chemistry.[13] These advances were made possible by the use of strictly anhydrous experimental conditions. Here we report the reduction of $UO_2I_2(thf)_3$[14] or $UO_2(OTf)_2$[15] with $Me_3SiX$ (X = Cl, Br, I) in acetonitrile, which provides a novel and convenient synthetic route to tetrahalides $UX_4(MeCN)_4$. These reactions, which involve deoxygenation, halide exchange and reduction processes, are much influenced by the nature of the solvent, the $Me_3SiX$ reagent and the uranyl salt.

## Results and Discussion

We previously reported that treatment of $UO_2(OTf)_2$ with pure $Me_3SiI$ led to the formation of $UO_2I_2$ in almost quantitative yield.[14] This compound, which likely has a polymeric structure, is quite insoluble and stable in $Me_3SiI$. However, after dissolution of $UO_2I_2$ in coordinating solvents, the molecular Lewis base adducts $UO_2I_2L_n$ (L = thf, py, MeCN) were found to react with the iodosilane. Reactions of $UO_2I_2(thf)_3$ with a large excess of $Me_3SiX$ (X = Cl, Br, I) were first examined in thf at 25° or 100 °C. Metathetical exchange with $Me_3SiCl$ afforded the uranyl chloride, which was inert in the presence of the chlorosilane, as previously observed in the dehydration of $UO_2Cl_2(H_2O)_n$.[16] However, $UO_2I_2(thf)_3$ was found to react with $Me_3SiBr$, as shown by the colour change of the solution, from red to green, characteristic of uranium(IV) compounds. Similar treatment of $UO_2I_2(thf)_3$ with $Me_3SiI$ gave a mixture of

complexes among which red crystals of $[U(O\{CH_2\}_4I)_2(thf)_5][I_3]_2[I_2]$ were characterized by X-ray diffraction analysis;[17] this alkoxide derivative obviously resulted from thf ring-opening reaction, which is currently initiated by $Me_3SiI$ and iodo uranium complexes.[18,19] The uranyl iodide $UO_2I_2(thf)_3$ was more reactive towards $Me_3SiX$ in pyridine, but the reduction led to a mixture of the two uranium(IV) complexes $UX_4(py)_4$ and $[UX_6]^{2-}$ (X = Cl, Br).[17]

Eventually, the uranium(IV) tetrahalides $UX_4(MeCN)_4$ [X = Cl (**1**), Br (**2**), I (**3**)] were simply obtained by the addition of an excess of $Me_3SiX$ to a solution of $UO_2I_2$ or $UO_2I_2(thf)_3$ in acetonitrile at room temperature [Equation (1)]; **1** and **2** were deposited as light green crystals and **3** as an orange powder in good yields (68– 93%).

$$UO_2I_2(thf)_3 \xrightarrow[MeCN]{\text{Excess } Me_3SiX} UX_4(MeCN)_4 \quad \begin{matrix}\mathbf{1}\text{: X = Cl}\\ \mathbf{2}\text{: X = Br}\\ \mathbf{3}\text{: X = I}\end{matrix} \qquad (1)$$

The rate of the reaction was found to depend markedly on X and followed the unusual order Br >> I > Cl. Thus, $UO_2I_2(thf)_3$ was immediately transformed into **2**, whereas its complete conversion into **1** and **3** required 24 h at 25 °C. The reasons for this trend, which could be related to opposite electronic and steric effects,[20] are not obvious.

While $MoO_2X'_2$ or $CrO_3$ reacted with $Me_3SiX$ to give the partially deoxygenated derivatives $MoOX_2X'_2$ or $CrO_2Cl_2$, respectively,[8a,8c] complete deoxygenation of the uranyl ion was achieved, as shown by the absence in the IR spectra of the reaction products of any band that could be assigned to the $\nu_{asym}(UO)$ frequency.

Compounds **1**–**3** were characterized by their elemental analyses (C, H, N) and their IR spectra. These spectra, which are identical to those of $UX_4(MeCN)_4$ that was prepared from the uranium tetrahalides, show two bands in the CN region; the strong stretching frequencies (2275–2277 $cm^{-1}$) correspond to those previously reported for $UX_4(MeCN)_4$ (X = Cl, Br, I),[3,21] and they show a ca. 25 $cm^{-1}$ increase in the coordinated nitrile CN stretching frequency relative to $\nu$(CN) = 2249 $cm^{-1}$ for free acetonitrile.[21]

Crystals of **2** were characterized by X-ray diffraction analysis; a view of the complex is shown in Figure 1 together with selected bond lengths. The structure is identical to that of $UCl_4(MeCN)_4$,[22] and the uranium atom is in a dodecahedral configuration defined by the two orthogonal trapezia Br1–N1–N1′–Br1′ and Br2–N2–N2′–Br2′, with the nitrogen atoms in the A sites.[23] The average U–N and U–Br distances of 2.56(3) and 2.80(2) Å, respectively, are comparable to those measured in $UCl_4(MeCN)_4$ [2.531(17) Å][22] and $UBr_4(OPPh_3)_2$ [2.771(2) Å].[24]

$UO_2(OTf)_2$ is a more accessible precursor than the iodide counterpart and access to the $UX_4(MeCN)_4$ compounds directly from $UO_2(OTf)_2$ would be a much more convenient route.[14] In agreement with previous observations on the distinct reactivities of analogous halide and triflate metal

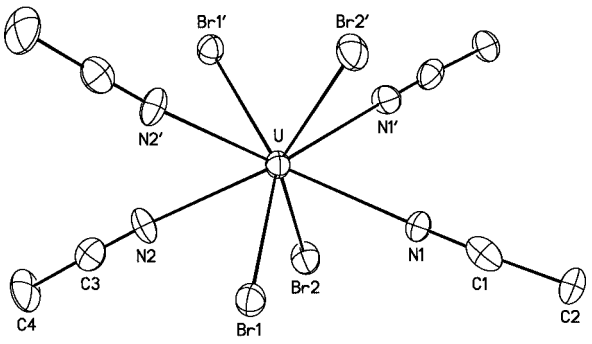

Figure 1. View of $UBr_4(MeCN)_4$ (**2**). Displacement ellipsoids are drawn at the 50% probability level. Symmetry code: ′ = *y*, *x*, 2 – *z*. Selected bond lengths [Å]: U–Br1 2.7751(6), U–Br2 2.8157(5), U–N1 2.527(4), U–N2 2.583(4), N1–C1 1.150(7), N2–C3 1.143(6).

compounds,[14–16,18,19] reactions of $UO_2(OTf)_2$ with $Me_3SiX$ in acetonitrile at 20 °C were slower than those of $UO_2I_2$ and required heating to go to completion. Whereas $UO_2(OTf)_2$ was inert towards an excess of $Me_3SiCl$ in acetonitrile at 100 °C, its treatment under the same conditions with $Me_3SiX$ led to the formation of $UX_4(MeCN)_4$ (X = Br, I) and the successful preparation of tetrabromide **2**, which was isolated in 72% yield. These results demonstrate that the nature of the uranyl precursor has a major influence on the course of its reactions with the halogenosilanes. The lower reactivity of $UO_2(OTf)_2$ likely reflects the weaker lability of $OTf^-$ versus $I^-$; however, the facile access to **2** constitutes the most convenient synthesis of this $U^{IV}$ compound.

## Conclusions

Reactions of $UO_2I_2(thf)_3$ or $UO_2(OTf)_2$ with $Me_3SiX$ provide rare examples of the controlled activation and reduction of the $[UO_2]^{2+}$ ion and new convenient and safe routes to the tetrahalides $UX_4(MeCN)_4$. In particular, the facile synthesis of **2** is attractive for extending the poorly developed chemistry of uranium bromides, which are susceptible to display solubility, structural and reactivity patterns different from those of the other halides and triflate species.[4,14,25]

## Experimental Section

**General:** All experiments were carried out under an atmosphere of argon (<5 ppm oxygen or water) by using standard Schlenk-vessel and vacuum-line techniques or in a glove box. Solvents were dried by standard methods and distilled immediately before use. IR samples were prepared as Nujol mulls between KBr round cell windows, and the spectra were recorded with a Perkin-Elmer FTIR 1725X spectrometer. Elemental analyses were performed by Analytische Laboratorien at Lindlar (Germany). The $Me_3SiX$ reagents (Aldrich) were distilled and stored over 4-Å molecular sieves; $UO_2I_2(thf)_3$[13] and $UO_2(OTf)_2$[14] were prepared by published methods.

**$UCl_4(MeCN)_4$ (1):** A flask was charged with $UO_2I_2(thf)_3$ (200 mg, 0.27 mmol), MeCN (6 mL) and $Me_3SiCl$ (6 mL, 49 mmol). After 24 h at 25 °C, light green crystals of **1** were deposited from the dark brown solution. After filtration, the crystals were washed with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

MeCN/$Et_2O$ (1:4, 25 mL) and dried under vacuum (99 mg, 68%). IR: $\tilde{\nu}$ = 2277 (s) (NC), 2307(m) (NC) $cm^{-1}$. $C_8H_{12}Cl_4N_4U$ (544.05): calcd. C 17.66, H 2.22, N 10.29; found C 17.41, H 2.22, N 10.12.

**Synthesis of $UBr_4(MeCN)_4$ (2)**

**(a) From $UO_2I_2(thf)_3$:** A flask was charged with $UO_2I_2(thf)_3$ (200 mg, 0.27 mmol) and MeCN (6 mL). The dark red solution immediately turned colourless upon the addition of $Me_3SiBr$ (6 mL, 46 mmol) at 25 °C, and light green crystals of **2** were deposited. The crystals were filtered off, washed with pentane and dried under vacuum (181 mg, 93%). IR: $\tilde{\nu}$ = 2275 (s) (NC), 2307(m) (NC) $cm^{-1}$. $C_8H_{12}Br_4N_4U$ (721.85): calcd. C 13.31, H 1.67, N 7.76; found C 13.41, H 1.87, N 7.90.

**(b) From $UO_2(OTf)_2$:** A flask was charged with $UO_2(OTf)_2$ (40 mg, 0.07 mmol) and MeCN (0.4 mL). The initially yellow solution immediately turned orange upon the addition of $Me_3SiBr$ (0.4 mL, 3 mmol) at 25 °C, and an orange powder was deposited. After 24 h at 100 °C, light green crystals of **2** were deposited from the dark brown solution, and another crop of crystals was collected after the addition of $Et_2O$ (1.5 mL) onto the concentrated MeCN solution (0.2 mL). The crystals were washed with MeCN/$Et_2O$ (1:4, 5 mL) and dried under vacuum (36.7 mg, 72%). IR: $\tilde{\nu}$ = 2275(s) (NC), 2307(m) (NC) $cm^{-1}$. $C_8H_{12}Br_4N_4U$ (721.85): calcd. C 13.31, H 1.67, N 7.76; found C 13.46, H 1.75, N 7.82.

**Synthesis of $UI_4(MeCN)_4$ (3)**

**(a) From $UO_2I_2(thf)_3$:** A flask was charged with $UO_2I_2(thf)_3$ (200 mg, 0.27 mmol) and MeCN (6 mL). The addition of $Me_3SiI$ (6 mL, 42 mmol) to the dark red solution immediately led to an orange precipitate. After 24 h at 25 °C, $Et_2O$ (30 mL) was condensed in, which induced increased precipitation of **3**. Product **3** (212 mg, 87%) was recovered as an orange powder after filtration, washing with pentane and drying under vacuum. IR: $\tilde{\nu}$ = 2275(s) (NC), 2301(m) (NC) $cm^{-1}$. $C_8H_{12}I_4N_4U$ (909.85): calcd C 10.56, H 1.33, N 6.15; found C 10.35, H 1.54, N 5.99.

**(b) From $UO_2(OTf)_2$:** An NMR tube was charged with $UO_2(OTf)_2$ (10 mg, 0.018 mmol) and acetonitrile (0.2 mL). The addition of $Me_3SiI$ (0.2 mL, 1.4 mmol) at 25 °C to the yellow solution gave immediately a dark red solution from which red-brown crystals of **3** were deposited in a few minutes. Further precipitation was induced by heating the mixture at 100 °C for 24 h.

**X-ray Crystallography:** The data were collected at 110(2) K with a Nonius Kappa-CCD area-detector diffractometer with Mo-$K_\alpha$ radiation and processed with HKL2000.[26] The structure was solved by direct methods and refined by full-matrix least-squares on $F^2$ with SHELXTL.[27] Absorption effects were corrected with SCALEPACK.[26] All non-hydrogen atoms were refined with anisotropic displacement parameters. Crystal data for **2**: $C_8H_{12}Br_4N_4U$, $M$ = 721.89, trigonal, space group $P3_221$, $a = b$ = 8.7269(3) Å, $c$ = 20.6198(10) Å, $V$ = 1359.99(9) $Å^3$, $Z$ = 3, $D_{calcd.}$ = 2.644 $g\,cm^{-3}$, $\mu$ = 17.753 $mm^{-1}$, $F(000)$ = 960, 31861 measured reflections, 1732 independent ($R_{int}$ = 0.085), 1703 with $I > 2\sigma(I)$, 81 parameters, $R_1$ = 0.025, $wR_2$ = 0.049, S = 1.054, $\Delta\rho_{min}$ = –1.47, $\Delta\rho_{max}$ = 1.18 $e\,Å^{-3}$.

CCDC-637174 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Kinetics and Magnetism of Phosphane Diadducts of Diruthenium(II,III) Tetraacetate

**Tara J. Burchell,[a] T. Stanley Cameron,[b] Donal H. Macartney,[c] Laurence K. Thompson,[d] and Manuel A. S. Aquino*[a]**

**Keywords:** Carboxylate ligands / P ligands / Ruthenium / Kinetics / Magnetic properties

The kinetic parameters for the axial-ligand-substitution reactions of $[Ru_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2]^+$ in acetonitrile (MeCN) with $PCy_3$ and $PCy_2Ph$ (Cy = cyclohexyl and Ph = phenyl) were investigated under pseudo first-order conditions of excess phosphane. The rate-determining formation of $[Ru_2(\mu\text{-}O_2CCH_3)_4(MeCN)(PCy_2R]^+$ appears independent of the nature of the incoming phosphane with an average $k_1$ (25.0 °C) = $(1.25 \pm 0.06) \times 10^3$ $M^{-1} s^{-1}$. A dissociatively activated mechanism is proposed for substitution of the axially coordinated acetonitrile, and the rate parameters are compared to earlier measurements carried out on $[Rh_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2]$. Variable-temperature magnetic susceptibility measurements were carried out on the two phosphane diadducts, $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]PF_6$, (**1**) and $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_2Ph)_2]PF_6$ (**2**), and showed behaviour unique to a Boltzmann distribution of states over the temperature range 2–300 K. To support the magnetic measurements, the single-crystal X-ray structure of **1** was redetermined at various temperatures down to –150 °C and showed a distinct decrease in the Ru–Ru bond length with decreasing temperature, consistent with a $\sigma^2\pi^4\delta^2\pi^{*3}$ configuration at low temperature (ground state) and a $\sigma^2\pi^4\delta^2\pi^{*2}\delta^{*1}$ configuration at room temp. In addition, the structure redeterminations of **1** were better resolved than the earlier reported structure and also corrected a minor error in that the molecule of solvation was found to be 1,2-dichloroethane instead of dichloromethane.

## Introduction

Diruthenium tetracarboxylates, both in their homovalent $Ru_2(II,II)$ and valent-averaged $Ru_2(II,III)$ forms, have received considerable attention in the past 20 years owing primarily to their interesting electronic and magnetic properties.[1–4] The basic diruthenium tetracarboxylate "building block", $[Ru_2(\mu\text{-}O_2CR)_4]^{+/0}$, has been modified in a wide variety of ways leading to compounds with mesomorphic, catalytic and cytotoxic properties. Numerous extended polymeric and network structures based on these building blocks have also been assembled and display properties ranging from gas-occlusion[5–7] to ferrimagnetic ordering[8,9] and significant electronic delocalization.[10]

We recently reported the structure and electrochemistry of the first axial phosphane diadduct of diruthenium(II,III) tetraacetate.[11] We were able to isolate and crystallographically characterize what, in essence, was a kinetic product, $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]PF_6$ (**1**), by using the bulky phosphane, $PCy_3$ (Cy = cyclohexyl), which has a Tolman cone angle of 170°.[12] The bulkiness of the phosphane slowed down its thermodynamically favoured migration to the equatorial positions and subsequent displacement of the carboxylate groups. This process eventually leads to Ru–Ru bond cleavage and a total disassembly of the dimer into mononuclear fragments.[13] The structure revealed the longest Ru–Ru bond length in a diruthenium tetracarboxylate to date at 2.427(1) Å. In addition, we were able to generate, by cyclic voltammetry, the one-electron oxidation product, $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]^{2+}$, in which we have a $Ru_2(III,III)$ core. This is unprecedented for any diruthenium *tetracarboxylate*. Unfortunately we have, to date, not been able to isolate X-ray quality crystals of this oxidized species.

The extraordinarily long Ru–Ru bond length, as well as a small but significant redshift in the $\pi^*(Ru_2)\leftarrow\pi(RuO,Ru_2)$ visible transition when the phosphane diadduct is formed, motivated us to study both the variable-temperature magnetic susceptibility behaviour and the ligand substitution kinetics of complex **1** as well as those of the related complex, $[Ru_2(\mu\text{-}O_2CCH_3)_4(PPhCy_2)_2]PF_6$ (**2**). In addition, we have redetermined the structure of **1** at various temperatures in order to be able to correlate the Ru–Ru bond length/temperature dependence with the magnetic behaviour. The re-

determination also corrects a minor mistake in the earlier structural formulation, replacing the original dichloromethane (DCM) of solvation with 1,2-dichloroethane (DCE). We report here as well the fully corrected structure, determined at –150 °C.

## Results and Discussion

### Synthesis

We found that the reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]^+$, in which we exchanged the axial waters with modest and strong π-acid ligands, must be carried out stoichiometrically and reasonably fast. This is due to the fact that any excess of ligand or reaction times greater than 10 min will result in decomposition (disassembly) of the diruthenium core, which would lead to mononuclear ruthenium(II) complexes or a disproportionation reaction leading to a μ-oxido $Ru_2$(III,III) dimer and mononuclear $Ru^{II}$ complex. These reactions have been seen, and exploited, by our group and others.[13,14] In a previous paper we synthesized a series of diadducts with modest π-acid N-heterocycles, $[Ru_2(\mu\text{-}O_2CCH_3)_4(\text{N-heterocycle})_2]^+$, by a rapid reaction of the diaqua adduct and 2 equiv. of the appropriate N-heterocycle in 2-propanol.[15] This reaction gave rapid precipitation of the desired product, which we were able to isolate, usually within 10 min.

We applied a similar strategy in trying to isolate adducts with the stronger π-acid phosphane ligands. It appears that for the reactions with phosphanes, $PPh_3$ in particular, a relatively rapid disproportionation occurs even when a relatively small excess of phosphane is employed.[14] The phosphane initially binds at the axial site and then performs an intramolecular migration to the equatorial positions leading to carboxylate displacement and Ru–Ru bond rupture. In our preliminary paper[11] we were able to somewhat slow down this migration process by using a significantly bulkier phosphane, $PCy_3$ (Cy = cyclohexyl), and hence we were able to isolate, purify and structurally characterize this diadduct. The electrochemistry was also reported. The detailed synthesis of this complex is given here. The bulkiness of the phosphane evidently slowed the axial–equatorial migration enough to allow us to isolate the diadduct. We can gauge the bulkiness of the phosphanes by looking at their Tolman cone angles.[12] For $PPh_3$, the angle is 145°, whereas for $PCy_3$, it is 170°. We also attempted to synthesize the $PPh_3$ diadduct along with diadducts involving phosphanes of intermediate cone angle, namely $PPh_2Cy$ (cone angle = 153°) and $PPhCy_2$ (cone angle = 162°). In all three cases we were able to obtain some solid products; however, the $PPh_3$ and $PPh_2Cy$ "products" gave very inconsistent elemental analyses, IR spectra and electrochemistry and could not be purified further, either by column chromatography or recrystallization, without appreciable decomposition. The $PPhCy_2$ reaction product **2** was more promising, and we were able to get reproducible analyses and spectra; however, X-ray quality crystals are still elusive.

The elemental analyses for adducts **1** and **2** are consistent with the formulations given. The IR spectra showed characteristic C–H stretching modes (primarily from the phenyl and cyclohexyl rings) in the range 2850–3070 $cm^{-1}$, asymmetric O–C–O stretching at 1440 $cm^{-1}$, symmetric O–C–O stretching at ≈ 1350 $cm^{-1}$, P–F stretching (from the $PF_6^-$ counterion) at ≈ 840 $cm^{-1}$ and the C–$CH_3$ bending mode at 692 $cm^{-1}$. The UV/Vis spectra were similar to the diaqua adduct except for a small bathochromic shift in the $\pi^*(Ru_2)\leftarrow\pi(RuO,Ru_2)$ band, a shift from 430 nm (in the diaqua complex) to 473 nm in **1** and 478 nm in **2** (Supporting Information, Figure S1).

### Ligand Substitution Kinetics

The redshifting of the $\pi^*(Ru_2)\leftarrow\pi(RuO,Ru_2)$ band in **1** and **2** allowed us to monitor the ligand substitution process using stopped-flow techniques at 475 nm in dry acetonitrile (0.100 M $TBAPF_6$). Owing to our inability to differentiate exactly the $\lambda_{max}$ value of the mono- from the diphosphane adduct (and hence determine accurately the absorptivity coefficients, $\varepsilon$) and the inherent instability of the diphosphane adduct once it is formed (particularly at high phosphane concentrations), we were not able to calculate successive equilibrium constants with sufficient accuracy to report here. Despite this fact, we assumed, as was the case with phosphane substitution reactions on the dirhodium(II,II) core in $Rh_2(\mu\text{-}O_2CCH_3)_4L_2$ complexes,[16] that the process should be dissociative with the substitution of the first axial ligand being rate determining, the second phosphane substituting rapidly owing to the *trans* effect (i.e. $k_2 >> k_1$). The steps required for substitution by $PCy_3$ are outlined in Equations (1) and (2).

$$[Ru_2(O_2CCH_3)_4(MeCN)_2] + PCy_3 \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} [Ru_2(O_2CCH_3)_4(MeCN)(PCy_3)] + MeCN \quad (1)$$

$$[Ru_2(O_2CCH_3)_4(MeCN)(PCy_3)] + PCy_3 \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} [Ru_2(O_2CCH_3)_4(PCy_3)_2] + MeCN \quad (2)$$

The formation of $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]^+$ was therefore monitored and, under pseudo first-order reaction conditions of excess phosphane concentrations {concentration of $[Ru_2(O_2CCH_3)_4(MeCN)_2]^+$ is $5.08\times10^{-4}$ M} the rate expression can be given as that shown in Equation (3).

$$d[Ru_2(O_2CCH_3)_4(PCy_3)_2]^+ / dt = k_{obs}[Ru_2(O_2CCH_3)_4(MeCN)_2]^+ \quad (3)$$

and $k_{obs} = k_1[PCy_3]$. It should be noted at this point that as soon as the diadduct is formed it begins to disassemble/disproportionate with the rate of disassembly increasing as the concentration of the phosphane increases. In fact, at high phosphane concentrations (>35 mM) this subsequent decay can be seen at the end of the stopped-flow trace. However, at none of the concentrations used here does this

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

slower decay interfere with the initial rapid pseudo first-order formation (phosphane binding axially). Plots of $k_{obs}$ against phosphane concentration are linear for the reactions with each of the two phosphanes. The plot for $PCy_3$ is shown in Figure 1a and, from the slope of the line, a value of $k_1(25\,°C) = 1.29(3) \times 10^3\ M^{-1}s^{-1}$ ($R^2 = 0.9981$) is obtained. Measurements of $k_{obs}$ at various temperatures at a constant concentration of $PCy_3$ yielded a reasonably linear ($R^2 = 0.9843$) Eyring plot (Figure 1b) from which the activation parameters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ could be determined. Identical treatment was used for the substitution with $PPhCy_2$. The basic rate data are reported in Table 1 with the second-order rate constants and activation parameters summarized in Table 2.

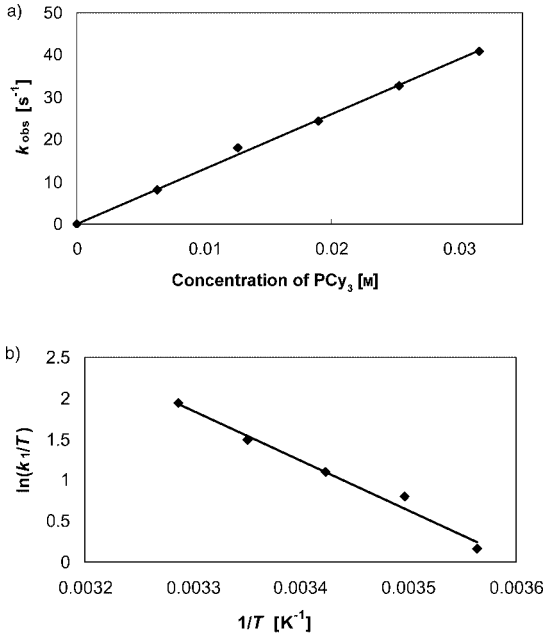

Figure 1. a) Plot of $k_{obs}$ vs. [$PCy_3$] for the reaction of $[Ru_2(O_2CCH_3)_4(MeCN)_2]^+$ with $PCy_3$ in acetonitrile. b) Eyring plot for the reaction in a) with [$PCy_3$] = 0.0210 mM.

Table 1. Kinetic data for the reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2]^+$ with $PCy_3$ and $PPhCy_2$. Lig = $PCy_3$ or $PPhCy_2$.

| T [°C] | [Lig] × $10^2$ [M] | $k_{obs}$ for $PCy_3$ [$s^{-1}$] | $k_{obs}$ for $PPhCy_2$ [$s^{-1}$] | $k_1 \times 10^{-3}$ for $PCy_3$ [$M^{-1}s^{-1}$] | $k_1 \times 10^{-3}$ for $PPhCy_2$ [$M^{-1}s^{-1}$] |
|---|---|---|---|---|---|
| 7.4 | 2.10 | 6.94 | 6.81 | 0.330(3) | 0.325(2) |
| 12.8 | 2.10 | 13.30 | 9.70 | 0.633(2) | 0.462(3) |
| 19.0 | 2.10 | 18.36 | 16.46 | 0.874(3) | 0.784(3) |
| 25.0 | 0.632 | 8.00 | 7.71 | 1.26(3) | 1.22(4) |
| 25.0 | 1.28 | 16.90 | 16.01 | 1.31(4) | 1.25(2) |
| 25.0 | 1.90 | 24.47 | 22.61 | 1.29(3) | 1.19(4) |
| 25.0 | 2.53 | 32.64 | 30.11 | 1.29(2) | 1.19(3) |
| 25.0 | 3.16 | 40.83 | 39.18 | 1.29(3) | 1.24(3) |
| 25.3 | 2.10 | 28.04 | 26.54 | 1.34(3) | 1.26(4) |
| 31.1 | 2.10 | 44.62 | 47.49 | 2.12(5) | 2.26(6) |

The rate law in Equation (3) implies that the formation of the monoadduct is the rate-determining step and that the redshifting of the $\pi^*(Ru_2) \leftarrow \pi(RuO,Ru_2)$ band is primarily due to the formation of $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)(MeCN)]^+$, and the subsequent rapid formation of $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]^+$ causes little further change in the electronic spectrum. Because phosphanes lie higher than nitriles in the *trans* effect (and *trans* influence) series, a rapid second step would appear most likely. The Ru–P bond length in $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]^+$ is the longest of any Ru–L bond in complexes of this type, consistent with its *trans* influence. Unfortunately, attempts to measure the substitution of $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]^+$ with $PPhCy_2$ did not meet with any success as there was no noticeable change in the electronic spectrum.

Table 2. Rate and activation parameters for the substitution reactions of diruthenium(II,III) tetraacetate with $PCy_3$ and $PPhCy_2$ in acetonitrile and their comparison to similar reactions involving dirhodium(II,II) tetraacetate.

| Ligand | $k_1$ [$M^{-1}s^{-1}$][a] | $\Delta H^{\neq}$ [kcal $mol^{-1}$] | $\Delta S^{\neq}$ [cal $K^{-1}mol^{-1}$] | Ref. |

[a] Measured at 25 °C. [b] This work.

Except for the *actual* value of the second-order rate constant, the substitution behaviour of the mixed-valent $[Ru_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2]^+$ complex is remarkably similar to that of $[Rh_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2]$.[16] The lack of dependence of $k_1$ on the nature of the phosphane would seem to imply a dissociatively activated formation of the monophosphane adduct. In addition, the highest occupied molecular orbitals (HOMO) of $[Ru_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2]^+$ are the partially filled, near-degenerate, Ru–Ru-based $\pi^{*2}\delta^{*1}$. The electron density in these orbitals, which would be situated somewhere between the Ru–O(acetate) and Ru–L(axial ligand) bond axes, as well as the inherent steric bulk of the phosphanes, should prevent any significant associative attack by an incoming ligand. The activation parameters for the two complexes tell us little about the mechanism, the error in $\Delta S^{\neq}$ being too large to tell whether it is significantly positive (dissociative) or negative (associative).

The rate of axial ligand substitution (acetonitrile for phosphane) is two orders of magnitude slower in the present diruthenium system than in the aforementioned dirhodium complex. This can, presumably, be attributed to the higher charge on the metal centres (+2.5 in diruthenium vs. +2 in dirhodium) and the decreased number of antibonding electrons in the metal-centred HOMO (3 vs. 6).

Only one previous study dealt with ligand substitution in $[Ru_2(\mu\text{-}O_2CCH_3)_4L_2]^+$-type complexes. Dema and Bose[17] reported the anation reaction in acidic aqueous solution (pH = 1) of $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]^+$ with $Cl^-$. They were able to determine successive equilibrium constants ($K_1$ = 15 $M^{-1}$, $K_2$ = 3.7 $M^{-1}$) because of the stability of the $[Ru_2(\mu\text{-}O_2CCH_3)_4Cl_2]^-$ diadduct and their ability to go to very high

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

concentrations of $Cl^-$, up to 2.0 M. Unfortunately, they were unable to measure the rates of anation, as more than 95% of the reaction was over in the time of mixing (4 ms) of their stopped-flow apparatus, which led them to estimate a lower limit for $k_1$ of $10^4\ M^{-1}s^{-1}$. This is not surprising (assuming a dissociative mechanism) as $H_2O$ is a more labile leaving group than MeCN. Substitution rate constants of $Rh_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2$ versus $Rh_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2$ in most cases tend to be one or two orders of magnitude higher.[16,18]

### Variable-Temperature Magnetic Susceptibility

Variable-temperature magnetic susceptibility measurements (2–300 K) were performed on complexes **1** and **2** as well as $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]PF_6$. Figure 2 shows the plot of $\mu_{eff}$ vs. $T$ for all three complexes. The plot for $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]PF_6$ shows a decrease in $\mu_{eff}$ at low temperature owing to a large zero-field splitting parameter typical of many diruthenium complexes of this form.[4] We have fit the data to a model previously developed by Drago[19] and adapted by Maldivi and co-workers[20] to fit the magnetic data for $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]BF_4$ (see ref[20] for details) and determined the $g$ factor ($g$), zero-field splitting parameter ($D$) and temperature independent paramagnetism (TIP). The parameters obtained for our $PF_6^-$ salt were $g = 2.186$, $D = 70.4\ cm^{-1}$ and TIP $< 10^{-6}\ cm^3\,mol^{-1}$ compared with $g = 2.190$, $D = 71.8\ cm^{-1}$ and TIP $< 10^{-6}\ cm^3\,mol^{-1}$ for the $BF_4^-$ salt. This data is consistent with a ground-state configuration of $\sigma^2\pi^4\delta^2\pi^{*2}\delta^{*1}$, which displays significant zero-field splitting as the temperature is lowered, and the π* and δ* orbitals are essentially degenerate and often written as $(\pi^*\delta^*)^3$.

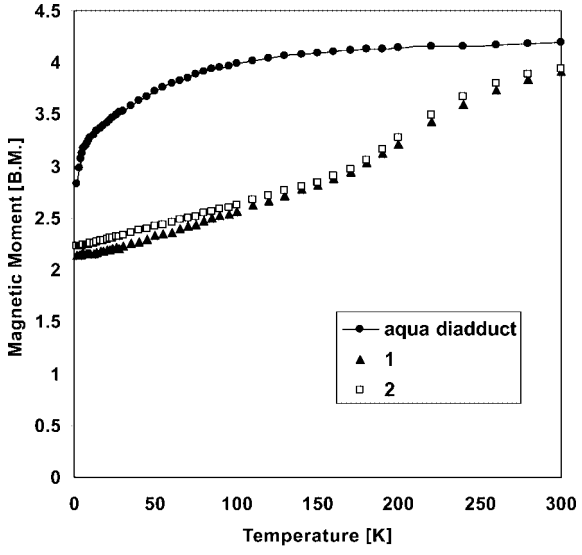

Figure 2. Plot of magnetic moment (B.M.) vs. temperature [K] for complexes **1**, **2** and $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]PF_6$ (aqua diadduct).

The plots for **1** and **2** are quite similar to each other but distinctly different from the diaqua complex. In both cases the curves assume a sigmoidal shape with a long tail at low temperatures. The $\mu_{eff}$ value for **1** is 3.92 B.M. at 300 K (consistent with three unpaired electrons) and drops to 2.14 B.M. at 2 K (consistent with one unpaired electron), and similarly for **2**, the $\mu_{eff}$ is 3.94 B.M. at 300 K and 2.23 B.M. at 2 K. The shallow break in both curves occurs in the range 180–220 K. The values of $\mu_{eff}$ at 200 K are 3.22 B.M. for **1** and 3.27 B.M. for **2**, consistent with two unpaired electrons and a spin-crossover from an $S = 3/2$ to $S = 1/2$ state.

A wide variety of variable temperature magnetic behaviour has been ascribed to various diruthenium(II,III) complexes over the years: (1) high-spin (three unpaired electrons)[1–4] with ZFS (similar to the diaqua complex above), (2) low-spin (one unpaired electron),[21] (3) quantum mechanical spin admixed,[22] (4) Boltzmann distribution between $\pi^{*3}$ and $\pi^{*2}\delta^*$ homoelectronic configurations[23] and (5) physical spin mixture.[24] From the temperature dependence and overall shape of our plots for complexes **1** and **2**, a Boltzmann distribution of configurations similar to what Cotton and co-workers[23] saw for the *para* isomer of the *N*,*N*′-diarylformamidinate derivative, $Ru_2(DArF)_4Cl$ with Ar = *p*-$C_6H_4OMe$, would seem reasonable. In this case, the π* orbital is somewhat more stable than the δ*, and one sees a Boltzmann distribution between the less stable $\pi^{*2}\delta^{*1}$ configuration (seen at room temp.) and the more stable $\pi^{*3}$ configuration. Unfortunately, similar behaviour can also be ascribed to the situation where the δ* orbital is somewhat more stable than the π* orbital, and a Boltzmann distribution between the more stable $\delta^{*2}\pi^{*1}$ and less stable $\delta^{*1}\pi^{*2}$ occurs. To resolve the issue, Cotton looked at the structural changes that would need to take place for the two different Boltzmann distributions to be possible. When the π* orbital is more stable than the δ* orbital, a δ* electron is lost and a π* electron is gained as the temperature is lowered. Because a π* electron has a greater effect on the Ru–Ru bond than a δ* electron, the bond length will increase by 0.02–0.05 Å (on going from room temp. to 3 K). When the δ* orbital is more stable than the π* orbital, a δ* electron is gained at the expense of a π* electron, and the Ru–Ru bond length should decrease by 0.02–0.03 Å over the same temperature range.

In order to resolve this problem in our case we have redetermined the X-ray structure of **1** at various temperatures.

### Redetermination of the X-ray Structure of Complex 1

The structure of **1** was redetermined at –150, –75, –60, –40, –25, –10, +20 and +50 °C. The redeterminations, performed on the same crystal we used in our earlier study,[11] were all better resolved than the original, and they also corrected an error in the nature of the molecule of solvation, with 1,2-dichloroethane replacing the dichloromethane (1,2-dichloroethane is often an impurity in dichloromethane). The new formulation is therefore $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]PF_6{\cdot}1,2\text{-}C_2H_4Cl_2$. Figure S2 (Supporting Information) shows the molecular structure, Table 3 gives the

All of the bond length and angle values for the redetermination at 20 °C are very similar to those of the earlier room temp. structure. For example, the redetermined bond length value for Ru–Ru is 2.42825(16) Å, for Ru–P it is 2.3717(4) Å and the Ru–Ru–P bond angle is 160.331(13)°. The values for the previous determination are 2.427(1) and 2.369(2) Å and 160.40(5)°, respectively.

Only two parameters, the Ru–Ru and Ru–P bond lengths, change significantly over the temperature range studied (50 to –150 °C) and this is shown in Figure 3. The Ru–Ru bond *increases* from 2.42373(15) Å at 50 °C to 2.44222(15) Å at –150 °C, a difference of +0.0185 Å. Despite the fact that we could not make measurements below –150 °C (123 K), this bond length *increase* is clearly significant and consistent with a $\pi^{*3}$ configuration at low temperature and a $\pi^{*2}\delta^{*1}$ configuration at room temp., as concluded by Cotton. In addition, the Ru–P bond length *decreases* from 2.3735(4) Å at 50 °C to 2.3445(3) Å at –150 °C, a difference of –0.029 Å, indicative of increased back-donation from the now more populated Ru–Ru-based π* orbital to the phosphane.

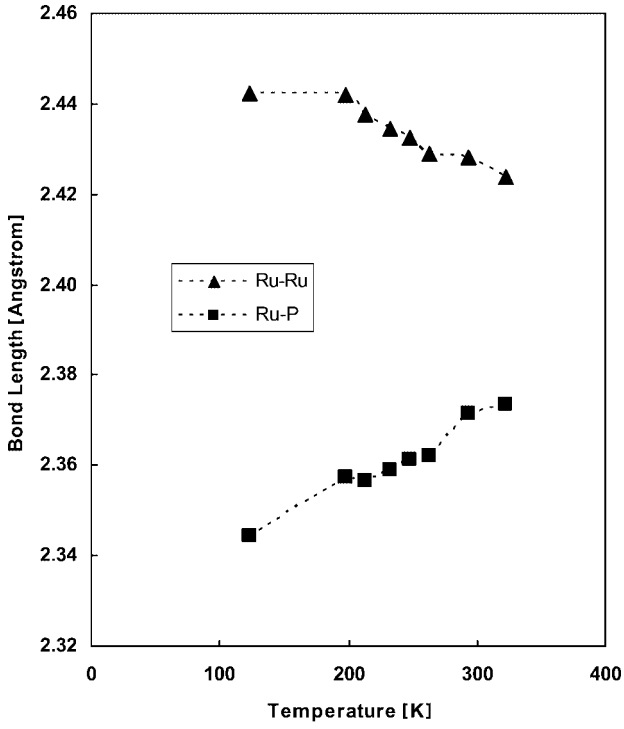

Figure 3. Plots of bond length vs. temperature for the Ru–Ru and Ru–P bonds in **1**.

It should be noted that no other major structural changes occur as the temperature is lowered. The space group is $P\bar{1}$ at all temperatures measured, and the unit cell volume contracts by about 3.7% over the range 50 °C to –150 °C, which is consistent with normal unit cell contraction as the temperature is lowered.

## Conclusions

In this paper we reported the rate constants and activation parameters for the axial-ligand-substitution reactions of $[Ru_2(\mu\text{-}O_2CCH_3)_4(MeCN)_2]^+$ with the phosphanes $PCy_3$ and $PCy_2Ph$. This is the first time rate constants were

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

measured for any substitution reaction on the $[Ru_2(\mu\text{-}O_2CR)_4L_2]^+$ core. The rate constants are found to be about two orders of magnitude less than similar axial-ligand substitutions on the $[Rh_2(\mu\text{-}O_2CR)_4L_2]$ core. The two phosphane diadducts thus formed, $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]PF_6$ (**1**) and $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_2Ph)_2]PF_6$ (**2**) were further investigated for their variable-temperature magnetic susceptibility properties and both displayed behaviour consistent with a Boltzmann distribution between a low temperature $\sigma^2\pi^4\delta^2\pi^{*3}$ doublet (ground-state) and a high temperature $\sigma^2\pi^4\delta^2\pi^{*2}\delta^{*1}$ quartet state. This conclusion is supported by the variable-temperature X-ray diffraction data of complex **1**, which shows an increase in the Ru–Ru bond length upon decreasing temperature, which is consistent with a metal–metal centred π* orbital being populated at the expense of a δ* orbital. Whereas Jiménez-Aparicio and co-workers[22] showed that the variation of the axial ligand in $[Ru_2(\mu\text{-}O_2CCH_3)(\mu\text{-}DPhF)_3X](BF_4)_n$-type systems ($DPhF^-$ = *N*,*N*′-diphenylformamidinate) can lead to high-spin (X = $Cl^-$, *n* = 0), low-spin (X = $SCN^-$, *n* = 0) or spin-admixed (X = $H_2O$, *n* = 1) complexes, Cotton and co-workers[23] showed that the variation of the equatorial ligand in $Ru_2(\mu\text{-}DArF)_4Cl$ systems ($DArF^-$ = *N*,*N*′-diarylformamidinate) can lead to a high-spin (Ar = *m*-$C_6H_4OMe$) complex or one showing a Boltzmann distribution of states (Ar = *p*-$C_6H_4OMe$); ours is the first example of a Boltzmann distribution being induced in a diruthenium(II,III) paddle-wheel-style complex by the variation of the *axial* ligand.

## Experimental Section

**General Remarks:** Unless otherwise indicated all reactions were carried out under an inert (Ar) atmosphere. Tricyclohexylphosphane, $PCy_3$, and dicyclohexylphenylphosphane, $PPhCy_2$, were obtained from Aldrich and used as received. $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]PF_6$ was prepared by a literature procedure.[25] IR spectra were recorded as KBr discs with a Bio-Rad FTS-175 spectrophotometer. UV/Vis spectra were recorded in 1-cm Hellma quartz cells with a Varian 100 spectrometer. C, H and P elemental analyses were performed by Canadian Microanalytical Service Ltd., Delta, BC, Canada. The variable temperature magnetic susceptibility data were recorded with a Quantum Design MPMS5S2 Superconducting Quantum Interference Device (SQUID) susceptometer at Memorial University over a temperature range of 2 to 300 K. Corrections for the diamagnetic contribution to the susceptibility of the samples and sample holder were performed on the raw data. The molar diamagnetic corrections for the complexes were calculated on the basis of Pascal's constants. The kinetics measurements were performed in acetonitrile with 0.100 M tetrabutylammonium hexafluorophosphate ($TBAPF_6$) with a SX-17MV stopped-flow spectrophotometer (Applied Photophysics), and the kinetic traces were fit to first-order reactions (4–6 replicate runs) by using the Applied Photophysics software on an Acorn A5000 workstation. The temperature was maintained at ±0.1 °C over the temperature range of 7–32 °C by using an external circulating water bath (VWR Scientific Model 1166).

**$[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy_3)_2]PF_6$ (1):** A brief outline of this synthesis was reported earlier.[11] $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2]PF_6$ (0.100 g, 0.16 mmol) was dissolved in 2-propanol (7 mL). A solution of tricyclohexylphosphane (0.090 g, 0.32 mmol) in 2-propanol (3 mL) was added, with stirring, at room temp. and allowed to react for no more than 5 min. The dark brown precipitate that formed was immediately filtered off in vacuo and washed with 2-propanol (30 mL) after which it was dried in vacuo. Crystals could be grown under an atmosphere of argon by rapid evaporation from DCM. Yield: 0.15 g (80%). IR (KBr): $\tilde{\nu}$ = 2931 (s), 2854 (s), 1440 (s), 1345 (s), 1271 (m), 1113 (m), 1005 (m), 843 (s), 731 (m), 692 (s), 558 (m), 510 (m) $cm^{-1}$. UV/Vis (1,2-dichloroethane): $\lambda$ ($\varepsilon$, $L\,mol^{-1}\,cm^{-1}$) = 473 (≈ 900) nm. $C_{44}H_{78}F_6O_8P_3Ru_2$ (1144.58): calcd. C 46.17, H 6.87, P 8.12; found C 45.84, H 6.55, P 8.08.

**$[Ru_2(\mu\text{-}O_2CCH_3)_4(PPhCy_2)_2]PF_6$ (2):** This diadduct was prepared in a similar fashion to **1** except that dicyclohexylphenylphosphane (0.088 g, 0.32 mmol) was used. Yield: 0.15 g (81%). IR (KBr): $\tilde{\nu}$ = 3064 (w), 2931 (s), 2852 (s), 1440 (s), 1355 (s), 1274 (m), 1189 (m), 1112 (m), 1003 (m), 843 (s), 692 (s), 558 (m) $cm^{-1}$. UV/Vis (1,2-dichloroethane): $\lambda$ ($\varepsilon$, $L\,mol^{-1}\,cm^{-1}$) = 479 (≈ 900) nm. $C_{44}H_{66}F_6O_8P_3Ru_2$ (1132.05): calcd. C 46.68, H 5.88, P 8.21; found C 46.84, H 6.13, P 8.01.

**X-ray Crystallographic Study:** All measurements were made with a Rigaku RAXIS RAPID imaging plate area detector with graphite monochromated Mo-$K_\alpha$ radiation. Indexing was performed from 4 oscillations that were exposed for 600 seconds. The data were collected at temperatures of (–150, –75, –60, –40, –25, –10, +20 and +50) ± 0.5 °C to a maximum $2\theta$ value of 145.2 °. The crystal-to-detector distance was 127.40 mm. Readout was performed in the 0.100 mm pixel mode. The data were corrected for Lorentz and polarization effects. A correction for secondary extinction was applied.[26] The structures were solved by direct methods[27] and expanded by using Fourier techniques.[28] The non-hydrogen atoms were refined anisotropically. Some hydrogen atoms were refined isotropically and the rest were refined by using the riding model. The final cycle of full-matrix least-squares refinement was on $F^2$.

Neutral atom scattering factors were taken from Cromer and Waber.[29] Anomalous dispersion effects were included in $F_{calcd.}$;[30] the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley.[31] The values for the mass attenuation coefficients are those of Creagh and Hubbell.[32] All calculations were performed by using the CrystalStructure[33–34] crystallographic software package except for the refinement, which was performed with SHELXL-97.[35] CCDC-640710 to -640717 (for **1** at the various temperatures) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Alkyl Chain Length Defines 2D Architecture of Salophen Complexes on Liquid–Graphite Interface

**Minna T. Räisänen,[a] Florian Mögele,[b] Santeri Feodorow,[a] Bernhard Rieger,[b] Ulrich Ziener,[c] Markku Leskelä,[a] and Timo Repo*[a]**

**Keywords:** Metal-containing monolayers / Nanopatterning / Scanning tunnelling microscopy (STM) / Self-assembly

A series of $Cu^{II}$, $Ni^{II}$ and $Co^{II}$ salophen [salophen = *N*,*N*′-(*o*-phenylene)bis(salicylideneimine)] complexes were prepared, and their two-dimensional (2D) assemblies on a liquid–graphite interface were studied by scanning tunnelling microscopy (STM). Depending on their varying alkyl chain lengths ($C_8$, $C_{10}$ or $C_{12}$), two different new adlayers, parallelogram and honeycomb, were recorded. According to STM data, the driving force for these assemblies is a subtle interplay between a maximum amount of attractive van der Waals interaction of the alkyl chains and weak hydrogen bonding of the phenoxy moieties. Thus, the alkyl chain length defines the favoured 2D structure for each metal complex. As shown here, the self-assembled monolayers of the salophen complexes studied provide an attractive approach to varying the surface architecture.

## Introduction

The formation of self-assembled monolayers (SAMs) is a useful methodology for the preparation of surfaces with well-defined composition, structure and thickness.[1] SAMs have found use in chemical sensors,[2] electrochemistry,[3] catalysis,[4] corrosion protection,[5] lubrication,[6] adhesion[7] and wetting.[7,8] Lately, SAMs of metal complexes on highly oriented pyrolytic graphite (HOPG) have captured significant interest,[9] as they provide a platform for the highly ordered metal-decorated surfaces required in such uses as functional nano devices and data storage.[10] For example, the controlled 2D or 3D assembly of [2 × 2] $M^{II}$ grid-type complexes of Co[11] and Fe[12] is important, as these complexes have many technologically interesting properties.[13] Furthermore, redox-active $Ru^{II}$ and $Pt^{II}$ Fréchet dendrons have been assembled on HOPG.[14] In addition to assemblies on HOPG, several metal–organic coordination networks have been studied on single crystalline Cu, Au and Ag surfaces for the preparation of functional nanomaterials.[15]

For application purposes, the highly oriented SAMs must be kinetically and thermodynamically stable in the long run in order to maintain their desired function. Intermolecular van der Waals interactions – especially those of long alkyl chains – as well as hydrogen bonding and adsorbate–substrate interactions within the 2D arrays provide strong driving forces for the formation of highly ordered surface structures. Long alkyl chains play a considerable role in the mutual recognition and stabilisation of the patterns formed and act as easily variable spacers.[9d,9f] In this context, we report herein a study of 2D assemblies for a series of $Co^{II}$, $Cu^{II}$ and $Ni^{II}$ salophen complexes (**1**–**9**) on a liquid–graphite interface (Figure 1). Depending on their varying alkyl chain lengths ($C_8$, $C_{10}$ or $C_{12}$), the salophen complexes formed two different new adlayers on HOPG.

## Results and Discussion

Salophen ligand precursors with varying alkyl chain lengths and their $Co^{II}$, $Cu^{II}$ and $Ni^{II}$ complexes (**1**–**9**) were prepared by standard synthetic procedures (see Exp. Sect.). The self-assembled monolayers of **1**–**9** were measured at room temperature in saturated 1,2,4-trichlorobenzene (TCB) solutions by STM at the liquid–solid interface on HOPG.[16] The images were measured in a constant-current mode, and the aromatic parts of the molecules appear brighter than the alkyl chains because of their higher electron density. In addition to the SAMs of the metal complexes, those of the uncomplexed salophen ligand **E** with $C_{12}$ alkyl chains were imaged. The surface structure formed was of lamellar type with interdigitating alkyl chains (Figure 2) and clearly distinct from those of the complexes deposited on HOPG from the same solvent (TCB). In the case of ligands with shorter alkyl chains ($C_{10}$ and $C_8$), no images were obtained under the same conditions as those used for the metal complexes.[16]

So far the most common 2D structure reported for metal complexes on HOPG is a highly ordered lamellar structure similar to that measured here for the uncomplexed salophen ligand.[9a,9b,9e–9g] Therefore, it was quite unexpected that all salophen complexes bearing short ($C_{10}$ or $C_8$) alkyl chains would assemble on the HOPG surface by forming an array of almost distinct parallelograms rather than striped lamellar structures (Figure 3). The attribution of the bright features to the aromatic parts of the molecule leads to a proposed model where each parallelogram consists of four salophen complexes. Detailed analysis of the 2D structure revealed its novelty.

The interatomic distances between neighbouring molecules in the structure can be estimated from the model coinciding with the high-resolution STM pattern. As shown

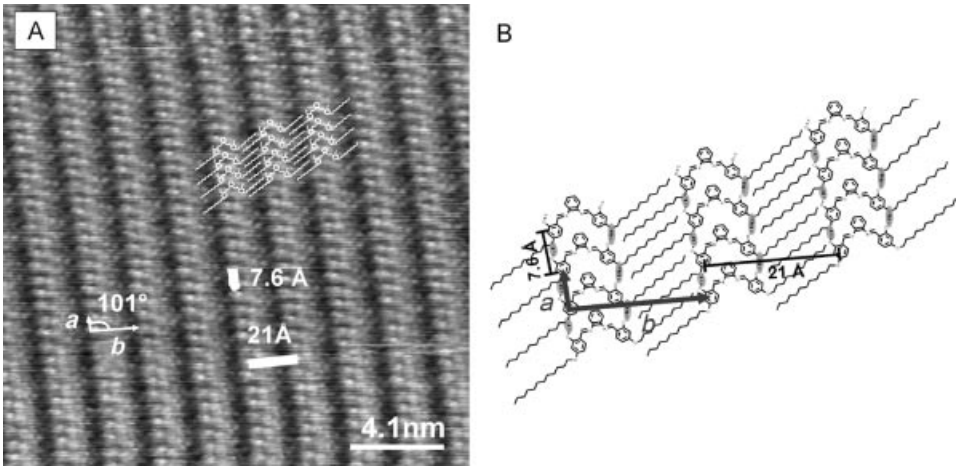

Figure 2. The STM image (A) and the proposed molecular model (B) for *N*,*N*′-(*o*-phenylene)bis(4-decyloxysalicylideneimine) (**E**) on HOPG. The image was obtained from saturated 1,2,4-trichlorobenzene solution. Image area: 203 Å × 203 Å; $U_{set}$ = –259 mV; $I_{set}$ = 18.2 pA. Unit cell dimensions: $a = 7.6 \pm 0.2$ Å; $b = 21.0 \pm 0.2$ Å; angle $101 \pm 2$ °. The hydrogen bonding of molecules is shown by the dotted lines and the grey overlay.

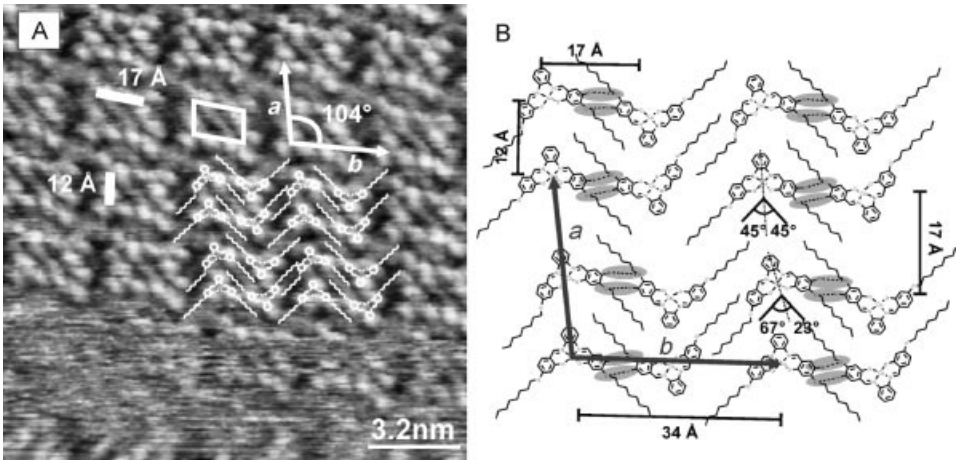

Figure 3. The high-resolution STM image (A) and the proposed molecular model (B) for complex **3** at the liquid–HOPG interface. Image area: 161 Å × 161 Å; $U_{set}$ = –630 mV; $I_{set}$ = 29.3 pA. Unit cell dimensions: $a = 28.5 \pm 0.2$ Å; $b = 34.0 \pm 0.2$ Å; angle $104 \pm 2$ . The hydrogen bonding in a parallelogram is shown by the dotted lines and the grey overlay.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

here for **3**, intermolecular metal–metal distances within a parallelogram alternate between $12.0 \pm 0.2$ Å (*a* axis) and $17.0 \pm 0.2$ Å (*b* axis), while the shortest metal–metal distances between the parallelograms, regardless of the axis, are constant at a value of $17.0 \pm 0.2$ Å (Figure 3). The metal–metal distances along the *b* axis can be considered as the distances between the lamellae. This structure consists of two different, alternating lamellae that differ from each other by the relative orientation of the salophen complexes. In the proposed structural model, every second complex within a lamella is also twisted by 18° with respect to the preceding molecule, which further distorts the classical lamellar structure. If a parallelogram is considered to be a unit, it can be seen that the periodicity of this structure is 34 Å along the *b* axis and 29 Å along the *a* axis. Specifically, the differing orientation of the molecules and the resulting loss of symmetry within a lamella distinguish this parallelogram-like structure from the traditional lamellar structure. A parallelogram-like structure similar to that of **3** was also obtained for Ni and Co complexes **5**, **6**, **8** and **9** bearing $C_{10}$ and $C_8$ alkyl chains (see Supporting Information). As illustrated in Table 1, the variation of the alkyl chain length and central metal ion has an observable influence on the geometry of the 2D structure obtained. For example, the Co complexes **8** ($C_{10}$) and **9** ($C_8$) have a rather constant *b* axis, whereas the change in the alkyl chain length has a substantial influence on the *a* axis. Similarly, the difference in the *b* axis is only ca. 1 Å in Ni complexes **5** ($C_{10}$) and **6** ($C_8$), whereas the *a* axis is longer by ca. 3 Å in the complex with the longer alkyl chain. Although the image resolutions of **5**, **6**, **8** and **9** do not facilitate the interpretation of the 2D fine structures, it is clear that the length of the alkyl chain and the nature of the metal ion play an interactive role in the formation of these structures.

Table 1. Unit cell dimensions of salophen complexes **3**, **5**, **6**, **8** and **9** with parallelogram-like 2D structures.

| Complex | Unit cell dimensions | | |
|---|---|---|---|
| | *a* [Å] | *b* [Å] | Angle [°] |
| $CuC_8$ (**3**) | $28.5 \pm 0.2$ | $34.0 \pm 0.2$ | $104 \pm 2$ |
| $NiC_{10}$ (**5**) | $28.0 \pm 0.2$ | $28.0 \pm 0.2$ | $90 \pm 2$ |
| $NiC_8$ (**6**) | $25.0 \pm 0.2$ | $27.0 \pm 0.2$ | $95 \pm 2$ |

The measured lamellar periodicities suggest that the alkyl chains of neighbouring lamellae interdigitate. The darker regions in Figure 3A exhibit a striped pattern that approximates the distance between the alkyl chains, which averages $5.0 \pm 0.2$ Å. This is a rather typical value for close-packed alkyl chains in van der Waals contact.[17] The alkyl chains need to adjust themselves to the adjacent molecule; this results in different angles (23°, 45° or 67°) between the alkyl chains and the bisectors of the molecules. As a result of the distorted lamellar structure, the interdigitation of the alkyl chains also varies in the assembly. In a parallelogram, one alkyl chain of a complex in the upper left-hand corner and one of a complex in the lower right-hand corner fully interdigitate with alkyl chains of complexes in two neighbouring parallelograms, and this particular interaction actually joins the individual parallelograms together to form a continuous pattern. Further on, the remaining alkyl chains of these complexes fully interdigitate with each other. Interdigitation of the alkyl chains of complexes in the lower left-hand and upper right-hand corners, even to a relatively low degree, with the molecules of neighbouring parallelograms provides additional stabilisation for the assembly.

In addition to the above-described van der Waals interactions, the parallelogram-like structure appears to be further stabilised by intermolecular $C_{Ar}H\cdots O_{alkoxy}$ hydrogen bonding. Inside a given parallelogram are two pairs of hydrogen-bond-coupled salophen complexes (Figure 3). The observed hydrogen bond lengths of ca. $2.7 \pm 0.2$ Å fall within the range of weak hydrogen bonds.[18] According to the molecular symmetry, these hydrogen-bonded couples inside each parallelogram are identical. In this respect, the 2D assembly can also be seen as an arrangement of those hydrogen-bonded couples rather than that of individual salophen complexes. It is noteworthy that there is no interparallelogram hydrogen bonding. We assume that the hydrogen bonding is essential in stabilising the 2D structure, which represents the global energetic minimum gained by a compromise between the hydrogen bonding and the maximum amount of van der Waals contacts. Both of these intermolecular interactions are known to be important structural parameters in 2D assemblies,[9a,19,20] and the influence of alkyl chain length on the 2D structure was described previously for the co-adsorption of trimesic acid with even- and odd-numbered alcohols on HOPG.[20]

In this series of salophen complexes, an increase in the alkyl chain length from $C_{10}$ to $C_{12}$ leads exclusively to a new, honeycomb-type network pattern consisting of hexagons with six molecules.[21] A structural model in which each molecule has its three nearest neighbours within a range of $12.0 \pm 0.2$ Å to $15.0 \pm 0.2$ Å is proposed (Figure 4). In this assembly, the alkyl chains of each molecule are parallel to the bisector of the salophen complex and interdigitate perfectly with those of the opposite molecule within each hexagon. Thus, in the honeycomb assembly, the alkyl chains only form van der Waals contacts inside the hexagons, whereas in the classical lamellar assembly as well as in the parallelogram-like one described above, they form a continuous network throughout the 2D structures. Instead, here the hydrogen-bonding network continues throughout the structure, and every complex has two intermolecular $C_{Ar}H\cdots O_{alkoxy}$ hydrogen bonds at an approximate distance of $2.6 \pm 0.2$ Å. This distance was estimated by applying typical geometric parameters to the structural model in Figure 4B. Apparently, both van der Waals contacts and hydrogen bonding are needed to stabilise this assembly.

The substantial differences in the 2D packings of the salophen-$C_{12}$ ligand **E** and its $Co^{II}$ complex **7** can be explained by the effect of the $Co^{II}$ ion on the ligand geometry upon complex formation. When the salophen ligand coordinates to the $Co^{II}$ ion, both hydroxy groups are forced towards the metal ion, and the complex acquires an overall $C_2$ symmetry. On the contrary, in the free ligand **E**, the OH groups

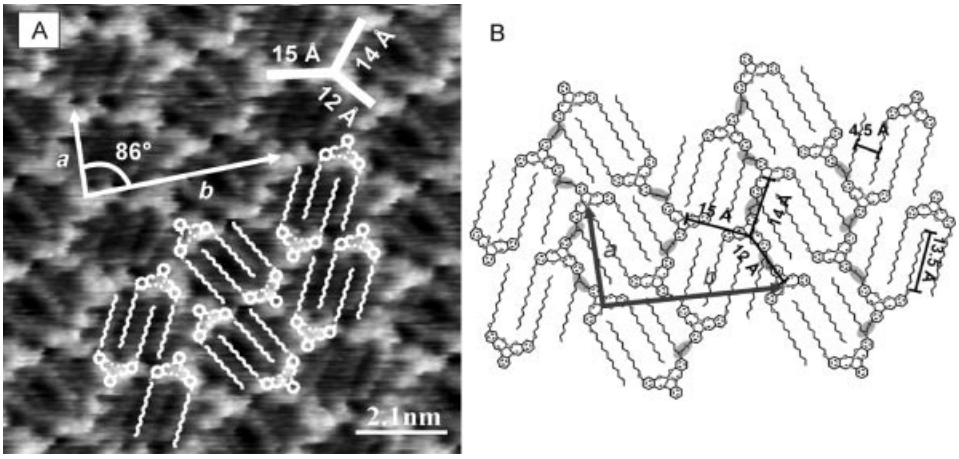

Figure 4. The high-resolution STM image (A) and the proposed molecular model (B) for complex **7**. Image area: 104 Å × 104 Å; $U_{set}$ = –180 mV; $I_{set}$ = 12.8 pA. Unit cell dimensions: $a = 19.5 \pm 0.2$ Å; $b = 46.0 \pm 0.2$ Å; angle = 86 ± 2 °. The hydrogen bonding in a honeycomb is shown by the dotted lines and the grey overlay.

can be located independently either inside or outside the ligand cavity as a result of rotation. In the 2D structure of **E** (Figure 2), both hydroxy groups point outwards, forming hydrogen bonds with the adjacent molecule.

Clear differences can be noted in the stabilisation of the 2D parallelogram-like and honeycomb structures. In the parallelogram-like structure the van der Waals forces are reduced as a result of the twisted orientation of every second complex in a lamella, but this reduced stability is compensated for by hydrogen bonds inside the parallelogram. The van der Waals interactions network the structure. In the honeycomb assembly, alkyl chains of an individual complex fully interdigitate with alkyl chains of another complex, but further networking is prohibited by the surrounding ligand frameworks. Hydrogen bonds form the required network and are essential in stabilising the honeycomb structure. Apparently, by tuning the alkyl chain length in salophen complexes, the balance between van der Waals and hydrogen bonding interactions can be controlled. As a consequence, the 2D assembly of the complexes changes. These findings are summarised in Table 2 to illustrate the interactive effects of van der Waals interactions, i.e. the alkyl chain length, and hydrogen bonding on the 2D morphology of the SAMs. Furthermore, metal ions have clear effects on the 2D assemblies, as shown by the formation of a lamellar structure by the uncomplexed $C_{12}$ ligand (Figure 2).

Table 2. The van der Waals interactions and number of hydrogen bonds in parallelogram-like and honeycomb structures.

| 2D structure | van der Waals interactions | H bonds per molecule | Networking by |
|---|---|---|---|
| Parallelogram-like: $CoC_8$, $CuC_8$, $NiC_8$, $CoC_{10}$, $NiC_{10}$ | Alkyl chains of every second molecule are fully interdigitating. | 2 | van der Waals interactions |
| Honeycomb: $CoC_{12}$, $NiC_{12}$ | Alkyl chains of each molecule are fully interdigitating. | 2 | Hydrogen bonds |

Regardless of the surface architecture and hence different metal ion patterning on the surface, both structures exhibit rather similar metal ion densities. The parallelogram-like assembly has a packing where the average metal ion coverage is ca. 0.52/nm$^2$, whereas in the honeycomb structure the value is ca. 0.48/nm$^2$ (values are estimated from a 5 nm × 5 nm area).

## Conclusions

STM studies of salophen complexes on liquid–graphite interfaces revealed new parallelogram-like and honeycomb structures. As demonstrated here, the alkyl chain length can have a significant influence in determining the assembly of the salophen complexes. Complexes bearing $C_8$ or $C_{10}$ alkyl chains assemble in the parallelogram-like 2D structure, while those with $C_{12}$ alkyl chains form the honeycomb assembly. The driving force for these new assemblies is a subtle interplay between a maximum amount of attractive van der Waals interactions of the alkyl chains and weak hydrogen bonding. Because of the ease of the methodology of SAM formation and the straightforward synthesis of salophen complexes, the SAMs of these compounds provide an attractive approach for the fine tuning of the surface architecture.

## Experimental Section

**General Methods and Materials:** $^1$H NMR spectra were recorded with a Varian Gemini 200 apparatus, and IR spectra were taken with a PerkinElmer Spectrum One. EI$^+$ and HRMS (ESI$^+$ TOF) mass spectra were recorded with a JEOL JMS-SX 102 (ionising voltage 70 eV) and with a Bruker micrOTOF mass spectrometer, respectively. Elemental analyses were performed with an EA 1110 CHNS-O CE instrument. For STM measurements, a low-current RHK scanning tunnelling microscope was used, which was operated in a constant-current mode under ambient conditions. STM tips were mechanically sharpened from Pt/Ir (80:20) wire, and HOPG was used as a substrate for the adlayers. The compounds

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were dissolved in 1,2,4-trichlorobenzene, and a droplet of the saturated solution was placed on freshly cleaved HOPG. All chemicals required for complex synthesis were purchased from Aldrich and used as received. STM images were processed with WSxM©.

**Ligands:** 4-dodecyloxy-2-hydroxybenzaldehyde (**A**), 4-decyloxy-2-hydroxybenzaldehyde (**B**) and 4-octyloxy-2-hydroxybenzaldehyde (**C**) were prepared with moderate yields according to a procedure by Binnemans et al.[22]

***N,N′*-(*o*-Phenylene)bis(4-dodecyloxysalicylideneimine) (D):** (*o*-Phenylene)diamine (1.412 g, 13 mmol) in MeOH (20 mL) was added to compound **A** (8.005 g, 26 mmol) dissolved in *n*-hexane (20 mL). A yellow colour immediately appeared, and the solution was stirred at room temperature for 18 h. The viscous product obtained was stirred in MeOH for 2 h, and the yellow powder that was formed was filtered, washed with MeOH and finally dried in vacuo (isolated yield 7.156 g, 40%). Analytical data for $C_{44}H_{64}N_2O_4$: $^1$H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta$ = 0.94 (t, $^3J_{H,H}$ = 7.0 Hz, 6 H, $CH_3$), 1.32 (s, 36 H, $CH_2$), 1.76–1.90 (m, 4 H, $CH_2$), 4.03 (t, $^3J_{H,H}$ = 6.7 Hz, 4 H, $OCH_2$), 6.51 (dd, $J_{H,H}$ = 2.4 Hz, $^3J_{H,H}$ = 8.5 Hz, 2 H, Ar-H), 6.58 (d, $^3J_{H,H}$ = 2.2 Hz, 2 H, Ar-H), 7.23–7.36 (m, 6 H, Ar-H), 8.58 (s, 2 H, HC=N) ppm. IR: $\tilde{\nu}$ = 1609 (C=N), 1583 (C=C), 1246 (C–O) cm$^{-1}$. HRMS (ESI-TOF): calcd. for $[M + H]^+$ 685.4939; found 685.4938; error 0.08 ppm.

Salophen ligands **E** and **F** were synthesised in the same manner as ligand **D**.

***N,N′*-(*o*-Phenylene)bis(4-decyloxysalicylideneimine) (E):** Yellow powder (isolated yield 31%). Analytical data for $C_{40}H_{56}N_2O_4$: $^1$H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta$ = 0.89 (t, $^3J_{H,H}$ = 6.9 Hz, 6 H, $CH_3$), 1.28 (s, 28 H, $CH_2$), 1.71–1.85 (m, 4 H, $CH_2$), 3.98 (t, $^3J_{H,H}$ = 6.7 Hz, 4 H, $OCH_2$), 6.38 (dd, $J_{H,H}$ = 2.4 Hz, $^3J_{H,H}$ = 8.9 Hz, 2 H, Ar-H), 6.45 (d, $^3J_{H,H}$ = 2.3 Hz, 2 H, Ar-H), 7.18–7.31 (m, 6 H, Ar-H), 8.53 (s, 2 H, HC=N) ppm. IR: $\tilde{\nu}$ = 1608 (C=N), 1582 (C=C), 1240 (C–O) cm$^{-1}$. HRMS (ESI-TOF): calcd. for $[M + H]^+$ 629.4313; found 629.4330; error –2.66 ppm.

***N,N′*-(*o*-Phenylene)bis(4-octyloxysalicylideneimine) (F):** Yellow powder (isolated yield 56%). Analytical data for $C_{36}H_{48}N_2O_4$: $^1$H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta$ = 0.89 (t, $^3J_{H,H}$ = 6.9 Hz, 6 H, $CH_3$), 1.30 (s, 20 H, $CH_2$), 1.72–1.85 (m, 4 H, $CH_2$), 3.98 (t, $^3J_{H,H}$ = 6.5 Hz, 4 H, $OCH_2$), 6.46 (dd, $J_{H,H}$ = 2.4 Hz, $^3J_{H,H}$ = 8.4 Hz, 2 H, Ar-H), 6.53 (d, $^3J_{H,H}$ = 2.0 Hz, 2 H, Ar-H), 7.18–7.31 (m, 6 H, Ar-H), 8.53 (s, 2 H, CH=N) ppm. IR: $\tilde{\nu}$ = 1608 (C=N), 1582 (C=C), 1240 (C–O) cm$^{-1}$. HRMS (ESI-TOF): calcd. for $[M + H]^+$ 573.3687; found 573.3701; error –2.44 ppm.

**Complexes:** Cobalt complexes were prepared under an Ar atmosphere by using standard Schlenk techniques. Copper and nickel complexes were synthesised under ambient conditions. Dry solvents were used in the preparation of cobalt complexes. Crude products of nickel and copper complexes were washed with MeOH and *n*-hexane, and they were finally recrystallised from $CHCl_3$ or $CH_2Cl_2$. Crude products of the cobalt complexes were washed with MeOH.

***N,N′*-(*o*-Phenylene)bis(4-dodecyloxysalicylideneiminato)copper(II) (1):** A warmed solution of $Cu(OOCCH_3)_2$ (0.133 g, 0.73 mmol) in MeOH (40 mL) was added to a solution of **D** (0.500 g, 0.74 mmol) in $CH_2Cl_2$ (10 mL). A brown suspension immediately formed and was stirred at room temperature for 20 h. A green precipitate was filtered and washed with MeOH and *n*-hexane. Finally the crude product was recrystallised from $CH_2Cl_2$, and the precipitate that formed was dried in vacuo. Complex **1** was obtained as a green powder (isolated yield 68%). $C_{44}H_{62}CuN_2O_4{\cdot}H_2O$ (746.5·$H_2O$): calcd. C 69.12, H 8.44, N 3.66; found C 69.41, H 8.57, N 3.72. IR: $\tilde{\nu}$ = 1610 (C=N), 1577 (C=C), 1244 (C–O) cm$^{-1}$. HRMS (ESI-TOF): calcd. for $[M + H]^+$ 746.4078; found 746.4070; error 1.18 ppm.

Complexes **2**–**6** were prepared similarly to **1**.

***N,N′*-(*o*-Phenylene)bis(4-decyloxysalicylideneiminato)copper(II) (2):** Green powder (isolated yield 57%). $C_{40}H_{54}CuN_2O_4{\cdot}2H_2O$ (690.4·2$H_2O$): calcd. C 66.13, H 8.05, N 3.86; found C 65.87, H 8.07, N 3.51. IR: $\tilde{\nu}$ = 1606 (C=N), 1578 (C=C), 1244 (C–O) cm$^{-1}$. HRMS (ESI-TOF): calcd. for $[M + H]^+$ 690.3452; found 690.3462; error –1.45 ppm.

***N,N′*-(*o*-Phenylene)bis(4-octyloxysalicylideneiminato)copper(II) (3):** Green powder (isolated yield 73%). $C_{36}H_{46}CuN_2O_4{\cdot}2H_2O$ (634.3·2$H_2O$): calcd. C 64.50, H 7.52, N 4.18; found C 65.06, H 7.61, N 3.66. IR: $\tilde{\nu}$ = 1604 (C=N), 1578 (C=C), 1239 (C–O) cm$^{-1}$. HRMS (ESI-TOF): calcd. for $[M + H]^+$ 634.2826; found 634.2821; error 0.81 ppm.

***N,N′*-(*o*-Phenylene)bis(4-dodecyloxysalicylideneiminato)nickel(II) (4):** Orange powder (isolated yield 57%). Analytical data for $C_{44}H_{62}N_2NiO_4$: $^1$H NMR (200 MHz, $CDCl_3$, 25 °C, TMS): $\delta$ = 0.88 (t, $^3J_{H,H}$ = 6.6 Hz, 6 H, $CH_3$), 1.27 (s, 36 H, $CH_2$), 1.70–1.85 (m, 4 H, $CH_2$), 3.95 (t, $^3J_{H,H}$ = 6.5 Hz, 4 H, $OCH_2$), 6.31 (dd, $J_{H,H}$ = 2.4 Hz, $^3J_{H,H}$ = 8.8 Hz, 2 H, Ar-H), 6.61 (d, $^3J_{H,H}$ = 2.0 Hz, 2 H, Ar-H), 7.13–7.21 (m, 4 H, Ar-H), 7.59–7.66 (m, 2 H, Ar-H), 8.06 (s, 2 H, HC=N) ppm. $C_{44}H_{62}N_2NiO_4{\cdot}H_2O$ (741.7·$H_2O$): calcd. [16] Though solvent molecules can be coordinated to the axial positions of the metal centres in the 2D assemblies of the studied complexes, this is believed to have only a minor influence on the surface patterns created. Also, attempts at imaging the corresponding salen complexes and the salophen complexes with hexyloxy side chains were not successful. We therefore propose that in particular, salen complexes with $C_6$–$C_{12}$ chains, salophen complexes with $C_6$ chains and salophen ligands with alkyl chains shorter than 12 carbons are too mobile on HOPG for successful STM imaging. It has been previously reported that even if the molecules are easily adsorbed on the surface, high-resolution images may be difficult to obtain because of the mobility of the molecules within the basal plane. Also, the scanning tip may introduce a perturbation which would interfere with the imaging. [see ref.[9a,9c,9d]] and D. M. Cyr, B. Venkataraman, G. W. Flynn, *Chem. Mater.* **1996**, *8*, 1600–1615].

[21] Cu complexes with $C_{10}$ and $C_{12}$ alkyl chains formed another new 2D pattern on the liquid–graphite interface. The only difference in these patterns is the periodicity in one of the directions which varies predictably with the alkyl chain length. Even though a high-resolution STM image was obtained for complex **2**, the resolution was still not high enough to allow us to propose a proper structural model.

# Ferrocenyl Oligo(phenylene-vinylene) Thiols for the Construction of Self-Assembled Monolayers

**Christian Amatore,*[a] Stephen Gazard,[a] Emmanuel Maisonhaute,[a] Cécile Pebay,[a] Bernd Schöllhorn,*[a] Jean-Laurent Syssa-Magalé,[a] and Jay Wadhawan[a]**

**Keywords:** Molecular wires / SAMs / Ferrocenes / Thiols / Redox chemistry / Self-assembly

A short and efficient preparation of conjugated oligo(phenylene-ethylene) thiols bearing redox-active ferrocene moieties is described. While minimising the number of synthetic steps, the proposed strategy permits the development of sets of oligomers with varying chain length. The redox properties of the compounds in solution are determined. Preliminary studies of self-assembled monolayers (SAMs) on gold electrodes are discussed, and indicate that electron transfer through the SAMs is indeed rapid.

## Introduction

There is growing interest in nanotechnologies for attaching and wiring conductive molecules onto surfaces for a wide series of applications. Electrochemical systems may be promising for developing, for example, molecular electronic devices,[1] efficient artificial photosynthetic systems,[2] organic liquid crystal light-emitting diodes[3] or biosensors. The use of self-assembly allows easy formation of monolayers of a redox-active species over an electrode by soaking an appropriate electrode surface in a nonaqueous solution of the suitably derivatised redox-active compound to enable it to tether to the surface. Typically, an electroactive moiety is located at one end of the molecule, whilst the grafting end is terminated by a Lewis base.[4] When using gold electrodes, such compounds often terminate with thiol moieties, owing to the exquisite affinity of sulfur groups for gold. This methodology is also highly attractive for electroanalytical sensors, as this method requires little preparative work, and furnishes a reagent-immobilised electrode relatively inexpensively. The attached compounds are able to carry electrons back and forth from the electrode to redox enzymes.

In this context, the investigation of electron transfer through molecular bridges has revealed that the rates usually decrease exponentially as the distance to the electrode decreases. The attenuation factor is typically 10 $nm^{-1}$ (i.e., 1 $Å^{-1}$) for alkyl bridges, a value that may be too high for fast signal processing over long distances. Recent contributions by the groups of Chidsey,[5] Creager[6] and Finklea[7] illustrate the tendency to use conjugated bridges because π-delocalisation increases the coupling between the redox probe and the electrode. For this reason conjugated π-systems are potentially the most adapted and most promising molecular wires, assuring fast electron transfer kinetics over distances up to 20 Å and longer. Hitherto, oligo(*p*-phenylene-*trans*-vinylene) chains have exhibited the fastest electron transfer rates of all investigated systems.[5] Ferrocene has been used in various studies as a convenient electroactive centre showing fast and reversible one-electron oxidation. Furthermore, ferrocenes may act as a local molecular switch as their Cp/Cp conduction (Cp = cyclopentadienyl ligand) is poor in the reduced state and effective in the ferricinium cations. It is thus important to develop rapid and efficient access for sets of ferrocenyl oligo(phenylene-ethylene) thiols with varying chain length. Our synthetic strategy described herein also permits the insertion of additional ferrocenyl groups into the bridge itself and thus the building of more complex structures leading eventually to more sophisticated signal processing functions such as field-effect transistors. We wish to report here the rapid access to a set of three ferrocenyl oligo(*p*-phenylene-*trans*-vinylene) derivatives, **1**, **2** and **3**, bearing a mercaptomethyl group on the terminating phenyl ring. The peculiar electrochemical properties of **3** will also be described.

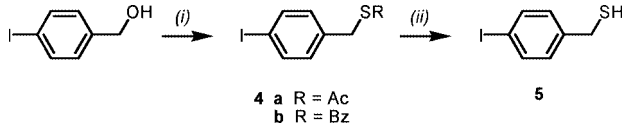
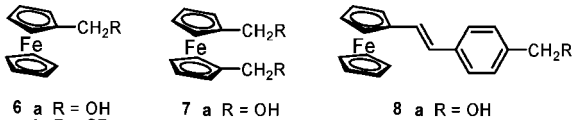
## Results and Discussion

Two main approaches are commonly used in the synthesis of free thiol derivatives: either the use of a protective group or the late introduction of the thiol group as a final step so as to avoid interferences during the earlier synthetic steps. In the case of benzyl derivatives, a possible approach involves masking a hydroxy group by an aldehyde, which, after reduction to the corresponding primary alcohol, can be converted in several steps to the desired thiol. Compounds **1** and **2** have been prepared in this way.[8] As an alternative, we opted for the late introduction of a thioester group. We chose the *S*-protected 4-iodobenzylthiol **4**, as this useful building block significantly reduces the number of synthetic steps. In a more convergent approach, **4a** can be easily obtained by treatment of 4-iodobenzyl bromide with sodium thioacetate.[9] As an alternative route, we tried to exploit the 4-iodobenzyl alcohol as a starting material, thus favouring the direct conversion of the generally more stable and readily available alcohol into the corresponding thioester without any preceding halogenation. The Mitsunobu reaction of 4-iodobenzyl alcohol with thioacetic acid affords **4a** in only low yield (30%) (Scheme 1). Hughes and Reamer[10] showed evidence for improved yields in the Mitsunobu esterification of alcohols in the presence of acids stronger than acetic acid. Accordingly, we employed thiobenzoic acid instead of thioacetic acid so that, under the same conditions, the thiobenzoic acid ester **4b** is obtained in high yield (95%).

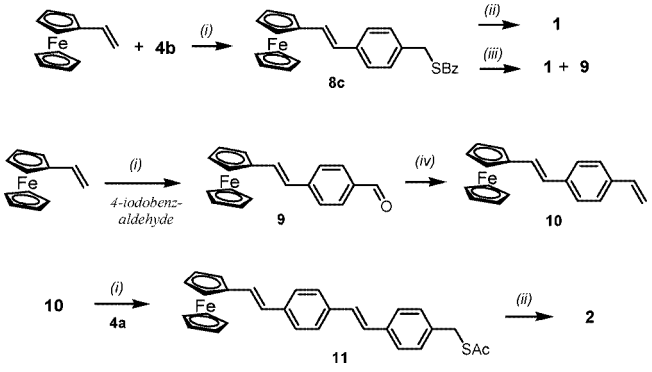


Scheme 1. Synthesis of the precursors **4a** and **4b**: (i) AcSH (for **4a**), BzSH (for **4b**), $PPh_3$, DEAD, THF, 0 °C; (ii) $LiAlH_4$, THF, 0 °C.

The thiobenzoates **6b** and **7b** are also formed in satisfactory yields (84 and 63%) from the respective hydroxymethyl derivatives **6a** and **7a**. The reaction of alcohol **8a** to the thioacetate **8b**[8] shows a low yield (20%) compared to the thiobenzoate **8c** (75%), confirming the observed tendency. All of the thiobenzoic acid esters discussed above were successfully converted into the respective free thiols **5**, **6c**, **7c** and **1** through reduction with sodium borohydride (Scheme 1). Both of the building blocks **4a** and **4b** were employed in the following syntheses leading to the target compounds **1**, **2** and **3**.



The preparation of the short ferrocenyl-vinylene-phenylene thiol **1** was achieved in only two steps. The Heck coupling of **4b** with vinylferrocene afforded thiobenzoate **8c** directly (Scheme 2). The subsequent reduction of the latter compound with sodium borohydride in a mixture of methanol and tetrahydrofuran afforded the desired free thiol (88%). The use of lithium aluminium hydride (LAH) as a reducing agent gave thiol **1** in only a 46% yield. Even with an excess of LAH, the aldehyde **9** was isolated as an unexpected sideproduct. Whilst the analytical characterisation data of **9** are consistent with previously published data for this compound,[11] it is important to note that in contrast to the earlier work, we also prepared compound **9** by Heck reaction of vinylferrocene with 4-iodobenzaldehyde, thus unambiguously identifying the structure of **9**.



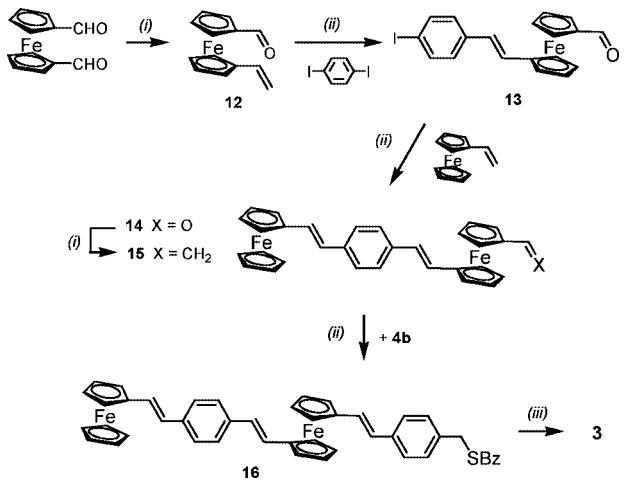
Scheme 2. Synthesis of compounds **1** and **2**: (i) $Pd(OAc)_2$, $P(Tol)_3$, tributylamine, dimethylacetamide; (ii) $NaBH_4$, THF, MeOH, 0 °C; (iii) $LiAlH_4$, THF, 0 °C.

Access to the ferrocene thiol **2** is achieved in only 3 steps starting from aldehyde **9** (Scheme 2). The Heck coupling of the olefin **10** and **4a** leads directly to the thioacetate **11**, which was subsequently converted into the free thiol **2** through reduction with lithium aluminium hydride.

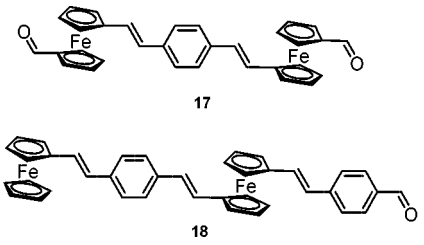
Taking into account our previous results, we performed the synthesis of the bis(ferrocenyl) thiol **3** in only 6 steps involving Heck coupling, standard methyl Wittig conversion and a final reduction (Scheme 3). Our synthetic strategy is based on the monofunctionalisation of 1,1′-ferrocenedicarbaldehyde leading, in two steps, to the key intermediate **13**. The methyl Wittig conversion of ferrocenedicarbaldehyde in dioxane allows for its selective monoolefination. Upon using the less polar tetrahydrofuran as a solvent, the reaction is faster (TLC analysis) but less selective, indicative of a strong kinetic control depending on the solvent polarity. In the following Heck reaction of **12** with a twofold excess of 1,4-diiodobenzene, the monoiodo derivative **13** was obtained as the major product. Only small amounts of the symmetric bis(ferrocenyl) derivative **17** (2%) are isolated. Inversion of the molar ratio of the starting compounds should afford this potential precursor of a tris(ferrocenyl) derivative in reasonable yields. An alternative, but longer and less efficient, synthesis of **13** involving a protective group is described in the literature.[12,13] A second Heck reaction of compound **13** with vinylferrocene affords the dissymmetric bis(ferrocenyl) monocarbaldehyde **14**. The

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$R_f$ values of starting material **13** and product **14** are very similar, and it is difficult to monitor the reaction by TLC. In order to obtain a complete conversion, a higher temperature has to be maintained during the reaction. The relatively low yield (53%) is probably due to a competitive degradation of either starting material or product under these conditions. A methyl Wittig conversion of **14** leads to the corresponding vinyl derivative **15**. This highly conjugated and relatively apolar compound displays low solubility in solvents such as diethyl ether or chloroform. The use of dichloromethane is necessary for the purification steps in the workup following the reaction. Unreacted starting compound **14** was recovered and the reaction repeated in order to improve the total yield to 60%. The thiobenzoate **16** was obtained by a third Heck reaction of **15** with **4b**. In the final step, **16** is reduced with sodium borohydride to the target compound **3**. The use of LAH as a reducing agent considerably lowers the yield and affords the aldehyde **18** as a side product, like in the reduction of **8c**.



Scheme 3. Synthesis of compound **3**: (i) methyltriphenylphosphonium bromide, *tert*-butoxide, dioxane/water; (ii) $Pd(OAc)_2$, $P(Tol)_3$, tributylamine, dimethylacetamide; (iii) $NaBH_4$, THF, MeOH, 0 °C.



## Exploring the Electron Transfer Properties of the Ferrocene-Based Compounds in Homogeneous Solution

We resorted to cyclic voltammetry to explore the electrochemical properties of **1**, **2**, **3**, **14**, **16** and **17**. Owing to the low solubility of some of the compounds in conventional electrochemical solvents, investigations were undertaken in dichloromethane with tetrabutylammonium tetrafluoroborate ($TBABF_4$) at 0.1 M concentration as the supporting electrolyte. In a preliminary study, we checked that **1** and **2**, bearing a single redox centre, behave similarly to ferrocene. Each gave a monoelectronic reversible wave whose current intensity was proportional to $v^{1/2}$, where $v$ is the scan rate. This is typical of a diffusive behaviour. The average of the forward and backward peak currents allows evaluation of a standard potential of $(0.55 \pm 0.01)$ V versus SCE for **1** and $(0.54 \pm 0.01)$ V versus SCE for **2**. Figure 1a depicts a cyclic voltammogram at a scan rate of 200 $mV\,s^{-1}$ of a 0.38 mM solution of **14** at a glassy carbon electrode. This bis(ferrocenyl) monocarbonyl species gives rise to two apparently reversible waves centred at $E°_1 = (0.54 \pm 0.01)$ V versus SCE and $(0.81 \pm 0.01)$ V versus SCE, both waves being of the same height. Given that the first wave occurs at the same potential as that of the nonderivatised ferrocene, we infer that this wave represents the one-electron oxidation of the ferrocene moiety within the conjugated chain to yield the corresponding ferricinium cation. The second wave is related to oxidation of the terminal ferrocenyl group bearing an electron-withdrawing substituent.

Conversely, the voltammetry of the thiobenzoate **16** (cf. Figure 1b) reveals a single oxidation wave, despite the presence of two redox centres. Complex **16** is a larger molecule

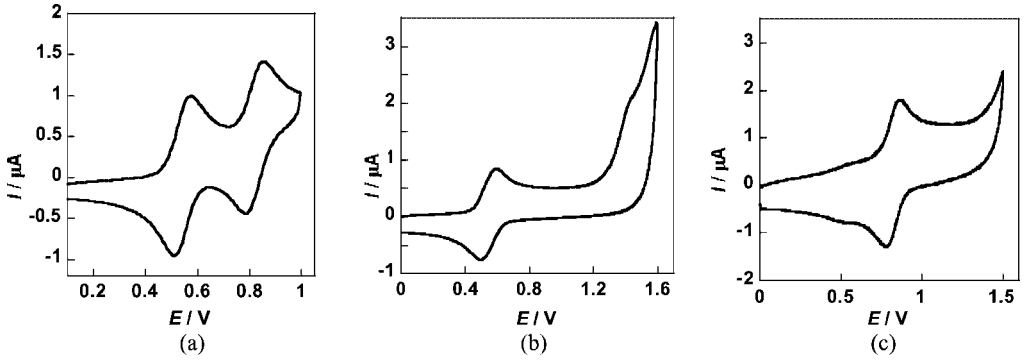


Figure 1. Cyclic voltammogram of (a) **14** ($3.8 \times 10^{-4}$ M), (b) **16** ($2.5 \times 10^{-4}$ M), (c) **17** ($2.7 \times 10^{-4}$ M) in dichloromethane containing 0.1 M $TBABF_4$ at a scan rate of 0.2 $V\,s^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

than **14**, so that its diffusion coefficient is necessarily smaller. Hence, we infer from the peak current intensities that two electrons are involved in the oxidation. Unfortunately, free thiol **3** adsorbs slightly even onto a carbon electrode, which prevents its full characterisation in solution. However, a single wave was also observed. This unusual behaviour may seem counterintuitive as the electrostatic repulsion should destabilise the dication and thus raise the potential of the second oxidation. In fact, such behaviour has already been observed by Launay et al. for polyvinylferrocenes,[14] and by Saveant et al. for carotenoids.[15] These authors proposed a rationalisation of this effect. As the monocationic species are in a mixed-valence state, the charge is delocalised inside the large volume defined between both redox centres, so that the solvation is necessarily weak. Conversely, in the dication, because of coulombic repulsion, the charges are localised onto the two redox centres, thus minimising the electrostatic repulsion and also allowing a much stronger stabilisation by the solvent. In some cases, this effect may balance the electrostatic repulsion and may result in a potential inversion. A single two-electron process then occurs, being thermodynamically and kinetically controlled by the first electron transfer. This effect corresponds with previous observations by Amatore and Kochi, revealing that for common aromatic compounds, there is a linear correlation between the standard potential $E°_1$ and the ionisation potential IP [Equation (1)],[16] where $0 < \mu < 1$ and $C^{te}$ is a constant depending on the reference electrode:

$$E° \approx \mu IP + C^{te} \quad (1)$$

Here, $\mu$ reflects how the variations in IP are transmitted to $E°$; $\mu = 1$ would mean that any variation in IP is fully reflected in the condensed phase. In this study, the electroactive moieties were normally solvated and $\mu = 0.71$ was obtained; $(1 - \mu)$ reflects the effects of solvation. For the monocation, the charge is only poorly solvated, so that $\mu$ should be close to 1 so that [Equation (2)]:

$$E°_1 \approx IP + C^{te} \quad (2)$$

Conversely, in the dication, the charges are normally solvated, so that in a very approximate model [Equation (3)], where $\Delta E_{coul}$ is the electrostatic contribution, we can evaluate that:

$$E°_2 - E°_1 \approx -2(1 - \mu)IP + \Delta E_{coul} \quad (3)$$

This formulation leads to [Equation (4)]:

$$E°_2 \approx (2\mu - 1)IP + \Delta E_{coul} + C^{te} \quad (4)$$

We can then predict that there is a potential inversion when [Equation (5)]:

$$IP > \Delta E_{coul}/(2 - 2\mu) \quad (5)$$

If the compound is dissymmetrical (for example **14**), another term, $\Delta E_{chim}$, should be added to Equation (2), taking into account the different chemical nature of both electroactive moieties. Agreeing with this analysis, the voltammetry of **17**, which is totally symmetrical, also reveals a single peak (cf. Figure 1c). The weak signal around 0.55 V may be attributed to an impurity in the crude product **17**.

In Figure 1b a second wave is observed as a shoulder on the medium discharge, reflecting an oxidative degradation of compound **16**, probably due to the irreversible thiobenzoate oxidation.

The electrochemical behaviour of **3** while attached to a gold electrode will be described elsewhere.[17] As a preliminary result, Figure 2 illustrates typical cyclic voltammograms for **3**, coadsorbed with diphenyl disulfide or pentanethiol diluents. A single two-electron wave is still observed as anticipated. Although the scan rate is high (cf. Figure 2b), the relatively low peak-to-peak potential difference confirms that electron transfer inside this molecule is indeed very fast.

## Conclusions

A particularly short and efficient preparation of conjugated oligo(phenylene-ethylene) thiols bearing redox-active ferrocene moieties is described. The proposed strategy to introduce the sulfur group by Heck reaction of a vinyl group with the key synthone **4** readily yields a set of oligomers with varying chain length in only 2 (compound **1**) or 4

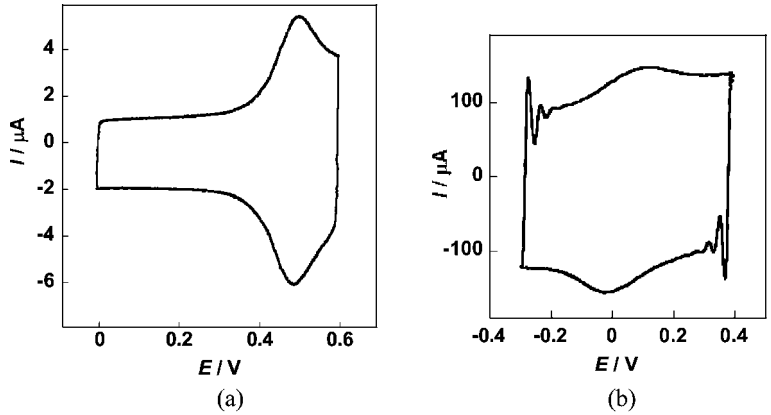

Figure 2. Cyclic voltammogram in 1 M perchloric acid of **3** coadsorbed (a) with pentanethiol onto a 111 gold single-crystal electrode, scan rate: 12 $V s^{-1}$; (b) with diphenyl disulfide onto a gold ball ultramicroelectrode, scan rate: 220000 $V s^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

synthetic steps (compound **2**). The preparation of the thioesters by Mitsunobu reaction of benzyl alcohol was improved by replacing thioacedic acid with thiobenzoic acid. The additional insertion of ferrocenyl units into the conjugated bridge can be easily achieved by the use of 1′-vinylferrocene-1-carbaldehyde (**12**), a key intermediate in the synthesis of the bis(ferrocenyl) derivative **3**. For the bis(ferrocenyl) derivatives, the nature of the second side chain attached to the second ferrocene species may have a significant effect on the redox thermodynamics, leading to an inverted series of electrode potentials, causing a single two-electron wave to occur. The ultrafast cyclic voltammetry of **1**, **2** and **3** when they are adsorbed onto gold electrodes confirms that these compounds are indeed very efficient molecular wires. A full kinetic analysis of electrochemical results for monolayers of these compounds will be published elsewhere.[17]

## Experimental Section

**General:** All reactions were performed with previously dried solvents under argon, if not stated otherwise. The compounds ferrocene, ferrocenemonocarbaldehyde, ferrocenylmethanol (**6a**) and ferrocene-1,1′-diyldimethanol (**7a**) were bought from Sigma/Aldrich (France). The commercially available vinylferrocene was obtained in larger quantities from ferrocenemonocarbaldehyde in a Wittig reaction with methyltriphenylphosphonium bromide. Ferrocene-1,1′-dicarbaldehyde was prepared from freshly sublimed ferrocene.[18] Thin layer chromatography (TLC) was performed on aluminium sheets precoated with 60 $F_{254}$ silica gel. Preparative flash column chromatography was performed on silica gel 60 (0.040–0.063 mm, Merck). $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker AC 250 or a Bruker DRX 400 spectrometer. Chemical shifts are reported using the deuterated ($^{13}C$ NMR) or the residual monoprotonated ($^1H$ NMR) solvent signals as reference, based on the values published by Gottlieb and Nudelman.[19] Mass spectra were recorded with a Jeol JMS-700 spectrometer and UV/Vis spectra with a Beckman DU 7400 spectrophotometer. Elemental analyses were conducted at the University of Pierre and Marie Curie (Paris, Jussieu, France) or the Centre Nationale de Recherche Scientifique (Gif-sur-Yvette, France).

**Electrochemistry:** The electrochemical experiments in dichloromethane were conducted in an air-tight, three-electrode glass cell, controlled by a commercially available computer-controlled potentiostat (AUTOLAB PGSTAT 30, Eco Chemie, the Netherlands). A platinum wire and an aqueous saturated calomel electrode (SCE) were used as a counter and a reference electrode, respectively. The reference electrode was kept in a side arm separated from the electrochemical cell by a porous frit. The side arm was filled with the solvent/supporting electrolyte solution. A glassy carbon disk electrode, having a disk radius of 0.5 mm, was used as the working electrode. The working electrode was polished prior to each experiment on successively finer grades of carborundum paper (P1200 down to P4000), and then using a 0.3 μM aqueous alumina slurry on a wetted, napped polishing cloth. The supporting electrolyte employed was a 0.1 M solution of tetrabutylammonium tetrafluoroborate ($TBAF_4$) in dichloromethane (distilled from barium oxide). $TBABF_4$ had been recrystallised and dried at 70 °C for at least 24 h before use. Prior to experimentation, argon gas was bubbled into the electrolyte solution to remove oxygen, and was flushed over the cell solution during the electrochemical measurements. Cyclic voltammograms (CV) were recorded at room temperature [(22 ± 1) °C] and at a potential sweep rate of 0.2 $V s^{-1}$. To form self-assembled monolayers, we left gold electrodes to bathe for one night in a mixture of **1** and pentanethiol or **1** and diphenyl disulfide in chloroform. Either a 111 Au single crystal or a gold ball ultramicroelectrode (made by melting a 10 μm diameter wire in a blue flame)[17] were used. Cyclic voltammograms were then recorded in $H_2O$ + 1 M $HClO_4$. For Figure 2b, a home-built potentiostat allowing scan rates up to 2.5 $MV s^{-1}$ was used.[20,21] A full analysis of the electrochemical behaviour of self-assembled monolayers will be described elsewhere.

**Synthesis**

**4-[(*E*)-2-Ferrocenylvinyl]benzylthiol (1). (a)** A solution of **8b** (45 mg, 0.12 mmol) in tetrahydrofuran (THF) (2 mL) was chilled with a water/ice bath. A 1 M solution of lithium aluminium hydride (LAH) in diethyl ether (0.24 mL, 0.24 mmol) was added slowly. The reaction mixture was stirred at room temperature for 30–60 min, and the reaction progress was monitored by thin layer chromatography (TLC). The mixture was neutralised with 1 M hydrochloric acid, and extracted with dichloromethane. The organic phase was washed with water, brine and then dried with magnesium sulfate. Purification by chromatography (silica gel, dichloromethane/petroleum ether using a solvent gradient of 20:80 to 50:50) yielded **1** as a red solid (39 mg, 97%). **(b) 8c** (45 mg, 0.10 mmol) was dissolved in a mixture of methanol (2 mL) and tetrahydrofuran (1 mL). Sodium borohydride (8 mg, 0.21 mmol) was added. The reaction mixture was stirred at room temperature for 12 h, and the reaction progress was monitored by TLC. The mixture was neutralised with 1 M hydrochloric acid, and extracted with dichloromethane. The organic phase was washed with water, brine and then dried with magnesium sulfate. Purification by chromatography (silica gel, dichloromethane/petroleum ether using a solvent gradient of 20:80 to 50:50) yielded **1** as a red solid (32 mg, 93%). **(c)** Compound **1** (10 mg, yield 47%) was prepared from **8c** (28 mg, 0.064 mmol) and lithium aluminium hydride as described. Compound **9** was found to be a sideproduct (7.4 mg, yield 36%).

**Compound 1:** $^1H$ NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.39 (d, $J$ = 8.2 Hz, 2 H, aromatic), 7.28 (d, $J$ = 8.2 Hz, 2 H, aromatic), 6.86 (d, $J$ = 16 Hz, 1 H, vinyl), 6.67 (d, $J$ = 16 Hz, 1 H, vinyl), 4.46 (t, $J$ = 1.7 Hz, 2 H, Cp), 4.28 (t, $J$ = 1.7 Hz, 2 H, Cp), 4.13 (s, 5 H, unsubstituted Cp), 3.74 (d, $J$ = 7.4 Hz, 2 H, $CH_2$), 1.76 (t, $J$ = 7.4 Hz, 1 H, SH) ppm. $^{13}C$ NMR ($CDCl_3$, 400 MHz): $\delta$ = 139.6, 136.8, 128.3, 127.0, 126.0, 125.5, 69.2, 69.1, 66.8, 28.8 ppm. MS ($CI^+$, $NH_3$): $m/z$ (%) = 335 (95) [M + 1], 303 (100). HRMS ($CI^+$, $CH_4$): calcd. for $[C_{19}H_{19}FeS]^+$ 335.0551; found 335.0546. UV ($CH_3Cl$): $\lambda$ ($\varepsilon$) = 456 (908) nm (br.).

**4-[(*E*)-2-{4-[(*E*)-2-Ferrocenylvinyl]phenyl}vinyl]benzylthiol (2):** Compound **2** (74 mg, yield 71%) was prepared from **11** (114 mg, 0.24 mmol) and lithium aluminium hydride as described for the preparation of **1** (procedure a). $^1H$ NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.45–7.19 (m, 10 H, aromatic, vinyl), 6.83 (d, $J$ = 16 Hz, 1 H, vinyl), 6.62 (d, $J$ = 16 Hz, 1 H, vinyl), 4.42 (d, $J$ = 2.7 Hz, 2 H, Cp), 4.23 (d, $J$ = 2.7 Hz, 2 H, Cp), 4.08 (s, 5 H, unsubstituted Cp), 3.68 (d, $J$ = 7.5 Hz, 2 H, $CH_2$), 1.60 (t, $J$ = 7.5 Hz, 1 H, SH) ppm. MS ($CI^+$, $CH_4$): $m/z$ (%) = 437 (50) [M + 1], 405 (100). HRMS ($CI^+$, $CH_4$): calcd. for $[C_{27}H_{25}FeS]^+$ 437.1021; found 437.1024.

**4-[(*E*)-2-{1′-[(*E*)-2-{4-[(*E*)-2-Ferrocenylvinyl]phenyl}vinyl]ferrocen-1-yl}vinyl]benzylthiol (3). (a)** Compound **3** (14 mg, yield 81%) was prepared from **16** (20 mg, 0.026 mmol) and sodium borohydride as described for the preparation of **1** (procedure b). Compound **16** is soluble in dichloromethane, whereas its solubility is very low in diethyl ether. Chromatography (silica gel; dichloromethane/petro-

leum ether gradient of 20:80 to 40:60) to yield pure compound **3**. **(b)** Compound **3** (7 mg, yield 46%) was prepared from **16** (18 mg, 0.023 mmol) and lithium aluminium hydride as described for the preparation of **1** (procedure a). Aldehyde **18** was isolated as a side-product {MS (CI; $NH_3$): *m*/*z* (%) = 648 (37) [M + 1], 631 (33), 613 (100)}.

**Compound 3:** $^1$H NMR ($CD_2Cl_2$, 400 MHz): $\delta$ = 7.25 (m, 6 H, aromatic), 7.14 (m, 2 H, aromatic), 6.88 (d, *J* = 16Hz, 1 H, vinyl), 6.76 (d, *J* = 16 Hz, 1 H, vinyl), 6.73 (d, *J* = 16 Hz, 1 H, vinyl), 6.68 (d, *J* = 16 Hz, 1 H, vinyl), 6.61 (d, *J* = 16 Hz, 1 H, vinyl), 6.59 (d, *J* = 16 Hz, 1 H, vinyl), 4.48 (t, *J* = 1.8 Hz, 2 H, Cp), 4.42 (m, 4 H, Cp), 4.28 (t, *J* = 1.8 Hz, 2 H, Cp), 4.25 (m, 4 H, Cp), 4.13 (s, 5 H, unsubst. Cp), 3.68 (m, 2 H, $CH_2$), 0.88 (t, *J* = 7.6 Hz, 1 H, SH) ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 647 (100) [M + 1], 615 (65). HRMS ($FAB^+$, $NH_3$): calcd. for $[C_{39}H_{35}FeS]^+$ 647.1153; found 647.1157. UV ($CH_3Cl$): $\lambda$ ($\varepsilon$) = 463 (4311) nm (br.).

***S*-(4-Iodobenzyl) Thioacetate (4a):** A solution of 4-iodobenzyl alcohol (200 mg, 0.85 mmol), triphenylphosphane (448 mg, 1.71 mmol) and thioacetic acid (122 μL, 1.71 mmol) in tetrahydrofuran (3.5 mL) was cooled to 0 °C, and diethyl diazodicarboxylate (298 mg, 1.71 mmol, 40% mixture in toluene) was added dropwise. The reaction mixture was stirred for 12 h. Diethyl ether was added and the organic phase was washed with aqueous sodium hydrogen carbonate solution, water and brine and then dried with magnesium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (silica gel; 40% dichloromethane in petroleum ether) to yield **4a** as a colourless oil (72 mg, 29%). $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.62 (d, *J* = 8.3 Hz, 2 H, aromatic) 7.03 (d, *J* = 8.3 Hz, 2 H, aromatic), 4.04 (s, 2 H, $CH_2$), 2.35 (s, 3 H, $CH_3$) ppm.

***S*-(4-Iodobenzyl) Thiobenzoate (4b):** A solution of 4-iodobenzyl alcohol (200 mg, 0.85 mmol), triphenylphosphane (448 mg, 1.71 mmol) and thiobenzoic acid (222 μL) in tetrahydrofuran (3.5 mL) was cooled to 0 °C, and diethyl diazodicarboxylate (298 mg, 1.71 mmol, 40% mixture in toluene) was added dropwise. The reaction mixture was stirred for 4–12 h (TLC control). Diethyl ether was added and the organic phase was washed with aqueous sodium hydrogen carbonate solution, water and brine and then dried with magnesium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (silica gel; 40% dichloromethane in petroleum ether) to yield **4b** as a colourless oil (287 mg, 95%). $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.95 (d, 2 H, *J* = 7.4 Hz, aromatic), 7.63 (d, 2 H, *J* = 8.2 Hz, aromatic), 7.58 (t, 1 H, *J* = 7.4 Hz, aromatic), 7.44 (t, 2 H, *J* = 7.4 Hz, aromatic), 7.12 (d, 2 H, *J* = 8.2 Hz, aromatic), 4.24 (s, 2 H, $CH_2$) ppm. $^{13}$C NMR ($CDCl_3$, 250 MHz): $\delta$ = 191.0, 137.7, 137.4, 136.7, 133.6, 130.9, 128.7, 127.3, 32.8 ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 372 (100) [M + $NH_4$], 355 (8) [M + 1], 246 (33) [M – I + $NH_4$]. $C_{14}H_{11}IOS$ (354.21): calcd. C 47.47, H 3.13; found C 47.40, H 3.13.

**(4-Iodophenyl)methanethiol (5):** Compound **5** (32 mg, yield 91%) was prepared from **4b** (50 mg, 0.14 mmol) and sodium borohydride as described for the preparation of **1** (procedure b). $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.64 (d, *J* = 8.2 Hz, 2 H, aromatic), 6.96 (d, *J* = 8.2 Hz, 2 H), 3.54 (s, 2 H, $CH_2$), 1.85 (s, 1 H, SH) ppm.

***S*-(Ferrocenylmethyl) Thiobenzoate (6b):** Compound **6b** (208 mg, yield 84%) was prepared from ferrocenylmethanol **6a** (159 mg, 0.74 mmol) and thiobenzoic acid as described for the preparation of **4b**. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.93 (d, *J* = 7.4 Hz, 2 H, aromatic), 7.54 (t, *J* = 7.4 Hz, 1 H, aromatic), 7.41 (t, *J* = 7.4 Hz, 2 H, aromatic), 4.33 (m, 2 H, Cp), 4.26 (m, 2 H, Cp), 4.22 (s, 5 H, Cp), 4.13 (s, 2 H, $CH_2$) ppm.

**Compound 7b:** Compound **7b** (194 mg, yield 63%) was prepared from **7a** (156 mg, 0.63 mmol) and thiobenzoic acid as described for the preparation of **4b**. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.96 (d, *J* = 7.4 Hz, 4 H, aromatic), 7.56 (m, 2 H, aromatic), 7.44 (m, 4 H, aromatic), 4.27 (s, 4 H, Cp), 4.18 (s, 4 H, Cp), 4.15 (s, 4 H, $CH_2$) ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 504 (62) [M + $NH_4$], 349 (96), 213 (100).

**{4-[(*E*)-2-Ferrocenevinyl]phenyl}methanol (8a):** Compound **8a** (436 mg, yield 85%) was prepared from **9** (510 mg, 1.61 mmol) and sodium borohydride as described for the preparation of **1** (procedure b). Chromatography (silica gel; dichloromethane) yielded a red-orange solid. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.44 (d, *J* = 8.1 Hz, 2 H, aromatic), 7.33 (d, *J* = 8.1 Hz, 2 H, aromatic), 6.89 (d, *J* = 16.1 Hz, 1 H, vinyl), 6.69 (d, *J* = 16.1 Hz, 1 H, vinyl), 4.68 (d, *J* = 5 Hz, 2 H, $CH_2$), 4.47 (s, 2 H, Cp), 4.29 (s, 2 H, Cp), 4.14 (s, 5 H, unsubstituted Cp), 1.61 (t, *J* = 5 Hz, 1 H, OH) ppm.

**S-{4-[(*E*)-2-Ferrocenylvinyl]benzyl} Thioacetate (8b):** Compound **8b** (78 mg, yield 22%), a red solid, was prepared from **8a** (300 mg, 0.94 mmol) and thioacetic acid as described for the preparation of **4a**. Chromatography: silica gel; dichloromethane/petroleum ether, 40:60 v/v. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.36 (d, *J* = 8.2 Hz, 2 H, aromatic), 7.24 (d, *J* = 8.2 Hz, 2 H, aromatic), 6.85 (d, *J* = 16.1 Hz, 1 H, vinyl), 6.66 (d, *J* = 16.1 Hz, 1 H, vinyl), 4.45 (t, *J* = 1.6 Hz, 2 H, Cp), 4.29 (t, *J* = 1.6 Hz, 2 H, Cp), 4.13 (s, 5 H, unsubstituted Cp), 4.11 (s, 2 H, $CH_2$), 2.35 (s, 3 H, $CH_3$) ppm. The $^1$H NMR data described in the literature[8] confirms the above data.

***S*-{4-[(*E*)-2-Ferrocenylvinyl]benzyl} Thiobenzoate (8c):** A solution of vinylferrocene (106 mg, 0.50 mmol), **4b** (176 mg, 0.50 mmol), palladium acetate (11 mg, 0.014 mmol) and tributylamine (180 μL, 0.75 mmol) in *N*,*N*-dimethylacetamide (10 mL) was stirred at room temperature for 1 h. Tri(*ortho*-tolyl)phosphane (3 mg, 0.01 mmol) was added. After 3 h of stirring at room temperature, the reaction mixture was heated at 100 °C for 12 h. After extraction with diethyl ether, the organic phase was washed with 1 M hydrochloric acid, water, brine and then dried with magnesium sulfate. After evaporation of the solvent, the residue was purified by column chromatography (silica gel; 50% dichloromethane in petroleum ether) to yield **8c** (138 mg, 63%). $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.97 (d, *J* = 7.2 Hz, 2 H, aromatic), 7.31–7.57 (m, 7 H, aromatic), 6.85 (d, *J* = 16 Hz, 1 H, vinyl), 6.66 (d, *J* = 16 Hz, 1 H, vinyl), 4.46 (m, 2 H, Cp), 4.31 (s, 2 H, $CH_2$), 4.28 (m, 2 H, Cp), 4.12 (s, 5 H, unsubstituted Cp) ppm. $^{13}$C NMR ($CDCl_3$, 250 MHz): $\delta$ = 185.0, 133.4, 129.3, 128.6, 127.3, 127.1, 126.0, 125.5, 69.2, 69.1, 66.9, 33.3 ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 456 (12) [M + $NH_4$], 439 [17] [M + 1], 303 (100).

**{4-[(*E*)-2-Ferrocenevinyl]phenyl}carbaldehyde (9):** Compound **9** (406 mg, yield 56%) was prepared from vinylferrocene (486 mg, 2.30 mmol) and 4-iodobenzaldehyde (532 mg, 2.29 mmol) as described for the preparation of **8c**. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 9.98 (s, 1 H, CHO), 7.84 (d, *J* = 8.2 Hz, 2 H, aromatic), 7.56 (d, *J* = 8.2 Hz, 2 H, aromatic), 7.08 (d, *J* = 16.1 Hz, 1 H, vinyl), 6.72 (d, *J* = 16.1 Hz, 1 H, vinyl), 4.52 (s, 2 H, Cp), 4.36 (s, 2 H, Cp), 4.16 (s, 5 H, unsubstituted Cp) ppm. $^{13}$C NMR ($CDCl_3$, 250 MHz): $\delta$ = 191.6, 131.5, 130.3, 126.0, 124.6, 69.8, 69.5, 69.4, 67.4 ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 317 (100) [M + 1].

**4-[(*E*)-2-Ferrocenylvinyl]styrene (10):** Compound **10** (301 mg, yield 86%) was prepared from aldehyde **9** (352 mg, 1.11 mmol) as described for the preparation of **12**. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.40 (s, 4 H, aromatic), 6.88 (d, *J* = 16.2 Hz, 1 H, vinyl), 6.70 (dd, *J* = 16.2, 10.7 Hz, 1 H, vinyl), 6.67 (d, *J* = 16.2 Hz, 1 H, vinyl), 5.75 (d, *J* = 17.5 Hz, 1 H, vinyl), 5.22 (d, *J* = 10.7 Hz, 1 H, vinyl),

4.46 (t, *J* = 1.6 Hz, 2 H, Cp), 4.3 (m, 2 H, Cp), 4.15 (s, 5 H, Cp) ppm.

***S*-{4-[(*E*)-2-{1′-[(*E*)-2-{4-[(*E*)-2-Ferrocenylvinyl]phenyl}vinyl]-ferrocen-1-yl}vinyl]benzyl} Thioacetate (11):** Compound **11** (152 mg, yield 83%) was prepared from **10** (120 mg, 0.38 mmol) and **4a** (233 mg, 0.80 mmol) as described for the preparation of **8c**. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.45 (m, 8 H, aromatic), 7.20 (2d, *J* = 17 Hz, 2 H, vinyl), 6.85 (2d, *J* = 16.1 Hz, 2 H, vinyl), 4.65 (s, 2 H, $CH_2$) 4.45 (d, *J* = 2.67 Hz, 2 H, Cp), 4.30 (d, *J* = 1.6 Hz, 2 H, Cp), 4.15 (s, 5 H, unsubstituted Cp), 3.95 (s, 3 H, $CH_3$) ppm. The $^1$H NMR data described in the literature[8] confirms the above data. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 479 (20) [M + 1], 295 (100). MS ($FAB^+$): *m*/*z* (%) = 478 (10) [M], 295 (100).

**1′-Vinylferrocene-1-carbaldehyde (12):** A solution of ferrocene-1,1′-dicarbaldehyde (0.849 g, 3.51 mmol) and methyltriphenylphosphonium bromide (1.25 g, 3.51 mmol) in dioxane (20 mL) was treated with potassium *tert*-butoxide (0.39 g, 3.5 mmol) and water (100 μL). After stirring at room temperature for 3 h, the reaction mixture was extracted with diethyl ether. The organic phase was washed with water and dried with magnesium sulfate. Purification by chromatography (silica gel; dichloromethane) yielded **12** as a brown oil (0.37 g, 44%). $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 9.88 (s, 1 H, CHO), 6.37 (dd, *J* = 17.5, 10.7 Hz, 1 H, vinyl), 5.40 (d, *J* = 17.5 Hz, 1 H, vinyl), 5.14 (d, *J* = 10.7 Hz, 1 H), 4.72 (s, 2 H, Cp), 4.54 (s, 2 H, Cp), 4.51 (s, 2 H, Cp), 4.31 (s, 2 H, Cp) ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 241 (100) [M + 1], 215 (12), 124 (7).

**1′-[(*E*)-2-(4-Iodophenyl)vinyl]ferrocene-1-carbaldehyde (13):** Compound **13** (276 mg, 57%) was prepared from **12** (271 mg, 1.1 mmol) and 1,4-diiodobenzene (0.74 g, 2.3 mmol), as described for the preparation of **8c**. However, the reaction mixture was not heated but stirred at room temperature for 3 d (chromatography: silica gel; dichloromethane). $^1$H NMR ($CDCl_3$, 400 MHz): $\delta$ = 9.90 (s, 1 H, CHO), 7.65 (d, *J* = 8.4 Hz, 2 H, aromatic), 7.17 (d, *J* = 8.4 Hz, 2 H, aromatic), 6.76 (d, *J* = 16.2 Hz, 1 H, vinyl), 6.63 (d, *J* = 16.2 Hz, 1 H, vinyl), 4.76 (t, *J* = 1.9 Hz, 2 H, Cp), 4.55 (multiplet, *J* = 1.9 Hz, 4 H, Cp), 4.38 (t, *J* = 1.9 Hz, 2 H, Cp) ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 443 (100) [M + 1], 317 (33). Only a small amount of the symmetrical bis(ferrocene) dicarbaldehyde **17** was isolated (12 mg, 2%). $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 9.90 (s, 2 H, CHO), 7.42 (s, 4 H, aromatic), 6.67 (s, 2 H, vinyl), 6.66 (s, 2 H, vinyl), 4.77 (t, *J* = 1.8 Hz, 4 H, Cp), 4.57 (m, 8 H, Cp), 4.39 (t, *J* = 1.8 Hz, 4 H, Cp) ppm. $^{13}$C NMR ($CDCl_3$, 250 MHz): $\delta$ = 193.8, 136.4, 127.8, 126.4, 124.8, 85.5, 79.9, 74.4, 70.7, 70.5, 68.2 ppm. MS ($CI^+$, $CH_4$): *m*/*z* (%) = 455 (15) [M + 1], 241 (100).

**1′-[(*E*)-2-{4-[(*E*)-2-Ferrocenylvinyl]phenyl}vinyl]ferrocene-1-carbaldehyde (14):** Compound **14** (180 mg, 55%) was prepared from **13** (276 mg, 0.63 mmol) and vinylferrocene (265 mg, 1.25 mmol) as described for the preparation of **8c** (chromatography: silica gel; dichloromethane/petroleum ether, 40:60 v/v). $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 9.91 (s, 1 H, CHO), 7.40 (s, 4 H, aromatic), 6.90 (d, *J* = 16 Hz, 1 H, vinyl), 6.72 (s, 2 H, vinyl), 6.66 (d, *J* = 16 Hz, 1 H, vinyl), 4.76 (t, *J* = 1.8 Hz, 2 H, Cp), 4.57 (t, *J* = 1.6 Hz, 4 H, Cp), 4.47 (t, *J* = 1.5 Hz, 2 H, Cp), 4.38 (t, *J* = 1.7 Hz, 2 H, Cp), 4.29 (t, *J* = 1.5 Hz, 2 H, Cp), 4.14 (s, 5 H, unsubstituted Cp) ppm. MS ($CI^+$, $CH_4$): *m*/*z* (%) = 527 (100) [M + 1], 391 (12), 345 (12), 317 (30), 279 (27). $C_{31}H_{26}Fe_2O$ (526.32): calcd. C 70.75, H 4.98; found C 69.78, H 4.87.

**1′-[(*E*)-2-{4-[(*E*)-2-Ferrocenylvinyl]phenyl}vinyl]-1-vinylferrocene (15):** A solution of **14** (127 mg, 0.20 mmol) and methyltriphenylphosphonium bromide (90 mg, 0.25 mmol) in dioxane (3 mL) was treated with potassium *tert*-butoxide (28 mg, 0.25 mmol) and the mixture stirred at room temperature for 12 h (TLC control). The reaction mixture was extracted with dichloromethane. The organic phase was washed with water and dried with magnesium sulfate. After evaporation of the solvent, the brown solid residue was purified by column chromatography (silica gel; dichloromethane/petroleum ether, 35:65 v/v) to yield **15** (56 mg, 44%). Repetition of the experiment with the recovered starting material afforded another 37 mg of **15**, increasing the total yield to 64%. $^1$H NMR ($CDCl_3$, 250 MHz): $\delta$ = 7.4 (s, 4 H, aromatic), 6.9 (d, *J* = 16 Hz, 1 H, vinyl), 6.81 (d, *J* = 16 Hz, 1 H, vinyl), 6.68 (d, *J* = 16 Hz, 1 H, vinyl), 6.64 (d, *J* = 16 Hz, 1 H, vinyl), 6.38 (dd, *J* = 17.5, 10.7 Hz, 1 H, C*H*=$CH_2$), 5.24 (d, *J* = 17.5 Hz, 1 H, CH=C$H_2$), 5.0 (d, *J* = 10.7 Hz, 1 H, CH=C$H_2$), 4.47 (t, *J* = 1.3 Hz, 2 H, Cp), 4.39 (t, *J* = 1.6 Hz, 2 H, Cp), 4.30 (t, *J* = 2.3 Hz, 4 H, Cp), 4.23 (t, *J* = 1.7 Hz, 2 H, Cp), 4.19 (t, *J* = 1.6 Hz, 2 H, Cp), 4.14 (s, 5 H, Cp) ppm. MS ($CI^+$, $NH_3$): *m*/*z* (%) = 525 (100) [M + 1], 391 (5), 315 (7).

***S*-{4-[(*E*)-2-{1′-[(*E*)-2-{4-[(*E*)-2-Ferrocenylvinyl]phenyl}vinyl]-ferrocen-1-yl}vinyl]benzyl} Thiobenzoate (16):** Compound **16** (24 mg, 91%) was prepared from **15** (22 mg, 0.035 mmol) and **4b** (30 mg, 0.084 mmol) as described for the preparation of **8c** (chromatography: silica gel; 50% dichloromethane in petroleum ether). $^1$H NMR ($CD_2Cl_2$, 400 MHz): $\delta$ = 7.99 (dd, *J* = 7.1, 1.4 Hz, 2 H, aromatic), 7.58 (tt, *J* = 7.4, 1.4 Hz, 1 H, aromatic), 7.45 (m, 2 H, aromatic), 7.29 (aromatic, *J* = 8.3 Hz, 2 H, d), 7.23 (s, 4 H, aromatic), 7.21 (aromatic, *J* = 8.3 Hz, 2 H, d), 6.9 (d, *J* = 16 Hz, 1 H, vinyl), 6.75 (d, *J* = 16 Hz, 2 H, vinyl), 6.68 (d, *J* = 16 Hz, 1 H, vinyl), 6.60 (d, *J* = 16 Hz, 2 H, vinyl), 4.47 (t, *J* = 1.8 Hz, 2 H, Cp), 4.41 (t, *J* = 1.8 Hz, 4 H Cp), 4.29 (s, 2 H, $CH_2$), 4.27 (t, *J* = 1.8 Hz, 2 H, Cp), 4.25 (t, *J* = 1.8 Hz, 4 H, Cp), 4.12 (s, 5 H, Cp) ppm. MS (CI+, $CH_4$): *m*/*z* (%) = 751 (62) [M + 1], 242 (100), 186 (40). HRMS ($CI^+$, $NH_3$): calcd. for $[C_{46}H_{39}Fe_2OS]^+$ 751.1415; found 751.1412.

# Mu-35: A Fluorogallophosphate Obtained by In Situ Generation of the Template

**Louwanda Lakiss,[a] Angélique Simon-Masseron,*[a] Florence Porcher,[b] Séverinne Rigolet,[a] and Joël Patarin[a]**

**Keywords:** Fluorine / Gallophosphate / Structure elucidation / Hydrothermal synthesis

A two-dimensional microporous fluorogallophosphate, named Mu-35, closely related to ULM-8, was hydrothermally synthesized by in situ generation of the structure-directing agent. The precursor of the structure-directing agent is ethylformamide, which is generated in situ by decomposition, and goes on to form ethylamine molecules that act as templates in the medium used for the synthesis. The fluorogallophosphate Mu-35 (Mu is Mulhouse), $Ga_3(PO_4)_2(HPO_4)F_3(C_2H_8N)_2$-$(C_2H_7N)_{0.5}$ ($Z$ = 8), crystallizes in the orthorhombic space group *Pbcn* with the following unit cell parameters: $a$ = 22.117(1), $b$ = 17.3740(8), $c$ = 10.1550(4) Å. The structure of fluorogallophosphate Mu-35 was determined from single-crystal XRD data. It exhibits anionic layers composed of an unusual arrangement of three-, five-, and eight-membered rings (MR) [$Ga_2PO_2F$, $Ga_3P_2O_4F$, and $Ga_3P_3O_8$, respectively], and intercalated by protonated and nonprotonated ethylamine molecules. Mu-35 was also characterized by powder XRD, SEM, elemental and thermal analyses, and solid-state NMR spectroscopy ($^1$H, $^{13}$C, $^{19}$F, and $^{31}$P MAS and $^1$H-$^{31}$P HETCOR experiments).

## Introduction

In the last years, the search for new microporous materials has attracted special interest due to their potential uses as molecular sieves, heterogeneous catalysts, or ion exchangers.[1] After the discovery of the aluminophosphates by Wilson et al.,[2] research in the field of microporous phosphates was extended to different metals. The substitution of aluminium by other metals (Zn, Ga, etc.) has been reported. Among these materials, gallophosphates have attracted special attention; they allow a wide variety of structures to be formed owing to the gallium atoms, which can adopt four-, five-, and six-coordinations. Moreover the use of fluorine in the starting mixture enabled us to investigate new systems.[3] By introducing fluorine in the medium used for the synthesis, numerous fluorogallophosphates were obtained[4–5] such as cloverite, which is molecular sieves that contain a large 3D pore channel system.[6] In most cases, $F^-$ was found to be present in the inorganic framework as terminal Ga–F groups, bridging gallium atoms, or trapped into small building units such as the so-called double four rings (D4R units). In this case, it seems that fluorine, besides its mineralizing role, plays a templating role and stabilizes these units.[5–8] A large number of metallophosphates with 0D, 1D, 2D, or 3D frameworks have been reported.[3–15] One way to obtain new materials is to exploit the in situ generation of the structure-directing agent. By this synthetic route, solvent or precursors of the templates are introduced into the starting mixtures, and during the synthesis, they partly decompose into molecules that act as templates. Few applications of such a synthetic technique have been reported; for instance, the in situ generation of structure-directing agents from 1,5-diaminopentane,[16] guanidinium cations,[17–19] piperazine,[20] dichloride of benzylviologen,[21] or urea derivatives.[22,23] In 1998, a new type of template precursor (i.e. alkylformamide molecules) was tested in the laboratory. Thus, it was possible to produce the two-layered aluminophosphates Mu-4[9] and Mu-7[10] and, more recently, the gallophosphates MIL30,[11] Mu-30,[12] Ea-TREN-GaPO,[13] Mu-33,[14] and Mu-34.[15]

In this paper, we report the synthesis, the structure determination, and the characterization of a new porous 2D fluorogallophosphate named Mu-35 that was obtained by using ethylformamide (EFD) as a precursor of ethylamine, which acts as the structure-directing agent (SDA).

## Results and Discussion

### Synthesis and Crystal Morphology

The results concerning the synthesis of fluorogallophosphate Mu-35 are summarized in Table 1. The fluoro-

[a] $H_2O$ arising from orthophosphoric (85% $H_3PO_4$) and hydrofluoric acid (40% HF). [b] Unknown phase. [c] Structure in progress. [d] Impurity eliminated by ultrasound.

gallophosphate Mu-35 was first prepared as white powder in a fluorine quasinonaqueous medium with a Ga/P molar ratio equal to 0.5 (sample A). The presence of fluorine is crucial as the $GaPO_4$-$C_4$[24] crystallizes when fluorine is not present in the mixture (sample B). A change in the heating temperature (samples A, C, and D) influences the nature of the crystallized phase. For a similar starting molar composition, but with a higher heating temperature (200 °C, sample C), a nonidentified phase (phase A) with traces of an impurity crystallizes. Moreover, for a lower heating temperature (130 °C, sample D), another phase, namely phase B, was obtained. Experiments were also performed in aqueous medium. In a diluted medium (sample E, 80 $H_2O$) a quartz-type gallophosphate was obtained, whereas in a more concentrated medium (sample F, 16.3 $H_2O$) large crystals of Mu-35 suitable for single crystal XRD determination were formed.

As shown in Figure 1, the crystals of the fluorogallophosphate Mu-35-sample A and Mu-35-sample F display rectangular shapes, with average sizes of $150 \times 20$ and $150 \times 30$ μm$^2$, respectively.

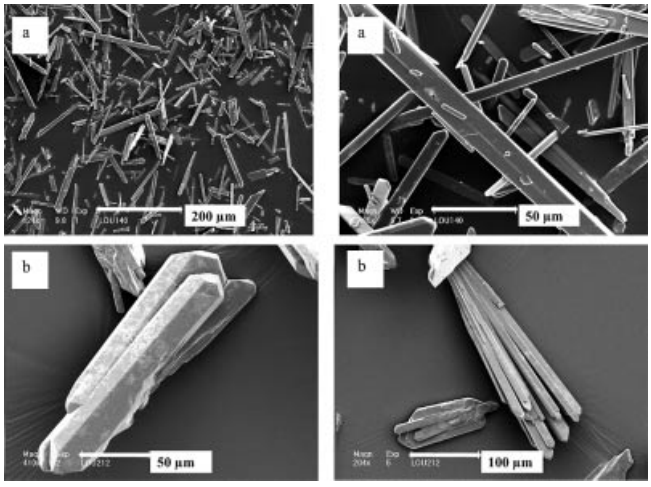

Figure 1. Scanning electron micrographs of (a) the fluorogallophosphate Mu-35-sample A, (b) the fluorogallophosphate Mu-35-sample F.

## XRD Analysis

The experimental powder diffraction pattern of the fluorogallophosphate Mu-35 is reported in Figure 2a. It was indexed in orthorhombic symmetry with the following unit cell parameters: $a$ = 22.410(3), $b$ = 17.478(3), $c$ = 10.2060(18) Å. For comparison, the simulated XRD pattern of Mu-35 is reported in Figure 2b.

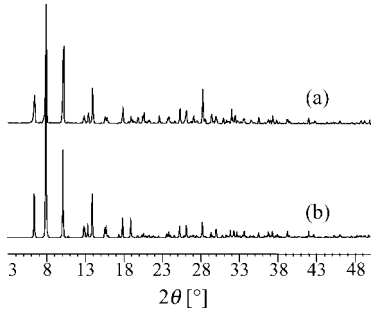

Figure 2. XRD patterns of the fluorogallophosphate Mu-35: (a) experimental pattern, (b) simulated pattern (radiation Cu-$K_{\alpha 1}$).

## Chemical and Thermal Analyses

According to elemental analyses, the as-synthesized Mu-35 sample has the following composition: Ga 30, P 15, F 8, N 5, C 9 wt.-%. Such results are in agreement with the composition obtained from the structure determined: Ga 31, P 14, F 8, N 5, C 9 wt.-%. The experimental C/N molar ratio equal to 2 is different from the value expected for ethylformamide (3C:1N), which proves that the solvent partly decomposes into ethylamine (EA) (3C:1N) during the synthesis. This was later confirmed by $^{13}C$ NMR spectroscopy (see below). As previously shown for other phosphate-based materials synthesized in the presence of alkylformamide,[9–15] the in situ release of the corresponding protonated amine during the synthesis appears to be a key step in the crystallization of this lamellar fluorogallophosphate. Indeed, experiments using ethylamine directly introduced in the starting mixture led to the crystallization of a quartz-type gallophosphate.

The thermal behavior of the fluorogallophosphate Mu-35 was investigated by TG/DTA thermal analyses. The TG and DTA curves of the as-synthesized material are reported in Figure 3. The total weight loss occurs mainly in two steps. A small weight loss close to 3 wt.-% appears before 250 °C. It might correspond to the removal of water molecules physisorbed and arise from the dehydroxylation reaction. The main weight loss (18.3 wt.-%) occurs between 250

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and 500 °C. It is associated with endothermic components on the DTA curve, and can be attributed to desorption and decomposition of the ethylamine molecules and to the removal of the fluorine atoms (probably under the form of HF). After heating at 800 °C, the XRD analysis of the residue shows that the starting material was transformed by an amorphization–recrystallization process into a cristobalite-type gallophosphate.

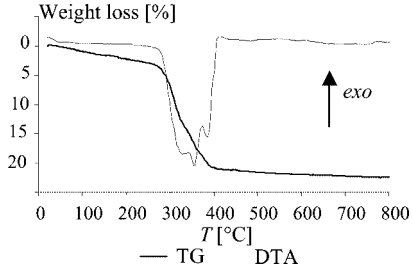

Figure 3. Thermal analyses (TG and DTA) under air of the fluorogallophosphate Mu-35.

## Structure Description

The structure of the fluorogallophosphate Mu-35 displays macroanionic layers composed of an arrangement of 3, 5, and 8 MR [$Ga_2PO_2F$, $Ga_3P_2O_4F$, and $Ga_4P_4O_8$, respectively]. These layers can be observed as the results of the condensation of fluorogallophosphate zig–zag chains (AAA) connected together along the *b* axis by the O5 oxygen atom (Figure 4). These zig–zag chains are built up from $GaO_4F$, $GaO_3F_2$, and $GaO_4F_2$ polyhedra linked by $PO_4$ tetrahedra. The asymmetric unit, reported in Figure 5, contains three crystallographically distinct Ga sites, two in fivefold coordination (Ga2 and Ga3) and one in sixfold coordination (Ga1). The structure also contains three crystallographically distinct P sites: the P1 and P2 sites share all their oxygen atoms with gallium neighbors, whereas P3 displays a hydroxy group O12, which points towards the layers. It should be noted that this oxygen atom, in addition to others (O1, O2, and O8), interact strongly with ethylamine molecules that are located between the layers through hydrogen bonds (‹N1–H1b···O1› = 1.92, N2–H2b···O2 = 2.02, ‹N2–H2c···O8› = 1.91, ‹N1–H1c···O12› = 1.85 Å). The structure could also be described as an arrangement of hexameric units ($Ga_3P_3$). These hexameric units are common in fluorinated gallium phosphates, as it has been observed in many 2D and 3D structures (ULM-8,[25] MIL-30,[11] MIL-50[26]). These units are joined together by two opposite orientations, which then generates the pseudo-membered rings described below. It is noteworthy that the structure of the Mu-35 is closely related to that of the fluorogallophosphate ULM-8.[25] Indeed, in comparison to the ULM-8 compound, the hexameric unit here possesses three fluorine ions instead of the usual two, and one hydroxy group P–OH. Furthermore, in our compound the sheets are shifted by a factor of *b*/2. Such a displacement could be a key factor for the transformation of the 2D Mu-35 compound into the 3D TREN-GaPO phase. To confirm this hypothesis, experimental study of the 2D Mu-35/3-D TREN-GaPO transformation, by hydrothermal treatment, is in progress.

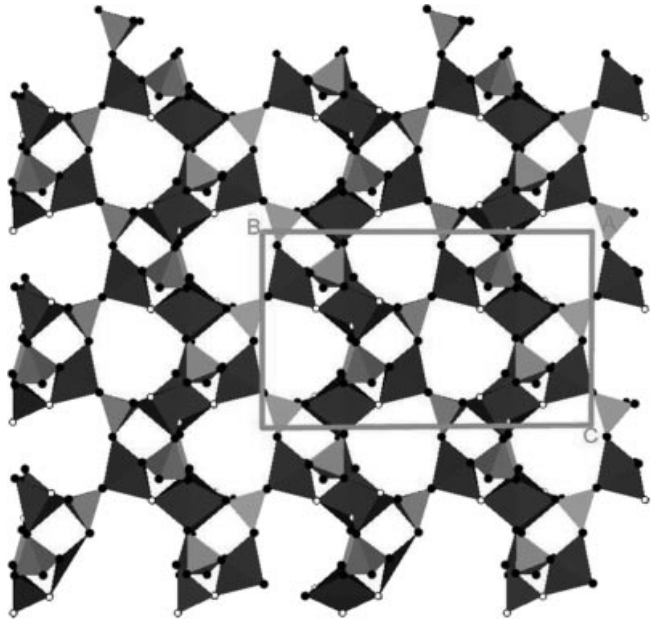

Figure 4. Projection of the structure of the fluorogallophosphate Mu-35 along the *a* axis, which shows the inorganic chains connected by O5 with 8-MR openings. Black spheres: O, open circles: F, dark grey polyhedra: Ga, light grey polyhedra: P.

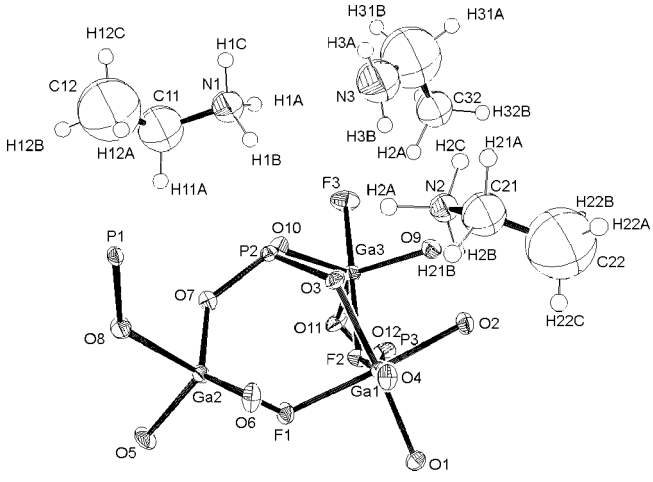

Figure 5. The asymmetric building unit of the fluorogallophosphate Mu-35.

The fluorine atoms are located on three nonequivalent crystallographic sites: two correspond to bridging species F1 and F2, which interact with the ethylamine molecules through hydrogen bonds [‹N2–H2a···F2› = 2.06(4), ‹N2–H2a···F1› = 2.22(4) Å; Table 2]. The third one (F3), which is connected to Ga3, is observed in the terminal position. The average ‹Ga–F› bond length is in good agreement with those reported for fluorogallophosphates.[15]

To compensate for the negative charges of the framework, two of the three ethylamine molecules that are intercalated between the layers (N1 and N2, 8 × 2 molecules), are protonated. These molecules, which occupy a general position, are located inside the pseudo 12-membered ring (Figure 6). The remaining ethylamine molecule, which occupies the special N3 position, has an occupancy factor of 0.5, and it is nonprotonated and localized in the pseudo 8 MR.

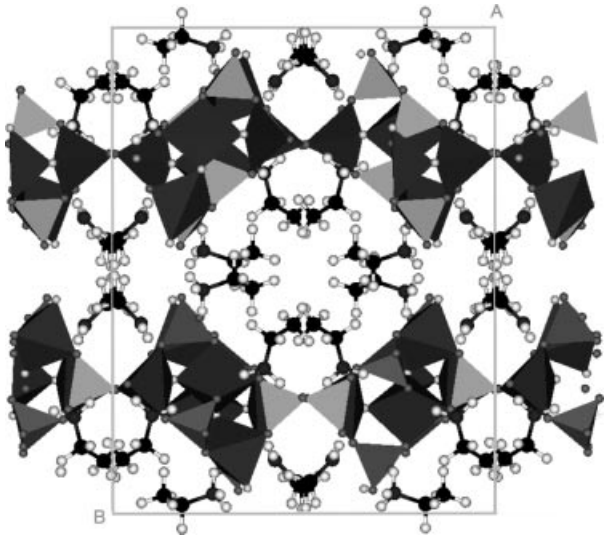

Figure 6. Projection of the structure of the fluorogallophosphate Mu-35 along the *c* axis, which shows the localization of the amine (black spheres). For a colored version of this figure see the Supporting Information.

### $^{13}$C CP MAS NMR Spectroscopy

Figure 7 shows the proton decoupled $^{13}$C MAS NMR spectrum of the fluorogallophosphate Mu-35. It displays two main signals located at ca. 13.1 and 35.2 ppm, which can be assigned to the $CH_3$ and $CH_2$ groups of the ethylamine molecules, respectively.[27] No carbonyl group is observed in this spectrum (resonance expected at about 160 ppm), which means that EFD is partly decomposed into ethylamine (EA) under our experimental conditions. The signal at $\delta$ = 13.1 ppm, which has a shoulder at $\delta$ = 14.1 ppm, can be attributed to the methyl groups of the ethylamine molecules. According to the $^{13}$C isotropic chemical shifts ($\delta$) known from liquid-state $^{13}$C NMR [$\delta(CH_3)$ protonated molecules: 12.5 ppm and $\delta(CH_3)$ nonprotonated molecules: 19 ppm], these two signals could be assigned to the $CH_3$ groups of protonated and nonprotonated EA, respectively. Such a result confirms with agreement with the structure determination: the hypothesis of amine protonation. Indeed the relative areas of the two signals are close to 4 ($\delta$ = 13.1 ppm):1 ($\delta$ = 14.1 ppm).

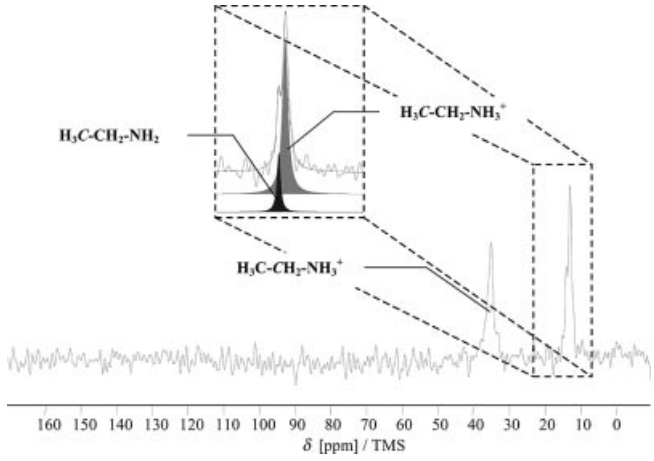

Figure 7. $^{1}$H decoupled $^{13}$C MAS spectrum of the fluorogallophosphate Mu-35 and its decomposition.

### $^{19}$F MAS NMR Spectroscopy

As shown in the Figure 8, the $^{19}$F MAS NMR spectrum of the as-synthesized product exhibits two signals located at –106.2 and –140.2 ppm. After decomposition, the relative areas are close to 2:1, respectively, indicating, in agreement with the structure determination, the existence of three crystallographically distinct fluorine sites. As observed for other fluorogallophosphates,[28–30] these signals could be assigned to the bridging fluorine species F1 and F2 and to the terminal fluorine species F3, respectively.

### $^{1}H$, $^{31}P$ and $^{1}H$-$^{31}P$ HETCOR NMR Spectroscopy

The $^{31}P$ MAS NMR spectrum of the fluorogallophosphate Mu-35, reported in Figure 9, displays three main signals at –3.4, –7, and –13.8 ppm. The relative areas are close to 1:1:1, which confirms, in agreement with the structure determination, the existence of three distinct crystallographic phosphorus sites. The decomposition shows that the signal at –7 ppm could be decomposed into two components (–6.2 and –7.2 ppm). It was noted that the intensity areas ratio between these two components varies with the amount of physisorbed water. This means that at the local order, the symmetry is probably lower, and the P3 phosphorus site splits into two different crystallographic sites.

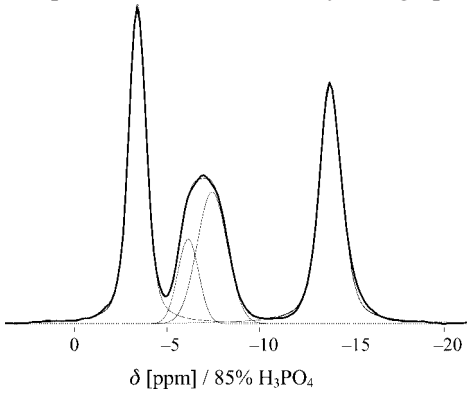

Figure 9. $^{31}P$ MAS NMR spectrum of the fluorogallophosphate Mu-35 and its decomposition.

The $^{1}H$ MAS NMR spectrum reported in Figure 10, displays at least four resonances at ca. 1.4, 3.4, 7.4, and 15.1 ppm. The resonances at $\delta$ = 1.4 and 3.4 ppm could be attributed to the $CH_3$ and $CH_2$ groups of the ethylamine molecules. According to the $^{1}H$ liquid-state NMR spectroscopic data, the signal located at 7.4 ppm could be assigned to the $NH_3^+$ and $NH_2$ groups. It is noteworthy that protons of $NH_2$ groups might be shielded because of the existence of hydrogen bonds with the oxygen atoms of physisorbed water molecules, which is expected to be observed at 4.7 ppm. The remaining signal at ca. 15.1 ppm could be assigned to the proton of the hydroxy group bound to the phosphorus atom (P–OH) that is in strong interaction with a water molecule through a hydrogen bond.

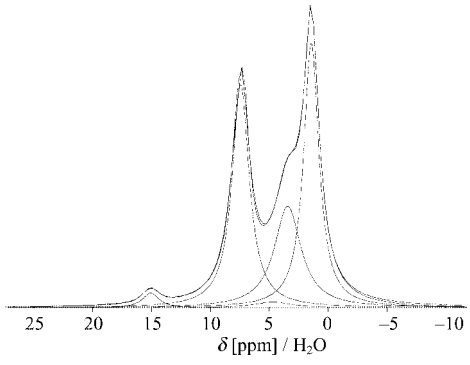

Figure 10. $^{1}H$ MAS NMR spectrum of the fluorogallophosphate Mu-35 and its decomposition.

A $^{1}H$-$^{31}P$ CP MAS NMR experiment was performed (spectrum not reported) to reveal the presence of the hydroxy group. For a contact time of 0.1 ms, an increase in the signal located at –7.0 ppm (Figure 9) was observed between the MAS and CP MAS spectra, which means, in agreement with the structure determination, that the corresponding phosphorus site is close to the proton and could be considered as a P–OH group. In Mu-35, this site could be assigned to P3.

To assign the different phosphorus signals, a 2D $^{1}H$-$^{31}P$ HETCOR experiment was performed. The 2D spectrum, shown in Figure 11, displays three signals for the P atoms located at –3.4, –7.0, and –13.8 ppm, which are characteristic of P*i*-H*j* interaction. It should be noted that only the phosphorus site associated to $\delta$ = –7.0 ppm has a strong interaction with the proton signal at ca. 15.1 ppm. Such a result confirms the assignment of the signal at –7.0 ppm to the phosphorus crystallographic P3 site. Unfortunately, it was not possible to clearly discriminate between P2 and P1.

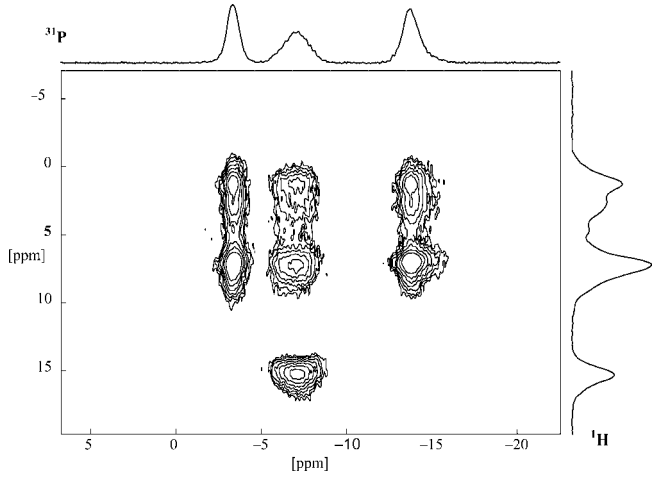

Figure 11. $^{1}H$-$^{31}P$ 2D HETCOR spectrum of the fluorogallophosphate Mu-35.

## Conclusion

In this paper the synthesis and the characterization of a fluorogallophosphate Mu-35, with a rather unusual structure, was reported. It was prepared in an aqueous medium by using ethylformamide as the precursor of the structure-directing agent. As in several similar syntheses, ethylformamide decomposes during the synthesis, and the corresponding amine is found occluded in the final structure. The in situ release of the amine during the synthesis appears to be a key step in the crystallization of this lamellar fluorogallophosphate. Indeed, experiments using ethylamine directly in the starting mixture did not lead to the crystallization of this material.

The fluorogallophosphate Mu-35 displays anionic layers closely related to ULM-8, built from three-, five- and eight-membered rings. To compensate for the negative charges of the anionic layers, the ethylamine molecules that are located inside the pseudo 12 MR are protonated, which is in contrast to the ones observed inside the pseudo 8 MR.

## Experimental Section

**General:** The fluorogallophosphate Mu-35 was prepared in an aqueous fluoride medium at 170 °C from a mixture containing ethylformamide as a precursor of the SDA (ethylamine). The molar composition of the starting mixture was 2 GaOOH/2 $H_3PO_4$/2 HF/2 ethylformamide (EFD)/16 $H_2O$. The water amount arises from the phosphorus and the fluoride sources. The pH value of the reaction mixture was adjusted to 2.5 with tripropylamine (TPA, Fluka 98 wt.-%), the latter presenting no structure-directing effect in the fluorine-containing gallophosphate system.[31] The amorphous gallium oxyhydroxide GaOOH was prepared by heating a gallium nitrate aqueous solution at 250 °C for 24 h. The other reactants were orthophosphoric acid (Labosi 85 wt.-%), hydrofluoric acid (Prolabo 40 wt.-%), and ethylformamide (EFD, Fluka 99 wt.-%).

**Synthesis:** The starting mixture was prepared by adding the amorphous gallium source (0.45 g) to water (0.36 g) under magnetic stirring. Then, ethylformamide (0.29 g), orthophosphoric acid (0.46 g), and hydrofluoric acid (0.2 g) were introduced. To increase the pH value of the solution to 2.5, tripropylamine (0.29 g) was added, and the mixture was stirred until homogeneous. Then, it was transferred to a 20-mL PTFE-lined stainless-steel autoclave and heated at 170 °C for 4 d. The product was filtered, washed with distilled water, and dried at 60 °C overnight.

**Characterization:** The as-synthesized product was characterized by powder X-ray diffraction (XRD) with a STOE STADI-P diffractometer equipped with a curved germanium (111) primary monochromator and a linear position-sensitive detector using Cu-$K_\alpha 1$ radiation ($\lambda$ = 1.5406 Å). The morphology and average size of the crystals were determined by scanning electron microscopy (SEM) with a Philips XL30 microscope. Elemental analyses were performed with an induced coupled plasma technique by using atomic energy spectroscopy (ICP AES) for Ga and P, and by coulometric and catharometric methods for C and N quantifications, respectively. Thermogravimetric (TGA) and differential thermal (DTA) analyses were performed under air with a Setaram Labsys thermoanalyser with a heating rate of 5 °C min$^{-1}$ up to 1000 °C. Solid-state NMR experiments were performed at r.t. with a Bruker DSX 400 spectrometer operating at $B_0$ = 9.4 T and a Bruker double channel high-speed 2.5 mm probe. The recording conditions are reported in Table 3. As the typical $T_1$ values measured for our sample by using inversion recovery was slightly less than 0.6 and 2.8 s for the $^1$H and $^{19}$F, respectively, the corresponding recycle delays were fixed to 3 and 15 s, respectively. Furthermore the $^{31}$P spin lattice relaxation times ($T_1$) was measured with the saturation-recovery pulse sequence and it was found to be less than 68 s. Decompositions of the spectra were performed with WINFIT programs.[32]

**Crystal Structure Determination:** A crystal plate was cut out of a larger aggregate and selected after optical examination under crossed polars. The single-crystal X-ray diffraction experiment was performed at r.t. with an Oxford diffraction Xcalibur diffractometer equipped with a CCD detector. A full redundant Ewald sphere was collected with Mo($K_\alpha$) radiation up to a maximum resolution $sin\theta/\lambda max = 0.88$ Å$^{-1}$. Bragg intensities were integrated with Crysalis software,[33] and averaged in Laue point group mmm with SORTAV program[34] after an absorption correction ($\mu = 4.45$ mm$^{-1}$) based on the crystal shape. Data collection details are summarized in Table 4. The crystal structure was solved by direct methods using SHELXS[35] and refined with JANA2000.[36] The positions of all non-hydrogen atoms were found straightforwardly on successive Fourier maps. Hydrogen atoms were introduced in the structural model by assuming ideal conformations for all ethylamine molecules. Atomic displacement parameters of H atoms were restrained to 1.5 times the value of that of the heavy atom they were attached to. All bond lengths and bond angles of ethylamine molecules were also restrained to the expected values observed in $CH_3$ (methyl), $CH_2$ (methylene), and $NH_3$ (amine) groups.[37] The refinement converged to $R = 0.054$ and $R_W = 0.058$ for the 4642 observed reflections [$I > 3\sigma(I)$]. Selected bond lengths are given in Table 5. CCDC-645100 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Nb-Doped $VO_2$ Thin Films Prepared by Aerosol-Assisted Chemical Vapour Deposition

Clara Piccirillo,[a] Russell Binions,[a] and Ivan P. Parkin*[a]

**Keywords:** Intelligent materials / Vanadium dioxide (M) / Transition temperature / Niobium doping

Niobium-doped vanadium dioxide ($V_xNb_{1-x}O_2$, $x$ = 0–0.037) thin films were prepared by aerosol-assisted chemical vapour deposition (AACVD) of vanadyl(IV) acetonate and niobium(V) ethoxide in ethanol. Samples were analysed by EDX, XRD, Raman, XPS and SEM. The analyses confirmed the deposition of niobium, even if no separated phase was formed; the morphological structure of the films was affected by the dopant presence. The thin films showed thermochromic behaviour, with a marked change in optical properties above and below the switching temperature.

## Introduction

Vanadium(IV) oxide ($VO_2$) is a material with many interesting characteristics, including a thermochromic phase transition. At room temperature, the most stable phase is the monoclinic $VO_2$ (M); at higher temperature the rutile phase $VO_2$ (R) is stabilised. Above a certain temperature, there is a spontaneous transition from the monoclinic to the rutile form, a metal-to-semiconductor transition (MST), that is completely reversible and takes place at 68 °C.[1] A remarkable change in the physical properties is detected on passing through the MST transition; $VO_2$ (M) behaves as a semiconductor and does not reflect much solar energy, whereas $VO_2$ (R) is a semimetal and shows markedly higher electrical conductivity and a much higher reflectance, particularly in the infrared range.[2]

Vanadium dioxide represents an ideal material for use as an intelligent window coating, that is a coating that modifies its behaviour in response to an external stimulus, i.e. heat. The low reflectance of the monoclinic phase assures that a coated window allows maximum solar gain on cooler days ($T$ below $T_c$). The transition to the rutile phase, on the other hand, can help to reduce the heat gain in hot days. The effect would be to have a comfortable environment with reduced air-conditioning costs, which has economical and environmental benefits.[2]

For practical application an intelligent window coating should have its phase-transition temperature closer to a comfortable room temperature value. It has been reported previously that a change in the transition temperature can be obtained by doping metal ions into the $VO_2$ lattice; doping with titanium, for instance, raises the value of $T_c$[3] while tungsten, molybdenum and niobium lower it.[4,5]

Up to now, the best reduction in the transition temperature has been obtained by the use of tungsten; in fact W-doped $VO_2$ thin films have been prepared with different methodologies such as sputtering,[6,7] sol-gel,[8] atmospheric-pressure and aerosol-assisted chemical vapour deposition (APCVD and AACVD).[2,9] These films show a decrease in the transition temperature that is proportional to the amount of tungsten incorporated; samples containing about 1% tungsten, show a decrease of 20–25 °C.[2,6,7] Considering in particular the AACVD methodology, films with values of $T_c$ close to room temperature were deposited.[9]

Niobium-doped $VO_2$ thin films have been prepared by sol-gel[10] and APCVD methodologies.[5] The results seemed particularly encouraging for APCVD samples; in fact, above the transition temperature, they showed a remarkable decrease in the transmittance in the infrared region, fulfilling the requirement for intelligent window coatings. The problem, however, was the difficulty to incorporate large enough amounts of niobium into the $VO_2$ films, in fact the highest niobium concentration achieved was 0.4%, corresponding to a $T_c$ value of 55 °C.[11]

In this paper we report the first synthesis of Nb-doped $VO_2$ thin films with AACVD. With this methodology the precursor is dissolved in a solvent and an aerosol generated ultrasonically. An inert carrier gas transports the precursor (within the aerosol droplets) to the deposition reactor where the reaction takes place. The main advantage of AACVD deposition is that, unlike for APCVD, the precursor does not need to be volatile but just soluble in a solvent appropriate for the aerosol formation.[12] In this way it is possible to use different precursors, not normally used in APCVD.[13,14] Previous work indicates a strong correlation between metal ratios in the precursor solution and those found in the resultant film.[9] AACVD provides an easy method to prepare multi-component and/or doped films.

Previous experiments were carried out by our group to deposit $VO_2$ (M) using AACVD methodology (Figure 1). The effect of different experimental parameters such as solvent, deposition temperature and gas-flow rate was studied and the deposition conditions were optimised to deposit $VO_2$(M) as the only phase and with no contamination.[15] The same experimental conditions were used to deposit Nb-doped $VO_2$, with $[Nb(OC_2H_5)_5]$ added as a niobium precursor. Depositions with different Nb/V ratios were performed; the deposited films were analysed to determine their composition, their structure and their behaviour as an intelligent window material.

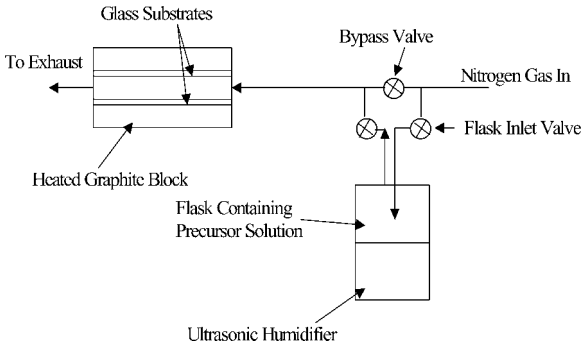

Figure 1. Schematic representation of AACVD experimental apparatus.

## Results and Discussion

### Film Deposition and Characterisation (Deposited Phases and Morphology)

Vanadium dioxide thin films with different amounts of niobium were deposited, by AACVD of a solution containing $[VO(acac)_2]$ and $[Nb(OEt)_5]$. Table 1 reports the Nb/V precursors ratio employed for the depositions. All deposited films were yellow in colour with some trace of brown, identical to undoped $VO_2$ films.[15] They all showed good adherence; they passed the Scotch tape test, but they could be scratched by a scalpel and were stable in air.

Table 1. Niobium/vanadium molar ratio for the initial solution and the deposited samples.

| Sample | Nb/V solution molar ratio (%) | Nb/V film molar ratio (%) | $T_c \pm$ hysteresis width (°C) |
|---|---|---|---|
| **1** | 1.3 | 0 | 58 ± 3 |
| **2** | 5.2 | 0 | 58 ± 3 |
| **3** | 7.5 | 2.6 | 42 ± 3.5 |
| **4** | 10.3 | 2.4 | 44 ± 3 |
| **5** | 12.4 | 2.2 | 35 ± 3 |
| **6** | 13.8 | 3.7 | 37 ± 3 |
| **7** | 14 | 3.0 | 35 ± 4 |
| **8** | 17 | 2.7 | 37 ± 3.5 |
| **9** | 18.9 | 2.8 | 41 ± 3 |

To determine the films' composition, i.e. the amount of niobium deposited in each film, EDX analyses were taken. The results are listed in Table 1. It can be seen that for precursor ratios in solution up to 5.2%, there is no niobium detected in the films. The reason for this behaviour is not clear, it is likely that the niobium precursor has to reach a critical concentration before it interacts with the vanadium; this would explain the sudden increase in the Nb/V film ratio from 0 to 2.6%.

For higher concentrations in solution, there is an increase of the niobium concentration in the deposits; however, the value reaches a plateau and it remains stable (within experimental error), despite the increase in concentration of niobium in solution. An explanation for these results can be that the value of the solubility limit on niobium in vanadium is reached; however, no data are available in literature to confirm this.

From this data it can be seen that niobium behaves very differently from tungsten in $VO_2$ films deposited by AACVD; in fact a linear correlation was observed for tungsten between the amounts of precursor in solution and the metal in the film.[9] Furthermore, a much greater proportion of the tungsten precursor was included in the $VO_2$ film as metal dopant (e.g. a W/V atom ratio of about 6% in solution corresponded to about 2% in the film).

The different behaviour of niobium confirms the difficulties previously reported with this metal already observed in APCVD.[11] In comparison a much greater amount of metal was deposited in the AACVD samples; this indicates the suitability of the technique for the deposition of multicomponent/doped films.

The XRD patterns of all samples were recorded to determine the nature of the phases present; Figure 2 shows the XRD spectrum of sample **5**. It can be seen, despite the glass background signal, that the deposited film is unambiguously $VO_2$(M).[2] Similarly to undoped $VO_2$ and W-doped $VO_2$ deposited by AACVD, no preferential orientation is observed.[9] No other phase was detected, neither for niobium nor for other vanadium oxides. Other areas of the same film showed the same pattern, indicating good homogeneity of the film. All the thin films investigated, with different niobium concentration, had the same characteristics; this indicates that the amount of dopant does not affect the nature of the phase deposited and that, under these conditions, it does not favour the formation of mixed phases.

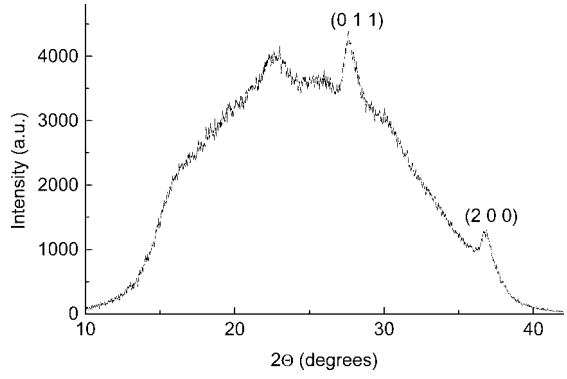

Figure 2. XRD spectrum of sample **5**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The Raman spectrum of sample **5** is shown in Figure 3. It can be seen that it shows the characteristics $VO_2$ pattern. In fact all the detected signals can be assigned to $VO_2$ (M); furthermore, there is no signal corresponding to graphitic carbon (i.e. at 1355 $cm^{-1}$), indicating no carbon contamination of the film.

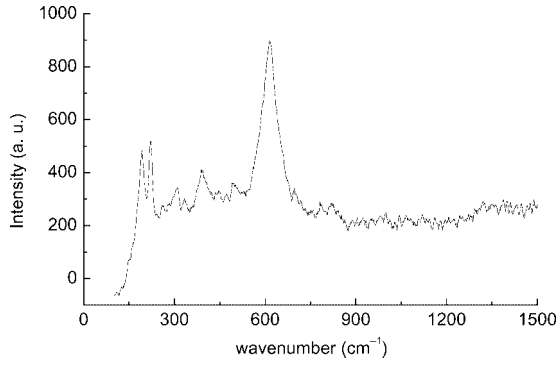

Figure 3. Raman spectrum for sample **5**.

XPS spectra of Nb-doped $VO_2$ samples were acquired to detect the possible other elements deposited in the film as impurities and to determine the oxidation states of the main film components. From the analysis of the survey spectrum (registered on the surface of the film), it was seen that the only additional element detected in the film is carbon. However, the intensity of the carbon signals decreased remarkably moving from the surface into the bulk of the film; this indicates the carbon is present only on the surface as contaminant from the external environment, but it is not present in the bulk of the film. This is in agreement with what was observed by Raman spectroscopy; in fact the signals in the Raman spectra are related to the bulk of a material and not just to its surface.

Figure 4(a) and (b) show the sections of the spectrum corresponding to the niobium and vanadium, respectively, for sample **5**; as mentioned above, the spectrum was registered on the surface of the film. The niobium peaks were detected for $Nb3d_{5/2}$ and $Nb3d_{3/2}$ at the binding energies of 207.0 and 209.2 eV. These values correspond to the binding energies of $Nb_2O_5$, therefore it follows that the niobium oxidation state is +5.[16] This is in agreement with previously published data,[11] hence it confirms that niobium does not change its oxidation state during the deposition. Spectra acquired in the bulk of the film show that niobium has the same oxidation state throughout the film.

The analysis of the part of the spectrum corresponding to vanadium shows that the main signal consists of two overlapping peaks at 516.2 and 517.4 eV (the deconvolution is shown in Figure 4). These two binding energies correspond to $V2p_{3/2}$ (+4) and $V2p_{3/2}$ (+5).[16] This indicates that, on the surface of the film, $VO_2$ is partly oxidised to $V_2O_5$.

Moving to the bulk of the film, however, only the peak corresponding to $V^{IV}$ is detected (spectrum is not shown). These results are in agreement with the XRD and Raman results; in fact no $V_2O_5$ signal was observed by either technique (see Figures 2 and 3), because they analyse the bulk of the film and not just the surface.

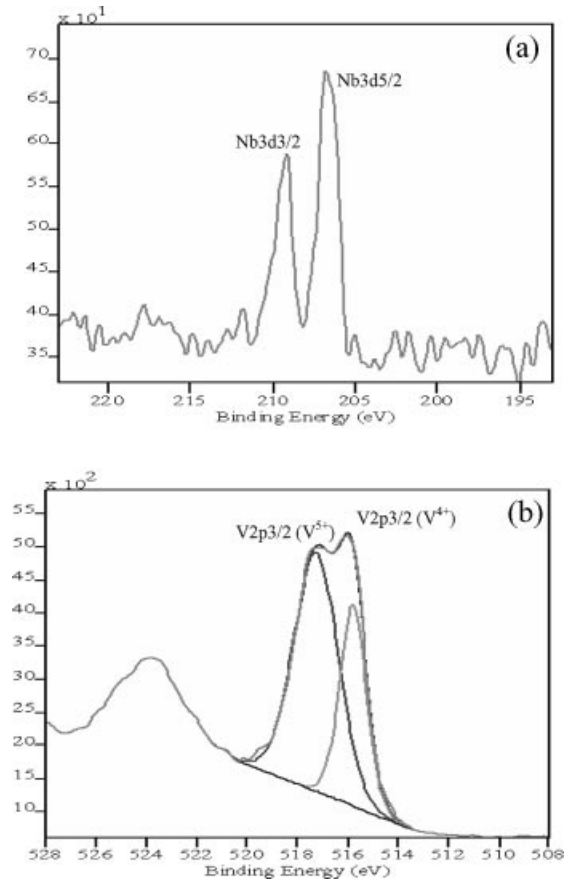

Figure 4. XPS spectrum for sample **5**: (a) niobium section; (b) vanadium section.

The morphology of the Nb-doped $VO_2$ thin films was studied by scanning electron microscopy (SEM). Figure 5 compares the surface structure of undoped $VO_2$ [Figure 5(a)] with the one of Nb-doped $VO_2$ [sample **7**, Fig-

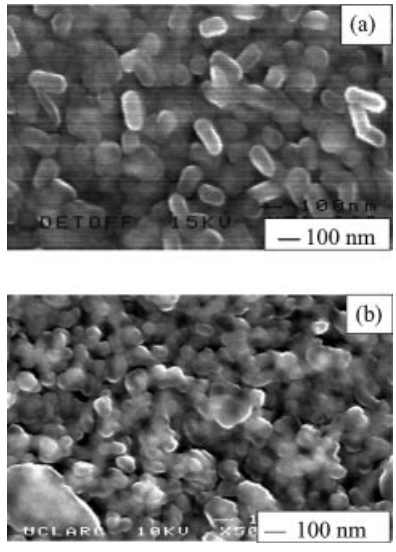

Figure 5. SEM images for (a) undoped $VO_2$; (b) sample **7**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 5(b)], both deposited using AACVD. It can be observed that they look quite different, indicating the effect of niobium on the film structure. Other films with different niobium concentrations have a similar morphology, indicating that the amount of niobium does not have any influence on the morphology.

### Film Characterisation: Functional Properties

The optical properties of the samples were investigated and their thermochromic change through the monoclinic-rutile phase transition studied. The change in transmittance and reflectance above and below the transition temperature was measured to assess the efficiency and the suitability of this material as an intelligent window coating.

Figure 6 shows the transmittance and reflectance spectra above and below the transition temperature for sample **9**. Considering the transmittance [Figure 6(a)], there is a significant decrease above the transition temperature (up to 30%) in the infrared range. The spectra of all the other samples showed the same features, with some changes in the extent of the decrease in the transmittance, which was dependant on the thickness of the films. This behaviour is analogous to the one shown by both undoped and W-doped $VO_2$.[9,15]

The change in the reflectance, however, has different characteristics depending on the niobium content of the film; Figure 6(b) and (c) show the reflectance spectra of samples **5** and **9**, respectively. For sample **5**, an increase above $T_c$ can be observed for the full infrared range; for sample **9**, on the contrary, such increase can be seen only for wavelengths larger than 1650 nm. At about 1650 nm the two lines cross over, therefore the curve corresponding to the reflectance above $T_c$ is slightly less intense than the one representing the reflectance below $T_c$. Similar to the Raman spectra, this different behaviour was observed for samples **6**, **7**, **8** and **9**, when the niobium concentration in the films is about 3%; the two curves cross over in a range of energy between 1550 and 1650 nm. The comparison of these results suggests that probably the presence of another phase affects the change in the reflectance, limiting it to a smaller energy range.

The value of the transition temperature was also determined for each sample. This was done by measuring the transmittance at 4000 $cm^{-1}$ as a function of the temperature. Figure 7 shows as an example the measurements for samples **4** and **7** (Nb/V = 2.4 and 3.0%, respectively). As shown in Figure 7, the transition temperature was determined considering the average value of the transmittance; the midpoint of the hysteresis loop for this value of transmittance is the transition temperature. It can be seen that the larger the Nb/V ratio, the lower is the value of the temperature. This shows the effectiveness of niobium to decrease $T_c$. Table 1 reports the value of $T_c$ for every sample ± the width of the hysteresis loop. Similarly to what is observed for W-doped $VO_2$ deposited with AACVD, the width of the hysteresis loop does not change with the decrease of the transition temperature which is constant between 3 and 4 °C.

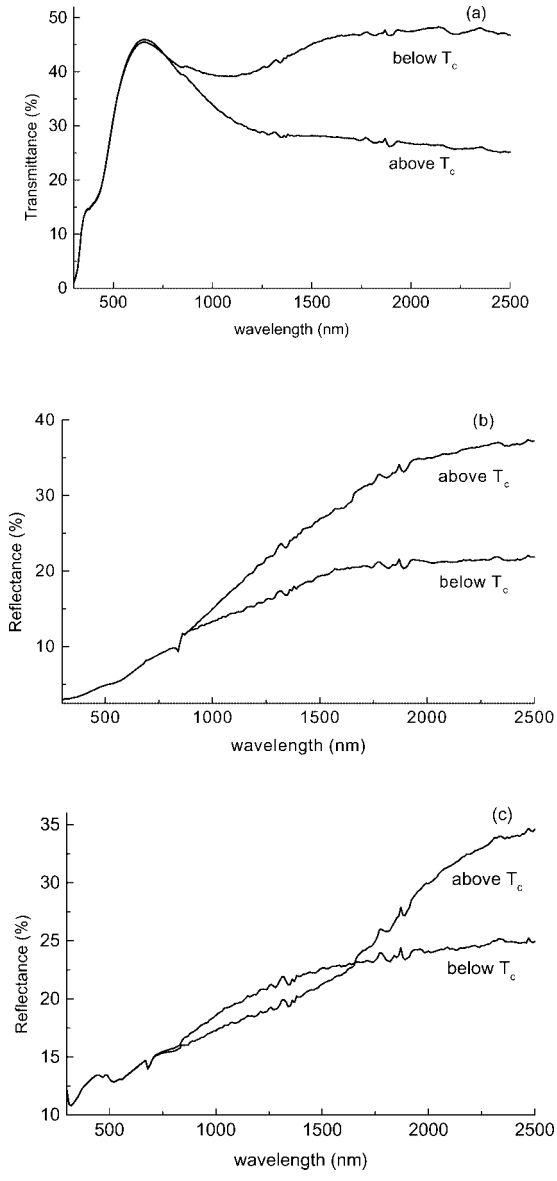

Figure 6. Optical properties above and below $T_c$. (a) Transmittance for sample **9**; (b) reflectance for sample **5**; (c) reflectance for sample **9**.

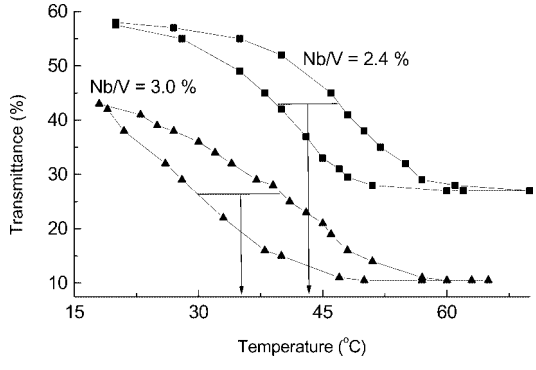

Figure 7. Transmittance at 4000 $cm^{-1}$ as a function of the temperature for samples **4** and **7** (Nb/V atom ratio 2.4 and 3%, respectively).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Figure 8 shows the value of $T_c$ as a function of the niobium content in the film and that a good linear correlation is established. From this data it can be seen that an amount of niobium in the film of 2% lowers the transition temperature by 15 °C. It follows that niobium is less effective than tungsten to decrease the value of $T_c$ (for tungsten, 1% of dopant decreases $T_c$ by about 22 °C);[9] it is, however, still possible to achieve values of transition temperatures close to room temperature.

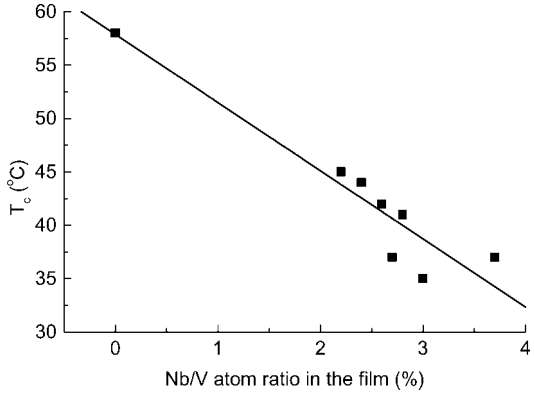

Figure 8. Transition temperature vs. the Nb/V atom ratio in the films.

## Conclusions

Nb-doped $VO_2$ thin films were successfully deposited by *A*erosol-*A*ssisted *C*hemical *V*apour *D*eposition (AACVD). EDX analysis showed that an increase in the niobium concentration in solution correlates to an increase in niobium in the film as well, until a plateau is reached. Samples with a niobium content up to 3.7% (atom ratio) were prepared, $VO_2$ films with such high niobium concentrations were never deposited before. This indicates the suitability of the AACVD methodology to deposit doped thin films.

Films were characterised by several analytical techniques (XRD, Raman, SEM, XPS) to determine the nature of the deposited phase and to detect possible impurities. The functional properties of the films (reflectance/transmittance, transition temperature) were studied as well, to test their application as an intelligent material for window coating. Significant changes in the transmittance and reflectance properties were observed on passing the transition temperature; furthermore, a decrease in the transition temperature was observed, with a linear correlation, between the films' niobium content and the value of the temperature. These features indicate Nb-doped $VO_2$ as a suitable material for application in smart windows.

## Experimental Section

**Film Deposition:** Vanadyl(IV) acetylacetonate $[VO(C_5H_8O_2)_2]$ = $[VO(acac)_2]$ and $Nb^V$ ethoxide $[Nb(OC_2H_5)_5]$ were purchased from Aldrich Chemical Co and used as supplied. The aerosol solution was prepared by dissolving both precursors in ethanol. For $[VO(acac)_2]$, a constant concentration of 0.05 mol dm$^{-3}$ was used. Different molar amounts of $[Nb(OC_2H_5)_5]$ were used, in order to have a varying Nb/V molar ratio (5.2–17 mol-%). An aerosol was generated from 50 mL of precursor solution using a Mountain Breeze humidifier; a nitrogen flow of 1.5 L min$^{-1}$ (BOC, 99.9%) was passed through the aerosol mist, directing the aerosol to a horizontal bed cold wall CVD reactor. Sheets of float glass ($150 \times 45 \times 4$, Pilkington Glass Plc.) were used as deposition substrates; an $SiO_2$ layer, about 50 nm thick, was used to suppress the diffusion of ions from the bulk glass. Prior to the deposition, the substrates were cleaned using water, acetone and 2-propanol and then dried in air. A Tempatron TC4800 thermostat was used to heat the substrates, with the temperature monitored by a Pt-Rh thermocouple. The substrates were heated to a temperature of 500 °C. The aerosol passed between the heated substrate and a glass top plate, placed 8 mm above the substrate and parallel to it. The exhaust was vented into a fume cupboard. The gas flow was continued until all the precursor solution had passed through the reactor; it normally took between 40 and 50 min. At the end of the deposition, the nitrogen flow through the aerosol was diverted and only nitrogen passed over the substrate. A schematic representation of the AACVD deposition apparatus is shown in Figure 1.

**Film Characterisation:** X-ray powder diffraction patterns were measured with a Bruker D8 diffractometer using filtered (Cu-$K_{\alpha 1+\alpha 2}$) radiation in the reflection mode using glancing angle incidence (1.5°). SEM was carried out with a Hitachi filament scanning microscop. EDAX was determined with a Philips XL30 ESEM instrument, data was quantified using Oxford Inca Software. Raman measurements were carried out with a Renishaw system 1000 Raman spectrometer, with an Ar laser excitation source (514 nm). The Raman system was calibrated against the emission lines of argon. X-ray photoelectron spectroscopy (XPS) measurements were carried out with a VG ESCALAB 220i XL instrument using monochromatic Al-$K_\alpha$ radiation. Binding energies were referenced to surface elemental carbon at 284.6 eV. Depth profiling was carried out using a 3-kV argon ion gun operating at 0.5 μA to sputter the surface of the film. Reflectance and transmission spectra were recorded between 300 and 2500 nm with a Perkin–Elmer Lambda 950 UV/Vis spectrometer. Measurements were standardised relative to a Spectralon® standard (reflectance) and air (transmission). For measurements at different temperatures, an aluminium temperature cell, controlled by RS resistive heaters, Eurotherm temperature controllers and k-type thermocouples were used to manipulate the sample temperature. The sample temperature was measured using a k-type thermocouple taped directly onto the film surface.

# Synthesis and Properties of Tetrasubstituted 1,10-Phenanthrolines and Their Ruthenium Complexes

**Bernhard Schäfer,[a] Helmar Görls,[a] Susann Meyer,[b] William Henry,[c] Johannes G. Vos,[c] and Sven Rau*[a]**

**Keywords:** Ruthenium / Phenanthroline / Luminescence / Photochemistry

The synthesis and the photophysical properties of a series of tetrasubstituted phenanthroline (phen) ruthenium complexes of the type $[Ru(tbbpy)_2(phen\text{-}R_4)]^{2+}$ (tbbpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine; phen = 1,10-phenanthroline; R represents the substitution at 3-, 5-, 6- and 8-positions with phenyl, 4-*tert*-butylphenyl and *para*-biphenyl) and of a homoleptic $[Ru(phen\text{-}R'_4)_3]^{2+}$ (R′ = 4-*tert*-butylphenyl) are described. The phen-$R_4$ ligands were obtained in high yields using Suzuki-type coupling reactions. The solid-state structure of 3,5,6,8-tetraphenylphenanthroline is reported. The investigation of the photophysical properties of the free ligands reveals a pronounced effect of the aryl substitution on absorption and emission properties. These properties are mirrored in the corresponding complexes, which possess room-temperature emission lifetimes of up to 2833 ns.

## Introduction

Luminescent polypyridyl–metal complexes, especially of ruthenium and osmium, have received considerable attention due to their favourable combination of interesting photophysical properties such as long-lived excited triplet states ($^3$MLCT) and high chemical stability.[1] This has also allowed them to play an important role in artificial photosynthesis,[2] dye sensitised solar cells[3] or luminescent sensors, for instance, for oxygen.[4] The photophysical properties of the ruthenium and osmium complexes can be easily tuned by variation of the ligand $\pi$-system.[5] Modification of the topology of the ligand structure allows the construction of elaborate supramolecular architectures containing multiple metal centres.[6] Within this context it is essential to be able to introduce substituents at a potential ligand at a predefined position and in variable numbers. Beside bipydines and terpyridines, derivatives of 1,10-phenanthroline (Figure 1) have received increasing attention since they can be easily transformed into various bridging ligands such as tetrapyridophenazins[7] or ligands which form the basis for luminescent DNA sensors.[8]

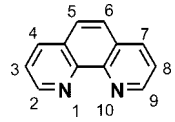

Figure 1. 1,10-Phenanthroline and the numbering scheme employed.

Strong effects on the electronic transitions of the 1,10-phenanthroline ligand and its $Ru^{II}$ complexes have been observed, which depend on the nature and position of the substituents of the phenanthroline scaffold.[9–11] In general, 1,10-phenanthroline ligands substituted at the 2,9- and the 4,7-positions are accessible using various synthetic pathways.[12–15]

However, access to phenanthrolines substituted in the 3- and 3,8-positions is rather limited and often requires tedious work up.[16–19] Tor and co-workers have shown that a multitude of different phenanthrolines can be synthesised by organometallic reactions starting from 3-bromo- and 3,8-dibromo-1,10-phenanthrolines.[20] Using this methodology, Br-phen ligands and the corresponding complexes have been employed in the construction of luminescent sensors for metal ions,[10] multinuclear metal complexes possessing interesting photophysical properties[10,11,16–22] and nucleotide labelled luminescent complexes.[23–25]

Substitutions at the 5,6-positions of the phenanthroline are very rarely reported.[26] 5,6-Bis-thiophenyl-1,10-phenanthrolines, which were obtained by a Suzuki coupling, were employed for the construction of light-driven switches.[27]

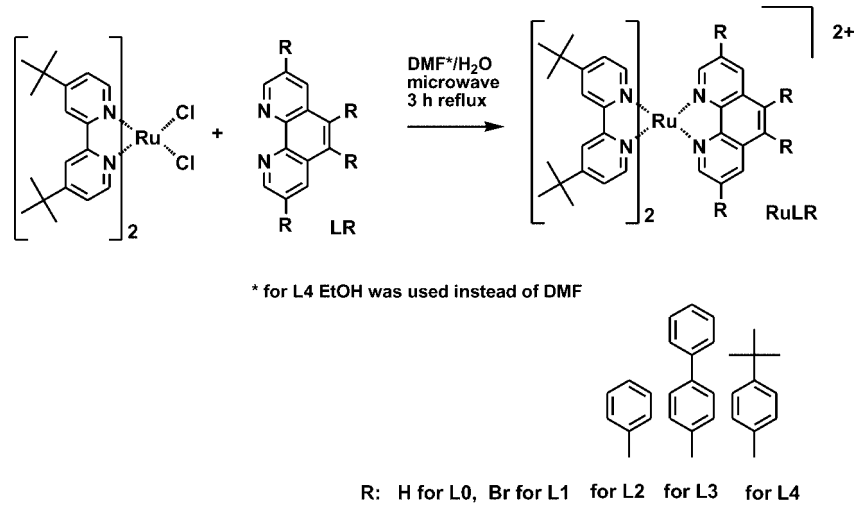

Figure 2. Naming of ruthenium complexes and corresponding ligands.

Recently we reported a bromination reaction of 1,10-phenanthroline which allowed the selective formation of 3,5,6,8-tetrabromophenanthroline (phen-$Br_4$) in an one-step multigram reaction.[28] There we showed that the regioselective nucleophilic substitution of phen-$Br_4$ in the $[Ru(tbbpy)_2(phen\text{-}Br_4)]^{2+}$ complex in the 3,8-position was possible under mild conditions and at room temperature. Furthermore, the synthesis of tetraalkynyl-substituted phenanthrolines based on phen-$Br_4$ was observed using Negishi-type conditions. Preliminary investigations showed that the tetraalkynyl-substituted phenanthrolines may serve as ligands for ruthenium(II) centres.[29]

It is noteworthy that the introduction of alkynyl functional groups in bipyridine or phenanthroline frames leads to the expansion of the conjugated π-system which will have a dramatic impact on the metal-to-ligand charge-transfer excited state of ruthenium complexes. The introduction of aryl substituents, however, does not necessarily lead to the expansion of the conjugated π-system since the torsion angle of these substituents relative to the phenanthroline main frame can be substantial, thus limiting delocalisation.[30] The extremely long lifetimes of the tris-(4,7-diphenylphenanthroline)ruthenium(II) complex of up to 9640 ns which is extensively used in oxygen sensing is, however, worth noting.[31]

In this contribution we present a series of tetraaryl-substituted 1,10-phenanthroline ligands, which were prepared by Suzuki reactions, and their corresponding ruthenium–polypyridyl complexes (see Figure 2).

To avoid solubility problems we utilised the bis(4,4′-di-*tert*-butyl-2,2′-bipyridine)$Ru^{II}$ core, $(tbbpy)_2Ru^{2+}$, since this ensures high solubility in organic solvents.[32] The novel ligands L**2** to L**4** were prepared to illustrate the potential of the building-block approach utilising organometallic C–C coupling reactions. We will focus this investigation on the synthetic accessibility of differently substituted ruthenium complexes with tetrasubstituted phenanthrolines and the preliminary characterisations of their photophysical properties.

## Results and Discussion

### Synthesis

All prepared complexes contain 4,4′-di-*tert*-butyl-2,2′-bipyridine (tbbpy) to increase the solubility of the ruthenium complexes in less polar organic solvents. The new ligands L**2** to L**4** rely on the accessibility of 3,5,6,8-tetrabromophenanthroline (L**1**, phen-$Br_4$) which was conveniently prepared using literature methods.[28] All four bromine functionalities in L**1** were easily substituted by aromatics using conventional Suzuki reactions utilising $Pd(PPh_3)_4$ as catalyst, yielding L**2**–L**4** in good yields (see Figure 3).

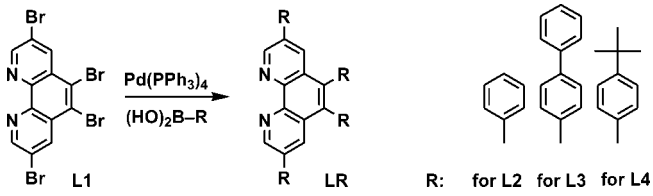

Figure 3. Synthetic route to tetraaryl-substituted phen ligands.

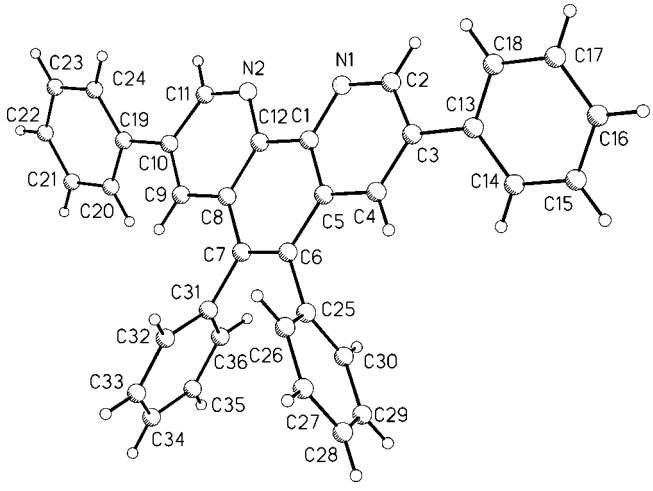

Figure 4. Solid-state structure of L**2**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The nature of the products was unambiguously identified using multidimensional NMR spectroscopic methods, MS and UV-Vis/emission spectroscopy. The nature of the reaction products and the interaction between the hydrogen substituents of the phenanthroline frame and the aryl substituents was confirmed by the solid-state structure obtained for **L2** shown in Figure 4.

The phenanthroline frame is nearly ideally planar (deviation from planarity is 0.015 Å), whereas the two phenyl substituents in the 3,8-positions of the phenanthroline are twisted out of the plane by 29° (C4, C3, C13, C14) and 33° (C9, C10, C19, C20). The two other phenyl substituents in the 5- and 6-positions of the phenanthroline are twisted even more relative to the plane by 82° (C5, C6, C25, C26) and 71° (C7, C8, C31, C32). The strong twisting of the 5,6-substituents is a consequence of the repulsion imposed by the two neighbouring phenyl rings on each other. The smaller steric pressure for the phenyl substituents in the 3,8-positions is a consequence of the interaction of the hydrogen atoms of the phenanthroline pyridine ring with the

neighbouring phenyl ring which results in significantly smaller torsion angles.

Complexation of **L0**–**L4** to $(tbbpy)_2Ru^{2+}$ fragments [Ru] was achieved using microwave irradiation.[33] Because of the poor solubility of **L2** and **L3**, DMF had to be used. The short reaction times made possible by the use of the microwave ensured that no significant formation of ruthenium–carbonyl complexes from the decomposition of the DMF occurred. The full characterisation of all complexes by multidimensional NMR spectroscopic methods, MS and UV-Vis/emission spectroscopy is outlined in the Experimental Section and in Table 1. The $^1H$ NMR spectrum of the heteroleptic complex Ru**L4** is depicted in Figure 5, and it shows four *tert*-butyl signals between 1.2 and 1.6 ppm. Two *tert*-butyl signals are tbbpy-based, with the third and the fourth stem from the *tert*-butyl groups of the substituents in the 3,8- and 5,6-positions, respectively. The signals in the aromatic region could be assigned to the two *tert*-butyl bipyridine ligands and to the phenanthroline ligand **L4** by H,H COSY NMR spectroscopy.

The compositions of the complexes Ru**L0**–Ru**L4** were additionally confirmed by ESI mass spectroscopy. The spectra always contained the $[M - PF_6]^+$ and $[M - 2PF_6]^{2+}$ peaks. These peaks were assigned to the corresponding molecular ion with the aid of a matching isotopic pattern as depicted for $[RuL4 - PF_6]^+$ in Figure 6.

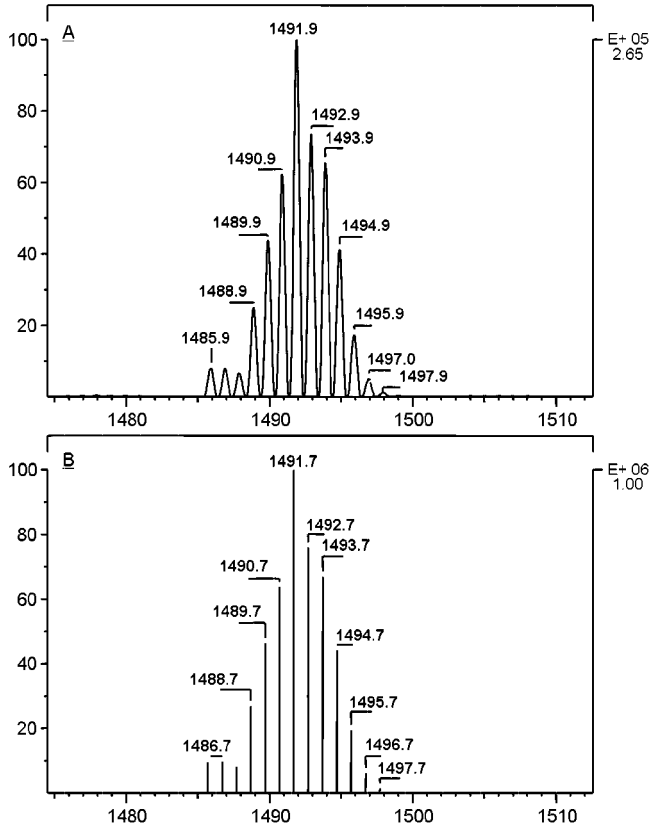

Figure 6. $[RuL4 - PF_6]^+$ peak of the ESI-MS of Ru**L4** in MeOH (A) and the corresponding isotopic pattern (B) of $C_{88}H_{104}N_6RuPF_6$.

We obtained the homoleptic complex $Ru(L4)_3$ using standard microwave-assisted reaction conditions. Attempts to synthesise $Ru(L1)_3$ did not yield any product that could be characterised but rather a mixture of different decomposition products.

## Electronic Spectra

All three new ligands **L2**–**L4** display redshifted absorption maxima relative to that of 1,10-phenanthroline, **L0**, at around 300 nm and a shoulder at around 340 nm and for **L3** up to 370 nm. A clear influence of the peripheral substitution pattern on the shape of the long wavelength maxima is observed (Figure 7). The absorption spectrum of **L0** features two distinct maxima at 265 and 233 nm.[34] All three aromatically substituted ligands (**L2** to **L4**) show relatively strong emission between 400 nm (**L2**) and 408 nm (**L4**) in dichloromethane (DCM). The influence of the aromatic substitution on the emission is obvious by a pronounced redshift of about 40 nm between **L0** and **L2** to **L4**.

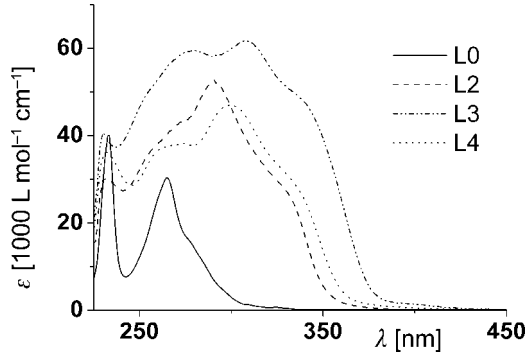

Figure 7. Absorption spectra of LR (R = 0, 2, 3, 4) in $CH_2Cl_2$ (DCM).

The absorption and emission data of **L2** to **L4** indicate that the substitution of the phenanthroline frame with aromatic moieties results in significant changes in the electronic properties of the ligands. A similar observation was previously made for substituted dipyrido[3,2-*a*:2′,3′-*c*]phenazine ligands.[35]

All four complexes Ru**L1** to Ru**L4** show absorption properties which are common for this class of ruthenium–polypyridyl compounds. The absorption spectra in acetonitrile (ACN) of the new complex Ru**L3** and Ru**L0** (for comparison) are depicted in Figure 8. The shape of the long wavelength maxima of the new complexes show an influence of the peripheral substitution pattern since shoulders of these MLCT bands appear slightly redshifted with regard to that of the related compound $[Ru(tbbpy)_2(phen)]^{2+}$ (Ru**L0**). The intensity of the phenanthroline-based transitions at ca. 286 nm increases from Ru**L0** ($63 \times 10^3$ M$^{-1}$ cm$^{-1}$) to Ru**L3** ($117 \times 10^3$ M$^{-1}$ cm$^{-1}$). The introduction of more extensive aromatic substituents leads to a new π–π* transition around 350 nm which decreases in energy and increases in intensity from Ru**L2** (347 nm, $22 \times 10^3$ M$^{-1}$ cm$^{-1}$) to Ru**L4** (351 nm, $36 \times 10^3$ M$^{-1}$ cm$^{-1}$) to Ru**L3** (355 nm, $53 \times 10^3$ M$^{-1}$ cm$^{-1}$).

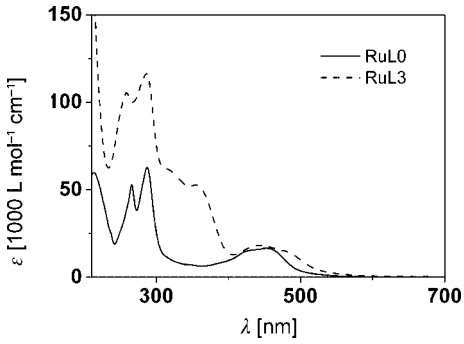

Figure 8. Absorption spectra of Ru**L0** and Ru**L3** in $CH_3CN$.

The homoleptic complex Ru(**L4**)$_3$ has a bathochromically shifted absorption maximum of 465 nm. The next highest energy transition is observed at 348 nm, similar to that of Ru**L4**, but with a higher extinction coefficient as expected. This allows the assignment of this band to a π–π* transition in the tetra(*tert*-butylphenyl)-substituted phenanthroline ligand **L4**. The absorption intensity of the band at 243 nm of the bisheteroleptic Ru**L4** is almost half of the homoleptic Ru(**L4**)$_3$ complexes which can also be considered as a **L4**-based transition. The investigation in dichloromethane shows that no significant changes in the absorption characteristics are observed except for Ru**L4** which displays a redshift of the long wavelength absorption maximum of 18 nm.

The luminescence data for all four complexes were obtained in acetonitrile and dichloromethane. The influence of the solvent on emission wavelength is evident by the ca. 15 nm redshift of the emission maxima upon going from dichloromethane to acetonitrile, which correlates to the increased polarity of the solvent and the nature of the MLCT transition. Similar effects of solvent polarity on the emission wavelength in substituted phenanthroline–ruthenium complexes have been observed.[36] The impact of the substitution at the phen core is observed for the phosphorescence maxima in $CH_3CN$ that shifts from 610 nm for Ru**L0** to 640 nm for Ru**L3** (see Table 1). The emission of the homoleptic Ru(**L4**)$_3$ slightly redshifts to 604 nm relative to the emission of Ru(**L0**)$_3$ (Table 1). Currently it is not possible to give a conclusive explanation for the observed effects of solvent polarity and substitution at the phenanthroline ligand; more detailed investigations using spectroscopic techniques such as resonance Raman and time-resolved spectroscopy in combination with theoretical methods might aid in the interpretation and characterisation of the nature of the emitting state. The information obtained so far indicates that the expansion of the 1,10-phenanthroline frame by aryl substituents does lead to a moderate change in the energies of the excited states which might be caused by limited delocalisation of the resulting aromatic frame due to the twisting of the aryl substituents caused by steric hindrance by neighbouring hydrogen atoms. A higher degree of delocalisation could be obtained by introduction of alkyne substituents like tri(isopropyl)silylacetylene.[29] In this case, the MLCT absorption of $[Ru(tbbpy)_2(L^*)]^{2+}$ {L* = 3,5,6,8-tetrakis[tri(isopropylsilyl)acetylene]phenanthroline} has a maximum at 439 nm with a shoulder at 505 nm and an emission maximum at 692 nm in acetonitrile.

The lifetimes of the excited states of all complexes in aerated solution lie in the expected range. Generally, longer lifetimes are identified in aerated dichloromethane solutions if compared with those in aerated acetonitrile solutions. Deaeration leads in both solvents to increasing lifetimes of the excited triplet MLCT as expected. However, this effect is more pronounced for acetonitrile solutions. In acetonitrile solution a nearly 15-fold increase from 189 to 2833 ns is detected for Ru**L2** upon removal of oxygen. This significant increase in lifetime renders the tetraaryl-substituted phenanthroline complexes potential candidates for applications as oxygen sensors.[4] In contrast to the data obtained for the heteroleptic complexes, the homoleptic complex Ru(**L4**)$_3$ shows relatively short lifetimes of 150 ns, especially if compared with the parent phenanthroline complex Ru(**L0**)$_3$ with 460 ns.

Photometric investigation of a solution of Ru**L2** which had been irradiated in acetonitrile for 72 hours with visible light $\lambda > 450$ nm showed that no significant photobleaching was detected.

## Electrochemistry

The electrochemical behaviour of the complexes was studied in acetonitrile and in DMF (Table 2). The reductions of complexes Ru**L3** and Ru(**L4**)$_3$ are not well-behaved in acetonitrile solution, probably due to the adsorption of the reduced species onto the surface of the electrode, and show abrupt and sharp adsorption and desorption spikes. In DMF this phenomenon disappears in the case of Ru**L3**. The behaviour of Ru(**L4**)$_3$ will be the subject of further investigations. A representative cyclic voltammogram for Ru**L2** is depicted in Figure 9.

[a] Data taken from ref.[28]

The oxidation potentials of the ruthenium complexes Ru**L2**–Ru**L4** are only slightly affected by the peripheral substitution at the phen ligand (Table 2). This can be observed by the increase in the oxidation potential of Ru**L0** (0.74 V) over Ru**L4** (0.80 V) followed by Ru**L2** (0.82 V) and Ru**L3** (0.82 V) vs. $Fc/Fc^+$. The presence of four bromo sub-

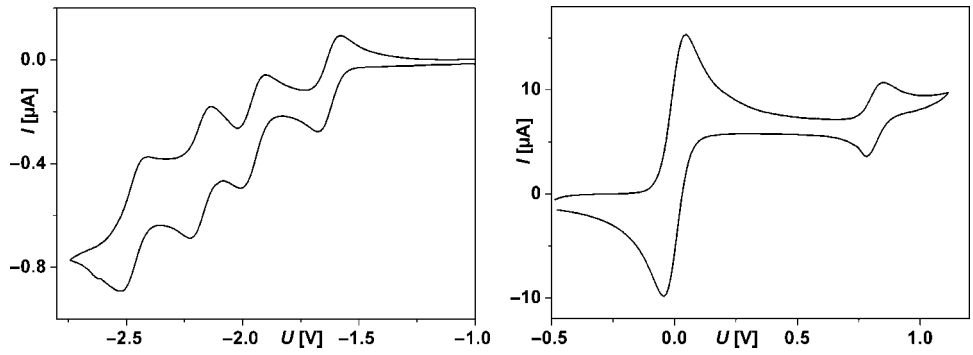

Figure 9. Cyclic voltammograms of RuL**2** (1 mM) in $CH_3CN$ containing $Bu_4NBF_4$ (0.1 M) vs. $Fc/Fc^+$ at 0.0 V (scan rate 0.05 $Vs^{-1}$, step potential 0.01 V).

stituents in RuL**1** shifts the oxidation potential of the ruthenium centre by 0.18 to 0.92 V. This suggests that the introduction of the aryl substituents has a relatively small influence on the metal-based ground state. The value observed for the first reduction potential suggests that L**2**–L**4** are easier to reduce than L**0**.

The reduction events of the complexes RuL**2**–RuL**4** in DMF show only small differences in their potentials of maximal 40 mV for the first reduction and ca. 10 mV for the second and third reduction processes. In contrast to this, the potentials of the ligand reduction of the unsubstituted RuL**0** show a cathodic shift with regard to the potentials of RuL**2**–RuL**4**. The differences of these shifts are 180 mV for the first, 40 mV for the second and 60 mV for the third reduction process.

## Conclusions

In conclusion we have shown that it is possible to introduce four substituents into a phenanthroline frame using Suzuki coupling reactions starting from the free ligand phen-$Br_4$, L**1**. The absorption spectra of the free ligands are highly dependent on the substitution pattern. Importantly, with increasing aryl character the ligand-centred π–π* transition of the LR ligand moves to lower energy. The substituted ligands form heteroleptic complexes in high yields. It is also possible to form a homoleptic complex with a *tert*-butyl-substituted 3,5,6,8-tetraphenylphenanthroline, Ru(L**4**)$_3$. The UV/Vis spectra of the complexes RuL**2**–RuL**4** show a redshift of the MLCT bands and the appearance of intensive π–π* transitions between 300 and 400 nm. The excited-state lifetimes of tetrasubstituted Ru–phenanthroline complexes are very sensitive to oxygen; the lifetime is almost 3 µs for RuL**2**. If compared with that of the unsubstituted phenanthroline complex RuL**0**, this represents an increase of 100% in the lifetime of the excited state. The synthetic accessibility of various tetrasubstituted phenanthrolines makes them ideal targets for further developments as building blocks for the construction of tuneable luminescent sensors or oligonuclear complexes.

## Experimental Section

Unless otherwise noted, all Pd-catalysed cross-coupling reactions were conducted under dry, deoxygenated argon using standard Schlenk techniques. Ru(tbbpy)$_2Cl_2$[33] and 3,5,6,8-tetrabromo-1,10-phenanthroline[28] were prepared using literature methods. Toluene was distilled from sodium benzophenone ketyl under argon prior to use. All other solvents were used as received. Boronic acids were purchased from Fluka, Aldrich and Lancaster.

$^1$H NMR spectra were recorded with a Bruker 400 MHz/200 MHz spectrophotometer. The mass spectra were obtained using a SSQ 170, Finnigan MAT at the Friedrich Schiller University, Jena. Electrospray mass spectra were recorded with a Finnigan MAT, MAT 95 XL. The positive ES mass spectra were obtained with voltages of 3–4 kV applied to the electrospray needle. The microwave-assisted reactions were carried out using the Microwave Laboratory Systems MLS EM-2 microwave system.

**Typical Procedure for Preparation of LR (R = 2, 3, 4) from phen-$Br_4$ (L1):** A Schlenk vessel was charged with phen-$Br_4$ (0.3 g, 0.61 mmol) and the corresponding boronic acid (2.54 mmol), $Pd(PPh_3)_4$ [0.044 g, $n = 3.81 \times 10^{-5}$ mol (1.5 mol-%)] in dry toluene (60 mL) and oxygen-free solution of 2 M aqueous $Na_2CO_3$ (20 mL). The suspension was refluxed under argon for 3 d. After cooling to room temp., the reaction mixture was taken up in water (100 mL) followed by extraction with chloroform. The solvent of the combined organic layers was removed, and the crude product was dried under vacuum. Column chromatography was performed using silica and a gradient eluent system starting with $CHCl_3$ and changing to $CHCl_3$/MeOH (99:1 and later to 9:1). The main fluorescent band was collected and yielded the pure ligand.

**3,5,6,8-Tetraphenylphenanthroline (L2):** Yield: 71%. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 7.24–7.65 (m, 20 H, phenyl), 8.07 [s, long-range coupling (lc), $^4J$ = 2 Hz, 2 H, H4,H7-phen], 9.41 [s(lc), $^4J$ = 2 Hz, 2 H, H2,H9-phen] ppm. MS (DEI, EI+Q1MS): *m*/*z* (%) = 484 (100) [$M^+$]. $C_{36}H_{24}N_2 \cdot 1CH_3OH$ (516.61): calcd. C 86.02, H 5.46, N 5.42; found C 85.93, H 5.25, N 5.14.

**3,5,6,8-Tetra(*para*-biphenyl)phenanthroline (L3):** Yield: 82%. $^1$H NMR ($CDCl_3$): $\delta$ = 7.30–7.75 (m, 36 H, phenyl), 8.36 (s, 2 H, H4,H7-phen), 9.68 [s(lc), 2 H, H2,H9-phen] ppm. MS (DEI, EI+Q1MS): *m*/*z* (%) = 788 (28) [$M^+$]. Recrystallisation from $CH_2Cl_2$. $C_{60}H_{40}N_2 \cdot 0.5CH_2Cl_2$ (831.43): calcd. C 87.4, H 4.97, N 3.37; found C 87.8, H 5.32, N 2.99.

**3,5,6,8-Tetra(4-*tert*-butylphenyl)phenanthroline (L4):** Yield: 76%. $^1$H NMR ($CDCl_3$): $\delta$ = 1.28 (s, 18 H, $CH_3$ *tert*-butyl), 1.35 (s, 18

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

H, $CH_3$ *tert*-butyl), 7.05 (d, $^3J$ = 8 Hz, 4 H, phenylA), 7.25 (d, $^3J$ = 8 Hz, 4 H, phenylA), 7.51 (d, $^3J$ = 8.4 Hz, 4 H, phenylB), 7.57 (d, $^3J$ = 8.4 Hz, 4 H, phenylB), 8.34 (s, 2 H, H4,H7-phen), 9.57 (s, 2 H, H2,H9-phen) ppm. MS (DEI, EI+Q1MS): *m*/*z* (%) = 709 (4) [$M^+$]. $C_{52}H_{56}N_2{\cdot}1CH_3OH$ (741.05): calcd. C 85.9, H 8.16, N 3.78; found C 85.81, H 7.72, N 3.33.

**Preparation of RuL2 and RuL3:** $Ru(tbbpy)_2Cl_2$ (0.1 g, 0.14 mmol) and the corresponding ligand (0.14 mmol) were suspended in DMF/$H_2O$ (80 mL/10 mL) and heated at reflux for 3 h using microwave irradiation (150 W). Afterwards the reaction mixture was filtered, and the solvent was removed under reduced pressure. The complexes were recrystallised from a mixture of ethanol and aqueous $NH_4PF_6$, and further purified by column chromatography using a stationary silica phase and a gradient changing from EtOH to EtOH/$H_2O$/$KNO_3$. The novel ruthenium complexes based on the aryl-substituted phenanthroline ligands did not yield satisfactory elemental analysis results, which might be due to the presence of multiple flexible substituents retaining varying amounts of solvents.

**$[Ru(tbbpy)_2(L2)](PF_6)_2$ (RuL2):** Yield 84%. $^1$H NMR ($CD_3CN$, 400 MHz): $\delta$ = 1.38 (s, 18 H, $CH_3$ *tert*-butyl), 1.45 (s, 18 H, $CH_3$ *tert*-butyl), 7.25–7.45 (m, 22 H, phenyl, H5-bpy), 7.52 (d, $^3J$ = 6 Hz, $^4J$ = 2 Hz, 2 H, H5′-bpy), 7.73 (d, $^3J$ = 6 Hz, 2 H, H6-bpy), 7.83 (d, $^3J$ = 6 Hz, 2 H, H6′-bpy), 8.00 (s, $^4J$ = 1.6 Hz, 2 H, phen), 8.11 (s, $^4J$ = 2 Hz, 2 H, phen), 8.49 (s, $^4J$ = 2 Hz, 2 H, H3-bpy), 8.56 (s, $^4J$ = 1.6 Hz, 2 H, H3′-bpy) ppm. MS (ESI, MeOH): *m*/*z* = 1267.5 ($[M - PF_6]^+$, 100% with matching isotopic pattern).

**$[Ru(tbbpy)_2(L3)](PF_6)_2$ (RuL3):** Yield: 70%. $^1$H NMR ($CD_3CN$, 400 MHz): $\delta$ = 1.39 (s, 18 H, $CH_3$ *tert*-butyl), 1.47 (s, 18 H, $CH_3$ *tert*-butyl), 7.3–7.5 (m, 18 H, phenyl, H5-bpy), 7.55 [d(lc), $^3J$ = 5.8, $^4J$ = 1.8 Hz, 2 H, H5′-bpy], 7.58–7.70 (m, 20 H, phenyl), 7.77 (d, $^3J$ = 6 Hz, 2 H, H6-bpy), 7.86 (d, $^3J$ = 5.6 Hz, 2 H, H6′-bpy), 8.09 [s(lc), $^4J$ = 2 Hz, 2 H, phen], 8.26 [s(lc), $^4J$ = 2 Hz, 2 H, phen], 8.517 [s(lc), $^4J$ = 2 Hz, 2 H, H3-bpy], 8.58 [s(lc), $^4J$ = 2 Hz, 2 H, H3′-bpy] ppm. MS (ESI, MeOH): *m*/*z* = 1571.5 ($[M - PF_6]^+$, 74%), 713.3 ($[M - 2PF_6]^{2+}$, 100% with matching isotopic pattern).

**Preparation of $[Ru(tbbpy)_2(L4)](PF_6)_2$ (RuL4):** $Ru(tbbpy)_2Cl_2$ (0.2 g, 0.282 mmol) and the corresponding ligand (0.282 mmol) were suspended in EtOH/$H_2O$ (60 mL/20 mL) and heated at reflux for 1 h using microwave irradiation (150 W). Afterwards the reaction mixture was filtered. The work-up procedure used was the same as that for Ru**L2** and Ru**L3**. Yield: 89%. Silica and chloroform were used for column chromatography. $^1$H NMR ($CD_3CN$, 400 MHz): $\delta$ = 1.27 (s, 18 H, $CH_3$ *tert*-butyl), 1.28 (s, 18 H, $CH_3$ *tert*-butyl), 1.38 (s, 18 H, $CH_3$ *tert*-butyl), 1.46 (s, 18 H, $CH_3$ *tert*-butyl), 7.15 (d, $^3J$ = 8 Hz, $^4J$ = 1.8 Hz, 2 H, phenylA), 7.22 (d, $^3J$ = 8 Hz, $^4J$ = 1.6 Hz, 2 H, phenylA), 7.25 (d, $^3J$ = 8.4 Hz, 4 H, phenylB), 7.31 (d, $^3J$ = 6.4 Hz, $^4J$ = 2 Hz, 2 H, H5-bpy), 7.36 (d, $^3J$ = 8.4 Hz, $^4J$ = 1.8 Hz, 2 H, phenylA), 7.40 (d, $^3J$ = 8 Hz, $^4J$ = 2.2 Hz, 2 H, phenylA), 7.44 (d, $^3J$ = 8.8 Hz, 4 H, phenylB), 7.53 (d, $^3J$ = 6, $^4J$ = 2 Hz, 2 H, H5′-bpy), 7.72 (d, $^3J$ = 6 Hz, 2 H, H6-bpy), 7.84 (d, $^3J$ = 6 Hz, 2 H, H6′-bpy), 7.95 (s, $^4J$ = 2 Hz, 2 H, H4,H7-phen), 8.12 (s, $^4J$ = 1.6 Hz, 2 H, H2,H9-phen), 8.49 (s, $^4J$ = 1.6 Hz, 2 H, H3-bpy), 8.55 (s, $^4J$ = 1.6 Hz, 2 H, H3′-bpy) ppm. MS (ESI, MeOH): *m*/*z* = 1491.5 ($[M - PF_6]^+$, 100% with matching isotopic pattern), 673.3 ($[M - 2PF_6]^{2+}$, 55% with matching isotopic pattern).

**Synthesis of the Homoleptic Complex of L4, $[Ru(L4)_3](PF_6)_2$ $[Ru(L4)_3]$:** A mixture of $RuCl_3{\cdot}3H_2O$ (0.012 g, 45.9 μmol) and L**4** (0.101 g, 0.143 mmol) was suspended in ethanol (30 mL), methanol (20 mL), DMF (15 mL) and water (15 mL). The reaction mixture was refluxed in a microwave oven for 3 h at 200 W and cooled down. Afterwards the solution was filtered, and the solvent was removed by rotary evaporation. The crude product was purified using column chromatography [silica, $CHCl_3$/heptane (v/v = 2)]. While the amount of heptane in the gradient was decreased, a violet band and a red main band were gathered from the column. Switching the eluent to $CHCl_3$/MeOH led to the collection of a brown band. The red band was recrystallised from acetone and aqueous $NH_4PF_6$ solution. Yield: 46%. $^1$H NMR ($CD_3CN$, 400 MHz): $\delta$ = 1.24 (s, 54 H, $CH_3$ *tert*-butyl), 1.29 (s, 54 H, $CH_3$ *tert*-butyl), 7.23 (d, $^3J$ = 8.4 Hz, 12 H, phenyl), 7.39 (d, $^3J$ = 8.4 Hz, 12 H, phenyl), 8.20 [s(lc), $^4J$ = 2 Hz, 6 H, phen], 8.47 [s(lc), $^4J$ = 2 Hz, 6 H, phen] ppm. MS (ESI, MeOH): *m*/*z* = 2372 ($[M - PF_6]^+$, 26% with matching isotopic pattern), 1114.4 ($[M - 2PF_6]^{2+}$, 100% with matching isotopic pattern).

**Crystal Structure Determination:** The intensity data for the compound were collected with a Nonius KappaCCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz and polarisation effects but not for absorption.[37,38] The structures were solved by direct methods (SHELRS[39]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELRL-97[40]). The hydrogen atoms of the structures were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[40] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations. CCDC-617531 (L**2**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Crystal Data for L2:** $C_{36}H_{24}N_2{\cdot}2CHCl_3$, $M_r$ = 723.31 g mol$^{-1}$, colourless prism, size 0.05 × 0.05 × 0.04 mm$^3$, triclinic, space group $P\bar{1}$, *a* = 12.8649(8), *b* = 12.9330(6), *c* = 12.9950(7) Å, *α* = 64.525(3), *β* = 64.591(3), *γ* = 68.457(3)°, *V* = 1718.31(16) Å$^3$, *T* = –90 °C, *Z* = 2, $\rho_{calcd.}$ = 1.398 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 5.31 cm$^{-1}$, *F*(000) = 740, 12260 reflections in *h*(–16/16), *k*(–15/16), *l*(–14/16), measured in the range 2.02° ≤ *Θ* ≤ 27.46°, completeness $\Theta_{max}$ = 98.7%, 7758 independent reflections, $R_{int}$ = 0.0281, 5185 reflections with $F_o > 4\sigma(F_o)$, 415 parameters, 0 restraints, $R_1$(obs) = 0.0527, $wR_2$(obs) = 0.1134, $R_1$(all) = 0.0933, $wR_2$(all) = 0.1338, GOOF = 1.003, largest difference peak and hole = 0.462/–0.492 e Å$^{-3}$.

**Electronic Spectroscopy:** UV/Vis absorption spectra (accuracy ±2 nm) were recorded with an Analytikjena Specord S 600 spectrometer with standard software-based tools. Emission spectra (accuracy ±5 nm) were recorded at 298 K using a Perkin–Elmer LS50B luminescence spectrophotometer, which was equipped with a red-sensitive Hamamatsu R298 PMT detector and interfaced with an Elonex PC466 employing Perkin–Elmer FlWinLab custom-built software. Emission spectra are uncorrected for photomultiplier response. 10-mm path length quartz cells were used for recording spectra.

**Emission Lifetime Measurements:** Luminescence lifetime measurements were obtained using an Edinburgh Analytical Instruments (EAI) time-correlated single photon counting apparatus (TCSPC) comprised of two model J-yA monochromators (emission and excitation), a single photon photomultiplier detection system model 5300 and a F900 nanosecond flashlamp (nitrogen filled at 1.1 atm pressure, 40 kHz or 0.3 atm pressure, 20 kHz) interfaced with a personal computer by a NorlandMCA card. A 410 nm cut-off filter was used in emission to attenuate scatter of the excitation light (337 nm); luminescence was monitored at the $k_{max}$ of the emission. Data correlation and manipulation was carried out using EAI F900 software version 6.24. Samples were de-aerated using argon for 30 min prior to measurements, followed by repeated purging to en-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sure complete oxygen exclusion. Emission lifetimes were calculated using a single-exponential fitting function, Levenberg–Marquardt algorithm with iterative deconvolution (Edinburgh instruments F900 software). The reduced $v2$ and residual plots were used to judge the quality of the fits. Lifetimes are ±5%.

**Electrochemistry:** The electrochemical measurements were executed with a PGSTAT booth (manufacturer: Autolab) with the aid of the appropriate GPES software. The experiments were carried out by means of a three-electrode technique in degassed acetonitrile with tetrabutylammoniumtetrafluoroborate (0.1 mol $L^{-1}$) as the conducting salt. A Hg-dropping electrode or a rotating-disc platinum electrode was used as the working electrode. The reference electrode was a Ag/AgCl electrode. The electrode's calibration took place according to the ferrocene standard potential in acetonitrile for which a value of +0.827 V was assumed. The concentration of the complexes measured was 1 mmol $L^{-1}$.

# Condensation of Nickel–Carbonyl Clusters with Soft Lewis Acids: Synthesis and Characterisation of the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ Dimer

**Cristina Femoni,[a] Maria Carmela Iapalucci,[a] Giuliano Longoni,[a] Fabrizio Ranuzzi,[a] Stefano Zacchini,*[a] Serena Fedi,[b] and Piero Zanello[b]**

**Keywords:** Cluster compounds / Carbonyl ligands / Structure elucidation / Lewis acids / Cyclic voltammetry

Reaction of $[Ni_6(CO)_{12}]^{2-}$ in thf with 2 equiv. of the soft Lewis acid $CdCl_2{\cdot}2.5H_2O$ gives the new dimeric species $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$. The formation of the latter is not the result of direct addition of $CdCl_2$ to $[Ni_6(CO)_{12}]^{2-}$, but it involves some intermediate species, i.e. $[Ni_9(CO)_{18}]^{2-}$ and $[Ni_9(CO)_{18}Cd_2Cl_4]^{2-}$. The crystal structure of $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}{\cdot}$thf was ascertained by X-ray crystallography. In the solid state, the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ cluster anions are pillared along the crystallographic *c* axis, forming infinite columns of perfectly alternating cluster anions and thf molecules. The chemical and electrochemical behaviours of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ are also reported and compared to those of the parent $[Ni_6(CO)_{12}]^{2-}$ dianion.

## 1. Introduction

Several low-valent metal clusters, stabilised mainly or uniquely by carbonyl ligands, apart from being molecules or molecular ions perfectly defined in composition and all structural details, trespass by size in the field of nanomaterials (1–1000 nm) from the lowest limit.[1] Pseudo 1D molecular carbonyl clusters (MCC) possessing nanometric size have been known for a long time. For instance, the $[Pt_{15}(CO)_{30}]^{2-}$[2] dianion has a metal frame length of ca. 1.5 nm. More-or-less spherical or ellipsoidal clusters, such as $[Ni_{32}Pt_{24}(CO)_{56}]^{6-}$,[3] $[Ni_{26}Pd_{20}(CO)_{54}]^{6-}$,[4] $Pd_{59}(CO)_{32}(PMe_3)_{21}$,[5] $Pd_{69}(CO)_{36}(PEt_3)_{18}$[6] and the giant three-shell $Pd_{145}(CO)_x(PEt_3)_{30}$ ($x \approx 30$),[7] display metallic core diameters in the 1–2-nm range. Moreover, several MCC aggregates close to or trespassing in the nanofield can be prepared, for instance by the fusion of two or more anionic clusters with a central core constituted by a single cation, for example $\{Hg[Os_{10}C(CO)_{24}]_2\}^{2-}$,[8] or cationic moieties, such as $[H_2Ru_{12}Cu_6Cl_2(CO)_{34}]^{2-}$,[9] $[H_4Ru_{20}Cu_6Cl_2(CO)_{48}]^{4-}$[10] and $[Ag_3Ru_{10}C_2(CO)_{28}Cl]^{2-}$.[11] The existence in solution of several fused MCC moieties such as $\{Ag[Rh_6C(CO)_{15}]_2\}^{3-}$ and higher $\{Ag_{n-1}[Rh_6C(CO)_{15}]_n\}^{n-}$ oligomers was demonstrated several years ago by multinuclear NMR spectroscopy,[12] and envisions the possibility to isolate MCC aggregates well beyond 2 nm. For instance, an infinite $\{[AgRu_6C(CO)_{16}]^-\}_\infty$ superwire was quantitatively assembled by the reaction of $[Ru_6C(CO)_{16}]^{2-}$ with $Ag^+$ ions.[13] Miscellaneous 1D and 2D arrays assembled through $\eta^2$-carbonyl groups of the previously unknown $[Co_4(CO)_{11}]^{2-}$ dianion with $Yb^{II}$ or $Eu^{II}$ cations were obtained by the reaction of $Hg[Co(CO)_4]_2$ with Yb or Eu metals.[14]

Recently, we reported two different strategies for the polymerisation of MCC. First, the controlled oxidation of $[Pt_6(CO)_{12}]^{2-}$ affords the $[Pt_{18}(CO)_{36}]^{2-}$ and $[Pt_{24}(CO)_{48}]^{2-}$ dianions that self-assemble by formation of homometallic Pt–Pt bonds into 1D $\{[Pt_{18}(CO)_{36}]^{2-}\}_\infty$ and $\{[Pt_{24}(CO)_{48}]^{2-}\}_\infty$ infinite wires upon crystallisation.[15] Secondly, the reaction of $[NBu_4]_2[Pt_9(CO)_{18}]$ with the soft Lewis acid $CdCl_2$ gives the $[Pt_9(CO)_{18}(\mu_3\text{-}CdCl_2)_2]^{2-}$ adduct, which self-assembles upon crystallisation into a 1D $\{[Pt_9(CO)_{18}(\mu_3\text{-}CdCl_2)_2]^{2-}\}_\infty$ polymer through the formation of chloride bridges.[16]

Nickel is known to have a more limited chemistry than platinum for what concerns homometallic carbonyl clusters. For instance, nickel displays only the first two species in the series $[Ni_{3n}(CO)_{6n}]^{2-}$ ($n$ = 2, 3),[17,18] whereas several compounds were prepared and characterised in the $[Pt_{3n}(CO)_{6n}]^{2-}$ ($n$ = 2–10) series.[2] Therefore, self-assembly of $[Ni_{3n}(CO)_{6n}]^{2-}$ ($n$ = 2, 3) units into 1D infinite wires seems unlikely owing to excessive electrostatic repulsion between anions, even if $[Ni_6(CO)_{12}]^{2-}$ in its $[NMe_4]^+$ salt gives rise to columnar stacks.[19] For this reason, we focused our attention on the possibility of building-up oligomeric species based on nickel MCC following the second route described above, i.e. the assembly of nickel clusters with Lewis acids. We report here our results on the oligomerisation of $[Ni_6(CO)_{12}]^{2-}$ with the soft Lewis acid $CdCl_2$.

## 2. Results and Discussion

### 2.1 Synthesis of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$

The reaction of $[Ni_6(CO)_{12}]^{2-}$ in thf with 2 equiv. of $CdCl_2{\cdot}2.5H_2O$ directly affords the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ oligomer in good yields (ca. 60% based on Ni). The IR spectrum shows $\nu$(CO) at higher frequencies [2025(vs), 1844(m) and 1819(m) $cm^{-1}$, in thf] relative to the parent $[Ni_6(CO)_{12}]^{2-}$ [1980(s), 1810(m) and 1790(m) $cm^{-1}$, in thf], in agreement with the lower negative charge per $[Ni_6(CO)_{12}]$ unit. Despite the fact that the formation of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ could appear to be the result of the addition of $CdCl_2$ to one triangular face of $[Ni_6(CO)_{12}]^{2-}$ followed by condensation of two of these units and loss of one $Cl^-$ ligand, according to Equation (1), this does not seem to be the case.

$$2\ [Ni_6(CO)_{12}]^{2-} + 2\ CdCl_2 \rightarrow \{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-} + Cl^- \quad (1)$$

In fact, careful study of the course of the reaction after the addition of $CdCl_2{\cdot}2.5H_2O$ in small portions to a solution of $[Ni_6(CO)_{12}]^{2-}$ indicates a more complex pathway. The first product formed is, in fact, the previously reported $[Ni_9(CO)_{18}]^{2-}$ anion,[17,18] which is the main species present in solution after the addition of ca. 0.5–1 equiv. of $CdCl_2{\cdot}2.5H_2O$. The formation of $[Ni_9(CO)_{18}]^{2-}$ can in principle arise by either the oxidation due to the $Cd^{2+}/Cd$ or the $H^+/H_2$ redox couple consequent to the Bronsted acidity of the water molecules that are coordinated to $Cd^{II}$. As detailed below in Section 2.4, the first oxidation of $[Ni_6(CO)_{12}]^{2-}$ irreversibly occurs at –0.22 V, and the oxidation potential is only slightly affected by the solvent and the nature of the electrode. By taking this potential and the standard redox potential in water of the $Cd^{2+}/Cd$ couple (–0.40 V) as very rough references, it may be suggested that reduction of $Cd^{II}$ to $Cd^0$ by $[Ni_6(CO)_{12}]^{2-}$ is not thermodynamically favoured. Therefore, the oxidation of $[Ni_6(CO)_{12}]^{2-}$ to $[Ni_9(CO)_{18}]^{2-}$ can probably be ascribed to the $H^+/1/2H_2$ redox couple brought about by the acidity of the coordinated water of the $CdCl_2{\cdot}2.5H_2O$ salt. Indeed, though the p$K_a$ of the hydrated $Cd^{II}$ ion is relatively high (10.1), it is known that $[Ni_6(CO)_{12}]^{2-}$ is converted into $[Ni_9(CO)_{18}]^{2-}$ and $[H_{4-n}Ni_{12}(CO)_{21}]^{n-}$ by weak protonic acids and even upon hydrolysis in neutral water.[20] Considering Equation (2), this process would require 0.67 mol of $CdCl_2{\cdot}2.5H_2O$ per mole of $[Ni_6(CO)_{12}]^{2-}$, in fair agreement with our experimental findings.

$$3\ [Ni_6(CO)_{12}]^{2-} + 2\ CdCl_2 + 2\ H_2O \rightarrow 2\ [Ni_9(CO)_{18}]^{2-} + H_2 + 2\ Cd(OH)Cl + 2\ Cl^- \quad (2)$$

Further addition of $CdCl_2{\cdot}2.5H_2O$ to the solution results in the formation of a new species that displays $\nu$(CO) in thf at 2036(vs) and 1824(ms) $cm^{-1}$. This species could not bet isolated and identified, as it was always obtained as a mixture with either $[Ni_9(CO)_{18}]^{2-}$ or $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$. Nonetheless, considering the fact that this species displays $\nu$(CO) at higher frequencies relative to both $[Ni_9(CO)_{18}]^{2-}$ and $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$, we speculatively assume that it could consist of an adduct between $[Ni_9(CO)_{18}]^{2-}$ and $CdCl_2$, probably featuring a $[Ni_9(CO)_{18}Cd_2Cl_4]^{2-}$ formula. Indeed, the species displays an IR spectrum almost coincident with that of the related $[Pt_9(CO)_{18}Cd_2Cl_4]^{2-}$ species, which was fully characterised.[16] Further addition of $CdCl_2{\cdot}2.5H_2O$, reaching the overall $Cd/Ni_6$ ratio of ca. 2 results in the complete conversion of this adduct into the final $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$. The suggestion that $[Ni_9(CO)_{18}]^{2-}$ is an intermediate during the formation of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ was examined by the reaction of $CdCl_2{\cdot}2.5H_2O$ with a preformed sample of $[Ni_9(CO)_{18}]^{2-}$ prepared by literature methods.[17,20] As shown by IR spectroscopic monitoring, this latter reaction occurs with elimination of $Ni_3(CO)_6$ moieties as $[Ni_3(CO)_6Cl]^-$, according to Equation (3). The $[Ni_3(CO)_6Cl]^-$ byproduct is very unstable and readily decomposes to Ni, chloride ions and $Ni(CO)_4$, which is indeed observed as the only carbonyl final byproduct:

$$2\ [Ni_9(CO)_{18}]^{2-} + 3\ CdCl_2 \rightarrow \{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-} + 2\ [Ni_3(CO)_6Cl]^- + CdCl^+ \quad (3)$$

The sum of Equations (2) and (3) suggests that the most plausible formal stoichiometry for the formation of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ requires 1.67 mol of $CdCl_2{\cdot}2.5H_2O$ per mole of $[Ni_6(CO)_{12}]^{2-}$, in fair agreement with the experimentally required ratio between the starting materials [Equation (4].

$$3\ [Ni_6(CO)_{12}]^{2-} + 5\ CdCl_2 + 2\ H_2O \rightarrow \{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-} + 2\ [Ni_3(CO)_6Cl]^- + CdCl_3^- + H_2 + 2\ Cd(OH)Cl \quad (4)$$

The fact that Ni carbonyl moieties are partially lost during this process explains why the yields based on Ni are not very high (ca. 60%). By considering the overall Equation (4), in fact, it is possible to conclude that the yield in $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ based on Ni cannot exceed 67%.

### 2.2 Crystal Structure of $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}{\cdot}thf$

The crystal structure of $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}{\cdot}$thf was ascertained by X-ray crystallography. The unit cell contains 6 cluster anions, 18 $[NBu_4]^+$ cations and 6 thf molecules. Some short contacts (below the sum of the van der Waals radii) exist between the carbonyl ligands of the cluster anions and the C–H groups of the $[NBu_4]^+$ cations and the thf molecules. Owing to the high symmetry of the $R\bar{3}c$ space group, only one sixth of one $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ anion, one half of $[NBu_4]^+$ and one thf molecule are independent. Moreover, both $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ and thf lay along the $\bar{3}$ axis, and they display some disorder. In particular, the thf molecule is disordered over six positions, the $[Ni_3(CO)_6]$ triangle bonded to Cd is disordered over three positions and the bridging Cl ligand is statistically disordered over six positions. All above positions are related by $\bar{3}$ symmetry and give an overall count of three chloride ligands and one thf molecule per cluster anion. As shown in Figure 1, the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ cluster can be described as being

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

composed of two $[Ni_6(CO)_{12}]^{2-}$ units joined by a $Cd_2Cl_3^+$ bridge. Therefore, $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ can be regarded as a Lewis acid–base adduct between the soft acid $Cd_2Cl_3^+$ and the soft basic sites of two $[Ni_6(CO)_{12}]^{2-}$ units, represented by the $Ni_3$ faces. Regarding the $[Ni_6(CO)_{12}]^{2-}$ units, these surprisingly display a distorted trigonal prismatic geometry, rather than the usual antiprismatic configuration found in the crystal structure of $[Ni_6(CO)_{12}]^{2-}$,[17] and for this it rather resembles the analogous platinum compound $[Pt_6(CO)_{12}]^{2-}$.[2,19] As shown in Table 1, which collects the most significant molecular parameters, the intratriangular Ni–Ni distances fall in the narrow range 2.349(6)–2.381(6) Å [average 2.366(10) Å], as previously found in $[Ni_6(CO)_{12}]^{2-}$ and $[Ni_9(CO)_{18}]^{2-}$.[17,18] Conversely, the intertriangular Ni–Ni distances span quite a wide range [2.416(4)–2.712(4) Å], showing also an unusually short contact; by comparison the average intertriangular distances is 2.77 Å in the antiprismatic cluster $[Ni_6(CO)_{12}]^{2-}$ and 2.766 Å and 2.719 Å for the antiprismatic and prismatic moieties of $[Ni_9(CO)_{18}]^{2-}$,[17,18] respectively. The unusually short Ni–Ni intertriangular distances displayed by $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ are due to its distorted trigonal prismatic structure. In particular, the distortion involves the inner triangle, which is slightly shifted and tilted with respect to the outer one, and this explains the very short Ni(1)–Ni(2) distance [2.416(4) Å]. As a consequence of this short bond, the diagonal contact of the corresponding distorted square face of the prism is quite shortened [Ni(2)–Ni(1)#1 2.982(5) Å] relative to the other diagonals [3.171(5)–3.854(4) Å]. Because the centre of the inner $Ni_3(CO)_6$ triangle is shifted with respect to the symmetry axis in which the Cd atom lies, three different Ni–Cd distances are present in the range 2.656(3)–2.802(4) Å. As far as we are aware, the only example of a structurally characterised molecule containing a Ni–Cd interaction is $Cp_2Ni_2Cd_3(GePh_3)_4$,[21] for which the bond lengths are 2.459 and 2.476 Å. The fact that the Ni–Cd bonds in $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ are considerably longer can be explained on the basis of the fact that in the latter the Cd atom is coordinated to a $Ni_3$ triangle probably by a 4c–2e bond, whereas it is connected to single Ni atoms in $Cp_2Ni_2Cd_3(GePh_3)_4$.

The $Cd_2Cl_3$ bridge shows a relatively short Cd–Cd distance [3.236(1) Å]. This contact is shorter than the Cd–Cd distances displayed by other compounds containing the $Cd_2(\mu\text{-}Cl)_3$ group [3.283–3.647 Å],[22] and even the loosest Cd–Cd contacts in metallic cadmium [3.286 Å]. Direct Cd–Cd bonds in molecular compounds, with distances below the sum of Pauling's single-bond metallic radii for cadmium [2.82 Å], are very rare and, as far as we are aware, the only two species structurally characterised so far are the $Cd^I$ derivatives of formula Ar′CdCdAr′ [Ar′ = $C_6H_3$-2,6-($C_6H_3$-2,6-*i*$Pr_3$)$_2$; Cd–Cd 2.6257(5) Å][23a] and $[Cd_2][AlCl_4]_2$ [Cd–Cd 2.576(1) Å].[23b] Therefore, even though the Cd–Cd contact in the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ anion is shorter than that in other $Cd_2(\mu\text{-}Cl)_3$ moieties, its length seems to argue against the presence of a significant direct bonding interaction. It may be speculated that electron donation from the $[Ni_6(CO)_{12}]^{2-}$ units would increase electron density onto the $Cd^{II}$ ions and may shorten the Cd–Cd distance, formally owing to their partial reduction. It is well-known that reduction of $Hg^{II}$ to $Hg^I$ results in the formation of a Hg–Hg bond.

The $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ cluster anions are pillared along the crystallographic *c* axis, forming infinite columns of perfectly alternating cluster anions and thf molecules (Figure 2). Viewing the packing of $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}$·thf along the crystallographic *c* axis (Figure 3) shows a perfect 2D hexagonal arrangements of these infinite columns, which are separated by the $[NBu_4]^+$ cat-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ions. Moreover, all the consecutive $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}\cdot$thf columns in this 2D arrangement are shifted along the *c* axis to optimise the crystal packing. The distance between the centroids of the outer $Ni_3(CO)_6$ triangles of two consecutive $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ cluster anions is 8.338 Å, whereas the analogous separation of the two inner triangles of the same anion is 7.893 Å, suggesting that replacement of the thf molecule with a second $Cd_2Cl_3^+$ bridge could result in the formation of a perfectly alternated copolymer.

Figure 2. View along the *b* axis of the crystal packing of $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}\cdot$thf.

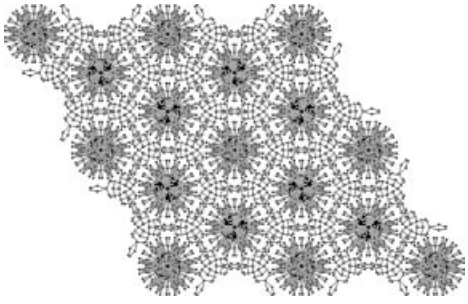

Figure 3. View along the *c* axis of the crystal packing of $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}\cdot$thf.

### 2.3. Reactivity of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$

With the aim to prepare the above-suggested alternating copolymer, the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ cluster was treated in thf with excess $CdCl_2$, but without any major success, apart from the formation of a small amount of an amorphous precipitate that was partially soluble only in dmf. IR spectra of the latter solution indicate the presence of uncoordinated $[Ni_6(CO)_{12}]^{2-}$. Because most of its salts are also well-soluble in less polar solvents, such as thf and acetone, the scarce solubility of the above material could be an indication of the formation of some Cd-rich copolymer containing intact $[Ni_6(CO)_{12}]^{2-}$ units, which is dismantled by dmf. ESI-MS spectra of dmf suspensions of this compound show the presence of $\{CdCl[Ni_6(CO)_{12}]\}^-$ (*m*/*z* = 836) and $[CdCl_3]^-$ (*m*/*z* = 219) ions, which could result from the fragmentation of a $\{Cd_2Cl_3[Ni_6(CO)_{12}]^-\}_\infty$ copolymer. The conclusion drawn from electrochemical studies of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ (see next section) did not encourage further attempts to prepare $\{Cd_2X_3[Ni_6(CO)_{12}]^-\}_\infty$ copolymers, as evidently the presence of Ni–Ni, Ni–Cd and chloride bridges (and perhaps, incipient Cd–Cd bonds) is not sufficient to guarantee electron communication between the $Ni_6(CO)_{12}$ moieties and, therefore, should not enable relevant electron conduction along the intertriangular axis.

The reaction of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ with [TBA]Cl results in the formation of $[Ni_6(CO)_{12}]^{2-}$ as outlined in Equation (5).

$$\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-} + 5\ Cl^- \rightarrow 2\ [Ni_6(CO)_{12}]^{2-} + 2\ CdCl_4^{2-} \quad (5)$$

This is a further indication of the acid–base interaction existing in $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$, which is broken because of the attack of the Lewis base $Cl^-$ at $Cd^{II}$.

Finally, $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ is nearly completely decomposed by a CO atmosphere into $Ni(CO)_4$ and $Cd^{II}$ salts. By carrying out the CO-induced decomposition of $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ in thf, the formation of very small amounts of a brown precipitate was noticed. This is soluble in acetonitrile and displays *ν*(CO) at 1983(s) and 1798(m) $cm^{-1}$, fairly similar to those of the $[Ni_6(CO)_{10}(In_2Br_5)_2]^{4-}$ species [*ν*(CO) 1976(s) and 1784(m) $cm^{-1}$], which was previously obtained from the reaction of $[Ni_6(CO)_{12}]^{2-}$ with $InBr_3$.[24] Its very meagre yields hampered further characterisation.

Aiming to extend the chemistry of bimetallic Ni–Cd carbonyl clusters, the reactions of $[Ni_6(CO)_{12}]^{2-}$ with other $Cd^{II}$ salts, such as $CdF_2$, $CdI_2$ and $[Cd(H_2O)_6][BF_4]_2$, were investigated. No reaction at all was observed with $CdF_2$, whereas the other two reactions on the basis of IR monitoring completely parallel those with $CdCl_2$. Thus, the final products can be formulated as $\{Cd_2I_3[Ni_6(CO)_{12}]_2\}^{3-}$ [*ν*(CO) in thf at 2021(s), 1846(m) and 1822(m) $cm^{-1}$] and $\{Cd_2(OH)_3[Ni_6(CO)_{12}]_2\}^{3-}$ [*ν*(CO) in thf at 2030(s), 1841(m) and 1819(m) $cm^{-1}$].

### 2.4. Electrochemical Studies

Figure 4 shows the redox activity of the trianion $[Cd_2Cl_3\{Ni_6(CO)_{12}\}_2]^{3-}$ in thf solution.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

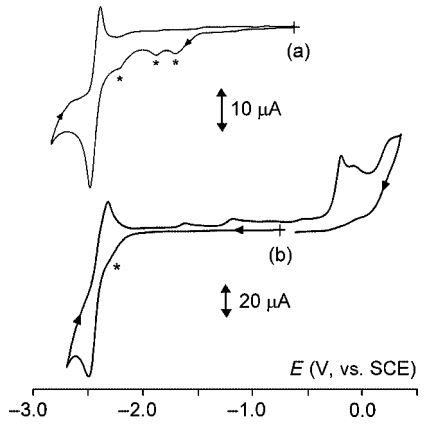

Figure 4. Cyclic voltammograms recorded at a gold electrode in thf solution of: (a) $[NBu_4]_3[Cd_2Cl_3\{Ni_6(CO)_{12}\}_2]$ ($1.7 \times 10^{-3}$ mol dm$^{-3}$); (b) $[NBu_4]_2[Ni_6(CO)_{12}]$ ($2.8 \times 10^{-3}$ mol dm$^{-3}$). $[NBu_4][PF_6]$ (0.2 mol dm$^{-3}$) supporting electrolyte. Scan rate 0.2 V s$^{-1}$.

Apart from a few unidentified processes (asterisked peaks) probably due to minor traces of impurities, the cyclic voltammogram exhibits one reduction, which displays features of partial chemical reversibility in the cyclic voltammetric timescale. In fact, analysis of the cyclic voltammetric responses with scan rates varying from 0.02 to 1.00 V s$^{-1}$ showed that the current ratio $i_{pa}/i_{pc}$ is about 0.7 at the lowest scan rate and progressively increases up to about 0.9 at the highest scan rate. Concomitantly, the peak-to-peak separation tends to increase progressively from 64 to 180 mV, and the current function $i_{pc}v^{-1/2}$ decreases by about 10% for a 10-fold increase in the scan rate. Such parameters are diagnostic for a (substantially) electrochemically reversible electron transfer coupled to slow chemical complications.[25] Unfortunately, the very negative potential value of such a cathodic process ($E°'$ = –2.43 V, vs. SCE) prevented any reliable coulometric determination of the number of electrons involved.

To better define the nature of such a process, it seemed useful to look at the redox properties of the precursor dianion $[Ni_6(CO)_{12}]^{2-}$. As illustrated in Figure 4b, the voltammogram exhibits two main irreversible oxidations ($E_{pa}$ = –0.22 and +0.25 V, respectively), and one reduction displaying features of chemical reversibility in the cyclic voltammetric timescale ($E°'$ = –2.41 V, vs. SCE), which is quite reminiscent of the cathodic process exhibited by $[Cd_2Cl_3\{Ni_6(CO)_{12}\}_2]^{3-}$.

Cyclic voltammetric tests recorded in correspondence of the first anodic step at scan rates varying from 0.02 to 2.00 V s$^{-1}$ showed that the process is rather complex, in that at high scan rates it splits into two separate processes, whereas the close-spaced minor peak ($E_{pa}$ = –0.08 V) tends to disappear. In addition, no directly associated response was detected in the backscan even at the highest scan rate.

Controlled potential coulometry ($E_w$ = 0.0 V) afforded a sudden decline in the electrolysis current after the consumption of about 0.6–0.7 electrons per molecule. Therefore, even if the process seems affected by electrode poisoning effects probably caused by electrogenerated byproducts, it does not seem too ventured to assign it as a one-electron step. Interestingly, a cyclic voltammogram recorded on the solution resulting from the incomplete exhaustive oxidation showed a quite untouched cathodic pattern, thus indirectly supporting that, as reported above, the dimeric trianion $[Cd_2Cl_3\{Ni_6(CO)_{12}\}_2]^{3-}$ arises from chemical oxidation of $[Ni_6(CO)_{12}]^{2-}$.

Also in this case, analysis of the cathodic cyclic voltammetric responses with scan rates varying from 0.02 to 1.00 V s$^{-1}$ showed that: (1) the current ratio $i_{pa}/i_{pc}$ is about 0.7 at the lowest scan rate and progressively increases up to about 0.9 at the highest scan rate, (2) the peak-to-peak separation tends to increase progressively from 75 to 165 mV and (3) the current function $i_{pc}v^{-1/2}$ decreases by about 10% for a 10-fold increase in the scan rate. In both cases, Osteryoung square-wave voltammetry did not appreciably improve the resolution of the voltammetric profiles.

On the basis of the above-mentioned coulometric measurements on the oxidation process of the monomeric dianion (which in cyclic voltammetry exhibits a peak-height substantially similar to that of the cathodic step), on the widths of the square wave peaks at half height (at 25°, $\Delta E_{p/2} = 126/n$ (mV),[25] which are 129 mV for $[Ni_6(CO)_{12}]^{2-}$ and 91 mV for $[Cd_2Cl_3\{Ni_6(CO)_{12}\}_2]^{3-}$, and upon the fact that, under the same concentrations, the peak height of the dimer is about two times that of the monomer, we assign the reduction processes as a one-electron step in the case of the monomeric dianion and as a two-electron step in the case of the dimeric trianion. On this basis, it seems plausible to deduce that the two $[Ni_6(CO)_{12}]$ subunits in $[Cd_2Cl_3\{Ni_6(CO)_{12}\}_2]^{3-}$ are electronically noninteracting.

## 3. Conclusions

The work reported in this paper confirms the Lewis base donor ability of the triangular faces of the clusters $[M_{3n}(CO)_{6n}]^{2-}$ (M = Ni, Pt) and the possibility of exploiting it to obtain oligomers and polymers based on MCC.[16] The use of soft Lewis acids is of paramount importance to address the reaction directly on the metal core of the MCC, rather than on the harder basic sites represented by the CO ligands. These reactions result in new direct heteronuclear M–M′ bonds that, together with ancillary bridging halides ligands M′–$X_n$–M′, cooperate at the formation of oligomers or polymers held together by M–M′–$X_n$–M′–M bridges.

The formation of the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ dimer indicates some important differences between the reactions of $[Ni_6(CO)_{12}]^{2-}$ and $[Pt_6(CO)_{12}]^{2-}$ with $CdCl_2$. In both cases, the reactions first proceeds by oxidation of $[M_6(CO)_{12}]^{2-}$ (M = Ni, Pt) to give $[M_9(CO)_{12}]^{2-}$ followed by addition of the Lewis acid to the metal frame of the cluster and resulting in the formation of the adducts $[M_9(CO)_{18}Cd_2Cl_4]^{2-}$. Nonetheless, when M = Pt, this adduct is stable and it self-assembles upon crystallisation into a 1D $\{[Pt_9(CO)_{18}(\mu_3\text{-}CdCl_2)_2]^{2-}\}_\infty$ polymer by the formation of chloride brid-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ges.[16] Conversely, the nickel analogue loses very easily a $[Ni_3(CO)_6Cl]^-$ unit and is transformed into the $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ dimer. Intrinsically weaker Ni–Ni bonds relative to the Pt–Pt bonds and increasing intraunit steric repulsion between the carbonyl groups upon dimerisation may account for the observed difference.

The different products isolated in the case of Ni and Pt, i.e. $\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}^{3-}$ and $\{[Pt_9(CO)_{18}(\mu_3\text{-}CdCl_2)_2]^{2-}\}_\infty$, display two alternative bridging modes of the $Cd^{II}$ chloride derivatives, i.e. $[Cd(\mu\text{-}Cl)_3Cd]^+$ and $Cd(Cl)(\mu\text{-}Cl)_2Cd(Cl)$, and suggest that $CdCl_2$ can be a versatile reagent used to assemble MCC.

The redox condensation of $[Ni_6(CO)_{12}]^{2-}$ with halides $MX_n$ of transition metals (e.g. Fe, Co, Rh, Pd, Pt, Cu, Ag, Au) and main group elements (e.g. C, Ge, Sn, Sb, Bi) has been widely exploited to obtain bi- and heterometallic MCC.[1,26] The formation of acid–base adducts, i.e. $[Ni_6(CO)_6(\mu_3\text{-}CO)_5(\mu_3\text{-}InBr_3)(\eta^2\text{-}\mu_6\text{–}In_2Br_5)]^{3-}$, $[Ni_{12}(CO)_{12}(\mu\text{-}CO)_{10}(\mu_6\text{-}In)(\eta^2\text{-}\mu_6\text{–}In_2Br_4OH)]^{4-}$ and $[Ni_6(CO)_{11}(In_2Br_5)_2]^{4-}$,[24] was previously observed only in the case of $InX_3$. This can be explained by the fact that both $Cd^{II}$ and $In^{III}$ are electropositive elements quite difficult to reduce, which form very weak homometallic bonds and with a high affinity for halides

Electrochemistry suggests that the two $[Ni_6(CO)_{12}]$ subunits present in the dimer are electronically independent. Attempts will be made in the future to replace the bridging $Cd_2Cl_3$ fragment with proper units that might favour the electronic interactions between the two peripheral clusters.

## Experimental Section

**General:** All reactions and sample manipulations were carried out by using standard Schlenk techniques under an atmosphere of nitrogen and in dried solvents. The $[Ni_6(CO_{12}]^{2-}$ and $[Ni_9(CO)_{18}]^{2-}$[17,18] salts were prepared according to the literature. Analysis of Ni and Cd were performed by atomic absorption with a Pye-Unicam instrument. Analyses of C, H and N were obtained with a ThermoQuest FlashEA 1112NC instrument. IR spectra were recorded with a Perkin–Elmer SpectrumOne interferometer in $CaF_2$ cells. ESI mass spectra were recorded with a Waters Micromass ZQ4000 instrument. Cyclic voltammetry was performed in a three-electrode cell containing a platinum working electrode surrounded by a platinum-spiral counter electrode, and an aqueous saturated calomel reference electrode (SCE) mounted with a Luggin capillary. A BAS 100W electrochemical analyser was used as the polarising unit. All the potential values are referred to the saturated calomel electrode (SCE). Under the present experimental conditions, the one-electron oxidation of ferrocene occurs at $E°' = +0.59$ V in thf solution. Controlled potential coulometry was performed in an H-shaped cell with anodic and cathodic compartments separated by a sintered-glass disk. The working macroelectrode was a platinum gauze; a mercury pool was used as the counter electrode. Structure drawings were performed with SCHAKAL99.[27]

**$[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}$:** $CdCl_2·2.5H_2O$ (0.82 g, 3.59 mmol) was added in portions to a solution of $[NBu_4]_2[Ni_6(CO)_{12}]$ (2.01 g, 1.71 mmol) in thf (40 mL) with stirring. The mixture was left to react for 2 h, and the resulting dark red solution was evaporated to dryness. The residue was washed with water (40 mL) and extracted into thf (30 mL). Precipitation by slow diffusion of *n*-hexane (50 mL) gave a red crystalline precipitate composed of crystals of $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}$·thf (yield 1.32 g, 61.5% based on Ni). The salt is soluble in thf, acetone, acetonitrile, dmf and dmso, sparingly soluble in alcohols and insoluble in nonpolar solvents. IR (thf, 293 K): $\tilde{\nu}$ = 2025 (vs), 1844 (m), 1819(m) $cm^{-1}$. $C_{76}H_{116}Cd_2Cl_3N_3Ni_{12}O_{25}$ (2507.39): calcd. C 36.41, H 4.66, N 1.68, Ni 28.09, Cd 8.97; found C 36.28, H 4.82, N 1.56, Ni 27.95, Cd 9.02.

**X-ray Crystallographic Study:** Crystal data and collection details for $[NBu_4]_3\{Cd_2Cl_3[Ni_6(CO)_{12}]_2\}$·thf are reported in Table 2. The diffraction experiments were carried out with a Bruker APEX II diffractometer equipped with a CCD detector using Mo-$K_\alpha$ radiation. Data were corrected for Lorentz polarisation and absorption effects (empirical absorption correction SADABS).[28] Structures were solved by direct methods and refined by full-matrix least-squares based on all data using $F^2$.[29] Hydrogen atoms were fixed at calculated positions and refined by a riding model. All non-hydrogen atoms were refined with anisotropic displacement parameters, unless otherwise stated. The $[Ni_3(CO)_6]$ unit bonded to Cd is disordered over three equally populated positions related by symmetry; similarly, the bridging chloride atom is disordered over two symmetry-related positions. Finally, the thf molecule appears disordered around the $\bar{3}$ axis over six symmetry-related positions. Only the independent part of the disordered groups were refined by using the following occupancy factors: 0.33333 for $[Ni_3(CO)_6]$, 0.5 for Cl(1) and 0.16667 for thf. The overall occupancy for each group is one, after applying the related symmetry operations. All the disordered atoms were refined isotropically, except the three Ni and the Cl atoms which were refined anisotropically. Restraints were applied to the C–O distances of the anion, the C–N and C–C dis-

# Silicon–Phosphorus and Silicon–Arsenic Cage Compounds with Bicyclo[2.2.1]heptane, Bicyclo[3.2.1]octane and Tricyclo[3.3.3.1.0$^{3,7}$]nonane Backbones

**Günter Tekautz,[a] Judith Baumgartner,[a] Alk Dransfeld,[a] and Karl Hassler*[a]**

**Keywords:** Cage compounds / Crystal structures / Ab initio calculations / Silicon

The reaction of tris(chlorodimethylsilyl)methylsilane (**1**) and 1,1,2,2-tetrakis(chlorodimethylsilyl)-1,2-dimethyldisilane (**2**) with sodium/potassium arsenide $Na_3As/K_3As$ afforded decamethyl-2,3,5,6,7-pentasila-1,4-diarsabicyclo[2.2.1]heptane (**3**) and dodecamethyl-2,3,4,6,7,8,9-heptasila-1,5-diarsatricyclo-[3.3.1.0$^{3,7}$]nonane (**4**). Compounds **3** and **4** were isolated from the reaction mixture by fractional crystallization and structurally characterized by single-crystal X-ray crystallography. The reaction of **1** with an excess amount of sodium/potassium phosphide ($Na_3P/K_3P$) afforded the cage-shaped anion sodium hexamethyl-2,4,6,7-tetrasila-1-phosphanido-3,5-diphosphabicyclo[3.2.1]octane (**5**), which reacts with chlorotrimethylsilane to form trimethylsilyl-substituted derivative **6**. The molecular structures of **5** and **6** were established by X-ray crystallography. Cages **3**–**6** were also characterized by $^{29}$Si- and $^{31}$P NMR spectroscopy. Owing to indirect spin–spin coupling between the $^{29}$Si and $^{31}$P nuclei, the resonances of the $^{29}$Si nuclei in the spectra of **5** and **6** are only of first order approximately. To account for the observed preferences of the cage structures in these reactions, extensive B3LYP/6-31G* quantum chemical calculations of relative energies of bicyclo[2.2.2] and bicyclo[3.2.1] isomers of $Si_8H_{14}$, $PSi_7H_{13}$, $P_2Si_6H_{12}$ and $P_3Si_5H_{11}$ were conducted. On the basis of the computed charge distributions, the concept of topological charge stabilization was used to predict the relative stabilities.

## Introduction

The exceptional tendency of the elements silicon (group 14) and phosphorus (group 15) to form rings and cages is well-known and has been reviewed extensively in the past.[1] Much less experimental and theoretical material is available for the heavier elements of these two groups, which are Ge, Sn and Pb and As, Sb and Bi, respectively. As the metallic character of the elements increases with increasing atomic number, the thermal stability of $E_nR_m$ (where R is an organic substituent, for example) decreases considerably. They easily decompose into the metal, thereby forming R–R bonds, as shown in Equation (1). Flasks with metallic-black coatings are a common sight with this type of chemistry.

$$E_nR_m \rightarrow E_{metal} + m/2\ (R_2) \quad (1)$$

It is clear that rings and cages composed of elements of both group 14 and 15 (for instance Si and P, As, Sb or Bi) will behave similarly in this respect. An important difference, however, is in the polar bonds that are present in these cage compounds as a result of the electronegativity difference between the two elements. Not only does this lead to increased chemical reactivity, but also to interesting electronic effects. For instance, in small ring systems such as 1,3-disiladiphosphabicyclobutanes, the ring-strain energy is considerably increased by the electropositive Si atoms, which is reflected in a unusually large P–P distance of 238 pm.[2] Moreover, cage compounds that are composed of elements from group 15 and silicon that also possess Si–Si bonds show unusual electronic interactions between the lone pairs of electrons of the group 15 element and the Si–Si σ electrons. A n→σ* interaction was shown by NBO ab initio calculations and photoelectron spectra of dodecamethyl-2,3,5,6,7,8-hexasila-1,4-diphosphabicyclo[2.2.2]-octane to be responsible for these interactions. X-ray analysis of the molecular structure confirmed the increased Si–Si bond length in the cage, which is reported as 235.9 and 236.3 pm.[3,4] Normal Si–Si bond lengths are 232–234 pm.

Previously, we have reported on the synthesis and molecular structure of decamethyl-2,3,5,6,7-pentasila-1,4-dibismuthabicyclo[2.2.1]heptane from $Na_3Bi/K_3Bi$ and dichlorodimethylsilane,[5] which decomposes quickly at room temperature forming metallic bismuth. We also reported the synthesis and structure of decamethyl-2,3,5,6,7-pentasila-1,4-diphosphabicyclo[2.2.1]heptane from $Na_3P/K_3P$ and 1,2-dichlorotetramethyldisilane.[4] These syntheses show that in the reactions between sodium/potassium pnictides and halogenated mono- and oligosilanes, Si–Si bonds are not only cleaved, but new bonds are formed depending on

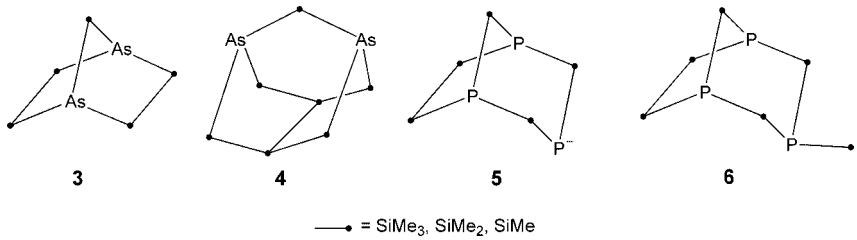

Figure 1. Cage compounds prepared in this work.

the reaction conditions. This was also reported for the reaction of $t$BuSi($SiMe_2Cl$)$_3$ with $LiPH_2$, which resulted in the formation of a hexasila-1,5-diphosphabicyclo[3.2.1]octane.[6]

These findings prompted us to not only use halogenated isotetrasilanes but larger oligosilanes as well to form novel cage compounds. Moreover, by varying the stoichiometric ratio between the halosilane and the sodium/potassium pnictide, we expected the formation of novel anionic species with cage-like structures. We were pleased to learn that this is indeed possible. Herein we report the synthesis of hitherto unknown silicon–arsenic cages **3** and **4** as well as anionic silicon–phosphorus cage **5** and its trimethylsilyl derivative **6** as shown in Figure 1 starting from the oligosilanes MeSi($SiMe_2Cl$)$_3$ (**1**) and ($SiMe_2Cl$)$_2$MeSiSiMe($SiMe_2Cl$)$_2$ (**2**) and $Na_xP/K_xP$ or $Na_xAs/K_xAs$.

## Results and Discussion

### Synthesis

As mentioned in the introduction, the products formed in the reactions between sodium/potassium pnictides and multiply halogenated oligosilanes depend strongly on the reaction conditions, and the largest influence comes from the solvent that is used. In polar solvents such as dimethoxyethane (dme), Si–Si bonds of the oligosilane are broken and reformed to a certain extent to give -E$SiMe_2$E- and even -E$Me_2$Si$SiMe_2$E atom arrangements when MeSi($SiMe_2Cl$)$_3$ is used. Even traces of ($SiMe_2$)$_6$ can be detected in the reaction mixtures with $^{29}$Si NMR spectroscopy. Of course, considerable quantities of polymers are also formed in these reactions. Whereas insoluble polymers are removed in the workup process, the soluble fraction may severely hamper successful crystallization of the cage compounds. We also found that the quantities of polymers that are formed are much larger for arsenic compounds than for phosphorus compounds, which we attribute to the much greater reducing power of sodium/potassium arsenide. So far, no systematic experimental studies on the influence of the solvent and the pnictogen/alkali metal ratio on the product distribution of these reactions have been described.

The mechanisms of these reactions are not known. The formation of silylenoide species $Me_2SiNaCl$ or dimethylsilylene, $SiMe_2$, as intermediates through Si–Si bond cleavage seems plausible. For instance, the formation of such species is thought to play a major role during the reduction of dichlorodimethylsilane with alkali metals.[7]

The silylenes can then insert into Si–Si, Si–P, Si–As or Si–Cl bonds to give a plethora of compounds. When $Na_3As/K_3As$ reacts with **1** at r.t., cage **3** can be isolated in about 5% yield. We did not attempt to optimize the reaction conditions. Cage **3** is not the only cage that forms under these conditions, because in the $^{29}$Si NMR spectrum of the reaction mixture we observed, besides the signal of hexasila-1,4-diarsabicyclo[2.2.2]octane, three resonances at –70.0, –17.1 and 5.0 ppm, which we attribute to an adamantane-like structure, as shown in Figure 2. So far, we were unable to purify this compound by crystallization. In this molecule, the $Si_4$ atom arrangement of **1** is still present.

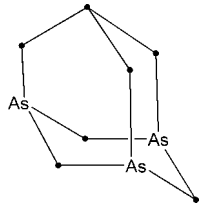

Figure 2. Proposed structure for adamantane $As_3Si_7Me_{13}$.

When $Na_3As/K_3As$ reacts with **2**, tricyclononane **4** forms in about 5% yield and can be separated by crystallization. Here again we performed no optimization of the reaction conditions. From the $^{29}$Si NMR spectra it can be concluded that there are other cage compounds present in the reaction mixture, such as bicycloheptane **3**, which can be identified unambiguously. So far, all attempts to isolate other cage compounds by fractional crystallization have failed.

Noteworthy is that the tricyclononane structure established for **5** by X-ray diffraction can also be found as $P_9$ groups (alternating with $P_8$ groups) in Hittorf's violet monoclinic phosphorus allotrope, as shown in Figure 3.[8] Recently, the crystal structure of a fibrous variation of violet phosphorus, which also contains the $P_8$ and $P_9$ units, was reported.[9] For us, the $P_2Si_7$ cage (analogous to **4**) and the

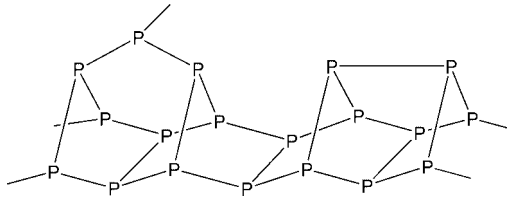

Figure 3. $P_9$ and $P_8$ substructures in violet phosphorus and in its fibrous variation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tricyclooctanes $E_2Si_6$ (E = As, P) analogous to $P_8$ are tempting synthetic targets that we are currently pursuing by reaction of **2** with $Na_3E/K_3E$ under various conditions.

When a suspension of an excess amount of $Na_3P/K_3P$ in dme is added to a solution of **1** in dme heated at reflux, anionic cage **5** can be separated by crystallization from pentane/dme. As a byproduct, decamethyl-2,3,5,6,7-pentasila-1,4-diphosphabicyclo[2.2.1]heptane is formed in considerable quantities.

## X-ray Crystallography

Crystals of cages **3**, **4**, **5** and **6** in a quality suitable for X-ray experiments could be obtained as described in the Experimental Section. Figure 4 presents the molecular structures of these compounds, and Table 1 summarizes selected bond lengths and bond angles by employing the numbering scheme of Figure 4. The molecular symmetry of all four molecules is $C_s$, characterized by a mirror plane bisecting the cages.

The Si–As and Si–P bond lengths are all within the expected range found in acyclic silylphosphanes and their arsenic analogues. Si–Si distances are longer than the normal 232–234 pm by about 30 pm for P cages **5** and **6**, and by about 10 pm for arsenic cage **3**, which reflects the decreasing n→σ* interaction of arsenic relative to phosphorus. The Si(2)–Si(3) bond length in **4** is in the normal range because just one As atom is available for this interaction. The central Si–Si bond in **4** is somewhat longer (235.2 pm), which certainly is due to steric reasons.

Table 1. Selected bond lengths [pm] and bond angles [°] for **3**, **4**, **5** and **6**.

| | **3** | **4** | **5** | **6** |
|---|---|---|---|---|
| Si(1)–E(1) | 236.73(9) | 237.19(16) | 224.83(30) | 226.25(11) |

| Si(4) | | | | | | | 2.4 | 0 | 0 | 39.8 |
| P(1) | | | –247.1 | | | 2.1 | –238.9 | | | 8.3 |
| P(2) | | | –261.9 | | | | –231.0 | | | |

just two signals for **3** and three signals for **4**. Table 2 summarizes the $\delta(^{29}Si)$ values with reference to the atom numbers that are used in Figure 4.

The spectra of phosphorus cages **5** and **6** are different, as not all signals are necessarily of first order as a result of indirect spin–spin coupling between the $^{29}Si$ and $^{31}P$ nuclei. For instance, Si(2) is part of an ABX system with $\delta(A) \approx \delta(B)$ because the shift differences between P(1) and P(1′) is due to isotopic effects only. The ABX system itself is weakly coupled to phosphorus atom P(2). From spectra simulations with various fixed values for $^2J_{P1,P1'}$ it is quickly deduced that this coupling constant must be quite small (<2–4 Hz), and that the spectra can be evaluated by using first-order rules to a very good accuracy. The g NMR software package was used for this purpose.

Figure 5 presents the measured $^{29}Si$ NMR spectra of **5** (top left) and **6** (top right), as well as the simulated spectra. The spectrum of **5** consists of a triplet of doublets for Si(1) at +17ppm, a doublet of doublets for Si(3) at +5 ppm and doublet of doublets of doublets for Si(3) at –4 ppm. The spectrum for **6** is very similar except that the resonance for Si(4) (the $SiMe_3$ group) overlaps the multiplet of Si(3). A view of the expanded spectrum for **6** is given at the bottom of Figure 5 and illustrates the effects of two- or three-bond couplings. All chemical shifts and coupling constants, treating all spectra as first order, are presented in Table 2.

The Si,P coupling constants of **5** and **6** are very similar, except between Si(3) and P(2). In anionic cage **5**, a $J$ value of 81.4 Hz was measured, but this value was only 49.5 Hz in cage **6** where the negative charge is replaced by the trimethylsilyl group. Bond lengths P(2)–Si(3), which are 218.7 and 226.1 pm, respectively (Table 1), are also quite different. A shortening of the Si–P bonds by 6–10 pm upon substitution of a $SiMe_3$ group with a negative charge is also observed for $P(SiMe_3)_3$ and the phosphanides $MP(SiMe_3)_2$, M = K, Rb and Cs.[10,11]

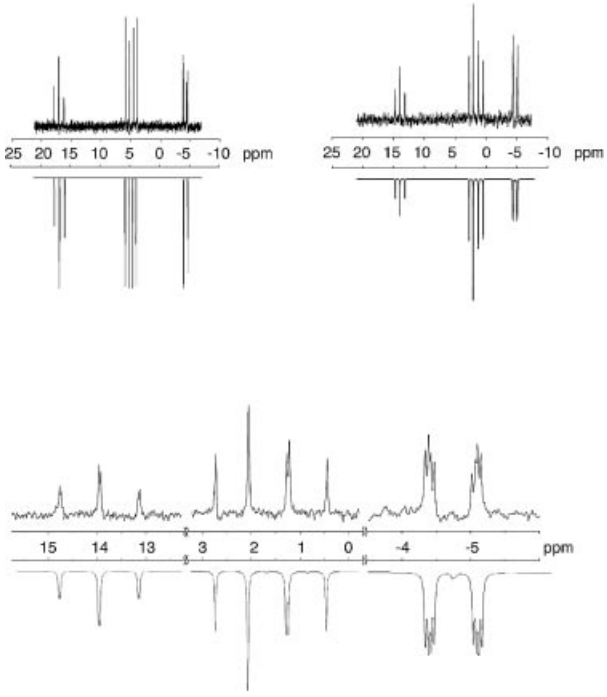

Figure 5. Proton decoupled $^{29}Si$ NMR spectra of **5** (top left) and **6** (top right), including simulated spectra shown with negative intensities. An expanded spectrum of **6** is presented at the bottom and illustrates the splitting due to two- and three-bond $^{29}Si,^{31}P$ couplings.

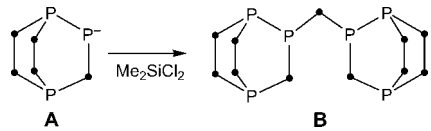
## Ab Initio Calculations

The number of different anionic species that are present in the "Zintl phases" prepared from the elements P or As and sodium/potassium alloy in a solvent such as dme is unknown. Most certainly, not all P–P or As–As bonds are broken in this reaction, and an equilibrium between the various anions is established depending on the stoichiometric ratio of phosphorus/alkaline metals used. For instance, $(Me_3Si)_2PP(SiMe_3)_2$ and $P_7(SiMe_3)_3$ are just two minor by-products in the synthesis of $P(SiMe_3)_3$ from "$Na_3P/K_3P$" and $Me_3SiCl$. An even larger variety of $Si_mP_n$ frameworks can be formed when Si–Si bonds in reagents **1** and **2** are broken under the attack by "$Na_3P/K_3P$". Because only a few of the potential species are observed, the question arises whether the obtained product distribution can be deduced from simple considerations. Cages such as diphosphabicyclo[2.2.1]heptanes and diphosphabicyclo[2.2.2]octanes are prevalent in the reaction mixtures, whereas triphosphabicyclo[2.2.2]octanes A or B shown in Scheme 1 do not form at all in the reaction with $Me_2SiClSiClMe_2$ or $Me_2SiCl_2$.



Scheme 1. Cages that are not formed.

Because the major products obtained experimentally comprise eight second-row atoms, the computational study focuses on bicyclic $Si_8$, $PSi_7$, $P_2Si_6$ and $P_3Si_5$ structures. Our approach to rationalize the observations is the concept of topological charge stabilization advocated by Gimarc 20 years ago.[12] It predicts that by replacing a silicon atom in one of the $Si_nP_m$ cages by an atom of higher electronegativity, P, at the site with the highest electron density leads to the most stable isomer.

We first calculated minimum structures, energies and Mulliken charges for the isomeric $Si_8H_{14}$ structures. The five lowest-energy isomers are shown in Figure 6 together with the Mulliken charge of the Si atom possessing the highest electron density. Replacing it by P should result in the best $PSi_7H_{13}$ structure. Only the two best homonuclear frameworks, the bicyclo[2.2.2] and bicyclo[3.2.1] cages that differ by just 0.9 kJ mol$^{-1}$, are considered in the further replacement study.[13] With a value of about 40 kJ mol$^{-1}$, the relative energies of the bicyclo[4.2.0] and bicyclo[4.1.1] structures are large. The bicyclo[5.1.0] cage has an even higher energy of 117 kJ mol$^{-1}$. These large values can be used to rationalize why we never observed their formation.

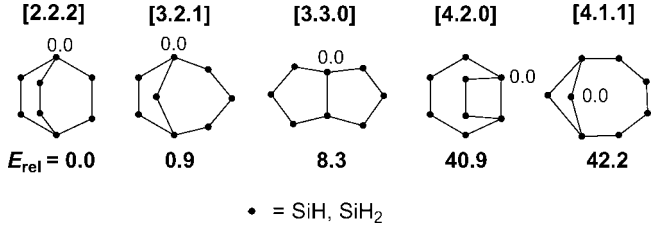

Figure 6. Relative energies [kJ mol$^{-1}$] of bicyclic $Si_8H_{14}$ isomers and the position of the Si atom possessing the smallest Mulliken charge. Relative energies are given for the most favourable stereoisomer or conformer. A dot represents a $SiH_2$ or SiH group.

As shown in Figure 7 (1st row), the relative energies of the two bicyclo[2.2.2] and the three bicyclo[3.2.1] topomers of $PSi_5H_{13}$ demonstrate the validity of the Gimarc rule. The Mulliken charges (the position with the smallest value is indicated in Figure 7) predict that the diphospha[2.2.2] and diphospha[3.2.1] cages with P atoms in 1,4- and 1,5-positions will be preferred, which is just what we observed in numerous experiments. In the second row of Figure 7, the relative energies of the two sets of $P_2Si_6H_{12}$ topomers are presented, again confirming the predictions of the Gimarc rules.

Although the bicyclo[2.2.2] structure is higher in energy than bicyclo[3.2.1] by 6.7 kJ mol$^{-1}$, both are considered in the final replacement for obtaining the energies of the triphospha cages. The results are summarized in the third row of Figure 7. The charge distribution in bicyclo[2.2.2] $P_2Si_6H_{12}$ clearly suggests that the 1,2,4-triphospha isomer will be preferred. Consequently, its energy relative to the 1,2,3- and 1,2,6-triphospha isomer is predicted to be lower by more than 45 kJ mol$^{-1}$. The situation is less clear for the bicyclo[3.2.1] framework, because in the lowest energy isomer the two smallest atomic charges differ by merely 0.01 units. According to Gimarc's rule, the 1,3,5- and the 1,5,8-

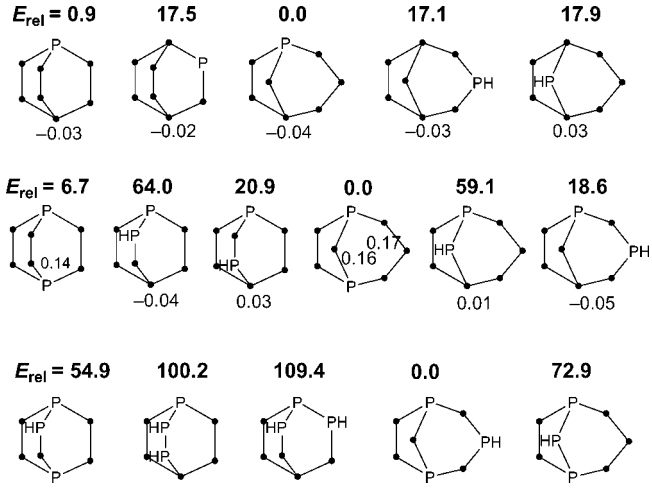

Figure 7. Relative energies [kJ mol$^{-1}$] of the bicyclic $PSi_7H_{13}$, $P_2Si_6H_{12}$ and $P_3Si_5H_{11}$ isomers, and the position of the Si atom possessing the smallest Mulliken charge. Relative energies are given for the most favourable stereoisomer or conformer.

isomer are predicted to possess very similar energies, and both should be present in the reaction mixture. Nevertheless, the charges in the second best structure indicate that the 1,3,5-$P_3Si_5$ backbone is preferred. The calculated relative energy of 72.9 kJ mol$^{-1}$ for the 1,5,8-structure provides clear preference for 1,3,5-isomer, which is what we found in the experiment.

Our ab initio calculations indicate that isomers with P–P bonds generally have higher energies. This agrees with the lack of observation of these isomers in the synthesis. Owing to $^{31}P,^{31}P$ one bond coupling, their presence would have been detected very easily by using NMR spectroscopy.

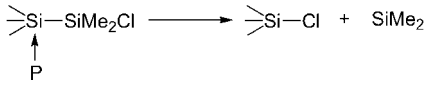
The general conclusion that the polar Si–P bond is favoured over the nonpolar Si–Si as well as the P–P bond was quantified by the comparative calculation of two saturated $P_2Si_2H_8$ isomers. $H_3Si–SiH_2–PH–PH_2$ has a relative energy of 32.8 kJ mol$^{-1}$ with respect to $H_3Si–PH–SiH_2–PH_2$, which both have the same number of Si–H and P–H bonds. In conclusion, the Si–P bond is favoured by about 16 kJ mol$^{-1}$ over a Si–Si or a P–P bond in phosphasilanes. Analysis of all investigated cage isomers deposited at nmr-sharc.tugraz.at shows that the relative energies are positively related to the $(n_{SiSi} + n_{PP})/n_{SiP}$ ratio, where $n_{SiSi}$, $n_{PP}$ and $n_{SiP}$ are the number of Si–Si, P–P and Si–P bonds, respectively. Therefore, it can be generalized that cage isomers with a maximum number of Si–P bonds will be energetically preferred.

## Conclusions

In the present publication we showed that by reaction of sodium/potassium phosphide and arsenide with chlorooligosilanes containing $SiMe_2Cl$ end groups, anionic and neutral cage compounds containing E–$SiMe_2$–E and E–$SiMe_2$–$SiMe_2$–E atom arrangements can be obtained. A plausible reaction mechanism explaining Si–Si bond cleavage involves dimethylsilylene as a reaction intermediate. In that case, a donor interaction with a P atom on the surface of the solid

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

must be assumed. Noteworthy, chlorodisilanes disproportionate by such a donor mechanism in the presence of amines, even in heterogeneous phase.[14]



The preferred formation of 1,4-diphosphahexasilabicyclo[2.2.2]octanes and 1,3,5-triphosphapentasilabicyclo-[3.2.1]octanes over other topological isomers could be rationalized by using the concept of topological charge stabilization.

## Experimental Section

**General:** All experiments were performed under anaerobic conditions by using standard Schlenk techniques. Solvents were dried with sodium or potassium and distilled under an atmosphere of $N_2$ prior to use. Starting materials **1** and **2** were prepared as described in the literature. $^{31}P$ and $^{29}Si$ NMR spectra were recorded with a BRUKER MSL 300 spectrometer (59.627 MHz for $^{29}Si$, 121.451 MHz for $^{31}P$). Chemical shifts are given in ppm relative to 85% aq. $H_3PO_4$ for $^{31}P$ and $SiMe_4$ for $^{29}Si$ (external). Elemental analyses were performed with a HERAEUS VARIO EL. As compounds **3**–**5** are extremely sensitive towards traces of oxygen and moisture, the quality of the elemental analyses is not as good as usually achieved.

**Decamethyl-2,3,5,6,7-pentasila-1,4-diarsabicyclo[2.2.1]heptane (3):** To a suspension of "$Na_xAs/K_xAs$" [prepared from Na (1.10 g, 48.22 mmol), K (1.50 g, 38.58 mmol) and As (5.0 g, 74.92 mmol) by a modified procedure described by Becker[15]] in dme (300 mL) was added dropwise a solution of **1** (9.37 g, 28.9 mmol) in dme (70 mL) over a period of 60 min. During the reaction, which is exothermic, the black colour of the suspension changed to yellow-green. The reaction mixture was then heated at reflux for 8 h, and the precipitated salts were separated by filtration. The solvent was then removed by evaporation in vacuo and replaced by heptane. Subsequently, the solution was decanted from the remaining salts, and **3** (1.7 g, 5%) was obtained by fractional crystallization at –30 °C. $C_{10}H_{30}As_2Si_5$ (440.62): calcd. C 27.26, H 6.86; found C 28.57, H 7.28.

**Dodecamethyl-2,3,4,6,7,8,9-heptasila-1,5-diarsatricyclo[3.3.1.0$^{3,7}$]-nonane (4):** To a suspension of "$Na_xAs/K_xAs$" [prepared from Na (1.71 g, 74.4 mmol), K (2.18 g, 55.8 mmol) and As (9.76 g, 130.25 mmol)] in dme (500 mL) was added a solution of **2** (15.0 g, 32.56 mmol) in dme (70 mL) over a period of 1 h. The reaction mixture was then submitted to the same procedure as described above. Crystallization from heptane at –30 °C gave **4** (1.7 g, 5%) as colourless crystals. $C_{12}H_{36}As_2Si_7$ (526.88): calcd. C 27.36, H 6.89; found C 28.05, H 7.08.

**Sodium Hexamethyl-2,4,6,7-tetrasila-1-phosphanido-3,5-diphosphabicyclo[3.2.1]octane (5):** To a solution of **1** (12.69 g, 39.2 mmol) in dme (150 mL) was added dropwise a suspension of "$Na_xP/K_xP$" [prepared from Na (1.53 g, 66.73 mmol), K (3.48 g, 88.97 mmol) and white phosphorus $P_4$ (3.30 g, 106.5 mmol] in dme (300 mL)

heated at reflux. After heating for 24 h, a considerable quantity of unreacted **1** was detected by $^{29}Si$ NMR spectroscopy, even after treatment in an ultrasonic bath. Therefore, the suspension of "$Na_xP/K_xP$" and the salts were removed by decantation, and a suspension of freshly prepared "$Na_xP/K_xP$" (from 3.3 g of white phosphorus) was added dropwise to the solution heated at reflux. The reaction mixture was heated at reflux for another 40 h and separated from the salts by filtration. The solvent was removed by evaporation in vacuo and replaced by pentane. The insoluble residue was dissolved in hexane/dme (1:1). At –30 °C, **5** (4.9 g, 23%) was obtained as colourless crystals. $C_{18}H_{50}NaO_4P_3Si_5$ (586.93): calcd. C 36.83, H 8.59; found C 35.74, H 7.92.

**Decamethyl-3-trimethylsilyl-1,3,5-triphospha-2,4,6,7-tetrasilabicyclo[3.2.1]octane (6):** To a solution of **5** (2.70 g, 4.6 mmol) in pentane/dme (1:1) at –80 °C was added dropwise chlorotrimethylsilane (0.5 g, 4.6 mmol). The reaction mixture was allowed to reach r.t., and the solvents are removed completely by evaporation in vacuo. *n*-Pentane was added, and the solid precipitates were separated by decantation. At –30 °C, **6** (1.2 g, 57%) was obtained as colourless crystals. $C_{13}H_{39}P_3Si_6$ (456.89): calcd. C 34.17, H 8.60; found C 33.52, H 8.41.

**X-Ray Crystal Structure Analysis:** Crystals were mounted onto the tip of a glass fibre, and the data collection was performed with a BRUKER-AXS SMART APEX CCD diffractometer for compounds **3**, **5** and **6**, and a STOE four-circle diffractometer for **4**. Graphite-monochromated Mo-$K_\alpha$ radiation (71.073 pm) was used for the measurements. Crystal data and details of the structure refinement are summarized in Table 3. The data were reduced to $F^2_o$ and corrected for absorption effects with SAINT[16] and SADABS.[17] The structures were solved by direct methods and refined by full-matrix least-squares method (SHELXL97).[18] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were located in calculated positions to correspond to standard bond lengths and angles.

CCDC-637289 (for **3**), -637287 (for **4**), -637288 (for **5**) and -637290 (for **6**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Quantum Chemical Calculations:** All considered geometries were optimized at the B3LYP/6-31G* level by using the Gaussian 03 software package.[19] The conformers with the lowest energy were considered in the discussion with their atomic charges as defined by Mullican.[20]

## COVER PICTURE

**The cover picture shows** the reaction between the phosphavinylidene complexes $[(\eta^5\text{-}C_5H_5)(CO)_2M{=}P{=}C(SiMe_3)_2]$ and the inversely polarized phosphaalkene $t$BuP=C(NMe$_2$)$_2$, which affords $\eta^3$-1,2-diphosphaallyl complexes by smooth transfer of the phosphinidene unit onto the electrophilic ligand of the precursors. The molecular structure underlines the unsymmetrical $\eta^3$-ligation of the heteroallyl ligand to the metal with the *tert*-butyl substituent *syn* to the central phosphorus atom. Treatment of the phosphavinylidene complexes with *P*-aroylphosphaalkenes leads to decomposition. In contrast, phosphavinylidene complexes and *As*-aroylarsaalkenes yield complexes featuring cyclic phosphenium ligands with an As=C bond. It is believed that the first step of this process is a formal [2+1] cycloaddition between the P=C bond and the aroylarsinidine to give a three-membered ring, which subsequently incorporates the CO unit to afford the final product. In all cases, tetrakis(dimethylamino)ethene is formed as a byproduct. Details are presented in the Microreview by L. Weber on p. 4095 ff.

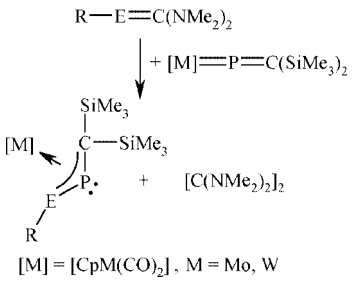
## MICROREVIEW

### Inversely Polarized Phosphaalkenes

**L. Weber* ..... 4095–4117**

Phospha- and Arsaalkenes $RE{=}C(NMe_2)_2$ (E = P, As) as Novel Phosphinidene- and Arsinidene-Transfer Reagents

**Keywords:** Phosphaalkenes / Arsaalkenes / Phosphinidene / Arsinidene



Inversely polarized phosphaalkenes $RP{=}C(NMe_2)_2$ serve as convenient sources of the phosphinidene unit PR, which can be transferred onto a broad variety of electrophilic ligands in transition-metal complexes such as complexes with carbene, vinylidene, phosphenium, and phosphavinylidene ligands. Similarly, inversely polarized arsaalkenes behave as arsinidene transfer reagents under mild conditions.

## SHORT COMMUNICATIONS

### Click Assemblies

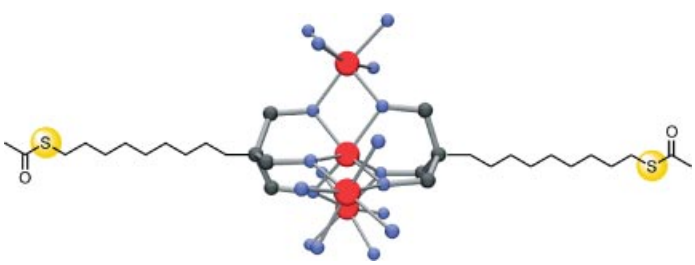
### Single-Molecule Magnets



Single-molecule magnets of the $Fe_4$ family have been functionalized with terminal "alligator clips" by exploiting the site-specific coordinating ability of 2-(hydroxymethyl)propane-1,3-diol derivatives. The complexes have an $S = 5$ ground state and energy barriers exceeding 15 K.

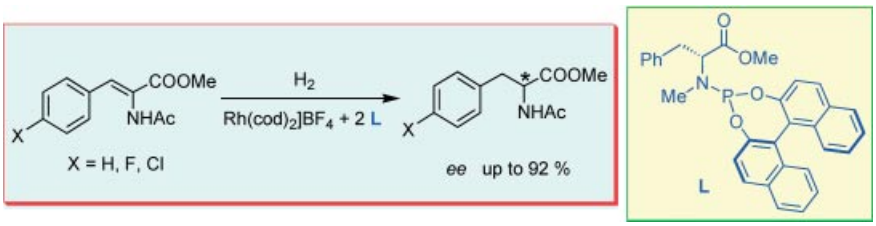
Synthesis of Chiral, Monodentate Aminophosphane and Phosphoramidite Ligands Derived from Amino Acid Esters: Application in Rh-Catalysed Asymmetric Olefin Hydrogenation Reactions

**Keywords:** Phosphoramidites / Binol / Asymmetric catalysis / Rhodium / Olefin hydrogenation / Amino acid esters



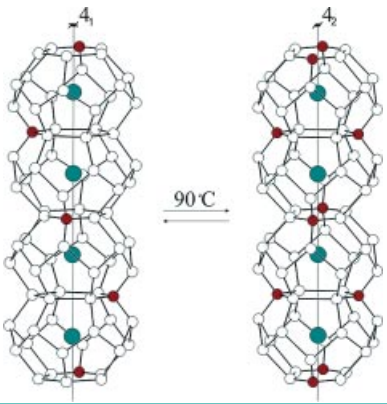
A series of chiral monodentate ligands combining a 3,5-dioxa-4-phosphacycloheptadinaphthyl unit either with a phenylalanine- or with an alanine-derived fragment were synthesised and tested in the hydrogenation of 2-(acetylamino)-3-(aryl)propenoic methyl esters.

## Understanding Clathrate-I Structures

**A. Kaltzoglou, S. D. Hoffmann, T. F. Fässler* ..... 4162–4167**

Order-Disorder Phase Transition in Type-I Clathrate $Cs_8Sn_{44}\square_2$

**Keywords:** Clathrates / Order-disorder transitions / Single-crystal structure analysis / Thermoelectricity / Tin



$Cs_8Sn_{44}\square_2$ adopts a $2 \times 2 \times 2$ superstructure of the type-I clathrate ($Ia\bar{3}d$) at room temperature and exhibits a high ordering of the vacancies (□) in the Sn framework (left). Its single crystals transform at 90 °C to a high-temperature modification ($Pm\bar{3}n$) with a lower ordering of the defects (right). DTA corroborates the totally reversible character of the phase transition.

## Zinc(II) Complexes

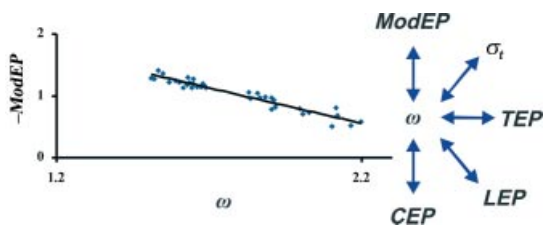
Introduction of Modified Electronic Parameters – Searching for a Unified Ligand Properties Scale through the Electrophilicity Index Concept

**Keywords:** Modified electronic parameters / Electrophilicity index / Diimine complexes / Reduction potential / Charge-transfer bands



The contribution of the diimine ligands to the electronic properties of the corresponding metal complexes is quantified by two novel indices, namely Modified Electronic Parameters, *ModEP*, and the electrophilicity, $\omega$. The latter correlates well with all known electronic parameters, such as *CEP*, *LEP*, *TEP*, *ModEP* and the Hammett constant. The method in which it is calculated avoids any experimental limitation; thus, it can be employed even for ligands that have not yet been synthesized, and its correlation with the known scales could provide the properties of the corresponding complexes.

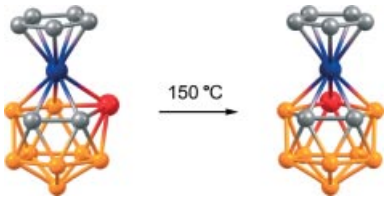
## Ferraphosphacarboranes

Room-temperature reactions of the phosphadicarbollide anion $[7,8,9\text{-}PC_2B_8H_{10}]^-$ with $[(C_5R_5)Fe]^+$ cations afford the expected 12-vertex ferraphosphadicarbollides $[1\text{-}C_5R_5\text{-}1,2,3,4\text{-}FePC_2B_8H_{10}]$, which undergo polyhedral rearrangement at 150 °C. The calculated value of the root-mean-square-amplitude-of-vibration of the iron atom, based on the Mössbauer effect data, is in good agreement with crystallographic data.



**A. R. Kudinov,* R. H. Herber,* P. Zanello,* D. S. Perekalin, I. V. Glukhov, I. Nowik, M. Corsini, S. Fedi, F. Laschi ..... 4190–4196**

## COVER PICTURE

**The cover picture shows** the reaction between the phosphavinylidene complexes $[(\eta^5\text{-}C_5H_5)(CO)_2M{=}P{=}C(SiMe_3)_2]$ and the inversely polarized phosphaalkene $t$BuP=C(NMe$_2$)$_2$, which affords $\eta^3$-1,2-diphosphaallyl complexes by smooth transfer of the phosphinidene unit onto the electrophilic ligand of the precursors. The molecular structure underlines the unsymmetrical $\eta^3$-ligation of the heteroallyl ligand to the metal with the *tert*-butyl substituent *syn* to the central phosphorus atom. Treatment of the phosphavinylidene complexes with *P*-aroylphosphaalkenes leads to decomposition. In contrast, phosphavinylidene complexes and *As*-aroylarsaalkenes yield complexes featuring cyclic phosphenium ligands with an As=C bond. It is believed that the first step of this process is a formal [2+1] cycloaddition between the P=C bond and the aroylarsinidine to give a three-membered ring, which subsequently incorporates the CO unit to afford the final product. In all cases, tetrakis(dimethylamino)ethene is formed as a byproduct. Details are presented in the Microreview by L. Weber on p. 4095 ff.

# Phospha- and Arsaalkenes RE=C(NMe$_2$)$_2$ (E = P, As) as Novel Phosphinidene- and Arsinidene-Transfer Reagents

**Lothar Weber*[a]**

**Keywords:** Phosphaalkenes / Arsaalkenes / Phosphinidene / Arsinidene

Phosphinidenes (phosphanylidenes) (RP) are electronically and coordinatively unsaturated phosphorus compounds, which, as six-electron species, are formally analogous to the more familiar carbenes and nitrenes. In contrast to carbenes ($CR_2$), the extremely reactive phosphinidenes cannot be isolated without decomposition. Thus, our knowledge on phosphinidenes is mainly limited to trapping reactions and quantum-chemical calculations. There are a number of synthetic methods for phosphinidenes available, for example photolysis or thermolysis of cyclic phosphanes and oligophosphanes, dehalogenation of organodihalophosphanes, liberation of dinitrogen from organodiazidophosphanes, or decomposition of phosphoranylidene-$\sigma^4$-phosphoranes (arylP=PMe$_3$). A plethora of information is available on the generation of highly reactive terminal phosphinidene complexes [RPW(CO)$_5$] and their chemistry. Many of these methods suffer from comparatively harsh conditions (strong base, heat, etc.) which limit their preparative use.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Phosphinidenes R–P (phosphanylidenes) are elusive six-electron species, which can only be evidenced by interception reactions or by their oligomerization to oligocyclophosphanes.[1]

The chemistry of unsupported phosphinidenes is only poorly developed in comparison to the rich chemistry displayed by free carbenes. One reason might be sought in the limited number of suitable precursors for these electron-deficient molecules. Moreover, general difficulties in the unambiguous identification of phosphinidenes as key compounds in reactions have to be noted at this point. Often it has not been sufficient to draw a conclusion about their identity solely from an observed product pattern.

Phosphinidenes occur as singlet and triplet species, whereby, like in the case of methylene, the parent compound [PH] has a triplet ground state with an experimentally determined triplet–singlet separation of 22 kcal mol$^{-1}$. Quantum chemical calculations have evidenced that, with π-donor substituents at the phosphorus atom, the energy of the open-shell particles approach the singlet state.

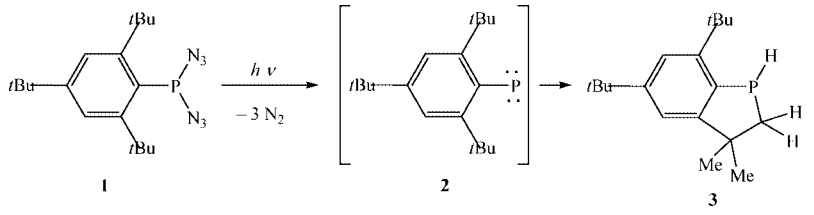
## 2. Synthesis and Trapping Reactions of Phosphinidenes

Convincing arguments for the intermediacy of phosphinidenes where obtained from their photochemical generation. Photolysis of Mes*P(N$_3$)$_2$ (**1**) (Mes* = 2,4,6-*t*Bu$_3$C$_6$H$_2$) with UV light (254 nm) afforded phosphaindane **3**, the formation of which was rationalized by the insertion of the P atom into a C–H bond of one *tert*-butyl group in the *ortho* position of the arene ring (Scheme 1).[2]

When the photolysis of **1** was conducted in deuterated solvents, *no* deuterium incorporation into product **3** was observed. Obviously, the intramolecular rearrangement of transient **2** into **3** occurred very rapidly. Photolyses of Mes*P=C=O and Mes*P=PMes* also gave compound **3** as the final product in high yields.[2]

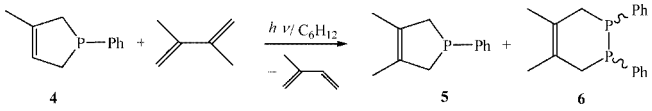
*Lothar Weber was born in 1944 in Langenöls in Schlesien. He studied at the University of Marburg and received his doctorate there under the direction of Professor Günter Schmid in 1973. Afterwards, he carried out postdoctoral studies with Professor Barry M. Trost at the University of Wisconsin in Madison, USA. On his return to Marburg, he began the experimental work leading to his Habilitation, which was completed in 1982 at the University of Essen. His work focused on the coordination chemistry of sulfur ylides. In 1985, he became a C2 Professor and then joined the Fakultät für Chemie der Universität Bielefeld. His research interests include the chemistry of compounds with low-coordinate elements of the fifth main group, the synthesis of homo- and heterocycles with heavy elements, as well as new aspects in boron chemistry.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. Generation of phosphaindane **3** by photolysis of **1**.

The "retro-addition strategy" seemed to be particularly useful for the synthesis of phosphinidenes. Thus, photolysis of 3-methyl-1-phenyl-3-phospholene (**4**) in the presence of 2,3-dimethylbutadiene furnished phospholene **5** in addition to a *cis*/*trans* mixture of 4,5-dimethyl-1,2-diphenyl-1,2-diphosphacyclohexenes **6** (Scheme 2).



Scheme 2. Photolysis of **4** in the presence of 2,3-dimethylbutadiene.

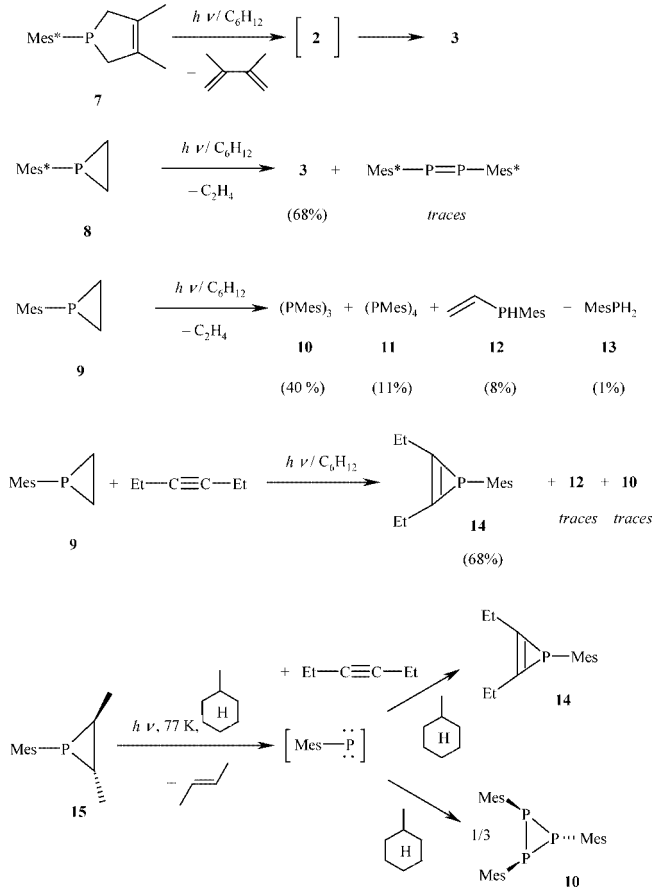
These observations were explained by invoking the photochemical extrusion of phenylphosphinidene from **4** and its subsequent cheletropic [1+4] cycloaddition to the diene. In a competing process, the phosphinidene dimerized to a diphosphene which underwent a Diels–Alder reaction to give isomers **6**.[3]

Irradiation of 3,4-dimethyl-1-supermesityl-3-phospholene (**7**) afforded phosphinidene **2**, which isomerized to **3**. Compound **3** was obtained in 68% yield upon photolysis of **8** even in the presence of potential trapping reagents such as alkenes, dienes, or alkynes. Only traces of diphosphene Mes*P=PMes* were observed (Scheme 3).

Photolysis of mesitylphosphirane **9** furnished a mixture of cyclophosphanes **10** (40%) and **11** (11%) in addition to mesitylvinylphosphane **12** (8%) and mesitylphosphane **13** (1%) (Scheme 3). In the presence of alkenes, dienes or alkynes, the yield of the oligocyclophosphanes decreased in favor of the formation of three-membered rings.

Frozen solutions of phosphirane **15** in methylcyclohexane at 77 K turned yellow upon irradiation with UV light ($\lambda$ = 254 nm). Thawing the glass in the absence of trapping reagents gave cyclotriphosphane **10** in 30% yield. In the presence of 3-hexyne, phosphirene **14** was formed in yields up to 88%, which was rationalized by the initial liberation of mesitylphosphinidene. In an ESR experiment at 4 K, the yellow glass displayed a strong signal at 11492 Gauss, which was assigned to the free [Mes–P] in the triplet ground state.[4a] A recent careful theoretical analysis of the fragmentation reaction demonstrated that free [Mes–P] was probably not generated in the presence of alkenes.[4b]

Phosphanylphosphinidene [$t$Bu$_2$P–P] has been known for some time.[5a] Its chemistry as well as theoretical calculations[5b] on it agree with a singlet ground state of the molecule.

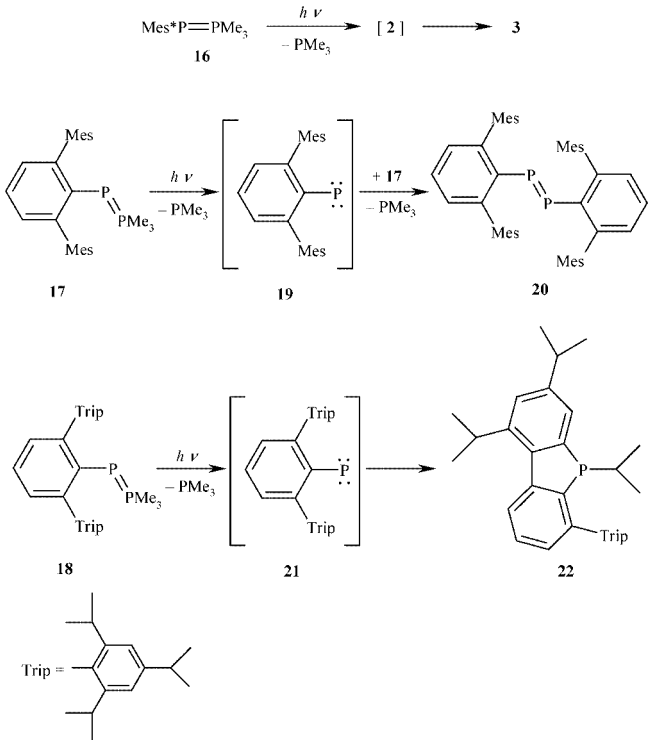


Scheme 3. Photolysis of phospholene **7** and phosphiranes **8**, **9**, and **15**.

Stimulated by the work of Burg and Mahler, who studied the decomposition of $CF_3P{=}PMe_3$,[6] Protasiewicz et al. photolyzed the phosphinidenephosphoranes **16**–**18** (Scheme 4).[7] Release of $PMe_3$ from derivative **16** gave phosphinidene **2**, which rearranged immediately to **3**.

In contrast, irradiation of **17** afforded diphosphene **20** in 90–95% yield, which was explained by an attack of phosphinidene **19** at the precursor. The photochemical treatment of phosphinidenephosphorane **18** led to phosphafluorene **22** as the product of the insertion of the P atom of transient **21** into the carbon–carbon bond of an *ortho*-isopropyl group. Interestingly, compound **22** was also formed in 68% yield during the magnesium reduction of 2,6-trip$_2$C$_6$H$_3$PCl$_2$.[7b,8] The reductive dechlorination of aryl-PCl$_2$, however, does not necessarily proceed via free phos-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4. Photolysis of phosphinidenephosphoranes **16**–**18**.

phinidenes as intermediates. It is equally conceivable that this process may involve radicals or species of the type arylP(Cl)MgCl.

## 3. Phosphinidene Complexes as Phosphinidene Transfer Reagents

A rich area of transition-metal complexes featuring terminal phosphinidene ligands contrasts with the scarcely developed chemistry of free phosphinidenes.[9] There was a considerable effort to develop a phosphinidene chemistry analogous to the well familiar carbene complex chemistry.[10] Here, however, it proved troublesome to employ synthetic methods that proved fruitful in carbene chemistry. In contrast, one had to face the task of individually modifying the reaction conditions according to the demands of the substituents at the P atoms. A useful approach was the stabilization and fixation of singlet phosphinidene in the coordination sphere of d-block metals. At this point, two different types of terminal phosphinidene complexes may be discriminated: coordination compounds with phosphinidenes as two electron donors with a nonlinear M–P–R arrangement (e.g. **23**)[11] or those with phosphinidenes that serve as four electron donors with a linear M–P–R skeleton (e.g. **24**).[12] It is obvious that complexes with $sp^2$-hybridized phosphorus atoms show $^{31}P$ NMR resonances at very low field, which is in sharp contrast to those with sp-hybridized phosphorus.

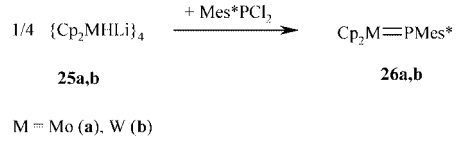
### 3.1 Nucleophilic Phosphinidene Complexes

The discrimination between nucleophilic and electrophilic phosphinidene complexes is mainly justified by their reactivity. Early transition metals with an electron-abundant coordination sphere favor a polarity $P^{\delta-}$–$M^{\delta+}$ of the metal–phosphorus bond. Thereby the gradual variation of the ancillary ligands to some extent allows tuning of the mode of reactivity of the PR ligand from nucleophilic to electrophilic. This aspect was analyzed in a theoretical study.[13]

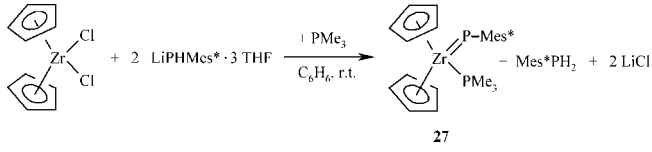
The first stable transition-metal complexes having nucleophilic phosphinidene ligands [$Cp_2M$=PMes*] (**26a**,**b**) (M = Mo, W) were synthesized as red solids by the reaction of Mes*$PCl_2$ with the hydridolithium species **25a**,**b** (Scheme 5).



Scheme 5. Synthesis of **26a**,**b**.

According to an X-ray structural analysis of the molybdenum complex **26a** the M–P–R skeleton is bent [115.8(2)°] with a MoP double bond of 2.370(2) Å.[14]

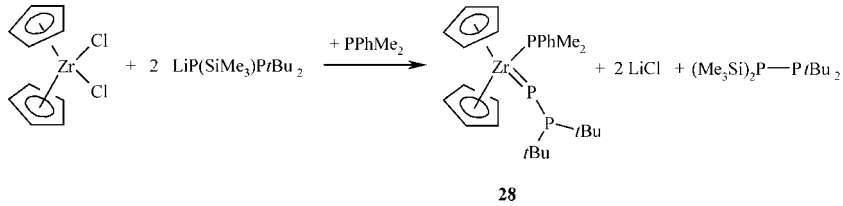
A bent terminal phosphinidene derivative, [$Cp_2$Zr(=PMes*)($PMe_3$)] (**27**), was isolated from the reaction of [$Cp_2ZrCl_2$] with LiPHMes* in the presence of $PMe_3$ (Scheme 6).



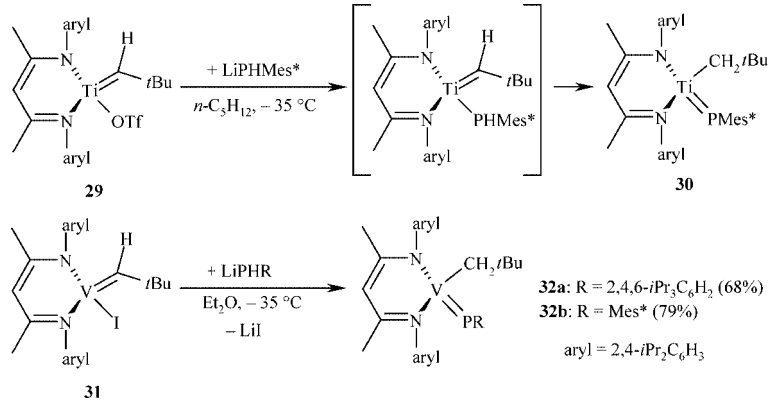
Scheme 6. Synthesis of **27**.

The outcome of such a protocol is crucially dependent on the steric requirements of the ligands at the metal and the phosphorus atom.[15] According to a comparable protocol, the synthesis of the first terminally bonded phosphanylphosphinidene complex [$Cp_2$Zr{=P–P($t$Bu)$_2$}($PPhMe_2$)] (**28**) was achieved. The ZrP contact to the phosphinidene ligand was considerably shorter [2.488(3) Å] than that to the phosphane ligand [2.734(3) Å] (Scheme 7).[16]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 7. Synthesis of **28**.



Scheme 8. Titanium and vanadium complexes with nucleophilic terminal phosphinidene ligands.

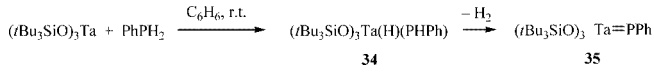
Until 2004, $\eta^2$-coordination was found to be essential to stabilize the $t$Bu$_2$PP ligand, whose source is phosphanylphosphinidine-$\sigma^4$-phosphoranes.[5a,17]

A strategy for preparing a terminal titanium phosphinidene complex, **30**, involved treatment of the nucleophilic and four-coordinate titanium alkylidene complex [(Nacnac)-Ti=CH$t$Bu(OTf)] (**29**) [Nacnac = 2,6-$i$Pr$_2$C$_6$H$_3$NC(Me)-CHC(Me)N-C$_6$H$_3$-$i$Pr$_2$-2,6] with LiPHMes* in pentane at –35 °C (Scheme 8). The structure of the molecule in the crystal displays a four-coordinate titanium–phosphinidene complex with an exceptionally short Ti=P bond [2.183(4) Å] and a nearly linear Ti=P–C$_{ipso}$ angle [164.44(5) Å].[18a]

Dark blocks of crystalline **32a** and **32b** were obtained in good yield from the layering of a cold ethereal solution (–35 °C) of the lithium phosphide onto a similarly cold ether solution of vanadium(IV) complex **31** (Scheme 8).[18b]

In contrast to a series of phosphinidene complexes, which owe their stability to very bulky substituents, Schrock developed a synthetic procedure for stable tantalum phosphinidenes **33**, which tolerate Ph, Cy, and $t$Bu groups as substituents. This is due to the bulky tetradentate amido ligand $\{N(CH_2CH_2NSiMe_3)_3\}^{3-}$ (Scheme 9).

The X-ray diffraction study of **33c** displays a nearly linear Ta–P–C unit with a short Ta–P bond of 2.145(7) Å. The $^{31}$P NMR resonances of the complexes range from 175.1 to 227.3 ppm.[19] Tantalum phosphinidene complex **35** ($\delta^{31}$P = 334.6 ppm) resulted from a 1,2-H$_2$-elimination of phosphanido complex ($t$Bu$_3$SiO)$_3$(H)Ta–P(H)Ph (**34**), (Scheme 10).[20] The angle Ta–P–C in **35** is 110.2(4)°, and the Ta=P bond length is 2.317(4) Å.



Scheme 10. Synthesis of **35**.

Terminal nucleophilic complexes of group 8 (**36**) and group 9 (**37**) transition metals were synthesized by Lammertsma et al. by the base-induced dehydrohalogenation of appropriate precursor complexes in the presence of stabilizing ligands. $^{31}$P NMR resonances of the Ru complexes were observed between 801 and 846 ppm, and in the Os compounds they range from 668 to 744 ppm. The $p$-cymene(PPh$_3$)Os complex displays a bent Os–P–C backbone [106.56(9)°] with an Os–P bond of 2.2195(7) Å (Scheme 11).[21]

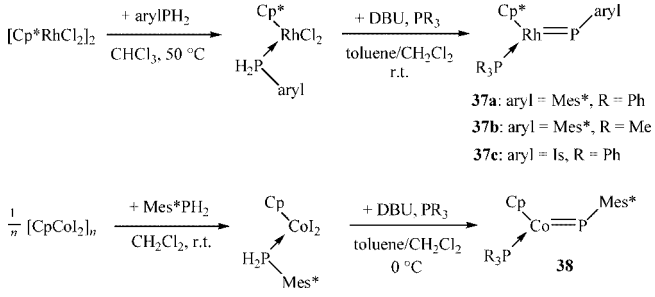
**36**

Scheme 11. Synthesis of phosphinidene complexes of Ru and Os.

Similarly, iridium complexes [Cp*(L)Ir=Paryl] (aryl = Mes, Is, Mes*), L = $PR_3$, $P(OR)_3$, $AsR_3$, dppe, RNC, and CO,[22] and the corresponding cobalt and rhodium complexes [Cp*($R_3P$)Rh=Paryl] (**37**) [aryl = Mes*, Is (Is = 2,4,6-$iPr_3C_6H_2$); R = Me, Ph], and [Cp*Co($PPh_3$)=PMes*][23] were synthesized (Scheme 12).



Scheme 12. Synthesis of phosphinidene complexes of Rh and Co.

Ether solutions of lithium-2,6-dimesitylphenylphosphanide [LiP(H)dmpp] reacted cleanly with **39** to give the paramagnetic primary phosphanido complex **40**, which, after oxidation to **41** by tropylium hexafluorophosphate and deprotonation, afforded the nickel–phosphinidene complex **42** as bright green crystals in 86% yield (Scheme 13).[24]

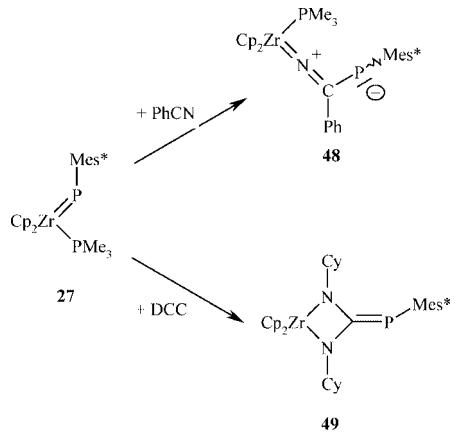
The terminal phosphinidene complex [$Cp_2Zr$=PMes*-($PMe_3$)] (**27**) proved useful in delivering the phosphinidene [PMes*] to suitable acceptors. The high oxo- and chlorophilicity of the zirconium center in **27** allows exchange of its phosphinidene unit for two chlorine atoms or an oxygen atom of a substrate to form either [$Cp_2ZrCl_2$] or [$Cp_2ZrO$]$_n$, respectively. For example, reactions of **27** with dichloromethane or chloroform readily afforded the phosphaalkenes Mes*P=$CH_2$ and (*E*/*Z*)-Mes*P=CHCl[25] (Scheme 14).

With 1,2-dichloroethane phosphirane **8** was formed in addition to [$Cp_2ZrCl_2$]. The use of *o*-dichloroxylene produced the new phospholane **43** in 53% yield. In contrast to these results, the reaction of **27** with 1,4-dichloro-2-butene did not produce the anticipated five-membered ring, but rather the *cis*-isomer of vinyl-substituted phosphirane **44** in 38% yield. Likewise, the reaction of **27** with 1,4-dichloro-2-butyne produced the vinylidenephosphirane **45** (53% yield). The reactions with alkyl halides were thought to involve phosphanide–halide intermediates of the form [$Cp_2Zr$(PMes*R)Cl].

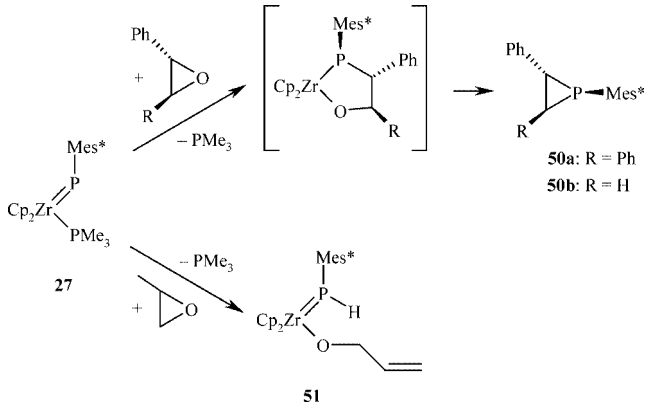
In a Wittig-type process, compound **27** reacted with benzaldehyde to give an insoluble colorless precipitate {presumably [($Cp_2ZrO$)$_n$]}, free $PMe_3$ and (*E*)-Mes*P=CHPh. An analogous synthetic procedure using benzophenone provided an 82% yield of Mes*P=$CPh_2$, and in the same manner the use of 2 equiv. of **27** and isophthalaldehyde furnished exclusively the *E*,*E* isomer of the bis(phosphaalkene) **46** in 86% yield. The related transformation of **27** with phenylisothiocyanate gave the heteroallene *trans*-PhN=C=P–Mes* **47** (81% yield) along with the crystalline blue byproduct [$Cp_2ZrS$]$_2$[25] (Scheme 15).

The reaction of **27** with benzonitrile afforded the red compounds **48** as a 55:45 isomeric mixture. The addition of **27** with dicyclohexyl carbodiimide (DCC) led to the phosphoguanidino complex **49**[23] (Scheme 16).

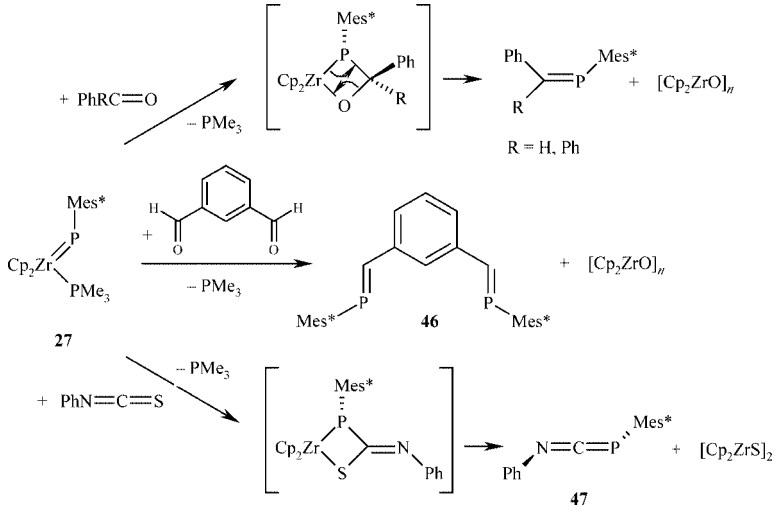
Phosphiranes **50a** and **50b** were derived from reactions of **27** with *trans*-stilbene oxide and styrene oxide, respectively. In the related reaction with propylene oxide, complex **51**, with a secondary phosphanido and a propenolato ligand, was obtained. This process probably involves precoordination of the epoxide to the zirconium center followed by abstraction of the enolizable proton and ring opening[25] (Scheme 17).



Scheme 16. Reaction of **27** with PhCN and DCC.



Scheme 17. Reaction of [$Cp_2Zr$=PMes*($PMe_3$)] (**27**) with epoxides.



Scheme 15. Reaction of **27** with carbonyl compounds and isothiocyanate.

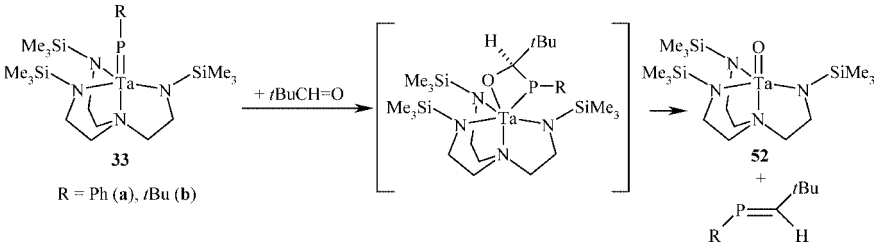
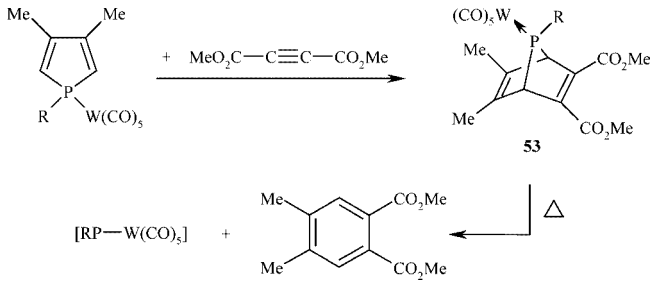


Scheme 18. Synthesis of phosphaalkenes from complex **33** and aldehydes.

Aldehydes react cleanly with tantalum–phosphinidene complexes **33**, providing the stable oxotantalum complex **52** in addition to the corresponding phosphaalkenes. The reaction of **33b** with pivaldehyde took 7 h at 95 °C to reach completion and furnished (*E*)-*t*BuP=CH*t*Bu. Phosphaalkene (*E*)-PhP=CH*t*Bu resulted as an oil in 83% yield from the treatment of **33a** with pivaldehyde[19a] (Scheme 18).

### 3.2 Electrophilic Phosphinidene Complexes

The synthetically most valuable phosphinidene complexes are unstable species exhibiting the [M(CO)$_5$] (M = Cr, Mo, W) fragment. In two recent reviews, is has been reported that these complexes almost always mirror the chemistry of singlet carbenes in Fischer-type complexes.[9,10] Thus, only a brief survey of this area with selected aspects is presented at this point. The most prominent access to these reagents involved the pyrolysis of [W(CO)$_5$] adducts of 7-phosphanorbornadienes **53** (Scheme 19).[9]



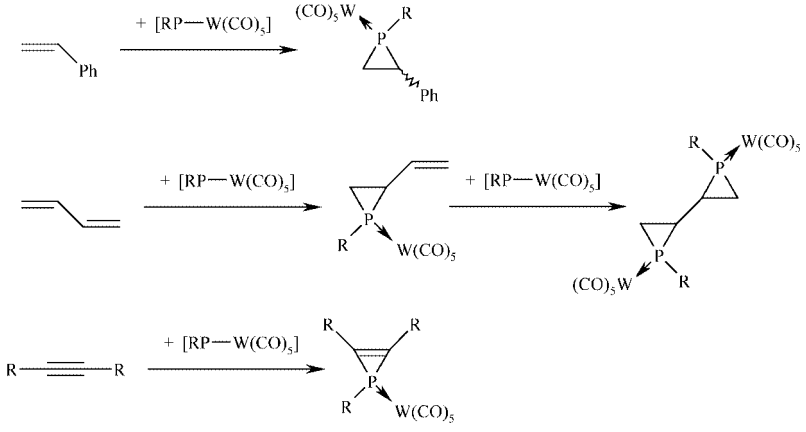
Scheme 19. Generation of [RP–W(CO)$_5$].

The concomitant interception of [RP–W(CO)$_5$] with alkenes proceeded with retention of stereochemistry (Scheme 20).[26] Reaction with alkynes preferentially afforded phosphirene complexes.[27] With 1,3-butadiene, vinyl phosphirane and 2,2′-bisphosphiranyl complexes were obtained.[26,28]

Recently, Lammertsma et al. used the thermolysis of benzophosphepine complexes **54** for the generation and trapping of [PhP–W(CO)$_5$] at 75–80 °C (Scheme 21). Apart from considerably milder reaction conditions, better yields were achieved than with other precursors.[29]

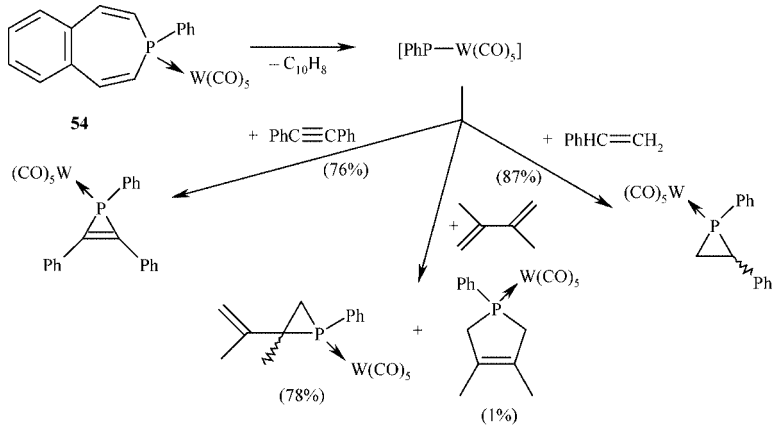
A striking difference between carbenes and electrophilic phosphinidene complexes became evident in their reactivity towards aromatic compounds. In contrast to the reaction of methylene [:CH$_2$] with benzene to afford mainly norcaradiene, which rearranges to cycloheptatriene and toluene, phosphinidene complexes are inert and may be generated in arenes such as toluene. Nevertheless, [RP–W(CO)$_5$] reacted with several selected aromatic compounds. The nucleophilic cyclopentadienyl ligand of ferrocene is an attractive target for the electrophilic phosphinidene, and the reaction results in C–H insertion.[30] Another rare example is the unique [1+4] cycloaddition to ansa compound **55** (Scheme 22) to afford **56**, because it describes the reverse of the cheletropic elimination of [RP–W(CO)$_5$].

The reaction of [PhP–W(CO)$_5$] generated from **53** in the presence of CuCl at 60 °C leads to C–H-insertion product **57a** (55%) and the formal 1,4 adducts **58a** and **58b** (45%) (Scheme 23). The analogous transformation with guaiazulene favors the formation of the 1,4 adducts **58c** and **58d** (77%) (Scheme 23).[31a]

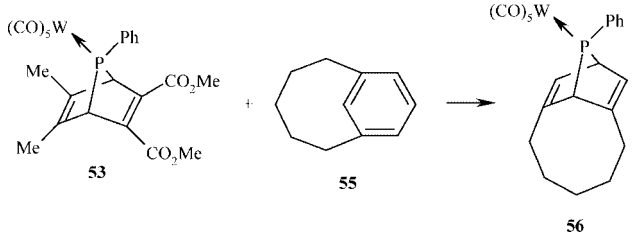


Scheme 20. Addition reactions of [RP–W(CO)$_5$].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 21. Thermolysis of **54** and selected trapping reactions of [PhP–W(CO)$_5$].



Scheme 22. Synthesis of **56**.

The reaction of electrophilic phosphinidene complex [MeP–W(CO)$_5$] with 1,6-methano[10]annulene (**59**) resulted in the exclusive formation of the isomeric C–C-insertion products **60a** (main) and **60b** (minor)[31b] (Scheme 24).

Treatment of [(CO)$_5$W–PPh] with 2,4,6-tri-*tert*-butyl-1,3,5-triphosphinine **61** in toluene at 110 °C unexpectedly afforded products **62** and **63a** in 25% and 39% isolated yields (Scheme 25).[32]

The reaction of [MeP–W(CO)$_5$] with **61**, however, resulted in a mixture of tetraphosphanorbornadiene **64**, a formal 1,4 adduct, and its corresponding quadricyclane **63b** as a 1:8 mixture.[32]

Interception of complexed phosphinidenes generated from **65** with 1-ethoxy-2-(triorganostannyl)acetylene afforded phosphaallene **66** in addition to the expected cycloadduct **67**, which was rationalized by the intermediacy of a zwitterion[33] (Scheme 26).

The reaction of tungsten–phosphinidene complexes with ketones and nitriles furnished zwitterionic 1,3-dipolar adducts whose structure depended on the substitution pattern at the P atom[34–36] (Scheme 27).

Functionalized phosphinidene complexes are frequently involved in interesting intramolecular rearrangement processes, which impressively underline the great versatility of the P-substituents[30,37–39] (Scheme 28).

Another type of intramolecular addition of a coordinated phosphinidene was realized by heating complex **68a** in tolu-

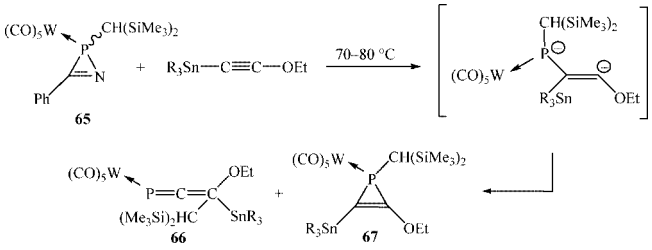
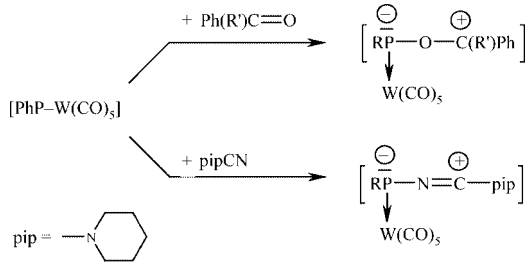
ene at 80 °C to give the diphosphane basket **69a** as the sole isolable product in 66% yield. Similarly, the diphosphane baskets **69b**,**c** were obtained (Scheme 29).[40]

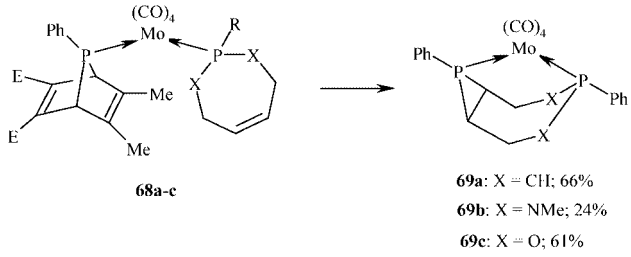


Scheme 26. Synthesis of **66** and **67**.



Scheme 27. Zwitterions from phosphinidene addition to ketones and nitriles.

A different route to electrophilic "Fischer Type" phosphinidene complexes of molybdenum, tungsten, ruthenium and cobalt was devised by Carty et al.[11,41,42] Their approach was based on the chloride abstraction from preformed chloro(diisopropylamino)phosphanido complexes **70a**,**b**, **72**, and **74** by using the Lewis acid aluminum chloride (Scheme 30).



Scheme 29. Formation of **69a**–**c**.

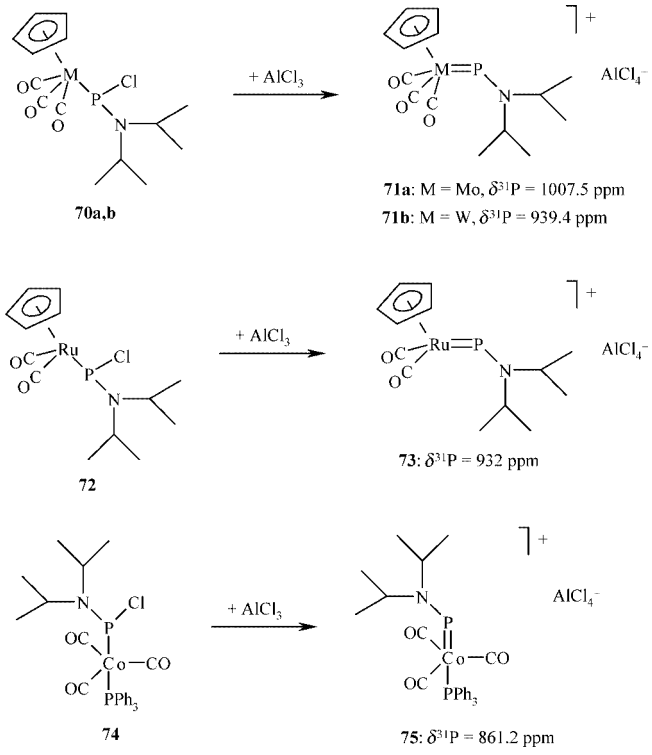


Scheme 30. Formation of cationic phosphinidene complexes.

So far, the reactivity studies of these cations are limited to alkyne additions.

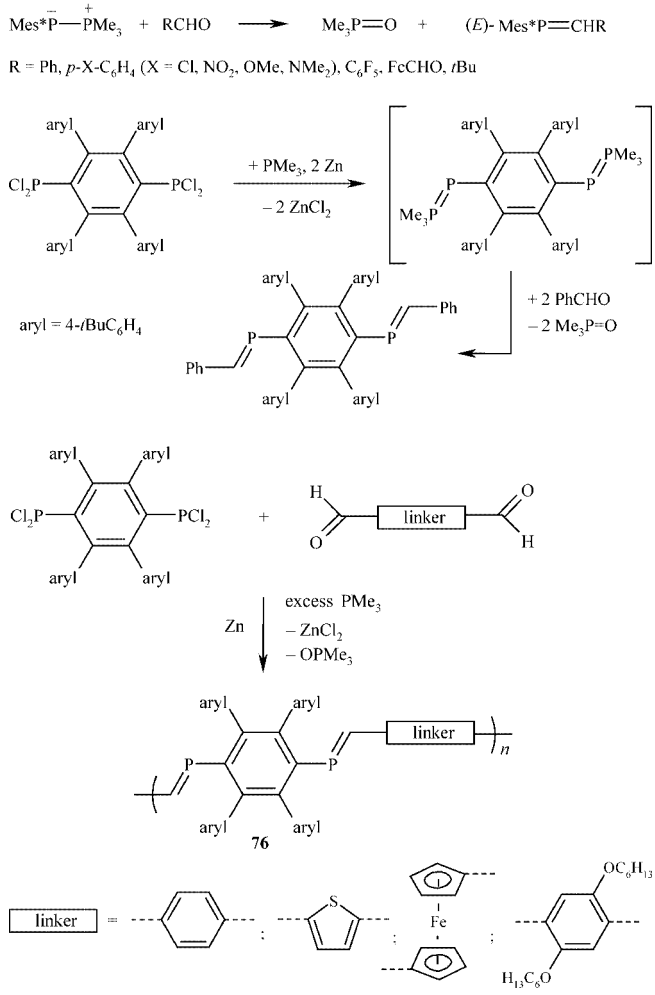
## 4. Phosphinidene Transfer from Phospha-Wittig Reagents

The Wittig reaction between phosphorus ylides $Ph_3P{=}CHR^1$ – these reagents may also be considered as carbanions with an α-phosphonium center – and aldehydes and ketones furnished alkenes. Particularly in the light of the diagonal relationship C/P in the periodic table, the quest for an analogous phospha-Wittig reaction was obvious. The required reagents $R^1{}_3P{=}PR^2$ are formed by a formal phosphinidene addition to a Lewis basic tertiary phosphane, and they are easily accessible by the reaction of dichlorophosphanes, trialkylphosphanes, and zinc metal. With aldehydes they form phosphaalkenes.[43–45]

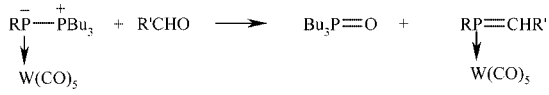
This approach was extended to the preparation of fluorescent (*E*)-poly-*p*-phenylenephosphaalkenes **76**[46] (Scheme 31).

A serious limitation of this protocol is the need of bulky substituents to provide the phospha-Wittig reagents with sufficient stability. This hurdle was circumvented by the coordination of the phosphinidene group to a transition-metal-complex fragment, preferentially to pentacarbonyltungsten, which stabilizes the organophosphorus precursor as well as the resulting phosphaalkene[47,48] (Scheme 32).

This type of reaction can only be performed with aldehydes and usually failed with ketones. This limitation can be overcome by the employment of anionic phosphorylphosphane complexes in a process analogous to the Horner–Wittig reaction[49,50] (Scheme 33).



Scheme 31. Phospha-Wittig reactions.



Scheme 32. Phospha-Wittig reactions with $[W(CO)_5]$-supported phosphinidenephosphoranes.

A different type of reaction was observed when phosphinidene-$\sigma^4$-phosphoranes arylP=$PMe_3$ (aryl = 2,6-$Mes_2C_6H_3$ or 2,4,6-$tBu_3C_6H_2$) were combined with selected *o*-quinones. The formation of 1,3,2-dioxophospholanes **79** and **80** was observed[51] (Scheme 34).

## 5. Phosphinidene Transfer from Inversely Polarized Phosphaalkenes

### 5.1 To Diphenylketene

The phosphorus atom of inversely polarized phosphaalkenes such as R–P=$C(NR'_2)_2$ (R = H, alkyl, aryl, $SiMe_3$; R′

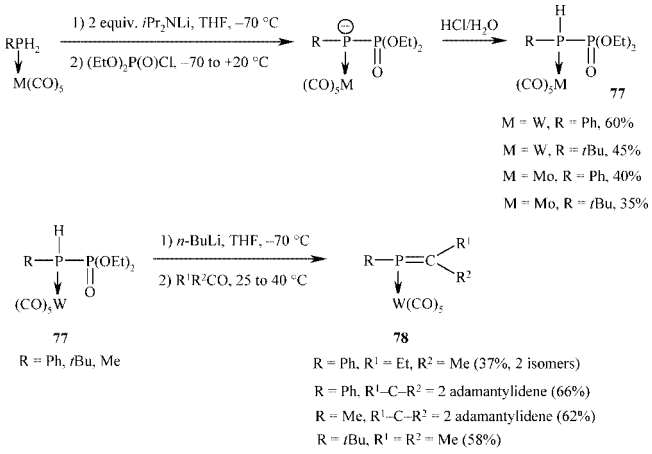
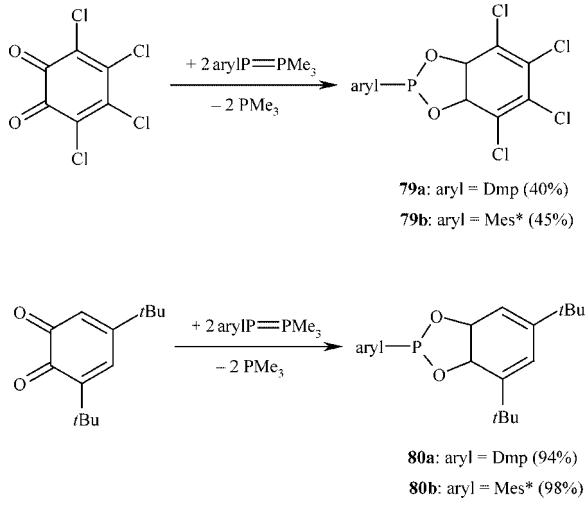
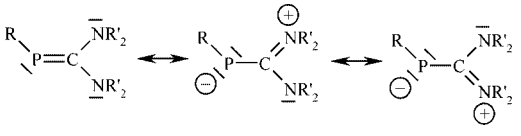


Scheme 33. Selected Phospha-Horner–Wittig reactions.



Scheme 34. Reaction of phosphinidenephosphorane with *o*-quinones.

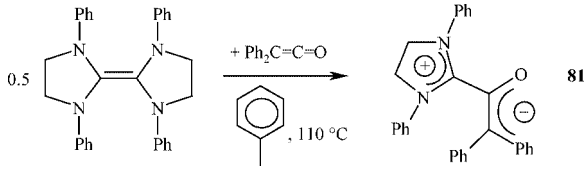
= Me, Et) is highly nucleophilic, which is rationalized by an effective π-electron delocalization of the lone pair of electrons at the trigonal-planar amino substituents into the P–C multiple bond[52] (Scheme 35).



Scheme 35. Limiting formulae of amino-substituted phosphaalkenes.

Quantum chemical calculations were performed on the parent methylenephosphane and its amino-substituted derivatives $(H_2N)(H)C{=}PH$ and $(H_2N)_2C{=}PH$ at the B3LYP/6-31g* level. The parent compound has a σ + π NBO charge of +0.387 *e* at the phosphorus atom and –0.810 *e* at the carbon atom, whereas its P–C π-bond is essentially nonpolar (+0.030 *e* at P; –0.039 *e* at C). The calculations on the C-amino-substituted phosphaalkenes predict a strong polarization of the π-bond. One, and to a greater extent, two amino groups at the carbon atom induce an inverse electron density distribution at the π-bond [for example, in $(H_2N)(H)C{=}PH$ a π NBO charge of –0.285 *e* at phosphorus and +0.013 *e* at carbon; in $(H_2N)_2C{=}PH$ values of –0.504 *e* at phosphorus and +0.059 *e* at carbon were determined].[52] This effect is mirrored in the P=C-double bond lengths, which in nonconjugated phosphaalkenes range from 1.65–1.67 Å, whereas in C-amino-functionalized phosphaalkenes P–C distances of 1.72–1.76 Å are frequently measured. $^{31}$P NMR shifts in normally polarized phosphaalkenes $R^1P^{\delta+}{=}C^{\delta-}R^2R^3$ are mainly governed by a paramagnetic contribution, which is influenced by the HOMO–LUMO gaps in such molecules. Small HOMO–LUMO gaps are responsible for low field shifts in the range between $\delta$ = 740 ppm in $[Cp^*(PEt_3)Ni{-}P{=}C(SiMe_3)_2]$ and $\delta$ = 233 ppm in $MesP{=}CPh_2$. In inversely polarized phosphaalkenes, where π-conjugation of the nitrogen lone pair with the P=C-double bond operates, the P atom in β-position to the N atoms experiences additional negative charge, which causes a pronounced high-field shift [e.g. $\delta$ = –62.6 ppm in $HP{=}C(NMe_2)_2$].[52]

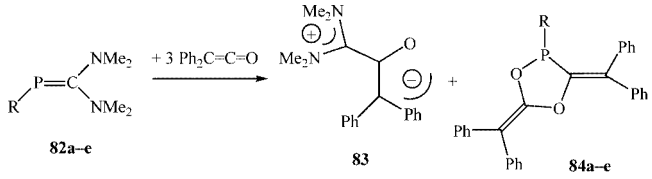
Protonation,[53] alkylation,[53,54] silylation,[54] and coordination to metal centers occur at the P atom with increase of the coordination number.[53,55,56] With regard to the diagonal relationship in the periodic table between the elements carbon and phosphorus, these electron-abundant C-amino phosphaalkenes are formally analogous to the tetraamino-substituted alkenes of the Wanzlick-type.[57] Accordingly, the homolytic cleavage of phosphaalkene should furnish a relatively stable bis(amino)carbene[58] and a highly reactive phosphinidene. Thus, the quest for Wanzlick-type reactions of the electron-rich bis(amino)phosphaalkenes was obvious. Thereby the reaction of 1,1′,3,3′-tetraphenyl-2,2′-bis(imidazolidinylidene) with diphenyl ketene to afford adduct **81**, performed previously by Regitz et al., served as a model reaction[59] (Scheme 36).



Scheme 36. Formation of a carbene/ketene adduct **81**.

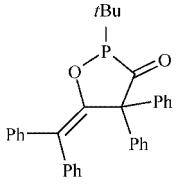
Combination of the phosphaalkenes $R{-}P{=}C(NMe_2)_2$ (**82**) [R = *t*Bu (**a**), Cy (**b**), 1-Ad (**c**), Ph (**d**), Mes (**e**)] with an excess of diphenyl ketene in *n*-pentane led to the precipitation of the light yellow zwitterionic compound **83** in about 85% yield. After removal of **83** and destruction of $Ph_2C{=}C{=}O$ with powdered NaOH, 3,5-dibenzhydrylidene-1,4,2-dioxophospholanes **84a**–**e** were isolated as colorless waxes in 45–53% yield[60] (Scheme 37).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



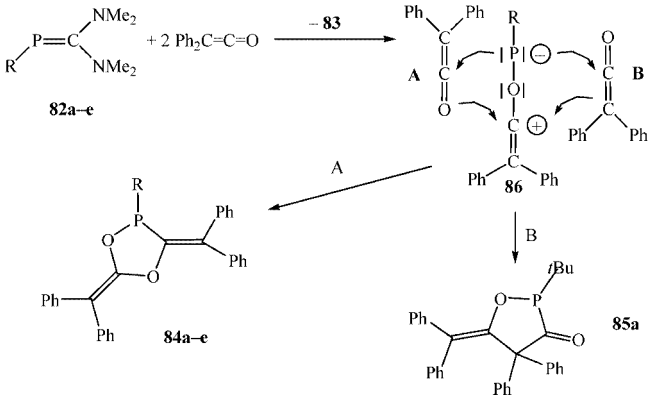
Scheme 37. Formation of compounds **83** and **84a**–**e**.

When the reaction of a concentrated solution **82a** was performed with neat $Ph_2C=C=O$, a dark-violet emulsion was formed, from which product **83** was obtained as previously from the pentane solution. Moreover, a few crystals of 5-benzhydrylidene-2-*tert*-butyl-4,4-diphenyl-1,2-oxaphospholan-3-one (**85a**) were isolated as a byproduct.



**85a**

According to a series of exchange experiments, transient, free electron-sextet species have to be excluded as intermediates. The following mechanism, invoking 1,3-dipolar species **86**, was proposed to explain the formation of **84a**–**c** and **85a** (Scheme 38).

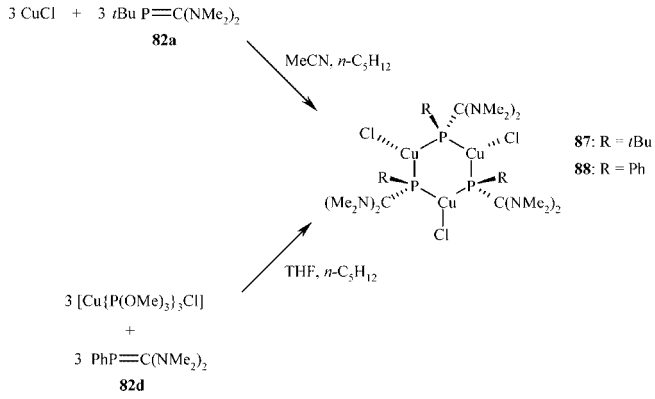


Scheme 38. Proposed mechanism for the formation of compounds **84a**–**e** and **85a**.

It is conceivable that zwitterion **86** and **83** were first formed from **82a**–**e** and two equiv. of ketene. Intermediate **86** then underwent a 1,3-dipolar addition to the C=O bond of another ketene molecule to yield major product **84** (path A). Alternatively, the 1,3-cycloaddition to the C=C double bond of the ketenes afforded **85a** (path B).[52] Reaction of inversely polarized phosphaalkenes with aldehydes did not succeed as yet.

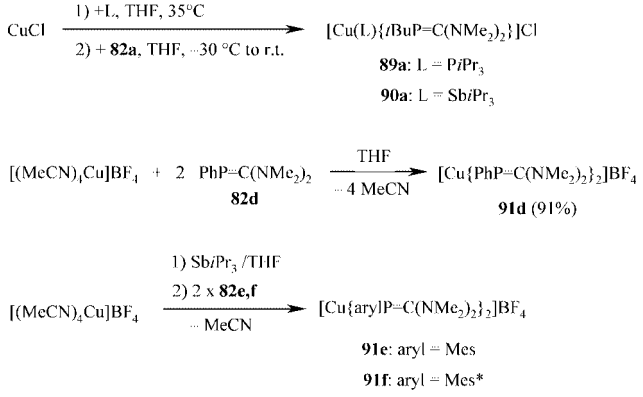
### 5.2 To Coinage Metal Complexes

In a recent study, the coordination behavior of inversely polarized phosphaalkenes towards copper and gold compounds were investigated. The reaction of equimolar amounts of $tBuP=C(NMe_2)_2$ (**82a**) and copper(I) chloride afforded the complex $[Cu_3Cl_3\{\mu_3\text{-}P(tBu)C(NMe_2)_2\}_3]$ (**87**) as the formal result of the cyclotrimerization of a 1:1 adduct (76% yield).[61] Analogously, complex **88** was synthesized in 66% yield from phosphaalkene $PhP=C(NMe_2)_2$ (**82d**) and $[Cu\{P(OMe)_3\}_3Cl]$ [38] (Scheme 39). Similarly, the analogous complexes $[Cu_3X_3\{\mu\text{-}P(tBu)C(NMe_2)_2\}_3]$ (X = Br, I) were generated.[62]



Scheme 39. Synthesis of complexes **87** and **88**.

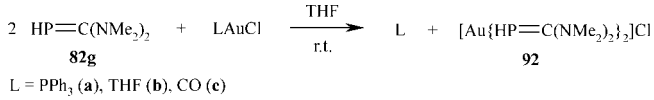
Treatment of **82a** with [Cu(L)Cl] (L = P*i*Pr$_3$; Sb*i*Pr$_3$) led to the formation of compounds $[CuCl(L)\{P(tBu)C(NMe_2)_2\}]$ **89a** (L = P*i*Pr$_3$) and **90** (L = Sb*i*Pr$_3$)[62] (Scheme 40). The reaction of $[(MeCN)_4Cu]BF_4$ with 2 equiv. of $PhP=C(NMe_2)_2$ (**82d**) yields compound $[Cu\{P(Ph)C(NMe_2)_2\}_2]BF_4$ (**91d**). Similarly, complexes $[Cu\{P(aryl)C(NMe_2)_2\}_2]BF_4$ (**91e**: aryl = Mes; **91f**: aryl = Mes*) are obtained from $arylP=C(NMe_2)_2$ [aryl = Mes (**82e**) and Mes* (**82f**)].



Scheme 40. Formation of the copper complexes **89a**, **90a**, and **91d**–**f**.

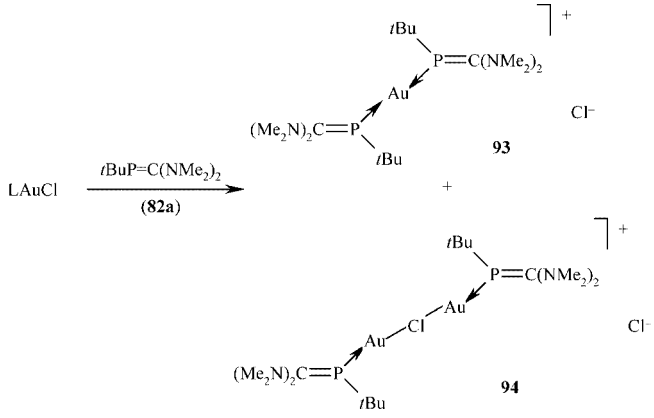
A different situation was observed with gold complexes. Combination of the gold complexes [Au(Cl)L] [**a**: L = $PPh_3$; **b**: L = tetrahydrothiophene(THF); **c**: L = CO] with two molar equivalents of phosphaalkene $HP=C(NMe_2)_2$ (**82g**) in THF at 20 °C led to the yellow mononuclear complex **92**[63] (Scheme 41).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



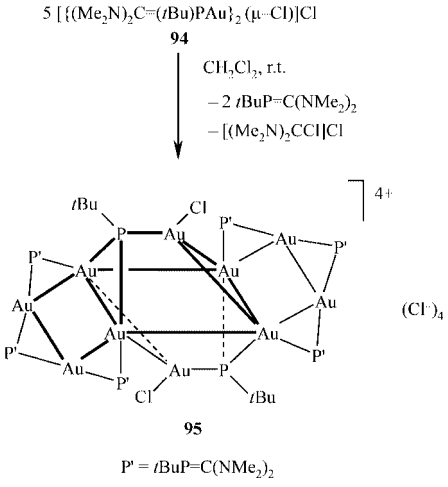
Scheme 41. Reaction of $HP=C(NMe_2)_2$ with [LAuCl].

The reaction of complexes [LAuCl] with the more bulky and more basic phosphaalkene $t$BuP=C(NMe$_2$)$_2$ (**82a**) under analogous conditions produced a mixture of cationic complexes **93** and **94** as an amorphous green-yellow precipitate (Scheme 42).



Scheme 42. Reaction of $t$BuP=C(NMe$_2$)$_2$ with [LAuCl].

Attempts to separate the compounds by crystallization from dichloromethane or acetonitrile led to the complete transformation of **93** and **94** into the yellow salt **95** with a decanuclear cluster cation (Scheme 43).



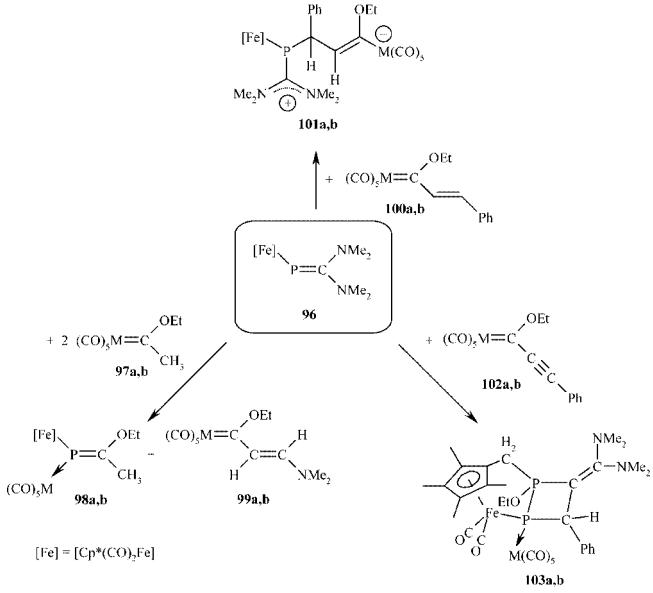
Scheme 43. Formation of **95** from **94** (idealized).

The cation $[(Me_2N)_2CCl]^+$ was formed from an unprecedented nucleophilic cleavage of a P=C double bond by a chloride. According to an X-ray structure analysis, eight gold atoms form a puckered ladder made up of three quadrangles. The central quadrangle is capped on both faces by a [$t$BuPAuCl] entity. Three edges of each peripheral rectangle are bridged by phosphaalkene ligands.

### 5.3 To Fischer Carbene Complexes

Fischer carbene complexes are organometallic electrophiles with a carbene ligand highly susceptible to nucleophilic attack, which renders them extremely useful as reagents and catalysts in modern preparative chemistry. Thus, the question of the reactivity of inversely polarized phosphaalkenes towards these compounds became relevant.

Ferriophosphaalkene **96** was allowed to react with two molar equivalents of carbene complexes **97a** and **97b** in diethyl ether, forming the novel ferriophosphaalkene complexes **98a**,**b** and β-aminoalkenyl(ethoxy)carbene complexes **99a**,**b** (Scheme 44).

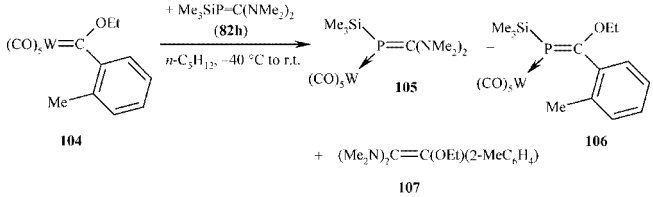


Scheme 44. Reaction of **96** with several Fischer carbene complexes.

Combination of **96** and the alkenyl carbene complexes **100a**,**b** in a mixture of $n$-pentane and diethyl ether at –30 °C led to the precipitation of orange zwitterionic Michael-type adducts **101a**,**b** (Scheme 44).

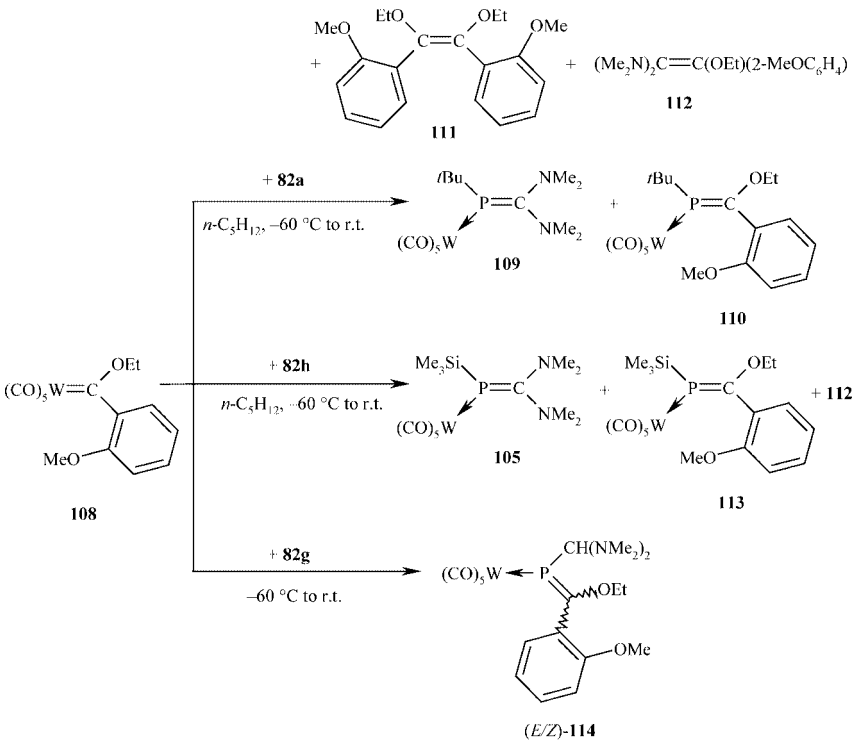
In sharp contrast to the synthesis of **98a**,**b** and **101a**,**b**, treatment of **96** with an equimolar amount of ethynyl(phenyl) carbene complexes **102a**,**b** in $n$-pentane at –60 °C afforded the yellow pentacarbonylmetal adducts **103a**,**b** of a 1-ferriophosphetane as the only tractable phosphorus-containing products (ca. 20% yield)[64] (Scheme 44).

When the ethoxy($o$-tolyl)carbene complex **104** was subjected to reaction with $Me_3SiP=C(NMe_2)_2$ (**82h**) in $n$-pentane at –40 °C, the yellow complex **105** (38%) was obtained in addition to the novel orange crystalline $\eta^1$-phosphaalkene complex **106** and alkene **107** (Scheme 45). No reaction oc-



Scheme 45. Reaction of **104** with phosphaalkene $Me_3SiP=C(NMe_2)_2$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



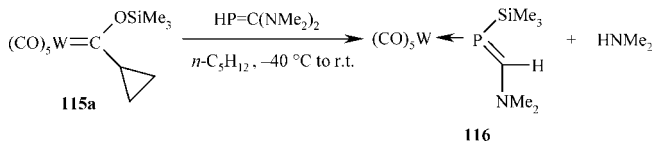
Scheme 46. Reaction of **108** with the phosphaalkenes $RP{=}C(NMe_2)_2$ (**82a**: R = *t*Bu; **82h**: R = $Me_3Si$; **82g**: R = H).

curred between **104** and *t*BuP=C(NMe$_2$)$_2$ (**82a**). Precursor **104** was decomposed by exposure to HP=C(NMe$_2$)$_2$ (**82g**).[65]

The reaction of *o*-methoxyphenyl carbene complex **108** with *t*BuP=C(NMe$_2$)$_2$ (**82a**) under comparable conditions yielded the yellow $\eta^1$-phosphaalkene complex **109** (29%) and the orange $\eta^1$-phosphaalkene complex **110** (39%), after fractioning crystallization from pentane. Small amounts of an oily 1:1 mixture of alkenes [(*E*/*Z*)-2-MeOC$_6$H$_4$(EtO)C]$_2$ (**111**) and (Me$_2$N)$_2$C=C(OEt)(2-MeOC$_6$H$_4$) (**112**) were identified as byproducts[65] (Scheme 46).

Similarly, combination of **108** with $Me_3SiP{=}C(NMe_2)_2$ (**82h**) gave rise to the formation of **105** (51%) and the metathesis product [{$Me_3SiP{=}C(OEt)(2\text{-}MeOC_6H_4)$}W(CO)$_5$] (**113**), which was isolated as an orange solid in 21% yield. Alkene **112** was also identified in the reaction residue (Scheme 46). The course of the reaction of carbene complex **108** with HP=C(NMe$_2$)$_2$ (**82g**) was completely different. Here [(CO)$_5$W] complexes of the two geometric isomers of the phosphaalkene (Me$_2$N)$_2$CH–P=C(OEt)(2-MeOC$_6$H$_4$) (*E*/*Z*)-**114** were obtained as orange crystals in 80% yield. The *E*/*Z* ratio was 1:2[65] (Scheme 46).

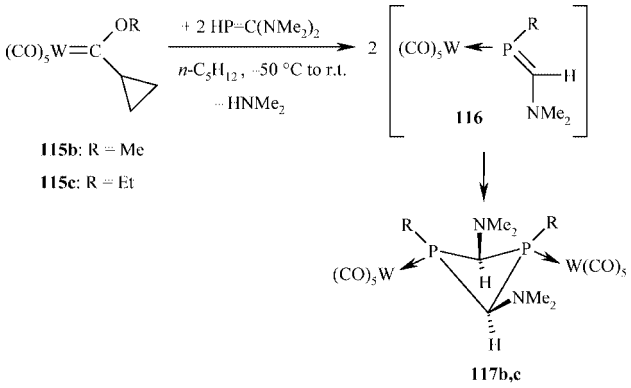
As pointed out, the course of the reaction and the product pattern of the processes under discussion are sensitively governed by the nature of substituents at the carbene ligand as well as at the P atom of the organophosphorus reagent. In keeping with this, yet different, results were obtained in the reaction of inversely polarized phosphaalkenes **82** with Fischer carbene complexes having secondary alkyl or cycloalkyl substituents at the carbene carbon atom, which are less electron-withdrawing than aryl groups, but cannot be involved in condensations as primary alkyl substituents at the carbene center. When cyclopropyl carbene complex **115a** was treated with an equimolar amount of phosphaalkene HP=C(NMe$_2$)$_2$ (**82g**) in *n*-pentane in the range –40 °C to room temperature, phosphaalkene complex **116** separated from the filtered reaction mixture at –16 °C as orange crystals in 47% yield, and dimethylamine was identified as a byproduct. The fate of the cyclopropyl moiety remained unclear (Scheme 47).



Scheme 47.

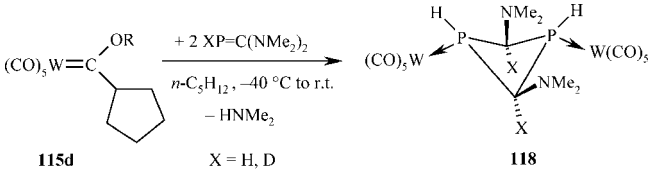
In contrast to this, cyclopropyl(methoxy)- and cyclopropyl(ethoxy)carbene complexes **115b** and **115c** were converted by HP=C(NMe$_2$)$_2$ (**82g**) into the 1,3-bis(pentacarbonyltungsten)-1,3-diphosphetane complexes **117b** and **117c**, which separated from pentane solutions at –16 °C as yellow-to-orange crystals in 60% and 72% yields, respectively.[66] In many cases 1,3-diphosphetanes result from a [2+2] head-to-tail dimerization of relatively unhindered phosphaalkenes. Accordingly, it is most likely that phosphaalkene complexes analogous to **116** were initially generated and subsequently suffered from self-dimerization[66] (Scheme 48).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

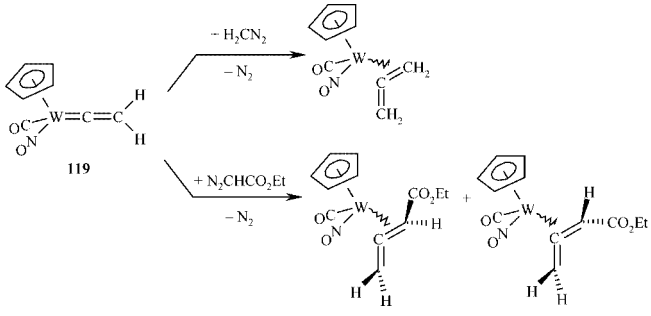


Scheme 48. Preparation of **117b,c**.

Cyclopentyl(ethoxy)carbene complex **115d** and $XP=C(NMe_2)_2$ (X = H, D) did not react to afford the expected 1,3-diphosphetane **117c**. Instead, the PH-functionalized 1,3-diphosphetane complex **118** was isolated from *n*-pentane at –16 °C as colorless crystals (42%) (Scheme 49). With $DP=C(NMe_2)_2$ product **[D$_2$]118** resulted, where the ring carbon atoms are deuterated. Thus the phosphaalkene cannot be the source of the hydrogen atom at phosphorus in the 1,3-diphosphetane.



Scheme 49. Synthesis of **118**.



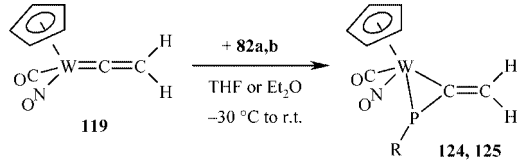
Scheme 50.

## 5.4 To Vinylidene Complexes

The obvious next step was to study the nucleophilic transfer of phosphinidenes from inversely polarized phosphaalkenes to the electrophilic ligand of vinylidene complexes, which are closely related to transition-metal carbenes. A motivation for this came from a recent paper of Ipaktschi et al. who succeeded in the transformation of vinylidene complex **119** into $\eta^2$-allene complexes by exposing it to diazomethane and ethyl diazoacetate[67] (Scheme 50).

Treatment of [Cp(CO)(NO)W=C=C(H)Ph] (**120**) with half a molar equivalent of phosphaalkenes $RP=C(NMe_2)_2$ **82** (**a**: R = *t*Bu; **b**: *c*-$C_6H_{11}$) in ethereal solvents at 0 °C to 20 °C afforded the crystalline $\eta^2$-1-phosphaallene complexes **121** (20% yield) and **122** (19%) after chromatography[68] (Scheme 51). Red crystalline carbene complex **123** was formed as a byproduct in these reactions.

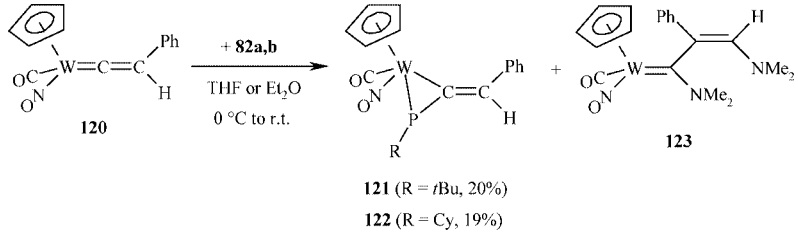
Similarly, yellow crystalline **124** (R = *t*Bu) resulted from the reaction of **82a** and vinylidene complex **119** in THF at 20 °C (30% yield). The synthesis of **125** (R = $C_6H_{11}$) from **119** and **82b** was accomplished in diethyl ether at –30 °C (12% yield) (Scheme 52).



Scheme 52. Preparation of the 1-phosphaallene complexes **124** and **125**.

## 5.5 To Phosphenium Complexes

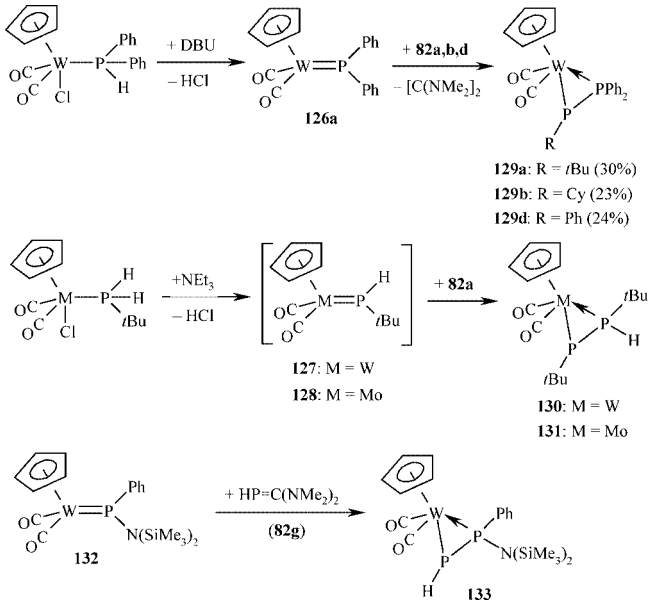
From a formal point of view, carbene $CR_2$- and phosphenium ligands [$PR_2^+$] are isolobal, both exhibiting pronounced electrophilic character. Thus it was obvious to also include transition-metal–phosphenium complexes in the investigations on the nucleophilicity and on the phosphinidene-transfer tendency of inversely polarized phosphaalkenes. Phosphenium complexes [$Cp(CO)_2W=PPh_2$] (**126**), [$Cp(CO)_2W=P(H)tBu$] (**127**), and [$Cp(CO)_2MoP(H)tBu$] (**128**) were freshly prepared by the dehydrochlorination of the chlorophosphane complexes [$Cp(CO)_2(Cl)W–P(H)Ph_2$], [$Cp(CO)_2(Cl)W–P(H)_2tBu$], and [$Cp(CO)_2(Cl)Mo–P(H)_2tBu$] with



Scheme 51. Preparation of $\eta^2$-1-phosphaallene complexes **121** and **122**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

DBU or triethylamine at –78 °C and subsequently combined with phosphaalkenes $RP{=}C(NMe_2)_2$ **82** (**a**: R = *t*Bu; **b**: R = Cy; **d**: R = Ph; **g**: R = H). Alternatively, the isolated compound $[Cp(CO)_2W{=}P(Ph)N(SiMe_3)_2]$ (**132**) was directly subjected to reaction with $HP{=}C(NMe_2)_2$. Thereby $\eta^2$-diphosphanyl complexes **129a**,**b**,**d**, **130**, **131**, and **133** were generated and isolated as crystalline compounds after column chromatography in 24–30% yield[69] (Scheme 53).



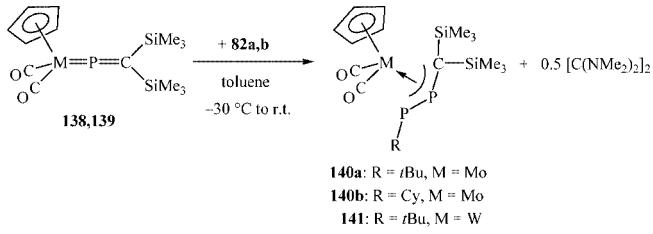
Scheme 53. Preparation of the $\eta^2$-diphosphanyl complexes **129a,b,d**, **130**, **131**, and **133**.

The reaction of **126a**,**b** was also conducted with an excess of carbonyl-stabilized phosphaalkenes $arylC(O)P{=}C(NMe_2)_2$ (**134**: aryl = Ph; **135**: aryl = 4-Et$C_6H_4$) in toluene in the range –30 °C to room temperature to afford metallophosphaalkenes **136a**,**b** and **137a**,**b** in modest yields (30–46%)[70] (Scheme 54).

As a mechanism for the formation of the chelates, an initial attack of the phosphaalkene onto the phosphenium center with formation of transient **A** was postulated. Extrusion of carbene $[C(NMe_2)_2]$ was accompanied by ring closure to give diphosphanyl complex **B**. Insertion of the C=O moiety of **B** into the P–P bond furnished the final products.

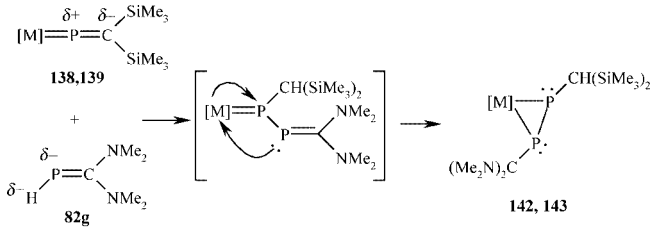
### 5.6 To Phosphavinylidene Complexes

Phosphavinylidene complexes $[Cp(CO)_2M{=}P{=}C(SiMe_3)_2]$ (**138**: M = Mo; **139**: M =W) are organometallic electrophiles closely related to vinylidene as well as to phosphenium complexes. The reaction of phosphavinylidene complex **138** with an equimolar amount of phosphaalkene $tBuP{=}C(NMe_2)_2$ (**82a**) in toluene afforded the yellow $\eta^3$-1,2-diphosphaallyl complex **140a** by a phosphinidene transfer process from the phosphaalkene onto the ligand (31% yield). Similarly, **138** was converted into orange product **140b** when allowed to react with $CyP{=}C(NMe_2)_2$ (**82b**) (49% yield). The reaction of **139** with **82a** under comparable conditions led to the formation of complex **141** (Scheme 55).

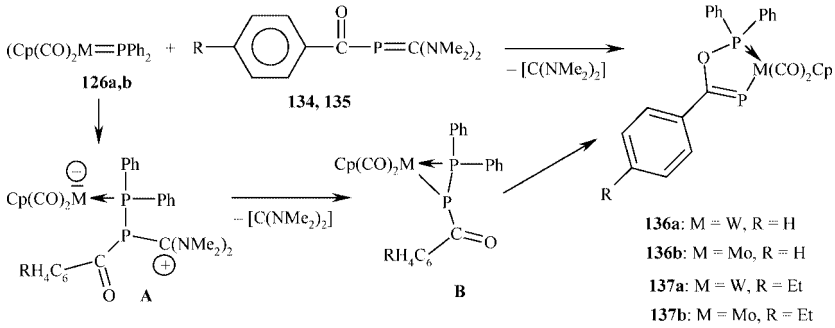


Scheme 55. Synthesis of 1,2-diphosphaallyl complexes.

The reaction of **138** and **139** with an equivalent amount of phosphaalkene $HP{=}C(NMe_2)_2$ (**82g**) in diethyl ether in the range –30 °C to room temperature took another course. Here, a proton transfer from the phosphorus atom on to the disilylmethylene unit of the precursor complex led to the formation of the unsymmetrical diphosphene complexes **142** and **143** as yellow-to-orange crystals[71] (Scheme 56).



Scheme 56. Formation of complexes **142** and **143**.

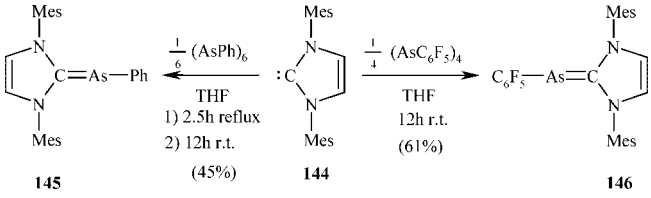


Scheme 54. Formation of **136a**,**b** and **137a**,**b**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

## 6. Arsinidenes

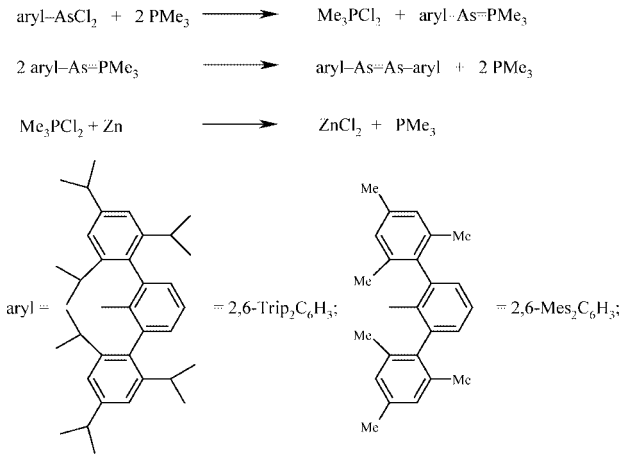
In comparison to the well-developed chemistry of phosphinidenes, little attention has been addressed to the homologous arsinidenes. A few adducts of arsinidenes to carbenes and trimethylphosphane have been prepared recently. Carbene **144** was treated with hexaphenylcyclohexaarsane to form the adduct **145** as a yellow crystalline solid melting at 148–152 °C with decomposition[72] (Scheme 57).



Scheme 57. Preparation of **145** and **146**.

Compound **146** was prepared similarly from **144** and tetrakis(pentafluorophenyl)cyclotetraarsane as a yellow solid in 61% yield.[72]

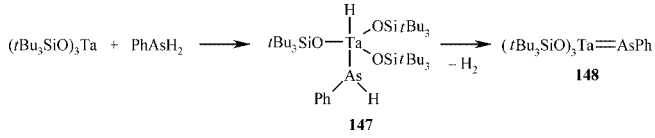
An arsa-Wittig reagent (arsanylidene-$\sigma^4$-phosphorane) was synthesized by the zinc reduction of 2,6-Trip$_2$C$_6$H$_3$AsCl$_2$ (Trip = 2,4,6-*i*Pr$_3$C$_6$H$_2$) in the presence of excess of PMe$_3$. The labile product decomposed upon attempted purification to the diarsene 2,6-Trip$_2$C$_6$H$_3$As=AsC$_6$H$_3$Trip$_2$-2,6. Thus, when heated in THF for a few minutes, the arsa-Wittig reagent was quantitatively converted into the diarsene. Attempts to synthesize the arsa-Wittig reagent 2,6-Mes$_2$C$_6$H$_3$-As=PMe$_3$ by reduction of 2,6-Mes$_2$C$_6$H$_3$AsCl$_2$ with zinc and PMe$_3$ gave only the corresponding diarsene in quantitative yield[73] (Scheme 58).



Scheme 58. Synthesis of diarsenes by using arsa-Wittig reagents.

Huttner et al.,[74] conducted pioneering studies of $\mu_2$-arsinidene complexes L$_n$M=As(R)=ML$_n$; however, only little information on complexes with terminal arsinidene ligands is available to date.

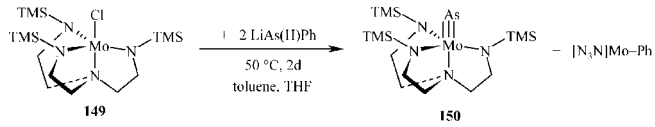
The need to employ bulky groups for the kinetic stabilization of the reactive metal–arsenic multiple bond was also fulfilled by the employment of sterically encumbering ancillary ligands at the metal. Thus, Wolczanski et al. have used the (*t*Bu$_3$SiO)$_3$Ta fragment to support the terminal AsPh group. This first terminal arsinidene complex **148** was prepared by a two-step process, the first of which was an oxidative addition reaction of (*t*Bu$_3$SiO)$_3$Ta with phenylarsane to afford the arsenido complex **147**[20] (Scheme 59).



Scheme 59. Synthesis of **148**.

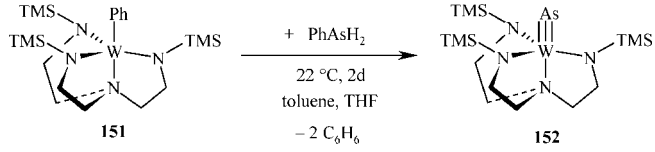
In benzene solution, the arsenido tantalum hydride **147** underwent loss of dihydrogen to yield the terminal arsinidene complex **148**.

The reaction between [N$_3$N]MoCl complex **149** and 2 equiv. of LiAsPhH in the absence of light afforded orange diamagnetic [N$_3$N]Mo≡As complex **150** in ca. 30% yield in addition to an equal amount of [N$_3$N]Mo–Ph, whereby no intermediates could be detected[75] (Scheme 60).



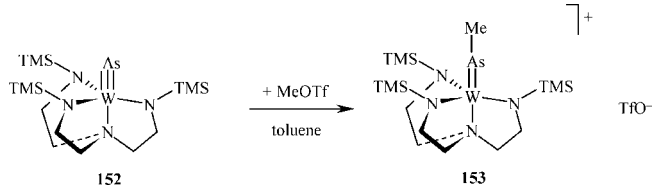
Scheme 60. Preparation of arsenido complex **150**.

The tungsten analogue **152** could not be prepared by a protocol analogous to Scheme 60. Instead, the treatment of phenyl tungsten complex **151** with phenylarsine led to the desired tungsten–arsenido complex[75] (Scheme 61).



Scheme 61. Synthesis of arsenido complex **152**.

This tungsten arsenido complex reacted readily with methyl triflate in toluene to give the cationic arsinidene complex **153**[75] (Scheme 62).



Scheme 62. Methylation of **152** to yield arsinidene complex **153**.

The most interesting features in the molecular structure of **153** are the essentially linear arsinidene ligand [W–As–C = 173.3(6)°] and a W=As bond length of 2.2494(14) Å, which is virtually the same as the Mo≡As bond length in [N$_3$N]Mo≡As. The linearity of the arsinidene ligand in **153** contrasts strongly with the dramatically bent phenylarsinidene li-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

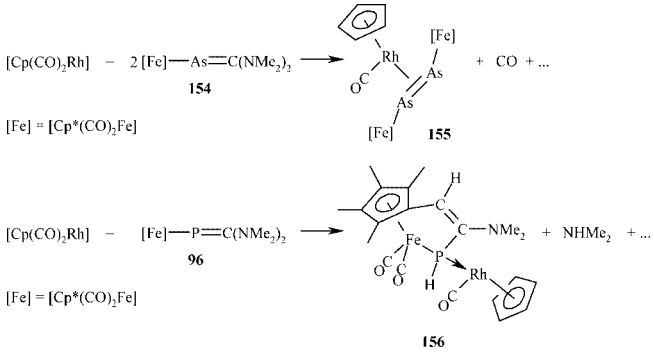
gand [107(4)°] and longer Ta=As bond length [2.428(2) Å] in $[(t\mathrm{Bu_3SiO})_3\mathrm{Ta{=}AsPh}]$.[20]

## 7. Arsinidene Transfer from Inversely Polarized Arsaalkenes

### 7.1 With the Formation of $(RAs)_n$ ($n$ = 2, 3)

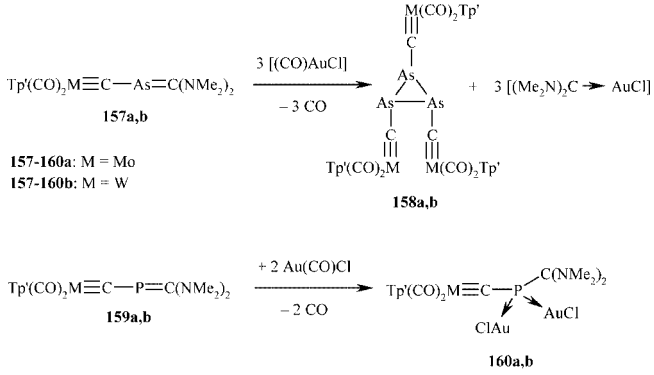
A first evidence for the facile cleavage of the As=C bond of arsaalkenes was observed in the reaction of $[Cp^*(CO)_2Fe{-}As{=}C(NMe_2)_2]$ (**154**) with $CpRh(CO)_2$ to afford an $\eta^2$-diarsene rhodium complex **155** as dark-red crystals in 63% yield[76] (Scheme 63).

This is in sharp contrast to the behavior of the analogous ferriophosphaalkene **96**, which, upon reaction with the rhodium complex, furnished compound **156** as the result of a condensation process of one methyl group of the Cp* ligand and the tricoordinate C atom of the P=C double bond[76] (Scheme 63).



Scheme 63. Formation of **155** and **156**.

During the studies on $[HB(3,5\text{-}Me_2HC_3N_2)_3(CO)_2M{\equiv}C{-}As{=}C(NMe_2)_2]$ (**157a**: M = Mo; **157b**: M = W) a facile metal-assisted cleavage of the As=C multiple bond was observed in the reaction of the arsaalkene was allowed to react with [(CO)AuCl]. Cyclotriarsanes **158a**,**b** resulted from the formal trimerization of the respective arsinidenes $[HB(3,5\text{-}Me_2HC_3N_2)_3(CO)_2M{\equiv}C{-}As]$. Thereby the carbene fragment $[C(NMe_2)_2]$ was intercepted as the known carbene complex $[(Me_2N)_2C{\rightarrow}AuCl]$[77] (Scheme 64).

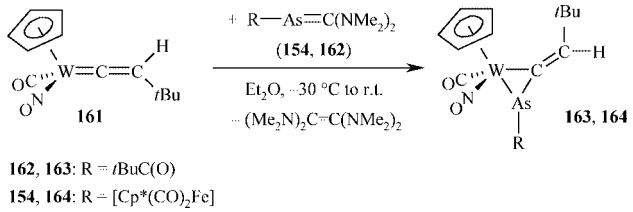


Scheme 64. Preparation of **158a**,**b** and **160a**,**b**.

Again, a completely different behavior was encountered in the reaction of phosphaalkenes **159a**,**b** with the gold compound, where simply a twofold addition of AuCl to the phosphorus atom occurred[77] (Scheme 64).

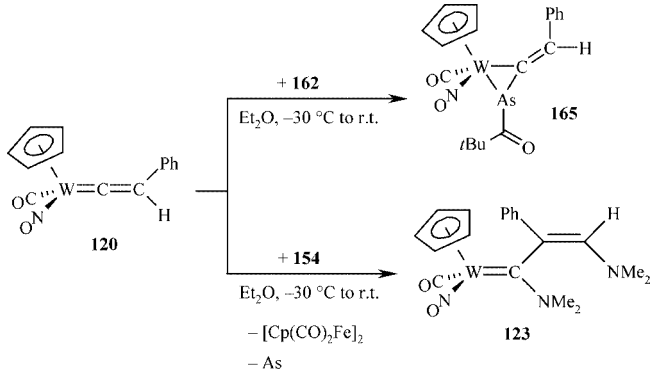
### 7.2 With Vinylidene Complexes

In order to explore the scope and limitations of inversely polarized arsaalkenes to formally act as a source for arsinidene species, the investigations were extended to vinylidene complexes. Treatment of complex [Cp(CO)(NO)W=C=C(H)($t$Bu)] (**161**) with an equimolar amount of arsaalkenes $R{-}As{=}C(NMe_2)_2$ {**162**: R = $t$BuC(O); **154**: R = $Cp^*(CO)_2Fe$} in diethyl ether solution in the range –30 °C to room temperature afforded the crystalline $\eta^1$-1-arsaallene complexes **163** (50% yield) and **164** (73% yield), respectively after chromatography. Compound **164** was obtained as a mixture of two isomers[78] (Scheme 65).



Scheme 65. Formation of the 1-arsaallene complexes **163** and **164**.

An analogous treatment of vinylidene complex **120** with the pivaloylarsaalkene **162** afforded the thermolabile complex **165** as orange crystals in 29% yield (Scheme 66).



Scheme 66. Reaction of **120** with arsaalkenes **154** and **162**.

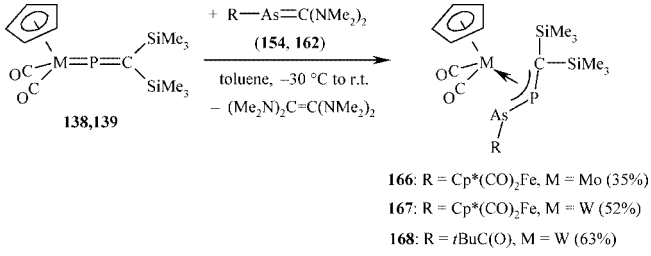
In sharp contrast to this, reaction of **120** with ferrioarsaalkene **154** did not lead to the anticipated arsaallene system. Instead, red crystalline carbene complex **123** was isolated in 69% yield. Elemental arsenic and complex $[Cp^*Fe(CO)_2]_2$ were also obtained (82% yield).[78] The generation of carbene complex **123** was previously observed in the reaction of **120** with phosphaalkenes $RP{=}C(NMe_2)_2$ **82** (**a**: R = $t$Bu; **b**: Cy).[68]

### 7.3 With Phosphavinylidene Complexes

Combination of complexes $[Cp(CO)_2M{=}P{=}C(SiMe_3)_2]$ (**138**: M = Mo; **139**: M = W) with an equimolar amount of

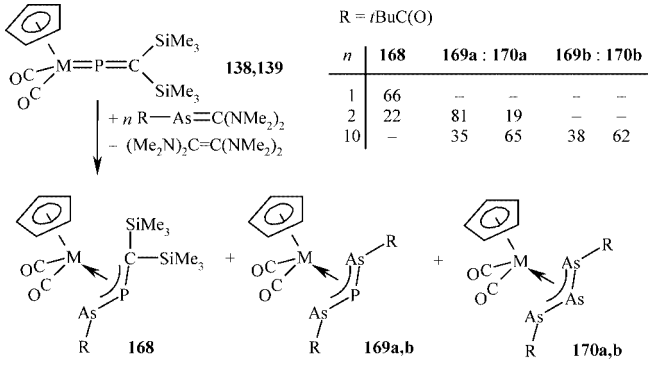
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ferrioarsaalkene [Cp*(CO)$_2$Fe–As=C(NMe$_2$)$_2$] (**154**) in toluene afforded the deep red crystalline η$^3$-2-phosphaarsaallyl complexes **166** and **167**. Analogously, reaction of compound **162** with an equimolar amount of **139** gave rise to the formation of heteroallyl complex **168** as an orange solid (63% yield). Tetrakis(dimethylamino)ethane was formed as a by-product[79] (Scheme 67).



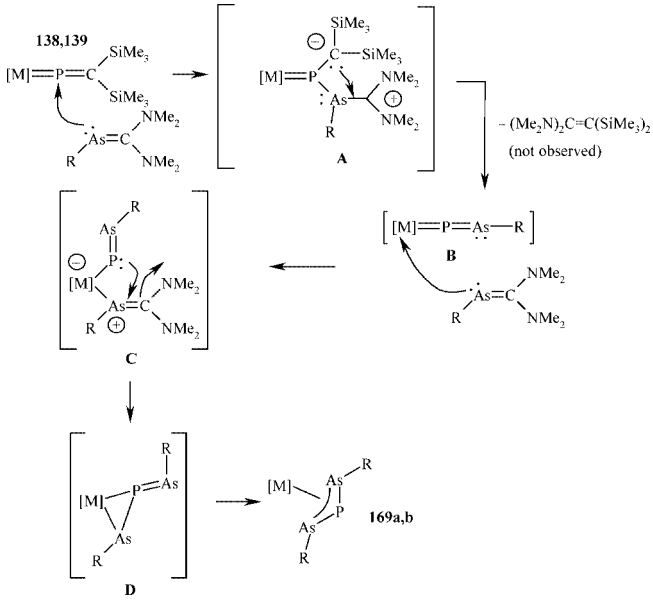
Scheme 67. Formation of the 2-phospha-1-arsaallyl complexes **166**–**168**.

The outcome of the reaction between precursors **138**, **139** and *t*BuC(O)As=C(NMe$_2$)$_2$ proved to be crucially dependent on the respective stoichiometry employed.[80] Thus, when the reaction of [Cp(CO)$_2$W=P=C(SiMe$_3$)$_2$] (**139**) was conducted with twice the molar equivalent of arsaalkene under otherwise comparable conditions, complex **168** was isolated in only 22% yield from the first orange-red zone of the column. From the second deep-red zone, dark-red crystals were obtained, which, according to an X-ray analysis, were disclosed as an inseparable 81:19 mixture of the η$^3$-2-phospha-1,3-diarsaallyl complex **169a** and the η$^3$-1,2,3-triarsaallyl complex **170a**. The employment of a 10-fold amount of arsaalkene in this process afforded a 35:65 mixture of **169a** and **170a**[80] (Scheme 68).



Scheme 68. Reactions of **138** and **139** with *t*BuC(O)As=C(NMe$_2$)$_2$.

Analogously, the reaction of **138** (M = Mo) with a 10-fold excess of arsaalkene gave a 38:62 mixture of [Cp(CO)$_2$-Mo{η$^3$-*t*BuC(O)AsPAsC(O)*t*Bu}] (**169b**) and [Cp(CO)$_2$-Mo{η$^3$-*t*BuC(O)AsAsAsC(O)*t*Bu}] (**170b**). A proposal for the mechanism of the formation of **169a**,**b** involves the initial formation of adduct **A**, which extrudes the putative alkene (Me$_2$N)$_2$C=C(SiMe$_3$)$_2$ with the formation of [Cp(CO)$_2$-M=P=As–C(O)(*t*Bu)] (**B**). The latter arsaphosphene adds a second equivalent of arsaalkene to give intermediate **C**. Liberation of [C(NMe$_2$)$_2$] to form **D** and rearrangement furnish the final products **169a**,**b**. The mechanism of the formation of **170** remained unclear[80] (Scheme 69).

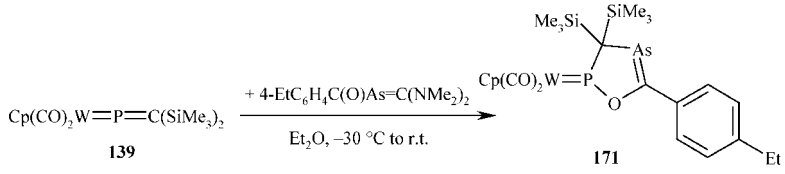


Scheme 69. Proposed mechanism for the formation of compounds **169a**,**b**.

In contrast to this, the more reactive arsaalkene 4-EtC$_6$H$_4$C(O)As=C(NMe$_2$)$_2$ and the tungsten complex **139** underwent reaction to afford the cyclic phosphenium complex **171** as red crystals in 41% yield[79b] (Scheme 70).

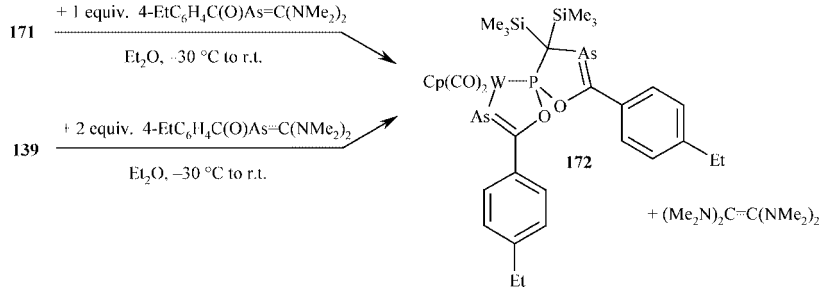
The reaction of complex **171** with a second equivalent of 4-EtC$_6$H$_4$C(O)As=C(NMe$_2$)$_2$ or, alternatively, treatment with **139** with two molar equivalents of arsaalkene led to the formation of the bicyclic metalloarsaalkene **172** as yellow crystals in 71% yield (Scheme 71).

Similarly, treatment of complexes **138**, **139** with 2 equiv. of freshly prepared arsaalkene PhC(O)As=C(NMe$_2$)$_2$ in diethyl ether solution afforded the yellow microcrystalline metalloarsaalkenes **173** (80%) and **174** (75%). In the case of the reaction of the molybdenum complex **138** with PhC(O)-As=C(NMe$_2$)$_2$, a few crystals of a second product, **175**, were isolated from the mother liquor after chromatography and



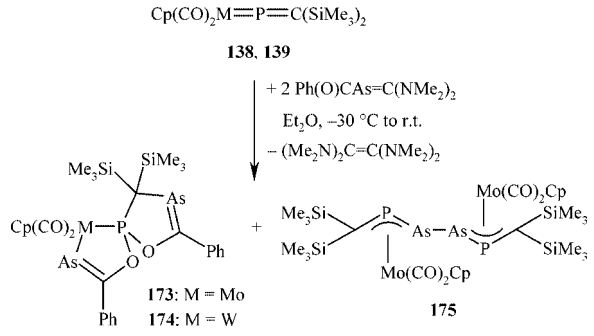
Scheme 70. Formation of phosphenium complex **171**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 71. Formation of spiro compound **172**.

separation of **173**. According to an X-ray structural analysis, compound **175** has to be regarded as the yet unknown {Cp(CO)$_2$Mo}$\eta^3$(1–3):$\eta^3$(3–6)-2,5-diphospha-3,4-diarsadiallyl system[80] (Scheme 72).

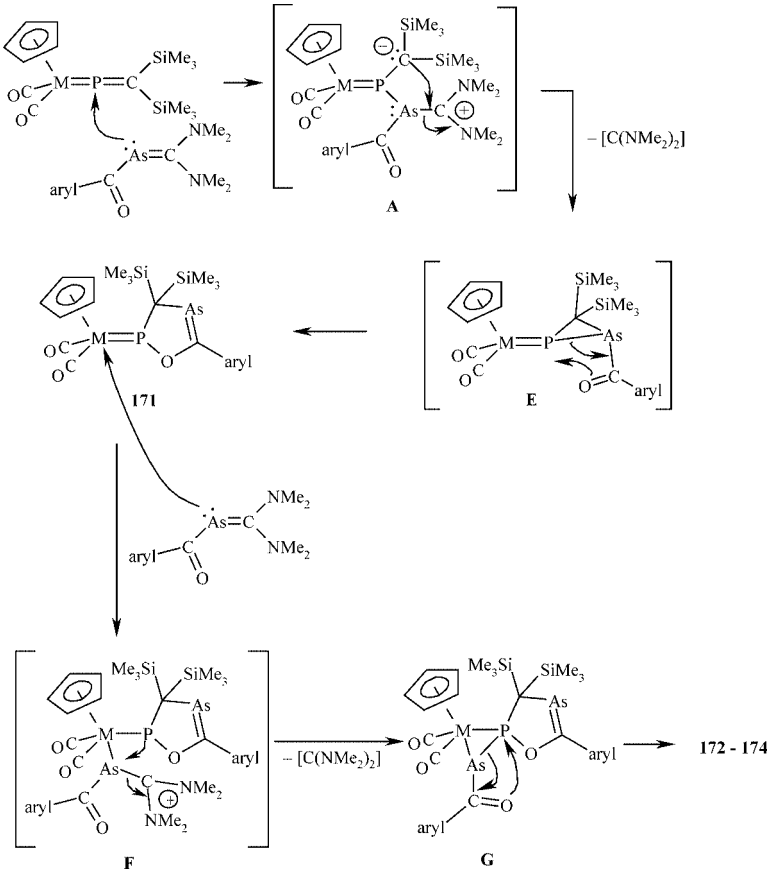


Scheme 72. Formation of **173**–**175**.

For a mechanism, it was suggested that adduct **A** is formed from the precursors, which lose [C(NMe$_2$)$_2$] with formation of intermediate **E**. Insertion of the carbonyl unit into the P–As bond of the three membered ring in **E** afforded the phosphenium complex **171**. Attack of the arsaalkene at the metal center of **171** would lead to intermediate **F**, which extrudes [C(NMe$_2$)$_2$] to give transient **G**.

The attack of the carbonyl oxygen atom at the P atom is responsible for the ring enlargement to give final products **172**–**174**[79,80] (Scheme 73).

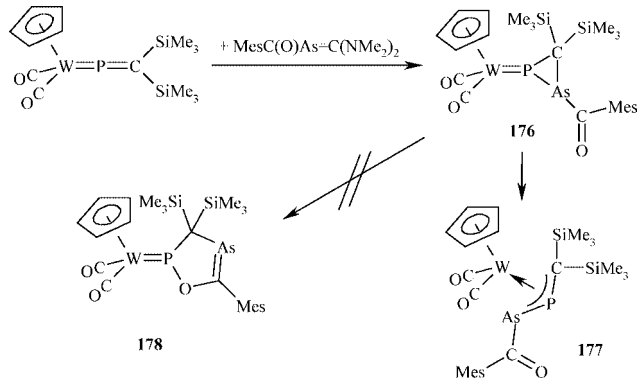
The increase of the steric demand of the substituent on going from the benzoyl and 4-ethylbenzoyl derivatives to MesC(O)As=C(NMe$_2$)$_2$ provided a situation where hetero-



Scheme 73. Proposed mechanism for the formation of **172**–**174**.

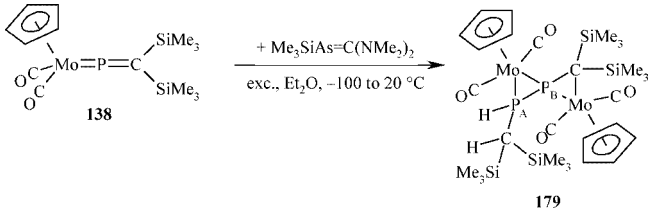
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cyclic ligands (e.g. in **178**) are no longer formed by CO incorporation. Instead, treatment of **139** with 1 equiv. of this arsaalkene generated the labile phosphenium complex **176**, which rearranged in solution within a few hours to the orange crystalline 2-phospha-1-arsaallyl complex **177** in 54% yield[80] (Scheme 74).



Scheme 74. Formation of 2-phospha-1-arsaallyl complex **177**.

The reaction of arsaalkene $Me_3SiAs=C(NMe_2)_2$ with molybdenum complex **138** proceeded with yet a different result. Combination of the reactants in a 2:1 molar ratio in diethyl ether at –100 to 20 °C afforded the As-free complex **179** as dark-red crystals after chromatographic work-up (yield 64%) [80] (Scheme 75).



Scheme 75. Formation of **179** from **138** and $Me_3SiAs=C(NMe_2)_2$.

## 8. Conclusions and Perspectives

Inversely polarized phosphaalkenes $RP=C(NMe_2)_2$ serve as convenient sources of the phosphinidene unit PR, which can be transferred onto a broad variety of electrophilic ligands in transition-metal complexes. Their combination with Fischer carbene complexes affords $\eta^1$-phosphaalkene complexes. This synthetic principle was extended to vinylidene complexes [$L_nM=CR'H$] and phosphenium complexes [$L_nM=PRR'$], which are cleanly converted into $\eta^1$-phosphaallene and diphosphanido complexes, respectively. Phosphaalkenes, in which the phosphorus atom carries benzoyl-type substituents, reacted with phosphenium complexes with the incorporation of the CO group into five-membered metalloheterocycles. Phosphavinylidene complexes [$L_nM=P=C(SiMe_3)_2$] are transformed into coordination compounds featuring the novel $\eta^3$-1,2-diphosphaallylic ligand. Inversely polarized arsaalkenes $RAs=C(NMe_2)_2$ also display a rich chemistry when allowed to react with organometallic electrophiles such as vinylidene and phosphavinylidene complexes. Here, the synthesis of phosphaallene, phosphaarsaallyl, diarsaphosphaallyl, and triarsaallyl complexes was achieved. Carbonyl-functionalized arsaalkenes led to phosphenium and spiro complexes featuring five-membered heterocycles.

Thus phospha- and arsaalkenes are valuable and versatile reagents in the arsenal of elementorganic and coordination chemists.

# Supramolecular Click Assembly of a Fused Double-Stranded [$Mn^{II}_3$] Dihelicate

**Jinkui Tang,[a] José Sánchez Costa,[a] Guillem Aromí,[b] Ilpo Mutikainen,[c] Urho Turpeinen,[c] Patrick Gamez,[a] and Jan Reedijk*[a]**

**Keywords:** Self-assembly / Helicates / Click chemistry / Manganese / Ferromagnetic interactions

A trinuclear $Mn^{II}$ complex was obtained by reaction of manganese(II) perchlorate with the ligand 2-methoxy-6-(pyridine-2-ylhydrazonomethyl)phenol in methanol. The X-ray crystal structure of $[Mn_3L_4](ClO_4)_2(H_2O)_2$ (**1**) reveals that the "bent" chain of the $Mn^{II}$ ions is assembled by a unique click-assembly of two double-stranded helicates. Magnetic susceptibility measurements show weak ferromagnetic interactions between the metal ions.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

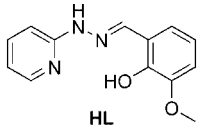
## Introduction

The self-assembly between metal centres and selected ligands into predetermined molecular architectures is now ubiquitous in chemistry.[1] This is especially relevant in the field of magnetic materials,[2–4] as remarkable metal–metal interactions may be achieved through the formation of such supramolecular architectures.[5] In this context, helicates are amazing metallosupramolecular assemblies that have been comprehensively investigated during the past two decades, both for their aesthetic nature and for their potential physical properties.[6–9] Most multistranded helicates reported feature two metal centres.[10] Examples containing a trinuclear (or higher) array of metal ions are less common, but they are increasingly described.[11]

In the course of our investigations on the design and preparation of polynuclear metal complexes with attractive magnetic properties, the potentially tetradentate, rigid N,O-ligand 2-methoxy-6-(pyridine-2-ylhydrazonomethyl)phenol[12] (HL) was used to generate metal clusters. We report here a new structural type in metallosupramolecular chemistry, namely, a double-stranded trinuclear dihelicate.

## Results and Discussion

The reaction of two equivalents of hydrated manganese(II) perchlorate with one equivalent of HL in methanol



produces orange block-shaped crystals of $[Mn_3L_4](ClO_4)_2(H_2O)_2$ (**1**), whose X-ray structure is depicted in Figures 1 and S1. The structure of **1** shows a dicationic trinuclear "bent" chain of $Mn^{II}$ ions [angle Mn1–Mn2–Mn3 147.6(1)°] assembled by four deprotonated $L^-$ ligands. Each $L^-$ ligand acts as a tetradentate and tris-chelating donor, and the pyridyl and imine N atoms and both the methoxy and phenoxide O atoms are used for coordination.

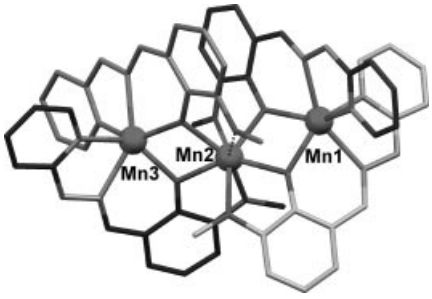


Figure 1. Representation of the trinuclear complex cation of **1**, which shows the three manganese(II) ions coordinated by four different deprotonated **L** ligands.

The bending of the metal array is most likely due to steric constraints around the central Mn2 ion. The charge of the complex is compensated by two $ClO_4^-$ anions. The oxidation state of +2 for the three manganese ions is corroborated by valence bond sum analysis[13] and the magnetic behaviour of the compound (see below). The external six-coordinate metal centres, Mn1 and Mn3, exhibit rare distorted trigonal-prismatic geometries with $N_4O_2$ donor sets.[14,15] This unusual coordination geometry is most likely

due to: (1) the small NN bite angles of the ligands [the N–Mn–N angles range from 70.8(2) to 71.6(2)°], (2) the rigidity of the dinucleating ligand HL and (3) steric constraints resulting from the coordination of four ligands to the central Mn2 ion (for instance, two ligands coordinated to Mn2 are stacked; Figures 1 and 2). The Mn–N and Mn–O bond lengths (Table S1) are within the usual ranges found for this type of coordination environment.[16] The coordination angles (Table S1) reflect the distortion of the trigonal prisms. Thus, the trigonal twist angles[17] (Figure S2) vary from 4.65 to 23.60° for Mn1 and from 4.07 to 26.47° for Mn3. These values suggest that the distortion of the trigonal prismatic geometry is more pronounced in Mn3. The central Mn2 ion is in fact heptacoordinated (Figure S3), and it has one additional Mn–O contact at a rather long distance of 2.616(5) Å [see bond lengths in Table S1; a longer bond at 3.022(7) Å neither is nor considered as coordination]. The unusual geometry around the Mn2 ion is best described as highly distorted capped trigonal-prismatic; the capping atom is O27 (Figure S4). The trigonal twist angles vary from 5.10 to 32.70°. The Mn–O bond lengths are comparable to those of seven-coordinate $Mn^{II}$ centres reported earlier.[18,19]

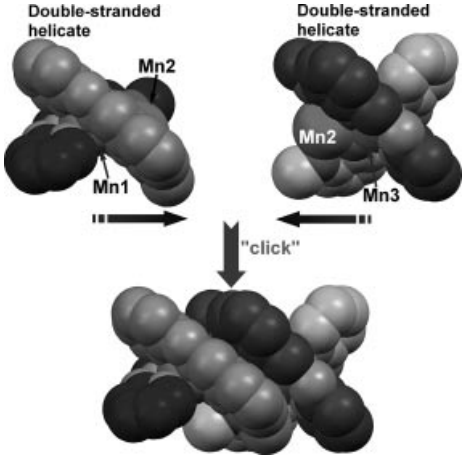

Figure 2. Fused double-stranded trinuclear dihelicate generated by supramolecular click self-assembly.

This compound exhibits fascinating features from a supramolecular point of view. It results from the fusion of two double-stranded helicates to form a unique trinuclear double-stranded dihelicate (Figure 2). Actually, the manganese(II) ions Mn1 and Mn2 are bridged by two $L^-$ ligands (Figure 2, top left), which constitutes a double-stranded bimetallic helicate with a Δ configuration[20] (Figure 3). Similarly, Mn2 and Mn3 can be regarded as a Δ-configured helicate together with two other $L^-$ ligands (Figure 2, top right). Because Mn2 belongs to both double-stranded helicates, it acts as a link between them, and it is thus coordinated by four different $L^-$ ligands (Figure 2 bottom and Figure 3). This "click self-assembly" leads to an unprecedented trinuclear helical structure (Figures 2 and 3). Indeed, to the best of our knowledge, all linear trimetallic helicates so far described in the literature exhibit metal arrays whose formation is achieved by trinucleating ligands.[8] In the present example, the trimetallic chain is assembled with only dinucleating ligands.

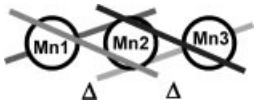

Figure 3. Schematic representation of the double-stranded dihelicate, which shows the stereochemistry of each helical subunit.

The X-band EPR spectrum of compound **1** (Figure S5), recorded at 77 K on a powdered sample, shows an intense and broad signal centred at $g = 2.14$ ($\Delta H_{pp} = 990$ G). A weaker line is also detected at 95 mT (Figure S5), which suggests that there are weak interactions between the Mn centres within complex **1**. Variable-temperature magnetic susceptibility measurements were performed on powdered **1** in the 3–300 K range under a constant magnetic field of 0.5 T. The results are shown in Figure 4 in form of a $\chi_M T$ vs. $T$ curve ($\chi_M$ is the molar paramagnetic susceptibility). The $\chi_M T$ value increases from 16.15 $cm^3 K mol^{-1}$ at 300 K (the expected value for three uncoupled $Mn^{II}$ ions with $S = 5/2$ and $g = 2.2$) and reaches a maximum value of 16.6 $cm^3 K mol^{-1}$ at 10 K, followed by a sudden drop at lower temperatures down to 13.95 $cm^3 K mol^{-1}$ at 3 K. To interpret this behaviour, the experimental data were simulated through a least-squares fitting procedure by using the isotropic Heisenberg Hamiltonian in Equation (1).

$$H = -2J_1(S_1S_2 + S_2S_3) - 2J_2(S_1S_3) \quad (1)$$

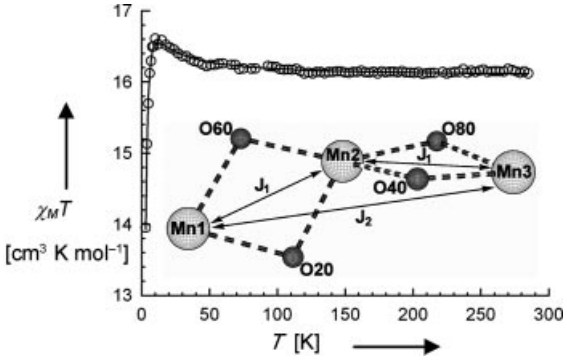

Figure 4. Plot of $\chi_M T$ vs. $T$ per mol of complex **1**. The solid line is a fit to the experimental data. The inset shows the core of the complex, together with the spin coupling scheme.

In this Hamiltonian (see inset of Figure 4 for coupling scheme), $S_1 = S_3 = S_2 = 5/2$, whereas the respective interactions within the Mn1–Mn2 and Mn2–Mn3 pairs were considered to be equal. This model does not include any effect arising from zero-field splitting. This approximation is reasonable here, as the $Mn^{II}$ ion ($d^5$) is quite isotropic, and thus, it does not usually conduce to any significant magnetoanisotropy. The solutions of the above Hamiltonian can be found analytically, and correspond to 27 $|S_A,S_T\rangle$ states ($S_A = S_1 + S_3$, $S_T$ = total spin) with a total degeneracy of 216. With these eigenvalues and their corresponding energies, a $\chi_M = f(T)$ expression can then be constructed by

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

using the van Vleck equation.[21] Initially, a term considering the effect of intermolecular magnetic interactions, $-2zJ'$, was added to the Hamiltonian and treated according to the molecular-field approximation approach.[22] The fit resulting from this model (Figure 4) produced the following parameters: $J_1 = +0.23\ cm^{-1}$, $J_2 = -0.03\ cm^{-1}$, $-zJ' = -0.07\ cm^{-1}$ and $g = 2.2$, which leads to a spin ground state of $S_T = 15/2$. These results reveal that all magnetic exchange interactions in this system are very weak (involving energies of less than $1\ cm^{-1}$) and also suggest that the coupling between Mn1 and Mn3 is negligible. A less satisfactory fit is obtained by fixing $zJ'$ to zero, which led to $J_1 = +0.31\ cm^{-1}$, $J_2 = -0.44\ cm^{-1}$ and $g = 2.2$, which conduces to a ground state $S_T = 7/2$. This solution was considered unlikely, because it attributes more weight to the interaction between the external Mn ions than to the coupling of adjacent metals, and therefore, the first solution was preferred. In both cases, the value of $g$ is slightly higher than normal. The $g$ values as obtained from bulk magnetization studies are affected by small experimental errors associated with the sample weight and the molecular mass. In this sense, the value obtained from EPR is more reliable. The above results add to a small collection of data relative to the nature and magnitude of the magnetic exchange between $Mn^{II}$ ions bridged only by two phenolate moieties. In all reported cases the coupling revealed itself to be very weak and examples have been found of both types of interactions, ferro-[23–27] and antiferromagnetic.[28–32]

This investigation is currently being extended to other metals to ascertain whether the concept of interconnected double-stranded trinuclear dihelicates can be generalized.

## Experimental Section

**Compound 1:** Prepared from $Mn(ClO_4)_2 \cdot 6H_2O$ (0.50 mmol) and HL (0.25 mmol) in methanol (10 mL). The resulting yellow solution was left unperturbed to allow slow evaporation of the solvent. Orange crystals, suitable for X-ray diffraction analysis, were formed after 1 d. Yield: 35 mg, 41% (based on the ligand HL). IR (neat): $\tilde{\nu}$ = 3266 (w), 1616 (vs), 1538 (s), 1485 (s), 1464 (s), 1456 (s), 1427 (vs), 1375 (w), 1346 (s), 1286 (s), 1220 (vs), 1074 (vs), 1004 (w), 980 (s), 850 (w), 772 (s), 732 (vs), 622 (vs), 499 (w), 448 (vs), 410 (s) $cm^{-1}$. $C_{52}H_{52}Cl_2Mn_3N_{12}O_{18}$ (1368.77): calcd. C 45.63, H 3.83, N 12.28; found C 45.60, H 3.49, N 12.11.

**X-ray Crystallographic Analysis:** Intensity data were recorded with a Nonius Kappa CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 173(2) K and were corrected for Lorentz and polarization effects and for absorption. The programs COLLECT,[33] SHELXS-97[34] and SHELXL-97[35] were used for data reduction, structure solution and structure refinement, respectively. All non-hydrogen atoms were refined anisotropically. The H atoms were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms. The H atoms were not located for the disordered water molecules. Crystal data for **1**: Monoclinic, $C2/c$; $a$ = 37.332(5) Å, $b$ = 15.075(3) Å, $c$ = 24.610(5) Å, $V$ = 12721(4) $Å^3$, $Z = 8$, $\rho_{calcd.} = 1.439\ g\,cm^{-3}$, $\mu = 0.747\ mm^{-1}$, final $R_1 = 0.0775$ for $I \geq 2\sigma(I)$, $wR_2 = 0.1806$ for all data. CCDC-648621 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

X-band EPR studies were carried out with a JEOL electron spin resonance spectrometer equipped with an Esprit 330 data system, with dpph as an internal reference ($g$ = 2.0036).

Magnetic susceptibility measurements on **1** were performed with a Quantum Design MPMS-5 5T SQUID magnetometer at 5000 Oe in the temperature range 3–300 K. Data were corrected for the diamagnetic contributions estimated from Pascal's Tables.[22]

**Supporting Information** (see footnote on the first page of this article): Schematic representations of the coordination environments of the three $Mn^{II}$ centres of **1**. Selected bond lengths and angles for **1**, as well as X-ray data. Solid-state EPR spectrum of complex **1**.

# In Vitro Formation of Nanocrystalline Carbonate Apatite – A Structural and Morphological Analogue of Atherosclerotic Plaques

**Lars-Fride Olsson,[a] Karin Sandin,[a] Rolf Odselius,[b] and Lars Kloo*[c]**

**Keywords:** Carbonate apatite / Crystallization / Calcification / Nanocrystalline / Calcium

The in vitro formation of carbonate apatite in solutions with ion concentrations comparable to those in human serum was studied. The composition and morphology of the resulting apatite precipitate displayed a hierarchical assembly of elongated plate-shaped nanocrystals of carbonate apatite analogous to previously characterized bioapatites formed in vivo. The main conclusion is that so-called bioapatites may form in vitro and that precipitation inhibitors most likely are essential for the prevention of spontaneous calcification at normal human serum ion concentrations.

## Introduction

Biological mineralization of solid calcium phosphates occurs in humans both under normal conditions, such as in bone and teeth formation, and under pathological conditions, such as vascular calcification related to advanced atherosclerosis,[1] diabetes[2] and chronic renal failure,[3] where the latter also includes end-stage renal disease pertinent to patients on hemodialysis.[4] Giachelli[5] recently published a comprehensive review on possible mechanisms behind vascular calcification, in which several mechanisms were discussed.

From a purely solution chemistry point of view, vascular calcification is expected: normal human serum calcium and inorganic phosphate concentrations are such that supersaturation exists with respect to hydroxyapatite, $Ca_5(PO_4)_3OH$, (OHAp),[6] octacalcium phosphate (OCP), and carbonate apatite (dahllite);[7] the latter is often denoted bioapatite, a name suggesting that it can be formed only in vivo. Investigations of atherosclerotic plaques show that bioapatite is an apatite with a significant amount of carbonate included[7,8] (cf. Table 2). Also, comparisons between synthetically made and biological apatites showed that phosphate, to a varying degree, was exchanged for carbonate in the latter type.[9]

Biomineralization of apatites has been host to renewed interest. The main reason is the hierarchical crystallization and observation of nano- and mesocrystalline features, especially in combination with composite formation. Spherical precipitates were identified and shown to consist of bundles of small crystallites.[11–13]

Despite supersaturation, spontaneous calcification under normal human serum conditions does not occur. This indicates that inhibitors must be present to maintain metastability. With regard to pathological vascular calcification, a pathway involving a lack of inhibition seems to be the most important of the mechanisms listed by Giachelli.[5] Both in vitro and mice in vivo experiments support this mechanism.[14] In vivo mice experiments with a reduced concentration of calcification inhibitors in the serum were shown to give calcification;[15,16] the "knock-out mice" that lacked inhibitors were severely calcified despite having normal mice serum ionized calcium and inorganic phosphate concentrations. However, applied to human vascular calcification, the mice results are inconclusive. The reason is that even though mice serum contains the same total calcium concentration as human serum, the inorganic phosphate concentrations are two to three times higher.[16,17] From a solution chemistry point of view, this mice and human serum phosphate concentration difference is essential, as it is related to the details of calcium phosphate precipitation; more precisely, this value is related to supersaturation with respect to brushite, $CaHPO_4{\cdot}2H_2O$. A number of in vitro studies have shown that once this species is formed,[18] it is transformed to the less-soluble OCP and in turn transformed into OHAp at physiological pH. Even formation of bioapatite as the end product is possible; according to LeGeros, OCP is transformed into carbonated apatite in the presence of hydrogen carbonate.[19] However, in normal human serum the calcium ion and inorganic phosphate concentrations are so low that the saturation limit for brushite is never exceeded. This was verified experimentally by Eidelman et al.,[20] who showed that brushite dissolves in ultrafiltered human serum, and by model equilibrium calculations.[21]

To test the mechanism based on the lack of inhibition in the case of human serum, we here report a study of salt solutions supersaturated with respect to OHAp, OCP, and carbonate apatite (cf. bioapatite), but not brushite, and with temperature, buffer (sodium hydrogen carbonate), and thus pH, ionic medium, and strength as close as possible to human serum conditions (cf. Table 1). These conditions ensure that the chemical potentials of all individual ionic species involved in the hypothetical precipitation process are close to those in human serum.

Our study is an extension of an earlier investigation, in which we characterized a carbonated apatite formed in solution with inorganic phosphate corresponding to hyperphosphatemic concentrations and determined the stoichiometry to be $Ca_5(PO_4)_3HCO_3 \cdot 4H_2O$.[22]

In the experiments reported here, phosphate was varied from human normal to hyperphosphatemic concentrations. To the best of our knowledge there is no experimental study published about in vitro formation of carbonate apatite (analogous to bioapatite) in solutions with calcium, phosphate, and hydrogen carbonate concentrations comparable to those in human serum. Even though the solutions in the experiments reported by Boskey et al. contained equally low concentrations of calcium and phosphate, hydrogen carbonate was not present thus excluding carbonate apatite as a potential mineral deposit.[23]

For the sake of completeness we have included experiments in a physiological sodium chloride medium containing very low hydrogen carbonate concentrations aimed at giving precipitation of a carbonate-free apatite, i.e. OHAp.

## Results

The time from preparation of the solution until a precipitate was visually observed in the polypropylene tubes amounted to 2–3 weeks for all phosphate concentrations, except $P_i$ = 0.99 mmol/L, for which the delay time was 5–6 weeks. After seven weeks all tubes contained precipitate. The precipitate observed in the glass flasks occur as relatively large half-spheres, few in number, and with a diameter of about 1 mm, similar to those found in glass flasks with an initial phosphate concentration of 1.8 mmol/L reported earlier and displayed in Figure 1.[21] Those in the polypropylene tubes occur as considerably smaller and more numerous half-spheres (Figure 2). However, for $P_i$ = 0.99 mmol/L, in a few polypropylene tubes we observed precipitates consisting solely of a few half-spheres with a diameter of about 0.3 mm.

In an earlier publication we showed that the precipitates formed in glass flasks with an initial phosphate concentration of 1.8 mmol/L consist of a hydrated carbonate apatite. A plausible formula was suggested, $Ca_5(PO_4)_3(HCO_3) \cdot 4H_2O$.[22] Our results reported here (cf. Figures 1, 2, and 3), show that the precipitates in the polypropylene tube are also calcium phosphates that contain carbon.

The EDS spectrum of a half-sphere removed from a glass flask with an initial phosphate concentration of 1.8 mmol/L is displayed in Figure 1. A comparison between that and the EDS spectra in Figures 2 and 3 shows that the atomic composition of the precipitates in the polypropylene tubes is approximately the same as that in the glass flask with an initial phosphate concentration of 1.8 mmol/L. Signals from calcium, phosphorus, oxygen carbon, and sodium are present, but those of chlorine are not. The IR spectrum in Figure 4 was not assigned in detail but only compared to the published and assigned IR spectra of OCP by Fowler et al.,[24] and to those of OHAp and high-temperature carbonate apatite by Nelson et al.;[25] our IR spectrum was also compared to that of calcified vascular deposits by Tomazic.[7] The spectrum by Nelson et al. with 6.7 wt.-% carbonate and that by Tomazic compare favorably with regard to both the positions and shapes of the bands and to the relative magnitude of the strong carbonate and phosphate bands. It should be noted that the strong band observed in the OHAp spectrum at 631 $cm^{-1}$ and assigned to hydroxy

Table 2. Composition (wt.-%) and Ca/P molar ratio of apatites and human vascular calcium phosphate deposits.

| Calcium phosphate stoichiometry | Ref. | Ca | $PO_4$ | $CO_3$ | Ca/P |
|---|---|---|---|---|---|
| OHAp, $Ca_5(PO_4)_3OH$ | | 39.9 | 56.7 | – | 1.67 |
| In vitro precipitated carbonate apatite, $Ca_5(PO_4)_3HCO_3{\cdot}4H_2O$ | [22] | 32.4 | 46.0 | 9.7 | 1.67 |
| Human atherosclerotic thoracic and abdominal aortas 4 samples. Recalculated assuming 15% protein. | [8] | 33.5–36.6 | 47.3–50.5 | 7.2–14.2 | 1.61–1.77 |
| Human atherosclerotic cardiovascular deposits (average) $Ca_{8.66}Mg_{0.22}Na_{0.32}H_{0.14}(PO_4)_5(CO_3)_{1.22}(OH,F,Cl)_{0.80}$ | [7] | 37.4 | 51.2 | 7.9 | 1.73 |

mately the same relative amounts of carbonate and phosphate as the cardiovascular deposits investigated by Tomazic.

The Ca/P molar ratios based on chemical analysis of the precipitates in the polypropylene tubes are consistently higher than those of OHAp and $Ca_5(PO_4)_3(HCO_3){\cdot}4H_2O$ (Ca/P = 1.67; cf. Table 1). The Ca/P molar ratio varies with the initial phosphate concentrations in the solution: the lower the phosphate concentration, the higher the ratio. This indicates that the composition of the precipitates to some extent varies as far as the relative amount of calcium and phosphate is concerned. Thus, from the electroneutrality requirement we can conclude that even the carbonate content may vary. An upper limit for the carbonate content can be calculated. For example, if Ca/P = 1.75 = 7/4, the electroneutrality condition requires one carbonate, stoichiometry $Ca_7(PO_4)_4CO_3$ (Ca/C = 7) or two hydrogen carbonates $Ca_7(PO_4)_4(HCO_3)_2$ (Ca/C = 3.5), and with Ca/P = 1.80 = 9/5, either two carbonates, $Ca_9(PO_4)_5(CO_3)(HCO_3)$ (Ca/C = 4.5) or, if also hydroxide is included, one carbonate $Ca_9(PO_4)_5(CO_3)OH$ (Ca/C = 9). The wt.-% calcium, phosphate, and carbonate of the in vivo calcified vascular deposits from atherosclerotic plaque $Ca_5(PO_4)_3(HCO_3){\cdot}4H_2O$ and OHAp are summarized in Table 2.

With respect to OHAp, which is assumed to form in the solutions with a very low amount of hydrogen carbonate, it does not show any tendency to precipitate in vitro after more than 16 months, neither under the prevailing conditions occurring in a so-called physiological salt solution (150 mmol/L sodium chloride and pH 7.4), nor in the presence of physiological amounts of hydrogen carbonate, where solely a carbonate apatite is formed. This is consistent with the finding that the composition of mineral deposits reported by Tomazic[7] and Schmid et al.[8] cannot be represented by the OHAp stoichiometry.

## Discussion

In a water solution with inorganic phosphate concentrations corresponding to normal human serum values, spontaneous precipitation of calcium phosphate occurs. Higher phosphate concentrations, corresponding to human hyperphosphatemic conditions, are not necessary to induce precipitation, even though they may accelerate it. The composition of the in vitro formed carbonate apatite precipitate agrees strikingly well with the findings of Tomazic[7] and Schmid et al.[8] with regard to calcified atherosclerotic plaque in a number of human blood vessels (cf. Table 2). The morphological characteristics of the precipitated carbonate apatite in vitro and in vivo are also comparable: small – a few μm – spherically shaped deposits depicted in Figures 2 and 5 are very similar to those found in human vascular deposits, see Schmid et al.,[8] Tomazic,[7] and Mohr.[26] The spherical shape thus exists both in calcification in vivo and in vitro. From the high magnification image displayed in Figure 5 it can be concluded that the spherical particles are built from units consisting of elongated plate-shaped "crystals", with a size of about a few hundred nm. Figure 5 gives the impression that there is successive assemblage of these small units first into rather irregular shaped aggregates and then, with an increasing number of units, a spherical shape. These results are in good agreement with old electron microscopy investigations and those observed for fluorapatites grown in gelatin media.[10–12]

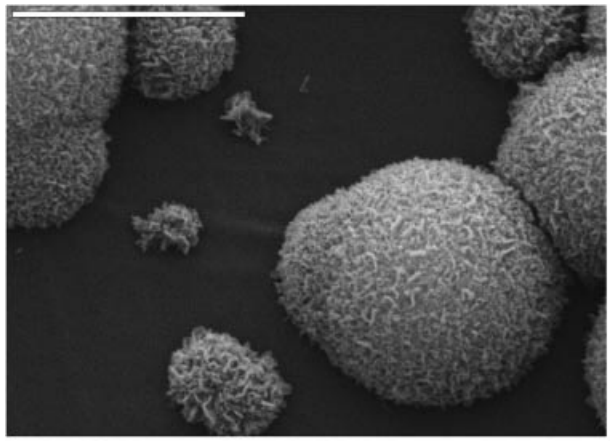

Figure 5. Assemblage of spherically shaped particles from small plate-shaped particles. The scale bar corresponds to 5 μm. Sample grown in a polypropylene tube. Original solution phosphate concentration: 1.90 mmol/L.

Our study shows that from a thermodynamic point of view we can assume that the in vitro and in vivo conditions required to induce precipitation are similar: the chemical potentials of the relevant individual ionic species are highly related and the precipitate formed in vitro is strikingly similar to that formed in vivo vascular deposits. We cannot, however, say anything about the details of the chemical reactions leading to in vitro precipitation, although we can exclude an "inorganic" mechanism assuming brushite as precursor. We can also exclude biological mechanisms that actively promote calcification, even though we obviously cannot exclude such mechanisms in vivo. From our study,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

we can also conclude that the absence of calcification in human serum with normal clinical levels of calcium and phosphate ions unconditionally requires at least one species that prevents the precipitation process to take place. From our work and the above-mentioned in vitro[14] and mice in vivo[14,15] experiments it follows that calcification is solely due to the presence of calcium, phosphate, and hydrogen carbonate ions and decreased levels of those specific proteins that act as calcification inhibitors. Other serum components may influence the rate of the precipitation process, but not the final outcome.

Our study shows that spontaneous calcification occurs at normal human serum ion concentrations of calcium, inorganic phosphate, and hydrogen carbonate and a lack of calcification inhibitors is the simplest explanation to pathological calcification. Biological processes regulating the serum concentration of these inhibitors are of vital importance for the prevention of vascular calcification.

## Experimental Section

All concentrations were chosen to give pH and ionic medium and strength similar to those in human serum, cf. Table 1. The expected solid deposit components, calcium, phosphate, and carbonate (from the buffer) were included, and carbon dioxide was present in the atmosphere surrounding the solutions with a partial pressure either corresponding to serum conditions or equal to that of air. Two hydrogen carbonate concentrations, one high physiological and one low were used, cf. Table 1.

False indications of precipitation due to bacterial growth were suppressed and bacterial growth was never observed. Solution preparation was designed to prevent precipitation of calcium phosphate or calcium carbonate at the time of mixing. The tubes and flasks were either stored in a climate chamber at $37.0 \pm 0.2$ °C, 5% $CO_2$(g), and 99% relative humidity (high hydrogen carbonate concentration) or in a heat chamber at $37 \pm 1$ °C with 65% relative humidity (low hydrogen carbonate concentration). The calcium and phosphate ion concentrations were determined by reflectance spectrophotometry with a KODAK Ektachem DTII (Eastman Kodak Company, Rochester, New York, US) instrument.

All tubes were periodically visually checked for precipitation and a few removed for pH, calcium, and phosphate ion analysis. Precipitates were dissolved and the calcium content was determined by atomic absorption spectrometry with a Varian SpectrAA 220FS with a hollow cathode lamp at 422.7 nm, and phosphate spectrophotometrically in the form of its molybdenum complex at 882 nm with a Perkin–Elmer Lambda 20 spectrophotometer. Precipitates were also characterized by energy-dispersive spectrometry (EDS) in a scanning electron microscope (SEM) and with Fourier transformation infrared (FTIR) spectroscopy. A Philips SEM 515, operated at 20 kV was used for imaging, and calcium, phosphorus, oxygen, and carbon contents were detected with a Link ISIS EDS. An IR transmission spectrum for the qualitative determination of carbonate and phosphate was recorded with a Perkin–Elmer Spectrum BX FTIR instrument with a spectral range from 450 to 4400 $cm^{-1}$.

# Effect of Deprotonation of a Benzimidazolyl Ligand on the Redox Potential and the Structures of Mononuclear Ruthenium(II) Complexes

**Hongfei Sun,[a] Mei Wang,*[a] Kun Jin,[a] Chengbing Ma,[b] Rong Zhang,[a] and Licheng Sun*[a,c]**

**Keywords:** Benzimidazolyl ligand / Redox switch / Reversible protonation and deprotonation / $Ru^{II}$ complex

A monoruthenium(II) complex of the benzimidazolyl ligand and its deprotonated counterpart were prepared and structurally characterized. The reversible protonation/deprotonation process of the ancillary ligand switches the redox potential of the ruthenium(II) core from 0.69 to 0.26 V vs. Ag/$AgNO_3$.

## Introduction

Reversible protonation/deprotonation of an ancillary ligand at a site remote from the metal–ligand bond is a simple reaction but a crucial step in some complicated biological processes. Many metal-containing proteins and enzymes, such as photosystem II,[1,2] cytochrome *c* oxidase[3,4] and non-heme iron enzymes,[5] play their function involving proton-coupled electron transfer (PCET) reactions. To understand the relationship between electron transfer and proton motion, the PCET reactions and the modulation of the redox potential of biomimetic model complexes by deprotonation of the ligand have been intensively studied.[6–9] In most cases, imidazole, benzimidazole and biimidazoline ligands were used as proton carriers because the metal centres of many metalloenzymes are coordinated by imidazole units from histidine residues.[10–12] The effect of the distal deprotonation of the ligands bearing imidazole and benzimidazole units on the physical and chemical properties of mono- and dinuclear ruthenium and osmium complexes has been reported.[13–19] In addition to the imidazole-containing ligands, mono- and dinuclear ruthenium complexes with ligands bearing triazole and pyrazole units were also extensively studied for their interesting electrochemical and photophysical properties.[20–24] In this communication, we describe the preparation of the mononuclear ruthenium(II) complex $[Ru(bbpaH)(bpy)](PF_6)_2$ [bbpaH = (2-benzimidazolylmethyl)bis(2-pyridylmethyl)amine, bpy = bipyridine], the influence of reversible protonation/deprotonation of the coordinated benzimidazolyl ligand on the redox potential of the ruthenium(II) complex, and the molecular structures of $[Ru(bbpaH)(bpy)](PF_6)_2$ (**1**) and its deprotonated species $[Ru(bbpa)(bpy)](PF_6)$ (**2**). This proton-coupled redox process might be relevant to some metalloenzymes active sites, such as the oxygen evolving complex (OEC) in photosystem II.

## Results and Discussion

The starting complex $[Ru(bbpaH)(dmso)Cl](PF_6)_2$ was prepared by the reaction of $Ru(dmso)_4Cl_2$[25] and the bbpaH ligand[26] according to the literature procedure for the preparation of the analogous complex $[Ru(tpa)(dmso)Cl](PF_6)$ [tpa = tris(2-pyridylmethyl)amine].[27] The subsequent reaction of $[Ru(bbpaH)(dmso)Cl](PF_6)$ with bipyridyl as ligand at room temperature afforded the target complex $[Ru(bbpaH)(bpy)](PF_6)_2$ in moderate yield. The deprotonated species $[Ru(bbpa)(bpy)](PF_6)$ was readily obtained by dissolving $[Ru(bbpaH)(bpy)](PF_6)_2$ in an acetone/water (1:1, v/v) mixture with pH = 11. Both complexes are stable in polar aprotic solvent such as acetone and acetonitrile.

The molecular structures of $[Ru(bbpaH)(bpy)]^{2+}$ and its deprotonated species $[Ru(bbpa)(bpy)]^{+}$ were determined at –80 °C by X-ray diffraction analyses. To the best of our knowledge, these are the first crystallographically characterized protonation/deprotonation pair of ruthenium complexes containing an imidazolyl ligand. The overall structures of both complexes are very similar (Figure 1), with distorted octahedral coordination geometry around their ruthenium centres. In both complexes, two $N_{py}$ atoms, one from the bbpaH or bbpa ligand and another from the bpy

ligand, an $N_{benz}$ and an $N_{amine}$ atom are located in a tetragonal plane. The remaining two $N_{py}$ atoms occupy the vertexes of the octahedron. The ruthenium atom in each complex lies slightly out of the tetragonal plane towards the pyridyl group of the bpy ligand, 0.0351 Å for $[Ru(bbpaH)(bpy)]^{2+}$ and 0.0314 Å for $[Ru(bbpa)(bpy)]^{+}$. The Ru(1)–N(1) bond length increases significantly in the deprotonated species, 2.058(6) Å for $[Ru(bbpaH)(bpy)]^{2+}$ and 2.100(3) Å for $[Ru(bbpa)(bpy)]^{+}$. In parallel, the Ru(1)–N(5) bond [2.064(3) Å] of $[Ru(bbpa)(bpy)]^{+}$, *trans* to the Ru(1)–N(1) bond, considerably shortens as compared to that [2.088(6) Å] of $[Ru(bbpaH)(bpy)]^{2+}$. The bond angles increase by ca. 18° for N(1)–Ru(1)–N(4) and 5° for N(1)–Ru(1)–N(6), while the N(1)–Ru(1)–N(7), N(1)–Ru(1)–N(3) and N(1)–Ru(1)–N(5) angles decrease by ca. 8, 4 and 1°, respectively, in the deprotonated complex. The other corresponding Ru–N bond lengths and N–Ru–N angles in the coordination sphere of two ruthenium complexes are quite similar. To the best of our knowledge there are only two examples of crystallographically characterized iron and cobalt complexes containing deprotonated imidazolylate and benzimidazolylate ligands.[8,9] The deprotonation of 2,6-bis(2-imidazolyl)pyridine as ligand in the iron complex leads to the oxidation of the iron(II) centre from $Fe^{II}$ to $Fe^{III}$,[9] while the formal oxidation state of the cobalt(II) centre in the cobalt complex of the tris(2-benzimidazolylmethyl)amine ligand does not change before and after deprotonation. During deprotonation, the ruthenium complex $[Ru(bbpaH)(bpy)]^{2+}$ behaves like the cobalt complex. Compared with the molecular structures of the reported cobalt complexes, there are two noteworthy points in the molecular structure of the deprotonated ruthenium complex. First, the lengthening of 0.042 Å for the $Ru–N_{benzimidazolylate}$ bond is contrary to the shortening of 0.026 Å for the $Co–N_{benzimidazolylate}$ bond.[8] Second, the length of the $Ru–N_{py}$ bond *trans* to the $Ru–N_{benzimidazolylate}$ bond decreases by 0.024 Å in the deprotonated ruthenium complex, while one of the $Co–N_{benz}$ bonds neighbouring the $Co–N_{benzimidazolylate}$ bond increases by 0.053 Å. These apparent contrasts in the changes of the M–N bond lengths after deprotonation of the prepared ruthenium complex and the reported cobalt complex are assumed to result from the strong coordination ability of the pyridyl group and from different coordination geometries of the ruthenium and cobalt complexes. In spite of the differences in the aforementioned two aspects, the lengthening (0.005 Å) of the average distance of the Ru–N bonds in the tetragonal plane of $[Ru(bbpa)(bpy)]^{+}$, as compared to that of the parent ruthenium complex, is consistent with the 0.009 Å increase in that of the Co–N bonds in the trigonal plane for the deprotonated cobalt complex.

The reversible protonation/deprotonation process was monitored by ESI mass spectrometry and $^1H$ NMR spectroscopy. The ESI mass spectra of $[Ru(bbpaH)(bpy)]^{2+}$ and the deprotonated complex $[Ru(bbpa)(bpy)]^{+}$ show signature peaks at $m/z$ = 293.6 and 586.1, respectively. Figure 2 shows the curves of relative intensities of the peaks for $[Ru(bbpaH)(bpy)]^{2+}$ and $[Ru(bbpa)(bpy)]^{+}$ vs. the equiv. of $NEt_3$ in the acetone solution of complex **1**. As shown in Figure 2, the peak at $m/z$ = 586.1 for $[Ru(bbpa)(bpy)]^{+}$ is enhanced gradually with the addition of $NEt_3$, and the peak at $m/z$ = 293.6 for $[Ru(bbpaH)(bpy)]^{2+}$ eventually disappears in the presence of 2 equiv. of $NEt_3$. No peak for dinuclear or larger cluster is found in mass spectra in the presence of $NEt_3$.

The $^1H$ NMR spectra of a selected region for $[Ru(bbpaH)(bpy)](PF_6)_2$ and the deprotonated complex $[Ru(bbpa)(bpy)](PF_6)$ in $[D_6]$acetone are shown in Figure 3. The six methylene protons are all inequivalent with respect to their chemical environment, and each $CH_2$ group displays an AB quartet (Figure 3a). Compared with the $^1H$ NMR spectra of the reported complex coordinated by the ligands bearing 2-pyridylmethyl moieties,[28] the quartet centered at $\delta$ = 5.08 is attributed to the $CH_2$ group attached to the benzimidazolyl unit, and the other two quartets to the $CH_2$ groups of the pyridylmethyl units. Upon addition

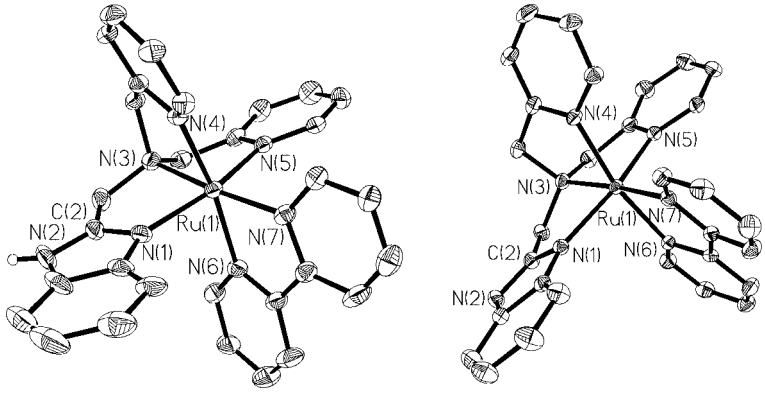

Figure 1. Thermal ellipsoid diagram of $[Ru(bpbaH)(bpy)]^{2+}$ (left) and $[Ru(bpba)(bpy)]^{+}$ (right). The ellipsoids are drawn at the 30% probability level, and only the benzimidazolyl hydrogen atom is shown. Selected bond lengths [Å] and angles [°] for $[Ru(bpbaH)(bpy)]^{2+}$ and $[Ru(bpba)(bpy)]^{+}$ [in brackets]: Ru(1)–N(1), 2.058(6) [2.100(3)]; Ru(1)–N(3), 2.119(6) [2.113(3)]; Ru(1)–N(4), 2.088(6) [2.100(3)]; Ru(1)–N(5), 2.088(6) [2.064(3)]; Ru(1)–N(6), 2.090(6) [2.090(3)]; Ru(1)–N(7), 2.072(6) [2.076(3)]; C(2)–N(1), 1.343(9) [1.366(4)]; C(2)–N(2), 1.354(10) [1.334(5)]; N(1)–Ru(1)–N(3), 82.2(2) [78.69(11)]; N(1)–Ru(1)–N(4), 82.3(2) [100.53(11)]; N(1)–Ru(1)–N(5), 161.4(2) [160.55(11)]; N(1)–Ru(1)–N(6), 86.6(2) [91.50(10)]; N(1)–Ru(1)–N(7), 103.1(2) [95.39(10)].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

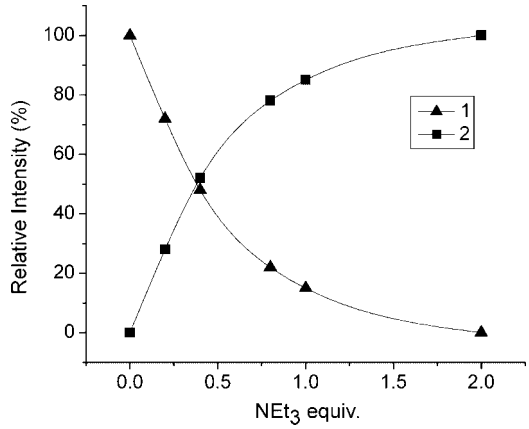

Figure 2. Plot of relative intensities of the peaks for $[Ru(bbpaH)(bpy)]^{2+}$ (trigonal) and $[Ru(bbpa)(bpy)]^{+}$ (square) vs. the equiv. of $NEt_3$ (0, 0.2, 0.4, 0.6, 1.0, 2.0 equiv.) in an acetone solution of complex **1** ($5 \times 10^{-4}$ M) monitored by ESI-MS.

of 2 equiv. of $NEt_3$, the signals for $[Ru(bbpaH)(bpy)](PF_6)_2$ completely disappear, and only the signals for $[Ru(bbpa)(bpy)](PF_6)$ are detected (Figure 3b), which suggests that no other reaction or decomposition occurs during the deprotonation process. Significant upfield shifts are observed in Figure 3b for the corresponding signals of three $CH_2$ groups of the deprotonated complex, which are expected for the monoanionic $bbpa^-$ ligand. The quartet at $\delta$ = 5.08 in the $^1H$ NMR spectrum of $[Ru(bbpaH)(bpy)](PF_6)_2$ changes to a singlet at $\delta$ = 4.78 upon deprotonation, indicating that the two protons on the $CH_2$ group of the benzimidazolylmethyl arm gain better symmetry in the deprotonated complex. The signals for the benzene ring of the deprotonated benzimidazolylmethyl ligand also apparently shift upfield. Sequential addition of 1 equiv. of $HClO_4$ recovers the original $^1H$ NMR spectrum of $[Ru(bbpaH)(bpy)](PF_6)_2$ as depicted in Figure 3a. This clearly indicates the complete reversibility of deprotonation and protonation.

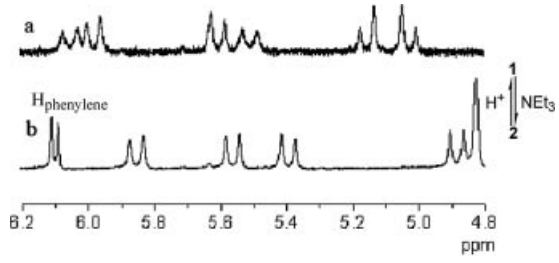

Figure 3. $^1H$ NMR spectra of a selected region: (a) $[Ru(bbpaH)(bpy)](PF_6)_2$ (**1**) and (b) $[Ru(bbpa)(bpy)](PF_6)$ (**2**) in $[D_6]$acetone.

The influence of deprotonation of the coordinated bbpaH ligand on the redox potential of the ruthenium centre was explored by cyclic voltammograms. The reversible $Ru^{II}/Ru^{III}$ oxidation wave of $[Ru(bbpaH)(bpy)](PF_6)_2$ appears at 0.69 V ($E_{1/2}$) vs. $Ag/AgNO_3$ in $CH_3CN$ and the deprotonated ruthenium complex $[Ru(bbpa)(bpy)](PF_6)$ displays the reversible oxidation wave at 0.26 V (Figures S1 and S2, see Supporting Information). It shows that the deprotonation of the coordinated bbpaH ligand can shift the redox potential of the ruthenium centre by 430 mV, which is larger than the shift (ca. 300–350 mV per proton) of the redox potentials reported for ruthenium, osmium and iron complexes with the ligands bearing multi-imidazolyl and -benzimidazolyl units,[9,14–16] but similar to the shift (350–420 mV) of the $Ru^{II}/Ru^{III}$ oxidation potentials reported for monoruthenium complexes with two bpy ligands and one triazole- or pyrazole-containing ligand.[21,23,29,30]

## Conclusions

We have prepared a pair of novel monoruthenium(II) complexes (**1** and **2**) with bpbaH or bpba and bipyridine as ligands. The structures of (benzimidazole)ruthenium complexes **1** and **2** were crystallographically characterized. The NH group of the bpbaH ligand readily undergoes a reversible protonation/deprotonation process, which is proven by spectroscopic and electrochemical evidence. The reversible protonation/deprotonation regulates the oxidation potential of the $Ru^{II}/Ru^{III}$ redox couple around 430 mV without changing the framework of the ruthenium complex.

## Experimental Section

**General Procedures:** All reactions and operations related to organometallic complexes were carried out under dry, oxygen-free dinitrogen with standard Schlenk techniques. Solvents were distilled prior to use with routine drying agents. Tetra-*n*-butylammonium hexafluorophosphate (TBAH) and bipyridine were used as received. Ligand (2-benzimidazolylmethyl)bis(2-pyridylmethyl)amine (bbpaH) and $[Ru(bbpa)(dmso)Cl](PF_6)$ were synthesized according to literature procedures for preparation of similar compounds.[25–27] $^1H$ NMR spectra were collected with a Varian INOVA 400 NMR spectrometer. Elemental analyses were performed with a Thermoquest-Flash EA 1112 elemental analyzer. Mass spectra were recorded with an HP 1100 MSD instrument.

**Complex $[Ru(bbpaH)(bpy)](PF_6)_2$ (1):** Complex **1** was synthesized according to a literature procedure for the preparation of the analogous complex $[Ru(TPA)(bpy)](PF_6)_2$.[27] The subsequent recrystallization of the crude product from acetone/diethyl ether afforded red crystals. Yield: 94 mg (37%). $^1H$ NMR ($CDCl_3$, 400 MHz): $\delta$ = 10.21 (d, 1 H, *J* = 5.6 Hz, Py of bbpaH), 9.47 (d, *J* = 6.0 Hz, 1 H, Py of bpy), 9.44 (d, *J* = 6.0 Hz, 1 H, Py of bpy), 8.80 (d, *J* = 8.2 Hz, 1 H, Py of bbpaH), 8.59 (d, *J* = 8.0 Hz, 1 H, Py of bbpaH), 8.42 (t, *J* = 8.2, 7.4 Hz, 1 H, Py of bbpaH), 8.21 (t, *J* = 5.6, 7.4 Hz, 1 H, Py of bbpaH), 7.96 (t, *J* = 8.0, 6.4 Hz, 1 H, Py of bbpaH), 7.94 (t, *J* = 5.8, 7.2 Hz, 1 H, Py of bpy), 7.78 (d, *J* = 7.8 Hz, 1 H, Py of bbpaH),7.77 (d, *J* = 5.8 Hz, 1 H, Py of bpy), 7.73 (t, *J* = 6.4, 6.4 Hz, 1 H, Py of bpy), 7.59 (d, *J* = 6.4 Hz, 1 H, Py of bpy), 7.53 (t, *J* = 7.8, 6.4 Hz, 1 H, Py of bbpaH), 7.53 (d, *J* = 6 Hz, 1 H, Py of bpy), 7.43 (d, *J* = 8.4 Hz, 1 H, Ph of bbpaH), 7.33 (t, *J* = 6.0, 6.4 Hz, 1 H, Py of bpy), 7.15 (t, *J* = 8.4, 7.2 Hz, 1 H, Ph of bbpaH), 7.00 (t, *J* = 7.2, 8.0 Hz, 1 H, Ph of bbpaH), 6.50 (d, *J* = 8.0 Hz, 1 H, Ph of bbpaH), 6.02 (d, *J* = 18.4 Hz, 1 H, CH of bbpaH), 5.96 (d, *J* = 18.4 Hz, 1 H, CH of bbpaH), 5.58 (d, *J* = 16.8 Hz, 1 H, CH of bbpaH), 5.48 (d, *J* = 17.6 Hz, 1 H, CH of bbpaH), 5.13 (d, *J* = 16.8 Hz, 1 H, CH of bbpaH), 5.01 (d, *J* = 17.6 Hz, 1 H, CH of bbpaH) ppm. ESI-MS: *m*/*z* = 293.5 $[Ru(bbpaH)(bpy)]^{2+}$.

**Complex [Ru(bbpa)(bpy)](PF$_6$) (2):** Complex **1** (50 mg, 0.057 mmol) was dissolved in an NaOH-containing acetone/water (1:1, v/v) mixture with pH = 11. A majority of the acetone was removed in a rotary evaporator and the product precipitated as the fully deprotonated species [Ru(bbpa)(bpy)](PF$_6$). The solid was dissolved in hot $CHCl_3$. After cooling, dark-red crystals were obtained. Yield: 13 mg (31%). $^1$H NMR ($CDCl_3$, 400 MHz): $\delta$ = 10.15 (d, 1 H, $J$ = 6.0 Hz, Py of bbpa), 9.37 (d, $J$ = 5.6 Hz, 1 H, Py of bbpa), 9.32 (d, $J$ = 6.0 Hz, 1 H, Py of bpy), 8.71 (d, $J$ = 8.0 Hz, 1 H, Py of bbpa), 8.49 (d, $J$ = 8.0 Hz, 1 H, Py of bbpa), 8.30 (t, $J$ = 6.8, 8.0 Hz, 1 H, Py of bbpa), 8.07 (t, $J$ = 6.0, 6.8 Hz, 1 H, Py of bbpa), 7.98 (d, $J$ = 5.6 Hz, 1 H, Py of bpy), 7.81 (t, $J$ = 7.2, 8.0 Hz, 1 H, Py of bbpa), 7.68 (t, $J$ = 7.2, 7.6 Hz, 1 H, Py of bpy), 7.58 (t, $J$ = 7.6, 6.8 Hz, 1 H, Py of bpy), 7.57 (d, $J$ = 7.6 Hz, 1 H, Py of bpy), 7.39 (t, $J$ = 5.6, 7.2 Hz, 1 H, Py of bbpa), 7.38 (d, $J$ = 6.8 Hz, 1 H, Py of bpy), 7.20 (d, $J$ = 8.4 Hz, 1 H, Ph of bbpa), 7.17 (t, $J$ = 6.0, 7.2 Hz, 1 H, Py of bpy), 7.14 (t, $J$ = 5.6, 7.6 Hz, 1 H, Py of bpy), 6.64 (t, $J$ = 8.4, 7.6 Hz, 1 H, Ph of bbpa), 6.51 (t, $J$ = 7.6, 7.6 Hz, 1 H, Ph of bbpa), 6.10 (d, $J$ = 7.6 Hz, 1 H, Ph of bbpa), 5.85 (d, $J$ = 16.8 Hz, 1 H, CH of bbpa), 5.56 (d, $J$ = 16.4 Hz, 1 H, CH of bbpa), 5.39 (d, $J$ = 16.8 Hz, 1 H, CH of bbpa), 4.89 (d, $J$ = 16.4 Hz, 1 H, CH of bbpa), 4.83 (s, 2 H, $CH_2$ of bbpa) ppm. ESI-MS: $m/z$ = 586.1 [Ru(bbpa)(bpy)]$^+$. $C_{31}H_{27}Cl_3F_6N_7PRu$ (849.99): calcd. C 43.80, H 3.20, N 11.54; found C 44.79, H 3.27, N 11.68.

**X-ray Structure Determination:** The single-crystal X-ray diffraction data were collected with a Siemens SMART CCD diffractomer, with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.071073 Å) at 153 K using the $\omega$-2$\theta$ scan mode. Data processing was accomplished with the SAINT processing program.[31] Intensity data were corrected for absorption by the SADABS program.[32] All structures were solved by direct methods and refined on $F^2$ by full-matrix least-squares methods using the SHELXTL 97 program package.[33] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located by geometrical calculation. Crystal data for [Ru(bbpaH)(bpy)](PF$_6$)$_2$ (**1**): $C_{30.50}H_{29}F_{12}N_7O_{0.50}P_2Ru$, $M$ = 892.62, monoclinic, space group $P2(1)/n$, $a$ = 12.4535(14), $b$ = 19.742(2), $c$ = 13.6163(15) Å, $\beta$ = 91.270°, $V$ = 3346.8(6) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.772 g cm$^{-3}$, $\mu$ = 0.67 mm$^{-1}$, $T$ = 153(2) K, 6565 reflections measured, 4243 unique, $R_{int}$ = 0.0650, $R_1$ = 0.0787 and $wR_2$ = 0.1138 (all data), GOF = 1.017. # Facile Synthesis of Aluminum-Bridged [3,3,3]Cyclophanes by Hydroalumination

**Werner Uhl,*[a] Alexander Hepp,[a] Madhat Matar,[a] and Andrej Vinogradov[a]**

**Keywords:** Aluminum / Hydroalumination / Cage compounds / Cyclophanes

The reaction of 1,3,5-tris(3,3-dimethyl-1-butinyl)benzene $C_6H_3(C{\equiv}C{-}CMe_3)_3$ with the dialkylaluminum hydrides $HAl(CMe_3)_2$ and $HAl(CH_2CMe_3)_2$ gave the addition of one Al–H bond to each C–C triple bond (hydroalumination). Spontaneous condensation by the release of the corresponding trialkylaluminum derivatives afforded [3,3,3]cyclophane derivatives **6** and **7** in which three tricoordinate Al atoms are in the bridging positions between two functionalized benzene rings. The aluminum atoms behave as Lewis acids, and treatment with thf yielded adduct **6**·3thf.

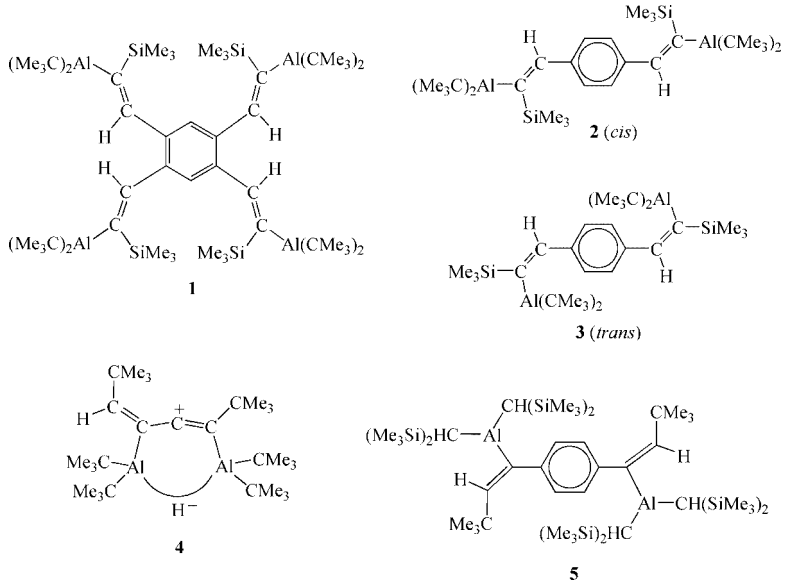
## Introduction

The addition of Al–H bonds to unsaturated compounds containing C=C and C≡C bonds (hydroalumination) is a powerful method for the reduction of organic compounds and the generation of new hydrocarbons.[1,2] In most cases, the organoaluminum intermediates were not isolated, but the organic components were released by hydrolysis. Other derivatives are accessible by particular oxidative workup such as halogenation.[3] Thus, suggestions concerning the structure of the organoaluminum intermediates are rather speculative in most cases. A preferred *cis* addition was postulated owing to the constitutions of the finally isolated hydrocarbons.[1] As was shown by our group only recently,[4,5] silyl-substituted alkynes gave the predicted products of hydroalumination with a dialkylaluminum group attached to that carbon atom that also bears the trimethylsilyl group (**1** and **2** in Scheme 1). This particular constitution may be favored by two reasons. Owing to the electronegativity difference between both elements, the carbon atom attached to silicon bears a negative partial charge and, hence, may be attacked preferentially by the positively charged alumi-



Scheme 1.

num ions. Furthermore, the enhanced negative charge at this position in the product, which is introduced by the polarity of the freshly formed Al–C bond, can be stabilized by

hyperconjugation with the Si–C bonds. In all cases the *cis* addition products are formed with the hydrogen and aluminum atoms on the same side of the C=C bonds. A *cis*/*trans* rearrangement was observed only for **3** (Scheme 1) upon elongated heating of solutions in benzene.[4] In contrast, spontaneous rearrangement occurred upon the similar addition of Ga–H bonds to silylalkynes (hydrogallation).[6] Exceptions were observed only for the reactions of the sterically shielded di(*tert*-butyl)gallium hydride. The products of these reactions contain up to three coordinatively unsaturated, tricoordinate aluminum or gallium atoms; however, only the *trans* isomers are able to act as powerful chelating Lewis acids. Secondary reactions with the release of trialkylaluminum derivatives occurred upon treatment of dialkylaluminum alkynides with dialkylaluminum hydrides. Clusters similar to carbaboranes were formed that contained aluminum and carbon atoms and had a delocalized bonding situation.[7] Analogous reactions of gallium compounds afforded heteroadamantane-type molecules possessing localized Ga–C bonds.[8] An unexpected and unprecedented product was formed upon treatment of di(*tert*-butyl)butadiyne with di(*tert*-butyl)aluminum hydride. C–H bond activation by hyperconjugation with Al–C bonds and the chelating coordination of the resulting hydride anion by two aluminum atoms afforded **4** as a singular, persistent butadienyl cation (Scheme 1), which was zwitterionic and did not require the application of a strictly noncoordinating counterion for its stabilization.[9] In contrast, benzene centered *tert*-butylethynes showed a more complicated reaction behavior. Secondary reactions occurred that could be clarified completely for the more selective hydrogallation reactions only.[10] Bulky substituents attached to the aluminum atoms as in $R_2Al–H$ [R = $CH(SiMe_3)_2$] prevented these secondary processes.[11] The persistent simple addition products, **5** (Scheme 1), had the aluminum atoms attached to the carbon atoms in the α position to the aromatic ring. This particular constitution may allow optimum mesomeric stabilization of the negative charge, which is localized at these atoms and resulted from the polarity of the Al–C bonds. We report here the first successful reactions of that type conducted with sterically less-shielded dialkylaluminum hydrides.

## Results and Discussion

Complete consumption of the starting compounds was observed when mixtures of 1,3,5-tris(*tert*-butylethynyl)benzene and the corresponding dialkylaluminum hydrides in *n*-pentane or *n*-hexane were stirred at r.t. for about 20 h [Equation (1)]. Thus, the hydroalumination reactions are much faster than hydrogallation reactions, which do not start at ambient temperature at all and require boiling *n*-hexane over a period of about 16 h for completion.[6,10] The difference in the reaction behaviors of the hydrides may depend on the lower polarity of the Ga–H bond relative to the Al–H bonds. Two aluminum hydrides $R_2Al–H$ (R = $CMe_3$, $CH_2CMe_3$) were employed. The $^1H$ NMR spectroscopic analysis of the reaction courses verified the release of the corresponding trialkylaluminum derivatives, tri(*tert*-butyl)- and trineopentylaluminum, respectively, in both cases. The reaction of di(*tert*-butyl)aluminum hydride proved to be complicated. Unknown byproducts were formed, and the yield of compound **6** varied between 10 and 80%. Despite intensive efforts with dozens of experiments, we did not succeed in finding suitable conditions for a more reproducible reaction course. A second problem arose from the poor crystallization behavior, which made the purification by recrystallization from different solvents rather difficult. Sometimes solutions of **6** must be stored at –45 °C for several weeks to isolate colorless crystals of the product. In contrast, the reaction of dineopentylaluminum hydride with the trialkyne was rather unproblematic. Colorless product **7** precipitated directly from the reaction mixture after concentration and cooling to –30 °C. The pure compound was isolated in 63% yield. Smaller substituents attached to aluminum such as methyl or ethyl groups or the application of the dialkyne 1,4-bis(*tert*-butylethynyl)benzene resulted in the formation of insoluble products or complicated reaction mixtures. Thus far, we were not able to isolate any product in a pure form or to unambiguously identify one component of the reaction mixtures.

Schematic drawings of the molecular structures are given in Equation (1). The integration ratio of the $^1H$ NMR spectra clearly confirms the condensation reaction and the formation of cyclophane-type molecules. The resonances of the vinylic hydrogen atoms and the protons attached to the aromatic ring are close together and resonate at $\delta$ = 6.00 and 6.32 ppm for **6** and at $\delta$ = 6.24 and 6.22 ppm for **7**. The

carbon atoms of the C=C bonds show chemical shifts of $\delta$ = 152 and 156 ppm on average; the resonances at higher field belong to the carbon atoms attached to the phenyl rings and to the aluminum atoms. This situation is in complete accordance with data obtained for the corresponding gallium compounds.[10]

Crystal-structure determinations verified the condensation reactions by the release of the corresponding trialkylaluminum derivatives and the formation of cyclophane-type molecules. All C≡C bonds of the starting trialkyne were reduced by the addition of Al–H bonds to yield alkenyl groups containing C=C bonds. The aluminum atoms attacked exclusively those carbon atoms of the triple bonds that are in the α position to the aromatic ring. Aluminum and hydrogen adopt a *cis* configuration across the double bonds, which is the expected arrangement under kinetically controlled conditions. Spontaneous *cis*/*trans* rearrangement with the formation of the *trans* products occurred only with the addition of Ga–H bonds to trimethylsilyl-substituted alkynes.[6] Condensation and release of trialkylaluminum species from the hypothetical intermediates containing dialkylaluminum groups attached to the C=C bonds gave three C–Al–C bridges between two aromatic rings with coordinatively unsaturated three-coordinate aluminum atoms. Thus, these compounds may be described as [3,3,3]cyclophanes. The molecular structures are depicted in Figures 1, 2, and 3. Considerable problems occurred with respect to the generation of single crystals and the determination of the molecular structure of compound **6** (see Experimental Section). Severe disorder was observed for two of the three independent molecules, which prevents a concise discussion of all the structural parameters. However, the result can be taken as clear structural evidence for the suggested constitution. Further evidence was achieved by the generation and structural characterization of the thf adduct, **6**·3thf, in which the cyclophane-type structure is retained and one thf molecule is bonded to each of its aluminum atoms. This compound is not only valuable for the structural characterization of **6**. It impressively shows that this particular type of compound is suitable to act as multipodal Lewis acids. Relevant bond lengths and angles of the adduct are quite similar to those of the ether-free products. The phenyl rings are almost ideally coplanar with angles between the normals of both rings smaller than 1°. They are not in an ideal

Only the oxygen atoms of the thf molecules are considered. Selected bond lengths [pm] and angles [°]: Al*x*–C0*y* (*x* = 1 to 3, *y* = 1 to 6) 198.8 (av.), Al*x*–Ct*x* 201.2(av.), Al*x*–O*x* 193.0 (av.), C0*y*=C0*y*1 134.6 (av.), C0*y*–Al*x*–C0*y* 119.8 (av.), Al*x*–C0*y*–C0*y*1 115.3 (av.), C0*y*–C0*y*1–C0*y*2 133.9 (av.).

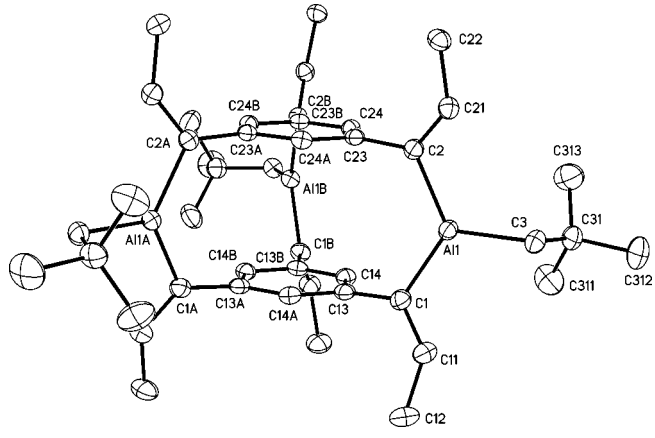

Figure 3. Molecular structure and numbering scheme of compound **7**. The thermal ellipsoids are drawn at the 40% probability level. Methyl groups and hydrogen atoms are omitted for clarity. Selected bond lengths [pm] and angles [°]: Al1–C1 195.6(2), Al1–C2 196.2(1), Al1–C3 196.9(2), C1–C11 134.6(2), C2–C21 134.6(2), C1–Al1–C2 122.40(6), Al1–C1–C11 114.7(1), Al1–C2–C21 112.9(1), C1–C11–C12 132.6(2), C2–C21–C22 132.6(1).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

eclipsed arrangement. This may also be deduced from the fact that the normals of the planes of the benzene rings and the C–Al–C groups deviate considerably from the ideal value of 90° (75 to 87°). The distance between the benzene rings of one molecule is close to 360 pm on average, which is in the characteristic range of van der Waals interactions.[12] Thus, the cavity seems to be suitable for the coordination of transition-metal atoms, and it may be an interesting task for future work to generate those products containing an encapsulated metal atom. The C=C bond lengths (135 pm on average) correspond to standard values.[13] The inner cage Al–C distances are quite similar to those including the terminal alkyl groups. Thus, there is no hint of steric stress in the cages. The angles at the aluminum atoms are close to 120°. Expectedly, only in the thf adduct did we observe an approach of the angles to the ideal tetrahedral angle with the exception of the inner cage angle, which remained unchanged relative to the ether-free compounds (about 120° on average).

## Experimental Section

**General:** All procedures were carried out under an atmosphere of purified argon. Cyclopentane, *n*-pentane, and *n*-hexane were dried with $LiAlH_4$; thf with Na/benzophenone. Di(*tert*-butyl)aluminum hydride,[14] dineopentylaluminum hydride[15] and 1,3,5-tris(*tert*-butylethynyl)benzene[10] were obtained according to literature procedures. The assignments of the signals in the NMR spectra were made on the basis of HMBC, HSQC, ROESY, and DEPT135 data.

**6:** A solution of 1,3,5-tris(*tert*-butylethynyl)benzene (0.227 g, 0.714 mmol) in *n*-hexane (20 mL) was added dropwise to a cooled (–10 °C) solution of di(*tert*-butyl)aluminum hydride (0.304 g, 2.14 mmol) in *n*-hexane (20 mL). The mixture was stirred at r.t. for 24 h. The solvent was distilled off in vacuo, and the residue was thoroughly evacuated ($10^{-3}$ Torr) to partially remove the tri(*tert*-butyl)aluminum byproduct. The oily product was dissolved in cyclopentane and stored at –45 °C for several weeks to afford **6** as a colorless solid. Yield: 0.080 g (25%). M.p. (argon, sealed capillary): 185 °C. $^1$H NMR (400 MHz, $C_6D_6$): $\delta$ = 1.11 (s, 54 H, $CMe_3$ of alkenyl group), 1.37 (s, 27 H, Al-$CMe_3$), 6.00 (s, 6 H, vinylic H), 6.32 (s, 6 H, benzene H) ppm. $^{13}$C NMR (100 MHz, $C_6D_6$): $\delta$ = 19.6 (Al-*C*Me$_3$), 30.9 (Al-C*Me*$_3$), 32.0 (*C*Me$_3$ of the alkenyl group), 37.4 (C*Me*$_3$ of the alkenyl group), 122.0 (CH of the aromatic rings), 145.9 (*ipso*-C), 150.1 (Al-*C*=C), 154.8 (Al-C=*C*) ppm. IR (CsBr plates, paraffin): $\tilde{\nu}$ = 1580 (vs, *v*C=C), phenyl, 1460 (vs, paraffin), 1404 (m, $\delta CH_3$), 1381 (s, paraffin), 1359 (vs, $\delta CH_3$), 1223 (s), 1200 (vs), 1135 (w), 1034 (m), 991 (s), 934 (m), 912 (s), 882 (s), 808 (s), 734 (s), 710 (s, *v*CC, $\delta$CH), 624 (vs), 573 (m), 538 (vw), 487 (s), 439 (w), 386 (m), 361 (s, *v*AlC, phenyl, $\delta$CC) cm$^{-1}$. $C_{60}H_{93}Al_3$ (895.3): C 80.5, H 10.5; found C 79.8, H 10.3.

**6·3thf:** An oily residue out of the synthesis of compound **6** was dissolved in thf. Slow concentration of the solution at r.t. over several days afforded crystals of the thf adduct of compound **6**. M.p. (argon, sealed capillary): **6**·3thf did not melt below 230 °C. $^1$H NMR (400 MHz, [D$_8$]thf): $\delta$ = 0.89 (s, 54 H, $CMe_3$ of alkenyl group), 1.08 (s, 27 H, Al-$CMe_3$), 1.77 (m, 12 H, thf), 3.62 (m, 12 H, thf), 5.54 (s, 6 H, vinylic H), 5.92 (s, 6 H, benzene H) ppm. $^{13}$C NMR (100 MHz, [D$_8$]thf): $\delta$ = 15.5 (Al-*C*Me$_3$), 26.3 (thf), 31.8 (Al-C*Me*$_3$), 32.7 (*C*Me$_3$ of the alkenyl group), 37.0 (C*Me*$_3$ of the alkenyl group), 68.2 (thf), 119.9 (CH of the aromatic rings), 147.1 (*ipso*-C), 147.8 (Al-*C*=C), 155.9 (Al-C=*C*) ppm. IR (CsBr plates, paraffin): $\tilde{\nu}$ = 1578 (vs), 1556 (vs, *v*C=C), phenyl, 1465 (vs, paraffin), 1403 (m, $\delta CH_3$), 1380 (vs, paraffin), 1355 (vs), 1318 (w), 1299 (w), 1281 (w), 1248 (m, $\delta CH_3$), 1224 (vs), 1200 (vs), 1181 (s), 1133 (m), 1071 (m), 1037 (vs), 1003 (vs), 970 (vs), 959 (m), 934 (s), 911 (vs), 893 (vs), 854 (vs), 795 (s), 733 (s), 707 (s, *v*CC, *v*CO, $\delta$CH), 688 (m), 651 (m), 616 (vs), 571 (s), 549 (s), 484 (vs), 442 (s), 394 (vs), 359 (vs), 336 (s, *v*AlC, *v*AlO, phenyl, $\delta$CC) cm$^{-1}$.

**7:** A solution of 1,3,5-tris(*tert*-butylethynyl)benzene (0.244 g, 0.767 mmol) in *n*-pentane (10 mL) was treated with a solution of dineopentylaluminum hydride (0.392 g, 2.30 mmol) in *n*-pentane (20 mL) at r.t. The mixture was stirred under these conditions for 20 h. After concentration and cooling of the solution to –30 °C, product **7** precipitated as a colorless amorphous powder. Yield: 0.227 g (63%). M.p. (argon, sealed capillary): 140 °C (dec.). $^1$H NMR (400 MHz, $C_6D_6$): $\delta$ = 0.76 (s, 6 H, Al-$CH_2$), 1.13 (s, 54 H, $CMe_3$ of alkenyl group), 1.31 (s, 27 H, $CMe_3$ of neopentyl), 6.22 (s, 6 H, benzene H), 6.24 (s, 6 H, vinylic H) ppm. $^{13}$C NMR (100 MHz, $C_6D_6$): $\delta$ = 25.2 (Al-$CH_2$), 31.9 (*C*Me$_3$ of neopentyl and C*Me*$_3$ of the alkenyl groups), 35.8 (C*Me*$_3$ of neopentyl), 37.4 (*C*Me$_3$ of the alkenyl group), 121.1 (CH of the aromatic rings), 145.3 (*ipso*-C), 153.3 (Al-*C*=C), 157.7 (Al-C=*C*) ppm. **Crystal Structure Determinations of 6, 6·3thf, and 7:** Single crystals of solvent-free **6** could only be obtained with enormous difficulties by recrystallization from *n*-pentane (20/–15 °C). It crystallized in the hexagonal space group $P6_3/m$ with 20 molecules in the unit cell. Twelve symmetry related molecules are in general positions. The molecular structure of that species could be refined to reasonable final structural parameters. Six molecules are localized on crystallographic mirror planes. They are severely disordered in particular with respect to the bridging C–Al–C groups. The refinement was done by severe restrictions and gave an insufficient result only, but verified clearly the occurrence of a structure identical to that of the molecule on a general position. Two further molecules are localized on $\bar{6}$ axes. They show a similar disorder of the C–Al–C bridges, but the refinement gave a more consistent result. Overall, the value of that structure determination should be seen in structural evidence only; it clearly does not meet the standard requirement of a sufficiently high quality. Crystals of **6**·3thf were generated by slow concentration of a thf solution at r.t. over several days. The crystals enclosed a thf molecule per formula unit of the adduct, which was refined with atomic occupation factors of 0.5. Recrystallization of the amorphous solid product from *n*-pentane afforded single crystals of **7**, which enclose strongly disordered solvent molecules. The cyclophane molecules of **7** reside on crystallographic threefold rotation axes. Crystal data, data collection parameters, and structure refinement details are given in Table 1. The crystallographic data of **6** and **6**·3thf were collected with a STOE image plate diffractometer, those of **7** were determined with a BRUKER apex diffractometer. The structures were solved by direct methods and refined with the program SHELXL-97[18] by a full-matrix least-squares method based on $F^2$.

# Proton NMR Study of Low-Spin *meso*-Unsubstituted β-Substituted Alkyl Iron Porphyrins: Remarkable Influence of Peripheral Substitution on Spin Density

**Sandrine Juillard,[a] Arnaud Bondon,[b] and Gérard Simonneaux*[a]**

**Keywords:** NMR spectroscopy / Porphyrinoids / Iron / HMBC / Saturation transfer

Paramagnetic NMR spectroscopy was used to characterize the influence of small alkyl groups on the spin density of a series of high-spin and low-spin iron(III) porphyrins. Assignment of the resonances was obtained by using a variety of NMR techniques including heteronuclear multiple bond correlation and saturation transfer experiments.

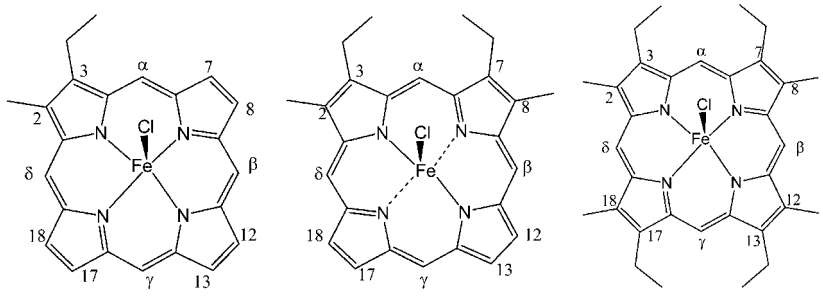
## Introduction

Heme is one of the most versatile prosthetic groups in metalloproteins, and different types of heme have been found in proteins.[1] The reconstitution of heme proteins with modified heme is a useful method for understanding the physiological function and creating a new function in heme proteins.[2] Many heme modifications with different substituents have been designed to optimize heme/apoprotein interaction and even an iron porphine complex has been employed as the smallest prosthetic group of heme protein to modify intensively the heme–globin interactions.[3] Recently, we prepared myoglobin (rMb) reconstituted with the iron complex of 3,7-diethyl-2,8-dimethylporphyrin[4] in which two ethyl groups were found to be large enough to avoid the free rotation movement of the heme.[5] However, to discuss the contribution of individual pyrroles in myoglobin, it is quite interesting to design smaller porphyrins such as 3-ethyl-2-methylporphyrin. In this study, we used paramagnetic NMR spectroscopy to characterize the influence of small alkyl groups on the spin density of a series of high-spin and low-spin iron(III) porphyrins, including low-spin bis(cyanido)-3-ethyl-2-methylporphyriniron(III).

## Results and Discussion

The synthesis of β-pyrrole-substituted porphyrins has been reported elsewhere,[4] and iron was inserted to produce $Fe^{III}Cl$ porphyrins as outlined in the Experimental Section. The UV/Vis spectra of these complexes are compatible with high-spin, five coordinate structures. The structures of the compounds are summarized in Figures 1 and 2.



**1**·$Fe^{III}Cl$ **2**·$Fe^{III}Cl$ **3**·$Fe^{III}Cl$

Figure 1. The structures of β-pyrrole-substituted FeCl porphyrin complexes.

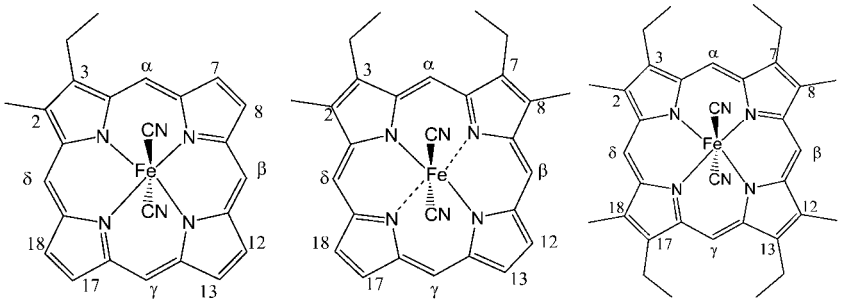

Figure 2. The structures of β-pyrrole-substituted $Fe(CN)_2$ porphyrin cmplexes.

results previously reported for octaethylporphyriniron chloride[6–8] determined their assignment. Two resonances for the *meso* protons are observed in the highfield region at $\delta$ = –63.3 and –58.3 ppm. In the downfield part of the spectrum, three resonances are found at $\delta \approx 78$ ppm for the β-pyrrole protons as a result of accidental overlap, as the absence of symmetry dictates that there should be six β-pyrrole resonances. Also in the downfield part of the spectrum, one resonance at $\delta$ = 51.3 ppm for 2-$CH_3$ and two resonances at $\delta$ = 39.9 and 43.7 ppm for the ethyl group of 3-$CH_2CH_3$ appear owing to diastereoisomerism. The $CH_3$ resonance of the ethyl group is not assigned because of its presence under the diamagnetic area. The $^1$H NMR spectra of the other complexes of this type **2**·FeCl and **3**·FeCl have related features, although the presence of idealized $C_s$ symmetry greatly simplifies the spectrum. Thus, **2**·FeCl has three *meso* protons with a 1:2:1 intensity ratio in the upfield region, two resonances at $\delta$ = 76.8 and 79.1 ppm for the β-pyrrole protons as a result of accidental overlap, two resonances at $\delta$ = 40.4 and 43.3 ppm for the 3,7-$CH_2CH_3$ group owing to diastereoisomerism, and a resonance at $\delta$ = 54 ppm for the 2,8-$CH_3$ group. As expected for **3**·FeCl, only two broad resonances are observed at $\delta$ = –54.9 and –56.6 ppm for the *meso* protons. The chemical shifts for the three complexes are summarized in Table 1 (298 K), and all of them are compatible with a high-spin state, $S$ = 5/2.[9]

Table 1. $^1$H NMR chemical shifts [ppm] of high-spin iron porphyrin chloride in $CDCl_3$ (298 K).

| Complex | *meso*-H | $CH_2CH_3$ | $CH_2CH_3$ | β-pyrrole-H |
|---|---|---|---|---|
| **1**·$Fe^{III}Cl$ | –58.3 | 39.9 | 51.3 | 76.8 |

| | | 43.7 | | |

[a] At 293 K, TPP: tetraphenylporphyrin.[33] [b] At 298 K, OEP: octaethylporphyrin.[8]

The typical spin delocalization pathways for high-spin iron(III) porphyrins produce resonances for the β-pyrrole and α-$CH_2$ protons that are strongly shifted downfield.[10] Accordingly, all the iron(III) chloride complexes **1**·FeCl, **2**·FeCl, and **3**·FeCl showed this behavior. This downfield shift is mainly a result of the σ-contact contribution that results from delocalization through the σ-framework by way of σ-donation to the half-occupied $d_{x^2-y^2}$ iron(III) orbital. Comparison of the $^1$H NMR spectroscopic data of the high-spin, five coordinate iron(III) complexes shown in Table 1 also shows that substitution produces a small effect on the chemical shift of the *meso* resonances with electron-donating groups (alkyl groups), shifting these resonances in a downfield fashion. The β-pyrrole protons are found to resonate in a narrow window from $\delta$ = 76 to 79 ppm.

## Low-Spin Complexes

The addition of an excess amount of potassium cyanide to the iron chloride complexes in the NMR tube gave the low-spin bis(cyanido)iron complexes (see Experimental Section). Thus the $^1$H NMR spectrum of K[**1**·$Fe(CN)_2$] in methanol/chloroform at 308 K (Figure 3b) shows six resonances for the β-pyrrole protons in the high-field region, as expected from the absence of symmetry in the structure. Because HMBC spectra were not informative in this particular case, assignments of these protons were obtained by means of 1D NOE difference spectroscopy as well as 2D COSY spectroscopy. For example, all required cross peaks were identified in the COSY spectrum (Figure 4), allowing notably the identification of each pair of the β-pyrrole protons. The NOE difference spectrum, recorded at 308 K (Figure 5a), outlines the increase in intensity for the *meso* proton α-H at $\delta$ = 2.93 ppm and the β-pyrrole proton 7-H at $\delta$ = –11.75 ppm when the ethyl group at $\delta$ = 8.51 ppm was irradiated. Following the COSY spectrum, this situation identifies the proton 8-H at $\delta$ = –14.75 ppm. To complete the assignment, the NOE difference spectrum showed an increase in the intensity for the *meso* proton δ-H at $\delta$ = 2.56 ppm and the β-pyrrole proton 18-H at $\delta$ = –11.89 ppm when the methyl group (2-$CH_3$) at $\delta$ = 18.46 ppm was irradiated (Figure 5b). The signal at $\delta$ = –14.37 ppm was as-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

signed to 17-H, whereas the last two *meso* protons at $\delta$ = 0.32 and 0.38 ppm were assigned to β-H and γ-H without a respective assignment. The last two β-pyrrole protons at $\delta$ = –12.96 and –13.05 ppm were assigned to 12-H and 13-H without a respective assignment. The chemical shift values obtained at 298 and 308 K for K[**1**·Fe(CN)$_2$] are summarized in Table 2. They are all compatible with a low-spin state, $S$ = 1/2.

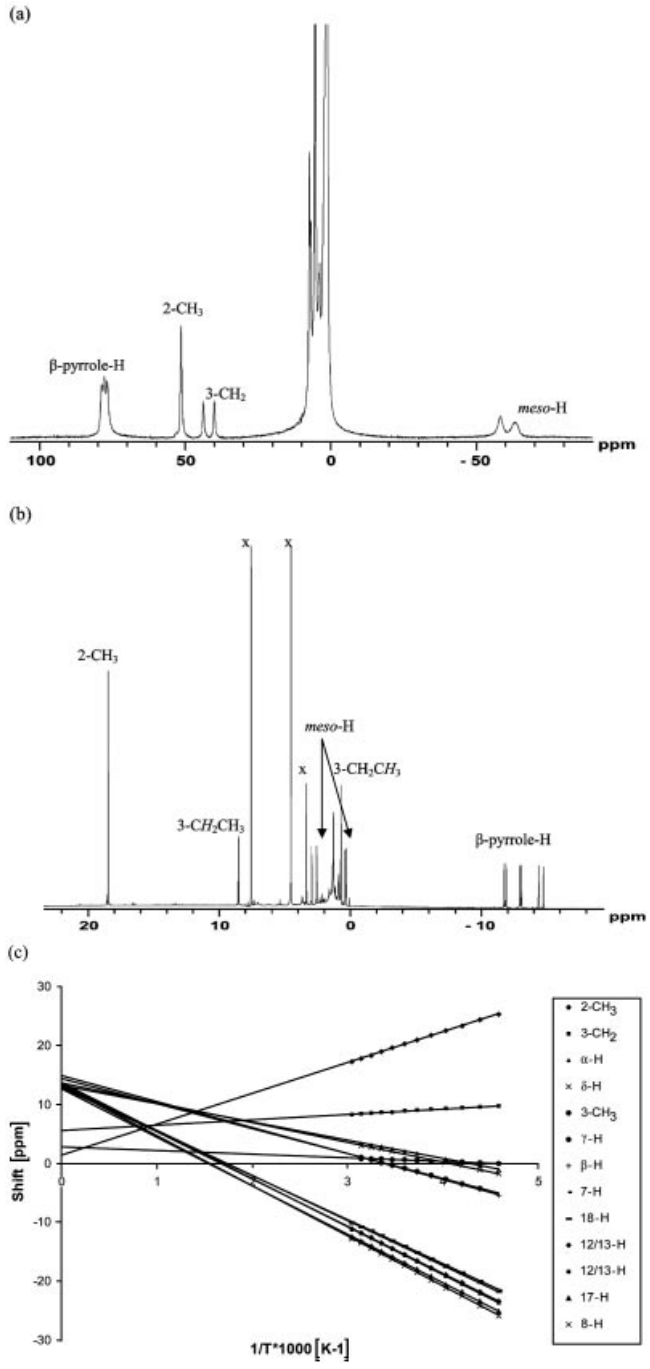

Figure 3. $^1$H NMR spectrum for (a) **1**·Fe$^{III}$Cl in $CDCl_3$ at 298 K, (b) K[**1**·Fe(CN)$_2$] in $CDCl_3$/MeOD (60:40) at 308 K, x: solvent peaks, and (c) Curie plots for K[**1**·Fe(CN)$_2$].

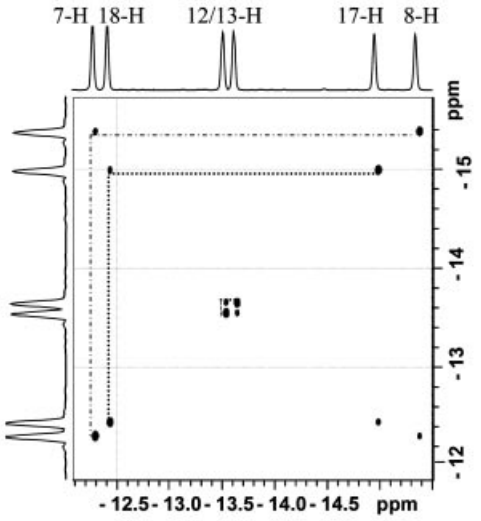

Figure 4. Part of the COSY spectrum showing β-pyrrole protons for K[**1**·Fe(CN)$_2$] (298 K).

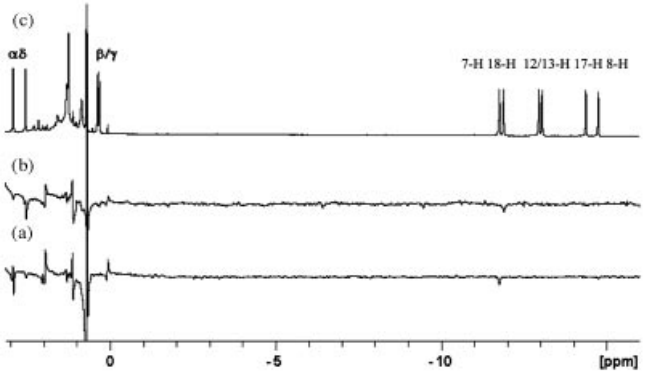

Figure 5. 1D NOE difference spectra for K[**1**·Fe(CN)$_2$] at 308 K: (a) irradiation of the $CH_2$ group at $\delta$ = 8.51 ppm, (b) irradiation of the $CH_3$ group at $\delta$ = 18.46 ppm, (c) high-field part of the spectrum.

The $^1$H NMR spectrum of K[**2**·Fe(CN)$_2$] in methanol/chloroform at 298 K (Figure 6a) shows two resonances for the β-pyrrole protons in the highfield region, as expected from the symmetry of the structure. A complete assignment of all the protons was obtained by means of heteronuclear correlation spectroscopy (HMQC and HMBC) as well as 2D COSY spectroscopy. The relative intensities of the resonances and the COSY spectrum allowed the assignment of all the protons except for the two *meso* protons, α and γ, and the β-pyrrole protons. It was previously reported that HMQC spectroscopy of paramagnetic iron porphyrins provides the scalar heterocorrelation under natural abundance conditions of $^{13}$C.[11] In the present study, this correlation technique offers a route to identify the β-pyrrole resonances by taking advantage of the fact that the full assignment of the proton signals of the β-$^{13}$C-$^1$H pairs has been established. Thus, the signal assignment of the carbons with directly bonded protons such as β-pyrrole protons and *meso* protons ($^{13}$C-$^1$H) was done on the basis of HMQC experiments. The assignment was then completed with the

[a] OEP: octaethylporphyrin in $CD_3OD$.[8] [b] TPP: tetraphenylporphyrin in $CD_2Cl_2/CD_3OD$ at 202 K.[21] [c] At 298 K.[23] [d] At 308 K.

HMBC spectrum (Figure 7). For example, the $^{13}$C signal at $\delta$ = 76.18 ppm (a β-pyrrole carbon) that showed correlation peaks with the proton signal at +1.29 ppm (*meso* β,δ-H) was assigned to C-12 and C-18. Consequently, the proton resonance at $\delta$ = –11.48 ppm was assigned to the β-pyrrole protons 12,18-H by using the HMQC spectrum. Similarly, the signals at $\delta$ = –14.49, –0.66, and 3.72 ppm were assigned to the identical β-pyrrole protons, 13-H and 17-H, and the *meso* protons, γ-H and α-H, respectively.

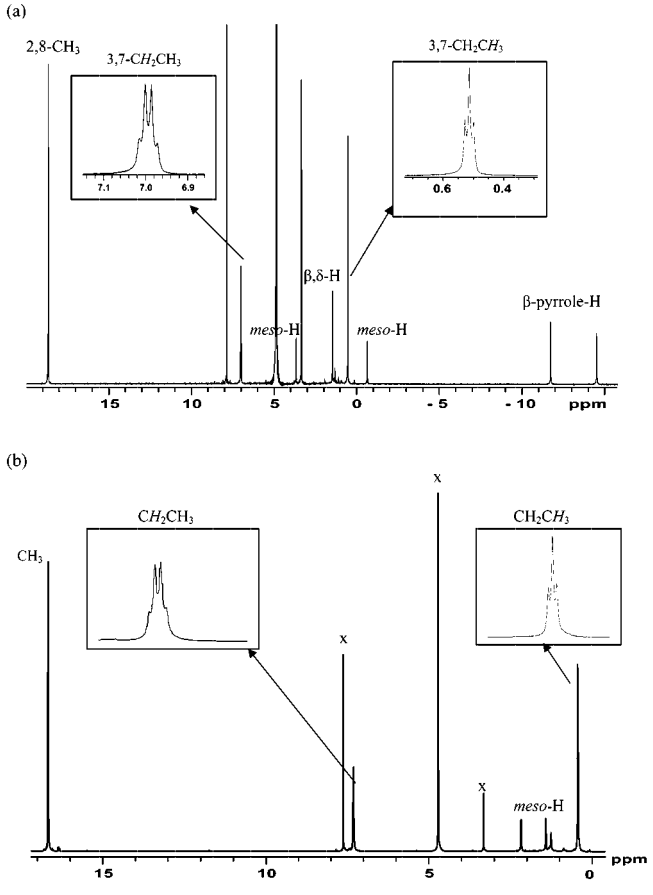

Figure 6. $^1$H NMR spectra at 298 K for (a) K[**2**·Fe(CN)$_2$] and (b) K[**3**·Fe(CN)$_2$] in $CDCl_3$/MeOD (60:40).

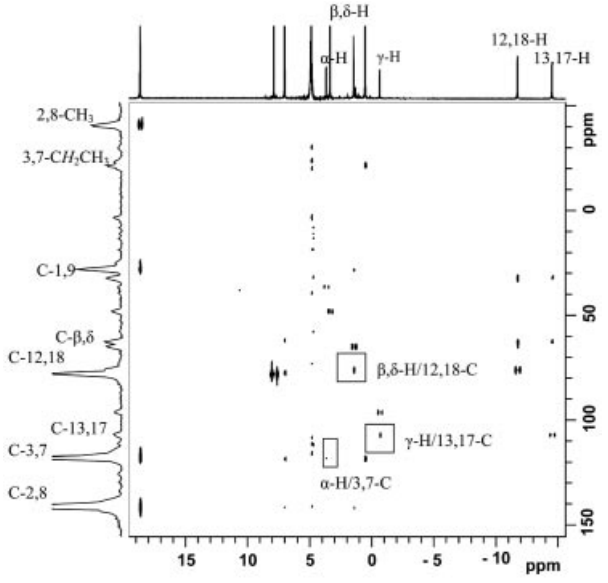

Figure 7. HMBC spectrum for K[**2**·Fe(CN)$_2$] at 298 K in $CDCl_3$/MeOD (60:40).

The $^1$H NMR spectrum of K[**3**·Fe(CN)$_2$] in methanol/chloroform at 298 K is shown in Figure 6b. As previously described for K[**2**·Fe(CN)$_2$], complete assignment of the protons and carbons was obtained by means of HMQC and HMBC spectroscopy as well as 2D COSY spectroscopy (not shown). Comparison of the *meso* proton and *meso* carbon chemical shifts of K[**3**·Fe(CN)$_2$] with K[**1**·Fe(CN)$_2$] and K[**2**·Fe(CN)$_2$] reveals that the former complex also shows mainly a $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic ground state. The proton chemical shifts for K[**2**·Fe(CN)$_2$] and K[**3**·Fe(CN)$_2$] are also summarized in Table 2; all are compatible with a low-spin state, $S$ = 1/2.

Analysis of the curve in the Curie plot was made for K[**1**·Fe(CN)$_2$], K[**2**·Fe(CN)$_2$], and K[**3**·Fe(CN)$_2$]. As an example, the temperature dependences of the chemical shifts of the protons of K[**1**·Fe(CN)$_2$] in MeOD/$CDCl_3$ are shown in Figure 3c. The chemical shifts vary linearly with 1/$T$, but the extrapolated lines do not pass through the diamagnetic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

value at $1/T = 0$. However, the intercepts at $1/T = 0$ for these signals were located between 0 and 15 ppm, and the chemical shift differences, if we consider the free-base porphyrin as a reference, do not vary to a great extent (less than 5 ppm). Similar results were obtained for the Curie plots of K[**2**·Fe(CN)$_2$] and K[**3**·Fe(CN)$_2$].

$^{13}$C NMR chemical shifts can also be a good probe to determine the electronic ground state, because they give the information on the spin distribution of any porphyrin carbons including *meso* and β-pyrrole carbons.[12,13] Table 3 shows the $^{13}$C NMR chemical shifts for K[**1**·Fe(CN)$_2$], K[**2**·Fe(CN)$_2$], and K[**3**·Fe(CN)$_2$] at 298 K. Signals were obtained and assigned on the basis of HMQC spectra. Examination of the data in Table 3 reveals that the *meso* carbons appear in a range of 35–97 ppm, and the β-pyrrole carbons appear in a range of 70–142 ppm.

Table 3. $^{13}$C chemical shifts [ppm] of low-spin bis(cyanido)iron porphyrins in $CDCl_3/CD_3OD$ (60:40) (298 K).

| Complex | β-pyrrole-C | *meso*-C | $CH_3$ | $CH_2CH_3$ | $CH_2CH_3$ |
|---|---|---|---|---|---|
| K[**1**·Fe(CN)$_2$] | 72.1 | 51.4 | –39.9 | –27.1 | 86.9 |
| | 74.1 | 53.8 | | | |
| | 94.6 | 83.1 | | | |

### Electronic Ground State of Low-Spin Complexes

The spin density distribution at the pyrrole positions in low-spin iron(III) complexes of disymmetrically substituted tetraphenylporphyrins[14] and natural porphyrin derivatives[15] was previously reported. The results herein indicate that the introduction of only two alkyl substituents at the β-pyrrole positions of porphine can also produce significant changes in the spin density of the resulting iron(III) complexes to be detected by $^1$H NMR spectroscopy.

The ground electronic state of low-spin iron(III) porphyrins evolves between two extreme cases, i.e. $(d_{xy})^2(d_{xz},d_{yz})^3$ and $(d_{xz}d_{yz})^4(d_{xy})^1$[9] The $^1$H NMR spectra of the bis(cyanido) complexes of many artificial iron(III) porphyrins[16] and some naturally derived ferriheme[15] complexes were reported. The former studies generally indicated that the electronic ground state was $(d_{xy})^2(d_{xz},d_{yz})^3$ for these complexes. However, more recently, it was shown that the bis(cyanido) complexes of *meso*-substituted Fe$^{III}$ porphyrins having alkyl substituents of increasing size[17] and other iron(III) porphyrins having bulky substituents in the *meso* position[18–21] show a large shift in the pyrrole protons towards the diamagnetic region, which is indicative of a large contribution of the unusual $(d_{xz}d_{yz})^4(d_{xy})^1$ electronic configuration to the ground state. Furthermore, this situation is amplified when the NMR spectroscopic solvent is methanol because of a possible hydrogen bond between the axial ligand and the solvent.[6,13,22]

$^1$H NMR spectroscopic resonances for the β-pyrrole protons in K[**1**·Fe(CN)$_2$] and K[**2**·Fe(CN)$_2$] appear at very high magnetic field ($\delta$ = –10 to –20 ppm). This large upfield shift of the β-pyrrole protons indicates the existence of large spin densities on the β-pyrrole carbons, which is induced by the interactions between porphyrin $3e_g$ and iron $d_\pi$ orbitals. Because the $3e_g$ orbital places large electron densities on the β-pyrrole carbons, the spin transfer from porphyrin $3e_g$ to iron $d_\pi$ results in the large spin densities to these carbons, which would be translated as a large upfield shift of the β-pyrrole protons. This is a typical observation for a $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic ground state.[10] By comparison with bis(cyanido)iron porphine,[23] (pyrrole –13.8 ppm, *meso* 1.8 ppm) it should be also noted that a large difference in the spin distribution of the pyrrole in K[**1**·Fe(CN)$_2$] is generated by adding only one methyl group and one ethyl group. In this particular case, all six β-pyrrole protons are detected separately, whereas a single peak at –13.8 ppm is observed for bis(cyanido)iron porphine.[23] It should also be noted that, generally, the $^1$H NMR spectra of dicyanohemin complexes are well-resolved, as the lines are quite narrow due to very rapid electron spin relaxation times and long proton relaxation times, $T_1$ and $T_2$, respectively.[9,24,25] This remarkable resolution was also detected with iron(III) geoporphyrins.[26]

It should be emphasized that the *meso* $^{13}$C chemical shift is also particularly useful to determine the electronic configuration.[27,28] Thus, the *meso* carbon signal in complexes with the $(d_{xy})^2(d_{xz},d_{yz})^3$ configuration appears more upfield than the corresponding signal in diamagnetic complexes because the $3e_g$ orbital, which interacts with the half-occupied $d_\pi$ orbital has a node at the *meso* carbon atom. By contrast, the complexes with a $(d_{xz},d_{yz})^4(d_{xy})^1$ ground state have large spin density at the *meso* carbon as a result of the $a_{2u}$–$d_{xy}$ interaction, exhibiting a *meso* carbon signal at a downfield position. Thus, it is quite obvious that the values summarized in Table 3 agree well with the $(d_{xy})^2(d_{xz},d_{yz})^3$ configuration and confirm the $^1$H NMR spectroscopic interpretation.

## Conclusions

$^1$H and $^{13}$C NMR spectroscopic analysis of β-alkyl-substituted iron porphyrins can be a very sensitive tool to probe the fine details of the electronic structure. This may be relevant to our protein studies with artificial hemes. Analysis of the pyrrole proton and *meso* carbon chemical shifts of K[**1**·Fe(CN)$_2$], K[**2**·Fe(CN)$_2$], and K[**3**·Fe(CN)$_2$] reveals that all complexes show mainly a low-spin $(d_{xy})^2(d_{xz},d_{yz})^3$ electronic ground state.

Thus, the spectroscopic observations are indicative of a metal-based electron in the $d_\pi$ orbitals of the iron(III) bis(cyano) complexes at any temperature. The change in ground state of low-spin Fe$^{III}$ from the usual

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$(d_{xy})^2(d_{xz},>d_{yz})^3$ to the unusual $(d_{xz}d_{yz})^4(d_{xy})^1$ electronic configuration, which was previously suggested to occur from weak hydrogen bonding to the cyanido ligand in methanol solution with *ortho*-substituted tetraphenylporphyrins and even more with highly ruffled porphyrins,[21] is not observed with these *meso*-unsubstituted porphyrins that bear few substituents on the β-pyrrole positions. Accordingly, these results demonstrate the high energy barrier to ruffling, which seems to prevent ring deformation and, consequently, the interaction of the $d_{xy}$ orbital with the $a_{2u}(\pi)$ porphyrin orbital.

## Experimental Section

**General:** All reactions were performed under an atmosphere of argon. Solvents were distilled from appropriate drying agent prior to use: $Et_2O$ and THF from sodium and benzophenone, toluene from sodium, $CH_2Cl_2$ from $CaH_2$, $CHCl_3$ from $P_2O_5$, and all other solvents were HPLC grade. Commercially available reagents were used without further purification unless otherwise stated. All reactions were monitored by TLC with Merck precoated aluminium foil sheets (Silica gel 60 with fluorescent indicator $UV_{254}$). Compounds were visualized with UV light at 254 and 365 nm. Column chromatography was carried out by using silica gel from Merck (0.063–0.200 mm). High-resolution mass spectra were recorded with a ZabSpec TOF Micromass spectrometer in ESI positive mode at the CRMPO. Liquid UV/Vis spectra were recorded with a UVIKON XL from Biotech. $^1$H and $^{13}$C NMR in $CDCl_3$ were recorded with a Bruker Avance 500 operating at 500.15 MHz for $^1$H and 125.769 MHz for $^{13}$C with a 5 mm broadband probe equipped with a *z*-gradient coil. The spectral widths were adjusted depending on the spin state of the compounds, with 200 and 45 ppm for the proton spectra of high-spin and low-spin complexes, respectively. The $^{13}$C spectral width was 400 ppm for the low-spin complexes. Standard Bruker pulse programs were used for the acquisition of the 2D COSY, HSQC, and HMBC[29,30] spectra. Because of the paramagnetism of the derivatives, relatively short relaxation rates ($R_1$ and $R_2$) are expected. Consequently, recycling times of 0.5 and 0.8 s were used for the high-spin and the low-spin complexes. For the heteronuclear experiments, despite the large spectral width in the $^{13}$C dimension spectra, 2 K × 256 points were recorded. Some spectra were recorded with a Bruker Avance 300. The syntheses of β-pyrrole-substituted porphyrins **1**, **2**, and **3** were previously reported.[4,31]

### Preparation of Iron Porphyrins

**1·Fe$^{III}$Cl:** Iron was inserted following the procedure of Borovkov et al.[32] 3-Ethyl-2-methylporphyrin **1** (190 mg, 0.51 mmol) was dissolved in distilled chloroform (75 mL). $FeCl_2{\cdot}4H_2O$ (16 equiv.) dissolved in distilled methanol (50 mL) and two drops of 2,6-lutidine were then added. The reaction mixture was stirred at 50 °C and monitored by thin-layer chromatography (TLC) until completion. After evaporation of the solvent, the crude product was purified by column chromatography ($CH_2Cl_2$/MeOH, 3%). Before total evaporation, two drops of concentrated hydrochloric acid were added. Recrystallization from dichloromethane/pentane afforded 3-ethyl-2-methylporphyrin iron chloride **1·FeCl** as a black powder (100 mg, 0.24 mmol, 40%). $^1$H NMR (500 MHz, $CDCl_3$, 298 K): $\delta$ = –63.3 (s, 2 H, *meso*-H), –58.3 (s, 2 H, *meso*-H), 39.9 and 43.7 (s, 2 H, $CH_2CH_3$), 51.3 (s, 3 H, $CH_3$), 76.8, 77.7, and 78.6 (6 H, pyrrol-H) ppm. UV/Vis: $\lambda$ ($\varepsilon$, mM$^{-1}$ cm$^{-1}$) = 371 (110), 496 (10), 522 (10.7), 564 (3.2), 623 (5.8) nm. HRMS (LSIMS-MS): calcd. for $C_{23}H_{18}{}^{35}Cl^{56}FeN_4$ $[M]^{+\cdot}$ 441.0569; found 441.0574.

**2·FeCl:** Prepared as per **1·FeCl**. Yield: 75%. $^1$H NMR (500 MHz, $CDCl_3$, 298 K): $\delta$ = –63.3 (s, 1 H, α/γ-H), –59.3 (s, 2 H, β,δ-H), –53.8 (s, 1 H, α/γ-H), 40.4 and 43.3 (s, 4 H, $CH_2CH_3$), 54.0 (s, 6 H, $CH_3$), 76.8 and 79.06 (s, 4 H, pyrrol-H) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ ($\varepsilon$, mM$^{-1}$ cm$^{-1}$) = 375 (114.6), 499 (12.4), 525 (10.7), 570 (3.8), 627 (5.8) nm. HRMS (ESI-MS): calcd. for $C_{26}H_{24}{}^{56}FeN_4$ $[M – Cl]^+$ 448.1350; found 448.1355.

3·FeCl: Prepared as per **1·FeCl**. Yield: 55%. $^1$H NMR (500 MHz, $CDCl_3$, 298 K): $\delta$ = –56.6 (s, 2 H, *meso*-H), –54.9 (s, 2 H, *meso*-H), 40.5 and 43.9 (s, 8 H, $CH_2CH_3$), 52.5 (s, 12 H, $CH_3$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ ($\varepsilon$, mM$^{-1}$ cm$^{-1}$) = 379 (98.9), 505 (8.4), 534 (8.5), 635 (4.4) nm. HRMS (ESI-MS): calcd. for $C_{32}H_{36}{}^{56}FeN_4$ $[M – Cl]^+$ 532.2289; found 532.2292.

**Preparation of the Dicyanido-Ligated Complexes:** Usually, these complexes were prepared in situ by dissolution of 2–3 mg of the respective high-spin complex in [$D_1$]chloroform/[$D_4$]MeOH solution (60:40) saturated with KCN. Under these experimental conditions, the black solution turned red, which is characteristic of the formation of the low-spin dicyano complex.

**K[1·Fe(CN)$_2$]:** $^1$H NMR (500 MHz; $CDCl_3$/MeOD, 60:40; 298 K): $\delta$ = –15.32 (s, 1 H, 8-H), –14.93 (s, 1 H, 17-H), –13.59 (s, 1 H, 12/13-H), –13.49 (s, 1 H, 12/13-H), –12.38 (s, 1 H, 18-H), –12.25 (s, 1 H, 7-H), 0.07 (s, 1 H, β/γ-H), 0.12 (s, 1 H, β/γ-H), 0.68 (t, $J$ = 5 Hz, 3 H, $CH_2CH_3$), 2.38 (s, 1 H, δ-H), 2.77 (s, 1 H, α-H), 8.62 (q, $J$ = 5 Hz, 2 H, $CH_2CH_3$), 18.89 (s, 3 H, $CH_3$) ppm. $^{13}$C NMR (125 MHz; $CDCl_3$/MeOD, 60:40): $\delta$ = –39.99 ($CH_3$), –27.10 ($CH_2CH_3$), 51.42 (C-α), 53.81 (C-δ), 72.14 (C-7), 74.14 (C-18), 83.10 (C-β), 83.30 (C-γ), 86.89 ($CH_2CH_3$), 94.66 (C-12/13), 94.86 (C-12/13), 102.04 (C-17), 104.03 (C-8) ppm.

**K[2·Fe(CN)$_2$]:** $^1$H NMR (500 MHz; $CDCl_3$/MeOD, 60:40; 298 K): $\delta$ = –14.43 (s, 2 H, 13,17-H), –11.48 (s, 2 H, 12,18-H), –0.98 (s, 1 H, γ-H), 0.50 (t, $J$ = 5 Hz, 6 H, $CH_2CH_3$), 1.29 (s, 2 H, β,δ-H), 3.72 (s, 1 H, α-H), 7.02 (q, $J$ = 5 Hz, 4 H, $CH_2CH_3$), 18.87 (s, 6 H, $CH_3$) ppm. $^{13}$C NMR (125 MHz; $CDCl_3$/MeOD, 60:40): $\delta$ = –42.2 ($CH_3$), –22.7 ($CH_3CH_2$), 28.3 (C-1,9), 32.19 (C-11,19), 35.83 (C-α), 62.14 (C-4,6), 62.96 (C-14,16), 65.4 (C-β,δ), 76.18 (C-12,18), 77.8 ($CH_2CH_3$), 97.26 (C-γ), 107.5 (C-13,17), 107.62 (C-3,7), 142.1 (C-2,8) ppm.

**K[3·Fe(CN)$_2$]:** $^1$H NMR (500 MHz; $CDCl_3$/MeOH, 60:40; 298 K): $\delta$ = 0.44 (t, $J$ = 5 Hz, 12 H, $CH_2CH_3$), 1.43 (s, 2 H, β,δ-H), 2.18 (s, 2 H, α,γ-H), 7.30 (q, $J$ = 5 Hz, 8 H, $CH_2CH_3$), 16.71 (s, 12 H, $CH_3$) ppm. $^{13}$C NMR (125 MHz; $CDCl_3$/MeOH, 60:40): $\delta$ = –37.46 ($CH_3$), –22.54 ($CH_2CH_3$), 39.85 (C-1,9,11,19), 47.22 (C-4,6,14,16), 57.06 (C-α,γ), 60.34 (C-β,δ), 77.72 ($CH_2CH_3$), 127.38 (C-2,8,12,18), 131.80 (C-3,7,13,17) ppm.

# New Single-Molecule Magnets by Site-Specific Substitution: Incorporation of "Alligator Clips" into $Fe_4$ Complexes

**Anne-Laure Barra,[a] Federica Bianchi,[b] Andrea Caneschi,[c] Andrea Cornia,*[d] Dante Gatteschi,[c] Lapo Gorini,[c] Luisa Gregoli,[d] Monica Maffini,[b] Francesca Parenti,[d] Roberta Sessoli,*[c] Lorenzo Sorace,[c] and Anna Maria Talarico[d]**

**Keywords:** Iron / Ligand design / Magnetic properties / EPR spectroscopy / Single molecule magnets

"Alligator clips" suitable for grafting on H-terminated silicon or gold surfaces have been incorporated into single-molecule magnets (SMMs) of the $Fe_4$ family. Tripodal ligands 2,2-bis-(hydroxymethyl)-10-undecen-1-ol ($H_3L^1$) and 11-(acetylthio)-2,2-bis(hydroxymethyl)undecan-1-ol ($H_3L^2$) have been used to replace the six methoxide bridges in $[Fe_4(OMe)_6(dpm)_6]$, affording new $Fe_4$ derivatives $[Fe_4(L^1)_2(dpm)_6]$ (**1**) and $[Fe_4(L^2)_2(dpm)_6]$ (**2**) in high yield (Hdpm = dipivaloylmethane). The molecular structures have been unambiguously established by XRD combined with ESI-MS and magnetic characterization techniques, including DC and AC magnetometry and high-frequency EPR spectroscopy. The two SMMs have an $S = 5$ ground state and an easy-axis magnetic anisotropy leading to slow relaxation of the magnetization at low temperature, with effective anisotropy barriers of 15.9(2) K in **1** and 15.1(2) K in **2**.

## Introduction

Single-molecule magnets (SMMs) are among the smallest magnetic structures that can be conceived, consisting of only a few magnetic atoms. The constituent magnetic units are d-block transition-metal or, more rarely, rare-earth ions.[1–3] The unique feature of SMMs is their large-spin ground state associated with a substantial easy-axis magnetic anisotropy. As a result, the "giant" total magnetic moment experiences a molecular anisotropy barrier $U_{eff}$, which governs relaxation. At sufficiently low temperatures the relaxation of the magnetic moment becomes so slow that hysteresis appears when the external field is cycled. In this respect, spin reversal occurs through a classical, thermally activated mechanism and is very similar to that observed in magnetic nanoparticles. However, because of the discreteness of the spin levels in SMMs, magnetic moment reversal may also occur through quantum tunneling (QT), giving rise to stepped hysteresis loops and making SMMs unique magnetic systems.[2]

In the last decade, SMM research has mainly focussed on large molecular assemblies such as single crystals, polycrystalline samples, solutions, and Langmuir–Blodgett films. The advances in nanotechnology nowadays enable the study of molecular magnetism in lower-dimensional systems.[4] For example, with scanning probe microscopy (sub)-monolayers of SMMs at surfaces are studied extensively.[5] Moreover, researchers have now reached the ultimate limit of electronic devices by connecting two wires to a single molecule, measuring the flow of electrons through it, and controlling this flow with a nearby gate electrode.[6] In this context, a key step is the development of strategies to introduce specific functionalities, like surface-binding sites, around the core of SMMs, without altering the magnetic behavior. As the grafting protocols usually involve liquid-phase operations, the complexes should additionally remain intact in solution and on surfaces. We are currently pursuing the functionalization of SMMs in order to realize molecular wires containing high-spin units that may be grafted on surfaces or linked to proximal electrodes. In a previous paper we demonstrated that four surface-binding groups can be linked to the core of $Mn_{12}$-type SMMs using proper ligand design.[7]

In this paper, we report the successful preparation of two novel iron(III)-based SMMs that exhibit a wire-like molecular geometry, **1** and **2** (Figure 1). The complexes feature long-chain alkyl tethers at opposite sides and terminal "alligator clips" of two different types: alkenyl (**1**) and thioacetyl (**2**) groups, which can be used for deposition on H-ter-

minated silicon[8a] and gold[8b] substrates, respectively. Using DC and AC magnetometry and HF-EPR spectroscopy, we additionally show that the site-specific functionalization occurs with full retention of the magnetic properties.

## Results and Discussion

### Synthesis

The derivatives of 2-(hydroxymethyl)propane-1,3-diol, $RC(CH_2OH)_3$, are widely used as versatile ligands in transition-metal chemistry because they can adopt a large variety of binding modes.[9] The $\eta^2,\eta^2,\eta^2,\mu_4$ mode is found in simple metal-centered $Fe^{III}$ triangles, commonly known as "ferric stars", which have an $S = 5$ ground state and behave as SMMs with energy barriers as high as 17 K.[10] The synthesis is very conveniently carried out starting from the archetypal $Fe_4$ compound $[Fe_4(OMe)_6(dpm)_6]$ (**3**) (Hdpm = dipivaloylmethane).[11] At variance with other "ferric stars",[5b,12] the bridging methoxide groups in **3** can be easily exchanged, leaving the bulky shell of terminal $dpm^-$ anions unchanged. The binding geometry of the tripods is such that the R groups lie on opposite sides of the flat $Fe_4$ moiety, thus providing access to molecular wire-like geometries (Figure 1).

In order to attach surface-binding functionalities to the $Fe_4$ core, we used the tripods 2,2-bis(hydroxymethyl)-10-undecen-1-ol ($H_3L^1$) and 11-(acetylthio)-2,2-bis(hydroxymethyl)undecan-1-ol ($H_3L^2$). The former was prepared from 10-undecenal and excess formaldehyde[13a] by Tollens condensation. The terminal double bond of $H_3L^1$ undergoes addition of thioacetic acid in the presence of 2,2′-azobis(2-methylpropionitrile) (AIBN) to afford the thioacetyl derivative $H_3L^2$ in moderate yield (Scheme 1).[13b]

The coordinating ability of the tripods $H_3L^1$ and $H_3L^2$ was first tested using $^2H$ NMR spectroscopy. Solutions of $[Fe_4(OMe)_6([D_{18}]dpm)_6]$ (**3D**) in dry $Et_2O$ are known[10a] to exhibit time-dependent spectra, which reveal progressive decomposition to afford monomeric Fe(dpm) species. By contrast, after the addition of excess tripodal ligands (R = Ph or Me), the spectra show persistent peaks at $\delta = 10.3$ and 12.7 ppm, arising from polynuclear iron(III) complexes ($Fe_4$ or structurally related species) and magnetically uncoupled Fe(dpm) complexes, respectively. From the same solutions, doubly substituted $Fe_4$ derivatives can be isolated in high yield.[10a,10b] Similar results were obtained with the two tripodal ligands prepared in this work. The spectra recorded several hours after the addition of $H_3L^1$ or $H_3L^2$ (2.7 equiv.) to a solution of **3D** in dry $Et_2O$ are characterized by peaks at $\delta = 10.3$ and 12.7 ppm in a 3:1 ratio (Figure 2a), suggesting that the coordinating ability of both $H_3L^1$ and $H_3L^2$ is comparable with that of simpler triols. The $Fe_4$ derivatives **1** and **2** could indeed be isolated in crystalline form (90–95% yield) by mixing **3** with an excess of

the appropriate tripodal ligand in an organic solvent and by either slow diffusion of methanol vapors or slow concentration.

## Characterization

In spite of the presence of the long $C_9$ chains, compound $[Fe_4(L^1)_2(dpm)_6]$ (**1**) crystallizes in large X-ray-quality blocks that were investigated by X-ray diffraction methods at 120 K. The crystals belong to monoclinic space group *C*2/*c* and the lattice contains no crystallization solvent. The molecular structure has crystallographic $C_2$ symmetry, which has a twofold axis passing through Fe atoms Fe1 and Fe2 (Figures 3 and 4), but closely approaches $D_3$ symmetry. Selected interatomic distances and angles are gathered in Table 1.

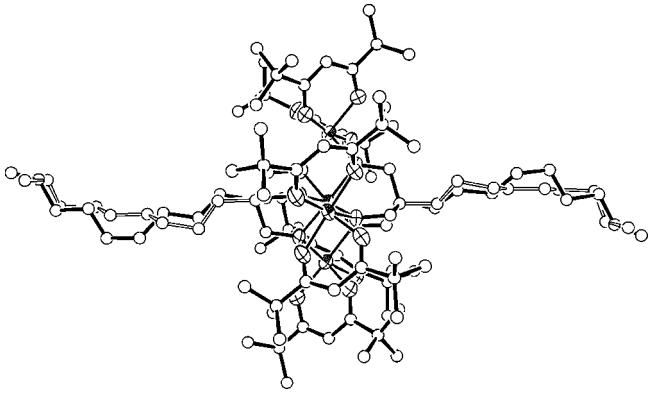

Figure 3. Molecular structure of **1** viewed approximately along the twofold axis. Iron and oxygen atoms are represented as 75%-probability ellipsoids, while carbon atoms are represented as spheres. H atoms have been omitted for clarity. The two positions occupied by the $C_9$ chain are drawn using solid and open bonds.

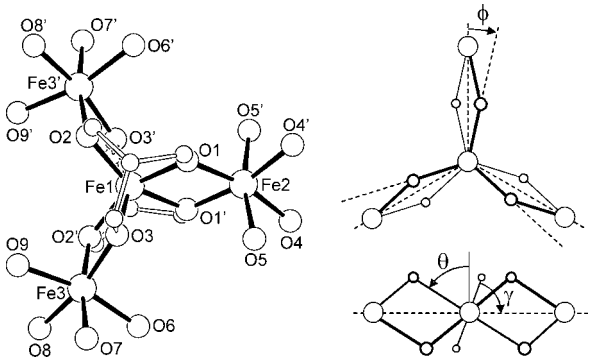

Figure 4. Left: structure of the Fe/O core in **1**, with four carbon atoms of the tripodal ligands and the atom-labeling scheme. Right: definition of the angles $\phi$, $\theta$, and $\gamma$. The dashed lines lie in the plane defined by the four metal centers.

The propeller-like structure of the precursor is retained, but replacement of the methoxide bridges with tripodal ligands leads to significant alterations of the core geometry (Figure 4). Assuming idealized $D_3$ symmetry, the angles $\theta$ and $\phi$, which define trigonal compression/elongation and trigonal rotation for Fe1, are 54.2° and 30.8°.[14] While $\theta$ differs from the octahedral value (54.74°) by less than 1°, $\phi$ departs from the value found in regular octahedral symmetry (60°) by almost 30°. Therefore, the dominant type of distortion for Fe1 is trigonal rotation, which is directly related to the propeller's pitch $\gamma$ (69.7°).[10a] Within the series of $Fe_4$ propellers so far synthesized, the structure of the Fe/O core in **1** is found to be intermediate between those observed for R = Me ($\theta$ = 54.1°, $\phi$ = 29.2°, $\gamma$ = 70.8°) and Ph ($\theta$ = 54.2°, $\phi$ = 32.3°, $\gamma$ = 68.8°), while it is very different from that of the precursor **3** ($\theta$ = 57.3°, $\phi$ = 37.7°, $\gamma$ = 63.2°).[10a,10b] As shown in Figure 3, the $C_9$ chains of the tripodal ligands are directed along the idealized threefold molecular axis and are disordered on two equally populated positions. The molecular size, evaluated from the distance between the two C11 carbon atoms (Scheme 1), is 2.5–2.6 nm.

[a] Symmetry transformations used to generate equivalent atoms: ′: $-x + 1$, $y$, $-z + 3/2$.

The second compound, $[Fe_4(L^2)_2(dpm)_6]$ (**2**), was isolated as weakly diffracting orange crystals, which turned out to be unsuitable for X-ray analysis. Structure elucidation was then based on elemental analysis, spectroscopic and spectrometric (ESI-MS) methods. The $^1H$ NMR spectra of **1** and **2** in $CDCl_3$ are compared in Figure 2b. In **1**, the very broad signal of paramagnetically shifted *t*Bu protons at $\delta$ = 10.4 ppm is accompanied by additional resonances at $\delta$ = 5.91 (2 H), 5.00 (4 H), and 2.16 (4 H) ppm due to C10, C11, and C9 hydrogen atoms, respectively, which undergo small paramagnetic shifts.[13a]

However, the signal from the $CH_2O$ hydrogen atoms of the tripod, which is observed as a sharp singlet at $\delta$ = 3.75 ppm in $H_3L^1$,[13a] is completely absent in the spectrum,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

as expected because of the proximity of $CH_2O$ hydrogen atoms to the paramagnetic metal centers. Similarly, the broad peak at $\delta \approx 1.5$ ppm integrates to about 16 H per molecule, and does not account for the remaining 24 aliphatic protons. The four $CH_2$ groups closer to the metal core are presumably paramagnetically shifted and broadened beyond detection, as suggested by the very broad signal observed at $\delta \approx 3$ ppm. Therefore, spectroscopic data strongly indicate that the solid-state structure of **1** is fully retained in solution. The $^1H$ NMR spectrum of **2** in $CDCl_3$ shows, in addition to the broad *t*Bu signal, two resonances at $\delta = 2.89$ (4 H) and 2.31 (6 H) ppm due to C11 and acetyl hydrogen atoms, respectively, and no signal from $CH_2O$ protons. Again, the broad peak at $\delta \approx 1.5$ ppm integrates to about 24 H, as expected assuming that two $CH_2$ groups per tripodal ligand are not detectable. The UV/Vis absorption spectra of **1** and **2** in toluene solution are identical (Figure S1). They have two bands at 349 and 400 nm assigned to $t_{2g} \rightarrow \pi^*$ and $\pi \rightarrow t_{2g}$ charge transfer transitions, respectively, involving the β-diketonate ligands.[15] The solid-state IR spectra denote a strong similarity between the two structures, except for the presence of the characteristic absorptions due to the different terminal functionalities (Figure S2). In particular, in **1** the absorption bands typical of alkene groups are observed at 909, 994, and 1644 $cm^{-1}$, corresponding to –C=C–H in-plane and out-of-plane bending and C=C stretching modes, respectively. In **2** these bands are not present, but we find a new strong absorption at 1699 $cm^{-1}$ typical of the stretching vibration of the acetyl C=O group. We conclude that, according to $^1H$ NMR, UV/Vis, and IR spectroscopy, the structures of **1** and **2** in the solid state and in solution are strictly similar.

Electrospray ionization mass spectrometry (ESI-MS) was additionally used for the characterization of **1** and **2**. Owing to the capability of providing an accurate determination of the molecular mass of relatively large and labile molecules,[16] this soft ionization technique has been widely used for the characterization of cationic complexes as well as in the study of metal-ion-induced self-assembly processes and SMMs.[17] In this study, **1** and **2** were dissolved in dichloromethane/nitromethane (2:1) and directly infused into the electrospray mass spectrometer system. The experimental isotope clusters obtained are in agreement with the theoretical masses and reconstructed ESI isotope patterns, thus increasing the confidence in the identification.

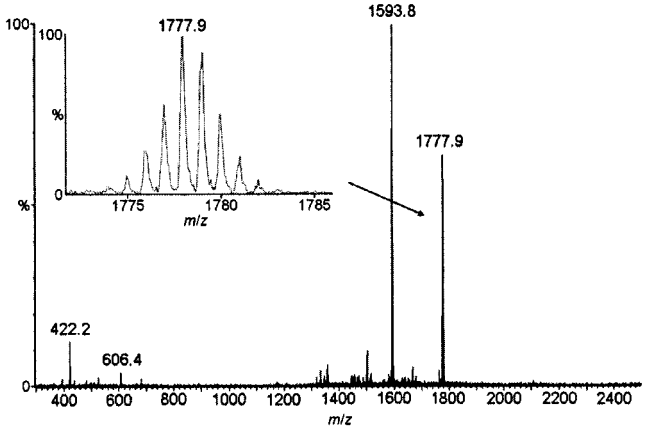

Figure 5. ESI(+)-MS full scan spectra of **1**. The inset shows a mass-scale-expanded segment of the ion signal at $m/z = 1777.9$ attributable to the $[\mathbf{1} + H]^+$ ion.

Both complexes appeared as ion distributions: more precisely, the ESI(+) spectra showed signals centered at $m/z = 1777.9$ and 1931.0, attributable to $[\mathbf{1} + H]^+$ and $[\mathbf{2} + H]^+$, respectively (Figures 5 and 6). As shown in the same figures, other signals were observed. The peaks occurring at $m/z = 1593.8$ and 1746.0 can be explained taking into account the loss of one $dpm^-$ group, thus being related to the presence of the ions $[\mathbf{1} - dpm]^+$ and $[\mathbf{2} - dpm]^+$, respectively. Other peaks, i.e., the signals at $m/z = 606.4$ and 422.2, observed in both **1** and **2**, were assigned to $[Fe(dpm)_3 + H]^+$ and $[Fe(dpm)_2]^+$, respectively.

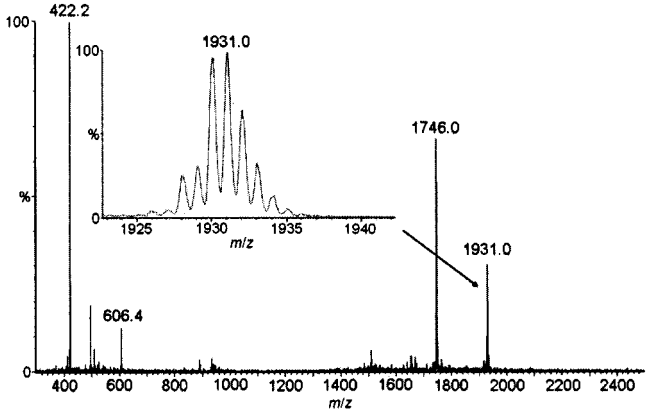

Figure 6. ESI(+)-MS full scan spectra of **2**. The inset shows a mass-scale-expanded segment of the ion signal at $m/z = 1931.0$ attributable to the $[\mathbf{2} + H]^+$ ion.

## Magnetic Properties

The incorporation of two tripodal ligands in the structure of **3** is known to preserve the ground $S = 5$ spin state of the parent compound, at the same time producing a more than twofold increase of magnetic anisotropy (from $D = -0.20$ $cm^{-1}$ in **3** to about $-0.45$ $cm^{-1}$).[10a,10b] The magnetic behavior of **1** and **2** was then compared in detail to support the proposed structural assignment. The molar magnetic susceptibility of **1** and **2**, reported in Figure 7 as a $\chi_m T$-versus-$T$ plot, is characteristic of "ferric stars", where the dominant antiferromagnetic interaction between the central and peripheral high-spin iron(III) centers generates an $S = 5$ ground state.[10,11] The $\chi_m T$ product first decreases upon cooling down from room temperature, goes through a minimum at around 100 K, and then reaches a maximum at 10–15 K. Further cooling results again in a decrease of the magnetic moment. The value at the maximum (14.1–14.6 emu K $mol^{-1}$) is close to the Curie constant for an $S = 5$ state (15.0 emu K $mol^{-1}$ for $g = 2.00$). The observation of a slightly lower magnetic moment, as well as the low-temperature decrease, is ascribed to saturation and/or anisotropy effects.

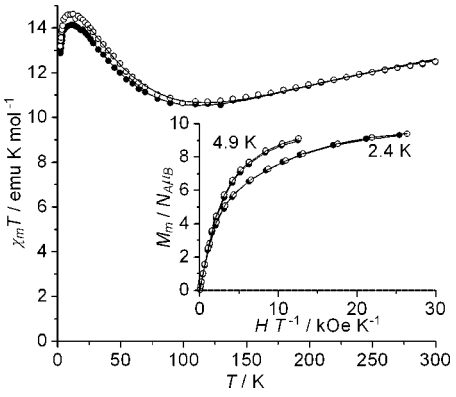

Figure 7. DC magnetic properties of **1** (open symbols) and **2** (solid symbols). The solid lines provide the best fit to the experimental data, as described in detail in the text.

Quantitative fitting of the data at $T > 20$ K using a Heisenberg spin-Hamiltonian with nearest-neighbor ($J_1$) and next-nearest-neighbor ($J_2$) coupling constants [Equation (1)] gives for **1**: $J_1 = 16.85(9)$ cm$^{-1}$, $J_2 = -0.07(9)$ cm$^{-1}$, and $g = 1.982(3)$; for **2**: $J_1 = 15.43(6)$ cm$^{-1}$, $J_2 = -0.54(5)$ cm$^{-1}$, and $g = 1.947(2)$.

$$\hat{\mathcal{H}}_0 = J_1(\hat{\mathbf{S}}_1\cdot\hat{\mathbf{S}}_2 + \hat{\mathbf{S}}_1\cdot\hat{\mathbf{S}}_3 + \hat{\mathbf{S}}_1\cdot\hat{\mathbf{S}}_4) + J_2(\hat{\mathbf{S}}_2\cdot\hat{\mathbf{S}}_3 + \hat{\mathbf{S}}_3\cdot\hat{\mathbf{S}}_4 + \hat{\mathbf{S}}_2\cdot\hat{\mathbf{S}}_4) + g\mu_B\hat{\mathbf{S}}\cdot\hat{\mathbf{H}} \quad (1)$$

As found in other $Fe_4$ complexes,[10a,10b] an accurate fit of magnetic data for **2** requires a small and ferromagnetic $J_2$ constant, though the real nature of next-nearest-neighbor interactions in this class of compounds remains to be fully ascertained. The isothermal molar magnetization measured at 4.9 and 2.4 K as a function of applied field (Figure 7, inset) approaches the appropriate value for an $S = 5$ state in high fields ($M_m/N_A\mu_B = 5g$). The fitting of experimental data with an axial zero-field splitting plus Zeeman Hamiltonian [Equation (2)] affords for **1**: $D = -0.450(5)$ cm$^{-1}$ and $g = 1.983(3)$; for **2**: $D = -0.437(7)$ cm$^{-1}$ and $g = 1.956(4)$.

$$\hat{\mathcal{H}}' = D[\hat{S}_z^2 - \tfrac{1}{3}S(S+1)] + g\mu_B\hat{\mathbf{S}}\cdot\hat{\mathbf{H}} \quad (2)$$

When imposing a positive $D$ parameter, the fit is much worse, thus clearly indicating the presence of Ising-type magnetic anisotropy in both compounds.

These findings were confirmed by HF-EPR spectra recorded at 190 GHz as a function of temperature (Figure 8). For both species the typical behavior of an $S = 5$ state with easy-axis type anisotropy ($D < 0$) was observed. Indeed, at the highest temperature five parallel and five perpendicular transitions are detected for magnetic fields lower and higher than that corresponding to $g = 2.0$ ($H_0 = 66.7$ kOe), respectively, thus confirming the $S = 5$ ground state. On lowering the temperature, the lowest-field parallel transition and the highest-field perpendicular one gain intensity, as expected for $D < 0$.[18] The line-to-line separations, which in the high-field limit correspond to $2|D|/g_{\parallel}\mu_B$ for parallel transitions and to $|D|/g_{\perp}\mu_B$ for perpendicular ones, are consistent with a $D$ value of about –0.43 cm$^{-1}$, which is characteristic of doubly substituted derivatives.[10a,10b] The spectra of **1** further evidence the presence of three isomers with slightly different zero-field splitting parameters. The relative intensity of the three signals is in the approximate ratio of 1:2:1, thus indicating that the three isomers are likely to arise from the disorder of the alkenyl chain. Indeed, given the two equally occupied positions (A and B) of the alkenyl chain observed in the X-ray structure, the three isomers should be AA (relative abundance = $0.5\times0.5 = 0.25$), AB = BA (relative abundance = $2\times0.5\times0.5 = 0.50$), and BB (relative abundance = $0.5\times0.5 = 0.25$).

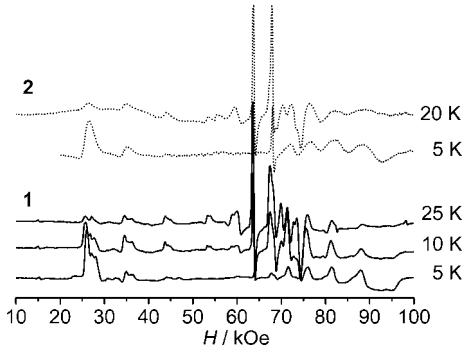

Figure 8. Temperature dependence of the HF-EPR spectra of **1** (continuous lines) and **2** (dotted lines) recorded at 190 GHz.

To obtain more detailed and precise information on the actual value of the zero-field splitting parameters, simulation of the spectra was undertaken. Given the monoclinic symmetry of derivative **1**, the following Hamiltonian was used for the simulation [Equation (3)].[19]

$$\hat{\mathcal{H}}_{EPR} = \mu_B\hat{\mathbf{S}}\cdot\mathbf{g}\cdot\hat{\mathbf{H}} + D\hat{\mathbf{S}}_z^2 + B_4^0\hat{\mathbf{O}}_4^0 + \frac{E}{2}\left(\hat{\mathbf{S}}_+^2 + \hat{\mathbf{S}}_-^2\right) \quad (3)$$

For both compounds $g$ was fixed at $2.000 \pm 0.005$, as expected for high-spin iron(III)-containing species.[20] For derivative **1** a satisfactory simulation (Figure 9, left) at both 10 and 25 K was obtained assuming a relative abundance 1:2:1 for the three isomers, with the following parameters: $D_1 = -0.431$ cm$^{-1}$, $E_1 = 0.010$ cm$^{-1}$; $D_2 = -0.442$ cm$^{-1}$, $E_2 = 0.024$ cm$^{-1}$; $D_3 = -0.420$ cm$^{-1}$, $E_3 = 0.021$ cm$^{-1}$; with $B_4^0 = 1.0\times10^{-5}$ cm$^{-1}$ for all isomers. The peculiar sharpness of the central lines of the spectrum has been accounted for by imposing different line widths for that group of resonances as well as by including the effect of a small distribution in the $D$ and $E$ values resulting from local strain-induced effects.

For compound **2**, the best simulations (Figure 9, right) were obtained with $D = -0.435$ cm$^{-1}$, $E = 0.018$ cm$^{-1}$, and $B_4^0 = 1.5\times10^{-5}$ cm$^{-1}$. The peculiar differences in line widths along the spectrum have been accounted for in the same way as for **1**. However, for this derivative strain effects are much more evident, especially for the $E$ parameter, as shown by the progressive broadening of the perpendicular transitions at higher fields.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

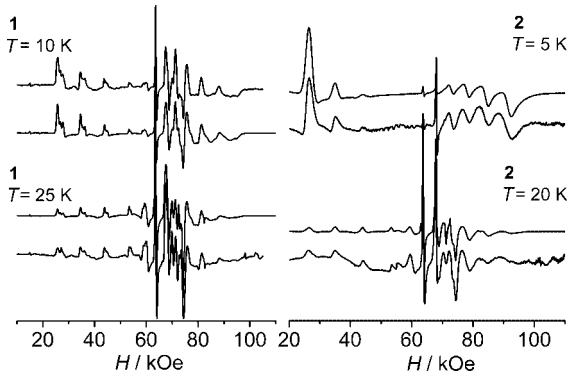

Figure 9. Best simulations (upper traces) of the experimental HF-EPR spectra recorded at 190 GHz (lower traces) at different temperatures for **1** (left) and **2** (right) obtained with the parameters reported in the text.

The zero-field splitting parameters obtained for **1** agree with the values expected on the basis of a recently proposed magnetostructural correlation between $D$, $B_4^0$, and the helical pitch $\gamma$.[10a] The presence of a small but non-negligible rhombic term ($E \neq 0$) confirms the deviation from ideal $D_3$ symmetry. The observation of slightly different $D$ values for the three isomers of **1** further indicates that a small modification in the structure, even when not directly involving the core of the molecule, might affect, in a measurable way, the zero-field splitting parameters. Finally, on the basis of the above-mentioned magnetostructural correlation,[10a] the results obtained for **2** unambiguously prove the strict structural similarity between **2** and **1**.

The spin ground state and the easy-axis magnetic anisotropy evidenced above suggest that **1** and **2** may behave as SMMs at low temperature, as indeed observed for **3** and other simpler $Fe_4$ compounds.[10,11] We have therefore measured the AC susceptibility in zero static field and we have found, below 6 K, a nonzero imaginary component that goes through a frequency-dependent maximum on lowering the temperature. The behaviors of **1** and **2** are very similar, as can be seen in Figure 10. From the same data, the temperature dependence of the relaxation time $\tau$ has been extracted, assuming that when $\chi''$ is maximum at a given frequency $\nu$, the condition $\tau = (2\pi\nu)^{-1}$ is satisfied. A linear behavior of $\ln(\tau)$ as a function of $1/T$ is observed over the investigated frequency range, confirming a thermally activated mechanism for the relaxation (Figure 11). The best-fit parameters using the Arrhenius law $\tau = \tau_0 \exp(U_{eff}/k_B T)$ are for **1**: $\tau_0 = 3.4(1) \times 10^{-8}$ s, $U_{eff}/k_B = 15.9(2)$ K; for **2**: $\tau_0 = 4.3(1) \times 10^{-8}$ s, $U_{eff}/k_B = 15.1(2)$ K. The $U_{eff}$ values are close to the anisotropy barriers predicted for integer spins by the formula $U = |D|S^2$, which neglects QT effects, as found in other doubly substituted $Fe_4$ derivatives.[10a,10b] The pre-exponential factors $\tau_0$ are also quite similar to those observed with simpler triols,[10a] suggesting that the bulkier and more flexible long aliphatic chains of **1** and **2** do not affect the spin-phonon coupling in a significant way.

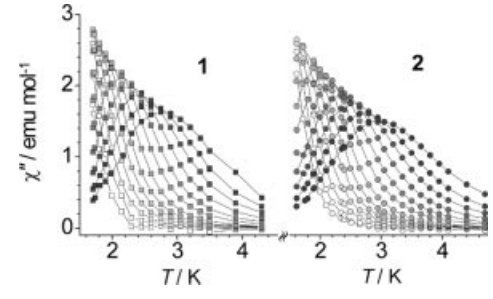

Figure 10. Imaginary component of the AC susceptibility measured for **1** (left) and **2** (right) in zero static field in the frequency range from 100 Hz (white) to 25 kHz (black).

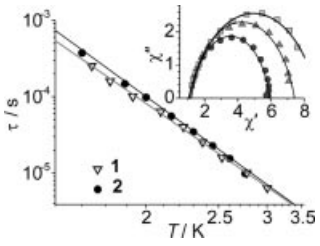

Figure 11. Temperature dependence of the relaxation time for **1** and **2**. The lines represent the best-fit curves using the Arrhenius law. The inset shows the Argand plot for **2** at 2.5 K (circles), 2.0 K (triangles), and 1.75 K (squares). The lines represent the best-fit curves using a modified Debye model. Susceptibilities are in emu mol$^{-1}$.

We have also investigated how the presence of different isomers, evidenced in **1**, or the sizeable strain effects in **2** influence the distribution of relaxation times. By plotting $\chi''$ versus $\chi'$ at a given temperature, a semicircumference centered on the $x$ axis should be observed in the absence of distribution, according to the Debye model.[21] The results are shown in the inset of Figure 11 for **2** and in Figure S3 of the Supporting Information for **1**. The presence of a distribution of relaxation times is accounted for by a parameter $\alpha$[1b,21] which has been evaluated for **1** and **2** and is found to increase on lowering the temperature to reach 0.26 at 1.75 K for both compounds. The closest-to-the-origin intercept of the semicircle with the $x$ axis represents the fraction of the magnetic susceptibility that relaxes much faster than the employed frequencies. Interestingly, both compounds show an almost temperature-independent fast relaxing component of the AC susceptibility of about 1 emu mol$^{-1}$. This value agrees well with the transverse component of the susceptibility of our randomly oriented powder samples evaluated by using the spin Hamiltonian parameters determined from HF-EPR experiments. The transverse component is not expected to experience any barrier when reversing its direction and thus is expected to relax much faster than the investigated frequency domain.

## Conclusions

Single-molecule magnets functionalized with terminal alkenyl and thioacetyl groups have been prepared by site-specific substitution on the complex $[Fe_4(OMe)_6(dpm)_6]$ (**3**) using derivatives of 2-(hydroxymethyl)propane-1,3-diol as incoming ligands. The two tripods are located along the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

idealized threefold molecular axis, leading to wire-like molecular geometries, which are particularly well suited for the construction of metal-molecule-metal junctions. The complexes are found to be stable in solution and afford intense molecular peaks in the ESI-MS spectra. The magnetic properties, as revealed by DC and AC magnetometry and HF-EPR spectroscopy, indicate that the compounds have an $S = 5$ ground spin state. The easy-axis anisotropy is enhanced as compared with **3** and the effective energy barrier reaches up to 15–16 K, leading to slow relaxation of the magnetization at low temperature. We are currently investigating the formation of monolayers of **1** and **2** on H-terminated Si(100) (by hydrosilylation) and Au(111), respectively. The estimated distance between the thioacetyl "alligator clips" in **2** is 2.8–2.9 nm, and the molecule is then expected to fit into state-of-the-art metal nanogaps prepared using break junctions or electromigration.[6]

## Experimental Section

**Synthesis:** All chemicals were reagent-grade and used as received, unless otherwise noted. Diethyl ether, benzene, and toluene were distilled from sodium/benzophenone shortly before use. Benzene and toluene were stored over KOH pellets. Methanol was carefully dried by treatment with $Mg/I_2$ and distilled prior to use.[22] Dimethoxyethane (DME) was distilled from NaH. 2,2-Bis(hydroxymethyl)-10-undecen-1-ol ($H_3L^1$) was prepared by CaO-catalyzed Tollens reaction of 10-undecenal and formaldehyde in an EtOH/water mixture, according to a literature procedure.[13a] The precursor $[Fe_4(OMe)_6(dpm)_6]$ (**3**) and its deuterated variant, $[Fe_4(OMe)_6([D_{18}]dpm)_6]$ (**3D**), were prepared as described elsewhere.[10a]

**11-(Acetylthio)-2,2-bis(hydroxymethyl)undecan-1-ol ($H_3L^2$):** Thioacetic acid (0.660 g, 8.67 mmol) and 2,2′-azobis(2-methylpropionitrile) (0.713 g, 4.34 mmol) were added to a hot solution of $H_3L^1$ (1.00 g, 4.34 mmol) in dry benzene (10 mL). After stirring for 4 h at reflux temperature, the solution was cooled down and diethyl ether was added. The organic mixture was washed with saturated $NaHCO_3$ solution (3×) and brine. The solution was dried with $Na_2SO_4$ and filtered. After purification by column chromatography (eluent ethyl acetate/petroleum ether = 3:1), the product $H_3L^2$ was obtained as a white solid (0.745 g, 56%). $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 3.74 [s, 6 H, C(1)$H_2$], 2.86 [t, $J$ = 2.0 Hz, 2 H, C(11)$H_2$], 2.47 (br. s, 3 H, OH), 2.32 (s, 3 H, $CH_3$), 1.62 [m, 2 H, C(10)$H_2$], 1.56 [m, 2 H, C(9)$H_2$], 1.40–1.10 (m, 12 H, Aliph) ppm. $C_{15}H_{30}O_4S_1$ (306.46): calcd. C 58.79, H 9.87, S 10.46; found C 58.58, H 9.96, S 10.32.

**$[Fe_4(L^1)_2(dpm)_6]$ (1):** Solid $H_3L^1$ (0.132 g, 0.573 mmol) and **3** (0.180 g, 0.119 mmol) were thoroughly mixed and heated to 70 °C under vacuum (0.1 Torr) for 15 min. The mixture was cooled down, powdered again, and reheated under the same conditions. After cooling, the solid was dissolved in dry toluene (12 mL) with gentle heating. Vapor diffusion of dry methanol (40 mL) into the filtered dark-orange solution afforded large dark-red blocks, which were washed with the external solvent mixture followed by pure methanol and then dried under vacuum (0.201 g, 95%). $C_{92}H_{160}Fe_4O_{18}$ (1777.60): calcd. C 62.16, H 9.07; found C 61.53, H 9.33. FTIR (KBr pellet): $\tilde{\nu}$ = 3080 (=C–H stretching), 1644 (C=C stretching), 994 (out-of-plane =C–H bending), 909 (in-plane =C–H bending) $cm^{-1}$.

**$[Fe_4(L^2)_2(dpm)_6]$ (2):** $H_3L^2$ (0.0658 g, 0.215 mmol) and **3** (0.120 g, 0.0795 mmol) were dissolved in dry DME/$Et_2O$ (1:1, v/v) (20 mL) with prolonged stirring. By slow concentration of the clear yellow-orange solution, a crystalline red-orange solid was obtained, which was washed with dry DME/MeOH (1:5, v/v) and dried under vacuum (0.1 Torr, 1 h) (0.138 g, 90%). $C_{96}H_{168}Fe_4O_{20}S_2$ (1929.89): calcd. C 59.75, H 8.77, S 3.32; found C 59.51, H 9.25, S 3.53. FTIR (KBr pellet): $\tilde{\nu}$ = 1699 (C=O stretching) $cm^{-1}$.

**X-ray Crystallography:** A single-crystal X-ray study was carried out on **1** with a four-circle Bruker X8APEX diffractometer equipped with a Kryo-Flex cryostat and controlled by Bruker-Nonius X8APEX software. Crystal structure data: $C_{92}H_{160}Fe_4O_{18}$, $M_r$ = 1777.60, crystal dimensions $0.42 \times 0.30 \times 0.24$ mm, monoclinic, space group $C2/c$ (no. 15), $a$ = 23.9416(3), $b$ = 15.6441(2), $c$ = 27.1433(4) Å, $\beta$ = 95.8450(10)°, $V$ = 10113.5(2) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.167 g cm$^{-3}$, $2\theta_{max}$ = 52.02, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, $T$ = 120(2) K, $\mu$ = 0.621 mm$^{-1}$, collected/independent reflections 73989/9888 [$R$(int) = 0.0260]. The structure was solved by direct methods using the SIR92[23a] program. Full-matrix least-squares refinement on $F_o^2$ was performed using the SHELXL-97 program[23b] implemented in the WINGX suite[23c] on 9888 data points with 596 parameters and 43 restraints. All non-hydrogen atoms were refined anisotropically, and hydrogen atoms were added in idealized positions and assigned isotropic displacement parameters 50% and 20% larger than the $U_{eq}$ of the attached carbon atoms for aliphatic and methine hydrogen atoms, respectively. The alkyl chain of the tripodal ligand was found to be disordered over two equally populated positions. Final $R$ indices [$I > 2\sigma(I)$]: $R_1$ = 0.0425, $wR_2$ = 0.1113; $R$ indices (on all data): $R_1$ = 0.0593, $wR_2$ = 0.1298. Goodness-of-fit on $F^2$ = 1.031. Largest difference peak/hole 0.989/–0.667 e Å$^{-3}$. CCDC-646831 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Physical Techniques:** NMR spectra of the complexes were recorded at 302 K with a Bruker FT-DPX200 NMR spectrometer. Samples for $^1$H NMR spectroscopy were solutions of **1** and **2** in $CDCl_3$ (concentration about 13.5 mg/mL). Samples for $^2$H NMR spectroscopy were solutions of **3D** in dry $Et_2O$ (about 2.6 mg/mL), to which solid $H_3L^1$ or $H_3L^2$ (2.7 equiv.) was added. Chemical shifts were referenced to [$D_6$]acetone as external standard ($\delta$ =2.16 ppm). IR spectra were recorded with an FTIR Perkin–Elmer 1600 spectrometer. Samples were ground thoroughly with KBr at approximately 1% by weight and pressed into a pellet with a thickness of about 1 mm. UV/Vis spectra in the range 200–900 nm were recorded in toluene solution with a UV/Vis Perkin–Elmer λ650 spectrometer using quartz cuvettes with a 1-mm optical path. Electrospray mass spectra were acquired with a Micromass® Q-TOF micro™ mass spectrometer (Waters, UK) equipped with a Z-spray electrospray interface. Masslynx v. 3.5 software (Micromass) was used for data acquisition and processing. ESI-MS analyses were performed by operating the mass spectrometer in positive-ion (PI) mode acquiring mass spectra over the scan range $m/z$ = 300–2500, with a scan time of 1.2 s and an interscan delay of 0.1 s. The nebulizing gas (nitrogen, 99.999% purity) and the desolvation gas (nitrogen, 99.999% purity) were delivered at a flow rate of 150 and 600 l h$^{-1}$, respectively. The operating parameters of the interface were as follows: source temperature 90 °C, desolvation temperature 150 °C, cone voltage 30 V, ES (+) voltage 3.5 and 4.0 kV for the analysis of **1** and **2**, respectively. Q-TOF external calibration was performed using 0.1% (v/v) aqueous phosphoric acid solution. DC magnetic data were recorded using a Cryogenic S600 SQUID magnetometer. Susceptibility versus $T$ data from 2.2 to 300 K were collected on 22.75- and 31.80-mg microcrystalline samples of **1** and **2** with applied fields of 10 kOe (for $T > 30$ K) and 1 kOe (for $T <$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

30 K) in order to reduce saturation effects. Isothermal magnetization versus $H$ curves were registered up to 60 kOe at about 2.4 and 4.9 K. Raw data were reduced with molecular weights equal to 1777.60 (**1**) and 1929.89 (**2**) and using diamagnetic corrections estimated from Pascal's constants $-1061.74 \times 10^{-6}$ and $-1146.72 \times 10^{-6}$ emu mol$^{-1}$ for **1** and **2**, respectively. The AC susceptibility of microcrystalline samples of **1** and **2** has been measured in the frequency range 100–25000 Hz with a home-made susceptometer[24] based on an Oxford Instruments MAGLAB2000 platform. High-frequency EPR (HF-EPR) spectra were recorded at the Grenoble High Magnetic Field Laboratory with a home-built spectrometer working in single-pass mode using a Gunn diode working at 95 GHz equipped with a frequency doubler as source excitation. Samples were pressed in pellets to avoid orientation effects.

**Spin Hamiltonian Calculations:** The NAG Fortran Library Routine E04FCF[25a] was used for fitting magnetic susceptibility and magnetization data with the aid of the ZHEEV routine (LAPACK Linear Algebra Package) for matrix diagonalization.[25b] Calculations were carried out with a Digital Alpha3000/800S computer.

**Supporting Information** (see footnote on the first page of this article): UV/Vis, IR, and fully labeled ESI-MS spectra for **1** and **2**, and Argand plot for **1**.

# Synthesis of Chiral, Monodentate Aminophosphane and Phosphoramidite Ligands Derived from Amino Acid Esters: Application in Rh-Catalysed Asymmetric Olefin Hydrogenation Reactions

**Luc Eberhardt,[a] Dominique Armspach,*[a] Dominique Matt,*[a] Loic Toupet,[b] and Benoît Oswald[c]**

**Keywords:** Phosphoramidites / Binol / Asymmetric catalysis / Rhodium / Olefin hydrogenation / Amino acid esters

Six chiral monodentate ligands combining a 1,3-dioxa-2-phosphacycloheptadinaphthyl moiety [(*R*)- or (*S*)-binoP] either with a phenylalanine- or with an alanine-derived fragment were synthesised. The new phosphoramidites are all relatively air stable. Related compounds in which the binoP moiety was replaced by a diphenylphosphanyl group were also prepared for comparison. The X-ray structures of two phosphoramidite complexes, *cis*-$PtCl_2$[(*R*)-binoP–NMeR]$_2$ [**5**, R = (*R*)-CH($CH_2$Ph)($CO_2$Me); **6**, R = (*S*)-CH($CH_2$Ph)-($CO_2$Me)], were determined by single X-ray analysis. In the solid state, both structures are nearly $C_2$ symmetric, and the nitrogen atoms lies out of the coordination plane. Owing to the particular orientation of the benzyl groups in **6**, the environment of the coordination sites occupied in this complex by the chlorine atoms is sterically more crowded than in **5**. In the hydrogenation of 2-(acetylamino)-3-(aryl)propenoic methyl esters (aryl = 4-X-$C_6H_4$, X = H, F, Cl; aryl = 3,4-$Cl_2$–$C_6H_3$), the alanine-derived phosphoramidites turned out to be ca. twice as active as the corresponding phenylalanine analogues. The highest *ee*'s were observed with the phenylalanine derivatives, for example 92 % in the hydrogenation of 2-(acetylamino)-3-(phenyl)propenoic methyl ester, by using (*R*)-binoP–NMe-(*R*)-CH($CH_2$Ph)($CO_2$Me).

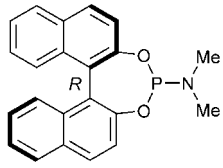
## Introduction

In the last three decades natural amino acids and their derivatives have been often used as chiral backbones in the synthesis of optically active diphosphanes suitable for the enantioselective rhodium(I)-, ruthenium(II)- or iridium(I)-catalysed hydrogenation of prochiral unsaturated substrates.[1–4] For example, amino alcohols such as valinol, leucinol and prolinol gave access to a variety of mixed bidentate ligands, in particular aminophosphonite–phosphites,[5] aminophosphonite–phosphinites or aminophosphane–phosphinites[6–18] many of which turned out to give high enantiomeric excesses (*ee*'s) in enantioselective catalysis.

Recently, Feringa and Reetz found that monodentate, chiral phosphoramidite ligands, such as **A**, in which the phosphorus atom is part of a rigid, seven-membered ring involving a 1,1′-binaphthyl unit may lead to high conversions and enantiomeric excesses in metal-catalysed hydrogenations.[19–27] In their seminal works, they independently demonstrated that these readily accessible monodentate ligands give equivalent if not better results than conventional $P^{III}$ bidentate ligands.[28] The way these catalysts operate is still a matter of debate and a better understanding of their performance requires not only the synthesis and study of new variants of such ligands, but also solid-state studies that may establish particular structural features of their metal complexes.



**A**

The present work describes the synthesis and structural characterisation of chiral *monodentate* ligands associating, for the first time, a phosphoramidite coordinating unit with the bulky and easily accessible *phenylalanine* backbone (Scheme 1). We also prepared ligands in which the latter was replaced by the less sterically demanding *alanine* fragment as well as some diphenylphosphanyl analogues of these phosphoramidites. A comparative study of their catalytic properties for the asymmetric rhodium-catalysed hydrogenation of α-*N*-acetaminoacrylic esters was carried out to assess the importance of the amino acid backbone on both catalyst selectivity and activity. In the following, the

indexes "Bn", "Me" and "bin" refer to molecules containing –NMeCH($CH_2Ph$)($CO_2$Me), –NMeCH($Me$)($CO_2$Me) and *binaphthyl* groups, respectively. To date, monophosphoramidites that bear oxygen-containing pending groups have only been mentioned in two publications, one dealing with an ester[25] and the other with an ether[29] substituent.

(*R* or *S*)-*N*-methylphenylalanine methyl ester (*S*)-*N*-methylalanine methyl ester

Scheme 1. Phenylalanine and alanine derivatives used in this study as building blocks for the construction of chiral phosphanes.

## Results and Discussion

### Ligand Synthesis and Characterisation

We began this study by preparing aminophosphanes ($S_{Bn}$)-**2a** and ($R_{Bn}$)-**2b** (Scheme 2). These were obtained in ca. 85% yield by treating chlorodiphenylphosphane with (*S*)- and (*R*)-*N*-methylphenylalanine methyl ester, respectively, in the presence of 1 equiv. of diisopropylethylamine. We noted that the replacement of the latter amine by a less sterically hindered one, notably triethylamine, produced significant amounts of byproducts. The two aminophosphanes are relatively air stable and can be stored in air without particular care for months. Both products are characterised by a single peak at $\delta$ = 67.9 ppm in their $^{31}P\{^1H\}$ NMR spectra, a value that lies in the range found for similar ligands.[30]

($R_{Bn}$)-**1b**

($S_{Bn}$)-**2a**
($R_{Bn}$)-**2b**

Scheme 2. Synthesis of aminophosphanes **2a** and **2b**.

To increase the chiral load of the molecules, we embarked on the synthesis of phosphoramidite ligands incorporating a 1,1′-binaphthyl unit in addition to a phenylalanine-derived fragment. Thus, the four stereoisomers ($S_{Bn}$,$S_{bin}$)-**3a**, ($R_{Bn}$,$R_{bin}$)-**3b**, ($R_{Bn}$,$S_{bin}$)-**3c** and ($S_{Bn}$,$R_{bin}$)-**3d**, all containing a –NMeCH($CH_2$Ph)($CO_2$Me) moiety, were synthesised (Scheme 3) from [(*R* or *S*)-(1,1′-binaphthalene-2,2′-diyl)] chlorophosphite (binoPCl[31]) and the appropriate amino acid ester according to the method described above. The two diastereoisomers ($S_{Me}$,$R_{bin}$)-**4a** and ($S_{Me}$,$S_{bin}$)-**4b**, containing the (*S*)-alanine-derived –NMeCH(Me)($CO_2$Me) fragment, were obtained by treatment of [($S_{Me}$)-**1c**]HCl with 2 equiv. of diisopropylethylamine and 1 equiv. of the corresponding chlorophosphite (Scheme 3). As expected for phosphoramidite ligands, all six compounds can be handled in air without noticeable oxidation, but they undergo P–N cleavage in the presence of water. The NMR spectra of the diastereoisomeric pairs of enantiomers ($S_{Bn}$,$S_{bin}$)-**3a**/($R_{Bn}$,$R_{bin}$)-**3b** and ($R_{Bn}$,$S_{bin}$)-**3c**/($S_{Bn}$,$R_{bin}$)-**3d**, in particular the $^{31}P\{^1H\}$ NMR spectra, which consist of single peaks at $\delta$ = 149.0 and 148.6 ppm,[32] are nearly identical. Similar small spectroscopic differences are observed between ($S_{Me}$,$R_{bin}$)-**4a** and ($S_{Me}$,$S_{bin}$)-**4b** [$\delta$($^{31}$P) = 148.5 and 148.2 ppm, respectively]. We note that whereas the H*C*(CO) carbon atom of ($S_{Bn}$)-**2a** is low-field shifted with respect to that of the parent amine, MeNHCHR($CO_2$Me), in the phosphoramidite ($S_{Bn}$,$S_{bin}$)-**3a** the corresponding carbon atom has undergone a high-field shift (Figure 1).

To verify that the phosphoramidites described above are suitable to form square-planar complexes having two *cis* disposed phosphanes, which is the typical stereochemistry in most hydrogenation catalysts, we investigated the coordination properties of ($R_{Bn}$,$R_{bin}$)-**3b** and ($S_{Bn}$,$R_{bin}$)-**3d** towards platinum(II). The reaction of these ligands with [$PtCl_2$(cod)] (cod = 1,5-cyclooctadiene) or [$PtCl_2$(dcpd)] (dcpd = dicyclopentadiene) afforded complexes **5** and **6**, respectively (Scheme 4; see Experimental Section). The stereochemistry of the complexes was inferred from the corresponding $^{31}P$ NMR spectra, which both consist of a singlet flanked by two Pt satellites, with a $J_{P,Pt}$ coupling constant (5579 Hz for both complexes) in accord with the value reported by Hope et al. for another platinum phosphoramidite complex, namely *cis*-[$PtCl_2$(monophos)$_2$] (where monophos stands for ligand **A**).[33,34]

The stereochemistry of the complexes was further confirmed by single-crystal X-ray diffraction studies (Figure 2). The unit cell of **5** contains two inequivalent molecules (**5a** and **5b**), which structurally differ only a little, whereas that of **6** contains a single type of molecule. In both structures the molecules are nearly $C_2$ symmetric, and the nitrogen atoms are located out of the coordination plane [N to plane distances in **5a**: +1.31(1) and –1.31(1) Å; in **5b**: +1.32(1) and –1.31(1) Å; in **6**: +1.38(1) and –1.39(1) Å]. In all these molecules, the metal centre lies in an almost planar coordination environment, but the P–Pt–P angles are considerably larger than 90° [97.5(1)° and 97.6(1)° in **5**; 100.6(1)° in **6**], thus reflecting the steric bulk of the phosphane moieties. Similar deviations from an ideal square-planar coordination geometry were observed in the few structurally characterised binaphthyl-containing [$MX_2$(phosphoramidite)$_2$] complexes.[20,33] In both structures the nitrogen atoms are in a quasiplanar environment, and hence show that the electron-donating effect of the nitrogen atom onto the phosphorus atom is operating. The bond lengths about the metal centres are normal (see caption of Figure 2).

If the coordination plane is taken as a reference plane, the halide atoms of complex **5** may be viewed both as apically protected by a –$CO_2$Me moiety and a naphthyl group; these fragments belong to the same $P^{III}$ ligand and are located on either side of the plane. In complex **6**, the steric protection about each halide is markedly increased on one side of the plane, because here the benzyl groups occupy domains previously occupied by the smaller ester moieties.

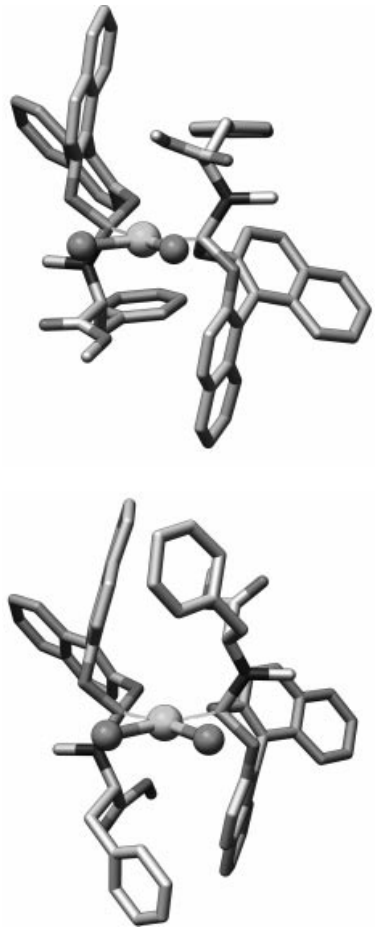

Figure 2. X-ray structures of compound **5a** (top) and compound **6** (bottom) showing the steric protection of the chloride atoms. Important bond lengths [Å]: **5a**: P(1)–Pt 2.207(3), P(2)–Pt 2.200(3), Pt–Cl(1) 2.336(3), Pt–Cl(2) 2.336(3), P(1)–N(1) 1.62(1), P(2)–N(2) 1.63(1); **6**: P(1)–Pt 2.222(2), P(2)–Pt 2.213(3), Pt–Cl(1) 2.349(3), Pt–Cl(2) 2.339(3), P(1)–N(1) 1.59(1), P(2)–N(2) 1.62(1). Dihedral angles [°] between the linked naphthyl units, in **5a**: 58.6 and 57.8; in **6**: 60.5 and 56.3.

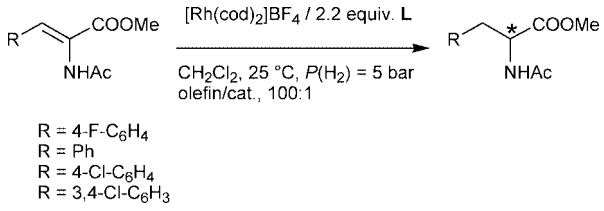
### Catalytic Studies

For the catalytic study, we focussed our attention on the reduction of 2-(acetylamino)-3-(4-fluorophenyl)propenoic methyl ester. A literature search revealed that this fluorinated amino acid has been relatively little studied. Some related compounds were also studied for comparison (Scheme 5).



Scheme 5. Hydrogenation of 2-(acetylamino)-3-arylpropenoic methyl esters.

All catalytic runs (Table 1) were performed with in-situ-generated catalysts under 5 bar pressure by using an olefin/rhodium ratio of 100:1. It turned out that operating at r.t. afforded slightly higher yields than at 0 °C (Table 1, Entries 4 and 21). Further, among the solvents tested (thf, MeOH, AcOEt, $CH_2Cl_2$), dichloromethane gave the highest enantioselectivity (Table 1, Entries 1–3 and 21). In the following, we will therefore only discuss those runs performed at r.t. and in dichloromethane. As expected, we found that enantiomeric complexes (e.g. **3a** and **3b**) gave enantiomeric hydrogenation compounds; the *ee*'s were the same within experimental error.

As a general trend, and consistent with literature reports, the hydrogenation rates observed with the phosphoramidites were ca. 2–4 times better than those obtained with the aminophosphanes. We also found that aminophosphanes **2a** and **2b** resulted in very weak *ee*'s in the hydrogenation of 2-(acetylamino)-3-(phenyl)propenoic methyl ester and 2-(acetylamino)-3-(4-fluorophenyl)propenoic methyl ester (Table 1, Entries 5, 6, 19 and 20). This may be attributed to the fact that in the corresponding aminophosphane complexes the stereogenic centres are relatively far from the metal centre. We further observed that higher enantioselectivities were found for L/Rh ratios ≥ 2 (Table 1, compare Entry 8 with Entries 9–11, and compare Entry 12 with Entries 13–15) than for lower ratios. It is likely that L/Rh ratios below 2 result in part in the formation of [RhL(cod)]-$BF_4$ complexes in which the phosphoramidite behaves as a chelating ligand (possibly as a P,O rather than a P,N che-

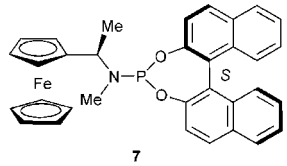
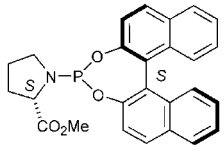
late), which in turn give lower *ee*'s than the corresponding [Rh(phosphoramidite)$_2$(cod)]$BF_4$ complexes. Note that complexes of the latter type are generally formed when 2 equiv. of a monophosphoramidite are reacted with [Rh(cod)$_2$]$BF_4$.[20]

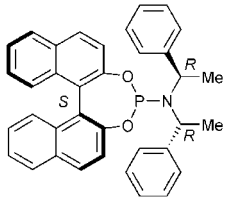
The highest *ee*'s, 92%, were obtained with phosphoramidite ($R_{Bn}$,$R_{bin}$)-**3b** (Table 1, Entries 8 and 30) in the hydrogenation of 2-(acetylamino)-3-(phenyl)propenoic methyl ester and 2-(acetylamino)-3-(4-chlorophenyl)propenoic methyl ester. The use of the same ligand for the hydrogenation of the fluorinated dehydroaminated ester (Table 1, Entry 22) gave an *ee* of 88%. It must be emphasised here that the performance of this ligand lies slightly below that of the reference ligand **A** [*ee*'s of ca. 95% for 2-(acetylamino)-3-(phenyl)propenoic methyl ester], which in contrast to **3b** contains an achiral amino substituent.[35] Interestingly, the number of binol-derived phosphoramidites in which the amino groups contains a stereogenic centre is limited. A literature survey revealed that, among this class of compounds, only Zheng's phosphoramidite **7**, which is derived from an expensive ferrocenyl–amine, gave better *ee*'s in the hydrogenation of cinammic acid esters than **A**.[36] Significantly lower enantioselectivities than those obtained for **3b** were obtained with proline derivative **8**[25] as well as with phosphoramidite **9**,[35] which contains two stereogenic centres in the amino group. Overall, these findings show that an improvement in the performances of **A** by using variants obtained from cheap, chiral amines remains a difficult task.



7



8



9

The most surprising result came from diastereomers ($R_{Bn}$,$S_{bin}$)-**3c** and ($R_{Bn}$,$R_{bin}$)-**3b**. Hydrogenation of the fluorinated olefin with ($R_{Bn}$,$S_{bin}$)-**3c** gave only 12% yield after 24 h (Table 1, Entries 23), whereas in the same time the reaction carried out with ($R_{Bn}$,$R_{bin}$)-**3b** was almost complete. Note that such a difference in activity was not observed with these ligands in the reduction of the slightly shorter 2-(acetylamino)-3-(phenyl)propenoic methyl ester (Table 1, Entries 12). Molecular models based on the X-ray structure of complex **6**, which contains ligand ($S_{Bn}$,$R_{bin}$)-**3d**, clearly show that in the hypothetical catalytic intermediates of type α and β (Figure 3), bidentate coordination of the fluorinated olefin results in considerable steric hindrance between the $Ar_{olefin}$ group and the benzyl groups. In the related **3b**-containing intermediates γ and δ, in which the amino acid ester moiety has a stereochemistry opposite to that of ($S_{Bn}$,$R_{bin}$)-**3d**, coordination of the olefin becomes much more favourable. The olefin–ligand interactions here mainly involve the smaller $CO_2Me$ group.

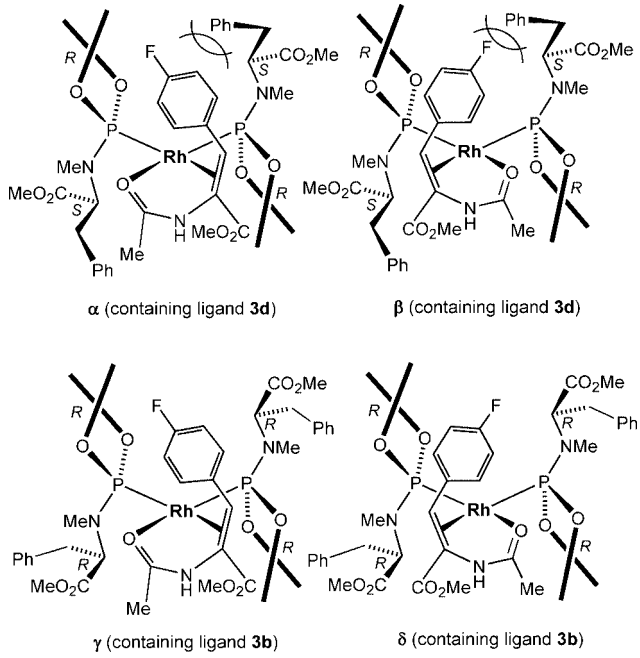


Figure 3. Possible coordination modes involving either complex **5** (α and β) or **6** (γ and δ) and 2-(acetylamino)-3-(4-fluorophenyl)-propenoic methyl ester.

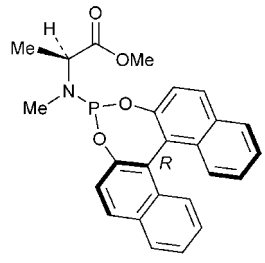
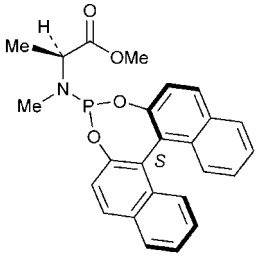
To verify that these interactions have a determining impact on the catalyst activity, we tested ligands ($S_{Me}$,$R_{bin}$)-**4a** and ($S_{Me}$,$S_{bin}$)-**4b**, which contain a methyl group in place of a benzyl group. As anticipated, the hydrogenation reactions carried out with these ligands occurred much faster than those performed with their benzyl analogues (full substrate conversion within 18 h).



($S_{Me}$,$R_{bin}$)-**4a**



($S_{Me}$,$S_{bin}$)-**4b**

Furthermore, in the case of ($S_{Me}$,$S_{bin}$)-**4b**, a nonnegligible drop in the asymmetric induction was observed with respect to ($S_{Bn}$,$S_{bin}$)-**3a** in the catalytic reduction of 2-(acetylamino)-3-(phenyl)- and of 2-(acetylamino)-3-(4-fluorophenyl)propenoic methyl ester as well; the *ee*'s decrease by 12 and 9%, respectively (Table 1, Entries 18/7 and 26/21). The same trend was observed on going from ($S_{Bn}$,$R_{bin}$)-**3d** to ($S_{Me}$,$R_{bin}$)-**4a** in the hydrogenation of 2-(acetylamino)-3-(phenyl)propenoic methyl ester; *ee*'s decreased

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

by 9% (Table 1, Entries 17/16). Of course, we have to remain cautious in correlating the observed selectivities and activities, as the rate-determining steps are not known. Note that the hydrogenation of 2-(acetylamino)-3-(4-fluorophenyl)propenoic methyl ester with **3d** was too slow to allow comparison of the corresponding *ee* value with that obtained with the faster catalyst **4a**.

Finally, we found that by using equimolar mixtures of ($R_{Bn}$,$R_{bin}$)-**3b** and ($S_{Bn}$,$R_{bin}$)-**3d** in the hydrogenation of 2-(acetylamino)-3-(phenyl)propenoic methyl ester did not significantly modify the *ee* (Table 1, Entry 31), although in this experiment the activity unexpectedly dropped. Similar observations were made by using the ($S_{Bn}$,$R_{bin}$)-**3d**/($S_{Me}$,$R_{bin}$)-**4a** couple (Table 1, Entry 32). Thus, these results contrast the recent findings of Reetz et al. who showed that the combination of different phosphanes, in particular mixtures of chiral phosphites and *achiral* phosphanes, may produce a selectivity increase in hydrogenation experiments.[37]

## Conclusions

In the present study we described the first monodentate $P^{III}$ ligands combining a chiral 1,3-dioxa-2-phosphacycloheptadinaphthyl unit with a cost effective and readily available phenylalanine- or alanine-derived fragment. Despite their relative bulkiness, these ligands were found to readily form $[PtCl_2L_2]$ complexes adopting a *cis* stereochemistry. When used in the rhodium-catalysed hydrogenation of prochiral olefins, the alanine–phosphoramidites displayed considerably higher hydrogenation rates than the sterically more crowded phenylalanine analogues. The highest enantioselectivities, 92%, were found with ($R_{Bn}$,$R_{bin}$)-**3b**. These are higher than those obtained with related, cheap phosphoramidites in which the amino group contains at least one stereogenic centre, but remain slightly below the performances of the "Feringa–de Vries" ligand **A** when used under similar conditions. Overall, this study confirms previous studies that have already established that the bulky, binoP moiety has a major impact on the enantioselectivity of hydrogenation reactions, overwhelming that of other stereogenic centres present in the molecule.

## Experimental Section

**General Procedures:** All manipulations involving aminophosphanes and phosphoramidites were performed in Schlenk-type flasks under an atmosphere of dry nitrogen. Solvents were dried by conventional methods and distilled immediately prior to use. $CDCl_3$ was passed through a 5 cm-thick alumina column and stored under an atmosphere of nitrogen over molecular sieves (4 Å). Routine $^1H$, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ spectra were recorded with Bruker FT Instruments (AC-200 and AC-300). $^1H$ NMR spectra were referenced to residual protonated solvents ($\delta$ = 7.26 ppm for $CDCl_3$ and 7.16 ppm for $C_6D_6$), $^{13}C$ chemical shifts are reported relative to deuterated solvents ($\delta$ = 77.16 ppm for $CDCl_3$ and 128.06 ppm for $C_6D_6$), and the $^{31}P$ NMR spectroscopic data are given relative to external $H_3PO_4$. Mass spectra were recorded with a Bruker MicroTOF spectrometer (ESI) and with $CH_2Cl_2$ as the solvent. Optical rotations were measured with a Perkin–Elmer 341 digital polarimeter with a 1 dm cell. The $^{13}C\{^1H\}$ NMR assignments for ($S_{Bn}$)-**2a** and ($R_{Bn}$)-**2b** are partially based on a literature reference.[38] The chlorophosphite binoPCl was prepared according to a procedure described in the literature.[31]

**Synthesis of Amino Esters**

**Methyl (*S*)-2-(Methylamino)-3-phenylpropionate [($S_{Bn}$)-1a]:** A solution of methyl (*S*)-2-(benzyloxycarbonylmethylamino)-3-phenylpropionate (3.196 g, 9.732 mmol), in MeOH (100 mL) was treated with 10% Pd/C (0.320 g, 10 wt.-% equiv.) and $H_2$ (1 atm) at 30 °C. After stirring for 2 h, the reaction mixture was filtered through Celite, and the solvent was evaporated under vacuum to afford a colourless oil. Yield: 1.891 g, 100%. $[\alpha]_D^{20}$ = +25.6 ($c$ = 0.30, $CHCl_3$) [ref.[38] $[\alpha]_D^{20}$ = +24.9 ($c$ = 0.30, $CHCl_3$)]. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.27–7.11 (m, 5 H, arom. H), 3.60 (s, 3 H, $OCH_3$), 3.42 [t, $^3J_{H,H}$ = 6.8 Hz, 1 H, HC(CO)], 2.91 (d, $^3J_{H,H}$ = 6.8 Hz, 2 H, PhC$H_2$), 2.32 (s, 3 H, $NCH_3$), 1.76 (s, 1 H, N$H$CH$_3$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 174.49 (s, C=O), 137.04 (s, quat. C), 128.96 (s, arom. CH), 128.74 (s, arom. CH), 128.31 (s, arom. CH), 128.00 (s, arom. CH), 126.59 (s, arom. CH), 64.47 [s, H$C$(CO)], 51.42 (s, $OCH_3$), 39.26 (s, Ph$C$H$_2$), 34.52 (s, $NCH_3$) ppm. $C_{11}H_{15}NO_2$ (193.24): calcd. C 68.4, H 7.8, N 7.3; found C 68.6, H 7.8, N 7.3.

**Methyl (*R*)-2-(Methylamino)-3-phenylpropionate [($R_{Bn}$)-1b]:** ($R_{Bn}$)-**1b** was prepared according to the above procedure from methyl (*R*)-2-(benzyloxycarbonylmethylamino)-3-phenylpropionate (5.240 g, 15.96 mmol). Yield: 3.100 g, 100%. $[\alpha]_D^{20}$ = –25.5 ($c$ = 1.00, $CHCl_3$) [ref.[38] $[\alpha]_D^{20}$ = –25.1 ($c$ = 1.00, $CHCl_3$)]. $C_{11}H_{15}NO_2$ (193.24): calcd. C 68.4, H 7.8, N 7.3; found C 68.3, H, 7.9, N 7.4.

**Methyl (*S*)-2-(Methylamino)propionate Monohydrochloride {[($S_{Me}$)-1c]HCl}:** Thionyl chloride (1.300 g, 11.30 mmol, ca. 0.83 mL) was added dropwise to MeOH (15 mL) at 0 °C. To this mixture was added a solution of (*S*)-2-(methylamino)propionic acid (0.400 g, 3.80 mmol) in MeOH (10 mL). After stirring at r.t. for 4 d, the solvent was evaporated to dryness in vacuo to afford the product as a white solid. Yield: 0.600 g, 100%. $[\alpha]_D^{20}$ = +0.5 ($c$ = 2.00, EtOH) [ref.[39] $[\alpha]_D^{20}$ = +1.0 ($c$ = 2.00, EtOH)]. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 10.06 (br., 1 H, N$H$), 3.94 [d, $^3J_{H,H}$ = 6.9 Hz, 1 H, HC(CO)], 3.84 (s, 3 H, OC$H_3$), 2.79 (s, 3 H, $NCH_3$), 1.73 (d, $^3J_{H,H}$ = 6.9 Hz, 3 H, CHC$H_3$) ppm. $^{13}C$ NMR (75 MHz, $CDCl_3$): $\delta$ = 169.09 (s, $C$=O), 56.20 [s, H$C$(CO)], 53.46 (s, $OCH_3$), 30.88 (s, $NCH_3$), 14.49 (s, CH$C$H$_3$) ppm. $C_5H_{12}ClNO_2$ (153.61): calcd. C 39.1, H 7.9, N 9.1; found C 39.2, H 7.8, N 9.1.

**Methyl (*S*)-2-(Methyldiphenylphosphanylamino)-3-phenylpropionate [($S_{Bn}$)-2a]:** To a solution of ($S_{Bn}$)-**1a** (2.110 g, 10.86 mmol) in toluene (30 mL) was added successively diisopropylethylamine (1.404 g, 13.90 mmol, ca. 1.88 mL) and chlorodiphenylphosphane (2.397 g, 10.86 mmol, ca. 1.95 mL). The mixture was stirred overnight at r.t., then filtered through $Al_2O_3$. The solvent was evaporated to dryness, after which the residue was purified by flash chromatography over silica (cyclohexane/ethyl acetate, 70:30). Product ($S_{Bn}$)-**2a** was obtained as a white solid. Yield: 3.510 g, 86%. M.p. 72–74 °C. $[\alpha]_D^{20}$ = –84.3 ($c$ = 1.00, toluene). $^1H$ NMR (300 MHz, $C_6D_6$): $\delta$ = 7.50–7.44 (m, 2 H, arom. H), 7.18–6.99 (m, 13 H, arom. H), 4.51 [ddd, $J_{H,H}$ = 6.2 Hz, $J_{H,H}$ = 9.8 Hz, $J_{H,P}$ = 11.6 Hz, 1 H, HC(CO)], 3.22 (s, 3 H, $OCH_3$), 3.23 and 3.02 (ABX spectrum, $^2J_{A,B}$ = 14.3 Hz, $^3J_{A,X}$ = 6.2 Hz, $^3J_{B,X}$ = 9.8 Hz, 2 H, PhC$H_2$), 2.43 (d, $^3J_{HP}$ = 2.6 Hz, 3 H, $NCH_3$) ppm. $^{13}C$ NMR (75 MHz, $C_6D_6$): $\delta$ = 172.74 (d, $^3J_{C,P}$ = 3.1 Hz, $C$=O), 139.44 (d, $^1J_{C,P}$ = 16.2 Hz, quat. **X-ray Crystal Structure Determination of 5:** Crystals of **5** suitable for X-ray diffraction were obtained by slow diffusion of pentane into a chloroform solution of the complex. $2(C_{62}H_{52}Cl_2N_2O_8Pt)\cdot 2(0.5CHCl_3)\cdot 0.5C_5H_{12}$, $M$ = 2717.41, tetragonal, $P4_1$, $a$ = $b$ = 11.5731(2) Å, $c$ = 89.444(2) Å, $V$ = 11979.8(4) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 1.507 g cm$^{-3}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å, $\mu$ = 26.08 cm$^{-1}$, $F$(000) = 5468, $T$ = 100 K. The sample (0.25 × 0.20 × 0.20 mm) was studied with a Bruker AXS X8-APEX II diffractometer with graphite monochromatized Mo-$K_\alpha$ radiation. Data collection was carried out by using the Bruker collect suite.[40] 51864 Reflections were collected ($1.76 < \theta < 27.54°$), of which 20757 had $I > 2.0\sigma(I)$. The structure was solved with SIR-97,[41] which revealed the non-hydrogen atoms of the molecule. After anisotropic refinement, many hydrogen atoms could be localized on Fourier difference map. The whole structure was refined with SHELXL-97.[42] Hydrogen atoms were included and refined by using a riding mode in SHELX-97. Final results: $R_1$ = 0.065, $wR_2$ = 0.152, goodness of fit 1.135, 1465 parameters, residual electron density: min/max = –2.47/1.89. Flack parameter: 0.064(7).

**Crystal Data for 6:** Crystals of **6** suitable for X-ray diffraction were obtained by slow diffusion of pentane into a dichloromethane solution of the complex. $PtCl_2P_2C_{62}H_{52}O_8N_2\cdot 3H_2O$, $M$ = 1335.03, orthorhombic, space group $P2_12_12_1$, $a$ = 9.9546(3) Å, $b$ = 26.5366(9) Å, $c$ = 26.8868(9) Å, $V$ = 7102.5(4) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 1.249 g cm$^{-3}$, $\lambda$(Mo-$K_\alpha$) = 0.71073 Å, $\mu$ = 21.47 cm$^{-1}$, $F$(000) = 2696, $T$ = 292(1) K. The sample (0.40 × 0.22 × 0.22 mm) was studied with an Oxford Diffraction Xcalibur Saphir 3 diffractometer with graphite monochromatized Mo-$K_\alpha$ radiation. The data collection was carried out by using CrysAlis RED.[43] 22955 Reflections collected ($1.76 < \theta < 27.54°$), 7763 observations with $I > 2.0\sigma(I)$. The structure was solved with SIR-97,[41] which revealed the non-hydrogen atoms of the molecule. After anisotropic refinement, many hydrogen atoms could be localized with a Fourier difference. The whole structure was refined with SHELXL97.[42] Hydrogen atoms were included and refined by using a riding mode in SHELX-97. Final results: $R_1$ = 0.060, $wR_2$ = 0.165, goodness of fit 0.917, 722 parameters, residual electron density: min/max = –0.957/1.526. Flack parameter: 0.069(10).

CCDC-613420 and -286303 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**General Procedure for Asymmetric Hydrogenation and Determination of Enantiomeric Excesses:** To a solution of $[Rh(cod)_2]BF_4$ (0.010 g, 0.025 mmol) in $CH_2Cl_2$ (10 mL) was added a solution of the ligand (2.2 equiv.) in $CH_2Cl_2$ (10 mL), and the resulting mixture was stirred for 30 min. before being used in the catalytic run. For those runs carried out with another solvent, the previous solution was evaporated to dryness; the residue was then dissolved in the desired solvent (20 mL). The solution was introduced by syringe into a 100-mL glass-lined, stainless steel autoclave containing a magnetic stirring bar and the substrate (2.5 mmol); the autoclave was then placed under an atmosphere of hydrogen (5 bar). At the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

end of the catalytic run, the autoclave was depressurized and the mixture was passed through a short silica column to remove the catalyst. Conversions were monitored by $^1$H NMR spectroscopy. Enantioselectivities were determined by chiral GC analysis by using a CHROMPAK chiral fused silica 25 m × 0.25 mm i.d. and/or specific rotation. Coating Chirasil-L-Val column.

# Order-Disorder Phase Transition in Type-I Clathrate $Cs_8Sn_{44}\square_2$

**Andreas Kaltzoglou,[a] Stephan D. Hoffmann,[a] and Thomas F. Fässler*[a]**

*Dedicated to Prof. Dr. G. Huttner on the occasion of his 70th birthday*

**Keywords:** Clathrates / Order-disorder transitions / Single-crystal structure analysis / Thermoelectricity / Tin

The clathrate compound α-$Cs_8Sn_{44}\square_2$ has been synthesized from its elements under inert gas conditions and has been characterized by single-crystal and powder X-ray diffraction. At room temperature, it crystallizes with cubic symmetry [$a$ = 24.256(3) Å, space group $Ia\bar{3}d$, $Z$ = 8] and adopts a $2\times2\times2$ superstructure of the type-I clathrate and a high ordering of the vacancies (□) in the Sn framework. Single crystals of α-$Cs_8Sn_{44}\square_2$ reversibly transform at 90 °C to the high-temperature β form with primitive symmetry [$a$ = 12.135(1) Å, space group $Pm\bar{3}n$, $Z$ = 1] and a lower ordering of the defects. Differential thermal analysis corroborates the reversible character of the phase transition, which occurs with an enthalpy change of approximately 0.38 $J\,g^{-1}$. An atom-migration mechanism describing the order-disorder transition involving spiro-connected six-membered rings only (scsr mechanism) is proposed.

## Introduction

The discovery of clathrates as a distinct class of materials opened up a wide area of research involving specifically further synthesis and studies of their properties. The binary systems composed primarily of alkali or alkaline earth metals as guests and Group 14 elements (Si, Ge, Sn) as hosts of the three-dimensional framework are known as semiconducting clathrates and behave mostly like Zintl phases rather than typical intermetallic compounds.[1] The idea that clathrate compounds fulfill the criteria for the Phonon Glass Electron Crystal (PGEC) concept[2] and thus may qualify as thermoelectric materials has led to the rapid development of this compound family. Over the last decades, five clathrate structure types denoted with the Latin numbers I, II, III, VIII, IX have been established, with type I as the most common (Figure 1). In clathrate I, the tetravalent host atoms form interconnected polyhedra with shared pentagonal and hexagonal faces. The structure is further stabilized in the presence of the encaged metal cations. Even though much data on the composition, crystal structures, and physical properties are now available,[3–5] there is still a lack of understanding of the physics involved in the PGEC approach. A strong glass-like rattling of the guest atoms inside the cages of the three-dimensional network of host atoms is necessary for achieving high-quality thermoelectric materials. Therefore, a fine grasp of the lattice defects and phase transitions in clathrate-I compounds must play a decisive role in the understanding of the structure–property relationships in stannide clathrates.

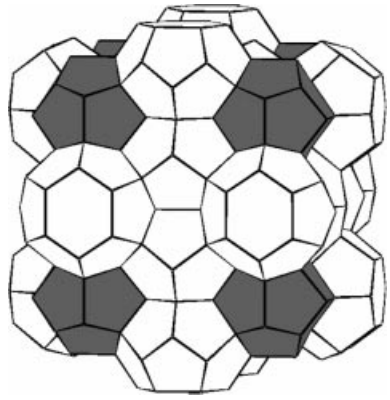

Figure 1. Structure of the type-I clathrate with pentagonal dodecahedra (grey [$5^{12}$]) and tetrakaidecahedra (white [$5^{12}6^2$]) in a 1:3 ratio.

A limited number of such compounds undergo phase transitions before melting. Interestingly, those temperature- or pressure-induced structural transformations can also affect certain physical properties. Recently, a magnetocaloric effect was reported for the doped $Eu_8Ga_{16}Ge_{30}$ resulting from the ferromagnetic transition from a type-I to a type-VIII structure.[6] Moreover, type-IX $Ba_6Ge_{25}$[7] tunes its electrical properties through a two-step phase transition, and phonon band structures of the non-defect type-I $K_8Si_{46}$ change drastically upon pressing.[8]

Since the first report of the non-defect $K_8Sn_{46}$,[9] the exact composition and structure of the type-I tin clathrates was brought into question several times.[10,11] The discrepancies involve the presence of defects – a prerequisite for fulfilling the Zintl–Klemm concept – and their ordering in the crystal. A Mulliken population analysis[12] on the basis of topological charge stabilization for the stannides showed that the vacancies in the three-dimensional host lattice of Sn atoms are favored and that they are statistically distributed only at the framework sites that are part of six-membered rings and that do not belong to pentagonal dodecahedra (6 out of 46 sites); those possess the lowest electron density. These assumptions were indeed confirmed experimentally as the $A_8Sn_{44}\square_2$ compounds (A = K, Rb, Cs)[4,5,13] were found to crystallize in the $Pm\bar{3}n$ space group and the partially occupied positions were distributed along a $4_2$ screw axis. More recently, theoretical calculations for $Cs_8Sn_{44}$[14] and $K_8Sn_{44}$[15] indicated that one vacancy per six-membered ring is favored over two such vacancies per ring. A superstructure was experimentally established for $Rb_8Sn_{44}\square_2$, which was found to crystallize in the $Ia\bar{3}d$ space group and the $2\times2\times2$ unit cell with vacancies distributed along a $4_1$ axis instead of the $4_2$ axis (see also Figure 2).[16] However, the conditions under which the two modifications occur, or if they may co-exist, still remained unclear.

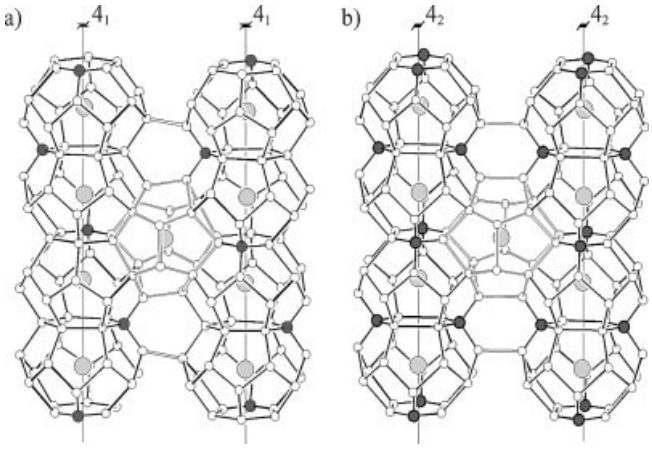

Figure 2. Partial view of the $Cs_8Sn_{44}\square_2$ structures composed of two chains of tetrakaidecahedra and one pentagonal dodecahedron. a) In the α form (space group $Ia\bar{3}d$), the partially occupied *24c* sites (dark grey Sn6 atoms, with an occupation factor of 0.339) are distributed along a $4_1$ helical axis. b) In the β form (space group $Pm\bar{3}n$), the partially occupied *6c* sites (dark grey Sn1 atoms, with an occupation factor of 0.687) are distributed along a $4_2$ axis. In both cases, only the Sn atoms of the split positions with closer contacts to the vacancy are shown.

Here we report on the discovery of a reversible phase transition of isostructural $Cs_8Sn_{44}\square_2$. The transformation sheds light on the structural trends of defect tin clathrates. Since we expect that most stannide clathrate-I compounds appear at low temperatures with a $2\times2\times2$ superstructure, the partial ordering of vacancies must be considered on the basis of property measurements and this might lead to a reinterpretation of several studies.[5,17]

## Results and Discussion

According to the room temperature powder X-ray analysis, $Cs_8Sn_{44}\square_2$ adopts the type-I clathrate structure with a superstructure as observed for $Rb_8Sn_{44}\square_2$.[16] The cell parameters and the space group [$a$ = 24.256(3) Å, space group $Ia\bar{3}d$] are confirmed by single-crystal analysis at room temperature. The single crystal of $Cs_8Sn_{44}\square_2$ was gradually heated on the diffractometer with steps of 20 °C. No significant changes in the reflection patterns occur until a temperature of 80 °C was reached. At 100 °C, the superstructure reflections of the low temperature form (α-$Cs_8Sn_{44}\square_2$) disappear (see Supporting Information) as the crystal transforms into the primitive lattice with smaller cell parameters. This has been observed previously for $Cs_8Sn_{44}$ (β form).[13] A full data set was collected at this temperature. The crystal was perfectly retained when cooled at a rate of 2 °C min$^{-1}$ to room temperature where a second set of data was collected, which confirmed the full reversibility of the phase transformation.

At 20 °C, the $Cs_8Sn_{44}\square_2$ clathrate crystallizes in the $Ia\bar{3}d$ centrosymmetric space group (Figure 2a). The partially occupied Sn6 sites of the polyanionic framework [Wyckoff position *24c*, occupation factor 0.339(6)] are distributed around a $4_1$ screw axis through the Cs atoms that reside in the tetrakaidecahedra. As a consequence, a split model for the adjacent *96h* site is adopted, which gives rise to Sn4a atoms [occupation factor 0.339(6)] and Sn5b atoms [occupation factor 0.661(6)] that correspond to occupied and vacant Sn6 sites, respectively. Further, the Sn3 atom has a relatively large $U_{eq}$ value [0.0263(3) Å$^2$], probably because three out of its four neighbors are the split Sn4a/Sn4b atoms (Table 1). Nevertheless, no split model could be applied for this position. Further, two crystallographically non-equivalent positions for the Cs atoms are observed: (i) The Cs1 atom located in the dodecahedra and (ii) The Cs2 atom located in the tetrakaidecahedra. In both cases the sites are fully occupied. The isotropic atomic displacement parameters are 0.0193(3) Å$^2$ and 0.0378(2) Å$^2$ for Cs1 and Cs2, respectively, proving the stronger "rattling" of the guest in the larger cavities. It is also worth mentioning that the Cs2 atoms do not reside exactly in the center of the cavities, but tend to the opposite site of the vacancy, namely closer to the Sn5 atom (*24d* Wyckoff position). Thus, a slight deviation from linearity (178.88°) is observed for the

Cs2–Cs2–Cs2 chain parallel to the cubic axes, which is expressed in terms of displacement of 0.0593 Å from the center of the cage.

In the high temperature modification (space group $Pm\bar{3}n$), the *6c* Wyckoff site corresponds to the Sn1 atom with occupation factor 0.687(7) (Table 2). Within the standard deviation, this value is equivalent to the value of the I-centered crystals at room temperature and to the value of 2/3, anticipated for an electron precise Zintl phase. As expected, the adjacent *24k* site is better refined by means of a Sn3a/Sn3b model with occupancies 0.687(7) and 0.313(7), respectively. Once again, the Cs atoms that reside in the large framework cavities exhibit much higher atomic displacement parameters than those in the smaller cavities. The β modification exhibits larger ADPs (ADP = anisotropic displacement parameter) than the α modification and the values obtained from the room temperature data refinement in ref.[13], as expected from the temperature dependence in the Einstein's oscillator model.[5a] On the other hand, the Sn–Sn–Sn angles have very comparable values: 94.84(7)°–126.52(9)° for the I lattice and 94.68(1)°–125.2(1)° for the primitive lattice.

The structure of α-$Cs_8Sn_{44}$ was verified by Rietveld refinement of the powder diffraction pattern. In this case as well, split models for the positions adjacent to the vacancies are applied.

The vacancy order–disorder transformation is also detectable by differential thermal analysis (DTA). At about 95 °C, a weak endothermic peak, which can be attributed to the $Ia\bar{3}d \rightarrow Pm\bar{3}n$ transition is observed (Figure 3). The reverse phenomenon takes place and is observed as an exothermic peak during cooling. The hysteresis of the peaks depends on the heating and cooling rate. From the average of the experimental maxima, one can define the transition temperature at $T_t$ = 89–90 °C. Further heating to 1000 °C at a rate of 10 °C min$^{-1}$ results in an endothermic peak at 580 °C (on set), which according to the phase diagram is attributed to peritectical decomposition of $Cs_8Sn_{44}$ into Sn and $CsSn_2$.[18] Finally, at 830 °C, a relatively weak and broad endothermic peak of the liquidus line is observed. On cooling, each peak has a corresponding exothermic phenomenon at 810 °C, 510 °C, and 215 °C, which corresponds to the solidification of Sn. Elemental Sn was initially not observed in the room temperature X-ray powder diffractogram. However, it has been shown by multitemperature diffraction experiments with synchrotron X-rays that the related compound $Rb_8Sn_{44}$ contains small amounts of impurities. The impurities are formed as a decomposition product already at 180 °C.[19] The X-ray powder diffraction pattern of the DTA residue after heating to 1000 °C was refined by the Rietveld method. It confirms the presence of α-$Cs_8Sn_{44}$ with a lower degree of crystallinity and also the formation of β-Sn, to approximately 6%.

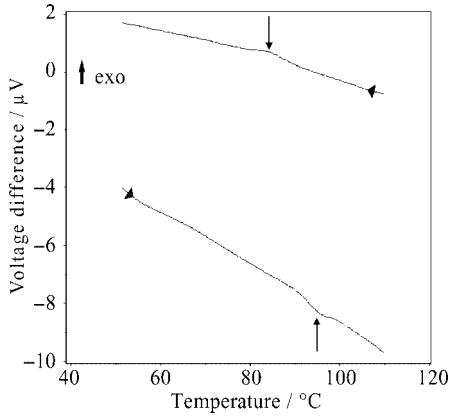

Figure 3. Section of the DTA diagram of $Cs_8Sn_{44}\square_2$ recorded in the range 25 °C–150 °C at a 1 °C min$^{-1}$ heating and cooling rate. Shown is the section between 50 °C and 110 °C. Vertical arrows show the endothermic and exothermic peaks.

The recent observation of a superstructure for clathrate-I $Rb_8Sn_{44}$[16] raises the question on the one hand if such an ordering of vacancies occurs in other stannides with clathrate-I structures and on the other hand why this superstructure has not been observed although many reports on those structures have been published. The detailed thermal analysis here shows that the phase transformation occurs at 89–90 °C with almost perfect reversibility. On the basis of the on set temperatures on heating and cooling the sample at 1 °C min$^{-1}$, the transition occurs with a hysteresis of approximately 2°. Even quenching of the reaction product from 100 °C or 700 °C into liquid nitrogen did not give rise to the high temperature β modification. During all transformations, no other impurity than small amounts of β-Sn was detected by X-ray powder diffraction, EDX, or DTA.

In general, superlattice formation can prevent under- or mixed occupancy of specific atomic sites, but can achieve vacancy formation and atom segregation. Four examples of superstructures have been discussed for doped and/or defect type-I clathrates: (a) $I_8[Sn_{14}In_{10}P_{21.2}\square_{0.8}]$ crystallizes in the tetragonal space group $P4_2/m$, exhibiting partial ordering of the defects;[20] (b) the orthorhombic (*Pbcn*) $Ba_8[Cu_{16}P_{30}]$ exhibits no disorder as P atoms exclusively occupy the *24k* and *6c* sites and Cu atoms the *16i* sites;[21] (c) more recently, the cubic ($Ia\bar{3}d$) $Rb_8Sn_{44}\square_2$ shows a partial ordering of the vacancies;[16] (d) $Ba_8Ge_{43}\square_3$ is characterized as a fully ordered superstructure when quenched quickly from 800 °C or as partially ordered when cooled slowly to ambient conditions.[22] In the present case as in $Rb_8Sn_{44}\square_2$ and $Ba_8Ge_{43}\square_3$, a "klassengleiche" symmetry reduction from

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*Pm*$\bar{3}$*n* to *Ia*$\bar{3}$*d* takes places. However, the absence of a distinct transition temperature and the higher thermodynamic stability of the disordered modification for $Ba_8Ge_{43}\square_3$ are in contrast to our results here. For $Cs_8Sn_{44}\square_2$, as expected, the model with a lower degree of atom ordering represents the high temperature modification.

The full ordering of the defects in $Ba_8Ge_{43}\square_3$ is also reflected in the larger deviation of the position of the guest atom Ba from the ideal center of the tetrakaidecahedra. The larger displacement of the Ba atoms (0.0844 Å) originates from the presence of a full vacancy and not from the statistics of a partially filled position, as found in $Cs_8Sn_{44}\square_2$ with a displacement of 0.0593 Å for Cs.

According to DTA experiments, the phase transition occurs well below the melting temperature and involves an enthalpy change of about $\Delta H_t = -0.38\ J\,g^{-1}$ ($-2.390\ kJ\,mol^{-1}$) and is thus lower in energy than the first-order transition α-Sn → β-Sn at 13.2 °C ($\Delta H_t = -17.6\ J\,g^{-1}$ or $-2.089\ kJ\,mol^{-1}$).[23] Perfect preservation of the single crystal during the phase transition suggests a second-order transition. However, the enthalpy change at a distinct transition temperature shows that first-order contributions must also be considered.

We rationalize the different thermodynamic stability of the two modifications by studying the possible configurations of the hexagons in $[5^{12}6^2]$. In α-$Cs_8Sn_{44}\square_2$, each hexagon may either be defect-free or possess one defect. In the latter case the neighboring atomic positions are shifted towards the vacancy (Figure 4). In β-$Cs_8Sn_{44}\square_2$, in addition to the two configurations in Figure 4 with virtually identical structures, a third configuration with two vacancies per hexagon in the *para* positions may also occur (Figure 5). Consequently, the bonds between the remaining four atoms are even more elongated, i.e. 3.26(1) Å, which is about 0.3 Å longer than typical distances between three-bonded Sn atoms [see for example the tetrahedral $Sn_4$ clusters in $Cs_4Sn_4$ in which Sn–Sn = 2.939(2) Å].[24]

This next-nearest neighbor interaction of two vacancies significantly affects the stability of the system. Local density approximation studies on the hypothetical $Cs@Sn_{22}\square_2$ with isolated 24-atom cages show that the situation with the vacancies on two different six-membered rings is favored over that in which both vacancies are on the same ring.[14] These theoretical results reflect the trend obtained here experimentally, i.e. vacancy ordering is favored at room temperature. Despite the low enthalpy, no equilibrium is observed between the two modifications, as is also indicated by the first-order contribution to the phase transformation. On the other hand, β-$Cs_8Sn_{44}\square_2$ possesses higher symmetry than α-$Cs_8Sn_{44}\square_2$. For this reason and despite the thermodynamic instability, the disordered modification is favored at elevated temperatures by means of an entropy-driven phase transition.

The mechanism of this low-energy enantiotropic solid-state transformation can be rationalized as a continuous path rather than a nucleation-and-growth process that begins at the imperfections of the crystal.[25] Two ways of achieving the migration of certain Sn atoms are proposed

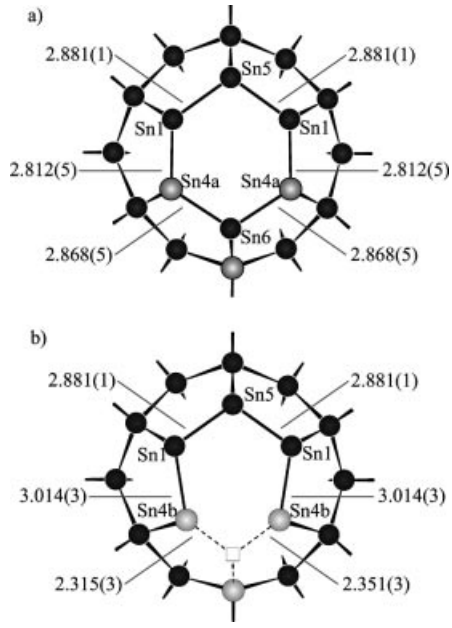

Figure 4. Perpendicular view of a hexagon in α-$Cs_8Sn_{44}\square_2$: a) no defects, b) one defect. All distances are given in Å.

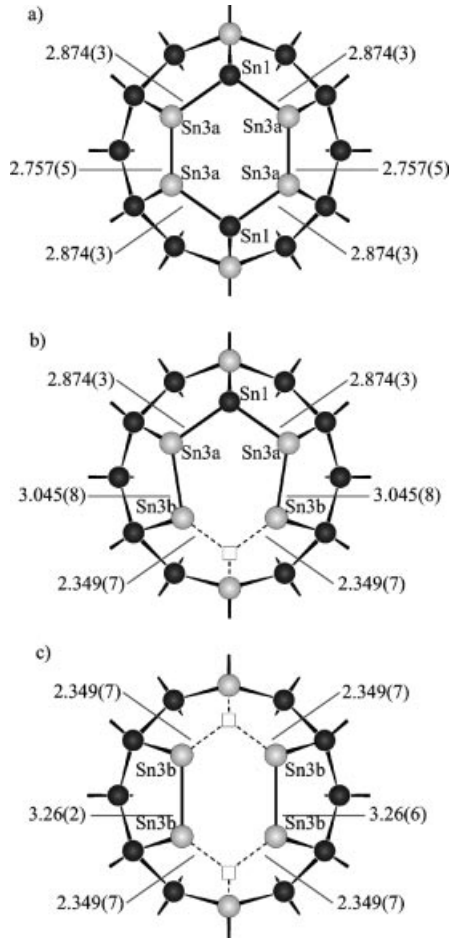

Figure 5. Perpendicular view of a hexagon in β-$Cs_8Sn_{44}\square_2$: a) no defects, b) one defect, c) two defects. All distances are given in Å.

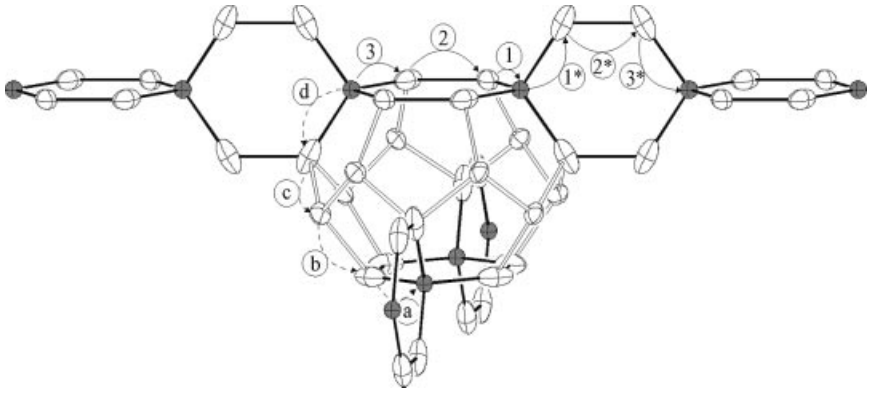

Figure 6. Two possible mechanisms of atom migration for the $Pm\bar{3}n$ to $Ia\bar{3}d$ phase transition. Fully and partially occupied Sn positions are drawn in white and grey, respectively, with thermal ellipsoids at the 80% probability level and without split positions for atoms adjacent to the vacancies.

(Figure 6): (a) A three-step mechanism including migration via two split positions within a six-membered ring is indicated as solid arrows. Migration occurs along spiro-connected six-membered rings (scsr) only. Because of the cubic symmetry, the spiro motive shown in Figure 6 appears in chains along all three directions and allows the rearrangement of the atoms in the three-dimensional framework. (b) A four-step mechanism with migration through two split and one non-split atomic positions, the latter being part of five-membered rings only, is indicated as dashed arrows. Large displacement vectors of the involved atoms favor the scsr mechanism.

## Conclusions

The present study establishes the temperature-dependent phase transition of $Cs_8Sn_{44}$ and sheds light on the controversial discussion of the properties of clathrate-I stannides. Still a question remains: could a fully ordered structure with the composition of an electron-precise Zintl phase $A_8Sn_{44}\square_2$ exist? The full ordering could occur in an enlarged $6\times6\times6$ unit cell with space group $Ia\bar{3}d$ or alternatively in a $3\times3\times3$ unit cell with $Pm\bar{3}n$ symmetry.[26] Nevertheless, no such superlattices were found by single-crystal analysis above –130 °C.

## Experimental Section

**Synthesis:** The $Cs_8Sn_{44}\square_2$ clathrate was prepared from the pure elements, which were handled in an Ar-filled glove box ($O_2$ and $H_2O$ levels <0.1 ppm). Stoichiometric amounts of Cs (ampoule, >98%, Riedel de Haën) and Sn (granules, 99.999%, Chempur) were weighted into Nb ampoules and sealed under reduced Ar pressure. The crucibles were subsequently closed in evacuated silica tubes (pressure ca. $3\times10^{-2}$ mbar), heated to 750 °C for 12 h (2 °C min$^{-1}$), slowly cooled to 500 °C (0.1 °C min$^{-1}$), held at this temperature for 10 d, and then air-quenched to ambient temperature. The title compound exhibits air and moisture stability and remains unchanged upon standing for months. Variation of the reactions conditions, such as reaction temperature between 700 °C and 950 °C, annealing steps, and cooling rates from 0.1 °C min$^{-1}$ to air-quenching, did not significantly affect the composition of the product; however, the quality of the crystals were affected and β-Sn disappeared by increasing the annealing times.

**X-ray Powder Diffraction:** The air-stable and metal-like products were identified on a STOE STADI powder diffractometer equipped with a linear position sensitive detector, using Cu-$K_\alpha$ radiation ($\lambda$ = 1.5406 Å, $10° \le 2\theta \le 90°$, step width = 0.01°) in transmission mode. Microcrystalline diamond was used as the internal standard. The patterns were indexed by using the software package WinXPOW (Stoe) and refined with the WinPLOTR program.[27]

**Single-Crystal X-ray Diffraction:** Reflection data sets were collected with a Stoe IPDS-IIT image plate diffractometer with graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and an open-flow $N_2$ blower for the temperature range –180 °C to 100 °C (Oxford Cryostream Cooler). The temperature at the crystal was additionally checked at various heating steps by using an external thermocouple. Good quality single crystals were obtained by annealing the samples at 400–500 °C for several days. One plate-like crystal was transferred into a glass capillary (Hilgenberg, length = 80 mm, diameter = 0.3 mm) that were in turn mounted on the diffractometer. After checking the cell parameters and the space group ($a$ = 24.256 Å, $Ia\bar{3}d$), the crystal was subsequently heated to 100 °C. Data sets were collected at 100 °C with $a$ = 12.135 Å and the space group $Pm\bar{3}n$ and after cooling to 20 °C with $a$ = 24.256 Å and the space group $Ia\bar{3}d$ (Table 3). For structure solutions and refinements (direct methods, full-matrix least-squares on $F^2$, anisotropic atomic displacement parameters for all atoms, with numerical absorption corrections[28]), SHELXTL97 was used.[29] Note also that the occupation factors for defects and split positions were coupled through the PART command for disordered groups. Further details of the crystal structure investigations can be obtained from the Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany [Fax: (+49)7247-808-666; E-mail: crysdata@fiz-karlsruhe.de] on quoting the depository numbers CSD-417969 (α form) and 417970 (β form).

**Differential Thermal Analysis:** DTA was carried out on an annealed sample ($m$ = 370 mg) sealed in an Nb-crucible under an argon, protective atmosphere in the temperature range 25–1000 °C. The diagrams were obtained in two cycles using heating and cooling rates from 0.1 to 5 °C min$^{-1}$. The calibration was carried out by using known latent heats for the melting points of naphthalene ($T_m$ = 80.3 °C, $\Delta H_m$ = –147 J g$^{-1}$), In ($T_m$ = 156.6 °C, $\Delta H_m$ = –28.6 J g$^{-1}$), β-Sn ($T_m$ = 231.9 °C, $\Delta H_m$ = –60.5 J g$^{-1}$), and Al ($T_m$ = 660.3 °C, $\Delta H_m$ = –397 J g$^{-1}$) at a rate of ±2 K min$^{-1}$. The latent

# Syntheses, Characterization, and Luminescent Properties of Monoethylzinc Complexes with Anilido–Imine Ligands

Qing Su,[a] Wei Gao,[a] Qiao-Lin Wu,[a] Ling Ye,[a] Guang-Hua Li,[b] and Ying Mu*[a]

**Keywords:** Luminescence / N ligands / Quinoline / Zinc

The syntheses of three anilido–imine ligands of the general formula *ortho*-$C_6H_4$(NHAr′)(CH=NAr′′ [Ar′ = 7-(2,4-$Me_2$)-$C_9H_4N$, Ar′′ = 2,6-$Me_2C_6H_3$ (**2a**); Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar′′= 2,6-$Et_2C_6H_3$ (**2b**); Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar′′= 2,6-*i*$Pr_2C_6H_3$ (**2c**)] and four zinc(II) complexes of the general formula [*ortho*-$C_6H_4$(NHAr′)(CH=NAr′′)]ZnEt [Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar′′= 2,6-$Me_2C_6H_3$ (**3a**); Ar′ = 7-(2,4-$Me_2$)-$C_9H_4N$, Ar′′= 2,6-$Et_2C_6H_3$ (**3b**); Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**3c**); Ar′′ = 2,6-$Me_2C_6H_3$, Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**3d**)] are described. The complexes were synthesized from the reaction of $ZnEt_2$ with corresponding ligands **2** by alkane elimination. All compounds were characterized by elemental analysis and $^1H$ and $^{13}C$ NMR spectroscopy. The molecular structures of compounds **2a**, **2b**, **3b**, and **3c** were determined by single-crystal X-ray crystallography. The X-ray analysis reveals that complexes **3b** and **3c** exist in the dimeric form with the N atom in the quinolyl ring coordinating to the other Zn atom to make the Zn atoms four coordinate. Luminescent properties of ligands **2a**–**2d** and complexes **3a**–**3d** in both solution and the solid state were studied.

## Introduction

Zinc(II) complexes as luminescent materials have been extensively studied in recent years.[1–9] Among these known luminescent Zn complexes, the ligands are mainly benzothiazolates,[1] quinolinolates,[2] salicylideneaminates,[3] dipyrrin,[6c] N-7-azaindolyl,[8] and 2,2′-dipyridylamino.[9] As $Zn^{II}$ with a closed shell is spectroscopically silent in essence, the luminescent properties of $Zn^{II}$ complexes can be easily tuned by the modification of the ligands. Meanwhile, $Zn^{II}$ complexes can have relatively flexible coordination numbers ranging from three-coordinate to six-coordinate depending on the structure of their ligands. Bis(8-hydroxyquinoline)-zinc(II) ($Znq_2$) was reported to be a good electroluminescent (EL) material that exists in the form of $(Znq_2)_4$.[2] Bis[2-(2-hydroxyphenyl)benzothiazolate]zinc $[Zn(BTZ)_2]_2$ was found to be an excellent white EL material.[1] Some polynuclear $Zn^{II}$ complexes[7,8] were also reported to have intriguing structural and photoluminescent properties. We reported a number of aluminum[10a,10b] and boron[10c] complexes with chelating anilido–imine ligands showing good luminescent properties. Similarly, zinc complexes with the anilido–imine ligands might also be efficient luminescent materials considering that the anilido–imine ligands and the salicylaldiminate ligands have similar structures. Recently, Lee et al. reported some dinuclear $Zn^{II}$ complexes with anilido–imine ligands.[11] As we are interested in tuning the luminescent properties of $Zn^{II}$ complexes by modification of the ligands and the coordination geometries of $Zn^{II}$ complexes, we synthesized three new anilido–imine ligands with a 7-amino-2,4-dimethylquinolyl chromophore, in which the nitrogen atom in the quinolyl ring might coordinate to the $Zn^{II}$ in another molecule to form dinuclear or polynuclear $Zn^{II}$ complexes. The results indicate that all three $Zn^{II}$ complexes with quinolyl exist in a novel dimeric form. Herein we report the syntheses, characterizations, and fluorescent properties of four new zinc complexes with anilido–imine ligands, *ortho*-$C_6H_4$(NHAr′)(CH=NAr′′)ZnEt [Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar′′ = 2,6-$Me_2C_6H_3$ (**3a**); Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar′′ = 2,6-$Et_2C_6H_3$ (**3b**); Ar′ = 7-(2,4-$Me_2$)-$C_9H_4N$, Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**3c**); Ar′ = 2,6-$Me_2C_6H_3$, Ar′′ = 2,6-*i*$Pr_2C_6H_3$ (**3d**)].

## Results and Discussion

### Syntheses of the Ligands

Preligands **1a**–**1c** *ortho*-$C_6H_4F$(CH=NAr′′) [Ar′′ = 2,6-$Me_2C_6H_3$ (**1a**), 2,6-$Et_2C_6H_3$ (**1b**), 2,6-*i*$Pr_2C_6H_3$ (**1c**)] were synthesized by a condensation reaction of *ortho*-fluorobenzaldehyde with 1 equiv. of the relevant amine in *n*-hexane in the presence of anhydrous $MgSO_4$ according to a modified literature method.[12] Among them, **1b** is a new compound and characterized by NMR spectroscopy along with ele-

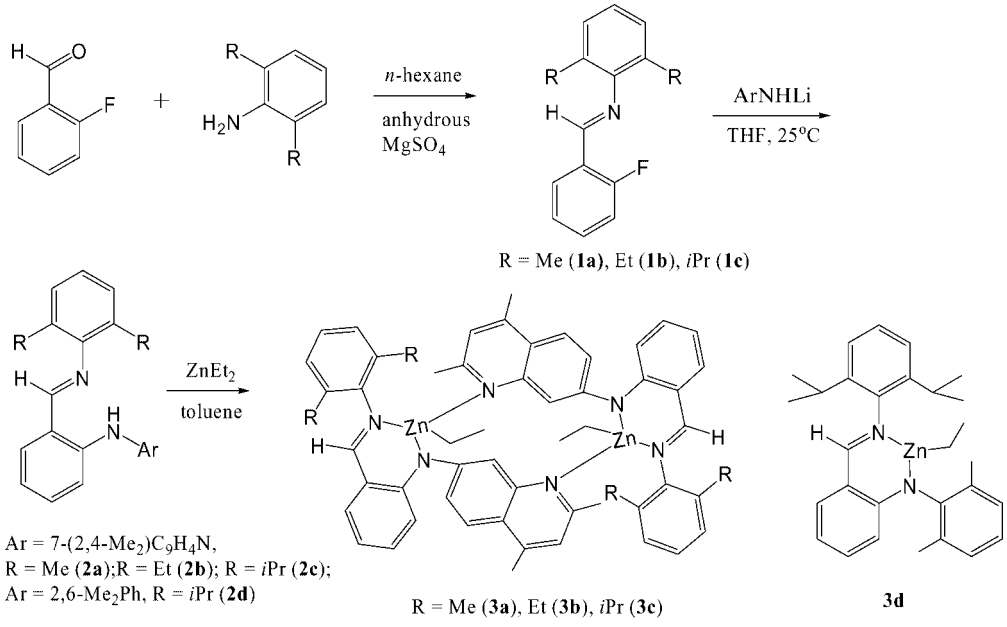
mental analysis. The imino CH proton of compound **1b** exhibits resonance at $\delta$ = 8.55 ppm and the corresponding imino CH carbon exhibits resonance at $\delta$ = 156.1 ppm. At room temperature, **1b** exists in the form of a yellow oil but as a yellow solid at lower temperatures. It can be purified by reduced-pressure distillation. Three new ligands, *ortho*-$C_6H_4(NHAr')(CH{=}NAr'')$ [Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar″ = 2,6-$Me_2C_6H_3$ (**2a**); Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar″ = 2,6-$Et_2C_6H_3$ (**2b**); Ar′ = 7-(2,4-$Me_2$)$C_9H_4N$, Ar″ = 2,6-*i*$Pr_2C_6H_3$ (**2c**)], were synthesized by nucleophilic aromatic substitution of fluoride in **1a**–**1c** by 7-amino-2,4-dimethylquinoline lithium salt according to a modified literature procedure[12] (Scheme 1) and characterized by $^1$H and $^{13}$C NMR spectroscopy along with elemental analysis. Ligands **2a** and **2b** were purified by chromatography on silica gel with ethyl acetate/petroleum ether as the eluent to give pure products as yellow crystals, whereas compound **2c** was purified by crystallization from methanol. For comparison, ligand **2d**[13] was synthesized according to a literature method and characterized by $^1$H NMR spectroscopy. The $^1$H NMR spectra of **2a**–**2c** exhibit resonances in the range of $\delta$ = 8.35–8.37 ppm for the imino CH proton, whereas the corresponding $^{13}$C NMR resonances are in the range of $\delta$ = 165.6–165.8 ppm. The NH proton resonance in **2a**–**2c** appears at relatively low field ($\delta$ = 11.64, 11.62, and 11.59 ppm, respectively) relative to those in compound **2d**[13] ($\delta$ =10.50 ppm) and other reported compounds of this type [$\delta$ =10.53 ppm for *ortho*-$C_6H_4${$NH(C_6H_3$*i*$Pr_2$-2,6)}-[$CH{=}NC_6H_3Me_2$-2,6],[10b] 10.60 ppm for *ortho*-$C_6H_4$-{$NH(C_6H_3Me_2$-2,6)}($CH{=}NC_6H_3Me_2$-2,6),[10a] 11.16 ppm for *ortho*-$C_6H_4${$NH(C_6H_4$Me-*p*)}($CH{=}NC_6H_3$*i*$Pr_2$-2,6),[10a] 11.24 ppm for *ortho*-$C_6H_4${$NH(C_6H_4$Me-*p*)}($CH{=}NC_6H_4$-Me-*p*)[10a]] as a result of the electron-withdrawing properties of the quinolyl group.

## Syntheses of the Complexes

Treatment of **2a**–**2d** with 1 equiv. of $ZnEt_2$ in toluene caused the elimination of ethane and afforded the corresponding monoethylzinc complexes **3a**–**3d** in good yields (78–85%). All complexes have good solubility in common solvents, such as toluene, dichloromethane, diethyl ether, THF, and *n*-hexane. All complexes were characterized by $^1$H and $^{13}$C NMR spectroscopy as well as elemental analysis, and satisfactory analytic results were obtained. The N–H proton signals of the free ligands disappear, and the new Zn–$CH_2$ proton signals appear at a higher field (0.55–0.02 ppm) in the $^1$H NMR spectra of complexes **3a**–**3d**, which is indicative of the formation of Zn–N bond in these compounds. The Zn–$CH_2$ carbon signals in the $^{13}$C NMR spectra are observed at –1.2 (for **3a**), –1.8 (for **3b**), –1.3 (for **3c**), and –2.9 (for **3d**) ppm. The two methyl groups of the isopropyl units in complex **3c** are inequivalent, for the coordination of the anilido–imine ligands to the zinc center causes the rotation about the N–aryl bond to become slow on the NMR timescale.[10a] All complexes have pretty good thermal stability and can be heated in boiling toluene for several hours without obvious decomposition. All complexes are air- and/or moisture-sensitive in solution and the solid state.

## Crystal Structures

The molecular structures of ligands **2a** and **2b** as well as complexes **3b** and **3c** were determined by X-ray crystallographic analysis. Crystals of ligands **2a** and **2b** suitable for X-ray crystal structure determination were grown from ethyl acetate/petroleum ether at room temp. Crystals of complexes **3b** and **3c** suitable for X-ray crystal structure de-



Scheme 1. Synthetic route for ligands **2a**–**2d** and complexes **3a**–**3d**.

termination were grown from *n*-hexane at room temp. The ORTEP drawings of the molecular structures of **2a**, **2b**, **3b**, and **3c** are shown in Figures 1 (top), 2, 3, and 4, respectively. Selected bond lengths and angles for **3b** and **3c** are given in Table 1. The crystal packing [Figure 1 (bottom)] of **2a** is consolidated by intramolecular N–H···N hydrogen bonds and weak intermolecular C–H···N interactions [3.496(2) Å, 170.2°, ($x$, 1.5 – $y$, 0.5 + $z$)] arising from the interactions between the nitrogen atom in the quinolyl ring and the hydrogen atom of the imino CH=N to form an infinite one-dimensional chain. There are no interactions between each adjacent chain. X-ray analysis revealed that the unit cell of **2b** contains two independent molecules, one of which is shown in Figure 2. There are intramolecular N–H···N hydrogen bonds but no intermolecular C–H···N interactions in the packing of **2b**. The C=N bond lengths in **2a** and **2b** [1.271(2) Å for **2a**, 1.267(4) and 1.275(4) Å for **2b**] are in the normal range.[11a] Complexes **3b** and **3c** belong to the monoclinic space group $C2/c$ and the triclinic space group $P\bar{1}$, respectively. There is an *n*-hexane solvent molecule in the unit cell of **3c**. Both **3b** and **3c** exist in the dimeric form with the nitrogen atom in the quinolyl ring coordinating to the zinc atom in another molecule. As seen in Figures 3 and 4, the zinc ions in both **3b** and **3c** adopt a distorted tetrahedral geometry with the metal center coordinated by an ethyl group, a quinolyl group, and the bidentate anilido–imine ligand. The anilido–imine ligand chelates to the zinc center to form a six-membered chelating ring that is nearly planar with the zinc atom lying 0.0371 Å (**3b**), 0.0327 Å, and 0.0926 Å (**3c**) out of the plane. The imino C=N bond [1.277(7) Å for **3b**] is slightly longer than that in the free ligand after coordination to $Zn^{II}$. The imino C=N bond in **3c** [1.290(5) Å] is longer than that in **3b** as a result of the increased steric hindrance of the isopropyl group rel-

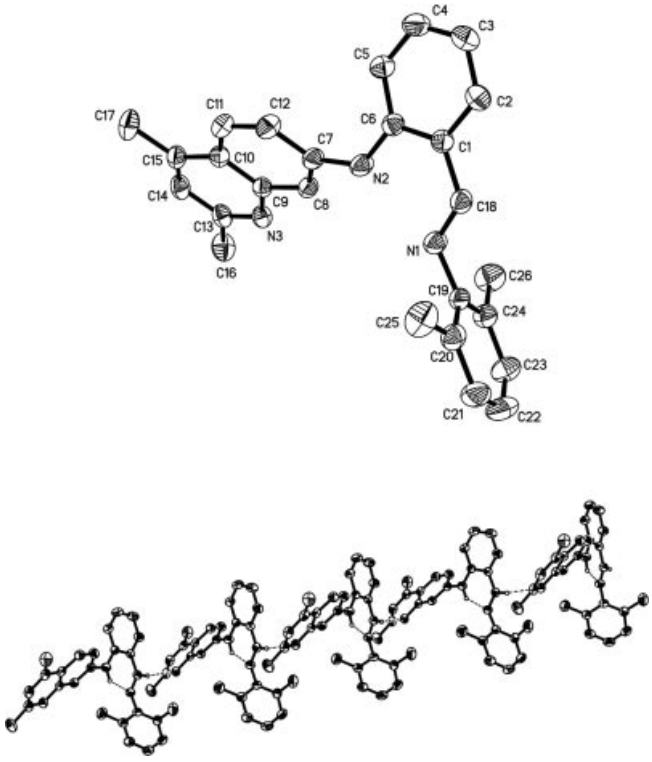

Figure 1. Top: Molecular structure of compound **2a**. Bottom: The packing of compound **2a** (hydrogen bonds are indicated by dashed lines and hydrogen atoms not involved in these interactions have been omitted for clarity, and the thermal ellipsoids are drawn at 30% probability levels).

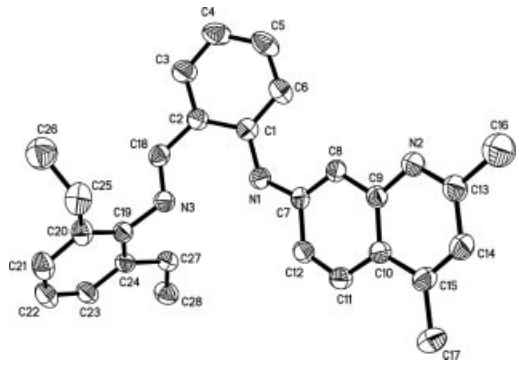

Figure 2. Molecular structure of compound **2b** (all hydrogen atoms and the other molecule have been omitted for clarity, and the thermal ellipsoids are drawn at 30% probability levels).

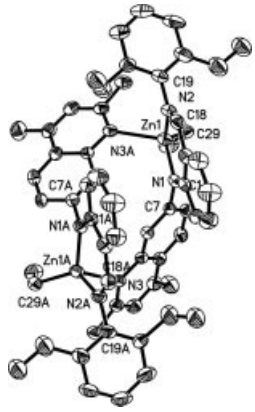

Figure 3. Molecular structure of complex **3b** (all hydrogen atoms have been omitted for clarity, and the thermal ellipsoids are drawn at 30% probability levels).

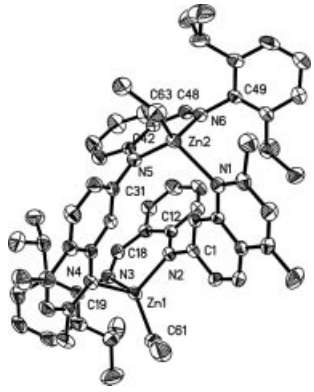

Figure 4. Molecular structure of complex **3c** (all hydrogen atoms and the *n*-hexane solvent molecule have been omitted for clarity, and the thermal ellipsoids are drawn at 30% probability levels).

ative to that of the ethyl group. The Zn–$N_{anilido}$ distances [2.014(4) Å in **3b**, 2.028(3) Å and 2.025(3) Å in **3c**] are shorter than the Zn–$N_{imine}$ distances [2.040(4) Å in **3b**, 2.055(4) Å and 2.063(3) Å in **3c**] owing to the formation of a polar (partially ionic) single bond from an electron-rich anilido nitrogen atom to the $Zn^{II}$ center as opposed to a coordination bond in the latter case. The Zn–$N_{quinolyl}$ distances [2.313(4) Å in **3b**, 2.290(4) Å and 2.266(3) Å in **3c**] are much longer than the Zn–$N_{imine}$ distances, indicating the weak coordination interaction between the zinc atom and the nitrogen atom in the quinolyl ring. The Zn–C lengths for complexes **3b** [2.012(6) Å] and **3c** [1.985(5) Å and 1.998(5) Å] are typical for such a bond[14] although slightly longer than that of similar [($C_6H_3iPr_2$)N=C(Me)CH=C(Me)N($C_6H_3iPr_2$)]ZnEt (1.96 Å).[15] The Zn–Zn separation distances are 6.625 Å in **3b** and 6.707 Å in **3c**, which is indicative of no metal–metal interaction. The $N_{imine}$–Zn–$N_{anilido}$ bite angles are 92.63(16)° (in **3b**), 92.33(14)° and 93.38(14)° (in **3c**), respectively. The dihedral angles between the six-membered chelating ring and the phenyl ring at the imine nitrogen are 80.7° (in **3b**), 77.7° and 85.6° (in **3c**), respectively. The dihedral angles between the six-membered chelating ring and the quinolyl ring are 58.7° (in **3b**), 59.9° and 122.3° (in **3c**), respectively.

## Fluorescent Properties

Table 2 summarizes the UV/Vis and fluorescent properties of compounds **2a**–**2d** and **3a**–**3d** determined in both solution and the solid state. In solution, free ligands **2a**–**2d** all have a weak emission band at $\lambda$ = 437, 437, 436, and 423 nm, respectively, whereas complexes **3a**–**3d** in solution show a stronger emission band (bandwidth at half-height = 77–79 nm) with $\lambda$ = 573, 565, 555, and 515 nm, respectively (Figure 5). The quantum yields of these complexes are relatively low in solution. According to the literature,[6a,6b,10] the observed luminescence of these complexes could be attributed to π*–π transitions of their conjugated ligands. The emission energies of these complexes are significantly red-shifted relative to those of the free ligands, which could be attributed to the fact that the coordination of the ligand to the metal center lowers the energy gap between π* and π of the ligand.[16] The emission energies of complexes **3a**–**3c** change in the order **3a** < **3b** < **3c**, depending on the size of the *ortho*-substituents of the rotatable aromatic ring attached to the imine N atom that might affect the dihedral angles between the aromatic ring and the six-membered chelating ring and thus the extent of conjugation in these complexes.[10a] The emission maxima of complexes **3a**–**3c**

Table 2. Optical properties of ligands **2a**–**2d** and complexes **3a**–**3d** in *n*-hexane and the solid state.

| Compound | Absorption [nm] ($\varepsilon$ [$dm^3 mol^{-1} cm^{-1}$]) | Emission $\lambda$ [nm] | Quantum yields[a] $\phi$ | Conditions (at $T$ = 298 K) |
|---|---|---|---|---|
| **2a** | 386 (14713) | 437 | 0.002 | *n*-hexane |
| | | 468 | | solid |
| **2b** | 383 (20480) | 437 | 0.002 | *n*-hexane |
| | | 468 | | solid |
| **2c** | 384 (23431) | 436 | 0.003 | *n*-hexane |
| | | 467 | | solid |
| **2d** | 372 (14253) | 423 | 0.015 | *n*-hexane |
| | | 436 | | solid |
| **3a** | 476 (11319) | 573 | 0.042 | *n*-hexane |

are redshifted by about 40–58 nm relative to the emission maximum of complex **3d** because of the larger conjugated quinolyl ring in **3a**–**3c**. All complexes **3a**–**3d** emit bright fluorescence in the solid state upon irradiation with an adequate excitation wavelength. The emission spectra of complexes **3a**–**3d** in the solid state are shown in Figure 6. Complexes **3a**–**3d** have a relatively narrow band (bandwidth at half-height = 72, 64, 55, and 60 nm) in the solid state with $\lambda$ = 583, 561, 553, and 523 nm, respectively. It seemed that the coordination number of zinc does not play a role in the fluorescence. The emission maxima of complexes **3b** and **3c** in the solid state are slightly blueshifted relative to their corresponding emission maxima in solution; this may be due to the reduced conjugation of the two complexes, as the free rotation of the aryl rings in these complexes is blocked in the solid state. The emission maxima of complexes **3a** and **3d** in the solid state show a redshift relative to their corresponding emission maximum in solution, which is normally observed for most fluorescent compounds in the solid state probably owing to π–π stacking of aromatic rings in the molecules.[6b]

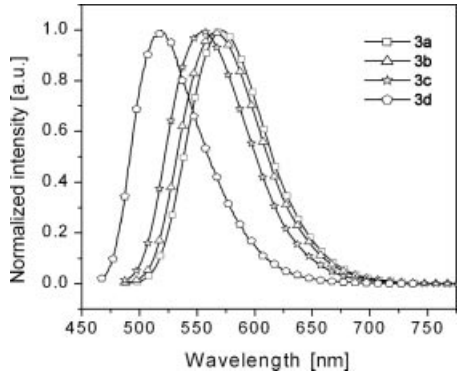

Figure 5. Emission spectra of complexes **3a**–**3d** in *n*-hexane.

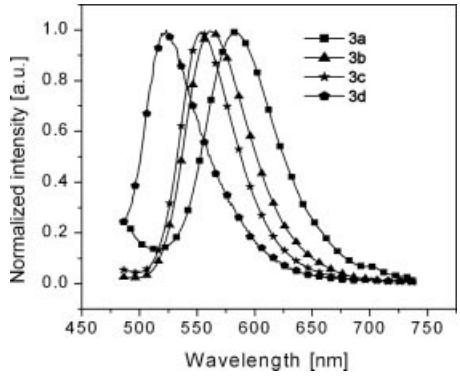

Figure 6. Emission spectra of complexes **3a**–**3d** in the solid state.

## Experimental Section

**General:** All organometallic reactions were performed by using standard Schlenk techniques under an atmosphere of high-purity argon or by using glove box techniques. Toluene, *n*-hexane, and THF were dried by refluxing over sodium and benzophenone and distilled under an atmosphere of argon prior to use. $C_6D_6$ was dried with activated 4 Å molecular sieves and vacuum-transferred to a sodium-mirrored air-free flask. $CDCl_3$ was dried with $CaH_2$ for 48 h and vacuum-transferred to an air-free flask. $ZnEt_2$ and *n*BuLi were purchased from Aldrich and used as received. *ortho*-$C_6H_4F(CH{=}NC_6H_3Me_2$-2,6) (**1a**) and *ortho*-$C_6H_4F(CH{=}NC_6H_3$-*i*$Pr_2$-2,6) (**1c**) were synthesized according to literature procedures.[11] 7-Amino-2,4-dimethylquinoline was synthesized according to a literature procedure.[17] The ligand *ortho*-$C_6H_4$-$(NHC_6H_3Me_2$-2,6)$(CH{=}NC_6H_3i Pr_2$-2,6) (**2d**) was synthesized according to a literature method.[12] $^1$H and $^{13}$C NMR spectra were measured with a Varian Mercury-300 or Bruker AVANCE-500 NMR spectrometer. Elemental analyses were performed with a Perkin–Elmer 2400 analyzer. UV/Vis absorption spectra were recorded with an UV-3100 spectrophotometer. Fluorescent measurements were carried out with an RF-5301PC.

***ortho*-$C_6H_4F(CH{=}NC_6H_3Et_2$-2,6) (1b):** A mixture of *ortho*-fluorobenzaldehyde (4.00 mL, 37.7 mmol), 2,6-diethylaniline (6.20 mL, 37.7 mmol), and anhydrous $MgSO_4$ (1 g) in *n*-hexane (40 mL) was stirred at room temp. for 2 h. The mixture was filtered, and the solvents were evaporated to dryness to give the product as salmon pink oil. The crude product was purified by reduced-pressure distillation. Yield: 6.0 g, 62%. $^1$H NMR (500 MHz, $CDCl_3$, 298 K): $\delta$ = 1.16 (t, $J$ = 7.5 Hz, 2×3 H, $CH_2CH_3$), 2.51 (q, $J$ = 7.5 Hz, 2×2 H, $CH_2CH_3$), 7.06 (d, $J$ = 6.5 Hz, 1 H), 7.11 (d, $J$ = 7.5 Hz, 2 H), 7.16 (t, $J$ = 9.5 Hz, 1 H), 7.29 (t, $J$ = 7.5 Hz, 1 H), 7.50 (q, $J$ = 7.5 Hz, 1 H), 8.25 (t, $J$ = 7.5 Hz, 1 H), 8.55 (s, 1 H, C*H*=N) ppm. $^{13}$C{$^1$H} NMR (125.1 MHz, $CDCl_3$, 298 K): $\delta$ = 15.1 ($CH_2CH_3$), 25.1 ($CH_2CH_3$), 116.3 (d, $^2J_{C,F}$ = 21 Hz), 124.2 (quaternary aromatic), 124.6, 124.9 (d, $^3J_{C,F}$ = 3.5 Hz), 126.7, 128.1 (d, $^4J_{C,F}$ = 2.6 Hz), 133.4 (d, $^3J_{C,F}$ = 8.5 Hz), 133.5 (quaternary aromatic), 150.8 (quaternary aromatic), 156.1 (d, $^3J_{C,F}$ = 4.8 Hz, *C*H=N), 163.2 (d, $^1J_{C,F}$ = 253.5 Hz, *C*F) ppm. $C_{17}H_{18}FN$ (255.33): calcd. C 79.97, H 7.11, N 5.49; found C 79.89, H 7.20, N 5.56.

***ortho*-$C_6H_4${7-NH(2,4-$Me_2$)$C_9H_4N$}$(CH{=}NC_6H_3Me_2$-2,6) (2a):** A solution of *n*BuLi (1.60 M, 22.5 mmol) in *n*-hexane was added to a solution of 7-amino-2,4-dimethylquinoline (3.89 g, 22.5 mmol) in THF (30 mL) at –78 °C. The mixture was warmed to room temp. and stirred overnight. The resulting solution was transferred into a solution of *ortho*-$C_6H_4F(CH{=}NC_6H_3Me_2$-2,6) (5.09 g, 22.5 mmol) in THF (30 mL) at 25 °C. After stirring for 2 d, the reaction was quenched with $H_2O$ (20 mL). The organic phase was evaporated to dryness to give the crude product as a brown oil that was purified by column chromatography on silica gel (ethyl acetate/petroleum ether, 1:5) to give the pure product as yellowish crystals (3.5 g, 41%). $^1$H NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 2.21 (s, 2×3 H, $CH_3$), 2.65 (s, 3 H, quinolyl-$CH_3$), 2.72 (s, 3 H, quinolyl-$CH_3$), 6.93 (t, $J$ = 7.5 Hz, 1 H, Ph-*H*), 6.98–7.03 (m, 2 H, Ph-*H* and quinolyl-*H*), 7.11–7.13 (d, 2 H, Ph-*H*), 7.33–7.42 (m, 3 H, Ph-*H* and quinolyl-*H*), 7.81 (d, $J$ = 8.4 Hz, 1 H, Ph-*H*), 7.86 (d, $J$ = 9.3 Hz, 1 H, Ph-*H*), 8.03 (s, 1 H, quinolyl-*H*), 8.36 (s, 1 H, C*H*=NAr), 11.64 (s, 1 H, quinolyl-N*H*) ppm. $^{13}$C{$^1$H} NMR (75.4 MHz, $CDCl_3$, 298 K): $\delta$ = 18.5 ($CH_3$), 18.6 ($CH_3$), 24.9 (quinolyl-$CH_3$), 114.3, 114.9, 118.3, 119.0, 121.0, 121.2, 122.4, 124.1, 124.7, 127.8, 128.2, 132.1, 134.8, 142.4, 144.3, 144.8, 148.7, 150.1, 158.9, 165.8 (*C*H=N) ppm. $C_{26}H_{25}N_3$ (379.50): calcd. **X-ray Structure Determinations of 2a, 2b, 3b, and 3c:** Single crystals of **2a** and **2b** suitable for X-ray structural analysis were obtained from ethyl acetate/petroleum ether at room temp. Single crystals of **3b** and **3c** suitable for X-ray structural analysis were obtained from *n*-hexane at room temp. Diffraction data were collected at 293 K with a Rigaku R-AXIS RAPID IP diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) for all compounds. The structures were solved by direct methods[18] and refined by full-matrix least-squares on $F^2$. All non-hydrogen atoms were refined anisotropically and the hydrogen atoms were included in idealized position. All calculations were performed by using the SHELXTL[19] crystallographic software packages. Details of the crystal data, data collections, and structure refinements are summarized in Tables 3 (**2a** and **2b**) and 4 (**3b** and **3c**). CCDC-636086 (for **2a**), -636087 (for **2b**), -636088 (for **3b**), and -636089 (for **3c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Introduction of Modified Electronic Parameters – Searching for a Unified Ligand Properties Scale through the Electrophilicity Index Concept

**Christodoulos Makedonas[a] and Christiana A. Mitsopoulou*[a]**

**Keywords:** Modified electronic parameters / Electrophilicity index / Diimine complexes / Reduction potential / Charge-transfer bands

In order to quantify the contribution of mainly, but not only, diimine ligands to the electronic properties of the corresponding complexes, two novel indices, namely modified electronic parameters (*ModEP*) and electrophilicity, $\omega$, are introduced and discussed in this report. First, we introduce the concept of *ModEP*, a novel scale relating to the electronic properties of diimine ligands. Mainly on the basis of well-characterized M(diimine)(dithiolato) complexes (M = Pt, Pd, or Ni), we derive the contribution of the diimine ligand to the reduction potentials of the complexes, and incorporating its contribution to the main charge-transfer band of the UV/Vis spectra, we obtain our *ModEP* values. The applicability of the introduced scale to several other classes of diimine compounds (W, Re, and Ru) is then tested. The performance of our scale in predicting the values of the reduction potentials and the position of the charge-transfer bands is very satisfactory. With this approach, some interesting aspects of ligand coordination were revealed. Next, we employ the recently introduced electrophilicity index $\omega$, in order to correlate our *ModEP* scale with various other empirical scales that are already known and extensively used. This permits us to unify most known scales, which were primarily derived for different types of ligands (e.g. *ModEP* for diimines, Tolman's for phosphanes). The proposed method of $\omega$ calculation (at the semiempirical AM1 level) avoids any experimental limitation and can be employed even for ligands that are not yet experimentally available, whereas its correlation to the known scales would immediately provide the properties of the compound. This supports the idea that the electrophilicity index could become a powerful tool in coordination and organometallic chemistry.

## Introduction

All the properties of inorganic and organometallic complexes and their potential applications, from the field of homogeneous catalysis to materials and from photochemistry to DNA binding and intercalation are determined by the combination of metal and ligand. However, for a given series of homologous compounds with the same metal, the role of the ligand in terms of both electronic and steric effects becomes dominant. For decades, coordination and organometallic chemists have been trying to find a way to predict the effect of a ligand change upon the properties of a complex,[1–7] trying to avoid the need for extensive synthetic work. This essential need for knowledge of ligand effects on a certain core or fragment is extended not only to different types of known ligands, but also to ones that have merely been considered for future work. In this sense, great effort has been put into the development of ligand parameters, on the basis of which properties of known compounds would be documented and properties of new ones could be predicted.

Of known importance is Tolman's electronic parameter (*TEP*) relating to phosphanes ($PR_3$).[1] It was derived on the basis of the $A_1$ $\nu$(CO) stretching vibration of $(R_3P)Ni(CO)_3$ complexes. As it is justified by backbonding theory, the greater the donor power of the phosphane the lower the stretching mode becomes. *TEP* has found wide usage over the years, but the expansion of the model is limited by the requirement that a new ligand L along with the corresponding $NiL(CO)_3$ complex should be synthesized and spectroscopically investigated, and this is not always an easy task.

This limitation is overcome by Crabtree's calculated electronic parameters (*CEP*).[2] In this approach, the $A_1$ $\nu$(CO) frequency is no longer experimentally derived, but it is calculated by means of density functional theory (DFT). The relative donor powers of a wide variety of cationic, neutral, and negatively charged ligands are reliably predicted; expanding the model, these parameters also correlate well with other empirically derived parameters. Even though the method avoids any experimental limitations, it incurs computational costs and provides no values for bidentate ligands, such as diimines.

Lever's electronic parameters (*LEP*)[3] are based on the electrochemical $E°$ value for various redox couples, notably $Ru^{III}/Ru^{II}$, in series of complexes containing the ligands of interest. *LEP* cover a much wider set of ligands than Tol-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

man's scale, including anionic, O- and N-donor ligands. On the other hand, it has the disadvantage that an electrochemical apparatus for measurements is necessary, which is not always available. Another disadvantage of *LEP* is that electrochemical irreversibility can degrade the quality of the data for certain ligands, and solvation and ion-pairing effects could interfere to some extent.

Hammett substitution constants $\sigma$ have found wide usage both with organic and inorganic compounds.[5] These were defined by the ionization constants of the appropriately substituted benzoic acids. The most extensively employed are $\sigma_p$ and $\sigma_m$, relating to *para*- and *meta*- substituent effects, respectively. Hammett constants in most of the cases have only qualitative value, providing synthetic chemists with trends, but not with accurate properties of compounds under preparation. Moreover, they are limited by their own nature. They provide the trends that would arise by the substitution of a ligand in certain positions, but they can not show which effects would arise from a different ligand. Thus, in the case of the 2,2′-bipyridine ligand, for example, Hammett substitution constants might work if the substituents are added in the 4 and 4′ positions, but they will fail to predict what will happen if bipyridine is replaced by 1,10-phenanthroline or an aliphatic ligand, such as diiminosuccinonitrile.

Recently, Arca et al.[6] gave a quantitative description of the effect induced by both the metal and the ligands to the value of $\lambda_{max}$ in a series of dithiolene complexes of the M(R,R′timdt)$_2$ type and Poë et al.[7] presented an analysis of CO dissociative kinetics of Ru(CO)$_4$L (L = P-donor ligands).

Keeping all of the above in mind, herein we present our efforts to obtain a unified ligand properties scale. Our investigation for a quantitative analysis of ligand effects (QALE)[8–14] was carried out at two levels. In the first, we introduce the concept of modified electronic parameters (*ModEP*), a novel scale relating to the electronic properties of diimine ligands. Mainly on the basis of the well-characterized M(diimine)(dithiolato) complexes (M = Pt, Pd, or Ni), we derive the contribution of the diimines to the reduction potential of the complexes; in the next step, we incorporate their effect on the main charge-transfer band of the visible spectra of the complexes, and then we obtain our *ModEP* values. There are two reasons for choosing this class of complexes for our analysis. First of all, an extensive series of this type of compounds has been presented.[15–72] Furthermore, the interest toward mixed diimine–dithiolato complexes of d$^8$ metals is related to their unique properties, which include solution luminescence, solvatochromism, large molecular hyperpolarizabilities, and large excited-state oxidation potentials. Because of these properties, they are considered to be very promising candidates for nonlinear optical (NLO) materials, molecular photochemical devices (MPD), and photosensitizers for solar cells.

The electronic properties depend most likely on the existence in the same molecule of two different unsaturated chelating ligands, one of which is a good π*-donor (the dithiolato ligand) and the other a good π*-acceptor (the diimine). The possibility of applying mixed diimine–dithiolato complexes to any of the above-mentioned technologies mainly relies on the intense solvatochromic, visible absorption in the neutral state, $E_{MMLL'CT}$, caused by the mixed-metal–ligand-to-ligand-charge-transfer (MMLL′CT)[26] transition between the HOMO and LUMO, where the former is a mixture of metal and dithiolato ligand orbital and the latter a π* orbital of the diimine. This assignment has been confirmed by TD-DFT calculations,[69–72] and both experimental[16–34] and theoretical results[69–72] indicate that its frequency can be tuned from near-Vis to NIR by changing the substituents both at the diimine and dithiolate moieties. These complexes face a reversible, diimine-based, reduction process, which is well characterized.

Up to now, despite the extensive study of M(diimine)(dithiolato) complexes, only some general trends of the nature of the substituent groups on the main substrate of the diimine or dithiolato ligand have been revealed, but none of this data is in quantitative form. Between the two ligands, the one that is less studied from the point of view of its effect on the properties of a molecule is certainly the diimine.

The applicability of the introduced scale is then tested on several other types of W, Re, and Ru diimine compounds. The performance of our scale in predicting the value of the reduction potentials and the position of the charge-transfer bands is very satisfactory.

In the next level of investigation, we employ the recently introduced electrophilicity index $\omega$,[73] in order to correlate our *ModEP* scale with various other empirical scales that are already known and extensively used. This procedure gives us the chance to unify all these scales, which were derived by investigating different types of ligands (e.g. *ModEP* on diimines, Tolman's on phosphanes). This supports the idea that the electrophilicity index could become a powerful tool in coordination and organometallic chemistry.

## Computational Details

All the experimental data presented are taken from already published reports. In the following discussion, the abbreviations used for compounds are as follows: tdt = toluene-3,4-dithiolato, bpy = 2,2′-bipyridine, php = 1,10-phenanthrolinopyrrole, tmphen = 3,4,7,8-tetramethyl-1,10-phenanthroline, 3,5,6,8-tetramethyl-1,10-phenanthroline, *i*Pr-pya = *N*-isopropylpyridine-2-carbaldimine, dmphen = 4,7-dimethyl-1,10-phenanthroline, Bu-pya = *N*-butylpyridine-2-carbaldimine, 6,6′-dmbpy = 6,6′-dimethyl-2,2′-bipyridine, dbbpy = 4,4′-di-*tert*-butyl-2,2′-bipyridine, dmbpy = 4,4′-dimethyl-2,2′-bipyridine, 5,5′-dmbpy = 5,5′-dimethyl-2,2′-bipyridine, 2,9-dmphen = 2,9-dimethyl-1,10-phenanthroline, 5,6-dmphen = 5,6-dimethyl-1,10-phenanthroline, 2,9-dm-4,7-dpphen = 2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline, mphen = 5-methyl-1,10-phenanthroline, dpphen = 4,7-diphenyl-1,10-phenanthroline, pphen = 4-phenyl-1,10-phenanthroline, phen = 1,10-phenanthroline, dpbpy = 4,4′-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

diphenyl-2,2′-bipyridine, Cl-phen = 5-chloro-1,10-phenanthroline, Br-phen = 5-bromo-1,10-phenanthroline, $Br_2$-bpy = 4,4′-dibromo-2,2′-bipyridine, $Cl_2$-bpy = 4,4′-dichloro-2,2′-bipyridine, $NO_2$-phen = 5-nitro-1,10-phenanthroline, bipym = 2,2′-bipyrimidine, EHC-bpy = 4,4′-bis(2-ethylhexyloxycarbonyl)-2,2′-bipyridine, *t*Bu-DAB = *tert*-butyl-*N*,*N*′-bis(1,4-diazabutadiene), EC-bpy = 4,4′-bis(ethoxycarbonyl)-2,2′-bipyridine, dcphen = 4,7-dicarboxy-1,10-phenanthroline, dcbpy = 4,4′-dicarboxy-2,2′-bipyridine, BABA = biacetylbisaniline, dthdi = *N*,*N*′-ditolyl-3,4-hexanediimine, $(CF_3)_2$-bpy = 4,4′-ditrifluoromethyl-2,2′-bipyridine, $(NO_2)_2$-bpy = 4,4′-dinitro-2,2′-bipyridine, disn = diiminosuccinonitrile, bbqdi = *semi*-4-benzoylbenzoquinonediimine.

The calculation of the ground-state electronic structure of a Pt(bpy)(tdt) complex has been performed by using density functional theory[73,74] methods with the GAUSSIAN 1998 software package.[75] The functional used throughout this study is the B3LYP, consisting of a hybrid exchange functional as defined by Becke's three-parameter equation[76] and the Lee–Yang–Parr correlation functional.[77] The ground-state geometry was obtained in the gas phase by full geometry optimization, under no symmetry constraint. The VeryTight option was used, which demands tighter convergence criteria than the default ones, while numerical integration was performed with the UltraFine option, which requests a pruned (99,590) grid. The optimum structures located as stationary points on the potential energy surfaces were verified by the absence of imaginary frequencies. The derived wavefunctions were found to be free from internal instabilities. The basis set used for all nonmetal atoms was the well-known valence triple-zeta 6-311+G*.[78,79] The quasi-relativistic Stuttgart–Dresden effective core potential of the type ECP60MWB was used for Pt, and complemented by the corresponding valence basis sets.[80] Percentage compositions of molecular orbitals from the three contributing fragments were calculated with the AOMix program.[81,82]

Ground-state electronic structure calculations of all other compounds including the net ligands have been performed by using the AM1[83] and PM3[84,85] semiempirical techniques, with MOPAC2000[86] as implemented in the CAChe software package.[87] Structures have been preoptimized under the MM3 force field.[88] The ground-state geometries were obtained in the gas phase by full geometry optimization, under no symmetry constraint. Structures of the 2,2′-bipyridine derivatives and nonaromatic bidentate ligands have been considered under their planar arrangement (the binding N–C–C–N dihedral angle was set to zero). These geometries correspond to the first-order saddle point (transition state) that links the two energy minima at the potential energy surface through rotation of the C1–C1′ bond. We preferred to use this structure, because the compounds have this structure at the time of complex formation. For the rest of the compounds under study, the optimum structures were verified by the absence of imaginary frequencies. Frontier orbital contour plots presented herein were prepared with the aid of MOLEKEL.[89]

## Results and Discussion

### Deriving the Model – Modified Electronic Parameters

Our methodology for obtaining a structure-to-properties relation (SPR) will be based on Lever's arguments[3] and the general theory of ligand properties additivity,[90–93] starting from electrochemical data. According to the additivity theory, redox potentials of the complexes can be regarded as an additive property made up of the contributions of both the metals and the coordinated ligands. The weight of these contributions is defined by the percentage of each component of the LUMO orbital of the complex, since the relation between $E°$ and LUMO energy is well documented.[67,68] Our approach has five levels and provides the following equation [Equation (1)].

$$ModEP = -0.0001343\ E_{MMLL'CT} + 1.1671129\ (R^2 = 1) \quad (1)$$

(1) As we have already mentioned, we set the basis of our reasoning on the M(diimine)(dithiolato) complexes and especially on those with Pt, not only for their plethora, but also because they are more important candidates for potential applications.[17] In these compounds, the LUMO orbital is localized mainly on the diimine core as has been indicated both experimentally and theoretically.[69–72] Moreover, we needed a model compound, and Pt(bpy)(tdt) contains all the necessary prerequisites for this. First of all, platinum is coordinated to two bidentate ligands; both of them are good σ-donors, having medium π*-donating (the dithiolato)/π*-accepting (the diimine) ability. Secondly, there is a series of eight Pt(diimine)(tdt) complexes that are well characterized, with defined electrochemical and spectroscopic behavior (vide infra).[24]

(2) The origin of our model is based on reduction potentials. Pt(bpy)(tdt) has a reversible reduction wave at –1.339 V in a DMF solution.[24] This value arises from the contribution of both the diimine and the Pt/tdt fragment. In order to determine the contribution of diimine to this, we performed ground-state electronic calculations for the complex under investigation at the DFT level of theory. The frontier orbital energies along with the contributions from the two ligands and the metal are given in Table 1, while the HOMO and LUMO are presented in Figure 1.

The HOMO, a $b_1$ orbital in the local sense, is composed mainly of sulfur $3p_z$ orbitals on the chelating ring, while the LUMO is calculated to be located almost on the diimine with a limited contribution from the metal and dithiolato ligand. The calculated contribution of 2,2′-bipyridine to the LUMO orbital is 87%. Thus, we dissect the first reduction potential into two parts and *credit by definition* a value of $E_1 = -1.165$ V to the diimine, according to its contribution to the whole potential (87% of $E(Pt^{0/-})$. The remaining $E_2 = -0.174$ V is attributed to the system Pt/tdt. Once these values are well defined, we can obtain the corresponding values for all diimine ligands that are bound to the Pt(tdt) fragment, bearing in mind that the experimental conditions for the derivation of the corresponding potentials must be the same.

Table 1. Contribution of different fragments to Pt(bpy)(tdt) valence orbitals. The HOMO and LUMO are shown in bold.

| MO | *E* [eV] | Metal | Dithiolato | Diimine |
|---|---|---|---|---|
| Unoccupied | | | | |
| 95 | –0.64 | 38.7 | 2.4 | 58.9 |
| 94 | –1.02 | 44.9 | 47.4 | 7.7 |
| 93 | –1.78 | 1.4 | 0.5 | 98.2 |
| 92 | –2.02 | 1.4 | 0.5 | 98.1 |
| **91** | **–2.90** | **5.4** | **7.4** | **87.2** |
| Occupied | | | | |
| **90** | **–4.67** | **9.5** | **80.5** | **10.0** |
| 89 | –5.05 | 13.8 | 84.5 | 1.7 |
| 88 | –6.37 | 68.5 | 23.9 | 7.6 |
| 87 | –6.60 | 28.5 | 67.2 | 4.3 |
| 86 | –6.74 | 33.7 | 60.5 | 5.8 |
| 85 | –7.23 | 43.6 | 52.6 | 3.8 |

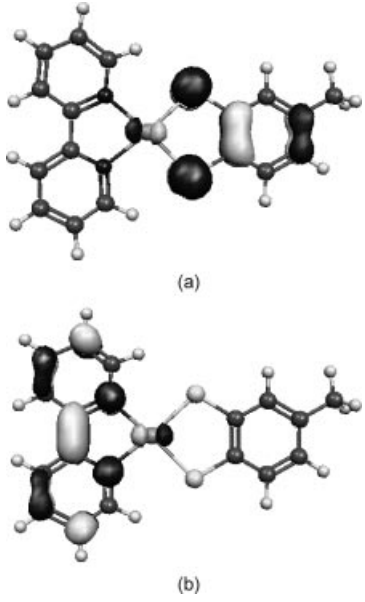

Figure 1. Contour plots of HOMO (a) and LUMO (b) orbitals of Pt(bpy)(tdt).

(3) Assuming that the $E_2$ value is kept constant along the series of eight Pt(diimine)(tdt) complexes,[24] we obtain the corresponding electronic parameters (*EP*) / contributions for the diimine ligands (taking the $E°$ values from Table 2) according to Equation (2).

$$EP = E_{\text{red (of each complex)}} - 0.13E_{\text{red/(dpy)Pt(tdt)}} \quad (2)$$

Thus, we get *EP* = –1.321 V for tmphen, –1.224 V for dbbpy, –1.197 V for dmbpy, –1.165 V for bpy, –1.145 V for phen, –1.083 V for Cl-phen, –0.869 V for $Cl_2$-bpy, and –0.788 V for EC-bpy.

On the basis of the well-documented interconnection of LUMO, $E_{red}$, and $E_{MML'CT}$, there should be a linear relation between the derived *EP* and the observed values of $E_{MML'CT}$ for the main low-energy solvatochromic band of these compounds. As a matter of fact, this is true, and an excellent correlation coefficient of 0.98 is derived (Figure 2).

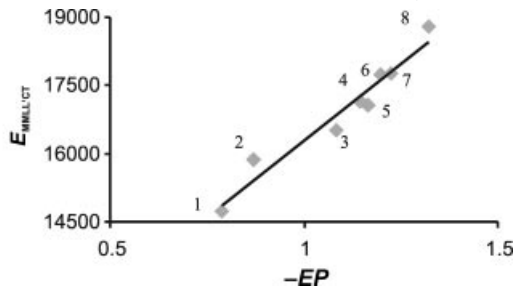

Figure 2. Graphic representation of the function $E_{MML'CT} = f(–EP)$ for M(diimine)(tdt) complexes. Spectra of Pt(EC-bpy(tdt) (1), Pt($Cl_2$-bpy)(tdt) (2), Pt(Cl-phen)(tdt) (3), Pt(bpy)(bdt) (4), Pt(phen)(tdt) (5), Pt(dmbpy)(tdt) (6), Pt(dbbpy)(tdt) (7), and Pt(tmphen)(tdt) (8) were recorded in $CH_2Cl_2$.

(4) Using the regression line derived from the original data, we recalculated *EP* values for any prespecified $E_{MML'CT}$. This recalculation was done in order to predict the *EP* values of the ligands not included in our primary data, on the basis of their $E_{MML'CT}$ values and also to reduce the error introduced by the assumption that the contribution of the Pt/tdt fragment to the reduction potential of the compound is the same.

So, *EP*s are reevaluated for these eight diimines, and the obtained values are called, for the needs of our discussion, modified electronic parameters (*ModEP*). Thus, *ModEP* becomes –1.359 V for tmphen, –1.220 V for dbbpy, –1.215 V for dmbpy, –1.126 V for bpy, –1.138 V for phen, –1.054 V for Cl-phen, –0.966 V for $Cl_2$-bpy, and –0.812 V for EC-bpy, according to Equation (1).

(5) Mainly on the basis of a large number of data for M(diimine)(dithiolato) compounds (Table 2) and the eight "starting" values derived in the previous paragraph, we have obtained the *ModEP* values for a satisfactory number of diimines (Table 3).

## Explanation and Physical Basis

Up to now, we have indicated the formulation employed in order to obtain *ModEP* values. In this section, we shall try to explain the properties of the new scale and the necessary prerequisites that a complex should satisfy in order for the additivity concept to be valid. First of all, *ModEP* values are given in V, but as soon as they are calculated they no longer depend on any experimental condition. This fact is justified, because *ModEP* values correspond to differences in reduction potentials and shifts in the energy of a charge-transfer band, measured under the same experimental conditions. So, for a series of compounds with different diimines, *ModEP* should correlate well with a ligand-based reduction potential and with the corresponding charge-transfer band as long as the experimental conditions are the same, no matter what these are. Subsequently, the *ModEP* values were calculated in order to provide the link between the ligands and the properties of the corresponding complexes. In this sense, diimines with large *ModEP* values when coordinated to a metal lead to easier reduction of the

resultant complexes in a way that can be accurately predicted. Moreover, they stabilize the LUMO of the complexes. In other words, they cause a red shift of the main charge-transfer band, and its $\lambda_{max}$ is accurately predicted by correlations of the $E_{MMLL'CT} = f(ModEP)$ type.

Furthermore, *ModEP* values are indicative of the σ- and π- bonding ability of the diimines, covering a range of 1000 mV. In addition to this, when comparing diimines of the same core, such as 1,10-phenanthroline derivatives (e.g. dpphen and phen), *ModEP* values could be used as indices of only π-effects, provided that in these ligands the σ-donating ability is almost the same.

On the basis of the aforementioned discussion, we can set up the necessary arguments in order for the additivity concept to be valid and the expected accuracy of a prediction to be high. Thus, (i) reduction potentials under consideration must be reversible or at least quasi-reversible, (ii) the reduction process must be described by the scheme ML(diimine$^{-}$), (iii) the reduction must occur to the same unoccupied orbital (from an energetic and symmetry point of view). In the complexes under study, this is the diimine-based LUMO. Further, (iv) the charge-transfer band must be attributed to the same orbital, for example, in the case of M(diimine)(dithiolato) compounds, the main UV/Vis band arises from a singlet state well described by the HOMO → LUMO notion,[69–72] and (v) the effect of the solvent must be taken into account: comparison between either spectroscopic or electrochemical results is only possible if the same solvent is used. The reason for this is quite obvious. M(diimine)(dithiolato) complexes are greatly solvatochromic as a result of their polar ground state, and the nonpolar (or even polar in the opposite direction) excited state and this solvatochromism affects also their redox behavior.

Before testing the applicability of *ModEP*, we investigated its correlation to Hammett constants, since the latter meet a general acceptance and have found wide application. These were defined by the ionization constants of the appropriately substituted benzoic acids. In the case under study and in order to find out whether there are any correlations, we had to make a concession that had to do with the applicability of Hammett constants. Hammett constants can find application only in cases of ligands that have the same core, differing in terms of the substituting groups in exact positions, e.g. 4,4′-X,X-2,2′-bipyridines. In order to partly overcome this problem, we employed $\sigma_t$ values, as defined by Equation (3), where $\sigma_p$, $\sigma_m$, and $\sigma_o$, represent *para*-, *meta*-, and *ortho*- substituent effects, respectively.

$$\sigma_t = \Sigma\sigma_p + \Sigma\sigma_m + \Sigma\sigma_o \quad (3)$$

It is obvious that the *ModEP* scale surpasses Hammett constants in the sense that the former contains at the same time aromatic (e.g. 1,10-phenanthroline), "semi-aromatic" (e.g. *N*-butyl-pyridine-2-carbaldimine), and aliphatic (e.g. diiminosuccinonitrile) entries, while the latter gives the relation among ligands that are derivatives of the same parent compound. The Hammett constants employed are presented in Table 4 (vide infra). For 13 bipyridine derivatives, we obtain the relation in Equation (4) (Figure 3).

$$\sigma_t = 2.74\ ModEP + 3.10 \quad (4)$$

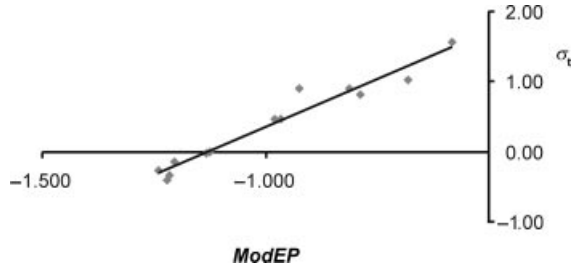

Figure 3. Graphic representation of the relation $\sigma_t = f(ModEP)$ for 13 2,2′-bipyridine derivatives ($R^2 = 0.96$).

The fit is excellent ($r = 0.96$). Moreover, in Figure 4, the corresponding correlation for 14 1,10-phenanthroline derivatives is depicted. A linear relation is also evident ($r = 0.93$) here [Equation (5)].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

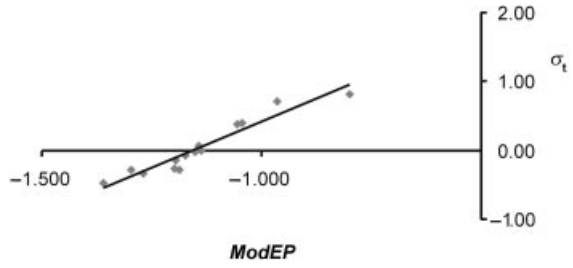

Figure 4. Graphic representation of the relation $\sigma_t = f(ModEP)$ for 14 1,10-phenanthroline derivatives ($R^2 = 0.93$).

$$\sigma_t = 2.68\ ModEP + 3.09 \quad (5)$$

Comparing Equations (4) and (5), we conclude that the same substituent groups on both aromatic ligands, namely phen and bpy, have a similar effect. Moreover, assuming that σ- donation is identical along the same series, this supports our belief that *ModEP* values are indicative of π- effects.

For an extensive series of M(diimine)(dithiolato) compounds, keeping the M(dithiolato) fragment constant and correlating *ModEP* with the experimentally derived reduction potentials and the charge-transfer energies, we conclude that our scale works fine with the compounds under consideration. The maximum error in the ligand-based reduction potential is 43 mV (the experimental error in most cases is around 10 mV) and a few nm in the case of the UV/Vis spectra. As a result, we are able to predict the properties of compounds that are not yet prepared. As an example, we employ again the series of Pt(diimine)(tdt) compounds mentioned earlier and three 1,10-phenanthroline derivatives, namely $NO_2$-phen (*ModEP* = –0.963 V), pphen (*ModEP* = –1.143 V), and 5,6-dmphen (*ModEP* = –1.194 V). Equation (6) gives the relation $E_{red} = f(ModEP)$ and Equation (7), the relation $E_{MMLL'CT} = f(ModEP)$.

$$E_{red} = 1.049\ ModEP - 0.107 \quad (6)$$

$$E_{MMLL'CT} = -7742\ ModEP + 8685 \quad (7)$$

$NO_2$-phen is anticipated to have a reduction potential of –1.117 V and a CT band at 631 nm, whereas the corresponding values for pphen and 5,6-dmphen should be –1.306 V and 582 nm, and –1.360 V and 569 nm, respectively. The standard deviation in all cases is around 39 mV and less than 1 nm (the low value for the latter comes also from the modification employed).

From all the experimental data available, we conclude that the *ModEP* scale finds application in M(diimine)(dithiolato) complexes. On the other hand this class of compounds was used in order for this scale to be extracted. So, the potential use of the *ModEP* scale must be tested on other classes of compounds. In the next two sections, several examples will be presented along with a discussion on the way in which the *ModEP* scale could be enriched and what its chemical meaning really is.

## Potential Applications

Trying to investigate the potential applications of the *ModEP* scale, we tested its response in several classes of compounds. In all cases, the rules i–v formulated in the previous section were observed to hold. The cases where the overall correlation was very good were employed to enrich the *ModEP* scale.

### *M(diimine)(CO)$_4$ (M = W, Mo, Cr)*

The first class of compounds on which we tested our model was M(diimine)$(CO)_4$. These compounds are known for their negative solvatochromism and luminescence in solution and find potential applications in material science.[94–101] They have a solvatochromic band that is attributed to a MLCT transition. On the basis of data from ref.[94–101] we obtain the correlation shown in Figure 5.

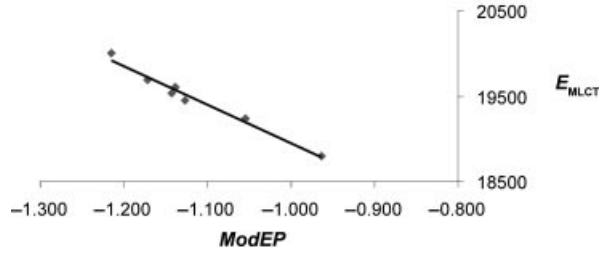

Figure 5. Graphic representation of the relation $E_{MLCT} = f(ModEP)$ for a series of W(diimine)$(CO)_4$ complexes ($R^2 = 0.98$). Transition energies were collected in benzene.

The relation $E_{MLCT} = f(ModEP)$ is linear and is described by Equation (8).

$$E_{MLCT} = -4502\ ModEP + 14449 \quad (8)$$

The maximum error anticipated for this range of transition energies is only 2 nm. Analogous relations hold also in the case of Mo and Cr, shown in Equations (9) ($R^2 = 0.97$) and (10) ($R^2 = 0.92$), respectively. Transition energies were collected in benzene.

$$E_{MLCT} = -5111\ ModEP + 14536 \quad (9)$$

$$E_{MLCT} = -4832\ ModEP + 13561 \quad (10)$$

The maximum errors in these cases are slightly larger, 3 and 5 nm, respectively, but they are certainly at a more than acceptable level. This fact supports the use of the *ModEP* scale for prediction purposes. For example, the charge-transfer band for the complex W(5,6-dmphen)$(CO)_4$, which, to the best of our knowledge, has not been prepared yet, is anticipated to be 504 ± 1 nm in benzene, on the basis of the *ModEP* value of the ligand (–1.194 V).

### *fac-[Re(CO)$_3$(CNx)(diimine)]$^+$*

Rhenium(I) tricarbonyl complexes containing bidentate heterocyclic ligands have been a source of interest for several years, largely because of their potential use in solar energy conversion.[95,102] These compounds display intense

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

luminescence in the visible region of the spectrum and have long emission lifetimes. Recently, Rillema et al. prepared a series of *fac*-[Re(CO)$_3$(CNx)(diimine)]$^+$ complexes.[103–106] These complexes have a diimine-based reversible reduction process. We tested the *ModEP* scale, searching for a correlation of the type $E_{red} = f(ModEP)$. In Figure 6, this correlation is schematically depicted, and Equation (11) gives the corresponding linear regression. The maximum deviation from linearity in this case is 42 mV.

$$E_{red} = 1.027\ ModEP - 0.035 \quad (11)$$

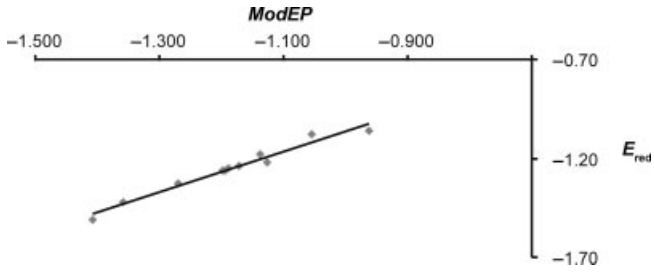

Figure 6. Graphic representation of the relation $E_{red} = f(ModEP)$ for a series of *fac*-[Re(CO)$_3$(CNx)(diimine)]$^+$ complexes ($R^2 = 0.98$). Potentials are reported vs. SSCE in $CH_3CN$ at room temperature, taken from ref.[103–106]

### *[{(diimine)Re(CO)$_3$}$_3$(μ-L)]$^+$*

The good correlation of $E_{red} = f(ModEP)$ obtained in the previous case, was tested also in a more demanding case. Sun and Lees prepared recently a series of trinuclear diimine Re$^I$ tricarbonyl complexes bridged by 1,3,5-tris-(4-ethenylpyridyl)benzene (L1) and 1,3,5-tris(4-ethynylpyridyl)benzene (L2).[107] These compounds have one or two reduction potentials, the first one representing the addition of one electron to the diimine ligands. Equations () and () give the corresponding correlations for the L1 and L2 bridges, respectively, and Figure 7 provides a graphic representation for the latter.

$$E_{red} = 2.638\ ModEP + 1.546 \quad (12)$$

$$E_{red} = 3.002\ ModEP + 1.902 \quad (13)$$

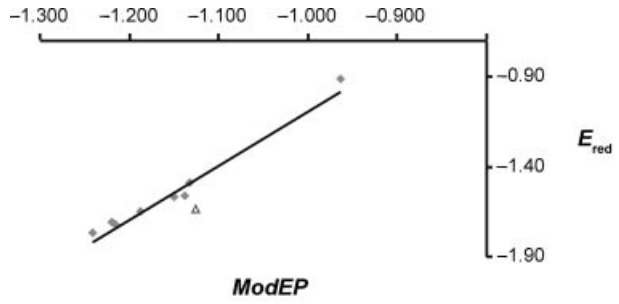

Figure 7. Graphic representation of the relation $E_{red} = f(ModEP)$ for a series of [{(diimine)Re(CO)$_3$}$_3$(μ-L2)]$^+$ complexes ($R^2 = 0.92$). The triangular point corresponds to bpy. Data taken from ref.[107]

For both cases very good correlations have been obtained. On the other hand, reduction potentials of the bpy complexes seem to deviate from linearity, but we can not provide a satisfactory explanation for that. Moreover, the slope of the linear relation is three times larger than the corresponding slope in *fac*-[Re(CO)$_3$(CNx)(dmbpy)]$^+$, which was previously described.

### *Cu$^{II}$ Uroporphyrin I Complexes*

In 1983, Shelnutt reported Raman shifts of copper uroporphyrin I induced by complex formation with phenanthroline derivatives.[108] We correlated these Raman shifts with our *ModEP* scale. A linear relation was obtained (Figure 8). Bulky derivatives have been excluded from the correlation. Shelnut observed an analogous relation to the Hammett constants and assigned this inconsistency to the fact that sterically hindered ligands can not lie flat on the porphyrin ring.

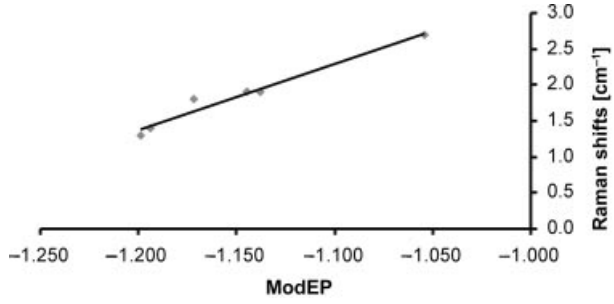

Figure 8. Graphic representation of the relation $\Delta\nu = f(ModEP)$ for the 1637 cm$^{-1}$ line for a series of 1,10-phenanthroline derivatives ($R^2 = 0.96$). Data taken from ref.[108] The experimental error is less than 1.0 cm$^{-1}$.

### *The Case of [Ru(diimine)$_3$]$^{2+}$*

[Ru(diimine)$_3$]$^{2+}$ complexes have proved to be one of the most important classes of photosensitizers ever synthesized.[109–113] Here, we shall investigate the applicability of the *ModEP* scale to these complexes and the way their properties could be predicted. First of all, this class of compounds is completely different in nature from those previously described. In their UV/Vis spectra, they have at least one MLCT band of a clear d → π* (diimine) type. This means that both the HOMO ($a_1$ and e with $D_3$ symmetry) and the LUMO ($a_2$ and e with $D_3$ symmetry) depend on the nature of the ligand. Thus, a correlation between $E_{MLCT}$ and *ModEP* or reduction potential is not expected. Moreover, more than one reversible reduction process is detected, but only one oxidation potential is present. The latter refers to the couple Ru$^{II}$/Ru$^{III}$ and can be assumed to involve the nonbonding or slightly π*-antibonding $t_{2g}$ ($a_1$ and e) metal-centered orbital.[3,82,109–115] Firstly, we tested the *ModEP* scale on the oxidation process, for which a large amount of data is available.[110] Although this process deviates from the rules previously established, it is evident that $E_{ox}$ is greatly dependent on the ligand. Thus, stronger σ-donors cause a lower oxidation potential of the Ru$^{II}$ complex, whereas more efficient π*-acceptors have the opposite ef-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fect.[110] Lever employed $E_{ox}$ also in order to derive his *LEP* parameters (vide infra). A graphic representation of the correlation $E_{ox} = f(ModEP)$ is provided in Figure 9. A regression coefficient of 0.92 is derived for this relation.

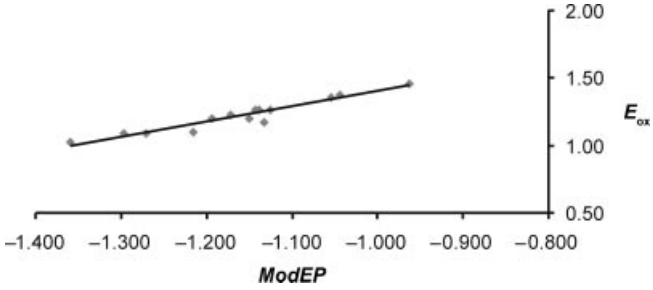

Figure 9. Graphic representation of the relation $E_{ox} = f(ModEP)$ for a series of $[Ru(diimine)_3]^{2+}$ complexes ($R^2 = 0.92$). Data taken from ref.[116]

A linear relation is obtained by employing data from ref.[116] Analogous results are extracted by employing data from ref.[110] [Equation (14)].

$$E_{red} = 1.133\ ModEP + 2.535 \quad (14)$$

Trying to find a net ligand process that could be correlated to the *ModEP* scale, we ended up with the excited-state oxidation potentials. $E_{ox}$* refers to an abstraction of an electron from the LUMO, and this process must certainly be dependent on the ligand, surpassing delocalization problems. An almost perfect correlation is observed (Figure 10).

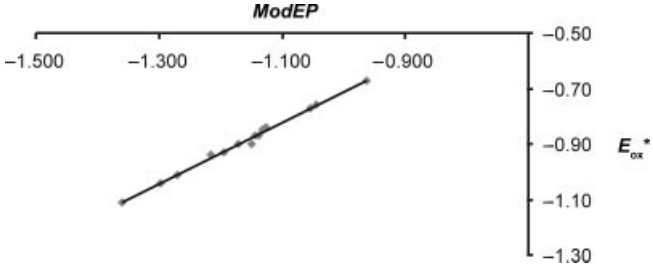

Figure 10. Graphic representation of the relation $E_{ox}^* = f(ModEP)$ for a series of $[Ru(diimine)_3]^{2+}$ complexes ($R^2 = 0.99$). Data taken from ref.[116]

The corresponding linear regression is given by Equation (15).

$$E_{ox}^* = 1.109\ ModEP + 0.397 \quad (15)$$

Equation (15) is of great importance since the excited-state oxidation potential of these complexes determines their ability to act as photosensitizers, and according to the best of our knowledge, it is presented for the first time.

The same trend is observed for M(diimine)(dithiolato) complexes, as given by Equation (16) ($r = 0.92$).

$$E_{ox}^* = 0.790\ ModEP - 0.561 \quad (16)$$

### *Interaction of $[Ru(NH_3)_4(diimine)]^{2+}$ with CT DNA*

In 2004, Mahesvari and Palaniandavar[112,113] reported the interaction of a series of mixed ligand complexes of the type $[Ru(NH_3)_4(diimine)]^{2+}$ with calf thymus DNA. Our *ModEP* scale correlates well with the oxidation and formal peak potentials of the complexes both with and without DNA. Moreover, a good correlation is obtained in the case of the reduction potentials of the complexes, but not with reduction potentials in the presence of DNA, a fact that is an indication that the nature of the reduction in the DNA-bound form is not the same. These correlations are provided in Equations (17), (18), (19), (20), and (21).

$$E_{ox} = 0.576\ ModEP + 1.044\ (R^2 = 0.94) \quad (17)$$

$$E_{red} = 0.452\ ModEP + 0.761\ (R^2 = 0.94) \quad (18)$$

$$E_{1/2} = 0.514\ ModEP + 0.883\ (R^2 = 0.99) \quad (19)$$

$$E_{ox} = 0.700\ ModEP + 1.135\ (R^2 = 0.95) \text{ (in the presence of CT DNA)} \quad (20)$$

$$E_{1/2} = 0.515\ ModEP + 0.853\ (R^2 = 0.97) \text{ (in the presence of CT DNA)} \quad (21)$$

The ligand 2,9-dmphen has been excluded from the regression analysis because of its deviation from linearity. This is in accord with its relatively high values for the ratio $i_{pa}/i_{pc}$ (1.39 in the case of DNA interaction) and $\Delta E_p$ (192 mV for the complex), which are strong indications of irreversible processes.

## The Role of the Coordinating Ligand – Expanding the Model

In the previous sections, we set up the basis of the *ModEP* scale and tested its applicability to several demanding cases. Moreover, we showed that *ModEP* finds potential application in the description of every ligand-based/determined process.

From all the examples mentioned above, covering a range of diimine compounds from material to biochemical science, we conclude that the role of the ligand in a complex can be predicted in a quantitative manner. In addition, the previously extracted correlations imply that the ligands act in a completely analogous way regardless of the metal fragment to which they are coordinated; this refers to all classes of ligands. Let's demonstrate a provocative example. From the previous discussion and the way *ModEP* is derived, we should expect that the energy of the *MMLL′CT* band in the M(diimine)(dithiolato) complexes correlates well with $[Ru(diimine)_3]^{2+}$ excited-state oxidation potentials. This argument has proved correct ($r = 0.998$). This idea is the result of a simple mathematical/numerical regression, but it also possesses an inherent chemical meaning. It denotes that ligands act in a fully predictable way upon coordination to a metal, and this is because of their electronic characteristics. Under this prism, the coordination of a metal to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a ligand determines a general property of a complex (e.g. luminescence) and causes the stabilization of ligands towards, for example, reduction, but it is the nature of the ligands that determines the extent of these properties. In other words, if we synthesize one or two compounds of a new family, we can predict with high accuracy their electronic properties with an extensive series of ligands, without the need to synthesize them individually.

In view of the above discussion, we conclude that a unified scale of ligand properties is what must become our main objective. In the Introduction, we mentioned some of the most widely accepted ligand scales. The major drawback of all of them is that they are oriented to certain types of ligands, e.g. diimines, phosphanes, and dithiolates. If we select one as the most appropriate, e.g. *CEP* or *TEP*, we must develop synthetic or computational routes in order to derive parameters for other types of ligands. In a different approach, for a large-scale comparison of data for different classes of compounds having different types of ligands, we could enrich the *ModEP* scale. However, both approaches are time consuming and constrained by experimental errors or different experimental conditions.

Herein, we suggest a different approach that can be employed for every type of ligand used or is under consideration for future work. This approach will be based on the electrophilicity index $\omega$.

### Electrophilicity Index $\omega$ – Application to Diimine Ligands

On the basis of an idea given by Maynard et.al.,[117] in 1999, Parr and co-workers defined the electrophilicity index, $\omega$, as a measure of the electrophilicity of a ligand[73] [Equation (22)].

$$\omega \equiv \mu^2/2\eta \tag{22}$$

where $\mu$ = chemical potential, defined by $\mu = [\partial E/\partial N]_v$ (and $\mu = -\chi$, $\chi$ = electronegativity) and $\eta$ = chemical hardness defined by $\eta = [\partial^2 E/\partial N^2]_v$.

Following Parr's arguments, Equation (23) is presented, where $\omega$ corresponds to the energy produced from the maximal flow of electrons between the donor and acceptor, where I is the compound's ionization potential and A is its electron affinity.

$$\omega = \frac{(I + A)^2}{8(I - A)} \tag{23}$$

Moreover, maximal electron flow is given by Equation (24).

$$\Delta N_{max} = \frac{I + A}{2(I - A)} \tag{24}$$

Both $\omega$ and electron affinity measure the capability of an agent to accept electrons. Nevertheless, the latter is by definition related strictly to a one-electron process, whereas the electrophilicity index measures the total energy lowering of a ligand due to maximal electron flow ($\Delta E = -\mu^2/2\eta$, $\Delta E < 0$, charge transfer being a spontaneous process), a value that could be different from unity.[73] The model was completed by Contreras et al., who introduced solvent effects,[118–121] and the importance of the electrophilicity index is well documented by Chattaraj et al.[122]

First of all, we tried to investigate the applicability of the electrophilicity index, $\omega$, to large molecules and, more precisely, in the detection of the behavior of the complexed diimines. To the best of our knowledge, this approach is employed for the first time.

We employed Koopmans' theorem, as given by the following relations [Equations (25) and (26)].

$$I \cong -E_{HOMO} \tag{25}$$

$$A \cong -E_{LUMO} \tag{26}$$

Equation (26) is not really part of the theorem. Nevertheless, it is usually used in the literature as a good approximation. In a first approach to the problem, the semiempirical AM1 model was employed (the PM3 model gave similar results). Although neither method matches the high precision of ab initio calculations, their main advantage is low computational cost and wide acceptance in the description of organic molecules. Some first calculations of diimine properties at the HF and MP2 level of theory gave similar results, but their application was not possible as soon as the structures became more complex.

In Table 4, the parameters for the diimines under study calculated at the AM1 level are presented. It is obvious that electron-accepting groups increase the electrophilicity and maximal electron flow of the diimine, whereas good σ-donors contribute to their reduction.

Both $\omega$ and *ModEP* give a measure of the maximal electron flow that a ligand can accept, and on the basis of this fact we anticipate the function $ModEP = f(\omega)$ to be linear. Figure 11 shows the linear correlation between *ModEP* and the computed $\omega$; a good correlation coefficient is found ($R^2 = 0.92$), and Equation (27) is obtained.

$$ModEP = 1.151\ \omega - 3.085 \tag{27}$$

Thus, both *ModEP* and $\omega$ can find application as quantitative indices of a ligand's electronic behavior. The great advantage of $\omega$ is that it can be easily calculated for a broad range of ligand types. Thus, by definition it must correlate satisfactorily with the electronic descriptors of all other ligands, either experimentally derived (*TEP* and *LEP*) or computed (*CEP*).

Employing data points from ref.[2] (Table 5), we derived the linear relations that are obtained for 17 molecules that are often used in synthesis as ligands. These relations are given by Equations (28), (29), (30), and (31). The majority of the entries are for phosphane ligands, because *TEP* and *CEP* have been derived for these types of compounds. The last column in Table 5 corresponds to *ModEP* values computed from Equation (27) for the given molecules.

| bbqdi | 11.873 | 1.399 | 2.102 | 0.634 | – | –0.508 |

The majority of the ligands in Table 5 are strong or weak π-donors. Hence, *ModEP* values are more negative than the corresponding values for the diimines.

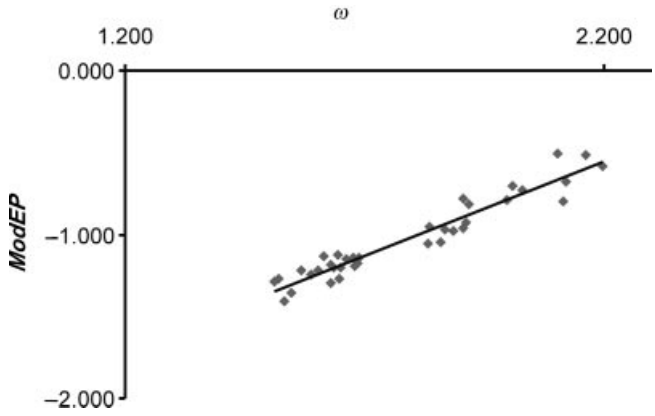

Figure 11. Graphic representation of the function $ModEP = f(\omega)$ for all compounds under study.

$$LEP_{(V)} = 0.9261\ \omega + 0.7124,\ R^2 = 0.90 \quad (28)$$

$$TEP_{(cm^{-1})} = 73.662\ \omega + 1989.2,\ R^2 = 0.95 \quad (29)$$

$$CEP_{(cm^{-1})} = 76.833\ \omega + 2074.3,\ R^2 = 0.94 \quad (30)$$

$$CEP^*_{(cm^{-1})} = 72.722\ \omega + 2077.1,\ R^2 = 0.93 \quad (31)$$

These relations enable us to express any experimental or computed parameter as a function of any other through the intermediacy of the easily computed $\omega$. In this way, existing empirical parameters like *ModEP* or *LEP* that express contrary properties of the ligands can be combined and enrich each other. This fact demonstrates that our attempt was successful and at the same time establishes the electrophilicity index as one of the most promising tools in the effort of synthesizing both inorganic and organometallic complexes with predefined properties. The combination of the above parameters would enrich not only the *ModEP* scale but also any other scale.

Table 5. Electrophilicity index $\omega$ and *ModEP* for the ligands studied. Values for *TEP* [$cm^{-1}$][1], *LEP* [V][3], *CEP* [$cm^{-1}$][2], and *CEP**[2] were taken from the corresponding references, while values in italics have been calculated from the corresponding linear regressions of the functions *TEP* = *f*(*CEP*) and *LEP* = *f*(*CEP*) as described in ref.[2]

The main advantage of the electrophilicity index $\omega$ over the only other computed parameter, namely *CEP*, is on one hand the very low computational cost and on the other the fact that the information provided is not only for the ligand as a unit but also for the given complex.

## Conclusions

In this paper, we report the derivation of a new empirical scale, namely the modified electronic parameters, and provide the necessary criteria for its use. The basis for our analysis was the electrochemical and spectroscopic data for M(diimine)(dithiolato) complexes, which are known for their peculiar electronic structure and are possible candidates for use in the NLO materials industry and as photosensitizers. Modified electronic parameters provide, by definition, the contribution of the ligand to the reduction potential of the corresponding complexes and can be employed in order to predict those properties of the complexes that are ligand-based. *ModEP* values for homologous compounds correlate with Hammett's $\sigma_t$ constants. This correlation implies the same behavior in response to a change in the π-bonding properties of aromatic ligands as a result of changing their substituents.

*ModEP* was tested in several classes of compounds. Its high applicability denotes that ligands act in a fully predictable way upon coordination to a metal and this is due to their electronic characteristics. In other words, when a given series of ligands is coordinated to a metal fragment, it causes a fully predictable change in the ligand-based properties of the complex.

Trying to extrapolate our approach to other types of ligands, we introduced the relatively new concept of the electrophilicity index $\omega$ and proved its efficiency as a measure of the capability of a molecule to accept electrons. Thus, $\omega$ can become an important index for describing the behavior of the complexes, an approach that is referred to for the first time in this manuscript.

The general correlation between $\omega$ and all other electronic parameters such as *ModEP*, *LEP*, *TEP*, *CEP*, and Hammet's $\sigma_t$ provides us with a useful tool to enrich each one of the aforementioned scales in a quantitative manner. On the basis of this fact, we conclude that, in our effort to find a unified ligand scale, the electrophilicity index, $\omega$, should play a central role.

More contributions to these results will enrich and fully establish our study.

## Acknowledgments

The project is co-funded by the European Social Fund and National Resources – (EPEAEK II) PYTHAGORAS. The Special Research Account of NKUA is also acknowledged.

# Synthesis, Structure, Electrochemistry, and Mössbauer Effect Studies of the Ferraphosphadicarbollides $[(C_5R_5)Fe(PC_2B_8H_{10})]$ (R = H, Me)

**Alexander R. Kudinov,*[a] Rolfe H. Herber,*[b] Piero Zanello,*[c] Dmitry S. Perekalin,[a] Ivan V. Glukhov,[a] Israel Nowik,[b] Maddalena Corsini,[c] Serena Fedi,[c] and Franco Laschi[c]**

**Keywords:** Iron / Carboranes / Electrochemistry / X-ray diffraction / Mössbauer spectroscopy

Reaction of the phosphadicarbollide anion $[7,8,9\text{-}PC_2B_8H_{10}]^-$ (**4**) with $[CpFe(C_6H_6)]^+$ or $[Cp^*Fe(MeCN)_3]^+$ gives the expected 12-vertex ferraphosphadicarbollides $[1\text{-}C_5R_5\text{-}1,2,3,4\text{-}FePC_2B_8H_{10}]$ [R = H (**5a**), Me (**5b**); the metal atom is assigned number 1] in around 35 % yield. Compounds **5a**,**b** undergo selective polyhedral rearrangement at 150 °C to give the corresponding isomers $[1\text{-}C_5R_5\text{-}1,2,4,5\text{-}FePC_2B_8H_{10}]$ (**6a**,**b**). The structure of **5a** has been determined by X-ray diffraction. An electrochemical investigation has revealed that all the compounds obtained display the $Fe^{II}/Fe^{III}$ oxidation process with features of chemical reversibility on the cyclic voltammetric timescale. However, only cation $[\mathbf{6b}]^+$ is reasonably stable on the long timescales of electrolysis. Ferraphospadicarbollides **5a** and **6a** are more difficult to oxidize than the related dicarbollide and tricarbollide derivatives $[CpFe(C_2B_9H_{11})]^-$ and $[CpFe(C_3B_8H_{11})]$, respectively. Temperature-dependent Mössbauer effect studies show that the recoil-free fraction over the temperature interval 110–342 K for **5a** is well accounted for by a linear regression, and a calculation of the root-mean-square-amplitude-of-vibration (rmsav) of the iron atom, based on the Mössbauer effect (ME) data, is in reasonable agreement with the value calculated from the single-crystal X-ray study at 120 K. Similarly, the ME and X-ray rmsav data for **6a** at 293 K are in excellent agreement with each other, and the value at 120 K calculated for **6a** is in good agreement with that observed for **5a**. The metal atom motion is nearly isotropic with respect to the major symmetry axis running through the Cp ring and the Fe atom.

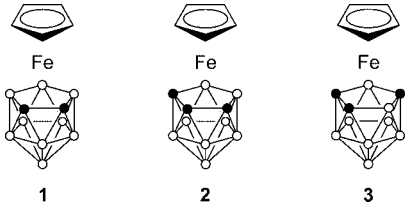
## Introduction

The ferracarborane anion $[CpFe(C_2B_9H_{11})]^-$ ($[\mathbf{1}]^-$)[1] can be considered as a ferrocene analog, although the different charges of the $[C_2B_9H_{11}]^{2-}$ and $Cp^-$ ligands lead to significant differences in the properties of $[\mathbf{1}]^-$ and $FeCp_2$. The use of monoanionic carborane ligands of two types, namely $[C_3B_8H_{11}]^-$ and $[9\text{-}L\text{-}7,8\text{-}C_2B_9H_{10}]^-$ (L = $SMe_2$, $NMe_3$, py), has allowed us to prepare closer analogs of ferrocene such as ferratricarbollides **2**, **3**[2] and charge-compensated ferradicarbollides $[CpFe(L\text{-}C_2B_9H_{10})]$ (for the meaning of the circles, see Scheme 1).[3]



We have recently shown that combined structural, electrochemical, and Mössbauer effect (ME) studies can provide detailed information concerning the static and dynamic properties of cyclopentadienylferracarboranes and their monocations.[3a] In particular, we showed that the replacement of a boron atom by carbon results in an increase of the electron-withdrawing properties of the carborane ring. Herein we report the extension of these investigations to a number of cyclopentadienylferraphosphadicarbollides in order to elucidate the effect of a phosphorus atom on the chemical and physico-chemical characteristics of these unique compounds.

## Results and Discussion

### Synthesis

Štibr et al. have recently reported the synthesis of the first ferraphosphadicarbollide complex [1-Cp-1,2,3,5-

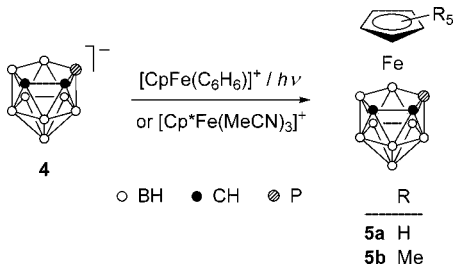
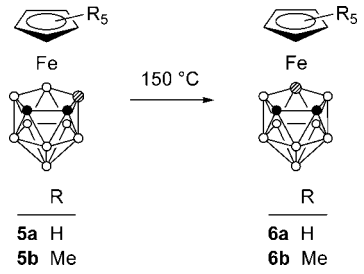
$FePC_2B_9H_{10}$] (**6a**) by interaction of 7,8,9-$PC_2B_8H_{11}$ with $[CpFe(CO)_2]_2$ in refluxing xylene.[4] However, owing to the drastic conditions, the reaction was accompanied by nonselective polyhedral rearrangements that gave a mixture of isomers.

We have found previously that room-temperature reactions of carborane anions with the $[CpFe]^+$ fragment (generated photochemically from $[CpFe(C_6H_6)]^+$) can be used for the synthesis of various ferracarboranes.[2,3,5] Employing this method with $[CpFe(C_6H_6)]^+$ and the phosphadicarbollide anion [7,8,9-$PC_2B_8H_{10}]^-$ (**4**) gave the unrearranged complex [1-Cp-1,2,3,4-$FePC_2B_9H_{10}$] (**5a**)[6] in 37% yield (Scheme 1). The pentamethylated derivative **5b** was obtained in 35% yield by reaction of **4** with the $[Cp^*Fe(MeCN)_3]^+$ cation. A significant amount (approx. 40%) of anion **4** remains unreacted in both cases, in accordance with the moderate yields, and this remains the same regardless of changes in reaction time/temperature. This may be due to σ-coordination of $[(C_5R_5)Fe]^+$ fragments to the phosphorus lone pair of anion **4**, which suppresses the formation of the π-complex.[7]



Scheme 1. Synthesis of complexes **5a**,**b**.

Complexes **5a**,**b** both undergo polyhedral rearrangement upon heating in refluxing nonane (150 °C) to give the 1,2,4,5-isomers **6a**,**b** (approx. 80% yield; Scheme 2). This rearrangement is highly selective, and no other isomers could be detected in the reaction mixture by means of $^{11}B$ and $^{31}P$ NMR spectroscopy. This observation is in sharp contrast to the nonselective isomerization of the analogous cobalt complex [1-($\eta^4$-$C_4Me_4$)-1,2,3,4-$CoPC_2B_9H_{10}$] at 110 °C[5] and the nonselective further rearrangement of **6a** in refluxing mesitylene.[8] The **5a** → **6a** isomerization process is exothermic by 12.8 kcal mol$^{-1}$, as estimated by DFT calculations at the B3LYP/6-31G* level.[9]



Scheme 2. Polyhedral rearrangement of complexes **5a**,**b**.

Compounds **5a**,**b** and **6a**,**b** were characterized by elemental analysis and $^1H$, $^{11}B$, and $^{31}P$ NMR spectroscopy. The $^{11}B$ signal assignment in **5a** and **6a** was performed with the help of DFT/GIAO calculations. The structure of **5a** was also investigated by X-ray diffraction (Figure 1).[10] The carbon atoms of the Cp ring as well as the P1 and B5 atoms were found to be disordered over two positions. The C3–C4 distance (1.609 Å) is notably longer than a typical C–C single bond but is in the usual range for *closo*-metallacarboranes.[11] The average Fe–$C_{cage}$ (2.020 Å) and Fe–P (2.237 Å) distances are close to those for isomer **6a** (2.018 and 2.251 Å).[4] The Fe···Cp distance in **5a** (1.683 Å) is also close to that in **6a** (1.681 Å), thus indicating similar coordinating properties of the isomeric phosphadicarbollide anions [7,8,9-$PC_2B_8H_{10}]^-$ and [7,9,10-$PC_2B_8H_{10}]^-$. The significantly longer Fe···Cp distances in **5a** and **6a** than in $FeCp_2$ (1.660 Å)[12] suggest a greater acceptor ability of the phosphadicarbollide ligands relative to $Cp^-$, in accordance with the electrochemical data (see below).

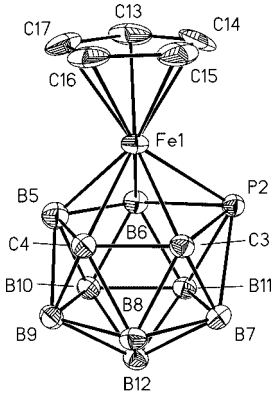


Figure 1. The molecular structure of **5a** (thermal ellipsoids at 50% probability). The hydrogen atoms and the second conformation of the Cp ring have been omitted for clarity. Selected interatomic distances [Å]: Fe1–P2 2.231(2), Fe1–C3 2.017(2), Fe1–C4 2.023(2), Fe1–B5 2.062(6), Fe1–B6 2.172(4), Fe1–C13 2.065(5), Fe1–C14 2.046(7), Fe1–C15 2.077(4), Fe1–C16 2.084(4), Fe1–C17 2.071(4), P2–B6 2.008(3), P2–C3 2.033(3), C3–C4 1.609(3).

## Mössbauer Effect (ME) Studies

As noted previously,[13] all diamagnetic iron compounds in which the sole metal atom does not occupy a cubic symmetry site give rise to doublet ME spectra which are characterized by their isomer shift (IS) and quadrupole splitting (QS) parameters. A typical ME spectrum (that of **6a** at 90 K) is shown in the bottom trace of Figure 2.

The ME parameters for compound **5a** are summarized in Table 1. The data for the $Fe^{III}$ complex [1-Cp-1,2,3-$FeC_2B_9H_{11}$] (**1**) are also included for comparison purposes. The temperature dependence of the IS of **5a** is well fitted by a linear regression in the range 110–342 K (correlation coefficient for 12 data points: 0.997) from which the effective vibrating mass $M_{eff}$ is calculated to be 94 ± 1 Da.[14] The difference between this value and the "bare" iron atom mass of 57 Da reflects the covalency of the metal–ligand

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

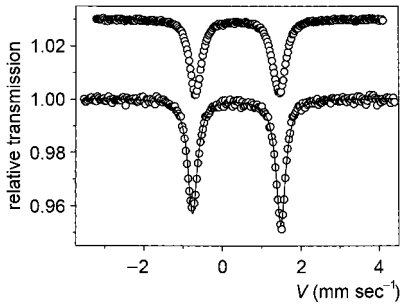

Figure 2. Mössbauer spectra of **6a** (bottom trace) and **6b** (top trace) at 90 K. The presence of a single Fe site is evident from the figure. The velocity scale is with reference to the centroid of an α-Fe absorber spectrum at room temperature.

interaction. It is worth noting that the IS of **5a** is significantly smaller than that of ferrocene itself ($0.536 \pm 1$ mm s$^{-1}$ at 90 K) and is slightly larger than that of **1** under the same conditions. The latter increase implies a decrease in the electron density at the metal atom center (since $\Delta r^2/r^2$ is negative for $^{57}$Fe), presumably due to an increase of the acceptor character of the ligand upon replacement of a B atom by P. The temperature dependence of the recoil-free fraction, extracted from the temperature dependence of ln $A$ (where $A$ is the area under the resonance curve for an optically thin absorber), is shown graphically in Figure 3 and is again well fitted by a linear regression.

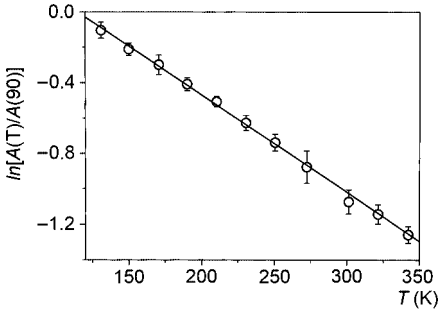

Figure 3. Temperature-dependence of the normalized logarithm of the area under the resonance curve for **5a**. The slope is $-(5.50 \pm 0.07) \times 10^{-3}$ K$^{-1}$ and the correlation coefficient for the 11 data points is 0.999.

As has been noted previously,[15] the recoil-free fraction data can be directly related to the $U_{ij}$ values for the iron atom determined from a single-crystal X-ray diffraction study. The average $U_{ij}$ value for **5a** at 120(2) K is 0.01740 Å$^2$. This translates into a root-mean-square-amplitude-of-vibration (rmsav) of the iron atom of 0.132 Å. The corresponding value extracted from the ME recoil-free fraction data is 0.111 Å, which is only a modest agreement. The analogous value for the dicarbollide complex **1** is $<x^2>^{1/2}_{ME} = 0.145$ Å, while $<x^2>^{1/2}_{X}$ is 0.151 Å at 120 K. The introduction of a P atom into the five-membered carborane face clearly leads to a small shortening of the rmsav of Fe. The area ratio, $R = [A(+)/A(-)]$ (where + and – indicate the position on the velocity scale of the resonance line with respect to the spectrum centroid), of the two QS components of the ME spectra shows only a very small temperature dependence, thereby indicating that the iron atom motion is nearly isotropic over the temperature range 91–341 K.

The ME spectroscopic results for **6a** are very similar to those observed for **5a** (see Table 1). Two points, however, must be made. First of all, the area ratio $R$ shows a significantly larger temperature dependence, which implies a larger anisotropy in the metal atom motion in **6a** compared to **5a** as a result of having the ring P atom flanked by two BH groups rather than flanked by a BH and a CH group as in **5a**. Secondly, the average $U_{ij}$ value reported for iron in the crystal structure of **6a** determined at 293(2) K[4] is 0.0344 Å$^2$, which translates into an rmsav of the iron atom of 0.183 Å. From the temperature dependence of the area under the resonance curve in the interval 135–303 K, the corresponding rmsav of the iron atom at 293 K is 0.180 Å, which is in good agreement (within 3.1%) with the X-ray value. Moreover, the rmsav value calculated from the ME data obtained at 120 K is 0.115 Å, which is in excellent agreement with the corresponding data reported for **5a** (see above) at the same temperature.

The ME spectroscopic parameters for the methylated compounds **5b** and **6b** are also given in Table 1. It should be noted that, while the IS parameters at 90 K are not sensitive to the replacement of Cp by Cp*, the QS parameters show a decrease of almost $0.123 \pm 0.009$ mm s$^{-1}$. Qualitatively, it may be surmised that the presence of the methyl groups increases the metal atom–ring distance and hence leads to a decrease in the electric field gradient at the metal center (see below). However, this increase is not sensitively reflected in the relative IS values as referred to above. The temperature dependence of ln[$A(T)$/$A$(90)] for both compounds is well accounted for by a linear regression. It should be noted, however, that the data for **6b** could only be extended over the range 90–272 K. At 272 K, the resonance

effect magnitude was found to be only around 1.3% and more than 6.6 million counts per channel were acquired to provide the necessary statistical accuracy.

Unfortunately, due to excessive crystalline disorder, it has not proved possible to acquire meaningful single X-ray data for these two compounds. However, it is possible to extract rmsav data for the iron atom at 120 K by assuming that the Mössbauer recoil-free fraction data are reasonably reliable over the cited temperature range. These vibrational amplitudes are 0.125 and 0.130 Å for **5b** and **6b**, respectively, and suggest an increase of this amplitude by about 0.014 Å on replacing Cp by Cp*, which agrees with the QS parameter results cited above. A comparison of the temperature dependence of $\ln[A(T)/A(90)]$ for **5a**, **5b**, and **1** is summarized in Figure 4.

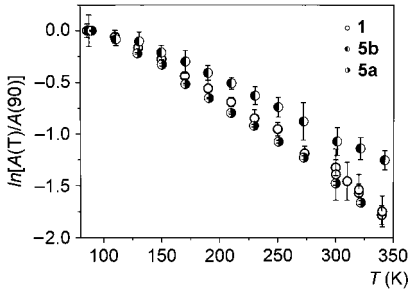

Figure 4. Temperature dependence of $\ln[A(T)/A(90)]$ for **5a** and **5b** showing the effect of substitution in the cyclopentadienido ring on the recoil-free fraction.

The slope difference between **5a** and **5b** provides evidence for lattice "softening" due to this interchange but is unexpected in view of the presumed increase in the metal atom–ring distance due to the presence of the methyl groups in the ring. A possible explanation for this observation lies in the assumption that replacing Cp with Cp* results in the presence of one or more low frequency vibrational modes that affect the dynamics of the whole molecule rather than just the metal atom center. In other words, both intra- and intermolecular motions must be considered to explain this observation. Note, however, that the Mössbauer lattice temperature,[15] $\Theta_M$, is smaller for **5b** and **6b** than for **5a** and **6a**.

Finally, it is worth noting that neither **5b** nor **6b** show a significant temperature dependence on R. The average value of this parameter for **5b** is $1.04 \pm 0.01$ over the range 90–322 K, which indicates an essentially isotropic motion of the metal atom parallel and perpendicular to the principal symmetry axis running through the metal atom.

## Electrochemistry

Figure 5 gives an overall picture of the $Fe^{II}/Fe^{III}$ electron-transfer process in the ferraphosphacarboranes **5a**,**b** and **6a**,**b**. The formal electrode potentials of the redox processes studied are compiled in Table 2, together with that of the classical dicarbollide [1-Cp-1,2,3-$FeC_2B_9H_{11}$] (**1**) and the ferratricarbollide isomers [1-Cp-1,2,3,4-$FeC_3B_8H_{11}$] (**2**) and [1-Cp-1,2,3,5-$FeC_3B_8H_{11}$] (**3**).

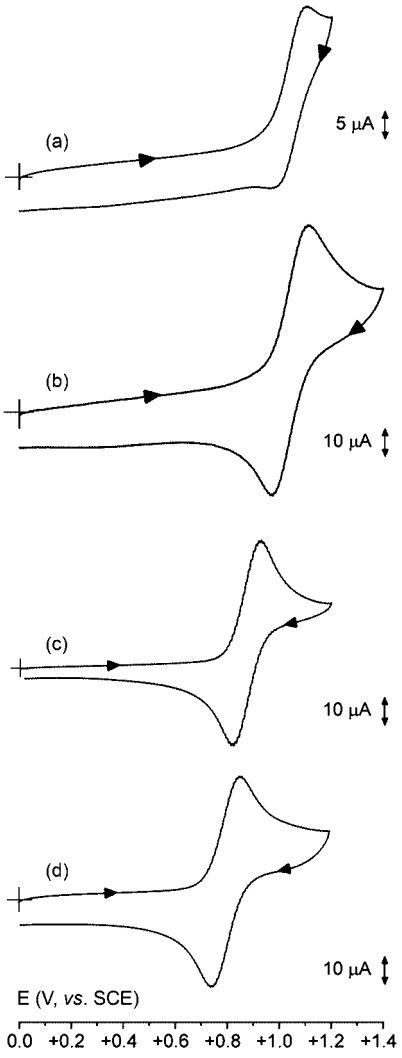

Figure 5. Comparison of the cyclic voltammetric responses given by ferraphosphacarboranes **5a**,**b** and **6a**,**b**: (a) **5a** ($0.7 \times 10^{-3}$ M); (b) **6a** ($1.2 \times 10^{-3}$ M); (c) **5b** ($1.0 \times 10^{-3}$ M); (d) **6b** ($0.7 \times 10^{-3}$ M). $CH_2Cl_2$ solutions contain $[Bu_4N][PF_6]$ (0.2 M) as supporting electrolyte. Gold working electrode. Scan rate: 0.5 $V s^{-1}$.

Table 2. Formal electrode potentials (V vs. SCE), peak-to-peak separation (mV), and current ratio for the redox changes exhibited by the compounds in $CH_2Cl_2$ solution.

| Compound | $E^{\circ\prime}_{Fe(II)/Fe(III)}$ | $\Delta E_p$[a] | $i_{pc}/i_{pa}$[b] | $E^{\circ\prime}_{Fe(II)/Fe(I)}$[a] |

The position of the phosphorus atom in the coordinating $PC_2B_2$ pentagonal face for the non-methylated compounds **5a** and **6a** seems to affect the kinetic rather than the thermodynamic parameters of the pertinent oxidation pro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cesses. In fact, while both processes occur at the same formal electrode potential (see Table 2), there is a marked difference in the chemical stability of monocations $[\mathbf{5a}]^+$ and $[\mathbf{6a}]^+$, as measured by the current ratio $i_{pc}/i_{pa}$, which is equal to 0.4 s for **5a** and 0.9 s for **6a** at 2.0 $V s^{-1}$. As a consequence, assuming that a first-order chemical reaction accompanies the $Fe^{II}/Fe^{III}$ change, a lifetime of 0.2 and 6 s can be calculated for $[\mathbf{5a}]^+$ and $[\mathbf{6a}]^+$, respectively.

The opposite trend holds for the methylated derivatives **5b** and **6b**: their monocations seem to be stable on the cyclic voltammetric time scale ($i_{pc}/i_{pa}$ almost constantly equal to 1 with an increase of the scan rate), although their formal electrode potentials are somewhat different (see Table 2). In reality, the electrogenerated monocation $[\mathbf{5b}]^+$ proved to be unstable under exhaustive macroelectrolysis at room temperature (20 °C), whereas $[\mathbf{6b}]^+$ is reasonably stable (a minor trace of an unidentified species able to oxidize reversibly at $E°' = +1.1$ V appeared). Thus, the original pink-orange solution of **6b** ($\lambda_{max}$ = 482 nm) turns pale green upon exhaustive one-electron oxidation and displays a new band at 780 nm with a shoulder at 650 nm.

It should be also noted that all the ferraphosphacarboranes display an essentially irreversible $Fe^{II}/Fe^{I}$ reduction.

As previously pointed out,[3a] the replacement of a boron atom by a carbon atom in the coordinating pentagon of the dicarbollide ligand (i.e. passing from **1** to the isomeric species **2** and **3**) makes the $Fe^{II}/Fe^{III}$ oxidation dramatically more difficult (by about 1 V). We now find that the replacement of a carbon atom in the ferratricarbollides for a phosphorus atom (i.e. passing from **2** and **3** to **5a** and **6a**, respectively) further increases the oxidation potentials (by about 0.3 V). Unfortunately, we have not yet been able to find an unequivocal thermodynamic effect for the non-methylated complexes resulting from the position of the phosphorus atom in the cage, although it appears that the non-adjacent position in both series increases the kinetic stability of the monocations more than the adjacent position, with the $PC_2B_2$ assembly lowering it more severely than $C_3B_2$. Obviously, the $Fe^{II}/Fe^{I}$ reduction becomes more facile (in the order $PC_2B_2 > C_3B_2 > C_2B_3$) as a consequence of the shifts of the $Fe^{II}/Fe^{III}$ redox potential.

In light of the complete, or almost complete, chemical reversibility of cations $[\mathbf{6a}]^+$, $[\mathbf{5b}]^+$, and $[\mathbf{6b}]^+$ at room temperature, they were electrogenerated at 253 K and characterized by EPR spectroscopy. Figure 6 shows the first-derivative X-band EPR spectrum of a $CH_2Cl_2$ solution of $[\mathbf{6b}]^+$ at 105 K.

The line-shape analysis was performed by assuming a low-spin $Fe^{III}$ complex with a doublet state electron spin Hamiltonian in a strongly axial structure (Zeeman interaction).[16] The intense anisotropic signal displays two well separated [$\delta g_i = g_{\parallel} - g_{\perp}$ = 231(5) G] and unresolved absorptions (multiple derivative analysis). The $g_i$ values ($g_{\parallel} > g_{\perp} \neq g_{electron} = 2.0023$) are typical of metallic absorptions arising from effective $3d^5$ spin-orbit $\lambda$ ($S$ = 1/2) coupling.[16] No direct $^{57}Fe$ hyperfine ($I_{^{57}Fe}$ = 1/2, natural abundance = 2.2%) or $^{31}P$, $^{11}B$, $^{10}B$, $^{1}H$, or $^{13}C$ superhyperfine ($I_{^{31}P}$ = 1/2, natural abundance = 100%; $I_{^{11}B}$ = 1/2, natural abundance = 81.2%; $I_{^{10}B}$ = 3/2, natural abundance 18.8%; $I_{^{1}H}$ = 1/2, natural abundance = 99.99%; $I_{^{13}C}$ = 1/2, natural abundance = 1.1%) splitting is evident in the two spectral regions. The computed[17] anisotropic features are collected in Table 3.

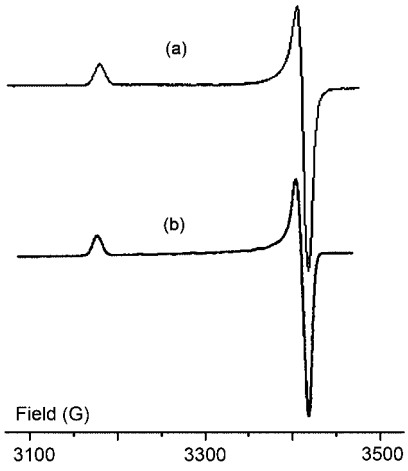

Figure 6. Experimental (a) and simulated (b) X-band EPR spectra of $[\mathbf{6b}]^+$ in $CH_2Cl_2$ solution containing $[Bu_4N][PF_6]$ (0.2 M). $T$ = 105 K. $\nu_o$ = 9.68 GHz.

Table 3. EPR parameters for the electrogenerated cations $[\mathbf{5b}]^+$, $[\mathbf{6a}]^+$, and $[\mathbf{6b}]^+$ in $CH_2Cl_2$ solution[a] [$<g> = 1/3(g_l + g_m + g_h) = 1/3(g_{\parallel} + 2g_{\perp})$; $\delta g_{l-h} = g_l - g_h$; error in $g_i$ and $\delta g_{l-h}$: ±0.005; error in $\Delta H_{iso}$: ±4 G].

| Complex | $g_l$ | $g_m$ | $g_h$ | $\delta g_{l-h}$ | $<g>$ | $g_{iso}$[b] | $\Delta H_{iso}$[b] |
|---|---|---|---|---|---|---|---|
| $[\mathbf{5b}]^+$ | 2.150 | 2.032 | 2.016 | 0.134 | 2.066 | 2.064 | 14 |
| $[\mathbf{6a}]^+$ | 2.183 | 2.029 | 2.029 | 0.154 | 2.080 | 2.066 | 10 |
| $[\mathbf{6b}]^+$ | 2.175 | 2.027 | 2.027 | 0.148 | 2.076 | – | – |

[a] $T$ = 105 K. [b] $T$ = 298 K.

Given the very low natural abundance of the magnetically active atoms present in the complex, particularly $^{57}Fe$ and $^{13}C$, the spectral features are expected to be significantly obscured by the experimental anisotropic linewidths [$\Delta H_{i(exp)}$]. The paramagnetic analysis strongly indicates that the actual SOMO is mainly constituted by the 3d atomic orbitals of the $Fe^{III}$ center, with minor contributions from the directly coordinating donor atoms.

Because of the effective speeding up of the electron paramagnetic relaxation mechanisms, raising the temperature to the glass/fluid transition causes the axial signals to disappear and the fluid solution becomes EPR-silent. Rapid refreezing restores the original anisotropic features. Such a temperature-dependent paramagnetic behavior is not unusual and is due to the effective speeding up of the electron paramagnetic relaxation mechanisms under fast motion conditions in the presence of active thermal effects.[16]

A substantially similar magnetic behavior is exhibited by the related non-methylated cation $[\mathbf{6a}]^+$, although the fluid solution ($T$ = 298 K) exhibits a broad signal with low intensity, the $g_{iso}$ value of which is slightly smaller than the $<g>$ value under glassy conditions because of the effective averaging of the original anisotropy.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Cation $[\mathbf{5b}]^+$ exhibits a different line-shape with a broader and unresolved rhombic pattern ($g_i \neq g_{electron}$) and a high field absorption that is partially split and overlapped. No hyperfine or superhyperfine resolution was visible in this case. In addition, a broad isotropic signal appears in the fluid solution at a $g_{iso}$ value that is essentially identical to the $<g>$ value in glassy solution. It should be noted that the paramagnetic features (see Table 3) suggest a slightly lower metallic character of the unpaired electron.

Since the EPR spectral symmetry (isotropic, axial, rhombic) reflects the local symmetry around the paramagnetic center, in other words the structure of the SOMO, the EPR evidence for different anisotropic line-shapes and linewidths must arise from significant differences in the geometrical coordinating frameworks.[16] In the present case, the fact that cation $[\mathbf{5b}]^+$ exhibits a less symmetrical ligand framework than cations $[\mathbf{6a}]^+$ and $[\mathbf{6b}]^+$ due to the adjacent vs. nonadjacent position of the heteroatoms could be responsible for the different spectral patterns.

We carried out a multiple derivatives analysis of the best-fit experimental anisotropic line-widths ($\Delta H_i$) in order to determine the upper limit for the unpaired electron couplings of cations $[\mathbf{5b}]^+$, $[\mathbf{6a}]^+$, and $[\mathbf{6b}]^+$ with the different magnetically active nuclei of the coordinating atoms (see Table S1 in the Supporting Information). This study clearly showed the metallic character of the X-band experimental spectra, although a significant interaction of the phosphorus nucleus seems to be involved in the magnetic interaction with the unpaired electron.

## Conclusions

Reaction of the phosphadicarbollide anion **4** with $[(C_5R_5)Fe]^+$ fragments under mild conditions leads to the non-rearranged ferraphosphacarboranes **5a**,**b**, whose thermal isomerization into **6a**,**b** correlates with an increase of the thermodynamic stability, as estimated by DFT calculations. The electrochemical data for these compounds suggest a greater acceptor character of the phosphadicarbollide ligands compared with their di- and tricarbollide analogues.

The isomer shifts of **5a**,**b** and **6a**,**b** at 90 K are significantly smaller than those for ferrocenes $Cp_2Fe$ and $Cp^*_2Fe$ (0.536 and 0.492 mm s$^{-1}$, respectively, at 90 K), which reflects a higher electron density at the metal atom in the former. This observation was somewhat unexpected, since the electrochemical data and electronegativity considerations would suggest the opposite. The quadrupole splitting parameter is not sensitive to the location (adjacent or not) of the two boron atoms facing the metal center in the carbollide structure. Temperature-dependent ME measurements of the rmsav of the metal atom in **6a** are in good agreement with the value extracted from single-crystal X-ray data at 293 K.

## Experimental Section

**General Remarks:** All reactions were carried out under argon in anhydrous solvents, which were purified and dried according to standard procedures. All products were isolated in air. The $^1$H, $^{11}$B, and $^{31}$P NMR spectra were recorded with a Bruker AMX-400 instrument at room temperature in $CDCl_3$. The salt $[Bu_4N][7,8,9\text{-}PC_2B_8H_{10}]$ ($[Bu_4N][\mathbf{4}]$) was prepared by mixing $7,8,9\text{-}PC_2B_8H_{11}$[18] and $Bu_4NBr$ in aqueous NaOH. Materials and apparatus for electrochemistry and joint EPR spectroscopy have been described elsewhere.[19] All the potential values are referred to the saturated calomel electrode (SCE). The one-electron oxidation of ferrocene occurs at $E^{\circ\prime}$ = +0.39 V under the present experimental conditions.

**[1-Cp-1,2,3,4-FePC$_2$B$_8$H$_{10}$] (5a):** A mixture of $[Bu_4N][\mathbf{4}]$ (230 mg, 0.6 mmol) and $[CpFe(C_6H_6)]PF_6$ (413 mg, 1.2 mmol) in $CH_2Cl_2$ (15 mL) was irradiated whilst stirring at room temperature for 4 h, during which time its color changed from yellow to bright-red. The reaction mixture was concentrated in vacuo and the residue eluted through a short (5 cm) silica gel column with a $CH_2Cl_2$/petroleum ether mixture (1:2) as eluent. Concentration of the red fraction by passing an argon stream over the solution gave red crystals of **5a** suitable for X-ray diffraction (60 mg, 37%). $^1$H NMR: $\delta$ = 5.03 (s, 5 H, Cp), 3.88 (s, 1 H, cage-CH), 3.55 (d, $J_{^{31}P,^1H}$ = 16 Hz, 1 H, cage-CH) ppm. $^{11}$B{$^1$H} NMR (exp./calcd.): $\delta$ = 1.9/3.1 (s, 1 B, B5), 0.3/–2.8 (s, 1 B, B12), –6.2/–5.0 (s, 1 B, B6), –6.4/–7.8 (s, 1 B, B10), –9.0/–10.3 (s, 1 B, B9 or B11), –10.8/–10.3 (s, 1 B, B9 or B11), –19.9/–21.4 (s, 1 B, B8), –27.0/–28.4 (s, 1 B, B7) ppm. $^{31}$P NMR: $\delta$ = 27.4 (s, 1 P, P2) ppm. $C_7H_{15}B_8FeP$ (272.50): calcd. C 30.87, H 5.51, B 31.75; found C 31.07, H 5.68, B 31.40.

**[1-Cp*-1,2,3,4-FePC$_2$B$_8$H$_{10}$] (5b):** A mixture of $[Bu_4N][\mathbf{4}]$ (157 mg, 0.4 mmol) and $[Cp^*Fe(MeCN)_3]PF_6$ (188 mg, 0.4 mmol) in thf (10 mL) was stirred at room temperature overnight, which resulted in a color change from dark- to bright-red. The reaction mixture was concentrated in vacuo and the residue eluted through a short (5 cm) silica gel column with a $CH_2Cl_2$/petroleum ether mixture (1:2) as eluent. Concentration of the red fraction gave red crystals of **5b** (47 mg, 35%). $^1$H NMR: $\delta$ = 2.88 (s, 1 H, cage-CH), 2.54 (d, $J_{^{31}P,^1H}$ = 13 Hz, 1 H, cage-CH), 1.84 (s, 15 H, Cp*) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = 3.0 (s, 1 B), –3.3 (s, 1 B), –4.2 (s, 1 B), –8.9 (s, 1 B), –10.5 (s, 1 B), –11.9 (s, 1 B), –20.6 (s, 1 B), –28.5 (s, 1 B) ppm. $^{31}$P NMR: $\delta$ = 38.3 (s, 1 P, P2) ppm. $C_{12}H_{25}B_8FeP$ (342.63): calcd. C 42.07, H 7.35, B 25.24; found C 42.23, H 7.14, B 25.11.

**Thermal Isomerization of 5a,b:** Complex **5a** (100 mg) was refluxed in nonane (5 mL) for 6 h. The course of isomerization was checked every 2 h by recording the $^{11}$B and $^{31}$P NMR spectra. After the reaction was complete, the solution was slowly cooled to 0 °C to give bright red crystals of **6a**, which were washed with cold pentane and dried in vacuo (77 mg, 77%). Complex **6b** was obtained from **5b** in a similar manner in 83% yield. **6a:** $^1$H NMR: $\delta$ = 4.96 (s, 5 H, Cp), 4.37 (s, 2 H, cage-CH) ppm. $^{11}$B{$^1$H} NMR (exp/calc): $\delta$ = –2.1/–6.0 (s, 1 B, B12), –11.4/–11.0 (s, $J_{^{31}P,^{11}B}$ = 39 Hz, 2 B, B3,6), –13.1/–14.7 (s, 1 B, B9), –13.8/–13.1 (s, 2 B, B7,11), –21.1/–18.8 (s, 2 B, B8,10) ppm. $^{31}$P NMR: $\delta$ = –14.8 (s, 1 P, P2) ppm. **6b:** $^1$H NMR: $\delta$ = 3.40 (s, 2 H, cage-CH), 1.85 (s, 15 H, Cp*) ppm. $^{11}$B{$^1$H} NMR: $\delta$ = –5.0 (s, 1 B), –9.5 (s, $J_{^{31}P,^{11}B}$ = 38 Hz, 2 B), –13.6 (s, 1 B), –14.9 (s, 2 B), –19.6 (s, 2 B) ppm. $^{31}$P NMR: $\delta$ = –6.6 (s, 1 P, P2) ppm. $C_{12}H_{25}B_8FeP$ (342.63): calcd. C 42.07, H 7.35, B 25.24; found C 42.38, H 7.01, B 25.20.

**Mössbauer Spectroscopy:** The samples were transferred into plastic holders and mounted in a variable-temperature cryostat as described previously.[13] The methods for spectrometer calibration, data analysis, and temperature control monitoring have been detailed previously.[13] All isomer shifts (IS) are given with respect to a room-temperature α-Fe absorber spectrum which was also used for spectrometer calibration. The ME spectral line widths for the optically "thin" samples was 0.248 ± 0.013 mm s$^{-1}$.

**X-ray Crystallography for 5a:** $C_7H_{15}B_8FeP$, $M$ = 272.49, monoclinic, space group $P2_1/c$, 120 K, $a$ = 6.8292(12), $b$ = 9.811(2), $c$ = 18.015(3) Å, $\beta$ = 90.816(8)°, $V$ = 1206.9(4) Å$^3$, $Z$ = 4, $F(000)$ = 552, $d_{calcd.}$ = 1.500 g cm$^{-3}$, $\mu$ = 1.340 mm$^{-1}$. The unit cell parameters and intensities of 10973 reflections were measured with a Bruker SMART 1000 CCD area detector, using graphite-monochromated Mo-$K_\alpha$ radiation, ϕ- and $\omega$-scans, $\theta_{max}$ = 27°. The temperature of the crystal was maintained with a Cryostream (Oxford Cryosystems) open-flow nitrogen gas cryostat. Reflection intensities were integrated using SAINT software,[20] and absorption correction was applied semi-empirically using the SADABS program. The structure was solved by direct methods and refined by full-matrix least squares against $F^2$ in an anisotropic approximation for all non-hydrogen atoms except B5 and P2, which were found to be disordered over two sites with respect to the mirror plane passing through the center of the C3–C4 bond (3:2 occupancy), and the carbon atoms of the Cp ring, which were found to be disordered over two sites (4:1 occupancy). The disordered atoms were refined in an isotropic approximation. The polyhedron hydrogen atoms were located from the Fourier density synthesis and refined in an isotropic approximation. All calculations were performed using the SHELXTL software.[21] Final $R$ factors are equal to $R_1$ = 0.0349 for 2068 reflections with $I > 2\sigma(I)$ and $wR_2$ = 0.0834 for all 2585 independent reflections. CCDC-635642 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** All calculations were performed using the Gaussian 98 (revision A.7) software[22] package at the B3LYP/6-31G* level. The structures of isomers **5a** and **6a** were optimized within $C_1$ and $C_s$ symmetry, respectively. The frequency calculations were performed to confirm the global minimum and include ZPE corrections to the energy. The $^{11}$B NMR shifts were calculated using the GIAO method by subtracting the calculated isotropic shielding values from that of $B_2H_6$ (93.50 at B3LYP/6-31G*). The experimental chemical shift of $B_2H_6$ was assigned to be $\delta$ = 16.6 ppm.[23]

**Supporting Information** (see footnote on the first page of this article): Computed upper limit values of the temperature-dependent hyperfine and superhyperfine couplings of cations **[5b]**$^+$, **[6a]**$^+$, and **[6b]**$^+$ in $CH_2Cl_2$ solution. Details of the DFT calculations of **5a** and **6a**, including the optimized coordinates, NBO charges, and NMR shielding tensors.

# Pyrazole-Based Ligands for the [Copper–TEMPO]-Mediated Oxidation of Benzyl Alcohol to Benzaldehyde and Structures of the Cu Coordination Compounds

**Jorge Salinas Uber,[a] Yorick Vogels,[a] Dave van den Helder,[a] Ilpo Mutikainen,[b] Urho Turpeinen,[b] Wen Tian Fu,[a] Olivier Roubeau,[c] Patrick Gamez,[a] and Jan Reedijk*[a]**

**Keywords:** Copper(I) and copper(II) complexes / Catalysis / Oxidation / Luminescence / Bioinorganic chemistry

New pyrazole-based ligands have been designed, and the catalytic performances of their copper(II) complexes for the [copper/TEMPO]-mediated oxidation of benzyl alcohol to benzaldehyde have been examined. The pyridine-pyrazole ligands give efficient catalysts, while the use of naphthol-pyrazole ligands results in inactive catalytic systems. Single-crystals of four Cu coordination compounds obtained from pyridine-pyrazole ligands and a free ligand have been isolated and were characterized by X-ray diffraction. Thus, the solid-state structures of three copper(II) complexes are described, together with a copper(I) coordination chain, exhibiting luminescent properties.

## Introduction

The selective production of aldehydes from primary alcohols is a very important chemical transformation of organic synthesis, since a wide variety of fine chemicals possess this carbonyl function.[1,2] Various effective methods have been developed to perform this oxidation reaction.[3,4] For example, the synthesis of aldehydes may commonly be achieved by heating the primary alcohol in an acidified solution of potassium dichromate, which is reduced to $Cr^{3+}$ during the reaction,[5] or by the so-called "Swern oxidation" [$(CO)_2Cl_2$ + $(Me)_2SO$].[6] However, these oxidation procedures often involve the use of stoichiometric amounts of reagents, which leads to the formation of copious quantities of unfriendly waste for the environment. Hence, catalytic oxidations mediated by transition metal complexes represent a crucial and topical area of catalysis in term of green and sustainable chemistry.[7] Several efficient catalytic systems, including TEMPO-based ones have been reported;[8–16] nevertheless, severe limitations remain that are the chemo-, regio- and stereoselectivity of the catalytic oxidations. Recently, some of us have developed a bio-inspired copper-based catalyst able to selectively convert primary alcohols to the corresponding aldehydes in the presence of TEMPO as co-catalyst.[17,18] This catalytic system has been further developed by other research groups, showing its high potential and versatility for the production of a broad range of aldehydes.[19,20] In the present study, a number of related pyrazole-based ligands have been used for the [copper(II)/TEMPO]-catalysed oxidation of benzyl alcohol to benzaldehyde in order to obtain a better insight of its mechanism.

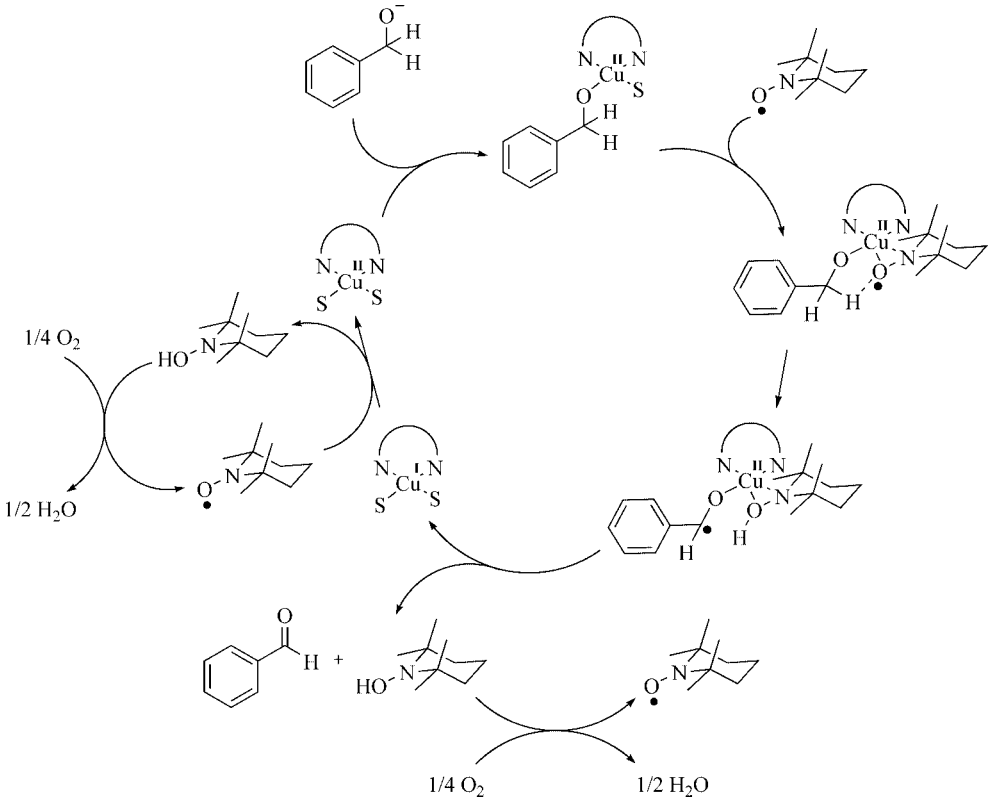
## Results and Discussion

### Preparation of the Ligands

A few years ago, an effective catalytic system for the conversion of primary alcohols to the corresponding aldehydes, under mild conditions, has been reported.[17] This catalytic oxidation reaction involves a copper complex, and it has been shown that the use of aromatic N-donor ligands leads to efficient catalysts.[21] The proposed catalytic cycle of this reaction brings in copper(II) and copper(I) species (Scheme 1).[21] 2,2′-Bipyridine (and derivatives) has been shown to be a prime ligand for this reaction.[21] The pyrazole ring is known to stabilize $Cu^{I}$ species. Thus, the use of mixed pyridine/pyrazole ligands is expected to generate active catalysts for the [Cu(ligand)-TEMPO]-mediated oxidation of primary alcohols, since both the $Cu^{I}$ and $Cu^{II}$ species may presumably be efficiently stabilised during the catalytic cycle. Therefore, a first series of new bidentate ligands have been designed and synthesized, which contain a pyridine unit connected to a less soft donor group, namely a pyrazole ring.

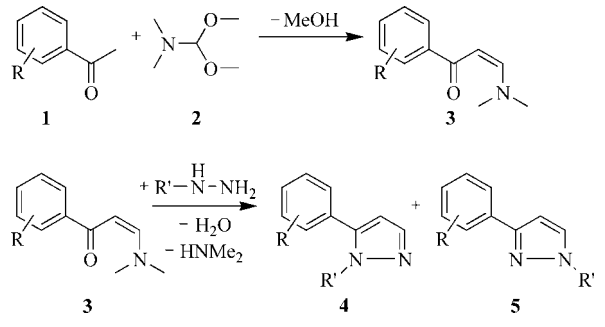
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. Proposed catalytic cycle for the [copper/TEMPO]-catalyzed oxidation of benzyl alcohol to benzaldehyde.[21]

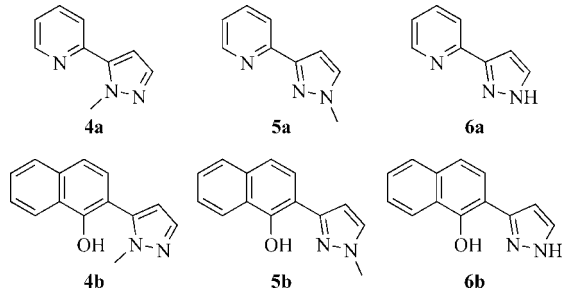
Moreover, the proposed catalytic cycle (Scheme 1)[21] of the [Cu(ligand)-TEMPO]-mediated oxidation is derived from the well-known mechanism of action of the copper enzyme galactose oxidase (GOase).[22] The active site of GOase contains a distorted square-pyramidal mononuclear copper(II) species, two of whose ligands are phenolic moieties (from tyrosinate side-chains).[22] A second series of pyrazole-based ligands possessing a naphthol group, have therefore been prepared to mimic the active site of GOase.

The synthetic procedure for the preparation of the pyrazole-containing ligands is based on an earlier reported method.[23] The first step of the synthesis is the reaction of an acyl derivative (**1**) with *N*,*N*-dimethylformamide dimethyl acetal (**2**) (Scheme 2). The resulting propenone (**3**) is treated with a hydrazine derivative to generate the pyrazole ring, via a ring-closure step (Scheme 2).



Scheme 2. Synthetic pathway for the preparation of the pyrazole-based ligands.

Using this straightforward synthetic route, the pyrazole-pyridine and the pyrazole-naphthol ligands depicted in Scheme 3 have been prepared in good yields (see Experimental section).



Scheme 3. Ligands used for the [copper–TEMPO]-catalysed oxidation of benzyl alcohol.

These pyrazole derivatives have been tested as ligands in the [copper–TEMPO]-catalysed oxidation of benzyl alcohol. Furthermore, various copper coordination compounds, whose crystal structures are described below, have been obtained by reaction of copper(II) bromide and some of these ligands.

## Description of the Structures

### *Crystal Structure of $[Cu_2(4a)_2Br_2]_n$ (7)*

Reaction of one equivalent of copper(II) bromide with one equivalent of ligand **4a** in methanol yields colourless

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plates of **7** after one day. **7** crystallizes in the triclinic space group $P\bar{1}$. An ORTEP[24] view of compound **7** is depicted in Figure 1. Selected bond lengths and angles are given in Table 1, and details for the structure solution and refinement are summarized in Table S1 (see electronic supporting information). Compound **7** is constituted by tetracoordinate copper(I) ions exhibiting distorted tetrahedral coordination, with a $\tau_4$ value of 0.85.[25] Each copper centre is coordinated by a pyrazole N atom and a pyridine N atom, belonging to two different ligands. These two ligands coordinate to a crystallographically related copper(I) ion, generating a dimer (Figure 1). The coordination sphere of the metal centre is completed by two bromide anions. The Cu–N and Cu–Br bond lengths, as well as the bond angles are within normal ranges for such $Cu^I$ coordination geometry.[26,27] The $Cu_2(\mathbf{4a})_2Br_2$ dinuclear units are bridged by the bromine ions to form infinite one-dimensional chains (Figure S1). As evidenced in Figure S1, the crystal packing of **7** shows a two-dimensional arrangement of the chains along the *a* axis. Indeed, each 1D chain interacts with two adjacent chains by means of π–π contacts [the separation between the ring centroids amounts to 3.652(3) Å].

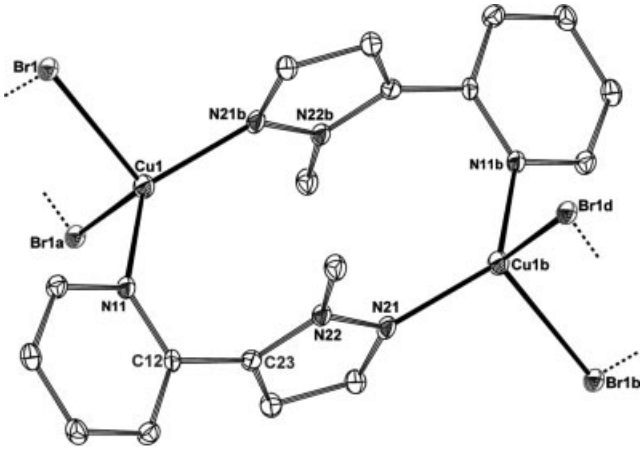


Figure 1. ORTEP drawing (30% probability level) of $[Cu_2(\mathbf{4a})_2Br_2]_n$ (**7**). Hydrogen atoms are omitted for clarity.

Table 1. Selected bond lengths [Å] and angles [°] for **7**–**10**.

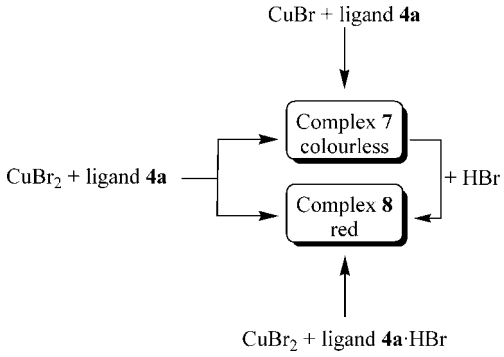
Complex **7** can be obtained by reaction of one equivalent of copper(I) bromide with one equivalent of **4a** in acetonitrile (see Exp. Sect. and Scheme 4).



Scheme 4. Possible aerobic synthetic pathways for the preparation of complexes **7** and **8** (see Exp. Sect. for details).

As observed for other copper(I) complexes,[28,29] compound **7** possesses luminescence properties (see Figure S2). Indeed, under ambient conditions, solid **7** exhibits an intense blue-green emission centred at 490 nm, when excited at 365 nm.

### *Crystal Structure of [Cu(4aH)Br$_3$] (8)*

Red block-shaped single-crystals start to grow up, after three weeks, in the previous solution (from which compound **7** had rapidly crystallized). X-ray diffraction analysis of these crystals reveal them to be the mononuclear compound [Cu(**4a**H)$Br_3$] (**8**) (Figure 2), in which the Cu atoms are divalent and the pyridine N atoms are protonated. Similarly to **7**, **8** crystallizes in the triclinic space group $P\bar{1}$. Selected bond lengths and angles are listed in Table 1, and crystallographic data for the structural analysis are given in Table S1. The copper(II) ion is tetracoordinate and adopts a highly distorted tetrahedral arrangement ($\tau_4$ = 0.62),[25] as in previously observed for analogous $Cu^{II}Br_3N$ chromophores.[30,31] The Cu–Br as well as the Cu–N bond lengths are within normal ranges.[30] The coordination angles, ranging from 96.1(2) to 138.4(2)°, reflect the strong distortion, most likely due to the hydrogen bond involving the bromine atom Br1 (see Figure 3).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

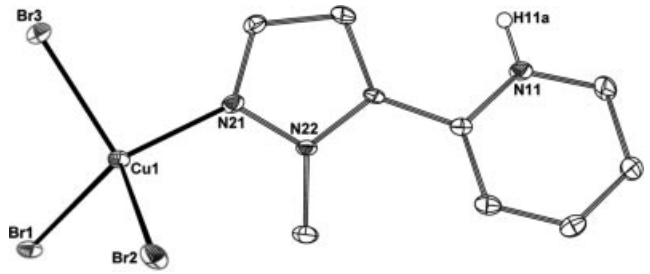


Figure 2. ORTEP drawing (30% probability level) of $[Cu(\mathbf{4a}H)_2Br_3]$ (**8**). Only the pyridinium hydrogen atom is shown.

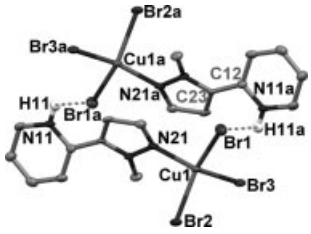

Figure 3. Representation of a dimer of complex **8**, assembled via double intermolecular hydrogen bonding interactions.

The crystal packing of **8** reveals interesting features (Figure 3 and S3). The bromide anion Br1 and the pyridinium hydrogen atom H11 are H-bonded to a neighbouring monocopper complex, producing a dimeric species resembling the dimer of **7** depicted in Figure 1. It thus appears that complex **8** is generated from the copper(I) complex **7** by addition of HBr, like reported by Haddad and Willett for the preparation of bis(dimethylaminopyridinium) tetrabromidocuprate(II).[32] HBr is most likely produced during the formation of complex **7** through decomposition of $CuBr_2$ to CuBr,[33] with concomitant oxidation of the solvent, i.e. methanol (see the section Catalytic Studies). The formal insertion of HBr between the atoms Cu1 and N11 of complex **7** under aerobic conditions (Figure 1) actually results in an increase of steric hindrance which prevents the generation of the 1D chains (observed in **7** and absent in **8**). In addition, the increased steric bulk owing to the additional bromine atom apparently forces the pyrazole ring to rotate around the C12–C23 bond (accordingly, the methyl groups are in opposite directions in Figure 1 and Figure 3).

The H-bonded dimer (Figure 3) is involved in multiple supramolecular interactions, generating a ladder-type framework (Figure S3). The pyrazole rings are π–π stacked with adjacent dimeric units [centroid-to-centroid distance of 3.647(4) Å]. Furthermore, the bromine atom Br3 is interacting with two pyridine rings, resulting in a π–anion–π motif [Figure S3, Br3···centroid $A$ = 3.796(3) Å, Br3···centroid $A'$ = 3.879(3) Å].[34]

To confirm the formation of **8** from **7**, via the addition of HBr under aerobic conditions (Scheme 4), the following experiment has been carried. As stated above, the reaction of $Cu^{I}Br$ with **4a** in acetonitrile produces complex **7**. The addition of HBr to this solution of **7** yields red crystals of **8** after one day, as confirmed by C, H, N, analyses and X-ray diffraction studies (see Exp. Sect.). Compound **8** can also be prepared by reaction of $Cu^{II}Br_2$ with the hydrobromic salt of **4a**, i.e **4a**·HBr (see Scheme 4 and Experimental Section).

### *Crystal Structure of $[Cu_3(5a)_3Br_6]$ (9)*

Reaction of one equivalent of copper(II) bromide with one equivalent of ligand **5a** in methanol produces red needle-shaped single crystals of **9** after one day. **9** crystallizes in the triclinic space group $P\bar{1}$. The important bond parameters and crystallographic data for the structural analysis are listed in Table 1 and S1, respectively. An ORTEP[24] view of compound **9** is depicted in Figure 4. The crystal lattice of this compound is composed of two different copper(II) ions identified as Cu1 and Cu2 (Figure 4). The coordination geometry around Cu1 is intermediate between square-plane and tetrahedral, with $\tau_4$ = 0.50.[25] The Cu–N and Cu–Br bond lengths can be considered as normal.[35,36] The coordination angles ranging from 96.1(2) to 146.7(2) reflect the strong distortion, most likely as a result of steric interactions between Br2 and the methyl substituent in the ligand (Figure S4). The geometry around the Cu2 atom is intermediate between the square-pyramid and the trigonal bipyramid ($\tau_5$ = 0.53).[37] The Cu–N and Cu–Br bond lengths are in normal ranges for this type of $CuBr_3N_2$ chromophore.[38] Cu2 is doubly bridged by two bromide anions to a crystallographically equivalent copper(II) ion, namely Cu2a, giving rise to a dinuclear moiety with a Cu2···Cu2a separation of 4.027(2) Å (Figure 4).

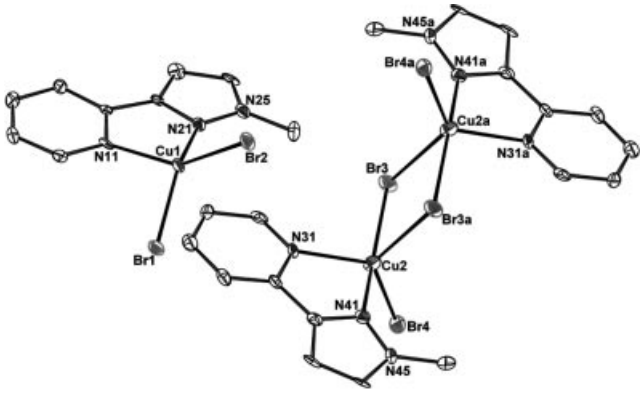

Figure 4. ORTEP drawing (30% probability level) of $[Cu_3(\mathbf{5a})_3Br_6]$ (**9**). Hydrogen atoms are omitted for clarity.

It has to be noted that, if the bromine atom Br3a, coordinated to Cu2 at a long distance of 2.932(2) Å, is omitted, the resulting tetracoordinate copper(II) centre (with $\tau_4$ = 0.53)[25] resembles the Cu1 ion (Figure S5). It thus appears that **9** is constituted by three $CuN_2Br_2$ units, two of them bridged via bromide anions. The crystal packing of **9** along the *a* axis reveals supramolecular interactions (Figure S6). The mononuclear units are π–π stacked in pairs [Figure S6; centroid-to-centroid distance of 3.654(5) Å], whereas the dinuclear units form a 1D chain by means of π–π interactions [see Figure S6: centroid-to-centroid distance of 3.605(5) Å].

### *Crystal Structure of [Cu(6a)$_2$Br]Br·H$_2$O·CH$_3$CN (10)*

Reaction of one equivalent of copper(II) bromide with one equivalent of ligand **6a** in acetonitrile yields green block-shaped single crystals of the mononuclear complex **10**. **10** crystallizes in the triclinic space group $P\bar{1}$. An ORTEP[24] view of compound **10** is depicted in Figure 5. Selected bond lengths and angles are given in Table 1, and details for the structure solution and refinement are summarized in Table S1. The copper(II) ion is pentacoordinate by two ligands **6a** and one bromide anion (Figure 5). The coordination geometry is best described as slightly distorted trigonal-bipyramidal with a $\tau_5$ value of 0.81.[37] The Cu–N and Cu–Br bond lengths are comparable to those of related $Cu^{II}N_4Br$ chromophores.[39,40] The lattice contains one water molecule and one acetonitrile of solvation as well as a bromide anion. The non-coordinating bromide ion and the water molecule are engaged in hydrogen bonding (Figure S7). Actually, the cationic part of **10**, namely [Cu(**6a**)$_2$-Br]$^+$, represents the building unit of a 1D supramolecular chain, assembled through π–π interactions [see Figure S7: centroid-to-centroid distances of 3.555(5) and 3.602(5) Å]. These chains are connected to two adjacent chains via H bonds between the bromine atom Br2, the water oxygen atom Ow, and the acidic pyrazolyl hydrogens H13A and H2A [see Figure S7: N13–H13A···Br2 3.286(7) Å, N2–H2A···Ow 2.801(9) Å].

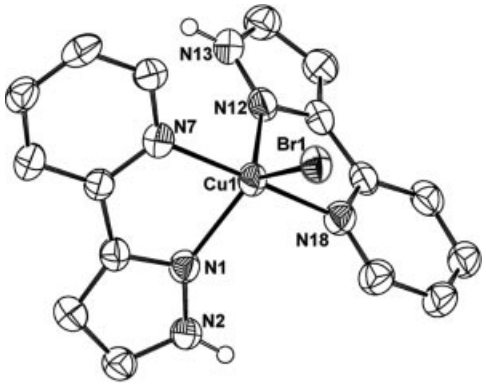

Figure 5. ORTEP drawing (30% probability level) of the cation [Cu(**6a**)$_2$Br]$^+$ of complex **10**. Only the N–H hydrogen atoms are shown for clarity.

## Catalytic Studies

All the ligands prepared have been tested in the [copper/TEMPO]-mediated oxidation of a model substrate, i.e. benzyl alcohol. The initial catalytic oxidations of benzyl alcohol to benzaldehyde were performed applying the experimental conditions reported earlier,[17,21] namely 5 mol-% $CuBr_2$/TEMPO in acetonitrile/water (2:1) with potassium *tert*-butoxide as basic co-catalyst (required to deprotonate the alcoholic substrate).[17,21] For comparison, the conversions achieved with the [$CuBr_2$(2,2′-bipyridine)]/TEMPO system, reported in earlier studies,[17] have been included (Table 2, entry 1). Thus, the use of **4a** as ligand only leads to a conversion of 8% after a reaction time of 1 h (Table 2, entry 2). This poor catalytic activity (1.6 catalytic cycles) is most likely due to the observed precipitation of copper species (green precipitate). Indeed, the insolubility of the copper catalyst obviously retards the rate of the chemical transformation. However, a good conversion of 89% to the exclusive benzaldehyde is reached after 24 h. A more homogeneous reaction system is obtained when acetonitrile is used as the sole solvent (Table 2, entry 3). In that case, a conversion of 31% to benzaldehyde is achieved after 1 h. As no immediate precipitation is observed in the present experiment, this result suggests that the presence of an excess of water (Table 2, entry 2) probably leads to the formation of (multi)copper hydroxide species, which are poorly soluble in the reaction medium. The use of tetrabutylammonium hydroxide (a base exhibiting a higher solubility in acetonitrile than potassium *tert*-butoxide) as basic co-catalyst results in an efficient catalytic system, able to fully and selectively convert benzyl alcohol, after a reaction time of 24 h (Table 2, entry 4). The best catalytic activity is obtained when triethylamine is used as co-catalyst, since more than 2 catalytic cycles are completed after 5 min, and about 40% of benzaldehyde is produced after 1 h (Table 2, entry 5). Interestingly, colourless crystals, exhibiting luminescent properties, start to appear in the reaction mixture after a reaction time of about 15 min. X-ray diffraction studies on these crystals reveals that their solid-state structure corresponds to complex **7**. Surprisingly, this copper(I) complex **7** is very stable in the oxidative conditions of the reaction. Indeed, the reaction is performed in air in the presence of TEMPO, which is believed to play a role in the re-oxidation of the $Cu^I$ species generated during the catalytic cycle (Scheme 1).[21,41] Thus, the lower catalytic activity achieved with this [copper/(pyrazole-pyridine)] system compared to the [copper/2,2′-bipyridine] one (Table 2, entry 1) may be justified by the gradual formation of **7** during the oxidation, resulting in a continuous decrease of active, homogeneous species in the reaction mixture. This high stability of **7** can be explained by the nature of the ligand **4a**. In fact, it has been lately established that a combination of hard/soft ligands appears to favour the stabilization of $Cu^I$ species.[42] **4a** has been purposely designed to contain both a pyridine ring and a pyrazole ring. Therefore, such ditopic ligands apparently can efficiently stabilise copper(I) centres. Thus, the use of dihydrogen peroxide to promote the re-oxidation of the $Cu^I$ ions to $Cu^{II}$ does not lead to an enhancement of the catalytic activity (Table 2, entries 5 and 7). Actually, less active species appear to be formed in the presence of dihydrogen peroxide, because the conversions to benzaldehyde are significantly decreased (Table 2, entries 5 and 7). No improvement in conversion rate is observed when the reaction is performed at 50 °C (see Table 2, entries 5 and 6). On the contrary, the catalyst seems to be less effective (27% conversion after 1 h, whereas 39% conversion can be reached at room temperature), most likely as a result of its partial degradation at a higher temperature. Finally, in contrast to the published catalytic system,[21] the presence of non-coordinating anions, i.e. tetrafluoridoborate and

[a] The catalytic oxidations of benzyl alcohol to benzaldehyde have been carried out using the procedure described in the Experimental Section. The ligand, copper(II) salt, solvent or solvent mixture, and basic co-catalyst used for each test reaction are mentioned in Table 2. [b] The use of 2 equiv. of *t*BuOK (instead of 1 equiv.) does not lead to a better catalytic activity (a conversion of 2% is achieved after a reaction time of 24 hours).

perchlorate, does not lead to an enhancement of the catalytic activity (see Table 2: entries 2 and 8, entries 3 and 9, entries 5 and 11, and entries 4 and 10). Presumably, coordinating anions, such as bromides, are required to complete the coordination sphere of the copper ion (see crystal structures of complexes **7** and **8**), giving rise to catalytically active species. Non-coordinating anions obviously leads to distinct coordination environments around the copper(II) centre, and actually to significantly less active species.

The use of **5a** (regioisomer of **4a**) as ligand in the copper-catalysed oxidation of benzyl alcohol gives less efficient catalysts (Table 2, entries 12–15). In fact, in all cases, a white precipitate rapidly develops in the reaction mixture which shows luminescent properties. This feature suggests the presence of copper(I) species (similarly to ligand **4a**, see above). Due to the fact that, contrary to **4a**, **5a** is a chelating ligand, its coordination probably induces an even better stabilisation of copper(I) entities. This hypothesis is corroborated by the interruption of the catalytic activity after about 1 h (only a conversion of 30% is achieved after a reaction time of 24 h, Table 2, entry 13), while the initial conversions (after a reaction time of 5 min) are comparable to those obtained with **4a** (see for instance Table 2, entries 5 and 12). Moreover, the addition of dihydrogen peroxide in the reaction medium does not favour the re-oxidation of the $Cu^{I}$ ions to $Cu^{II}$ (Table 2, entries 14 and 15), once again indicative of very stable copper(I) species.

The use of **6a** as a ligand generates poorly active catalysts (Table 2, entries 16–19). A maximum conversion of only 33% has been reached in pure acetonitrile, with triethylamine as co-catalyst, after a reaction time of 24 h (Table 2, entry 17). This lack of activity can be justified by the presence of the acidic N-pyrazolyl proton in the ligand. Indeed, under basic conditions, pyrazoles can be deprotonated, and the resulting pyrazolato ligands are known to promote the formation of cluster species.[43] In the present case, the addition of the base (to initiate the catalytic reaction, see experimental section) immediately results in the development of a green precipitate, which may originate from the deprotonation of the pyrazole ring, followed by the formation of insoluble (hence inactive) copper clusters.

Finally, the use of the naphthol-containing compounds **4b**–**6b** (Scheme 3) as ligands does not result in active catalytic systems (Table 2, entries 20–22). This lack of reactivity is obviously due to the presence of the naphtholic donor group in the ligands. In all cases, a dark brown-reddish solution is obtained while a light orange colour is observed with the first series of ligands (compounds **4a**–**6a**). Thus, the different coordination environment around the copper ions has a dramatic effect on the catalytic competence of the corresponding complex. In previous investigations, a bidentate donor, namely 2,2′-bipyridine (see also Table 2, entry 1), has been reported as an efficient ligand for the [copper/TEMPO]-catalysed oxidation of primary alcohols.[21] In the present study, bidentate pyridine/pyrazole donors (ligands **4a**–**6a**) and pyridine/phenol donors (ligands **4b**–**6b**) have been designed and tested in this copper-mediated reaction. It clearly appears that the use of pyridine/phenol bidentate ligands is not beneficial for this reaction, which should be considered for the design of new catalysts for this reaction.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

## Conclusions

Two series of pyrazole-based bidentate ligands have been designed and used to coordinate copper ions. As expected and recently suggested by theoretical investigations,[42] the pyridine-pyrazole ligands are capable of stabilizing copper(I) species, so that an air-stable copper(I) coordination polymer could be isolated and characterized by X-ray diffraction. The copper complexes from these ligands show interesting catalytic behaviours. Indeed, high catalytic activities are observed at the beginning of the reaction, which start to significantly decrease after one hour reaction time. Actually, a colourless crystalline precipitate develops in the reaction medium after a reaction time of approximately 15 min. This luminescent solid material is ascribed to copper(I) species (in one case, the crystals obtained in the reaction mixture have been characterized by X-ray diffraction). Therefore, the amount of active species in solution decreases in time, resulting in the observed diminution of the catalytic activity. However, the total conversion of the substrate after a reaction time of 24 h suggests that the (very stable) copper(I) species are slowly re-oxidized by atmospheric oxygen, since the catalyst is not "dead". It appears that the use of naphthol-pyrazole ligands inhibits the catalytic abilities of the corresponding copper complexes, but more studies are required to appraise this ligand effect. For instance, the use of bis-pyrazole and pyridine-phenol ligands are now investigated to compare the catalytic activities of their copper(II) complexes with those reported in the previous[21] and present reports, and evaluate the influence of the phenol (naphthol) ring on the catalysis.

In summary, the results reported in this paper strongly indicate that the combination of well-chosen donors to design a bidentate ligand for this reaction would most likely lead to a very efficient copper catalyst. The mixed ligand should be able to stabilise both the $Cu^{I}$ and $Cu^{II}$ species occurring during the catalytic cycle, but also to allow an easy "switching" between the two oxidation states. Investigations are currently ongoing to find the right combination of donor groups.

## Experimental Section

**General Remarks:** All chemicals were of reagent grade and were used as commercially obtained. Elemental analyses for C, H, and N were performed with a Perkin–Elmer 2400 analyzer. FTIR spectra were recorded with a Perkin–Elmer Paragon 1000 FTIR spectrophotometer, equipped with a Golden Gate ATR device, using the reflectance technique (4000–300 $cm^{-1}$). $^1H$ NMR spectra were recorded on a Bruker DPX 300 (300 MHz) instrument. Chemical shifts are reported in $\delta$ (parts per million) relative to an internal standard of tetramethylsilane. ESI mass analyses were carried out on a Voyager Elite from PerSeptive Biosystems. The excitation and emission spectra were recorded with a Perkin–Elmer LS50B luminescence spectrometer. The intensity of the emission spectra was corrected for the sensitivity of the detector.

**Syntheses of the Ligands:** The preparation of the different ligands was based on an earlier published procedure.[44]

**Synthesis of 3-(Dimethylamino)-1-(pyridin-2-yl)prop-2-en-1-one (3a):**[45] 10 g (0.0825 mol) of 2-acetylpyridine (**1a**) were introduced in a round-bottomed flask. Then, 20 mL (17.9 g, 0.1504 mol) of *N*,*N*-dimethylformamide dimethyl acetal (**2**) were added, and the resulting reaction mixture was refluxed overnight. The dark brown solution obtained was evaporated to dryness. The resulting dark-brown crystalline material was washed with hexane (3 × 100 mL) and with diethyl ether (3 × 100 mL), yielding 10.6 g (yield 73%) of pure, bright yellow **3a**, as previously obtained by Balavoine et al.[45]

**Synthesis of 3-(Dimethylamino)-1-(1-hydroxynaphthalen-2-yl)prop-2-en-1-one (3b):**[46] **3b** was synthesized using the procedure described above for the preparation of **3a**, starting from 5 g (0.0269 mol) of 2-acetyl-1-naphthol. **3b** was obtained as a pure yellow powder,[46] with a yield of 75% (4.9 g).

**Synthesis of 2-(1-Methyl-1*H*-pyrazol-5-yl)pyridine (4a) and 2-(1-Methyl-1*H*-pyrazol-3-yl)pyridine (5a):** 3 g (0.0170 mol) of **3a** and 6 mL (0.1120 mol) of methylhydrazine were mixed in a 50 mL round-bottomed flask containing 10 mL of ethanol. The reaction mixture was heated at 60 °C and stirred for 30 min. After cooling to room temperature, 30 mL of distilled water were added, giving rise to the precipitation of a light yellow solid. This crude product containing both regioisomers, namely **4a** and **5a**, was purified by column chromatography ($SiO_2$, eluent ethyl acetate/hexane, 1:1 until the isolation of the first isomer **4a**; then an ethyl acetate/hexane mixture (8:2) was used as eluent to isolate pure **5a**). Yield 1.43 g of **4a** (53%) and 0.32 g of **5a** (17%).

**Isomer 4a:** $C_9H_9N_3$ (159.19): calcd. C 67.90, H 5.70, N 26.40; found C 68.20, H 5.32, N 25.95. ES(+)-MS: *m*/*z* = 160.04 [M + $H^+$], 181.99 [M + $Na^+$]. FT-IR (neat solid): $\tilde{\nu}$ = 2949, 1589, 1461, 1422, 1388, 1278, 1152, 996, 928, 765, 688, 648, 622, 403 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 3.99 (s, 3 H, $CH_3$), 6.35 (d, $^3J_{H,H}$ = 1.9 Hz, 1 H, 4-H pz), 6.95 (dd, $^3J_{H,H}$ = 4.9, $^3J_{H,H}$ = 7.7 Hz, 1 H, 5-H py), 7.29 (d, $^3J_{H,H}$ = 1.9 Hz, 1 H, 3-H pz), 7.32 (d, $^3J_{H,H}$ = 2.0 Hz, 1 H, 3-H py), 7.42 (dd, $^3J_{H,H}$ = 2.0, $^3J_{H,H}$ = 7.7 Hz, 1 H, 4-H py), 8.41 (d, $^3J_{H,H}$ = 4.9 Hz, 1 H, 6-H pz) ppm.

**Isomer 5a:**[47] $C_9H_9N_3$ (159.19): calcd. C 67.90, H 5.70, N 26.40; found C 67.85, H 5.65, N 25.94. ES(+)-MS: *m*/*z* = 160.01 [M + $H^+$]. FT-IR (neat solid): $\tilde{\nu}$ = 2949, 1589, 1459, 1423, 1388, 1277, 1152, 996, 928, 764, 688, 648, 622, 402 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 3.97 (s, 3 H, $CH_3$), 6.85 (d, $^3J_{H,H}$ = 2.2 Hz, 1 H, 4-H pz), 7.28 (dd, $^3J_{H,H}$ = 4.8, $^3J_{H,H}$ = 7.8 Hz, 1 H, 5-H py), 7.40 (d, $^3J_{H,H}$ = 2.2 Hz, 1 H, 3-H pz), 7.54 (dd, $^3J_{H,H}$ = 7.8, $^3J_{H,H}$ = 7.9 Hz, 1 H, 4-H py), (d, $^3J_{H,H}$ = 7.9 Hz, 1 H, 3-H py), 8.61 (d, $^3J_{H,H}$ = 4.8 Hz, 1 H, 6-H pz) ppm.

**Synthesis of 2-(1*H*-Pyrazol-3-yl)pyridine (6a):** 3 g (0.0170 mol) of **3a** and 6 mL (0.1235 mol) of hydrazine monohydrate were mixed in a 50 mL round-bottomed flask containing 10 mL of ethanol. The reaction mixture was heated at 60 °C and stirred for 30 min at this temperature. After cooling to room temperature, 30 mL of distilled water were added, producing a light yellow precipitate. This solid was washed on a glass filter with hexane (2 × 200 mL) and diethyl ether (2 × 200 mL). After drying at 100 °C for 4 h, the pure ligand **6a** is obtained. Yield 0.74 g (30%). $C_8H_7N_3$ (145.16): calcd. C 66.19, H 4.86, N 28.95; found C 65.89, H 4.82, N 29.12. ES(+)-MS: *m*/*z* = 146.07 [M + $H^+$], 167.99 [M + $Na^+$]. FT-IR (neat solid): $\tilde{\nu}$ = 3122, 2896, 1590, 1503, 1454, 1417, 1356, 1191, 1000, 876, 758, 615, 403 $cm^{-1}$. $^1H$ NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 6.84 (d, $^3J_{H,H}$ = 1.9 Hz, 1 H, 4-H pz), 7.28 (dd, $^3J_{H,H}$ = 3.6, $^3J_{H,H}$ = 4.9 Hz, 1 H, 5-H py), 7.69 (d, $^3J_{H,H}$ = 1.9 Hz, 1 H, 3-H pz), 7.78 (d, $^3J_{H,H}$ = 3.6 Hz, 1 H, 4-H py), 8.69 (d, $^3J_{H,H}$ = 4.9 Hz, 1 H, 6-H py), 12.11 (s, 1 H, N–H) ppm.

**Synthesis of 2-(1-Methyl-1*H*-pyrazol-5-yl)naphthalen-1-ol (4b) and 2-(1-Methyl-1*H*-pyrazol-3-yl)naphthalen-1-ol (5b):** 3 g (0.0124 mol) of **3b** and 6 mL (0.1120 mol) of methylhydrazine were mixed in a 50 mL round-bottomed flask containing 10 mL of ethanol. The reaction mixture was heated at 60 °C, and stirred for 30 min at this temperature. After cooling to room temperature, 30 mL of distilled water were added, resulting in a light brown emulsion. This solution was extracted with dichloromethane (3 × 50 mL). The pooled organic phase was dried with magnesium sulfate, filtered, and the solvent was evaporated under reduced pressure. The resulting brown viscous crude compound was purified by column chromatography ($SiO_2$, ethyl acetate/hexane, 1:1), yielding 1.6 g of **4b** (58%) and 0.78 g of **5b** (28%).

**Isomer 4b:**[48] $C_{14}H_{12}N_2O$ (224.26): calcd. C 74.98, H 5.39, N 12.49; found C 74.92, H 5.17, N 12.53. M.p. 85 °C. ES(+)-MS: *m*/*z* = 224.91 [M + H$^+$]. FT-IR (neat solid): $\tilde{\nu}$ = 2938, 1576, 1495, 1386, 1354, 1089, 805, 755, 745, 698, 659, 572, 486, 422 cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 3.98 (s, 3 H, $CH_3$), 6.68 (d, $^3J_{H,H}$ = 2.3 Hz, 1 H, 4-H pz), 7.38 (d, $^3J_{H,H}$ = 8.6 Hz, 1 H, 4-H naphthol), 7.43 (d, $^3J_{H,H}$ = 2.3 Hz, 1 H, 3-H pz), 7.45 (dd, $^3J_{H,H}$ = 4.8 Hz, 1 H, 6-H naphthol), 7.49 (dd, $^3J_{H,H}$ = 3.9 Hz, 1 H, 7-H naphthol), 7.65 (d, $^3J_{H,H}$ = 8.6 Hz, 1 H, 3-H naphthol), 7.77 (d, $^3J_{H,H}$ = 4.8 Hz, 1 H, 5-H naphthol), 8.42 (d, $^3J_{H,H}$ = 3.9 Hz, 1 H, 8-H naphthol), 11.60 (br. s, 1 H, O–H) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, 20 °C): $\delta$ = 38.3, 101.9, 109.7, 118.5, 122.7, 123.6, 125.0, 125.3, 126.2, 127.2, 130.7, 133.8, 151.2, 151.4 ppm.

Single-crystals of **4b** were obtained, which were analysed by X-ray diffraction. An ORTEP view of ligand **4b** is depicted in Figure S8. The molecular structure is uneventful and as expected.

**Isomer 5b:**[48] $C_{14}H_{12}N_2O$ (224.26): calcd. C 74.98, H 5.39, N 12.49; found C 74.57, H 5.14, N 12.49. M.p. 142 °C. ES(+)-MS: *m*/*z* = 224.98 [M + H$^+$]. FT-IR (neat solid): $\tilde{\nu}$ = 2943, 1571, 1389, 1292, 1199, 1074, 809, 788, 739, 667, 570, 484, 436, 423 cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 3.80 (s, 3 H, $CH_3$), 6.43 (d, $^3J_{H,H}$ = 1.8 Hz, 1 H, 4-H pz), 7.25 (d, $^3J_{H,H}$ = 8.2 Hz, 1 H, 4-H naphthol), 7.49 (d, $^3J_{H,H}$ = 8.2 Hz, 1 H, 3-H naphthol), 7.53–7.59 (m, 2 H, 6-H naphthol + 7-H naphthol), 7.61 (d, $^3J_{H,H}$ = 1.8 Hz, 1 H, 3-H pz), 7.84 (d, $^3J_{H,H}$ = 9.3 Hz, 1 H, 5-H naphthol), 8.33 (d, $^3J_{H,H}$ = 9.5 Hz, 1 H, 8-H naphthol), 11.72 (br. s, 1 H, O–H) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, 20 °C): $\delta$ = 36.8, 106.8, 110.3, 119.8, 122.8, 125.1, 125.6, 127.1, 127.2, 127.4, 134.8, 138.7, 139.6, 150.4 ppm.

**Synthesis of 2-(1*H*-Pyrazol-5-yl)naphthalen-1-ol (6b):**[48] 2.76 g (0.0114 mol) of **3b** and 6 mL (0.1235 mol) of hydrazine monohydrate were mixed in a 50 mL round-bottomed flask containing 9 mL of ethanol. The reaction mixture was heated at 60 °C and stirred for 30 min at this temperature. After cooling to room temperature, 30 mL of distilled water were added, producing a light brown crystalline product. This solid was filtered off, and washed with hexane (2 × 200 mL). After drying at 100 °C for 4 h, the pure ligand **6b** was obtained. Yield 1.8 g (75%). $C_{13}H_{10}N_2O$ (210.23): calcd. C 74.27, H 4.79, N 13.33; found C 74.16, H 4.99, N 13.18. ES(+)-MS: *m*/*z* = 210.92 [M$^+$], 232.92 [M + Na$^+$]. FT-IR (neat solid): $\tilde{\nu}$ = 3303, 3054, 1636, 1579, 1505, 1389, 1283, 1077, 976, 878, 759, 720, 656, 571, 484, 420 cm$^{-1}$. $^1$H NMR (300 MHz, $CDCl_3$, 20 °C): $\delta$ = 6.80 (d, $^3J_{H,H}$ = 2.6 Hz, 1 H, 4-H pz), 7.41 (d, $^3J_{H,H}$ = 8.6 Hz, 1 H, 4-H naphthol), 7.46–7.53 (m, 2 H, 3-H naphthol + 6-H naphthol), 7.67–7.70 (m, 2 H, 7-H naphthol + 3-H pz), 7.78 (d, $^3J_{H,H}$ = 9.4 Hz, 1 H, 5-H naphthol), 8.43 (d, $^3J_{H,H}$ = 9.7 Hz, 1 H, 8-H naphthol), 10.2–10.8 (v br. s, 2 H, O–H + N–H) ppm.

**Preparation of the Coordination Compounds**

**Synthesis of [$Cu_2$(4a)$_2Br_2$]$_n$ (7):** A solution of ligand **4a** (100 mg, 0.628 mmol) in methanol (10 mL) was added to a solution of copper(II) bromide (140 mg, 0.628 mmol) in methanol (10 mL). The resulting dark-green solution was filtered and the filtrate was left unperturbed for the slow evaporation of the solvent. After one day, colourless crystals of **7** were collected (yield 146 mg, 77%). $C_{18}H_{18}Br_2Cu_2N_6$ (605.28): calcd. C 35.72, H 3.00, N 13.88; found C 35.20, H 2.93, N 13.72. IR (neat): $\tilde{\nu}$ = 3119, 3051, 1599, 1465, 1420, 1390, 1284, 1225, 1009, 940, 808, 786, 755, 700, 645, 542, 414 cm$^{-1}$. Unit cell parameters: *a* = 7.668(2) Å, *b* = 8.492(2) Å, *c* = 9.174(2) Å, $\alpha$ = 96.90(3)°, $\beta$ = 114.06(3)°, $\gamma$ = 107.49(3)° (see Table S1).

The same coordination compound (as evidenced by single-crystal X-ray analysis) was obtained from an acetonitrile solution of the reactants (using the same concentration), but after one week (instead of one day in methanol).

Complex **7** has also been isolated during the catalysis reactions, and characterized by X-ray diffraction analysis.

Complex **7** is insoluble in common solvents such as methanol, acetonitrile, THF, chloroform and dichloromethane. Consequently, NMR studies of the solution structure of the diamagnetic complex are not possible.

Complex **7** can also be prepared directly from CuBr and the ligand **4a**, using the following reaction conditions: a solution of ligand **4a** (25 mg, 0.157 mmol) in acetonitrile (5 mL) was added to a solution of copper(I) bromide (23 mg, 0.157 mmol) in acetonitrile (5 mL). The resulting light-green solution was filtered and the filtrate was left unperturbed for the slow evaporation of the solvent. After two hours, colourless crystals of **7** started to grow. The crystals were collected after one day (yield 31 mg, 33%). $C_{18}H_{18}Br_2Cu_2N_6$ (605.28): calcd. C 35.72, H 3.00, N 13.88; found C 35.31, H 2.82, N 13.75. IR (neat): $\tilde{\nu}$ = 3119, 3054, 1560, 1464, 1418, 1392, 1284, 1225, 1010, 940, 808, 786, 755, 700, 645, 543, 414 cm$^{-1}$. The structure, corresponding to complex **7**, was confirmed by X-ray diffraction analysis. Unit cell parameters: *a* = 7.661(2) Å, *b* = 8.502(2) Å, *c* = 9.160(2) Å, $\alpha$ = 96.90(3)°, $\beta$ = 114.12(3)°, $\gamma$ = 107.39(3)°.

**Synthesis of [Cu(4aH)Br$_3$] (8):** Red crystals of **8** were obtained from the solution above. Since these few single-crystals were mixed with crystals of **7**, they were only characterised by X-ray diffraction (see Discussion). Unit cell parameters: *a* = 7.611(2) Å, *b* = 7.908(2) Å, *c* = 11.787(2) Å, $\alpha$ = 104.99(3)°, $\beta$ = 100.48(3)°, $\gamma$ = 94.75(3)° (see Table S1).

However, complex **8** could also be synthesized from $CuBr_2$ and **4a**·HBr according to the following procedure: 18 μL (0.157 mmol) of $HBr_{aq}$ 48% were added to a solution of ligand **4a** (25 mg, 0.157 mmol) in 5 mL of acetonitrile. The solution was stirred for 10 min, and 35 mg (0.157 mmol) of $CuBr_2$ were subsequently added. The resulting dark-green solution was filtered and the filtrate was left unperturbed for the slow evaporation of the solvent. After one day, red needle-shaped crystals were collected (yield 17 mg, 23%). $C_9H_{10}Br_3CuN_3$ (463.45): calcd. C 23.32, H 2.17, N 9.07; found C 23.10, H 2.63, N 9.12. IR (neat): $\tilde{\nu}$ = 2934, 2879, 1633, 1612, 1558, 1490, 1447, 1422, 1392, 1285, 1226, 1186, 1168, 1062, 1009, 914, 815, 764, 684, 640, 524, 469, 378 cm$^{-1}$. The structure, corresponding to complex **8**, was confirmed by X-ray diffraction analysis. Unit cell parameters: *a* = 7.598(2) Å, *b* = 7.892(2) Å, *c* = 11.785(2) Å, $\alpha$ = 105.12(3)°, $\beta$ = 100.39(3)°, $\gamma$ = 94.81(3)°.

Complex **8** could be obtained as well by addition of HBr to a solution of complex **7**. As for the preparation of complex **7** (from CuBr,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

see above), a solution of one equivalent (25 mg, 0.157 mmol) of **4a** in 5 mL of acetonitrile was added to a solution of one equivalent of copper(I) bromide (23 mg, 0.157 mmol) in acetonitrile (5 mL). The resulting light-green solution was stirred for 15 min. Next, 18 μL (0.157 mmol) of $HBr_{aq}$ 48% were added, which resulted in an immediate change of the colour of the reaction mixture to dark-green. The solution was filtered and the filtrate was left unperturbed for the slow evaporation of the solvent. After one day, red needle-shaped crystals were collected (yield 10 mg, 14%). $C_9H_{10}Br_3CuN_3$ (463.45): calcd. C 23.32, H 2.17, N 9.07; found C 23.15, H 2.25, N 8.93. IR (neat): $\tilde{\nu}$ = 2934, 2878, 1633, 1612, 1558, 1490, 1447, 1423, 1393, 1285, 1226, 1186, 1168, 1063, 1010, 914, 815, 764, 684, 640, 524, 470, 379 $cm^{-1}$. The structure, corresponding to complex **8**, was confirmed by X-ray diffraction analysis. Unit cell parameters: $a$ = 7.605(2) Å, $b$ = 7.911(2) Å, $c$ = 11.792(2) Å, $\alpha$ = 104.96(3)°, $\beta$ = 100.45(3)°, $\gamma$ = 94.70(3)°.

**Synthesis of $[Cu_3(5a)_3Br_6]$ (9):** A solution of ligand **5a** (100 mg, 0.628 mmol) in acetonitrile (10 mL) was added to a solution of copper(II) bromide (140 mg, 0.628 mmol) in acetonitrile (10 mL). The resulting dark green-brown solution was filtered, and the filtrate was left unperturbed. After 10 min, red needle-shaped crystals of **9**, suitable for X-ray diffraction analysis, started to grow. After one day, the crystals were collected (yield 204 mg, 85%). $C_{27}H_{27}Br_6Cu_3N_9$ (1147.63): calcd. C 28.26, H 2.37, N 10.98; found C 28.29, H 1.95, N 11.19. IR (neat): $\tilde{\nu}$ = 3130, 1609, 1502, 1436, 1366, 1284, 1234, 1154, 1075, 1019, 896, 772, 719, 685, 643, 610, 417 $cm^{-1}$.

Complex **9** was also obtained (as evidenced by single-crystal X-ray analysis) from a methanolic solution of the reactants, exhibiting the same molar concentration.

**Synthesis of $[Cu(6a)_2Br]Br\cdot H_2O\cdot CH_3CN$ (10):** A solution of ligand **6a** (100 mg, 0.689 mmol) in acetonitrile (10 mL) was added to a solution of copper(II) bromide (154 mg, 0.689 mmol) in acetonitrile (10 mL). The resulting green solution was filtered, and the filtrate was left unperturbed for the slow evaporation of the solvent. After a few days, green block-shaped crystals of **10** were obtained (yield 142 mg, based on the ligand, 72%). $C_{18}H_{19}Br_2CuN_7O$ (572.74): calcd. C 37.75, H 3.34, N 17.12; found C 37.50, H 3.62, N 17.03. IR (neat): $\tilde{\nu}$ = 3301, 3113, 1610, 1454, 1442, 1432, 1375, 1290, 1187, 1090, 1060, 1016, 972, 768, 699, 642, 568, 487, 419 $cm^{-1}$.

**Typical Catalytic Experiment:** Benzyl alcohol (1.08 g, 10 mmol) was dissolved in 15 mL of acetonitrile. 112 mg (0.5 mmol) of copper(II) bromide were then added, followed by 0.5 mmol of ligand. Next, 78 mg (0.5 mmol) of TEMPO were added, resulting in a dark green solution. Finally, the oxidation reaction was initiated by the addition of 51 mg (0.5 mmol, 70 μL) of triethylamine, causing an instantaneous change of colour, from dark green to orange. The course of the reaction was monitored by gas chromatography (GC).

**X-Ray Crystal Structure Determinations:** Crystallographic data and refinement details are given in Tables S1 and S2. A crystal was selected for the X-ray measurements and mounted to the glass fiber using the oil drop method[49] and data were collected at 173 K (or 150 K for compound **10**) on a Nonius Kappa CCD diffractometer (Mo-$K_\alpha$ radiation, graphite monochromator, $\lambda$ = 0.71073). The intensity data were corrected for Lorentz and polarization effects, and for absorption. The programs collect,[50] SHELXS-97,[51] SHELXL-97[52] were used for data reduction, structure solution and structure refinement, respectively. The non-hydrogen atoms were refined anisotropically. The H atoms were introduced in calculated positions and refined with fixed geometry with respect to their carrier atoms.

CCDC-643549 to -643552 (for **4b**–**9**) and -643309 (for **10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Crystallographic data for compounds **4b** and **7**–**10**, crystal structure of **4b**, crystal packing diagrams for **7**–**10**, excitation and luminescent spectra of **7**.

## Acknowledgments

This work has been supported financially by the Graduate Research School Combination "Catalysis", a joint activity of the graduate research schools NIOK, HRSMC and PTN. Financial support from European Cooperation in the Field of Science and Technology (COST) Action D35/0011, Werkgroep Fundamenteel Materialen Onderzoek (WFMO) Nederlandse Organisatie voor Wetenschappelijk Onderzoek (NWO) – Foundation for the Chemical Sciences (Chemische Wetenschappen, CW), are gratefully acknowledged. Coordination by the FP6 Network of Excellence "Magmanet" (contract number 515767) is also kindly acknowledged. We would also like to thank Paul de Hoog for his help with the NMR studies.

# Organoiridium Quinolinolate Complexes: Synthesis, Structures, Thermal Stabilities and Photophysical Properties

**Stefan Kappaun,[a] Sabrina Eder,[b] Stefan Sax,[b] Kurt Mereiter,[c] Emil J. W. List,[b] and Christian Slugovc*[a]**

**Keywords:** Iridium / N,O ligands / Luminescence / Nitrogen heterocycles

The syntheses, solid-state structures, thermal properties and photophysics of a series of heteroleptic iridium(III) complexes with phenylpyridine as the cyclometalating ligands and quinolinolates are reported. The title compounds were formed by reaction of di-μ-chloro-tetrakis[$\kappa^2(C^2,N)$-2-phenylpyridine]-diiridium(III) with the corresponding 8-hydroxyquinolines in 56 to 86 % yield. The crystal structures of two of the complexes have been determined. Both complexes show the two carbon ligands in a *cis* disposition and the 2-phenylpyridine nitrogen atoms in a *trans* disposition. Assessment of the thermal stabilities of the compounds revealed huge differences depending on the substituents on the quinolinolato ligand. Most complexes are poor emitters in solution, in films and in OLEDs. Substitution of the quinolinolato ligand with electron-withdrawing functional groups in the 5-position caused additional absorption features in the visible region facilitating the finding of appropriate host materials for OLEDs and gave emission properties governed by the quinolinolato ligand.

## Introduction

The design, synthesis and characterisation of phosphorescent light-emitting materials have received considerable attention in the last couple of years due to a series of possible practical applications such as in organic light-emitting diodes (OLEDs),[1] light-emitting electrochemical cells (LECs)[2] or for sensing purposes.[3] Although tremendous improvements concerning device lifetimes, efficiencies, brightness and device structures[4] have been made for phosphorescent metal complexes containing platinum, osmium and iridium,[1,5] there is still a great demand for stable emitter materials that cover the entire visible spectrum.[6]

Among this class of materials, cyclometalated iridium(III) complexes have emerged as very promising candidates because of the powerful colour-tuning from blue to red brought about by variations in the cyclometalating ligands or extension of the corresponding conjugated ligand systems.[4] However, the drawbacks of this approach are the cumbersome synthesis of the μ-chloro-bridged precursor material. Harsh conditions are needed for the preparation of tris(cyclometallated) iridium(III) complexes and the formation of several by-products also occurs.[4,7] In contrast to the difficulties with the preparation of these homoleptic iridium(III) complexes, an alternative approach is based on the incorporation of ancillary ligands such as acetylacetonato, picolinato, triazolato or tetrazolato derivatives with clearly facilitated synthetic procedures.[4a] On the other hand, only a few examples of heteroleptic iridium(III) complexes with emission properties dominated by the third ligand have been reported[4,8] which is clearly disadvantageous for a fast and versatile approach to colour-tuneable phosphorescent emitter materials.

During the last two decades a large number of reports have been published concentrating on the design and characterisation of luminescent metal complexes bearing 8-hydroxyquinoline and its derivatives as ligands.[9] 8-Hydroxyquinolines are of particular interest because of the possibility of tuning the energy gap by the simple attachment of electron-donating or electron-withdrawing groups and the commercial availability of many 8-hydroxyquinoline derivatives.[6,9] Although considerable scientific efforts have been focused on studying luminescent metal complexes of aluminium, platinum, palladium or boron containing 8-hydroxyquinolines as ligands, corresponding investigations on the impact of ligand modifications on the materials properties of organoiridium quinolinolate complexes are rare.[10]

Recently we reported on heteroleptic iridium(III) complexes bearing 8-hydroxyquinolines as ligands for the preparation of white organic light-emitting diodes (WOLEDs)

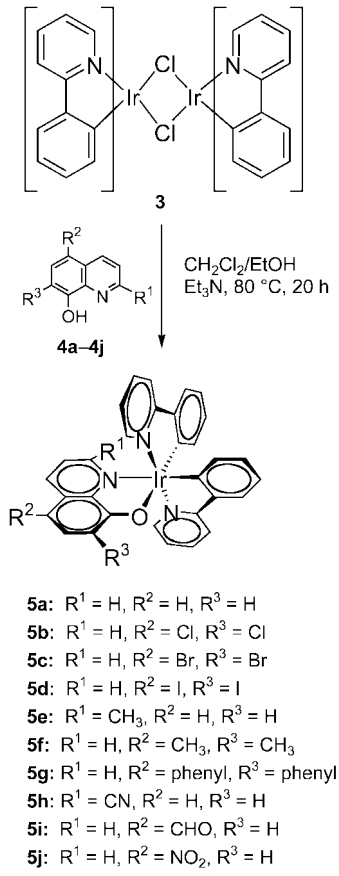
and communicated our first results on the colour-tuning of organoiridium quinolinolate complexes with emission properties controlled by the quinolinolato ligand.[11] In this work we wish to present the synthesis, structures, thermal and photophysical properties of a series of derivatives of bis[κ²(*C*²,*N*)-2-phenylpyridine][κ²(*N*,*O*)-8-quinolinolato]iridium(III). The presented systematic study on the influence of functional groups on materials properties corresponds to recent reports on iridium(III) complexes tailored towards particular needs[1c,11] and provides a step towards a general toolbox for realising low-cost and colour-tuneable iridium(III) compounds for, e.g., OLED applications. Parts of this work have been communicated briefly.[11b]

## Results and Discussion

The compounds under investigation were prepared as depicted in Scheme 1. According to a literature procedure starting from $IrCl_3 \cdot nH_2O$ (**1**) and 2-phenylpyridine (**2**),[12] the μ-chloro-bridged precursor material di-μ-chloro-tetrakis[κ²(*C*²,*N*)-2-phenylpyridine]diiridium(III) (**3**) could be obtained by heating the black coloured reaction mixture to reflux, in 2-ethoxyethanol and water, at 120 °C for 24 h. Purification of **3** was achieved by filtration of the greenish precipitate which formed during the reaction and repeated washing of the solid residue with hot MeOH. The various derivatives of bis[κ²(*C*²,*N*)-2-phenylpyridine][κ²(*N*,*O*)-8-quinolinolato]iridium(III) (**5a**–**5j**; for nomenclature see Exp. Sect.) were synthesised by treating **3** with 2.1 to 2.5 equiv. of the corresponding 8-hydroxyquinoline (**4a**–**4j**) in $CH_2Cl_2$, EtOH and $Et_3N$ at 80 °C for 20 h.[11] Work-up of the organoiridium(III) complexes **5a**–**5j** turned out to be straightforward and was achieved by filtration and subsequent washing of the yellow to deeply red solids with hot MeOH several times affording yields between 56 and 86% of the pure products. It is worth noting that with the exception of **4g** all 8-hydroxyquinoline derivatives were obtained from commercial sources. Compound **4g** was prepared by means of a Suzuki cross-coupling reaction of 8-benzyloxy-5,7-dibromoquinoline and phenylboronic acid in a solvent mixture of toluene, EtOH and water with $Na_2CO_3$ as a base and $[Pd(PPh_3)_4]$ as catalyst. Removal of the benzyloxy protecting group was achieved by treatment with $BF_3 \cdot Et_2O$ and KI in $CH_3CN$ as reported recently.[13]



Scheme 1. Synthesis of bis[κ²(*C*²,*N*)-2-phenylpyridine][κ²(*N*,*O*)-8-quinolinolato]iridium(III) derivatives **5a**–**5j**.

Compounds **5a**–**5j** were characterised by $^1$H- and $^{13}$C-NMR spectroscopy, absorption and fluorescence measurements as well as matrix-assisted laser desorption ionisation time-of-flight (MALDI-TOF) MS. Furthermore, the thermal behaviour and the impact of ligand modifications on the thermal stability were probed by combined DSC/TGA measurements.

NMR spectroscopy has been shown to be a powerful tool for the characterisation of homo- and heteroleptic iridium(III) complexes.[14] Because organoiridium quinolinolate complexes have hitherto rarely been studied,[10,11] we herein present our interpretation and assignment of the proton NMR spectroscopic peaks of **5b** (Figure 1). Based on these results, the interpretation of the NMR spectra of the other studied compounds can also be easily performed as given in the Experimental Section.[11]

As shown in Figure 1 for **5b** in $[D_6]$DMSO, there are considerable differences in the shift values of the protons of the two phenylpyridine ligands resulting from the asymmetrical character of the quinolinolato ligand. Thus, different shifts especially for the protons of $Py^6$ ($\delta$ = 8.39 and 7.59–7.55 ppm), $Py^3$ (8.21 and 8.16 ppm) and $Py^5$ (7.30 and 7.10 ppm) can be observed. Less drastic differences may be found for the protons of the phenyl rings. While the peaks of $Ph^6$ are located at low-field around 7.91–7.80 ppm, the peaks for $Ph^5$ (6.93–6.87 ppm), $Ph^4$ (6.79 and 6.74 ppm) and $Ph^3$ (6.26 and 6.11 ppm) are shifted towards higher fields with an increased proximity to the metalation centre. For the quinolinolato ligand, the protons of $Q^4$, $Q^6$, $Q^2$ and $Q^3$ are located at 8.35, 7.74, 7.71 and 7.59–7.55 ppm, respectively. It is worth noting that for these complexes metalation causes a shift to higher-fields for $Q^2$, while for other metal complexes of quinolinolates, e.g. for organoboron quinolinolates, significantly higher shift-values are obtained.[9d]

For the corresponding carbon NMR spectra, similar results caused by the asymmetrical character of the quinolinolato ligand can be found for **5b** in $[D_6]$DMSO. Consequently, slightly different shift-values were obtained for all

carbon atoms of the phenylpyridine ligands as they are listed in the Experimental Section. For the other compounds under investigation, no unexpected NMR spectroscopic features were observed and all spectra are in accordance with the proposed structures.[11]

To further confirm the structural identities of the described organoiridium quinolinolate complexes, we tried to grow single-crystals from ether diffusion into saturated $CH_2Cl_2$ solutions and by layering $CH_2Cl_2$ solutions with *n*-pentane. Although all complexes could be crystallised by these methodologies, single-crystals suitable for X-ray diffraction were obtained only for **5a**, **5c**,[11a] **5g**,[11a] **5h** and **5j**.[11b] Structural views of the complexes **5a** and **5h** are shown in Figure 2. Key bond lengths and angles for all five complexes are shown for comparison in Table 1.

In all complexes the iridium exhibits a moderately distorted octahedral coordination environment with relatively uniform bond lengths and angles with mean bond lengths of 2.000(8) Å for the Ir–C distance, 2.037(8) Å for the Ir–

$N_{pyridine}$ distance, 2.145(22) Å for the Ir–$N_{quinoline}$ distance and 2.155(17) Å for the Ir–O distance. Characteristic for all complexes is that the two carbon ligands are in a *cis* disposition and that the 2-phenylpyridine nitrogen atoms are in a *trans* disposition. No indication for a reversal of this geometry was found and this is consistent with related bis(phenylpyridine)(acetylacetonato)iridium(III) [$ppy_2Ir(acac)$] complexes or similar compounds for which no bond breaking or spatial rearrangement of the phenylpyridine ligands was observed during complex formation from the precursor **3**.[4d,4e] Compared with the O–Ir–O bite angles of the acetylacetonato complexes, the N–Ir–O bite angles of the quinolinato complexes are systematically smaller by about 5°.

Whereas the quinolinato ligands are in all cases practically perfectly planar, the 2-phenylpyridine ligands occasionally show larger deviations from planarity by being either curved or twisted, e.g. in **5a** or **5g**,[11a] due to crystal packing effects. In the case of **5h** it is interesting to note that the 2-cyano group is in close intramolecular contact with the second 2-phenylpyridine ligand showing π-π interactions with comparatively short distances of C(32)–C(22) 3.112 Å and N(4)–C(21) 3.259 Å. This contact appears to be responsible for the slightly aberrant Ir–N(3) and Ir–O bond lengths of **5h** (Table 1).

To determine the thermal stabilities of **5a**–**5j**, heat flux DSC/TGA measurements were performed. For practical applications such as in OLEDs, materials with good thermal stabilities are very desirable due to the resultant improved device lifetimes.[15] For comparison of the compounds under investigation, a weight loss of 5% was chosen as a measure for the thermal stability. As depicted in Figure 3 and summarised in Table 2, a significant impact on the corresponding thermal stabilities can be observed as a result of ligand modifications.

While the unmodified organoiridium quinolinolate complex **5a** exhibits a 5% weight-loss at 136 °C,[11] the halogen-substituted derivatives **5b**–**5d** show noticeably increased thermal stabilities with temperature values of 380 °C, 347 °C and 328 °C, respectively.[11] Note that the thermal stabilities of the complexes **5b**–**5d** increase within the series I < Br < Cl which is presumably a result of steric effects of the halogen substituents. Also, for the alkyl and aryl-substituted derivatives **5e**–**5g**, a considerably higher thermal stability can be observed. While **5g** bearing phenyl rings at the 5 and 7 positions of the quinolinolato ligand shows only a slightly increased temperature value for a 5% weight loss at 211 °C, the 2-methyl- and 5,7-dimethyl-substituted derivatives **5e** and **5f** are thermally stable up to 380 and 357 °C, respectively. The most striking impact on the thermal properties is exhibited by **5h** with a weight loss of 5% at 422 °C. As reported recently,[11] significantly increased thermal stabilities compared with **5a** are also found for the formyl- and nitro-substituted derivatives **5i** and **5j** at 354 and 395 °C, respectively.

From these data, the significant influence of ligand modifications on the thermal stabilities of the organoiridium(III) complexes becomes evident. While electron-donating as well as electron-withdrawing groups improve the thermal properties of this class of materials, the cyano substituent in position 2 of the quinolinolato ligand causes the highest thermal stability.

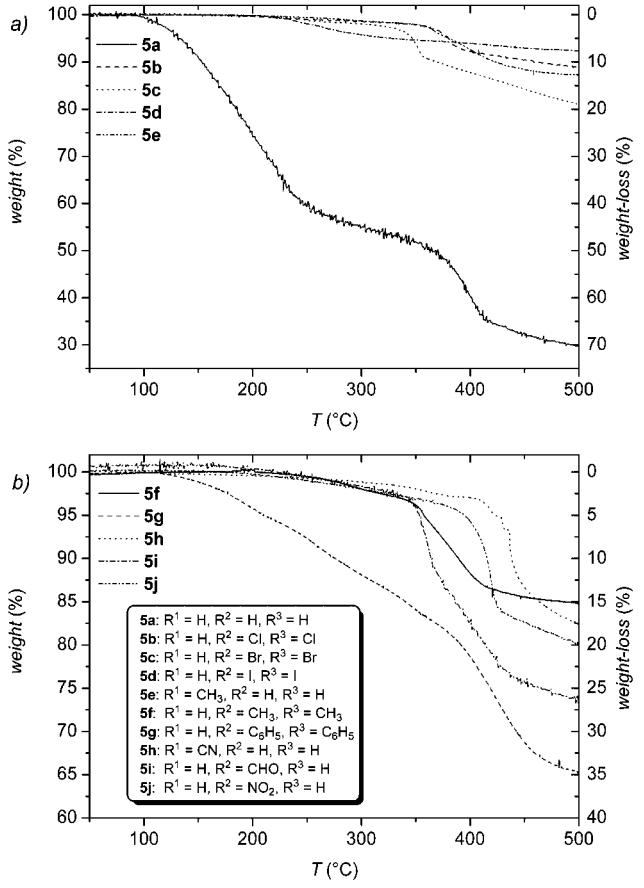

Figure 3. TGA runs of a) compounds **5a**–**5e** and b) **5f**–**5j** indicate increased thermal stability compared with **5a**.

Table 2. Temperatures at 5% weight loss $T_{5\%}$, absorption wavelengths $\lambda_{abs}$, molecular coefficients of extinction $\varepsilon$, emission wavelengths $\lambda_{em}$ in solution and emission wavelengths $\lambda_{77K}$ of films recorded at 77 K. Note that the spectra of **5a**, **5c**, **5g**, **5i** and **5j** have already been communicated elsewhere.[11]

To investigate the photophysical properties of the studied compounds (see Table 2), UV/Vis absorption and photoluminescence (PL) spectra were recorded in dilute solutions of $CHCl_3$ at room temperature. In Figure 4 the UV/Vis absorption spectra of **5a**–**5j** are shown. The complexes **5a**–**5g** exhibit comparably weak absorption bands in the range of approximately 530 to 350 nm which can be assigned to spin-allowed and spin-forbidden metal–ligand charge transfer (MLCT) transitions. Significantly stronger absorption peaks resulting from π-π* transitions can be found in the higher energy region around 250 nm for all complexes.

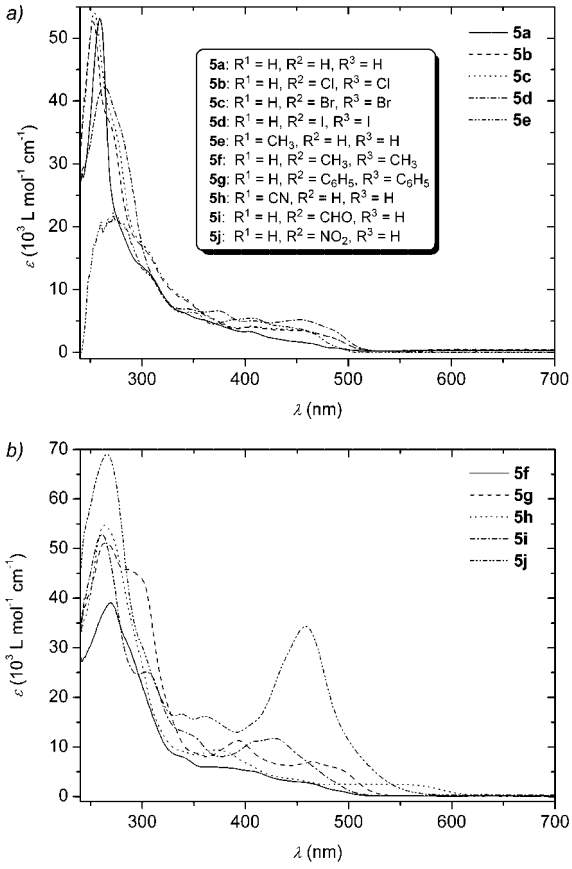

Figure 4. Absorption spectra of a) compounds **5a**–**5e** and b) **5f**–**5j** recorded in dilute $CHCl_3$ solutions.

Although the cyano, formyl and nitro modified compounds **5h**–**5j** exhibit, in general, the same spectroscopic features, the corresponding functional groups lead to additional absorption bands. Whereas for **5h** a shift of the onset of absorption towards longer wavelengths can be observed (i.e. approx. 615 nm), **5i** and **5j** feature distinct new absorption bands at 427 and 459 nm, respectively.

For practical applications, iridium(III) complexes with emission properties controlled by the "ancillary ligand" are desirable. Although this description can be frequently found in the literature, it is important to note that in such compounds this ligand is certainly not ancillary and therefore this term should be avoided. In any case, only a few successful examples of heteroleptic iridium(III) complexes with photophysical properties controlled by the third ligand have been reported.[4] Organoiridium quinolinolate complexes are known to be red phosphorescent emitter materials and thus the emission characteristics are dominated by the quinolinolato ligand.[10,11] From this point of view it is surprising that a systematic investigation of the impact of ligand modifications on the emission characteristics is missing since there is a significant demand for phosphorescent materials with easily tuneable photophysical properties.

To study the photoluminescence of the compounds under investigation, we tried to record the corresponding PL spectra of dilute $CHCl_3$ solutions at room temperature in aerated as well as degassed solutions (Figure 5). Among the studied complexes only **5f**, **5i** and **5j** gave weak photoluminescence with quantum yields ($\Phi$) smaller than 1% (apparent lifetimes at room temperature $\tau = 3 \pm 1$ μs for **5f** and $20 \pm 4$ μs for **5i** and **5j**)[11] while the other compounds were not found to be luminescent in solution (even in degassed solutions) indicating an unfavourable mixing of singlet and triplet excited states for these complexes when compared with, for example, $ppy_2Ir(acac)$ ($\Phi = 34\%$; $\tau = 1.6$ μs).[4]

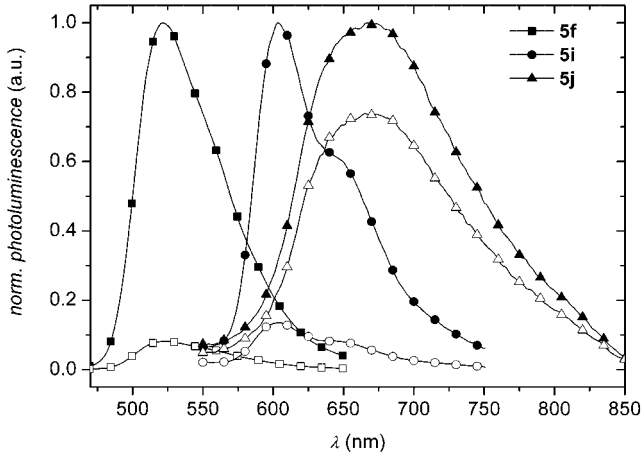

Figure 5. Photoluminescence spectra of **5f**, **5i** and **5j** in aerated (open symbols) and degassed (filled symbols) $CHCl_3$ solutions.

As depicted in Figure 5, significantly different emission wavelengths were achieved with these three luminescent compounds. While **5f** exhibits its emission maximum at 521 nm ($\lambda_{exc}$ = 390 nm), a structured PL spectrum with the maximum at 603 nm and a shoulder at 645 nm ($\lambda_{exc}$ = 400 nm) may be obtained for **5i**. Compound **5j** gave the most red-shifted spectrum displaying a broad and unstructured emission band peaking at 670 nm ($\lambda_{exc}$ = 450 nm). Although most of the studied materials were not luminescent in solution, film spectra of the organoiridium quinolinolate complexes blended into polystyrene were recorded at room temperature and also after cooling with liquid nitrogen to 77 K. With the exception of **5f** and **5h**, all compounds were found to be weakly luminescent in the red spectroscopic region at room temperature. However, cooling the samples gave slightly increased luminescence intensities (see Table 2 and Supporting Information).

From these data a striking impact of the ligand modifications on the emission properties becomes evident. While the

5-formyl- and 5-nitro-substituted complexes emit orange to red light dominated by the quinolinolato ligand in solution, the 5,7-dimethyl derivative gives greenish phosphorescence which is very similar to $ppy_2Ir(acac)$ suggesting a phenylpyridine governed emission in this case [for comparison, green-emitting $ppy_2Ir(acac)$ exhibits its emission maximum at 516 nm].[4c,4d] To further support this hypothesis, the photophysical properties of tris[$\kappa^2$(*N*,*O*)-5,7-dimethyl-8-quinolinolato]iridium(III) were investigated.[10b] From the corresponding emission spectrum peaking around 695 nm (see Supporting Information) a phenylpyridine-centred emission for **5f** can be concluded.

The luminescent compounds **5f**, **5i** and **5j** as well as **5a**, **5b**, **5c** and **5h** were tested as emitting materials in OLEDs using various host materials. As communicated recently, efficient light-emitting diodes were obtained from **5i** and **5j**. For example, a maximum luminance of 940 cd m$^{-2}$ was obtained at 13 V for diodes containing 1 wt.-% of **5i** in poly(vinylcarbazole) (PVK) as the host material.[11b] In contrast, attempts to prepare OLEDs from **5a**, **5b**, **5c**, **5f** and **5h** were unsuccessful. Similar to the above mentioned diodes built from **5i**, the herein studied complexes were investigated as the emitting guest using PVK as the host (1 wt.-% complex loading). OLEDs of the configuration ITO/PEDOT:PSS/host-guest emitting layer/Ca/Al gave weak electroluminescence at wavelengths similar to those listed in Table 2 for the 77 K measurements, with low luminescence intensities of 0.8–10 cd m$^{-2}$ at comparably high turn on voltages of more than 8 V (see Supporting Information). These findings distinctly underline the importance of introducing an electron-withdrawing group in the 5-position of the quinolinolato for obtaining efficient OLEDs. In these cases (i.e. **5i** and **5j**) the additional absorption bands with high extinction coefficients in the blue region are beneficial for providing efficient Förster energy transfer from the blue emitting host material. At the same time, the electron-withdrawing groups offer appropriate energy level tuning[11b] so that endothermic Dexter triplet energy back transfer from the phosphorescent iridium complex to the host material is prevented.[16]

## Conclusions

Herein we have reported the synthesis, structure, thermal stabilities and photophysical properties of a rarely studied class of materials, namely derivatives of bis[$\kappa^2$(*C*$^2$,*N*)-2-phenylpyridine][$\kappa^2$(*N*,*O*)-8-quinolinolato]iridium(III). Photophysical measurements revealed only minor changes in the absorption characteristics for most derivatives except that bearing electron-withdrawing groups in the 5-position of the quinolinolato ligand. These complexes exhibit absorption features with comparably high extinction coefficients in the visible suitable for finding appropriate host materials for OLED applications.[11] Only the 5-formyl, 5-nitro and 5,7-dimethyl derivatives were found to be luminescent in solution, whereas measurements at 77 K showed red photoluminescence in the solid state for most compounds under investigation. While in the case of **5f** the quinolinolate is rather a spectator ligand similar to acac and emission originates from the $ppy_2Ir$ fragment, the emissions of **5a**–**5e**, **5g**, **5i** and **5j** are quinolinolato-dominated. From the corresponding film measurements, PL spectra in degassed solutions and comparison with the photophysical properties of tris[$\kappa^2$(*N*,*O*)-8-quinolinolato]iridium(III) derivatives (see Supporting Information),[10b] an unfavourable mixing of singlet and triplet excited states of these complexes can be concluded rendering most of the described compounds insufficiently luminescent for typical OLED applications. With this information, the rational design of (electro-)luminescent iridium complexes bearing quinolinolato ligands has been revealed and further easily accessible iridium complexes based on 5-electron acceptor-substituted quinolinolato ligands can be foreseen to enter the stage of (electro)luminescent emitter materials.

## Experimental Section

**General:** Unless otherwise noted, materials were obtained from commercial sources (Aldrich, Fluka or Lancaster) and were used without further purification. Solvents for reactions were freshly distilled from appropriate drying agents prior to use (ee = ethyl acetate, cy = cyclohexane). Reactions were carried out under an inert atmosphere of Ar using standard Schlenk techniques. $^1$H NMR spectra were recorded on a Varian INOVA 500 MHz spectrometer at 500 MHz and $^{13}$C{$^1$H} NMR spectra were recorded at 125 MHz. Assignment of the peaks was carried out by DEPT and COSY NMR spectroscopy. Residual solvent peaks were used for referencing the NMR spectra to the corresponding values given in the literature.[17] UV/Vis absorption spectra were recorded on a Cary 50 Bio UV/Vis spectrophotometer and fluorescence spectra on a Perkin–Elmer luminescence spectrometer LS50B. MALDI-TOF mass spectra were recorded on a Micromass TofSpec 2E. The instrument was equipped with a nitrogen laser (337 nm wavelength, operated at a frequency of 5 Hz) and a time lag focusing unit. Spectra were taken in reflection mode at an accelerating voltage of +20 kV. Analysis of data was done with MassLynx 3.4 (Micromass, Manchester, UK). Samples were dissolved in THF (1 mg mL$^{-1}$). Dithranol or retinoic acid was used as the matrix (10 mg mL$^{-1}$ in THF). Solutions were mixed in the cap of a microtube in the ratio of 1 μL:10 μL. Then, 0.5 μL of the resultant mixture was spotted onto the target and air-dried. Combined DSC/TGA measurements were performed with a Netzsch STA 449C instrument equipped with a Quadrupole MS QMS 403C or with a Polymer Laboratories simultaneous thermal analyser STA 625 (crucibles: aluminium from Rheometric Scientific). The thermal properties were determined in aluminium pans with a heat rate of 10 °C min$^{-1}$ in a helium flow of approximately 50 mL min$^{-1}$ (Netzsch STA 449C) or a nitrogen flow of 20 mL min$^{-1}$ (Polymer Laboratories simultaneous thermal analyser STA 625).

**Di-μ-chloro-tetrakis[$\kappa^2$(*C*$^2$,*N*)-2-phenylpyridine]diiridium(III) (3):** $IrCl_3 \cdot nH_2O$ (**1**, 0.2123 g, 0.711 mmol) was suspended in a mixture of 2-ethoxyethanol (6 mL) and water (2 mL) under Ar. After the addition of 2-phenylpyridine (**2**, 270 μL, 1.889 mmol) the dark brown reaction mixture was stirred for 24 h at 120 °C. The greenish suspension formed was cooled to room temperature and the solvent was removed in vacuo. Washing the residue with hot methanol gave rise to 0.2025 g (53.1%) of a yellow-greenish powder of **3**. NMR spectra were found to be identical with that described in the literature.[11]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**General Procedure for the Preparation of Organoiridium Quinolinolate Complexes:** For the preparation of **5a**–**5j** 1 equiv. of **3** was suspended with 2.1 to 2.5 equiv. of the corresponding 8-hydroxyquinoline derivative **4a**–**4j** in a solvent mixture of degassed $CH_2Cl_2$/EtOH/$Et_3N$ under Ar and was heated to reflux at 80 °C for 20 h. The solvent was removed in vacuo and the residue was washed with hot methanol. Filtration of the precipitate gave the corresponding product in analytically pure form.

**Bis[κ²(C²,*N*)-2-phenylpyridine][κ²(*N*,*O*)-8-quinolinolato]iridium(III) (5a):** Compound **5a** was prepared starting from **3** (0.0403 g, 0.038 mmol) and **4a** (0.0126 g, 0.087 mmol) in $CH_2Cl_2$ (1 mL), EtOH (1 mL) and $Et_3N$ (300 μL) giving 0.0379 g (78.2%) of a yellow-orange powder. $R_f$(acetone) = 0.86. The recorded NMR and MALDI-TOF MS spectra are in accordance with literature data.[11]

**[κ²(*N*,*O*)-5,7-Dichloro-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]iridium(III) (5b):** Complex **5b** was obtained from **3** (0.0509 g, 0.047 mmol) and **4b** (0.0214 g, 0.100 mmol) in $CH_2Cl_2$ (2 mL), EtOH (1 mL) and $Et_3N$ (300 μL) yielding 0.0459 g (67.7%) of an orange solid. $R_f$(cy:ee = 3:1) = 0.27. $^1$H NMR ([D$_6$]DMSO, 500 MHz): $\delta$ = 8.39 (d, $J$ = 5.9 Hz, 1 H, *Py*$^6$), 8.35 (d, $J$ = 8.8 Hz, 1 H, *Q*$^4$), 8.21 (d, $J$ = 7.8 Hz, 1 H, *Py*$^3$), 8.16 (d, $J$ = 8.3 Hz, 1 H, *Py*$^3$), 7.91–7.80 (m, 4 H, *Py*$^4$, *Ph*$^6$), 7.74 (s, 1 H, *Q*$^6$), 7.71 (d, $J$ = 4.9 Hz, 1 H, *Q*$^2$), 7.59–7.55 (m, 2 H, *Py*$^6$, *Q*$^3$), 7.30 (t, $J$ = 7.3 Hz, 1 H, *Py*$^5$), 7.10 (t, $J$ = 7.3 Hz, 1 H, *Py*$^5$), 6.93–6.87 (2 t, $J$ = 7.3 Hz, 2 H, *Ph*$^5$), 6.79 (t, $J$ = 7.3 Hz, 1 H, *Ph*$^4$), 6.74 (t, $J$ = 7.3 Hz, 1 H, *Ph*$^4$), 6.26 (d, $J$ = 7.3 Hz, 1 H, *Ph*$^3$), 6.11 (d, $J$ = 7.3 Hz, 1 H, *Ph*$^3$) ppm. $^{13}$C NMR ([D$_6$]DMSO, 125 MHz): $\delta$ = 167.8, 167.0 (2 C, *Py*$^2$), 164.3 (1 C, *Q*$^8$), 150.7, 148.4 (2 C, *Ph*$^2$), 148.2, 147.4, 147.3 (3 C, *Py*$^6$, *Q*$^2$), 144.7, 144.3, 143.7 (3 C, *Ph*$^1$, *Q*$^{8a}$), 138.0, 134.0, 134.0, 132.0, 131.7, 129.7, 129.4, 129.0, 124.7, 124.3, 123.8, 123.3, 123.0, 121.1, 120.9, 119.4, 119.3 (17 C, *Ph*$^{3,4,5,6}$, *Py*$^{3,4,5}$, *Q*$^{3,4,6}$), 127.2 (1 C, *Q*$^{4a}$), 118.8 (1 C, *Q*$^5$), 110.7 (1 C, *Q*$^7$) ppm. HRMS: calcd. for $C_{31}H_{20}Cl_2IrN_3O$ 711.0590; found 711.0631.

**[κ²(*N*,*O*)-5,7-Dibromo-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]iridium(III) (5c):** The dibromo complex **5c** was synthesised from **3** (0.0520 g, 0.049 mmol) and **4c** (0.0293 g, 0.097 mmol) in $CH_2Cl_2$ (2 mL), EtOH (1 mL) and $Et_3N$ (300 μL). The product was obtained as orange powder in a yield of 0.0599 g (76.9%). $R_f$(cy:ee = 3:1) = 0.30. NMR and MALDI-TOF MS characterisation of this compound can be found in the literature.[11]

**[κ²(*N*,*O*)-5,7-Diiodo-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]iridium(III) (5d):** Compound **5d** resulted from the reaction of **3** (0.1000 g, 0.093 mmol) with **4d** (0.0820 g, 0.207 mmol) in $CH_2Cl_2$ (4 mL), EtOH (2 mL) and $Et_3N$ (600 μL). The complex was isolated in a yield of 0.1437 g (85.9%) as a yellow-brownish powder. $R_f$(cy:ee = 1:1) = 0.72. $^1$H NMR ([D$_6$]DMSO, 500 MHz): $\delta$ = 8.37 (d, $J$ = 5.8 Hz, 1 H, *Py*$^6$), 8.22 (s, 1 H, *Q*$^6$), 8.20 (d, $J$ = 8.3 Hz, 1 H, *Q*$^4$), 8.15–8.12 (2 d, each $J$ = 8.1 Hz, 2 H, *Py*$^3$), 7.88, 7.85–7.78 (dd, 2 × $J$ = 7.8 Hz, 1 H, m, 3 H, *Ph*$^6$, *Py*$^4$), 7.62 (d, $J$ = 4.6 Hz, 1 H, *Q*$^2$), 7.54–7.52 (m, 2 H, *Py*$^6$, *Q*$^3$), 7.29 (dd, 2 × $J$ = 6.6 Hz, 1 H, *Py*$^5$), 7.09 (dd, 2 × $J$ = 6.6 Hz, 1 H, *Py*$^5$), 6.92–6.86 (2 dd, each 2 x $J$ = 7.5 Hz, 2 H, *Ph*$^5$), 6.78 (dd, 2 × $J$ = 7.4 Hz, 1 H, *Ph*$^4$), 6.73 (dd, 2 × $J$ = 7.4 Hz, 1 H, *Ph*$^4$), 6.22 (d, $J$ = 7.5 Hz, 1 H, *Ph*$^3$), 6.11 (d, $J$ = 7.5 Hz, 1 H, *Ph*$^3$) ppm. $^{13}$C NMR ([D$_6$]DMSO, 125 MHz): $\delta$ = 169.4 (1 C, *Q*$^8$), 167.7, 167.0 (2 C, *Py*$^2$), 150.9, 148.5 (2 C, *Ph*$^2$), 148.1, 147.2, 147.2, 146.1 (4 C, *Py*$^6$, *Q*$^{2,6}$), 144.6, 144.2 (2 C, *Ph*$^1$), 142.1 (1 C, *Q*$^{8a}$), 140.9, 138.0, 137.9, 132.0, 131.6, 129.6, 129.1, 124.7, 124.6, 124.3, 123.2, 123.0, 121.0, 120.9, 119.4, 119.3 (16 C, *Ph*$^{3,4,5,6}$, *Py*$^{3,4,5}$, *Q*$^{3,4}$), 132.2 (1 C, *Q*$^{4a}$), 86.7 (1 C, *Q*$^5$), 74.3 (1 C, *Q*$^7$) ppm. HRMS: calcd. for $C_{31}H_{20}I_2IrN_3O$ 894.9302; found 894.9327.

**[κ²(*N*,*O*)-2-Methyl-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]iridium(III) (5e):** Complex **5e** was synthesised from **3** (0.0722 g, 0.067 mmol) and **4e** (0.0256 g, 0.161 mmol) in $CH_2Cl_2$ (4 mL), EtOH (2 mL) and $Et_3N$ (600 μL). The orange solid was isolated in a yield of 0.0669 g (75.4%). $R_f$(cy:ee = 1:1) = 0.23. $^1$H NMR ([D$_6$]-DMSO, 500 MHz): $\delta$ = 8.48 (d, $J$ = 5.6 Hz, 1 H, *Py*$^6$), 8.18 (d, $J$ = 8.1 Hz, 1 H, *Py*$^3$), 8.13 (d, $J$ = 8.1 Hz, 1 H, *Py*$^3$), 8.11 (d, $J$ = 8.5 Hz, 1 H, *Q*$^4$), 7.86, 7.83–7.81, 7.77, 7.74 (dd, 2 × $J$ = 7.9 Hz, 1 H, m, 2 H, d, $J$ = 7.8 Hz, 1 H, d, $J$ = 7.8 Hz, 1 H, *Ph*$^6$, *Py*$^{4,6}$), 7.25–7.19 (m, 3 H, *Py*$^5$, *Q*$^{3,6}$), 7.10 (dd, 2 × $J$ = 6.7 Hz, 1 H, *Py*$^5$), 6.83 (dd, 2 × $J$ = 7.3 Hz, 1 H, *Ph*$^5$), 6.79 (dd, 2 × $J$ = 7.3 Hz, 1 H, *Ph*$^5$), 6.74 (d, $J$ = 7.8 Hz, 1 H, *Q*$^5$), 6.68–6.65 (m, 3 H, *Ph*$^4$, *Q*$^7$), 6.25 (d, $J$ = 7.5 Hz, 1 H, *Ph*$^3$), 5.91 (d, $J$ = 7.5 Hz, 1 H, *Ph*$^3$), 2.00 (s, 3 H, *Q*-*CH*$_3$) ppm. $^{13}$C NMR ([D$_6$]DMSO, 125 MHz): $\delta$ = 169.6, 167.9, 167.5 (3 C, *Py*$^2$, *Q*$^8$), 158.1, 153.5, 149.2 (3 C, *Ph*$^2$, *Q*$^2$), 148.8, 147.5 (2 C, *Py*$^6$), 144.2, 143.7, 143.4 (3 C, *Ph*$^1$, *Q*$^{8a}$), 138.1, 137.4, 137.4, 132.4, 130.9, 129.3, 128.8, 128.7, 124.7, 123.9, 123.7, 123.1, 122.0, 120.9, 119.7, 119.3, 118.8, 116.2 (18 C, *Ph*$^{3,4,5,6}$, *Py*$^{3,4,5}$, *Q*$^{3,4,5,6}$), 129.8 (1 C, *Q*$^{4a}$), 110.1 (1 C, *Q*$^7$), 26.9 (1 C, *Q*-*CH*$_3$) ppm. HRMS: calcd. for $C_{32}H_{24}IrN_3O$ 657.1525; found 657.1474.

**[κ²(*N*,*O*)-5,7-Dimethyl-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]iridium(III) (5f):** The dimethyl complex **5f** was prepared starting from **3** (0.1006 g, 0.094 mmol) and **4f** (0.0362 g, 0.209 mmol) in $CH_2Cl_2$ (4 mL), EtOH (2 mL) and $Et_3N$ (600 μL). The product was obtained as dark orange solid in a yield of 0.1038 g (82.2%). $R_f$(cy:ee = 1:1) = 0.56. $^1$H NMR ([D$_6$]DMSO, 500 MHz): $\delta$ = 8.54 (d, $J$ = 5.6 Hz, 1 H, *Py*$^6$), 8.18–8.17 (2 d, each $J$ = 7.8 Hz, 2 H, *Py*$^3$), 8.10 (d, $J$ = 8.3 Hz, 1 H, *Q*$^4$), 7.86, 7.79–7.76 (dd, 2 × $J$ = 7.3 Hz, 1 H, m, 3 H, *Ph*$^6$, *Py*$^4$), 7.58 (d, $J$ = 4.4 Hz, 1 H, *Q*$^2$), 7.51 (d, $J$ = 5.6 Hz, 1 H, *Py*$^6$), 7.30–7.27 (dd, $J$ = 8.5 Hz, $J$ = 4.5 Hz, 1 H, *Q*$^3$), 7.22 (dd, 2 × $J$ = 6.5 Hz, 1 H, *Py*$^5$), 7.19 (s, 1 H, *Q*$^6$), 7.07 (dd, 2 × $J$ = 6.6 Hz, 1 H, *Py*$^5$), 6.89–6.83 (2 dd, each 2 × $J$ ≈ 7.3 Hz, 2 H, *Ph*$^5$), 6.77 (dd, 2 × $J$ ≈ 7.2 Hz, 1 H, *Ph*$^4$), 6.71 (dd, 2 × $J$ ≈ 7.2 Hz, 1 H, *Ph*$^4$), 6.28 (d, $J$ = 7.3 Hz, 1 H, *Ph*$^3$), 6.14 (d, $J$ = 7.3 Hz, 1 H, *Ph*$^3$), 2.46 (s, 3 H, *Q*$^5$-*CH*$_3$), 2.25 (s, 3 H, *Q*$^7$-*CH*$_3$) ppm. $^{13}$C NMR ([D$_6$]DMSO, 125 MHz): $\delta$ = 168.0, 167.3 (2 C, *Py*$^2$), 165.3 (1 C, *Q*$^8$), 152.8, 151.3 (2 C, *Ph*$^2$), 147.7, 147.4, 145.0 (3 C, *Py*$^6$, *Q*$^2$), 144.6, 144.4 (2 C, *Ph*$^1$), 142.6 (1 C, *Q*$^{8a}$), 137.5, 137.4, 134.0, 132.8, 132.1, 131.7, 129.5, 128.8, 124.5, 124.2, 122.9, 122.5, 120.6, 120.5, 120.4, 119.2, 118.9 (17 C, *Ph*$^{3,4,5,6}$, *Py*$^{3,4,5}$, *Q*$^{3,4,6}$), 128.0 (1 C, *Q*$^{4a}$), 123.8 (1 C, *Q*$^5$), 115.0 (1 C, *Q*$^7$), 16.9, 16.7 (2 C, *Q*$^5$-*CH*$_3$, *Q*$^7$-*CH*$_3$) ppm. HRMS: calcd. for $C_{33}H_{26}IrN_3O$ 671.1682; found 671.1752.

**[κ²(*N*,*O*)-5,7-Diphenyl-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]iridium(III) (5g):** The diphenyl-substituted compound **5g** was obtained from **3** (0.0930 g, 0.087 mmol) and **4g** (0.0500 g, 0.168 mmol) in $CH_2Cl_2$ (3 mL), EtOH (2 mL) and $Et_3N$ (300 μL) giving 0.0768 g (55.5%) of a yellow-orange powder. $R_f$(cy:ee = 1:1) = 0.77. NMR and MALDI-TOF MS spectra were found to be in accordance with literature.[11]

**[κ²(*N*,*O*)-2-Cyano-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]iridium(III) (5h):** Compound **5h** resulted from reacting **3** (0.0497 g, 0.046 mmol) with **4h** (0.0183 g, 0.108 mmol) in $CH_2Cl_2$ (2 mL), EtOH (1 mL) and $Et_3N$ (300 μL). From this complex 0.0468 g (75.4%) could be isolated as deeply red solid. $R_f$(acetone) = 0.9. $^1$H NMR ([D$_6$]DMSO, 500 MHz): $\delta$ = 8.39 (d, $J$ = 8.5 Hz, 1 H, *Q*$^4$), 8.31 (d, $J$ = 5.6 Hz, 1 H, *Py*$^6$), 8.19 (d, $J$ = 8.3 Hz, 1 H, *Py*$^3$), 8.15 (d, $J$ = 8.3 Hz, 1 H, *Py*$^3$), 7.90 (ddd, 2 × $J$ = ca. 7.8 Hz, $J$ = 1.2 Hz, 1 H, *Py*$^4$), 7.85–7.82 (m, 2 H, *Py*$^{4,6}$), 7.77 (d, $J$ = 7.8 Hz, 1 H, *Ph*$^6$), 7.74 (d, $J$ = 7.8 Hz, 1 H, *Ph*$^6$), 7.69 (d, $J$ = 8.5 Hz, 1 H, *Q*$^3$), 7.51 (dd, 2 × $J$ = 7.8 Hz, 1 H, *Q*$^6$), 7.21–7.18 (ddd, 2 × $J$ ≈

6.6 Hz, $J$ = 1.2 Hz, 1 H, $Py^5$), 7.12–7.10 (ddd, $2\times J \approx 6.6$ Hz, $J$ = 1.2 Hz, 1 H, $Py^5$), 6.90, 6.87–6.82 (dd, $J$ = 7.8 Hz, $J \approx 1$ Hz, 1 H, m, 2 H, $Ph^5$, $Q^{5,7}$), 6.80–6.77 (ddd, $2\times J$ = ca. 7.2 Hz, $J$ = 1.2 Hz, 1 H, $Ph^5$), 6.71–6.68 (ddd, $2\times J \approx 6.8$ Hz, $J$ = 1.2 Hz, 1 H, $Ph^4$), 6.64–6.61 (ddd, $2\times J \approx 6.8$ Hz, $J$ = 1.2 Hz, 1 H, $Ph^4$), 6.20 (d, $J$ = 7.6 Hz, 1 H, $Ph^3$), 5.93 (d, $J$ = 7.6 Hz, 1 H, $Ph^3$) ppm. $^{13}$C NMR ([D$_6$]DMSO, 125 MHz): $\delta$ = 170.6, 168.1, 167.1 (3 C, $Py^2$, $Q^8$), 150.5, 147.6 (2 C, $Ph^2$), 149.0, 147.4 (2 C, $Py^6$), 144.2, 144.0, 143.8 (3 C, $Ph^1$, $Q^{8a}$), 138.8, 138.0, 137.9, 132.7, 132.7, 131.2, 129.4, 128.9, 126.5, 124.7, 124.0, 123.4, 122.1, 121.3, 120.6, 119.5, 119.0, 118.2 (18 C, $Ph^{3,4,5,6}$, $Py^{3,4,5}$, $Q^{3,4,5,6}$), 132.1 (1 C, $Q^2$), 129.4 (1 C, $Q^{4a}$), 114.8 (1 C, *Q-CN*), 110.3 (1 C, $Q^7$) ppm. HRMS: calcd. for $C_{32}H_{21}IrN_4O$ 668.1321; found 668.1302.

**[κ²(*N*,*O*)-5-Formyl-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]-iridium(III) (5i):** The recently reported complex **5i** was synthesised from **3** (0.0500 g, 0.047 mmol) and **4i** (0.0184 g, 0.106 mmol) in $CH_2Cl_2$ (2 mL), EtOH (1 mL) and $Et_3N$ (300 μL) yielding 0.0474 g (75.5%) of an orange solid. $R_f$(acetone) = 0.88. NMR and MALDI-TOF MS characterisation can be found in the literature.[11]

**[κ²(*N*,*O*)-5-Nitro-8-quinolinolato]bis[κ²(C²,*N*)-2-phenylpyridine]-iridium(III) (5j):** The nitro complex **5j** was prepared from **3** (0.1010 g, 0.094 mmol) and **4j** (0.0446 g, 0.235 mmol) in $CH_2Cl_2$ (4 mL), EtOH (2 mL) and $Et_3N$ (600 μL). The deeply red product was isolated in a yield of 0.1091 g (84.0%). $R_f$(cy:ee = 1:1) = 0.57. NMR and MALDI-TOF MS spectra have been reported in the literature.[11]

**Crystal Structure Determinations of 5a and 5h:** X-ray data of **5a** and **5h** (in the form of the diethyl ether solvate **5h**·0.5 $C_4H_{10}O$) were collected on a Bruker Smart APEX CCD area detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and 0.3° $\omega$-scan frames. Corrections for absorption, $\lambda/2$ effects and crystal decay were applied.[18] After structure solution with SHELXS-97, refinement on $F^2$ was carried out with SHELXL-97.[19] Non-hydrogen atoms were refined anisotropically. All H atoms were placed in calculated positions and thereafter treated as riding. Salient crystallographic data are:

**5a:** $C_{31}H_{22}IrN_3O$, $M_r$ = 644.72, brown prism, 0.54 × 0.14 × 0.05 mm, monoclinic, space group $P2_1/n$ (no. 14), $a$ = 11.3945(7) Å, $b$ = 9.2935(6) Å, $c$ = 22.5274(15) Å, $\beta$ = 93.013(2)°, $V$ = 2382.2(3) Å$^3$, $Z$ = 4, $\mu$ = 5.635 mm$^{-1}$, $T$ = 100 K. 25068 reflections were collected up to $\theta_{max}$ = 30.05° and, after applying absorption corrections, merged to 5486 independent data ($R_{int}$ = 0.050). Final $R$ indices: $R_1$ = 0.0468 [6859 reflections with $I > 2\sigma(I)$], $wR_1$ = 0.0943 (all data), 325 parameters.

**5h·0.5 $C_4H_{10}O$:** $C_{32}H_{21}IrN_4O$·0.5 $C_4H_{10}O$, $M_r$ = 706.79, brown prism, 0.32 × 0.24 × 0.18 mm, monoclinic, space group $P2_1/n$ (no. 14), $a$ = 11.5085(8) Å, $b$ = 19.7715(14) Å, $c$ = 12.5921(9) Å, $\beta$ = 110.578(1)°, $V$ = 2682.4(3) Å$^3$, $Z$ = 4, $\mu$ = 5.016 mm$^{-1}$, $T$ = 100 K. 44953 reflections were collected up to $\theta_{max}$ = 30.07° and, after applying absorption corrections, merged to 7760 independent data ($R_{int}$ = 0.034). Final $R$ indices: $R_1$ = 0.0296 [6669 reflections with $I > 2\sigma(I)$], $wR_1$ = 0.0628 (all data), 371 parameters. A disorder of the solvent in was taken into account.

CCDC-634415 and -634416 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Film measurements, photophysical measurements of tris[κ²(*N*,*O*)-8-quinolinolato]iridium(III) derivatives and OLED characteristics.

## Acknowledgments

Financial support by the Austrian Science Fund in the framework of the Austrian Nano Initiative, RPC ISOTEC (RP 0701, RP 702) is gratefully acknowledged. The authors thank Prof. Robert Saf and Karin Bartl for MALDI TOF-MS measurements, Kerstin Waich for the lifetime measurement of **5h** and Gregor Trimmel for thermal analysis. Umicore's Precious Metals Chemistry division is acknowledged for a generous loan of $IrCl_3$.
