Steric reasons may also account for the fact that the cluster $RuOs_3(\mu\text{-H})(CO)_9(\mu\text{-CO})_2(\eta^5\text{-}C_5Me_4SiMe_3)$ was not isolated in the reaction of **1** with trimethyl(2,3,4,5-tetramethyl-2,4-cyclopentadien-1-yl)silane. Instead the major products isolated from the reaction were **2f**, in which the trimethylsilyl group was lost, and another species $RuOs_3(\mu\text{-H})_3(CO)_8(\mu\text{-CO})(\eta^5\text{-}C_5Me_4SiMe_3)$ (**4**) (see below). The steric crowding around the $C_5Me_4H$ ring in **2f** is reflected by the out-of-plane displacement of the methyl groups (average 6°) away from the $RuOs_3$ core. The cyclopentadienyl ring is also tilted at an angle of 36° with respect to the triosmium basal plane. The presence of an additional bulky trimethylsilyl substituent would have resulted in an even larger displacement of the silicon and methyl carbon atoms out of the plane of the cyclopentadienyl ring. This steric strain may similarly account for our observation that prolonged thermolysis of pentaphenylcyclopentadiene with **1** failed to give the expected product $RuOs_3(\mu\text{-H})(CO)_9(\mu\text{-CO})_2(\eta^5\text{-}C_5Ph_5)$, but resulted in the recovery of **1**.

The clusters appear to retain their solid-state structures in solution. The singlet resonance in the high-field region for the hydride shows a systematic downfield shift with increasing number of electron donating groups (such as methyl) on the cyclopentadienyl ring. Furthermore, a comparison of the hydride chemical shift for **2d** ($\delta$ = –18.34 ppm) with that reported for the tetraosmium analogue, $Os_4(\mu\text{-H})(CO)_9(\mu\text{-CO})_2(\eta^5\text{-Cp*})$ ($\delta$ = –20.71 ppm),[9] shows that replacement of the osmium atom at the apex of the tetrahedron with the relatively more electronegative ruthenium atom results in a decrease in electron density at the hydride.[10]

Some of the reactions with the $C_5$ carbocyclic rings also afforded other minor products other than **2**. The reaction of **1** with propylcyclopentane afforded, after TLC separation, unreacted **1**, $Os_3(\mu\text{-H})_2(CO)_{10}$ (a decomposition product of **1**), **2c**, and another novel cluster $Ru_2Os_3(\mu\text{-H})_2(CO)_{13}(\mu\text{-CO})(\mu_3,\eta^5\text{:}\sigma^2\text{-}C_5H_3C_3H_7)$ (**3**). Clusters **2c** and **3** could not be separated by chromatographic methods although NMR integration suggested that they were present in a ratio of 5:2. We managed to obtain some pure samples by fractional crystallization. Cluster **3** has been completely characterized, also by a single-crystal X-ray crystallographic study; the ORTEP diagram showing the molecular structure of **3** is depicted in Figure 2, together with selected bond parameters.

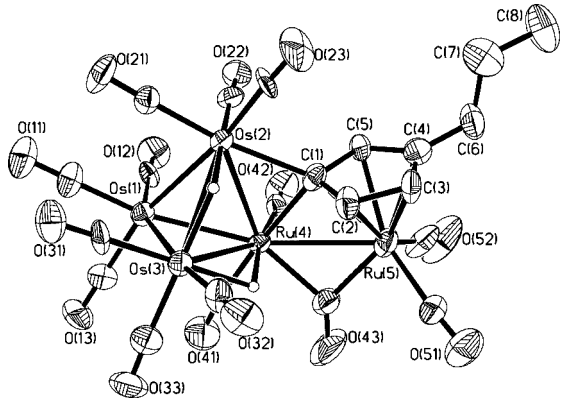

Figure 2. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted) and selected bond lengths [Å] and angles [°] for **3**. Os(1)–Os(2) = 2.8420(11); Os(1)–Os(3) = 2.7746(11); Os(1)–Ru(4) = 2.7729(17); Os(2)–Os(3) = 2.9572(11); Os(2)–Ru(4) = 2.8291(16); Os(3)–Ru(4) = 2.9571(17); Ru(4)–Ru(5) = 2.933(2); Os(2)–C(1) = 2.217(19); Ru(4)–C(1) = 2.30(2); Ru(5)–Cp(centroid) = 1.90(2); Ru(4)–C(43) = 2.08(2); Ru(5)–C(43) = 2.09(2); Os(2)–C(1)–Ru(4) = 77.5(7); Ru(4)–C(43)–Ru(5) = 89.5(9).

The metal framework in **3** consists of a ruthenium-spiked $RuOs_3$ tetrahedron. In metal carbonyl chemistry the spiked tetrahedron metal framework has been rarely reported. Amongst the few known clusters with this arrangement are $Os_6(\mu\text{-H})(\eta^2\text{-}C_6F_5NNNC_6F_5)(\mu\text{-CO})(CO)_{19}$,[11] $ReOs_4(\mu\text{-H})(\mu\text{-CO})(CO)_{17}$,[12] $RuOs_4(\mu\text{-H})_3(\mu_3\text{-}\eta^6\text{-}C_6H_5)(CO)_{12}[P(OMe)_3]$[13] and $Ru_2Os_3(\mu\text{-H})(\mu_3\text{-}\eta^5\text{-}C_5H_4)(\eta^5\text{-}C_5H_5)(CO)_{11}[P(OMe)_3]$.[14] The spike Ru(4)–Ru(5) edge at 2.933(2) Å in **3** is long despite its being bridged by a carbonyl group; usually the shortest metal–metal distance is associated with a bridging CO. For the metal tetrahedron, the two longest metal–metal bonds are bridged by metal hydrides [Os(2)–Os(3) and Os(3)–Ru(4), at 2.9572(11) and 2.9571(11) Å, respectively], whereas the other metal–metal vectors are significantly shorter [2.7729(11)–2.8420(11) Å]. The propylcyclopentadienylidene ligand is bonded to Os(2), Ru(4), and Ru(5) via an uncommon $\mu_3,\eta^5\text{:}\sigma^2$ mode; the ligand caps Ru(5) in a $\eta^5$-cyclopentadienyl manner, and C(1) is also asymmetrically bound to Os(2) [2.217(19) Å] and Ru(4) [2.30(2) Å]. The C(1) carbon acts as a one-electron donor, and the coordination of this atom to the Os(2)–Ru(4) edge can be considered as a "three-center-two-electron" bond. This gives **3** a cluster valence electron count of 76, consistent with the observed spiked tetrahedron metal core.[15] Cluster **3** can be envisaged as having been formed by the addition of a "$Ru(\eta^5\text{-}C_5H_4C_3H_7)(CO)_2$" fragment, from decomposition of **2c**, to **1** followed by oxidative addition of the substituted cyclopentadienyl group; the reaction of **1** with **2c** indeed afforded **3**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The $^1$H NMR spectrum, in the hydride region, of **3** indicated the presence of three species, together with **2c**. The major species exhibited a broad singlet at –19.54 ppm (I); the two other sets comprised singlets at –20.73 and –21.70 ppm (II) and at –20.74 and –21.62 ppm (III). We were unable to obtain a pure sample of **3** free of **2c**, and the relative intensities of the other resonances remained unchanged across repeated recrystallizations. Integration of the spectrum taken at 198 K indicated the ratio I/II/III to be 4.6:2.7:1.0. Below 233 K, the signals due to I appeared as two sharp singlets at –19.06 and –20.12 ppm; the other signals showed no variation except for minor changes in chemical shifts due to temperature. The major resonances (I) can be attributed to the solid-state structure, and the EXSY spectrum at 198 K confirmed the chemical exchange between the two hydride resonances. The identities of the species giving rise to the other two sets of resonances are uncertain, but there was an absence of crosspeaks involving these resonances, and the chemical shift ranges indicated that these hydrides may be bridging Os–Os bonds.[16]

As already mentioned above, besides **2f**, the reaction with trimethyl(2,3,4,5-tetramethyl-2,4-cyclopentadien-1-yl)silane also afforded $RuOs_3(\mu\text{-}H)_3(CO)_9(\mu\text{-}CO)(\eta^5\text{-}C_5Me_4SiMe_3)$ (**4**), which has also been completely characterized, also by a single-crystal X-ray diffraction analysis; the ORTEP plot together with selected bond parameters is shown in Figure 3.

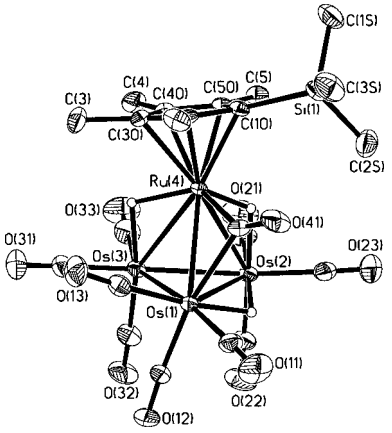

Figure 3. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted) and selected bond lengths [Å] and angles [°] for **4**. Os(1)–Os(2) = 2.9454(3); Os(1)–Os(3) = 2.8153(3); Os(1)–Ru(4) = 2.8292(4); Os(2)–Os(3) = 2.7988(3); Os(2)–Ru(4) = 2.9612(4); Os(3)–Ru(4) = 2.9626(4); Os(1)–C(41) = 2.208(5); Ru(4)–C(41) = 1.949(5); Ru(4)–Cp(centroid) = 1.840(5); Ru(4)–C(41)-Os(1) = 85.53(19).

The silicon atom of the $C_5Me_4SiMe_3$ ligand is displaced by 9°, while the four methyl groups are displaced at an average of 5°, out of the plane of the central carbon ring. These indicate that the replacement of a carbonyl ligand with two bridging hydrides enabled the cyclopentadienyl ring to coordinate to the metal tetrahedron with less steric strain, and may explain why the $SiMe_3$ group was retained, unlike in **2f**.

The ambient temperature $^1$H NMR spectrum in the hydride region of **4** comprised a sharp singlet at –18.46 ppm. At 183 K, this was replaced by broad resonances centered at –16.95 ppm (A), –18.62 (B), and –20.75 (C), as well as a relatively sharper resonance at –21.07 ppm (D), in an integration ratio A/B/C/D of 8:2:1:4. These resonances may be ascribed to two inter-converting isomers existing in a 4:1 ratio; their proposed structures and tentative assignments are given in Figure 4. It is assumed that the major isomer has the structure as that in the X-ray crystallographic study, and that the resonances due to the two hydrides bridging the Ru–Os edges have collapsed into one broad resonance even at 183 K. The proposed structure of the minor isomer is based on the reported structures of $WM_3(\mu\text{-}H)_3(CO)_{11}(\eta^5\text{-}L)$ (M = Os or Ru, L = $C_5H_5$ or $C_5Me_5$).[17] The poor solubility of **4** at low temperatures precluded any attempt at studying the hydride exchange pathways further.

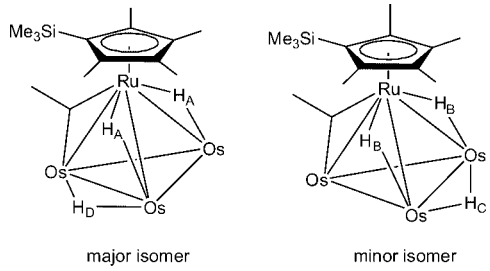

Figure 4. Proposed structures and tentative $^1$H NMR assignments (hydride region) for **4**.

Among the reactions giving rise to clusters **2**, however, the most interesting was that involving the reaction with cyclopentene. The yield of **2a** from this reaction in refluxing octane was rather low (10%). In contrast, the reaction carried out at 120 °C in a Carius tube with hexane as solvent afforded an orange product in essentially quantitative yield, which was identified as the novel cluster $RuOs_3(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}C_5H_7)$ (**5**). Attempts at purification by TLC on silica led to decomposition. Cluster **5** has been completely characterized, also by a single-crystal X-ray crystallographic analysis. An ORTEP plot of **5** showing the atomic numbering scheme, together with selected bond parameters, is given in Figure 5.

The crystal structure exhibits disorder of the metal framework, with ruthenium occupancies on the M(4) and M(1) positions refined to about 0.88 and 0.12, respectively. The cyclopentenyl ligand bridges one of the metal–metal edges in a $\mu,\eta^1\text{:}\eta^2$ manner. This bonding mode has been previously encountered, for example, in $Os_4(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}C_6H_9)$,[2b,18] $Os_4(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}CHCHPh)$,[19] $Os_3(\mu\text{-}H)(CO)_{10}(\mu,\eta^1\text{:}\eta^2\text{-}CHCHCH_2CH_3)$, $Os_3(\mu\text{-}H)(CO)_{10}(\mu,\eta^1\text{:}\eta^2\text{-}CHCH_2)$, and $Os_3(\mu\text{-}H)(CO)_{10}(\mu,\eta^1\text{:}\eta^2\text{-}CHCHPh)$.[20] The alkene C=C bond [1.392(9) Å], is elongated with respect to the typical alkene bond length of 1.33 Å,[21] consistent with a decrease in the bond order. The hydrides were placed by potential energy calculations[22] and are consistent with the elongation of the bridged metal–metal bonds.[23] Moreover, the M–M–C angles for CO ligands adjacent to, and in the same plane as, the bridging hydrides are observed to be abnormally large, ranging from 116 to 122°, relative to usual M–M–C angles of 70 to

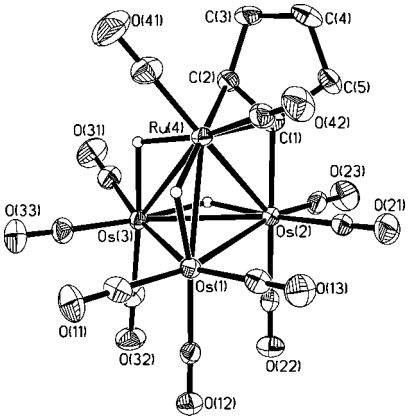

Figure 5. ORTEP diagram (50% probability thermal ellipsoids) and selected bond lengths [Å] and angles [°] for **5**. Os(1)–Os(2) = 2.9252(3); Os(1)–Os(3) = 2.7903(4); Os(1)–Ru(4) = 2.8020(5); Os(2)–Os(3) = 2.9763(4); Os(2)–Ru(4) = 2.7974(5); Os(3)–Ru(4) = 2.9452(5); Os(2)–C(1) = 2.112(7); Ru(4)–C(1) = 2.172(6); Ru(4)–C(2) = 2.307(7); C(1)–C(2) = 1.392(9); Os(2)–C(1)–Ru(4) = 81.5(2).

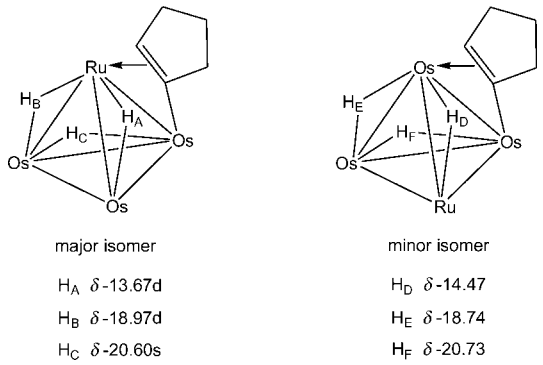

Figure 6. Proposed solution structures (carbonyl groups omitted) for the isomers of **5** and tentative NMR assignments for the bridging hydrides.

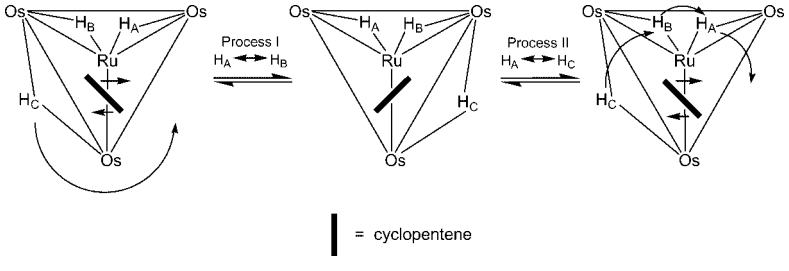
95°. This provides additional evidence for the location of the bridging hydride ligands. As has been observed in the case of $Os_4(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}C_6H_9)$ and $Os_4(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}CHCHPh)$,[18b] one of the longer metal–metal bonds is not bridged [Os(1)–Os(2) = 2.9252(3) Å].

The $^1H$ resonances for the organic moiety have been tentatively assigned with the aid of COSY and NOESY experiments, and the coupling constants have been determined by selective decoupling experiments. The $^1H$ NMR spectrum in the high-field region suggested the presence of two isomers in a 9:1 ratio, consistent with the disorder ratio observed in the solid-state crystal structure. The major set of resonances consists of doublets at –13.67 and –18.97 ppm, and a singlet at –20.60 ppm. The H–H coupling has been confirmed by COSY and selective decoupling experiments. The resonances of the minor isomer were very low in intensity and appeared as singlets. We have tentatively assigned the resonances as shown in Figure 6. The assignments were corroborated by a NOESY spectrum which showed a crosspeak between the resonances at –18.97 and –20.60 ppm, indicating spatial proximity of the hydrides giving rise to them.

In addition to the two sets of resonances described above, the $^1H$ NMR spectrum of **5** at ambient temperature displayed two broad signals at –19.70 and –21.20 ppm, suggesting the presence of another fluxional species. A variable-temperature experiment showed that at 213 K, three singlet resonances at –19.33, –20.41, and –21.41 ppm resulted. An EXSY experiment (213 K and 343 K) indicated exchange crosspeaks between the first two resonances, but no intermolecular exchange was observed between this species and either isomer of **5**. Together with the rather different chemical shifts for these hydrides relative to the others, this species may be unrelated to **5**, although at this point in time a structure cannot be unambiguously assigned.

The EXSY experiment at 343 K also indicated hydride fluxionality in each of the two isomers of **5** but no isomerization between them. Two fluxional processes that can account for the exchange crosspeaks in the major isomer are depicted in Scheme 2. Both processes involve rapid reorientation of the cyclopentenyl moiety about the Ru–Os edge; a similar process has earlier been proposed for the norbornene triosmium cluster $Os_3(\mu\text{-}H)(CO)_{10}(\mu,\eta^1\text{:}\eta^2\text{-}C_7H_9)$.[24] In process I, the flipping of $H_C$ from one Os–Os edge to another, coupled with the reorientation of the cyclopentenyl ligand interchanges $H_A$ and $H_B$. The movement of the organic moiety together with simultaneous flipping of all three hydrides in process II exchanges $H_A$ with $H_C$. Process I is expected to occur at a faster rate than II, and this is supported by the variable-temperature NMR spectra, which show that the signals ascribable to $H_A$ and $H_B$ broaden more rapidly than that attributable to $H_C$. This is further supported by the more intense exchange crosspeak between $H_A$ and $H_B$; the weaker intensity of the exchange crosspeak between $H_B$ and $H_C$ may be attributed to a combination of processes I and II.



Scheme 2.

The interesting question is why the reaction of **1** with cyclopentene should afford only **5**. This is particularly in contrast with the reaction with methylcyclopentene, which afforded **2b** in comparatively good yield. Furthermore, no methylcyclopentenyl analogue of **5** could be identified spectroscopically despite attempts to decrease the reaction time or temperature. It is tempting to view cluster **5** as a possible precursor to **2a**; indeed, heating a sample of **5** in hexane for 12 h afforded **2a**. However, the low yield (20%) and the great number of side products obtained from this thermolysis seem to indicate that this is not so. The transformation of **5** to **2a** would require not only dehydrogenation but also the rehydrogenation of the metallated carbon atom. This situation is similar to that in the related tetraosmium cluster $Os_4(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}C_6H_9)$,[18c] which was determined not to be an active intermediate in the dehydrogenation of the cluster-bound cyclohexa-1,3-diene to give $Os_4(\mu\text{-}H)_2(CO)_{10}(\eta^6\text{-}C_6H_6)$.[2c] We believe that **5** was formed preferentially because of faster C–H activation of an $sp^2$ carbon than an allylic $sp^3$ carbon;[25] the latter is what would be required for aromatization to **2a**.

The reason why methylcyclopentene failed to give an analogue to **5** is probably steric; the hydrogen atom on C(2) (which is where the methyl substituent would be) points towards CO(31) in **5** (Figure 5). In the case of the dienes, presumably the fact that one C–H activation at an $sp^3$ carbon would be sufficient to bring about aromatization may have tilted the balance against the formation of an analogue of **5**. This is corroborated by the observation that to date, only $Os_3(CO)_{10}(\eta^4\text{-}C_5H_6)$, obtained in the reaction of $Os_3(CO)_{10}(MeCN)_2$ with cyclopentadiene in dichloromethane, has been successfully characterized by infrared spectroscopy; in the absence of excess cyclopentadiene the cluster decomposed rapidly.[26]

The clusters **2** have also been subjected to thermolysis in cyclohexane. While **2a**, **2d**, and **2f** were found to be thermally stable, **2b** and **2e** afforded the novel products $RuOs_3(\mu\text{-}H)_2(CO)_{11}(\mu,\eta^5\text{:}\eta^1\text{-}C_5H_3Me)$(**6b**)and$RuOs_3(\mu\text{-}H)_2(CO)_{11}(\mu,\eta^5\text{:}\eta^1\text{-}C_5H_3SiMe_3)$ (**6e**) respectively. Both **6b** and **6e** have been completely characterized by spectroscopic, elemental, and single-crystal X-ray crystallographic analyses. An ORTEP plot of the molecular structure of **6e** is displayed in Figure 7; selected bond parameters for **6b** and **6e** are given in Table 2, together with a common atomic numbering scheme. There were two molecules in the asymmetric unit of **6b**.

Clusters **6b** and **6e** are isomers of **2b** and **2e**, respectively, in which it may be considered that oxidative addition of a C–H bond of the cyclopentadienyl across a metal–metal bond has occurred, so that the resulting ligand bridges the wingtip metal atoms of a butterfly cluster core. The cluster valence electron count of 62 for these clusters is consistent with the butterfly structure. The dihedral angle between the two "wings" of the butterfly – the Ru(4)–Os(1)–Os(3) and Os(1)–Os(2)–Os(3) planes – is 87.8° for **6b** and 88.6° for **6e**. While the Os(1)–Os(3) bonds in **6b** [3.0488(5) Å, molecule A; 3.0451(5) Å, molecule B] as well as **6e** [3.0212(3) Å] show the lengthening associated with a metal–metal vector bridged by a hydride ligand,[7] the hinge bond [2.7948(5)–2.8004(3) Å] is short despite the presence of a bridging hydride. Similar behavior has been observed for the tetraosmium butterfly clusters $Os_4(\mu\text{-}H)_2(CO)_{13}(PMe_3)$ and $Os_4(\mu\text{-}H)(CO)_{12}(Cp^*)$,[27,28] and this has been attributed to the different coordination numbers of the metal atoms; without exception, the osmium atoms linked to only three terminal ligands in these tetraosmium clusters are associated with shorter metal–metal bond lengths.

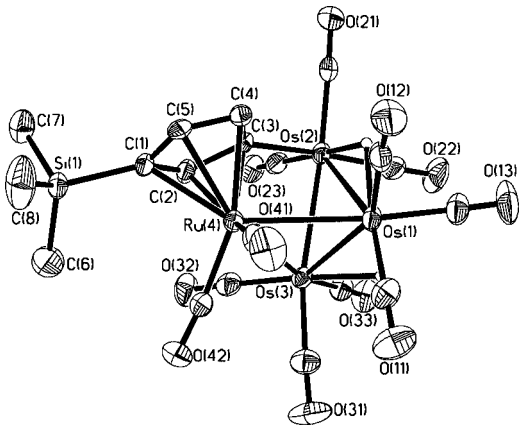

Figure 7. ORTEP diagram (50% probability thermal ellipsoids, organic hydrogen atoms omitted) for **6e**.

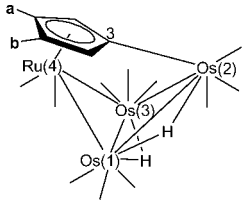
Table 2. Common atomic numbering scheme and selected bond parameters for **6b** and **6e**.



| | **a** | **b** |
|---|---|---|
| **6b** | H | Me |
| **6e** | $SiMe_3$ | H |

| Bond lengths [Å] | **6b** (Molecule A) | **6b** (Molecule B) | **6e** |
|---|---|---|---|
| Os(1)–Os(2) | 3.0488(5) | 3.0451(5) | 3.0212(3) |
| Os(1)–Os(3) | 2.7953(5) | 2.7948(5) | 2.8009(3) |
| Os(1)–Ru(4) | 2.9043(10) | 2.9111(10) | 2.9172(5) |
| Os(2)–Os(3) | 2.8289(5) | 2.8335(5) | 2.8527(3) |
| Os(3)–Ru(4) | 2.9469(9) | 2.9367(9) | 2.9393(4) |
| Os(2)–C(3) | 2.122(11) | 2.120(12) | 2.096(5) |
| Ru(4)–Cp(centroid) | 1.880(11) | 1.880(11) | 1.886(5) |
| Bond angles [°] | | | |
| Os(2)–C(3)–Cp(centroid) | 168.55 | 167.16 | 169.67 |

The $^1H$ NMR spectrum for **6e** indicated that the solid-state structure persisted in solution. In contrast, the ambient-temperature $^1H$ NMR spectrum of **6b** showed a broad singlet at –17.05 ppm. On prolonged standing in solution, the compound isomerized to **2b**, as well as decomposing into some unidentified products. On cooling **6b** to 183 K, we observed three sets of resonances, which may be attributed to the presence of three isomers. However, it is not possible to assign solution-state structures for these isomers unambiguously.

## Concluding Remarks

Our investigations show that thermolysis of **1** with both saturated and unsaturated $C_5$ rings led to ring aromatization via C–H activation and/or loss of a trimethylsilyl moiety, resulting in the formation of clusters **2**; binding of the resulting cyclopentadienyl moiety was specifically at the ruthenium vertex. Loss of the trimethylsilyl group appeared to be dictated by steric factors, so that two products were formed in the reaction with trimethyl(2,3,4,5-tetramethyl-2,4-cyclopentadien-1-yl)silane, viz., **2f** via loss of the silyl group, or **4** via loss of a carbonyl. The reaction with cyclopentene gave, in high yields, the unusual cluster **5** via C–H activation at an $sp^2$ carbon rather than aromatization of the cyclopentene via activation of an allylic $sp^3$ carbon, and again steric reason seemed to explain the fact that an analogue was not observed in the case of 1-methylcyclopentene. Under prolonged thermolysis, cluster fragmentation and condensation can occur, and this accounts for the low yields of **2** observed in some of the reactions.

## Experimental Section

**General Procedures:** All reactions and manipulations were carried out under nitrogen by using standard Schlenk techniques. Solvents were purified, dried, distilled, and stored under nitrogen prior to use. The products were separated by thin layer chromatography (TLC), using plates coated with silica gel 60 F254 of 0.25 or 0.5 mm thickness and extracted with dichloromethane. Routine NMR spectra were acquired with a Bruker ACF300 NMR spectrometer, while decoupling, variable-temperature and 2D NMR spectra were obtained with a Bruker Avance DRX500 or Bruker AMX500 machine. EXSY spectra were recorded with a mixing time of 0.5 s unless otherwise stated. The solvent used was deuterated chloroform unless otherwise stated. $^1$H chemical shifts reported are referenced against the residual proton of the solvents. Mass spectra were obtained with a Finnigan MAT95XL-T spectrometer in an *m*-nitrobenzyl alcohol matrix. Microanalyses were carried out by the microanalytical laboratory at the National University of Singapore. The preparation of cluster **1** appears in our earlier report.[3a] All other reagents were from commercial sources and used as supplied.

**Reactions of $RuOs_3(\mu\text{-}H)_2(CO)_{13}$ (1) with $C_5$ Rings:** In a typical reaction, to a solution of **1** in the solvent in a Carius tube was added an excess of the substrate. The solution was degassed by three freeze-pump-thaw cycles and heated. The solvent was removed under reduced pressure, and the residue so obtained was redissolved in the minimum of dichloromethane and chromatographed on TLC plates with hexane/dichloromethane (3:2, v/v) as the mobile phase. The reaction conditions and yields are summarized in Table 3, and the spectroscopic and analytical data for the products are in Table 4 and Table 5.

**Reaction of 1 with Cyclopentene:** To a Carius tube containing **1** (20.5 mg, 0.020 mmol) and hexane (30 mL) was added cyclopentene (0.1 mL). The reaction mixture was degassed by three freeze-pump-thaw cycles and stirred at 120 °C for 12 h, after which the solvent was removed under reduced pressure. Recrystallization of the red solid in hexane/dichloromethane gave dark orange crystals of **5** as the sole product (19.7 mg, 95%).

**Thermolysis of $RuOs_3(\mu\text{-}H)_3(CO)_{11}(\mu,\eta^1\text{:}\eta^2\text{-}C_5H_7)$ (5):** To a Carius tube containing hexane (30 mL) was added **5** (10.1 mg, 0.010 mmol). The reaction mixture was degassed by three freeze-pump-thaw cycles and stirred at 120 °C for 12 h, after which the solvent was removed under reduced pressure. The residue so obtained was redissolved in the minimum of dichloromethane and chromatographed on TLC plates. Elution with hexane/dichloromethane (7:3, v/v) gave a plethora of products, amongst which **2a** was identified (2.1 mg, 20%).

**Reaction of 1 with 2c:** To a Carius tube containing hexane (30 mL) was added **1** (8.2 mg, 0.079 mmol) and **2c** (5.1 mg, 0.047 mmol). The reaction mixture was degassed by three freeze-pump-thaw cycles and stirred at 120 °C for 24 h, after which the solvent was removed under reduced pressure. The residue so obtained was redissolved in the minimum of dichloromethane and chromatographed on TLC plates. Elution with hexane/dichloromethane (7:3,

Table 3. Reaction conditions and yields for the reaction of **1** with $C_5$ rings.

| Amount of **1** | Substrate (volume) | Conditions | Prod. | $R_f$ | Color | Yield |
|---|---|---|---|---|---|---|

[a] In $C_6D_6$.

v/v) gave unreacted **1** (4.1 mg), $Os_3(\mu\text{-}H)_2(CO)_{10}$ (1.3 mg), and a mixture of **2c** and **3** (5.9 mg; **2c**/**3** : 1.3:1.0).

**Thermolysis of 2b:** To a Carius tube containing cyclohexane (30 mL) was added **2b** (20.2 mg, 0.019 mmol). The reaction mixture was degassed by three freeze-pump-thaw cycles and stirred at 120 °C for 18 h, after which the solvent was removed on the vacuum line. The residue so obtained was redissolved in the minimum of dichloromethane and chromatographed on TLC plates. Elution with hexane/dichloromethane (3:2, v/v) yielded two bands, identified as **6b** (3.6 mg, 18%) and unreacted **2b** (16.2 mg), respectively.

**Thermolysis of 2e:** To a Carius tube containing cyclohexane (30 mL) was added **2e** (10.7 mg, 0.010 mmol). The reaction mixture was degassed by three freeze-pump-thaw cycles and stirred at 120 °C for 20 h, after which the solvent was removed on the vacuum line. The residue so obtained was redissolved in the minimum of dichloromethane and chromatographed on TLC plates. Elution with hexane/dichloromethane (3:2, v/v) yielded two bands, identified as **6e** (1.5 mg, 14%) and unreacted **2e** (8.7 mg), respectively.

**X-ray Crystal Structure Determinations**

Crystals were mounted on quartz fibers. X-ray data were collected on a Bruker AXS APEX system, using Mo-$K_\alpha$ radiation, at 223 K with the SMART suite of programs.[29] Data were processed and corrected for Lorentz and polarization effects with SAINT[30] and for absorption effects with SADABS.[31] Structural solution and refinement were carried out with the SHELXTL suite of programs.[32] Crystal and refinement data are summarized in Table 6 and Table 7.

The structures were solved by direct methods to locate the heavy atoms, followed by difference maps for the light, non-hydrogen atoms. There were two molecules in the asymmetric unit for **2a** and **6b**. The hydrides were either located in low-angle difference electron density maps or were placed by potential energy calculations with the program XHYDEX,[22] given fixed isotropic thermal parameters, and were either refined freely, with restraints on the M–H bond lengths, or with a riding model. Organic hydrogen atoms were placed in calculated positions and refined with a riding model. All non-hydrogen atoms were generally given anisotropic displacement parameters in the final model.

Cluster **5** exhibited disorder of the heavy atom positions; the ruthenium atom was modeled as disordered over two sites – M(1) and M(4). The disordered atoms at the same site were given the same coordinate and shifts and thermal parameters, and the Ru occupancy refined and restrained to add up to unity; the refined occupancies were 0.12 and 0.88 for M(1) and M(4), respectively.

# Bis-μ-pyrazolate-Bridged Dinickel(II) and Dicopper(II) Complexes: An Example of Stereoelectronic Preference of Metal Ions and Stabilization of Mixed-Valence $Ni^{III}Ni^{II}$ Species

**Vibha Mishra,[a] Francesc Lloret,[b] and Rabindranath Mukherjee*[a]**

**Keywords:** Nickel / Copper / Dinuclear complexes / Pyrazolate bridge / $Ni^{III}$-$Ni^{II}$ species

New dimeric nickel(II) and copper(II) complexes $[(L)Ni(\mu\text{-}L')]_2[ClO_4]_2$ **1** and $[(L)Cu(\mu\text{-}L')]_2[ClO_4]_2$ **2**, [2-[3-(2′-pyridyl)-pyrazol-1-ylmethyl]pyridine (L) and 3-(2-pyridyl)pyrazole (HL′)] have been synthesized, structurally characterized, and their absorption, magnetic, EPR and redox properties investigated. The crystal structure of **1**·MeCN reveals a planar $\{Ni_2(\mu\text{-}L')_2\}^{2+}$ core [Ni···Ni separation: 4.0765(10) Å] in which each distorted octahedral $Ni^{II}$ ions is terminally coordinated by a tridentate ligand L and bridged by two HL′ units, in their deprotonated form. The structural analysis of **2**·2MeCN reveals two five-coordinate $Cu^{II}$ ions, each terminally coordinated by adopting only a bidentate coordination mode of L, in which the $-CH_2$py arm remains uncoordinated. A similar bridging [Cu···Cu separation: 3.9382(24) Å] as in **1**·MeCN is observed. Thus stereoelectronic preferences of $Ni^{II}$ and $Cu^{II}$ are clearly revealed. Closer inspection of crystal packing diagram of **1**·MeCN reveals the formation of 2-D network structure assembled solely via C–H···π interaction [pyridyl C–H (4-position) of pyridylpyrazole unit of L and π cloud of pyridine of bridging deprotonated L′ unit]. In **2**·2MeCN, however, π···π interactions between uncoordinated pyridyl arms are observed. Variable-temperature magnetic studies on both complexes indicate the existence of strong antiferromagnetic coupling between the two metal ions (singlet-triplet energy separation, $J = -20\ cm^{-1}$ for **1** and $-200\ cm^{-1}$ for **2**). When investigated by cyclic voltammetry complex **1** displays two quasi-reversible electron-transfer reactions at $E_{1/2}$ = 1.36 V ($\Delta E_p$ = 110 mV) and 1.79 V ($\Delta E_p$ = 120 mV) vs. SCE, due to $Ni^{III}Ni^{II}/Ni^{II}{}_2$ and $Ni^{III}{}_2/Ni^{III}Ni^{II}$ redox processes, respectively. Constant potential electrolysis at 1.50 V vs. SCE leads to the generation of dark green mixed-valence $Ni^{III}Ni^{II}$ species, which is stable enough to be subjected to characterization by UV/Vis and EPR spectroscopy. Compound **2** exhibits only irreversible reductions (cathodic peak potential, $E_{pc}$ = –0.28 V and –0.50 V vs. SCE).

## Introduction

There has been continuing interest in the investigation of the magneto-structural properties of symmetrical dibridged metal(II) dimers.[1] As part of our continued involvement in the exploration of interesting coordination chemistry of pyridyl/pyrazole-based chelating ligands,[2] we have investigated the magneto-structural properties of a large variety of dinuclear/trinuclear/polymeric complexes with a varied combinations of endogenous/exogenous and solely exogenous bridging ligands (alkoxo/pyrazolato,[3] acetato/pyrazolato,[4] carbonato,[5] diacetato,[4,6] dichloro,[7] dihydroxo,[4,8] monohydroxo,[9] oxo/bis-acetato,[10,11] phenoxo/chloro,[12] phenoxo/hydroxo,[8,13] diphenoxo[14]).

Among the diverse bridging ligands/ligand frameworks that have been employed in holding two metal centers for efficient mediation of magnetic exchange interactions, pyrazolates are extensively explored, due to their coordination flexibility, versatility and potential to fine-tune metal–metal distance over a wide range of 2.4–4.6 Å affording oligo- and polymetallic compounds.[15]

This work finds impetus from the fact that a combination of carefully designed chelating ligands and judicious choice of metal ions with stereoelectronic preference can lead to the synthesis of metal complexes with interesting molecular and electronic structural properties.[16,17] The choice of terminal ligands of this work stems from our continued activity in the coordination chemistry of nonplanar pyridyl/pyrazole ligands toward transition metal ions.[2,4,6,7,18,19] Specifically, in the present work our target has been to synthesize and structurally characterize dimetal(II) complexes, satisfying the following requirements. (i) The metal ions should show stereoelectronic preference in their coordination. (ii) The terminal coordination of the metal ions should be provided by tridentate ligand L and bridging coordination by deprotonated form of 3-(2-pyridyl)pyrazole

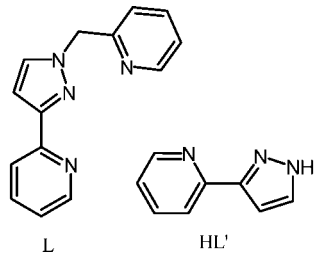
(HL′).[16,17,20] (iii) The magneto-structural behavior should be investigated. Thus we report here the synthesis, crystal structure of bis-μ-pyrazolate-bridged dimetal(II) complexes $[(L)M^{II}(\mu\text{-}L')]_2[ClO_4]_2$ (M = Ni **1**, Cu **2**), and investigation of their spectroscopic, magnetic, and redox properties.



## Results and Discussion

### Synthesis and General Characterization

The designed synthesis of two complexes $[\{(L)M^{II}(\mu\text{-}L')\}_2][ClO_4]_2$ (M = Ni **1**, Cu **2**) are based on the following considerations: (i) L is a potential tridentate ligand,[18d] (ii) 3-(2-pyridyl)pyrazole (HL′)[20] can assume several coordination modes and the one adopted in the complex formation is governed by the reaction conditions.[21] Notably, it can act as a terdentate bridging ligand via deprotonation of the pyrazolyl NH group and coordination of the pyrazolyl N atom to a second metal ion, and (iii) The $Cu^{II}$ ion is well-known to produce variable and distorted coordination geometries[22] and the $Ni^{II}$ ion is expected to produce six-coordinate geometry with the given combination of ligands L and deprotonated L′. Keeping these points in mind a common synthetic strategy was followed for preparing the two complexes. The metal salt $Ni(OAc)_2{\cdot}4H_2O$/$[Cu(H_2O)_6][ClO_4]_2$ and L (1:1) were allowed initially to react in MeOH, addition of 1 equiv. of HL′, followed by addition of $Et_3N$ led to the formation/isolation of the complexes.

As expected, both complexes behave as 1:2 electrolytes in MeCN solution.[23] IR spectra show the characteristic bands at ca. 1100 $cm^{-1}$ and ca. 620 $cm^{-1}$ for ionic perchlorate vibrations. Elemental analysis, IR, and solution electrical conductivity data are in excellent agreement with the above formulations of the two new complexes.

### Crystal Structure of $[\{(L)Ni(\mu\text{-}L')\}_2][ClO_4]_2$ (1·MeCN)

A perspective view of the cation of **1**·MeCN with atom numbering scheme is shown in Figure 1 and selected metric parameters are given in Table 1. Each $Ni^{II}$ ion is in six-coordinate geometry with coordination by two bridging pyrazolate nitrogen atoms [N(6) and N(14) to Ni1; N(7) and N(13) to Ni2], a terminal pyridyl coordination from 3-(2-pyridyl)pyrazole units N(5) to Ni1 and N(12) to Ni2. Two additional coordinations are achieved by pyrazole nitrogen of ligand L: N(2) to Ni1 and N(9) to Ni2. Two long axial coordinations are achieved by the pyridyl nitrogen atoms of L: N(1) and N(4) for Ni1; N(8) and N(11) for Ni2. Both $Ni^{II}$ ions are bridged by the deprotonated 3-(2-pyridyl)pyrazole unit, leading to a Ni···Ni separation of 4.0765(10) Å. In essence, it is a bis(μ-pyrazolate)-bridged six-coordinate dinickel(II) complex. Metric parameters indicate that the coordination geometry deviates from regular octahedron. While the *trans* angles vary in the range 160–175° the *cis* angle variation is in the range 77–101° (Table 1).

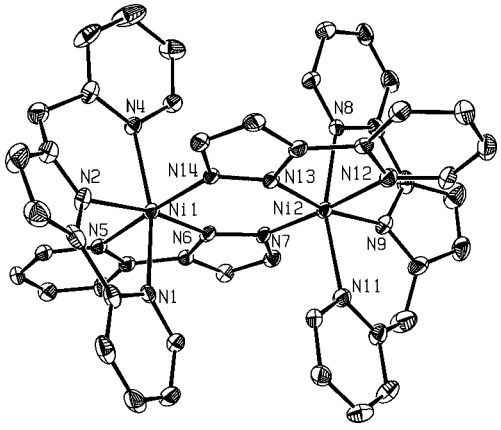


Figure 1. View of the dication $[(L)_2Ni_2(\mu\text{-}L')_2]^{2+}$ in complex **1**·MeCN, showing the atom numbering scheme. Atoms are drawn at 30% probability level. All hydrogen atoms are excluded for clarity.

The two nickel(II) ions deviate from the mean plane passing through bridging pyrazolate units by only 0.1482 Å and 0.0765 Å (Ni1 and Ni2, respectively). Dihedral angle between the plane of pyrazolate ring of {Ni1(μ-L′)} unit and {Ni2(μ-L′)} is 5.529(172)°. In this structure there are three types of donor atoms: pyrazole nitrogen and two types of pyridyl nitrogen atoms. Average distances for Ni–$N_{py}$ (directly attached pyridyl ring), Ni–$N_{py}$ (pyridyl ring with $CH_2$-spacer), and Ni–$N_{pz}$ (pyrazole ring) are 2.1575(4), 2.173(4) and 2.0333(4) Å, respectively. It is found that pyrazole rings from terminal ligands are more strongly bonded to the $Ni^{II}$ ions than the bridging ones. In fact, the observed Ni–$N_{py}$ (N5/N12) (bridging pyrazolate) distances are shorter than Ni–$N_{py}$ (N1/N8) bond lengths from terminally coordinated L ligand [2.128(4) and 2.152(4) Å vs. 2.160(4) and 2.189(4) Å]. The present complex is amongst relatively few structurally characterized bis(μ-pyrazolate)-bridged dinickel(II) complexes.[2a,24,25]

### Crystal Structure of $[\{(L)Cu(\mu\text{-}L')\}_2][ClO_4]_2{\cdot}2MeCN$ (2·2MeCN)

A perspective view of the cation of **2**·2MeCN is displayed in Figure 2, along with the atom-numbering scheme. The structural analysis reveals that crystallographic asymmetric unit consists of a binuclear dipyrazolate-bridged copper(II) cation, two perchlorate ions, and two MeCN molecules. The dication sits on a crystallographically imposed inversion center and hence only half of the dimeric unit is unique and the other half is symmetry-related. Each $Cu^{II}$ ion is in five-coordinate geometry with coordination by two bridging pyrazolate nitrogen atoms [N(6) and N(7) for Cu1;

Symmetry code: (i) = $-x + 2, -y + 1, -z + 1$

N(6′) and N(7′) for Cu1′], a terminal pyridyl coordination N(5)/N(5′) from 3-(2-pyridyl)pyrazole units, and a pyridyl nitrogen atom N(1)/N(1′) from the ligand L in the equatorial plane. Axial coordination is achieved by the pyrazole nitrogen atom [Cu–N(2): 2.302(7) Å] of ligand L. A noteworthy feature of this structure is that in each ligand L the methyl pyridine arm remains uncoordinated. Thus the $Cu^{II}$ center has square-pyramidal geometry [precisely it is slightly distorted ($\tau = 0.035$)],[26] which is achieved by having the two potentially tridentate chelating units of L acting as bidentate ligands. The preference of the $Cu^{II}$ ion for five-coordination over six, is a consequence of Jahn–Teller distortion.[18c] The Cu(1) atom lies above the equatorial plane by 0.118 Å towards pyrazole nitrogen N(2) of terminally coordinated L. The sum of four angles provided by the equatorial nitrogen donors is 359.2°, consistent with a small displacement of the copper atom from the equatorial plane. The two $Cu^{II}$ ions are bridged by the deprotonated 3-(2-pyridyl)pyrazole unit, leading to a Cu···Cu separation of 3.9382(24) Å. In essence, it is a bis(μ-pyrazolate)-bridged dicopper(II) complex in which a planar $\{Cu_2(\mu\text{-}L')_2\}^{2+}$ core is terminally coordinated by two L ligands, in which methyl-pyridine arms remain uncoordinated. The Cu···Cu distance is on the higher end of distances reported for complexes with similar structural motif.[2,21,27–29]

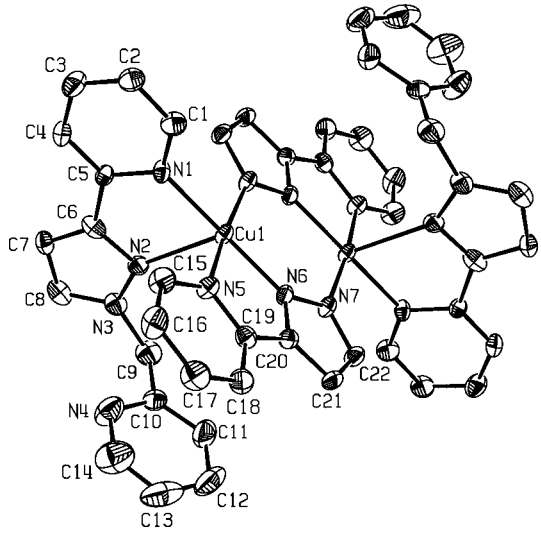

Figure 2. View of the dication $[(L)_2Cu_2(\mu\text{-}L')_2]^{2+}$ in complex **2**·2MeCN, showing the atom numbering scheme. Atoms are drawn at 30% probability level. All hydrogen atoms are excluded for clarity.

### Noncovalent Interactions

A closer inspection of the crystal packing diagram of **1**·MeCN reveals that the cations are engaged in an extensive intermolecular C–H···π interactions[18f,30a,30b] involving *para*-C–H of coordinating pyridine ring of pyridylpyrazole unit of L with the π-electron cloud of pyridine ring of bridging 3-(2-pyridylpyrazole) unit. Interaction parameters are given in Table 2. These C–H···π interactions led to the formation of linear one-dimensional chains (Figure 3, a). These chains are interconnected via neighboring molecules of adjacent chain through another C–H···π interaction involving *para*-C–H of pyridine ring of bridging 3-(2-pyridyl)pyrazole unit with the π-electron cloud of coordinating pyridine ring of pyridylpyrazole unit of L. This resulted in the formation of 2D network (Figure 3, b). This is rather interesting that

Table 2. Hydrogen-bonding (C–H···π) parameters for $[(L)_2Ni_2(\mu\text{-}L')_2]^{2+}$ in **1**·MeCN.

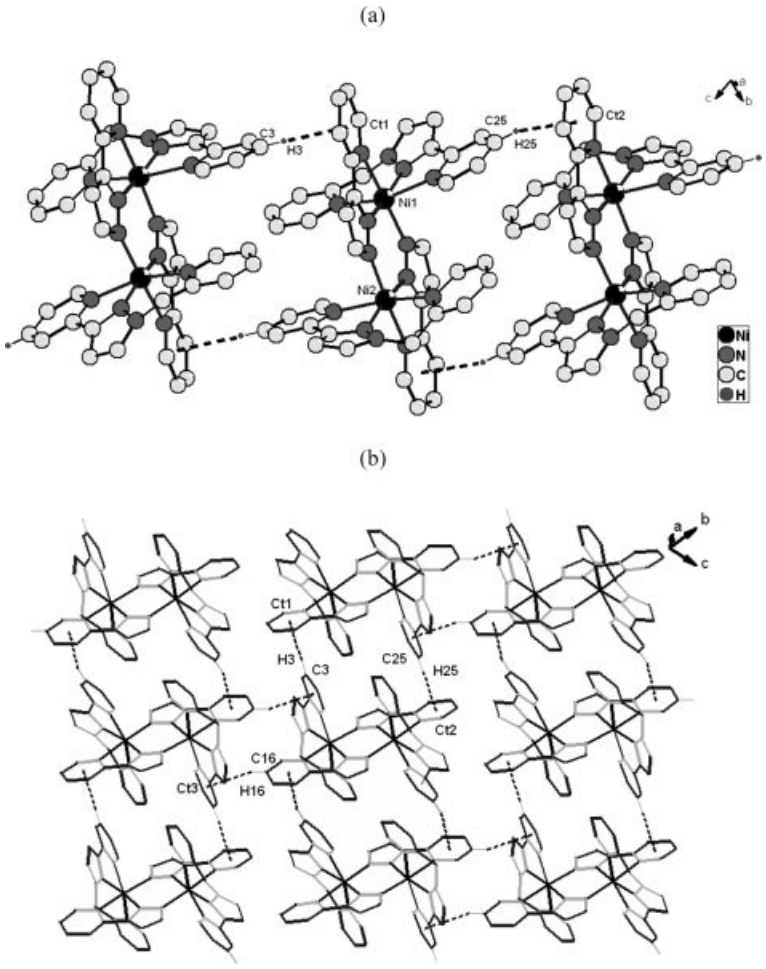

Figure 3. (a) A perspective view of the formation of a linear chain and (b) Formation of 2D-network solely via C–H···π interactions in the dication $[(L)_2Ni_2(\mu\text{-}L')_2]^{2+}$ of complex **1**·MeCN. All hydrogen atoms except those involved in hydrogen-bonding are excluded for clarity.

such 2D architecture has formed solely via C–H···π interactions.

The molecular packing in the crystal structure of **2**·2MeCN does not reveal C–H···π interactions, as observed for **1**·MeCN. However, it is realized that uncoordinated pyridine arm of L is involved in intermolecular π-π stacking,[19a,30c] leading to the formation of staircase-like arrangement of molecules (see Figure S1 in the electronic Supporting Information). The π···π stacking parameters are as follows: centroid–centroid distance: 3.9570(17) Å; perpendicular distance between two $CH_2$-py arm: 3.5682 Å; dihedral angle between the planes is 0.0°; displacement angle $\beta$ = 25.60°.[18f,30] The difference in the nature of noncovalent interactions observed for **1**·MeCN and **2**·2MeCN must have originated from dissimilar nature of metal coordination mode of ligand L. While for the former complex the potential tridentate ligand L acts as a tridentate ligand in the case of the latter complex it acts as a bidentate ligand leaving the $CH_2$py arm uncoordinated. This effect caused by stereoelectronic geometric preference of metal ions is manifested in the observed noncovalent interactions for these two structures.

We present here a rationalization of observed secondary interactions. C–H···π interactions observed in **1**·MeCN is facilitated due to *meridional* coordination of L which forces the ligand L to attain planar and perpendicular orientation to the bridging 3-(2-pyridylpyrazole) unit (Figure 1). Hence we believe that the relative disposition of L and bridging 3-(2-pyridylpyrazole) unit in **1**·MeCN favors the formation of 2D network via extensive C–H···π interactions. Such a situation is absent in **2**·2MeCN due to uncoordinated $CH_2$-py arm of L (Figure 2) and therefore C–H···π interaction is not observed in **2**·2MeCN. In **2**·2MeCN, however, the uncoordinated $CH_2$-py arms are suitably placed away from the metal center and remains almost parallel to the pyridine ring of the bridging 3-(2-pyridylpyrazole) unit. This in turn triggers to engage in weak intermolecular π-π stacking interactions (Figure S1) involving $CH_2$-py arm of L.

## Absorption Spectra

Absorption spectra for both complexes in MeCN are displayed in Figure S2. Purplish-green solutions of complex **1**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

exhibit crystal-field transitions at 966 nm and 526 nm, which could be assigned as $^3A_{2g}\rightarrow{}^3T_{2g}$ and $^3A_{2g}\rightarrow{}^3T_{1g}$ (in octahedral coordination environment), respectively. A spin forbidden transition could be identified at 800 nm ($^3A_{2g}\rightarrow{}^1E_g$).[31] Compound **2** exhibits a crystal-field transition at 640 nm with a shoulder at 850 nm, typical of square-pyramidal $Cu^{II}$ stereochemistry.[22] An intense transition occurs as a shoulder at ca. 300 nm probably due to pyrazolate $\rightarrow Cu^{II}$ charge-transfer. Absorptions at higher energy originate in the intraligand.

### Magnetic Properties

Complexes **1** and **2** have the same planar $[M^{II}(\mu\text{-}L')]_2$ (M = Ni and Cu) binuclear entities, with the $Ni^{II}$ ion having distorted octahedral and $Cu^{II}$ ion assuming square-pyramidal geometry. From the magnetic point of view these complexes are clearly of interest and give us a unique opportunity to compare their magnetostructural behavior. The magnetic behavior of **1** (Figure 4) deserves special attention owing to the status of this complex as one among very few examples of bis(μ-pyrazolate)-bridged $Ni^{II}$ dimers.[2a,24,25] The temperature-dependence of the magnetic behavior is shown in Figure 4 in the form of $\chi_M T$ and $\chi_M$ vs. $T$ plots. The observed $\chi_M T$ value of 2.16 $cm^3 mol^{-1} K$ (2.94 $\mu_B$/Ni) at room temperature is indicative of $S = 1$ system. The value of $\chi_M T$ decreases very smoothly when cooling and it is 1.87 $cm^3 mol^{-1} K$ at 100 K (2.73 $\mu_B$/Ni). Below this temperature $\chi_M T$ decreases rapidly and it vanishes when $T$ tends to zero. The $\chi_M$ curve shows a maximum at 30 K. It clearly reveals the presence of antiferromagnetically coupled $Ni^{II}$ ions in **1**. According to the dinuclear nature of the complex, the experimental data were modeled through the Hamiltonian $H = -J\hat{S}_1\hat{S}_2 + D(\hat{S}_{z1}^2 + \hat{S}_{z2}^2)$ (with $\hat{S}_1 = \hat{S}_2 = 1$)[32] in the range from 298 K to 2.1 K. In this case, the magnetic susceptibility for a $Ni^{II}$ dimer is given by Equation (1).

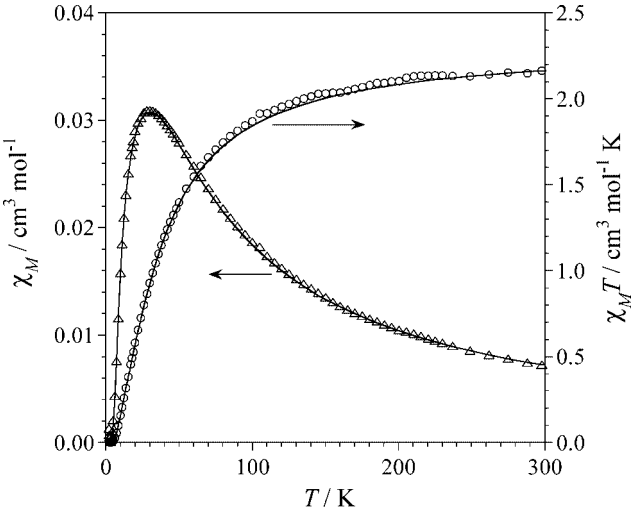

Figure 4. Temperature-dependence of the $\chi_M$ and $\chi_M T$ product for powdered sample of $[(L)_2Ni_2(\mu\text{-}L')_2][ClO_4]_2$ (**1**). The solid lines represent the best theoretical fit using the equation described in the text.

$$\chi_M = \frac{2N\beta^2 g^2}{3\alpha}\left(\frac{F_1}{kT} + \frac{2F_2}{D} + \frac{6a^2F_3}{3J-\Delta} + \frac{6b^2F_4}{3J+\Delta}\right)$$

$$F_1 = 1 + \exp(2x) + 4\exp(2x+y)$$

$$F_2 = -1 + 2\exp(2x+y) + \exp(y) - 2\exp(2x)$$

$$F_3 = \exp(2x) - \exp(\frac{x}{2} + z)$$

$$F_4 = \exp(2x) - \exp(\frac{x}{2} - z)$$

$$\alpha = 2 + \exp(y) + \exp(\frac{x}{2} - z) + \exp(\frac{x}{2} + z) + \ldots$$
$$\ldots\ 2\exp(2x) + 2\exp(2x+y)$$

$$x = \frac{J}{kT};\quad y = \frac{D}{kT};\quad z = \frac{\Delta}{kT};\quad \Delta = \left[(3J+D)^2 - 8JD\right]^{1/2}$$

$$a = \frac{9J - D + 3\Delta}{\left[(9J - D + 3\Delta)^2 + 8D^2\right]^{1/2}}$$

$$b = \frac{2\sqrt{2D}}{\left[(9J - D + 3\Delta)^2 + 8D^2\right]^{1/2}} \qquad (1)$$

To reduce the number of variables the $D$ (zero-field splitting parameter) and g values were considered to be identical for the two nickel(II) ions. A satisfactory fit was obtained with the set of parameters $J = -20.6\ cm^{-1}$, $|D| = 1.2\ cm^{-1}$ and $g = 2.15$ [$R = 1.3\times10^{-5}$, $R = \Sigma(\chi_M{}^{obs} - \chi|_M{}^{calc})^2/\Sigma(\chi_M{}^{obs})^2$], confirming the intramolecular antiferromagnetic coupling between nickel(II) centers. The temperature-independent paramagnetism, TIP, was observed to be 90 $cm^3 mol^{-1}$ for each $Ni^{II}$ ion, which was corrected on the magnetic curve of Figure 4. No paramagnetic impurities were observed. The magnitude of the exchange interaction is comparable to that observed for closely similar compounds.[25]

Generally, the dicopper(II) complexes with pyrazolate-bridge show a very strong antiferromagnetic coupling.[2,21,27–29] Variable-temperature (5–300 K) magnetic studies were done on powdered samples in order to determine the magnitude of the magnetic coupling of **2**. In fact, compound **2** shows a subnormal magnetic moment at room temperature ($\mu_{eff}$/Cu = 1.58 $\mu_B$). The $\chi_M T$ value decreases gradually upon cooling and it reaches a plateau below 50 K. A plot of $\chi_M T$ vs. $T$ for **2** (Figure 5) is typical of a moderate antiferromagnetically coupled dicopper(II) complex. The experimentally observed $\chi_M$ values (per dimer) were fitted to the modified[3,4,8b,9,12–14] Bleaney–Bowers equation based on the Heisenberg spin Hamiltonian, $H = -JS_1 \cdot S_2$ [Equation (2)], allowing for the presence of monomeric copper(II) impurity behaving as a Curie paramagnet, where $\rho$ is the mole fraction of such an impurity and $N_\alpha$ is the temperature-independent paramagnetism per $Cu^{II}$ ion; other symbols have their usual meaning. Keeping $g$ and $N_\alpha$ fixed at 2.1 [obtained from the EPR spectrum of the complex, Figure S3 {typical value for a tetragonal $Cu^{II}$[4]}] and $60\times10^{-6}\ cm^3 mol^{-1}$, the $J$ and $\rho$ parameters

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were determined by minimizing $R = \Sigma(\chi_M^{obs} - \chi_M^{calc})^2/\Sigma(\chi_M^{obs})^2$ using Equation (2) gave good data fits. As shown by the trace in Figure 5, an excellent simulation (non-linear regression analyses) of the data could be attained with the following parameters: $J = -200\ cm^{-1}$ and $\rho = 0.86\%$. $R = 1.84 \times 10^{-7}$ for **2**. The magnitude of the exchange interaction is similar to that observed for other bis(μ-pyrazolate)-bridged[28,29] and the related bis(μ-$N^1$,$N^2$)triazole-bridged[33] dinuclear $Cu^{II}$ complexes. Solution-state $\mu_{eff}$/Cu value for **2** at 298 K is 1.4 $\mu_B$, slightly lower than that obtained as a solid.

$$\chi_M = 2N\beta^2g^2/3kT\,[1 + 1/3\exp(-J/kT)]^{-1}(1-\rho) + (N\beta^2g^2/2kT)\rho + 2N\alpha \quad (2)$$

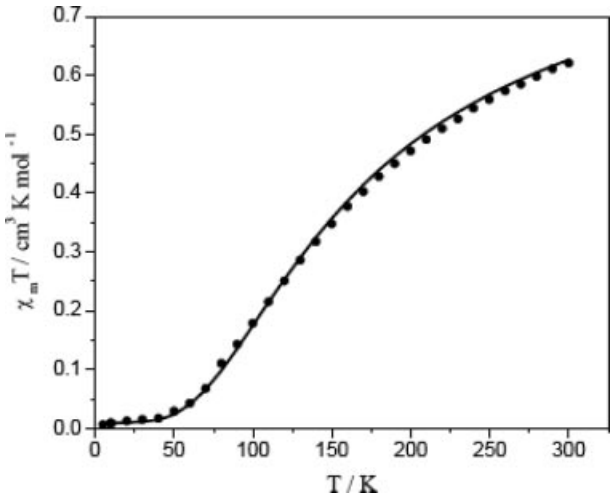

Figure 5. Temperature dependence of the $\chi_M T$ product for powdered samples of $[(L)_2Cu_2(\mu\text{-}L')]_2[ClO_4]_2$ (**2**). The solid lines represent the best theoretical fit using the equation described in the text.

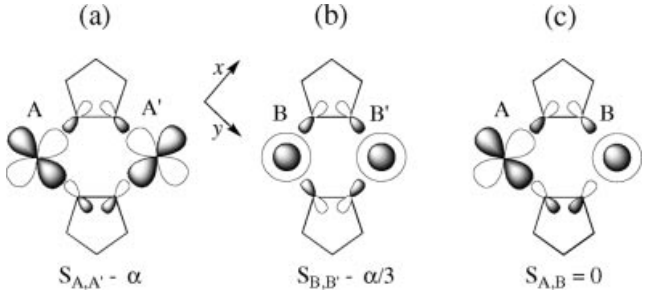
In these complexes the pathway for magnetic exchange is propagated through the bridging pyrazolate ligands. From the molecular structure of **2**, one can conclude that the unpaired electron in each metal center is clearly described by $d_{x^2-y^2}$ magnetic orbital, which is coplanar with the pyrazolate skeleton (see part a of Scheme 1). The significant overlap between these magnetic orbitals accounts for the strong antiferromagnetic coupling observed.



Scheme 1.

It is interesting to observe that the value of $J$ for $Ni^{II}$ dimer (ca. $-20\ cm^{-1}$) is much lower than the corresponding value for the $Cu^{II}$ dimer (ca. $-200\ cm^{-1}$).[34] In **1**, the $Ni^{II}$ ion has two magnetic orbitals, $d_{x^2-y^2}$ and $d_{z^2}$ (see Scheme 1). In order to evaluate both magnetic exchange pathways, we can describe the unpaired electrons on each $Ni^{II}$ ion by the orbitals $\Psi_A$ and $\Psi_B$ [Equations (3) and (4)], where &πηι;$_L$ is the orbital of the bridging ligand.[35] The participation of the peripheral ligands is neglected and the same energy for both metal orbitals was assumed (the same mixing coefficient $a$).

$$\Psi_A = N(d_{x^2-y^2} - a\phi_L) \quad (3)$$

$$\Psi_B = N(d_{z^2} - \frac{a}{\sqrt{3}}\ \phi_L) \quad (4)$$

In the frame of Kahn's orbital model[36] it is found that $J$ varies as $S_{u,v}^2$ ($S_{u,v}$ being the overlap integral between the magnetic orbitals $u$ and $v$). The values of $S_{u,v}$ can be approximated to be $S_{A,A'} = \langle\Psi_A|\Psi_{A'}\rangle \propto a^2$ and $S_{B,B'} = \langle\Psi_B|\Psi_{B'}\rangle \propto \frac{a^2}{3}$, where the prime refers to the second magnetic orbital in the dimer. In this approach, our prediction concerning the relative magnitudes of both pathways is $\frac{J_{x^2-y^2,x^2-y^2}}{J_{z^2,z^2}} \approx \frac{S_{A,A'}^2}{S_{B,B'}^2} \approx 9$, showing the greater magnetic exchange through the $d_{x^2-y^2}$ pathway.[35]

When the metal ion has more than one unpaired electron, the experimental $J$ parameter must be decomposed into a sum of individual contributions, $J_{uv}$, concerning each pair of magnetic orbitals involved in the exchange phenomenon [Equation (5)], where $n_A$ and $n_B$ are the number of unpaired electrons associated with the transition metal ions A and B, respectively.[36,37] Equations (5), (6), and (7) show how the magnitude of the antiferromagnetic interaction is not properly described by $J$ but by $n_An_BJ$. In the present case ca. $-80\ cm^{-1}$ for $Ni^{II}$ ($n_A = n_B = 2$) respect to ca. $-200\ cm^{-1}$ for $Cu^{II}$ dimer ($n_A = n_B = 1$), values which are still too different.

$$J = \frac{1}{n_An_B}\sum_{u=1}^{n_A}\sum_{v=1}^{n_B} J_{uv} \quad (5)$$

$$J_{CuCu} = J_{x^2-y^2,x^2-y^2} \approx -200\ cm^{-1} \quad (6)$$

$$J_{NiNi} = \frac{1}{4}(J_{x^2-y^2,x^2-y^2} + J_{z^2,z^2} + J_{x^2-y^2,z^2}) \approx -20\ cm^{-1} \quad (7)$$

The low value for the $Ni^{II}$ dimer can be attributed to the existence of ferromagnetic terms between the magnetic orbitals $d_{x^2-y^2}$ and $d_{z^2}$ (strict orthogonality, Scheme 1, c), which can be important when the distance between paramagnetic centers is short (cases of mono- and diatomic bridges).[38] Assuming a similar energy and bond lengths for $Ni^{II}$ and $Cu^{II}$ complexes and taking into account that $J_{x^2-y^2,x^2-y^2} \approx 9J_{z^2,z^2} \approx -200\ cm^{-1}$ (see above), a rough value of $J_{x^2-y^2,z^2} \approx +70\ cm^{-1}$ can be inferred from Equation (7), which is of the same order as that observed for diatomic bridges such as oximes.[37]

### Redox Properties

The redox behavior of these complexes has been investigated by cyclic voltammetry (CV) in MeCN at a platinum electrode (scan rate 100 mV s$^{-1}$). Complex **1** exhibits both oxidative as well as reductive redox behavior. In the potential range 0.0 to 2.0 V it undergoes two one-electron quasi-reversible oxidations (Figure 6) at [$E_{1/2}$ = +1.36 V ($\Delta E_p$ = 110 mV)] and [$E_{1/2}$ = +1.79 V ($\Delta E_p$ = 120 mV) vs. SCE], respectively. The two processes are tentatively assigned to the formation of $Ni^{III}Ni^{II}$ and $Ni^{III}Ni^{III}$ species. During negative scan 0.0 to –2.0 V it exhibits an irreversible response at –1.52 V vs. SCE. Such oxidative redox behavior is similar to other dinickel(II) complexes reported in the literature.[39] Notably, the difference between the successive redox processes in **1** is sufficient (ca. 450 mV) to stabilize the mixed-valence $Ni^{III}Ni^{II}$ species. Controlled-potential electrolysis of **1** at an applied potential of +1.50 V vs. SCE in MeCN solution consumed $n = 0.95 \pm 0.02$ e$^-$/complex (mean value of three independent measurements) and produced dark green solutions. Such solutions display the same CV response as that of $Ni^{II}Ni^{II}$ species. However, this time the response at 1.36 V is reductive, as expected (Figure S4). Re-reduction of such solutions at 0.0 V caused a transfer of 85% of the charge that passed during oxidation, attesting reasonable stability of the oxidized mixed-valence $Ni^{III}Ni^{II}$ species. Absorption spectra of dark green solutions (Figure 7) display a characteristic broad band at 755 nm ($\varepsilon$ = 930 M$^{-1}$ cm$^{-1}$). No other absorption is noted. In more likelihood this has happened either due to superposition of the spectra of individual $Ni^{II}$ and $Ni^{III}$ ions or due to strong delocalization (X-ray structure of **1**·MeCN), properties of the component species have been replaced by a new delocalized species. However, the high molar extinction coefficient value than that expected for a d-d band indicates it to be an IVCT band. The dark green color of the oxidized solution is similar to those of similar $Ni^{III}$-$Ni^{II}$ mixed-valence species reported in the literature.[40]

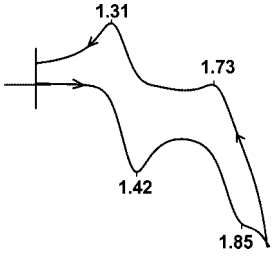

Figure 6. Cyclic voltammogram (100 mV s$^{-1}$) of [$(L)_2Ni_2$ ($\mu$-L′)$_2$]-[$ClO_4$]$_2$ (**1**) at a Pt electrode in MeCN (ca. 0.1 dm$^3$ mol$^{-1}$ in TBAP). Indicated potentials (in V) are vs. SCE.

To throw more light on the nature of this supposedly mixed-valence species the dark green solution has been further characterized by EPR spectral measurements. The EPR spectrum of coulometrically generated solutions recorded at 120 K is shown in Figure 8. The spectrum is characteristics of $S$ = 3/2 system with $g$ values 2.08, 3.20, and 5.29, arising out of spin-exchange coupling between $S$ = 1 $Ni^{II}$ state and $S$ = 1/2 $Ni^{III}$ state.[39] The $Ni^{III}$ ion is considered to be low-spin since all known $Ni^{III}$ complexes to date are low-spin.[41] To strengthen our hypothesis we measured solution-state magnetic susceptibility of the green solution. The $\mu_{eff}$ value of 4.33 $\mu_B$ at 293 K (Evans method),[42] for two independent measurements, confirm our claim that it is a $S$ = 3/2 system.

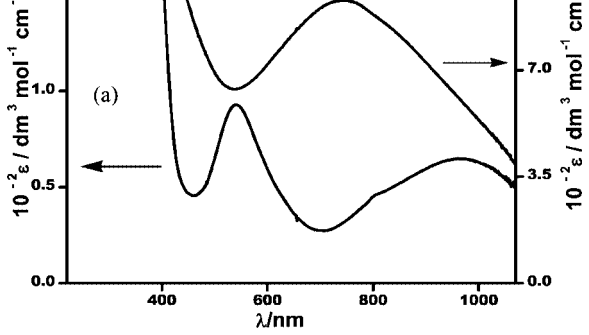

Figure 7. UV/Vis spectra in the range 400–1100 nm (in MeCN) of (a) [{$(L)_2Ni_2(\mu\text{-}L')$}$_2$][$ClO_4$]$_2$ (**1**) and (b) coulometrically oxidized green solution (1.67 mM) at 1.50 V vs. SCE.

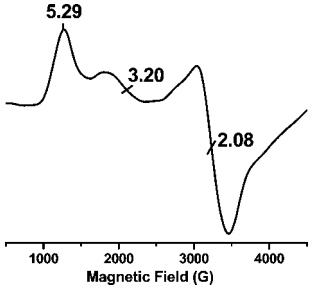

Figure 8. EPR spectrum at 120 K of coulometrically generated green solution of $[(L)_2Ni_2(\mu\text{-}L')_2]^{3+}$ in MeCN.

Dicopper(II) complex **2** displays two cathodic responses with $E_{pc}$ values of –0.28 V and –0.50 V vs. SCE (Figure S5), due to $Cu^{II}{}_2$/$Cu^{II}Cu^{I}$ and $Cu^{II}Cu^{I}$/$Cu^{I}{}_2$ redox processes, respectively. On reversal scan, only one anodic response at 0.24 V vs. SCE was observed. This behavior is indicative of an unstable mixed-valence $Cu^{II}Cu^{I}$ and $Cu^{I}{}_2$ species. Given the planarity of the $\{Cu(\mu\text{-}L')\}_2{}^{2+}$ unit, this result is understandable, as $Cu^{I}$ would prefer to assume tetrahedral geometry.

### Concluding Remarks

In this report designed synthesis of bis(μ-pyrazolate)-bridged dinickel(II) and dicopper(II) complexes has been achieved with a simple potentially tridentate ligand L and bridging ligand 3-(2-pyridyl)pyrazole. Structural proof for the complexes illustrates a neat example of stereoelectronic geometric requirement of $M^{II}$ ion: $Ni^{II}$ preferring six- and $Cu^{II}$ preferring five-coordination. The outcome of stereoelectronic preference is manifested in the observed noncovalent interactions: C–H···π in the case of **1**·MeCN and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

π···π for **2**·MeCN, dictated by the spatial disposition of L around $M^{II}$ ion. Temperature-dependent magnetic studies reveal the presence of antiferromagnetic coupling in both, the extent of coupling is more in the case $Cu^{II}$ dimer than in the case of $Ni^{II}$ dimer. Generation and stabilization of mixed-valence $Ni^{III}$-$Ni^{II}$ species presented in this work encourage the synthesis of other variety of pyrazolate-bridged nickel(II) complexes in order to gain a better understanding of redox chemistry of dinickel(II) systems.

## Experimental Section

**General:** All chemicals were obtained from commercial sources and used as received. Solvents were purified/dried following standard procedures.[3–14] The ligand L was prepared as before.[18d] 3-(2-pyridyl)pyrazole (HL′) was synthesized following a reported procedure.[20] Tetra-*n*-butylammonium perchlorate (TBAP), was prepared/purified as before.[11]

**Syntheses**

**Preparation of [{(L)Ni(μ-L′)}$_2$][ClO$_4$]$_2$ (1):** To a stirred solution of $Ni(OAc)_2{\cdot}4H_2O$ (0.052 g, 0.212 mmol) in MeOH (3 cm$^3$), L (0.050 g, 0.212 mmol) was added in small portions. After stirring for 30 min, HL′ (0.031 g, 0.212 mmol) was added and the resulting mixture was stirred for 5 min, followed by addition of $Et_3N$ (0.021 g, 0.212 mmol). The reaction mixture was then allowed to stir for a further 30 min. Solid sodium perchlorate (0.052 g, 0.424 mmol) was added to it and the mixture was kept in air for slow evaporation, which led to the precipitation of a purple microcrystalline solid. It was filtered, washed with MeOH and dried in vacuo (yield: 0.052 g, ca. 45%). $C_{44}H_{36}Cl_2N_{14}Ni_2O_8$ (1077.98): calcd. C 49.02, H 3.36, N 18.19%; found C 48.95, H 3.41, N 17.83%. Molar conductance, $\Lambda_M$ (MeCN, 298 K) = 240 Ω$^{-1}$cm$^2$mol$^{-1}$ (expected range[23] for 1:2 electrolytes: 220–300 Ω$^{-1}$cm$^2$mol$^{-1}$). UV/Vis (MeCN), $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$cm$^{-1}$): 966 (65), 800 (sh) (48), 526 (93), 315 (sh) (20 000), 290 (sh) (33 200), 254 (44 729). $\mu_{eff}$/Ni: 2.94 $\mu_B$ (solid, 298 K) and 3.20 $\mu_B$ (in MeCN, 298 K). Diffraction quality single crystals containing a molecule of MeCN as a solvent of crystallization (**1**·MeCN) were grown by diffusion of diethyl ether into a MeCN solution of the complex.

**Preparation of [{(L)Cu(μ-L′)}$_2$][ClO$_4$]$_2$ (2):** To a stirred solution of L (0.050 g, 0.212 mmol) in MeOH (3 cm$^3$) $[Cu(H_2O)_6][ClO_4]_2$ (0.079 g, 0.212 mmol) was added in small portions. After stirring for 30 min, HL′ (0.031 g, 0.212 mmol) was added and the resulting mixture was refluxed for one and half hour. Addition of $Et_3N$ (0.021 g, 0.212 mmol) led to the precipitation of a bluish green microcrystalline solid. It was filtered, washed with a minimum amount of MeOH and dried in vacuo. Recrystallization was achieved by diffusion of diethyl ether (5 cm$^3$) into a MeCN solution (3 cm$^3$) of the complex (yield: 0.052 g, ca. 45%). $C_{44}H_{36}Cl_2Cu_2N_{14}O_8$ (1086.84): calcd. C 48.62, H 3.34, N 18.04%; found C 48.95, H 3.41, N 17.83%. Molar conductance, $\Lambda_M$ (MeCN, 298 K) = 226 Ω$^{-1}$cm$^2$mol$^{-1}$. UV/Vis (MeCN), $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$cm$^{-1}$): 770 (sh) (70), 640 (120), 300 (sh) (19 400), 290 (sh) (22 700), 253 (46 550). $\mu_{eff}$/Cu: 1.58 $\mu_B$ (solid, 299 K) and 1.40 $\mu_B$ (in MeCN, 298 K). Diffraction quality single crystals containing two molecules of MeCN as solvent of crystallization (**2**·2MeCN) were grown by diffusion of diethyl ether into a MeCN solution of the complex.

***Caution:*** *Perchlorate salts of compounds containing organic ligands are potentially explosive!*

**Physical Measurements:** Elemental analyses (C, H, N) were obtained at the Microanalytical Laboratory at this Department. Infrared spectra were recorded on a Bruker Vector 22 spectrophotometer using KBr discs. Electronic spectra were recorded using Agilent 8453 diode-array spectrophotometer. $^1$H NMR spectral measurements were performed on a Bruker WP 80 (80 MHz) NMR spectrometer. Solution electrical conductivity measurements (298 K) were carried out with an Elico (Hyderabad, India) Type CM-82 T conductivity bridge. X-band EPR were obtained on a Bruker EMX 1444 EPR spectrometer operating at 9.455 GHz (fitted with a quartz Dewar for measurements at 120 K). The spectra were calibrated with diphenylpicrylhydrazyl, DPPH ($g$ = 2.0037).

**Magnetism:** Magnetic susceptibility measurements on polycrystalline sample of **1** were performed in the temperature range of 2–298 K with a Quantum Design SQUID magnetometer [(Model MPMSXL-5) Valencia, Spain]. For **2** variable temperature magnetic susceptibility measurements in the range 5–300 K was obtained in the solid state using a Quantum Design (Model MPMSXL-5) SQUID (Kanpur, India) magnetic susceptometer operating at a magnetic field of 0.5 T. Magnetic susceptibility measurements in MeCN solution were obtained by Evans's method[42] using a PMX-60 JEOL (60 MHz) NMR spectrometer. Susceptibilities were corrected for diamagnetic contributions, by using literature values.[32] Effective magnetic moments were calculated from $\mu_{eff} = 2.828\,[\chi_M T]^{1/2}$, where $\chi_M$ is the corrected molar susceptibility.

**Cyclic Voltammetry:** Cyclic voltammograms were recorded at 298 K on PAR model 370 electrochemistry system consisting of model 174A polarographic analyzer and model 175 universal programmer. A standard three-electrode cell was employed with a Beckman M-39273 platinum-inlay working electrode, a platinum-wire auxiliary electrode and a saturated calomel electrode (SCE) as reference; no correction was made for junction potentials.

**Crystallography:** For complex **1**·MeCN diffracted intensities were collected on a Bruker SMART APEX CCD diffractometer, with graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation at 100(2) K. For data reduction 'Bruker Saint Plus' program was used. Data for **2**·2MeCN were collected at 293 K on a Enraf Nonius MACH2 diffractometer, equipped with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data were corrected for absorption and the Lorentz and polarization effects. The structures were solved with SIR-92 and refined with the SHELXL-97 package incorporated in WinGX 1.64 crystallographic collective package.[43] Anisotropic refinements were performed by full-matrix least-squares procedure on $F^2$. The positions of the hydrogen atoms were calculated assuming ideal geometries, but not refined. The data-set of **1**·MeCN was treated with the SQUEEZE filter of PLATON[44] due to the presence of severely disordered solvent molecule(s) (probably acetonitrile, water) which could not be modeled satisfactorily. PLATON estimated the electron count to be 15 electron/cell in a volume of 398.0 Å$^3$ out of a unit volume of 4307.0 Å$^3$ (9.2%). Pertinent crystallographic parameters are summarized in Table 3. Intermolecular contacts of the C–H···π and π···π stacking were examined with the DIAMOND package.[45] C–H distances were normalized along the same vectors to the neutron derived values of 1.083 Å.[46]

CCDC-632189 (for **1**·MeCN) and -240140 (for **2**·2MeCN) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[a] $R(F) = \Sigma(||F_o| - |F_c||)/\Sigma|F_o|$. [b] $R_w(F^2) = \{\Sigma[w(|F_o|^2 - |F_c|^2)^2]/\Sigma[w(|F_o|^2)^2]\}^{1/2}$.

in complex **2**·2MeCN. Figure S2 shows absorption spectral features for both complexes in MeCN. Figure S3 shows the EPR spectra of complex **2** at 293 K and Figure S4 the CV response of electrochemically generated green solution from complex **1**. Figure S5 deals with the CV response of complex **2**.

## Acknowledgments

Financial assistance received from the Department of Science and Technology (DST) and the Council of Scientific & Industrial Research (CSIR), Government of India is gratefully acknowledged. We acknowledge the National Single Crystal Diffractometer Facility at the Department of Chemistry, Indian Institute of Technology Kanpur, for data collection of **1**·MeCN. We acknowledge Prof. M. S. Hundal and Dr. G. Hundal (Guru Nanak Dev University, Amritsar, India) for data collection of **2**·2MeCN. We sincerely thank Dr. Jhumpa Mukherjee for variable-temperature magnetic data analysis of complex **2** and Mr. Haritosh Mishra for analysis of noncovalent interactions in the crystal structures. Comments of the reviewers at the revision stage were very helpful.

# Theoretical Studies of the Electronic Structure and Spectroscopic Properties of $[Ru(Htcterpy)(NCS)_3]^{3-}$

**Ming-Xia Li,[a,b] Hong-Xing Zhang,*[a] Xin Zhou,[a] Qing-Jiang Pan,[b] Hong-Gang Fu,[b] and Chia-Chung Sun[a]**

**Keywords:** Black dyes / Electronic structure / Spectroscopic properties / Solvent effects

The ground- and excited-state structures of $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) (tcterpy = 4,4′,4′′-tricarboxy-2,2′:6′,2′′-terpyridine) are optimized by the DFT and CIS methods, respectively. Absorption and emission spectra in the gas phase and in solution (ethanol and water) are predicted at the TD-DFT/B3LYP level. Experimental spectra are roughly reproduced by our calculated results. In ethanol solution, the HOMOs of the absorption spectra are dominated by d orbitals of the ruthenium atom and thiocyanate ligands, and the LUMOs possess π*(tcterpy) character with considerable carboxyl contribution. In the theoretically simulated absorption spectra, the first four bands are attributed to Ru/NCS→π*(tcterpy) charge-transfer (MLCT/LLCT) transitions, whereas the fifth one with the strongest intensity arises from intraligand tcterpy π→π* charge transfer (ILCT) mixed with some $O(p_z)$→terpy charge transfer (LLCT). Our calculations reveal that the MLCT/LLCT absorption bands in water are blue-shifted with respect to those in ethanol, agreeing with experimental observations. This can be rationalized by a decreased dipole moment in the excited state. The phosphorescent emissions are calculated to occur at 724, 711, and 691 nm in the gas phase, in ethanol, and in water, respectively, all with the same $^3$LMCT/$^3$LLCT character.

## 1. Introduction

In recent years, dye-sensitized solar cells (DSSCs) have attracted considerable interest for the conversion of sunlight into electricity because of their low cost and high efficiency.[1–4] The DSSCs comprise four major parts: a nanocrystalline metal oxide semiconductor film, a dye sensitizer, a redox electrolyte, and a counter electrode. Undoubtedly, one of the key components of these cells is the dye sensitizer, which is used to sensitize the semiconductor electrode. An efficient solar cell sensitizer should fulfill several requirements: (1) it must be strongly adsorbed onto the semiconductor surface to ensure device stability and good electronic coupling for charge injection; (2) it should exhibit intense absorption in the visible part of the spectrum and form long-lived excited states with energies matching those of the conduction band of the semiconductor substrate;[3] (3) its redox potential should be sufficiently high, so that it can be regenerated rapidly by electron donation from the electrolyte or a hole conductor.

In the search for a promising sensitizer, a considerable number of complexes have been synthesized and analyzed.[4–10] Among these dyes, *cis*-dithiocyanatobis(2,2′-bipyridyl-4,4′-dicarboxylate)ruthenium(II) (hereafter referred to as N3 or red dye)[5] and trithiocyanato(4,4′,4′′-tricarboxy-2,2′:6′,2′′-terpyridine)ruthenium(II) (black dye)[6] are the most well-known. The N3 dye has been regarded as an efficient photosensitizer because of its broad range of visible light absorption, relatively long-lived excited states, and high thermal stability; moreover, the presence of terminal acidic carboxyl group allows stable anchoring of the dye to the semiconductor surface.[11–15] The incident photon to current conversion efficiency (IPCE) values are reported to be nearly 80% in the range 400–600 nm. However, the main drawback of this sensitizer is its lack of absorption in the red region of the visible spectrum. Numerous attempts to synthesize superior sensitizers[16–19] failed to improve the efficiency and to enhance the spectral response in the red and infrared region until 1997. In 1997, Grätzel and co-workers[20] reported a terpyridine–$Ru^{II}$ complex, the "black dye", with visible absorption extending into the near-IR region up to 920 nm, yielding over 80% IPCE, and producing an overall efficiency of 10.4%.

Black dyes having different degrees of protonation have been fully characterized by Grätzel and co-workers.[6,20–22] It is conceived that the absorption spectra of the black dyes are dominated by metal-to-ligand-charge-transfer (MLCT) transitions. For example, the absorption spectrum of the

monoprotonated black dye complex (hereafter named **1H**) in ethanol exhibits three MLCT bands in the visible region centered at 610, 536, and 411 nm, and a high-energy $\pi\rightarrow\pi^*$ band at about 340 nm. It shows a strong negative solvatochromism, resulting in a red-shift of the UV/Vis absorption bands from 570 nm (in $H_2O$) to 620 nm (in γ-butyrolactone).[6] The observed emission of the complex **1H** (854 nm) has been assigned as arising from the Ru→tcterpy CT excited state.[6] Similarly, the emissions of the complex **1H** in different solvents also show a strong solvent dependence.

Since the spectroscopic properties of the dye are crucial in determining its long-term stability, the light-harvesting efficiency of the DSSCs, and the charge-transfer dynamics at the semiconductor interface,[16,23] a full understanding of its electronic properties, especially in the excited state, is very essential. In contrast to the numerous experimental studies, only a few theoretical calculations have been performed for dye molecules.[23–30] Most of these investigations are focused on the calculations of the N3 dye.[25–30] To date, one investigation for the fully protonated black dye is limited to the gas-phase calculations of molecular structure and absorption spectrum.[23] Another theoretical investigation focuses on the comparative study of ground-state properties (such as energies, geometries, and population analysis in molecular orbitals) and the absorption spectra of the black dye complex and its linkage isomers.[24] These theoretical calculations all focus on the fully protonated black dye complex. However, the photovoltaic performance of the monoprotonated black dye, **1H**, is superior to the other three black dye complexes. Moreover, no theoretical study was conducted on the geometry and electronic structure of the excited states and the emission properties of the black dye. In addition, in the solar cell, the dye sensitizer is adsorbed on the semiconductor electrode on one hand and interacts with the redox electrolyte on the other hand; therefore, it may not be possible to directly apply calculations excluding environment effects. Thus, in this paper, we employed DFT, the CIS method, and the TD-DFT approach to study the electronic structure, spectroscopic properties, and solvatochromic properties of the monoprotonated black dye **1H**. The solvent effects are seriously considered by using the conductor-like polarizable continuum model (CPCM). These results will provide a direct insight into the origins of the observed transitions and their possible role in dye–sensitized solar cell injection dynamics as well as the design of new and more efficient solar cell sensitizers.

## 2. Computational Details and Theory

In this work, $C_s$ symmetry was adopted to set the conformation of $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) in both the ground and the excited states. The geometry of the ground-state structure is fully optimized by using the density functional theory (DFT) with the B3LYP functional (Becke's three-parameter functional and the Lee–Yang–Parr functional),[31] while the geometry of the excited-state structure is fully optimized by the single-excitation configuration interaction (CIS) method.[32,33] With such calculations, the spectroscopic properties related to absorption and emission are obtained by the time-dependent density functional theory (TD-DFT),[34] and the conductor-like polarizable continuum model (CPCM)[35] is employed to account for the effects of the solvent molecules water and ethanol.

It is well-known that for excited states, the CIS method is most similar to the HF method for the ground state. However, through the use of analytic gradients and methods properly by including the effects of electronic correlation, this method gives bond lengths, frequencies, and dipole moments well in line with the experimental values. In addition, the application of the method to very large molecules is possible.[32] Although a reasonable excited-state structure can be obtained by the CIS method, the predicted transition energies deviate from experimental values commonly by about 1 eV or more. In the recent years, the TD-DFT methods have been successfully used to calculate singlet–singlet and singlet–triplet transitions in many reports.[36] More electronic correlations are involved in the TD-DFT (B3LYP) approach, which then yields more accurate excitation energies than the CIS method. This approach overcomes many of the problems encountered in vertical energies with the CIS method, providing accurate excitation energies of valence and Rydberg states. Therefore, on the basis of CIS optimized structures, we have employed the TD-DFT method to calculate the emission energies.

In the calculations, quasi-relativistic pseudopotentials of the Ru, C, N, and S atoms proposed by Hay and Wadt[37] with 16, 4, 5, and 6 valence electrons, respectively, are employed, and the LanL2DZ basis sets associated with the pseudopotential are adopted. Here, the basis sets are taken as Ru(8s7p6d/6s5p3d), S(3s3p1d/2s2p1d), N(10s5p/3s2p), C(10s5p/3s2p), and H(4s/2s). Thus, 361 basis functions and 262 electrons are included for the complex **1H**. All the calculations were accomplished by using the Gaussian (Revision B.03) program package[38] on an Origin/3900 server.

## 3. Results and Discussion

### 3.1 The Ground- and Excited-State Structures of 1H

The DFT optimization on **1H** indicates that the complex has a $^1A'$ ground state with the $[101(a'^2)30(a''^2)]$ electronic configuration. The geometry of the structure is depicted in Figure 1, and the main optimized geometry parameters in the gas phase are listed in Table 1 together with the X-ray crystal structure data of $(NBu_4^+)_2[Ru(H_2tcterpy)(NCS)_3]^{2-}$.[22] As shown in Figure 1, complex **1H** has a slightly distorted octahedral coordination with $C_s$ symmetry. The geometry of the structure of complex **1H** displays a RuN6 central core derived from three nitrogen atoms of the terpyridine ligand and three nitrogen atoms of the isothiocyanate ligands. The coordination axis is also shown in Figure 1; the tcterpy-Ru-N1C1S1 moiety lies on the *xy* plane, and the other two isothiocyanate ligands are slightly tilted with respect to the *z* axis. As shown in Table 1,

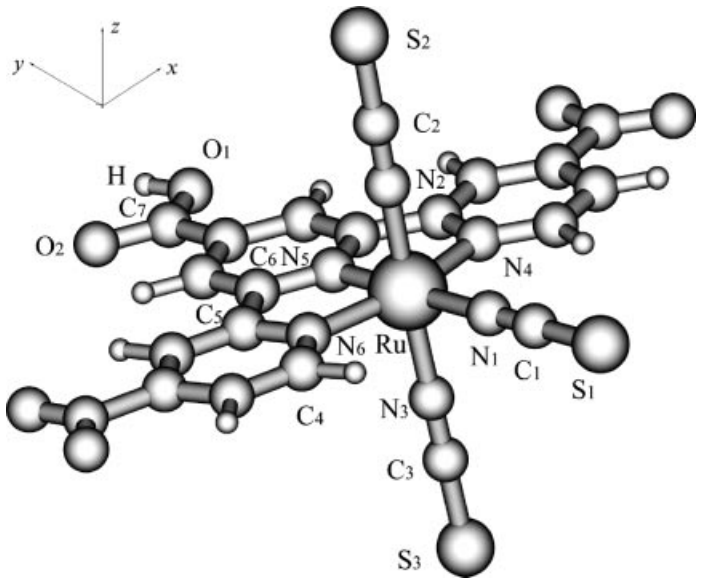

Figure 1. Ground-state structure of $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) optimized by DFT(B3LYP).

the optimized geometrical parameters are in excellent agreement with the available X-ray data, and consistent with those calculated by Aiga and co-workers[23] by the PBE0 approach.[39] The N–C bond lengths in the terpyridine rings are about 1.38 Å and are much shorter than a normal N–C single-bond length of 1.48 Å, indicating that there is some delocalization of the lone pairs of the nitrogen atoms. It is noted that there exits an extended π bonding between the central pyridine (nitrogen p orbitals), the Ru atom (d π orbitals), and the N1C1S1 ligand (π electrons). The effective π bonding makes the bond lengths of Ru–N1 and Ru–N5 quite similar. Therefore, the Ru–N5 bond length (1.939 Å) is ca. 0.16 Å shorter than that of Ru–N4 (or Ru–N6), whereas the Ru–N1 bond length is ca. 0.05 Å longer than that of Ru–N2 (or Ru–N3). In addition to the bond lengths, the important bond angles are also accurately reproduced.

On the basis of the optimized ground-state structure, the CIS method is used to optimize the geometry of the excited-state structure of the **1H** complex, and the lowest-energy triplet excited state with $^3A'$ symmetry is obtained. The main geometry parameters of the excited state are presented in Table 1. Three conclusions can be drawn from the excited-state results: (1) The coordination geometry of Ru in the $^3A'$ excited state still keeps the quasi-octahedral structure similar to the ground state. (2) A general elongation of all the metal–ligand bonds is observed. For example, the Ru–N bond lengths in the excited state are elongated by ca. 0.04–0.07 Å relative to the ground-state ones. (3) The most nonmetallic bonds (N–C, C–C, C–O, and O–H) of tcterpy in the triplet excited state are shorter than those in the ground state, on the contrary, the C–S bond lengths for the NCS ligands are slightly longer upon excitation. It is noteworthy that the comparison of the bond lengths is between the ground state and the excited state obtained with two different methods (DFT/B3LYP for the ground state and CIS for the excited state). So the conclusions drawn from those comparisons are only used as relative results. However, this has no impact on the nature of the charge-transfer transition related to the emissions for the complex **1H**.

Table 1. Optimized geometry parameters for the $^1A'$ ground state calculated by DFT and for the $^3A'$ triplet excited state calculated by CIS for $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**), together with the experimental data.

| Parameters | Ground state ($^1A'$) | Triplet excited state ($^3A'$) | Exp.[a] |
|---|---|---|---|
| Bond lengths [Å] | | | |
| Ru–N1 | 2.107 | 2.147 | 2.032 |

properties of **1H** in ethanol solution are obtained by the combination of the TD-DFT and CPCM methods. The frontier orbitals play a relevant role in complex **1H**, because they rule the electronic excitations and the transition character. The following assignment for each molecular orbital was made according to its composition (Table 2) and by visual inspection of its three-dimensional representation (e.g. Figure 2). Some lower-lying occupied molecular orbitals (such as 95a′, 26a′′, 96a′, and 27a′′) are centered on the carboxyl groups. The $COO^-$ character of the lower-lying HOMOs was already found in the bipyridine–$Ru^{II}$ complex by De Angelis et al.[40,41] The HOMO(30a′′) and HOMO-1(29a′′), lying within 0.02eV, are a set of quasi-degenerate orbitals arising from the antibonding combinations of ruthenium d orbitals ($d_{xz}$ and $d_{yz}$, respectively) with sulfur p orbitals and nitrogen lone pairs of the two NCS ligands which are perpendicular to the tcterpy ring. HOMO-2(101a′), lying ca. 0.23 eV below the HOMO, is characterized by the antibonding combination nature between the ruthenium $d_{xy}$ orbital and the NCS π orbital of the thiocyanate ligand that is in the plane of the tcterpy ligand. The HOMO-3(100a′) and HOMO-4(99a′), lying 0.46 and 0.47 eV below the HOMO, respectively, are mainly localized on the $COO^-$ ligands which are attached to the peripheral pyridines, and have vanishing metal character. The HOMO-5(28a′′), HOMO-6(98a′), and HOMO-7(97a′), lying 0.51, 0.64, and 0.66 eV below the HOMO, respectively, are all pure NCS π orbitals. This significant thiocyanate character in the HOMOs was already found in the N3 dye[29,30] and seems to play an important role in the regeneration of dye-sensitized solar cells.[30]

The five lowest LUMOs of the **1H** complex, lying 1.92 eV above the HOMO within a range of ca. 1.86 eV, are π* orbitals localized over the pyridine ligands with considerable contributions arising from the carboxyl groups. In particular, the LUMO(31a′′) is localized on the central pyridine, while LUMO+3(34a′′) and LUMO+4(35a′′) are localized on the two peripheral pyridine groups. LUMO+1(32a′′) and LUMO+2(33a′′) are completely delo-

calized over the full tcterpy ring ligands. Such a contribution from the carboxyl groups to the π* LUMOs should favor the electron injection process from the dye excited state to the semiconductor surface, because the carboxyl units serve as anchoring groups to the $TiO_2$ semiconductor surface.[2,3] Moreover, another role of the terminal carboxyl groups is to ensure intimate electronic coupling between the donor energy level of the excited dye and the acceptor $TiO_2$ conduction band.

### *3.2.2. Absorption Spectra in Ethanol*

The absorption spectra of the complex **1H** are simulated with Gaussian curves based on the transitions with oscillator strength $f > 0$ in ethanol solution calculated by TD-DFT/CPCM. The fitting absorption curve is depicted as oscillator strength vs. wavelength in Figure 3; the most representative calculated optical transitions are collected in Table 3. Within the considered energy range, the absorption spectrum of **1H** shows five bands, labeled I, II, III, IV, and V in order of decreasing wavelength; band V is more intense than other bands.

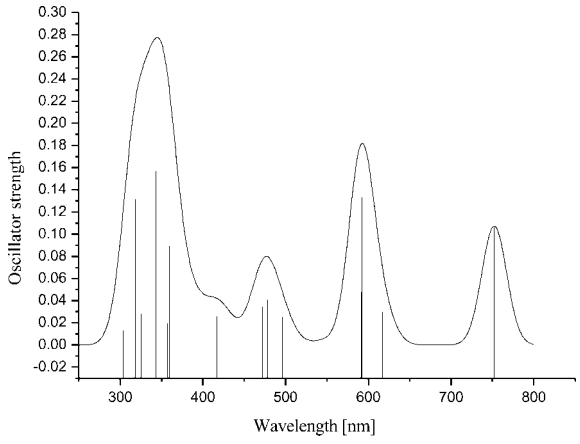

Figure 3. Absorption spectra and excited states of $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) in ethanol calculated by TD-DFT.

The peak of the lowest-energy band, I, which results from one transition and has the oscillator strength 0.1073, is calculated to be at 752 nm. As shown in Table 3, the transition is mainly contributed by the excitations 29a′′(HOMO-1)→31a′′(LUMO) and 30a′′(HOMO)→32a′′(LUMO+1) with CI coefficients of ca. 0.58 and 0.25, respectively. It has been mentioned in the above section that the HOMO and HOMO-1 are antibonding combinations of the d orbitals ($d_{xz,yz}$) of the ruthenium atom with the π orbitals of the NCS ligand. The LUMO and LUMO+1 are π* orbitals localized over the tcterpy ring ligand. Therefore, we assign the lowest-energy band as a mixed Ru–NCS-to-tcterpy-charge-transfer (MLCT/LLCT) transition. The absorption band at 752 nm is not observed in the experimental absorption spectra. We calculated the maximum of band II to be at 592 nm, whose position is in excellent agreement with the experimental value of 610 nm. This band is caused by three transitions calculated at 617, 592, and 591 nm. As depicted in Table 2 and Table 3, band II is assigned as a mixed Ru–NCS-to-tcterpy charge transfer (MLCT/LLCT) with a little LMCT character. The dominating transition in this band, at 592 nm with an oscillator strength of 0.1300, is mainly contributed by the 28a′′(HOMO-5)→31a′′(LUMO) and 30a′′(HOMO)→32a′′(LUMO+1) configurations with CI coefficients of about 0.48 and 0.42, respectively. The molecular orbital 28a′′(HOMO-5) is localized on three NCS ligands up to 99% in composition, and the molecular orbital 31a′′(LUMO) is composed of $Ru(d_{yz})$ (15%), and tcterpy (82%). So we attribute the 592 nm absorption band to NCS→tcterpy charge transfer (LLCT), NCS→$Ru(d_{yz})$ charge transfer (LMCT), and $Ru(d_{xz})$→tcterpy charge transfer (MLCT) transitions. The maximum of band III is calculated at ca. 478 nm, which is only 58 nm blue-shifted with respect to the experimental datum of 536 nm, and has a multitransition character and involves excitations from the 25a′′(HOMO-12), 29a′′(HOMO-1), and 30a′′(HOMO) to the 31a′′(LUMO) and 33a′′(LUMO+2). This set of HOMOs have ruthenium-d-orbital nature (44%, 31%, and 41%, respectively) with sizeable contribution from the orbitals of the NCS ligand (36%, 50%, and 54%, respectively), while the LUMO and LUMO+2 are localized on the tcterpy ligands. Therefore, in the same way as for band I, the origin of band III is assigned to be the Ru–NCS to tcterpy charge transfer (MLCT/LLCT) transitions. Band IV, with the smallest oscillator strength, is calculated to have its maximum at 417 nm, which is in close accord with the experimental data of 411 nm. This band arises from one transition with a small oscillator strength of 0.0228, which mainly comes from the combination of 24a′′(HOMO-14)→31a′′(LUMO) and 30a′′(HOMO)→34a′′(LUMO+3) configurations with CI coefficients of around 0.50 and 0.42, respectively. In Table 2 and Figure 2, the 24a′′ orbital and 30a′′ orbital are both the antibonding combinations of Ru(d) orbitals and the NCS π orbitals, whereas the 31a′′ orbital and 34a′′ orbital are localized on tcterpy ring ligands. So the 417-nm band is unambiguously attributed to a mixed Ru–NCS to tcterpy charge transfer (MLCT/LLCT) transition. At the highest energy, the strongest band V, appears to be composed of multitransitions spanning the range 360–300 nm. The dominating transition in this band, at about 343 nm ($f$ = 0.1536), is mainly contributed by the 23a′′(HOMO-15)→31a′′(LUMO) and 24a′′(HOMO-14)→32a′′(LUMO+1) configurations with CI coefficients of around 0.46 and 0.47, respectively. As show in Table 2 and Figure 2, we can see that the 23a′′ orbital (HOMO-15) and 31a′′ orbital (LUMO) are π combinations and π* combinations, respectively, localized on the tcterpy ligands. Thus the 343 nm absorption is attributed to the intraligand tcterpy π→π* charge transfer (ILCT) involved in a mixed Ru–NCS to tcterpy charge transfer (MLCT/LLCT) transition. The next most intense transition, at about 318 nm ($f$ = 0.1283), arises from the combination of 25a′′(HOMO-12)→33a′′(LUMO+2), 26a′′(HOMO-10)→34a′′(LUMO+3), and 26a′′(HOMO-10)→35a′′(LUMO+4) configurations with CI coefficients of around 0.53, 0.32, and 0.21, respectively. The 25a′′ orbital (HOMO-12) is the anti-

bonding combination of the Ru($d_{xz}$) orbital and the NCS π orbitals, and the 26a′′ orbital (HOMO-10) is mainly composed of O($p_z$) from the $COO^-$ group. However, the 33a′′, 34a′′, and 35a′′ orbitals are all localized on tcterpy ligands. So the 318 nm transition is assigned as a mixed Ru–NCS-to-tcterpy charge transfer (MLCT/LLCT) and O($p_z$)→terpy charge transfer (LLCT) transition. We also notice that a few weak ($f$ = 0.0248) d–d transitions, at 325 nm, contribute to band V.

In experiments, the 610–400 nm regions have been assigned as the Ru-to-tcterpy-charge-transfer bands, while the 360–300 nm absorptions are attributed to the π→π* charge transfer transitions.[6] By comparing this experimental spectrum with the absorption spectrum of **1H** calculated in ethanol solution, we notice that our calculation is in rough agreement with experimental observations. However, there are some differences between the theoretical calculation and the experimental investigation. As mentioned above, we assign the low energy bands I–IV to mixed Ru–NCS-to-tcterpy charge transfer (MLCT/LLCT) rather than to pure metal–ligand-charge-transfer (MLCT) transitions, results from a set of Ru–NCS d-π* orbitals, while the highest energy band V, arises from intraligand tcterpy π→π* charge transfer (ILCT) and is involved in a sizeable O($p_z$)→terpy charge transfer (LLCT) transition. Furthermore, the calculated absorption spectra have two peaks at long wavelengths around 600–800 nm, while the experimental spectra[6] have one peak. The calculated absorption peak at 752 nm is not observed in experiment. Moreover, the calculated absorption spectra have lesser intense bands at short wavelengths around 500–350 nm than those at longer wavelengths between 500–700 nm, but the experimental spectra have the reverse trend. Our calculation overestimates the intensity of band II (500–700) and underestimates that of band III (350–500 nm). This is perhaps not surprising, since from a comparison between TD-DFT and the more expansive CASPT2 method, the results of Full et al. show that TD-DFT oscillator strengths diverge from the CASPT2 values.[42] In addition, a similar comparison by Tozer et al. show that TD-DFT has difficulty distributing intensity properly;[43] it is thus possible that intensity is erroneously shifted from band III to band II in our calculation.

### *3.2.3. Solvent Effects*

To check the solvent dependence of spectroscopic properties, we also calculated the absorptions of **1H** in the gas phase and in water solution, and the results are listed in Tables S1 and S2 (see Supporting Information). A compari-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

son of the molecular orbital energy levels of the absorptions for complex **1H** in the gas phase, in ethanol and in water is presented in Figure 4. From Figure 4, we can see that the solvent effect leads to a sizeable change of the molecular orbital energies. However, the occupied and unoccupied orbitals maintain similar compositions in the gas phase and in solution (ethanol and water). In ethanol, the HOMOs (from HOMO to HOMO-7) are significantly stabilized by about 5.1 eV with respect to the corresponding values computed in the gas phase, while they maintain a similar composition. In the same way as the HOMOs, the five lowest LUMOs are stabilized by ca. 5.0–5.1 eV with respect to the corresponding values computed in the gas phase, even though they maintain similar compositions based on terpyridine and carboxyl group contributions. The LUMO+5 of the absorption in the gas phase has the C7–O1 π-bonding properties from the carboxyl group which is attached to the central pyridine, while in ethanol, the LUMO+5 orbital shows a higher contribution of d orbitals of the ruthenium atom (45%) mixed with π orbitals of the NCS ligand (28%). Altogether, the presence of the solvent leads to a slight increase of the HOMO–LUMO gap, which changes from 1.80 eV in the gas phase to 1.92 eV in ethanol. Moreover, the electronic structure of the absorption for complex **1H** in water is rather similar to that found in ethanol. The LUMOs and HOMOs are further stabilized, resulting in a HOMO–LUMO gap of 2.0 eV, namely 0.08 eV larger than that computed in ethanol.

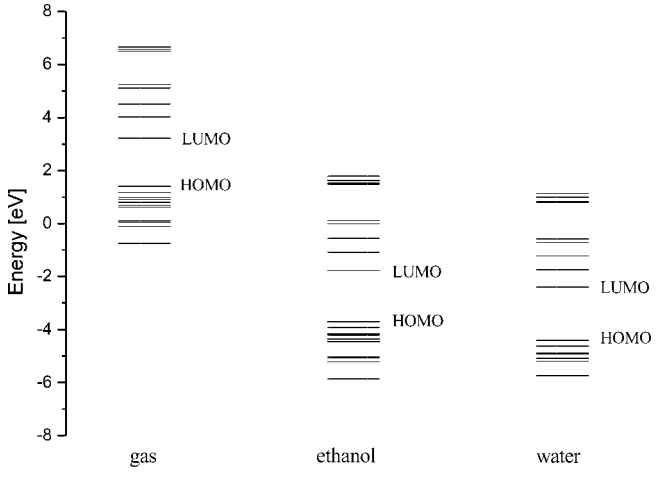

Figure 4. Energy-level diagrams of the orbitals involved in absorption for $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) in the gas phase, in ethanol, and in water calculated by TD-DFT.

The calculated absorption spectra of complex **1H** in the gas phase, in ethanol and in water are shown in Figure 5. With the inclusion of seventy excitation states, all of these spectra exhibit five bands. As listed in Table 3 and Table S2, the CI configurations, oscillator strengths, and transition characters calculated in ethanol and water are rather similar. In both solvents, the four low-lying absorption bands have a mixed Ru–NCS-to-tcterpy charge transfer (MLCT/LLCT) character, whereas the high-lying absorption band V with the greatest intensity is attributed to the intraligand π→π* charge transfer mixed with $O(p_z)$→terpy charge transfer transitions. In the gas phase, the compositions of the transitions show a small variation relative to those in ethanol and water. As depicted in Table 2 and Table S1, we can see that the $O(p_z)$→terpy charge transfer character already appears in band VI in the gas phase. In the first two lowest-energy absorption bands, the wavelengths are blue-shifted by about 20 and 45 nm in ethanol and water with respect to those for the gas phase.

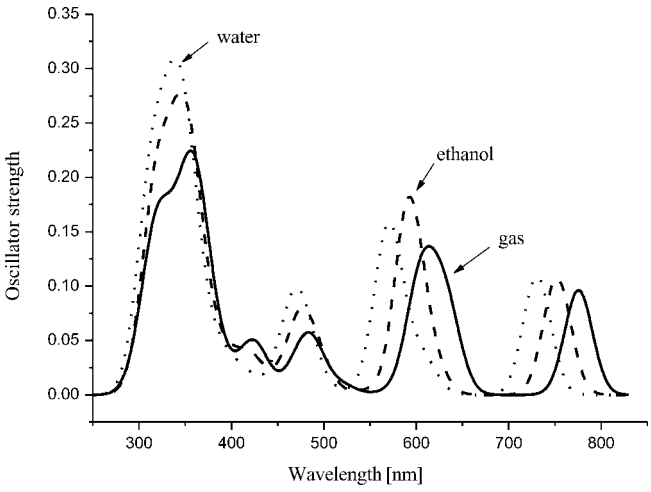

Figure 5. The simulated absorption spectra for $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) in the gas phase, in ethanol, and in water.

As shown in Figure 5, negative solvatochromism is observed in the MLCT/LLCT band ($\lambda$ = 400–800 nm) of complex **1H**. With increasing solvent polarity from ethanol to water, the wavelengths are blue-shifted by about 20 nm. In addition, we find that the π→π* band is only weakly affected by the change in solvent polarity. The calculated values are in excellent agreement with the experimental data. There is a factor that can be responsible for the observed blue-shift from ethanol to water: the electrostatic interaction between the solvent water and the NCS ligand is stronger than that between the solvent ethanol and the NCS ligand.

To get an insight into the origin of the negative solvatochromism of the MLCT/LLCT bands, it is useful to keep in mind the dipole moments of the complexes. As discussed above, the MLCT/LLCT transitions involve displacement of the electron charge from the Ru center and the NCS ligand toward the tcterpy π* orbitals. Thus, to approximately evaluate the dipole moment in the excited states, we considered the electronic state in which one electron is promoted from the HOMO(30a′′) to the LUMO(31a′′). The excited-state dipole moments in the gas phase, in ethanol and in water are predicted at the B3LYP/LAN2DZ level on the basis of the optimized ground-state geometry. Table S3 gives the dipole moments of complex **1H** in the ground and excited states in the gas phase, in ethanol, and in water. From Table S3, we can see that the dipole moments are apparently reduced from the ground state to the excited state. That is to say, the excited state should be less stabilized by polar solvents than the ground state. For instance,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in ethanol, the dipole moment in the excited state is 3.95 D, with a reduction $\Delta\mu$ = 5.81 D with respect to the dipole moment in the ground state (9.76 D). Similarly, in water, the dipole moment in the excited state is 2.96 D, with a reduction $\Delta\mu$ = 7.76 D with respect to the dipole moment in the ground state (10.72 D). The small increase in $\Delta\mu$ with increasing solvent polarity from ethanol to water correlates well with the calculated negative solvatochromism in the MLCT/LLCT band. It is noted that the definition of the dipole moment for neutral systems is independent of the choice of the origin of the reference system, while the dipole moment of charged systems will change as the molecule is shifted. However, in the present paper, the ground state and excited state exist as ions in the solvents. In addition, as discussed above, the excited-state dipole moments are predicted on the basis of the optimized ground-state geometry. So the center of coordinates of the ground and excited state do not change. Thus, though the complex **1H** is a charged molecule, we think it is reliable to discuss solvent effects in terms of the variation of dipole moment between the ground and excited states.

### 3.3. Emission Spectra

In view of obtaining a feasible emissive energy on the basis of the excited-state structures optimized by the CIS method, the emission spectrum of complex **1H** in ethanol is calculated by the TD-DFT approach at the B3LYP level associated with the CPCM model. The corresponding emissions of **1H** in the gas phase, in ethanol, and in water are listed in Table 4, associated with the emissive energies, transition assignments, and experimental values. To conveniently discuss the transition properties of the emissions, we present the partial compositions of the frontier molecular orbitals related to the emissions in Table 5.

The calculated lowest-energy emission for complex **1H** occurs at 711 nm in ethanol solution with a transition of $^3A'\rightarrow{}^1A'$ nature. As shown in Table 4, the phosphorescence is mainly from the transitions of 32a′′(LUMO+1)→24a′′(HOMO-14) and 32a′′(LUMO+1)→30a′′(HOMO) configuration with CI coefficients of 0.12 and 0.71, respectively. Furthermore, as seen in Table 4 and Table 5, this emission has tcterpy→Ru ($^3$LMCT) and tcterpy→NCS ($^3$LLCT)

Table 4. The lowest-energy phosphorescent emission of $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) in the gas phase, in ethanol, and in water calculated by TD-DFT, together with experimental values.

| Medium | Transition | Config.(CI coef.) | $\lambda$ [nm] ($E$ [eV]) | Character | Exp.[a] |
|---|---|---|---|---|---|
| gas | $^3A'\rightarrow{}^1A'$ | 32a′′→24a′′(0.12)<br>32a′′→29a′′(0.16)<br>32a′′→30a′′(0.69) | 724 (1.71) | $^3$LMCT/$^3$LLCT | |
| $CH_3CH_2OH$ | $^3A'\rightarrow{}^1A'$ | 32a′′→24a′′(0.11)<br>32a′′→30a′′(0.71) | 711 (1.74) | $^3$LMCT/$^3$LLCT | 854 |
| $H_2O$ | $^3A'\rightarrow{}^1A'$ | 32a′′→24a′′(0.11)<br>32a′′→30a′′(0.71) | 690 (1.80) | $^3$LMCT/$^3$LLCT | 829 |

character. The electron density diagrams of the frontier molecular orbitals for the 711 nm emission in Figure 6 provide intuitive evidence for the above assignment. As shown in Table 5 and Figure 6, the electron density mainly focuses around the tcterpy ligands: about 98% in the 32a′′(LUMO+1) orbital. The 24a′′(HOMO-14) and 30a′′(HOMO) orbitals are both composed of $Ru^{II}$ and NCS ligands. The former is composed of 48% Ru($d_{yz}$), 39% NCS ligands, and 12% tcterpy ligand, while the latter comprises 33% Ru($d_{yz}$), 53% NCS ligands, and 12% tcterpy ligands.

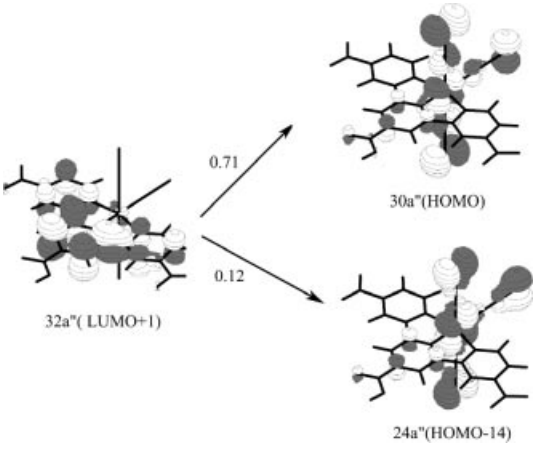

Figure 6. Single-electron transitions with |CI coefficient| > 0.1 calculated by TD-DFT for the 711-nm emission of $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) in ethanol.

On the basis of the optimized $^3A'$ excited state, the 724- and 691-nm phosphorescence in the gas phase and in water solution are calculated by the TD-DFT method and the TD-DFT/CPCM method, respectively; these bands also have tcterpy→Ru/NCS-charge-transfer ($^3$LMCT/$^3$LLCT) character. The electron density diagrams of the frontier molecular orbitals related to the 724- and 691-nm emissions displayed in Figures S1–S2 can help us intuitively understand the nature of the transitions causing the emissions. The emission spectroscopic data of complex **1H** calculated in ethanol and water solution show a certain solvent dependence. In water, the emission maximum is blue-shifted (20 nm) relative to that in ethanol solution, because the electrostatic interaction between the solvent water and the NCS ligand is stronger than that between the solvent ethanol and the NCS ligand.

## 4. Conclusions

The electronic structure and spectroscopic properties of $[Ru(Htcterpy)(NCS)_3]^{3-}$ (**1H**) are investigated theoretically. We predict absorption and emission spectra in the gas phase and in solution by using the TD-DFT method without and with the solvent-effect CPCM model, respectively. The analysis of electronic structure in ethanol solution shows that the HOMOs are composed of d orbitals of the ruthenium atom and the thiocyanate ligands and the LUMOs are the admixture of π* orbitals localized on the terpyridine ring ligand and the carboxyl groups. The contributions of the thiocyanate and carboxyl group to the HOMOs and LUMOs, respectively, are believed to play an important role in the regeneration and electron-injection performance of dye-sensitized $TiO_2$ solar cells.

The calculated absorption spectra in ethanol solution are in rough agreement with the experimental data. The theoretically simulated spectra based on TD-DFT calculations contain four intense peaks and a shoulder. The calculated absorption peak at 752 nm is not observed in experiment. We assign four lower-energy bands as d(Ru) and NCS-to-tcterpy-charge-transfer (MLCT and LLCT) transitions, different from a previous assignment of pure MLCT transitions.[6] The fifth absorption band with the greatest intensity is attributed to a π→π* transition localized on the tcterpy ligand mixed with some O($p_z$)→tcterpy charge transfer. Furthermore, our calculation overestimates the intensity of band II and underestimates that of band III.

To explore the effect of solvents on the spectra, we also calculated the absorptions of **1H** in the gas phase and in solution. The results quantitatively reproduce the negative solvatochromism (the MLCT/LLCT electronic transition energies of complex **1H** decrease upon increasing solvent polarity). We find that the MLCT/LLCT absorption bands are blue-shifted by about 20 nm in going from ethanol solvent to water solvent. The appearance of negative solvatochromism is closely related to a negative change of dipole moment in the excited state with respect to the ground state, which results in a higher stabilization of the ground state in solvents with increasing polarity.

TD-DFT predicts phosphorescent emissions at 724, 711, and 691 nm in the gas phase, in ethanol, and in water, respectively. We attribute them to tcterpy→Ru/NCS charge transfer ($^3$LMCT/$^3$LLCT) transitions.

**Supporting Information** (see footnote on the first page of this article): Figures S1 and S2 are the diagrams of the single-electron transitions for the emissions in the gas phase and in water solution, respectively. Tables S1 and S2 present the calculated absorptions of **1H** in the gas phase and in water. The calculated dipole moments of the ground and excited states of **1H** in the gas phase, in ethanol, and in water are given in Table S3.

# Electronic Structures and Spectroscopic Properties of $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4): A Theoretical Exploration of Promising Phosphorescent Materials

**Xin Zhou,[a] Hong-Xing Zhang,*[a] Qing-Jiang Pan,[b] Ming-Xia Li,[a,b] Yue Wang,[c] and Chi-Ming Che[d]**

**Keywords:** Ab initio calculations / DFT calculations / Luminescence / Excited states / Platinum(II) oligomer

The structures of $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) in the ground states ($S_0$) and lowest-energy triplet excited states ($T_1$) were calculated by using the second-order Møller–Plesset perturbation (MP2) and density functional theory (DFT) methods, respectively. The MP2 results show that the formation of the dimer causes a significant red shift in emission energy, and the frequency calculations reveal that a weak metal–metal interaction exists in the $S_0$ state, which is greatly enhanced in the $^3[d_\sigma \cdot p_\sigma]$ excited state. The aggregation of $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) was explored by using the slate-type VWN functional in the DFT method. The $^3B_u \rightarrow {}^1A_g$ transition in the dimer at 509 nm corresponds to the experimental higher-energy emission at 530 nm in $CH_3CN$ solution, while the $^3A' \rightarrow {}^1A'$ transitions in the trimer and tetramer at 557 and 650 nm, respectively, are responsible for the low-energy emission at 584 nm observed experimentally. The analyses of the Wiberg bond indices for the Pt–Pt bond indicate that the dimer may be the most stable form in solution and that the oligomer species ($n$ = 3 and 4) can be treated as a special dimer in which the excess z electron ligand is bonded to the Pt atoms of the central dimer.

## Introduction

In the past three decades, there has been a continuous interest in luminescent platinum(II) complexes. The distinctive molecular and electronic structures that occur in $d^8$ platinum(II) systems give rise to some unusual and potentially useful excited-state properties, in particular, those containing weak $d^8$–$d^8$ interaction in the range of 2.7–3.5 Å.[1] Generally, $Pt^{II}$–$Pt^{II}$ contacts exist not only in the solid state but also in solution. Unusual colors and strong emissions, as well as highly anisotropic properties, are often the result of such stacking interactions. Platinum(II) complexes having a weak Pt–Pt interaction are classified into two types: (a) dimers with bridging ligands connecting two platinum(II) atoms[2] and (b) one-dimensional (1D) linear-chain platinum(II) oligomers with a zigzag Pt–Pt–Pt chain stacked equidistantly.[3]

Platinum(II) dimers have been extensively investigated in the last century. For example, $[Pt_2(pop)_4]^{4-}$ ($pop^{2-}$ = $P_2O_5H_2^{2-}$) with rich photophysical and photochemical properties greatly motivated the study of binuclear $d^8$ complexes.[2a,2b,4–11] The light-induced $^3A_{2u}$ excited state of $[Pt_2(pop)_4]^{4-}$ is highly reactive. It reacts with a wide range of quenchers by mechanisms that involve the platinum complex as an oxidant, reductant, or atom-transfer reagent. Coppens[12a] and Rillema[12b] have investigated $[Pt_2(pop)_4]^{4-}$ by DFT, and the featured absorptions and emissions were attributed to the metal-localized $\sigma^*(d) \rightarrow \sigma(p)$ transition. Another case is the well-studied *trans*-$[Pt_2(CN)_4(PR_2CH_2PR_2)_2]$ (R = Me and cyclohexyl) and *trans*-$[Pt_2(CN)_4(PPh_2CH_2PPh_2)_2]$ complexes.[2c–2f] These platinum(II) dimers exhibit an intense emission both in the solid state and in solution at room temperature in the visible region, which has been assigned to a $\sigma(p) \rightarrow \sigma^*(d)$ (metal-centered, MC) transition. Recently, a great interest in 1D platinum(II) linear structures has developed because they are expected to play a critical role in the fabrication of nanodevices with novel electrical, magnetic, and optical properties. The most-investigated 1D platinum(II) complex with a linear-chain structure is platinum(II) polypyridine.[3] Compounds with polypyridyl ligands show intense luminescence and typically exhibit $\pi^*(L) \rightarrow d_{\sigma^*}$ (Pt) emission from a metal-metal-to-ligand-charge-transfer (MMLCT) excited state. Furthermore, the nature and lifetime of the excited

state of these complexes can be changed greatly through modifying the ligands.

In our previous works, Wang and Che et al. found that $[Pt(CNtBu)_2(CN)_2]$[13] can form 1D luminescent nanowires through weak Pt–Pt interactions, which are rare in the reported self-assembly 1D architectures. As suggested, the metal-localized $5d_{\sigma^*} \rightarrow 6p_{\sigma}$ transition of $[Pt(CNtBu)_2(CN)_2]_2$ can lead to the effective construction of 1D functional nanomaterials and intense green emission; the oligomerization of the monomers does impact on the luminescence behavior and the electronic structures. In fact, similar neutral platinum(II) complexes with the general formulas $[Pt(CNR)_4][Pt(CN)_4]$ and $[Pt(CNR)_2(CN)_2]_2$ (R = alkyl and aryl) have been extensively studied by Mann and coworkers.[14] However, their investigation was limited to their application towards chemical sensors and their vapochromic behavior, and there was little discussion on their luminescence properties and the effect of oligomerization on the luminescence and the electronic structures. Furthermore, to the best of our knowledge, the luminescent properties for oligomerized $[Pt(CNtBu)_2(CN)_2]_n$ have not been theoretically investigated for the platinum(II) complexes.

In this paper, we have examined the ground- and excited-state properties of $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) by using ab initio and DFT calculations. We aimed at elucidating three points: (1) the ground- and excited-state geometrical and electronic structures of $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4), (2) the relationship between the weak $Pt^{II}$–$Pt^{II}$ interaction and the electronic structure as well as the luminescence properties, (3) whether the oligomerization of the platinum(II) chain will strengthen the weak inter- and/or intra-interaction in solution and lower the emission energies. Here we present the study of the electronic structures, geometrical structures, and spectroscopic properties.

## Computational Details

$[Pt(CNMe)_2(CN)_2]$ was used as the computational model to represent the real complex $[Pt(CNtBu)_2(CN)_2]$. This strategy was employed in our previous work to save computational cost, and it proved to be suitable for reproducing the experimental results.[15]

The electronic structures and emission spectra of monomer $[Pt(CNMe)_2(CN)_2]$ (**1**) and dimer $[Pt(CNMe)_2(CN)_2]_2$ (**2**) were carried out with the Gaussian 03 program package (G03).[16] Full optimizations on the ground state ($S_0$) and lowest-energy triplet excited state ($T_1$) were performed at the second-order Møller–Plesset perturbation (MP2) and UMP2 levels of theory, respectively.[17] On the basis of the optimized $T_1$ geometries of the complexes, we employed the time-dependent density functional theory (TDDFT)[18] method at the PBE0 functional level[19] to predict the emission spectra. By considering the differences in the emission spectra in gas and solution, the solvent effect of acetonitrile was taken into account by using the polarizable continuum model (PCM).[20] The above calculations were performed by using the LanL2DZ basis sets with effective core potentials (ECPs) for the Pt atom proposed by Hay and Wadt.[21] To describe the Pt–Pt interaction and the molecular properties precisely, one additional function was implemented for the Pt atom ($\alpha_f$ = 0.14).[22]

One of the objectives of this paper is to discuss whether the formation of oligomers can affect the electronic structure and emission energy of $[Pt(CNMe)_2(CN)_2]_n$. However, to achieve these goals with ab initio calculations will require very long computational resources, because we are dealing with large oligomers containing rather heavy atoms, the modeling of which requires an extremely large number of basis functions. Therefore, in order to pursue these goals, we performed DFT calculations with relativistic effects by using the Amsterdam Density Functional (ADF2005.01) program.[23] As concluded by Pyykkö,[24] the weakly- or non-overlapping systems are not reasonably calculated by the DFT method, because the dispersion interaction of $R^{-6}$ is not explicitly included in the present DFT method. Nevertheless, in some recent papers, it was reported that the experimental results of weak metal–metal bonding can be reproduced by a simple local density functional (such as SVWN or Xα), rather than the gradient corrected density functionals (DFs) [B3LYP, BLYP, BP86, and PBE0].[25] Although the intrinsic reason is not yet clear, the application of the DFT approach to study large oligomers seems to be feasible. Similar $[AuCN_2^-]_n$ oligomers have been studied with Extended Hückel calculations, and the corresponding results were satisfactory.[26]

In the ADF calculations, the geometrical structures of $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) in the $S_0$ and $T_1$ states were optimized by spin-restricted and spin-unrestricted Vosko–Wilk–Nusair (VWN) calculations, respectively.[27] The valence atomic orbitals of the platinum, nitrogen, carbon, and hydrogen atoms were described by the TZP basis sets. The cores (1s2s2p3s3p4s4p for Pt and 1s for C, N and O) were kept frozen. Relativistic effects were included by means of the Zero Order Regular Approximation (ZORA).[28] TDDFT (PBE0) calculations were performed on the equilibrium excited-state geometries of $[Pt(CNMe)_2(CN)_2]_n$. The conductor-like screening model (COSMO)[29] was used to simulate the solvent effects, as implemented in the ADF code. In order to describe the asymptotic behavior well, a combination of the local VWN and the Becke–Perdew (BP86)[30] gradient correction term was employed.

## Results and Discussion

### The Monomer and Dimer in the $S_0$ State

In this work, $C_{2v}$ symmetry is assigned to monomer **1**, with the two mutually *cis* CN ligands. For dimer **2**, the initial $C_1$ symmetry is adopted with a torsion angle C1–Pt1–Pt2–C3 of 55°, as indicated in the X-ray results. The torsion angle is subjected to geometry optimization and decreases by ca. 0.2° for the dimer, the framework of which is close to $C_{2h}$ symmetry. Such a big difference in the torsion angle results from the replacement of *tert*-butyl groups used experimentally by methyl groups used in the calculation. As

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a result, the steric repulsion between the bulky *tert*-butyl groups is eliminated, and the torsion angle is greatly reduced. Therefore, the $C_{2h}$ symmetry for the dimer is adopted throughout this paper. The optimized $S_0$ structures of the platinum(II) monomer and dimer, with the coordination axis, are depicted in Figure 1, and the corresponding important parameters are listed in Table 1. As shown in Table 1, the geometrical parameters for the monomer and dimer are very close and agree well with most of the experimental values for $[Pt(CN)_4^{2-}]$ ions and for double salts such as $[Pt(CNR)_4(CN)_4]$ (R = toluene),[14] which indicates that the eclipsed structures do not have an impact on the geometrical structure of the monomer. The Pt–C1 and C1≡N1 bonds are ca. 0.017 and 0.023 Å longer than the Pt–C2 and C2≡N2 bonds. The small increase in length results from the different electronic structures of the *iso*cyanide and cyanide ligands as discussed in most textbooks. The C1≡N1 and C2≡N2 bonds are slightly long, but fall in the range of C≡N distances generally measured experimentally for these types of complexes. The deviations are thought to arise because the experimental values are measured with rather large uncertainties and because smaller basis sets are applied to the C and N atoms. To test the dependence of the Pt–C and C≡N bond lengths on the basis sets, we optimized **1** at the MP2 level with different basis sets (Table S1). The results suggest that with the increase in the size of the basis sets (BS I–VII), the lengths of the Pt–C and C≡N bonds decrease greatly and are much closer to the experimental values. Because the Pt–Pt bond is obviously shortened, a definite hydrogen bond between the N (CN) and H (Me) atoms is formed and the N1–H1 bond length is 2.468 Å, which falls within the normal range of hydrogen bond lengths. Further, the stacking of $[Pt(CNMe)_2(CN)_2]_2$ may be partially stabilized by hydrogen bonds in the solid state and in solution. In addition, the formation of the hydrogen bond gives rise to a tilted angle of 9.6° for the Pt–Pt vector relative to the *z* axis, which is in accordance with that observed experimentally.

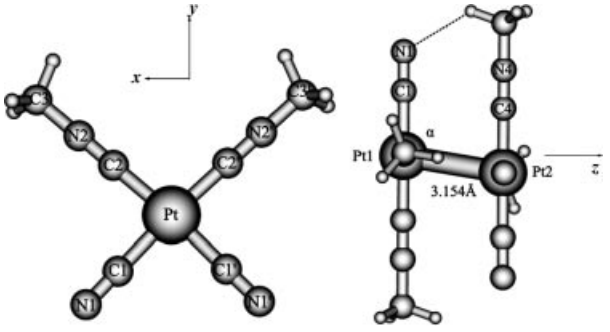

Figure 1. Optimized $S_0$ structures for **1**–**2** determined by MP2 methods.

The most important Pt–Pt bond length was calculated to be 3.154 Å, which falls in the usual range for most platinum(II) dimers (2.7–3.5 Å) and is comparable to those calculated previously for the $[Pt_2(pop)_4]^{4-}$ and $[Pt_2(pop)_4]^{4-}$ ions[15c] and for the neutral molecule $[Pt_2(CN)_4(PH_2CH_2PH_2)_2]$.[31] The slightly shorter Pt–Pt distance than the van der Waals contact of 3.2 Å indicates the presence of a possible weak bonding interaction between the two $Pt^{II}$ centers in **2**. It should also be noted that the calculated Pt–Pt bond length is ca. 0.2 Å shorter than that determined by X-ray diffraction. This is because excess electron correlation effects are included in the MP2 calculation (which considerably shortens the Pt–Pt bond length) and because methyl groups are used in the calculation. To evaluate the interaction strength between the two monomers, the interaction energy is obtained by taking into account the counterpoise (CP) correction; these results are summarized in Table 1. The calculated interaction energy after CP correction is ca. 35 kJ/mol, comparable to that of hydrogen bonds. The interaction energy should result from three contributions. In addition to the contribution from the metallophilic interaction between Pt–Pt and from the hydrogen bond of N1–H1, the attraction between the π-electron clouds of $CN^-$ and *iso*-$CN^-$ also partially contributes to the interaction energy. To further understand the Pt–Pt bonding nature, the frequency calculation was preformed on the dimer (Table 1). Table 1 shows that the stretching vibration of Pt–Pt is 87 $cm^{-1}$ and the force constant is 0.309 mDyne/A. The two values agree well with those in systems in which there are weak $Au^I$–$Au^I$ interactions,[26] and suggest the presence of Pt–Pt bonding. The MO diagram of **2**, represented in Figure 2, is used to elucidate the formation of the Pt–Pt bond. The fully occupied $5d_{z^2}$ atomic orbitals of adjacent platinum centers split to give $d_\sigma$ bonding and $d_{\sigma^*}$ antibonding molecular orbitals, as has been reported in other papers.[32] Similarly, the unoccupied $6p_z$ atomic orbitals split to give $p_\sigma$ and $p_{\sigma^*}$ molecular orbitals. There exist two kinds of

bonding interactions between two platinum(II) atoms: the first interaction is a four-electron repulsion between the $d_{z^2}$ orbitals that prevents the two platinum(II) atoms from approaching one another, and the second interaction is a bonding donor–acceptor interaction between the $d_{z^2}$ and $p_z$ orbitals. The combination of the two interactions can account for the weak Pt–Pt bonding.

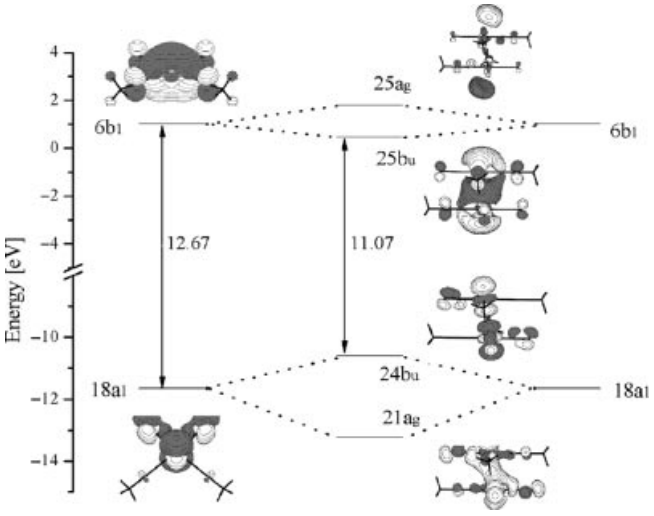

Figure 2. Energy level of **2**.

### Monomer and Dimer in the $T_1$ State and Lowest-Energy Emission Spectra

The structures of **1** and **2** in the $T_1$ states were determined by the UMP2 method. Optimizations on **1** and **2** predict that their $T_1$ states have $^3B_2$ and $^3B_u$ symmetry, respectively. Selected structural parameters are listed in Table 1. The $T_1$ geometries of the monomer and dimer are found to differ from those in the $S_0$ state. Both the Pt–C1 and Pt–C2 bonds are elongated slightly in the $T_1$ state. The formation of Pt–Pt single bond in the $T_1$ state weakens the Pt–C covalent bonds and Pt←C dative bonds, which can account for the elongation of the Pt–C bond. The C1–N1 and C2–N2 bonds are shorter in the $S_0$ state than in the $T_1$ state, in particular, the C1–N1 bond length is reduced by roughly 5.0%. For the dimer, the Pt–Pt distance decreases by ca. 0.324 Å on going from the $S_0$ state to the $T_1$ state, while the N1–H1 distance increases by ca. 0.23 Å. The opposite trend for the Pt–Pt and N1–H1 bond lengths implies that the hydrogen bonding of N1–H1 only plays a secondary role in the stabilization of the dimer. Upon excitation, the coordination geometry of the platinum(II) atom is much closer to the regular square-planar structure, as indicated by the C1–Pt–C2 and C2–Pt–C2′ bond angles of ca. 90°. The tilted angle $\alpha$ for **2** decreases by ca. 4°, which suggests that the complex has a straighter chain in the $T_1$ state. We performed the frequency calculation for the optimized geometry of $T_1$ at the UMP2 level for **2** in order to further characterize the Pt–Pt bonding in the excited state (Table 1). Table 1 shows that Pt–Pt stretching frequency undergoes a moderate increase from ca. 87.7 to 116 $cm^{-1}$, and the force constant increases by ca. 0.15, which is consistent with a single electron that is promoted from the $d_{\sigma^*}$ antibonding to $p_\sigma$ bonding orbital and with the formation of Pt–Pt single bond in the excited state. In addition, the calculated overlap population between the two Pt atoms is 0.0278 and 0.0169 for the $^3B_u$ excited state and $^1A_g$ ground state, respectively. From such calculated frequencies and overlap populations between the two Pt atoms, it can easily be seen that the Pt–Pt interaction in the former is stronger. This suggests that there may be some electron transfer to the 6p bonding orbitals of the Pt atoms. More evidence for the enhancement of the Pt–Pt bonding is the increased interaction energy between the two monomers. UMP2 calculations show that the interaction energy is ca. 176 kJ $mol^{-1}$, which is of the same order of magnitude as that for the covalent bonding energy. All of the above results illustrate the obvious contraction of Pt–Pt bond that results from the formation of single bond between the two platinum(II) atoms. The conclusion is in agreement with other weakly interacting systems involving heavy transition metals such as $Au^I$ and $Pt^{II}$ etc.[12,26,33]

According to the Franck–Condon vertical transition principle, the emission properties of **1** and **2** were calculated on the basis of their corresponding $T_1$ geometries. Complexes **1** and **2** give rise to the lowest-energy phosphorescent emissions at 301 and 512 nm (Table 2), which mainly originate from the excited states with the transitions $^3B_1 \rightarrow {}^1A_1$ and $^3B_u \rightarrow {}^1A_g$, respectively. Table 3 gives the partial MO compositions for the two complexes in the phosphorescence, the results from which can be used to further shed light on the emission nature. With respect to the $^3B_1 \rightarrow {}^1A_1$ transition of **1**, the $19a_1 \rightarrow 6b_1$ configuration has the largest CI coefficient of ca. 0.72. As shown in Table 3, the MO $19a_1$ (HOMO) results largely from the contributions of the Pt $d_{z^2}$ orbital (83.6%), whereas the MO $6b_1$ (LUMO) is localized on the Pt $p_z$ and *iso*-$CN^-$ π* orbital. Therefore, the calculation shows that the $^3B_1$ excited state of **1** can give rise to the $p_z/\pi^*(iso\text{-}CN^-) \rightarrow d_{z^2}$ phosphorescent emission. With regard to the $^3B_u \rightarrow {}^1A_g$ transition of **2**, the configuration of $24b_u \rightarrow 25a_g$ corresponds to the largest CI coefficient of ca. 0.72. Analyses of the wavefunctions of the $^3B_u$ excited state of **2** indicate that the $24b_u$ orbital (HOMO) is a σ* antibonding orbital that results from the Pt $5d_{z^2}$ atomic orbital, and the $25a_g$ orbital (LUMO) has bonding charac-

ter that arises mainly from the Pt $6p_z$ atomic orbital. Thus, we assign the 512 nm phosphorescence as a $\sigma[p_z(Pt_2)]\rightarrow\sigma^*[d_{z^2}(Pt_2)]$ transition from the triplet to the singlet $S_0$ state, which is comparable to the 542 nm phosphorescence observed experimentally.

### The $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) in the $S_0$ and $T_1$ States

In previous experimental work,[13] it was found that the emission of $[Pt(CNtBu)_2(CN)_2]$ at 542 nm can be resolved into two bands at 530 and 584 nm, which suggests that two different emissions originate from $[Pt(CNtBu)_2(CN)_2]_n$ oligomers with different values of $n$ in $CH_3CN$ solution. Similar split bands have also been observed in most platinum(II) dimers that exhibit rich excited states such as $^{1,3}$MLCT, $^{1,3}$ILCT, and $^3\pi$–$\pi$ transition. However, the various excited states are mostly dominated by the different ligands not by the stacking of the oligomers. Thus, our interest is in whether oligomerization might occur in $CH_3CN$ solution and in the consequent change in geometry and luminescence behavior. In fact, the photophysics of $[Pt(CN)_4^{2-}]_n$[34] with $n$ = 1–5 has been experimentally investigated by Schindler and co-workers in detail; different absorption bands were attributed to the $^1[5d_{\sigma^*},6p_\sigma]$ and $^3[5d_{\sigma^*},6p_\sigma]$ excited states for different values of $n$. Nevertheless, to the best of our knowledge, there is no theoretical study on the electronic structure and luminescence for similar platinum(II) compounds that are affected by the degree of oligomerization.

The DF approach was employed to obtain the geometrical and electronic structures for $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4, **1**–**4**). Because the choice of functional is very important for the reproduction of the weak interaction for multiplatinum(II) complexes, the optimization of dimer $[Pt(CNMe)_2(CN)_2]_2$ was carried out with several different versions of the exchange-correlation DF (BP86, PBE0, BLYP, and VWN) to test which DF is better suited to the $[Pt(CNMe)_2(CN)_2]_n$ species. Table S2 presents the partial geometrical parameters of the $[Pt(CNMe)_2(CN)_2]_2$ species. The results show that, analogous to those found in $Au^I$ clusters,[25] the most important Pt–Pt distance was reproduced well by the VWN DF (3.257 Å) but not by the DF involving the gradient-corrected (GGA) exchange potential (BLYP: 3.631 Å, BP86: 3.505 Å, PBE0: 3.498 Å). Therefore, all the $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) species were investigated by using the local VWN DF. The Pt–Pt parameters for **1**–**4** are shown in Table 4, and the complete data are tabulated in Table S3. As depicted in Table 4, the Pt–Pt bond lengths are sensitive to $n$, and all compounds show stronger Pt–Pt bonding in the $T_1$ state than in the $S_0$ state, which is reflected by the shorter Pt–Pt equilibrium distances. The Pt–C bond length of **1** and **2** (Table S3) is in agreement with those obtained by the MP2 calculations, but the C≡N bond length is ca. 0.06 Å shorter than those obtained by the MP2 calculations with small basis sets (BS I) and compares to those from calculations with the largest basis set (BS VII). This result is not surprising because the MP2 method is known to be unreliable in the prediction of triple bond lengths.[31]

Table 4. Optimized $S_0$ and $T_1$ geometrical parameters in **2**–**4** determined by DFT (VWN) calculations.

| | | Pt1–Pt2 [Å] | Pt2–Pt3 [Å] | Pt1–Pt2–Pt3 [°] | $\alpha$ [°] |
|---|---|---|---|---|---|
| dimer | $^1A_g$ | 3.257 | – | – | 104.8 |
| | $^3B_u$ | 2.819 | – | – | 99.6 |
| trimer | $^1A'$ | 3.225 | 3.260 | 130.8 | 107.9 |
| | $^3A'$ | 2.954 | 3.000 | 142.0 | 105.7 |
| tetramer | $^1A'$ | 3.282 | 3.187 | 135.3 | 106.1 |
| | $^3A'$ | 3.091 | 2.936 | 156.9 | 100.5 |

A scheme of the geometric structures of the $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 2–4) species in the $S_0$ and $T_1$ state is presented in Figure 3 to intuitively understand the geometry change upon oligomerization. Three points can be drawn from Figure 3. (1) The chain of the complexes is straighter in the $T_1$ state than in the $S_0$ state, as reflected by the smaller $\alpha$ angles and larger Pt–Pt–Pt bond angles. (2) In the dimer, a larger reduction (ca. 13%) of the Pt–Pt distance on going from the $S_0$ state to the $T_1$ state is observed, whereas a smaller reduction of 6–8% occurs in the trimer and tetramer. This larger contraction in the dimer implies that the dimer in the triplet excited state may be the most stable species in $[Pt(CNMe)_2(CN)_2]_n$. This conclusion is in agreement with that by Rillima et al.[33] for the platinum(II) diphenyl dicarbonyl complex. (3) With respect to the trimer in both the $S_0$ and $T_1$ state, the distance between one pair of adjacent monomers is smaller than that between the other pair. The case is different for the tetramer; the distance between the central two monomers (Pt2–Pt3) is much smaller than that between the other adjacent pairs (Pt1–Pt2 and Pt3–Pt4). In fact, there are two different interactions in the trimer and tetramer, e.g. intramolecular and intermolecular interactions. In **2**–**4**, the Pt1–Pt2 interactions of **2** and **3** and the Pt2–Pt3 interactions of **4** are intramolecular contacts (d1), while the Pt2–Pt3 interactions of **3** and the Pt1–Pt2 and Pt3–Pt4 interactions of **4** are of the intermolecular type (d2). We can see that the d1 distances are moderately shorter than the d2 distances, and d1 gradually decreases on going from the trimer to tetramer. With reference to previous remarks by Novoa et al.,[35] in platinum(II) dimers, four electrons in one Pt–Pt bond contribute to the excess electrons in the $z$ direction. If the trimer or tetramer can be treated as a special dimer in which a monomer is bonded

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to the axial positions, the attacked $Pt^{II}$ unit could act as a base and could contribute two $d_{z^2}$ electrons to bind in the axial direction in a face-to-face fashion. Therefore, the forming of two or three bonds with a total of six or eight $d_{z^2}$ electrons will result in a greater excess of *z* electron density and enhance the interactions of the stacked complexes. Preliminary extended Hückel calculations[36] on the corresponding $d^8$–$d^8$ dimers suggested that binding of Lewis acid and/or base to metal atoms at the axial positions has an increasing effect on the M–M bond strength. Our results are in agreement with these conclusions, and excess electrons in the axial direction can account for the variation in the Pt–Pt distance.

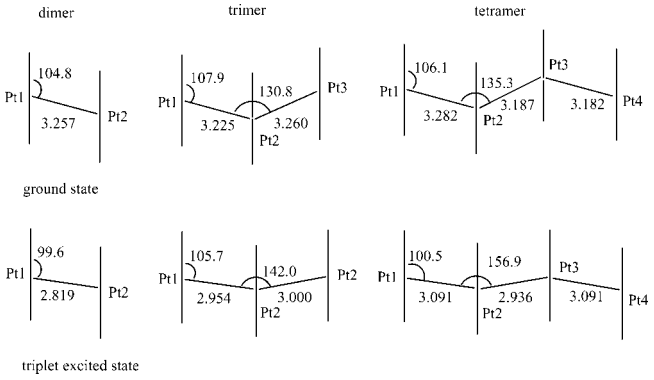

Figure 3. Schematic representation of the $S_0$ and $T_1$ structures for **2**–**4**.

The above description is based on only a qualitative analysis, quantitative proof must be obtained with the bond order indices. Bond order is a measure of the number of bonding electron pairs between atoms. Here, we use bond order to qualitatively compare the relative strength of the Pt–Pt bond in **2**–**4**. As suggested previously in the literature,[12a,12b] the Pt–Pt bonding of such complexes is mainly determined by the electrons in the $\sigma[d_{z^2}(Pt_2)]$ and $\sigma^*[d_{z^2}(Pt_2)]$ orbitals. We investigated the Pt–Pt bonding for **2**–**4** by using the Wiberg bond indices (WBIs)[37] in the Natural Bond Orbital (NBO 5.0) program;[38] the details of the WBIs are presented in Table 5. As seen from Table 5, the Pt–Pt WBIs in **2**–**4** are 0.0141 (**2**), 0.0157 and 0.0149 (**3**), and 0.0139, 0.0199, and 0.0139 (**4**), respectively, and they are one magnitude order less than that of an ordinary single bond (for example: Pt1–C3 WBI in **2** is 0.5445), which implies that the Pt–Pt bond is weak. There is a correlation between Pt–Pt WBIs and Pt–Pt bond lengths – the shorter the bond length, the higher the WBI. Therefore, the largest WBI (Pt2–Pt3, 0.0199 in **4**) results in the shortest Pt–Pt contact in **2**–**4**. From another point of view, the proportion of $\sigma[d_{z^2}(Pt_2)]$ orbitals relative to $\sigma^*[d_{z^2}(Pt_2)]$ orbitals in Pt2–Pt3 of **4** is the largest.

We have analyzed the effect of aggregation on the Pt–Pt distances, we will now further discuss the effect on the HOMO–LUMO gap for the $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) species. Figure 4 shows the trend in the HOMO–LUMO gap as the value of $n$ increases. A progressive reduction in the HOMO–LUMO gap is observed upon aggregation. The

Table 5. Wiberg bond orders of **2**–**4** calculated by the program NBO 5.0.

| | | Pt1–Pt2 | Pt2–Pt3 | Pt3–Pt4 |
|---|---|---|---|---|
| **2** | Bond length [Å] | 3.257 | – | – |
| | WBI | 0.0141 | – | – |
| **3** | Bond length [Å] | 3.225 | 3.260 | – |
| | WBI | 0.0157 | 0.0149 | – |
| **4** | Bond length [Å] | 3.282 | 3.187 | 3.182 |
| | WBI | 0.0139 | 0.0199 | 0.0139 |

HOMOs for **2**–**4** are all of the $d_{\sigma^*}(d_{z^2}$–$d_{z^2})$ type, while the LUMOs are mainly localized on the mixed $p_\sigma(p_z$–$p_z)$ and *iso*-$CN^-$ π orbital. The reduction in the HOMO–LUMO gap due to 1D aggregation is a result of concomitant destabilization of the HOMOs and stabilization of the LUMOs. It is noticeable that the decrease in the energy of the LUMOs is more gentle than the increase in energy of the HOMOs, which implies that aggregation has a greater impact on $d_{\sigma^*}(d_{z^2}$–$d_{z^2})$ than on $p_\sigma(p_z$–$p_z)$. This observation is in agreement with the results predicted by other calculations. We do not consider 2D aggregation similar to that observed in $[Au(CN)^-]_n$, because 2D aggregation is prohibited from the square-planar geometry of the $Pt^{II}$ atom.

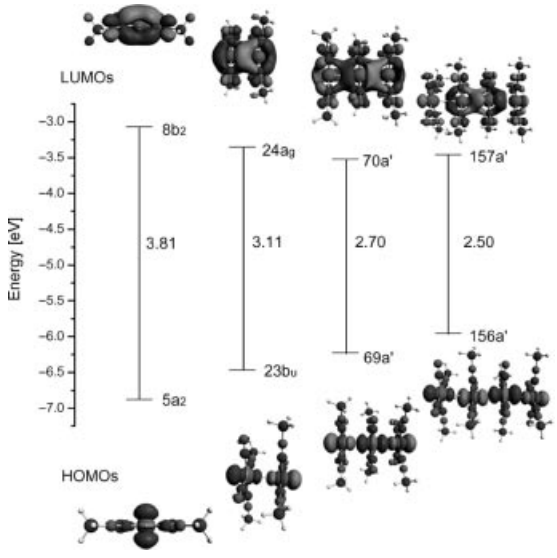

Figure 4. The HOMO and LUMO energy levels for **1**–**4** in the $S_0$ state.

On the basis of the optimized $T_1$ geometry for the $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4) species, the emission spectra were determined by the TD-DFT method embedded in the ADF2005.01 package (see Table 6). As shown in Figure 4, the emissions are all attributed to the excitation of HOMO→LUMO, and the emission energies decrease in the order **1** > **2** > **3** > **4**, in accordance with the sequence of the HOMO–LUMO gap. The emission energies of **1** and **2** calculated by VWN DF are close to those calculated by the MP2 method, which shows the relative reliability of the DFT approach. With respect to the four lowest-energy excite states, $^3B_2$, $^3B_u$, $^3A'$, and $^3A'$, the excitation configura-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion of HOMO→LUMO contributes the largest weight of ca. 0.99 and should be responsible for the character of the emissions. According to above description, the emissions of **1** and **2** are identical to those predicted by the MP2 method and arise from the $d_{z^2}$→$p_z$/*iso*-$CN^-$ transitions (MC and MLCT) for **1** and $d_{\sigma^*}$→$p_\sigma$/*iso*-$CN^-$ transitions (MC and MLCT) for **2**. It should be noted that the emission energies for **3** and **4** are red-shifted by ca. 0.21 and 0.53 eV relative to **2**, respectively. Although the Pt–Pt intramolecular distances for **3** and **4** are shorter than that for **2**, the contraction of intramolecular contacts alone cannot account for the distinctive red-shift. For example, our previous work showed that the Pt–Pt distance in $[Pt_2(pop)_4]^{4-}$ is ca. 0.08 Å shorter than that in $[Pt_2(pcp)_4]^{4-}$ (pop = $P_2O_5H_2^{2-}$ and pcp = $P_2O_4CH_4^{2-}$), but the difference in their emission energies is only 0.07 eV. Thus, we conceive that the intermolecular $5d_{z^2}$–$5d_{z^2}$ interactions also play an important role in the red-shift of the emission energy. The 557 and 650 nm emissions for **3** and **4** are attributed to the combination of intermolecular and intramolecular $d_{\sigma^*}$→$p_\sigma$/*iso*-$CN^-$ transitions (intra/inter MC and MLCT). This can be intuitively understood from the electron density diagram (Figure 4). This assignment also indicates that the 584 nm emission observed experimentally may arise from the combined contribution of the trimer and tetramer oligomers.

Table 6. Emissions of **1**–**4** in $CH_3CN$ solution determined by TD-DFT (VWN/BP86) calculations.

| | Excited state | Configuration (contribution weight) | *E* [eV] ($\lambda$ [nm]) Calcd. | Exp. |
|---|---|---|---|---|
| monomer | $^3B_2$ | $16a_2$→$8b_2$ (0.99) | 3.81 (326) | – |
| dimer | $^3B_u$ | $23b_u$→$24a_g$(0.99) | 2.44 (509) | 2.34 (530)[a] |
| trimer | $^3A'$ | 69a′→70a′(0.99) | 2.23 (557) | 2.13 (584)[a] |
| tetramer | $^3A'$ | 156a′→157a′(0.99) | 1.91 (650) | 2.13 (584)[a] |

[a] Ref.[13]

## Conclusions

We explored the electronic properties of the $S_0$ and $T_1$ states of $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–2) complexes at the MP2 and UMP2 levels. The geometrical parameters of the monomer and dimer are in agreement with that observed experimentally. In the $S_0$ state, the calculated Pt–Pt distance of the dimer is 3.154 Å. The shorter Pt–Pt distance than the van der Waals distance of 3.2 Å indicates the presence of a weak interaction between the two platinum(II) atoms, and the frequency calculations further prove that there is a weak bonding interaction. In the $T_1$ state, the Pt–Pt distance undergoes a significant reduction, which results from the promotion of an electron from the σ*[$Pt(d_{z^2})$] to σ[$Pt(p_z)$] orbital. As a consequence, a red-shift in the emission energy is observed from monomer to dimer, and the luminescence arises from the $^3[d_{\sigma^*}p_\sigma]$ excited state.

The slate type VWN functional in the DF method was used to predict the impact of oligomerization on $[Pt(CNMe)_2(CN)_2]_n$ ($n$ = 1–4). In the calculation, the dimer is proposed to be the most stable form in the solid state and in solution. The trimer and tetramer can be treated as a special dimer in which the donor ligand is bonded to the central Pt atoms of the dimer. The excess $z$ electrons increase the electron density localized on the Pt–Pt bond and hence enhance the strength of the Pt–Pt bonding. The Pt–Pt distance in the tetramer (3.187 Å) is the shortest, which is consistent with the highest WBI in the investigated Pt–Pt bond.

The experimentally observed lower- and higher-energy emission bands result from the different oligomers in solution. The emission at 530 nm mainly originates from the dimer, while the lower-energy emission at 584 nm derives from the associated contribution of the trimer and tetramer. It should be noted that, aside from intramolecular Pt–Pt interactions, intermolecular Pt–Pt contacts also plays an important role in the red-shift of the emission energy.

# Syntheses, Structures and Optical Nonlinearities of Heteroselenometallic W–Se–Cu Cluster Compounds Containing Bridging Phosphane Ligands

**Zhan Yu,[a] Qian-Feng Zhang,*[a] Yinglin Song,[b] Wai-Yeung Wong,[c] Alexander Rothenberger,[d] and Wa-Hung Leung[e]**

*Dedicated to Professor Dieter Fenske on the occasion of his 65th birthday*

**Keywords:** Heterometallic complexes / Copper / Selenium / Nonlinear optical properties / Cluster compounds

Treatment of $[Et_4N]_2[WSe_4]$ with the trinuclear trigonal-bipyramidal copper(I) complexes $[Cu_3(\mu_3\text{-}X)_2(\mu\text{-}L)_3]X$ [X = I, L = bis(diphenylphosphanyl)methane (dppm) (**1a**); X = Cl, L = bis(diphenylphosphanyl)amine (dppa) (**1b**)] affords the tetranuclear cluster compounds $[(\mu_3\text{-}WSe_4)Cu_3(\mu\text{-}X)(\mu\text{-}L)_2]$ [X = I, L = dppm (**2a**); X = Cl, L = dppa (**2b**)], which exhibit an open butterfly configuration. Interaction of $[Et_4N]_2[WSe_4]$ with $[Cu(MeCN)_4][PF_6]$ and L gives the pentanuclear cluster compounds $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}L)_4][PF_6]_2$ [L = dppm (**3a**), dppa (**3b**)] which contain an open co-planar $WCu_4$ core. The solid-state structures of cluster compounds **2a**, **2b**, and **3a** have been established by X-ray crystallography. The nonlinear optical properties of **2a** and **3a** have been examined by z-scan techniques with 7-ns pulses at 532 nm. The pentanuclear co-planar cluster **3a** exhibits a large optical limiting effect (the limiting threshold is about 0.40 J cm$^{-2}$).

## Introduction

The coordination chemistry of $[MS_4]^{2-}$ anions (M = Mo, W) with transition metal ions has been well developed owing to their relevance to biological systems,[1–3] special optical properties,[4–6] and rich structural variations.[7] However, analogous heterometallic complexes with $[MSe_4]^{2-}$ anions have not been well explored. Heterometallic selenium complexes are of significance, in part, due to their interesting nonlinear optical and electronic properties.[8–10] Studies of the interaction of $[MSe_4]^{2-}$ with the coinage-metal cations, namely $Cu^+$, $Ag^+$, and $Au^+$, have resulted in the isolation of a series of heterometallic selenium clusters with various structural types, including linear, cubane, incomplete cubane, co-planar T-frame and open cross-frame, crown, cage, and pin-wheel shapes, and polymeric frameworks.[11–19] We have a long-standing interest in heterometallic selenium cluster compounds based on the $[MSe_4]^{2-}$ anions.[20] It is noteworthy that the structure of coinage-metal/$[MSe_4]^{2-}$ clusters is closely related to the number of coinage metal ions coordinated to the six $MSe_2$ edges of the tetrahedral $[MSe_4]^{2-}$ moiety, which depends upon the reaction conditions, especially the M′/$[MSe_4]^{2-}$ (M′ = coinage metal) ratio, and the peripheral ligands.[21] In this context, we report here the synthesis of two types of heterometallic selenium W–Se–Cu cluster compounds, namely tetranuclear butterfly-like $[(\mu_3\text{-}WSe_4)Cu_3(\mu\text{-}I)(\mu\text{-}L)_2]$ [L = dppm (**2a**), dppa (**2b**)] and pentanuclear open co-planar $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}L)_4][PF_6]_2$ [L = dppm (**3a**), dppa (**3b**)], from reactions of tetraselenotungstate anion with copper species in the presence of the bridging phosphane ligands bis(diphenylphosphanyl)methane (dppm) and bis(diphenylphosphanyl)amine (dppa). The nonlinear optical data of the newly prepared heterometallic selenium clusters have been investigated to provide some evidence regarding the structure/property relationships of this class of cluster compounds.

## Results and Discussion

### Syntheses and Spectral Characterizations

It has been reported previously that reactions of copper halides with dppm give a series of trinuclear trigonal-bipyramidal complexes $[Cu_3(\mu_3\text{-}X)_2(\mu\text{-dppm})_3]X$ (X = Cl,[22] Br,[23] I[24]). Similarly, treatment of [CuCl] powder with

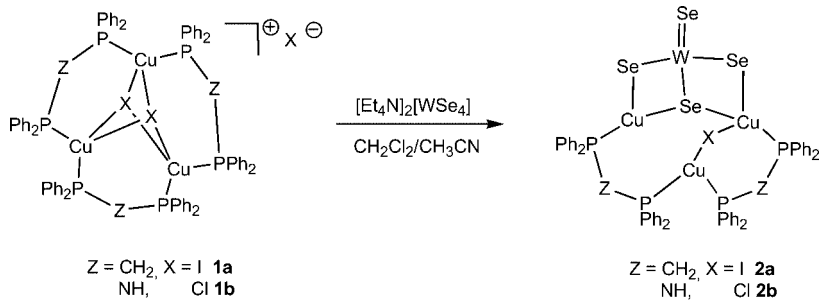
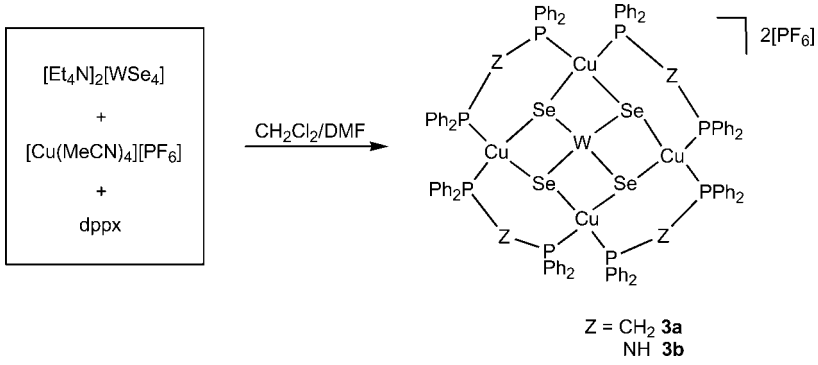


Scheme 1.

1 equiv. of dppa in $CH_2Cl_2$ affords the complex $[Cu_3(\mu_3\text{-}Cl)_2(\mu\text{-}dppa)_3]Cl$ (**1b**) in nearly quantitative yield. It is therefore not surprising to find a similar behavior between the bridging ligands dppa and dppm in their reaction with copper halides. A similar reaction in thf solution results in the formation of the same cationic complex but with a $[Cu^ICl_2]^-$ anion, which seems to be easily formed in thf.[25] The $^{31}P\{^1H\}$ NMR spectrum of **1b** shows one singlet at $\delta$ = 38.2 ppm assignable to the dppa ligands.

The reaction of $[Et_4N]_2[WSe_4]$ with **1a** and **1b** affords the neutral tetranuclear cluster compounds $[(\mu_3\text{-}WSe_4)Cu_3(\mu\text{-}I)(\mu\text{-}dppm)_2]$ (**2a**) and $[(\mu_3\text{-}WSe_4)Cu_3(\mu\text{-}Cl)(\mu\text{-}dppa)_2]$ (**2b**), respectively (Scheme 1). This implies that the formation of **2a** and **2b** involves the metathesis of $[Cu_3(\mu_3\text{-}X)_2(\mu\text{-}L)_3]^+$ (L = dppm and dppa) with the $[WSe_4]^{2-}$ anion. It seems that the displacement of one halide ion and one L molecule from $[Cu_3(\mu_3\text{-}X)_2(\mu\text{-}L)_3]^+$ gives an unsaturated intermediate $[Cu_3(\mu_3\text{-}X)(\mu\text{-}L)_2]^{2+}$, which subsequently coordinates to $[WSe_4]^{2-}$. The trigonal $Cu_3$ core in these compounds is maintained after the cluster formation, as confirmed by X-ray crystallography (see below). The treatment of $[Et_4N]_2[WSe_4]$ with $[Cu(MeCN)_4][PF_6]$ in the presence of the bidentate phosphane ligands dppm and dppa affords the cationic pentanuclear cluster compounds $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppm)_4][PF_6]_2$ (**3a**) and $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppa)_4][PF_6]_2$ (**3b**), respectively (Scheme 2). In this reaction, dppm and dppa act as bridging ligands for the construction of a dinuclear $[Cu_2(L)]^{2+}$ species obtained from the 1:1 mixture of $[Cu(MeCN)_4]^-$ and L.[26] Formation of the pentanuclear cluster **3** is not surprising for a co-planar $WCu_4$ core because the four faces of the tetrahedral $[WSe_4]^{2-}$ anion are equally capable of coordinating to $Cu^I$ species in polar dmf solution. A similar cluster compound $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppm)_4][ClO_4]_2$ has been reported previously.[27]

The IR and electronic spectra for **2** and **3** are in agreement with those observed for other known $[WSe_4]^{2-}$ anion derivatives.[11–13,16–19] The W–Se stretching modes of the clusters can be identified as sharp peaks in the low-wavenumber region below 400 $cm^{-1}$.[11,20,28] The terminal W–$Se_t$ absorptions at 316 $cm^{-1}$ for **2a** and 319 $cm^{-1}$ for **2b** appear at higher wavenumber than the ν(W–Se) absorption (305 $cm^{-1}$ in the $[WSe_4]^{2-}$ anion).[1] The bridging W–Se vibrations are observed in the range 285–300 $cm^{-1}$, at lower wavenumbers relative to that of $[WSe_4]^{2-}$.[1] The strong absorption at 2011 $cm^{-1}$ in the IR spectrum of **2b** may be attributed to the C≡N stretching vibration of the co-crystallization acetonitrile solvent. The electronic absorption spectrum of each cluster shows several intense bands in the UV region with weaker bands in the visible region (see Figure 1). These bands are not of the d-d type but probably arise from ligand-to-metal charge transfer. Band assignments for heterometallic selenium complexes containing the $[WSe_4]^{2-}$ anion have been reported in the literature.[11–19,28,29] The patterns for both the intense and weaker bands can be assigned to the internal Se-to-W charge-transfer transition of the $[WSe_4]^{2-}$ moiety and a relatively weak ligand $[WSe_4]^{2-}$-to-copper interaction, respectively. It is interesting to note that the $[WSe_4]^{2-}\rightarrow$Cu charge-transfer transition peaks at 470–478 nm in the present clusters are blueshifted by around 20 nm with respect to the $[WSe_4]^{2-}\rightarrow$Ag charge-transfer transition peaks (450–460 nm) in the argentoselenotungstate clusters, while the



Scheme 2. dppx = dppm for **3a** and dppa for **3b**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Se→W charge-transfer peaks at 310–325 nm are less influenced by the different coinage metals in the heteroselenotungstate clusters containing phosphane ligands.[11,18]

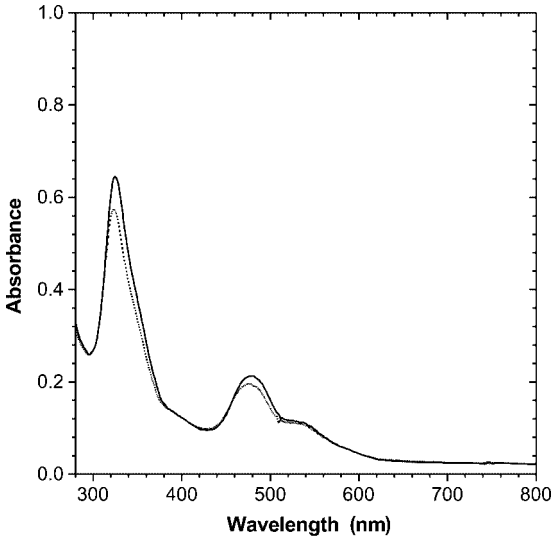


Figure 1. Electronic absorption (UV/Vis) spectra of **2a** (dash) and **2b** (solid), both as $2.75 \times 10^{-4}$ M $CH_2Cl_2$ solutions. The optical path is 1 cm.

The $^{31}P\{^1H\}$ NMR spectrum of **2a** shows two singlets at $\delta$ = 6.34 and 9.16 ppm, which suggests that there are two magnetically inequivalent phosphorus atoms in the open butterfly cluster. Similarly, two singlets at $\delta$ = 41.6 and 47.2 ppm in the $^{31}P$ NMR spectrum of **2b** may be ascribed to the two phosphorus atoms with different coordination environments. Two $^{31}P$ signals at $\delta$ = 2.57 and –142.5 ppm for **3a** are assigned to the phosphorus atoms of the dppm ligand and $[PF_6]^-$ anion, respectively. Similar $^{31}P$ signals at $\delta$ = 34.3 and –141.2 ppm are observed in the $^{31}P$ NMR spectrum of **3b**. The $FAB^+$ mass spectra of compounds **2** and **3** exhibit molecular ions corresponding to $[M^+ + 1]$ and $[M^+ - 2\ [PF_6]^-]$, respectively, with the appropriate isotopic distribution patterns.

## Crystal Structures

The structure of **1b**·0.5$CH_2Cl_2$ comprises a well-separated cation and anion along with the lattice solvent. The molecular structure of the $[Cu_3(\mu_3\text{-}Cl)_2(\mu\text{-}dppa)_3]^+$ cation in **1b** is illustrated in Figure 2, and selected bond lengths and angles are listed in Table 1. Similar to the structures of $[Cu_3(\mu_3\text{-}X)_2(\mu\text{-}dppm)_3]^+$ (X = Cl, Br, I),[22–24] two chloride ions cap the triangle from both sides to form a $[Cu_3Cl_2]$ trigonal bipyramid. Each dppa bidentate ligand bridges one Cu···Cu edge to give a roughly planar $[Cu_3P_6]$ structure. The average distance between two copper atoms in **1b**·0.5$CH_2Cl_2$ [2.988(2) Å] is slightly shorter than those observed in $[Cu_3(\mu_3\text{-}X)_2(\mu\text{-}dppm)_3]^+$ [X = Cl 3.210(4),[22] Br 3.081(3),[23] I 3.214(2) Å[24]], possibly due to the relatively stronger phosphorus σ-donor of dppa (amide) vs. dppm (methane).[25]

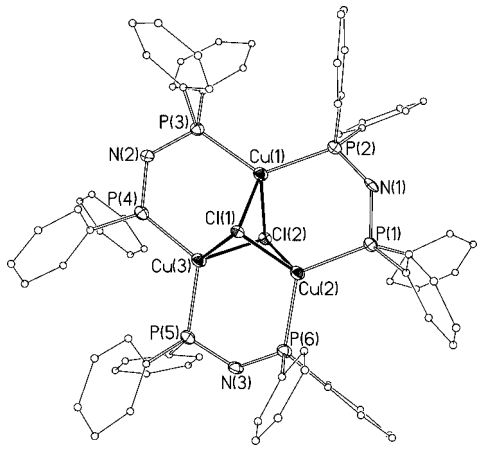

Figure 2. Molecular structure of the $[Cu_3(\mu_3\text{-}Cl)_2(\mu\text{-}dppa)_3]^+$ cation in **1b**.

The structures of **2a** and **2b**·$CH_3CN$ were also determined by X-ray diffraction. The molecular structures of **2a** and **2b** are shown in Figures 3 and 4, respectively, and selected bond lengths and angles are listed in Tables 2 and 3, respectively. The structural frameworks in both neutral compounds **2a** and **2b** have an open butterfly configuration. The structures of **2a** and **2b**·$CH_3CN$ consist of trigonal $[Cu_3(\mu\text{-}I)(\mu\text{-}dppm)_2]^{2+}$ and $[Cu_3(\mu\text{-}Cl)(\mu\text{-}dppa)_2]^{2+}$ fragments, respectively, that are bound to a tetrahedral $[WSe_4]^{2-}$ moiety. The coordination geometry of the W atom in **2a** or **2b** remains nearly tetrahedral with the Se–W–Se angles ranging from 107.10(12)° to 114.60(15)° in **2a** and from 108.05(8)° to 110.92(10)° in **2b**. The W–Se bond lengths fall into three categories: the W–$Se_t$, W–μ-Se, and W–$\mu_3$-Se bond lengths are 2.254(3), 2.310(3) (av.), and 2.479(3) Å, respectively, in **2a** [2.251(3), 2.325(3) (av.), and 2.429(2) Å, respectively, in **2b**]. There are three different types of copper atoms in **2**: one has a tetrahedral geometry (bonded to two selenium atoms, one halide ion, and one phosphorus atom) and the other two have a trigonal-planar geometry (one is bonded to two selenium atoms and one

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phosphorus atom, and the other to two phosphorus atoms and one halide ion). The Cu–Se distances in **2** are slightly influenced by the coordination modes of Se and Cu. For example, the Cu–Se distances involving μ-Se and three-coordinate Cu, μ-Se and four-coordinate Cu, $\mu_3$-Se and three-coordinate Cu, and $\mu_3$-Se and four-coordinate Cu are 2.369(4), 2.391(4), 2.396(4), and 2.430(4) Å, respectively, in **2a**. A similar situation is observed in **2b** (see Table 3). The Cu(3)–Se(3) bond in **2a** [2.702(4) Å] and the Cu(3)–Se(4) bond in **2b** [2.742(2) Å] are much longer than those observed in related systems such as $[Cu_4(dppm)_4(\mu_4\text{-Se})][PF_6]_2$ [Cu–$\mu_4$-Se: 2.384(3)–2.387(3) Å][30] and $[Cu_8(\mu_8\text{-Se})\{Se_2P(OiPr)_2\}_6]$ [Cu–$\mu_8$-Se: 2.539(3)–2.624(3) Å],[31] which is indicative of no bonding between the $\mu_3$-Se and $Cu(XP_2)$ moieties. The W···Cu separations for the three-coordinate copper atom [2.718(3) Å in **2a** and 2.698(3) Å in **2b**] are obviously shorter than those for their four-coordinate counterparts [2.779(4) Å in **2a** and 2.780(3) Å in **2b**]. The Cu(1)···Cu(3)···Cu(2) angles of 66.62(11)° in **2a** and 69.30(8)° in **2b** are more obtuse than those in **1a** [60.36(2)°] and **1b** [61.91(5)°], respectively; such an enlargement of the trigonal $Cu_3$ angles is due to the coordination of $[Cu_3(\mu\text{-}X)(\mu\text{-}L)_2]^{2+}$ species to the $[WSe_4]^{2-}$ anion. Accordingly, the Cu(1)···Cu(3) separations bridged by the halide ion [2.763(4) Å in **2a** and 2.795(3) Å in **2b**] are much shorter than those in **1a** [3.214(2) Å][24] and **1b** [2.988(2) Å], which is suggestive of weak metal–metal interactions between the $[Cu_2(\mu\text{-}X)]$ moieties of the present clusters. The Cu(1)–I(1)–Cu(3) bond angle in **2a** [61.23(10)°] is more acute than the Cu(1)–Cl(1)–Cu(3) bond angle in **2b** [68.95(10)°], whereas the average Cu–I bond in **2a** [2.709(3) Å] is longer than the average Cu–Cl bond in **2b** [2.465(3) Å].

The structure of the $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppm)_4]^{2+}$ cluster cation in **3a** is shown in Figure 5, and selected bond lengths and angles are listed in Table 4. Similar core structures have been found previously in pentanuclear clusters with a coplanar $WCu_4$ core, such as the anionic cluster $[Et_4N]_2[(\mu_4\text{-}WSe_4)(CuS_2CNMe_2)_4]$,[32] the neutral cluster $[(\mu_4\text{-}WSe_4)Cu_4Cl_6(py)_4]$[33] (py = pyridine), and the cationic cluster $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppm)_4][ClO_4]_2$.[27] The W atom is at the center of a slightly distorted tetrahedral $WSe_4$ unit with an average W–Se bond length of 2.347(1) Å and Se–W–Se angles in the range 105.44(3)–111.85(3)°. Four copper atoms are almost symmetrically bound to the four $WSe_2$ edges of the tetrahedral $[WSe_4]^{2-}$ anion. Four distorted chair-type six-membered $CP_2Cu_2Se$ rings around the $[WSe_4]^{2-}$ anion enhance the structural stability of the cationic cluster **3a**. The five metal atoms in the $WCu_4$ core are nearly coplanar with deviations of not more than 0.01 Å from the least-squares plane. The average W–Cu distance of 2.820(1) Å in **3a** is similar to those in $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppm)_4][ClO_4]_2$ [2.815(2) Å][27] and $(\mu_2\text{-}WSe_4)[Cu(PMe_2Ph)_2]_2$ [2.873(2) Å], which contain σ-donor phosphane ligands,[11] but clearly longer than those in $[Et_4N]_2[(\mu_3\text{-}WSe_4)(CuS_2CNEt_2)_3]$ [av. 2.737(2) Å] and $[Et_4N]_2[(\mu_4\text{-}WSe_4)(CuS_2CNMe_2)_4]$ [av. 2.707(2) Å], which contain π-conjugated dithiocarbamate ligands.[32]

## NLO Properties

The nonlinear absorption component of cluster compounds **2a** and **3a** was evaluated by a *z*-scan experiment in an open-aperture configuration (see Figure 6). Although the detailed mechanism is still not clear, it is interesting to note that the NLO absorption data obtained under the conditions used in this study can be well described by Equations (1) and (2), which describe a third-order NLO process, where $\alpha_0$ and $\alpha_2^{eff}$ are the linear and effective third-order NLO absorptivities, respectively.[34,35]

$$T(Z) = \{1/[\pi^{1/2}q(Z)]\}\int_{-\infty}^{\infty}\ln[1 + q(Z)]e^{-\tau^2}d\tau \quad (1)$$

$$q(Z) = \alpha_2^{eff}I_0[(1 - e^{-\alpha_0 L})/\alpha_0] \quad (2)$$

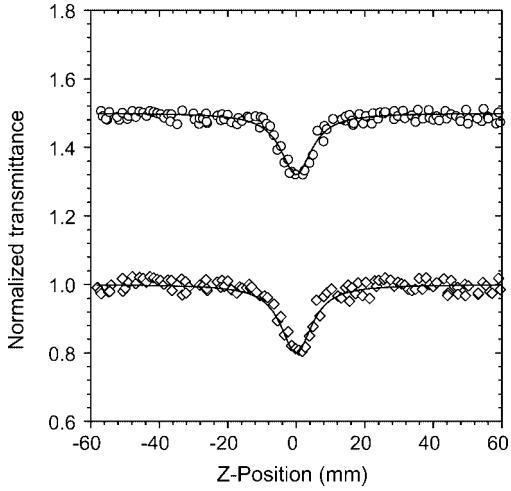

Figure 6. *z*-Scan data of cluster compounds **2a** (circle) and **3a** (diamond) in $2.75 \times 10^{-4}$ M $CH_2Cl_2$ solution. The data were collected in an open-aperture configuration. The solid curves are fits based on theoretical calculations.

The best fit of the theoretical curve (the solid curve in Figure 6) to the experimental data clearly illustrates that the absorption increases as the incident light irradiance arises, which is characteristic of a reverse saturable absorption (RSA) process.[34] The origin of the observed RSA in cluster

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compounds **2a** and **3a** can be attributed to excited-state absorption. Figure 7 shows the *z*-scan data measured with the aperture and indicates that the two cluster compounds **2a** and **3a** have a negative sign for the refractive nonlinearity, which gives rise to self-defocusing. The measurements confirm that the observed NLO effects are effectively third-order in nature, which implies that both the absorption coefficient and refractive index should be expressed as $\alpha = \alpha_0 + \alpha_2 I$ and $n = n_0 + n_2 I$, respectively, where $\alpha_0$ and $\alpha_2$ are the linear and nonlinear absorption coefficients and $n_0$ and $n_2$ are the linear and nonlinear refractive indices, respectively, and $I$ is the irradiance of the laser beam within the sample. By applying the *z*-scan theory, the solid curves in Figures 6 and 7 can be fitted to the experimental data. The best fits reveal that $\alpha_2 = 1.74 \times 10^{-6}\ m\,W^{-1}\,M^{-1}$ and $n_2 = -5.32 \times 10^{-13}\ m^2\,W^{-1}\,M^{-1}$ for cluster **2a**, and $\alpha_2 = 2.56 \times 10^{-6}\ m\,W^{-1}\,M^{-1}$ and $n_2 = -1.54 \times 10^{-12}\ m^2\,W^{-1}\,M^{-1}$ for cluster **3a**.

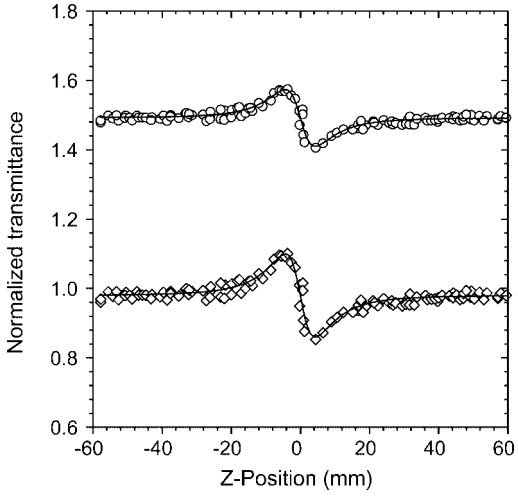

Figure 7. *z*-Scan data of cluster compounds **2a** (circle) and **3a** (diamond) in $2.75 \times 10^{-4}$ M $CH_2Cl_2$ solution. The data were obtained by dividing the normalized *z*-scan data obtained in a closed-aperture configuration by the normalized *z*-scan data obtained in an open-aperture configuration. The solid curves are fits based on theoretical calculations.

The optical limiting effects of cluster compounds **2a** and **3a** are depicted in Figure 8. At very low fluences, they respond linearly to the incident light and therefore obey Beer's law. Deviation from the linear response takes place when the incident fluence reaches about 0.35 $J\,cm^{-2}$ for **2a** and 0.12 $J\,cm^{-2}$ for **3a**. The cluster materials become increasingly less transparent as the light fluence rises. Experiments with the solvents alone showed no detectable optical limiting effect. These observations indicate that solvent contributions are negligible. The limiting threshold, which is defined as the incident fluence at which the actual transmittance falls to 55% of the corresponding linear transmittance, was found to be 1.2 $J\,cm^{-2}$ for **2a** and 0.4 $J\,cm^{-2}$ for **3a**. Cluster **2a**, which has a butterfly configuration, therefore has a higher threshold than that of cluster **3a**, which has an open co-planar $WCu_4$ core, an obvious indication of the influence of structural types on the non-linear optical properties. The butterfly-shaped clusters have two different types of coordinated selenium atoms, therefore the electronic interactions between μ-Se- and $\mu_3$-Se-bridged metal atoms may result in different electron delocalization in the cluster molecule, which needs a higher pump energy to generate the plasma and further leads to degradation of the limiting effect.[36] Similar to the butterfly-shaped clusters, the clusters of other structural types, including incomplete cubane-like, T-frame, and nest-shapes with non-equivalent bridging selenium or sulfur atoms, have lower optical limiting effects.[32,37,38] Previous reports have shown that cluster compounds with an open co-planar cross $MCu_4$ (M = Mo, W) core, for example the neutral clusters $[(\mu_4\text{-}MS_4)Cu_4(SCN)_2(py)_6]$ (0.3 $J\,cm^{-2}$)[39] and $[(\mu_4\text{-}MS_4)Cu_4(CN)_2(py)_6]$ (0.1 $J\,cm^{-2}$),[40] the anionic clusters $[\{Et_4N\}_2\{(\mu_4\text{-}MS_4)Cu_4(CN)_4\}]_n$ (0.2 $J\,cm^{-2}$)[41] and $[\{Et_4N\}_2\{(\mu_4\text{-}WSe_4)Cu_4(CN)_4\}]_n$ (0.3 $J\,cm^{-2}$),[18] and the cationic clusters $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppm)_4][ClO_4]_2$ (0.35 $J\,cm^{-2}$), have a large optical limiting effect.[27] These clusters have four equivalent $\mu_4$-Se atoms, therefore the plasma in the polarized nanosecond pulses may be generated at a lower pump energy, and lower limiting thresholds are therefore found for this class of clusters.[42] The lower limiting threshold of cluster compound **3a** (0.40 $J\,cm^{-2}$) may provide effective proof for this class of clusters that possess an open co-planar structure.

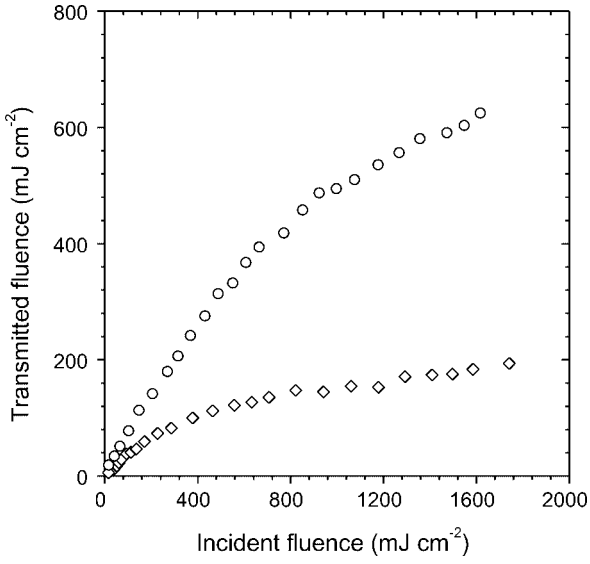

Figure 8. Optical limiting effect of cluster compounds **2a** (circle) and **3a** (diamond) in $2.75 \times 10^{-3}$ M $CH_2Cl_2$ solution.

## Conclusion

We have investigated the reaction of the anion $[WSe_4]^{2-}$ with copper(I) species in the presence of bridging phosphane ligands dppm and dppa and have isolated two types of heterometallic selenium cluster compounds, namely tetranuclear, butterfly-like $[(\mu_3\text{-}WSe_4)Cu_3(\mu\text{-}X)(\mu\text{-}L)_2]$ and pentanuclear, open co-planar $[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}L)_4][PF_6]_2$ (X = Cl, I; L = dppm, dppa). The open co-planar cluster with a $WCu_4$ core structure has a relatively large optical

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

limiting effect and therefore may be considered as a promising candidate for a nonlinear optical limiting cluster material. We are currently investigating the design and synthesis of new heterometallic selenium clusters with strong NLO properties.

## Experimental Section

**General:** All reactions were performed using Schlenk techniques under nitrogen. $[Et_4N]_2[WSe_4]$[43] and $[Cu_3(\mu_3\text{-}I)_2(\mu\text{-}dppm)_3]I$[24] (**1a**) were prepared according to literature methods. $[Cu(MeCN)_4][PF_6]$ was synthesized by the reaction of $Cu_2O$ powder with $HPF_6$ in acetonitrile.[44] Bis(diphenylphosphanyl)amine (dppa) was synthesized by the reaction of $Ph_2PCl$ with $(Me_3Si)NH(SiMe_3)$ in toluene.[45] CuI and bis(diphenylphosphanyl)methane (dppm) were purchased from Aldrich Ltd. and used without further purification. IR spectra were recorded with a Digilab FTS-40 spectrophotometer. Electronic spectra were recorded with a Hitachi U-3410 spectrophotometer. NMR spectra were recorded with a Bruker ALX 300 spectrometer operating at 300 and 121.5 MHz for $^1H$ and $^{31}P$, respectively; chemical shifts ($\delta$ in ppm) are quoted relative to $SiMe_4$ ($^1H$) and $H_3PO_4$ ($^{31}P$). Mass spectra were recorded with a Finnigan TSQ 7000 spectrometer. All elemental analyses were performed with a Perkin–Elmer 2400 CHN analyzer.

**$[Cu_3(\mu_3\text{-}Cl)_2(\mu\text{-}dppa)_3]Cl$ (1b):** A mixture of CuCl powder (150 mg, 0.15 mmol) and dppa (578 mg, 0.15 mmol) in $CH_2Cl_2$ (20 mL) was stirred at room temperature overnight. The resulting colorless solution was filtered and the volume of filtrate was reduced to about 10 mL. Colorless block crystals of $[Cu_3(\mu_3\text{-}Cl)_2(\mu\text{-}dppa)_3]Cl$ (**1b**) were obtained by layering hexane on top of the filtrate at room temperature. Yield: 746 mg (96%). IR (KBr): $\tilde{\nu}$ = 3335 [br ν(N–H)]; 531 (s), 509 (s), 492 (m) [ν(P–C)] $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.05 (br., 3 H, N*H*), 7.21–7.52 (m, 60 H, Ph) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 37.2 (s) ppm. MS (FAB): *m*/*z* = 1414 $[Cu_3(\mu_3\text{-}Cl)_2(\mu\text{-}dppa)_3]^+$, 512 $[[Cu_2(\mu\text{-}dppa)]^+ - 1]$. $C_{72}H_{63}Cl_2Cu_3N_3P_6\cdot 0.5CH_2Cl_2$ (1495.5): calcd. C 58.2, H 4.28, N 2.81; found C 57.7, H 4.15, N, 2.78.

**$[(\mu_3\text{-}WSe_4)Cu_3(\mu\text{-}I)(\mu\text{-}dppm)_2]$ (2a):** A solution of **1a** (346 mg, 0.25 mmol) in $CH_2Cl_2$ (15 mL) was added to a solution of $[Et_4N]_2[WSe_4]$ (152 mg, 0.20 mmol) in dmf (5 mL). After stirring at room temperature for 45 min, the mixture was filtered through a filter paper to provide an orange filtrate. Slow addition of $Et_2O$ resulted in the formation of orange block crystals suitable for single-crystal X-ray diffraction analysis, which were subsequently identified as **2a**. Yield: 183 mg (52%). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 315 ($6.94\times10^{-3}$), 475 ($2.91\times10^{-3}$ $M^{-1}cm^{-1}$) nm. IR (KBr): $\tilde{\nu}$ = 312 (s), 295 (m), 291 (w) [ν(W–Se)] $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.33–7.51 (m, 40 H, Ph), 5.42 (s, 4 H, $CH_2$) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 6.34, 9.16 ppm. MS (FAB): *m*/*z* = 1587 $[M^+ + 1]$. $C_{50}H_{44}Cu_3I_2P_4Se_4W$ (1585.9): calcd. C 37.8, H 2.77; found C 37.3, H 2.76.

**$[(\mu_3\text{-}WSe_4)Cu_3(\mu\text{-}Cl)(\mu\text{-}dppa)_2]$ (2b):** This compound was prepared similarly to **2a** but using **1b** (291 mg, 0.20 mmol) instead of **1a**. It was recrystallized from $CH_2Cl_2$/MeCN/$Et_2O$. Yield: 168 mg (46%). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 318 ($5.63\times10^{-3}$), 472 ($3.04\times10^{-3}$ $M^{-1}cm^{-1}$) nm. IR (KBr): $\tilde{\nu}$ = 311 (s), 298 (m), 292 (w) [ν(W–Se)] $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.84 (br., 2 H, N*H*), 7.23–7.45 (m, 40 H, Ph) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 41.6, 47.2 ppm. MS (FAB): *m*/*z* = 1496 $[M^+ + 1]$. $C_{48}H_{41}ClCu_3N_2P_4Se_4W\cdot CH_3CN$ (1536.5): calcd. C 39.0, H 2.86, N 2.73; found C 38.1, H 2.74, N 2.71.

**$[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppm)_4][PF_6]_2$ (3a):** A mixture of $[Cu(MeCN)_4][PF_6]$ (300 mg, 0.80 mmol) and dppm (320 mg, 0.80 mmol) in $CH_2Cl_2$ (20 mL) was added to a solution of $[Et_4N]_2[WSe_4]$ (152 mg, 0.20 mmol) in dmf (10 mL). After stirring at room temperature for 45 min, the mixture was filtered through a filter paper to provide an orange-red filtrate. Slow addition of $Et_2O$ afforded red block-shaped crystals suitable for a single-crystal X-ray diffraction analysis, which were subsequently identified as **3a**. Yield: 279 mg (73%). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 324 ($6.62\times10^{-3}$), 478 ($3.06\times10^{-3}$ $M^{-1}cm^{-1}$) nm. IR (KBr): $\tilde{\nu}$ = 312 (s), 297 (m), 290 (w) [ν(W–Se)] $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 7.16–7.52 (m, 80 H, Ph), 5.42 (s, 8 H, C*H*$_2$) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 2.57, –142.5 ppm. MS (FAB): *m*/*z* 2291 $[M^+ - 2\ PF_6]$. $C_{100}H_{88}Cu_4F_{12}P_{10}Se_4W$ (2581.3): calcd. C 46.5, H 3.41; found C 46.2, H 3.37.

**$[(\mu_4\text{-}WSe_4)Cu_4(\mu\text{-}dppa)_4][PF_6]_2$ (3b):** This compound was prepared similarly to **3a** but using dppa (320 mg, 0.80 mmol) instead of dppm. It was recrystallized from $CH_2Cl_2$/MeCN/$Et_2O$. Yield: 184 mg (49%). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 319 ($6.82\times10^{-3}$), 473 ($2.75\times10^{-3}$ $M^{-1}cm^{-1}$) nm. IR (KBr): 313 (s), 298 (m), 294 (w) [ν(W–Se)] $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.06 (br., 4 H, N*H*), 7.32–7.57 (m, 80 H, Ph) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 34.3, –141.2 ppm. MS (FAB): *m*/*z* = 2290 $[M^+ - 2\ PF_6]$. $C_{96}H_{84}Cu_4F_{12}N_4P_{10}Se_4W$ (2585.2): calcd. C 44.6, H 3.25, N 2.17; found C 44.2, H 3.18, N 2.13.

**Crystal Structure Determination:** Data for **1b**·$0.5CH_2Cl_2$ were collected at 293 K with a Bruker SMART-CCD area detector diffractometer with a graphite monochromator using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data for **2a**, **2b**·$CH_3CN$, and **3a** were collected at 153 K with a Siemens Stoe-IPDS diffractometer (Mo-$K_\alpha$ radiation; $\lambda$ = 0.71073 Å) equipped with an imaging plate area detector and a rotating anode. The intensities were corrected for Lorentz, polarization, and absorption effects. The structures were solved by direct methods using the SHELXTL software package.[46] The positions of all W, Se, Cu, I (Cl), and P atoms were revealed on the first refinement. Other non-hydrogen atoms were located from subsequent difference Fourier syntheses. The structures were refined by full-matrix least-squares methods on $F^2$. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. Two of the phenyl rings of the dppm ligands in **2b**·$CH_3CN$ were refined with bond-length restraints due to disorder. Further details of the structure analyses are given in Table 5. CCDC-628300 (**1b**·$0.5CH_2Cl_2$), -628301 (**2a**), -628302 (**2b**·$CH_3CN$), and -628303 (**3a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Optical Measurements:** A $CH_2Cl_2$ solution of cluster **2a** or **3a** was placed in a 1-mm quartz cuvette for nonlinear optical measurements, which were performed with linearity polarized 7-ns pulses at 532 nm generated from a Q-switched frequency-doubled Nd:YAG laser. Both clusters are stable toward air and laser light under these conditions. The spatial profiles of the pulsed laser were focused on the sample cell with a 30-cm focal length mirror. The spot radius of the laser beam was measured to be 55 μm (half-width at $1/e^2$ maximum). The incident and transmitted pulse energies were measured simultaneously with two energy detectors (Laser Precision Rjp-735), which were linked to a computer by an IEEE interface.[34,35] The NLO properties of the samples were manifested by moving the samples along the axis of the incident laser irradiance beam (*z*-direction) with respect to the focal point and with the incident laser irradiance kept constant (*z*-scan methods). The closed-aperture curves are normalized to the open-aperture curves. An

# Metal Ion Complementarity: Effect of Ring-Size Variation on the Conformation and Stability of Lead(II) and Cadmium(II) Complexes with Pendant-Armed Crowns

**Martín Regueiro-Figueroa,[a] David Esteban-Gómez,[a] Carlos Platas-Iglesias,[a] Andrés de Blas,*[a] and Teresa Rodríguez-Blas*[a]**

**Keywords:** Lead / Cadmium / Macrocycles / N,O ligands / Density functional calculations

The binding tendencies of the pendant-armed crown ethers $L^1$–$L^3$ [$L^1$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-1,7-diaza-12-crown-4, $L^2$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-1,10-diaza-15-crown-5) and $L^3$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-4,13-diaza-18-crown-6] towards $Pb^{II}$ and $Cd^{II}$ have been investigated. The X-ray crystal structure of $[Cd(L^3)](ClO_4)_2$·EtOH shows that, in the solid state, the $Cd^{II}$ ion is eight-coordinate and fits quite well into the crown hole, favouring an *anti* arrangement of the organic receptor. NMR measurements recorded in acetonitrile solution indicate that increasing the crown size induces a conformational change in the series of $Cd^{II}$ complexes. The conformation goes from a *syn* arrangement for $L^1$ to an *anti* arrangement for $L^3$, passing through a *syn* ⇆ *anti* equilibrium in the complex derived from $L^2$. On the contrary, no conformational change was observed for the corresponding $Pb^{II}$ complexes, which have a *syn* conformation in all cases. These results have been confirmed by means of density functional theory (DFT) calculations performed by using the B3LYP model. The binding constants obtained from UV/Vis titration experiments in DMSO solution demonstrate that a decrease in the crown size provokes a $10^2$-fold enhancement of the stability for this series of $Cd^{II}$ complexes, whereas for $Pb^{II}$ a gradual decrease of the binding constants is observed. Receptor $L^1$ shows a certain degree of selectivity for $Cd^{II}$ over $Pb^{II}$, with a selectivity factor $> 10^2$.

## Introduction

Rational ligand design for selective complexation of metal ions is a field of great interest for chemists. Indeed, selective complexation of metal ions is a condition required for practical applications in many research areas such as the design of ligands as therapeutic reagents for the treatment of metal intoxication, design of antibiotics that owe their antibiotic action to specific metal complexation, design of complexes for imaging agents in the body or design of functional groups for chelating ion-exchange materials, selective metal extractants and metal ion sequestering agents, among others. Some interesting papers and reviews have been written on this subject.[1] Ligand design essentially consists of selecting appropriate donor atoms for the target metal ion and connecting them in an architecture that satisfies the geometric and electronic requirements of the metal ion. Two important concepts must be taken into account for ligand design: preorganization[2] and complementarity.[3] The former may be considered as an entropic effect[4] related to the different conformational states that the ligand can adopt in the free and bound form. Complementarity corresponds to the degree of structural correspondence between the binding sites offered by the ligand structure and the binding sites required by the metal ion. One of the criteria for optimal complementarity is that the metal ion should be able to contact all the donor atoms of the ligand at an optimal metal–donor distance, and therefore the concept of size-match (matching the size of the ligand cavity to the size of the metal ion) must be taken into account in ligand design. Commonly, this has been used as the key concept for the design of complementary ligand architecture; however, many examples have pointed out that when size-match is the sole criterion for the design, the results are often undesired.[1e,5] From the examples given in the literature, it follows that although size-match is a necessary condition for complementarity, it is not sufficient, and that there are other structural factors that must be considered in assessing the degree of metal ion complementarity, in particular the spatial distribution of donor atoms around the metal ion and the orientation of the donor groups.[1e] The application of the complementarity concept is not only restricted to the interaction between a ligand and a given metal ion, but it can also be generalized to any kind of host–guest interaction (i.e. supramolecular assemblies).[6]

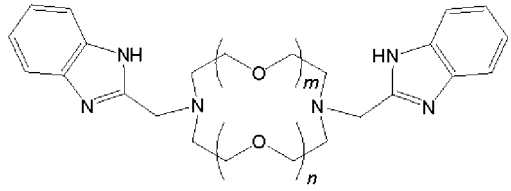
In this paper, we report the binding tendencies of the pendant-armed crown ethers $L^1$–$L^3$ [$L^1$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-1,7-diaza-12-crown-4, $L^2$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-1,10-diaza-15-crown-5) and $L^3$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-4,13-diaza-18-crown-6; see Scheme 1] towards $Pb^{II}$ and $Cd^{II}$. The cyclic framework of crown ethers affords an interesting platform for the complexation of metal ions, and they have been commonly used for studying metal ion complementarity. On the other hand, $Pb^{II}$ and $Cd^{II}$ have been selected by taking into account their ionic radius and particular coordination properties. $Pb^{II}$ exhibits the "inert pair effect" and has variable coordination numbers and geometries.[7] The so-called "inert pair effect" refers to the resistance of the pair of outer electrons on $Pb^{II}$ to removal or to participation in covalent bond formation, and it has been explained as a relativistic effect causing the 6s orbital to contract, thereby increasing the energy required to remove or interact with the 6s lone pair of electrons. Likewise, $Cd^{II}$ is capable of considerable plasticity in the lengths of its bonds, and recently Hancock et al.[5] have proved that this metal ion shows an unusual ability to complex almost equally strongly with 12-crown-4, 15-crown-5 and 18-crown-6, in spite of the very different metal ion size requirements of these crown ethers. These authors attribute this behaviour to relativistic effects.



$L^1$: *m* = 1, *n* = 1
$L^2$: *m* = 1, *n* = 2
$L^3$: *m* = 2, *n* = 2

Scheme 1.

## Results and Discussion

### Synthesis and Characterization of Complexes

The reaction of receptors $L^1$, $L^2$ or $L^3$ (Scheme 1) with $Cd^{II}$ or $Pb^{II}$ perchlorates in absolute ethanol or acetonitrile led to compounds of formula $[Cd(L^1)](ClO_4)_2 \cdot EtOH$ (**1**), $[Pb(L^1)](ClO_4)_2 \cdot 2H_2O$ (**2**), $[Cd(L^2)](ClO_4)_2 \cdot CH_3CN \cdot EtOH$ (**3**), $[Pb(L^2)](ClO_4)_2$ (**4**), $[Cd(L^3)](ClO_4)_2 \cdot EtOH$ (**5**) and $[Pb(L^3)](ClO_4)_2 \cdot EtOH$ (**6**) in good yields (66–76%). The IR spectra (KBr disks) show bands at ca. 1540 and 1120 $cm^{-1}$ due to the ν(C=C) and ν(C–O) stretching frequencies of the benzimidazole and ether groups, respectively. These bands are shifted by 10–15 $cm^{-1}$ to higher wavenumbers with respect to their position in the spectra of the free receptors. The spectra also show absorption bands at ca. 1090 and 625 $cm^{-1}$ attributable to the asymmetric $\nu_{as}$(Cl–O) stretching and $\delta_{as}$(O–Cl–O) bending modes of the perchlorate groups. These bands appear without splitting, as befit uncoordinated anions. The FAB mass spectra of each complex shows intense peaks corresponding to the fragments $[M(L^n)(ClO_4)]^+$ and $[M(L^n–H)]^+$ ($L^n$ = $L^1$, $L^2$ or $L^3$), which confirms the formation of the complexes. Conductivity measurements were carried out in ca. $10^{-3}$ M acetonitrile solutions at 20 °C. The molar conductivity values revealed that all complexes behave as 2:1 electrolytes in this solvent.[8]

### X-ray Crystal Structures

The structure of the uncoordinated receptor $L^1$ was determined by X-ray diffraction analysis. The receptor crystallizes in the $P2_1/n$ monoclinic space group. The arms of the lariat ether are arranged on the same side of the crown moiety, resulting in a *syn* conformation (Figure 1), with the lone pairs of both pivotal nitrogen atoms directed into the receptor cavity in an *endo-endo* arrangement. The conformation of the receptor is conditioned by two strong intramolecular hydrogen-bonding interactions between the NH groups of the benzimidazole subunits and the oxygen atoms of the crown moiety [N2···O1 2.936(3) Å, N2···H2 0.88(2) Å, O1···H2 2.07(3) Å, N2–H2–O1 166(2)°; N6···O2 2.911(2) Å, N6···H6 0.91(2) Å, O2···H6 2.02(2) Å, N6–H6–O2 = 166(2)°]. The *syn* conformation brings the two benzimidazole units close together, so that intramolecular π–π interactions are possible.[9–11] The distance between the centres of the two rings is 3.681 Å, while the C5–C19 distance amounts to 3.371(3) Å, and the angle between the least-squares planes of the two benzimidazole units is 13.77(7)°.

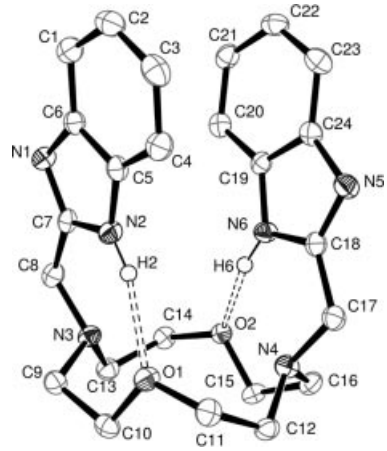


Figure 1. X-ray crystal structure of receptor $L^1$ with atom labelling; hydrogen atoms are omitted for simplicity; the ORTEP plot is drawn at the 50% probability level.

The solid-state structure of compound **5** was also determined by single-crystal X-ray diffraction analysis. Crystals contain the cation $[Cd(L^3)]^{2+}$, two perchlorate anions and one ethanol molecule. The compound crystallizes in the centrosymmetric $P2_1/c$ monoclinic space group. One of the perchlorate anions and the ethanol molecule are quite disordered: the site occupancy factor is 0.776(5) for the perchlorate group [Cl1A, O10A, O11A, O12A and O13A], and 0.641(9) for the ethanol molecule [O100, C100 and C101].

Table 1 summarizes selected bond lengths of the metal coordination environment, while Figure 2 displays a view of the structure of the cation. The complex cation $[Cd(L^3)]^{2+}$ contains a $CdN_4O_4$ core in which the eight heteroatoms of $L^3$ are coordinated to the metal ion. The organic receptor $L^3$ adopts an *anti* arrangement in which both benzimidazole pendant arms are disposed on opposite sides of the crown moiety. The $Cd^{II}$ ion is asymmetrically placed inside the macrocyclic ring, being closer to the donor atoms O2 and O3 [Cd1–O2: 2.585(2) Å; Cd1–O3: 2.526(2) Å] than to O1 and O4 [Cd1–O1: 2.594(2) Å; Cd1–O4: 2.604(2) Å]. The distances between $Cd^{II}$ and the two pivotal nitrogen atoms differ by ca. 0.1 Å [Cd1–N3: 2.516(3) Å and Cd1–N4: 2.627(3) Å], whereas the distances between $Cd^{II}$ and nitrogen atoms of the benzimidazole groups are similar and fall within the range reported for Cd–N distances in complexes with ligands containing benzimidazole groups.[12,13] On the other hand, the distances between the metal ion and nitrogen pivotal atoms and oxygen atoms of the crown moiety are ca. 0.2 Å longer than those observed in a cadmium(II) cryptate derived from 1,10-diaza-15-crown-5 containing a pyridinyl Schiff base spacer, where the metal ion is seven-coordinate.[14] The Cd–O bond lengths are also ca. 0.2 Å longer than those observed for $Cd^{II}$ complexes of 12-crown-4[15] and 15-crown-5,[16] but similar to those observed for different $Cd^{II}$ complexes of 18-crown-6.[16] These data reflect the ability of $Cd^{II}$ to change Cd–O bond lengths to meet the requirements of crown ethers of different size, which has been attributed to relativistic effects.[5] Relativistic effects lower the energy of the valence shell s orbital next in energy to a filled d orbital in heavy $d^{10}$ metal ions, which leads to a tendency to sp hybridization and the formation of more covalent M–L bonds.[17] In the case of compound **5**, the presence of two axial nitrogen donor atoms of the benzimidazole groups [N1 and N5] causes a distortion toward linear coordination geometry with long equatorial Cd–O bonds.

Table 1. Selected bond lengths [Å] and angles [°] of the metal coordination environment in $[Cd(L^3)]^{2+}$.

The coordination polyhedron around the $Cd^{II}$ ion can be described as a distorted square antiprism composed of two

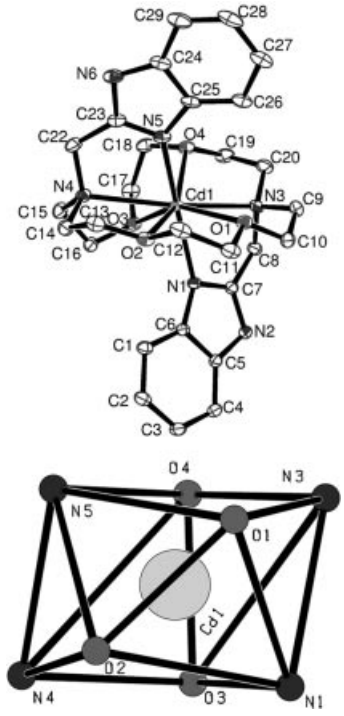

Figure 2. Top: X-ray crystal structure of the cation $[Cd(L^3)]^{2+}$ in compound **5** with atom labelling; hydrogen atoms are omitted for simplicity; the ORTEP plot is drawn at the 30% probability level. Bottom: Coordination polyhedron around $Cd^{II}$ in compound **5**.

parallel pseudoplanes (see Figure 2): O1, O4, N3 and N5 define the upper pseudoplane (mean deviation from planarity 0.0889 Å), while O2, O3, N4 and N1 define the lower pseudoplane (mean deviation from planarity 0.0982 Å). The angle between the two least-squares planes is 9.14°. The mean twist angle, $\omega$,[18] between these nearly parallel squares is 26.0°, showing a deformation of the coordination polyhedron from a square antiprism (ideal value 45°) toward a square prism (ideal value 0°) by ca. 19°.

## Solution Structure

The behaviour of compounds **1** to **6** in [$D_3$]acetonitrile solution was investigated by $^1H$ and $^{13}C$ NMR spectroscopy. The spectra were assigned on the basis of two-dimensional COSY, HSQC and HMBC experiments. Significant changes in the chemical shifts, the structures of the signals and even the number of signals are observed in the $^1H$ NMR spectra upon coordination of the ligands to the metal ions (Tables S1–S3, Supporting Information). The most complicated region of the spectra is the part where the ethylene and methylene proton signals are observed. The coordination to the metal ion increases the rigidity of the ligand, limiting conformational exchange processes, so that the geminal $CH_2$ protons are no longer equivalent. Since assignments to specific axial/equatorial $CH_2$ protons were not possible on the basis of the 2D NMR spectra, they were carried out by using the stereochemical dependence of their shifts on the polarization of the C–H bonds derived from

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the coordination of the metal ion.[19] This polarization results in a deshielding of the equatorial protons, which point away from the metal ion. The aromatic region appears to be usually more clearly resolved for metal ion complexes than for free ligands. This is due to the presence in the latter of exchange processes involving the NH and N positions of the benzimidazole groups that are prevented by coordination to the metal ion.

The $^{13}C$ NMR spectra of **1** and **2** display ten resonances for the 24 proton nuclei present in the ligand backbone, in agreement with an effective $C_{2v}$ symmetry for both complexes in solution. Upon coordination to the metal ion, the signals corresponding to the ethylene and methylene protons shift downfield (Figure 3), confirming the coordination of the ligand in the complexes. The ethylene protons at the five-membered chelate rings formed by the coordination of the ligand to the metal ion give an AA′XX′ spectrum, where the equatorial protons are more deshielded by the electric field effect of the cation (Figure 3). The methylene proton signals of the pendant arms in the $^1H$ NMR spectra of **1** and **2** show satellites attributable to proton coupling to the naturally abundant $^{113}Cd$ ($I$ = 1/2) and $^{207}Pb$ ($I$ = 1/2), respectively, reflecting kinetic inertness in the complexes as well as a degree of covalence in the interaction with the nearby donor atom. So, the signals at $\delta$ = 4.28 ppm for **1** and $\delta$ = 4.51 ppm for **2** appear as a singlet flanked by the satellites, with a $^3J(H_8–^{113}Cd)$ of 9.96 Hz and $^3J(H_8–^{207}Pb)$ of 10.10 Hz. A $^3J(H–^{113}Cd)$ of 8.00 Hz has been reported for the methylene protons of a $Cd^{II}$ complex with a multidentate nitrogen receptor, for which a Cd–N bond length of 2.53 Å was found in the solid state,[20] while $^3J(H–^{207}Pb)$ values of 14.30 and 17.00 Hz have been observed for $[Pb(EDTA–N_4)]^{2+}$, where the Pb–N bond length in the solid state was found to be 2.61 Å.[21]

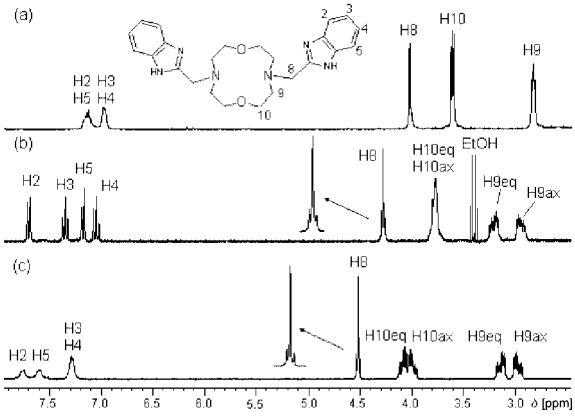

Figure 3. $^1H$ NMR spectra of (a) $L^1$, (b) compound **1** and (c) compound **2** as recorded in [$D_3$]acetonitrile solution at 298 K.

The $^1H$ NMR spectrum of **3** shows two different resonances with different intensities for the NH groups of the benzimidazole subunits, which suggests the presence of two different isomers of **3** in acetonitrile solution. The spectrum recorded at 298 K displays broad resonances for the signals of the aromatic protons, but the signals become better resolved upon decreasing the temperature below 233 K. A detailed analysis of the $^1H$ and $^{13}C$ NMR spectra at this temperature clearly confirms the presence of two complex species in solution that are in equilibrium. The signals corresponding to both species were fully assigned with the aid of two-dimensional COSY, HSQC and HMBC spectra (Table S2, Supporting Information). The $^1H$ NMR spectrum of **3** recorded at 233 K is shown in Figure 4a. The spectrum of the major species shows 26 resonances in the $^{13}C$ NMR spectrum, indicating $C_1$ symmetry in solution, while the minor species shows 13 resonances, which indicates an effective $C_2$ symmetry of the complex where the benzimidazole pendant arms are equivalent. In a previous work, we reported a similar situation for lanthanide complexes with lariat ethers derived from 1,10-diaza-15-crown-5 containing salicylaldimine groups, which show a *syn* conformation with a $C_1$ symmetry.[11] A striking feature of the $^1H$ NMR spectrum of the species with $C_1$ symmetry is the unusually large low-frequency shift found for the signal of the H5′ protons ($\delta$ =6.18 ppm, Figure 4a). Similar shielding effects have been observed in lanthanide complexes with lariat ethers having a *syn* conformation, which have been explained by the observation that these protons are directed toward the aromatic ring current of the neighbouring pendant arm.[22] On this basis, we assign the major species of $[Cd(L^2)]^{2+}$ in solution, which shows $C_1$ symmetry, to a complex with a *syn* arrangement of the pendant arms, while the minor species (with an effective $C_2$ symmetry in solution) is assigned to an *anti* isomer. An equilibrium in solution between the *syn* and *anti* conformations has been previously reported for $Ba^{II}$ complexes with pendant-armed crowns derived from 4,13-diaza-18-crown-6.[23] The smaller $Cd^{II}$ ion fits quite well inside the crown moiety hole of $L^2$, which makes possible an equilibrium between *syn* and *anti* isomers in acetonitrile solution. To confirm this we have performed DFT calculations at the B3LYP level on the $[Cd(L^2)]^{2+}$ system. Our calculations provide two minimum-energy conformations for $[Cd(L^2)]^{2+}$, which correspond to the *syn* and *anti* isomers (Figure 5). The calculated geometry for the *syn*

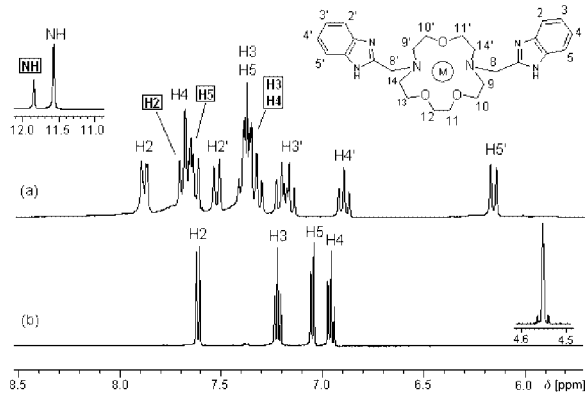

Figure 4. (a) Partial $^1H$ NMR spectrum of compound **3** recorded in [$D_3$]acetonitrile at 233 K. The labels within rectangles correspond to the signals of the *anti* isomer (effective $C_2$ symmetry), while the remaining ones denote signals of the *syn* one ($C_1$ symmetry). (b) Partial $^1H$ NMR spectrum of compound **4** recorded in [$D_3$]acetonitrile at 298 K.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

isomer shows the H5′ proton placed above the plane of the benzimidazole group of the neighbour pendant arm, in agreement with the high-field shift observed for this proton in the NMR spectrum.

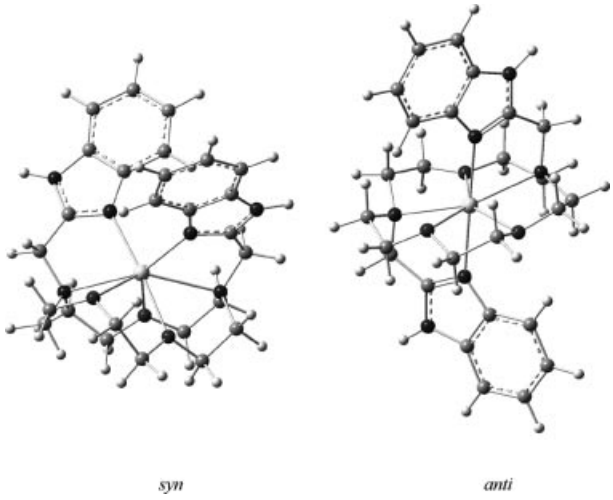

Figure 5. Structures of the two isomers of $[Cd(L^2)]^{+2}$ obtained from DFT calculations at the B3LYP level.

The equilibrium between the *syn* and *anti* isomers of $[Cd(L^2)]^{2+}$ is shown in Equation (1).

$$[Cd(L^2)]^{2+}_{syn} \leftrightarrows [Cd(L^2)]^{2+}_{anti} \quad (1)$$

The equilibrium constant defined by Equation (1), $K_{eq}$, was determined at several temperatures between 233 to 294 K from the relative integrations of the $^1$H NMR signals due to the NH protons of the benzimidazole groups. The ratio between the intensity of the peaks corresponding to the *syn* and *anti* species was found to be constant within experimental error in the range of temperatures studied. This indicates that $\Delta S^0 \approx 0$ for the interconversion process described by Equation (1), in agreement with an intramolecular rearrangement. From the $^1$H NMR in acetonitrile solution, we obtain $K_{eq} = 0.33 \pm 0.02$, pointing out that the *syn* isomer predominates in acetonitrile solution at any temperature.

The $^1$H NMR spectrum of the $Pb^{II}$ derivative **4** (Figure 4b) is clearly more simple than that of the corresponding $Cd^{II}$ analogue. In this case, a single species with an effective $C_s$ symmetry in solution is observed. This is confirmed by the $^{13}$C NMR spectrum, which shows 13 signals for the 26 nuclei of the ligand backbone (Table S2, Supporting information). DFT calculations predict a *syn* conformation for the receptor in the $[Pb(L^2)]^{2+}$ system, where the metal ion is placed over the crown moiety interacting with all the donor atoms present in the receptor (Figure S1, Supporting Information). An identical situation has been observed in complexes with lariat ethers derived from 1,10-diaza-15-crown-5.[14] It may be surprising to observe an effective $C_s$ symmetry for $[Pb(L^2)]^{2+}$ while the analogous $[Cd(L^2)]^{2+}$ *syn* isomer displays a $C_1$ symmetry in solution. This can be explained if one considers the smaller size of $Cd^{II}$ compared to $Pb^{II}$, which allows the two benzimidazole pendants to adopt a face-to-face conformation (Figure 6). In $[Pb(L^2)]^{2+}$ the two pendant arms adopt a more open conformation (see Figure 5 and Figure S1, Supporting Information), which allows an easy interconversion between the two optical isomers ($\Delta$ and $\Lambda$) characteristic of the *syn* conformation.[24] When this interconversion is fast enough on the $^1$H NMR time scale, an effective $C_s$ symmetry in solution is observed (Figure 6).

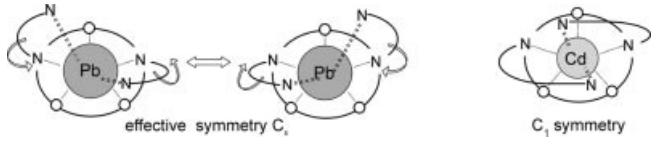

Figure 6. Schematic representation of the different *syn* conformations adopted by lariat ethers derived from 1,10-diaza-15-crown-5 depending on the size of the metal ion.

As observed for the complex of $L^1$, the $^1$H NMR spectrum of $[Pb(L^2)]^{2+}$ shows the singlet due to the H8 protons at $\delta = 4.52$ ppm flanked by satellites with a $^3J(H_8–^{207}Pb)$ of 20.40 Hz (Figure 4b), reflecting a strong interaction between $Pb^{II}$ and the coordinated nitrogen pivot atoms of the receptor. This value is much higher than that observed for the analogous complex derived from $L^1$ (10.10 Hz, vide supra), suggesting that a greater crown size favours a better fit between the $Pb^{II}$ ions and the macrocyclic cavity.

The $^{13}$C NMR spectrum of **5** displays eleven resonances for the 28 carbon nuclei present in the ligand backbone, in agreement with an effective $C_{2h}$ symmetry in solution. This is consistent with an *anti* arrangement of the pendant arms in the complex, as observed in the solid-state structure of this compound described above. In the $^1$H NMR spectra (Figure 7), the signals corresponding to the ethylene protons are again complicated because of the coordination to the metal ion. The signal of the methylene protons of the pendant arms appears as a singlet flanked by the satellites attributable to proton coupling to the naturally abundant $^{113}$Cd ($I = 1/2$) at $\delta = 4.25$ ppm with a $^3J(H_8–^{113}Cd)$ of 7.41 Hz. If we compare this value with that found for **1** (9.96 Hz) we can conclude that, for $Cd^{II}$, increasing the crown size weakens the interaction between the metal ion and the coordinated pivotal nitrogen atoms.

Unlike the $Cd^{II}$ analogue, the $^1$H NMR and the $^{13}$C NMR spectra of the lead(II) complex **6**, (Figure 7b) registered at 233 K are in agreement with an effective $C_2$ symmetry of the complex in solution. The $^1$H-$^1$H COSY spectrum clearly shows a coupling between protons H11 and H12 (see the labelling scheme in Figure 7), which indicates that the $C_2$ axis of the complex is perpendicular to the pseudoplane formed by the donor atoms of the crown moiety. This result indicates a *syn* arrangement of the receptor in the complex.[24] The H8 protons appear as an AB spin system ($^2J_{8a,8b} = 18.40$ Hz) in the spectrum of **6**, while a singlet is observed for the H8 protons in the $Cd^{II}$ analogue **5**. These results are in agreement with a *syn* conformation of the $Pb^{II}$ complex with the pendant arms adopting a face-to-face conformation, as observed for $[Cd(L^2)]^{2+}$.

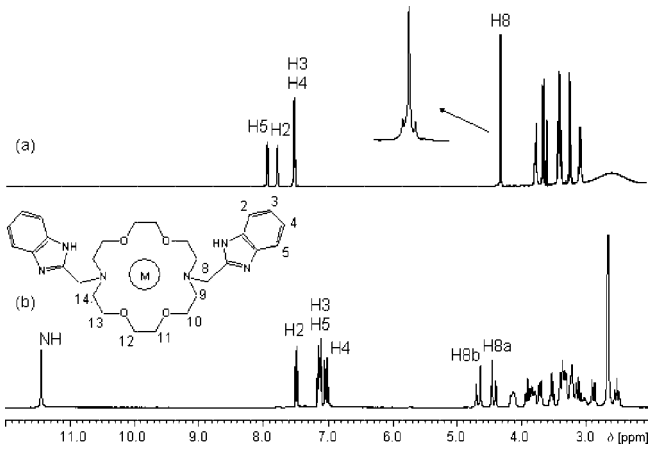

Figure 7. $^1$H NMR spectra of compounds (a) **5** and (b) **6** recorded in [$D_3$]acetonitrile at 298 K.

In order to obtain structural information on this complex in solution we performed geometry optimizations of the $[Pb(L^3)]^{2+}$ system. Our DFT calculations predict two minimum-energy conformations corresponding to a *syn* and an *anti* conformation (Figure S2, Supporting Information). From the conformational energies of the *syn* and *anti* isomers of $[Pb(L^3)]^{2+}$ we have calculated an in vacuo relative free energy, $\Delta G°_{298K} = G°_{anti} - G°_{syn}$, of 3.54 kcal mol$^{-1}$. Likewise, from the results obtained in acetonitrile solution (COSMORS model) we have obtained a relative free energy, $\Delta G^{sol} = G^{sol}_{anti} - G^{sol}_{syn}$, of 4.79 kcal mol$^{-1}$. Thus, our quantum mechanical calculations predict that the *syn* isomer is the most stable one both in vacuo and in solution. These results confirm that the complex adopts a *syn* conformation in solution. This situation contrasts that observed for a related lead(II) complex derived from the same crown moiety and containing aniline pendants, for which an *anti* arrangement of the receptor was found.[25] In that complex, the aniline pendants form six-membered chelate rings upon coordination to the metal ion, which probably favour an *anti* arrangement of the macrocyclic receptor in the complex.

### Stability of the Complexes in Solution

The binding of $Cd^{II}$ and $Pb^{II}$ by the three receptors was investigated by means of spectrophotometric titrations in DMSO solution. The electronic spectra of the free ligands show two typical absorption bands in the near UV attributable to the benzimidazole groups, which can be assigned as $\pi^* \leftarrow \pi$ singlet–singlet transitions[26] ($^1L_a \leftarrow S_0$ and $^1L_b \leftarrow S_0$, where the two excited states are labelled by $^1L_a$ and $^1L_b$ following the suggestion of Platt).[27] Addition of the metal ion salt causes appreciable modification of the spectral patterns. In particular, metal ion addition induces blue shifts of the bands centred at 277 and 284 nm as their intensity increases. These results indicate the coordination of the benzimidazole groups to the metal ion in this solvent. In the course of the titration of $Cd^{II}$ with $L^3$, the development of a weak band centred at ca. 330 nm is also observed. The family of UV/Vis spectra recorded over the course of the titrations of $L^1$ and $L^3$ with $Cd^{II}$ are shown in Figure 8. Nonlinear least-squares analysis of the titration profiles (absorbance against the number of equivalents of $Cd^{II}$, see insets of Figure 8) clearly indicates the formation of 1:1 complexes in every case; the association constants are summarized in Table 2. In all cases, the three ligands form stable complexes with both $Cd^{II}$ and $Pb^{II}$ ($\log K > 5$, Table 2). For $[Cd(L^1)]^{2+}$ the steep curvature of the profile at the addition of 1 equiv. prevents a safe determination of the binding constant, and a lower threshold value of $\log K > 7.5$ can be estimated (Figure 8).

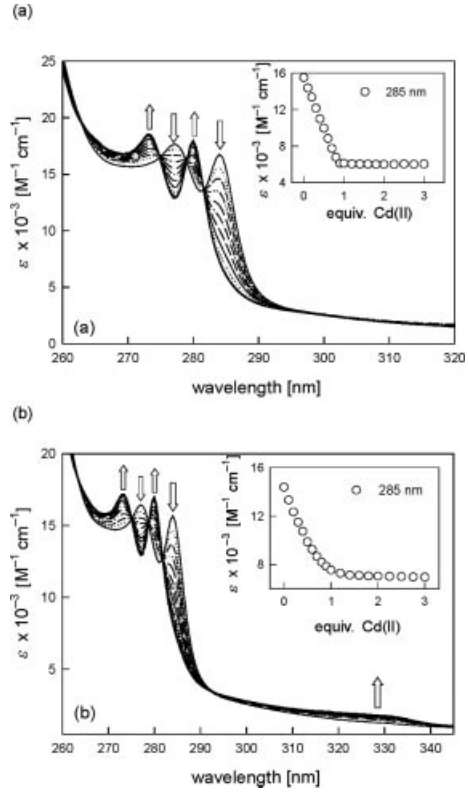

Figure 8. Spectra recorded over the course of the titration of a $10^{-4}$ M solution of (a) $L^1$ and (b) $L^3$ with a standard solution of cadmium(II) perchlorate. Insets: titration profiles at selected wavelengths.

Table 2. Binding constants of the $Cd^{II}$ and $Pb^{II}$ complexes with $L^1$, $L^2$ and $L^3$ obtained from spectrophotometric titrations in DMSO solutions at 25 °C. Log $K$ refers to $L^n + M^{2+} \leftrightarrows [ML^n]^{2+}$.[a]

| Ligand | Ring size | $\log K_{Cd^{II}}$ | $\log K_{Pb^{II}}$ |
|---|---|---|---|
| $L^1$ | 12 | >7.5[b] | 5.65(5) |
| $L^2$ | 15 | 6.23(3) | 6.15(5) |
| $L^3$ | 18 | 5.41(1) | 6.63(9) |

[a] The errors given correspond to one statistical deviation; the experimental errors are estimated to be ±0.2 log $K$ units. [b] The complex is too stable to allow a safe determination of the binding constant.

The log $K$ values obtained show different trends in the binding of $Cd^{II}$ and $Pb^{II}$ on changing the macrocyclic ring size. For $Cd^{II}$, a gradual decrease of the binding constants is observed as the macrocyclic ring size increases, while the $Pb^{II}$ complexes show the opposite behaviour. As a result,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

receptor $L^1$ shows a certain degree of selectivity for $Cd^{II}$ over $Pb^{II}$, with a selectivity factor $> 10^2$. It is interesting to note that the stability of $Cd^{II}$ complexes with crown ethers such as 18-crown-6, 15-crown-5 or 12-crown-4 increases as the macrocyclic cavity is enlarged.[5] Thus, the introduction of pendant arms into the framework of these crown ethers appears to reverse this trend, revealing the complementarity of $L^1$ and $Cd^{II}$.

The binding affinity trend of the above ligand series toward $Pb^{II}$ is probably the result of a better size-match of the ligand for this metal ion as the size of the crown moiety increases. Moreover, $Pb^{II}$ usually prefers higher coordination numbers than $Cd^{II}$, and therefore one expects an increasing stability of the $Pb^{II}$ complexes with this series of ligands as the number of oxygen atoms of the crown moiety increases. The introduction of an oxygen atom into the crown moiety increases the stability of the corresponding $Pb^{II}$ complex by ca. 0.5 $\log K$ units. The $Pb^{II}$ complex of $L^3$ is more stable than the $Cd^{II}$ analogue by ca. 1 $\log K$ units. A similar difference in the $\log K$ values has been previously reported for $Pb^{II}$ and $Cd^{II}$ complexes of a bibracchial lariat ether derived from diaza-18-crown-6 containing 5-chloro-8-methoxyquinoline pendants ($\log K_{Pb}$ = 7.0 and $\log K_{Cd}$ = 6.1 in MeOH).[28] The binding tendencies discussed above for the $Pb^{II}$ and $Cd^{II}$ complexes described in this work parallel the $^3J(H_8–^{113}Cd)$ and $^3J(H_8–^{207}Pb)$ coupling constants observed in the $^1H$ NMR spectra recorded in acetonitrile solution (vide supra), which are related to the strength of the interaction between the cation and the pivotal nitrogen atoms of the ligand.

## Conclusions

The pendant-armed macrocycles $L^1$, $L^2$ and $L^3$ ($L^1$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-1,7-diaza-12-crown-4, $L^2$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-1,10-diaza-15-crown-5) and $L^3$ = *N*,*N*′-bis(benzimidazol-2-ylmethyl)-4,13-diaza-18-crown-6) form mononuclear complexes with both $Cd^{II}$ and $Pb^{II}$. NMR measurements recorded in acetonitrile solution indicate that increasing the crown size induces a conformational change in the series of cadmium(II) complexes that goes from a *syn* arrangement for $L^1$ to an *anti* arrangement for $L^3$, passing through a *syn* ⇆ *anti* equilibrium in the complex derived from $L^2$. The X-ray structure of the $[Cd(L^3)]^{2+}$ complex confirms the *anti* arrangement observed in acetonitrile solution. On the contrary, no conformational change was observed for the corresponding lead(II) complexes, which show a *syn* conformation in all cases. DFT calculations (B3LYP model) support the results of the conformational analyses performed on the basis of the NMR spectroscopic data. The binding constants obtained from UV/Vis titration experiments in DMSO solution indicate that a diminution of the crown moiety size provokes a $> 10^2$-fold enhancement of the stability for this series of $Cd^{II}$ complexes, whereas for $Pb^{II}$ a smooth decrease of the binding constants is observed. Receptor $L^1$ shows a certain degree of selectivity for $Cd^{II}$ over $Pb^{II}$, with a selectivity factor $> 10^2$.

## Experimental Section

**General Considerations:** All chemicals were purchased from commercial sources and used without further purification. Solvents were of reagent grade and were purified by the usual methods. *N*,*N*′-Bis(benzimidazol-2-ylmethyl)-4,13-diaza-18-crown-6 ($L^3$) was prepared according to the literature method.[29] ***Caution!*** Although we have experienced no difficulties with perchlorate salts, these should be regarded as potentially explosive and handled with care.[30]

Elemental analyses were carried out with a Carlo Erba 1108 elemental analyzer. FAB mass spectra were recorded by using a FISONS QUATRO mass spectrometer with Cs ion gun in a 3-nitrobenzyl alcohol matrix. $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker AMX300 or a Bruker WM-500 spectrometer. IR spectra were recorded, as KBr discs, by using a Bruker Vector 22 spectrometer. Conductivity measurements were carried out at 20 °C with a Crison Micro CM 2201 conductimeter by using ca.$10^{-3}$-M solutions of the complexes in acetonitrile. UV/Vis spectra were recorded with a Perkin–Elmer Lambda 900 spectrophotometer, in quartz cells (path length: 1 cm). The cell holder was thermostatted at 25.0 °C with circulating water. Spectrophotometric titrations were performed at 25 °C on $10^{-4}$-M solutions of the ligand in DMSO (polarographic grade). Typically, aliquots of a fresh standard solution of the envisaged perchlorate salt (Pb or Cd, $10^{-2}$ M) were added and the UV/Vis spectra of the samples were recorded. All spectrophotometric titration curves were fitted with the HYPERQUAD program.[31]

**Preparation of the Ligands**

***N*,*N*′-Bis(benzimidazol-2-ylmethyl)-1,7-diaza-12-crown-4 ($L^1$):** 1,7-Diaza-12-crown-4 (1.0 g, 5.7 mmol), *N*,*N*-diisopropylethylamine (4.0 mL, 23.1 mmol) and 2-(chloromethyl)benzimidazole (2.1 g, 12.7 mmol) in acetonitrile (200 mL) were heated under reflux for 12 h and cooled to room temperature. The reaction mixture was concentrated in a rotary evaporator and after being kept at –4 °C for 24 h, a brown precipitate was filtered off and the filtrate was concentrated under vacuum. The resulting yellow oily residue was extracted with $CH_2Cl_2$/water, and the organic phase was dried with anhydrous $MgSO_4$ and concentrated in vacuo. Addition of cold diethyl ether to the oily residue led to the deposition of a light yellow precipitate, which was purified by column chromatography on $Al_2O_3$ with a $CH_2Cl_2$/MeOH 2% mixture as eluent to give a brown solid (1.7229 g, 65%). $C_{24}H_{30}N_6O_2{\cdot}0.5CH_3CN{\cdot}0.5H_2O$ (475.08): calcd. C 64.70, H 7.06, N 19.62; found C 65.32, H 7.83, N 19.36. M.p. 190 °C. $^1H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.90 (t, $^3J_{H,H}$ = 4.6 Hz, 8 H), 3.66 (t, $^3J_{H,H}$ = 4.6 Hz, 8 H), 4.10 (s, 4 H), 7.14–7.08 (m, 4 H), 7.66 (br., 4 H), 11.56 (br., 2 H) ppm. $^{13}C$ NMR (75.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 53.8, 55.4, 69.0, 122.6, 153.8 ppm. MS (FAB): *m*/*z* (%BPI) = 435 (100) $[C_{24}H_{30}N_6O_2]^+$. IR (KBr): $\tilde{\nu}$ = 1623 [ν(C=N)], 1531 [ν(C=C)], 1443 [δ(N–H)], 1428 [$\delta(C–H)_{ar}$], 1355, 1274 [$\delta(C–H)_{crown}$], 1104 [ν(C–O)], [ν(C–N) and ν(C–C)], 744 [π(C–H) and π(N–H)] $cm^{-1}$. Single crystals of $L^1$ suitable for X-ray diffraction were grown by recrystallization from acetonitrile.

***N*,*N*′-Bis(benzimidazol-2-ylmethyl)-1,10-diaza-15-crown-5 ($L^2$):** 1,10-Diaza-15-crown-5 (1.0 g, 4.7 mmol), *N*,*N*-diisopropylethyl amine (3.2 mL, 18.4 mmol) and 2-(chloromethyl)benzimidazole (1.7 g, 10.1 mmol) in acetonitrile (200 mL) were heated under reflux for 12 h and cooled to room temperature. The reaction mixture was concentrated in a rotary evaporator and after being kept at –4 °C overnight, the precipitate formed was filtered and air-dried to give a brown solid (1.2411 g, 52%). $C_{26}H_{34}N_6O_3{\cdot}0.5CH_3CN{\cdot}H_2O$

**Preparation of the Lead(II) and Cadmium(II) Complexes**

**General Procedure:** A stoichiometric amount (1:1) of the corresponding metal salt was added to a stirred solution of ligand (0.100 g) in absolute ethanol or acetonitrile (50 mL). The mixture was vigorously stirred and heated for 4 h, and the resulting pale-yellow solution was filtered while hot. Quantities of reactants, isolation procedures and characterization of the compounds are described below for each compound.

**[Cd(L$^1$)](ClO$_4$)$_2$·EtOH (1):** Solvent: absolute ethanol. Cd(ClO$_4$)$_2$·3H$_2$O (0.096 g, 0.230 mmol). Slow diffusion of diethyl ether into the former solution at room temperature produced pale-yellow crystals that were collected by filtration and air-dried (0.113 g, 62%). $C_{26}H_{36}CdCl_2N_6O_{11}$ (791.91): calcd. C 39.43, H 4.58, N 10.61; found C 39.88, H 4.58, N 10.90. $\Lambda_M$ (acetonitrile) = 264 cm$^2$Ω$^{-1}$mol$^{-1}$ (2:1 electrolyte). MS (FAB): *m/z* (%BPI) = 647 (70) $[Cd(L^1)(ClO_4)]^+$, 547 (100) $[Cd(L^1–H)]^+$. IR (KBr): $\tilde{\nu}$ = 1622 [ν(C=N)], 1542 [ν(C=C)], 1456 [δ(N–H) δ(C–H)$_{ar}$], 1339, 1277 [δ(C–H)$_{crown}$], 1113 [ν(C–O)], 758 [π(C–H)], 1090 [ν$_a$(Cl–O)], 623 [δ$_a$(O–Cl–O)] cm$^{-1}$.

**[Pb(L$^1$)](ClO$_4$)$_2$·2H$_2$O (2):** Solvent: absolute ethanol. Pb(ClO$_4$)$_2$·3H$_2$O (0.106 g, 0.230 mmol). Slow diffusion of diethyl ether into the former solution at room temperature produced pale-yellow crystals that were collected by filtration and air-dried (0.132 g, 66%). $C_{24}H_{34}Cl_2PbN_6O_{12}$ (876.67): calcd. C 32.88, H 3.91, N 9.59; found C 32.80, H 4.13, N 9.54. $\Lambda_M$ (acetonitrile): 276 cm$^2$Ω$^{-1}$mol$^{-1}$ (2:1 electrolyte). MS (FAB): *m/z* (%BPI) = 741 (100) $[Pb(L^1)(ClO_4)]^+$, 641 (85) $[Pb(L^1–H)]^+$. IR (KBr): $\tilde{\nu}$ = 1621 [ν(C=N)], 1536 [ν(C=C)], 1481 [δ(N–H)], 1452 [δ(C–H)$_{ar}$], 1340, 1274 [δ-(C–H)$_{crown}$], 1118 [ν(C–O)], 762 [π(C–H)], 1086 [ν$_a$(Cl–O)], 625 [δ$_a$(O–Cl–O)] cm$^{-1}$.

**[Cd(L$^2$)](ClO$_4$)$_2$·CH$_3$CN·EtOH (3):** Solvent: acetonitrile. Cd(ClO$_4$)$_2$·3H$_2$O (0.109 g, 0.259 mmol). The reaction mixture was concentrated in a rotary evaporator and addition of cold diethyl ether to the residue led to the deposition of a brown precipitate that was filtered and air-dried (0.155 g, 72%). $C_{30}H_{43}CdCl_2N_7O_{12}$ (877.02): calcd. C 41.08, H 4.94, N 11.18; found C 41.73, H 4.95, N 11.20. $\Lambda_M$ (acetonitrile) = 251 cm$^2$Ω$^{-1}$mol$^{-1}$ (2:1 electrolyte). MS (FAB): *m/z* (%BPI) = 691 (15) $[Cd(L^2)(ClO_4)]^+$, 591 (65) $[Cd(L^2–H)]^+$. IR (KBr): $\tilde{\nu}$ = 1622 [ν(C=N)], 1539 [ν(C=C)], 1452 [δ(N–H) δ(C–H)$_{ar}$], 1333, 1273 [δ(C–H)$_{crown}$], 1117 [ν(C–O)], 752 [π(C–H)], 1088 [ν$_a$(Cl–O)], 626 [δ$_a$(O–Cl–O)] cm$^{-1}$.

**[Pb(L$^2$)](ClO$_4$)$_2$ (4):** Solvent: absolute ethanol. Pb(ClO$_4$)$_2$·3H$_2$O (0.108 g, 0.235 mmol). Slow evaporation of the filtrate produced white crystals that were collected by filtration and air-dried (0.145 g, 70%). $C_{26}H_{34}Cl_2PbN_6O_{11}$ (884.69): calcd. C 35.30, H 3.87, N 9.50; found C 35.16, H 4.10, N 9.52. $\Lambda_M$ (acetonitrile): 300 cm$^2$Ω$^{-1}$mol$^{-1}$ (2:1 electrolyte). MS (FAB): *m/z* (%BPI) = 785 (80) $[Pb(L^2)(ClO_4)]^+$, 685 (100) $[Pb(L^2–H)]^+$. IR (KBr): $\tilde{\nu}$ = 1621 [ν(C=N)], 1536 [ν(C=C)], 1452 [δ(N–H) δ(C–H)$_{ar}$], 1337, 1272 [δ(C–H)$_{crown}$], 1121 [ν(C–O)], 752 [π(C–H)], 1090 [ν$_a$(Cl–O)], 621 [δ$_a$(O–Cl–O)] cm$^{-1}$.

**[Cd(L$^3$)](ClO$_4$)$_2$·EtOH (5):** Solvent: absolute ethanol. Cd(ClO$_4$)$_2$·3H$_2$O (0.086 g, 0.191 mmol). Slow evaporation of the filtrate produced pale-brown crystals that were collected by filtration and air-dried (0.107 g, 64%). $C_{30}H_{44}CdCl_2N_6O_{13}$ (880.02): calcd. C 40.94, H 5.04, N 9.55; found C 41.09, H 5.27, N 9.76. $\Lambda_M$ (acetonitrile): 282 cm$^2$Ω$^{-1}$mol$^{-1}$ (2:1 electrolyte). MS (FAB): *m/z* (%BPI) = 735 (20) $[Cd(L^3)(ClO_4)]^+$, 635 (100) $[Cd(L^3–H)]^+$. IR (KBr): $\tilde{\nu}$ = 1624 [ν(C=N)], 1540 [ν(C=C)], 1471 [δ(N–H)], 1453 [δ(C–H)$_{ar}$], 1345, 1269 [δ(C–H)$_{crown}$], 752 [π(C–H)], 1090 [ν$_a$(Cl–O)], 625 [δ$_a$(O–Cl–O)] cm$^{-1}$. Single crystals of formula [Cd(L$^3$)](ClO$_4$)$_2$·EtOH suitable for X-ray diffraction were grown by slow diffusion of diethyl ether into solutions of the complex in acetonitrile.

**[Pb(L$^3$)](ClO$_4$)$_2$·EtOH (6):** Solvent: absolute ethanol. Pb(ClO$_4$)$_2$·3H$_2$O (0.088 g, 0.191 mmol). Slow evaporation of the filtrate produced pale-brown crystals that were collected by filtration and air-dried (0.112 g, 60%). $C_{30}H_{44}Cl_2PbN_6O_{13}$ (974.81): calcd. C 36.96, H 4.55, N 8.62; found C 36.83, H 4.65, N 8.72. $\Lambda_M$ (acetonitrile): 304 cm$^2$Ω$^{-1}$mol$^{-1}$ (2:1 electrolyte). MS (FAB) = *m/z* (%BPI): 829 (50) $[Pb(L^3)(ClO_4)]^+$, 729 (100) $[Pb(L^3–H)]^+$. IR (KBr): $\tilde{\nu}$ = 1621 [ν(C=N)], 1535 [ν(C=C)], 1464 [δ(N–H)], 1448 [δ(C–H)$_{ar}$], 1343, 1270 [δ(C–H)$_{crown}$], 1116 [ν(C–O)], 754 [π(C–H)], 1091 [ν$_a$(Cl–O)], 626 [δ$_a$(O–Cl–O)] cm$^{-1}$.

**Crystal Structure Determination**

Crystal data and details of data collection and refinement are summarized in Table 3. Three-dimensional X-ray data were collected with a Bruker SMART 1000 CCD diffractometer by the *&πη;-ω* scan method. Reflections were measured from a hemisphere of data collected of frames each covering 0.3° in *ω*. Of the 26720 reflections measured for L$^1$ and the 33146 measured for compound **5**, all were corrected for Lorentz and polarization effects and for absorption by semiempirical methods[32] on the basis of symmetry-equivalent and repeated reflections. Of the 4825 independent reflections measured for the receptor L$^1$ and 8645 for compound **5**, 2734 and 7598 reflections, respectively, exceeded the significance level $I > 2\sigma I$. Complex scattering factors were taken from the program SHELX97[33] included in the WinGX program system[34] as implemented on a Pentium® computer. The structure of L$^1$ was solved by direct methods (SHELX97), whereas the structure of **5** was solved by Patterson methods (DIRDIF99).[35] Both structures were refined by full-matrix least-squares methods on $F^2$. The hydrogen

atoms were included in calculated positions and refined by using a riding mode, except for the hydrogen atoms H2 and H6 of $L^1$, which were freely refined. Refinement converged with allowance for thermal anisotropy of all non-hydrogen atoms.

CCDC 623182 and 623183 contain the supplementary crystallographic data for the structures included in this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via http://www.ccdc.cam.ac.uk/datarequest/cif.

**Computational Methods:** The $[M(L^n)]^{2+}$ (M = Cd or Pb, $n$ = 2 or 3) systems were fully optimized in vacuo by using the B3LYP density functional model[36,37] and the Gaussian 03 package (Revision C.01).[38] In these calculations, we used the 6-31G(d) basis set for ligand atoms, while for Cd and Pb the LanL2DZ valence and effective core potential functions were used.[39,40] The stationary points found on the potential energy surfaces as a result of the geometry optimizations have been tested by frequency analysis to represent energy minima rather than saddle points. The relative free energies of the two isomers of $[Pb(L^3)]^{2+}$ were calculated in vacuo at the same computational level, and they include nonpotential energy contributions (that is, zero-point energy and thermal terms) obtained by frequency analysis. Relative free energies of the two isomers of $[Pb(L^3)]^{2+}$ were also calculated in acetonitrile solution (COSMO-RS model).[41] Final free energies include both electrostatic and nonelectrostatic contributions.

**Supporting Information** (see footnote on the first page of this article): Figures S1 and S2 showing the B3LYP optimized structures of the $[Pb(L^2)]^{2+}$ and $[Pb(L^3)]^{2+}$ systems, Tables S1–S3 reporting $^1H$ and $^{13}C$ NMR spectroscopic data of the ligands and $Cd^{II}$ and $Pb^{II}$ complexes and in vacuo optimized Cartesian coordinates [Å] for the $[M(L^2)]^{2+}$ and $[M(L^3)]^{2+}$ systems (M = Cd or Pb).

## Acknowledgments

The authors thank Xunta de Galicia (PGIDIT03TAM10301PR and PGIDIT06TAM10301PR) for generous financial support. The authors are indebted to Centro de Supercomputación of Galicia (CESGA) for providing the computer facilities.

# Hydrolysis of a (2-Propanol)yttrium Triiodide Complex in the Presence of Glymes: Synthesis and X-ray Structures of Hydroxo-Bridged Dinuclear Yttrium Complexes and Their Applications in Materials Science

**Shashank Mishra,*[a] Stéphane Daniele,*[a] Liliane G. Hubert-Pfalzgraf,[a][†] and Erwann Jeanneau[b]**

**Keywords:** Yttrium / Iodine / Glymes / Structure / Dinuclear complexes

The reactions of (2-propanol)yttrium triiodide, $Y(i\text{PrOH})_4I_3$, with stoichiometric amounts of water in the presence of di-, tri-, and tetraglyme yield a facile synthetic route to hydroxo-bridged, centrosymmetric dimeric yttrium complexes. These ionic derivatives, $[Y_2L_2(\mu\text{-}OH)_2(H_2O)_x(ROH)_y]I_4$ [**1**: L = triglyme, x = 2, y = 2, R = *i*Pr; **2**: L = tetraglyme, x = 2, y = 0; **3**·2EtOH: L = diglyme, x = 2, y = 4, R = Et; **4**·2EtOH: L = triglyme, x = 4, y = 0; **5**: L = tetraglyme, x = 2, y = 2, R = Et] have been characterized by elemental analysis, IR and $^1$H NMR spectroscopy, as well as by single-crystal X-ray diffraction for **3**, **4**, and **5**. Preliminary results on the utility of these ionic derivatives as potential sources of yttrium oxide in high $T_c$ superconductors are also presented.

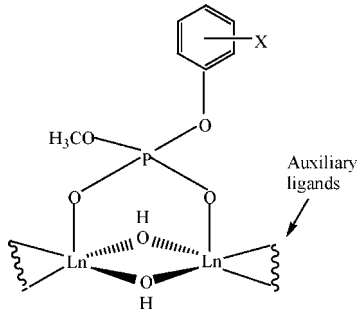
## Introduction

Yttrium triiodide is an attractive alternative to yttrium trifluoroacetate derivatives as a source of yttrium oxide in chemical routes to $YBa_2Cu_3O_{7-x}$ (YBCO) high $T_c$ superconductors, because it does not form corrosive hydrofluoric acid during decomposition.[1] Hydroxo ligands are of interest in yttrium and lanthanide chemistry as reaction sites for condensation to bridged oxides[2] and as nucleophiles in RNA cleavage as well as in the catalytic hydrolysis of phosphate diesters.[3] It is generally accepted that the catalysis of phosphate diester cleavage involves substrate activation by a dinuclear lanthanide core followed by nucleophilic attack by an activated hydroxide (Scheme 1).[3] Hydroxo complexes are also often proposed as intermediates in the degradation pathways of f-element organometallic and coordination compounds.[4] Polynuclear oxo and/or hydroxo complexes of lanthanides with $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$,[5] $[Ln_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(H_2O)_{24}]^{8+}$,[6] or $[Ln_{15}(\mu_3\text{-}OH)_{20}(\mu_5\text{-}X)]^{24+}$[7] (X = halide) cores have been obtained by direct hydrolysis of lanthanide nitrates, perchlorates, or halides (chloride and iodide) in aqueous media. However, the high charge and polarizing power of lanthanides as well as the absence of any organic auxiliary ligands result in a high tendency to readily hydrolyze, thus making it difficult to control oligomerization of rare-earth centers.[8] A common synthetic strategy for controlling the advancement of hydrolysis is to introduce auxiliary ligands such as carboxylates, polyketonates, polyamines, polyols, pyridonates, alkoxides, and amino acids in the metal coordination sphere (ligand-controlled hydrolysis).[9] We have previously reported octa- and nonanuclear oxo-hydroxo yttrium species, namely $[Y_8(\mu_4\text{-}O)_2(\mu_3\text{-}OH)_4(\mu,\eta^2\text{-}AAA)_4(\eta^4\text{-}AAA)_6(\mu\text{-}OEt)_4(\mu_3\text{-}OEt)_2]$[10] and $[Y_9O_2(OH)_8(\mu,\eta^2\text{-}AAA)_8(\eta^2\text{-}AAA)_8]^-$,[11] using allylacetatoacetate $MeCOCH_2COOCH_2CH{=}CH_2$ (HAAA) as an auxiliary ligand.



Scheme 1. A possible mechanism for the activation and cleavage of a phosphate diester substrate by a hydroxo-bridged dinuclear lanthanide species.

Although a few examples of hydroxo-bridged yttrium and lanthanide complexes with chelating ligands exist in the literature (Table 1), they have mostly been obtained from nonaqueous solutions as the result of serendipitous hydrolysis and include N-donor ligands.[12–21] The reaction conditions that lead to hydroxo formation in nonaqueous solvents have rarely been elucidated, and general synthetic pro-

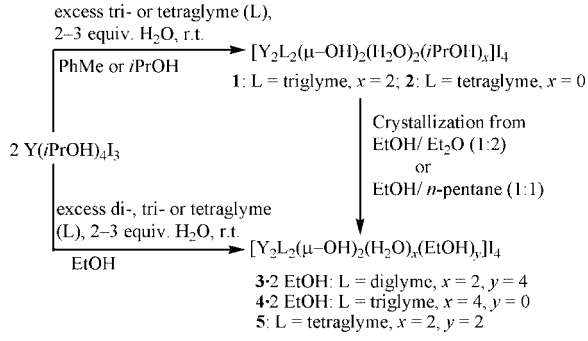
cedures for the preparation of dinuclear hydroxo complexes are lacking. In continuation of our earlier studies on the reactivity of $Y(i\text{PrOH})_4I_3$,[22,23] we wish to report in this manuscript its hydrolytic reactions in the presence of glymes. The obtained compounds **1**–**5** are the first examples of hydroxo-bridged dimeric yttrium (or lanthanide) complexes with an all-oxygen environment (Table 1). These compounds are potentially good starting materials for the synthesis of larger yttrium oxo/hydroxo clusters.[24] In addition, their utility as sources of yttrium oxide for high $T_c$ superconductors has also been evaluated, and the preliminary results are presented in this paper.

## Results and Discussion

The hydrolytic reactions of (2-propanol)yttrium triiodide, $Y(i\text{PrOH})_4I_3$, with stoichiometric amounts of water in the presence of glymes have been evaluated by using different solvents. Reactions of $Y(i\text{PrOH})_4I_3$ in toluene with triglyme or tetraglyme containing two to three equivalents of water proceed with an immediate precipitation of compounds **1** and **2** as yellow solids in good yield. The same compounds were obtained when 2-propanol was used as the reaction medium, though in lower yields because of the moderate solubility of these compounds in 2-propanol. Crystallization of these compounds from an EtOH/*n*-pentane (1:1) or EtOH/$Et_2O$ (1:2) solution gave ethanol-solvated, hydroxo-bridged, ionic dimeric yttrium compounds **3**–**5** (Scheme 2), as established by X-ray crystallography. Similar ethanol-solvated, hydroxo-bridged dinuclear compounds were isolated in better yields by using ethanol as the reaction medium. The stability of a dinuclear $Y_2(OH)_2$ core in complexes **1**–**5** is reflected by the fact that the yttrium/glyme ratio always remained at 1:1 even if glymes were added in excess (up to 2.5 equiv.; IR and $^1H$ NMR evidence), the remaining coordination sites of eight-coordinated yttrium centers being filled by water and/or alcohol molecules.



Scheme 2. Hydrolysis of $Y(i\text{PrOH})_4I_3$ in the presence of glymes.

### Spectroscopic Characterization

The FT-IR spectra of **1**–**5** show the presence of alcohol functionalities as well as glyme ligands in the metal coordination sphere (Table 2). A broad strong IR absorption at 3100–3350 $cm^{-1}$ due to ν(OH) and a weak-to-medium-intensity band at 1600–1630 $cm^{-1}$ due to δ(OH) confirm the presence of the hydroxy functionality in **1**–**5**, the ν(Y–O) frequency appearing as medium-intensity bands in the region 400–700 $cm^{-1}$. The presence of di-, tri-, or tetraglyme is also confirmed by their characteristic IR absorptions. $^1H$ NMR spectra of compounds **1**–**5** at ambient temperature are independent of concentration and are consistent with a single-ligand environment. These spectra show peaks for the polydentate glymes, bridging hydroxy groups, and coordinated water and/or alcohol molecules in the expected

[a] $^1$H NMR spectrum of **3** in $CD_2Cl_2$.

multiplicities and integrated intensity ratios (Table 2). The bridging hydroxo groups exhibit the greatest downfield shifting and appear as a singlet at $\delta$ = 5.40–6.40 ppm for compounds **1**–**4** but as two singlets (1:1) at $\delta$ = 5.23 and 5.35 ppm for compound **5**, probably as a result of some asymmetric interactions with the pendant oxygen atoms O5 and O5$^i$ of the tetraglyme ligands in solution. The signals due to the coordinated water molecules appear as a relatively broad singlet in the region $\delta$ = 4.95–5.50 ppm. The signals of the methylene groups of glyme and coordinated ethanol are well resolved in the spectra of compounds **3** and **5** and show two distinct multiplets ($J$ = 7 Hz) at $\delta$ = 3.85–3.95 and 3.45–3.62 ppm, respectively, while they appear as overlapping multiplets centered at $\delta$ = 3.60 ppm in the spectrum of complex **4**.

It is worth noting that some hydroxo-bridged dinuclear metal complexes have been shown to form dinuclear/mononuclear equilibrium mixtures in solution on the basis of their concentration-dependent NMR spectra.[25,26] The driving force for the formation of monomer units usually involves either the coordination of an additional Lewis base (e.g. $R_3P$) to the metal center[25] or the formation of new, stronger secondary hydrogen-bond interactions with the terminal metal hydroxide moiety.[26] Concentration-independent $^1$H NMR spectra of **1**–**5** suggest that none of above-mentioned driving forces are important in the present case and indicate that the dimeric structure is probably retained upon dissolution.

### Molecular Structures of $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_4(\eta^3\text{-diglyme})_2]I_4\cdot 2EtOH$ (3), $[Y_2(\mu\text{-}OH)_2(H_2O)_4(\eta^4\text{-triglyme})_2]I_4\cdot 2EtOH$ (4), and $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (5)

The selected interatomic bond lengths and angles for compounds **3**, **4**, and **5** are given in Table 3, 4, and 5, respectively, whereas intramolecular hydrogen bond lengths are summarized in Table 6. All three structures are based on a centrosymmetric $Y_2(\mu\text{-}OH)_2$ diamond core (Figure 1). The oxygen atoms of the di-, tri-, or tetraglymes, ethanol and/or water molecules complete the eight-coordinate environment about each yttrium center in **3**–**5**. All iodides act as noncoordinating counteranions. Although all the yttrium centers in **3**–**5** are eight-coordinate, their stereochemistry is different. The geometry around yttrium in the $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_4(\eta^3\text{-diglyme})_2]^{4+}$ cation of (**3**·2EtOH) can best be described as a square antiprism, which is slightly distorted towards dodecahedral geometry (Figure 2).[27]

Table 3. Selected bond lengths and angles for $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_4(\eta^3\text{-diglyme})_2]I_4\cdot 2EtOH$ (**3**).

The tridentate diglyme (O3, O4, and O5) and a water molecule (O7) occupy four adjacent corners of the square antiprism, the remaining sites being occupied by two ethanol molecules (O1 and O2) and the two bridging hydroxides (O6 and O6$^{i}$). The stereochemistry around the yttrium atoms in $[Y_2(\mu\text{-}OH)_2(H_2O)_4(\eta^4\text{-triglyme})_2]I_4\cdot 2EtOH$ (**4**) is slightly distorted dodecahedral (Figure 3).[27] The oxygen atoms of two bridging hydroxides (O5 and O5$^{i}$) and two water molecules (O6 and O7) form four corners of the first trapezoid, whereas the second trapezoid consists of four oxygen atoms, O1, O2, O3, and O4, of a triglyme ligand.

The yttrium centers in the complex $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (**5**) have a bicapped trigonal prismatic geometry.[27] The six corners of the trigonal prism are occupied by the O1, O2, O4 (tetraglyme), O6, O6$^{i}$ (bridging hydroxide), and O8 (ethanol) atoms, whereas O3 (tetraglyme) and O7 (water) atoms occupy the two capping positions (Figure 4).

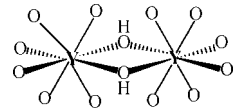

Figure 1. Coordination environment around yttrium centers in complexes **1**–**5**.

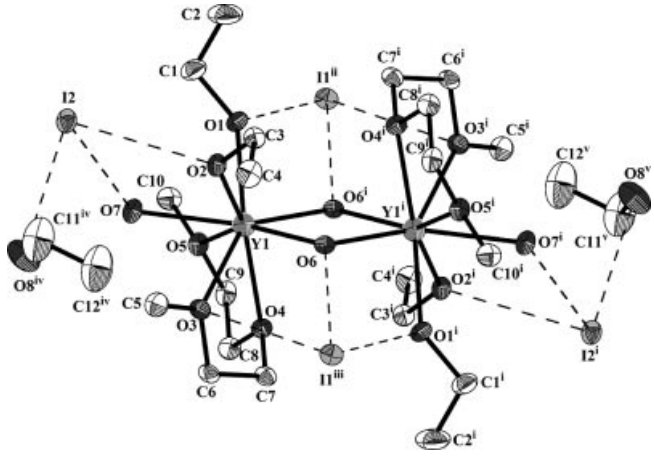

Figure 2. Molecular structure of $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_4(\eta^3\text{-diglyme})_2]I_4\cdot 2EtOH$ (**3**) with 30% ellipsoids. Hydrogen atoms have been omitted for clarity. Intramolecular hydrogen bonds are shown as broken lines (-----). Symmetry codes: (i) $2-x$, $1-y$, $1-z$; (ii) $2-x$, $-y$, $-z$; (iii) $x$, $1+y$, $1+z$; (iv) $1-x$, $1-y$, $-z$; (v) $1+x$, $y$, $1+z$.

Other than the stereochemistry, the structures of **3**–**5** appear to be affected only minimally by the change in the chelating glyme ligand. The average Y–O(glyme) bond lengths, decreasing slightly in the order diglyme (2.46 Å) > triglyme (2.44 Å) > tetraglyme (2.42 Å), are comparable with those in other yttrium complexes with glymes.[28] As expected, the average Y–O(μ-OH) length, 2.24 Å, is shorter than that of terminal Y–O ($H_2O$/EtOH), 2.38 Å. These values are consistent with those in the literature.[3b,12] Overall,

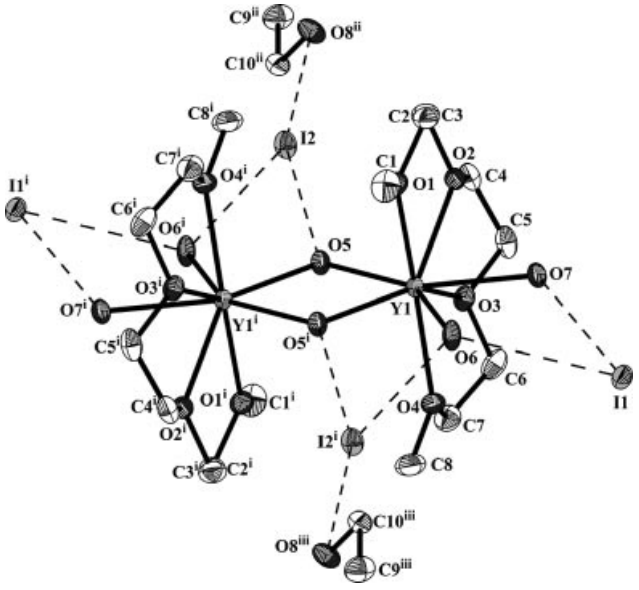

Figure 3. Molecular structure of $[Y_2(\mu\text{-}OH)_2(H_2O)_4(\eta^4\text{-triglyme})_2]I_4\cdot 2EtOH$ (**4**) with 30% ellipsoids. Hydrogen atoms have been omitted for clarity. Intramolecular hydrogen bonds are shown as broken lines (-----). Symmetry codes: (i) $-x, 1-y, 1-z$; (ii) $1-x, 1-y, 2-z$; (iii) $-1+x, y, -1+z$.

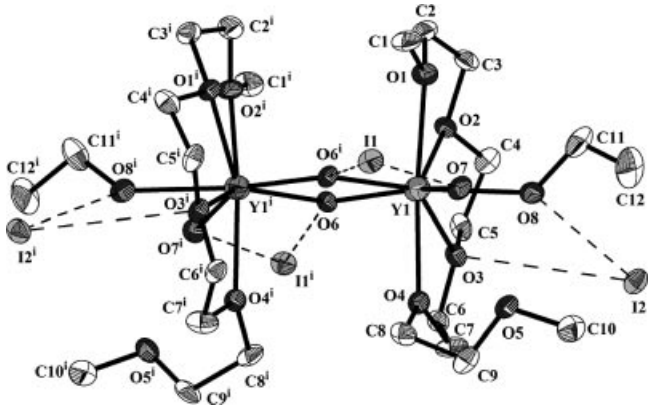

Figure 4. Molecular structure of $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (**5**) with 30% ellipsoids. Hydrogen atoms have been omitted for clarity. Intramolecular hydrogen bonds are shown as broken lines (-----). Symmetry code: (i) $-x, y, 3/2-z$.

the Y–O bond lengths vary from 2.209(7) to 2.500(4) Å, the order of variation being Y–O(μ-OH) < Y–O($H_2O$) ≈ Y–O(EtOH) < Y–O(glyme). The tetraglyme ligands in **5** are coordinated through four of their five oxygen atoms, the oxygen atoms, O5 and O5$^i$, lie too far away [4.116(9) Å] to interact with yttrium atoms (Figure 4). These pendant oxygen atoms, O5 and O5$^i$, are also far from the bridging hydroxide groups [4.811(1) Å]. The potentially pentadentate tetraglyme ligand has previously been shown to bind the metal centers in the $\eta^3$ or $\eta^4$ manner as well, depending upon steric considerations and the nature of metals.[29] The Y···Y distances [3.684(1)–3.719(1) Å] are also comparable with those reported for other hydroxo-bridged dinuclear yttrium complexes.[3b,12] In fact, a perusal of structural data for hydroxo-bridged dinuclear yttrium and lanthanide complexes with O- and N-donor ligands (Table 1) reveals that, despite differences in coordination number (7, 8, or 9), coordinating atoms (O and N), or central lanthanide atoms among these complexes, the dimensions of the $Ln_2(\mu\text{-}OH)_2$ diamond core vary little, as indicated by the small range of Ln···Ln [3.608(1)–3.988(1) Å] and Ln–μ-OH [2.19(1)–2.421(2) Å] distances as well as Ln–O–Ln angles [110.2(2)–112.7(3)°]. One additional feature of the $Y_2(\mu\text{-}OH)_2$ diamond core in the structures reported here is the presence of intramolecular hydrogen bonds between iodide anions and bridging hydroxide groups and coordinated water/ethanol molecules; the I···O distances vary in the range 3.412(8)–3.934(8) Å (Table 6). These distances are in agreement with those reported for hydrogen bonding involving iodides.[23]

### $YBa_2Cu_3O_{7-x}$ (YBCO) Powder from $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (5), $[Ba(tetraglyme)_2]I_2\cdot C_7H_8$, and CuI by Metal Organic Decomposition (MOD)

Iodides of yttrium, barium, and copper have been shown to be among the most attractive precursors for the formation of YBCO, since they do not form stable $BaCO_3$ during the decomposition.[1,30] However, formation of ionic Y-Cu clusters was recently reported by us from an all-iodide solution in DMF and 2-isopropoxyethanol.[23] This results in an inhomogeneous solution, which is inappropriate for MOD. The use of hydroxo-bridged dinuclear complex **5** instead of yttrium triiodide successfully suppressed this tendency, because of the presence of chelating glymes in the coordination sphere and also fewer iodide atoms than required for Y-Cu clusters. Another advantage of using derivatives $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (**5**) and $[Ba(tetraglyme)_2]I_2\cdot C_7H_8$[31] as precursors is that they provide, as a result of their ionic nature, good solubility in ionic liquids (ILs). We then carried out the MOD process in high-boiling 1-butyl(methylimidazolium) bis[(trifluoromethyl)-sulfonyl]amide (IL) as the medium for the decomposition of an all-iodide solution containing $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (**5**), $[Ba(tetraglyme)_2]I_2\cdot C_7H_8$, and CuI in the ratio 0.5:2:3. The as-prepared powder, after 1 h at 260 °C, was analyzed by FT-IR spectroscopy, TGA-DTA, and XRD. FT-IR data of the as-prepared powder show the presence of the tetraglyme ligand (1457m, 1351s, 1197s, 1138s, 791m $cm^{-1}$) and other absorption bands corresponding to ν(OH) (3470br $cm^{-1}$) and ν(Y–O) (678m, 572m, 514m $cm^{-1}$). No absorption bands characteristic of the IL could be observed. The TGA and DTA patterns (Figure 5) of this powder showed a two-step decomposition process in the range 270–420 °C associated with strong exothermic peaks corresponding to the combustion of the remaining organics. The total weight loss was 65.5%. The as-prepared powder was amorphous, and crystallization of the $YBa_2Cu_3O_{6.35}$ phase started after annealing in air at only 500 °C. This temperature is much lower than that reported for YBCO powder/films obtained from trifluoroacetate derivatives.[32] XRD analysis of the sample annealed at 900 °C showed the well-crystallized $YBa_2Cu_3O_{6.35}$ phase (Fig-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ure 6), though some additional peaks indexing as $YBa_2Cu_4O_8$ were also observed. Crystallite sizes of 25–44 nm were calculated by using the Debye–Scherrer formula. To the best of our knowledge, this is the first report of the use of a neat ionic liquid for synthesis of a high $T_c$ superconductor material.[33]

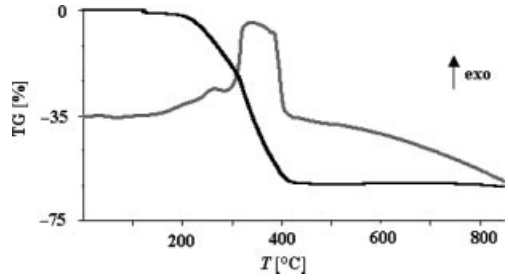

Figure 5. TGA-DTA curve of the powder obtained from the MOD of $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (**5**), $[Ba(tetraglyme)_2]I_2{\cdot}C_7H_8$, and CuI.

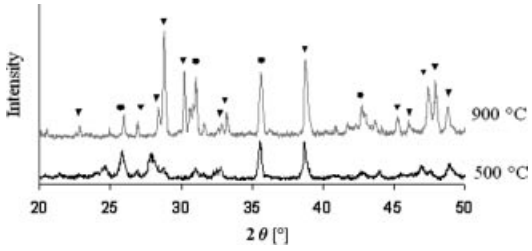

Figure 6. XRD of the powder obtained from the MOD of **5**, $[Ba(tetraglyme)_2]I_2{\cdot}C_7H_8$, and CuI (▼ = $YBa_2Cu_3O_{6.35}$ phase; ■ = $YBa_2Cu_4O_8$ phase).

## Conclusion

We described here a facile synthetic route to ionic, centrosymmetric, hydroxo-bridged, dimeric yttrium iodide complexes with glymes. It is the first report of hydroxo-bridged dimeric yttrium (or lanthanide) complexes with an all-oxygen environment. Such dimeric hydroxo species are potentially good starting materials for the synthesis of larger yttrium oxo/hydroxo clusters. Unlike yttrium triiodide, use of these dinuclear yttrium hydroxo iodide species in an all-iodide solution for high $T_c$ superconductors successfully suppresses the formation of ionic Y–Cu species and thus provides a homogeneous solution for MOD. Preliminary studies show that the $YBa_2Cu_3O_{6.35}$ phase starts after annealing the as-prepared powder in air at 500 °C, though some additional peaks indexing as $YBa_2Cu_4O_8$ were also observed. Further studies are now in progress to obtain the desired $YBa_2Cu_3O_{7-x}$ phase only.

## Experimental Section

All reactions were carried out under argon by using Schlenk tubes and vacuum line techniques. $Y(i\text{PrOH})_4I_3$[22] and $[Ba(tetraglyme)_2]I_2{\cdot}C_7H_8$[31] were prepared as reported, whereas CuI was purchased from Aldrich Co. and used as received. Solvents were purified by standard methods. Di-, tri-, and tetraglyme (Aldrich) were stored over molecular sieves. The ionic liquid 1-butyl(methylimidazolium) bis[(trifluoromethyl)sulfonyl]amide was purchased from Solvionic and used without purification. $^1$H NMR spectra were registered with a Bruker AC-300 spectrometer. FT-IR spectra of **1**–**5** were recorded as Nujol mulls with a Perkin–Elmer Paragon 500 spectrometer, whereas IR spectra of YBCO powder were recorded as KBr pellets with a Bruker Vector-22 spectrometer. TGA/DTA data were collected with a Setaram 92 system in air (thermal ramp 10 °C/min, 20–900 °C). XRD were obtained with a Bruker (Siemens) D 500 diffractometer by using Cu-$K_\alpha$ radiation. Analytical data were obtained from the Service Central d′Analyses du CNRS.

### Synthesis of Compounds 1–5

**$[Y_2(\mu\text{-}OH)_2(H_2O)_2(i\text{PrOH})_2(\text{triglyme})_2]I_4$ (1):** Addition of a toluene solution (5 mL) of triglyme (0.5 mL) and $H_2O$ (47 μL, 2.65 mmol) to a suspension of $Y(i\text{PrOH})_4I_3$ (0.94 g, 1.32 mmol) in toluene (3 mL) led to an immediate precipitation of a yellow-orange solid. After the mixture was stirred at room temp. for 6 h, the precipitate was separated by filtration and washed twice with *n*-hexane. Crystallization by slow cooling of a hot 2-propanol solution of this solid gave needle-shaped crystals, which were unsuitable for X-ray crystallography (0.62 g, 77%). $C_{22}H_{58}I_4O_{14}Y_2$ (1231.4): calcd. C 21.43, H 4.71; found C 21.82, H 4.54.

**$[Y_2(\mu\text{-}OH)_2(H_2O)_2(\text{tetraglyme})_2]I_4$ (2):** With the same procedure, **2** was obtained from $Y(i\text{PrOH})_4I_3$ (0.99 g, 1.38 mmol), tetraglyme (0.3 mL) and $H_2O$ (50 μL, 2.78 mmol) in toluene (10 mL) as a yellow solid and crystallized by slow cooling of its hot 2-propanol solution (0.61 g, 73%). $C_{20}H_{25}I_4O_{14}Y_2$ (1199.4): calcd. C 20.01, H 4.16; found C 19.17, H 4.16.

**$[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_4(\eta^3\text{-diglyme})_2]I_4{\cdot}2EtOH$ (3):** An ethanol (5 mL) solution of diglyme (0.4 mL) and $H_2O$ (27 μL, 1.49 mmol) was added to a solution of $Y(i\text{PrOH})_4I_3$ (0.55 g, 0.77 mmol) in EtOH (5 mL), and the resulting solution was stirred at room temp. for 6 h. Removal of solvents under vacuum afforded **3** as a yellow solid, which was crystallized from EtOH/*n*-pentane (1:1) at room temp. (0.74 g, 74%). $C_{24}H_{70}I_4O_{16}Y_2$ (1300.3): calcd. C 22.15, H 5.38; found C 21.93, H 5.27.

**$[Y_2(\mu\text{-}OH)_2(H_2O)_4(\eta^4\text{-triglyme})_2]I_4{\cdot}2EtOH$ (4):** This compound was obtained as yellow solid by using the same procedure from $Y(i\text{PrOH})_4I_3$ (0.71 g, 1.0 mmol), triglyme (0.5 mL), and $H_2O$ (55 μL, 3.05 mmol) in ethanol (5 mL) followed by crystallization from EtOH/*n*-pentane (1:1) at –20 °C (0.81 g, 68%). $C_{20}H_{54}I_4O_{14}Y_2$ (1238.1): calcd. C 19.90, H 4.47; found C 19.78, H 4.41. Compound **4** was also obtained by crystallization of **1** from EtOH/*n*-pentane (1:1) at –20 °C in 60% yield.

**$[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (5):** In a similar procedure, the reaction of $Y(i\text{PrOH})_4I_3$ (0.69 g, 0.97 mmol) with tetraglyme (0.5 mL) and $H_2O$ (35 μL, 1.94 mmol) in ethanol (5 mL) followed by crystallization from EtOH/$Et_2O$ (1:2) at –20 °C afforded $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (**5**) as a pale yellow crystalline solid (0.87 g, 70%). $C_{24}H_{62}I_4O_{16}Y_2$ (1292.2): calcd. C 22.29, H 4.79; found C 22.11, H 4.72. Compound **5** was also obtained by crystallization of **2** from EtOH/$Et_2O$ (1:2) at –20 °C in 57% yield.

Compounds **1**–**5** are yellow or orange-yellow solids, insoluble in aliphatic or aromatic hydrocarbons but soluble in acetonitrile and ethanol. They are only moderately soluble in 2-propanol and dichloromethane.

**Preparation of $YBa_2Cu_3O_{7-x}$ (YBCO) Powder from $[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$, $[Ba(tetraglyme)_2]I_2{\cdot}C_7H_8$, and CuI by Metal Organic Decomposition**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$[Y_2(\mu\text{-}OH)_2(H_2O)_2(EtOH)_2(\eta^4\text{-tetraglyme})_2]I_4$ (0.54 g, 0.42 mmol) and $[Ba(tetraglyme)_2]I_2{\cdot}C_7H_8$ (1.55 g, 1.66 mmol) were each dissolved in ethanol (5 mL). Dissolution of CuI (0.47 g, 2.50 mmol) in ethanol (5 mL) was achieved by using a solution of $NH_4I$ in ethanol (3.4 M, 3 mL). Mixing of these solutions gave an orange-yellow clear solution. After addition of the ionic liquid 1-butyl-(methylimidazolium) bis[(trifluoromethyl)sulfonyl]amide (10 mL) into this solution, ethanol was removed under vacuum to give a yellow pasty liquid. After this solution was heated at 260 °C for 1 h, the brownish-black powder was precipitated by adding methanol (30 mL). This powder was then removed by centrifugation and washed twice with hexane (0.36 g).

**X-ray Crystallography**

Suitable crystals of **3**–**5** were obtained from EtOH/pentane (1:1, room temp. or –20 °C) or EtOH/$Et_2O$ (1:2, –20 °C) solutions and mounted on a Nonius Kappa CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Crystallographic and refinement data for **3**–**5** are given in Table 7. Intensities were collected at 150 K by means of the program COLLECT.[34] Reflection indexing, Lorentz-polarization correction, peak integration, and background determination were carried out with the DENZO program.[35] Frame scaling and refinement of unit-cell parameters were carried out with the program SCALEPACK.[35] Absorption correction was achieved with the program DIFABS.[36] The starting structure was solved by direct methods with SIR92.[37] The remaining non-hydrogen atoms were located by successive difference Fourier map analyses. The structure refinement was carried out with CRYSTALS.[38] The H atoms were placed geometrically and refined with riding constraints.

# An Inorganic Aggregate Based on a Sandwich-Type Polyoxometalate with Lanthanide and Potassium Cations: From 1D Chiral Ladder-Like Chains to a 3D Open Framework

**Weilin Chen,[a] Yangguang Li,[a] Yonghui Wang,[a] and Enbo Wang*[a]**

**Keywords:** Polyoxometalates / Sandwich complexes / Lanthanides / Chirality / Open framework

The reaction of sandwich-type polyanion $[Mn_4Si_2W_{18}O_{68}(H_2O)_2]^{12-}$, ceric sulfate, and potassium citrate in an acidic aqueous solution led to the isolation of a new compound $K_4Na_2[\{Ce(H_2O)_7\}_2Mn_4Si_2W_{18}O_{68}(H_2O)_2]\cdot 21.5H_2O$ (**1**), which crystallizes in the space group $P2_12_12_1$ with $a$ = 12.040(2) Å, $b$ = 26.094(5) Å, $c$ = 30.043(6) Å, $V$ = 9439(3) Å$^3$, $Z$ = 4, and flack parameter $x$ = 0.63(1). X-ray diffraction analysis reveals that **1** consists of novel chiral ladder-like chains based on sandwich-type polyanions and lanthanide cations, which are further connected into a three-dimensional open framework by potassium cations.

## Introduction

The use of polyoxometalates (POMs) as basic building blocks to construct novel extended materials by means of different cationic linkers is of great interest and stems not only from their intriguing variety of architectures and topologies, but also from their numerous potential applications in catalysis, sorption, nonlinear optics, magnetic materials, and bioinorganic pharmaceuticals.[1] In this field, lanthanide cations ($Ln^{3+/4+}$) are popular linkers due to their high coordination numbers and oxyphilic activities, as well as their multiple physicochemical properties.[2] To date, a series of POM-based extended aggregates linked by lanthanide ions have been extensively reported as follows: (1) Keggin[3] polyanions and their monovacant derivatives are linked by $Ln^{3+/4+}$ ions to form one-dimensional zigzag chains, such as $[Ln_n(SiW_{11}O_{39})]$,[4a] $[Ln(SiW_{11}O_{39})_2]^{13-}$,[4b] and $[Ce_2(BW_{11}O_{39})_2(H_2O)_6]^{12-}$,[4d] a two-dimensional layer $[\varepsilon\text{-}PMo_{12}O_{36}(OH)_4\{La(H_2O)_4\}_4]^{5-}$,[4e] and a three-dimensional framework $[Gd(H_2O)_3]_3[GdMo_{12}O_{42}]$.[4i] Further, a series of trivacant Keggin polyanions can be self-assembled with $Ln^{3+/4+}$ ions to form nanoscale inorganic aggregates, such as $[Ln_{16}As_{12}W_{148}O_{524}(H_2O)_{36}]^{76-}$,[4g] $[(PM_2W_{10}O_{38})_4(W_3O_{14})]^{30-}$ (M = Eu, Y),[4h] and $[K\subset\{Eu(H_2O)_2(\alpha\text{-}AsW_9O_{33})\}_6]^{35-}$.[4f] (2) Wells–Dawson[5] polyanions and their monovacant congeners[6] are another kind of popular building blocks[7] assembled with lanthanide ions. A current report in this family is $[Ln(H_2O)_2(\alpha_2\text{-}P_2W_{17}O_{61})]_n^{7n-}$,[7b] which displays a series of extended structures with 1D chains and 2D layers. (3) Recently, Anderson-type polyanions have become a new class of precursors for the construction of extended inorganic aggregates,[8] such as $[La(H_2O)_7CrMo_6H_6O_{24}]^{2-}$[8a] and $[\{(C_6H_5NO_2)_2Ln(H_2O)_4\}_2\{IMo_6O_{24}\}]$.[8b] (4) Various isopolyoxoanion units connected with $Ln^{3+/4+}$ ions have also been reported,[9] exemplified by $[Ce(H_2O)(DMF)_6(W_{10}O_{32})]$,[9a] $[La(W_5O_{18})_2]^{9-}$,[9b] and $[\{Ln(H_2O)_5\}_2(H_2M_{12}O_{42})\}]^{2-}$ (M = Mo, W).[9c] (5) A series of large molybdenum and vanadium clusters have also been linked by lanthanide ions, which led to a series of infinite chains and networks.[10] As a continuation of the exploration of novel extended POM-based aggregates in this subfield with the "property-adding" feature, transition-metal-substituted POMs should be suitable precursors owing to their optical, electronic, and magnetic properties, which are largely dependent on the changeable transition metal centers.[11] In this aspect, the sandwich-type POMs with tetranuclear transitional-metal centers are an ideal class of candidates. However, no such extended inorganic aggregates based on sandwich-type POMs and lanthanide linkers have been reported. Because the pH stability ranges for sandwich-type POMs in aqueous solutions are different from those of lanthanide ions, together with the obvious reactive activity between the highly negative polyanions and strongly oxyphilic lanthanide cations,[12] most reactions between such two units result in immediate precipitates but not crystals. Thus, it is still a challenge to explore suitable synthetic conditions that would enable the acquisition of novel inorganic aggregates that are based on

these two building blocks. Nevertheless, some current efforts indicate that the introduction of organic N- and O-donor ligands or solvents during the preparation could somewhat stabilize the lanthanide cations, reduce the reactivity between POMs and lanthanide linkers, and improve the solubility of the final products. Therefore, the use of multidentate O-donor ligands (such as citrate, tartrate, and EDTA salts) were fully considered during our preparation of novel inorganic aggregates based on sandwich-type POMs and lanthanide cations. Although most of the sandwiching POMs possess lower symmetry in the crystal form, if they were to coordinate to different linkers they may present chirality and improve their functionality. On the basis of the above consideration, we synthesized a new compound with the assistance of citrate ligands, $K_4Na_2[\{Ce(H_2O)_7\}_2Mn_4Si_2W_{18}O_{68}(H_2O)_2]\cdot 21.5H_2O$ (**1**), which represents the first extended inorganic aggregate composed of sandwich-type POMs and lanthanide linkers. The structure of **1** possesses a chiral ladder-like chain based on $[Mn_4Si_2W_{18}O_{68}(H_2O)_2]^{12-}$ polyanions and cerium cations. These chains are further connected into a 3D open framework by potassium cation linkers.

## Results and Discussion

### Syntheses

Compound **1** was synthesized by boiling a mixed aqueous solution of $K_4Na_6Mn[Mn_4Si_2W_{18}O_{68}(H_2O)_2]\cdot\approx 33H_2O$, $Ce(SO_4)_2\cdot 4H_2O$ and potassium citrate for 2 h. Yellow block crystals were isolated after the filtrate stood at room temperature for one week. The precursor $K_4Na_6Mn[Mn_4Si_2W_{18}O_{68}(H_2O)_2]\cdot\approx 33H_2O$ was synthesized according to the published procedure.[13] Two important problems must be fully considered during the synthesis. Firstly, the pH value of the reaction system should be carefully controlled so as to stabilize the structure of the sandwich-type polyanions and avoid early precipitation of cerium cations. However, a series of reports indicate that the surface oxygen atoms of POMs are rather active to react with the oxyphilic lanthanide ions,[12] and in most cases precipitation instead of crystallization occurs. Thus, a multidentate O-donor ligand of potassium citrate was used to stabilize the cerium ions or maybe reduce the reactivity of cerium ions owing to the high coordination ability of such organic ligand with metal ions. Although the citrate ligand was not observed in the final structure of **1**, it is definitely necessary during the preparation of **1**. It is also noteworthy that there are two obvious color changes during the reaction. At the beginning of the reaction, the yellow aqueous solution of $K_4Na_6Mn[Mn_4Si_2W_{18}O_{68}(H_2O)_2]$ immediately changed to brown when the mixed solution of $Ce(SO_4)_2\cdot 4H_2O$ and potassium citrate was added. However, the brown color changed back to yellow after boiling for 2 h. It is presumed that the redox reactions between $Mn^{2+}$ and $Ce^{4+}$ ions in the first step led to the formation of $Mn^{3+}$ and $Ce^{3+}$ ions, which exhibit the brown color. After boiling for 2 h, the disproportionation reaction of the metastable $Mn^{3+}$ ions occurred, which resulted in the transformation of $Mn^{3+}$ into $Mn^{2+}$; thus, the brown solution changed back to yellow.

### Structure Description

Single-crystal X-ray diffraction analysis revealed that **1** consists of a novel chiral ladder-like chain based on sandwich-type $[Mn_4Si_2W_{18}O_{68}(H_2O)_2]^{12-}$ polyanions and cerium cation linkers. In **1**, the well-known sandwich-type polyanion (as shown in Figures 1 and S1) consists of two trivacant $[B\text{-}\alpha\text{-}SiW_9O_{34}]^{10-}$ Keggin moieties sandwiching a central symmetric rhomb-like $[Mn_4O_{16}(H_2O)_2]$ segment through the W–O–Mn and Si–O–Mn connecting modes. All the W and Mn centers exhibit an octahedral coordination environment. The bond lengths of W–O are in the range 1.664(2)–2.471(2) Å, whereas the bond lengths of Mn–O are between 2.107(2) and 2.250(2) Å. It is interesting that two cerium cations are coordinated directly to the surface oxygen atoms (O45, O27, O14, O47) of the sandwich-type polyanion (see Figures 1 and S1). The bond lengths of the four Ce–O bond lengths are 2.541(2) Å, 2.492(2) Å, 2.519(2) Å, and 2.578(2) Å, respectively. The residual coordination sites of two nona-coordinated cerium cations are fulfilled by coordinated water molecules. The distances of Ce–Ow vary from 2.394(14) Å to 2.68(3) Å. Further, these Ce cations can be viewed as $\mu_2$-bridges that link the sandwich-type polyanions into an infinite ladder-like chain along the *c* axis (Figure 2). It is also noteworthy that the central symmetric sandwich-type polyanions change into asymmetric moieties as a result of the connection with two different $[Ce(H_2O)_7]$ linkers. On the basis of the space group $P2_12_12_1$ of **1**, it is considered that a $2_1$ screw axis passes through the central part of the ladder-like chain (as shown in Figure 2) and the whole chain possesses the chirality. However, the flack parameter

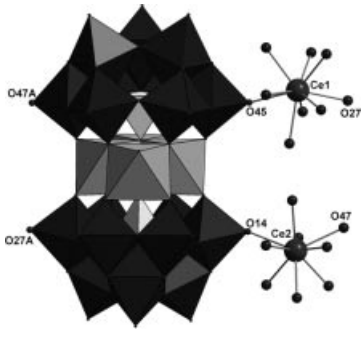

Figure 1. Polyhedral and ball-and-stick representation of the sandwich-type polyanion and the cerium cations of **1**.

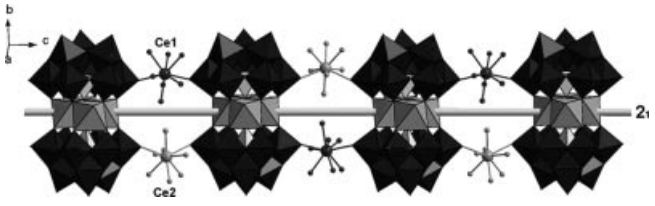

Figure 2. View of the 1D chiral ladder-like chain of **1**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[0.63(1)] indicates that **1** is just a twin crystal containing two enantiomers simultaneously with the content of ca. 63 and 37%, respectively.[14]

In the unit cell of **1**, there are four independent potassium cations that exhibit a hepta-coordinated environment with six O atoms derived from the three different polyanions and one solvent water molecule (Figure S2). The bond lengths of K–$O_{POM}$ are in the range 2.680(2)–3.073(2) Å, whereas the distances of K–Ow is in the range 2.710(3)–2.860(5) Å. Thus, all the potassium cations can be viewed as $\mu_3$-bridges and each of them links with three polyanion moieties (Figure S3). On the *ac* plane, adjacent ladder-like chains are connected by the four types of potassium cations to form a two-dimensional framework (Figure 3a). Interestingly, adjacent four polyanions together with four cerium linkers and four potassium linkers constitute a relatively closed space with the total volume of ca. 124.7 $Å^3$ estimated with PLATON software (Figures 3b and S4). The entrances of the closed space seem to be somewhat small with the size of ca. 7.7 × 8.0 Å (along the *a* axis) and ca. 6.2 × 12.3 Å (along the *c* axis) based on the distances among cerium, potassium, and tungsten centers. However, all the lattice water molecules and sodium cations are sealed in these "containers" during the self-assembly process of **1** (Figure S4). Furthermore, these 2D porous layers are linked by potassium cations in a stagger way to form a 3D open framework (Figures 4 and S5).

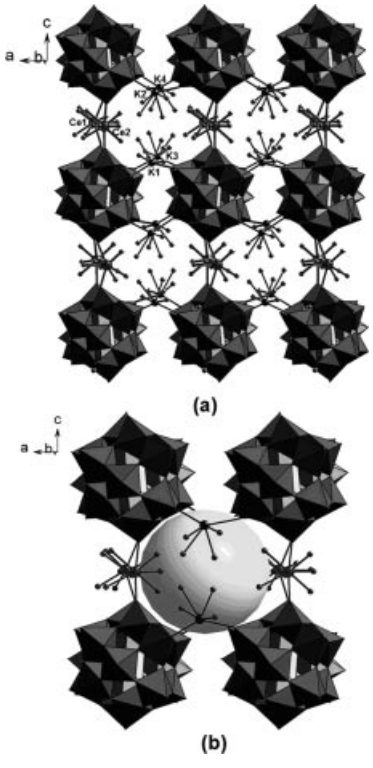

Figure 3. (a) View of the 2D double porous framework on the *ac* plane. (b) View of the simulated closed-space based on four polyanions, four $[Ce(H_2O)_7O_2]$, and four $[K(H_2O)O_6]$ linkers. The sodium cations and crystal water molecules are omitted for clarity.

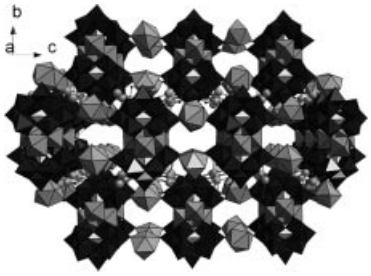

Figure 4. Polyhedral and ball-and-stick view of the 3D open framework along the *a* axis.

The oxidation states of Si, W, Mn, and Ce sites are +4, +6, +2, and +3, respectively, on the basis of the bond lengths and angles, charge balance consideration, and bond valence sum calculations.[15]

## Spectroscopic and Electrochemical Analyses

The IR spectrum of **1** (Figure S6) shows the characteristic bands at 946, 905, 873, 770, 722, 536, 511, and 489 $cm^{-1}$, which are similar to the IR peaks of $[Mn_4Si_2W_{18}O_{68}(H_2O)_2]$[11–13] except for some slight shifts owing to the influence of coordinated cerium cations on polyanions in the range 450–1000 $cm^{-1}$. This similarity indicates that the polyanion of **1** still keeps the basic sandwich-type structure, which is consistent with the result of single-crystal X-ray diffraction analysis.

The UV/Vis spectrum of **1** (Figure S7) was recorded in a solution of $H_2SO_4/Na_2SO_4$ at pH = 3.5 and shows absorbance bands between 200 and 400 nm, which can be attributed to the characteristics of charge-transfer bands of terminal oxygen and bridging oxygen atoms to tungsten centers, respectively.

To investigate the solution properties of **1**, the cyclic voltammogram (CV) (Figure S8) was recorded for 1 mM solutions of **1** in 0.5 M $H_2SO_4/Na_2SO_4$ at pH = 3.50. The voltammogram shows two similar quasi reversible peaks at $E_{1/2}$ = –1.09 and –0.76 V [$E_{1/2} = (E_{pa} + E_{pc})/2$] that can be attributed to two two-electron redox cycles of $W^{6+}$ and one quasi reversible peak at $E_{1/2}$ = +0.68 V that indicates a one-electron redox process of $Ce^{3+}$ to $Ce^{4+}$. The redox peaks of $Mn^{2+}$ are too weak to be assigned.[16] (Figures S8 and S9). The blurry redox peaks and quasi reversible CV feature of **1** probably result from slow electron transfer rather than chemical irreversibility.

## TG and XRPD Analyses

Thermogravimetric (TG) analysis of compound **1** was carried out with a Perkin–Elmer TGA7 instrument under an $N_2$ atmosphere. The TG curve (Figure 5) exhibits a continuous weight loss step from 35 to 250 °C, attributed to the loss of all lattice and coordinated water molecules. The weight loss is about 11.51%, in correspondence with the calculated value of 11.57%. Then, no weight loss occurs in the temperature range 250–650 °C. There is another minor

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

weight loss of 1.8% in the temperature range 650–800 °C, which might be attributable to the loss of oxygen atoms from the residual metal oxides.

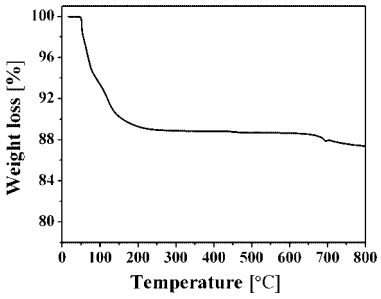

Figure 5. TG curve of **1**.

To check the stability of the open framework of **1**, the X-ray powder diffraction (XRPD) of **1** was checked at 20, 70, and 120 °C. As shown in Figure 6, the peak positions of the simulated and experimental XRPD pattern at 20 °C are in agreement with each other, which indicates the good phase purity of the compound. The differences in intensity may be due to the preferred orientation of the crystalline powder samples. The main peaks of the XRPD pattern at 20 and 70 °C are also similar to each other except for the minor differences in peak intensity, which are due to the loss of some crystal water molecules; this indicates that the open framework of **1** is still stable below 70 °C. However, most peaks of the XRPD pattern of **1** disappeared at 120 °C, which suggests that compound **1** is not in the crystalline state. This could be ascribed to a collapsed framework resulting from the loss of most of the coordinated water molecules from the cerium and potassium cation linkers.

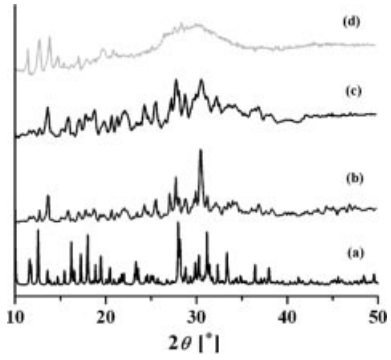

Figure 6. Stimulated and experimental XRPD patterns of **1**. (a) Stimulated XRPD; (b) XRPD at 20 °C; (c) XRPD at 70 °C; (d) XRPD at 120 °C.

## Conclusions

A new compound, $K_4Na_2[\{Ce(H_2O)_7\}_2Mn_4Si_2W_{18}O_{68}(H_2O)_2]\cdot 21.5H_2O$ (**1**), was successfully synthesized with the assistance of a citrate ligand, and this complex represents the first extended inorganic aggregate composed of sandwich-type POMs and lanthanide cations. Compound **1** consists of novel chiral ladder-like chains based on $[Mn_4Si_2W_{18}O_{68}(H_2O)_2]^{12-}$ polyanions and two different $[Ce(H_2O)_7]^{3+}$ linkers, which are further connected by potassium cations into a 3D open framework with a space volume of ca. 124.7 Å$^3$ per unit cell. TG and XRD analyses indicate that the porous framework of **1** is stable (around 70 °C) just before losing most of its coordinated water molecules. The successful synthesis of **1** suggests a new model for the construction of POM-based extended frameworks. The properties and functionalities of such compounds might be adjusted by the choice of different transition-metal ions in the sandwich sites and lanthanide cation linkers. More work in this field is underway.

## Experimental Section

**Materials:** All chemicals purchased were of reagent grade and used without further purification.

**Physical Methods:** Elemental analyses W, Mn, and Ce were determined with a Leaman inductively coupled plasma (ICP) spectrometer. IR spectra were recorded in the range of 400–4000 cm$^{-1}$ with an Alpha Centaurt FT/IR Spectrophotometer with pressed KBr pellets. UV/Vis absorption spectra were obtained with the use of a 752 PC UV/Vis spectrophotometer. TG analyses were performed with a Perkin–Elmer TGA7 instrument in flowing $N_2$ with a heating rate of 10 °C min$^{-1}$. The electrochemical measurement was carried out with a CHI 660 electrochemical workstation at room temperature (25–30 °C). X-ray powder diffractometry (XRPD) studies of **1** were performed with a NETZSCH STA 449C instrument, with a Panalytical X-Pert pro diffractometer and Cu-$K_\alpha$ radiation.

**Compound 1:** The precursor $K_4Na_6Mn[Mn_4Si_2W_{18}O_{68}(H_2O)_2]\cdot\approx 33H_2O$ was synthesized according to the published procedure.[13] The molecular formula was presumed by elemental analysis and thermogravimetric analysis. An aqueous solution (15 mL, pH = 4.5) of $Ce(SO_4)_2\cdot 4H_2O$ (0.16 g, 0.4 mmol) and potassium citrate (0.12 g, 0.4 mmol) was added to an aqueous solution (15 mL) of $K_4Na_6Mn[\{SiMn_2W_9O_{34}(H_2O)\}_2]\cdot 33H_2O$ (1.12 g, 0.2 mmol) with stirring. The color changed from yellow to brown. The solution was then heated to boiling for 2 h, and the color changed again from brown to yellow. After cooling to room temperature, the final yellow suspension was filtered, and the pH value of the filtrate was ca. 3.5. The filtrate was slowly evaporated at room temperature. The yellow columnar crystals of **1** were isolated after 10 d (yield 60% based on W). $H_{79}Ce_2K_4Mn_4Na_2O_{105.5}Si_2W_{18}$ (5835.49): calcd. Ce 4.80, Mn 3.77, W 56.71; found Ce 4.71, Mn 3.87, W 56.85.

**X-ray Crystallography:** Crystallographic data for **1** was collected at 298 K with a Rigaku R-axis Rapid IP diffractometer with the use of graphite monochromatic Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and IP technique. The structure was solved by direct methods and refined by the full-matrix least-squares method on $F^2$ by using the SHELXTL-97 crystallographic software package.[17] Anisotropic thermal parameters were used to refine all atoms on polyanions, cerium, potassium, and sodium cations. All the water molecules were refined isotropically. Non-hydrogen atoms were included. Some crystal water molecules were disordered. Their occupancies were determined by fixing the atomic displacement parameter factors (0.08) at the beginning, and then occupancy numbers were fixed to refine their atomic displacement parameter factors. Atoms with occupancies lower than 0.25 were ignored. Further details of the X-ray structural analysis are given in Table 1. Further details of the crystal-structure investigation may be obtained from the

# Synthesis of Chiral Imidazolinium Carbene from a Carbohydrate and Its Rhodium(I) Complex[‡]

**Ji-cheng Shi,*[a,b] Ni Lei,[b,c] Qingsong Tong,[a] Yiru Peng,[a] Junfa Wei,[b] and Li Jia[a]**

**Keywords:** Nitrogen heterocycles / Carbenes / Rhodium / Carbohydrates / Chirality

A chiral imidazolinium salt with two bulky carbohydrate subunits, *N*,*N*′-1,3-bis(methyl 4,6-*O*-benzylidene-3-deoxy-α-D-altropyrano-3-yl)imidazolinium chloride (**4**), was synthesized in high yield. Deprotonation of **4** with sodium *tert*-butoxide in the presence of $[RhCl(COD)]_2$ produced NHC-coordinated rhodium complex **5** along with water adduct **6** to a lesser extent depending on the moisture content of the reaction mixture. These compounds were fully characterized by IR, MS, and $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy.

## 1. Introduction

Since the isolation and characterization of stable N-heterocyclic carbenes (NHCs) by Arduengo in 1991,[1] these compounds have generated considerable interest in catalysis reactions, both as a transition metal ligand[2] and directly as a nucleophilic catalyst.[3] The strong σ-donating character of NHCs combined with their poor π-accepting properties generate metal centers that are electron-rich relative to the corresponding phosphane-coordinated complexes.[4] Consequently, these carbene ligands do not appear to dissociate from the metal centers, and their complexes tend to be highly active in oxidative addition steps.[5] These properties of NHCs have led to significant improvements in some reactions that originally used phosphane-coordinated catalysts, such as Ru-catalyzed olefin metathesis[6] and Pt-catalyzed olefin hydrosilylation.[7]

Chiral phosphanes have been widely used in asymmetric catalysis, and the advances achieved have had a significant impact on both academic and industrial research. It was therefore a logical extension to similarly modify NHCs with a chiral moiety.[8] An advantage of chiral NHCs is that an excess of the ligand is not necessary as a result of its low propensity to dissociate from the metal center. Recently, high levels of enantiomeric excess were reported in several catalysis reactions using chiral NHCs. These reactions include the iridium-catalyzed asymmetric hydrogenation of aryl alkenes,[9] Ru-catalyzed symmetry-breaking olefin metathesis,[10] Rh-catalyzed hydrogenation of α,β-unsaturated esters,[11] and the hydrosilylation of methyl ketones.[12] In addition to these examples of bidentate NHC ligands, a monodentate NHC ligand with two bulky chiral [2,2]-paracyclophane groups was reported to give excellent enantiomeric excess in the rhodium-catalyzed enone addition.[13] These examples highlight the potential and promise of chiral NHC ligands in asymmetric catalysis. However, when compared to chiral phosphanes, the field of asymmetric catalysis with chiral NHCs remains in its infancy and further work in the area, primarily the synthesis of new chiral NHCs, is well justified.

Carbohydrates are a diverse and widely available source of chirality. Chiral phosphanes derived from carbohydrates have been used in the commercial synthesis of optically pure products; however, there have been no reports of chiral NHCs prepared from carbohydrates so far. Previously, we have selectively incorporated diphenylphosphanyl groups into the C-2 and C-3 positions of a pyrano rings in high yields through an epoxide ring-opening reaction.[14] The resulting chiral phosphanes were found to be versatile ligands in the coordination of late transition metals[15] and were successfully applied in nickel-catalyzed asymmetric hydrovinylation reactions.[16] Herein we wish to report the synthesis of a chiral imidazolinium salt with two bulky subunits derived from D-glucose, as well as the synthesis of a rhodium complex from the corresponding chiral N-heterocyclic carbene ligand.

## 2. Results and Discussion

Methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (**1**) can be easily prepared from D-glucose on a large

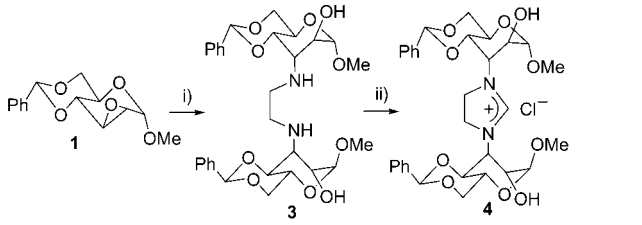
scale, and it is also commercially available (Scheme 1).[17] Our initial synthetic approach to the imidazolium salt by the co-condensation of methyl 3-deoxy-3-amino-4,6-benzylidene-α-D-altropyranoside (**2**), made from ammonolysis of epoxide **1**,[18] with glyoxal and formaldehyde was unsuccessful.[19] The failure of this approach seemed to result from the hydrolysis of the protecting groups in **1** and with difficulties in the isolation of the desired product. Therefore, an alternative route was pursued that used ethane-1,2-diamine instead of ammonia.

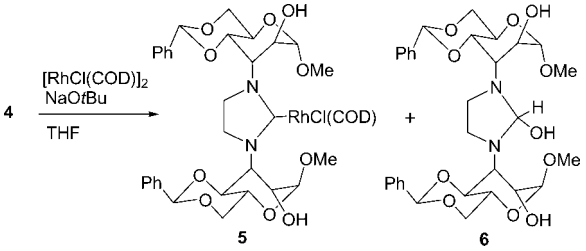


[a] Conditions: i) ethane-1,2-diamine, MeOH, 140 °C; ii) $NH_4Cl$, $CH(OEt)_3$, 110 °C.

Scheme 1. Synthesis of an imidazolinium chloride.[a]

By raising the reaction temperature to 140 °C, an 86% yield of diamine **3** was readily obtained. The higher reaction temperature that was necessary for this reaction was attributed to the steric hindrance in the reaction of the second epoxide with the diamine. By heating **3** at 110 °C for 3 h in neat triethylorthoformate in the presence of $NH_4Cl$, imidazolinium salt **4** was produced in 92% yield as a precipitate upon cooling the reaction mixture. Crude **4** was pure enough to be used directly in the next step. It is worth noting that when the reaction was conducted with $NH_4BF_4$ instead of $NH_4Cl$, which is more frequently used for the ring-closure of imidazolinium salts,[20] several side products resulted, which made isolation of the desired imidazolium salt tedious. At the present time, the reason for this is uncertain, but we speculate that $NH_4BF_4$ may be unstable at high temperature and that it may generate trace amounts of acid that hydrolyze the protecting groups in **1**. Compounds **3** and **4** were fully characterized by IR, MS, and $^1H$ and $^{13}C\{^1H\}$ NMR spectroscopy (see Supporting Information). The $^1H$ and $^{13}C\{^1H\}$ NMR spectra of chiral products **3** and **4** are indicative of a $C_2$-symmetric product, and the presence of only one set of signals also suggests that no racemization occurred in the synthesis of **4**. The signal at $\delta$ = 8.83 ppm in the $^1H$ NMR spectrum of **4** is characteristic of the NCHN proton in the imidazolinium salt.[21]

We next examined the coordination properties of the chiral N-heterocyclic carbene generated from **4**. Deprotonation of **4** with sodium *tert*-butoxide in a THF solution of $[RhCl(COD)]_2$ at 45 °C for 48 h afforded NHC-coordinated Rh complex **5** in 76% yield. The extent of dryness of imidazolinium salt **4** was found to be crucial to the yield of **5**; if **4** was not carefully dried with $P_2O_5$ under vacuum, the yield of **5** dropped significantly to 20–50%, and the water adduct of the carbene, compound **6**, could be seen at approximately 20% yield (Scheme 2). The fact that nearly no reaction occurred at room temperature suggests that steric hindrance around the carbene hampered its coordination to rhodium. This would further suggest that the carbene reaction with water to yield **6** is faster than its complexation to yield **5**, as our observations would indicate. Evidence for a highly steric environment around rhodium can be seen in the $^1H$ and $^{13}C\{^1H\}$ NMR spectrum. The $C_2$-symmetry seen in **4** disappeared in **5**, and in **6** as well. The loss of $C_2$-symmetry in **6**, with its relatively small hydroxy group in the imidazolidine ring, is indicative of a carbene center surrounded by two bulky chiral substituents. It would be interesting to evaluate the chiral induction ability of the NHC-coordinated rhodium complex with its two large carbohydrate subunits. The assignments of **5** and **6** are based on MS and NMR spectroscopic data. The HRMS measurement of 809.2529 $[M - Cl]^+$ for NHC-coordinated Rh complex **5** is consistent with the calculated value of 809.2520. A peak at 617 $[M + 1]^+$ in the MS of **6** suggests that it is an $H_2O$ adduct of the carbene derived from **4**.



Scheme 2. Synthesis of NHC-coordinated $Rh^I$ complex.

In conclusion, we have synthesized the first example of a chiral imidazolinium salt with two bulky carbohydrate subunits and its corresponding rhodium complex. The reaction conditions for the rhodium complex and the NMR signals suggest that the carbene center is highly encumbered by the two bulky chiral subunits. Future studies will focus on (1) the use of rhodium complex **5** in asymmetric catalysis, (2) the deprotection of **5** to form a polyhydroxy complex as a potential water-soluble asymmetric catalyst, and (3) the synthesis of more chiral N-heterocyclic carbenes from carbohydrates and their corresponding transition-metal complexes.

## 3. Experimental Section

**General Procedures.** All reactions and manipulations involving air- and/or moisture-sensitive compounds were carried out by using standard Schlenk techniques under an atmosphere of nitrogen. NMR spectra were recorded with a BRUKER DRX 400 MHz or Varian INOVA 400 MHz spectrometer. Chemical shifts are reported in $\delta$ relative to $CDCl_3$. High-resolution mass spectra (HRMS, ESI) were obtained with a Micromass Q-Tof Micro (Micromass Inc., Manchester, England). THF was distilled from sodium benzophenone ketyl under an atmosphere of nitrogen. NaO*t*Bu was used as received. $[RhCl(COD)]_2$ and methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (**1**)[17] were prepared according to the literature methods, respectively.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

***N*,*N*′-Bis(methyl 4,6-*O*-benzylidene-3-deoxy-α-D-altropyrano-3-yl)-1,2-diaminoethane (3):** A mixture of methyl 2,3-anhydro-4,6-*O*-benzylidene-α-D-mannopyranoside (**1**; 4.1 g, 15.5 mmol) and ethane-1,2-diamine (0.4 g, 6.67 mmol) in methanol (60 mL) was stirred in an autoclave at 140 °C for 12 h. After cooling the reaction mixture, the solvent was evaporated, and the residue was purified by chromatography (3–10% methanol in dichloromethane) to afford the product. Yield: 3.4 g (86%). M.p. 91–93 °C. $[\alpha]_D^{21}$ = +112.2 (*c* = 1.0, ethanol). $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 7.50–7.30 (m, 10 H), 5.47 (s, 2 H), 4.52 (s, 2 H), 4.30–4.25 (m, 2 H), 4.10–4.00 (m, 2 H), 3.95–3.90 (m, 2 H), 3.91 (br., 2 H), 3.80–3.70 (m, 2 H), 3.34 (s, 6 H), 3.22 (br., 2 H), 3.10–3.05 (m, 2 H), 2.90–2.85 (m, 2 H), 2.65–2.55 (m, 2 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 137.64 129.06 128.38 (2 C), 126.21 (2 C), 102.05 (2 C), 77.86, 70.80, 69.50, 58.69, 57.10, 55.47, 47.08, 46.11 ppm. IR (KBr): $\tilde{\nu}$ = 3440, 2907, 1637, 1457, 1380, 1105, 1067, 1044, 974, 755, 670 cm$^{-1}$. MS (ES): *m*/*z* (%) = 589 (100) $[M + 1]^+$.

***N*,*N*′-1,3-Bis(methyl 4,6-*O*-benzylidene-3-deoxy-α-D-altropyrano-3-yl)imidazolinium chloride (4):** A mixture of diaminoethane **3** (2.0 g, 3.4 mmol) and $NH_4Cl$ (0.3 g, 5.6 mmol) in triethylorthoformate (40 mL) was stirred at 110 °C for 3 h. Upon cooling of the reaction mixture to room temperature, ashen solids appeared and were collected by filtration and washed with hexane. The solid was dissolved in dichloromethane and purified through a short column to remove excess $NH_4Cl$. Yield: 2.0 g (92%). M.p. 153–154 °C. $[\alpha]_D^{20}$ = +127.9 (*c* = 1.0, ethanol). $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 8.83 (s, 1 H), 7.40–7.15 (m, 10 H), 5.88 (br., 2 H), 5.50 (s, 2 H), 4.57 (s, 2 H), 4.30–4.05 (m, 8 H), 3.90 (br., 2 H), 3.75–3.60 (m, 4 H), 3.10 (s, 6 H), 3.06 (s, 2 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 157.29, 136.96, 129.44, 128.45 (2 C), 126.12 (2 C), 102.55, 100.70, 74.51, 69.30, 66.86, 58.66, 58.22, 55.43, 50.09 ppm. IR (KBr): $\tilde{\nu}$ = 3440, 3257, 2930, 1642, 1459, 1409, 1262, 1138, 1104, 995, 964, 772, 707 cm$^{-1}$. MS (ESI): *m*/*z* (%) = 599 (100) $[M - Cl]^+$.

**NHC-Coordinated Rh complex 5:** A mixture of dried imidazolinium salt **4** (1.35 g, 2.15 mmol), $[RhCl(COD)]_2$ (0.40 g, 0.82 mmol), and NaO*t*Bu (0.31 g, 3.2 mmol) was stirred in THF (20 mL) at 45 °C for 48 h. The reaction mixture was filtered through celite, evaporated, and the residue was then purified by silica gel chromatography (2% methanol in dichloromethane). Yield: 1.06 g (77%). M.p. 157–159 °C. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 7.60–7.20 (m, 11 H), 6.60–6.62 (m, 1 H), 5.80 (br., 1 H), 5.71 (s, 1 H), 5.64 (s, 1 H), 5.05–4.90 (m, 2 H), 4.69 (d, *J* = 3.2 Hz, 1 H), 4.66 (s, 1 H), 4.42 (br., 1 H), 4.35–4.25 (m, 3 H), 4.11 (br., 2 H), 4.05–3.98 (m, 1 H), 3.92–3.81 (m, 2 H), 3.80–3.65 (m, 5 H), 3.64–3.55 (m, 2 H), 3.46 (s, 3 H), 3.39 (br., 1 H), 3.27 (s, 3 H), 2.55–2.42 (m, 2 H), 2.35–2.22 (m, 2 H), 2.10–1.98 (m, 2 H), 1.82–1.67 (m, 4 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 137 ppm. 65, 137.42, 129.00, 128.56, 128.40, 128.04, 126.30, 126.01, 102.31, 101.40, 101.21, 74.70, 73.80, 71.67, 70.22, 69.94, 69.04, 68.90, 62.41, 61.72, 59.38, 58.52, 55.48, 55.09, 49.23, 47.41, 34.18, 31.68, 29.96, 27.96. IR (KBr): $\tilde{\nu}$ = 3421, 2933, 2875, 1486, 1452, 1378, 1266, 1133, 1112, 1087, 972, 819, 754, 689 cm$^{-1}$. MS (ESI): *m*/*z* (%) = positive 809 (100) $[M - Cl^-]$; negative 879 (100) $[M + Cl^-]$. HRMS: calcd. for $C_{39}H_{50}N_2O_{10}Rh$ $[M - Cl]^+$ 809.2520; found 809.2529.

***N*,*N*′-1,3-Bis(methyl 4,6-*O*-benzylidene-3-deoxy-α-D-altropyrano-3-yl)-2-hydroxyimidazolidine (6):** The compound was isolated as a side product in the preparation of **5**; its yield is around 5–20% depending on the dryness of imidazolinium salt **4** used. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 8.35 (s, 1 H), 7.50–7.30 (m, 10 H), 5.55 (s, 1 H), 5.44 (s, 1 H), 4.65–4.60 (m, 2 H), 4.35–4.25 (m, 2 H), 4.15–4.10 (m, 2 H), 4.07–4.00 (m, 2 H), 3.95–3.91 (m, 2 H), 3.90–3.77 (m, 4 H), 3.68–3.60 (m, 2 H), 3.51–3.40 (m, 8 H), 3.38–3.10 (m, 3 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 165.28, 137.38, 137.07, 129.17, 128.36, 128.29, 126.46, 126.31, 126.08, 102.51, 102.33, 102.03, 101.88, 77.40, 75.80, 69.88, 69.68, 69.49, 69.08, 61.74, 59.55, 58.92, 58.66, 55.60, 55.54, 47.16, 45.51 ppm. **The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** three types of nickel complexes that are stabilized by 1,1′-bis(phosphanyl)-ferrocene ligands, which can be considered as model complexes for the hypothetical metal-mediated reaction between $CO_2$ and ethylene to form acrylic acid. The (acrylic acid)nickel(0) complexes are of particular interest as they represent the first stable combination between $Ni^0$ and this strong acid as a ligand. These complexes form hydrogen-bonded dimers in the solid state and are surprisingly stable. Details of their synthesis and reactivity along with the description of the other complexes are discussed in the article by D. Walther et al. on p. 2257ff. The artwork was created by Ulf Walther.

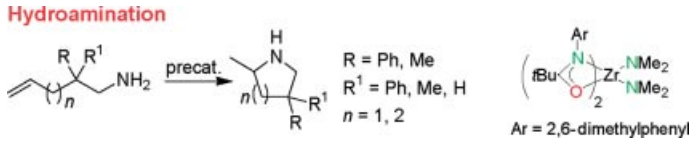
## MICROREVIEW

### Catalytic Hydroamination

**A. V. Lee, L. L. Schafer* ..... 2243–2255**

Modular *N,O*-Chelating Ligands: Group-4 Amidate Complexes for Catalytic Hydroamination

**Keywords:** Amidate ligands / Group-4 metal complexes / Hydroamination / Homogeneous catalysis / Asymmetric catalysis



This microreview of transition metal amidate complexes and their applications in catalysis focuses on a new family of easily prepared, modular group 4 complexes for use in alkyne, allene and alkene hydroamination catalysis.

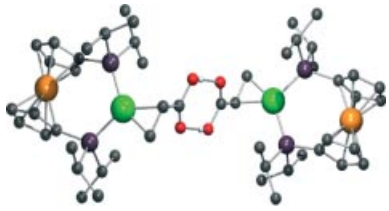
## FULL PAPERS

### Acrylic Acid $Ni^0$ Complexes

**J. Langer, R. Fischer, H. Görls, D. Walther* ..... 2257–2264**

Low-Valent Nickel and Palladium Complexes with 1,1′-Bis(phosphanyl)ferrocenes: Syntheses and Structures of Acrylic Acid and Ethylene Complexes

**Keywords:** Alkene ligands / Chelates / Nickel / Palladium / P ligands



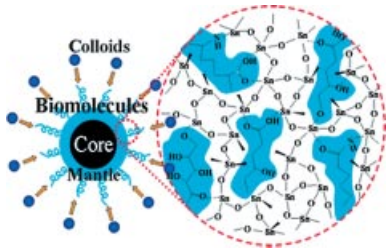
$Ni^0$ complexes of the type [(L)Ni($\eta^2$-$CH_2$=CH-COOH)] [L = 1,1′-bis(phosphanyl)-ferrocenes] containing acrylic acid as olefinic ligand are hydrogen bonded dimers in the solid state. Their isomers [(L)Ni($CH_2CH_2COO$)] can not be interconverted into the acrylic acid complexes, but undergo reductive decoupling to form complexes of the type (L)Ni($\eta^2$-$CH_2$=$CH_2$).

### Biomimetic Nanomaterials

**Q. Dong, H. Su,* W. Cao, D. Zhang, Q. Guo, F. Zhang ..... 2265–2273**

Assembly and Formation of Biomorphic Tin Dioxide by a Biomimetic Sol–Gel Approach Involving Glycoprotein

**Keywords:** Biomimetic synthesis / Colloids / Hierarchy / Nanotubes / Sol–gel processes



The eggshell membrane (ESM) plays a crucial role as the physical substrate and functional macromolecule template in achieving the synthesis of hierarchical $SnO_2$ through an interfacial sol–gel approach combined with calcination treatment. The formation mechanism is attributed to a protein-directed sol–gel process.

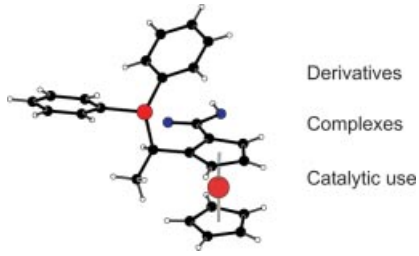
## Chiral Ferrocene-Based Ligands

A novel (phosphanylalkyl)ferrocenecarboxylic acid with combined planar and central chirality and its selected derivatives modified at both the phosphane and carboxyl groups have been prepared and used as ligands in palladium and rhodium complexes. These complexes are applied in enantioselective rhodium-catalysed hydrogenation and in palladium-catalysed allylic alkylation reactions.



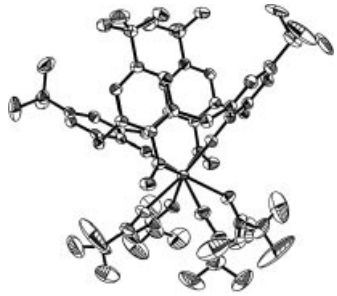
**M. Lamač, I. Císařová, P. Štěpnička* ..... 2274–2287**

Synthesis, Coordination and Catalytic Utility of Novel Phosphanyl–ferrocenecarboxylic Ligands Combining Planar and Central Chirality

**Keywords:** Asymmetric catalysis / Ferrocene ligands / Rhodium / Palladium / Allylic alkylation

## $Ce^{IV}$ Calixarene Complexes

The synthesis of $Ce^{IV}$ calixarene complexes is performed by two different synthetic approaches; the direct reaction of the Ce–β-diketonate with the calix[4]arene ligand and a complex modification of a bromination reaction. XPS studies revealed X-ray-induced changes in the effective Ce oxidation state of the two complexes in question.

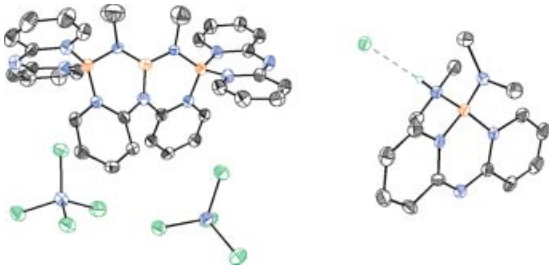


**J. Gottfriedsen,* R. Hagner, M. Spoida, Y. Suchorski ..... 2288–2295**

Synthesis, Structure, and Reactivity of Cerium(IV) Calix[4]arene Complexes

**Keywords:** Cerium / Calixarenes / Photoelectron spectroscopy

## Boratoheterocycles



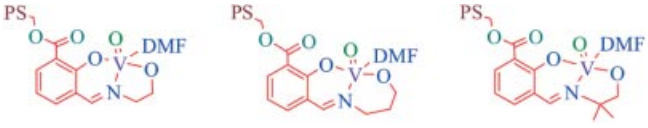
Transamination of di(pyrid-2-yl)amine with $B(NMe_2)_3$ yields a cyclic *B*-bis(dimethylamino)boratoheterocycle, which reacts with $CHCl_3$ to give the corresponding boronium chloride. With $AlCl_3$, the first diboronium salt is formed in a complex reaction and is isolated as its bis(tetrachloro)aluminate.

**U. Braun, H. Nöth* ..... 2296–2302**

Synthesis and Structures of Two New Types of Boronium Salts

**Keywords:** Boronium Cations / Transamination / X-ray structures

## Polymer-Anchored Complexes



Three polymer-anchored oxidovanadium(IV) complexes were synthesized and their catalytic applications for the oxidation of styrene and cumene were studied.

**M. R. Maurya,* U. Kumar, P. Manikandan ..... 2303–2314**

Synthesis and Characterisation of Polymer-Anchored Oxidovanadium(IV) Complexes and Their Use for the Oxidation of Styrene and Cumene

**Keywords:** Vanadium(IV) complexes / Polymer support / Heterogeneous catalysts / Oxidations

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

# CONTENTS

## Lanthanide Complexes

**L. N. Puntus, A.-S. Chauvin, S. Varbanov, J.-C. G. Bünzli* ..... 2315–2326**

Lanthanide Complexes with a Calix[8]-arene Bearing Phosphinoyl Pendant Arms

**Keywords:** Lanthanides / Calixarenes / Europium / Luminescence

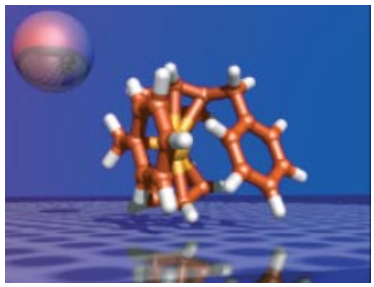
The phosphinoyl-substituted *p-tert*-butyl-calix[8]arene $B_8bL^8$ reacts with $Ln^{III}$ ions to form predominantly 1:1 complexes, but also 2:1 complexes. The final coordination environment of the ligand depends on the counterion. Optical electronegativity can be used to predict the charge transfer energies.

## Cationic Zirconocenes

**J. Saßmannshausen,* A. Track, T. A. D. S. Dias ..... 2327–2333**

Synthesis, Reactivity and DFT Investigation of a Cationic Zirconocene Benzyl Compound with an Appended Phenyl Group

**Keywords:** Density functional calculations / NMR spectroscopy / Polymerisation



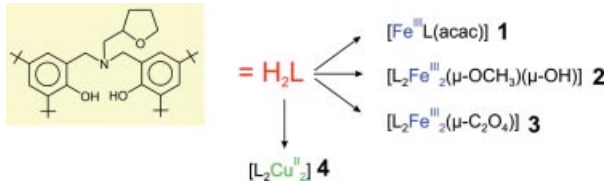
The reaction of $[\eta^5\text{-}C_5H_5\text{-}(\eta^5\text{-}C_5H_4CMe_2C_6H_4Me)Zr(CH_2Ph)_2]$ with $B(C_6F_5)_3$ was studied by multinuclear NMR spectroscopy and density functional theory (DFT). Detailed DFT calculations of the product explain the unusual chemical shift of the coordinated *ortho* atom of the tolyl moiety; the coordination was further elaborated by Bader and NBO analysis.

## Tetradentate Ligands

**E. Safaei, T. Weyhermüller, E. Bothe, K. Wieghardt, P. Chaudhuri* ..... 2334–2344**

A Magnetostructural and Electrochemical Study of $Cu^{II}$ and $Fe^{III}$ Complexes Containing a Tetradentate Aminebis(phenolate) Ligand with a Pendent Tetrahydrofuran Group

**Keywords:** Iron / Copper / Aminebis(phenol) / Electrochemistry / Magnetism



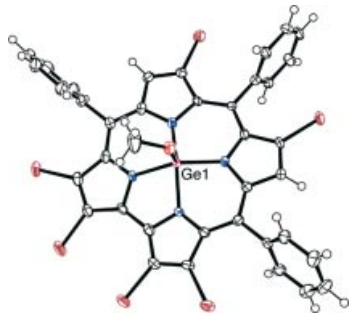
The tetradentate ligand $H_2L$ yields complexes **1**–**4**, which were characterized by various physical techniques, including X-ray diffraction, Mössbauer, electrochemical and magnetic susceptibility (2–290 K) measurements. Electrochemical oxidations are ligand-centered, the formation of phenoxyl radicals occurs from the coordinated phenolates.

## Partially Brominated Corroles

**S. Nardis, F. Mandoj, R. Paolesse,* F. R. Fronczek, K. M. Smith, L. Prodi, M. Montalti, G. Battistini ..... 2345–2352**

Synthesis and Functionalization of Germanium Triphenylcorrolate: The First Example of a Partially Brominated Corrole

**Keywords:** Corrole / Bromination / Regioselectivity / Porphyrinoid



Ge complexes of 5,10,15-triphenylcorrole were prepared using $GeCl_4$ as the metal source. By reaction with $Br_2$ under a variety of reaction conditions, the first examples of partially brominated corroles have been obtained.. Photophysical characterization of Ge corrolates confirmed the high fluorescence quantum yield of such complexes, and also led to the first observation of phosphorescence emissions from corrole complexes.

# Modular *N*,*O*-Chelating Ligands: Group-4 Amidate Complexes for Catalytic Hydroamination

**Alison V. Lee[a] and Laurel L. Schafer*[a]**

**Keywords:** Amidate ligands / Group-4 metal complexes / Hydroamination / Homogeneous catalysis / Asymmetric catalysis

Amidate ligands have been used as a modular ligand set for early transition-metal complexes, and have been found to exhibit high reactivity in the catalytic hydroamination of alkynes, allenes, and alkenes. This microreview focuses on coordination metal complexes containing amidate functionality including their bonding, structure and reactivity trends. The synthesis and characterization of a number of different group-4 metal complexes is presented, and their applications in both hydroamination and organic synthesis are discussed.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Investigations involving cyclopentadienyl (Cp) complexes have been widespread, and their application in many catalytic and stoichiometric synthetic transformations is well established.[1] However, there are several limitations associated with the modification of Cp, leading to extensive research into broadly applicable non-Cp-based ligand sets in which ligand tuning is more easily accomplished.[2,3] Examples of these classes of ligands have included, but are not restricted to, amidinates,[4–8] troponiminates,[9,10] guanidinates,[11–13] sulfonamides,[14,15] nitrogen-based ligands[16–18] and chelating nitrogen and oxygen ligand sets.[19–21] In surveying the literature, it became apparent that while many elaborate ligand classes have been studied, a very simple group of *N*,*O*-chelating molecules, namely deprotonated organic amides (amidates), has been largely overlooked.

Amides are readily synthesized and the starting materials are widely available. Amidate steric and electronic properties are easily varied, resulting in the modular synthesis of a simple, tunable ligand set. An existing limitation of this class of ligands is the variable coordination modes that amidates can adopt when binding to a metal (Figure 1). Poss-

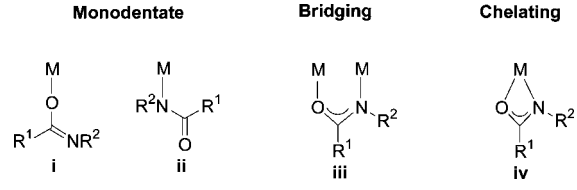

Figure 1. Some of the possible bonding modes of amidate ligands.

ibly it is the numerous potential coordination isomers in resultant complexes that has kept amidates from being fully exploited as auxiliary ligands.

A survey of the literature shows that most characterized examples of amidate metal complexes fall into one of the following four categories: i) monodentate, *O*-bound, ii) mondentate, *N*-bound, iii) bridging and iv) chelating. Examples of several complexes that are used for bioinorganic[22–24] and lanthanide coordination chemistry display these coordination modes,[25,26] however, these are outside the scope of this review, and only a few select examples will be discussed. Also, there are several examples of catalytically relevant complexes with coordinated neutral amides as ligands,[22,27,28] which will be largely excluded from our discussion. In summary, this microreview highlights recent contributions that have used the modular amidate ligand framework to advantage in the facile synthesis of catalytically active complexes. Recent results have shown that with a chelating ligand motif (bonding mode iv) a new family of catalytically active group-4 complexes can be prepared and used for hydroamination. The structure, bonding and reactivity trends observed in this easily synthesized class of compounds will be summarized here.

## Monodentate

There are several examples of amidate ligands coordinating to a metal center in a monomeric fashion through either the oxygen (**i**) or the nitrogen (**ii**). In general, coordination occurs through the more basic oxygen with "hard" metals (**1**),[29] but through the nitrogen to "soft" metals (**2**).[30,31] Most examples are reported as either type **i** or type **ii**, without reference to isomerism between the two. Furthermore, if the amide is in its neutral form, typically the ligand coordinates through the oxygen to the metal center (eg. **1**), (Figure 2).

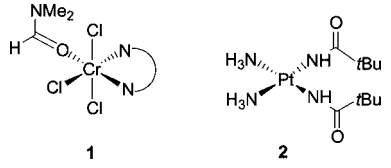

Figure 2. Examples of complexes that are bound through the amide oxygen, or the amidate nitrogen without further donation from another atom in the same ligand.

Typically, ligands that bind to a metal center solely through the amidate nitrogen have a constrained geometry such that donation through the carbonyl is unfavorable. For example, the diamidate chelating ligands in **3** and **4** in Figure 3 both have other donor atoms in their backbone that restrict the coordination environment. Complexes **3** and **4** were investigated as models for the interaction between metalloenzymes and amides of peptides in biological chemistry[23] and in medicinal inorganic chemistry,[32,33] respectively.

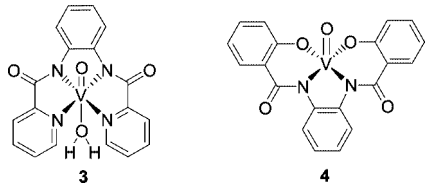

Figure 3. Examples of constrained bis(amidate) ligands that bind the metal through both the amidate nitrogen, and other atoms in the molecule.

Variations of **4** have been made with $Cu^{II}$, $Ni^{II}$, $Zn^{II}$, $Cr^{III}$, $Fe^{III}$, and $Bi^{III}$ metal centers and were used for catalytic investigations in the selective liquid-phase hydroxylation of phenol.[34,35]

While many examples in coordination chemistry investigations have monodentate binding modes of amidates, few examples of well characterized complexes for catalytic applications have been reported. The few examples included here illustrate the aspects of ligand design which must be considered in preparing well-defined complexes with discrete binding modes for use in further applications.

## Bridging

One of the most common bonding motifs observed with amidates is bonding type **iii** in which the amidate ligand bridges two metal centers. Many of these examples use very simple amidate ligands, to form complexes that have been investigated for their interesting structural features (Figure 4) and stoichiometric reactivity (Figure 5). For example, in 1979 the first Cr (**5**) and Mo complexes containing metal–metal bonds and bridging amidates were reported.[36]

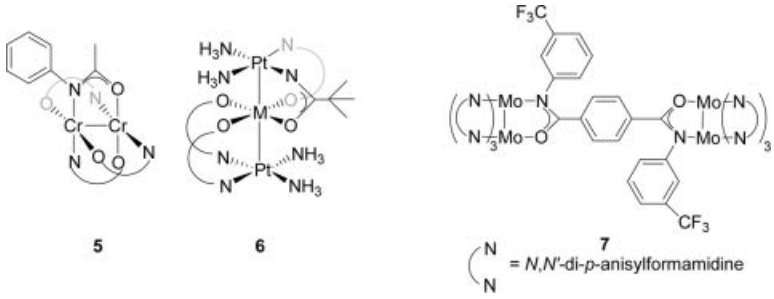

Figure 4. Examples of structurally investigated bridging amidate complexes. Complex **5** showed a very short Cr–Cr bond. Complex **6** is a heterotrimetallic complex in which amidate ligands are bridging two different metal centers, M = Cu, Co, Mn, Cd, In, Ni. Complex **7** is a tetranuclear complex with bridging amidate ligands.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

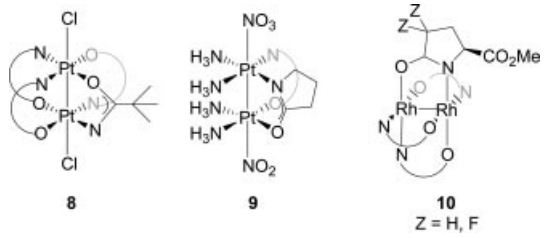

Figure 5. Bridging amidates forming lantern-type Pt dimers (**8**) or head-to-head complexes (**9**). Dirhodium(II) carboxamidates (**10**) used in metal carbene transformations.

Another example of type **iii** bonding is seen in complex **6**. These heterotrimetallic complexes contain two platinum atoms and a Cu, Co, Mn, Cd, In, or Ni atom and have been formed with various amidate ligands in which the amidate ligands bridge two metal centers (**6**).[37] Finally, structurally interesting tetranuclear complexes with bridging amidate ligands have been reported with both Mo[38] (**7**) and Re[39] metal centers.

While the aforementioned examples have been used for structural chemistry studies, similar complexes have also been used to probe stoichiometric reactivity and catalysis (Figure 5). For example, bridging amidate complexes involving Pt, as seen in **8** and **9** have been reported,[31,40–42] and their reactivity has been been investigated,[43–45] including their application in catalytic olefin functionalization.[46]

Notably, the group of Doyle and co-workers have made a series of dirhodium(II) carboxamidates of the type shown in complex **10**. These compounds have shown important reactivity in a wide variety of metal carbene transformations[47,48] and as catalysts for enantioselective hetero-Diels–Alder reactions.[49]

## Chelating

Of particular interest to this review are examples of amidates that chelate through nitrogen and oxygen to a single metal center (bonding type **iv**), which have been more rarely reported in the literature. In one example, simple amidates, such as *N*-*tert*-butylbenzamidate and substituted derivatives have been investigated in conjunction with organoaluminum compounds, such as $AlMe_3$. They have been used for the synthesis of aluminum deketiminates.[27] Furthermore, tris(amidate) aluminum(III) compounds have been synthesized and identified as the catalyst resting state in $Al^{III}$-catalyzed transamidation of carboxamides.[50]

Many of the examples of amidates chelating to metal centers have resulted from organometallic compounds reacting with isocyanates. For example, Nb and Ta complexes of the sort $M(Me)_xCl_y$ readily insert phenyl or methyl isocyanates, resulting in the methyl group adding to the carbon of the newly formed amidate chelate [Equation (1)].[51]

$$M(Me)_3Cl_2 \xrightarrow{RNCO} M(Me)Cl_2(NRC(O)Me)_2 \quad (1)$$

M = Nb, Ta
R = Ph, Me

Analogous reactions occur with $[Cp_2ZrMe_2]$[52] and $Cp_2TiR$[51] complexes and various isocyanates to give complexes of the type **12** (Figure 6).

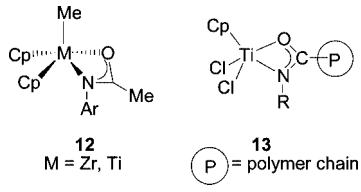

Figure 6. Amidate complex resulting from reactions with isocyanates.

With respect to polymerization catalysis, complexes like **12** are relevant to more recent examples using $TiCl_3OCH_2CF_3$ and $CpTiCl_2L$ [L = $–OCH_2CF_3$, $–N(CH_3)_2$, $–CH_3$] as catalysts for the living polymerization of isocyanates.[53] It was proposed, based on IR spectroscopic analysis, that the propagating endgroup during chain growth is an amidate-Ti complex, **13** (Figure 6), with a chelating bonding motif.[53]

There have only been a few reports of titanium amidate chelates that were not formed as intermediates in organometallic reactions. One example includes the use of caprolactam as a precursor to form the titanium complex **14** (Figure 7), which is postulated to be an intermediate in the ring-opening polymerization of lactams to form polyamides.[54]

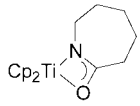

Figure 7. Example of a chelating lactamidate on titanium.

Another example of a sterically congested Cp*–Ti complex was synthesized by Stahl and co-workers, **15** (Figure 8), during investigations of $Ti^{IV}$-catalyzed transamidation.[55]

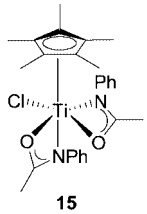

Figure 8. Chelating amidate complexes in transamidation investigations.

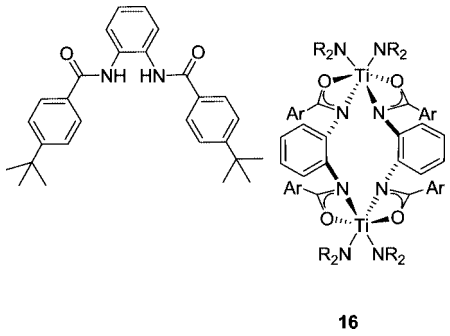
Finally, an example of a Ti complex with chelating amidates that did not contain any Cp ligands was described in 2001 by the Arnold group.[56] They employed a diamide proligand (Figure 9, left), which reacted cleanly with homoleptic titanium amides to generate a crystalline bimetallic complex **16** which maintained the chelating bonding motif.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



16

Figure 9. Proligand and resultant bimetallic bis(amidate) complex.

The two reactive $NR_2$ groups on each Ti are oriented in a *cisoid* fashion to one another, and bond lengths indicate delocalization of the amidate double bond. These compounds were screened and showed modest activity for the polymerization of ethylene with methylalumoxane activation.[56]

While a large variety of amidate structures using different metal centers and bonding motifs have been reported in the literature, it is clear that little work has been disclosed using neutral amides as easily synthesized and readily modified precursors to amidate auxiliary ligands. In particular, the variation of electronic and steric effects within the amidate backbone and their impacts on the structural properties of early transition metal complexes had not been investigated, previous to our work in the area. Most importantly, the catalytic potential of these tunable complexes were largely unexplored. The remainder of this microreview will focus on our contributions in the area of amidate-supported group-4 complexes and their applications in hydroamination catalysis.

## Monomeric Chelating Amidate Complexes of Early Transition Metals

### Proligands

Amides are easily synthesized with a variety of steric and electronic properties as the starting materials, acid chlorides and amines, are inexpensive, and commercially available. Once deprotonated, the monoanionic amidate ligand can adopt a conformation to bind the metal in a chelating fashion, in which the anion is delocalized throughout the N,C,O backbone. The hard nature of both the donor atoms in combination with early transition metals suggests that the bonding in these complexes will be largely ionic in character.

The steric nature of both the groups on the carbonyl and on the nitrogen affects the resultant metal complex as the smaller the degree of steric bulk, the greater the possibility of synthesizing dimers and oligomers. Consequently, to minimize this possibility, a certain degree of steric bulk must be maintained in the ligand design.

There are five possible geometric isomers that can result from the formation of monomeric bis(amidate) complexes, as shown in Figure 10. This large number of potential isomers complicates spectral assignments and could be a reason why amidates have been largely overlooked as auxiliary ligands.

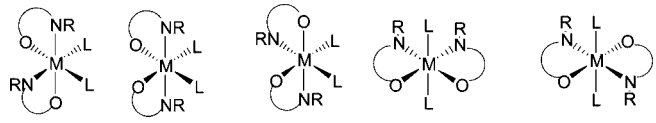


Figure 10. Possible coordination isomers of bis(amidate) complexes; L = chloro, alkyl, amido.

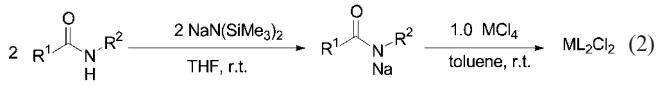
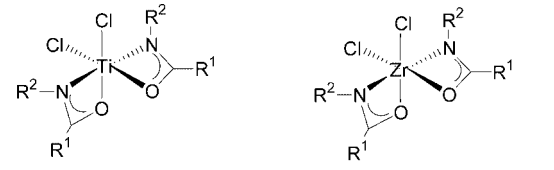
## Coordination Chemistry

### Bis(amidate) Dichloro Complexes

With several proligands in hand, we set out to make bis(amidate)metal dichloride complexes using group-4 metals such as titanium and zirconium. Metal chlorides of titanium and zirconium are inexpensive and readily available, making them attractive starting materials for the preparation of amidate supported organometallic complexes. However, we found salt metathesis with amide proligands to be very base dependent. For example, use of typical bases such as *n*BuLi, NaH, or KH resulted in only insoluble powders, while the Arnold group reported limited success with lithium bis(trimethylsilylamide).[56] However, use of sodium bis(trimethylsilylamide) resulted in a more general route for forming titanium dichlorides with several amidate ligands; see Equation (2) and Figure 11.[57]



(2)



**16a**: $R^1$ = Ph, $R^2$ = 2,6-di*i*Pr-$C_6H_3$
**16b**: $R^1$ = *t*Bu, $R^2$ = 2,6-diMe-$C_6H_3$
**16c**: $R^1$ = $C_6F_5$, $R^2$ = 2,6-di*i*Pr-$C_6H_3$
**16d**: $R^1$ = Ph, $R^2$ = 2,6-di*i*Pr-$C_6H_3$
**16e**: $R^1$ = *t*Bu, $R^2$ = adamantyl

Figure 11. Bis(amidate)titanium and -zirconium dichlorides formed through salt metathesis with $NaN(SiMe_3)_2$.

The sodium amidate salts, though isolated as crude materials, are used immediately without any further purification.

Many of these complexes have been crystallographically characterized[57] and an example (**16a**) is shown in Figure 12.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

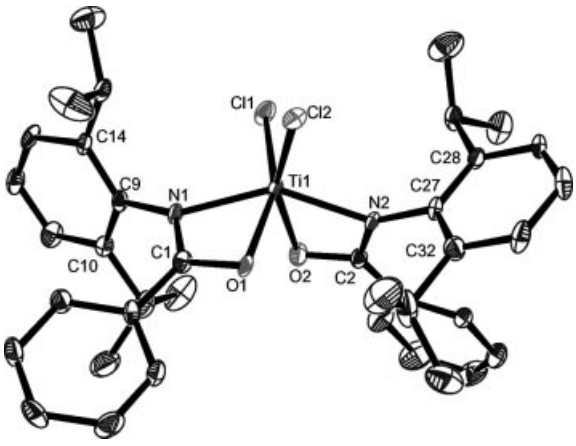


Figure 12. ORTEP plot of bis(amidate)titanium dichloride complex **16a**. Hydrogen atoms have been removed for clarity. Selected bond lengths [Å] and angles [°]: Ti–O(1) 2.025(4), Ti–N(1) 2.087(5), Ti–Cl(1) 2.2479(19), O(1)–C(1) 1.313(7), N(1)–C(1) 1.304(8), Ti–N(1)–C(2) 121.6(2), O(1)–C(1)–N(1) 111.7(6).

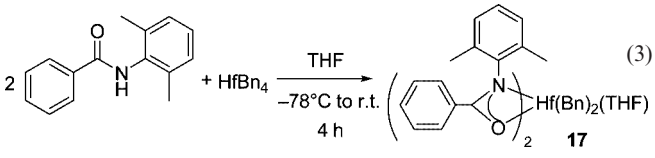
Complex **16** is pseudo-octahedral and $C_2$ symmetric. The C–O and the C–N bond lengths in the amidate backbone are nearly identical [1.313(7) Å and 1.304(8) Å, respectively] suggesting significant electron delocalization. The Ti–O bond length [2.025(4) Å] is only slightly shorter then the Ti–N bond length [2.087(5) Å]. The Ti–Cl bond lengths of 2.2479(19) Å are typical.[8] The bulky diisopropyl-substituted aryl substituents of the *N*-groups on the amidate backbone are *trans* to one another.

### Bis(amidate) Bis(alkyl) Complexes

While transition metal dichloride complexes are flexible starting materials for the preparation of many different organometallic complexes, an alternative route into organometallic compounds is to start with a homoleptic alkyl metal complex in a protonolysis reaction. Synthesis of group-4 bis(alkyl) complexes with the amidate ligand is easily achieved using this reaction. For example, a protonolysis reaction between *N*-(2,6-dimethylphenyl)benzamide and $Hf(Bn)_4$ [Equation (3)] led to the fully characterized bis(amidate)-dibenzylhafnium complex **17**.[58]



(3)

Complex **17** exhibits pseudo-$C_{2v}$ symmetry in a slightly distorted pentagonal bipyramidal geometry. A THF molecule occupies the final equatorial coordination site, which, while bound in the solid state, is labile in solution phase. This complex is stable to heat and light, though sensitive to moisture, such that exposure of **17** to a small amount of adventious moisture led to the formation of an interesting tetrametallic bridged oxo species, in which the amidates adopted both a chelating and a bridging mode of metal coordination.[58] An analogous protonolysis reaction led to the bis(amidate)-dibenzyl-$Zr^{IV}$ complex **18** (Figure 13).

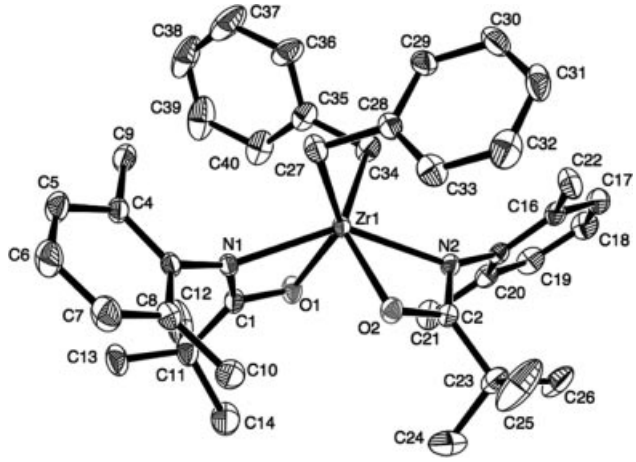


Figure 13. ORTEP plot of bis(amidate)-dibenzyl-zirconium complex (**18**). Selected bond lengths [Å] and angles [°]: Zr–O(1) 2.0988(13), Zr–O(2) 2.1080(13), Zr–N(1) 2.2836(14), Zr–N(2) 2.875(13), Zr–C(27) 2.2440(13), Zr–C(34) 2.2390(19), N(1)–C(1) 1.286(2), C(1)–O(1) 1.307(2), O(2)–Zr–N(2) 58.39(5), C(27)–Zr–C(34) 97.18, N(2)–C(2)–O(2) 112.29(14).

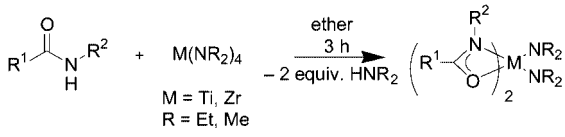
In contrast to the 7-coordinate **17**, **18** is a $C_2$-symmetric, slightly distorted octahedral compound that does not have a bound THF molecule in the solid state.

### Bis(amidate) Bis(amido) Complexes

The most widely synthesized and studied metal complexes in our laboratories are bis(amidate) bis(amido)-titanium and -zirconium complexes. These complexes are both precursors to other organometallic compounds and catalytically active species for synthetic transformations such as hydroamination. Bis(amidate) bis(amido) complexes of titanium and zirconium are easily synthesized in high yields by a protonolysis reaction as shown in Equation (4).



(4)

A wide variety of organic amides have been used for making these bis(amidate) bis(amido) complexes.[59] In general, amides containing alkyl groups on both the carbonyl and the nitrogen yield metal complexes that are oily and difficult to purify. A simple switch to a phenyl group on either the nitrogen or the carbonyl yields crystalline metal complexes suitable for X-ray analysis (**19**, Figure 14).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

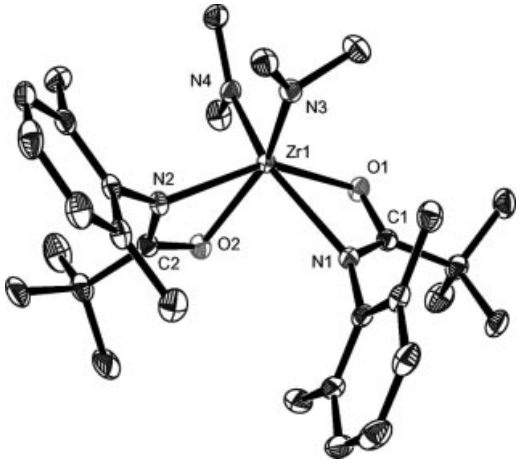


Figure 14. ORTEP plot of bis(amidate) bis(amido)-zirconium complex **19**. Hydrogen atoms have been removed for clarity. Selected bond lengths [Å] and angles [°]: Zr–O(1) 2.1524(19), Zr–O(2) 2.201(2), Zr–N(1) 2.403(2), Zr–N(2) 2.3055(19), Zr–N(3) 2.038(3), Zr–N(4) 2.044(2), O(1)–Zr–N(1) 57.25(8), O(1)–C(1)–N(1) 113.8(3).

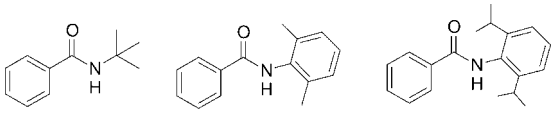
This $C_2$-symmetric compound **19** exhibits pseudo-octahedral geometry with the dimethylamido ligands oriented in a *cisoid* fashion, which is advantageous for catalytic applications. A switch to proligand *N*-*tert*-butylbenzamide yielded bis(amido) complexes of both titanium and zirconium as different geometric isomers, although the amido ligands remain *cis* to one another. A subsequent investigation kept the phenyl substituent on the carbonyl constant, and varied the steric properties of the nitrogen substituent as shown in Figure 15.[60]



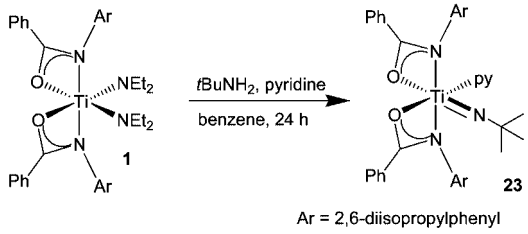
**20** **21** **22**

Figure 15. Proligands with varying degrees of steric bulk on the nitrogen.

Bis(amidate) bis(amido)-titanium complexes were formed using **20**–**22**, and characterized by X-ray crystallography. The steric properties of the proligand affect the geometric isomer observed in the solid state, such that the bulky substituent of **22** ensured that the *N*-substituents are *trans* to each other, in contrast to **20**, where the *N*-substituents are *cis*-oriented. DFT calculations were performed on these complexes in order to better understand the different possible coordination geometries and bonding interactions.[60] The calculations predicted the lowest energy isomers for proligands **20** and **22**, which also matched the structures observed in the solid state. However, in NMR spectroscopic investigations, fluxional behavior is observed suggesting that there is an interconversion between low-energy isomers.

## Bis(amidate) Imido Complexes

As the bis(amidate) bis(amido)-metal complexes proved to be easily accessed with this ligand set, we extended this chemistry further to synthesize bis(amidate) imido complexes. As well as exhibiting interesting coordination chemistry, these complexes are implicated as model systems of mechanistic intermediates (vide infra). The first reported characterized amidate-supported titanium–imido complex **23** was synthesized; see Equation (5).[61]



(5)

This reaction is general to this class of complexes and other terminal imido compounds **24** have been prepared using amidate auxiliary ligands (Figure 16).

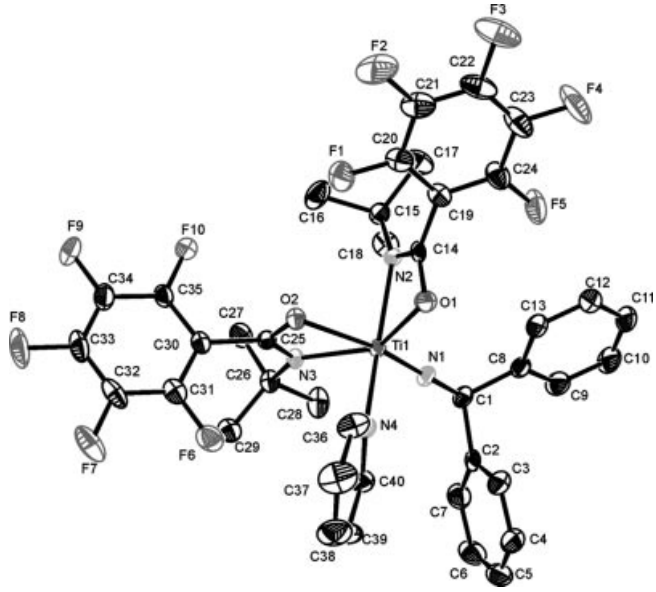


Figure 16. Solid-state molecular structure of bis(amidate) imido-titanium complex **24**. Hydrogen atoms are removed for clarity. Selected bond lengths [Å] and angles [°]: Ti–N(5) 1.705(3), Ti–O(3) 2.259(2), Ti–O(4) 2.111(2), Ti–N(6) 2.125(3), Ti–N(7) 2.165(3), Ti–N(8) 2.214(3), C(41)–N(5)–Ti 176.3(2), O(3)–C(54)–N(6) 117.9(3).

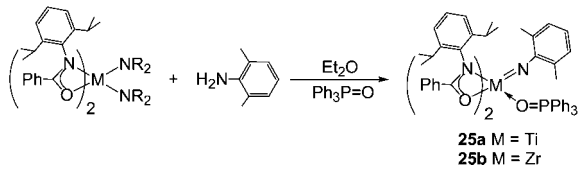
These group-4 imido complexes can also be trapped with triphenylphosphane oxide as shown in Equation (6).



(6)

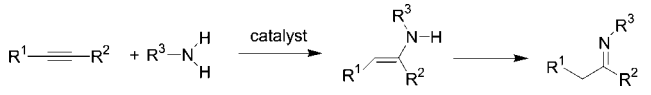
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The solid-state molecular structure of the Zr-imido complex **25b** is of distorted pentagonal-pyramidal geometry where both the amidate and the TPPO ligands are pseudo-equatorial and the imido is in the axial position.[62]

Amidates are a modular ligand set and they have been used in the synthesis of a wide variety of metal complexes. The ease with which both the proligand and the metal complexes are synthesized makes this auxiliary ligand set very desirable for catalytic investigations. As both the steric and the electronic properties of the system can be readily varied, there is enormous potential for tuning of catalytic reactivity.

## Hydroamination Catalysis

One area in which early transition metal bis(amido) complexes have found wide-spread catalytic application is in hydroamination. Hydroamination is the addition of nitrogen and hydrogen across a carbon–carbon multiple bond such as an alkyne (shown), allene or alkene; see Equation (7).

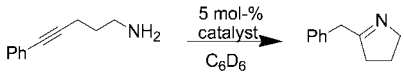


(7)

This leads to the formation of enamines, imines, and amines, which are important building blocks in pharmaceuticals, detergents, and dyes.[63] Furthermore, as many procedures for the synthesis of amines are multi-step and inefficient,[64] catalytic hydroamination has the potential to greatly improve existing methodology. There are no side products in this reaction, thus hydroamination can be used in a tandem reaction sequence, utilizing the imine as an in situ intermediate.[65–68] Following an initial report of titanium catalyzed hydroamination by Rothwell and coworkers,[69] research into hydroamination catalysis has also followed the trend of focusing on Cp-based ligand systems and then moving onto non-Cp-based catalysts. A variety of systems have been developed for hydroamination reactions including work from the groups of Bergman,[15,64,70–73] Livinghouse,[74,75] Odom,[67,76–81] Beller,[65,82–86] Doye,[87–94] ourselves,[59,61,62,95,96] and others.[11,97–105] The low toxicity, low cost, and high availability of group-4 metals make them attractive systems for catalytic applications.[106] To this end, we have established amidate complexes of Ti as tunable catalytic systems for highly reactive and regioselective hydroamination.

### Alkyne Hydroamination

Initial investigations into catalytic hydroamination began using three different proligands: *N*-*tert*-butyl-2-methylpropanamide (**26**), *N*-*tert*-butylbenzamide (**27**), and *N*-*tert*-butylperfluorophenylamide (**28**). Bis(amidate) bis(amido)-titanium and -zirconium complexes were synthesized and the tunable reactivity accessible through modification of the metal and electronic properties of the ligand is shown in Table 1 and Equation (8).



(8)

Table 1. Results for intramolecular hydroamination of alkynes.

| Entry | Proligand | Metal | *T* [°C] | *t* [h] | % Yield[a] |
|---|---|---|---|---|---|
| 1 | **27** | Zr | 60 | 24 | 95 |
| 2 | **28** | Zr | 60 | 7 | 98 |

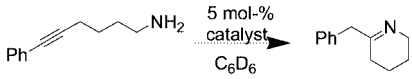
[a] NMR conversion vs. 1,3,5-trimethoxybenzene. [b] Reported yield for the isolated amine product after reduction of imine.

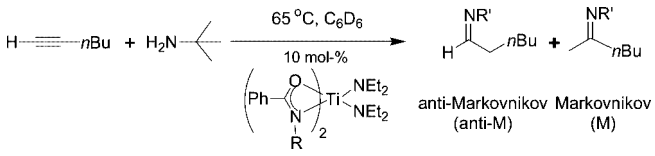
The titanium-based complexes were more active than the corresponding zirconium complexes. It is also apparent that electron-withdrawing substituents enhance the catalytic activity of the complex. Moreover, the most active species (Entry 5) is more active then both the corresponding Cp complex, and $Ti(NMe_2)_4$. As a further comparison to $Ti(NMe_2)_4$, a more challenging intramolecular substrate was attempted; see Equation (9).



(9)

In this case our system went to completion within 3 h at 40 °C whereas use of $Ti(NMe_2)_4$ only went to 30% completion in the same time period.

Encouraged by these initial findings, we set out to screen a number of our bis(amidate) bis(amido)-titanium complexes, particularly to see how steric bulk on the nitrogen would affect the catalytic activity. Furthermore, we wanted to investigate the more challenging intermolecular hydroamination reaction. This transformation can lead to the formation of two regioisomers and thus regioselectivity is also an important concern; see Equation (10) and Table 2.



(10)

The complex derived from the proligand with the bulkiest substituent on the nitrogen (Entry 5) was the most effective, giving the highest yield, the lowest reaction time and excellent regioselectivity. Most importantly, this complex **29** affected regioselective hydroamination, in high yield, with a broad range of substrates including the most challenging benzylamine substrate.[65] The wide range of alkynes and functional groups tolerated is illustrated in Table 3.

Table 3. Hydroamination of various terminal alkynes with alkylamines.

[a] Isolated yield.

In our initial investigations into hydroamination, it was noted that secondary amines did not lead to hydroamination products and only unreacted starting materials were recovered. This suggests that our system mediates alkyne hydroamination via an imido intermediate as elucidated by Bergman and co-workers in the early 90's (Figure 17).[73]

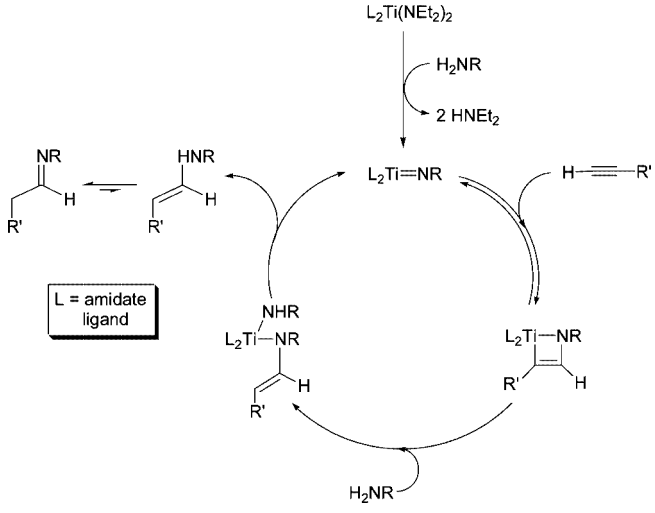

Figure 17. Proposed simplified catalytic cycle for alkyne hydroamination.

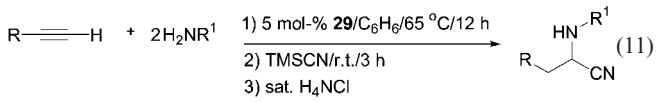
The bis(amido) precatalyst reacts with the primary amine to form the requisite titanium–imido complex. Coordination by the alkyne to this electrophilic metal center, followed by cycloaddition leads to the formation of titanaazacyclobutene. Protonation of the Ti–C bond by another equivalent of primary amine gives the enamide-amide complex, which then undergoes α-elimination to give the hydroamination product and regenerate the catalytically active imido species.

We have been successful in synthesizing titanium–imido complexes through reactions of the amido complexes with a stoichiometric amount of primary amine (vide supra). Our system forms the imido species very quickly such that when two hydroamination reactions are carried out side by side, one with the bis(amidate) bis(amido)-titanium precatalyst and the other with the bis(amidate) imido-titanium precatalyst, both show 50% product formation after approximately 50 min.[61] This is in contrast to many literature reports that state that there is a significant induction period required for conversion to the catalytically active imido complex.[70] We propose that the polarization of the M–N bonds and highly electrophilic metal center of the amidate complexes affects both the rate of conversion from the precatalyst to the imido complex, and the subsequent reactivity of this imido species. It is important to note that during all of the aforementioned reactions we have not observed any loss of the amidate ligands.

## Applications in Synthesis

The hydroamination of terminal alkynes with precatalyst **29** leads to the formation of synthetically useful aldimines. These often unstable intermediates are useful in organic chemistry for synthesizing other more complex molecules. For example, catalytic hydroamination has been combined with the Strecker reaction, to give a tandem C–N, C–C bond forming sequence for the synthesis of α-cyano amines; see Equation (11).[66]



α-Cyano amines are useful molecules for the synthesis of diamines, amino acids, amino acid derivatives and amino alcohols. This methodology has been applied to the synthesis of a number of amino methyl esters that were synthesized in good overall yields (Table 4).

Precatalyst **29** has also been applied toward the synthesis of a number of biologically important molecules. For example substituted tetrahydroisoquinolines (THIQs), molecules that have promising biological and pharmacological properties, can be synthesized using hydroamination as a key step.[61] Hydroamination can also be used to construct the more complex tricyclic benzo[*a*]quinolizine framework in three tandem reactions (Figure 18).

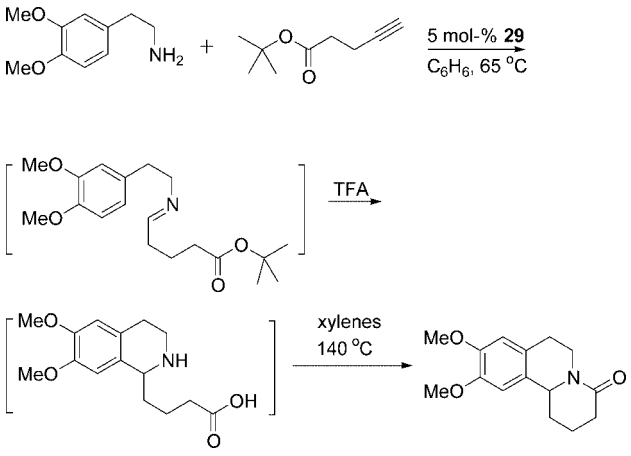

Figure 18. One pot synthesis of tricyclic benzo[*a*]quinolizine framework using hydroamination.

## Allene Hydroamination

The intermolecular hydroamination of allenes is notably more challenging then both the intramolecular hydroamination of allenes and the intermolecular hydroamination of alkynes.[15,64] This reaction can result in the formation of three regioisomers as shown in Figure 19.

While this transformation has received limited attention in the literature, in general it has been found that with early transition metals it is usually regioisomer **30** that is formed (in both the *E* and *Z* isomers).[15,70,73,98,104] With late transition metals, on the other hand, it is regioisomers **31** and **32** that are reported, and the double hydroamination side-product is also observed.[107–111] To begin our investigations into the hydroamination of allenes, we used our most active alkyne hydroamination catalyst, **29**, and investigated the hydroamination of aryl and alkyl allenes with a variety of amines (Table 5).

While these reactions were slower then the corresponding alkyne reactions, the products were formed in 7–24 h at 85–90 °C. In all cases, regioisomer **30** was observed as both the *E* and *Z* isomers. These first examples of intermolecular allene hydroamination with alkylamines require higher temperatures, but are compatible with primary amines of varying steric bulk.[112] The ketimine products isolated here contrast with the aldimine products obtained from terminal al-

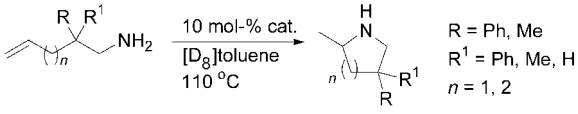
kyne hydroamination. Interestingly, the allene substrates used here were prepared from terminal alkyne substrates.[111] Therefore, by judicious selection of the hydroamination substrate either the ketimine or the aldimine products can be selectively obtained with precatalyst **29**.

### Alkene Hydroamination

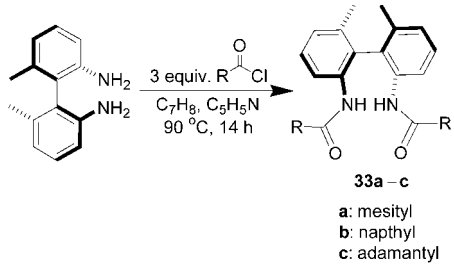
Alkene hydroamination is more challenging then both alkyne and allene hydroamination, and thus initial investigations have focused on the intramolecular hydroamination of aminoalkenes. In general, examples of group-4 metal complexes for alkene hydroamination are much less numerous than alkyne hydroamination. There have been a few reports of cationic group-4 complexes that can catalyze the hydroamination of secondary aminoalkenes.[113,114] These reactions are thought to proceed through a σ-bond insertion mechanism, analogous to the established mechanism for the isovalent lanthanide catalysts.[115,116] Furthermore, these cationic group-4 complexes are unable to catalyze the cyclization of primary aminoalkenes, an observation that was attributed to the formation of catalytically inactive imido complexes. Very recently there have been a few reported examples of neutral group-4 metal complexes for the hydroamination of primary aminoalkenes.[117,118] In light of these results, we wanted to investigate our bis(amidate) bis(amido) complexes for this reaction.[62] Intramolecular reactions can be carried out as shown in Equation (12).



(12)

Both the Ti complex **29** and the Zr analogue can catalyze this reaction, although the Zr complex is the more active. In order to probe the application of Zr-imido complexes for alkene hydroamination, we tested the bis(amidate) imidometal complexes **25a**,**b** for this desirable hydroamination reaction. Again, both were active in this cyclization, and the Zr complex **25b** was more active then the Ti analogue **25a**. These are the first examples of isolable group-4 imido complexes for the hydroamination of alkenes. Kinetic experiments revealed that the reaction is first-order in catalyst, and first order in substrate. It was also shown that there was no appreciable difference in the half-lives for the bis(amido) and imido precatalysts, implying that both precatalysts share a common catalytically active species. Most importantly, there was no observed activity when these catalysts were used with secondary aminoalkenes. This further supports the imido complex as being the catalytically active species. Preliminary substrate scope investigations showed that both substituted pyrrolidine and piperidine complexes could be formed with this system.[62]

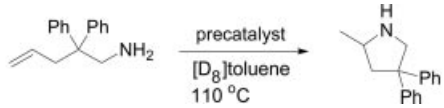
Catalytic asymmetric alkene hydroamination is an extremely attractive goal as it leads to the generation of enantioenriched α-chiral amines. To date, there is no general catalyst that can perform this reaction. Most breakthroughs in this area have been with rare-earth metal catalysts.[119–127] There have also been some chiral late-transition metals that have been investigated for enantioselective intermolecular hydroamination with activated alkene and alkyne substrates.[128–134] The cationic group-4 complexes that were mentioned in the preceding section are capable of asymmetric hydroamination of secondary aminoalkenes, albeit with modest enantioselectivities.[114] Very recently, Bergman and co-workers reported a number of neutral bis(amido)zirconium precatalysts for the asymmetric hydroamination of aminoalkenes which displayed *ee* values of up to 80%.[135] Our efforts in this area include the synthesis of tethered bis(amidate) ligands using 2,2′-diamino-6,6′-dimethylbiphenyl as the diamine backbone to control both the coordination isomerism and the chirality. Three different bis(amides) **33a**–**c** were synthesized with mesityl, naphthyl, and adamantyl substituents on the carbonyl; see Equation (13).



(13)

After synthesis of the proligands, neutral κ⁴-tethered bis(amidate) bis(amido)-zirconium complexes were made to give precatalysts **34a**–**c** which were screened for catalytic activity in the test reaction shown below (Table 6).

Table 6. Screening for asymmetric hydroamination with precatalysts **34a**–**c**.



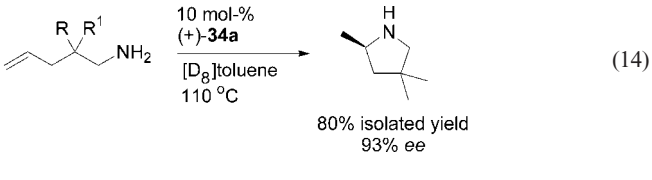
| Entry | Precatalyst | mol-% | *t* [h] | % Conversion[a] | % *ee*[b] |
|---|---|---|---|---|---|
| 1 | (+)-**34a** | 10 | 1.25 | >98 (93)[c] | 74 (*R*)[d] |
| 2 | (+)-**34b** | 10 | 18 | >98 | 31 |
| 3 | (+)-**34c** | 10 | 3 | >98 | 39 |
| 4 | (–)-**34a** | 10 | 1.25 | >98 (93)[c] | 72 (*S*)[d] |
| 5 | (+)-**34a** | 5 | 2.5 | >98 | 74 |

[a] Measured by $^1$H NMR spectroscopy. [b] Enantiomeric excess based on $^1$H NMR spectroscopy of the product following derivatization with (+)-(*S*)-α-methoxy-α-trifluoromethylphenylacetyl chloride. [c] Isolated yield. [d] Absolute stereochemistry assigned based on $^{19}$F NMR of the (+)-(*S*)-α-methoxy-α-trifluoromethylphenylacetyl chloride derivative.

The zirconium complex **34a** gave the highest *ee* values (74%) for this reaction. Comparable *ee* values could be obtained with the other enantiomer of the proligand (72%). When this optimized catalyst is used with the commonly

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tested dimethyl-substituted substrate [Equation (14)], a remarkable enantioselectivity of 93% was observed.[96] This complex was then fully characterized, and a solid-state molecular structure of the $HNMe_2$ adduct is shown in Figure 20.



(14)

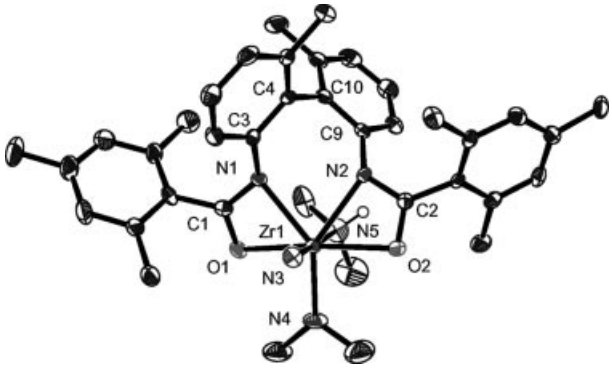


Figure 20. The ORTEP plot of (+)-**34a** (-$CH_3$ substituents omitted from the N4 dimethylamido ligand for clarity).

This is a seven-coordinate monomeric complex with distorted pentagonal-bipyramidal geometry.[96]

Investigations into the mechanism of this reaction are ongoing. As we understand more about how this reaction progresses, we can modify our ligand set to optimize reactivity and enantioselectivity. Ultimately, the goal is to design a precatalyst that would be capable of performing intermolecular alkene hydroamination leading to the general synthesis of enantioenriched α-chiral amines.

## Conclusions

As has been shown in this review, amidates are an excellent class of modular ligands for the synthesis of a wide variety of metal complexes, including catalytically active Group-4 compounds. Most importantly, the bis(amidate) bis(amido) and imido complexes have shown excellent catalytic reactivity for the hydroamination of alkynes, allenes, and alkenes. The ease of synthesis of the proligands has led to the facile tuning of catalytic reactivity and ready evaluation of structure–activity relationships. These catalytic systems show promise for the development of new catalysts that can be used for the synthesis of complex molecules with enantiomerically enriched α-chiral amines.

# Low-Valent Nickel and Palladium Complexes with 1,1′-Bis(phosphanyl)-ferrocenes: Syntheses and Structures of Acrylic Acid and Ethylene Complexes

Jens Langer,[a] Reinald Fischer,[a] Helmar Görls,[a] and Dirk Walther*[a]

**Keywords:** Alkene ligands / Chelates / Nickel / Palladium / P ligands

Thermally stable acrylic acid complexes with low-valent nickel or palladium of the type [(L)M($\eta^2$-$CH_2$=CH-COOH)] [**1a**: M = Ni, L = 1,1′-bis(diphenylphosphanyl)ferrocene (dppf), **1b**: M = Ni, L = 1,1′-bis(diisopropylphosphanyl)ferrocene (dippf), **1c**: M = Pd, L = dippf] were obtained by reaction of [Ni(cod)$_2$] or [(L)Pd(nb)] with acrylic acid in the presence of the phosphane ligands. X-ray diffraction analysis of **1a** and **1c**, respectively display that only the olefin part is coordinated. Hydrogen bonds between two carboxyl groups result in dimers in the solid state. The isomeric nickela-cyclic carboxylates of the type [(L)Ni($CH_2CH_2COO$)] are stable complexes in case of **2a** (L = dppf) and **2b** (L = dippf) whereas the unstable compound **2c** [L = 1,1′-bis(di-*tert*-butylphosphanyl)-ferrocene (dtbpf)] undergoes fast reductive decoupling to form $CO_2$ and the ethylene complex [(dtbpf)Ni(ethylene)] (**3c**). The related complex [(dippf)Ni(ethylene)] (**3b**) was prepared from nickel(0) complexes by ligand exchange reaction. **3b** and **3c** were characterized by elemental analyses, NMR spectroscopy and X-ray structure analysis of single crystals.

## Introduction

Recently we have described some model complexes of the hypothetical catalytic reactions between ethylene and $CO_2$ to form acrylic acid or its derivatives.[1] In connection with these investigations we have also tried to synthesize the hitherto unknown nickel(0) complexes with $\eta^2$-coordinated acrylic acid which are assumed to be model compounds of the final intermediate of the catalytic cycle. However, such complexes could not be obtained with N-donor ligands or phosphanes of the type $R_2P(CH_2)_nPR_2$.

In this paper we report that some 1,1′-bis(phosphanyl)-ferrocenes (L) are able to form surprisingly stable complexes of the type [(L)M($\eta^2$-acrylic acid)]. Furthermore, we have isolated the isomeric form of [(dippf)Ni(acrylic acid)], the metallacycle [(dippf)Ni($CH_2CH_2COO$)], and we also succeeded in obtaining ethylene nickel(0) complexes with bis(phosphanyl)ferrocene ligands which are also hitherto unknown. These three types of complexes may also be considered as model compounds for intermediates of the metal-mediated reaction between ethylene and $CO_2$ to form acrylic acid.

Generally, the low-valent nickel chemistry with 1,1′-bis-(phosphanyl)ferrocene ligands L is rather limited. To the best of our knowledge the only isolated nickel(0) compounds are some carbonyl complexes[2,3] and [(dppf)-Ni(cod)].[4] The compound [(dppf)$_2$Ni] was only prepared in situ.[5,6] This is somewhat surprising since low-valent nickel complexes with 1,1′-bis(phosphanyl)ferrocene ligands are known to be intermediates in numerous homogeneous catalytic reactions.[7–13] In addition, they may serve as precursors for new catalysts and for the study, in a stoichiometric manner, of key steps in the catalytic reactions.

## Results and Discussion

### Nickel(0) and Palladium(0) Complexes with Acrylic Acid

The acrylic acid complexes **1a** and **1b** were obtained by reacting a mixture of [Ni(cod)$_2$], dppf or dippf and acrylic acid in a solution of THF at 0 °C according to Scheme 1.

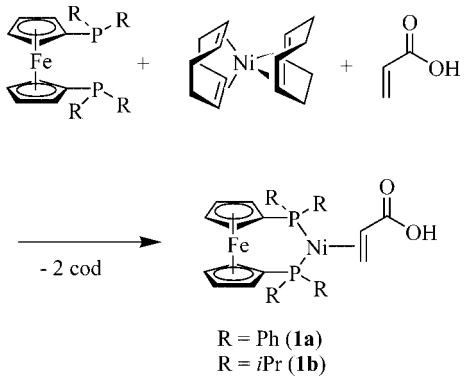

Scheme 1. Formation of nickel complexes with acrylic acid.

**1a** was isolated in good yields (71%) as red crystalline compound. NMR spectroscopic data showed that both phosphorus donor atoms coordinate to the nickel in a different chemical environment ($^{31}P\{^1H\}$ NMR ([D$_8$]THF): 26.7 and 32.6 ppm). In the $^1H$ NMR spectrum ([D$_8$]THF) the proton signals of the olefinic $CH_2$ group appeared at $\delta$ = 1.95 and 2.25 ppm and the resonance of the olefinic CH group was found at $\delta$ = 2.98 ppm. A broad signal for the COOH proton appeared at $\delta$ = 9.64 ppm. Furthermore, six different signals of the cp groups integrating together to eight protons were observed, and the 20 protons of phenyl groups appeared between 7.28 and 7.80 ppm. The $^{13}C$ NMR spectrum also confirmed the olefin-like coordination of the acrylic acid with the two signals for the olefinic carbons at $\delta$ = 43.9 and 49.8 ppm and the signal of the COOH group at $\delta$ = 175.9 ppm.

Single crystals of **1a** were grown from a solution of THF and an X-ray diffraction analysis (Figure 1) showed the nickel atom, surrounded by two phosphorus atoms and the two carbon atoms C1 and C2 of the alkene group. Since the angle between the P1,P2,Ni plane and the C1,C2,Ni plane is only 6.24°, the coordination geometry around the metal centre can be considered as essentially planar. The COOH group is not coordinated. Complex **1a** forms a dimer in the solid state since two carboxylic groups are connected by the typical hydrogen bond pattern of carboxylic acids. As expected, the bond length between C1 and C2 of the olefin group [1.417(4) Å] is slightly enlarged compared with the uncoordinated state of acrylic acid. Other relevant bond lengths and angles (see caption of Figure 1) are within the normal range and need therefore no further discussion.

The reaction between [Ni(cod)$_2$], dippf und acrylic acid in THF resulted in a mixture of the acrylic acid complex **1b** as main product and traces of a second compound, suspected to be the isomeric nickela-cyclic carboxylate [(dippf)-Ni($CH_2CH_2COO$)] (**2b**, see below) according to the signals in the $^{31}P$ NMR spectrum of the mother liquor.

The pure complex **1b** was isolated upon crystallisation from a solution of THF or DMF in good yields. $^1H$ NMR spectroscopy of **1b** revealed that the compound has a similar structure as found for **1a**: The proton signals of the coordinated $CH_2$=CH- group at 2.57 and 2.88 are only slightly downfield shifted compared with those of **1a**, and

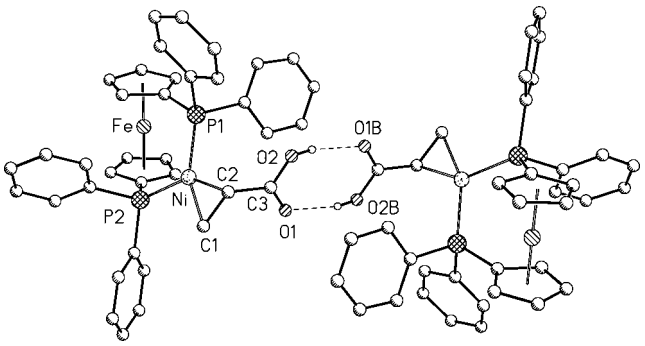

Figure 1. Molecular structure of **1a** (H atoms except the one at O2 are omitted for clarity, cocrystallized THF not shown). Selected bond lengths [Å] and angles [°]: Ni–C1 1.945(2), Ni–C2 1.993(3), Ni–P1 2.1781(7), Ni–P2 2.1411(8), C1–C2 1.417(4), C2–C3 1.446(4), C3–O1 1.275(4), C3–O2 1.291(4), P1–Ni–P2 109.71(3), P1–Ni–C2 111.55(9), P2–Ni–C1 109.71(3), C1–Ni–C2 42.2(1), plane(P1,P2,Ni)-plane(Ni,C1,C2) 6.24.

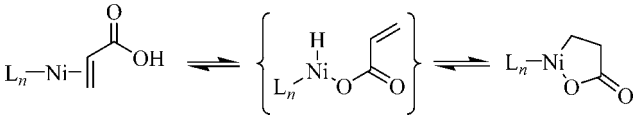
the resonance of the COOH proton appeared at $\delta$ = 10.35 ppm. The $^{13}C$ resonances of **1b** for the olefin group were found at 32.7 (=$CH_2$) and 42.7 (=CH) ppm and the signal of the COOH group was observed at $\delta$ = 177.7 ppm confirming the olefin-like coordination of the acrylic acid ligand as well. In addition, X-ray structure of single crystals (not depicted) showed that **1b** has essentially the same solid-state structure as **1a** with the $\eta^2$ coordination of the acrylic acid ligand and hydrogen bonds between two acrylic acid ligands resulting in a dimer.

Reaction between acrylic acid and nickel(0) complexes in the presence of $Cy_3P$ was already investigated by Yamamoto et al.[14] In this case, however, no stable nickel(0) complex of acrylic acid was formed, instead the interconversion into the isomeric nickela-cyclic carboxylate [($Cy_3P$)-Ni($CH_2CH_2COO$)]$_n$ was observed. This clearly demonstrates the strong influence of the supporting ligands on the following equilibrium (Scheme 2).



Scheme 2. Equilibrium between L$_n$Ni($CH_2$=CH-COOH)) and [(L$n$)Ni($CH_2CH_2COO$)].

**1a** is surprisingly thermally stable in THF as well in the solid state. Even heating the complex for 3 h in refluxing THF did not result in any reaction. This demonstrates that the isomerization into the nickela-cyclic carboxylate (see Scheme 2) is in this case an energetically unfavourable pathway.

So far, only the metal(0) acrylic acid complex [(acrylic acid)Fe(CO)$_4$] was described.[15] Furthermore, the dimeric $Cu^I$ compound [ClCu(acrylic acid)]$_2$ with $\eta^2$ coordinated acrylic acid has been prepared.[16] In addition, Carmona has found that acrylate hydrido molybdenum(II) and tungsten(II) complexes were formed by reaction of ethylene and $CO_2$ at an electron-rich Mo(0) or $W^0$ fragment.[17] In contrast, acrylic ester complexes with $Ni^0$ or $Pd^0$ have been

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

found to be stable[18,19] due to the lack of the reactive COOH group.

To demonstrate that the ability of 1,1′-bis(phosphanyl)-ferrocene ligands in stabilizing acrylic acid complexes is not restricted to nickel(0) we also prepared the related $Pd^0$ complex [(dippf)Pd(acrylic acid)] **1c** by reacting of [(dippf)-Pd(nb)] (nb = norbornene) with an excess of acrylic acid in THF [Equation (1)].

$$[(\text{dippf})\text{Pd(nb)}] + \text{HOOC–CH=CH}_2 \rightarrow [(\text{dippf})\text{Pd}(\eta^2\text{-CH}_2\text{=CH–COOH})]\ (\mathbf{1c}) + \text{nb} \quad (1)$$

Isolation of the orange solid and recrystallisation from diethyl ether resulted in orange single crystals. To confirm the structure in the solid state, the X-ray crystal structure analysis of **1c** was carried out. Figure 2 reveals the molecule structure which shows that **1c** has the same arrangement of the ligands as the related nickel(0) acrylic acid complexes with the olefin part of acrylic acid being coordinated at $Pd^0$ centre and with a C=C bond lengths of 1.419(3) Å. Also, the other bond lengths and angles lie within a typical range. The angle between the plane (P1,P2,Pd) and the (Pd, C1,C2) is only 2.27° which undoubtedly shows that the $Pd^0$ centre is in a planar environment formed by the two P donor atoms and the carbons C1 and C2 of the olefinic part of the acrylic acid ligand. **1c** forms also a dimer in the solid state in which two carboxylic groups are connected by hydrogen bonds.

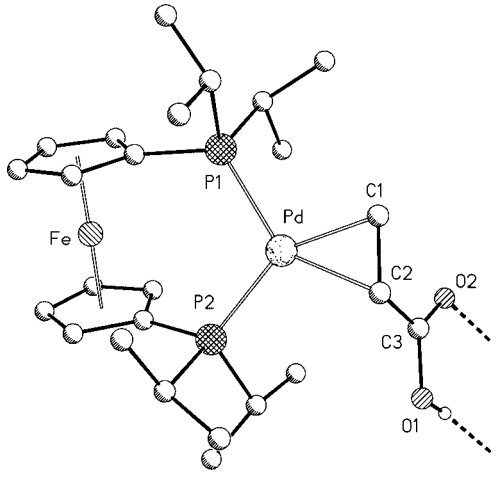


Figure 2. Molecular structure of **1c** (the formation of hydrogen bonds analogously to fig. 1 is indicated by the dotted lines indicating the points at which the dimer is formed; H atoms except the one at O1, and cocrystallized THF have been omitted clarity). Selected bond lengths [Å] and angles [°]: Pd–C1 2.100(2), Pd–C2 2.154(2), Pd–P1 2.3116(7), Pd–P2 2.3215(8), C1–C2 1.419(3), C2–C3 1.457(3), C3–O1 1.327(3), C3–O2 1.237(3), P1–Pd–P2 105.98(3), P1–Pd–C1 104.35(7), P2–Pd–C2 110.67(7), C1–Pd–C2 38.95(9), plane (P1,P2,Pd)-plane(Pd, C1,C2) 2.27.

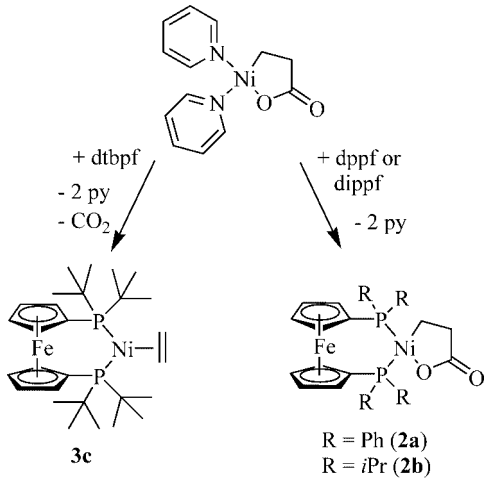
### Nickela-Cyclic Carboxylates of the Type [(L)NiCH$_2$CH$_2$COO] (L = dppf, dippf)

In order to proof whether the isomers of **1**, the nickela-cyclic carboxylates of the type [(L)Ni($CH_2CH_2COO$)] (L: dppf, dippf, dtbpf) (**2**) are stable compounds, we reacted [$(py)_2$Ni($CH_2CH_2COO$)] with these ligands in DMF at room temperature. This pyridine complex is a labile ligand complex which serves as precursor for many other reactions.[20–22] Scheme 3 displays that, depending on the bis-(phosphanyl)ferrocene ligands, different products were formed.



Scheme 3. Reactions of bis(phosphanyl)ferrocene ligands with a nickela-lactone.

In contrast to the formation of the thermally unstable complex **2a** from dppf and [$(py)_2$Ni($CH_2CH_2COO$)], the reaction with dippf resulted in the formation of the thermally stable nickela-cyclic carboxylate **2b** which was isolated as orange crystals in high yields (85%). **2b** was fully characterized by elemental analyses, IR, and NMR spectroscopy, and by X-ray analysis of single crystals. In the $^1$H NMR spectrum of **2b** in [$D_8$]THF the Ni-$CH_2$ protons were observed at $\delta$ = 0.96 ppm and those of the $CH_2COO$ unit resonated at $\delta$ = 1.96 ppm; each of these signals correspond to two protons. The signals of the $CH_3$ groups appeared at 1.23–1.54 ppm, the signals of the CH groups were found at 2.20–2.47 ppm and the cp protons were observed as singlets at $\delta$ = 4.40 and 4.44 ppm. In addition, the $^{13}$C NMR spectrum showed the expected simple pattern of signals for the Ni–$CH_2$ group at 12.4 and for the $CH_2$-COO- fragment at $\delta$ = 37.2 ppm, besides the resonances for the ligand carbons, and in the $^{31}P\{^1H\}$ NMR spectrum in [$D_7$]DMF the $^{31}$P signals appeared at $\delta$ = 36.4 and 44.7 ppm. In the IR spectrum the ν(C=O) band was found at 1634 cm$^{-1}$.

Single crystals were grown from DMF at –20 °C and the crystal structure of **2b** has been solved by X-ray diffraction analysis. Its molecule structure is displayed in Figure 3 and shows it to be very similar to the starting complex [$(py)_2$Ni($CH_2CH_2COO$)][22] and other closely related nickela-cyclic carboxylates.[1,21] However, due to the disorder of the nickela-cylopentanone unit a closer comparison with other nickela-cyclic carboxylates is not possible.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

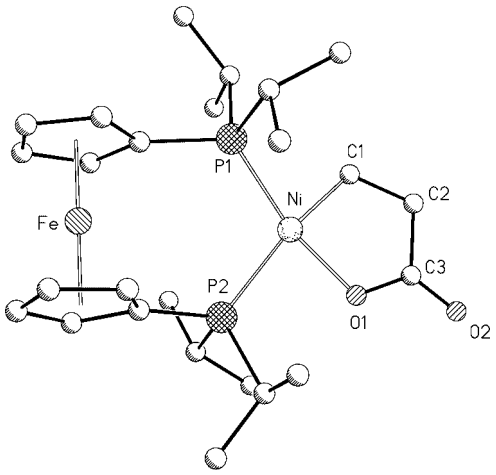


Figure 3. Molecular structure of **2b** (H atoms have been omitted for clarity).

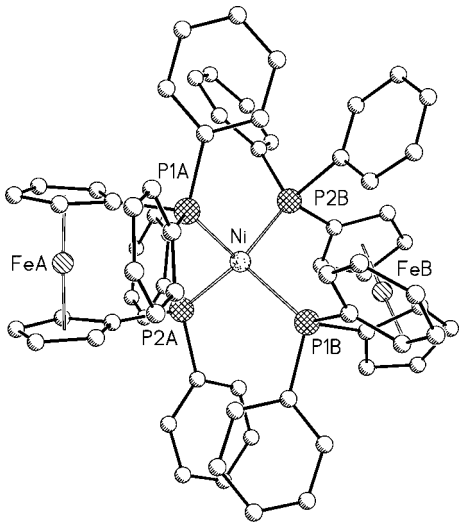

Figure 4. Molecular structure of **4** (H atoms have been omitted for clarity). Selected bond lengths [Å] and angles [°]: Ni–P1A 2.269(2), Ni–P2A 2.238(2), Ni–P1B 2.243(2), Ni–P2B 2.237(2), P1A–Ni–P1B 120.93(4), P1A–Ni–P2A 106.28(5), P1A–Ni–P2B 115.62(4), P1B–Ni–P2A 106.47(5), P1B–Ni–P2B 101.64(4), P2A–Ni–P2B 115.62(4).

**2a** is extremely sparingly soluble in organic solvents preventing complete characterization by NMR spectroscopy. The compound shows the typical ν(C=O) band for a nickela-cyclic carboxylate at 1642 $cm^{-1}$ in nujol suspension. Furthermore, $^{31}P$ NMR measurements in [$D_7$]DMF at 25 °C gave two signals for the coordinated P atoms in a different chemical environment at $\delta$ = 19.4 and 39.0 ppm. In addition, in the $^1H$ NMR spectrum the two resonances of the coordinated $CH_2CH_2COO$ fragment were observed at $\delta$ = 0.64 ppm (as a multiplet of the Ni-$CH_2$ group) and at $\delta$ = 1.93 ppm. The latter appears as a triplet and is assigned to the $CH_2COO$ protons. Comparison of these data with those of the nickela-cyclic carboxylate **2b** suggest that **2a** is also the expected nickela-cyclic carboxylate according to Scheme 3.

**2a** is a thermally unstable compound. Even at 40 °C in DMF the complex decomposes into a mixture of compounds. One product isolated from the reaction mixture was the nickel(0) complex [$(dppf)_2Ni$] (**4**). This compound was already generated in situ either by reaction of $NiBr_2$, dppf and Zn or by reduction of [$Ni(acac)_2$] using DIBAL-H in the presence of dppf,[5,6] however to the best of our knowledge it has not been isolated so far. Complex **4** was characterized by elemental analyses, $^1H$ and $^{13}C$ NMR spectroscopy and by a single crystal structure analysis. Figure 4 shows its molecule structure and contains the most relevant bond lengths and angles in the caption.

The nickel centre is in the tetrahedral environment of four P donor atoms with typical Ni–P bond lengths. In the dppf ligand A the two cp ligands have a synclinal staggered conformation with a torsion angle $\tau$ of 43.9°. This conformation is the most common one found for dppf in its metal complexes (characteristic values: 18° < $\tau$ < 54°).[23] In the other ligand B, however, the torsion angle is only 15.0° and the cp ligands have a synperiplanar eclipsed conformation (characteristic region: 0° < $\tau$ < 18°).[23] This different arrangement results in different bite angles (106.3° for P1A–Ni–P2A and 101.6° for P1B–Ni–P2B).

### Complexes of the Type [(L)Ni(ethylene)] [L: dtbpf, (dippf)]

The steric bulky ligand dtbpf yielded in the reaction with [$(py)_2Ni(CH_2CH_2COO)$] under similar conditions a different product compared to the dippf complex. In this case reductive decoupling of the $NiCH_2CH_2COO$- unit was observed resulting in the formation of the nickel(0) ethylene complex [(dtbpf)Ni(ethylene)] **3c** and $CO_2$ (Scheme 1). This demonstrates how sensitive the reactivity can be influenced by the steric demand of the ligands. **3c** was characterized by NMR spectroscopy in [$D_7$]DMF and by an X-ray analysis of single crystals grown from DMF. When the nickelacycle **2b** was heated at 80 °C, reductive decoupling was observed as well, resulting in the formation of [(dippf)Ni(ethylene)] (**3b**) in good yields.

As expected for a symmetrical structure in solution, the $^{31}P\{^1H\}$ NMR spectrum of **3c** in [$D_7$]DMF at room temperature showed only one signal at $\delta$ = 65.6 ppm. In the $^1H$ NMR spectrum the ethylene protons appeared at $\delta$ = 1.86 ppm. The methyl protons of the *tert*-butyl group resonated at $\delta$ = 1.35 ppm and the singlets at $\delta$ = 4.06 and 4.21 ppm (each integrating to four protons) were assigned the cp ring protons. Single crystals of **3c** were grown from DMF suitable for X-ray structure determination, and its molecule structure is shown in Figure 5.

The nickel(0) centre is in the distorted tetrahedral environment of the two P donor groups and the carbons of the ethylene ligand with typical bond lengths for the Ni–P and Ni–C bonds. As expected, the double bond of the coordinated ethylene ligand [C(1)–C(2) 1.399(4) Å] is significantly elongated compared to free ethylene.

It is noteworthy, that the hitherto unknown ethylene complexes with 1,1′-bis(phosphanyl)ferrocene ligands can also be formed by other methods. For example, the ethylene

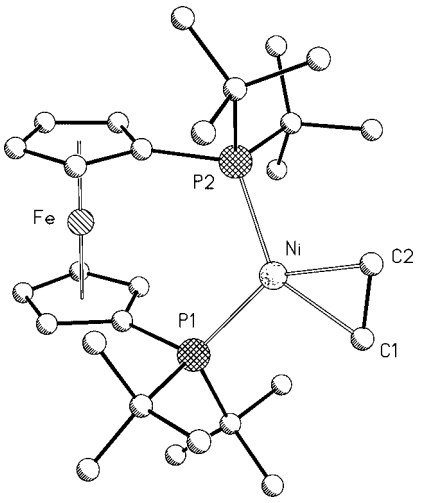

Figure 5. Molecular structure of **3c** (H atoms have been omitted for clarity). Selected bond lengths [Å] and angles [°]: Ni–C1 1.980(3), Ni–C2 1.984(3), Ni–P1 2.1893(6), Ni–P2 2.1908(6), C1–C2 1.399(4), P1–Ni–P2 111.95(3), P1–Ni–C1 103.96(9), P2–Ni–C2 104.03(9), C1–Ni–C2 41.3(2), plane (P1,P2,Ni)-plane(Ni,C1,C2) 15.71.

complex **3b** was additionally prepared by ligand displacement from (cyclododeca-1,5,9-triene)nickel(0) [Equation (2)].

$$[Ni(cdt)] + dippf + C_2H_4 \rightarrow [(dippf)Ni(C_2H_4)] + cdt \quad (2)$$

NMR spectroscopic data are very similar to those of the dtbpf complex **3c**, and the crystal structure of single crystals of **3b** (not depicted) is also comparable with that of the closely related complex **3c** and need therefore no further discussion.

## Conclusions

Complexes of the type [(L)M($\eta^2$-$CH_2$=CH-COOH)] (**1a**–**1c**) are the first Ni- and $Pd^0$ complexes with acrylic acid as olefin-like ligand. Due to the rigidity and the bulkiness of the ferrocenyl-bisphosphane ligands these complexes are surprisingly stable and do not thermally interconvert into the isomeric nickela-lactones of the type [(L)Ni($CH_2CH_2$-COO)] (**2**) which could be independently prepared by ligand exchange from [$(py)_2$Ni($CH_2CH_2COO$)] as thermally stable compounds. The nickela-lactones **2b** and **2c** react at heating under reductive decoupling to yield the new ethylene complexes of the type **3**, however, the isomerization of the complexes of the type **2** to form the acrylic acid complexes **1** was not observed.

## Experimental Section

**General:** Infrared spectra were recorded using a Perkin–Elmer 2000 FT-IR; $^1$H-NMR spectra were recorded on a Bruker 400 MHz/200 MHz spectrophotometer. The mass spectra were recorded using a SSQ 170, Finnigan Mat. Electro spray mass spectra were recorded on a Finnnigan MAT, MAT 95 XL. Values for *m*/*z* are for the most intense peak of isotope envelope.

All manipulations were carried out by using modified Schlenk techniques under an atmosphere of argon. Prior to use, THF, benzene and diethyl ether were dried with potassium hydroxide and distilled from sodium/benzophenone. DMF was dried with $CaH_2$.

dppf, dippf, and dtbpf were prepared in analogy to known procedures by reaction of *n*BuLi/tmeda with ferrocene, followed by addition of the chlorodiphenylphoshane, chlorodiisopropylphosphane or chlorodi-*tert*-butylphosphane.[24–27] [Ni(cod)$_2$],[28] [$(py)_2$-Ni($C_2H_4COO$)][22] and [Pd($\eta^2$-$C_7H_{10}$)$_3$][29] were prepared according to literature procedures.

**[(dppf)Ni($\eta^2$-$CH_2$=CH-COOH)] (1a):** A solution of dppf (2.67 g, 4.82 mmol) in THF (30 mL) was added to solid [Ni(cod)$_2$] (1.32 g, 4.80 mmol). The suspension was stirred until all solids had dissolved. Afterwards the stirred solution was cooled to 0 °C and acrylic acid (0.37 g, 5.13 mmol) was added, resulting in formation of a yellow precipitate. This solid was isolated by filtration and dried in a vacuum. Yield: 2.83 g (71%). Suitable crystals of (**1a**)·2THF for X-ray measurement were obtained by slowly cooling a saturated solution in THF from room temperature to 5 °C. In a similar manner, crystals of [(dppf)Ni($\eta^2$-$CH_2$=CH-COOH)]·1.5DMF were obtained from a solution of DMF. Those crystals were used for elemental analysis. $C_{41.5}H_{42.5}FeN_{1.5}NiO_{3.5}P_2$ (794.8) calcd. 38.6 Hz, 2×CH-P), 26.7 (d, $^1J_{P,C}$ = 23.5 Hz, 2×CH-P), 32.7 (br., =$CH_2$), 42.7 (br., =CH), 69.3 (CH, cp), 69.4 (CH, cp), 71.0 (2×CH, cp), 72.4 (CH, cp), 72.7 (CH, cp), 73.8 (d, $J_{P,C}$ = 4.0 Hz, CH, cp), 73.9 (d, $J_{P,C}$ = 4.7 Hz, CH, cp), 83.8 (dd, $^1J_{P,C}$ = 23.7 Hz, $^3J_{P,C}$ = 5.1 Hz, C-P, cp), 84.7 (d, $^1J_{P,C}$ = 25.4 Hz, C-P, cp), 177.7 (br., COOH). $^{31}P\{^1H\}$ NMR ([$D_8$]THF, 25 °C): $\delta$ = 46.9 (d, $^2J_{P,P}$ = 15.3 Hz), 39.3 (d, $^2J_{P,P}$ = 15.3 Hz).

**[(dippf)Pd(nb)]:** A solution of dippf (0.36 g, 0.86 mmol) in THF (20 mL) was cooled to –30 °C and added to solid [$(nb)_3$Pd] (0.30 g, 0.77 mmol) at this temperature. The stirred solution was allowed to slowly warm to room temperature. Afterwards half of the solvent was distilled of under reduced pressure. The remaining orange coloured solution was stored at –20 °C for several days, resulting in the formation of orange red crystals. These crystals were separated by filtration and dried in a vacuum. From the mother liquor a second crop of product was obtain by further reduction of the volume and layering with diethyl ether. Yield: 120 mg (25%). $C_{29}H_{46}P_2FePd$ (618.9) calcd. C 56.28, H 7.49; found C 56.12, H 7.52. $^1H$ NMR ([$D_8$]THF, 25 °C): $\delta$ = 0.58 (d, $^2J_{H,H}$ = 7.6 Hz, 1 H, C*H*H′ bridge), 1.05–1.30 (m, 15 H, 4×$CH_3$, 2×C*H*H′, CH*H*′ bridge), 1.52 (m, 2 H, 2×CH*H*′), 2.19 (m, $^2J_{H,P}$ = 6.0 Hz, 4 H, CH *i*Pr), 2.88 (s, 2 H, CH), 2.99 (d, $^2J_{H,P}$ = 6.0 Hz, 2 H, CH), 4.23 (s, 2 H, CH cp), 4.28 (s, 6 H, CH cp). $^{13}C\{^1H\}$ NMR ([$D_8$]THF): $\delta$ = 20.0 (t, $^2J_{C,P}$ = 5.0 Hz, 4×$CH_3$ *i*Pr), 20.4 (br., 4×$CH_3$ *i*Pr), 26.9 (t, $^1J_{C,P}$ = 6.3 Hz, 2×CH *i*Pr), 27.0 (t, $^1J_{C,P}$ = 7.6 Hz, 2×CH *i*Pr), 29.9 (t, $^4J_{CP}$ = 5.0 Hz, 2×CHH′), 43.4 (s, CHH′), 45.6 (s, 2×CH), 64.2 (pseudo-dt, 2×= CH-), 69.8 (s, 4×CH cp), 73.7 (t, $^2J_{C,P}$ = 3.8 Hz, 4×CH cp), 85.3 (t, $^1J_{C,P}$ = 9.5 Hz, 2×C cp). $^{31}P\{^1H\}$ NMR (81 MHz, [$D_8$]THF, 25 °C): $\delta$ = 36.4 (s).

**[(dippf)Pd($\eta^2$-$CH_2$=CH-COOH)] (1c):** Acrylic acid (0.03 mL, 0.44 mmol) was added to a solution of [(dippf)Pd(nb)] (40 mg, 0.065 mmol) in THF (1 mL) at 0 °C with rapid stirring. The resulting mixture was warmed to room temperature and stirred for additional 30 min. Afterwards the solvent was completely removed by distillation under reduced pressure. The remaining orange red sticky oil was treated with diethyl ether (2 mL) and stirred for 20 min. The resulting suspension was filtered and the clear yellow solution was stored at –20 °C. The isolated solid was redissolved in a few drops of THF and that solution was kept at 5 °C for several days. From both solutions, suitable crystals for X-ray measurement were obtained; [(dippf)Pd($\eta^2$-$CH_2$=CH-COOH)] from ether, [[(dippf)Pd($\eta^2$-$CH_2$=CH-COOH)]·THF from THF]. The yield was not determined.

**[(dppf)Ni($C_2H_4$-COO)] (2a):** Yellow dppf (0.77 g, 1.39 mmol) was added to a suspension of green [$(py)_2$Ni($C_2H_4$COO)] (0.40 g, 1.38 mmol) in DMF (8 mL) at 0 °C. The solution was allowed to slowly warm to room temperature, while the starting materials dissolved and a yellow precipitate was formed. To remove liberated pyridine, 2 mL of DMF was distilled of under reduced pressure at room temperature. Afterwards the yellow solid was isolated by filtration, washed with diethyl ether and dried in a vacuum. Yield: 0.91 g (96%) yellow powder. $^1H$ NMR ([$D_7$]DMF, 25 °C): $\delta$ = 0.64 (m, 2 H, Ni-$CH_2$), 1.93 (t, $J$ = 6.9 Hz, 2 H, $CH_2$-COO), 4.45 (s, 4 H, CH cp), 7.45–8.00 (m, 20 H Phenyl). $^{31}P\{^1H\}$ NMR ([$D_7$]DMF, 25 °C): $\delta$ = 19.4 (br), 39.0 (br). IR (nujol): $\tilde{\nu}$ = (C=O) 1642 $cm^{-1}$.

**[(dippf)Ni($C_2H_4$-COO)] (2b):** A solution of dippf (0.83 g, 1.98 mmol) in DMF (4 mL) was added to a suspension of green [$(py)_2$Ni($C_2H_4$COO)] (0.49 g, 1.70 mmol) in DMF (4 mL) at room temperature. The resulting solution was stirred for 1 h. Meanwhile an orange yellow precipitate was formed. The solid was afterwards collected by filtration and dried in a vacuum. Suitable crystals for X-ray measurement were obtained from a saturated solution of the complex in DMF at room temp. und subsequent cooling to –20 °C. Yield: 0.8 g (85%). $C_{25}H_{40}P_2O_2FeNi$ (549.08) calcd. C 54.69, H 7.34; found. C 54.21, H 7.39. $^1H$ NMR ([$D_8$]THF, 25 °C): $\delta$ = 0.96 (tdd, $^3J_{H,H}$ = 6.9 Hz, $^3J_{P,H}$ = 4.0 Hz, $^3J_{P,H}$ = 8.7 Hz, 2 H, Ni–$CH_2$), 1.23–1.54 (m, 24 H, $CH_3$), 1.96 (tdd, $^3J_{H,H}$ = 7.0 Hz, $^4J_{P,H}$ = 5.1 Hz, $^4J_{P,H}$ = 7.2 Hz, 2 H, $CH_2$-COO), 2.20–2.47 (m, 4 H, CH), 4.40 (m, 4 H, CH cp), 4.44 (m, 4 H, CH cp). $^{13}C\{^1H\}$ NMR ([$D_8$]THF, 25 °C): $\delta$ = 12.4 (dd, $J$ = 31.6 Hz, $J$ = 59.9 Hz, Ni-$CH_2$), 19.8 (d, $J$ = 11.5 Hz, $CH_3$), 20.6 (d, $J$ = 5.7 Hz, $CH_3$), 37.2 (dd, $J$ = 2.7 Hz, $J$ = 4.6 Hz, *C*$H_2$-COO), 71.1 (d, $J$ = 4.5 Hz, CH cp), 71.9 (d, $J$ = 3.9 Hz, CH′ cp), 73.3 (d, $J$ = 6.3 Hz, CH cp), 73.5 (d, $J$ = 6.2 Hz, CH′ cp), 82.2 (d, $J$ = 10.7 Hz, C cp), 82.8 (d, $J$ = 10.7 Hz, C′ cp), 185.5 (m, COO). The signals for CH groups of the isopropyl substituents overlap with the signals of the used solvent and were therefore not detected. $^{31}P\{^1H\}$ NMR ([$D_7$]DMF, 25 °C): $\delta$ = 36.5 (d, $J_{P,P}$ = 14.4 Hz), 44.7 (d, $J_{P,P}$ = 14.4 Hz). IR (nujol): $\tilde{\nu}$ = (C=O) 1634 $cm^{-1}$ (s).

**[(dippf)Ni($\eta^2$-$C_2H_4$)] (3b):** a) A suspension of [(dippf)Ni($C_2H_4$-COO)] (**2b**) (200 mg, 0.36 mmol) in DMF (5 mL) was heated to 80 °C. The resulting clear solution was stirred at this temperature for additional 3 h. Upon slow cooling to room temperature orange coloured crystals were formed overnight. These crystals were collected by filtration and dried in a vacuum. A second crop of product was obtained by storing the mother liquor at 0 °C for 3 d. Yield: 130 mg (70%). $C_{24}H_{40}FeNiP_2$ (505.06) calcd. C 57.07, H 7.98; found 57.17, H 8.16. $^1H$ NMR ($C_6D_6$, 25 °C): $\delta$ = 1.13 (sext, $J$ 6.8 Hz, 24 H, $CH_3$), 2.05 (m, 4 H, CH *i*Pr), 2.19 (br., 4 H, $C_2H_4$), 4.06 (br., 4 H, CH cp), 4.21 (br., 4 H, CH cp). $^{13}C\{^1H\}$ NMR ($C_6D_6$, 25 °C): $\delta$ = 19.9 (t, $^2J_{P,C}$ = 3.2 Hz, $CH_3$), 20.1 (t, $^2J_{P,C}$ = 3.2 Hz, $CH_3$), 26.0 (t, $^1J_{P,C}$ = 10.6 Hz, CH *i*Pr), 34.7 (t, $^2J_{P,C}$ = 7.3 Hz, $CH_2$), 69.3 (br., CH, cp), 72.7 (t, $^2J_{P,C}$ = 2.9 Hz, CH cp), 86.4 (t, $^1J_{P,C}$ = 12.6 Hz, C cp). $^{31}P\{^1H\}$ NMR ($C_6D_6$, 25 °C): $\delta$ = 42.4 (s).

**[(dtbpf)Ni($\eta^2$-$C_2H_4$)] (3c):** A solution of dtbpf (0.50 g, 1.05 mmol) in DMF (3 mL) was added to a suspension of green [$(py)_2$Ni($C_2H_4$-COO)] (0.29 g, 1.00 mmol) in DMF (3 mL) at room temperature. The resulting orange brown solution was stirred for 2 h and afterwards 3 mL of DMF were distilled of under reduced pressure at room temperature. The resulting orange coloured precipitate was collected by filtration and dried in a vacuum. Suitable crystals for X-ray measurement were obtained from a saturated solution of the complex in DMF at room temp. und subsequent cooling. Yield: 0.3 g (50%). $C_{28}H_{48}P_2FeNi$ (561.18). $^1H$ NMR ([$D_7$]DMF, 25 °C): $\delta$ = 1.35 (d, $^3J_{H,P}$ = 11.5 Hz, 36 H, $CH_3$ *t*Bu), 1.80 (s, 4 H, $CH_2$), 4.40 (m, 4 H, CH cp), 4.45 (br., 4 H, CH cp). $^{13}C\{^1H\}$ NMR ([$D_8$]-THF, 25 °C): $\delta$ = 32.0 (s, $CH_3$ *t*Bu), 36.6 (t, $^2J_{C,P}$ = 7.0 Hz, $C_2H_4$), 37.3 (t, $^1J_{C,P}$ = 6.2 Hz, C *t*Bu), 69.6 (s, CH cp), 75.4 (s, CH cp), 87.0 (t, $^1J_{C,P}$ = 8.4 Hz, C cp). $^{31}P\{^1H\}$ NMR ([$D_7$]DMF, 25 °C): $\delta$ = 65.6 (s).

**[$(dppf)_2$Ni] (4):**[5,6] A suspension of **2a** in THF was heated to 40 °C and DMF was added with rapid stirring until nearly all solids have dissolved. The resulting solution was filtered through celite and stored for 2 weeks at 5 °C. During this period, some precipitate was formed and afterwards removed by decantation. The remaining solution was concentrated in vacuo until all THF was removed. The residual orange brown coloured solution in DMF was stored for several weeks at –20 °C, after which orange red crystals had occurred. These crystals were collected by filtration and dried in a vacuum. The yield was not determined. $C_{68}H_{60}P_4Fe_2Ni$ (1171.51) calcd. 7.45–7.55 (m, 16 H, *m*-CH ph). $^{13}C\{^1H\}$ NMR ([D$_8$]THF, 25 °C): $\delta$ = 70.5 (s, 8 × CH cp), 75.2 (s, 8 × CH cp), 87.5 (m, 4 × C cp), 127.4 (s, 16 × *m*-CH ph), 128.1 (s, 8 × *p*-CH ph), 135.1 (pt, $J_{C,P}$ = 7.5 Hz, 16 × *o*-CH ph), 142.0 (m, 8 × C ph).

**X-ray Crystallographic Studies:** The intensity data for the compounds were collected on a Nonius KappaCCD diffractometer by using graphite-monochromated Mo-$K_\alpha$ radiation. Data were corrected for Lorentz and polarization effects, but not for absorption effects.[30,31] The structures were solved by direct methods (SHELXS[32]) and refined by full-matrix least-squares techniques against $F_o^2$ (SHELXL-97[33]). All hydrogen atoms were included at calculated positions with fixed thermal parameters. All non-hydrogen atoms were refined anisotropically.[4] XP (SIEMENS Analytical X-ray Instruments, Inc.) was used for structure representations.

**Crystal Data for 1a·1.5DMF:**[34] $C_{37}H_{32}FeNNiO_2P_2 \cdot 1.5C_3H_7ON$, *Mr* = 795.78 g mol$^{-1}$, orange prism, size 0.12 × 0.12 × 0.10 mm$^3$, monoclinic, space group $P2_1/n$, *a* = 14.5426(3), *b* = 13.9250(6), *c* = 19.0968(7) Å, $\beta$ = 108.237(2)°, *V* = 3673.0(2) Å$^3$, *T* = –90 °C, *Z* = 4, $\rho_{calcd.}$ = 1.439 g cm$^{-3}$, $\mu$ (Mo-$K_\alpha$) = 10.38 cm$^{-1}$, *F*(000) = 1660, 12426 reflections in *h*(–18/18), *k*(–18/16), *l*(–24/24), measured in the range 1.55° ≤ $\Theta$ ≤ 27.60°, completeness $\Theta_{max}$ = 93%, 7921 independent reflections, $R_{int}$ = 0.0553, 4887 reflections with $F_o > 4\sigma(F_o)$, 441 parameters, 0 restraints, $R_{1obs}$ = 0.0743, $wR_{2obs}$ = 0.2116, $R_{1all}$ = 0.1110, $wR_{2all}$ = 0.2206, GOOF = 1.058, largest difference peak and hole: 0.815/–0.499 e·Å$^{-3}$.

# Assembly and Formation of Biomorphic Tin Dioxide by a Biomimetic Sol–Gel Approach Involving Glycoprotein

Qun Dong,[a] Huilan Su,*[a] Wei Cao,[a] Di Zhang,[a] Qixin Guo,[b] and Fangying Zhang[c]

**Keywords:** Biomimetic synthesis / Colloids / Hierarchy / Nanotubes / Sol–gel processes

Three diverse layers of eggshell membrane (ESM) were introduced in a biogenic sol–gel technique for the synthesis of hierarchical $SnO_2$ nanomaterials with corresponding configurations. Typically, the biomorphic replication of the interwoven inner eggshell membrane was systematically investigated by controlling synthesis conditions such as pH value, dipping time, and calcination temperature. The as-prepared $SnO_2$ tubes consisting of interconnected 5-nm nanocrystallite units were successfully interwoven into ESM-morphic films. Herein, the biomaterial ESM served both as the physical substrate and the functional macromolecule template to realize the precision replication, by the interactions between ESM macromolecules (containing carboxyl, hydroxy, amino groups, etc.) and Sn colloid ingredients. Moreover, some biomacromolecules also acted as the surfactant to yield small-scaled and well-distributed $SnO_2$ nanocrystallites based on the strong bondage of short-chained amino acids within ESM glycoprotein with $SnO_2$ nuclei. This technique can be attributed to a biomimetic sol–gel process and is widely applicable to the synthesis of other functional material systems.

## Introduction

Lately, nanoscale functional materials have attracted much attention because of their potentially excellent and fascinating properties. In the progressive stage, the assembly of the nanoscale units into a hierarchical architecture would be required to obtain higher functionality and performance. Nevertheless, there are few feasible reports on the construction of hierarchical nanomaterials, especially practical and functional metal or metal oxide nanocomposites. Notably, natural organisms or biological structures that have evolved as a result of highly complex and elegant mechanisms[1] are a great inspiration for materials scientists and chemists in the imitation of the hierarchical structures. The work in this field is based on the premise that amphiphilic and bioorganic macromolecules could be utilized for tailoring elaborate structures through the self-assembly of nanoscale units[2] to engender new functional properties.[3] Quite a few biological species have been utilized to construct hierarchical inorganic materials: the list includes DNA,[4] viruses,[5] diatoms and skeletal plates,[6] butterfly wings,[7] shell membrane,[8] silk fiber,[9] hair,[10] wood,[11] and other plants (leaves, paper, pollen grains),[7,12] etc.

Recently, mimicking vital functions in aqueous systems has been noteworthy as a promising nanofabrication technique for functional materials.[3a,13] These biomimetic techniques enable the construction of hierarchical architectures including macro- and nanostructures by growing inorganic crystals with coexisting biospecies under ambient conditions. Quoting from Cook et al.,[7] "the synthetic replication of evidently useful biological structures by a simple casting process is expected to introduce some of the superb properties of biological structures into man-made materials." The most feasible method of attaining this goal at a high level seems to be the aqueous sol–gel technique.[14] The colloid components could interact with some biomacromolecules and undergo surface-preferred gelation to form the coats on the biomaterials, even to veraciously replicate the biotemplate frameworks down to the nanoscale. Moreover, the sol–gel process offers several advantages over other methods, including simplicity of procedure, lower processing temperature, and better homogeneity. Commonly, metallic alkoxides are used as starting materials to prepare fine-scaled metallic oxides by the sol–gel processes. However, metallic alkoxides are both expensive and extremely sensitive to moisture, heat, and light, implying that the process is relatively difficult to control and not economical. Therefore, various metal salts[15] are preferred as the precursors. Once biomaterials are introduced to the reformative sol–gel techniques, a series of intricate hydrolysis and condensation reactions happen in the sol–gel process. It seems to be a process that would enable the easy preparation of hierarchical

metal oxides, such as $TiO_2$, $SiO_2$, ZnO, $ZrO_2$, and so on. Therefore, biomimetic synthesis associated with the sol–gel technique would be an ideal approach for the design and fabrication of functional materials with predetermined physical and chemical properties.

Having a large bandgap of 3.6 eV at 300 K, a high achievable carrier concentration of up to $6 \times 10^{20}$ $cm^{-3}$, and an expected exciton Bohr radius of about 2.4 nm,[16] nanocrystalline tin oxide is of great technological and scientific interest as a key functional semiconductor that is used extensively for photovoltaic devices,[17] transparent conductive electrodes,[18] gas sensors,[19] antistatic coatings,[20] dye-sensitized solar cells,[21] etc. It has also been demonstrated that, when such ultrafine nanocrystallites are arrayed into a macroscale hierarchical structure (such as tubes, hollow spheres, etc), these materials sometimes exhibit novel properties.[22] However, fresh tin gel has a hydrous skeleton and is either amorphous or pseudocrystalline. To achieve well-crystallized $SnO_2$, further calcination treatment at a higher temperature would be advisable to remove organic substrates and improve the stability and the purity of the target materials. As the growth of particles is controlled by the motion of the boundaries between the particles, calcination usually results in the increase and wider distribution of particle size.[23] Therefore, the growth inhibition of $SnO_2$ nanocrystallites was recently implemented with the addition of heterogeneous particles or in-situ secondary-phase particle generation. However, this solution may result in interface poisoning or poor purity. It has been discovered that, in biological systems such as diatoms and sponges, the formation of solid silica nanostructures with precisely controlled morphologies is the function of proteins and polysaccharides.[24] These biomacromolecules could direct and bind the nucleation and the growth of inorganic particles. Attracted by this bioinspiration, we introduce a convenient biomaterial, the eggshell membrane (ESM), in combination with a tin salt precursor, with the intent of synthesizing hierarchical $SnO_2$ semiconductors by suitable vehicles of special protein structures and functional residues of ESM biomacromolecules in a sol–gel process. In contrast to the metallic alkoxide precursors used by Yang et al.,[8] we attempted to employ a trilayer bio-scaffold in tin nitrate solution as a template for the structure of $SnO_2$. The natural trilayer ESM composed of the outer shell membrane (OSM), the inner shell membrane (ISM), and the limiting membrane (LM) with dissimilar hierarchical structures and morphologies, has been faithfully reproduced from the macroscopic to the nanometer scale by $SnO_2$ nanosemiconductors. Additionally, the reaction mechanism involving a biomimetic sol–gel process was explored. This method provides a simple but efficient and universal route to the biomimetic synthesis of advanced functional materials.

## Results and Discussion

### Overview of ESM Hierarchical Structures

The avian eggshell is composed of multilayered membranes and a calcified extracellular matrix, which are sequentially assembled during the motion of the egg along the oviduct.[25] The examination of cross-fractured eggshell by FESEM, shown in Figure 1a, reveals that the calcified shell is composed of an inner mammillary layer (ML) and an outer palisade layer (PL) resting upon the shell membranes. In fact, ESM consists of the organic OSM, ISM, and LM, which are nonmineralized, collagen-based matrices interposed between the egg white and the mineralized shell. From the images of ESM shown in Figure 1b, the three layers are readily distinguished. Sparsely deposited on the outer layer of the shell membranes are the mammillary knobs for penetrating into the tips of the mammillary cones. In addition, the interwoven and coalescing nature of the shell membrane fibers with an average width ranging from 500 nm to 2 μm is evident both in the OSM and the ISM. Furthermore, some of the broader fibers have a longitudinally striated appearance, where two or more narrower fibers join each other for part of their length. The amorphous LM shows an undulant appearance, which is due to a layer of spherical protein granules formed between the ISM and the LM. In this work, the distinct membranes were utilized as biotemplates for the synthesis of hierarchical $SnO_2$.

### Characterization of Biomorphic Tin Dioxide

The calcination process was traced by conducting TGA and DTA surveys to follow the formation of hierarchical

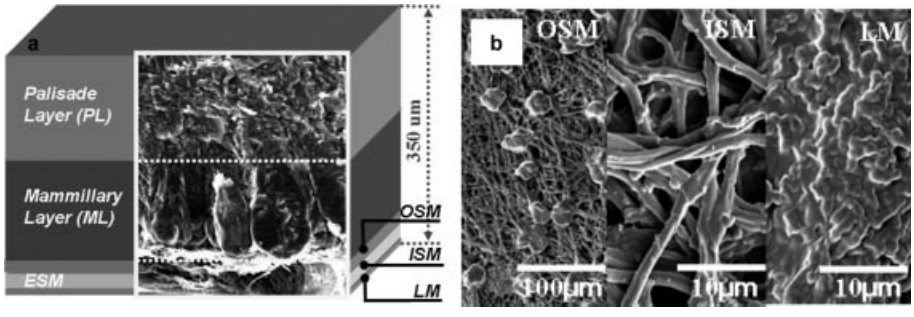

Figure 1. (a) FESEM images of eggshell and eggshell membrane and the corresponding schematic illustration of eggshell structures. (b) FESEM images of OSM, ISM, and LM.

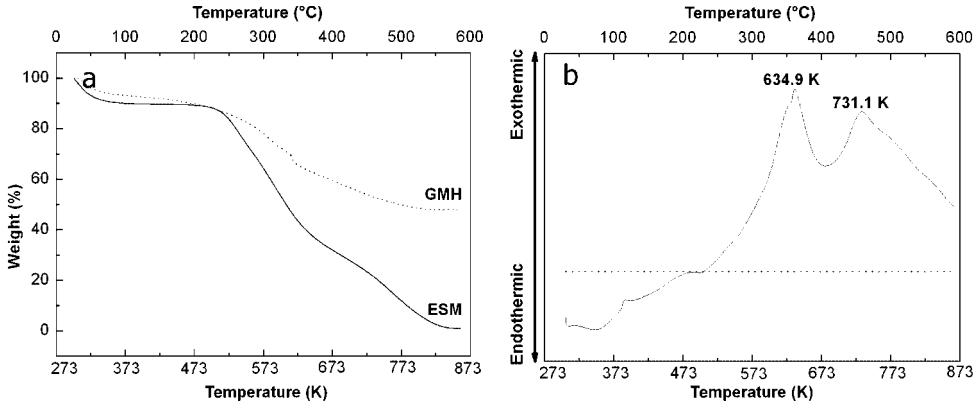

Figure 2. (a) TGA curves of the natural ESM and the intergradation of GMH; (b) DTA curve of GMH.

$SnO_2$. The corresponding curves for the natural ESM and gel–membrane hybrids (GMH) are shown in Figure 2. It is evident that the ESM starts pyrolyzing at 473 K and is absolutely decomposed by 823 K. Although GMH are also decomposed around 473 K, they can preserve up to 47.2% (by mass) inorganic matter at 823 K, at which temperature the organic ESM is completely removed. As seen from the differential curve, when GMH are heated from room temperature to 473 K, the weight loss of 9.8 wt-% is due to the removal of adsorbed water, and above 473 K they experience a two-step weight loss. Congruously, the DTA curve shows two peaks at 635 K and 731 K, which should represent the decomposition of Sn–ligand hybrids and organic ESM components, respectively.

To clarify the crystalline structure, the XRD patterns of the ESM and GMH as well as the corresponding sinters at 673 K and 823 K are shown in Figure 3. It can be seen that the natural ESM and GMH are totally amorphous. After calcination at 673 K, the amorphous hybrids are found to be crystallized. However, according to the TGA and DTA results, the ESM is not thoroughly decomposed at this temperature: although the intensities of some peaks are enhanced, there are new diffraction peaks accompanying the complete pyrolysis of ESM, indicating the well-established crystallization process at 823 K. All these diffraction peaks can be indexed to tetragonal $SnO_2$ with a rutile structure (JCPDS 41–1445), which indicates that the specimens consist of pure single tetragonal $SnO_2$. The fairly broadened diffraction peaks are assigned to $SnO_2$ nanocrystallites with very small dimensions. The average crystallite sizes of about 2.8 nm at 673 K and 5.2 nm at 823 K, are estimated according to the line-width analysis of the diffraction peaks based on the Scherrer formula. The chemical states of tin and oxygen during the sol–gel process were investigated by XPS analysis (Supporting Information, Figure S1). The corrected XPS spectra of the O1s emissions are different, where the peak with binding energy around 532.3 eV corresponds to the hydroxyl bonds of GMH, while the weaker peak around 531.1 eV corresponds to the Sn–O–Sn bonds of the sinters.[26] Moreover, GMH appear as a spin-orbit doublet at 487.9 ($3d_{5/2}$) and 496.4 eV ($3d_{3/2}$) in the Sn3d emission spectra with an area ratio of 1.5:1. Thus, the chemical state of the element tin in as-prepared GMH corresponds to $Sn^{IV}$, but not to $Sn^{II}$ or $Sn^{III}$.

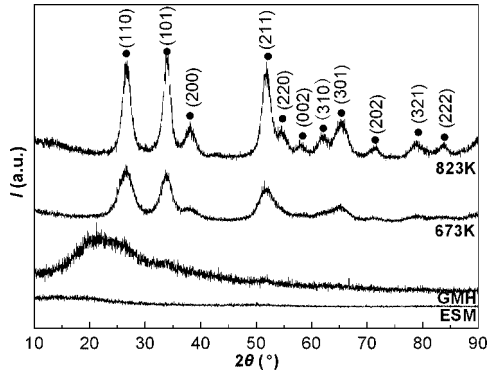

Figure 3. XRD patterns of the sinters calcined at 673 K and 823 K, compared with those of ESM and GMH.

It has been demonstrated that the interfacial sol–gel process is a facile chemical method to deposit ultrathin metal oxide layers with molecular precision.[27] This process is usually based on the chemical adsorption of metal alkoxides or metallic salts from the colloid medium onto the substrate surface to form a covalently bound monolayer, followed by hydrolysis to give a new hydroxylated gel layer for the successive film deposition. Organic molecules of the substrate can be readily incorporated as second components if they are reactive toward the as-deposited amorphous gel layer, thus the configuration and structure of the substrate can be accurately traced by the metal oxide network.[28] Here, the three diverse layers of organic ESM have the same ingredients containing amine, amide, and carboxyl surface functional groups, which may lead to complicated reactions to achieve the duplication of ESM configuration during the interfacial sol–gel process.

Representative FESEM images of as-prepared $SnO_2$ with various morphologies calcined at 823 K are shown in Figure 4a, 4b, and 4c. A comparison with the original OSM, ISM, and LM (insets) suggests that the refined reprography of the natural ESM hierarchy is achieved, although there

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

exists modest shrinkage. Analysis with energy-dispersive X-ray spectroscopy reveals that the atomic ratio Sn/O is close to 1:2, further confirming the stoichiometry of the replicas as $SnO_2$, in agreement with XRD results. As shown in Figure 4a, the obtained $SnO_2$ is composed of interwoven fibers and sparse crunodes depositing on the ceramic fibers with an average interval of about 18 μm. The interval is smaller than the original spacing of 30 μm as a result of heat shrinkage. Moreover, the refined meshworks of the natural OSM are also duplicated in addition to the larger intersectional crunodes. Figure 4b shows the interwoven and coalescing $SnO_2$ fibers ranging from 200 to 500 nm in diameter in comparison with the original ISM fibers. When using LM as the template, a lumpy layer of $SnO_2$ composed of consecutive ravines is obtained (Figure 4c). These special silkworm-like structures may come into being and array according to the spherical protein granules under the ultrathin LM. Therefore, it can be concluded that hierarchical $SnO_2$ accurately replicates the hierarchy of the biotemplate ESM from the OSM to the innermost LM. However, a shrinkage rate of nearly 55% is sometimes observed during the calcination treatment. By repeating the immersing manipulation, heat constringency in size could be lowed to below 30%, and up to 47.2% of the mass of the sinters was preserved without changes in configuration and structure.

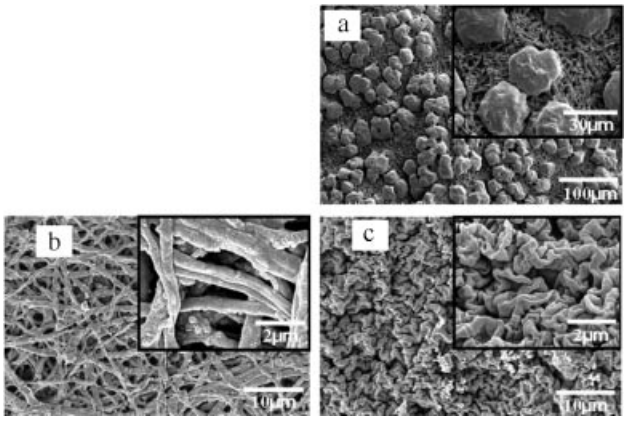

Figure 4. FESEM images of (a) OSM-based, (b) ISM-based, and (c) LM-based $SnO_2$. Insets show the corresponding detailed morphologies of the original OSM, ISM, and LM.

Figure 5a and 5b show the relative location of the hierarchical $SnO_2$ replicated from the three diverse membranes. It is clearly seen in Figure 5a that the LM-based one has been sheltered by the upper layers composed of the ISM-based and OSM-based $SnO_2$ layers. However, the replica of the LM layer can be identified when the other side of this sheet is observed (Figure 5b). The configuration of the intermeshed ISM consisting of interwoven fibers is intact, whereas the LM-based layer (denoted by an arrow) is curled up thoroughly. Moreover, the thickness of the obtained $SnO_2$ film can be tuned by removing the multilayers of the ISM. Thus, an $SnO_2$ film with a continuous thickness up to 20 μm can be achieved by varying the original thickness of remnant ISM layers (see Supporting Information, Figure S2). Figure 5c and 5d display higher magnifications of the cross section and the vertical section of these $SnO_2$ interwoven fibrous films, respectively. The tubular structures have an inner-diameter range from 100 nm to 300 nm and an average wall thickness of less than 90 nm. These $SnO_2$ tubes are rather uniform, and the hollow cores are glabrous and continuous throughout their length. Notably, these interwoven tubular structures are actually interconnected at junctions. A special kind of tube wrapping several smaller collateral cannulations is also observed, which likewise reproduces the original structures of the membrane fibers (see Supporting Information, Figure S3). To further investigate the replication process, we selected the organic ISM as a typical template to achieve the synthesis of hierarchical biomorphic $SnO_2$ under different experimental conditions.

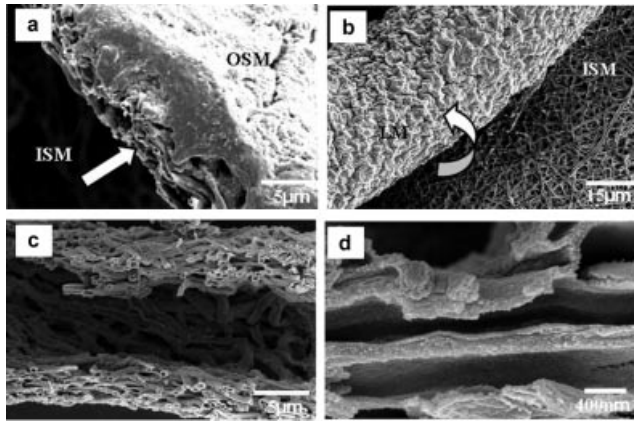

Figure 5. (a), (b) Typical FESEM images of as-prepared ISM-morphic $SnO_2$ revealing relative locations of the three distinct layers of the original ESM. (c), (d) FESEM images showing the cross-section and the vertical section of the ISM-based $SnO_2$, respectively.

### Controllable Synthesis of ISM-Morphic $SnO_2$ Tubes

Figure 6 shows the micrographs of $SnO_2$ tubes synthesized at different calcination temperatures (823 to 1073 K). All the replicas have similar microscopic features and preserve the interwoven tubular structures of the natural ISM, but their building blocks, $SnO_2$ nanocrystallites, may grow with the increase in calcination temperature. The surface of $SnO_2$ tubes synthesized below 973 K looks more glazed in virtue of the smaller particle units, which was further proved by TEM results. Above 1073 K, the tubular structure is apparently composed of a network of interconnected $SnO_2$ particles, and it may collapse down into zonary form at 1273 K. On the contrary, if the calcination temperature is lowered to 673 K, characteristic tubular structures appear partially, and some look puffy, which may be caused by the organic remnants (see Supporting Information, Figure S4). It is reasonable that some residues of organic ESM remain at 673 K even though $SnO_2$ nanocrystallites have formed, which is in agreement with the TGA and XRD results.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

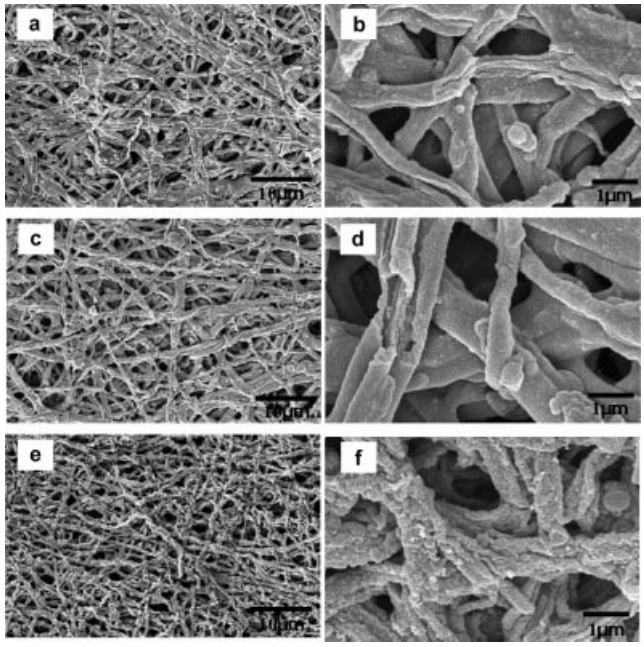

Figure 6. FESEM images of as-prepared ISM-morphic $SnO_2$ at different temperatures: (a) 823 K, (c) 973 K, and (e) 1073 K. Images (b), (d), and (f) show relevant higher magnifications of (a), (c), and (e), respectively.

Figure 7 gives the XRD patterns of the samples calcined at various temperatures between 823 and 1273 K for 1.5 h. All the diffraction peaks are assigned to the tetragonal rutile structure of $SnO_2$. It is found that the XRD peaks gradually become sharper with increasing temperature, indicating that the $SnO_2$ nanocrystallites grow larger. The crystallite sizes determined from the Scherrer equation are 5.2, 9.5, 10.3, and 20 nm, which have also been supported by the TEM results.

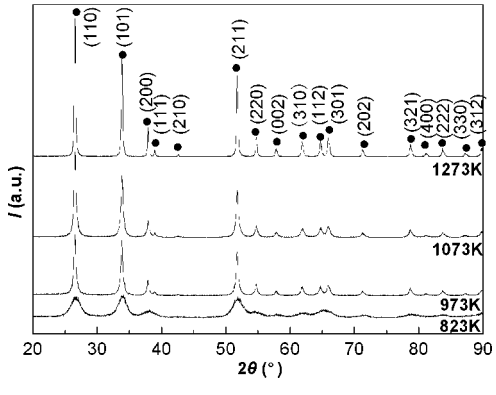

Figure 7. XRD patterns of ISM-based $SnO_2$ calcined at 823, 973, 1073, and 1273 K.

The TEM images in Figure 8a further reveal the tubular interwoven character of ISM-based $SnO_2$. The hollow tubular structure is clearly identified, and the wall thickness (50–60 nm) is found to be uniform along its entire length. This indicates that at 1073 K each tube has been transformed from a dense structure with a smooth surface into a highly porous structure consisting of interconnected nanocrystallites of ca. 10 nm in size (bottom inset in Figure 8a). In addition, the SAED patterns (top inset in Figure 8a) show that nanoscaled $SnO_2$ at 1073 K has polycrystalline tetragonal rutile structure (cassiterite) due to the uniform central and diffraction spots, and the diffraction rings are indexed to the (110), (101), (200), (211), and (301) diffractions of rutile-phase $SnO_2$. There are other supporting TEM data (see Supporting Information, Figure S5) supporting the construction of $SnO_2$ nanotubes by nanocrystallites calcined at different temperatures. Although the sinters at 673 K contain some impurities from ESM residues, the characteristic crystalline structure of tetragonal $SnO_2$ is observed in the electron diffraction image. This can be explained by the exothermic reactions occurring during the removal of the ESM: oxidation of the organic biomaterial emits heat locally, causing an increase in the temperature around the adsorbed Sn colloids, thereby accelerating the gelation and bringing on nanocrystalline $SnO_2$. These nanoparticles are ultrafine below 823 K while growing more quickly above 1073 K, and the average sizes of the nanoparticles are coincident with the crystallite sizes calculated from the XRD analyses by the Scherrer equation. As the nanoparticles grow with the increase in calcination temperatures, the diffraction patterns gradually transform from ring (nanoscale) to spot (bulk scale). This indicates that accurately defined, size-controlled $SnO_2$ nanoparticles in the range 2 to 20 nm are obtained to enable the construction of hierarchical nanomaterials at the corresponding calcination temperatures.

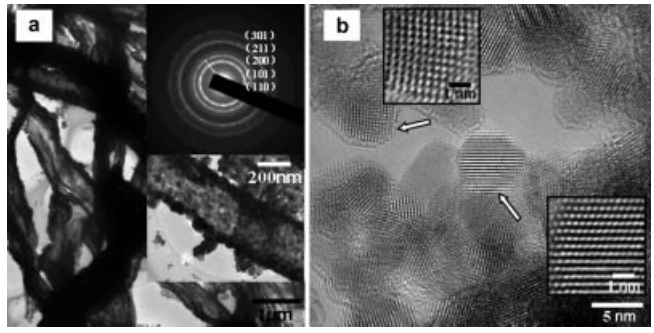

Figure 8. (a) TEM images of ISM-based $SnO_2$ synthesized at 1073 K and pH 1. Insets in (a) show an individual $SnO_2$ tube and the corresponding SAED pattern. (b) HRTEM image of ISM-based $SnO_2$ obtained at 823 K and pH 1. Insets in (b) correspond to the tetragonal $SnO_2$ (101) plane (top left) and the (110) plane (bottom right).

Figure 8b shows the typical HRTEM images of $SnO_2$ nanocrystallite units calcined at 823 K for 1.5 h. The lattice image can be clearly seen as a result of phase contrast. The distances between the adjacent lattice fringes correspond to the interplanar distances of the tetragonal $SnO_2$ (101) and (110), $d_{101}$ = 0.264 nm and $d_{110}$ = 0.335 nm, respectively. Considering that each domain having parallel lattice fringes is a single crystal of $SnO_2$, the average crystallite size is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

observed to be 5 nm. The HRTEM results are in accord with the XRD analysis. A careful look at the images also reveals that the present $SnO_2$ is characterized by larger "nanostructured" particles consisting of nanocrystalline domains with structural defects such as twins.

### Mechanism of the Biomimetic Sol–Gel Approach

To understand the multilevel interactions between the Sn colloids and the ESM biomacromolecules during the biomimetic sol–gel process, FTIR spectroscopic analysis was carried out on the original ESM, the GMH and the sinters. Figure 9 presents the typical FTIR spectra of GMH before and after calcination at 823 K compared with those of the original ISM. The spectrum of the original ISM shows the diagnostic peaks at 1641, 1532, and 1234 $cm^{-1}$, which are assigned to the amide I, amide II, and amide III bands of the proteins from the natural ISM, respectively. After interaction with the sol precursor, the red shift to 1630 $cm^{-1}$ of the peak in the spectrum of GMH may be partly attributed to the superposition of the bending mode of water with the broad band around 3450 $cm^{-1}$ (not 3400 $cm^{-1}$). The peak at 3430 to 3450 $cm^{-1}$ is believed to be caused by adsorbed water. In general, the absorption band centered at 1630 $cm^{-1}$, as well as the one at 3450 $cm^{-1}$, is also ascribed to water adsorbed on the surface of the samples. Here, there would be no other corresponding peaks of amide I after immersion in the sol medium, if the peak at 1630 $cm^{-1}$ (near 1620 $cm^{-1}$) in the spectrum of GMH were only due to the bending mode of water. The spectrum shows an increase in intensity of the amide I band relative to that of the amide II band. It does confirm the presence of a water deformation mode. Actually, the red shift of the amide I peak is probably overlapped by the above-mentioned water bending-mode peak. This red shift indicates that the C=O bonds in the peptide chains may be weakened because of the formation of new chelate bonds between C=O bonds and Sn colloids. This can be further corroborated by the NMR spectroscopic results (Supporting Information, Figure S6). It is also detected that the peak corresponds to the Sn–OH vibration band at around 3400 $cm^{-1}$,[29] which is superimposed on the underlying C–H stretching signals of the polypeptides at 3290 $cm^{-1}$ and close to the hydroxy bands of the water. As mentioned above, the bands of the sinters observed at around 3450 and 1630 $cm^{-1}$ are assigned to the hydroxy bands of the adsorbed water. Below 700 $cm^{-1}$, the intense bands appearing both in GMH and the sinters at lower frequencies around 600 $cm^{-1}$ are typical of the Sn–O–Sn antisymmetric and symmetric vibrations.[30] In addition, the bands appearing in the range between 850 and 1350 $cm^{-1}$ are assigned to the bending mode of different types of surface hydroxy groups, which goes well with the previous research results.[31] The surface of the GMH could be terminated with the–OH groups after the ESM was dipped in the Sn sol medium. However, the calcination treatment would bring on weak IR bands between 850 and 1350 $cm^{-1}$, contributed by the decomposition of Sn–OH hydrate compounds into tin oxides. Accordingly, the interactions between Sn colloids and ESM macromolecules are mostly ascribed to the coordination of carboxyl, hydroxy, and other groups.

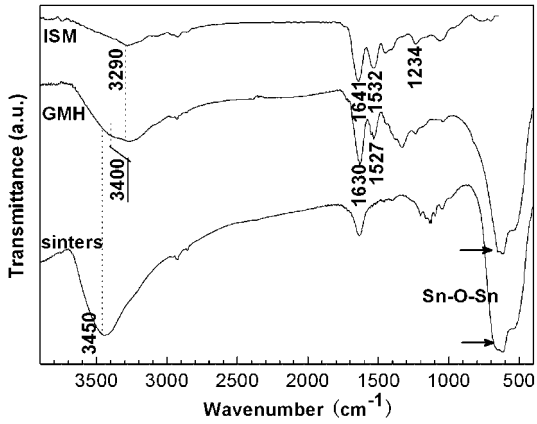

Figure 9. FTIR spectra of the original ISM, the corresponding GMH, and the relevant sinters at 823 K.

As we know, the shell membranes are nonmineralized, collagen-based matrices consisting of type I, V, and X collagens located in the core of each fiber. Each fiber is composed of a collagenous core surrounded by a glycoprotein mantle. It has been documented that the core is predominantly composed of collagen and osteopontin proteins, while the mantle is rich in polyanions exhibiting a variety of keratan sulfate (KS) epitopes and dermatan sulfate (DS).[25,32] Lysozyme and clusterin are also present at high levels in ESMs, and both have been detected within the membrane fibers, distributed discontinuously with no apparent partitioning between the core and the mantle. It is considered that the cationic lysozyme is bound to the anionic sites of DS and particularly those of KS in the membrane.[32b] Elegant studies[33] with clusterin have demonstrated that it exerts a powerful chaperone-like activity on lysozyme, as well as other purified proteins. Herein, the interfacial sol–gel process is presumably based on the adsorption of cationic groups from the colloid medium into the glycoprotein mantle of the ESM fiber containing an abundance of carboxylic, hydroxy, and amino residues; subsequently a series of complicated reactions proceed to give hierarchical $SnO_2$ films composed of ultrafine nanoparticles. The formation of $SnO_2$ can be denoted as follows:

$$Sn^0 \rightarrow Sn^{IV} \text{ ions (hydrate ions)} \rightarrow Sn^{IV} \text{ colloids} \rightarrow Sn^{IV} \text{oxo species (Sn-gel)} \rightarrow \text{amorphous } SnO_2 \rightarrow \text{nanocrystalline } SnO_2$$

The cationic $Sn^{IV}$ species in the sol system are prone to interaction with the residues of the ESM glycoprotein, as proved by FTIR- and NMR spectroscopic results (Supporting Information, Figure S6). The formation of amorphous Sn colloid/glycoprotein hybrids arises from the strong binding affinity of some residues that involves multiple hydrogen bonds, van der Waals interactions, and the ordering of surface polypeptide loops. The Sn colloids are bound to the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

amino groups of the glycoprotein in the biotemplate ESM and to the –OH and $–NH_2$ groups of the sugar chains linked to polypeptides. Amorphous Sn–O networks can be derived from these reactions, and indeed an amorphous $SnO_2$ film located in the mantle is obtained without changing the original morphologies at room temperature. The $Sn^{IV}$ oxo species are assumed to be intermediates consisting of partly dehydrated polymeric $Sn^{IV}$ hydroxides.

Amorphous $SnO_2$ ripens into well-defined nanocrystallites during the calcination treatment. Heat treatment frequently causes agglomeration and enlargement. However, $SnO_2$ nanocrystallites in our work have small size and good crystallization as well as a narrow size distribution (Supporting Information, Figure S7). This can probably be ascribed to some short-chained amino acids of glycoprotein, which function as capping agents, since the binding is strong enough for controlling the growth of tin dioxide nuclei.[34] For comparison, a blank sample is synthesized through a similar sol–gel approach and calcination treatment at 823 K only without using the biomaterials. $SnO_2$ nanoparticles in the blank sample are disorganized and have an average size of 21 nm, while the ESM-based $SnO_2$ nanocrystallites with an average size of 5 nm are arranged into orderly hierarchical structures. This observation proves the significance of the biotemplate and supports the above analysis. It is also concluded that the ESM peptidoglycan functioning as the surfactant may play a key role in the aggregation and further crystallization of tin oxide nanoparticles. In addition, electrostatic forces assist the biomimetic sol–gel process. Because of the higher acidity of the system (with ample $H^+$ ions), the tin oxide clusters in the colloid are likely to be positively charged at the surface by reference to the isoelectric point of cassiterite $SnO_2$ (7.3).[26] By electrostatic force, they would preferably attach onto the negatively charged $DS^–$ ions on the surface of the membrane. As surface coating is always dependent on surfactant concentration, it is difficult and complicated to determine the precise dosage. However, in our work the "surfactant molecules" could be released systematically by the dissociation and reforming of ESM biomolecules. With the aid of "surfactant molecules", the construction of biostructure hierarchy can be achieved to synthesize subtle biomorphic functional nanomaterials, which is similar to biomolecule-micelle systems.

Notably, a completely morphologic conversion from $SnO_2$ tubes to $SnO_2$ belts occurred as a result of tuning the pH value of the sol media. As lysozyme is a kind of protein that is unstable in alkaline medium, it is clear that the mantle of ESM fiber containing lysozyme is prone to dissociation, its glucide contents not in the collagenous core end up in the colloid system. Therefore, the resultant morphologies of the $SnO_2$ products might have an inherent affiliation with the structures and constituents of the glycoprotein mantle. It is observed that the mantle can exist as a steady covering layer at $pH < 2$, while the distortions and dissociations of this protein layer occur as the pH value is elevated. The mantle protein seems to flow and reform evidently when $pH > 3$, as depicted in Supporting Information (Figure S8). Under these circumstances, lysozyme is most active, and it functions as a kind of enzyme leading to the dissociation and disintegration of the peptidoglycan-based mantle layer. These protein chains then interact with the Sn colloids. Simultaneously, the proteins formerly carrying tubular hybrids start to dissociate and stretch into planar fibers as a result of decreased acidity as illustrated in Scheme 1. Moreover, it is revealed that clusterin, exhibiting powerful chaperone-like action on lysozyme, binds to and stabilizes aggregating proteins, thus leading to irreversible precipitation by preferentially recognizing partially folded protein conformations.[33] This process conduces to the stabilization of the final structures of $SnO_2$. The special layer thus makes it possible for $SnO_2$ fibers to transform from tubular to solid fibrous structures. However, the interaction of the strongly cationic lysozyme with the collagenous matrix may

Scheme 1.  © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be mediated by proteoglycans.[35] It is difficult for Sn colloids to interact with the core matrix under the current concentrations. Accordingly, hollow tubes form under higher acidity, while fibrous structures are obtained at lower acidity after the ESM is removed.

Prompted by their porous appearance and small-scale nanocrystalline units, we speculate that as-prepared hierarchical ESM-based $SnO_2$ must be useful in fabricating semiconducting sensors. When the grain size is reduced to a scale comparable to the space-charge length (for $SnO_2$, this value is 6 nm), the sensitivity could be exponentially enhanced.[23c,36] As an n-type semiconductor, $SnO_2$ has been extensively exploited in applications related to gas sensing. Most of these studies have focused on polycrystalline films made of small $SnO_2$ particles.[37] In contrast to some sensors made of individual single crystalline nanostructures or polycrystalline films, hierarchical nanostructured $SnO_2$ in our work, assembled by the small-scale, well-crystallized nanocrystallite units into tubular or zonary $SnO_2$ fibers with porous conformations and interconnected fibrous meshworks, would allow the sensors to be operated in the most sensitive, grain-controlled mode.

## Conclusions

Hierarchical biomorphic $SnO_2$ has been successfully synthesized, by utilizing the biomaterial ESM as template, through a biomimetic sol–gel approach. The detailed configurations of three ESM layers from the outermost OSM to the ISM, then to the innermost LM, are duplicated with their typical mammillary knobs, interwoven fibers, and silkworm-like structures, respectively. Notably, the average size of $SnO_2$ nanocrystallite units could be tuned in the range 2 to 20 nm by the control over synthesis temperatures and could be restricted to an average size about 5 nm even at 823 K. It has been revealed that some functional groups such as the carboxyl, hydroxy, and amido groups of ESM macromolecules and the specific colloid medium as well as the relationship between them predominantly determine the formation of biomorphic $SnO_2$. ESM provides both a physical substrate and an inductive template for the interfacial sol–gel process to direct the chemical reactions between the sol ingredients and functional residues of ESM macromolecules. Moreover, on the basis of the "surfactant" action of short-chain amino acids of the ESM glycoprotein, the precision assembly from the nanoscale to the micrometer scale could be further realized. As-prepared hierarchical nanostructured films consisting of interwoven tubular $SnO_2$ with inner interconnectivity may be valuable gas-sensing materials in view of their intrinsically small grain size and high surface-to-volume ratios, allowing them to be operated in the most sensitive, grain-controlled mode. As a mild, green, and universal technique, biomimetic sol–gel synthesis is a versatile and feasible route to functional inorganic hierarchical materials. We envisage that, inspired by natural biostructures, the design and assembly of inorganic materials with predetermined structures and properties would lead to a new family of advanced functional systems.

## Experimental Section

### Preparation of the Biotemplates

Commercial eggs were gently broken and cleaned up. The eggshells were washed with distilled water, then the LM and the ISM were manually and successively removed. After the remaining eggshell was immersed in HCl solution (0.5 M) for 5 min, the OSM was separated from the $CaCO_3$ shell. All three layers of fresh membranes were washed with distilled water and subsequently dried by blast at room temperature. They were finally conserved in a vacuum desiccator for the following synthesis.

### Synthesis of $SnO_2$ Hierarchical Nanomaterials

In a typical procedure, Sn powder (ca. 1.45 g) was added stepwise into $HNO_3$ solution (50 mL, 2 M) and stirred for 2 h. Then, distilled water (30 mL) was added slowly within 10 min to promote the hydrolysis of tin ions. It could be observed that a clear solution was obtained incipiently. It then turned into a slightly yellow colloid after being filtered. The pH values of the colloid media were generally kept at 1. For comparison, NaOH solution (1 M) was also added to modify the pH value of the media to 2 and 3. Then the OSM, the ISM, and the LM were immersed in the above-mentioned colloid systems for 13 h at room temperature. The GMH obtained were rinsed with distilled water and directly dried under air flow. Finally, the dry GMH were subjected to calcination treatments in air at 673 K, 823 K, 973 K, 1073 K, and 1273 K for 1.5 h. In all cases, white sheets were obtained and stored in vacuo for characterization.

### Characterization

The morphology and composition were investigated with an FEI Sirion 200 field emission gun scanning electron microscope (FESEM) attached to an X-ray microanalyzer. Transmission electron microscopy (TEM) and high-resolution transmission electron microscopy (HRTEM) images were obtained as bright-field images and were examined by selected area electron diffraction (SAED), conducted with a JEOL JEM-2010 instrument and a JEOL JEM-2100F instrument, respectively. X-ray diffraction (XRD) measurements of the samples were carried out with a Rigaku Dmax 2550V instrument operating at a voltage of 40 kV and a current of 200 mA with Cu-$K_\alpha$ radiation ($\lambda$ = 1.5406 Å) in the range 10–90°. X-ray photoelectron spectroscopy (XPS) was carried out with a VG Microlab 310F using Mg radiation to analyze the chemical states of tin oxide before and after calcination. Thermogravimetric analysis (TGA) and differential thermal analysis (DTA) were conducted to trace the calcination process with a TA 2050 thermoanalyzer and a TA 1600 thermal analysis system, respectively. For Fourier-transform infrared (FTIR) spectroscopy measurements, the spectra of the samples were recorded with a Bruker EQUINOX55 instrument at a resolution of 0.5 $cm^{-1}$ and in a spectral range 4000–400 $cm^{-1}$.

# Synthesis, Coordination and Catalytic Utility of Novel Phosphanyl–ferrocenecarboxylic Ligands Combining Planar and Central Chirality

Martin Lamač,[a] Ivana Císařová,[a] and Petr Štěpnička*[a]

**Keywords:** Asymmetric catalysis / Ferrocene ligands / Rhodium / Palladium / Allylic alkylation

The chiral ferrocene derivative ($R,R_p$)-2-[1-(diphenylphosphanyl)ethyl]ferrocenecarboxylic acid (**1**) is prepared together with selected derivatives resulting from modification at the phosphane moiety [*P*-oxide (**5**) and *P*-sulfide (**4**)] and the carboxyl group {amides bearing benzyl (**6**) and (*R*)- or (*S*)-1-phenylethyl substituents [(*R*)-**7** and (*S*)-**7**] at the amide nitrogen atom}. Acid **1** and amide **6** are studied as ligands in rhodium and palladium complexes. Bridge cleavage of the dimer [{Rh(μ-Cl)Cl($\eta^5$-$C_5Me_5$)}$_2$] with **1** gives [RhCl$_2$($\eta^5$-$C_5Me_5$)(**1**-κ*P*)] (**9**) containing P-monodentate **1**, which undergoes smooth conversion to the (phosphanylalkyl)ferrocenecarboxylato complex [RhCl($\eta^5$-$C_5Me_5$){Fe($\eta^5$-$C_5H_5$)($\eta^5$-$C_5H_3$-1-CH(Me)PPh$_2$-2-COO-κ$^2$*O*,*P*}] (**10**) upon treatment with silica gel or alumina. Yet another *O*,*P*-chelate complex, [Rh{Fe($\eta^5$-$C_5H_5$)($\eta^5$-$C_5H_3$-1-CH(Me)PPh$_2$-2-COO-κ$^2$*O*,*P*}(CO)(PCy$_3$)] (**11**; Cy = cyclohexyl) is obtained directly by an acid-base reaction between the acetylacetonato complex [Rh(acac)(CO)(PCy$_3$)] and **1**. Amide **6** reacts with [{Pd(μ-Cl)($\eta^3$-$C_3H_5$)}$_2$] to give the expected phosphane complex [PdCl($\eta^3$-$C_3H_5$)(**6**-κ*P*)] (**12**), while the replacement of the cyclooctadiene (cod) ligand in [PdCl(Me)(cod)] affords the chelate complex [PdCl(Me)(**6**-κ$^2$*O*,*P*)] (**13**). All compounds are characterised by spectroscopic methods and the solid-state structures of **5**, **9**, **11**, **13**, ($R,S_p$)-2-[1-(diphenylphosphoryl)-ethyl]-1-[*N*-(*R*)-(1-phenylethyl)carbamoyl]ferrocene [(*R*)-**8**; phosphane oxide from (*R*)-**7**], and the synthetic precursors ($R,S_p$)-1-bromo-2-[1-(diphenylphosphanyl)ethyl]ferrocene (**2**) and ($R,S_p$)-1-bromo-2-[1-(diphenylthiophosphoryl)ethyl]ferrocene (**3**) determined by single-crystal X-ray diffraction. The catalytic properties of **1** and the amides are probed in enanatioselective rhodium-catalysed hydrogenation and palladium-catalysed asymmetric allylic alkylation.

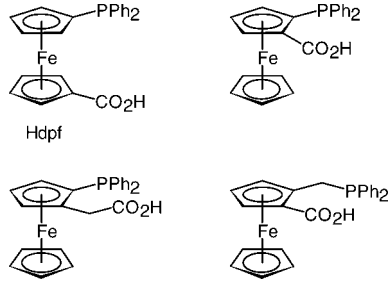
## Introduction

The chemistry of ferrocene has attracted a great deal of attention ever since its discovery in the early 1950s.[1] Ferrocene derivatives have become some of the most frequently studied organometallic compounds, finding applications in organometallic synthesis, materials science, bioorganometallic chemistry and, above all, in catalysis.[2,3] To date an enormous number of chiral and achiral ligands derived from ferrocene have been reported and utilised as donors in the preparation of various coordination compounds[2a] and as catalyst components in transition metal-mediated reactions on both a laboratory and industrial scale.[2a,4]

We have focused our research mainly on phosphanyl–ferrocenecarboxylic donors. The first ligand of this kind, 1′-(diphenylphosphanyl)ferrocenecarboxylic acid (Hdpf), was reported in 1996,[5] and since then we have synthesised several other phosphanyl–ferrocenecarboxylic ligands (see Scheme 1) and studied their structural and coordination properties. More recently, we have extended our interest towards the utilisation of these phosphane–carboxylic acids and their derivatives as organometallic synthons and catalyst components.[6]



Scheme 1.

In this contribution we report the synthesis of a novel phosphanyl–ferrocenecarboxylic ligand combining planar and central chirality, namely ($R,R_p$)-2-[1-(diphenylphosphanyl)ethyl]ferrocenecarboxylic acid (**1**), which is a homologue of *rac*-2-[(diphenylphosphanyl)methyl]ferrocenecarboxylic acid.[7] We also describe the preparation of selected derivatives of **1** modified at both the phosphanyl and carboxyl groups, and use of the acid and amides thereof as ligands in rhodium and palladium complexes and as catalyst components in enantioselective rhodium-catalysed hydrogenation and palladium-catalysed allylic alkylation reactions.

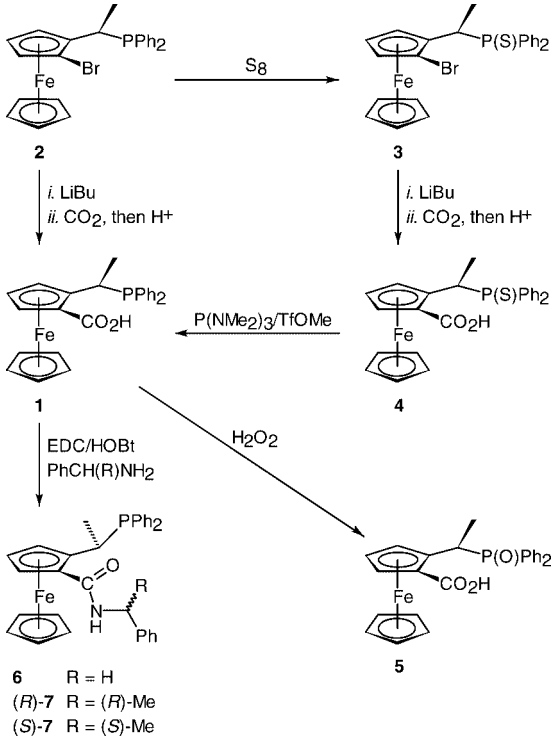
## Results and Discussion

### Preparation and Structural Characterisation of the Ligands

The key compound in this study, ($R$,$R_p$)-2-[1-(diphenylphosphanyl)ethyl]ferrocenecarboxylic acid (**1**), was synthesised from the known chiral precursor ($R$,$S_p$)-1-bromo-2-[1-(diphenyphosphanyl)ethyl]ferrocene (**2**)[8] by lithiation and subsequent carboxylation with carbon dioxide (Scheme 2). Alternatively, **1** was prepared first in its *P*-protected form **4** according to a similar methodology and the bromo-substituted phosphane sulfide **3** as the precursor. Following desulfurisation of **4** with $P(NMe_2)_3$/methyl triflate[9] afforded acid **1**. The structures of the bromo precursors **2** and **3**, including their absolute configuration, have been determined by X-ray crystallography (see Figure 1, Figure S1 in the Supporting Information and Table 1).



Scheme 2.

Acid **1** was further converted into its corresponding phosphane oxide **5** by treatment with aqueous hydrogen peroxide in acetone. A small amount of crystalline **5** was unintentionally obtained during the attempted crystallisation of **1** from ethyl acetate/hexane and its structure was established by single-crystal X-ray diffraction (see below). All compounds have been characterised by spectroscopic methods and elemental analysis. The $^1H$ and $^{13}C$ NMR spectra of **1**, **4** and **5** are in agreement with their formulations and show signals due to phosphorus-coupled ethane-1,1-diyl and phenyl groups and a 1,2-disubstituted ferrocene unit. The $^{31}P$ NMR chemical shifts follow the expected trend [$\delta_P$ = 11.1 (**1**), 36.5 (**5**) and 54.7 ppm (**4**)],[10] with the $^1J_{P,C}$ coupling constants of the $C_{ipso}$ carbon atoms within the cyclopentadienido and phenyl rings increasing in the same order (**1** < **5** < **4**).[11] In addition, the NMR spectra of **2**–**5** indicate the presence of only one diastereoisomeric form for each compound.

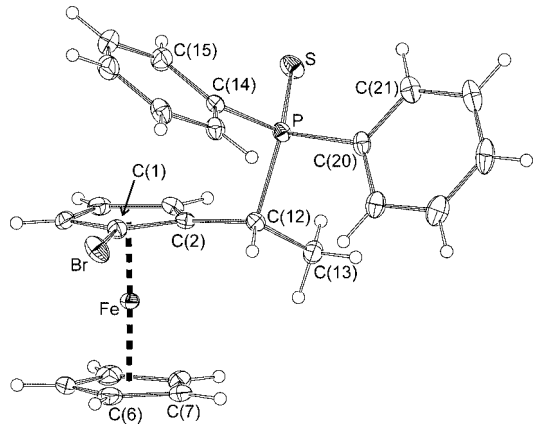


Figure 1. PLATON view of the molecular structure of **3** showing displacement ellipsoids with 30% probability. Note: a structural drawing of the corresponding phosphane **2** is available as Supporting Information (Figure S1).

Table 1. Selected bond lengths [Å] and angles [°] for **2** and **3**.[a]

| | **2** | **3** |
|---|---|---|
| Fe–Cg(1) | 1.6499(8) | 1.6387(1) |
| Fe–Cg(2) | 1.655(1) | 1.650(1) |
| ∠Cp(1),Cp(2) | 5.6(1) | 3.2(2) |
| C(1)–Br | 1.887(2) | 1.888(2) |
| C(2)–C(12) | 1.499(3) | 1.502(3) |
| C(12)–C(13) | 1.528(3) | 1.532(3) |
| P–C(12) | 1.885(2) | 1.852(3) |
| P–C(14) | 1.842(2) | 1.813(3) |
| P–C(20) | 1.838(2) | 1.819(3) |
| P–S | – | 1.957(1) |
| C(2)–C(12)–P | 108.5(1) | 110.2(2) |
| C–P–C[b] | 101.3(1)–103.20(9) | 104.9(1)–105.9(1) |
| S–P–C[c] | – | 112.73(8)–113.74(8) |

[a] The ring planes are defined as follows: Cp(1) = C(1–5); Cp(2) = C(6–10). Cg(1) and Cg(2) denote the respective ring centroids. [b] Range of C(12)–P–C(14,20) and C(14)–P–C(20) angles. [c] Range of S–P–C(12,14,20) angles.

Acids **1**, **4** and **5** display characteristic carbonyl stretching bands in their IR spectra, the position of which varies with substitution at the phosphorus atom. Thus, whereas phosphane **1** and phosphane sulfide **4** show similar $\nu_{C=O}$ frequencies (1667 and 1663 $cm^{-1}$, respectively), the $\nu_{C=O}$ band of phosphane oxide **5** is shifted to higher energy (1685 $cm^{-1}$). This difference probably reflects different hydrogen-bonding patterns in the solid samples.[6]

The crystal structure of **5** (Figure 2a, Table 2) confirms both the expected connectivity and configuration [i.e., ($R$,$R_p$)-**5**]. The geometry of the ferrocene unit is quite regular except for a slight torsion at the substituted cyclopentadienido (Cp) ring, as indicated by the torsion angle C(11)–C(1)–C(2)–C(12) of –11.5(4)°. This can be accounted for by steric interactions between the sterically demanding ferrocene substituents and intermolecular interactions (see below). Nonetheless, the substituents bind symmetrically to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the ferrocene unit, the C(11)–C(1)–C(2/5) and C(12)–C(2)–C(1/3) angles being similar. The carboxyl group [C(11)O(1) O(2)] is rotated from the Cp(1) plane (see Table 2) by 6.4(3)°, while the phosphorus-substituted side arm is oriented above the Cp(1) plane, with an angle between the C(12)–P bond and the Cp(1) plane of 78.0(1)°. The P=O bond is directed outward the carboxyl group [torsion angle C(2)–C(12)–P–O(3) 61.1(2)°], which brings the P=O(3) and C(12)–C(13) bonds into a synclinal orientation [C(13)–C(12)–P–O(3) –63.1(2)°]. Such an arrangement, as well as the individual geometric parameters, compares favourably with those of racemic 2-[(diphenylphosphoryl)methyl]ferrocenecarboxylic acid.[7]

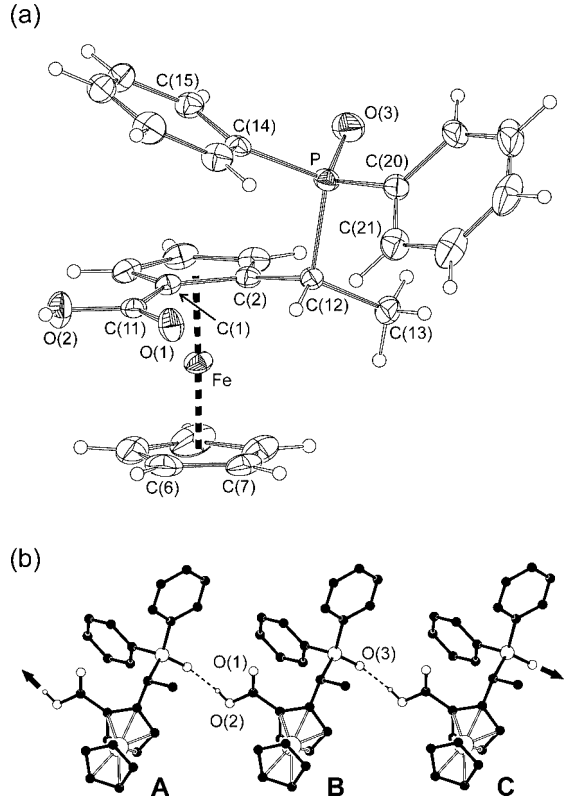

Figure 2. (a) Molecular structure of **5**. Displacement ellipsoids are shown at the 30% probability level. (b) Section of the infinite hydrogen-bonded chain in the structure of **5** showing the hydrogen bonds as dashed lines. Symmetry operations: A ($x$, 1 + $y$, $z$), B ($x$, $y$, $z$), C ($x$, $y$ – 1, $z$).

Individual molecules in the crystal of **5** are linked into infinite chains along the crystallographic $b$ axis by means of hydrogen bonds between the carboxylic OH group and the phosphoryl oxygen atom [O(2)–H(90)···O(3$^{i}$): O(2)···O(3$^{i}$) 2.517(3) Å (i: $x$, 1 + $y$, $z$); angle at H: 162(4)°; Figure 2b]. Similar hydrogen-bonding patterns have been found in the crystal structures of 1′-(diphenylphosphoryl)-ferrocenecarboxylic acid [O···O 2.588(4) Å][12] and ($S_p$)-2-(diphenylphosphoryl)ferrocenecarboxylic acid [O···O 2.556(4) Å].[13]

For the purpose of catalytic testing we prepared a series of *N*-benzylamides without (**6**) and with [(*R*)- and (*S*)-**7**] additional asymmetric centres (Scheme 2). The amides were

Table 2. Selected bond lengths [Å] and angles [°] for **5** and (*R*)-**8**.[a]

| | **5** | (*R*)-**8**[d] |
|---|---|---|

| C–P=O[b] | 108.1(1)–114.1(1) | 112.0(1)–114.4(1) |
| C–P–C[c] | 104.7(1)–108.1(1) | 103.0(1)–107.32(9) |

[a] The ring planes are defined as for **2** and **3**; see Table 1. [b] Range of O(3)–P–C(12,14,20) (**5**) or O(2)–P–C(12,14,20) [(*R*)-**8**] angles. [c] Range of C(12)–P–C(14,20) and C(14)–P–C(20) angles. [d] Further data: N–C(26) 1.465(3), C(26)–C(27) 1.513(3), C(26)–C(28) 1.526(4) Å; C(11)–N–C(26) 122.4(2), N–C(26)–C(27) 109.1(2), N–C(26)–C(28) 111.0(2)°.

obtained in very good yields by standard amidation of **1** with the appropriate amine in the presence of 1-hydroxybenzotriazole (HOBt) and *N*-[3-(dimethylamino)propyl]-*N*′-ethylcarbodiimide (EDC),[14] and characterised by spectroscopic methods. An independent confirmation of the structures came from the structure determination of the ferrocene amide–phosphane oxide (*R*)-**8** (Figure 3, Table 2), which was obtained in small amounts during prolonged recrystallisation of (*R*)-**7** from ethyl acetate/hexane under aerobic conditions.

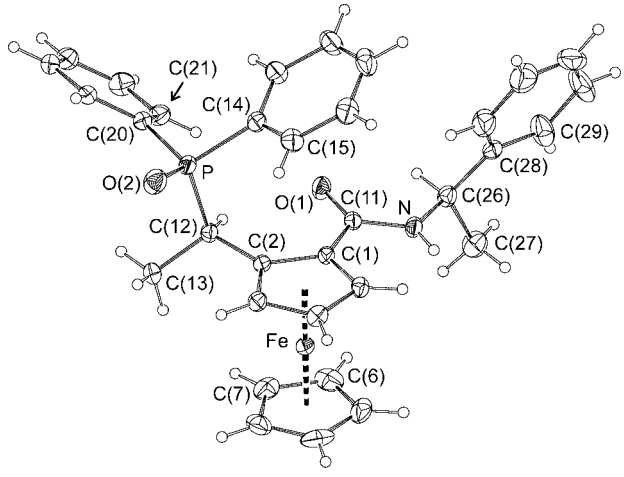

Figure 3. Molecular structure of (*R*)-**8**. Displacement ellipsoids are shown at the 30% probability.

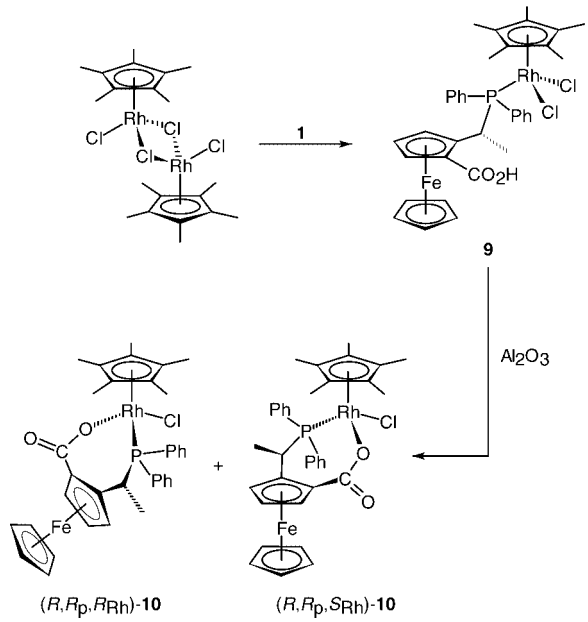
Again, the structure confirms the expected configuration at the stereogenic elements, with the (*R*)-1-phenylethyl group acting as the reference chirality centre. The molecular geometry and conformation, including the mutual orienta-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion of the functional groups, are similar to those in **5**. The C(12)–P vector points above the Cp(1) plane, intersecting the latter at an angle of 74.8(1)°, whilst the substituents at the P–C(12) bond adopt a conformation similar to **5**, departing slightly from the ideal staggered arrangement [cf. C(2)–C(12)–P–O(2) 74.0(2)° and C(13)–C(12)–P–O(2) –49.9(2)°]. Finally, the amide moiety [C(11)O(1)N] is rotated from the Cp(1) plane by 9.5(2)° and adopts a *syn* geometry [C(26)–N–C(11)–O(1) –1.2(3)°], with the phenyl group oriented away from the ferrocene plane [the dihedral angle between the C(26)–C(28) bond and the C(28–33) ring is 49.0(2)°]. In the crystal, the molecules of (*R*)-**8** associate through N–H(90)···O(2$^{ii}$) (ii: 1 – *x*, –1/2 + *y*, 1/2 – *z*) hydrogen bonds [N···O(2) 3.066(2) Å; angle at H(90): 158°] to form infinite angular chains parallel to the crystallographic *b* axis. The crystal assembly is further supported by relatively weaker C–H···O(2) interactions.



Scheme 3.

## Coordination Studies: Rhodium Complexes

With the aim of using these newly prepared ferrocene-linked phosphane–carboxylate donors in rhodium- and palladium-catalysed reactions, we first tested the coordination ability of acid **1** and amide **6** towards these metal ions. Thus, the reaction between **1** and di-μ-chlorobis[chloro(η$^5$-pentamethylcyclopentadienido)rhodium(III)] gave the expected product of bridge cleavage (**9**; Scheme 3). When treated with chromatography grade alumina or silica gel (during column chromatography or in a batch mode), complex **9** underwent clean dehydrohalogenation to give phosphane–carboxylato complex **10** as a mixture of diastereoisomers that differ in their configuration at the newly formed stereogenic centre (Rh atom). The diastereoisomeric ratio of about 1:9 determined by NMR spectroscopy clearly indicates that the ferrocene phosphane–carboxylato ligand provides a pronounced steric bias during the chelate formation.

The P-monodentate coordination of **1** in compound **9** is reflected mainly in a low-shift of the $^{31}$P NMR signal [cf. the coordination shift, $\Delta_P = \delta_P$(complex) – $\delta_P$(ligand) = 23.2 ppm for **9**] and its splitting into a $^{103}$Rh-coupled doublet ($^1J_{Rh,P}$ = 140 Hz). On the contrary, the carboxyl $^{13}$C NMR signal and the $\nu_{C=O}$ band of the IR spectrum differ only slightly from those in the free ligand. On going from **9** to **10**, the $^{31}$P NMR resonance shifts to even lower fields ($\Delta_P$ = 40.9/38.7 ppm for the major/minor diastereoisomer) while coordination of the deprotonated carboxyl group is clearly manifested by characteristic carboxylate bands in the IR spectrum (1581 and 1307 cm$^{-1}$; cf. 1664 cm$^{-1}$ for **9** and 1321 cm$^{-1}$ for **11**).

It is noteworthy that complex **9** shows markedly broad $^1$H NMR resonances at +25 °C, particularly those due to the CH*Me* and $C_5H_3$ protons, which sharpen upon both heating to 50 °C and cooling to 0 °C. Such behaviour is indicative of a hindered intramolecular motion, which most likely results from steric interaction between the bulky (η$^5$-$C_5Me_5$)Rh unit and the ligand. The motion apparently becomes slow at low temperature, where the "equilibrium" shifts in favour of the preferred (low-energy) conformer, while higher temperatures result in a fast molecular motion and, hence, signal averaging. The expected nature of the observed dynamic behaviour is supported by the $^{31}$P NMR spectra, which show a rather minor shift of the main signal over the whole temperature range monitored ($\delta_P$ = 34.9 ppm at 50 °C, and 34.0 ppm at 0 °C; $^1J_{Rh,P} \approx$ 145 Hz in both cases), thus excluding that chemically different forms are involved in the equilibrium.

The structure of **9** was corroborated by X-ray crystallography. The unit cell of **9** comprises two crystallographically distinct, but structurally very similar, molecules (Figure 4a, Table 3). This multiplication of otherwise almost identical moieties within the asymmetric unit apparently results from the crystal packing. The independent molecules aggregate into familiar dimers through double hydrogen bonds between their carboxyl groups [(C=O···H–O)$_2$ with O···O 2.652(4)/2.541(4) Å; Figure 4b]. However, such a bonding pattern requires two appropriately oriented carboxyl groups which, in a *chiral* space group, necessitates multiplication of the "repeating" units (instead of the crystallographically imposed symmetry typically observed in centrosymmetric space groups). Indeed, the most notable difference between the two independent molecules is the orientation of their carboxyl groups, which are mutually rotated by 180°. The hydrogen-bonded dimers further assemble into columnar stacks through π···π interactions between the non-substituted ferrocene and Rh-bonded cyclopentadienido rings [Cg(12)···Cg(13) 3.455(3) Å, tilt 2.5°; Cg(22)···Cg(23) 3.460(3) Å, tilt 7.5°; see Table 3 for definitions].

The different steric demands of the donors around the rhodium atom in **9** naturally result in angular deformation of the coordination environment (see the interligand angles

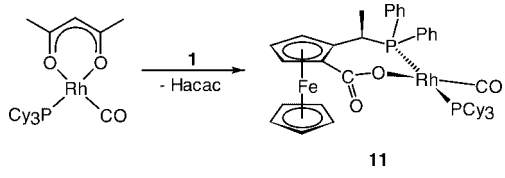
[a] Definitions: Cp(11) = C(1–5), Cp(12) = C(6–10), Cp(21) = C(41–45), Cp(22) = C(46–50), Cp(13) = C(26–30), and Cp(23) = C(66–70). Cg($n$1,$n$2,$n$3) represent the respective centroids. For a note on the atom labelling scheme, see Figure 4. [b] C(11)–O(11) (molecule 1) or C(51)–O(21) (molecule 2). [c] C(11)–O(12) (molecule 1) or C(51)–O(22) (molecule 2). [d] O(11)–C(11)–O(12) (molecule 1) or O(21)–C(51)–O(22) (molecule 2). [e] Range of P(1)–C(12,14,20) (molecule 1) or P(2)–C(52,54,60) (molecule 2) distances. [f] Range of C(12)–P(1)–C(14,20) and C(14)–P(1)–C(20) (molecule 1) or C(52)–P(2)–C(54,60) and C(54)–P(2)–C(60) (molecule 2) angles.

in Table 3), albeit without any significant slanting of the three-legged piano-stool geometry, as evidenced by the dihedral angles of the basal [Cl($n$1),Cl($n$2),P($n$)] and Cp($n$3) planes of 8.1(2)° and 7.0(2)° for molecules 1 and 2 (≡ $n$), respectively. The overall molecular geometry is similar to that of the analogous complex with P-monodentate 2-[(diphenylphosphanyl)methyl]ferrocenecarboxylic acid.[7] The P-monodentate phosphane–carboxylic ligand is oriented such that its ferrocene and phenyl groups are kept clear of the ($\eta^5$-$C_5Me_5$)Rh moiety while the methyl group of the ethane-1,1-diyl linker is located approximately below the rhodium atom [cf. Rh(1)–P(1)–C(12)–C(2/13) and Rh(2)–P(2)–C(52)–C(42/53) torsion angles of –85.9(3)/45.6(3)° and –85.4(3)/44.9(3)°, respectively]. The Cp($n$1) and Cp($n$3) rings are nearly parallel in both molecules, the respective dihedral angles being 7.3(2)° [Cp(11)/Cp(13) in molecule 1] and 8.2(2)° [Cp(21)/Cp(23) in molecule 2]. This arrangement obviously corresponds with the π···π stacking interactions mentioned above.

Similarly to other ferrocene-based phosphane–carboxylic acids,[6,7,15] **1** reacts with [Rh(acac)(CO)($PCy_3$)] (Hacac = pentane-2,5-dione, Cy = cyclohexyl) to give a complex with *O*,*P*-chelating phosphane–carboxylate (**11**, Scheme 4) by replacement of the acetylacetonate and concomitant proton transfer. Compound **11** shows characteristic strong bands due to $\nu_{C\equiv O}$ at 1959 $cm^{-1}$ and carboxylate vibrations at 1612 and 1321 $cm^{-1}$ in its IR spectrum. The presence of two different phosphane donors in *trans* positions is best manifested in the $^{31}P$ NMR spectrum, which shows two doublets of doublets at $\delta_P$ = 40.9 and 46.5 ppm with typical coupling constants ($^1J_{Rh,P} \approx 125$, $^2J_{P,P}$ = 319 Hz),[7,15,16] and further by $^{31}P$-$^{13}C$ coupling patterns in the $^{13}C$ NMR spectrum (e.g., by a doublet of triplets at $\delta_C$ = 190.20 ppm with $^1J_{Rh,C}$ = 73 and $^2J_{P,C}$ = 16 Hz for Rh-*C*O).



Scheme 4.

As revealed by X-ray diffraction analysis (Figure 5, Table 4), the coordination environment of the rhodium atom in **11** is almost planar with the phosphane moieties in *trans* positions. The maximum deviation of the donor atoms and the metal atom from the mean coordination plane [Rh]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(see Table 4 for definitions) is much less than 0.1 Å. Likewise, the interligand angles differ only marginally from 90° which, together with their sum of 360.4°, rules out any tetrahedral deformation of the coordination polyhedron.

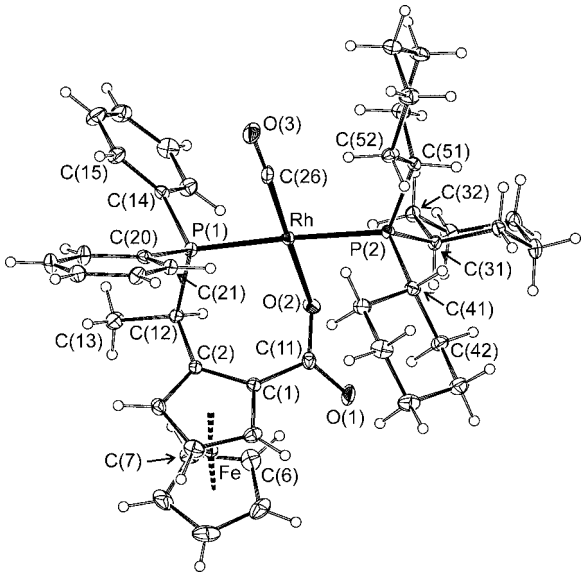


Figure 5. PLATON view of the molecular structure of **11** showing displacement ellipsoids at the 30% probability level.

On the whole, the coordination geometry compares favourably with that in similar complexes featuring 2-[(diphenylphosphanyl)methyl]ferrocenecarboxylate[7] and 1′-(diphenylphosphanyl)ferrocenecarboxylate as the *O*,*P*-chelating ligands.[15a] The pendant phosphane and, consequently, the [Rh] plane in **11** are directed above the ferrocene framework such that the [Rh] and Cp(1) planes subtend a dihedral angle of about 73° (see Table 4 for definition of the ring planes). The methyl and rhodium "substituents" at the P(1)–C(12) bond are arranged in an antiperiplanar manner [C(13)–C(12)–P(1)–Rh 169.3(2)°] whilst the ferrocene unit and the rhodium atom are close to synperiplanar [C(2)–C(12)–P(1)–Rh –62.3(2)°]. In such an arrangement, the formation of the Rh–O(2) bonds leads to a rotation of the carboxyl group from its parent Cp(1) plane by about 33° (note that the carboxyl and [Rh] planes are rotated by about 53°). The overall conformation is similar to the 2-[(diphenylphosphanyl)methyl]ferrocenecarboxylato complex mentioned above from which **11** differs only by substitution at the phosphanyl side chain (methyl vs. H). Similarly to the mentioned complex, the "$PC_3$" moieties of the phosphane donors in **11** appear staggered when looking in the P(1)–P(2) direction and all cyclohexyl rings adopt a chair conformation,[17] binding the phosphorus atom in equatorial positions.

### Palladium Complexes

When studying palladium(II) complexes we focused on amide **6** due to its expected ability to ligate metal centres in different ways. First, we turned to (allyl)palladium species as they are relevant to palladium-mediated allylic alkylation reactions (see below). The reaction of [{Pd(μ-Cl)($\eta^3$-$C_3H_5$)}$_2$] with **6** in a 1:2 molar ratio was monitored in situ. A single "product" **12** was detected in the $^1$H NMR spectrum, which shows two sets of broad signals at room temperature (25 °C). Heating to 50 °C resulted in the coalescence of most signals (see Experimental Section). On the other hand, cooling to 0 °C and below caused the broad resonances to sharpen and split into two distinct sets of signals attributable to isomers due to a fluxional $\eta^3$-allyl moiety.[18] The $^{31}$P NMR spectra are in agreement with these observations, showing two narrow-spaced signals ($\delta_P$ = 34.8 and 34.6 ppm at 0 °C), which collapse into a sharp singlet at higher temperature ($\delta_P$ = 35.3 ppm at 50 °C). The $^{31}$P NMR shift and unaffected $\nu_{C=O}$ band in the IR spectrum allowed us to formulate **12** as a fluxional complex with P-monodentate **6**, i.e. [PdCl($\eta^3$-$C_3H_5$)(**6**-κ*P*)], which results from a simple bridge-cleavage reaction. Support for this formulation was obtained from the ESI mass spectrum, which shows a peak at *m*/*z* = 678 attributable to [($\eta^3$-$C_3H_5$)-Pd(**6**)]$^+$.

The chelating, non-fluxional palladium(II) complex **13** was obtained from the reaction of **6** with [PdCl(Me)(cod)] (cod = $\eta^2$:$\eta^2$-cycloocta-1,5,-diene; Scheme 5). The spectro-

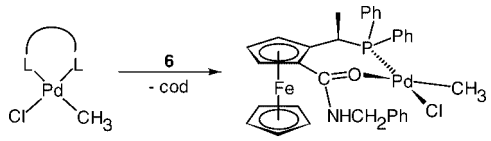
scopic data of **13** clearly indicate the formation of only one of all possible isomers that differ in the coordination mode of the amide ligand (*P,O* vs. *P,N*) *and* configuration (*trans*-P,Cl and *trans*-P,C) in solution. Whereas the P-coordination was clearly inferred from the shift of the $^{31}P$ NMR resonance to lower fields ($\Delta_P$ = 44.0 ppm), the shift of the $\nu_{C=O}$ (amide I) band to lower energies and a low-field shift of the C=O resonance in the $^{13}C$ NMR spectrum ($\Delta_C$ = 5.3 ppm) suggested coordination through the amide oxygen atom. A *trans*-P,Cl configuration was proposed on the basis of a comparison of $^3J_{P,H}$ values for the palladium-bonded methyl group obtained from the $^1H$ NMR spectrum with literature data.[19,20]



**13**

Scheme 5. Preparation of complex **13** (L–L is cycloocta-1,5-diene).

The crystal structure of **13** (Figure 6, Table 5) confirmed both the anticipated coordination mode of **6** and the *trans*-P,Cl disposition of the donors. The palladium atom and its four donor atoms are coplanar within 0.1 Å; the sum of the interligand angles is 360.15°. The Pd–donor distances are rather unexceptional, comparing well with those in [PdCl($C_6F_5$){2-$Ph_2PC_6H_4CONHCHMe_2$-$\kappa^2$*O,P*}] [Pd–Cl 2.3691(4), Pd–P 2.2114(4), Pd–O 2.098(1) Å],[21] [PdCl(Me)(L-$\kappa^2$*P,P′*)] (L = various chiral ferrocene-derived diphosphanes of the type [Fe{$\eta^5$-$C_5H_3$($PR_2$-1)[CH(Me)-$PR'_2$-2]}($\eta^5$-$C_5H_5$)]; Pd–C 2.081–2.141 Å)[20a,22] and bis{μ-[2-(diphenylphosphanyl)ferrocenyl]carboxylato-*O,O′,P*}bis-{methylpalladium(II)}] [Pd–C 2.013(3) Å], for example.[23]

The structural data of the related amido phosphane oxide (*R*)-**8** enable an inspection of the changes in the amide group geometry upon coordination. On going from (*R*)-**8** to **13**, for example, the C=O bond elongates by about 0.03 Å while the C(11)–N/C(1) bond lengths decrease by about 0.02 Å. This is consistent with donation from the amide oxygen atom and a corresponding electron density shift towards C11. As usual, the amide moiety is almost

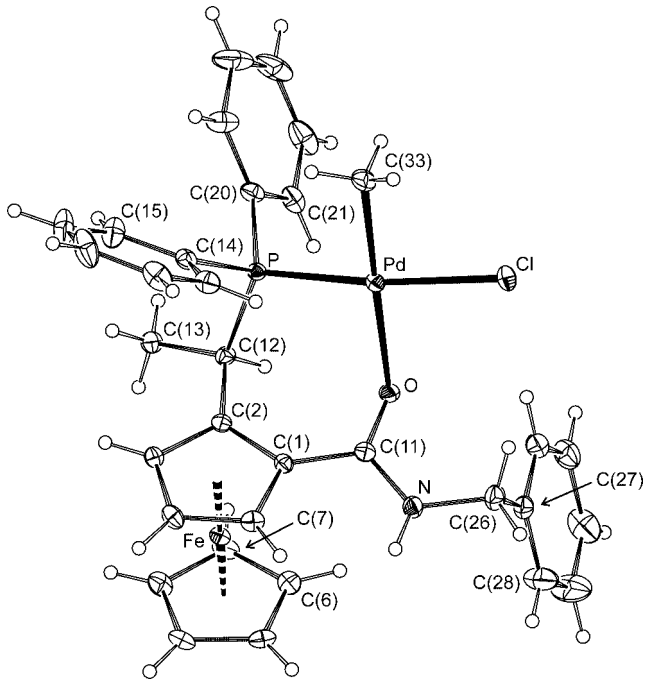


Figure 6. PLATON view of the molecular structure of **13** showing 30% probability displacement ellipsoids.

planar [τ(O–C(11)–N–C(26) 7.0(4)°] but is rotated from the Cp1 plane by 16.8(3)° along the C1–C11 bond, which brings the O atom above the ferrocene unit and in the vicinity of the palladium atom. The geometry of the ferrocene unit remains practically unaffected: the Fe–Cg distances are nearly the same as in (*R*)-**8** and the cyclopentadienido ligands show a tilt of 3.7(2)°. However, a minor deformation, not detectable in (*R*)-**8**, can be found at the amide-linking bond C(1)–C(11), which is bent away from the phosphanylalkyl chain. The C(11)–C(1)–C(2/5) angles differ by as much as 18° [125.9(2)/107.9(2)°] whereas the difference between the C(12)–C(2)–C(1/3) angles is only 2.5°. Such a distortion of the valence angles can be attributed to *O,P*-chelate coordination, making the donor sites more distant.

In the solid state, the molecules of **13** interact predominantly through N–H(90)···Cl$^{iii}$ bonds [N–H(90)···Cl$^{iii}$ (iii: 1 – *x*, 1/2 + *y*, 2 – *z*) 3.281(2) Å; angle at H(90) 160°], which

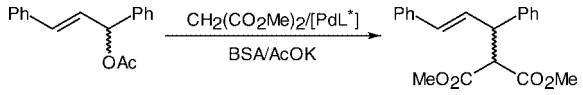
gives rise to infinite helical chains running along the crystallographic $2_1$ screw axis.

### Catalytic Tests

In order to probe the catalytic performance of this newly synthesised family of ligands derived from **1**, we first chose the rhodium-catalysed hydrogenation of methyl β-acetamidocinnamate.[24] Somewhat unexpectedly, the reductions performed under standard conditions (see Experimental Section) did not proceed at all. As the next step, we turned to palladium-mediated asymmetric allylic alkylation,[25] which is a widely used benchmark test that often allows a direct comparison with other chiral ferrocene-based ligands.

When performing allylic substitutions (Scheme 6) we used 1,3-diphenylprop-2-en-1-yl acetate as the substrate, dimethyl malonate/*N*,*O*-bis(trimethylsilyl)acetamide/potassium acetate as the nucleophile source, and pre-catalysts formed in situ from [{Pd(μ-Cl)(η$^3$-$C_3H_5$)}$_2$] and a slight excess of the appropriate ligand. All reactions were carried out in dichloromethane at room temperature. The results are summarised in Table 6.



Scheme 6.

Table 6. Application of **1** and its amides in palladium-catalysed enantioselective allylic alkylation.[a]

| Entry | Ligand | Conv. (isolated yield) [%][b] | *ee* [%] (config.)[c] |
|---|---|---|---|
| 1 | **1** | 100 (94) | 10 (*S*) |
| 2 | **6** | 55 | 41 (*R*) |
| 3 | (*R*)-**7** | 42 | 43 (*R*) |
| 4 | (*S*)-**7** | 22 | 35 (*R*) |

[a] See Experimental Section for conditions. [b] Conversion determined by $^1$H NMR spectroscopy. [c] Absolute configuration assigned by comparison of the sign of the optical rotation with the literature data.

The reaction in the presence of the catalyst obtained from **1** proceeded with the highest rate (conversion) but with disappointingly low enantioselectivity (Table 6, Entry 1). Replacement of the carboxy group with a carbamoyl moiety resulted in lower chemical yields and higher *ee* values, although with an *opposite* configuration of the major product (Table 6, Entries 2–4). This change of configuration of the preferred alkylated product can be attributed to a changed donor ability of the ligands (P,O for **1** vs. P,N or P,O for the amides) or to a changed access for the nucleophile towards the η$^3$-allyl intermediate. A comparison of the results obtained with amides that differ only in their *N*-substituents (type and chirality) indicates that the nature of the benzylic group has only a small influence on the course of the catalytic reaction in terms of enantioselectivity while changing the reaction rate. Our observations correspond with previous attempts to clarify the role of individual chirality elements in ferrocene-based donors possessing both central and planar chirality, which clearly showed that the reaction course is governed not only by both chirality elements but also by their *mutual* matching.[26]

Despite the numerous reports concerning the use of ferrocene-based donors in allylic alkylations, there seems to be no example available in the literature relating directly to the compounds under study (same reaction, similar ligands). Most reports involving phosphanyl–ferrocenecarboxylic acids and their amides deal, with varying success, with reactions involving *cyclic* allylic acetates.[27,28] Nonetheless, acid **1** and its amides show *ee* values inferior to those reported for the chemically related (phosphanylferrocenyl)oxazolines[4b,26d,29] and for *meso*-1,1′-bis(diphenylphosphanyl)-2,2′-bis{*N*-(ω-hydroxyalkyl)carbamoyl}ferrocenes, which combine *two* phosphane and amide moieties.[30] Even so, the catalytic performance observed for **1** and the related amido phosphanes is lower than that of Josiphos-type ligands[31] where, however, a stronger ligand–palladium interaction can be expected due to the presence of two phosphane moieties.

## Conclusions

We have reported the preparation of a novel, enantiopure phosphanyl–ferrocenecarboxylic ligand combining planar and central chirality elements, namely (*R*,*R*$_p$)-2-[1-(diphenylphosphanyl)ethyl]ferrocenecarboxylic acid (**1**), and its derivatives modified at both the phosphorus (**4** and **5**) and carboxyl groups [amides **6**, (*S*)-**7** and (*R*)-**7**]. A study of the representative phosphanes as ligands for rhodium (**1**→**9**, **10**, **11**) and palladium(II) (**6**→**12** and **13**) clearly has shown their coordination versatility and the potentially multidentate nature of these phosphanyl–ferrocenecarboxylic donors. Based on these results, we have also investigated the catalytic performance of the modified phosphanes in enantioselective rhodium-catalysed hydrogenation and asymmetric palladium-catalysed allylic alkylation. Whereas the former reaction gave disappointing results, not proceeding with any of the ligands tested [**1**, **6**, (*R*)-**7**, and (*S*)-**7**], the latter proved more successful, thereby providing an insight into the role of the individual molecular parts on the reaction rate and stereodiscrimination.

## Experimental Section

**Materials and Methods:** All syntheses were performed under argon with exclusion of direct daylight. Tetrahydrofuran was dried by refluxing with potassium/benzophenone ketyl and distilled. Toluene was dried with sodium metal and distilled. Dichloromethane and chloroform were predried by standing over anhydrous potassium carbonate and then distilled from calcium hydride. Butan-2-one was dried with phosphorus pentaoxide and distilled prior to use. (*R*,*S*$_p$)-1-Bromo-2-[1-(diphenylphosphanyl)ethyl]ferrocene (**2**), [{(μ-Cl)RhCl(η$^5$-$C_5Me_5$)}$_2$],[32] [Rh(acac)(CO)(PCy$_3$)][15c] and [PdCl(Me)(cod)][33] were prepared according to the literature procedures. Other chemicals (Lachema, Fluka) and solvents used for crystallisations (Lach-Ner) were used without further purification. NMR

spectra were recorded with a Varian Unity Inova spectrometer ($^1$H: 399.95; $^{13}$C: 100.58; $^{31}$P: 161.90 MHz) at 25 °C unless indicated otherwise. Chemical shifts ($\delta$) are given relative to internal tetramethylsilane ($^{13}$C and $^1$H) or to external 85% aqueous $H_3PO_4$ ($^{31}$P). IR spectra were recorded with an FT IR Nicolet Magna 650 spectrometer. Positive ion electron impact (EI) and fast atom bombardment (FAB) mass spectra [including high resolution (HR) measurements] were obtained with a ZAB SEQ spectrometer. Electrospray (ESI) mass spectra were recorded with a Micromass Q-TOF spectrometer (acetonitrile solvent). Optical rotations were measured with an automatic polarimeter Autopol III (Rudolph Research) at room temperature.

**Preparation of ($R$,$R_p$)-2-[1-(Diphenylphosphanyl)ethyl]ferrocenecarboxylic Acid (1):** Butyllithium (2.1 mL, 2.5 M in hexanes, 5.3 mmol) was added dropwise to a stirred solution of **2** (1.91 g, 4.0 mmol) in thf (50 mL) at –78 °C. After stirring at –78 °C for 1 h, the reaction solution was poured onto crushed solid $CO_2$ (approx. 50 g) and allowed to stand at room temperature overnight. The mixture was then diluted with water and diethyl ether (approx. 30 mL each), and washed with saturated aqueous NaCl solution (2 × 30 mL). The organic phase was dried with anhydrous $MgSO_4$ and the solvents were evaporated under vacuum. The residue was purified by chromatography on silica gel, eluting with dichloromethane/methanol (20:1). A minor band of (*R*)-[1-(diphenylphosphanyl)ethyl]ferrocene eluted first, followed by the band of the product, which, after evaporation of the solvent, afforded **1** as an orange solid foam. Yield: 1.482 g (84%). $^1$H NMR ($CDCl_3$): $\delta$ = 1.55 (dd, $^3J_{H,H}$ = 7.1, $^3J_{P,H}$ = 13.9 Hz, 3 H, CHC*H*$_3$), 4.21 (s, 5 H, $C_5H_5$), 4.28 (qd, $^3J_{H,H}$ = 7.1, $^2J_{P,H}$ = 5.7 Hz, 1 H, C*H*CH$_3$), 4.36 (m, 1 H, $C_5H_3$), 4.40 (apparent t, $J \approx$ 2.7 Hz, 1 H, $C_5H_3$), 4.68 (m, 1 H, $C_5H_3$), 7.01–7.64 (m, 10 H, P*Ph*$_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 18.49 (d, $^2J_{P,C}$ = 19 Hz, CH*C*H$_3$), 28.90 (d, $^1J_{P,C}$ = 15 Hz, *C*HCH$_3$), 67.44 (d, $^3J_{P,C}$ = 2 Hz, $C_5H_3$ *C*-CO$_2$H), 69.95 ($C_5H_3$ *C*H), 69.97 ($C_5H_3$ *C*H), 70.32 ($C_5H_5$), 70.85 (d, $J_{P,C}$ = 5 Hz, $C_5H_3$ *C*H), 95.82 (d, $^2J_{P,C}$ = 16 Hz, $C_5H_3$ *C*-CH), 127.48 (d, $^3J_{P,C}$ = 6 Hz, PPh$_2$ *C*H$_m$), 128.07 (PPh$_2$ *C*H$_p$), 128.31 (d, $^3J_{P,C}$ = 6 Hz, PPh$_2$ *C*H$_m$), 129.09 (PPh$_2$ *C*H$_p$), 133.23 (d, $^2J_{P,C}$ = 18 Hz, PPh$_2$ *C*H$_o$), 134.40 (d, $^2J_{P,C}$ = 20 Hz, PPh$_2$ *C*H$_o$), 135.78, 136.69 (2 × d, $^1J_{P,C}$ = 16 Hz, PPh$_2$ *C*$_{ipso}$), 178.06 (*C*O$_2$H) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 11.1 (s) ppm. **Preparation of ($R$,$R_p$)-2-[1-(Diphenylphosphoryl)ethyl]ferrocenecarboxylic Acid (5):** In air, hydrogen peroxide (0.3 mL 30%, 2.5 mmol) was added to a solution of acid **1** (93 mg, 0.21 mmol) in acetone (5 mL) whilst stirring and cooling in an ice bath. The cooling bath was removed after 5 min and stirring was continued at room temperature for 30 min. A saturated aqueous solution of $Na_2S_2O_3$ (5 mL) was added to remove the excess of $H_2O_2$ and, after an additional 10 min, acetone was removed under reduced pressure, the residue diluted with water (10 mL) and extracted with dichloromethane (3 × 10 mL). The combined extracts were washed with saturated aqueous NaCl solution (20 mL), dried with $MgSO_4$, and the solvents were evaporated under vacuum. The residue was immediately purified by column chromatography (silica gel, dichloromethane/methanol mixture, 10:1) to yield **4** as a yellow solid foam after solvent evaporation. Yield: 48 mg (50%); the reaction is accompanied by decomposition, which results in the formation of a dark material that remains adsorbed at the top of the chromatographic column. $^1$H NMR ($CDCl_3$): $\delta$ = 1.71 (dd, $^3J_{H,H}$ = 7.3, $^3J_{P,H}$ = 15.7 Hz, 3 H, CHC*H*$_3$), 4.23 (s, 5 H, $C_5H_5$), 4.43 (apparent t, $J \approx$ 2.7 Hz, 1 H, $C_5H_3$), 4.46 (dq, $^3J_{H,H} \approx {}^2J_{P,H} \approx$ 7.5 Hz, 1 H, C*H*CH$_3$), 4.66 (m, 2 H, 2 × $C_5H_3$), 7.12–8.02 (m, 10 H, P*Ph*$_2$) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 15.21 (d, $^2J_{P,C}$ = 2 Hz, CH*C*H$_3$), 31.91 (d, $^1J_{P,C}$ = 65 Hz, *C*HCH$_3$), 68.67 ($C_5H_3$ *C*-CO$_2$H), 70.31 ($C_5H_3$ *C*H), 70.49 ($C_5H_5$), 70.51 ($C_5H_3$ *C*H), 71.84 (d, $J_{P,C}$ = 2 Hz, $C_5H_3$ *C*H), 89.79 ($C_5H_3$ *C*-CH), 127.58, 128.59 (2 × d, $^3J_{P,C}$ = 12 Hz, PPh$_2$ *C*H$_m$), 130.32, (d, $^1J_{P,C}$ = 52 Hz, PPh$_2$ *C*$_{ipso}$), 131.27 (d, $^1J_{P,C}$ = 57 Hz, PPh$_2$ *C*$_{ipso}$), 131.29 (d, $^4J_{P,C}$ = 2.5 Hz, PPh$_2$ *C*H$_p$), 131.41, 131.68 (2 × d, $^2J_{P,C}$ = 9 Hz, PPh$_2$ *C*H$_o$), 131.89 (d, $^4J_{P,C}$ = 2 Hz, PPh$_2$ *C*H$_p$), 175.99 (*C*O$_2$H) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 36.5 (s) ppm. IR (Nujol): $\tilde{\nu}$ = 1685 (s), 1281 (m), 1215 (m), 1153 (s), 1118 (m), 1105 (m), 1083 (m), 1027 (w), 1000 (w), 820 (w), 742 (m), 723 (s), 696 (m), 541 (m), 497 (m), 472 (w) cm$^{-1}$. ($CDCl_3$): $\delta$ = 53.5 (s) ppm. MS (EI+): *m*/*z* (%) = 510 (40)/508 (40) $[M]^+$, 445 (3)/443 (3) $[M - C_5H_5]^+$, 363 (9), 338 (8), 308 (67), 293 (97)/291 (100) $[M - Ph_2PS]^+$, 260 (13), 217 (18) $[Ph_2PPS]^+$, 196 (14), 185 (16), 183 (30) $[Ph_2P - 2\ H]^+$, 155 (25), 153 (18), 139 (26), 121 (21) $[C_5H_5Fe]^+$. HR MS calcd. for $C_{24}H_{22}{}^{56}FePS^{79}Br$ $[M]^{+\cdot}$ 507.9713; found 507.9703. $C_{24}H_{22}Br^{56}FePS$ (509.2): calcd. C 56.61, H 4.35; found C 56.29, H 4.34. $[\alpha]_D$ = 55.5 (*c* = 1.0, $CHCl_3$).

**Alternative Preparation of 1:** The reaction was performed as described above for the preparation of **1**, starting from bromide **3** (280 mg, 0.55 mmol in 10 mL of thf) and butyllithium (0.3 mL, 2.5 M in hexanes, 0.75 mmol). Purification of the crude product by column chromatography (silica gel; dichloromethane/methanol, 10:1) afforded **4** as an orange glassy solid. Yield: 138 mg (53%). In the next step, phosphane sulfide **4** (58 mg, 0.12 mmol) was dissolved in dichloromethane (5 mL) and MeOTf (0.05 mL, 0.44 mmol) was added. The mixture was stirred at room temperature for 3 h. The solvent was removed under reduced pressure, the residue immediately dissolved in dichloromethane (5 mL), and treated with $P(NMe_2)_3$ (0.06 mL, 0.33 mmol). After stirring the resulting mixture at room temperature overnight, the volatiles were removed under vacuum and the residue was purified by column chromatography (silica gel, dichloromethane/methanol, 20:1). Concentration of the appropriate fraction gave acid **1** as an orange glassy solid. Yield: 23 mg (43%).

**General Procedure for the Preparation of Amides:** 1-Hydroxybenzotriazole (HOBt) was added to a solution of acid **1** in dichloromethane (15 mL) and the reaction mixture was stirred at 0 °C for 5 min (some HOBt, which is used in excess, remained undissolved). *N*-(3-Dimethylaminopropyl)-*N*′-ethylcarbodiimide (EDC) was then added dropwise and the formed solution was stirred at 0 °C for another 30 min, during which time the colour of the solution turned from orange to red. Finally, the appropriate amine (neat) was added and stirring was continued at room temperature for an additional 20 h. The mixture was then extracted with 3 M HCl (10 mL), twice with saturated aqueous $NaHCO_3$ (10 mL), and brine (10 mL). The organic phase was dried with $MgSO_4$, and the solvents were evaporated under vacuum. The residual orange oil was purified by column chromatography on silica gel, eluting with dichloromethane/methanol (20:1).

***N*-Benzyl-(*R*,*R*$_p$)-2-[1-(diphenylphosphanyl)ethyl]ferrocenecarboxamide (6):** Starting from **1** (221 mg, 0.50 mmol), HOBt (78 mg, 0.56 mmol), EDC (0.1 mL, 0.6 mmol) and benzylamine (57 mg, 0.53 mmol), the above procedure gave **6** as an orange solid foam. Yield: 195 mg (73%). $^1H$ NMR ($CDCl_3$): $\delta$ = 1.55 (dd, $^3J_{H,H}$ = 7.1, $^3J_{P,H}$ = 14.9 Hz, 3 H, CHC*H*$_3$), 3.99 (dd, *J* = 5.0, *J* = 14.9 Hz, 1 H, NHC*H*$_2$Ph), 4.18 (s, 5 H, $C_5H_5$), 4.19 (m, 1 H, $C_5H_3$), 4.22 (apparent t, *J* ≈ 2.6 Hz, 1 H, $C_5H_3$), 4.26 (m, 1 H, $C_5H_3$), 4.47 (dq, $^3J_{H,H} \approx {}^2J_{P,H} \approx 7$ Hz, 1 H, C*H*CH$_3$), 4.48 (dd, $^3J_{H,H}$ = 5.0, $^2J_{H,H}$ = 14.9 Hz, 1 H, NHC*H*$_2$Ph), 5.38 (t, $^3J_{H,H}$ = 5.5 Hz, 1 H, CON*H*), 6.85–7.65 (m, 15 H, P*Ph*$_2$ and CH$_2$*Ph*) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 18.62 (d, $^2J_{P,C}$ = 20 Hz, CH*C*H$_3$), 28.47 (d, $^1J_{P,C}$ = 13 Hz, *C*HCH$_3$), 43.33 (NH*C*H$_2$Ph), 65.41 ($C_5H_3$ *C*H), 67.81 ($C_5H_3$ *C*H), 69.13 (d, $J_{P,C}$ = 6 Hz, $C_5H_3$ *C*H), 70.04 ($C_5H_5$), 75.65 ($C_5H_3$ *C*-CONH), 95.06 (d, $^2J_{P,C}$ = 18 Hz, $C_5H_3$ *C*-CH), 127.30 (d, $^3J_{P,C}$ = 6 Hz, PPh$_2$ *C*H$_m$), 127.30 (CH$_2$Ph *C*H$_p$), 127.68 (br. s, PPh$_2$ *C*H$_p$), 127.69 (CH$_2$Ph *C*H$_o$), 128.33 (d, $^3J_{P,C}$ = 6 Hz, PPh$_2$ *C*H$_m$), 128.60 (CH$_2$Ph *C*H$_m$), 129.14 (br. s, PPh$_2$ *C*H$_p$), 133.50 (d, $^2J_{P,C}$ = 18 Hz, PPh$_2$ *C*H$_o$), 134.45 (d, $^2J_{P,C}$ = 20 Hz, PPh$_2$ *C*H$_o$), 138.72 (CH$_2$Ph $C_{ipso}$), 170.11 (*C*ONH) ppm; (PPh$_2$ $C_{ipso}$) signals not observed. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 10.3 (s) ppm. **(η$^3$-Allyl)palladium Complexes with 6. An in situ NMR Study:** Amide **6** (11 mg, 0.02 mmol) was added to a solution of [{Pd(μ-Cl)(η$^3$-$C_3H_5$)}$_2$] (3.7 mg, 0.01 mmol) in $CDCl_3$ (1 mL). The mixture was stirred in the dark for 1 h, then filtered through a PTFE syringe filter (0.45 μm) and the filtrate used directly for NMR measurements. The sample used for IR measurements was obtained by concentrating the reaction mixture under vacuum. $^1$H NMR ($CDCl_3$, 50 °C): δ = 1.83 (dd, $^3J_{P,H}$ = 18.0, $^3J_{H,H}$ = 7.2 Hz, 3 H, CHC$H_3$), 4.00 (dd, $^2J_{H,H}$ = 14.8, $^3J_{H,H}$ = 4.9 Hz, 1 H, C$H_2$Ph), 4.16 (s, 5 H, $C_5H_5$), 4.21 (m, 1 H, $C_5H_3$), 4.31 (m, 1 H, $C_5H_3$), 4.46 (dd, $^2J_{H,H}$ = 14.8, $^3J_{H,H}$ = 6.6 Hz, 1 H, C$H_2$Ph), 5.01 (dq, $^3J_{H,H} \approx {}^2J_{P,H} \approx 7$ Hz, 1 H, C*H*CH$_3$), 5.47 (br. t, $^3J_{H,H} \approx 6$ Hz, 1 H, N*H*), 7.06–7.94 (m, 15 H, P*Ph*$_2$ and CH$_2$*Ph*) ppm; the remaining three signals of the allyl moiety and one $C_5H_3$ resonance are observed as broad bands between δ = 2.1 and 3.1 ppm and at δ ≈ 4.93 and 5.40 ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$, 50 °C): δ = 35.3 (s) ppm. IR (Nujol): ν̃ = 3314 (m br.), 1639 (s), 1522 (s), 1302 (m), 1266 (m), 1234 (m), 1104 (m), 1099 (m), 1003 (m), 821 (m), 746 (m), 697 (vs), 609 (m), 514 (m), 482 (s), 460 (m) cm$^{-1}$. MS (ESI+): *m*/*z* = 678 [M – Cl]$^+$; the isotopic envelope agrees with the calculated one.

**Preparation of (*SP*-4-2)-{(*R*,$R_p$)-*N*-Benzyl-2-[1-(diphenylphosphanyl)ethyl]ferrocenecarboxamido-κ$^2$*O*,*P*}chloro(methyl)palladium(II) (13):** A solution of amide **6** (64 mg, 0.12 mmol) in dichloromethane (5 mL) was added to a solution of [PdCl(Me)(cod)] (33 mg, 0.12 mmol) in the same solvent (5 mL) and the mixture was stirred in the dark for 20 h. The reaction solution was then filtered through a PTFE syringe filter (0.45 μm). The product crystallised upon diffusion of diethyl ether to afford **12** as an orange crystalline solid, which was filtered off and dried in vacuo. Yield: 60 mg (70%). $^1$H NMR ($CDCl_3$): δ = 0.60 (d, $^3J_{P,H}$ = 2.8 Hz, 3 H, PdC$H_3$), 1.41 (dd, $^3J_{P,H}$ = 11.5, $^3J_{H,H}$ = 7.2 Hz, 3 H, CHC$H_3$), 3.43 (m, 1 H, $C_5H_3$), 4.04 (s, 5 H, $C_5H_5$), 4.05 (m, 1 H, $C_5H_3$), 4.16 (dq, $^3J_{H,H} \approx {}^2J_{P,H} \approx 7.5$ Hz, 1 H, C*H*CH$_3$), 4.68 (dd, $^2J_{H,H}$ = 14.4, $^3J_{H,H}$ = 5.1 Hz, 1 H, C$H_2$Ph), 4.99 (m, 1 H, $C_5H_3$), 5.14 (dd, $^2J_{H,H}$ = 14.4, $^3J_{H,H}$ = 6.5 Hz, 1 H, C$H_2$Ph), 7.15 (br. t, $^3J_{H,H} \approx 6$ Hz, 1 H,

C 57.58, H 4.83, N 2.04; found C 57.27, H 4.62, N 1.95.

**Catalytic Experiments. Rhodium-Catalysed Hydrogenation:** Hydrogenation of methyl (*Z*)-acetamidocinnamate was performed as described in ref.[34] using [Rh(cod)$_2$]BF$_4$ or [{(μ-Cl)Rh(cod)}$_2$] as the metal source and **1**, **6**, (*R*)-**7** and (*S*)-**7** as the ligands. However, no reaction occurred even after 1 d. Racemic *N*,*N*-dimethyl{[2-(diphenylphosphanyl)ferrocenyl]methyl}amine[35] utilized as the ligand in a parallel run showed 80% conversion under otherwise identical conditions.

**Allylic Substitution. General Procedure:**[36] Ligand (25 μmol) and [{Pd($\eta^3$-C$_3$H$_5$)Cl}$_2$] (4.8 mg, 13 μmol) were dissolved in dry dichloromethane (3 mL). The solution was stirred at room temperature for 10 min and then added to a mixture of *rac*-1,3-diphenyl-2-propenyl acetate (126 mg, 0.5 mmol), potassium acetate (5 mg, 0.05 mmol) and dichloromethane (3 mL). After stirring for another 5 min, *N*,*O*-bis(trimethylsily)acetamide (BSA; 0.37 mL, 1.5 mmol), and dimethyl malonate (0.17 mL, 1.5 mmol) were added successively and the reaction mixture was stirred at room temperature for 20 h. The reaction solution was then washed with saturated aqueous $NH_4Cl$ solution (2 × 5 mL), the organic layer was dried with $MgSO_4$ and the solvents were evaporated in vacuo. Purification by column chromatography (silica gel, hexane/ethyl acetate, 3:1) afforded the product mixture (in the case of an incomplete conversion, mixtures with the starting allyl acetate were collected). Enantiomeric excesses were determined from $^1$H NMR spectra recorded in $C_6D_6$ in the presence of chiral lanthanide shift reagent tris(3-trifluoroacetyl-*d*-camphorato)europium(III), Eu(facam)$_3$, while the configuration of the major component was assigned on the basis of optical rotation of the mixture.[37]

**X-ray Crystallography:** Crystals suitable for single-crystal X-ray diffraction analysis were selected directly from the reaction batch (**2**: orange prism, 0.13 × 0.20 × 0.28 mm) or grown by recrystallisation from hot hexane (**3**: yellow prism, 0.09 × 0.13 × 0.28 mm), ethyl acetate/hexane (**9**: dark red prism, 0.13 × 0.20 × 0.33 mm; **11**: yellow plate, 0.08 × 0.15 × 0.38 mm), or chloroform/diethyl ether (**13**: orange prism, 0.10 × 0.13 × 0.25 mm). X-ray quality crystals of phosphane oxides **5** and (*R*)-**8** formed during prolonged recrystallisation of the respective phosphanes from ethyl acetate/hexane (**5**: orange block, 0.18 × 0.25 × 0.35 mm; (*R*)-**8**: red-brown block, 0.08 × 0.25 × 0.45 mm). Full-set diffraction data ($\pm h \pm k \pm l$; $2\theta \leq 55°$ for **2**, **3**, **9**, **11**, and **13**; $2\theta \leq 54°$ for **5**) were collected with a Nonius KappaCCD diffractometer equipped with a Cryostream Cooler (Oxford Cryosystems) at 150(2) K using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and analysed with the HKL program package.[38] When appropriate, the data were corrected for absorption by using the Gaussian absorption correction incorporated in the diffractometer software; the transmission factor ranges are given in Table 7. The structures were solved by direct methods (SIR97[39]) and refined by weighted full-matrix least-squares procedure on $F^2$ (SHELXL97[40]). All non-hydrogen atoms were refined with anisotropic thermal motion parameters, whilst the hydrogen atoms were included in their calculated positions and refined as riding atoms with $U_{iso}$(H) assigned to a multiple of $U_{eq}$ of their bonding atom. Selected crystallographic data are given in

# Synthesis, Structure, and Reactivity of Cerium(IV) Calix[4]arene Complexes

Jochen Gottfriedsen,*[a] Reimo Hagner,[a] Marlies Spoida,[a] and Yuri Suchorski[a]

**Keywords:** Cerium / Calixarenes / Photoelectron spectroscopy

The equimolar reaction of $Ce(hfac)_4$ (**1**) (hfac = 1,1,1,5,5,5-hexafluoropentanedionato) with *p*-*t*Bu-calix[4](OMe)$_2$(OH)$_2$ in toluene gave the new cerium(IV) calix[4]arene complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(hfac)$_2$ (**2**). The single-crystal X-ray structure shows the cone geometry of the calixarene ligand with the methoxy groups coordinated to the cerium; it shows slightly longer cerium–oxygen (acetylacetonate ligand) bond lengths than the corresponding bonds in the analogous nonfluorinated complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(acac)$_2$ (**3**). The bromination reaction of **3** gave the bisbrominated complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(Br-acac)$_2$ (**4**). $^1$H NMR spectroscopic studies and a single-crystal X-ray structure of **4** revealed that the bromination took place in the 3-position of the acac ligand. Furthermore, the first X-ray photoelectron spectroscopy (XPS) evaluation of the Ce oxidation state in cerium calix[4]arene complexes **2** and **3** is presented, and X-ray induced changes of $Ce_{ox}$ in these complexes are detected.

## Introduction

The coordination chemistry of cerium in the oxidation state +4 is dominated by its alkoxy and β-diketonate complexes. β-Diketonate complexes of cerium(IV) are well established as precursors in MOCVD (metal organic chemical vapor deposition) or ALE (atomic layer epitaxy) processes. The deposition of $CeO_2$ films as buffer layers for YBCO high temperature super conductor devices[1] were studied, and doped $Ce_{1-x}M_xO_{2-y}$ (M = Sm, Y, Gd) materials, which exhibit high oxygen ion conductivity, have been presented. These compounds are considered to be promising materials for solid oxide fuel cells, oxygen pumps, and methane conversion reactors.[2] Furthermore, the application of $Ce(tmhd)_4$ (tmhdH = 2,2,6,6-tetramethyl-3,5-heptanedione) as a dopant in SrS and $CaGa_2S_4$ thin films has been examined owing to the fact that cerium doping in these materials can produce blue–green and blue electroluminescent (EL) phosphors.[3] In addition to the studies on $Ce(tmhd)_4$,[1b,4] the suitabilities of the following other volatile β-diketonate complexes were investigated: $Ce(fdh)_4$ (fdhH = 6,6,6-trifluoro-2,2-dimethyl-3,5-hexanedione),[5] $Ce(fod)_4$ (fodH = 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctane-4,6-dione),[6] $Ce(tmod)_4$ (tmodH = 2,2,7-trimethyl-3,5-octanedione),[7] and $Ce(txhd)_4$ (txhdH = 2,2,6-trimethyl-3,6-heptanedione).[7]

The high synthetic potential of $Ce^{IV}$ β-diketonate complexes remains largely unexplored. Recently, literature reports indicated the synthesis of double-decker tetrapyrrole cerium complexes starting from $Ce(acac)_3(H_2O)_n$,[8] and our group reported the synthesis of {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(acac)$_2$ (**3**) from $Ce(acac)_4$.[9] A variety of methods have been used to study the valency of Ce in cerium complexes. Theoretical calculations[10] and XANES (X-ray absorption near-edge spectroscopy)[11] experiments, as well as studies of their magnetic properties,[11b] have been used to study the oxidation states of cerium COT (COT = cyclooctatetraenyl) and substituted COT complexes in detail,[12] which led to the conclusion that cerium is trivalent in these complexes. XANES studies of a series of double-decker tetrapyrrole cerium complexes[8a] also suggest partial delocalization of the ligand π electrons into a cerium 4f orbital, which results in a valency of 3.59 to 3.68. The XPS data of [Ce(Pc)$_2$] (Pc = phthalocyaninate) complexes revealed a valency that is neither tri- nor tetravalent, but a mixed valent state of them.[13] Calix[4]arene ligand systems are widely used to form complexes with almost all metal ions.[14] Complexes with cerium are still rare and mainly focused on $Ce^{III}$ {e.g. cerium(III) calix[4]arene complexes [Ce(LH$_{-2}$)(MeOH)$_2$A]HA (L = 5,11,17,23-tetra-*tert*-butyl-25,27-bis(diethylcarbamoylmethoxy)-26,28-dihydroxycalix[4]arene, HA = picric acid)[15] and Ce(H$_2$O)$_5$(*p*-sulfonatocalix[4]arene + H$^+$)}.[16] Studies of the coordination behavior of *p*-*tert*-butylcalix[*n*]arene (*n* = 4–6) with tetravalent cerium in solution have also been performed.[17]

Here we present the synthesis of novel calix[4]arene complexes of $Ce^{IV}$ using two different synthetic approaches. In addition to the synthesis starting from a homoleptic cerium β-diketonato complex, the reaction of {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$Ce(acac)$_2$} (**3**) with $Br_2$ will be described to demonstrate its high synthetic potential in this class of cerium

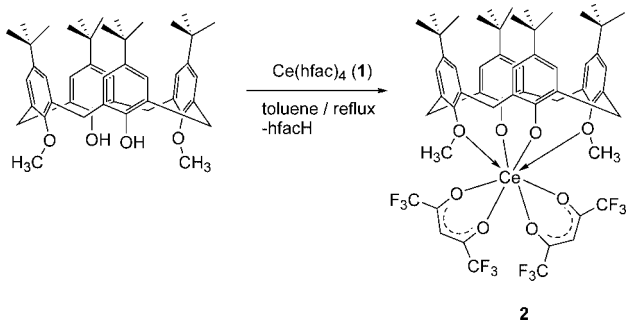
complexes. In addition to the standard characterization methods, NMR spectroscopy, MS, and single-crystal X-ray determination studies, we performed XPS experiments for two of the cerium calix[4]arene complexes to obtain the effective oxidation state of Ce in these complexes.

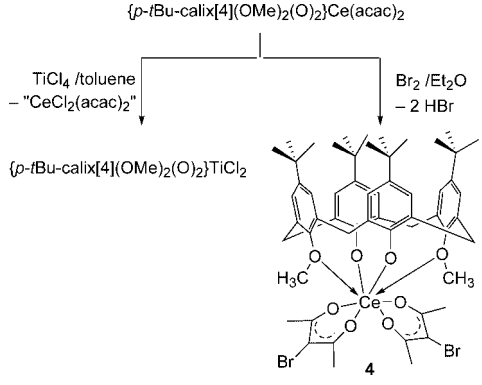
## Results and Discussion

The equimolar reaction of $Ce(hfac)_4$ (**1**) (hfac = 1,1,1,5,5,5-hexafluoropentanedionato) with *p*-*t*Bu-calix[4](OMe)$_2$(OH)$_2$ in boiling toluene gave an immediate color change upon reaching the boiling point. After workup, the new cerium(IV) calix[4]arene complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(hfac)$_2$ (**2**) could be isolated as blue crystalline blocks (Scheme 1). Complex **2** is highly soluble in nonpolar organic solvents such as hexane, pentane, and toluene as well as in the polar solvents diethyl ether, THF, dichloromethane, and chloroform.



Scheme 1. Synthesis of **2**.

The reaction of the corresponding nonfluorinated Ce calix[4]arene complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(acac)$_2$ (**3**) with bromine in a 1:2 ratio in diethyl ether resulted in bromination of the acac ligand in the 3-position with formation of the bisbrominated complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(Br-acac)$_2$ (**4**) (Br-acac = 3-bromo-pentanedionato) (Scheme 2).



Scheme 2. Reactivity of **3** towards $Br_2$ and $TiCl_4$.

The reaction of **3** with bromine in a 1:1 ratio produced a monobrominated species which was detected by $^1$H NMR spectroscopy but not isolated or further studied. Complex **4** exhibits the same solubility as that of **2** and the same blue color. The bromination of $Ce(acac)_4$ was described previously[18] by using NBS (*N*-bromosuccinimide) to yield $Ce(Br\text{-}acac)_4$. A ligand transfer to $TiCl_4$ was investigated to further elucidate the reactivity of complex **3**. Red crystals were obtained after crystallization from toluene, which where characterized by NMR spectroscopy and shown to be the known titanium complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}$TiCl_2$.[19] $^1$H and $^{13}$C NMR spectroscopic studies revealed the typical cone geometry of the calix[4]arene ligands for both complexes **2** and **4** in benzene solution. The $^1$H NMR (Table 1) spectroscopic data show that the chemical shifts of the calix[4]arene ligand of brominated complex **4** are basically identical with those of starting material **3**, whereas the chemical shifts of **2** are significantly different, which is due to the electron-withdrawing fluorine substituents. The resonances of the methoxy group of complexes **2**, **3**, and **4** show the highest change in their chemical shifts compared with the corresponding ones of the free calix[4]arene ligand. Resonances of the methoxy group in all three complexes are shifted downfield by nearly 1.5 ppm for **2**, 1.25 ppm for **3**, and approximately 1 ppm for **4** relative to the chemical shift of the free ligand ($\delta$ =3.47 ppm). This is due to the electron-withdrawing fluorine atoms that induce a decrease in the electron density on the cerium atom, which is compensated by the coordinated methoxy group thus deshielding the $CH_3$ group. Doublets at 5.11 and 3.27 ppm for **2** and 5.04 and 3.35 ppm for **4** in the $^1$H NMR spectra are attributable to the *endo* and *exo* protons of the $CH_2$ bridges of the calix[4]arene ligand. Whereas the chemical shifts of the *endo* protons are shifted downfield (nearly 0.7 ppm for **2** and 0.6 ppm for **4**) relative to the free calix[4]arene ligand, the resonances for the *exo* protons are not influenced by coordination to the cerium center. Two sets of signals for the aromatic hydrogens and the substituted tertiary butyl groups were found for each new complex, **2** and **4**, by assigning the two different ring systems of the calix[4]arene ligands (Table 1). The $^{13}$C NMR spectra also show the two unequally substituted phenyl groups of the calixarene ligand in **2** and **4**. The different coordinationenvironments that are adopted by **1** (–76.51 ppm), **2** (–75.93 ppm), and 1,1,1,5,5,5-hexafluoropentanedione (–77.40 ppm) are made apparent in their $^{19}$F NMR spectra,

which shows a small influence of the $CF_3$ groups on the chemical shift for this β-diketone. Mass spectrometric data of complexes **2** and **4** show the molecular ions as the signals with the highest mass. The signals with the highest abundance can be interpreted as the molecular ions reduced by the mass of the corresponding β-diketonate.

### X-ray Structure Determinations

A single-crystal X-ray structure determination of the starting material $Ce(hfac)_4$ (**1**), which crystallized from toluene as dark brown crystals, was carried out. The molecular structure exhibits an eight-coordinate cerium in a distorted square antiprismatic coordination sphere (Figure 1).

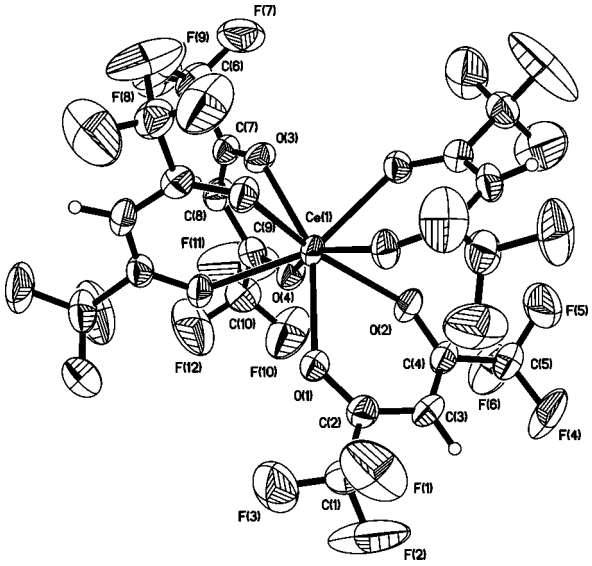

Figure 1. ORTEP plot of the molecular structure of **1**. Thermal ellipsoids are drawn with 50% probability. Hydrogen atoms are omitted for clarity.

The Ce–O bond lengths of the O,O′-bidentate hexafluoropentanedionato ligands range from 2.325(3) to 2.346(3) Å, which is in good agreement with similar distances found for cerium acetylacetonato complexes {e.g. α-$Ce(acac)_4$,[20a,20b] β-$Ce(acac)_4$,[20c] and $[Ce(acac)_4]\cdot 10H_2O$[21]}, which have a mean distance of 2.32 Å. Other cerium β-diketonato complexes display Ce–O distances between 2.24 Å and 2.36 Å [e.g. $Ce(fda)_4$, $Ce(tmhd)_4$, $Ce(txhd)_4$, and $Ce(tmod)_4$].

{*p*-*t*Bu-calix[4]$(OMe)_2(O)_2$}$Ce(hfac)_2$ (**2**) was crystallized from toluene at 5 °C and single crystals of the brominated complex {*p*-*t*Bu-calix[4]$(OMe)_2(O)_2$}$Ce(Br\text{-}acac)_2$ (**4**) were obtained from $CH_2Cl_2$ at 5 °C. The single-crystal X-ray structures of both complexes showed the typical cone geometry of the calixarene ligand with the methoxy groups coordinated to the cerium, which gave an eight coordinate cerium center with square antiprismatic coordination spheres (Figures 2 and 3).

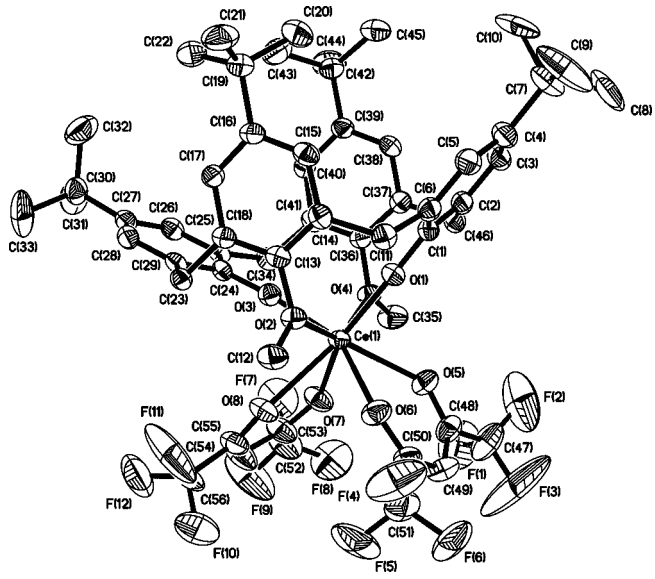

Figure 2. ORTEP plot of the molecular structure of **2**. Thermal ellipsoids are drawn with 50% probability. Hydrogen atoms are omitted for clarity.

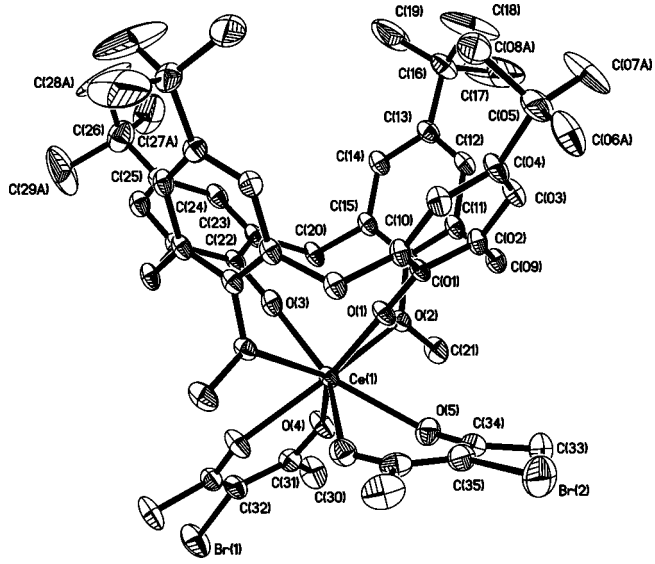

Figure 3. ORTEP plot of the molecular structure of **4**. Thermal ellipsoids are drawn with 50% probability. Hydrogen atoms are omitted for clarity.

The Ce–O phenoxy bond lengths in **2** [2.069(3)/2.089(3) Å] are slightly shorter than the corresponding distances in **4** [2.111(4)/2.134(5) Å], which are equal to the ones found for {*p*-*t*Bu-calix[4]$(OMe)_2(O)_2$}$Ce(acac)_2$ (**3**) (2.130 Å average)[9] (Table 2). They are in the same range as those in other cerium alkoxides {e.g. the hexafluoroisopropoxide (hfip) adducts $Ce(hfip)_4(TMEDA)$ and $Ce(hfip)_4$(diglyme) (2.13 Å average)M,[22] the terminal Ce–OR alkoxide groups in $Ce_2(O\text{i}Pr)_8(\text{i}PrOH)_2$ (2.088 Å average),[23] $Ce(O\text{t}Bu)_2(NO_3)_2(HO\text{t}Bu)_2$ (2.088 Å average),[24] and $Ce(O\text{t}Bu)_2(\mu\text{-}O\text{t}Bu)_2(\mu_3\text{-}O\text{t}Bu)_2Na_2(dme)_2$ [2.136–2.146 Å for the terminal (O*t*Bu) ligands]},[24] although they are longer than those observed for $Cp_3Ce^{IV}(O\text{t}Bu)$ (2.045 Å).[24] The

[a] Atoms that are generated by using the symmetry transformation $-x + 1, y, -z + 1$ (**1**), and $x, -y, z$ (**4**), respectively.

Ce–O bond lengths for the two coordinated methoxy groups Ce(1)–O(2) and Ce(1)–O(4) in **2** [2.560(3)/2.577(3) Å] and Ce(1)–O(2) and Ce(1)–O(2)# in **4** [2.581(3) Å] are in the typical range of Ce–O coordination bonds[22] and fit well with the corresponding bonds in {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(acac)$_2$ (**3**) (2.604 Å average).[9] The Ce–O distances of the O,O′-bidentate hexafluoropentanedionato ligands in **2** range from 2.408(3) to 2.461(3) Å and are thus slightly longer than the distances found for starting material **1** [2.325(3) to 2.346(3) Å] and the Ce–O bonds of the two O,O′-bidentate acetylacetonate ligands in the analogous nonfluorinated complex {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(acac)$_2$ (**3**) (2.338 to 2.371 Å).[9] The corresponding Ce–O distances of the O,O′-bidentate 3-bromo-2,4-pentanedionato ligands to cerium in **4** [2.365(3) and 2.372(3) Å] match well with the ones of complex **3**. The Ce–O (β-diketonato) lengths of complexes **2** and **4** are only slightly longer than the Ce–O lengths found for the homoleptic cerium β-diketonate complexes. However, they are in good agreement with these lengths {e.g. α-Ce(acac)$_4$,[20a,20b] β-Ce(acac)$_4$,[20c] and [Ce(acac)$_4$](H$_2$O)$_{10}$,[21] with a mean distance of 2.32 Å, as well as Ce(fda)$_4$, Ce(tmhd)$_4$, Ce(txhd)$_4$, and Ce(tmod)$_4$, which exhibit Ce–O distances between 2.24 Å and 2.36 Å}.

The four donor atoms of the calixarene in **2**, **3**, and **4** define a mean O$_4$ plane with a rms deviation of 0.2464 Å in **2**, 0.2549 Å in **3**, and 0.2774 Å in **4** and the cerium atom is located at 1.0607(14) Å from this mean plane in **2**, 1.1641(10) Å in **3**, and 1.1686(20) Å in **4**. The macrocycles in new complexes **2** and **4**, as well as in **3**,[9] are in a distorted cone conformation, with dihedral angles between the four aromatic rings and the O$_4$ plane of 39.50(16), 89.50(11), 34.66(8), and 83.31(11)° in **2** [46.16(24), 71.72(9), 37.45(13), and 72.02(11)° in **4**]. The dihedral angles of the cone in **2** are similar to the ones in **3** [38.09(7), 83.86(7), 36.90(13), and 84.02(7)°], and to those found in [UCl$_2$(Me$_2$-calix)(THF)$_2$], [UCl$_2$(Me$_2$calix)(py)$_2$], and [U(acac)$_2$(Me$_2$calix)(THF)$_2$].[25] The slightly different values of the homologous angles in **4** might be due to crystal packing effects.

## XPS Studies

High-resolution XPS spectra of complexes **2** and **3** were obtained by using monochromatic X-ray excitation. From

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

this spectra we determined the effective oxidation state of Ce (in the sense of an effective charge state of the Ce atoms in the ground state of the solid), $Ce_{ox}$. The $Ce_{ox}$ value does not necessary represent the integral "formal valence" of Ce (in compounds with largely covalent character the formal valence does not approximate the actual ionic charge), but it reflects objectively the electronic structure of the studied materials. The direct use of established techniques, such as the commonly used deconvolution of high-resolution XPS spectra to evaluate the $Ce_{ox}$ in coordination complexes, is still difficult despite a great effort devoted to the electronic structure of ceria and similar compounds. The main uncertainties are associated with the complex features in the Ce3d XPS-spectra and result from the variable occupancy of the Ce4f level, redistribution of the levels as a result of the core hole creation, and changed hybridization at different oxidation states.[26] Therefore, the interpretation of the spectra is not always unambiguous and can even be contradictory. In addition, artifacts created merely by the X-ray exposure have to be considered.[27] In the present work we evaluated $Ce_{ox}$ in **2** and **3** by correlation of the XPS data for the studied samples with those of reference samples with a known oxidation state.

Ar-sputtered $CeO_2$ was used as the reference sample where the preferential release of oxygen atoms in the surface region, as a result of the impact of $Ar^+$ ions in ultrahigh vacuum (UHV), allows the creation of $Ce_xO_y$ oxides in the top surface layers with continuously variable artificial $Ce_{ox}$ in the range from 4 to 3.4. The details of the $Ce_{ox}$ evaluation are published elsewhere.[28] A similar method was recently applied by us for the determination of the oxidation state of vanadium in vanadium oxide and vanadium/phosphate oxide catalysts.[29] The measurements of samples of both the studied complexes revealed an X-ray induced "photoreduction", an effect in principle known (but not entirely understood) for some rare earth containing materials such as, for example, $Sm^{3+}$-doped fluoroaluminate glasses[30] or for the pure $CeO_2$.[31] Thorough long-time studies of the X-ray-induced evolution of the $Ce_{ox}$ revealed its exponential decay with increasing irradiation time (from 3.60 to 3.28 for **2** and from 3.62 to 3.27 for **3**) (Figure 4), where the extrapolation to "zero irradiation" (zero exposure) allows the determination of the initial oxidation state in the freshly synthesized complexes (3.61 for **2** and 3.65 for **3**). It has to be noted that in contrast to vanadium-containing oxide compounds, no UHV-induced modification of the cerium oxidation state was observed in the present study, that is, the observed effect is a pure X-ray-induced "photoreduction". The X-ray modified $Ce_{ox}$ of cerium remained also stable after exposure to air at room temperature. Concerning the interpretation of the observed "photoreduction", we noted that the local irradiation-induced heating, proposed as a reduction mechanism for ceria,[31] cannot explain our observation as no significant increase in the surface temperature was observed. Apparently, alternative mechanisms such as the electron-hole pair formation and Auger decay have to be taken into account.[32] Another possible mechanism, associated with an impact of the numerous low-energy electrons,[33] which could cause desorption due to their large cross-section seems to be less probable, as was proven by low-energy electron bombardment from an external electron gun. Furthermore, a possible reason for the decrease in $Ce_{ox}$ might be due to decomposition processes that are induced by the X-ray radiation, which leads to the formation of a mixture of cerium centers in the oxidation state 3 and 4. It should also be noted that the attenuation length of the Al $K_\alpha$ photons exceeds the XPS information depth of ≈ 2.5 nm, by at least three orders of magnitude, in the present case. Therefore, the irradiation-caused changes in the Ce oxidation state may extend to a significant depth.

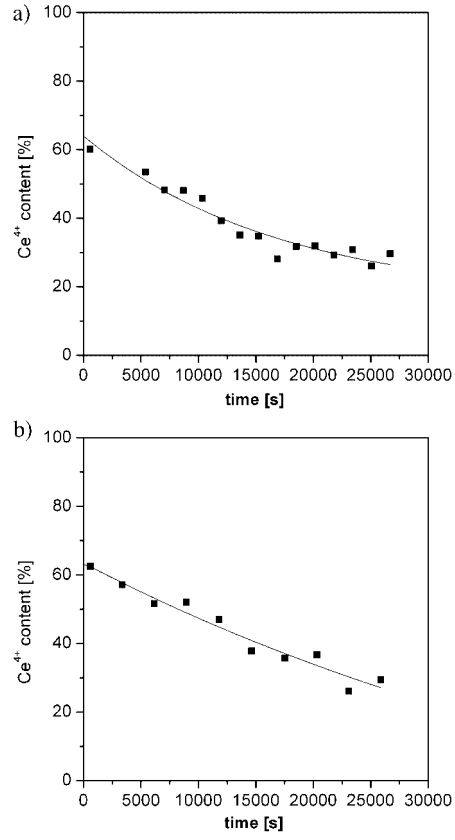

Figure 4. Dependencies of the $Ce^{4+}$ content for **2** and **3**, respectively, on the X-ray exposure. Extrapolation to "zero irradiation" provides the initial values of $Ce_{ox}$.

## Conclusions

Two novel cerium calix[4]arene complexes could be synthesized by using two different synthetic approaches. {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(hfac)$_2$ (**2**) was generated starting from a homoleptic cerium β-diketonato complex Ce(hfac)$_4$ (**1**). However, {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(Br-acac)$_2$ (**4**) was obtained from the reaction of {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(acac)$_2$ (**3**) with $Br_2$; thus, the high synthetic potential of this class of cerium complexes was demonstrated. Furthermore, we detected X-ray-induced changes in the effective Ce oxidation state in cerium calix-

[4]arene complexes **2** and **3**, and performed the first evaluation of $Ce_{ox}$ in these complexes.

## Experimental Section

**General:** All reactions were carried out under an inert atmosphere of dry nitrogen by using standard dry box and Schlenk techniques. Melting points were determined in a sealed capillary without correction. NMR spectra were recorded with a Bruker DPX 400 or AVANCE 600 NMR spectrometer. Chemical shifts (all reported in ppm) are referenced to tetramethylsilane as internal standard. Chemical shifts of the $^{13}C$ NMR were assigned to the corresponding carbons by using HSQC, HMBC, and NOSY techniques. In turn, chemical shifts of the $^{19}F$ NMR spectra are referenced to trifluorotoluene as external standard. The single-crystal X-ray diffraction studies were performed with a Bruker CCD SMART (**2**, **4**) or Stoe IPDS (**1**) diffractometer. Crystal data are given in Table 3. The structures were solved by Patterson methods (SHELXS-97).[34] Refinements were carried out by using full-matrix least-squares techniques on $F^2$ with the SHELXL-97 program.[35] CCDC-624482 (for **1**), -616674 (for **2**), and -624481 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Mass spectra (EI, 70 eV) were obtained with a Finnigan SSQ 7000 or a Finnigan MAT 95 (70 eV). Only characteristic fragments containing the isotopes of the highest abundance are listed. The starting materials *p*-*t*Bu-calix[4](OMe)$_2$(OH)$_2$[36] and {*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(acac)$_2$[9] were produced according to a published procedure. Ce(hfac)$_4$ was synthesized by using a slightly modified procedure.[37] Elemental analyses were performed with a LECO CHNS932 apparatus. Hexafluoroacetylacetone and $(NH_4)_4[Ce(SO_4)_4]\cdot 2H_2O$ were purchased from Aldrich Chemical Co. and used as received. X-ray photoelectron spectra were obtained from the dry powders of **2** and **3**, which were carefully grinded and fixed on Mo sample-carrier plates under an argon atmosphere in a glove box and transferred inertly to the multipurpose UHV surface analysis apparatus (SPECS, Germany) where the XPS analyses were performed. To avoid the vacuum-induced reduction of the samples, a "fast transfer" XPS mode[29] was used: the SPECS load-lock and transfer systems allows sample-transfer times of less than 5 min between the start of the evacuation of the load lock and the first XPS spectrum at a pressure better than $5\times10^{-9}$ mbar. The monochromatic X-ray source (FOCUS-500, SPECS, excitation energy 1253.74 eV, Al-$K_\alpha$, linewidth after monochromatization $<$ 0.3 eV) was used. High-resolution spectra (pass energy 10 eV, step size 0.1–0.2 eV) were recorded at room temperature with a hemispherical energy analyzer (PHOIBOS-150, SPECS), which provides the possibility of simultaneous photo-electron detection on nine channels, and allows fast data acquisition times (0.5 s per data point) with a satisfactory signal-to-noise ratio.

**Ce(hfac)$_4$ (1):** $(NH_4)_4[Ce(SO_4)_4]\cdot 2H_2O$ (3.8 g, 6 mmol) in $H_2O$ (200 mL) and 1,1,1,5,5,5-hexafluoro-2,4-pentanedione (5.0 g, 24 mmol) in toluene (100 mL) were mixed and stirred for 15 min, which resulted in a fast color change in the organic layer to dark brown. The two phases were separated, and toluene was removed under vacuum to leave a brown solid that was recrystallized from dry toluene (15 mL) to yield dark brown crystal blocks in 35% yield (2.03 g). $^1H$ NMR (400 MHz, $C_6D_6$, 25 °C): $\delta$ = 6.05 (s, 4 H, C*H*) ppm. $^{19}F$ NMR (376.5 MHz, $C_6D_6$, 25 °C): $\delta$ = –76.51 ppm. UV/Vis (250–800 nm, $CHCl_3$): $\lambda$ = 275.6 nm.

**{*p*-*t*Bu-calix[4](OMe)$_2$(O)$_2$}Ce(hfac)$_2$ (2):** Ce(hfac)$_4$ (1.0 g, 1.03 mmol) and *p*-*t*Bu-calix[4](OMe)$_2$(OH)$_2$ (0.7 g, 1.03 mmol) were dissolved in toluene (50 mL), stirred at reflux temperature for 2 h, and another 12 h at room temperature. The reaction mixture was dried under vacuum ($10^{-2}$ mbar) at 40 °C, and the resulting

# Synthesis and Structures of Two New Types of Boronium Salts[‡]

Ulrike Braun[a] and Heinrich Nöth*[a]

**Keywords:** Boronium Cations / Transamination / X-ray structures

Transamination of di(pyrid-2-yl)amine (**1**) with $B(NMe_2)_3$ leads to the isomeric heterocyclic bis(dimethylamino)boryl compound **4** and not to bis(dimethylamino)di(pyrid-2-yl)aminoborane (**2**). $B(NMe_2)_3$ reacts with aniline (1:2 ratio) to yield a 1:1 mixture of $B(NHPh)_3$ and $(Me_2N)_2BNHPh$. Transamination of this mixture with **1** yields the anilinodimethylamino analogue of **4** (compound **7**). Compound **4** reacts with $CHCl_3$ to generate the boronium salt **5** by the abstraction of HCl from $CHCl_3$ and addition of HCl to one of the dimethylamino groups. Compound **5** crystallizes with 4 molecules of $CHCl_3$. Compound **4** is attacked by $AlCl_3$ in toluene to give a mixture of unidentified products from which the tetrachloroaluminate of a new type of spirocyclic diboronium cation, **8**, was isolated and characterized by X-ray crystallography.

## Introduction

The cationic chemistry of boron started in 1955.[1] At that time, there was a lively discussion on the structure of the so-called diammoniate of diborane $B_2H_6{\cdot}2NH_3$. Two structures were favored, $[NH_4][H_3B{-}NH_2{-}BH_3]$[1] and $[H_2B(NH_3)_2]BH_4$.[2] The classical papers by Parry and Shore[2–7] revealed that the latter structure is correct. Since then, many cations with tri- and di-coordinated boron atoms have been characterized in addition to those with tetra-coordinated boron atoms. A recent review summarizes the present status in this field.[8] The interest in gaseous cations, such as $BF_2^+$ or $BMe_2^+$, as reagents has also grown.[9] In spite of these advances, the cationic chemistry of boron, over the last decade, is still a somewhat neglected part of boron chemistry.

Here we present a study that was actually not directed towards the synthesis of new boron cations, but that resulted from reactions aimed at the preparation of aminoboranes suitable for *N*-lithiation.[10]

### Transamination of $B(NMe_2)_3$ with Di(pyrid-2-yl)amine and Formation of a New Type of Heterocyclic Boronium Salt

*N*-lithiation of tris(pyridylamino)borane leads to an interesting cluster structure.[10] For this reason, the unknown bis(phenylamino)di(pyrid-2-yl)aminoborane (**3**) appeared as a potential candidate for *N*-lithiation. We tried to achieve its synthesis in a two step reaction as shown in Equation (1). The transamination of di(pyrid-2-yl)amine (**1**) with tris(dimethylamino)borane was expected to yield bis(dimethylamino)di(pyrid-2-yl)aminoborane (**2**), which on further transamination with aniline should have given the target compound **3**.

However, the $^{11}B$ NMR spectrum definitely excludes the formation of **2**. The solution obtained shows intense yellow fluorescence and a sharp $^{11}B$ NMR signal at 5.0 ppm in its spectrum, which is typical for a tetra-coordinated boron atom. The elemental analysis corresponds with the composition expected for **2**. However, in the $^1H$ NMR spectrum, no signal for an NH proton is observed, and all NMR spectroscopic data are in accord with the structure of **4**, as shown in Equation (2). The position of attack of the boron atom of $B(NMe_2)_3$ is at one of the pyridine N atoms of **1** and not at the NH nitrogen atom, as shown in Equation (3). Elimination of $Me_2NH$ is expected to be favored because of the formation of an N–H···N hydrogen bridge bond. Rotation about the N–C bond of the non-coordinated pyridyl unit allows the formation of a six-membered ring.

The hydrogen atoms on the *o*-positions of the pyridine rings of **4** give rise to an $^1H$ NMR signal at 7.64 ppm, and the carbon atoms at the *o*-positions to a $^{13}C$ NMR signal at 138.4 ppm. These nuclei are better shielded than those in **1** (8.23 and 147.6 ppm). This can be compared with the corresponding $^1H$ and $^{13}C$ NMR signals for pyridine (8.59 and 149.8 ppm) and pyridine *N*-oxide (8.36 and 138.5 ppm), which carries, like **4**, a formal positive charge at the N atom.[11] In addition, the $^1H$ resonance for the dimethylamino groups of **4** are found at slightly higher field ($\delta$ =2.36 ppm) relative to those of $B(NMe_2)_3$ ($\delta$ =2.48 ppm). The coordination mode in compound **4** is similar to that in pyrazaboles **A**[12] or in the boron biguanidine complexes **B**.[13] The structures of pyrazaboles have been extensively investigated,[14–16] although no species is yet known in

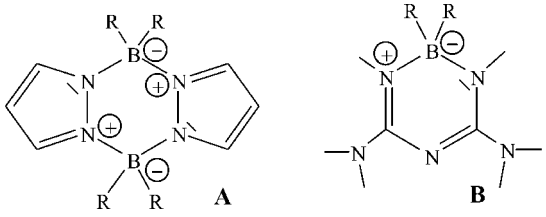
which the boron atoms of the pyrazaboles carry two exocyclic amino groups at the boron atoms; however, CNDO calculations on a *N*,*N*′-dimethylethylenediamino species have been performed.[17]



In order to prove the structure of compound **4**, we attempted to obtain single crystals of this compound; but, only polycrystalline material separated from various solvents. Single crystals, however, did form from a 1:1 mixture of chloroform and pentane at –78 °C. The X-ray structure determination of a monoclinic crystal (space group $P2_1/n$, $Z = 4$) shows that the investigated species is not compound **4**, but rather its hydrochloride. The crystals have the composition $C_{14}H_{20}BN_5 \cdot HCl \cdot 4CHCl_3$. The molecular structure of **4·HCl** (**5**) is depicted in Figure 1.

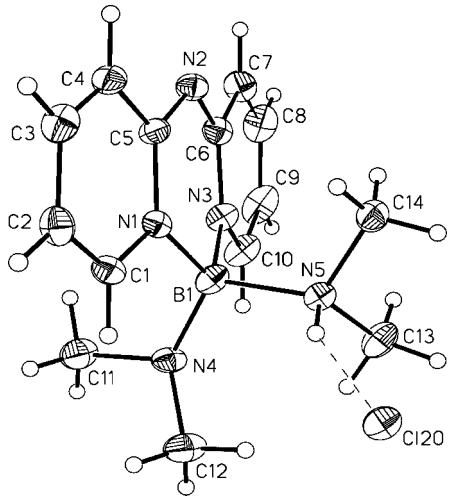


Figure 1. ORTEP plot of the molecular structure **5**. Selected bond lengths [Å]: B1–N1 1.566(8), B1–N3 1.565(8), B1–N4 1.453(9), B1–N5 1.636(8), N4–C12 1.461(7), N4–C11, 1.463(8), N5–C13 1.492(7), N5–C14 1.481(8), N5–H1 0.86 Cl20–H1 2.307. Selected bond angles [°]: C1–N1–B1 118.5(5), C5–N1–B1 122.7(5), C10–N3–B1 118.3(5), C6–N3–B1 121.7(5), C12–N4–B1 126.5(5), C11–N4–B1 117.0(5), B11–N4–C12 111.0(5), C13–N5–C14 108.0(5), C14–N5–B1 115.7(5), C13–N5–B1 114.2(5), N3–B1–N4 112.5(5), N1–B1–N4 115.6(5), N1–B1–N3 105.0(5), N4–B1–N5 110.6(5), N3–B1–N5 106.5(5), N1–B1–N5 106.1(5), N1–C5–N2 122.7(5), N2–C6–N3 123.7(5).

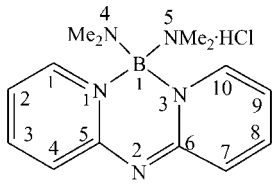

**5**

Its $N_3C_2B$ ring adopts a tub-shape conformation. Atoms C6, C5, and N1 lay almost in a plane (interplanar angle C6-C5-N1/N1-N3-C6 = 1.1°). The N3-B1-N1 plane forms an interplanar angle of 18.3° with the C6-C5-N3-N1 plane and 7.7° with the C6-N2-C5 plane. The N2 atom sits only 0.095 Å above the N3-B1-N1 plane. Therefore, it is incorporated into the π-system of the heterocycle. This is also shown by the presence of short C–N bonds. The annulated six-membered rings are bent backwards from the central ring. Their interplanar angles with the C6-C5-N3-N1 plane is 13.4°. The two endocyclic B–N bonds, B1–N1 and B1–N3, have the same lengths, while the two exocyclic B–N bonds are different [B1–N4 = 1.453(9) Å and B1–N5 = 1.636(8) Å]. The N4 atom has an almost planar environment (Σ = 354.4°), in contrast to the tetra-coordinated N5 atom with its significantly longer B–N bond. Bond angles at the tri-coordinated N4 atom range from 111.0(5) to 126.5(5)°. Similarly, bond angles at the tetra-coordinated N5 atom span from 108.0(5) to 115.7(5)°. It is obvious that

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

most of the positive charge is located at the tetra-coordinated N5 atom. Its H1 atom forms a hydrogen bond to the chloride ion as shown by the bond lengths of 0.98 Å for N5–H1 and 2.307 Å for H1···Cl20. This H···Cl distance is shorter than the NH···Cl bond in 2,2,4,4-tetramethylpiperidinium chloride [2.232(5) Å].[18] The N5–H1–Cl2 bond angle is 154.0°.

Figure 2 represents a stereoplot of the unit cell of compound **5** that shows that the chloroform molecules fill the spaces between the atoms of the boronium salt. The H atom of the chloroform molecules interact either with the chloride ions or with *p*-N atoms of the heterocycles.

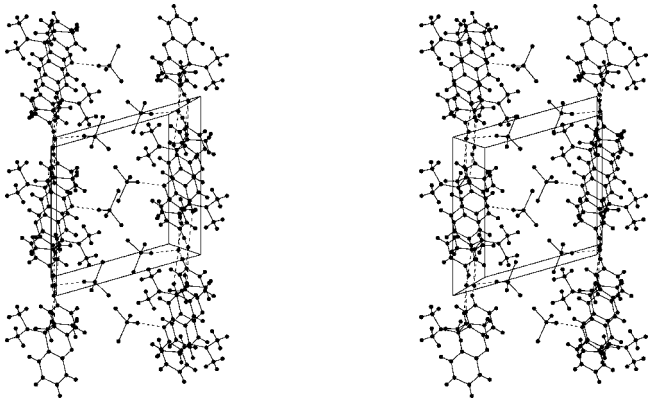

Figure 2. Stereoplot of the unit cell of compound **5**·$(CHCl_3)_4$. View down the *b* axis. The chloroform molecules are "lined" up between two strands of **5** molecules.

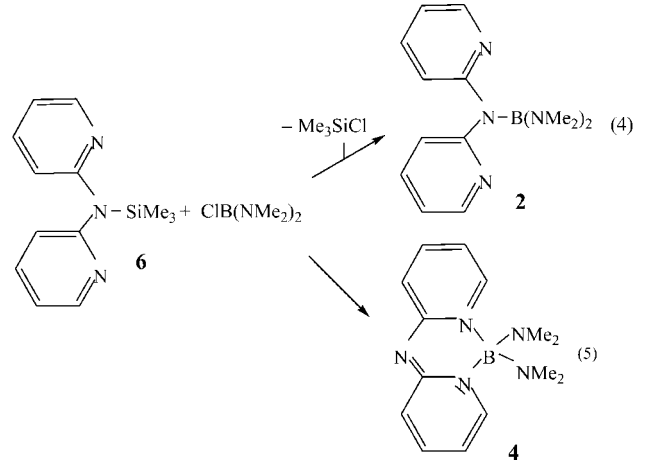
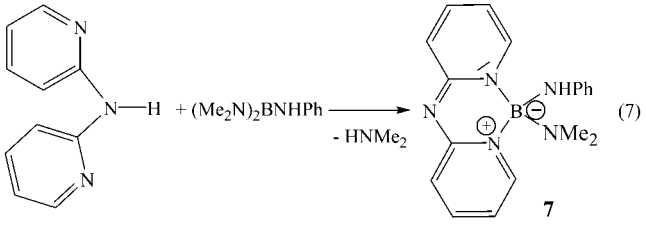
It is obvious that HCl is necessary to form **5**, and chloroform is the HCl source. It is known that strong bases can be protonated by $CHCl_3$, with subsequent removal of HCl to form dichlorocarbene as an intermediate. Compound **4** possesses a high proton affinity as was already demonstrated for the ready synthesis of the related 2,2′-dipyridylbis(dimethylamino)boronium salt.[19]

A possible alternative synthesis for compound **2** is shown in Equation (4). The components, **6** and $ClB(NMe_2)_2$, react readily with the formation of chlorotrimethylsilane, but again the product is **4** [Equation (5)]. This shows that the chlorobis(dimethylamino)borane attacks also at a pyridine nitrogen atom of **1**. Another possible route is to first synthesize dianilinodimethylaminoborane followed by transamination with **1**. However, treatment of $B(NMe_2)_3$ with 2 mol of aniline resulted in a 1:1 mixture of $B(NHPh)_3$ and $(Me_2N)_2BNHPh$ as shown in Equation (6). Two $^{11}B$ NMR signals at $\delta$ = 24.9 and 23.6 ppm of equal intensity are observed in the solution. The latter signal is assigned to $B(NHPh)_3$[10] and the former to bis(dimethylamino)organylaminoborane.[20] Treatment of the mixture of $B(NHPh)_3$ and $(Me_2N)_2BNHPh$ with **1** produced a solution with resonances in the $^{11}B$ NMR spectrum at 23.7 and 2.0 ppm ($h_{1/2}$ = 83 Hz). Obviously, $B(NHPh)_3$ remained untouched, while $(Me_2N)_2BNHPh$ reacted with the di(pyrid-2-yl)amine with elimination of $Me_2NH$ and formation of **7** [see Equation (7)]. $B(NHPh)_3$ precipitated from the concentrated solution, and it was possible to isolate compound **7** from the red-brown fluorescent filtrate. Compound **7** was characterized by NMR spectroscopy and elemental analysis.



$$2\ B(NMe_2)_3 + 4\ PhNH_2 \rightarrow (Me_2N)_2BNHPh + B(NHPh)_3 + 4\ HNMe_2 \quad (6)$$



## The Formation of a Spirocyclic Diboronium Cation as Its Tetrachloroaluminate

While the HCl adduct of **4** is a boronium salt with a tetra-coordinated boron atom, compound **4** may also be the source for a boronium cation with a tri-coordinated boron atom. The first boronium salts with tri-coordinated boron atoms were reported in 1962.[21] In this case, the pyridine adduct of $Ph_2BCl$ was treated with $AgClO_4$ to generate $(pyBPh_2)ClO_4$. It was also reported later[22] that the abstraction of a chloride ion from $Ph_2BCl$ by $AlCl_3$ would produce the di-coordinated boron cation $BPh_2^+$. But because all these reactions were performed in solvents like nitromethane or ethylmethyl ketone, it is more likely that adducts with the solvents were formed. None of these cations could be isolated as salts. Their existence was, therefore, disputed.[22,23] Today, sterically and electronically stabilized cations of boron are readily accessible.[9] In particular, suitable anion acceptors have been widely used for hydride or halide abstraction from base adducts $L{\cdot}BY_2X$ (X = H, Hal; Y = organyl, OR, $NR_2$).[24–26] Compound **4** could form a cation with a tri-coordinated boron atom because this cation should be stabilized by electron delocalization as shown in formula **C**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

To generate this cation we treated **4** with $AlCl_3$ in a 1:1 ratio in toluene. No reaction occurs at ambient temperature, but after keeping the mixture at reflux, a yellow-green precipitate and a yellow solution forms. The $^{11}B$ NMR spectrum of the solution shows an intense signal at 26.5 ppm and a very weak multiplet around 0.7 ppm. The intense signal indicates the presence of a triaminoborane[27] or a triaminoborane cation.[28] The $^{27}Al$ NMR spectrum of the solution shows signals at 68.0 and 31.9 ppm (broad) as well as a group of signals with peaks at 80.4, 92.2, and 104.4 ppm. The sharp signal at 104.4 ppm arises from $AlCl_4^-$.[29] The others are indicative of a mixture of $AlCl_{4-n}(NMe_2)_n^-$ anions. Signals in the range 80–108 ppm have been observed for these anions.[30,31] Most likely, the first anion formed is $AlCl_3NMe_2^-$, followed by redistribution of the substituents, a well-known phenomenon in the chemistry of mixed tetrahaloaluminate anions.[32]

The yellow solid that remains after evaporation of toluene from the filtrate was almost insoluble in all common solvents, and this was also observed for the precipitate. Only $CH_2Cl_2$ proved to be a suitable solvent. The spectrum of the dissolved part of the precipitate shows a $^{27}Al$ NMR signal at $\delta$ = 106.4 ppm ($h_{1/2}$ = 25 Hz), which is typical for $AlCl_4^-$, and a broad weak signal around 26.8 ppm, which is due to a hexacoordinate Al species.$^{11}B$ NMR signals were observed at 1.1 and 0.36 ppm and also at 26.5 ppm. These data show that the reaction between **4** and $AlCl_3$ is rather complex.

Fortunately, yellow single crystals could be obtained from a $CH_2Cl_2$ solution at –20 °C. They are monoclinic and crystallize in the space group $P2_1/c$ with $Z$ = 4. The X-ray structure determination shows the presence of a new kind of spiroheterocyclic molecular cation **8** containing two tetra-coordinated boron atoms and one tri-coordinated boron atom. It crystallizes as a bis(tetrachloroaluminate) with the composition [**8**][$AlCl_4$]$_2$($CH_2Cl_2$)$_2$ (Figure 3 shows the atoms in the asymmetric unit).

The central part of the molecule is a naphthalene-like $B_3N_5C_2$ ring with formal positive charges that reside preferably on the four pyridine nitrogen atoms N1, N3, N9 and N11, while the boron atoms B1 and B2 are formally negatively charged. The ring B–N bond lengths in the tricyclic rings are comparatively long and range from 1.542(7) to 1.569(7) Å. On the other hand, the B1–N5 and B2–N7 bonds are shorter (1.472 and 1.467 Å). The bonds B1–N4 and B2–N8 [1.610(8) and 1.603(8) Å] to the di(pyrid-2-yl)-amino group are much longer despite the fact that these two N atoms are tri-coordinate. By taking the B–N bond lengths as a criterion, these two bonds have to be considered as coordinative B–N bonds.

A tub-shaped conformation is observed for the central ring of the two heteroanthracene groups. The C5-N1-N3 plane is almost coplanar with the N3-C6-C5 plane (1.3°), and the interplanar angle of the C5-C6-N1-N3 plane to the N3-B1-N1 plane is 19.9°, but 29.6° to the C6-N3-C10 plane. Analogous interplanar angles between C25-C26-N9-N11 and N9-B2-N11 or C25-N11-C21 are 11.7° and 5.7°, respectively. N2–C6–C7–C8 and N10–C25–C24–C23 torsion angles are 3.5° and 1.1°. The central B3 atom is present in a trigonal-planar environment (Σ = 360.1°) with a wide N5–B3–N7 bond angle of 126.7(5)°. This open angle is a steric consequence of the interaction between the two NMe groups, because the B3-N5-C31 plane is twisted against the B3-N5-B1 plane by 27.8° but is almost coplanar with the B3-N7-C32 plane. The B3–N5 and B3–N7 bond lengths are 1.382(7) and 1.401(7) Å. This is in the typical range for B–N π-bonding. A significantly longer B–N bond with less double bond character is observed for B3–N6 with a length of 1.455(7) Å. Although the C15–N6–C16 bond angle is 118.7(4)°, this plane is twisted against the N5-B3-N7 plane by 31.3°. The respective $N_2B$ planes N5-B1-N4 and N7-B2-N8 stand almost perpendicular to the C31-N5-B3 and B3-N7-C32 planes (94.3° and 97.3°, respectively), while the N7-B2-N8 plane forms an interplanar angle with the N5-B1-N4 plane of only 3.5°. The semichair conformation of the central two six-membered rings is typical of what is usually observed.

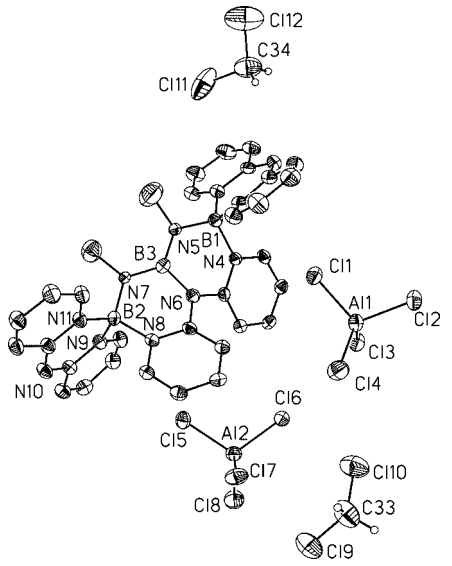


Figure 3. ORTEP plot of the contents of the asymmetric unit in the cell of **8**($AlCl_4$)$_2$·2$CH_2Cl_2$. Hydrogen atoms of cation **8** are omitted for clarity.Selected bond lengths [Å]: N1–B1 1.561(7), N3–B1 1.543(8), N4–B1 1.610(8), N8–B2 1.603(8), N5–B3 1.382(7), N5–B1 1.472(7), N6–B3 1.455(7), N7–B3 1.401(7), N5–C31 1.495(9). Selected bond angles [°]: N1–B1–N5 111.4(5), N5–B1–N4 114.3(5), N3–B1–N1 106.8(5), N5–B1–N4 108.1(5), N3–B1–N4 108.9(4), N1–B1–N4 107.0(4), N5–B3–N7 126.7(5), N7–B3–N6 116.5(5), N4–C15–N6 115.8(5), N8–C16–C6 116.3(5), C15–N6–B3 120.5(4), C15–N6–C16 118.7(4), C16–N6–B3 120.7(4), C11–N3–B1 120.3(4), C11–Ne4C15 117.5(4), C15–N4–B1 122.1(4).

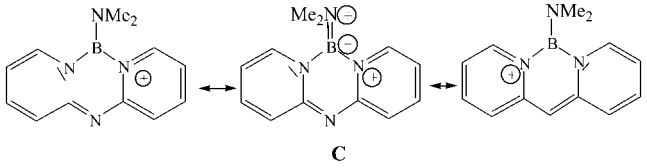
In spite of the NMR spectroscopic data, the route from **4** to **8** remains speculative because not all of the $^{27}Al$ NMR signals could be unequivocally assigned. For instance, the signal at 68 ppm might result form $AlCl_3$·2$NMe_3$ (71 ppm),[30] but it seems unlikely that $AlCl_3$ would first form $AlCl_3$·$NMe_3$ during its attack on **4**, which then must attack a second molecule of **4** in order to form $AlCl_3$·2$NMe_3$. It is more likely that $AlCl_3$ removes a $Me_2N$ group by BN cleavage to form a cation of type **C**, which then attacks another molecule of **4**. Too little information

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

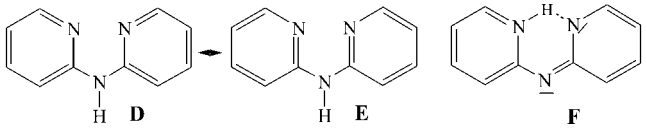
can be extracted from the NMR spectroscopic data to suggest a route from **4** to **8**. However, it should be noted that **8** contains a di(pyrid-2-yl)amino group. This suggests that isomer **2** is generated during the process.



**C**

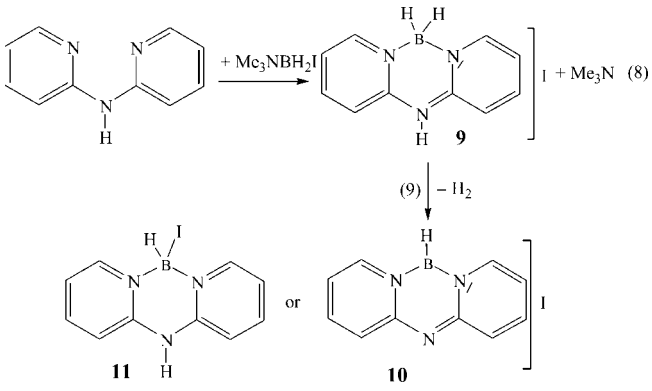
## Discussion

Transamination of 2-aminopyridine with $B(NMe_2)_3$ led to 2-aminopyridine(dimethylamino)boranes $(pyNH)_nB(NMe_2)_{3-n}$,[10] amongst which $B(HNpy)_3$ is most readily isolated. In contrast, di(pyrid-2-yl)amine (**1**) reacts in a different manner. This is due to the different basicity of the $NH_2$/NH groups as well as to the sterically more shielded NH group. In addition, the driving force for the formation of **4** is not only a consequence of steric factors, but also because of greater electron delocalization, as shown by the formulae **D/E**. In principle, **1** might exist in two forms, **D/E** and **F**. The structure of the isomer **D/E** is said to remain intact on reaction with $Me_3N{\cdot}BH_2I$, which generates the boronium iodide **9** [see Equation (8)].



**D** **E** **F**

Since the proton of **1** can be readily removed in strong basic solutions,[33] it is surprising that compound **9** is stable. One would expect that this compound would readily loose hydrogen gas, as shown in Equation (9), with formation of a tri-coordinate borenium salt **10** or the intramolecular iodoborane dipyrid-2-yl complex **11**.



**11** **10**

Although we have only studied the transamination of $B(NMe_2)_3$ with **1** in a 1:1 ratio, it would be interesting to also perform the transamination reaction with 2 and 3 mol of this amine in order to see whether the 1:3 transamination product $B(Npy'_2)_3$ contains structural elements in analogy to those in **4** or whether it is a "normal" triaminoborane $B(Npy'_2)_3$. In this context, one should note that cation **8** contains a di(pyrid-2-yl)amino group, an indication that isomers **2** and **4** may interconvert.

The transamination of $B(NMe_2)_3$ with aniline leads to a mixture of $(Me_2N)_2BNHPh$ and $B(NHPh)_3$. This is in accord with earlier observations,[34] although it has been reported that $(Me_2N)_2BNHPh$ and $Me_2NB(NHPh)_2$ can be prepared by transamination.[35] We did not find any $^{11}B$ NMR evidence for the formation of the latter compound.

The removal of a $Me_2N$ anion from compound **4** by $AlCl_3$ leads finally to the heterocyclic boronium dication in the salt $[\mathbf{8}][AlCl_4]_2$ (Figure 4). As far as we know, this is the first example of a diboronium cation and the second example[25] in which a cationic boron species has been generated from a triaminoborane. Particularly surprising is the fact that, in the course of this reaction, the dimethylamino groups are transformed by loss of a methyl group into NMe

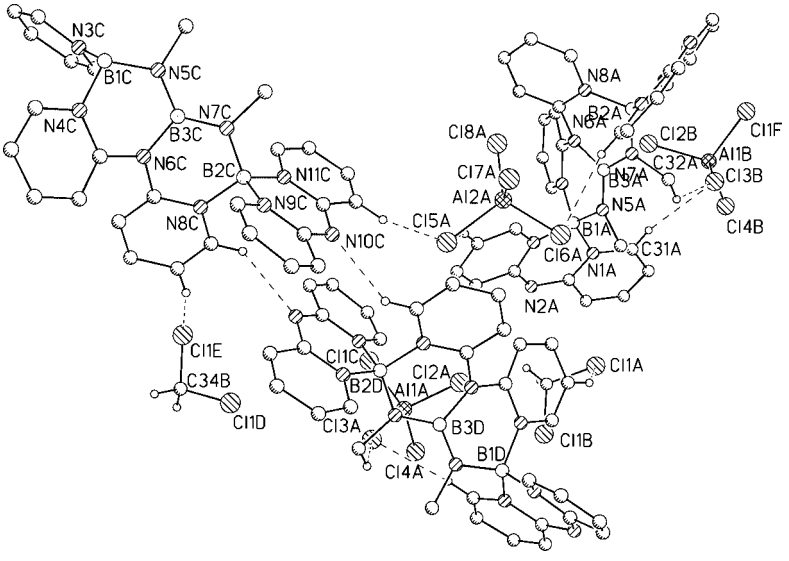


Figure 4. Section representing three cations of **8**, three $AlCl_4$ anions, and two $CH_2Cl_2$ molcules. Cl···HC distances are in the order of 2.7(0.2) Å, and CHN distances in the order of 2.1 Å. Only relevant H atoms are shown.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

units. As far as we know, this N–C bond cleavage is rather unusual, although this step must occur in order to reasonably explain the formation of **8**. Obviously, aminoboron halides are better suited[8] to generate borenium cations than triaminoborane systems. However, there is no doubt that this result opens up new aspects for the chemistry of cationic boron compounds. Reactions that take unexpected routes are certainly more interesting than those that occur along a "normal" route, and this example shows that BN chemistry still offers surprises.

## Experimental Section

All experiments have been performed under anhydrous conditions using $N_2$ or Ar as protective gases. All compounds were freshly crystallized or distilled. Solvents were dried by conventional methods. NMR spectroscopy: Bruker ACP-200 and Jeol EX 400. Standards for $^{11}B$, $^{14}N$ and $^{27}Al$: external $BF_3{\cdot}OEt_2$, nitromethane, and 1 M $AlCl_3$ in water, respectively. UV/Vis Spectroscopy: Varian Cray 60 CONC spectrometer. Elemental analysis: microanalytical laboratory of the department. X-ray structure determinations: Bruker P4 four circle diffractometer equipped with an area detector and a LT2 cooling device; Mo-$K_\alpha$ radiation, graphite monochromator. Thermal ellipsoids are represented at a 25% probability level.

**Compound 4:** To a stirred solution of **1** (1.59 g, 9.3 mmol) in toluene (40 mL) was added tris(dimethylamino)borane (1.6 mL, 9.3 mmol). After heating to reflux for 20 h, a bright yellow fluorescing solution formed, which presented an $^{11}B$ NMR signal at 4.7 ppm ($h_{1/2}$ = 57 Hz). The solvent was removed, and a yellow powder of **4** remained. Yield: 2.3 g (91%). $C_{14}H_{20}BN_5$ (269.22): calcd. C 63.46, H 7.48, N 26.02; found C 61.87, H 7.53, N 25.92. $^1H$ NMR (270 MHz, $C_6D_6$): $\delta$ = 2.36 (N–*Me*)$_2$ ppm. $^{13}C$ NMR (100 MHz): $\delta$ = 39.5 (N–*Me*)$_2$ ppm, as well as the resonances listed for **5**. $^{11}B$ NMR (64 MHz): $\delta$ = 4.7 ($h_{1/2}$ = 57 Hz) ppm.

**Compound 5:** The yellow solid that remained after evaporation of the solvent from **4** was dissolved in $CHCl_3$ (30 mL). After 10 d, addition of pentane (20 mL) to the top of the solution led to the formation of only a few very small crystals in two days. A few days later, the homogeneous solution was cooled to –78 °C. Yellow fluorescing crystals of **5**·$(CHCl_3)_4$ separated. On drying the crystals in vacuo, they turned turbid as they lost weight. Yield: 2.19 g (83%). M.p. 180 °C. $C_{14}H_{21}BClN_5$ (305.62): calcd. C 55.02, H 6.93, N 22.92, Cl 11.60; found C 54.12, H 6.88, N 21.75, Cl 10.74. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 2.54 (s, 6 H, HN–*Me*), 5.47 (br. s, 1 H, N–*H*), 6.06 [td, $^3J$ ($^1H^1H$) = 6.6 Hz, $^4J$ ($^1H^1H$) = 1.2 Hz, 2 H, C2–*H*], 6.81 [td, $^3J$ ($^1H^1H$) = 8.3 Hz, $^4J$ ($^1H^1H$) = 3.1 Hz, 2 H, C3–*H*], 7.06 [br. d, $^3J$ ($^1H^1H$) = 8.7 Hz, 2 H, C4–*H*], 7.64 [dd, $^3J$ ($^1H^1H$) = 6.4, $^4J$ ($^1H^1H$) = 1.7 Hz, 2 H, C1–*H*] ppm. $^{13}C$ NMR (100 MHz): $\delta$ = 48.7 (N–*Me*$_2$), 111.7 (py-*C*2), 121.9 (py-*C*4), 131.8 (py-*C*3), 138.4 (py-*C*1), 156.5 (py-*C*5) ppm. $^{11}B$ NMR (64 MHz): $\delta$ = 5.0 ppm. $^{14}N$ NMR (28.9 MHz): $\delta$ = –92.5 (py-*N*), –203.8 (*N*–H), –356.2 (*N*–Me$_2$, H*N*–Me$_2$) ppm. UV/Vis (toluene): $\lambda_{max}$ = 320, 393 cm$^{-1}$.

**Compound 7:** A mixture of $B(NMe_2)_3$ (3.45 mL, 20 mmol) and aniline (3.65 mL, 40 mmol) in toluene (150 mL) was kept at reflux for 20 h. After cooling the solution, $^{11}B$ NMR signals (1:1 intensity) at 24.9 ppm for $(Me_2N)_2BNHPh$[10] and at 23.6 ppm for $B(NHPh)_3$ were observed in the spectrum.[6] **1** (3.42 g, 20 mmol) was added to the reaction mixture, which was kept at reflux for another 20 h. The $^{11}B$ NMR spectrum showed a signal for $B(NHPh)_3$ in addition to one at 2.0 ppm. On cooling the mixture to –20 °C, most of the $B(NHPh)_3$ separated as a solid, which was removed by filtration. The filtrate exhibited red brown fluorescence. It was then reduced in volume to 20 mL. At –50 °C, only a few additional crystals of $B(NHPh)_3$ separated, which were removed by filtration. All the volatile material from the filtrate was then evaporated under vacuum to leave behind a light brown powder of **7**. $C_{18}H_{20}BN_5$ (317.18): calcd. C 68.10, H 6.35, N 22.07; found C 68.29, H 5.22, N 22.20. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta^1$ = 2.11 (N–*Me*$_2$), 2.82 (br., N–*H*), 6.42, 6.70, 6.72, 6.96, 7.63, 7.97 (Ar-*H*, Ph-*H*) ppm. $^{11}B$ NMR (64 MHz, toluene): $\delta$ = 2.0 ppm ($h_{1/2}$ = 83 Hz).

**Di(pyrid-2-yl)aminotrimethylsilane (6):** To a solution of **1** (1.712 g, 10.1 mmol) in toluene (80 mL) was added a solution of *n*BuLi (6.4 mmol, 1.56 M, 10 mmol) at –78 °C. A precipitate of $(py')_2NLi$ formed immediately. At room temperature, the suspension was treated with $Me_3SiCl$ (1.3 mL, 10 mmol). After stirring for 2 h, the insoluble material (LiCl) was removed by filtration, and the filtrate reduced in volume to about 15 mL. White needles of **6** separated over a week by keeping the solution at 0 °C. Yield: 1.97 g (81%). $C_{13}H_{17}N_3Si$ (243.59): calcd. C 64.17, H 6.99, N 17.28; found C 66.18, H 7.06, N 17.88. $^1H$ NMR (400 MHz, $C_6D_6$): $\delta$ = 0.44 (s, 9 H, Si–*Me*$_3$), 6.38 [br. d, $^3J$($^1H^1H$) = 8.5 Hz, 2 H, py-C3–*H*], 6.48 [ddd, $^3J$($^1H^1H$) = 6.5 Hz, $^3J$($^1H^1H$) = 5.6 Hz, $^4J$($^1H^1H$) = 1.3 Hz, 2 H, py-C5–*H*], 7.02 [ddd, $^3J$($^1H^1H$) = 7.0 Hz, $^4J$($^1H^1H$) = 1.1 Hz, 2 H, py-C4–*H*], 8.27 [dd, br, $^3J$($^1H^1H$) = 5.4 Hz, $^4J$($^1H^1H$) = 2.1 Hz, 2 H, py-C6–*H*] ppm. $^{13}C$ NMR (100 MHz, $C_6D_6$): $\delta$ = 1.3 (Si–*Me*$_3$), 116.9 (py-*C*5), 117.7 (py-*C*3), 137.6 (py-*C*4), 149.0 (py-*C*6), 160.0 (py-*C*2) ppm. $^{29}Si$ NMR (80 MHz, $C_6D_6$): $\delta$ = 6.8 ppm. $^{14}N$ NMR (28.9 MHz, toluene): $\delta$ = –85.9 (py-*N*), –266.6 (*N*–Si) ppm.

**Reaction of 6 with Chlorobis(dimethylamino)borane:** A solution of **6** (2.44 g, 10 mmol) in toluene (40 mL) was cooled to 0 °C. $(Me_2N)_2BCl$ (1.35 mL, 10 mmol) in toluene (20 mL) was then added. After stirring the solution for several hours and warming to ambient temperature, a single $^{11}B$ NMR signal at 4.7 ppm was observed in the spectrum, which shows a quantitative conversion to **4**. All other NMR spectroscopic data were identical to those found for **4**. Yield: 2.6 g of **4** (97%).

**Diboroniumbis(tetrachloroaluminate) 8$(AlCl_4)_2$:** To a solution of **4** (2.05 g, 7.6 mmol) in toluene (70 mL) was added $AlCl_3$ powder (1.00 g, 7.6 mmol). The suspension was stirred for 1 d. The $^{11}B$ NMR spectrum shows that no reaction had occurred. The mixture was then kept at reflux for 20 h. During this period, a green-yellow precipitate formed. The yellow solution presented a $^{11}B$ NMR signal at $\delta$ = 26.5 ppm (70%) and a multiplet at 0.7 ppm (≈30%). Two signals were observed in the $^{27}Al$ NMR spectrum at 80.4 and 68 ppm, in addition to overlapping bands in the range 92–104 ppm. After filtration, the solid material was dried and treated with $CH_2Cl_2$. Only part of the material dissolved. The concentrated solution was then cooled to –20 °C. Fairly large yellow-orange crystals with an octahedral shape formed over a few days. As revealed by the X-ray structure determination, the crystals have the composition **8**$(AlCl_4)_2{\cdot}2CH_2Cl_2$. Yield: not determined. M.p. 200 °C. $C_{34}H_{34}Al_2B_3Cl_{12}N_{11}$ (1108.51): calcd. C 36.81, H 3.07, N 13.90, Cl 38.38; found C 36.00, H 2.78, N 12.84, Cl 37.89. $^1H$ NMR (400 MHz, $CH_2Cl_2/C_6D_6$): $\delta$ = 2.13 (s, C–*Me*) ppm. $^{13}C$ NMR (100 MHz, $CH_2Cl_2/C_6D_6$): $\delta$ = 21.2 (N–*Me*) ppm. $^{11}B$ NMR (64 MHz): $\delta$ = 2.0, –26.5 ppm. $^{27}Al$ NMR: $\delta$ = 106.4 ($AlCl_4^-$, $h_{1/2}$ = 20 Hz) ppm.

**X-ray Structure Determinations:** Single crystals were suspended in perfluoro ether oil, and a suitable crystal was selected, fixed on a glass fibre and mounted on the goniometer head flushed with nitrogen gas cooled to –80 °C. The unit cell was determined from the reflections recorded on 5 sets of 15 different exposures each. Data

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

collection was performed in the hemisphere mode. Data were reduced with the program SMART.[36] For the structure solution, the SHELXTL program system[37] was used. Hydrogen atoms bound to N atoms were taken from the Fourier maps as well as those in $CH_2Cl_2$ and $CHCl_3$. All other hydrogen atoms were placed in calculated positions. Crystallographic data and structural parameters are summarized in Table 1. CCDC-626869 and -626870 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Characterisation of Polymer-Anchored Oxidovanadium(IV) Complexes and Their Use for the Oxidation of Styrene and Cumene

**Mannar R. Maurya,*[a] Umesh Kumar,[a] and P. Manikandan[b]**

**Keywords:** Vanadium(IV) complexes / Polymer support / Heterogeneous catalysts / Oxidations

The Schiff bases $H_2$fsal-ea (**I**), $H_2$fsal-pa (**II**) and $H_2$fsal-amp (**III**), derived from 3-formylsalicylic acid and 2-aminoethanol, 3-aminopropanol and 2-amino-2-methylpropanol, respectively, have been connected, by means of covalent bonds, to chloromethylated polystyrene cross-linked with 5% divinylbenzene. On treatment with [VO(acac)$_2$] in dimethylformamide (DMF), these polymer-anchored ligands PS-$H_2$fsal-ea (**IV**), PS-$H_2$fsal-pa (**V**) and PS-$H_2$fsal-amp (**VI**) gave the oxidovanadium(IV) complexes, PS-[VO(fsal-ea)·DMF] (**4**), PS-[VO(fsal-pa)·DMF] (**5**) and PS-[VO(fsal-amp)·DMF] (**6**), respectively. The corresponding neat complexes [VO(fsal-ea)]$_2$ (**1**), [VO(fsal-pa)]$_2$ (**2**) and [VO(fsal-amp)]$_2$ (**3**) have also been similarly prepared. These complexes all exhibit a medium intensity band between 964 and 993 cm$^{-1}$ in their IR spectra resulting from the V=O stretch. The EPR spectra of the polymer-anchored complexes are characteristics of monomeric $V^{IV}$ centres with a simple $S = ½$ electronic spin and with an axial pattern typical of square pyramidal geometry. Broad features for the neat complexes along with magnetic susceptibility studies suggest the presence of antiferromagnetic exchange interactions between two vanadium centres in close proximity. These catalysts have been tested for the oxidation of styrene and cumene and were found to be efficient. Styrene gives five reaction products namely styrene epoxide, benzaldehyde, 1-phenylethane-1,2-diol, benzoic acid and phenylacetaldehyde, whereas cumene gives acetophenone, 2-phenylpropanal, α-methyl styrene epoxide, 2-phenyl-2-propanol, 2-isopropyl-1,4-benzoquinone and α-methyl styrene. The polymer-anchored heterogeneous catalysts are recyclable. The catalytic activities of the neat complexes have also been examined and compared with the corresponding anchored analogues.

## Introduction

Advances in the coordination chemistry of vanadium with multidentate ligands stem from the discovery of the vanadium containing enzymes, namely vanadate-dependent haloperoxidases,[1] vanadium nitrogenases[2] and vanadium containing nitrate reductases.[3] Vanadate-dependent haloperoxidases catalyse the peroxide mediated oxidation of halides to hypohalous acid which further halogenates hydrocarbons in a non-enzymatic process.[4] Many vanadium complexes provide a suitable structural and/or functional model for these enzymes.[5,6] Oxidations of aliphatic as well as aromatic substrates including (prochiral) organic sulfides to (chiral) sulfoxides, catalysed by vanadium complexes, have also been achieved in excellent yield.[7,8]

The catalytic potential of [VO(sal-ohyba)] and [K(H$_2$O)][-VO$_2$(sal-ohyba)] ($H_2$sal-ohyba = Schiff base derived from salicylaldehyde and *o*-hydroxybenzylamine) for the oxidation and oxidative bromination of organic substrates has been recently investigated in our group.[9] The stability and potential of these complexes to be recycled were improved remarkably by immobilizing them onto a polymer support. For the development of industrial processes, such modifications to homogeneous catalysts would be very important and this, in addition, would lead to operational flexibility of the catalyst as well.[10] Recently, Ando et al. reported oxidovanadium(IV) complexes covalently bonded to Merrifield resin as a heterogeneous catalysts for the oxidation of organic sulfide selectively.[11]

In continuation of our efforts on the development of polymeric supported/anchored vanadium complexes and their catalytic potential, we report herein the preparation and characterisation of polymer-anchored oxidovanadium(IV) complexes of ligands **I**, **II** and **III**, Scheme 1, along with their neat complexes. The catalytic potential of these complexes has been demonstrated by studying the oxidation of styrene and cumene.

## Results and Discussion

### Synthesis, Reactivity and Solid-State Characteristics

The elemental and spectroscopic data (IR, $^1$H and $^{13}$C NMR) of the ligands $H_2$fsal-ea (**I**), $H_2$fsal-pa (**II**) and $H_2$fsal-amp (**III**) used in the present study, described in the experimental section, confirm the structures of ligands. The chloromethylated polystyrene, cross-linked with 5% divinylbenzene, reacts with these ligands in DMF in the presence of triethylamine to give the polymer-anchored ligands PS-$H_2$fsal-ea(IV), PS-$H_2$fsal-pa (**V**) and PS-$H_2$fsal-amp (**VI**), respectively. During this process the -COOH group of 3-formylsalicylic acid reacts with the -$CH_2Cl$ group of polystyrene. Covalent bonding through the -COOH group of the ligand has been further demonstrated by treating benzylchloride with $H_2$fsal-ea (**I**) under the above reaction conditions. Scheme 2 depicts the structures of the ligands isolated; a representative synthetic procedure for **IV** is also shown. The remaining chlorine content of 1.7% (0.49 mmol Cl/g of resin) in PS-$H_2$fsal-ea, 1.8% (0.51 mmol Cl/g of resin) in PS-$H_2$fsal-pa and 2.2% (0.62 mmol Cl/g of resin) in PS-$H_2$fsal-amp suggested roughly a 90% load of the ligands.

These anchored ligands react with [VO(acac)$_2$] in DMF at ca. 90 °C to give the polymer-anchored oxidovanadium(IV) complexes PS-[VO(fsal-ea)·DMF] (**4**), PS-[VO(fsal-pa)·DMF] (**5**) and PS-[VO(fsal-amp)·DMF] (**6**) which are dark green in colour. Equation (1) represents the synthetic procedure.

$$\text{PS-H}_2\text{fsal-ea} + [\text{VO(acac)}_2] \xrightarrow{\text{DMF}} \text{PS-[V}^{\text{IV}}\text{O(fsal-ea)·DMF]} + 2\ \text{Hacac} \quad (1)$$

**4**

Similarly, the reaction of [VO(acac)$_2$] with an equimolar amount of the neat ligands **I**, **II** and **III** in acetonitrile at reflux yields the neat oxidovanadium(IV) complexes [VO(fsal-ea)]$_2$ (**1**), [VO(fsal-pa)]$_2$ (**2**) and [VO(fsal-amp)]$_2$ (**3**), respectively. The neat complexes exhibit effective magnetic moments of 1.31 (for **1**), 1.34 (for **2**) and 1.49 $\mu_B$ (for **3**) at 298 K which are lower than the expected value of 1.73 $\mu_B$ for a $d^1$ ($S$ = ½) system. We have also studied the magnetic susceptibilities of these complexes as a function of temperature in the 298–90 K range. Figure 1 shows a plot of the magnetic susceptibility $\chi_M^{corr}$ as a function of temperature for **1**. The $\chi_M^{corr}$ values show a slight dependence on temperature, the observed magnetic moment values varied in the range 1.31–1.15 $\mu_B$ and the Curie–Weiss plot [$1/\chi_M^{corr}$ vs. $T$], as shown in Figure 2, was found to be a straight line with a Weiss constant of –40. Similarly, the magnetic moment values of **2** and **3** varied in the ranges 1.34–1.10 and 1.49–1.23 $\mu_B$, respectively, with Weiss constant values of ca. –50. These data all indicate an antiferromagnetic interaction possibly due to dimerisation of the complexes.[12,13] Based on the variations in magnetic moments with temperature and the spectroscopic studies of, for example, complexes [VO(X-sal-ea)]$_2$ (where X-sal-ea = Schiff bases derived from salicylaldehyde and 2-aminoethanol or 3-aminopropanol, X = 5-Cl, 5-Br, 5-$NO_2$, 3-$NO_2$,

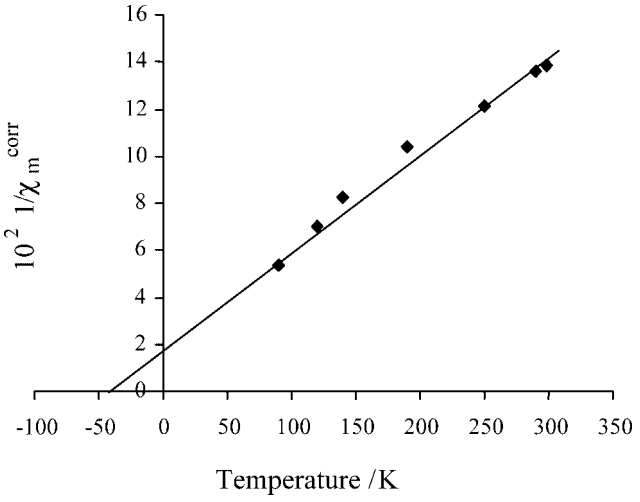

Figure 2. Curie–Weiss plot $[1/\chi_m^{corr}$ vs. $T]$ for $[VO(fsal\text{-}ea)]_2$ (**1**).

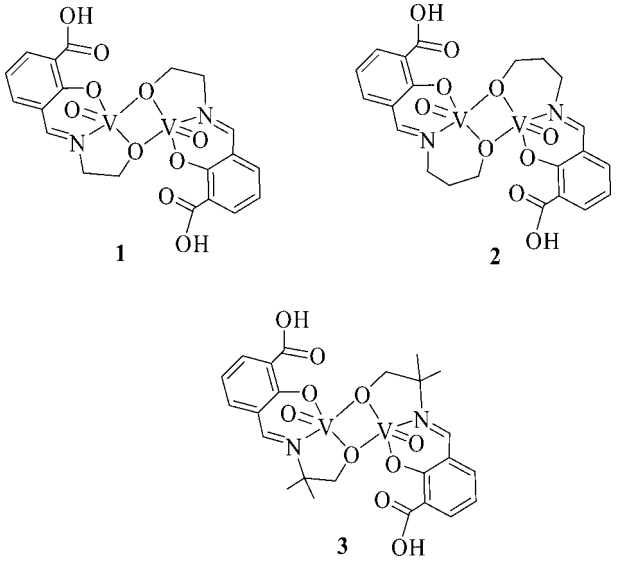

Scheme 3. Proposed structure for neat oxidovanadium(IV) complexes.

5-OMe, 3-OMe), Syamal et al. suggested antiferromagnetic exchange interactions along with a dimeric structure.[14] Thus, the dimeric structure as shown in Scheme 3 for the neat complexes may also be proposed here. A dimeric structure for $[VO(sal\text{-}ea)]_2$ has been confirmed by a single-crystal X-ray diffraction study.[15]

### Scanning Electron Micrograph

Scanning electron micrographs (SEM) for a single bead of pure chloromethylated polystyrene, the polymer-anchored ligand and the polymer-anchored vanadium complexes were recorded in order to observe the morphological changes. Images of PS-$H_2$fsal-ea (**IV**) and PS-[VO(fsal-ea)·DMF] (**4**) are reproduced in Figure 3. As expected, the pure polystyrene bead has a smooth and flat surface while the anchored ligands and complexes show a very slight roughening of the top layer. This roughening is relatively greater in the complexes possibly due to the interaction of vanadium with the anchored ligand which resulted in the formation of complexes with a fixed geometry. Accurate information on the morphological changes in terms of the exact orientation of the ligands coordinated to the metal ion has not been possible due to poor loading of the metal complex.

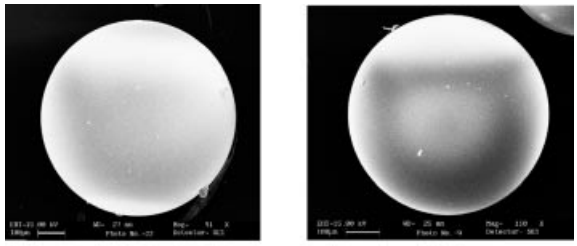

Figure 3. Scanning Electron Micrographs (SEM) of PS-$H_2$fsal-ea (**IV**) and PS-[VO(fsal-ea)·DMF] (**4**); magnification ca. ×200.

### TGA Study

Thermogravimetric analyses in an oxygen atmosphere showed good stabilities for polymer-anchored complexes **4**, **5** and **6** up to ca. 175 °C. The first weight loss starting just above 175 °C is possibly due to the loss of coordinated DMF. The complexes, thereafter, decompose in multiple steps. Quantitative measurement of weight loss at various stages was not possible due to the overlapping nature of the decompositions. However, the stabilities of the final residues at ca. 700 °C suggest the formation of $V_2O_5$. The metal content calculated from the final residue in each case was close to that recorded by atomic absorption spectroscopy.

### IR Spectroscopic Study

The experimental section contains a partial list of the IR spectroscopic data of all ligands and complexes. The chloromethylated polystyrene exhibits strong peaks at 1264 and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

673 $cm^{-1}$ due to $CH_2Cl$ group and the absence of these peaks in the polymer-anchored ligands suggests covalent bonding of the chloromethylated polystyrene to the ligands.[16] A sharp band due to ν(C=O) of the carboxylate group appears at 1670–1676 $cm^{-1}$ in the polymer-anchored ligands and complexes. In the corresponding neat ligands and complexes, this band appears at either the same or a slightly lower wavenumber. The ν(C=N) (azomethine) stretch of the neat ligands mostly appears along with the ν(C=O). However, a sharp peak due to the ν(C=N) (azomethine) stretch is observable in the spectra of the corresponding complexes at a lower wavenumber. The polymer-anchored ligands show a medium intensity band at 1630–1635 $cm^{-1}$ and this band shifts to a lower wavenumber by ca. 30 $cm^{-1}$ in the complexes thereby indicating the coordination of the azomethine nitrogen atom. The coordination of phenolic oxygen could not be assigned unequivocally in most complexes because of the appearance of a weak broad band in the 3400 $cm^{-1}$ region. Similarly, coordination of DMF in **4**, **5** and **6** could not be possible because of the strong ν(C=O) absorption band of the carboxylate in the same region. In addition to this, all the complexes exhibit a sharp ν(V=O) band in the 964–993 $cm^{-1}$ region.[6]

### Electronic and Fluorescence Spectroscopic Studies

The electronic spectra of the neat and anchored complexes in Figure S1 and relevant data in Table S2 are given in the Supporting Information (see also the footnote on the first page of this article). The spectroscopic patterns shown by the neat as well as the supported ligands are essentially the same except for the broadness of the bands in nujol. The expected charge-transfer band at ca. 400 nm could not be distinguished due to the appearance of an n→π* transition in the same region. In addition, two additional weak bands at ca. 570 and 690 nm were observed for neat complexes in DMF due to d-d transitions thus indicating the presence of a vanadium(IV) ion at the centre.

The fluorescence excitation and emission spectra of $10^{-6}$ M methanolic solution of oxidovanadium(IV) complexes **1**, **2** and **3** were recorded at room temperature and are presented in Figure 4. All neat complexes have approximately the same chromophore units and exhibit similar spectroscopic patterns. On excitation at 257 nm (in the UV region) complex **1** exhibited a strong band at $\lambda_{max}$ = 483 nm (in the visible region) with a shoulder band at 556 nm and, on excitation at 387.5 nm, exhibited a broad peak with $\lambda_{max}$ = 501 nm. In the case of complexes **2** and **3**, excitation at 258 (in **2**) and 255 (in **3**) nm gave emission bands at 464 and 466 nm, respectively, along with weak shoulder bands at 517 and 554 nm. Similarly, broad peaks at 503 (in **2**) and 502 nm (in **3**) were obtained with excitation at 382 and 385.5 nm, respectively. As, expected, the overtone at ca. 510 nm was observed as a sharp band in all complexes. All these spectroscopic patterns hint towards the photo-catalytic utility of these complexes.

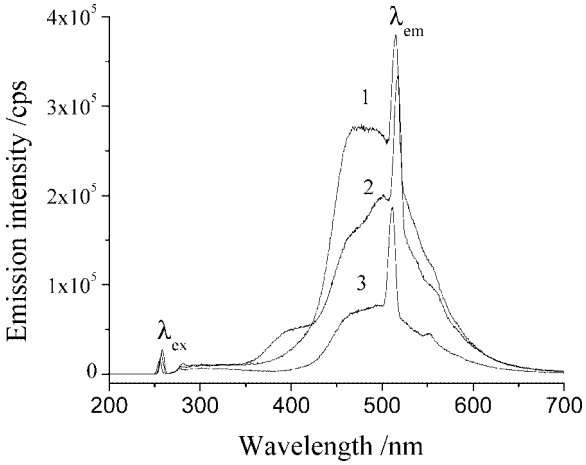

Figure 4. Emission spectra of complexes $[VO(fsal\text{-}ea)]_2$ (**1**), $[VO(fsal\text{-}pa)]_2$ (**2**) and $[VO(fsal\text{-}amp)]_2$ (**3**) recorded in methanol at ambient temperature.

### EPR Spectroscopic Study

The room temperature X-band EPR spectra of the polymer-anchored samples are reproduced in Figure 5. They are characteristics of monomeric $V^{IV}$ centres with a simple $S$ = ½ electronic spin and a typical axial pattern for a possible square pyramidal geometry, Scheme 4. The hyperfine features are well resolved in both the parallel and perpendicular regions. These resolved hyperfine features reflect the fact that the vanadium centres are well separated by the polymer backbones which causes least dipolar vanadium–vanadium coupling. Such arrangements generally broaden the EPR pattern. The hyperfine lines are typical for an interaction of the unpaired electron of the vanadium(IV) ion with its nucleus, $^{51}V$ having a high abundance of 99.75% and a nuclear

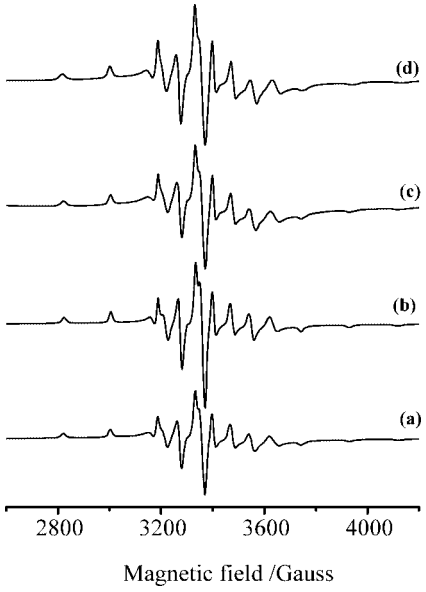

Figure 5. Room temperature EPR spectra of polymer-anchored complexes (a) PS-[VO(fsal-ea)·DMF] (**4**), (b) PS-[VO(fsal-pa)·DMF] (**5**), (c) PS-[VO(fsal-amp)·DMF] (**6**) and (d) PS-[VO(fsal-pa)·DMF] (**5**) (recovered); the microwave frequency was 9.4458 GHz.

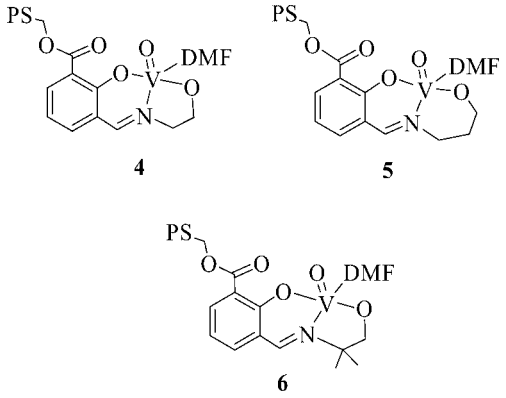
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spin $I = {}^{7}/_{2}$. The anisotropic EPR spectrum of the $V^{IV}$ ion with $g_{\|} < g_{\perp}$ and $A_{\|} > A_{\perp}$ is characteristic of square pyramidal complexes with possible $C_{4v}$ symmetry in which the V=O bond is along the $z$ axis and the other four coordinating atoms are along the $x$ and $y$ axes.[17] Simulation of the EPR spectra was carried to extract the Hamiltonian parameters and the resultant parameters are given in Table 1. As seen in the table and Figure 5, the Hamiltonian parameters are more or less the same for the all three polymer-anchored samples indicating that local symmetry and environments around the V centres are more or less the same.



Scheme 4. Possible structure for polymer-anchored complexes.

After carrying out the catalytic reactions, the polymer-anchored catalysts were filtered, washed with acetonitrile and dried. The EPR spectra were then recorded under identical conditions. The EPR spectrum for one of the recovered catalysts, PS-[VO(fsal-amp)·DMF] (**6**), is also reproduced in Figure 5 as a representative example. The EPR spectra of the recovered (spent) samples were only slightly different from the fresh samples indicating the environment and coordination geometry of the vanadium centres is retained to the maximum extent after the catalytic reaction. A slight increase in the $A_{\|}$ component for the recovered catalyst can be observed from 18.6 mT to 18.8 mT. A higher $A_{\|}$ value is generally due to reduced delocalisation of the paramagnetic electron density of the V centre indicating a slight displacement in the coordinating atom of the ligand. In other words, the vanadium–nitrogen bond is slightly weaker than that in the neat compound.

The EPR spectra for the neat compounds were also recorded and are reproduced in Figure 6. The broad spectroscopic features are typical for dimeric or polymeric species with dipolar interactions or exchange interactions with $V^{4+}$–$V^{4+}$ pairs with spin $S = 1$.[18] In the absence of any hyperfine features, the spectra could be best fitted by superimposing features of at least two $V^{4+}$–$V^{4+}$ pairs having slightly different environments with different zero-field splitting parameters, $D$ and $E$, and the resultant parameters are given in Table 1. As seen in the table, one of the $V^{4+}$–$V^{4+}$ pairs has a $D$ value in the range 1850–1900 MHz and an $E$ value of 500 MHz indicating a strong rhombic distortion site. The other species could be fitted with $D$ in the range 1250–1350 MHz with no $E$ splitting thus indicating less distortion. The broad features in the EPR spectra for the complexes $[VO(X\text{-sal-ea})]_2$ (X = 5-Cl, 5-Br, 5-$NO_2$, 5-OMe, 3-OMe) have also been noted previously and interpreted on the basis of the presence of antiferromagnetic exchange interactions between two vanadium centres in close proximity.[12–14]

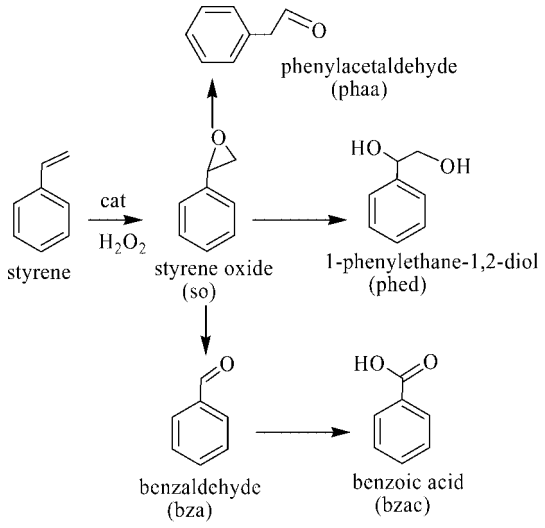
### Catalytic Activity Study

The catalytic potential of the polymer-anchored as well as the neat complexes were studied for the oxidation of styrene and cumene.

#### *Oxidation of Styrene*

Oxidation of styrene catalysed by the polymer-anchored complexes PS-[VO(fsal-ea)·DMF] (**4**), PS-[VO(fsal-pa)·DMF] (**5**) and PS-[VO(fsal-amp)·DMF] (**6**) gave styrene oxide, benzaldehyde, benzoic acid, phenylacetic acid and 1-phenylethane-1,2-diol as indicated in Scheme 5. These reaction products are common and have also been identified earlier by other workers.[19–21]



Scheme 5.

Complex **5** was taken as a representative amongst these catalysts and its catalytic activity was studied as a function of the amount of $H_2O_2$ (mol of $H_2O_2$ per mol of styrene) and catalyst as well as the temperature of the reaction mixture. These parameters were varied in order to obtain suitable reaction conditions for the maximum oxidation of styrene. Reactions were carried out with three different molar ratios of 1:1, 1:1.5 and 1:2 of styrene to aqueous 30% $H_2O_2$ for a fixed amount of styrene (1.04 g, 10 mmol) and catalyst (0.040 g) in $CH_3CN$ (10 mL) at 80 °C. The results were analysed periodically for up to 6 h. As illustrated in Figure 7, a maximum conversion of 42% was achieved in 6 h with a styrene to $H_2O_2$ molar ratio of 1:1. On increasing the ratio to 1:1.5 the conversion was improved to 65% while a 1:2 molar ratio showed a maximum conversion of 95%. No further improvement in the oxidation was observed on increasing the molar ratio to 1:3 (not shown in Figure) which suggests that a large amount of oxidant is not an essential condition for improving the oxidation of styrene. In another experiment, three different catalyst loadings, viz. 0.030, 0.040 and 0.070 g, were varied at styrene to $H_2O_2$ ratios of 1:2 under the above reaction conditions and the results are shown in Figure 8. As seen in the figure, 0.030 g of catalyst gave only a 52.5% conversion while catalyst loadings of 0.040 and 0.070 g showed maximum conversions of 95 and 97.3%, respectively, at the end of the 6 h. Thus, at the expense of $H_2O_2$, 0.040 g of catalyst was found to be sufficient to carry out the reaction. The temperature of the reaction mixture also influenced the performance of the catalyst. Figure 9 shows the effect of the reaction temperature on the performance of the catalysts and at 80 °C a much better conversion was achieved.

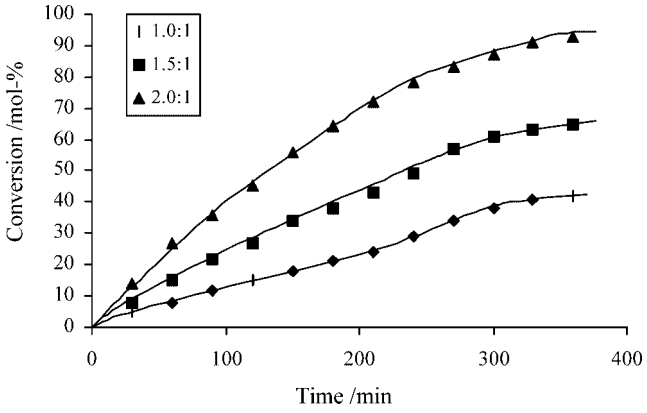


Figure 7. Effect of amount of $H_2O_2$ on the oxidation of styrene. Reaction conditions: styrene (1.04 g, 10 mmol), PS-[VO(fsal-pa)·DMF] (**5**) (0.040 g), $CH_3CN$ (10 mL) and temp. (80 °C).

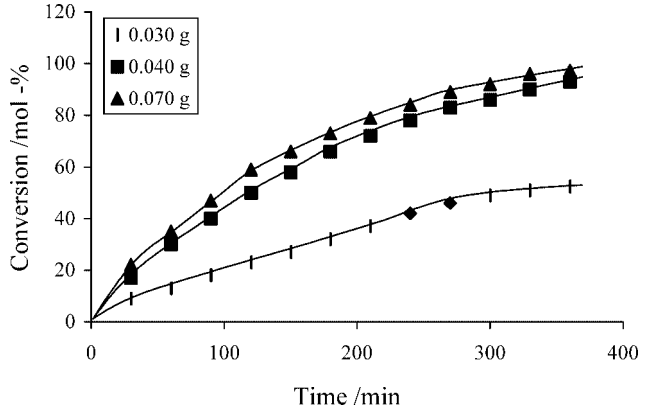

Figure 8. Effect of amount of catalyst on the oxidation of styrene. Reaction conditions: styrene (1.04 g, 10 mmol), $H_2O_2$ (2.27 g, 20 mmol), $CH_3CN$ (10 mL) and temp. (80 °C).

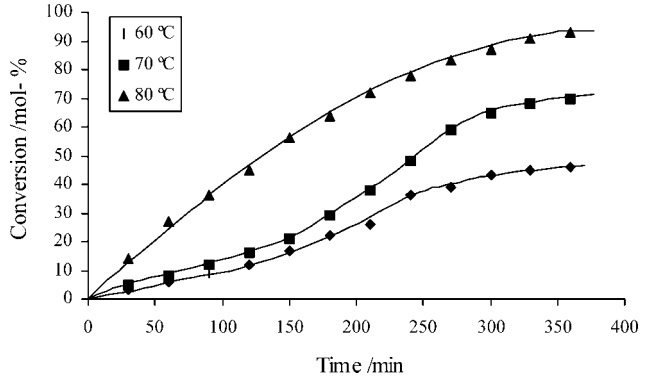

Figure 9. Effect of temperature on the oxidation of styrene. Reaction conditions: styrene (1.04 g, 10 mmol), PS-[VO(fsal-pa)·DMF] (**5**) (0.040 g), $H_2O_2$ (2.27 g, 20 mmol) and $CH_3CN$ (10 mL).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Other catalysts e.g. **4** and **6** were tested under the reaction conditions as optimised above. Thus, for 10 mmol of substrate, aqueous 30% $H_2O_2$ (20 mmol) and catalyst (0.040 g) were added in $CH_3CN$ (10 mL) and the reaction was carried out at 80 °C. Table 2 shows a comparison of percent conversion of styrene and the selectivity of various reaction products along with the turnover frequency of the catalysts. Catalyst **4** exhibits a 90% conversion of styrene while **6** exhibits only an 82% conversion. Thus, the performances of these catalysts follow the order: **5** (95%) > **4** (90%) > **6** (82%). The good performance of these catalysts is possibly due to easy formation of peroxo species in the presence of $H_2O_2$ (vide infra) as well as the ease in transferring oxygen from the intermediate peroxo species to the substrate.

We also tested the catalytic activity of the neat complexes for the oxidation of styrene. Their performances after 6 h are also presented in Table 2. Figure 10 provides conversion percentages for each catalyst as a function of time. For 0.020 g of each the neat vanadium complexes **1**, **2** and **3**, and with reaction conditions fixed as above, the obtained conversions were 65, 70 and 62%, respectively. Their calculated turnover frequencies vary in the range 15.3–17.6 $h^{-1}$. Thus, the catalytic performances of the neat complexes are also good. However, in the light of special features e.g. easy recovery, no leaching and the ability of the polymer-anchored complexes to be recycled, it may be concluded that polymer-anchored vanadium complexes are better catalysts.

The product selectivity for the polymer-anchored complexes follows the order: benzaldehyde > 1-phenylethane-1,2-diol > benzoic acid > styrene oxide > phenylacetaldehyde while for the neat complexes the order is: benzaldehyde > benzoic acid >1-phenylethane-1,2-diol > styrene oxide > phenylacetaldehyde. The formation of benzaldehyde in the highest yield is possibly due to a nucleophilic attack of $H_2O_2$ on styrene oxide formed in the first step followed by a cleavage of the intermediate hydroperoxystyrene as shown in Scheme 6. Benzaldehyde formation may also be facilitated by direct oxidative cleavage of the styrene side chain double bond by a radical mechanism.[19] Formation of other products such as benzoic acid from benzaldehyde is rather slow in all reactions. Similarly the formation of phenylacetaldehyde, a product formed by isomerisation of styrene oxide, is less in all cases. Water present in $H_2O_2$ is probably responsible for the hydrolysis of styrene oxide to 1-phenylethane-1,2-diol to some extent. Low formation of styrene oxide, an important product, is understandable because of its further conversion into other products.

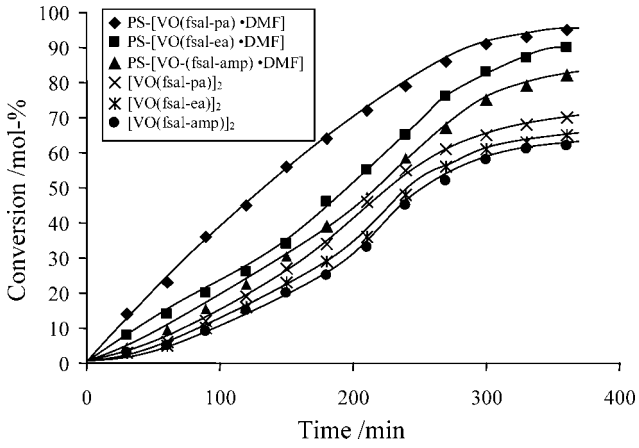

Figure 10. Catalytic comparison of polymer-anchored and neat complexes for the oxidation of styrene. Reaction conditions: styrene (1.04 g, 10 mmol), catalyst (0.040 g for polymer anchored and 0.020 g for neat complexes), $H_2O_2$ (1.27 g, 20 mmol), $CH_3CN$ (10 mL) and temp. (80 °C).

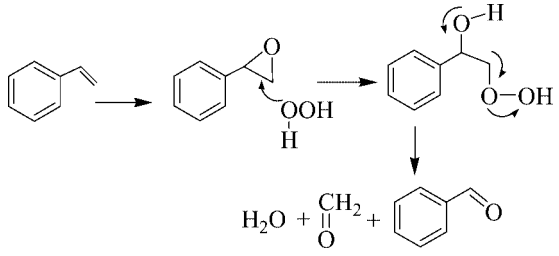

Scheme 6.

Several other polymer-anchored oxidovanadium(IV) complexes e.g. PS-[VO(hmbmz)$_2$] [where PS-Hhmbmz = polymer-anchored 2-(α-hydroxymethyl)benzimidazole],[22] PS-K[VO(O$_2$)$_2$(2-pybzm)] [where 2-pybzm = 2-(2-pyridyl)-benzimidazole][20] and PS-[VO(sal-ohyba)·DMF][9] have been used as catalysts in our laboratory for the oxidation of styrene. Though all these catalysts gave all five products with nearly similar selectivity patterns, the conversions with the catalysts reported here are higher.

Table 2. Turn over frequencies of various catalysts, percent conversion of styrene and product selectivities.

| Catalyst | Conv. /mol-% | TOF /$h^{-1}$ | Selectivity /mol-% | | | | | |
|---|---|---|---|---|---|---|---|---|

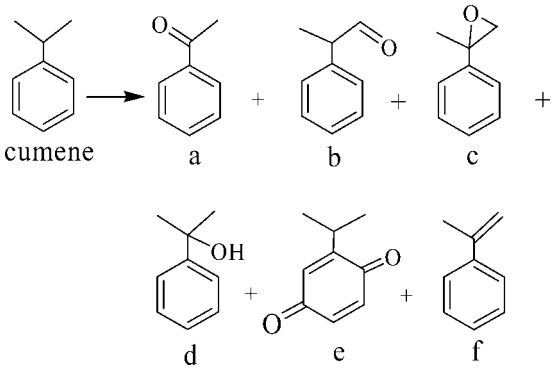
### *Oxidation of Cumene*

Oxidation of cumene by the polymer-anchored complexes **4**, **5** and **6** gave acetophenone, 2-phenylpropanal, α-methylstyrene epoxide, 2-phenyl-2-propanol, 2-isopropyl-1,4-benzoquinone and α-methylstyrene, as indicated in Scheme 7.



Scheme 7. a = acetophenone, b = 2-phenylpropanal, c = α-methylstyrene epoxide, d = 2-phenyl-2-propanol, e = 2-isopropyl-1,4-benzoquinone and f = α-methylstyrene.

In order to achieve suitable reaction conditions for the maximum oxidation of cumene, complex **5** was taken as a representative catalyst and three different parameters were varied, viz. the amounts of $H_2O_2$ (mol of $H_2O_2$ per mol of cumene) and catalyst as well as the temperature of the reaction mixture. The effect of $H_2O_2$ concentration on the oxidation of cumene is illustrated in Figure 11. A conversion of about 13% was achieved at a cumene to 30% $H_2O_2$ molar ratio of 1:1 in 6 h when cumene (1.20 g, 10 mmol), 30% $H_2O_2$ (1.14 g, 10 mmol) and catalyst (0.060 g) were placed in acetonitrile (10 mL) and the reaction was carried out at 80 °C. This conversion improved to ca. 18% on increasing the ratio to 1:1.5 and to 41% at a cumene to 30% $H_2O_2$ molar ratio of 1:2. This oxidation remained nearly constant on further increasing the amount of oxidant which suggests that a 1:2 (cumene to oxidant) ratio is sufficient enough to maximise the oxidation of cumene.

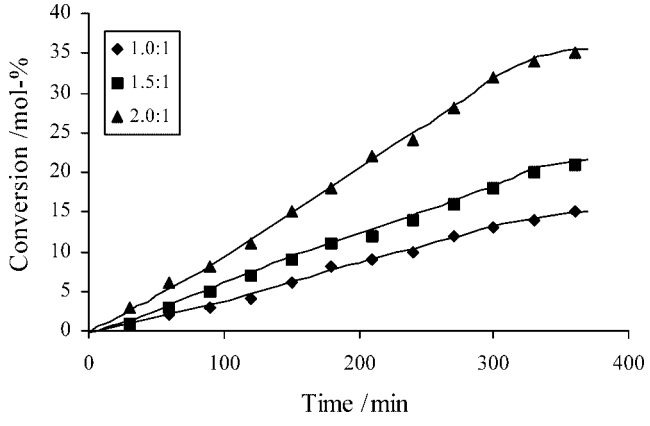


Figure 11. Effect of amount of $H_2O_2$ on the oxidation of cumene. Reaction conditions: cumene (1.20 g, 10 mmol), PS-[VO(fsal-pa)·DMF] (**5**) (0.060 g), $CH_3CN$ (10 mL) and temp. (80 °C).

Similarly, for a cumene to $H_2O_2$ ratio of 1:2, three different amounts of catalyst were used, viz. 0.040, 0.060 and 0.080 g, under above reaction conditions and the results are summarised in Figure 12. An amount of 0.040 g of catalyst gave only a 29% conversion while 0.060 g and 0.080 g of catalyst showed maximum conversions of 41 and 44%, respectively. Since the conversion is not significantly higher using 0.080 g of catalyst, an amount of 0.060 g of catalyst can be considered sufficient to carry out the oxidation. Moreover, the turnover rates of the catalyst for the catalytic conversions using 0.060 g and 0.080 g are comparable (7.32 $h^{-1}$ for 0.060 g and 5.9 $h^{-1}$ for 0.080 g). As observed in the case of styrene oxidation, a temperature of at least 80 °C was required to carry out the above reaction effectively. Moreover, time required in achieving the maximum conversion was also reduced on carrying out the reaction at 80 °C.

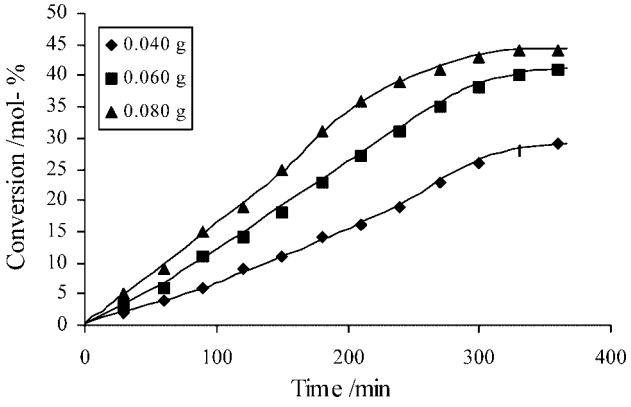

Figure 12. Effect of amount of catalyst PS-[VO(fsal-pa)·DMF] on the oxidation of cumene. Reaction conditions: cumene (1.20 g, 10 mmol), $H_2O_2$ (2.27 g, 20 mmol), $CH_3CN$ (10 mL) and temp. (80 °C).

Thus, suitable reaction conditions for the maximum oxidation of cumene were fixed as follows: cumene (1.20 g, 10 mmol), 30% $H_2O_2$ (2.27 g, 20 mmol), catalyst (0.060 g), acetonitrile (10 mL) and a temperature of 80 °C. Catalysts **4** and **6** were also tested under the above optimised reaction conditions and results are summarised in Table 3. Figure 13 shows a comparison of the percentage conversions of all three catalysts as a function of time. The conversion percentages of cumene after 6 h follow the order: **5** (41%) > **4** (39%) > **6** (35%). Independent of the type of catalyst, the percent yield of various products follow the order: acetophenone > 2-phenyl-2-propanal > α-methylstyrene epoxide > 2-phenylpropanol > 2-isopropyl-1,4-benzoquinone ≈ α-methylstyrene.

We have also compared the catalytic activity of these polymer-anchored complexes with their respective neat ones. Table 3 shows a comparison of the percentage conversion of cumene as well as product selectivity of various catalysts obtained after a reaction time of 6 h. For 0.030 g of each of the neat vanadium complexes and keeping other reaction conditions fixed as above, oxidation of cumene in

Table 3. Percent conversion of cumene and selectivity of various oxidation products.

| Catalyst | Conv. /mol-% | TOF /$h^{-1}$ | Selectivity /mol-% | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | | | a[a] | b | c | d | e | f | Others |
| $[VO(fsal\text{-}ea)]_2$ (**1**) | 25 | 3.92 | 62 | 18 | 10 | 4 | 3 | 2 | 1 |
| $[VO(fsal\text{-}pa)]_2$ (**2**) | 27 | 4.46 | 63 | 19 | 9 | 3 | 2 | 2 | 2 |
| $[VO(fsal\text{-}amp)]_2$ (**3**) | 21 | 3.52 | 66 | 17 | 8 | 3 | 2 | 3 | 1 |
| PS-[VO(fsal-ea)·DMF (**4**) | 39 | 6.50 | 60 | 13 | 17 | 3 | 2 | 3 | 3 |
| PS-[VO(fsal-pa)·DMF] (**5**) | 41 | 7.32 | 63 | 13 | 14 | 4 | 2 | 2 | 1 |
| PS-[VO(fsal-amp)·DMF] (**6**) | 35 | 6.83 | 59 | 12 | 17 | 3 | 3 | 2 | 3 |

[a] a = acetophenone, b = 2-phenylpropanal, c = α-methylstyrene epoxide, d = 2-phenyl-2-propanol, e = 2-isopropyl-1,4-benzoquinone, f = α-methylstyrene.

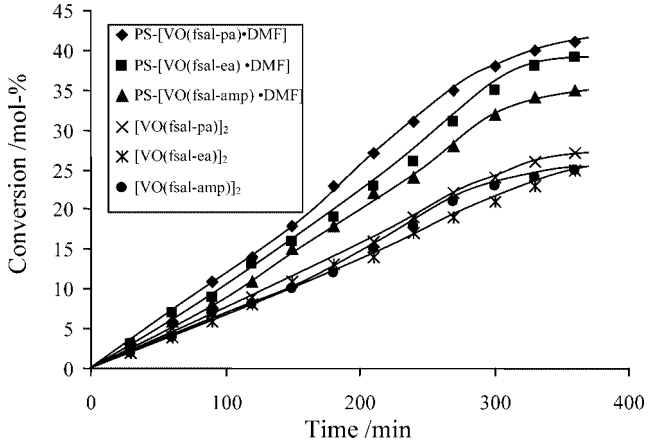

Figure 13. Catalytic comparison of catalysts for the oxidation of cumene. Reaction conditions: cumene (1.20 g, 10 mmol), catalyst (0.060 g), $H_2O_2$ (2.27 g, 20 mmol), $CH_3CN$ (10 mL), temp. (80 °C).

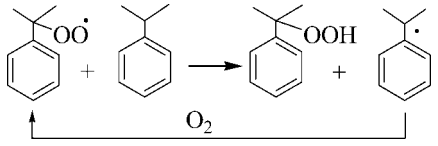
the 21–27% range was observed which is less than the corresponding values recorded for the anchored complexes. The percentage yields of various products follow the order: acetophenone > 2-phenylpropanal > α-methylstyrene epoxide > 2-phenyl-2-propanol ≈ 2-isopropyl-1,4-benzoquinone ≈ α-methylstyrene. Thus, the yield of α-methylstyrene epoxide is slightly better than 2-phenyl-2-propanal in the case of the neat complexes. However, the selectivity as well as the yield of the major product acetophenone is comparable in all cases.

Homogeneous catalysts such as metal complexes[23] and metalloporphyrins,[24] and heterogeneous catalysts such as platinum metals,[25] metal oxides,[26] metal oxides supported on alumina[27] and metals or metal oxides supported MCM-41[28] have been used for the oxidation of cumene. Only limited literature deals with the oxidation of cumene using polymer-supported catalysts e.g. metal salts[29] and $[Fe(phen)_2]^{2+}$ (phen = phenanthroline)[30] supported on a polymer. Catalytic activity of the complexes reported here compares well with the literature data. However, cumene hydroperoxide, in most cases, has been reported to be the major product amongst the various products formed whereas we observed the formation of acetophenone with a selectivity of 59–66%. This difference is possibly due to the use of different oxidants as well as different metal centres in catalysts.

**Proposed Mechanism**

As observed earlier, the reaction of cumene proceeds by means of a radical mechanism if molecular oxygen is used as the oxidant. The cumene radical, formed by abstracting the tertiary hydrogen of the cumene by a metal ion, reacts with molecular oxygen to produce an alkyl peroxide, which in turn abstracts hydrogen from cumene to form hydroperoxide (Scheme 8).[28,31] The oxidant $H_2O_2$ is likely to form peroxidovanadium(V) species with the oxidovanadium(IV) complexes reported here, which finally transfer oxygen to the substrate to give the various products. As cumene hydroperoxide was not observed among the reaction products, the reaction pathway either does not follow any secondary mechanism, e.g. through radical formation, or the cumene hydroperoxide, if formed at all, decomposes catalytically to yield acetophenone and other products.



Scheme 8.

Similarly, the formation of styrene oxide may proceed through the transfer of oxygen from oxidoperoxidovanadium(V) species to styrene. The oxidoperoxido species is finally converted to dioxidovanadium(V) and the catalytic cycle moves through these intermediates. These are the most common species observed during the catalytic action of oxidovanadium(IV)/dioxidovanadium(V) complexes for most oxidation reactions carried out in the presence of peroxide.[5a,7b] As the recovered species is EPR active, it seems that dioxidovanadium(V) species are slowly converted to oxidovanadium(IV) during the washing and drying processes and exhibit EPR spectroscopic patterns similar to that of the neat oxidovanadium(IV) complex (cf. Figure 5).

To support the reaction mechanism through peroxidovanadium(V) species formation, we tried the isolation of neat peroxidovanadium(V) complexes with ligands **I**, **II** and **III** but were unsuccessful possibly due to their poor stability at ambient temperature. Nevertheless, the generation of the oxido-monoperoxidovanadium(V) complex, $[VO(O_2)(fsal\text{-}pa)]^-$ has been established in methanol by electronic absorption spectroscopy. In a typical reaction, 10 mL of a ca.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$1 \times 10^{-4}$ M solution of $[VO(fsal\text{-}pa)]_2$ (**2**) was treated with one drop portions of 30% $H_2O_2$ dissolved in methanol and the resultant spectroscopic changes are presented in Figure 14 Thus, the intensity of the 390 nm band increases slowly along with a corresponding shift to 399 nm by dropwise addition of $H_2O_2$ dissolved in methanol. The shoulder band at 279 nm does not change its position but undergoes an increase in intensity. Two other bands centred at 255 and 212.5 nm remain constant while a shoulder band at 223 nm slowly appears. We have interpreted this result in terms of the formation of the oxidoperoxidovanadium(V) complex $[VO(O_2)(sal\text{-}pa)]^-$.

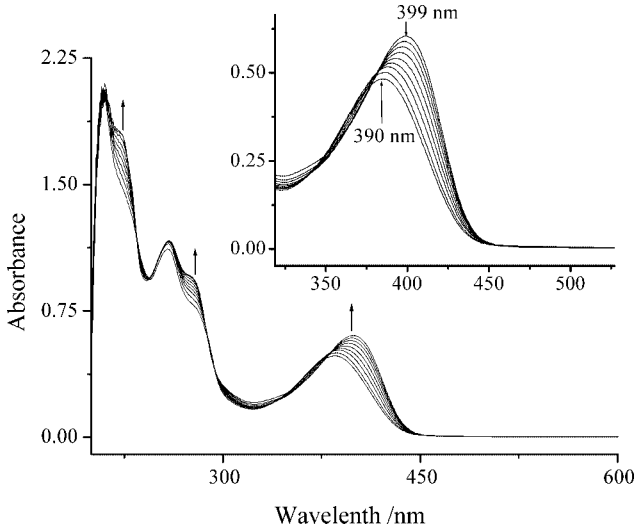


Figure 14. Titration of $[VO(fsal\text{-}pa]_2$ (**2**) with 30% $H_2O_2$; the spectra were recorded after the successive addition of 1-drop portions of $H_2O_2$ dissolved in methanol to 10 mL of ca. $10^{-4}$ M solution of **2** in methanol.

Similar spectroscopic patterns were also observed for complexes **1** and **3**. Oxidoperoxidovanadium(V) complexes have also been generated previously on treatment of, for example, complexes [VO(sal-ohyba)][9] and $K[VO_2(sal\text{-}inh)(H_2O)]$[32] with $H_2O_2$ in methanol.

### Leaching and Heterogeneity of the Catalytic Reaction and Potential of the Catalyst to be Recycled

The polymer-anchored complexes **4**, **5** and **6** have been tested for their ability to be recycled. The reaction mixture was filtered after a contact time of 6 h. The catalysts separated from the reaction mixture after catalytic action in all three cases were washed with acetonitrile, dried and subjected to further catalytic reactions under similar conditions. No appreciable loss in the activity in all cases suggests that catalysts were active even after the first cycle. During catalytic oxidation of styrene and cumene, the solid catalyst was separated from the reaction mixture by filtration after 2 h and the reaction was continued for a further 4 h. The gas chromatographic analyses showed barely a 1% increment in the conversion. This confirms no leaching of the catalyst during the catalytic reaction. No further oxidation of substrates on removal of the solid catalysts is consistent with a heterogeneous process.

## Conclusions

Polymer-anchored oxidovanadium(IV) complexes with polymer-anchored ligand PS-$H_2$fsal-ea, PS-$H_2$fsal-pa and PS-$H_2$fsal-amp, having potential catalytic activities for the oxidation of styrene and cumene, have been isolated and characterised. The oxidation of styrene follows the order: PS-[VO(fsal-pa)·DMF] (95%) > PS-[VO(fsal-ea)·DMF] (90%) > PS-[VO(fsal-amp)·DMF] (82%) where the selectivity of the five different products follows the order: benzaldehyde > 1-phenylethane-1,2-diol > benzoic acid > phenylacetaldehyde > styrene oxide. The oxidation of cumene gives at least six different products with the following order of selectivity: acetophenone > 2-phenyl-2-propanal > α-methylstyrene epoxide > 2-phenylpropanol > 2-isopropyl-1,4-benzoquinone and α-methylstyrene. The good performance of these catalysts is possibly due to the facile formation of peroxido species in the presence of $H_2O_2$ as well as the ease in transferring oxygen from the intermediate peroxido species to the substrate. However, complexes slowly convert back to the oxidovanadium(IV) species since the recycled species exhibit similar EPR spectroscopic patterns. The catalytic activities of these complexes have also been compared with the corresponding neat complexes and it was observed that the neat complexes are, however, good catalyst but exhibit less catalytic activity than the anchored ones. The easy separation of the polymer anchored complexes from the reaction mixture and their ability to be recycled makes them better catalyst compared wit the neat ones. They can pass through up to three cycles without significant loss in their catalytic activities.

## Experimental Section

**Materials:** Analytical reagent grade $V_2O_5$, (Loba Chemie, India), salicylaldehyde, acetylacetone (Ranbaxy, India), styrene, cumene, 3-aminopropanol (Acros organics, USA), 2-aminoethanol, 2-amino-2-methylpropanol (S.D. Fine Chemicals, India), aqueous 30% $H_2O_2$ (Qualigens, India) were used as obtained. Other chemicals and solvents were of AR grade. Chloromethylated polystyrene [18.9% Cl (5.3 mmol Cl per gram of resin)] cross-linked with 5% divinylbenzene was obtained as gift from Thermax limited, Pune, India. $[VO(acac)_2]$[33] and 3-formylsalicylic acid[34] were prepared following the methods reported in the literature.

**Methods:** Elemental analyses of the ligands and complexes were obtained using an Elementar model Vario-EI-III instrument. IR spectra were recorded as KBr pellets on a Nicolet NEXUS Aligent 1100 FT-IR spectrometer. Electronic spectra of the polymer-anchored compounds were recorded in Nujol on a Shimadzu1601 UV/Vis spectrophotometer by layering a mull of the sample inside one of the cuvettes while keeping other one layered with Nujol as a reference. The spectra of other ligands and complexes were recorded in methanol or DMF. $^1$H NMR spectra were obtained using a Bruker 500 NMR spectrometer in $[D_6]$DMSO. EPR spectra were

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

recorded at room temperature on a Bruker EMX X-band spectrometer operating at 100-kHz field modulation at room temperature. The microwave frequency was calibrated using a frequency counter of the Microwave Bridge ER 041 XG-D. The Bruker Simfonia software package was used in the spectroscopic simulations and to calculate hyperfine coupling constant. The magnetic susceptibilities of simple oxidovanadium(IV) complexes were measured at 298 K with a Vibrating Sample Magnetometer model 155, using nickel as a standard. Diamagnetic corrections were carried out using Pascal's increments.[35] Thermogravimetric analyses of the complexes were carried out using a Perkin–Elmer (Pyris Diamond) instrument. Scanning Electron Micrographs (SEM) of polymer anchored ligands and complexes were recorded on a Leo instrument model 435 VP. The samples were coated with a thin film of gold to prevent the surface changing and to protect the surface material from thermal damage by the electron beam.

### Preparations

**$H_2$fsal-ea (I):** A stirred solution of 2-aminoethanol (0.61 g, 10 mmol) in acetonitrile (10 mL) was added to a solution of 3-formylsalicylic acid (1.66 g, 10 mmol) in hot acetonitrile (30 mL) and the reaction mixture was heated to reflux on a water bath for 5 h. After reducing the solvent volume to ca. 10 mL, the flask was kept at room temperature. A yellow solid of **I** slowly separated out overnight. This was filtered, washed with petroleum ether and dried in vacuo. Yield 72%. $C_{10}H_{11}NO_4$ (209.2): calcd. C 57.40, H 5.30, N 5.70; found C 57.43, H 5.32, N 5.68. IR (KBr): $\tilde{\nu}_{max}$ = 1658 ($\nu_{C=O}$) $cm^{-1}$. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 12.89 (br., 1 H, carboxylic –OH), 5.20 (br., 1 H, phenolic OH), 8.37 (s, 1 H, –CH=N–), 8.09 (d, 1 H, aromatic), 7.69 (d, 1 H, aromatic), 6.75 (t, 1 H, aromatic), 3.77 (s, 2 H, –$CH_2$–), 3.70 (s, 2 H, –$CH_2$–) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 190.1 (carboxyl), 175.2 (azomethine), 168.4 (phenolic), 141.1, 139.9, 119.5, 116.1, 114.2 (aromatic), 59.3, 54.2 (alkyl chain) ppm.

**$H_2$fsal-pa (II) and $H_2$fsal-amp (III):** These ligands were prepared following the above procedure using 3-formylsalicylic acid (1.66 g, 10 mmol) and 3-aminopropanol (0.89 g, 10 mmol) or 2-amino-2-methylpropanol (0.89 g, 10 mmol).

**Data for II:** Yield 55%. $C_{11}H_{13}NO_4$ (223.2): calcd. C 59.17, H 5.87, N 6.28; found C 59.39, H 5.84, N 6.23. IR (KBr): $\tilde{\nu}_{max}$ = 1657 ($\nu_{C=O}$) $cm^{-1}$. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 12.09 (br., 1 H, carboxylic –OH), 4.80 (br., 1 H, phenolic –OH), 8.76 (s, 1 H, –CH = N–), 8.08 (d, 1 H, aromatic), 7.65 (d, 1 H, aromatic), 6.67 (t, 1 H, aromatic), 3.81 (t, 2 H, –$CH_2$–), 3.53 (t, 2 H, –$CH_2$–), 1.89 (quin, 2 H, –$CH_2$) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 190.8 (carboxyl), 175.2 (azomethine), 168.4 (phenolic), 141.0, 139.8, 119.5, 116.1, 114.1 (aromatic), 58.4, 49.7, 32.1 (alkyl chain) ppm.

**Data for III:** Yield 60%. $C_{12}H_{15}NO_4$ (237.2): calcd. C 60.73, H 6.38, N 5.91; found C 60.60, H 6.31, N 5.94. IR (KBr): $\tilde{\nu}_{max}$ = 1680 ($\nu_{C=O}$) $cm^{-1}$. $^1H$ NMR ([D$_6$]DMSO): $\delta$ = 13.57 (br., 1 H, carboxylic –OH), 5.57 (br., 1 H, phenolic –OH), 8.81 (s, 1 H, –CH = N–), 8.84 (d, 1 H, aromatic), 7.79 (d, 1 H, aromatic), 6.71 (t, 1 H, aromatic), 3.49 (s, 2 H, –$CH_2$–), 1.42 (s, 3 H, –$CH_3$), 1.17 (s, 3 H, –$CH_3$) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 190.1 (carboxyl), 168.2 (azomethine), 165.7 (phenolic), 141.2, 139.7, 119.4, 116.2, 114.2 (aromatic), 68.0, 61.2 (alkyl chain), 23.2 (methyl) ppm.

**PS-$H_2$fsal-ea (IV):** The polymer-anchored ligand PS-$H_2$fsal-ea was prepared following the procedure developed by Syamal et al.[36] Chloromethylated polystyrene (3.0 g) was allowed to swell in DMF (30 mL) for 2 h. A solution of $H_2$fsal-ea (9.96 g, 45 mmol) in DMF (30 mL) was added to the above suspension followed by triethylamine (4.50 g, 45 mmol) in ethyl acetate (50 mL). The reaction mixture was heated in an oil bath at 80 °C for 20 h with mechanical stirring. After cooling to room temperature, the yellow resins were filtered, washed thoroughly with hot DMF followed by hot methanol and dried in an air oven at 120 °C. Found: C 70.76, H 8.64, N 3.16. IR (KBr): $\tilde{\nu}_{max}$ = 1675 ($\nu_{C=O}$), 1635 ($\nu_{C=N}$) $cm^{-1}$.

**PS-$H_2$fsal-pa (V) and PS-$H_2$fsal-amp (VI):** The ligands PS-$H_2$fsal-pa and PS-$H_2$fsal-amp were prepared by following the procedure out lined for PS-$H_2$fsal-ea.

**Data for V:** Found: C 71.58, H 8.63, N 3.25. IR (KBr): $\tilde{\nu}_{max}$ = 1675 ($\nu_{C=O}$), 1637 ($\nu_{C=N}$) $cm^{-1}$.

**Data for VI:** Found: C 69.21, H 7.43, N 3.05. IR (KBr): $\tilde{\nu}_{max}$ = 1673 ($\nu_{C=O}$), 1630 ($\nu_{C=N}$) $cm^{-1}$.

**[VO(fsal-ea)]$_2$ (1):** A stirred solution of $H_2$fsal-ea (1.05 g, 5 mmol) in acetonitrile (30 mL) was added with stirring to [VO(acac)$_2$] (1.33 g, 5 mmol) dissolved in acetonitrile (25 mL) and the resultant reaction mixture was heated to reflux on a water bath for 3 h. After cooling to room temperature, a green precipitate of **1** was filtered, washed with acetonitrile and dried in vacuo. Yield 78%. $C_{10}H_9NO_5V$ (274.13): calcd. C 43.80, H 3.31, N 5.11, V 18.59; found C 43.62, H 3.42, N 5.05, V 18.06. IR (KBr): $\tilde{\nu}_{max}$ = 1670 ($\nu_{C=O}$), 1607 ($\nu_{C=N}$), 987 ($\nu_{V=O}$) $cm^{-1}$.

**[VO(fsal-pa)]$_2$ (2) and [VO(fsal-amp)]$_2$ (3):** Complexes **2** and **3** were prepared analogously to **1**, replacing $H_2$fsal-ea for $H_2$fsal-pa and $H_2$fsal-amp, respectively.

**Data for 2:** Yield 76%. $C_{11}H_{11}NO_5V$ (288.15): calcd. C 45.83, H 3.85, N 4.86, V 17.69; found C 45.91, H 3.65, N 4.74, V 17.14. IR (KBr): $\tilde{\nu}_{max}$ = 1673 ($\nu_{C=O}$), 1603 ($\nu_{C=N}$), 985 ($\nu_{V=O}$) $cm^{-1}$.

**Data for 3:** Yield 70%. $C_{12}H_{13}NO_5V$ (302.18): calcd. C 47.68, H 4.34, N 4.64, V 16.87; found C 47.30, H 4.54, N 4.41, V 16.36. IR (KBr): $\tilde{\nu}_{max}$ = 1674 ($\nu_{C=O}$), 1600 ($\nu_{C=N}$), 988 ($\nu_{V=O}$) $cm^{-1}$.

**PS-[VO(fsal-ea)·DMF] (4):** Polymer-anchored ligand PS-$H_2$fsal-ea (2.0 g) was allowed to swell in DMF (30 mL) for 2 h. A solution of [VO(acac)$_2$] (5.30 g, 20 mmol) in DMF (20 mL) was added to the above suspension and the reaction mixture was heated at 90 °C in an oil bath for 15 h while slow mechanical stirring. The blackish green beads of polymer-anchored complex **4** were filtered off, washed with hot DMF followed by hot methanol and dried at 120 °C in an air oven. Found: C 67.08, H 7.74, N 5.04, V 8.5. IR (KBr): $\tilde{\nu}_{max}$ = 1655 ($\nu_{C=O}$), 1607 ($\nu_{C=N}$), 977 ($\nu_{V=O}$) $cm^{-1}$.

**PS-[VO(fsal-pa)·DMF] (5) and PS-[VO(fsal-amp)·DMF] (6):** Complexes **5** and **6** were prepared by following the procedure out lined for **4**.

**Data for 5:** Found: C 68.18, H 7.86, N 4.83, V 7.93. IR (KBr): $\tilde{\nu}_{max}$ = 1659 ($\nu_{C=O}$), 1609 ($\nu_{C=N}$), 993 ($\nu_{V=O}$) $cm^{-1}$.

**Data for 6:** Found: C 64.19, H 7.31, N 4.66, V 7.26. IR (KBr): $\tilde{\nu}_{max}$ = 1675 ($\nu_{C=O}$), 1609 ($\nu_{C=N}$), 964 ($\nu_{V=O}$) $cm^{-1}$.

### Catalytic Activity Studies

**Oxidation of Styrene:** The oxidation of styrene was carried out in a 50 mL reaction flask fitted with a water condenser. All anchored catalysts were allowed to swell in acetonitrile for 2 h prior to their use. In a typical oxidation reaction, styrene (1.04 g, 10 mmol) and aqueous 30% $H_2O_2$ (2.27 g, 20 mmol) were mixed in acetonitrile (10 mL) and the reaction mixture was heated to 80 °C with stirring. The appropriate catalyst (0.040 g) was added to the reaction mixture and stirred for 6 h. The progress of the reaction was monitored by withdrawing small amounts of the reaction mixture at different time intervals and analysing them quantitatively by gas chromatography. The identities of the products were confirmed by GC–MS

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(Perkin–Elmer, Clarus 500). The effects of various parameters such as temperature, amount of oxidant and catalyst were studied to obtain suitable reaction conditions for the best performance of the catalyst.

**Oxidation of Cumene:** Cumene (1.20 g, 10 mmol), 30% aqueous $H_2O_2$ (2.26 g, 20 mmol) and anchored catalyst (0.060 g), after swelling in acetonitrile as stated above in acetonitrile (10 mL), were heated at 80 °C with stirring and the reaction was monitored as mentioned above. Various parameters such as amount of oxidant and catalyst and temperature of the reaction were considered to see their effect on the reaction products. However, the basic procedure was the same as outlined above.

**Supporting Information** (see also the footnote on the first page of this article): Electronic spectral data (Table S1) and electronic spectra of neat and polymer-anchored oxidovanadium(IV) complexes (Figue S1).

# Lanthanide Complexes with a Calix[8]arene Bearing Phosphinoyl Pendant Arms

**Lada N. Puntus,[a,b] Anne-Sophie Chauvin,[a] Sabi Varbanov,[a,c] and Jean-Claude G. Bünzli*[a]**

**Keywords:** Lanthanides / Calixarenes / Europium / Luminescence

The phosphinoyl-substituted macrocyclic receptor $B_8bL^8$, derived from *p-tert*-butylcalix[8]arene, was synthesized and its structure was studied in solution. According to temperature-dependent $^1H$ and $^{31}P$ NMR spectroscopic data, the calix[8]arene adopts a so-called *in–out* cone conformation. To investigate the influence of the narrow rim substitution, interaction with trivalent lanthanide ions, $Ln^{III}$ (Ln = La, Eu, Tb, Lu), was probed by MS, UV/Vis and NMR spectroscopic titrations. Although both 1:1 (in the presence of triflate) and 2:1 (in the presence of nitrate) $Ln:B_8bL^8$ complexes could be isolated in the solid state, the major species present in methanol is the 1:1 complex, irrespective of the anion. NMR spectroscopic data point to a common conformation for the 1:1 complexes in solution, the lanthanide ions being coordinated by four of the eight phosphinoyl arms, with a coordination sphere completed by methanol molecules or by nitrate ions, as ascertained by IR and MS spectra. The ligand displays a weak absorption at 360 nm that can be assigned to an intraligand charge-transfer (ILCT) state, which is very sensitive to coordination. Photophysical data of the $Eu^{III}$ 2:1 complex point to both metal ion sites providing a very similar chemical environment for the lanthanide ions, with no coordinated water, which is contrary to what is observed for the 1:1 complex. The use of optical electronegativity to predict the energy of the charge-transfer states in the lanthanide systems with inequivalent ligands is discussed and extensive analysis of the vibronic satellites of the $Eu(^5D_0 \rightarrow {}^7F_J)$ transitions ascertains conclusions drawn on the $Eu^{III}$ coordination.

## Introduction

Calix[*n*]arenes, or [1$_n$]metacyclophanes, present excellent coordination[1] and extraction[2–4] capabilities, in addition to being adequate platforms for the design of catalysts[5] or optical sensors.[6] They also provide suitable frameworks for the construction of more complex noncovalent structures.[7–9] Central to these applications are (1) the availability of calixarenes in various ring sizes, up to $n = 20$,[10] (2) their capacity to assume different conformations that can be tuned by the nature of the substituents and/or by two- or four-point intramolecular bridging,[11] which leads to controlled luminescent properties[12] and (3) their easy functionalization both at the wide and narrow rims, a versatility that opens perspectives in many fields of chemistry. Our interest in lanthanide complexes with calixarenes lies in the development of bimetallic model molecules for the study of energy transfer processes and magnetic interactions,[13] as well as in the design of lanthanide/actinide extraction systems and luminescent probes. With respect to the latter goals, we, among others, have been focusing on *p-tert*-butylcalix[*n*]arenes fitted with dimethylphosphinoylmethylene pendant groups on the narrow rim (Scheme 1) because the latter are known to be good complexation groups for trivalent lanthanide ions, $Ln^{III}$. In addition, similar hosts bearing diphenylphosphinoylmethylene arms have been previously proposed.[14–16] The smaller macrocyclic receptor derived from calix[4]arene, $B_4bL^4$, adopts a flattened cone conformation. It reacts with lanthanide ions to yield both 1:1 and 1:2 (Ln/L) stable complexes with $Ln^{III}$ ions in acetonitrile; the solvent composition, particularly its water content, influences strongly the solvation state of the macrocyclic edifices as well as their luminescent properties.[17] This macrocycle is also quite convenient for the binding of 3d metal ions.[18] When the number of phenolic units is increased to six to yield $B_6bL^6$, the resulting macrocycle exists as a mixture of conformers in dmso with a time-averaged alternate *in–out* conformation at elevated temperature (405 K) of $C_{6v}$ symmetry. Because of the larger conformational flexibility, both 1:1 and 1:2 complexes with $Ln^{III}$ ions are less stable than the corresponding ones with the

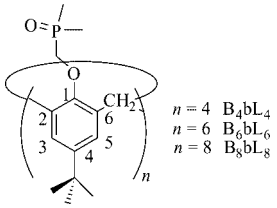
analogous calix[4]arene, but these complexes still display interesting photophysical properties.[19] Liquid–liquid extraction studies have demonstrated the separation ability of $B_4bL^4$ and $B_6bL^6$ for the lighter actinides, as compared to $Ln^{III}$ ions, and the calix[6]arene receptor revealed to be the best extractant.[20] Owing to the large dimension of their annulus, calix[8]arenes are promising receptors both for medium-sized organic compounds[21] and large metal cations; for instance, they can encapsulate up to two $Ln^{III}$ ions in the same molecular edifice.[13,22] For *p*-substituted calix[8]-arenes, the 1:1 versus 2:1 stoichiometry is simply tuned by the strength of the base used to deprotonate the hydroxy groups.[23,24] However, most of the reported complexes have 2:1 stoichiometry,[25,26] whereas 1:2 molecular ratios are less common.[27] The purpose of this paper is to investigate the influence of the narrow rim substitution of *p*-*tert*-butylcalix[8]arene by phosphinoyl groups on the coordination and photophysical properties of both the octamer toward trivalent lanthanide ions and the resulting complexes. In addition, we probe the effect of the coordination strength of the anion with regard to both the stoichiometry of the complexes and the coordination mode of the macrocycle.

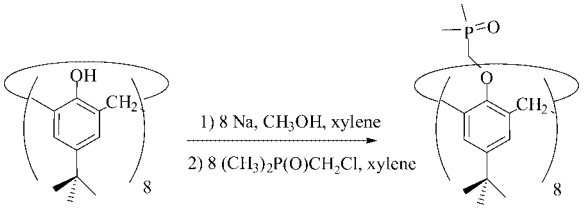


Scheme 1.

## Results and Discussion

### Synthesis and Structural Characterisation of Calixarene $B_8bL^8$ in Solution

The macrocyclic receptor $B_8bL^8$ (Scheme 1) was prepared in 46% yield by a Williamson reaction by refluxing the octasodium derivative of *p*-*tert*-butylcalix[8]arene and chloro(dimethylphosphinoyl)methane in xylene (Scheme 2).



Scheme 2.

The structure of $B_8bL^8$ in a $3.4\times10^{-3}$ M [$D_4$]methanol solution was established by temperature-dependent NMR spectroscopy. At 293 K, the $^{31}P\{^1H\}$ NMR spectrum displays a singlet at $\delta$ = 44.8 ppm, which indicates that the eight phosphorus atoms are equivalent. $^1H$ NMR spectroscopic signals for all protons appear as singlets (Figure 1), except for the $CH_2(P{=}O)$ and $CH_3(P{=}O)$ groups, which generate doublets owing to the coupling with the $^{31}P$ atom.[19,28,29] All $^1H$ and $^{13}C$ NMR spectroscopic data are consistent with a cone conformation,[14,30–32] which suggests a time-averaged molecular structure resulting from fast interconversion between the different conformers. At 213 K, the $^1H$ NMR spectrum is less well-resolved with moderately broadened signals owing to higher solvent viscosity (Figure 1). A double quantum filtered correlation spectroscopic (DQF-COSY) experiment points again to only one conformation for the isomers: the observed correlation peaks can be assigned to (1) $CH_3$ groups bound to the same carbon atom ($\delta$ = 1.36 and 0.82 ppm), (2) aromatic protons belonging to one phenol ring ($\delta$ = 7.36 and 6.56 ppm) and (3) protons from the AB spin system of the eight bridging methylene groups ($\delta$ = 4.3 and 3.9 ppm). Appearance of a correlation peak between the $CH_2$ and $CH_3P{=}O$ groups (see Figure 2) in the rotating frame Overhauser enhancement spectroscopic experiment (ROESY) could be the result of partial inversion, which results from *p*-*tert*-butyl moieties that swing through the annulus. Indeed, two dynamic processes were detected in large calixarenes with substituted phenol groups: macrocyclic ring interconversion and pinched conformer interconversion. The former takes place by way of two different mechanisms: *tert*-butyl-through-the-annulus and oxygen-through-the-annulus pathways,[8,33] The first mechanism, in which the aryl groups swing through the annulus in sequence, always operates in unbridged large calixarenes, as demonstrated for *p*-*tert*-butylcalix[6]arenes.[30,34,35] Alternatively, the presence of sufficiently bulky groups at the narrow rim, as it is the case for $B_8bL^8$, inhibits oxygen-through-the-annulus interconversion so that ring interconversion can only proceed by the *tert*-butyl-through-the-annulus route.

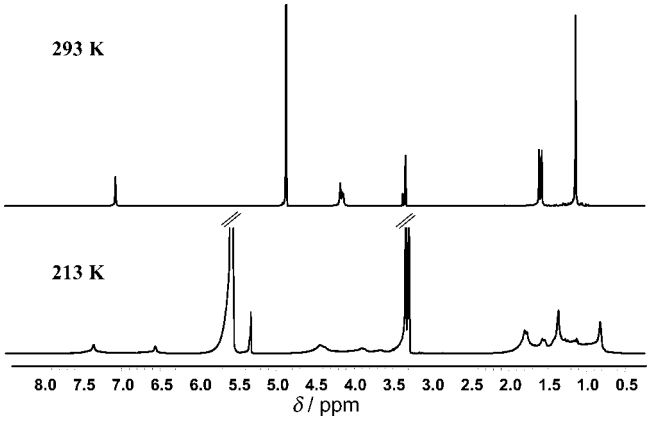


Figure 1. $^1H$ NMR spectra of the $3.4\times10^{-3}$ M solution of $B_8bL^8$ in $CD_3OD$ at (a) 293 and (b) 213 K.

$^1H$ and $^{31}P$ NMR spectroscopic data were obtained over a wide temperature range (193–353 K; Figure S1, Supporting Information). At the lowest temperature, the conformational interconversion processes are not yet completely frozen despite the observation of two distinct resonances in the $^{31}P$ spectrum. For $T \geq 293$ K, sharp, well-resolved reso-

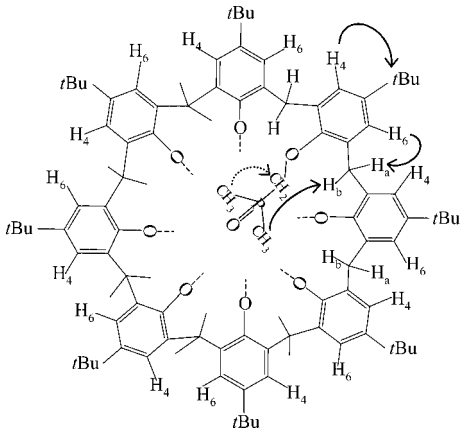

Figure 2. ROESY contacts observed at 213 K for $B_8bL^8$ in $CD_3OD$: plain arrows are for the ligand alone and dotted arrows for the solution containing one equivalent of $Lu(Otf)_3$.

nances are recorded in both the $^1H$ and $^{31}P$ NMR spectra. This reveals that the activation barrier for macrocyclic ring interconversion is low.

### Interaction of $B_8bL^8$ with $Ln^{III}$ in Methanol

To obtain information on the interaction between $B_8bL^8$ and lanthanide ions, a $8.1–8.6 \times 10^{-4}$ M solution of the macrocycle in MeOH was titrated with $Ln(OTf)_3 \cdot xH_2O$ (Ln = La, Eu, Lu; typically $10^{-4}$ M, $x = 10$ for La, 7 for Eu and 9 for Lu) and $Ln(NO_3)_3 \cdot xH_2O$ (Ln = La, Eu; typically $10^{-3}$ M, $x = 4$ for Eu and 3 for Lu) up to a ratio of $R = [Ln^{III}]_{tot}/[B_8bL^8]_{tot} = 4.5$. Titrations were first monitored by electrospray mass spectrometry (ESMS, see Tables S1 and S2, Supporting Information). For $R \leq 1$, both 1:2 $[Eu(B_8bL^8)_2]^{3+}$ ($m/z$ = 1396.40, calcd. 1396.22) and 1:1 $[Eu(B_8bL^8)(CH_3COOH)]^{3+}$ ($m/z$ = 743.32, calcd. 743.45) species are observed. An increase in $R$ leads to the disappearance of the 1:2 species. When $R$ reaches 2, the main species is $[Eu(B_8bL^8)(Otf)]^{2+}$ ($m/z$ = 1159.24, calcd. 1158.95), but $[Eu(B_8bL^8)]^{3+}$ ($m/z$ = 723.20, calcd. 723.44) is also observed. No signal from the free ligand is detected in the latter case, which points to the formation of a stable 1:1 species. Titration of the macrocycle solution with $Eu(NO_3)_3 \cdot 4H_2O$ shows a similar behaviour, except for the stronger coordination of the counterions, as demonstrated by the presence of $[Eu(B_8bL^8)(NO_3)]^{2+}$ ($m/z$ = 1114.97, calcd. 1115.49), $[Eu(B_8bL^8)(NO_3)(H_2O)_2]^{2+}$ ($m/z$ = 1133.44, calcd. 1134.16) and $[Eu(B_8bL^8)(NO_3)(CH_3COOH)]^{2+}$ ($m/z$ = 1145.47, calcd. 1145.52) species for $R = 1$ (Table S2, Supporting Information). Formation of species with stoichiometric ratio $Eu/B_8bL^8$ of 2:1 was not detected in this case, probably owing to its low solubility; a precipitate starts to appear when $R > 1$.

The titrations were repeated with UV/Vis monitoring, starting from concentrations of $1.1 \times 10^{-4}$ M for $B_8bL^8$ and adding lanthanide triflates with concentrations of $\approx 8 \times 10^{-3}$ M. Plots of absorbance versus $R$ evidenced at least two complexed species (Figure S2, Supporting Information) and factor analysis revealed four absorbing species ($B_8bL^8$, 1:2, 1:1, 2:1), which could be satisfactorily fitted to the following model (Table 1):

$Ln^{3+} + B_8bL^8 \rightarrow [Ln(B_8bL^8)]^{3+}$ $\log K_{11}$

$Ln^{3+} + 2\ B_8bL^8 \rightarrow [Ln(B_8bL^8)_2]^{3+}$ $\log K_{12}$

$2\ Ln^{3+} + B_8bL^8 \rightarrow [Ln_2(B_8bL^8)]^{6+}$ $\log K_{21}$

Table 1. Log $K_{ij}$ values ($\pm$ 0.2) extracted from the titration of $B_8bL^8$ with lanthanide triflates in methanol, at 293 K.

| Ln | $\log K_{12}$ | $\log K_{11}$ | $\log K_{21}$ |
|---|---|---|---|
| La | 4.4 | 6.9 | 4.9 |
| Eu | 4.3 | 7.2 | 5.0 |
| Lu | 5.6 | 7.4 | 4.9 |

Because the UV/Vis spectra of the complexes are heavily correlated, these data should be taken as a first estimate. The stability constants obtained are smaller than the ones reported for $B_4bL^4$[17] and $B_6bL^6$[19] as a consequence of the smaller degree of preorganisation of the octamer. The $K_{11}$ values are about two orders of magnitude larger than the $K_{12}$ and $K_{21}$ constants. Calculation of the speciation of $Eu^{III}$ with these data and a total ligand concentration between $10^{-4}$ and $10^{-3}$ M shows that for $R = 1$, the 1:1 species is always largely predominant (> 93%). For all the concentrations at which the titrations have been conducted, and for $R$ in the range 0.5–2.0, the concentration of the bimetallic 2:1 complex remains extremely small.

Finally, the speciation was confirmed by $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopic titration at 293 K. The free ligand, 1:2 and 1:1 species coexist in $3.3 \times 10^{-3}$ M methanolic solutions of $B_8bL^8$ that contain lutetium triflate when $R < 1$ (Figure 3). For $1 < R < 1.6$, the minor 1:2 species disappears whereas the 1:1 species grows until $R > 1.6$. Together with ESMS and spectrophotometric titration data, this can be interpreted as the formation of a thermodynamically stable complex with 1:1 stoichiometry. Coordination through the phosphinoyl groups is established as both the $^1H$ and

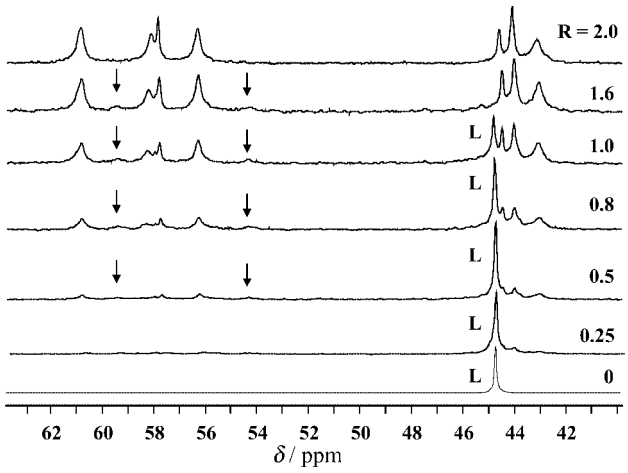

Figure 3. Titration of a $B_8bL^8$ solution ($3.3 \times 10^{-3}$ M) by $Lu(OTf)_3 \cdot 9H_2O$ ($4.5 \times 10^{-2}$ M) in $CD_3OD$ as monitored by $^{31}P\{^1H\}$ NMR spectroscopy at 293 K, $R = [Lu^{III}]_t/[B_8bL^8]_t$; arrows point to the signal of the minor 1:2 species, while L denotes the free ligand signals.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$^{31}P\{^1H\}$ NMR signals from the phosphinoyl arms are affected by the complexation. Two $^{31}P$ signals are observed, shifted from 44.6 ppm for the free ligand to 43.7 ppm ($\Delta\delta$ = 0.9 ppm) and 58.5 ppm ($\Delta\delta$ = 13.8 ppm) for the 1:1 lutetium complex. This points to two different chemical environments for the phosphorus atoms in a 1:1 ratio, which suggests that the octamer has four coordinated and four uncoordinated arms. This was further ascertained by temperature-dependent 1D and 2D NMR experiments described in the next section. Taking into account all the results obtained during the titrations, one can conclude that the ESMS, UV/Vis and NMR spectroscopic data are consistent and point to the predominance of the 1:1 species.

### Solution Structure of the 1:1 Complexes with $Lu(OTf)_3$ and $Lu(NO_3)_3$

The $^1H$ NMR spectrum of a $B_8bL^8$ solution $3.3\times10^{-3}$ M in [$D_4$]methanol containing one equivalent of lutetium triflate (Figure 4) displays three typical groups of resonances at 213 K: (1) four signals between 6.6 and 7.6 ppm from the 16 aromatic protons, (2) three pairs of doublets in the range 3.8 to 4.7 ppm from the eight bridging methylene groups and two signals from eight ($CH_2$)P=O groups, and (3) two groups of signals between 0.8 and 1.5 ppm for methylic protons and four doublets from($CH_3$)P=O units in the range 2.1 to 1.6 ppm, which correspond to 24 and 16 protons, respectively. In the DQF-COSY spectrum at the same temperature (Figure S3, Supporting Information) the strongest cross peaks arise from methylene groups. For instance, cross peaks in the aromatic region correspond to protons 3 and 5 (see Scheme 1 for the numbering) for both sets of resonances ($\delta$ = 7.52/7.46 ppm and 6.73/6.56 ppm), which points to two different types of phenol rings. The ratio of their integrated intensities (1:1) and the remarkable difference in the chemical shift ($\Delta$ = 0.85 ppm) fully back the interpretation that four phosphinoyl arms are coordinated. Moreover, the NOE effect evidenced at 293 K between $CH_2P$=O ($\delta$ =4.58 ppm) and $CH_3P$=O ($\delta$ =1.75 ppm) is consistent with a bent conformation of the phosphinoyl arm at this temperature, at which the unbound octamer is conformationally most labile, again pointing to the coordination of the pendant arms.

The methylene resonances give important information on the conformation of the bound calixarene because the $\Delta\delta$ shifts can be used for differentiating between *sin* or *anti* aromatic protons.[30] Assignment of axial and equatorial protons is dependent on DQF-COSY experiments (Figure 5, Table 2). Three types of resonances from the Ar-$CH_2$Ar methylene protons ($H^a$, $H^b$, $H^c$) with intensity ratios 6:4:6 are observed at 213 K in the presence of triflate; two of them appear as pairs of doublets ($H^a$ and $H^c$). The presence of distinct signals for both equatorial and axial protons for every $CH_2$ group points to a cone-like conformation of the corresponding phenolic units.[32] Comparison of the chemical shift differences ($\Delta\delta$ = ≈ 0.6 for $H^a$, ≈ 0.1 ppm for $H^b$ and $H^c$) with those obtained for unbound $B_8bL^8$ ($\delta$ =0.6 ppm) and the anhydrous $[LaB_4bL^4]^{3+}$ complex ($\delta$ =0.15 ppm)[17] leads to the assignment of the signals corresponding to the largest $\Delta\delta$ value to the uncoordinated units of the macrocycle. In favour of this assignment is the fact that unusually small $\Delta\delta$ values are observed when a small guest − in our case the lanthanide ion − enters a calixarene cavity.[15] Upon increasing the temperature to 293 K, methylene bridges give rise to four pairs of resonances ($H^{a'}$, $H^{b'}$, $H^{c'}$, $H^{d'}$) in the ratio 4:4:4:4; two of them ($H^b$, $H^c$) appear as pairs of doublets whereas the other two ($H^a$, $H^d$) feature three components. Finally, two and three signals from $CH_2P$=O in a ratio 4:4 and 4:2:2 were observed at 213 and

293 K, respectively. These data can be interpreted by a proposed structure (Figure 6a) in which coordination occurs through the central four phosphinoyl pendant arms and possibly implies binding by the phenolic units. Interconversion processes through annulus are then more difficult and the NMR spectrum at room temperature features sharper signals. Alternatively, the coordination sphere may be completed by methanol molecules. Because triflate is very weakly coordinating in methanol,[36] it is reasonable to surmise that this counterion only interacts in the second coordination sphere.

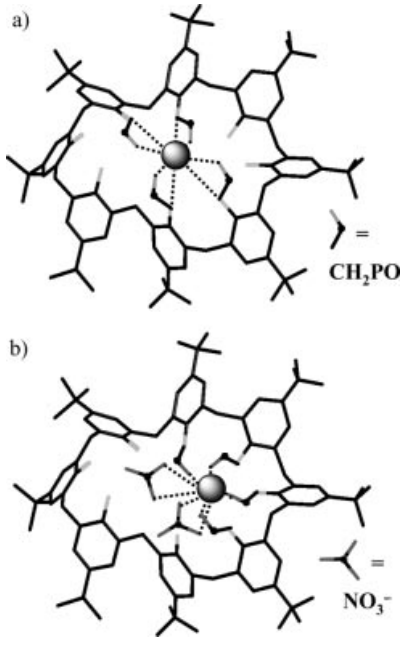

Figure 6. Schematic representation of the possible solution structure of the 1:1 complexes with $B_8bL^8$ compatible with NMR spectroscopic data: (a) central coordination involving phenolic groups in the case of the triflate, (b) side complexation in the case of the nitrate. Note that phosphinoyl arms are only shown when coordinating, for the sake of clarity.

Next we tested the influence of nitrate, which is more strongly coordinating than triflate,[36] by measuring the spectra of 1:1 solutions of $B_8bL^8$ and lutetium nitrate at a concentration of $1.9 \times 10^{-3}$ M. At 213 K, both the 1D (Figure 5) and 2D (Figure S4, Supporting Information) spectra are quite similar to the ones discussed above for lutetium triflate with the exception of the methylene bridge region, which displays only two types of signals instead of three. These signals appear as a pair of doublets (Hα, $\Delta\delta$ = 0.6 ppm) and a singlet ($H_\beta$, $\Delta\delta$ = 0.1 ppm) in a ratio 5:3. By comparing the $\Delta\delta$ values with those obtained for lutetium triflate, this ratio may be explained as arising from the presence of three methylene bridges connecting four units of the octamer with coordinated pendant arms (smaller $\Delta\delta$) and five methylene bridges connecting the other four units with uncoordinated arms (larger $\Delta\delta$). In line with this interpretation is the observation of three resonances in a ratio 4:2:2 for the $CH_2(P{=}O)$ methylene groups; in view of the fluxionality of the calix[8]arene, the uncoordinated pendants experience two different chemical environments.

In contrast, the spectrum recorded at 293 K is remarkably different from the one for the triflate complex: much broader and unresolved signals in the methylene region are observed. The two distinguishable pairs of signals from the methylene groups $H^{\alpha'}$ and $H^{\beta'}$ have average $\Delta\delta \approx 0.4$ ppm, which is in line with faster chemical exchanges on the NMR timescale. Only one averaged resonance is seen for the eight $CH_2P{=}O$ units. Interpretation of these data can be made by reference to a complex with the parent *p-tert*-butylcalix[8]arene $H_8L^8$, $[Eu(H_6L^8)(NO_3)(DMF)_4]$, in which both nitrate and calixarene act as bidentate ligands.[24] In our case, in view of the strong coordinating nature of the pendant arms and of their length and flexibility, one could postulate a "side" coordination as well, but involving one (or two) bidentate nitrate anion(s), as the mono- (85%) and bis(nitrato) (15%) complexes are the predominant species in $Ln(NO_3)_3$ methanol solutions at the concentrations used in this work.[37] Therefore, the above-described data may be interpreted by considering a side coordination of the lutetium ion by four phosphinoyl arms out of the octamer "cavity" (see Figure 6b). The lutetium ion may not be coordinated as deeply in the macrocycle as in the case of the triflate and, as a consequence, methanol molecules may complete the inner coordination sphere or compete with the

phosphoryl and nitrate groups. In such a model, the system is more fluxional relative to the triflate complex, which explains the average $\Delta\delta$ values observed at room temperature. Consequently, the choice of the counterion, triflate or nitrate, allows the final structure of the lanthanide complexes to be tuned: four phosphinoyl arms are bound in each case but the coordination geometry and the cation orientation in the calixarene cavity depend on the counterion used.

### Isolation and Characterization of the 1:1 and 2:1 $Ln^{III}$ Complexes

The 1:1 and 2:1 $Ln^{III}$ complexes (Ln = La, Eu, Tb, and Lu) evidenced in solution studies could be isolated from stoichiometric solutions of $B_8bL^8$ ($\approx 3.4 \times 10^{-3}$ M) and lanthanide triflate or nitrate in methanol. For $Eu^{III}$, elemental analyses correspond to formulae $Eu(OTf)_3(B_8bL^8)\cdot 13H_2O$ and $Eu_2(B_8bL^8)(NO_3)_6\cdot H_2O$. Unfortunately, no single crystals of X-ray quality could be obtained, despite numerous trials. The $^1H$ NMR spectra of a methanolic solution of the isolated 1:1 and 2:1 lutetium complexes are similar to the spectra obtained for a solution of $B_8bL^8$ containing one equivalent of lutetium triflate and nitrate, respectively (Figure S5, Supporting Information). The low solubility of these complexes, particularly the lutetium 2:1 species, required heating the solutions and high dilution; as a consequence, the $^1H$ NMR spectra contain traces attributed to the free octamer, which reveals partial decomplexation. High resolution MS (FAB) data for 1:1 (Lu) and 2:1 (Tb) complexes in methanol are shown in Table 3 and Figure S6 (Supporting Information). For the bimetallic complex, only peaks corresponding to a 1:1 species are observed, in line with the corresponding NMR spectroscopic data and pointing again to the low stability of the 2:1 species in solution.

Table 3. Molecular peaks and main fragments observed by MS (FAB) analysis of $Lu(B_8bL^8)(OTf)_3\cdot 13H_2O$ and $Tb_2(B_8bL^8)(NO_3)_6\cdot H_2O$.

The IR spectra of the 1:1 and 2:1 $Eu^{III}$ complexes (Figure S7, Supporting Information) reveal bathochromic shifts of 25 and 40 $cm^{-1}$, respectively, relative to that of the free ligand, for the ν(P=O) vibration; these shifts confirm the coordination of the macrocycle by the metal ion. A similar redshift (35 $cm^{-1}$) was reported for a 1:2 (Ln/L) lanthanide complex with $B_4bL^4$.[17] Typical vibrations of $CH_2$ groups are observed in the spectral ranges 750 to 760, 935 to 945 and 1290 to 1295 $cm^{-1}$, and they are assigned to out-of-plane C–H twisting, rocking and wagging modes, respectively. Anion vibrations were assigned by comparison with $Eu(OTf)_3\cdot 5H_2O$ and $Eu(NO_3)_3\cdot 6H_2O$. The presence of both coordinated and uncoordinated triflate groups is consequently ascertained for the $Eu^{III}$ 1:1 complex. In the 1100 to 1300 $cm^{-1}$ range, higher frequency $\nu(SO_3)$ and $\nu(CF_3)$ modes of this complex overlap to form a broad structured band that remarkably differs from the corresponding bands for the triflate salt. The presence of a coordinated triflate anion is also confirmed by the appearance of $\nu_s(SO_3)$ and $\nu_{as}(SO_3)$ modes at 1028 and 1238 $cm^{-1}$, respectively.[38] The latter overlaps with the $\nu_s(CF_3)$ mode. Bands at 1280, 1222 and 1164 $cm^{-1}$ are assigned to the $\nu_{as}(SO_3)$, $\nu_s(CF_3)$ and $\nu_{as}(CF_3)$ modes of uncoordinated triflate. In the FIR range, the intense peak at 638 $cm^{-1}$ and the less intense band at 518 $cm^{-1}$ correspond to the $\delta_s(SO_3)$ and $\delta_{as}(SO_3)$ modes. The integral intensity ratio $\delta_s(SO_3)/\delta_{as}(SO_3)$ is 1.6 and 0.9 for the 1:1 complex and triflate salt, respectively. The bands at 570 and 750 $cm^{-1}$ are associated with $\delta_{as}(CF_3)$ and $\delta_s(CF_3)$ but overlap of the latter with $\delta$(CH) vibrations prevents further intensity analysis. The difference in the intensities of the $\delta(SO_3)$ vibrations, as well as the redshift of the $\delta_{as}(SO_3)$ and $\delta_{as}(CF_3)$ bands for the octamer complex in comparison with corresponding bands for europium triflate are compatible with the presence of two uncoordinated triflate anions in the isolated 1:1 complex.

In the IR spectrum of the 2:1 europium nitrato complex, the characteristic nitrate bands appear at 1510 ($\nu_5$), 1280 ($\nu_1$), 1030 ($\nu_2$), 738 and 755 ($\nu_3$) $cm^{-1}$. The splitting of the two strongest absorptions ($\nu_5$ and $\nu_1$) is ≈ 230 $cm^{-1}$, which indicates bidentate coordination by the europium ion with a relatively strong metal–nitrate interaction.[39] All the nitrate groups appear to be coordinated by the lanthanide ion as no band from the free $NO_3^-$ was detected.

Raman spectra of the 1:1 and 2:1 complexes are in line with the above analysis. In addition, the lower effective cross-section of the Raman scattering, as measured by the area of the $\nu$(CH) modes, observed for the 2:1 complex, indicates less changes in polarizability relative to the 1:1 complex. Finally, the appearance of the $\nu$(–O–$CH_2$–) vibration as a doublet with frequencies 1012 and 1028 $cm^{-1}$ in the 1:1 europium complex, relative to a single band at 1012 $cm^{-1}$ for uncoordinated $B_8bL^8$ may be evidence for coordinated ether O atoms.[17]

### Ligand-Centred Photophysical Properties

The absorption spectrum of $B_8bL^8$ in methanol at 293 K (Figure 7) displays a broad band with a maximum at

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

43500 $cm^{-1}$ (230 nm, $\varepsilon$ = 8995 $M^{-1}cm^{-1}$), assigned to a transition mainly involving orbitals located on the phosphinoyl groups, and a less intense and split band at 37170 and 36230 $cm^{-1}$ (276 and 279 nm, $\varepsilon$ = 2910 and 2720 $M^{-1}cm^{-1}$) for transitions mainly located on the phenyl rings. These absorption bands are not affected by the complexation. Finally, a very weak band is observed around 27600 $cm^{-1}$ (360 nm, $\varepsilon$ = 110 $M^{-1}cm^{-1}$), which sustains a large bathochromic shift (≈ 3500 $cm^{-1}$) upon complexation to $Ln^{III}$. Because the energy of this band is independent of the lanthanide ion, it can be assigned to a transition connected with an intraligand charge transfer (ILCT) state. The latter is seen at 27000 $cm^{-1}$ in the excitation spectrum of a powdered sample of $B_8bL^8$ at 293 K, in addition to a band centred at 32800 $cm^{-1}$ and attributed to the $^1\pi\pi^*$ level (Figure S8, Supporting Information). The redshift of the ILCT band in the absorption spectra of solutions containing $B_8bL^8$ and one equivalent of lanthanide salt confirms the complex formation.[40] A similar weak ILCT band was reported at 27030 $cm^{-1}$ in the excitation spectrum of europium benzoate.[41] Moreover, it is known that ILCT energy depends on the position of the carboxylate group in heterocyclic pyridine–carboxylic ligands containing nonbonding electron pairs.[42] According to these data, the large intensity of the ILCT band in complexes with $B_8bL^8$, as well as its strong redshift upon complexation, are typical of a charge transfer from the phenol ring to the oxygen atom of the phosphinoyl groups. Because the ILCT band of the complexes lies at lower energy and is more intense than the corresponding band for the uncoordinated ligand, the transition dipole moment is larger for the complexes.[43]

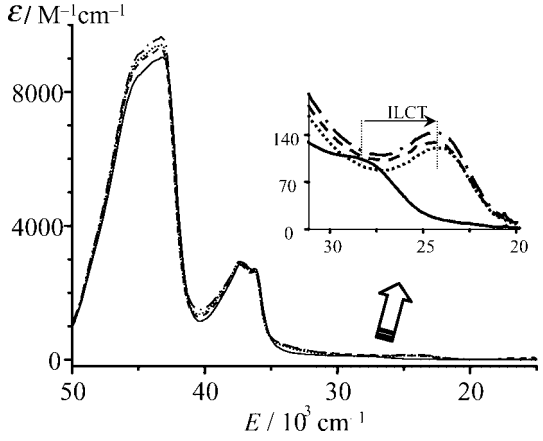

Figure 7. Absorption spectra of $B_8bL^8$ (1.7 × $10^{-4}$ M) in MeOH at 293 K (black curves) with 1 equiv. of $Lu(OTf)_3$ (dot), $Eu(OTf)_3$ (dash) and 2 equiv. of $Eu(OTf)_3$ (dash-dot). The inset zooms on the intraligand charge transfer absorption.

According to emission spectra at 77 K, the $^1\pi\pi^*$ state of a powdered sample of the octameric ligand is located at 32800 $cm^{-1}$. The singlet state energy is not affected by the complexation in the $Lu^{III}$ 1:1 complex but sustains a slight blueshift in the 2:1 complex (+320 $cm^{-1}$). The triplet state emission occurs at 23600 $cm^{-1}$ for $B_8bL^8$ and is only seen for the $Lu^{III}$ complexes, for which it is blueshifted by +400 and +130 $cm^{-1}$ for the 1:1 and 2:1 complexes, respectively. It displays a fine structure with vibronic progressions of ≈ 1470 $cm^{-1}$ (1:1) and 1280 $cm^{-1}$ (2:1) which can be attributed to the vibrational mode of the phenol moieties and nitrate groups, respectively (Figure S9, Supporting Information). The luminescence decay associated with the $^3\pi\pi^*$ state of $B_8bL^8$ is a single exponential function corresponding to a lifetime of 2.61 ms which increases to 3.5–3.6 ms upon complexation. The energy gap $\Delta E(^3\pi\pi^* - {}^1\pi\pi^*)$ amounts to ≈ 8450 and 9150 $cm^{-1}$ (0-phonon transitions) for the investigated 1:1 and 2:1 lutetium complexes, respectively, which is not quite optimum for an efficient ISC.[44] The $^3\pi\pi^*$-to-metal energy transfer efficiency also depends on the energy gap between the feeding triplet state and the accepting $Ln^{III}$ levels. In our case, it appears to be adequate for $Tb^{III}$, with $\Delta E(^3\pi\pi^* - {}^5D_4)$ ≈ 3600–3800 $cm^{-1}$, but somewhat less well-suited for $Eu^{III}$, with $\Delta E(^3\pi\pi^* - {}^5D_0)$ ≈ 6800–7000 $cm^{-1}$.

The excitation spectra of the luminescent lanthanide complexes contain typical broad bands arising from ligand levels, which confirm the energy transfer from coordinated $B_8bL^8$ to $Ln^{III}$, and narrow and characteristic lines from the metal ions. Comparison of the excitation spectra of the 1:1 europium and terbium complexes at 77 K reveals an additional intense broad band centred at 24200 $cm^{-1}$ and expanding to 21400 $cm^{-1}$ in the spectrum of the former, which is assigned to a ligand-to-metal charge transfer (LMCT) band (Figure 8). The strong intensity of this LMCT band is uncommon and could be produced by intensity stealing as the LMCT and ILCT states overlap. A weak band assigned to the LMCT state was also found in the excitation spectrum of the $Eu^{III}$ 2:1 complex with a low-energy edge at 21800 $cm^{-1}$ at 77 K (Figure S10, Supporting Information). The broad band observed in the range 26000 to 28000 $cm^{-1}$ for the 2:1 $Tb^{III}$ complex is assigned to an f–d transition. The optical electronegativity[45] of the ligand in the $Eu^{III}$ 1:1 and 2:1 complexes can be calculated from the energy of the LMCT band and amounts to $\chi_L$ = 2.80 and 2.78, respectively. The slightly smaller $\chi_L$ value for the 2:1 complex is caused by the presence of coordinated nitrate groups. It has indeed been found for mixed-ligand complexes that ligands with high optical electronegativity

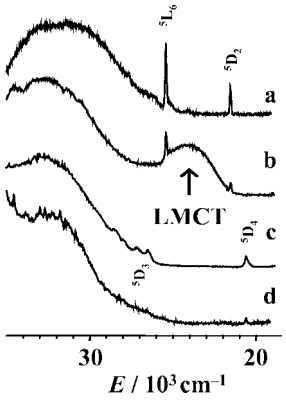

Figure 8. Normalized excitation spectra of the 1:1 powdered complexes with $Eu^{III}$ (a, b) and $Tb^{III}$ (c, d) at 293 K (a, c) and 77 K (b, d). Analysing wavelength set at 612 ($Eu^{III}$) and 545 ($Tb^{III}$) nm, respectively.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

weaken the metal–ligand interaction of the other ligands with lower $\chi_L$ values.[46,47] Therefore, when nitrate, with high optical electronegativity and low polarizability, is coordinated in the 2:1 $Eu^{III}$ complex, the interaction between the metal ion and the calixarene is weakened, henceforth the smaller intensity of the LMCT band. In absence of nitrate, which is the case for the 1:1 complex, the Eu–$B_8bL^8$ interaction is larger, which leads to a mixing between the ILCT and LMCT states and a concomitant reduction in the efficiency of the excitation of $Eu^{III}$ by the ligand states. Finally, by using the $\chi_L$ values found for $B_8bL^8$, the energy of the LMCT state in the terbium complexes can be estimated to be larger than 51000 $cm^{-1}$.

### Metal-Centred Photophysical Properties in the Solid State

The $^5D_0 \rightarrow {}^7F_J$ transitions of the 1:1 and 2:1 europium complexes recorded at 77 K under broad band excitation display a maximum number of Stark components, which points to low site symmetry (Figure 9; see listing of crystal-field splitting in Table S3, Supporting Information). The integrated intensities of the $^5D_0 \rightarrow {}^7F_J$ transitions relative to $^5D_0 \rightarrow {}^7F_1$, 0.06, 2.28, 0.14 (1:1 complex) and 0.09, 2.55, 0.34 (2:1 complex) for $J$ = 0, 2, 4, respectively, are similar for the two types of complexes.

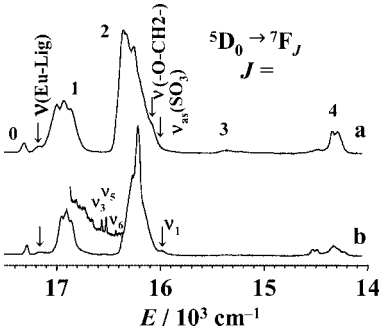

Figure 9. Luminescence spectra of 1:1 (a) and 2:1 (b) europium complexes at 77 K.

Data relevant to the 2:1 complex will first be discussed. The excitation profile of the $^5D_0 \leftarrow {}^7F_0$ transition obtained upon monitoring the $^5D_0 \rightarrow {}^7F_2$ transition (Figure S11, Supporting Information) is symmetric, narrow (full width at half height, fwhh = 7.6 $cm^{-1}$), and occurs at 17254 $cm^{-1}$ at room temperature and at 17242 $cm^{-1}$ at 10 K. This points to a very similar chemical environment for the two $Eu^{III}$ ions, a fact which is further ascertained by the identical emission spectra obtained upon selective laser excitation through the 0–0 band profile (Figure S12, Supporting Information). Moreover, emission from the Eu($^5D_1$) level could also be obtained at 10 K, which is typical of nitrato complexes (Figure S13, Supporting Information). A number of vibronic satellites related to ligand vibrations and associated with the $^5D_0 \rightarrow {}^7F_J$ ($J$ = 0, 1, and 2) transitions are observed in both excitation and emission spectra. At 10 K, we denote the following satellites (see Figure 9): (1) $\nu$(Eu–Lig) with frequencies 195 and 405 $cm^{-1}$ in the range 17400 to 16850 $cm^{-1}$, (2) $\nu_5(NO_3^-)$, $\nu_3(NO_3^-)$ and $\nu_6(NO_3^-)$ around ca. 705, 740 and 820 $cm^{-1}$, respectively, in the range 16420 to 16530 $cm^{-1}$, (3) vibronic repetition of the $^5D_0 \rightarrow {}^7F_1$ transition with frequency 195 $cm^{-1}$ in the range 16800 to 16450 $cm^{-1}$, (4) two stretching vibrations $\nu_1(NO_3^-)$ with frequencies 1280 and 1315 $cm^{-1}$ attributed to nonequivalent nitrates, in the range 15960 to 15930 $cm^{-1}$. In the excitation spectrum, vibronic sidebands appear on the $^5D_2 \leftarrow {}^7F_0$ transition with frequencies 200 (Ln–Lig), 670 ($\delta_{ring}$), 940 (out-of-plane C–H rocking mode), 1020 [$\nu$(–O–$CH_2$–)], 1120 [$\nu$(P=O)] and 1480 $cm^{-1}$ ($\nu_{ring}$). These data confirm the coordination of the P=O groups, which is in line with ES-MS, NMR, and IR data; they also indicate the presence of different types of coordinated nitrate groups. Furthermore, the luminescence decays of the Eu($^5D_0$) and Tb($^5D_4$) levels are single exponential functions (Table 4). They are long enough to ascertain the absence of water molecules in the inner coordination sphere of the lanthanide ion, the latter is protected from such an interaction by the coordination of nitrate ions. The lifetimes vary only slightly with temperature, which points to a small influence of temperature-dependent nonradiative deactivation processes.

Table 4. Lifetimes (ms) of the metal-centred luminescence upon ligand excitation of powdered samples of $Eu^{III}$ and $Tb^{III}$ 1:1 and 2:1 complexes with $B_8bL^8$ in the solid state (ss) and of a $2 \times 10^{-3}$ M solutions (sol) in methanol ($\nu_{exc}$ = 37040 $cm^{-1}$). Standard deviations are given in parentheses.

| T/K | Sample | Eu 1:1 (OTf) | Eu 1:1 ($NO_3$) | Eu 2:1 ($NO_3$) | Tb 1:1 (OTf) | Tb 1:1 ($NO_3$) | Tb 2:1 ($NO_3$) |
|---|---|---|---|---|---|---|---|
| 10 | ss | 1.27(1), 72% 0.39(1), 38% | | 1.62(3) | – | | – |
| 77 | ss | 1.18(4) | | 1.38(2) | 1.35(2) | | 1.93(4) |
| | sol | 1.11(1), 62% 0.5(3), 38% | 1.28(4) | | 1.72(2) | 1.72(2) | |
| 295 | ss | 1.09(2) 53% 0.22(3), 47% | | 1.29(1) | 1.59(1) | | 1.66(3) |
| | sol | 0.93(2), 58% 0.30(2), 42% | 1.10(2) | | 1.52(3) | 1.66(3) | |

Relative to the 2:1 complex, the $^5D_0 \leftarrow {}^7F_0$ transition of the 1:1 species is broader (fwhh ≈ 38 $cm^{-1}$) and weaker. It has a maximum around 17280 $cm^{-1}$ at 293 K and features at least three distinct components separated by about 20 $cm^{-1}$. Such large energy differences point to the presence of differently coordinated europium ions. The analysis could not, however, be pursued further; the very small intensity of the 0–0 transition prevented the selective laser excitation of the various components. Luminescence lifetime data (Table 4) shed more light on the potential $Eu^{III}$ species present in the complex. While data recorded under low resolution reflect one averaged lifetime for both $Eu^{III}$ and $Tb^{III}$, high-resolution conditions used for $Eu^{III}$ led to double exponential functions. The longer lifetime, which contributes 60–70% to the decay, corresponds to an $Eu^{III}$ environment devoid of O–H vibrations, whereas the shorter lifetime corresponds to a metal ion bound to water molecules. Assuming that the extra quenching corresponding to the shorter lifetime

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

only arises from coordinated water molecules, which is reasonable in view of the elemental analysis, an average hydration number $q \approx 2$ can be estimated. As a result, interpretation of both the $^5D_0 \leftarrow ^7F_0$ excitation profile and the lifetime data leads to postulate that two of the three coordination environments have the same hydration number $q \approx 2$, whereas the third environment has $q \approx 0$. This model is feasible in view of the large conformational mobility of the macrocycle and interaction with triflate anions, as shown below. Vibration satellites are also found in the luminescence spectrum of the $Eu^{III}$ 1:1 complex at 10 K: (1) $\nu$(Eu–Lig) with frequencies 107 and 195 $cm^{-1}$ in the range 17160 to 17070 $cm^{-1}$, (2) $\nu_{as}(SO_3)$ and $\nu_s(CF_3)$ vibrations with frequencies 1260 and 1180 $cm^{-1}$, respectively (16000–16090 $cm^{-1}$), (3) a line with frequency 1025 $cm^{-1}$ (16240–16040 $cm^{-1}$) which is a superposition of $\nu_{as}(SO_3)$ and $\nu$(C–O–$CH_2$–) vibrational modes. The appearance of vibronic satellites corresponding to triflate vibrations ascertains coordination to the europium ion. The presence of two lower frequency $\nu$(Eu–Lig) satellites is in line with the biexponential lifetime obtained and confirms the presence of at least two different chemical environments for $Eu^{III}$. Moreover, lines with frequencies 200 (Eu–Lig), 638 ($OTf^-$), 765 (out-of-plane C–H twist) and 1140 $cm^{-1}$ [$\nu$(P=O)] appear in the excitation spectrum at 77 K as vibronic sidebands of the $^5D_2 \leftarrow ^7F_0$ transition. The presence of the second and fourth lines points to the simultaneous coordination of triflate and phosphinoyl arms of the calixarene. The comparatively large intensity of the vibronic sidebands of the $^5D_0 \rightarrow ^7F_2$ electronic transition in both 1:1 and 2:1 complexes is caused by a resonant vibronic effect in which intensity is borrowed from neighbouring electronic transitions.[48] The intensity of the vibronic interaction is slightly higher in the 1:1 complex, which is judged from the integral intensity of the $^5D_0 \rightarrow ^7F_2$ vibronic sidebands normalized to the intensity of the Stark components of this transition. This observation is in agreement with the presence of a LMCT state in the latter complex and with all the previously discussed data regarding the coordination mode of $B_8bL^8$ in 1:1 complexes.

### Metal-Centred Photophysical Properties in Solution

The luminescence decay of an equimolar solution of europium triflate and $B_8bL^8$ in methanol is biexponential with lifetimes similar to those determined for the powdered 1:1 sample (Table 4). In addition, the emission spectra of these two samples are very alike (Figure S14, Supporting Information). This is in line with NMR and MS data and points to a solution structure of the complex similar to the solid state one. In contrast, a single exponential decay with a lifetime slightly shorter than the one for the powdered 2:1 sample is observed for the equimolar solution of europium nitrate and $B_8bL^8$. The emission spectra of this solution and of a powdered 2:1 sample are quite different: (1) the frequency of the $\nu$(Eu–Lig) vibronic satellite is $\approx 10$ $cm^{-1}$ larger in solution, (2) the Stark components of the hypersensitive $^5D_0 \rightarrow ^7F_2$ transition are very different and (3) the relative intensity of the $^5D_0 \rightarrow ^7F_0$ transition is larger in solution. These data could be explained by a transformation of the 1:1 complex into a 2:1 species upon crystallization, as observed with other calix[8]arenes,[22] whereas an inverse 2:1→1:1 transformation occurs upon dissolution.

The absolute quantum yield of the metal-centred luminescence upon ligand excitation for $B_8L^8$ solutions containing one equivalent of $Eu(OTf)_3$ or $Tb(OTf)_3$ in methanol at 293 K is equal to 0.23 and 0.70%, respectively. These low values could be caused by high-energy vibration quenching in addition to a relatively inefficient intersystem crossing process. The quantum yields are somewhat smaller for the solutions containing nitrate, 0.18% (Eu) and 0.53% (Tb). It is worth noting that the powdered 2:1 europium complex has a much higher luminescence intensity than the 1:1 complex.

## Conclusions

The results reported here allow us to discuss the influence of the calixarene size on the complexation properties toward lanthanide ions. The smallest calix[4]arene analogue, $B_4bL^4$, exists in the cone conformation in organic solution and forms stable 1:1 and 1:2 complexes with $Ln^{III}$ ions ($\log\beta_1 \approx 11$ and $\log\beta_2 \approx 20$ in acetonitrile).[17] When the size is increased to yield $B_6bL^6$, the larger flexibility of the macrocyclic host is reflected in an alternate *in–out* conformation, but complexes with the same stoichiometry form, with similar stability ($\log\beta_1 \approx 10$ and $\log\beta_2 \approx 20$ in acetonitrile).[19] With the larger octamer $B_8bL^8$, the major species that forms in methanol (solubility problems prevented the study in acetonitrile) has a 1:1 stoichiometry, whereas the 1:2 species is hardly detected; a minor 2:1 species also forms and can be isolated in the solid state. Observation of the latter species is consistent with the bimetallic complexes usually isolated with calix[8]arenes but only in the presence of a nitrate counterion because of its bidentate chelating mode. However, the strong coordination ability of the phosphinoyl groups toward lanthanide ions tends to equalize the ligand–$Ln^{III}$ interaction in the 1:1 species with the three receptors ($\log K_{11} \approx 7$ in methanol for $B_8bL^8$ compares favourably with $\log\beta_1 \approx 10$ in acetonitrile for the other macrocycles). With respect to the complexes with $B_6bL^6$, the photophysical properties appear to be less interesting, but they were recorded in a more polar solvent, methanol versus acetonitrile, which prevents strict comparison. However, they are better than with the smallest macrocyclic host, $B_4bL^4$, at least as far as $Eu^{III}$ is concerned. In addition, a correlation was observed between the optical electronegativities of the ligands and the luminescence efficiency, in relationship with the energy of the LMCT states in lanthanide complexes with the investigated calix[8]arene. The coordination ability and optical electronegativity of the counterion used can be considered as an instrument for assembling lanthanide complexes with a predetermined structure. This opens perspectives for the molecular design of new luminescent lanthanide systems with inequivalent ligands. With these

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

data at hand, we are now testing the extraction and separation capabilities of the three calixarene receptors towards both lanthanide and actinide cations.[20]

## Experimental Section

**Starting Materials and General Procedures:** All reagents and solvents were of analytical grade and were used without further purification. Chloro(dimethylphosphinoyl)methane was purchased from Hoechst AG (Germany). Stock solutions of lanthanides were made in freshly boiled, doubly distilled water from the corresponding nitrates and triflates, $Ln(NO_3)_3{\cdot}xH_2O$ ($x$ = 3, 4) and $Ln(OTf)_3{\cdot}xH_2O$ (Ln = La, Eu, Tb, Lu; $x$ = 6–10), prepared from their oxides (Rhône–Poulenc, 99.99%) in the usual way.[49] Concentrations of the solutions were determined by complexometric titrations using a standardized $Na_2H_2EDTA$ solution in urotropine buffered medium and with xylenol orange as indicator.[50] Elemental analyses were performed by the Ilse Beetz Laboratory (96301 Kronach, Germany). ESMS spectra were measured with a Finnigan SSQ 710C spectrometer by using a capillary temperature of 200 °C and acceleration potential of 4.5 kV; $10^{-5}$–$10^{-4}$ M solutions of the free ligand or its complexes dissolved in methanol were infused in a mixture of $CH_3CN/H_2O/HCOOH$ (50:50:1) for the ligand, or pure $CH_3OH$ for the complexes. High resolution MS (FAB) spectra were recorded with an FTMS 4.7T BioApex II spectrometer from Bruker by the MS-Service unit of the University of Fribourg (Switzerland).

**5,11,16,23,29,35,41,47-Octa-*tert*-butyl-49,50,51,52,53,54,55,56-octakis(dimethylphosphinoylmethyleneoxy)calix[8]arene ($B_8bL^8$):** A warm solution of chloro(dimethylphosphinoyl)methane (9.24 g, 73.05 mmol) in xylene (20 mL) was added to fine suspension of octasodium derivative of *p*-*tert*-butylcalix[8]arene in refluxing xylene. The latter was prepared by the addition of Na (0.64 g, 27.89 mmol) to a mixture of *p*-*tert*-butylcalix[8]arene (2.26 g, 1.74 mmol), MeOH (70 mL) and xylene (200 mL), followed by distillation of MeOH and part of the xylene. The resulting mixture was heated at reflux and stirred under an atmosphere of nitrogen for 97 h. After cooling to 50–60 °C, the mother liquor was separated by centrifugation, and the precipitate was washed with warm (40–50 °C) xylene (5 × 25 mL) and dichloromethane (150 mL, stirring at room temp. for 2 h). After filtration, the white solid residue (3.73 g) was washed with distilled water (8 × 60 mL), separated by centrifugation and redissolved in MeOH (200 mL). Concentrated HCl (2 mL) was added, the transparent colourless methanol solution was filtered and methanol was evaporated. The residue was washed with water (7 × 80 mL), dried and recrystallised from DMF to give a white solid (1.74 g, 49.5%). $B_8bL^8$ does not melt until 300 °C and is soluble at room temp. in MeOH, EtOH, 2-propanol and chloroform and sparingly soluble at elevated temperatures in DMSO, DMF and acetonitrile; $B_8bL^8$ is insoluble in water, aromatic and aliphatic hydrocarbons (heptane, toluene, xylene), acetone, diethyl ether, THF, acetic acid and diisopropyl ether. It can be recrystallised from DMF, DMSO, and acetonitrile. $^1$H NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 6.98 (s, 16 H, Ar-H), 4.04 (s, 16 H, Ar-$CH_2$-Ar), 3.97 (s, 16 H, $CH_2$P=O), 1.36 [d, $^2J_{HP}$ = 9.2 Hz, 48 H, $(CH_3)_2$PO], 1.04 (s, 72 H, C$(CH_3)_3$]) ppm. $^1$H NMR (400 MHz, $CD_3OD$, 293 K): $\delta$ = 7.07 (s, 16 H, Ar-H), 4.16 (s, 16 H, Ar-$CH_2$-Ar), 4.15 (d, $^2J_{HH}$ = 5.64 Hz, 16 H, $CH_2$P=O), 1.59 [d, $^2J_{HP}$ = 13.32 Hz, 48 H, $(CH_3)_2$P=O], 1.13 (s, 72 H, C$(CH_3)_3$]) ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, [D$_6$]DMSO): $\delta$ = 39.8 ppm. $^{13}$C NMR (100.6 MHz, $CDCl_3$): $\delta$ = 153.2 (d, $^3J_{CP}$ = 11.3 Hz, Ar-*i*), 147.6(s, Ar-*o*), 132.0 (s, Ar-*m*), 126.7 (s, Ar-*p*), 71.5 (d, $J_{CP}$ = 80 Hz, $CH_2$P=O), 34.7(s, tert. C), 31.8 ($CH_3$-*tert*), 29.9 (s, Ar-$CH_2$-Ar), 14.9 (d, $J_{CP}$ = 68.3 Hz, $CH_3$P=O) ppm. IR (KBr disk): $\tilde{\nu}$ = 1171 (P=O) cm$^{-1}$. ESMS: $m/z$ = 1009.98 [$B_8bL^8$ + 2H]$^{2+}$, 2018.35 [$B_8bL^8$ + H]$^{1+}$, 2040.95 [$B_8bL^8$ + Na]$^{1+}$. IR: $\tilde{\nu}$ = 1160 and 1173 (P=O) cm$^{-1}$ (before and after heating for 20 h at 413 K). Raman: $\nu_{ring}$ 1592, 1112 cm$^{-1}$; breathing mode of phenol ring 1008 cm$^{-1}$ for $B_8bL^8{\cdot}5H_2O$. $C_{112}H_{184}O_{24}P_8$ (= $B_8bL^8{\cdot}8H_2O$) (2162.44): calcd. C 62.21, H 8.58, P 11.46; found C 62.34, H 8.99, P 11.42.

**1:1 Complexes:** A methanolic solution (3 mL) of $B_8bL^8$ (0.0215 g, 0.0102 mmol) was heated at 60 °C and a solution of $Ln(OTf)_3{\cdot}xH_2O$ (Ln = La, $x$ = 10; Eu, $x$ = 7; Tb, $x$ = 6; Lu, $x$ = 9; 0.0106 g, 0.0142 mmol for Eu) in MeOH (1.75 mL) was slowly added. A precipitate appeared, and the mixture was stirred for 2 h under an atmosphere of nitrogen at 60 °C. The precipitate was centrifuged, washed repeatedly with MeOH and dried for 48 h at 60 °C and $10^{-2}$ Torr. All compounds are extremely hygroscopic yellow powders. Yields: 62 (La), 58 (Eu), 44 (Tb) and 72% (Lu). $Eu(B_8bL^8)(OTf)_3{\cdot}13H_2O$ (2851.72): calcd. C 48.44, H 6.86, O 21.32, P 8.69, S 3.37; found C 47.43, H 6.26, O 26.15, P 9.02, S 3.51. Formulae of the other complexes were established by $^1$H and $^{31}$P{$^1$H} NMR spectroscopy. HRMS (FAB): $m/z$ = 723.20 [$Eu(B_8bL^8)$]$^{3+}$, 730.99 [$Lu(B_8bL^8)$]$^{3+}$, experimental isotopic distribution patterns matched the calculated ones (Figure S5, Supporting Information). IR: $\tilde{\nu}$ = 1130 (P=O), shift 7, 2, 3 and 9 cm$^{-1}$ for La, Eu, Tb, and Lu, respectively; 635 cm$^{-1}$ ($OTf^-$), shift 1, 2, 1 and 2 for La, Eu, Tb, and Lu, respectively. Raman: $\nu_{ring}$ 1592, 1112 cm$^{-1}$; breathing mode of phenol ring 1012, 1028 cm$^{-1}$ for $Tb(B_8bL^8)$ $(OTf)_3{\cdot}13H_2O$.

**2:1 Complexes:** A MeOH solution (4 mL) of $B_8bL^8$ (0.0226 g; 0.0107 mmol) was heated at 60 °C, and a solution of $Ln(NO_3)_3{\cdot}xH_2O$ (0.0912 g; 0.0222 mmol for Eu; Ln = La, $x$ = 4; Eu, $x$ = 4; Tb, Lu, $x$ = 3) in MeOH (1.4 mL) was added dropwise. A precipitate appeared, and the mixture was stirred for 4 h under an atmosphere of nitrogen at 60 °C. The precipitate was centrifuged, washed with MeOH (2×6 mL) and dried for 48 h at 60 °C and $10^{-2}$ Torr. All the compounds appeared as white hygroscopic powders. Yields: 58 (La), 52 (Eu), 48 (Tb) and 64% (Lu). $Eu_2(B_8bL^8)(NO_3)_6{\cdot}H_2O$ (2712.32): calcd. C 49.60, H 6.32, O 20.62, P 9.13, N 3.10; found C 51.52, H 6.35, O 15.30, P 9.38, N 2.18. Formulae of the other complexes were established by $^1$H and $^{31}$P{$^1$H} NMR experiments. HRMS (FAB): $m/z$ = 723.28 [$Eu(B_8bL^8)$]$^{3+}$, 725.99 [$Tb(B_8bL^8)$]$^{3+}$, experimental isotopic distribution patterns matched the calculated ones. IR: $\tilde{\nu}$ = 1115 (P=O), shift 3, 5 and 10 cm$^{-1}$ for Eu, Tb and Lu, respectively; 735 ($NO_3^-$), shift 3, 5 and 8 cm$^{-1}$ for Eu, Tb and Lu. Raman: $\nu_{ring}$ 1592, 1112 cm$^{-1}$; breathing mode of phenol ring 1036 cm$^{-1}$ for $Lu_2(B_8bL^8)$ $(NO_3)_6{\cdot}H_2O$.

**Analytical and Physicochemical Measurements:** UV/Vis absorption spectra were measured with a Perkin–Elmer Lambda 900 spectrometer with the use of quartz Suprasil® cells of 0.2- and 1-cm path length. Reflectance IR spectra were obtained from powdered samples with a Perkin–Elmer Spectrum One FTIR spectrometer. FIR spectra were recorded with an IFS 13v FTIR spectrometer from Bruker equipped with a pyroelectric DTGS detector. Raman spectra were obtained by means of a Spex 1403 spectrometer with RCA photomultiplier and an argon laser Stabilite 2017 from Spectra-Physics. 1D $^1$H and $^{31}$P{$^1$H} NMR experiments as well as 2D DQF-COSY and ROESY experiments were performed with a Bruker Avance DRX 400 spectrometer. Chemical shifts are given in ppm relative to TMS. All spectra were recorded in $CD_3OD$ (99.9%, Aldrich). Spectrophotometric titrations were performed on a J&M diode-array spectrometer (Tidas series) connected to an external computer in a thermostatted (25.0 ± 0.1 °C) glass-jacketed vessel

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with quartz cells of 0.100 cm path length. In a typical experiment, $B_8bL^8$ ($10^{-4}$ M; 12 mL) was titrated with solutions of the $Ln^{III}$ salt ($10^{-3}$ M); the titrant (0.1 mL) was added by means of a Socorex® micropipette, and spectra were measured after 5 min to equilibrate the solution. The solvent used (MeOH) was of spectroscopic grade (Fluka AG, Buchs, Switzerland). Factor analysis[51] and mathematical treatment of the spectrophotometric data were performed with the SPECFIT[52,53] program.

Low-resolution luminescence measurements (spectra and lifetimes) were recorded with a Fluorolog FL 3–22 spectrometer from Spex-Jobin–Yvon-Horiba at 293 and 77 K and corrected for the instrumental function. Emission and excitation spectra of solutions were measured in 1-cm path length quartz Suprasil cell. The temperature was kept constant by using a FL-1027 thermostatted cell holder connected to a water bath. Phosphorescence lifetimes ($\tau$, averages of at least three measurements) were measured by using a quartz capillary, monitoring the maxima of the emission spectra, and enforcing a 0.05 ms delay. The decays were analysed with Origin 7.0. Quantum yields of $Eu^{III}$- and $Tb^{III}$-centred luminescence were determined relative to those of the corresponding tris(dipicolinates) in 0.2-cm Quartz Suprasil cells.[54] The refractive indices were 1.333 for solutions in water and 1.3288 for solutions in MeOH, $\lambda_{exc}$ = 279 (ref. $A$ = 0.1938) and 276 (sample, $A$ = 0.1911) nm; a filter (320 nm) was inserted to eliminate Raleigh diffusion and second order spectra. High resolution laser-excited luminescence spectra and lifetimes were measured by using published procedures.[55]

**Supporting Information** (see footnote on the first page of this article): Additional tables of the MS spectrum analysis of $B_8bL^8$ containing different equivalents of $Eu(OTf)_3{\cdot}7H_2O$ or $Eu(NO_3)_3{\cdot}4H_2O$, $^1H$, DQF-COSY and ROESY NMR spectroscopic data of the Lu complexes and their HRMS (FAB) spectra. IR and luminescence data of the europium complexes.

## Acknowledgments

# Synthesis, Reactivity and DFT Investigation of a Cationic Zirconocene Benzyl Compound with an Appended Phenyl Group

**Jörg Saßmannshausen,*[a] Anna Track,[a] and Tiago A. D. S. Dias[b]**

*Dedicated to M. L. H. Green*

**Keywords:** Density functional calculations / NMR spectroscopy / Polymerisation

The reaction of $[\eta^5\text{-}C_5H_5\text{-}(\eta^5\text{-}C_5H_4CMe_2C_6H_4Me)Zr(CH_2Ph)_2]$ (**1**) with the cation generating agent $B(C_6F_5)_3$ was studied by means of multinuclear NMR and density functional theory (DFT) methods. The clean reaction in $CD_2Cl_2$ at –60 °C yielded the cationic compound $[\eta^5\text{-}C_5H_5\text{-}(\eta^5\text{:}\eta^1\text{-}C_5H_4\text{-}CR_2C_6H_4R)Zr(\eta^2\text{-}CH_2Ph)]$ (R = Me: **2**, R = H: **3**), with a tolyl moiety coordinated to the cationic zirconium centre, in addition to the expected $\eta^2$-coordination of the benzyl moiety. Both coordinations were unambiguously assigned by multinuclear one- and two-dimensional NMR spectroscopy. Detailed DFT calculations of congener **3** at the B3LYP level of theory explain the unusual chemical shift of the coordinated atom of the tolyl moiety. Furthermore, detailed electronic analysis (Bader and NBO analysis) were undertaken to ascertain the type of coordination (agostic versus electrostatic) that the tolyl moiety adopts.

## Introduction

Group 4 metallocenes are still a point of research interest as they can serve not only as the catalyst in hydrosilylation and hydration reactions, but they are also well known for their ability to polymerise monomers such as ethene, propene and styrene. In the last decades, much effort, both experimentally and theoretically,[1–5] was undertaken to elucidate the role and the nature of the active species in these polymerisation reactions; thus, we have obtained a reasonably good picture of the catalytic process.[6–15] The interaction of the cationic group 4 metallocene, which is accepted as the active species in the catalytic process, with both the neutral catalytic precursor and the anion has been extensively studied.[6,7,9,14] The role of the solvent has been, by comparison, less investigated. Some time ago, we started to develop suitable models for the role of the solvent and showed by low-temperature NMR studies that arenes can coordinate to the cationic metal centre (compound **4**).[16,17] We were also the first to report the formation of a zirconocene *dication*, such as **5**, which is stabilised by intramolecular phenyl coordination (Scheme 1).[18] Recently, we extended this model and used silicon, instead of carbon, as a bridging atom. Here we noticed the formation of two different compounds: the expected formation of zirconocene compound **6**, which is in equilibrium with inner sphere ion pair **7**.[19] Furthermore, we obtained evidence for the formation of dichloromethane adducts in the case of cationic zirconocene *benzyl* compounds **8a**,**b** and explored the electronic properties by DFT calculations.[20]

As mentioned above, group 4 compounds are also used as catalysts for the polymerisation of styrene.[21–23] Recently, Jo et al. demonstrated that in the case of *ansa*-titanocene compounds, secondary insertion of styrene, albeit slower than primary insertion, is actually the process that leads to the formation of polystyrene.[24] One of the identified interim products was a metallocene benzyl compound. With this background, we decided to prepare compound **1** as a precursor to cation **2** to address the following: (1) the possible coordination of the pendant tolyl group, and, if this happens, (2) the nature of the coordination mode of the tolyl group (agostic versus electrostatic). To demonstrate the usability of our model, we firstly report the DFT calculations of **3**, and secondly we discuss the experimentally obtained NMR spectroscopic data of **2** (Scheme 2). Although this might be seen as an unusual way to present the obtained results, we believe that this way not only emphasises the validation of our model systems, but also allows the NMR results to be more easily understood.

## Results and Discussion

### DFT Calculations

#### *Structural Investigation*

To save computational time, we substituted the *para* methyl group of the tolyl moiety in **2** with hydrogen, thus converting the tolyl moiety into a phenyl moiety to give **3** (Scheme 2).

We explored the possibility of different coordination modes of both the benzyl and the phenyl moiety to the cationic zirconium centre, and hence, calculated various conformers of **3**. A thorough scan of the potential energy surface revealed that **3a** is the global minimum of all considered coordination modes and that it is in rapid equilibrium with **3b** as confirmed by low-temperature NMR spectroscopy (Figure 1). Significant bond lengths, angles and dihedral angels are summarised in Table 1; the remaining energetically-higher-lying conformers are summarised in Table 2.

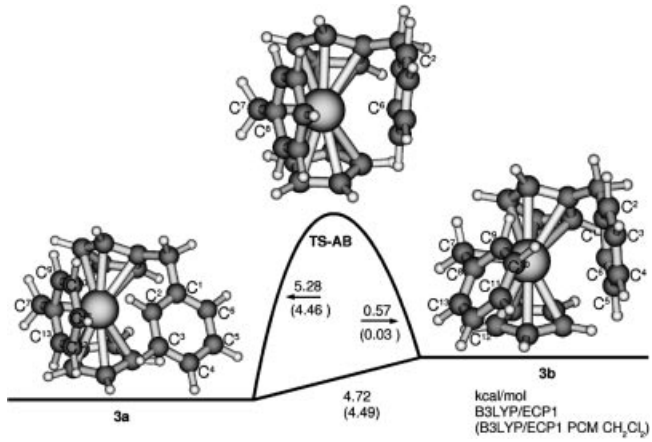

Figure 1. Scan of the potential energy surface of **3**. Values in parenthesis are calculated energies with the PCM solvent model (see text).

Table 1. Significant bond lengths, angles and dihedral angles of **3a** and **3b**.

| | **3a** | **TS-AB** | **3b** |
|---|---|---|---|
| $d$(Zr–C$^7$) | 2.33 Å | 2.32 Å | 2.34 Å |
| $d$(Zr–C$^8$) | 2.71 Å | 2.71 Å | 2.71 Å |
| $d$(Zr–C$^2$) | 2.92 Å | 4.60 Å | |
| $d$(Zr–C$^6$) | – | 3.02 Å | 3.16 Å |
| ∠(Zr–C$^7$–C$^8$) | 87.7° | 88.2° | 87.5° |
| ∠(Zr–C$^7$–C$^8$–C$^9$) | 95.5° | 93.74° | 61.2° |

Here, the benzyl-moiety is bonded in an $\eta^2$ fashion to the zirconium centre and the phenyl moiety is coordinated in the previously described $\eta^1$ mode to the metal.[16,17,25] The Zr–C$^7$–C$^8$–C$^9$ dihedral angle of 95.5° indicates symmetric coordination, with only a small distortion that is probably caused by the coordinated phenyl moiety. As previously reported,[16,19] the hydrogen attached to the coordinated carbon of the phenyl moiety is bent out of the phenyl plane by 9.62°, away from the zirconium metal. A second minimum, **3b**, which is 4.72 kcal/mol higher in energy than **3a**, was obtained by coordination of the second *ortho* carbon of the phenyl moiety to the zirconium centre. Here, the benzyl moiety is slanted significantly (Zr–C$^7$–C$^8$–C$^9$ = 61.2°) towards the metal and adopts an $\eta^3$ coordination to the metal centre. The phenyl moiety, which now points towards the "back" of the metallocene wedge, presumably leaves more space on the "front"; hence, the benzyl moiety

| Energy relative to **3a** [kcal/mol] | 6.65 | 7.18 | 7.38 | |

can adopt a coordination mode more suitable to satisfy the electron-deficient cationic metal centre. A similar coordination of cationic zirconocene benzyl compounds has been observed before.[20] In the absence of coordinating solvents such as dichloromethane, we recently reported the formation of an $\eta^3$-coordinated benzyl moiety to the cationic metallocene centre, compound **8a** ($Zr–C^7–C^8–C^9 = 51.8°$). The addition of one molecule of dichloromethane furnished compound **8b** (cf. Scheme 1). Although in **3b** the electron deficiency of the metal is somehow compensated as a result of the coordination of the phenyl moiety, it is still strong enough to force the benzyl moiety into an $\eta^3$ coordination, albeit the slanting angle is about 10° smaller than that in **8a**. Further exploration of the potential energy surface furnished compounds **3c**–**e**. The last considered structure, **3f**, with no coordination of the benzyl or tolyl moiety, could not be obtained without restricted rotation of the $Zr–CH_2$ bond. In all calculations performed, the benzyl moiety had a strong tendency to move towards the metal centre to yield structures similar to **3c**. To investigate any possible solvent effects, we computed single-point calculations for the optimised energy structures, including the polarisable continuum model (PCM) solvent model implemented in GAUSSIAN03, with dichloromethane as a solvent. In general, the calculated single-point energies are somewhat lower than the solvent-free calculations, and the largest difference was 0.82 kcal/mol (Figure 1, values in parenthesis).

The small energy difference between **3a** and **3b** is important for styrene polymerisation: the incoming monomer (the tolyl group in our model) is attracted by the cationic metal centre and can coordinate to the free coordination site. This coordination can be envisaged for any of the conformers of **3**. However, as the energy barrier of rearrangement between any of the conformers is sufficiently small, the styrene monomer can move into a position so that the C–C double bond adopts a suitable position for insertion to occur.

### *Electronic Structure Investigations*

To ascertain the coordination mode (agostic versus electrostatic) of the phenyl moiety to the zirconium centre, we performed detailed Bader analysis[26] of compounds **3a**,**b**. Scherer and McGrady recently reported a very detailed investigation into the agostic bonding criteria of titanium ethyl compounds and we are using their criteria here to assign the bonding mode of the phenyl group.[27–29] They extended the original definition of agostic bond ("used to discuss the various manifestations of covalent interactions between carbon–hydrogen groups and transition-metal centres in organometallic compounds, in which a hydrogen atom is covalently bonded simultaneously to both a carbon and to a transition-metal atom"[30,31]) to a broader context ("agostic interactions are characterized by the distortion of an organometallic moiety which brings an appended C–H bond into close proximity with the metal centre"[29]), and included heteroatoms such as silicon. Their main criterion for the definition of an agostic bond was the relationship of the electron density distribution $\rho(\boldsymbol{r})$ and the Laplacian of the charge density $\nabla^2\rho(\boldsymbol{r})$ in connection with Bader AIM analysis.[26] To support these so-obtained results, we undertook a detailed NBO analysis to investigate the relevant orbitals that were involved in the coordination of the phenyl moiety.[32]

For **3a**, we found a bonding path and a bond critical point between the zirconium centre and the *ortho* carbon of the phenyl group (BCP1). We did not observe a bonding path or a bond critical point between the zirconium centre and the hydrogen atom bonded to the *ortho* carbon (Figure 2). The electron density at the bond critical point was determined to be $\rho(\boldsymbol{r}) = 0.0171$ and the Laplacian of the charge density $\nabla^2\rho(\boldsymbol{r}) = –0.0136$. For comparison, the bond critical point between the zirconium centre and the $CH_2$ group (BCP2) was $\rho(\boldsymbol{r}) = 0.0812$ and a Laplacian of $\nabla^2\rho(\boldsymbol{r}) = –0.0165$ found. Obviously, as the electron density of BCP1 is lower than the electron density of the BCP2 bond,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

we concluded that rather than a typical Lewis-type bond between the zirconium centre and the *ortho* carbon of the phenyl moiety, a more polarised bonding mode as we have previously described existed.[16]

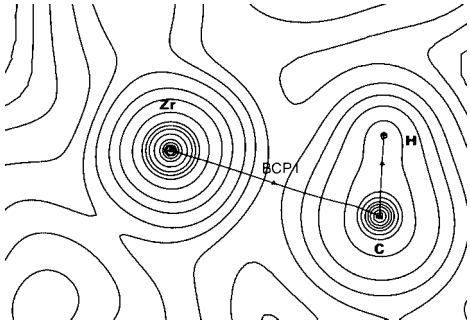

Figure 2. Contour plot of the electron density $\rho(\mathbf{r})$ of **3a**. Plane through zirconium, *ortho* phenyl carbon and hydrogen. Default contour lines used.

NBO analysis revealed electron donation between the CH bonding orbital [$\sigma_{CH} = 0.794(sp^{2.30})_C + 0.607(s)_H$] and the empty Zr orbital of mainly d-character ($LP^*_{Zr} = sd^{3.81}$) with a second-order perturbation energy of 5.12 kcal/mol. For comparison, for the CH bonding orbital in the *para* position of the coordinated carbon, similar values were obtained [$\sigma_{CH} = 0.794(sp^{2.34})_C + 0.608(s)_H$]. Thus, as the second-order perturbation energy for this carbon to zirconium is zero (i.e. no bond), we concluded that although there is a bonding path between the *ortho* carbon and the zirconium centre, the NHO of the two carbons are very similar, which indicates that an electrostatic rather than a covalent bond exists. Coloured plots of the orbitals are available in the Supporting Information (Figures S1–S3).

For **3b**, Bader analysis revealed a bonding path from the zirconium centre to the coordinated *ortho* carbon of the phenyl moiety; however, in this case, a straight line, as in **3a**, was not detected, but a more curved line was found (cf. Figure 3). It appears as if the bonding path first steers towards the bond critical point of the CH bond and just before it reaches this point it turns sharply towards the carbon atom. A similar kind of "conflict catastrophe structure" has been observed before, notably with alkyl titanium chloride cations[33] and for unusual H···π interactions.[34]

The relevant values of the bond critical point (BCP3) were calculated as $\rho(\mathbf{r}) = 0.0114$ and $\nabla^2\rho(\mathbf{r}) = -0.0086$. For comparison, the values of the bond critical point (BCP4) between the zirconium centre and the $CH_2$ group were calculated to be $\rho(\mathbf{r}) = 0.0803$ and $\nabla^2\rho(\mathbf{r}) = -0.0160$, which are similar to BCP2. The values for BCP1 are somewhat higher than the values of BCP3, which indicates a higher electron density between the zirconium centre and the *ortho* carbon of the phenyl moiety in the case of **3a**. NBO analysis of **3b** revealed the expected interaction between the CH bond [$\sigma_{CH} = 0.786(sp^{2.30})_C + 0.618(s)_H$] and the empty orbital ($LP^*_{Zr} = sd^{3.81}$) with a second-order perturbation energy of 3.09 kcal/mol, but furthermore, an interaction between the C–C bond [$\pi_{CC} = 0.675(p)_{C\text{-}ipso} + 0.738(p)_{C\text{-}ortho}$] with an energy of 5.88 kcal/mol (cf. Figures S4–S7). For

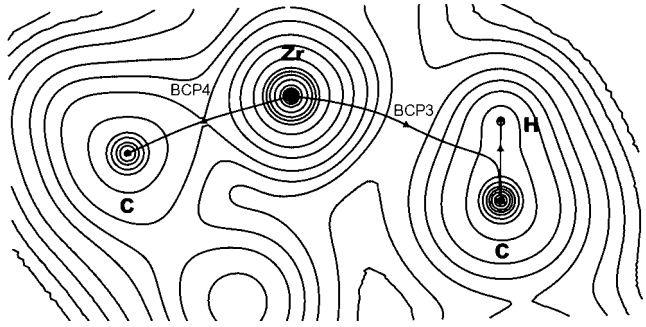

Figure 3. Contour plot of the electron density $\rho(\mathbf{r})$ of **3b**. Plane through zirconium, *ortho*-phenyl carbon and hydrogen. Benzyl $CH_2$ is on the left hand side. Default contour lines used.

comparison, the second C–C bond between the *ipso* and the *ortho* carbon bond [$\pi_{CC} = 0.716(p)_{C\text{-}ipso} + 0.699(p)_{C\text{-}ortho}$] only has an energy of 1.21 kcal/mol. It is tempting to assign this coordination to *agostic coordination*; however, unlike in the cases reported by Scherer and McGrady, we did not find a bonding path between the zirconium centre and the hydrogen atom. It is possible that by replacing the benzyl moiety with a stronger donor this could be shifted towards agostic bonding. Owing to the curvature of the bonding path in **3b**, we concluded that, in this case, a "transition state" somewhere in between a covalent bond and an agostic bond must be present.

### *Chemical Shift Computations*

To verify our computed structures with experimental results, we calculated the chemical shifts of **3a** and **3b**. Because of the low activation barrier between **3a** and **3b** (5.28 kcal/mol), we can assume that both compounds are in equilibrium even at –60 °C. Furthermore, we predict a chemical shift of $\delta_H = 2.64$ ppm for the *ortho* hydrogen of the phenyl moiety. This unusual highfield shift for an aromatic hydrogen can be explained very easily because of the magnetic anisotropy cone of the $\eta^2$-bonded benzyl moiety. This cone points straight to the *ortho* hydrogen of the phenyl moiety, and thus explains the unusual shift for an aromatic hydrogen. Similar observations have been made before.[18] The experimental and calculated shifts are summarised in Table 3.

## Low-Temperature VT-NMR Studies

The reaction between **2** and $B(C_6F_5)_3$ in $CD_2Cl_2$ was monitored by NMR spectroscopy (Figure 4). The spectrum recorded at –60 °C indicates the coordination of both the tolyl and benzyl moieties. The chemical shift of the benzylic $CH_2$ group at $\delta_H = 2.69$ ppm and $\delta_{C\{H\}} = 45.5$ ppm together with the coupling constant $J_{C,H} = 149.0$ Hz clearly indicate an $\eta^2$-coordinated benzyl moiety.[35,36] The chemical shift of the diastereotopic C*Me*$_2$ groups at 1.05 and 1.62 ppm are indicative of coordination of the tolyl moiety. Similar values, albeit with a smaller difference, have been reported before.[18] As predicted, a peak at $\delta_H = 2.33$ ppm

can be assigned to the *ortho* hydrogen of the coordinated tolyl moiety. The predicted equilibrium between **3a** and **3b** could be confirmed by EXSY spectroscopy (Figure 5). The cross peak between $\delta_H$ = 2.33 ppm and $\delta_H \approx$ 7.2 ppm can only be explained by the interconversion between **3a** and **3b**, and fits very well with the predicted values of 2.64 and

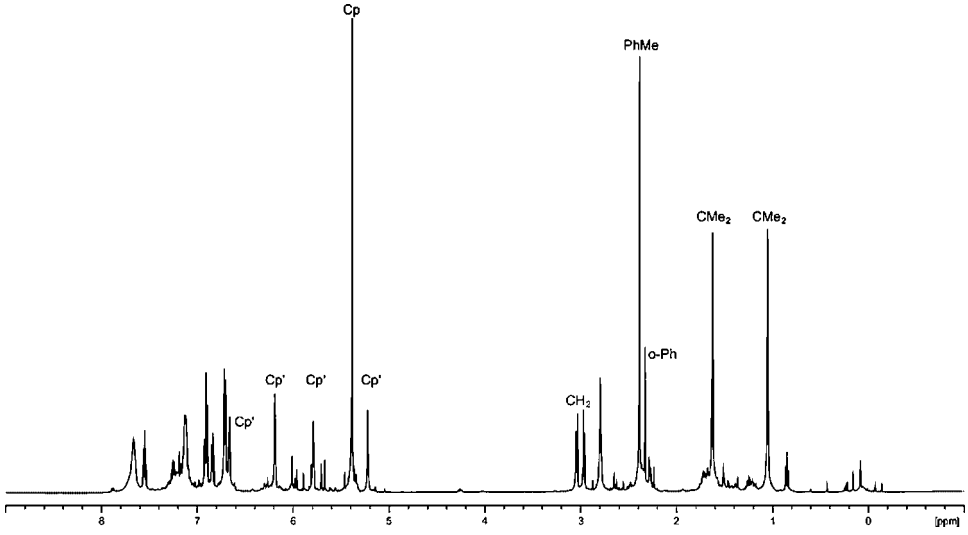

Figure 4. 500 MHz $^1$H NMR spectrum of **2** at –60 °C. Significant peaks of the cation are labelled.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

7.25 ppm.[37] As expected, this exchange is rapid, even at –60 °C, and thus some broad peaks in the aromatic region of the spectrum can be observed. Lowering the temperature to –90 °C did not resolve the broad peaks, which hampered a detailed kinetic investigation. All calculated and observed chemical shifts are summarised in Table 3.

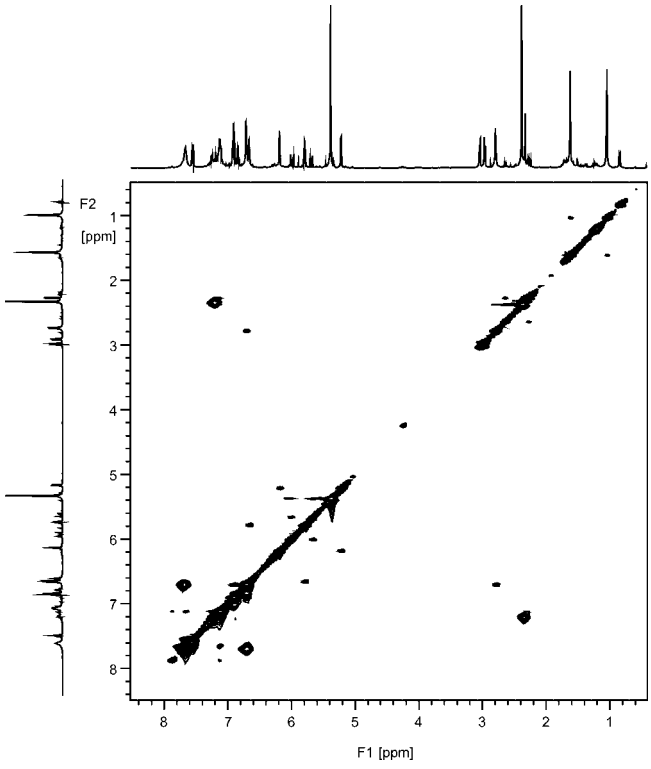

Figure 5. EXSY spectrum of **2** at –60 °C in $CD_2Cl_2$. Strong cross peaks are EXSY, medium ones are NOSY.

## Conclusions

We prepared the benzyl congener [$\eta^5$-$C_5H_5$-($\eta^5$-$C_5H_4CMe_2C_6H_4Me$)Zr($CH_2Ph$)$_2$] (**1**) of the previously reported zirconocene compound [$\eta^5$-$C_5H_5$($\eta^5$-$C_5H_4$-$CMe_2C_6H_4Me$)Zr$Me_2$]. The reaction of **1** with $B(C_6F_5)_3$ in $CD_2Cl_2$ was monitored by low-temperature NMR spectroscopy, and we obtained evidence for the coordination of both the benzyl moiety in the expected and previously reported $\eta^2$-bonding mode and the tolyl moiety. Our experimentally obtained data were predicted correctly from our computational studies. Furthermore, our model system predicted correctly the unusual chemical shift of $\delta_H$ = 2.33 ppm (observed) and $\delta_H$ = 2.64 ppm (calculated) for the *ortho* hydrogen of the coordinated tolyl (phenyl) moiety. Detailed AIM and NBO analysis revealed that although it is tempting to name this coordination "agostic", strictly spoken it is not agostic but rather an electrostatic interaction for **3a**. For **3b**, this coordination mode can be best described as a "transition state" between a covalent bond an agostic bond. These results fit quite well with the reported bonding modes of Ti(Et)$Cl_3$ and dmpeTi(Et)$Cl_3$: only in the case of the dmpe adduct could agostic bonding of the Et moiety be observed. Our model clearly indicates that for styrene polymerisation with *ansa* group 4 metallocenes, the coordination of the phenyl ring from the growing chain does not hamper the coordination of the free monomer: it is possible for the monomer to get caught by the catalyst, rearrange and insert into the polymer chain.

## Experimental Section

**General:** All experiments were carried out under a nitrogen atmosphere by using standard Schlenk techniques. Solvents were dried with sodium (toluene, low in sulfur), sodium/potassium alloy (diethyl ether, light petroleum, b.p. 40–60 °C, pentane), potassium (thf) and calcium hydride (dichloromethane). All chemicals were purchased from Aldrich and used as received. NMR solvents were dried with activated molecular sieves, freeze thawed and stored in Young's Tap sealed ampoules. NMR spectra were recorded with a VARIAN Unity Plus 500 spectrometer and referenced to the residual proton solvent peak for $^1$H. Chemical shifts are quoted in ppm relative to tetramethylsilane. $^{13}$C NMR spectra were referenced with the solvent peak relative to tetramethylsilane and were proton decoupled by using a WALTZ sequence. CH coupling constants were measured with a coupled gHSQC pulse sequence. Low-temperature NMR studies were conducted as previously reported.[19]

**Computational Details:** Density functional theory calculations were carried out by using the GAUSSIAN03[38] program package, running on a Mandrake Linux Dual-Opteron or a Dual-Xeon system, respectively. Geometries were fully optimised without symmetry constraints, which involved the functional combinations according to Becke[39] (hybrid) and Lee, Yang and Parr[40] (denoted B3LYP), with the corresponding pseudopotential basis set for Zr (Stuttgart-Dresden, keyword SDD in Gaussian) and the standard 6-31G* basis set[41] for C, H, Cl and F (denoted as ECP1). The stationary points and transition states were characterised as minima by analytical harmonic frequencies (zero or one imaginary frequency, respectively), which were used without scaling for zero-point and thermal corrections.

Magnetic shieldings $\sigma$ were evaluated for the B3LYP/ECP1 geometries by using a recent implementation of the GIAO (gauge-including atomic orbitals)-DFT method,[42] which involved the same B3LYP level of theory, together with the recommended IGLO II basis[43] on C, H and F. The former approach with this particular combination of functionals and basis sets has proven to be quite effective for chemical shift computations for transition metal complexes.[16] $^1$H and $^{13}$C NMR chemical shifts were calculated relative to benzene, with absolute shieldings for benzene $\sigma$($^1$H) 24.54 and $\sigma$($^{13}$C) 47.83 with the IGLO II basis set. The values for benzene were converted into the TMS scale by using the experimental $\delta$ values of benzene ($\delta$ =7.26 ppm and 128.5 ppm, respectively). Bader analysis was performed using the DZVP all-electron basis set,[44] drawing of the electron charge density plots were performed with the use of an Aim2000 instrument.[45] MOLDEN[46] was used for the chemical representation of the calculated compounds and NBO-View for the representation of the orbitals.[32]

**[$\eta^5$-$C_5H_5$-($\eta^5$-$C_5H_4CMe_2C_6H_4Me$)Zr($CH_2Ph$)$_2$] (1):** Previously prepared [$\eta^5$-$C_5H_5$-($\eta^5$-$C_5H_4CMe_2C_6H_4Me$)Zr$Cl_2$][17] (2.4 g, 5.65 mmol) was added to a rapidly stirred solution of benzylmagnesium chloride in diethyl ether.[20] The colour of the solution changed to orange. The reaction mixture was stirred overnight. The volatiles were removed under reduced pressure, and the orange residue was extracted into pentane. Fractionated crystallisation yielded

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the desired compound in a moderate yield as orange microcrystals. Yield: 410 mg (13.5%). $^1$H NMR (500 MHz, $CDCl_3$, 20 °C): $\delta$ = 1.51 (s, 6 H, $CCH_3$), 1.82 (s, 4 H, $CH_2$-Ph), 2.24 (2, 3 H, PhC$H_3$), 5.71 (s, 5 H, Cp), 5.76 (apparent t, $J$ = 5 Hz, 2 H, Cp′), 5.87 (apparent t, $J$ = 5 Hz, 2 H, Cp′), 6.76 (t, $J$ = 10 Hz, 2 H, *p*-H-Ph), 7.05 (d, $J$ = 10 Hz, 4 H, *o*-H-Ph), 7.06 (d, $J$ = 10 Hz, 4 H, -$C_4H_4$-Me), 7.09 (t, $J$ = 10 Hz, 4 H, *m*-H-Ph) ppm. $^{12}$C NMR (125 MHz, $CDCl_3$, 20 °C): $\delta$ = 21.1 (-$C_4H_4$-$CH_3$), 30.9 ($CCH_3$), 39.7 ($CCH_3$), 61.4 ($CH_2$-), 111.8 (Cp′), 112.8 (Cp), 120.9 (*p*-C-Ph), 125.7 (*o*-C-Ph), 126.2 (*o*-C-tolyl), 128.2 (*m*-C-Ph), 129.1 (*m*-C-tolyl), 136.0 (*ispo*-C), 138.3 (*ispo*-C), 146.7 (*ispo*-C), 152.5 (*ispo*-C) ppm. $C_{34}H_{36}Zr$ (535.59): calcd. [37] A cross peak between the two methyl groups on the bridging carbon should also be observed. However, the chemical shift difference between the two isomers is probably too small to be observed. For our model compound, we computed a difference around 0.5 ppm.

# A Magnetostructural and Electrochemical Study of $Cu^{II}$ and $Fe^{III}$ Complexes Containing a Tetradentate Aminebis(phenolate) Ligand with a Pendent Tetrahydrofuran Group

**Elham Safaei,[a] Thomas Weyhermüller,[a] Eberhard Bothe,[a] Karl Wieghardt,[a] and Phalguni Chaudhuri*[a]**

**Keywords:** Iron / Copper / Aminebis(phenol) / Electrochemistry / Magnetism

Ligating properties of a tetradentate ligand 2-{bis[(3,5-di-*tert*-butyl-2-hydroxybenzyl)amino]methyl}tetrahydrofuran, $H_2L$, with [O,O,N,O]-donor atoms towards $Cu^{II}$ and $Fe^{III}$ are described. The ligand $H_2L$ yields both mononuclear $LFe^{III}$(acac) (**1**) and dinuclear $[L_2Fe^{III}{}_2(\mu\text{-}OCH_3)\text{-}(\mu\text{-}OH)]$ (**2**), $[L_2Fe^{III}{}_2(\mu\text{-}C_2O_4)]$ (**3**) and $[L_2Cu^{II}{}_2]$ (**4**) complexes, which were characterized by various physical techniques, including X-ray diffraction, Mössbauer, electrochemical and magnetic susceptibility (2–290 K) measurements. That the electrochemical oxidations are ligand-centered, i.e. formation of phenoxyl radicals from the coordinated phenolates, have been shown by voltammetric methods. Complexes **2**–**4** display antiferromagnetic exchange coupling of the neighbouring metal centers. Comparison of the evaluated weak exchange coupling constants ($J$) with the literature values leads to the conclusion that the angle Cu–O–Cu′ is not the only determinant for the nature of the exchange coupling and the capability of the bridging ligands as mediators for spin coupling in case of $Fe^{III}$ follows the order phenoxide ≈ methoxide > hydroxide.

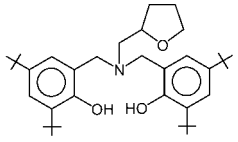
## Introduction

The amino acid tyrosine and its one-electron oxidized tyrosyl radical are quite common at the active centers of metalloenzymes involved in oxygen-dependent enzymatic radical catalysis.[1] Copper-containing galactose oxidase (GO), iron-containing ribonucleotide reductase (RR) are just two examples among others. This finding has elicited the interest of bioinorganic chemists in using phenol-containing ligands to mimic both structure and function of such metalloenzymes.[2] In this area, we have reported some bioinspired complexes as functional models of metalloenzymes[3] viz. galactose oxidase, catechol oxidase, and amine oxidases. These low-molecular weight complexes exhibit catalytic activity for aerial oxidation of organic substrates like alcohols, amines and catechols.

In continuation of our continuing interest in aminebis(phenol) ligands with O,N,O-donor atoms[4] and with the aim to scrutinize the effect of an additional pendent arm on the ligating property of the resulting tetradentate ligand towards transition metals, we argued for a weak-field donor pendent arm containing an ether group. An obvious choice is a tetrahydrofuran pendent arm. Thus the ligand $H_2L$ was selected for the investigation.



$H_2L$

Such aminebis(phenol) ligands with different pendent arms, such as amines with tetrahydrofuran, have already been used in the field of phosphorus chemistry[5] and for catalytic olefin polymerization involving group IV metal complexes.[6] Scheme 1 shows the complexes prepared with the ligand $H_2L$ together with the labels. We report herein the synthesis, the structural, spectroscopic and magnetic properties of complexes $[LFe^{III}(acac)]$ (**1**), $[L_2Fe^{III}{}_2(\mu\text{-}OCH_3)(\mu\text{-}OH)]$ (**2**), and $[L_2Fe^{III}{}_2(\mu\text{-}C_2O_4)]$ (**3**). The dinuclear $Cu^{II}$ complex $[L_2Cu^{II}{}_2]$ (**4**) will also be described.

## Results and Discussion

The ligand 2-{bis[(3,5-di-*tert*-butyl-2-hydroxybenzyl)-amino]methyl}tetrahydrofuran, $H_2L$, was prepared according to a procedure reported in the literature.[6b] The purity of the ligand was checked by liquid chromatography to be 98.7%. The IR, $^1H$ NMR and MS data are in agreement with the literature data (see Experimental Section), no further discussion is necessary here. To gain insight into the metrical parameters of the ligand, we have determined the structure of the ligand by X-ray diffractometry. Figure 1 displays the structure of the ligand $H_2L$ in the solid state. The X-ray analysis of single crystals of $H_2L$, performed at 100 K, reveals moderate hydrogen bonding between the phenolic hydroxy group O(15) and the ether group O(1) of the tetrahydrofuran ring, whereas the second phenolic group O(23) and the amine nitrogen N(7) are hydrogen-bonded [O(15)···O(1) 2.786 Å and O(23)···N(7) 2.731 Å]. The bond lengths and angles for the ligand, listed in Table 1, seem reasonable and do not warrant any special discussion.

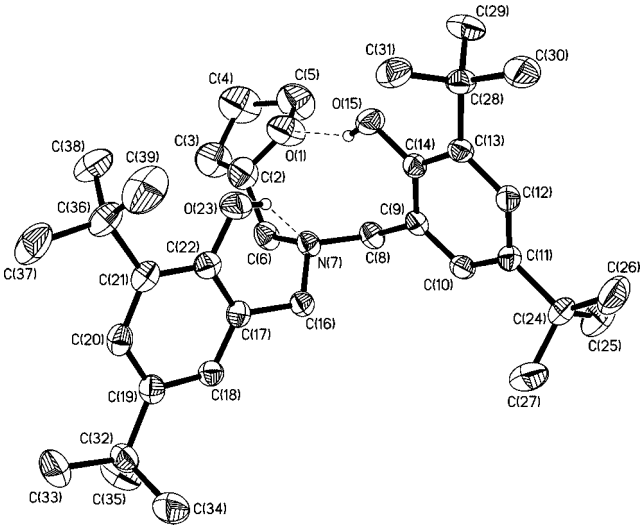

Figure 1. ORTEP representation for the amine bis (phenolato) THF ligand(L) (thermal ellipsoid probability 40%).

Methanolic solutions of $H_2L$ were treated with metal salts, $Et_3N$ and an additional ligand in some cases in suitable ratio and the solutions were heated at reflux to yield the complexes **1**–**4** in good yields. EI mass spectrometry was helpful in detecting the mononuclear nature for **1** and the dinuclear nature for **2**–**4**. The molecular ion peaks at *m*/*z* 690 (47.7%) for **1**, at *m*/*z* 1198 (11%) for **4** and *m*/*z* 1270 (47%) for **3** were observed. The signal at *m*/*z* 1198 (intensity about 12%) for **2** supports the dinuclear nature of **2**.

The ν(OH) stretch for the pure ligand, strong and sharp at 3372 $cm^{-1}$, vanishes after complex formation and is replaced by a very broad signal indicating the coordination of the phenol group to the metal. For **1** the most relevant features occur at 1598 and 1519 $cm^{-1}$ corresponding to the ν(C=O) of the coligand acetylacetonate (acac). A new peak at 1067 $cm^{-1}$ observed for **2** is ascribed to the ν($OCH_3$) group of the bridging methoxide ligand. Complex **3** exhibits strong to moderate vibrations at 1655 $cm^{-1}$ ($\nu_{as}OCO$), 1400 $cm^{-1}$ ($\nu_sOCO$) and 837 $cm^{-1}$ ($\nu_\delta OCO$) as has been observed earlier for similar oxalate-bridged complexes.[7] Selected IR data for complexes **1**–**4** are given in the Experimental Section.

### X-ray Diffraction Studies of 1, 2, 3 and 4

Single crystals of deep red [LFe(acac)]·$C_2H_5OC_2H_5$ (**1**) were obtained from an ethereal solution by slow evaporation. As no substantial differences in bond lengths and angles are found for the two crystallographically non-equivalent molecules, only one ORTEP diagram for the structure of compound **1** is displayed in Figure 2. Selected bond lengths and angles are summarized in Table 2. The overall geometry around the iron ion Fe(1) is best described as a distorted octahedron with two *cis* positioned oxygens O(41) and O(45) of the acetylacetonato coligand acac, whereas the doubly deprotonated tripodal ligand $[O\cap N(O)\cap O]^{2-}$ occupies the remaining four coordination sites. All the phenyl rings attached to the phenolate oxygen atoms are found to be planar, indicating that upon coordination the aromaticity of the phenyl rings is retained. The distortion from octahedral geometry is mainly caused by the acute bite angles involving the tetrahydrofuran oxygen O(1). The O(1)–Fe(1)–O(15) and O(23)–Fe(1)–O(45) angles are 166.00(8)° and 167.61(8)°, respectively, while the corresponding O(41)–Fe(1)–N(7) angle at 170.17(9)° also deviates from linearity. All the C–O bond lengths found in complex **1** are unremarkable, average 1.337(5) Å.

It is noteworthy that the Fe(1)–O(1) bond length of 2.223(2) Å, involving the THF oxygen atom, is exceedingly long. This probably results in the comparatively short *trans*-positioned Fe(1)–O(15) bond length of 1.883(2) Å, thus indicating stronger Fe–O(phenolate) interactions in comparison to that for Fe–O(THF). The Fe(1)–N(7) distance at 2.193(2) Å falls into the range reported for the structurally characterized mononuclear $Fe^{III}$ complexes.[8] The Fe–O and Fe–N bond lengths are in agreement with those of a high-spin $d^5$ $Fe^{III}$ complex,[9] which corroborates also with the magnetic and Mössbauer measurements.

The structure of complex **2** consists of neutral, well-isolated dinuclear units $[L_2Fe^{III}_2(\mu\text{-}OH)(\mu\text{-}OCH_3)]\cdot C_2H_5\text{-}OC_2H_5$. Selected bond lengths and angles are listed in Table 3. An ORTEP view of the dimeric unit is shown in Figure 3. The two iron(III) atoms are asymmetrically bridged by one methoxy O(81) and one hydroxy O(80) ligands. The iron ion Fe(2) is in distorted octahedral environment, having $FeNO_5$ coordination sphere, whereas five-coordinate Fe(1) is in a square pyramidal $FeNO_4$ environment. The phenolate O(63), the amine N(47) and the bridging O(81) and O(80) form the equatorial plane for the Fe(2) center, whereas the phenolate O(55) and O(41) from the tetrahydrofuran unit are axially *trans*-disposed. As expected for *trans*-influence, the Fe(2)–O(41) distance is long with 2.207(5) Å, while the *trans*-bonded Fe(2) is hydrogen-bonded to the bridging hydroxide O(80). Thus, a distorted square-pyramidal Fe(1) prevails in complex **2**. The $FeNO_4$ coordination sphere is not very common for trivalent iron with O,N-based ligation,[10] octahedral coordination is by far the most commonly observed arrangement for $Fe^{III}$.[11] The bond lengths for the five-coordinate iron center Fe(1) is shorter than those for the six-coordinate Fe(2) center. The asymmetry in the bridging bond lengths is also noteworthy. The angles Fe(1)–O(81)–Fe(2) and Fe(1)–O(80)–Fe(2) at the bridging ligands are 103.3(1)° and 101.5(3)°, respectively and comparable with the reported values for similarly bridged iron(III) complexes.[12] The Fe(1)···Fe(2) separation of 3.116 Å fall in the range reported earlier. The Fe–N and Fe–O bond lengths are consistent with $d^5$ high-spin electron configuration for both $Fe^{III}$ centers with amine nitrogen and phenolate oxygen-donor ligands. The $d^5$ high-spin configuration has also been confirmed both by Mössbauer and magnetic susceptibility measurements.

A perspective drawing of complex **3** [$L_2Fe^{III}_2(\mu\text{-}C_2O_4)$] and the atom-labeling Scheme are shown in Figure 4. Crystals of **3** contain two molecules of $CH_2Cl_2$ as solvent molecules of crystallization. Selected bond lengths and angles are given in Table 4. The asymmetric unit contains half of the dimer and consequently the geometries of the two iron centers are identical, with ligation provided by the two oxygen atoms of the bridging oxalate, two phenolate oxygens, one amine nitrogen and one ethereal oxygen belonging to the terminal ligand L resulting in a distorted octahedral arrangement. The two iron centers and the oxalate bridge are coplanar with a maximum deviation of 0.093 Å. As is expected and observed for the structures **1** and **2**, the Fe–O (ether) bond length at 2.178(2) is long and the *trans*-disposed Fe–O (phenolate) length at 1.867(2) Å is significantly short. The Fe–O and Fe–N bond lengths are in conformation with the high-spin $d^5$ electron configuration for the ferric centers in **3**, which corroborates with the Mössbauer and magnetic measurements. The Fe···Fe separation of 5.465 Å is comparable with those reported for other oxalate-bridged differic(III) complexes.[13]

Complex **4**·$C_2H_5OC_2H_5$ adopts a dimeric structure and the molecular structure is shown in Figure 5 along with the atom numbering scheme. Selected bond lengths and angles are listed in Table 5. Each copper atom has a $CuNO_4$ pentacoordinate environment and is bridged by two phenoxide oxygens O(15) and O(63). The $Cu_2O_2$ core is essentially planar, and none of the atoms deviates from the least-square plane by more than 0.38 Å. However, the Cu–O(63) and Cu–O(15) distances are different and the copper centers are separated by 2.766 Å, which is significantly shorter than those reported for phenoxy-bridged dicopper(II) complexes.[14]

The geometrical parameters $\tau$ of 0.31 and 0.29 for Cu(1) and Cu(2), respectively, suggest that the complex has a geometry closer to square-pyramidal ($\tau$ = 0) than to trigonal bipyramidal ($\tau$ = 1).[15] Thus, complex **4** adopts an folded structure with the two square-pyramidal copper centers bridged by the two phenoxide oxygen atoms, O(15) and O(63), with the Cu(1)–O–Cu(2) angles of 87.88(5)° and 88.65(5)°, respectively. The dispositions of the ligands are such that the equatorial tripodal nitrogen atoms N(7) and N(47), are in *syn* positions. Thus, the equatorial plane for each copper center consists of $CuO_3N$ resulting from three phenolate oxygen atoms and the amine nitrogen atom. The oxygen atoms originating from the tetrahydrofuran arms of

## Mössbauer Isomer Shifts and Quadrupole Splittings

The zero-field Mössbauer spectrum of solid **1** at 80 K is broad and hence the spectrum was recorded in an applied field of 7 T at 4.2 K. This record shows a well-resolved six-line spectrum (Figure 6). A least-square fit of the spectrum yields isomer shift $\delta = 0.54$ mm·s$^{-1}$ and quadrupole splitting $\Delta E_q = 1.55$ mm·s$^{-1}$. The Mössbauer data support the high-spin state of the ferric ion in a distorted octahedral field for complex **1** and are in agreement with the structural data.

Analysis of the zero-field Mössbauer spectra at 80 K for **2** and **3** yields the following parameters: isomer shift $\delta =$ 0.497 mm·s$^{-1}$, quadrupole splitting $\Delta E_q = 1.12$ mm s$^{-1}$ for **2**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

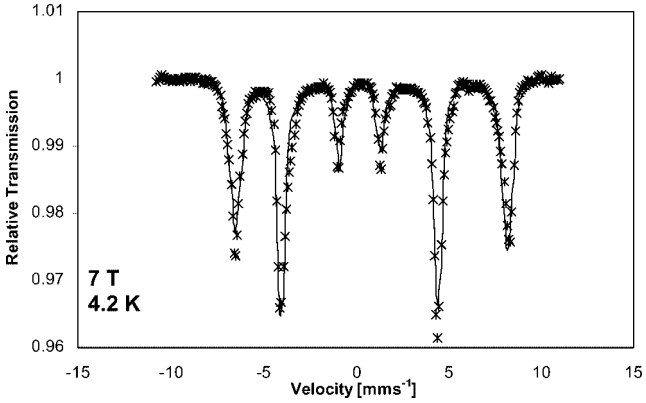

Figure 6. Mössbauer spectrum of **1** (applied field strength 7 T, $T$ = 4.2 K.

and isomer shift $\delta$ = 0.531 mm s$^{-1}$ and quadrupole splitting $\Delta E_q$ = 1.23 mm s$^{-1}$ for **3**. These data indicate the presence of high-spin electronic configuration for the $d^5$ ferric(III) ions present in **2** and **3**.

### Magnetic Susceptibility Measurements

Magnetic susceptibility data for polycrystalline samples of complexes **1**–**4** were collected in the temperature range 2–290 K in an applied magnetic field of 1 T. We start our discussion with the magnetic properties of the mononuclear complex **1**, [LFe$^{III}$(acac]. Complex **1** exhibits above 20 K essentially temperature-independent magnetic moment values $\mu_{eff}$ = 5.90 + 0.01 $\mu_B$, and thus contains clearly a high-spin $d^5$ ion, h.s.Fe$^{III}$.

The magnetic behaviour of **2**, [$Fe_2L_2(\mu\text{-}OCH_3)(\mu\text{-}OH)$] is characteristic of an antiferromagnetically coupled dinuclear complex (Figure 7). At 290 K the $\mu_{eff}$ value of 7.76 $\mu_B$ ($\chi_M \cdot T$ = 7.5295 cm$^3$ K mol$^{-1}$) decreases monotonically with decreasing temperature until it reaches a value of 0.70 $\mu_B$ ($\chi_M \cdot T$ = 0.06127 cm$^3$ K mol$^{-1}$) at 1.9 K; this is a clear indication of exchange coupling between two paramagnetic high-spin Fe$^{III}$ centers ($S_{Fe}$ = $^5/_2$) with a resulting $S_t$ = 0 ground state. We used the Heisenberg–Dirac–van Vleck spin-Hamiltonian in the form $\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2$ for an isotropic exchange coupling between two spins $S_1$ and $S_2$. The solid line in Figure 7 represents the best fit with the following parameters: $J$ = –5.84 cm$^{-1}$, $g_1 = g_2$ = 2.00 (fixed) and TIP = 140 × 10$^{-6}$ cm$^3$ mol$^{-1}$ emu. The evaluated antiparallel exchange falls in the range observed for comparable diferric complexes containing alkoxo-, phenoxo- and hydroxo-bridges.[12] For comparison purposes, we report here some of our unpublished results on dibridged diferric(III) complexes **A**, **B**, **C**, and **D** comprising of six-coordinate Fe$^{III}_2(\mu\text{-}OH)_2$, 5-coordinated Fe$^{III}_2(\mu\text{-}OH)_2$, six-coordinate Fe$^{III}_2(\mu\text{-}OH)(\mu\text{-}$phenoxo) and six-coordinate Fe$^{III}_2(\mu\text{-}OCH_3)(\mu\text{-}$OAc), respectively.[16] Additionally, we have earlier reported a bis(μ-phenoxo)differic complex (**E**)[4a] containing a five-coordinate and a six-coordinate iron(III) center exhibiting an antiferromagnetic exchange coupling $J$ = –7.4 cm$^{-1}$. Examination of **2** together with complexes **A**–**E** confirms the earlier notion about the exchange coupling ability of the bridging ligands following the trend $OH^- < OC_6H_5^- \approx OCH_3^-$. In addition, the strength of exchange coupling is weaker in five-coordinate Fe$^{III}$ than that in six-coordinate species. The strongest coupling $|J|$ = 14.1 cm$^{-1}$ observed for **D** with the widest bridging angle Fe(1)–O–Fe(2) of about 127°, resulting in an effective overlap between the metal and bridging-atom orbitals, is also in agreement with the existing magneto-structural correlation for the hydroxo-, alkoxo- and phenoxo-bridged diferric complexes.

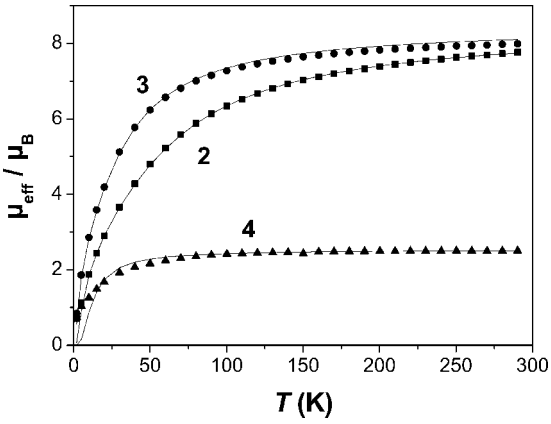

Figure 7. Magnetic measurements for complex **2**, **3** and **4**.

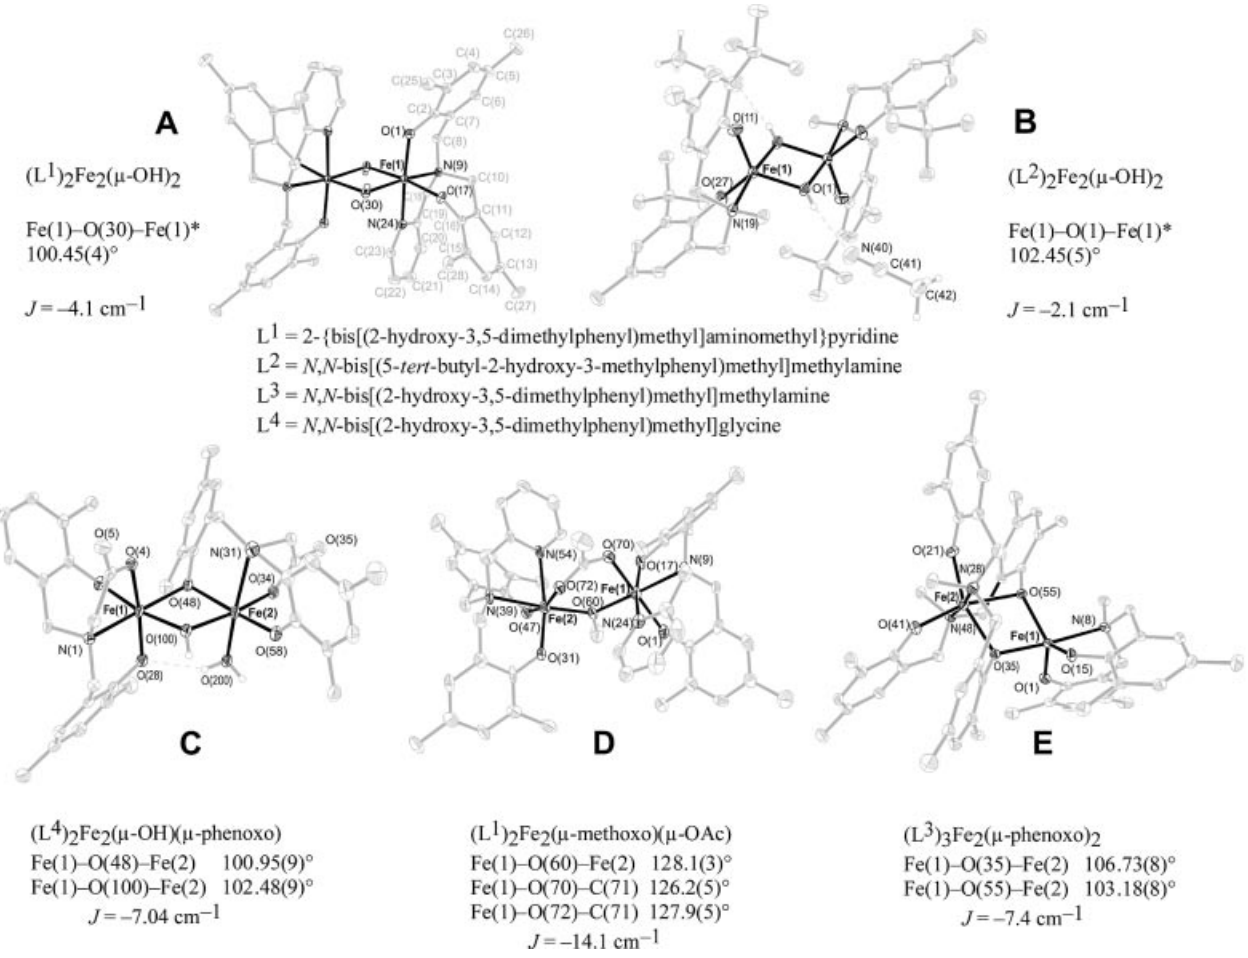
The $\mu_{eff}$ vs. $T$-plot for **3** is also shown in Figure 7 and indicates the nature of coupling operatiang between the two high-spin $d^5$ centers through the oxalate-bridge to be antiferromagnetic. The best parameters evaluated by simulation of the magnetic data are $J$ = –3.1 cm$^{-1}$, $g$ = 2.00. The exchange coupling constant in **3** compares well with those reported previously for oxalato-bridged dinuclear iron(III) complexes[13,17] and emphasizes the remarkable ability of the oxalate-bridge to transmit exchange interactions between paramagnetic centers separated by a distance more than 5 Å. It is noteworthy that structurally characterized oxalato-bridged differic(III) complexes are scarce in the literature.

The effective magnetic moment per molecule, $\mu_{eff}$, for complex **4** (Figure 7) in the temperature range 290–90 K remains nearly constant, 2.50–2.39 $\mu_B$, which is very close to the value of magnetic moment for two uncoupled spins of $S$ = $^1/_2$. Below 90 K, $\mu_{eff}$ starts to decrease with decreasing temperature and reaches a value of $\mu_{eff}$ = 0.74 $\mu_B$ at 1.9 K. The observed temperature dependent magnetic moments for **4** confirms the dimeric nature with an antiferromagnetic exchange coupling of this compound. Simulation of these experimental data results in the following best fit parameters: $J$ = –12.0 cm$^{-1}$, $g$ = 2.05. The exchange coupling is much weaker than those reported for the bis(μ-phenoxide)dicopper(II) core, which in most of the cases is characterized by very strong antiferromagnetic interaction ($|J| \geq$ 100 cm$^{-1}$) with the Cu–O(Ph)–Cu angles ranging from 98.9° to 104.8°;[14] for examples of ferromagnetic coupling the Cu–O(Ph)–Cu angle lies in the range 90.8–96.1° and they are very rare.[14e,14i,14m] The remarkably weak antiferromagnetic interaction in **4** can be accounted for by con-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



sidering the following major factors controlling the exchange interactions: (i) the equatorial planes of the copper centers, Cu(1)O(15)O(63)N(7)O(23) and Cu(2)O(63)N(47)O(55)O(15) are not planar with a dihedral angle of 81° between the planes, thus reducing the overlap of the magnetic orbitals of the copper centers via the *p*-orbitals of the bridging phenoxide oxygens; (ii) the angles at the bridging oxygen Cu–O(Ph)–Cu of about 88°, the smallest reported so far in the literature, result in considerable ferromagnetic contribution to the overall exchange interactions; (iii) the phenoxo oxygens, O(15) and O(63), adopt distorted pyramidal geometry (340.2° and 342.0°), thus increasing ferromagnetic contributions,[18] and (iv) small Cu···Cu distance of 2.766 Å also favors for decreasing the overall antiferromagnetic interaction by increasing ferromagnetism.[19] Hence, all these combined effects reduce the overall antiferromagnetic interactions drastically. It is remarkable that the Cu–O(Ph)–Cu angle at 88° for **4** with an antiferromagnetic coupling is even smaller than those for the ferromagnetically coupled diphenoxodicopper(II) complexes reported in the literature.[14e,14i,14m] These results suggest for a more intricate rationalization of exchange coupling in such phenoxo-bridged copper(II) complexes.

In this context we would like to point out that the Cu···Cu separation of 2.766 Å is the shortest known for bis(μ-phenoxide)dicopper(II) complexes. A similar bisphenoxo compound, $Cu_2L'_2$, ($H_2L'$ = *N*,*N*-bis(2-hydroxylbenzyl)-*N*,*N*-dimethylethylenediamine) has been reported to exhibit a weak exchange coupling ($J = -10$ cm$^{-1}$);[14h] the two copper centers in $Cu_2L'_2$ are in distorted trigonal-bipyramidal environments with the Cu–O(Ph)–Cu angle at 99.7° and the Cu(1)···Cu(1′) separation of 3.190 Å.

### Electrochemistry and Spectroelectrochemistry

Cyclic- and square-wave voltammograms (CV and SQW) of complexes **1**–**4** have been recorded in $CH_2Cl_2$ solutions containing 0.2 M $[(n\text{Bu})_4\text{N}]PF_6$ as supporting electrolyte. A conventional three electrode arrangement was used, consisting of a glassy carbon working electrode, an $Ag/AgNO_3$ reference electrode and a platinum-wire counter electrode. Ferrocene was added as an internal standard after completion of a set of experiments, and potentials are referenced vs. the ferrocenium/ferrocene couple ($Fc^+$/Fc). Coulometric experiments were performed (at –25 °C) at appropriate fixed potentials to determine the number of electrons/molecule transferred in the redox process under investigation. During coulometry electronic spectra were recorded in order to obtain information about the mechanism of the redox process.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The CV and SQW voltammograms (Figure 8) observed with **1**–**4** revealed that each complex can be stepwise two times reversibly oxidized ($E_1^{ox}$ and $E_2^{ox}$ in Table 6). $E_1^{ox}$ and $E_2^{ox}$ are similar for **1**–**4**, which suggests that the oxidation mechanism might be the same for all complexes.

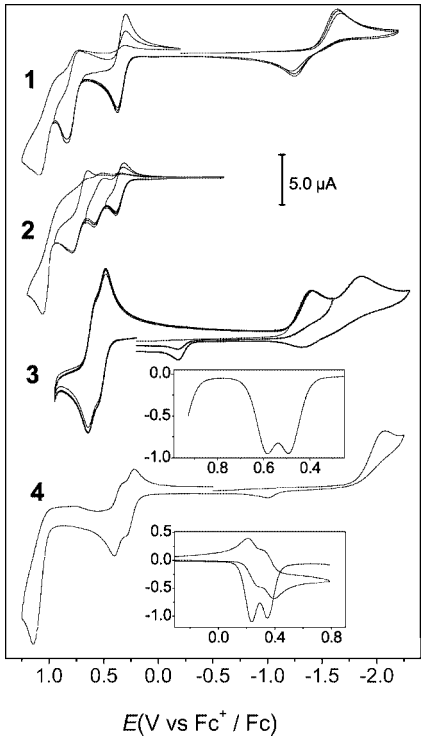


Figure 8. Cyclic and square-wave voltammogramms of complexes **1**–**4** in $CH_2Cl_2$ at room temperature.

Table 6. Electrode potentials (in Volt) for oxidation and reduction of complexes **1**–**4**, measured at ambient temperature in $CH_2Cl_2$ solutions and referenced vs. the $Fc^+/Fc$ couple.

[a] Reversible reaction, redox potential $E_{1/2}$ is given. [b] Electrochemical quasi-reversible reaction; estimated $E_{1/2}$ is given. [c] Irreversible reaction, peak potential is given.

In a coulometric experiment with the dimeric iron complex **3** it was found that 2 electrons per molecule had passed after completion of electrolysis at +0.8 V. The SQW voltammograms before and after coulometry were identical, indicating that the resulting monocation and dication were stable on the time scale of coulometry (20 min at –25 °C). The electronic spectral changes observed during $2e^-$ oxidation are shown in Figure 9. It is seen that the pattern of the changes is the same for both oxidation steps: a sharp band at 410 nm and a much broader one at 750 nm develop, which are typical for the formation of two phenoxyl radicals. Therefore the two oxidations are ligand centred. The small difference of the two redox potentials (90 mV) suggests that both ligands of the two respective iron-ions get mono-oxidized.

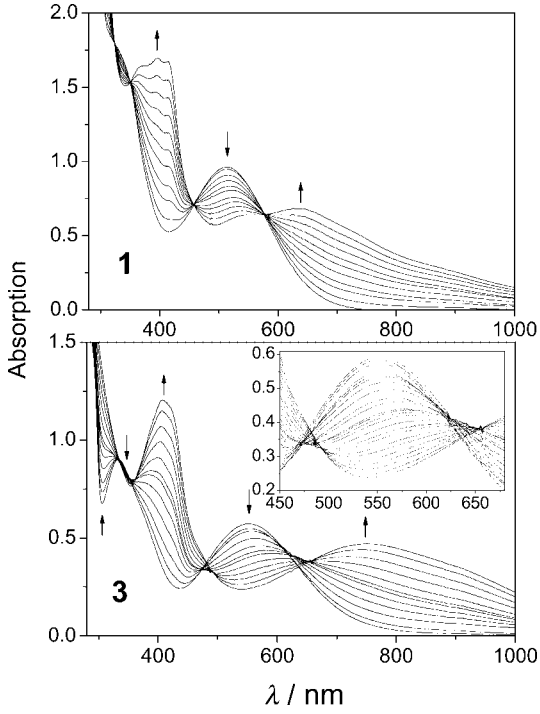

Figure 9. The electronic spectral changes during 1-e-oxidation for **1** and 2-e-oxidation for **3** (coulometry at $T$ = –25 °C).

The CV of the dimeric copper complex **4** exhibits two reversible oxidations with a similar small difference in their redox potentials (110 mV) and also the absolute values of the redox potentials of this copper complex are similar to those of the iron complex **3**. Since furthermore the electronic spectrum of coulometrically generated monocation of **4** has a pronounced and sharp absorption band at 415 nm, we assume the same ligand centred oxidation mechanism for **4** as that for **3**.

The CV of the monomeric iron complex **1** exhibits at room temperature two oxidation waves of reversible appearance, followed by an irreversible oxidation (Figure 8). Already the dication, however, should be quite unstable, since the third oxidation is not observed at low temperatures (–25 °C) and, therefore, most possibly arises from a decomposition product of the dication. The monocation was stable under coulometric conditions and the UV/Vis absorption changes again indicate phenoxyl radical formation: an increase around 400 nm was observed and a new broad range centering around 630 nm (Figure 9).

All oxidized forms of **2** turned out to be unstable under coulometric conditions and, therefore, reliable spectroscopic data of them could not be obtained. However, the similarity of the redox potentials to those of the other complexes speaks again for ligand based oxidations.

At more positive potentials, the cyclic voltammograms of the dimeric complexes **2** and **4** show further oxidation waves, see Table 6. They are most possibly arising from oxidation of further phenolate moieties of the complexes, but there is no direct evidence for this interpretation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In the negative potential range there are reductions discernible in the voltammograms which must be metal-centred. Only the $Fe^{III}/Fe^{II}$ reduction of **1** is chemically reversible and occurs with a low rate of heterogeneous charge transfer, from the electrochemical view the reduction is quasi-reversible. This can be deduced from the high separation of the peaks of reduction and re-oxidation ($\Delta E_p$). The separation is strongly dependent on the scan rate in a way that is typical of quasi-reversible reactions ($\Delta E_p$ = 0.53 V and 0.31 V at scan rates of 0.8 V/s and 0.05 V/s, respectively). The reductions of all other complexes are (chemically) irreversible, even on the time scale of cyclic voltammetry.

## Concluding Remarks

The paper has described diversified ligating properties of a tetradentate ligand with [O,N,O,O] donor atoms. Both mononuclear and dinuclear complexes have been isolated and thoroughly studied. It has been shown that electrochemical oxidations are ligand-centered, i.e. formation of phenoxyl radicals from the coordinated phenolates.

Emphasis has been given in this work to structural and electronic effects arising from the incorporation of a pendent tetrahydrofuran moiety to the aminebis(phenolate) ligand, described earlier by us.[4] As expected the metal–O-(tetrahydrofuran) interactions are weak as judged by the comparatively long M–O(THF) distances. The use of a weak donor atom, THF-O, has made the isolation of an asymmetric diferric(III) complex containing a 5- and a six-coordinate ferric centers viable. A comparison with the hydroxo-, alkoxo- and phenoxo-bridged dinuclear $Fe^{III}$ complexes from our laboratory has allowed us to judge the spin-exchange ability of the mentioned groups as exchange mediators. Moreover, for the diferric series it has been conclusively shown that the Fe–O–Fe angle is a major factor in determining the strength of the exchange interaction.

A bis(μ-phenoxo)dicopper(II) compound **4** with a remarkably weak antiferromagnetic exchange interaction ($J$ = –12 $cm^{-1}$) along with the structural factors contributing to the weak interaction has been described. The copper(II) compound **4** is unique with the most short metal–metal separation of 2.766 Å and the smallest bridging angle Cu–O(Ph)–Cu of about 88° in the literature reported for bis(μ-phenoxo)dicopper(II) systems.

## Experimental Section

**Materials and Physical Measurements:** Reagent or analytical grade materials were obtained from commercial suppliers and used without further purification, except those for electrochemical measurements. Elemental analyses (C,H,N) were performed by the Microanalytical Laboratory Dornis & Kolbe, Mülheim, Germany. Fourier transform infrared spectroscopy on KBr pellets was performed on a Perkin–Elmer 2000 FT IR instrument. Electronic absorption spectra in solution were measured on a Perkin–Elmer Lambda 19 spectrophotometer. Magnetic susceptibilities of *powdered samples* were recorded on a SQUID magnetometer in the temperature range 2–295 K with an applied field of 1 T. Experimental susceptibility data were corrected for the underlying diamagnetism using Pascal's constants and for the TIP contributions.

The Mössbauer spectrometer worked in the conventional constant-acceleration mode with a $^{57}Co/Rh$ source. Isomer shifts are given relative to α-Fe at room temperature (room temp.). Cyclic voltammetric and coulometric measurements were performed on EG&G equipment (potentiostat/galvanostat model 273A). Mass spectra were obtained with either a Finnigan MAT 8200 (electron ionization, EI MS) or a MAT 95 (electrospray ESI MS) instrument; a Bruker DRX 400 instrument was used for NMR spectra. Instrumental conditions for liquid chromatography are as follows: Shimadzu SPD-10 AV, Phenomenex Luna-5 C18, 150 × 4.6 mm column, UV 280 nm, eluent: $CH_3OH/H_2O$ (9:1), room temp., sample size 5 μL, recording speed 0.5 cm $min^{-1}$.

**Synthesis of $H_2L$:** The ligand 2-{bis[(3,5-di-*tert*-butyl-2-hydroxybenzyl)amino]methyl}tetrahydrofuran was prepared as described in the literature.[6b] The purity (98.9%) of the ligand was checked by liquid chromatography; retention time 7.2 min for the eluent methanol with a flow rate of 0.8 mL $min^{-1}$; m.p. 148–149 °C. EI-MS: *m/z* (%) = 537 (32) [$M^+$], 466 (99.7) [$M^+ - C_4H_8O$], 219 (100) [$M^+ - C_{15}H_{23}O$]. $^1H$ NMR ($CDCl_3$): $\delta$ = 8.79 (br. s, 2 H), 7.24 (d, $J$ = 2 Hz, 2 H), 6.86 (d, $J$ = 2 Hz, 2 H), 4.26 (m, 1 H), 4.01 (m, 1 H), 3.88 (m, 1 H), 3.75 (m, 4 H), 2.60 (m, 1 H), 2.51 (m, 1 H), 1.91 (m, 3 H), 1.54 (m, 1 H), 1.40 (s, 18 H), 1.26 (s, 18 H) ppm. IR (KBr): $\tilde{\nu}$ = 3372 (s), 2963 (vs), 2867 (s), 1481 (s), 1443 (m), 1360 (s), 1302 (m), 1241 (s), 1217 (s), 1042 (m), 880 (s) $cm^{-1}$.

**[LFe(acetylacetonate)], [LFe(acac)] (1):** Solid $Fe(acac)_3$ (1 mmol, 0.35 g) was added to a solution of $H_2L$ (1 mmol, 0.54 g) and $Et_3N$ (2.8 mL) in distilled methanol (70 mL). The resulting red-orange solution was refluxed for 0.5 h, whereupon the color changed to dark red. On cooling a dark red solid precipitated. X-ray-quality crystals were grown by recrystallization from a 1:1 mixture of diethyl ether and methanol. Yield 0.47 g (68%). IR (KBr): $\tilde{\nu}$ = 2959, 2902, 1588, 1519, 1474, 1443, 1415, 1379, 1360, 1304, 1271, 1240, 1202, 1169, 1018, 976, 877, 838, 746 $cm^{-1}$. EI-MS: *m/z* (%) = 690 (47.7) [$M^+$], 591 (14) [$M - C_5H_7O_2$], 472 (100) [$M - C_{15}H_{23}O$], 372 (80) [$M - C_5H_7O_2 - C_{15}H_{23}O$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 329 sh (8224), 517 (4620) nm. $Fe(C_{35}H_{53}NO_3)(C_5H_7O_2)$ (690.87): calcd. C 69.54, H 8.77, N 2.02, Fe 8.08; found C 69.4, H 8.2, N 2.0, Fe 8.1.

**[$L_2Fe_2$(μ-$OCH_3$)(μ-OH)] (2):** Dry $FeCl_2$ (1 mmol, 0.126 g) was added under argon to a thoroughly degassed methanolic solution (70 mL) of $H_2L$ (1 mmol, 0.537 g), $Et_3N$ (2.8 mL) and $PPh_3$ (2 mmol, 0.524 g). The resulting mixture was refluxed for 0.5 h resulting in a pale green solution, which upon exposure to air turned to dark red. The dark red solid was filtered and washed with methanol and air-dried. Yield 0.59 g (55%). X-ray-quality crystals were grown from a 1:1 solvent mixture of ether/methanol. IR (KBr): $\tilde{\nu}$ = 2954, 2902, 2868, 1602, 1471, 1439, 1413, 1361, 1274, 1239, 1203, 1169, 1132, 1067, 914, 874, 841, 809, 749 $cm^{-1}$. ESI-MS (positive mode, diethyl ether solution): *m/z* = 1201.7 (55) [$M^+ - OCH_3$], 591.3 (100) [$FeC_{35}H_{53}NO_3$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 329 (12540), 465 (7560) nm. $C_{71}H_{110}Fe_2N_2O_8$ (1231.56): calcd. C 70.62, H 8.51, N 2.42, Fe 8.33; found C 69.2, H 9.0, N 2.3, Fe 9.0.

**[$L_2Fe_2$(μ-$C_2O_4$)] (3):** Solid $FeCl_2$ (1 mmol, 0.126 g) was added under argon to a degassed solution in methanol (70 mL) of $H_2L$ (0.537, 1 mmol), $Et_3N$ (5.4 mL) and oxalic acid (0.5 mmol, 0.06 g). The resulting mixture was stirred for 1 h and then exposed to air to yield a violet solution. The solution was filtered to get rid of any solid particles. The mother liquor was evaporated on a rotary evaporator to obtain a violet microcrystalline solid with an yield

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of 0.51 g (40%). Violet single crystals were grown in a mixture of methanol/dichloromethane (1:1). IR (KBr): $\tilde{\nu}$ = 2952, 2903, 2869, 1655, 1470, 1443, 1438, 1414, 1304, 1268, 1241, 1170, 837, 7.33 $cm^{-1}$. ESI-MS (positive mode, $CH_2Cl_2$ solution): *m/z* = 1271 (68) [$M^+$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 335 (10340), 554 (6620) nm. $C_{72}H_{106}Fe_2N_2O_{10}$ (1271.3): calcd. C 68.02, H 8.40, N 2.20, Fe 8.78; found C 67.8, H 8.3, N 2.2, Fe 8.7.

**$L_2Cu_2$ (4):** A methanolic solution (75 mL) of $H_2L$ (1 mmol, 0.537 g) containing sodium methoxide (10 mmol, 0.54 g) was treated with solid $Cu(OAc)_2{\cdot}2H_2O$ (1 mmol, 0.199 g) and the resulting mixture was refluxed for 1 h whereupon a dark red solid appeared. The precipitate was collected by filtration, washed with methanol and air-dried; yield 0.74 g (62%). Red-brown single crystals were obtained from a mixture of diethyl ether/methanol (1:1). IR (KBr): $\tilde{\nu}$ = 2952, 2901, 2868, 1606, 1471, 1436, 1415, 1360, 1304, 1298, 1248, 1237, 1204, 1168, 1131, 1071, 1012, 875, 830, 740 $cm^{-1}$. EI-MS: *m/z* (%) = 1198 (1) [$M^+$], 598 (40) [$CuC_{35}H_{53}NO_3$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 234 sh (8685), 423 (5260), ca. 730 (800) nm. $C_{70}H_{106}Cu_2N_2O_6$ (1198.9): calcd. C 70.13, H 8.91, N 2.34, Cu 10.6; found C 70.1, H 8.9, N 2.2, Cu 10.4.

**X-ray Crystallographic Data Collection and Refinement of the Structures:** Data collection for $H_2L$, **1**–**4**, was carried out on a Bruker-Nonius Kappa CCD diffractometer at 100(2) K by using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Final cell constants were obtained from a least-squares fit of all integrated reflections. Intensity data were corrected for Lorentz and polarization effects. The data sets for **1** and **2** were corrected for absorption (SADABS, Bruker-Nonius 2004).[20] The structures were solved by direct method and refined by full-matrix least-squares techniques based on $F^2$ (ShelXTL software package);[21] the neutral atom scattering factors of the program were used. Crystal data and refinement details are listed in Table 7.

Table 7. Crystallographic data for **1**·$C_2H_5OC_2H_5$, **2**·$C_2H_5OC_2H_5$ and **3**·$2CH_2Cl_2$.

# Synthesis and Functionalization of Germanium Triphenylcorrolate: The First Example of a Partially Brominated Corrole

Sara Nardis,[a] Federica Mandoj,[a] Roberto Paolesse,*[a] Frank R. Fronczek,[b] Kevin M. Smith,[b] Luca Prodi,[c] Marco Montalti,[c] and Gionata Battistini[c]

**Keywords:** Corrole / Bromination / Regioselectivity / Porphyrinoids

Ge complexes of 5,10,15-triphenylcorrole were prepared in refluxing dry DMF using $GeCl_4$ as the source of Ge. Chromatographic separation of the crude reaction mixture afforded the μ-oxo dimer **1** and the methoxy derivative **2a**. The corresponding chloride **2b** can be obtained by treatment of **1** or **2a** with HCl. The reaction of **2a** with $Br_2$ in $CHCl_3$/py afforded the hexabromo derivative **3** as the main product, giving the first indication of the regioselective substitution of pyrroles B and C on the corrole ring. The fully brominated open-chain tetrapyrrole **4** was also characterized as a reaction by-product. Different partially brominated Ge complexes **5** and **6** have been obtained by variation of reaction conditions, while the heptabromo derivative was obtained in a mixture with the corresponding fully brominated Ge corrole. Photophysical characterization of Ge corrolates confirmed the high fluorescence quantum yield of such complexes, and also led to the first observation of phosphorescence emissions from corrole complexes.

## Introduction

In the last few years corrole has been the object of an increasing number of studies, which have resulted in the exploitation of this macrocycle in different fields, such as catalysis,[1] PDT[2] and chemical sensors.[3] The impetus for this renewed interest is the intriguing behaviour shown by corrole, which makes its chemistry unique in the porphyrinoid scenario. This intriguing character can be related to the molecular structure; since it lacks the C20 *meso* bridge (which confers a corrin-like skeleton) corrole retains an 18 π electron aromatic system, closely resembling porphyrins. It is a trianionic ligand, a feature which, together with a contracted porphyrinoid skeleton, leads to the stabilization of formal high oxidation states[4,5] for coordinated metals, and also to the pronounced non-innocent character of corrole as a ligand.[6] The coordination chemistry of this macrocycle is therefore a challenging arena.

Besides its coordination characteristics, another intriguing aspect of corrole chemistry is the reactivity of the peripheral positions of corrole. The recent definition of different synthetic routes[7] for the preparation of *meso*-arylcorroles from commercially available precursors has allowed the functionalization of β-pyrrolic positions to be studied. This constitutes the first step towards the preparation of more elaborate molecular architectures based on corroles.

The β-functionalization of triphenylcorroles, however, introduces the possible formation of different regioisomers due to the lower symmetry of corrole compared with porphyrin, a further challenging feature that should be taken into account. Many research groups have studied different electrophilic reactions such as nitration, formylation, chlorosulfonation or bromination;[8–13] it is worth mentioning that the first three of these were shown to be regioselective, leading to the isolation of partially substituted corroles. For example, chlorosulfonation and nitration reactions[8] were successfully carried out both on the free base and on the gallium complex of tris-pentafluorophenylcorrole, using chlorosulfonic acid and $NaNO_2$/$CH_3CN$ respectively. The interesting result of these synthetic approaches is that it has been possible to isolate only a few isomers among the several possible regioisomers. In the case of the chlorosulfonation reaction, purification of the 2,17- and the 3,17-sulfonic acid derivatives has been reported, while the $NaNO_2$/$CH_3CN$ reaction afforded the mono-nitro, the 3,17-dinitro and the 2,3,7-trinitro derivative, depending on the amount of the nitrating agent used.

Also, in the case of the formylation[8,9] and carboxylation[13] reactions, mono and bis β-regiosubstituted corroles have been obtained as the major products, even though the novelty of these kinds of reactions is probably better deter-

mined by the isolation of inner nitrogen substituted compounds. A general feature of these functionalizations is the regioselectivity; 3 and 17 β-pyrrolic positions of the directly linked A and D pyrroles are the sites of the substitution, in agreement with calculations of electron density at those positions already reported in the literature.[8]

It is interesting to note that in the case of bromination,[10–12] attempts to isolate partially brominated corroles have failed to date. Previous studies have demonstrated that bromination reactions carried out on corroles mainly afford the octabromo products both using the corrole free-base and metal complexes, even in the presence of very small amounts of the brominating agent (either NBS and $Br_2$).

Since brominated corroles have been shown to be useful substrates for palladium(0) mediated cross-coupling reactions,[14] we have been keen to explore the possibility of preparing partially brominated corroles. We have previously reported the bromination of the corrole free base,[10] while other groups studied the same reaction with metal complexes, mainly copper[11] and manganese[12] derivatives. In these studies the major reaction product was always the β-octabromocorrole, in which all pyrrolic positions were substituted. No partially substituted derivatives have been isolated, although mixtures of different isomers were reported when the stoichiometry of the brominating agent was reduced. Yields of reaction carried out with the corrole free base, and either NBS or $Br_2$ as brominating agent, are in general quite low; this is probably due to the instability of the macrocycle, which undergoes decomposition before the substitution takes place if oxidizing reagents are present. For this reason, we decided to investigate the reactivity of germanium derivatives of corroles. We chose this metal complex because it is diamagnetic, thereby allowing an easier characterization of the reaction products, and because corrole stabilizes the coordinated metal in the +4 oxidation state. We suspected that this would allow us to better control the substitution reaction and obtain partially brominated derivatives.

## Results and Discussion

The first phase of our study focused on the preparation of the Ge corrole complex. We have reported the preparation of germanium derivatives in the case of β-alkylcorroles,[15] and, to the best of our knowledge, in the triphenylcorrole series there is only one example of a Ge complex, the Ge($TPF_5PC$)OH reported by Gross.[16] We used the same metalation procedure, reacting triphenylcorrole with $GeCl_4$ in refluxing anhydrous DMF, and observed a prompt colour change of the solution from green to red-violet. The UV/Vis spectrum of the reaction mixture also indicated the formation of the complex, with the disappearance of the free base absorbance bands.

TLC of the crude mixture obtained after vacuum evaporation of the DMF showed the presence of two reaction products. We decided to perform a chromatographic separation of the reaction mixture, despite the possible hydrolysis of the Ge–Cl bond, as observed in the case of previous Ge corrole derivatives. Column chromatography on alumina, using $CH_2Cl_2$ as the eluent, afforded a dichroic green-purple fraction followed by a second purple compound which required a mixture of $CHCl_3$/MeOH (95:5) for elution. The UV/Vis spectra of both fractions were in agreement with the coordination of germanium to the corrole macrocycle, but with a significant blue shift of the absorbance bands of the first fraction with respect to the second. This result, together with a high-field shift of the β-pyrrolic proton resonances in the $^1$H NMR spectrum suggested the formation of a μ-oxo dimer derivative (**1**), which was unambiguously characterized by X-ray crystallography. To the best of our knowledge, this is the first example of such a derivative in the corrole series, other than the iron corrole complexes.[16]

Figure 1 shows one of the two Ge μ-oxo dimers in the asymmetric unit. The Ge atoms have square-pyramidal coordination, lying 0.439 Å (average of four) from the $N_4$ plane. The Ge–N distances are in the range 1.881(9)–1.930(9) Å, with axial Ge–O distances in the range 1.718(11)–1.773(13) Å and Ge–O–Ge angles 147.3(5) and 149.0(4)°. Thus the $N_4$ planes within each dimer are not parallel, forming dihedral angles of 19.4(6) and 19.9(5)°.

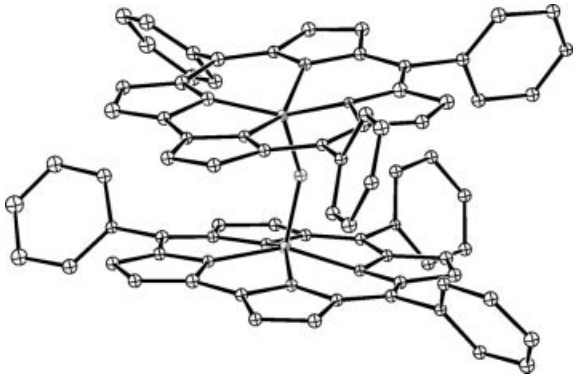

Figure 1. The X-ray structure of **1**.

The characterization of the second fraction indicated the formation of **2a**, in which a methoxy group is present at the axial position. The presence of the methoxy group is due to the well know lability of the Ge–Cl bond toward oxygen ligands and in this case to the solvent mixture used for the elution of the second chromatographic fraction. We also explored the possibility of modifying the nature of the axial ligand, as already observed in the case of β-alkylcorrole complexes,[15] but found not to be possible in the case of $TF_5PC$.[16] Treating a $CHCl_3$ solution of **1** or **2a** with a dilute HCl solution afforded the complex GeTPCCl (**2b**): in the case of **2a** the formation of the chloride complex was monitored by observing the disappearance of the $^1$H NMR signal characteristic of the axial methoxy group which appears at around –1 ppm (Figure 2).

However it should be noted that, in some cases, the isolated complex was contaminated with variable amounts of the corresponding hydroxy derivative, as demonstrated by

**2a:** X = $OCH_3$
**2b:** X = Cl

Figure 2. Molecular structures of the germanium complexes **2a** and **2b**.

the $^1$H NMR signal for the –OH at –4.4 ppm, thus confirming the easy hydrolysis of the Ge–Cl bond under acidic conditions (Figure 2). The bromination of complex **2a** was carried out according to the previously reported procedure,[11,18] by using liquid bromine in $CHCl_3$/py at room temperature. The reaction was initially carried out with an excess of $Br_2$ in order to drive the reaction to the formation of the fully substituted derivative. This protocol is usually adopted with other metal complexes[11,12] to avoid the potential formation of a mixture of regioisomers. The progress of the reaction was followed by spectrophotometry. A clear red shift of the Soret band was observed, consistent with the presence of halogen atoms in the metal complex structure. However, also with a large excess of $Br_2$, in the case of **2a** TLC of the crude reaction mixture showed a number of products. Work up and purification with a silica plug afforded two main fractions, eluted with $CHCl_3$ and $CHCl_3$/$CH_3OH$ (95:5) respectively. The first fraction contained some residual impurities and was further purified with a silica gel column and $CHCl_3$ as eluent to give an analytically pure product.

The UV/Vis spectrum of this fraction showed the presence of a Soret band, indicating the retention of the corrole macrocycle, but it was interesting to note the presence of a singlet in the β-pyrrolic proton region of the $^1$H NMR, also indicating incomplete peripheral substitution of the complex. The integration ratio corresponded to the presence of two pyrrolic protons, but the presence of a single resonance indicated that substitution had occurred with good regioselectivity. This hypothesis was fully confirmed by the X-ray structure of crystals obtained from $CHCl_3$/$CH_3OH$.

The complex obtained was identified as **3**, possessing six bromine atoms on the peripheral positions. To the best of our knowledge this is the first example of an isolated and characterized partially brominated corrole. The formation of **3**, not only confirms the higher reactivity of the pyrrolic positions on the two directly linked pyrroles A and D, but also gives an indication of the substitution regioselectivity on pyrrole subunits B and C. In this case the reaction leads to the substitution of the protons H8 and H12, closer to the *meso* bridge, with the formation of only one of the three possible regioisomers. This result confirms the behaviour previously observed by Gross and Mahammed in the deuteration of the tris-(pentafluorophenyl)corrole, for which a similar reactivity order, C3 > C2 >> C8 > C7, was reported[19] (Figure 3).

Characterization of the material isolated from the second fraction was more difficult. A Soret-like band was absent from the UV/Vis spectrum, and we observed more resonances than expected in the $^1$H NMR spectrum. In this case, X-ray crystallography was necessary to characterize compound **4**: this derivative is a fully brominated open chain tetrapyrrole (Figure 4).

There are several peculiar features of this compound to be noted. An ethoxy group is added at the former 10-methine bridge of the corrole ring, with the formation of a methane bridge and the consequent interruption of the π conjugation. The ring is opened at the 5-methine bridge and the pyrrole-pyrrole direct link is retained in the tetrapyrrole. The ring opening in this case is different from that observed previously with 10-phenyl-substituted corrole, which afforded the corresponding biliverdin derivatives on reaction with molecular oxygen.[20] As a consequence of the ring opening, a benzoyl group and a pyridinium substituent are present at the terminal α-pyrrolic positions. While the origin of the benzoyl group can be confidently attributed to the oxidation of the methine bridge, the presence of the pyridinium group is more surprising. Furthermore, the positive charge of this group is balanced by the presence of a central divalent ion, which consequently infers a zwitterionic character to the complex. While the identity of the central metal atom is not completely unambiguous, Zn appears most consistent with all available information. Its coordination geometry is square planar, somewhat twisted from planarity by the spiral nature of the ligand. Thus N2 lies 0.62(1) Å and N5 lies –0.43(1) Å out of the plane defined by the metal and the two central N atoms. Zn–N distances vary 1.901(9)–2.016(1) Å.

Further confirmation of the presence of Zn as coordinated metal was given by MALDI mass spectrum, in which a molecular peak at 1360 *m*/*z* was observed. In the FAB spectrum a peak was found at 1299 *m*/*z*, corresponding to the free base derivative after loss of the Zn ion, probably induced by the acidic matrix used in this technique. The source of the coordinated Zn is probably the silica gel used for the chromatographic separation. A similar Zn complex of a fully brominated open chain tetrapyrrole has recently been reported in the literature and was obtained by bromination induced ring-opening of tetraphenylporphyrin.[21]

To explore the possibility of achieving complete bromination of **2a**, the reaction was carried out at reflux for a prolonged time (2 h); in this case we observed significant decomposition of the starting material, with the formation of a mixture of three brominated products. A complete chromatographic separation was difficult to achieve from this mixture, although $^1$H NMR and MALDI-MS charac-

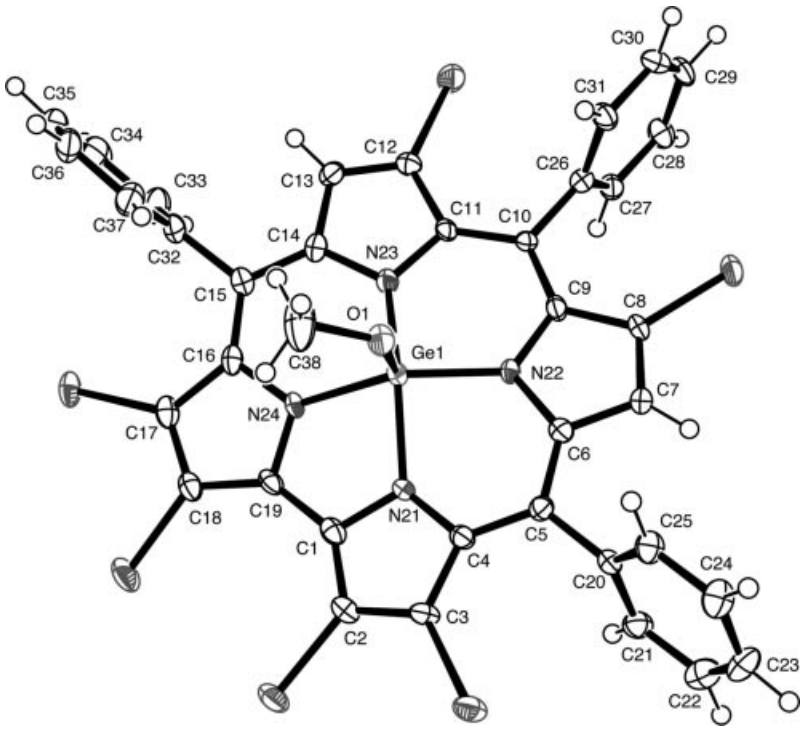

Figure 3. Characterization of **3** by X-ray crystallography.

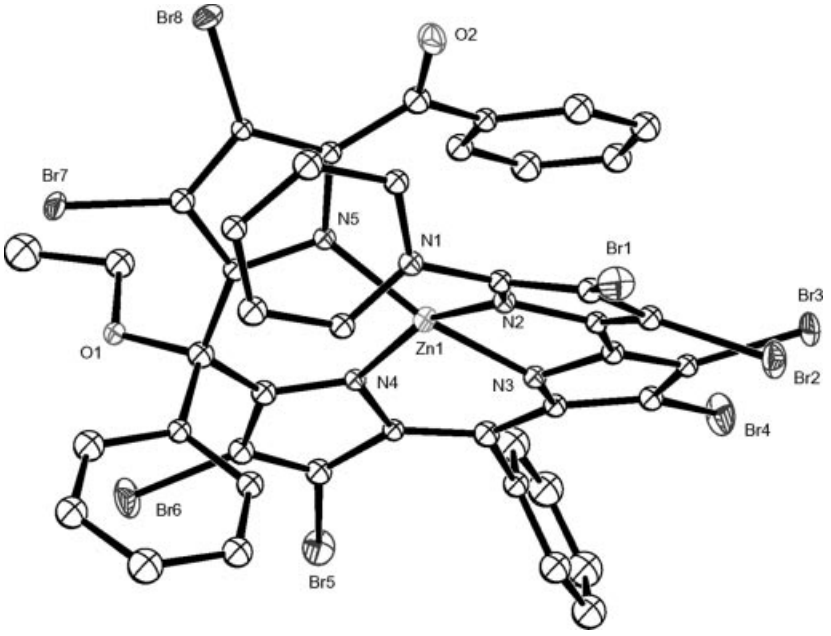

Figure 4. The X-ray structure of **4** (hydrogen atoms omitted).

terization indicated that the main component of the mixture was the heptabromo derivative, with the presence of the fully brominated complex as a minor component. The third component of the mixture, although in a significantly lower amount, was easily identified as **3**, by comparison of the spectroscopic data.

Consequently, these results led us to explore the possibility of obtaining other partially brominated Ge derivatives by reducing the $Br_2$:**2a** ratio. Initially we carried out the reactions reducing the reagent ratio in the range 70:1 to 10:1, obtaining the corresponding pentasubstituted complex as the reaction product. This complex can be reasonably assumed to be **5**, considering that it is the necessary precursor of **3** (Figure 5).

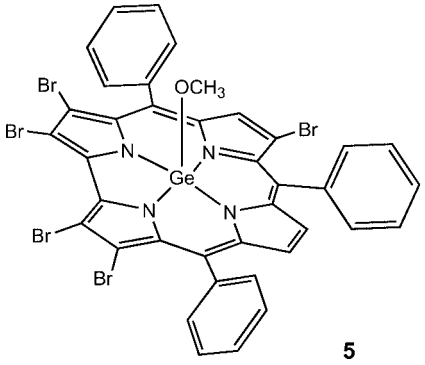
The formation of **5** even with a slight excess of bromine seems to indicate a pronounced reactivity of pyrrole sub-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

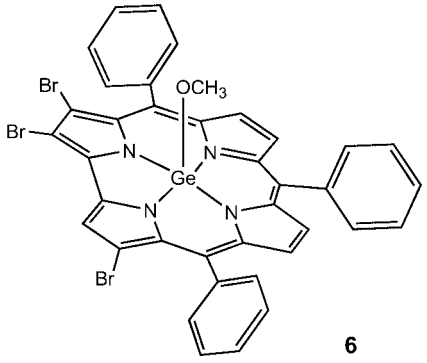
units A and D, which are completely substituted, while the substitution of pyrroles B and C can be modulated by the amount of reagent used.

When we further reduced the amount of $Br_2$ to 1.1 equiv., adding methanol as co-solvent, we observed the formation of a tri-substituted derivative, which can be confidently assumed to be (**6**). Significant decomposition of the starting material was observed in this case, however.

The unprecedented formation of **1** led us to perform a photo-physical characterization of the Ge corrole derivatives, considering that corroles present quantum yield values higher[17] than those of the corresponding porphyrins and that the efficiency of the photophysical process can even be increased by the coordination of small metal ions such as Gallium.[13]



**5**



**6**

Figure 5. Molecular structures of **5** and **6**.

The absorption spectra of compounds **1**, **2a** and **3** in dichloromethane are reported in Figure 6, with the most relevant photophysical data reported in Table 1. As expected, because of the already observed validity of the porphyrin four-orbital model for corroles, all three compounds show a Soret band in the 380–440 nm region, and a set of Q bands in the 540–620 nm region. The absorption spectrum of **2a** [that of **2b** is almost identical] is very similar to the one described for Ge(TPF$_5$PC)Cl. This is as expected because the positions of the absorption maxima of corroles are typically unaffected by the nature of the *meso* substituents.[22] For **1**, relevant differences are observed instead: its Soret band, while undergoing an expected almost doubling in intensity, is shifted to a shorter wavelength by 13 nm. On the other hand, the Q bands are much broader and shifted to longer wavelengths. These findings clearly indicate a strong interaction between the two macrocycles in the dimer. It is interesting to note that, at concentrations lower than $10^{-6}$ M, **1** is not stable, since its spectrum slowly changes to become very similar to that of **2a**. As already mentioned, all the bands in **3** are red-shifted compared to **2a**, indicating that the substituents on the β positions are able to affect the photophysical properties of corroles, as already observed for Ga complexes.[23] As far as the fluorescence spectra are concerned, the maximum of the fluorescence band of **2a** (Figure 7) is close to that observed for Ga(TPF$_5$PC)Py (no fluorescence has been previously reported for Ge corroles). In this case, the fluorescence quantum yield, although higher than that of a metallated porphyrin, is lower than that reported for Ga(TPF$_5$PC)Py, probably because of a lower planarity of the macrocycle (Table 2).

Table 2. Most relevant luminescence parameters of **1**, **2a** and **3** in $CH_2Cl_2$ solutions at room temperature and at 77 K.

| | Room temperature | | | 77 K | | 77 K | |
|---|---|---|---|---|---|---|---|
| Compd. | $\lambda_{max}$ [nm] | $\Phi$ | $\tau$ [ns] | $\lambda_{max}$ [nm] | $\tau$ [ns] | $\lambda_{max}$ [nm] | $\tau$ [ms] |
| **1** | 660 | 0.033 | < 0.4 | 660 | 2.3 | 818 | 35.2 |
| **2a** | 598 | 0.14 | < 0.4 | 599 | 2.1 | 784 | 28.4 |
| **3** | 614 | 0.005 | < 0.4 | 603 | 3.0 | 806 | 3.2 |

The very short excited state lifetime observed in this case supports this hypothesis, indicating the presence of a very fast ($k_{nr} \geq 2 \times 10^9\ s^{-1}$) non radiative deactivation process. It is interesting to note, however, that the radiative rate constant is also very high ($k_r \geq 2 \times 10^8\ s^{-1}$), especially if compared with other porphyrins and corroles.[22b] This finding is clearly in line with the indication that corroles can be of great interest for their photophysical properties, especially if it is possible to design new systems showing slower non radiative processes. Additionally, for **2a** this latter process is thermally activated as shown by the remarkable increase in the excited state lifetime at 77 K. The brominated compound **3** shows a red shifted fluorescence spectrum in line with its absorption spectrum, with a relatively low quantum yield, most probably due to the heavy atom effect introduced by the presence of bromine atoms. The fluorescence maximum of this compound at 77 K is the only one that shows a blue shift with respect to the maximum observed at room temperature, most probably because its excited state shows a reduced dipole moment compared to the ground state.[22b] The fluorescence spectrum of the dimer **1** is much broader and shifted even more towards longer wavelengths in comparison to the monomer **2a**, again indicating a strong interaction between the two macrocycles. The quantum yield (0.033), although reduced, is still in the same range as those of two very well known metal complexes, ZnTPP and $Ru(bpy)_3^{2+}$. Again, the lifetime is very short, indicating the occurrence of a relatively fast radiative deactivation process also in this case.

Finally, we were able, for the first time, to observe the phosphorescence coming from a corrole complex at 77 K (Figure 8).

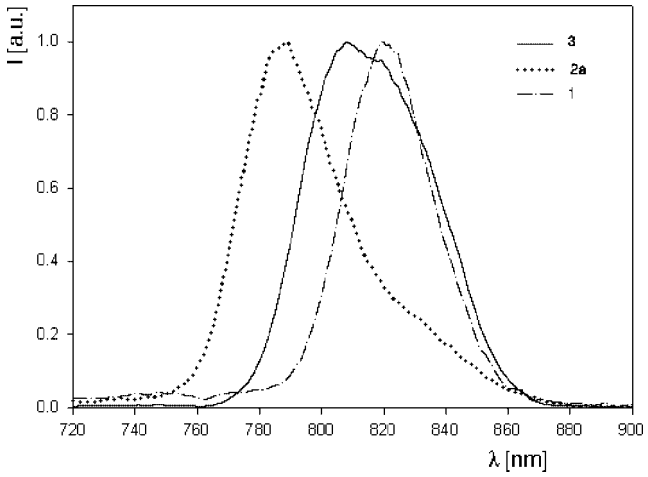

Figure 8. Phosphorescence spectra of germanium corrolates.

All the phosphorescence bands observed were in the 760–840 nm region, following the energetic order observed for the fluorescence bands. It is worth noting that **1** and **2a** showed an excited state lifetime of around 30 ms, while **3** decayed ten times more quickly, indicating a much faster inter-system crossing process, which confirms the presence of the already invoked heavy atom effect in **3**.

## Conclusions

In conclusion, we have detailed here a useful, never previously reported route for the preparation of partially substituted corroles by bromination of the Ge triphenylcorrole complex, together with a further example of the peculiar reactivity of this macrocycle. Photophysical characterization of Ge complexes also led to the first example of phosphorescence emission from corrole derivatives.

## Experimental Section

**Physical Methods:** $^1H$ NMR spectra were recorded with a Bruker AM400 (400 MHz) or Bruker Advance 300 (300 MHz) spectrometer. Chemical shifts are given in ppm relative to tetramethylsilane (TMS). Routine UV/Vis spectra were measured with a Varian Cary

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

50 Spectrophotometer, whereas more precise measurements were performed with a Perkin–Elmer 18 Spectrophotometer equipped with a temperature-controlled cell holder.

**Materials:** Silica gel 60 (70 ± 230 mesh) was used for column chromatography. Reagents and solvents (Aldrich, Merck or Fluka) were of the highest grade available and were used without further purification. $CH_2Cl_2$ used for the spectrophotometric measurements was stored over activated molecular sieves.

**Synthetic Methods:** Triphenylcorrole was prepared as previously reported in the literature.[7b]

**Germanium 5,10,15-Triphenylcorrolates:** In a 100 mL round-bottomed flask equipped with a stirring bar, corrole (0.1 g; 0.2 mmol), was dissolved in anhydrous DMF (20 mL). $GeCl_4$ (96 μL; 0.8 mmol) was added under nitrogen and the mixture was refluxed for about two hours, monitoring the progress of the reaction by UV/Vis spectroscopy. After the absorption peaks of the starting material had disappeared (the color of the solution changed from green to deep purple), the solvent was evaporated and the product purified by chromatography on silica gel, using $CHCl_3$ as the eluent. The first fraction eluted corresponded to the μ-oxo dimer (**1**), while the second fraction, eluted with a mixture of $CHCl_3$/MeOH (95:5), was characterized as the monomeric germanium methoxide (**2a**). GeTPC-Cl was obtained by treatment of fractions (**1**) and (**2a**) with HCl (4 M). Recrystallization from $CH_2Cl_2$/hexane (1:2), afforded GeTPC–Cl (**2b**) in 60% yield (76 mg, 0.12 mmol).

**Spectroscopic Data for 1:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 8.92 (d, $^1J$ = 4.2 Hz, 4 H, β-pyrrolic), 8.62 (d, $^1J$ = 4.2 Hz, 4 H, β-pyrrolic), 8.55 (d, $^1J$ = 4.8 Hz, 4 H, β-pyrrolic), 8.18 (d, $^1J$ = 4.8 Hz, 4 H, β-pyrrolic), 7.67 (m, 30 H, phenyl) ppm. MS (FAB): *m/z* (%): 1208 (60) [M$^+$]. $C_{74}H_{46}Ge_2N_8O$ (1208.45): calcd. C 73.55, H 3.83, N 9.27; found C 73.42, H 3.61, N 9.55.

**Crystal Data for 1:** Color: dark purple, $C_{74}H_{46}Ge_2N_8O{\cdot}0.5\,CH_2Cl_2$, $M_r$ = 1250.9, triclinic space group *P*-1, $a$ = 14.6167(15), $b$ = 19.802(3), $c$ = 23.156(4) Å, $\alpha$ = 72.715(7), $\beta$ = 85.464(8), $\gamma$ = 68.930(6)°, $V$ = 5968.8(15) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.440 g cm$^{-3}$, Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å; $\mu$ = 1.11 mm$^{-1}$), $T$ = 110 K, 31760 data by Nonius KappaCCD, $R$ = 0.098 ($F^2 > 2\sigma$), $R_w$ = 0.269 (all $F^2$) for 16529 unique data having $\theta < 23.2°$ and 759 refined parameters. Two Ge oxo dimers were found in the asymmetric unit. Because of the limited crystal quality, it was possible to refine only Ge, Cl and O anisotropically. Further disordered solvent was modeled with partially-populated C positions.

**Spectroscopic Data for 2a:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 9.40 (d, $^1J$ = 4.2 Hz, 2 H, β-pyrrolic), 9.21 (d, $^1J$ = 4.8 Hz, 2 H, β-pyrrolic), 9.08 (d, $^1J$ = 4.2 Hz, 2 H, β-pyrrolic), 8.91 (d, $^1J$ = 4.8 Hz, 2 H, β-pyrrolic), 8.44 (m, 2 H, phenyl), 8.35 (m, 1 H, phenyl), 8.21 (m, 2 H, phenyl), 8.09 (m, 1 H, phenyl), 7.81 (m, 9 H, phenyl), –0.96 (s, 3 H, O$CH_3$) ppm. MS (FAB): *m/z* (%): 627 (100) [M$^+$]. $C_{38}H_{26}GeN_4O$ (627.26): calcd. C 72.76, H 4.18, N 8.93; found C 72.83, H 4.42, N 8.96.

**Spectroscopic Data for 2b:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 9.45 (d, $^1J$ = 4.3 Hz, 2 H, β-pyrrolic), 9.24 (d, $^1J$ = 4.9 Hz, 2 H, β-pyrrolic), 9.12 (d, $^1J$ = 4.3 Hz, 2 H, β-pyrrolic), 8.94 (d, $^1J$ = 4.9 Hz, 2 H, β-pyrrolic), 8.42 (m, 2 H, phenyl), 8.34 (m, 1 H, phenyl), 8.24 (m, 2 H, phenyl), 8.11 (m, 1 H, phenyl), 7.81 (m, 9 H, phenyl) ppm. MS (FAB): *m/z* (%): 631 (100) [M$^+$]. $C_{37}H_{23}ClGeN_4$ (631.68): calcd. C 70.35, H 3.67, N 8.87; found C 70.44, H 3.69, N 8.96.

**Bromination of 2 ($Br_2$:2 = 300:1):** In a 250 mL round-bottomed flask equipped with a dropping funnel, complex **2a** (50 mg, 0.08 mmol) was dissolved in $CHCl_3$ (80 mL) and a solution of $Br_2$ (1.2 mL, 24 mmol; d = 3.119) in 30 mL of $CHCl_3$ was added dropwise during 15 min. The resulting mixture was stirred at room temperature for one hour; after this period, pyridine (0.24 mL, 3.02 mmol; d = 0.978) dissolved in $CHCl_3$ (30 mL) was added and the mixture stirred for a further hour. The crude mixture was then washed with an aqueous solution of $Na_2S_2O_5$ (20% w/v). The organic phase was dried with anhydrous $Na_2SO_4$, the solvent was evaporated and the crude mixture purified with silica gel (plug), using $CHCl_3$ as the eluent. A second fraction was eluted with a mixture of $CHCl_3$/MeOH (95:5). The first fraction was further purified by column chromatography on silica gel, using $CHCl_3$ as the eluent. Recrystallization from $CH_2Cl_2$/MeOH (1:2) of both fractions afforded respectively **3** (34%, 30 mg, 0.027 mmol) and **4** (5%, 5.3 mg, 0.004 mmol).

**Spectroscopic Data for 3:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 9.11 (s, 1 H, β-pyrrolic), 7.99 (m, 5 H, phenyl), 7.78 (m, 10 H, phenyl), –0.78 (s, 3 H, -O$CH_3$) ppm. MS (MALDI): *m/z* (%): 1101.6 (50) [M$^+$]. $C_{38}H_{20}Br_6GeN_4O$ (1100.64): calcd. C 41.47, H 1.83, N 5.09; found C 41.58, H 1.79, N 5.22.

**Crystal Data for 3:** Color: maroon, $C_{38}H_{20}GeBr_6N_4O$, $M_r$ = 1105.2, monoclinic space group $P2_1/n$, $a$ = 13.330(2), $b$ = 17.952(3), $c$ = 15.974(3) Å, $\beta$ = 114.325(6)°, $V$ = 3483.2(10) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 2.107 g cm$^{-3}$, Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å; $\mu$ = 7.87 mm$^{-1}$), $T$ = 110 K, 48918 data points by Nonius KappaCCD, $R$ = 0.051 ($F^2 > 2\sigma$), $R_w$ = 0.115 (all $F^2$) for 10534 unique data points having $\theta < 30.5°$ and 460 refined parameters. Residual electron density peaks near C7 and C13 indicated the presence of small amounts of heptabromo and/or octabromo compounds. Refinement of partially populated Br atoms at these positions led to populations of 2.6%.

**Spectroscopic Data for 4:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.78–7.41 (m, 20 H), 3.77 (q, 2 H, -O$CH_2$CH$_3$), 1.25 (t, 3 H, -OCH$_2CH_3$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon \times 10^{-3}$) = 440 (9.3), 601 (3.7), 642 nm (2.4). MS (MALDI): *m/z* (%): 1360.2 (20) [M$^+$]. $C_{44}H_{25}Br_8N_5O_2Zn$ (1360.33): calcd. C 38.85, H 1.85, N 5.15; found C 38.90, H 1.83, N 5.24.

**Crystal Data for 4:** Color: dark blue, $C_{44}H_{25}Br_8N_5O_2Zn{\cdot}CHCl_3{\cdot}C_4H_{10}O$, $M_r$ = 1457.1, monoclinic space group $P2_1/a$, $a$ = 15.599(10), $b$ = 13.913(7), $c$ = 24.280(17) Å, $\beta$ = 90.87(2)°, $V$ = 5269(6) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.837 g cm$^{-3}$, Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å; $\mu$ = 6.65 mm$^{-1}$), $T$ = 110 K, 22209 data points by Nonius KappaCCD, $R$ = 0.072 ($F^2 > 2\sigma$), $R_w$ = 0.154 (all $F^2$) for 7321 unique data having $\theta < 23.5°$ and 352 refined parameters. Because of limited crystal quality and disordered solvent, it was possible to refine only Zn, Br, Cl and O anisotropically. Refinement of the central metal as Ge led to unrealistically high displacement parameters for this atom as well as significantly higher $R$ values.

**Bromination of 2 ($Br_2$:2 = 70:1):** When the bromination is carried out under the reaction conditions described above, with a reduced amount of $Br_2$ (0.3 mL, 5.8 mmol; $d$ = 3.119), the subsequent chromatographic purification afforded **5** in 43% yield (35 mg, 0.034 mmol).

**Spectroscopic Data for 5:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 9.07 (s, 1 H, β-pyrrolic), 8.91 (d, $^1J$ = 4.98 Hz, 1 H, β-pyrrolic), 8.66 (d, $^1J$ = 4.98 Hz, 1 H, β-pyrrolic), 7.85 (m, 15 H, phenyl), –0.78 (s, 3 H, O$CH_3$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon \times 10^{-3}$) = 423 (215), 533 (10.3), 575 (22), 596 nm (33) ppm. MS (FAB): *m/z* (%): 1022 (60) [M$^+$]. $C_{38}H_{21}Br_5GeN_4O$ (1021.74): calcd. C 44.67, H 2.07, N 5.48; found C 44.56, H 1.98, N 5.52.

**Bromination of 2 ($Br_2$:2 = 1.1:1):** When the bromination is carried out under the reaction conditions described above, with **2** (70 mg,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.11 mmol) and 1.1 equiv. of $Br_2$ (6.3 μL, 0.12 mmol; d 3.119), the subsequent chromatographic purification afforded **6** in 49% yield (47 mg, 0.054 mmol).

**Spectroscopic Data for 6:** $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 9.38 (s, 1 H, β-pyrrolic), 8.96 (d, $^1J$ = 4.80 Hz, 2 H, β-pyrrolic), 8.81 (d, $^1J$ = 4.80 Hz, 2 H, β-pyrrolic), 8.12 (m, 5 H, phenyl), 7.77 (m, 10 H, phenyl), –0.84 (s, 3 H, O*CH*$_3$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon \times 10^{-3}$) = 414 (198), 525 (8.2), 565 (21.5), 589 nm (30.8) ppm. MS (FAB): *m*/*z* (%): 864 (70) [$M^+$]. $C_{38}H_{23}Br_3GeN_4O$ (863.95): calcd. C 52.83, H 2.68, N 6.49; found C 52.71, H 2.73, N 6.34.

CCDC631925 (for **1**), -631926 (for **3**) and -631927 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): $^1$H NMR spectra of new compounds are reported.

# Photochemistry of *trans*- and *cis*-[$RuCl_2(dmso)_4$] in Aqueous and Nonaqueous Solutions

**Małgorzata Brindell,[a] Grażyna Stochel,*[a] Valerio Bertolasi,[b] Rita Boaretto,[b] and Silvana Sostero[b]**

**Keywords:** Ruthenium / Photochemistry / Photolabilization / Photoisomerization / Antitumor agents

The photochemical behavior of the *trans*- and *cis*-[$RuCl_2(dmso)_4$] complexes has been investigated in organic coordinating solvents (dmso, $CH_3CN$) and aqueous solutions by means of electronic and $^1H$ NMR spectroscopy as well as chloride-selective electrode measurements. Excitation in the UVA and visible region of the *cis*-[$RuCl_2(dmso)_4$] complex in dmso leads to geometric isomerization with quantum yields $\Phi_{313} = 0.41$ and $\Phi_{365} = 0.49$ to give the photostable *trans* complex, whereas in acetonitrile and aqueous solutions, both isomerization and substitution processes occur. Moreover, in the latter two solvents, the *trans* isomer is photoactive and undergoes substitution reactions. In acetonitrile, for both *trans*- and *cis*-[$RuCl_2(dmso)_4$] isomers, selective photolabilization of the dimethylsulfoxide ligands results in the formation of the *trans*-[$RuCl_2(CH_3CN)_4$] complex. In aqueous solutions, the dmso and $Cl^-$ ligands are gradually substituted by water molecules to give as a final product a mixture of (aqua)ruthenium(II) and (aqua)(chlorido)ruthenium(II) complexes. These species may prove to be useful in the binding of cellular components.

## Introduction

The *trans* and *cis* isomers of the [$RuCl_2(dmso)_4$] complex exhibit antimetastasizing activity against several experimental tumors such as P388 leukemia, Lewis lung carcinoma, B16 melanoma, and MCa mammary carcinoma.[1–4] However, the side effects associated with the administration of the therapeutically required high doses of the compounds have promoted the search for alternative methods leading to enhanced anticancer activity of these complexes. A new approach involving site-specific photochemical activation of the metal complex in the tumor cells, which minimizes undesired toxic effects on normal cells, has been suggested recently.[5–8] Moreover, our previous results have shown that the cytotoxicity of the *trans* and *cis* isomers of [$RuCl_2(dmso)_4$] complexes against human (SK-Mel 188) and mouse (S91) melanoma cells is significantly increased by irradiation with UVA light.[9] It has been suggested that one of the factors that contribute to the enhanced antiproliferative activity of the two complexes after illumination is phototransformation of the complexes into more active species, which undergo reactions with cellular components.[9] In this respect it is interesting to understand the photochemical behavior of *trans* and *cis* isomers of ruthenium(II) complexes in greater detail. To the best of our knowledge, the photochemistry of the *cis*- and *trans*-[$RuCl_2(dmso)_4$] complexes in aqueous solution has never been investigated, and the only aspect mentioned in the literature concerns the application of light for the synthesis of the *trans* isomer from the *cis* analogue in dmso solution.[10] In this work we have investigated the photochemical behavior of the *trans*- and *cis*-[$RuCl_2(dmso)_4$] complexes upon irradiation with UVA and/or visible light in organic coordinating solvents like dimethylsulfoxide (dmso) and acetonitrile ($CH_3CN$) as well as in aqueous solutions. The results of Alessio et al.[10] are further corroborated by our present studies: the photochemistry is extended into a more synthetically useful area, and the photochemical properties of the [$RuCl_2(dmso)_4$] complexes are discussed in detail.

## Results and Discussion

### Photochemistry of *trans*- and *cis*-[$RuCl_2(dmso)_4$] in dmso

The electronic absorption spectra for the *trans*-[$RuCl_2(dmso)_4$] (**Ia**) and *cis*-[$RuCl_2(dmso)_4$] (**IIa**) complexes dissolved in dmso are presented in Figure 1 (see also Table 1S, Supporting Information).

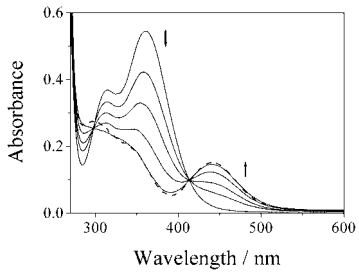

Figure 1. UV/Vis absorption spectra for a 1-mM dmso solution of *cis*-[$RuCl_2(dmso)_4$] irradiated at 365 nm at room temperature for 0, 0.5, 1, 2, and 5 min; the dashed line denotes the spectrum of *trans*-[$RuCl_2(dmso)_4$] in dmso solution.

The *cis* isomer is thermally very stable, whereas the *trans* complex can undergo isomerization to the *cis* analogue [Equation (1)]; however, this process is relatively slow at room temperature ($t_{1/2} \approx 75$ h).[10] Our results have shown that irradiation of a dmso solution of *cis*-[$RuCl_2(dmso)_4$] (**IIa**) with UVA (313 and 365 nm) or visible (400–600 nm) light results in the formation of *trans*-[$RuCl_2(dmso)_4$] (**Ia**). This is in agreement with a previous report by Alessio et al. showing that *trans*-[$RuCl_2(dmso)_4$] can be generated in situ by irradiation of *cis*-[$RuCl_2(dmso)_4$] dissolved in dmso solution with white light.[10]

$$cis\text{-}[RuCl_2(dmso)_3(dmso)] \underset{\Delta}{\overset{h\nu}{\rightleftharpoons}} trans\text{-}[RuCl_2(dmso)_4] \quad (1)$$

The photoisomerization process has been followed by UV/Vis spectroscopic measurements. The absorption band characteristic for the *cis* isomer ($\lambda_{max}$ = 360 nm) decreases in intensity, and a new band characteristic for the *trans* isomer at 441 nm appears upon irradiation (Figure 1). Isosbestic points occurring at 415 and 298 nm confirm simple *cis* to *trans* isomerization. The quantum yields for the photoisomerization reaction have been found to be $0.41 \pm 0.05$ and $0.49 \pm 0.03$ for irradiation at 313 and 365 nm, respectively. The photoisomerization is an efficient process, and the quantum yields are nearly independent of the wavelength of irradiation. This indicates that a good internal conversion of the charge-transfer (CT) manifold to the lowest ligand-field (LF) excited state occurs as observed in early studies of $Ru^{II}$ complexes.[11] No spectral changes have been observed during the irradiation of *trans*-[$RuCl_2(dmso)_4$].

### Photochemistry of *trans*- and *cis*-[$RuCl_2(dmso)_4$] in $CH_3CN$

Given the potential synthetic utility of the photoreaction reported in the Equation (1), we decided to find out whether derivatives of [$RuCl_2(dmso)_4$] could be prepared by photolysis in the presence of almost any coordinating agent L. Our objective here was to see whether sequential substitution of dmso by L is possible until every dmso has been replaced, i.e. whether [$RuCl_2(dmso)_4$] can be converted to [$RuCl_2(CH_3CN)_4$] if L ($CH_3CN$ in this case) resembles dmso in its bonding properties.

The analysis of $^1H$ NMR spectra for the *trans*- and *cis*-[$RuCl_2(dmso)_4$] complexes recorded after their dissolution in $CD_3CN$ indicates that two dmso ligands from the *trans* isomer and one from the *cis* isomer are immediately released and substituted by solvent molecules (Figure 2). These results indicate the formation of [$RuCl_2(dmso)_2(CH_3CN)_2$] from the *trans* isomer and [$RuCl_2(dmso)_3(CH_3CN)$] from the *cis* analogue. The $^1H$ NMR observations are interpreted in terms of the pathways outlined in Scheme 1.

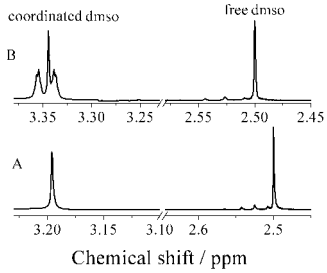

Figure 2. $^1H$ NMR spectra for *trans*-[$RuCl_2(dmso)_4$] (A) and *cis*-[$RuCl_2(dmso)_4$] (B) immediately after dissolution in $CD_3CN$ solution (for the *trans* isomer, the ratio of the integration area of the peak at 3.20 ppm to that at 2.50 ppm is 1:1; for the *cis* isomer, the ratio of the integration area of the peaks at 3.35–3.34 ppm to that at 2.50 ppm is 3:1); $T$ = 20 °C.

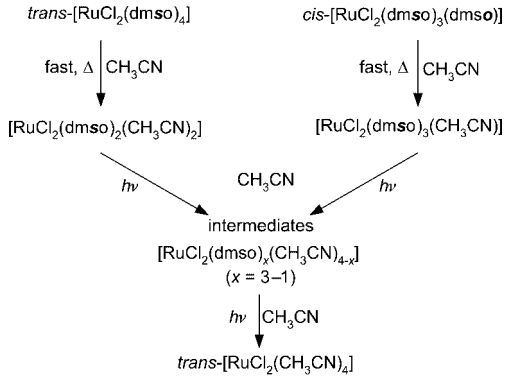

Scheme 1.

The electronic spectra for both complexes in acetonitrile indicated that the complexes are thermally relatively stable and that their further solvolysis process is slow enough not to interfere with our photochemical studies (see Figure 3 for the *trans* isomer).

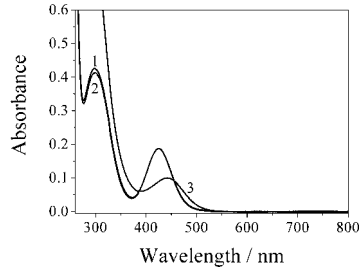

Figure 3. UV/Vis absorption spectra for a 1-mM acetonitrile solution of *trans*-[$RuCl_2(dmso)_4$] recorded immediately after dissolution (1), after 15 min at 20 °C (2), and upon irradiation at $\lambda_{irr} > 400$ nm for 15 min (3); $T$ = 20 °C.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Irradiation of the *trans* complex with visible light ($\lambda_{irr} > 400$ nm) results in the gradual dissociation of the remaining coordinated dmso ligands, as revealed in the $^1H$ NMR spectra by the decrease in the intensity of the $CH_3$ resonance at $\delta = 3.20$ ppm originating from the coordinated dmso ligands and the concomitant increase in the intensity of the $CH_3$ resonance at $\delta = 2.50$ ppm ascribed to free dmso in $CD_3CN$ solvent (Figure 4).

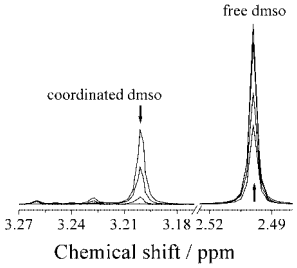

Figure 4. $^1H$ NMR spectra for *trans*-[$RuCl_2(dmso)_4$] ($CD_3CN$ solution) before irradiation (the ratio of the integration area of the peak at 3.20 ppm to that at 2.50 ppm is 1:1) and after being irradiated for 1, 5, and 15 min at $\lambda_{irr} > 400$ nm; $T = 20$ °C.

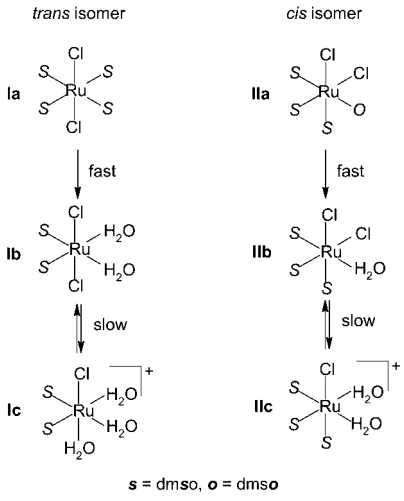
The photolysis of the *cis* complex proceeds according to the same sequence as that of the *trans* isomer. The possible photolabilization of the $Cl^-$ ligands can be excluded, because $Cl^-$ ions were not detected after photolysis of the complex. Prolonged photolysis of concentrated solutions of the *trans*- or *cis*-[$RuCl_2(dmso)_4$] complexes in $CH_3CN$ led to the formation of the complex *trans*-[$RuCl_2(CH_3CN)_4$]. This was established by elemental analysis, crystallographic data, and by $^1H$ NMR spectra. The resulting *trans* geometry of the complex (see crystallographic data in ref.[17]) was identical to that previously reported for *trans*-[$RuCl_2(CH_3CN)_4$] prepared by classical thermal routes[12–16] or by the photolysis of the [$RuCl_2(\eta^6$-*o*-*n*$Bu_2C_6H_4)]_2$ complex.[17] The new route for the synthesis of *trans*-[$RuCl_2(CH_3CN)_4$] by photosubstitution of dmso ligand with $CH_3CN$ from either the *trans* or *cis* isomer of the [$RuCl_2(dmso)_4$] complex is reported in detail in the Experimental Section.

### Photochemistry of *trans*- and *cis*-[$RuCl_2(dmso)_4$] in $H_2O$

To provide another possible pathway for the photochemical formation of the substitution products, we studied the photochemistry of *trans*- and *cis*-[$RuCl_2(dmso)_4$] in $H_2O$. In water solution, the complexes have been demonstrated[10,18,19] to undergo thermal hydrolysis as shown in Scheme 2.

According to Scheme 2, the two isomers, **Ia** and **IIa**, release two and one dmso ligands, directly after dissolution to afford *trans*,*cis*,*cis*-[$RuCl_2(dmso)_2(H_2O)_2$] (**Ib**) and *cis*,*fac*-[$RuCl_2(dmso)_3(H_2O)$] (**IIb**), respectively. For both complexes, a subsequent slow dissociation of chloride ions occurs. However, this is a very slow process: the half life of the reaction at 37 °C is ca. 1.5 and 1 h for the *trans* and *cis* isomer, respectively.[19] Binding of $H_2O$ to the ruthenium center gives rise to new electronic spectral features for **Ib** and **IIb**. The electronic spectrum of *trans*,*cis*,*cis*-[$RuCl_2(dmso)_2(H_2O)_2$] (**Ib**) (Figure 5A, curve 1), consists of two bands at 432 and 322 nm assigned to LF transitions and one band at 227 nm of CT character.[20,21] Similarly, the electronic spectrum of *cis*,*fac*-[$RuCl_2(dmso)_3(H_2O)$] (**IIb**) is characterized by three bands at 355 nm (LF transition), 310 nm (LF transition), and 255 nm (CT transition)[22] (Figure 5B, curve 1). For both isomers, the molar absorption coefficients for the two lower-energy bands were found to be higher than those for the usual LF transition (Table 1S). This may be due to the mixing of the LF energy levels with those corresponding to the neighboring intense CT band.[22]



Scheme 2.

The irradiation of a deaerated aqueous solution of the *trans* complex, **Ib**, with visible light induces significant UV/Vis spectral changes as shown in Figure 5A. The absorption maxima at 322 and 432 nm decrease gradually, and a new very weak band at ca. 540 nm and a shoulder at ca. 400 nm appear. Three isosbestic points at 285, 349, and 417 nm are observed upon very short irradiation of **Ib** (up to ca. 1 min, Figure 1S, Supporting Information). Further irradiation leads to the disappearance of these isosbestic points. These results could be interpreted in terms of a subsequent photochemical reaction with conversion of the initial product into new species. Irradiation of a deaerated aqueous solution of the *cis* complex, **IIb**, leads to a regular decrease in the intensity of the band at 355 nm and the concomitant appearance of a shoulder at ca. 420 nm (after 3 min of irradiation, Figure 5B). Further irradiation gives rise to spectral changes similar to those observed for the primary photochemical process of the *trans* analogue. The UV/Vis spectral changes observed for aerated solutions of both isomers, **Ib** and **IIb**, during their irradiation with visible light indicate the initial formation of products similar to those found in the absence of oxygen (Figure 5C and Figure 5D, for **Ib** and **IIb**, respectively).

The prolonged photolysis of both solutions (up to 15 min) results in the appearance of a new relatively intense band at ca. 300 nm, which is not observed for the oxygen-

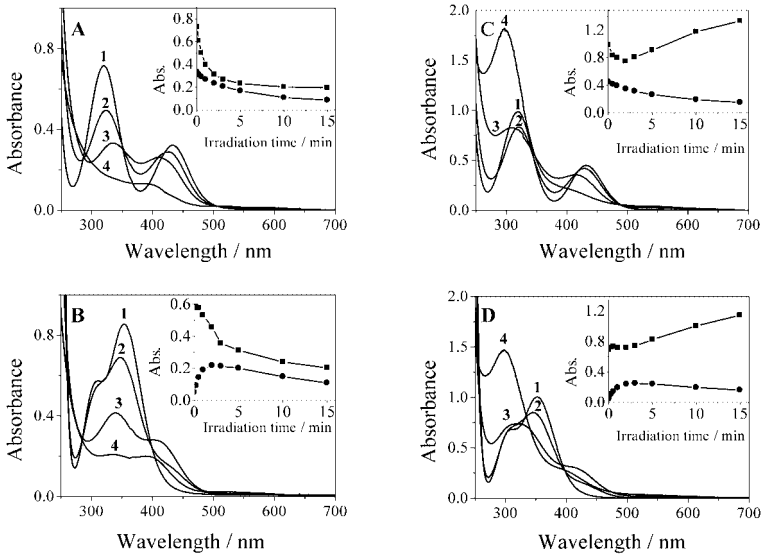

Figure 5. UV/Vis spectral changes during the photolysis ($\lambda_{irr}$ in the range 400–600 nm) of 2-mM aqueous solutions of **Ib** (A) and **IIb** (B) in an argon-saturated solution, and **Ib** (C) and **IIb** (D) in an air-saturated solution at room temperature. Spectra recorded after irradiation times of: 0 (1), 0.5 (2), 3 (3), and 15 min (4); $T$ = 20 °C. Insets: absorbance against irradiation time at 320 (■) and 432 nm (●).

free solution. The same product is also formed, as confirmed by UV/Vis spectra, when previously irradiated deaerated aqueous solutions of complexes **Ib** or **IIb** are purged with oxygen. These findings suggest that, after a long irradiation period in aerated solution, secondary thermal oxidation reactions of the primary photoproducts occur. Photolysis of **Ib** and **IIb** in the presence of $Cl^-$ ions was expected to yield additional information on the reactivity. Irradiation of **Ib** and **IIb** in aqueous solution in the presence of excess of NaCl (0.2 M solution, 100-fold excess over $Ru^{II}$ complexes) yielded the same spectral changes as those described above. The processes occurred with a lower efficiency, however, indicating that the overall mechanism includes a photodissociation of the $Cl^-$ ligands. It is likely that the UV/Vis spectral changes observed for complexes **Ib** and **IIb** occur as a consequence of photosubstitution reactions of the dmso and $Cl^-$ ligands with water molecules. To make sure that substitution of dmso by $H_2O$ occurs, we decided to take advantage of the different chemical shifts in the $^1H$ NMR spectra of the free ligands and of those coordinated to the $Ru^{II}$ center. The $^1H$ NMR spectrum of **Ib** recorded immediately after dissolution of the *trans* complex in $D_2O$ consist of two resonances of equal intensity at 2.73 and 3.36 ppm assigned to the $CH_3$ groups of the free and coordinated dmso ligands, respectively.(Figure 6A and Table 1).

The observation of two resonances is consistent with the mechanism in Scheme 2 showing that dissolution of the *trans*-$[RuCl_2(dmso)_4]$ complex leads to the formation of *trans,cis,cis*-$[RuCl_2(dmso)_2(H_2O)_2]$ (**Ib**) and two free molecules of dmso. Observation of the increase in the intensity of the $CH_3$ resonance at $\delta$ = 2.73 ppm in the $^1H$ NMR spectra (Figure 6A) during photolysis of complex **Ib** is indicative of a gradual dissociation of the dmso ligand. The resulting mixture of products was analyzed by $^1H$ NMR, and it was determined that (99 ± 4)% of the final products is a complex without dmso and the remaining is a complex

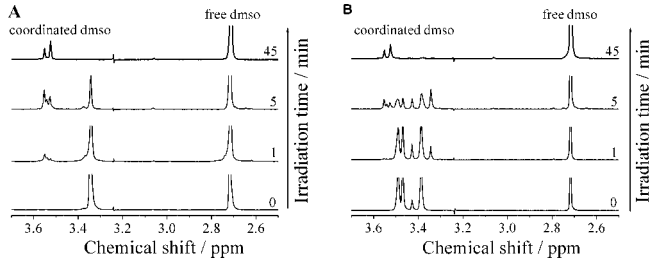

Figure 6. $^1H$ NMR spectra of the complex **Ib** (A) and **IIb** (B) ($D_2O$ solution) at various irradiation times; $\lambda_{irr}$ > 400 nm, $T$ = 20 °C.

Table 1. $^1H$ NMR chemical shifts ($\delta$/ppm) recorded for *trans,cis,cis*-$[RuCl_2(dmso)_2(H_2O)_2]$ (**Ib**) in $D_2O$ solution after irradiation in the range 400–600 nm at $T$ = 20 °C.

[a] Resonance assigned to $CH_3$ protons of free dmso.

still containing the dmso ligand (Figure 6A, Figure 7, and Table 1). Upon further investigation, we determined that, during the course of the irradiation, the dmso ligand rather than the $Cl^-$ ligand is labilized first. The analysis of the $^1H$ NMR spectrum indicates the absence of the resonance at $\delta$ = 3.39 ppm attributable to the $CH_3$ group of dmso in *cis,fac*-$[RuCl(dmso)_2(H_2O)_3]^+$ (**Ic**), a possible intermediate complex if $Cl^-$ dissociation is operative in the primary photochemical event.[23] In addition, a comparison of the quantitative data for the release of dmso and $Cl^-$ ligands (Figure 7 and Figure 8, respectively) supports the conclusion that the dmso ligand is more photolabile than the chlorido ligand.

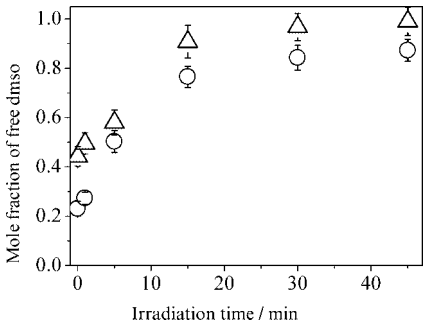

Figure 7. Mole fraction of free dmso molecules [defined as $(n_f)/(n_c + n_f)$, where $n_f$ denotes the number of moles of free dmso and $n_c$ denotes the number of moles of dmso coordinated to ruthenium ion] for **Ib** (Δ) and **IIb** (○) released during irradiation ($\lambda_{irr}$ in the range 400–600 nm; $T$ = 20 °C).

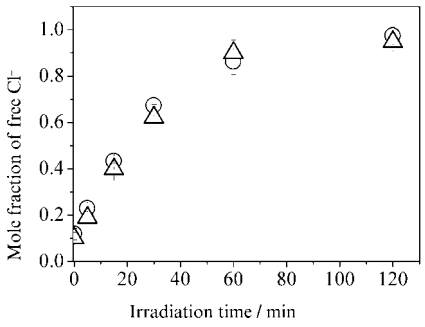

Figure 8. Mole fraction of free chloride ions [defined as $(n_f)/(n_c + n_f)$, where $n_f$ denotes the number of moles of free chloride ions and $n_c$ denotes the number of moles of chloride ions coordinated to ruthenium ion] for **Ib** (Δ) and **IIb** (○) released during irradiation ($\lambda_{irr}$ in the range 400–600 nm; $T$ = 20 °C).

Given the difficulties which can arise in elucidating the mechanism of the photoreactions described above, in order to conclude that Scheme 1 and Scheme 2 are the most likely pathways for the reactions, we felt that some care should be taken in ruling out other possibilities, especially those involving possible intermediates. The $^1$H NMR spectrum of *cis,fac*-[$RuCl_2(dmso)_3(H_2O)$] (**IIb**) presents thee resonances at $\delta$ = 3.40, 3.48, and 3.50 ppm assigned to the $CH_3$ groups of the three coordinated dmso ligands (Table 2).

Table 2. $^1$H NMR chemical shifts ($\delta$/ppm) recorded for *cis,fac*-[$RuCl_2(dmso)_3(H_2O)$] (**IIb**) in $D_2O$ solution after irradiation in the range 400–600 nm at $T$ = 20 °C.

| Irradiation time/min | $\delta$/ppm | | | | | | | | |

[a] Resonance assigned to $CH_3$ protons of free dmso.

The resonance at $\delta$ = 2.73 ppm is attributed to the $CH_3$ group of the free dmso present in the solution after dissolution of the *cis* isomer (Figure 6B, see also Scheme 2). A very small peak at $\delta$ = 3.44 ppm (the intensity is lower than 10% of the other resonances) is also observed and is attributed to one of the $CH_3$ groups of the dmso ligand in the hydrolyzed form of complex **IIb** (Scheme 2, complex **IIc**). The short irradiation of complex **IIb** leads to the formation of **Ib** as an intermediate. This is confirmed by the appearance in the $^1$H NMR spectrum of the peak at 3.36 ppm, assignable to the $CH_3$ group of the dmso ligand in complex **Ib**. Longer irradiation results in further formation of the intermediate **Ib**, which is photochemically unstable and undergoes secondary photolysis. These processes give rise to changes in the $^1$H NMR spectra leading to (i) gradual disappearance of peaks for the $CH_3$ protons of the dmso ligand of **IIb**; (ii) appearance of a new resonance, the same as that found for the irradiated complex **Ib**. The $^1$H NMR spectrum for the final photoproducts of **IIb** is the same as that observed for complex **Ib** (Figure 6). For both ruthenium(II) complexes, **Ib** and **IIb**, the increase of the peak intensity at $\delta$ = 2.73 ppm assigned to free dmso is a consequence of photolysis, since the increase of the resonance is not observed in thermal hydrolysis. The concentration of dissociated dmso ligands has been estimated by calculation of the area under the $CH_3$ resonance peak at $\delta$ = 2.73 ppm. The relevant measurements indicate an almost complete photodissociation of dmso ligands (Figure 7).

The *trans,cis,cis*-[$RuCl_2(dmso)_2(H_2O)_2$] (**Ib**) and *cis,fac*-[$RuCl_2(dmso)_3(H_2O)$] (**IIb**) complexes have two chlorido ligands in the *trans* and *cis* configuration, respectively. To provide trustworthy estimates of the amount of $Cl^-$ ions which might be present in the photoreaction mixture, we have carried out electrochemical experiments by using the ion-selective chloride electrode. Upon photolysis of complexes **Ib** and **IIb**, one begins to see the formation of $Cl^-$ ions as quantitatively reported in Figure 8. It is important to note that the thermal hydrolysis of the chlorido ligand in both complexes is relatively slow (vide supra). Thus, at the selected temperature (20 °C), the major contribution to the amount of free chloride ions in solution originates from the photodissociation of $Cl^-$ ligands. It appears that the release of chlorido ligands from both isomers takes place with similar yields. Longer irradiation (ca. 2 h) leads to nearly complete chloride dissociation.

The obtained results have shown that LF irradiation of *trans,cis,cis*-[$RuCl_2(dmso)_2(H_2O)_2$] (**Ib**) and *cis,fac*-[$RuCl_2(dmso)_3(H_2O)$] (**IIb**) leads to the photodissociation of dmso and $Cl^-$ ligands, which are substituted by water molecules. The photolysis of the *cis* isomer, **IIb**, generates the *trans* analogue, **Ib**, as an intermediate, which itself is also photoactive, giving the same products as those obtained in the direct photolysis of the *trans* isomer, **Ib** (Scheme 3).

The photolysis of the *trans* and *cis* isomers, **Ib** and **IIb**, results in the formation of the same final products, as confirmed by UV/Vis and $^1$H NMR spectra. On the basis of our findings and literature data,[24–27] these products could be a mixture of (aqua)ruthenium(II) and (aqua)(chlorido) ruthenium(II) complexes (Scheme 3). The photoproducts are very unstable in the presence of oxygen, as demonstrated by UV/Vis spectral changes. The gradual increase in

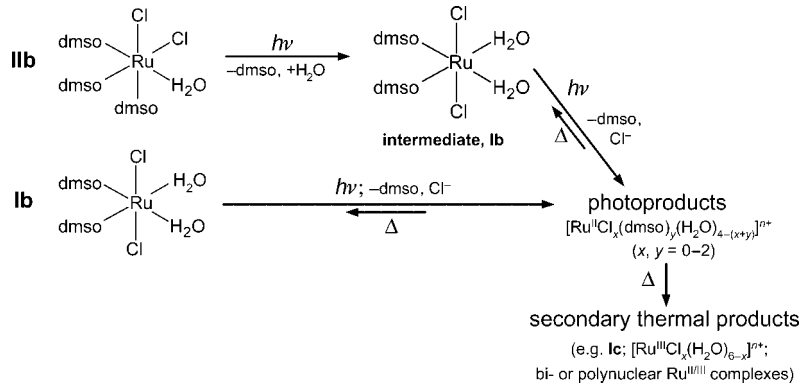

Scheme 3.

the intensity of the maximum at ca. 300 nm observed for aerated solutions, but not observed for deaerated solutions, could be ascribed to a slow thermal oxidation of the (aqua)-ruthenium(II) and (aqua)(chlorido)ruthenium(II) complexes to ruthenium(III) species.[25,27–30] Moreover, the prolonged thermal reaction (over a period of 24 h) at 20 °C results in a darkening of the irradiated solution. This result indicates that polymerization occurs along with hydrolysis, forming bi- or polynuclear species containing chlorido, oxido, or hydroxido bridges.[25,31] In addition to the above products, the $^1$H NMR spectra of photolyzed solutions of complexes **Ib** and **IIb** kept in the dark for 24 h have shown that still minor amounts of **Ib** and **Ic** are present for both isomers. Only in the presence of an excess of chloride ions (ca. 17-fold excess over $Ru^{II}$) are the photoproducts converted back to complex **Ib** (up to 60%) in the prolonged thermal reaction (Scheme 3).

## Conclusions

The various studies that have been conducted point to two main photoreactions of *trans*- and *cis*-$[RuCl_2(dmso)_4]$ complexes. The first is the photoinduced isomerization of the *cis* isomer to the *trans*-$[RuCl_2(dmso)_4]$ complex through the LF excited state. The second reaction appears to involve breakage of the metal–dmso bond, which results in the substitution of dmso with $CH_3CN$ and $H_2O$, when the photoreaction is conducted in acetonitrile and in water, respectively. In aqueous solution, photolysis of *trans*- and *cis*-$[RuCl_2(dmso)_4]$ leads first to the dissociation of the dmso ligand and then, in a secondary photochemical event, dissociation of the $Cl^-$ ligands. The ligand-loss photochemistry of *trans*- and *cis*-$[RuCl_2(dmso)_4]$ results in the formation of products of the type $[RuCl_x(dmso)_y(H_2O)_{4-(x+y)}]^{n+}$ ($x$, $y$ = 0–2). These new species, formed upon irradiation in $H_2O$ solution, have a considerable substitution lability relative to the *cis* and *trans*-$[RuCl_2(dmso)_4]$ complexes. These photoproducts may react quickly and with high efficiency with cellular components through sequential ligand exchange. This judgment is confirmed by our previous results,[9] which demonstrated an enhancement of the antiproliferative activity of the *trans*- and *cis*-$[RuCl_2(dmso)_4]$ complexes upon irradiation. Furthermore, the reaction of both isomers with a short oligonucleotide ($T_2GGT_2$) in aqueous solution is significantly facilitated by irradiation of the reaction mixture with UVA light.[9] These are interesting results, because they suggest that the photolysis of $Ru^{II}$ complexes with photolabile ligands will allow the covalent binding of cellular components.

## Experimental Section

### Materials and Syntheses

The ruthenium complexes, *trans*-$[RuCl_2(dmso)_4]$ (**Ia**) and *cis*-$[RuCl_2(dmso)_4]$ (**IIa**) were synthesized and purified according to published procedures.[10,32] Both elemental analysis {For *trans*-$[RuCl_2(dmso)_4]$ (484.54): calcd. C 19.81, H 4.95, S 26.41; found C 19.72, H 5.01, S 26.83 and for *cis*-$[RuCl_2(dmso)_4]$ (484.54): calcd. C 19.81, H 4.95, S 26.41; found C 19.92, H 5.03, S 27.21.} and electronic spectroscopy have been used for checking their purity (Table 1S, Supporting Information).[10,20–22] All other chemicals used were of analytical grade.

**Synthesis of *trans*-$[RuCl_2(CH_3CN)_4]$:** The complex was synthesized by irradiation of *trans*- or *cis*-$[RuCl_2(dmso)_4]$ (200 mg, 0.41 mmol) dissolved in acetonitrile (20 cm$^3$) with visible light (500-W high-pressure mercury lamp, cut-off: 400 nm) for 1.5 h. The irradiation resulted in the precipitation of a yellow solid, which was collected by filtration, washed with a little acetonitrile, and vacuum-dried at room temperature (98 mg, 71%). $[RuCl_2(CH_3CN)_4]$ (336.19): calcd. C 28.58, H 3.59, N 16.66; found C 28.62, H 3.40, N 16.64. $^1$H NMR (200 MHz, $D_2O$): $\delta$ = 2.60 (s) ppm. X-ray crystallographic analysis was used for the confirmation of the *trans* position of the chlorido ligands in this complex.

**X-ray Structure Determination:** An orange prismatic crystal of compound $[RuCl_2(CH_3CN)_4]$ was mounted on a Nonius Kappa CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at room temperature. The cell constants [$a$ = 11.8001(3), $b$ = 8.5722(3), $c$ = 13.1258(4) Å, $\alpha = \beta = \gamma$ = 90°] and the space group *Pbca* were obtained by least-squares refinement of the diffraction data from 7566 reflections with $1° < \theta < 30°$. The obtained crystallographic data perfectly agree with a previous report,[17] showing that the crystals of compound $[RuCl_2(CH_3CN)_4]$ consist of molecules of the complex *trans*-tetrakis(acetonitrile)(dichlorido)ruthenium(II).

**UV/Vis Spectroscopy:** Electronic absorption spectra were recorded in 1-cm quartz cells with a Shimadzu UVPC 2100 or a Hewlett–Packard HP 8463 spectrophotometer.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**$^1$H NMR Spectroscopy:** $^1$H NMR spectra were recorded with a BRUKER AC 200 spectrometer operating at 200.13 MHz. The chemical shift values were internally referenced to the dmso resonances ($\delta$ = 2.50 ppm in $CD_3CN$ or 2.73 ppm in $D_2O$).

**Chloride-Selective Electrode Measurements:** A chloride-ion-selective electrode (Carison) was used for the determination of the free chloride ion concentration. Each point in the plot is an average value of at least three independent experiments, and the error corresponds to the standard deviation.

**Photochemical Studies**

Continuous photolysis was carried out in the $\lambda_{irr}$ range from 400 to 600 nm by using a 500-W high-pressure mercury lamp equipped with a 400-nm cut-off filter (Oriel, Stradford – USA). The photolysis of *trans*- and *cis*-[$RuCl_2(dmso)_4$] complexes was carried out in solutions of dmso, $CH_3CN$, and $H_2O$ in 1-cm quartz spectrophotometer cells or in deuterated solvents ($CD_3CN$ and $D_2O$) in NMR tubes at 20 °C. All solutions of ruthenium(II) complexes were freshly prepared before use and deaerated when needed by bubbling argon through them. During irradiation, the solutions were stirred, and the temperature was kept at 20 °C by a refrigerated circulator (JULAB F12-EC). The progress of the photolysis was monitored by UV/Vis and $^1$H NMR spectroscopy, and chloride-selective electrode measurements. For spectroscopic measurements, samples were used as prepared for irradiation (2-mM solutions for UV/Vis and 3.5 mg complex/0.6 mL solvent for $^1$H NMR spectroscopy), whereas for the determination of free chloride ion concentration, the irradiated samples were diluted in 0.1-M $KNO_3$ solution.

For quantum yield determination, a 200-W high-pressure mercury lamp was used as a source of light, and interference filters (VEB Carl Zeiss JENA) were employed for wavelength selection (365 and 313 nm). Ferrioxalate actinometry was used at both wavelengths for light intensity determination.[33] Quantum yields of the photoisomerization of the *cis*-[$RuCl_2(dmso)_4$] into the *trans* analogue was determined from UV/Vis spectral changes upon irradiation of a 5.5-mM dmso solution of the *cis* isomer (the chosen concentration provides a complete absorption of light at both wavelengths).

**Supporting Information** (see footnote on the first page of this article): Electronic spectral data for complexes **Ia**, **IIa**, **Ib**, and **IIb**, and UV/Vis absorption spectra for a 2-mM, argon-saturated aqueous solution of **Ib** upon irradiation at $T$ = 20 °C for various time intervals up to 1 min; ORTEP view of *trans*-[$RuCl_2(dmso)_4$].

## COVER PICTURE

**The cover picture shows** the active site of galactose oxidase, as it was crystallized in the middle of the 1990s. Its active form featured an unprecedented copper(II)-tyrosyl (Tyr272•) radical system. Since 1996, several model compounds of this entity have been developed worldwide. They contributed significantly to the enhanced understanding of the spectral properties, structural attributes, and even to the reactivity of the enzyme's active site. Four prototypical complexes are shown; each of them is representative of the main classes of ligands developed (tripodal, salen, TACN, and iminosemiquinone scaffolds). Phenoxyl radicals typically exhibit absorption bands at around 420 and 600−800 nm, as shown in the UV/Vis spectrum. Ten years of this bioinorganic story is discussed in the Microreview by F. Thomas on p. 2379 ff.

# Focus on France – The French Chemical Society Is 150 Years Old

Several of the national Chemical Societies of European countries agreed to merge their journals about 10 years ago and create a selected number of thematic European Journals. The 10th anniversary issues of the *European Journal of Inorganic Chemistry* (*EurJIC*) and of the *European Journal of Organic Chemistry* (*EurJOC*), two of the first such journals to see the light of day, will be published later this year. It is therefore not only appropriate, but also incumbent on the European Journals to highlight and contribute to the celebration of the important events of their owner societies. This year is marked by the sesquicentennial anniversary of the *Société Française de Chimie* (SFC, French Chemical Society), one of the oldest in the world. Apparently, only the RSC (UK) has older roots, while the chemical societies of Germany, the United States, and Japan, to name a few, were established later.

The SFC was founded in 1857, though under a different name that has evolved through changes of status and mergers. As a matter of fact, it will soon switch back to its previous name *Société Chimique de France*, or SCF. The purpose of the Society is to gather both natural persons and legal entities from the public or private sector who are involved in the science of chemistry and its applications. It intends to contribute to the development of all aspects of the chemical disciplines, to be the center of information, to provide avenues for the meeting of interested members to diffuse their thoughts and propositions on questions of teaching and research, as well as on industrial, economical, and professional issues, and to represent its members and their disciplines within the society at large. The SFC is currently strong with ca. 4500 active members and has 9 thematic divisions, 13 scientific groups, 15 regional sections, and 15 clubs for younger members. A scientific general meeting is held every two years, and numerous annual meetings are organized by the individual divisions. The Society bestows a number of prestigious awards on French and international chemists and assists young scientists in their entrance into active professional life with an employment clearing house. It publishes, since 1973, a monthly magazine "*L'Actualité Chimique*" for the broad dissemination of knowledge in the chemical sciences and co-publishes, together with other European Societies, the above-mentioned European Journals. Last but not least, it cooperates with other national Chemical Societies through the European Association for Chemical and Molecular Sciences (EuCheMS).

Founded in 1857 as SCF

The SFC has 4500 Active Members

This year's meeting SFC07: "*Chimie du Futur, Futur de la Chimie*", held in Paris between July 16 and 18, 2007, marks the celebration of 150 years of the French Chemical Society. It is impossible to summarize in this short Editorial the impact of the multiple activities that the Society has had in its long and distinguished history. A detailed account of these will appear in a feature article published by "*L'Actualité Chimique*".

SFC07, "*Chimie du Futur, Futur de la Chimie*"

The co-ownership of *EurJIC* and *EurJOC* by the French Chemical Society fulfils one of its goals, to distribute research results. Part of the success of a chemical society (although by no means all of it) can be measured by the success of the research activities of its members. We would like to highlight this particular aspect in this Editorial. The impact of French chemistry research in the past 150 years has been enormous, as is detailed in the article by L. Lestel and I. Tkatchenko (pp. 2368–2371). One may ask the question: where does French chemistry research stand today? It is our proposition that modern French chemistry research is as lively and as vibrant as ever. This conclusion could be simply based on recent individual achievements, as measured, for instance, by recognition with international prizes, or by the number of publications in important international chemical journals. The percentages of papers published in *EurJIC* and *EurJOC* by French chemists are 9 and 12%, respectively, for the year 2006. These figures reflect the importance of French chemistry, in view of the fact that chemists from more than 30 countries publish in *EurJIC* and *EurJOC*. More important, in our opinion, is the active role that France plays in the process of globalization of research. Globalization is not only an economical, a cultural, and a technological phenomenon, but it also affects scientific research. This argument is not restricted to chemistry but applies to all scientific disciplines.

French Chemistry Research is as Lively as Ever

Like in many other European countries, funding of research in France relies in part on national resources (the Ministry of Research, through the newly created and inde-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pendently run "*Agence Nationale de la Recherche*", ANR, the "*Centre National de la Recherche Scientifique*", CNRS, and local governmental authorities), but a major portion of research support originates from the European Commission through a multitude of transnational programs. The French Ministry of Foreign Affairs is a leading actor in establishing bilateral scientific cooperation programs (called "Hubert Curien Partnerships", currently extended to almost 50 countries in all continents). Other bilateral programs are sponsored in different forms by the CNRS, including the establishment of virtual thematic research institutes ("*Laboratoire Européen Associé*", LEA; "*Laboratoire International Associé*", LIA) or networks ("*Groupe de Recherche Européen*", GDRE; "*Groupe de Recherche International*", GDRI) that join researchers from France and from other countries on the basis of a common research goal. These cooperation activities are not restricted to other developed countries but also include, and in some cases target specifically, developing ones. The establishment of shared transnational supervision of Ph.D. theses is encouraged and financially supported. Finally, visits of international scientists at all levels are sponsored by a variety of programs offered by Universities (open positions for visiting professors), by the CNRS (post-doctoral and higher-level fellowships), and by the local governmental authorities.

It is likely that globalization of research will continue to expand and that a growing fraction of major advances in science will be achieved through international cooperation. Thus, France and the French scientists seem well equipped to participate in this game by playing a leading role. It is worth underlining that the consolidation of the European Journals can be seen as an expression of this research globalization phenomenon and that chemists (by way of their national chemical societies) have been pioneers, at least at the European level. Within this operation, the French Chemical Society has been proactive since the very beginning of its history. As a matter of fact, the SFC was created by a group of European chemists, only a minority of whom were French. The first two presidents were an Italian (Jacques Arnaudon, from June 30 to the end of 1857) and a Norwegian (Hans Anton Rosing, from January to June 1858). French chemistry has been highly visible since the 19th century, and many European chemists, for instance Justus von Liebig, were attracted to France to pursue their training. In more recent times, besides the above-mentioned important role played in the creation of the new European Journals, the SFC has established, by agreement with its sister societies, binational prizes with Germany, Italy, Spain, Poland, and, since last year, the United Kingdom. These prizes allow extensive scientific exchange through lecture tours of the recipients in the host countries.

**Bilateral Scientific Cooperation Programs**

**Globalization of Research**

To conclude, the SFC is an Old Lady who has found a way to continued youth. Let her live forever!

# Chemical Pathways: 150 Years of Evolution of Chemistry

**Laurence Lestel[a] and Igor Tkatchenko[b]**

In 1857, a small group of chemists began to meet for informal discussions in Paris, founding the *Société Chimique*. Taking note of its national stature, the society was transformed into the "Société Chimique de France" in 1906. Then, after having merged with the "Société de Chimie Physique", it became the "Société Française de Chimie" in 1984. It celebrates its 150th anniversary this year. The "Société" witnessed the evolution of chemistry and chemists, of their knowledge, and of their goals, as did the other chemical societies created in this era, for example, the Chemical Society of London in 1841, the German Chemical Society in 1867, the Russian Chemical Society in 1868, the American Chemical Society in 1876 or the Chemical Society of Japan in 1878. Can one in a few words seize the impact of these changes?

**Marcellin Berthelot**

**Charles Friedel**

In 1857, organic synthesis was still in its infancy. Berthelot achieved the formation of fats by the combination of glycerol with acids in 1854. In addition his syntheses of organic compounds by means of simple chemical methods, such as those used at that time for inorganic derivatives in the famous "electric egg" apparatus, led to the final fall of the theory of a "vital force" inherent in organic compounds. His book *"Chimie Organique Fondée sur la Synthèse"* (1860) had considerable success and presents Berthelot as the founder of this discipline. At the same time, Perkin deposited his patent "Dyeing fabrics" (1856) in England, describing how to obtain dyes starting from residues of the distillation of coal, and this opened the way for the dye industry. After having deposited 152 patents to cover the development of the industrial process, BASF began the production of indigo in 1897. In these crucial years, the structures that allowed the development of the organic chemical industry fell into place: chemical companies (BASF, Hoechst, Bayer, Ciba, Geigy, British Alizarin, les Usines du Rhône, ...), industrial research laboratories associated to academic research, and new developments in chemistry such as chemical engineering, a term that was introduced in England in 1887 by Davis and rose to greater recognition at MIT, expanded rapidly as a required step for industrial scale-up. After having used "simple" reactions like nitration, reduction or oxidation of organic molecules, chemists started to use reactions specific to organic chemistry, for example, preparation of zinc alkyl iodides by Frankland for hydrocarbon synthesis, the Williamson synthesis for the preparation of ethers, and the use of sodium for the condensation of alkyl or aryl halides by Wurtz and then by Fittig. In 1877, Friedel and Crafts used anhydrous aluminum chloride as catalysts for the condensation of aromatic hydrocarbons and alkyl halides. The Friedel–Crafts reaction was applied to the preparation of perfumes, pharmaceutical products, dyes, and then monomers. It is essential to the chemical industry still today, albeit in more eco-compatible forms. A few years later, the Grignard reaction (1900), which allows the formation of a wide variety of organic compounds by the reaction of magnesium with organic iodides, was acquainted with a singular development, unique in the history of chemistry. Another useful tool was the hydrogenation of olefins by using catalysts as studied by Sabatier and Senderens. Progress in organic chemistry was accompanied by the set-up of its nomenclature during the congress of Geneva in April 1892, after two years of work by the Parisian commission of nomenclature chaired by Friedel.

Then a competition started between nature and artifice, between products resulting from nature and those imitating it or exceeding it. To understand the structure of natural products, the chemist decomposed them into small units, and then tried their synthesis. The apotheosis is the total synthesis of vitamin B12, undertaken by Woodward and his team in Harvard, in collaboration with Eschenmoser of Zürich. More than 100 researchers, including Lehn, took part in it. It was completed in eleven years and was announced in Delhi in 1972.

To fight against the shortage of resources and to improve productivity, the chemist found new synthetic routes (e.g. sodium

carbonate by the Solvay process; ammonia through hydrogenation of nitrogen; hydrocarbons and methanol starting from coal). The list is endless. It widened with the isolation of fluorine by Moissan, the discovery of rare gases by Ramsay, and the disclosure of radio elements by the Curie family.

The chemist also created completely new entities, for example, macromolecules. Polymer chemistry took off in the 1920s with Staudinger, who led the scientific community in the synthesis of long chain polymers, the physicochemical properties of which were intriguing for a long time and began to be explained with the soft matter concepts of de Gennes. The understanding of the organization of soft matter thanks to a large variety of weak interactions between molecules, not atoms, led to the design of numerous new man-made materials with improved performances, or "smart" materials mimicking natural ones. This was further extended to the area of liquid crystals, which are essential components of our everyday life. The design of new synthetic strategies and their industrial achievement allowed the development of alternatives to polymeric natural products like silk (Nylon) and rubber (polychloroprene, polybutadiene, polyisoprene, ...). Moreover, new materials appeared with the design of polyesters and polyolefins starting from $C_2-C_6$ building blocks obtained from petroleum cuts. Such developments demonstrate again the continuum existing between basic research and industrial processes: the best example is certainly the discovery of the Ziegler−Natta catalysts, which have heavily contributed to the rise of the petrochemical industry.

**Marie Curie**

**Pierre-Gilles de Gennes**

**Jean Rouxel**

The development in the second half of the 19th century of terrestrial (railways, metallic bridges) and maritime communications (and also armament) triggered the progress of metallurgy. Bessemer, Thomas, Siemens, and Martin designed new processes to obtain steels from cast iron; Hall and Héroult patented the electrolysis of alumina and the arc furnace. A scientific vision of industry is also shown by many contributions from Le Châtelier, professor at College de France then at Sorbonne, both in the fields of metallurgy and cements. Although used in the Neolithic era, ceramics were made in a much more rational manner, leading to a broad diversity of properties and applications. A better understanding of these materials, in which defects are, at the same time, a major disadvantage and a source of original behavior, led to solid-state chemistry, which appeared as a mature discipline at a Bordeaux congress held in 1964. From "hard", "shake and bake" chemistry, it became a tailored, "soft" chemistry, thanks, in particular, to the work of Rouxel and Livage, who approached this new world either with the chemical treatment of preformed materials or the stepwise and controlled synthesis from molecular species in solution. Again, natural structures and synthetic products are intrinsically linked through replication of constructions like the silica architectures of diatoma! A complementary approach relates to microporous materials, sources of "shape-selective" catalysts, membranes, and, even in its latest achievements, traps and reservoirs for molecular species.

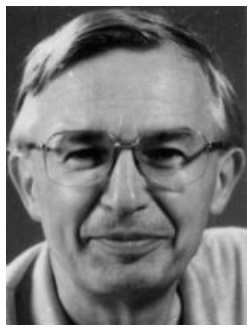
The identification of new sources of natural products that have astonishing structures with an impressive number of chiral centers shows the immense diversity of the molecular, macromolecular, and inorganic structures. An Alsatian, Werner, by proposing spatial arrangements of molecular entities around a metal cation to describe coordination complexes, laid the foundations of organization at a supramolecular level. Another Alsatian, Lehn, developed this concept, leading in a rational way to supramolecular chemistry with auto-organization and then self-assembly of increasingly complex entities. Nature, while being based on the multiplicity of ion−ion, ion−molecule, and molecule−molecule interaction modes, exploits this concept with increasing complexity, leading finally to living organisms capable of self-replication. Supramolecular chemistry suggests that if these interactions can be broken in the same way as they are made, a genuine constitutional dynamic chemistry would be in operation, providing original structures capable of auto-repair, another property related to all living things.

Many of these developments would not have taken place if the structure of the organic molecule had not been understood. In 1858, Kekulé proposed to describe organic molecules by their carbonaceous sequence, the carbon atom being tetravalent. The same year, Couper, who worked in the Wurtz laboratory in Paris, presented at the young "Société Chimique de Paris" his ideas on the "forces of attraction" that exist between the various elements of an organic molecule, what we call now bonds between atoms. The Couper formulae were used by Meyer in Germany, then by Boutleroff in France, who proposed the term "chemical structure" in 1864 "to indicate the chemical sequence or the way in which the atoms are connected" in a molecule. In the same year, modern chemical writing was introduced, thanks to Brown who depicted the atoms by their symbols and each connection by a continuous line. In 1874, the tetrahedral image of carbon was proposed by van't Hoff and Le Bel, hence opening the way to the three-dimensional representations of organic molecules. Thus, we can understand why apparently identical molecules are in fact dissymmetrical and deflect light differently. If "only the products born under the influence of Life are dissymmetrical", then "all the molecules prepared in our laboratories are symmetrical", said Pasteur. However, in 1894, Fischer, who studied the stereospecificity of enzymes, deduced from his observations the

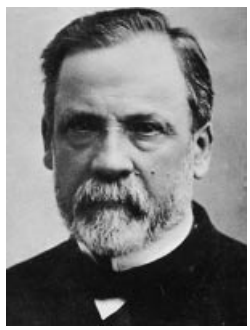
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structural "key−lock" relationship between a sugar and its enzyme. Prelog, Kagan, and many others used all the subtlety of asymmetric synthesis, then of enantioselective catalysis, to obtain man-made optically active compounds.

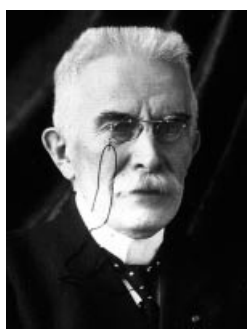
We have such a clear vision of atoms in our mind that we may have forgotten how strong the opposition was to atoms in France during the 19th century. At that time, atoms were a theoretical concept introduced by Dalton at the beginning of the 19th century, and this concept was adopted by the whole chemistry community during the Karlsruhe meeting in September 1860. In 1877, the Academy of Sciences was the witness of a violent controversy between Berthelot, opposed to, and Wurtz, defender of atomism. Wurtz and his many students employed the "Société Chimique de Paris" and its Bulletin as a mighty place for defending atomism in France, which gradually enabled the conversion of French chemists to this theory. Bohr applied the quantum theory to the planetary model of the atom proposed by Rutherford in 1911. To describe chemical bonding Lewis and Kossel developed, in 1916, the octet relationship, based upon the outer electrons. Hückel in Germany and Mulliken in the United States introduced molecular orbitals; however, Pauling is the true holder of this new approach, by introducing the notion of hybridization of carbon orbitals in a paper issued in 1931, and by publishing his famous book: "The Nature of the Chemical Bond" in 1939. If this era represents the golden age of the covalent bond, then other interactions were already taken into account: from dative bonds, first introduced by Werner, to the generalization of Lewis interactions, to weaker interactions like van der Waals forces present in soft matter. The importance of the hydrogen bond, exemplified by Pimentel's work, strongly contributed to the understanding of interactions occurring in biological systems: let us recall that the DNA structure is controlled by hydrogen bonds, which are also present in supramolecular chemistry. In addition to this diversity of bonding modes, the introduction of new concepts and the improvement of mathematical methods and data-processing led to descriptive and predictive tools for these connections and the resulting properties. Forty years after the foundations were set down by Schrödinger, the work of Hartree and Fock, Kohn and Pople have provided tools like density functional theory (DFT), now unavoidable for the understanding of physical and chemical properties.



**Jean-Marie Lehn**



**Louis Pasteur**



**Henry Le Châtelier**

Parallel to the development of this writing that makes chemistry a science which has its own alphabet, the desire of comprehension of the chemical reactivity was also very strong. Following the seminal works of Carnot, Kelvin, and Clausius, the development of thermodynamics led to the birth of physical chemistry — a junction of chemistry and physics — exemplified by Le Châtelier, Gibbs, Arrhenius, van't Hoff, and Ostwald, who often were chemists as much as they were physicists: Didn't Ostwald develop the ammonia oxidation process? It is worth noting the subtle differences that have appeared since between physical chemistry and chemical physics, if one considers the microscopic and now nanoscopic domains at which new chemical reactivity is being born. Physical chemistry, like analytical sciences, irrigates all the disciplines of chemistry, and the younger generations often neglect its importance; it is, for example, behind the classification of fundamental reactions of organic chemistry established by Ingold!

All these advancements could not have been done without a panoply of analytical tools pushing back the limits of detection and temporal scales of observation for more than two centuries. Centesimal analysis introduced after the works of Lavoisier and Priestley by Gay-Lussac and Thenard, Berzelius, Dumas, Liebig, and Pregl, to quote only the major contributors, was supplemented by isotopic analysis and determination of exact masses by high-resolution mass spectrometry. Separative analysis experienced extraordinary developments following the invention of chromatography by Tswett, a Russian botanist with a predestined name. If we had to wait until 1931 for the work of Kuhn on the separation of carotenes, then the post-war period saw the systematic recourse to this technique and its numerous alternatives, crowned by the Nobel Prize of Sanger in 1958. The pharmaceutical industry even exploits Tswett's technique to obtain optically active molecules from racemates.

Emission and absorption spectroscopy can be applied to an extremely broad frequency range, providing information on the structure and the movement of the chemical objects. This development goes hand in hand with a growing mastery of technology: in 1939, Beckmann introduced the first UV/Vis spectrophotometer, which enabled Woodward to achieve his PhD within one year − the first of the Woodward rules. The advancement of mass spectrometry led to considerable achievements as a spin off of the Manhattan project. In the same way, the rise in the use of increasingly high radio frequencies and intense magnetic fields benefited resonance spectroscopy, leading to the emergence, for example, of 1 GHz NMR spectrometers able to solve the structure of proteins of several tens of thousands of daltons. Lastly, the current data-processing resources has made it possible to systematize the use of Fourier transform with respect to NMR, IR, and EPR spectroscopy, mass spectrometry, and so forth. The discovery of X-rays on the eve of the 20th century has also contributed to the knowledge of the crystalline structure of increasingly complex molecules. In fact, the develop-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ment of intense and focused sources (synchrotron radiation), two-dimensional detectors (a consequence of Charpak's work), and powerful computational tools supplements the spectroscopic studies of molecules and macromolecules.

As never satisfied, the chemist also seeks to directly see the object of his studies. The development of magnetic lenses has allowed the visualization of nanometric and sub-nanometric objects by electron microscopy. Scanning electron microscopy is of primary importance for the development of materials and the study of their behavior. A new stage was reached with the work of Rohrer and Binning on scanning tunnelling microscopy (STM) and its derivatives, which allows not only the observation at atomic scale, but also writing on this scale with atoms. The last achievement in microscopy techniques, recently developed by Zewail, takes advantage of laser coherent electron packets generated with femtosecond laser pulses. The combination of spatial and temporal dimensions makes possible the analysis of the dynamic structure of inorganic, organic, and biological materials without damaging the objects by high-resolution electron microscopy.

**Joseph Fourier**

This extraordinary rise in laser technology largely opened the field of the studies including time as the fourth dimension in chemistry. The exploration of the "Femtoland" by Zewail, associated to the modeling of the processes studied, offers extraordinary prospects for the comprehension of chemical reactivity. Other methodologies, with other timescales, also make it possible to access various types of chemical events. Thus, cyclic voltammetry at very high scanning rates contributes to the mechanistic studies of electroactive systems; synchrotron radiation allows time-resolved diffraction experiments, and so forth.

Will we attend the birth of a virtual chemistry? It should be hoped that it does nothing but supplement the pallet of chemistry now extending to constitutional dynamic chemistry. To return to Berthelot, in conclusion, let us recall his remark: "the chemist creates the object of his study". The objects become only more complex and offer a promising future to chemistry and to chemists.

## Acknowledgments

## Iron Porphyrins

$Fe^{II}$ porphyrins, $[Fe(OEPy_4P)(B)_2]^{4+}$, B = Im or Py, were synthesized in three steps from Zn-*β*-octaethylporphyrin and characterized by mass spectrometry, UV/Vis spectroscopy, electrochemistry, and X-ray diffraction (B = Py). They are stable in air, show a highly distorted saddle-shape structure, and bear four positive charges close to the metal.

# Ten Years of a Biomimetic Approach to the Copper(II) Radical Site of Galactose Oxidase

**Fabrice Thomas*[a]**

**Keywords:** Biomimetic chemistry / Copper / Radicals / Bioinorganic chemistry / Enzyme models

An overview of recent progress in the modeling of the copper(II)-phenoxyl entity of the metalloenzyme Galactose Oxidase (GO) is presented. GO is an enzyme that is extremely engineered by nature: its active site exhibits several unusual features, such as a coordinated tyrosyl radical, post-translationally modified amino acids, and π-stacked residues. Understanding each of these particularities has posed a challenge for chemists, who have consequently developed several biomimetic complexes during the last decade. The properties of representative complexes are described herein, with special emphasis given to copper(II) complexes involving tripodal ligands. All these biomimetic compounds have been developed with the aim of better understanding biologically relevant problems. I show here that the structural attributes, reactivity, electronic properties, self-processing, and many other properties of GO can be addressed successfully using model complexes.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Various strategies are used by metalloproteins to store and transfer electrons in biochemical processes.[1] In the simplest case, the number of metal ions required for the reaction matches the number of electrons to be transferred. This is illustrated by tyrosinases that catalyze the hydroxylation of phenols, which have an active site that contains two copper ions. An organic cofactor could also complete the metal-driven electron transfer, as in copper amine oxidases that catalyze the oxidative deamination of amines using topaquinone. It has been shown recently that some metalloenzymes are able to generate an organic radical cofactor directly on their own peptidic chain to complete metal-driven electron transfers.[2,3] Galactose oxidase (GO), whose active site includes a tyrosyl radical coordinated to a copper(II) ion, is a prototypical enzyme of this class and is a fascinating example of synergy between a metal and a radical to perform oxidation reactions. The metal-radical array in these systems is much more than an association, and the advantage of maintaining a tyrosyl radical close to the metal ion is that hydrogen abstraction from a C–H bond by radicals is energetically favored over a hydrogen atom transfer to an inorganic metal-based oxidant (the thermodynamic affinity of a tyrosyl radical for a hydrogen atom is high).[4] The tyrosyl radical in GO thus performs the hydrogen atom abstraction while the metal ion is involved in a classical single electron transfer. GO is an enzyme that is extremely engineered by nature: its active site exhibits several unusual features such as post-translationally modified amino acids and π-stacked residues, and understanding each of these particularities poses a challenge for biologists and chemists alike. In studies aimed at understanding this enzyme, biochemists commonly use directed mutagenesis while chemists use a biomimetic approach. The latter consists of synthesizing and characterizing abiotic compounds that exhibit some or all of the enzyme's features. The devel-

*Fabrice Thomas was born in 1973. He did his undergraduate studies in Biochemistry at the University of Grenoble, where he received his Ph.D. degree in Molecular Chemistry in 1999. He then spent one year at the Institute of Physics at the University of Lübeck (Germany) as a postdoctoral fellow supervised by Prof. Trautwein. He worked on the characterization of iron centers in metalloproteins and models by Mössbauer spectroscopy. He is currently assistant professor in the Department of Molecular Chemistry, in the Inorganic Redox Biomimetic Chemistry team (CIRE) at the University of Grenoble. His main research interests are in the areas of inorganic and biomimetic chemistry. More specifically, he works on the metal-radical association in complexes that are bio-inspired by galactose oxidase.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

opment of mimics of GO began in 1996, and has contributed significantly to an enhanced understanding of the spectral properties, structural attributes, and even reactivity of its active site. Two reviews concerning the first-generation models of both the active $Cu^{II}$-phenoxyl and inactive $Cu^{II}$-phenolate forms of the GO active site[5,6] appeared in the literature in 2000.

Several complexes involving phenoxyl moieties coordinated to other divalent metal ions, or even trivalent metal ions, have also been synthesized. Many of these have been described by Wieghardt et al., and were reviewed in 2001.[7] These studies gave a lot of insights into the properties of coordinated phenoxyl radicals. More recently, a review focused on the aerobic oxidation of various substrates catalyzed by copper and manganese radical complexes has been published by the same group.[8] In this review I will briefly present the literature prior to 2000 and then focus my attention on more recent $Cu^{II}$-phenoxyl complexes. As a preamble, an overview of the biochemical properties of the GO active site is given. I then describe the properties of representative complexes that have been used as models of GO, with special emphasis on copper(II) complexes involving tripodal ligands, as their rich chemistry has been extensively studied by several groups. Next, I present the biologically relevant problems that have been addressed and solved by biomimetic studies, and finally I describe GO-inspired systems dedicated to the storage of three oxidizing equivalents (i.e. complexes containing either two phenoxyl radicals coordinated to a single copper ion, or a single phenoxyl radical coordinated to two copper ions).

## Galactose Oxidase

The most important aspects of GO chemistry have been recently reviewed, so only a brief presentation of the essential facts will be given here.[9–11] Galactose oxidase is an extracellular type II mononuclear copper protein (68 kDa) of fungal origin. GO catalyses the two-electron oxidation of a wide range of primary alcohols to their corresponding aldehydes with the concomitant reduction of molecular oxygen to hydrogen peroxide. The apparent paradox − a two-electron oxidation performed by a single copper ion − is explained by the involvement of another redox center, namely a tyrosyl radical from the protein, during the catalytic cycle. The physiological role of GO is not clear, although it could be involved in the production of $H_2O_2$ for further use as an co-oxidant for lignin- and cellulose-degrading peroxidases and could also provide an antibiotic defense within the rhizosphere.[10]

### Structure of the Active Site

GO has been crystallized and its X-ray crystal structure was reported about ten years ago (Figure 1).[12,13] Its active site comprises a copper atom in a distorted square-based pyramidal geometry with Tyr495 occupying the axial position. His581, His496, Tyr272, and an exogenous ligand ($H_2O$ or acetate, replacing the substrate) coordinate the copper in equatorial positions. The most striking feature of this complex is the cross-linking of Tyr272 to Cys228 through a thioether bond at the *ortho* position of the OH group, which presumably lowers the tyrosyl/tyrosine redox potential. The indole ring of Trp290 is π-stacked with Tyr272 and is believed to control the access to the active site and shield the Cys-Tyr cofactor from exposure to solvent. The enzyme can exist in three well-defined oxidation levels: the $Cu^{II}$-tyrosyl radical oxidized form, an intermediate $Cu^{II}$-tyrosinate form, and the reduced $Cu^{I}$-tyrosine form. Only the former and latter forms are catalytically active. The $Cu^{II}/Cu^{I}$ redox couple has been estimated to be –0.24 V vs. $Fc^+/Fc$ at pH 7,[14,15] while the tyrosyl/tyrosinate one has been estimated to be 0.01 V vs. $Fc^+/Fc$. The $Cu^{II}$-tyrosyl radical and the fully reduced copper(I) form undergo a rapid bimolecular comproportionation that affords the catalytically inactive $Cu^{II}$-tyrosinate form.[15]

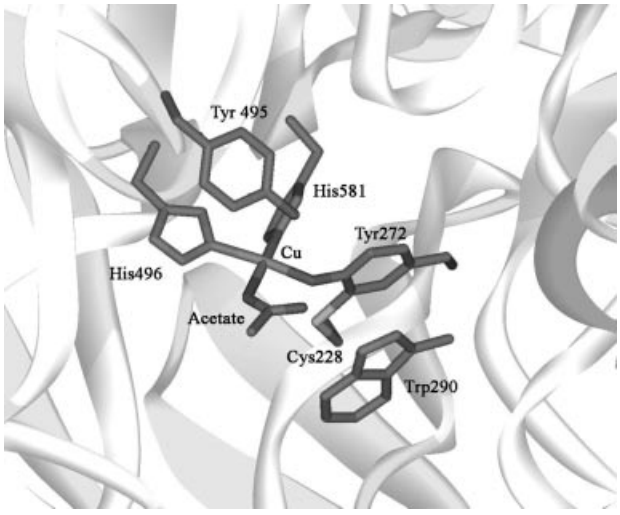

Figure 1. X-ray crystal structure of the active site of GO (adapted from ref.[12]).

The $Cu^{II}$-tyrosinate form possesses spectroscopic signatures that are typical of mononuclear copper(II) complexes, while the reduced form is EPR-silent and colorless. Extensive spectroscopic studies on the active oxidized form have shown that the radical is mainly harbored by the equatorially bound Tyr272 residue. Strong antiferromagnetic exchange coupling between the tyrosyl radical and the paramagnetic copper(II) ion results in a diamagnetic ground state, with a singlet–triplet splitting greater than 200 $cm^{-1}$.[16] A value of 752 $cm^{-1}$ has recently been reported from TD DFT calculations.[17] GO exhibits an unusually intense optical spectrum with absorption bands at around 445 and 800 nm[18] that are assigned to π–π* transitions of the tyrosyl radical.[9–11,17] The enzyme is relatively stable in this form, with a half life ($t_{1/2}$) of 7.2 days for its self-decomposition.[19]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Free Radical Catalysis**

Catalysis by GO proceeds according to a ping-pong turnover reaction.[18,19] In the first half-reaction the alcohol substrate binds to the oxidized $Cu^{II}$-radical active site and reduces both redox centers [tyrosyl radical and copper(II) ion], and the aldehyde product is released. This aldehyde product, which has a low affinity for the complex, is then released into the medium. In the second half-reaction, the $Cu^{I}$-tyrosine site binds $O_2$ and reduces it to $H_2O_2$, thus regenerating the initial $Cu^{II}$-tyrosyl radical state. A proposed catalytic mechanism is shown in path A of Figure 2.[9–11,18–21]

The catalysis is initiated by a weak (almost collisional) association with the substrate. The structure of GO reveals a shallow channel through which substrates bound by Phe194, Phe464, Arg330, and Trp290 reach the catalytic site. Reaction over a wide range of concentrations shows that the enzyme is saturable with a dissociation constant of 71 mM for the formation of the initial complex with D-galactose.[10] This low affinity, which is a consequence of a quite open active site, is consistent with a lack of substrate selectivity. In contrast, the enzyme strictly constrains the orientation of the substrate in its active site, thereby allowing a stereospecific abstraction of the pro-*S* hydrogen by the nearby tyrosyl radical. Modeling galactose coordinated to the copper(II) ion of the native enzyme shows that the pro-α-*S*-hydrogen is located at a hydrogen-bonding distance from Tyr272 (ca. 2.5 Å), while the pro-*R* hydrogen is away from the pro-radical cofactor.[11] The steric constraints that lead to this stereoselectivity are not limited to galactose, as similar selectivity as been demonstrated for any substrate bearing a branched β-C. After binding of the substrate to the copper equatorial position, the first step involves a proton transfer (step 1, Figure 2).[22] Deprotonation of the alcohol is facilitated by copper coordination and a short H-OTyr495 bond (estimated to be around 2.8 Å).[23] This process occurs with a low barrier (nearly isothermic), on a nanosecond timescale, due to the optimized hydrogen-bonding geometry and the close matching of tyrosine $pK_a$ and coordinated alcohol $pK_a$. Two crucial facts result from this first step: the $Cu^{II}$–substrate interaction is strengthened and the C–H bond energy of the deprotonated substrate is lowered by 10 kcal mol$^{-1}$. The second step involves a hydrogen-atom transfer from the alkoxide substrate to the equatorial Tyr272 radical (step 2, Figure 2). This is the major rate-limiting step (at high $O_2$ concentrations) in the whole catalytic pathway, as reflected by the

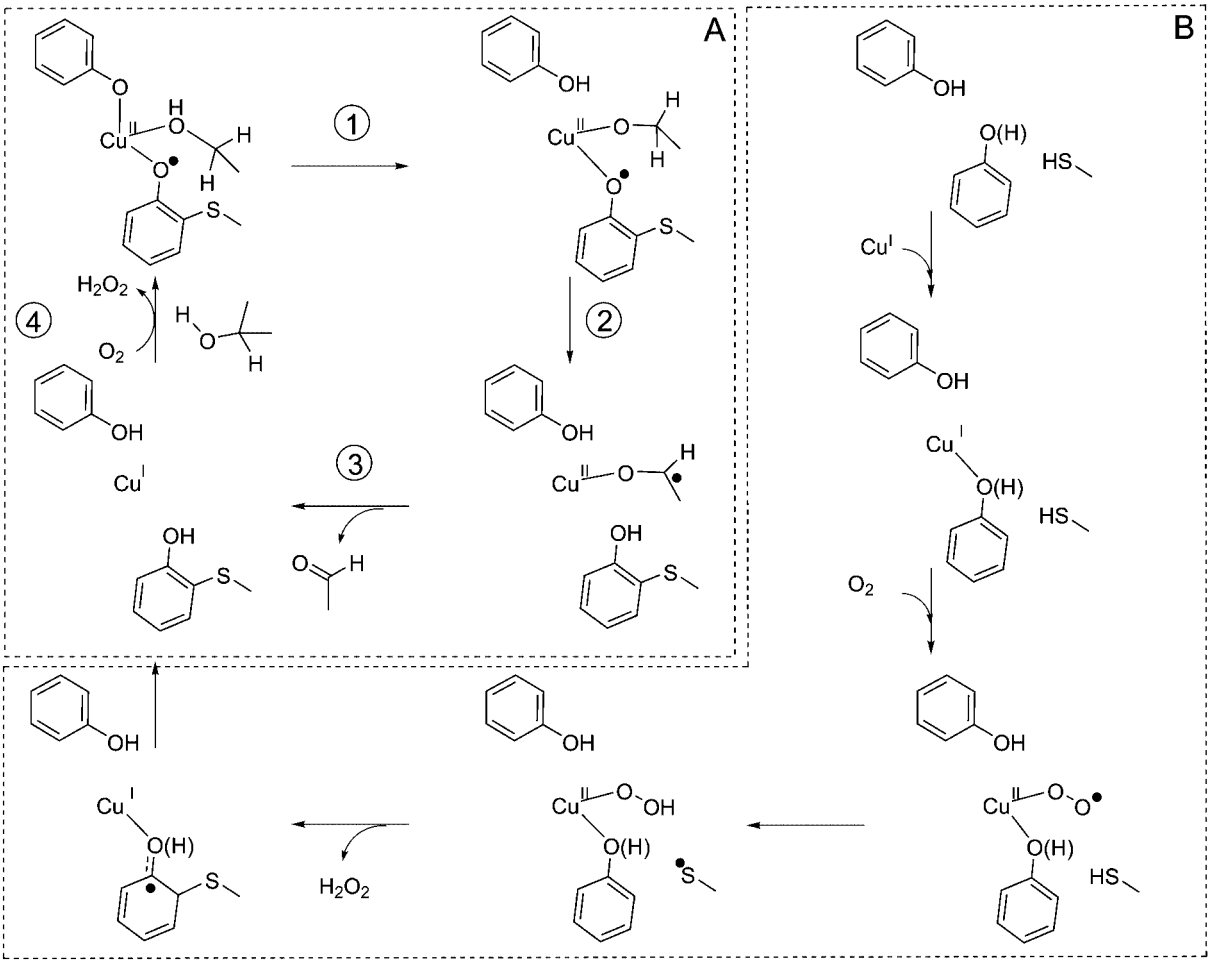

Figure 2. Free radical catalysis by mature GO (A) and self-processing of the pre-form of GO (B) (adapted from ref.[19,30] respectively).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

large kinetic isotope effect (KIE) of 7.7 for D-galactose (an even larger KIE of 22 has been reported for 1-*O*-methyl-α-D-galactopyranoside)[18] and the fact that GO remains essentially fully oxidized during turnover. The large non classical KIE of 22 as well as a strong temperature dependence of the KIE are clear evidence of the tunneling of a hydrogen atom in the rate-limiting step.

The free activation energy for hydrogen abstraction has been estimated to be 13.6 kcal mol$^{-1}$. An optimized structure for the transition state can be obtained from B3LYP calculations:[23] it has a five-atom cyclic structure in which the O–H bond length is 1.24 Å while the C–H bond length is stretched to 1.36 Å. The hydrogen atom is then transferred perpendicularly to the phenol ring plane, in agreement with a π character of the radical. Mechanism-based inactivation of GO by ultrafast radical probes confirms that a short-lived substrate ketyl radical anion results from the H-abstraction (hydrogen abstraction is rate limiting).[24] The ketyl radical then reduces the metal center (single-electron transfer; step 3, Figure 2) and is released to allow $O_2$ binding (step 4, Figure 2).[9–11,18–21,25]

Quantitative structure–activity relationship correlations using the steady-state rate data for the oxidation of benzyl alcohol derivatives have revealed that the three elementary events, namely proton transfer, single electron transfer, and hydrogen-atom abstraction, are asynchronous components of the whole catalytic process rather than distinct kinetic intermediates.[26,27] The difficult-to-oxidize nitro derivatives as well as pyranosides and physiological substrates exhibit a large substrate KIE associated with a negligible solvent KIE: C–H bond cleavage (hydrogen-atom abstraction) is here fully rate limiting. In contrast, the easier-to-oxidize methoxybenzyl alcohols exhibit a smaller substrate KIE and a non-negligible solvent KIE, thus reflecting a small proton transfer contribution in the transition state and a pronounced single electron transfer character for substrate oxidation.

The re-oxidation step of GO (step 4, Figure 2) is a remarkable example of two-electron chemistry catalyzed by dioxygen, as the ratio of superoxide released does not exceed one for 2000 turnovers. Kinetic data have shown that re-oxygenation of the GO active site occurs with a rate constant of around $8 \times 10^6$ M$^{-1}$ s$^{-1}$ at 277 K.[18] However, the high instability of the oxygenated complex makes this step much less certain than the former, in spite of a main role for the enzyme being formation of hydrogen peroxide.

## Radical Cofactor Formation

GO is a secretory protein, which means that its maturation requires several successive steps: cleavage of a signal sequence that directs translocation, metal binding, and cofactor processing. The structure of a metal-free unprocessed pre-form of the protein has been described recently.[28] Its active site does not contain the Cys-Tyr cross-link, and Cys228 has been found oxidized into a sulfenic acid. This latter modification likely arises from oxidative damage to the protein. Conversion of this pre-form into the catalytically active form appears to be a self-processing event that requires only copper and $O_2$.[29] Copper in both oxidation states induces cross-linking and radical cofactor formation, but with very different time scales [$t_{1/2}$ = 3.9 s at pH 7 with copper(I) and 5.1 h with copper(II)]. The $Cu^I$-dependent biogenesis reaction may thus more closely resemble the physiological process.[30] A mechanism for this reaction, which involves initial copper(I) binding to the pre-form to afford a trigonal copper(I) complex that reacts with $O_2$, has been proposed recently (Figure 2, B). The resulting species is a reactive $Cu^{II}$-$O_2^{\cdot-}$ compound that abstracts a hydrogen atom from Cys228 and releases $H_2O_2$. The thiyl radical then attacks the ε-C ring carbon of Tyr272, and rearomatization occurs by proton and electron transfer to the metal. At this stage, the fully reduced form of the mature GO is obtained. This then readily undergoes two-electron oxidation by $O_2$ to give the catalytically active $Cu^{II}$-tyrosyl radical form of the enzyme and $H_2O_2$.

## Main Classes of Model Compounds for the GO Active Site

The discovery of a $Cu^{II}$-phenoxyl radical entity in the GO active site has stimulated a number of chemists to incorporate this unknown unit in coordination complexes. For phenoxyl radicals to exist as more than a transient intermediate in solution, the *ortho* and *para* positions of the phenol must be blocked by groups that give increased steric protection or resonance stabilization.[31] The phenoxyl radicals are strongly colored − they exhibit characteristic absorption bands in the regions between 400 and 450 nm and above 600 nm that are attributed to π–π* transitions − which makes them easy to detect.[32] During the last decade many efforts have thus been made to incorporate such modified phenols in ligands, leading to the isolation of complexes able to model (functionally or structurally) the GO active site. The main ligand scaffolds developed will be listed below, together with the general properties of the corresponding copper(II) complexes. The following nomenclature will be used: $H_xL^y$ for a ligand $y$ possessing $x$ acido-basic sites and $[Cu(H_xL^y)(X)_z]$ for the copper(II) complex of $H_xL^y$ bearing $z$ coordinated exogenous ligands (X being an anion or solvent molecule). For clarity, the overall charge of the ligands and complexes is omitted. When the oxidation number of the copper ion is not indicated it is +2.

## Salen Ligands

A wide number of copper(II) complexes of salen-type ligands have been described so far, therefore the discussion here will be limited to general considerations and complexes specifically designed to model the GO active site,[33–43] in other words those bearing a sterically bulky substituent at the *ortho* and *para* positions of each phenol to prevent bis(μ-phenolate) dimer formation and to stabilize a phenoxyl radical (Figure 3). The copper(II) ion in these com-

plexes is tetracoordinate in a square planar or tetrahedral geometry, as shown by their X-ray crystal structures and EPR spectroscopy. The flexibility and degree of distortion from square planar towards a tetrahedral geometry can be modulated by the nature of the linker between each salicylidene moiety. The electrochemical behavior of salen complexes is characterized by two oxidation waves at potentials higher than 0.3 V vs. $Fc^+/Fc$ {$[Cu(L^2)]$,[34,35] $[Cu(L^5)]$,[37] $[Cu(L^7)]$,[37,39,40] and $[Cu(L^8)]$[37]}, corresponding to the successive formation of mono- and bis(phenoxyl) radical species (Table 1). The reduced salen complexes {$[Cu(L^{3,4})]$[36–38] and $[Cu(L^6)]$[39,40]} exhibit a similar oxidative behavior, although they are much more easily oxidized. On a spectroscopic point of view, the UV/Vis spectra of the salen complexes is dominated by intense charge-transfer (CT) transitions at around 400 nm ($\varepsilon > 8000\ M^{-1}cm^{-1}$), while the reduced salens exhibit a much less intense phenolate-to-copper CT ($\varepsilon < 2000\ M^{-1}cm^{-1}$). Both exhibit low intensity copper(II) d–d transitions at wavelengths higher than 500 nm. Upon one-electron oxidation, the highest intensity bands of the salen complexes are shifted towards higher wavelengths (Table 1). The UV/Vis spectra of the $Cu^{II}$-phenoxyl complexes of reduced salen complexes are more similar to those of uncoordinated phenoxyl radicals, with classical π–π* transitions at around 400–450 and 600–700 nm (Table 1). Stack et al. have also measured the NIR

spectra of [Cu($L^{6\cdot}$)] and [Cu($L^{7\cdot}$)] and found intense transitions at 1600 and 1750 nm, respectively, attributed to phenolate-phenoxyl charge transfers.[39,40] All the $Cu^{II}$-monophenoxyl radical complexes were found to be EPR-silent as the result of a magnetic coupling between the coordinated radical and the metal spins.

The first use of salen copper(II) complexes to mimic the reactivity of GO towards alcohol oxidation was reported in 1986 by Katajima et al.[33] Unfortunately, no evidence for a "true" GO-like reactivity, such as phenoxyl radical formation, was shown in the reaction of the copper(II) complex of $H_2L^1$ with alcohols.[33] Stack et al. revisited these kinds of complexes 10 years later. He reported that the copper(II) complex of $H_2L^1$ is able to catalyze the aerobic oxidation of benzyl alcohol into benzaldehyde with high turnovers (1300 at 295 K in 20 h).[34,35] The ligand structure was improved to achieve such reactivity: the phenolate moieties were *ortho*- and *para*-substituted by electron-donating groups to stabilize the phenoxyl radical, and a significant tetrahedral distortion was induced around the copper atom [thus stabilizing the copper(I) ion] by using a binaphthyl linker. They showed experimentally that the active species is the $Cu^{II}$-phenoxyl form of the complex. The substrate adduct was a five-coordinate square-pyramidal $Cu^{II}$-phenoxyl complex (further theoretical studies on its reactivity are presented below). Oxidation of the initial $Cu^{II}$-phenolate complex into the catalytically active $Cu^{II}$-phenoxyl radical species, however, requires addition of a strong oxidant. For this reason we have synthesized the copper(II) complex of the reduced salen ligand $H_2L^3$.[36,37] This complex is much more readily oxidizable, as judged by its redox potential, which is around 0.5 V lower than for Stack's model complex (Table 1). The $Cu^{II}$-phenoxyl complex leads to the oxidation of several unactivated primary alcohols (such as methanol) into aldehydes in the presence of catalytic amounts of base; secondary alcohols are not affected.[36] More recently, copper(II) complexes of reduced salen ligands have also been described by Palaniandavar et al. ($H_2L^4$)[38] as well as Stack et al.[39,40] [Cu($L^6$)], for instance, was shown to model the acceleration of the reaction rate by substrate binding as does GO. Its "true" salen complex derivative [Cu($L^7$)], however, does not exhibit such reactivity. In another approach, we focused our interest on developing planar scaffolds such as $H_2L^5$ and $H_2L^8$ to stabilize copper(II) coordinated bis(phenoxyl) radicals.[37] The $Cu^{II}$-phenoxyl radical complex of [Cu($L^{8\cdot}$)] has been further utilized by other groups[41] for different purposes.[42] A pentadentate reduced salen ligand, which could be oxidized into a $Cu^{II}$-phenoxyl radical species, as shown by its EPR-silence and π–π* transitions at 390 and 408 ($\varepsilon > 1000\ M^{-1}cm^{-1}$) and 600–900 nm ($\varepsilon < 1000\ M^{-1}cm^{-1}$), has also been described by Neves et al.[43]

### Imino-, Thio-, and Semiquinonate Ligands

Wieghardt et al.[44–51] have contributed widely to the development of an extraordinary class of model compounds for GO that involves imino-, thio-, and semiquinonate ligands (Figure 4). These are much more easily oxidizable (the phenolate oxidation potentials are negative vs. $Fc^+/Fc$, which makes them oxidizable by air; Table 2) than other classes of ligands, and are so stable in their radical form that structural characterization could be envisaged. Some of these complexes were also found to be efficient catalysts for the aerobic oxidation of alcohols. Mixing the tridentate ligand $H_2L^9$ with copper(II) in the presence of triethylamine and air affords the EPR-silent dinuclear $Cu^{II}$-phenoxyl complex [Cu($L^{9\cdot}$)]$_2$, which exhibits absorption bands at 408 and 650 nm (Table 2).[44] The mononuclear $Cu^{II}$-phenoxyl complex [Cu($L^{10\cdot}$)($NEt_3$)] was obtained under similar conditions by replacing $H_2L^9$ with $H_3L^{10}$ and structurally characterized.[45] The tridentate ligand is coordinated to a single copper(II) ion and the fourth coordination site is occupied by an $NEt_3$ molecule. This complex is also EPR-silent as a result of an antiferromagnetic coupling between the radical and the metal spin ($J$ estimated at $-137\ cm^{-1}$). Both [Cu($L^{9\cdot}$)]$_2$ and [Cu($L^{10\cdot}$)($NEt_3$)] were found to be very efficient catalysts for the aerobic oxidation of alcohols. Interestingly, treatment of a solution of copper(I) and $H_3L^{10}$ neutralized by $NEt_3$ with pure dry $O_2$ yielded crystals of a copper(II) complex containing a bound superoxide ion, an intermediate suggested in the catalytic pathway of GO. Recently, $H_2L^{11}$, the selenium analogue of $H_2L^9$, has been described.[51] This ligand reacts with copper ions in the pres-

ence of different amines to give rise to a variety of mono-, di-, and even trinuclear complexes that exhibit distinct reactivities towards alcohol oxidation.

The coordinated tetradentate ligand $H_4L^{12}$ can exist in five oxidation levels (each of which has been fully characterized), two of which are paramagnetic monoradicals and another is a diamagnetic diradical.[46] $[Cu(L^{12\cdot})]$ (and its zinc analog) selectively oxidizes primary alcohols in a stoichiometric fashion under anaerobic conditions to yield the corresponding aldehyde and a protonated form of the two-electron-reduced catalyst. This latter complex can reduce molecular dioxygen into $H_2O_2$, thus regenerating $[Cu(L^{12\cdot})]$. This makes oxidation of alcohols into aldehydes catalytic under aerobic conditions. $H_2L^{13}$, the sulfur analogue of $H_2L^{12}$, has been described along with its copper(II) complexes.[48] Electrochemical experiments showed that the coordinated *o*-thioetherphenolate moieties could be oxidized into phenoxyl radicals. Unfortunately, the oxidized species are very unstable and do not allow further spectroscopic characterization.

## TACN Ligands

The macrocycle 1,4,7-triazacyclononane (TACN) coordinates one metal ion through its three amine groups and can be further derivatized to incorporate one, two, or three additional coordinating groups such as phenols (Figure 5). Many mono- and bis(phenolate) copper(II) complexes have been structurally characterized that show a five-coordinate copper(II) ion in a slightly distorted square-pyramidal geometry. A coordination number of six can be achieved by addition of exogenous bidentate ligands such as $Ph_2acac$.[52] In all of the structures the phenolate donor(s) reside(s) in the equatorial plane (*cis* to each other if two are present), while one amine nitrogen coordinates weakly in the axial position.

Tolman et al. reported one of the first model compounds for the $Cu^{II}$-radical site of GO using this TACN framework, namely the copper(II) complex $[Cu(L^{15})(CH_3CN)]$, in 1996.[53,54]. Its $Cu^{II}$-phenoxyl radical form was found to be relatively stable in $CH_2Cl_2$, as judged in the cyclic voltammograms by the reversible signal at 0.31 V (vs. $Fc^+$/Fc) obtained for the phenoxyl/phenolate redox couple. It is EPR-silent as the result of a magnetic coupling between the radical and the metal. No more phenolate-to-copper CT transitions are observed at 538 nm in the radical complex $[Cu(L^{15\cdot})(CH_3CN)]$. Instead, absorption bands typical for

phenoxyl radicals are observed at 410 and 672 nm (Table 3). The benzyl alkoxide adduct $[Cu(L^{15})(benzyl\ alkoxide)]$ has been crystallized and shows an $O_{phenolato}\cdots H–C_{substrate}$ interaction similar to that proposed for GO during enzyme turnover. More recently, the $Cu^I$-phenolate complexes of $HL^{15}$ and $HL^{16}$ have been isolated with the aim of modeling the reduced form of the GO active site.[55] Their reactivity towards molecular dioxygen will be discussed below.

This TACN scaffold has been developed concomitantly by Wieghardt et al.: the $Cu^{II}$-bis(phenolate) complex $[Cu(L^{17})]$ and its counterpart phenol-phenolate complex $[Cu(HL^{17})]$ could be isolated from the ligand $H_2L^{17}$.[57] The CV curves of $[Cu(L^{17})]$ exhibit two ligand-centered oxi-

[a] V vs. $Fc^+/Fc$. [b] $\lambda$ [nm] ($\varepsilon$ [$M^{-1}cm^{-1}$]). [c] X-band. The $Cu^{II}$-phenolate complexes exhibit an $S_{Cu} = ½$ signal.

dation waves, while a single wave is observed for [Cu($HL^{17}$)] (Table 3). The electrochemically generated $Cu^{II}$-phenoxyl complexes [Cu($L^{17\cdot}$)] and [Cu($HL^{17\cdot}$)] are X-band EPR-silent (Table 3), which may be interpreted either by an antiferromagnetic exchange, which yields an $S_t = 0$ ground state, or large ZFS parameters of an $S_t = 1$ ground state.

The phenol-bis(phenolate) copper(II) complexes [Cu($HL^{18,19}$)] and phenolate-bis(phenol) copper(II) complexes [Cu($H_2L^{18,19}$)] have also been isolated from the ligands $H_3L^{18,19}$ (Figure 5).[56] The tris(phenol) form was found not to be stable in solution for prolonged periods. The phenol-bis(phenolate) and phenolate-bis(phenol) forms can interconvert easily by adding one equivalent of base or acid. The X-ray crystal structure of [Cu($HL^{19}$)] shows that one phenol unit is not coordinated to the metal ion. The CV curves of [Cu($HL^{18,19}$)] exhibit two one-electron transfer waves in the –0.06 to 0.38 V range assigned to the successive oxidation of each phenolate moiety. [Cu($H_2L^{18,19}$)], which possess a single phenolate moiety, exhibit a single wave in the 0.26–0.44 V potential range (Table 3). EPR spectroscopy reveals that [Cu($HL^{18,19\cdot}$)] and [Cu($HL^{18,19\cdot}$)], similar to [Cu($L^{17\cdot}$)] and [Cu($HL^{17\cdot}$)], are difficult to detect as they are EPR-silent (Table 3). They exhibit features in their UV/Vis spectra (Table 3) at around 400 nm ($\varepsilon$ values ranging between 2000 and 6000 $M^{-1}cm^{-1}$) and in the 500–800 nm region ($\varepsilon$ values lower than 1300 $M^{-1}cm^{-1}$). The intensity of the 400-nm absorption increases significantly upon protonation and its position is shifted bathochromically. This shows that protonation affects the electronic structure of the $Cu^{II}$-phenoxyl chromophore. The electronic hole of the phenoxyl radical in the [Cu($HL^{18,19\cdot}$)] complexes is thus proposed to be delocalized over both the phenoxyl and the phenolate moieties, whereas the spin of the unpaired electron of the phenoxyl radical is more localized on one aromatic ring in [Cu($H_2L^{18,19\cdot}$)].

## Tripodal Ligands

Several research groups have adapted the well-known tripodal aromatic framework bis(pyridyl)alkylamine connected to a single phenol ($N_3O$ donor set), or mono(pyridyl)alkylamine attached to two phenols ($N_2O_2$ donor set), for GO chemistry (Figure 6).[58–75] The ligand framework has been extensively studied and modulated by modifing (i) the length of the alkyl chain linking the pyridine and the pivotal nitrogen, (ii) the steric bulk provided by the *ortho* substituent of the phenol, (iii) the electronic properties of the *para* substituent of the phenol, and (iv) the basicity of the pyridine donors. A number of monomeric or dimeric complexes have been prepared from different copper(II) salts. The potential of an $N_2O_2$ aliphatic tripodal ligand, where the pyridine has been replaced by a primary amine and one phenol by a hydroxyl, to mimic the GO active site was explored by Hahn et al. in 2001.[76] The copper(II) complex of this ligand was isolated as a dimer that exhibits a phenolate-centered electrochemical activity. Since the coordination chemistry of tripodal aromatic ligands has been widely described during the last decade and now allows the rational design of new complexes, it will be presented in more detail than that of other ligands.

Mononuclear $Cu^{II}$-phenolate complexes of general formula [Cu($L^{N_3O}$)(X)] can be obtained from $N_3O$ ligands in the presence of $NEt_3$ if the following conditions are fulfilled: large steric bulk (*tert*-butyl group) provided by the *ortho* substituent of the phenol[58,59,61] and/or use of a copper(II) salt containing a strong monoanionic donor $X^-$.[71,72] Many of these complexes have been structurally characterized by X-ray crystallography[58–61,64,69,71,72] and show that the copper(II) ion is pentacoordinate, with a solvent or exogenous anion that completes the $N_3O$ donor set of the ligand (Figure 7). The phenolate donor can bind

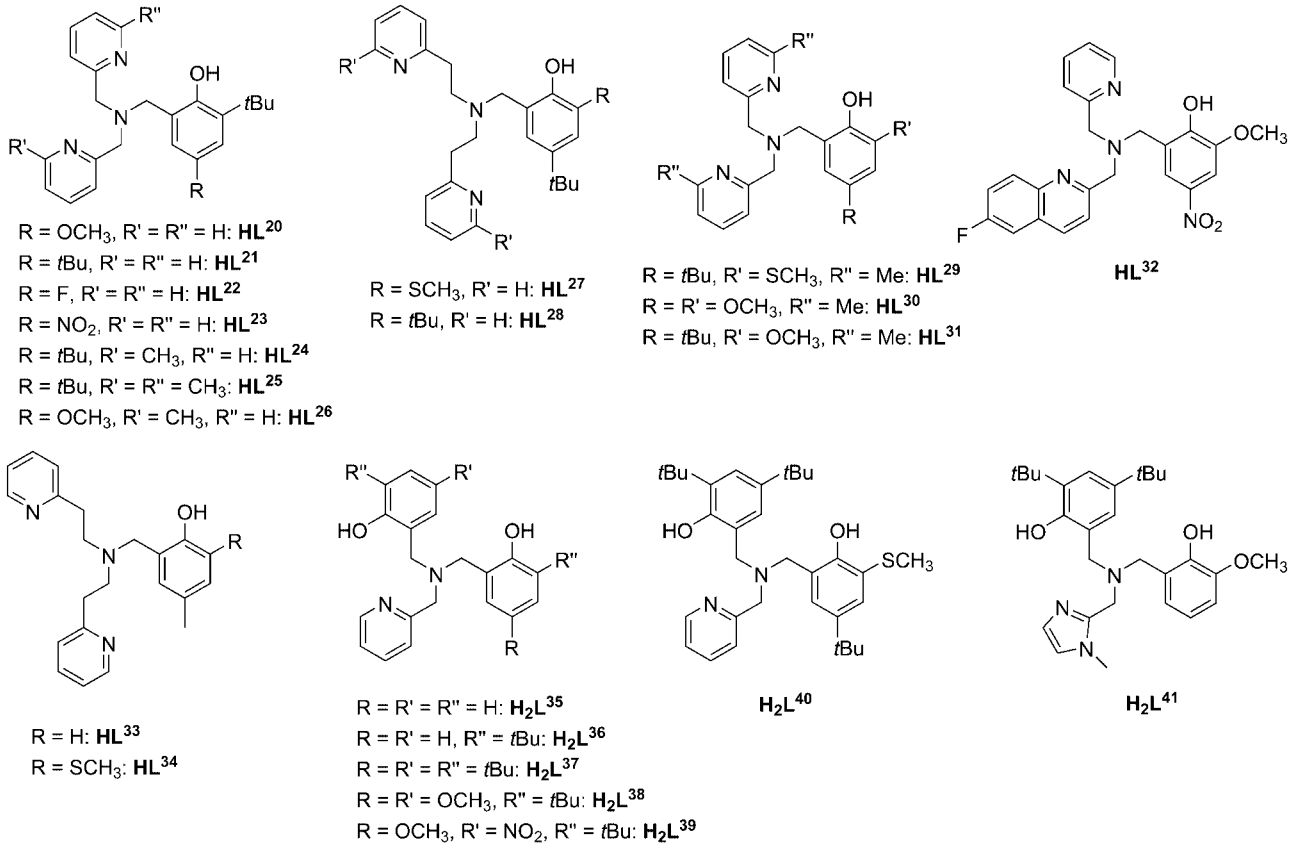

Figure 6. Formulae of some representative tripodal ligands: $HL^{20–23}$ (ref.[58]), $HL^{24,25}$ (ref.[59]), $HL^{26}$ (ref.[60]), $HL^{27,28}$ (ref.[61]), $HL^{29}$ (ref.[62]), $HL^{30,31}$ (ref.[63]), $HL^{32}$ (ref.[64]), $HL^{33,34}$ (ref.[74]), $H_2L^{35}$ (ref.[75]), $H_2L^{36}$ (ref.[65]), $H_2L^{37}$ (ref.[66]), $H_2L^{38}$ (ref.[58]), $H_2L^{39}$ (ref.[58,67]), $H_2L^{40}$ (ref.[68]), $H_2L^{41}$ (ref.[69]).

either in an equatorial[58–61,64,69] or axial[58,71,72] position. The respective influence of the phenolate *para* substituent and alkyl linker arm length on the position of this phenolate have been well documented by Palaniandavar et al. and Fenton et al. (see below). The relative extent of the trigonal-bipyramidal distortion is indicated by the value of $\tau$, which represents the degree of trigonality within the structural continuum between square-planar and trigonal-bipyramidal structures.[70] $\tau$ is usually lower than 0.35 for these complexes, which shows that the geometry around the metal ion is predominantly square pyramidal with a slight distortion towards trigonal bipyramidal.[58–61,64,69,71,72] A sample structure is given in Figure 7. In the $Cu^{II}$-phenolate complexes of $HL^{24,25}$,[59] as well as the $Cu^{II}$-phenol complexes of $HL^{20}$ and $HL^{26}$,[58,60] the $Cu–N_{methylpyridine}$ bond is longer than the $Cu–N_{pyridine}$ one, which is ascribed to steric hindrance around the methylpyridine nitrogen. All these complexes exhibit a phenolate-to-copper CT transition and less intense d–d transitions as a lower energy tail ($\lambda_{max}$ > 600 nm, Table 4) in their UV/Vis spectra. $\lambda_{max}$ of the CT transition is shifted according to the electronic properties of the phenolate substituent (from 565 nm for $[Cu(L^{20})(CH_3CN)]$ to 517 nm for $[Cu(L^{23})(CH_3CN)]$). The EPR spectrum is characterized by a signal that is typical for mononuclear copper(II) species ($S$ = ½; Table 4).

[a] V vs. $Fc^+/Fc$. [b] $\lambda$ [nm] ($\varepsilon$ [$M^{-1}cm^{-1}$]). [c] At –40 °C. [d] X-band. The $Cu^{II}$-phenolate complexes exhibit an $S_{Cu} = ½$ signal except $[Cu(L^{27})]_2$, $[Cu(L^{29–31})]_2$, $[Cu(L^{36})]_2$, $[Cu(L^{38})]_2$ and $[Cu(L^{40})]_2$ (dimeric species). [e] Generated by copper(II) oxidation. [f] Underestimated due to its low stability. [g] Obtained by a disproportionation reaction. No structure reported.

When the complexation reaction is performed with a copper(II) salt that does not contain a strong monoanionic donor and ligands that bear a phenol without steric bulk at its *ortho* position, dimeric species of general formula $[Cu(L^{N_3O})]_2$ are obtained.[61–63,71–75] X-ray structural analysis of $[Cu(L^{30})]_2$ has shown that the two copper ions are

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

square pyramidal but slightly distorted towards trigonal bipyramidal (Figure 7).[60] The copper ions are bridged by the oxygen atoms of two phenolates, one from each ligand, which can occupy either a mixed axial/equatorial[62,71–73] or exclusively equatorial[62,63,73,74] position in the coordination polyhedron of each copper(II) ion. The two copper ions in these structures are separated by 3.1–3.2 Å and exhibit either an $S = 1$ signal or no signal at all in their EPR spectrum, which indicates that the copper(II) spins interact magnetically (Table 4).[61,62,71–74] The CuOCuO core is almost planar when the phenolate coordinates one copper atom in the axial position, while it shows a slight "butterfly" structure when it coordinates exclusively in the equatorial position.

The copper(II) complexes isolated from $N_2O_2$ ligands in the presence of $NEt_3$ are usually dimeric species of general formula $[Cu(L^{N_2O_2})]_2$ irrespective of the bulkiness of the phenolate *o*-substituent.[58,65–67] One example of a mononuclear $[Cu(L^{N_2O_2})(X)]$ structure has been characterized by X-ray diffraction as a biomimetic model of GO,[70] while many others have been obtained by adding coordinating solvents or bases to the $[Cu(L^{N_2O_2})]_2$ dimers.[58,65,75] Even though the chemical formula $[Cu(L^{N_2O_2})]_2$ seems similar to that of $[Cu(L^{N_3O})]_2$, significant differences can be observed between the two. In the $[Cu(L^{N_2O_2})]_2$ dimers, for example, the geometry around the copper(II) ion is more distorted towards trigonal bipyramidal ($\tau = 0.35$ for $[Cu(L^{38})]_2$ shown in Figure 7) and the intermetallic distance is shorter (2.869 Å for $[Cu(L^{38})]_2$). Consequently, the CuOCuO core is not flattened as in $[Cu(L^{N_3O})]_2$ but shows a marked "butterfly" structure (with a dihedral angle of 126° for $[Cu(L^{38})]_2$). The dimers are EPR-silent (Table 4) as a result of a strong antiferromagnetic interaction between the copper(II) ions that we have estimated to be $-189\ cm^{-1}$ for $[Cu(L^{35})]_2$[75] and $-31\ cm^{-1}$ for $[Cu(L^{36})]_2$.[65] The presence of two phenolates per ligand makes the phenolate-to-copper CT transition more intense than in the $[Cu(L^{N_3O})(X)]$ and $[Cu(L^{N_3O})]_2$ complexes (Table 4). We[67] and Fukuzumi et al.[68] have isolated dimeric copper(II) complexes of $N_2O_2$ ligands possessing two differentiated phenolate arms. In $H_2L^{39}$, for example, one phenolate bears an electron -withdrawing nitro group while the other possesses an electron-donating methoxy group. We have shown that the electron-donating methoxyl group compensates more efficiently than the nitro group for the electron deficiency on the bridging oxygen atom. The substitution thus orients the position of the phenolate groups in $[Cu(L^{39})]_2$ according to their electronic properties.[67]

In general, conversion of the dimers $[Cu(L^{N_2O_2})]_2$ and $[Cu(L^{N_3O})]_2$ into monomeric structures can be promoted by addition of exogenous donor ligands (pyridine, acetate) or protons.[58,61–63,65,67,68,73–75] In the case of $[Cu(L^{N_3O})]_2$, oxidation (chemical or electrochemical) has also been shown to induce this dimer-to-monomer conversion.[61–63] Dissociation constants can be obtained from spectrophotometric titration of $[Cu(L^{N_3O})]_2$ in the presence of pyridine or acetate. Steric repulsions caused by the 6-methyl groups of the pyridine nucleus significantly lower (one to two orders of magnitude) the stability of the dimers,[62] while an increase in the length of the alkyl linker arm does not significantly affect the dissociation constant.[73,74] The most striking feature is the influence of the phenol *para* substituent: in the presence of pyridine, the dimer $[Cu(L^{33})]_2$ exhibits a dissociation constant 100 times lower than that of $[Cu(L^{34})]_2$. This fact is consistent with an increased steric bulk at the phenolate *ortho* position caused by the methylthio group in $[Cu(L^{34})]_2$ compared to a hydrogen atom in $[Cu(L^{33})]_2$.[74] The coordination sphere has also been found to influence the solution behavior of the dimers. Thus, $[Cu(L^{38})]_2$ remains dimeric in $CH_3CN$ while no such structures could be detected in the solution of the $Cu^{II}$-phenolate complex of $HL^{20}$, which suggests a greater stability of the $[Cu(L^{N_2O_2})]_2$ dimer than $[Cu(L^{N_3O})]_2$.[58]

Addition of one molar equivalent of proton [relative to the copper(II) concentration] to the $Cu^{II}$-phenolate complexes $[Cu(L^{N_2O_2})]_2$, $[Cu(L^{N_3O})]_2$, and $[Cu(L^{N_3O})(X)]$ results in the formation of the corresponding $Cu^{II}$-phenol complexes $[Cu(HL^{N_2O_2})(X)]$ and $[Cu(HL^{N_3O})(X)]$, as judged by the mononuclear copper(II) signal observed in the final EPR spectrum.[58,63,67,75] The protonation state of these complexes can be confirmed by UV/Vis spectrophotometry as $[Cu(HL^{N_2O_2})(X)]$ and $[Cu(HL^{N_3O})(X)]$ lack the phenolate-to-copper CT transition and only the copper(II) d–d transitions at around 600 nm are observed (Table 4). The copper(II) atom exhibits essentially the same geometry as in the mononuclear $Cu^{II}$-phenolate complexes, in other words square planar slightly distorted towards trigonal bipyramidal (Figure 7). The X-ray crystal structures of the $[Cu(HL^{20–23})(CH_3CN)]$ complexes (ligand with a $N_3O$ donor set) show that the phenol moiety systematically occupies the more labile axial position in the copper coordination sphere, regardless of the substituent.[58] The axial Cu–O distance is usually longer than 2.4 Å in $[Cu(HL^{20–23})(CH_3CN)]$, while it is around 2.2 Å for axially coordinated phenolates. The phenol group thus only coordinates the copper ion weakly. We have recently shown that deprotonation of the complex $[Cu(HL^{32})(CH_3CN)]$, in which the phenol is *axial*, induces an isomerization (Figure 7):[64] the phenolate moiety coordinates in an *equatorial* position in the deprotonated complex $[Cu(L^{32})(CH_3CN)]$. $^{19}F$ NMR spectroscopy allowed us to determine a rate constant of $3000 \pm 100\ s^{-1}$ for the following equilibrium at $T = 226$ K:

$$[Cu(HL^{32})(CH_3CN)]^1 + [Cu(L^{32})(CH_3CN)]^2 \rightleftharpoons [Cu(L^{32})(CH_3CN)]^1 + [Cu(HL^{32})(CH_3CN)]^2$$

where superscripts 1 and 2 represent the two distinct complexes that interconvert.

This rate constant is large, thereby indicating that proton transfer and/or molecular rearrangement is extremely rapid.

In the crystal structures of $[Cu(HL^{37})(OAc)]$[64] and $[Cu(HL^{39})(OAc)]$[65] ($N_2O_2$ ligands) only one phenol is protonated. The ligand in $[Cu(HL^{39})(OAc)]$ possesses two differentiated phenolic arms: since the electron-donating effect of $OCH_3$ relative to $NO_2$ makes deprotonation of the hy-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

droxyl group more difficult, only that exhibiting the highest $pK_a$ (and thus the lowest oxidation potential) is protonated. This provides evidence for the geometric control of the two different phenolic arms.[67]

The electrochemical behavior of the mononuclear [Cu($L^{20–32}$)(X)] complexes shows an anodic, one-electron redox wave that corresponds to the oxidation of the phenolate moiety to a phenoxyl radical (Figure 8). The oxidation potentials and the chemical stability of the $Cu^{II}$-phenoxyl radical complexes [Cu($L^{20–23\cdot}$)(X)] are strongly correlated to the $\sigma^+_{Hammet}$ of the phenolate *p*-substituent ($E_{1/2}$ ranges between 0.01 and 0.70 V vs. $Fc^+$/Fc, Table 4):[58] The more

electron-donating substituent affords the more stable radical. In addition, a dependence of the radical stability on the N-donor properties has been observed within the $[Cu(L^{24,25})(Cl)]$ and $[Cu(L^{20,26})(CH_3CN)]$ series.[59,60] Thus the weaker N-donor ability of the 2-methylpyridine group compared to pyridine strongly destabilizes the radical complex. The electrochemically (or chemically) generated radical species are either EPR silent or exhibit an $S = 1$ signal (Table 4), thereby showing that the phenoxyl group remains coordinated to the copper(II) ion.[58–64]

The dinuclear species $[Cu(L^{30,31})]_2$ (Figure 8) exhibit an anodic peak, $E_p^a$, in their CV curves at +0.45 and +0.66 V, respectively, which is associated with a cathodic peak, $E_p^c$, at much lower potential values (+0.03 and +0.12 V respectively). These $E_p^a$ values are much higher than those of the mononuclear complexes $[Cu(L^{30,31})(py)]$ (py = pyridine; Figure 8, Table 4, $E_{1/2}$ = +0.00 and +0.14 respectively) due to the lower electron density on the bridging phenolate oxygen atom. In addition, the $E_p^c$ values for the dimers are close to those obtained for the monomers $[Cu(L^{30,31})(py)]$. We therefore concluded that the dimers are converted into the monomeric form $[Cu(L^{20–31\cdot})(X)]$ upon oxidation (Figure 8).[63]

Few data concerning the oxidation behavior of the phenolate complexes of $N_2O_2$ ligands exist.[58,63,65–69,74] The $Cu^{II}$-phenoxyl complex of $HL^{41}$ has been obtained by treating the ligand with one equivalent of $Cu(ClO_4)_2{\cdot}6H_2O$. A dimeric structure $[Cu(L^{41\cdot})]_2$ with two $Cu^{II}$-phenoxyl radical molecules bridged by phenolato groups has been proposed for this complex.[69] It is EPR-silent as the result of an antiferromagnetic exchange coupling mediated by the phenolato bridges. We have proposed a similar structure for the radical complex $[Cu(L^{38\cdot})]_2$ (Figure 8).[63] The mononuclear $Cu^{II}$-phenoxyl complex $[Cu(L^{38\cdot})(py)]$ (Figure 8) was generated by both chemical oxidation and electrolysis[63] and was found to be much less stable than $[Cu(L^{20\cdot})(py)]$, which possesses a similar phenoxyl moiety.[58] This suggests a lower stability of the radical entity formed with $HL^{N_2O_2}$ ligands compared to $HL^{N_3O}$ ligands in spite of their lower oxidation potentials (the difference of oxidation potentials may be at least partially due to the difference of overall charge of the complex). The radical complex $[Cu(L^{36\cdot})(CH_3CN)]$ has been synthesized by chemical oxidation of $[Cu(L^{36})(CH_3CN)]$ with silver acetate.[65] It was found to be EPR-active, which was interpreted as evidence for a weak ferromagnetic or a dipole–dipole interaction between the copper(II) and the axial phenoxyl radical spins. The electrochemically generated $[Cu(HL^{39\cdot})(OAc)]$ species was found to be relatively stable, in agreement with the reversible redox process observed on the electrolysis timescale.[67] Such behavior suggests that no chemical reaction, for example protonation-deprotonation, is associated with the electron transfer, as expected for the oxidation of a protonated phenol.[77] The radical has thus been proposed to be located on the equatorial nitrophenolate group.[67]

The $Cu^{II}$-phenol complexes $[Cu(HL^{N_3O})(X)]$ exhibit high oxidation potentials (>0.8 V, Table 4) and irreversible cyclic voltammograms,[58,59,63] which can be ascribed to two facts. In uncoordinated phenoxyl radicals, it has been shown that (i) the phenoxonium/phenoxyl redox couple is lower than that for phenoxyl/phenol and (ii) a proton transfer is associated with the electron transfer,[77] which means that the $Cu^{II}$-phenoxyl radical system cannot be generated from $Cu^{II}$-phenol complexes. On the other hand, reversible redox waves are observed within the –0.5 to 0.0 V range for these complexes {for example at $E_{1/2}$ = –0.39 V vs. $Fc^+/Fc$ for $[Cu(HL^{21})(Cl)]$}.[59] These waves are attributed to the $Cu^{II}/Cu^{I}$ redox couple. Their relatively high values suggest that the ligand in these $Cu^{II}$-phenol complexes can efficiently accommodate the copper(I) redox state. In addition, this value is close to that reported for the coordinated phenoxyl/phenolate couple {reversible system at $E_{1/2}$ = +0.02 V vs. $Fc^+/Fc$ for $[Cu(L^{21})(CH_3CN)]$} in the presence of $NEt_3$.[58] For comparison, the $Cu^{II}/Cu^{I}$ redox potential is –0.24 V in GO vs. $Fc^+/Fc$, while the tyrosyl/tyrosinate one has been estimated to be –0.01 V vs. $Fc^+/Fc$ at neutral pH.[12,13] The thermodynamic gap between the $Cu^{II}/Cu^{I}$ and phenoxyl/phenolate redox couples of $[Cu(HL^{21})(Cl)]$ and $[Cu(L^{21})(CH_3CN)]$, respectively, is thus close to that measured for GO (0.25 V).

## Emerging Classes of Model Compounds for the GO Active Site: Peptide Ligands

A general limitation for the use of chemical analogues of metalloenzyme active sites is their low water-solubility and their poor enantioselectivity when catalyzing reactions. Moreover, structural and reactivity studies on metalloproteins have revealed that the properties of their active sites depend on more than the metal coordination sphere. Modeling the second-sphere interaction in order to improve the biological relevance of complexes mimicking the metalloprotein active sites is therefore a new challenge. An emerging approach that accounts for these factors is the use of oligopeptides as ligands. While the copper(II) coordination chemistry of oligopeptides has been extensively studied, much less is known about the incorporation of biologically relevant radicals in such peptides.

The peptidic approach to modeling the active site of GO has been pioneered by Kojima et al.[78] Their approach concerns the use of cyclic tripeptides such as Boc-Gly-e(His-Tyr-OEt) (e is an ethylene bridge) that incorporate both a tyrosine and a histidine ligand for the copper ion. A 2:1 ligand:metal complex is predominantly formed in solution whose structure involves a square-pyramidal monomer complex coordinated to two imidazole nitrogens atoms, two phenolate oxygen atoms, and one external water or solvent molecule. Its electrochemical behavior shows an irreversible ligand-centered oxidation process at +0.91 V vs. $Fc^+/Fc$ attributed to the phenoxyl/phenolate redox couple. This value is much higher than that of GO, which shows that the radical is not stable.

Five years later, two reports by Berkessel[79] and ourselves[80] appeared in the literature, both of which concern the synthesis of peptides designed to stabilize phenoxyl rad-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

icals generated on their side chains. Berkessel et al. used a strategy based on combinatorial synthesis using peptide chemistry.[79] The general design of the solid-phase-bound decapeptide library is shown in Figure 9. A Pro-Gly sequence is included in order to induce a hairpin that makes the $X_1$–$X_4$ residues orient properly to chelate a copper(II) ion. These four positions ($X_1$–$X_4$) are occupied in a combinatorial manner by histidine, tyrosine, modified cysteine (cross-linked with a di-*tert*-phenol moieties), or a modified TEMPO (stable nitroxide radical). Incubation of the solid-phase-bound library with copper results in a color change, which indicates metal binding. The His-rich sequences gave blue beads, Tyr-rich sequences pale yellow to green complexes, while the presence of the modified TEMPO in the peptide resulted in an orange coloration. The solid-phase-bound peptide libraries were screened for their activity towards benzyl alcohol and 3-methoxybenzyl alcohol oxidation. A pronounced sequence-dependence of the catalytic activity was observed: the most active ligands were those incorporating the modified TEMPO group, which allow up to six turnovers. No deactivation of the catalyst due to oxidative demetalation was observed, and characterization of the (radical) copper complexes is currently in progress.

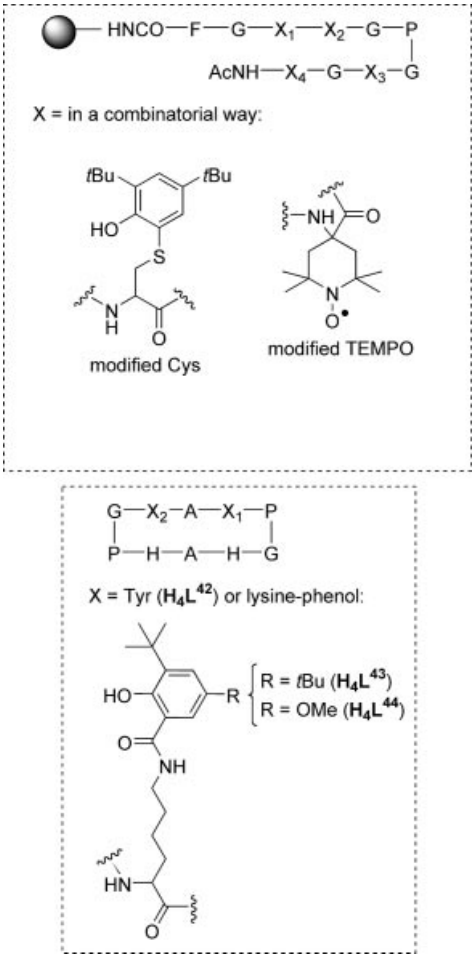

Figure 9. Formulae of peptide ligands. The top structure is adapted from ref.[79] and the bottom one from ref.[80]

In another approach, we have used cyclic decapeptides incorporating two proline-glycine sequences to induce β-turn hairpins.[80] The resulting peptide conformation is constrained into an anti-parallel β sheet and functionalization is achieved above the plane of this motif by two histidines and two amino acids $X_1$ and $X_2$ [$X_1$ and $X_2$ being either tyrosines ($H_4L^{42}$) or a lysine-phenol conjugate ($H_4L^{43,44}$)]. Potentiometric titrations have shown that deprotonation of the phenol moieties requires a pH higher than 12 (the corresponding p$K_a$ values range between 8.96 and 11.34, depending on the amino acid X). At pH 12.2 only the decapeptides incorporating a lysine-phenol conjugate exhibit reversible signals [$E_{1/2}$ = –0.03 V for R = *t*Bu ($L^{43}$) and –0.20 V vs. $Fc^+$/Fc for R = OMe ($L^{44}$)], thereby showing that the stability of the oxidized species is noteworthy. This stability is confirmed by electrochemical oxidation of the peptides, which affords EPR-active species whose spectra are typical of phenoxyl radicals. These compounds are among the first radical-peptides to be generated and persist in solution long enough to be characterized. Evaluation of their coordination chemistry is currently in progress.

### Emerging Classes of Model Compounds for the GO Active Site: Calix[6]arene Ligands

Another platform, namely calix[6]arenes, has been pioneered by Reinaud et al.[81] In these systems, a four- or five-coordinate metal ion is constrained in a mononuclear environment that preserves a binding site buried inside a hydrophobic pocket accessible to small molecules. In order to get model compounds for the GO active site, the calix[6]arene core has been functionalized with one phenol and three *N*-methylimidazole groups. In the copper(II) complex, the metal ion is pentacoordinate and has a square-pyramidal geometry. The phenolate oxygen and one solvent molecule (acetonitrile) bind in equatorial positions, while the three *N*-methylimidazole nitrogens complete the pyramid. The solvent is buried in the conic cavity of the calixarene in a *trans* position relative to the phenolate group, which caps the copper(II) complex. The $Cu^{II}$-phenoxyl radical complex was found to be able to mediate the stoichiometric two-electron oxidation of benzyl alcohol. This reaction is promoted by coordination to the copper and proceeds in an inner-cavity process.

## Modeling the Properties of the GO Active Site

### Influence of the Cys-Tyr Crosslink

In order to better understand the influence of the Cys-Tyr crosslink on the properties of the redox-active Tyr272 residue of the enzyme, Itoh et al. have synthesized a series of 2-methylsulfanylphenols.[74] These compounds exhibit oxidation potentials that are much lower than those of the nonsubstituted parent phenols, with, for example, a drop of 0.35 V on going from the 4-methylphenol to the 4-methyl-2-methylsulfanylphenol. Such behavior is interpreted in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

terms of the electron-sharing conjugative effect of the methylsulfanyl substituent.

The corresponding phenoxyl radicals have been generated by pulse radiolysis. The 4-methylphenoxyl radical species exhibits two intense absorptions in its UV/Vis spectrum at around 400 nm corresponding to π–π* transitions. The UV/Vis spectrum of the 4-methyl-2-methylsulfanylphenoxyl radical also shows such absorptions at around 400 nm, but exhibits an additional strong absorption band at 850 nm. The origin of this latter absorption has been attributed to an intramolecular charge transfer from the benzene ring to the methylsulfanyl group. It is important to note that this lower-energy feature is quite similar to that of the enzyme in its radical form. It has been proposed that the larger $\varepsilon$ value obtained for GO arises from an interligand charge transfer from the Tyr272 radical to Tyr495.[82] EPR spectroscopy has revealed that a methylsulfanyl substituent induces larger *g*-tensor values for the phenoxyl radical due to the large spin-orbit coupling on the sulfur atom ($g$ = 2.0060 for the 4-methyl-2-methylsulfanylphenoxyl radical; $g$ = 2.0036 for the 2,4,6-trimethylphenoxyl radical).[74] A large amount of spin density thus delocalizes over the sulfur atom of the methylsulfanyl substituent.

Some copper(II) complexes bearing coordinated 2-(alkylsulfanyl)phenoxyl radical derivatives have been synthesized (Figure 10).[34,61,62,83,84] The complex [Cu($L^{45}$)(ppb)], for example, which is obtained by treating one equivalent of 2-hydroxy-5-methyl-3-(methylsulfanyl)benzaldehyde with one equivalent of tris(3-phenylpyrazolyl)borate (ppb) and copper(II), can be oxidized into a radical species. The 2-alkylsulfanylphenol moiety has also been incorporated into Schiff bases ($H_2L^2$)[34] and tripodal ligands ($HL^{27,28}$, $H_2L^{40}$)[61–68] and the corresponding mononuclear $Cu^{II}$-phenoxyl complexes characterized. The UV/Vis spectra of all the non-Schiff base species typically exhibit both the strong absorption bands at around 400 nm and the NIR feature above 800 nm that were observed in the 2-(methylsulfanyl)-phenols. In the Schiff-base series, the anticipated phenoxyl radical absorption feature at 400 nm is obscured by intense ligand absorption bands. All the $Cu^{II}$-phenoxyl species were found to be X-band EPR-silent as a result of a magnetic coupling between the copper(II) and the radical spins.

It has previously been proposed by Stack et al. that salen complexes fail to reproduce the high turnovers of GO because of their inability to form stable copper(I) complexes.[34,35] A pentadentate $NO_2S_2$ ligand ($H_2L^{46}$) that incorporates *ortho*-(alkylsulfanyl)phenol moieties has therefore been prepared.[85] A major difference between this ligand and most of the previous ones is that the sulfanyl groups here are designed to coordinate the copper atom, which is expected to both lower the phenol oxidation potential and increase the redox potential of the $Cu^{II}/Cu^{I}$ couple. Unfortunately, the X-ray crystal structure of its copper(II) complex [Cu($L^{46}$)] shows that the occupied electron-donating sulfur p orbitals are aligned to bond to the copper center rather than π-conjugated with the phenolates, and that the copper(II)–sulfur bonds are long (>2.4 Å). Its high oxidation potentials (+0.47 and +0.62 V vs. $Fc^+/Fc$) confirm

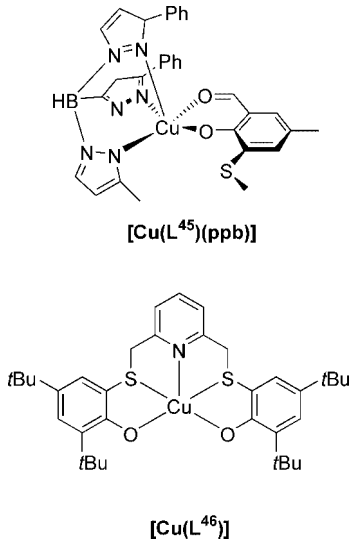

Figure 10. Copper(II) complexes of ligands possessing a 2-(alkylsulfanyl)phenoxyl moiety: [Cu($L^{45}$)(ppb)] (ref.[83]) and [Cu($L^{46}$)] (ref.[85]).

that the sulfur groups behave as electron-withdrawing groups. The reduction wave, which is attributed to the $Cu^{II}/Cu^{I}$ couple, is observed at –1.23 V, close to the value reported for binaphthyl-salen complexes such as [Cu($L^2$)]; all attempts to isolate the copper(I) complex were unsuccessful.

### Modelling the Tyr-Trp π–π Interaction

The X-ray crystal structure of the GO active site has revealed that the redox-active tyrosine is π-stacked with the indole ring of a neighboring tryptophan Trp290 residue. This interaction has been modeled in several ways by Halcrow et al.[86–90] In one approach, they synthesized 3,4-benzo-8,9-(3′-hydroxy-4′-methylsulfanylbenzo)bicyclo-[4.4.1]undeca-3,8-dien-11-one ($HL^{47}$) and its ethylene acetal $HL^{48}$ (Figure 11).[86,87] The ketone adopts a boat/chair conformation while the acetal exhibits a chair/chair conformation with layered benzo rings. The oxidation potential, which is 0.15 V lower for $HL^{48}$ than for $HL^{47}$, may suggest that the π–π interaction contributes to the thermodynamic stability of the oxidized species, although an alternative explanation is that the identity of the bridgehead group (ketone vs. acetal) has an effect on the p-orbital energy. As this suggestion has not yet been quantified, the authors still entertain both possibilities. The cyclic voltammograms also revealed an improved reversibility for $HL^{47}$, which could be attributed to both an intramolecular O–H···S hydrogen bond that would hinder deprotonation of the oxidation product and steric protection afforded by the intramolecular π–π interaction.

In another approach, they have synthesized the ligand $L^{49}$, which contains an oxidizable dimethoxyphenyl substituent.[88–90] In its copper(II) complexes [Cu($L^{49}$)(TpPh)] and [Cu($L^{49}$)(TpCy)] {Tp = tris(3-arylpyrazolyl)hydroborate; TpPh: R = phenyl, TpCy: R = cyclohexyl} the metal ion

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

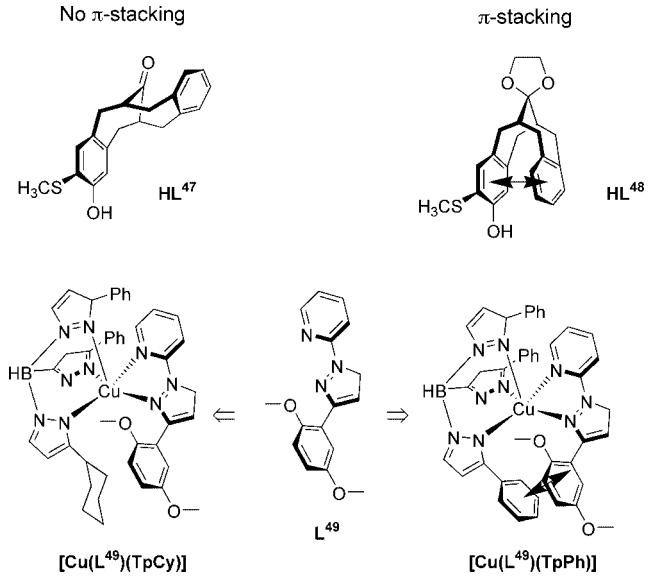

Figure 11. Model compounds for the Tyr-Trp π–π interaction: $HL^{47}$ and $HL^{48}$ (ref.[86,87]), $[Cu(L^{49})(TpCy)]$ and $[Cu(L^{49})(TpPh)]$ (ref.[88–90]).

resides within the same square-pyramidal geometry. Nevertheless, a major difference exists between each complex: The dimethoxyphenyl group in $[Cu(L^{49})(TpPh)]$ takes part in a π–π interaction with a phenyl ring from the TpPh coligand while no such interaction exists within $[Cu(L^{49})(TpCy)]$. The authors have shown that the π–π interaction exhibited by $[Cu(L^{49})(TpPh)]$ is retained following its one-electron oxidation, although deconvolution of the voltammograms led to the conclusion that this interaction has no measurable effect on the kinetic stability of the resultant aryl radical.

Recently, we have suggested a structural role for this interaction:[64] The metal in $[Cu(HL^{32})(CH_3CN)]$ has a square-pyramidal geometry whose apical position is occupied by the phenol moiety. In the deprotonated complex $[Cu(L^{32})(CH_3CN)]$, this phenolate group has shifted to an equatorial position, which means that an isomerization is induced by deprotonation. π–π stacking interactions between the phenolate and quinoline rings that have been detected in the solid state are proposed to contribute, at least partially, to the isomerization and thus the phenolate positioning.

In summary, the Tyr-Trp π–π interaction in GO is supposed to have little or no effect on the chemical reactivity of the tyrosyl radical, except to shield it from external solvent. All these biomimetic studies thus suggest that the role of this interaction in GO is structural rather than electronic – it has been proposed recently that it may be involved in maintaining the cofactor orientation that results in the diamagnetic ground state of GO.[17]

## Understanding the Diamagnetic Ground State of the Oxidized Form of GO

GO is EPR-silent in its copper(II)-tyrosyl radical form as the result of an antiferromagnetic coupling between the radical and the $Cu^{II}$ spins.[16] The relative orientations of the magnetic orbitals of the $Cu^{II}$ ion ($d_{x^2-y^2}$) and of the phenoxyl radical (half-occupied π orbital) are expected to determine the multiplicity of the electronic ground state (Figure 12). Quantification of this orientation can be roughly achieved by measuring the $Cu^{II}$–O–C bond angle ($\alpha$) and the dihedral angle ($\beta$) between the $x,y$ plane at the $Cu^{II}$ ion and the phenyl ring of the radical ligand in the X-ray crystal structures of $Cu^{II}$-phenolate complexes (Figure 12). Wieghardt et al. have been able to tune these angles, and thus the multiplicity of the electronic ground state, in a series of copper(II) complexes of TACN ligands.[52] Increasing the coordination number from five to six does not change $\alpha$ significantly {125.2° in $[Cu(L^{15})(Cl)]$ vs. 129.2° in

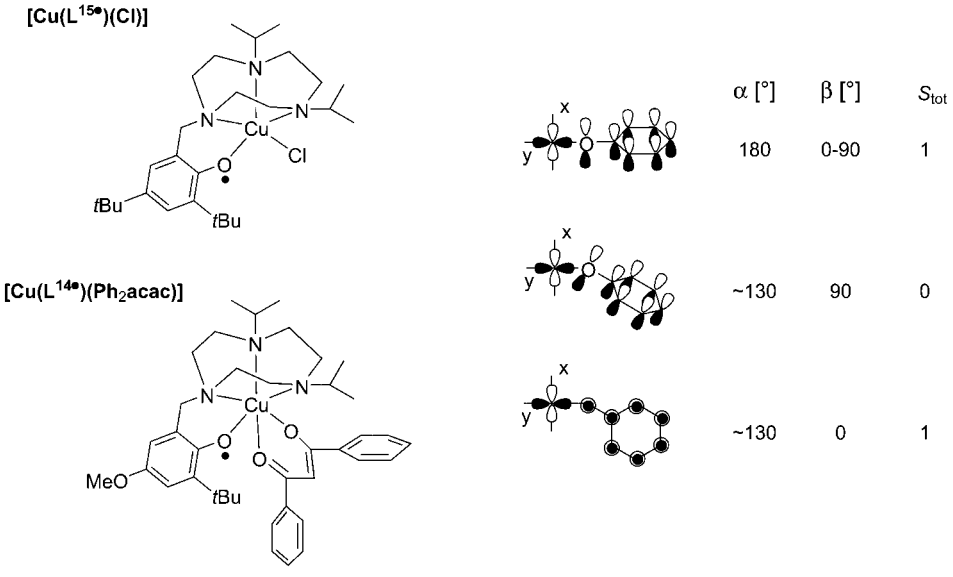

Figure 12. Models for the multiplicity of the ground state of GO (adapted from ref.[52]).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

[$Cu(L^{14})(Ph_2acac)$]}, whereas $\beta$ decreases by nearly 10° {27.4° in [$Cu(L^{15})(Cl)$] vs. 17.6° in [$Cu(L^{14})(Ph_2acac)$]}. These structural changes induce the inversion of the sign of the magnetic coupling, from antiferromagnetic in [$Cu(L^{15\cdot})(Cl)$] to ferromagnetic in [$Cu(L^{14\cdot})(Ph_2acac)$] ($J = 16 \pm 3$ $cm^{-1}$ for the latter complex). In GO, the bond angles $\alpha$ and $\beta$ are about 129° and 75°, respectively, consistent with an antiferromagnetic coupling, as in [$Cu(L^{15\cdot})(Cl)$].[12,13,52]

### Structural Approaches to the GO Active Site [Axial Copper(II)-Tyrosinate Bond and Coordinated Phenoxyl Radical]

One of the first biomimetic approaches to the GO active site involved modeling the axial copper(II)-tyrosinate bond. Three groups have reported X-ray crystal structures of copper(II) complexes involving unusually axially coordinated phenolates as model compounds for GO.[58,71,72,91–93] The ligands used in these studies possess a tripodal structure with a pendent phenol arm that is substituted at its *para* position by an electron-withdrawing nitro group. In the copper(II) complex [$Cu(L^{50})(Cl)$] (Figure 13), the geometry around the metal center is square pyramidal, with two pyridine nitrogens, one tertiary amine nitrogen, and an exogenous ligand (chloride ion) in the basal plane. The phenolate oxygen binds weakly in the *apical* position, thus making this complex the first that reproduces the axial $Cu^{II}$-phenolate bond of GO.[94] It was initially proposed that the apical coordination of the phenolate is due to the introduction of the nitro substituent *para* to the phenolate group, as in its absence phenolates occupy the equatorial position.[91] The polarity rule, which states that the more electronegative ligand will preferentially occupy the axial position of a tetragonal-based pyramid, was proposed to account for these results in combination with crystal-packing forces. Lately, Fenton et al. have published the X-ray crystal structure of the copper(II) complex of $HL^{51}$ (Figure 13),[71,92] in which the nitrophenolate occupies the *equatorial* position. These contradictory results can be rationalized by considering the size of the chelate rings, since a five/five/six-membered chelate ring sequence is observed in Palaniandavar's complexes whereas a six/six/six-membered chelate ring sequence is observed in Fenton's complex. We have structurally characterized the $Cu^{II}$-phenolate complexes of $HL^{23}$ and $HL^{32}$.[58,64] Both ligands possess similar 2-*tert*-butyl-4-nitrophenol and pyridine moieties but differ in their third chelating arm (a pyridyl group for $HL^{23}$ and a fluoroquinolyl group for $HL^{32}$). The nitrophenolate moiety in [$Cu(L^{23})(Cl)$] is found to coordinate in an axial position while in [$Cu(L^{32})(CH_3CN)$] it occupies the equatorial position. Formation of an axial phenolate oxygen–copper bond thus appears not only related to the electronic properties of the phenolate *para* substituent but also to steric factors arising from the ligand and to the nature of the chelate rings formed.

To duplicate and better understand the anion interactions in the inactive enzyme and the spectral changes ac-

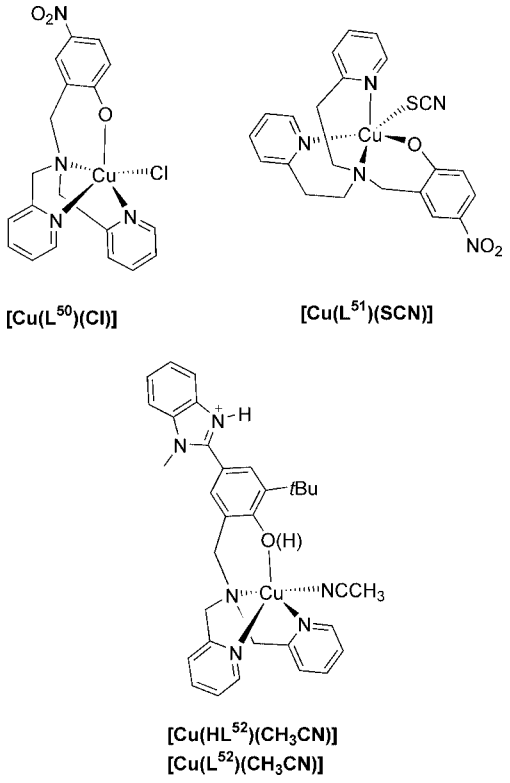

Figure 13. Models for the axial copper-phenolate bond: [$Cu(L^{50})(Cl)$] (ref.[91]), [$Cu(L^{51})(SCN)$] (ref.[92]), [$Cu(HL^{52})(CH_3CN)$] and [$Cu(L^{52})(CH_3CN)$] (ref.[93]).

companying it, )Palaniandavar et al. have determined the crystal structures of a series of [$Cu(L^{50})(X)$] complexes (X = $ClO_4^-$, $SCN^-$, $CH_3CO_2^-$).[72] Replacement of a weakly coordinating ligand X by a strongly coordinating one in the equatorial position has been shown to decrease the electronic interaction between the metal center and the axially coordinated phenolate, and consequently contributes to a lengthening of the axial Cu–O bond [2.186(2), 2.200(3), and 2.268(1) Å for X = $SCN^-$, $XCH_3CO_2^-$ and $Cl^-$, respectively].

With the aim of visualizing the effect of protonation of the axial phenolate on the metal–ligand bonds, we have synthesized the $Cu^{II}$-phenol and $Cu^{II}$-phenolate complexes of $HL^{23}$.[58] The phenolate complex [$Cu(L^{23})(Cl)$] exhibits a geometry that is roughly similar to that of [$Cu(L^{50})(Cl)$] described by Palaniandavar et al.[94] We also reported the X-ray crystal structures of the phenol complex [$Cu(HL^{23})(CH_3CN)$], but as the exogenous ligand is different in the phenolate and phenol structures (an acetonitrile molecule in the former and a chloride ion in the latter) it was difficult to estimate the influence of the protonation of the axial phenolate on the equatorial bonds. We therefore synthesized the copper(II) complex of $HL^{52}$, which bears an electron-withdrawing *N*-methylbenzimidazolium instead of a nitro substituent.[93] The phenolate and phenol complexes could be crystallized with the same exogenous ligand (acetonitrile molecule). From the X-ray structure analysis, it appears clear that deprotonation of the axial phenol forces the metal to move out of the basal plane towards the oxygen atom (as a consequence of a stronger axial bond),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and that both Cu–$N_{pyridine}$ bond lengths increase, thereby reflecting the weakening of the equatorial bonds (Figure 14). Interestingly, the phenolate compound [Cu($L^{52}$)($CH_3CN$)] exhibits the shortest axial Cu–$O_{phenolate}$ distance in the whole series of complexes [2.133(4) Å].

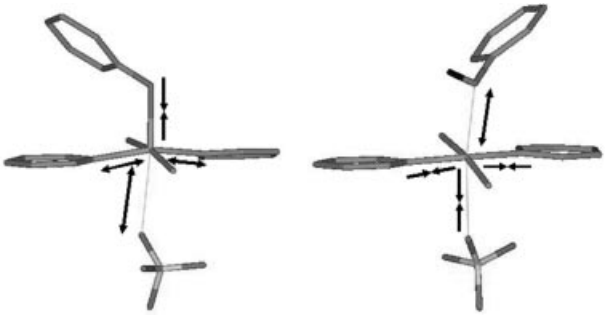

Figure 14. Effect of the protonation of the phenolate moiety on the bond lengths around the copper atom (reproduced from ref.[93]).

Several X-ray crystal structures of transition metal complexes of ligands possessing iminosemiquinonate moieties have been reported.[45,95] The first X-ray crystal structure of coordinated phenoxyl radical was reported in 1996 by Wieghardt et al.[96] for a phenoxylchromium complex. The crystal structure of a copper(II)-coordinated phenoxyl radical was obtained in 2001.[97,98] The complex [Cu($L^{53}$)$_2$] has been structurally characterized (Figure 15) and chemically oxidized to [Cu($L^{53\cdot}$)($L^{53}$)]. The two ligands in [Cu($L^{53\cdot}$)($L^{53}$)] are structurally inequivalent (Figure 15): one ($L^{53}$) exhibits C–C, C–O, and C–N bond lengths that are similar to those of [Cu($L^{53}$)$_2$], whereas in the second ($L^{53\cdot}$) the phenol C–O distance is significantly shorter and the two adjacent C–C bonds and the Cu–O bond are longer than those in [Cu($L^{53}$)$_2$]. The C–O distance of 1.264(5) Å reported for $L^{53\cdot}$ emphasizes the C=O character of this bond [it is 1.322(5) Å in $L^{53}$]. The other metal–ligand bonds in [Cu($L^{53\cdot}$)($L^{53}$)] are significantly shorter than in [Cu($L^{53}$)$_2$]. All these C–O and C–C bond lengths are in agreement with the electronic structure depicted in Figure 15, where the unpaired electron of the phenoxyl group is delocalized over both *ortho* positions.

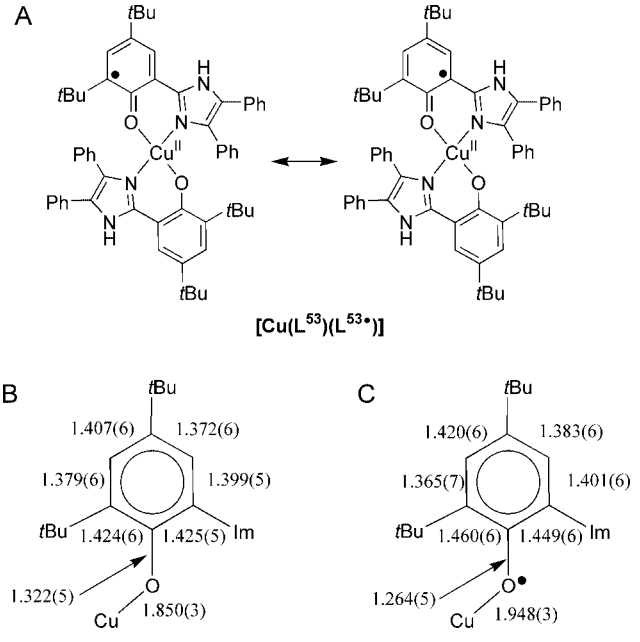

Figure 15. Formula of [Cu($L^{53}$)($L^{53\cdot}$)] and its resonance structures (A) and bond lengths of the phenolate moiety (B) and phenoxyl radical moiety (C) coordinated to the copper(II) ion of [Cu($L^{53}$)($L^{53\cdot}$)] (adapted from ref.[97]).

## Reactivity of Copper(I) Complexes Towards $O_2$

The catalytic reaction for GO occurs via a ping-pong mechanism.[9–11] The first half-reaction involves binding and oxidation of the alcohol substrate by the $Cu^{II}$-tyrosyl radical form to yield aldehyde and the reduced copper(I) state. In the second half-reaction dioxygen is bound and reduced, releasing $H_2O_2$ and the $Cu^{II}$-tyrosyl radical form of the enzyme. The first step has been studied extensively, while very little is known about the dioxygen reactivation step. It has been speculated that $O_2$ binds to the three-coordinate copper(I) site to form a $Cu^{II}$-superoxide species, which evolves into a $Cu^{II}$-hydroperoxide-tyrosyl radical intermediate. A proton transfer from the axial tyrosine leads to the release of $H_2O_2$ and regeneration of the initial $Cu^{II}$-tyrosyl radical form of the enzyme. With the goal of obtaining insights into the dioxygen reactivation step, Tolman et al. have characterized $Cu^{I}$-phenolate complexes and studied their reactivity towards $O_2$ by low-temperature stopped-flow experiments.[55] They have shown that the copper(I) phenolate complex [$Cu^{I}$($L^{15}$)] has a four-coordi-

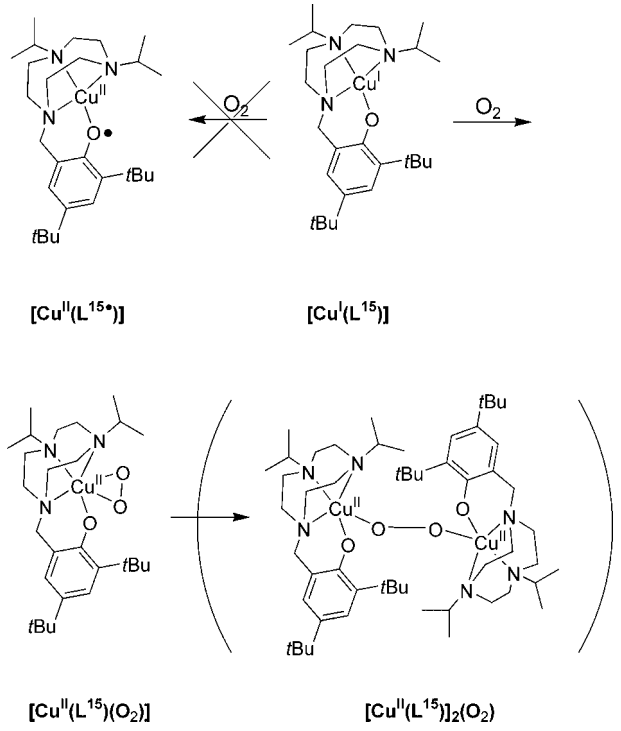

Figure 16. Reactivity of TACN complexes with $O_2$ (ref.[55]).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nate geometry (Figure 16) while $[Cu^{I}(L^{16})]$ adopts a planar three-coordinate geometry. The average metal–ligand bond lengths are 2.13 Å in $[Cu^{I}(L^{15})]$ and 2.05 Å in $[Cu^{I}(L^{16})]$. The former fits much better with the value of 1.99 Å determined from EXAFS measurements in the enzyme, thereby suggesting that a coordination number of about three is more appropriate for the enzyme. $[Cu^{I}(L^{16})]$ was found to be too reactive with $O_2$ even at cryogenic temperatures, thus precluding a detailed investigation. Mixing $[Cu^{I}(L^{15})]$ with excess $O_2$ produced dark-green solutions, while sub-stoichiometric amounts of $O_2$ afforded a green solution that reacted rapidly to form an intensely purple species.

This was interpreted in terms of the following reaction sequence (see also Figure 16).

$[Cu^{I}(L^{15})] + O_2 \rightleftharpoons [Cu^{II}(L^{15})(O_2)]$ "green species"

$[Cu^{II}(L^{15})(O_2)] + [Cu^{I}(L^{15})] \rightarrow [Cu^{II}(L^{15})]_2(O_2)$ "purple species"

$2 \times [Cu^{II}(L^{15})(O_2)] \rightarrow [Cu^{II}(L^{15})]_2(O_2) + O_2$ "purple species"

$[Cu^{II}(L^{15})]_2(O_2) \rightarrow$ decomposition

The dark-green species $[Cu^{II}(L^{15})(O_2)]$ exhibits $\lambda_{max}$ values at 416 ($\varepsilon$ = 4600) and 654 nm (1800 $M^{-1}cm^{-1}$), which are slightly different than those of the corresponding and fully characterized $Cu^{II}$-phenoxyl radical species $[Cu^{II}(L^{15\cdot})(CH_3CN)]$ [$\lambda_{max}$ = 410 ($\varepsilon$ = 4000) and 672 nm (1000 $M^{-1}cm^{-1}$); Table 3].[54] The Raman spectrum of $[Cu^{II}(L^{15})(O_2)]$ is characterized by a peak at 1120 $cm^{-1}$, for the $^{16}O_2$ sample, which shifts to 1058 $cm^{-1}$ when $^{18}O_2$ is used. Based on comparison with literature data, this could be attributed to the ν(O–O) mode of a superoxidocopper(II) complex (Figure 16). With mixed isotopically labeled gas an additional sharp peak was observed at 1093 $cm^{-1}$, without splitting, which suggests a symmetric ($\eta^2$) binding of the superoxide ligand (Figure 16). The ν(Cu–$O_2$) mode was observed at 422 and 450 $cm^{-1}$, while additional features not sensitive to $^{18}O_2$ substitution, corresponding to a phenolate mode, are observed at approximately 1300 $cm^{-1}$ and in the region 1500–1700 $cm^{-1}$. This species is EPR-silent as the result of a magnetic coupling between the copper(II) and the superoxide ligand.

The purple species $[Cu^{II}(L^{15})]_2(O_2)$, which exhibits multiple broad bands that are sensitive to $^{18}O$-isotope substitution in the regions 500–550 and 700–850 $cm^{-1}$, could be described as a peroxidodicopper complex (Figure 16). The unusual broadening of these signals is attributed to the existence of multiple conformational isomers that differ with respect to the metal ion geometry and/or the relative ligand donor disposition (Figure 15).

The peroxido species $[Cu^{II}(L^{15})]_2(O_2)$ prevails at all temperatures while the superoxido one $[Cu^{II}(L^{15})(O_2)]$ cannot be observed unless $[Cu^{I}(L^{15})]$ is present in excess. In contrast, in most previously described systems the peroxido compound is the stable species in the presence of excess $O_2$ while the superoxido complex is no more than an intermediate. Such a difference may result from the presence of a phenolate (and its electronic effect) or steric bulk provided by the *i*Pr and *t*Bu substituents in $HL^{15}$. The light-green decomposition products are probably multinuclear copper(II)-containing species, although their exact nature is unknown.

We have studied the reactivity of copper(I) complexes of tripodal ligands that are precursors of stable phenoxyl radicals with $O_2$.[63] The copper(I) complexes were generated in situ and oxygenation was performed at 233 K. We have shown in the case of the copper(I) complex of the $N_3O$ ligands $HL^{20}$ and $HL^{30}$ that $O_2$ does not oxidize the phenol into a phenoxyl radical. Instead, a $Cu^{II}$-phenolate complex is obtained. In contrast, reaction of $O_2$ with the copper(I) complex of the $N_2O_2$ ligand $H_2L^{38}$ affords products whose spectral properties are quite different to those of isolated $Cu^{II}$-phenolate and $Cu^{II}$-phenoxyl species. A highly reactive transient species is then formed and decomposes in solution, although its nature remains unclear.

### Radical Cofactor Formation: Reactivity of Tripodal Ligands Towards $Cu^{2+}$

It has recently been shown that formation of the radical cofactor of GO can be achieved by treating copper and $O_2$ with the pre-form of GO.[29,30] With the aim of better understanding the way in which copper(II) might be involved in GO activation, we have studied the reactivity of several tripodal ligands at various copper(II) [added as its $Cu(ClO_4)_2{\cdot}6H_2O$ salt], base, and dioxygen concentrations in $CH_3CN$.[63] Addition of 0–1 molar equivalents of $Cu^{2+}$ to the phenolate complex $[Cu(L^{20})(CH_3CN)]$ (ligand possessing a $N_3O$ donor set) or 1–2 molar equivalents of $Cu^{2+}$ to the ligand $HL^{20}$ in the presence of $NEt_3$ results in dramatic color changes. No more changes were observed beyond two molar equivalents of added copper(II). UV/Vis, EPR, and electrochemical characterizations indicated that the reaction product was the $Cu^{II}$-phenoxyl radical complex $[Cu(L^{20\cdot})(CH_3CN)]$, which is quantitatively formed by chemical oxidation of $[Cu(L^{20})(CH_3CN)]$ by excess solvated $Cu^{2+}$ according to:

$$[Cu(L^{20})(CH_3CN)] + Cu^{2+} \rightarrow [Cu(L^{20\cdot})(CH_3CN)] + Cu^{+}$$

A reverse titration, in other words addition of $HL^{20}$ to $Cu^{2+}$ in the presence of $NEt_3$, showed that half an equivalent of $[Cu(L^{20\cdot})(CH_3CN)]$ is formed at a $HL^{20}/Cu^{2+}$ ratio of 0.5, the remaining copper being in the $Cu^{+}$ redox state. At one molar equivalent of added ligand, $[Cu(L^{20})(CH_3CN)]$ is formed quantitatively in a comproportionation reaction.

$$\mathbf{[Cu(L^{20\cdot})(CH_3CN)]} + Cu^{+} + \mathbf{HL^{20}} \xrightarrow{NEt_3} \mathbf{2\,[Cu(L^{20})(CH_3CN)]}$$

Addition of one molar equivalent of $Cu^{2+}$ to the phenol complex $[Cu(HL^{20})(CH_3CN)]$ ($N_3O$ ligand) or two molar equivalents of $Cu^{2+}$ to $HL^{20}$ without base results in the formation of less than 8% of $[Cu(L^{20\cdot})(CH_3CN)]$. This low

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

yield for the $Cu^{2+}$-promoted oxidation reaction is consistent with an oxidation potential that is much higher for a phenol than for a phenolate group. Similar results were obtained when $HL^{20}$ was replaced by $HL^{30}$ (and also $[Cu(L^{20})(CH_3CN)]$ by $[Cu(L^{30})]_2$), thus showing that the nuclearity of the $Cu^{II}$-phenolate complex does not significantly influence the $Cu^{2+}$-promoted oxidation reaction.

A completely different behavior was observed upon treating $HL^{37}$ and $HL^{38}$ (ligand possessing a $N_2O_2$ donor set) with $Cu^{2+}$: as soon as copper is added a $Cu^{II}$-phenoxyl radical complex is formed in a disproportionation reaction.[63,66] The radical species $[Cu(L^{38\cdot})]_2$ is formed quantitatively in the presence of $NEt_3$ at two molar equivalent of added $Cu^{2+}$.[63] This species can also be formed in the absence of base, although it decomposes much faster. Addition of $Cu^{2+}$ to $[Cu(L^{38\cdot})]_2$ results in the formation of a $Cu^{II}$ bis(phenoxyl) species whose structure is proposed to be the monomeric complex $[Cu(L^{38\cdot\cdot})(CH_3CN)]$.

These results show that a change in the donor set of the ligand can direct the reaction from comproportionation towards disproportionation.

Ligands with $N_2O_2$ donor set:

$$2\ Cu^{II}\text{-}O \rightleftharpoons Cu^{II}\text{-}O^{\bullet} + \text{copper(I)}$$

Ligands with $N_3O$ donor set:

$$2\ Cu^{II}\text{-}O \rightleftharpoons Cu^{II}\text{-}O^{\bullet} + \text{copper(I)}$$

A phenoxyl radical can thus be spontaneously formed by adding small amounts of $Cu^{2+}$ to ligands possessing the same donor set as this enzyme.

### Metamorphosing a GO's Reactivity by Using a Ligand Possessing a Five-Atom Donor Set

A ligand built on a triiminocyclohexane scaffold ($H_2L^{54}$; Figure 17) has been described by Walton et al.[99] The X-ray crystal structure of its copper(II) complex $[Cu(L^{54})]$ shows a pentacoordinate metal ion that resides in a square-pyramidal geometry as in GO. Unlike GO, however, which has a four-atom donor set with the fifth position vacant for substrate binding, no position seems to be available for substrate binding (and subsequent catalytic activity) in $[Cu(L^{54})]$ as the ligand already provides the five-atom donor set. Nevertheless, $[Cu(L^{54})]$ has been found to be active for the oxidation of benzyl alcohol (the substrate being added in its deprotonated alkoxide form) with molecular dioxygen as co-oxidant.[99] This result can be explained by considering the formation of an octahedral six-coordinate copper(II) complex in which the alcoholate is bound to the metal (see Figure 17).

### Reactivity Studies

Several $Cu^{II}$-radical complexes have been found to be active towards oxidation of various substrates; we present here the reactivity of selected complexes belonging to each class. Theoretical approaches to catalytic mechanisms will be presented in the next chapter.

In 1996 Tolman et al. described $[Cu(L^{15})(CH_3CN)]$ as one of the first model complexes for the GO active site.[53] Bulk electrolysis of $[Cu(L^{15})(CH_3CN)]$ at a potential slightly higher than $E_{1/2}$ corresponding to the phenoxyl/phenolate redox couple affords a relatively stable $Cu^{II}$-phenoxyl radical complex. The electrochemical behavior of $[Cu(L^{15})$(benzyl alkoxide)] is characterized by a total loss of reversibility of the redox wave corresponding to the phenoxyl/phenolate couple ($E_p^a$ = –0.01 V vs. $Fc^+$/Fc), as expected for an electrocatalytic process. In addition, bulk electrolysis of $[Cu(L^{15})$(benzyl alcoholate)] affords benzaldehyde in 46% yield, thus showing that the catalyst is only active as its $Cu^{II}$-phenoxyl radical form and that it exhibits a reactivity similar to that of GO towards the oxidation of alcohols.

The mononuclear $Cu^{II}$-diphenolate complex $[Cu(L^{11})]$ described by Wieghardt et al. catalyzes the aerobic oxidation of benzyl alcohol into benzaldehyde with a turnover number of 95 (24 h in the presence of catalytic amounts of base).[51] The proposed mechanism is similar to that reported for GO, in other words the active species is a $Cu^{II}$-phenoxyl radical species. In the presence of copper(I) and $H_2L^{11}$, primary amines with a least one α-H atom undergo an oxidative deamination reaction to yield Schiff base condensation products (17 turnovers in 24 h with benzylamine as substrate). The copper(II) complexes of $H_2L^{11}$ are thus interesting examples of functional models for both GO and copper amine oxidase.

The copper(II) complex $[Cu(L^{12\cdot})]$ {and its zinc analog $[Zn(L^{12\cdot})]$} selectively oxidizes primary alcohols (methanol, ethanol, benzyl alcohol) stoichiometrically under anaerobic conditions in the presence of two equivalents of $NEt_3$ to yield the corresponding aldehyde, two equivalents of $HNEt_3^+$, and a protonated form of the two-electron-reduced catalyst (Figure 17, A).[46] No reaction was observed when using secondary alcohols such as 2-propanol or diphenylcarbinol, or when replacing $[Cu(L^{12\cdot})]$ with $[Cu(L^{12})]$. The mechanism involves reversible binding of an alkoxide ligand to $[Cu(L^{12\cdot})]$ to afford a five-coordinate, square-based-pyramidal complex where the axially bound phenolate is *cis* to the phenoxyl moiety (Figure 17, A). Irreversible oxidation of the substrate into a coordinated ketyl radical anion is the rate-determining step, with a remarkable KIE ($k_H/k_D$) of 54 for the reaction of methanol with $[Cu(L^{12\cdot})]$. The resulting intermediate is proposed to undergo a rapid intramolecular one-electron transfer, with the formation of aldehyde that dissociates. The ultimate electron acceptor is the *o*-diiminoquinone moiety of the doubly protonated ligand. The two-electron-reduced catalyst then reacts with molecular dioxygen to yield $H_2O_2$ in the presence of protons, thus regenerating $[Cu(L^{12\cdot})]$. A copper(II)-coordinated superoxide intermediate is proposed (Figure 17, A). Up to 5000 turnovers in 50 h are achieved for aerobic oxidation of methanol (turnover frequency of 0.03 $s^{-1}$). In contrast, the zinc analog is less efficient, with 170 turnovers achieved

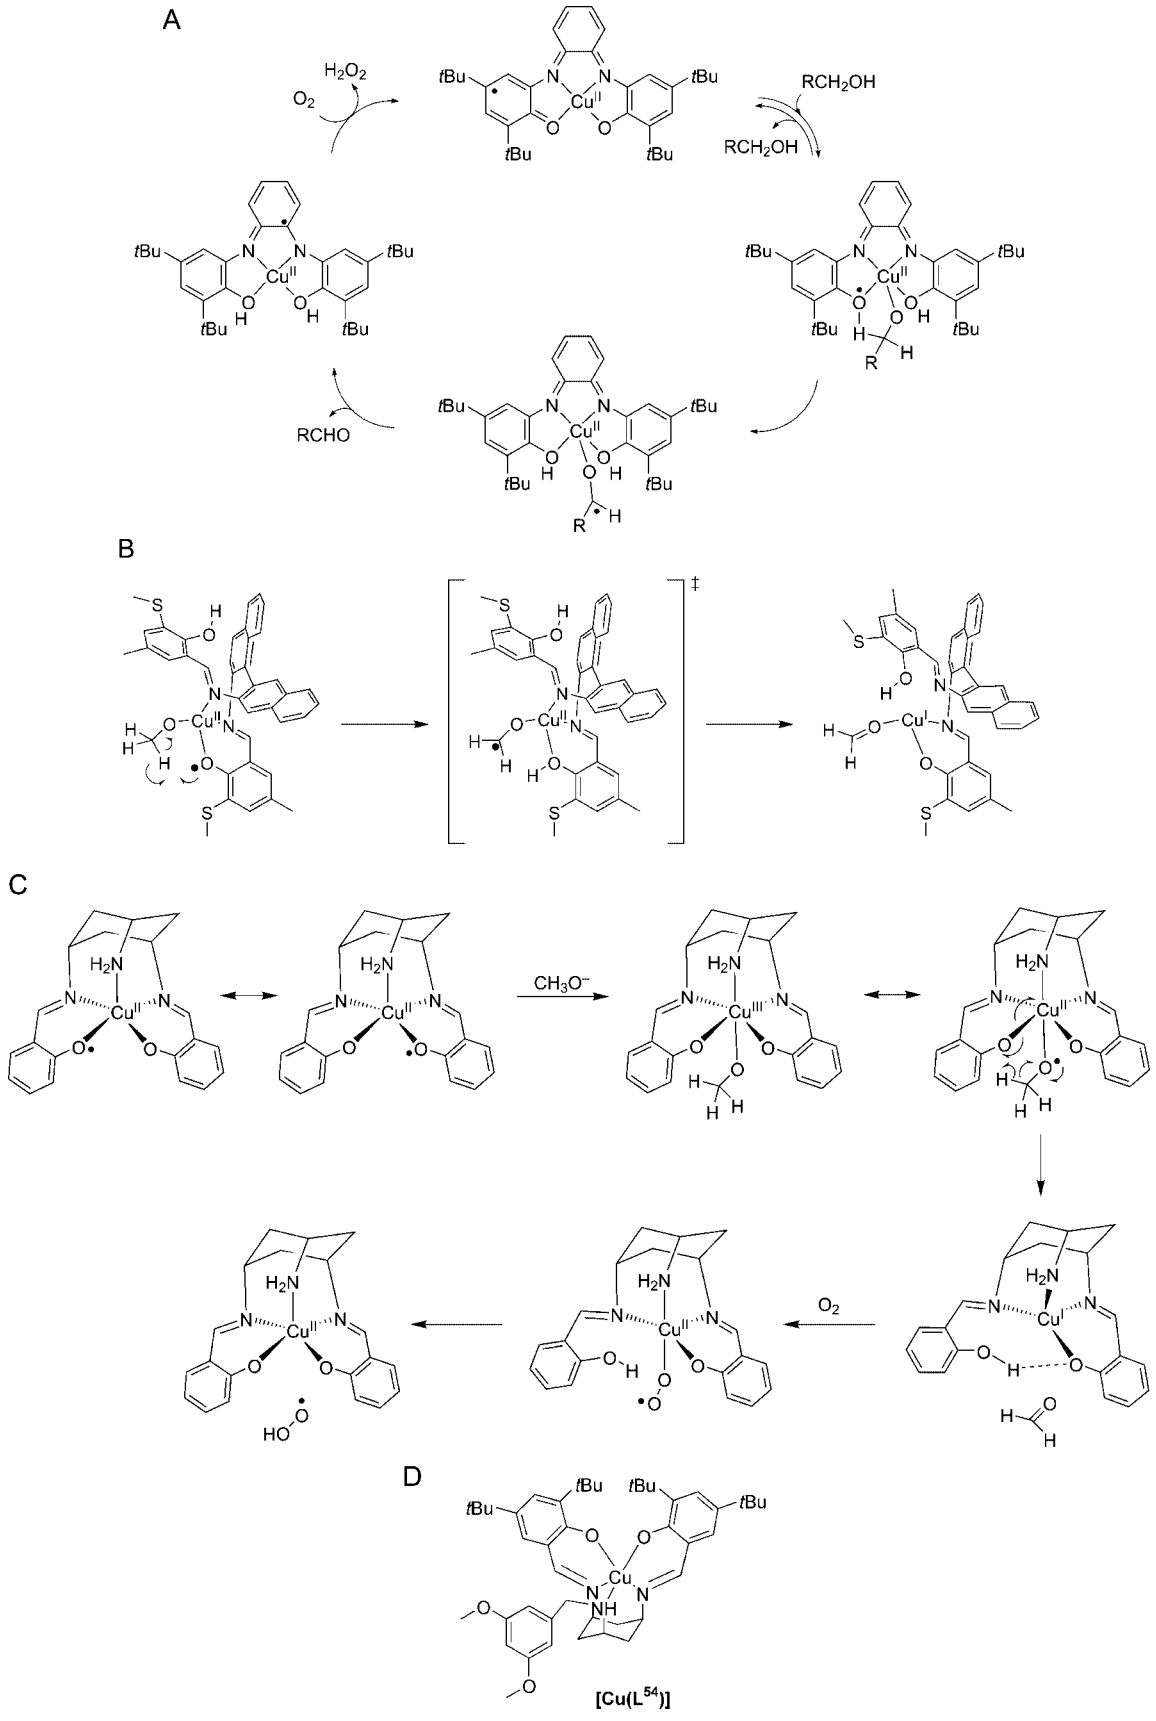

Figure 17. Proposed mechanisms for the catalytic oxidation of alcohols by [Cu($L^{12\cdot}$)] (A), and simplified models of [Cu($L^{2}$)] (B) and [Cu($L^{54}$)] (C) [adapted from ref.[46] (A), ref.[102,103] (B) and ref.[104] (C)]. The formula of [Cu($L^{54}$)] is also shown (D).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in 24 h (turnover frequency of 0.002 $s^{-1}$), which is attributed to a slower rate constant for hydrogen abstraction.

Itoh et al. have shown that [Cu($L^{27\cdot}$)($NO_3$)] oxidizes benzyl alcohol stoichiometrically to benzaldehyde following pseudo-first-order kinetics.[100] The $Cu^{I}$-phenol complex of $HL^{27}$ was recovered almost quantitatively at the end of reaction. In addition, a KIE of 8 was reported when $\alpha_D$-benzyl alcohol was used, which shows that hydrogen abstraction is the rate-determining step in the reaction. [Cu($L^{27\cdot}$)($NO_3$)] could thus be considered as a functional model of GO that stores two oxidative equivalents, one at the radical and the other at the copper(II) ion. It also stoichiometrically oxidizes phenols into phenoxyl radicals and 1,4-cyclohexadiene into benzene without a redox reaction at the metal center.[101] Phenol substrates are oxidized much faster than 1,4-cyclohexadiene in spite of the larger bond dissociation energy of the former. In addition, the steric effects of the phenol substituents are significant, with the reactivity order being 2,4,6-tri-*tert*-butylphenol < 2,6-di-*tert*-butylphenol < 2,4-di-*tert*-butylphenol. This strongly suggests that hydrogen atom abstraction from the phenol substrates is significantly enhanced by the coordinative interaction of the OH group to the metal ion center of the complex.

Yamauchi et al.[69] and ourselves[58,67] have reported that $Cu^{II}$-radical complexes of tripodal ligands possessing an $N_2O_2$ donor oxidize unactivated alcohols catalytically in the presence of small amounts of base. Using [Cu($HL^{39\cdot}$)(OAc)] as catalyst, 80 turnovers were achieved in one day for the oxidation of ethanol and 300 for the oxidation of benzyl alcohol, although the secondary alcohol cyclohexanol was not oxidized.[67] This catalyst thus reproduces the chemoselectivity of GO. A KIE was observed for the oxidation of benzyl alcohol, thereby suggesting that the rate-determining step is hydrogen abstraction. Hydrogen peroxide could not be detected, presumably due to its fast decomposition in the basic medium used, although its presence could be detected upon treating $H_2L^{39}$ with CuCl.

Stack et al. have studied the reactivity of [Cu($L^6$)] and [Cu($L^7$)] with benzyl alcohol and 9,10-dihydroanthracene as substrates.[40] Regardless of the substrate or complex, the same overall stoichiometry of the reaction was observed: two equivalents of complex oxidize one equivalent of substrate, in other words the complex is effectively only a one-electron oxidant. More surprisingly, the reaction of benzyl alcohol with [Cu($L^6$)] proceeds 10 times faster than with [Cu($L^7$)] despite the fact that the former is a significantly weaker oxidant ($\Delta E$ = 0.37 V). These differences in rate constants have been interpreted as being due to mechanistic differences between the two reactions: The rate-determining step is a simple bimolecular reaction between [Cu($L^7$)] and benzyl alcohol, while an associative mechanism involving a substrate-binding equilibrium prevails for the reaction of [Cu($L^6$)] with $PhCH_2OH$. The opposite behavior was observed with 9,10-dihydroanthracene as substrate − the simple bimolecular reaction is observed between [Cu($L^6$)] and 9,10-dihydroanthracene and the substrate-binding equilibrium preceding a unimolecular reaction in the reaction of [Cu($L^7$)] with 9,10-dihydroanthracene. Reactions that include a substrate-binding equilibrium are faster than those occurring in simple bimolecular reactions due to the lowering of the entropic cost of the rate-determining steps induced by the substrate-binding equilibrium. The fact that saturation behavior could be observed for the reaction of [Cu($L^7$)] with 9,10-dihydroanthracene indicates that the substrate-binding interaction is not associated with the presence of a polar hydroxyl group but may arise from either π–π stacking interactions or cation–π interactions (a high concentration of substrate may also change the solvent properties and thereby affect the reaction rates). 9,10-Dihydroanthracene reacts 25–300 times faster than benzyl alcohol, as expected for the lower bond dissociation energy of the former substrate. Large kinetic isotope effects were observed for all the substrates ($k_H/k_D > 5$) with a remarkable value of 19 for the reaction of [Cu($L^7$)] with benzyl alcohol. These results show that the rate-determining step in the reaction is the homolytic cleavage of the C–H bond and that deprotonation of the alcoholic substrate probably does not occur prior to hydrogen atom abstraction. Results concerning the rate of reaction with 9,10-dihydroanthracene also indicate that the hydrogen atom abstraction abilities of the two $Cu^{II}$-phenoxyl species are comparable. The products of this hydrogen abstraction step are a highly reactive radical and the protonated form of the copper(II) complexes ([Cu($HL^6$)] or [Cu($HL^7$)]). The activation energies, and thus the rates for atom transfer reactions, were found to be correlated to the strength of the O(phenolate)–H bonds being formed in [Cu($HL^6$)] and [Cu($HL^7$)].

Complex [Cu($L^{6\cdot}$)] thus models the acceleration of the reaction rate upon substrate binding found in GO, although in the enzyme the acceleration is amplified by several orders of magnitude, presumably due to the formation of an extended hydrogen-bond network between the substrate and GO and deprotonation of the substrate by Tyr495 prior to hydrogen atom abstraction, which lowers the bond dissociation energy of its α-C–H bond.

### Theoretical Approaches to Catalytic Mechanisms

Theoretical approaches to the oxidation of methoxide by [Cu($L^{2\cdot}$)][102,103] and [Cu($L^{54\cdot}$)][104] (in their $Cu^{II}$-phenoxyl radical form) have been undertaken. Ab initio molecular dynamics studies on [Cu($L^{2\cdot}$)] have shown that the methoxide adduct is a five-coordinate distorted pyramidal phenoxylcopper(II) complex.[102,103] The methoxide binds in the equatorial plane with a short Cu–O bond (1.93 Å), whereas the phenoxyl becomes an axial ligand with a much longer Cu–O bond (2.54 Å). This optimized structure is in good agreement with the EXAFS data. The unpaired electron switches from the axial to the equatorial position upon protonation of one phenolate (Figure 17, B). The $p_z$ orbital hosting the unpaired electron in this structure is found to be orthogonal to the $d_{x^2-y^2}$ orbital of the copper.[103] In the transition state, the structural rearrangements are concentrated on the substrate, which moves towards the equatorial

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

oxygen. The unpaired electron that was previously located on the phenoxyl oxygen (and sulfur atom) mainly moves to the substrate, which may explain why this system only converts aromatic but not aliphatic alcohols. The electron transfer from the ketyl species to the copper ion then occurs spontaneously upon relaxation, thereby suggesting that hydrogen atom abstraction and electron transfer take place quasi-simultaneously, unlike in GO. A copper(I) compound is obtained as the product of the hydrogen atom abstraction step. Substantial geometric rearrangements are observed upon going from the transition state to this compound: one of the imine nitrogen moves away from the copper in such a way that the whole aromatic system (naphthyl and phenol) lies essentially in the same plane. The $Cu^{I}$ ion in the resulting complex is tightly bound to one imine nitrogen and the aldehyde substrate, with one phenol oxygen being weakly bound as a third ligand. This suggests that release of the substrate is difficult and that molecular oxygen may bind when the aldehyde is still present.

DFT studies on [Cu($L^{54\cdot}$)] have revealed that substrate binding, as a sixth ligand, drives an intramolecular electron transfer that reduces the phenoxyl radical back to phenolate (Figure 17, C).[104] The substrate adduct is therefore formally an octahedral $Cu^{III}$-phenolate species, unlike in GO. This dramatic difference can be explained in terms of a proton transfer that occurs only in GO. Thus, after binding, the substrate transfers its alcohol proton to the axial tyrosinate Tyr495 residue that consequently coordinates only very weakly to afford an almost square-planar copper center (see part A of Figure 2, path 1). In [Cu($L^{54\cdot}$)], proton transfer leading to decoordination of a phenolate ring is prevented by the rigidity of the ligand framework and substrate binding generates an octahedral copper center instead. The substrate adduct of [Cu($L^{54\cdot}$)] also exhibits a large spin density on the methoxide oxygen, which indicates that it should be best formulated as lying between the $Cu^{III}$-OMe and $Cu^{II}$-$OMe^{\cdot}$ limits. In the hydrogen-transfer transition state, the SOMO is shifted to the carbon and rotated so that it points towards the phenolate oxygen. The barrier is 11.9 kcal mol$^{-1}$ above that of GO (estimated with $CH_3OH$ as substrate), which suggests a reduced activity of [Cu($L^{54\cdot}$)] relative to the enzyme and is consistent with a low turnover rate. A weakly bound $Cu^{I}$-aldehyde complex is obtained following the hydrogen atom and electron transfer, then the aldehyde is released and the metallic center is re-oxidized by molecular dioxygen into [Cu($L^{54\cdot}$)].

## Bio-Inspired Systems

### From Coordinated Mono- to Bis(phenoxyl) Radicals

Copper(II)-coordinated bis(phenoxyl) radicals have been described by Wieghardt et al. and ourselves with two types of ligands (TACN and salen).[37,56,57] This choice of ligand was dictated by the geometry of the copper(II) complexes: both phenolate moieties occupy the equatorial positions in the square-pyramidal copper(II)-TACN complex, while a square-planar (slightly distorted towards tetrahedral) environment is observed around the copper(II) ion in salen complexes [phenolate axial ligation consequently does not occur in any of these complexes, unlike copper(II) complexes of tripodal ligands].

The modular macrocycle TACN was used by Wieghardt et al.[56,57] The ligands $H_3L^{18,19}$ (Figure 5)[56] exhibit two one-electron transfer waves assigned to the successive oxidation of each phenolate moiety in their CV curve. The electrochemically generated $Cu^{II}$-phenoxyl complexes [Cu($HL^{18,19\cdot}$)] and [Cu($HL^{18,19\cdot}$)] could be obtained, but it was not possible to obtain the diradical form of [Cu($HL^{18,19\cdot}$)] even by performing controlled potential electrolysis at 243 K. The diradical complex [Cu($L^{17\cdot\cdot}$)] (Figure 18) could be obtained from the ligand $H_2L^{17}$.[57] It exhibits signals in the broad field range at effective $g$ factors close to 5 and 3 in its EPR spectrum. This spectrum has been interpreted by considering a ferromagnetic coupling of $Cu^{II}$ and each of the radicals that dominates the weaker antiferromagnetic radical–radical interaction. Simulation yielded a large $D$ value of 0.4 cm$^{-1}$, in agreement with a strong dipolar interaction between the $Cu^{II}$ and coordinated phenoxyl radicals. This situation thus contrasts sharply with that of the $Cu^{II}$-bis(iminosemiquinonate) diradical complex [Cu($L^{12\cdot\cdot}$)], which exhibits an $S$ = 1/2 ground state.[46]

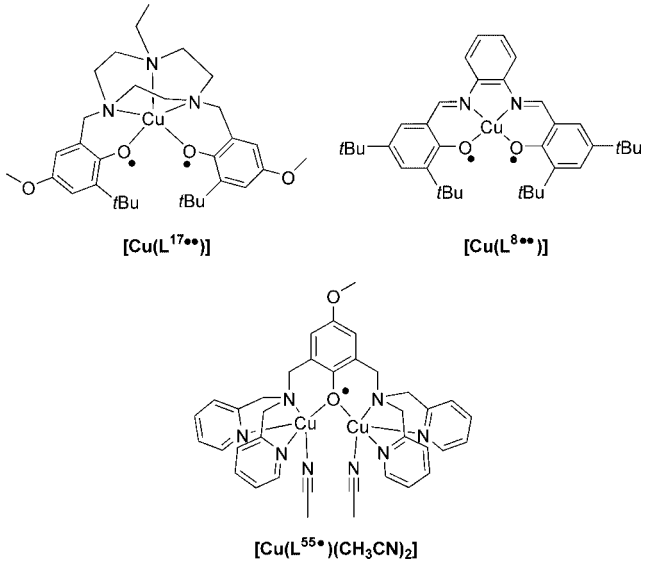

Figure 18. Bio-inspired system formally storing three oxidizing equivalents: [Cu($L^{17\cdot\cdot}$)] (ref.[57]), [Cu($L^{8\cdot\cdot}$)] (ref.[37]), [Cu($L^{55\cdot}$)-$(CH_3CN)_2$] (ref.[73]).

In another approach we have used salen-type ligands to study the respective influence of the hybridization of the nitrogens and flexibility of the linker between these two atoms on the properties of the electrogenerated $Cu^{II}$-phenoxyl and $Cu^{II}$-bis(phenoxyl) radical complexes (Figure 18).[37] The copper(II) complexes used are those of $H_2L^3$, $H_2L^5$, and $H_2L^{7,8}$ (Figure 3). While [Cu($L^7$)] and [Cu($L^8$)] incorporate a rigid linker, [Cu($L^3$)] and [Cu($L^5$)] contain a flexible one. The geometry around the metal ion is planar for [Cu($L^5$)] and [Cu($L^8$)] while it is slightly distorted towards tetrahedral for [Cu($L^3$)] and [Cu($L^7$)].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The electrochemically generated monoradical species [Cu(L$^{3\cdot}$)], [Cu(L$^{5\cdot}$)], and [Cu(L$^{7,8\cdot}$)] are relatively stable and X-band EPR-silent at 4–100 K, similar to other Cu$^{II}$-phenoxyl salen complexes,[34,35,39,43] thereby indicating that the phenoxyl moiety remains coordinated to the copper atom. The two-electron-oxidized species exhibit X-band EPR spectra that depend strongly on the ligand structure. The EPR spectra of [Cu(L$^{7\cdot\cdot}$)] and [Cu(L$^{8\cdot\cdot}$)] at 4 K exhibit signals that are distributed over the entire spectral width, similar to the Cu$^{II}$-bis(phenoxyl) radical complex [Cu(L$^{17\cdot\cdot}$)] described by Wieghardt et al.[57] A similar electronic structure is thus proposed, in other words a dominant ferromagnetic coupling between the Cu$^{II}$ and each of the radicals that yields large $D$ values. The EPR spectra of [Cu(L$^{3\cdot\cdot}$)] and [Cu(L$^{5\cdot\cdot}$)] are completely different as they are the superposition of two spectra, one typical of an organic radical (narrow signal at $g$ = 2.005) and the other corresponding to a mononuclear copper(II) complex. The ethyl linker is thus too flexible to maintain both phenoxyl moieties coordinated to the metal ion. The rigid linkers prevent decomplexation, regardless of whether the geometry around the metal center is planar {[Cu(L$^{8\cdot\cdot}$)]} or distorted towards tetrahedral {[Cu(L$^{7\cdot\cdot}$)]}.

### A Bridging Phenoxyl Radical in Dicopper(II) Complexes

In order to get a μ-phenoxyldicopper(II) system, a building block comprising at least one μ-phenolatedicopper(II) entity has to be oxidized. As discussed above, tripodal ligands show a marked tendency to assemble as dimers (of formula [Cu(L$^{N_3O}$)]$_2$ and [Cu(L$^{N_2O_2}$)]$_2$) that possess such a core when the steric bulk at the *o*-position of the phenolate is small to moderate (Figure 7). Unfortunately, we have shown that oxidation of [Cu(L$^{30,31}$)]$_2$ affords the corresponding mononuclear [Cu(L$^{30,31\cdot}$)(CH$_3$CN)] species,[63] while oxidation of [Cu(L$^{38,41}$)]$_2$ takes place at the nonbridging phenolate group to afford dimeric structures [Cu(L$^{38,41\cdot}$)]$_2$ with two Cu$^{II}$-phenoxyl radical molecules bridged by phenolato groups.[58,69] We have therefore synthesized the dicopper(II) complexes of the dinucleating ligand HL$^{55}$.[73] Two complexes were isolated, whose structures depend on the amount of NEt$_3$ added during the synthesis. [Cu(L$^{55}$)(CH$_3$CN)$_2$] was obtained in the presence of a single equivalent. This complex contains two copper(II) atoms with square-pyramidal geometries that are coordinated to one μ-phenolate oxygen and three nitrogens from the ligand, and one nitrogen from an exogenous acetonitrile molecule. The metal centers are separated by 4.059(5) Å and interact magnetically, as shown by the spin triplet resonance in the EPR spectrum of this complex. [Cu(L$^{55}$)(μ-OH)] was isolated when two molar equivalents of NEt$_3$ were used. Its structure differs from that of [Cu(L$^{55}$)(CH$_3$CN)$_2$] in several points: the geometry around the copper atom is trigonal bipyramidal, the exogenous acetonitrile ligands are replaced by a single μ-OH molecule, and the intermetallic distance is much shorter [2.980(9) Å]. Consequently, the interaction between the copper(II) atoms in [Cu(L$^{55}$)(μ-OH)] is strongly antiferromagnetic, as opposed to the ferromagnetic interaction observed in [Cu(L$^{55}$)(CH$_3$CN)$_2$]. These two complexes are oxidized to the μ-phenoxyl radical species [Cu(L$^{55\cdot}$)(μ-OH)] and [Cu(L$^{55\cdot}$)(CH$_3$CN)$_2$] over the same potential range (0.36–0.45 V). The former was found to be much less stable than the latter (the half-lives are <20 s and 22.3 min, respectively, at 298 K), thus showing that the reactivity is finely tuned by the nature of the coordinating ligand. The EPR spectrum of the most stable complex [Cu(L$^{55\cdot}$)(CH$_3$CN)$_2$] at 4 K exhibits a $\Delta M_S = \pm 3$ transition at $g$ = 8 that is the signature of an $S$ = 3/2 system. Its temperature dependence shows that it corresponds to the ground state. The $D$ value (–0.056 cm$^{-1}$) is close to that reported for an excited $S$ = 3/2 spin state in a triangular tricopper(II) system, but much higher than those reported for triradicals and lower than those reported for copper(II)-coordinated bis(phenoxyl) radicals. Since tyrosyl radicals are ubiquitous in metalloenzymes, such species could be biologically relevant. In addition, Karlin et al. have recently proposed the involvement of such species in a ligand cross-linking reaction promoted by a hydroperoxidodicopper(II) complex.[105]

## Conclusions

The biomimetic approach to the GO active site developed concomitantly by a number of research groups has led to the synthesis and characterization of a wide range of Cu$^{II}$-phenoxyl complexes. Enormous progress has thus been made from an entity that was unknown in coordination chemistry ten years ago. Many features of the GO active site have been reproduced successfully, providing valuable information on its spectroscopic signature, structure, and even reactivity. Replication of its oxidative chemistry has been achieved, although this reactivity is limited compared to that of the enzyme. Recent results in this field concerning bio-inspired complexes of aminyl radical ligands[106,107] or theoretical calculations[108] suggest that a catalytic efficiency approaching that of the enzyme is conceivable. This bio-inorganic story concerning coordinated radicals is thus far from finished, and the number of articles concerning radical metalloenzymes, specifically new copper(II)-radical metalloenzymes,[109–111] and metal-radical complexes will increase further in the near future.

## Acknowledgments

# Preparation and Molecular Structures of Stable Bis(germylenes) with Pincer Topology

F. Ekkehardt Hahn,*[a] Alexander V. Zabula,[a] Tania Pape,[a] and Alexander Hepp[a]

**Keywords:** N-Heterocycles / Germylenes / Pincer ligands

Benzannulated N-heterocyclic bis(germylenes) with pincer ligand topology have been prepared by the reaction of *N*,*N*′,*N*′′,*N*′′′-tetralithiated tetraamines with $GeCl_2$·1,4-dioxane or by the transamination reaction between a tetraamine and $Ge[N(SiMe_3)_2]_2$. X-ray diffraction studies have shown, that the bis(germylenes) exist as monomers in the solid state. Significant intramolecular Ge···Ge and Ge···N interactions have been observed for the lutidine-bridged bis(germylene). (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Polydentate N-heterocyclic carbene (NHC) ligands[1] containing two imidazolin-2-ylidene[2] or benzimidazolin-2-ylidene[3] donor groups, which are capable of forming chelate complexes including tridentate derivatives with pincer topology,[4] are known. In addition, some tris(imidazolin-2-ylidenes)[5] and complexes with cyclic tetrakis(benzimidazolin-2-ylidene)[6] and [11]ane-$P_2C^{NHC}$ ligands[7] have been described. Much less is known about polydentate silylenes, germylenes and stannylenes which can act as chelate ligands, although the monodentate derivatives have been prepared.[8–10]

Previously we described the preparation and coordination chemistry of germanium analogues of benzannulated N-heterocyclic bis(carbenes) in which two benzimidazolin-2-germylene moieties are linked together with an aryl or an alkyl group.[11] It has been demonstrated that these bis(germylenes) can act as bidentate chelate ligands. Continuing our investigations in this field, we report now on the preparation of the N-heterocyclic benzannulated bis(germylenes) with pincer topology which are potentially tridentate ligands.

## Results and Discussion

The N-heterocyclic bis(germylenes) were obtained from the tetraamines **2a** and **2b** which were prepared by reduction of the carbonyl groups in the corresponding tetraamides **1a** and **1b** (Scheme 1). The tetraamides are obtained by acylation of *N*-(*ortho*-aminophenyl)amides with benzene- (**1a**) or lutidine-2,6-bis(carboxylic chlorides) (**1b**) in the presence of $Et_3N$. The bridging unit present in the tetraamides determined which reducing agent had to be used in the subsequent reaction. Reduction of the carbonyl groups in the phenylene-bridged tetraamide **1a** was achieved with $AlH_3$ in THF at ambient temperature. The four carbonyl groups in tetraamide **1b** were reduced in good yield (81%) by an excess of freshly prepared $BH_3$ in THF.

The bis(germylene) **3** was obtained by lithiation of the corresponding tetraamine **2a** at –78 °C in THF followed by the reaction of the generated organolithium compound with $GeCl_2$·1,4-dioxane (Scheme 2). An analogous reaction sequence gave also the bis(germylene) **4**, but the product was quite impure and the overall yield was finally less than 30% after multiple recrystallization steps. The yield of bis(germylene) **4** could be impoved significantly to 60–65% by reaction of the tetraamine **2b** with $Ge[N(SiMe_3)_2]_2$ in boiling THF.

Bis(germylene) **3** was crystallized from hexane. The structure analysis shows monomeric units of the bis(germylene) which exhibit no significant inter- or intramolecular interactions (Figure 1). Bond lengths and angles in **3** are similar to those reported for a monodentate benzannulated germylene[9e] and other related bis(germylenes).[11] The nitrogen atoms are planarized as was observed for the analogous benzannulated N-heteroclic carbenes.[12] The shortest distance between two germanium atoms is the intermolecular separation between Ge1 and Ge2 [4.226(5) Å] which is too long to be regarded as an interaction. The lack of Ge···Ge interactions in **3** is possibly caused by the sterically demanding *N*-substituents. We have observed such Ge···Ge interactions in bis(germylenes) with sterically less demanding *N*-substituents.[11]

The molecular structure of bis(germylene) **4** containing a lutidine bridge between the germylene units is depicted in Figure 2. Its conformation is distincly different to that of **3**. While no significant intermolecular interactions were noticed, short intramolecular Ge···Ge and Ge···N contacts

were found in the molecular structure of **4**. The Ge1···Ge2 separation is 3.041(5) Å which is significantly shorter than twice the van der Waals radius of the germanium atom.[13] It is also shorter than the Ge···Ge separation which we found for alkyl-bridged bis(germylenes) [3.577(2) Å].[11] The

geometry of the $N_2Ge1\cdots Ge2N_2$ moiety is similar to the distorted *trans*-bent arrangement found for E=E double bonds of heavier homologues of alkenes. The intramolecular distances Ge1···N3 [3.386(7) Å] and Ge2···N3 [3.154(7) Å] are again shorter than those found in bimolecular aggregates of bis(germylene) with intermolecular Ge···N separations of about 3.53 Å.[11]

## Conclusions

We have prepared the bis(germylenes) **3** and **4** containing two N-heterocyclic germylene (NHGe) units bridged by a 1,3-phenylene- or 1,3-pyridinediylbis(methylene) group, respectively. These compounds are germanium analogues of N-heterocyclic pincer-type bis(carbene) ligands. Their use in the complex formation with transition metal ions and the properties of such pincer complexes are currently investigated.

## Experimental Section

**Starting Materials, Reaction Conditions and Instrumentation:** All manipulation were carried out under argon using Schlenk or glovebox techniques. Toluene and *n*-hexane were dried with sodium/benzophenone and were freshly distilled prior to use. [$D_8$]Toluene was dried with Na/K alloy. The preparation of the tetraamide **1a** and the tetraamine **2a** have been described.[11] Compounds **1a** and **1b** were obtained by similar methods. However, **2b** was prepared in analogy to **2a** by using $BH_3$ instead of $AlH_3$ as a reducing agent. $Ge[N(SiMe_3)_2]_2$ was prepared as described in the literature.[14] $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker AC-200 spectrometer.

**Tetraamide 1b:** Yield 75%, white solid. $^1H$ NMR (200 MHz, [$D_6$]-DMSO): $\delta$ = 10.91 [s, 2 H, N*H*–C(O)–$C_5H_3N$], 9.07 [s, 2 H, N*H*–C(O)–$C(CH_3)_3$], 8.45–8.34 (m, 3 H, Ar–H $C_5H_3N$), 7.73–7.68 (m, 2 H, Ar–H $C_6H_4$), 7.52–7.47 (m, 2 H, Ar–H $C_6H_4$), 7.31–7.26 (m, 4 H, Ar–H $C_6H_4$), 1.01 [s, 18 H, $C(CH_3)_3$] ppm. $^{13}C$ NMR (50.3 MHz, [$D_6$]DMSO): $\delta$ = 176.9 [*C*(O)–$C_5H_3N$], 161.4 ($C_\alpha$-$C_5H_3N$), 148.2 [*C*(O)–$C(CH_3)_3$], 140.5 ($C_\gamma$-$C_5H_3N$), 131.4, 130.6 (Ar–$C_{ipso}$ $C_6H_4$), 126.2 ($C_\beta$-$C_5H_3N$), 125.7, 125.5, 125.1, 125.0 (Ar–$C_{meta}$ and Ar–$C_{ortho}$ $C_6H_4$), 38.7 [*C*$(CH_3)_3$], 26.9 [C(*C*$H_3)_3$] ppm. MS (MALDI): *m*/*z* (%) = 516 $[M + H]^+$, 538 $[M + Na]^+$.

**Tetraamine 2b:** A 1 M solution of $BH_3$ in THF (40 mmol, 40 mL) was added to the solid tetraamide **1b** (500 mg, 0.97 mmol) at 0 °C. The mixture was stirred at room temperature for 3 h, than heated under reflux for 4 h. Excess $BH_3$ was hydrolyzed with $CH_3OH$ at 0 °C. The resulting boron compound was transformed into the tetraamine by hydrolysis in a THF/$H_2O$ mixture with NaOH. **2b** was extracted from the reaction mixture 3 times with $CH_2Cl_2$ (20 mL each). The combined organic phases were dried with $Na_2SO_4$. Removal of the solvent gave an oil, which was dissolved in hexane and filtered. Evaporation of the hexane gave **2b** as a colorless or yellowish air-sensitive oil. Yield 360 mg (81%). $^1H$ NMR (200 MHz, $CDCl_3$): $\delta$ = 7.52 (t, 1 H, $H_\gamma$-$C_5H_3N$), 7.11 (d, 2 H, $H_\beta$-$C_5H_3N$), 6.75–6.52 (m, 8 H, Ar–H $C_6H_4$), 4.37 (s, 4 H, NC*H*$_2$–$C_5H_3N$), 3.81 (s br, 4 H, NH), 2.79 [s, 4 H, NC*H*$_2$–$C(CH_3)_3$], 0.96 [s, 18 H, $C(CH_3)_3$] ppm. $^{13}C$ NMR (50.3 MHz, $CDCl_3$): $\delta$ = 158.2 ($C_\alpha$-$C_5H_3N$), 138.0, 137.2, 137.0 [Ar–$C_{ipso}$ for $(NH)_2C_6H_4$ and $C_\gamma$-$C_5H_3N$], 119.7 ($C_\beta$-$C_5H_3N$), 119.4, 118.9 [Ar–$C_{meta}$ for $(NH)_2$-$C_6H_4$], 112.1, 111.8 [Ar–$C_{ortho}$ for $(NH)_2C_6H_4$], 56.1 (N*C*$H_2$–$C_5H_3N$), 49.7 [N*C*$H_2$–$C(CH_3)_3$], 31.4 [*C*$(CH_3)_3$], 27.8 [C(*C*$H_3)_3$] ppm. MS (EI, 70 eV): *m*/*z* (%) = 459 (100) $[M]^+$.

**Bis(germylenes) 3 and 4:** The bis(germylenes) were prepared from $GeCl_2$·1,4-dioxane or $Ge[N(SiMe_3)_2]_2$ as described by us for related derivatives.[11] Crystals for the X-ray analyses were grown by slow diffusion of hexane into a saturated solution of **4** in toluene or directly from an *n*-hexane solution of **3**.

**Selected Spectroscopic Data for 3:** Yield 80%. $^1H$ NMR (200 MHz, [$D_8$]toluene): $\delta$ = 7.14–7.00 (m, 12 H, Ar–H), 4.82 (s, 4 H, NC*H*$_2$–$C_6H_4$), 3.85 [s, 4 H, NC*H*$_2$–$C(CH_3)_3$], 0.86 [s, 18 H, $C(CH_3)_3$] ppm. $^{13}C$ NMR (50.3 MHz, [$D_8$]toluene): $\delta$ = 144.2, 142.2 (Ar–$C_{ipso}$ $GeN_2$–$C_6H_4$), 140.6 (Ar–$C_{ipso}$ $NCH_2$–*C*$_6H_4$), 129.2, 128.3, 127.3 ($NCH_2$–*C*$_6H_4$), 118.7, 118.1 (Ar–$C_{meta}$ $GeN_2$–$C_6H_4$),110.5, 110.3 (Ar–$C_{ortho}$ $GeN_2$–$C_6H_4$), 56.8 (N*C*$H_2$–$C_6H_4$), 50.5 [N*C*$H_2$–$C(CH_3)_3$], 33.0 [*C*$(CH_3)_3$], 28.6 [C(*C*$H_3)_3$] ppm. MS (EI, 70 eV): *m*/*z* (%) = 600 (68) $[M]^+$, 543 (91) $[M - t\text{Bu}]^+$.

**Selected Spectroscopic Data for 4:** Yield 240 mg (64%). $^1H$ NMR (200 MHz, [$D_8$]toluene): $\delta$ = 7.02–6.59 (m, 11 H, Ar–H), 5.18 (s, 4 H, NC*H*$_2$–$C_5H_3N$), 3.77 [s, 4 H, NC*H*$_2$–$C(CH_3)_3$], 0.90 [s, 18 H, $C(CH_3)_3$] ppm. $^{13}C$ NMR (50.3 MHz, [$D_8$]toluene): $\delta$ = 159.3 ($C_\alpha$-$C_5H_3N$), 144.0, 142.1 (Ar–$C_{ipso}$ $C_6H_4$), 137.2 ($C_\gamma$-$C_5H_3N$), 119.8 ($C_\beta$-$C_5H_3N$), 118.6, 118.1 (Ar–$C_{meta}$ $C_6H_4$), 110.4, 110.3 (Ar–$C_{ortho}$ $C_6H_4$), 56.8 (N*C*$H_2$–$C_5H_3N$), 51.9 [N*C*$H_2$–$C(CH_3)_3$], 33.0 [*C*$(CH_3)_3$], 28.6 [C(*C*$H_3)_3$] ppm. MS (EI, 70 eV): *m*/*z* (%) = 601 (46) $[M]^+$, 544 (100) $[M - t\text{Bu}]^+$.

**X-ray Diffraction Studies:** Diffraction data for **3** and **4** were collected with a Bruker AXS APEX CCD diffractometer equipped with a rotation anode at 153(2) K using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Diffraction data were collected over the full sphere and were corrected for absorption. The data reduction was performed with the Bruker SMART[15] program package. The structures were solved with the SHELXS-97[16] package using the heavy-atom method and were refined with SHELXL-97[17] against $|F^2|$ using first isotropic and then anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were added to the structure models in calculated positions. CCDC-641062 (**3**) and -641063 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk./data/request/cif.

**Crystal Data for Bis(germylene) 3:** $C_{30}H_{38}Ge_2N_4$, $M$ = 599.82, triclinic, $P\bar{1}$, $Z$ = 2, $a$ = 9.4855(12), $b$ = 9.8055(12), $c$ = 15.744(2) Å, $\alpha$ = 85.590(3), $\beta$ = 89.526(2), $\gamma$ = 77.424(2)°, $V$ = 1427.7(3) Å$^3$, 14127 measured reflections, 6544 unique reflections ($R_{int}$ = 0.0371), $R$ = 0.0414, $wR$ = 0.0905 for 4947 contributing reflections [$I \geq 2\sigma(I)$], refinement against $|F^2|$ with anisotropic thermal parameters for all non-hydrogen atoms and hydrogen atoms in calculated positions.

**Crystal Data for Bis(germylene) 4:** $C_{29}H_{37}Ge_2N_5$, $M$ = 600.82, triclinic, $P\bar{1}$, $Z$ = 2, $a$ = 9.690(2), $b$ = 9.807(2), $c$ = 14.792(3) Å, $\alpha$ = 91.743(4), $\beta$ = 96.699(4), $\gamma$ = 96.715(4)°, $V$ = 1385.1(4) Å$^3$, 11194 measured reflections, 4890 unique reflections ($R_{int}$ = 0.0392), $R$ = 0.0449, $wR$ = 0.1143 for 3839 contributing reflections [$I \geq 2\sigma(I)$], refinement against $|F^2|$ with anisotropic thermal parameters for all non-hydrogen atoms and hydrogen atoms in calculated positions.

# A Diferrous Single-Molecule Magnet

**Athanassios K. Boudalis,*[a] Yiannis Sanakis,*[a] Juan Modesto Clemente-Juan,[b] Alain Mari,[c] and Jean-Pierre Tuchagues[c]**

**Keywords:** Single-molecule studies / Cluster compounds / Magnetic properties / Iron

The diferrous complex $[Fe_2(acpypentO)(NCO)_3]$ (**1**), (acpypentO$^-$ = the anion of 1,5-bis[2-pyridyl(1-ethylimino)]-pentane-3-ol) was studied by spectroscopic (dual-mode X-band EPR and $^{57}$Fe-Mössbauer) and magnetic (AC magnetic susceptibility) techniques. Complex **1** (A. K. Boudalis et al., *Inorg. Chem.* **2004**, *43*, 1574) was previously shown to exhibit an intramolecular ferromagnetic coupling with important single-ion anisotropies with marked differences in the single-ion electronic parameters of the two iron sites. In this contribution, additional studies are carried out to probe its dynamic magnetic properties. Mössbauer spectra recorded at liquid helium temperatures indicate slow paramagnetic relaxation and a ground state of the system characterized by a non-Kramers doublet with an Ising-type anisotropy, a condition which favours single-molecule magnet (SMM) behaviour. A frequency-dependent out-of-phase signal observed below 3 K in AC susceptibility measurements is in line with such a picture. The out-of-phase signal, however, is relatively weak in comparison with the in-phase signal. Dual mode X-band EPR spectroscopy revealed characteristic signals, the analysis of which suggests inhomogeneities in the system. For some molecules, the splitting $\Delta_0$ of the non-Kramers ground doublet is vanishingly small, which gives rise to out-of-phase signals in AC susceptibility measurements and magnetically split Mössbauer spectra in the absence of external magnetic fields. Other molecules, however, are characterized by a non-negligible $\Delta_0$, which gives rise to the dual mode X-band EPR signals. For these molecules the magnetic relaxation is fast.

## Introduction

Molecule-based magnetic materials have been a field of intense scientific research during the past decades. A reason for their increasing interest both to chemists and physicists is that molecular objects like complexes (0D) or chains (1D), which otherwise are best described by quantum mechanics, display phenomena like slow magnetic relaxation, usually seen in classical magnetic materials. These classical phenomena are observed alongside purely quantum phenomena like quantum tunnelling of the magnetization (QTM) thus bridging the classical (macroscopic) and the quantum (microscopic) worlds. In this field, single-molecule magnets (SMMs) and single-chain magnets (SCMs) are classes of molecules that have generated much excitement because they exhibit both slow magnetic relaxation and Arrhenius kinetics due to strong uniaxial anisotropy, without experiencing 3D magnetic ordering.

Since the first observation of the SMM phenomenon for the dodecanuclear manganese cluster $[Mn_{12}O_{12}(O_2CMe)_{16}(H_2O)_4]$, many other clusters have been shown to exhibit the same phenomenon, with nuclearities reaching 84, as observed in the giant $\{Mn_{84}\}$[1] torus reported by Christou et al. The maximum ground spin-state ever attained is 83/2 reported for a $\{Mn_{19}\}$ complex by Powell et al.[2] However, smaller molecules have been reported to exhibit slow relaxation of their magnetization, like mononuclear $Co^{II}$[3,4] and $Ln^{III}$ (Ln = Tb, Dy) complexes[5] or dinuclear $Fe^{III}$,[6] $Mn^{III}$,[7] $Tb^{III}$–$Cu^{II}$[8] and $Fe^{III}$–$Dy^{III}$[9] clusters. These species are particularly interesting as their small size allows us to study their electronic properties with exact methods, and fewer approximations. It is thus possible to correlate their observable behaviour with more fundamental parameters and to subsequently gain insight into the behaviour of larger systems. Moreover, they allow us to envisage applications concerning memory recording at the smallest scale.[10]

Dinuclear complexes comprising high-spin ferrous ions have been synthesized and studied as synthetic models for the active sites of metalloenzymes.[11] In a number of cases, ferromagnetic interactions have been observed that result in magnetic ground states.[12] Moreover, electron paramagnetic resonance (EPR) and Mössbauer spectroscopy indicate that the ground state is characterized by a non-Kramers doublet with an Ising-type magnetic anisotropy. This special feature, in combination with the relatively large spin, is one of the requirements for a molecule to exhibit single-molecule magnetic behaviour.

Recently, we reported the synthesis and physical characterization of a series of polynuclear $Fe^{II}$ complexes including the dinuclear species $[Fe_2(acpypentO)(NCO)_3]$ (**1**),[13] where $acpypentO^-$ is the anion of 1,5-bis[2-pyridyl(1-ethylimino)]pentane-3-ol (Figure 1). This complex was found to contain two pentacoordinate $Fe^{II}$ ions bridged by one alkoxido oxygen belonging to the ligand, and one end-on cyanato anion. Analysis of the thermal variation of the $\chi_M T$ product of **1** indicated that the two $S = 2$ spins are ferromagnetically coupled with $J = 3\ cm^{-1}$. In addition, the analysis of the magnetic susceptibility measurements indicated the critical involvement of zero-field splitting interactions. Under appropriate conditions, these interactions might eventually lead to an important anisotropy of the ground state. Indeed, the two $Fe^{II}$ ions showed important differences in their axial and rhombic single-ion anisotropies with $D_1 = 1.6\ cm^{-1}$, $E_1 = -0.35\ cm^{-1}$ ($\lambda_1 = 0.22\ cm^{-1}$) and $D_2 = -12.2\ cm^{-1}$, $E_2 = 1.1\ cm^{-1}$ ($\lambda_2 = 0.09\ cm^{-1}$).

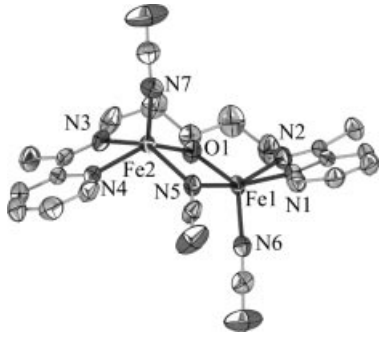

Figure 1. Molecular structure of complex **1**.

With these in mind, we considered it worthy to examine the properties of the ground state of this system in more detail and to monitor its dynamic magnetic properties at low temperatures. Taking into account the ferrous nature and the high reactivity of this dinuclear complex with dioxygen, we considered Mössbauer and X-band EPR ($\perp$ and $\parallel$ modes) spectroscopy to be the most appropriate techniques for elucidating the properties of its ground state.

### Mössbauer Spectroscopy

The Mössbauer spectra at temperatures above liquid nitrogen consist of two quadrupole-split doublets attributed to the two different irons sites of the molecule. At 78 K, the two ferrous sites are characterized by $\delta_1 = 1.01\ mm\,s^{-1}$, $\Delta E_{Q1} = 2.27\ mm\,s^{-1}$ and $\delta_2 = 1.01\ mm\,s^{-1}$, $\Delta E_{Q2} = 3.38\ mm\,s^{-1}$.[13] The temperature dependence of the isomer shifts above 78 K is attributed to the second-order Doppler effect whereas the dependence of the quadrupole splitting values is typical for high-spin ferrous ions.

In the present work, we study spectra recorded at temperatures below 78 K. Representative spectra are shown in Figure 2. In the temperature range 10–78 K, there is no significant variation of the doublets: the two sites exhibit almost temperature-independent isomer shifts and quadrupole splittings. For temperatures below 10 K, the spectra exhibit line-broadening and a spectrum with magnetic features is observed at 4.2 K. These spectra look slightly different from those recorded previously[13] *essentially* because of a remarkable sensitivity related to a strong dependence of the relaxation times on temperature below 7 K.

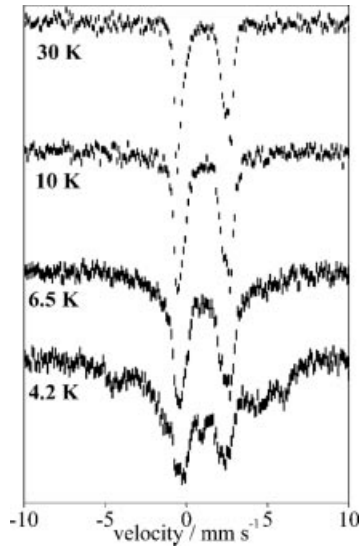

Figure 2. Zero-field Mössbauer spectra from a powdered sample of **1** at liquid helium temperatures.

From DC magnetic susceptibility measurements, no evidence for long-range effects were observed, which suggests that the magnetically split spectrum at 4.2 K is due to slow paramagnetic relaxation. The Mössbauer spectra are in line with the magnetic susceptibility measurements, which indicate ferromagnetic coupling between the ferrous ions. In the case of antiferromagnetic coupling, the ground state would be diamagnetic ($S_T = 0$) and quadrupole-split doublets would be observed in zero-field at liquid helium temperatures. The magnetic ground state of **1** is further supported by spectra recorded in the presence of applied magnetic fields.

Figure 3 shows the Mössbauer spectra of a powdered sample of **1** in the presence of external magnetic fields up to 5.0 T applied perpendicularly to the γ-rays. Clearly, the magnetically perturbed spectra are incompatible with an $S_T = 0$ ground state.[12d] Useful information may be derived by considering the dependence of the spectra on the strength of the applied magnetic field. This can be visualized by following the shift of the absorption peak at ca. $-4.5\ mm\,s^{-1}$ in the zero-field spectrum. This peak does not shift further to more negative velocities under a 0.55 T field, but its intensity increases. For higher magnetic fields, this peak shifts *inwards*, which indicates that the external magnetic field opposes the intrinsic one. This indicates that the internal magnetic field has reached saturation for a relatively small external magnetic field (vide infra). This overall behaviour implies a number of properties regarding the nature of the electronic ground state of the system as commented next.

The $^{57}Fe$ Mössbauer spectra of high-spin ferrous compounds usually exhibit fast spin relaxation even at liquid helium temperatures and in such a case quadrupole-split

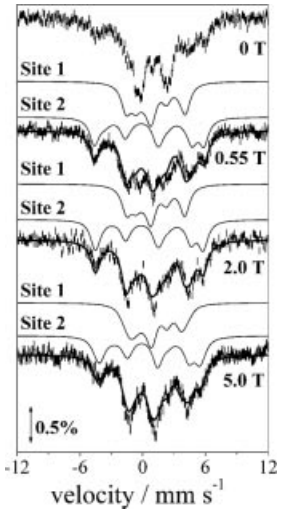

Figure 3. Mössbauer spectra of a powdered sample of **1** at 4.2 K in the absence and in the presence of external magnetic fields applied perpendicular to the γ-rays. Continuous lines are theoretical simulations obtained by assuming two different ferrous sites as described in the text. The contribution of each site is shown separately.

doublets are observed. However, slow paramagnetic relaxation effects were observed in the spectra of a number of high-spin ferrous compounds.[14] The magnetic spectra resulting from paramagnetic relaxation are related with non-Kramers doublets exhibiting a significant Ising-type anisotropy. The magnetically split spectra at zero external magnetic field are due to mixing between the electronic and nuclear spin states.[15] On the contrary, the Mössbauer spectra associated with singlets from such systems consist of quadrupole-split doublets.[16] The non-Kramers character of the ground state with an Ising-type anisotropy is further supported by simulations of the Mössbauer spectra described in a subsequent section.

### Dynamic Magnetic Properties

The Mössbauer spectroscopic results presented above indicate that the ground state of complex **1** is characterized by a uniaxial doublet. This, in combination with the nominally high spin of the system, encouraged us to investigate the possibility of slow magnetic relaxation phenomena in **1**, using AC magnetic susceptibility (Figure 4). Indeed, the out-of-phase data clearly show a frequency-dependent signal below ca. 3 K, which indicates the occurrence of slow relaxation phenomena. The maximum of the signal was not observed down to 2 K, which was the lower limit of our SQUID facility. This hampered us from carrying out a quantitative analysis of the relaxation phenomena, but it was clear evidence for the onset of slow magnetic relaxation. Rough estimations may be obtained by considering the following.[17,18h] From the temperature dependence of the zero-field spectra, we may assume that at 4.2 K the spin relaxation time $\tau \approx 10^{-7}$–$10^{-8}$ s, the characteristic time of the Mössbauer spectroscopy.[17d] From the AC susceptibility data we may estimate that at 2 K, $\tau \approx 10^{-3}$ s. Assuming an Arrhenius dependence of $\tau$ ($\tau = \tau_0 e^{\Delta E/kT}$), we estimate $\tau_0 \approx 10^{-11}$–$10^{-13}$ s and $\Delta E < 40$ K (28 cm$^{-1}$). Under a zero applied static field, and for a 250 Hz oscillating field, the $\chi_M'T$ product at 2 K was 9.72 cm$^3$ mol$^{-1}$ K, which is close to the expected value on the basis of the analysis of the DC susceptibility data.[13] Upon raising the static magnetic field, there is a decrease in the $\chi_M'T$ product that is due to the increased splitting of the Zeeman states. This is similar to the sudden drop of the $\chi_M T$ product at low temperatures, as evidenced in the DC data.[13]

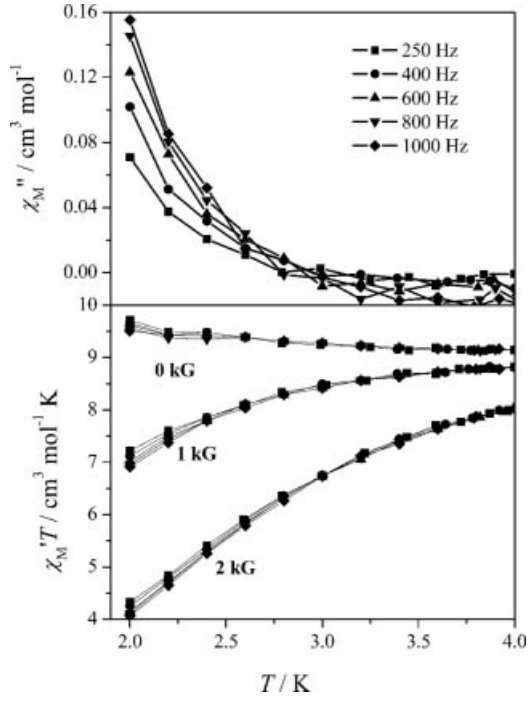

Figure 4. Out-of-phase, $\chi_M''$ vs. $T$, AC magnetic susceptibility data for complex **1** (top) under a zero static magnetic field and with oscillating frequencies of 250, 400, 600, 800 and 1000 Hz. The effect of the static magnetic field on the in-phase signals is depicted in the $\chi_M'T$ vs. $T$ curves (bottom), for fields of 1 and 2 kG.

The imaginary component of the ac susceptibility signal is rather small (≈3.5% of the real part). This is not unprecedented as many molecules exhibiting SMM behaviour have a similarly weak $\chi''/\chi'$ ratio.[18] A possible origin for this behaviour might be the existence of heterogeneities concerning the relaxation properties of the molecules. Namely, a fraction of the molecules is characterized by slow relaxation whereas another fraction is relaxing fast, as further commented below.

The pertinent spin Hamiltonian that describes the magnetic properties of **1** is depicted in Equation (1).[19]

$$\hat{H}_1 = -2J\hat{\mathbf{S}}_1 \cdot \hat{\mathbf{S}}_2 + \sum_{i=1}^{2}\left[D_i\left(\hat{S}_{z,i}^2 - 2\right) + E_i\left(\hat{S}_{x,i}^2 - \hat{S}_{y,i}^2\right) + \beta\hat{\mathbf{S}}_i\mathbf{g}_i\mathbf{H}\right] \quad (1)$$

In the case of axial symmetry ($E = 0$), the ground state of the system is characterized by a non-Kramers doublet with an Ising-type anisotropy. In this case, slow relaxation

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

might be favoured. If, however, rhombic distortions ($E \neq 0$) are present, the degeneracy of the non-Kramers doublet splits by an amount $\Delta_0$[20] and in this case, fast relaxation may occur through quantum tunnelling effects.[21] The existence of molecules for which $\Delta_0$ is nonzero can be monitored by dual-mode X-band EPR spectroscopy (vide infra).

### Dual-Mode EPR Studies

For an isolated non-Kramers doublet, intradoublet transition is expected provided that the transition probability $P \neq 0$. Because $P \approx \Delta_0^2$, no signals are observed in the case of $\Delta_0 \approx 0$, whereas signals are observed for $0 < \Delta_0 < h\nu$ ($h\nu \approx 0.3\ cm^{-1}$ at X-band). In Figure 5, we show X-band EPR spectra of a powdered sample of **1** recorded at 4.2 K. Strong signals are observed in the low-field region in both the parallel and perpendicular modes. No signals attributable to half-integer spin systems are observed (i.e. a "$g \approx 4.3$" signal at ≈1500 G), which indicates that the samples are not oxidized. The signals exhibit saturation effects at 4.2 K and decrease as the temperature increases. The latter indicates that the signals arise from the ground state.

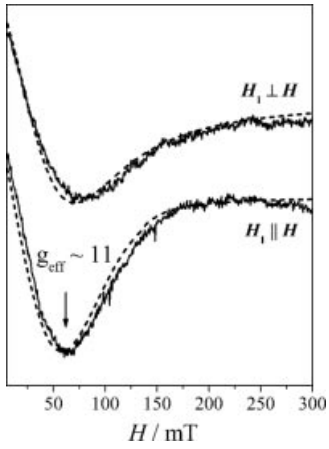

Figure 5. Dual-mode X-band EPR spectra for a powdered sample of **1** at 4.2 K under nonsaturating conditions. Dashed lines are theoretical simulations obtained as described in the text. EPR conditions: Microwave power: 0.13 mW, modulation amplitude: 1.0 mT, microwave frequency: 9.60 (perpendicular mode), 9.36 GHz (parallel mode).

The line-shape of the EPR signals is consistent with an integer spin system[22] as expected for **1**. The EPR properties of diferrous complexes have been extensively studied by Hendrich et al.[11,23] The dashed lines superimposed above the experimental spectra are simulated spectra considering an effective $S = 4$ spin Hamiltonian [Equation (2)].[24]

$$\hat{H}_2 = D\left(\hat{S}_z^2 - 20/3\right) + E\left(\hat{S}_x^2 - \hat{S}_y^2\right) + \beta\hat{\mathbf{S}}\mathbf{g}\mathbf{H} \quad (2)$$

Satisfactory simulations were obtained with different sets of parameters [from Equation (1)] that is, there is not a unique set of parameters for simulating the spectra. However, these different sets result in a unique description regarding the magnetic properties of the doublet giving rise to the signal.[24] The signal arises from transitions within a non-Kramers doublet with uniaxial magnetic properties which is split by an amount $\Delta_0 \approx 0.3\ cm^{-1}$ at zero field.[23a,20] To account properly for the line shape of the EPR spectra, a Gaussian distribution of $\Delta_0$ with an apparent width $\sigma\Delta_0 = 0.06\ cm^{-1}$ must be incorporated. The $\Delta_0$ distribution is due to a distribution of parameters such as *D*, *E* and *J*. Alternatively, solid-state effects may effectively lead to line broadening. As a conclusion, the results from dual mode X-band EPR spectroscopy indicate that the system contains molecules for which $\Delta_0$ is nonnegligible.

### Simulations of the Mössbauer spectra

It was noticed that the analysis of Mössbauer spectra from diferrous complexes is not trivial when the zero-field splitting terms and the exchange coupling constant are of comparable magnitude[12a,12d,25] because the number of parameters involved is large. Therefore, a unique set of parameters cannot be obtained unambiguously. A complete analysis of the spectra was not pursued; however, we checked whether the behaviour of the magnetically perturbed Mössbauer spectra is consistent with the results from X-band EPR spectroscopy discussed above. The EPR spectra were analyzed within the framework of Hamiltonian in Equation (2) and it was found that the ground non-Kramers doublet of the system is characterized by a distributed $\Delta_0$, centred at $0.3\ cm^{-1}$.

For the magnetically perturbed Mössbauer spectra we assumed two sites at a 1:1 ratio and we used the effective spin Hamiltonian $\hat{H}_3$ for $S = 4$ (strong exchange limit) [Equation (3)]:

$$\hat{H}_3 = \hat{H}_2 + \sum_{i=1,2}\left[\hat{\mathbf{S}}\tilde{\mathbf{A}}_i\hat{\mathbf{I}}_i - g_n\beta_n\hat{\mathbf{I}}_i\mathbf{H} + \hat{H}_{Q,i}\right] \quad (3)$$

with [Equation (4)]:

$$\hat{H}_{Qi} = \frac{eQV_{\zeta\zeta}}{12}\left[3\hat{I}_{\zeta i}^2 - \frac{15}{4} + \eta_i\left(\hat{I}_{\xi i}^2 - \hat{I}_{\eta i}^2\right)\right] \quad (4)$$

where ($\xi$, $\eta$, $\zeta$) designates the principal axis system of the electric field gradient (EFG) tensor and where $\eta_i = (V_{\xi\xi i} - V_{\eta\eta i})/V_{\zeta\zeta i}$ is the asymmetry parameter. Equation (3) is written in the coupled representation.

For the isomer shift and quadrupole splittings we used the values obtained from the zero-field spectra recorded at 78 K ($\delta_1 = 1.01\ mm\,s^{-1}$, $\Delta E_{Q1} = 2.27\ mm\,s^{-1}$ and $\delta_2 = 1.01\ mm\,s^{-1}$, $\Delta E_{Q2} = 3.38\ mm\,s^{-1}$). For the parameters involved in the electronic part of Hamiltonian $\hat{H}_2$ we used the values from the analysis of the EPR spectra.[24] The

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

splittings observed in the magnetically perturbed spectra reflect a total magnetic field acting on the $^{57}$Fe nucleus, $\mathbf{H} = \mathbf{H}_{appl} + \mathbf{H}_{int}$ where the internal field is given by Equation (5).

$$\mathbf{H}_{int} = -\frac{\langle \hat{\mathbf{S}}_i \rangle \tilde{\mathbf{A}}_i}{g_n \beta_n} \quad (5)$$

For the given zero-field splitting values $D$, $E/D$, the easy axis of magnetization is $y$ for the ground non-Kramers doublet, and the magnetically perturbed Mössbauer spectra at liquid helium temperature are sensitive only on $\langle \hat{S}_{yi} \rangle$. Therefore, as far as the hyperfine tensor of the ferrous ions is concerned, only the $A_{yi}$ components may be estimated. The spectra recorded at different magnetic fields can be reasonably reproduced with a common set of parameters (Figure 3) with $A_{y1}$ = –6.2 MHz and $A_{y2}$ = –10.2 MHz. With this model, the characteristic feature at –4.5 mm s$^{-1}$ observed in the low-field spectra belongs to the spectrum from site 2.

It is inferred that the magnetically perturbed spectra are consistent with the dual-mode X-band EPR results. For non-Kramers systems, saturation of the internal magnetic field, $\mathbf{H}_{int}$, requires the application of an external magnetic field, $\mathbf{H}_{ext}$, the value of which depends on $\Delta_0$ (Figure 6). For $\Delta_0 = 0$, a very small magnetic field suffices to saturate $H_{int}$. In that case, a characteristic magnetic Mössbauer spectrum is observed. In the present case, a magnetic spectrum is already observed in the absence of external magnetic fields. We assume that this spectrum arises from a fraction of molecules for which $\Delta_0$ is vanishingly small. Application of a moderate magnetic field (0.55 T) induces an intensity increase in the ca. –4.5 mm s$^{-1}$ peak. We suggest that this increase arises from molecules that require an external magnetic field to induce saturation of $\mathbf{H}_{int}$ and therefore for these molecules $\Delta_0 \neq 0$.

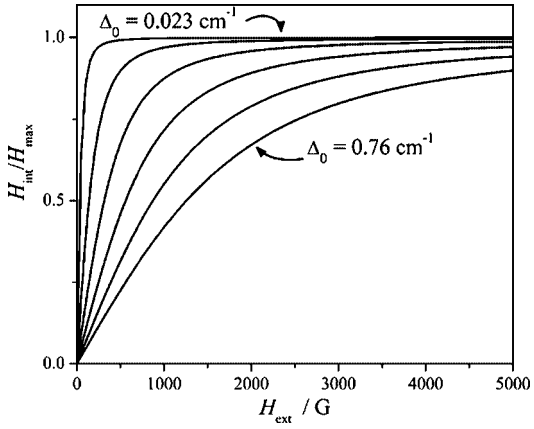

Figure 6. Dependence of the $H_{int}/H_{sat}$ ratio on the externally applied magnetic field along the easy axis ($H_{ext}$) for a non-Kramers doublet with various $\Delta_0$ values (0.023, 0.090, 0.200, 0.352, 0.540 and 0.760 cm$^{-1}$).

## Discussion and Conclusions

In the present work we study the dynamic magnetic behaviour of differous compound **1** by applying AC susceptibility measurements and dual mode X-band EPR and Mössbauer spectroscopic techniques. The incentive for this study stems from the bulk DC magnetic measurements which revealed ferromagnetic interactions between the two ferrous ions leading to a ground state with a relatively large nominal spin.[13] AC susceptibility measurements presented herein indicate slow relaxation effects at liquid helium temperatures.

The combined results from the present studies offer an explanation for the relaxation behaviour of **1**. We suggest that the molecules are characterized by inhomogeneities which eventually affect the splitting of the non-Kramers ground doublet. For a fraction of molecules, $\Delta_0$ is negligible (ideally 0), which gives rise to the magnetically split Mössbauer spectrum at zero-field. Because the quantum tunnelling rate is proportional to $\Delta_0$, these molecules are expected to have slow relaxation properties and cause an out-of-phase AC signal. On the contrary, a fraction of the molecules appears to be characterized by significant $\Delta_0$ as deduced by the dual mode X-band EPR measurements. For these molecules, quantum tunnelling is expected to be favoured, which results in fast relaxation. We should stress that as a result of the molecular nature of **1**, these inhomogeneities must be at the molecular level, that is, not discernible by X-ray crystallography.

In assessing the origin of the slow magnetic relaxation in **1**, one might readily argue that the relatively high effective spin of the ground state in combination with a high uniaxial magnetic anisotropy established by spectroscopic techniques leads to an SMM behaviour. However, we explored the possibility that slow relaxation might stem from an SCM behaviour due to weak intermolecular interactions.[26] The packing diagram of **1** (Figure S1) revealed weak π–π interactions between pyridyl rings of the ligand in adjacent molecules (2 – $x$, 1 – $y$, 1 – $z$), but not the presence of 1D chains.[27] This finding excludes to possibly attribute the observed slow relaxation to single-chain magnetism; thus, the slow relaxation must be related to superparamagnetism. From this point of view, **1** can be viewed as a rare example of an iron(II) single-molecule magnet, with the only other examples being three {$Fe_4$} cubanes prepared by Oshio et al.[28] and the enneanuclear complex [$Fe_9(O_2CMe)_8\{(py)_2CO_2\}_4(N_3)_2$].[29] Further originality of this compound stems from the fact that the two $Fe^{II}$ centres have different ligand field symmetries.

In the literature, several examples of diferrous complexes exhibiting ferromagnetic interactions yielding a magnetic ground state exist. To the best of our knowledge, **1** is the first for which the spin dynamics has been monitored directly by AC susceptibility and slow relaxation was observed. It would be interesting to explore the possibility of slow magnetic relaxation in other similar diferrous complexes as well. A majority of these complexes, apart from DC susceptibility measurements, were studied by spectro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

scopic techniques, which give additional information regarding the nature of the ground state. We showed here that Mössbauer spectroscopy is a useful technique, which can probe whether the ground state satisfies the conditions for slow relaxation. We suggest that observation of a magnetically split spectrum in the absence of applied magnetic field (not arising from long-range magnetic ordering) indicates that these complexes may be suitable SMM candidates. On the contrary, quadrupole-split doublets are related either to singlets, fast relaxation ($<10^{-7}$ s), or non-Kramers doublets with relatively large zero-field splitting, $\Delta_0$. For the cases found in the literature, quadrupole-split doublets have been observed at liquid helium temperatures: these complexes are thus unlikely candidates for slow magnetic relaxation.

The above discussion may be extended to ferrous complexes of higher nuclearity. We have recently observed single-molecule magnet behaviour for enneanuclear ferrous compounds.[29] In these cases, magnetically split Mössbauer spectra are observed in the absence of an applied magnetic field as a result of slow paramagnetic relaxation in the temperature range 4.2–10 K. At present, we are not aware of relevant studies for the cubanes reported by Oshio et al.[28]

In the present work we report the first example of a diferrous single-molecule magnet and a rare example of ferrous SMM. In addition, we probe the relaxation mechanism through various techniques and show that owing to molecular-level inhomogeneities, slow relaxation requirements are fulfilled for a fraction of the molecules only. This realization is particularly important for molecular species, which are generally considered as "monodisperse". Although it is reasonable to assume that this situation may occur in other SMMs as well, its verification in the present system was possible mainly due to the probing of its ground state and relaxation mechanism through techniques like AC susceptibility and Mössbauer and dual-mode X-band EPR spectroscopy.

## Experimental Section

Complex **1** was synthesized as described previously.[13] Mössbauer measurements were recorded with a constant-acceleration conventional spectrometer with a 50 mCi source of $^{57}$Co (Rh matrix). The absorber was a powdered sample enclosed in a 20-mm diameter cylindrical plastic sample holder, the size of which was determined to optimize the absorption. To avoid oxidation of the sample, the sample holder was sealed with Araldite and stored in liquid nitrogen. Variable-temperature spectra were obtained in the 4.2–300 K range, by using Oxford cryostats, operating at 4.2–300 K. One cryostat was equipped with a superconducting magnet that allowed application of external magnetic fields up to 5.0 T perpendicular to the $\gamma$-rays. Isomer shift values ($\delta$) are relative to iron foil at 293 K. The magnetically perturbed spectra were analyzed with the WMOSS software package (WEB Research, Edina, MN). Variable-temperature (2.0–5.0 K) AC magnetic susceptibility data were collected from a powdered microcrystalline sample with a Quantum Design MPMS SQUID susceptometer. The sample was moulded into a pellet inside the glove box to avoid orientation in the magnetic field. Data were corrected with the standard procedure for the contribution of the sample holder and diamagnetism of the sample. X-band EPR measurements were carried out with a Bruker ER-200D spectrometer equipped with a Bruker Dual Mode cavity, an Anritsu frequency counter, an NMR Gaussmeter and an Oxford ESR-9 cryostat. EPR tubes were flame-sealed under vacuum to avoid air-oxidation of the sample. ***Caution:*** *Molten quartz generates large amounts of harmful UV radiation, thus proper eye-protection should be worn.* Simulations of the spectra were carried out with SpinCount software kindly provided to us by Prof. M. Hendrich, Dept. of Chemistry, Carnegie Mellon University, Pittsburgh, PA, USA.

[27] In the original paper it was inadvertently noted that **1** forms pairs of 1D chains through π–π interactions in the crystal lattice. This was not detrimental to the discussion of its magnetic properties to that particular direction, but for the purposes of the present work a more careful structural analysis was carried out. This revealed that **1** actually forms pairs of molecules through π–π stacking.

# A 1,10-Phenanthroline-Containing Ring Connected to a Porphyrin by a Rigid Aromatic Spacer and Its Copper-Complexed Pseudorotaxane

**Julien Frey,[a] William Dobbs,[a] Valérie Heitz,*[a] and Jean-Pierre Sauvage*[a]**

**Keywords:** Ligand design / Porphyrinoids / Macrocycles / Template synthesis / Rotaxane

A condensation reaction involving a free base tetraarylporphyrin-2,3-dione, a macrocyclic compound containing a 1,10-phenanthroline-5,6-dione and a 1,2,4,5-tetraminobenzene as a linker affords the corresponding conjugate in good yield. The porphyrin ring and the phenanthroline fragment of the other ring are connected in such a way that mutual rotation between these two groups is prohibited. Metallation of the porphyrinic site affords the corresponding zinc complex. By reacting this zinc porphyrin with copper(I), followed by the addition of the bidentate chelate 2,9-bis(*p*-anisyl)-1,10-phenanthroline, the threading reaction leading to the corresponding pseudorotaxane takes place quantitatively.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

Porphyrins have been incorporated in rotaxanes and catenanes as electro- and photoactive components, mostly in relation to models of the photosynthetic reaction centre, to host–guest chemistry or to dynamic systems able to undergo large amplitude motions.[1] Our group has been particularly interested in energy and electron transfer studies within such rotaxanes or catenanes.[2] The porphyrin nucleus can be used as a stopper (for rotaxanes), either attached to or part of the ring.[3] Till now, limited geometrical control could be achieved as the mutual orientation between the porphyrin and the ring was not controlled, especially when the porphyrin fragment was appended to the cyclic component(s) of the rotaxane or the catenane. To have strict geometrical control over the system, it is necessary to connect the porphyrin and the ring by a rigid spacer, for which free rotation is not allowed. In the present report, we would like to describe the synthesis of such a conjugate consisting of a 30-membered ring built from 2,9-diaryl-1,10-phenanthroline and a free-base porphyrin or a zinc-complexed porphyrin. The spacer between these two components is a rigid aromatic nucleus. In addition, to demonstrate that the rigidly held porphyrin-macrocycle conjugates prepared can be used as components of interlocking structure, we have assembled a pseudorotaxane using the copper(I)-based strategy already applied in other related reactions.[2,3] The threaded species obtained by mixing the Zn-containing porphyrin-ring conjugate, copper(I) and a coordinating fragment of the 1,10-phenanthroline family, is indeed obtained in quantitative yield.

The synthetic strategy relies on porphyrin α-dione **1** similar to that used by Crossley and coworkers for making di- and multiporphyrins as well as electrodeficient porphyrins with quinoxaline groups at their periphery.[4] The other important fragment, namely the macrocycle containing phenanthroline dione **2**, was prepared in our group in the frame of another project dealing with multirotaxanes.[5] Phenanthroline–porphyrin conjugates with back-to-back connection were described recently by other groups but in these examples, the 1,10-phenanthroline part was not contained within the macrocycle.[6]

Starting diones **1** and **2**, as well as the condensation reaction leading to porphyrin conjugates **4** and **5**, are represented in Figure 1.

The synthesis of porphyrin α-dione **1** proceeds from the copper(II) complex of *meso*-tetra(3′,5′-di-*tert*-butylphenyl)-porphyrin, which was first reacted with $LiNO_3$ in AcOH/$Ac_2O$ to afford the corresponding β-nitro copper(II) porphyrin in high yield (90%) as described by Callot.[7] Then, adapted from Burn's methodology,[8] this porphyrin was demetallated with $H_2SO_4$ and the $NO_2$ function was reduced to an $NH_2$ group by $SnCl_2$ and HCl in $CH_2Cl_2$. The subsequent oxidation reaction leading to **1** was carried out by using Dess–Martin periodinane. The analytical and spectroscopic properties of the compound obtained are similar to those of the literature.[8] Compound **1** was obtained from the starting copper(II) porphyrin in four steps (nitration, demetallation, reduction and oxidation) with an overall yield of approximately 40%.

The coupling reaction between **1** and **2**[5] was performed by a stepwise condensation using 1,2,4,5-benzenetetramine.[6] Porphyrin α-dione **1** and benzenetetramine tetrahydrochloride **3** (1.2 equiv.) were dissolved in freshly distilled pyridine, and the reaction mixture was kept in the

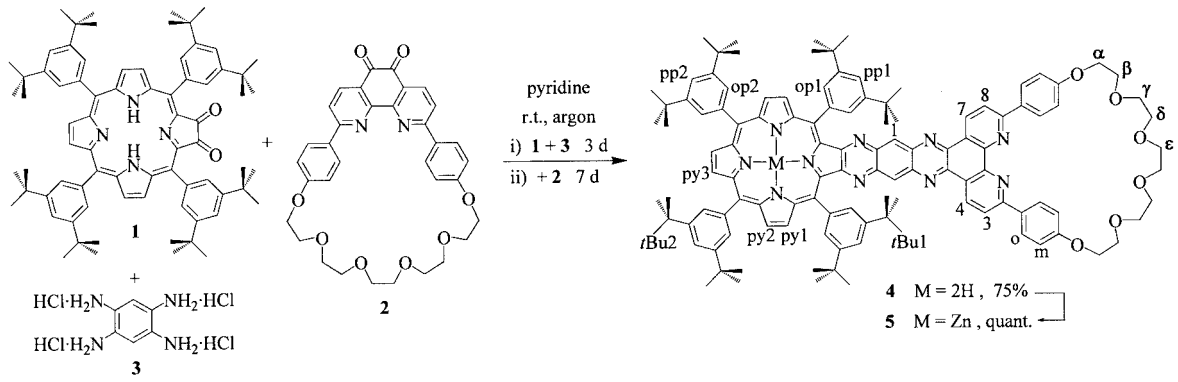

Figure 1. Stepwise condensation of the two diones with the bridging spacer.

dark. After gentle stirring at room temperature under an atmosphere of argon for 3 d, macrocycle **2** (1.5 equiv.) was added, and the reaction was prolonged under the same reaction conditions for an additional week. After workup and chromatographic purification (silica gel, $CH_2Cl_2$ with increasing amounts of $CH_3OH$ – up to 0.3% – as eluent), **4** was obtained as a violet solid in 75% yield. It was fully characterised by $^1H$ NMR spectroscopy and high resolution (HR) ESMS.

Metallation of the porphyrinic site of **4** was selectively carried out by the addition of $Zn(OAc)_2$ (5 equiv., dissolved in $CH_3OH$) to a solution of **4** in $CH_2Cl_2$ heated at reflux.[6] Further treatment with an EDTA solution to remove $Zn^{II}$ from the phenanthroline chelate allowed **5** to be obtained quantitatively from **4**.

The $^1H$ NMR spectra are in accordance with the structures of the compounds (Figure 2). As expected from the formation of the bridge at the back of the phenanthroline, protons 1 and 4,7 are strongly shifted upfield. Owing to the $C_{2v}$ symmetry of the molecule, protons *t*Bu1 differ from protons *t*Bu2, which gives rise to two sets of signals. For the same reason, proton py3 is assigned to a characteristic singlet at $\delta$ = 8.76 ppm.

Compounds **4** and **5** are well adapted to the synthesis of more elaborate catenanes and rotaxanes. As an example, pseudorotaxane **7**·$PF_6$ was prepared quantitatively from the various corresponding organic fragments, **5** and **6**, in the presence of copper(I), acting as a gathering and threading centre. As represented in Figure 3, **6** is a 2,9-disubstituted 1,10-phenanthroline that is able to form very stable four-coordinate complexes with copper(I) once associated to another bidentate chelate of the 1,10-phenanthroline family. As expected, the reaction proceeded very cleanly: stoichiometric amounts of **5** and $[Cu(CH_3CN)_4](PF_6)$ were first mixed in dichloromethane to afford the desired copper(I) complex. Subsequently, a stoichiometric quantity of **6** was added, which led to desired pseudorotaxane **7** quantitatively after workup. Compound **7**·$PF_6$ is a deep purple solid, which was characterised by $^1H$ NMR (COSY-ROESY) and electronic spectroscopy and HRESMS.

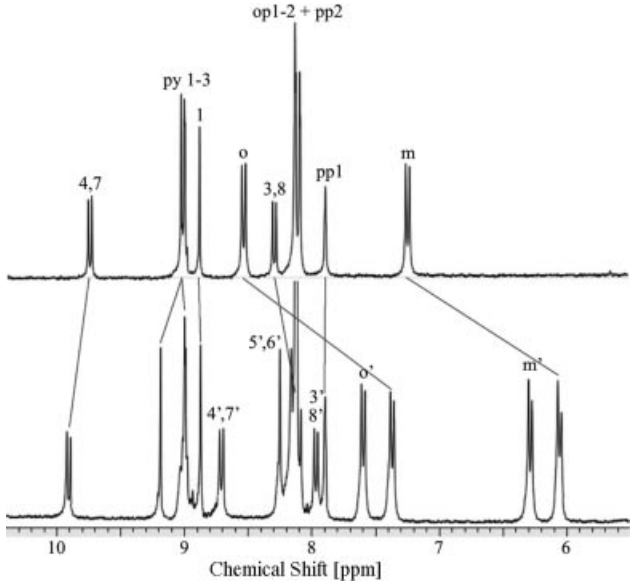

Figure 2. $^1H$ NMR spectra (aromatic region) of compounds **5** and **7**·$PF_6$ in $CD_2Cl_2$.

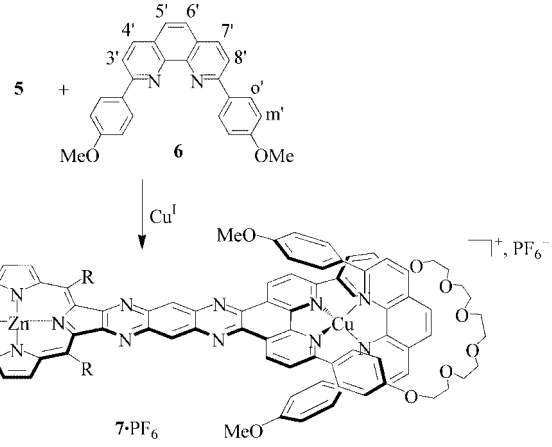

Figure 3. The threading reaction affording pseudorotaxane **7**.

To estimate the electronic coupling between the various aromatic fragments of **5** and **7** (the 1,10-phenanthroline chelate and the zinc-containing porphyrin), electronic absorption and emission measurements were performed. The absorption and emission spectra of the two compounds are represented in Figure 4.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

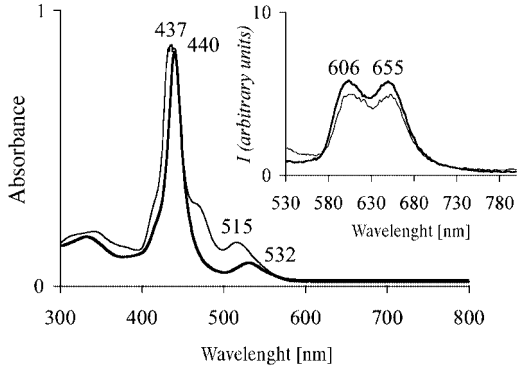

Figure 4. Normalised absorption and emission spectra (inset) of an optically matched solution of **5** (thin) and **7**·$PF_6$ (bold) (excitation at 438 nm) at 298 K in dichloromethane.

Interestingly, the Soret band for the two porphyrin-containing compounds is bathochromically shifted relative to that of the classical tetraaryl porphyrins.[9] Whereas a normal Soret band is typically observed around 420 nm for Zn porphyrins of this series, the present compounds show a Soret band in the range 435–440 nm. In addition, significant broadening is observed, which is a clear indication that the aromatic system is perturbed by the presence of the tetraazaanthracene nucleus at the periphery of the porphyrin, as already observed by Flamigni and coworkers.[10] The observed broadening is likely to be due to the loss of symmetry of the porphyrin aromatic system by introducing a tetraazaanthracene fragment at its rim. A contribution of a hypothetical 1,10-phenanthroline-porphyrin electronic coupling cannot be excluded.

Whereas the absorption spectra of **5** and **7** are significantly different from that of a normal zinc(II) tetraarylporphyrin, their emission spectra have emission maxima at similar values (**5** and **7**; $\lambda$ = 606, 655 nm). The tetraazaanthracene phenanthroline aromatic fragment at the back of the porphyrin has therefore little influence on the energy level of the lowest excited state of the porphyrin ring. This is quite surprising considering that in related tetraazaanthracene-substituted porphyrins studied by Flamigni and coworkers,[10] the excited state was stabilised by 0.2 eV. Nevertheless, in **5** and **7**, the emission intensity decreases dramatically and the quantum yield of the emission relative to that of zinc(II) 5,10,15,20-tetrakis(3,5-di-*tert*-butylphenyl)porphyrin is only 0.3%. Further photophysical studies will be performed to understand these results.

In conclusion, a new conjugate consisting of a porphyrin and a coordinating ring was prepared in a few steps from sophisticated organic fragments, with a relatively good overall yield. The zinc-complexed porphyrinic system was further utilised to prepare a novel pseudorotaxane by taking advantage of the template effect of copper(I). The conjugate itself, either containing a free base or a zinc porphyrin, is rigid, which allows strict control over the geometry of the system and over that of the pseudorotaxane prepared. The same will hold true for future, more complex rotaxanes and catenanes containing **4** and **5**.

## Experimental Section

**General:** Nuclear Magnetic Resonance (NMR) spectra were acquired with a Bruker AM300 spectrometer operating at 300.17 MHz. The spectra were referenced internally to residual proton-solvent reference. High resolution electrospray mass spectra (HRESMS) were recorded with a VG BOIQ triple quadrupole spectrometer by the Service de Spectrométrie de Masse (ISIS, Strasbourg). All anhydrous solvents were prepared by distillation under an atmosphere of argon with the use of the appropriate drying agents. All commercial chemicals were at the best commercially available grade and used without further purification. Thin layer chromatography was carried out with precoated polymeric sheets of silica gel (Macheray-Nagel, POLYGRAM, SIL G/$UV_{254}$) and preparative column chromatography was carried out by using silica gel (Merck Kiesegel, silica gel 60, 0.063–0.200 mm).

**Compound 4:** Avoiding light exposure, porphyrin tetraone **1** (50 mg, $4.58 \times 10^{-5}$ mol) and benzene tetramine tetrahydrochloride **3** (15.7 mg, $5.53 \times 10^{-5}$ mol, 1.2 equiv.) were dissolved in freshly distilled pyridine (25 mL), and the mixture was stirred at room temperature under an atmosphere of argon. After 2 d, macrocyclic dione **2** (41 mg, $6.87 \times 10^{-5}$ mol, 1.5 equiv.) was added under a stream of argon, and the solution was reacted for another week under the same conditions. After removal of the solvent, the product was extracted with $CH_2Cl_2$ (50 mL) and water (50 mL). The organic layers were separated, washed with water ($2 \times 50$ mL) and the solvents evaporated to dryness. The crude product (154 mg) was subjected to column chromatography (110 g of silica, prepared in $CH_2Cl_2$, gradient elution from $CH_2Cl_2$/MeOH 0 to 0.3%) to give compound **4** as a purple solid (60 mg, 75%). $^1$H NMR (300 MHz, $CD_2Cl_2$, COSY-ROESY, 25 °C): $\delta$ = 9.75 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, $H_{4,7}$), 9.10 (d, $^3J_{H,H}$ = 4.9 Hz, 2 H, $H_{py1}$), 9.03 (d, $^3J_{H,H}$ = 4.9 Hz, 2 H, $H_{py2}$), 8.95 (s, 2 H, $H_{py3}$), 8.76 (s, 2 H, $H_1$), 8.56 (m, $^3J_{H,H}$ = 8.8 Hz, 4 H, $H_o$), 8.31 (d, $^3J_{H,H}$ = 8.5 Hz, 2 H, $H_{3,8}$), 8.12–8.05 (m, 10 H, $H_{op1}$, $H_{op2}$, $H_{pp2}$), 7.86 (t, $^4J_{H,H}$ = 1.8 Hz, 2 H, $H_{pp1}$), 7.28 (m, $^3J_{H,H}$ = 8.9 Hz, 4 H, $H_m$), 4.39 (t, $^3J_{H,H}$ = 5.9 Hz, 4 H, $H_\alpha$), 3.88 (t, $^3J_{H,H}$ = 5.9 Hz, 4 H, $H_\beta$), 3.76–3.64 (m, 12 H, $H_\gamma$, $H_\delta$, $H_\varepsilon$), 1.57 (s, 36 H, $H_{tBu2}$), 1.54 (s, 36 H, $H_{tBu1}$), –2.35 (br. s, 2 H, $H_{NH}$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ (log$\varepsilon$) = 434 (5.54) nm. HRESMS: calcd. for $C_{166}H_{127}N_{10}O_6$ and for 1/2[$C_{166}H_{127}N_{10}O_6$]$_2$ [**4** + H]$^+$ and [**4** + H]$_2^{2+}$ 1756.9967; found 1757.0025.

**Compound 5:** A solution of $Zn(OAc)_2$ (34 mg, $1.55 \times 10^{-4}$ mol, ca. 5 equiv.) in MeOH (7 mL) was added to a boiling solution of compound **4** (50 mg, $2.85 \times 10^{-5}$ mol) in $CH_2Cl_2$ (25 mL), and the mixture was heated at reflux for 6 h. After removal of the solvents, the product was extracted with $CH_2Cl_2$ (50 mL) and water ($2 \times 50$ mL). The organic layers were separated, and the volume of the solution was reduced to approximately 30 mL. A solution of [EDTA]$Na_4$ (0.1 M, pH ca. 4–5, 10 mL) was added, and the mixture was stirred for 24 h. The organic layers were then extracted with $CH_2Cl_2$ (80 mL), separated, washed with saturated $Na_2CO_3$ (50 mL), brine (50 mL) and water (100 mL) and the solvents evaporated to dryness to give quantitatively compound **5** (51 mg). $^1$H NMR (300 MHz, $CD_2Cl_2$, COSY-ROESY, 25 °C): $\delta$ = 9.69 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, $H_{4,7}$), 8.98 (s, 2 H, $H_{py3}$), 8.97–8.94 (2d, $^3J_{H,H}$ = 4.8 Hz, 4 H, $H_{py1}$, $H_{py2}$), 8.85 (s, 2 H, $H_1$), 8.48 (m, $^3J_{H,H}$ = 8.8 Hz, 4 H, $H_o$), 8.24 (d, $^3J_{H,H}$ = 8.5 Hz, 2 H, $H_{3,8}$), 8.11–8.04 (m, 10 H, $H_{op1}$, $H_{op2}$, $H_{pp2}$), 7.85 (t, $^4J_{H,H}$ = 1.8 Hz, 2 H, $H_{pp1}$), 7.18 (m, $^3J_{H,H}$ = 8.8 Hz, 4 H, $H_m$), 4.26 (t, $^3J_{H,H}$ = 5.9 Hz, 4 H, $H_\alpha$), 3.73 (t, $^3J_{H,H}$ = 5.9 Hz, 4 H, $H_\beta$), 3.62–3.51 (m, 12 H, $H_\gamma$, $H_\delta$, $H_\varepsilon$), 1.57 (s, 36 H, $H_{tBu2}$), 1.55 (s, 36 H, $H_{tBu1}$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ (log$\varepsilon$) = 437 (5.47), 515 (4.66) nm. HRESMS: calcd. for $C_{116}H_{124}N_{10}O_6Zn$ [**5** – e]$^+$

1818.9017; found 1818.8987 and calcd. for $C_{116}H_{125}N_{10}O_6Zn$ [**5** + H]$^+$ 1819.9095; found 1819.9013.

**Compound 7·PF$_6$:** A solution of $[Cu(MeCN)_4](PF_6)$ (3.6 mg, $9.34 \times 10^{-6}$ mol) in MeCN (5 mL) was added by cannula to a degassed solution of **4** (17.0 mg, $9.34 \times 10^{-6}$ mol) in $CH_2Cl_2$ (5 mL), and the mixture was stirred under an atmosphere of argon for 30 min. A degassed solution of dianisyl phenanthroline **6** (3.67 mg, $9.34 \times 10^{-6}$ mol) in $CH_2Cl_2$ (5 mL) was then also added by cannula. After stirring for 2 h, the solution was extracted with $CH_2Cl_2$ (50 mL) and water (50 mL); the organic layers were separated, dried with $MgSO_4$ and evaporated to give pure rotaxane **7** as its $PF_6$ salt (22 mg, 97%). $^1$H NMR (300 MHz, $CD_2Cl_2$, COSY-ROESY, 25 °C): $\delta$ = 9.88 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, $H_{4,7}$), 9.16 (s, 2 H, $H_{py3}$), 8.97–8.98 (2d, $^3J_{H,H}$ = 4.6 Hz, 4 H, $H_{py1}$, $H_{py2}$), 8.86 (s, 2 H, $H_1$), 8.68 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, $H_{4',7'}$), 8.22 (s, 2 H, $H_{5',6'}$), 8.13 (t, $^4J_{H,H}$ = 1.8 Hz, 2 H, $H_{pp2}$), 8.13 (t, $^4J_{H,H}$ = 1.7 Hz, 2 H, $H_{pp1}$), 8.06 (m, 10 H, $H_{3,8}$, $H_{op1}$, $H_{op2}$), 7.94 (d, $^3J_{H,H}$ = 8.4 Hz, 2 H, $H_{3',8'}$), 7.87 (t, $^4J_{H,H}$ = 1.7 Hz, 2 H, $H_{pp1}$), 7.57 (m, $^3J_{H,H}$ = 8.6 Hz, 4 H, $H_{o'}$), 7.35 (m, $^3J_{H,H}$ = 8.6 Hz, 4 H, $H_o$), 6.27 (m, $^3J_{H,H}$ = 8.6 Hz, 4 H, $H_{m'}$), 6.04 (m, $^3J_{H,H}$ = 8.6 Hz, 4 H, $H_m$), 3.85 (s, 4 H, $H_\varepsilon$), 3.79–3.55 (3m, 16 H, $H_\delta$, $H_\gamma$, $H_\beta$, $H_\alpha$), 3.26 (s, 6 H, $H_{OMe}$), 1.60 (s, 36 H, $H_{tBu2}$), 1.55 (s, 36 H, $H_{tBu1}$) ppm. UV/Vis ($CH_2Cl_2$): $\lambda$ (log$\varepsilon$) = 440 (5.55), 532 (4.55) nm. HRESMS: calcd. for $C_{142}H_{144}N_{12}O_8CuZn$ 2274.9843; found 2274.9647.

# Pirouetting Copper(I)-Assembled Pseudo-Rotaxanes: Strong Influence of the Axle Structure on the Motion Rate

**Jean-Paul Collin,[a] Fabien Durola,[a] Pierre Mobian,[a] and Jean-Pierre Sauvage*[a]**

**Keywords:** Pseudo-rotaxanes / Diimine ligands / Copper complexes / Coordination modes / Pirouetting motion

Based on the gathering and threading effect of copper(I), three different pseudo-rotaxanes have been prepared and characterised in solution. They consist of the same two-chelate ring and various coordinating fragments threaded through the ring. The ring-incorporated chelates are a 2,2′,6′,6′′-terpyridine (terpy) unit and a 2,9-diphenyl-1,10-phenanthroline (dpp) motif. The threaded chelates are a 2,9-bis(*p*-anisyl)-1,10-phenanthroline (dap), a 6,6′-bis(*p*-anisyl)-2,2′-bipyridine (dabipy) or a 8,8′-diphenyl-3,3′-biisoquinoline (dpbiiq) derivative. Using electrochemical techniques, the pirouetting motions of the axle within the ring through which it is threaded have been investigated. In dichloromethane/acetonitrile, a strong dependence of the motion rate on the structure of the threaded chelate has been observed, evidencing that rigidity of the thread-contained chelate and steric hindrance lead to slow moving molecular machines. Pirouetting is the main dynamic process observed but unthreading of the string-like organic component represents another minor electrochemically induced reaction.

## Introduction

The field of synthetic molecular machines and motors is receiving much attention,[1] either in relation to catenanes and rotaxanes[2] or based on non-interlocking molecules.[3] In this former family of compounds, transition metal-containing systems have been much investigated.[4] As far as interlocking molecular assemblies are concerned, transition metals play an equally important role. Our group has proposed several types of dynamic systems, the mobile components of the machine being set in motion either by an electrochemical signal,[5] a photochemical stimulus[6] or a chemical reaction.[7] Copper-containing pirouetting rotaxanes represent an interesting subclass of such dynamic systems. They can be regarded as simple models of future rotary motors, whose elaboration seems today to be highly complex when interlocking compounds are used.[8] They can also be of interest by themselves as bistable species whose states display very different geometrical properties.

In this article we would like to report on the synthesis and the dynamic properties of three copper-complexed pseudo-rotaxanes whose motions are triggered by a redox process ($Cu^{II}/Cu^{I}$). By comparing the electrochemical behaviour of these three compounds, important information on the influence of the structural parameters on the motion rate could be obtained. As far as we are aware, limited studies have been carried out on the controlled dynamic properties of pseudo-rotaxanes. The first one is particularly significant since it triggered the interest of the scientific community for interlocking compounds-based molecular machines.[9] Later on, our group has made and investigated a shuttle-like pseudo-rotaxane[10] and its corresponding rotaxane.[11] Although shuttling of the pseudo-rotaxane was clearly evidenced, we could also identify another process, the unthreading reaction, which interfered with the ring translation motion. Obviously, the rates of both processes must be related since some of the rearrangement steps for these distinct reactions are identical.

## Results and Discussions

The pirouetting rearrangement described herein is sketched in Scheme 1. The three threaded species have been prepared according to the classical procedure from our group, based on coordination of two bidentate chelates on a copper(I) centre.[12] Obviously, the cyclic nature of **4** prevents formation of tetrahedral copper(I) complexes consisting of two such dpp-containing ligands. This simple principle has important consequences since the coordination reaction will necessarily lead to the formation of a threaded species provided the correct copper(I)-two-bidentate ligand stoichiometry is respected.[13] The copper(I)-induced gathering and threading reaction is represented in Figure 1 along with the chemical formulae of the various precursors and the products.

Compound **4** is a 33-membered ring that has been used in several studies carried out in our group on controlled dynamic catenanes and rotaxanes. The presence of the terpy

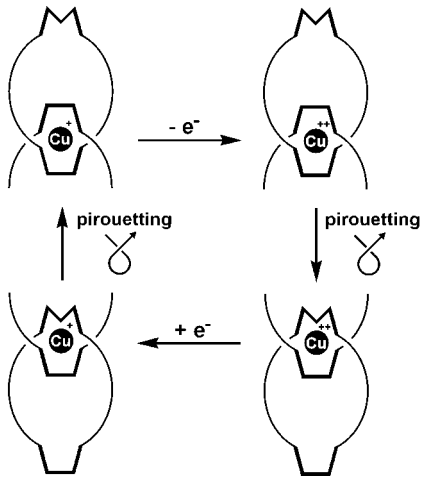

Scheme 1. Pirouetting principle of copper complexed pseudo-rotaxanes. The U-shaped symbols represent bidentate chelates (dpp for the ring-comprised chelate and dap, dabipy or dpbiiq for the chelates belonging to the thread). The M-shaped symbol designates the tridentate terpy coordinating motif.

site in its structure does not interfere with the threading reaction since copper(I) interacts preferably with bidentate chelates such as dpp. This behaviour has been unambiguously demonstrated by $^1$H-NMR analysis of the concerned pseudo-rotaxanes. The three string-like fragments contain markedly different chelates. **5** incorporates a dpp unit. It is thus a highly rigid block due to the presence of the 1,10-phenanthroline core. At the same time it is rather bulky due to the two phenyl groups close to the coordination site of the ligand. **6** is equally sterically hindering but the pyridine nuclei of the 2,2′-bipy fragment can easily rotate with respect to one another about the $C^2$–$C^{2'}$ bond. Finally, the dpbiiq fragment of **7** is such that steric hindrance around the complexing site of the ligand is limited, due to the large separation between the two lateral phenyl rings borne by the 3,3′-biisoquinoline nucleus. In addition, free rotation about the $C^3$–$C^{3'}$ bond allows this ligand to rearrange easily. Ligand **7** could be obtained in high yield via a two-step procedure as depicted in Figure 2. The first step concerns the formation of diphenol compound **9** from 8,8′-dianisyl-3,3′-biisoquinoline (**8**) using a classical ether deprotection method. The resulting diphenol **9** was then converted into the target ligand **7** following a classical Williamson methodology ($Cs_2CO_3$, DMF, 55 °C) by reaction with 2 equiv. of commercially available 2-(6-bromohexyloxy)-tetrahydro-2*H*-pyran.

Three complexes $\mathbf{1}_4^+$, $\mathbf{2}_4^+$ and $\mathbf{3}_4^+$ were synthesized as shown in Figure 1. The synthesis of these copper complexes were performed using a methodology usually employed in our group. In a typical procedure, the macrocycle **4** was dissolved in a degassed solution of dichloromethane and

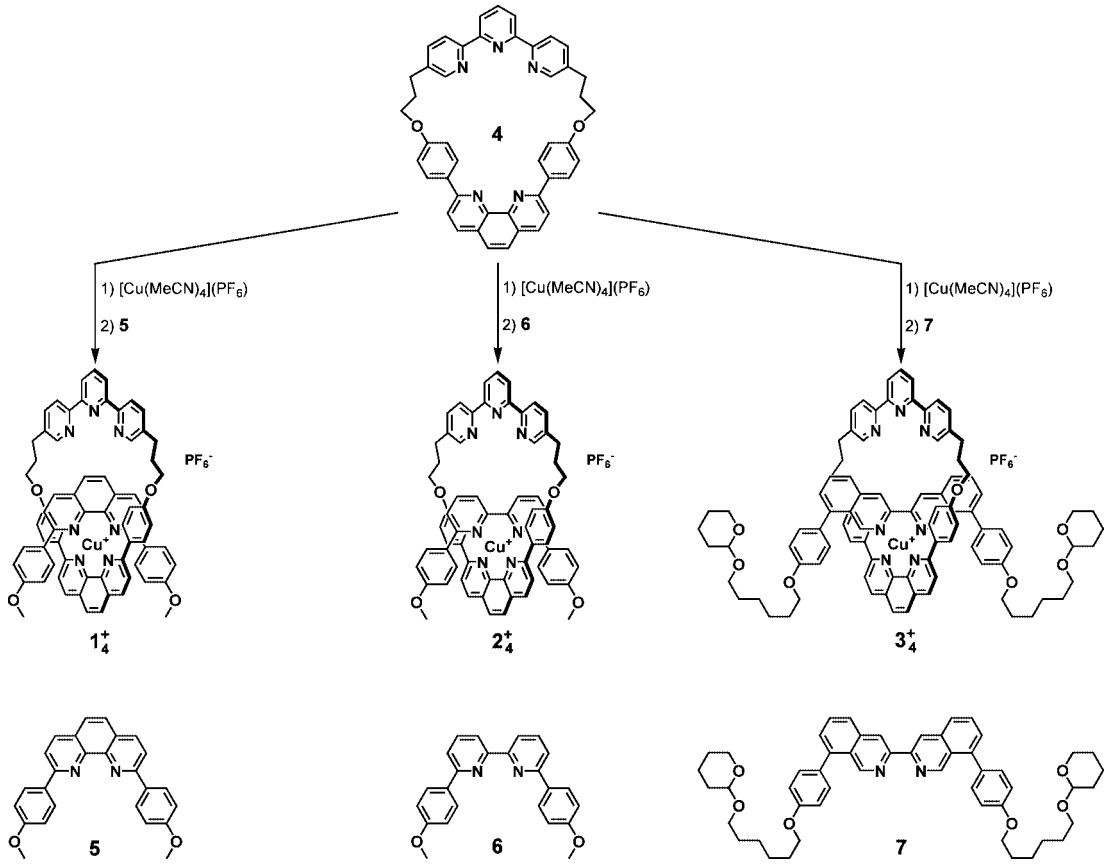

Figure 1. Copper(I)-directed synthesis of the three pseudo-rotaxanes $\mathbf{1}_4^+$, $\mathbf{2}_4^+$ and $\mathbf{3}_4^+$ described in this article. The subscript 4 refers to the coordination number of the copper centre. In the copper(I) complexes of the graphic, the coordination number is equal to 4 since the metal is coordinated to a dpp fragment and another bidentate chelate belonging to the thread.

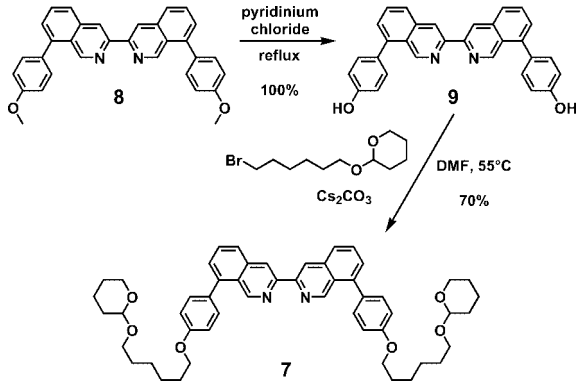

Figure 2. Preparation of ligand **7** from 8,8′-bis(*p*-anisyl)-3,3′-biisoquinoline (**8**). The demethylation reaction is quantitative. Compound **7** can be obtained in good yield from **9** after chromatographic separation.

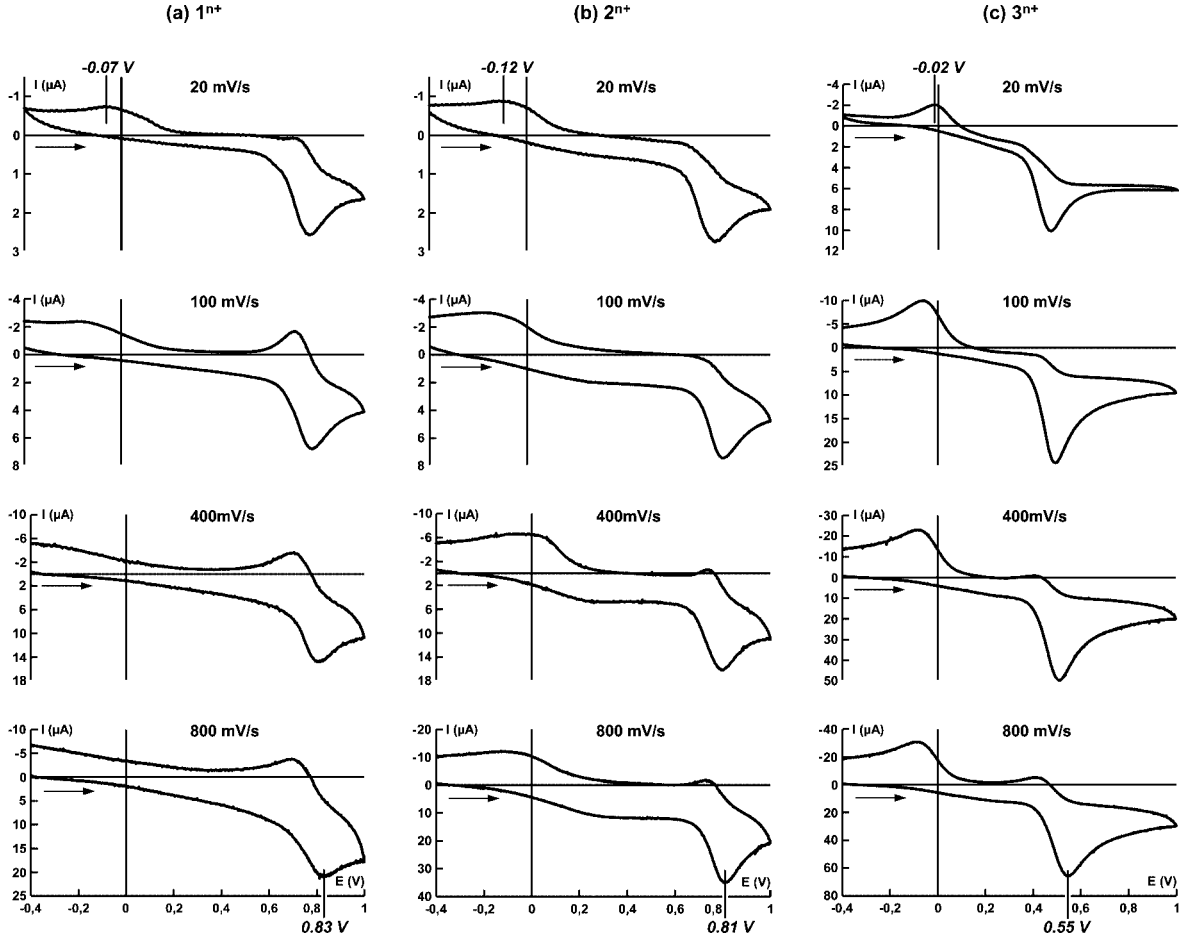
acetonitrile (1:1). Upon addition of the copper salt (1 equiv.), the solution turned immediately to dark orange. The reaction mixture was stirred for 20 min and the diimine ligand (respectively **5**, **6** and **7**) was then added. A dark red solution was instantaneously obtained. This color, which is characteristic of copper(I) complexes of aromatic diimine ligands, indicates that the complexation process occurred efficiently. After, the solution was stirred for two hours under argon at room temperature, and the solvents were evaporated. The complexation process occurred quasi-quantitavely as evidence by $^1$H-NMR spectroscopy. Due to their instability on chromatographic supports, complexes $\mathbf{1}_4^+$, $\mathbf{2}_4^+$ or $\mathbf{3}_4^+$ were not further purified and were directly submitted to the electrochemical measurements.

## Electrochemically-Driven Molecular Motions

The cyclic voltammograms of Scheme 2 have been obtained by scanning first from –0.4 V to +1.0 V, with a silver wire as a pseudo-reference electrode, the return scan being carried out immediately after the potential of +1.0 V was reached. The oxidation potential for the reaction

4-coordinate $Cu^I$ complex – $e^- \rightarrow$ 4-coordinate $Cu^{II}$ complex

is thus easily read from the cyclic voltammograms. Their values at a scan rate of 800 mV/s are indicated on the Scheme 2.



Scheme 2. Cyclic voltammograms of complexes $\mathbf{1}_4^+$, $\mathbf{2}_4^+$ and $\mathbf{3}_4^+$ recorded with a Pt working electrode in $CH_2Cl_2/CH_3CN$ (1:9) with 0.1 M $Bu_4NBF_4$ at four different scan rates (20, 100, 400 and 800 mV/s). The electrochemical responses of the four-coordinate copper(II) complexes are found around +0.7 V (for $\mathbf{1}^{2+}$ and $\mathbf{2}^{2+}$) or around +0.5 V (for $\mathbf{3}^{2+}$), whereas reduction of five-coordinate copper(II) complexes $\mathbf{1}_5^{2+}$, $\mathbf{2}_5^{2+}$ and $\mathbf{3}_5^{2+}$ occurs around –0.1 V.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

At a high scan rate, the return wave corresponding to the following process

4-coordinate $Cu^{II}$ complex + $e^- \rightarrow$ 4-coordinate $Cu^{I}$ complex

is easily observed, which allows to determine $E_{1/2}$ and $\Delta Ep$ for the three studied complexes:

$\mathbf{1}_4^{2+}/\mathbf{1}_4^{+}$: $E_{1/2}$ = +0.76 V

$\mathbf{2}_4^{2+}/\mathbf{2}_4^{+}$: $E_{1/2}$ = +0.77 V

$\mathbf{3}_4^{2+}/\mathbf{3}_4^{+}$: $E_{1/2}$ = +0.49 V

$\Delta Ep$ varies between 80 mV and 120 mV within the series of three complexes. At a lower scan rate, rearrangement of the thermodynamically unstable four-coordinate copper(II) takes place, at least in part, before this complex is reduced back to its monovalent corresponding state. This is clearly seen by the presence of a peak between –0.2 V and 0 V.

From the $E_{1/2}$ values of the four-coordinate complexes, it is clear that the four-coordinate copper(I) state is more stabilised in $\mathbf{1}_4^{+}$ and $\mathbf{2}_4^{+}$ than in complex $\mathbf{3}_4^{+}$. This can easily be understood by considering the steric arrangements of the compounds. Whereas $\mathbf{1}_4^{+}$ and $\mathbf{2}_4^{+}$ contain a highly shielding set of ligands (both chelates of each complex bear phenyl rings attached on the *ortho* positions to the N atoms), the thread of $\mathbf{3}_4^{+}$ is less encumbering.

As far as the five-coordinate copper(I) or copper(II) states are concerned, important information can be obtained at low scan rate. By analogy with the oxidation potentials of the four-coordinate copper(I) complexe, the reduction potentials of the corresponding five-coordinate copper(II) complexes can easily be estimated from the cyclic voltammograms. They are also indicated on Scheme 2, for a scan rate of 20 mV/s. It is noteworthy that the reduction potentials ($Cu^{II}/Cu^{I}$) for the three studied complexes are almost identical ($E_{red} \approx$ –0.07 V). This observation tends to indicate that, as expected, the five-coordinate state is less sensitive to steric hindrance than the tetrahedral or pseudo-tetrahedral geometry.

The chemical reversibility of the redox processes depends much on the nature of the complex and on the scan rate. As already observed with pirouetting rotaxanes,[5] as the scan rate is increased, the reversibility of the four-coordinate copper(I) complex oxidation reaction increases. By scanning at a lower and lower rate, rearrangement of the system becomes more and more noticeable, as evidenced by the increase of the wave corresponding to the reduction of the five-coordinate copper(II) complex. In parallel, the reduction wave for the four-coordinate complex decreases. Generally speaking, if this latter one is intense, this implies that the compound has no time to rearrange substantially. By contrast, if the reduction wave around +0.42 V (for $\mathbf{3}_4^{2+}$) is small, the complex undergoes a complete rearrangement to a large proportion.

If the scan rate is sufficently slow (< 20 mV/s), the three complexes have time to rearrange as shown by the absence of any reduction wave at +0.4 V to +0.8 V. On the other hand, the presence of a reduction wave at a slightly negative potential may indicate that a certain proportion of the four-coordinate copper(II) complex underwent a pirouetting motion, which does not exclude that a certain amount led to unthreading and dissociation.

By comparing $\mathbf{1}^{n+}$ and $\mathbf{2}^{n+}$, especially at 100 mV/s, it is obvious that $\mathbf{1}_4^{2+}$ is much less mobile than $\mathbf{2}_4^{2+}$. This is confirmed at 400 mV/s since at this scan rate, $\mathbf{1}_4^{2+}$ does not seem to rearrange significantly whereas the major part of $\mathbf{2}_4^{2+}$ is converted into the rearranged complex $\mathbf{2}_5^{2+}$. The difference between $\mathbf{1}^{n+}$ and $\mathbf{2}^{n+}$ holds to the presence of a 1,10-phenanthroline (phen) unit in the thread of the former complex and 2,2′-bipyridine (bipy) chelate for the latter complex. The comparison between their electrochemical properties allows to estimate the effect of having a rigid block (phen) vs. a potentially flexible chelate (bipy) with rotation around the C–C bond connecting the two pyridine nuclei. It should be noticed that both threads (in $\mathbf{1}^{n+}$ and $\mathbf{2}^{n+}$) are equally sterically hindering since they contain the same number of phenyl rings at identical positions.

Very spectacular is the effect of the biisoquinoline ligand, as demonstrated by the electrochemical behaviour of $\mathbf{3}^{n+}$. Even at 800 mV/s reversibility is almost completely lost, with the appearance of a relatively intense wave at ≈ –0.1 V corresponding to the reduction process of the rearranged complex $\mathbf{3}_5^{2+}$. This observation is directly related to the non sterically hindering nature of **7** which facilitates ligand exchange in the coordination sphere of the metal. The presence of two elongating groups attached on the phenolic oxygen atoms of **7** may also increase the chemical reversibility of the pirouetting process, inhibiting at least in part the unthreading reaction.

A rough estimation of the rate constant for the rearrangement of the four-coordinate copper(II) complex can be obtained from electrochemical measurements and, in particular, from Scheme 2:

$\mathbf{1}_4^{2+} \rightarrow \mathbf{1}_5^{2+}$, $k \approx 0.1\ s^{-1}$

$\mathbf{2}_4^{2+} \rightarrow \mathbf{2}_5^{2+}$, $k \approx 1\ s^{-1}$

$\mathbf{3}_4^{2+} \rightarrow \mathbf{3}_5^{2+}$, $k \approx 5\ s^{-1}$

Concerning the pirouetting motion, pseudo-rotaxane $\mathbf{3}^{n+}$, incorporating a dpbiiq fragment in its thread, is about 50 times more efficient than pseudo-rotaxane $\mathbf{1}^{n+}$, which threaded ligand (dap) is more rigid and more sterically hindering.

As far as the rearrangement of the five-coordinate copper(I) complexes is concerned, the reaction was shown to be too fast for the presently used electrochemical techniques. This is in good agreement with previous studies.[5]

## Conclusion

Three copper(I)-assembled pseudo-rotaxanes were synthesized. These molecular machine precursors contain the same two-chelate ring and three different diimine ligands threaded through the macrocycle. The rearrangement of these complexes from the four-coordinate $Cu^{II}$ to the five-coordinate $Cu^{II}$ species has been investigated by cyclic voltammetry. The electrochemical responses clearly show a great difference of dynamic behaviour between these three

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

prepared pseudo-rotaxanes. An estimation of the rate of ligand exchange was possible. These results highlight that the flexibility of the threaded chelate and low steric hindrance of its coordination site give rise to fast-moving molecular machines.

## Experimental Section

The following chemicals were obtained commercially and were used without further purification: 2-(6-bromohexyloxy)-tetrahydro-2*H*-pyran (Aldrich), cesium carbonate (Aldrich).

Dry solvents were obtained with suitable dessicants: *N*,*N*-dimethylformamide was distilled from anhydrous aluminum oxide, dichloromethane from calcium hydride. Fluka aluminum oxide (no. 17994) was used for alumina columns and filtrations.

$^1$H NMR spectra were recorded with a Bruker AVANCE 300 (300 MHz, $^1$H) spectrometer using deuterated solvents. The spectra were collected at 25 °C and the chemical shifts were referenced to residual solvent protons as internal standards. $^1$H: [D$_6$]DMSO δ = 2.50 ppm, $CD_2Cl_2$ δ = 5.32 ppm, $CD_3CN$ δ = 1.93 ppm. Mass spectra were obtained with a VG ZAB-HF spectrometer (FAB) and a VG-BIOQ triple quadrupole in positive or negative mode (ES-MS).

Electrochemical measurements were performed with a three-electrode system consisting of a platinum working electrode, a platinum wire counter electrode, and a silver wire as a pseudo-reference electrode. All measurements were carried out at room temperature under Ar, in degassed spectroscopic grade solvents, using 0.1 M $n$Bu$_4$NBF$_4$ solutions in $CH_2Cl_2$/$CH_3CN$ (1:9) as supporting electrolyte. An EG&G Princeton Applied Research model 273A potentiostat connected to a computer was used (software from Electrochemistry Research).

**8,8′-Dihydroxyphenyl-3,3′-biisoquinoline (9):** 8,8′-Dianisyl-3,3′-biisoquinoline (**8**) (1.00 g, 2.13 mmol) and pyridinium chloride (about 10 equiv., 2.5 g) are mixed into a little flask and heated to reflux in an adapted microwave oven for 10 min. Twice, the same quantity of pyridinium chloride is added and the mixture heated to reflux again for 10 min. The mixture is dissolved in distilled water (1 L) and then neutralised with sodium hydroxide to give a suspension of a pale yellow precipitate. After filtration, the given compound is quantitatively obtained without further purification (pale yellow solid, 94 mg, 100%). M.p. > 300 °C. $^1$H NMR ([D$_6$]-DMSO, 300 MHz): $\delta$ = 9.35 (s, 2 H), 9.09 (s, 2 H), 8.15 (d, $J$ = 8.2 Hz, 2 H), 7.94 (t, $J$ = 7.7 Hz, 2 H), 7.65 (d, $J$ = 7.0 Hz, 2 H), 7.45 (d, $J$ = 8.4 Hz, 4 H), 7.00 (d, $J$ = 8.4 Hz, 4 H) ppm. ES-MS: $m/z$ = 441.1559 (calculated 441.1598 for $C_{30}H_{20}N_2O_2 + H^+$).

**Ligand 7:** 2-(6-Bromohexyloxy)-tetrahydro-2*H*-pyran (180 mg, 0.68 mmol), cesium carbonate (150 mg, 0.45 mmol) and 8,8′-dihydroxyphenyl-3,3′-biisoquinoline **9** (50 mg, 0.11 mmol) were mixed in dry DMF (10 mL) and stirred under Ar at 55 °C overnight. The solvent was removed and the residue was taken up with $CH_2Cl_2$/$H_2O$. The organic phase was separated and the aqueous phase extracted twice with dichloromethane. The combined organic phases were washed first with brine, then with distilled water. The solvent was removed and the residue purified by chromatography over aluminium oxide by using dichloromethane/pentane (1:4) as the eluent to give the title compound (white solid, 60 mg, 65%). $^1$H NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 9.47 (s, 2 H), 8.98 (s, 2 H), 8.00 (d, $J$ = 8.4 Hz, 2 H), 7.78 (dd, $J$ = 8.1, 8.4 Hz, 2 H), 7.55 (d, $J$ = 8.1 Hz, 2 H), 7.54 (d, $J$ = 8.7 Hz, 4 H), 7.12 (d, $J$ = 8.7 Hz, 4 H), 4.60 (t, $J$ = 3.7 Hz, 2 H), 4.12 (t, $J$ = 6.6 Hz, 4 H), 3.92–3.74 (m, 4 H), 3.54–3.40 (m, 4 H), 1.93–1.42 (m, 28 H) ppm. ES-MS: $m/z$ = 809.4720 (calculated 809.4530 for $C_{52}H_{60}N_2O_6 + H^+$).

**Cu$^I$ Complexes $1_4^+$, $2_4^+$ and $3_4^+$:** In a typical procedure, $Cu(CH_3CN)_4PF_6$ was added to a stirred and degassed solution of macrocycle **4** dissolved in $CH_2Cl_2$/$CH_3CN$ (50:50). A deep orange coloration appeared instantly. After 30 min at room temperature, the diimine ligand (respectively **5**, **6** or **7**) was added as a solid to the solution, which immediately turned dark red. After the solution was stirred for two hours under argon at room temperature, the solvents were removed under high vacuum. A dark red solid was obtained quasi-quantitavely (NMR control). Due to its instability on alumina and on silica gel, complexes were not further purified and were directly submitted to the electrochemical measurements.

**$1_4^+$:** $^1$H NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.76 (d, $J$ = 7.2 Hz, 2 H), 8.68 (br., 2 H), 8.49 (d, $J$ = 8.4 Hz, 2 H), 8.45 (d, $J$ = 8.7 Hz, 2 H), 8.41 (br., 2 H), 8.10 (t, $J$ = 7.2 Hz, 1 H), 8.04 (s, 2 H), 7.99 (s, 2 H), 7.89 (d, $J$ = 8.4 Hz, 2 H), 7.85 (d, $J$ = 8.7 Hz, 2 H), 7.75 (br., 2 H), 7.48 (d, $J$ = 8.7 Hz, 4 H), 7.40–7.34 (m, 4 H), 6.11–6.00 (m, 8 H), 3.49 (s, 6 H), 3.25 (br., 4 H), 2.95 (br., 4 H), 2.14 (br., 4 H) ppm. ES-MS: $m/z$ = 1132.3584 (calculated 1132.3606 for $C_{71}H_{55}CuN_7O_4^+$).

**$2_4^+$:** $^1$H NMR ($CD_2Cl_2$, 300 MHz): $\delta$ = 8.84 (d, $J$ = 7.8 Hz, 2 H), 8.75 (br. s, 2 H), 8.51 (d, $J$ = 7.8 Hz, 2 H), 8.40 (d, $J$ = 8.4 Hz, 2 H), 8.05 (t, $J$ = 7.5 Hz, 1 H), 7.92 (s, 2 H), 7.84 (d, $J$ = 8.4 Hz, 4 H), 7.74–7.67 (m, 4 H), 7.57 (d, $J$ = 8.7 Hz, 4 H), 7.35 (d, $J$ = 6.9 Hz, 2 H), 7.21 (d, $J$ = 8.7 Hz, 4 H), 6.36 (d, $J$ = 8.7 Hz, 4 H), 5.95 (d, $J$ = 8.7 Hz, 4 H), 3.69 (br., 4 H), 3.35 (s, 6 H), 3.06 (br., 4 H), 2.29 (br., 4 H) ppm. ES-MS: $m/z$ = 1108.3585 (calculated 1108.3606 for $C_{69}H_{55}CuN_7O_4^+$).

**$3_4^+$:** $^1$H NMR ($CD_3CN$, 300 MHz): $\delta$ = 9.03 (s, 2 H), 8.71 (br. s, 2 H), 8.59 (d, $J$ = 8.4 Hz, 2 H), 8.55 (s, 2 H), 8.50 (d, $J$ = 7.8 Hz, 2 H), 8.32 (s, 2 H), 8.12 (t, $J$ = 7.8 Hz, 1 H), 8.04 (d, $J$ = 8.4 Hz, 2 H), 8.01 (s, 2 H), 7.80–7.74 (m, 6 H), 7.56–7.53 (m, 6 H), 7.15 (d, $J$ = 8.7 Hz, 4 H), 6.86 (d, $J$ = 8.4 Hz, 4 H), 6.14 (d, $J$ = 8.7 Hz, 4 H), 4.48 (t, $J$ = 4.5 Hz, 2 H), 3.94–3.90 (m, 4 H), 3.74–3.60 (m, 4 H), 3.35 (br., 8 H), 2.90 (br., 4 H), 2.03 (br., 4 H), 1.70–1.38 (m, 28 H) ppm. ES-MS: $m/z$ = 1548.6520 (calculated 1548.6533 for $C_{97}H_{95}CuN_7O_8^+$).

# Structural, Electrochemical, and Spectroscopic Properties of a Class of Dodecasubstituted Iron Porphyrins Bearing Four Positive Charges Close to the Metal

**Mark W. Renner,[a] Constance Bochot,[b] Annie Héroux,[c] Daniel Mansuy,[b] and Pierrette Battioni*[b]**

**Keywords:** Iron / Porphyrins / Ligand design / X-ray diffraction / Voltammetry

The first iron complexes of the tetracationic 2,3,7,8,12,13,17,18-octaethyl-5,10,15,20-tetra-*N*-pyridiniumylporphyrin, (OEPy$_4$P)$^{4+}$, in which four pyridine molecules are attached to the *meso*-carbon atoms through their nitrogen atoms, were synthesized in three steps starting from Zn(OEP) (Zn-β-octaethylporphyrin) with an overall yield of ca. 30 %. The X-ray structure of [Fe$^{II}$(OEPy$_4$P)(pyridine)$_2$](CF$_3$SO$_3$)$_3$(Br) established that the molecule adopts a severely distorted nonplanar saddle conformation. $^1$H NMR spectroscopy showed that the [Fe$^{II}$(OEPy$_4$P)(B)$_2$]$^{4+}$ ligated complexes, B = pyridine (Py) or imidazole (Im), are low-spin, Fe$^{II}$, $S$ = 0. These complexes exhibit redox potentials for the Fe$^{III}$/Fe$^{II}$ couple that range between 0.62 and 0.38 V (vs. Ag/AgCl) and are shifted by as much as +0.7 V relative to those of the corresponding planar iron complexes of OEP and of the nonplanar complexes of OETPP. Such highly positive redox potentials explain the stability of these iron(II) porphyrins in air. As previously found for dodecasubstituted iron porphyrins bearing electron-withdrawing groups, the UV/Vis spectra of the [Fe$^{II}$(OEPy$_4$P)(B)$_2$]$^{4+}$ complexes exhibit Soret and visible bands which are redshifted by ca. 40 nm relative to those of Fe(OEP)(Py)$_2$. These metallo-OEPy$_4$P$^{4+}$complexes offer promising synthetic avenues to novel classes of highly charged porphyrins and multiporphyrin arrays, which are soluble in aqueous and polar organic solvents.

## Introduction

Many porphyrin cofactors that are present in living systems, such as photosynthetic reaction centers, light harvesting antenna complexes, and heme proteins, exhibit nonplanar macrocycles.[1] Such macrocycle distortions are believed to influence the biological functions of these cofactors. In vivo, the scaffolding, hydrogen bonding, macrocycle saturation, and axial ligation modulate the porphyrin conformations. In model porphyrins, specific macrocycle configurations have been generated by introduction of bulky and multiple peripheral substituents. By varying the macrocycle modes and degrees of distortion, as well as the nature of the metal, the chemical and physical properties of the tetrapyrroles can thus be fine-tuned. Indeed, such nonplanar distortions have been shown to alter the redox, magnetic, electronic, ligand binding, and excited-state properties of metalloporphyrins.[1,2]

In some cytochromes, the heme iron is coordinated by two axial histidine residues whose relative orientation with respect to each other can alter both their spectroscopic and redox properties.[1,3] In model studies of bis-ligated iron porphyrins, the relative and absolute orientation of the axial ligands have also been shown to modulate the electronic structure, and the magnetic and redox properties of the hemes.[3] In the numerous crystal structures of bis-ligated iron porphyrins reported so far, the relative orientations of the axial ligands are preferentially perpendicular in Fe$^{III}$ and parallel in Fe$^{II}$ porphyrins.[3,4] However, structures of iron(II) porphyrins with perpendicular axial pyridine or imidazole orientations have been reported in which this orientation was controlled by steric interactions imposed by the porphyrin and its substituents.[3,4] As well, crystallographic studies of highly saddled metalloporphyrins have further shown that the combination of macrocycle distortion and peripheral substituents forms trenches which tend to orient the axial ligands perpendicular to each other.[5]

Many dodecasubstituted porphyrins have been synthesized, most of which exhibit nonplanar, highly distorted structures.[1,2] Iron and manganese porphyrins bearing up to twelve electron-withdrawing substituents are especially interesting because of their significantly altered redox potentials and their catalytic properties.[1,6–9] Dodecasubstituted metalloporphyrins bearing multiple charges should be

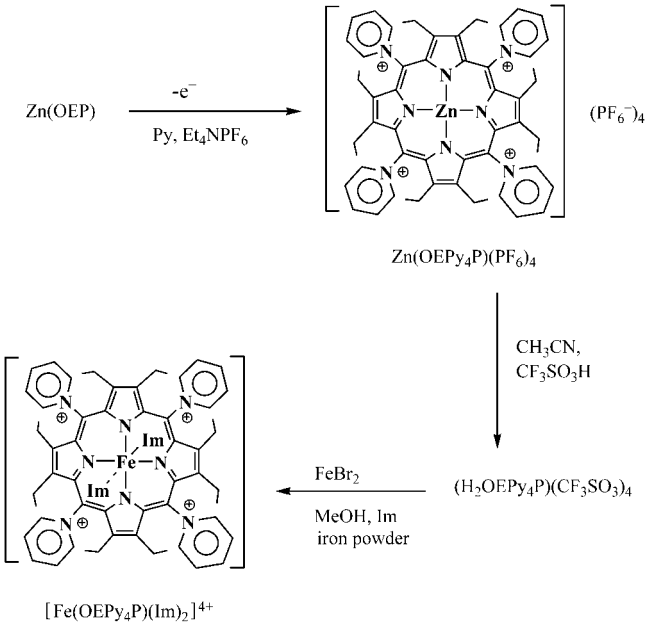
of particular interest because of their solubility in water and their possible interactions with various biological targets such as proteins and nucleic acids. Water-soluble metalloporphyrins exhibit interesting properties as photosensitizers for photodynamic therapy of cancer,[10] and as antimalarial,[11] antibacterial,[12] anti-HIV,[13,14] and antiprion[15] agents. Moreover, cationic metalloporphyrins have been explored for the treatment of pathologies in which the superoxide radical and its progeny are suspected of playing important roles.[16–19] *N*-methylpyridiniumyl-*meso*-substituted metalloporphyrins have been used very often for this purpose. This is indeed the case for the first reported dodecasubstituted tetracationic metalloporphyrins that were derived from β-octabromo-*meso*-tetra(*N*-methylpyridiniumyl)porphyrin.[16]

Recently, a polycationic porphyrin bearing 20 positive charges was obtained by nucleophilic substitution of the F substituents of *meso*-tetra(pentafluorophenyl)porphyrin ($H_2$TFPP) with 4-dimethylaminopyridine in the presence of trimethysilyl triflate.[20] Moreover, a tetracationic $Zn^{II}$ dodecasubstituted porphyrin, $Zn(OEPy_4P)^{4+}$ ($OEPy_4P$: β-octaethyl-*meso*-tetra-(pyridiniumyl-1)porphyrinato) (Scheme 1), bearing four pyridinium groups bound at the *meso* position through their nitrogen atom, was reported.[21] It was the first representative of a new class of dodecasubstituted, nonplanar metalloporphyrins bearing four positive charges less than 5 Å from the metal center. Even more recently, the corresponding free-base porphyrin $H_2OEPy_4P^{4+}$, and its Mn complexes, were synthesized.[22] The latter are new biomimetic hydroxylation catalysts that exhibit good solubility in both polar aprotic solvents and water.[22]



Scheme 1. Synthesis of $[Fe(OEPy_4P)(Im)_2]^{4+}$ in three steps from Zn(OEP).

We report here the synthesis and the spectral and electrochemical properties of iron complexes of $H_2OEPy_4P^{4+}$, and the first X-ray structure of a bis(pyridine)$Fe^{II}$ complex of this novel class of tetracationic dodecasubstituted porphyrins. These metallo-$OEPy_4P^{4+}$ complexes offer promising synthetic avenues to additional novel classes of highly charged porphyrins and multiporphyrin arrays that are soluble in aqueous and polar organic solvents.[23]

## Results and Discussion

### Synthesis of $[Fe(OEPy_4P)(Im)_2]^{4+}$

The iron complex of $OEPy_4P$ was prepared in three steps starting from Zn(OEP) (OEP: β-octaethylporphyrinato) (Scheme 1). The first step that led to $[Zn(OEPy_4P)](PF_6)_4$ was done according to published procedures[21] (Scheme 1). Demetallation of this Zn complex involved its treatment with excess $CF_3SO_3H$,[24,25] which led to the $CF_3SO_3^-$ salt of $[H_2OEPy_4P]^{4+}$ in a 80% yield.[22] The last step, the insertion of iron, was done under an atmosphere of argon by using 2.5 equiv. of $FeBr_2$ in the presence of imidazole (Im) and iron powder. The resulting complex was found to be a diamagnetic $Fe^{II}$ complex of $OEPy_4P$ including two axial imidazole ligands as shown by $^1$H NMR spectroscopy. Its $^1$H NMR spectrum exhibits all the signals expected for the pyridinium (in the 8.5–10.5 ppm region) and ethyl (in the 0.5–2.6 ppm region) substituents of the porphyrin ring, and for the imidazole ligands (signals at $\delta$ = 3.05, 3.83, and 5.20 ppm) (see Experimental Section). Integration of these signals is consistent with two imidazole ligands per porphyrin. In the presence of excess imidazole, the signals of the free and bound imidazole coexist in the $^1$H NMR spectra, which indicates that the exchange between free and bound imidazole is slow on the NMR time scale. Temperature-dependent $^1$H NMR spectroscopic studies performed in $CD_3OD$ in the presence of either 5 or 50 equiv. of imidazole, between 300 and 200 K, did not show significant changes in the shape of the peaks, and only showed small variations in the chemical shifts.

A high resolution mass spectrometry (HRMS) analysis of the $[Fe(OEPy_4P)(Im)_2]^{4+}$ complex, with the use of nanoelectrospray ionization and Fourier transform mass spectrometry (nano-ESI-FTMS), showed a molecular ion at $m/z$ = 1496.2405, which corresponds to $[Fe(OEPy_4P)(CF_3SO_3)_4]^+$ (monoisotopic $m/z$ calculated for $C_{60}H_{60}N_8S_4O_{12}F_{12}Fe$ = 1496.2368; isotopic distribution of the peaks cluster identical to that calculated for the above formula). This molecular ion should derive from the $[Fe(OEPy_4P)(Im)_2](CF_3SO_3)_4$ complex having lost its two axial ligands under the MS conditions, as usually found for such Fe(porphyrin)$(Im)_2$ complexes. A smaller peak at $m/z$ = 1426.1999, which corresponds to $[Fe(OEPy_4P)(CF_3SO_3)_3(Br)]^+$ (theoretical monoisotopic $m/z$ = 1426.2033; isotopic distribution in agreement with the formula $C_{59}H_{60}N_8S_3O_9F_9BrFe$), was also observed. This peak should come from the $[Fe(OEPy_4P)(Im)_2](CF_3SO_3)_3(Br)$ complex, which was present in the analyzed sample as a result of the exchange of a $CF_3SO_3^-$ counterion of $[Fe(OEPy_4P)(Im)_2](CF_3SO_3)_4$ by $Br^-$ coming from $FeBr_2$ in the metallation step. The presence of such a $[Fe(OEPy_4P)(Im)_2]^{4+}$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complex associated with three $CF_3SO_3^-$ counterions and one $Br^-$ counterion is in agreement with the X-ray study performed on the complex obtained by replacement of the Im ligands with pyridine. This X-ray study definitely established a $[Fe(OEPy_4P)(Py)_2](CF_3SO_3)_3(Br)$ structure for the latter complex (see below). Obviously, the nature of the counterions of these $[Fe(OEPy_4P)(B)_2]^{4+}$ complexes, with B = Im or Py, should greatly depend on the synthesis protocol and on the medium in which they are studied. Therefore, these complexes will simply be called $[Fe(OEPy_4P)(B)_2]^{4+}$ in the following sections.

The UV/Vis spectra of $[Fe(OEPy_4P)(B)_2]^{4+}$, with B = Im or Py, exhibit Soret and visible bands that are all redshifted ca. 40 nm relative to $Fe^{II}(OEP)(Py)_2$ (Table 1). These UV/Vis spectra are similar to those of the previously reported low-spin bispyridine dodecasubstituted $Fe^{II}$ porphyrins bearing electron-withdrawing groups [see $Fe(F_{20}DPP)(Py)_2$ in Table 1, $F_{20}DPP$: β-octaphenyl-*meso*-tetrapentafluorophenylporphyrinato], whereas they clearly differ from the spectra of $[Fe^{III}(porphyrin)(Py)_2]^+$ and $Fe^{II}(porphyrin)$ complexes (Table 1). The redshifted optical spectra of $[Fe(OEPy_4P)(B)_2]^{4+}$ are likely due to the presence of the four electron-withdrawing pyridinium substituents and to the distorted structure of the porphyrin macrocycle (see below), relative to that of $Fe^{II}(OEP)(Py)_2$ which is planar.[4] In distorted porphyrins, the highest occupied molecular orbital (HOMO) is destabilized more than the lowest unoccupied orbital (LUMO), which results in a decrease in the HOMO to LUMO energy gap and a redshift in the absorption bands.[26–28]

Table 1. UV/Vis characteristics of the $[Fe(OEPy_4P)(B)_2]^{4+}$ complexes and related iron porphyrins.[a]

| Compound | Solvent | $\lambda_{max}$ [nm, Soret] |
|---|---|---|
| $Fe(F_{20}DPP)$[37] | benzonitrile | 327, 432, 534, 586 |
| $Fe(F_{20}DPP)(Py)_2$[37] | pyridine | 351, 447, 551, 588 |
| $[Fe(Br_8TFPP)(Py)_2]^+$[33] | $CH_2Cl_2$ | 454, 556, 588 |
| $[Fe(OEP)(Py)_2]Cl$[38] | pyridine | 396, 510, 529, 625 |
| Fe(OEP)[39] | $CH_2Cl_2$ | 405, 531, 556 |
| $Fe(OEP)(Py)_2$[40] | pyridine | 408, 517, 546 |
| $[Fe(OEPy_4P)(Py)_2]^{4+}$[a] | MeCN, Py | 366, 439, 458, 556, 588 |
| $[Fe(OEPy_4P)(Im)_2]^{4+}$[a] | MeCN, Im | 366, 458, 568, 601 |

[a] This work, spectra in MeCN containing 5% Py or 100 μM Im.

### Electrochemical Properties of $[Fe(OEPy_4P)(B)_2]^{4+}$

The redox chemistry of these iron complexes was studied by cyclic voltammetry (Figure 1 and Table 2). The $E_{1/2}$ values for $[Fe(OEPy_4P)(Im)_2]^{4+}$ and $[Fe(OEPy_4P)(Py)_2]^{4+}$ are +0.38 and +0.62 V respectively, vs. Ag/AgCl in MeCN. The $E_{1/2}$ peak potential separations for these complexes are 100 and 60 mV, respectively. The $Fe^{III/II}$ couple is obviously sensitive to the axial ligands and shifts − 240 mV upon replacement of the pyridine groups with imidazole moieties. For bis-ligated $Fe^{III}$ porphyrins, the $Fe^{III/II}$ $E_{1/2}$ potential undergoes a negative shift as the pKa of the axial ligands increases.[6] The electron-withdrawing *meso*-pyridinium substituents on the porphyrin shift the $Fe^{III/II}$ couple anodically, which stabilizes the iron(II) oxidation state. The redox potentials of iron porphyrins with a varying number of electron-withdrawing substituents have been reported, and the $Fe^{III/II}$ redox couple undergoes a positive shift with an increasing number of electron-withdrawing groups.[6,29] Comparison of the $E_{1/2}$ of $Fe(OETPP)(B)_2$ (OETPP: β-octaethyl-*meso*-tetraphenylporphyrinato) and $[Fe(OEPy_4P)(B)_2]^{4+}$ shows a large positive shift in the metal redox potentials upon replacing the *meso*-phenyl with *meso*-pyridinium groups (+730 mV and +870 mV for B = Im and Py, respectively, Table 2). Because these compounds have similar nonplanar conformations (see below), electronic, rather than structural, factors seem to cause this large positive shift.

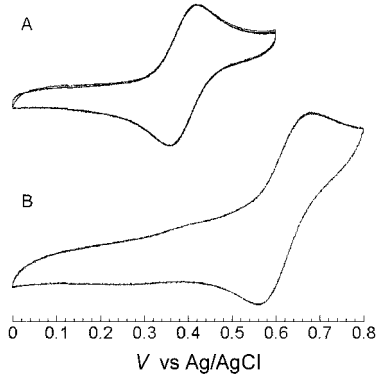


Figure 1. Cyclic voltammograms of $[Fe(OEPy_4P)(Im)_2]^{4+}$ (A) and $[Fe(OEPy_4P)(Py)_2]^{4+}$ (B) in MeCN containing 0.1 M TBAP. Scan rate: 100 mV $s^{-1}$.

Table 2. Electrochemical data for the $[Fe(OEPy_4P)(B)_2]^{4+}$ complexes and related iron porphyrins.

| Compound | $Fe^{III}/Fe^{II}$ [V] | Conditions[a] |
|---|---|---|
| $[Fe(OEP)(Py)_2]^+$[41] | –0.02 | PrCN, TBAP, SCE |
| $[Fe(OEP)(1\text{-}MeIm)_2]^+$[41] | –0.39 | $CH_2Cl_2$, TBAP, SCE |
| $[Fe(F_{20}DPP)(Py)_2]^+$[41] | +0.53 | Pyr, TBAP, SCE |
| $[Fe(Br_8TFPP)(Py)_2]^+$[33] | +0.82 | $CH_2Cl_2$, TBAP, Ag/AgCl |
| $[Fe(OETPP)(Im)_2]^+$[b] | –0.31 | PrCN, TBAP, SCE |
| $[Fe(OETPP)(Py)_2]^+$[b] | –0.21 | PrCN, TBAP, SCE |
| $[Fe(OEPy_4P)(Py)_2]^{4+}$[c] | +0.62 | MeCN, TBAP, Ag/AgCl |
| $[Fe(OEPy_4P)(Im)_2]^{4+}$[c] | +0.38 | MeCN, TBAP, Ag/AgCl |

[a] Redox potentials were measured in the indicated solvent containing 0.1 M TBAP (tetrabutylammonium perchlorate). Values are in V relative either to the saturated calomel electrode (SCE) or to the Ag/AgCl electrode. [b] M. W. Renner and J. Fajer, unpublished results. [c] This work.

Two electronic structures are theoretically possible for $S = 0$ $Fe(porphyrin)(L)_2$ complexes, a low-spin d6 $Fe^{II}$ porphyrin structure and a structure involving a low-spin d5 $Fe^{III}$ ion antiferromagnetically coupled to a porphyrin radical. However, presently, there is no indication in favor of the latter structure for all the $S = 0$ $Fe(porphyrin)(L)_2$ complexes published so far in the literature. An electronic structure resulting from an intramolecular electron transfer from $Fe^{II}$ to the porphyrin should be favored by the presence of porphyrin electron withdrawing substituents. However,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Mössbauer data of the β-octanitrated Fe[TDCP$(NO_2)_8$P]-$(EtOH)_2$ complex, which exhibits the highest redox potential described so far for a Fe(porphyrin)$(L)_2$ complex (1030 mV vs. SCE[30]), clearly showed that it is a $Fe^{II}$ complex.[30] Moreover, metal(porphyrin radical) complexes usually exhibit a characteristic porphyrin radical absorption in the 700–1000 nm region; for instance $Zn^{II}$[TDCP$(NO_2)_7$-P]$^{\cdot-}$ and $Ni^{II}$[TDCP$(NO_2)_7$P]$^{\cdot-}$ complexes show bands at 900 and 770 nm, respectively.[31] However, the UV/Vis spectra of [Fe$(OEPy_4P)(Im)_2]^{4+}$ and [Fe$(OEPy_4P)(Py)_2]^{4+}$ failed to show any band in the 700–1000 nm region. Finally, the $^1$H NMR spectra of [Fe$(OEPy_4P)(B)_2]^{4+}$ complexes exhibit peaks, whose shapes and chemical shifts are highly similar to those of Zn[$(OEPy_4P)]^{4+}$ and $H_2$[$(OEPy_4P)]^{4+}$ in which the porphyrin ligand does not involve any radical species. All these data are in favor of the low-spin d6 $Fe^{II}$ porphyrin electronic structure, as the one proposed for all the previously described $S = 0$ Fe(porphyrin)$(L)_2$ complexes.[4]

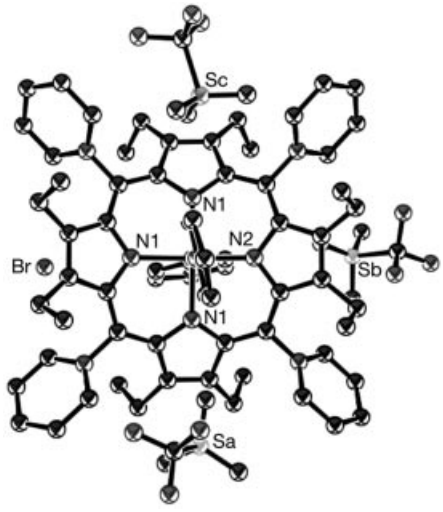

Figure 2. ORTEP diagram of **1** with the anions included. The thermal ellipsoids are drawn at the 30% probability level.

## Structural Studies

Owing to the small crystal size ($0.6 \times 0.4 \times 0.1$ mm) and quality, the X-ray diffraction experiments were performed with the use of high intensity X-rays from the National Synchrotron Light Source at Brookhaven National Laboratory beamline X26C. The molecular structure of [Fe(OE-$Py_4P)(Py)_2](CF_3SO_3)_3(Br)$ (**1**) and the atom numbering scheme are displayed in Figures 2 and 3. Selected bond lengths and angles are listed in Table 3. [Fe$(OEPy_4P)$-$(Py)_2]^{4+}$ crystallizes with four anions, three $CF_3SO_3^-$, and one $Br^-$, which are located between adjacent *meso*-pyridinium groups and above the pyrrole rings (Figure 2). One of the original $CF_3SO_3^-$ ions of the free base must therefore have been replaced by a $Br^-$ during the metal insertion reaction with $FeBr_2$. The molecular structure of **1** exhibits a $S_4$ saddle-shape distortion with an absolute displacement of 1.22 Å for the pyrrole $C_\beta$ atoms relative to the 24-atom plane; an edge-on view of **1** is shown in Figure 3. The displacements of the porphyrin atoms from the 24-atom core, the axial ligand plane orientations, and a "clothesline" representation of the macrocycle distortions are shown in Figure 4.

The trenches formed by the nonplanar porphyrin conformation and the β-ethyl groups align the axial pyridines perpendicular to each other and along the $N_p$–Fe–$N_p$ axes. The dihedral angle between the axial pyridine and the closest $N_p$–Fe–$N_{ax}$ plane (ϕ) are 11.2 and 13.3° for pyridine N9 and N10, respectively. The pyridines are effectively orthogonal to each other with a dihedral angle between the two axial pyridine planes of 87°. A comparison of the structural parameters of **1** and other related bispyridine iron porphyrins are listed in Table 4. As with other bispyridine iron(II) porphyrins,[4] the iron atom resides in the $4N_p$ plane, displaced 0.01 Å toward the axial pyridine N10. The axial pyridines are approximately perpendicular to the macrocycle plane with dihedral angles of 81.1° and 89.3° for pyridine N9 and N10, respectively. Pyridine N9 is tilted ca. 9° relative to the $4N_p$ plane which could be a result of hydrogen bonding between the pyridine C–H and the oxygen atom of a nearby $CF_3SO_3^-$ anion; the C59···O distance is 3.33 Å.

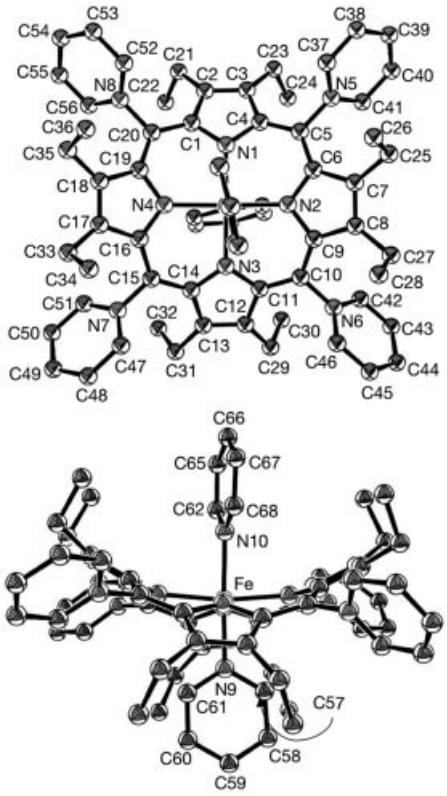

Figure 3. Molecular structure and numbering scheme for **1**, thermal ellipsoids drawn at the 30% probability level; the hydrogen atoms and the counterions are removed for clarity.

Typically, for bis-ligated low-spin iron(II) porphyrins[4] the equatorial Fe–$N_p$ distances are ca. 2.00 Å. The average equatorial Fe–$N_p$ distance in complex **1** [1.953(3) Å] is slightly shorter than in the dodecasubstituted complexes [$Fe^{III}$(OETPP)$(Py)_2]ClO_4$ at 80 K [1.957(3) Å] and $Fe^{II}$-

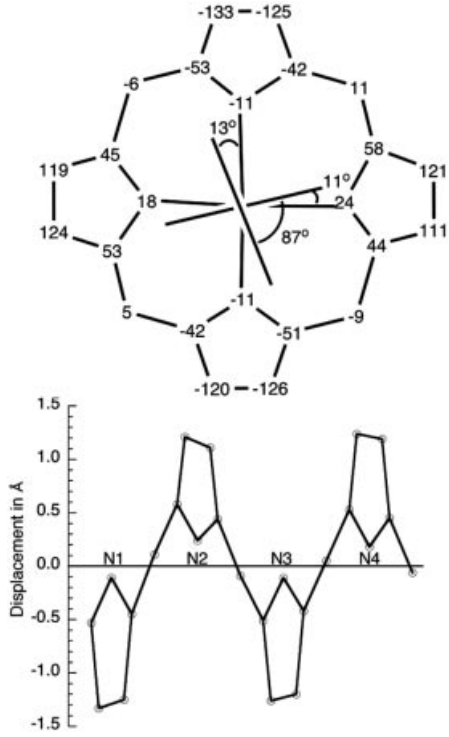

Figure 4. Top: Displacements of the 24-atom core in units of 0.01 Å and the orientation of the axial pyridine ligand planes of **1**. Bottom: Linear display of the out-of-plane displacements of the core atoms of **1** from the average plane of the 24 atoms (the horizontal axis is not to scale).

$(Br_8TFPP)(Py)_2$ ($Br_8TFPP$: β-octabromo-*meso*-tetrapentafluorophenylporphyrinato) [1.963(7) Å].[32,33] The increased distortion in **1** relative to $Fe^{II}(Br_8TFPP)(Py)_2$, (see below), could account for the decreased Fe–$N_p$ distance. In planar porphyrins, the Fe–$N_{ax}$ bond lengths are longer in $Fe^{II}$ than in $Fe^{III}$ porphyrins[4] and this trend is maintained in **1** [2.028(3) Å] when compared to $[Fe^{III}(OETPP)(Py)_2]ClO_4$ [1.993(3) Å].[32] As a result of the limited structural data available for highly saddled bis-ligated low-spin $Fe^{II}$ and $Fe^{III}$ porphyrins, no meaningful conclusions can be made regarding any relationship between the Fe–$N_p$ or Fe–$N_{ax}$ distances and the oxidation state of the metal.

A normal-coordinate structural decomposition (NSD)[34] analysis of the macrocycle distortions in **1** and several related iron porphyrins are listed in Table 5. The results from the analysis indicate that the predominant distortion in **1** is *sad* with a small *ruf* contribution. Recently, Scheidt et al. reported a correlation between the Fe–$N_p$ distance and the absolute *meso*-carbon displacement in ruffled $Fe^{II}$ and $Fe^{III}$ porphyrins.[35] This correlation does not appear to hold for porphyrins with a saddled conformation within the limited data available.

In saddled porphyrins there is a significant increase in the $C_m$–$C_\alpha$–$C_\beta$ angle and a decrease in the N–$C_\alpha$–$C_\beta$ and N–$C_\alpha$–$C_m$ angles relative to planar porphyrins. This trend holds for **1** and, in addition, there is a ca. 3° increase in the

Table 4. Average bond lengths [Å] and angles [°] for **1** and related complexes.

[a] This work.

$C_\alpha$–$C_m$–$C_\alpha$ angle (Table 4).[4] Another consequence of the increased saddle distortion in **1** is a decrease in the dihedral angle of the *meso*-pyridinum rings relative to the 4$N_p$ plane, 47.3°. However, the average $C_m$–*meso*–$N_{py}$ distance [1.462(4) Å] does not suggest any significant increased π–π overlap. Similar observations were noted in highly saddled OETPP porphyrins, again without any indication of increased porphyrin–phenyl π overlap.[1,36]

## Conclusions

A procedure was developed for the synthesis of iron complexes of [$H_2$OEPy$_4$P](CF$_3$SO$_3$)$_4$, in three steps starting from Zn(OEP) with an overall yield of ca. 30%. The molecular structure of [Fe(OEPy$_4$P)(Py)$_2$](CF$_3$SO$_3$)$_3$(Br) was determined by X-ray crystallography. The molecule was shown to adopt a severely nonplanar distorted saddle conformation, and the nonplanar macrocycle and its substituents form cavities that orient the axial ligands orthogonally to each other and along the Np–Fe–Np axes. [Fe(OEPy$_4$P)(B)$_2$]$^{4+}$, B = Py or Im, are the first iron complexes of a dodecasubstituted porphyrin bearing four positive charges close to the metal (<5 Å). The $Fe^{III}/Fe^{II}$ redox potentials of +0.62 (B = Py) and +0.38 V (B = Im) (relative to Ag/AgCl) are shifted by as much as ca. +0.7 V when compared to the redox potentials of the corresponding planar complexes of OEP and of the nonplanar, saddle-shaped, complexes of OETPP. These highly positive redox potentials values, that are comparable to those previously reported for dodecasubstituted iron porphyrins bearing electron-withdrawing groups, such as Fe(Br$_8$TFPP)(Py)$_2$ or Fe(F$_{20}$DPP)(Py)$_2$,[33,37] explain the stability of these $Fe^{II}$ porphyrins in air. As previously reported for other iron dodecasubstituted porphyrins bearing electron-withdrawing groups,[29,33,37] the UV/Vis absorption spectra of the [Fe(OEPy$_4$P)(B)$_2$]$^{4+}$ complexes exhibit Soret and visible bands greatly redshifted relative to Fe(OEP)(Py)$_2$. Potential applications in biomedicine, catalysis, and material sciences of these novel iron porphyrins that offer the advantage of being stable in air and also soluble in polar organic solvents as well as in water are currently being pursued.

## Experimental Section

**Materials and Methods:** Methanol (MeOH), diethyl ether ($Et_2O$) and Celite 545 were purchased from SDS and used without further purification. Trifluoromethanesulfonic acid, Zn(β-octaethylporphyrin = OEP), dichloromethane ($CH_2Cl_2$), [$D_2$]dichloromethane ($CD_2Cl_2$), pyridine (Py), [$D_5$]pyridine, imidazole (Im), tetraethylammonium hexafluorophosphate ($Et_4NPF_6$), acetonitrile (MeCN), and Sephadex LH20 were purchased from Aldrich. Tetrabutylammonium perchlorate ($Bu_4NClO_4$) was obtained from Alfa, pyridine (Py) (extra dry, water <50 ppm) from Acros, and anhydrous $FeBr_2$ and iron powder from Alfa-Ventron.

At BNL, UV/Vis absorption spectra were recorded with a Cary 500 spectrophotometer. Cyclic voltammetry was carried out with a Voltalab 80 electrochemical analyzer. A three-electrode system was used and consisted of a glassy carbon working electrode (GCE, 3.0 mm diameter, BAS), a Pt wire counter electrode, and a Ag/AgCl reference electrode. The solvent was MeCN with 0.1 M $Bu_4NClO_4$ as the supporting electrolyte and they were purified by standard techniques. $^1$H NMR spectra were recorded with a Bruker DRX-400 spectrophotometer operating at 400.132 MHz $^1$H frequency. The NMR spectra were referenced to the residual $CD_2Cl_2$ solvent peak ($\delta$ =5.32 ppm). The DQF-COSY data were recorded at 296 K and processed by using the Xwinnmr software package.

At Paris 5, UV/Vis absorption spectra were recorded with a SAFAS mc2 spectrophotometer operating at room temperature and $^1$H NMR spectra were recorded at 300 K with a Bruker WR250 spectrometer. Electrochemical experiments were carried out with an EGG-PAR model 173 potentiostat, or with a Tacussel PJT 120–1 potentiostat controlled by a PC computer by a Tacussel IMT-1 interface.

HRMS analyses were carried out at Ecole Polytechnique, Palaiseau, France with a 7-T APEX III FT-ICR mass spectrometer (Bruker Daltonik, Bremen, Germany) equipped with a 7 Tesla actively shielded superconducting magnet and an infinity cell. Nanoelectrospray was used as the ionization source, and nanoelectrospray needles were purchased from Proxeon (Odense, Denmark) and filled with 2 μL of a solution of complex (20 pmol L$^{-1}$ in 50% MeOH/water/0.2% formic acid). Mass spectra were acquired from *m*/*z* 500 to 3000 with 256k data points. MS analysis were performed at "Laboratoire de spectrométrie de masse bio-organique" ECPM, Strasbourg, France with a MicroTof apparatus (Bruker, Wissembourg France) (electrospray).

**[Fe(OEPy$_4$P)(Im)$_2$]$^{4+}$:** The preparation of Zn(OEPy$_4$P)(PF$_6$)$_4$ from Zn(OEP) was performed as described previously.[21] This complex was demetallated by treatment with $CF_3SO_3H$.[22] Iron was inserted into the free base porphyrin as follows: $H_2$OEPy$_4$P(CF$_3$SO$_3$)$_4$ (100 mg, 0.069 mmol) was dissolved in MeOH (3 mL) in the presence of imidazole (5 equiv.). The solution was deoxygenated, anhydrous $FeBr_2$ (36.6 mg, 2.5 equiv.) and Fe powder were added, and the solution was heated at reflux under an argon atmosphere for 18 h. Iron powder was added to reduce the ferric impurities present in $FeBr_2$. After cooling to room temperature, the solution was passed through a short celite column (to remove iron salts). After

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

evaporation of the solvent, the resulting product was washed with $Et_2O$ (300 mL). Yield: 50 mg (48% assuming a $[Fe(OEPy_4P)(Im)_2]^{4+}$ structure with 4 $CF_3SO_3^-$ counterions as suggested by HRMS). $^1H$ NMR (250 MHz, $CD_3OD$, of $[Fe^{II}(OEPy_4P)(Im)_2]^{4+}$ in the presence of 5 equiv. of Im, 300 K): $\delta$ = 10.45 (d, $J$ = 6 Hz, 8 H, *o*-H of $Py^+$), 9.21 (t, $J$ = 7.5 Hz, 4 H, *p*-H of $Py^+$), 8.65 (dd, $J$ = 6.8 Hz, 8 H, *m*-H of $Py^+$), 8.18–7.29 (free Im), 5.20 (2 H, bound Im), 3.83 (2 H, bound Im), 3.06 (2 H, bound Im), 2.58 (m, 8 H, $CH_2$ of $CH_2CH_3$), 1.15 (m, 8 H, $CH_2$ of $CH_2CH_3$), 0.41 (m, 24 H, $CH_3$) ppm. UV/Vis ($CH_3CN$ containing 100 μM Im, under Ar): $\lambda$ ($\varepsilon$, $M^{-1}cm^{-1}$) = 366 (70530), 458 (88280), 568 (23250), 601(24170) nm. MS (electrospray, TOF): $m/z$ = 1347.4 $[Fe(OEPy_4P)(CF_3SO_3)_3]^+$, 1279.3 $[Fe(OEPy_4P)(CF_3SO_3)_2(Br)]^+$, 599.3 $[Fe(OEPy_4P)(CF_3SO_3)_2]^{2+}$, 349.9 $[Fe(OEPy_4P)(CF_3SO_3)]^{3+}$, 326.8 $[Fe(OEPy_4P)(Br)]^{3+}$, 225.7 $[Fe(OEPy_4P)]^{4+}$.

**$[Fe(OEPy_4P)(Py)_2]^{4+}$:** A dichloromethane solution of the above $[Fe^{II}(OEPy_4P)(Im)_2]^{4+}$ complex was treated with an excess of pyridine (5% vol). The NMR sample was prepared directly in the NMR tube by adding an excess of [$D_5$]pyridine to a $CD_2Cl_2$ solution of the $[Fe^{II}(OEPy_4P)(Im)_2]^{4+}$ complex. $^1H$ NMR [400 MHz, $CD_2Cl_2$ containing 5% (vol) of $C_5D_5N$, 296 K]: $\delta$ = 10.46 (d, $J$ = 6 Hz, 8 H, *o*-H of $Py^+$), 8.99 (t, $J$ = 7.5 Hz, 4 H, *p*-H of $Py^+$), 8.45 (t, $J$ = 6.8 Hz, *m*-H of $Py^+$), 2.48 (m, 16 H, $CH_2$ of $CH_2CH_3$), 0.22 (t, $J$ = 7.1 Hz, 24 H, $CH_3$). The peaks assignments were made from the DQF-COSY spectrum. UV/Vis ($CH_3CN$): $\lambda$ = 366, 439, 458, 556, 588 nm.

**Crystallography:** Selected crystallographic experimental data are presented in Table 6. Crystals of $[Fe(OEPy_4P)(Py)_2](CF_3SO_3)_3(Br)$ were grown by vapor diffusion of pentane into a solution of the complex in $CH_2Cl_2$. A crystalline sample was placed in Paratone-N, the single crystal was suspended in a nylon loop and transferred to the liquid nitrogen cold stream of the diffractometer. Crystallographic data were collected at beamline X26C of the National Synchrotron Light Source at Brookhaven National Laboratory. 360° of data were collected by the rotation method on an ADSC Quantum 4 area detector and processed with Denzo/Scalepack. Lattice parameters for the synchrotron data were determined separately for each recorded image and are mean values derived from the reproducibility of the determinations. The structures were solved by direct methods and refined against $F^2$ by using SHELXL-97 in the SHELXTL version 5 package. Hydrogens were included in idealized positions by using a riding model. CCDC-630557 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Mixed Titanium–Hafnium Chloridometallate Complexes

**Emmanuel Robé,[a] Sébastien Maria,[a] Philippe Richard,[a] and Rinaldo Poli*[b]**

**Keywords:** Titanium / Hafnium / Chloridometallate complexes / Mixed-metal complexes

The addition of either $NEt_3BzCl$ or $[Ph_3PNPPh_3]Cl$ (1 equiv. chloride per metal) to a 1:1 mixture of $HfCl_4$ and $TiCl_3$ in $SOCl_2$ results in Ti oxidation and leads to the corresponding salts of the $[TiHfCl_{10}]^{2-}$ ion. A solution IR investigation in the ν(M–Cl) region indicates that this ion is in equilibrium with the homodimetallic $[Ti_2Cl_{10}]^{2-}$ and $[Hf_2Cl_{10}]^{2-}$ ions. An X-ray study of the $NEt_3Bz^+$ salt reveals an edge-sharing bioctahedral dianion sitting on a crystallographic inversion centre. The crystal is a solid solution of different species with compositional disorder at the metal site, each metal position having the occupancy $Ti_{0.685}Hf_{0.315}$. The M–M and M–Cl distances have intermediate values between those of the homodimetallic analogues. The results of DFT calculations rationalize the structural, energetic and M–Cl bonding differences. An electrochemical investigation, in comparison with that of $[Ti_2Cl_{10}]^{2-}$ and the parallel IR studies, provides further information on the solution equilibria. Adventitious hydrolysis during the crystallization of the $[Ph_3PNPPh_3]^+$ salt affords crystals of $[Ph_3PNPPh_3]_2[Cl_3Ti(\mu\text{-}O)HfCl_5]$, whose dianion contains a tetrahedral $Ti^{IV}$ centre and an octahedral $Hf^{IV}$ centre bridged by an oxygen atom. A bond-length analysis allows the description of this dianion as containing the hitherto unknown $[Ti(O)Cl_3]^-$ complex, which acts as an oxygen-based donor ligand to $[HfCl_5]^-$.

## Introduction

Titanium chlorides are of fundamental importance in Ziegler–Natta polymerization. The first catalyst for this process was prepared by mixing $TiCl_4$ and $AlEt_3$ or $Et_2AlCl$.[1–3] Other metal halides have been extensively investigated, and the literature abounds with reviews and patents on this subject, but the characterization of heterogeneous Ziegler–Natta catalysts at the atomic level is still actively pursued.[4–15] Among several improvements over the original catalyst, the use of mixed-metal systems, for instance Ti–V systems, are worth of particular mention.[16–18] Recently, mixed hafnium–titanium based catalysts have been explored as substitutes for the high-temperature polyethylene process.[19–21] To the best of our knowledge, the role played by the Hf metal has not yet been elucidated. Far from answering questions related to the structure and mechanism of the heterogeneous catalyst active sites, simple model compounds may nevertheless provide at least a basis to address the nature of the resting state of a surface active site, and the effect that a second (additive) metal may have on the ground-state properties of the first (catalytically active) one.

Only a limited number of well-defined compounds that contain both titanium and hafnium in the same molecule can be found in the literature. The only examples that we have been able to find are restricted to $(NMe_2)_2Ti(\mu\text{-}NMe_2)_2HfCl_4$,[22] $Cp_2Ti(\mu\text{-}CH_2)_2HfCp_2$,[23,24] $Cl_4Ti(\mu\text{-}C_{12}H_6N_2O_2)HfCl_4$ and $Cp_2Ti(\mu\text{-}C_{12}H_6N_2O_2)HfCl_4$ ($C_{12}H_6N_2O_2$ = 1,10-phenanthroline-5,6-dione, $\kappa^2$-*N*,*N*-coordinated to $HfCl_2$ and $\kappa^2$-*O*,*O*-coordinated to $TiCl_4$ or $Cp_2Ti$)[25] and two octametallic oxo- and methacrylato-bridged compounds, $Ti_4Hf_4O_6(OPr)_4(O_2CCMe{=}CH_2)_{16}$ and $Ti_2Zr_5HfO_6(O_2CCMe{=}CH_2)_{20}$,[26] the latter ones being apparently the only structurally characterized examples. Since the preparation of Ziegler–Natta catalysts is generally performed from simple, commercially available chloride compounds, it is of interest to explore mixed-metal systems where chlorides are the only available supporting ligands. In catalyst preparation, intimate mixtures or solid solutions of the metal halides are generally treated in situ with the organoaluminium activating agent, which therefore introduces alkylated active sites on the surface of the mixed-metal halide material.

In general, simple molecular chloridometallate complexes can be viewed as stabilized chunks of solid-state structures. For instance, the solid-state $HfCl_4$ structure displays hexagonal packing of chloride ions; the $Hf^{4+}$ ions occupy 1/4 of the octahedral sites, which results in bioctahedral moieties that are arranged pairwise and share an edge or a triangular face.[27,28] The well-defined dinuclear

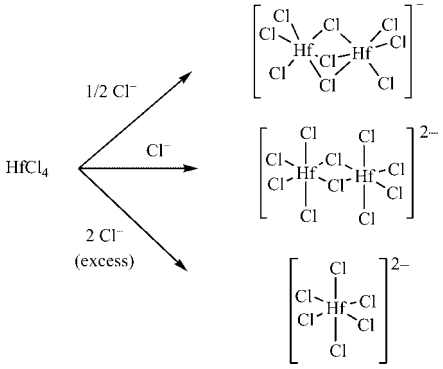
$[Hf_2Cl_{10}]^{2-}$ and $[Hf_2Cl_9]^-$ complexes, described a few years ago by Calderazzo and co-workers,[29,30] may be considered to be derived from the solid-state structure of $HfCl_4$ by chopping off "$Hf_2Cl_8$" pieces and stabilizing them by addition of controlled amounts of additional chloride ions to the resulting unsaturations, whereas the addition of excess $Cl^-$ leads to the mononuclear octahedral $[HfCl_6]^{2-}$ complex[31] (Scheme 1). $Ti^{IV}$ edge-sharing and face-sharing bioctahedral analogues ($[Ti_2Cl_{10}]^{2-}$ and $[Ti_2Cl_9]^-$) also exist,[32] and we have recently reported spectroscopic evidence for the existence of $[Ti_2Cl_{11}]^{3-}$.[33] On the other hand, the neutral system is a molecular, mononuclear four-coordinate complex, $TiCl_4$, rather than an extended solid. A face-sharing bioctahedral complex, $[Ti_2Cl_9]^{3-}$, is also known for $Ti^{III}$.[34,35] This is related to the solid-state structure of the catalytically relevant violet $TiCl_3$, whereas hafnium analogues are not known. We set out to prepare and characterize mixed-metal (Ti,Hf) chloridometallate complexes by addition of chloride ions to a mixture of Ti and Hf chlorides in the appropriate stoichiometry and report here the results of these investigations.



Scheme 1.

## Results and Discussion

### Synthetic Work

Before attempting to prepare mixed-metal complexes, we optimized the conditions for the preparation of single-metal species. Our strategy is described in Scheme 1, using the chloride salts $NEt_3Bz^+Cl^-$ and $[Ph_3PNPPh_3]^+Cl^-$ (the latter one will be abbreviated as $PPN^+Cl^-$). The addition of these salts to commercially available $HfCl_4$ suspended in $CH_2Cl_2$, however, did not result in any apparent interaction. Since this is in apparent contradiction with the literature (a decachloridodihafnate salt of the $Ph_3C^+$ cation has been obtained by addition of $Ph_3CX$ to $HfCl_4$)[29] and since commercial $HfCl_4$ is typically contaminated by partially hydrolyzed oxo impurities, the reaction was then conducted in $SOCl_2$ in order to reconvert in situ any impurities to $HfCl_4$. Under these conditions the reaction takes place smoothly [Equation (1), ($Cat^+ = NEt_3Bz^+$, $PPN^+$)], leading to the isolation of white, analytically pure $[NEt_3Bz]_2[Hf_2Cl_{10}]$ and $[PPN]_2[Hf_2Cl_{10}]$ in excellent yields. We have also successfully used an alternative two-step procedure, consisting of the regeneration of pure $HfCl_4$ from the commercial source by treatment with $SOCl_2$ followed by reaction with $Cat^+Cl^-$ in $CH_2Cl_2$. However, the direct reaction in $SOCl_2$ is a more practical procedure. After isolation, the compounds are readily soluble in dichloridomethane (the PPN salt has a significantly higher solubility). Analogous titanium complexes have been obtained and reported recently by us from the reaction of the same chloride salts with $TiCl_3$ in $SOCl_2$ [Equation (2)],[33] where the oxidation of the titanium centre occurs by intervention of the solvent as a source of chlorine atoms. Since $TiCl_3$ is more convenient to handle than $TiCl_4$ as starting compound, we have used the same strategy to access mixed-metal systems in this work. When the same reaction shown in Equation (1) and Equation (2) was carried out with a 1:1 mixture of $TiCl_3$ and $HfCl_4$, products corresponding to the expected mixed-metal $TiHfCl_{10}^{2-}$ stoichiometry were obtained in excellent yields [Equation (3), ($Cat^+ = NEt_3Bz^+$, $PPN^+$)]. The isolated compounds are yellow, which is the expected colour for $Ti^{IV}$ (the $[Ti_2Cl_{10}]^{2-}$ salts are also yellow).

$$2\ HfCl_4 + 2\ Cat^+Cl^- \rightarrow Cat_2[Hf_2Cl_{10}] \quad (1)$$

$$2\ TiCl_3 + 2\ Cat^+Cl^- + 2\ \{Cl\} \rightarrow Cat_2[Ti_2Cl_{10}] \quad (2)$$

$$TiCl_3 + HfCl_4 + 2\ Cat^+Cl^- + 2\ \{Cl\} \rightarrow Cat_2[TiHfCl_{10}] \quad (3)$$

The major issue at this point is to find evidence for the existence of the mixed-metal species, as opposed to a 1:1 mixture of the homoleptic dimers, and to measure or at least estimate the position of the corresponding equilibrium [Equation (4)]. Both the homometallic and the heterodimetallic complexes are devoid of simple spectroscopic probes such as nuclei with a spin of 1/2 that would be suitable for an NMR investigation or with unpaired electrons for an EPR investigation, allowing them to be easily distinguished. The use of $^{47}Ti$, $^{49}Ti$, $^{177}Hf$ and $^{179}Hf$ NMR spectroscopy is unsatisfactory for compounds in which the metal centre has lower than cubic symmetry.[36,37]

$$[Ti_2Cl_{10}]^{2-} + [Hf_2Cl_{10}]^{2-} \rightleftarrows 2\ [TiHfCl_{10}]^{2-} \quad (4)$$

### Infrared Characterization

Useful information was obtained from far-IR spectroscopy, which is sensitive to M–Cl modes, with samples in $CH_2Cl_2$ solutions in polyethylene cells. The effectiveness of this technique was previously shown for the homoleptic chloridotitanate species, in that the existence and solution-stability of the previously unknown $[Ti_2Cl_{11}]^{3-}$ ion could be unambiguously demonstrated.[33] Only the more soluble $PPN^+$ series of compounds gave sufficiently intense bands, and the results are shown in Figure 1. Note that the most distinct band of the $PPN^+$ cation at ca. 465 $cm^{-1}$ (as measured for a PPNCl solution, Figure 1c) is seen in all spectra. A less distinct $PPN^+$ band at 393 $cm^{-1}$ is also found in all other spectra, but at much higher relative intensity. How-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ever, our previous studies on the $[Ti_2Cl_{10}]^{2-}$ species have shown that adventitious hydrolytic impurities also generate a band at this frequency.[33] The relative intensity of this band varies as a function of the care with which the solutions are handled and increases when undried dichloromethane is used as solvent. All reported spectra were recorded in carefully dried solvent and all glassware and transfer syringes were silylated by rinsing with a 10% v/v chloroform solution of $Me_3SiCl$. However, we have been unable to completely eliminate this band. Given the extreme moisture-sensitivity of the $Ti^{IV}$–Cl bonds, it is possible that some hydrolysis occurred during the isolation procedure (washing and transfer into the storage ampoules). An analogous band is observed here also for the hafnium sample. This may also be a hydrolytic impurity coincidentally absorbing at the same frequency, or a real band for this complex. Anyhow, we will disregard this particular band in our conclusions.

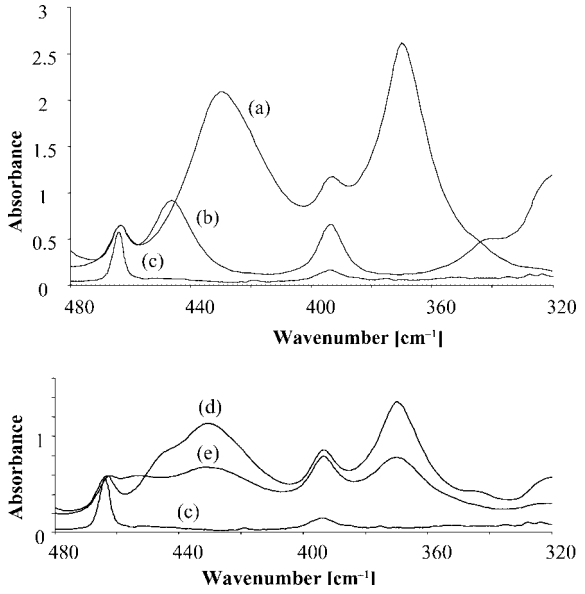


Figure 1. Far-IR spectra of PPN salts in $CH_2Cl_2$. All spectra are recorded at the same $PPN^+$ cation concentration ($10^{-2}$ M). (a) $[PPN]_2[Ti_2Cl_{10}]$; (b) $[PPN]_2[Hf_2Cl_{10}]$; (c) [PPN]Cl; (d) electronic average of $[PPN]_2[Ti_2Cl_{10}]$ and $[PPN]_2[Hf_2Cl_{10}]$; (e) 1:1 mixture of $[PPN]_2[Ti_2Cl_{10}]$ and $[PPN]_2[Hf_2Cl_{10}]$.

$[Ti_2Cl_{10}]^{2-}$ displays two major bands at ca. 370 and 430 $cm^{-1}$ (Figure 1a) of much stronger intensity than the band of the hafnium analogue at ca. 450 $cm^{-1}$ (Figure 1b). The spectrum of a solution of the mixed-metal complex, at the same molar concentration of the $PPN^+$ cation, is shown in Figure 1e. This spectrum is identical with that obtained by mixing equimolar amounts of $Ti_2Cl_{10}^{2-}$ and $Hf_2Cl_{10}^{2-}$. This observation establishes the notion that the equilibrium shown in Equation (4) is very rapid. This spectrum shows the same maxima that are individually observed in the spectra of the two homoleptic species, and any new bands are absent. However, the overall intensity is distinctly *lower* relative to the electronic average of the spectra of the two homoleptic species (Figure 1d). The height of the peak of the $PPN^+$ cation at 465 $cm^{-1}$ serves as an internal consistency check, showing the reliability of the difference between spectra (d) and (e). Since the intensity of the $[Hf_2Cl_{10}]^{2-}$ bands are so much lower than those of the corresponding titanium species, a mixed-metal analogue is likely to have intermediate intensity. Thus, the presence of some amount of the mixed-metal species is consistent with the decrease in intensity in going from the 1:1 mixture of $[Ti_2Cl_{10}]^{2-}$ and $[Hf_2Cl_{10}]^{2-}$ (Figure 1d) to the equilibrium mixture (Figure 1e). In other words, this decrease constitutes experimental evidence for the presence of mixed-metal species at equilibrium.

## Structural Characterization

Single crystals have been obtained from the mixed-metal solution of the $NEt_3Bz^+$ salt and have been investigated by X-ray diffraction (Figure 2). Unfortunately, the compound crystallizes in a centrosymmetric space group with one half of the dianion in the asymmetric unit. Consequently, the two metal sites in the bioctahedral geometry are symmetry-disordered. Furthermore, a free occupancy refinement for the metal site as $x$Ti + $(1 - x)$Hf gives $x = 0.685$. Therefore, the compound has excess titanium relative to the 1:1 stoichiometry. It is a solid solution containing 37% $[Ti_2Cl_{10}]^{2-}$, while the remaining 63% could be either pure $[TiHfCl_{10}]^{2-}$, or a 1:1 mixture of the $Ti_2$ and $Hf_2$ salts, or anything between these two extremes. The presence of excess titanium indicates a lower solubility for the lighter $Ti_2$ salt, which is then expected to shift the equilibrium of Equation (4) toward the left during the crystallization process. However, the geometrical features and the distances and angles, in comparison with those of the $[Ti_2Cl_{10}]^{2-}$ and $[Hf_2Cl_{10}]^{2-}$ anions (Table 1), are as expected and confirm the mixed-metal nature of the dianion. While the bond angles are approximately identical for the three dianions, the M–M/M′ and M–Cl bond lengths steadily increase in the order $Ti_2$ < $Ti_{1.37}Hf_{0.63}$ < $Hf_2$, as expected from the increase in the metal radius.

## DFT Studies

DFT calculations have been carried out on complexes $[Ti_2Cl_{10}]^{2-}$, $[TiHfCl_{10}]^{2-}$ and $[Hf_2Cl_{10}]^{2-}$ by using two different functionals (B3LYP and B3PW91) and the LANL2DZ basis set. These combinations usually give good-quality results for geometries and energies of transition-metal compounds. The calculations included a frequency analysis, and the zero-point energy, thermal and entropy corrections to give the free energies at room temperature. According to these calculations, the mixed complex is favoured relative to the mixture of the two homometallic dinuclear species by 2.04 (B3LYP) and 1.99 (B3PW91) kcal mole$^{-1}$, corresponding to $K \approx 30$ for the above equilibrium. More precisely, the equilibrium would consist of 13% of each of the homometallic species and 74% of the dimetallic species for a Ti/Hf ratio of 1:1. This result is in qualitative agreement with the IR results. The optimized distances (Table 2) tend to be slightly long (cf. Table 1); the B3PW91 results are closer to the experimental observations. Interestingly, whereas the M–Cl distances in the TiHf compound are, as expected, shorter for Ti than for Hf when bonded to $Cl_{ax}$ and to $Cl_{eq}$, there is very little difference in the M–$Cl_{br}$ distances involving the two different metals. This is rationalized in the next paragraph.

A charge analysis (Table 3) was carried out on the B3PW91 results both at the Mulliken and at the NBO (Natural Bond Orbital) level. The latter is believed to be more descriptive for highly ionic and for weak interactions,[38] while the Mulliken analysis tends to overemphasize bond covalency. At both levels, it is clear that the Ti–Cl interactions are less polarized than the Hf–Cl interactions, as expected. The greatest difference is in the calculated charge for the bridging Cl atoms. For the TiHf compound, the calculated charges for the $Cl_{ax}$ and $Cl_{eq}$ atoms attached to each metal are rather close to the values of the same type of atoms in the corresponding monometallic species. The calculated charges on the $Cl_{br}$ atoms, on the other hand, are intermediate between those of the $Ti_2$ and $Hf_2$ compounds. The result is that the Ti–$Cl_{br}$ bond becomes more polarized (and consequently longer) in the mixed-metal complex rela-

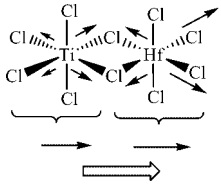
tive to the $Ti_2$ complex, whereas the Hf–$Cl_{br}$ bond becomes less polarized (and consequently shorter) in the mixed-metal complex relative to the $Hf_2$ complex. Conversely, the other Ti–Cl bonds become less polarized, and the Hf–Cl more polarized, in the mixed-metal system. This charge shift introduces a permanent dipole in the dianion (Scheme 2). The variation of the Ti–Cl bond polarity may affect the performance of the catalytic site for the ethylene polymerization process.



Scheme 2.

### Electrochemical Investigation

A dichloromethane solution of the $[NBzEt_3]_2[TiHfCl_{10}]$ salt was investigated by cyclic voltammetry, in comparison with the analogous study reported recently for $[Ti_2Cl_{10}]^{2-}$.[33] The results are shown in Figure 3. The mixed-metal dianion exhibits a broad irreversible peak with a maximum cathode current at ca. –0.9 V vs. ferrocene, whereas the $[Ti_2Cl_{10}]^{2-}$ dianion shows two overlapping waves (a peak at ca. –1.06 V with a shoulder at ca. –0.7 V). As expected, the $[Hf_2Cl_{10}]^{2-}$ species does not exhibit any reduction process in this potential range (an irreversible reduction takes place only below –2 V).

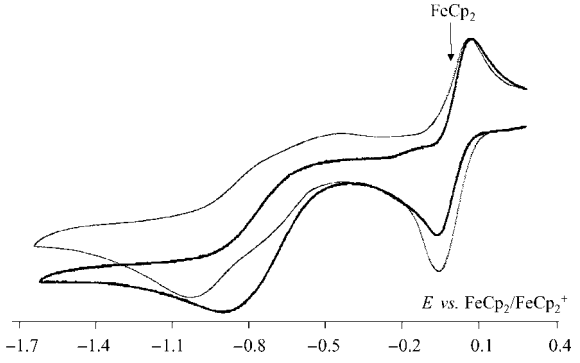


Figure 3. Cyclic voltammograms of $[NBzEt_3]_2[Ti_2Cl_{10}]$ (thinner line) and $[NBzEt_3]_2[TiHfCl_{10}]$ (thicker line). Solvent: $CH_2Cl_2$.

The two processes of the $[Ti_2Cl_{10}]^{2-}$ solution were shown to be related to the existence of the ligand redistribution equilibrium between the dianionic complex and complexes $[Ti_2Cl_9]^-$ and $[Ti_2Cl_{11}]^{3-}$ [Equation (5)]. Although the equilibrium is shifted to the left hand side in solution (as shown by IR spectroscopy), the easier reduction of the $[Ti_2Cl_9]^-$ ion (which is responsible for the shoulder at –0.7 V), coupled to the fast ligand redistribution process, shifts the equilibrium to the right in the diffusion layer. Thus, the peak with maximum cathode current at ca. –1.06 V is due to the reduction of the $[Ti_2Cl_{11}]^{3-}$ species. It is logical that the reduction of the latter species is placed at a more negative potential, since the positive charge density on the Ti centres is lower. The shape and position of the reduction wave for the mixed-metal dianion shows that it may correspond to a species whose charge density is similar to that of $[Ti_2Cl_9]^-$, whereas there is definitely no activity in the characteristic region of $[Ti_2Cl_{11}]^{3-}$. It is therefore rather logical to formulate the hypothesis of a similar chloride redistribution equilibrium for the mixed-metal dianion. However, because of the greater Lewis acidity of $Hf^{IV}$ relative to $Ti^{IV}$, the former metal centre will preferentially form the chloride-richer species while $Ti^{IV}$ will preferentially form the chloride-poorer species, as shown in Equation (6). Obviously, other species such as $[TiHfCl_9]^-$ may also be present in solution, given the complexity of the coupled equilibria, and contribute to the shape of the observed reduction wave.

$$2\,[Ti_2Cl_{10}]^{2-} \rightleftarrows [Ti_2Cl_9]^- + [Ti_2Cl_{11}]^{3-} \quad (5)$$

$$2\,[TiHfCl_{10}]^{2-} \rightleftarrows [Ti_2Cl_9]^- + [Hf_2Cl_{11}]^{3-} \quad (6)$$

### Structure of a Partial Hydrolysis Product

With the objective of obtaining a nondisordered solid-state structure of the mixed-metal dianion, we attempted to grow crystals of the $PPN^+$ salt. The crystals that slowly formed, however, turned out to be $[PPN]_2[Cl_3Ti(\mu\text{-}O)HfCl_5]$. The structure of the oxo-bridged dianion is shown in Figure 4. The two metal centres are bridged by a single oxygen atom and possess different coordination geometries, tetrahedral with three terminal Cl atoms and the bridging O atom for titanium, octahedral with five terminal Cl atoms and the bridging O atom for hafnium. Therefore, the two metal centres are not disordered in this structure. The formation of this compound can be explained by a partial hydrolysis of the decachlorido mixed-metal dianion, as shown in Equation (7). The possibility that it is obtained directly from a $HfOCl_2$ impurity in $HfCl_4$ is unlikely, since the synthesis was conducted in $SOCl_2$ as solvent (see Experimental Section). Unfortunately, we did not obtain a sufficient amount of this product to carry out an analytical and spectroscopic characterization. Its formation, however, validates the notion that well-defined mixed-metal titanium-hafnium complexes may be formed with this strategy. Given the high oxophilicity of both $Ti^{IV}$ and $Hf^{IV}$ chlorides, it is quite possible that Ziegler–Natta catalyst precursors contain oxo-bridged dimetallic units in the bulk or on the surface, for which this complex may represent a suitable structural model. Even though partial alkylation of the catalyst occurs in the presence of the aluminium alkyl activator, the metal–chloride bonds are expected to be alkylated preferentially, and oxo ligands may be present in the active form of the catalyst.

$$[TiHfCl_{10}]^{2-} + H_2O \rightarrow [TiHf(O)Cl_8]^{2-} + 2\,HCl \quad (7)$$

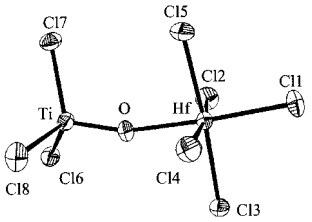

Figure 4. ORTEP view of the $[Cl_3Ti(\mu\text{-}O)HfCl_5]^{2-}$ ion.

Relevant bond lengths and angles for the $[Cl_3Ti(\mu\text{-}O)HfCl_5]^{2-}$ ion are collected in Table 4. The most interesting feature is the marked asymmetry of the oxo bridge, the Ti–O distance [1.655(4) Å] being much shorter than the Hf–O distance [2.142(3) Å]. The former is typical for terminal $Ti^{IV}O$ bond lengths, of which 25 were found in the Cambridge Structural Database (CSD), with an average value of 1.65(5) Å. There are also 7 structures in the CSD containing a Ti=O···M moiety (M = any metal). After discarding one of them (KATPUQ01), whose extremely long (> 2.1 Å) Ti=O bond length suggests a possible crystallographic problem, the remaining six bonds give an average length of 1.69(3) Å. On the other hand, the Hf–O distance is much longer than that in terminal Hf=O moieties [only one example, $(C_5Me_4Et)Hf(O)(py)$,[39] with a distance of 1.826(9) Å, has apparently been reported] and even longer than the distance of typical covalent single Hf–O bonds. For these bonds, an average of 1.97(4) Å is calculated from 148 distances found in the CSD (after excluding the values for π-delocalized donors such as carboxylates and acetylacetonates, which are significantly longer). An example where an oxygen atom bridges two metal atoms is $Cp_2(Me)Hf\text{–}O\text{–}Hf(Me)Cp_2$, with Hf–O distances of 1.941(3) Å.[40] The Hf–O distance in our ion is much closer to that of dative bonds established by neutral donors, as for instance in complex $[Hf(DMSO)_8]^{4+}$ [(2.160(12) Å].[41] Therefore, the $[Cl_3Ti(\mu\text{-}O)HfCl_5]^{2-}$ ion is best interpreted as resulting from the coordination of the hypothetical $[Ti(=O)Cl_3]^-$ anion, via a lone pair of the oxo ligand, to a $[HfCl_5]^-$ anion. Interestingly, $[TiOCl_3]^-$ does not appear to exist as an isolated species, whereas its chloride adducts $[TiOCl_4]^{2-}$ and $[TiOCl_5]^{3-}$ have been reported,[31,42–45] the former being structurally characterized as the $NEt_4^+$ salt (Ti–O: 1.79 Å).[46] A substructure search in the CSD for the four-coordinate $Cl_3TiO$ moiety only reveals neutral compounds where the oxygen atom is further bonded to an alkyl, aryl or silyl group.

The Ti–Cl distances in the $[Cl_3Ti(\mu\text{-}O)HfCl_5]^{2-}$ ion average 2.232(5) Å; they are significantly longer than the average of all Ti–Cl distances in four-coordinate $Cl_3TiX$ structures from the CSD [2.18(3) Å over 150 distances]. This is certainly related to the negative charge in this complex (formally –1 on the Ti atom), while all the literature examples are neutral complexes. The average Ti–Cl distance in the above-mentioned $[TiOCl_4]^{2-}$ ion is even longer, 2.33 Å.[46] The Hf–Cl distance *trans* to the Hf–O bond (2.4074(13) Å] is significantly shorter than the other four Hf–Cl distances, which average 2.442(9) Å. The latter compare very well with the average of all Hf–Cl distances found in all six-coordinate $Cl_5HfX$ structures from the CSD [2.44(2) Å over 55 distances]. This is not surprising, since all CSD complexes are also anionic (monoanions with X = thf or the dinuclear $Hf_2Cl_{10}^{2-}$, or dianions of $HfCl_6^{2-}$). As expected, the distance is shorter [average of 2.302(9) Å] in the cationic complex $[(\eta^6\text{-}C_6Me_6)HfCl_3]^+$,[30] which is also formally six-coordinate from the electronic point of view. The shorter Hf–Cl1 distance in $[Cl_3Ti(\mu\text{-}O)HfCl_5]^{2-}$ indicates that the oxygen donor $[TiOCl_3]^-$ "ligand" exerts a weaker *trans* influence relative to the chloride ion.

## Conclusions

This work has explored the existence and relative stability of mixed-metal Ti–Hf chloridometallate complexes, focusing on the edge-sharing bioctahedral system, $[MM'Cl_{10}]^{2-}$ (M, M′ = Ti, Hf). We have provided evidence (by a combination of low-energy IR, X-ray crystallography, DFT calculations and cyclic voltammetry) that the mixed-metal system $[TiHfCl_{10}]^{2-}$ does exist and that it is thermodynamically more stable by a small amount than the equivalent 1:1 mixture of the homodinuclear complexes, $[Ti_2Cl_{10}]^{2-}$ and $[Hf_2Cl_{10}]^{2-}$. The comparison with the previously reported electrochemical behaviour of $[Ti_2Cl_{10}]^{2-}$ suggests a stronger preference for the $Ti_2$ complex to lose one $Cl^-$ ligand, yielding $[Ti_2Cl_9]^-$, and a corresponding stronger preference for the $Hf_2$ complex to add one more $Cl^-$ ligand, yielding $[Hf_2Cl_{11}]^{3-}$. A partial hydrolysis product obtained from the above mixture is an unprecedented mixed Ti–Hf chloridometallate ion, $[Cl_3Ti(\mu\text{-}O)HfCl_5]^{2-}$, the structure of which is best interpreted as an octahedral $[HfCl_5X]^{2-}$ complex where X is the previously unknown tetrahedral $[Cl_3Ti(O)]^-$ ion. The oxygen atom that bridges the two metals is doubly bonded to the Ti centre and donates a lone pair to the Hf centre.

## Experimental Section

**General Procedures:** All preparations and manipulations were carried out with Schlenk techniques under an oxygen-free argon atmo-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sphere. All glassware was oven-dried at 120 °C. For particular applications (see Results and Discussion) it was silylated by being washed with a $CHCl_3$ solution of $Me_3SiCl$ (10% v/v). Solvents were dried by standard procedures and distilled under dinitrogen prior to use.

**Materials:** $CH_2Cl_2$ was purified by reflux and distillation over $P_4O_{10}$ under argon. Pentane was purified by reflux over sodium benzophenone ketyl and distilled under argon. $TiCl_3$, $HfCl_4$ and the chloride salts triethylbenzylammonium chloride, $[NEt_3Bz]Cl$, and bis(triphenylphosphanyl)iminium chloride, [PPN]Cl, were purchased from Aldrich and used as received. Complexes $[NEt_3Bz]_2[Ti_2Cl_{10}]$ and $[PPN]_2[Ti_2Cl_{10}]$ were prepared as recently described.[33]

**Instrumentation:** The infrared spectra were recorded with a Bruker Vector 22 instrument equipped with a Globar (MIR) source. The solution spectra in the far-IR (480–300 $cm^{-1}$) region were obtained from $CH_2Cl_2$ solutions in polyethylene cells (0.5 mm path length). Cyclic voltammograms were recorded with an EG&G 362 potentiostat connected to a Macintosh computer through MacLab hardware/software. The electrochemical cell was fitted with an Ag/AgCl reference electrode, a platinum disk working electrode and a platinum wire counterelectrode. $[Bu_4N]PF_6$ (ca. 0.1 M) was used as supporting electrolyte in thf. All potentials are reported relative to the ferrocene standard, which was added to each solution and measured at the end of the experiments. Elemental analyses were carried out with a Fisons EA 1108 instrument by the analytical services of LSEO.

**Preparation of $[NEt_3Bz]_2[Hf_2Cl_{10}]$:** A Schlenk tube was charged with $HfCl_4$ (1.161 g, 3.62 mmol) and $[NEt_3Bz]Cl$ (0.826 g, 3.62 mmol). Thionyl chloride (10 mL) was added by syringe under magnetic stirring and the apparatus was connected to an oil bubbler. *Warning: The reaction between $SOCl_2$ and water (potentially present as a contaminant in the starting salts) produces toxic $SO_2$ and HCl; therefore, the reaction must be carried out under a well-ventilated fume hood.* A white suspension was observed. The reaction mixture was heated to 65 °C for 1 h in an oil bath and then cooled to room temperature. After stirring for 1 h at room temperature, pentane (20 mL) was added, causing the precipitation of the product as a white powder. After being filtered, the solid was washed with pentane and dried under vacuum overnight. Yield: 1.858 g (94%). $C_{26}H_{44}Cl_{10}Hf_2N_2$ (1096.14): calcd. C 28.5, H 4.0, N 2.6; found C 27.8, H 4.2, N 2.7.

**Preparation of $[PPN]_2[Hf_2Cl_{10}]$:** By following a procedure identical to that described above for $[NEt_3Bz]_2[Hf_2Cl_{10}]$, $[PPN]_2[Hf_2Cl_{10}]$ (3.292 g, 92%) was obtained starting from $HfCl_4$ (1.994 g, 6.23 mmol) and PPNCl (3.570 g, 6.23 mmol). $C_{72}H_{60}Cl_{10}Hf_2N_2P_4$ (1788.66): calcd. C 48.4, H 3.4, N 1.6; found C 48.1, H 3.4, N 1.8.

**Preparation of $[NEt_3Bz]_2[TiHfCl_{10}]$:** A Schlenk tube was charged with $HfCl_4$ (1.688 g, 5.27 mmol), $TiCl_3$ (0.809 g, 5.25 mmol) and $[NEt_3Bz]Cl$ (2.392 g, 10.50 mmol). Thionyl chloride (50 mL) was

**Preparation of $[PPN]_2[TiHfCl_{10}]$:** By following a procedure identical to that described above for $[NEt_3Bz]_2[TiHfCl_{10}]$, $[PPN]_2[TiHfCl_{10}]$ (2.463 g, 94%) was obtained starting from $HfCl_4$ (0.506 g, 1.58 mmol), $TiCl_3$ (0.244 g, 1.58 mmol) and PPNCl (1.816 g, 3.16 mmol). $C_{72}H_{60}Cl_{10}HfN_2P_4Ti$ (1658.03): calcd. C 52.2, H 3.6, N 1.7; found C 53.0, H 3.6, N 2.0.

**X-ray Diffraction Studies:** Intensity data for both compounds were collected with a Nonius Kappa CSD at 110 K. The structures were solved by a Patterson search program and refined with full-matrix least-squares methods based on $F^2$ (SHELXL-97)[47] with the aid of the WINGX program.[48] All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in their calculated positions and refined with a riding model. The $[Ti_xHf_{2-x}Cl_{10}]^{2-}$ dimetallic complex is located on a centre of inversion; as a consequence, the two metal atoms are disordered and occupy the same crystallographic position. Furthermore, the two metal atoms are not in a 1:1 ratio, the occupation factors converged to $m_1 = 0.685$ for the Ti atom and $m_2 = 1 - m_1$ for the Hf atom. A first attempt to refine independently both metallic positions lead to a nonrealistic result; therefore, the two positions and the anisotropic displacement parameters where constrained to be identical for both metallic centres. The molecules were drawn with ORTEP32.[49] Crystal data and refinement parameters are shown in Table 5.

CCDC-633154 and CCDC-633155 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Computational Details:** Calculations were carried out with the Gaussian 03 package[50] at the DFT level by means of either the B3LYP[51–53] or the B3PW91[54,55] functional and the LANL2DZ basis set.[56] All geometries were fully optimized without symmetry restrictions and were characterized as local minima of the potential energy surface (PES) by inspection of the sign of the second derivatives obtained from frequency calculations. The Gibbs free energies were obtained after correction for the ZPVE, PV and TS terms under the ideal gas approximation. The temperature used was 298.15 K.

# Electronic Structure of Linearly Coordinated EQ Complexes of the Type [$(N_3N)W(EQ)$] [$N_3N = N(CH_2CH_2NSiMe_3)_3$; E = P, As, Sb, Bi; Q = O, S, Se, Te]: A DFT Study

**Gábor Balázs,[a] Jennifer C. Green,*[a] and D. Michael P. Mingos*[b]**

**Keywords:** Bonding / Pnicogens / Chalcogens / Tungsten / Density functional calculations

Density functional theory (DFT) calculations were carried out on the terminal EQ complexes [$(N_3N)W(EQ)$] {$N_3N = N(CH_2CH_2NSiMe_3)_3$; E = P, As, Sb, Bi; Q = O, S, Se Te} to clarify the bonding situation within the linear $N_{ax}$–W–E–Q core. This unusual structural motif gives rise to a bonding arrangement in which the π-electron density is delocalised over the three atoms of the W–E–Q unit. Fragment calculations and natural bond order (NBO) data indicated that the σ-bonding component of the $N_{ax}$–W–E–Q unit comprises two occupied σ orbitals, while the π component of bonding comprises two sets of degenerate π orbitals. In general, the π orbitals of the $N_{ax}$–W–E–Q core are higher in energy compared to the σ orbitals. The phosphorus monoxide (EQ = PO) complexes provide an exception to this rule, with the 1π orbitals of the W–P–O core lower in energy than the σ orbitals. Generally, as the atomic number of either the pnicogen (E) or chalcogen (Q) atom increases the extent of σ-orbital delocalisation decreases, whereas the π-orbital delocalisation increases. Fractional bond orders and Wiberg bond indices were used to establish whether localisation of the π-electron density gives rise to a W–E or an E–Q double or triple bond. Both methods indicate a W–E as well as an E–Q double bond. The ionic nature of the complexes were analysed by inspection of the Hirschfeld charge distribution which shows only a moderate ionic character. Exceptions are the pnicogen monoxide complexes, which are more ionic.

## Introduction

Transition metal complexes of nitrogen monoxide (NO) underwent significant research in the early 1970s as a result of the wide range of bonding motifs that can be adopted by this versatile ligand. NO represented the fore-runner of a wider range of the pnicogen–chalcogen (E–Q) moieties bonding to a variety of transition metal fragments.[1] The coordination chemistries of the heavier EQ analogues (E = P, As, Sb, Bi; Q = O, S, Se, Te) remain relatively poorly studied. This is partly due to the unavailability of the free EQ ligands as well as to their poor coordinating abilities.[2] The majority of transition metal complexes bearing heavier EQ ligands contain PQ (Q = O, S, Se and Te) ligands that are coordinated to three metal centres in a $\mu_3$ fashion. Selected examples include [$\{Ni(C_5iPr_4H)\}_2W(CO)_4(\mu_3\text{-}PO)_2$],[3] [$\{Ru(CO)\}_3(\mu_3\text{-}PO)]^-[iPr_2NH_2]^+$[4] [$\{W(CO)_2Cp\}_3(\mu_3\text{-}PS)$],[5] [$\{Co(C_5tBu_2H_3)\}_3(\mu_3\text{-}PQ)_2$] (Q = O, S, Se),[6] [$\{Co(C_5tBu_2H_3)\}_3(\mu_3\text{-}PQ)(\mu_3\text{-}P)$] (Q = Se,[5] Te[6]), [$\{Ni(C_5iPr_4H)\}_2W(CO)_4(\mu_3\text{-}PS)_2$][7] and [$\{FeCp(CO)_2\}\{Fe_2(CO)_3Cp_2\}(\mu_3\text{-}PS)_2$].[8] The synthesis of such PQ-containing complexes is typically achieved by oxidation of the corresponding phosphido complex with the chalcogen (e.g. S, Se, Te) or a suitable chalcogen source (e.g. dimethyldioxirane, ethylene sulfide). Hydrolysis of a $\mu_3$-$P(NiPr_2)$ functional group has also been effective in preparation of the more polar PO complex [$\{Ru(CO)\}_3(\mu_3\text{-}PO)]^-[iPr_2NH_2]^+$.[4]

Synthesis of the terminal pnictido complexes [$(ArRN)_3Mo{\equiv}P$] [Ar = 3,5-$Me_2C_6H_3$, R = $C(CD_3)_2Me$][9] and [$(N_3N)W{\equiv}E$] [$N_3N{=}N(CH_2CH_2NSiMe_3)_3$; E = P,[10] As[11,12] and Sb[13]] presented clear opportunities for the preparation of transition metal complexes containing an $\eta^1$-coordinated EQ ligands. Indeed, Cummins et al. reported the isolation and characterisation of the PO [$(ArRN)_3Mo(PO)$][14] and PS [$(ArRN)_3Mo(PS)$][9,15] complexes, which were prepared by oxidation of the corresponding phosphido complex [$(ArRN)_3Mo{\equiv}P$] with dimethyldioxirane and sulfur, respectively. More recently, Scheer et al. reported preparation of the $\eta^1$-coordinated PS and AsS complexes [$(N_3N)W(ES)$] (E = P and As)[16] by oxidation of the terminal phosphido and arsenido complexes [$(N_3N)W{\equiv}E$] (E = P and As) with cyclohexene sulfide.

The bonding in the $\eta^1$-coordinated PS complexes was investigated by Frenking and Wagener who performed calculations on a series of model complexes of the type [$(NH_2)_3M(PS)$] and [$NH_3(NH_2)_3M(PS)$] (M = Mo, W). They proposed two Lewis formulae, one based on an NBO partitioning Scheme (**I**) and a second one based on Wiberg

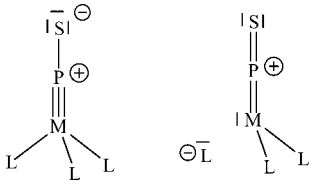
bond indices (**II**). Both resonance canonical forms represented as Lewis structures are depicted in Scheme 1.[18] The dissociation of an amido ligand from the metal atom in **II** makes that Lewis structure less likely. The electron count of complexes of the type $[NH_3(NH_2)_3M(EQ)]$ depend on whether the amido nitrogen atoms are one- or three-electron donors. Since the $a_2$ combination of the lone-pair orbitals of the three amido ligands does not have a symmetry match among the tungsten orbitals (the three amido nitrogen atoms effectively donate seven electrons altogether), it follows that complexes of the type $[NH_3(NH_2)_3M(EQ)]$ obey the 18-electron rule, and the complexes of the type $[(NH_2)_3M(PS)]$ are 16-electron species.



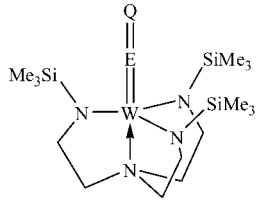
Scheme 1. Proposed Lewis structures of $[L_nM(PS)]$ complexes.[17]

Recently, we reported the results of calculations on $[(N_3N)W(ES)]$ $[N_3N=N(CH_2CH_2NSiMe_3)_3$; E = P, As and Sb].[16] Inclusion of the $Me_3Si$ substituents on the imido nitrogen atoms was important for achieving good agreement of our calculated geometries with structural parameters obtained from X-ray crystallographic analyses of these complexes. We assume this is due to the strong electron-donating properties of these substituents. Most significantly, our study demonstrated that π bonding in the W–E–Q unit can best be described as two three-centre four-electron bonds (3c-4e).[16] To further our understanding of the structural and electronic properties of $\eta^1$-coordinated EQ complexes, we have extended our analysis to the complete series of $[(N_3N)W(EQ)]$ complexes (E = P, As, Sb, Bi; Q = O, S, Se and Te). In this paper we analyse the structural trends and use several theoretical tools to gain insight into the important bonding features for the heavier EQ ligands.

## Results and Discussion

### Geometries and Binding Energies

Calculated geometries for complexes **1**–**4** were pseudo-$C_3$-symmetric with the $N_{ax}$–W–E–Q core aligned with the $C_3$ axis. Given the isostructural nature of these complexes, the optimised geometry of $[(N_3N)W(PO)]$ (**1a**) is depicted in Figure 1 as representative of this series. Selected bond lengths and angles for the calculated structures are provided in Table 1. Our benchmarks for the optimised structures are the complexes **1b** and **2b**, whose crystal structures were reported recently.[16] The calculated geometrical parameters for **1b** (P–S 1.94 Å; W–P 2.15 Å) and **2b** (As–S 2.05 Å; W–As 2.25 Å) compare excellently with the reported experimental values [E–S 1.9410(16) Å and 2.048(2) Å; W–E 2.1579(10) Å and 2.2557(8) Å for **1b** and **2b**, respectively].[16] The $N_{ax}$–W distances in **1b** (2.22 Å) and **2b** (2.21 Å) also agree favourably with the reported experimental values for these complexes [**1b** 2.217(3) Å; **2b** 2.214(6) Å].[16] Earlier calculations on the pnictido complexes $[(N_3N)W{\equiv}E]$ (E = P, As, Sb and Bi)[12,13] provided $N_{ax}$–W distances that were longer than those measured in single-crystal X-ray analysis of these complexes.



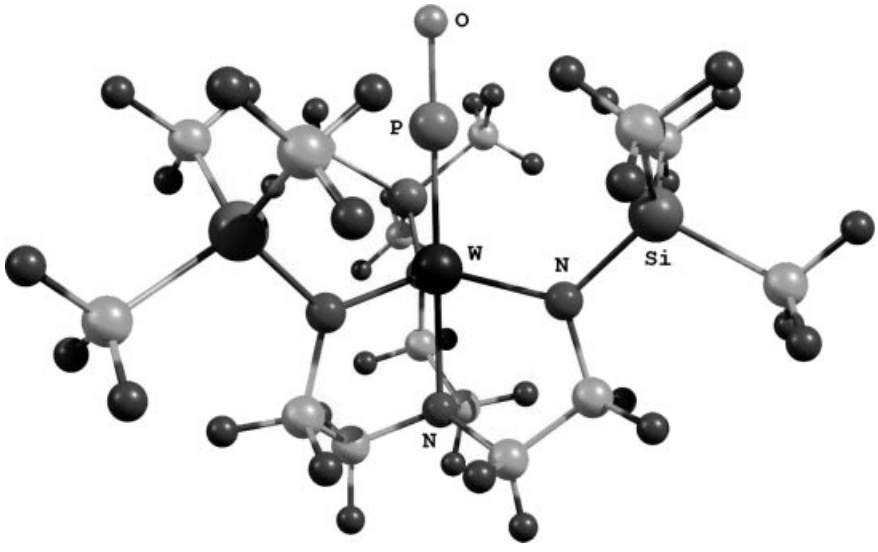


Figure 1. Calculated geometry of $[(N_3N)W(PO)]$ (**1a**).

Table 1. Calculated bond lengths [Å] and W–E and E–Q bond dissociation energies (BDE). The experimental bond lengths for **1b** and **2b** are given in parentheses.

| | E | Q | E–Q | W–E | $N_{ax}$–W | $N_{eq}$–W (av.) | W–E BDE [kJ/mol] | E–Q BDE [kJ/mol] |
|---|---|---|---|---|---|---|---|---|
| **1a** | P | O | 1.48 | 2.13 | 2.21 | 1.995 | –414.6 | –557.6 |
| **1b** | | S | 1.94 (1.940) | 2.15 (2.158) | 2.22 (2.217) | 1.98 (1.99) | –400.9 | –348.8 |
| **1c** | | Se | 2.08 | 2.15 | 2.23 | 1.98 | –399.6 | –286.6 |
| **1d** | | Te | 2.30 | 2.16 | 2.23 | 1.98 | –401.0 | –211.9 |
| **2a** | As | O | 1.64 | 2.24 | 2.20 | 1.99 | –340.9 | –438.5 |
| **2b** | | S | 2.05 (2.048) | 2.25 (2.256) | 2.21 (2.214) | 1.98 (1.99) | –338.9 | –301.6 |
| **2c** | | Se | 2.18 | 2.25 | 2.22 | 1.98 | –339.4 | –255.3 |
| **2d** | | Te | 2.39 | 2.26 | 2.22 | 1.98 | –340.2 | –196.5 |
| **3a** | Sb | O | 1.84 | 2.44 | 2.19 | 1.99 | –259.1 | –382.9 |
| **3b** | | S | 2.25 | 2.45 | 2.20 | 1.98 | –262.4 | –280.6 |
| **3c** | | Se | 2.36 | 2.46 | 2.20 | 1.98 | –258.9 | –244.3 |
| **3d** | | Te | 2.58 | 2.46 | 2.21 | 1.98 | –261.3 | –189.5 |
| **4a** | Bi | O | 1.94 | 2.53 | 2.19 | 1.99 | –203.7 | –326.1 |
| **4b** | | S | 2.34 | 2.53 | 2.19 | 1.99 | –206.8 | –248.4 |
| **4c** | | Se | 2.46 | 2.54 | 2.19 | 1.99 | –205.4 | –218.7 |
| **4d** | | Te | 2.662 | 2.54 | 2.19 | 1.99 | –207.6 | –172.6 |

The experimental $N_{ax}$–W distances in pnictido complexes [$(N_3N)W{\equiv}E$] [2.34(1) Å, 2.336(6) Å and 2.33(1) Å for E = P,[10] As[12] and Sb,[13] respectively] are longer than in the complexes **1**–**4**, showing the stronger *trans* influence of an E ligand compared to an EQ ligand. Although the variation of the $N_{ax}$–W distance with the nature of the EQ ligand is small a trend can clearly be observed. In general, the $N_{ax}$–W distance decreases as the atomic number of E increases, indicating that EQ ligands of the heavier pnicogens exhibit a weaker *trans* influence than their lighter analogues (Figure 2). In contrast, as the atomic number of Q increases the $N_{ax}$–W distance increases, indicating that EQ ligands of the heavier chalcogens exhibit a stronger *trans* influence.

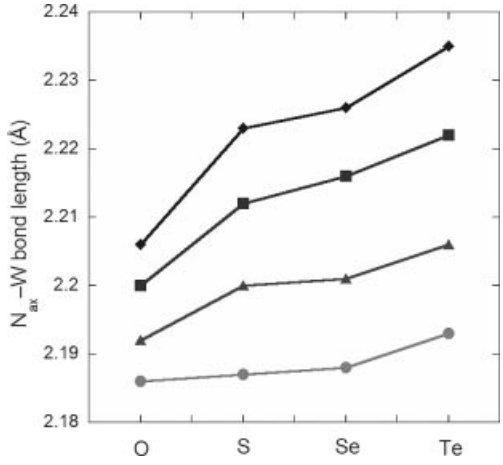

Figure 2. Variation of the $N_{ax}$–W distances [Å] with Q in complexes [$(N_3N)W(EQ)$] (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●.

The major differences in the structure upon moving from the lighter to the heavier congeners is observed in the W–E and E–Q distances. As expected, as the atomic number of E or Q increases, the E–Q and the W–E bond lengths also increase. The shortest E–Q distance is predicted for **1a** (1.48 Å) and the longest distance for **4d** (2.66 Å). The W–E distance increases only slightly for a particular E, as Q becomes heavier (Figure 3). This trend is observed when E = P, As and Sb, whereas for the BiQ complexes the W–Bi distance remains constant on going from Q = O to Te.

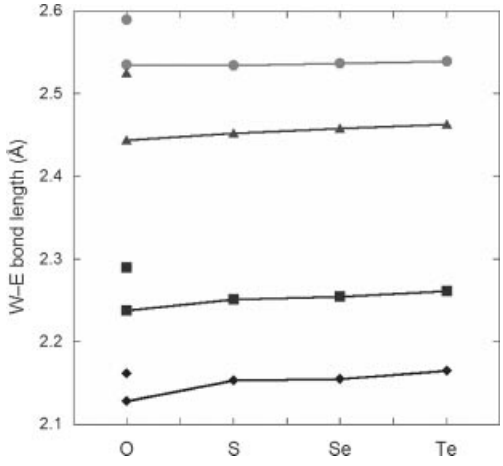

Figure 3. Variation of the W–E distances in complexes [$(N_3N)$-W(EQ)] (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●. The detached points correspond to the experimental W–E distances in the corresponding [$(N_3N)W{\equiv}E$] complexes for E = P, As and Sb and with the calculated distance for E = Bi.

Comparison of the W–E distances in the complexes **1**–**4** with the experimental W–E distances in the pnictido complexes [$(N_3N)W{\equiv}E$] (E = P, As, and Sb) [2.162(4) Å,[10] 2.2903(11) Å[12] and 2.5255(17) Å[13] for E = P, As and Sb, respectively] shows that, upon oxidation of the [$(N_3N)$-$W{\equiv}E$] complexes, the W–E distance became shorter, a phenomenon which is more accentuated for the heavier homologues of E (Figure 3). The exception is the phosphorus monotelluride complex **1d** in which the predicted W–P dis-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tance is slightly longer than the W–P distance in the corresponding phosphido complex. A similar shortening is observed for the experimental Mo–P distance in [$(ArRN)_3$-Mo(PQ)] (Q = O,[14] S[15]) where the Mo–P distances are 0.04 Å and 0.09 Å shorter than in the parent pnictido complex [$(ArRN)_3Mo{\equiv}P$].[9] The W–E distances in complexes **2**–**4** are comparable to the sum of the triple-bond covalent radii[19] of the corresponding elements, whereas in complexes **1** the W–E distances are slightly longer.

In order to gain insight into the strength of the E–Q bonding and stability of the complexes, the E–Q bond dissociation energies were calculated (Table 1). This shows that complexes **1**–**4** are stable with respect to the dissociation into the pnictido complexes and chalcogen. Furthermore, the E–Q bond dissociation energies present the expected periodic variation; an approximately linear decrease for a given pnicogen (E) upon going from Q = S to Te (Figure 4). The pnicogen monoxide complexes (**a**) exhibit a larger BDE than would be anticipated upon linear extrapolation of the BDE plots for complexes **b**–**d**. The stability of the complexes is also supported by the high HOMO–LUMO gap.

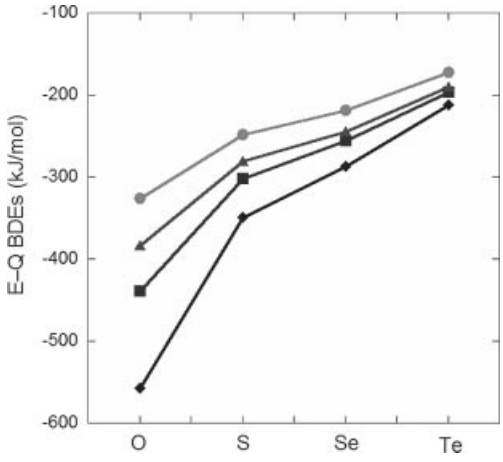

Figure 4. Variation of the E–Q bond dissociation energies [kJ/mol] in complexes [$(N_3N)W(EQ)$] (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●.

The E–Q BDEs also demonstrate a dependence on the atomic number of the pnicogen (E) for a given chalcogen (Q). For example, complexes **a** (Q = O), show a decrease in the BDE going from **1a** to **4a**.

To enable the comparison of the strength of the W–E bonding in the complexes **1**–**4** with the parent pnictido [$(N_3N)W{\equiv}E$] complexes, the W–E BDEs were calculated. Similarly to the E–Q BDEs, the W–E BDEs decrease as the atomic number of E increases for a particular Q, but are not influenced by the nature of Q (Table 1). The comparison of the W–E BDEs in complexes **1**–**4** (Table 1) and the pnictido complexes [$(N_3N)W{\equiv}E$] (481.9 kJ/mol, 429.0 kJ/mol, 333.4 kJ/mol and 293.3 kJ/mol for E = P, As, Sb and Bi, respectively)[13] shows that the strength of the W–E bonding is ca. 80–100 kJ/mol weaker in the complexes **1**–**4** than in the parent pnictido complexes. This shows that upon oxidation of the pnictido complexes the W–E triple bond is weakened thermodynamically.

## Bonding Analysis

The bonding arrangement in complexes **1**–**4** was further probed using fragment calculations and Natural Bond Orbital (NBO) analyses. Complexes **1**–**4** were separated into two fragments either by cleavage of the E–Q bond, to provide ($N_3N$)WE and Q fragments, or by cleavage of the W–E bond to provide ($N_3N$)W and EQ fragments. Contributions to the bonding in the [$(N_3N)W(EQ)$] complex can then be understood in terms of linear combinations of the fragment MOs. The bonding in the complex [($N_3N$)W-

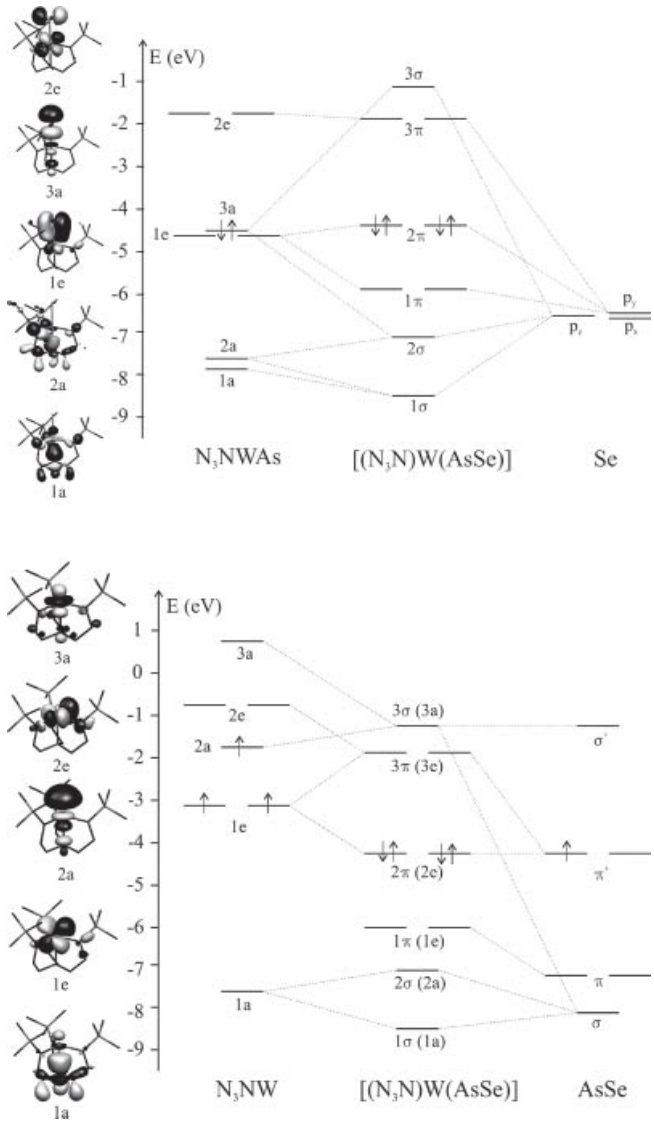

Figure 5. Molecular orbital interaction scheme for [$(N_3N)W(AsSe)$] (**2c**). The ($N_3N$)W and ($N_3N$)WAs fragment levels are labelled in $C_3$ symmetry and those of **2c** with σ and π symmetry with respect to the NWAs axis (the labels in parentheses are in $C_3$ symmetry). The relevant molecular orbitals of the ($N_3N$)W and ($N_3N$)WAs fragments are given on the left-hand side of the diagram.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(AsS)] (**2b**) was described elsewhere.[16] Here we describe the bonding in the complex [(N3N)W(AsSe)] (**2c**) as a representative example of this series of structures in order to give a basis for discussion of the trends in the bonding upon moving from the lighter EQ congeners to the heavier ones.

The molecular orbital interaction scheme for the complex **2c** is depicted in Figure 5. The (N3N)W and (N3N)WAs fragment levels are labelled in $C_3$ symmetry and those of the complex with σ and π symmetry (the labels in the $C_3$ symmetry are given in parentheses) with respect to the NWAs axis. The relevant molecular orbitals of the (N3N)W and (N3N)WAs fragments are given on the left-hand side of the diagram.

The results of a fragment analysis, in which the complex **2c** was separated into an Se and an (N3N)WAs fragment, shows that the $p_z$ orbital of Se mixes with the 1a orbitals of the (N3N)WAs fragment, containing contributions from $N_{ax}$ ($p_z$), As ($p_z$) and W ($d_{z^2}$ and s) to form two occupied molecular orbitals of σ symmetry (1σ and 2σ, Figures 5 and 6). 1σ is an all-in-phase combination, whereas 2σ is As–Se bonding, but has minimal W contribution and thus is W–As and W–$N_{ax}$ nonbonding. The $p_x$ and $p_y$ orbitals of the Se interact with the two degenerate π orbitals of the WAs unit (1e) to give two occupied sets of π orbitals (1π and 2π) from which the 1π set is bonding over all three atoms (W, As and Se) but with only a minor contribution from W. The 2π set is antibonding with respect to the AsSe and bonding with respect to the WAs unit (Figure 6).

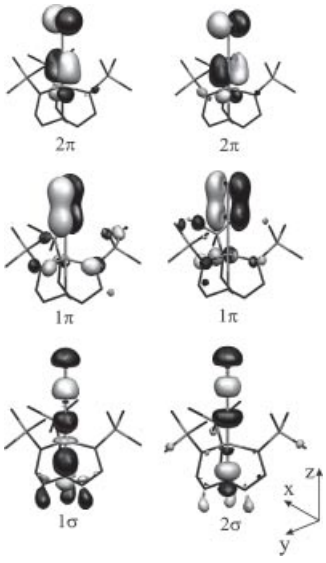

Figure 6. Isosurfaces of 2π (2e), 1π (1e) and 1σ (1a) and 2σ (2a) MO of [(N3N)W(AsSe)] (**2c**).

An analysis of the interaction of the AsSe fragment with the (N3N)W fragment shows that the π orbitals of the AsSe fragment increase slightly in energy due to the increasing charge, but do not mix significantly with the orbitals of the (N3N)W fragment, remaining localised as As–Se π bonds (forming 1π in the complex; Figures 5 and 6). In contrast, the π* orbitals of the AsSe fragment interact with the orbitals 1e of the (N3N)W fragment, containing mainly the tungsten $d_{yz}$ and $d_{xz}$ orbitals, respectively, to give a W–As π-bonding interaction (2π). The out-of-phase combination is unoccupied and forms the LUMO (3π). The 2π MO encapsulates back-donation of the tungsten atom to the AsSe ligand. Overall, the WAsSe π system is best described by two three-centre four-electron (3c-4e) bonds. This orbital interaction scheme describes qualitatively the bonding in complexes **1**–**4**.

## General Trends

Although the bonding in complexes **1**–**4** is similar, significant changes appear in the σ bonding going from the lighter to the heavier homologues. In the pnicogen monoxide complexes (**1a**–**4a**) the contribution of atomic orbitals of E to 1σ decreases as its atomic number increases (Figure 7). However, the most distinct changes were observed for the pnicogen monotelluride complexes **1d**–**4d** (Figure 8). In the PTe complex (**1d**) the 1σ is an extended bonding MO over the $N_{ax}$–W–E–Q core. In contrast to that the 1σ in the bismuth monotelluride complex (**4d**) is a localised $N_{ax}$–W bonding molecular orbital, having a strong 1a contribution

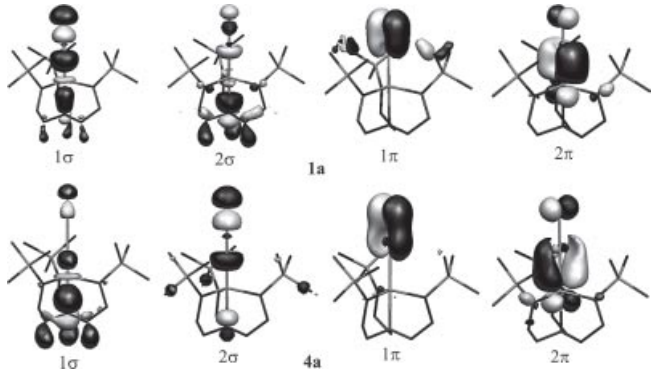

Figure 7. Isosurfaces of the 1σ, 2σ, 1π and 2π MOs of the phosphorus monoxide and bismuth monoxide complexes **1a** and **4a**, respectively. From the degenerated 1π and 2π sets only one orbital is represented.

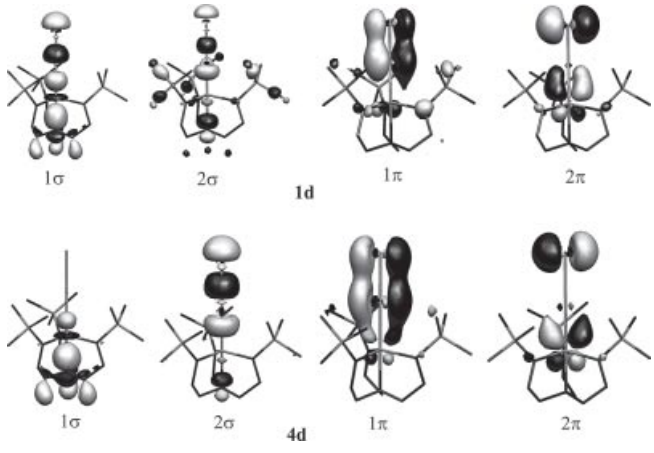

Figure 8. Isosurfaces of the 1σ, 2σ, 1π and 2π MOs of the phosphorus monotelluride complexes **1d** and **4d**, respectively. From the degenerate 1π and 2π sets only one orbital is represented.

(88.2%) of the $N_3NW$ fragment. The bonding in the arsenic and antimony montelluride complexes (**2d** and **3d**, respectively) constitute a transition between the two extremes (**1d** and **4d**). In **2d** and **3d** there is a mixing of the ETe (E = As, Sb) fragment σ orbital with $(N_3N)W$ fragment orbitals containing Si and C p-orbital contributions. A comparative energy level diagram is given in Figure 9. For 2σ the opposite trend than for 1σ was observed, but the changes are not so accentuated. Generally, as the atomic number of E increases, its contribution to 2σ increases. Also, the contribution of the EQ fragment σ orbital to 2σ increases as the atomic number of either E or Q increases. This leads to a localised E–Q bonding MO.

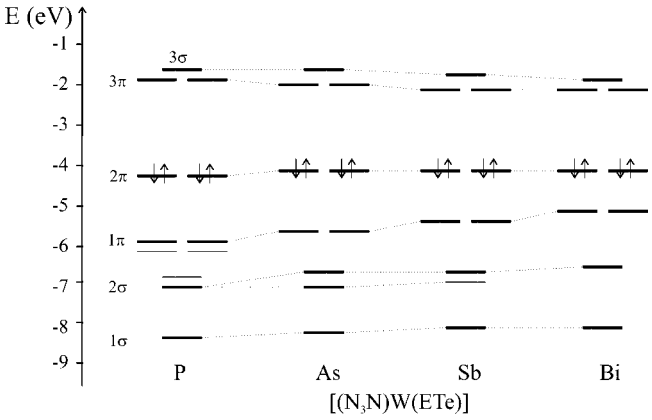

Figure 9. Comparative MO energy level diagram for the pnictido monotelluride complexes $[(N_3N)W(ETe)]$ (**1d**–**4d**). The energy levels marked with thin lines ("ghost" levels) represent combinations of the ETe fragment σ or π orbitals with energetically close-lying orbitals of the $(N_3N)W$ fragment localised on the $N_3N$ ligand. The contribution of the ETe fragment orbitals to the "ghost" levels is relatively small, except for E = As.

The nature of the 1σ MO can explain the relative strength of the *trans* influence of the EQ ligands. The complexes with an extended 1σ MO over the $N_{ax}$–W–E–Q core, such as the phosphorus monotelluride complex (**1d**) have a stronger *trans* influence than the complexes with 1σ localised on $N_{ax}$–W (Figures 2 and 8). However, the *trans* influence of the EQ ligands in complexes **1**–**4** (Figure 2) can easily be rationalised in terms of the interaction of the $(N_3N)W$ and EQ fragments σ-type orbitals. The stronger the interaction of the EQ σ orbital with the 1a orbital of the $(N_3N)W$ fragment (Figure 5) the weaker the $N_{ax}$–W orbital interaction. Since the energy of the 1a orbital of the relaxed $(N_3N)W$ fragment does not change, the *trans* influence will be determined by the relative energy of the EQ fragment σ orbitals. For example, in the case of the PQ complexes (**1**) the energy difference between the σ orbital of the PQ fragments varies strongly between the PO and PTe ($\Delta E$ = 1.793 eV), leading to a variation in the mixing with the $(N_3N)W$ fragment 1a orbital. This variation affects strongly the $N_{ax}$–W distances and hence leads to a variation in the *trans* influence of the different PQ ligands. In contrast, in the BiQ complexes (**4**) the σ orbitals of the BiQ fragments lie energetically close to each other (overall variation in energy $\Delta E$ = 0.616 eV) and therefore the variation in the *trans* influence of the BiQ ligands is much lower.

The analysis of the π bonding in the pnicogen monoxide complexes **1a**–**4a** (Figure 10) shows that the relative energy of the 1π set increases considerably as the atomic number of E increases, whereas the 2π set increases and the 3π set decreases only slightly in energy. The more pronounced increase in the energy of the 1π set going from E = P to As (**1a** to **2a**) is not unexpected if we consider that it contains a higher contribution of the EO fragment π orbitals (69.2, 73.8, 86.8 and 86.7% for E = P, As, Sb and Bi, respectively), as well as a high energy difference of the PO and EO (E = As, Sb and Bi) fragments π orbitals. The consequence of the low energy of the PO fragment π orbital is that in the phosphorus monoxide complex (**1a**) the 1π set is lower in energy than 2σ. A similar orbital energy ordering as for **1a** was reported by Carty et al. for the model complex $[(H_2N)_3Mo(PO)]$.[20] In the EQ complexes **b**, **c** and **d** a similar increase in energy of 1π and 2π set and a decrease in energy of 3π set occurs upon increasing the atomic number of E.

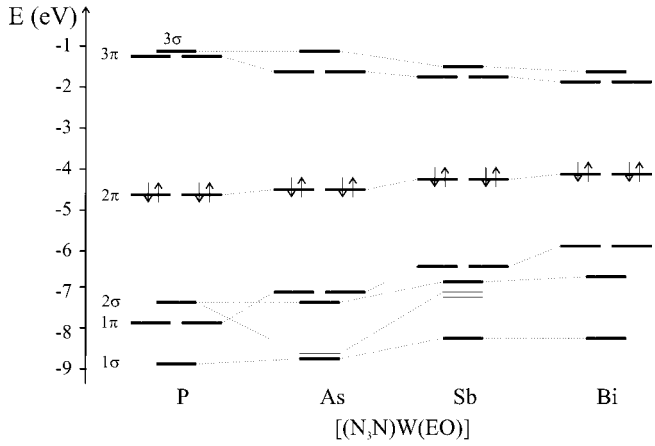

Figure 10. Comparative MO energy level diagram for the pnicogen monoxide complexes $[(N_3N)W(EO)]$ (**1a**–**4a**). The energy levels marked with thin lines ("ghost" levels) represent combination of the EO fragment σ orbitals with energetically close-lying orbitals of the $(N_3N)W$ fragment localised on the $N_3N$ ligand. The contribution of the EO fragment orbitals to the "ghost" levels is relatively small.

Apart from the changes in the energy of the 1π set upon increasing the atomic number of E or Q, changes in the extent of its delocalisation are also apparent. The delocalisation is more accentuated for the heavier congeners (Figures 7 and 8). As the atomic number of the pnicogen E increases, the contribution of the $(N_3N)W$ fragment (1e orbital of the fragment) to the 1π set also increases. Since the 1π set is an in-phase combination over all three atoms (W, E and Q), that leads to a stronger delocalisation of 1π. It is noteworthy, that in phosphorus monotelluride complex **1d** the π set of the PTe fragment mixes not only with the 1e set of the $N_3NW$ fragment to give the 1π set, but also mixes slightly with other orbitals of the $N_3NW$ fragment (containing mainly C, H and Si contributions). That mixing decreases as E becomes heavier so that in the arsenic monotel-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

luride complex **2d** only the 1π set contains considerable AsTe π contribution. Changes appears also in the 2π set, which represents the back-bonding of tungsten to the EQ ligand moving from the lighter to the heavier congeners. As the atomic number of E increases, its contribution to the 2π set decreases. That has the effect that 2π becomes permanently weaker bonding (Figure 8). The nature of Q has a similar effect to the nature of E on the 1π and 2π set MOs. Overall, the changes in the π bonding in the complexes **1**–**4** are similar to those in the σ-bonding mainfold; however, they progress in opposite directions.

Based on the fragment calculations we have determined the overall W–E fractional bond order by considering the $(N_3N)$WE fragment 1e orbitals as W–E bonding, the 2e as W–E antibonding and the 3a orbital as bonding and considering the fragment occupation in the molecule. Similarly, the E–Q fractional bond order can be calculated by considering the occupation of the π, π*, σ and σ* orbitals of the EQ fragment in the complex. Furthermore, by considering the occupations of the fragment σ-type orbitals or π-type orbitals the fractional bond order can be split into a σ- and a π-contribution term. The W–E and E–Q fractional bond orders as well as its σ and π components are summarised in Table 2.

Table 2. Fractional W–E and E–Q bond orders in complexes $[(N_3N)W(EQ)]$ (**1**–**4**).

| | E | W–E | E–Q | W–E | | E–Q | |
|---|---|---|---|---|---|---|---|
| | | | | σ | π | σ | π |
| | | | | Q = O | | | |
| **1a** | P | 2.12 | 2.07 | 0.35 | 1.77 | 0.88 | 1.19 |
| **2a** | As | 2.09 | 1.97 | 0.34 | 1.75 | 0.92 | 1.05 |
| **3a** | Sb | 2.12 | 2.13 | 0.34 | 1.79 | 0.82 | 1.31 |
| **4a** | Bi | 2.14 | 2.18 | 0.35 | 1.79 | 0.87 | 1.31 |
| | | | | Q = S | | | |
| **1b** | P | 2.22 | 2.03 | 0.50 | 1.73 | 0.86 | 1.17 |
| **2b** | As | 2.24 | 1.83 | 0.49 | 1.75 | 0.84 | 0.99 |
| **3b** | Sb | 2.20 | 2.12 | 0.46 | 1.74 | 0.83 | 1.29 |
| **4b** | Bi | 2.23 | 2.10 | 0.47 | 1.76 | 0.88 | 1.22 |
| | | | | Q = Se | | | |
| **1c** | P | 2.24 | 1.98 | 0.52 | 1.72 | 0.87 | 1.11 |
| **2c** | As | 2.26 | 1.82 | 0.50 | 1.76 | 0.84 | 0.98 |
| **3c** | Sb | 2.23 | 2.09 | 0.48 | 1.75 | 0.84 | 1.25 |
| **4c** | Bi | 2.26 | 2.08 | 0.50 | 1.76 | 0.89 | 1.19 |
| | | | | Q = Te | | | |
| **1d** | P | 2.32 | 1.92 | 0.59 | 1.73 | 0.81 | 1.11 |
| **2d** | As | 2.33 | 1.73 | 0.58 | 1.75 | 0.74 | 0.97 |
| **3d** | Sb | 2.28 | 2.05 | 0.55 | 1.73 | 0.84 | 1.21 |
| **4d** | Bi | 2.30 | 2.06 | 0.56 | 1.74 | 0.88 | 1.18 |

From Table 2 it may be seen, that the W–E fractional bond orders are lower for the pnicogen monoxide complexes (**1a**–**4a**) than for the complexes of the **b**, **c** or **d** series. For a particular Q the W–E fractional bond order can be considered to be constant within the standard errors. However, as the atomic number of Q increases, for a particular E the fractional bond order increases slightly (Figure 11). The E–Q fractional bond orders do not vary strongly between the complexes **1**–**4**. They increase slightly for a particular Q on going from P to Bi, this being in accordance with the decrease of the tungsten back-donation to the EQ ligand. For a particular E the E–Q fractional bond order decreases on going from O to Te (Figure 12). It is noteworthy that the As–Q fractional bond orders are generally lower, for which the low oxidation ability of As is responsible.

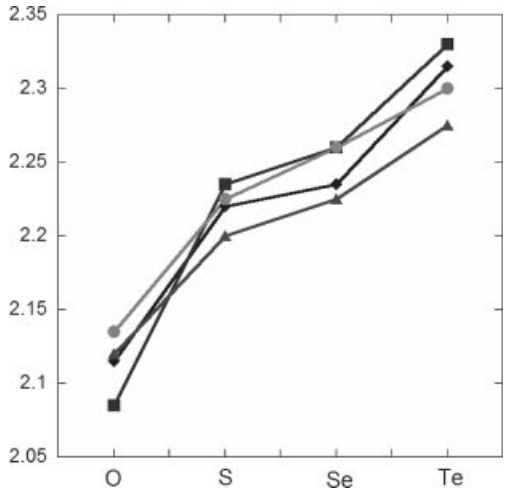

Figure 11. Variation of the W–E fractional bond orders with Q in complexes $[(N_3N)W(EQ)]$ (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●.

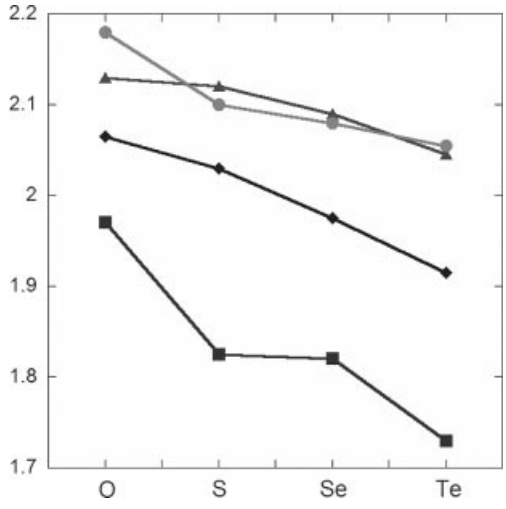

Figure 12. Variation of the E–Q fractional bond orders in complexes $[(N_3N)W(EQ)]$ (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●.

To determine whether the σ and π components of the W–E bond order go in opposite directions, and to obtain insight into the strengths of the σ- and π-bonding ratio, the fractional bond orders were split into their σ and π components (Table 2). The inspection of the σ contributions to the bond orders reveals that the σ part is responsible for the low W–E bond order in the phosphorus monoxide complexes **1a**–**4a**. This increases slightly for a particular E by going from O to Te (Figure 13), while for a particular Q (Q = S, Se and Te) it decreases slightly as the atomic number of E increases. In the pnictido monoxide complexes

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the σ component of the W–E fractional bond order stays approximately constant as the atomic number of E increases.

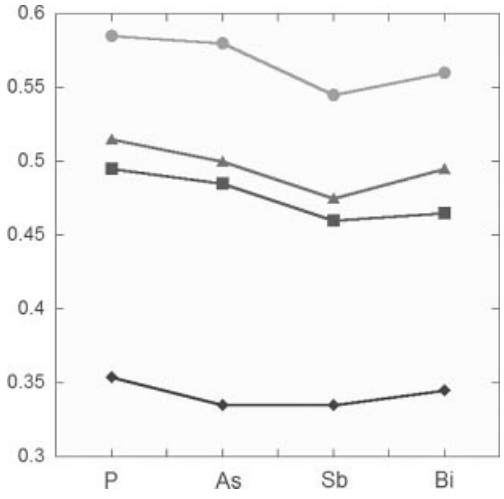

Figure 13. Variation of the σ component of the W–E fractional bond order with E in complexes [$(N_3N)W(EQ)$] (**1**–**4**). Legend: O = ♦, S = ■, Se = ▲ and Te = ●.

The π components of the W–E fractional bond order are not affected by the nature of Q for a particular E and stay essentially constant. Instead, for a particular Q the W–E fractional bond order increases slightly moving from P to Bi. The σ component of the E–Q, as judged by the fractional bond order, is not influenced by either the nature of E or Q, remaining constant. In contrast, the π component of the E–Q bond shows a decrease for a particular E as the atomic number of Q increases and an increase for a particular Q as the atomic number of E increases (Figure 14). The π component of the As–Q fractional bond orders are lower compared with the other complexes, confirming the lower oxidising ability of the arsenic.

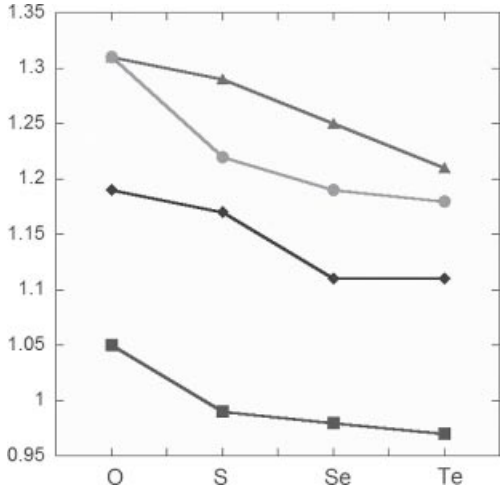

Figure 14. Variation of the π component of the E–Q fractional bond order with Q in complexes [$(N_3N)W(EQ)$] (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●.

The relative small variation of the fractional bond orders does not indicate that the bond strength stays constant. The strength of the bonding or antibonding of the molecular orbitals is not explicitly incorporated in this model and as shown in Table 1 the bond strengths decrease with atomic number.

The relative composition of the σ and π components to the fractional bond order was also investigated. The W–E and the E–Q bonds show a very different σ and π composition. Whereas in the W–E bond σ/π ratio (ca. 1:5 for the EQ complexes and 1:3.6 for the complexes of the series **b**, **c** and **d**) is relatively low, the σ/π ratio of the E–Q bond is much higher (1:1.4).

To enable the comparison of the results obtained with the literature data, we have calculated the Wiberg bond indices (WBI)[21] for the W–E and E–Q bonds of the complexes **1**–**4** (Table 3). Generally, the WBI either of the W–E and E–Q bonds are lower than the corresponding fractional bond orders, but that is compensated by adding a W–Q bond index of which the magnitude varies between 0.3 and 0.4. Similar WBIs were reported for [$NH_3(NH_2)_3W(PS)$] (W–P 1.89 and P–S 1.59). For the W–E triple bond in the pnictido complexes [$(N_3N)W{\equiv}E$] (2.38, 2.35, 2.28 and 2.27 for E = P, As, Sb and Bi, respectively)[13] and [$(MeO)_3W{\equiv}E$] (2.56, 2.55, 2.54 and 2.54 for E = P, As, Sb and Bi, respectively) higher WBI were reported.[22]

Table 3. Wiberg bond indices for the W–E and E–Q bonds in complexes [$(N_3N)W(EQ)$] (**1**–**4**).

| | E | W–E | E–Q | W–Q |
|---|---|---|---|---|
| | | Q = O | | |
| **1a** | P | 1.83 | 1.34 | 0.30 |
| **2a** | As | 1.80 | 1.30 | 0.30 |
| **3a** | Sb | 1.70 | 1.20 | 0.28 |
| **4a** | Bi | 1.61 | 1.17 | 0.30 |
| | | Q = S | | |
| **1b** | P | 1.79 | 1.54 | 0.41 |
| **2b** | As | 1.79 | 1.49 | 0.39 |
| **3b** | Sb | 1.70 | 1.43 | 0.35 |
| **4b** | Bi | 1.62 | 1.39 | 0.35 |
| | | Q = Se | | |
| **1c** | P | 1.81 | 1.52 | 0.43 |
| **2c** | As | 1.79 | 1.48 | 0.41 |
| **3c** | Sb | 1.67 | 1.44 | 0.37 |
| **4c** | Bi | 1.59 | 1.41 | 0.37 |
| | | Q = Te | | |
| **1d** | P | 1.81 | 1.44 | 0.43 |
| **2d** | As | 1.79 | 1.43 | 0.41 |
| **3d** | Sb | 1.73 | 1.42 | 0.38 |
| **4d** | Bi | 1.64 | 1.42 | 0.38 |

In general, the W–E WBI decreases as the atomic number of E increases for a particular Q. The W–E WBI is not influenced by the nature of Q for a particular E and remains constant in the series. Also, the E–Q WIB decreases as the atomic number of E increases for a particular Q, but for the series **b**, **c** and **d** it is lower in magnitude then the decrease of the W–E WBI. For a particular E by moving from S to Te only a slight decrease of the E–Q WIB is observed. The WBI for the pnicogen monoxide complexes (**a**) are ca. 0.2 lower than for the other EQ complexes (**b**, **c**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and **d**). This is probably due to the higher ionicity of the pnicogen monoxide complexes.

To evaluate the ionic character of the complexes **1**–**4** we have analysed the Hirshfeld charge distribution (Table 4).[23,24] This shows that the equatorial nitrogen atoms of the amido ($N_3N$) ligands are negatively charged (–0.23), whereas the axial nitrogen atom is almost neutral (varies between 0 to –0.01) and both are not influenced by the nature of the EQ ligand. The positive charge on the tungsten atom is only slightly influenced by the nature of the EQ ligand (it varies between 0.33 and 0.40). As the atomic number of Q increases for a particular E the charge on the tungsten atom increases but it decreases as the atomic number of E increases for a particular Q (Figure 15). The charges on the pnicogen atom (E) vary between 0 and 0.34 for the PTe and BiO complexes, respectively (**1d** and **4a**, respectively), indicating a relatively strong variation (Table 4). Similarly, the negative charge on the chalcogen atoms also varies relatively strongly between the two extremes –0.12 and –0.44 for **1d** and **4a**, respectively. Generally, for a particular E the charges on either E and Q decrease as Q become heavier, while for a particular Q the charges on either E and Q increase as E becomes heavier (Figure 16). The Hirshfeld charge analysis shows that the complexes **b**–**d** are only moderately charged, while the pnicogen monoxide complexes (**a**) are more polar.

Table 4. Selected Hirshfeld charges in complexes [($N_3N$)W(EQ)] (**1**–**4**).

| | E | W | E | Q |
|---|---|---|---|---|
| | | Q = O | | |
| **1a** | P | 0.36 | 0.17 | –0.31 |
| **2a** | As | 0.36 | 0.21 | –0.35 |
| **3a** | Sb | 0.33 | 0.32 | –0.42 |
| **4a** | Bi | 0.33 | 0.34 | –0.44 |
| | | Q = S | | |
| **1b** | P | 0.38 | 0.05 | –0.18 |
| **2b** | As | 0.38 | 0.10 | –0.22 |
| **3b** | Sb | 0.35 | 0.22 | –0.30 |
| **4b** | Bi | 0.34 | 0.25 | –0.32 |
| | | Q = Se | | |
| **1c** | P | 0.39 | 0.03 | –0.15 |
| **2c** | As | 0.39 | 0.08 | –0.20 |
| **3c** | Sb | 0.35 | 0.19 | –0.27 |
| **4c** | Bi | 0.34 | 0.22 | –0.30 |
| | | Q = Te | | |
| **1d** | P | 0.40 | 0.00 | –0.12 |
| **2d** | As | 0.39 | 0.04 | –0.16 |
| **3d** | Sb | 0.36 | 0.15 | –0.22 |
| **4d** | Bi | 0.35 | 0.18 | –0.25 |

One might expect that the decrease of the W–E bond strength (BDEs in Table 1) would be accompanied by an increase of the W–E distance. However, in the complexes **1**–**4** the W–E distances are shorter (except for **1d**) than in the pnictido complexes [($N_3N$)W≡E], although the W–E BDEs are lower. This can be explained by the different hybridisation of the pnicogens in the two types of complexes. In the complexes **1**–**4** the pnicogen atom in the σ bonding is almost sp-hybridised ($sp^{0.5–0.7}$), while in the pnictido complexes it is $sp^{3.30}$- (E = P) to $sp^{6.06}$-hybridised (E = Bi).[13]

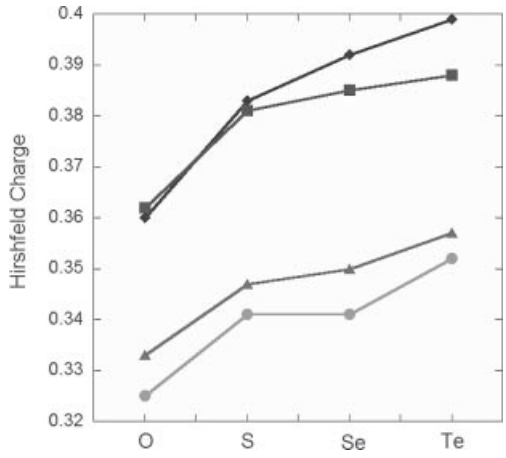

Figure 15. Variation of the Hirshfeld charges on tungsten in complexes [($N_3N$)W(EQ)] (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●.

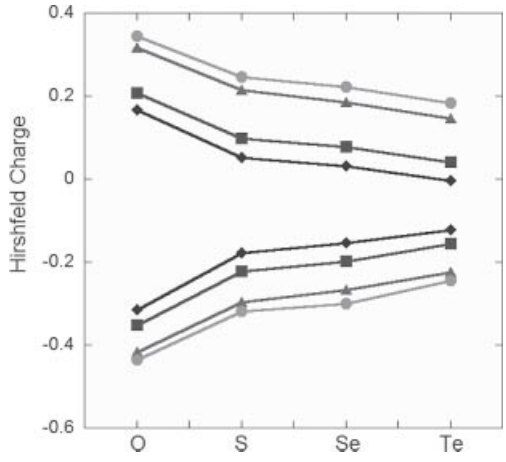

Figure 16. Variation of the Hirshfeld charges on E (positive) and Q (negative) in complexes [($N_3N$)W(EQ)] (**1**–**4**). Legend: P = ♦, As = ■, Sb = ▲ and Bi = ●.

Since the s orbitals are more compact compared with the more diffuse p orbitals it is not unexpected that the effective radius of the pnicogen decreases with increase of the s contribution to the hybrid orbital through which the W–E σ bonding is realised. This decrease of the effective radius of E due to hybridisation is responsible for the shorter W–E bond in complexes **1**–**4** than in the corresponding pnictido [($N_3N$)W≡E] complexes. Since the s-orbital contraction is more accentuated for the heavy elements, the shortening of the W–E bond will be more pronounced for the heavier congeners of E. This is consistent with the results of our calculations. It has to be noted that for the π bonding the pnicogen atoms use almost pure p orbitals in complexes **1**–**4** and [($N_3N$)W≡E].

Conclusions about the hybridisation of the pnicogen atom in the phosphido complex [($N_3N$)W≡P] was made based on $^{31}P$ NMR spectroscopy. The phosphido complex [($N_3N$)W≡P] shows an unusual $^{31}P$ chemical shift ($\delta$ = 1080.0 ppm) and a small tungsten-phosphorus coupling constant ($^1J_{W-P}$ = 138 Hz).[10] The small tungsten-phospho-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rus coupling in the phosphido complex [($N_3N$)W≡P] was attributed to the low s-orbital contribution to the W–P σ bonding[25] while the chemical shift was attributed to the paramagnetic shilding perpendicular to the W≡P triple bond.[26] In contrast to that, the phosphorus monosulfide complex **1b** presents a large phosphorus-tungsten coupling ($^1J_{W\text{-}P}$ = 771.5 Hz),[16] indicating a considerably higher amount of s-orbital contribution to the W–P σ bonding. We have calculated the $^{31}$P chemical shift ($\delta$ = 356.8 ppm) and tungsten-phosphorus coupling ($^1J_{W\text{-}P}$ = 753.9 Hz) for **1b** which compare well with the experimental data ($\delta$ = 342.3 ppm, $^1J_{W\text{-}P}$ = 771.5 Hz). The NMR data and its predictibilty by computational procedures provides good evidence for the inferred cause of this unusual anti-correlation between bond strength and bond length.

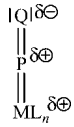
Throughout chemistry there is a general correlation between bond length and bond strength, i.e. shorter bonds are stronger than longer bonds. However, there are exceptions. There are known examples where the bond lengths do not correlate with the bond strengths or force constants. For example in the $H_nNF_{3-n}$ or $Me_nNF_{3-n}$ series the N–F force constants increase with increasing bond length.[27] Also, for some polyfluorinated hydrocarbons an increase of the C–C dissociation energy with the bond length and increasing fluorine substitution was observed.[28] Distances were analysed computationally by Kaupp et al. with respect to their bond length/bond strength abnormality.[29] It was found that the Sn–Sn bond dissociation energy decreases clearly with increasing fluorine substitution but the Sn–Sn distance remains constant. Also, no correlation between the bond lengths and force constants was observed. This abnormality was attributed to "hybridisation-deficiency"[30] caused by "hybridisation defects" (reduced mixing and non-uniformity of the s and p orbitals due to their different radial distributions).[31] This work provides evidence that similar effects, i.e. hybridisation defects, cause the shortening of the W–E bond in complexes **1**–**4** compared to the pnictido complexes [($N_3N$)W≡E].

## Conclusions

In this paper we have shown, that the linear arrangement of the $N_{ax}$–W–E–Q framework in complexes of the type [($N_3N$)W(EQ)] renders a bonding situation with a π-delocalised electron system which is best described as two three-centred four-electron bonds. The σ-electron systems becomes more localised as the atomic number of either E or Q increases. In contrast to the σ-electron system the π bonding becomes more delocalised as the atomic number of either E and Q increases. The strength of the *trans* influence of the EQ ligands in the complexes **1**–**4** is determined by the relative energy of the EQ fragment σ orbitals.

The shorter W–E distances in complexes **1**–**4** than in the pnictido complexes [($N_3N$)W≡E] (E = P, As, Sb and Bi) have been attributed to the different hybridisation, i.e. considerable increase of s contribution to the σ MOs of the pnicogen atoms in complexes **1**–**4** compared to the pnictido [($N_3N$)W≡E] complexes. Complexes **1**–**4** are moderately charged, except for the phosphorus monoxide complexes (**a**) which exhibit a more significant ionic character.

The W–E and E–Q bond dissociation energies of complexes **1**–**4** are relatively high, and show the expected periodic variations. The BDEs indicate that even the heavier congeners should be stable enough to be isolated. Both fragment calculations and WIB give very similar bond orders and trends herein. Overall, the bonding in the W–E–Q unit is best pictorially represented by two double bonds (Scheme 2).



Scheme 2. Proposed Lewis structure for the complexes [($N_3N$)-W(EQ)].

## Computational Methods

DFT calculations were carried out using the Amsterdam Density Functional program (ADF) versions 2004.01 and 2005.01.[32–35] Scalar relativistic corrections were included via the Zero Order Regular Approximation (ZORA) method.[36–40] The generalized gradient approximation was employed, using the local density approximation of Vosko, Wilk, and Nusair[41] together with the nonlocal exchange correction by Becke[42,43] and nonlocal correlation corrections by Perdew.[44] The Slater-type orbital (STO) basis sets were of triple-ζ quality augmented with a single polarization function and two diffuse functions (ADF basis TZP++). The cores of the atoms were frozen up to 1s for C and N, 2p for P, S and Si, 3p for As and Se, 4p for Sb and Te, 5p for Bi and 4d for W. Optimisations were performed without symmetry restraints. Fragment calculations were performed to enable analysis of the orbital interactions to the W–E and E–Q bonds. In these calculations the complex is divided into two fragments, whose molecular and electronic structures are calculated in a single-point optimisation with a restricted singlet spin state. The geometry of the fragment is preserved from the optimised structure of the full complex. The molecular orbitals (MOs) of the complex are formed through linear combination of the MOs of the two fragments. The bond dissociation energies (BDEs) were calculated as the difference between the energy of the complex and the energy of the fragments in their ground state [Q triplet, ($N_3N$)WE singlet, EQ doublet and ($N_3N$)W quartet]. For the BDEs the SCF energies were used without correction. The $^{31}$P NMR chemical shift and P–W coupling constant for **1b** were calculated on the optimised geometry using the corresponding program modules as implemented in ADF.[45–49] The geometry of **1b** was optimised with the TZ2P basis sets for all atoms, with no core electrons and using a tight convergence criterion as well as an integration grid of 6. The relativistic effects were incorporated via the ZORA method. NBO analyses were performed with the Gaussian03 program[50] using the BP86[42–44] functional and the 6-31G* basis sets[51–59] with one diffuse function added, for C, H, N, Si, P, S, As and Se. The Dunning–Hunzinaga[60] type basis set with Stuttgart–Dresden SDD[61,62] core potentials was applied for Sb, Te, W and Bi.

**Supporting Information** (see footnote on the first page of this article): Tables of the fragment analyses and cartesian coordinates for all optimised structures. Figures in colour are also included.

# Dehydration and Dehydrogenation of Alcohols with Mononuclear Cationic Vanadium Oxides in the Gas Phase and Energetics of $VO_nH^{0/+}$ ($n$ = 2, 3)

**Marianne Engeser,[a] Detlef Schröder,*[b] and Helmut Schwarz[c]**

*Dedicated to Professor Peter Hofmann on the occasion of his 60th birthday*

**Keywords:** Alcohol oxidation / Dehydration / Mass spectrometry / Metal alkoxides / Vanadium

The ion/molecule reactions of selected alcohols with the vanadium oxide cations $VO^+$ and $VO_2^+$ are studied by Fourier-transform ion-cyclotron resonance (FT-ICR) mass spectrometry. Dehydrogenation is the dominating reaction pathway for methanol and allyl alcohols. With larger or less unsaturated alcohols, dehydration and carbocation formations prevail. While the valence in $VO^+$ remains unchanged during alcohol dehydrogenation, $VO_2^+$ is reduced to $V^{III}$. Thermochemical data for $VO_2H^{0/+}$, $VO_3H$ and $VO_3H_2^+$ are derived by means of ICR bracketing. The experimental results are further complemented by ab initio calculations using density functional theory.

## Introduction

Part of the large interest in transition-metal oxides is due to their key role in heterogeneous catalysis,[1] particularly in oxidation reactions. For example, vanadium oxide compounds are used as heterogeneous catalysts[2] for the oxidation of $SO_2$ in the production of sulfuric acid and for selective hydrocarbon oxidation, i.e. the production of maleic anhydride directly from butane. The mechanisms of such complicated hydrocarbon activations are still not fully understood and widely debated.[1] Among others, alcohols and alkoxides have been proposed as intermediates in alkane oxidation catalyzed by metal-oxide compounds.[1–3] Further, the oxidation of alcohols itself is important for industrial processes, e.g. the production of formaldehyde from methanol.[1,4] For larger molecules containing alcoholic OH groups, acidic properties of an oxide catalyst may induce dehydration instead of dehydrogenation.[1,2] Hence, a selective oxidation catalyst is characterized by handling the delicate interplay between oxidizing and acidic properties. The roles of formal oxidation states and of functional groups that form the active sites of a catalyst are of particular interest in this respect.

Gas-phase experiments represent a powerful means for conducting model studies of complicated reactions,[5,6] ranging even to models for heterogeneous catalysis,[7] because they facilitate an understanding of mechanistic details at a molecular level. It has to be stated though that the extreme simplification also entails that a direct extrapolation of the findings to applied catalysis may be impossible.[8] The gas-phase behavior of vanadium alkoxides have been studied for methanol[9,10] and larger homologues.[11] As far as detailed studies are concerned, only methanol dehydrogenation by vanadium cations has been previously addressed.[12–14] Here, we present an experimental investigation of the gas-phase ion/molecule reactions of the mononuclear vanadium-oxide cations $VO^+$ and $VO_2^+$ with a variety of alcohols. The results have some implications for the ion thermochemistry of the vanadium-oxide hydroxides $VO_2H$ and $VO_3H$, which has not been reported so far.

## Results

### Ion/Molecule Reactions of $VO^+$ with Selected Alcohols

In the comparatively sluggish reaction of $VO^+$ with methanol, the major process corresponds to dehydrogenation, which has been shown to proceed via a selective 1,2-elimination.[13] In contrast, dehydrogenation is an only minor pathway in the reaction of $VO^+$ with ethanol (Table 1). The longer carbon chain enables a new reaction pathway (alkene formation) which is also reflected in an enhanced overall reaction efficiency ($\phi$ = 35%).[15] Use of the labeled reactant [2,2,2-$D_3$]ethanol leads to an exclusive loss of $C_2H_2D_2$. Thus, ethene formation takes place via a selective 1,2-elimination. The cationic product $[VO_2H_2]^+$ may be both the water complex $VO(H_2O)^+$ or the more

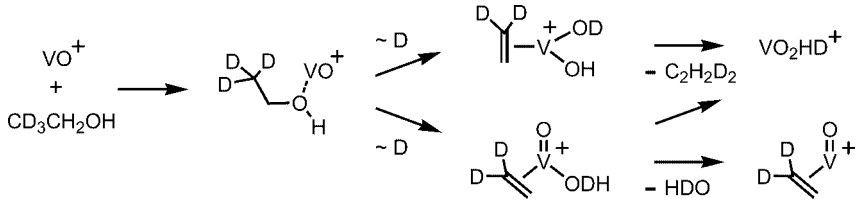
[a] Intensities are normalized to a sum of 100%. For all systems, fragmentation channels with abundances ≤ 1% are neglected. [b] Taken from ref.[13] [c] Given in $10^{-10}$ $cm^3$ $molecule^{-1}$ $s^{-1}$; the absolute error is assumed to be ± 30%. [d] This ion is formed in a quick and efficient secondary reaction, which may contribute to the primary branching ratio with max. 2%.



Scheme 1.

stable dihydroxide $V(OH)_2^+$.[16,17] In competition with ethene loss, water is expelled in a much smaller amount, and as far as site-selectivity is concerned, investigation of [2,2,2-$D_3$]ethanol demonstrates high selectivity (Scheme 1). Both reaction pathways result in a dehydration of ethanol to ethene, even though the bisligated complex $VO(C_2H_4)(H_2O)^+$ does not necessarily need to serve as a common intermediate in both cases.[18]

Most of the fragmentation pathways in the ion/molecule reaction of $VO^+$ with propanol (Table 1) resemble the ethanol case, i.e. elimination of propene concomitant with formation of $VO_2H_2^+$ represents the most abundant reaction channel and dehydrogenation takes place in even lower amounts. The latter yields the ion $[VC_3H_6O_2]^+$, which has been previously characterized as the allyl complex $(C_3H_5)$-$VO(OH)^+$.[19] Further, formation of the carbocation $C_3H_7^+$ appears as a new pathway which is not observed for the smaller alcohols (Scheme 2). The nature of the neutral species $[VO_2H]$ lost in this process cannot be probed in our type of experiments. Nevertheless, it is reasonable to interpret it as a vanadium-oxide hydroxide O=V–OH, because combined elimination of VO and HO· is endothermic ($\Delta_r H$ = 415 kJ/mol for 2-propanol) and hence for this channel impossible in ion/molecule reactions with thermalized reactants. The overall oxidation state of vanadium therefore does not change during this reaction which can be viewed as a transfer of a hydroxide anion from the alcohol to the metal cation. Even though the hydroxy group is situated at different positions in the two propanol isomers, the spectra of 1- and 2-propanol are indistinguishable (Table 1). Starting from 1-propanol, a direct hydroxide transfer would lead to an energetically demanding primary carbocation. On the other hand, an additional hydrogen rearrangement in the positively polarized hydrocarbon ligand yields the more stable secondary carbocation which is formed directly in the 2-propanol case and can thus account for the experimental observations.

Similar to propanol, the reactions of $VO^+$ with isomeric butanols predominantly result in the formation of $VO_2H_2^+$ concomitant with loss of butene. In addition, hydroxide abstraction, yielding $C_4H_9^+$ is also observed. No significant differences between the two butanol isomers are observed, again indicating the formation of a secondary carbocation in both cases. As a new reaction channel, a combined elimination of $H_2O$ and $H_2$ takes place, which leads to $[VC_4H_6O]^+$. Tentatively, this product ion is assigned to the complex $VO(C_4H_6)^+$ with 1,3-butadiene as a bidentate ligand.[19] In addition, some C=C bond cleaving channels are observed, which do not take place for the smaller alcohols. Among these, the formation of $[VC_2H_4O_2]^+$ via loss of ethane or $C_2H_4$ + $H_2$ is especially noteworthy because it is strongly enhanced for *sec*-butyl alcohol compared to 1-butanol. The pronounced difference demonstrates that the position of the hydroxy group is crucial for this kind of C–C bond cleavage and that OH abstraction should not be involved.

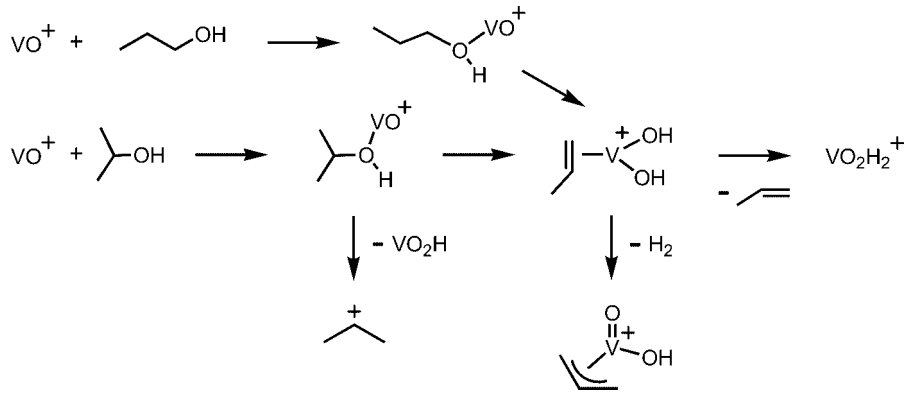

Scheme 2.

Allyl alcohol is also dehydrated by $VO^+$, but dehydrogenation and OH-transfer give rise to the dominating reaction channels. In analogy to the methanol case, the cationic dehydrogenation product is tentatively assigned to the acrolein complex $VO(CH_2CHCHO)^+$. Further, losses of ethene and $[CH_2O]$ are detected in small amounts, the latter may be formaldehyde or, less probable, a consecutive expulsion of CO after dehydrogenation. Interestingly, OH-abstraction does not only lead to the allyl cation $C_3H_5^+$ and neutral $VO_2H$, but also to the alternative couple of products with the opposite charge distribution $VO_2H^+ + C_3H_5^{\cdot}$: note that this the only case in the present investigation in which the cationic species $VO_2H^+$ was observed (see below).

Finally, the reactions of $VO^+$ with isomeric butenoles result in the main fragmentation channels expected according to the preceding results: Dehydration leads to both $VO(C_4H_6)^+$ and $VO_2H_2^+$, whereas hydroxide transfer results in $C_4H_7^+$. Note that $VO_2H^+$ is not observed reflecting the lower ionization energy of $C_4H_7^{\cdot}$ compared to $C_3H_5^{\cdot}$ (7.9 eV vs. 8.18 eV).[20] Further, small amounts of ethene loss are detected which may correspond to the expulsion of $[C_2H_6]$ as observed for the butanols. With regard to the three butenol isomers studied here, the differences between the two allylic alcohols are mostly confined to relatively small variations of abundances, whereas two additional products are observed for $CH_2CHCH_2CH_2OH$; these correspond to the eliminations of propene and $[CH_2O]$, respectively. The latter processes resemble the expulsions of ethene as well as $[CH_2O]$ from allyl alcohol/$VO^+$ (see above).

In summary, the main pathway in the reactions of $VO^+$ with alcohols is dehydration. Both alkenes and water may be expelled as neutral products, but alkene loss is far more favored. Dehydrogenation to aldehyde or ketone complexes is also possible, but can only compete efficiently if alkene formation cannot take place (methanol) or if the substrate already is too unsaturated (allyl alcohol). As a third important reaction pathway, hydroxide abstraction by $VO^+$ is observed. The $C_4$-alcohols further undergo cracking processes in which C–C bonds are cleaved. In any case, the metal's oxidation state ($V^{III}$) remains unchanged in the products formed.

### Ion/Molecule Reactions of $VO_2^+$ with Selected Alcohols

When reacted with bare $VO_2^+$, methanol is converted to formaldehyde with $VO(CH_2O)^+$ and $VO_2H_2^+$ as the corresponding ionic products.[13] In contrast to the $VO^+$ case, the reaction can be termed as an oxidative dehydrogenation, i.e. water is formed instead of $H_2$, while the metal is reduced from $V^V$ to $V^{III}$. In the reaction of $VO_2^+$ with ethanol (Table 2), oxidative dehydrogenation is expressed in the losses of $H_2O$ and $[C_2H_4O]$. The latter is tentatively assigned to acetaldehyde. Yet, the enhancement in reaction rate ($\phi$ = 50% as compared to $\phi$ = 10% for the $VO_2^+$/$CH_3OH$ system) is attributed to ethene formation representing the by far most abundant reaction channel. This scenario resembles very much the behavior of $VO^+$ described above. The product ion $VO_3H_2^+$ may be interpreted as doubly protonated vanadate $VO_3^-$. In solution, condensation to polyvanadates takes place upon acidification of vanadate solutions.[21] In the gas phase, however, any oligomerization is strictly prevented by the real Coulomb charge of the ions. Therefore, stable protonated monomeric species such as $VO_3H_2^+$ are feasible as well. A reaction pathway unique to the ethanol/$VO_2^+$ system leads to $[VCH_3O_2]^+$ via methyl loss. Whereas expulsion of $CH_3^{\cdot}$ has also been reported for the reaction of $FeO^+$ with ethanol,[22] a similar process has not been observed so far in any ion/molecule reaction of vanadium oxides with alcohols or hydrocarbons.[19] Formation of an open-shell fragment results in a reduction of $V^V$ in $VO_2^+$ to $V^{IV}$ in the product ion. A reasonable structure is $OV(OH)(CH_2O)^+$ formed by methyl loss from the putative ethoxy intermediate $OVOH(OC_2H_5)^+$ (Scheme 3). However, the reaction with [2,2,2-$D_3$]ethanol demonstrates that partial H/D exchange precedes all reaction pathways depicted in Scheme 3. As a possible candidate for an intermediate in the H/D equilibration one may consider the structure $VO(OH)_2(C_2H_4)^+$ with two identical hydroxy and methylene groups.

The ion/molecule reactions of $VO_2^+$ with 1- and 2-propanol do not show any significant differences. Similar to dehydration of ethanol by $VO^+$, formation of $VO_3H_2^+$ concomitant with elimination of propene is a prominent reaction

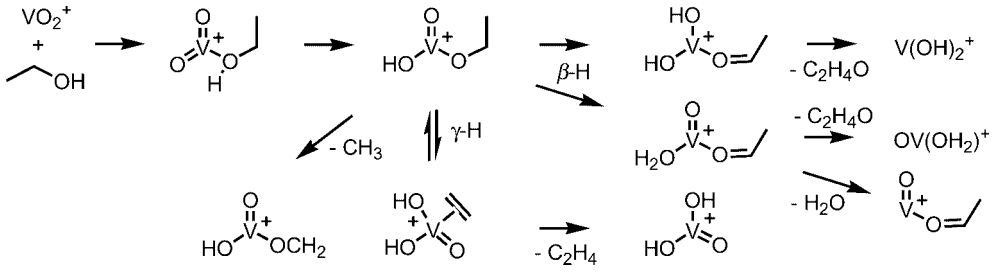

Scheme 3.

pathway. The major route is associated with hydroxide abstraction to afford neutral $VO_3H$. The facile formation of a carbenium ion may also account for the lack of differentiation between 1- and 2-propanol.

In the reactions with isomeric butanols, butene formation and hydroxide abstraction represent the main reaction pathways. However, they are not as favored as in the propanol cases. In addition, a manifold of minor and almost negligible reaction channels is observed as well, which we do not pursue in any further detail.[23] Further, several types of C–C bond cleavages take place, some of which exhibit significant differences between *n*-butyl and *sec*-butyl alcohol. For example, *sec*-butyl alcohol/$VO_2^+$ shows loss of $C_2H_6$, whereas $C_3H_8$ is expelled in the case of 1-butanol. Thus, the position of the OH group has a significant effect on the cracking processes both in the reactions of $VO^+$ and $VO_2^+$.

The spectra of ion/molecule reactions of $VO_2^+$ with unsaturated alcohols are comparatively simple (Table 2). With allyl alcohol, the formations of $C_3H_5^+$ as the major and $VO^+$, $VO_2H_2^+$, $VO_3H_2^+$ as minor primary products are observed in analogy to the results described above. The reaction of $VO_2^+$ with butenol isomers finally reveals a pronounced preference for carbocation formation; only traces of other reaction channels are observed.

In summary, the two most favored pathways in the alcohol/$VO_2^+$ systems, alkene expulsion and carbocation formation, both include C–O bond cleavage of the alcohol. Hydroxide transfer takes place if the resulting carbenium ion is sufficiently stabilized. Labeling experiments suggest that the two pathways are connected by tautomerism between alkene and hydroxide complexes before dissociation. With unsaturated alcohols, hydroxide abstraction is observed almost exclusively in accordance with the enhanced stability of allyl cations.

### Secondary Ion/Molecule Reactions in the Alcohol/$VO^+$ and Alcohol/$VO_2^+$ Systems

Cascades of the subsequent ion/molecule reactions of $VO_n^+$ cations with methanol have previously been studied in detail.[13] The key reactions steps comprise condensation reactions of the type [V]OH + $CH_3OH$ → [V]$OCH_3$ + $H_2O$, where [V] stands for a bare or ligated, neutral or charged vanadium core. A similar behavior is observed for other

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

alcohols ROH as well, for which ions of the formula $V(OH)(OR)^+$ and $V(OR)_2^+$ are formed from $VO_2H_2^+$ and the respective alcohol. On the other hand, isomeric complexes $VO(ROH)^+$ may be present too. They stem from other intermediates and are formed via ligand exchange according to $VO(L)^+ + ROH \rightarrow VO(ROH)^+ + L$ (L = $CH_3CHO$, for example), even though they should be significantly less stable than the alkoxide isomers.[13] Further, the presence of complexes of the type $OVOH(R)^+$ as a third class of isomers is quite reasonable for larger alcohols which form more stable carbenium ions.[19] $VO_3H_4^+$ is another common product observed at longer reaction times with alcohols larger than methanol. This ion is produced via alcohol dehydration/alkene loss from the precursor ion $VO_2H_2^+$. Similarly, $VO_4H_4^+$ is formed from $VO_3H_2^+$; condensation leads to $VO(OH)(OR)^+$ and $VO(OR)_2^+$ in this case. If a carbocation is generated in the first step, it readily reacts with alcohol molecules in acid-base type reactions, yielding protonated alcohols and a typical series of organic cations derived there from. In addition to these more general observations, the reaction of $VO^+$ with the isomeric butanols shows a peculiarity in that the expected alkoxide product $[VC_4H_{10}O_2]^+$ is less abundant than the dehydrogenated ion $[VC_4H_8O_2]^+$. The latter may be assigned to a mixture of a butadiene complex $V(OH)_2(C_4H_6)^+$ and an unsaturated alkoxide $HOVC_4H_7^+$ formed via remote functionalization,[24] because a similar product is not observed for smaller alcohols.

Finally, the reactivity of the product $VO_2H^+$, generated from allyl alcohol/$VO^+$, was explored with regard to possible thermochemical implications. In the reaction of $VO_2H^+$ with allyl alcohol, mostly $C_3H_5^+$ concomitant with neutral $[VO_3H_2]$ are formed via a second hydroxide abstraction. Additional minor products correspond to $VO_2H_2^+$, $VO_3H_3^+$, $[C_3H_5O]^+$, and $[VC_3H_7O_3]^+$. The hydrogen-atom abstraction to yield a hydroxy-substituted allyl cation will again be addressed in the thermochemical section further below (Table 3).

### Fragmentation of VO(alcohol)$^+$ Complexes in a Sector-Field Instrument

To gain further insight into the reaction mechanisms, an alternative instrumental technique has been used to study some of the postulated intermediates. To this end, the complexes $VO(alcohol)^+$ were attempted to be generated by chemical ionization of a mixture of $(C_5H_5)V(CO)_3$ and the respective alcohol with $N_2O$ as reagent gas. The cations emerging from the CI source were then analyzed in a four-sector instrument by recording metastable ion spectra. By this technique, the charged fragments formed via unimolecular dissociations in the field-free region of the mass spectrometer are detected.

In the presence of methanol, a signal at *m*/*z* 99, as expected for $VO(CH_3OH)^+$, can be generated under CI conditions. The MI spectrum of the mass-selected ion shows $H_2$-loss as the main fragmentation channel (Table 3) with $VO^+$ and $VO_2^+$ as additional ionic fragments. All pathways are in accordance with previous findings[9] and the results obtained in ion/molecule reaction of $VO^+$ with methanol (see above). The exclusive loss of HD from $CD_3OH/VO^+$ confirms once more the operation of a selective 1,2-elimination. Similarly, selecting the ion at *m*/*z* 113 observed in the presence of ethanol leads to the observation of the same ions as in the respective ICR ion/molecule reaction. However, the relative abundances of the fragmentation channels differ significantly: dehydrogenation is now much more pronounced than dehydration, which can in part be associated with the conservation of angular momentum which leads to a preference for the losses of light fragments in the metastable ion spectra.[25,26] Further, the loss of 28 u shifts to 32 u when perdeuterated [$D_6$]ethanol is used, thus corroborating the formation of $VO_2H_2^+$ and neutral ethene. Elimination of $H_2$ remains the main fragmentation channel also for the two isomeric propanol complexes; minor losses of water or propene are observed as well. A difference between the two propanol isomers occurs with respect to the abundance of

propene expulsion, which is significantly enhanced for 2-propanol. Interestingly, the formation of $C_3H_7^+$ via loss of neutral $VO_2H$, as observed in the corresponding ion/molecule reactions, is not observed in the MI-spectra. In addition, two other fragment ions corresponding to losses 19 u and 28 u, respectively, are observed. Whereas the latter is assigned to $C_2H_4$ because it is only detected for 1-propanol, but not for 2-propanol,[27] with regard to the former we cannot strictly exclude an isobaric interference in the MI experiments. Finally, the MI spectra obtained for the $VO^+$ complex of allyl alcohol display dehydrogenation as the most abundant process, but also significant amounts of water are lost. Instead of the loss of $CH_2O$ observed in the ICR measurements, cleavage of atomic $H^{\cdot}$ is found. In conclusion, the sector experiments are consistent with the other data obtained, but at least for this particular system their information content remains somewhat limited due to the relatively weak signal abundances, caused by the lack of a suitable precursor for high yields of reasonably clean $VO^+$ ions.

## Discussion

### Ion/Molecule Reactions of $VO^+$ and $VO_2^+$ with Alcohols

Comparison of the observed reactions of $VO^+$ with those of $VO_2^+$ reveals similarities as well as some differences. Intuitively, similarities are expected for the reaction channels in which the cations act like Lewis acids, i.e. hydroxide abstraction and dehydration, whereas differences should appear in oxidation reactions like dehydrogenation, because $V^V$ compounds ($VO_2^+$) are stronger oxidizing agents than $V^{III}$-species ($VO^+$). The reaction efficiencies do not differ significantly. In contrast to the reactions of $VO^+$ and $VO_2^+$ with alkanes,[19] the reactivity towards alcohols is not enhanced significantly by the second oxygen atom in $VO_2^+$. This behavior is in agreement with a Lewis-acid type interaction of the metal with the OH-group dominating the reactions of the two cations with alcohols larger than methanol, whereas the C–H bond activation necessary for alkane dehydrogenation is affected by the oxidation state of the metal.

The most important reaction channel in the methanol/$VO^+$ system is the formation of a formaldehyde complex by elimination of $H_2$. In the respective reaction with $VO_2^+$, two complementary fragmentation channels involve oxidation of methanol to $CH_2O$, i.e. loss of water and loss of $CH_2O$. As already stated above, oxidative dehydrogenation instead of pure dehydrogenation occurs with $VO_2^+$ instead of $VO^+$. In the $VO^+$ system, formaldehyde is not expelled, most probably because the hypothetical cationic product $HVOH^+$ is not as stable as the observed complex $VO(CH_2O)^+$. In contrast, $V(OH)_2^+$ is a likely product when the system contains an additional oxygen atom. A similar reasoning applies for the ethanol case simply by replacing an α-H atom by a methyl group. Still, oxidative dehydrogenation is less favored than dehydration to ethene for both vanadium-oxide cations. The discrimination of $H_2$-loss is even stronger with larger alcohols. From propanol on, the possible generation of stabilized secondary carbocations enables hydroxide abstraction from the substrate. The latter is more pronounced than dehydration only with $VO_2^+$, but not with $VO^+$, indicating that the proton affinity of $VO_2H$ is lower than the one of $VO_3H$. Similarly, in the reactions with allyl alcohol, carbocation formation is significantly more pronounced with $VO_2^+$ than with $VO^+$. Further, the reverse charge distribution is only observed with $VO^+$, but not with $VO_2^+$. Therefore, the ionization energy of $VO_3H$ must be significantly larger than $IE(C_3H_5^{\cdot})$ and thus $IE(VO_2H)$, in accordance with the more general observation of increasing ionization energies of vanadium-oxide species with increasing oxygen content.[28]

### Comparison with Ion/Molecule Reactions of Other Cationic Transition-Metal Oxides

The reactions of $FeO^+$ with alcohols may be chosen for comparison with a typical late transition-metal oxide.[22,29] As compared to the behavior of $FeO^+$, the selectivity of $VO^+$ is markedly enhanced. Thus, losses of radicals are not observed at all for the latter, and a cleavage of propanol C–C bonds does not occur either in the ion/molecule reactions of $VO^+$. Further, carbocation formation does not occur for primary alcohols and $FeO^+$, whereas rearrangement to the more stable secondary carbocation obviously takes place in the alcohol/$VO^+$ systems. The main products in the reactions of $FeO^+$ with alcohols have been divided into three categories: α-oxidation, alkene loss, and carbocation formation. The same classification can be applied for the $VO^+$ reactions as well, but the channels follow rather different reaction mechanisms. For example, α-oxidation with $FeO^+$ leads to loss of $H_2O$, whereas $H_2$ is formed in the $VO^+$ reaction. This behavior reflects the significantly larger oxophilicity of the early transition metal vanadium in comparison to the late transition metal iron.[8] With respect to alcohol dehydrogenation, $FeO^+$ resembles more the vanadium dioxide $VO_2^+$ rather than the monoxide $VO^+$, as has already been predicted from similar M–O bond dissociation energies in $FeO^+$ and $VO_2^+$.[8]

In addition, the ion/molecule reactions of $MoO^+$ with alcohols have been reported.[30] Not surprisingly, the similarities to $VO^+$ are much more pronounced here. Thus, the strong M–O bond is never cleaved for both $VO^+$ and $MoO^+$. Nevertheless, some deviations still are detectable. For example, a selective α-oxidation of methanol occurs for both metal oxides. However, $H_2$ is lost as a neutral molecule in the case of $VO^+$, whereas $CH_2O$ is expelled with $MoO^+$. Similarly, dehydration of ethanol to ethene takes place with both metal oxides, but water instead of ethene is lost with $MoO^+$. Finally, $MoO^+$ does not show any cracking products with butanols, again in contrast to the reactions of $VO^+$. In summary, $VO^+$ only effectively dehydrogenates alcohols if dehydration cannot compete, whereas dehydro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

genation is always a good choice for $MoO^+$. Further, loss of oxygen-containing neutral molecules like aldehydes or water takes place with $MoO^+$, but is almost prohibited for $VO^+$.

### Comparison of ICR and Sector-Field Results

According to the elemental composition, the same ions are sampled in the ICR- and MI-spectra described above. Nevertheless, quite large deviations in relative intensities are observed which cannot be explained only by mass discrimination effects known to enhance losses of small neutral molecules in sector instruments[31] and effects of angular momentum.[25,26] As another likely reason for the differences we therefore propose different ion internal energies in both experiments. In general, unimolecular fragmentation channels of metastable ions generated under CI conditions are less energy-demanding than fragmentations of the corresponding encounter complexes formed in ion/molecule reactions under single-collision conditions.[32] In the alcohol/$VO^+$ systems discussed here, the main difference concerns the enhanced amount of dehydrogenation instead of dehydration as observed in the MI spectra. According to DFT calculations of *n*-propanol/$VO^+$, dehydrogenation indeed is the lowest exit channel.[19] The strong preference for the energetically slightly more demanding dehydration of propanol in the ICR experiments might be due to spin restrictions,[33] such an argumentation has been proposed for the related system propane/$VO_2^+$.[19] However, spin restrictions cannot explain the similar results observed for ethanol, because both dehydrogenation and dehydration occur only on one (triplet) spin state in this case. Nevertheless, dehydrogenation again is preferred in the MI spectra, whereas dehydration to $VO_2H_2^+$ prevails under ICR conditions. As an alternative, rearrangements taking place during the formation and stabilization of the ions by collisions in the CI source should be taken into account. In our case, isomerization from an alcohol complex $VO(ROH)^+$ to the more stable alkoxide $V(OH)(OR)^+$ is likely to happen and should even be catalyzed by collisions with alcohol molecules.[17,34] Some indications for the presence of an alkoxide structure can be found in the CA spectra which show signals at *m*/*z* 68 ($VOH^+$) and *m*/*z* 84 ($VO_2H^+$) in addition to the one at *m*/*z* 67 ($VO^+$). Formation of these ions in high-energy collisions is more likely from $V(OH)(OR)^+$ isomers than from $VO(ROH)^+$. In conclusion, the observed MI spectra might stem from a mixture of two non-interconverting isomers. With the assumption that the ICR branching ratios roughly represent the fragmentations of the alcohol complexes $VO(ROH)^+$, the differences to the MI spectra can be ascribed to the alkoxides $V(OH)(OR)^+$. Thus, the alcohol complex mostly yields alkene formation, whereas $H_2$-loss is preferred for the alkoxide. The different reactivities can be understood as follows. In the alcohol complex, the C–OH bond is weakened to some extent due to coordination to the Lewis-acidic metal oxide cation. It is even broken completely for allyl alcohol resulting in a complex $(C_3H_5)V(O)(OH)^+$. Dehydration of the alcohol to an alkene is then easily accomplished by transfer of a hydrogen atom from the hydrocarbon backbone to the vanadyl oxygen which may proceed directly via a six-membered transition structure (Scheme 4). In contrast, the isomeric alkoxide could undergo a $\beta$-H elimination to initiate hydrogen elimination leading to aldehyde or ketone complexes, respectively. For example, formaldehyde expulsion is observed upon dissociation of gaseous $OV(OCH_3)_3^+$ and several of its fragment ions.[9] Thus, the assumption of a mixture of isomers can explain the observed results reasonably well (Table 4).

### Thermochemical Implications

For several of the molecules mentioned above, no thermochemical data have been reported so far, i.e. the hydroxide-oxides $VO_2H^{0/+}$, $VO_3H$ and $VO_3H_2^+$. Accordingly, we summarize the thermochemical information which can be derived from the ICR experiments in which endothermic reactions cannot take place ("bracketing approach").

Neutral $VO_2H$ cannot be observed directly by mass spectrometric means. Nevertheless, its formation can be deduced from carbocation observation in the reactions of $VO^+$ with alcohols. As already mentioned above, the alternative of generating two neutral molecules (VO + OH$^{\cdot}$) can be excluded due to its endothermicity. Therefore, carbocation formation can be used to derive upper limits for the enthalpy of formation $\Delta_fH(VO_2H)$. The lowest upper boundary $\Delta_fH(VO_2H) \leq -242 \pm 16$ kJ mol$^{-1}$ results from the reaction $VO^+$ + 2-propanol → *sec*-$C_3H_7^+$ + $VO_2H$. An estimate of a lower limit may be calculated from the non-occurrence of a similar process in the ethanol case: $\Delta_fH(VO_2H) \geq -305 \pm 16$ kJ/mol. The corresponding cation $VO_2H^+$ is formed from $VO^+$ and allyl alcohol: $VO^+$ + $C_2H_3CH_2OH$ → $C_3H_5^{\cdot}$ + $VO_2H^+$, thus yielding $\Delta_fH(VO_2H^+) \leq 547 \pm 20$ kJ mol$^{-1}$. For a lower boundary, the subsequent reactions of $VO_2H^+$ with allyl alcohol are examined. However, the heat of formation of at least one product is not known for all reaction pathways. In the H-atom abstraction $VO_2H^+$ + $C_2H_3CH_2OH$ → $VO_2H_2^+$ + $[C_3H_5O]$, the formation of the radical $CH_2CHC^{\cdot}HOH$ may be assumed. Combined with an estimate for the enthalpy of formation $\Delta_fH(V(OH)_2^+)$ (Table 4), this leads to a lower bound of $\Delta_fH(VO_2H^+) \geq 511 \pm 40$ kJ mol$^{-1}$. A comparison of the two bracketed values gives an estimate for the ionization energy $IE(VO_2H) = 8.3 \pm 0.2$ eV. This ionization energy can also be deduced directly. In the allyl alcohol/$VO^+$ system, the product channels $C_3H_5^+$ + $VO_2H$ and $VO_2H^+$ + $C_3H_5^{\cdot}$ are observed in a ratio of about 2:1, thus indicating $IE(VO_2H) \approx IE(C_3H_5^{\cdot}) = 8.18$ eV.[20] This result is further confirmed by the formation of $C_4H_7^+$ from but-3-en-2-ol/$VO^+$, whereas $VO_2H^+$ is not formed at all in this case, thus $IE(VO_2H) > IE(C_4H_7^{\cdot}) = 7.49$ eV.[20] On the other hand, hydroxide abstraction is not observed in the reaction of $VO^+$ with phenol,[35] which might be interpreted as an indication for $IE(VO_2H) < IE(C_6H_5^{\cdot}) = 8.32$ eV.[20]

In addition, DFT calculations on neutral and cationic $V(O)(OH)^{0/+}$ have been performed (Table 5). Previous benchmark calculations[9,36,37] have shown that the chosen level is convenient for a sufficiently accurate comparison with experimental results on mononuclear vanadium-oxide compounds, even though further calculations at highest ab initio levels are still desirable. The results obtained for the fragments fully confirm geometries and energetics reported previously.[19,36–40] The geometry of cationic $V(O)(OH)^+$ in the energetically most favorable doublet spin state ($^2A''$) meets the expectations: The V–O bond length ($d_{VO}$ = 1.55 Å) is typical for cationic vanadyl units and the V–OH bond length fits to previous calculations of related compounds.[12] Compared to the cation, the V–O bonds in neutral V(O)(OH) with a triplet ground state ($^3A''$) are elongated. The calculated adiabatic ionization energy $IE_{calc}(V(O)(OH)) = 8.22$ eV is in perfect agreement with the experimental value $IE_{exp}(V(O)(OH)) = 8.18$ eV derived above. Comparison of the experimental and calculated bond energies (Table 6) further shows that the theoretical level is sufficiently high because the deviations are in acceptable ranges.

Table 5. Total energies $E_{tot}$ (in Hartree) and selected geometric parameters[a] of neutral and cationic V(O)(OH) and some fragments calculated with B3LYP/TZVP.

[a] Bond lengths *d* [Å] and bond angles *a* [°]. [b] The first value given corresponds to the vanadyl V=O bond, the second to the V–O single bond.

Table 6. Comparison of some selected calculated and experimental bond dissociation energies for $VO_2H_n^{0/+}$ (*n* = 0–2) in kJ mol$^{-1}$.

| X–Y | $D(X–Y)_{calc}$ | $D(X–Y)_{exp}$ |
|---|---|---|
| $OV^+$–O | 357 | $365 \pm 20$[a] |
| OV–O | 503 | $585 \pm 60$[a] |
| $OV^+$–OH | 335 | $340 \pm 40$[b] |
| OV–OH | 412 | $450 \pm 40$[b] |
| $OVO^+$–H | 399 | $405 \pm 40$[b] |
| OVO–H | 330 | $290 \pm 40$[b] |

[a] Derived from the data in Table 4. [b] This work.

In conclusion, the bond dissociation energy $D(OVO–H) = 290 \pm 40$ kJ mol$^{-1}$ in neutral $VO_2H$ reflects a weak O–H bond, whereas the OV–OH bond is rather strong ($D(OV–OH) = 450 \pm 40$ kJ mol$^{-1}$). Ionization of V(O)(OH) to $V(O)(OH)^+$ requires $IE_{exp}(OVOH) = 8.18$ eV and leads to a decrease in V–OH bond strength $D(OV^+–OH) = 340 \pm 40$ kJ mol$^{-1}$, whereas the strength of the VO–H bond rises to $D(OVO^+–H) = 405 \pm 40$ kJ mol$^{-1}$, which is significantly more than $D(VO^+–H) = 282 \pm 15$ kJ mol$^{-1}$ in $VOH^+$.

Very similar to the $VO_2H$ case, reasonable boundaries for the enthalpy of formation of neutral $VO_3H$ can be obtained from its formation in the reaction of $VO_2^+$ with 2-propanol ($\Delta_fH(VO_3H) \leq -358 \pm 16$ kJ mol$^{-1}$) and its non-occurrence in the reaction with ethanol ($\Delta_fH(VO_3H) \geq -421 \pm 16$ kJ mol$^{-1}$). For the corresponding protonated species $VO_3H_2^+$, the upper limit $\Delta_fH(VO_3H_2^+) \leq 407 \pm 17$ kJ mol$^{-1}$ is based on the reaction $VO_2^+$ +

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$C_2H_3CH_2OH \rightarrow VO_3H_2^+$ + propyne. As stated above, formation of protonated alcohols is one of the major subsequent products in the alcohol/$VO_2^+$ systems. Thus, the reaction $VO_3H_2^+ + C_2H_5OH \rightarrow VO_3H + C_2H_5OH_2^+$ may be used to derive $\Delta_fH(VO_3H_2^+) \geq 350 \pm 50$ kJ mol$^{-1}$. Note that this limit might be too high because the intermediate $VO_3H_2^+$ has not been thermalized.

In the reactions of $VO_2^+$ with alcohols, formation of both product channels $VO_3H_2^+$ + alkene and $VO_3H$ + alkyl$^+$ takes place. The relative carbocation abundance $I_{rel}$ correlates with the proton affinity of the hydrocarbon involved (Figure 1). This is an indication for the presence of a tautomer equilibrium before dissociation, i.e. $[C_mH_n^+ \cdot VO_3H]$ and $[C_mH_{n-1} \cdot VO_3H_2^+]$. The former complex can arise by direct hydroxide transfer from the alcohol to $VO_2^+$. The existence of the latter has already been proposed in the discussion (Scheme 3) due to partial H/D exchange observed during the reaction. A similar mechanistic scenario has been described earlier for the reactions of $FeO^+$ with alcohols.[22] According to Figure 1, the proton affinity $PA(VO_3H)$ lies between $PA(C_2H_4)$ = 680 kJ mol$^{-1}$ and $PA(C_4H_6)$ = 783 kJ mol$^{-1}$, because for ethanol the equilibrium is shifted completely on the side of $VO_3H_2^+$ and mostly to the carbocation side for the isomeric butenols. $I_{rel}$ = 0.5 is expected for a proton affinity slightly lower than the one of propene, thus leading to $PA(VO_3H) = 730 \pm 10$ kJ mol$^{-1}$. Note that $I_{rel} = I(C_3H_5^+)/(I(VO_3H_2^+) + I(C_3H_5^+)) = 0.88$ for the reaction of allyl alcohol with $VO_2^+$ suggests that the hydroxide abstraction is not followed by a rearrangement of allene to the thermochemically more stable propyne,[20] because the amount of $VO_3H_2^+$ is significantly lower than in the butanol systems even though the proton affinities of propyne and *trans*-butene are similar. Combination of $\Delta_fH(VO_3H) = -390 \pm 50$ kJ mol$^{-1}$ and $PA(VO_3H) = 730 \pm 10$ kJ mol$^{-1}$ leads to $\Delta_fH(VO_3H_2^+) = 410 \pm 60$ kJ mol$^{-1}$, which compares reasonably well with the lower boundary derived above.

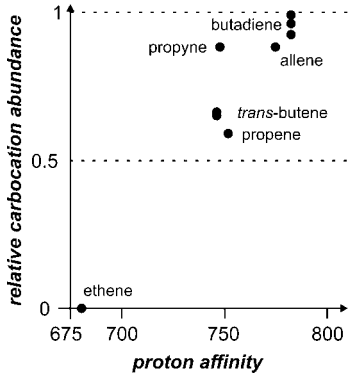

Figure 1. Relative carbocation abundance $I_{rel} = I(\text{carbocation})/[I(\text{carbocation}) + I(VO_3H_2^+)]$ vs. proton affinities[20] (in kJ mol$^{-1}$) of the produced alkenes in the reactions of $VO_2^+$ with alcohols.

The different branching ratios for the reactions of $VO_2^+$ and $VO^+$ with alcohols cannot be explained by the stability of the carbocations formed because they are the same in both cases. But one may assume that the difference in selectivity might be due to an enhanced exothermicity of the charge recombination reaction $VO_2^+ + OH^- \rightarrow VO_3H$ compared to the similar formation of $VO_2H$ from $VO^+$ which could also lower the corresponding transition structure. However, the formation of neutral $VO_3H$ from $VO_2^+ + OH^-$ ($\Delta_rH$ = –1245 kJ mol$^{-1}$) is not favored compared to $VO^+ + OH^- \rightarrow VO_2H$ ($\Delta_rH$ = –1246 kJ mol$^{-1}$) according to the data derived here. Thus, the different bond dissociation energies simply reflect the different ionization energies of VO and $VO_2$.

## Conclusions

Due to the Lewis-acidic character of vanadium-oxide cations, dehydration prevails in their ion/molecule reactions with most alcohols investigated. Oxidation of the alcohol can only compete efficiently for methanol and allyl alcohol, for which dehydration is unfavorable. The monoxide $VO^+$ mediates dehydrogenation without changing the metal's oxidation state ($V^{III}$). The reaction with $VO_2^+$ ($V^V$) leads to the very same product ions. The metal therefore is reduced and water instead of hydrogen is formed. Thus, $VO_2^+$ induces an oxidative dehydrogenation of alcohols. During the major pathways of larger alcohols with $VO_2^+$, a pre-equilibrium between alkene and hydroxide complexes is proposed as the relative amount of carbocation vs. alkene formation clearly reflects the respective proton affinities. In contrast to the fragmentation behavior of the alcohol complexes $VO(ROH)^+$, the metastable ion spectra of the isomeric alkoxides $V(OH)(OR)^+$ reveal a preference for dehydrogenation even for alcohols larger than methanol.

## Experimental Section and Computational Details

Ion/molecule reactions were examined with a Spectrospin CMS 47X FT-ICR mass spectrometer equipped with an external ion source as described elsewhere.[32,41] In brief, $V^+$ is generated by laser ablation of a vanadium target using a Nd:YAG laser operating at 1064 nm. A series of potentials and ion lenses is used to transfer the ions into the ICR cell, which is positioned in the bore of a 7.05 T superconducting magnet. Mass-selected $^{51}V^+$ is then converted to $VO^+$ or $VO_2^+$ by reaction with pulsed-in $O_2$ or $N_2O$, respectively.[17,42] During the gas pulses, the ions undergo several hundreds of collisions such that the product ions are assumed to be thermalized.[43] The reactivity of the mass-selected ion of interest was studied by introducing neutral reactants via leak valves at stationary pressures in the order of $10^{-8}$ mbar. The experimental second-order rate constants are evaluated assuming the pseudo first-order kinetic approximation after calibration of the measured pressures and acknowledgement of the ion gauge sensitivities;[44] the error of the absolute rate constants is assumed to be ± 30%, while the error for the relative rate constants is only 10%.

Additional experiments were performed with a modified VG ZAB/HF/AMD 604 four-sector mass spectrometer of BEBE configuration (B stands for magnetic and E for electric sector) which has been described in detail previously.[45] Briefly, cations were generated by chemical ionization (CI) of mixture of $(C_5H_5)V(CO)_4$ and the respective alcohol using $N_2O$ as reagent gas. After acceleration to a kinetic energy of 8 keV, the ions were mass-selected and subjected to metastable ion (MI) and collisional activation (CA) stud-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ies. MI spectra of B(1)/E(1) mass-selected ions were recorded by detection of the charged fragments formed unimolecularly in the field-free region between E(1) and B(2) by scanning the latter sector. CA spectra were recorded in the same manner using helium (80% transmission) as a stationary collision gas. As the CA spectra were all dominated by the MI signals, only the MI spectra are discussed here. Nevertheless, the CA spectra confirm that the selected ion really is a vanadium-oxide species as indicated by the presence of signals for $V^+$, $VO^+$, $VOH^+$, $VO_2^+$, $VO_2H^+$ or $VO_2H_2^+$. The error of the reported abundances amounts up to 10% due to low yields in the gas-phase synthesis of the desired complexes.

All unlabeled reagents and $(C_5H_5)V(CO)_4$ were used as purchased and introduced by conventional vacuum techniques. The labeled alcohols were synthesized following well-known laboratory procedures.[27]

All calculations employed the hybrid density-functional theory (DFT) B3LYP method[46] implemented in the Gaussian 98 program package[47] in combination with Ahlrichs' valence triple-ζ basis sets with polarization functions on all atoms[48] which yielded good results in a previous benchmark study of vanadium alkoxides.[9] Vibrational frequencies were computed for all stationary points obtained in order to confirm that each optimized geometry corresponds to a local minimum. All energies given below refer to 0 K and include zero-point energy correction.

# On In Situ Prepared Cu–Phenanthroline Complexes in Aqueous Alkaline Solutions and Their Use in the Catalytic Oxidation of Veratryl Alcohol

**Heikki Korpi,[a] Paweł J. Figiel,[a] Elina Lankinen,[a] Paul Ryan,[a] Markku Leskelä,[a] and Timo Repo*[a]**

**Keywords:** Catalysis / Copper / Dioxygen / Active species / Oxidation

The in situ prepared complex based on copper(II) sulfate and 1,10-phenanthroline (phen) and its performance in the catalytic oxidation of veratryl alcohol (3,4-dimethoxybenzyl alcohol) to veratraldehyde with $O_2$ in alkaline aqueous solutions have been studied. In aqueous solution, the structure of Cu–phen complexes varies with reaction conditions; by changing either the copper-to-ligand molar ratio or the pH, the amount of coordinated 1,10-phenanthroline and hydroxido ligands in the coordination sphere of copper can be altered in a controlled manner. The highest activities are achieved in the pH range 12.6–13.3, which correlates with the presence of the [Cu(phen)$(OH)_2$] species according to complex distribution curves. According to the UV/Vis and EPR studies, the oxidation reaction is initiated by the reduction of [Cu(phen)$(OH)_2$] to $Cu^I$ species by veratryl alcohol, which can be seen as a disappearance of the $Cu^{2+}$ EPR signal and as a shift of the UV/Vis absorbance maximum from about 690 nm to the 410 and 525 nm regions. When molecular oxygen is added, the $Cu^I$ species is readily oxidised back to $Cu^{II}$ species, and the catalytic formation of aldehyde is initiated. On the basis of these observations, a mechanism for the catalytic oxidation is proposed.

## Introduction

Selective oxidation of alcohols to the corresponding aldehydes, ketones and acids finds its importance in the pharmaceutical industry as well as in the large-scale chemical industry. For further development of these applications towards more sustainable processes, the use of aqueous solutions and molecular oxygen as a cheap, easily available and environmentally friendly oxidant would be highly beneficial.[1]

(Diimine)copper complexes with different polypyridyl ligands like 2,2′-bipyridine (bipy) and 1,10-phenanthroline (phen) have been studied as catalysts in the oxidation of primary alcohols since the 1970s.[2,3] Because of their potency to activate molecular oxygen, various applications have been developed including (diimine)copper-catalysed DNA scission,[4] oxidation reactions[2,3] and pulp bleaching.[5,6] Lately, highly active catalysts combining Cu–diimine complexes and TEMPO,[7] $DEADH_2$ (= diethylhydrazine dicarboxylate) or $DBADH_2$ (= di-*tert*-butylhydrazine dicarboxylate)[8] as co-activators have been reported for the oxidation of primary and secondary alcohols to corresponding aldehydes and ketones by air. In addition to the diimine-based catalysts, efficient copper phenoxyl radical catalysts have recently been introduced for the oxidation of alcohols.[9,10]

We recently reported that various in situ prepared (diimine)copper complexes catalyse selective oxidation of veratryl alcohol in aqueous solutions.[6,11] However, the alkaline reaction conditions needed for high catalytic activity together with the presence of paramagnetic Cu species reduce the choice of the analytical methods that can be used to elucidate the solution structures of the complexes and their catalytic reactions. By combining UV/Vis measurements with EPR spectroscopy, complementary pH and GC monitoring of the reaction, consistent information about the catalyst structure and the oxidation reaction were gathered. As a result of these measurements, we report herein the studies of the structure of an in situ prepared (phenanthroline)copper(II) complex under alkaline conditions and its use in the catalytic oxidation reaction.

## Results and Discussion

### The Nature of In Situ Prepared $Cu^{II}$ Complexes

UV/Vis spectroscopy is a method that is widely used to investigate qualitative as well as quantitative changes in the coordination sphere of transition-metal complexes, and extensive studies on $Cu^{II}$ species in aqueous media have been reported. In fact, the first visible spectra of (diimine)copper complexes were reported already in the 1950s[12] followed by numerous studies elucidating the structures of these complexes and their spectroscopic properties.[13a] Because of the available data and simple sample preparation, we

Table 1. Main UV/Vis absorbances of selected Cu–phen complexes at a copper concentration of 0.01 M.

| Molar ratio M/L | $[OH^-]$ /M | $\lambda_{max}$ /nm | $\varepsilon_{max}$ /$M^{-1}cm^{-1}$ | Main species |
|---|---|---|---|---|
| $CuSO_4$ | – | 800 | 12 | $[Cu(H_2O)_6]^{2+}$ |
| 1:1 | – | 710 | 12 | $[Cu(phen)]^{2+}$, $Cu(phen)SO_4$ precipitates |
| 1:2 | – | 720, ≈920 | 57 | $[Cu(phen)_2]^{2+}$ |
| 1:4 | – | 680 | 46 | $[Cu(phen)_3]^{2+}$ |
| 1:1 | 0.05 | 660 | 45 | $[Cu(phen)(OH)]_2^{2+}$ |
| 1:2 | 0.01–0.05 | 690, ≈920 | 55 | $[Cu(phen)_{2-3}]^{2+}$, $[Cu(phen)(OH)_2]$ |
| 1:2 | 0.1–0.5 | 690 | 44 | $[Cu(phen)(OH)_2]$ |
| 1:2 | 0.5–2.0 | 620–600 | 40–38 | $[Cu(OH)_4]^{2-}$ |
| 1:4 | 0.05 | 690, ≈920 | 56 | $[Cu(phen)_{2-3}]^{2+}$, $[Cu(phen)(OH)_2]$ |

found UV/Vis spectroscopy to be a useful method to investigate these efficient in situ prepared Cu–phenanthroline catalysts under alkaline conditions.

When reaction conditions are varied, the formation of different Cu–phen complexes in aqueous solutions is fast and reversible. In pure aqueous solution, copper(II) sulfate forms a light blue (aqua)copper complex, $[Cu(H_2O)_6]^{2+}$ (Figure 1, species A), which has a wide absorbance maximum at the 800-nm region (Table 1). When one equivalent of the phenanthroline ligand is added, the absorbance is shifted to 710 nm and light blue $Cu(phen)SO_4$ precipitates. Addition of a second equivalent of the ligand dissolves this precipitate and forms a $[Cu(phen)_2]^{2+}$ complex in which either a sulfate anion or water molecules complete the coordination sphere of copper. This solution has its main peak in the 720-nm region, while another peak/shoulder is observed at 920 nm (Figure 1, species B). When more than two equivalents of phenanthroline are added, a tris(chelated) $[Cu(phen)_3]^{2+}$ complex (Figure 1, species C) becomes the major species in neutral solution, the absorbance maximum is shifted to 680 nm and the shoulder at 920 nm assigned to the $[Cu(phen)_2]^{2+}$ complex disappears.

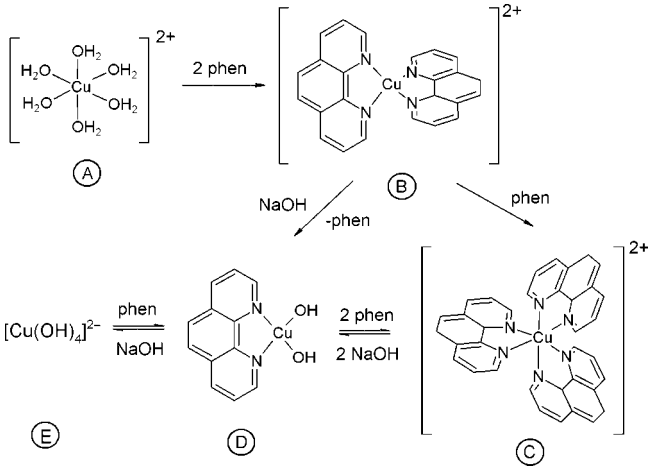

Figure 1. Formation of the catalytically active species D. The amount of coordinated phenanthroline and hydroxido ligands (marked as phen and NaOH) can be controlled by varying the concentration.

The $Cu(phen)SO_4$ precipitate can also be dissolved with an addition of sodium hydroxide (0.05 M), which leads to the formation of a dark blue solution with an absorbance maximum at around 660 nm. According to the distribution plots, the $[Cu(phen)(OH)]_2^{2+}$ dimer is the major component in this solution (Figure 2A). Similar spectra have previously been measured for isolated dihydroxido-bridged Cu–phen complexes.[14] Apparently, in alkaline conditions, the system studied becomes dynamic, and as a result, the $\lambda$ values are rather a sum of different species than those for one independent complex in the solution.

Addition of 0.05 M NaOH to the $[Cu(phen)_2]^{2+}$ solution leads readily to the formation of the $[Cu(phen)(OH)_2]$ complex, and the main absorbance maximum is shifted to a wavelength of 690 nm (Figure 2B and Figure 1, species D). Similarly, when $OH^-$ is added to a $[Cu(phen)_3]^{2+}$ solution, the absorbance maximum is again shifted to 690 nm (Figure 1, species D), indicating the replacement of two phenanthroline ligands by hydroxido ligands and formation of the $[Cu(phen)(OH)_2]$ species. Increasing the $OH^-$ concentration above 0.5 M shifts the absorbance maximum towards shorter wavelengths as the coordinated phenanthroline ligand is replaced by hydroxido ligands (Figure 1, species E, Figure 2). On the basis of the above results, it is obvious that, by varying hydroxide ion and ligand concentrations, the amount of coordinated phenanthroline and hydroxido ligands can be controlled. These observations are comparable with the studies of Garribba et al., in which they demonstrated by UV/Vis and EPR spectroscopic measurements how the structure of the (2,2′-bipyridine)copper complex changes in alkaline solutions.[13a]

Our previous oxidation studies have revealed that the catalytic activity of these in situ prepared copper complexes is significantly dependent on the applied pH and the ligand concentration.[6,11] The stability constant of a complex determines the optimum copper-to-ligand molar ratio at a chosen $OH^-$ concentration, and thus strongly coordinating phenanthroline has maximum activity at the copper/ligand molar ratio 1:5 at high pH (>12.6; 0.05 M NaOH). Under these optimised reaction conditions, the $[Cu(phen)(OH)_2]$ complex is the predominant species (the absorbance maximum of the solution is at about 690 nm) and seems to be responsible for the catalytic activity (Figure 2C). When the copper/ligand molar ratio 1:2 is employed, $OH^-$ concentrations above 0.05 M shift the absorbance maximum towards shorter wavelengths as a result of complex decomposition and $Cu(OH)_4^{2-}$ formation (Figure 2B). However, when the optimised copper/ligand molar ratio is applied, the absorption maximum at 690 nm remains until the $OH^-$ concentration exceeds 0.5 M. While the high pH is a prerequisite for

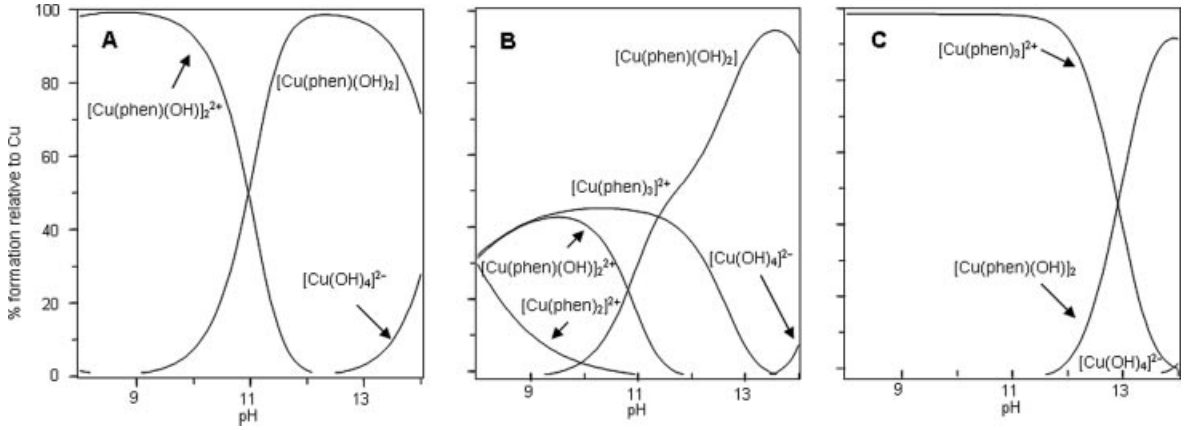

Figure 2. Complex distribution curves for (phenanthroline)copper complexes in alkaline water solutions. Calculated for [Cu] = 0.01 M, ionic strength = 0.1 M, Cu/phen = 1:1 (A), 1:2 (B) and 1:4 (C). See the Experimental Section for details.

the efficiency of the oxidation reaction, the role of the ligand excess is, according to these results, to protect the [Cu(phen)(OH)$_2$] complex from the destructive coordination of a hydroxide ion.

### Isolated [Cu(phen)$_2$]$^{2+}$ Complex

When the authentic catalyst solution is allowed to stand in an open vessel, the Cu(phen)$_2$CO$_3$·7H$_2$O complex crystallises out as a result of the slow evaporation of water. X-ray crystallographic analysis of the crystals revealed that the coordination polyhedron of the copper atom has a square pyramidal geometry as reported previously by van Eldik et al. (cell parameters are given in the Experimental Section).[15] In the complex, the OH$^-$ ligand is replaced by a carbonate anion as a consequence of $CO_2$ dissolution during the crystallisation procedure (Figure 3).

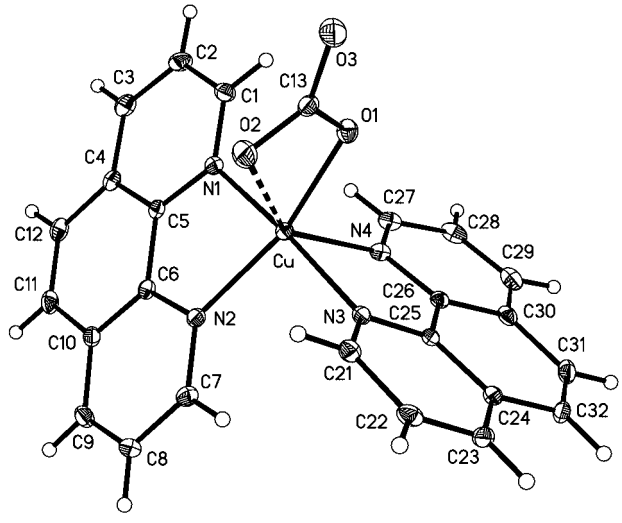

Figure 3. Solid-state structure of Cu(phen)$_2$CO$_3$ which crystallised out from the authentic catalyst solution kept in an open vessel.

The isolated Cu(phen)$_2$CO$_3$ complex behaves quite similarly to the in situ prepared catalyst upon variation of the reaction conditions. When the Cu(phen)$_2$CO$_3$ complex is dissolved in water, an absorbance maximum appears in the visible spectrum at 680 nm, while addition of excess ligand (total M/L molar ratio 1:4) to the solution removes the carbonate anion from the coordination sphere of copper, and the $\lambda_{max}$ of [Cu(phen)$_3$]$^{2+}$ appears. In alkaline solution (0.05 M), the absorbance maximum of the isolated complex is shifted to 690 nm, which indicates the formation of the [Cu(phen)(OH)$_2$] complex. In highly basic conditions, the absorbance maximum is shifted to shorter wavelengths as the phenanthroline ligand is replaced by a hydroxide ion. Analogously, in oxidation experiments at pH 12.6, the addition of free ligand to the Cu(phen)$_2$CO$_3$ solution enhanced the catalytic activity.[16]

### Reaction Monitoring by pH and GC Analysis

The oxidation of veratryl alcohol with Cu–phen catalyst was monitored with parallel pH and GC analysis in order to determine any possible correlations between aldehyde formation and the consumption of hydroxide ions. In these reactions, an initial pH of 11.6 (0.005 M NaOH) was applied, as even modern pH electrodes seem to be too inaccurate for such a study at pH values higher than 12. During the first 20 min of the reaction the pH decreases rapidly. This decrease is mainly related to the initiation of the catalytic reaction. In general, veratryl alcohol oxidation and OH$^-$ consumption proceed parallel to one another (Figure 4); the actual molar ratio of these two species is around 10. After 2 h, the pH is reduced to around 10 and the oxidation decelerates. The reaction rate can be increased again by the addition of NaOH (marked in Figure 4). The high aldehyde/OH$^-$ ratio indicates that, after initiation, the catalytic oxidation reaction itself does not consume OH$^-$ ions. A possible reason for the minor OH$^-$ consumption during the reaction is the formation of a hydroperoxyl radical, which consumes base when forming the superoxide radical anion.[17] Another reason for the decrease in pH is the formation of traces of veratric acid as detected by GC–MS.

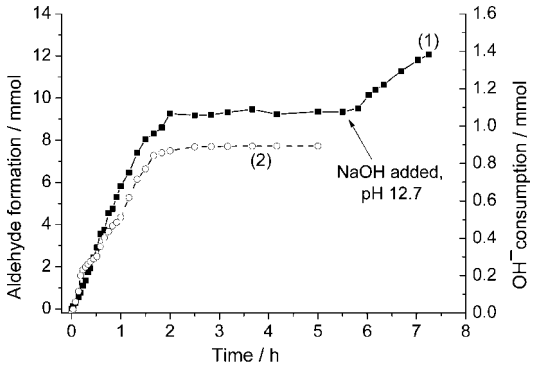

Figure 4. Rate of oxidation and total $OH^-$ consumption in the Cu–phen-catalysed reaction: (1) formation of veratraldehyde and (2) consumption of $OH^-$ ions. Reaction conditions: 80 °C, 10 bar $O_2$, initial pH 11.6, Cu/veratryl alcohol molar ratio 1:500.

### Visible Spectrum of $Cu^I$–phen

A copper(I) complex prepared from $Cu_2O$ and phenanthroline gives a dark red solution in alkaline aqueous media under an argon atmosphere. In solution, the bis(phenanthroline)copper(I) should possess nearly regular $D_{2d}$ symmetry.[18,19] As a result of the presence of the low-energy π* orbitals of the phenanthroline ligand, the complex exhibits strong metal-to-ligand charge-transfer absorption bands in the visible spectrum (Figure 5). The absorption involves the transfer of an electron from the d shell of the copper centre to π* orbitals of the coordinated ligand. Solutions of the $Cu^I$–phen complex can be stored under argon, but are oxidised to $[Cu(phen)(OH)_2]$ by oxygen after a few minutes as the absorbances maxima at 405 and 535 nm disappear and that at 690 nm strengthens. This process is assisted by hydrogen peroxide formation; when a solution of the bis(phenanthroline)copper(I) complex was exposed to air, small amounts (≈2 mg $L^{-1}$) of $H_2O_2$ were detected.[20] In conclusion, changes in the oxidation state of copper can be determined in the visible region as $Cu^I$ and $Cu^{II}$ species have characteristic absorbances at different wavelengths.

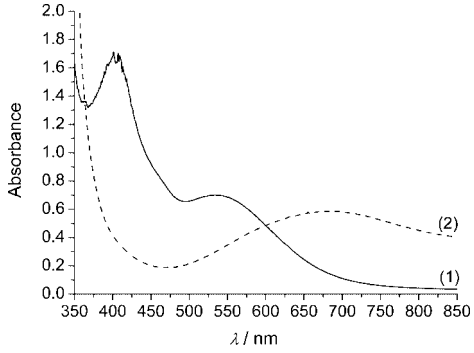

Figure 5. UV/Vis spectrum of $[Cu(phen)_2]^+$ oxidation by $O_2$: (1) the spectrum of the complex under an argon atmosphere, (2) the spectrum after $O_2$ bubbling. The $Cu^I$ sample was diluted for the measurement. Conditions: 25 °C, [NaOH] 0.05 M, [Cu] 0.01 M.

### Reaction Monitoring by UV/Vis Spectroscopy

UV/Vis spectroscopy turned out to be highly useful for monitoring the reaction. The addition of veratryl alcohol to an alkaline catalyst solution results in the formation of small absorption bands in the 410 and 525 nm regions, which indicates the presence of the $Cu^I$ species. The reduction of $Cu^{II}$ is seen more clearly when the reaction is carried out under an argon atmosphere (Figure 6, spectra 1–3); the absorbance maximum at 690 nm decreases while absorbances at 410 nm and 525 nm increase. Upon addition of oxygen, the characteristic absorbance maximum of the $Cu^{II}$ species increases again (spectra 4–5).

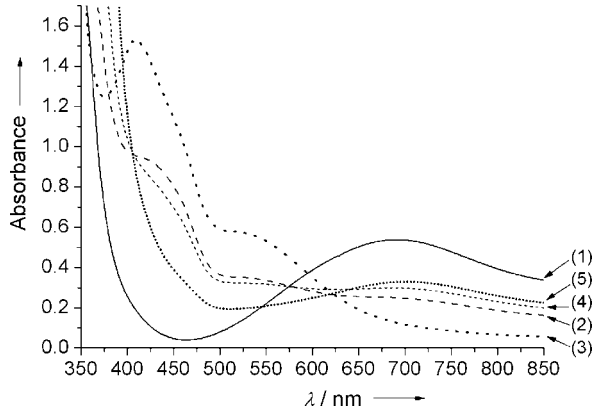

Figure 6. A UV/Vis spectrum of $Cu^{II}$ reduction to $Cu^I$ by alcohol under argon and reoxidation after oxygen addition. (1) $Cu^{II}$–phen complex under argon, (2) veratryl alcohol added, (3) 60 h under argon, (4) 1 h after $O_2$ addition, 18% aldehyde (5) 23 h, 93% aldehyde. Reaction conditions: 80 °C, 1 bar $O_2$, pH 12.6, [Cu] 0.01 M, Cu/veratryl alcohol molar ratio 1:20. The $Cu^I$ samples were diluted for the measurement.

A small percentage of aldehyde (4%) can be detected when a 10 mol-% loading of Cu vs. alcohol is used under an argon atmosphere. In these conditions, the Cu/aldehyde ratio is 2.5, which indicates that two electrons are involved in veratryl alcohol oxidation. However, significant aldehyde formation only begins after the addition of oxygen. If $Cu^I$–phen (prepared from $Cu_2O$ and phen) is used in the reaction in place of $Cu^{II}$–phen, no aldehyde is formed under an argon atmosphere. This shows that the alcohol is able to reduce copper(II) under anaerobic conditions, and the catalytic cycle begins when oxygen is added. If the reaction solution is degassed and set under an argon atmosphere again, the colour changes to dark brown, and the absorbances of $Cu^I$ strengthen again.

Formation of the $Cu^I$ species has also been observed in the oxidation of benzyl alcohol with $[Cu(bipy)_2]^{2+}$ catalyst, but it was concluded that in acetonitrile solution the $Cu^I$ species inhibits the oxidation while the actual catalysis proceeds via $Cu^{III}$ intermediates.[2f] However, under the applied reaction conditions here, the reduction of $Cu^{II}$ to $Cu^I$ is a prerequisite for the formation of aldehyde, and during the reaction both $Cu^I$ and $Cu^{II}$ complexes are present. In this respect, the redox behaviour of the Cu species resembles that observed by Tretyakov et al. for the oxidation of propanol.[3]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### EPR Studies

The EPR spectrum of the in situ prepared $Cu^{II}$–phen complex in alkaline medium at room temperature is shown in Figure 7a. The typical four-line Cu hyperfine split signal (without sfhs from N atoms) with $g_{\|} = 2.33$, $g_{\perp} = 2.06$ and hfs constant $A_{\|} = 75$ G is in good agreement with previous reports for $Cu^{II}$–diamine tetragonal complexes with ground state $d_{x^2-y^2}$.[13]

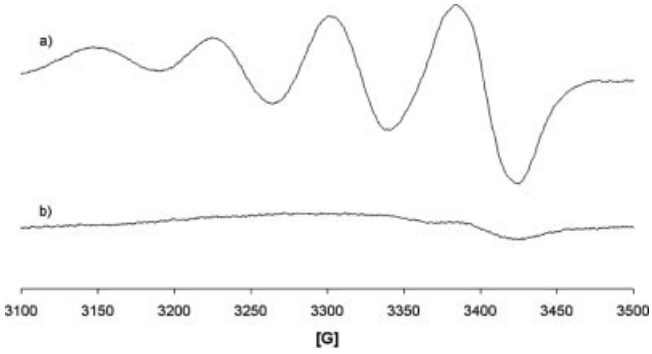

Figure 7. X-band EPR spectrum of the reduction of $Cu^{II}$ to $Cu^{I}$ by alcohol under nitrogen, (a) $Cu^{II}$–phen complex under nitrogen, (b) excess veratryl alcohol added. Reaction conditions: room temp., pH 12.6, [Cu] = 0.01 M, Cu/veratryl alcohol molar ratio ca. 1:200.

The addition of an excess of veratryl alcohol (alcohol/[Cu]: c.a. 200) to the $Cu^{II}$–phen complex solution in the absence of oxygen (nitrogen atmosphere) results in the disappearance of the $Cu^{II}$ signal (Figure 7b). This suggests that alcohol can reduce the $Cu^{II}$–phen complex to an EPR-silent $Cu^{I}$ ($d^{10}$) species. An identical solution of the $Cu^{II}$–phen complex in alkaline medium containing an excess of veratryl alcohol exposed to air under the same conditions exhibits no reduction of $Cu^{II}$ to $Cu^{I}$. These EPR spectroscopic observations confirm the previous UV/Vis spectroscopic interpretations (see previous section).

### Catalytically Active Species

The correlation between the catalytic activity and absorbance of the in situ prepared complex in alkaline aqueous solution indicates that high pH and the presence of the $[Cu(phen)(OH)_2]$ complex are essential for catalytic activity. As demonstrated above, in the presence of hydroxide ions and veratryl alcohol, the $[Cu^{II}(phen)(OH)_2]$ species is reduced by veratryl alcohol to $[Cu^{I}(phen)(OH)]$ [Equation (1)]. Consequently, in the absence of oxygen, the formation a small percentage of aldehyde is observed at low copper/alcohol ratios (1:10). In neutral or acidic solutions, neither catalyst reduction nor aldehyde formation was observed.

The $Cu^{I}$–phen complex formed is oxidised to $Cu^{II}$–phen species by oxygen as shown in Figure 5. In this process, hydrogen peroxide is formed even in the absence of veratryl alcohol [Equation (2)]. As shown in Figure 1 and Figure 2, the coordination sphere of the $Cu^{II}$ complex is balanced by a dynamic self-assembly process under alkaline conditions, and the formation of initial species, $Cu^{II}(phen)(OH)_2$ is feasible [Equation (3)].

$$2[Cu^{(II)}(phen)(OH)_2] + RCH_2OH \longrightarrow 2[Cu^{(I)}(phen)(OH)] + RCHO + 2H_2O \quad (1)$$

$$2[Cu^{(I)}(phen)(OH)] + O_2 + 2H_2O \longrightarrow 2[Cu^{(II)}(phen)(OH)] + H_2O_2 + 2OH^- \quad (2)$$

$$2[Cu^{(II)}(phen)(OH)] + 2\ OH^- \longrightarrow 2[Cu^{(I)}(phen)(OH)_2] \quad (3)$$

$$\text{overall: } RCH_2OH + O_2 \longrightarrow RCHO + H_2O_2 \quad (4)$$

On the basis of these results, a proposed mechanism for the Cu–phen-catalysed oxidation reaction is summarised in Figure 8. Unfortunately, direct spectroscopic evidence for the short-lived intermediates in the catalytic cycle is not available. Therefore, it can not be excluded that, under alkaline conditions, an alcohol molecule could also coordinate to the $[Cu^{I}(phen)(OH)]$ complex to form a $Cu^{I}$–alkoxide complex, which converts alcohol to aldehyde via a copper(II) alkoxide peroxo species. Also in this pathway hydrogen peroxide is released, but $Cu^{I}$ works as the actual catalyst. The formation of hydrogen peroxide with the catalyst but in the presence of alcohol has also been shown earlier.[21] However, all of the experimental observations, such as the reduction of $Cu^{II}$ by alcohol, the minor $OH^-$ consumption during the catalytic cycle, the oxidation of $Cu^{I}$ by oxygen and the formation of hydrogen peroxide even in the absence of alcohol can be reasonably explained by the proposed mechanism in Figure 8. After all, the proposed catalytic cycle has similarities with a ping-pong mechanism proposed previously for galactose oxidase.[22]

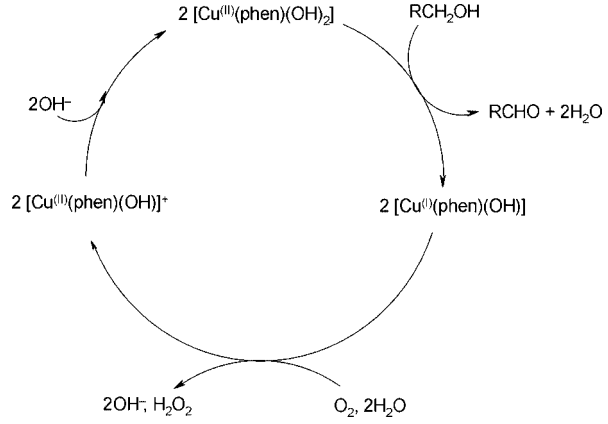

Figure 8. The proposed catalytic cycle for the oxidation of veratryl alcohol in alkaline media with the in situ prepared Cu–phen catalyst by using dioxygen as the end-oxidant.

## Conclusions

In alkaline aqueous solution, in situ addition of copper sulfate to phenanthroline leads to the formation of various complexes by a self-assembly process depending on the $OH^-$ concentration and phenanthroline-to-copper molar ratio. The dynamic changes in the coordination sphere of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

catalyst upon variation of the reaction conditions were identified by UV/Vis spectroscopy and verified with the complex distribution curves. As the ligand concentration and pH are interdependent, under optimum reaction conditions the $OH^-$ concentration needs to be adequate for efficient alcohol oxidation, and the phenanthroline concentration should be high enough to preserve the structure of the $[Cu(phen)(OH)_2]$ species, whose presence is essential for high catalytic activity.

Under alkaline conditions and in the presence of veratryl alcohol, $[Cu^{II}(phen)(OH)_2]$ is reduced to the $[Cu^{I}(phen)(OH)]$ species. When oxygen is added, the $Cu^{I}$ species is readily oxidised back to the $Cu^{II}$ species, and the catalytic formation of aldehyde is initiated. The catalytic reaction was further studied by combining pH and gas chromatographic monitoring with UV/Vis and EPR spectroscopy. On the basis of these results, a catalytic cycle for the oxidation of veratryl alcohol was proposed.

## Experimental Section

Commercially available copper sulfate, 1,10-phenanthroline and veratryl alcohol (3,4-dimethoxybenzyl alcohol, 96%) were used without further purification. Deionised water and oxygen (AGA 99.5) were used for the reactions.

### pH and Oxidation Monitoring

For the pH and gas chromatographic reaction monitoring, veratryl alcohol (4.0 mL, 27.5 mmol) and catalyst in a molar ratio of 1:500 (0.055 mmol) to veratryl alcohol were mixed in NaOH solution (200 mL). A copper/phenanthroline molar ratio of 1:2 was used. A 400-mL glass vessel with a magnetic stirring bar was fitted inside a 1-L steel autoclave, and the desired oxygen pressure (10 bar) and temperature (80 °C) were set. Samples were taken from the reactor and cooled to room temperature. The pH was measured, and a sample was prepared for GC analysis by a method described earlier (extraction with ethyl acetate) and analysed with GC/FID Agilent 6890N using an HP-5 30 m × 320 μm × 0.25 μm capillary column.[11] After extraction, the aldehyde was the only product. However, if alcohol conversions were remarkably high, also a small amount of veratric acid (< 1%) was detected by HPLC analysis.

### UV/Vis Spectroscopy

UV/Vis spectroscopic measurements were carried out with a HP 8453 spectrophotometer, and the data was analysed with UV/Vis ChemStation software. To see the changes in the visible region of the UV/Vis spectra, high catalyst concentrations (0.01 M) were used. For a usual reaction $CuSO_4$ (0.160 g, 1.0 mmol), 1,10-phenanthroline (0.3965 g, 2.0 mmol) and veratryl alcohol (2.9 mL, 20 mmol) were mixed in $H_2O$ (100 mL). In the oxidation reactions monitored with UV/Vis spectroscopy, the oxygen atmosphere was maintained by using a balloon of oxygen. For the $Cu^{I}$ species, the samples were diluted to 0.001–0.0015-M solutions (of copper) with degassed solvent. Complex distribution charts (Figure 2) were calculated by using the HySS program.[23] Stability constants for the relevant species were obtained from the NIST Standard Reference Database 46.[24]

### EPR Spectroscopy

For an EPR experiment, a solution of Cu–phenanthroline complex (0.01 M) in NaOH (0.05 M) was prepared from $CuSO_4$ (0.016 g, 0.1 mmol) and 1,10-phenanthroline (0.0396 g, 0.2 mmol) in $H_2O$ (10 mL). To observe the decay of the $Cu^{II}$ signal, veratryl alcohol (2.9 mL, 20 mmol) was mixed with the Cu–phenanthroline complex. Samples were degassed with flow of nitrogen gas (30 min) and contained in quartz capillary tubes.

X-band EPR spectra were measured with a Bruker ESP 300E spectrophotometer equipped with the Bruker NMR gaussmeter ER035 M and the Hewlett–Packard microwave frequency counter with 100-kHz field modulation and a microwave power of 20 mW at room temperature. The data obtained was analysed with Bruker WinEPR software.

### Isolated $Cu(phen)_2CO_3·7H_2O$

Crystallisation of the Cu–phen complex was achieved by dissolving $CuSO_4$ (0.10 g, 0.63 mmol) and 1,10-phenanthroline (0.25 g, 1.26 mmol) in NaOH solution (0.05 M). Slow evaporation of water in room temperature yielded blue crystals of $Cu(phen)_2CO_3·7H_2O$. Crystal data for $C_{25}H_{30}CuN_4O_{10}$: $M_r$ = 610.07, space group $P2_1/c$, $a$ = 9.87930(10), $b$ = 26.2067(3), $c$ = 10.49350(10) Å, $\beta$ = 105.8390(10)°, $V$ = 2613.66(5) Å$^3$, $Z$ = 4, $D_c$ = 1.550 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 0.901 mm$^{-1}$, $T$ = 120(2) K, 5984 reflections measured, $F^2$ refinement, $R_1$ = 0.0555, $wR_2$ = 0.0856, 4647 independent observed absorption-corrected reflections, 363 parameters.

# Reactions of $t$Bu$_2$AlH and RE(SiMe$_3$)$_2$ (R = H, SiMe$_3$) – Synthesis and X-ray Crystal Structures of [$t$Bu$_2$AlP(H)SiMe$_3$]$_2$ and [$t$Bu$_2$AlE(SiMe$_3$)$_2$]$_2$ (E = Sb, Bi)

**Madhat Matar,[a] Andreas Kuczkowski,[a] Ulrich Keßler,[a] Stephan Schulz,*[a] and Ulrich Flörke[a]**

**Keywords:** Main group elements / Heterocycles / Solid state structures

Dehydrosilylation reactions between $t$Bu$_2$AlH and E(SiMe$_3$)$_3$ yielded the four-membered heterocycles [$t$Bu$_2$AlE(SiMe$_3$)$_2$]$_2$ (E = Sb, **1**; Bi, **2**), whereas no reaction was observed with P(SiMe$_3$)$_3$. In contrast, the reaction of $t$Bu$_2$AlH with HP(SiMe$_3$)$_2$ also proceeds with elimination of Me$_3$SiH and subsequent formation of [$t$Bu$_2$AlP(H)SiMe$_3$]$_2$ (**3**). Complexes **1**–**3** were characterized by multinuclear NMR ($^1$H, $^{13}$C{$^1$H}, $^{31}$P{$^1$H}) and mass spectroscopy, elemental analysis, and single-crystal X-ray diffraction.

## Introduction

Heterocyclic group 13/15 compounds of the type [R$_2$MER′$_2$]$_x$ have been studied for many years. In particular, amino-, phosphanyl- and arsinoalanes, -gallanes and -indanes [R$_2$MER′$_2$]$_x$ (M = Al, Ga, In; E = N, P, As) have been synthesized in large numbers by standard synthetic procedures such as alkane, hydrogen, and salt elimination reactions and structurally characterized.[1] Unfortunately, these reaction types almost completely failed to synthesize analogous group 13 stibides and bismuthides [R$_2$MER′$_2$]$_x$ (M = Al, Ga, In; E = Sb, Bi).[2] Therefore, alternative synthetic pathways had to be developed. The dehalosilylation reaction, which was introduced by Wells et al. for the synthesis of arsinogallanes in 1986,[3] was found to be suitable for the preparation of stibinogallanes and -indanes,[4] whereas the corresponding stibinoalanes,[5] as well as bismuthinoalanes[6] and -gallanes,[7] were synthesized by the dehydrosilylation reaction. This particular reaction sequence, which was introduced by Nöth et al. for the synthesis of phosphanylboranes [H$_2$BPR$_2$]$_3$,[8] is generally applicable for the synthesis of the desired group 13/15 heterocycles [R$_2$MER′$_2$]$_x$ (M = Al, Ga; E = P, As, Sb, Bi), as the reaction can be performed under kinetically controlled reaction conditions at low reaction temperatures,[9] which were found to be essential for the synthesis of group 13/Bi heterocycles such as [Me$_2$GaBi(SiMe$_3$)$_2$]$_3$ and [Me$_2$InBi(SiMe$_3$)$_2$]$_3$.[10] Mechanistic studies on the reactions of Et$_2$PSiMe$_3$ with HAlCl$_2$ and H$_2$AlCl clearly demonstrated that the dehydrosilylation reaction is favored over the dehalosilylation reaction.[11] In addition, the reaction of Me$_2$AlH with HP(SiMe$_3$)$_2$ also proceeds preferably with dehydrosilylation rather than H$_2$ elimination, even though subsequent transphosphanation reactions resulted in the formation of several Me$_2$AlP(SiMe$_3$)$_2$-containing species such as the trimeric phosphanylalane [(Me$_2$Al)$_3$(P(H)SiMe$_3$)$_2$P(SiMe$_3$)$_2$], which could be isolated[12] and structurally characterized.[13] In remarkable contrast to these findings, $i$Bu$_2$AlH preferably reacts with HP(SiMe$_3$)$_2$ with H$_2$ elimination and subsequent formation of [$i$Bu$_2$AlP(SiMe$_3$)$_2$]$_2$.[14] An analogous reaction sequence was observed for the reaction of $i$Bu$_2$AlH with Ph$_3$SiPH$_2$, also yielding the H$_2$ elimination product [$i$Bu$_2$AlP(H)SiPh$_3$]$_2$.[15] Obviously, the reaction mode is strongly influenced by the organic substituents bound to the Al atom.

Because of our general interest in group 13/15 chemistry of the heavier group 15 elements (Sb, Bi), we investigated reactions of $t$Bu$_2$AlH with E(SiMe$_3$)$_3$ (E = P, Sb, Bi) and HP(SiMe$_3$)$_2$ and report herein on the synthesis and single-crystal X-ray analyses of [$t$Bu$_2$AlE(SiMe$_3$)$_2$]$_2$ (E = Sb, **1**; Bi, **2**) and [$t$Bu$_2$AlP(H)SiMe$_3$]$_2$ (**3**), respectively.

## Results and Discussion

Equimolar amounts of $t$Bu$_2$AlH and E(SiMe$_3$)$_3$ (E = Sb, Bi) react at ambient temperature with elimination of Me$_3$SiH and subsequent formation of [$t$Bu$_2$AlE(SiMe$_3$)$_2$]$_2$ (E = Sb, **1**; Bi, **2**). In contrast, no reaction was observed with P(SiMe$_3$)$_3$, even at 180 °C.[16] Complex **2** was formed in only 25% yield because of decomposition reactions with subsequent formation of Bi$_2$(SiMe$_3$)$_4$, which has been previously shown to be the typical decomposition product of [Me$_2$MBi(SiMe$_3$)$_2$]$_3$ (M = Al,[6] Ga,[7] In[10]). To the best of our knowledge, **2** represents only the second structurally characterized heterocyclic bismuthinoalane to date [Equation (1)].

$$2\ t\mathrm{Bu_2AlH} + 2\ \mathrm{E(SiMe_3)_3} \xrightarrow[-\ 2\ \mathrm{Me_3SiH}]{} [t\mathrm{Bu_2AlE(SiMe_3)_2}]_2 \quad \mathrm{E = Sb\ \mathbf{1},\ Bi\ \mathbf{2}} \qquad (1)$$

Complexes **1** and **2** were characterized in detail by multinuclear NMR spectroscopy. $^1$H and $^{13}$C{$^1$H} NMR spectra of both compounds each show two sets of resonances due to the organic substituents (*t*Bu, $SiMe_3$). Mass spectra of **1** and **2** do not show the molecular ion peaks. The peak with the highest mass observed in both spectra corresponds to the monomeric unit ($M^+/2$).

Single crystals of **1** and **2** suitable for X-ray structure determination were obtained from solutions in toluene at –40 °C (Figures 1 and 2).

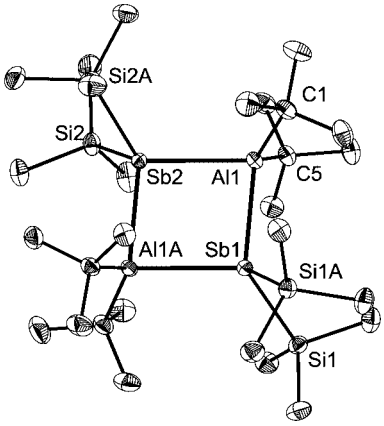

Figure 1. ORTEP plot (50% probability level; H omitted for clarity) showing the solid-state structure and atom-numbering scheme for **1**. Selected bond lengths [Å] and angles [°]: Al1–Sb1 2.786(1), Al1–Sb2 2.781(1), Sb1–Si1 2.587(1), Sb1–Si1A 2.587(1), Al1–C1 2.004(2), Al1–C5 2.005(2); Al1–Sb1–Al1A 94.1(1), Al1–Sb2–Al1A 94.3(1), Sb1–Al1–Sb2 85.8(1), C1–Al1–C5 117.5(1), Si1–Sb1–Si1A2 96.7(1), Si2–Sb2–Si2A2 96.2(1).

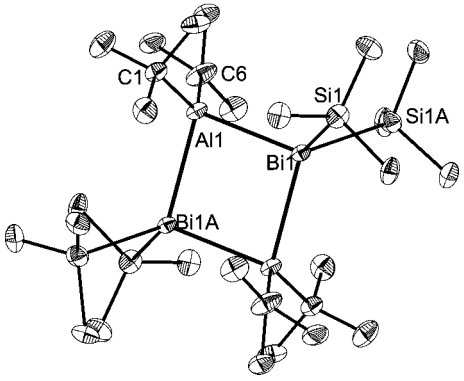

Figure 2. ORTEP plot (50% probability level; H omitted for clarity) showing the solid-state structure and atom-numbering scheme for **2**. Selected bond lengths [Å] and angles [°]: Al1–Bi1 2.840(2), Al1–Bi1A 2.840(2), Bi1–Si1 2.660(2), Bi1–Si1A 2.660(2), Al1–C1 2.008(7), Al1–C6 1.999(8); Al1–Bi1–Al1A 94.1(1), Al1–Bi2–Al1A 95.9(1), Bi1–Al1–Bi1A 84.1(1), C1–Al1–C6 118.9(3), Si1–Bi1–Si1A2 95.6(1).

Complexes **1** and **2** crystallize in the monoclinic space group *C*2/*c* (no. 15) **1** and *C*2/*m* (no. 12) **2** and adopt planar four-membered rings. The ring atoms reside in distorted tetrahedral environments, as is typical for this type of compound. The Al–Sb bond length (av. 2.784 Å **1**) is elongated compared to that of other heterocyclic stibinoalanes $[R_2AlSb(SiMe_3)_2]_x$ (av. values: R = Me, 2.719;[5b] Et, 2.726;[5a] *i*Bu, 2.744 Å[5a]) and base-stabilized monomeric derivatives dmap–$AlR_2Sb(SiMe_3)_2$ [R = Me, 2.691(1); Et, 2.680(1) Å],[17] most likely because of increased repulsive interactions between the sterically demanding organic substituents. Analogous trends are observed for the average Al–Bi bond length in **2** [2.840(2) Å], which is also longer than the average Al–Bi bond length observed in $[Me_2AlBi(SiMe_3)_2]_3$ (2.774 Å)[6] and dmap–$AlR_2Bi(SiMe_3)_2$ [R = Me, 2.755(2); Et, 2.750(2) Å],[18] the only structurally characterized organometallic Al–Bi compounds to date. The endocyclic Al–E–Al bond angles (94.2°, **1**; 95.9°, **2**) are bigger than the Al–E–Al bond angles (85.8°, **1**; 84.1°, **2**), as is typical for this type of heterocycle. The presence of bulky *t*Bu substituents leads to elongated Al–C bond lengths (av. 2.005 Å, **1**) compared to other four-membered Al–Sb heterocycles $[R_2AlSb(SiMe_3)_2]_2$ [R = Et, 1.971 Å, 117.3(1)°; *i*Bu, 1.983 Å, 121.3(1)°], as was previously reported for heterocyclic phosphanylalanes $[R_2AlP(SiMe_3)_2]_2$ (R = Me,[19] Et,[20] *i*Bu[12]). Surprisingly, the C–Al–C bond angle in **1** [117.5(1)°] is smaller than that observed for $[i\mathrm{Bu_2AlSb(SiMe_3)_2}]_2$ [121.3(1)°] and almost identical to that of $[Et_2AlSb(SiMe_3)_2]_2$ [117.3(1)°] despite the increased steric demand of the *t*Bu groups. The Al–C bond length (av. 2.004 Å) and C–Al–C bond angle in **2** [118.9(3)°] are comparable to those in **1**. The Sb–Si and Bi–Si bond lengths (av. 2.587 Å, **1**; 2.660 Å, **2**) are within the expected ranges; the average Si–Sb–Si bond angle in **1** (96.5°) is slightly bigger than the Si–Bi–Si bond angle of **2** (95.6°).

To our surprise, no reaction occurred when $t\mathrm{Bu_2AlH}$ and $P(SiMe_3)_3$ were heated up to 180 °C.[16] In contrast, $i\mathrm{Bu_2AlH}$ was reported to react slowly with $P(SiMe_3)_3$ at ambient temperature with formation of $[i\mathrm{Bu_2AlP(SiMe_3)_2}]_2$.[14,21] This finding prompted our interest in the reaction of $t\mathrm{Bu_2AlH}$ and $HP(SiMe_3)_2$, yielding $[t\mathrm{Bu_2AlP(H)SiMe_3}]_2$ **3** in high yield. $^{31}$P NMR spectroscopic studies gave no sign of any transphosphanation reaction involving species such as $PH_3$ and $Me_3SiPH_2$ as was reported for the reaction of $Me_2AlH$ and $HP(SiMe_3)_2$[12] [Equation (2)].

$$2\ t\mathrm{Bu_2AlH} + 2\ \mathrm{HP(SiMe_3)_2} \xrightarrow[-\ 2\ \mathrm{Me_3SiH}]{} [t\mathrm{Bu_2AlP(H)SiMe_3}]_2\ \ \mathbf{3} \qquad (2)$$

Complex **3** was characterized in detail by multinuclear NMR spectroscopy ($^1$H, $^{13}$C{$^1$H}, $^{31}$P{$^1$H}). The NMR spectra clearly proved the presence of a mixture of the *cis* and *trans* isomers of the four-membered ring in solution. The integration of the three resonances of the *t*Bu groups in the $^1$H NMR spectrum revealed the formation of a 1:1 mixture of the *trans* (one signal) and *cis* isomer (two signals). The $^{31}$P spectrum of **3** shows two multiplets of the AA′XX′ spin system (AA′ parts) and the $^{31}$P{$^1$H} spectrum shows two singlets of almost equal intensity at –229.6 and –232.8 ppm, respectively, for the *cis* and the *trans* iso-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mer. The $^{31}P\{^{1}H\}$ spectra of the mother liquor and the recrystallized product show the same relative intensities of both isomers (Figure 3).

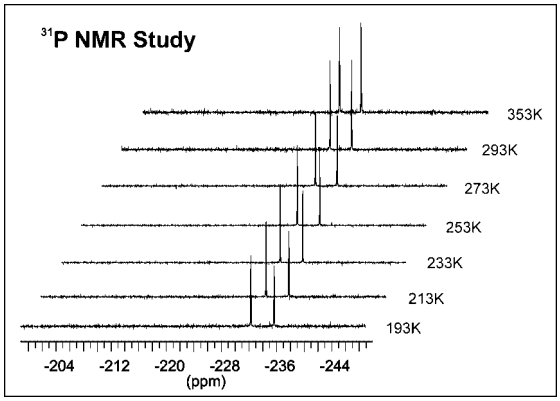

Figure 3. Temperature-dependent $^{31}P\{^{1}H\}$ NMR study of **3** in $[D_8]$toluene.

The formation of *cis* and *trans* isomers has been described previously for four-membered $M_2P_2$ heterocycles of the type $[R_2MP(H)R']_2$ such as $[Et_2InP(H)Si(iPr)_3]_2$,[22] $[Et_2GaP(H)SiMe_2(CMe_2iPr)]_2$,[23] and $[tBu_2InP(H)SiMe_3]_2$.[24] Surprisingly, a temperature-dependent $^{31}P\{^{1}H\}$ NMR study in $[D_8]$toluene of recrystallized **3** clearly revealed that there is no dynamic equilibrium between both isomers in solution in the temperature range from –80 to +80 °C. The relative concentrations of both isomers do not change and no coalescence was observed. A powder X-ray diffraction study proved the crystalline material to be exclusively the *trans* isomer (Figure 4). According to this result, cocrystallization of the *trans* and the *cis* isomer can be excluded.[25]

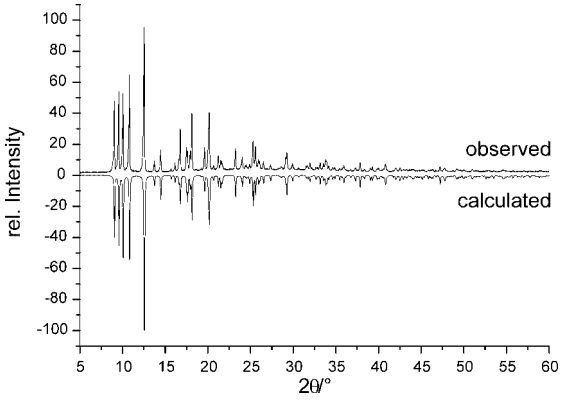

Figure 4. Experimental and calculated powder X-ray diffraction pattern of **3**.

The mass spectrum of **3** does not show the molecular ion peak but $M^+/2$ as was observed for **1** and **2**. An additional signal at *m*/*z* 363 ($[tBuAl_2P_2(SiMe_3)H]^+$) at very high intensity indicates the stability of the central four-membered $Al_2P_2$ ring under these specific conditions.

Single crystals of **3** suitable for X-ray structure determination were obtained from a solution in *n*-hexane at –40 °C. Figure 5 shows the solid-state structure of **3**.

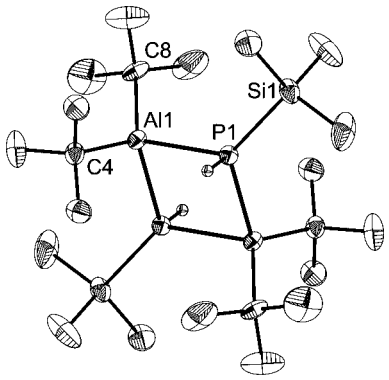

Figure 5. ORTEP plot (50% probability level; H omitted for clarity) showing the solid-state structure and atom-numbering scheme for **3**. Selected bond lengths [Å] and angles [°]: Al1–P1 2.465(1), Al1–P1A 2.459(1), P1–Si1 2.255(1), Al1–C4 1.998(2), Al1–C8 1.994(2); Al1–P1–Al1A 94.4(1), P1–Al1–P1A 85.6(1), C4–Al1–C8 121.0(2), Si1–P1–Al1 129.9(1), Si1–P1–Al1A 127.3(1).

Complex **3** crystallizes in the triclinic space group $P\bar{1}$ (no. 2) and adopts a planar four-membered heterocyclic structure. To the best of our knowledge, **3** represents the first structurally characterized dimeric phosphanylalane containing primary phosphido ($[RPH]^-$) bridges.[26] Comparable phosphanylgallanes $[R_2GaPHR']_2$ were shown to form either planar ($[Cl_2GaP(H)Si(tBu)_3]_2$,[27] $[tBu_2GaP(H)tBu]_2$,[28] $[tBu_2GaP(H)Cp]_2$[29]) or butterfly-type ring structures ($[Me_2GaP(H)Si(tBu)_3]_2$[27]). The formation of a four-membered ring is caused by the steric demand of the *t*Bu substituents, as can be seen when comparing **3** with sterically less hindered phosphanylalanes $[(Me_2Al)_3(P(H)SiMe_3)_2P(SiMe_3)_2]$[13] and $[Me_2AlP(H)Si(iPr)_3]_2$,[30] which form six-membered rings in the solid state. The Al–P bond length in **3** (av. 2.462 Å) is comparable to those reported for $[Me_2AlP(SiMe_3)_2]_2$ (2.457 Å), $[Et_2AlP(SiMe_3)_2]_2$ (2.458 Å), and $[iBu_2AlP(SiMe_3)_2]_2$ (2.476 Å). The central ring atoms reside in distorted tetrahedral environments with the $SiMe_3$ groups and H atoms bound to the P atoms showing a *transoid* orientation. The endocyclic Al–P–Al bond angle of 94.4(1)° is bigger than the P–Al–P angle of 85.6(1)°, as was expected. Both bond angles significantly deviate from those of $[R_2AlP(SiMe_3)_2]_2$ [Al–P–Al: R = Me, 90.6(1); Et, 90.2(1); *i*Bu, 91.0(1); P–Al–P: R = Me, 89.4(1); Et, 89.8(1); *i*Bu, 89.0(1)°]. The average Al–C bond length as observed for **3** (1.996 Å) is elongated and the C–Al–C bond angle [121.0(2)°] is bigger than in $[R_2AlP(SiMe_3)_2]_2$ [R = Me, 1.959 Å, 113.4(2)°; Et, 1.972 Å, 114.2(2)°; *i*Bu, 1.977 Å, 117.1(2)°], in accordance with the higher steric demand of the *t*Bu groups, whereas the P–Si bond lengths [2.255(1) Å] are almost identical.

## Experimental Section

**General:** All manipulations were performed in a glovebox under $N_2$ or by standard Schlenk techniques. $tBu_2AlH$,[31] $HP(SiMe_3)_2$,[32] $P(SiMe_3)_3$,[33] $Sb(SiMe_3)_3$,[33] and $Bi(SiMe_3)_3$[33] were prepared according to literature methods. $^{1}H$, $^{13}C\{^{1}H\}$, and $^{31}P\{^{1}H\}$ spectra were recorded with a Bruker Avance 500 spectrometer and are ref-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

erenced to internal $C_6D_5H$ ($^1H$ $\delta$ = 7.154, $^{13}C$ $\delta$ = 128.0 ppm) and external $H_3PO_4$, respectively. Melting points were measured in sealed capillaries and are not corrected. Mass spectra (EI) were recorded with a Finnigan MAT 8230 spectrometer. Melting points were measured in sealed capillaries and were not corrected. Elemental analyses were performed at the Elementaranalyse Labor of the University of Paderborn. The results obtained for **1** and **2** deviate from the calculated values because of their expressed sensitivity toward air and moisture.

**Synthesis of [*t*Bu$_2$AlE(SiMe$_3$)$_2$]$_2$:** Equimolar amounts of *t*Bu$_2$AlH (0.14 g, 1 mmol) and E(SiMe$_3$)$_3$ (E = Sb, 0.34 g; Bi, 0.43 g) were combined at ambient temperature and stirred until gas evolution had stopped. The resulting solids were dissolved in toluene (10 mL) and stored at –40 °C. Colorless crystals of **1** and **2** were formed within 24 h. Yields are given for isolated compounds after recrystallization.

**[*t*Bu$_2$AlSb(SiMe$_3$)$_2$]$_2$ (1):** Yield 0.37 g, 0.45 mmol, 90%. *M* = 818.68 g/mol; m.p. 220 °C (dec.). Found: C 40.2, H 8.6; $C_{28}H_{72}Al_2Sb_2Si_4$ requires C 41.1, H 8.9. $^1H$ NMR (500 MHz, $C_6D_5H$, 25 °C): $\delta$ = 0.59 (18 H, s, *Me*$_3$Si), 1.29 (18 H, s, *Me*$_3$CAl) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $C_6D_5H$, 25 °C): $\delta$ = 6.0 [s, *Me*$_3$Si], 31.4 [s, *Me*$_3$CAl] ppm. EI-MS (70 eV, 70 °C): *m*/*z* (%) = 534 (5) [Sb$_2$(SiMe$_3$)$_4$]$^+$, 498 (5) [M/2 + H]$^+$, 408 (55) [M/2]$^+$, 351 (75) [M/2 – (*t*Bu)]$^+$, 295 (60) [M/2 – 2*t*Bu]$^+$, 221 (60) [M/2 – 2*t*Bu – SiMe$_3$]$^+$, 73 (100) [SiMe$_3$]$^+$, 58 (80) [*t*BuH]$^+$, 43 (65) [*t*BuH – Me]$^+$.

**[*t*Bu$_2$AlBi(SiMe$_3$)$_2$]$_2$ (2):** Yield 0.13 g, 0.13 mmol, 25%. *M* = 993.14 g/mol; m.p. 165 °C (dec.). Found: C 32.8, H 6.9; $C_{28}H_{72}Al_2Bi_2Si_4$ requires C 33.9, H 7.3. $^1H$ NMR (500 MHz, $C_6D_5H$, 25 °C): $\delta$ = 0.82 (18 H, s, *Me*$_3$Si), 1.30 (18 H, s, *Me*$_3$CAl) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $C_6D_5H$, 25 °C): $\delta$ = 7.1 (s, *Me*$_3$Si), 31.1 (s, *Me*$_3$CAl) ppm. EI-MS (70 eV, 70 °C): *m*/*z* (%) = 498 (5) [M/2 + H]$^+$, 423 (15) [M/2 – SiMe$_3$]$^+$, 366 (25) [M/2 – SiMe$_3$ – (*t*Bu)]$^+$, 146 (65) [Si$_2$Me$_6$]$^+$, 73 (100) [SiMe$_3$]$^+$, 58 (45) [*t*BuH]$^+$, 43 (70) [*t*BuH – Me]$^+$.

**Synthesis of [*t*Bu$_2$AlP(H)SiMe$_3$]$_2$ (3):** *t*Bu$_2$AlH (1 mmol, 0.14 g) was added to HP(SiMe$_3$)$_2$ (1 mmol, 0.17 g) at ambient temperature. Immediately, a gas evolution was observed and after a few minutes the mixture solidified. The colorless solid was dissolved in *n*-hexane (10 mL) and stored at –40 °C. Colorless crystals of **3** were formed within 48 h. The yield is given for the isolated compound after recrystallization. Yield 0.21 g, 0.43 mmol, 86%. *M* = 492.75 g/mol; m.p. 98–100 °C. Found: C 53.4, H 11.3; $C_{22}H_{56}Al_2Si_2P_2$ requires C 53.6, H 11.5. $^1H$ NMR (500 MHz, $C_6D_5H$, 25 °C): $\delta$ = 0.26–0.28 (18 H, *Me*$_3$Si), 1.22 (9 H, s, *Me*$_3$CAl, *cis* isomer), 1.23 (18 H, s, *Me*$_3$CAl, *trans* isomer), 1.26 (9 H, s, *Me*$_3$CAl, *cis* isomer) ppm. $^{13}C\{^1H\}$ NMR (125 MHz, $C_6D_5H$, 25 °C): $\delta$ = 3.1 [dt, $^2J$(C-P) = 4.2, $^4J$(C-P) = 2.0 Hz, *Me*$_3$Si], 30.9 (s, *Me*$_3$CAl), 31.3 (s, *Me*$_3$CAl), 31.8 (s, *Me*$_3$CAl) ppm. $^{31}P\{^1H\}$ NMR (200 MHz, $C_6D_5H$, 25 °C): $\delta$ = –229.6 [dd, $^1J$(P-H) = 167.6, $^2J$(P-P) = 67.7 Hz, *cis* isomer], –232.8 [dd, $^1J$(P-H) = 171.3, $^2J$(P-P) = 71.4 Hz, *trans* isomer] ppm. EI-MS (70 eV, 70 °C): *m*/*z* (%) = 363 (90) [*t*BuAl$_2$P$_2$(SiMe$_3$)H]$^+$, 246 (50) [M/2]$^+$, 147 (80) [Si$_2$Me$_6$]$^+$, 73 (75) [SiMe$_3$]$^+$, 58 (60) [*t*BuH]$^+$, 43 (100) [*t*BuH – Me]$^+$.

**X-ray Structure Solution and Refinement:** Crystallographic data of **1**–**3** are summarized in Table 1. Figures 1, 2 and 5 show ORTEP diagrams of the solid-state structures of **1**–**3**. Data were collected with a Bruker SMART APEX CCD diffractometer[34] using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at *T* = 120(2) K, and data reduction and absorption corrections were done with SAINT[34] and SADABS.[34] The structures were solved by direct and Fourier methods (SHELXTL),[34] and refined by full-matrix least-squares on $F^2$. All non-hydrogen atoms in **1**–**3** were refined anisotropically and hydrogen atoms were located from $\Delta F$ maps and refined at idealized positions with a riding model (SHELXTL). The Si–C distances of the disordered SiMe$_3$ group in **2** have been restrained with the SADI command of SHELX.

CCDC-626081 (for **1**), -626082 (for **2**), and -626083 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 1. Crystallographic data for [*t*Bu$_2$AlSb(SiMe$_3$)$_2$]$_2$ (**1**), [*t*Bu$_2$AlBi(SiMe$_3$)$_2$]$_2$ (**2**) and [*t*Bu$_2$AlP(H)SiMe$_3$]$_2$ (**3**).

# Synthesis and Characterization of Iron, Cobalt, and Nickel Complexes Bearing Novel *N*,*N*-Chelate Ligands and Their Catalytic Properties in Ethylene Oligomerization

**Li Wang,[a] Cheng Zhang,[a] and Zhong-Xia Wang*[a]**

**Keywords:** Iron / Cobalt / Nickel / Catalysis / Ethylene / Oligomerization

Treatment of *o*-$ROC_6H_4NC$ (R = $PhCH_2$, *i*Pr) with [Li{2-$CH(SiMe_3)C_5H_4N$}] afforded dimeric lithium complexes [Li{N(*o*-$ROC_6H_4$)$C(SiMe_3)CH(2$-$C_5H_4N)$}]$_2$ (**3**, R = $PhCH_2$; **4**, R = *i*Pr). Reaction of the lithium complexes with 1 equiv. of (dme)$NiCl_2$ gave nickel complexes [Ni{N(*o*-$ROC_6H_4$)-$C(SiMe_3)CH(2$-$C_5H_4N)$}$_2$] (**5**, R = $PhCH_2$; **6**, R = *i*Pr). The stoichiometric reaction of complexes **3** and **4** with $Et_3NH^+Cl^-$ formed 2-{*o*-$ROC_6H_4NHC(SiMe_3)CH$}$C_5H_4N$ (**7**, R = $PhCH_2$; **8**, R = *i*Pr) in quantitative yields. Reaction of **7** or **8** with metal halides, including (dme)$NiCl_2$, $NiBr_2$, $FeCl_2{\cdot}4H_2O$, and $CoCl_2$ yielded complexes [$MX_2${(*o*-$ROC_6H_4$)$N{=}C(SiMe_3)CH_2$(2-$C_5H_4N$)}] (**9**, R = $PhCH_2$, M = Ni, X = Cl; **10**, R = *i*Pr, M = Ni, X = Cl; **11**, R = $PhCH_2$, M = Ni, X = Br; **12**, R = *i*Pr, M = Ni, X = Br; **13**, R = $PhCH_2$, M = Fe, X = Cl; **14**, R = *i*Pr, M = Fe, X = Cl; **15**, R = $PhCH_2$, M = Co, X = Cl; **16**, R = *i*Pr, M = Co, X = Cl). For comparasion, nickel and cobalt complexes [$MX_2${(*o*-$MeC_6H_4$)$N{=}C(SiMe_3)CH_2$(2-$C_5H_4N$)}] (M = Ni, X = Br, **18**; M = Co, X = Cl, **19**) were similarly synthesized through reaction of 2-{*o*-$MeC_6H_4NHC(SiMe_3)CH$}$C_5H_4N$ (**17**) with $NiBr_2$ and $CoCl_2$, respectively. These compounds were characterized by NMR (for **3**, **4**, **7**, **8**, and **17**) and IR (for **5**–**19**) spectroscopy, elemental analyses and HRMS (for **5**, **6**, and **9**–**19**). The molecular structures of complexes **3**, **6**, **12**, and **14** were characterized by single-crystal X-ray diffraction techniques. The catalytic behavior in ethylene oligomerization of complexes **5**, **6**, **9**–**16**, **18**, and **19** was investigated. Under optimal conditions, the complexes showed good catalytic activities upon activation with appropriate aluminum co-catalysts ($8.72\times10^2$ to $18.2\times10^2$ kg/mol h atm for the nickel complexes upon activation with $Et_2AlCl$ and $4.3\times10^2$ to $8.1\times10^2$ kg/mol h atm for the iron and cobalt complexes upon activation with MMAO).

## Introduction

Late-transition-metal complexes with *N*,*N*-chelate ligands have attracted considerable attention due to their catalytic actions, especially for developing non-metallocene catalysts for the polymerization of ethylene and α-olefins.[1] Following the pioneering studies of Keim and Fink,[1d,2] Brookhart and co-workers reported on the discovery of the α-diimine complexes of $Ni^{II}$ and $Pd^{II}$ catalysts for the polymerization of ethylene and α-olefins.[3] Subsequently, the number of academic publications and patents for polyolefins and oligomers obtained with late-transition-metal complexes increased remarkably.[1,4] A large number of structural variations of diimines have also been reported to adjust the steric and electronic properties of the *N*,*N*-chelate ligands.[1,5] These include β-diimines and analogues whose complexes of $Ni^{II}$ and $Pd^{II}$, however, usually exhibit lower catalytic activities than the α-diimine complexes.[1a,6] A further modification is to append a donor sidearm, constructing tridentate chelating ligands such as *N*,*N*,*O*,[7] *N*,*N*,*P*,[8] and *N*,*N*,*N* ligands.[9] A representative example are bis(imino)pyridine ligands whose iron complexes showed exceptionally high activities for ethylene polymerization when activated with MAO.[10]

Furthermore, late-transition-metal complexes could act as better candidates for ethylene oligomerization because of their facile β-H elimination.[11] Many neutral and cationic late-transition-metal complexes with chelate ligands have been successfully applied in the field of olefin oligomerization.[12,13] The Shell Higher Olefin Process (SHOP) is an excellent example. However, the demand for linear α-olefins in the $C_4$–$C_{10}$ range is growing fast. Much effort is still devoted to the development of highly selective ethylene oligomerization catalysts, and identifying and fine-tuning the parameters that influence the activity and selectivity of suitable catalysts continues to represent a challenge.[13] Our current efforts focus on the synthesis of new functional ligands and their corresponding late-transition-metal complexes as well as the catalytic behavior for ethylene oligomerization. Herein, we report on the synthesis and characterization of new ligands and their lithium and late-transition-metal complexes, while their catalytic behavior for ethylene oligomerization was also investigated and discussed.

## Results and Discussion

### Synthesis and Characterization

Compounds **1** and **2** were prepared according to a literature method.[14] Syntheses of **3**–**16** are summarized in Scheme 1. Reaction of *o*-$ROC_6H_4NC$ (R = $PhCH_2$, *i*Pr) with [Li{2-$CH(SiMe_3)C_5H_4N$}] afforded dimeric lithium complexes [Li{$N(o\text{-}ROC_6H_4)C(SiMe_3)CH(2\text{-}C_5H_4N)$}]$_2$ (**3**, R = $PhCH_2$; **4**, R = *i*Pr) as yellow, air-sensitive solids. In the reaction, a 1,2-$SiMe_3$ migration from the α- to the β-carbon atom took place. This type of reaction between an isocyanide and (trimethylsilyl)methyllithium has been reported.[15] Reaction of **3** and **4** with 1 equiv. of (dme)$NiCl_2$ gave nickel complexes [Ni{$N(o\text{-}ROC_6H_4)C(SiMe_3)CH(2\text{-}C_5H_4N)$}$_2$] (**5**, R = $PhCH_2$; **6**, R = *i*Pr). Attempts to synthesize [NiCl{$N(o\text{-}ROC_6H_4)C(SiMe_3)CH(2\text{-}C_5H_4N)$}] by reaction of **3** or **4** with various amounts of (dme)$NiCl_2$ were unsuccessful. Complexes **3** and **4** were treated with 1 equiv. of $Et_3NH^+Cl^-$ to afford 2-{*o*-$ROC_6H_4NHC(SiMe_3)CH$}$C_5H_4N$ (**7**, R = $PhCH_2$; **8**, R = *i*Pr) as a pale yellow solid (**7**) or a yellowish oil (**8**), each existing in an enamine form. Reaction of **7** or **8** with metal halides, including (dme)$NiCl_2$, $NiBr_2$, $FeCl_2{\cdot}4H_2O$ and $CoCl_2$, yielded [$MX_2${$(o\text{-}ROC_6H_4)N{=}C(SiMe_3)CH_2(2\text{-}C_5H_4N)$}] (**9**, R = $PhCH_2$, M = Ni, X = Cl; **10**, R = *i*Pr, M = Ni, X = Cl; **11**, R = $PhCH_2$, M = Ni, X = Br; **12**, R = *i*Pr, M = Ni, X = Br; **13**, R = $PhCH_2$, M = Fe, X = Cl; **14**, R = *i*Pr, M = Fe, X = Cl; **15**, R = $PhCH_2$, M = Co, X = Cl; **16**, R = *i*Pr, M = Co, X = Cl). Compound **17** was prepared with a similar procedure as for **7** and **8** (Scheme 2). Thus, reaction of *o*-$MeC_6H_4NC$ with [Li{2-$CH(SiMe_3)C_5H_4N$}] in $Et_2O$ gave the lithium complex [Li{$N(o\text{-}MeC_6H_4)C(SiMe_3)CH(2\text{-}C_5H_4N)$}], which was hydrolyzed directly by treatment with 1 equiv. of water to afford neutral enamine **17**. Complexes **18** and **19** were synthesized through reaction of **17** with $NiBr_2$ or $CoCl_2$ in thf, just as for complexes **9**–**16**.

Complexes **3** and **4** were fully characterized by $^1H$ and $^{13}C$ NMR spectroscopy and elemental analyses. The data are consistent with their respective structure. Complexes **5** and **6** are paramagnetic and were characterized by IR spectroscopy, elemental analyses, and high-resolution mass spectrometry. Compounds **7** and **8** were characterized by $^1H$, $^{13}C$ NMR, and IR spectroscopy and elemental analyses. The $^1H$ NMR spectra of **7** and **8** exhibit NH proton signals at δ = 11.77 and 11.58 ppm, respectively, and ethenyl proton signals at δ = 5.69 and 5.59 ppm, respectively. Their $^{13}C$ NMR spectra also show the existence of the C–C double bonds. These data prove the enamine forms of **7** and **8**. The similar compound **17** also exists in an enamine form, being a mixture of (*Z*) and (*E*) isomers. It was characterized by $^1H$ NMR and IR spectroscopy and high-resolution mass spectrometry. Complexes **9**–**16**, **18**, and **19** are crystalline solids or powders and paramagnetic; the complexes are yellow (**9**, **13**, and **14**), purple (**10** and **18**), red (**11** and **12**), or blue (**15**, **16**, and **19**). They gave satisfactory elemental analyses and high-resolution mass spectra. The IR spectra show C=N double-bond absorptions, proving

the coordinated ligands as imine forms in the complexes. This is also consistent with the single-crystal X-ray diffraction results of complexes **12** and **14**.

Complexes **3**, **6**, **12**, and **14** were further characterized by single-crystal X-ray diffraction techniques. The structure of complex **3** is presented in Figure 1 along with selected bond lengths and bond angles. The structure shows that complex **3** is dimeric in the solid state, in which two lithium atoms are bridged by two enamine nitrogen atoms, forming a 1,3-$Li_2N_2$ four-membered ring. With the 1,3-$Li_2N_2$ ring as the base, the $NC_3NLi$ and $NC_2OLi$ rings form the flaps of an "open-box"-like structural framework, in which each four-coordinate lithium atom has a distorted tetrahedral geometry. The Li–N distances from 1.967(8) to 2.108(8) Å are in the normal range. For example, the Li–N distances in

$[Li\{N(SiMe_3)C(R^2)C(R^1)(C_5H_4N\text{-}2)\}]_2$ ($R^1$ = H, $R^2$ = *t*Bu; $R^1$ = $SiMe_3$, $R^2$ = Ph) vary from 1.968(6) to 2.032(6) Å, and in $[Li\{N(SiMe_3)C(Ph)\}_2CH]_2$ from 1.952(10) to 2.095(2) Å.[16]

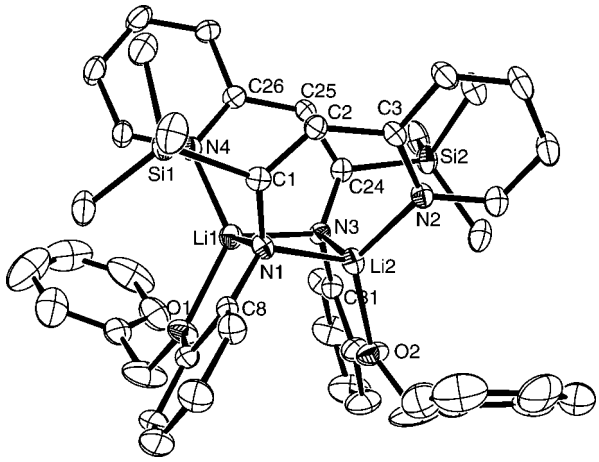

Figure 1. ORTEP drawing of complex **3** with 30% probability thermal ellipsoids. Selected bond lengths [Å] and bond angles [°]: Li(1)–N(1) 2.108(8), Li(1)–N(3) 1.990(8), Li(1)–N(4) 1.967(8), Li(1)–O(1) 2.055(8), Li(2)–N(1) 2.016(8), Li(2)–N(2) 1.982(8), Li(2)–N(3) 2.072(8), Li(2)–O(2) 2.037(8), Li(1)–Li(2) 2.495(10), N(1)–C(1) 1.403(5), C(1)–C(2) 1.363(5), N(3)–C(24) 1.394(5), C(24)–C(25) 1.363(5); N(1)–Li(1)–N(3) 103.8(3), N(1)–Li(1)–N(4) 119.0(4), N(3)–Li(1)–N(4) 98.9(4), N(3)–Li(1)–O(1) 121.7(4), N(4)–Li(1)–O(1) 130.7(4), N(1)–Li(1)–O(1) 79.8(3), N(1)–Li(2)–N(2) 98.4(3), N(1)–Li(2)–N(3) 104.2(3), N(2)–Li(2)–N(3) 119.3(4), N(1)–Li(2)–O(2) 122.2(4), N(2)–Li(2)–O(2) 129.2(4), N(3)–Li(2)–O(2) 81.3(3), Li(1)–N(1)–Li(2) 74.4(3), Li(1)–N(3)–Li(2) 75.8(3).

The molecular structure of complex **6** is depicted in Figure 2 along with selected bond lengths and bond angles. In the structure, a noteworthy feature is the distances between the Ni atom and the oxygen atoms. The Ni···O distances (2.574 and 2.586 Å, respectively) are longer than the sum of the covalent radii, however, much shorter than the sum of the van der Waals radii.[17] Hence, interactions between the Ni atom and the O atoms should be present. In this case, the coordination geometry of the Ni atom can be regarded as a distorted octahedron. The N1,N4,O1,N2 atoms are approximately coplanar, the torsion angle of N1–N4–O1–N2 being 0.7°, while the Ni atom is out of the plane.

The molecular structure of complex **12** is depicted in Figure 3 along with selected bond lengths and bond angles. The crystalline complex **12** is monomeric and the Ni center is in a distorted tetrahedral environment. The Ni···O distance of 3.781 Å shows no interactions between the atoms. The six-membered metallacycle exhibits a boat conformation. This is very similar to that of $[CH_2\{C(Me)=NAr\}_2]NiBr_2$ (Ar = 2,6-*i*$Pr_2C_6H_3$).[6a] The C5,N1,N2,C7 atoms are approximately coplanar, the torsion angle being 1.5°. The distance of Ni1–N1 [1.986(3) Å] is slightly shorter than that of Ni1–N2 [1.993(3) Å], and both are close to those found in $[2\text{-}\{Ph_2P=N(2',6'\text{-}Me_2C_6H_3)\}\text{-}6\text{-}Me_3SiC_5H_3N]NiBr_2$ [1.996(8) Å] and $[2\text{-}(Ph_3P=NCH_2)\text{-}6\text{-}MeC_5H_3N]NiBr_2$ [1.983(3) Å],[18] and slightly shorter than those of

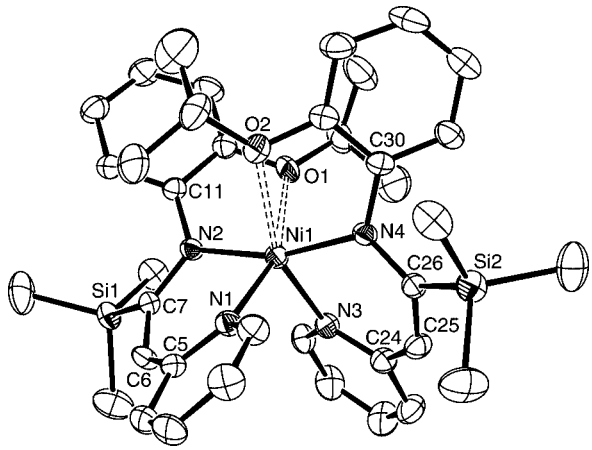

Figure 2. ORTEP drawing of complex **6** with 30% probability thermal ellipsoids. Selected bond lengths [Å] and bond angles [°]: Ni(1)–N(1) 2.045(3), Ni(1)–N(2) 1.968(3), Ni(1)–N(3) 2.043(4), Ni(1)–N(4) 1.976(3), Ni(1)···O(1) 2.574, Ni(1)···O(2) 2.586, C(6)–C(7) 1.377(6), C(25)–C(26) 1.371(6), N(2)–C(7) 1.377(5), N(4)–C(26) 1.373(5); N(1)–Ni(1)–N(2) 90.42(14), N(1)–Ni(1)–N(3) 100.11(14), N(1)–Ni(1)–N(4) 100.42(14), N(2)–Ni(1)–N(3) 100.77(14), N(2)–Ni(1)–N(4) 163.29(13), N(3)–Ni(1)–N(4) 89.88(14), O(1)–Ni(1)–N(1) 158.89, O(2)–Ni(1)–N(3) 158.58.

$[CH_2\{C(Me)=NAr\}_2]NiBr_2$ [2.010(5) and 2.022(5) Å, respectively].[6a] The Ni1–Br1 distance [2.3599(7) Å] is longer than that of Ni1–Br2 [2.3419(7) Å], and both are normal for four-coordinate $Ni^{II}$ complexes.[19] The N2–C7 distance of 1.288(4) Å agrees with that of a C=N double bond, indicating that the enamine tautomerizes to an imine after coordination to $Ni^{II}$. The N1–Ni1–N2 bond angle of 91.76(12)° is close to that of $[CH_2\{C(Me)=NAr\}_2]NiBr_2$ [93.7(2)°].[6a] However, the Br1–Ni1–Br2 bond angle of 124.78(3)° is wider than that of $[CH_2\{C(Me)=NAr\}_2]NiBr_2$ [118.54(5)°].[6a]

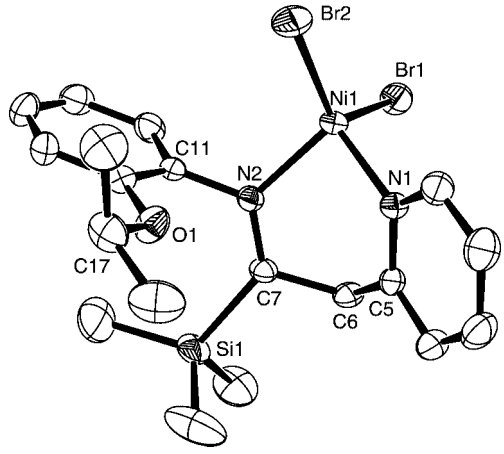

Figure 3. ORTEP drawing of complex **12** with 30% probability thermal ellipsoids. The structure of complex **14** is presented in Figure 4 along with selected bond lengths and bond angles. The crystalline **14** is monomeric and has a skeletal structure similar to that of **12**, including tetrahedral metal coordination geometry and the boat conformation of the six-membered metallacycle. The Fe1–N1 distance of 2.103(2) Å is slightly shorter than that of Fe1–N2 [2.115(2) Å], and both are within the normal range for this class of four-coordinate iron complexes. The Fe1–Cl1 distance of 2.2405(11) Å is longer than that of Fe1–Cl2 [2.2264(10) Å]. They are close to those in [2-{$Ph_2P$=N(2′,6′-$R'_2C_6H_3$)}-6-$RC_5H_3N$]$FeCl_2$ (R = Ph, $SiMe_3$; R′ = Me, *i*Pr) [2.2451(11)–2.2754(15) Å].[18] The Fe···O distance of 3.812 Å is beyond the distance of bonding interaction. The N2–C7 distance of 1.287(3) Å is almost the same as that of complex **12**, showing the ligand also to exist in an imine form.

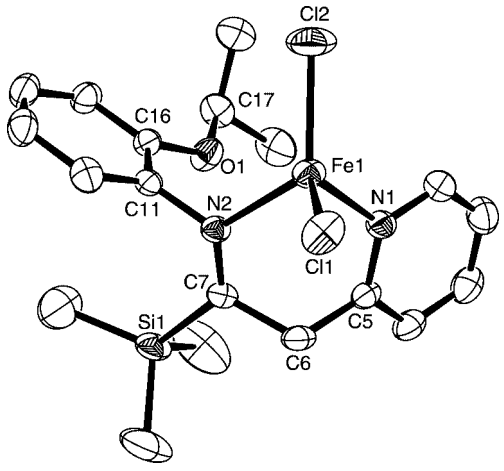

Figure 4. ORTEP drawing of complex **14** with 30% probability thermal ellipsoids. Selected bond lengths [Å] and bond angles [°]: Fe(1)–N(1) 2.103(2), Fe(1)–N(2) 2.115(2), Fe(1)–Cl(1) 2.2405(11), Fe(1)–Cl(2) 2.2264(10), Fe(1)···O(1) 3.812, N(2)–C(7) 1.287(3); N(1)–Fe(1)–N(2) 86.08(9), N(1)–Fe(1)–Cl(1) 112.84(7), N(1)–Fe(1)–Cl(2) 108.80(7), N(2)–Fe(1)–Cl(1) 108.49(7), N(2)–Fe(1)–Cl(2) 113.78(7), Cl(1)–Fe(1)–Cl(2) 121.39(4).

### Catalytic Properties of Complexes 5, 6, 9–16, 18, and 19 for Ethylene Oligomerization

It has been reported that bis(chelate)nickel complexes can catalyze vinylic polymerization of norbornene, polymerization or oligomerization of ethylene or α-olefins in the presence of appropriate organoaluminum co-catalysts. Some showed high catalytic activity and good selectivity.[5f,20] We determined the catalytic activity for ethylene polymerization or oligomerization of complexes **5** and **6** upon activation with MAO or MMAO and the results are listed in Table 1. All catalytic reactions shown in Table 1 were carried out at 20 °C and 1 atm ethylene pressure for 0.5 h. When MMAO was used as the co-catalyst, the Al/Ni ratio of 800:1 revealed very low catalytic activity for complexes **5** and **6**. Complex **5** exhibited the highest catalytic activity upon activation with 1000 equiv. of MMAO, while complex **6** reached its best activity in the presence of 1500 equiv. of MMAO (Entries 2 and 6 in Table 1). When MAO was used as the co-catalyst, the Al/Ni ratio of 800:1 gave the best catalytic activities for both complexes **5** and **6** (Entries 1 and 4 in Table 1). Higher or lower Al/Ni ratios resulted in a decline of the catalytic activities. The catalytic reactions predominantly formed dimers of ethylene in the presence of either MAO or MMAO, and the content of α-olefin is from 24.9 to 77.8%.

It was reported that in the catalytic reaction of bis(chelate)nickel complexes the active species was in situ generated by treatment of the nickel complexes with the organoaluminum compound under ethylene.[20c–20e,21] In our catalytic systems, the bis(chelate)nickel complexes **5** and **6** may go through a similar reaction in the presence of MAO and ethylene as shown in Figure 5. Thus, active species **I** was generated by reaction of **5** or **6** with MAO and ethylene. The active intermediate may be stabilized by a weak coordination of the RO group to the nickel center. Subsequently, the ethylene molecule coordinates to the nickel center to carry out the further reactions.

The nickel complexes **9**–**12** can catalyze ethylene dimerization and trimerization in the presence of MAO, MMAO, or $Et_2AlCl$. However, using $Et_2AlCl$ as the co-catalyst revealed higher activity. Therefore, a systematic investigation of the catalytic behavior of complexes **9**–**12** was performed using $Et_2AlCl$ as the co-catalyst (Table 2). In each case the polymerization reaction gave a mixture of $C_4$ and $C_6$ species. At 20 °C and 1 atm ethylene pressure for 0.5 h, the Al/Ni molar ratio of 200:1 afforded the highest catalytic activity for complexes **9**–**12** (**9**, $1.2\times10^3$; **10**, $1.21\times10^3$; **11**, $1.82\times10^3$; and **12**, $1.25\times10^3$ kg/mol h, respectively, Entries 2, 5, 8, and 17 in Table 2). Longer reaction times resulted in decline of both turnover frequency and the proportion of $C_4$ components (Entries 15 and 18 in Table 2). The decrease of the activity can be attributed to the deactivation of the active species during a longer reaction period. In the reaction catalyzed by **9**/$Et_2AlCl$, augmentation of the Al/Ni ratio resulted in enhancement of the proportion of

[a] Conditions: 5 μmol of pre-catalyst, $Et_2AlCl$ as co-catalyst, 30 mL of toluene (120 mL of toluene when determined under 10 atm ethylene). [b] $10^2$ kg/mol h. [c] Weight percent determined by GC analysis.

$C_4$ component in the products. While in the reaction catalyzed by the **11**/$Et_2AlCl$ system, the Al/Ni ratio of 400:1 gave the highest proportion of $C_4$ component. A change in the reaction temperature also dramatically affected the distribution of the polymerization products. We tested the catalytic reaction of the **11**/$Et_2AlCl$ system with a 200:1 Al/Ni ratio under 1 atm ethylene pressure at 0 °C, 20 °C, 40 °C, and 60 °C, respectively, and found that the proportion of $C_6$ component increased as the reaction temperature increased (Entries 8 and 12–14 in Table 2). In addition, it was also noted that an increase in ethylene pressure did not enhance the catalytic activity of the catalysts in terms of unit pressure (Entries 16 and 19 in Table 2).

It has been reported that (β-diimine)nickel and (8-quinolylimine)nickel catalysts (Scheme 3) showed very low catalytic activity for ethylene polymerization compared with (α-diimine)nickel complexes and the difference was attributed to the chelate ring size.[6] In our catalytic systems each of the complexes **9**–**12** exhibited good catalytic activity under the optimal conditions. Single-crystal X-ray diffraction results show that complex **12** has a similar skeletal structure and bond lengths and angles to that of the (β-diimine)nickel complex $[CH_2\{C(Me)=NAr\}_2]NiBr_2$ (Ar = 2,6-$i$Pr$_2$C$_6$H$_3$).[6a] Therefore, the relatively high catalytic activity of **9**–**12** is most likely the result of the existence of the *o*-

OR substituent on the phenylene ring of the ligands. The oxygen atom of the OR group may stabilize the active intermediate through coordination to the metal center during the reaction (see below).

The nature of aluminum co-catalysts greatly affected the catalytic activities of the pre-catalysts and the distribution of the products. The cobalt and iron complexes **13**–**16** were inactive for ethylene oligomerization when $Et_2AlCl$ was used as the co-catalyst. However, these cobalt and iron complexes exhibited catalytic activities for ethylene oligomerization in the presence of MMAO or MAO (Table 3). When MMAO was used as the co-catalyst, the complexes revealed high catalytic activity (up to $8.01 \times 10^2$ kg/mol h, Entry 12 in Table 3) and the polymerization products were almost solely $C_4$ species in most cases. When MAO was used as the co-catalyst, complexes **13** and **14** showed very low catalytic activity, while **15** and **16** exhibited moderate activity (up to 24.6 kg/mol h, Entry 14 in Table 3) and the major polymerization products were $C_6$ species. We also examined the effect of Al/M ratio for complexes **13** and **15**, respectively. When MMAO was used as co-catalyst, the catalytic activity increased with the enhancement of Al/M molar ratio until 1500:1 for complex **13** and 2000:1 for complex **15** (Entries 4 and 11 in Table 3). When MAO was used as co-catalyst, the Al/Co ratio of 800:1 resulted in the highest catalytic activity for complex **15** (Entry 14 in Table 3), higher or lower Al/Co ratios leading to decrease of the catalytic activity.

Table 3. Ethylene oligomerization with complexes **13**–**16**.[a]

| Entry | Complex | Co-catalyst | Al/M | Activity[b] | $C_4$ [%][c] | $C_6$ [%][c] |

[a] Conditions: 5 μmol of pre-catalyst, 30 mL of toluene, 1 atm ethylene, 20 °C, 0.5 h. [b] kg/mol h. [c] Weight percent determined by GC analysis.

It is very rare to see that iron and cobalt complexes with a six-membered *N*,*N*-chelate ring exhibit high catalytic activity for ethylene polymerization or oligomerization. Good activity shown by complexes **13**–**16** upon activation with MMAO is also attributed to the existence of *o*-OR substituents on the phenylene ring of the ligands.

The proportion of terminal olefins in the dimers or trimers was also determined for the reactions catalyzed by complexes **9**–**16** under representative reaction conditions (Table 4). At 20 °C and 1 atm ethylene pressure for 0.5 h, the reactions catalyzed by the **9**–**12**/$Et_2AlCl$ (1:200) systems gave relatively low α-butene and α-hexene proportions. When activated with MMAO, each of the complexes **13**–**16** led to relatively high α-butene proportions, from 84.5 to 90.7%.

In order to understand the role of *o*-OR substituents on the phenylene ring of the ligands in complexes **9**–**16**, we investigated the catalytic behavior of complex **18** whose ligand does not contain an extra donor group on the phenylene ring. The results are shown in Table 5. Compared with complexes **11** and **12** under the same polymerization conditions, complex **18** exhibited lower catalytic activity. Hence, we think that the existence of *o*-RO substituents on the phenylene ring in the nickel complexes may stabilize the active intermediate through a weak coordination of the oxygen atom to the metal center, which leads to the rise in their catalytic activities (Scheme 4). Although the stabilizing action of the aluminum activator to the active intermediate is usually important, the intramolecular coordination may provide extra stabilization in our catalytic systems. Bianchini and co-workers also observed that complex **IX** exhibits higher catalytic activity than complex **X** in ethylene oligomerization upon activation with MAO and they thought that the sulfur atom of the former may play an active role (Scheme 5).[22] In addition, the activity of complex **19** is also lower than that of complexes **15** or **16** whether MAO or MMAO was used as the co-catalyst. This is possibly due to the existence of the same stabilization in the **15** or **16**/activator system.

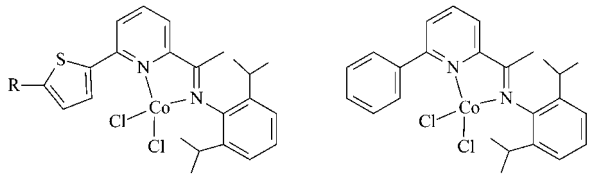

Scheme 5.

## Conclusions

We have synthesized novel anionic and neutral *N*,*N*-chelate ligands and their iron, cobalt, and nickel complexes. Single-crystal X-ray diffraction revealed that in bis(chelate)-nickel complex **6** there are relatively weak bonding interactions between the O atoms and the Ni atoms. Investigation of catalytic behavior for ethylene oligomerization showed that complexes **5** and **6** could catalyze ethylene oligomerization with good activity in the presence of MAO or MMAO, giving mainly $C_4$ species. The nickel complexes with neutral ligands exhibited high catalytic activity upon activation with $Et_2AlCl$. This relatively high activity compared with previously reported (β-diimine)nickel complexes and analogues is attributed to the stabilizing action of the *o*-OR group on the phenylene ring of the ligands to the active species through coordination of the oxygen atom to the metal center. The iron and cobalt complexes bearing neutral ligands also exhibited good catalytic activity upon activation with MMAO. However, when MAO was used as the co-catalyst, the iron and cobalt complexes showed relatively low activities.

## Experimental Section

**General Procedure:** All air-sensitive manipulations were performed under $N_2$ using standard Schlenk and vacuum-line techniques. Solvents were distilled under $N_2$ from sodium/benzophenone (toluene, *n*-hexane, thf, and $Et_2O$) or $CaH_2$ ($CH_2Cl_2$) and degassed prior to use. NMR spectra were recorded with a Bruker av300 spectrometer at ambient temperature. The chemical shifts of $^1H$ and $^{13}C$ NMR spectra are referenced to internal solvent resonances. IR spectra were recorded with a Bruker VECTOR-22 spectrometer. HRMS data were determined with an Agilent6890/Micromass GCT-MS spectrometer. Elemental analyses were performed by the Analytical Center of the University of Science and Technology of China. The magnetic moments of the paramagnetic complexes were determined by the Evans NMR method.[23] Gas chromatographic analyses were performed with a Carlo Erba Strumentazione gas chromatograph equipped with a flame-ionization detector and a 30 m (0.25 mm i.d., 0.25-μm film thickness) DM-1 silica capillary column or with an HP5890 gas chromatograph equipped with a flame-ionization detector and a 30 m (0.25 mm i.d., 0.25-μm film thickness) CAT-7221 silica capillary column. High-purity ethylene was purchased from Beijing Yanshan Petrochemical Co. and used as received. Methylaluminoxane (MAO, 1.46 M in toluene) and modified methylaluminoxane (MMAO, 1.93 M in heptane) were purchased from Akzo Nobel Corp. $Et_2AlCl$ was purchased from Fluka as a 1.90 M solution in hexane.

### Preparations

***o*-PhCH$_2$OC$_6$H$_4$NC (1):** Compound **1** was prepared according to a literature method.[12] $^1H$ NMR ($CDCl_3$): $\delta$ = 5.20 (s, 2 H, $CH_2$), 6.91–7.01 (m, 2 H, Ph, $C_6H_4$), 7.26–7.49 (m, 7 H, Ph, $C_6H_4$) ppm. IR (KBr): $\tilde{\nu}$ = 3072 (w), 3034 (w), 2947 (w), 2936 (w), 2876 (w), 2127 (vs), 1593 (s), 1492 (vs), 1469 (m), 1454 (s), 1382 (m), 1301 (m), 1287 (vs), 1251 (vs), 1162 (m), 1109 (s), 1080 (w), 1040 (w), 1001 (s), 932 (w), 917 (m), 857 (m), 760 (m), 744 (vs), 695 (s), 617 (w) $cm^{-1}$.

***o*-*i*PrOC$_6$H$_4$NC (2):** Compound **2** was prepared according to the same method as for **1** as a colorless oil, b.p. 100 °C/2 Torr. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.33 (d, $J$ = 6.1 Hz, 6 H, *i*Pr), 4.55 (sept, $J$ = 6 Hz, 1 H, CH), 6.80–6.91 (m, 2 H, $C_6H_4$), 7.21–7.27 (m, 2 H, $C_6H_4$) ppm. IR (liquid film): $\tilde{\nu}$ = 3076 (w), 2981 (s), 2935 (m), 2125 (vs), 1596 (s), 1492 (vs), 1455 (m), 1386 (m), 1376 (m), 1286 (s), 1260 (s), 1176 (w), 1162 (m), 1139 (m), 1117 (s), 1043 (m), 952 (s), 867 (w), 752 (s) $cm^{-1}$.

**[LiN(*o*-PhCH$_2$OC$_6$H$_4$){C(SiMe$_3$)CHC$_5$H$_4$N-2}]$_2$ (3):** To a stirred solution of [Li(TMEDA){2-CH(SiMe$_3$)C$_5$H$_4$N}] (3.84 g, 13.38 mmol) in diethyl ether (20 mL) was added compound **1** (2.80 g, 13.40 mmol) at –30 °C. The resultant solution was warmed to room temperature and stirred overnight. The mixture was filtered and the precipitate was washed with diethyl ether (2 × 5 mL). The solid was dried in vacuo to give a yellow powder of **3** (4.21 g, 82.7%), m.p. 181–182 °C. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.48 (s, 9 H, $SiMe_3$), 4.42 (d, $J$ = 11.7 Hz, 1 H, $CH_2$), 4.58 (d, $J$ = 11.4 Hz, 1 H, $CH_2$), 5.62 (s, 1 H, CH), 6.48–6.53 (m, 1 H, Ar), 6.57 (d, $J$ = 8.4 Hz, 1 H, Ar), 6.66 (d, $J$ = 7.8 Hz, 1 H, Ar), 6.92–7.22 (m, 6 H,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Ar), 7.42 (d, $J$ = 7.8 Hz, 1 H, Ar), 7.98–8.01 (m, 1 H, Ar) ppm. $^{13}$C NMR ($C_6D_6$): $\delta$ = 2.60, 70.17, 110.49, 110.88, 114.93, 119.02, 121.95, 122.38, 125.24, 128.22, 128.57, 128.81, 135.52, 136.35, 147.24, 148.87, 151.64, 157.50, 168.08 ppm. $C_{23}H_{25}LiN_2OSi$ (380.484): calcd. C 72.60, H 6.62, N 7.36; found C 71.92, H 6.62, N 7.30.

**[LiN(*o*-*i*PrOC$_6$H$_4$){C(SiMe$_3$)CHC$_5$H$_4$N-2}]$_2$ (4):** Complex **4** was prepared according to the same method as for **3**. To a solution of [Li(TMEDA){2-CH(SiMe$_3$)C$_5$H$_4$N}] (3.55 g, 12.37 mmol) in diethyl ether (20 mL) was added compound **2** (2.00 g, 12.42 mmol) at –30 °C. The mixture was warmed to room temperature and stirred overnight. The resultant precipitate was washed with diethyl ether and dried in vacuo to afford a yellow powder of **4** (3.85 g, 93.5%), m.p. 242–243 °C. $^1$H NMR ($C_6D_6$): $\delta$ = 0.46 (s, 9 H, SiMe$_3$), 0.97 (d, $J$ = 6 Hz, 3 H, *i*Pr), 1.35 (d, $J$ = 6 Hz, 3 H, *i*Pr), 4.36 (heptet, $J$ = 6 Hz, 1 H, *i*Pr), 5.81 (s, 1 H, CH), 6.68–6.75 (m, 2 H, Ar), 6.84 (d, $J$ = 8.4 Hz, 1 H, Ar), 7.01–7.06 (m, 1 H, Ar), 7.14–7.17 (m, 2 H, Ar), 7.21–7.27 (m, 1 H, Ar), 8.40 (dd, $J$ = 1.2, 5.1 Hz, 1 H, Ar) ppm. $^{13}$C NMR ($C_6D_6$): $\delta$ = 2.40, 20.43, 22.01, 70.29, 110.85, 110.93, 115.39, 119.21, 121.71, 123.20, 125.70, 135.86, 147.17, 149.42, 150.43, 157.97, 169.99 ppm. $C_{19}H_{25}LiN_2OSi$ (332.441): calcd. C 68.64, H 7.58, N 8.43; found C 68.21, H 7.57, N 8.26.

**Ni[N(*o*-PhCH$_2$OC$_6$H$_4$){C(SiMe$_3$)CHC$_5$H$_4$N-2}]$_2$ (5):** To a stirred suspension of (dme)NiCl$_2$ (0.15 g, 0.684 mmol) in thf (5 mL) was added compound **3** (0.26 g, 0.684 mmol) at about –80 °C. The resultant mixture was warmed to room temperature and stirred overnight. Volatiles were removed in vacuo and the residue was extracted with Et$_2$O. The diethyl ether solution was filtered and the filtrate concentrated in vacuo to form dark red-brown crystals of **5** (0.25 g, 91%), m.p. 169–170 °C. IR (KBr): $\tilde{\nu}$ = 3088 (vw), 3053 (w), 3024 (w), 2951 (w), 2894 (vw), 1600 (m), 1572 (w), 1557 (w), 1501 (m), 1481 (s), 1469 (vs), 1453 (m), 1418 (m), 1384 (vs), 1314 (w), 1277 (m), 1260 (m), 1246 (m), 1208 (m), 1189 (m), 1153 (m), 1113 (w), 1102 (vw), 1022 (w), 1004 (w), 847 (m), 783 (w), 751 (w), 732 (m), 693 (w) cm$^{-1}$. $C_{46}H_{50}N_4NiO_2Si_2$ (805.779): calcd. C 68.57, H 6.25, N 6.95; found C 68.77, H 6.43, N 6.90. HRMS (EI): calcd. for $C_{46}H_{50}N_4NiO_2Si_2$ [M]$^+$ 804.2826; found 804.2820. $\mu_{eff}$ = 3.77 BM.

**Ni[N(*o*-*i*PrOC$_6$H$_4$){C(SiMe$_3$)CHC$_5$H$_4$N-2}]$_2$ (6):** Complex **6** was prepared according to a procedure similar to that of **5**. Reaction of (dme)NiCl$_2$ (0.195 g, 0.886 mmol) with **4** (0.30 g, 0.904 mmol) in thf gave, after workup, dark red-brown crystals of **6** (0.295 g, 92%), m.p. 180–182 °C. IR (KBr): $\tilde{\nu}$ = 3052 (vw), 2974 (w), 2948 (w), 2894 (w), 1599 (m), 1572 (w), 1558 (w), 1503 (m), 1480, 1469 (vs), 1420 (s), 1369 (vs), 1309 (w), 1289 (s), 1265 (s), 1244 (m), 1207 (m), 1154 (m), 1138 (m), 1117 (m), 1048 (w), 1005 (w), 948 (w), 846 (s), 786 (s), 740 (s), 684 (vw), 621 (vw) cm$^{-1}$. $C_{38}H_{50}N_4NiO_2Si_2$ (709.694): calcd. C 64.31, H 7.10, N 7.89; found C 64.39, H 7.03, N 8.01. HRMS (EI): calcd. for $C_{38}H_{50}N_4NiO_2Si_2$ [M]$^+$ 708.2826; found 708.2823. $\mu_{eff}$ = 3.70 BM.

***o*-PhCH$_2$OC$_6$H$_4$NHC(SiMe$_3$)CHC$_5$H$_4$N-2 (7):** To a stirred solution of **3** (1.488 g, 3.92 mmol) in toluene (20 mL) was added Et$_3$NH$^+$Cl$^-$ (0.54 g, 3.93 mmol) at 0 °C. The resultant mixture was warmed to room temperature and stirred for 20 h. The solution was filtered and volatiles were removed from the filtrate in vacuo to afford **7** as a yellowish oil (1.464 g, 100%). The oil was dissolved in hexane and cooled to –30 °C to form a pale yellow precipitate. The precipitate was filtered at –30 °C and then dried in vacuo to afford a pale yellow solid, m.p. 81–83 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 0.20 (s, 9 H, SiMe$_3$), 5.17 (s, 2 H, CH$_2$), 5.69 (s, 1 H, CH), 6.84–6.95 (m, 4 H, Ar), 7.02 (d, $J$ = 8.1 Hz, 1 H, Ar), 7.10 (d, $J$ = 7.5 Hz, 1 H, Ar), 7.29–7.37 (m, 3 H, Ar), 7.48–7.55 (m, 3 H, Ar), 8.23–8.25 (m, 1 H, Ar), 11.77 (s, 1 H, NH) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 1.01, 70.29, 109.88, 112.66, 118.26, 120.78, 122.16, 122.32, 122.65, 127.22, 127.72, 128.53, 134.31, 135.63, 137.55, 147.37, 150.62, 152.84, 159.30 ppm. **Crystal Structure Determination:** Crystals were mounted in Lindemann capillaries under $N_2$. Diffraction data were collected with a Siemens CCD area-detector at 294(2) K with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). A semi-empirical absorption correction was applied to the data. The structures were solved by direct methods using SHELXS-97[24] and refined against $F^2$ by full-matrix least squares using SHELXL-97.[25] Crystal data and experimental details of the structure determinations are listed in Table 6. CCDC-632191 to -632194 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Catalytic Oligomerization of Ethylene:** The oligomerization with 1 atm ethylene was carried out in a Schlenk tube. In a dried Schlenk tube was placed the pre-catalyst (5 μmol) and then the Schlenk tube was back-filled three times with $N_2$ and twice with ethylene. Toluene (30 mL) was added to the Schlenk tube and then the appropriate co-catalyst solution was added through a syringe. The reaction mixture was vigorously stirred at the given temperature under 1 atm ethylene. After the desired period of time (30 min or 60 min), the reaction was terminated by cooling the system to about –10 °C and then adding 10% HCl solution (30 mL). About 1 mL of the organic layer was dried with anhydrous $Na_2SO_4$ in a sealed Schlenk tube at about –10 °C for gas chromatographic analysis. To the remaining solution was added ethanol (100 mL), no polymer was observed. The oligomerization with 10 atm ethylene was carried out in a stainless steel autoclave (0.25 L capacity) equipped with gas ballast through a solenoid valve for continuous feeding of ethylene at constant pressure. Toluene (120 mL) containing the pre-catalyst was transferred into the fully dried reactor under $N_2$. The required amount of co-catalyst was injected into the reactor through a syringe. As the desired temperature was reached, the reactor was pressurized to 10 atm. After stirring for 30 min, the reactor was cooled to about –10 °C and depressurized. The contents were transferred into a cooled flask and then 10% HCl solution (30 mL) was added. The mixture was worked up and analyzed using the same procedure as described above for the 1 atm reaction.

## Acknowledgments

We thank the National Natural Science Foundation of China (Grant No. 20272056) for support. We are also grateful to Professor W.-H. Sun of the Institute of Chemistry, The Chinese Academy of Sciences, for his kind help in determining the catalytic ethylene oligomerization activities of the complexes and Professors H.-B. Song and H.-G. Wang of Nankai University for single-crystal X-ray structure determinations.

# Synthesis, Spectroscopic and Structural Systematics of Complexes of Germanium(IV) Halides ($GeX_4$, X = F, Cl, Br or I) with Phosphane Oxides and Related Oxygen Donor Ligands

**Fei Cheng,[a] Martin F. Davis,[a] Andrew L. Hector,[a] William Levason,*[a] Gillian Reid,[a] Michael Webster,[a] and Wenjian Zhang[a]**

**Keywords:** Germanium / Coordination complexes / Phosphane oxides

The first series of phosphane oxide complexes of germanium(IV) halides have been prepared, including *trans*-$[GeF_4(R_3PO)_2]$ (R = Me, Et or Ph), *trans*-$[GeCl_4(Et_3PO)_2]$, *fac*-$[GeCl_3(Me_3PO)_3]_2[GeCl_6]$ and *cis*-$[GeX_2(Me_3PO)_4]X_2$ (X = Cl or Br) and characterised by IR and multinuclear NMR ($^1H$, $^{19}F\{^1H\}$ and $^{31}P\{^1H\}$) spectroscopy. Crystal structures of all the above (except *trans*-$[GeCl_4(Et_3PO)_2]$) are described. Remarkably, under mild conditions $Me_3PO$ displaces halide ligands from $GeX_4$ (X = Cl, Br) to form the cationic species above. $Ph_3AsO$ forms *trans*-$[GeF_4(Ph_3AsO)_2]$, but reaction of $Ph_3AsO$ or $Me_3AsO$ with $GeCl_4$ leads to the corresponding $R_3AsCl_2$. The complexes $[GeF_4(MeCN)_2]$, $[GeF_4(thf)_2]$ and $[GeF_4(MeOCH_2CH_2OMe)]$ are also described and the relative Lewis acidities of $GeX_4$ established.

## Introduction

Germanium is a technologically important element, particularly in the electronics field, and of growing interest in optics and ceramics,[1,2] and new applications often require new Ge-containing precursor compounds. Whilst organogermanium chemistry[3] has been studied in great detail, the coordination chemistry remains little explored.[4] This is in marked contrast to the heavier analogue, tin, whose coordination chemistry is among the most extensive of the p-block metals and metalloids. Studies in the 1960–1970s established that germanium(IV) halides exhibited modest Lewis acidity, although markedly less than that of the $Sn^{IV}$ analogues.[5] A few more examples have been reported in the intervening years, including structurally characterised $[GeCl_3(Me_3[9]aneN_3)]^+$ and $[GeBr_3(1,3,5\text{-trimethyl-1,3,5-triazacyclohexane})]^+$,[6] $[GeCl_4(2,2'\text{-bipy})]$,[7] $[GeCl_4(Me_2NCH_2CH_2NMe_2)]$,[8] and $[GeCl_4(AsMe_3)_2]$,[9] but data on series of complexes (to reveal trends), solution speciation studies, or even determination of the boundaries of complex formation are lacking. Only two examples with O-donor ligands have been fully characterised, $[GeF_4(Et_2O)_2]$,[10] and $[GeCl_4(dmso)_2]$.[11] We report here studies of the four tetrahalides as Lewis acids towards some neutral oxygen donor ligands.

## Results and Discussion

The germanium(IV) halides and their complexes are all moisture sensitive to varying degrees and all syntheses were carried out using rigorously anhydrous conditions. $GeF_4$ is a gas (sub. 236 K) and although it can be used directly in the syntheses, a solid precursor would be more convenient to handle. One possibility is $[GeF_4(Et_2O)_2]$[10] but this sublimes and dissociates at near ambient temperatures; the adduct $[GeF_4(MeCN)_2]$[12] is a more convenient precursor. The $[GeF_4(MeCN)_2]$ is made by bubbling $GeF_4$ into excess MeCN at room temperature, whereupon it separates as a white solid, which can be kept indefinitely in a glove box or Schlenk, although it vapourises slowly in a dynamic vacuum. The IR spectrum shows three ν(CN) at 2333, 2295 and 2252 $cm^{-1}$ and broad overlapping features assignable as ν(GeF) at 688, 657 and 639 $cm^{-1}$, suggesting a mixture of *cis* and *trans* isomers. In $CD_2Cl_2$ solution at ambient temperatures both the $^1H$ and $^{19}F\{^1H\}$ NMR spectra are single lines, but at 180 K the $^{19}F\{^1H\}$ NMR spectrum shows a singlet at –108.2 and two rather broad triplets, $\delta$ = –101.2 and –134.2 ($^2J_{FF} \approx 55$ Hz), attributable to *trans* and *cis* isomers respectively in approximate ratio 1:10, showing the complex is dynamic in solution down to quite low temperatures.

### Phosphane Oxides

The reactions of $[GeF_4(MeCN)_2]$ with $R_3PO$ (R = Me, Et or Ph) in 1:2 molar ratio in dry $CH_2Cl_2$ afford white powders $[GeF_4(R_3PO)_2]$. Colourless crystals of $[GeF_4(R_3PO)_2]$ (R = Me or Et) were grown from MeCN solution, and crystals of $[GeF_4(Ph_3PO)_2]$ serendipitously from the reaction mixture of $[GeF_4(MeCN)_2]$ and $Ph_3P$ in $CH_2Cl_2$[13] and crystal structure determinations showed all

to be the *trans* isomers. The P–O distances are significantly lengthened from those in the parent phosphane oxide 1.489(6) Å ($Me_3PO$),[14] 1.483(2) Å ($Ph_3PO$).[15] The *trans*-[$GeF_4(Me_3PO)_2$] (Figure 1, Table 1) is isostructural with the tin(IV) analogue,[16] and the *d*(P–O) 1.528(5) Å is very similar to that in *trans*-[$SnF_4(Me_3PO)_2$] [1.532(3) Å]. The *d*(Ge–F) 1.772(4) and 1.776(4) Å are longer than in the diethyl ether adduct [$GeF_4(Et_2O)_2$][10] [1.754(2), 1.747(2) Å] and considerably longer than in crystalline $GeF_4$ [1.661(1) Å].[17] In the ether adduct the *d*(Ge–O) is 1.975(2) Å consistent with the much weaker binding of the ether to the germanium. Similar bond length patterns are seen in the other phosphane oxide structures (Tables 2 and 3, Figures 2 and 3). The trialkylphosphane oxide complexes are easily soluble in chlorocarbons and MeCN, that of $Ph_3PO$ poorly soluble, and in marked contrast to the analogues with the heavier halides, are relatively air-stable in the solid state and do not hydrolyse rapidly even in solution. The $^{19}F\{^1H\}$ NMR spectrum of [$GeF_4(Me_3PO)_2$] in $CH_2Cl_2$ shows a singlet at $\delta$ = –109.9 ppm due to the *trans* isomer and much weaker triplets at $\delta$ = –107.6 and –121.6 ppm ($^2J_{FF}$ = 58 Hz) of the *cis* isomer, with the latter making up ca. 5% of the sample. The $^{31}P\{^1H\}$ NMR spectrum confirms the assignment with resonances at $\delta$ = 65.8 (*trans*) and $\delta$ = 65.1 ppm (*cis*). In the presence of added $Me_3PO$ no other complexes were formed, showing that in contrast to the case with the heavier halides (below), the phosphane oxide cannot displace fluoride from the $Ge^{IV}$ centre. The IR spectrum of [$GeF_4(Me_3PO)_2$] shows a very strong, broad band at 1087 $cm^{-1}$, assigned as ν(PO) (compare 1166 $cm^{-1}$ in $Me_3PO$) and ν(Ge–F) at 626 and 612 $cm^{-1}$. The presence of two ν(Ge–F) stretches of similar intensity is a solid state effect (theory for a *trans* isomer is one – $e_u$), since in $CH_2Cl_2$ solution a single band at 629 $cm^{-1}$ is present. The [$GeF_4(Et_3PO)_2$] is very similar (Experimental Section) although the *cis* isomer is rather more abundant (≈10% in $CH_2Cl_2$ solution). The [$GeF_4(Ph_3PO)_2$] shows approximately equal amounts of *cis* and *trans* isomers present in both the $^{19}F\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra at 253 K ($CDCl_3$ solution), but at 295 K only the resonances of the *trans* isomer are evident. The chemical shift in the room temperature $^{19}F\{^1H\}$ spectrum is not a weighted average of the low temperature values, but corresponds to that of the *trans* isomer, indicating that the *cis* isomer is undergoing some dynamic process at ambient temperatures, but that *cis*-*trans* exchange is slow. The reaction of $Et_3PO$ and $GeCl_4$ in $CH_2Cl_2$ gave a white solid [$GeCl_4(Et_3PO)_2$]. Although this has not been characterised by an X-ray structure, the spectroscopic properties ν(PO) = 1087 $cm^{-1}$, ν(Ge–Cl) = 321 $cm^{-1}$ and $\delta(^{31}P\{^1H\})$ = 60.1 ($Et_3PO$: $\delta$ = 52.1 ppm) are consistent with its formulation as the *trans* isomer (cf. the fluoride described above).

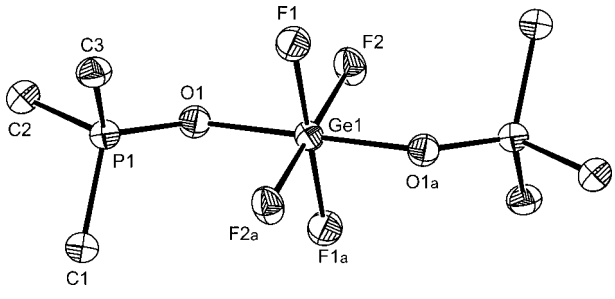

Figure 1. View of the molecule of [$GeF_4(Me_3PO)_2$] with the atom numbering scheme adopted. Ellipsoids are drawn at the 50% probability level and H atoms are omitted for clarity. Symmetry operation, a: –*x*, –*y*, 1 – *z*.

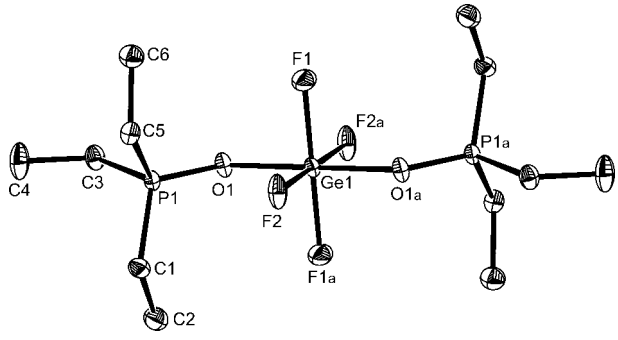

Figure 2. View of the molecule of [$GeF_4(Et_3PO)_2$] with the atom numbering scheme adopted. Ellipsoids are drawn at the 50% probability level and H atoms are omitted for clarity. Symmetry operation, a: 1 – *x*, 1 – *y*, –*z*.

In marked contrast to the stable fluoride adduct, the phosphane oxide complexes of $GeCl_4$ and $GeBr_4$ with $Me_3PO$ are moisture sensitive and very labile in solution. The reaction of $Me_3PO$ and $GeCl_4$ in a 2:1 molar ratio in rigorously anhydrous $CH_2Cl_2$ resulted in a white powder with an analytical composition corresponding to $GeCl_4(Me_3PO)_2$. Crystals grown from an $CH_2Cl_2$ solution of this material were found to be *fac*-[$GeCl_3(Me_3PO)_3]_2$-

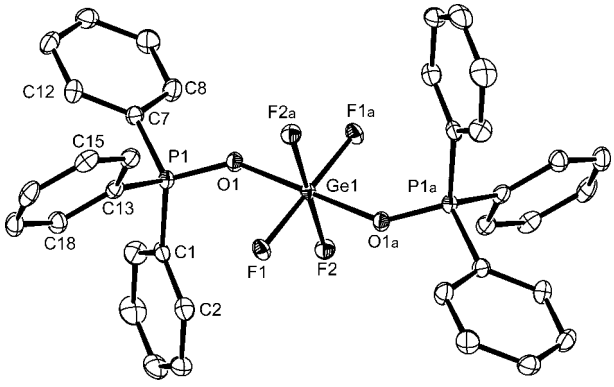

Figure 3. View of the molecule of $[GeF_4(Ph_3PO)_2]$ with the atom numbering scheme adopted. Ellipsoids are drawn at the 50% probability level and H atoms are omitted for clarity. Symmetry operation, a: $1 - x$, $1 - y$, $1 - z$.

$[GeCl_6]$, (which has the same 1:2 Ge:$Me_3PO$ stoichiometry). The structure (Figure 4, Table 4) shows an octahedral cation with a *facial* arrangement of ligands $d$(Ge–O) = 1.891(3) Å, not significantly different from that in the fluoride complex above, and with $d$(Ge–Cl) = 2.260(1) Å. The $[GeCl_6]^{2-}$ anion is very close to a regular octahedron with $d$(Ge–Cl) = 2.289(1) Å, which compares with the values in $[Ph_4P]_2[GeCl_6]$ of 2.283–2.298 Å.[19] The Nujol mull IR spectrum of the bulk powder and of the crystals were the same and showed two ν(PO) absorptions at 1122(m) and 1065 (s, br) $cm^{-1}$, and ν(Ge–Cl) at 344 (m), 308 (m), 293 (s) $cm^{-1}$. The 293 $cm^{-1}$ band is assigned as the $t_{1u}$ mode of $[GeCl_6]^{2-}$,[20] and the higher frequency Ge–Cl modes are the $a_1$ and e expected for the *fac* ($C_{3v}$) cation. The material has an essentially identical IR spectrum to the compound formulated as $[GeCl_4(Me_3PO)_2]$ in an early report[21] and it is clear from the results above that this complex should be reformulated. In anhydrous $CH_2Cl_2$ solution at ambient temperatures the complex exhibits a broad singlet in the $^{31}P\{^1H\}$ NMR spectrum at $\delta$ ca. 41. On cooling the solution the resonance broadens, then sharpens on further cooling, and at 180 K the major resonance is now at $\delta$ = 63.7 ppm with much weaker features at $\delta$ = 67.4, 66.5 and 65.7 ppm. The behaviour suggests a rapidly exchanging system, extensively dissociated at room temperature and which has several species present at low temperatures (no "free" $Me_3PO$, $\delta$ = 38 ppm, was observed at low temperature). In the presence of added $Me_3PO$ the solution shows a broad resonance consistent with fast exchange at $T > 220$ K, but at 180 K several resonances are resolved in addition to that of uncoordinated $Me_3PO$, notably the species with $\delta$ = 63.7 ppm is absent and the three higher frequency resonances are now dominant. Under different experimental conditions a second complex, identified as *cis*-$[GeCl_2(Me_3PO)_4]Cl_2$ was produced, also as colourless crystals. The structure (Figure 5, Table 5) shows a distorted octahedral cation with rather shorter $d$(Ge–Cl) [2.228(2) Å] than in the $[GeCl_3(Me_3PO)_3]^+$ [2.260(1) Å] and the $d(Ge–O)_{trans\text{-}O}$ [1.886(4) Å] is significantly longer than $d(Ge–O)_{trans\text{-}Cl}$ [1.857(4) Å]. In solution the variable temperature $^{31}P\{^1H\}$ NMR spectra are qualitatively similar to those described above for $[GeCl_3(Me_3PO)_3]^+$, except that at 180 K some "free" $Me_3PO$ is present. Whilst a definitive assignment of the low temperature spectra of the two $GeCl_4/Me_3PO$ systems is not possible, a plausible interpretation consistent with the ratios of $GeCl_4$:$Me_3PO$ present, and the effect of added $Me_3PO$, is that the resonances at $\delta$ = 67.4 and 66.5 ppm (which are always of equal intensity) correspond to the di-cation *cis*-$[GeCl_2(Me_3PO)_4]^{2+}$, the resonance at $\delta$ = 65.7 ppm is of the *fac*-$[GeCl_3(Me_3PO)_3]^+$ and the major feature at $\delta$ = 63.7 ppm is a $[GeCl_4(Me_3PO)_2]$ complex (since this resonance largely disappears when a large excess of $Me_3PO$ is present). Repeated attempts to isolate adducts of $GeCl_4$ with $Ph_3PO$ were unsuccessful, no solids separated from solutions of the constituents in anhydrous $CH_2Cl_2$, and removal of all volatiles from the reaction mixtures in vacuo resulted in loss of the $GeCl_4$. Attempts to isolate complexes with the diphosphane dioxides $Ph_2P(O)CH_2P(O)Ph_2$ or *o*-$C_6H_4[P(O)Ph_2]_2$ also failed. All of these form complexes with $SnCl_4$,[16,18] and although $GeCl_4$ is clearly a weaker Lewis acid, it is possible that steric factors disfavour complexes with these bulky ligands on the small $Ge^{IV}$ centre.

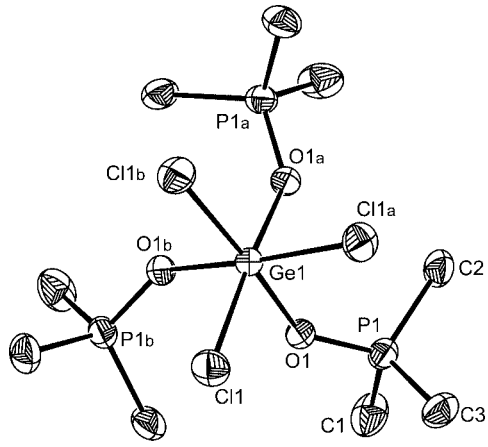

Figure 4. View of the cation in $[GeCl_3(Me_3PO)_3]_2$ $[GeCl_6]$ with the atom numbering scheme adopted. Ellipsoids are drawn at the 50% probability level and H atoms are omitted for clarity. Symmetry operation, a: $1 - y$, $1 + x - y$, $z$; b = $-x + y$, $1 - x$, $z$.

The $GeBr_4/R_3PO$ systems in $CH_2Cl_2$ or MeCN are more extensively dissociated and it is harder to obtain a pure complex. However, as described in the Experimental Section, colourless crystals were obtained which proved to be *cis*-$[GeBr_2(Me_3PO)_4]Br_2$ (Table 6, Figure 6). The structure

[a] Symmetry operation, a: $1 - x$, $y$, $1/2 - z$.

is analogous to that of the chloride, with a corresponding pattern of bond lengths. In $CH_2Cl_2$ solution the complex exhibits a very broad $^{31}P\{^1H\}$ NMR resonance at $\delta$ ca. 42 ppm, which on cooling to < 220 K resolves into a major peak at 65.5 ppm, and very minor features at 67.6 and 68.7 ppm in addition to some "free" $Me_3PO$. Addition of excess $Me_3PO$ to the solution results in a broad signal, typical of an exchanging system, down to very low temperatures, and even at 180 K the features $\delta$ ca. 65–69 ppm are broad, showing that the low temperature limiting spectrum cannot be reached before the solvent freezes. Based upon the spectroscopic data it can be concluded that solution lability increases in these systems with halide F << Cl < Br. Comparison of the four crystal structures containing $Me_3PO$ (Table 1, 4, 5 and 6) shows only small differences in $d$(Ge–O), although only for the two $[GeX_2(Me_3PO)_4]^{2+}$ ions are the Ge environments the same. It is possible that the effects of increasing formal charge on the Ge along the series $[GeF_4(Me_3PO)_2]$, $[GeCl_3(Me_3PO)_3]^+$, $[GeCl_2(Me_3PO)_4]^{2+}$ obscures any differences due to stronger Lewis acidity in the fluoride. Certainly charge seems to have a marked effect on $d$(Ge–Cl) along the series $[GeCl_6]^{2-}$ [2.289(1) Å], $[GeCl_3(Me_3PO)_3]^+$ [2.260(1) Å], $[GeCl_2(Me_3PO)_4]^{2+}$ [2.228(2) Å].

[a] Symmetry operation, a: $1 - x$, $y$, $1/2 - z$.

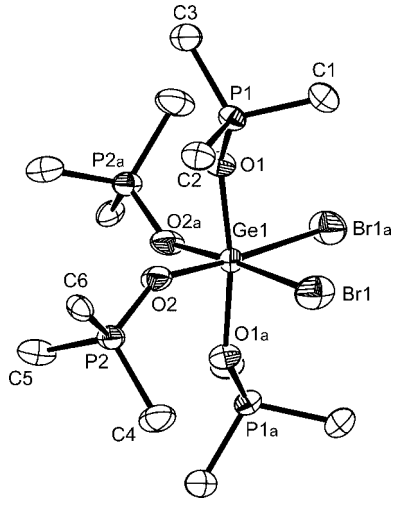

Figure 6. View of the cation in $[GeBr_2(Me_3PO)_4]Br_2$ with the atom numbering scheme adopted. Ellipsoids are drawn at the 50% probability level and H atoms are omitted for clarity. Symmetry operation, a: $1 - x$, $y$, $1/2 - z$.

The reactions of $GeI_4$ with $Me_3PO$ in $CH_2Cl_2$ gave red solutions, but crystals obtained from these were found by crystal structure determinations to be $GeI_4$ and $[Me_3POH][I_3]$, and we have been unable to isolate any phosphane oxide adducts.

The ability of $Me_3PO$ to displace chloride or bromide from the germanium centre was entirely unexpected; in the extensively studied systems $SnX_4$–$R_3PO$ (X = Cl, Br or I; R = Me, Ph etc)[21,22] all the complexes are of type $[SnX_4(R_3PO)_2]$ (usually a mixture of *cis*/*trans* isomers) and complexes with higher $R_3PO/SnX_4$ ratios do not form.

### Arsane Oxides

The reaction of $[GeF_4(MeCN)_2]$ with $Ph_3AsO$ in $CH_2Cl_2$ gave white $[GeF_4(Ph_3AsO)_2]$ which exhibited a strong broad $\nu$(AsO) at 868 $cm^{-1}$ and $\nu$(Ge–F) at 608 $cm^{-1}$. In solution the $^{19}F\{^1H\}$ NMR spectrum in $CH_2Cl_2$ contains a singlet at $\delta$ = –98.2, and two triplets at –94.4 and –112.9 ($^2J_{FF}$ = 60 Hz), consistent with a mixture of *cis* and *trans* isomers.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

However, the products isolated from stirring $R_3AsO$ (R = Me or Ph) with $GeCl_4$ in MeCN or $CH_2Cl_2$ solution were colourless crystalline solids which showed no evidence for ν(AsO) vibrations in their IR spectra. The crystals were identified by comparison of their unit cells with literature data,[23,24] as the dichlorotriorganoarsenic(V), $R_3AsCl_2$, and this was confirmed by comparison of their IR spectra with literature data.[25,26] In a similar way, $GeBr_4$ and $Me_3AsO$ gave $Me_3AsBr_2$. The conversion of $R_3AsO$ to $R_3AsCl_2$ has been reported to be achieved by a number of reagents including MeCOCl,[27] $COCl_2$,[28] $PCl_3$ and $AsCl_3$,[29] and with aqueous HCl,[30] but for $GeCl_4$ to behave in this way under such mild conditions was unexpected, and again contrasts with $SnCl_4$ which readily forms $[SnCl_4(R_3AsO)_2]$ adducts.[31]

The ether adducts $[GeF_4(thf)_2]$ and $[GeF_4(MeOCH_2CH_2OMe)]$, both reported some years ago[12,32] but with few details, were reexamined. Both are moisture sensitive white solids, with unexceptional spectroscopic properties (see Experimental section). The $[GeF_4(thf)_2]$ is a mixture of *cis* and *trans* isomers in solution in $CH_2Cl_2$ at low temperatures, but on warming the solution to > ca. 243 K the triplets in the $^{19}F\{^1H\}$ NMR spectrum due to the *cis* isomer collapse and then disappear, whilst the singlet due to the *trans* form is unchanged. This behaviour is similar to that of $[GeF_4(Ph_3PO)_2]$ (q.v.) and similarly rationalised.

## Conclusions

A series of neutral O-donor complexes of $GeX_4$ have been prepared and characterised structurally and spectroscopically. The data support the expected trend that Lewis acidity decreases $GeF_4 > GeCl_4 > GeBr_4 >> GeI_4$, and are consistent with lower acceptor power for Ge compared with Sn. We note that the overall trends will reflect both the strength of the donor-acceptor interaction and also the reorganisation energy ("floppiness") consumed in deforming the tetrahedral $GeX_4$ into a four-coordinate fragment of the octahedron produced on bonding the Lewis base.[33] Completely unexpected was the displacement of halide by $Me_3PO$ in $GeX_4$ (X = Cl or Br) to form mono- or di-cations; whilst the cationic species are probably stabilised in the solid state by the lattice, the displacement of $X^-$ by the weakly bound phosphane oxide in solution is surprising. The stronger Ge–F bond presumably prevents this happening in the fluorides under similar conditions. Also surprising was the conversion of $R_3AsO$ into $R_3AsX_2$ by $GeX_4$ (X = Cl or Br) under mild conditions, again the strength of the Ge–F bond would account for the different reaction (simple adduct formation) observed with $GeF_4$.

## Experimental Section

All reactions were conducted using Schlenk, vacuum line and glove-box techniques and under a dry dinitrogen atmosphere. The germanium(IV) halides $GeF_4$, $GeBr_4$ and $GeI_4$ were obtained from Aldrich and used as received. $GeCl_4$ (Aldrich) was distilled from a mixture of $CaCl_2/Na_2CO_3$, which removes traces of water and HCl. MeCN and $CH_2Cl_2$ were dried by distillation from $CaH_2$, THF and $MeOCH_2CH_2OMe$ distilled from Na-benzophenone ketyl. $Me_3PO$ and $Et_3PO$ were freshly sublimed in vacuo. $Ph_3PO$ and $Ph_3AsO$ were heated in vacuo. IR spectra were recorded as Nujol mulls with a Perkin–Elmer PE 983G spectrometer, $^1H$ NMR spectra in $CDCl_3$, $CD_2Cl_2$ or $CD_3CN$ solutions with a Bruker AV300, $^{31}P\{^1H\}$ and $^{19}F\{^1H\}$ NMR spectra with a Bruker DPX400 and referenced to 85% $H_3PO_4$ and $CFCl_3$, respectively. Microanalytical measurements on new complexes were performed by the microanalytical service at Strathclyde University.

**$[GeF_4(MeCN)_2]$:** Prepared as described.[12] $^1H$ NMR (300 MHz, $CDCl_3$, 293 K): $\delta$ = 1.99 (s) ppm. $^{19}F\{^1H\}$ NMR ($CDCl_3$, 180 K): $\delta$ = –101.2 (t, $^2J_{FF} \approx 55$ Hz), –108.2 (s), –134.2 (t) ppm. IR (Nujol): $\tilde{\nu}$ = 2333, 2295, 2252 [ν(CN)], 688 (s), 657 (vs), 639 (s) [ν(Ge–F)] $cm^{-1}$.

**$[GeF_4(Me_3PO)_2]$:** Freshly sublimed $Me_3PO$ (0.046 g, 0.50 mmol) was added to a solution of $[GeF_4(MeCN)_2]$ (0.058 g, 0.25 mmol) in $CH_2Cl_2$ (20 mL) at room temperature with stirring. A white precipitate formed gradually in the reaction mixture. After stirring for 10 min, the $^{19}F\{^1H\}$ NMR spectrum showed one major singlet at $\delta$ = –109.9 ppm and two minor triplets at –107.6 and –121.6 ppm. The solvent was removed in vacuo, and the white residue was dissolved in $CH_3CN$. Colourless air-stable crystals were obtained by vapour diffusion of diethyl ether into the solution. Yield 0.07 g, 85%. $C_6H_{18}F_4GeO_2P_2$ (332.7): calcd. C 21.7, H 5.5; found C 22.0, H 5.5. $^1H$ NMR (300 MHz, $CDCl_3$, 293 K): $\delta$ = 1.76 (*d*, $^2J_{HP}$ = 13.5 Hz) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 293 K): $\delta$ = 65.8 (s, major), 65.1 (s, minor) ppm. $^{19}F\{^1H\}$ NMR ($CDCl_3$, 293 K): $\delta$ = –107.6 (t, $^2J_{FF}$ = 58 Hz), –109.9 (s), –121.6 (t) ppm. IR (Nujol): $\tilde{\nu}$ = 1087 (vs, br) [ν(P=O)], 626 (s), 612 (s) [ν(Ge–F)] $cm^{-1}$.

**$[GeF_4(Et_3PO)_2]$:** $Et_3PO$ (0.067 g, 0.50 mmol) was added to a solution of $[GeF_4(MeCN)_2]$ (0.058 g, 0.25 mmol) in $CH_2Cl_2$ (20 mL) at room temperature to give a clear solution. The $^{19}F\{^1H\}$ NMR spectrum showed one major singlet at –110.2 and two minor triplets at –107.8 and –121.8 ppm. The solvent and volatiles were evaporated, and the white residue was washed with diethyl ether (10 mL) and dried. Yield 0.93 g, 90%. Colourless crystals were obtained from $CH_2Cl_2$ solution by slow evaporation of solvent under $N_2$. $C_{12}H_{30}F_4GeO_2P_2$ (416.9): calcd. C 34.4, H 7.2; found C 34.8, H 7.1. $^1H$ NMR (300 MHz, $CDCl_3$, 295 K): $\delta$ = 1.1 (m, 3 H), 2.05 (m, 2 H) ppm. $^{19}F\{^1H\}$ NMR ($CDCl_3$): $\delta$ = –107.8 (t, $^2J_{FF}$ = 59 Hz), –110.1 (s), –122.1 (t) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 76.4 (s, major), 76.1 (s, minor) ppm. IR (Nujol): $\tilde{\nu}$ = 1092 (vs, br) [ν(P=O)], 614 (s) [ν(Ge–F)] $cm^{-1}$.

**$[GeF_4(Ph_3PO)_2]$:** $Ph_3PO$ (0.146 g, 0.50 mmol) was added to a solution of $[GeF_4(MeCN)_2]$ (0.058 g, 0.25 mmol) in MeCN (20 mL) at room temperature, which led to the gradual formation of a white precipitate. After stirring for 10 min, the solvent was removed in vacuo, and the white residue was washed with small amount of $CH_2Cl_2$ and dried in vacuo. Yield 0.090 g, 90%. $C_{36}H_{30}F_4GeO_2P_2$ (705.2): calcd. C 61.3, H 4.3; found C 60.7, H 4.2. $^{19}F\{^1H\}$ NMR ($CDCl_3$, 253 K): $\delta$ = –100.9 (t, $^2J_{FF}$ = 64 Hz), –105.3 (s), –120.6 (t) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 253 K): $\delta$ = 40.8, 40.2 ppm. IR (Nujol): $\tilde{\nu}$ = 1133, 1078 [ν(P=O)], 636 (s) [ν(Ge–F)] $cm^{-1}$.

**$[GeCl_3(Me_3PO)_3]_2[GeCl_6]$:** Trimethylphosphane oxide (0.09 g, 1.0 mmol) was added to a solution of $GeCl_4$ (0.11 g, 0.5 mmol) in $CH_2Cl_2$ (20 mL) at room temperature, and stirred overnight. The solution, now containing some precipitate, was taken to dryness in vacuo to leave the white solid. Yield 0.15 g, 90%. Colourless crystals separated from the solution in $CH_2Cl_2$ kept at –20 °C for a few days. $C_{18}H_{54}Cl_{12}Ge_3O_6P_6$ (1195.7): calcd. C 18.1, H 4.6; found C

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

18.6, H 4.7. $^1$H NMR (300 MHz, $CDCl_3$, 295 K): $\delta$ = 1.45 (d, $^2J_{HP}$ = 13.5 Hz) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 298 K): $\delta$ = 45.0 (br) ppm. IR (Nujol): $\tilde{\nu}$ = 1065 [$\nu$(P=O)], 344, 308, 295 [$\nu$(Ge–Cl)] cm$^{-1}$.

**[$GeCl_2(Me_3PO)_4$]$Cl_2$:** Trimethylphosphane oxide (0.18 g, 2.0 mmol) was added to a solution of $GeCl_4$ (0.11 g, 0.5 mmol) in MeCN (20 mL) at room temperature, and stirred overnight. The solution was filtered and concentrated to ca. 5 mL. Colourless crystals separated from the solution kept at –20 °C for a few days. Yield 0.23 g, 80%. $C_{12}H_{36}Cl_4GeO_4P_4$ (582.7): calcd. C 24.7, H 6.2; found C 24.6, H 6.6. $^1$H NMR (300 MHz, $CDCl_3$, 295 K): $\delta$ = 1.40 (d, $^2J_{HP}$ = 13.5 Hz) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 295 K): $\delta$ = 40.1 (br) ppm. IR (Nujol): $\tilde{\nu}$ = 1138 (sh), 1053 (s, br) [$\nu$(P=O)], 352 (m), 300 (w) [$\nu$(Ge–Cl)] cm$^{-1}$.

**[$GeBr_2(Me_3PO)_4$]$Br_2$:** Trimethylphosphane oxide (0.09 g, 1.0 mmol) was added to a solution of $GeBr_4$ (0.19 g, 0.5 mmol) in $CH_2Cl_2$ (20 mL) at room temperature that lead to the immediate formation of a white solid. After stirring for several minutes, the solvent was removed in vacuo. The solid residue was dissolved in MeCN (20 mL), filtered, and concentrated. Colourless crystals separated from the solution kept at –20 °C for a few days. Yield 0.16 g, 55%. $C_{12}H_{36}Br_4GeO_4P_4$ (760.5): calcd. C 19.0, H 4.8; found C 19.2, H 4.7. $^1$H NMR (300 MHz, $CDCl_3$, 295 K): $\delta$ = 1.40 (d, $^2J_{HP}$ = 13.5 Hz) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 295 K): $\delta$ = 41.8 (v.br) ppm. See text for low temperature data. IR (Nujol): $\tilde{\nu}$ = 1131 (sh), 1101 (sh), 1051 (s, br) [$\nu$(P=O)], 245 (m) [$\nu$(Ge–Br)] cm$^{-1}$.

**[$GeCl_4(Et_3PO)_2$]:** Freshly sublimed $Et_3PO$ (0.13 g, 1.0 mmol) was added to a solution of $GeCl_4$ (0.11 g, 0.5 mmol) in $CH_2Cl_2$ (20 mL) at room temperature. The reaction mixture was stirred overnight giving a clear solution. The solvent and all volatiles were removed in vacuo, leaving the product as solid. Yield 0.22 g, 90%. $C_{12}H_{30}Cl_4GeO_2P_2$ (481.96): calcd. C 30.0, H 6.3; found C 29.8, H 6.1. $^{31}P\{^1H\}$ NMR ($CH_2Cl_2$, 295 K): $\delta$ = 60.1 (s) ppm. IR (Nujol): $\tilde{\nu}$ = 1087 (br) [$\nu$(P=O)], 321 (m, br) [$\nu$(Ge–Cl)] cm$^{-1}$.

**[$GeF_4(Ph_3AsO)_2$]:** $Ph_3AsO$ (0.16 g, 0.5 mmol) was added to a solution of [$GeF_4(MeCN)_2$] (0.058 g, 0.25 mmol) in $CH_2Cl_2$ (20 mL) at room temperature with stirring. A white precipitate formed gradually in the reaction mixture. After continued stirring overnight, the solution was filtered. The white solid residue was washed with $CH_2Cl_2$ (10 mL) and dried in vacuo. Yield 0.22 g, 90%. $C_{36}H_{30}As_2F_4GeO_2{\cdot}CH_2Cl_2$ (878.0): calcd. C 50.6, H 3.7; found C 50.1, H 3.3. $^{19}F\{^1H\}$ NMR ($CD_2Cl_2$, 298 K): $\delta$ = –94.4 (t, $^2J_{FF}$ = 60 Hz), –98.2 (s), –112.9 (t) ppm. IR (Nujol): $\tilde{\nu}$ = 868 (s) [$\nu$(As=O)], 608 (s) [$\nu$(Ge–F)] cm$^{-1}$.

**[$GeF_4(MeOCH_2CH_2OMe)$]:**[12,32] [$GeF_4(MeCN)_2$] (0.550 g, 2.38 mmol) was dissolved in $CH_2Cl_2$ (10 mL) and stirred while $MeOCH_2CH_2OMe$ (0.215 g, 2.39 mmol) was added dropwise. The solution was stirred for 3 h before half the solvent was removed in vacuo. Hexane (15 mL) was added and stirring continued for a further 30 min. The solid was filtered and dried briefly in vacuo. Yield 0.25 g, 44%. $^1$H NMR (300 MHz, $CDCl_3$, 243 K): $\delta$ = 4.22 (s, $CH_2$), 4.00 (s, Me) ppm. $^{19}F\{^1H\}$ NMR ($CH_2Cl_2$, 223 K): $\delta$ = –131.0 (t, $^2J_{FF}$ = 81 Hz), –151.1 (t) ppm. IR (Nujol): $\tilde{\nu}$ = 671 (s), 639 (s) [$\nu$(Ge–F)] cm$^{-1}$.

**[$GeF_4(thf)_2$]:**[32] [$GeF_4(MeCN)_2$] (0.62 g, 2.67 mmol) was stirred in thf (20 mL) for 3 h. The solvent was then removed in vacuo to leave a white solid. Yield 0.75 g, 96%. $^1$H NMR (300 MHz, $CDCl_3$, 298 K): $\delta$ = 2.13 (s), 4.45 (s) ppm. $^{19}F\{^1H\}$ NMR ($CH_2Cl_2$, 243 K): $\delta$ = –166.7 (s), –166.2 (t, $^2J_{FF}$ = 72 Hz), –178.8 (t) ppm. IR (Nujol): $\tilde{\nu}$ = 1017 (s, br), 852 (s, br) [$\nu$(COC)], 650 (vbr) [$\nu$(Ge–F)] cm$^{-1}$.

**X-ray Crystallography:** Details of the crystallographic data collection and refinement parameters are given in Table 7 and Table 8. Colourless, air-stable crystals of [$GeF_4(Me_3PO)_2$] were obtained by diffusion of diethyl ether vapour into a MeCN solution; [$GeF_4(Et_3PO)_2$]·1/3$CH_2Cl_2$ crystals were obtained from a $CH_2Cl_2$ solution by slow evaporation of the solvent under $N_2$; [$GeF_4(Ph_3PO)_2$]·2$CH_2Cl_2$ crystals were obtained from $CH_2Cl_2$; crystals of [$GeCl_3(Me_3PO)_3$]$_2$[$GeCl_6$] separated from the $CH_2Cl_2$ reactant solution kept at –20 °C for a few days; [$GeCl_2(Me_3PO)_4$]$Cl_2$ and [$GeBr_2(Me_3PO)_4$]$Br_2$ crystals separated from a MeCN solution kept at –20 °C for a few days. Data collections used a Bruker-Nonius Kappa CCD diffractometer fitted with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and either a graphite monochromator or confocal mirrors, with the crystals held at 120 K in a nitrogen gas stream. # Colloidal $CdS/SiO_2$ Nanocomposite Particles from Charged Colloids of CdS and Silica

**Meike Roskamp,[a] Andreas K. Schaper,[b] Joachim H. Wendorff,[b,c] and Sabine Schlecht*[a]**

**Keywords:** Colloids / Nanostructures / Semiconductors / CdS / Silica particles

Colloidal $CdS/SiO_2$ nanocomposite particles were prepared from soluble negatively charged silica particles ($d$ = 150 nm) and positively charged ligand-stabilised CdS particles ($d$ = 3 nm). The positively charged ligand shell of the CdS particles is constituted of thiocholine [TC, trimethyl(2-sulfanylethyl)azanium chloride]. As a quaternary nitrogen atom carries the charge in this ligand, the positive charge on the particles is basically independent of the pH value of the solution. A neutral pH value was chosen for the deposition of the CdS particles on the larger silica particles which already contain a significant negative charge under these conditions. The obtained nanocomposite particles were characterised by optical spectroscopy, gel electrophoresis and electron microscopy.

## Introduction

The preparation and investigation of nanocomposite systems are very generally motivated by the idea of a superior combination of different property profiles brought to the nanocomposite by its individual components. Different types of systems can be considered nanocomposites in this context: small nanoparticles that are embedded in a macroscopic polymeric or oxidic matrix,[1–5] loose assemblies of nanoparticles and silica spheres[6] or isolated spherical structures consisting of chemically different components such as silica-coated quantum dots[7,8] or silica spheres decorated with smaller nanoparticles. With this last type of composite structure, a desired combination of properties such as photoluminescence and solubility in water[7] or magnetism combined with optical emission[9] can be realised. When water solubility together with either magnetic or optical properties is required, silica particles are frequently the component of choice as they are optically inactive and are soluble in water up to a much bigger particle size than most other nanoparticles.[10] Consequently, nanocomposites containing silica particles in combination with particles of II/VI compound semiconductors,[11] of noble metals[12] or of other oxides[13] were described. Ideally, the nanocomposite will exhibit the properties of the smaller particles in the quantum size regime such as blueshifted photoluminescence, plasmon bands or superparamagnetism together with the convenience in handling that the larger silica particles can provide. Regarding the attachment of the semiconductor particles or metal particles on silica, several modes of connectivity were described in the literature. The two most prominent methods to attach smaller functional particles on silica are the coordinative binding of salts or other precursors with subsequent formation of the desired particles on the silica surface[14] and the deposition of preformed small particles on the surface of the silica. The latter concept has the advantage that monodisperse functionalized particles can be used whereas the formation of small particles directly on the surface of the silica support yields quite polydisperse and aggregated products[11a,14,15] because no protecting agent surrounds the primary grains at the moment of their formation. When preformed monodisperse quantum dots such as CdS particles are deposited on a silica support, this can either be done on functionalised silica with a modified surface covered by, for example, thiol groups[3,4] or by the use of appropriately functionalized small particles that are deposited on pure silica spheres. As silica spheres are negatively charged at neutral pH, the application of polycationic polymers as mediators for an attachment of neutral particles proved successful.[16] As an additional variant of such nanocomposites, embedded small functional particles that are covered by an additional silica layer on the original silica sphere were introduced recently.[17] The direct addition of oppositely charged particles as it is applied for the production of ordered superstructures of polymer spheres or semiconductor particles[18] is much less common for the deposition of particles in nanocomposite synthesis. Here, we present the preparation of $CdS/SiO_2$ nanocomposite structures with monodisperse CdS particles and without the need of additional reagents.

## Results and Discussion

Colloidal nanoparticles of cadmium sulfide CdS capped with a thiocholin (TC) shell were prepared from cadmium chloride, hexamethyldisilathiane $(Me_3Si)_2S$ and freshly prepared thiocholine in an experimental procedure similar to the one described by Barglik-Chory et al.[19] (Scheme 1).

Instead of a mixture of water and ethanol, ultrapure water was used as a reaction medium and the reaction time was shortened to 15 min. This protocol yielded colloidal CdS particles with a mean diameter of 2.9 nm after dialysis at a pH value of 7. The stability of the resulting colloid was significantly improved by the use of ultrapure water and by previous extensive rinsing of all glassware with ultrapure water. Whereas colloids in glassware without prior treatment precipitated within a few days, those in rinsed glassware could be stored at 4 °C for at least three months without precipitation. However, even with this precaution taken, strongly diluted colloid solutions precipitated within 24 h because the equilibrium of the cooordinated thiocholin ligand and its uncoordinated form is shifted away from a stabilising coordination. The resulting precipitation was found to be irreversible.

The stable colloids of thiocholine-capped CdS particles were characterized by UV/Vis spectroscopy and by transmission electron microscopy (TEM). The UV/Vis absorption spectrum of the colloidal particles in aqueous solution (Figure 1) shows an absorption maximum at $\lambda_{max}$ = 369 nm. This value indicates a mean diameter of the particles of 2.8–3.0 nm.[20] This particle size was confirmed by TEM images of the stabilized particles (Figure 2). An overview of the CdS particles (Figure 2a) shows that they are not agglomerated but evenly distributed on the TEM grid. A high resolution TEM image (Figure 2b) shows individual particles of 3 nm size. For some particles, the lattice planes of CdS are also visible.

To give evidence for a charged ligand shell on the particles in solution, the CdS particles were subjected to gel electrophoresis. To compare the charge and the mobility of the thiocholine-capped particles with similar charged colloids, we ran solutions of colloidal particles with ligand shells of 11-mercaptoundecanoic acid (MUDA), reduced glutathione (GSH) and dimethylaminoethanethiol (DMAET) as well as negatively charged particles of $SiO_2$ in parallel. The results are depicted in Figure 3. As expected, the silica particles and the CdS particles with ligand

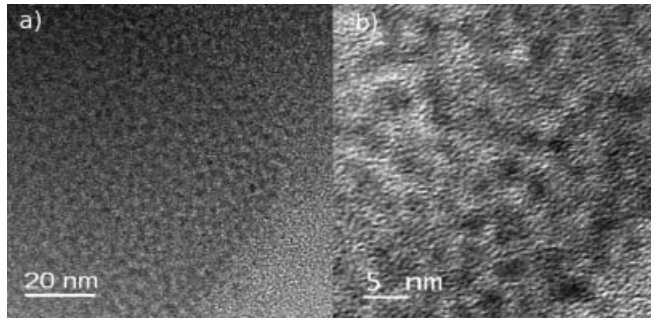

Figure 2. (a) Overview TEM image of thiocholine-capped CdS nanoparticles ($d$ = 3 nm); (b) high resolution TEM image of the particles.

shells of MUDA and GSH were found to move towards the anode in the gel. In contrast, the particles covered by ammonium-functionalized ligands such as DMAET or TC moved towards the cathode. This shows that the TC colloid is sufficiently stable at pH 7 and that it can be used as a

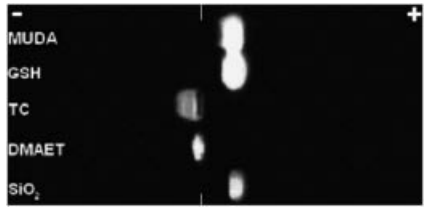

Figure 3. Agarose gel of colloidal nanoparticles of CdS with capping shells of mercaptoundecanoic acid (MUDA), glutathione (GSH), thiocholine (TC) and dimethylaminoethanethiol (DMAET) as well as of silica particles.

carrier of a permanent positive charge on the shell in nanocomposite synthesis.

Starting from these stable, positively charged particles of CdS and soluble negatively charged particles of silica, we prepared colloidal nanocomposites of $SiO_2$/CdS where the smaller CdS particles are deposited on the surface of the anionic silica particles at neutral pH value. As the negative charge is situated directly on the particle surface, not on a ligand covering the silica particles, no ligand exchange of oppositely charged ligands of the two types of particles can occur. The silica particles used for the formation of $SiO_2$/CdS composite particles have a diameter of 150 nm which is much larger than the diameter of only 3 nm of the CdS particles with the thiocholine shell. Thus, no regular packing of spheres as in ordered superstructures of particles of similar size, but a coverage of the bigger particles with a large number of small ones is to be expected. An investigation of the nanocomposite particles by UV/Vis spectroscopy, by TEM and by gel electrophoresis confirmed this picture. In the TEM images (Figure 4) of the nanocomposite particles it can be seen that the surface of the big silica spheres is covered by a large number of darker CdS particles of a few nanometres size. This confirms a significant interaction between the oppositely charged particles making the formation of a stable nanocomposite possible.

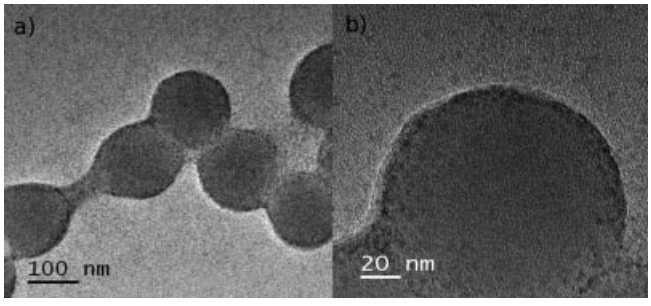

Figure 4. (a) TEM overview image of $SiO_2$/CdS nanocomposite particles; (b) TEM image of a single $SiO_2$/CdS nanocomposite particle, which shows the small CdS particles on the surface of the silica sphere.

It was shown by gel electrophoresis that the degree of coverage of the silica spheres with CdS particles is determined by electroneutrality. In contrast to the pure silica particles, which moved towards the anode (Figure 3), and the thiocholine-capped particles of CdS, which moved towards the cathode (Figures 3 and 5), the nanocomposite particles acted as neutral species (Figure 5). For comparison, anionic CdS particles with shells of MUDA and GSH were run in the gel.

Additional evidence for the formation of nanocomposite particles of $SiO_2$/CdS with a relatively close coverage of the silica surface comes from UV/Vis absorption spectroscopy on aqueous solutions of the particles. The absorption band of the TC-capped CdS particles (Figure 6) is shifted after the deposition from an absorption maximum of $\lambda_{max}$ = 369 nm to a value of $\lambda_{max}$ = 400 nm and it is significantly broadened. Both effects are expected for a closer contact of

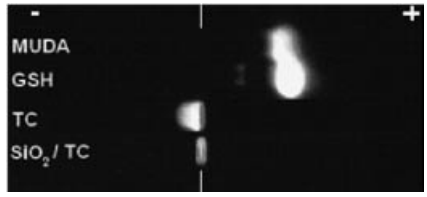

Figure 5. Agarose gel of pure CdS nanoparticles with capping shells of 11-mercaptoundecanoic acid (MUDA), glutathione (GSH) and thiocholine (TC) as well as of $SiO_2$/TC nanocomposite particles.

CdS particles on the surface of the silica particles. The shift of the absorption band towards lower energy can be attributed to dipolar interaction between the CdS particles as well as between the CdS particles and the silica. Changes in the electronic structure of the CdS due to their close contacts with each other are known to lead to a broadening of the absorption band.[21]

## Summary and Conclusions

The addition of thiocholine-capped CdS nanoparticles to a colloidal solution of larger silica particles at pH 7 leads to a deposition of the cationic CdS particles on the negatively charged surface of the silica until neutrality of the composite particles is reached. The optical properties of the CdS particles are altered by the deposition, and the absorption maximum is shifter to longer wavelengths. The $SiO_2$/CdS particles can be handled as a colloidal solution under neutral aqueous conditions. Thus, it was shown that the direct deposition of positively charged nanoparticles of CdS with a thiocholine shell on anionic silica particles as a support is well feasible and leads to a soluble nanocomposite material with the mechanical properties of the larger silica spheres but with the optical characteristics of small quantum confined systems.

## Experimental Section

**General:** For the syntheses and for rinsing all glassware, ultrapure water taken from a purifier of the type Seralpur Pro 90 CN was used. Cadmium chloride $CdCl_2 \cdot 2.5H_2O$ and hexamethyldisilathiane $(Me_3Si)_2S$ (HMDST) were purchased from Acros. Glutathione

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(GSH), *N*,*N*-dimethylaminoethanethiol·HCl (DMAET·HCl), tetramethylammonium hydroxide solution (TMAH, 25 wt.% in methanol) and an aqueous suspension of silica particles (d = 150 nm) were purchased from Fluka. 11-Mercaptoundecanoic acid (MUDA) and *S*-acetylthiocholine chloride (S–Ac–TC) were obtained from Sigma–Aldrich. All chemicals were used as received.

**Preparation of Thiocholine-capped CdS Particles:** In an argon-flooded Schlenk flask, S–Ac–TC (0.188 g, 0.95 mmol, 5 equiv.) was dissolved in ethanol (10 mL). After the addition of concentrated hydrochloric acid (20 mL), the reaction mixture was stirred for 3 h at 80 °C. The solvent was then removed under vacuum at 70 °C, and the residue was dissolved in pure water (40 mL). Subsequently, $CdCl_2·2.5H_2O$ (43 mg, 0.19 mmol) was added and as much TMAH as was needed to reach a pH value of 7.0 was also added. Fast addition of HMDST (36 μL, 0.19 mmol) resulted in a yellowish solution. After 15 min, the reaction solution was transferred to dialysis tubing and dialysed against pure water (3 × 600 mL). The resulting slightly cloudy solution was filtered through a 0.2 μm filter to give a clear yellowish solution that was stable at 4 °C for several weeks. $^1H$ NMR (300 MHz, $D_2O$, 25 °C): $\delta$ = 2.92 (m, 2 H, $CH_2$), 3.12 (s, 9 H, $CH_3$), 3.52 (m, 2 H, $CH_2$) ppm.

**Preparation of Glutathione-capped CdS Particles:** A sample of GSH (0.544 g, 1.80 mmol, 3 equiv.) and $CdCl_2·2.5H_2O$ (0.135 g, 0.59 mmol) was dissolved in pure water (30 mL) in an argon-flooded Schlenk flask and stirred at room temperature for 5 min. TMAH (1.4 mL, 3.4 mmol) and pure water (53 mL) were then added. After an additional 10 min of stirring, HMDST (124 μL, 0.59 mmol) was quickly added. After 15 min, the reaction solution was transferred to dialysis tubing and dialysed against pure water (4 × 300 mL). The resulting slightly cloudy solution was filtered through a 0.2 μm filter to give a clear yellowish solution that was stable at 4 °C for several weeks.

**Preparation of MUDA-capped CdS Particles:** A sample of MUDA (0.500 g, 2.30 mmol, 1.9 equiv.) and $CdCl_2·2.5H_2O$ (0.285 g, 0.59 mmol) was suspended in pure water (60 mL) in an argon-flooded Schlenk flask. After the addition of TMAH (2.5 mL, 5.9 mmol) and 10 min of stirring, MUDA completely dissolved and HMDST (263 μL, 1.24 mmol) was quickly added. After 15 min, the reaction solution was transferred to a dialysis tube and dialysed against pure water (4 × 400 mL). The resulting slightly cloudy solution was filtered through a 0.2 μm filter to give a clear yellowish solution that was stable at 4 °C for several weeks.

**Preparation of DMAET-capped CdS Particles:** A sample of DMAET·HCl (0.533 g, 3.77 mmol, 6 equiv.) and $CdCl_2·2.5H_2O$ (0.143 g, 0.62 mmol) was dissolved in pure water (38 mL) in an argon-flooded Schlenk flask and stirred at room temperature for 5 min. TMAH (0.9 mL, 2.1 mmol) was then added. After an additional 10 min of stirring, HMDST (132 μL, 0.62 mmol) was quickly added. After 30 min, the reaction solution was transferred to dialysis tubing and dialysed against pure water (4 × 300 mL). The resulting slightly cloudy solution was filtered through a 0.2 μm filter to give a clear yellowish solution that was stable at 4 °C for several weeks.

**Preparation of $SiO_2$/CdS Nanocomposite Particles:** An aqueous suspension of silica particles (10 μL) and a concentrated aqueous solution of thiocholin-capped CdS colloids (250 μL) were added one after the other to pure water (1 mL). This procedure ensures an excess of CdS colloids in the mixture. The resulting suspension was diluted and dropped on a grid without further purification.

**Transmission Electron Microscopy:** TEM images were taken with a JEOL JEM 3010 electron microscope operated at an accelerating voltage of 300 kV. All samples were deposited on a carbon foil covering a copper grid. The colloids were diluted by a factor of ca. 30 before they were transferred to the grid.

# Transition-Metal ($Mn^{II}$ and $Co^{II}$) Complexes with the Heteropolymolybdate Fragment $[As^{V}Mo_9O_{33}]^{7-}$: Crystal Structures, Electrochemical and Magnetic Properties

**Yanyan Yang,[a] Lin Xu,*[a] Guanggang Gao,[a] Fengyan Li,[a] Yunfeng Qiu,[a] Xiaoshu Qu,[a] and Hong Liu[a]**

**Keywords:** Polyoxometalates / Molybdenum / Arsenic / Magnetic properties

Two novel heteropolymolybdates, $[(CH_3)_4N]_{8n}[M(H_2O)_5]_{2n}(H_3O)_{2n}[\{M(H_2O)_5\}_2(MAs^{V}Mo_9O_{33})_2]_n[M(H_2O)_4(MAs^{V}Mo_9O_{33})_2]_n{\cdot}20nH_2O$ (M = $Mn^{2+}$, **1**; M = $Co^{2+}$, **2**), constructed from the new fragment $(As^{V}Mo_9O_{33})^{7-}$ and a transition metal have been synthesized in aqueous solution and characterized by elemental analysis, IR spectroscopy, thermal gravimetric analysis, and single-crystal X-ray diffraction. Structurally the title complexes resemble a sandwich-type complex because they involve the coordination of two transition metals to two $[As^{V}Mo_9O_{33}]^{7-}$ fragments, which derive from the well-known *B*-β-Keggin structure. Compounds **1** and **2** exhibit a one-dimensional chain-like framework $[M(H_2O)_4(MAs^{V}Mo_9O_{33})_2]^{8n-}$ with isolated $\{[M(H_2O)_5]_2(MAs^{V}Mo_9O_{33})_2\}^{6-}$ units residing among the chains. The magnetic properties of the two complexes were investigated to indicate typical antiferromagnetic interactions through the $Mn^{II}$–O–$Mn^{II}$ bridge unit for complex **1** and the $Co^{II}$–O–$Co^{II}$ bridge unit for complex **2**.

## Introduction

Polyoxometalates (POMs), a well-known class of metal oxygen clusters with a large variety of compositions and structures, together with their physicochemical properties, are of considerable interest because of their potential application in areas of catalysis, materials science, medicine, and so forth.[1–7] In virtue of a great family of POM building blocks, significant effort has gone into creating rational assemblies to obtain new compounds with desired functional properties. In the class of polyoxometalates, the sandwich-type complexes consisting of polyoxometalates and a transition-metal ion are an important subfamily because of their structural and magnetic diversity.[8–12] Recently, the sandwich-type complexes based on the lacunary heteropolytungstates have been synthesized and structurally characterized in increasing numbers.[13–15] In addition, among the sandwich-type complexes, a large number of magnetic clusters with various nuclearities and original topologies were formed by using the lacunary heteropolytungstates as the main ligand units. In contrast with the above situation, a true heteropolymolybdate analogue of a sandwich-type cluster has not been reported so far, and only a heteropolymolybdate formulated as $[Cu_2(SiMo_9O_{33})_2]^{12-}$, whose structure resembles a sandwich-type POM cluster, has been isolated and structurally characterized since 1981.[16] Why has only one example of a heteropolymolybdate with this structure appeared in the past 25 years? This is mainly because the lacunary heteropolymolybdate behaves with structural lability in aqueous solution, so that the isolation of a stable sandwich-type complex of lacunary heteropolymolybdate is considerably difficult. Müller and co-workers reported the existence of an $\{As^{III}Mo_9O_{33}\}$ fragment in the complexes $K_7[(AsOH)_3(MoO_3)_3(AsMo_9O_{33})]{\cdot}15H_2O$, $K_{10}[(AsOH)_6(MoO_3)_2(O_2Mo{-}O{-}MoO_2)_2(AsMo_9O_{33})_2]{\cdot}12H_2O$, and $(HNMe_3)_8[H_6As_{10}Mo_{24}O_{90}]{\cdot}9H_2O$,[17,18] but the $\{As^{III}Mo_9O_{33}\}$ fragment can rapidly rearrange into a Keggin-type cluster of $\{As^{V}Mo_{12}O_{40}\}$, suggesting that it is very difficult to obtain complexes consisting of the $\{As^{V}Mo_9O_{33}\}$ fragment from aqueous solution. Hence, the successful synthesis of a heteropolymolybdate-based sandwich complex remains a challenge. In particular, the complexes consisting of both heteropolymolybdates and a transition metal may produce unexpected magnetic properties, providing a great opportunity to explore heteropolymolybdate-based magnetic materials.

In our work, we try to find the rational reaction condition to obtain stable sandwich-type complexes consisting of heteropolymolybdates and a transition metal. Herein we report the syntheses, crystal structures, and magnetic properties of two new complexes consisting of arsenomolybdates and transition metals, $[(CH_3)_4N]_{8n}[M(H_2O)_5]_{2n}(H_3O)_{2n}$-

$[\{M(H_2O)_5\}_2(MAs^{V}Mo_9O_{33})_2]_n[M(H_2O)_4(MAs^{V}Mo_9O_{33})_2]_n\cdot 20nH_2O$, in which two crystallographically independent $[\{M(H_2O)_5\}_2(MAs^{V}Mo_9O_{33})_2]^{6-}$ (**1a**) and $[M(H_2O)_4(MAs^{V}Mo_9O_{33})_2]^{8n-}$ (**1b**) units coexist in their crystal structure. Notably, the complexes structurally resemble a sandwich-type complex because they involve the coordination of two transition metals to two $[As^{V}Mo_9O_{33}]^{7-}$ fragments, and the $[As^{V}Mo_9O_{33}]^{7-}$ fragment in **1** and **2** is not an ordinary trivacant α-Keggin ion but a special derivative of the well-known *B*-β-Keggin structure. To the best of our knowledge, they represent the first example of structurally characterized complexes containing both a $\{As^{V}Mo_9O_{33}\}$ fragment and a transition metal, although the component of the unit is isostructural with the reported $[Cu_2(SiMo_9O_{33})_2]^{12-}$ anion. The physicochemical properties of the two complexes were also characterized by thermal gravimetric analysis, cyclic voltammograms, and magnetic susceptibility measurement.

## Results and Discussion

In contrast to heteropolytungstates, heteropolymolybdate anions generally show more structural lability in aqueous solution, so it is very difficult to isolate a sandwich-type complex containing lacunary heteropolymolybdate species. The reaction of $Mn^{2+}$ ions with α-$As^{V}Mo_{12}O_{40}^{3-}$ in the ratio 16:1 (pH adjusted to 4.2) produced the unexpected $[(CH_3)_4N]_{8n}[M(H_2O)_5]_{2n}(H_3O)_{2n}[\{M(H_2O)_5\}_2(MAs^{V}Mo_9O_{33})_2]_n[M(H_2O)_4(MAs^{V}Mo_9O_{33})_2]_n\cdot 20nH_2O$ (M = $Mn^{2+}$, **1**; M = $Co^{2+}$, **2**), in which the $[As^{V}Mo_9O_{33}]^{7-}$ fragment derives from the well-known (*B*-β-$XMo_9O_{33}$) structure, and whose structure resembles that of the sandwich-type complex. Syntheses of **1** and **2** were conveniently carried out in aqueous solution, and the key factor for the successful synthesis was a rational choice of the solution pH and a suitable countercation. A solution pH of 4.2 is appropriate for both the generation of a $[As^{V}Mo_9O_{33}]^{7-}$ fragment and the formation of complexes **1** and **2**. However, some larger countercations, such as $[Bu_4N]^+$, $[Et_4N]^+$, and $Cs^+$, could quickly cause the precipitation of all the cluster anions in the solution, making it impossible to obtain a stable single crystal.

Single-crystal X-ray diffraction analysis revealed that complex **1** consists of six kinds of subunits: $[\{Mn(H_2O)_5\}_2(MnAs^{V}Mo_9O_{33})_2]^{6-}$ fragment (**1a**), one-dimension chain built of $[Mn(H_2O)_4(MnAs^{V}Mo_9O_{33})_2]^{8n-}$ fragment (**1b**), $[(CH_3)_4N]^+$ cation, $Mn^{2+}$ cation, coordinated water molecules, and isolated water molecules. The bond-valence sum calculation for complex **1** suggests that all Mo atoms are in the +6 oxidation state with an average value of 5.947, all As atoms are in the +5 oxidation state with an average value of 4.881, and all O atoms are in the –2 oxidation state with an average value of 1.964.[19] As complex **1** was isolated from acidic aqueous solution, two protons were attached to isolated water molecules to compensate for charge balance. The thermal gravimetric (TG) curve indicated the existence of 22 crystalline water molecules in complex **1**. In complex **1**, a novel building block $[\{Mn(H_2O)_5\}_2(MnAs^{V}Mo_9O_{33})_2]^{6-}$ (**1a**), whose structure is shown in Figure 1a, displays $C_{2h}$ symmetry with a $C_2$ axis through two $Mn^{II}$ centers. The building block is composed of two unusual $[As^{V}Mo_9O_{33}]^{7-}$ (**1c**) moieties linked with a $\{Mn_2O_{10}\}$ group. As shown in Scheme 1, the unusual $\{XMo_9O_{33}\}$ unit in **1c** derives from the well-known (*B*-β-$XMo_9O_{33}$) structure by moving one $MoO_6$ octahedron from the *B*-β-$XMo_9O_{33}$ unit to the other side itself, and the $MoO_6$ octahedron covers what would otherwise be a hole (as compared with the Keggin structure) between the two $Mo_3O_{13}$ units.[20] The $MoO_6$ octahedron has two terminal oxygen atoms, and this structural feature is similar to the first reported example of $(NH_4)_{12}[Cu_2Si_2Mo_{18}O_{66}]\cdot 14H_2O$. Also, the geometric topology of the $Mn_2O_{10}$ group is similar to that of the $\{Cu_2O_{10}\}$ group in $(NH_4)_{12}[Cu_2Si_2Mo_{18}O_{66}]\cdot 14H_2O$. One notable feature of **1a** is that one terminal oxygen atom from the $MoO_6$ octahedron of two terminal oxygen atoms acts as a ligand, together with five ligand water molecules, to bond with a $Mn^{2+}$ ion, resulting in the formation of a six-coordinate mononuclear $Mn^{II}$ complex.

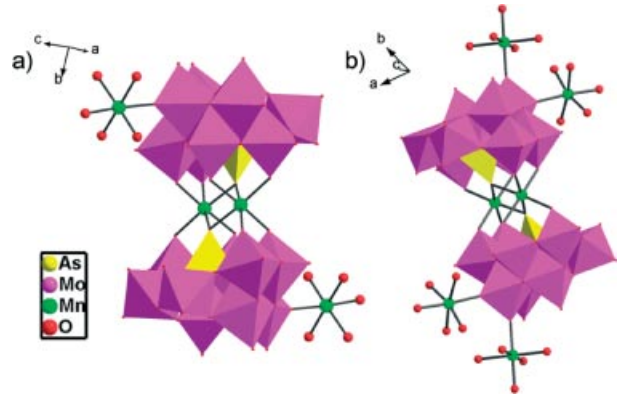

Figure 1. Combined polyhedral/ball-and-stick representation of the $[\{Mn(H_2O)_5\}_2(MnAs^{V}Mo_9O_{33})_2]^{6-}$ fragment (**1a**) and a part of the one-dimensional chain-like $[Mn(H_2O)_4(MnAs^{V}Mo_9O_{33})_2]^{8n-}$ fragment (**1b**). The color code: $MoO_6$ (purple), $AsO_4$ (yellow), Mn (green), O (red).

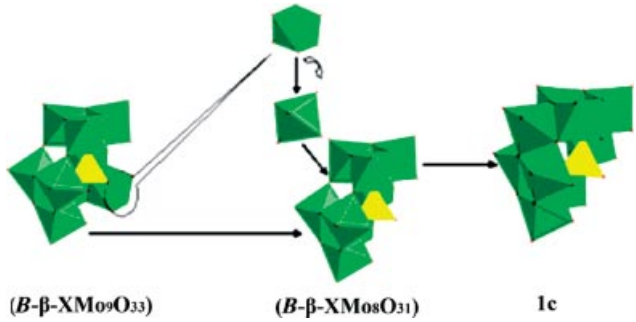

Scheme 1. The unusual $\{XMo_9O_{33}\}$ unit in **1c** derives from the well-known (*B*-β-$XMo_9O_{33}$) structure.

The other interesting feature of **1** is its novel one-dimensional chain structure, which consists of the **1b** unit linked by an octahedral $\{MnO_2(H_2O)_4\}$ group (see Figure 2). A

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mirror plane through the chain and mononuclear $Mn^{II}$ ions can be found if the slight deviations from two Mn–O bonds are omitted. As shown in Figure 2, the linkage between the **1b** unit and $\{MnO_2(H_2O)_4\}$ group depends entirely on a ligand oxygen atom coming from the end of a **1b** unit. It is noteworthy that the ligand oxygen atom is one of two terminal oxygen atoms from a $MoO_6$ octahedron of **1b**, and the other terminal oxygen atom from the $MoO_6$ octahedron becomes a ligand of the mononuclear $Mn^{II}$ complex attached to the $[As^{V}Mo_9O_{33}]^{7-}$ moiety. In the mononuclear $Mn^{II}$ complex acting as chain linker, Mn–O bond lengths related with water ligands appear to differ little [2.236(10) Å, 2.311(9) Å], while two Mn–O bond lengths related with the terminal oxygen atoms from two different $MoO_6$ octahedra are obviously shorter [2.130(6) Å]. It was well known that the electron delocalization generally occurs in the reduced heteropolymolybdate (heteropoly blue).[20–22] If this type of one-dimensional chain can be reduced reversibly, the additional electrons on the reduced heteropolymolybdate group will behave as electron delocalization, so that an indirect magnetic exchange interaction may happen between the magnetic groups and the reduced heteropolymolybdate groups. Thus, the development of such a magnetic chain is of considerable significance for exploring new molecular magnets. A further investigation on the heteropoly blue of **1** and its magnetic and electrochemical properties is in progress in our research group. The packing diagrams of **1** along the *a* axis are shown in Figure 2, in which those free anions of **1a** were alternately located between the parallel one-dimensional chains. In addition, all the $[(CH_3)_4N]^+$ cations, the $Mn^{2+}$ cation and crystallized water molecules freely fill in the space of the crystal structure. Multipoint hydrogen bonds also exist between the surface oxygen atoms of the $[AsMo_9O_{33}]^{7-}$ fragment and the water molecules to stabilize the solid-state framework of **1**. The crystal structure of **2** is mostly similar to that of **1**, though the replacement of $Mn^{II}$ by $Co^{II}$ causes some differences in bond lengths. The two Co–O bond lengths related with the terminal oxygen atoms from two different $MoO_6$ octahedra are obviously shorter (2.046 Å) than the Mn–O bond lengths [2.130(6) Å]. The Co–O bond lengths related with water ligands are 2.074(13), 2.106(12), 2.074(13), and 2.106(12) Å.

The building blocks of **1a** and **1b** are composed of two $[As^{V}Mo_9O_{33}]^{7-}$ fragments derived from the well-known (*B*-β-$AsMo_9O_{33}$) structure. In polyoxoanion chemistry, this $[As^{V}Mo_9O_{33}]^{7-}$ fragment had not been observed until our work. By the same synthesis method, we have recently obtained another manganese-substituted arsenomolybdate containing the same fragment, which will be reported elsewhere. We should note that complexes **1** and **2** were synthesized from the starting material of $[\alpha\text{-}As^{V}Mo_{12}O_{40}]^{3-}$, but the resulting product was a derivative of the *B*-β-$AsMo_9O_{33}$ unit. Therefore, the mechanism of the formation of **1** and **2** must involve a loss of molybdenum atoms, rotational isomerization (α-Keggin → *B*-β-$AsMo_9O_{33}$), and metal insertion. It is not clear if **1** and **2** are formed by initial loss of molybdenum atom or first by rotational isomerization.[23]

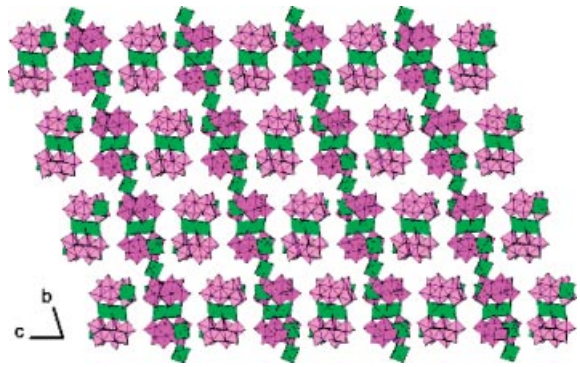

Figure 2. Polyhedral representation of plane in complexes **1** and **2**, viewed along the *a* axis. The cations and water molecules are omitted for clarity. The color code: $MoO_6$ (purple), $MnO_6$ (green).

To investigate the solution stability of complex **1**, we carried out a control measurement for the cyclic voltammograms and UV/Vis spectra in the solid state and in aqueous solutions. First, the redox peaks and shape of the cyclic voltammogram in solid state [using the carbon paste electrode (CPE)] is clearly different from those of the voltammogram in aqueous solution (1 M $H_2SO_4$). Second, in the UV/Vis spectra, the absorption peak positions for the solid state of complex **1** (using the diffuse reflectance electronic spectra) are also different from those for the aqueous solution of complex **1**. Thus, considering these experimental results, we infer that the one-dimensional chain-like framework of complex **1** may have been disintegrated into some fragments once it was dissolved in aqueous solution, indicating its instability in aqueous solution. However, the aqueous solution of **1** can retain stability with a pH value of 0–4; this is confirmed by the fact that the UV/Vis spectra of the solution with a pH value of 0–4 did not change when monitored for 12 h at room temperature, showing that the resulting fragments are stable in aqueous solution.

The electrochemical behavior of complex **1** was investigated using complex **1**-modified carbon paste electrode (CPE) as the working electrode to measure cyclic voltammograms both in the solid state (see Figure 3, a) and aqueous solutions (see Figure 3, b). There are only two anodic peaks in solution: $E_{pa}$ of 284.5 and 467.9 mV. In contrast, by using the **1**-modified CPE, three reversible redox peaks appeared in the potential range from +600 to –130 mV and the peak potentials $E_{1/2} = (E_{pa} + E_{pc})/2$ are 400 (I), 262.5 (II), and –39 (III) mV (scan rate: 100 mV $s^{-1}$). The redox peaks I–I′ and II–II′ should be ascribed to two consecutive two-electron processes, and redox peak III–III′ should be ascribed to a one-electron process.

The thermal gravimetric (TG) curve of complex **1** exhibits two steps of weight loss in the temperature range 30–700 °C (see Figure 4, a). The first weight loss of 5.06% in the temperature range 30–191 °C corresponds to the release of 22 crystalline water molecules. The second stage, which occurs from 291 to 461 °C, is attributed to the loss of 8 organic molecules and 24 coordinated water molecules; the observed weight loss (12.89%) is in agreement with the calculated value (13.01%). The thermal gravimetric (TG) curve

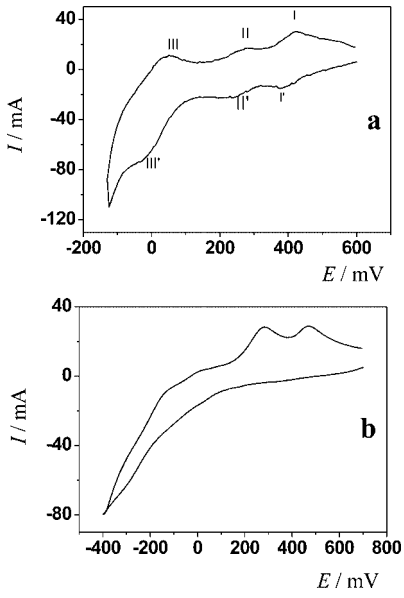

Figure 3. (a) Cyclic voltammogram of the carbon paste electrode (CPE) in 1 M $H_2SO_4$ aqueous solution for **1**. (b) Cyclic voltammogram of **1** in $H_2SO_4$ solution (pH = 2). Cyclic voltammograms were obtained with a CHI 660 electrochemical workstation at room temperature. A platinum wire was used as counter electrode and an Ag/AgCl (KCl 3 mol $L^{-1}$) was used as reference electrode. A chemically bulk-modified CPE or glassy carbon was used as working electrode. Potentials are quoted against a saturated calomel electrode (SCE).

of compound **2** (see Figure 4, b) is similar to that of **1**. The first weight loss of 4.97% in the temperature range 20–194 °C is attributed to the loss of crystalline water and the second weight loss of 12.79% in temperature range 300–465 °C is in agreement with the calculated value (13.84%).

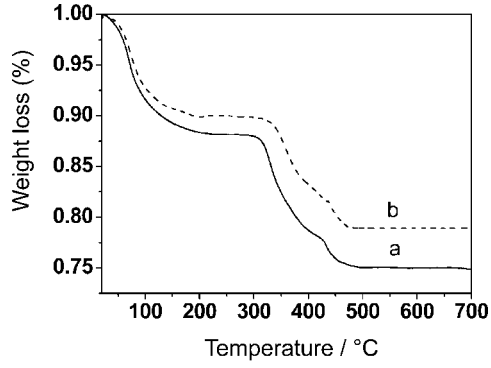

Figure 4. TGA curves of compound **1** (a) and **2** (b).

The magnetic behaviors of the two sandwich-type complexes in the temperature range 2–300 K are shown as plots of the product $\chi_m T$ versus $T$ in Figures S12a and S12b for **1** and **2**, respectively. Because of the coexistence of dimeric and different monomeric magnetic entities in the two compounds, the exact theoretical treatment fitting the experimental data becomes practically difficult, if not impossible. The $\chi_m T$ value of complex **1** at 300 K is about 32.38 $cm^3 K mol^{-1}$ (16.09 μB); this value is slightly smaller than that expected (17.74 μB) for the isolated nine $Mn^{II}$ ion ($S$ = 45/2; $g$ = 2.00). The $1/\chi_m$ versus $T$ plot in Figure S8 for **1** displays Curie–Weiss paramagnetic behavior from 10 to 300 K. The best linear fit of $\chi_m^{-1}(T)$ data above 40 K yields $C$ = 45.1 emu $mol^{-1}$ and $\theta$ = –1.10 K. The experimental data can approximately be fitted to a modified Heisenberg–Dirac–Van-Vleck $\mathbf{S}_A = \mathbf{S}_B$ = 5/2 spin-coupled model assuming $\mathbf{H} = -2J\mathbf{S}_A\mathbf{S}_B$ (see Supporting Information).[24] The best fit gives magnetic coupling constant $J$ = –0.43 $cm^{-1}$ assuming $g$ = 2.00, $C$ = 82.1 emu $mol^{-1}$, and $\theta$ = –1.76 K, with agreement factor $R$ {defined as $\sum_i[(\chi_m T)_{obs}(i) - (\chi_m T)_{calc}(i)]^2/\sum_i[(\chi_m T)_{obs}(i)]^2$} being $7.0 \times 10^{-5}$. The small negative $J$ and $\theta$ values suggest the occurrence of a weak antiferromagnetic $Mn^{II}$–$Mn^{II}$ interaction in **1**, being in good agreement with the result of linear fitting based on Curie–Weiss equation.

The $\chi_m T$ value of complex **2** at 300 K is about 27.59 $cm^3 K mol^{-1}$ (14.85 μB), which is higher than that expected (11.60 μB) for the isolated nine $Co^{II}$ ion ($S$ = 45/2; $g$ = 2.00). The experimental magnetic data for complex **2** can approximately be fitted to a modified Heisenberg spin Hamiltonian $\mathbf{H} = -2J\mathbf{S}_A\mathbf{S}_B$ (see electronic supporting information).[25] The best fit gives magnetic coupling constant $J$ = –0.64 $cm^{-1}$, $g$ = 2.24, $C$ = 21.61 emu $mol^{-1}$, and $\theta$ = –1.31 K, with agreement factor $R$ {defined as $\sum_i[(\chi_m T)_{obs}(i) - (\chi_m T)_{calc}(i)]^2/\sum_i[(\chi_m T)_{obs}(i)]^2$} being $8.2 \times 10^{-4}$ (see Figure S12). As shown in Figure S12b, the plot of $\chi_m T$ versus $T$ for **2** shows an obvious decrease from 300 to 20 K, followed by a quick drop to 2 K, being indicative of a typical antiferromagnetic $Co^{II}$–$Co^{II}$ interaction. The bridge linkage of $Co^{II}$–O–$Co^{II}$ in the $Co_2O_{10}$ group may be responsible for the behavior of antiferromagnetic interactions in **2**. In the same way, a best linear fit of $\chi_m^{-1}(T)$ data above 20 K gives $C$ = 20.6 emu $mol^{-1}$ and $\theta$ = –0.49 K, which is in agreement with the result from the plot of $\chi_m T$ versus $T$. However, a good least-squares fit for **2** cannot be achieved because of the possible deviation of the theoretical model.

## Conclusions

Two unusual heteropolymolybdates, $[(CH_3)_4N]_{8n}[M(H_2O)_5]_{2n}(H_3O)_{2n}[\{M(H_2O)_5\}_2(MAs^{V}Mo_9O_{33})_2]_n[M(H_2O)_4(MAs^{V}Mo_9O_{33})_2]_n \cdot 20nH_2O$ (M = $Mn^{2+}$, **1**; M = $Co^{2+}$, **2**), were synthesized by reaction of $MnSO_4$ ($CoSO_4$) with α-$H_3As^{V}Mo_{12}O_{40} \cdot 30H_2O$ in aqueous acidic medium (pH 4.2), isolated as a mixed tetramethyl ammonium salt and characterized by single-crystal X-ray diffraction. This work shows a promising perspective to develop the class of complexes consisting of arsenomolybdates and transition metals. The two typical compounds of this class with M = $Mn^{II}$ and $Co^{II}$ establish a new series of heteropolymolybdate complexes based on an $[As^{V}Mo_9O_{33}]^{7-}$ fragment. The magnetic properties of the two complexes were investigated to indicate typical antiferromagnetic interaction through the $Mn^{II}$–O–$Mn^{II}$ bridge unit for complex **1** and the $Co^{II}$–O–$Co^{II}$ bridge unit for complex **2**.

## Experimental Section

**General Methods and Materials:** As, Mn, Co, and Mo were determined by a Leaman inductively coupled plasma (ICP) spectrometer. IR spectra were obtained with an Alpha Centaurt FTIR spectrometer with KBr pellets in the 400–4000 $cm^{-1}$ region. The UV/Vis spectra were recorded with a 756 CRT UV/Vis spectrophotometer with $2\times10^{-6}$ M solutions of the relevant polyanion. Matched 1.000 cm optical path quartz cuvettes were used. The TG analyses were performed on a Perkin–Elmer TGA7 instrument in flowing $N_2$ with a heating rate of 10 °C $min^{-1}$. Cyclic voltammograms were obtained with a CHI 660 electrochemical workstation at room temperature. A platinum wire was used as counter electrode and a Ag/AgCl was used as reference electrode. A chemically bulk-modified CPE was used as working electrode. The glassy carbon samples had a diameter of 3 mm. Potentials are quoted against a saturated calomel electrode (SCE). All experiments were performed at room temperature. The polyanion precursor α-$H_3As^VMo_{12}O_{40}\cdot30H_2O$ was prepared according to the literature method.[26] The purity of α-$H_3As^VMo_{12}O_{40}\cdot30H_2O$ was checked by cyclic voltammogram. All reagents and solvents for the syntheses were purchased from commercial sources and used as received.

**Synthesis of $[(CH_3)_4N]_{8n}[Mn(H_2O)_5]_{2n}(H_3O)_{2n}[\{Mn(H_2O)_5\}_2(MnAs^VMo_9O_{33})_2]_n[Mn(H_2O)_4(MnAs^VMo_9O_{33})_2]_n\cdot20nH_2O$ (1):** α-$H_3As^VMo_{12}O_{40}\cdot30H_2O$ (1.78 g, 1 mmol) was dissolved in $H_2O$ (40 mL), and $MnSO_4$ (8 mL of 1 mol $L^{-1}$ solution) was added. The solution was heated to 60 °C on the water bath. The pH of the solution was adjusted to 4.2 by addition of the saturated $NaHCO_3$ solution, and then the color of the solution changed from yellow to orange. After 2 h, the solution was cooled to room temperature, and $(CH_3)_4NBr$ (4 mL of 1 mol $L^{-1}$ solution) was added into the stirred solution. After about 48 h, the yellow block crystals deposited from the filtrate by evaporation at room temperature. The crystals exposed in air quickly lost luster because of the volatilization of crystallized water molecules. Elemental analysis (%): calcd. (found) for **1**: Mn 6.35 (6.40), As 3.85 (3.92), Mo 44.37 (45.20). IR (KBr disk) for **1**: $\tilde{\nu}$ = 3419, 2359, 1635, 1483, 946, 860, 787, 703, 508 $cm^{-1}$.

**Synthesis of $[(CH_3)_4N]_{8n}[Co(H_2O)_5]_{2n}(H_3O)_{2n}[\{Co(H_2O)_5\}_2(CoAs^VMo_9O_{33})_2]_n[Co(H_2O)_4(CoAs^VMo_9O_{33})_2]_n\cdot20nH_2O$ (2):** The preparation of **2** was similar to that of **1**, except that $CoSO_4$ (8 mL of 1 mol $L^{-1}$ solution) was added. Elemental analysis (%): calcd. (found) for **2**: Co 6.78 (6.89), As 3.83 (3.89), Mo 44.17 (44.39). IR (KBr disk) for **2**: $\tilde{\nu}$ = 3419, 2360, 1616, 1483, 946, 861, 702, 508 $cm^{-1}$.

**X-ray Crystallography:** Crystal data for $[(CH_3)_4N]_{8n}[Mn(H_2O)_5]_{2n}(H_3O)_{2n}[\{Mn(H_2O)_5\}_2(MnAs^VMo_9O_{33})_2]_n[Mn(H_2O)_4(MnAs^VMo_9O_{33})_2]_n\cdot20nH_2O$ (**1**): triclinic, $P\bar{1}$ (no. 2), $a$ = 14.2108(10) Å, $b$ = 18.8804(13) Å, $c$ = 22.5052(16) Å, $\alpha$ = 71.6940(10)°, $\beta$ = 83.8250(10)°, $\gamma$ = 71.5560(10)°, $V$ = 5438.0(7) $Å^3$, $\rho_{calcd}$ = 2.338 g $cm^{-3}$, 21517 independent reflections with $I > 2\sigma(I)$, $1.68 < \theta < 26.05$, 1195 parameters, final $R$ factors $R_1$ = 0.0646 and $wR_2$ = 0.1203. Crystal data for $[(CH_3)_4N]_{8n}[Co(H_2O)_5]_{2n}(H_3O)_{2n}[\{Co(H_2O)_5\}_2(CoAs^VMo_9O_{33})_2]_n[Co(H_2O)_4(CoAs^VMo_9O_{33})_2]_n\cdot20nH_2O$ (**2**): triclinic, $P\bar{1}$ (no. 2), $a$ = 14.102(2) Å, $b$ = 18.880(3) Å, $c$ = 22.783(3) Å, $\alpha$ = 71.074(3)°, $\beta$ = 83.106(3)°, $\gamma$ = 70.615(2)°, $V$ = 5412.3(14) $Å^3$, $\rho_{calcd}$ = 2.331 g $cm^{-3}$, 21504 independent reflections with $I > 2\sigma(I)$, $1.81 < \theta < 26.10$, 1168 parameters, final $R$ factors $R_1$ = 0.0664 and $wR_2$ = 0.1311. The X-ray crystallographic data were collected at 183 K for **1** and **2** on a Bruker SMART CCD single-crystal diffractometer using Mo-$K_\alpha$ radiation (0.71073 Å). Direct methods were used to solve the structure and to locate the heavy atoms (SHELX97). Both compounds exhibit some disorder in the range of counterions and water molecules, as is often the case with polyoxometalates. Some of the oxygen atoms are disordered, which indicates that the quality of **1** is rather poor. Although we have repeated the experiment a few times, the suitable single crystal data cannot be obtained yet. This is most likely due to the result of the low-quality single crystals (thin plates). Nevertheless, the identity of fragment **2** was clearly established (Table 1).

Table 1. Crystal data and structure refinement for compounds **1** and **2**.

| | **1** | **2** |
|---|---|---|
| Empirial formula | $C_{32}H_{190}As_4Mn_9Mo_{36}N_8O_{178}$ | $C_{32}H_{190}As_4Co_9Mo_{36}N_8O_{178}$ |
| Formula mass | 7783.77 | 7819.72 |
| Space group | $P\bar{1}$ | $P\bar{1}$ |
| $a$ [Å] | 14.2108(10) | 14.102(2) |
| $b$ [Å] | 18.8804(13) | 18.880(3) |
| $c$ [Å] | 22.5052(16) | 22.783(3) |

| $T_{min}$, $T_{max}$ | 0.328, 0.382 | 0.532, 0.805 |
| Final $R_1$[a], $wR_2$[b] [$I > 2\sigma(I)$] | 0.0646, 0.1203 | 0.0664, 0.1311 |
| Final $R_1$[a], $wR_2$[b] [all data] | 0.0815, 0.1272 | 0.1334, 0.1594 |

[a] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{0.5}$.

CCDC-269468 (for **1**) and -269311 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electrochemical Experiments:** The compositions of the various media used for UV/Vis spectroscopy were as follows: for pH 0, $H_2SO_4$; for pH 1–3, 0.2 M $Na_2SO_4$ + $H_2SO_4$; for pH 4 and 5, 0.4 M $CH_3COONa$ + $CH_3COOH$. The test was realized on $2\times10^{-6}$ M solutions of compound **1**. The solutions were deaerated thoroughly for at least 30 min with pure argon and kept under a positive pressure of this gas during the experiments.

**Preparation of Compound 1-Modified Carbon Paste Electrode (CPE):** Compound **1**-modified CPE was fabricated as follows: 0.5 g graphite powder and 0.05 g compound **1** were mixed, and ground together by an agate mortar and pestle to achieve an even, dry mixture; 0.50 mL paraffin oil was added to the mixture and stirred with a glass rod; then the mixture was packed into a glass tube with the diameter of 3 mm, and the surface was pressed tightly onto weighing paper with a copper rod through the back. Electrical contact was established with a copper rod through the back of the electrode.

**Stability Studies:** For identifying the solution stability of complex **1**, the UV/Vis spectrum of the solution was monitored as a function of pH over a period of at least 12 h at room temperature. The spectra reproducible with respect to shape, absorbance, and wavelength location over this period of time were considered to indicate complete stability.

**Supporting Information** (see also the footnote on the first page of this article): Several ball-and-stick representations, IR spectra, magnetic data and selected bond lengths angles for **1** and **2**.

Karen Hindson

## The Changing Face of Chemistry Society Publishing

The start of the European Journal of Inorganic Chemistry ten years ago added another major player to the field of Inorganic Chemistry society journals. The move was unprecedented: attempts at European cooperation in the earliest stages of chemistry publishing had not got off the ground. By the second half of the 20th century three major single society publishing hubs had emerged, besides many other societies that published their own national general chemistry journal, often with commercial publishers. The time was ripe for change. European chemists began to work for a paradigm shift.

Upon the initiative of Jean-Marie Lehn, Peter Gölitz, the GDCh, and Wiley-VCH (the publishing partner of the GDCh), the publication of one journal (*Chemistry – A European Journal*) coowned by a union of societies was started in 1995. Understandably the vision of two journals with a strong base in Inorganic and Organic Chemistry to replace the many national journals took longer (see the view of Jan Reedijk who was active from the start), as the societies had to secure an equitable partnership. Heindirk tom Dieck of the German Chemical Society and Eva Wille of Wiley-VCH worked ceaselessly, travelling across Europe to meet with society officials to discuss terms of the amalgamation. First two (see the first cover at), then six, nine, ten and finally thirteen European chemical societies now profit from the development. Originally the editors of the individual journals acted as a panel of Editors-in-Chief for the new journals, till the growing number of submissions led to the formation of an editorial board and one editor employed by Wiley-VCH, similar to the structure of the other European Journals. The changeover was exactly in the middle of the ten years!

Not only was the union of societies growing. The growing trust in each other and their publisher Wiley-VCH led the French society to give up their journal *Journal de Chimie Physique et de Physico-Chimie Biologique* to make way for a co-owned, high-quality platform for the union's members whose research lies on the border of physics, chemistry and biophysics. Scientists working in interdisciplinary research in chemistry and biology could not be left out – *ChemPhysChem* and *ChemBioChem* were born in 2000. The growing family of journals prompted the societies to formalize their union as the Editorial Union of Chemical Societies (EUChemSoc) in 2002. Again the closer ties led the Italian society to offer two journals to the family, *Il Farmaco – An International Journal of Medicinal Chemistry and Pharmaceutical Chemistry* as springboard for *ChemMedChem* (2006) and *Annali di Chimica* as basis for the imminent journal *ChemSusChem* (2008).

In line with the development in Europe, chemical societies in Asia have banded together to form the Asian Chemical Editorial Society (ACES). Thus in 2007 with the emergence of multisociety publishing groupings, the number of society publishing hubs has grown and smaller societies also share in the advantages. Finally, Wiley-VCH is part of John Wiley & Sons, who in this February – in *their* bicentennial year – merged with Blackwell Publishing to form Wiley-Blackwell, now the world's leading society publisher. The strengthened global outlook of the company ensures that the European Journals family will combine the European touch with an international appeal. May not only EurJIC, but also the sister journals and the societies in EUChemSoc, go from strength to strength.

Karen Hindson
Editor, EurJIC

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## GREETING

An anniversary is a time both to look forward and to look back. Ten years ago, the seminal bilateral cooperation between the Gesellschaft Deutscher Chemiker and the Koninklijke Nederlandse Chemische Vereniging that enabled the publication of "Chemische Berichte/Recueil" and "Liebigs Annalen/Recueil" was successfully expanded by agreements with the chemical societies of France (Société Française de Chimie), Italy (Società Chimica Italiana), and Belgium (Koninklijke Vlaamse Chemische Vereniging and the Société Royale de Chimie) to bring together their journals to create two truly European journals, the European Journal of Inorganic Chemistry (*EurJIC*) and the European Journal of Organic Chemistry (*EurJOC*). The first issue of these journals appeared on January 1, 1998. The journals of the chemical societies of Spain (Real Sociedad Española de Química), Portugal (Sociedade Portuguesa de Química), and Greece (Association of Greek Chemists) were also amalgamated in 1998.

The integration of nine individual national journals into two high-quality European journals has undoubtedly created an important sense of union within the European community of chemists. Some guiding principles have been quality and flexibility, with the aim of fewer but better journals dealing with inorganic and organic chemistry. In 2002, the Magyar Tudományos Akadémia / Magyar Kémikusok by Egyesülete (Hungary) joined the consortium by merging the journal ACH – Models in Chemistry, and in 2003, Svenska Kemistsamfundet (Sweden), Gesellschaft Österreichischer Chemiker (Austria), and Česká Společnost Chemická (Czech Republic) also joined the consortium as Associate Members. Actually, the Editorial Union of Chemical Societies (EuChemSoc) is an organization of 14 European institutions.

As president of the EuChemSoc partnership for *EurJIC* and *EurJOC*, I note with great satisfaction that the initiative of merging nine national journals to create *EurJIC* and *EurJOC* has been a very important development. Furthermore, the journals are attracting a growing number of authors from outside Europe, and the continued success of these specialized journals has led to the decision to increase the frequency of publication from 24 to 36 issues for both journals. With the on-going vigorous support of our societies, authors, reviewers, and readers I am confident that the stature of *EurJIC* and *EurJOC* will grow as rapidly as it has over the last ten years. A sustained emphasis on the publication of papers reporting high-quality work, especially at the cutting-edge of the disciplines, should help to ensure that the journals will continue their successful development.

Luis A. Oro

# The Jubilee Issue

This issue marks the 10th Anniversary of the *European Journal of Inorganic Chemistry (EurJIC)* and represents a major landmark in the still young history of this journal. *EurJIC* was launched as a new journal in 1998 as a result of the merging of eight historical chemical journals owned by eight national chemical societies. The editor of the first issue was Heinrich Nöth. The number of chemical societies that own the journal, however, has been steadily growing, reflecting the increasing integration of European research. Nowadays *EurJIC* provides a European and international forum respected worldwide for Short Communications, Full Papers, and Microreviews, covering all topics of modern inorganic chemistry. As stated in the 1999 editorial of *EurJIC*, "the objective to reach the level of the top three Inorganic Chemistry journals on a worldwide scale within 3−5 years" has indeed been achieved beyond expectations. In fact, *EurJIC* is the fastest growing inorganic chemistry journal with a current impact factor of 2.514.

H. Nöth

**Fastest Growing Inorganic Chemistry Journal**

In order to pay tribute to the successful story of *EurJIC*, a journal which is truly European in spirit and fully international in appeal, the idea of publishing a special issue of the journal seemed timely to the Editorial Board. It has been a great honour for us to serve as Guest Editors for this celebratory 10th Anniversary issue of *EurJIC*, and it has been a great challenge to fulfil our duty. Beyond doubt, *EurJIC* is a cornerstone in the vital area of inorganic chemistry, and, to reflect its internationality, we decided to invite some leading scientists from all over the world with expertise in a wide range of research areas. The response to this invitation was indeed enthusiastic and has resulted in the present collection of 45 excellent articles coming from 11 European countries as well as from China, Israel, Japan, and the USA. The quality of the articles received, all of which have undergone a top-level independent evaluation process that is proper of *EurJIC*, is very high, making this issue a truly outstanding one and, we hope, a memorable snapshot of the hot topics in inorganic chemistry at the beginning of the 21st century.

**European in Spirit and International in Appeal**

The selection of the cover picture was also a difficult task as many of the articles received were worth highlighting on the cover. Accordingly, we decided, for the first time in *EurJIC* history, to highlight two contributions on the front and the back cover. Those we have chosen are the papers received from the Fontecave and Hou groups, two of the most valuable articles in this celebratory issue.

I. Bertini

Of the contributions received, there are six Microreviews, including a sound contribution on metalloproteoma by Ivano Bertini who served with proverbial energy and competence as Chairman of the Editorial Board of *EurJIC* from 1999 to 2006. Moreover, this issue includes the usual mix of Microreviews, Full Papers, and Short Communications, 45 articles in all, reflecting the full spectrum of modern inorganic chemistry from main group to bioinorganic, organometallic/catalysis, coordination, supramolecular, and material/solid-state chemistry, and, in some cases, the content of the articles clearly crosses these boundaries. It has to be mentioned that five of the articles received are from members of the Journal's Boards, including articles from Jan Reedijk, the present Chairman of the Editorial Board, and Rinaldo Poli, a member of the Editorial Board, as well as from Hansjörg Grützmacher, Lechosław Latos-Grażyński, and Carlos Romão, current Members of the International Advisory Board.

**The Full Spectrum of Modern Inorganic Chemistry**

It is not by chance that the Anniversary issue of *EurJIC* will be distributed at the 9th FIGIPAS Meeting in Inorganic Chemistry that takes place in Vienna this July, as both of these events represent sound milestones in the efforts of European Inorganic Chemists to achieve not only strong European ties but worldwide integration as well.

**9th FIGIPAS Meeting in Inorganic Chemistry**

In closing, we would like to mention that it has been a pleasure for us to collaborate and interact with the Editor, Karen Hindson, and her staff in the preparation of this Celebratory *EurJIC* issue. Heartfelt thanks to our authors, referees, and readers, and Happy Anniversary to *EurJIC*.

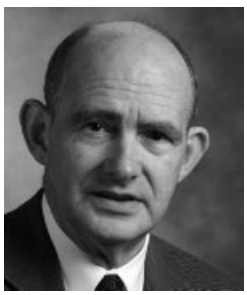
# Celebrating Ten Years



Ten years ago in an editorial I wrote "*In 1997 a new journal structure for the chemical literature in Europe will begin to evolve*". The occasion was the appearance of the first issue of the joint journal *Chemische Berichte/Recueil*, the prelude to the *European Journal of Inorganic Chemistry* (*EurJIC*) that came into being in 1998 with the participation of six European Chemical Societies. Another group of societies was waiting in the wings to amalgamate their journals, the criterion for entry, a year later. More recently, others joined as Associate Members, without merging journals, to bring the total number of societies that are now involved to 13 from 12 different countries (see Table 1).

Table 1. The European Chemical Societies that co-own *EurJIC*.

| Country | Society | Founded |
|---|---|---|
| Austria | Gesellschaft Österreichischer Chemiker (GÖCh) | 1897 |
| Belgium | La Société Royale de Chimie (SRC) | 1887 |
| Belgium | Koninklijke Vlaamse Chemische Vereniging (KVCV) | 1939 |
| Czech Republic | Česká Společnost Chemická (ČSCh) | 1866 |
| France | Société Française de Chimie (SFC) | 1857 |
| Germany | Gesellschaft Deutscher Chemiker (GDCh) | 1867 |
| Greece | Association of Greek Chemists (AGC) | 1924 |
| Hungary | Magyar Kémikusok Egyesülete (MKE) | 1907 |
| | Magyar Tudományos Akadémia (MTA) | 1825 |
| Italy | Società Chimica Italiana (SCI) | 1909 |
| The Netherlands | Koninklijke Nederlandse Chemische Vereniging (KNCV) | 1903 |
| Portugal | Sociedade Portuguesa de Química (SPQ) | 1911 |
| Spain | Real Sociedad Española de Química (RSEQ) | 1903 |
| Sweden | Svenska Kemistsamfundet | 1883 |

**13 Societies from 12 Countries**

On this 10th Anniversary of the merger journal *EurJIC*, a number of people will still remember that the discussions on the foundation of joint European Journals in the field of chemistry had started gaining momentum in the 1980s. The process was long and time-consuming, even more so because many chemical societies were not ready to give up their own specialized journals at the same time. Furthermore, not all interested societies owned a journal. The regular changing of boards and chairs of the several societies, as was required by their by-laws, also did not help to speed up the process. In Europe, the Royal Society had, and still has, its own publishing house, and understandably, wanted to keep that successful institution.

In addition, some commercial publishers in the 1970s and 1980s had launched a number of new journals, with titles containing the words "European Journal of .....". Already in the early 1990s, to protect some titles, the names *European Journal of Organic Chemistry* (*EurJOC*) and *European Journal of Inorganic Chemistry* were deposited for possible future use. The key societies from five countries were almost ready to begin the new journals in 1993, but at that stage only the new general chemistry journal, *Chemistry – A European Journal*, was realized. That journal, which several societies co-own, was eventually launched in 1995.

**A Growing Family of European Journals**

At a crucial meeting in 1996, the German and Dutch chemical societies made the historic decision to merge their journals *Chemische Berichte* and *Recueil des Travaux Chimiques des Pays-Bas* (J. Royal Neth. Chem. Soc.), initially under the name of *Chemische Berichte / Recueil*. This process appeared to be a good catalyst, as in 1997 the six chemical societies indeed decided to merge their organic/inorganic chemistry journals to form two new journals with the names that had been deposited earlier: *EurJIC* and *EurJOC*. The first issues of the two journals appeared on January 1, 1998.

**First Issue in January 1998**

The national chemical societies must be congratulated on implementing their modern concept for European publishing, which today still remains open for further European Chemical Societies to benefit.

Of course the authorship and readership of the journal is not restricted to these countries and societies but is open to the international community – as we say "*EurJIC* is made in Europe for the world". We can, in fact, see the international interest, for instance, by the percentage of downloads of published papers distributed over the globe (see Figure 1). A high-quality journal, nowadays, is by definition international. The ACS and RSC journals have always been open to non-member chemists; likewise, *EurJIC* (and the family of European Journals) has always welcomed scientists from non-partner countries (see Figure 2). It is indeed a pleasure to see that we enjoy an increasing interest from

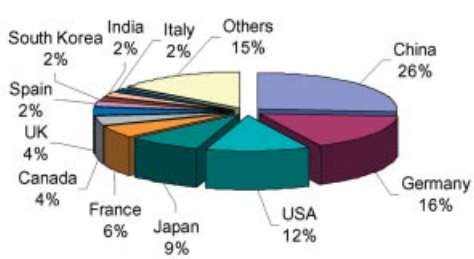


**Figure 1.** International interest in *EurJIC* as reflected by the percentage of downloads from each country.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

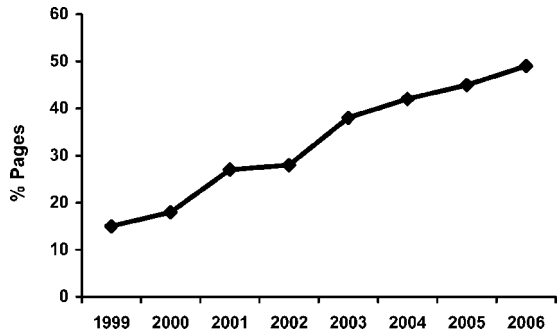

**Figure 2.** The percentage of published papers by scentists from non-partner countries.

top scientists outside Europe. The dominance of any one country as a result of the merger of national journals has been reduced, and the authorship has become international.

After 10 volumes it is legitimate to ask: How has the journal evolved over these years? Since the inauguration of the journal, the success of *EurJIC* can be seen in terms of the increase in the number of submissions (see Figure 3) and the number of pages published (see Figure 4). More importantly, the rejection rate, which can serve as an indicator of high quality, has also increased substantially (see Figure 5). The ISI impact factor has also risen and is currently stable at a value of 2.5. In 1998, *EurJIC* started with 12 issues per year. This number rose to 24 in the year 2003, and, to enable quick access to the latest developments in inorganic chemistry, *EurJIC* publishes 36 issues per year from 2007.

36 Issues per Year from 2007

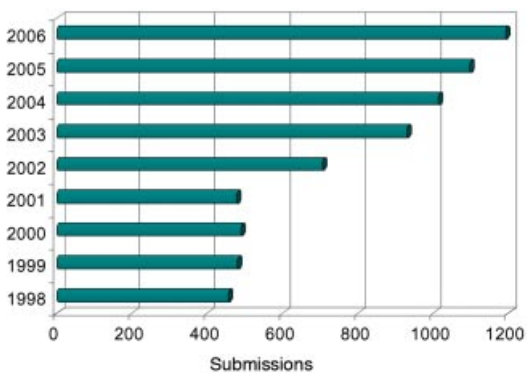

**Figure 3.** Number of submissions to *EurJIC* per year from 1998 to 2006.

The first new cover, with a changing cover picture for each issue, appeared in 2002. The authors of high-quality contributions were invited to submit proposals for the cover picture. As this concept was well received, we have continued with this tradition.

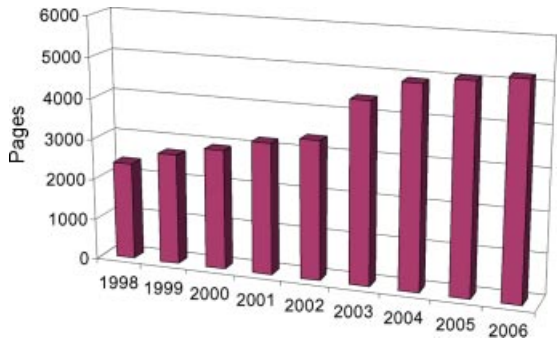

**Figure 4.** Page development of *EurJIC* from 1998 to 2006.

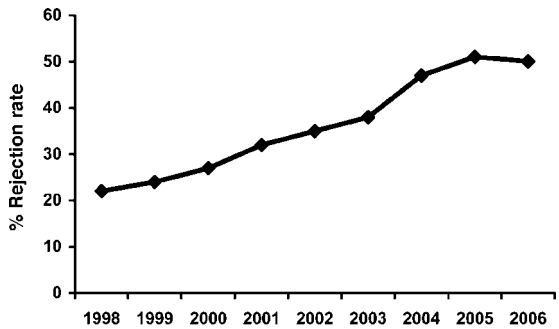

**Figure 5.** Rejection rates from 1998 to 2006.

A new layout to assist browsing with a colored table of contents, text as well as graphic, and a "Key Topic" rang in the 10th year.

As we live in an ever-changing and rapidly growing technological world, *EurJIC* realizes the importance of not only keeping up-to-date, but of being at the forefront. Although our readers have had access to e-mailing Alerts for some time, RSS feeds are now available (an RSS feed provides updates of the content of web pages to a computer, or even to a mobile phone). Also *EurJIC* is a member of CrossRef, which is a service that links reference citations to the online content of those references.

In 1997 I already wrote: "The word *European* is not meant to be exclusive". The present jubilee issue shows that the chemistry world has fully accepted the *European Journal of Inorganic Chemistry* as a high-ranking inorganic chemistry journal by the wide range of contributions from all over the world. Now we can congratulate the authors, reviewers, readers, editors, societies, and publisher on a mature journal, which has found its position in the international community. I wish *EurJIC* a successful continuation.

Made in Europe for the World

Jan Reedijk
Chairman of the Editorial Board, *EurJIC*

# CONTENTS

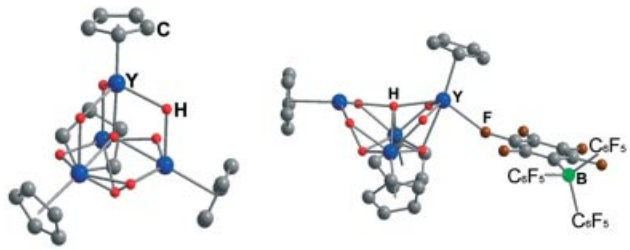
## MICROREVIEWS

### Rare Earth Metal Polyhydrides

**Z. Hou,* M. Nishiura, T. Shima ..... 2535–2545**

Synthesis and Reactions of Polynuclear Polyhydrido Rare Earth Metal Complexes Containing "$(C_5Me_4SiMe_3)LnH_2$" Units: A New Frontier in Rare Earth Metal Hydride Chemistry

**Keywords:** are earths / Hydride ligands / Cyclopentadienyl ligands / Cluster compounds / Hydrogenation



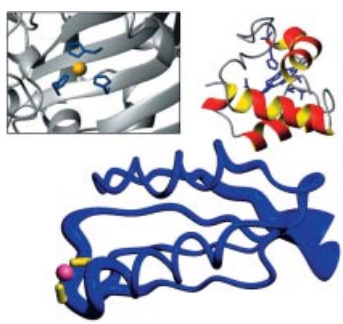
The synthesis, structures, and novel reactions of a series of neutral (left) and cationic (right) polyhydrido rare earth metal complexes are reviewed.

### Metalloproteomes

**I. Bertini*, A. Rosato ..... 2546–2555**

From Genes to Metalloproteins: A Bioinformatic Approach

**Keywords:** Iron / Zinc / Copper / Heme proteins / Metalloproteins / Bioinformatics



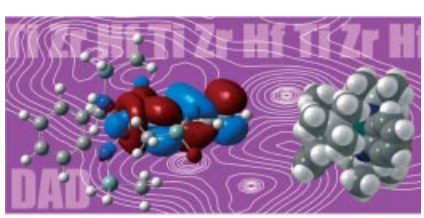
A significant fraction of the proteins that organisms produce and exploit to sustain cellular life require metal ions for their biological function (metalloproteins). Because the experimental characterization of metal requirements at the whole genome level is still not routinely feasible, catalogues of metalloproteins can only be compiled through bioinformatic methods. This review discusses the results of the application of bioinformatics to the identification of various metalloprotein types in selected organisms whose complete genome sequence is available. An overview of the usage of different essential metal ions across domains of life is provided.

### Diimino/Enediamido Complexes

**C. Mealli,* A. Ienco, A. D. Phillips, A. Galindo* ..... 2556–2568**

A Critical Review of Electronic Effects in Enediamido and α-Diimino Complexes of the Group 4 Metals

**Keywords:** N ligands / Group 4 metals / Metallacycles / Density functional calculations / Electronic structure



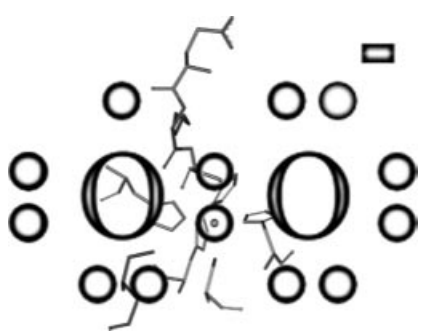
The stereochemical features of the group 4 metal complexes with *noninnocent* α-diimino chelates such as 1,4-diaza-1,3-butadiene (DAD) are systematically reviewed from an electronic point of view with the help of density functional calculations. The Quantum Theory of Atoms in Molecules (QTAIM) approach is also used to interpret the dichotomy of planar/bent metallacycles which is observed in very similar homoleptic $[M(DAD)_2]$ complexes.

### Metalloenzymes

**A. S. Pereira, P. Tavares, F. Folgosa, R. M. Almeida, I. Moura,* J. J. G. Moura ..... 2569–2581**

Superoxide Reductases

**Keywords:** Bioinorganic chemistry / Non-heme iron centres / Superoxide / Structure-activity relationships

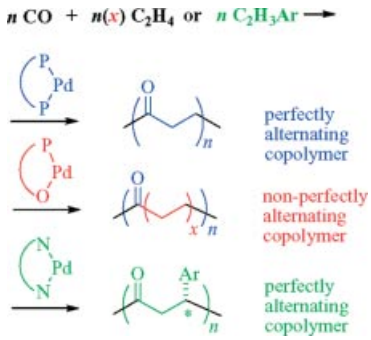


This review aims to describe the structural characteristics of superoxide reductases and the mechanistic aspects of biological superoxide anion reduction. The geometry of the active site, the possible electron donors in vivo and the current hypothesis for the catalytic mechanism are discussed. Some phylogenetic considerations are presented.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**Pd-Catalysed Copolymerisation**

Co- and terpolymerisations of carbon monoxide and alkenes are usually catalysed by palladium complexes, and the recent introduction of phosphane-sulfonate ligands has allowed this reactivity to be extended to non-alternating CO/ethene copolymerisation. After a general overview of the topic, selected recent advances in this field are described.



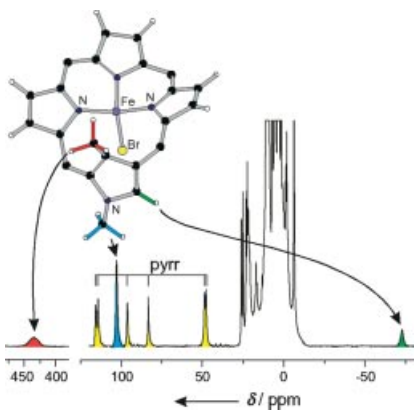
**E. J. García Suárez, C. Godard, A. Ruiz, C. Claver* ..... 2582–2593**

Alternating and Non-Alternating Pd-Catalysed Co- and Terpolymerisation of Carbon Monoxide and Alkenes

**Keywords:** Polymerisation / Polyketones / Palladium / Carbon monoxide / Alkenes

**Metallocarbaporphyrinoids**

This microreview presents the general characteristics of paramagnetic metallocarbaporphyrinoids with a focus on NMR studies. NMR spectroscopy of paramagnetic molecules is a powerful probe of several intriguing aspects of their molecular and electronic structures, structural rearrangements, and reactivity, including oxidation and oxygenation.



**E. Pacholska-Dudziak, L. Latos-Grażyński* ..... 2594–2608**

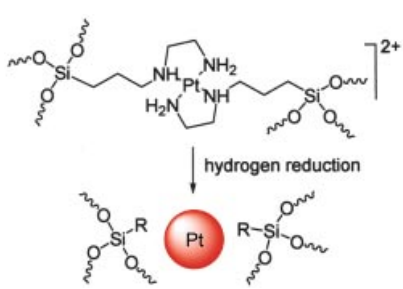
NMR Studies of Paramagnetic Metallocarbaporphyrinoids

**Keywords:** Carbaporphyrinoids / Porphyrinoids / NMR spectroscopy / Organometallic chemistry

# SHORT COMMUNICATION

**Sol-Gel Films**

Silica films on glass substrates with homogeneously dispersed platinum, gold or silver nanoparticles were prepared by sol-gel processing of triethoxysilyl-substituted complexes, followed by hydrogen treatment of the films at elevated temperatures.



**M. Malenovska, S. Martinez, M.-A. Neouze, U. Schubert* ..... 2609–2611**

Growth of Metal Nanoparticles in a Sol-Gel Silica Thin Film

**Keywords:** Thin films / Nanostructures / Inorganic-organic hybrid materials / Nanocomposites

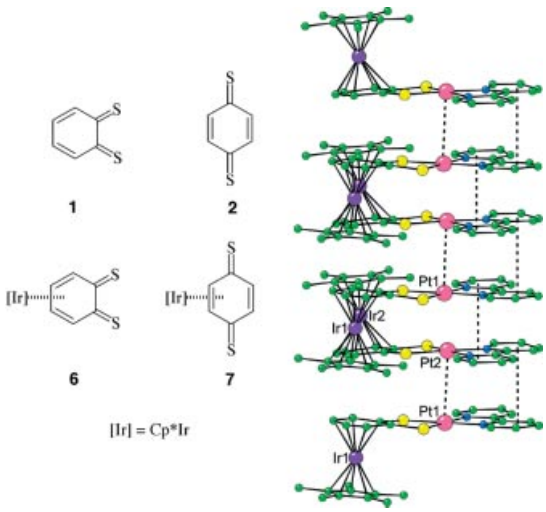
## Dithiobenzoquinone Complexes



Overcoming a long-standing challenge, the *o*- and *p*-dithiobenzoquinone iridium complexes **6** and **7** were synthesized for the first time, and the X-ray molecular structure of [Cp*Ir-*p*-($\eta^4$-$C_6H_4S_2$)] (**7**) is reported. The organometallic linker **6** reacts with "Pt(bpy)" subunits to give the complex [Pt(bpy){Cp*Ir-*o*-($\eta^4$-$C_6H_4S_2$)}][OTf]$_2$ (**10**), which forms a supramolecular chain through π−π/Pt···Pt interactions.

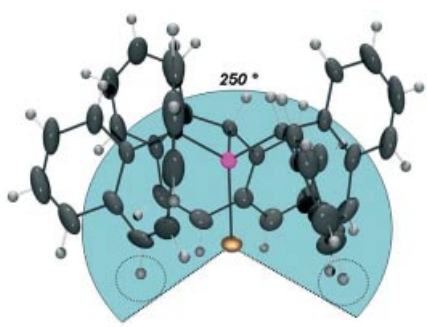
**J. Moussa, M. N. Rager, K. Boubekeur, H. Amouri* ..... 2648−2653**

*ortho*- and *para*-Thioquinonoid π-Complexes: First Synthesis, Reactivity, and Crystal Structure Determination

**Keywords:** Reactive intermediates / Coordination modes / Sulfur / Thioquinones / Iridium

## Coordination Polymorphism

Either a very bulky monodenate phosphane ligand (cone angle about 250°) or a tetradentate $\kappa^1$:$\eta^6$ ligand. These are the coordination modes of the highly rigid tris(5*H*-dibenzo[*a*,*d*]cyclohepten-5-yl)phosphane (trop$_3$P) in $d^{10}$ [$Ag^I$, $Au^I$] and $d^8$ [$Rh^I$, $Ir^I$, $Pd^{II}$] valence configured metal complexes.

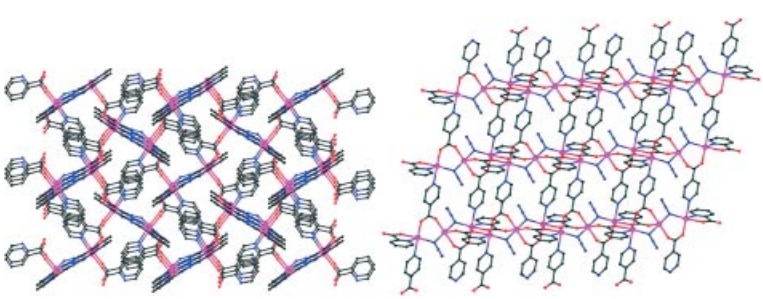


**U. Fischbach, H. Rüegger, H. Grützmacher* ..... 2654−2667**

Tris(dibenzo[*a*,*d*]cycloheptenyl)phosphane: A Bulky Monodentate or Tetrapodal Ligand

**Keywords:** Alkene ligands / Gold / Iridium / Palladium / Phosphane ligands / Rhodium / Silver / Tetradentate ligands / Solid-state NMR spectroscopy

## Coordination Polymers



Two $Mn^{II}$ coordination polymers, $[Mn_2(bpt)(pa)_2(N_3)]_n$ [**1**; Hpa = picolinic acid, Hbpt = 3,5-bis(2-pyridyl)-4*H*-1,2,4-triazole] and $[Mn_3(ina)_2(pa)_2(N_3)_2]_n$ (**2**; Hina = isonicotinic acid), containing in situ generated bpt and pa ligands have been synthesized under solvothermal conditions. They exhibit spin-canting magnetism and topological ferrimagnetism with an AF-AF-F sequence, respectively.

**L. Cheng, W.-X. Zhang, B.-H. Ye,* J.-B. Lin, X.-M. Chen* ..... 2668−2676**

Spin Canting and Topological Ferrimagnetism in Two Manganese(II) Coordination Polymers Generated by In Situ Solvothermal Ligand Reactions

**Keywords:** Solvothermal ligand reaction / Coordination polymers / Spin canting / Topological ferrimagnetism

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

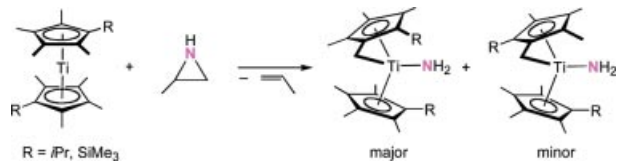
# CONTENTS

## Titanium Chemistry

**T. E. Hanna, E. Lobkovsky, P. J. Chirik* ..... 2677–2685**

N–H Group Transfer and Oxidative Addition Chemistry Promoted by Isolable Bis(cyclopentadienyl)titanium Sandwich Complexes

**Keywords:** Titanium / Oxidative addition / Cyclopentadienyl / Group transfer / Nitrogen



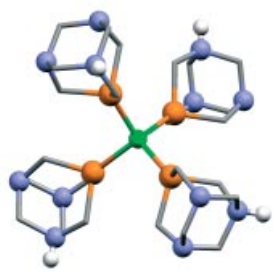
Addition of propylenimine to isolable titanocene complexes has resulted in [NH] group transfer which is followed by rapid cyclometalation. This reactivity contrasts [O] atom transfer where isolable titanocene oxides were obtained.

## Phosphane Complexes

**A. M. Kirillov, P. Smoleński, M. F. C. Guedes da Silva, A. J. L. Pombeiro* ..... 2686–2692**

The First Copper Complexes Bearing the 1,3,5-Triaza-7-phosphaadamantane (PTA) Ligand

**Keywords:** Copper / N,P ligands / Structure elucidation / Phosphane ligands



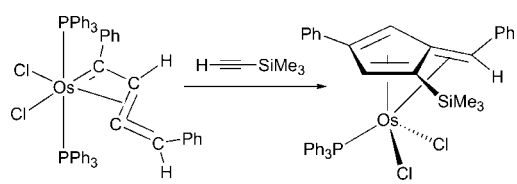
The water-soluble $Cu^{I}$ compounds $[Cu(PTAH)_4](NO_3)_5$ and $[Cu(PTA)_4](NO_3)$ were easily prepared and fully characterized, providing the first examples of Cu complexes bearing PTA or any derived ligand with a cagelike PTA core.

## Alkyne Oligomerization

**T. B. Wen, W. Y. Hung, H. H.-Y. Sung, Z. Zhou, I. D. Williams, G. Jia* ..... 2693–2701**

Coupling Reactions of an Allenylcarbene Complex with Alkynes and Styrene

**Keywords:** Osmium / Fulvenes / Carbenes / Alkynes / Alkenes



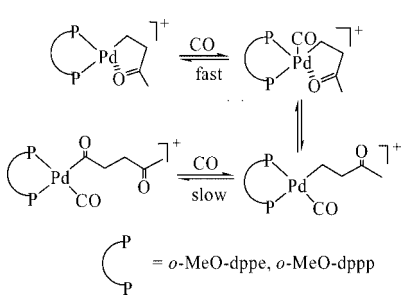
The allenylcarbene complex $[OsCl_2\{=CPh(\eta^2\text{-}CH=C=CHPh)\}(PPh_3)_2]$ undergoes coupling reactions with alkynes to produce fulvene complexes. A similar coupling reaction also occurs between this complex and styrene.

## CO/Ethene Copolymerization

**C. Bianchini,* A. Meli, W. Oberhauser,* C. Claver, E. J. Garcia Suarez ..... 2702–2710**

Unraveling the *o*-Methoxy Effect in the CO/Ethene Copolymerization Reaction by Diphosphanepalladium(II) Catalysis

**Keywords:** Polyketones / Palladium / Diphosphane ligands / Catalysis / Copolymerization / Kinetics

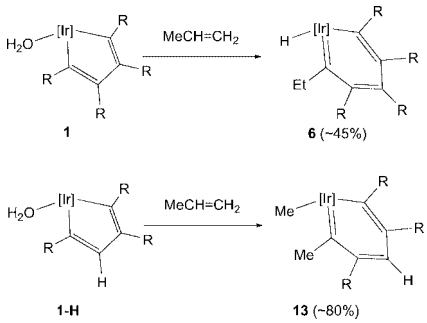


*o*-MeO substituents on the phosphorus aryl rings of chelating diphosphane ligands increase the activity of $Pd^{II}$ catalysts for the alternating CO/ethene copolymerization in either protic or aprotic solvents. In particular, the presence of *o*-MeO substituents affects the kinetics of the copolymerization process that becomes independent of the CO pressure. In situ high-pressure NMR experiments have provided valuable information on relevant steps of the copolymerization process.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

## Iridabenzenes

A new synthesis of iridabenzene species is described. Surprisingly, the coupling of the iridacyclopentadienes **1** and **1-H** with propene is highly dependent on the nature of the substituents in the starting metallacycle.

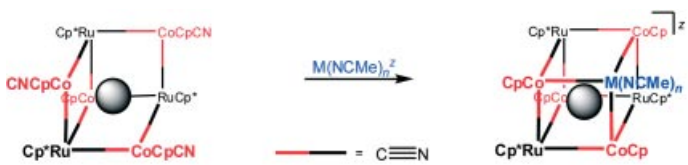


**M. Paneque,* M. L. Poveda,* N. Rendón, E. Álvarez, E. Carmona ..... 2711–2720**

The Synthesis of Iridabenzenes by the Coupling of Iridacyclopentadienes and Olefins

**Keywords:** Metallacycles / Olefins / Insertion / Isomerisation / Alkylidenes

## Supramolecular Cages



The coordination chemistry of the unusual metallo-ligand $Cs\subset[CpCo(CN)_3]_4[Cp^*Ru]_3$ ($Cs\subset Co_4Ru_3$) is described with attention to the behavior of the ligand itself, its binding to Lewis-acidic metal cations, and its ability to stabilize catalytically relevant $Ru-PPh_3$ fragments.

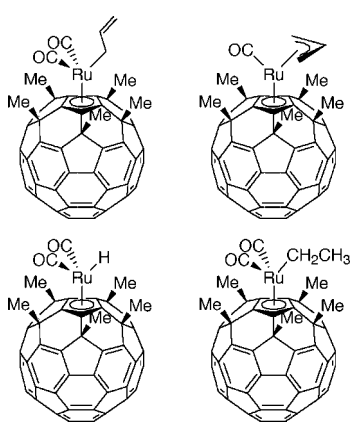
## Metal–Fullerene Complexes

$\eta^1$-Allyl and $\eta^3$-allyl, ethyl, and hydrido ruthenium complexes of pentamethyl[60]-fullerene, $Ru(\eta^5\text{-}C_{60}Me_5)R(CO)_2$ (R = $\eta^1$-allyl, Et, H) and $Ru(\eta^5\text{-}C_{60}Me_5)(\eta^3\text{-allyl})(CO)$, were prepared. Conversion of the $\eta^1$-allyl complex to the $\eta^3$-allyl complex and catalytic performance of the hydrido complex in the isomerization of 1-decene to internal decenes are described.



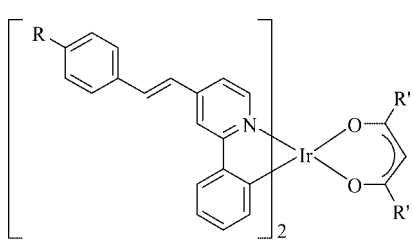
**Y. Matsuo, T. Uematsu, E. Nakamura* ..... 2729–2733**

Synthesis and Catalytic Activity of $\eta^1$-Allyl and $\eta^3$-Allyl, Ethyl, and Hydrido Complexes of Ruthenium–Pentamethyl[60]-fullerene

**Keywords:** Ruthenium / Fullerenes / Allyl complexes / Hydrido complexes / Isomerization

## Coordination Chemistry

Large bathochromic shifts in emission energy at 77 K can be achieved by adding a conjugated styryl group to the ppy ligand of the $[Ir(C^{\wedge}N\text{-ppy})_2(acac)]$ complex and by introducing either a strong electron-donating (dialkylamino, $\lambda_{em}$ = 651 nm) or -withdrawing (nitro, $\lambda_{em}$ = 647 nm) group.



R' = $CH_3$; R = OMe, $NEt_2$, H, $NO_2$
R' = *t*Bu; R = OMe, $NEt_2$

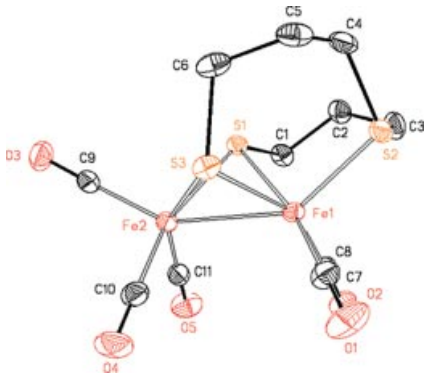
## [Fe-only]-Hydrogenase Models

**J. Windhager, M. Rudolph,* S. Bräutigam, H. Görls, W. Weigand* ..... 2748–2760**

Reactions of 1,2,4-Trithiolane, 1,2,5-Trithiepane, 1,2,5-Trithiocane and 1,2,6-Trithionane with Nonacarbonyldiiron: Structural Determination and Electrochemical Investigation

**Keywords:** Iron / Cluster compounds / S ligands / Hydrogenase / Electrocatalysis / Dihydrogen



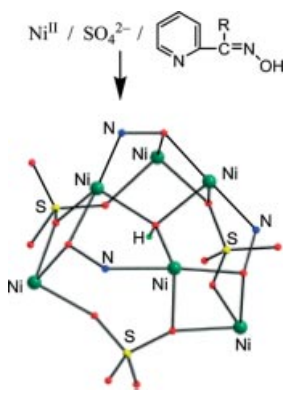
The syntheses of novel [Fe-only]-hydrogenase models starting from 1,2,4-trithiolane, 1,2,5-trithiepane, 1,2,5-trithiocane and 1,2,6-trithionane are described. The products were characterised by spectroscopic methods and X-ray structure analyses. The electrochemical behaviour of one representative complex is described in detail.

## Nickel Cluster Chemistry

**C. Papatriantafyllopoulou, G. Aromi, A. J. Tasiopoulos, V. Nastopoulos, C. P. Raptopoulou, S. J. Teat,* A. Escuer,* S. P. Perlepes* ..... 2761–2774**

Use of the Sulfato Ligand in 3d-Metal Cluster Chemistry: A Family of Hexanuclear Nickel(II) Complexes with 2-Pyridyl-Substituted Oxime Ligands

**Keywords:** Nickel(II) clusters / Magnetic properties / Sulfato complexes / Oxime complexes



The shown general reaction scheme (R = Me, Ph) gives a family of hexanuclear nickel(II) clusters containing the $[Ni_3(\mu_3\text{-}OH)(\mu_3\text{-}SO_4)_3(\mu_3\text{-}ONR')_3]^{2+}$ core. The complexes exhibit an overall antiferromagnetic behavior, with a simple 2-*J* model adequately describing the thermal variation of the molar magnetic susceptibility.

## Coordination Polymers

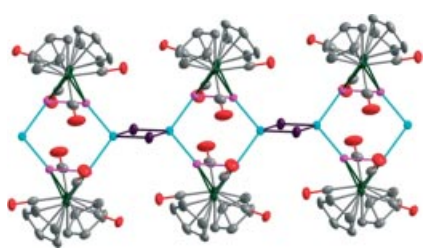
Conformational Analysis of One-Dimensional Coordination Polymers Based on $[Cp_2Cr_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ by Solid-State Multinuclear NMR Spectroscopy and Density Functional Calculations

**Keywords:** Chromium / Copper / Halides / Density functional calculations / NMR spectroscopy / Phosphorus



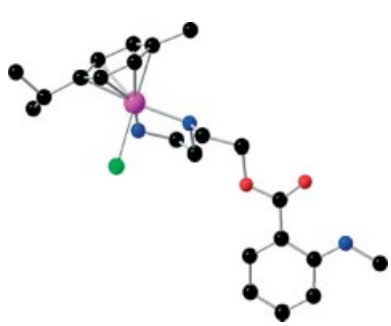
The complex $[Cp_2Cr_2(CO)_4(\mu,\eta^2\text{-}P_2)]$ reacts with copper(I) halides to yield new 1D coordination polymers (iodide derivative shown). Solid-state multinuclear NMR spectroscopy demonstrates the extreme sensitivity of the chemical shift to apparently minor structural variations, and density functional calculations corroborate the conclusions deduced from the experimental evidence.

## Fluorescent (Arene)Ru$^{II}$ Complexes

**F. Zobi, B. B. Mood, P. A. Wood, F. P. A. Fabbiani, S. Parsons, P. J. Sadler* ..... 2783–2796**

Tagging (Arene)ruthenium(II) Anticancer Complexes with Fluorescent Labels

**Keywords:** Anticancer agents / Organometallic compounds / Fluorescence / Ruthenium / Hydrolysis



Fluorescent (arene)ruthenium(II) complexes, obtained from the reaction of the $[(p\text{-cymene})RuCl_2]_2$ dimer with isatoic acid based ligands, were structurally characterized and their solution and fluorescence properties investigated. When the fluorogenic reporter is tagged onto the complex through an ester bond, the resulting compound is a substrate for cytosolic esterases. Compounds bearing an ester bond may be models for esterase-activated Ru-based prodrug delivery systems.

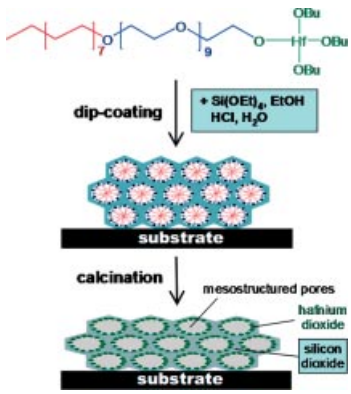
## Doped Silica Films

A surfactant–hafnium alkoxide complex was used as a template in a sol–gel dip-coating process to produce hafnium oxide doped silica films with ratios between 1:60 and 1:6. The influence of subsequent heat treatment was studied by GISAXS and TEM. The surface and in-depth molecular composition of the films was studied by XPS.



**R. Supplit, N. Hüsing,* S. Gross, S. Bernstorff, M. Puchberger ... 2797–2802**

Hafnium Oxide Doped Mesostructured Silica Films

**Keywords:** Mesostructured films / Ligand-assisted templating / Self-assembly / Surfactants

## Water-Soluble Ru Complexes

Water-soluble ruthenium(II) complexes have been synthesized and characterised. The crystal structure of [RuCp-(mTPPMS)($PPh_3$)(PTA)]·$2H_2O$, which is the first half-sandwich ruthenium complex to contain three different phosphanes, has been determined. The binding properties of the complexes obtained and of the ligand mTPPMS towards DNA have been studied using the mobility shift assay.

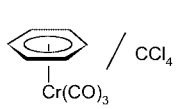
Water-soluble gold(I) and palladium(II) complexes containing different thiolates and the phosphane ligands 1,3,5-triaza-7-phosphaadamantane (PTA) and 3,7-diacetyl-1,3,7-triaza-5-phosphabicyclo[3.3.1]-nonane (DAPTA) are described and were characterised by spectroscopic techniques and X-ray crystallography.

## Unimolecular Photoinitiators

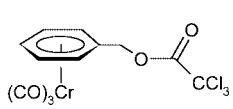
**E. P. Kündig,* L.-H. Xu, M. Kondratenko, A. F. Cunningham Jr.,* M. Kunz ..... 2934–2943**

Photoinitiation of Acrylate Polymerization with (Arene)chromium Complexes

**Keywords:** Acrylate polymerization / Photoinitiators / Arene complexes / Chromium / Radiation curing



**1**



**17a**

It is known that the couple **1**/$CCl_4$ can induce photoinitiated polymerization (radiation curing) of acrylates. A new investigation into the mechanism of this process shows that photolytic CO/acrylate exchange leads to a complex in which the arene–metal bond is labilized. This then creates a highly reactive metal center that initiates $CCl_3$ radical formation. The proximity of the $COCCl_3$ group makes **17a** a much more active catalyst than **1**/$CCl_4$.

# Synthesis and Reactions of Polynuclear Polyhydrido Rare Earth Metal Complexes Containing "$(C_5Me_4SiMe_3)LnH_2$" Units: A New Frontier in Rare Earth Metal Hydride Chemistry

**Zhaomin Hou,*[a] Masayoshi Nishiura,[a] and Takanori Shima[a]**

**Keywords:** Rare earths / Hydride ligands / Cyclopentadienyl ligands / Cluster compounds / Hydrogenation

A series of tetranuclear octahydrido rare earth metal complexes of general formula $[(C_5Me_4SiMe_3)Ln(\mu\text{-}H)_2]_4(THF)_n$ (Ln = Sc, Y, Gd, Dy, Ho, Er, Tm, Lu; $n$ = 0, 1, or 2) that contain $C_5Me_4SiMe_3$ as an ancillary ligand have been prepared and structurally characterized. These hydride clusters are soluble in common organic solvents such as THF, toluene, and hexane, and maintain their tetranuclear framework in solution. Such polynuclear polyhydrido complexes exhibit extremely high and unique reactivity toward a variety of unsaturated substrates including CO, $CO_2$, and nitriles. The reaction of these neutral polyhydrides with one equivalent of $[Ph_3C][B(C_6F_5)_4]$ affords the corresponding cationic hydride clusters $[(C_5Me_4SiMe_3)_4Ln_4H_7(THF)_n][B(C_6F_5)_4]$, which can act as catalysts for the syndiospecific polymerization of styrene and regio- and stereospecific *cis*-1,4-polymerization of 1,3-cyclohexadiene.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Metal hydrides are fundamental components in a wide range of stoichiometric and catalytic reactions, and their importance in modern inorganic and organic chemistry cannot be overemphasized.[1,2] A large number of monohydride complexes of the rare earth (group 3 and lanthanide) metals of the general type "$L_2MH$" or "(L)(L′)MH", which are supported by two anionic ancillary ligands per metal, have been synthesized and studied[2] since the first rare earth metallocene hydride complex was reported in the early 1980s.[3] In contrast, dihydrido rare earth metal complexes of the type "$LMH_2$", which bear one anionic ancillary ligand per metal, have been much less extensively investigated even though such complexes are of great interest both structurally and chemically. A major factor that has hampered the investigation of rare earth metal dihydride or polyhydride complexes is the difficulty in isolating structurally well defined complexes. Early attempts to prepare a dihydrido rare earth metal complex by reaction of dialkyl complexes such as $[(C_5Me_5)Lu(CH_2CMe_3)_2(THF)]$[4] or $[(C_5Me_4SiMe_3)Y(CH_2SiMe_3)_2(THF)]$[5] with $H_2$ did not afford a structurally characterized hydride species. The first structurally characterized dihydrido rare earth metal species was isolated as the $Sm^{III}$/K heteropolymetallic form $[\{(C_5Me_5)Sm(\mu\text{-}H)_2\}_6\{KH(THF)_2\}_3]$, which formally consists of six "$(C_5Me_5)SmH_2$" units and three "$KH(THF)_2$" units.[6a] This complex was serendipitously obtained by the reaction (σ-bond metathesis and subsequent oxidation) of the $Sm^{II}$ alkyl complex $[\{(C_5Me_5)SmCH(SiMe_3)_2[(C_5Me_5)K(THF)_2]\}_n]$[6] with an excess of $PhSiH_3$. Very recently, a series of salt-free polynuclear polyhydrido rare earth metal complexes that contain "$(C_5Me_4SiMe_3)LnH_2$" units has been synthesized from the $C_5Me_4SiMe_3$-ligated dialkyl complexes $[(C_5Me_4SiMe_3)Ln(CH_2SiMe_3)_2(THF)]$ (Ln = Sc, Y, Gd, Dy, Ho, Er, Tm, Lu). It has been found that these polyhydrido rare earth metal complexes show a unique reactivity that differs from that of conventional monohydride complexes. This article summarizes recent studies on this new class of rare earth metal hydride complexes.

## 2. Synthesis and Structures of Tetranuclear Octahydrido Rare Earth Metal Complexes

Hydrogenolysis of the $C_5Me_4SiMe_3$-ligated bis(trimethylsilylmethyl)scandium complex $[(C_5Me_4SiMe_3)Sc(CH_2SiMe_3)_2(THF)]$ with $H_2$ in toluene at room temperature gives the THF-free tetranuclear octahydride complex $[\{(C_5Me_4SiMe_3)Sc(\mu\text{-}H)_2\}_4]$ (**1**) (Scheme 1).[7] This complex can be viewed as being the result of a self-assembly of four "$(C_5Me_4SiMe_3)ScH_2$" units in a tetrahedron through "intermolecular" Sc–H interactions. There are a total of eight hydride ligands in the molecule, one of which is body-centered in a $\mu_4$-H–$Sc_4$ fashion, one is face-capped in a $\mu_3$-

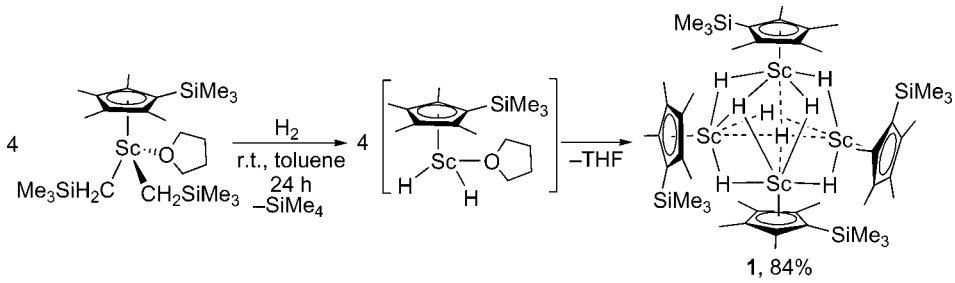

Scheme 1. Synthesis of a tetranuclear octahydrido scandium complex.

$H–Sc_3$ form, and six are edge-bridged in a $\mu_2$-H–$Sc_2$ style. The THF ligand bonded originally to the scandium metal center of the alkyl precursor is squeezed out in the hydride complex due to the formation of "intermolecular" Sc–H bonds.

Hydrogenolysis of the bis(trimethylsilylmethyl) complexes of larger rare earth metals such as Y, Er, and Tm in toluene affords the corresponding tetranuclear octahydride complexes $[\{(C_5Me_4SiMe_3)Ln(\mu\text{-}H)_2\}_4(THF)]$ (**2**: Ln = Y;[8] **3**: Ln = Er;[9] **4**: Ln = Tm[9]) where one of the four metal centers in these complexes bears an additional THF ligand (Scheme 2). The overall structure of the mono(THF)-containing polyhydride complexes **2**–**4** is almost the same as that of the THF-free Sc complex **1**. In the case of the analogous complexes of larger metals such as Gd (**5**),[9] Dy (**6**),[9] and Ho (**7**),[9] an agostic interaction between the metal center and a methyl group of an adjacent $C_5Me_4SiMe_3$ ligand is also observed, probably due to the greater steric unsaturation of these larger metal centers (Scheme 2).[9,10] These results show that the fine structures of the tetranuclear octahydride complexes are, to some extent, dependent on the ionic radius of the metal centers.

In the case of lutetium, the reaction of the bisalkyl complex $[(C_5Me_4SiMe_3)Lu(CH_2SiMe_3)_2(THF)]$ with $H_2$ did not give a single hydride complex.[11] However, hydrogenolysis of the hydride-bridged dimeric mixed alkyl/hydride complex $[\{(C_5Me_4SiMe_3)Lu(CH_2SiMe_3)(\mu\text{-}H)(THF)\}_2]$ (**8**), which was prepared by reaction of $[(C_5Me_4SiMe_3)Lu(CH_2SiMe_3)_2$-(THF)] with one equivalent of $PhSiH_3$, affords the tetranuclear mono(THF)-coordinated lutetium octahydride complex $[\{(C_5Me_4SiMe_3)Lu(\mu\text{-}H)_2\}_4(THF)]$ (**9**) in THF (Scheme 3).[12] The structure of **9** is identical with those of the analogous mono(THF)-containing complexes **2**–**4**. When the reaction of the alkyl/hydride complex **8** with $H_2$

*Zhaomin Hou was born in Shandong Province, China, in 1961. He received his B.Sc. from the China University of Petroleum (Shandong, China) in 1982, and his M.Sc. and Ph.D. from Kyushu University (Fukuoka, Japan) in 1986 and 1989, respectively. He joined RIKEN (The Institute of Physical and Chemical Research) in 1989, where he is now Chief Scientist and Director of the Organometallic Chemistry Laboratory. The current research activity in his group includes development of new catalysts for regio- and stereospecific olefin polymerization/copolymerization, new catalysts for efficient organic synthesis, and rare earth metal complexes with novel structures and reactivities, as well as synthesis of new functional materials. He is a recipient of the Japan Society of Coordination Chemistry Award for Young Scientists (1996), the Rare Earth Society of Japan Award for Young Scientists (1997), the Progress Award in Synthetic Organic Chemistry, Japan (2000), the JSPS Prize (2007), the Chemical Society of Japan Award for Creative Work for 2007, and the Mitsui Chemicals Catalysis Science Award (2007).*

*Masayoshi Nishiura was born in Hokkaido, Japan in 1971. He did his graduate studies at Chiba University under the supervision of Professor Tsuneo Imamoto, and received his Ph.D. in 2000 from the same University. He moved to RIKEN as a special postdoctoral researcher in 2000 and was promoted to Research Scientist at RIKEN in 2003. His research focuses on development of organometallic catalysts for organic synthesis and olefin polymerization.*

*Takanori Shima was born in Osaka, Japan, in 1972. He obtained his Ph.D. degree in 2001 from Tokyo Institute of Technology on the study of multinuclear polyhydrido complexes, under the supervision of Prof. Hiroharu Suzuki. He undertook postdoctoral research in the group of Prof. John A. Gladysz in the Institute für Organische Chemie of Friedrich-Alexander Universität (Erlangen, Germany) as an Alexander von Humboldt fellow in 2002. He joined RIKEN in 2004. His research interests include the synthesis and development of new rare earth metal polyhydrido complexes.*

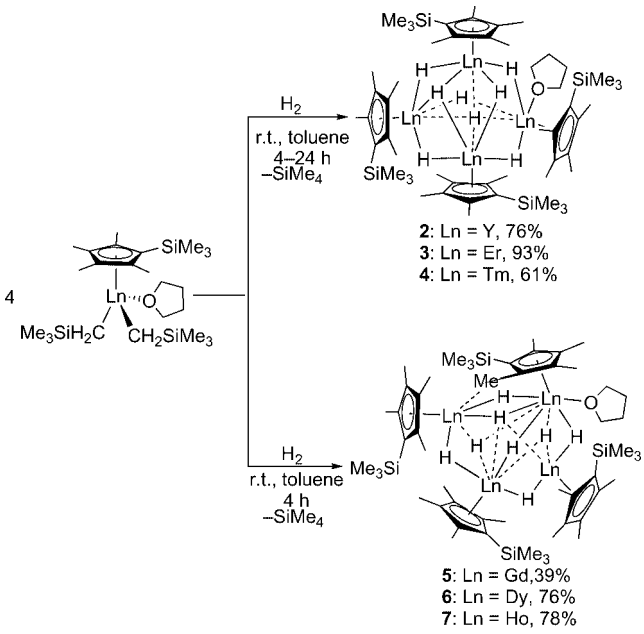
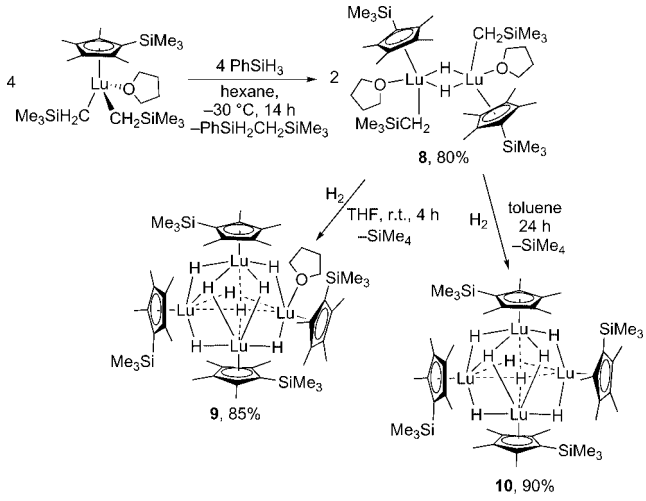


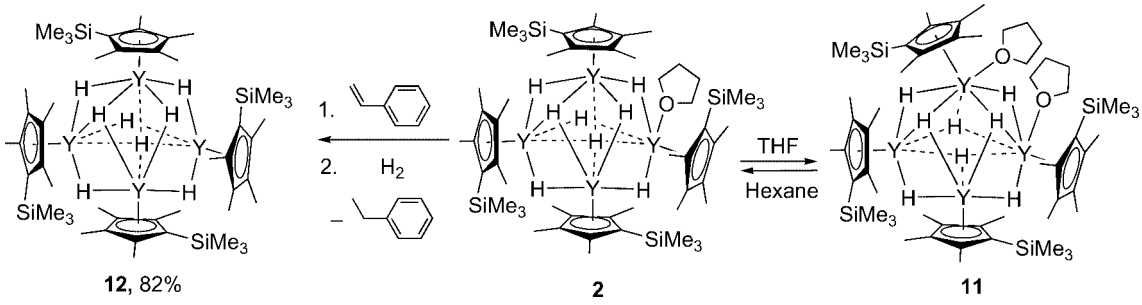
Scheme 2. Synthesis of mono(THF)-coordinated tetranuclear octahydrido rare earth metal complexes.



Scheme 3. Synthesis of THF-free and mono(THF)-coordinated lutetium polyhydride complexes.

was carried out in toluene, the corresponding THF-free tetranuclear lutetium octahydride complex **10** was obtained (Scheme 3).[12]

The octahydride complexes **1**–**7**, **9**, and **10** are all soluble in common organic solvents such as THF, toluene, and hexane, and their tetranuclear frameworks are maintained in solution. In the case of yttrium, recrystallization of the mono(THF) complex **2** from THF gives the structurally characterizable bis(THF)-coordinated complex **11** (Scheme 4);[9,12,13] formation of an analogous bis(THF)



Scheme 4. Formation of yttrium polyhydride complexes with and without THF ligands.

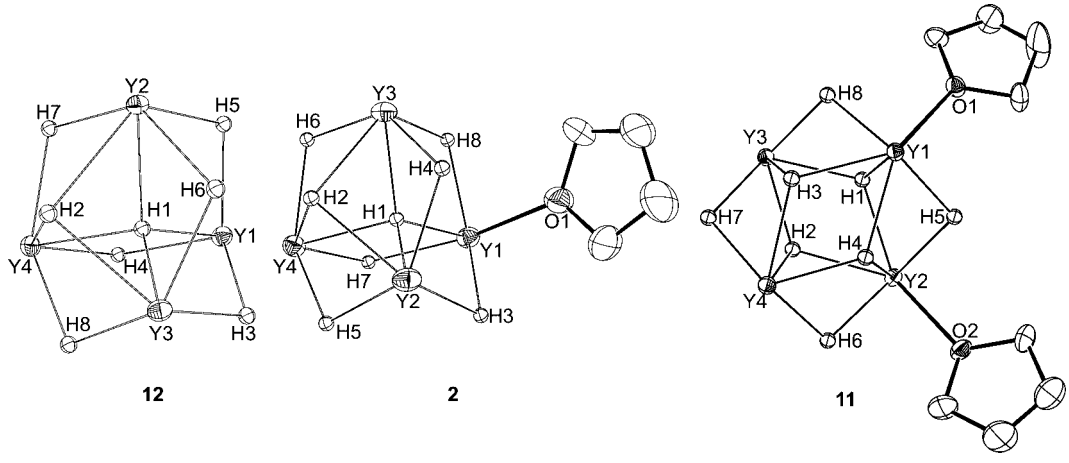


Figure 1. ORTEP drawings of the $Y_4H_8$ core structures of **12** (left, THF-free), **2** (middle, with one THF ligand), and **11** (right, with two THF ligands).

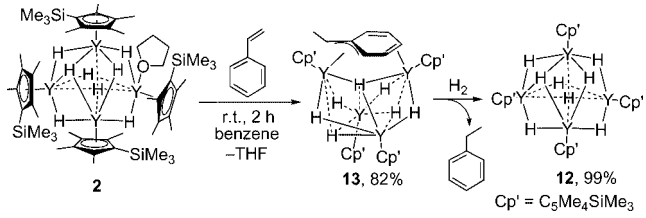
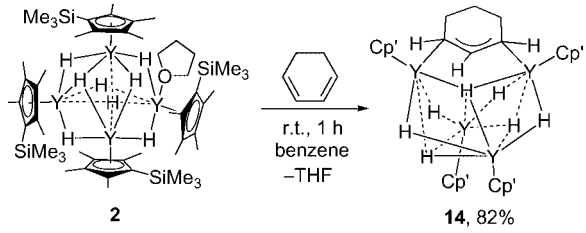
complex was not observed under the same conditions for the smaller Sc and Lu complexes **1**, **9**, and **10**. The bis(THF)-coordinated yttrium polyhydride **11** also adopts a tetrahedral metal skeleton, but it has four $\mu_3$-H and four $\mu_2$-H ligands whereas the mono(THF) analogue **2** possesses one $\mu_4$-H, one $\mu_3$-H, and six $\mu_2$-H ligands (Figure 1). Recrystallization of the bis(THF) complex **11** from hexane regenerates the mono(THF) complex **2**, while treatment of the mono(THF) yttrium complex **2** with styrene followed by hydrogenolysis of the resultant product in benzene yields the corresponding THF-free octahydride complex **12** (Schemes 4 and 5).[8,14] ORTEP drawings of the $Y_4H_8$ core structures of **2**, **11**, and **12** are shown in Figure 1.

## 3. Reaction of Rare Earth Metal Polyhydrides with Unsaturated C–C Bonds

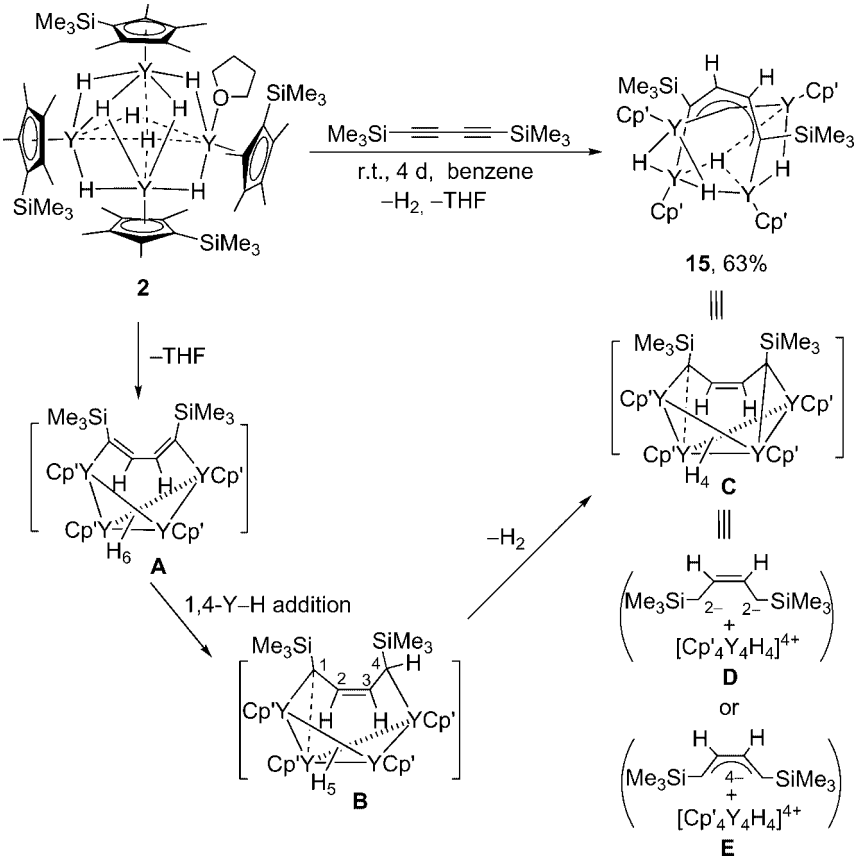
Reaction of the mono(THF)-coordinated tetranuclear yttrium octahydride complex **2** with styrene yields a product formed by insertion of a single molecule of styrene − the benzylic allyl heptahydride complex **13** − in which the allyl part is bonded to one Y atom in an $\eta^3$-fashion and the phenyl part is bonded to another Y atom in an $\eta^2$-form (Scheme 5).[8] No further reaction was observed even when an excess of styrene was present. Hydrogenolysis of the benzylic allyl complex **13** with $H_2$ (1 atm) in benzene affords ethylbenzene and the THF-free yttrium octahydride complex $[\{(C_5Me_4SiMe_3)Y(\mu\text{-}H)_2\}_4]$ (**12**).[14] Under 1 atm of $H_2$, styrene can be catalytically hydrogenated into ethylbenzene by **2** or **12**.



Scheme 5. Formation of a tetranuclear yttrium benzylic allyl heptahydride complex and its reaction with $H_2$.



Scheme 6. Reaction of an yttrium polyhydride complex with 1,3-cyclohexadiene. Cp′ = $C_5Me_4SiMe_3$.



Scheme 7. Reaction of an yttrium polyhydride complex with 1,4-bis(trimethylsilyl)-1,3-butadiyne. Cp′ = $C_5Me_4SiMe_3$.

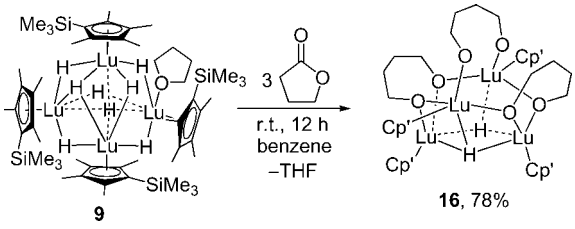
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The reaction of **2** with 1,3-cyclohexadiene (CHD) yields the 1,4-addition product **14** in which the resulting allyl unit interacts with two Y atoms through the two "terminal" carbon atoms, each of which bonds to one metal center in an $\eta^1$-fashion (Scheme 6).[9] As in the case of styrene, the use of an excess amount of CHD does not lead to further reaction.

The reaction of **2** with 1,4-bis(trimethylsilyl)-1,3-butadiyne affords the tetranuclear yttrium tetrahydride complex **15**, which formally consists of a $[(C_5Me_4SiMe_3)YH]_4^{4+}$ unit and a butene-tetraanion species (Scheme 7).[8] This butene-tetraanion moiety is bonded to two yttrium atoms in a $\pi,\eta^4$-"inverse-sandwich" fashion and to the other two yttrium atoms in a $\sigma_1,\mu_1$-terminal form at the two terminal carbon atoms. The formation of **15** can be explained as follows. Addition of two Y–H units of **2** to the two C≡C units of 1,4-bis(trimethylsilyl)-1,3-butadiyne in a "2,1" fashion yields the 1,3-butadien-1,4-diyl (or butadiene-dianion)/hexahydride species **A** (Scheme 7). Subsequent 1,4-Y–H addition to the 1,3-butadiene unit in **A** could give the 2-buten-1,1′4-triyl/pentahydride species **B**. Deprotonation at the C4 position of the butene species by a Y–H unit in **B** should afford the 2-buten-1,1′,4,4′-tetrayl/tetrahydride species **C**. This species can be regarded as a resonance structure (a localized form) of **15** (cf. alo **D** and **E**).

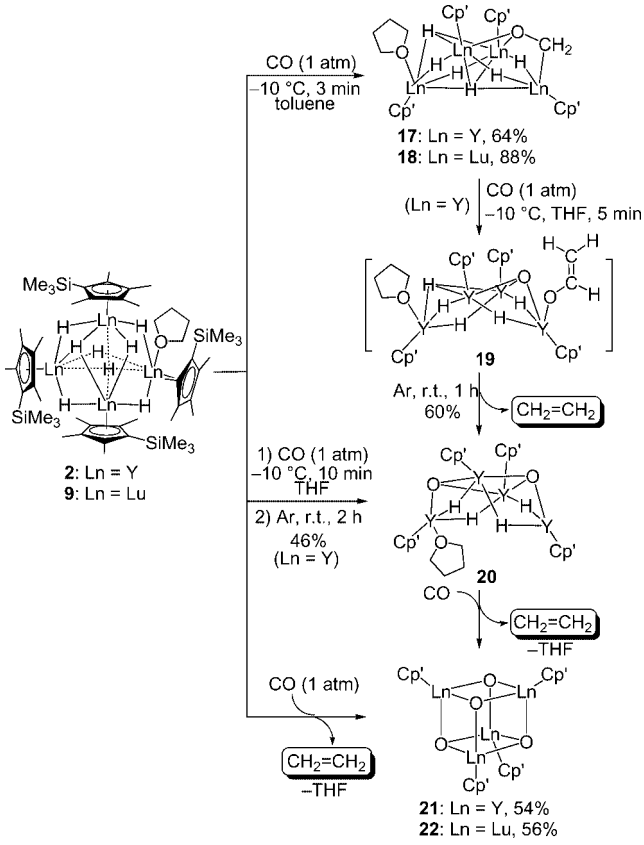
## 4. Reaction of Rare Earth Metal Polyhydrides with Unsaturated C–O Bonds

Reaction of the lutetium octahydride complex **9** with γ-butyrolactone gives the tetranuclear mixed alkoxido/dihydrido complex **16** (Scheme 8).[8] γ-Butyrolactone is a stable, non-polymerizable cyclic ester. In this reaction, three molecules of γ-butyrolactone are completely reductively ring-opened by six of the eight hydride ligands in **9** to give the linear diolate species "-O(CH$_2$)$_4$O-", thus demonstrating the unusually high reactivity of this rare earth metal polyhydride complex. Further reaction between **16** and γ-butyrolactone was not observed, even when an excess amount of γ-butyrolactone was present. However, both **9** and **16** show high activity for the ring-opening polymerization of ε-caprolactone.



Scheme 8. Reaction of a lutetium polyhydride complex with γ-butyrolactone. Cp′ = $C_5Me_4SiMe_3$.

The reaction of **2** with CO in toluene at –10 °C occurs rapidly to give the hexahydrido/oxymethylene yttrium complex **17** (Scheme 9).[15] When **17** is stirred at –10 °C in the presence of CO for a few minutes and then at room temperature in the absence of CO for 1 h, the dioxo/tetrahydrido complex $[(C_5Me_4SiMe_3Y)_4(\mu_3\text{-}O)_2(\mu\text{-}H)_4(THF)]$ (**20**) is obtained with simultaneous release of ethylene. Complex **20** can also be isolated directly from the reaction of **2** with CO without isolating **17**. $^1$H NMR monitoring of the reaction of **17** with CO in [D$_8$]THF at low temperatures revealed the formation of an enolate intermediate such as $[(C_5Me_4SiMe_3Y)_4(OCH{=}CH_2)(\mu\text{-}O)(\mu\text{-}H)_5(THF)]$ (**19**). Further reaction of the yttrium tetrahydrido/dioxo complex **20** with CO gives the corresponding tetraoxo complex **21** and ethylene.



Scheme 9. Selective formation of ethylene by deoxygenative C–C coupling of carbon monoxide. Cp′ = $C_5Me_4SiMe_3$.

Reaction of the lutetium octahydride complex **9** with CO (1 atm) affords the analogous lutetium hexahydrido/oxymethylene complex **18** and the tetraoxo lutetium cubane complex **22** with release of ethylene (Scheme 9); formation of a tetrahydrido/dioxo Lu complex intermediate analogous to **20** was not observed. The solid-state structure of **22** is shown in Figure 2.

Although the reactions of CO with various transition metal hydrides, including lanthanide and actinide metallocene hydrides, have been reported,[16] the selective formation of ethylene by reduction of CO is unprecedented. These results demonstrate again the unique reactivity of polyhydrido rare earth metal complexes.

A possible reaction mechanism for the formation of ethylene is shown in Scheme 10. Addition of two Y–H bonds in **2** across the C–O triple bond of one molecule of CO could give the oxymethylene complex **17**. Subsequent inser-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

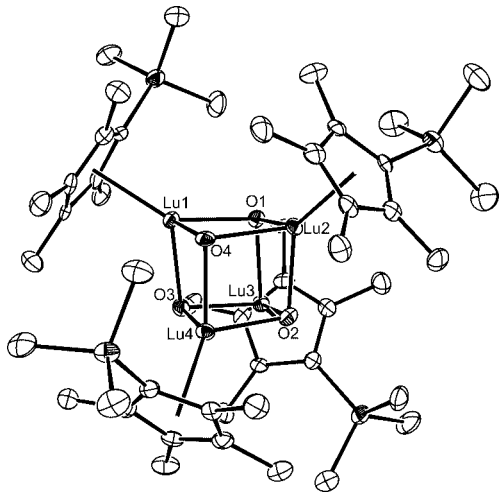


Figure 2. ORTEP drawing of **22**.

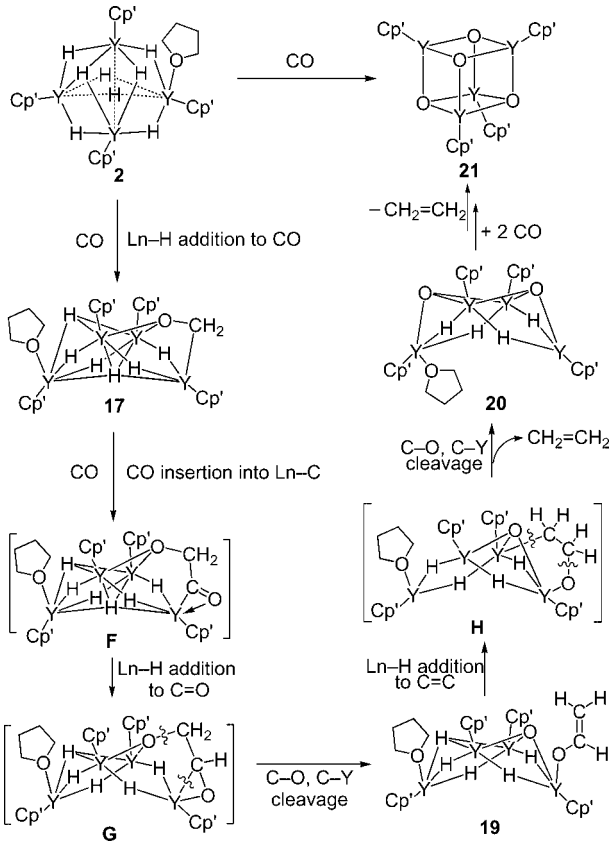
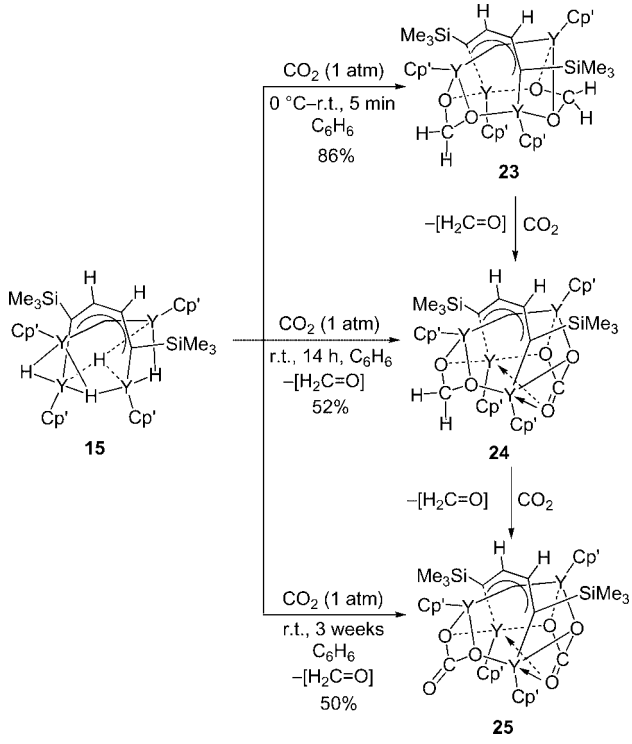
tion of another molecule of CO into the Y–$CH_2$ bond in **17** would afford an α-oxyacetyl species such as **F** (or its carbenoid isomer). Y–H bond addition across the acyl C–O double bond in **F** could yield the oxametallacyclopropane species **G**, which would produce the enolate species **19** by rupture of a C–O and the C–Y bond. Addition of another Y–H bond across the C–C double bond of the enolate unit might give the β-oxyethylene species **H**, which, after cleavage of the C–Y and the C–O bond, yields the dioxo complex **20** with release of ethylene. Formation of the tetraoxo complex **21** and ethylene from the reaction of **20** with CO could follow an analogous process, although intermediate species analogous to the oxymethylene **17** or an enolate species **19** have not been observed.

Reaction of the octahydride complex **2** with $CO_2$ also takes place very rapidly, although a characterizable product could not be isolated from this reaction. However, the structurally characterizable bis(methylene diolate) complex **23** was obtained in high yield from the reaction of the butene-tetraanion/tetrahydrido complex **15** with $CO_2$, (Scheme 11).[17] In this reaction, the two C–O double bonds of $CO_2$ are completely reduced to C–O single bonds. This reaction takes place only at the hydride sites and the butene-tetraanion unit remains unchanged. Although a large number of studies on the hydrogenation of $CO_2$ with both homogeneous and heterogeneous systems have been reported, the observation of formation of a methylene diolate species remains rare.[18] The present formation of the methylene diolate species is in sharp contrast with what was observed previously in the case of other transition metal polyhydride complexes such as $[\{(C_5H_5)Ti(\mu\text{-}H)\}_2(C_{10}H_8)]$,[19] $[(C_5H_5)_2Zr(H)(\mu\text{-}H)(\mu\text{-}N\textit{t}Bu)Ir(C_5Me_5)]$,[20] $[H_2Ru(dmpe)_2]$,[21] and $[H_4Mo(dmpe)_2]$,[22] [dmpe = 1,2-bis(dimethylphosphanyl)ethane] which yield either bis(formate),[18,21] mixed hydride/formate,[19,20] or mixed hydride/carbonate complexes[21] upon reaction with $CO_2$. Further insertion of $CO_2$ into the metal-diolate bonds in **23** could also take place to give the mono- and dicarbonate complexes **24** and **25** in a stepwise manner, with possible release of formaldehyde (HCHO; Scheme 11).



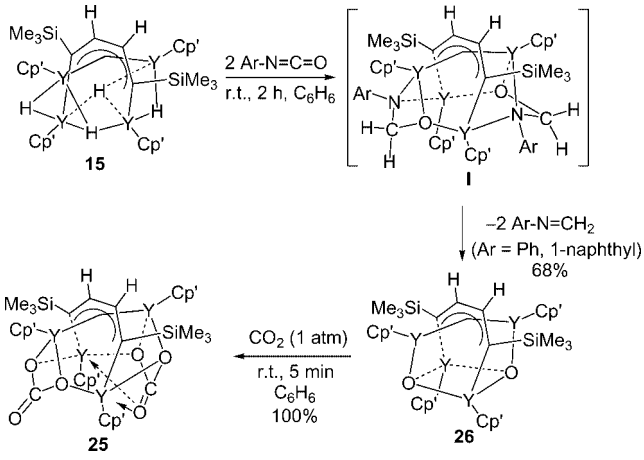
Scheme 10. A possible mechanism for the reaction of an yttrium polyhydride complex with carbon monoxide. Cp′ = $C_5Me_4SiMe_3$.



Scheme 11. Reduction of $CO_2$ into methylene diolate species and subsequent $CO_2$ insertion reactions. Cp′ = $C_5Me_4SiMe_3$.

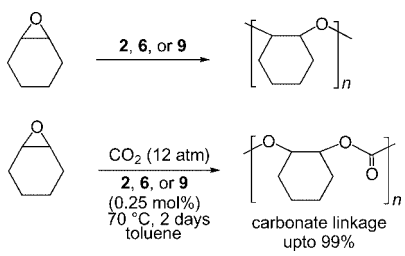
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

To see how complex **15** would behave toward an isocyanate, which is a commonly accepted model for $CO_2$ with respect to reaction patterns,[23] the reactions of **15** with aryl isocyanates have been studied.[17] When **15** was allowed to react with two equivalents of phenyl isocyanate or 1-naphthyl isocyanate, the dioxo complex **26** was formed together with the corresponding aromatic imine compounds, probably via the bis(methylene olate/amido) intermediate **I** (Scheme 12). Exposure of the di-$\mu_3$-oxo complex **26** to an atmosphere of $CO_2$ at room temperature led to immediate formation of the dicarbonate complex **25** (Scheme 12). Although formation of metal oxo complexes, such as $[\{Cp_2ZrCl\}_2(\mu\text{-}O)]$,[24] $[\{Cp_2Zr(\mu\text{-}O)\}_3]$,[25] and $[\{(C_5H_4SiMe_3)_3U\}_2(\mu\text{-}O)]$,[26] has been observed in various $CO_2$ reduction reactions, the insertion of $CO_2$ into such a metal oxo species has not been reported previously. The present reaction of **26** with $CO_2$ may provide, at a molecular level, a nice piece of evidence for interactions of $CO_2$ with metal oxides.[27]



Scheme 12. Formation of a $\mu_3$-oxo yttrium complex and its reaction with $CO_2$. Cp′ = $C_5Me_4SiMe_3$.

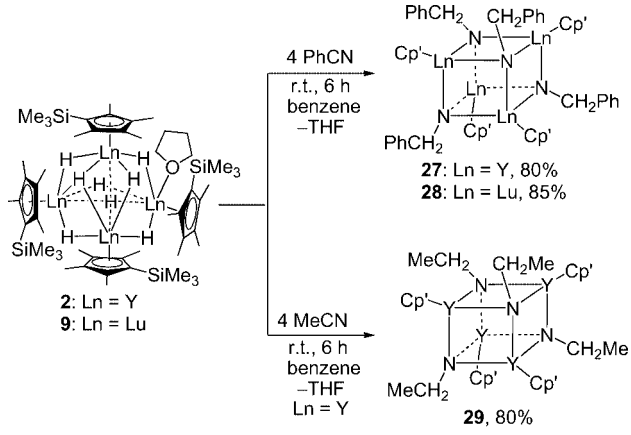
Polyhydride complexes such as **2**, **6**, and **9** can also act as single-component catalysts for the ring-opening homopolymerization of cyclohexene oxide (CHO) and the alternating copolymerization of CHO and $CO_2$. The homopolymerization of CHO in bulk takes place much more rapidly than in solution and affords the corresponding polyethers [$M_n = (60\text{–}80) \times 10^3$ and $M_w/M_n \approx 2$] in high yields in most cases. The copolymerization of CHO and $CO_2$ at 70–110 °C under 12 atm of $CO_2$ yields the corresponding polycarbonates [$M_n = (20\text{–}40) \times 10^3$, $M_w/M_n = 4\text{–}5$; carbonate linkages = 95–99%] with a TOF of up to 2000 g polymer/(mol Ln h)$^{-1}$ (Scheme 13).[28] The first step in the copolymerization could be the formation of a methylene diolate species by insertion of one molecule of $CO_2$ into two Ln–H bonds.



Scheme 13. Homopolymerization of cyclohexene oxide (CHO) and copolymerization of CHO with $CO_2$.

## 5. Reaction of Rare Earth Metal Polyhydrides with Nitriles

The reaction of the yttrium or lutetium octahydride complex (**2**, **9**) with four equivalents of benzonitrile or acetonitrile affords the corresponding tetranuclear cubane-like imido complexes $[\{(C_5Me_4SiMe_3)Ln(\mu_3\text{-}NCH_2Ph)\}_4]$ (Ln = Y (**27**), Lu (**28**)] or $[\{(C_5Me_4SiMe_3)Y(\mu_3\text{-}NCH_2Ph)\}_4]$ (**29**), respectively (Scheme 14).[8] The solid-state structure of the yttrium complex **27** is shown in Figure 3. In these reactions, the C–N triple bond of a nitrile compound is completely reduced to a C–N single bond by double Ln–H addition. This is in sharp contrast to the previously reported reactions of rare earth metallocene hydride complexes[29] or zirconocene dihydride complexes[30] with nitriles, which yielded only single-insertion products such as $[\{(C_5H_5)_2Y(\mu\text{-}N{=}CH\textit{t}Bu)\}_2]$ or $[(C_5Me_5)_2Zr(H)(N{=}CHR)]$ (R = $C_6H_4Me$-*p*). The reaction of polyhydrido rare earth metal complexes with nitriles may offer a convenient salt-free route to the corresponding rare earth metal imido complexes, a class of compounds that are of considerable current interest but still remain very limited in number.[31]



Scheme 14. Formation of cubane-type imido complexes by reduction of nitriles. Cp′ = $C_5Me_4SiMe_3$.

Further reactions of the rare earth metal imido complexes with nitriles can also take place. The reaction of the benzylimidolutetium complex $[\{(C_5Me_4SiMe_3)Lu(\mu_3\text{-}NCH_2Ph)\}_4]$ (**28**) with four equivalents of benzonitrile at room temperature, for instance, gives the benzamidinate-dianion complex **30** (Scheme 15).[32] An X-ray analysis showed that **30** possesses a dimeric structure in which the two Lu atoms are bridged by the ketimido nitrogen atom and the amido nitrogen atom is bonded terminally to one Lu atom. The formation of **30** apparently proceeds by nucleophilic addition of the imido unit in **28** to the CN group of benzonitrile, which demonstrates that a rare earth metal imido bond, even in a bridging form, is very reactive. This

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

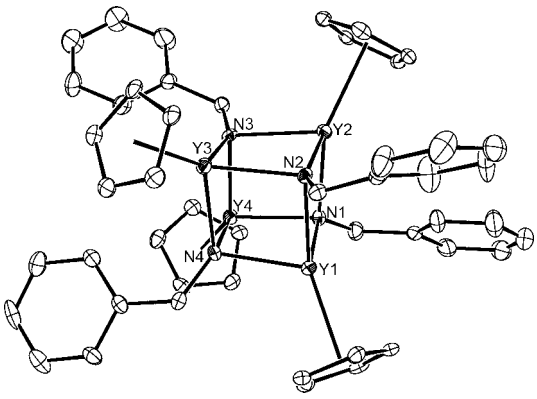


Figure 3. ORTEP drawing of **27**. The $Me_3Si$ and Me groups in $C_5Me_4SiMe_3$ have been omitted for clarity.

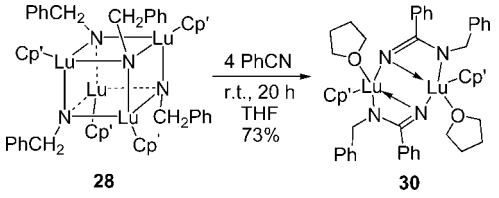
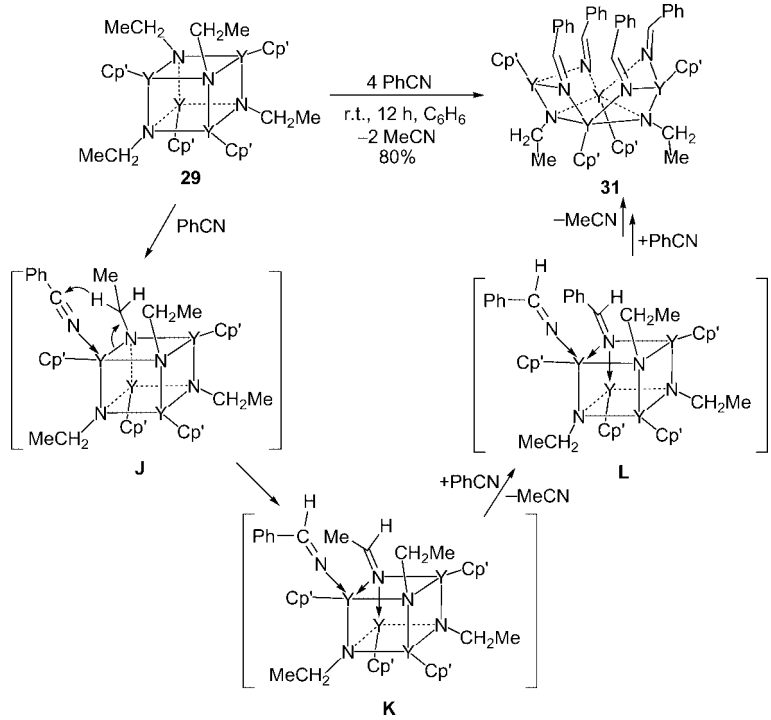
contrasts with what was observed previously for transition metal imido bridging bonds, which are usually robust and unreactive.[33]



Scheme 15. Nucleophilic addition of an imido complex to benzonitrile. Cp′ = $C_5Me_4SiMe_3$.

In sharp contrast to the above-mentioned nucleophilic addition reaction of the benzylimido complex **28**, the reaction of the ethylimido complex [{$(C_5Me_4SiMe_3)Y(\mu_3$-$NCH_2CH_3)$}$_4$] (**29**) with benzonitrile gives the mixed benzaldimido/ethylimido complex **31** rather than an insertion product (Scheme 16). An X-ray analysis established that **31** adopts a tetranuclear crown-like core structure in which the four Y atoms are unsymmetrically bridged by four $\mu_2$-benzaldimido and two $\mu_3$-ethylimido ligands. Four molecules of benzonitrile are hydrogenated in this reaction to give four benzaldimido species (PhCH=N$^-$) by abstraction of four methylene hydrogen atoms from two of the four ethylimido units ($CH_3CH_2N^{2-}$) in **29** with the release of two molecules of acetonitrile ($CH_3CN$); the other two ethylimido units remain unchanged (Scheme 16). This formation of an aldimido species through hydrogen transfer from an alkyl imido species to a nitrile compound is, as far as we are aware, unprecedented.

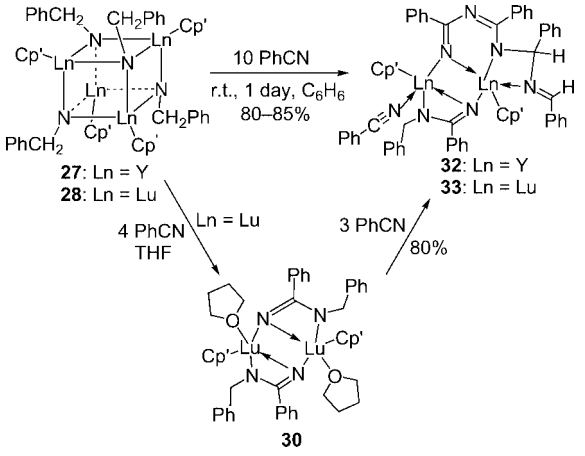
The reaction of 10 equivalents of benzonitrile with the benzylimido complexes **27** or **28** gives the benzonitrile tetramerization products **32** or **33**, respectively (Scheme 17). The reaction of the benzamidinate-dianion complex **30** with three equivalents of benzonitrile also affords **33** in high yield. These results suggest that **30** should be an intermediate in the formation of **33** from **28**. The reaction of the polyhydride complex **2** with 14 equivalents of benzonitrile also affords **32**. A possible reaction mechanism for the formation of the benzonitrile tetramerization product **32** or **33** is shown in Scheme 18. The coordination of one molecule of benzonitrile to each metal atom in **30** should yield **M**. Hydrogen transfer from a methylene group to a coordinated PhCN in **M** (path *a*) should then afford **N**. Nucleophilic addition of the newly formed benzaldimido unit to the aldimine group (path *b*) could yield **O**, which gives **P** upon coordination of one molecule of PhCN. Migration of the



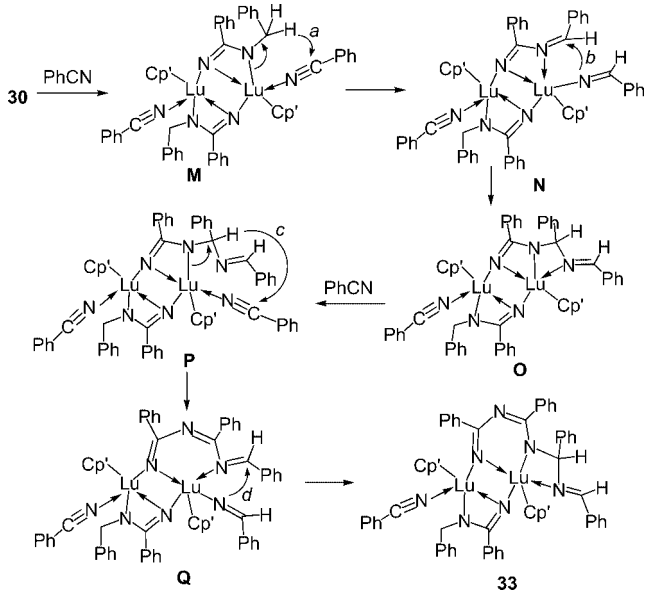
Scheme 16. Unique hydrogen transfer from ethyl imido species to benzonitrile. Cp′ = $C_5Me_4SiMe_3$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methine hydrogen to the PhCN unit in **P** (path *c*), followed by addition of the resulting aldimido unit to the aldimine group in the resultant **Q** (path *d*), should give **33**.

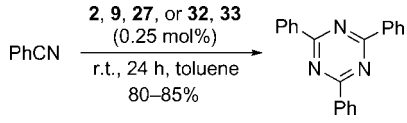


Scheme 17. Tetramerization of benzonitrile. Cp′ = $C_5Me_4SiMe_3$.

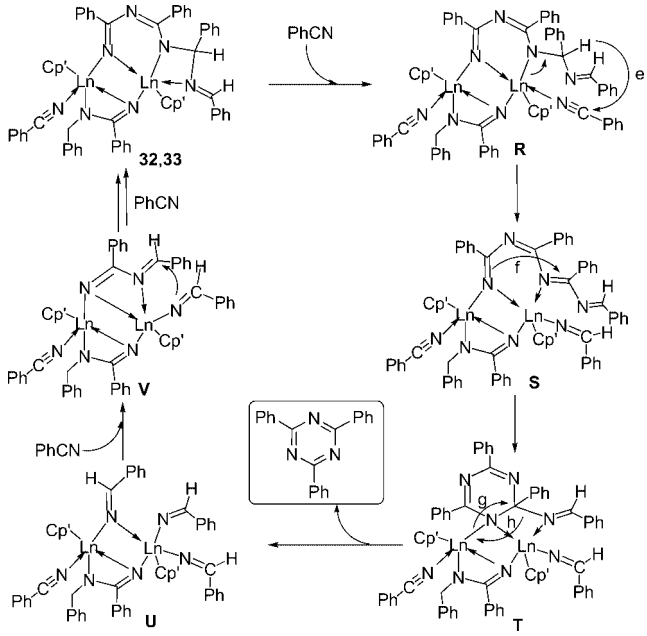


Scheme 18. Possible mechanism for the formation of **33**. Cp′ = $C_5Me_4SiMe_3$.

When an excess amount of benzonitrile was added to a toluene solution of **32** or **33**, the benzonitrile-cyclotrimerization product, namely triphenyl triazine $(PhCN)_3$, is formed selectively (Scheme 19).[32] The recovery of **32** or **33** from these reactions confirms that these benzonitrile-tetramerized complexes are true catalysts. The polyhydride complexes **2** and **9**, the imido complexes **27** and **28**, and the benzamidinate-dianion complex **30** are also active for the catalytic trimerization of benzonitrile. A possible mechanism for the catalytic cyclotrimerization of benzonitrile by **32** or **33** is shown in Scheme 20. The coordination of one molecule of benzonitrile to a metal center in **32** (or **33**) could give **R**, and methine hydrogen transfer (step *e*) to coordinated benzonitrile would afford **S**. Subsequent intramolecular nucleophilic addition of the ketimido unit to the newly formed imine moiety (step *f*) could give **T**, and aromatization of the resultant six-membered ring in **T** (step *g*, Ln–N bond cleavage and C=N bond formation and step *h*, C–N bond cleavage and Ln–N bond formation) should release the triazine and generate **U**. Insertion of benzonitrile into **U** would then give **V**, which resembles intermediate **N** in Scheme 18 and could regenerate **32** (or **33**) as described above. Thus, the combination of C–N bond formation, hydrogen transfer, and C–N bond cleavage steps constitutes a unique catalytic cycle for the cyclotrimerization of benzonitrile.[34]



Scheme 19. Catalytic cyclotrimerization of benzonitrile. Cp′ = $C_5Me_4SiMe_3$.



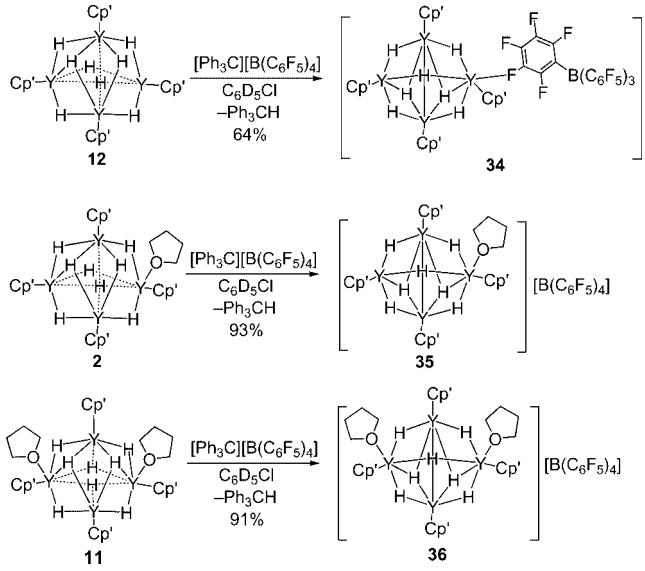
Scheme 20. A possible mechanism for the catalytic cyclotrimerization of benzonitrile. Cp′ = $C_5Me_4SiMe_3$.

## 6. Cationic Rare Earth Metal Polyhydride Complexes

In contrast to cationic rare earth metal alkyl complexes, which have received much interest as novel polymerization catalysts,[35,36] cationic hydrido rare earth metal complexes remain almost unexplored. It has recently been found that tetranuclear rare earth metal octahydride complexes such as **1**–**7** and **9**–**12** are suitable precursors for the preparation of cationic hydrido rare earth metal species.[9] For example, the reactions of the yttrium octahydride complexes **2**, **11**, and **12** with one equivalent of $[Ph_3C][B(C_6F_5)_4]$ afford the corresponding cationic heptahydride complexes **35**, **36**, and **34**, respectively, in high yields (Scheme 21). An direct bonding interaction between the $[(C_5Me_4SiMe_3)_4Y_4H_7]^+$ cation and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the $[B(C_6F_5)_4]^-$ anion via a Y–F bond is observed in the THF-free complex **34**, while complexes **35** and **36** are solvent (THF)-separated ion pairs. The X-ray structures of **34** and **36** are shown in Figures 4 and 5, respectively. These complexes are the first examples of well-defined cationic hydrido rare earth metal complexes.



Scheme 21. Synthesis of cationic yttrium polyhydride complexes. Cp′ = $C_5Me_4SiMe_3$.

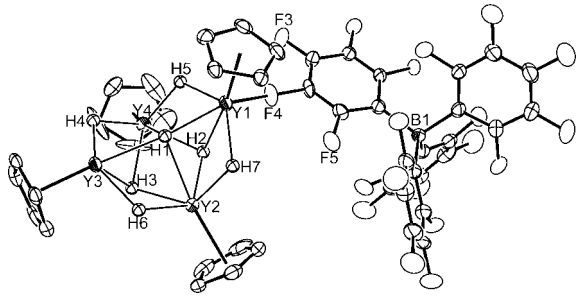


Figure 4. ORTEP drawing of **34**. The $Me_3Si$ and Me groups in $C_5Me_4SiMe_3$ have been omitted for clarity.

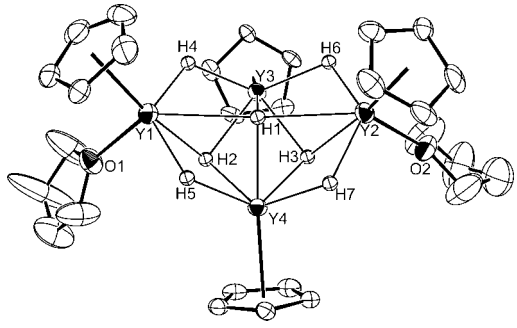

Figure 5. ORTEP drawing of **36**. The $Me_3Si$ and Me groups in $C_5Me_4SiMe_3$ and the $[B(C_6F_5)_4]$ ion have been omitted for clarity.

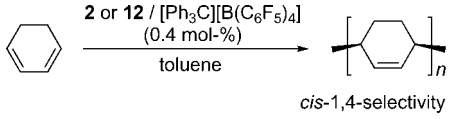
In contrast to the neutral hydride cluster **2**, which yields a single Y–H addition product **13** or **14** on reaction with styrene or 1,3-cyclohexadiene (CHD), respectively, as described above, the THF-free or mono(THF)-coordinated cationic hydride clusters such as **34** or **35** (either isolated or generated in situ) are active catalysts for the syndiospecific polymerization of styrene and the regio- and stereoselective *cis*-1,4-polymerization of CHD (Scheme 22).[9] The bis(THF)-coordinated cationic complex **36**, however, is not catalytically activity under the same conditions, probably due to the occupation of the active metal centers by two strongly coordinative THF ligands.



Scheme 22. *cis*-1,4-Selective polymerization of 1,3-cyclohexadiene by cationic yttrium polyhydride complexes.

## 7. Conclusion and Perspective

Hydrogenolysis of the bisalkyl complexes $[(C_5Me_4SiMe_3)Ln(CH_2SiMe_3)_2(THF)]$ leads to the formation of a series of structurally characterizable polyhydrido polynuclear rare earth metal complexes. These polyhydride complexes show a unique reactivity towards various substrates, such as hydrogenation of the C–N triple bond of a nitrile compound into a C–N single bond, reduction of carbon dioxide into a methylene diolate species, and deoxygenative C–C coupling of CO into ethylene. These reactions are in sharp contrast with what has been observed for the analogous monohydrido metallocene complexes. A new class of polynuclear rare earth metal complexes, such as cubane-type imido and oxo complexes, has also been derived from the polyhydride complexes. Abstraction of a hydride ligand from the neutral hydride clusters leads to the formation of structurally characterizable cationic polyhydrido rare earth metal complexes.

It should also be noted, however, that the synthesis and reactivity studies of polyhydrido rare earth metal complexes is still in its infancy, and well defined polyhydrido rare earth metal complexes reported in the literature are limited essentially to those bearing a $C_5Me_4SiMe_3$ ligand. As the expertise in this field increases and more complexes with new ligand systems are prepared,[37] the diverse chemistry of polyhydrido rare earth metal complexes will certainly be further extended. An exciting and prosperous future in this area can therefore be expected.

# From Genes to Metalloproteins: A Bioinformatic Approach

Ivano Bertini*[a] and Antonio Rosato[a]

**Keywords:** Iron / Zinc / Copper / Heme proteins / Metalloproteins / Bioinformatics

Genome sequencing projects have provided researchers with detailed information on every gene present in a large variety of organisms. Each of these genes is responsible for producing one or more proteins (depending on processes such as alternative splicing and post-translational modification) that constitute the machineries needed to sustain cellular life. The ensemble of proteins that an organism is capable of producing is called the proteome. A significant share of each organism's proteome requires metal ions or metal-containing cofactors to carry out its physiological function (metalloproteome). Experimental methods for the characterization of the metalloproteome of even simple prokaryotic organisms are still not routinely available, therefore significant insights can currently be only obtained using bioinformatic approaches. Herein we review the results obtained from the bioinformatic analyses of a variety of organisms, including humans, in which the distribution of iron-, copper-, and zinc-binding proteins across the kingdoms of life were investigated. It was found that among the metals, zinc is required by the largest number of proteins in most organisms (on average, 10 % of the proteome in eukaryota is predicted to be zinc-binding), whereas copper is the least common. In addition, the majority of non-heme iron-binding proteins have homologs in each taxonomic domain (archaea, bacteria, eukaryota), whereas zinc- and copper-binding proteins are substantially differentiated in eukaryota with respect to prokaryotic organisms.

## Introduction

The term bioinorganic chemistry (or biological inorganic chemistry or inorganic biochemistry) refers to the discipline in which the interactions between inorganic ions or complexes and molecules of biological interest are studied.[1] This is a vast field of science whose importance stems from the fact that life originated and developed on the Earth's crust, an eminently inorganic environment. A core part of bioinorganic chemistry is focused on the study of metalloproteins, which are defined as those proteins that bind tightly (with an association constant greater than $10^8$ $M^{-1}$) to one or more metal ions or metal-containing cofactors,

*Ivano Bertini (http://www.cerm.unifi.it/bertini.html) received his doctorate in chemistry from the University of Florence in 1964 and became full professor of Chemistry in 1975 at the same University. He is the Director of the Magnetic Resonance Center (CERM http://www.cerm.unifi.it/) of the University of Florence. His main research interests are NMR spectroscopy, the expression and preparation of metalloproteins, their structural characterization, and the investigation of their interactions with emphasis on understanding cellular processes at the molecular level. He has authored over 600 papers and many books. He received the Chugaev Diploma of the Kurnakov Institute of the Academy of Science, USSR, in 1981, the Golden Medal of the Magnetic Resonance Group of the Italian Chemical Society in 1991, the Prize Accademia dei Lincei, Italy in 1993, the Bijvoet Medal, Utrecht, NL, in 1998, the Sapio NMR Prize, Italy, in 1999, the Cannizzaro Medal of the Italian Chemical Society and the Basolo medal in 2006. Amongst the special lectures: A. D. Little Lecturer at MIT, Cambridge, MS, USA, in 1997, E. L. Mütterties Lecturer at Berkeley, CA, USA, in 1997, and FECS lecturer, Athens, Greece, in 2002. He has received three honorary doctorates and is a member of the Accademia Nazionale dei Lincei and of the Academia Europaea.*

*Antonio Rosato (http://www.cerm.unifi.it/rosato/) obtained his doctorate from the University of Florence (Italy) in 1998. He is now Associate Professor of Chemistry at the same University. His research interests focus on the theory and practice of NMR spectroscopy applied to paramagnetic systems, metal-mediated protein–protein interactions, and on the application and development of bioinformatic tools to browse gene banks and genome sequences, with a particular interest in metalloproteins. He has co-authored more than 60 articles in peer-reviewed journals.*

and of metal–protein adducts, which are defined as adducts formed by metal ions or metal-containing cofactors with proteins (with an association constant lower than $10^8$ $M^{-1}$). The metal may play a physiologically relevant role in both metalloproteins and metal–protein adducts. For simplicity, from here on we will collectively refer to "true" metalloproteins and metal–protein adducts as metalloproteins. From a more biologically oriented point of view, metalloproteins can be defined as those proteins requiring one or more metal ions or metal-containing cofactors to carry out their biological function. The two definitions overlap to a large extent. Note that the metal may be required not only because it is the center of catalysis, as in many metalloenzymes, but also for structural reasons (i.e. to stabilize the metalloprotein's fold) or regulatory ones (e.g. as in calmodulin).

In the early years of bioinorganic chemistry, the quantification of the interactions of metal ions with living organisms focused mainly on determining the quantity of metal present in a healthy organism per kilogram of weight (in the case of higher organisms such as mammals or plants) or per cell (in the case of unicellular organisms). These investigations provided valuable information on the importance of metal ions for the correct functioning of cells as well as on several diseases caused by defects in the metabolism of metal ions and metal-containing cofactors. The success of genome sequencing initiatives, however, has added a new dimension to bioinorganic chemistry, namely the quantification of *how many proteins are metalloproteins*. This aspect deals with identifying how many and which metabolic pathways require or involve metal ions in addition to establishing how much of a metal is needed to support the life of an organism. These two facets are highly complementary and are both essential in order for bioinorganic chemistry to fully contribute to the Life Sciences.

Genome sequencing projects have provided the amino acid sequences of proteins encoded in the genome (besides the possible effects of alternative splicing or of post-translational modifications, which contribute to effectively expanding the proteome) of an ever increasing number of organisms. The large majority of these proteins lack any experimental functional information, as functional characterization of proteins at the whole proteome level is still not routinely possible. To cope with this limitation, bioinformatic tools have been extensively exploited to predict functional features from the analysis of amino acid sequences.[2–5] In addition, projects in structural biology and structural genomics (the structural characterization of all proteins in a proteome) have prompted the development of several bioinformatic approaches to predict function from structure.[6–9] The functional information obtained either experimentally or through bioinformatics is generally summarized in an annotation, which is associated with the various individual proteins in any sequenced genome. The annotation of gene products is still, however, a far from trivial process. Predicting function from sequence, even when structural information is available,[10–12] often remains an elusive endeavor that is further complicated by difficulties in the exact identification of the coding sequence, especially in higher organisms.[13,14]

The concepts outlined in the preceding paragraph also apply to metalloproteins,[15] although these systems are even more challenging because metal-binding ability is not easily detected from standard sequence analysis. On the other hand, the presence of a motif suitable for protein binding to metal ion(s) can be exploited for more reliable identification and classification (including functional inferences) of these proteins.[15–18] Genome-wide identification and classification of metalloproteins is also difficult experimentally, although some systematic efforts in this direction have been described.[19–21] Since 2004, specific bioinformatic approaches have been developed, refined, and applied at the whole genome level to identify the fraction of an organism's proteome that (putatively) requires metal ions for its function, in other words to identify all metalloproteins encoded by an organism's genome.[18,22–24] The ensemble of the metalloproteins of an organism is hereafter called the *metalloproteome*. Herein we review the results of these efforts and provide an overview of the use of different essential metal ions by organisms in the three domains of life, including humans.

## On the Reasons Why Identifying Metal-Binding Sites is Difficult

Metal ions can bind to metalloproteins at a variety of different sites. However, the specificity of a metal-binding site for a metal may be poor as the same site can often bind different metal ions with similar affinities (the physiologically relevant metal ion may sometimes actually not be the tightest binder), a phenomenon that has allowed researchers to obtain structural details of metal-binding sites through a combination of spectroscopic tools and metal replacement.[25,26] This can also be true for polymetallic cofactors such as iron-sulfur clusters.[27] When preference for a given metal ion indeed occurs at a binding site, it can be tuned through site-directed mutagenesis, typically by substituting one or two protein residues.[28]

Even when 3D data are available from X-ray crystallography, the identification of the presence of a metal-binding site or the identification of the metal bound at a site is often far from trivial.[29,30] There have been several examinations of the whole protein data bank (PDB) in order to identify, classify, and attempt to devise general rules for confirming the presence of metal-binding sites.[31–34] However, these efforts have not provided guidelines that can be applied safely and systematically, even with structural data in hand. When the protein structure is solved in its apo form, a further obstacle to the prediction of the presence of a metal-binding site may arise because of structural rearrangements between the apo and holo forms of the protein, especially, but not exclusively, those involving the side chain atoms of the amino acidic metal ligands.[35]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

X-ray fluorescence analysis is a suitable strategy to experimentally identify the nature of an unknown metal ion bound to a protein.[36] Another suitable approach is the study of X-ray anomalous diffraction.[37] NMR analysis can also be informative.[38] The exact details of metal coordination can often be obtained upon substitution of the metal with a paramagnetic metal ion through the application of purposefully designed NMR experiments[39,40] and/or of advanced computational approaches.[41] Alternatively, NMR-active diamagnetic metals, such as Ag, Cd, or Hg, can be exploited to directly detect proton–metal correlations in heteronuclear two-dimensional experiments.[42–45]

Another possible approach to the identification of metalloproteins is high-throughput screening.[19–21] These methods, which are based on XAS or colorimetry, can identify unprecedented metalloproteins and provide hints about the identity of the bound metal. They do not, however, provide detailed information on the nature, identity, and location of amino acidic ligands within the protein sequence.

## Sequence-Based Bioinformatic Identification of Metalloproteins

Because of the difficulties mentioned in the preceding section, it is important to develop methods that can predict metal-binding capabilities and metal-binding sites based only on the experimental information directly obtainable from genome sequencing, namely the amino acid sequence of the proteins. In other words, the scientific community working in bioinorganic chemistry would benefit from bioinformatic tools that can identify metalloproteins within proteomes.

Bioinformatic resources designed for bioinorganic chemists are relatively limited with respect to the plethora of resources available to the general biologists' community.[15] In particular, no web servers are currently available for the prediction of metal-binding capabilities based on protein sequence. On the other hand, a few algorithms suitable for the identification of metalloproteins in proteomes have been published; these are addressed below.

Before discussing the methods available for the prediction of metal-binding properties based on sequence, it is useful to briefly describe the application to metalloproteins of protein structure modeling based on homology (so-called homology modeling or comparative modeling).[46,47] Homology modeling has been applied to metalloproteins with success in a number of instances, yielding interesting insights into the determinants of structure and function of the systems investigated.[16,48–58] If one is uncertain about the metal-binding properties of a given protein, homology modeling is a potential method for building a 3D structural model that may subsequently be inspected for the presence of putative metal-binding sites. This approach, however, presents various potential pitfalls, some of which are linked to the intrinsic shortcomings of the homology modeling approach, such as the difficulty in correctly modeling the conformation of amino acid side-chains and loop regions,[46] where metal-binding sites are often located. However, it has been suggested that, especially in systems binding metal-containing cofactors of a relatively large size, such as iron-sulfur clusters or iron porphyrins, modeling of a metalloprotein structure in its apo form can lead to significant distortions of even the global protein fold with respect to the structure of the holo protein.[16,48] Such distortions would prevent reliable use of the modeled structure for the identification of binding sites.

The simplest approach to assigning metal-binding capabilities to a protein is to look for the presence of a known metal-binding pattern (MBP). MBPs can be automatically extracted from the PDB and can be described in detail using the COMe formalism.[17] Simpler formalisms essentially report the identity of ligands, the spacing between them, and, sometimes, the presence of other conserved residues within or near the MBP. The simplest representation of an MBP is in the format $AX_nBX_mC$..., where A, B, and C are the metal-binding amino acids and $n$, $m$,... are the number of amino acid residues in between two subsequent ligands. A non-specialized database of functional patterns is PROSITE.[59] However, simply looking for the occurrence of an MBP within a sequence can be misleading[18] and may lead to the assignment of an excessively high number of metalloproteins. A simple example is given by the case of proteins that bind metals with pairs of cysteines, which in many systems are involved in the formation of disulfide bridges rather than in metal binding. Based on the presence of cysteine pairs (with a given spacing), these proteins would be erroneously assigned as metalloproteins (note that in fact they may be able to bind metals in vitro in their reduced state). A more refined, less error-prone approach takes into account the presence of local sequence similarity around the MBP[18] with respect to a known metalloprotein. The presence of local sequence similarity is indicative of local structural similarity, which implies similar conformation for the amino acidic ligands of the MBP and thus formation of the metal-binding site.[18] The main weakness of this approach lies in the detection of metalloproteins containing an MBP site where the spacing between ligands is very large. As an example, consider a case where two ligands are close to one another, say within five amino acids, a third one is 30 amino acids away, and a fourth one is another 30 amino acids away; these types of situations are relatively easy to overlook. To enhance sensitivity and reliability, the analysis of MBPs can be successfully complemented by analyzing the occurrence of protein domains known to be metal-binding taken from domain libraries such as Pfam[60] or SCOP.[61] In the case of human zinc-binding proteins, it has been shown that these two approaches independently provide metal-binding predictions that are in good agreement with one another, and at the same time their combination enhances coverage in terms of zinc-binding proteins detected.[22] The combined use of MBPs and protein domains for metalloprotein identification is also useful in the reduction of the number of false positives (i.e. of non-metalloproteins that are erroneously

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

assigned as metalloproteins).[23,24] The use of only metal-binding protein domains does not provide the same benefits.

Alternatively, machine learning methods have shown better performance than an approach based on the simple detection of the occurrence of an MBP within a sequence.[62] These methods can provide indications at the level of an individual cysteine or histidine residue and predict whether it is bound to a metal or not. Metalloproteins are identified as proteins containing one or more metal-bound cysteines or histidines.[62] Although this approach may be promising, especially because it may identify unprecedented MBPs, significant improvement is still needed, especially as other amino acids (aspartic acid, glutamic acid, tyrosine, etc.) must be taken into account as possible ligands.

It must be remembered that the performance of any predictive method depends not only on the quality and ingenuity of the underlying algorithm(s) but also on the quality and amount of experimental data available to perfect the computational approach. Figure 1 shows the number of predictions for zinc-binding proteins based on the approach described by Andreini et al.,[18] which is based solely on structural information available from the PDB, as a function of the number of structures of zinc proteins available. It can clearly be seen that a dramatic increase in the number of predicted human zinc proteins occurs after a "critical mass" of available structures is reached. However, the subsequent growth of the number of structures of zinc proteins in the PDB that occurred after the mid-90s yielded only a relatively small additional increase in the number of predicted zinc-binding proteins (a 10-fold increase in structures corresponds to slightly less than a twofold increase in predicted sequences). This is presumably a consequence of the relatively low structural diversity additionally contained in the newest structures.

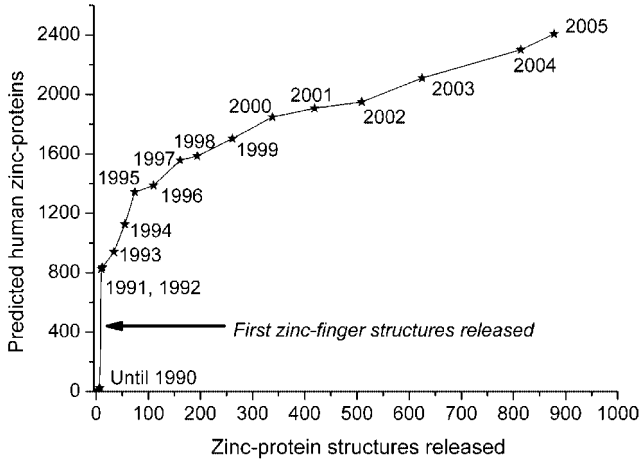

Figure 1. Number of human zinc proteins predicted as a function of the number of experimental zinc protein structures available from the PDB. The abscissa of each point corresponds to the number of structures availble at the end of the indicated year.

## The Metalloproteomes

### The Zinc Metalloproteome

Zinc-binding proteins are found in essentially all organisms[24] and are quite abundant in eukaryotic organisms such as humans.[22] Zinc-binding patterns most commonly include four (70% of instances in the PDB) or three (23% of instances in the PDB) protein ligands (not distinguishing between mono- and bidentate carboxylate ligands). In zinc-binding patterns with three protein ligands, the metal ion often completes its first coordination sphere by binding a water or buffer molecule. The most common amino acidic ligands for zinc are cysteine and histidine: 68% of the patterns contain at least one cysteine while 65% contain at least one histidine. Figure 2 shows a distribution of the various types of zinc-binding patterns grouped on the basis of the number, identity, and order in sequence of protein ligands, in predicted human zinc-binding proteins.[22]

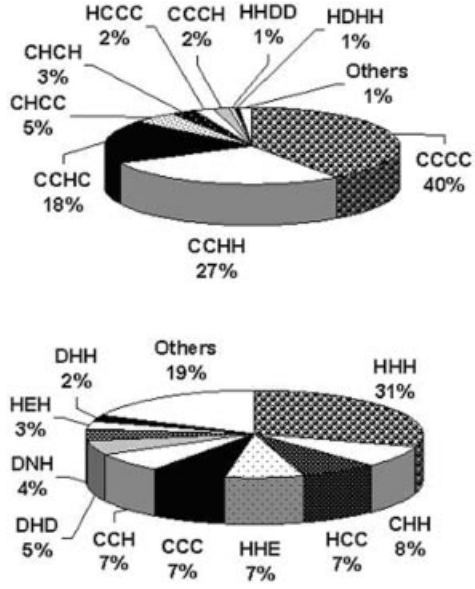

Figure 2. Distribution of four- and three-ligand MBP types detected in putative human zinc proteins. MBPs are grouped based on their amino acid composition and on the order of the protein ligands in the sequence. For example, the MBPs $HX_3HX_5C$ and $HX_8HX_4C$ are grouped together as HHC; all MBPs containing four cysteines are grouped together as CCCC.

Human zinc enzymes are present in all enzyme classes, with hydrolases being the most common zinc-dependent enzymes.[22] Indeed, it is well known that a zinc-activated water molecule is responsible for nucleophilic attack on the substrate in these systems.[63,64] However, the largest percentage of all human zinc-binding proteins for which a function can be proposed (>40%) are transcription factors. These consist mainly of zinc fingers; note, however, that zinc fingers do not interact only with DNA, but can also mediate interactions with RNA or proteins.[65] As the human zinc proteome makes up approximately 10% of the entire proteome, it follows from the above figures that 4%

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of the human proteome is involved in zinc-dependent regulation of gene expression. Of course, to have a full picture of the importance of gene regulation in humans, one should add to this figure all the proteins involved in regulation that do not depend on zinc.

Some types of zinc-binding patterns are specifically associated with a given function, such as the CCHH type (C = cysteine, H = histidine), which is characteristic for transcription factors and contributes crucially to the stabilization of their 3D structure, whereas others can be associated with very different functional groups spanning different enzyme classes.[22] Even when contained in enzymes, the zinc ion is not necessarily the center of catalysis, but, as in the case of transcription factors, it may act as a contributor to the stability of the structure of the protein. Zinc-binding sites are thus useful modules that can be exploited not only for catalysis but also for structural purposes, for example to drive/stabilize the fold of a protein.

As mentioned, zinc-binding proteins are present in organisms from all domains of life (archaea, bacteria, eukaryotes), although they constitute a significantly diverse proportion of their proteomes.[24] General trends can be readily identified that point to archaeal and bacterial proteomes having a similar content of zinc proteins (5% to 6%), while the zinc proteomes of eukaryotic organisms constitute a much more important fraction of the whole proteome (around 9%). The incidence of eukaryotic zinc proteomes is higher due mainly to increased needs for regulation of gene expression, cell compartmentalization, and cell differentiation in multicellular organisms. Indeed, eukaryotic zinc-binding proteins involved in regulation of expression contribute nearly all the additional zinc proteins with respect to simpler organisms. Eukaryotes have recruited new zinc-binding proteins that are not needed, and indeed are not encoded, by archaea and bacteria specifically for the above purpose. As a result, the majority of the eukaryotic zinc proteome is unique to eukaryotes, in other words the majority of eukaryotic zinc proteins do not have homologs in archaeal or bacterial proteomes (Figure 3).

The role of zinc in the latter organisms is mainly as the catalytic center of hydrolytic enzymes, while very little use is made of zinc in regulatory proteins.[24] An interesting example is that of a metal-binding helix-turn-helix domain present in some bacterial and archaeal metal-sensing repressors where transcription is regulated as a function of intracellular metal concentration, such as that in the zinc-sensing SmtB protein from *Synechococcus* PCC 7942.[66,67] Intriguingly, an analysis of the zinc-proteome size of archaeal and bacterial organisms based on their range of growth temperature (i.e. by dividing them into hyperthermophilic, thermophilic, mesophilic, or psychrophilic organisms) suggests that the proteome of organisms living at higher temperatures is enriched in putative zinc-binding proteins. The zinc proteome of the 11 hyperthermophilic organisms studied in a previous paper[24] constitutes 7.0% ± 1.1% of the entire proteome, compared to 6.0% ± 1.0% of five thermophilic organisms, 5.3% ± 1.0% of 34 mesophilic organisms, and 4.5% ± 0.2% of two psychrophilic organisms. This effect may be due to an increased use of zinc for structural stability by organisms living at higher temperatures.

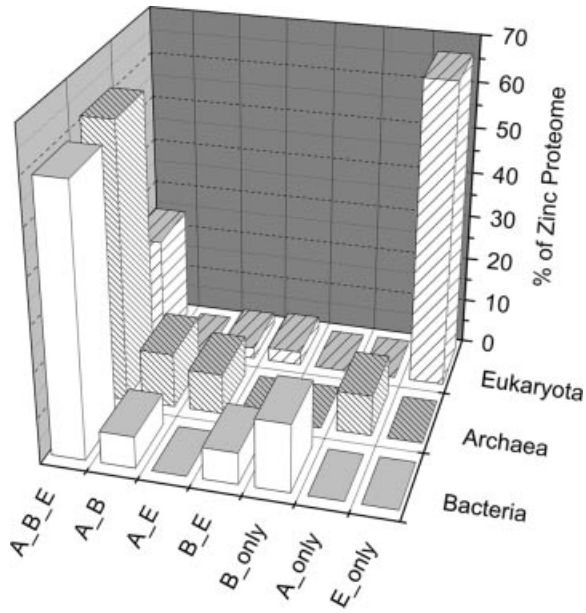

Figure 3. Fraction (with respect to the entire zinc-proteome) of predicted zinc-binding proteins in each domain of life having homologues in all three, two, or only one domain of life (A: archaea; B: bacteria; E: eukaryota). As an example, 60% of archaeal zinc-binding proteins have bacterial and eukaryotic homologues.

## The Non-Heme-Iron Metalloproteome

In biological systems, iron can be incorporated into metalloproteins in a variety of cofactors, usually in the oxidation states +3 or +2 (other oxidation states may be generated during the catalytic cycle of iron enzymes). The simplest iron-binding protein is probably rubredoxin, a small electron-transfer protein that binds a single iron ion through the side-chain sulfur atoms of four cysteines. Due to its simplicity and ease of preparation and purification, the three-dimensional structure of rubredoxin has been studied in great detail.[68–71] However, iron-binding proteins are normally much more complicated than rubredoxin, as discussed below. The chemical complexity of most iron-containing cofactors (as well as, at least in the case of heme, their poor solubility), together with the need to control the extremely versatile reactivity of this metal to prevent undesired reactions, have resulted in the evolution of complex molecular machineries dedicated to the uptake/assembly and intracellular distribution of the cofactors.[72–76]

Many proteins bind iron in polymetallic clusters composed of iron and sulfide ions that can have various stoichiometries (e.g., $Fe_2S_2$, $Fe_3S_4$, $Fe_4S_4$).[77] These proteins are therefore called iron-sulfur proteins (or ferredoxins) and typically employ the side chains of cysteines or cysteines together with histidines to bind the iron-sulfur complex, although some exceptions exist. Clearly, the properties of these systems depend crucially on the bound cluster, but

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

also on the protein environment surrounding it.[78–80] A variety of heterometallic clusters containing iron together with other metals can also be formed and bound by proteins.[81] Finally, in very many metalloproteins iron is contained at the center of a variously substituted porphyrin (heme). The porphyrin provides four nitrogen ligands to the metal ion while the fifth coordination position is filled by a protein ligand and the sixth is filled by either a protein ligand or water, or remains vacant. The most common of these heme-containing systems are called cytochromes and are distinguished by the type of heme bound, which, in turn, is determined by the chemical nature of the substituents of the porphyrin. In some cytochrome variants, called *c*-type cytochromes, the heme substituents react with the protein to form covalent bonds between the polypeptide chain and the cofactor. Proteome-level analyses of the occurrence of heme-containing proteins cannot be carried out by exploiting MBPs as these involve only one or two protein ligands. In addition, the extensive hydrophobic interactions between the porphyrin moiety and the protein chain provide a significant contribution in driving binding, which must be taken into account. For these reasons, the heme proteome must be analyzed using approaches based on fold recognition together with the analysis of the occurrence of known protein sequence motifs, as done recently for mitochondrial-type mono-heme cytochromes *c*.[82] For proteins containing *b*-type heme, initial analyses based on the known folds (e.g., the globin fold or the peroxidase fold) indicate that their percentage in eukaryotic proteomes is in the range 0.3–1.0% (unpublished data from our laboratory). The corresponding figures for bacteria and archaea are also quite variable but have a clear tendency toward being smaller than for eukaryotes (in the range 0.0–0.5%).

The methods described in the section on "Sequence-based bioinformatic identification of metalloproteins" exploiting known MBPs can be successfully applied to the analysis of proteins binding non-heme iron.[23] Of the various types of MBPs relevant to this section, the most common ones contain only cysteine residues. This is presumably due to the fact that cysteine-only MBPs are involved in binding iron-sulfur clusters by most ferredoxins. Approximately half of all MBPs that bind non-heme iron are formed by various combinations of histidine, glutamic acid, and aspartic acid residues, without cysteines.

At variance with what is observed for zinc-binding proteins, in the case of non-heme iron-proteins there is no expansion of the fraction of the proteome that is metal-binding in eukaryotes with respect to simpler organisms. For some organisms, such as yeast, a contraction is actually observed.[23] Non-heme iron proteins constitute, on average, 7.1% ± 2.1% of archaeal proteomes, 3.9% ± 1.6% of bacterial proteomes, and only 1.1% ± 0.4% of eukaryotic proteomes (Figure 4).

Because eukaryotic proteomes are somewhat larger than those of simpler organisms, possibly with the exception of yeast, the above numbers mainly indicate that the non-heme

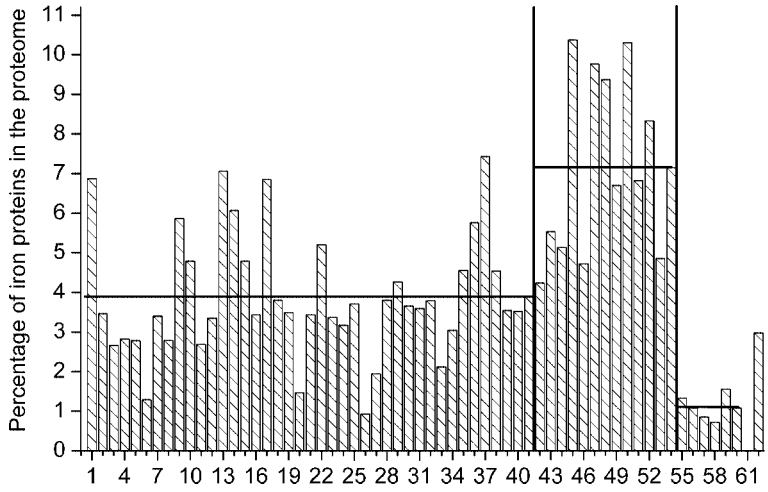

Figure 4. Percentage of iron-binding proteins identified in each proteome analyzed. The average values for all bacterial, archaeal, and eukaryotic organisms are also shown. Vertical lines separate the three domains and horizontal lines show the average values within each domain. The horizontal axis reports the data for, from left to right: 1. *Aquifex aeolicus*, 2. *Bacillus subtilis*, 3. *Bacteroides thetaiotaomicron*, 4. *Bdellovibrio bacteriovorus*, 5. *Bifidobacterium longum*, 6. *Borrelia burgdorferi*, 7. *Caulobacter crescentus*, 8. *Chlamydia trachomatis*, 9. *Chlorobium tepidum*, 10. *Clostridium acetobutylicum*, 11. *Coxiella burnetii*, 12. *Deinococcus radiodurans*, 13. *Desulfotalea psychrophila*, 14. *Desulfovibrio vulgaris*, 15. *Escherichia coli*, 16. *Fusobacterium nucleatum*, 17. *Geobacter sulfurreducens*, 18. *Haemophilus influenzae*, 19. *Helicobacter pylori*, 20. *Mesoplasma florum*, 21. *Mesorhizobium loti*, 22. *Methylococcus capsulatus*, 23. *Neisseria meningitides*, 24. *Nitrosomonas europaea*, 25. *Nostoc sp*, 26. iron proteome does not expand with the increase of proteome size that accompanies the increase in complexity of higher eukaryotic organisms. Indeed, in absolute terms, the number of non-heme iron proteins predicted in eukaryotes and in the bacteria with the largest proteomes span the same range. Figure 5 shows that the majority of non-heme iron proteins have homologues in all domains of life and that only about 10% of the non-heme iron proteome is specific to an individual domain. Taken together, these data point to non-heme iron being a cofactor of a set of metalloproteins that carry out an ensemble of basic functions which have changed very little with evolution. It can thus be concluded that the protein repertoire that sustains the increased complexity of eukaryotic organisms, and which is unique to these organisms, comprises very few predicted non-heme iron proteins.

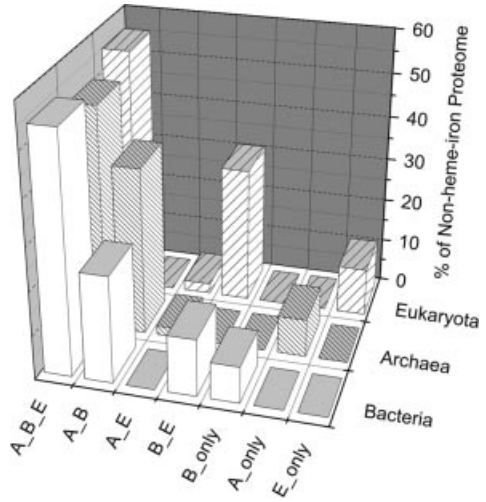

Figure 5. Fraction (with respect to the entire non-heme iron-proteome) of predicted iron-binding proteins in each domain of life having homologues in all three, two or only one domain of Life (A: Archaea; B: Bacteria; E: Eukaryota).

Overall, the non-heme iron proteome of organisms appears to be evolutionarily more ancient than the zinc proteome, with variations in its composition driven much more by loss of genes due to changes in environmental conditions that made some functions unnecessary than by recruitment of new iron proteins to cope with new functional needs (e.g. due to the evolution of multicellular organisms).[23]

### The Copper Proteome

Copper is the least pervasive of all the metallic cofactors described in this review. Nevertheless, copper plays a crucial role in a number of fundamental biological processes such as aerobic respiration (in the enzyme cytochrome *c* oxidase). Copper is a redox-active metal that can shuttle between the +2 and +1 states. It is potentially toxic to the cell, as it can lead to the formation of reactive oxygen species (ROS), in particular hydroxyl radicals, through a Fenton reaction. Consequently, nature has evolved complex pathways to control the intracellular concentration and distribution of copper,[83–85] parts of which have been structurally characterized.[86] Recent structural studies of proteins involved in the above pathways in eukaryotic systems are available, for example of proteins involved in copper delivery to cytochrome *c* oxidase[87] or in copper delivery to the trans-Golgi network.[88,89]

Copper ions are most commonly bound by cysteine and histidine side-chains, followed by methionine, and, to a lesser extent, glutamic and aspartic acid. Copper-binding proteins are typically predicted (by applying essentially the same approach as for non-heme iron proteins) to account for less than 1% of an organism's proteome (unpublished data from our laboratory). In particular, eukaryotic proteomes contain between 0.2% and 0.5% of copper proteins, with an average of 0.3%. These figures correspond to eukaryotic organisms encoding a few tens up to around one hundred copper-binding proteins. Among eukaryotes, the plant *Arabidopsis thaliana* seems to be richer in copper enzymes (as well as in non-heme iron proteins, see preceding section) than the average. The copper proteome of archaea and bacteria is composed mainly of proteins that have homologs either in all domains of life or at least in the two prokaryotic domains (unpublished data from our laboratory, Figure 6). Eukaryotes instead contain a significant share of eukaryote-specific copper proteins. These proteins are mainly copper-dependent oxidoreductases, whose number could be higher with respect to what is found in less complex organisms because of the compartmentalization of the eukaryotic cell. In agreement with this, a parallel increase, albeit less important in numerical terms, of copper-ion transporters is also observed.

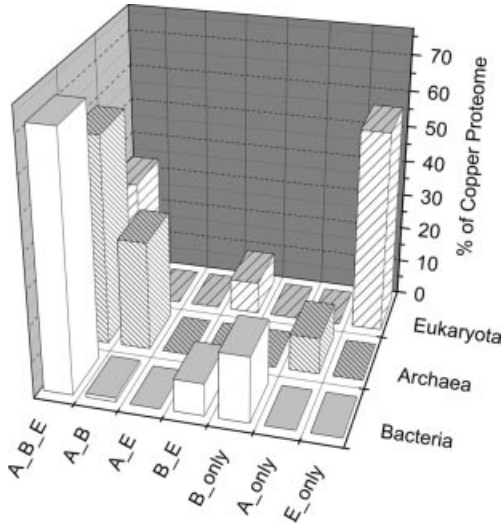

Figure 6. Fraction (with respect to the entire copper proteome) of predicted copper-binding proteins in each domain of life having homologues in all three, two, or only one domain of life (A: archaea; B: Bacteria; E: Eukaryota).

With the exception of hemocyanins, which have a role in dioxygen transport, the vast majority of copper enzymes can be assigned as catalyzing redox reactions. The second most common role for copper proteins is in metal-ion transport (e.g. these proteins are devoted to shuttling copper ions

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

within the cell, or to the uptake or excretion of copper). Copper transport is generally coupled to ATP hydrolysis.

Because of the extensively discussed (potential) toxicity of copper ions, systems devoted to controlling copper trafficking with the cells are present in a very large majority of all organisms that encode copper-dependent proteins. Some of these mechanisms have been so successful that they have significant similarities across a wide variety of prokaryotic as well as eukaryotic organisms. These include, for example, the chaperone/metalloATPase system for copper removal from the cytosol[53] or the Sco proteins, which are devoted to the assembly of cytochrome *c* oxidase and possibly of other copper-dependent oxidases.[90,91]

## Concluding Remarks

As mentioned for iron and copper, the uptake, transport, release, and incorporation of metal cofactors in proteins may require a specialized machinery whose malfunction may even lead to illness.[92] This could be expected for particularly large or chemically complex metal-containing cofactors such as heme or iron-sulfur clusters, but also holds for individual metal ions. As an example, the covalent attachment of heme to *c*-type cytochromes requires up to eight different proteins in bacteria (so called cytochrome *c* maturation genes, *c*cm*ABCDEFGH*).[93] Of the proteins encoded by these genes, one (ccmE) is devoted to transporting the insoluble heme cofactor, which is bound to ccmE through a very unusual heme–protein covalent bond, in the bacterial periplasm.[94] The structure of ccmE, however, has only been solved only in the apo form.[74,95] As regards individual metal ions, the most intensely studied soluble transporters (called metallochaperones) are probably those that handle copper,[96–99] although metallochaperones are also known for other metal ions such as nickel[100] or arsenic.[101]

The presence of delivery systems for metal ions serves two purposes, namely to prevent metals from binding to adventitious sites on proteins different from the intended targets and to incorporate the appropriate metal ion at each site regardless of the affinity of other metals for the same site. This second aspect is particularly relevant because of the need to overcome the intrinsic trend in the variation of stability of the metal complexes along the *d* series (the so-called Irving–Williams series) in order to incorporate the metal needed for the biochemical function of the system and not the most thermodynamically favored metal at each site. In other words, metallochaperones allow the incorporation of metal ions into metalloproteins to take place under kinetic rather than thermodynamic control, thereby ensuring proper maturation and thus functioning of metalloenzymes and metalloproteins in general. From the chemical point of view, this unfortunately poses some problems, because predictions cannot rely on thermodynamic properties to define which metal is bound at which site, even if the presence of a metal-binding site is known. In addition, experimental procedures for protein purification may lead to exchange of the biologically relevant metal ion with other ions contained in the buffers that bind to the protein more tightly (e.g. metallophosphatases).[102,103] On the other hand, nature can exploit this property to incorporate different metals in a protein, depending on their availability.[104]

In summary, there are now methods available that allow the prediction of an organism's metalloprotein content with some confidence. A systematic application of these methods shows significant differences in the use of metals by archaeal, bacterial, and eukaryotic organisms, the latter of which have significantly expanded their zinc proteome over evolutionary time to cope with the increased need for regulatory proteins arising from increased cell complexity and cellular differentiation. On the other hand, non-heme iron-binding proteins have not evolved significantly from simpler to more complex organisms; in fact, their number has actually diminished, with the exception of *Arabidopsis thaliana*, in eukaryotes, possibly reflecting reduced iron bioavailability. Finally, copper proteins are relatively uncommon in all organisms across the three domains of life and their number and distribution does not show significant trends. It should be kept in mind, however, that at the level of the individual protein metal binding is also dependent on the action of suitable metal-delivery pathways, which may always leave some uncertainty regarding the correctness of predictions but also of experimental data when the metalloprotein has been expressed heterologously or manipulated in some ways.

# A Critical Review of Electronic Effects in Enediamido and α-Diimino Complexes of the Group 4 Metals

Carlo Mealli,*[a] Andrea Ienco,[a] Andrew D. Phillips,[a] and Agustín Galindo*[b]

**Keywords:** N ligands / Group 4 metals / Metallacycles / Density functional calculations / Electronic structure

The α-diimino chelating ligand 1,4-diaza-1,3-butadiene, or its dianionic enediamido form (generically defined as DAD), forms a variety of complexes with group 4 transition metals either with or without other co-ligands. The known species are either pseudo-octahedral [$L_4M(DAD)$] or tetracoordinate [$L_2M(DAD)$] with a lower degree of metal saturation in the latter case. Additionally, there are a number of known $CpML_n$ species and homoleptic complexes with the formula [$M(DAD)_3$] or [$M(DAD)_2$]. The M-DAD metallacycle is generally either planar or folded at the N···N vector, the latter arrangement being observed when the number of co-ligands is reduced and hence there is insufficient saturation at the metal. The conformation also depends on the relative electron population of DAD, which is a *noninnocent* ligand and exists as a continuum between the neutral and dianionic resonance forms. Herein some theoretical concepts, that have previously been developed to describe the bonding capabilities of DAD toward different triads of transition metals, are extended to complexes of the group 4 metals. New electronic aspects of the [$M(DAD)_3$] complexes are described together with a completely new analysis of the [$M(DAD)_2$] complexes. These exhibit the planar/bent conformational dichotomy, which may have an electronic and/or steric origin as it is affected by the type of substituent at the nitrogen atoms. A reasonable justification of the observed conformational preferences is found from a combination of density functional and QTAIM analyses. The latter clearly demonstrates that a peculiar intramolecular hydrogen bonding can contribute to the stabilization of planar-type structures.

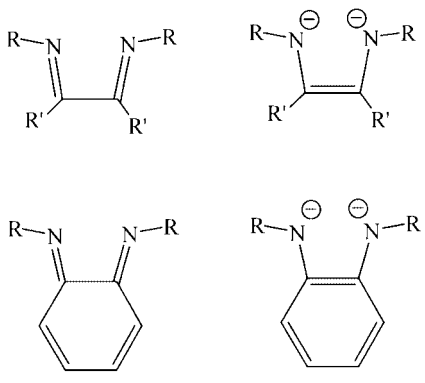
## 1. Introduction

This article analyzes the bonding capabilities of ligands based on the 1,4-diaza-1,3-butadiene or *o*-diiminobenzene skeleton (generally abbreviated as DAD) towards a transition metal of group 4. The electron population in these molecules varies depending on the nature of the coordinated metal atom.[1] Thus, the chelate is considered a neutral α-diimino species when bound to late transition metals as occurs, for example, in the nickel(II) and palladium(II) complexes, which are capable of converting ethylene into high molecular weight polymers with low polydispersity.[2] More commonly, the ligand behaves as an enediamido dianion with early transition metals. The corresponding complexes have been proposed as a more versatile alternative to metallocene catalysts for polymerization reactions.[3]

With a few exceptions, the coordination of DAD in the enediamido form is characterized by a nonplanar arrangement of the five-membered metallacycle (an N–N folded envelope). We have already dedicated a number of theoretical studies to interpreting the general bonding capabilities of these ligands with metal atoms of groups 5,[4] 6,[5] and 8.[6] Herein, the dichotomy between the diimino and enediamido forms (see Scheme 1), which is a classic example of *noninnocent* behavior,[7] is discussed on the basis of the electronic and structural characteristics of the $ML_n$ metal fragment (M = Ti, Zr, Hf).



Scheme 1. Diimino vs. enediamido resonance forms in ligands derived from the 1,4-diaza-1,3-butadiene or *o*-diiminobenzene skeletons (DAD).

A search of the Cambridge Crystallographic Database[8] for mononuclear[9,10] complexes of a group 4 metal with at least one DAD ligand yields examples that exhibit both resonance forms depending on the nature of the supporting $ML_n$ fragment, which are of the type $MX_2$, CpMX, $Cp_2M$, $MX_2L_2$, and $MX_4$ (L = two-electron-donor ligand, X = halide, Cp = cyclopentadienido anion). The set of ancillary ligands may occasionally include other DAD chelates, and homoleptic complexes of formulae $[M(DAD)_2]$ or $[M(DAD)_3]$ are observed in some cases. A few transition metals exhibit examples of both types,[11] although interconversion between the species has only been found to occur in the case of group 4 metals. This unique behavior requires a reasonable interpretation of the electronic structure and ligand-metal bonding as the mentioned dichotomy of the M(DAD) metallacycle (folded or planar) applies to homoleptic complexes as well.

In reviewing the general electronic features of all the group 4 complexes, we focus on the homoleptic species in particular. Given the interest raised by some of the examined species, new ad hoc quantum-chemical calculations have been performed and are presented here for the first time. For this reason, Supporting Information is also available.

## 2. General Considerations Regarding the Structural and Electronic Aspects of the α-Diimino and Enediamido Forms

The electronic aspects of the 1,4-diaza-1,3-butadiene ligand have been discussed previously in terms of a qualitative assessment of the relevant molecular orbitals [MOs; the various combinations of atomic orbitals (AOs) are represented in Scheme 2].[12] These include two filled nitrogen σ lone pairs (in-phase $\sigma_{ip}$ and out-of-phase $\sigma_{op}$ combinations) and four π levels. Only two of the latter are filled ($\pi_1$, $\pi_2$) when DAD has the α-diimino form, whereas $\pi_3$* is also populated (ligand's HOMO) when DAD behaves as an enediamido dianion.

*Carlo Mealli received his doctoral degree in chemistry from the Università di Firenze in 1969. After postdoctoral work with Prof. E. C. Lingafelter at the University of Washington (Seattle), he joined the CNR Institute of Florence directed by Prof. L. Sacconi, where he reached the position of Research Director in 1991. As visiting scientist, he has worked in famous laboratories around the world, including that of the Nobel Laureate Prof. R. Hoffmann (Cornell University). His research interests currently involve the relationship between 3D structures and chemical aspects (including reactivity) of transition metal complexes through computational analysis. For the latter, he has developed, together with D. M. Proserpio and A. Ienco the worldwide used package CACAO. He is the author of more than 200 publications in the field of inorganic/organometallic chemistry.*

*Andrea Ienco was born in Florence, Italy. He received his chemistry degree from the Università di Firenze in 1993. He then worked in Roald Hoffmann's group at Cornell University. He presently has a research position in Florence at the Istituto di Chimica dei Composti Organometallici of the CNR. His main scientific interest is the application of computational methods in organometallic and transition metal systems.*

*Agustín Galindo was born in 1960 in Seville, Spain, where he received both his graduate and doctoral (1986, under the direction of Prof. Ernesto Carmona) degrees. After postdoctoral work with Prof. René Mathieu and Prof. Jean-Pierre Majoral (Toulouse), he returned to the Universidad de Sevilla, where he reached the position of Lecturer (1989) and finally that of Professor of Inorganic Chemistry (2001). His research interests are related to transition metal chemistry and the application of coordination/organometallic complexes in homogeneous catalysis (recently extended to nonconventional media).*

*Andrew D. Phillips completed his B.Sc at the University of Toronto, before proceeding to Dalhousie University, Halifax, where he completed his Ph.D. with Dr. Neil Burford in low-coordinate phosphorus-nitrogen chemistry. Continuing his passion for the synthesis of main-group complexes, a two-year postdoctoral study was completed with Dr. Philip P. Power at U.C. Davis, with whom he is a co-author of over 22 publications. His interest in organometallics and computational chemistry was aroused by research performed at the CNR in Firenze with Drs. Maurizio Peruzzini and Carlo Mealli. At present he is partaking in an independent research project funded by the European Commission's Marie Curie Fellowship program at the Ecole Polytechnique Fédérale de Lasuanne, in collaboration with Dr. Paul J. Dyson. His primary interests include the development of catalytic processes using complexes with sterically demanding ligands.*

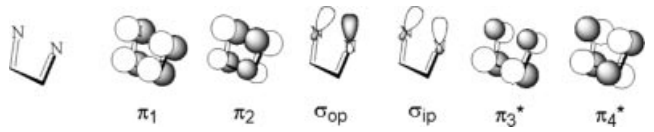

Scheme 2. Relevant MOs of the 1,4-diaza-1,3-butadiene ligand.

The complexes reported in the Cambridge Crystallographic Database can be separated into two distinct groups in which the M(DAD) metallacycle is either planar or bent depending on the value of the torsion angle M–N–N–C. If the latter is less than 170° the system is considered bent. We have previously addressed the electronic factors which determine the structural arrangement of enediamido ligands in complexes such as $[TiCl_2(DAD)]$ and $[W(NR)Cl_2(DAD)]$.[13] In particular, we pointed out that a dianionic character is acquired on bending (oxidized metal center) and the ligand becomes the donor of three rather than two electron pairs. At variance with other interpretations, which attribute the extra donation to the localized C=C π bond in the dianionic DAD,[14] we proposed that the electron pair involved is a filled combination of the nitrogen pπ orbitals that are acting as σ donors.[15] The present study confirms this point of view and discusses other factors that govern the electron distribution and shape of the metallacycle.

As mentioned above, a planar metallacycle implies an extended π-type delocalization of the metal's electrons over the entire skeleton of the chelate. Thus, one electron pair available at the $d^4$ metal is involved in back-donation to DAD without necessarily implying a complete electron transfer from the metal to DAD (oxidative addition). In contrast, a dianionic enediamido formulation of the ligand seems more appropriate when the ring is folded. A key factor for discriminating between the neutral or dianionic forms of the chelate is the population of the $\pi^*_3$ MO (see Scheme 2). Since this is a combination of both C=C π-bonding and C–N π*-antibonding character, a larger electron transfer from the metal atom (up to the point of oxidative addition) is manifested by the elongation of the C–N bonds and shortening of the intermediate C=C bond. This point has been extensively discussed by Wieghardt in several papers devoted to complexes of the late transition metals with *o*-diiminobenzene (alternatively behaving as *o*-diiminobenzosemiquinonato) and other related ligands.[16] This author concluded that the discrimination between the diimino or enediamido forms cannot be based solely on the geometric parameters, especially when the crystallographic data are not of the highest quality.

Finally, the recent discovery of planar metallacycles in $[Zr\{(Me_3SiN)_2C_6H_4\}_2]$[17] has shown that the bent/planar dichotomy is also present in homoleptic $[M(DAD)_2]$ complexes. This point requires special consideration and has been treated by a combination of MO calculations and electron density analysis.

## 3. $[M(DAD)_3]$ Complexes

Our examination of the electron-richer complexes, in which the group 4 metal is hexacoordinate, starts with the homoleptic $[M(DAD)_3]$ species. These will be later correlated with the general pseudo-octahedral complexes. Table 1 summarizes the known $[M(DAD)_3]$ complexes along with their CCDC refcode.[8] All the M(DAD) metallacycles are planar.

Table 1. Structurally characterized homoleptic $[M(DAD)_3]$ complexes.

| Composition (M, DAD) | CCDC refcode |
|---|---|
| Ti, *i*PrNC(H)C(Ph)N*i*Pr | WIMROZ[18] |
| Zr, *p*-TolNC(Ph)C(Ph)N-*p*-Tol | YOBYAP[19] |
| Hf, *p*-TolNC(Ph)C(Ph)N-*p*-Tol | YOBYET[19] |

A density functional analysis of an equivalent group 5 metal complex, namely the redox species $[M(iPrNC(H)=C(H)NiPr)_3]^{0,+1}$ (M = Nb, Ta), is available.[20] Based on the MO architecture, it has been suggested that conversion between the two redox complexes is ligand-based. We have examined analogous group 4 complexes and have optimized the model $[Ti\{MeNC(H)=C(H)NMe\}_3]$ (**1**; Figure 1).

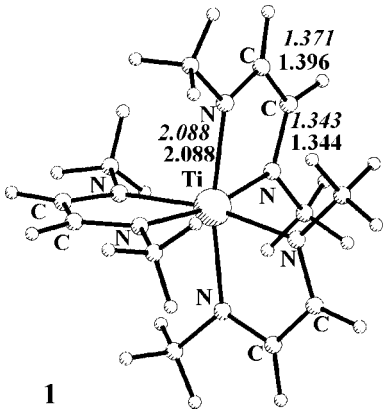

Figure 1. Optimized structure of the model $[Ti\{MeNC(H)=C(H)NMe\}_3]$ (**1**). The experimental geometric parameters of WIMROZ are given in italics.

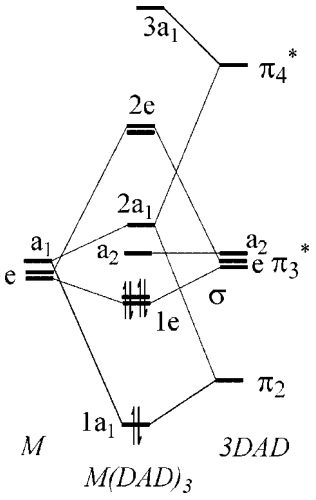
The structure has essential $D_3$ symmetry and the agreement with the experimental parameters of $[Ti\{iPrNC(H)=C(H)NiPr\}_3]$ (WIMROZ) is satisfactory since the metallacycles are planar and only the C=C double bond is slightly overestimated (by about 0.02 Å).

The MO picture is similar to that proposed for the analogous group 5 system. Amongst the important MOs of the DAD ligands (see Scheme 2) we can highlight the in-phase ($\sigma_{ip}$) and out-of-phase ($\sigma_{op}$) combinations of the nitrogen lone pairs, which donate a total of 12 electrons to the metal. Other interactions involve the π-orbitals of the ligands, some symmetry combinations ($D_3$ point group) of which are shown on the right-hand side of Scheme 3. Of these, the combinations of $\pi_1$ and $\pi_2$ orbitals (see Scheme 2) are all populated but are only partially involved in metal interactions (see below). The most critical relationships concern the $\pi_3$* orbitals, which determine the *noninnocent* character of the ligands. Given the pseudo-octahedral geometry of the complex, the classical metal "$t_{2g}$" levels (presented as the $a_1$ and e levels on the left-hand side of Scheme 3) are

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

close in energy to the $\pi_3$* combinations of the ligands ($a_2$ and e), hence a strong interaction occurs between the two degenerate e sets. The combined 1e MO (the degenerate HOMO depicted in Figure 2) is stabilized due to its bonding character.



Scheme 3. Simplified MO diagram for [M(DAD)$_3$] complexes.

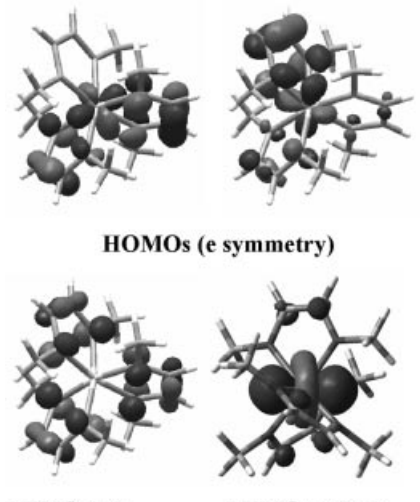


Figure 2. Important frontier MOs associated with model complex **1**.

Given the small energy gap between the interacting levels, it is difficult to discriminate the actual amount of metal- or ligand-based character associated with the four frontier electrons in the 1e level. However, even if a complete metal-to-ligand charge transfer has occurred (oxidative addition), only a maximum of two out of the three ligands could be considered completely dianionic. This is inconsistent with the equivalence of all the ligands constrained by the threefold symmetry. Also, in view of the planarity of the metallacycles, it seems reasonable that the metal is synergetically engaged in back-donation of four electrons into the three DAD ligands.

The two lowest and unpopulated levels (LUMOs in Figure 2) are a combination of pure $\pi_3$* ligand-based orbitals ($a_2$) and a metal "$t_{2g}$" orbital with some M–L antibonding character ($2a_1$). As shown in Scheme 3, the $2a_1$ level arises from a weak dative interaction between a combination of lower and filled C=N $\pi_2$ bonding levels. There is also a stabilizing effect connected with the higher $3a_1$ level (based on a $\pi_4$* combination), which justifies why there is no nitrogen contribution in $2a_1$ (see Scheme 2). In any case, the participation of the DAD $\pi_2$ MOs in metal donation allows the $d^4$ metal center to reach a formal 18 electron count. Curiously, it should be noted that the electron richer $d^5$ complex also has 18 electrons since experimental and computational studies for the neutral [Ta(*i*Pr$_2$-DAD)$_3$] complex confirm that the SOMO has exclusively ligand-based character.[20] This is consistent with the EPR spectra. Moreover, a significantly larger energy gain is computed for singly populating $a_2$ instead of $a_1$, while the C–C bond and C–N distances are comparatively shorter and longer, respectively, in the neutral species than in the monocation.[20] In spite of the ligand-based redox chemistry, it might be improper to formulate a prevailing dianionic character of the ligands as this would imply intra-ligand repulsion. Although the additional electron in [Ta(*i*Pr$_2$-DAD)$_3$] is assigned to the ligand, there is no evidence of Ta–N bond elongation. This in an indirect confirmation that the electrons in 1e are mainly metallic in character.

The other two known structures of homoleptic [M(DAD)$_3$] complexes, namely [M{[*p*-TolNC(Ph)]$_2$}$_3$] (YOBYAP and YOBYET for M = Zr and Hf, respectively),[19] are remarkable for having one metallacycle that is different from the other two. In YOBYET,[19] for instance, the two Hf–N distances for one chelate are significantly shorter than the other four (average values of 2.150(12) vs. 2.216(15) Å] and the C–C distance in the unique metallacycle is correspondingly shorter [1.34(2) vs. 1.405(19) Å]. Since this effect is common to two structures, it cannot be attributed to the poor quality of the crystal data. In principle, a break of the threefold symmetry could be due to an electronic effect of the Jahn–Teller type, since there four electrons are available for three metal–ligand π interactions and the HOMO–LUMO gap is relatively small (see Scheme 3). A DFT optimization of the simple model [Zr{MeNC(H)=C(H)NMe}$_3$], which is similar to the Ti species **1**, shows no electronic bias toward a broken threefold symmetry. A careful examination of the intramolecular contacts in the Zr and Hf structures indicates that the bulky phenyl and tolyl substituents at any core atom of DAD determine the steric hindrance. Rather than a symmetrical weakening of all the M–N distances, the system allows one ligand to be more strongly bound than the other two. A Walsh diagram, constructed at the Extended Hückel Molecular Orbital (EHMO) level,[21] for the simultaneous lengthening of two out of three metal–ligand interactions (the ideal $D_3$ symmetry of the complete model is lowered to $C_2$) shows that this distortion produces a large energy gain of about 30 kcal mol$^{-1}$. Evidently, some four-electron repulsions between the H atoms of the aromatic rings are progressively relieved. Remarkably, the energy minimum found at this low computational level almost corresponds to the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

experimental structure. Further metal–ligand weakening steeply raises the energy.

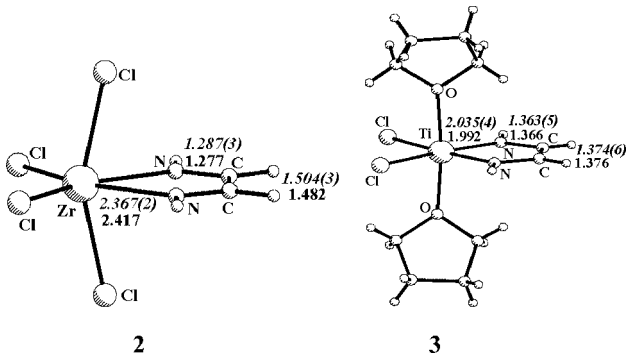
## 4. Pseudo-Octahedral Complexes with $ML_4$ Fragments

In order to gain further insight on the electronic peculiarities of the homoleptic $[M(DAD)_3]$ species, it is useful to draw a comparison with pseudo-octahedral DAD complexes supported by an $ML_4$ fragment (L = two-electron-donor ligand or a halide X). Table 2 lists the structurally characterized examples. In particular, the complexes $[ZrCl_4\{RNC(Ph)=C(Ph)NR\}]$ (**2**; YOBXUI,[19] R = *p*-MeO-$C_6H_4$), $[TiCl_2(thf)_2\{CyNC(H)=C(H)NCy\}]$ (**3**; PEBCOQ[22]), and $[ZrCl_2(tmeda)\{o\text{-}(Me_3SiN)_2C_6H_4\}]$ (**4**; GUHYEN,[23] tmeda = $Me_2NCH_2CH_2NMe_2$) have been examined. Complex **4** uniquely features a somewhat folded metallacycle.

Table 2. Structurally characterized pseudo-octahedral complexes with $ML_4$ fragments.

| Ancillary fragment | Composition | CCDC refcode |
|---|---|---|
| $ML_4$ | [Zr(DAD)(macrocycle)] | NOVNUH[24] |
| | | POCKAT[25] |
| | | POCKUN[25] |
| $ML_2X_2$ | $[TiCl_2(DAD)(thf)_2]$ | PEBQOC[22] |
| | $[ZrCl_2(DAD)(tmeda)]$, *bent* | GUHYEN[23] |
| | [Zr(guanidinate)$_2$(DAD)] | PUXTEH[26] |
| $M(NR)X_2L$ | $[TiCl_2(DAD)(NAr)(py)]$ | VEBYIK[27] |
| $MX_4$ | $[ZrCl_4(DAD)]$ | YOBXUI[19] |

First of all, we satisfactorily optimized models of complexes **2** and **3** with the unsubstituted DAD ligand (see Figure 3). The Ti–N distances and Cl–Ti–Cl angle are underestimated and overestimated with respect to the experimental structure of PEBCOQ[22] by about 0.04 Å and 13°, respectively, in **3**. This is most likely due to important C–H···Cl intramolecular interactions involving the cyclohexyl substituents that are present in the experimental complex but neglected in the calculations.

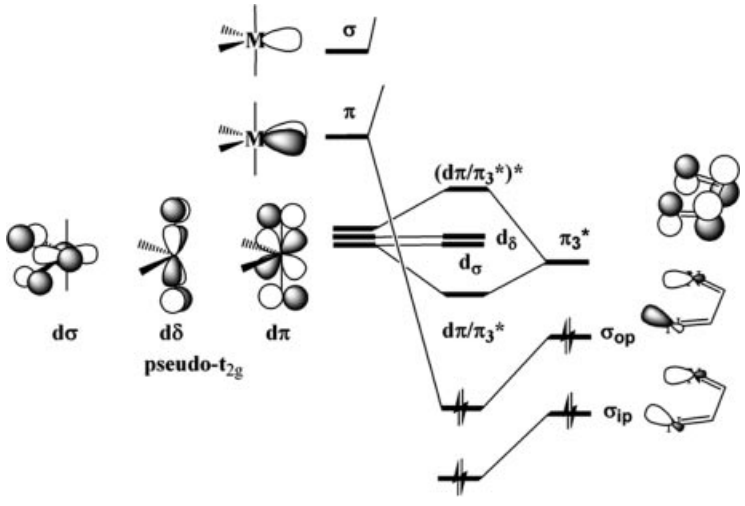


**2** **3**

Figure 3. Optimized structures of the model complexes **2** and **3**.

Given the common pseudo-octahedral geometry of complexes **1**, **2**, and **3** and the variety of formal oxidation states (0, IV, and II, respectively), the metallacycle(s) must have a different electronic nature even though they are all planar. For instance, four Cl co-ligands in **2** ($d^0$ configuration) exclude both the enediamido character of DAD and the metal back-donation. Such a limiting situation is well expressed by the longer C–C (1.482 Å) and shorter C–N (av. 1.278 Å) distances, which suggest that the α-diimino ligand ideally features a single C–C bond and two double C=N bonds. The lack of back-donation should also be reflected by long Zr–N bonds in **2**, which are not directly comparable with the Ti–N distances of 1.992 and 2.088 Å in **3** and **1**, respectively. The latter significant difference is probably due to full engagement of the unique electron pair in **3** ($d^2$ configuration) in back-donation to one DAD ligand, whereas the two electron pairs ($d^4$ configuration) in **1** are shared by three DAD ligands.

The diagram for the interaction between the metal fragment and DAD (see Scheme 4) is general for complexes containing four π-donor co-ligands (e.g., halides) and is essentially similar to that proposed by us previously to interpret the features of octahedral *o*-phenylendiamido complexes of group 6 metals.[5] Taking into account these latter



Scheme 4. Simplified MO diagram for $[L_4M(DAD)]$ complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complexes, the population of the four highest frontier MOs in this scheme can vary between 0 and 6 electrons.

Donations of the ligand $\sigma_{op}$ and $\sigma_{ip}$ lone-pair combinations into the appropriate σ and dπ hybrid orbitals of the metal are the most effective and general. In **3**, there is a π-type interaction (see the bonding HOMO dπ/$\pi_3$* in Figure 4), while the two remaining "$t_{2g}$" orbitals (dσ and dδ) are apparently unsaturated. This is not completely true, since electron density is provided by the filled pπ orbitals of the halide co-ligands. This point is highlighted by the drawings of the $ML_4$ frontier orbitals on the left-hand side of Scheme 4.

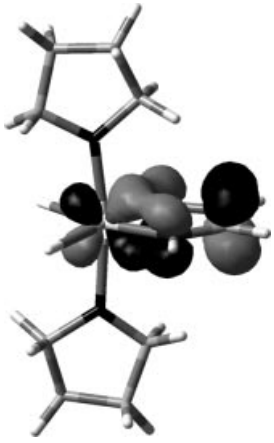


Figure 4. 3D isosurfaces corresponding to the computed HOMO of complex **3**.

Switching the Cl and thf ligands between the equatorial and axial positions in **3** should reduce the saturation of the dσ level because of the weaker π donor capabilities of thf. Conversely, dδ is less affected because it continues to receive the electron density donated from the low-lying $\pi_2$ orbital of DAD (see Scheme 2), which complements to the better donation from the Cl ligands. These trends were verified by optimizing three possible isomers, namely *trans*-thf,*cis*-chloride, *trans*-chloride,*cis*-thf and *trans*-chloride/thf,*cis*-chloride/thf. The latter two species are significantly less stable than the observed structure by +14.3 and +13.3 kcal mol$^{-1}$, respectively (see Supporting Information). A similar problem is found for the formally $d^2$ complex [$ZrCl_2$(tmeda){*o*-($Me_3SiN)_2C_6H_4$}][28] (**4**), which uniquely features a folded Zr(DAD) metallacycle (42° rotation about the N···N vector). In this case, the most stable conformer with the two chloride ligands in the equatorial plane is prevented from forming by the presence of the ethylenediamine chelate, which has no π-donor capabilities. Optimization of the simplest model [$ZrCl_2$(eda)(DAD)] (eda = $H_2NCH_2CH_2NH_2$) did not reproduce any bending of the metallacycle (see Supporting Information). A better result is obtained for the model **4a** with $SiH_3$ substituents at the nitrogen atoms of DAD, since this ligand exhibits a limited folding of 20°. The other geometric parameters are also in better agreement with the experimental ones (see Figure 5, a). The HOMO of the species in question (Figure 5, b) clearly shows that the $\pi_3$* level of DAD exerts a σ-type interaction with one lobe of a d orbital rather than the classic dπ/$\pi_3$* one. This was also our original interpretation of the chelate's bending in highly electron-deficient species such as [$TiCl_2$(DAD)],[13] for which a dianionic character of the chelate must be assumed.

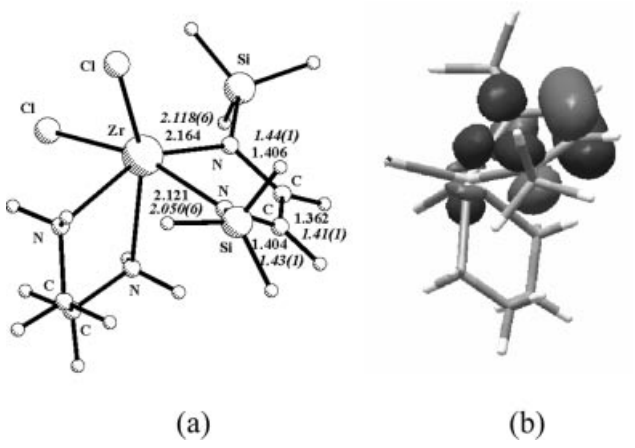

Figure 5. (a) Optimized structure of the model [$ZrCl_2$($H_3$Si-DAD)(eda)] (**4a**). (b) 3D isosurfaces corresponding to the computed HOMO of **4a**.

Folding of the metallacycle is as large as 54° in the optimized structure of an isomer of **4a** with two axial Cl ligands and the equatorial eda chelating, although the total energy is only 1.0 kcal mol$^{-1}$ higher. In this case, the larger unsaturation of the metal dσ orbital may again be partially compensated by an interaction with the nitrogen pπ lobes of the $\pi_3$* level as σ donors.

In summary, the examined pseudo-octahedral complexes have four frontier levels that are relatively close in energy (see Schemes 3 and 4) and can host up to four electrons (or five in the group 5 derivative). In the homoleptic systems, all the $t_2$-based orbitals ($a_1$ + e) are sufficiently saturated by electron donation from suitable combinations of the three DAD ligands. In halide complexes, the electron deficiency at the metal is compensated by the π-donor capabilities of the co-ligands. However, if the co-ligands do not have sufficient donor power or are not properly arranged, insufficient destabilization of a $t_{2g}$ orbital may cause a second-order Jahn–Teller effect. This is likely the cause for the bending of the metallacycle and the shift of the electrons toward DAD, with a consequent improvement of its donor capabilities.

## 5. Compounds Containing the Fragments $CpML_n$ and $Cp_2M$

Cyclopentadienido rings can also stabilize an M(DAD) metallacycle. A complex of the type [CpLM(DAD)] can be considered pseudo-octahedral, similarly to the species examined in the previous sections. In some cases, however, the number of co-ligands is higher. In fact, metal fragments of the type $CpML_2$, $CpML_3$ (L = two-electron donor or halide), and $Cp_2M$ can also support DAD coordination. Table 3 summarizes all the species containing at least one

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Cp ligand that have been characterized by X-ray diffraction methods. The DAD ligand is generally folded in the latter, with a few exceptions, and hence is dianionic and the oxidation state of the group 4 metal is +4 ($d^0$ configuration). As underlined before, DAD behaves as the equivalent of a six-electron donor by exploiting a filled combination of the N pπ orbitals for the third σ-type donation.

Table 3. Structurally characterized mononuclear complexes formed by the fragments $CpML_n$ or $Cp_2M$ and one DAD ligand.

[a] Cp* = $C_5Me_5^-$, Cp = $C_5H_5^-$, Cp′ = substituted cyclopentadienido ligand.

Two of the complexes in Table 3 are exceptional in that they contain a planar M(DAD) metallacycle. Their simplified formulae are [Cp′Zr($NR_2$)($NHR_2$)(DAD)] and [Cp′ZrCl($NHR_2$)$_2$(DAD)] (see Figure 6) and refer to the species WOJLAI and WOJLEM,[29] respectively. The supporting metal fragments in the latter are electron rich because of the large number of co-ligands. In fact, both complexes can be assigned 18 electrons by assuming a formally uncharged DAD ligand ($d^2$ metal configuration). The fragments $CpML_2$ (in WOJLAI) and $CpML_3$ (in WOJLEM) can be considered isoelectronic by assuming that the amido ligand is able to donate as many as two electron pairs to the metal.

Also, it cannot be excluded that the planar coordination of DAD is not directly correlated with an uncharged α-diimino character but is a consequence of a geometric constraint in this case. In fact, the Cp′ and DAD units in both complexes are linked to each other by a $Si(CH_3)_2$ bridge between one N atom and one Cp′ carbon atom. Such a connectivity can reduce the flexibility of DAD and therefore its capability for bending. Moreover, the octacoordinate complex (the geometry can be roughly described as a capped four-legged piano stool, see Figure 6) is highly hindered and the metal may not be able to receive an extra lone pair on the side opposite to the Cp′ ring. Interestingly, the complex [CpHfL(Cl)(DAD)] (refcode YADYEH[40]), which is also of the type [$CpML_2$(DAD)], adopts a four-legged, uncapped piano-stool coordination and shows an evident, although not large, folding of the metallacycle (about 20°). The DAD ligand is also not isolated in this case but is directly connected to other co-ligands.

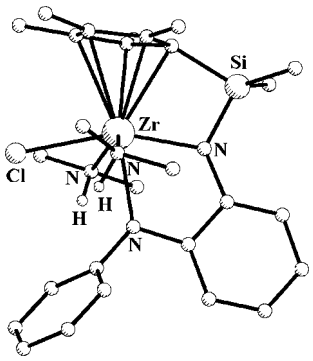

Figure 6. Experimental structure of [Cp′Zr(DAD)Cl($NHR_2$)$_2$] (refcode WOJLEM).

The relation between the rigidity and electronic structure of these complexes might deserve an ad hoc theoretical study. In general, the concept of isolobality is helpful for drawing useful relations between the Cp derivatives in question and other [$L_n$M(DAD)] complexes. MO diagrams similar to those in Schemes 3 and 4 can also be constructed for the $Cp_2M$ and $CpL_nM$ complexes of DAD. The easiest parallelism applies to the orbital interactions in the [$L_4$M(DAD)] and [CpMCl(DAD)] models, and these qualitative arguments can also be extended to more complex systems. Some of the points concerning the electronic structures of selected Cp metal complexes of DAD have been addressed by some of us in a previous theoretical paper.[50] Here, we simply note that DFT calculations with a QTAIM analysis[51] fully confirmed that, upon bending of DAD, the donation of a third electron pair to the metal occurs through the nitrogen pπ orbitals and not through the C=C π bond of the dianionic enediamido ligand, as often stressed by other authors.[14]

## 6. Electron-Deficient [$X_2$M(DAD)] Complexes and Related Homoleptic [M(DAD)$_2$] Species

The DAD ligand, together with only two co-ligands, is found to stabilize pseudo-tetrahedral coordination at a group 4 metal. The upper part of Table 4 lists the known structures of type [$L_2$M(DAD)], where the metallacycle is invariably folded. For this reason DAD is considered dianionic. In turn, the metal has a $d^0$ configuration and the

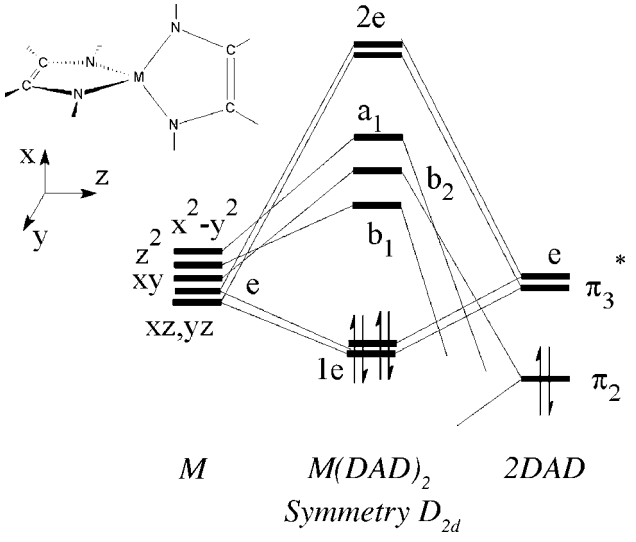
| | $[Zr\{(Me_3SiN)_2C_6H_4\}_2]$ | FIFQER[17] |

system can, in principle, be related to classical tetrahedral complexes of the main group elements. On the other hand, the ability of a bent DAD to donate three electron pairs confirms that the d orbitals play a role, although they obviously cannot be saturated by a single DAD ligand. Thus, the two co-ligands (e.g. halides, phenoxides, and $BH_4^-$; see Table 4) also act as π donors. The electronic structure of $[X_2M(DAD)]$ species has previously been investigated by us from a theoretical viewpoint[13] and will therefore not be addressed in detail here. $[L_2M(DAD)]$ complexes have also been analyzed theoretically as the end-products of the intramolecular coupling of two $\eta^2$-iminoacyl ligands in bis(aryloxide) complexes of zirconium.[52] We therefore focus on the homoleptic species $[M(DAD)_2]$ (see the lower part of Table 4), which raise the most intriguing questions because of the recently ascertained dichotomy of planar or bent metallacycles.

We start with a qualitative MO Scheme for a $[M(DAD)_2]$ model with two planar perpendicularly oriented metallacycles (see Scheme 5).



Scheme 5. Simplified MO diagram for $D_{2d}$-symmetric $[M(DAD)_2]$ complexes.

Four low-lying σ bonding MOs, which correspond to the donation from nitrogen lone pairs into s and p metal orbitals, are not shown. It is evident from the frontier region of the diagram that a degenerate bonding set (1e) is formed between the metal *xz* and *yz* orbitals and suitable $\pi_3$* orbitals of the two ligands. The three remaining d orbitals are destabilized from other low-lying and filled ligand orbitals, which means that the HOMO–LUMO gap is sufficiently large (>1 eV). In particular, the *xy* orbital interacts with a combination of the $\pi_2$ ligand levels (see Scheme 2), while $x^2$–$y^2$ and $z^2$ are pushed higher by suitable combinations of the nitrogen σ lone pairs, which are already used for donation into high lying s and p metal orbitals. If the saturation of $x^2$–$y^2$ and $z^2$ is insufficient, folding of the two metallacycles may be induced by a second-order Jahn–Teller effect similar to that mentioned above for some pseudo-octahedral species.

The first two complexes of the type $[M(DAD)_2]$ to be characterized, namely $[Ti\{(o\text{-}MeC_6H_4)N(CMe)\}_2]$ (**5**; WEZXAA[59]) and $[Zr\{(iPr_3SiN)_2C_6H_4\}_2]$ (**6**; ZUJSAY[58]) are bent metallacycles, while in the more recently characterized species $[Zr\{(Me_3SiN)_2C_6H_4\}_2]$ (**7**; FIFQER[17]) the two rings are perfectly planar and orthogonal. It is noteworthy that the two non-isostructural zirconium complexes **6** and **7** have the same $C_6H_4$ backbone and differ only in the nature of the silyl substituents at the N atoms. The subtle electronic factors that affect the dichotomy have therefore been examined by different computational techniques.

The simplest models $[M\{MeNC(H)=C(H)NMe\}_2]$ (M = Ti **5a**, Zr **6a**) with $C_2$ symmetry were optimized first at the DFT level. The absolute minima invariably contain bent metallacycles, as indicated in Figure 7.

The pseudo-tetrahedral geometry observed in the X-ray structures of **5** and **6** is satisfactorily reproduced, as is the amount of twisting of each metallacycle (about 50° about the N···N vector). The shorter C–C distance in **6a** (by 0.05 Å) is most likely a consequence of the replacement of the more delocalized $C_6H_4$ backbone with the CH=CH grouping in the DAD ligand.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

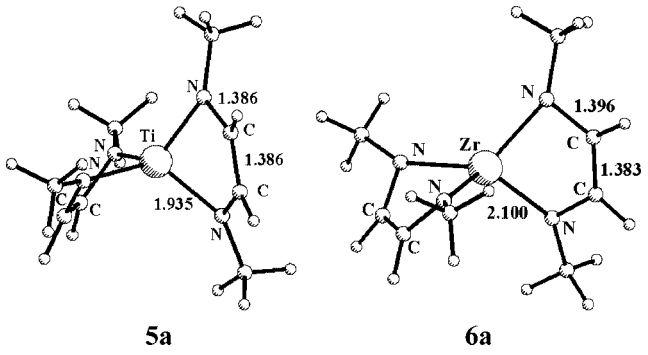


Figure 7. Optimized structures of the homoleptic model complexes [M(Me-DAD)$_2$] (M = Ti **5a**, Zr **6a**) with bent metallacycles.

With respect to the MOs in Scheme 5, the lowering of the symmetry from $D_{2d}$ to $C_2$ mixes the character of the barely saturated $x^2$–$y^2$ and $z^2$ orbitals into the highest two filled MOs (the previous 1e HOMOs). As pointed out in our original work on [TiCl$_2$(DAD)][13] and here for some [L$_4$M(DAD)] species, bending transforms most of the dπ–pπ bonding character of the frontier orbitals into a σ-type interaction between the nitrogen pπ lobes and single lobes of the $x^2$–$y^2$ and $z^2$ orbitals. This aspect is highlighted by the HOMO and HOMO–1 for complex **5a** (see Figure 8).

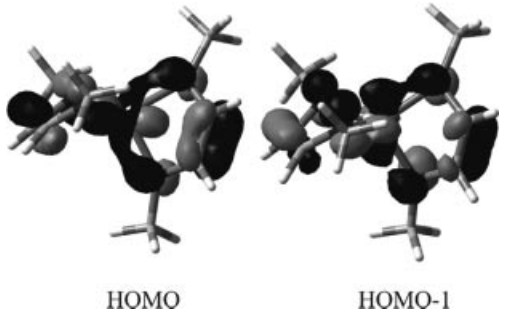

Figure 8. 3D isosurfaces corresponding to the computed HOMO and HOMO–1 of **5a**.

The optimized model complexes **5b** and **6b** with planar metallacycles ($D_{2d}$ symmetry) are associated with two high imaginary frequencies, which clearly indicates the preference of the two ligands to fold. The total energy is higher than that at the absolute $C_2$ minimum by as much as 20 kcal mol$^{-1}$. The energy difference between the planar and bent forms is reduced to the order of only 1–3 kcal mol$^{-1}$, when the calculations are repeated with DAD ligands having a C$_6$H$_4$ backbone. This is most likely due to a significant delocalization of the electron density toward the aromatic ring and away from the nitrogen atoms. This reduces the possibility of the latter jointly becoming the donors of a third electron pair when the metallacycle is bent. Under these circumstances, it is possible for DAD to maintain the enediamido character associated with the planar conformation, which means that the dichotomy of the two geometries and the existence of two isomers is plausible. Since the zirconium complexes **6** and **7** have different ring geometries and differ only in having *i*Pr$_3$Si or Me$_3$Si substituents, respectively, the relative effects of the latter on the stability of each isomer must be rationalized.

One CH$_3$ group of each silyl substituent in the experimental structure of **7** hangs over the metal atom with two relatively close H atoms and one C–H vector pointing away. Although the shortest Zr···H separation is as long as 3.04 Å, such an arrangement is reminiscent of the Zr–η$^3$-CH$_2$ agostic interactions that have been classified by some of us recently,[60] and this is also the classical bonding mode between a metal center and a free alkane.[61] Thus, the metal center in **7** seems to be involved in four simultaneous interactions of the latter type with four different CH$_3$ groups, which are pairwise aligned roughly along the two main perpendicular directions.

To verify whether the agostic interactions really exist, various models of **7** have been investigated (see Figure 9).

First of all two $D_{2d}$ structures (**7a** and **7b** in Figure 9) were optimized with MeH$_2$Si substituents in place of the Me$_3$Si ones. These model complexes have imposed planar metallacycles but differ in the orientation of the unique methyl groups, which can either lie close to or away from the metal center. The shortest Zr···H distances in **7a** are much longer than the experimental ones (3.45 vs. 3.043 Å) and the computed N–Si–C angle is less closed [107.5° vs. 103.5(1)°], which suggests that the agostic interactions, if real, are not reproduced by the calculations. Further information was expected from model **7b** which, due to its stereochemistry, cannot feature any agostic interaction. This conformer, which is not even a minimum on the PES (imaginary frequencies are present), is energetically disfavored with respect to **7a** by 22 kcal mol$^{-1}$. This difference is not a proof of the agostic interactions in **7a** but has a clear steric origin. In fact, the significantly open N–Si–C angles (120.7°) best highlight the short contacts between the C$_6$H$_4$ backbone and the coplanar methyl groups, and hence their repulsive effects.

Finally, the most complete model of complex **7**, with actual Me$_3$Si substituents, was optimized in both $D_{2d}$ and $C_2$ symmetries (**7c** and **7d**, respectively, in Figure 9). The results with these complexes show that the molecule can exist in the gas phase with either planar or bent metallacycles since both models are real minima on the PES. Importantly, the folding of the ligand in **7d** still causes a stabilization of only 2 kcal mol$^{-1}$, which is one order of magnitude smaller than that found for species without the aryl backbone. For this reason, it is not totally surprising that isomer **7c** is found in the solid state. Furthermore, the small energy difference is in agreement with the fluxional behavior observed in several [X$_2$M(DAD)] complexes,[38,47,58,59] as shown schematically in Scheme 6.

With regard to the critical geometrical parameters of the Me$_3$Si displacement in **7c**, the agreement with those of the experimental structure is good but not excellent. In any case, the trends with respect to **7a** indicate shorter Zr···H contact distances (3.30 Å) and more acute N–Si–C angles (105.5°). Again, the closeness of one methyl group to the metal atom seems due to the steric repulsions between the C$_6$H$_4$ ring and the other methyl groups rather than to an actual agostic interaction.

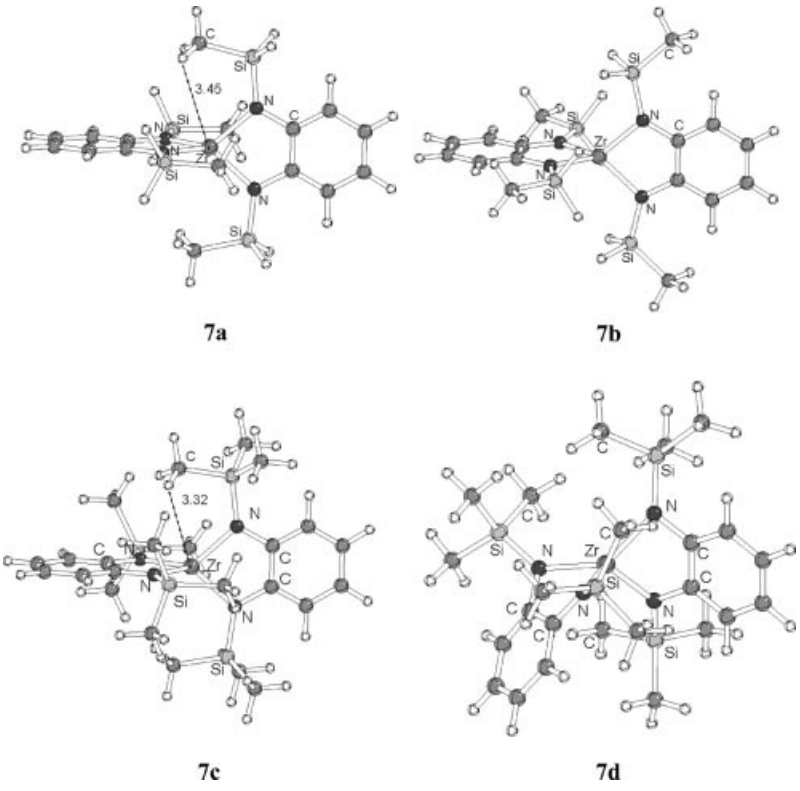

Figure 9. Optimized $D_{2d}$ structures of $[Zr\{(MeH_2SiN)_2C_6H_4\}_2]$ with 180°-reoriented $MeH_2Si$ substituents (models **7a** and **7b**). Structures **7c** and **7d** are $D_{2d}$- (planar metallacycles) and $C_2$-symmetric (bent metallacycles) models of complex **7** with $Me_3Si$ substituents. The dotted lines in **7a** and **7c** highlight one of the equivalent shortest Zr···H contacts.

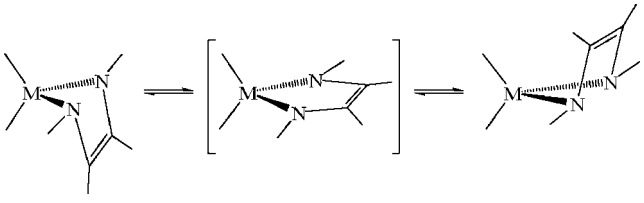

Scheme 6. Dynamic equilibrium between the conformers of folded DAD complexes.

## 7. QTAIM Analysis of the Homoleptic [Zr(DAD)$_2$] Species

In order to find a reasonable answer to the nature of the interaction, which in complex **7** pushes four methyl groups toward the inner coordination sphere of the metal, a QTAIM[51] analysis was carried out for model **7c** as other QTAIM studies have been able to clearly highlight Ti···H and Zr···H interactions in systems where they really exist.[62]

The structures in Figure 10 (see part A) show all the expected bond critical points (bcp's) for the normal interatomic interactions, none of which appears in the region of possible Zr···H interactions. Furthermore, the Laplacian map indicates a localized depletion in these regions, which means that no confirmation of the agostic bonds is found. A similar study by Coppens et al., also using the QTAIM method, was also unable to detect any agostic interactions in the open zirconocene complex $[Zr(2,4\text{-}C_7H_{11})\{(i\text{Pr})NCHPhCH_2\text{-}CMe{=}CHCMe{=}CH_2\}]$.[63]

Remarkably, another type of attractive interaction can be seen from Figure 10 (A), namely eight bcp's appear between the N atoms and the methyl H atoms, which were initially supposed to participate in agostic interactions with the metal. These bcp's essentially correspond to weak C–H···N hydrogen bonds, although it remains questionable whether these can be the driving force for the $Me_3Si$ group to lean toward the metal. The computed N···H separations of 3.12 Å (av.) are somewhat longer than the experimental average value of 3.05 Å, which also means that the electron density at the bcp's is rather small (0.005 e Å$^{-3}$). In any case, the cumulative strength of as many as eight interactions of this type could be stabilizing. Incidentally, an equivalent situation (not shown) is found for the structure of $[Zr\{(Me_3SiN)_2C_6H_{10}\}_2]$,[64] which differs from **7** in having a cyclohexyl backbone instead of an aryl one (in other words the carbon atoms of the metallacycle are fully saturated). The DFT calculations for this molecule indicate that there is only one conformer with two quasi-planar and perpendicular metallacycles.

Rather different results are obtained from the QTAIM analysis of the $C_2$ isomer **7d** with bent metallacycles (Figure 10, B). Recall that the latter conformation is observed in complex **6** (ZUJSAY) with $i\text{Pr}_3Si$ substituents in place of the $Me_3Si$ ones. Only two of the eight C–H···N bcp's remain in isomer **7d**, and their densities are at least 20% lower than those in **7c**.

In conclusion, the larger number of stabilizing N···H interactions in **7a** seem to justify the reduced energy difference

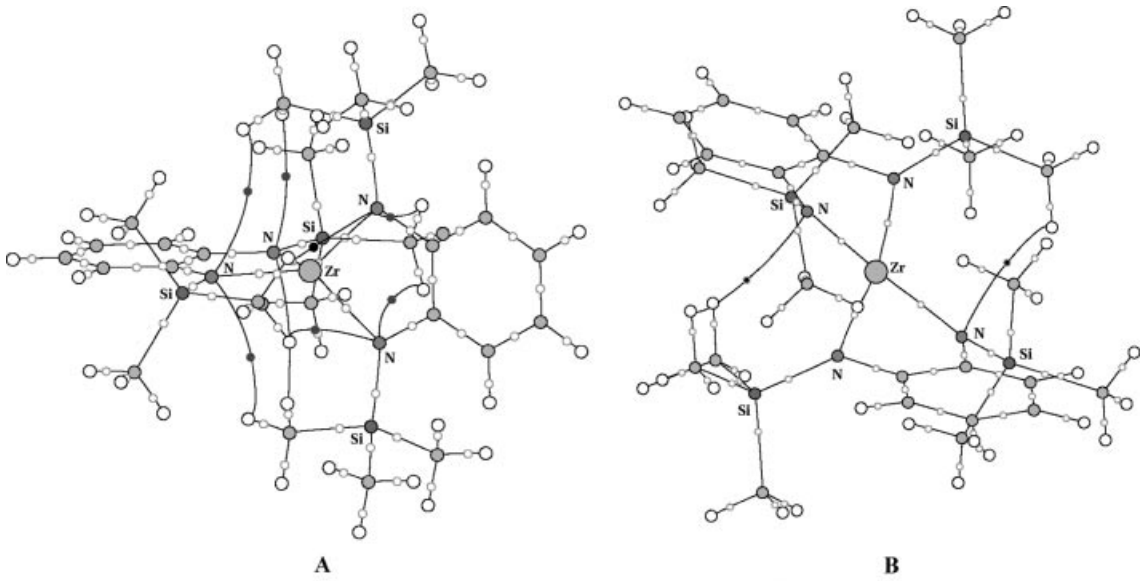

Figure 10. Molecular graphs of the $D_{2d}$- and $C_2$-symmetric models **7c** and **7d** (A and B, respectively). All calculated bcp's are shown except for ring and cage critical points. The black bcp's represent curves associated with the N···H interactions.

between the isomers and the isolation of this complex in the solid state. Recall that when the metallacycles are folded, the N pπ orbitals of the DAD ligands (lone pair combinations) give rise to σ-type interactions with the metal center. In this case, the feature is contrasted by the hydrogen bonding, which, by restricting the added donor capabilities of the combined nitrogen atoms, can partially favor the planar conformation.

In any case, the planar metallacycles observed in complex **7** must be considered rather exceptional and are only possible when at least three main factors occur simultaneously. These are: i) the peculiar conformation of the $Me_3Si$-substituted DAD ligands, which places one $CH_3$ group over the Zr–N bonds; ii) the role played by the eight N···H interactions; iii) the incorporation of the aromatic backbone in DAD. In fact, when [Zr($Me_3$Si-DAD)$_2$] models are optimized with the simplest enediamido skeleton in place of the *o*-phenylenediamido one, the bent conformation is stabilized by as much as –19.3 kcal mol$^{-1}$. In this case, a QTAIM analysis reveals no bcp's associated with any N···H interaction.

## 8. Relationship Between [M(DAD)$_3$] and [M(DAD)$_2$] Complexes

The existence of both the 1:2 and 1:3 homoleptic species also raises the interesting problem of their interconvertibility. The energies of all the species that appear in Equation (1) are available, which means that it should be possible to gain some useful hints regarding their interconversion.

$$[Ti(Me\text{-}DAD)_2] + Me\text{-}DAD \rightleftharpoons [Ti(Me\text{-}DAD)_3] \quad (1)$$
