This structure is similar to those reported for $[Au_4(SMe)_2(PMe_3)_4]^{2+}$[6d] and $[Au_4(SCMe_3)_2(PPh_3)_4]^{2+}$,[15] prepared by different routes.

The structure of the tetranuclear cation present in the crystal of **5e**·$CH_2Cl_2$ is shown in Figure 5 and the bond lengths and angles around the metal are listed in Table 4. The projection has been done down the twofold axis, which relates the two moieties of the cation, point group 2 ($C_2$ in the Schoenflies notation). The gold atoms are arranged in a sort of zigzag chain. A similar metal arrangement has been found in Ag,[16a,16b] Ag–Pd[16c] Ni,[16d] Mo[16e] and Ta[16f] derivatives, but it has never been reported for gold. Different from almost all these examples, where the metal chain is lying on a plane, the chain of gold atoms is mark-

edly puckered so that it may be described as a tetrahedron heavily distorted by the stretching of some edges. The three shortest edges correspond to the drawn bonds Au(1)–Au(2), Au(2)–Au(2′) and Au(2′)–Au(1′), while the other three, Au(1)···Au(2′) and Au(2)···Au(1′), 3.717 Å, and Au(1)···Au(1′), 4.903 Å, correspond to non-bonding distances. The torsion angle Au(1)–Au(2)–Au(2′)–Au(1′), which in an undistorted tetrahedron is 70.5°, in our chain rises to 107.8° and only one of the twofold axes of the ideal tetrahedron is preserved.

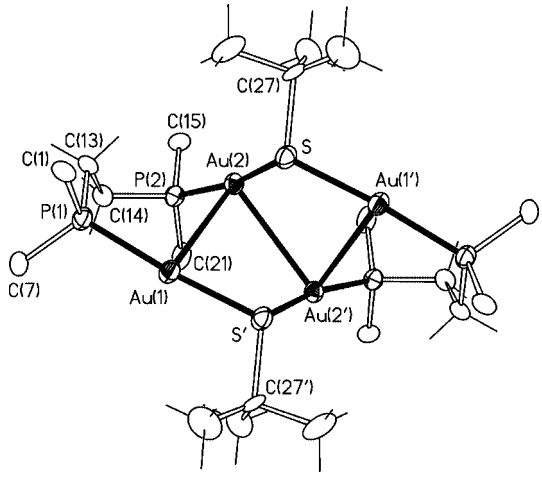

Figure 5. View of the structure of the cationic part of **5e** projected down the twofold axis. The phenyl groups of dppe have been omitted apart from the carbon atoms connected to the phosphorus atoms. Thermal ellipsoids are at 30% probability. ′ = –*x*, *y*, 1/2 – *z*.

Table 4. Selected bond lenghts [Å] and angles [°] in **3d**. The apexes in the atom labels have the same meaning as in Figure 4.

| | | | |

| Au(1)–P(1)–C(13) | 112.5(6) | Au(2)–P(2)–C(14) | 110.3(6) |
| Au(2)–P(2)–C(15) | 112.2(7) | Au(2)–P(2)–C(21) | 118.0(6) |

Although both Au(1)–Au(2) and Au(2)–Au(2′) distances fall within the aurophilic bond range, the second one, 3.152 Å, suggests a rather weak interaction and being associated with a wide Au–S–Au angle, 105.6°, is in keeping with the suggested relationship between this angle and the strength of the gold–gold interaction.[15]

Hence, the corrected formulations for the complexes in the solid state are $[Au_4(SR)_2(L)_4][BF_4]_2$. On the basis of these results and on the literature reports we think that the other cationic compounds prepared have a similar structure, based on a core of four gold atoms associated by aurophilic interactions.

It is not clear if such structures will survive in solution (the literature is not conclusive in this regard). ESI-MS spectra of these complexes in methanol show peaks that can be attributed both to the corresponding dinuclear monocation and to the tetranuclear dication. However, in the case of $[Au_4(SCH_2CHMe_2)_2(PMe_3)_4][BF_4]_2$ (**6a**) and $[Au_4(SCH_2CHMe_2)_2(PPh_3)_4][BF_4]_2$ (**6d**), the spectra show, in addition to the peaks at *m*/*z* = 635 and 1007 for $[Au_2(SR)(PMe_3)_2]^+$ and $[Au_4(SR)_2(PMe_3)_4]^{2+}$, respectively, species at high molecular weights, e.g. $[Au_3(SR)_3(PMe_3)_2]^+$, $[Au_3(SR)_2(PMe_3)_2]^+$ and $[Au_3(SR)(PMe_3)_3]^+$, but it is not certain if those species derive from fragmentation of the tetranuclear species or from the aggregation of small fragments. Moreover, close inspection of the peak corresponding to $[Au_2(SR)(PMe_3)_2]^+$ shows that, in addition to the expected M, M + 1, M + 2 peaks, signals at M + 1/2 are present, which are assigned to the dicationic species $[Au_4(SR)_2(PMe_3)_4]^{2+}$. These observations suggest that tetranuclear species are present in solution (perhaps together with the dinuclear ones) although further experimental evidences are necessary in order to draw clear-cut conclusions.

## Reactions with Nucleophiles

### *Thiolate Anions*

The cationic gold clusters can be converted back to the neutral thiolates by reaction with the thiolato anion generated in situ: in fact reacting $[Au_4(SCMe_3)_2(PMe_3)_4][BF_4]_2$ (**4a**) with 2 equiv. of 2-methyl-2-propanethiol in the presence of a base (ethanolamine) produces almost quantitatively $[Au(SCMe_3)(PMe_3)]$ (**2a**). The reaction can easily be followed by $^1$H NMR spectroscopy. By adding a stoichiometric amount of 2-methyl-2-propanethiol and ethanolamine in a 1:1 molar ratio to a $CD_2Cl_2$ solution of the dication the signals from the initial cationic complex **4a** disappear immediately and the resonances from the protons of the neutral thiolate **2a** arise.

$$[Au_4(SCMe_3)_2(PMe_3)_4]^{2+} \xrightarrow[Me_3CSH/ethanolamine]{CH_2Cl_2} [Au_2(SCMe_3)_2(PMe_3)_4]$$

### *Lithium Alkyls*

We decided to study the reaction of $[Au_4(SCMe_3)_2(PMe_3)_4][BF_4]_2$ with LiMe and $LiCH_2CMe_3$ because of the spectral simplicity of the expected alkyl derivatives.

The reactions have been carried out with an excess of the alkylating agent in dichloromethane. When $[Au_4(SCMe_3)(PMe_3)_4][BF_4]_2$ was reacted with LiMe, after hydrolysis and extraction with benzene, a solid was obtained whose $^1$H NMR spectrum shows, in addition to the signals of $[Au(SCMe_3)(PMe_3)]$, two doublets at $\delta$ = 0.59 ppm ($J$ = 8.8 Hz) and 1.23 ppm ($J$ = 8.4 Hz). These signals, having a relative intensity of 3:1, could be attributed quite naturally to the $PMe_3$ and AuMe protons in $[Au(Me)(PMe_3)]$. Accordingly the $^{31}$P NMR spectrum of the reaction mixture shows the presence of signals at $\delta$ =

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

–3.51 ppm, corresponding to the gold phosphanyl thiolate $[Au(SCMe_3)(PMe_3)]$, and $\delta$ = 10.74 ppm, which seems logical to attribute to $[Au(Me)(PMe_3)]$.

Surprisingly our NMR spectroscopic data are not in agreement with those reported in the literature for $[Au(Me)(PMe_3)]$, prepared from $[Au(Cl)(PMe_3)]$ by alkylation with LiMe in diethyl ether ($\delta$ = 0.21 ppm, $J_{P,H}$ = 8.9 Hz and $\delta$ = 0.57 ppm, $J_{H,H}$ = 8.7 Hz).[17] We have prepared $[Au(Me)(PMe_3)]$ following the reported procedure,[18] and we found the same $^1H$ NMR signals as the methyl derivative formed by reacting $[Au_4(SCH_2CHMe_2)_2(PMe_3)_4][BF_4]_2$ with LiMe. The $^{31}P$ NMR spectrum showing a signal at $\delta$ = 12.35 ppm is rather consistent with the above value of $\delta$ = 10.74 ppm. The product reacts rapidly and quantitatively in deuterated benzene with an excess of trifluoroacetic acid, forming methane and $[Au(OOCF_3)(PMe_3)]$ as shown by the immediate appearance in the $^1H$ NMR spectrum of a singlet at $\delta$ = 0.14 ppm (methane) and in the $^{31}P$ NMR spectrum of a signal at $\delta$ = –16.14 ppm, to be attributed to $[Au(OOCF_3)(PMe_3)]$. This was unequivocally identified by purification and comparison of the $^1H$ NMR spectrum in $CDCl_3$ with that reported in the same solvent ($\delta$ = 1.68 ppm, d, $J_{P,H}$ = 11.36 Hz).[19]

Only an X-ray single-crystal determination could positively clarify this point but so far we have not been able to prepare suitable crystals.

$[Au_4(SCMe_3)_2(PMe_3)_4][BF_4]_2$ was similarly reacted with $LiCH_2CMe_3$ yielding an equimolar mixture of $[Au(SCMe_3)(PMe_3)]$ and $[Au(CH_2CMe_3)(PMe_3)]$. The neopentylgold derivative, which has not been reported in the literature thus far, was prepared by alkylation of the corresponding chloro derivative with $LiCH_2CMe_3$ in diethyl ether. The product was isolated as a white crystalline solid, which, even when stored under nitrogen at room temperature and out of light, becomes gradually grey after a few weeks. However, the complex shows well resolved NMR spectra in $CD_2Cl_2$. The $^1H$ NMR spectrum shows a singlet at $\delta$ = 1.01 ppm and a doublet at $\delta$ = 1.22 ppm ($J_{H,H}$ = 8.4 Hz) corresponding to the methyl and methylene protons, respectively, of the neopentyl group and a doublet at $\delta$ = 1.41 ppm ($J_{P,H}$ = 8.4 Hz) corresponding to the trimethylphosphane; accordingly the $^{31}P$ NMR spectrum shows a singlet at $\delta$ = 16.60 ppm. The reaction with trifluoroacetic acid in deuteriobenzene gave neopentane (singlet at $\delta$ = 0.89 ppm) and $[Au(OOCF_3)(PMe_3)]$, as expected.

These results show that, from the reaction of the above cationic gold thiolates with alkyllithium reagents, half of the metal centres undergo alkylation and the other half are released as a neutral phosphane thiolate:

$$[Au_4(SCMe_3)(PMe_3)_4]^{2+} \xrightarrow{LiR} [Au(SCMe_3)(PMe_3)] + 2\,[Au(R)(PMe_3)]$$

$R = Me, CH_2CMe_3$

## Conclusions

We report here the synthesis and characterization of a series of gold(I) thiolates, in which the thiolato ligands contain aliphatic $C_4$ and $C_5$ alkyls with different steric hindrance, or a trityl group. The aliphatic thiols give neutral gold thiolates that do not exhibit any Au–Au bonding interactions in the solid state, but upon oxidation afford cationic derivatives that at least in the solid state dimerize to dicationic tetranuclear species with pairs of gold atoms bonded by aurophilic interactions. As in the majority of the literature reports, the arrangement was found to be almost square in the case of **7a** but in the case of **5e**, where dppe is the phosphane supporting ligand, an unusual zigzag organization has been found. It is obviously premature to make a pertinent theory but we are attempting to attribute this peculiar structure to the presence of a chelating phosphane.

Apart from this dinuclear–tetranuclear issue, these cationic thiolates behave towards nucleophiles as $[Au(SR)(PMe_3)]$-stabilized $[Au(PMe_3)]^+$ cations losing the neutral complex and adding the nucleophile. This reactivity confirms that the aurophilic interactions and also the bridging thiolato ligands, which are responsible for the variety of structures in the solid state for gold(I), are easily disrupted in solution.

## Experimental Section

All manipulations and reactions were carried out under dinitrogen or argon using standard techniques. Diethyl ether and benzene were distilled prior to use, first over K/benzophenone and later over $LiAlH_4$. *n*-Pentane, $CH_2Cl_2$ and ethanol were dried under vacuum over molecular sieves. $^1H$ and $^{31}P$ NMR spectra were recorded with a Varian Gemini 200 instrument, working at 200 MHz. Centesimal analysis have been executed in the microanalysis laboratory of Dipartimento di Scienze Farmaceutiche dell'Università di Pisa. The mass spectra were obtained by an Ion Spray technique with the Perkin–Elmer instrument SCIEX API III, in methanol solution. Material and apparatus for electrochemistry have been described elsewhere.[20] All of the potential values refer to the Saturated Calomel Electrode (SCE). Under the present experimental conditions the one-electron oxidation of ferrocene occurs at +0.39 V. $[Au(SCMe_3)]_n$ was prepared according to the literature.[3a] $[Au(SCH_2CHMe_2)]_n$ was prepared in the same way (yield 93%). $C_4H_9AuS$ (286.15): calcd. C 16.79, H 3.17; found C 16.64, H 3.20. Neopentanethiol was prepared by a literature procedure[21] from the corresponding neopentyl tosylate, obtained from neopentyl alcohol and tosyl chloride in pyridine [yield 95%. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.91 (s, 9 H, $CMe_3$), 2.46 (s, 3 H, MePh), 3.67 (s, 2 H, $CH_2S$) ppm] by treatment with NaSH in methoxyethanol [yield 21%. $^1H$ NMR ($CDCl_3$): $\delta$ = 0.96 (s, 9 H, Me), 1.20 (t, 1 H, $J_{H,H}$ = 8.8 Hz, SH), 2.41 (d, 2 H, $J_{H,H}$ = 8.8 Hz, $CH_2S$) ppm].

**Preparation of $[Au(SCH_2CMe_3)]_n$**

**Method A:** Neopentanethiol (0.327 g, 3.14 mmol) was added dropwise to an aqueous solution of $H[AuCl_4]$ (29.34 wt.-% Au) (0.676 g, 1 mmol Au) in EtOH (2.6 mL). An exothermic reaction occurred with the formation of a brown solid that turned white in 30 min. The mixture was heated at 50 °C for 10 min, and the white solid was then separated from the solvent by settling, washed first with

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

EtOH (2 × 10 mL) and then with $Et_2O$ (2 × 10 mL). The residual solvent was removed under vacuum to give a solid product (0.294 g, 98%), which is insoluble in the most common organic solvent. $C_5H_{11}AuS$ (300.17): calcd. C 20.01, H 3.69; found C 20.0, H 4.0.

**Method B:** An aqueous solution of bis(2-hydroxyethyl) sulfide (2 mL, 2.0 mmol) was added dropwise at 0 °C to a solution of $H[AuCl_4]\cdot xH_2O$ (1.05 mmol) in water (1 mL) and EtOH (2.6 mL). The stirring was maintained until the solution turned colourless. Neopentanethiol (0.109 g, 1.05 mmol) was added and a white solid began to precipitate immediately from the solution. After stirring for 30 min, the solid product was separated, washed as described above and dried under vacuum (0.234 g, 78%).

**Reaction of $[Au(SCMe_3)]_n$ with L (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$, dppe). Formation of $[Au(SCMe_3)(L)]$ (1a, 1b, 1c, 1d, 1e):** The reaction of $[Au(SCMe_3)]_n$ with $PMe_3$ is reported as an example. Trimethylphosphane (0.6 mL of a 1 M solution in toluene, 0.6 mmol) was added to a suspension of $[Au(SCMe_3)]_n$ (0.152 g, 0.53 mmol) in toluene (10 mL) while stirring. The solid immediately dissolved to give a clear colourless solution, which was kept stirring for a further 30 min. The solution was concentrated under vacuum to ca 3 mL and pentane (15 mL) was added causing a white solid to precipitate. The solid was washed twice with pentane (15 mL) and recrystallized from toluene to give 0.187 g (98%) of **1a**. $C_7H_{18}AuPS$ (362.23): calcd. C 23.21, H 5.01; found C 23.3, H 5.3. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.90 (s, 9 H, $CMe_3$), 0.55 (d, 9 H, $J_{H,P}$ = 9.5 Hz, $PMe_3$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 0.61 ppm.

The complexes **1b**–**1e** were prepared in a similar manner to that of $[Au(SCMe_3)]_n$ by reaction with the appropriate phosphane.

**Complex 1b:** Yield 90%. $C_{12}H_{20}AuPS$ (424.30): calcd. C 33.97, H 4.75; found C 33.52, H 4.95. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.95 (s, 9 H, $CMe_3$), 0.81 (d, 6 H, $J_{H,P}$ = 9.5 Hz $PMe_2$), 7.02 (5 H, br. m, PPh) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 13.01 ppm.

**Complex 1c:** Yield 97%. $C_{17}H_{22}AuPS$ (486.37): calcd. C 41.98, H 4.56; found C 41.79, H 4.45. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.94 (s, 9 H, $CMe_3$), 1.21 (d, 3 H, $J_{H,P}$ = 8.8 Hz, PMe), 7.10 (10 H, br. m, $PPh_2$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 25.00 ppm.

**Complex 1d:** Yield 95%. $C_{22}H_{24}AuPS$ (548.44): calcd. C 48.18, H 4.41; found C 47.96, H 4.27. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.92 (s, 9 H, $CMe_3$), 6.80–6.92 (9 H, br. m, $PPh_3$), 7.25–7.40 (6 H, br. m, $PPh_3$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 38.77 ppm.

**Complex 1e:** Yield 89%. $C_{34}H_{42}Au_2P_2S_2$ (970.72): calcd. C 42.07, H 4.36; found C 41.95, H 4.28. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.90 (s, 9 H, $CMe_3$), 2.68 (s, 4 H, $PCH_2$), 6.8–7.0, 7.4–7.6 (20 H, br. m, $PPh_2$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 37.64 ppm.

**Reaction of $[Au(SCH_2CHMe_2)]_n$ with L (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$, dppe). Formation of $[Au(SCH_2CHMe_2)(L)]$ (2a, 2b, 2c, 2d, 2e):** The following complexes were prepared as described before.

**Complex 2a:** White solid. Yield 79%. $C_7H_{18}AuPS$ (362.23): calcd. C 23.21, H 5.01; found C 22.97, H 4.88. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.45 (d, 9 H, $J_{H,P}$ = 9.9 Hz, $PMe_3$), 1.23 (d, 6 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 2.10 (m, 1 H, $J_{H,H}$ = 6.6 Hz, CH), 3.32 (d, 2 H, $J_{H,H}$ = 6.6 Hz, $SCH_2$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = –0.40 ppm.

**Complex 2b:** Grey oil. Yield 77%. $C_{12}H_{20}AuPS$ (424.30): calcd. C 33.97, H 4.75; found C 33.77, H 4.53. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.86 (d, 6 H, $J_{H,P}$ = 9.9 Hz, $PMe_2$), 1.30 (d, 6 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 2.14 (m, 1 H, $J_{H,H}$ = 6.6 Hz, CH), 3.37 (d, 2 H, $J_{H,H}$ = 6.6 Hz, $SCH_2$), 6.8–7.3 (5 H, br. m, PPh) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 11.31 ppm.

**Complex 2c:** Grey oil. Yield 81%. $C_{17}H_{22}AuPS$ (486.37): calcd. C 41.98, H 4.56; found C 41.78, H 4.25. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.26 (d, 6 H, $J_{H,H}$ = 6.2 Hz, $Me_2$), 1.34 (d, 3 H, $J_{H,P}$ = 9.5 Hz, PMe), 2.11 (m, 1 H, $J_{H,H}$ = 6.4 Hz, CH), 3.38 (d, 2 H, $J_{H,H}$ = 6.2 Hz, $CH_2$), 6.8–7.4 (10 H, br. m, $PPh_2$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 23.53 ppm.

**Complex 2d:** White crystals. Yield 75%. $C_{22}H_{24}AuPS$ (548.44): calcd. C 48.18, H 4.41; found C 48.0, H 4.3. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.27 (d, 6 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 2.10 (m, 1 H, $J_{H,H}$ = 6.6 Hz, CH), 3.37 (d, 2 H, $J_{H,H}$ = 6.6 Hz, $SCH_2$), 6.7–7.4 (15 H, br. m, $PPh_3$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 38.64 ppm.

**Complex 2e:** White solid. Yield 65%. $C_{34}H_{42}Au_2P_2S_2$ (970.72): calcd. C 42.07, H 4.36; found C 41.8, H 4.2. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.25 (d, 12 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 2.09 (m, 2 H, $J_{H,H}$ = 6,6 Hz, CH), 2.57 (br. s, 4 H, $PCH_2$), 3.37 (d, 4 H, $J_{H,H}$ = 6.6 Hz, $CH_2$), 6.7–7.5 (20 H, br. m, $PPh_2$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 37.60 ppm.

**Reaction of $[Au(SCH_2CMe_3)]_n$ with L (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$, dppe). Formation of $[Au(SCH_2CMe_3)(L)]$ (3a, 3b, 3c, 3d, 3e):** The following complexes were prepared as described above.

**Complex 3a:** White crystals. Yield 99%. $C_8H_{20}AuPS$ (376.25): calcd. C 25.5, H 5.4; found C 25.54, H 5.36. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.02 (s, 9 H, $CMe_3$), 1.56 (d, 9 H, $J_{H,P}$ = 10.3 Hz, $PMe_3$), 2.80 (s, 2 H, $SCH_2$) ppm. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.62 (d, 9 H, $J_{H,P}$ = 10.3 Hz, $PMe_3$), 1.33 (s, 9 H, $CMe_3$), 3.37 (s, 2 H, $SCH_2$) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 0.10 ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = –1.03 ppm.

**Complex 3b:** Crystallized from $Et_2O$. Yield 85%. $C_{13}H_{22}AuPS$ (438.32): calcd. C 35.62, H 5.06; found C 35.52, H 5.4. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.98 (d, 6 H, $J_{H,P}$ = 7.3 Hz 1.34, $PMe_2$), (s, 9 H, $CMe_3$); 3.42 (s, 2 H, $CH_2S$), 7.00 (3 H, br. m, PPh), 7.27 (2 H, br. m, PPh) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 3.53 ppm.

**Complex 3c:** Crystallized from $Et_2O$. Yield 90%. $C_{18}H_{24}AuPS$ (500.39): calcd. C 43.21, H 4.83; found C 43.10; H 5.01. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.29 (d, 3 H, PMe), 1.32 (s, 9 H, $CMe_3$); 3.41 (s, 2 H, $CH_2S$); 6.92 (6 H, br. m, PPh); 7.28 (m, 4 H, $PPh_2$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 16.64 ppm.

**Complex 3d:** White crystals from toluene at –5 °C. Yield 97%. $C_{23}H_{26}AuPS$ (562.47): calcd. C 49.11, H 4.66; found C 48.93, H 4.8. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.05 (s, 9 H, $CMe_3$), 2.92 (s, 2 H, $SCH_2$), 7.53–7.54 (15 H, br. m, $PPh_3$) ppm. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.31 (s, 9 H, $CMe_3$), 3,40 (s, 2 H, $SCH_2$), 6.88 (m, 9 H, $PPh_3$), 7.29 (6 H, br. m, $PPh_3$) ppm. $^{31}P$ NMR ($CDCl_3$): $\delta$ = 39.26 ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 36.21 ppm.

**Complex 3e:** Crystallized from toluene at –5 °C. Yield 90%. $C_{36}H_{46}P_2S_2Au_2$ (998.77): calcd. C 43.29, H 4.64; found C 43.09, H 4.47. $^1H$ NMR ($CDCl_3$): $\delta$ = 1.07 (s, 18 H, $CMe_3$), 2.71 (s, 4 H, $CH_2S$), 3.02 (s, 4 H, $PCH_2$), 7.29–7.67 (20 H, br. m, $PPh_2$) ppm. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.29 (s, 18 H, $CMe_3$), 2.68 (s, 4 H, $PCH_2$), 3.41(s, 4 H, $CH_2S$), 6.91 (12 H, br. m, $PPh_2$), 7.51 (8 H, br. m, $PPh_2$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 37.38 ppm.

**Preparation of $[Au(SCPh_3)]_n$. Method A:** Triphenylmethanethiol (1.076 g, 3.9 mmol) suspended in EtOH (10 mL) was added slowly to a solution of $H[AuCl_4]\cdot xH_2O$ (1.3 mmol) in water (1 mL) and EtOH (5 mL): the mixture was stirred for 3 h and a beige solid was formed. The solid was separated and washed with water (2 × 30 mL), EtOH (20 mL) and $Et_2O$ (20 mL). A beige solid was obtained (0.565 g, 92%). $C_{19}H_{15}AuS$ (472.36): calcd. C 48.31, H 3.20; found C 46.7, H 2.9. Mp: 128° (dec).

**Method B:** Bis(2-hydroxyethyl) sulfide (0.3 mL, 3 mmol) was added dropwise whilst stirring to 0.671 g of a solution of $H[AuCl_4]\cdot xH_2O$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(1.0 mmol) in water (10 mL) at 0 °C, causing a precipitate to form. Triphenylmethanethiol (0.276 g, 1 mmol) in $CHCl_3$ (20 mL) was added slowly in ca. 20 min and the reaction mixture stirred for 1 hour giving a grey precipitate. After addition of MeOH (40 mL), the solid was separated, washed with MeOH (2 × 40 mL) and dried (0.40 g, 85%).

**Reaction of $[Au(SCPh_3)]_n$ with L (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$, dppe): Formation of $[Au(SCPh_3)(L)]$ (4a, 4b, 4c, 4d, 4e)**

**Complex 4a:** pale yellow crystals. Yield 61%. $C_{21}H_{24}AuPS$ (536.43): calcd. C 46.0, H 4.4; found C 45.7, H 4.2. Mp = 118 °C (dec). $^1H$ NMR ($C_6D_6$): $\delta$ = 0.37 (d, 9 H, $J_{PH}$ = 10.2 Hz, $PMe_3$), 6.8–7.4 (9 H, br. m, $CPh_3$), 8.06 (d, 6 H, $J_{H,H}$ = 7.3 Hz, $CPh_3$) ppm.$^{31}P$ NMR ($C_6D_6$): $\delta$ = 6.41 ppm.

**Complex 4b:** Pale yellow crystals. Yield 46%. $C_{26}H_{26}AuPS$ (598.50): calcd. C 51.1, H 4.3; found C 50.7, H 4.1. $^1H$ NMR ($C_6D_6$): $\delta$ = 0.69 (d, 6 H, $J_{H,P}$ = 9.9 Hz, $PMe_2$), 6.8–8.2 (m, 14 H, $CPh_3$ + PPh), 8.08 (d, 6 H, $J_{H,H}$ = 7.3 Hz, $CPh_3$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 40.18 ppm.

**Complex 4c:** Pale yellow microcrystals. Yield 52%. $C_{31}H_{28}AuPS$ (660.57): calcd. C 55.4, H 4.2; found C 55.2, H 4.1. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.07 (d, 3 H, $J_{H,P}$ = 9.2 Hz, PMe), 6.8–8.2 (m, 19 H, $CPh_3$ + $PPh_2$), 8.09 (d, 6 H, $J_{H,H}$ = 7.7 Hz, $CPh_3$) ppm.$^{31}P$ NMR ($C_6D_6$): $\delta$ = 42.07 ppm.

**Complex 4d:** White solid. Yield 71%. $C_{36}H_{30}AuPS$ (722.64): calcd. C 59.0, H 4.1; found C 58.7, H 3.9. Mp = 140 °C (dec). $^1H$ NMR ($C_6D_6$): $\delta$ = 6.8–7.3 (m, 24 H, $PPh_3$ + $CPh_3$), 8.08 (d, 6 H, $J_{H,H}$ = 7.3 Hz, $CPh_3$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 48.22 ppm.

**Complex 4e:** Pale yellow microcrystals. Yield 87%. $C_{64}H_{54}Au_2P_2S_2$ (1343.14): calcd. C 57.2, H 4.0; found C 56.8, H 4.2. $^1H$ NMR ($C_6D_6$): $\delta$ = 2.0–2.5 (4 H, br. m, $PCH_2$), 6.8–7.4 (m, 50 H, $PPh_2$ + $CPh_3$), 8.05 (d, 12 H, $J_{H,H}$ = 7.7 Hz, $CPh_3$) ppm. $^{31}P$ NMR ($C_6D_6$): $\delta$ = 42.88 ppm.

**Reaction of $[Au(SCMe_3)(L)]$ (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$) with $[FeCp_2][BF_4]$. Formation of $[Au_4(SCMe_3)_2(L)_4][BF_4]_2$ (L = 5a, 5b, 5c, 5d):** The reaction of $[Au(SCMe_3)(PMe_3)]$ with $[FeCp_2][BF_4]$ is reported as an example. $[FeCp_2][BF_4]$ (0.037 g, 0.136 mmol) was added to a solution of $[Au(SCMe_3)(PMe_3)]$ (0.100 g, 0.276 mmol) in dichloromethane (10 mL) and the mixture was stirred for 30 min giving a deep yellow solution. The solvent was evaporated and the solid residue was washed with $Et_2O$ (2 × 10 mL), followed by benzene (10 mL), dried under vacuum and crystallized from dichloromethane at –5 °C as colourless crystals (0.094 g, 94%). $C_{20}H_{54}Au_4B_2F_8P_4S_2$ (1444.15): calcd. C 16.6, H 3.8; found C 16.9, H 3.4. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.60 (s, 18 H, $CMe_3$), 1.83 (d, 36 H, $J_{H,P}$ = 11.7 Hz, $PMe_3$) ppm. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.60 (s, 18 H, $CMe_3$), 1.71 (d, 36 H, $J_{H,P}$ = 11.0 Hz, $PMe_3$) ppm. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 4.58 ppm. ESI-MS (methanol): *m/z* = 635 $[Au_2(SCMe_3)(PMe_3)_2]^+$, 579 $\{[Au_2(SCMe_3)(PMe_3)_2]^+ - C_4H_8\}$, 273 $[Au(PMe_3)]^+$, 87 $[BF_4]^-$. The organic phase was evaporated to dryness giving a solid from which ferrocene sublimates as yellow-orange crystals at 40 °C under high vacuum. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 4.18 ppm. The white residue was identified as $(SCMe_3)_2$. $^1H$ NMR($CD_2Cl_2$): $\delta$ = 1.31 ppm.

**Complex 5b:** Colourless crystals. Yield 92%. $C_{40}H_{62}Au_4B_2F_8P_4S_2$ (1692.43): calcd. C 28.4, H 3.7; found C 28.1, H 3.5. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.65 (s, 18 H, $CMe_3$); 7.60 (m, 12 H, PPh); 7.95 (m, 8 H, PPh) ppm. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.67 (s, 18 H, $CMe_3$), 1.93 (d, 24 H, $J_{H,P}$ = 11.0 Hz, $PMe_2$), 7.62 (m, 20 H, PPh) ppm. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 15.92 ppm. ESI-MS (methanol): *m/z* = 759 $[Au_2(SCMe_3)(PMe_2Ph)_2]^+$, 703 $\{[Au_2(SCMe_3)(PMe_2Ph)_2]^+ - C_4H_8\}$.

**Complex 5c:** Colourless crystals. Yield 95%. $C_{60}H_{70}Au_4B_2F_8P_4S_2$ (1940.72): calcd. C 37.1, H 3.6; found C 37.4, H 3.7. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.68 (s, 18 H, $CMe_3$), 2.42 (d, 12 H, $J_{H,P}$ = 10,3 Hz, PMe), 7.58 (m, 24 H, PPh), 7.84 (m, 16 H, PPh) ppm. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.67 (s, 18 H, $CMe_2Ph_3$), 2.20 (d, 12 H, $J_{H,P}$ = 10.3 Hz, PMe), 7.52 (40 H, br. m, PPh) ppm. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 27.51 ppm. ESI-MS (methanol): *m/z* = 883 $[Au_2(SCMe_3)(PMePh_2)_2]^+$, 817 $\{[Au_2(SCMe_3)(PMePh_2)_2]^+ - C_4H_8\}$.

**Complex 5d:** Colourless crystals. Yield 96%. $C_{80}H_{78}Au_4B_2F_8P_4S_2$ (2189.00): calcd. C 43.9, H 3.6; found C 43.6, H 3.4. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.70 (s, 9 H, $CMe_3$), 7.62 (15 H, br. m, $PPh_3$) ppm. $^1H$ NMR (200 MHz, $CD_2Cl_2$): $\delta$ = 1.75 (s, 9 H, $CMe_3$), 7.48 (15 H, br. m, $PPh_3$) ppm. $^1H$ NMR ($CD_3OD$): $\delta$ = 1.64 (s, 9 H, $CMe_3$), 7.49 (15 H, br. m, $PPh_3$) ppm. $^{31}P$ NMR ($CD_2Cl_2$): $\delta$ = 43.02 ppm. ESI-MS (methanol): *m/z* = 1007.3 $[Au_2(SCMe_3)(PPh_3)_2]^+$, 87 $[BF_4]^-$.

**Reaction of $[Au(SCH_2CHMe_2)(L)]$ (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$) with $[FeCp_2][BF_4]$. Formation of $[Au_4(SCH_2CHMe_2)_2(L)_4][BF_4]_2$ (6a, 6b, 6c, 6d):** Following the above procedure $[Au(SCH_2CHMe_2)(PMe_3)]$ (0.130 g, 0.36 mmol) in $CH_2Cl_2$ (10 mL) was treated with $[FeCp_2][BF_4]$ (0.050 g, 0.18 mmol). The solvent was evaporated under vacuum and the residue was washed with pentane (2 × 30 mL) and benzene (2 × 30 mL). Crystallization from $CH_2Cl_2/Et_2O$ afforded a white solid (0.111 g, 86%). $C_{20}H_{54}Au_4B_2F_8P_4S_2$ (1444.15): calcd. C 16.6, H 3.7; found C 16.5, H 3.7. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.22 (d, 12 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 1.81 (d, 36 H, $J_{PH}$ = 11.7 Hz, $PMe_3$), 3.17 (d, 4 H, $J_{H,H}$ = 6,6 Hz, $CH_2$) ppm. $^{31}P$ NMR ($CD_3COCD_3$): $\delta$ = 2.80 ppm. ESI (MeOH): *m/z* = 635 $[Au_2(SCH_2CHMe_2)(PMe_3)_2]^+$, 349 $[Au(PMe_3)_2]^+$, 273 $[Au(PMe_3)]^+$. From the hydrocarbon extracts the solvent was evaporated leaving a solid residue, from which ferrocene [$^1H$ NMR ($CD_2Cl_2$): $\delta$ = 4.12 ppm] was obtained by sublimation under vacuum at 40 °C leaving a residue identified as $(SCH_2CHMe_2)_2$ [$^1H$ NMR (200 MHz, $CD_2Cl_2$): $\delta$ = 0.99 (d, 12 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 1.83 (m, 2 H, $J_{H,H}$ = 6.6 Hz, CH), 2.59 (d, 4 H, $J_{H,H}$ = 6.6 Hz, $CH_2$) ppm].

**Complex 6b:** Off-white crystals. Yield 55%. $C_{40}H_{62}Au_4B_2F_8P_4S_2$ (1692.43): calcd. C 28.4, H 3.7; found C 28.2, H 3.5. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.12 (d, 12 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 2.06 (d, 24 H, $J_{PH}$ = 11.0 Hz, $PMe_2$), 3.21 (d, 4 H, $J_{H,H}$ = 6.2 Hz, $CH_2$), 7.6–8.0 (20 H, br. m, PPh) ppm. $^{31}P$ NMR ($CD_3COCD_3$): $\delta$ = 14.83 ppm.

**Complex 6c:** Pale yellow solid. Yield 57%. $C_{60}H_{70}Au_4B_2F_8P_4S_2$ (1940.72): calcd. C 37.1, H 3.6; found C 36.8, H 3.4. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.16 (d, 12 H, $J_{H,H}$ = 6.6 Hz, $Me_2$); 3.26 (d, 4 H, $J_{H,H}$ = 6.2 Hz, $CH_2$), 2.39 (d, 12 H, $J_{PH}$ = 10.3 Hz, PMe), 7.2–8.0 (40 H, br. m, $PPh_2$) ppm. $^{31}P$ NMR ($CD_3COCD_3$): $\delta$ = 27.86 ppm.

**Complex 6d:** Grey solid. Yield 79%. $C_{80}H_{78}Au_4B_2F_8P_4S_2$ (2189.00): calcd. C 43.9, H 3.6; found C 43.8, H 3.3. $^1H$ NMR ($CD_3COCD_3$): $\delta$ = 1.06 (d, 12 H, $J_{H,H}$ = 6.2 Hz, $Me_2$), 1.86 (m, 2 H, $J_{H,H}$ = 6.4 Hz, CH), 3.13 (d, 4 H, $J_{H,H}$ = 6.2 Hz, $CH_2$), 7.3–7.8 (60 H, br. m, $PPh_3$) ppm. $^{31}P$ NMR ($CD_3COCD_3$): $\delta$ = 35.00 ppm. ESI-MS (MeOH): *m/z* = 1007 $[Au_2(SCH_2CHMe_2)(PPh_3)_2]^+$, 721 $[Au(PPh_3)_2]^+$, 459 $[Au(PPh_3)]^+$.

**Reaction of $[Au(SCH_2CMe_3)(L)]$ (L = $PMe_3$, $PMe_2Ph$, $PMePh_2$, $PPh_3$) with $[FeCp_2][BF_4]$. Formation of $[Au_4(SCH_2CMe_3)_2(L)_4][BF_4]_2$ (7a, 7b, 7c, 7d)**

**Complex 7a:** crystallized from dichloromethane/n-hexane to give a beige product. Yield 90%. $C_{22}H_{58}Au_4B_2F_8P_4S_2$ (1472.20): calcd. C 17.9, H 4.0; found C 17.7, H 3.8. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 1.11 (s,

18 H, $CMe_3$), 1.69 (d, 36 H, $J_{H,P}$ = 10,8 Hz, $PMe_3$), 3.10 (s, 4 H, $CH_2S$) ppm. $^1$H NMR ($CD_3COCD_3$): $\delta$ = 1.12 (s, 18 H, $CMe_3$), 1.82 (d, 36 H, $J_{H,P}$ = 11.3 Hz, $PMe_3$), 3.19 (s, 4 H, $CH_2S$) ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 2.96 ppm. ESI-MS (methanol): *m/z* 649 $[Au_2(SCH_2CMe_3)(PMe_3)_2]^+$, 349.1 $[Au(PMe_3)_2]^+$, 87 $[BF_4]^-$ ppm. From the ethereal phase ferrocene and $(SCH_2CMe_3)_2$ were isolated.

**Complex 7b:** Crystallized as off-white crystals from $CH_2Cl_2$. Yield 86%. $C_{42}H_{66}Au_4B_2F_8P_4S_2$ (1720.49): calcd. C 29.3, H 3.9; found C 29.5, H 4.2. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.15 (s, 18 H, $CMe_3$), 1.93 (d, 6 H, $J_{H,P}$ = 12.8 Hz, $PMe_2$), 3.20 (s, 4 H, $CH_2S$), 7.67 (5 H, br. m, PPh) ppm. $^1$H NMR ($CD_3COCD_3$): $\delta$ = 1.12 (s, 18 H, $CMe_3$), 3.22 (s, 4 H, $CH_2S$), 7.63 (3 H, br. m, PPh), 7.94 (2 H, br. m, PPh) ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 15.23 ppm.

**Complex 7c:** Crystallized from $CH_2Cl_2$. Yield 82%. $C_{62}H_{74}Au_4B_2F_8P_4S_2$ (1968.77): calcd. C 37.8, H 3.8; found C 37.7, H 3.6. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.17 (s, 18 H, $CMe_3$), 2.19 (d, 3 H, $J_{H,P}$ = 9.2 Hz, PMe), 3.26 (s, 4 H, $CH_2S$); 7.60 (10 H, br. m, $PPh_2$) ppm. $^1$H NMR ($CD_3COCD_3$): $\delta$ = 1.14 (s, 18 H, $CMe_3$); 2.41 (s, 3 H, PMe), 3.37 (s, 4 H, $CH_2S$), 7.58 (6 H, br. m, $PPh_2$), 7.84 (4 H, br. m, $PPh_2$) ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 28.32 ppm.

**Complex 7d:** Yellow crystals from dichloromethane/hexane. Yield 90%. $C_{82}H_{82}Au_4B_2F_8P_4S_2$ (2217.05): calcd. C 44.4, H 3.7; found C 44.5, H 3.9. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.19 (s, 18 H, $CMe_3$), 3.32 (s, 4 H, $CH_2S$), 7.44 (m, 15 H, $PPh_3$) ppm.$^1$H NMR ($CD_3COCD_3$): $\delta$ = 1.16 (s, 18 H, $CMe_3$), 3.46 (s, 4 H, $CH_2S$), 7.51 (m, 15 H, $PPh_3$) ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 42.90 ppm.

**Reaction of $[Au_2(SR)_2(dppe)]$ (R = $CMe_3$, $CH_2CHMe_2$, $CH_2CMe_3$) with $[FeCp_2][BF_4]$. Formation of $[Au_4(SR)_2(dppe)_2][BF_4]_2$ (5e, 6e, 7e)**

**Complex 5e:** pale yellow crystals. Yield 93%. $C_{60}H_{66}Au_4B_2F_8P_4S_2$ (1936.69): calcd. C 37.2, H 3.4; found C 36.7, H 3.0. $^1$H NMR ($CD_3COCD_3$): $\delta$ = 1.65 (s, 18 H, $CMe_3$), 3.28 (d, 8 H, $J_{H,P}$ = 13.2 Hz, $PCH_2$), 7.72 (20 H, br. m, $PPh_2$) ppm. $^1$H NMR (200 MHz, $CD_2Cl_2$): $\delta$ = 1.58 (s, 18 H, $CMe_3$), 2.97 (d, 8 H, $J_{H,P}$ = 12.8 Hz, $PCH_2$), 7.60 (20 H, br. m, $PPh_2$) ppm. $^1$H NMR ($CD_3OD$): $\delta$ = 1.57 (s, 18 H, $CMe_3$), 3.04 (d, 8 H, $J_{H,P}$ = 13.2 Hz, $PCH_2$), 7.62 (15 H, br. m, $PPh_2$) ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 37.87 ppm. ESI-MS (methanol): *m/z* = 880.9 ($[Au_2(SCMe_3)$-$(dppe)]^+$), 1167 $[Au_3(SCMe_3)_2(dppe)]^+$, 87 $[BF_4]^-$.

**Complex 6e:** Pale grey solid. Yield 82%. $C_{60}H_{66}Au_4B_2F_8P_4S_2$ (1936.69): calcd. C 37.2, H 3.4; found C 36.8, H 3.3. $^1$H NMR ($CD_3COCD_3$): $\delta$ = 1.00 (d, 12 H, $J_{H,H}$ = 6.6 Hz, $Me_2$), 1.84 (m, 2 H, $J_{H,H}$ = 6.6 Hz, CH), 2.84 (d, 4 H, $J_{H,H}$ = 5.9 Hz, $CH_2$), 3.17 (m, 8 H, $PCH_2$), 7.2–8.0 (40 H, br. m, $PPh_2$) ppm. $^{31}$P NMR ($CD_3COCD_3$): $\delta$ = 37.91 ppm.

**Complex 7e:** Clear beige crystals. Yield 89%. $C_{62}H_{70}Au_4B_2F_8P_4S_2$ (1964.74): calcd. C 37.9, H 3.6; found C 38.0, H 4.0. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.13 (s, 18 H, $CMe_3$), 2.94 (d, 8 H, $J_{H,P}$ = 12.5 Hz $CH_2P$), 3.36 (s, 4 H, $CH_2S$), 7.50 (20 H, br. m, $PPh_2$) ppm. $^1$H NMR ($CD_3COCD_3$): $\delta$ = 1.10 (s, 18 H, $CMe_3$), 3.15 (d, 8 H, $J_{H,P}$ = 13.2 Hz $CH_2P$), 3.60 (s, 4 H, $CH_2S$), 7.48 (m, 20 H, $PPh_2$) ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 39.11 ppm. ESI-MS (methanol): *m/z* = 895 $[Au_2(SCMe_3)(dppe)]^+$, 87 $[BF_4]^-$.

**Reaction of $[Au_4(SC_4H_9)_2(PMe_3)_4][BF_4]_2$ with 2-Methyl-2-propanethiol in the Presence of Ethanolamine:** The reaction was monitored by $^1$H NMR spectroscopy. Two NMR tubes were prepared containing a solution of $[Au_4(SC_4H_9)_2(PMe_3)_4][BF_4]_2$ (0.010 g, 0.0069 mmol) in $CD_2Cl_2$ (0.5 mL) and a solution of 2-methyl-2-propanethiol (0.0138 mmol) and ethanolamine (0.0138 mmol) in $CD_2Cl_2$ (0.5 mL). After recording the NMR spectra of the two samples as a blank the two solutions were added together and after a few minutes the resulting spectra showed the disappearance of the starting products and the presence of the signals of pure $[Au(SC_4H_9)(PMe_3)]$.

**[Au(Me)(PMe$_3$)]:** LiMe (0.3 mL of a 1.6 M solution in $Et_2O$, 0.5 mmol) was added to a suspension of $[Au(Cl)(PMe_3)]$ (0.150 g, 0.5 mmol) in $Et_2O$ (10 mL) and kept at –10 °C. The solution became yellow, then returned slowly to colourless. The reaction mixture was kept for 30 min at –10 °C and then for 2 h at room temperature. The mixture was cooled to 0 °C and was hydrolyzed with $H_2O$ (10 mL). The ethereal phase was separated, desiccated over anhydrous sodium sulfate and the solvents evaporated to dryness under vacuum. A light grey solid was recovered (0.094 g, 65%), which was stored away from the light. $C_4H_{12}AuP$ (288.08): calcd. C 16.68, H 4.20; found C 16.49, H 4.05. $^1$H NMR ($C_6D_6$): $\delta$ = 0.55 (9 H, d, $J_{H,P}$ = 8.4 Hz, $PMe_3$), 1.26 (3 H, d, $J_{H,H}$ = 8.4 Hz, $CH_3$) ppm. $^{31}$P NMR ($C_6D_6$): $\delta$ = 12.35 ppm.

**[Au(CH$_2$CMe$_3$)(PMe$_3$)]:** $Li(CH_2CMe_3)$ (0.038 g, 0.49 mmol) was added to a suspension of $[Au(Cl)(PMe_3)]$ (0.150 g, 0.49 mmol) in diethyl ether (15 mL) and the reaction was carried out as above. The mixture was then hydrolyzed with water (10 mL), the organic phase was dried with $Na_2SO_4$, concentrated and kept overnight at –20 °C. A white solid was obtained (0.149 g, 89%). $C_8H_{20}AuP$ (344.19): calcd. C 27.92, H 5.86; found C 27.65, H 5.90. $^1$H NMR ($C_6D_6$): $\delta$ = 0.53 (d, 9 H, $J_{H,P}$ = 8.8 Hz, $PMe_3$), 1.55 (s, 9 H, $CH_3$), 2.10 (d, 2 H, $J_{H,H}$ = 8.8 Hz, $CH_2$) ppm. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.01 (s, 9 H, $CH_3$), 1.23 (d, 2 H, $J_{H,H}$ = 8.4 Hz, $CH_2$), 1.41 (d, 9 H, $J_{H,P}$ = 8.4 Hz, $PMe_3$) ppm. $^{31}$P NMR ($C_6D_6$): $\delta$ = 13.16 ppm.

**Reaction of $[Au_4(SCMe_3)_2(PMe_3)_4][BF_4]_2$ with Methyllithium. Formation of [Au(SCMe$_3$)(PMe$_3$)] and [Au(Me)(PMe$_3$)]:** A large excess of LiMe (0.5 mL of a 1.6 M solution in $Et_2O$, 0.8 mmol), was added to a solution of $[Au_4(SCH_2CHMe_2)_2(PMe_3)_4][BF_4]_2$ (0.052 g, 0.04 mmol) in $CH_2Cl_2$ (15 mL). A white precipitate formed immediately. The mixture was stirred for 2 h, and then water (10 mL) was added. The organic layer was separated, desiccated over anhydrous sodium sulfate, and was then evaporated to dryness to leave a light yellow solid showing NMR spectra that are the sum of of both the signals of $[Au(SCMe_3)(PMe_3)]$ and $[Au(Me)(PMe_3)]$. $^1$H NMR ($C_6D_6$): $\delta$ = 0.62 (d, 9 H, $J_{P,H}$ = 8.8 Hz, $[Au(Me)PMe_3]$, 1.20 (d, 3 H, $J_{H,H}$ = 8.4 Hz, $CH_3$) $[Au(Me)(PMe_3)]$, 1.48 (s, 9 H, $SCMe_3$), 1.57 (d, 9 H, $J_{H,P}$ = 10.3 Hz, $SAuPMe_3$) ppm. $^{31}$P NMR ($C_6D_6$): $\delta$ = 10.74 ($[Au(Me)(PMe_3)]$), 2.95 ($[Au(SCMe_3)(PMe_3)]$) ppm.

**Reaction of $[Au_4(SCMe_3)_2(PMe_3)_4][BF_4]_2$ with Neopentyllithium. Formation of [Au(SCMe$_3$)(PMe$_3$)] and [Au(CH$_2$CMe$_3$)(PMe$_3$)]:** Solid $LiCH_2CMe_3$ (0.004 g, 0.05 mmol) was added to a solution of $[Au_4(SCMe_3)_2(PMe_3)_4][BF_4]_2$ (0.034 g, 0.025 mmol) in $CH_2Cl_2$ (15 mL) kept at –20 °C. The mixture was warmed to room temperature. After stirring for 2 h water (10 mL) was added dropwise, the organic phase was separated, dried with anhydrous sodium sulfate and the solvents evaporated to dryness to give a light yellow solid whose NMR spectra show both the signals of $[Au(SCMe_3)(PMe_3)]$ and $[Au(CH_2CMe_3)(PMe_3)]$. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 1.01 (s, 9 H, $CCMe_3$), 1.23 (d, 2 H, $J_{H,H}$ = 8.8 Hz, $CH_2$), 1.41 (d, 9 H, $J_{H,P}$ = 8.4 Hz, $CAuPMe_3$), 1.48 (s, 9 H, $SCMe_3$), 1.57 (d, 9 H, $J_{H,P}$ = 10.3 Hz, $SAuPMe_3$) ppm. $^{31}$P NMR ($CD_2Cl_2$): $\delta$ = 2.95 ($[Au(SCMe_3)(PMe_3)]$); 16.58 ($[Au(CH_2CMe_3)(PMe_3)]$) ppm.

**X-ray Diffraction:** Crystals of **1c**, **1e** and **3d** were obtained by cooling toluene solutions, and **5e** and **7a** were obtained from dichloromethane/pentane solutions. The X-ray diffraction experiments were carried out at room temperature ($T$ = 293 K) by means of a Bruker P4 diffractometer by operating with a graphite-monochromated Mo-$K_\alpha$ radiation. The samples were sealed in glass capillaries under an atmosphere of dinitrogen. The intensity data collection was car-

[a] $R(F_o) = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; $Rw(F_o^2) = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; $w = 1/[\sigma^2(F_o^2) + (AQ)^2 + BQ]$ where $Q = [MAX(F_o^2,0) + 2F_c^2]/3$; GOF = $\{\Sigma[w(F_o^2 - F_c^2)^2]/(N - P)\}1/2$, where $N$, $P$ are the numbers of observations and parameters, respectively.

ried out with the $\omega/2\theta$ scan mode, collecting a redundant set of data. Three standard reflections were measured every 97 measurements to for check sample decay. The intensities were corrected for Lorentz and polarization effects and for absorption. In the case of **1e** and **7a** the absorption correction was made by means of an integration method based on the crystal habit.[22] For **1e**, **3d** and **5e**, the crystal fragments used in the data collection were rather irregular, therefore a precise numerical correction was impossible and a semi-empirical method was used.[22] The structure solutions were obtained by means of the automatic direct methods contained in the SHELXS97 program.[23] The refinement, based on full-matrix least-squares on $F^2$, were done by means of the SHELXL97 program.[22] Some other utilities contained in the WINGX suite were also used.[24] The more relevant crystal parameters are listed in Table 1.

The asymmetric unit of compound **1c** consists of one molecule [Au(S*t*Bu)($PMePh_2$)]. The hydrogen atoms were placed in calculated positions and during the refinement were allowed to "ride" on the connected carbon atoms. In the last of the refinement cycles all the heavy atoms were refined with anisotropic thermal parameters obtaining the reliability factors listed in Table 5.

The asymmetric unit of compound **1e** consists of one half of the molecule [$Au_2$(S*t*Bu)$_2$(dppe)] riding the inversion centre. A series of maxima around another inversion centre was interpreted as a disordered ethyl ether molecule. The maxima were fitted with the positional parameters of a well-refined ethyl ether molecule from the literature and were refined as a rigid group with isotropic thermal parameters. The hydrogen atoms were placed in calculated positions and anisotropic thermal parameters were used for the heavy atoms of the main molecule. The reliability factors obtained in the last refinement cycle are listed in Table 5.

The asymmetric unit of compound **3d** consists of one molecule [Au($SCH_2t$Bu)($PPh_3$)]. The hydrogen atoms were placed in calculated positions and during the refinement were allowed to "ride" on the connected carbon atoms. In the last of the refinement cycles all the heavy atoms were refined with anisotropic thermal parameters thus obtaining the reliability factors listed in Table 5.

The asymmetric unit of compound **5e** is made up of one half of the cation $[Au_4(StBu)_2(dppe)_2]^{2+}$ located on the twofold axis, one half of a dichloromethane molecule similarly located on the twofold axis and one $BF_4^-$ anion. The $BF_4^-$ anion presents a remarkable disorder and was refined as a rigid group distributed on two limit positions with variable occupancy, fixing the total occupancy to 1.0. The hydrogen atoms were placed in calculated positions and were allowed to "ride" on the connected carbon atoms. Anisotropic thermal parameters were used for all the heavy atoms, excluding those of the disordered anion. The reliability factors obtained in the last refinement cycle are listed in Table 5.

The asymmetric unit of compound **7a** is made up of one fourth of the cation $[Au_4(SCH_2tBu)_2(PMe_3)_4]^{2+}$, with 2/*m* symmetry and one $BF_4^-$ anion located on the twofold axis. Both the $-PMe_3$ group and the anion present a remarkable disorder. The $-PMe_3$ group was refined as a rigid group distributed, with different occupancy, on two positions related by rotation around the Au–P bond; the occupancies were refined fixing the total occupancy to 1.0. The disorder of the tetrahedral anion was instead due to a misalignment between the twofold axis of the crystal and the corresponding operator of the group. The $BF_4^-$ unit was therefore simply introduced in the model with occupancy 1/2. The hydrogen atoms were placed in calculated positions and were allowed to "ride" on the connected carbon atoms. Anisotropic thermal parameters were used for all the heavy atoms, excluding those of the disordered groups. The reliability factors obtained in the last refinement cycle are listed in Table 5.

CCDC-603883 (for **1c**), -603884 (for **1e**), -603885 (for **3d**), -603886 (for **5e**) and -603887 (for **7a**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Additional figures for compounds **1c**, **1e**, **3d**, **5e** and **7a** (crystal structure, cyclic voltammogram) and a table relating electrochemical behaviour and the inductive electronic effects of the ligands are available.

# Bis(phosphinimino)methanides as Ligands in Divalent Samarium Chemistry: Synthesis, Structures and Catalysis

**Michal Wiecko,[a] Peter W. Roesky,*[a] Vladimir V. Burlakov,[b] and Anke Spannenberg*[b]**

**Keywords:** Catalysis / Caprolactone / N,P ligands / Polymerization / Samarium

The reaction of $K\{CH(PPh_2NSiMe_3)_2\}$ with samarium diiodide in a 1:1 molar ratio in thf affords the corresponding divalent samarium complex $[\{(Me_3SiNPPh_2)_2CH\}Sm(\mu\text{-}I)(thf)]_2$ (**1**), whereas treatment of $K\{CH(PPh_2NSiMe_3)_2\}$ with samarium diiodide in a 2:1 molar ratio in thf gives the homoleptic complex $[\{(Me_3SiNPPh_2)_2CH\}_2Sm]$ (**2**). When **1** is treated with $KNPh_2$ in toluene in a 2:1 molar ratio the mixed dimeric compound $[(\{(Me_3SiNPPh_2)CH\}_2Sm)_2(\mu\text{-}I)(\mu\text{-}NPh_2)]$ (**3**) is obtained. The single-crystal X-ray structures of all these complexes have been determined. $[\{(Me_3SiNPPh_2)_2CH\}Sm(\mu\text{-}I)(thf)]_2$ has also been successfully used as a catalyst for the polymerization of ε-caprolactone. Good activities and molecular masses are observed with this catalyst.

## Introduction

Over the past decade lanthanide reagents have become more and more recognized as useful reagents in organic synthesis.[1,2] Of the low-valent lanthanides, samarium has found the most widespread application.[3] In this context, the mild reducing agent $SmI_2$, introduced by Kagan and co-workers in the late 1970s, is still receiving much interest today.[4] Kagan showed that $SmI_2$ promotes the reduction of halides, aldehydes, ketones, and carboxylic acids, and reductive eliminations and deoxygenations. Although the use of other metals such as Yb, Eu, Tm, and Dy has been reported, $SmI_2$ has turned out to be the most versatile reagent with respect to the ease of preparation concomitant with a high redox potential. On the other hand, it is often necessary to enhance the reactivity by adding various salts and co-solvents such as the carcinogenic HMPTA. Other divalent samarium reagents such as $[(\eta^5\text{-}C_5H_5)_2Sm]$,[5] $SmBr_2$,[6] and $[Sm\{N(SiMe_3)_2\}_2(thf)_2]$[7] have also been used, although less frequently.

Beside $SmI_2$, the reactivity of the divalent samarocene $[(\eta^5\text{-}C_5Me_5)_2Sm(thf)_2]$[8] toward organic compounds has been extensively investigated by Evans and co-workers,[9,10] and it has also been shown that $[(\eta^5\text{-}C_5Me_5)_2Sm(thf)_2]$ is an active polymerization system for ε-caprolactone that maintains its activity after all of the initial batch of monomer is consumed.[11] An ε-caprolactone polymerization activity has also been observed for $[(\eta^5\text{-}C_5H_5)_2Sm]$,[12] $SmBr_2$, and $[(\eta^5\text{-indenyl})_2Yb(thf)_2]$.[13] In this context, Yasuda and co-workers have investigated the efficiency of divalent lanthanide complexes such as $[(\eta^5\text{-}C_5Me_5)_2Yb(thf)_2]$, $[(\eta^5\text{-}C_5Me_5)_2Sm(thf)_2]$, and $[(\eta^5\text{-indenyl})_2Yb(thf)_2]$ as catalysts for the polymerization of methyl methacrylate (MMA).[14] Although the living polymerization of MMA is initiated by these complexes, their initiator efficiencies are much smaller than those obtained by organolanthanide(III) complexes.

Based on these results, we became interested in the synthesis of new samarium(II) complexes and their application as catalysts in the polymerization of polar monomers. Recently, we introduced the monoanionic bis(phosphinimino)methanide $\{CH(PPh_2NSiMe_3)_2\}^-$ as a versatile ligand in di- and trivalent lanthanide chemistry. We have previously reported the synthesis of a series of bis(phosphinimino)methanide dichloride complexes of trivalent lanthanides, namely $[\{CH(PPh_2NSiMe_3)_2\}LnCl_2]_2$ (Ln = Y, Sm, Dy, Er, Yb, Lu).[15] These compounds were obtained by the reaction of $K\{CH(PPh_2NSiMe_3)_2\}$[16] with the corresponding yttrium or lanthanide trichloride. Further reactions of $[\{CH(PPh_2NSiMe_3)_2\}LnCl_2]_2$ have led to the corresponding amido complexes $[\{CH(PPh_2NSiMe_3)_2\}Ln(NPh_2)_2]$ (Ln = Y, Sm),[15] diphosphanylamido complexes $[\{CH(PPh_2NSiMe_3)_2\}Ln\{(Ph_2P)_2N\}Cl]$ (Ln = Y, La, Nd, Yb),[17] cyclopentadienido complexes $[\{CH(PPh_2NSiMe_3)_2\}Ln(\eta^5\text{-}C_5H_5)_2]$ (Ln = Y, Sm, Er),[18] and cyclooctatetraene complexes $[\{CH(PPh_2NSiMe_3)_2\}Ln(\eta^8\text{-}C_8H_8)]$ (Ln = Y, Sm, Er, Yb, Lu).[19] These derivatives have been used as homogeneous catalysts for a number of different catalytic applications. Thus, the complexes $[\{CH(PPh_2NSiMe_3)_2\}Ln\{(Ph_2P)_2N\}Cl]$ are active catalysts for the ring-opening polymerization of ε-caprolactone and the polymerization of MMA.[17]

In divalent lanthanide chemistry we have synthesized bis(phosphinimino)methanide complexes of composition $[\{(Me_3SiNPPh_2)_2CH\}Eu(\mu\text{-}I)(thf)]_2$ and $[\{(Me_3SiNPPh_2)_2$-

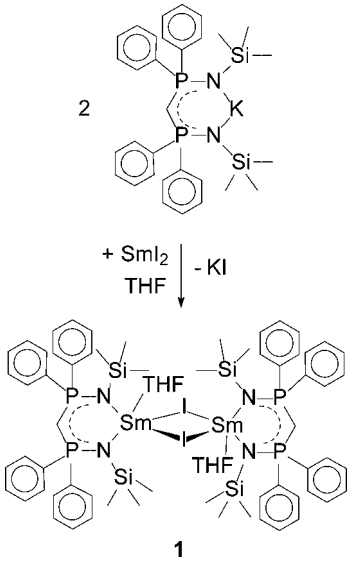
CH}YbI(thf)$_2$] by salt metathesis reactions from K{CH(PPh$_2$NSiMe$_3$)$_2$} and LnI$_2$.[20] Further reaction of these complexes with [K(thf)$_n$N(PPh$_2$)$_2$] has led selectively to the heteroleptic amido complexes [{(Me$_3$SiNPPh$_2$)$_2$CH}-Ln{(Ph$_2$P)$_2$N}(thf)] (Ln = Eu, Yb). The ytterbium complex can also be obtained by reduction of [{CH(PPh$_2$NSiMe$_3$)$_2$}-Yb{(Ph$_2$P)$_2$N}Cl]. So far the {CH(PPh$_2$NSiMe$_3$)$_2$}$^-$ ligand has not been used in the more redox-sensitive chemistry of samarium(II). Only the homoleptic samarium(II) complex [{CH(PPh$_2$NC$_6$H$_2$-2,4,6-Me$_3$)$_2$}$_2$Sm] of the related *N*-mesityl-substituted bis(phosphinimino)methanide has been reported recently by Hill and co-workers.[21] We report here on the synthesis of three bis(phosphinimino)methanide complexes of divalent samarium and their application in ε-caprolactone polymerization.

## Results and Discussion

### Synthesis and Structures

Reaction of K{CH(PPh$_2$NSiMe$_3$)$_2$} with samarium diiodide in a 1:1 molar ratio in thf afforded the corresponding divalent samarium complex [{(Me$_3$SiNPPh$_2$)$_2$CH}Sm(μ-I)(thf)]$_2$ (**1**) as crystals in good yields (Scheme 1).[22] The potassium reagent K{CH(PPh$_2$NSiMe$_3$)$_2$}, which was described earlier,[16] was used as starting material to avoid coordination of lighter alkali halides such as lithium chloride. The new complex was characterized by standard analytical and spectroscopic techniques, and its solid-state structure was established by single-crystal X-ray diffraction. The signals in the NMR spectra are broadened due to the presence of the paramagnetic metal. The signal of the SiMe$_3$ groups ($\delta$ = –0.16 ppm) is in the expected range. A similar shift is observed for the diamagnetic divalent complex [{(Me$_3$SiNPPh$_2$)$_2$CH}YbI(thf)$_2$] ($\delta$ = 0.44 ppm). The signal of the methine proton in the $^1$H NMR spectrum could not be clearly assigned, and those of the phenyl protons ($\delta$ = 7.05–7.70 ppm) are uncharacteristically broadened.



Scheme 1.

The solid-state structure of **1** is isostructural to the previously reported europium compound [{(Me$_3$SiNPPh$_2$)$_2$-CH}Eu(μ-I)(thf)]$_2$.[20] In **1**, which crystallizes in the monoclinic space group $P2_1/c$ the metal centers of the dimeric complexes are asymmetrically bridged by two iodine atoms [Sm–I 332.14(4) and Sm–I′ 335.74(4) pm; Figure 1]. A crystallographic inversion center is observed in the center of the Sm–I–Sm′–I′ plane. The bis(phosphinimino)methanide ligand forms a six-membered metallacycle (N1–P1–C1–P2–N2–Sm) by chelation of the two trimethylsilylimine groups to the lanthanide metal. The Sm–N distances [Sm–N1 259.2(3) and Sm–N2 256.3(3) pm] show an almost symmetrical attachment of the ligand to the metal center. The metallacycle adopts a twist-boat conformation in which the central carbon atom and the samarium atom are displaced from the N$_2$P$_2$ least-squares plane. As shown earlier, this displacement depends on the metal center and also on the packing in the solid state.[17]

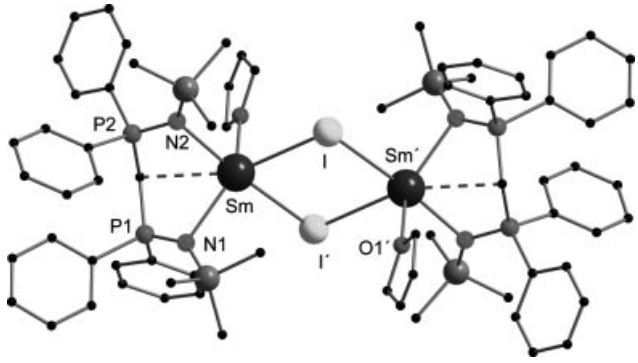


Figure 1. Solid-state structure of **1** showing the atom-labeling scheme. Hydrogen atoms have been omitted. Selected bond lengths [pm] and angles [°]: Sm–N1 259.2(3), Sm–N2 256.3(3), Sm–C1 297.7(4), Sm–I 332.14(4), Sm–I′ 335.74(4), Sm–O1 250.4(3), P1–N1 157.9(3), P2–N2 158.7(3); N1–Sm–N2 90.66(10), N1–Sm–C1 57.90(10), N2–Sm–C1 59.66(10), N1–Sm–I 133.19(8), N2–Sm–I 99.33(7), N1–Sm–I′ 95.02(7), N2–Sm–I′ 171.95(8), N1–Sm–O1 134.35(12), N2–Sm–O1 87.04(12), C1–Sm–I 158.36(6), C1–Sm–I′ 119.11(7), C1–Sm–O1 82.37(13), I–Sm–O1 92.01(9), I′–Sm–O1 84.92(9), I–Sm–I′ 80.896(10), Sm–I–Sm′ 99.104(10).

Reaction of **1** with a second equivalent of K{CH-(PPh$_2$NSiMe$_3$)$_2$} or treatment of K{CH(PPh$_2$NSiMe$_3$)$_2$} with samarium diiodide in a 2:1 molar ratio in thf gave the homoleptic complex [{(Me$_3$SiNPPh$_2$)$_2$CH}$_2$Sm] (**2**) as purple crystals (Scheme 2).[22] Compound **2** is similar to the *N*-mesityl-substituted bis(phosphinimino)methanide complex [{CH(PPh$_2$NC$_6$H$_2$-2,4,6-Me$_3$)$_2$}$_2$Sm].[21] Dark purple crystals suitable for X-ray crystallographic studies formed in concentrated *n*-pentane. Compound **2**, which crystallizes in the triclinic space group $P\bar{1}$ forms discrete homoleptic monomers in the solid state (Figure 2). As observed for **1**, six-membered metallacycles (N1–P1–C1–P2–N2–Sm), which adopt a twist-boat conformation, are formed by the {CH(PPh$_2$NSiMe$_3$)$_2$}$^-$ ligands and the samarium atom. The two {CH(PPh$_2$NSiMe$_3$)$_2$}$^-$ ligands act as tridentate donors. Thus, the samarium atom is six-coordinated. The distances

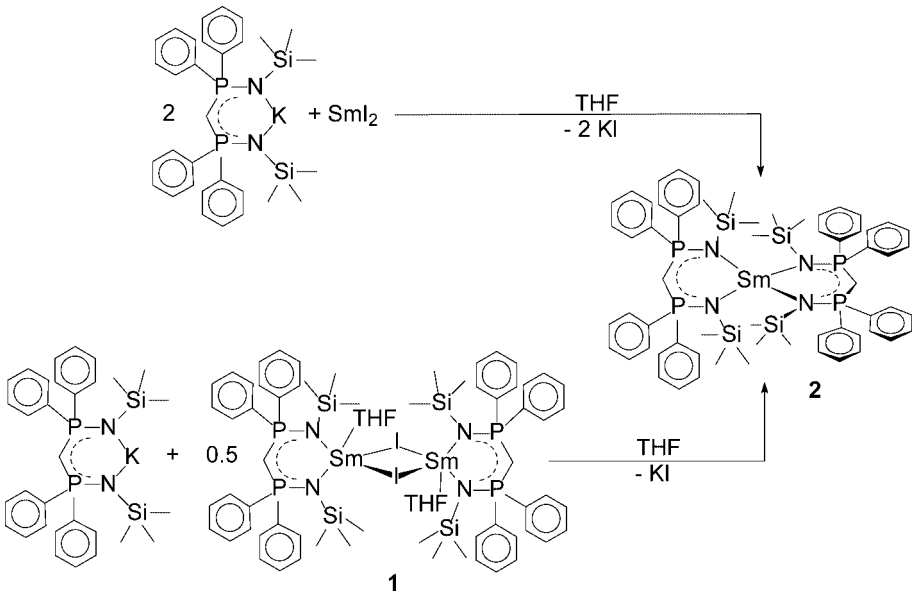

Scheme 2.

between the central carbon atom C1 and the samarium atom [Sm–C1 289.91(15) and Sm–C32 289.84(14) pm] are in the range of those for [{CH(PPh$_2$NC$_6$H$_2$-2,4,6-Me$_3$)$_2$}$_2$-Sm] [290.0(5) and 287.7(5) pm][21] and [Sm{C(SiMe$_3$)$_2$-(SiMe$_2$OMe)}$_2$(thf)] [278.7(5) and 284.5(5) pm][23] but significantly shorter than in **1** [297.7(4) pm]. On the other hand, the Sm–C$_{methine}$ bond lengths are significantly longer than in [($\eta^5$-C$_5$Me$_5$)Sm{CH$_2$(SiMe$_3$)$_2$}($\eta^5$-C$_5$Me$_5$)·K(thf)$_2$]$_n$ [265.2(9) pm].[24]

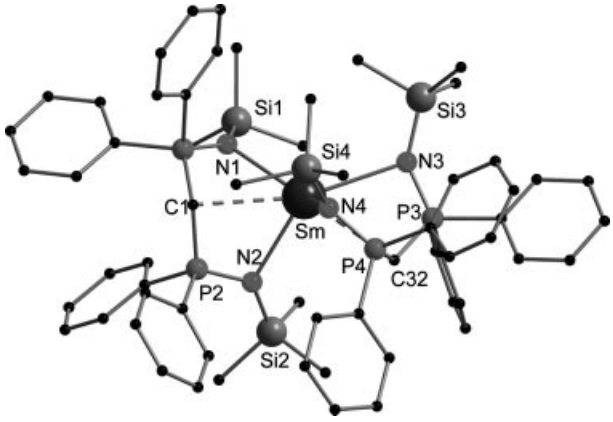

Figure 2. Solid-state structure of **2** showing the atom labeling scheme. Hydrogen atoms have been omitted. Selected bond lengths [pm] and angles [°]: Sm–N1 278.51(12), Sm–N2 260.70(10), Sm–N3 277.41(12), Sm–N4 261.25(11), Sm–C1 289.91(15), Sm–C32 289.84(14), N1–P1 157.81(15), N2–P2 158.30(14), N3–P3 157.86(13), N4–P4 158.13(14); N1–Sm–N2 85.34(3), N1–Sm–N3 116.48(4), N1–Sm–N4 136.31(4), N2–Sm–N3 135.46(4), N2–Sm–N4 105.16(4), N3–Sm–N4 85.69(4), N1–Sm–C32 163.78(4), N2–Sm–C32 90.27(4), N3–Sm–C32 57.63(4), N4–Sm–C32 59.90(4), N1–Sm–C1 57.09(4), N2–Sm–C1 59.97(4), N3–Sm–C1 164.50(4), N4–Sm–C1 91.23(4), C1–Sm–C32 132.66(4).

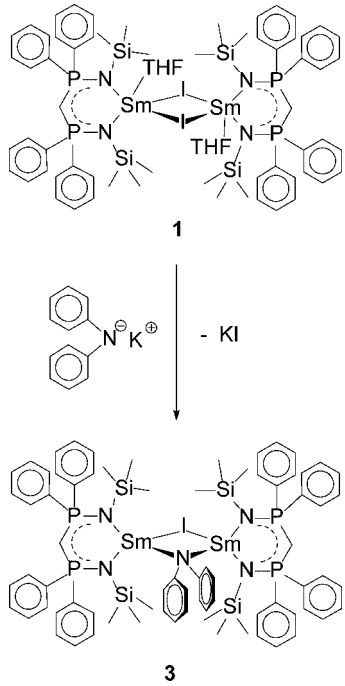
Earlier attempts to synthesize a heteroleptic complex of composition [{CH(PPh$_2$NC$_6$H$_2$-2,4,6-Me$_3$)$_2$}Sm{N(SiMe$_3$)$_2$}] did not succeed.[21] Therefore, to obtain another heteroleptic amido complex, **1** was treated with KNPh$_2$ in toluene in a 2:1 molar ratio. Surprisingly, we did not obtain the desired complex [{(Me$_3$SiNPPh$_2$)$_2$CH}Sm(NPh$_2$)$_2$] but instead repeatedly isolated the mixed dimeric compound [({(Me$_3$SiNPPh$_2$)$_2$CH}Sm)$_2$(μ-I)(μ-NPh$_2$)] (**3**) in high yields (Scheme 3).[22] Compound **3** was characterized by elemental analysis and Raman spectroscopy. The solid-state structure of **3** was also determined by single-crystal X-ray diffraction (Figure 3). It crystallizes in the monoclinic space group *C*2/*c* with one molecule of toluene and forms a dimer in the solid state in which the metal centers are symmetrically bridged by one iodine atom and the nitrogen atom of the



Scheme 3.

$Ph_2N^-$ group. A crystallographic $C_2$ axis is observed along I and N3. As a result of the bridging nature of the nitrogen atom, the Sm–N3 bond length [259.4(3) pm] is longer than in $[Sm\{N(SiMe_3)_2\}(thf)_2]$ [244.2(9) and 242.4(9) pm],[25] in which the $\{N(SiMe_3)_2\}^-$ groups are terminally bonded. The Sm–I bond length of 328.33(4) pm is a bit shorter than in $[Sm\{N(SiMe_3)_2\}(\mu\text{-}I)(DME)(thf)]_2$ [e.g. 334.14(9) and 335.53(9) pm].[25] As observed for **1** and **2**, the six-membered N1–P1–C1–P2–N2–Sm ring in **3**, which is formed by the $\{CH(PPh_2NSiMe_3)_2\}^-$ ligand and the samarium atom, adopts a twist-boat conformation. The distance between the central carbon atom C1 and the lanthanide atom [292.2(4) pm] lies between the values observed for **1** [297.7(4) pm] and **2** [Sm–C1 289.91(15) and Sm–C32 289.84(14) pm]. The Sm–N1 and Sm–N2 distances are 255.0(3) and 253.8(3) pm, respectively; and indicate an almost symmetrical attachment of the ligand at the metal center.

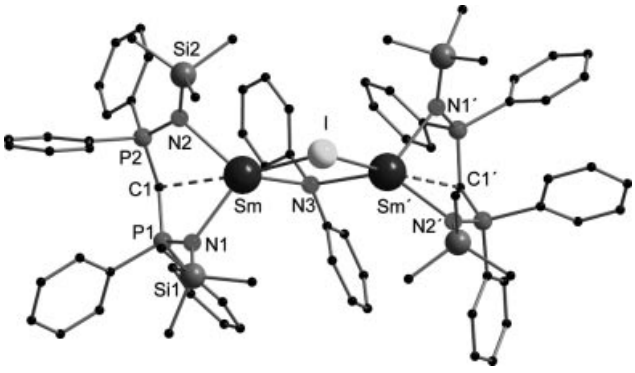

Figure 3. Solid-state structure of **3** showing the atom labeling scheme. Hydrogen atoms have been omitted. Selected bond lengths [pm] and angles [°]: Sm–N1 255.0(3), Sm–N2 253.8(3), Sm–N3 259.4(3), Sm–C1 292.2(4), Sm–I 328.33(4), N1–P1 159.1(3), N2–P2 158.4(3); N1–Sm–N2 94.24(10), N1–Sm–N3 118.45(8), N2–Sm–N3 135.65(8), N1–Sm–C1 59.33(9), N2–Sm–C1 60.46(10), N3–Sm–C1 109.64(11), N1–Sm–I 117.43(7), N2–Sm–I 109.95(7), N3–Sm–I 82.14(8), C1–Sm–I 168.06(7), Sm–N3–Sm 113.19(17), Sm–I–Sm 82.521(14).

### Catalysis

Since it is known that divalent lanthanide complexes such as $[(\eta^5\text{-}C_5H_5)_2Sm]$,[12] $[(\eta^5\text{-}C_5Me_5)_2Sm(thf)_2]$,[11] and $[(\eta^5\text{-indenyl})_2Yb(thf)_2]$[13] are efficient catalysts for the polymerization of ε-caprolactone (CL),[14] we were interested in using compound **1** as a precatalyst for this polymerization. Complex **1** showed high activity in polymerization of CL at room temperature. Monomer/initiator molar ratios of 1/2000 and 1/10000 afforded the corresponding poly(caprolactone)s with excellent yields (92–95%) within short reaction times. The molecular weights obtained depend strongly on the amount of initiator. Poly(caprolactone) with a $\bar{M}_n$ of 723000 was obtained in toluene with a [CL]/[**1**] ratio of 10000/1 in one hour with complete conversion at room temperature (Table 1, entry 2). The molecular weights decrease at elevated temperature (Table 1, entries 3 and 4). Moderate $\bar{M}_w/\bar{M}_n$ values (1.81–2.75) were observed.

## Conclusions

In summary, a series of bis(phosphinimino)methanide complexes of divalent samarium have been reported. Reaction of $K\{CH(PPh_2NSiMe_3)_2\}$ with samarium diiodide in a 1:1 molar ratio in thf affords the corresponding divalent samarium complex $[\{(Me_3SiNPPh_2)_2CH\}Sm(\mu\text{-}I)(thf)]_2$ (**1**). Reaction of **1** with a second equivalent of $K\{CH(PPh_2NSiMe_3)_2\}$ or treatment of $K\{CH(PPh_2NSiMe_3)_2\}$ with samarium diiodide in a 2:1 molar ratio in thf gives the homoleptic complex $[\{(Me_3SiNPPh_2)_2CH\}_2Sm]$ (**2**). When **1** is treated with $KNPh_2$ in toluene in a 2:1 molar ratio the mixed dimeric compound $[(\{(Me_3SiNPPh_2)_2CH\}_2Sm)_2(\mu\text{-}I)(\mu\text{-}NPh_2)]$ (**3**) is obtained. The single-crystal X-ray structures of all three complexes show that the $\{CH(PPh_2NSiMe_3)_2\}^-$ ligand is bound in an uncommon coordination mode to the metal atom. A six-membered N1–P1–C1–P2–N2–Sm metallacycle, which adopts a pseudo-boat conformation, is formed by chelation of the two trimethylsilylimine groups to the metal center. The heteroleptic complex **1** is an efficient catalyst for the polymerization of CL. Good polydispersity and molecular masses are obtained with this catalyst.

## Experimental Section

**General Considerations:** All manipulations of air-sensitive materials were performed with the rigorous exclusion of oxygen and moisture in flame-dried, Schlenk-type glassware either on a dual-manifold Schlenk line interfaced with a high vacuum ($10^{-3}$ Torr) line, or in an argon-filled MBraun glove box. Thf was pre-dried with Na wire and distilled under nitrogen from Na/K alloy benzophenone ketyl prior to use. Hydrocarbon solvents (toluene and *n*-pentane) were distilled under nitrogen from $LiAlH_4$. All solvents for vacuum line manipulations were stored in vacuo over $LiAlH_4$ in resealable flasks. Deuterated solvents were obtained from Chemotrade or Euriso-Top GmbH (99 atom% D). NMR spectra were recorded with

a Jeol JNM-LA 400 FT-NMR spectrometer. Chemical shifts are referenced to internal solvent resonances and are reported relative to tetramethylsilane or 85% phosphoric acid ($^{31}$P). Raman spectra were recorded with a Bruker RFS 100. Elemental analyses were performed with an Elementar vario EL. $SmI_2(thf)_2$,[26] K{CH($PPh_2NSiMe_3$)$_2$},[16] and {$CH_2(PPh_2NSiMe_3)_2$}[27] were prepared according to literature procedures.

**[{($Me_3SiNPPh_2$)$_2$CH}Sm(μ-I)(thf)]$_2$ (1):** $SmI_2(thf)_2$ (1.20 g, 2.2 mmol) and K{CH($PPh_2NSiMe_3$)$_2$} (1.20 g, 2.0 mmol) were placed in a flask and 15 mL of thf was condensed onto the mixture. The mixture was stirred for 16 h at room temperature and filtered. The thf was removed from the resulting dark-purple solution in vacuo. The obtained dark solid was washed with 10 mL of cold toluene yielding 1.72 g (95%) of **1**. Crystals of **1** suitable for X-ray crystallographic studies were obtained by concentrating a hot thf/toluene (2:1) solution. $^1$H NMR ([D$_8$]THF, 400 MHz): $\delta$ = –0.16 (s, 36 H, $SiMe_3$), 4.97 (br. s), 6.75 (br. s) 7.05–7.70 (m, 40 H, Ph) ppm. $^{13}$C{H} NMR ([D$_8$]THF, 100.4 MHz): $\delta$ = 4.0 ($SiMe_3$), 128.5, 129.6, 130.4, 131.9 (Ph) ppm. Raman (solid): $\tilde{\nu}$ = 604 cm$^{-1}$ (s), 618 (m), 1000 (s), 1027 (m), 1104 (w), 1157 (w), 1573 (w), 1588 (m), 2889 (br), 3049 (s), 3059 (m). $C_{70}H_{92}I_2N_4O_2P_4Si_4Sm_2$ (1812.3): calcd. C 46.39, H 5.12, N 3.09; found C 46.77, H 4.47, N 2.67.

**[{($Me_3SiNPPh_2$)$_2$CH}$_2$Sm] (2):** $SmI_2(thf)_2$ (273 mg, 0.5 mmol) and K{CH($PPh_2NSiMe_3$)$_2$} (597 mg, 1.0 mmol) were placed in a flask and 15 mL of thf was condensed onto the mixture. The mixture was stirred for 16 h at room temperature. The solvent was removed in vacuo and the resulting residue was suspended in 15 mL of *n*-pentane and filtered. The obtained solution was concentrated at 35 °C. Dark crystals suitable for X-ray crystallographic studies formed after several hours. By further concentration of the mother liqueur an overall yield of 560 mg (89%) of **2** was obtained. Raman (solid): $\tilde{\nu}$ = 609 cm$^{-1}$ (m), 617 (w), 999 (s), 1027 (m), 1103 (w), 1156 (w), 1182 (w), 1572 (w), 1587 (m), 2897 (br), 2952 (br), 3055 (m). $C_{62}H_{78}N_4P_4Si_4Sm\cdot\frac{1}{2}C_5H_{12}$ (1265.91 + 36.08): calcd. C 59.50, H 6.50, N 4.30; found C 59.90, H 6.59, N 4.09.

**[({($Me_3SiNPPh_2$)$_2$CH}Sm)$_2$(μ-I)(μ-$NPh_2$)] (3):** Freshly prepared **1** (453 mg, 0.25 mmol) and $KNPh_2$ (104 mg, 0.50 mmol) were suspended in 15 mL of toluene. The dark mixture was stirred for 6 h at about 70 °C and another 10 h at room temperature. Filtration and concentration of the resulting solution yielded 676 mg (79%) of **3** as very dark purple crystals. $^{31}$P{$^1$H} NMR ($C_6D_6$, 161.7 MHz, 25 °C): $\delta$ = 341.7 ppm. Raman (solid): $\tilde{\nu}$ = 607 cm$^{-1}$ (s), 617 (m), 987 (m), 999 (s), 1026 (m), 1102 (w), 1157 (w), 1572 (w), 1588 (m), 2891 (br), 2944 (br), 3056 (m). $C_{74}H_{88}IN_5P_4Si_4Sm_2$ (1711.4): calcd. C 51.93, H 5.18, N 4.09; found C 52.10, H 5.14, N 3.73.

**Polymerization of ε-Caprolactone:** A 5 M solution of the ε-caprolactone in toluene (4 mL for 1:2000 or 20 mL for 1:10000) was added to **1** (0.018 g, 0.01 mmol). The mixture was stirred and left at room temperature or warmed to 75 °C. After one hour the reaction mixture was treated with an excess of methanol. After 2–3 h the polymer was separated from the mother liquor by decanting and dried in vacuo. The residue was dissolved in 20 mL (1:2000) or in 60 mL (1:10000) of toluene and the solution was transferred to a beaker and treated with an excess of methanol. The poly-ε-caprolactone was separated and dried in vacuo until the weight remained constant.

The molecular masses of poly(ε-caprolactone)s were measured by the GPC method on a Hewlett–Packard liquid chromatograph 1090 HP [SDV column $10^4 \times 10^3 \times 100$ Å (Polymer Standard Service); eluent: thf] and were corrected by calibration relative to polystyrene standards.

**X-ray Crystallographic Studies of 1–3:** Suitable crystals of **1**–**3** were covered in mineral oil (Aldrich) and mounted on a glass fiber. The crystal was transferred directly to the cold $N_2$ stream (–73 °C) of a Stoe IPDS 2T diffractometer. Subsequent computations were carried out with an Intel Pentium IV PC. Data collection and refinement were performed with SHELXS-97[28a] and SHELXL-97.[28b]

# Thallium Halides – New Aspects of the Stereochemical Activity of Electron Lone Pairs of Heavier Main-Group Elements

**Anja-Verena Mudring*[a]**

*Dedicated to Prof. Dr. Josef Hahn on the occasion of his 65th birthday*

**Keywords:** Halides / Thallium / Electron lone pairs

Density functional theory studies in the linear muffin tin approximation on thallium halides (TlX; X = F, Cl, Br, I) show that structural distortions due to a stereochemically active lone pair of electrons depend crucially on cation–anion interactions. Such distortions do not originate from a 6s–6p hybridisation on the heavy metal as the Tl 6s and 6p states are energetically too far apart to mix directly. In the case of TlF, the Tl 6s and the F 2p states are located in the same energy region, which leads to an efficient interaction that produces strongly antibonding Tl–F states directly below the Fermi level that would destabilize the solid. Minimisation of these unfavourable covalent antibonding interactions is the driving force for structural distortion. In the case of the heavier thallium halides, the growing energetic mismatch between Tl 6s states and X *n*p states leads to weaker covalent interactions. Thus, the compounds become more ionic and high symmetry structures are adopted as covalent interactions play only a minor role. The low symmetry structure of TlI observed at low temperatures is stabilized by attractive metal–metal bonding.

## Introduction

Thallium shows a strong preference for the oxidation state +1, which has been attributed to the effect of the "inert electron pair", a term introduced by Sidgwick[1] to describe the tendency of the heavier main-group elements to adopt oxidation numbers that are two less than the respective group number.[2] Traditional considerations assume that this inert electron pair is generated by mixing of the 6s and 6p orbitals on the heavy metal cation. The hybrid orbital is therefore often considered to behave like an additional ligand in the coordination sphere.[3] The corresponding pair of electrons is thought to be chemically inert but stereochemically active. However, this would imply that the lone pair is stereochemically active in any environment, which is obviously not the case. Many thallium compounds are known where the lone pair is not stereochemically active, many of which even show interesting phase transitions between structures where the lone pair is active or not. So far, no comprehensive studies on the origin and nature of the lone pair in thallium compounds have appeared that can explain or even predict the stereochemistry of the $6s^2$ lone pair.

Thallium halides (TlX; X = F–I) offer a unique possibility to study the stereochemistry of the (chemically) inert electron pair since a large variety of TlX phases are known even though these compounds are simple 1:1 salts. Much work has been done over the years on the study of phase transitions of these simple compounds, mainly to investigate the temperature- and pressure-dependent behaviour of the $6s^2$ lone pair on the thallium atom.

Thallium(I) fluoride adopts an orthorhombic structure in the space group *Pbcm*, which can be regarded as a distorted rock-salt-type structure (Figure 1), under ambient conditions where both thallium and fluorine are coordinated by six counterions. However, the coordination polyhedron around the thallium cation deviates strongly from ideal octahedral symmetry. This fact has been ascribed to the presence of a stereochemically active lone pair. Although the orthorhombic structure of TlF is stable up to 3.5 GPa,[4] a structural phase transition apparently takes place at temperatures above 355 K to a higher symmetrical tetragonal structure, which still can be derived from a rock-salt-type structure.[5] The space group *I*4/*mmm* has been proposed for this structure. $^{205}$Tl and $^{19}$F NMR studies question this assumption, however, as they indicate different coordination polyhedra around Tl and F.[6] In contrast to TlF, the thallium halides with heavier halogens (TlCl and TlBr) adopt highly symmetrical cubic structures. Both compounds crystallise in the CsCl structure type under ambient conditions,[7] whereas at low temperatures a

transition to the NaCl structure takes place.[8] TlI also crystallises in a CsCl-type structure under ambient conditions.[9] Interestingly it undergoes a phase transition, at low temperatures to a structure type in the space group *Cmcm*[10] (Figure 2) that is also found for indium monohalides.[11] Reliable crystallographic structure determinations are a requirement for further studies as wrong crystallographic studies, for example for TlF, have led to wrong interpretations of the lone pair effect[6] and even speculations about Tl–Tl interactions.[12]

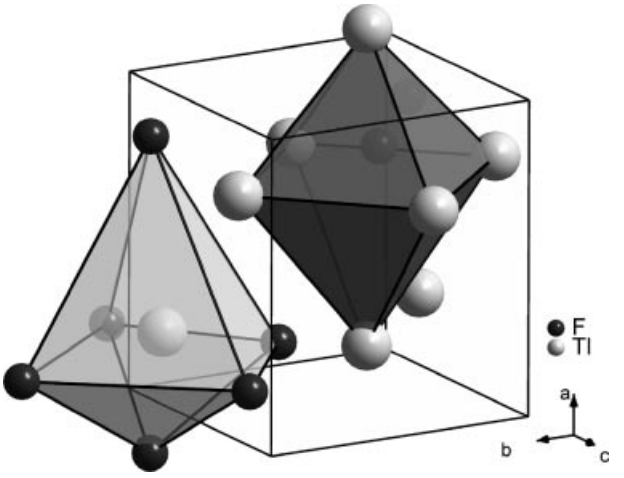

Figure 1. Crystal structure of TlF (*Pbcm*). The coordination polyhedra surrounding thallium and fluorine are shaded.

Recent studies on thallium(I) coordination compounds[13] show that s–p mixing on the heavy atom is neither the origin nor a necessity for a structural distortion that might otherwise be associated with a stereochemically active lone pair. Instead, antibonding Tl 6s/ligand-p interactions are the origin of these structural distortions. In order to investigate the lone pair effect in extended solid materials, calculations have been carried out on the different modifications of the thallium halides using density functional theory.[14]

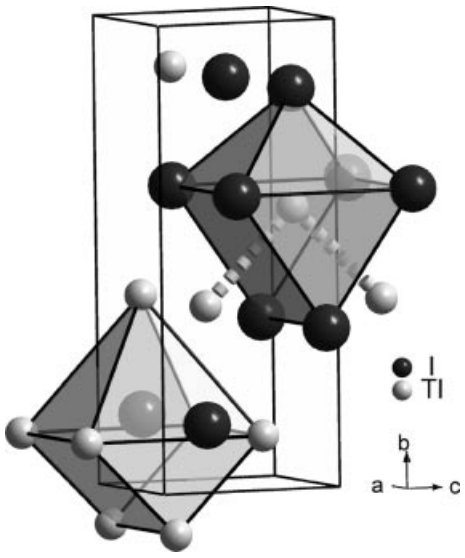

Figure 2. Crystal structure of TlI (*Cmcm*). The coordination polyhedra surrounding thallium and iodine are shaded. Closest Tl–Tl contacts indicated by broken bonds.

## Results and Discussion

The density of states for TlX (X = F, Cl, I) in the NaCl and CsCl structure types as well as for TlF and TlI in their own structure types are shown in Figures 3, 6 and 9, respec-

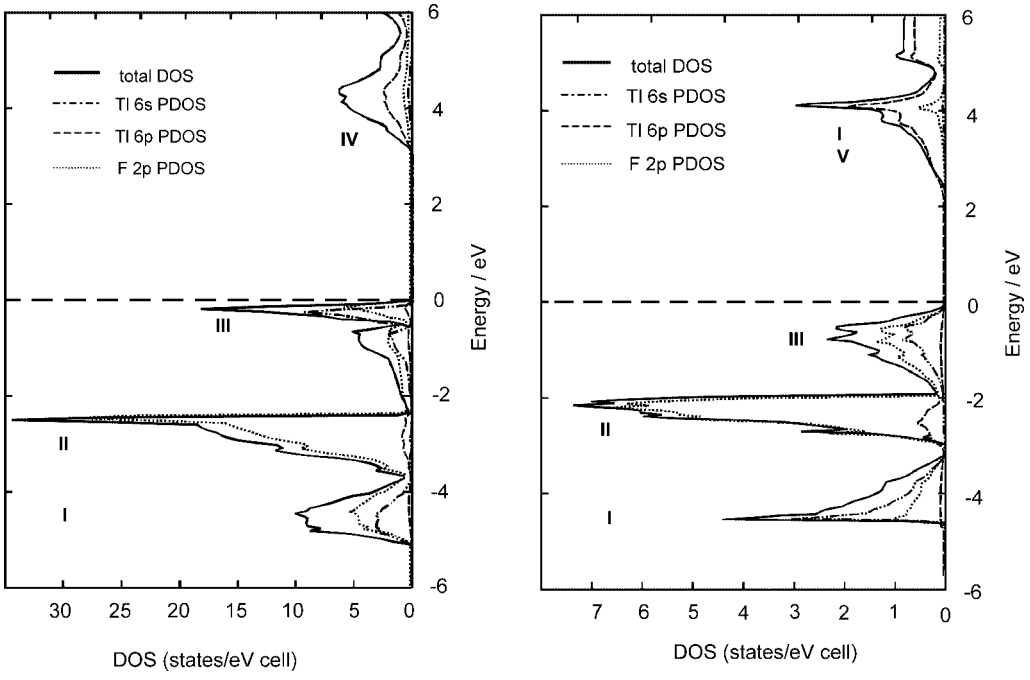

Figure 3. Total and partial densities of states for TlF (left: *Pbcm*; right: $Fm\bar{3}m$).

tively, between –6 and +6 eV (with respect to the highest occupied state). As both the halogen *n*s states and the Tl 5d states are located at energies significantly lower than –6 eV and have no impact on the chemical bonding, they are not shown.

### Thallium Fluoride (TlF)

The density of states (DOS) for TlF (Figure 3) in its room-temperature structure (space group *Pbcm*) and in the hypothetically idealised NaCl-type of structure (space group $Fm\bar{3}m$) can be partitioned into four significant sections, a region above the Fermi level which is mainly of Tl 6p character (IV) and a complex area below the Fermi level. This latter area shows three different segments (I–III). A region at lower energies around –4/–5 eV, which is of Tl 6s and F 2p character (I), is followed by a region of high DOS mainly made up by F 2p with small Tl 6p contributions (II). Then, up to the highest occupied states, a region is observed which again shows Tl 6s as well as F 2p contributions (III). The crystal orbital Hamiltonian population (COHP) curves for the Tl–F interactions (Figure 4) reveal that regions I and II are Tl–F bonding and region III right below the Fermi level is Tl–F antibonding. This clearly shows the ambivalent bonding situation in thallium halides: on the one hand there is a strong Coulombic attraction between cations and anions in the solid, whereas on the other unfavourable covalent antibonding Tl 6s/F 2p interactions take place right at the Fermi level. If these are reduced, the whole solid is energetically stabilized. A more thorough study of the DOS for TlF in both structures reveals some rather significant differences between the different structures (Table 1). The integrated DOSs show a higher F p and lower Tl s contribution for region I in the distorted NaCl structure compared to the undistorted (hypothetical) NaCl structure, whereas for region III the opposite is found. Furthermore, a significantly larger Tl p contribution is found for region II in the idealised NaCl structure. These observations can best be explained by a simple interaction

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

scheme (Figure 5). The Tl 6s and F 2p levels are found in a similar energy region and thus are able to interact efficiently which, however, leads to both strong bonding Tl 6s/F 2p combinations (region I) and antibonding Tl 6s/F 2p states right at the Fermi level (region III).

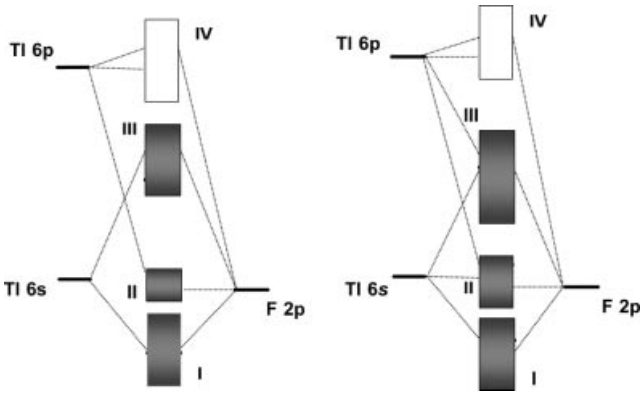

Figure 5. Schematic orbital interaction diagrams for TlF (a) in its actual distorted structure (*Pbcm*) and (b) in a hypothetical symmetrical structure ($Fm\bar{3}m$). Shaded blocks symbolize occupied levels, open blocks correspond to empty levels.

If the antibonding Tl 6s/F 2p interactions were reduced, an energetic stabilisation of the whole solid would be achieved. This can indeed be accomplished by a structural distortion [Figure 5(b)]. A comparison of the total energies per formula unit shows the distorted structure to be more stable than the undistorted NaCl type of structure. Upon distortion, the low-lying region I loses some of its Tl 6s character to region III right below the Fermi level. In exchange, region I gains F 2p character and region III loses F 2p character. Note also the high integrated crystal orbital Hamiltonian population (ICOHP) for region I (Table 1). Accordingly, the high lying antibonding Tl 6s/F 2p states in particular come closer in energy to the Tl 6p states, which now can mix into the antibonding region III. This introduces some additional Tl 6p/F 2p bonding, as noted earlier,[15] and, more importantly, moves the antibonding states partially above the Fermi level so that a net gain in bonding is achieved. Indeed, the ICOHP value for the Tl–F bond is higher for the distorted structure than for the symmetric structure (Table 1). In the distorted structure, the Tl–F contacts are unevenly distributed. Four shorter contacts at 243, 255 and 271 pm (2×) and two rather long Tl–F distances of 312 and 370 pm are observed. Closer inspection of the COHP curves (see Supporting Information) shows that the four shorter Tl–F distances essentially determine the whole Tl–F interaction, whereas the interactions at the two larger distances become essentially non-bonding.

It has been realized previously that the crystal orbital Hamiltonian population can be used as an indicator in trends of lone pair stereochemical activity.[16] This mixing cannot occur in highly symmetric (cubic) structures like the rock-salt-type structure, however, as it would be symmetry-forbidden. Note that for this gedankenexperiment the mean Tl–F distance is the same in all cases.

### Thallium Chloride and Bromide (TlCl and TlBr)

In contrast to TlF, no distortions associated with the stereochemistry of a lone pair have been observed so far for TlCl and TlBr. This becomes obvious by comparing the density of states and COHP curves for the thallium–halogen bond for hypothetically cubic TlF (Figures 3 and 4) with that for TlCl (Figures 6 and 7). As for TlF in the rock-salt structure, the density of states and COHP curves for

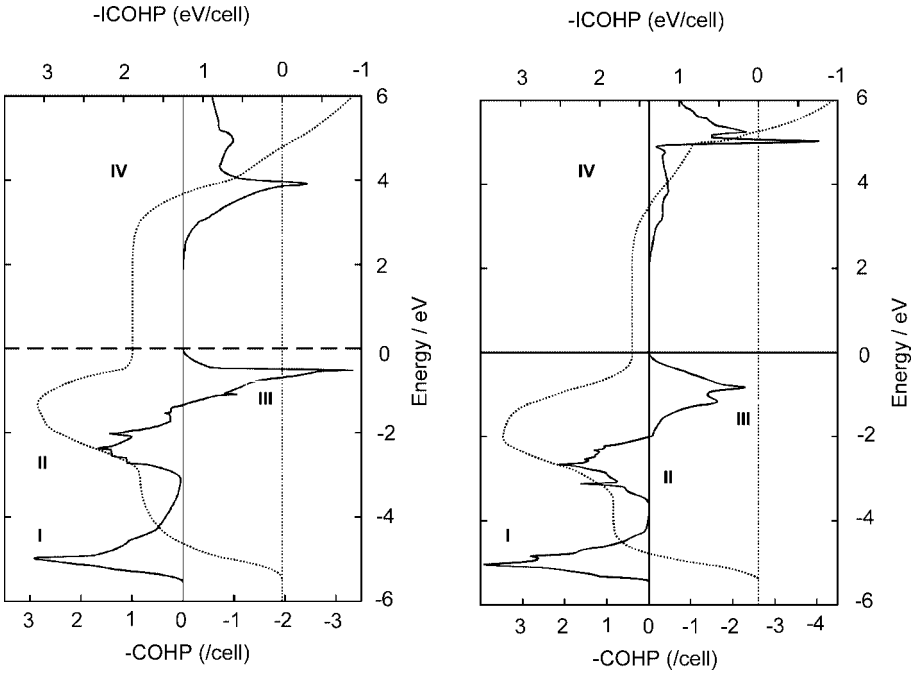

Figure 7. COHP and ICOHP of the Tl–Cl interaction (left: *Pbcm*; right: $Fm\bar{3}m$).

TlCl can be separated into four distinct regions. In the case of the CsCl-type structure, regions II and III have grown together when compared with the situation for TlF. However, it becomes clear that the principal features are still present, particularly when looking at the partial density of states and COHP curves. In the low energy region the states have predominantly Tl 6s/Cl 3p bonding character whereas the highest occupied states are Tl 6s/Cl 3p antibonding. the low lying states have substantially more Tl 6s character compared to TlF, and the states right below the Fermi level more Cl 3p character (Table 1). This can, again, be illustrated by a simple interaction scheme (Figure 8). As the Cl 3p states are located at higher energies than the F 2p states, they are farther apart from the Tl 6s states and thus the Tl 6s/Cl 3p interaction is less strong. This becomes particularly obvious when the band structures of TlF and TlCl in the CsCl-type structure are compared. The effects described for TlCl are even more pronounced for TlBr. The heavier the halogen atom, the larger the energy separation between Tl 6s and X-*n*p states and the weaker the covalent and the stronger the ionic interaction between $Tl^+$ and $X^-$. The energy separations between distorted and undistorted structures are reduced. Thus, in compounds with heavier halogens the necessity for a structural distortion from a highly symmetric structure with a large lattice energy (Madelung factor) to minimize unfavourable (antibonding) covalent interactions gradually vanishes.

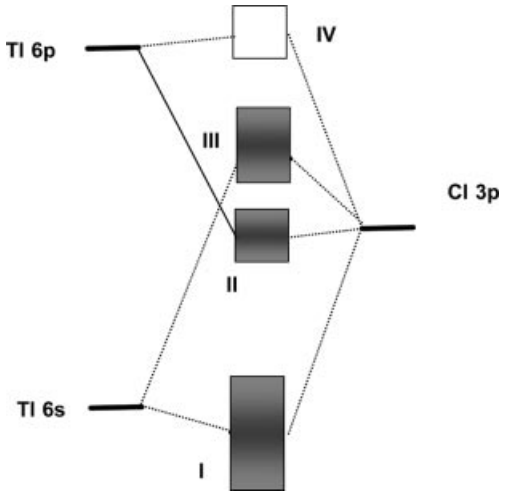

Figure 8. Schematic orbital interaction diagram for TlCl.

### Thallium Iodide (TlI)

The total and partial DOS diagrams for TlCl and TlI in the CsCl-type structure show similar features. The more ionic character of TlI becomes obvious by the fact that a pseudo gap opens up around about –3 eV due to the increasing ionic nature of the compound, this is in agreement with the trend observed for TlCl and TlBr (see above). However, the question remains as to why TlI adopts a comparatively low symmetry structure at low temperatures (Figure 2), which is also seen for the red monohalides of indium(I) (InX; X = Cl, Br, I).[17] This TlI type of structure (Figure 9) has the special property that the contraction of one sublattice (the cations) can be coupled with the dilatation of the other sublattice (the anions).[18] In the case of the low-temperature modification of TlI, the anions move apart from each other and the cations come closer. At the same time the mean cation–anion distance remains almost the same. Most importantly, short metal–metal contacts are created (two of about 371 pm and two of 457 pm). The

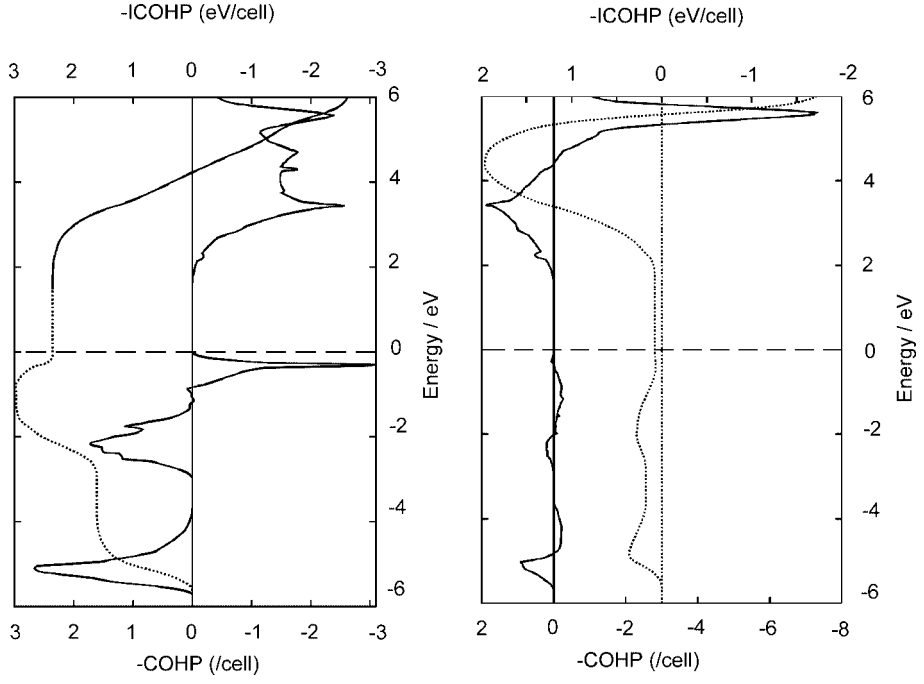

Figure 10. TlI ($Pm\bar{3}m$): COHP and ICOHP of the Tl–I (left) and Tl–Tl interactions.

COHP curves for the Tl–Tl interactions in TlI in the CsCl ($Pm\bar{3}m$; Figure 10, right) and InX (*Cmcm*; Figure 11, right) types of structure make it clear that Tl–Tl bonding becomes important in the case of the low-temperature (InX) structure whereas it is negligible for the room temperature structure (CsCl). Accordingly, the ICOPH values (Table 2) for the Tl–Tl interaction up to the Fermi level are higher for TlI in the InX type of structure than in the CsCl type of structure, which accounts for a stabilisation of the distorted structure at low temperatures through Tl–Tl bonding. Inter-

Table 2. ICOHP values of Tl–Tl interactions for TlI in the InX (*Cmcm*) and CsCl ($Pm\bar{3}m$) structure types.

| Region | Space group | |
|---|---|---|
| | *Cmcm* | $Pm\bar{3}m$ |
| I | 0.29 | 0.36 |
| II | –0.14 | –0.18 |
| III | 0.05 | 0.10 |
| IV | –0.08 | –0.21 |
| V | 0.05 | 0.01 |
| Total ICOHP | 0.17 | 0.07 |

estingly, the shortest observed Tl–Tl distance of 371 pm in TlI is comparable to that found in pentabenzylcyclopentadienidothallium(I) (363 pm).[19]

## Conclusions

In summary, the calculations on thallium halides show, just like previous theoretical work on $Tl^{I}$ coordination compounds,[20] that structural distortions in $Tl^{I}$ compounds do not originate from a stereochemically active lone pair in the sense that Tl 6s and Tl 6p mix directly (or hybridize) to give the electron pair on thallium a directional character. The Tl 6s and Tl 6p states are energetically too far apart from each other to mix efficiently.[21,22] Instead, the minimisation of unfavourable covalent antibonding states, which originate from the interaction of the Tl 6s lone pair with lone pairs of the bonding partner, is the driving force for structural distortions. A comparison of TlF with the heavier thallium halides TlX (X = Cl, Br, I) shows that such lone pair distortions depend crucially on the relative energy levels of the valence states of the constituting elements and, in turn, on the number of occupied antibonding states within the crystal.

In the case of TlF, the Tl 6s and the F 2p states are located in the same energy region, which leads to a strong covalent interaction between both bonding partners that produces strongly antibonding Tl–F states just below the Fermi level that destabilize the solid. Due to the strong splitting, the highest states move closer in energy to the Tl 6p states. The admixture of empty Tl 6p states at the top of the valence band becomes allowed through a structural distortion (symmetry reduction). This leads to a decrease in energy of the antibonding states and thereby a net stabilisation of the structure. The large dispersion in the case of fluorine thus minimizes the energy gap between the Tl 6s and Tl 6p states such that the latter can participate in chemical bonding.

The heavier the anion the larger the energy mismatch between Tl 6s states and X *n*p states. This leads to weaker covalent interactions. The highest occupied valence states gain increasingly higher X p character while the lower valence states are mainly Tl 6s like. Thus, the compounds become more ionic and the gain of Coulombic energy outweighs the (decreasing) covalent antibonding forces at the Fermi level (note that this observation is in contrast to what would have been expected judging from relative electronegativities). Consequently, typical ionic structures like the rock-salt or cesium chloride types of structure are adopted. Similar observations have been made recently for lead chalcogenides.[23] That covalent forces may, under certain conditions, lead to unsymmetrical structures even in the case of heavier anions is exhibited by the example of TlI, which gains stability at low temperatures by attractive metal–metal bonding.

## Computational Details

Calculations of the electronic structure of the thallium halides were carried out using the tight-binding linear-muffin-tin orbital (LMTO) method in the local density (LDA) and atomic sphere (ASA) approximation within the framework of the density functional theory (DFT) method.[24,25] All major relativistic effects except spin-orbit coupling were taken into account using the scalar

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

relativistic approximation. The calculations include corrections for the neglect of the interstitial regions and the partial waves of higher order. To reduce the overlap of atomic spheres (AS), empty interstitial spheres were added to the crystal potential and the basis set. The construction of the atomic sphere radii was performed according to an automatic procedure of the program package until the empty space was sufficiently filled.[26] Reciprocal space integrations were carried out using the tetrahedron method.[27] The basis set of short-range, atom-centred TB-LMTOs contained 6s, 6p, 6d and 5f wave functions for Tl ($n$ = 5). The 6d and 5f partial waves were included only in the tails of the LMTOs according to the Löwdin downfolding procedure.[28] For fluorine, 3s and 2p were taken into account as valence orbitals and the 3s orbital was treated by the downfolding technique; for chlorine ($n$ = 4) and bromine ($n$ = 5), $n$s, ($n$ – 1)p and ($n$ – 1)d functions were treated as valence orbitals, with $n$s and ($n$ – 1)d being downfolded. For iodine, 6s, 5p, 5d and 4f orbitals were considered as valence orbitals and 6s and 5d were downfolded. The partial ($l$ and $m$ quantum number decomposed) electronic DOSs were calculated to examine the effect of the anion on the electronic density of states in detail. These were calculated by projecting the wave functions onto spherical harmonics centred on each atom. For bond analysis, the crystal orbital Hamiltonian population (COHP) method was used together with its integration, the ICOHP.[29] COHP gives the energy contributions for all electronic states for selected bonds by partitioning the band structure energy in terms of the respective orbital pair contributions. Note, however, that the values are negative for bonding and positive for antibonding interactions. Thus, the sign is inverted with respect to the crystal orbital overlap population (COOP) diagrams originally used in semi-empirical extended-Hückel calculations.[30]

For TlF[31] in space group *Pbnm*, TlCl[32] and TlBr[32] in the CsCl ($Pm\bar{3}m$) and NaCl ($Fm\bar{3}m$) structures as well as for TlI in the CsCl[8] structure and its low-temperature modification,[33] the structural data were employed as reported in the literature. Lattice constants for a hypothetical TlF in the rock-salt structure were estimated from the molar volume of room temperature TlF in space group *Pbcm*.

**Supporting Information** (see footnote on the first page of this article) contains COHP and ICOHP curves for the Tl–F interaction in TlF (*Pbcm*).

# Synthesis of Novel Vinylic P–Se Heterocycles from Selenation of Alkynes by $[PhP(Se)(\mu\text{-}Se)]_2$

**Guoxiong Hua,[a] Yang Li,[a] Alexandra M. Z. Slawin,[a] and J. Derek Woollins*[a]**

**Keywords:** Selenium / Heterocycles / Alkynes / Woollins' reagent / Cycloaddition

Eleven novel five-membered $PSe_2C_2$ heterocycles have been synthesised from $[PhP(Se)(\mu\text{-}Se)]_2$ (Woollins' reagent) and alkynes (one or two C≡C triple bonds) by insertion of a Ph(Se)-$PSe_2$ fragment into alkyne triple bonds. An unusual diselenide formed by an intramolecular cycloaddition/rearrangement is also reported. All compounds have been characterised spectroscopically and four demonstrative X-ray crystal structures are reported.

## Introduction

Organoselenenium chemistry has attracted increasing attention in recent years. The interest in selenium-containing compound lies not only in their chemo-, regio-, and stereoselective reactions but also their useful biological activity.[1–7] However, the synthesis of selenium-containing organic heterocycles can be problematic involving use of toxic selenium reagents which are often difficult to handle. 2,4-Bis(phenyl)-1,3-diselenadiphosphetane 2,4-diselenide $[\{PhP(Se)(\mu\text{-}Se)\}_2]$ [**1**, Woollins' reagent (WR)], a selenium analogue of the well-known Lawesson's reagent, $[\{(p\text{-}MeOC_6H_4)P(S)(\mu\text{-}S)\}_2]$ has less unpleasant chemical properties than many systems and can be easily prepared and safely handled.[8,9]

WR has been shown to act as an efficient selenium transfer reagent for the synthesis of a range of selenoamides and selenoaldehydes by, for example, simple O/Se exchange reactions or reaction with ArCN followed by hydrolysis.[10–13] We have also reported the use of $FcP(S)S_2P(S)Fc$ (Fc = ferrocenyl) and WR in the preparation of novel metal complexes, C–P–S and C–P–Se heterocycles by reaction with a variety of reactive organic substrates/functionalities including $CS_2$, C=O, C=C double bond and C≡N triple bonds.[8,14–19]

To date, no general method for the synthesis of vinylic selenium-containing heterocycles has been established. We have focused our attention on the preparation of a series of novel vinylic heterocycles by reaction of WR with alkynes and here describe a series of new heterocycles. Four X-ray crystal structures have been determined.

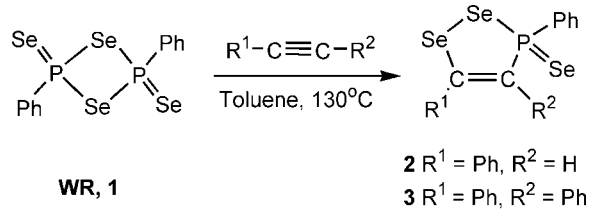
## Results and Discussion

### Reaction of WR with Alkynes Containing one C≡C Triple Bond

WR reacts with one molar equivalent of phenylacetylene or diphenylacetylene in toluene at 130 °C over 12 h to give brown, air-stable crystals of $PhP(Se)Se_2(PhC{=}CH)$ (**2**) or $PhP(Se)Se_2(PhC{=}CPh)$ (**3**), respectively, in high yields (91% and 94%, based on WR) after column chromatographic purification (silica gel, toluene as eluent) and recrystallisation from dichloromethane/*n*-hexane (Scheme 1).



Scheme 1. Synthesis of **2** and **3**.

Although **2** was described previously by us no crystal structure has been published. The data obtained here from microanalysis and spectroscopic analysis match the literature data from our previous study of **2**[15] except that the yield was much improved by lengthening the reaction time and increasing the reaction scale. The $^{31}P\{^1H\}$ NMR spectrum of **3** consists of a sharp singlet at $\delta$ = 74.3 ppm, accompanied by a pattern of selenium satellites with $^{31}P$-$^{77}Se$ couplings of 357 and 779 Hz, respectively, similar to that observed in **2**. The $^{77}Se\{^1H\}$ NMR spectrum shows three distinct doublet signals at $\delta$ = 519.3 ppm [$^2J_{P,Se}$ 7 Hz], $\delta$ = 373.4 ppm [$^1J_{P,Se}$ 358 Hz] and $\delta$ = –28.6 ppm [$^1J_{P,Se}$ 777 Hz] assigned as C–Se, P–Se and P=Se, respectively. The $^1H$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

NMR spectrum of **3** shows that only aryl protons are present.

The molecular structures of **2** and **3** (Figure 1 and Figure 2, Table 1 and Table 3) are composed of approximately planar five-membered $C_2PSe_2$ rings generated by the addition of $Ph(Se)PSe_2$ fragments from WR to the C≡C bond of alkynes. For **2**, the mean deviation of the Se(1)–C(7)–P(1)–C(8)–Se(2) plane is 0.13 Å, while in **3** the value is 0.25 Å, the extra deviation from planarity in **3** is also evident in a contraction of the P(1)–Se(2)–Se(3) and C(8)–P(1)–Se(2) internal angles on going from **2** to **3** [92.18(3)° and 101.02(12)° for **2**, 89.56(5)° and 98.6(2)° for **3**] and both effects probably reflect the steric influence of the phenyl group in **3** compared to a hydrogen atom in **2**. The majority of the other geometric parameters in these two compounds are similar, thus the exocyclic P(1)–Se(1) bond lengths in **2** and **3** [2.1137(11) and 2.0965(18) Å, respectively] are in good agreement with each other and consistent with the related selenides containing $P^V$=Se bonds [2.08–2.12 Å].[9,15–18] The P(1)–Se(2) distances [2.2616(10) Å for **2** and 2.2511(17) Å for **3**] are in the range for reported values of heterocycles containing $P^V$–Se single bonds.[8,9,15–18,20] The C(7)–C(8) bond lengths in **2** and **3** are not significantly different [1.339(4) and 1.345(9) Å, respectively], however, the P(1)–C(8) bond length in **2** is shorter than that in **3** [1.783(3) vs. 1.822(7) Å] which may reflect the different electronic effect of a hydrogen atom compared to a phenyl group. Finally, we note that the structure of **3** is chiral in the solid state, i.e. the crystal examined was a single enantiomer.

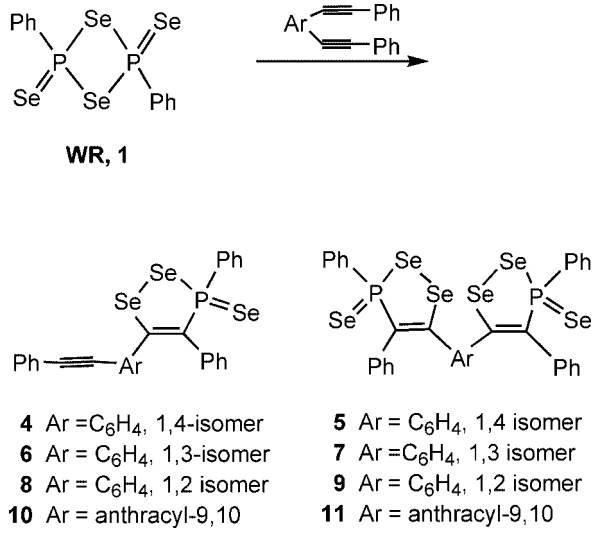
### Reaction of WR with Alkynes Containing two C≡C Triple Bonds

The reaction between WR and bis(phenylethynyl)benzene or 9,10-bis(phenylethynyl)anthracene in refluxing toluene over 12 h gave two types of products, one involving cycloaddition at one C≡C triple bond (**4**, **6**, **8** and **10**) and the other involving cycloaddition at both C≡C triple bonds (**5**, **7**, **9** and **11**) (Scheme 2). In **4**–**11** the phosphorus atoms are potentially chiral but because there is no particular stereocontrol in the reaction we would expect to see racemic mixtures. Thus, **5, 7, 9** and **11** are diastereotopic with (*R*,*R*), (*R*,*S*), (*S*,*R*) and (*S*,*S*) isomers being possible. In the $^{31}P\{^1H\}$ NMR of **5** we observed two phosphorus signals with similar selenium satellites at $\delta_P$ = 73.3 and 73.0 ppm (intensity ratio 9:1) [$J_{P,Se}$ = 357/774 and 360/770 Hz, respectively] though we cannot assign them specifically to (*R*,*R*), (*S*,*S*) and (*R*,*S*), (*S*,*R*). Further purification of **5**, **7**, **9**, and **11** by recrystallisation from $CH_2Cl_2$/petroleum ether gave a single signal arising from one pair of enantiomers which are indistinguishable by NMR, [**5a** (11% yield), **7a** (18% yield), **9a** (15% yield) and **11a** (17% yield)].



Scheme 2. Synthesis of **4**–**11**.

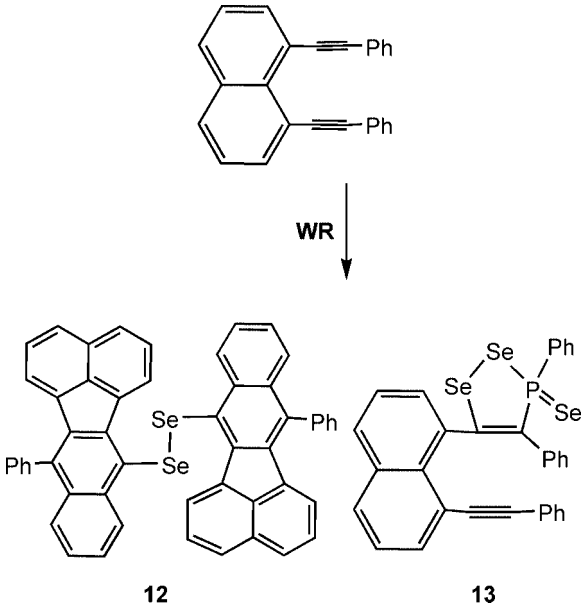
The reaction between WR and 1,8-bis(phenylethynyl)-naphthalene gave the expected compound **13** and a surprising diselenide **12**, which arises from an intramolecular cycloaddition, but no product with cycloaddition at two triple bonds (Scheme 3). Compound **12** has an analogue in sulfur chemistry, which was synthesised by Blum et al. from the reaction of 1,8-bis(phenylethynyl)naphthalene with elemental sulfur.[21] However, we failed to obtain **12** by the reaction of 1,8-bis(phenylethynyl)naphthalene with elemental selenium under identical conditions. This suggests that **12** was formed from the reaction of WR and 1,8-bis(phenylethynyl)-naphthalene. The mechanism of this reaction must be rather complex and to test if **13** is involved we heated pure **13** at reflux in toluene for 5 h and obtained **12** in 18% isolated yield.



Scheme 3. Synthesis of **12** and **13**.

Heterocycles **4**–**13** are soluble in chlorinated solvents, toluene, methanol and diethyl ether, with lower solubility in hexane. They are air-stable in the solid state, however, their solutions are not stable at room temperature; red selenium crystals precipitated after a couple of days except for **12**. Characterisations of **4**–**13** were achieved by microanalysis, IR, $^{1}H$, $^{13}C$, $^{31}P\{^{1}H\}$ and $^{77}Se\{^{1}H\}$ NMR spectroscopy and mass spectrometry.

In the $^{31}P\{^{1}H\}$ NMR spectra for compounds **4**–**11** and **13** the magnitudes of $^{1}J_{P,Se}$ and $^{1}J_{P,Se}$ (348–380 Hz, 771–820 Hz, respectively) are normal.[15–18] For the products in which one C≡C triple bond has undergone P(Se)SeSe addition the $^{31}P\{^{1}H\}$ NMR spectra show singlets with similar patterns of $^{77}Se$ satellites. As mentioned above, in the crude products with two $C_2PSe_2$ rings the $^{31}P\{^{1}H\}$ NMR spectra are mixtures as a consequence of the chirality at phosphorus but after purification by crystallisation we were able to obtain spectrally pure samples which also display singlets with $^{77}Se$ satellites. Compounds **4**–**11** and **13** were further investigated by $^{77}Se\{^{1}H\}$ NMR which exhibit three signals, assigned as C–Se, P–Se and P=Se, respectively, indicating that in each compound there is one or more identical PhP(Se)–Se–Se fragment present and supporting the presence of both P–Se single and double bonds.[18]

The composition of **4**–**13** was confirmed by mass spectrometric data with a parent $M^+$, accompanied by major fragment ions. In their IR spectra the $\nu_{(P=Se)}$ vibration, observed in the range of 528–559 $cm^{-1}$ for **4**–**11** and **13**, are consistent with the published P–Se five-membered heterocycles.[8,15]

The $^{77}Se\{^{1}H\}$ NMR spectrum of **12** shows a singlet at $\delta_{Se}$ = 279.7 ppm and its $^{1}H$ NMR spectrum displays only aromatic protons present in a wide range at $\delta_{H}$ = 6.08–9.64 ppm. Several of the $^{1}H$ NMR peaks are broad at room temp. which we attribute to lack of free rotation of the two phenyl rings. The broadening is particularly pronounced for the low field signals of the more hindered protons (see experimental section). We did carry out VT-$^{1}H$ experiments and were able to sharpen the signals at 55 °C, whilst cooling to –61 °C gave considerable broadening, but no coalescence. The complexity of the overlapping peaks in the aromatic region precluded detailed analysis/extraction of activation barriers.

Attempts to grow single crystals of **4**–**13** for X-ray analysis have, to date, been successful for only **12** and **13**. The X-ray structure of **12** shows some interesting features (Figure 3, Table 2 and Table 3). The two diselenide-bound benzo[*k*]fluoranthene moieties are not parallel planes with a dihedral angle of 162.4°, which is markedly different from sulfur analogue [157°].[21] The two terminal phenyl rings, which are connected to C8 and C38, respectively, are twisted, so that the dihedral angles between them and the two benzo[*k*]fluoranthene planes are 103° and 92.4° [corresponding angles in the sulfur analogue 106° and 103°].[21]

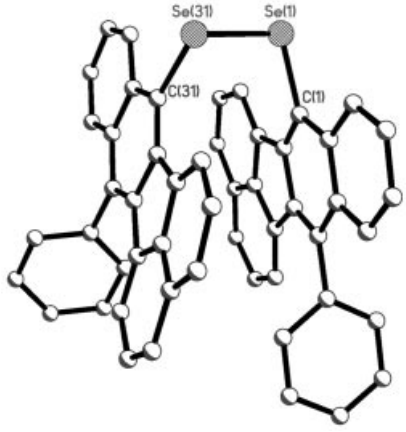


Figure 3. Molecular structure of **12** (C–H bonds omitted for clarity).

The structure of **13** contains two independent molecules within the unit cell (Figure 4, Table 1 and Table 3), the rotation of aryl ring C(27)–C(32) leads to some steric interactions in the second independent molecule, which account for the differences in metric parameters in the two molecules. Like **2** and **3**, and triselenapentalenes with carbon- and nitrogen-containing backbones,[22,23] **13** is approximately planar; the mean deviation of $P(Se)Se_2C_2$ is 0.22 Å [0.26 Å for molecule 2], while Se(3) lies 0.26 Å [0.30 Å for molecule 2] out of this plane. The Se(2)–Se(3) bond length of 2.3483(5) Å [2.3474(5) Å for molecule 2] is identical to that in $PhP(Se)Se_2$-containing five membered ring.[15,18]

In order to gain some mechanistic insight, we examined the $^{31}P\{^1H\}$ and $^{77}Se$ NMR of a crude reaction mixture during the reaction of phenylacetylene with WR. Apart from the major product **2** [δ = 67.1 ppm] there are several smaller doublets centred at δ = 76.2, 58.1, 40.1, 9.2, –15.7 ppm indicating different phosphorus environments present in the reaction mixture. None of these values corres-

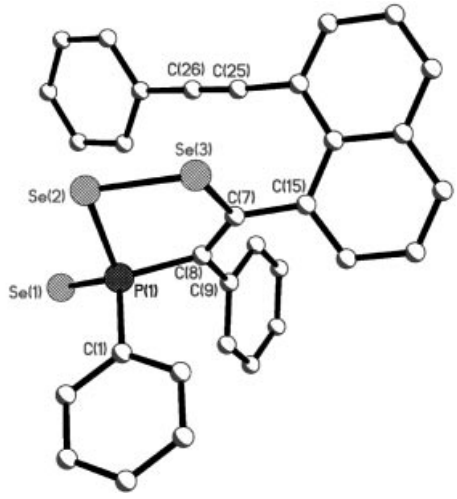

Figure 4. Molecular structure of one of the independent molecules in **13** (C–H bonds omitted for clarity).

pond to known Ph–P–Se rings[9] or WR [$\delta_P$ (solid state) = 18.7 ppm] The $^{31}$P-$^{31}$P coupling, typically ca. 270 Hz, along with $^{31}$P-$^{77}$Se coupling constant of ca. 220 Hz, suggest P–P–Se or P–Se–P linkages but does not provide any discriminatory evidence. The $^{77}$Se NMR showed >95% of the selenium present as the product **2** with only a very weak doublet at $\delta_{Se}$ = –308 ppm ($J$ = 765 Hz) and a singlet at $\delta_{Se}$ = 317 ppm. We can only speculate on a mechanism. At elevated temperatures **1** is believed to be in equilibrium with a diselenaphosphorane $PhPSe_2$, which is the true reactive species in refluxing solution. The first step in the reaction is a [2 + 2] cycloaddition of a P=Se bond from $PhPSe_2$ across the C≡C bond, giving an intermediate **I**, which exists in equilibrium in solution in two forms: the 1,2-selenaphosphacyclobutene **I** and the dipolar species **II**. We speculate that the latter species **II** can react with $PhPSe_2$ to give a second dipolar intermediate **III**, which rapidly eliminates $[PhPSe]_n$ to cyclise to subsequently afford **2**–**11** and **13** (Scheme 4).

In conclusion, we have successfully used Woollins' reagent for the syntheses of a series of novel vinylic P–Se heterocycles from alkyl C≡C triple bond organic substrates. Using $^1$H, $^{31}$P{$^1$H} and $^{77}$Se{$^1$H} NMR spectroscopy in conjunction with single-crystal X-ray crystallography we have elucidated the structures of the novel heterocycles.

## Experimental Section

Unless otherwise stated, all reactions were carried out under oxygen-free nitrogenusing pre-dried solvents and standard Schlenk techniques, subsequent chromatographic and work-up procedures were performed in air. Solvents were dried, purified, and stored according to common procedures.[24] 1,4-Bis(phenylethynyl)benzene,[25] 1,2-bis(phenylethynyl)benzene,[26] 1,3-bis(phenylethynyl)-benzene,[27] and 1,8-bis(phenylethynyl)naphthalene[28] were synthesised according to the literature methods.

$^1$H (270 Hz), $^{13}$C (67.9 Hz), $^{31}$P{$^1$H} (109 Hz) and $^{77}$Se{$^1$H} (51.4 Hz referenced to external $Me_2Se$) NMR spectra were recorded in $CDCl_3$ at 25 °C (unless stated otherwise) with a JEOL GSX 270. IR spectra were recorded as KBr pellets in the range of 4000–250 cm$^{-1}$ with a Perkin–Elmer 2000 FTIR/Raman spectrometer. Microanalysis was performed by the University of St Andrews microanalysis service. Mass spectrometry was performed by the EPSRC National Mass Spectrometry Service Centre, Swansea and the University of St Andrews Mass Spectrometry Service.

X-ray crystal data for **2**, **3**, **12** and **13** (Table 2 and Table 3) were collected at 93 K with a Rigaku MM007 High brilliance RA generator and Mercury CCD system. Intensities were corrected for Lorentz polarisation and for absorption. The structures were solved by direct methods. Hydrogen atoms bound to carbon were idealised. Structural refinements were obtained with full-matrix least squares based on $F^2$ by using the program SHELXTL.[29]

CCDC-6139164 to -613917 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**3,5-Diphenyl-1,2,3-diselenaphosphole 3-Selenide (2):** A mixture of phenylacetylene (0.10 g, 1 mmol) and WR (0.54 g, 1 mmol) in 10 cm$^3$ of dry toluene was refluxed over 12 h to give a brown solution. Upon cooling to room temperature the solution was column-chromatographed (silica gel, toluene as eluent) to give a brown fraction of **2**, which was crystallised from dichloromethane/hexane. Yield 401 mg, 91%. $C_{14}H_{11}PSe_3$ (447.09): calcd. C 37.6, H 2.5; found C 37.7, H 2.6. IR (KBr): $\tilde{\nu}$ = 523 (s, $\nu_{P=Se}$) cm$^{-1}$. $^1$H NMR: $\delta$ = 8.29 (m, 2 H, Ph), 7.75 (m, 2 H, Ph), 7.65 (m, 3 H, Ph), 7.56 (m, 3 H, Ph), 7.26 (d, $^2J_{P,H}$ = 34 Hz, 1 H, =C–H) ppm. $^{13}$C NMR: $\delta$ = 132.7, 131.9, 131.7, 131.0, 129.3, 128.8, 128.6, 127.9, 121.9, 120.7 ppm. $^{31}$P NMR: $\delta$ = 67.1 (s, $^1J_{P,Se}$ = 350 Hz, $^1J_{P,Se}$ = 771 Hz) ppm. $^{77}$Se NMR: $\delta$ = 559.9 (d, $^2J_{P,Se}$ = 7 Hz), 411.7 (d, $^1J_{P,Se}$ = 350 Hz), –15.4 (d, $^1J_{P,Se}$ = 774 Hz) ppm. MS (CI): $m/z$ = 448 [M + H]$^+$.

**3,4,5-Triphenyl-3*H*-1,2,3-diselenaphosphole 3-Selenide (3):** A refluxing mixture of diphenylacetylene (0.18 g, 1 mmol) and WR (0.54 g, 1 mmol) in toluene was heated at 130 °C over 12 h to give a brown solution. Upon cooling to room temperature the solution was column-chromatographed (silica gel, toluene as eluent) to give an orange crystal of **3**, which was crystallised from dichloromethane/hexane. Yield 495 mg, 94 %. $C_{20}H_{15}PSe_3$ (523.19): calcd. C 45.9, H 2.9; found C 45.8, H 3.1. IR (KBr): $\tilde{\nu}$ = 539 (s, $\nu_{P=Se}$) cm$^{-1}$. $^1$H NMR: $\delta$ = 8.13 (m, 2 H, Ph), 7.45 (m, 3 H, Ph), 7.24 (m, 5 H, Ph), 7.01 (m, 5 H, Ph) ppm. $^1$H NMR: $\delta$ = 132.6, 132.4, 132.2, 130.7, 130.6, 129.8, 128.7, 128.6, 128.4, 128.2, 127.8 ppm. $^{31}$P NMR: $\delta$ = 74.3 (s, $^1J_{P,Se}$ = 357 Hz, $^1J_{P,Se}$ = 779 Hz) ppm. $^{77}$Se NMR: $\delta$ = 519.3 (d, $^2J_{P,Se}$ = 7 Hz), 373.4 (d, $^1J_{P,Se}$ = 358 Hz), –28.6 (d, $^1J_{P,Se}$ = 777 Hz) ppm. MS (ES$^+$): $m/z$ (%) = 546 [M + Na]$^+$.

**3,4-Diphenyl-5-[4-(phenylethynyl)phenyl]-3*H*-1,2,3-diselenaphosphole 3-Selenide (4) and 5,5′-(1,4-Phenylene)bis(3,4-diphenyl-3*H*-1,2,3-diselenaphosphole) 3,3′-Diselenide (5):** A solution of WR (1.08 g, 2 mmol) and 1,4-bis(phenylethynyl)benzene (0.28 g, 1 mmol) in toluene (10 cm$^3$) in a sealed tube was refluxed for 12 h, giving a yellow solution. Upon cooling to room temperature, the toluene solution was purified by column chromatography (silica gel, toluene as eluent) to afford a yellow fraction of **4** followed by another orange band, which was proved to be a mixture of conformational isomers by $^{31}$P NMR spectroscopy. Layering a dichloromethane solution of the mixture with hexane gave a major orange powder of **5a**.

**Compound 4:** Yield 180 mg, 29%. $C_{28}H_{19}PSe_3$ (623.30): calcd. C 54.0, H 3.1; found C 53.4, H 3.7. IR (KBr): $\tilde{\nu}$ = 539 (s, $\nu_{P=Se}$) cm$^{-1}$. $^1$H NMR: $\delta$ = 7.29–8.15 (m, 19 H, Ph) ppm. $^1$H NMR: $\delta$ = 140.6, 139.6, 134.8, 134.0, 133.0, 132.8, 132.6, 132.4, 132.2, 131.9, 129.8, 128.7, 128.6, 128.5, 128. 3, 125.4, 121.8, 121.4, 104.1, 83.6, 83.2, 81.7, 74.0 ppm. $^{31}$P NMR: $\delta$ = 73.9 (s, $^1J_{P,Se}$ = 357 Hz, $^1J_{P,Se}$ = 779 Hz) ppm. $^{77}$Se NMR: $\delta$ = 519.8 (d, $^2J_{P,Se}$ = 7 Hz), 382.3 (d, $^1J_{P,Se}$ = 355 Hz), –16.4 (d, $^1J_{P,Se}$ = 779 Hz) ppm. MS (EI): $m/z$ = 623 [M]$^+$, 278 [M – $PhPSe_3$]$^+$.

**Compound 5a:** Yield 105 mg, 11%. $C_{34}H_{24}P_2Se_6$ (968.26): calcd. C 42.2, H 2.5; found C 42.7, H 2.5. IR (KBr): $\tilde{\nu}$ = 559 (s, $\nu_{P=Se}$) cm$^{-1}$. $^1$H NMR: $\delta$ = 6.94–8.09 (m, 24 H, Ph) ppm. $^1$H NMR: $\delta$ = 132.4, 132.3, 132.2, 132.0, 130.5, 130.2, 130.1, 129.9, 129.6, 128.7, 128.5, 128.4, 128.2, 128.0, 127.6 ppm. $^{31}$P NMR: $\delta$ = 73.3 (s, $^1J_{P,Se}$ = 357 Hz, $^1J_{P,Se}$ = 774 Hz) ppm. $^{77}$Se NMR: $\delta$ = 522.9 (d, $^2J_{P,Se}$ = 7 Hz), 384.7 (d, $^1J_{P,Se}$ = 355 Hz), –16.3 (d, $^1J_{P,Se}$ = 773 Hz) ppm. MS (EI): $m/z$ = 968 [M]$^+$, 278 [M – 2$PhPSe_3$]$^+$.

**3,4-Diphenyl-5-[3-(phenylethynyl)phenyl]-3*H*-1,2,3-diselenaphosphole 3-Selenide (6) and 5,5′-(1,3-Phenylene)bis(3,4-diphenyl-3*H*-1,2,3-diselenaphosphole) 3,3′-Diselenide (7):** WR (1.08 g, 2 mmol) and 1,3-bisphenylethynylbenzene (0.28 g, 1 mmol) were stirred in 10 cm$^3$ of dry toluene at 130 °C in a sealed tube for 12 h, producing a dark yellow solution plus a tiny amount of black solid (selenium, resulted from the decomposition of WR). Column chromatography

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(silica gel, toluene as eluent) produced a yellow fraction of **6** and subsequent another yellow band whose $^{31}P\{^{1}H\}$ NMR spectrum revealed a mixture of conformational isomers. Layering a dichloromethane solution of the mixture with hexane gave a yellow powder of **7a**.

**Compound 6:** Yield 360 mg, 58%. $C_{34}H_{24}P_2Se_6$ (968.26): calcd. C 54.0, H 3.1; found C 53.7, H 3.2. IR (KBr): $\tilde{\nu}$ = 532 (s, $\nu_{P=Se}$) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 6.95–8.18 (m, 19 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 135.5, 135.3, 134.6, 134.3, 133.5, 133.5, 132.7, 132.5, 132.2, 131.7, 131.6, 131.1, 130.7, 130.6, 130.0, 129.7, 129.3, 128.8, 128.4, 128.3, 122.8 ppm. $^{31}P$ NMR: $\delta$ = 74.3 (s, $^{1}J_{P,Se}$ = 356 Hz, $^{1}J_{P,Se}$ = 778 Hz) ppm. $^{77}Se$ NMR: $\delta$ = 520.7 (d, $^{2}J_{P,Se}$ = 7 Hz), 379.4 (d, $^{1}J_{P,Se}$ = 358 Hz), –25.3 (d, $^{1}J_{P,Se}$ = 777 Hz) ppm. MS (EI): *m*/*z* = 623 $[M]^+$, 278 $[M - PhPSe_3]^+$.

**Compound 7a:** Yield 175 mg, 18%. $C_{34}H_{24}P_2Se_6$ (968.26): calcd. C 42.2, H 2.5; found C 42.8, H 2.2. IR (KBr): $\tilde{\nu}$ = 538 (s, $\nu_{P=Se}$) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 7.13–8.06 (m, 24 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 132.0, 129.9, 129.7, 128.8, 128.7, 128.6, 128.5, 128.4 ppm. $^{31}P$ NMR: $\delta$ = 74.28 (s, $^{1}J_{P,Se}$ = 352 Hz, $^{1}J_{P,Se}$ = 771 Hz) ppm. $^{77}Se$ NMR: $\delta$ = 525.0 (d, $^{2}J_{P,Se}$ = 7 Hz), 381.9 (d, $^{1}J_{P,Se}$ = 354 Hz), –14.6 (d, $^{1}J_{P,Se}$ = 771 Hz) ppm. MS (EI): *m*/*z* = 968 $[M]^+$, 546 [M – Ph or Se – $PhPSe_3]^+$, 278 $[M - 2PhPSe_3]^+$.

**3,4-Diphenyl-5-[2-(phenylethynyl)phenyl]-3*H*-1,2,3-diselenaphosphole 3-Selenide (8) and 5,5′-(1,2-Phenylene)bis(3,4-diphenyl-3*H*-1,2,3-diselenaphosphole) 3,3′-Diselenide (9):** 1,2-Bis(phenylethynyl)-benzene (0.28 g, 1 mmol) and WR (1.08 g, 2 mmol) in toluene (10 $cm^3$) were refluxed for 12 h, giving a brownish yellow solution. Column chromatography (silica gel, toluene) gave a yellow fraction of **8** followed by a yellow band whose $^{31}P\{^{1}H\}$ NMR spectrum revealed a mixture of conformational isomers once again. Layering a dichloromethane solution of the mixture with hexane afforded a yellow powder of **9a**.

**Compound 8:** Yield 437 mg, 70%. $C_{34}H_{24}P_2Se_6$ (968.26): calcd. C 54.0, H 3.1; found C 54.2, H 3.8. IR (KBr): $\tilde{\nu}$ = 539 (s, $\nu_{P=Se}$) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 6.98–7.67 (m, 19 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 133.6, 133.3, 132.5, 132.3, 132.1, 132.0, 131.9, 131.4, 130.5, 129.7, 129.2, 129.0, 128.7, 128.5, 128.1, 128.0, 127.7 ppm. $^{31}P$ NMR: $\delta$ = 73.8 (s, $^{1}J_{P,Se}$ = 343 Hz, $^{1}J_{P,Se}$ = 779 Hz) ppm. $^{77}Se$ NMR: $\delta$ = 528.6 (d, $^{2}J_{P,Se}$ = 7 Hz), 409.8 (d, $^{1}J_{P,Se}$ = 346 Hz), –22.2 (d, $^{1}J_{P,Se}$ = 778 Hz) ppm. MS (EI): *m*/*z* = 623 $[M]^+$, 278 $[M - PhPSe_3]^+$.

**Compound 9a:** Yield 144 mg, 15%. $C_{34}H_{24}P_2Se_6$ (968.26): calcd. C 42.2, H 2.5; found C 42.7, H 2.6. IR (KBr): $\tilde{\nu}$ = 528 (s, $\nu_{P=Se}$) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 7.00–7.41 (m, 24 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 133.6, 133.4, 132.5, 132.3, 132.1, 131.9, 131.4, 130.6, 129.7, 129.2, 128.7, 128.5, 128.2, 128.1, 127.7 ppm. $^{31}P$ NMR: $\delta$ = 77.5 (s, $^{1}J_{P,Se}$ = 364 Hz, $^{1}J_{P,Se}$ = 822 Hz) ppm. $^{77}Se$ NMR: $\delta$ = 528.4 (d, $^{2}J_{P,Se}$ = 8 Hz), 409.8 (d, $^{1}J_{P,Se}$ = 365 Hz), –21.9 (d, $^{1}J_{P,Se}$ = 820 Hz) ppm. MS (EI): *m*/*z* = 968 $[M]^+$, 624 $[M - PhPSe_3]^+$, 278 $[M - 2PhPSe_3]^+$.

**3,4-Diphenyl-5-[10-(phenylethnyl)anthracen-9-yl]-3*H*-1,2,3-diselenaphosphole 3-Selenide (10) and 5,5′-Anthracene-9,10-diylbis(3,4-diphenyl-3*H*-1,2,3-diselenaphosphole) 3,3′-Diselenide (11):** A solution of WR (1.08 g, 2 mmol) and bis(phenylethynyl)anthracene (0.38 g, 1 mmol) in toluene (10 $cm^3$) in a sealed tube was refluxed for 12 h, giving a yellow solution. After cooling to room temperature the toluene solution was purified by column chromatography ($SiO_2$, toluene as eluent) to afford a yellow fraction of **10** followed by another orange band of the mixture. Layering a dichloromethane solution of the mixture with hexane gave orange powder of **11a**.

**Compound 10:** Yield 410 mg, 57%. $C_{36}H_{23}P_2Se_6$ (991.28): calcd. C 59.8, H 3.2; found C 59.9, H 3.4. IR (KBr): $\tilde{\nu}$ = 533 (s, $\nu_{P=Se}$) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 6.66–8.56 (m, 23 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 134.5, 134.3, 133.2, 133.0, 132.4, 132.1, 131.5, 130.1, 129.1, 128.8, 128.5, 128.2, 128.0, 127.1, 127.0, 126.7, 126.3, 126.0, 123.2, 119.8 ppm. $^{31}P$ NMR: $\delta$ = 73.3 (s, $^{1}J_{P,Se}$ = 352 Hz, $^{1}J_{P,Se}$ = 794 Hz) ppm. $^{77}Se$ NMR: $\delta$ = 529.3 (d, $^{2}J_{P,Se}$ = 7 Hz), 414.4 (d, $^{1}J_{P,Se}$ = 353 Hz), –19.6 (d, $^{1}J_{P,Se}$ = 792 Hz) ppm. MS (CI): *m*/*z* = 727 $[M + H]^+$, 378 $[M - PhPSe_3]^+$.

**Compound 11a:** Yield 183 mg, 17%. $C_{34}H_{24}P_2Se_6$ (968.26): calcd. C 47.2, H 2.6; found C 46.7, H 2.7. IR (KBr): $\tilde{\nu}$ = 533 (s, $\nu_{P=Se}$) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 6.63–8.26 (m, 28 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 133.2, 132.9, 132.8, 132.2, 132.0, 131.7, 129.9, 129.1, 128.7, 128.5, 127.9, 127.4, 127.0, 126.0 ppm. $^{31}P$ NMR: $\delta$ = 73.3 (s, $^{1}J_{P,Se}$ = 352 Hz, $^{1}J_{P,Se}$ = 779 Hz) ppm. $^{77}Se$ NMR: $\delta$ = 535.2 (d, $^{2}J_{P,Se}$ = 7 Hz), 404.0 (d, $^{1}J_{P,Se}$ = 355 Hz), –16.8 (d, $^{1}J_{P,Se}$ = 780 Hz) ppm. MS (CI): *m*/*z* = 1069 $[M + H]^+$, 726 $[M - PhPSe_3]^+$, 565 [M – $PhPSe_3$ – 2Se or 2Ph]$^+$, 378 $[M - 2PhPSe_3]^+$.

**Synthesis of Diselane 12 and 3,4-Diphenyl-5-[8-(phenylethynyl)-1-naphthyl]-3*H*-1,2,3-diselenaphosphole 3-Selenide (13):** A mixture of Woollins' reagent (1.08 g, 2 mmol) and 1,8-bis(phenylethynyl)naphthalene (0.45 g, 1 mmol) in toluene (20 $cm^3$) was heated at reflux for 12 h resulting in red solution. After cooling to room temperature, the solution was subjected to column chromatography ($SiO_2$, toluene as eluent) and afforded successively red **12** followed a pale yellow **13**.

**Compound 12:** Yield 57 mg, 14%. $C_{52}H_{30}Se_2$ (812.71): calcd. C 76.8, H 3.7; found C 76.1, H 3.9. IR (KBr): $\tilde{\nu}$ = 825 (w), 759 (m), 701 (w), 448 (w) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 6.08 (br., d, 1 H, Ph), 6.56–8.67 (br., m, 28 H, Ph), 9.64 (br., d, 1 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 135.7, 135.0, 134.2, 132.1, 131.7, 130.0, 129.9, 129.7, 129.3, 128.9, 128.0, 127.9, 125.7, 124.9, 124.8, 123.9, 122.3, 121.7, 120.9, 119.9, 119.1, 118.8 ppm. $^{77}Se$ NMR: $\delta$ = 279.7 (s, 2Se) ppm. MS (CI): *m*/*z* = 831 $[M + NH_4]^+$.

**Compound 13:** Yield 147 mg, 22%. $C_{32}H_{21}PSe_3$ (673.36): calcd. C 57.1, H 3.1; found C 57.7, H 3.3. IR (KBr): $\tilde{\nu}$ = 546 (s, $\nu_{P=Se}$) $cm^{-1}$. $^{1}H$ NMR: $\delta$ = 6.81–8.70 (m, 21 H, Ph) ppm. $^{1}H$ NMR: $\delta$ = 135.6, 134.0, 133.0, 132.4, 131.4, 131.0, 130.9, 130.0, 129.5, 129.4, 128.9, 128.7, 128.5, 127.3, 126.1, 125.8 ppm. $^{31}P$ NMR: $\delta$ = 66.5 (s, $^{1}J_{P,Se}$ = 380 Hz, $^{1}J_{P,Se}$ = 803 Hz) ppm. $^{77}Se$ NMR: $\delta$ = 564.9 (d, $^{2}J_{P,Se}$ = 11 Hz), 461.5 (d, $^{1}J_{P,Se}$ = 383 Hz), –14.7 (d, $^{1}J_{P,Se}$ = 802 Hz) ppm. MS ($CI^+$): *m*/*z* = 674 $[M + H]^+$, 436 [M – 3Se or 3Ph]$^+$, 328 $[M - PhPSe_3]^+$.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** the photograph of Robert Bunsen and the statue of Jöns Jakob Berzelius in the centre of Berzeli Park (Stockholm). Both famous chemists investigated the chemistry of tetramethyldiarsane $As_2Me_4$ (*kakodyl*), one of the first organometallic compounds that were initially prepared by Claude-Louis Cadet de Gassicourt (*Cadet's fuming liquid*) in 1757. Distibanes $Sb_2R_4$, the heavier congeners of diarsanes, exhibit much weaker metal−metal bonds and can be used for interesting bond-making and bond-breaking reactions with group 13 organometallic compounds. Details are discussed in the article by S. Schulz et al. on p. 931ff. The artwork was designed by Dr. Edgar Luttmann.

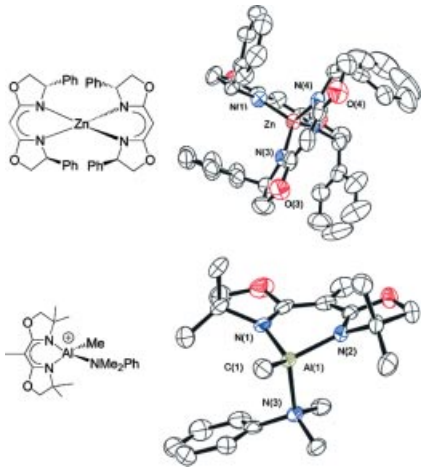
## MICROREVIEW

### Asymmetric Catalysis

**S. Dagorne,* S. Bellemin-Laponnaz,***
**A. Maisse-François ..... 913–925**

Metal Complexes Incorporating Monoanionic Bisoxazolinate Ligands: Synthesis, Structures, Reactivity and Applications in Asymmetric Catalysis

**Keywords:** Bisoxazolinate ligand / Asymmetric catalysis / Metal complex / Coordination chemistry



The anionic and bidentate bisoxazolinate ligand may be seen as an nitrogenated version of the acetylacetonate unit and as closely related to the diketiminate bidentate ligand; bisoxazolinate ligands exhibit a rich and versatile coordination chemistry with various metal centers. These excellent coordination properties combined with their ready accessibility in an enantiomerically pure form has opened the way to various applications in asymmetric catalysis involving this class of bidentate ligands.

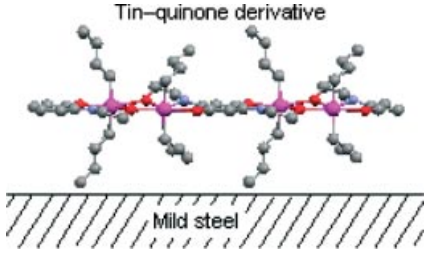
A Bis(di-*n*-butyltin)–Quinone Derivative as a Simultaneous Chemo- and Bioactive Corrosion Inhibitor

**Keywords:** Tin / Quinones / Corrosion / Biocide activity / X-ray structure



A bis(di-*n*-butyltin)–quinone derivative was synthesized and characterized; it was shown that the organometallic complex has a discrete structure in solution. In the solid state a coordination polymer is formed through Sn···O intermolecular bonds. The corrosion inhibition efficiency for steel and the inhibitory effect on aerobic and anaerobic bacteria were evaluated, showing that the title compound is a simultaneous chemo- and bioactive anticorrosion agent. Acute toxicity tests indicated a relatively low toxicity level for the environment.

## Inorganic Supramolecular Chemistry

The supramolecular complexes $[Hg_6Z_4](MX_6)Hg_y$ (Z = As, Sb; M = Hg, Cd; X = Cl, Br, I; $y$ = 0, 0.5, 0.6) consist of discrete anion guests and a perovskite-like, 3D cationic framework composed of corner-sharing distorted $As_2Hg_6$ or $Sb_2Hg_6$ octahedra that possesses two types of closed cavities with different sizes. The octahedral anion guests $(MX_6)^{4-}$ are embedded in the larger cavities, while the smaller cavities trap the excess mercury atoms or remain empty. The electronic band structures and density of states (DOS) for these compounds are calculated by density functional methods.

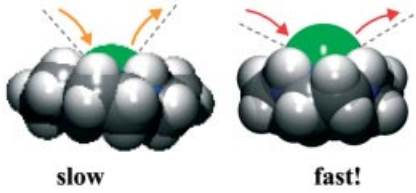
## Cationic Zinc Thiolates

**J. Notni, W. Günther, E. Anders* ..... 985–993**

Zinc Thiolate Complexes $[ZnL_n(SR)]^+$ with Azamacrocyclic Ligands, Part III: The Influence of the Ligand $L_n$ on the Reactivity of Zinc-Bound Thiolate



Reactions proceeding by an associated (metal-bound) mechanism are faster in cases of decreased obstruction of the zinc(II) ion by the macrocyclic ligand. This effect overrides electronic and/or orbital reaction control, as inferred from correlation plots of kinetic data against structural and electronic parameters obtained from density functional calculations.

## Metalloenzyme Models

A truly functional model system for molybdenum oxotransferases provides evidence for all biologically realistic intermediates, namely mononuclear $Mo^{VI}$, $Mo^{V}$ and $Mo^{IV}$ species. Dinucleation to EPR-silent $[Mo^{V}_2O_3]$ species prevailing in homogeneous solution is suppressed by immobilising the active species to a polymeric support by two-point attachment.

## Keggin-Type Polyoxotungstates

A systematic study of metal coordination in the Keggin-type anions $[PW_{12}O_{40}]^{3-}$, $[PW_{11}O_{39}]^{7-}$, $[PW_{11}M(H_2O)O_{39}]^{4-}$, M = Fe, Ru, and $[XW_{11}Mn^{III}(H_2O)O_{39}]^{n-}$, X = P, Si, B, was performed by EXAFS spectroscopy using multiple- and single-scattering analysis. This study allowed for the comparison of average inter-atomic distances in the different heteropolyanions of the same family in tetrabutylammonium salts and in acetonitrile solution.

# Metal Complexes Incorporating Monoanionic Bisoxazolinate Ligands: Synthesis, Structures, Reactivity and Applications in Asymmetric Catalysis

**Samuel Dagorne,*[a] Stéphane Bellemin-Laponnaz,*[a] and Aline Maisse-François[a]**

**Keywords:** Bisoxazolinate ligand / Asymmetric catalysis / Metal complex / Coordination chemistry

The present contribution reviews the synthesis, structures, reactivity and applications in asymmetric catalysis of metal complexes containing monoanionic bisoxazolinate ligands. The anionic and bidentate bisoxazolinate ligand, which may be seen as a nitrogenated version of the acetylacetonate unit and may also be closely related to the diketiminate bidentate ligand, appears to exhibit a rich and versatile coordination chemistry with various metal centers. These excellent coordination properties, combined with the ready accessibility of chiral bisoxazolinate ligands in an enantiomerically pure form, has opened the way to various applications in asymmetric catalysis involving this class of bidentate ligands. Thus, the use of chiral bisoxazolinate ligands in asymmetric catalysis constitutes a central part of this review.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Chiral oxazolines are among the most widely used ligands in asymmetric catalysis.[1] The success of this "privileged" class of ligands in numerous metal-complex-catalyzed transformations may be related both to their ready accessibility and the possibility of using them as building blocks for the design of multidentate ligands, thereby allowing access to various chelating ligands with finely tuned coordination properties.[2] In addition to these attractive features, the intrinsic skeleton of the chiral oxazoline unit is expected to favor a high level of asymmetric induction as it incorporates a stereogenic center that is usually located on the carbon next to the metal-coordinated nitrogen. The latter feature, which is of obvious importance in asymmetric catalysis, is also largely responsible for the widespread use of these ligands in this field. Thus, since the earliest studies on the use of chiral oxazolines in catalysis, ligands incorporating an oxazoline with various donating groups include bisoxazolines,[3] trisoxazolines,[4] and oxazoline ligands with an additional chiral element attached to their skeleton or with a characteristic structure.[5]

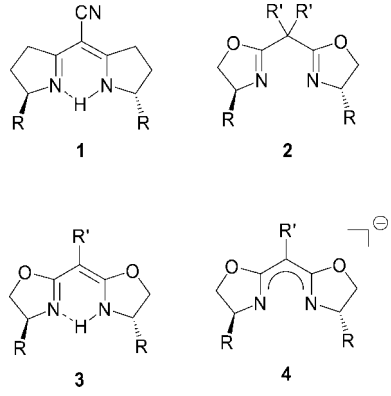
Among the above class of ligands, neutral $C_2$-symmetric bisoxazoline ligands have been the most studied as $C_2$-symmetric chelates have become landmark ligands for use in asymmetric catalysis since the pioneering work of Kagan in this area.[6] In general, bisoxazoline ligands in which one carbon atom links two oxazoline rings are the most frequently used (Scheme 1). Such entities, which can be structurally related to the semicorrin ligands **1** developed by Pfaltz and co-workers,[7] are neutral bidentate ligands of the type **2** and **3**. While derivatives **2** and **3** may be used as $L_2$ chelates, monoanionic bisoxazolinates **4** that act as $LX^-$ chelates may be obtained by deprotonation of **3**. Such anionic bidentate ligands may be seen as a chiral, nitrogenated version of the acetylacetonate (acac) unit, which is known to exhibit a rich and versatile coordination behavior with various metal centers.[8] Over the last few years, the use of chiral bisoxazolinate ligands of type **4** for coordination to metal centers has received a growing attention as the derived complexes may be of interest in asymmetric catalysis. In this regard, remarkable catalytic systems have already been developed based on this ligand structure. In addition, several recent reports on the coordination chemistry of bisoxazolinate to various metal centers have provided an insight into the structural trends that might be expected for this class of complexes.



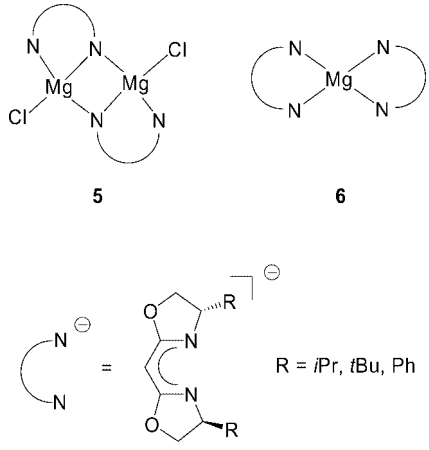
Scheme 1.

Although the coordination chemistry and the potential applications in catalysis of metal complexes bearing neutral bisoxazolines have been reviewed previously,[9] those of bisoxazolinato ligands has not been the subject of a similar survey despite the interesting results reported over the past few years with these monoanionic ligands. The present contribution thus reviews metal complexes incorporating monoanionic bisoxazolinate ligands of type **4** that have been prepared and structurally characterized thus far and the catalytic applications involving these metal complexes. A special emphasis will also be given to their use in asymmetric catalysis.

## Group 1 and 2 Metal Complexes

To date, coordination of the bisoxazolinate ligand to group 1 and 2 metals has been the subject of very few reports. Bisoxazolinatolithium salts, for example, which can be easily generated by reaction of neutral bisoxazolines of type **3** with Brönsted bases such as *n*BuLi and amidolithium salts, have been mainly used as convenient starting materials for subsequent salt metathesis reactions with various metal halides, thereby allowing access to the corresponding bisoxazolinate metal complexes. However, to date, no structural data are available on group 1 bisoxazolinate metal complexes.

As for group 2 derivatives, reports on these complexes have thus far been restricted to magnesium derivatives. An initial report by Singh concluded, on the basis of NMR, IR, and cryoscopic data, that bisoxazolines readily react with $R_2Mg$ or RMgCl to form the corresponding dinuclear magnesium complexes **5** by an alkane elimination (Scheme 2).[10] The use of two equivalents of bisoxazolines was reported to yield the homoleptic bis(bisoxazolinato)-magnesium complex **6** (Scheme 2).

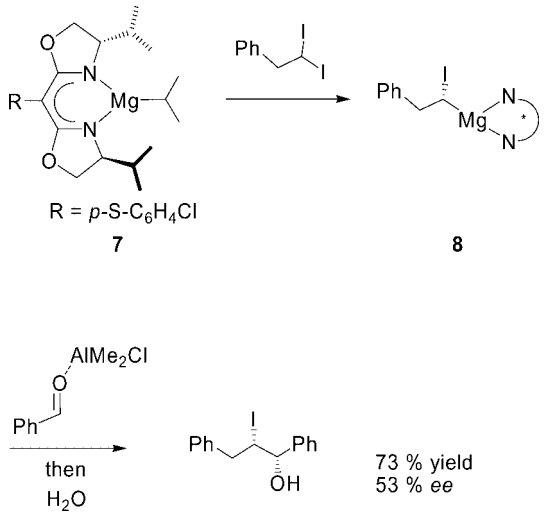


Scheme 2. Proposed structures of complexes **5** and **6**.

More recently, Hoffmann et al. have elegantly illustrated the potential use of chiral bisoxazolinatomagnesium complexes in enantioselective synthesis.[11] Thus, for example, the chiral alkylmagnesium complex **7**, which can be readily prepared by treatment of the corresponding chiral bisoxazoline with $iPr_2Mg$, can be used to differentiate the enantiotopic iodine atoms of 1,1-dihaloalkanes by a halogen/metal exchange reaction (Scheme 3).

The kinetically controlled iodine/magnesium exchange between **7** and a 1,1-dihaloalkane preferentially affords the diastereomer **8**, which was proposed to be configurationally stable at –78 °C on the basis of careful monitoring experiments and can be trapped by a combination of $AlMe_2Cl$ and benzaldehyde to afford the corresponding iodohydrins in good yield (73%) and with a reasonable *ee* (53%). The chiral bisoxazolinatomagnesium complex **7** was also used for an enantioselective halogen/metal exchange reaction of a racemic bromoiodo compound, thus providing access to an enantiomerically enriched bromohydrin, albeit in low *ee*, by a kinetic resolution process (33% yield, 18% *ee*, Scheme 4). The unreacted enantiomer of the racemic bromoiodo compound could be re-isolated in 62% yield with 8% *ee*.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Reaction of a 1,1-diiodoalkane with complex **7**.

From a reactivity point of view, these studies show that the basicity of the monoanionic bisoxazolinate ligand can greatly influence the outcome of the reaction between the neutral bisoxazoline and $i$Pr$_2$Mg. Thus, while the reaction of the simple bisoxazoline (BOX-$i$Pr$_2$)H with $i$Pr$_2$Mg yields a statistical mixture of $i$Pr$_2$Mg, the mono-bisoxazolinato, and the bis(bisoxazolinato)magnesium complexes (Scheme 5), that of the arylthio-substituted bisoxazoline yields the mono-bisoxazolinatomagnesium complex quantitatively (Scheme 5). This difference in reactivity may be ascribed to the less basic character of the arylthio-substituted bisoxazolinate with respect to (BOX-$i$Pr)$^-$.

### Group 3 Transition Metal Complexes

The use of nitrogen-based chelating ligands for coordination to rare earth metals (including scandium and yttrium) has been increasing over the last years, with the diketiminate bidentate ligand being a ligand of choice in this area.[12] It is therefore easily understood that bisoxazolinates have become of interest for coordination to group 3 metal complexes. In this regard, Anwander and collaborators first synthesized lanthanide complexes incorporating bisoxazolinate ligands.[13] The precursors Ln[N(SiHMe$_2$)$_2$]$_3$(thf)$_2$ (Ln = Y, La) were found to react smoothly with one or two equivalents of a lithium bisoxazolinate salt to give the corresponding chiral complexes **9** or **10** in good yields (Scheme 6). Yttrium and lanthanum were chosen for this study because

they are representative of small and large lanthanides, respectively. The yttrium derivative **9** was characterized by an X-ray crystallographic study (Figure 1). The complex lies on a $C_2$-symmetric axis and the metal center adopts a distorted tetrahedral structure. The silylamide ligands are oriented away from the bulky *tert*-butyl groups, thereby minimizing the steric interactions. The bis(bisoxazolinato) complexes **10** were characterized by classical techniques, although no X-ray study was reported. Attempts to synthesize the homoleptic complexes $Ln(Box)_3$ failed, presumably for steric reasons.

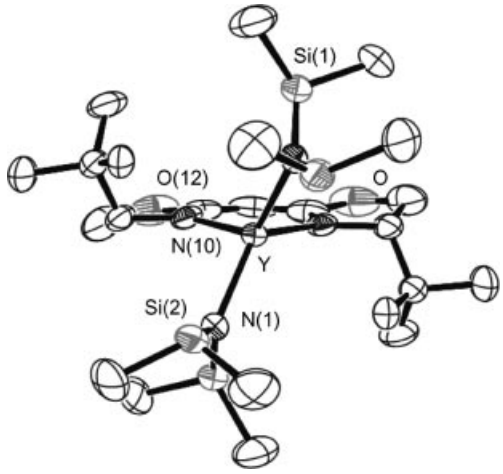

Figure 1. Molecular structure of **9**. Selected distances [Å] and angles [°]: Y–N(1) 2.222(6), Y–N(10) 2.288(5); N(10)–Y–N(10)′ 82.0(2), N(1)–Y–N(1)′ 126.4(2).

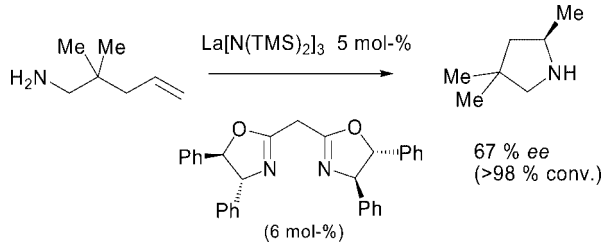
The ready and straightforward accessibility of chiral bisoxazolinato lanthanide complexes has prompted studies of their potential in enantioselective catalysis. In this area, Marks et al. have already thoroughly shown the usefulness of this new class of chiral complexes as catalysts for the enantioselective intramolecular hydroamination reaction − a formal addition of an N–H bond across a C=C double bond.[14] In the 1990s, chiral *ansa*-lanthanocenes were found to be efficient catalysts for this reaction, with *ee* values of up to 74% being reported for the formation of five-membered rings[15] and *ee* values of up to 67% for six-membered rings.[16] However, these chiral *ansa*-metallocene derivatives were found to racemize in the presence of amines, which lowers the enantioselectivity and also hampers accessibility to the substrate. In the search for a new catalyst class that may outperform chiral lanthanocenes, various lanthanide bisoxazolinate complexes were tested.[17]

Different screening experiments showed that lanthanide mono-bisoxazolinate complexes $(Box)Ln[N(TMS)_2]_2$ effectively catalyze the enantioselective intramolecular hydroamination with good rates and enantioselectivities (up to 67% *ee*; Scheme 7), which constitutes a rare example of an enantioselective hydroamination by non-Cp lanthanide complexes. Interestingly, and unlike the trend observed in metallocenes derivatives, the enantioselectivities were found to increase with the ionic radius of the metal, with the best results being observed for the chiral lanthanum derivatives. As for the bis(bisoxazolinato) lanthanide compounds, these were also found to catalyze the reaction, with similar enantioselectivities but lower activity.



Scheme 7. Intramolecular hydroamination/cyclization with a chiral bis(oxazolinato)lanthanide catalyst generated in situ.

More recently, Carpentier et al. have reinvestigated the chemistry of bis(bisoxazolinato) lanthanide complexes such as **10** and synthesized new chiral and achiral bis(bisoxazolinato)yttrium and -lanthanum complexes.[18] The aim of their studies was to probe the potential of these complexes as initiators of the ring-opening polymerization (ROP) of (D,L)-lactide and (D,L)-β-butyrolactone. Along the way, the molecular structure of the achiral dimethylbisoxazolinate derivative **11** was established by X-ray crystallography; this is the first solid-state structure reported for a bis(bisoxazolinato) lanthanide compound (Figure 2). The geometry at the metal center in **11** is distorted trigonal bipyramidal, with the apical sites being occupied by two bisoxazolinate nitro-

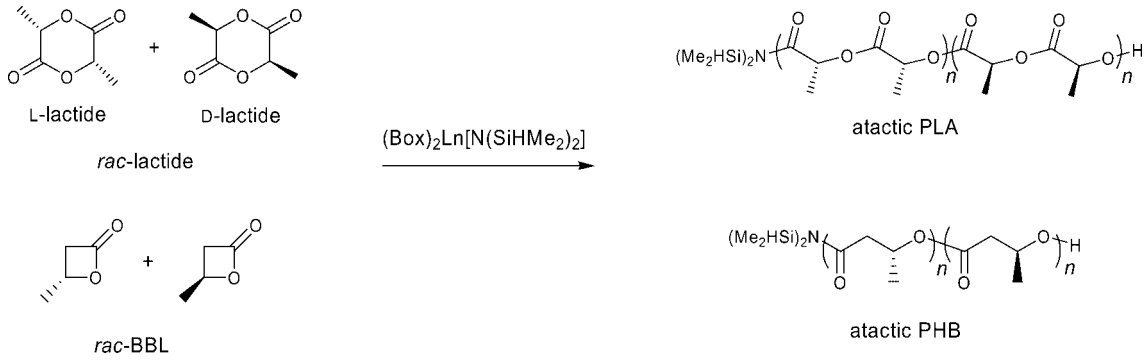


Scheme 8. Ring-opening polymerization of *rac*-lactide and *rac*-β-butyrolactone.

gens. As expected, a significant delocalization of the ligand's negative charge is indicated by an elongation of the N–C and a decrease of the C–C bond lengths of the bisoxazolinate chelating backbone with respect to those in the neutral bisoxazoline analogs.

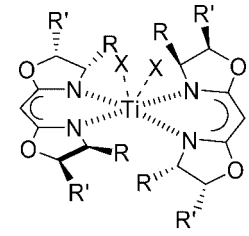
The prepared complexes were found to be highly active and productive in the ROP of (D,L)-lactide and (D,L)-β-butyrolactone, with turnover frequencies of up to 31200 $h^{-1}$ and turnover numbers of up to 2400 (at room temperature; Scheme 8). These polymerizations proceed in a controlled manner and give polymers with relatively narrow polydispersities ($M_w/M_n$ = 1.08–1.44). However, in all cases, and regardless of the nature of the chelating bisoxazolinate ligand, the microstructure of the polymer exhibits no stereoregularity − only atactic polymers are produced.[19]

## Group 4–7 Transition Metal Complexes

### *Ti Complexes*

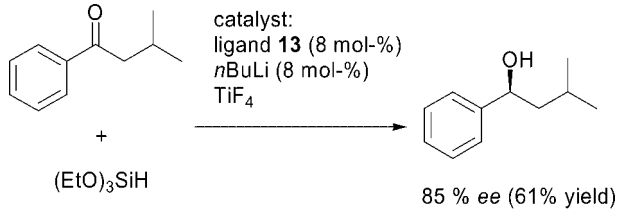
Taking advantage of the ready accessibility of enantiomerically pure bisoxazolines, an enantioselective reduction of ketones catalyzed by $Ti^{IV}$/chiral bisoxazolinate systems (using a silane as a stoichiometric hydride source) has recently been reported by Cozzi et al.[20] Once again, the main driving force for this work was the design and synthesis of alternative catalysts to the chiral Ti metallocenes originally developed by Buchwald, which were shown to be quite effective catalysts of the aforementioned reduction but whose isolation requires a tedious resolution process. The titanium(IV)/chiral bisoxazolinate catalytic systems were generated in situ by reaction of a chiral bisoxazoline with *n*BuLi followed by addition of a titanium(IV) ($TiX_4$) precursor. Since two equivalents of bisoxazolinates were used, the titanium complex was proposed to be an octahedral complex of the general formula [$(Box)_2TiX_2$] (**12**; Scheme 9).

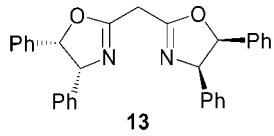
According to their studies, the best results were obtained using ligand **13**, $TiF_4$, and $(EtO)_3SiH$ as the hydride source. Under these conditions, the reduction of various aryl alkyl ketones proceeds with enantiomeric excess of up to 85% (Scheme 10). However, in the present case, the *ee* values are, in general, lower than those observed with chiral titanium metallocenes.



**12**

Scheme 9. Proposed structure of the titanium precatalyst.





**13**

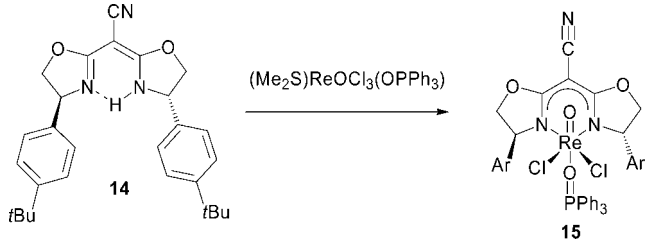
Scheme 10. Enantioselective reduction of isovalerophenone catalyzed by a chiral bisoxazolinatotitanium complex generated in situ.

Thorough theoretical investigations together with some NMR monitoring experiments were also carried out to gain insight into the mechanism of the $Ti^{IV}$/chiral bisoxazolinate-catalyzed reaction.[21] DFT calculations performed for two possible reaction pathways, one involving a $Ti^{IV}$ hydride as the active catalytic species and the other one a $Ti^{III}$ hydride species, concluded that the energetically favored mechanism involves a $Ti^{IV}$ hydride as the active species. These computational results apparently matched the experimental NMR spectroscopic data, since no formation of paramagnetic species could be detected. However, it is noteworthy that a titanium(III) hydride complex has been proposed as the active species in the case of chiral titanium metallocene catalysis.[45]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *Re Complexes*

A chiral bisoxazolinato(oxido)rhenium(V) complex [(CN-BOX)($PPh_3O$)$ReOCl_2$] (**15**; Scheme 11 and Figure 3) that was found to catalyze the enantioselective hydrosilylation of ketones and imines has also been synthesized and structurally characterized recently. Initial studies by Toste et al. showed that the $Re^V$ complex [$(Ph_3P)_2Re(O)_2I$] efficiently catalyzes the hydrosilylation of ketones.[22] Based on mechanistic studies of the latter system, they anticipated that the use of a chiral and monoanionic bidentate ligand may open the way to an enantioselective catalytic system. While classical monoanionic bisoxazolinates do not react with [$(Ph_3P)_2Re(O)_2I$], the more acidic cyanobisoxazolines, first reported by Corey and Wang in 1993, do.[23] Thus, the reaction of cyanobisoxazoline **14** and [$(Me_2S)ReCl_3O(OPPh_3)$] affords complex **15** (Figure 3 and Scheme 11). The metal possesses a distorted octahedral geometry in which the oxido ligand is *trans* to the $Ph_3PO$ ligand.[24] This chiral $Re^V$ species is an active catalyst for the enantioselective phosphanyl imine reduction,[25] with good to excellent enantiomeric excesses (>99% *ee*) for aromatic imines (including heteroaromatic), α-imino esters, and α,β-unsaturated imines (Scheme 12). We also note that these reactions were carried out without the need for rigorous exclusion of air and moisture, thus rendering this catalytic system particularly attractive.



Scheme 11. Synthesis of the rhenium complex **15** from the cyanobisoxazoline **14**.

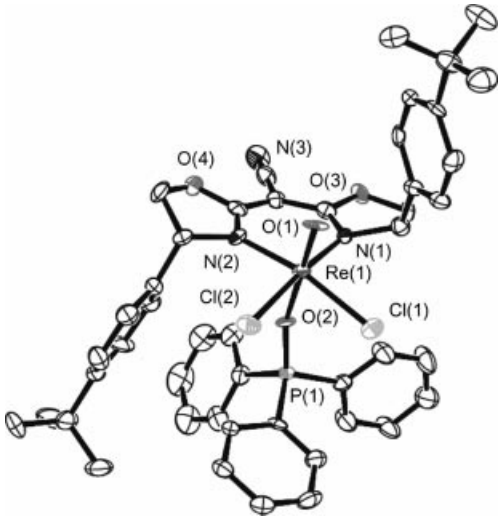


Figure 3. Molecular structure of **15**. Selected distances [Å] and angles [°]: Re(1)–O(1) 1.672(5), Re(1)–O(2) 2.131(6), Re(1)–N(1) 2.068(7), Re(1)–N(2) 2.045(7), Re(1)–Cl(1) 2.378(3), Re(1)–Cl(2) 2.368(2); N(1)–Re(1)–N(2) 90.1(3), O(1)–Re(1)–O(2) 174.7(3).

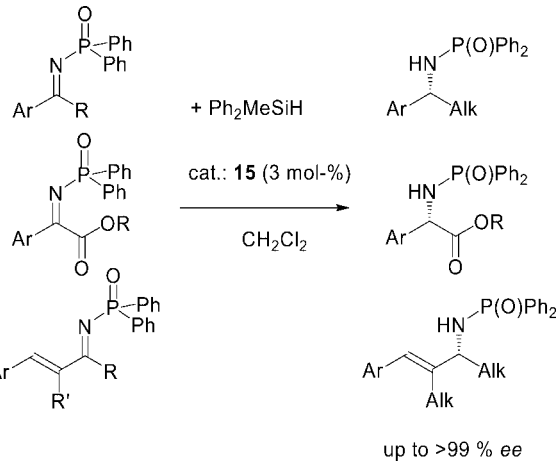
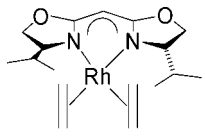


Scheme 12. Enantioselective imine reduction with rhenium precatalyst **15**.

## Group 9–12 Metal Complexes

### *Rh Complexes*

Bisoxazolinate ligands have also been found to be suitable for coordination to rhodium. In 1994, Brown et al. reported the synthesis and solid-state structure of the bisoxazolinato complex [(BOX-*i*Pr)$Rh^I(\eta^2\text{-ethene})_2$] (**16**; Figure 4).[26]



**16**

(BOX-Ph)$Rh^I$-(η-ethene)$_2$ (**17**)

(BOX-*t*Bu)$Rh^I$-(η-ethene)$_2$ (**18**)

Figure 4. Structure of the Rh complexes **16**–**18**.

The most interesting feature of **16** is that both ethenes are displaced from the ideal perpendicular geometry in a rotatory or "rolling" fashion by about 10°. This distortion occurs with little or no energetic cost according to theoretical calculations. More recently, the related $Rh^I$ complexes [(BOX-Ph)$Rh^I(\eta^2\text{-ethene})_2$] (**17**) and [(BOX-*t*Bu)$Rh^I(\eta^2\text{-ethene})_2$] (**18**) have also been characterized and found to exhibit similar distortions to those observed for **16**.[27] Interestingly, the $Rh^I$ complex **18** disproportionates to $Rh^0$ and the $Rh^{II}$ species [(BOX-*t*Bu)$_2Rh^{II}$] (**19**), whose identity was unambiguously established by X-ray crystallography (Figure 5).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

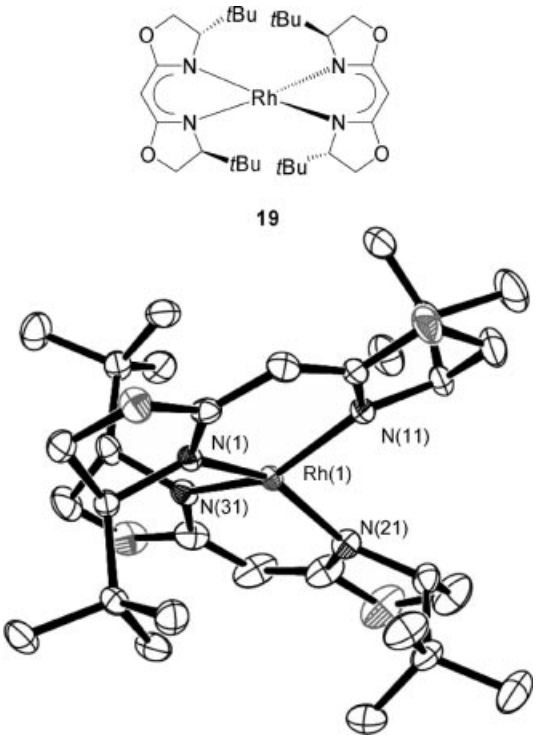


Figure 5. Molecular structure of **19**. Selected distances [Å] and angles [°]: Rh(1)–N(1) 2.041(2), Rh(1)–N(11) 2.0511(18), Rh(1)–N(21) 2.049(2), Rh(1)–N(31) 2.037(2); N(1)–Rh(1)–N(11) 90.14(10), N(21)–Rh(1)–N(31) 89.80(10).

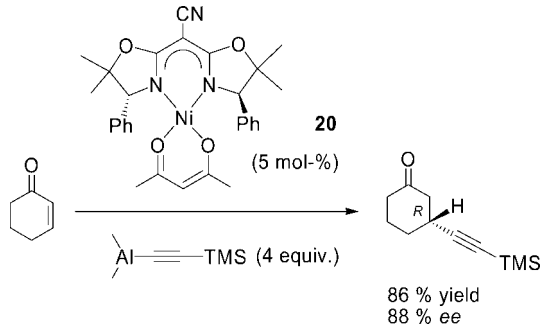
$Rh^{II}$ complexes are especially rare owing to the relative instability of the +II oxidation state. In light of this, complex **19** is the first example of a fully characterized mononuclear $Rh^{II}$ complex obtained by disproportionation of a rhodium(I) complex species into $Rh^0$ and $Rh^{II}$, thus illustrating the excellent stabilizing properties of bidentate bisoxazolinate ligands. As shown in Figure 5, unlike other structurally characterized $Rh^{II}$ complexes, which are square planar, the coordination geometry of the Rh center in **19** is approximately halfway between square planar and tetrahedral. On the basis of DFT calculations, this unusual, distorted orientation of the ligands around $Rh^{II}$ apparently stems from an electronic preference rather than steric influences.

## Group 10–12 Metal Complexes

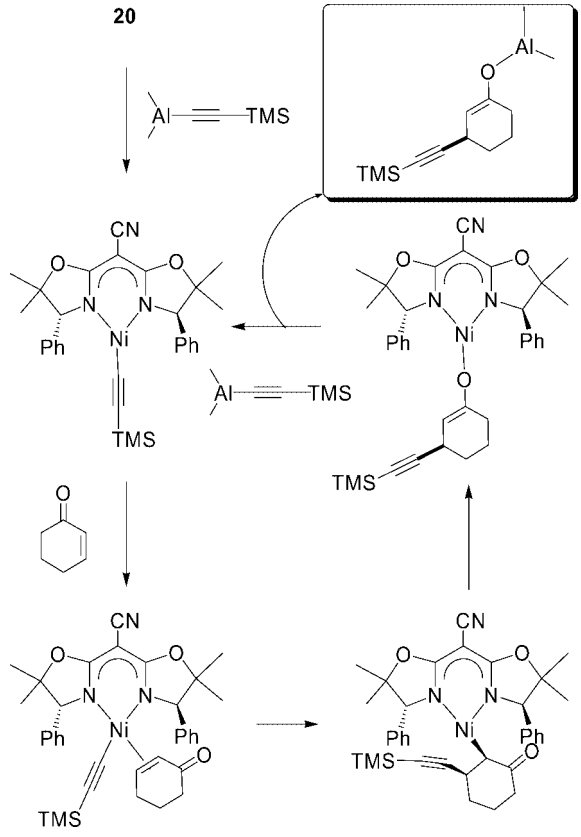
### *Ni Complexes*

The first example of an asymmetric conjugate addition of an alkynyl group to a cyclic α,β-enone was recently reported by Corey et al. using the well-defined chiral bisoxazolinatonickel complex **20** as a catalyst and an aluminum derivative as alkynyl source (Scheme 13).[28] This unprecedented $Ni^{II}$-catalyzed reaction proceeds with good yields (up to 86%) and *ee* values (up to 88%) under mild conditions.



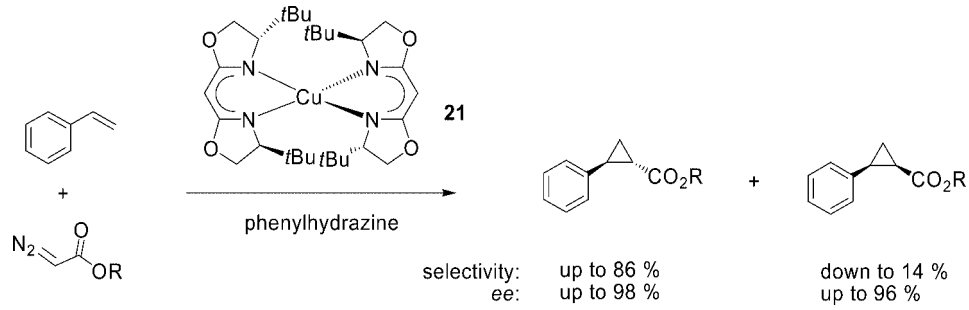
Scheme 13. Nickel-catalyzed asymmetric alkylynation of cyclohexenone.

To rationalize the observed results, the authors proposed a mechanism involving the carbometalation of the α,β-enone by an alkynylnickel intermediate (Scheme 14). Complex **20** constitutes the only reported example of a bisoxazolinatonickel complex. It is noteworthy that the outcome of this catalysis is quite different when performed with Ni(acac)$_2$ as the catalyst, where a coupled diacetylene, presumably derived from a bis(alkynyl)nickel(II) complex, was obtained as the major product. As conjectured by Corey et al., the fact that the bisoxazolinato ligand binds more tightly than the acac ligand most likely precludes the formation of this undesired bis(alkynyl)nickel(II) species.



Scheme 14. Proposed mechanism for the Ni-catalyzed conjugate addition of TMS–C≡C–$AlMe_2$ to 2-cyclohexenone.

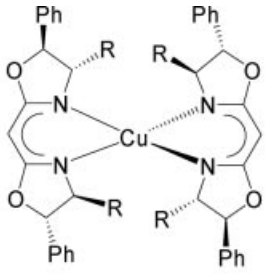
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 15. Copper-catalyzed cyclopropanation of styrene.

### *Cu Complexes*

While numerous examples of neutral chiral bisoxazolines/Cu catalytic systems have been investigated since the late 1980s due to their great utility in asymmetric catalysis, the use of copper complexes incorporating monoanionic bisoxazolinate ligands is much less common and only a few derivatives have been fully characterized. In this area, Masamune et al. first reported in 1990 the synthesis of several chiral bisoxazolinatocopper(II) complexes of the type [(BOX-R)$_2$Cu] (**21**) that are able to catalyze the asymmetric cyclopropanation of olefins with *ee* values of up to 98% for the cyclopropanation of styrene with alkyl diazoacetate (Scheme 15).[3a] These cyclopropanation reactions, however, usually proceed with poor to moderate *cis*/*trans* diastereoselectivity.



**22**
R = -CH$_2$OSi(Me$_2$)(*t*Bu)

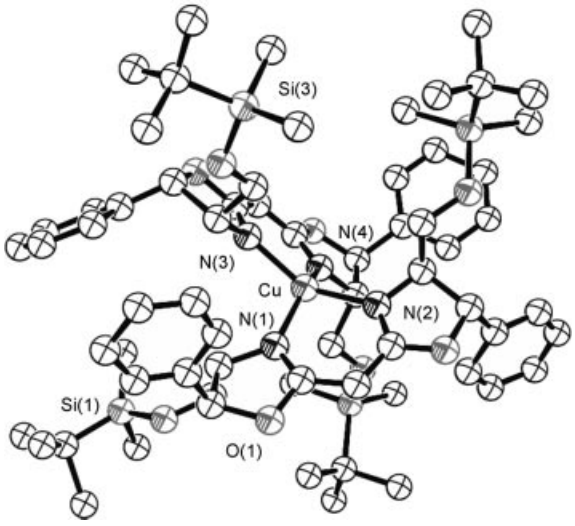


Figure 6. Molecular structure of **22**. Selected distances [Å] and angles [°]: Cu–N(1) 1.93, Cu–N(2) 1.96, Cu–N(3) 1.96, Cu–N(4) 1.91; N(1)–Cu–N(2) 91.6, N(3)–Cu–N(4) 90.8.

A little later, the first X-ray structure of a bisoxazolinatocopper(II) complex, namely [(BOX-CH$_2$OSi*t*BuMe$_2$)$_2$Cu] (**22**), was reported by Lehn et al. and showed the effective chelating ability of the bisoxazolinate unit toward Cu$^{II}$.[29] As illustrated in Figure 6, the copper atom in **22** adopts a distorted tetrahedral geometry, which may be ascribed to an increase of the ring strain between the R substituents of each bisoxazolinate ligand as they approach the Cu metal center. Precatalyst **22** was used in the asymmetric cyclopropanation of silyl enol ethers but gave poor yields and enantioselectivities.[30]

### *Zn Complexes*

While initial spectroscopic studies by Singh suggested that the bisoxazolinate ligand might be suitable for coordination to Zn$^{II}$, the potential interest and usefulness of bisoxazolinatozinc complexes have only been discovered quite recently.[31] Thus, bis(bisoxazolinato)zinc [(BOX)$_2$-Zn$^{II}$] complexes have been prepared in an elegant manner by Takacs et al. by chiral self-discrimination of enantiomeric bisoxazoline ligands. The reaction of a racemic mixture of phenyl-substituted BOX ligands (*R*,*R*)-**23** and (*S*,*S*)-**23** with Zn(OAc)$_2$ leads to the sole formation of the heteroleptic and tetrahedral Zn complex (*RR*,*SS*)-**24** (Scheme 16).[32]

This strong preference for (*RR*,*SS*)-**24** is most likely dictated by the steric interactions between the pendant aryl groups, as illustrated by its molecular structure (Figure 7).

This approach is an effective strategy for the development of modular metal complexes based upon self-assembly of subunits (such as bisoxazolinates) around a metal complex. Thus, using this modular approach, a library of chiral bidentate P,P-ligands **25** has been synthesized and the derived chiral diphosphane ligands found to be suitable for asymmetric palladium-catalyzed allylic amination reactions with excellent yields and *ee* values (Scheme 17).[33]

The most interesting feature in the above approach is that it is a remarkably flexible and effective strategy for catalyst design. In a similar strategy, the synthesis of single-enantiomer, chiral donor–acceptor zinc complexes incorporating bisoxazolinate pseudo racemates **26** has also been performed, thereby further illustrating the chiral self-dis-

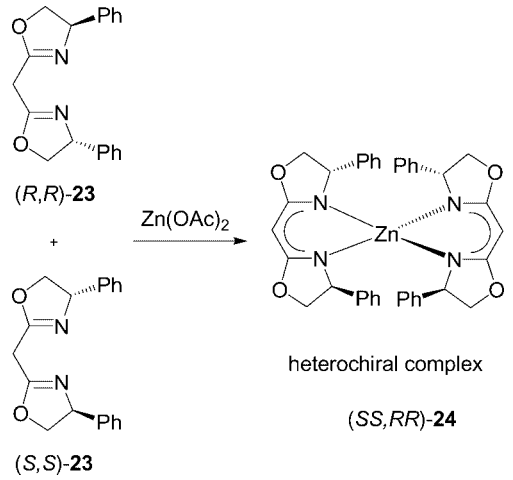

Scheme 16. Synthesis of the heterochiral complex **24**.

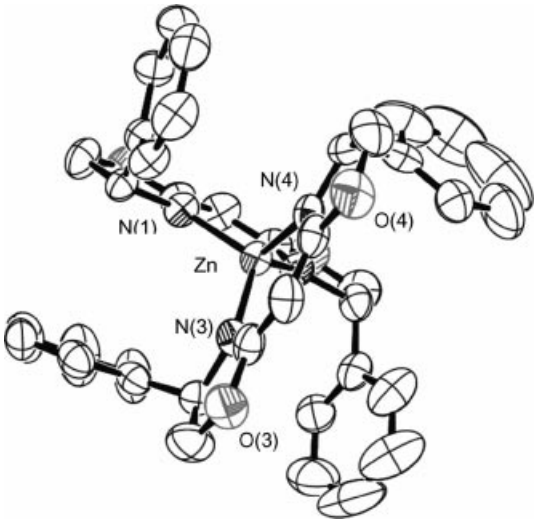

Figure 7. Molecular structure of **24**. Selected distances [Å] and angles [°]: Zn–N(1) 1.971(3), Zn–N(2) 1.973(3), Zn–N(3) 1.975(3), Zn–N(4) 1.976(3); N(1)–Zn–N(2) 94.21; N(3)–Zn–N(4) 93.56.

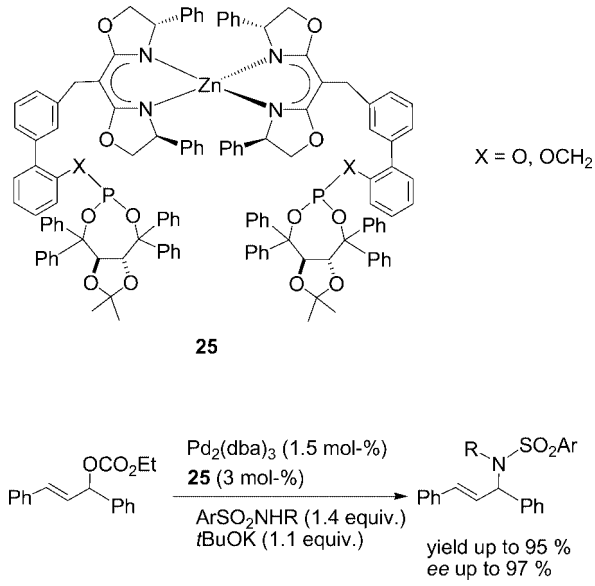
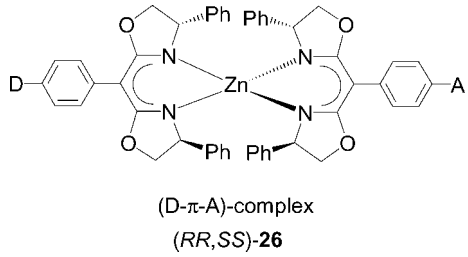
crimination approach (Scheme 18).[34] Such metal-organic complexes comprising electron donor, π-bridge, and acceptor (D-π-A) subunits are believed to be of potential interest for their nonlinear optical properties.

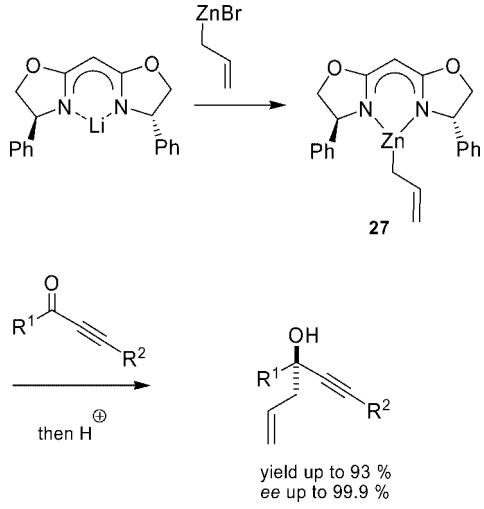
Apart from the above work, it is noteworthy that the chiral bisoxazolinate(allyl)zinc(II) complex **27**, which is readily accessible by reaction of an allylzinc bromide derivative with the corresponding bisoxazolinatolithium salt, has been shown to add in an enantioselective manner to various substrates such as olefins,[35] imines,[36] or ketones.[37] For example, addition of the allyl complex **27** to alkynyl ketones proceeds with excellent yields and *ee* values of up to 99.9% when the reaction is carried out at –100 °C (Scheme 19). This enantioselective allylic addition represents a rare example of a highly enantioselective addition to alkyl alkenyl ketones; in general, addition to ketone substrates other than alkyl aryl ketones occurs with a lower selectivity than that observed here.



Scheme 17. Asymmetric allylic amination using self-assembled chiral bidentate P,P-ligands **25**.



Scheme 18. Chiral self-assembly of bisoxazolinates containing an electron donor and acceptor.



Scheme 19. Stoichiometric allylation of alkynyl ketones with **27**.

Nakamura further extended his studies on zinc complexes similar to **27** and briefly reported their use in the regioselective allylzincation of alkenyboronate; however, poor asymmetric inductions (up to 41% *ee*) as well as low yields were observed (Scheme 20).[38]

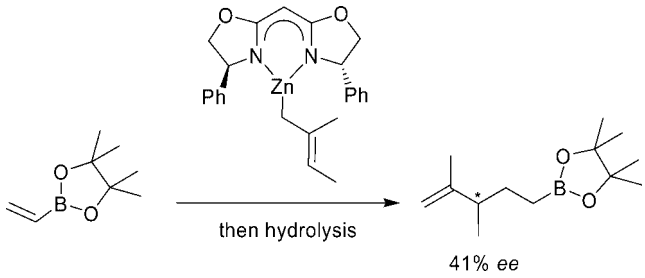

Scheme 20. Stoichiometric allylation of vinylboronate.

Coates et al. have probed the potential of the chiral bisoxazolinato(amido)zinc complex **28** (Scheme 22) as a catalyst for the copolymerization of $CO_2$ and cyclohexene oxide.[39] Surprisingly, complex **28** was found to be inactive in the aforementioned catalysis even though the structurally similar β-diketiminato(amido)zinc analogs exhibit an excellent activity. Finally, the chiral bis(bisoxazolinato)zinc(II) complex **29** (Scheme 21) has also been structurally characterized by Halcrow, Kee et al. and tested in for phospho-aldol catalysis, albeit with no success.[40]

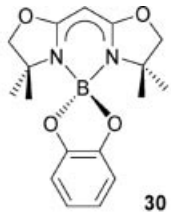
## Group 13 Metal Complexes

Boron bisoxazolinate complexes have also been structurally characterized and employed as chiral catalysts for the asymmetric reduction of various prochiral ketones. Thus, in 2001, Cozzi, Umani-Ronchi et al. reported that catecholborane readily reacts with neutral bisoxazolines to afford the corresponding four-coordinate bisoxazolinate boron complexes **30**, whose molecular structure was determined by X-ray crystallography, thereby confirming the formation of a four-coordinate coordinatively saturated boron complex and the effective chelation of one bisoxazolinate ligand to the boron center (Figure 8).[41]

Chiral versions of **30** were found to be effective catalysts in the enantioselective reduction of various ketones in the presence of catecholborane. This catalysis proceeds with *ee* values up to 86% and good yields when the bisoxazoline **31** is used as the supporting chiral ligand (Scheme 22).[42]



**30**

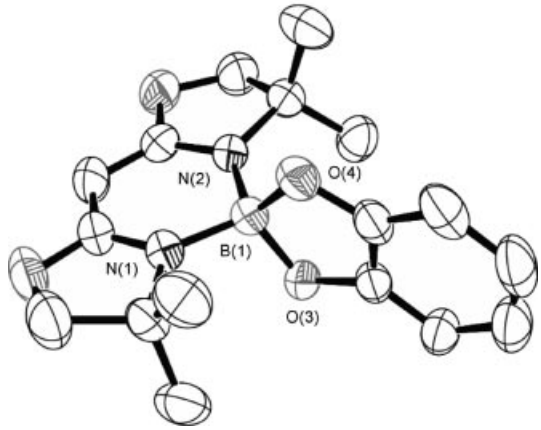


Figure 8. Molecular structure of **30**. Selected distances [Å] and angles [°]: B(1)–N(1) 1.541(2), B(1)–N(2) 1.548(2), B(1)–O(3) 1.481(2), B(1)–O(4) 1.479(2); N(1)–B(1)–N(2) 105.8(1), O(3)–B(1)–O(4) 104.5(1).

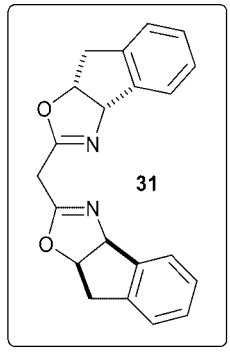
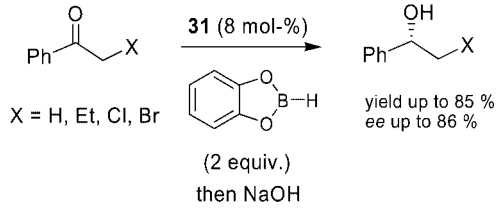


**31**

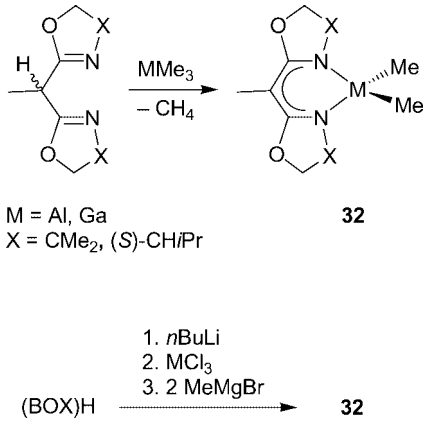


Scheme 22. Enantioselective reduction of ketones in the presence of **31**.

On the basis of detailed DFT calculations, the authors managed to gain insight into the mechanism of this reduction reaction and proposed that the transfer of the hydride ion from the boron atom of the catecholborane to the carbonyl of the prochiral ketone is the rate-determining step of the catalytic process. They also concluded that the origin of the enantioselectivity arises from a complex interplay involving, for the most part, steric repulsions between the ketone substituents and the boron-bisoxazolinate ring.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Monoanionic bisoxazolinate ligands are also suitable for coordination to aluminum and gallium, thus allowing the synthesis of the corresponding dimethyl and dichlorido mono-bisoxazolinate complexes **32** by either salt metathesis or an alkane elimination (Scheme 23).[43,44]



Scheme 23. Synthesis of aluminum and gallium bisoxazolinates **32**.

As illustrated in Figure 9, the molecular structure of the chiral bisoxazolinate aluminum derivative [{BOX-*i*Pr}-$AlMe_2$] exhibits a nearly perfectly planar six-membered Al metallacycle, with the Al metal center adopting a distorted tetrahedral geometry and being chelated by a π-delocalized bisoxazolinate ligand.

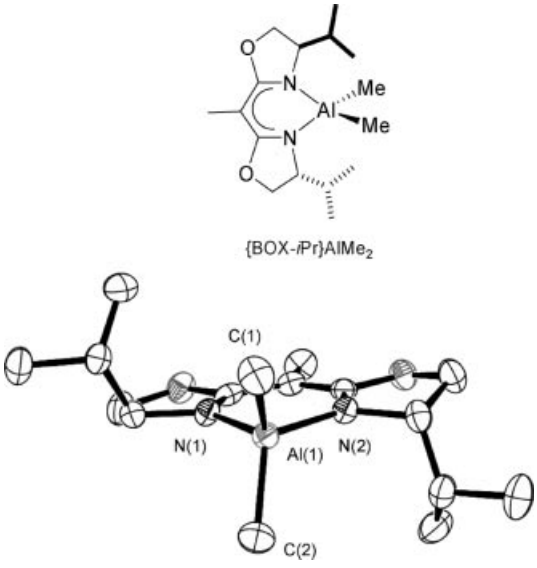


Figure 9. Molecular structure of **32** [M = Al]. Selected distances [Å] and angles [°]: Al(1)–N(1) 1.906(2), Al(1)–N(2) 1.899(2), Al(1)–C(1) 1.967(2), Al(1)–C(2) 1.968(3); N(1)–Al(1)–N(2) 93.13(7), C(1)–Al(1)–C(2) 111.8(1).

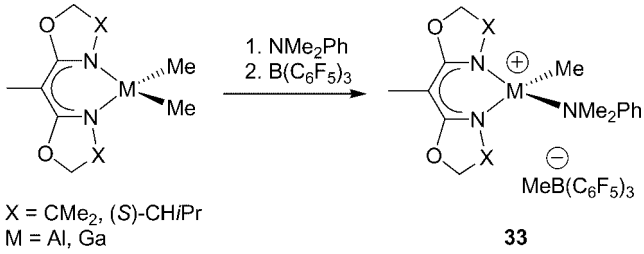
More importantly, the dimethylaluminum and -gallium mono-bisoxazolinato derivatives can be readily converted into four-coordinate metal cations **33** by a $Me^-$ abstraction reaction with $B(C_6F_5)_3$ in the presence of an external Lewis base such as an amine (Scheme 24). The excellent stability of the highly Lewis acidic cations **33** illustrates the suitability of the bisoxazolinate ligand for the generation of cationic chiral group 13 alkyl derivatives. The molecular structures of these complexes were unambiguously confirmed by X-ray crystallographic studies. The molecular structure of the aniline-stabilized, four-coordinate bisoxazolinate Al cation $[\{BOX\text{-}Me_2\}Al(Me)(NMe_2Ph)]^+$ is illustrated in Figure 10 as an example. Unlike [{BOX-*i*Pr}$AlMe_2$], the Al chelated six-membered ring is significantly distorted from planarity, with the Al center lying out of the plane of the bisoxazolinate backbone. In fact, the bidentate chelating ligand appears to be pushed away from the Al-$NMe_2Ph$ group, which may be to avoid significant steric interactions between the aniline and the bidentate ligand. Preliminary reactivity studies suggest that these cationic Lewis acids may be of interest as catalysts of hetero-Diels–Alder reactions and propylene oxide polymerizations.



Scheme 24. Synthesis of the cationic species **33**.

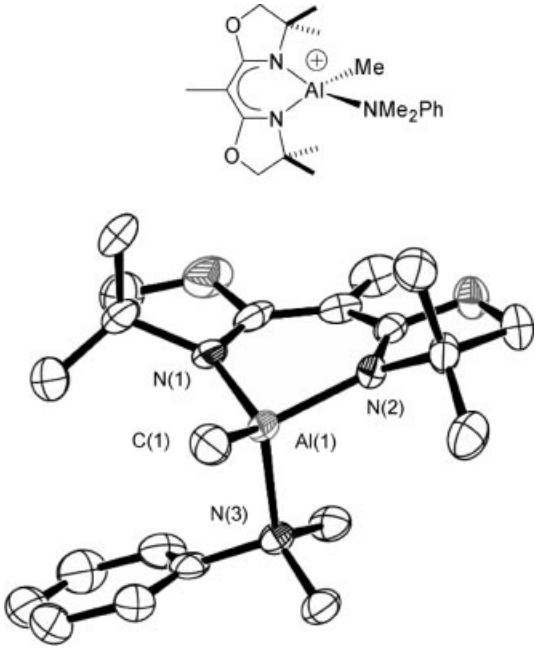


Figure 10. Molecular structure of **33** (M = Al; X = $CMe_2$). Selected distances [Å] and angles [°]: Al(1)–N(1) 1.852(5), Al(1)–N(2) 1.857(4), Al(1)–N(3) 2.018(4), Al(1)–C(1) 1.942(6); N(1)–Al(1)–N(2) 95.8(2), C(1)–Al(1)–N(3) 111.3(2).

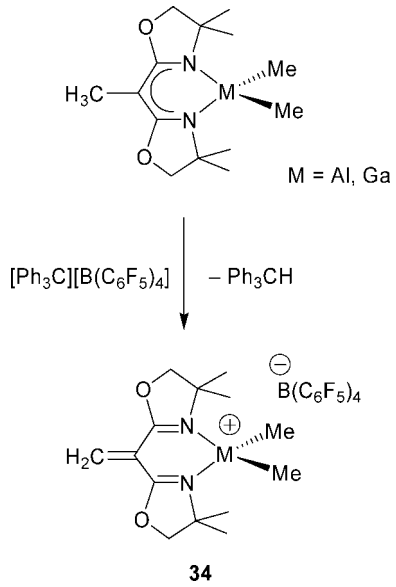
Finally, from a reactivity point of view, it is interesting to note that, unlike $B(C_6F_5)_3$, $[Ph_3C][B(C_6F_5)_4]$ does not abstract a $Me^-$ from the Al or Ga metal center when treated with the dimethyl bisoxazolinate derivatives **32**; rather, it abstracts a hydride from the back of the bisoxazolinate ligand to afford the unexpected bisoxazoline metal complex

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**34** (Scheme 25). This observed reactivity illustrates an unusual Lewis base character for a bisoxazolinate ligand incorporated in a metal complex.



**34**

Scheme 25. Hydride abstraction reaction by $[Ph_3C]^+$ on **32**.

## Conclusions

Over the past few years, bisoxazolinate ligands have established themselves as a versatile class of monoanionic bidentate N,N-ligands that are able to effectively chelate various metal centers, with a coordination chemistry, for the most part, reminiscent of that of the β-diketiminate ligand. It is thus not surprising to find chiral $C_2$-symmetric bisoxazolinate ligands involved as supporting ligands in numerous metal-complex-catalyzed enantioselective reactions, as summarized in the present contribution. Overall, the excellent stability and robustness of this class of ligands, their good level of asymmetric induction in various enantioselective catalyses, and their frequent commercial availability at a moderate cost in an enantiomerically pure form are three major advantages that should promote the use of bisoxazolinato–metal complexes in the near future so as to extent their scope of applications.

# A Bis(di-*n*-butyltin)–Quinone Derivative as a Simultaneous Chemo- and Bioactive Corrosion Inhibitor

**Victor Barba,*[a] Edgar Vega,[a] Herbert Höpfl,[a] Luis S. Zamudio-Rivera,*[b] Marco A. Domínguez-Aguilar,[b] Rocío George-Tellez,[b] Fernando Godínez-Salomon,[b] José M. Hallen-Lopez,[c] and Hiram I. Beltran[d]**

**Keywords:** Tin / Quinones / Corrosion / Biocide activity / X-ray structure

The bis(di-*n*-butyltin) derivative of 2,5-bis(2-hydroxyethylamino)-1,4-benzoquinone was synthesized and characterized by common spectroscopic techniques. In solution, discrete molecules with pentacoordinate tin atoms were observed, whereas the X-ray diffraction analysis of the solid-state structure revealed polymeric chains that were due to intermolecular Sn···O bonds. In vitro tests demonstrated that the tin compound displays bactericidal activity against a wide range of aerobic and anaerobic bacteria. Acute toxicity tests indicated that the di-*n*-butyltin compound has a relatively low toxicity level. The corrosion inhibition efficiency of the ligand and the tin compound were evaluated by polarization scans of mild steel samples that had been exposed to a sour brine environment. The tin–quinone compound showed good inhibition efficiency (about 75 %) at relatively low concentrations (25–50 ppm) and at different testing times (0.25–20 h).

## Introduction

At present, organic compounds are widely used as corrosion inhibitors, since their structural features can be manipulated in order to improve properties such as solubility and chemical biodegradability. For that purpose, the formation of strong coordinative bonds with metallic surfaces is required, in particular in the very aggressive media present in oil manufacturing plants and pipelines. In this respect, nitrogen-based inhibitors have demonstrated excellent properties.[1]

It is well known that ligands based on quinones confer the ability to couple redox reactions, thus enabling the interaction with metallic ions and surfaces.[2] Earlier studies have shown that metal surfaces covered with poly(aminoquinones) (PAQs) form effective anticorrosive coatings because of their excellent corrosion resistance and adhesion to metal atoms.[3] Such films even displace water from rusted steel surfaces.[4] Hubbard and co-workers have attributed the high affinity of PAQs towards metal surfaces to a chemisorption process[5] in which the free electron pairs of the amine nitrogen and quinone oxygen atoms interact with the electron-deficient molecular orbital of the metal atom. Surprisingly, so far there is no reference related to the use of organometallic components containing benzoquinones as corrosion inhibitors for steel, and the manner in which coordination to metal atoms influences the corrosion inhibition properties has not been clarified yet.

Tin phthalocyanines were previously tested as corrosion inhibitors for carbon steel by using sour brine at pH 4.[6] The corrosion inhibition activity of these compounds provided efficiencies in the range 61–87% at concentrations of 500 ppm, and it was proposed that the concave π-electron-delocalized nanocap morphology of these compounds may induce an effective adsorption on the steel surface. In addition, tin compounds are capable of acting as biocides and have relatively low toxicities,[7] thus making them an attractive object of research for the development of chemicals having combined anticorrosive and antibacterial properties. This is because anaerobic bacteria are able to catalyze the corrosion processes in oil plants and pipelines.

Our interdisciplinary research group is interested in developing evironment-friendly multifunctional compounds, and, we describe herein the synthesis and properties of a new di-*n*-butyltin derivative of 2,5-bis(2-hydroxyethylamino)-1,4-benzoquinone (**1**). As far as we know, this is

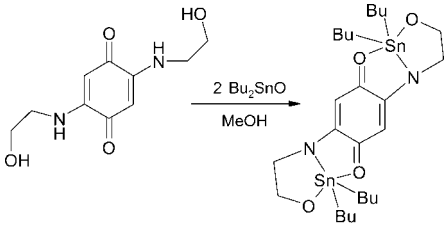
the first report on a tin compound that is able to protect steel simultaneously from electrochemical and microbiological corrosion.

## Results and Discussion

The 1,4-benzoquinone derivative **1** was prepared as described previously,[8] and its condensation reaction with di-*n*-butyltin oxide in methanol under reflux gave compound **2** in 80% yield (Scheme 1). Recrystallization of the product from methanol gave a deep red crystalline material. EI mass spectrometry revealed a peak at $m/z$ = 688 that corresponds to the molecular ion of compound **2**. The analysis of the $^1$H NMR spectroscopic data suggests that the structure of this compound is symmetric in solution, having a $C_2$ rotation axis. By using the equation developed by Holeček et al.,[9] the $^1J(^{119}Sn–^{13}C)$ coupling constant (628 Hz) was used to estimate the C–Sn–C angle, 127.4°, which is typical of pentacoordinate tin species. The $^{119}$Sn NMR chemical shift was observed at $\delta$ = –129 ppm, a value displaced to higher frequencies relative to parent diorganotin compounds derived from ONO Schiff base tridentate ligands (–150 to –180 ppm).[10] The difference can be attributed to the enhanced covalent character of the N–Sn bond that is mostly dative in analogous systems.



**1** **2**

Scheme 1. Synthesis of the tin–quinone compound **2**.

The X-ray analysis of compound **2** allowed to establish that in the solid state the point group of the tin molecules is $C_1$ (Figure 1). When the molecular packing was examined, intermolecular Sn···O interactions were found, providing hexacoordinate tin atoms that are surrounded by the ONO donor atoms of one ligand molecule (meridional distribution), two *n*Bu groups located in a *trans* orientation, and one additional oxygen atom from a neighboring molecule. The *n*-butyl groups attached to the tin atoms and the –$CH_2CH_2O$– fragments of the ligand are disordered over two different positions, indicating the presence of a low-density polymorphous arrangement. The N–Sn and O–Sn bond lengths are comparable to those already described for other ONO–tin compounds (for values see Figure 1).[10,11]

The formation of intermolecular Sn···O bonds, 2.488(6) (O2–Sn2) and 2.379(4) (Sn1–O3A) Å, situated at an equatorial position of the tin atom coordination sphere, gives rise to the formation of four-membered $Sn_2O_2$ rings that organize the individual molecules in linear 1D coordination polymers (Figure 2). This Sn···O intermolecular interaction

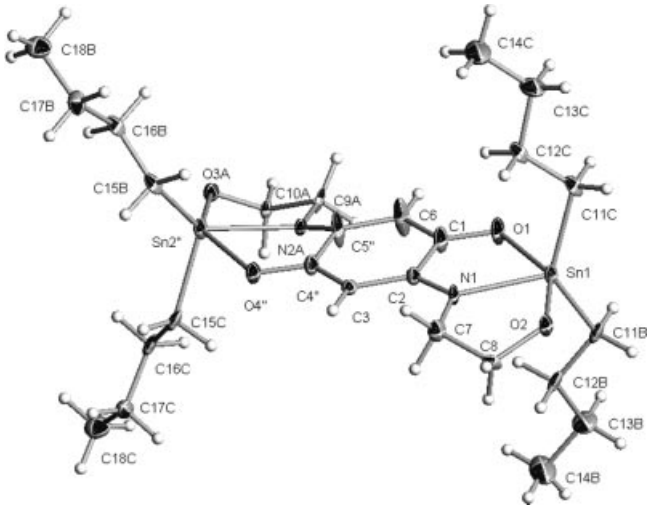


Figure 1. Fragment of the polymeric structure of compound **2** (50% thermal ellipsoids). Selected bond lengths [Å] and angles [°]: Sn1–O1 2.336(5), Sn1–O2 2.092(4), Sn1–N1 2.172(5), Sn1–C11B 2.1011(11), Sn1–C11C 2.1003(11), O1–Sn1–O2 147.17(16), O1–Sn1–N1 70.66(18), O2–Sn1–N1 76.51(19), C11C–Sn1–C11B 140.7(3).

has also been observed for other pentacoordinate di-*n*-butyltin complexes derived from ONO ligands.[12] The polymeric fragments are organized in layers, between which the *n*Bu moieties are located (Figure 2).

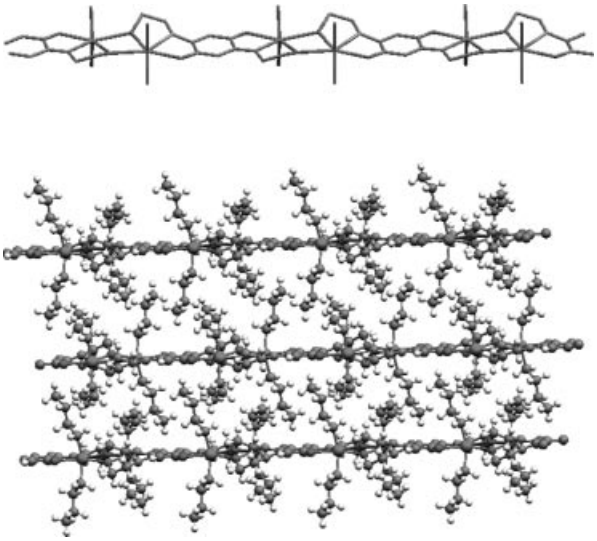

Figure 2. Schematic representation of the 1D coordination polymer formed through Sn···O intermolecular interactions (part of the *n*Bu groups are omitted, top). View of the parallel orientation for the polymeric chains, the *n*Bu groups are located in between (bottom).

The benzoquinone ligand **1** and the bis(di-*n*-butyltin)–quinone derivative **2** were screened in vitro for their antibacterial activity against three types of aerobic bacteria, *Bacillus subtilis* (Gram-positive, strain ATCC 6633), *Escherichia coli* (Gram-negative, strain DH5) and *Pseudomona fluorescens* (Gram-negative, strain BH3), and two types of anaerobic species (sulfate-reducing bacteria, SRB), *Desulfovibrio vulgaris* (strain DSM 644) and a bacteria con-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sortium (strain 82) isolated from a hydrocarbon pipeline of the Mexican oil industry (PEMEX). The agar well diffusion method[13] was used to determine the minimum inhibitory concentrations (MICs), showing that compound **2** has a higher biocide activity than the free quinone **1** (Table 1). The results also show that the presence of the di-*n*-butyl group confers selectivity in toxicity against certain bacterial species, which is important for the development of new prototypes of environmentally friendly biocides.

Table 1. Agar MICs of compounds **1** and **2** (ppm).[a]

| Compound | *B. subtilis* | *E. coli* | *P. fluorescens* | *D. vulgaris* | *Strain 82* |
|---|---|---|---|---|---|
| **1** | ≥ 200 | ≥ 200 | ≥ 200 | > 200 | > 200 |
| **2** | 10 | 100 | 10 | ≥ 100 | 150 |

[a] For *B. subtilis*, *E. coli*, and *P. fluorescens*, the MICs were measured after 16 h of incubation at 30 °C. For *D. vulgaris* and *Strain 82* the MICs were measured after 7 days of incubation at 32 °C.

The acute toxicity was determined by using luminescent bacteria toxicity (LBT) Mycrotox tests to record their environmental impact. The $EC_{50}$ values obtained from 5- and 15-min assays were very similar for the two compounds (Table 2), which permits their classification in the "slightly toxic" category.[14]

Table 2. Acute toxicity of compounds **1** and **2** against *P. phosphoreum*.[a]

| Compound | Toxicity $EC_{50}$ | | |
|---|---|---|---|
| | 5 min | 15 min | Category |
| **1** | 61 | 58 | slightly toxic |
| **2** | 62 | 60 | slightly toxic |

[a] Concentration range in ppm, classification, category 5: 0.01–0.10, extremely toxic; 4: 0.1–1.0, highly toxic; 3: 1–10, moderately toxic; 2: 10–100, slightly toxic; 1: 100–1000, particularly nontoxic; and 0: > 1000, nontoxic. See ref.[14] for further details.

The carbon steel corrosion inhibition properties of compounds **1** and **2** were tested in an aqueous hydrogen sulfide corrosive environment by electrochemical methods, which included the linear polarization resistance (LPR) technique and the Tafel extrapolation measurements. Upon electrode immersion for 15 minutes in sour brine at different inhibitor concentrations, the corrosion inhibition efficiencies of the benzoquinone ligand **1** were in the range 37–61%, whereas those of compound **2** were within 35–83%. The detailed analysis of the data shown in Table 3 shows that compound **2** is a better corrosion inhibitor than **1**, since a molar concentration of only one third of compound **2** is required to provide a higher inhibitive efficiency than that of compound **1**. After 20 h of electrode immersion, the results show that the inhibition efficiency of compound **1** tends to increase slightly, while that of compound **2** tends to decrease. There exists some evidence that planar compounds such as **1** give a parallel accommodation on the steel surface due to π-bonding interactions with the metal atoms.[2] In the case of compound **2**, the molecular volume is increased, which apparently improves the surface coverage.[15] The inhibition efficiencies of this new di-*n*-butyltin compound are in the order of those found for the tin phthalocyanines previously reported;[6a] however, the inhibitor concentration is five times lower.

Table 3. Corrosion inhibition efficiency (IE,%) for compounds **1** and **2**.

| Compound | Concentration | | IE (%) | |
|---|---|---|---|---|
| | ppm | mmol $L^{-1}$ | [a] | [b] |
| **1** | 10 | 0.0442 | 37 | 15 |
| | 25 | 0.1100 | 57 | 69 |
| | 50 | 0.2210 | 55 | 74 |
| | 100 | 0.4420 | 61 | 66 |
| **2** | 10 | 0.0145 | 35 | 8 |
| | 25 | 0.0363 | 82 | 66 |
| | 50 | 0.0726 | 87 | 70 |
| | 100 | 0.1453 | 83 | 72 |

[a] IE determined after 15 min. [b] IE after 20 h.

## Conclusion

The tin compound described herein can protect steel surfaces by serving as a chemo- and bioactive corrosion inhibitor. Further investigations considering similar tin–quinone derivatives are currently carried out in our laboratory.

## Experimental Section

**Synthesis and Spectroscopic Data for Compound 2:** Compound **2** was prepared from compound **1** (0.10 g, 0.442 mmol) and di-*n*-butyltin oxide (0.22 g, 0.884 mmol) in methanol under reflux (2 h). The product precipitated as a red solid in 80% yield (0.24 g). M.p. 247–250 °C. IR (KBr): $\tilde{\nu}_{max}$ = 2956, 2921, 2854, 1523 (C=O), 1433, 1398, 1329, 1288, 1066, 920, 872, 800, 680, 593 $cm^{-1}$. EI-MS: *m*/*z* (%) = 688 [$M^+$] (10), 661 (45), 632 [M – Bu]$^+$ (100), 604 (33), 543 (24), 513 (12), 486 (56), 400 (60), 371 (45), 280 (34), 203 (64), 174 (43), 123 (17), 91 (26). $^1$H NMR (200 MHz, $CDCl_3$): $\delta$ = 5.61 (s, 2 H, CH), 3.96 and 3.30 (AB, $J$ = 5.8 Hz, 8 H, $OCH_2CH_2N$), 1.60–1.16 (m, 24 H, $CH_{2Bu}$), 0.82 (t, $J$ = 6.9 Hz, 12 H, $CH_{3Bu}$) ppm. $^{13}$C NMR (50 MHz, $CDCl_3$), $\delta$: 181.0 (C=O), 151.1 ($C_{quin}$–N), 93.3 (C–H), 61.6 ($C_{aliph}$–O), 48.2 ($C_{aliph}$–N), 27.5 [$^2J$($^{119}$Sn–$^{13}$C) = 29 Hz, $C_{\beta\text{-Bu}}$], 26.9 [$^3J$($^{119}$Sn–$^{13}$C) = 87 Hz, $C_{\gamma\text{-Bu}}$], 19.7 [$^1J$($^{119}$Sn–$^{13}$C) = 628 Hz, $C_{\alpha\text{-Bu}}$], 13.8 ($C_{\delta\text{-Bu}}$) ppm. $^{119}$Sn NMR (75 MHz, $CDCl_3$): $\delta$ = –129 ppm. $C_{26}H_{46}N_2O_4Sn_2$ (688.07) calcd. C 45.38, H 6.73, N 4.07; found C 46.01, H 6.86, N 4.22.

**Antibacterial Activity Test:** The agar method was used to determine the minimum concentration of compound **1** and **2** capable of inhibiting the bacterial activity of the aerobic and anaerobic strains previously developed. The medium for the aerobic bacteria was prepared by cooling the molten agar to 40 °C and then adding the required amount of bacterial suspension ($8 \times 10^8$ bacteria per mL). The wells were dug in the media with the help of a sterile metallic borer of 24 mm diameter; into these wells the testing compounds were introduced (2.5, 10, 25, 50, 75, 100, 150 and 200 ppm). Additional wells were filled with ethanol to serve as a negative control, whereas the positive reference was a piperazine compound. The flat-bottomed, 90-mm Petri dishes were kept at 4 °C for 60 minutes and then stored in an incubator at a suitable growth temperature (30 ± 2 °C) for 16 hours. The strains prepared for the anaerobic bacteria were exposed to the testing compounds in the range 2.5–200 ppm, whereby the anaerobic strains were grown in 40-mL

flasks with a Postgate C modified medium. The bottles were inoculated with SRB (sulfate-reducing bacteria) cultures (1 mL) from the stock and incubated at 32 ± 2 °C for 7 d. Finally, the minimum inhibitor concentration (MIC) for each compound was determined by comparing positive (bottle without chemical) and negative (bottle not inoculated with culture) controls and recording the presence or absence of visible growth in the bottles.

**X-ray Crystallography:** X-ray diffraction studies were performed on a Bruker-APEX diffractometer with a CCD area detector, Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, graphite monochromator. Frames were collected at $T$ = 100 K. The measured intensities were reduced to $F^2$ and corrected for absorption with SADABS (SAINT-NT).[16] Corrections were made for Lorentz and polarization effects. Structure solution, refinement and data output were carried out with the SHELXTL-NT program package.[16] Crystal system: Monoclinic, space group $P2_1/m$, $a$ = 6.9974(7), $b$ = 17.3487(17), $c$ = 11.7734(12) Å, $\beta$ = 91.799(2), $V$ = 1428.5(3) Å$^3$, $Z$ = 4, $D_{calcd.}$ = 1.604 g cm$^{-3}$, $\mu$ = 1.781 mm$^{-1}$, $F(000)$ = 700. For 2319 independent reflections and 245 parameters, final $R$ indices [$I > 2\sigma I$]: $R_1$ = 0.0370 and $wR_2$ = 0.0825. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in geometrically calculated positions by using a riding model. The *n*Bu groups attached to the tin atoms and the –$CH_2CH_2O$– fragments of the ligand are disordered over two positions. CCDC-296858 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Reactions of Group 13 Organometallics $t$Bu$_3$M with Distibanes Sb$_2$R$_4$

**Daniella Schuchmann,[a] Andreas Kuczkowski,[a] Sonja Fahrenholz,[a] Stephan Schulz,*[a] and Ulrich Flörke[a]**

**Keywords:** Main group elements / Lewis acids / Lewis bases / Solid-state structures

Tetraalkyldistibanes Sb$_2$R$_4$ (R = *n*Pr, *i*Bu) react with $t$Bu$_3$M (M = Al, Ga) at –30 °C with the formation of the Lewis acid–base adducts [$t$Bu$_3$M]$_2$[Sb$_2$R$_4$] [M = Al, R = *n*Pr (**1**), *i*Bu (**2**); M = Ga, R = *n*Pr (**3**), *i*Pr **4**)]. Compounds **1** and **2** are stable in solution whereas **3** undergoes a Sb–Sb bond-breakage reaction with the subsequent formation of [$t$Bu$_2$GaSb(*n*Pr)$_2$]$_2$ (**5**). The same trend was observed for the reaction of Sb$_2$(*i*Bu)$_4$ with $t$Bu$_3$Ga, which yielded the heterocyclic stibanylgallane [$t$Bu$_2$GaSb(*i*Bu)$_2$]$_2$ (**6**). In addition, the simple trialkylstibane adduct $t$Bu$_3$Al–Sb(*i*Bu)$_3$ (**7**) was obtained as a byproduct from the reaction of Sb$_2$(*i*Bu)$_4$ with $t$Bu$_3$Al. Compounds **1**–**7** were characterized by multinuclear NMR ($^1$H, $^{13}$C{$^1$H}) and mass spectroscopy and elemental analysis. Compounds **1**, **3**, **5**, and **7** were also investigated by single-crystal X-ray diffraction.

## Introduction

Lewis basic tetraalkyldipenteles R′$_2$E–ER′$_2$ (E = N to Bi) are capable of acting as monodentate[1] or bidentate ligands[2] as was shown in several reactions with transition metal complexes.[3] Surprisingly, reactions with main group Lewis acids such as group 13 organometallics MR$_3$ (M = B to Tl) have been studied to a far lesser extent even though Lewis acid–base adducts of trialkylpenteles ER′$_3$ are long known in group 13/15 chemistry. Only two diphosphane-borane adducts ([Me$_4$P$_2$][BH$_3$]$_2$ and [Me$_4$P$_2$][BH$_2$Br]$_2$)[4] have been structurally characterized prior to our studies. We started to investigate reactions of distibanes R′$_2$Sb–SbR′$_2$ and dibismuthines R′$_2$Bi–BiR′$_2$ with group 13 organometallics MR$_3$ (M = Al, Ga, In) because of our general interest in group 13/15 chemistry. These reactions typically yielded bisadducts of the type [R$_3$M]$_2$[E$_2$R′$_4$] (M = Al, Ga; E = Sb,[5] Bi[6]), with the dipenteles serving as bidentate ligands. Only tetraisopropyldistibane was found to form the monoadduct [$t$Bu$_3$Al][Sb$_2$(*i*Pr)$_4$] when reacted with $t$Bu$_3$Al, most likely because of the increased repulsive interactions caused by the bulky *i*Pr substituents.[7] The distibane alane adducts [R$_3$Al]$_2$[Sb$_2$R′$_4$] were found to be stable in their pure form and in solution,[8] whereas the corresponding gallane and indane adducts [R$_3$M]$_2$[Sb$_2$R′$_4$] (M = Ga, In) tended to undergo Sb–Sb bond-breakage reactions in solution with the subsequent formation of heterocyclic stibanylgallanes and -indanes [R$_2$MSbR′$_2$]$_x$ ($x$ = 2, 3). Comparable findings have previously been observed by Breunig et al. in reactions with main group[9] and transition metal complexes.[10]

Because of our interest in completely alkyl-substituted heterocycles [R$_2$MSbR′$_2$]$_x$, which are promising candidates for the deposition of MSb thin films by the MOCVD process (metal organic chemical vapor deposition),[11] we extended our studies to the reaction of Sb$_2$R′$_4$ (R′ = *n*Pr, *i*Pr, *i*Bu) with trialkylalanes and gallanes MR$_3$. The influence of the organic ligand on the stability of the initially formed distibane adducts was of particular interest.

## Results and Discussion

In order to establish the distibane cleavage reaction as a general reaction type for the formation of completely alkyl-substituted heterocycles of the type [R$_2$MSbR′$_2$]$_x$ (M = Al, Ga) and to verify the influence of both the central group 13 metal and the organic ligands bound to the metal centers on the formation of the M–Sb heterocycles, reactions of three different distibanes Sb$_2$R$_4$ (R = *n*Pr, *i*Pr, *i*Bu) with $t$Bu$_3$Al and $t$Bu$_3$Ga, respectively, were investigated. The reaction of Sb$_2$(*i*Pr)$_4$ with $t$Bu$_3$Al was previously shown to yield [$t$Bu$_3$Al][Sb$_2$(*i*Pr)$_4$].[7]

Reactions of Sb$_2$R$_4$ (R′ = *n*Pr, *i*Pr, *i*Bu) with $t$Bu$_3$M (M = Al, Ga) yielded Lewis acid–base adducts [$t$Bu$_3$M]$_2$[Sb$_2$R$_4$] [M = Al, R = *n*Pr (**1**), *i*Bu (**2**); M = Ga, R = *n*Pr (**3**), *i*Pr (**4**)], which were isolated as light-yellow, crystalline solids after crystallization from solutions in pentane at –40 °C [Equation (1)].

$^1$H NMR spectra of **1**–**4** show resonances from the organic ligands in a 2:3 molar ratio as was expected from the formation of the bisadducts $[t\mathrm{Bu_3M}]_2[\mathrm{Sb_2R_4}]$. The Sb centers in the distibane adducts are prochiral, leading to two separated sets of resonances of the diasterotropic α-$CH_2$ protons of the *n*Pr and *i*Bu groups in **1**, **2**, and **3**. Mass spectra of **1**–**4** only show signals arising from the dissociation into $Sb_2R_4$ and $t\mathrm{Bu_3M}$ as well as from typical fragmentation reactions. Single crystals of **1** suitable for an X-ray structure determination were obtained from a solution in pentane at –30 °C. In addition, the trialkylstibane adduct $t\mathrm{Bu_3Al–Sb}(i\mathrm{Bu})_3$ (**7**) was isolated from the reaction of $t\mathrm{Bu_3Al}$ with $\mathrm{Sb}_2(i\mathrm{Bu})_4$, which was contaminated with $\mathrm{Sb}(i\mathrm{Bu})_3$ (about 10%) as was shown by NMR spectroscopy. Figure 1, Figure 2 and Figure 3 show solid-state structures of **1**, **3**, and **7**, respectively [Equation (2)].

$$\mathrm{R_2Sb\text{-}SbR_2} + t\mathrm{Bu_3Ga} \xrightarrow[-t\mathrm{BuSbR_2}]{} 1/2\,[t\mathrm{Bu_2GaSbR_2}]_2 \quad \mathrm{R} = n\mathrm{Pr}\ \mathbf{5},\ i\mathrm{Bu}\ \mathbf{6} \tag{2}$$

Selected bond lengths [Å] and angles [°]: Sb1–Sb1a 2.822(1), Sb1–Ga1 2.988(1), Ga1–C1 2.056(5), Ga1–C5 2.030(4), Ga1–C9 2.033(4), Sb1–C13 2.172(4), Sb1–C16 2.160(3), C1–Ga1–C5 116.5(2), C1–Ga1–C9 116.7(2), C5–Ga1–C9 117.3(2), C13–Sb1–C16 96.2(2), C13–Sb1–Sb1a 97.1(1), C16–Sb1–Sb1a 97.4(1), Sb1a–Sb1–Ga1 127.5(2).

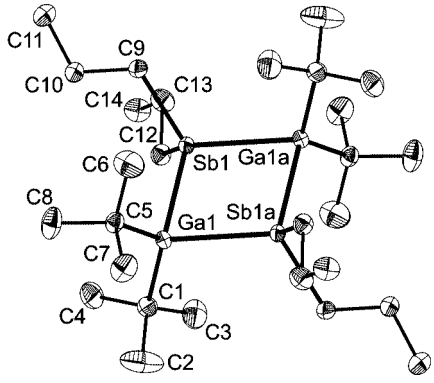

Figure 3. ORTEP plot (50% probability level; H omitted for clarity) showing the solid-state structure and atom-numbering scheme for **7**. Al1–Sb1 2.903(2), Sb1–C1 2.159(4), Sb1–C5 2.153(4), Sb1–C9 2.157(4), Al1–C13 2.028(4), Al1–C17 2.016(5), Al1–C21 2.013(4); C1–Sb1–C5 106.91(16), C1–Sb1–C9 95.84(15), C5–Sb1–C9 99.61(16), C13–Al1–C17 116.20(19), C13–Al1–C21 115.96(18), C17–Al1–C21 115.01(18).

Compounds **1** and **3** crystallize in the monoclinic space group $P2_1/n$ (No. 14) and **7** in $P2_1/c$ (No. 14), respectively. Compounds **1** and **3** possess crystallographic $C_i$ symmetry with the center of symmetry at the Sb–Sb bond. The central Sb–Sb bond lengths observed in **1** [2.839(1) Å] and **3** [2.822(5) Å] are almost identical to those of pure distibanes $Sb_2R_4$ {R = Me 2.862(2) Å,[12] 2.830(1), 2.838(1) Å;[13] *t*Bu 2.817(1) Å;[14] Ph 2.844(1) Å;[15] $SiMe_3$ 2.867(1) Å;[15] $SnMe_3$ 2.866(1) Å[16]}. There is no sign of any Sb–Sb bond weakening upon coordination to Lewis acidic $t\mathrm{Bu_3M}$. Comparable findings have been previously observed for other distibane adducts $[t\mathrm{Bu_3Al}]_x[\mathrm{Sb_2R_4}]$ [R = Me 2.811(1),[5] Et 2.838(1),[5] *i*Pr 2.855(1) Å[7]]. The most significant structural change of the distibane moiety due to the adduct formation is the increase of the degree of pyramidalization of the central Sb atoms. The sums of the C–Sb–C and C–Sb–Sb bond angles observed for **1** (292.2°) and **3** (290.6°) are significantly increased compared with uncomplexed distibanes such as $Me_4Sb_2$ (283.1°), resulting from an increase in p character of the former Sb electron lone pair and an increase in s character of the former Sb–C and Sb–Sb bonding electrons pairs. The Al–Sb bond length observed for **1** [2.964(1) Å] is elongated compared to that of $[t\mathrm{Bu_3Al}]_2[\mathrm{Sb_2Me_4}]$ [2.919(1) Å],[5] whereas $[t\mathrm{Bu_3Al}]_2[\mathrm{Sb_2Et_4}]$ [3.001(1) Å][5] and $[t\mathrm{Bu_3Al}][\mathrm{Sb}_2(i\mathrm{Pr})_4]$ [3.003(2) Å][7] exhibit slightly longer intermetallic Al–Sb distances. In particular the longer Al–Sb distance of $[t\mathrm{Bu_3Al}]_2[\mathrm{Sb_2Et_4}]$ is somehow surprising since repulsive interactions between the organic substituents were expected to be more pronounced for the *n*Pr substituents than the sterically slightly less demanding Et substituents. Comparable trends are observed for gallane adduct **3** [2.988(1) Å], which shows a slightly shorter inter-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metallic Ga–Sb bond length compared with $[t\mathrm{Bu_3Ga}]_2$-$[\mathrm{Sb_2Et_4}]$ [3.022(1) Å], whereas that observed for $[t\mathrm{Bu_3Ga}]_2$-$[\mathrm{Sb_2Me_4}]$ [2.919(1) Å] is significantly shorter. The Al–Sb bond length of **7** [2.903(2) Å] is slightly shorter than that of **1** and in between those observed for $t\mathrm{Bu_3Al–SbEt_3}$ [2.845(1)] and $t\mathrm{Bu_3Al–Sb}(i\mathrm{Pr})_3$ [2.927(1) Å]. The average Al–C bond lengths [average values of **1** (2.022) and **7** (2.019 Å)] and C–Al–C bond angles [**1** (116.7°) and **7** (115.7°)] are comparable to those of previously reported alane adducts of trialkylstibanes.[17]

Distibane adducts of trialkylgallanes and -indanes have been previously found to tend to undergo consecutive Sb–Sb bond-cleavage reactions in solution with subsequent formation of heterocyclic stibanylgallanes and -indanes $[\mathrm{R_2MSbR'_2}]_x$, whereas the corresponding Al–Sb heterocycles were not formed.[5,7] The same trends were observed for the distibane adducts **1**–**4**. Alane adducts **1** and **2** remained unchanged in solutions of pentane or hexane and can be stirred for days without any sign of decomposition whereas $t\mathrm{Bu_3Ga}$ reacts with $\mathrm{Sb_2R_4}$ (R = *i*Pr, *i*Bu) with almost quantitative formation of the corresponding Ga–Sb heterocycles $[t\mathrm{Bu_2GaSb}(n\mathrm{Pr})_2]_2$ (**5**) and $[t\mathrm{Bu_2GaSb}(i\mathrm{Bu})_2]_2$ (**6**) within four days.[18] In contrast, the reaction of $t\mathrm{Bu_3Ga}$ with $\mathrm{Sb_2}(i\mathrm{Pr})_4$ proceeds much slower. Even after the reaction mixture was stirred for 10 days there is still some distibane adduct **4** detectable in solution. Unfortunately, $[t\mathrm{Bu_2GaSb}(i\mathrm{Pr})_2]_2$ could not be isolated from byproducts, to date, but its formation is clearly indicated by NMR spectroscopy. Obviously, the steric demand of the organic substituents bound to the Sb centers plays the key role for the required reaction time. Sterically less hindered distibanes such as $\mathrm{Sb_2Me_4}$ and $\mathrm{Sb_2Et_4}$ react with $t\mathrm{Bu_3Ga}$ within two days with almost quantitative formation of the corresponding stibanylgallanes $[t\mathrm{Bu_2GaSbMe_2}]_3$ and $[t\mathrm{Bu_2GaSbEt_2}]_2$,[5] whereas the formation of **5** and **6** requires longer reaction times. Compounds **5** and **6** were obtained as colorless crystalline solids in almost quantitative yields, which were recrystallized from solutions in hexane.

$^1$H and $^{13}$C NMR spectra of **5** and **6** show resonances of the organic ligands in the expected 1:1 molar ratio. Since the Sb centers in the distibane adducts are no longer prochiral only a single resonance of the α-$CH_2$ protons of the *n*Pr and *i*Bu groups occurs. The mass spectra of **5** and **6** show typical fragmentation patterns of the heterocycles, whereas no molecular ion peak could be detected. Suitable crystals of **5** for a single-crystal X-ray diffraction study were obtained from a solution in hexane at –30 °C. (Figure 4).

Compound **5** crystallizes in the monoclinic space group $P2_1/c$ (No. 14) and adopts a planar four-membered ring. The metal atoms reside in distorted tetrahedral environments. The Ga–Sb bond lengths [2.736(1), 2.738(1) Å] are almost identical to those observed for $[t\mathrm{Bu_2GaSbEt_2}]_2$ [2.731(1)–2.735(1) Å] and $[\mathrm{Et_2GaSb(SiMe_3)_2}]_2$ [2.718(1), 2.729(1) Å],[19] whereas $[t\mathrm{Bu_2GaSb(SiMe_3)_2}]_2$ [2.768(1) Å][20] shows slightly longer Ga–Sb distances due to increased repulsive interactions between the sterically more demanding organic substituents. The C–Sb–C bond angles [97.3(2)°] are smaller than the C–Ga–C bond angles [122.2(2)°] as is typical for this type of compound and the Ga–C [2.016(4), 2.011(3) Å] and Sb–C bond lengths [2.161(3), 2.166(3) Å] are within typical ranges.

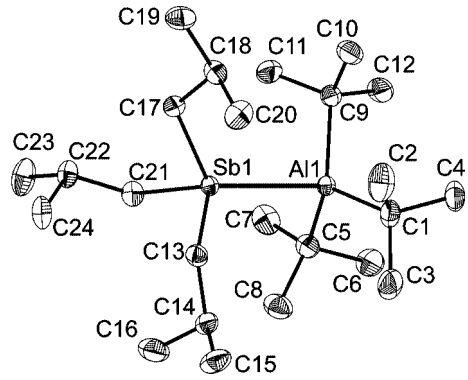

Figure 4. ORTEP plot (50% probability level; H omitted for clarity) showing the solid-state structure and atom-numbering scheme for **5**. Ga1–Sb1 2.736(1), Ga1a–Sb1 2.738(1), Sb1–C9 2.161(3), Sb1–C12 2.166(3), Ga1–C1 2.016(4), Ga1–C5 2.011(3), Sb1–Ga1–Sb1a 83.4(1), Ga1–Sb1–Ga1a 96.6(1), C9–Sb1–Ga1 117.1(1), C12–Sb1–Ga1 113.8(1), C1–Ga1–Sb1 108.8(1), C5–Ga1–Sb1 113.4(1), C1–Ga1–C5 122.2(2), C9–Sb1–C12 97.3(2).

## Conclusions

Distibanes $\mathrm{Sb_2R_4}$ (R = *n*Pr, *i*Pr, *i*Bu) react with trialkylalanes and -gallanes $t\mathrm{Bu_3M}$ with the initial formation of Lewis acid–base adducts $[t\mathrm{Bu_3M}]_2[\mathrm{Sb_2R_4}]$. The gallane adducts were found to tend to undergo Sb–Sb bond-cleavage reactions with the subsequent formation of heterocyclic stibanylgallanes $[t\mathrm{Bu_2GaSbR_2}]_2$, whereas the alane adducts remained unchanged in solution.

## Experimental Section

**General:** All manipulations were performed in a glovebox under an Ar atmosphere or by standard Schlenk techniques. $t\mathrm{Bu_3Al}$,[21] $t\mathrm{Bu_3Ga}$,[22] $\mathrm{Sb_2}(n\mathrm{Pr})_4$,[23] $\mathrm{Sb_2}(i\mathrm{Pr})_4$,[23] and $\mathrm{Sb_2}(i\mathrm{Bu})_4$[23] were prepared according to literature methods. $^1$H and $^{13}$C{$^1$H} spectra were recorded using a Bruker Avance 500 spectrometer and are referenced to internal $C_6D_5H$ ($^1$H NMR: $\delta$ = 7.154, $^{13}$C NMR: $\delta$ = 128.0 ppm). Melting points were measured in sealed capillaries and are not corrected. Mass spectra (EI) were recorded with a Finnigan MAT 8230 spectrometer. Melting points were measured in sealed capillaries and were not corrected. Elemental analyses were performed at the Elementaranalyse Labor of the University of Paderborn. Yields are given for the pure products after recrystallization.

**Synthesis of $[t\mathrm{Bu_3M}]_2[\mathrm{Sb_2R_4}]$:** $t\mathrm{Bu_3M}$ (1 mmol) and $\mathrm{Sb_2R_4}$ (0.5 mmol) were combined in the glovebox, and the resulting yellow oil was dissolved in *n*-pentane (5 mL) and stored at –40 °C. Light yellow crystals of **1**–**4** were formed within 2 d. Yields are given for isolated compounds after recrystallization.

**$[t\mathrm{Bu_3Al}]_2[\mathrm{Sb_2}(n\mathrm{Pr})_4]$ (1):** Yield 0.22 g, 0.35 mmol, 70%. M.p. 85 °C. $C_{36}H_{82}Al_2Sb_2$ (812.51): calcd. **X-ray Structure Solution and Refinement:** Crystallographic data of **1**, **3**, **5**, and **7** are summarized in Table 1. Figures 1–4 show ORTEP diagrams of the solid-state structures of **1**, **3**, **5**, and **7**. Data were collected with a Bruker SMART APEX CCD diffractometer[24] using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at $T$ = 120(2) K and the structures were solved by Direct and Fourier Methods (SHELXTL),[24] and refined by full-matrix least-squares on $F^2$. All non-hydrogen atoms in **1**, **3**, **5** and **7** were refined anisotropically and hydrogen atoms were located from $\Delta F$ maps and refined at idealized positions with a riding model (SHELXTL).

CCDC-623814 (for **1**), -623815 (for **3**), -623816 (for **5**), and -623813 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Electronic Control of the Rotational Barrier in $\eta^2$-Alkyne-1-thio Complexes

**Wolfram W. Seidel,*[a] Beatriz López Sánchez,[a] Matthias J. Meel,[a] Alexander Hepp,[a] and Tania Pape[a]**

**Keywords:** (Alkylthio)alkyne ligands / Alkyne complexes / Molybdenum / Fluxionality / Ligand effects

A family of thio-alkyne complexes [Tp′Mo(CO)(L)($BnSC_2S$)] {Bn = benzyl, Tp′ = hydrotris(3,5-dimethylpyrazolyl)borate, L = carbonyl (**2**), 2,6-dimethylphenyl isocyanide (**7**), *tert*-butyl isocyanide (**8**), 4-(dimethylamino)pyridine (**9**)} was prepared by reductive removal of a benzyl group in the corresponding bis(benzylthio)acetylene complexes [Tp′Mo(CO)(L)-($BnSC_2SBn$)]($PF_6$) (**1**-$PF_6$, **4**-$PF_6$, **5**-$PF_6$ and **6**-$PF_6$). All complexes were characterized by IR, $^1H$, $^{13}C$ spectroscopy and cyclic voltammetry. X-ray diffraction studies of **5**-$PF_6$, **8** and **9** were carried out. The alkyne ligand is bound symmetrically to molybdenum in **5**-$PF_6$ and unsymmetrically in **8** and **9**. The trend in the π-acidity of ligand L is reflected in the spectroscopic and electrochemical data as well as in the molecular structures. Variable temperature $^1H$ NMR investigations with **7**, **8** and **9** disclosed that the barrier of the alkyne rotation at molybdenum decreases in the order of rising electron density at the metal center while the steric demand increases. Therefore, electronic control of the barrier by the specific character of the ligand L is evident.

## Introduction

Applying the terms of simple VB theory alkynes can act in their complexes as two-, three- or four-electron donor ligands. The possible interaction of two occupied π- and two unoccupied π*-alkyne orbitals with metal orbitals renders an appropriate description of the binding situation more complex compared to the Dewar–Chatt–Duncanson model for coordinated alkenes. However, the easy rotation of the side on bound ligand is of typical behaviour for both alkene and alkyne complexes. In asymmetric alkyne complexes this dynamic behaviour can regularly be studied by variable temperature NMR spectroscopy. In this context, the evaluation of both the alkyne-$\pi_\perp$-donation into the metal dπ manifold, and the alkyne-$\pi_\parallel$*-acceptance of metal dπ density seems feasible, because the activation barrier of the rotation should reflect the strength of the metal alkyne π-interaction. The dependence of the rotational barrier from electronic factors such as the π-acid-π-base properties of ancillary ligands[1] and the type of the alkyne[2] is evident in many examples. Electronic factors must be involved, when the observed trend within related complexes does not follow the varying steric demand.[1c] Large barrier differences in complexes with high electronic and steric similarity like [Mo($\eta^5$-$C_5H_5$)(dppe)($MeC_2Me$)]($BF_4$) and [Mo($\eta^5$-$C_5H_5$)($PPh_2Me$)$_2$($MeC_2Me$)]($BF_4$) emphasize the importance of the particular position of the ligand π-orbitals with respect to the metal dπ manifold.[1b] In contrast, the size of the alkyl substituents R predominantly accounts for barrier differences in [Nb($\eta^5$-$C_5H_4SiMe_3$)(R)$_2$($Me_3SiC_2SiMe_3$)] complexes.[3] However, frequently the differences in the activation enthalpies are small and the interfering steric and electronic factors can not be separated.[4] Thus, neutral $Mo^{II}$ and $W^{II}$ alkyne complexes with the hydrotris(3,5-dimethylpyrazolyl)borate (Tp′) ancillary ligand show distinctively higher barriers[5] compared to those with hydrotris(pyrazolyl)borate. However, the small differences within [TpM($RC_2R'$)(CO)I] complexes (M = Mo, W) upon variation of R/R′ can be attributed to both steric and electronic reasons.[6] In formal $Mo^{VI}$ complexes with a strong π-donating imido ligand the rotational barrier is even independent of the type of the alkyne.[7] Recently, in paramagnetic complexes [Mo($\eta^5$-$C_5H_5$){P(OMe)$_3$}$_2$($RC_2R$)] temperature-dependent EPR spectroscopy was used to determine much lower barriers of an approximately quarter-turn alkyne oscillation process at the metal.[8] Depending on the particular $d^8$-metal[9] or type of the ancillary ligand, observation of rotamers with respect to 90° rotation at the metal, that can be considered as the extreme of an "inverted" rotational barrier, emphasizes the delicate balance of steric and electronic influences.[10]

In the course of our studies on the coordination chemistry of sulfur-substituted alkynes[11] we isolated and characterized a number of closely related (R–S)-alkyne complexes, which allow a surprising insight into the problem discussed above. In the complexes [Tp′Mo(CO)(L)($\eta^2$-$BnSC_2S$)], in

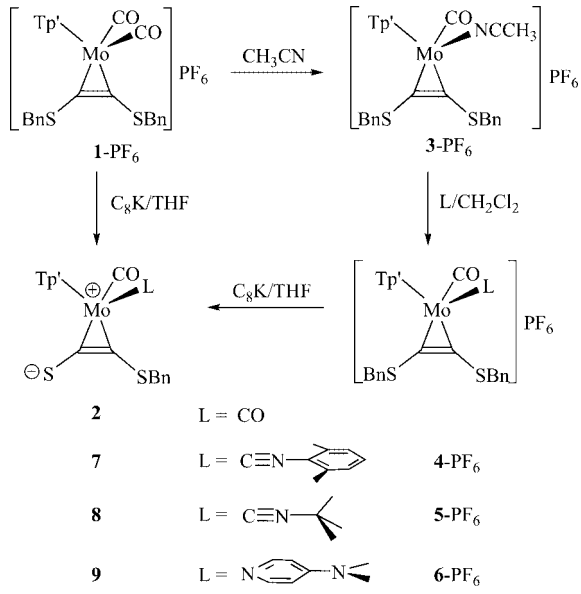
which the ligand L represents either carbonyl, an isocyanide or a pyridine derivative, the electron density at the metal is increased in this order as can be concluded from IR spectroscopic and electrochemical evidence. The variable-temperature $^1$H NMR spectroscopic investigations of these complexes showed that the free activation enthalpy of the alkyne rotation is notably lowered, while the steric demand of the ligands rises, respectively. Therefore, the electronic determination of the rotational barrier in the complexes [Tp′Mo(CO)(L)(η²-BnSC$_2$S)], described in this contribution, is remarkably obvious.

## Results and Discussion

The (BnS)(S)-alkyne complex [Tp′Mo(CO)$_2$(η²-BnSC$_2$S)] (**2**) with a terminal sulfur atom is accessible by a single electron reduction of the corresponding cationic bis(benzylthio)acetylene complex [Tp′Mo(CO)$_2$(η²-BnSC$_2$SBn)](PF$_6$) **1**-PF$_6$ and the subsequent removal of a benzyl radical.[11] The desired substitution of one carbonyl ligand in **2** was preferably performed with **1**-PF$_6$, since the carbonyls are easier to remove in the electron-poorer cation **1**$^+$. Following a procedure described by Templeton,[5] complex **1**-PF$_6$ was transformed into the acetonitrile complex [Tp′Mo(CO)(CH$_3$CN)(η²-BnSC$_2$SBn)](PF$_6$) (**3**-PF$_6$), which served as a convenient starting material for the introduction of other neutral ligands. The substitution of acetonitrile in **3**-PF$_6$ by 2,6-dimethylphenyl isocyanide, *tert*-butyl isocyanide or 4-(dimethylamino)pyridine in boiling dichloromethane (Scheme 1) proceeds very clean, if **3**-PF$_6$ is analytically pure. A facile and fast purification of **3**-PF$_6$, which is unexpectedly stable, is possible by column chromatography using SiO$_2$ as solid phase and dichloromethane as eluent. The products of the substitution according to Scheme 1, [Tp′Mo(CO)(Me$_2$C$_6$H$_3$NC)(η²-BnSC$_2$SBn)](PF$_6$) (**4**-PF$_6$), [Tp′Mo(CO)(Me$_3$CNC)(η²-BnSC$_2$SBn)](PF$_6$) (**5**-PF$_6$) and [Tp′Mo(CO)(Me$_2$NC$_5$H$_4$N)(η²-BnSC$_2$SBn)](PF$_6$) (**6**-PF$_6$), were isolated by crystallization from dichloromethane solutions after layering with diethyl ether.

The preparation of [Tp′Mo(CO)(Me$_2$C$_6$H$_3$NC)(η²-BnSC$_2$S)] (**7**), [Tp′Mo(CO)(Me$_3$CNC)(η²-BnSC$_2$S)] (**8**) and [Tp′Mo(CO)(Me$_2$NC$_5$H$_4$N)(η²-BnSC$_2$S)] (**9**) was achieved by one-electron reduction of **4**-PF$_6$, **5**-PF$_6$ and **6**-PF$_6$ according to Scheme 1. The reduction at –78 °C resulted in all cases in intensely red molybdenum(I) species, which are characterized by low frequencies of the carbonyl and, in the case of **4** and **5**, isocyanide C–N vibrations. A color change to dark green at ambient temperature indicates the formation of the final products by cleavage of a benzyl radical. The dicarbonyl complex **2** is synthesized following the same procedure using **1**-PF$_6$ as starting material.[11] However, the removal of one benzyl group proceeds much faster with improved yields after reduction of **4**-PF$_6$, **5**-PF$_6$ and **6**-PF$_6$. We believe that this benefit can be attributed to both steric and electronic reasons. The higher steric demand of the ligands L compared to CO hamper the formation of undesired by-products, which were shown to involve attack of



Scheme 1. Synthesis of complexes **2**–**9**, Tp′ = hydrotris(3,5-dimethylpyrazolyl)borate, Bn = benzyl.

benzyl radicals at the coordinated carbonyl.[11] In addition, delocalization of unpaired spin density into the alkyne has been shown to cause the homolytic C–S bond cleavage.[11] Therefore, the facilitated benzyl cleavage in the synthesis of **7**, **8** and **9** compared to that of **2** reflect the higher electron density at the Mo$^I$ species with L. While **7** and **8** can be purified by column chromatography with toluene as eluent, the (dimethylamino)pyridine complex **9** is not sufficiently stable. However, analytically pure **9**·CH$_2$Cl$_2$ was obtained by crystallization from a toluene/CH$_2$Cl$_2$ solution.

The molecular structures of cationic [**5**]$^+$ as well as neutral **8** and **9** (Figure 1 and Figure 2, Table 1) were determined by X-ray structure analysis in order to investigate the steric interference of ligand L with the rotational process of the alkyne ligand. The molecular structures are generally similar and show roughly octahedral polyhedrons considering the alkyne as occupying a single coordination site. The alkyne SCCS planes lie between the two σ-donor-π-acceptor ligands, but rather tilted to the Mo–CO vector to a varying extent. In consideration of the overall similarly complex structures, the removal of one benzyl group ensues one major difference between cationic [**5**]$^+$ and neutral **8** and **9**. While the bis(benzylthio)acetylene ligand is bound symmetrically to molybdenum in [**5**]$^+$, **8** and **9** show one short and one long molybdenum–carbon bond. This observation is reflected in the resonance structure **B** with a thioketo group and one metal carbon double bond (Figure 3). In addition, the SCCS alkyne plane in **8** and **9** is more clearly aligned with the remaining carbonyl ligand compared to [**5**]$^+$. The torsion angle C3–Mo–C2–C1 amounts to 11.6° in **8** and 11.9° in **9**. Despite the rather bulky isocyanides used, replacement of one carbonyl in **2** by an isocyanide does not seem to increase the hindrance of alkyne rotation due to the linear nature of the CNR unit and the longer Mo–CNR bond (compare Mo–C4 2.117(4) Å and Mo–C3 1.996(4) Å

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in [**5**]$^+$). However, the steric demand in proximity to the alkyne unit clearly increases from **2** to the 4-(dimethylamino)pyridine complex **9**, in which a $sp^2$-hybridisized nitrogen atom as a part of an aromatic ring serves as donor. In addition, inspection of the molybdenum alkyne–carbon bond lengths reveals that the Mo–C1 bond is significantly shorter in the 4-(dimethylamino)pyridine complex **9** [2.104(4) Å] compared to the dicarbonyl complex **2** [2.143(3) Å].[11] Therefore, taking into account solely geometric factors the highest rotational barrier is expected for **9**.

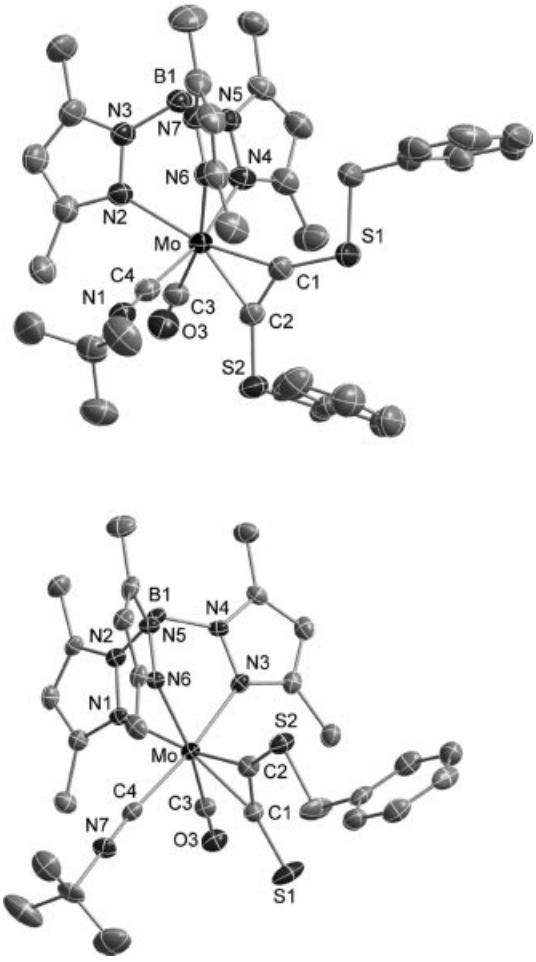


Figure 1. Molecular structures of [**5**]$^+$ (top) and **8** (bottom). Hydrogen atoms have been omitted for clarity.

The increase of the electron density at the molybdenum atom while substituting one carbonyl in **1**-$PF_6$ with isocyanides in **4**-$PF_6$ and **5**-$PF_6$ and 4-(dimethylamino)pyridine in **6**-$PF_6$ is evident by IR spectroscopy and cyclic voltammetry. Similar observations apply to the series **2**, **7**, **8** and **9**. The prototype complex **1**-$PF_6$ shows two reversible electron transfer waves at $E_{p,c}$ = –0.80 V and –1.65 V (cathodic peak potentials referenced vs. ferrocene/ferrocenium). The first one at moderate potential is shifted to lower potential, while going to **4**-$PF_6$ and finally to **6**-$PF_6$. In turn the CVs. of the more electron rich complexes **4**-$PF_6$ and **6**-$PF_6$ show an additional oxidation process (see supporting information). As a result, the second reduction could not even be recorded in the CV of **6**-$PF_6$. The neutral thio-alkyne complexes **2**, **7** and **8** show concordantly one quasi-reversible electron transfer wave at low potential, while the corresponding reduction process in **9** appears irreversible (Figure 4, Table 2). The cathodic peak potential estimated vs. ferrocene/ferrocenium at a scan rate of 100 mV s$^{-1}$ changes from –1.64 V for **2** to –1.91 V for **7**, –2.01 V for **8** and finally to –2.31 V for **9**. Consistently, in the same order the force constant of the CO stretching vibration decreases from 16.57 N cm$^{-1}$ in **2** to 15.10 N cm$^{-1}$ in **7**, 14.93 N cm$^{-1}$ in **8** and finally to 14.48 N cm$^{-1}$ in **9**. Additionally, the high π-backbonding capacity of molybdenum in **9** is reflected in the hindrance of the pyridine rotation about the Mo–N bond as indicated by $^1$H NMR spectroscopy.

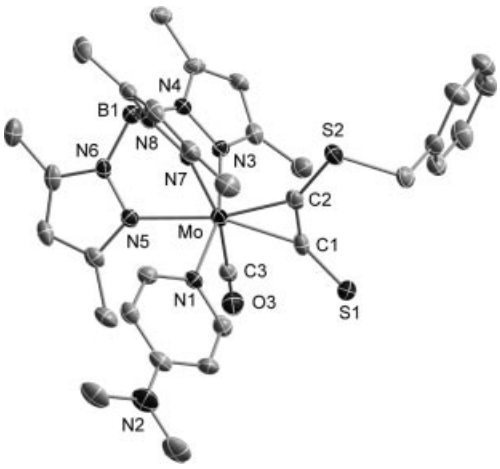

Figure 2. Molecular structure of **9**. Hydrogen atoms have been omitted for clarity.

The room temperature $^1$H NMR spectra of **2** and **7**–**9** show fluxional behavior, which is particularly evident for the benzylic protons. The alkyne resonances in the $^{13}$C NMR spectra of **7** and **8** are in coalescence at ambient temperature. However, at 220 K a double set of signals with one carbonyl and two alkyne resonances for each isomer are found between $\delta$ = 220 and 250 ppm. Complex **9** is in fast exchange in the room temperature $^{13}$C NMR spectrum and three resonances at 227, 233 and 238 ppm are observed. These values are typical for four-electron donor alkyne complexes.[1a] The underlying dynamic behavior can be attributed to rotation of the unsymmetric thio-alkyne ligand at the metal center based on the following reasons. Alkyne rotation in complexes **2** and **7**–**9** implies an isomer interconversion and both rotamers for **2** and **7**–**9** were observed in the low temperature NMR spectra. The $^1$H NMR shifts of the benzylic $CH_2$ protons show a considerable difference of 2 ppm between the two isomers. The similarity of these chemical shifts to the shifts of the two benzyl groups in the cationic bis(benzylthio)acetylene complexes were considered a first hint that alkyne rotation accounts for the fluxional behavior. The resonances of the benzylic $CH_2$ groups in either *syn* or *anti* position to the carbonyl differ so much because of opposing anisotropy effects by the pyrazole rings and the triple bonds of carbonyl and isocyanide. Therefore, the low field shifted signal is assigned to the *syn* position with respect to the carbonyl ligand, while the high field shifted signal reflects the proximity of the $CH_2$ group to the pyrazolyl pocket. This perception is proven by 2D NMR spectroscopic experiments.

A gHMBC spectrum of **2** in the slow exchange at 210 K shows the correlation of the PhC$H_2$ resonance pair with the low field shifted alkyne carbon pair.[11] Accordingly, the gHMBC spectrum of **9** at 300 K in the fast exchange displays correlation of only one of the alkyne carbon atoms with the PhC*H*H resonances (Figure 5). These observations rule out a migration process of the benzyl group from one sulfur atom to the other as reason for the fluxionality because the benzylthio group remains attached to one of the alkyne carbon atoms. In addition, the protons in both isomers of **7**, **8** and **9** are diastereotopic because of the $C_1$ symmetry of the whole complex. The stereochemistry of the PhC*H*H group is generally retained in the fast exchange, which is evident in the spectrum of **9** at 300 K (Figure 6) and of **8** at 335 K (Figure S7). The difference between the high temperature signal of **9** in $CDCl_3$ (Figure 6) and in $CD_2Cl_2$ (Figure S9) indicates that the observation of a singlet in the latter case is coincidental. The identity of the isomers, which are not observed in the crystal structures, as *syn* isomer with respect to the benzyl group and the carbonyl ligand, and not as rotamer with respect to the $C_{sp}$–S bond, is confirmed by a low-temperature ROESY spectrum of **8**. At 210 K both isomers of **8** show proximity of one of the benzyl-CH*H* protons with one of the Tp′ methyl groups, while no correlation to the pyrazol-CH protons was found. In contrast, a weak correlation peak of one benzyl-CH*H* proton of the major isomer with the methyl groups of the isocyanide ligand was detected (see supporting information for details).[12] In addition, DFT calculations were performed in order to estimate the energy differences between four different isomers of the slightly reduced model complex [TpMo(CO)$_2$(MeSC$_2$S)]. Geometry optimizations resulted that the energy differences between the rotational isomers with respect to the $C_{sp}$–S bond are smaller (approximately 5 kJ/mol) compared to the differences between the isomers with respect to the alkyne rotation at the metal (approximately 10 kJ/mol, see supporting information for details). Finally, the observation of comparable rotational barriers in K[Tp′W(CO)$_2$($\eta^2$-C$_2$S$_2$)] and its complexes without any benzyl group strongly supports our isomer assignment.[13]

While the isomer ratio is largely balanced in **2**, the isomer with the benzyl group directed at the carbonyl is found at the low temperature limit in proportion of 64% in **7**, of 60% in **8** and of 83% in **9**. The primary crystallization of the minor isomers could be attributed to lower solubilities and crystal packing forces. Variable temperature $^1$H NMR spectra were measured with **7**, **8** and **9** (Figure 6). The coalescence temperature is about ambient temperature for complex **7** and **8**, while the very fast exchange area is out of range. In contrast, the rotational barrier in **9** is so low that the coalescence temperature is just reached at 220 K, while the exchange is fast at room temperature. The activation parameters of **7**–**9** were estimated by line-shape simulation performed with the MEXICO program package[14] (see supporting information for details). The corresponding values of **2** have already been published.[11] The activation parameters obtained are listed in Table 2. The differences are substantial in consideration of the fact that the complexes are very similar and that only one σ-donor/π-ac-

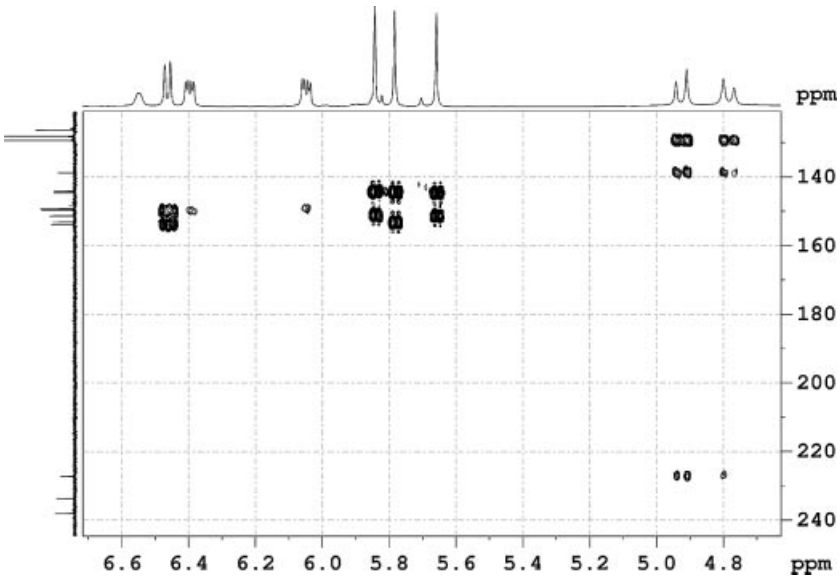

Figure 5. Part of the gHMBC spectrum of **9** at 300 K.

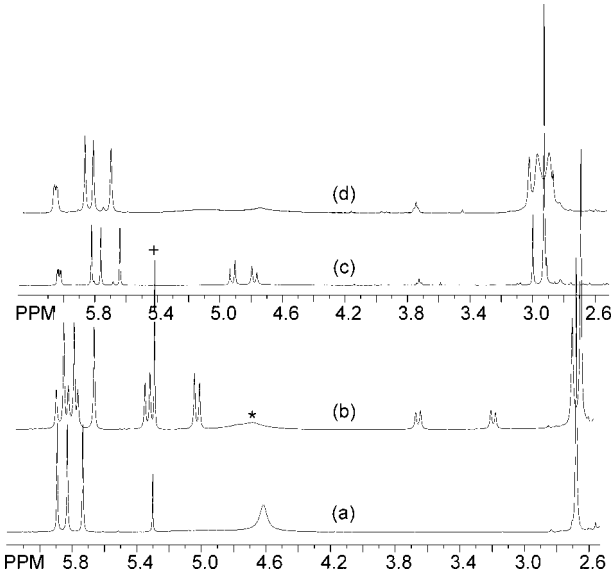

Figure 6. Variable-temperature $^1$H-NMR spectra in $CDCl_3$: **7** at 335 K (a), **7** at 220 K (b), **9** at 300 K (c) and **9** at 220 K (d), + $CH_2Cl_2$, * B*H*.

ceptor ligand is varied. The barrier decreases clearly with rising electron density at molybdenum despite increasing steric demand. Therefore the rate of the alkyne rotation must be determined electronically in complexes **2** and **7**–**9** and a crucial contribution of steric factors can be ruled out.

The facilitated rotation of the alkyne with increasing electron density at the metal is not easy to explain, because a stronger back-donation from the metal generally strengthens the π interaction, which is associated with a higher rotational barrier. However, according to a qualitative molecular orbital Scheme for octahedral alkyne d$^4$-metal complexes presented by Templeton[15,5] two of the frontier orbitals involve metal alkyne π interactions. The bonding combination of the $d_{yz}$ orbital and the $\pi^*_{\|}$ orbital, which represents the π back-donation from the metal, is considered occupied (Figure 7). In contrast, the antibonding combination of the $d_{xy}$ orbital with the $\pi_\perp$-orbital of the alkyne is accounted the LUMO. Templeton has pointed out[1a] that both $\pi_\perp$ and $\pi^*_{\|}$ interchange their partners on the metal, if the alkyne rotates away from the ground state orientation to the orthogonal position with respect to the CO ligand. The π-acidity of the ligand L is particularly important for the $d_{xy}$ orbital, which is considered populated in the excited rotational state.[1a] The perception that ligand L and the alkyne compete for the electron density of the $d_{xy}$ orbital in the excited rotational state reflects the strong influence of the ligand L on the barrier. The decreasing π-acceptor ability in the order CO, isocyanide and pyridine ensues an enhanced π-back bonding to the thio-alkyne ligand resulting in a stabilization of this state. Therefore, the decrease of the rotational barrier can predominantly be attributed to a stabilization of the excited rotational state. In addition, this interpretation explains the otherwise paradox trend of shorter metal–C(alkyne) bonds in the ground-state structure and a facilitated rotation of the alkyne in solution.

## Conclusions

Alkyne complexes with a terminal sulfur atom attached to the alkyne are accessible at the Tp′Mo(CO)(L) fragment by reductive cleavage of one benzyl group in the corresponding bis(benzylthio)acetylene complexes [Tp′Mo(CO)(L)(BnSC$_2$SBn)](PF$_6$). The resulting thio-alkyne complexes [Tp′Mo(CO)(L)(BnSC$_2$S)] are interesting as neutral sulfur ligands[16] and as starting materials for the preparation of η²-*C*,*C*′ complexes with acetylenedithiolate.[13] The variation of L with respect to a modified σ-donor-π-acceptor character leads to altered reaction rates in the benzyl cleavage and pronounced trends in the molecular structures, the electrochemical parameters and the solution dynamics. Decreasing π-acidity of L leads to a facilitated rotation of the alkyne at molybdenum. These observations substantiate our strategy to adjust the donor ability on the sulfur atoms in heterobimetallic complexes by slight variations in the coordination sphere of the alkyne complex moiety.

## Experimental Section

**General Procedures:** All operations were carried out under a dry argon atmosphere using standard Schlenk and glove box techniques. All solvents were dried and saturated with argon by standard methods and freshly distilled prior to use. [Tp′Mo(CO)$_2$(BnSC$_2$SBn)]PF$_6$ (**1**-PF$_6$) {Tp′ = hydrotris(3,5-dimethylpyrazolyl)borate}[11] and C$_8$K[17] were prepared according to literature methods. 2,6-dimethylphenyl isocyanide, *tert*-butyl isocyanide and 4-(dimethylamino)pyridine were purchased from Aldrich. $^1$H and $^{13}$C NMR spectra were recorded on a Bruker AC 200 and Bruker Avance 400 NMR spectrometer. Elemental analyses were performed on a Vario EL III CHNS elemental analyzer. ESI mass spectra were obtained using a QUATTRO LCZ (Waters-Micromass). Infrared spectra were recorded on a Bruker Vektor 22. Cyclic voltammetry data was acquired on a ECO/Metrohm PGSTAT 30 potentiostat using a glassy carbon working electrode, an Ag/0.01 M AgNO$_3$/CH$_3$CN reference electrode, (NBu$_4$)(PF$_6$) as supporting electrolyte and ferrocene as internal standard.

**[Tp′Mo(CO)(CH$_3$CN){η²-(BnS)CC(SBn)}](PF$_6$) (3-PF$_6$):** A solution of **1**-PF$_6$ (3.02 g, 3.50 mmol) in acetonitrile (50 mL) was heated to reflux. After two days the product was isolated by column chromatography at SiO$_2$ using CH$_2$Cl$_2$ as eluent (2.53 g, 83%). Recrystallization from CH$_2$Cl$_2$/Et$_2$O yielded dark green crystals. MS (ESI in CH$_2$Cl$_2$): *m*/*z* = 734 [M]$^+$ with the expected isotopic pattern. IR (KBr): $\tilde{\nu}_{CN}$ = 2179, $\tilde{\nu}_{CO}$ = 1956 cm$^{-1}$. $^1$H NMR (200 MHz, CDCl$_3$, 20 °C): $\delta$ = 7.46–7.26 (m, 8 H, Ph-*H*), 6.86 (m, 2 H, Ph-*H*), 6.01 (s, 2 H, Tp′-C*H*), 5.95 (s, 1 H, Tp′-C*H*), 5.00 (d, $^2J_{HH}$ = 12.9 Hz, 1 H, SCH*H*), 4.91 (d, $^2J_{HH}$ = 12.9 Hz, 1 H, SC*H*H), 3.49 (d, $^2J_{HH}$ = 12.0 Hz, 1 H, SCH*H*), 2.80 (d, $^2J_{HH}$ = 12.0 Hz, 1 H, SC*H*H), 2.62 (s, 3 H, Tp′-*Me*), 2.51 (s, 9 H, Tp′-*Me*), 2.44 (s, 3 H, Tp′-*Me*), 2.01 (s, 3 H, Tp′-*Me*), 1.42 ppm (s, 3 H, NCC*H*$_3$). $^{13}$C NMR (50 MHz, CDCl$_3$, 20 °C): $\delta$ = 230.4 (Mo*C*SCH$_2$), 216.5 (*C*O), 207.6 (Mo*C*SCH$_2$), 152.8, 152.1, 149.9, 146.8, 145.8, 142.9 (Tp′-*C*Me), 134.8, 134.0, 129.2, 128.9, 128.8, 128.7, 128.1, 128.0 (Ph-*C*), 108.2, 107.5, 107.3 (Tp′-*C*H), 43.1, 40.5 (S*C*H$_2$), 15.1, 14.2, 14.0, 12.7, 12.5, 7.0 (Tp′-*C*H$_3$), 3.9 ppm (NC*C*H$_3$).

**[Tp′Mo(CO)(CN-C$_6$H$_3$Me$_2$-2,6){η²-(BnS)CC(SBn)}](PF$_6$) (4-PF$_6$):** A solution of **3**-PF$_6$ (5 g, 5.7 mmol) in dichloromethane (80 mL) was treated with 2,6-dimethylphenyl isocyanide (0.75 g, 5.72 mmol) and heated under reflux for two days. The solution was cooled to ambient temperature and the formation of **4**-PF$_6$ was checked by IR spectroscopy. The solution was reduced in vacuo to 20 mL and layered with diethyl ether (80 mL). After 24 hours green crystals, which had formed, were collected by removing the mother liquor, washing with diethyl ether and drying in vacuo. Yield: 4.4 g (80%). IR (KBr): $\tilde{\nu}_{CN}$ = 2146, $\tilde{\nu}_{CO}$ = 1971 cm$^{-1}$. $^1$H NMR (200 MHz, CDCl$_3$, 20 °C): $\delta$ = 7.40–7.25 (m,10 H, Ph-*H*), 7.16 (m, 1 H, Ph-*H*), 6.85 (m, 2 H, Ph-*H*), 6.07 (s, 1 H, Tp′-C*H*), 5.97 (s, 1 H, Tp′-C*H*),5.96 (s, 1 H, Tp′-C*H*), 5.41 (br. s, 1 H, B*H*), 4.86 (d, $^2J$ = 19 Hz, 1 H, SCH*H*), 4.82 (d, $^2J$ = 19 Hz, 1 H, SC*H*H), 3.35 (d, $^2J$ = 12 Hz, 1 H, SCH*H*), 2.29 (d, $^2J$ = 12 Hz, 1 H, SC*H*H), 2.55 (s, 3 H, Tp′-*Me*), 2.53 (s, 3 H, Tp′-*Me*), 2.51 (s, 3 H, Tp′-*Me*), 2.43 (s, 3 H, Tp′-*Me*), 2.24 (s, 6 H, PhC*H*$_3$), 1.88 (s, 3 H, Tp′-*Me*), 1.52 ppm (s, 3 H, Tp′-*Me*). $^{13}$C NMR (200 MHz, CDCl$_3$, 20 °C): $\delta$ = 226.2 (Mo*C*SCH$_2$), 221.1 (*C*O), 205.1 (Mo*C*SCH$_2$), 168.9 (Mo*C*N), 152.7, 151.6, 150.1, 147.7, 146.4, 146.3 (Tp′-*C*Me), 134.5, 133.2, 130.6, 129.0, 128.9, 128.9, 128.8, 128.8, 129.7, 128.5, 128.3, 128.2 (Ph-*C*), 108.5, 107.4, 107.3 (Tp′-*C*H), 44.1, 41.4 (S*C*H$_2$), 18.5 (Ph-*C*H$_3$), 15.6, 14.6, 14.0, 13.0, 12.6, 12.5 ppm (Tp′-*C*H$_3$).

**[Tp′Mo(CO)(Me$_3$CNC){η²-(BnS)CC(SBn)}](PF$_6$) (5-PF$_6$):** The complex was synthesized analogously to **4**-PF$_6$ using **3**-PF$_6$ (2.58 g, 2.95 mmol) and *tert*-butyl isocyanide (0.34 mL, 2.95 mmol). Recrystallization from CH$_2$Cl$_2$/Et$_2$O yielded green crystals (2.58 g, 76%). MS (ESI in CH$_2$Cl$_2$): *m*/*z* = 776 [M]$^+$ with the expected isotopic pattern. IR (KBr): $\tilde{\nu}_{CN}$ = 2179, $\tilde{\nu}_{CO}$ = 1971 cm$^{-1}$. $^1$H NMR (200 MHz, CDCl$_3$, 20 °C): $\delta$ = 7.37–7.26 (m, 8 H, Ph-*H*), 6.89 (m, 2 H, Ph-*H*), 6.05 (s, 1 H, Tp′-C*H*), 5.99 (s, 1 H, Tp′-C*H*), 5.96 (s, 1 H, Tp′-C*H*), 4.88 (d, $^2J_{HH}$ = 13.5 Hz, 1 H, SCH*H*), 4.75 (d, $^2J_{HH}$ = 13.5 Hz, 1 H, SC*H*H), 3.28 (d, $^2J_{HH}$ = 12.0 Hz, 1 H, SCH*H*), 2.85 (d, $^2J_{HH}$ = 12.0 Hz, 1 H, SC*H*H), 2.63 (s, 3 H, Tp′-*Me*), 2.51 (s, 3 H, Tp′-*Me*), 2.50 (s, 3 H, Tp′-*Me*), 2.41 (s, 3 H, Tp′-*Me*), 1.84 (s, 3 H, Tp′-*Me*), 1.49 [s, 9 H, C(C*H*$_3$)$_3$], 1.48 ppm (s, 3 H, Tp′-*Me*). $^{13}$C NMR (100 MHz, CDCl$_3$, 20 °C): $\delta$ = 228.4 (Mo*C*SCH$_2$), 219.7 (*C*O), 204.0 (Mo*C*SCH$_2$), 152.8, 151.5, 150.0, 147.7, 146.3 (Tp′-*C*Me, two resonances are accidentally isochronic), 135.2, 133.4, 129.1, 129.0, 128.8, 128.7, 128.4, 128.3 (Ph-*C*), 108.5, 107.4, 107.3 (Tp′-*C*H), 60.0 [*C*(CH$_3$)$_3$], 44.0, 41.0 (S*C*H$_2$), 30.0 [C-(*C*H$_3$)$_3$], 15.6, 14.3, 14.1, 13.0, 12.6, 12.5 ppm (Tp′-*C*H$_3$).

**[Tp′Mo(CO)(NC$_5$H$_4$NMe$_2$){η²-(BnS)CC(SBn)}](PF$_6$) (6-PF$_6$):** The complex was synthesized analogously to **4**-PF$_6$ using **3**-PF$_6$ (3.24 g, 3.65 mmol) and 4-(dimethylamino)pyridine (668 mg, 5.48 mmol). Recrystallization from CH$_2$Cl$_2$/Et$_2$O yielded dark green crystals (2.75 g, 79%). MS (ESI in CH$_2$Cl$_2$): *m*/*z* = 815 [M]$^+$ with the expected isotopic pattern. IR (KBr): $\tilde{\nu}_{CO}$ = 1937 cm$^{-1}$. $^1$H NMR (200 MHz, CDCl$_3$, 20 °C): $\delta$ = 8.10 (d, $^3J$ = 6.1 Hz, 1 H, NC*H*), 7.40–7.26 (m, 8 H, Ph-*H*), 6.83 (m, 2 H, Ph-*H*), 6.40 (d, $^3J$ = 6.1 Hz, 1 H, NC*H*), 6.30 (m, 1 H, NCHC*H*), 6.25 (m, 1 H, NCHC*H*), 6.04 (s, 1 H, Tp′-C*H*), 5.93 (s, 1 H, Tp′-C*H*), 5.91 (s, 1 H, Tp′-C*H*), 4.98 (d, $^2J_{HH}$ = 12.8 Hz, 1 H, SCH*H*), 4.87 (d, $^2J_{HH}$ = 12.8 Hz, 1 H, SC*H*H), 3.48 (d, $^2J_{HH}$ = 11.7 Hz, 1 H, SCH*H*), 3.06 [s, 6 H, N(C*H*$_3$)$_2$], 2.65 (d, $^2J_{HH}$ = 11.7 Hz, 1 H, SC*H*H), 2.54 (s, 3 H, Tp′-*Me*), 2.48 (s, 3 H, Tp′-*Me*), 2.44 (s, 3 H, Tp′-*Me*), 1.92 (s, 3 H, Tp′-*Me*), 1.55 (s, 3 H, Tp′-*Me*), 1.39 ppm (s, 3 H, Tp′-*Me*). $^{13}$C NMR (100 MHz, CDCl$_3$, 20 °C): $\delta$ = 233.2 (Mo*C*SCH$_2$), 213.8 (*C*O), 205.4 (Mo*C*SCH$_2$), 154.5, 153.1, 152.6, 150.4, 149.7, 149.2 (Tp′-*C*Me), 146.8 (N*C*H), 146.5 (N*C*H), 146.2 [*C*N(CH$_3$)$_2$], 135.0, 134.4, 129.2, 129.1, 128.9, 128.8, 128.4, 128.1 (Ph-*C*), 108.6 (Tp′-*C*H), 108.3 (NCH*C*H), 108.2, 107.6 (Tp′-*C*H), 106.9

**Crystal Structure Determination:** Single crystals suitable for X-ray analysis were coated in perfluoropolyether oil and mounted on a glass fiber. The intensity data of the complexes were collected on a Bruker AXS Apex system equipped with a rotating anode. The data were measured using either graphite-monochromated Mo-$K_a$ radiation or Cu-$K_a$ radiation monochromated by a Goebel mirror. Data collection, cell refinement, data reduction and integration as well as absorption correction were performed with the Bruker AXS program packages SMART, SAINT and SADABS. Crystal and space group symmetries were determined using the XPREP program. All crystal structures were solved with SHELXS[18] by direct methods and were refined by full-matrix least-square techniques against $F_o^2$ with SHELXL.[19] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included at calculated positions with fixed thermal parameters.

**Crystal Data for 5-PF$_6$:**[20] $C_{37}H_{45}BF_6MoN_7OPS_2$, $M_r$ = 919.64 g mol$^{-1}$, dark green prisms, size 0.23 × 0.19 × 0.14 mm$^3$, monoclinic, space group *P*2(1)/*n*, *a* = 10.695(2), *b* = 21.182(4), *c* = 18.879(4) Å, β = 102.883(4)°, *V* = 4169.1(14) Å$^3$, *T* = 153 K, *Z* = 4, $\rho_{calcd.}$ = 1.465 g cm$^{-1}$, μ(Mo-$K_a$) = 0.519 mm$^{-1}$, reflections: 40384 collected, 9563 unique, 8034 observed $F_o \geq 2\sigma(F_o)$, $1.47 \leq \Theta \leq 27.50$, $R_{int}$ = 0.0542, 514 parameter, 0 restrains, $R_1$(obs) = 0.0577, $wR_2$(obs) = 0.1406, $R_1$(all) = 0.0696, $wR_2$(all) = 0.1470, GOF = 1.089, largest difference peak/hole: 1.077/–0.766 eÅ$^3$.

# Investigation of the Thermal Decomposition of [biphen(QP*i*Pr)Pt(alk)$_2$]: An Entry to C–C Single Bond Activation?

**Klaus Ruhland,*[a] Andreas Brück,[a] and Eberhardt Herdtweck[a]**

**Keywords:** Platinum / Reaction mechanisms / C–H activation / C–C activation / Agostic interactions

The reaction of [(COD)PtCl$_2$] with biphen(QP*i*Pr)(Q′P*i*Pr) (Q, Q′ = O, CH$_2$O) yields *cis*-[{biphen(QP*i*Pr)(Q′P*i*Pr)}PtCl$_2$]. Treatment of *trans*-[PtCl$_2$(ethene)(py)] with biphen(QP*i*Pr)-(Q′P*i*Pr) (Q, Q′ = O, CH$_2$O) gives *trans*-[{biphen(QP*i*Pr)-(Q′P*i*Pr)}PtCl$_2$] for Q or Q′ ≠ O. No *trans*/*cis* isomerization can be observed for these compounds after 24 h at 105 °C in [D$_8$]toluene. In the case of Q = Q′ = O a *trans*/*cis* isomerization takes place at room temperature. X-ray structures of a molecule in the solid state were determined for the compounds *cis*/*trans*-[{biphen(QP*i*Pr)(Q′P*i*Pr)}PtCl$_2$] with Q or Q′ ≠ O. In the case of Q = O and Q′ = CH$_2$O the closer of the two bridging C atoms in the biphenyl fragment of the ligand is only 3.42 Å away from the Pt center but does not show a coupling to it in the $^{13}$C NMR spectrum. Treatment of both *cis*- and *trans*-[{biphen(QP*i*Pr)(Q′P*i*Pr)}PtCl$_2$] with two equivalents of ethyl- or *n*-propylmagnesium chloride gives *cis*-[{biphen(QP*i*Pr)(Q′P*i*Pr)}PtAlk$_2$]; the X-ray structures of *cis*-[{biphen(CH$_2$OP*i*Pr)$_2$}PtEt$_2$] and *cis*-[{biphen(OP*i*Pr)$_2$}Pt-(*n*Pr)$_2$] are discussed. These complexes give the related alkene complexes as a result of β-H elimination/reductive elimination if heated to temperatures above 90 °C in [D$_8$]toluene, but none of the complexes with Q or Q′ ≠ O is stable at 95 °C. The thus-formed Pt(alkene) complex loses the alkene (ethene or propene) in a consecutive reaction. For [{biphen(CH$_2$OP*i*Pr)$_2$}PtEt$_2$], selective deuteration of the CH$_2$O group and the Pt-ethyl group proves that scrambling of deuterium into the *i*Pr methyl groups occurs (by a CH activation/insertion/β-H elimination/reductive elimination sequence) after the β-H elimination and before the loss of ethene, which at 95 °C is almost as fast as the loss of ethene. In the final alkene-free 14 e complex a fast dynamic C–H activation of the *i*Pr CH$_3$ protons by the Pt center (one H at a time) can be detected [an Isotopic Perturbation of Resonance (IPR) is found for the partially deuterated compound], which most probably prevents a further reaction of the complex (e.g. activation of the bridging C–C single bond in the biphenyl backbone or permanent coordination of PPh$_3$). H$_2$, however, is activated by the final complex, and the use of D$_2$ proves that deuterium is incorporated into the *i*Pr groups of the ligand. The reaction of [(COD)PtCl$_2$] with *o*-Br-phen(QP*i*Pr) gives *cis*-[PtCl$_2${*o*-Br-phen(QP*i*Pr)}$_2$] (X-ray structure reported), which forms *cis*-[Pt{phen(QP*i*Pr)}$_2$] upon treatment with *s*BuLi. The reaction of *trans*-[PtCl$_2$(ethene)-(py)] with *o*-I-phen(QP*i*Pr) gives *trans*-[PtCl$_2${*o*-I-phen-(QP*i*Pr)}$_2$] (X-ray structure reported), which also forms *cis*-[Pt{phen(QP*i*Pr)}$_2$] upon treatment with *s*BuLi. *cis*-[Pt{phen(CH$_2$OP*i*Pr)}$_2$] (X-ray structure reported) slowly isomerizes quantitatively at 95 °C in toluene to the *trans* complex. No product of reductive elimination can be detected up to 150 °C in mesitylene. *cis*-[Pt{phen(OP*i*Pr)}$_2$] (X-ray structure reported) forms two products − the *trans* isomer (X-ray structure reported) and most likely a dimeric *trans*-configured complex − upon heating to 95 °C. Again, no reductive elimination is observed regardless of whether the reaction is performed under argon or ethene atmosphere up to 150 °C in mesitylene. All materials were characterized by means of $^1$H, $^2$H, $^{13}$C, $^{31}$P, and $^{195}$Pt NMR spectroscopy, FAB mass spectrometry, FT-IR spectroscopy, elemental analysis, and X-ray crystallography. DFT calculations (B3PW91/LANL2DZ) are also included for the most important compounds.

## Introduction

We are currently searching for a way to activate and cleave the bridging C–C single bond in nonstrained biphenyl fragments, a reaction that is still without precedent, although the strained biphenylene has been successfully activated.[1] Other groups have reported their strategies, successes, and challenges in the area of C–C single bond activation.[2] Several advantages of focusing on the activation of the bridging C–C single bond in a biphenyl fragment have been discussed by us earlier,[3] and in light of this we decided to use the well-known principle of chelating assistance[4] to enhance the chance of observing the activation. Additionally, the ligand architecture is chosen in a way that in the course of the reaction a vibrational bending mode of the coordinated ligand forces the C–C single bond to approach the metal center in a promising orientation concerning an activation of it (compound **c** in Scheme 1).

Our former work[3] showed that Scheme 1 describes the behavior of [{biphen(OP*i*Pr)$_2$}PtEt$_2$] ([**1**]PtEt$_2$) well, except that the most decisive reaction (D) was not observed. Herein we report our progress with this strategy.

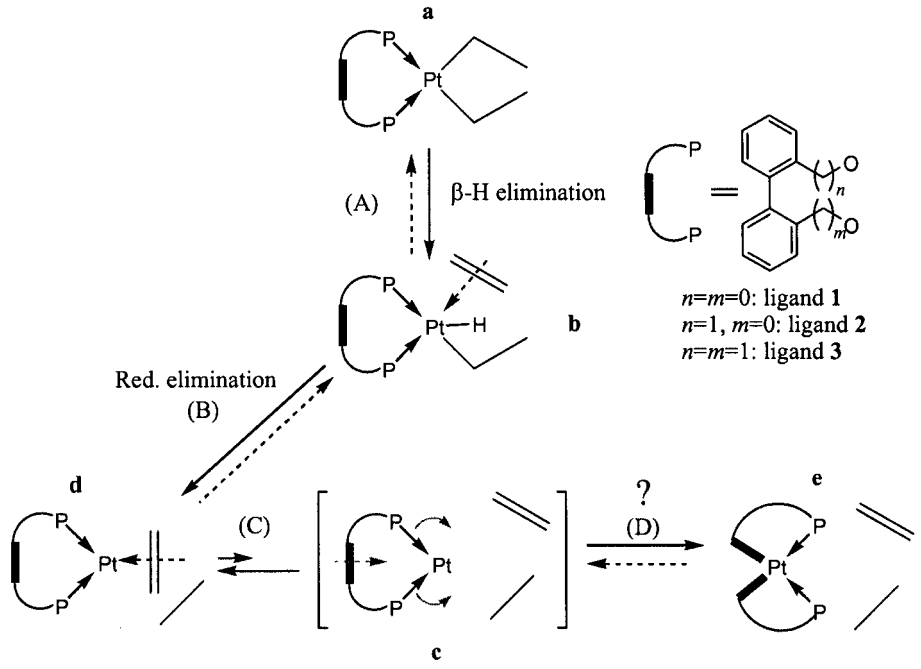

Scheme 1.

## Results and Discussion

### Calculations on the Reaction Path

One critical point about the strategy in Scheme 1 is that the ligand architecture used in intermediate **c** might be too strained to allow the desired movement along the reaction coordinate (bending vibration of P–Pt–P) if the biphenyl fragment and the coordinating phosphorus atoms are connected only by an oxo group. To gain more insight into this question, we calculated the energy profile of the P–Pt–P bending vibration mode with an oxo group (ligand **1**) and a $CH_2O$ group as connector (ligand **3**). This was done with Gaussian03[5] using density functional theory (functional: B3PW91; basis set: LANL2DZ) and employing the "frozen coordinate" function implemented in the program package. Table 1 contains the calculated data and Figure 1 shows the plot of $\Delta G$ as a function of the P–Pt–P angle.

Table 1. Calculated differences between $G$ and $G_{min}$ of the P–Pt–P bending vibration and its dependence on the bending angle, $\alpha$, for both [**1**]Pt and [**3**]Pt.

| P–Pt–P $\alpha$ [°] | $G - G_{min}$ for [**1**]Pt [kcal mol$^{-1}$] | $G - G_{min}$ for [**3**]Pt [kcal mol$^{-1}$] |
|---|---|---|
| 120 | 14.84 | 33.18 |
| 130 | 7.70 | 17.36 |
| 140 | 2.84 | 9.43 |
| 150 | 1.27 | 4.54 |
| 153 | 0 | – |
| 160 | – | 18.29 |
| 165 | 2.48 | – |
| 170 | 4.72 | 0.065 |
| 175 | 7.38 | – |
| 177 | – | 0 |

The following conclusions can be drawn from the calculated data:

> For ligand **1** the additional kinetic driving force concerning the C–C single bond activation is high and "downhill" at the beginning but, because of the small P–Pt–P equilibrium angle (153°), decisively "uphill" at the end of the reaction pathway. In the range $120° < \alpha < 180°$ no decisive gain in energy is predicted by the calculations because the two effects cancel each other out (energy gain of about 7 kcal mol$^{-1}$ at most). The angle determined for [**1**]Pt-(ethene) by X-ray analysis is 120°.[3]

> For ligand **3** the additional kinetic driving force is even greater than for **1** at the beginning of the C–C single bond approach, and the equilibrium P–Pt–P angle is larger (178°). Thus, the approach of the C–C single bond to be activated is less hindered at the end of the reaction pathway. The calculations predict an energy gain of about 33 kcal mol$^{-1}$ in the best case. Moreover, the force constant (determined using the harmonic potential approximation) in the case of ligand **3** is calculated to be 0.438 mdyn Å rad$^{-2}$ and is thus softer than for ligand **1** (0.636 mdyn Å rad$^{-2}$). As a consequence, ligand **3** enhances the flexibility of the bending vibration in the area of its minimum in comparison to ligand **1**.

It must be stated at this point that the calculations give no indication of any kind of agostic interaction between parts of the ligand and the Pt center, neither through geometric proximity (the nearest H atom is more than 3 Å away from Pt) nor through the calculated wavenumbers of the vibration modes. This fact will become important below. Figure 2 shows a plot of the calculated minimum structure of [**3**]Pt.

### Ligand Synthesis and Complexation

In light of the results of the calculations we synthesized the three biphen ligands **1**, **2**, and **3** (Scheme 2) to examine

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

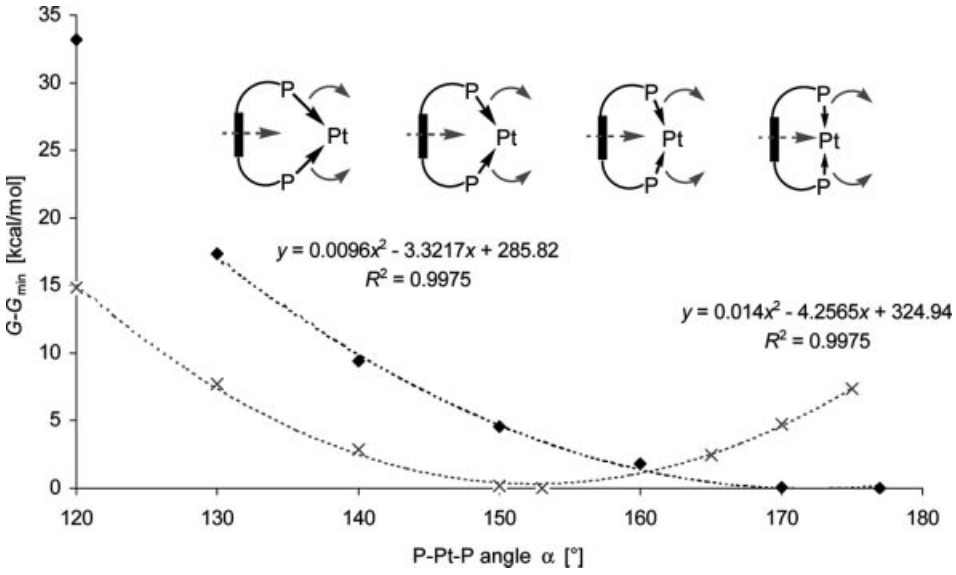

Figure 1. Potential of the P–Pt–P bending vibration for [**1**]Pt (×) and [**3**]Pt (♦) calculated using DFT theory (functional: B3PW91; basis set: LANL2DZ).

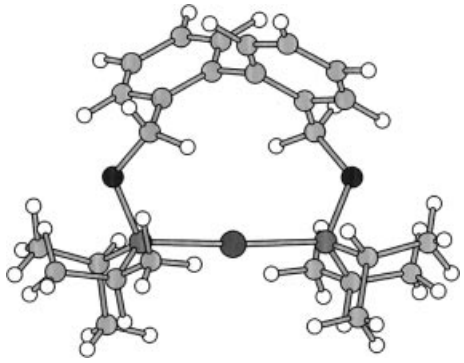

Figure 2. Plot of the calculated minimum structure of [**3**]Pt.

the influence of the ligand "arm" length on the basic strategy of Scheme 1.

The synthesis was performed analogously to our previously published procedures.[3] The precursor for **2** was synthesized from fluoren-9-one by a Baeyer–Villiger oxidation and reduction of the resulting lactone with $LiAlH_4$. We were interested in the corresponding *cis*- and *trans*-$PtCl_2$ complexes of the ligands as the *cis* compounds could serve as a precursor for the dialkyl complexes and the *trans* compounds as an experimentally available model for the transition state of the potential activation step in the thermolysis. In this context, the Cl ligands have two functions, namely they stabilize the potential transition state structure, thereby allowing us to do X-ray analysis, and because of the Cl ligands the Pt center is in the oxidation state +2, which is the oxidation state of the desired product.

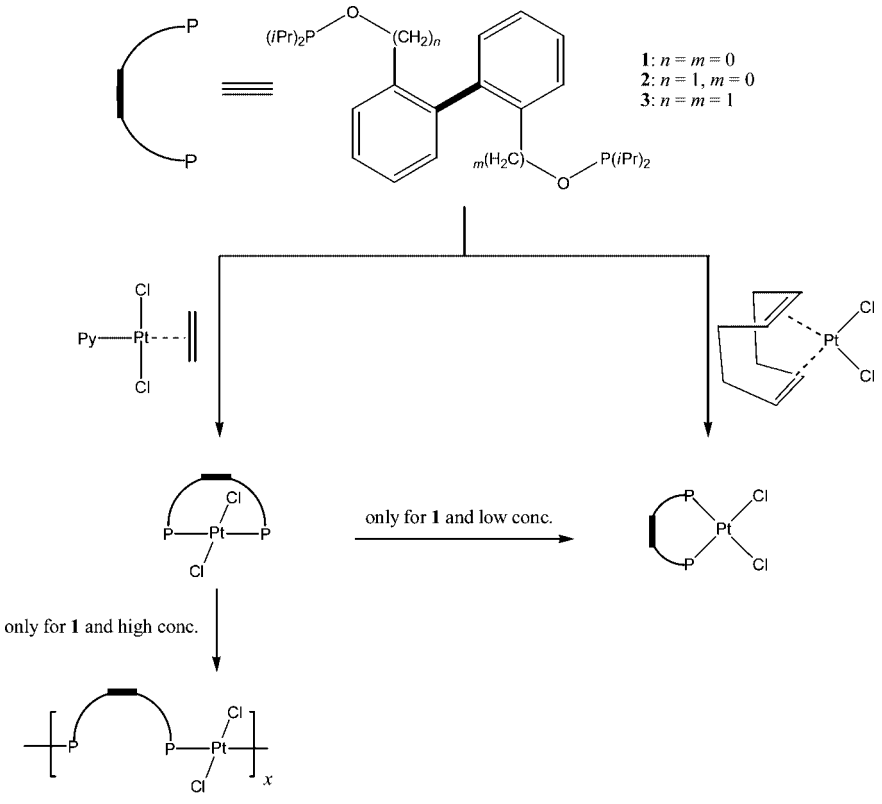
In the transition state the oxidation number should, of course, be somewhere between 0 and +2. The complexes were also synthesized according to Scheme 2. The complexation reaction with ligands **2** and **3** is less clean than that with **1**, and thorough and repeated washing of the product with diethyl ether and recrystallization from dichloromethane is necessary to isolate analytically pure compounds. For **1**, which has the shortest backbone, the *trans* complex could not be isolated because it isomerizes to *cis*-[**1**]$PtCl_2$ too fast if the ligand-exchange reaction is performed at low concentrations (0.1 mmol $L^{-1}$) whereas a weakly soluble *trans*-configured coordination polymer is formed at higher concentrations. We propose that strain in the *trans*-[**1**]$PtCl_2$ complex is the reason for this behavior. All the other *cis*/*trans*-(ligand)$PtCl_2$ complexes show no isomerization upon heating to 105 °C in toluene for 24 h, thus demonstrating that the activation barrier for this process must be high and supporting the fact that no strain is to be expected in the transition state **c** for **2** and **3** (Scheme 1) in accordance with the results of the calculations. It should be mentioned that the synthesis of the complexes (ligand)$PtCl_2$ [*trans* (*cis*) precursor results in *trans* (*cis*) complex] is only stereoselective for $P(iPr)_2$ or $PCy_2$ ligand groups and not for $PPh_2$.

## Structural and Spectroscopic Comparison of the Dichlorido Complexes

The most confident parameter to distinguish between *cis* and *trans* (diphosphane)$PtCl_2$ complexes besides an X-ray structure is the $^1J_{Pt,P}$ coupling constant, which shows values of about 4000–4200 Hz for *cis* complexes and values of about 2650 Hz for *trans* complexes.[6] This is confirmed in our case (Table 2).

The fairly large value of the *trans*-[**1**]$PtCl_2$ coupling constant (2865.5 Hz) might be due to the strain present in this compound. Additionally, the $^2J_{P,P}$ coupling constant for **2**, which has two inequivalent phosphorus atoms, shows the expected small value for the *cis* configuration (5 Hz) and a much larger value for the *trans* configuration (488.5 Hz). As can be seen from Table 2, the chemical shift in the $^{195}Pt$ NMR spectrum can be used as a diagnostic criterion for the complex configuration (*cis*: $\delta \approx -4100$ ppm; *trans*: $\delta \approx$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 2.

Table 2. A comparison of the NMR spectroscopic data for the compounds (ligand)$PtCl_2$.

| Compound | $\delta_{^{31}P}$ [ppm] | $^1J_{Pt,P}$ [Hz] | $\delta_{^{195}Pt}$ [ppm] | $^2J_{P,P}$ [Hz] |
|---|---|---|---|---|
| *cis*-[**1**]$PtCl_2$ | 123.4 | 4147.2 | –4122.8 | – |
| *trans*-[**1**]$PtCl_2$ | 117.0 | 2865.5 | n.d. | – |
| *cis*-[**2**]$PtCl_2$ | 112.5, 115.7 | 4099.0, 4149.6 | –4116.8 | 5.0 |
| *trans*-[**2**]$PtCl_2$ | 109.3, 118.8 | 2624.9, 2690.7 | –3805.7 | 488.5 |
| *cis*-[**3**]$PtCl_2$ | 115.7 | 4267.2 | –4223.4 | – |
| *trans*-[**3**]$PtCl_2$ | 118.4 | 2627.5 | –3763.1 | – |

–3800 ppm), in contrast to the chemical shift in the $^{31}P$ NMR spectrum. In the case of **2** and **3**, a $^3J_{H,P}$ coupling of about 8 Hz is found for the $CH_2$ group in the *trans* complexes, while no H–P coupling is resolved in the *cis* complexes for the $CH_2$ groups. This behavior can be explained by using the structural data of a molecule in the solid state determined by X-ray diffraction. The structures of *trans*-[**2**]$PtCl_2$ and *trans*-[**3**]$PtCl_2$ are shown in Figure 3 (Table 3). Details on the the X-ray structures of *cis*-[**2**]$PtCl_2$ and *cis*-[**3**]$PtCl_2$ can be obtained from the CCDC (for more information see Exp. Sect.; relevant quality parameters of the structure determination are given in the Exp. Sect. together with all other characterization data of the compounds).

A Karplus equation for the $^3J_{P,H}$(POCH) coupling has been reported for phosphites.[7] According to this equation, the coupling constant should be small for POCH torsional angles of about 60° and have maximum values for angles of about 150–180° and 0–30°. As can be seen from Table 3, the POCH torsional angles for the *cis* complexes are about 60° and no $^3J_{P,H}$ coupling is resolved in the $^1H$ NMR spectra, whereas for the *trans* complexes the torsional angles are in an area for which the $^3J_{P,H}$ coupling constants are expected be about 10 Hz, in accordance with what we find in the $^1H$ NMR spectra. Some other structural parameters in Table 3 can be compared and discussed as follows:

> Due to a canceling *trans* influence in the *trans* complexes, the Pt–P bond is significantly longer than those in the *cis* complexes (the Pt–Cl bond behaves in the opposite manner as it is longer in the *cis* complexes).

> In spite of the fact that the bridging C–C single bond of the biphenyl fragment in *trans*-[**2**]$PtCl_2$ is only about 3.42 Å

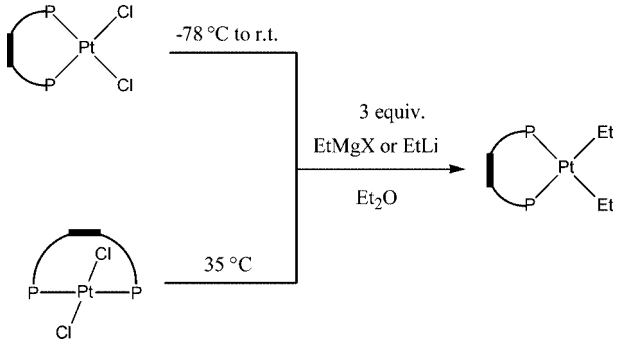
apart from the metal center, no $J_{Pt,C}$ coupling can be detected in the $^{13}C$ NMR spectrum and, thus, no evidence for an interaction between these two centers can be found.

> In accordance with this finding no significant elongation of the bridging C–C single bond in the biphenyl fragment is found in *trans*-[**2**]$PtCl_2$ or *trans*-[**3**]$PtCl_2$.

> The P–Pt–P bond angle of about 178° in *trans*-[**3**]$PtCl_2$ is in good agreement with the calculated data for [**3**]Pt, thereby showing that the theoretical results are fairly confident and a structural comparison of the two compounds is justified.



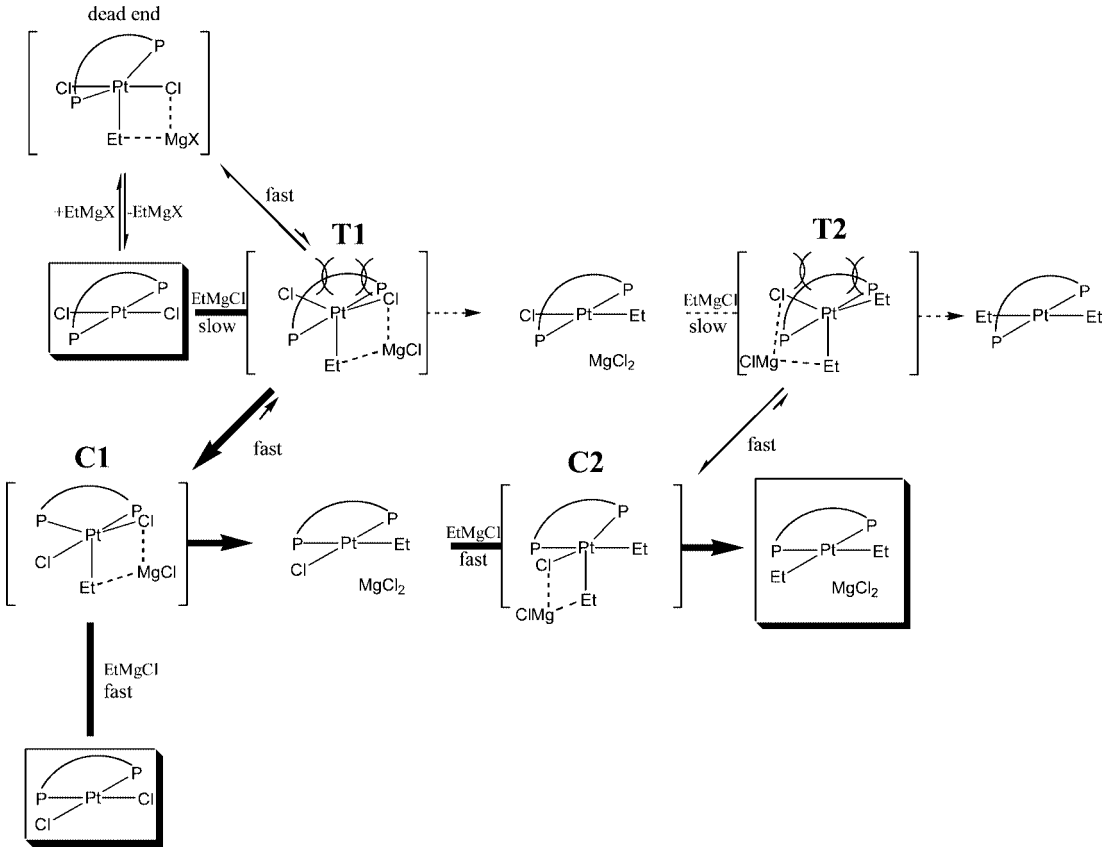
Scheme 3.

### Alkylation of the Dichlorido Complexes

Treatment of *cis*-[**2**]$PtCl_2$ and *cis*-[**3**]$PtCl_2$ with ethylmagnesium chloride at low temperatures in diethyl ether yielded the corresponding *cis*-(ligand)$PtEt_2$ complexes, which are the starting compounds **a** in Scheme 1. The analogous complexes *trans*-[**2**]$PtCl_2$ and *trans*-[**3**]$PtCl_2$ showed no reaction at low temperature, even with EtLi. Alkylation was possible, though, in refluxing diethyl ether with both ethylmagnesium chloride and EtLi to give *cis*-(ligand)$PtEt_2$ rather than the *trans* complexes (Scheme 3).

We propose the following mechanism to explain this behavior (Scheme 4). The slower reaction of the *trans*-(ligand)$PtCl_2$ complexes is explained by transition state **T1**, which is sterically crowded and is therefore formed slowly in comparison to transition state **C1**. It is proposed that a fast Berry pseudorotation transforms **T1** into the sterically and electronically preferred **C1**. It will be shown later in this publication that the chelating character of the phosphinite ligand is not the decisive factor in this mechanism. We propose that the combination of an alkyl substituent, a halide,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 4.

and a phosphinite in an equatorial position in **C1** and **C2** is electronically favored because of a synergistic cooperation of a strong σ-donor (alkyl) and a strong π-acceptor (phosphinite), both of which weaken the Pt–Cl bond and thus lower the activation energy. Even if the *trans*-(ligand)PtEtCl complex is partly formed, when generating **T2** there is a second chance for the reaction to switch into the *cis* pathway (**C2**), again by a Berry pseudorotation. This is the reason why *cis*-(ligand)PtEt$_2$ is formed exclusively from the *trans*-(ligand)PtCl$_2$ complex. The mechanism proposed in Scheme 4 is supported by the finding that the use of one equivalent of ethylmagnesium chloride results in the formation of a mixture of *cis*-(ligand)PtCl$_2$, *cis*-(ligand)PtEtCl, and *cis*-(ligand)PtEt$_2$ (3:2:1) if *cis*-(ligand)PtCl$_2$ is the starting material. In the case of *trans*-(ligand)PtCl$_2$, though, the product is a mixture of unchanged *trans*-(ligand)PtCl$_2$ and *cis*-(ligand)PtEt$_2$ only; no monoethyl complex is formed.

Relevant quality parameters of the crystal structure determinations of compounds *cis*-[**1**]Pt(*n*Pr)$_2$ and *cis*-[**3**]PtEt$_2$ are given in the Exp. Sect. together with all other characterization data of the compounds. Some key data are summarized in Table 4. The X-ray structures of *cis*-[**1**]PtEt$_2$ and *cis*-[**1′**]PtEt$_2$ (**1′** = **1**, but with phenyl substituents at the phosphorus atom instead of *i*Pr) have been published by us previously.[3]

Table 4. A comparison of the geometric data for two (ligand)-Pt(alk)$_2$ compounds, as determined by X-ray analysis.

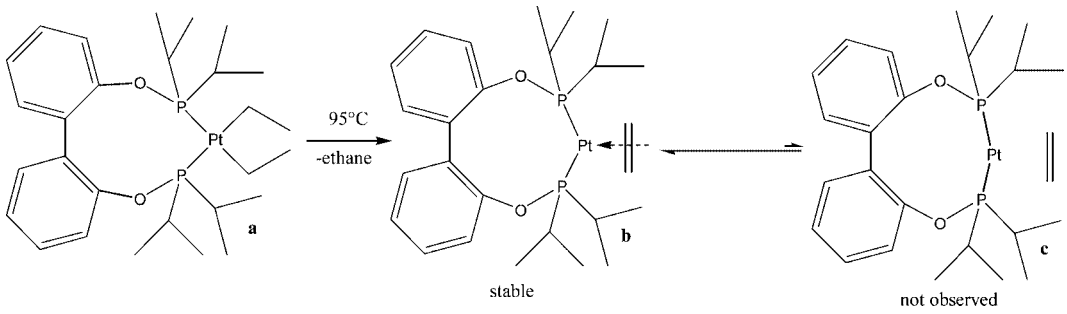
| | [**1**]Pt(*n*Pr)$_2$ | [**3**]PtEt$_2$ |
|---|---|---|
| Pt–P [Å] | 2.2784(6) | 2.2657(14) |
| Pt–C [Å] | 2.152(3) | 2.124(4) |
| $C_a$–$C_b$(bridge) [Å] | 1.477(4) | 1.480(7) |
| Pt···$C_a$ [Å] | 4.377(3) | 6.316(5) |
| P–Pt–P [°] | 111.87(2) | 96.15(4) |
| alk–Pt–alk [°] | 86.56(10) | 82.72(17) |

The main difference in the structures of *cis*-[**1**]Pt(alk)$_2$ and *cis*-[**3**]PtEt$_2$ is that a decisive extension of the P–Pt–P angle in **1** to values larger than 90° is observed; this is much less pronounced in the case of **3**.

## Thermolysis Behavior

The thermolysis of *cis*-[**1**]PtEt$_2$ in the temperature range 60–110 °C has been reported by us in detail.[3] The major result concerning our strategy in Scheme 1 is that [**1**]Pt(ethene) is formed by β-H elimination and reductive elimination of ethane without the permanent loss of ethene. This means that the ethene is firmly bound. Its dissociation could be proven only indirectly by trapping reactions and kinetic analysis of the Pt(ethene)/(free ethene) exchange (Scheme 5).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 5.

To labilize the alkene sterically we examined *cis*-[**1**]-Pt(*n*Pr)$_2$ in the thermolysis reaction. *cis*-[**1**]Pt(*n*Pr)$_2$ forms [**1**]Pt(propene) at 80 °C, which is not stable and decomposes in a not well defined manner while losing propene, further supporting the proposal that the ligand backbone architecture in **1** is too rigid to approach the metal center. The [**1**]-Pt thus formed can be trapped cleanly by treatment with $H_2SiEt_2$ to give the Si-H oxidative addition product. For *cis*-[**2**]PtEt$_2$ and *cis*-[**3**]PtEt$_2$ the (ligand)Pt(ethene) complex is clearly formed in the course of the thermolysis, but it is not stable at 95 °C and further reacts cleanly and completely to a final product with the formation of free ethene (which was not observed in the case of [**1**]PtEt$_2$) and ethane ($\delta$ = 5.3 and 0.8 ppm, respectively in the $^1$H NMR spectrum; ethene/ethane ratio of 1:1. This quantification is better performed by $^2$H NMR spectroscopy and [**3**]Pt(D$_5$-Et)$_2$ as starting material because in this case no peak overlaps with the *i*Pr groups are observed in the region around $\delta$ = 0.8 ppm). The compound thus formed could not be isolated but its assignment as a (ligand)Pt(ethene) complex due to its chemical shift in the $^{31}$P and $^{195}$Pt NMR spectra as well as the $^1J_{P,Pt}$ coupling constants (Table 5) is unequivocal. The small $^2J_{P,P}$ coupling constant in [**2**]Pt(ethene) suggests that the P–Pt–P bond angle is not much larger than 90° and it is similar to that found for [**1**]Pt(propene).

Table 5. NMR spectroscopic data for the compounds (ligand)Pt(alkene) and (ligand)Pt.

| Compound | $\delta_{^{31}P}$ [ppm] | $\delta_{^{195}Pt}$ [ppm] | $^1J_{P,Pt}$ [Hz] | $^2J_{P,P}$ [Hz] |
|---|---|---|---|---|
| [**1**]Pt(ethene)[3] | 186.3 | –5105.4 | 3999.7 | – |
| [**1**]Pt(propene) | 185.7, 185.5 | n.d. | 4181.5, 3658.9 | 16.2 |
| [**2**]Pt(ethene) | 172.1, 172.4 | –5002.7 | 3881.1, 3959.4 | 11.8 |
| [**3**]Pt(ethene) | 177.5 | –5077.9 | 4133.7 | – |
| [**2**]Pt | 144.8, 156.3 | –4770.7 | 3178.8, 3262.0 | 486.6 |
| [**3**]Pt | 160.1 | –4894.8 | 3158.8 | – |

Figure 4 shows the kinetic development of the thermolysis of [**3**]PtEt$_2$ followed by $^{31}$P NMR spectroscopy at 95 °C. The pseudo triplet at about $\delta$ = 145 ppm belongs to the starting material, the [**3**]Pt(ethene) intermediate shows up at about $\delta$ = 177 ppm, and the final product at 95 °C appears at about $\delta$ = 160 ppm quantitatively. The question now arises as to what is the nature of this final product.

In order to answer this question we examined the final product by means of FAB-MS and FT-IR, $^1$H, $^{13}$C, $^{31}$P, and $^{195}$Pt NMR spectroscopy. The FAB mass spectrum for [**3**]-PtEt$_2$ shows the mass peak at *m*/*z* 641.3 (M minus ethene and ethane with correct isotopic pattern). The mass peak for the final product [**3**]Pt shows up at *m*/*z* 642.3 and the

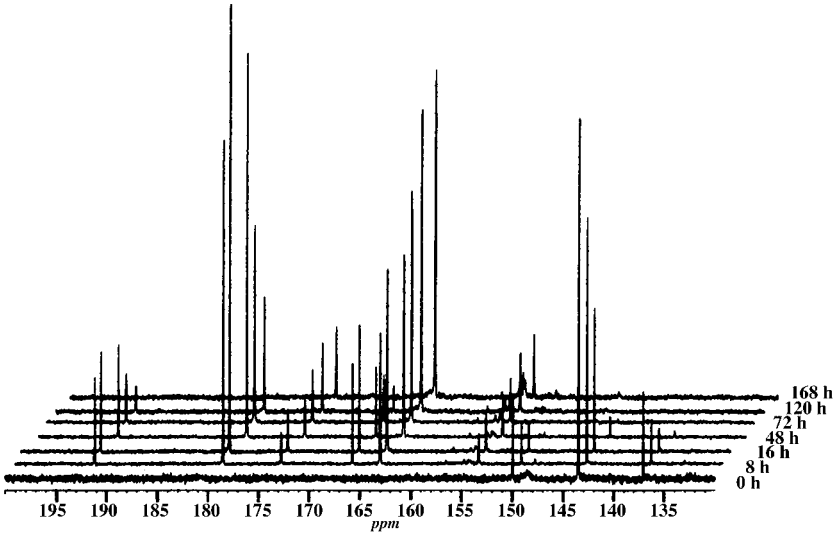


Figure 4. $^{31}$P NMR spectra recorded during the thermolysis of [**3**]PtEt$_2$ at 95 °C in [D$_8$]toluene.

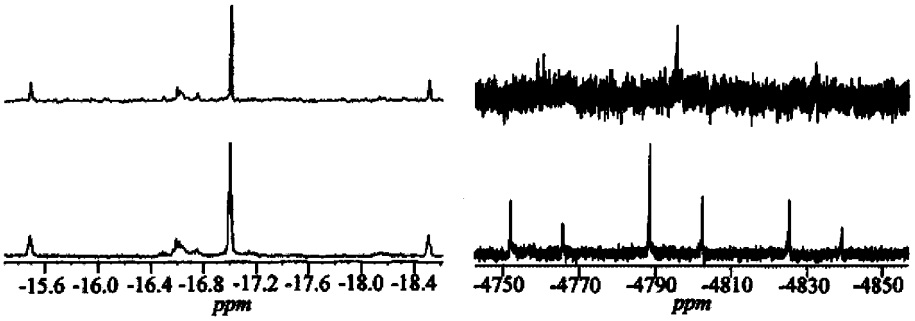

Figure 5. Portions of the $^1$H (left) and $^{195}$Pt (right) NMR spectra showing the Pt–H signals. Top: $^1$H{$^{31}$P} and $^{195}$Pt{$^1$H}.

isotopic pattern is correctly reproduced assuming the loss of both ethane and ethene during the course of the thermolysis (98% M + 1 and 2% M with M = $C_{26}H_{40}O_2P_2Pt$ = [**3**]Pt). That the final product contains only the ligand **3** and Pt is also supported by the fact that performing the thermolysis with [**3**]Pt(*n*Pr)$_2$ results in the same final product as is found with [**3**]PtEt$_2$, according to $^1$H, $^{13}$C, $^{31}$P, and $^{195}$Pt NMR spectroscopy as well as FT-IR spectroscopy and FAB-MS. In the case of [**3**]Pt(*n*Pr)$_2$ the intermediate [**3**]Pt(propene) was not observed and free propene instead of ethene was found ($^1$H NMR spectroscopy). However, $^1$H NMR spectroscopy shows a peculiarity concerning the final product [**3**]Pt: a triplet of pseudo triplets at $\delta$ = –17 ppm can be found which integrates to about 0.7 H atoms relative to the $CH_2$–O protons and the phenyl C–H protons as internal standard (Figure 5). In the FT-IR spectrum an unusual peak of low intensity appears at $\tilde{\nu}$ = 1945 cm$^{-1}$ (Figure 9).

The pseudo triplet (1208.5 Hz splitting) is unequivocally due to a $^1J_{Pt,H}$ coupling, while the triplet (4.9 Hz splitting) was proven to be a $^2J_{P,H}$ coupling from the $^1$H{$^{31}$P} NMR spectrum, in which this coupling disappears (Figure 5, top left). A doublet (1208.5 Hz) of triplets (3160 Hz) in the $^{195}$Pt NMR spectrum can be found using the default $^{195}$Pt{$^1$H} acquisition program with the $^1$H decoupler center at $\delta$ = 5 ppm (Figure 5, bottom right). If the decoupler center is changed to $\delta$ = –17 ppm the doublet splitting in the $^{195}$Pt NMR spectrum vanishes (Figure 5, top right). From this finding we conclude that one and only one H atom (at a time) is in strong electronic interaction with the Pt center. This H atom must be placed in such a manner that the complex (at least in average) has at least $C_2$ symmetry since only one signal (pseudo triplet) is found for the P atoms (Figure 4). The small $^2J_{P,H}$ coupling constant of about 5 Hz mentioned before suggests that the angle between the P atoms and the H atom is about 90°. The $^1J_{Pt,P}$ coupling constant of 3160 Hz is in accordance with the *trans* P–Pt–P orientation that would be expected for [**3**]Pt in light of the above calculations. Furthermore, the $^3J_{P,H}$ coupling constants of 7 and 12 Hz in the $POCH_2$ fragment indicate a *trans* configuration. This is further supported by the fact that a $^2J_{P,P}$ coupling constant of 485 Hz is found for [**2**]Pt, which shows similar peculiarities in the $^1$H and $^{195}$Pt NMR spectra but is not stable even at room temperature and decomposes into as-yet unknown products within a few hours. In the $^{13}$C{$^1$H} NMR spectrum of [**3**]Pt a coupling to the Pt center is observed for the $CH_2O$ carbons (83.7 Hz) and one $CH_3$ group (22.1 Hz), which is slightly separated from the other methyl groups to higher fields by about 1 ppm. The signals of the other $CH_3$ groups overlap but clearly show a structure different from simple singlets. For the P-CH carbons only a coupling to phosphorus is found. No coupling of Pt to any of the aromatic carbons could be detected.

### Deuteration Experiments

We wanted to get more insight into the peculiarity mentioned above. Thus, we first selectively deuterated the $CH_2O$ groups to examine whether they are the origin of the peak at $\delta$ = –17 ppm in the $^1$H NMR spectrum. This deuteration was achieved by reduction of biphenic acid with $LiAlD_4$. The [$D_4$-**3**]Pt formed in the course of thermolysis shows, analogously to [**3**]Pt, the expected peak at M + 1 (*m*/*z* 646.1) with the correct isotopic pattern in the FAB mass spectrum. In the $^2$H NMR spectrum the $CD_2O$ protons show up as two broad, unresolved peaks at the same chemical shift as was found for the $CH_2O$ groups of [**3**]Pt in the $^1$H NMR spectrum, while no peak is observed at $\delta$ = –17 ppm. In the $^1$H NMR spectrum the multiplets for the $CH_2O$ groups are missing and the peak at $\delta$ = –17 ppm is present with the same intensity as was observed for [**3**]Pt. In the $^{31}$P and $^{195}$Pt NMR spectra no difference with respect to the unlabeled complex can be seen. From these findings we conclude that the $CH_2O$ protons are not responsible for the observed interaction with the platinum center. We next selectively deuterated the ethyl groups in [**3**]-$PtEt_2$ by using commercial $CD_3CD_2Br$ in a Grignard reaction. The thermolysis of [**3**]Pt($D_5$-Et)$_2$ occurs slower than that of [**3**]PtEt$_2$, thus indicating a normal kinetic isotope effect for the reaction, which we did not quantify. The product of the thermolysis shows a peak pattern for the mass peak in the FAB mass spectrum that is best described as a superposition of 65% [**3**]Pt and 35% of [$D_1$-**3**]Pt, thus giving a first hint that the complete reaction is more complicated than we had anticipated initially. In the $^1$H NMR spectrum the most obvious difference is that besides the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

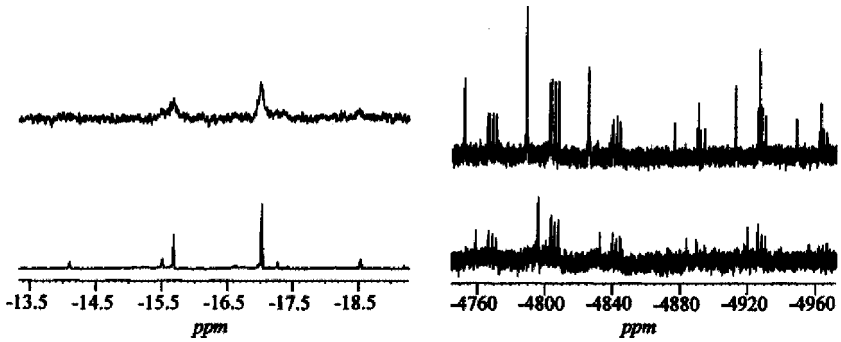

Figure 6. Excerpt of the $^{1}H$ (bottom left), $^{2}H$ (top left), $^{195}Pt$ (top right ), and $^{195}Pt\{^{1}H\}$ (bottom right ) NMR spectra showing the Pt–H(D) signals.

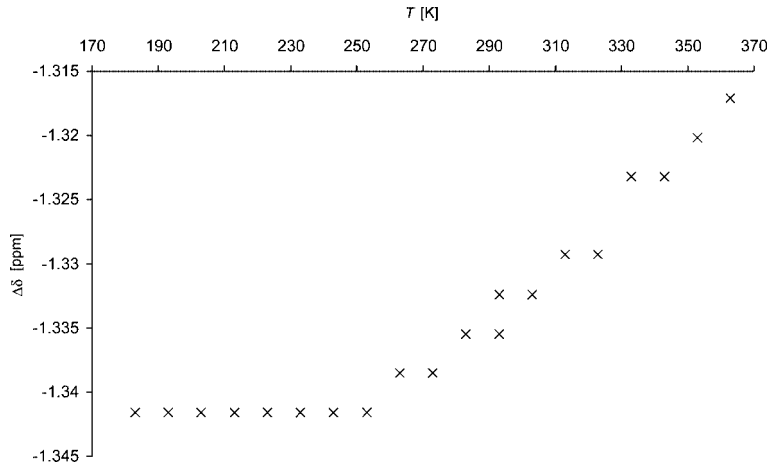

Figure 7. Temperature dependence of the chemical-shift difference, $\Delta\delta$, in the $^{1}H$ NMR spectrum between the two peaks at about $\delta$ = –15.5 and –17 ppm.

pseudo triplet of triplets at $\delta$ = –17 ppm an additional peak with the same multiplicity shows up (ratio 2:1) at about $\delta$ = –15.5 ppm ($^{1}J_{Pt,H}$ = 1266.1, $^{2}J_{P,H}$ = 3.7 Hz), which together integrate to 0.7 protons (Figure 6).

Since we expected that the origin of the second peak should be an isotopic perturbation of resonance (IPR[9]) we performed variable-temperature measurements in the temperature range –90 °C to +90 °C (Figure 7).

As can be seen from Figure 7, a small but significant temperature-dependent change in $\Delta\delta$ between the two peaks at about $\delta$ = –15.5 and –17 ppm is observed, which supports the existence of an IPR. In the temperature range in which $\Delta\delta$ remains constant (below 253 K), the signals in the $^{2}H$ NMR spectrum broaden significantly and almost disappear with decreasing temperature. We conclude from this that $^{1}H$ and not $^{2}H$ atoms are predominantly found at low temperatures in the "hydrido" position (responsible for the peaks at negative ppm), which is in accordance with theory.

In the $^{2}H$ NMR spectrum peaks for ethene and ethane appear along with the signals at $\delta$ = –15.5 and –17 ppm, and a peak group in the area of 1 ppm also shows up where the $CH_3$ groups are found in the $^{1}H$ NMR spectrum (Figure 8).

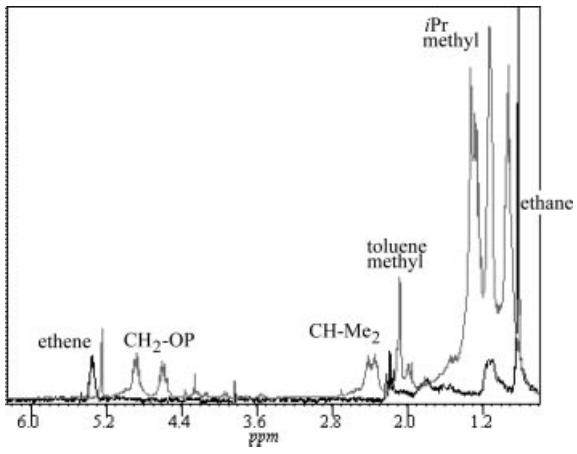

Figure 8. $^{1}H$ NMR spectrum (grey) of [**3**]Pt in [$D_8$]toluene and the $^{2}H$ NMR spectrum of [$D_m$-**3**]Pt (m: number of incorporated deuterium atoms into the ligand in the course of the thermolysis) in non-deuterated toluene (black) in the region between 0.7 and 6 ppm.

The FT-IR spectrum shows two new peaks (Figure 9), one at 2224 $cm^{-1}$, which in accordance with the $^{2}H$ NMR findings we assign to aliphatic C–D stretching vibrations,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

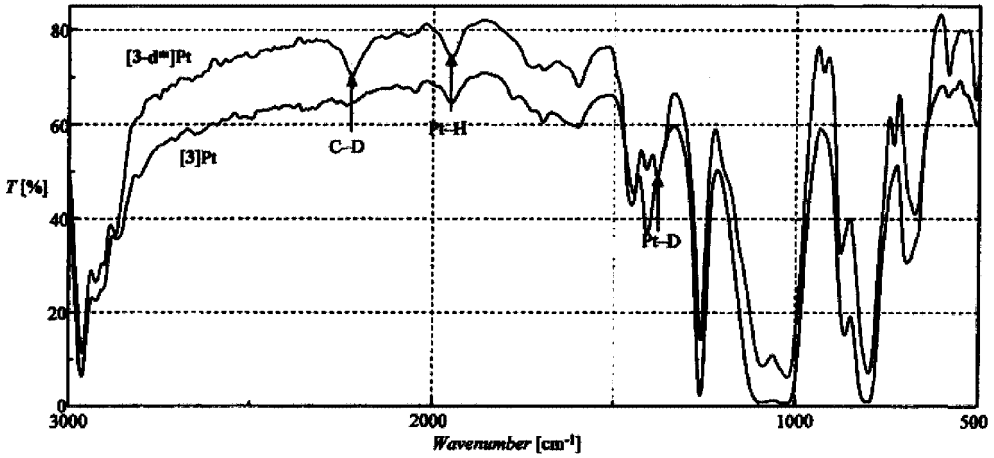

Figure 9. FT-IR spectra for [D$_m$-**3**]Pt and [**3**]Pt.

and one at 1383 cm$^{-1}$, which we assign to a Pt–D stretching vibration corresponding to the peak at 1945 cm$^{-1}$.

The $^{13}$C NMR spectrum, in accordance with the $^{1}$H NMR results, contains two very close sets of signals for each carbon ($\Delta\delta \approx -0.15$ ppm, ratio 2:1), with the more intense set being identical to the unlabeled case. A $J_{C,D}$ coupling could not be unequivocally detected for any of the carbons, although the methyl signals overlap and, thus, are not clearly resolved. A similar kind of experimental finding in the $^{13}$C NMR spectrum (desymmetrization by partial deuteration) has been used (among several other cases) to prove that the keto–enol tautomerization equilibrium in acetylacetone contains two energetic minima with asymmetric hydrogen bonds between the oxygens, the symmetric connectivity being a transition state rather than an intermediate.[9f] This supports our findings and conclusions concerning the $^{1}$H and $^{2}$H NMR spectra.

The $^{31}$P NMR spectrum shows two very close groups of signals ($\delta$ = 163.6 and 164.1 ppm, ratio 1:2; Figure 10), which correspond to the two signals at negative ppm in the $^{1}$H NMR spectrum, thus demonstrating that several different compounds are present at the end of the thermolysis that are very similar to each other (Figure 10). $^{195}$Pt NMR spectroscopy, which, in general, provides only limited information, is very powerful in this specific case. In accordance with the $^{1}$H and $^{2}$H NMR spectra four different compounds are detected at very similar chemical shifts, two of them have an almost identical chemical shift and can only be distinguished by the coupling pattern, which provides a $^{1}J_{Pt,H}$ coupling (doublet splitting, $^{1}J_{Pt,H}$ identical to that in the $^{1}$H NMR spectrum) in one case and a $^{1}J_{Pt,D}$ coupling (triplet splitting with about 1/7th of the magnitude of $^{1}J_{Pt,H}$) in the second case (Figure 6). This is further support for the desymmetrization by partial deuteration found by $^{1}$H, $^{2}$H, $^{13}$C, and $^{31}$P NMR spectroscopy.

A more detailed examination of the thermolysis was performed by $^{2}$H and $^{31}$P NMR spectroscopy (Figure 10).

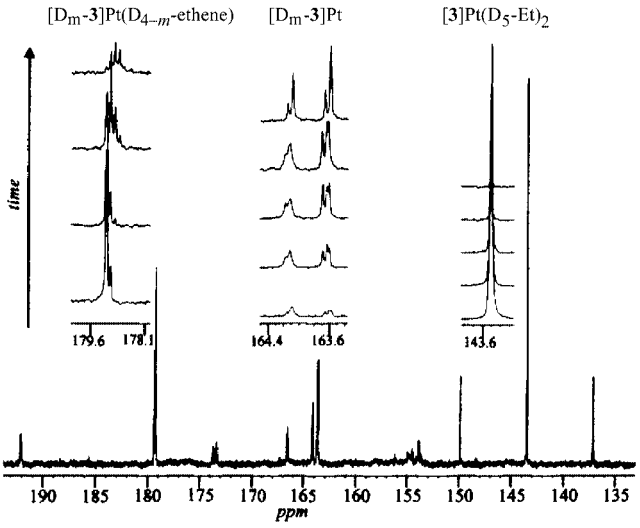

Figure 10. Time-dependent $^{31}$P NMR spectra for the thermolysis of [**3**]Pt(D$_5$-Et)$_2$ showing the scrambling of deuterium into the ligand during the reaction.

As can be seen from Figure 10, the signal of the intermediate [**3**]Pt(D$_4$-ethene) splits with time due to a scrambling of deuterium into the *i*Pr groups of the ligand, as proven by $^{2}$H NMR spectroscopy (Figure 8). This scrambling also leads to a peak splitting in the final product [**3**]Pt. The starting material does not show any splitting. Isolated [D$_m$-**3**]Pt does not change its peak pattern upon further heating. If the same experiment is performed with [**3**]Pt(D$_5$-Et)$_2$ under an atmosphere of unlabeled ethene the scrambling in both [D$_m$-**3**]Pt(D$_{4-m}$-ethene) and [D$_m$-**3**]Pt is still observed, thus proving that the scrambling process is faster than the loss or exchange of ethene. If the thermolysis of [**3**]PtEt$_2$ is performed under an atmosphere of H$_2$, no ethene can be detected. Instead, *trans*-PtH$_2$ shows up in small amounts in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the $^1$H NMR spectrum ($\delta$ = –2.45 ppm, $^2J_{P,H}$ = 21.2, $^1J_{Pt,H}$ = 799 Hz; cf. *cis*-[**1**]PtH$_2$: $\delta$ = –3.43 ppm, $^2J_{P,Hcis}$ = 31.8, $^1J_{Pt,H}$ = 1029.5 Hz[3]). [**3**]Pt is still the final product. If $D_2$ is used instead of $H_2$, the final product is [$D_m$-**3**]Pt, which shows the same splitting in the $^1$H and $^{31}$P NMR spectra due to deuterium scrambling into the ligand as is found with [**3**]Pt($D_5$-Et)$_2$ as starting material (although in different ratios), whereas this time no scrambling is found in the intermediate [**3**]Pt(ethene) (or in [**3**]PtEt$_2$). Additionally, when using $D_2$ a small peak for *trans*-[**3**]PtH$_2$ and an even smaller peak for *trans*-[**3**]PtHD ($\delta$ = –2.27 ppm, $^2J_{P,H}$ = 21.2, $^2J_{HD}$ ≈ 1 Hz) can be detected in the $^1$H NMR spectrum after some time. If the final product [**3**]Pt (without labelling) is heated under an atmosphere of $D_2$, incorporation of deuterium can again be detected, but this occurs more slowly than during the thermolysis starting from [**3**]PtEt$_2$.

Finally, if [**3**]Pt is treated with $PPh_3$ in excess in [$D_8$]toluene the signal for $PPh_3$ in the $^{31}$P NMR spectrum is broadened and appears almost at the same position as free $PPh_3$. This broadening cannot be frozen out even at –100 °C. For [**3**]Pt, the only peaks that broaden are those in the $^{195}$Pt NMR spectrum. We can therefore conclude from these findings that there is contact between the $PPh_3$ and the Pt center, but the interaction is only weak. [**1**]Pt(ethene), in contrast, quantitatively coordinates $PPh_3$ at room temperature (triplet at $\delta$ = 41 ppm with $^1J_{Pt,P(Ph)}$ = 3969.3, $^2J_{P,P}$ = 192.2 Hz and doublet at $\delta$ = 199.2 ppm with $^1J_{Pt,P(iPr)}$ = 4910.6, $^2J_{P,P}$ = 192.2 Hz).

### Explanation of the Behavior

Agostic interactions between the ligands' H atoms and the metal center are not uncommon, especially in 14-electron complexes.[8] There is precedence for this (at least) with group 8, group 9, and group 10 metals, for which agostic interactions to C–H bonds in P-Ph, P-*t*Bu, and P-Cy ligand fragments have been found. However, in all these cases the P-*i*Pr fragment turned out to be an exception and showed no such interaction, especially not in {P(*i*Pr)$_3$}$_2$Pt.[8a] However, in our case there is strong experimental evidence for an interaction between the *i*Pr methyl groups and the Pt$^0$ center.

We ascribe the second peak at $\delta$ = –15.5 ppm in the $^1$H NMR spectrum of the final product when performing the thermolysis with [**3**]Pt($D_5$-Et)$_2$ to a dynamic equilibrium concerning a C–H activation of the *i*Pr methyl groups by the Pt$^0$ center as shown in Scheme 6.

This peak at δ = –15.5 ppm proves that the symmetric structure with two agostic interactions shown in the center of Scheme 6 can only be a transition state. The ground states must therefore be asymmetric (IPR). This is supported by the $^{195}$Pt NMR spectrum, which shows only one Pt···H interaction at a time, and by the second set of signals in the $^{13}$C NMR spectrum upon partial deuteration, which is an additional indicator for an IPR.

We propose the behavior in Scheme 7 to explain the experimental results. [**3**]PtEt$_2$ irreversibly loses ethane by a β-H elimination/reductive elimination if heated to 95 °C. The [**3**]Pt(ethene) complex (**2**) intramolecularly C–H activates the *i*Pr methyl groups of the ligand and the coordinated ethene inserts reversibly into the Pt–H bond via compound **4b**. Indirect evidence for the existence of **4b** is given by the incorporation of deuterium into the *i*Pr methyl groups if the thermolysis is performed with [**3**]Pt($D_5$-Et)$_2$ (Figure 8 and Figure 10). Compounds **2** and **4a** in Scheme 7 lose ethene reversibly to form ethene-free [**3**]Pt, which must be thermodynamically more stable than **2** and **4** because if [$D_m$-**3**]Pt is heated to 95 °C under an atmosphere of unlabeled ethene instead of argon, **2** cannot be detected and the degree of labelling in [$D_m$-**3**]Pt slowly decreases (over days). The loss of ethene is compensated in [**3**]Pt by the dynamic interaction of two *i*Pr methyl groups of the ligand with the Pt center (one at a time, because an IPR was found).

That the interaction between the Pt center and the *i*Pr groups of the ligand (**3** in Scheme 7) must be strong is further supported by the finding that pyridine and $PPh_3$ are not permanently coordinated even at 100 °C in toluene.

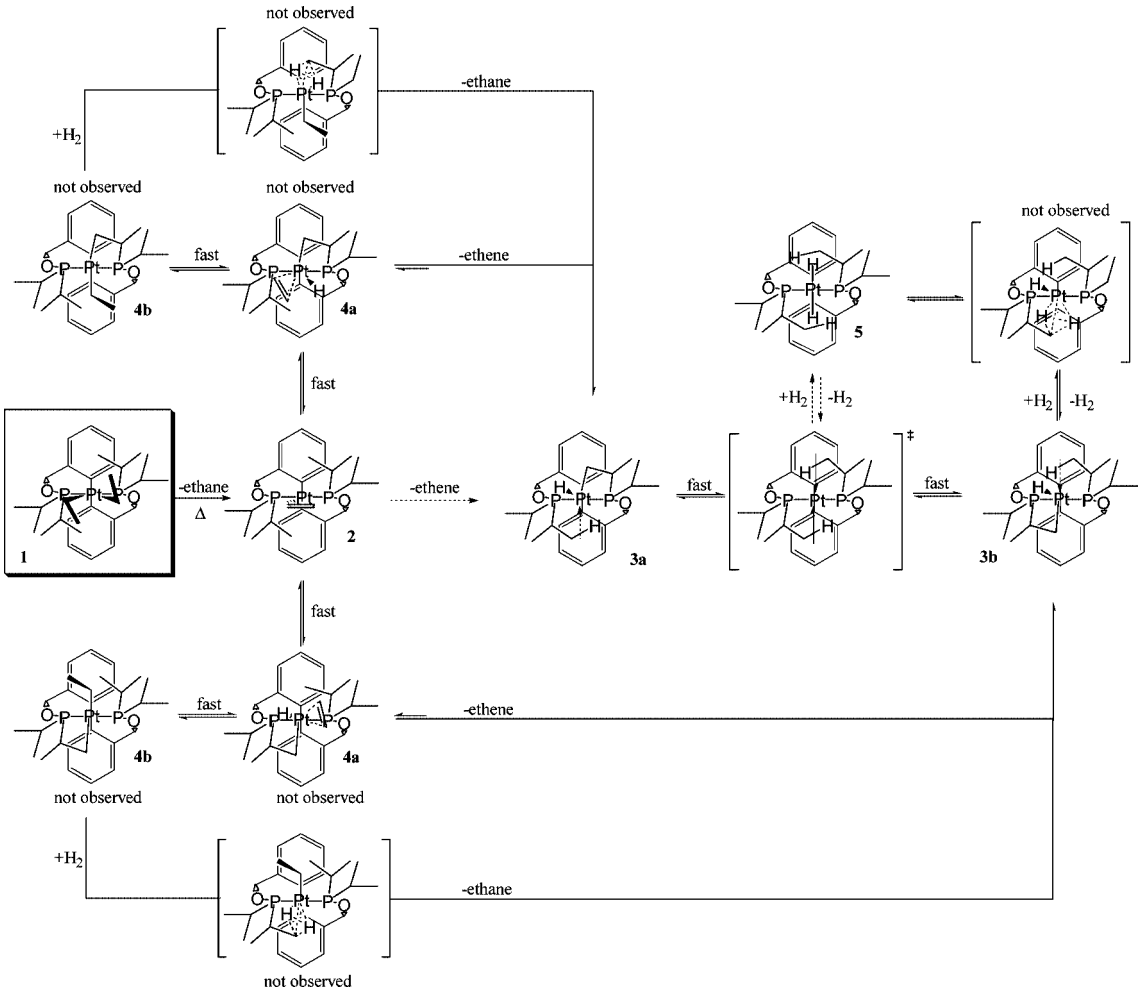

Scheme 7.

Since no incorporation of deuterium into **2** can be detected when doing the thermolysis under an atmosphere of $D_2$, neither **2** nor **4a** can be attacked by $D_2$ (nor can **1**). The finding that the incorporation of deuterium into **3** is faster during the thermolysis under $D_2$ atmosphere than when heating **3** under $D_2$ at the same temperature is further indirect evidence for the existence of **4b**. The reaction pathway via **4b** also explains why no ethene can be detected during the thermolysis under an atmosphere of $H_2$.

All these findings can be explained by the mechanism proposed in Scheme 7. Unfortunately, we have not yet been able to grow single crystals of [**3**]Pt suitable for X-ray analysis. The most similar kind of interaction to the one described here, that we are aware of, was reported by Crabtree et al. with an $Ir^{III}$ complex,[8l] where two *ortho*-phenyl C–H bonds are found to dynamically oxidatively add to the Ir center.

### Approach from the Product Side

In a previous publication we reported on the problems to synthesize the expected products of the anticipated activation process via orthometalated precursors because of a rearrangement taking place.[3] We have since overcome these problems by first coordinating the phosphinites to the platinum center and then performing the orthometalation followed by salt metathesis (the last two steps in a one-pot reaction) using *s*BuLi in toluene.

The complexes *trans*-(ligand)$^X$PtCl$_2$ can be synthesized from the *ortho*-iodophosphinite as precursor (relevant quality parameters of the crystal structure determination are given in the Exp. Sect. together with all other characterization data of the compounds). For the *cis* isomers the *ortho*-iodophosphinite precursor cannot be used, presumably because of an intramolecular oxidative addition. Only an unidentified mixture of products can be isolated if (COD)PtCl$_2$ is treated with *ortho*-iodophosphinite. Switching to the less reactive *ortho*-bromophosphinite solves this problem and leads to the desired product in good yield (relevant quality parameters of the crystal structure determination are given in the Exp. Sect. together with all other characterization data of the compounds).

The $^{31}$P NMR signal of *cis*-[**1***]$^{Br}$PtCl$_2$ broadens with decreasing temperature, thus indicating a dynamic process with an approximate activation enthalpy of about 6 kcal mol$^{-1}$ (line shape analysis), which we assign to a re-

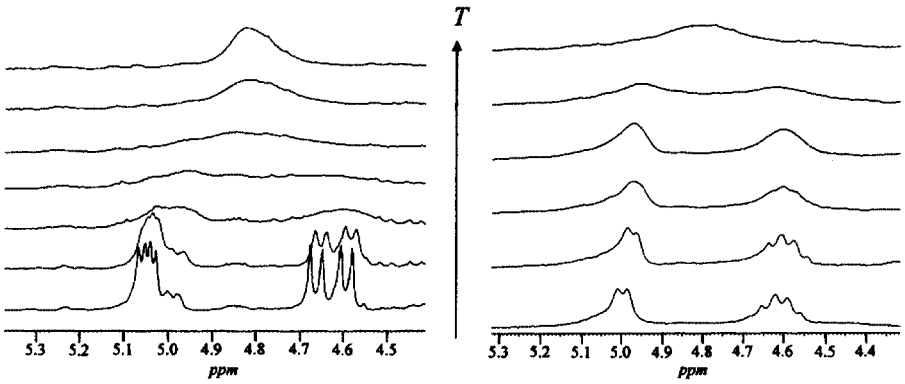

Figure 11. Results of the variable-temperature $^1$H NMR measurements for the $OCH_2$ protons in *cis*-[**3***]Pt (left) and *trans*-[**3***]Pt (right) between –90 and 100 °C.

stricted rotation about the P–Pt axis. This is supported by the crystal structure determination. Similar to the behavior described in Scheme 4, we find that both *cis*- and *trans*-(ligand)$^X$PtCl$_2$ form the *cis*-(ligand)Pt product upon treatment with four equivalents of *s*BuLi. The configuration of this product was deduced from the $^1J_{P,Pt}$ coupling constant of about 2000 Hz and the $^2J_{P,C}$ coupling constants of about 10 Hz for the *cis* coupling and about 105 Hz for the *trans* coupling (cf. *cis*-[**2**]PtEt$_2$: $^2J_{C,Pcis}$ = 8.1, $^2J_{C,Ptrans}$ = 110.5 Hz and *cis*-[**3**]PtEt$_2$: $^2J_{C,Pcis}$ = 10.7, $^2J_{C,Ptrans}$ = 113.4 Hz). The question to be examined for the *cis*-(ligand)Pt complexes was how they behave under the thermolysis conditions employed for *cis*-(ligand)PtEt$_2$ (80–100 °C, ethene present).

*cis*-[**3***]Pt isomerizes slowly and quantitatively at 95 °C in toluene (with and without ethene) to give *trans*-[**3***]Pt ($\delta_{trans}$ = 122.1 ppm, $^1J_{Pt,P}$ = 3038.1 Hz). Variable-temperature measurements by $^1$H NMR spectroscopy between –90 °C and 100 °C in toluene indicate a dynamic process in *cis*-[**3***]-Pt [broadening of the $OCH_2$ protons and the *i*Pr groups; line shape analysis: $\Delta H^{\neq}$ = 7.6 kcal mol$^{-1}$, $\Delta S^{\neq}$ = –14.6 cal mol$^{-1}$ K$^{-1}$, coalescence point 0 °C; Figure 11 (left)]. Since no line broadening is observed in the $^{31}$P NMR spectrum we can conclude that the phosphorus atoms remain coordinated during the dynamic process, which we assign to restricted conformational change of the chelating six-membered rings.

This is supported by the X-ray structure of a molecule in the solid state (Figure 12, Table 6). P1, P2, Pt1, C6, and C7 are almost in one plane in *cis*-[**3***]Pt and the P–Pt–P angle is 105° (larger than 90°). The distance between the "cleaved" C atoms C6 and C7 is 2.8 Å and the C6–Pt–C7 angle is 85°.

The same kind of broadening is observed in the $^1$H NMR spectrum of *trans*-[**3***]Pt [broadening of the $OCH_2$ protons and the *i*Pr groups; line shape analysis: $\Delta H^{\neq}$ = 6.1 kcal mol$^{-1}$, $\Delta S^{\neq}$ = –20.5 cal mol$^{-1}$ K$^{-1}$, coalescence point 0 °C; Figure 11 (right)]. These are the only changes taking place. No back reaction to [**3**]Pt(ethene) or [**3**]Pt is found up to 150 °C in mesitylene under ethene atmosphere either for the *cis*- or for the *trans* complex.

*cis*-[**1***]Pt is slowly and quantitatively transformed into two new products when heated to 95 °C. One of these has

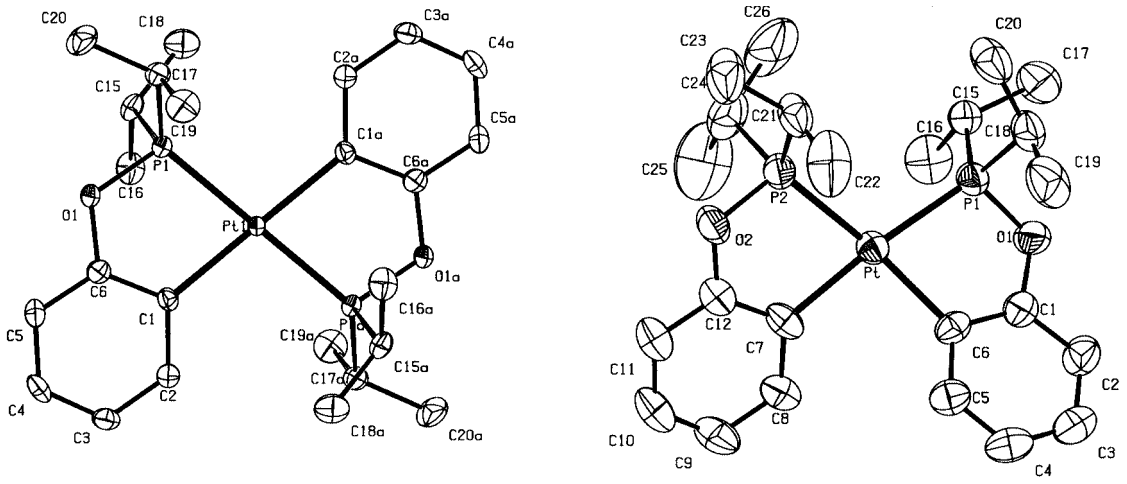

Figure 14. ORTEP style plot of the compounds *trans*-[**1***]Pt (left) and *cis*-[**1***]Pt (right) in the solid. Thermal ellipsoids are drawn at the 50% probability level. Hydrogen atoms have been omitted for clarity.

equivalent P atoms and the other one has inequivalent ones (all of them bound to Pt) and they are formed regardless of whether the reaction is performed under an atmosphere of argon or ethene. The product with equivalent P atoms is *trans*-[**1***]Pt, which was isolated and single crystals were grown from toluene solution. We assume the second product to be a *trans*-configured dimer (Figure 13), although we could not support this supposition by FAB mass spectrometry. A *trans* configuration would be in accordance with the $^1J_{P,Pt}$ coupling constants of 3073.6 and 2867.5 Hz and the $^2J_{P,P}$ coupling constant of 439.9 Hz. In this connectivity the two phenyl planes of one Pt center should be oriented perpendicular to each other and thus prevent close contacts with the *i*Pr groups.

X-ray structures of *cis*/*trans*-[**1***]Pt were determined and are shown in Figure 14 (Table 6). In contrast to *trans*-[**1***]-Pt, which is almost square planar, *cis*-[**1***]Pt is significantly distorted out of the square plane, most probably to avoid close contacts between the two *i*Pr groups and/or the two *ortho* protons in the phenyl groups. Compound **d** of Scheme 1 ([**1**]Pt(ethene)) is not observed in the course of the *cis*/*trans* isomerization, thus demonstrating that both the *cis*- and *trans*-[**1***]Pt complexes are stable or inert against a reductive elimination and should thus be observable if formed in the course of the reactions proposed in Scheme 1.

## Conclusions

We have been able to push our master plan to activate and cleave a C–C single bond in a non-strained biphenyl fragment one step further (loss of the alkene) by allowing the backbone of the chelating ligand to be more flexible, although we have still not been able to reach our final target. We have shown that loss of the alkene is not the limiting factor and we have found convincing evidence that a dynamic C–H activation of the methyl groups in the *i*Pr substituents of the chelating ligand prevents a further reaction of the 14e intermediate, especially a potential activation of the bridging C–C single bond in the biphenyl fragment of the chelating ligand. We have also proved that the potential C–C single bond activation products are stable (or inert) under the reaction conditions employed. The scrambling of deuterium into the methyl groups of the ligand in the course of thermolysis underlines the ability of the intermediate to activate less reactive bonds. Although the investigation of the dynamic C–H activation is an interesting exercise, this is not our main target. One solution to successfully finish our strategy might be to exchange the H atoms in the *i*Pr methyl groups by F atoms. Preliminary attempts in this direction have shown that the synthesis of the fluorinated ligand will be tedious and expensive. The exchange of our oxo group for a $CH_2$ might be advantageous too.[4m] Detailed DFT calculations in order to determine the C–C single bond activation barrier are also underway.

## Experimental Section

Manipulations and experiments were performed under argon using standard Schlenk techniques and/or in an argon-filled glove-box if not mentioned otherwise. Diethyl ether, pentane, acetonitrile, dichloromethane, toluene and thf were dried and degassed using a two-column drying system (MBraun) and stored under argon over molecular sieves. $CDCl_3$, [$D_8$]toluene, and [$D_5$]pyridine were stored under argon over molecular sieves. Ethene 2.7, $H_2$ 5.0, and $D_2$ 2.7 were purchased from Messer Grießheim and used as delivered. $K_2PtCl_4$ was purchased from Strem Chemicals and used without further manipulation. (1*Z*,5*Z*)-cyclooctadiene (COD), chlorodiphenylphosphane, chlorodiisopropylphosphane, 2,2′-dihydroxybiphenyl, 2,2′-biphenylmethanol, biphenic acid, *n*-propyl- and ethylmagnesium chloride (2 M in diethyl ether), $CD_3CD_2Br$, $LiAlH_4$, $LiAlD_4$, and chloroperoxobenzoic acid were purchased from Aldrich and used without further purification. [(COD)$PtCl_2$] and *trans*-[$PtCl_2$(ethene)(py)] were synthesized according to the literature.[10]

NMR spectra were recorded on a Bruker AMX400. $^1H$ ($\delta$ = 7.24 ppm, 400 MHz) and $^{13}C$ ($\delta$ = 77.0 ppm, 100 MHz) were referenced to the $CDCl_3/CHCl_3$ resonances, $^{31}P$ (161 MHz) to 85% $H_3PO_4$ as external standard, and $^{195}Pt$ ($\delta$ = –3329 ppm, 85.6 MHz) to [(COD)$PtCl_2$] as external standard. FTIR spectra were recorded

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with a JASCO FI7IR-460plus machine using KBr pellets. Variable-temperature measurements were performed as reported previously.[3,11]

**Benzo[*c*]chromen-6-one:** Fluoren-9-one (1.0 g, 5.55 mmol) and of *m*-chloroperoxobenzoic acid (1.91 g, at least 77%/8.52 mmol) were dissolved in 12 mL of glacial acetic acid and 2 mL of conc. sulfuric acid and the mixture refluxed for 2 d. After cooling to room temperature, 200 mL of diethyl ether was added followed by a saturated sodium sulfite solution to destroy the unreacted peroxide until no more gas evolution was observed. The organic phase was then washed with a saturated sodium carbonate solution until the water phase was clear and slightly basic. The light yellow ether phase was washed with 100 mL of distilled water, dried with $MgSO_4$, and the solvent was removed in vacuo to give 0.86 g (4.38 mmol, 79%) of the pure product as a yellow solid. $^1$H NMR ($CDCl_3$): $\delta$ = 7.35 (t, $^3J_{H,H}$ = 9.8 Hz, 2 H, CH arom.), 7.49 (m, 1 H, CH arom.), 7.63 (m, 1 H, CH arom.), 7.87 (t, $^3J_{H,H}$ = 7.4 Hz, 1 H, CH arom.), 8.04 (d, $^3J_{H,H}$ = 7.4 Hz, 1 H, CH arom.), 8.11 (d, $^3J_{H,H}$ = 7.4 Hz, 1 H, CH arom.), 8.40 (d, $^3J_{H,H}$ = 9.8 Hz, 1 H, CH arom.) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 117.8 (s, CH arom.), 118.1 (s, CH arom.), 121.3 (s, CH arom.), 121.7 (s, CH arom.), 122.8 (s, CH arom.), 124.5 (s, CH arom.), 128.9 (s, CH arom.), 130.4 (s, CH arom.), 130.6 (s, CH arom.), 134.8 (s, CH arom.), 135.6 (s, CH-arom.), 151.3 (s, CH arom.), 161.2 (s, -CO-) ppm.

**2-Hydroxy-2′-(hydroxymethyl)biphenyl:** Lithium aluminum hydride (0.58 g, 15.3 mmol) was suspended in 100 mL of diethyl ether in a 500-mL, two-necked vessel equipped with a condenser and dropping funnel and of benzo[*c*]chromen-6-one (1.0 g, 5.10 mmol) in 100 mL of diethyl ether was dropwise added while stirring. The mixture was then refluxed in a water bath for 3.5 h. After cooling to 0 °C the grey suspension was treated slowly with 100 mL of cold water, then 0.1 M aqueous HCl was added until the grey precipitate had dissolved completely. The yellow organic phase was separated and the water phase was extracted three times with 100 mL of diethyl ether. The combined organic phases were dried with $MgSO_4$ and the solvent was removed in vacuo. The light brownish solid was recrystallized from methanol. Yield: 94%. $^1$H NMR ($CDCl_3$): $\delta$ = 2.18 (br. s, 1 H, -$CH_2$-O*H*), 4.48 (s, 2 H, -C*H*$_2$-), 5.76 (br. s, 1 H, benzyl-OH), 6.97 (m, 2 H, CH arom.), 7.10 (m, 1 H, CH arom.), 7.26 (m, 2 H, CH arom.), 7.38–7.44 (m, 2 H, CH arom.), 7.53 (m, 1 H, CH arom.) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 63.7 (s, CH arom.), 116.4 (s, CH arom.), 120.9 (s, CH arom.), 127.6 (s, CH arom.), 128.6 (s, CH arom.), 128.7 (s, CH arom.), 129.3 (s, CH arom.), 129.4 (s, CH arom.), 130.7 (s, CH arom.), 130.9 (s, CH arom.), 136.3 (s, CH arom.), 138.9 (s, CH arom.), 152.8 (s, -CO-) ppm.

**2-(Diisopropylphosphanyloxy)-2′-[(diisopropylphosphanyl)oxymethyl]biphenyl (2):** The synthesis was performed according to our previous published procedure.[3] Colorless oil, yield: 75%. $^1$H NMR ($CDCl_3$): $\delta$ = 0.71–1.33 (m, 28 H, CHC*H*$_3$), 1.57–1.76 (m, 4 H, C*H*CH$_3$), 4.46 (m, 2 H, $CH_2$), 7.00 (d, $^3J_{H,H}$ = 7.4 Hz, 1 H, CH arom.), 7.16 (m, 2 H, CH arom.), 7.26–7.36 (m, 4 H, CH arom.), 7.58 (d, $^3J_{H,H}$ = 7.4 Hz, 1 H, CH arom.) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 17.9 (d, $^2J_{C,P}$ = 19.6 Hz, CH*C*H$_3$), 28.0 (d, $^1J_{C,P}$ = 16.8 Hz, *C*HCH$_3$), 72.0 (d, $^2J_{C,P}$ = 21.2 Hz, $CH_2$), 117.2 (s, CH arom.), 117.4 (s, CH arom.), 121.2 (s, CH arom.), 126.6 (s, CH arom.), 126.9 (s, CH arom.), 127.1 (s, CH arom.), 130.3 (s, CH arom.), 130.9 (s, CH arom.), 137.0 (s, CH arom.), 138.3 (d, $^3J_{C,P}$ = 8.8 Hz, *C*-$CH_2$OP), 155.8 (d, $^2J_{C,P}$ = 8.1 Hz, COP) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 155.0 (s), 158.3 (s) ppm.

**2,2′-Bis[(diisopropylphosphanyl)oxymethyl]biphenyl (3):** The synthesis was performed according to our previous published procedure.[3] Clear oily liquid, yield: 70%. $^1$H NMR ($CDCl_3$): $\delta$ = 0.91–1.04 (m, 28 H, CHC*H*$_3$), 1.68 (sept, $^2J_{H,H}$ = 7.4 Hz, 4 H, CHCH$_3$), 4.42 (d, $^2J_{H,H}$ = 12.3 Hz, 1 H, -$CH_2$-), 4.47 (d, $^2J_{H,H}$ = 12.3 Hz, 1 H, -$CH_2$-), 7.14 (d, $^3J_{H,H}$ = 7.3 Hz, 2 H, 1 H, CH arom.), 7.29 (d, $^3J_{H,H}$ = 7.3 Hz, 1 H, CH-arom.), 7.31 (d, $^3J_{H,H}$ = 7.4 Hz, 1 H, CH arom.), 7.36 (d, $^3J_{H,H}$ = 7.3 Hz, 1 H, CH arom.), 7.38 (d, $^3J_{H,H}$ = 7.4 Hz, 1 H, CH arom.), 7.57 (d, $^3J_{H,H}$ = 7.3 Hz, 2 H, CH arom.) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 16.9 (d, $^2J_{C,P}$ = 8.1 Hz, CH*C*H$_3$), 17.0 (d, $^2J_{C,P}$ = 8.8 Hz, CH*C*H$_3$), 17.7 (d, $^2J_{C,P}$ = 6.6 Hz, CH*C*H$_3$), 17.9 (d, $^2J_{C,P}$ = 6.6 Hz, CH*C*H$_3$), 27.9 (d, $^2J_{C,P}$ = 16.1 Hz, *C*HCH$_3$), 28.1 (d, $^2J_{C,P}$ = 16.1 Hz, *C*HCH$_3$), 71.9 (d, $^2J_{C,P}$ = 20.5 Hz, $CH_2$OP), 127.0 (s, CH arom.), 127.6 (s, CH arom.), 128.1 (s, CH arom.), 129.6 (s, CH arom.), 137.3 (d, $^3J_{C,P}$ = 8.8 Hz, *C*-$CH_2$-O), 138.8 (s, CH arom.) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 154, 4 (s) ppm.

**Synthesis of the Dichloridodiphosphinite Complexes. General Procedure for the Synthesis of the Complexes [Y]PtCl$_2$ (Y = 2, 3):** A solution of 0.3 mmol of ligand Y in 5 mL of dichloromethane was added with a syringe to a suspension of 0.3 mmol of precursor in 20 mL of dichloromethane. The mixture was stirred overnight at room temperature and the solvent was then removed in vacuo. The white to light-yellow residue was washed with 10 mL of pentane (in some cases additionally with 4 mL of diethyl ether) and dried for 2 h in vacuo. Recrystallization from dichloromethane was necessary to give analytically pure material.

***cis*-[2]PtCl$_2$:** Light-yellow powder, yield: 70%. $^1$H NMR ($CDCl_3$): $\delta$ = 0.63 (d, $^3J_{H,H}$ = 7.8 Hz, 3 H, CHC*H*$_3$), 0.65 (d, $^3J_{H,H}$ = 6.9 Hz, 3 H, CHC*H*$_3$), 0.88 (d, $^3J_{H,H}$ = 7.8 Hz, 3 H, CHC*H*$_3$), 0.92 (d, $^3J_{H,H}$ = 6.8 Hz, 3 H, CHC*H*$_3$), 0.98 (d, $^3J_{H,H}$ = 6.9 Hz, 3 H, CHC*H*$_3$), 1.06 (d, $^3J_{H,H}$ = 7.8 Hz, 3 H, CHC*H*$_3$), 1.45 (d, $^3J_{H,H}$ = 6.9 Hz, 3 H, CHC*H*$_3$), 1.48 (d, $^3J_{H,H}$ = 7.8 Hz, 3 H, CHC*H*$_3$), 2.51 (m, 1 H, C*H*CH$_3$), 2.60 (m, 1 H, C*H*CH$_3$), 2.75 (m, 1 H, C*H*CH$_3$), 3.46 (m, 1 H, C*H*CH$_3$), 4.61 (d, $^3J_{H,H}$ = 8.8 Hz, 1 H, -$CH_2$-), 4.70 (d, $^3J_{H,H}$ = 6.9 Hz, 1 H, -$CH_2$-), 7.14–7.50 (m, 8 H, CH arom.) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 16.4 (d, $^2J_{C,P}$ = 6.2 Hz, CH*C*H$_3$), 17.1 (d, $^2J_{C,P}$ = 6.2 Hz, CH*C*H$_3$), 17.8 (d, $^2J_{C,P}$ = 2.5 Hz, CH*C*H$_3$), 18.7 (br. d, $^2J_{C,P}$ = 13.3 Hz, CH*C*H$_3$), 19.5 (br.s, CH*C*H$_3$), 20.4 (d, $^2J_{C,P}$ = 3.7 Hz, CH*C*H$_3$), 28.6 (d, $^2J_{C,P}$ = 32.1 Hz, *C*HCH$_3$), 31.0 (d, $^2J_{C,P}$ = 35.7 Hz, *C*HCH$_3$), 31.8 (d, $^2J_{C,P}$ = 35.8 Hz, *C*HCH$_3$), 34.2 (d, $^2J_{C,P}$ = 43.2 Hz, *C*HCH$_3$), 69.2 (d, $^1J_{C,P}$ = 13.6 Hz, $CH_2$), 119.3 (d, $^4J_{C,P}$ = 6.2 Hz, *C*HCCH$_2$), 123.3 (s, CH arom.), 128.1 (s, CH arom.), 129.4 (s, CH arom.), 129.5 (s, CH arom.), 129.8 (s, CH arom.), 130.3 (s, CH arom.), 132.1 (d, $^3J_{C,P}$ = 6.2 Hz, *C*HCOP), 134.1 (d, $^4J_{C,P}$ = 6.2 Hz, *C*HCCH$_2$), 139.6 (s, CH arom.), 151.9 (d, $^3J_{C,P}$ = 8.6 Hz, C-O-P) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 112.5 (pseudo t, $^1J_{P,Pt}$ = 4099.0, $^2J_{P,P}$ = 5.0 Hz), 110.5 (pseudo t, $^1J_{P,Pt}$ = 4149.6, $^2J_{P,P}$ = 5.0 Hz) ppm. $^{195}$Pt{$^1$H} NMR ($CDCl_3$): $\delta$ = –4116.8 (dd, $^1J_{P,Pt}$ = 4099.0, 4149.6 Hz) ppm. $C_{25}H_{38}Cl_2O_2P_2Pt$ (698.50): calcd. C 42.99, H 5.48, Cl 10.15, P 8.87; found C 43.07, H 5.55, Cl 9.78, P 8.05.

**Crystal-Structure Analysis of *cis*-[2]PtCl$_2$·2(CHCl$_3$):** $C_{27}H_{40}Cl_8O_2P_2Pt$, $M_r$ = 937.26, colorless fragment ($0.06 \times 0.18 \times 0.12$ mm$^3$), monoclinic, $P2_1/c$ (no. 14), $a$ = 9.9002(1), $b$ = 17.7053(2), $c$ = 21.2118(3) Å, $\beta$ = 100.9809(5)°, $V$ = 3650.06(8) Å$^3$, $Z$ = 4, $D_{calc}$ = 1.706 g cm$^{-3}$, $F(000)$ = 1848, $\mu$ = 4.542 mm$^{-1}$. Preliminary examination and data collection were carried out on a κ-CCD device (Nonius, Mach3) with an Oxford Cryosystems cooling system at the window of a rotating anode (Nonius FR591) with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data collection was performed at 173 K within the $\Theta$ range $1.51° < \Theta < 25.36°$. A total of 44141 intensities were integrated. Raw data were corrected for Lorentz, polarization, and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

latent decay and absorption effects arising from the scaling procedure. After merging ($R_{int}$ = 0.0429), 6670 [5689: $I_0 > 2\sigma(I_0)$] independent reflections remained and all were used to refine 369 parameters. The structure was solved by a combination of direct methods and difference-Fourier syntheses. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in calculated positions and refined using a riding model. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ and converged with $R1$ = 0.0380 [$I_0 > 2\sigma(I_0)$], $wR2$ = 0.0702 (all data), GOF = 1.162, and shift/error < 0.001. The final difference-Fourier map showed no striking features ($\Delta e_{min/max}$ = +1.01/–1.02 e Å$^{-3}$). CCDC-613907.

**Synthesis of the Dialkyldiphosphinite Complexes. General Procedure for the Synthesis of the Complexes [Y]PtR′$_2$ (Y = 1, 1′, 2, 3; R′ = Alkyl):** The dichlorido complex (0.15 mmol) was suspended in 10 mL of diethyl ether and cooled to –78 °C. Then, 0.45 mmol of Alkyl-Grignard were added while stirring and it was warmed up to room temperature overnight. The next day, 0.45 mmol of 1,4-dioxane were added, the white residue was filtered through alumina and washed with 10 mL of diethyl ether. The solvent was removed from the ether extracts in vacuo and the resulting solid was dried in vacuo for two hours.

Yield: 89%. $^1$H NMR ($CDCl_3$): $\delta$ = 1.33 (dd, $^3J_{H,H}$ = 7.4, $^3J_{P,H}$ = 6.1 Hz, 12 H, CHC$H_3$), 1.57 (d, $^3J_{H,H}$ = 7.4, $^3J_{P,H}$ = 6.1 Hz, 12 H, CHC$H_3$), 3.05 (dsept, $^3J_{H,H}$ = 7.4, $^1J_{P,H}$ = 6.1 Hz, 4 H, C$H$CH$_3$), 4.76 (d, $^3J_{P,H}$ = 4.9 Hz, 4 H, O-C$H_2$), 7.04 (t, $^3J_{H,H}$ = 7.4 Hz, 2 H, CH arom.), 7.14 (t, $^3J_{H,H}$ = 7.4 Hz, 2 H, CH arom.), 7.29 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, CH arom.), 7.36 (d, $^3J_{H,H}$ = 7.4 Hz, 2 H, CH arom.) ppm. $^{13}$C{$^1$H} NMR ($CDCl_3$): $\delta$ = 18.2 (s, CH$C$H$_3$), 19.6 (s, CH$C$H$_3$), 29.6 (d, $^1J_{C,P}$ = 4.0 Hz, $C$HCH$_3$), 68.8 (d, $^2J_{C,P}$ = 11.0 Hz, C$H_2$), 121.0 (s, CH arom.), 127.2 (s, CH arom.), 127.4 (s, CH arom.), 129.3 (s, CH arom.), 132.5 (s, CH arom.), 135.1 (s, CH arom.) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 123.1 (s, $^1J_{P,Pt}$ = 4191.4 Hz) ppm. $^{195}$Pt{$^1$H} NMR ($CDCl_3$): $\delta$ = –4299.7 (t, $^1J_{P,Pt}$ = 4191.4 Hz) ppm. $C_{26}H_{40}Br_2Cl_2O_2P_2Pt$ (872.33): calcd. C 35.80, H 4.62; found C 35.70, H 4.71.

**General Synthetic Procedure for the [Ligand*]Pt Complexes:** The complex (ligand)$^X$PtCl$_2$ (0.27 mol) was dissolved in 20 mL of toluene and the solution was cooled with dry ice. Then 0.54 mol of *s*BuLi (1.3 M solution in benzene/hexane) was added with a syringe and the solution was stirred overnight while warming up to room temperature. The next day it was filtered and the solvent removed in vacuo. The remaining white solid was washed with three 5-mL portions of pentane and dried in vacuo.

***cis*-[1*]Pt:** White powder, yield: 85%. $^1$H NMR ($CDCl_3$): $\delta$ = 1.10 (d, $^3J_{H,H}$ = 6.84 Hz, 6 H, CHC$H_3$), 1.15 (d, $^3J_{H,H}$ = 7.8 Hz, 6 H, CHC$H_3$), 1.19 (d, $^3J_{H,H}$ = 6.84 Hz, 6 H, CHC$H_3$), 1.22 (d, $^3J_{H,H}$ = 6.84 Hz, 6 H, CHC$H_3$), 2.36 (m, 4 H, C$H$CH$_3$), 6.91 (m, 2 H, CH arom.), 6.99–7.07 (m, 4 H, CH arom.), 7.74 (t, $^3J_{H,H}$ = 6.3, $J_{H,Pt}$ = 47.0 Hz, 2 H, CH arom.) ppm. $^{13}$C{$^1$H} NMR ($C_7D_8$): $\delta$ = 16.8 (pseudo t, $J_{C,Pt}$ = 15.4 Hz, P-CH-$C$H$_3$), 17.8 (m, P-CH-$C$H$_3$), 30.8 (d pseudo t, $^1J_{C,P}$ = 22.0, $^2J_{C,Pt}$ = 21.2 Hz, P-$C$H), 110.2 (d pseudo t, $^3J_{C,P}$ = 13.2, $^2J_{C,Pt}$ = 6.6 Hz, *C*-arom.), 122.4 (pseudo t, $^3J_{C,Pt}$ = 53.4 Hz, *C*-arom.), 126.6 (s, *C*-arom.), 141.2 (pseudo t, $^3J_{C,Pt}$ = 38.1 Hz, *C*-arom.), 150.0 (d pseudo t, $^1J_{C,Pt}$ = 850.4, $^2J_{C,P}$*cis* = 9.0, $^2J_{C,P}$*trans* = 104.7 Hz, *C*-Pt), 167.6 (d pseudo t, $^2J_{C,P}$ = 8.8, $^2J_{C,Pt}$ = 8.8 Hz, O-*C*) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 179.0 (pseudo t, $^1J_{P,Pt}$ = 2147.2 Hz) ppm. $^{195}$Pt{$^1$H} NMR ($CDCl_3$): $\delta$ = –4583.9 (t, $^1J_{P,Pt}$ = 2147.2 Hz) ppm. MS (FAB): *m*/*z* (%) 613.1 (100) [M], with correct isotope pattern for $C_{24}H_{36}O_2P_2Pt$. $C_{24}H_{36}O_2P_2Pt$ (613.57): calcd. C 46.98, H 5.91; found C 46.76, H 5.82.

**Crystal-Structure Analysis of *cis*-[1*]Pt:** $C_{24}H_{36}O_2P_2Pt$, $M_r$ = 613.56, colorless fragment ($0.11 \times 0.14 \times 0.20$ mm$^3$), monoclinic, $P2_1/n$ (no. 14), $a$ = 12.5818(1), $b$ = 13.8769(1), $c$ = 15.2961(1) Å, $\beta$ = 106.9606(4)°, $V$ = 2554.49(3) Å$^3$, $Z$ = 4, $D_{calc}$ = 1.595 g cm$^{-3}$, $F(000)$ = 1216, $\mu$ = 5.635 mm$^{-1}$. Preliminary examination and data collection were carried out on a κ-CCD device (Nonius, Mach3) with an Oxford Cryosystems cooling system at the window of a rotating anode (Nonius FR591) with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data collection was performed at 173 K within the $\Theta$ range 1.85° < $\Theta$ < 25.35°. A total of 55295 intensities were integrated. Raw data were corrected for Lorentz, polarization, and latent decay and absorption effects arising from the scaling procedure. After merging ($R_{int}$ = 0.0789), 4739 [3137: $I_0 > 2\sigma(I_0)$] independent reflections remained and all were used to refine 270 parameters. The structure was solved by a combination of direct methods and difference-Fourier syntheses. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were placed in calculated positions and refined using a riding model. Full-matrix least-squares refinements were carried out by minimizing $\Sigma w(F_o^2 - F_c^2)^2$ and converged with $R1$ = 0.0399 [$I_0 > 2\sigma(I_0)$], $wR2$ = 0.0709 (all data), GOF = 0.997, and shift/error < 0.001. The final difference-Fourier map showed no striking features ($\Delta e_{min/max}$ = +1.43/–1.16 e Å$^{-3}$). CCDC-613903.

***cis*-[3*]Pt:** White powder, yield: 91%. $^1$H NMR ($C_7D_8$, –80 °C): $\delta$ = 0.59 (dd, $^3J_{H,H}$ = 7.36, $^3J_{P,H}$ = 6.12 Hz, 3 H, C$H_3$), 0.79 (dd, $^3J_{H,H}$ = 7.36, $^3J_{P,H}$ = 11.00 Hz, 3 H, C$H_3$), 1.07 (dd, $^3J_{H,H}$ = 9.80, $^3J_{P,H}$ = 6.16 Hz, 3 H, C$H_3$), 1.60 (dsept, $^3J_{H,H}$ = 7.36, $^2J_{P,H}$ = 7.36 Hz, 2 H, P-C$H$), 1.80 (dsept, $^3J_{H,H}$ = 7.36, $^2J_{P,H}$ = 4.88 Hz, 2 H, P-C$H$), 4.62 (dd, $^2J_{H,H}$ = 9.8, $^4J_{P,H}$ = 27.59 Hz, 2 H, CH$H$-O), 5.04 (dd, $^2J_{H,H}$ = 9.8, $^4J_{P,H}$ = 10.42 Hz, 2 H, CH$H$-O), 7.31 (m, 2 H, arom. C), 126.55 (s, arom. C), 130.14 (s, arom. C), 136.87 (s, arom. C), 138.49 (s, arom. C) ppm. $^{31}$P{$^1$H} NMR ($C_7D_8$): $\delta$ = 160.1 (pseudo t, $^1J_{P,Pt}$ = 3158.8 Hz) ppm. $^{195}$Pt{$^1$H} NMR ($C_7D_8$): $\delta$ = –4894.8 (t, $^1J_{P,Pt}$ = 3158.8 Hz) ppm. MS (FAB): *m*/*z* 642.3 [M + 1], with correct isotopic pattern. FT-IR (KBr): $\tilde{\nu}$ = 1945 cm$^{-1}$ (w, Pt–H).

**Calculations:** The DFT calculations were performed using the program suite Gaussian 03.[5] All molecular geometries were fully optimized. The DFT method used includes Becke's three parameter hybrid exchange functional in combination with the correlation functional of Perdew and Wang (B3PW91). Geometry optimizations and frequency calculations were performed using the valence double-zeta LANL2DZ basis set. The frozen-coordinate analysis was done using the program codes implemented in Gaussian 03.

**Single Crystal X-ray Structure Determination of Compounds *cis*-[2]PtCl$_2$·2(CHCl$_3$), *trans*-[2]PtCl$_2$, *cis*-[3]PtCl$_2$·3(CHCl$_3$), *trans*-[3]PtCl$_2$, *cis*-[1]Pt(*n*Pr)$_2$, *cis*-[3]PtEt$_2$, *trans*-[1*]$^1$PtCl$_2$, *cis*-[1*]$^{Br}$PtCl$_2$·(CH$_2$Cl$_2$), *trans*-[1*]Pt, *cis*-[1*]Pt, and *cis*-[3*]Pt:** The crystal was stored under perfluorinated ether, transferred into a Lindemann capillary, fixed, and sealed. Preliminary examination and data collection were carried out as described above for each complex. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for Crystallography.[12d] All calculations were performed on an Intel Pentium II PC, with the STRUX-V system, including the programs PLATON, SIR92, and SHELXL-97.[12]

CCDC-613903 to -613913 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# The Electrochemical Behaviour of Organonickel Complexes: Mono-, Di- and Trivalent Nickel

**Axel Klein,*[a] André Kaiser,[a] Biprajit Sarkar,[b] Matthias Wanner,[b] and Jan Fiedler[c]**

**Keywords:** Electron transfer / Nickel / Electrochemistry / EPR spectroscopy / Spectroelectrochemistry

The redox properties of organometallic nickel complexes of the type [(α-diimine)Ni(Mes)Br], [(α-diimine)Ni(Mes)$_2$] and the complexes *trans*-[(PPh$_3$)$_2$Ni(Mes)Br] and *trans*-[(PPh$_3$)$_2$-Ni(Fmes)Br] [Mes = mesityl (2,4,6-trimethylphenyl); Fmes = tris(2,4,6-trifluoromethyl)phenyl] have been studied in detail by various electrochemical and spectroelectrochemical (UV/Vis/NIR and EPR) methods. Upon electrochemical reduction, the bromido mesityl derivatives undergo cleavage of the bromide ligand. The resulting reactive species and their products from follow-up reactions are investigated. Electrochemical oxidation leads to formally trivalent nickel species. The metal contribution to the unpaired electron for the formally monovalent and trivalent nickel species can be estimated from EPR spectroscopy.

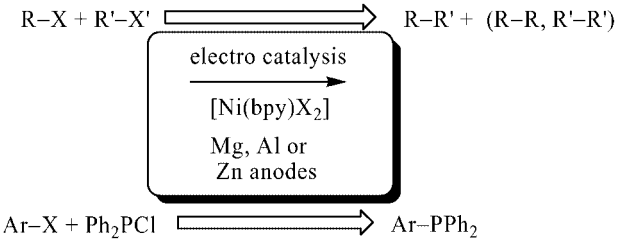
## Introduction

Organonickel(II) complexes are widely used in organometallic catalysis. One of the first benchmarks in that field were the nickel phosphane complexes used in the Shell higher olefin process (SHOP).[1] In the last decade the interest in organonickel catalysts has mainly focused on nickel diimine complexes. Highly reactive catalysts for olefin polymerisation have been developed on the basis of methylnickel complexes of various diimine ligands, mainly by Brookhart.[2] The active catalyst species were found to be mainly cationic complexes of the type [(N^N)Ni(R)L]$^+$ (N^N = α-diimine; L = easily replaceable ligand). Furthermore, nickel diimine complexes have gained an enormous interest in electrocatalytic applications[3] such as electrocatalytic C–C or C–P coupling reactions with various aryl, vinyl or alkyl halides R–X (see Scheme 1),[4–7] homogeneous electromediated reduction (HEMR) of olefins, ketones or alkyl halides,[8–10] electrochemical carboxylation of bromostyrenes[11] or aziridines,[12] electroreductive carbonylation of organic halides[13] and electroreductive coupling of olefins and polyhalo compounds.[14]

A mechanism for the C–C coupling reactions was initially proposed by Amatore and Jutand[15] for the corresponding diphosphane (dppe) complexes and was subsequently established for 2,2′-bipyridine-containing systems



Scheme 1. Electrocatalytic C–C or C–P coupling reactions of aryl, vinyl or alkyl halides.

mainly based on kinetic investigations.[6,16,17] For a system starting from [(bpy)NiX$_2$] (X = halide) pre-catalysts it can be depicted as in Scheme 2.

In addition to these kinetic investigations, the oxidative addition reaction of ArBr to zero-valent nickel species formed in situ as the first part of the catalytic cycle has been proved by preparative electrochemistry. Thus, the oxidative addition of aryl halides to species formed upon electrochemical reduction of [(bpy)$_n$NiX$_2$] ($n$ = 1–3; X = Br, BF$_4$) leads to the nickel(II) complexes [(bpy)Ni$^{II}$(Ar)Br] in reasonably high yields.[18,19] The complex [(bpy)Ni(Mes)Br], which is an excellent catalyst precursor for the oligomerisation of ethylene, is obtained from [(bpy)NiBr$_2$] and MesBr in 87% yield.[18]

The subsequent steps of the proposed catalytic cycle comprise a single electron transfer and subsequent scission of the bromide ligand to give the monovalent species [(bpy)-Ni$^{I}$(Ar)]. Oxidative addition of RX then leads to trivalent pentacoordinate [(bpy)Ni$^{III}$(Ar)(R)X], which finally eliminates the coupling product ArR. The resulting nickel(I) species is then reduced to the aforementioned nickel(0) catalyst [(bpy)Ni$^0$]. So far very little preparative or spectroscopic

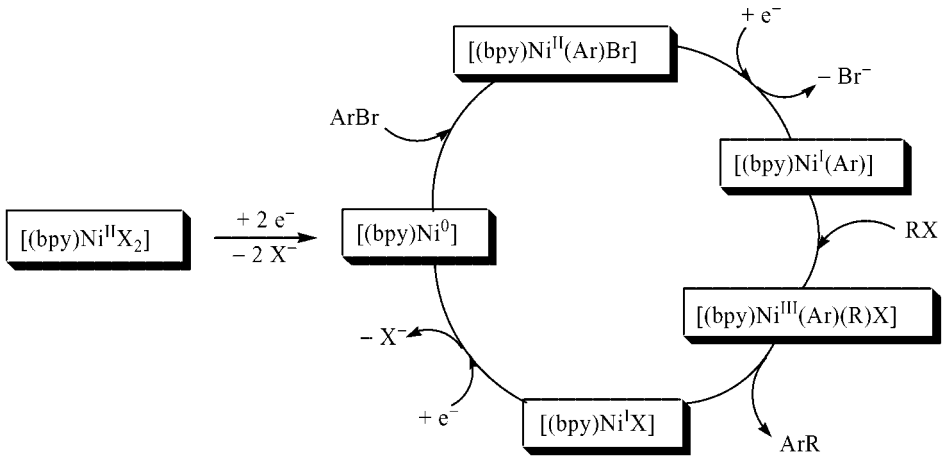
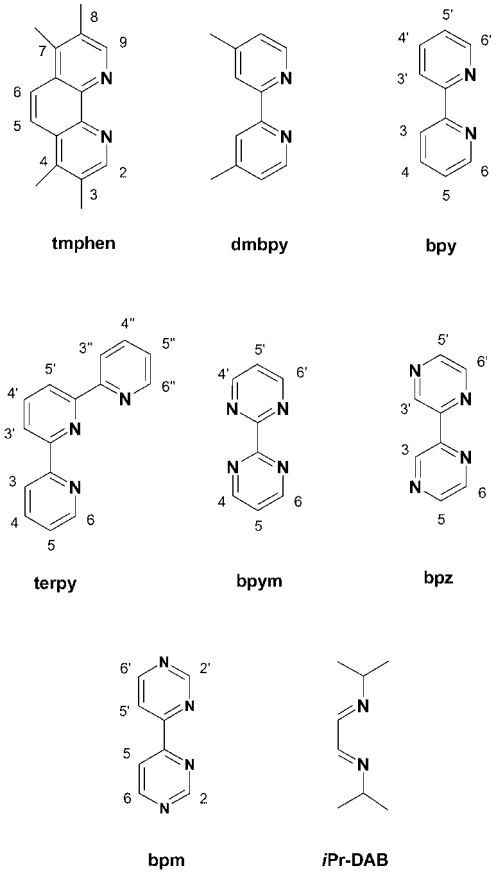


Scheme 2. Proposed mechanism for the C–C coupling reactions.

evidence has been published for this part. The NMR spectroscopic data of the proposed nickel(III) species [(bpy)-Ni(Mes)$_2$Br] have been reported,[19] but these data do not show any sign of paramagnetic shifts, and the characterisation of these species by EPR spectroscopy was not performed. No spectroscopic evidence has been found so far for the nickel(I) species in the next catalytic step.

To explore the mechanism of this interesting electrocatalytic reaction in further details we have started an investigation on the electrochemistry of a number of mesitylnickel complexes of various α-diimine ligands [(N^N)Ni(Mes)Br], thus starting at the point of the proposed cycle which has remained largely unclear so far. We have used spectroelectrochemical methods (UV/Vis/NIR and EPR) to characterise the resulting species as these techniques allow the in situ generation and spectroscopic characterisation of labile or even transient species.[20]

The complexes [(N^N)Ni(Mes)Br] used in this investigation, with the α-diimine ligands depicted in Scheme 3, have been described in preliminary detailed studies using optical spectroscopy, XRD and EXAFS spectroscopy in combination with quantum chemical calculations.[21–23] It was shown that the LUMOs were mainly localised in the diimine π* levels, which means that the diimine ligands should be largely involved in electrochemical reduction of these complexes. Since the splitting of the bromide ligand is presumed from the reduced states of these complexes, the related dimesityl complexes [(N^N)Ni(Mes)$_2$], which have been described recently,[21,23] were also included in this study. For further comparison we also incorporated the complex *trans*-[(PPh$_3$)$_2$Ni(Mes)Br], which usually serves as a precursor to the title complexes,[22,23] and the perfluorinated derivatives *trans*-[(PPh$_3$)$_2$Ni(Fmes)Br] and [(bpy)-Ni(Fmes)Br] [Fmes = nonafluoromesityl = 2,4,6-tris(trifluoromethyl)phenyl], the preparation and analytical data of which are given in the Experimental Section.



Scheme 3. Diimine ligands (N^N). tmphen = 3,4,7,8-tetramethyl-1,10-phenanthroline, dmbpy = 4,4′-dimethyl-2,2′-bipyridine, bpy = 2,2′-bipyridine, terpy = 2,2′,6′′-terpyridine, bpym = 2,2′-bipyrimidine, bpz = 2,2′-bipyrazine, bpm = 4,4′-bipyrimidine, *i*Pr-DAB = *N*,*N*′-diisopropyl-1,2-ethanediimine (*N*,*N*′-diisopropyl-1,4-diazabutadiene).

## Results and Discussion

### Electrochemistry

#### *Reduction Reactions*

The bromido mesityl complexes [(N^N)Ni(Mes)Br] exhibit rather complex electrochemical behaviour at 298 K, as shown in Figure 1 (data summarised in Table 1).

After a first irreversible reduction wave ($E_{R1}$) we observe a reversible wave $E_2$ ($E_{R2}/E_{O2}$) for the more basic ligands tmphen, dmbpy and bpy. The cathodic peak potentials $E_{R1}$ and $E_{R2}$ increase (shift positively) along the series tmphen > dmbpy > bpy > bpym > bpz > *i*Pr-DAB > bpm. Since the values for $E_{R2}$ increase more rapidly, $E_{R1}$ and $E_{R2}$ overlap partially at the lower end of the series, starting from bpym. Here, square-wave voltammetry helped to determine the individual values. This series represents the decreasing basicity or increasing π-accepting ability (in accordance with the low-lying π* LUMOs) of the diimine ligand. On the reverse scan a re-oxidation wave ($E_{O1'}$) is observed at around –1 V. The two reduction waves are followed by further waves that are partly reversible ($E_{R3}$) for the less basic ligands. An exception for this complex behaviour can be observed for the terpy complex $[(terpy)Ni(Mes)]^+$, for which two reversible reduction waves are found. The corresponding dimesityl complexes $[(N^N)Ni(Mes)_2]$ also exhibit full reversibility of the first two reduction processes (Figure 2, Table 2). Since no bromide co-ligand is present in these systems a first strong evidence emerges that the splitting of the bromide from the complexes [(N^N)Ni(Mes)Br] after the first reduction reaction is the reason for their complicated behaviour. This splitting reaction has been proposed before by others,[16,18,19] but no convincing proof was provided.

At low temperature (213 K) the situation is altered. For the dmbpy complex a re-oxidation $E_{O1}$ to the first electrochemical process (E) is observed. At normal scan rates the ratio $I_{pa}/I_{pc}$ is less than 1, although it reaches unity when scanned at rates above 500 mV s$^{-1}$. For the complexes with bpy (Figure 3), bpym, *i*Pr-DAB and bpm the process $E_1$ ($E_{R1}/E_{O1}$) is fully reversible even at normal scan rates. Com-

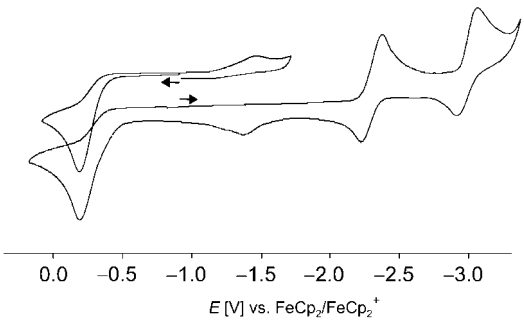

Figure 2. Cyclic voltammograms of [(bpy)Ni(Mes)$_2$] in thf/$Bu_4NPF_6$; scan rate: 100 mV s$^{-1}$ at 298 K.

pared to measurements at 298 K, the peaks $E_{R2}$ and $E_{R3}$ are much smaller and further small reduction waves, for example $E_{R2'}$, are observed. We can therefore conclude that $E_2$ and $E_3$ are processes that are due to products emerging from the first electrochemical reduction (E) followed by a chemical reaction (C; EC mechanism). Evidence that the C process is the cleavage of $Br^-$ thus comes from the reversible behaviour of the terpy complex, the dimesityl complexes (Figure 2, Table 2) and, as tested subsequently, from the increasing reversibility of the $E_1$ process upon addition of an excess of $Bu_4NBr$. Such an EC mechanism has been established for a number of diimine complexes of other transition metals such as Ru, Os, Rh, Ir or Re with halide coligands,[20b,24–26] and also for related phosphane complexes of Pd and Ni.[27]

If we examine the details further we find that in comparison to the dimesityl complexes the first reduction potentials of the bromido mesityl complexes are shifted to less negative values and that within the series of complexes the potentials depend strongly on the nature of the diimine ligand. Quantitative measurements using the Baranski method[28] revealed two successive one-electron reductions for the dimesityl complexes. Polarographic measurements on the bromido mesityl complexes also confirmed the uptake of one electron for the $E_{R1}$ process. Other studies have shown that in the presence of additional MesBr the first reduction wave of [(bpy)Ni(Mes)Br] comprises two electrons and the complex [(bpy)Ni(Mes)$_2$] is formed under these conditions.[16,18,19] Corresponding experiments by us confirm these results. However, without additional MesBr only small amounts of the dimesityl complexes are formed during the reduction, therefore these species cannot account for the reversible waves $E_2$.

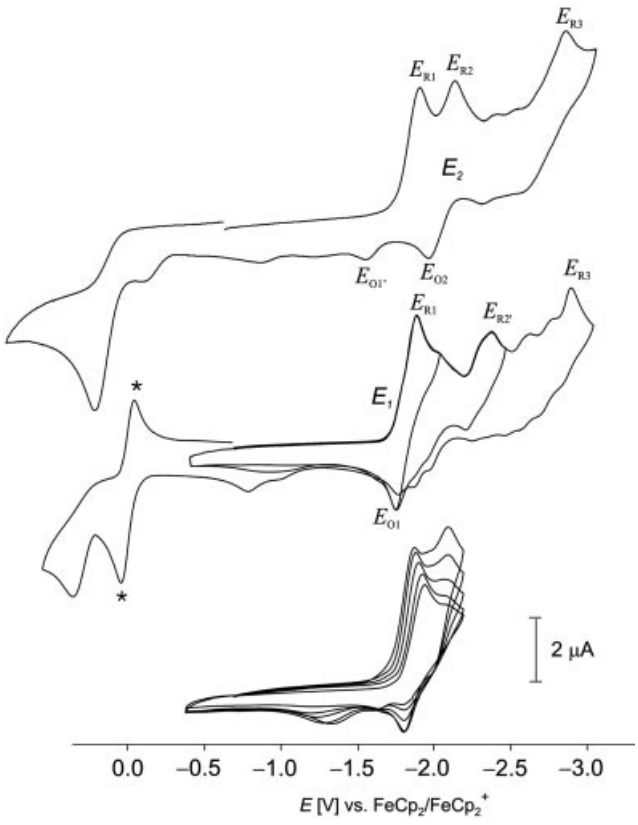

Figure 3. Cyclic voltammograms of [(bpy)Ni(Mes)Br] in thf/$Bu_4NPF_6$ solution at 298 K (top), in dmf/$Bu_4NPF_6$ solution at 238 K (middle), and dmf/$Bu_4NPF_6$ solution at temperatures varying between 238 and 278 K (bottom); * marks the redox waves of the ferrocene/ferrocenium standard.

The reductive electrochemistry of the perfluorinated derivative [(bpy)Ni(Fmes)Br] occurs at much less negative potential, as expected due to the presence of the electron-withdrawing F substituents (Table 3). Under normal experimental conditions (scan rate: 100 mV s$^{-1}$ at 298 K) the first wave appears almost reversible ($\Delta E_{pp}$ = 66 mV; peak-current ratio = 0.91). This is interesting, since the use of very poor bases like *i*Pr-DAB or bpz also increases the reduction potential but does not lead to reversible behaviour to the same extent. Obviously, the rate of bromide splitting depends on the net electron density on the nickel atom, which is not

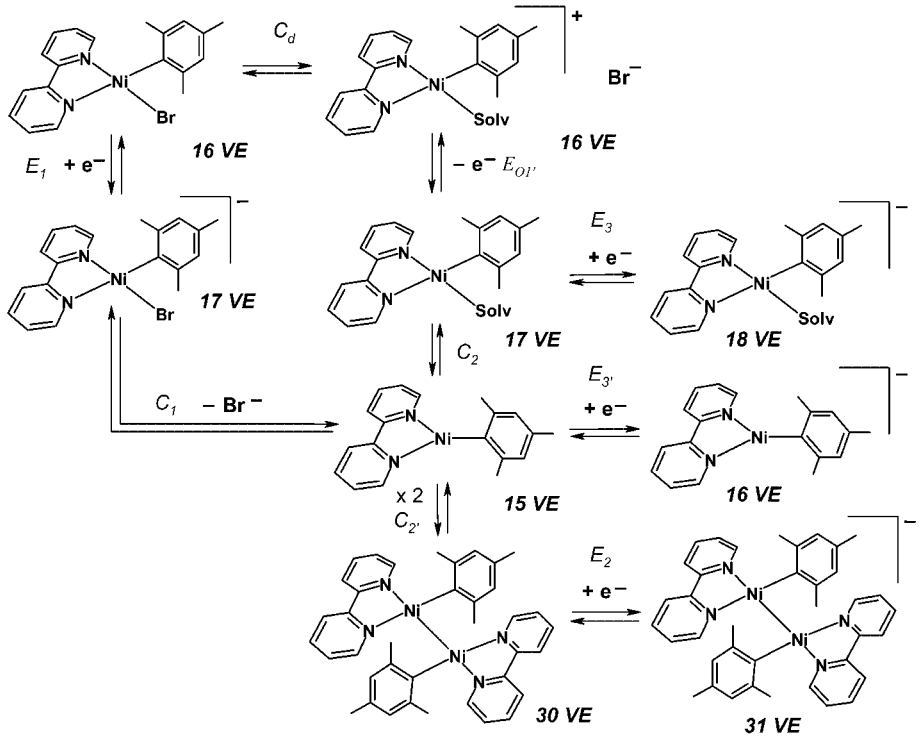
adequately reflected by the reduction potential. For the phosphane complexes $[(PPh_3)_2Ni(Mes)Br]$ and $[(PPh_3)_2Ni(Fmes)Br]$ the reductions occur at rather negative potentials and are irreversible even at low temperatures and in the presence of excess bromide.

For the diimine complexes [(N^N)Ni(Mes)Br] we can now draw a reaction scheme (Scheme 4) to illustrate the proposed EC mechanism as well as further feasible electrochemical or chemical reactions.

The first reduction ($E_1$) is followed by a rapid cleavage of bromide ($C_1$). The transient 15 VE species can be stabilised by coordinating a solvent molecule ($C_2$) or by dimerisation ($C_{2'}$). Coordinatively unsaturated species have been observed for other late transition metal complexes[29] but can be ruled out for our investigation since thf or dmf should have sufficient donor capacity to act as a ligand. The solvent complexes can be described by two different canonical forms $[(N\hat{}N^{\cdot-})Ni^{II}(Mes)(solv)] \leftrightarrow [(N\hat{}N)Ni^{I}(Mes)(solv)]$, which have either a reduced diimine ligand or monovalent nickel. The dimerisation occurs upon formation of a nickel–nickel bond with a formal $Ni^{I}$–$Ni^{I}$ unit. Examples of this type of reaction have been found, for example, in the $Ru^{I}$–$Ru^{I}$ dimers that are formed after electrochemical reduction of the $Ru^{II}$ complexes $[(bpy)Ru(CO)_2X_2]$,[24] or in the formation of $Re^0$–$Re^0$ dimers $[(L)(CO)_3Re–Re(CO)_3(L)]$ from $[Re(CO)_3(L)X]$ (L = bpy or phen; X = Cl or CN).[26] Both are formal $d^7$–$d^7$ systems. Examples for related $d^9$–$d^9$ dimers are the $Pd^{I}$–$Pd^{I}$ systems [(phen)(MeCN)Pd–Pd(MeCN)(phen)]$^{2+}$, formed from a comproportionation reaction of $Pd^{II}$ and $Pd^0$ precursors,[30] and $[(L)(RNC)Pd–Pd(RNC)(L)]^{2+}$ (L = bpy, phen or dmphen; RNC = 2,4,6-$Me_3C_6H_2NC$).[31] A bpy-bridged $Pt^{I}$–$Pt^{I}$ dimer is present in $[Pt_2(bpy)_3]^{2+}$, which is formed upon electroreduction of $[Pt(bpy)_2]^{2+}$.[32]

The $E_{R2}$ and $E_{R3}$ processes might thus correspond to the reduction of the solvent complexes or dimers, respectively. From the observation that the reduction wave $E_{R2}$ is dominant in the case of the more basic ligands like bpy, whereas for the good acceptor ligands like bpz or bpm the second electron is accepted predominantly in the more negative



Scheme 4. Proposed mechanism for the electrochemical (E) and chemical reactions (C).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

wave $E_{R3}$, we can assume a higher tendency of the complexes with basic diimine ligands to form dimeric species (30 VE) and a higher preference for the monomer radicals (17 VE) in the case of complexes with good acceptor ligands. Support for this assumption comes from the fact that using dmf instead of thf shifts the equilibrium between monomeric and dimeric species towards the monomeric solvent-stabilised species. At low temperatures the chemical processes are hampered and therefore we can partially observe the second reduction wave of the parent complexes $E_{R3'}$.

### *Oxidation Reactions*

When measured at 298 K the nickel diimine complexes all exhibit irreversible oxidation waves (Tables 1, 2 and 3), which can be attributed to $Ni^{II}/Ni^{III}$ couples. The potentials are quite low and vary according to the expected influence of the chelate ligand. For rather basic ligands like tmphen they occur at the least positive potentials. The bromido mesityl complexes generally show higher potentials than the dimesityl derivatives. The precursor complex $[(PPh_3)_2Ni(Mes)Br]$ exhibits a far higher potential than the corresponding diimine complexes and the Fmes co-ligand shifts the oxidation potentials to higher values. At lower temperatures the dimesitylnickel complexes exhibit some degree of reversibility for the first oxidation wave, which is in agreement with observations for related platinum(II)[33] or palladium(II)[34] complexes where sterically shielding mesityl ligands have allowed the observation of trivalent states. However, the latter exhibit reversible waves already at 298 K, whereas the nickel analogues are not fully reversible even at 213 K. The phosphane complex $[(PPh_3)_2Ni(Mes)Br]$ shows irreversible oxidation behaviour even at 213 K. A remarkable difference is observed for the oxidation waves of the Fmes derivatives. [(bpy)Ni(Fmes)Br] exhibits a fully reversible first oxidation at 243 K and $[(PPh_3)_2Ni(Fmes)Br]$ shows full reversibility at 298 K. Since a stabilisation of the trivalent nickel species for the non-fluorinated derivatives cannot be achieved even with two shielding mesityl groups, we assume that this enhancement is not only due to the better steric shielding by the $CF_3$ groups but also to the electron-withdrawing effect. Furthermore, we assume that C–H activation of the axial methyl groups plays an essential role in the decomposition of the corresponding mesityl derivatives. The superior stability of the $CF_3$ analogues might thus be due to the hampering of this pathway. Future investigations will therefore focus on the follow-up products of these oxidation reactions.

### *Bulk Reductive Electrolysis*

To support the assumptions depicted in Scheme 4 we tried to isolate defined products from solutions of [(bpy)Ni(Mes)Br] in thf/$Bu_4NPF_6$ that had been submitted to bulk electrolysis (see Experimental Section). When the electrolysis was not driven to completeness, the main species isolated was the starting material together with the free bpy ligand as by-product. After exhaustive electrolysis mainly free bpy ligand and traces of the dimesityl complex [(bpy)Ni(Mes)$_2$] were found, as already mentioned above.

### Spectroelectrochemistry

In order to support the above assignments we studied the products of the electrochemical or chemical reactions by controlled electrolyses combined with in situ spectroscopy (UV/Vis/NIR or EPR).

### *Reductive UV/Vis/NIR Spectroelectrochemistry*

Optical spectroscopy was used to study the products generated in situ from the reductive electrochemistry as this should allow us to answer the question whether the chelate ligand or the metal is hosting the odd electron in the reduced species and furthermore help to discriminate between the formation of solvent complexes [(N^N)Ni(Mes)(solv)] or dimers [(N^N)(Mes)Ni–Ni(Mes)(N^N)] and allow us to characterise them. Figures 4, 5 and 6 show some representative spectra, and Tables 4 and 5 summarise the obtained data.

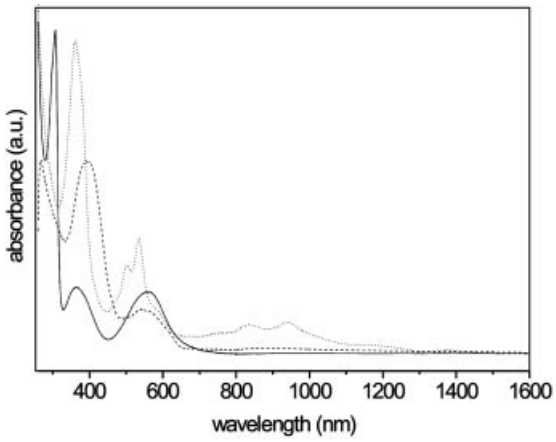


Figure 4. Absorption spectra of $[(bpy)Ni(Mes)_2]^n$ ($n$ = 0: solid line; –1: dotted; –2: dashed) from UV/Vis/NIR spectroelectrochemistry in dmf/$Bu_4NPF_6$ solution. Note that in the last spectrum there is some residual absorption around 900 nm, which is due to an incomplete second reduction.

[a] Generated and measured in dmf/$Bu_4NPF_6$ solution, absorption maxima in nm with extinction coefficients $\varepsilon$ ($\times 1000\ M^{-1}cm^{-1}$) in parentheses.

Figure 4 shows the optical spectra of $[(bpy)Ni(Mes)_2]$ in the parent, singly reduced and doubly reduced state. The long-wavelength absorption bands of the reduced species can be assigned to intra-ligand transition from the singly (or doubly) occupied former LUMO,[23,31] which has been calculated recently to be 96% centred on the bpy ligand,[21] thus clearly showing the mainly bpy-centred character of the reductions. The same assignments can be made for the bpz and tmphen derivatives (see Table 4).

When performing the same spectroelectrochemical experiment for the bromido mesityl derivative (Figure 5 and Table 5) we found that the observed absorption bands of the one-electron-reduced complex were concentration dependent. At high concentrations (about $5 \times 10^{-2}$ M) the spectrum is characterised by a weak broad long-wavelength band around 1300 nm, two medium strong bands around 600 and 350 nm and a very strong band at 300 nm. In dilute solutions ($<10^{-4}$ M) two structured band systems around 900 and 500 nm are visible together with a UV band at around 350 nm. At 1300 nm there is only a very weak residual absorption. Medium concentrated solutions show all the above-described band systems simultaneously. In view of the dimesityl system (Figure 4) and the corresponding spectra of the free ligands,[35] we can ascribe the spectral features of dilute solutions to a species containing a reduced bipyridine ligand and we assume this to be the radical complex $[(bpy^{-})Ni(Mes)(solv)]^{\cdot}$. Apart from the 1300-nm band, the spectra of concentrated solutions resemble those of the starting complex. We tentatively assign this species to the dimer [(bpy)(Mes)Ni–Ni(Mes)(bpy)] since the observed species does not seem to contain a reduced bpy ligand. The 1300-nm band might be ascribed to a transition arising from the nickel–nickel bond (probably a σ–σ* transition).

Furthermore, the spectra exhibit two broad medium-strong bands in the visible and a strong band in the UV region. From comparison with the mononuclear dimesityl and bromido mesityl complexes[21] the first two are assigned to mixed MLCT/L′LCT and the latter to π–π* transitions. Careful inspection of the depicted spectra reveals that all spectra exhibit both of the species in varying amounts, which is in line with the assumed equilibrium in Scheme 4. Comparison of all the studied systems (Table 5) shows that after one-electron reduction the spectra of complexes with more basic diimine ligands preferably show the broad band systems indicative for dimeric species. In the extreme case of the tmphen derivative we assign the spectral features to solely the dimeric species. In contrast to this, for the good π-acceptor ligands bpz or bpm no dimer formation is observed, and instead only the monomeric radical complexes are detected (several structured band systems). Furthermore, in systems where both monomeric and dimeric species are observed we found an influence of the solvent on the equilibrium. In thf solution a higher tendency to form dimeric species is observed, whereas in dmf the monomeric radicals (solvent stabilised) are favoured; this is due to the better donor behaviour of the latter solvent.

Figure 6 shows the addition of a second electron to a solution of [(bpy)Ni(Mes)Br] in dmf. We assume that the starting spectrum represents a mixture of the mononuclear species [(bpy$^{-}$)Ni(Mes)Br]$^{\bullet}$ and the dimer [(bpy)(Mes)Ni–Ni(Mes)(bpy)]. At the potential applied behind the peak $E_{R2}$ the dimer is reduced to form the radical [(bpy$^{-}$)(Mes)-Ni–Ni(Mes)(bpy)]$^{\bullet-}$ whereas the monomeric species does not undergo any change. This consideration is based on the red-shift of the long-wavelength band and the increase of the structured band systems around 500 and 350 nm. The two latter bands are indicative of a mono-reduced bipyridine ligand (in the dimeric complex); no evidence is found for a doubly reduced ligand.

For the good π-acceptor ligands bpz and bpm all spectral features clearly represent the reduced ligand and no long-wavelength band indicative of the dimer formation can be detected. Therefore, we assign the two observed reduction processes to the sequence $E_1$–$C_1$–$C_2$–$E_3$.

### *Oxidative UV/Vis/NIR Spectroelectrochemistry*

Oxidation of the diimine nickel(II) complexes [(N^N)-Ni(Mes)Br] or [(N^N)Ni(Mes)$_2$] leads to rapid decomposition of the complexes at 298 K under the conditions of our spectroelectrochemical experiments, therefore we cannot present any spectroscopic data for the generated trivalent species. Spectroelectrochemical experiments at low temperature might help but are not possible for us at present.

### *EPR Spectroelectrochemistry*

Since many of the proposed species are radicals, EPR spectroscopy should give some evidence for the proposed mechanisms for the reductive electrochemistry. EPR data can also provide conclusive information on the metal or ligand contribution to the singly occupied molecular orbital (SOMO)[20] for species from both reductive and oxidative electrochemistry.

#### *Reductive EPR Spectroelectrochemistry*

The EPR spectra of the anion radicals of the dimesitylnickel complexes [(N^N)Ni(Mes)$_2$]$^{\bullet-}$ all exhibit relatively narrow resonances with hyperfine splitting (HFS) in the range of 0.1–0.5 mT. Such HFS constants are typical for couplings of the unpaired electron to the protons and nitrogen atoms of the diimine ligand. Together with the *g* values, which are close to the free-electron value of 2.0023, this is a strong indication for an almost pure π*(diimine) character of the singly occupied molecular orbital (SOMO). For bpy a simulation of the spectrum gave 0.335 mT for N, 0.408 mT for H5, 0.150 mT for H3, 0.081 mT for H4 and 0.065 mT for H6.[23]

At low temperatures in glassy frozen solutions a rhombic-type spectrum was obtained for [(bpy)Ni(Mes)$_2$]$^{\bullet-}$ with $g_1$ = 2.014, $g_2$ = 2.004 and $g_3$ = 1.996. The averaged value is in agreement with $g_{iso}$ = 2.0049. The small *g* anisotropy ($\Delta g$ = 0.018) is indicative of a quite small metal contribution to the radical anion, in agreement with the $g_{iso}$ and the HFS signal found at 298 K. Therefore, and in agreement with the findings from UV/Vis/NIR spectroelectrochemistry and from previous studies on the frontier orbitals of these complexes,[21] we can conclude that the first reduction of the dimesityl complexes occurs into orbitals with mainly π*(diimine) character. Very similar spectra were obtained for the tmphen and bpz derivatives (Table 6). The corresponding radicals are best described as reduced diimine ligands bound to a nickel(II) centre [(N^N$^{-}$)Ni$^{II}$(Mes)$_2$]$^{\bullet-}$.

The first signal observed during reductive electrolysis of [(bpy)Ni(Mes)Br] in thf/$Bu_4NPF_6$ solution at the first reduction wave is rather narrow, shows partial HFS and has a *g* value of 2.0016 (Figure 7, top). Electrolysis at more negative potential (second wave) first leads to an increase of the intensity of this signal and, after a few minutes, an additional, comparably broad signal appears (Figure 7, bottom left) which lies at far higher *g* (2.140) and does not show any HFS. Measurements of this solution at 110 K (glassy frozen solution) reveal that the high-*g* species now exhibits a rhombic-type spectrum, whereas the low-*g* species remains isotropic and narrow (Figure 8).

Table 6. EPR data from reductive spectroelectrochemistry of dimesitylnickel complexes.[a]

| Complex | *T* [K] | $g_{iso}/g_{av}$ | $g_1$ | $g_2$ | $g_3$ | $\Delta g$ [b] | $\Delta H$ [c] [mT] |

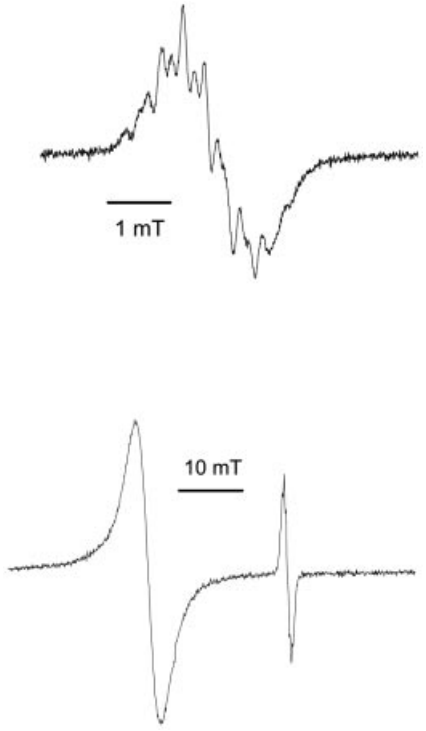

Figure 7. EPR spectra obtained during electrochemical reduction of [(bpy)Ni(Mes)Br] in thf/$Bu_4NPF_6$ at 298 K. Signals obtained upon first (top) and second reduction (bottom).

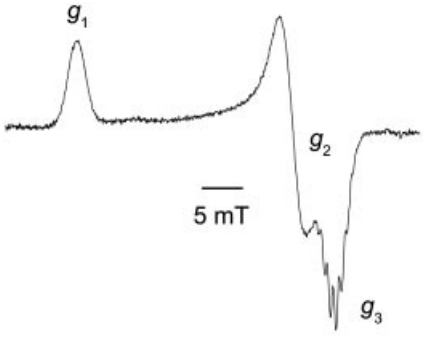

Figure 8. EPR spectrum of a solution obtained at the second reduction wave of [(bpy)Ni(Mes)Br] in thf/$Bu_4NPF_6$, measured at 110 K (glassy frozen solution). The isotropic spectrum (with HFS) of the monomeric complex is overlapping with the $g_3$ component of the main signal (see text and Table 7).

No signal was observed for tmphen at 298 K, although freezing the electrolysed solutions to 110 K allowed the observation of an unresolved narrow signal at $g = 1.9999$ that is comparable to the low-$g$ signal of the bpy derivative. For bpym, bpz, bpm and *i*Pr-DAB we obtained narrow signals with HFS and $g$ values of about 2. For the bpm derivative the solution frozen at 110 K yielded an axial signal with very small $g$ anisotropy. Summarising the data collected in Table 7 we can make the following assignments and conclusions. The signals with $g$ values around the value of the free electron (2.0023) and with detectable HFS were assigned to monomeric nickel(II) complexes containing reduced diimine ligands $[(N\text{^}N^{-})Ni^{II}(Mes)L]^{\cdot}$ (L = Br or solvent). These are the only signals obtained for most of the complexes, which is in line with the observation from UV/Vis/NIR absorption spectroscopy for the good acceptor ligands (vide supra). A second signal was observed for bpy after the reduction at more negative potential, with no HFS, a far higher isotropic $g$ value and a rather high $g$ anisotropy. The two latter parameters point to a far higher nickel contribution to the unpaired electron in this species, which is in line with the assumption that the corresponding species is the proposed dimer in its reduced state $[(bpy^{-})(Mes)Ni^{I}–Ni^{I}(Mes)(bpy)]^{\cdot-}$. For tmphen the observation of such dimeric species would be also expected from the trend of monomer–dimer equilibrium discussed in the electrochemistry section. So far we do not understand the reason why we did not observe any signal at 298 K. At low temperatures we observed only a narrow signal indicative of a monomeric radical.

It is also noteworthy that the EPR results did not give any evidence for the corresponding radicals $[(N\text{^}N^{-})Ni^{II}(Mes)_2]^{\cdot-}$. This confirms our conclusion from the electrochemistry that no large amounts of the dimesityl complexes are formed during reductive electrolysis on the first two reduction waves.

### *Oxidative EPR Spectroelectrochemistry*

As outlined above the UV/Vis/NIR spectroelectrochemical experiments did not allow the observation of nickel(III) species due to rapid decomposition at 298 K. Since the spectroelectrochemical cell used for EPR studies allows electrolysis at lower temperature we tried to study the oxi-

dation process of selected nickel(II) complexes and the generated nickel(III) species by EPR spectroscopy. Although we examined a number of compounds, only the complex *trans*-[$(PPh_3)_2$Ni(Fmes)Br] gave a reasonable EPR signal (Figure 9). This is not unexpected in view of its promising reversible cyclic voltammetric behaviour (Table 3).

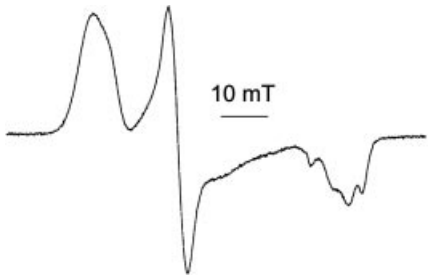

Figure 9. X-band EPR spectrum obtained during electrochemical oxidation of *trans*-[$(PPh_3)_2$Ni(Fmes)Br] in $CH_2Cl_2$/$Bu_4NPF_6$ at 258 K. Measured at 4 K in a glassy frozen solution.

No signal was observed at the corresponding electrolysis temperature of 258 K. At 4 K a rhombic signal (Figure 9) was obtained with very large anisotropy and high averaged $g$ value ($g_1$ = 2.825, $g_2$ = 2.453, $g_3$ = 1.947, $\Delta g$ = 0.878, $g_{av.}$ = 2.435). The $g_3$ component shows a partial HFS of about 5–6 mT and $g_1$ also shows some signs of HFS, whereas the $g_2$ component is sharp and unstructured. In view of the rather high $g$ anisotropy we assign this signal to a radical with a very high nickel contribution to the unpaired electron, and thus to a "real" nickel(III) complex [$(PPh_3)_2Ni^{III}$(Fmes)Br]$^{\cdot+}$ with square-planar geometry, a $d^7$ low-spin configuration and $S$ = 1/2 spin state. There are only very few comparable monomolecular organonickel(III) species reported so far. EPR measurements at low-temperature for the homoleptic complex [$Ni(C_6Cl_5)_4$]$^{\cdot-}$ gave an axial signal with $g_\perp$ = 2.84, $g_\parallel$ = 1.92 and a $g$ anisotropy of 0.92,[36] which is comparable to the value found for our species. For the arylnickel(III) species [(*NCN*)$NiCl_2$], which contains a bis(dimethylamino)phenyl pincer ligand, a $g$ anisotropy of 0.345 has been found.[37] For non-organometallic, formally nickel(III) species the $g$ anisotropy is usually much lower, for example $\Delta g$ = 0.486 for [Ni(emi)]$^-$ [$H_4$emi = *N*,*N*-ethylenebis(2-mercaptoisobutyramide)],[38] $\Delta g$ = 0.372 for the related tetramidonickel complex [Ni(L)]$^{\cdot-}$ ($H_4$L = 6,6-diethyl-3,3,9,9,12,12,14,14-octamethyl-1,4,8,11-tetraazacyclotetradecane-2,5,7,10,13-pentaone; see Scheme 5),[39] or $\Delta g$ = 0.247 for the oxamato complex [Ni(L′)]$^{\cdot-}$ ($H_4$L′ = *N*-[2-(oxalylamino)phenyl]oxalamic acid).[40] Whereas for many species formally described as nickel(III) an appropriate ligand contribution to the unpaired electron from non-innocent ligands such as imines, oxamates or thiolates must be assumed, the [Ni(L)]$^{\cdot-}$ system contains an innocent tetramido ligand, thus an almost pure metal-centred SOMO can be supposed.[39] Comparing its $g$ anisotropy with the values obtained for the two organonickel systems discussed above, it seems that organo ligands lead to distinctly higher $g$ anisotropy and thus highly metal-centred radical states. However, the very small number of examples allows only very tentative conclusions and it would be worthwhile to synthesise further examples of trivalent organonickel complexes.

## Conclusions

Electrochemical reduction of the organometallic nickel(II) complexes [(N^N)Ni(Mes)Br] leads to highly reactive radicals which undergo follow-up chemical reactions. The nature of the products could not be established unambiguously, but strong evidence was found from optical and EPR spectroelectrochemistry that radical solvent complexes [(N^N)NiMes(Solv)]$^{\cdot}$ with a mainly diimine ligand centred SOMO are formed in processes that start with a ligand-centred one-electron reduction, followed by a splitting of the bromide ligand (EC process). Strong evidence for this comes from various electrochemical experiments and comparison with UV/Vis/NIR absorption and EPR spectra of the corresponding dimesityl radical complexes [(N^N)-$Ni(Mes)_2$]$^{\cdot-}$. For both dimesityl and bromido mesityl complexes a description as monovalent nickel species is not appropriate.

In the case of the comparably basic ligands tmphen, dmbpy or bpy additional spectroscopic features were assigned to the formation of dimers [(N^N)(Mes)Ni–Ni-(Mes)(N^N)] with monovalent nickel after the splitting of the bromide ligand. Evidence comes from long-wavelength bands in the corresponding UV/Vis/NIR spectra and from the EPR signals of the corresponding reduced species at more negative potentials (second reduction) with comparably high $g$ values and $g$ anisotropy in the solid state. Unfortunately, attempts to isolate the proposed dimer complexes using preparative electrochemical reduction (bulk electrolysis) have failed so far, which is a pity in view of catalytic applications.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Oxidation of the nickel(II) complexes leads to very short-lived trivalent nickel species that have been characterised by EPR spectroscopy for the perfluorinated complex $[(PPh_3)_2Ni(Fmes)Br]^{\cdot+}$. An almost pure metal-centred character for the SOMO can be concluded from the very high *g* anisotropy of the rhombic signal obtained at 4 K.

Thus, we can add some new evidence to the proposed mechanism for the electrochemical C–C coupling reactions catalysed by nickel diimine complexes. The mechanism has so far been explored in detail up to the catalytically active species [(N^N)Ni(aryl)X]. We can conclude from our work that: i) the assumption of nickel(I) species after the first electrochemical reduction must be corrected towards a mainly diimine ligand centred reduction. Nevertheless, the splitting of the bromide occurs very rapidly, regardless of the character of the SOMO; ii) the diaryl complexes $[(N^N)Ni(aryl)_2]$ are formed in only very small quantities from decomposed material during reductive electrolysis; the formation of nickel(I)–nickel(I) dimers [(N^N)(aryl)Ni–Ni(aryl)(N^N)], which might have an impact on the catalysis, seems to be more important; iii) the proposed monomeric nickel(III) species after oxidative addition of aryl halides have gained some evidence as plausible transient states from our investigations. It seems that organo ligands favour nickel-centred radical states; although this has been demonstrated for a complex containing phosphane instead of diimine ligands. The trivalent diimine nickel species generated upon one-electron oxidation of [(N^N)Ni(Mes)(L)] (L = Mes or Br] are highly unstable even at low temperatures and could not be detected by us.

## Experimental Section

**Instrumentation:** $^1$H NMR spectra were recorded with Bruker Avance300 or AC250 spectrometers. UV/Vis/NIR absorption spectra were recorded with a Bruins Instruments Omega 10 photospectrometer. Cyclic voltammetry and square-wave voltammetry were carried out in 0.1 M $Bu_4NPF_6$ solutions using a three-electrode configuration (glassy-carbon working electrode, Pt counter electrode, Ag/AgCl reference) and a PAR 273 potentiostat and function generator. Half-wave ($E_{1/2}$), anionic ($E_{pa}$) or cationic peak potentials ($E_{pc}$) are given with respect to the ferrocene/ferrocenium couple, which also serves as internal reference. Polarographic measurements were carried out with a PAR Model 263A device. EPR spectra at X-band frequency (ca. 9.5 GHz) were obtained with a Bruker ESP300 spectrometer equipped with a Bruker ER035M gaussmeter and a HP 5350B microwave counter. Spectral simulations were performed with Bruker SimFonia V1.25. UV/Vis/NIR spectroelectrochemical measurements were performed with an optically transparent thin-layer electrode (OTTLE) cell.[41] EPR spectroelectrochemical studies were performed with a platinum two-electrode cell.

**Materials and Procedures:** The preparation of the complex $[(PPh_3)_2Ni(Mes)Br]$ and the diimine complexes [(N^N)Ni(Mes)Br] and $[(N^N)Ni(Mes)_2]$ has been reported recently.[21–23] All preparations and physical measurements in this work were carried out in dry solvents under argon, using Schlenk techniques.

**Preparation of *trans*-[$(PPh_3)_2$Ni(Fmes)Br]:** $NiBr_2$ (218 mg, 1 mmol) was suspended in 200 mL of thf. After addition of $PPh_3$ (524 mg, 2 mmol) the solution turned green. After refluxing for 2 h the reaction mixture was cooled to 298 K and Li(Fmes) (374 mg, 1.3 mmol) in 100 mL of diethyl ether was added. The mixture was stirred for 18 h then 10 mL of aqueous saturated $NH_4Cl$ solution was slowly added to give orange precipitate in the aqueous phase. After separation of the phases and washing the aqueous phase with three 10-mL portions of thf the combined thf solutions were dried with anhydrous $Na_2SO_4$ (1 h) then filtered and the solvents evaporated to dryness. The resulting orange material was recrystallised twice from thf to give red crystals. Yield: 651 mg (0.69 mmol, 69%). $C_{45}H_{32}BrF_9NiP_2$ (944.30): calcd. C 57.24, H 3.42; found C 57.28, H 3.46. $^1$H NMR ([D$_6$]acetone): $\delta$ = 7.9–7.3 (m, 30 H, Ph–P), 7.03 (s, 2 H, Fmes) ppm. $^1$H NMR ($CDCl_3$): $\delta$ = 8.2–7.1 (m, 30 H, Ph–P), 6.93 (s, 2 H, Fmes) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 137.1 ($C^1$–P), 136.4 ($C^1$Fmes), 133.6 ($C^{2,6}$P), 131.5 ($C^4$Fmes), 131.0 ($C^{2,6}$Fmes), 128.6 ($C^4$–P), 128.4 ($C^{3,5}$–P), 125.0 ($C^{3,5}$Fmes) ppm. $^{31}$P NMR ($CDCl_3$): $\delta$ = 15.55 ppm (s). $^{19}$F NMR ($CDCl_3$): $\delta$ = –56.59 (t, $^5J_{P,F}$ = 5.9 Hz, 3 F, *o*-$CF_3$), –63.13 (s, 3 F, *p*-$CF_3$) ppm.

**Preparation of [(bpy)Ni(Fmes)Br]:** The compound was prepared by stirring a solution of *trans*-[$(PPh_3)_2$Ni(Fmes)Br] (110 mg, 0.116 mmol) together with bpy (28 mg, 0.18 mmol) in diethyl ether overnight. After evaporation to dryness, the resulting orange-brown solid was washed with *n*-heptane to remove the $PPh_3$ and excess bpy. It was then recrystallised from acetone to give orange needles. Yield: 57 mg (0.1 mmol, 85%). $C_{19}H_{10}BrF_9N_2Ni$ (575.91): calcd. C 39.63, H 1.75, N 4.87; found C 39.61, H 1.78, N 4.88. $^1$H NMR ([D$_6$]acetone): $\delta$ = 9.07 (d, $^3J_{6,5}$ = 5.62 Hz, 2 H, bpy-H6), 8.42 (d, $^3J_{3,4}$ = 8.1 Hz, 2 H, bpy-H3), 8.40 (d, $^3J_{3',4'}$ = 7.86 Hz, 2 H, bpy-H3′), 8.28 (dd, $^3J_{4,5}$ = 6.23 Hz, 2 H, bpy-H4), 8.25 (dd, $^3J_{4',5'}$ = 5.62 Hz, 2 H, bpy-H4′), 7.80 (s, 2 H, Fmes), 7.75 (ddd, 2 H, bpy-H5), 7.40 (ddd, $^3J_{6',5'}$ = 5.72 Hz, 2 H, bpy-H5′), 7.18 (d, 2 H, bpy-H6′) ppm. $^{19}$F NMR ([D$_6$]acetone): $\delta$ = –58.1 (s, 6 F, *o*-$CF_3$), –62.97 (s, 3 F, *p*-$CF_3$) ppm.

**Bulk Reductive Electrolysis:** Electrolysis experiments were carried out with solutions of [(bpy)Ni(Mes)Br] in thf/$Bu_4NPF_6$ using a Pt grid working electrode (total surface are of about 10 cm$^2$), a Pt counter electrode in a separate compartment (separated by a G4 glass frit) and an Ag/AgCl reference electrode. A PAR 273 potentiostat and function generator served to perform the electrolysis and allowed the control of electrons passed into the solution. Cyclic voltammograms were taken from time to time during the electrolysis and after electrolysis the solutions were evaporated to dryness. $^1$H NMR spectra were either recorded for [D$_6$]acetone solutions of the obtained residues or recrystallised material (from thf/diethyl ether, 1:5).

# The Synthesis, Crystal and Band Structures, and Properties of the Quaternary Supramolecular Complexes $[Hg_6Z_4](MX_6)Hg_y$ (Z = As, Sb; M = Hg, Cd; X = Cl, Br, I; $y$ = 0, 0.5, 0.6)

**Jian-Ping Zou,[a,b] Yan Li,[a] Ming-Lai Fu,[a] Guo-Cong Guo,*[a] Gang Xu,[a] Xue-Hui Liu,[a] Wei-Wei Zhou,[a] and Jin-Shun Huang[a]**

**Keywords:** Density functional calculations / Host–guest systems / Pnictides / Semiconductors / Supramolecular chemistry

The series of supramolecular complexes $(Hg_6As_4)(CdCl_6)Hg_{0.5}$ (**1**), $(Hg_6As_4)(HgCl_6)Hg_{0.5}$ (**2**), $(Hg_6As_4)(CdBr_6)$ (**3**), and $(Hg_6Sb_4)(CdI_6)Hg_{0.6}$ (**4**) has been prepared by a solid-state reaction and their crystal structures determined by single-crystal X-ray diffraction. All these compounds crystallize in the space group $Pa\bar{3}$ with four formula units in a cell: $a$ = 12.172(2) (**1**), 12.189(1) (**2**), 12.3738(5) (**3**), and 13.234(2) Å (**4**). Their structures feature a 3D cationic host framework that is built up of linearly coordinated mercury and tetrahedrally coordinated pnicogen atoms to form distorted $As_2Hg_6$ or $Sb_2Hg_6$ octahedra, and discrete guest anions. The distorted octahedra corner-share with each other to form a perovskite-like, 3D cationic framework that possess two types of closed cavities with different sizes. The octahedral guest anions $(MX_6)^{4-}$ are embedded in the larger cavities, whereas the smaller cavities trap the excess mercury atoms or remain empty. The optical properties were investigated by diffuse reflectance and FT IR spectroscopy. The electronic band structures and density of states (DOS) calculated by DFT methods indicate that the present compounds are semiconductors and that the optical absorption mainly originates from the charge transitions from the p orbital of the pnicogen (As or Sb) and halogen (Cl, Br or I) atoms states to the Hg1 6s states for **1**, **3**, and **4**, and to Hg1 6s and Hg3 6s states for **2**.

## Introduction

The field of inorganic supramolecular chemistry has attracted more and more attention and has experienced enormous growth because it covers a large diversity of compounds that possess a huge variety of crystal and electronic structures and physical and chemical properties.[1] For instance, a broad family of supramolecular assemblies based on mercury pnicogen cationic frameworks has been reported since the 1990s.[2] Among them, the three dimensional host frameworks with positive charges are ordinarily built up of linearly coordinated mercury and tetrahedrally coordinated pnicogen atoms, whereas the guest anions are usually composed of halometalate or monoatomic anions with different shapes and sizes.[3] Two principal types of networks can be distinguished in these compounds according to the dimensions of the voids. The first type are analogues of the well-known Millon's base salts,[4] which are composed of cationic frameworks with the formula $(Hg_2Z)^+$ (Z = P, As) and adopt a tridymite-like topology filled with different tetrahedral anions such as $ZnI_4^{2-}$[3c,3d] or $CdI_4^{2-}$.[3g] The second one is the topology with the formula $(Hg_6Z_4)^{4+}$ (Z = P, As, Sb),[3,5] among which the frameworks possess cavities of two different sizes in close proximity. These are capable of trapping guests of two different types: octahedral guests with the formula $(MX_6)^{4-}$ or $(M'X_6)^{3-}$ (M = divalent metal atoms; M′ = trivalent metal atoms; X = Cl, Br, I)[2b,2c,3] in the bigger cavities and monoatomic guests in the smaller ones. In most cases, the coordination centers of the octahedral guests are trivalent metal atoms rather than divalent metal atoms. Until now, two divalent metals, namely Hg[3b,6] and Fe,[2b] acting as the coordination centers of the octahedral guest anions have been reported, among which only one quaternary supramolecular mercury pnictide halide, $(Hg_4As_6)(FeBr_6)Hg_{0.6}$,[2b] has been characterized.

Recently, we have begun a systematic investigation of mercury pnictide-based mixed-framework compounds to further explore new self-assembly supramolecular materials. The idea is to exploit cationic host framework that have various structures together with different cavities for trapping different guest anions. Because the II–V group compounds have good semiconducting and thermoelectric properties,[7] we have chosen mercury and cadmium in combination with pnicogens in order to obtain new semicon-

ducting compounds with unique physical properties and abundant structural features. Our ongoing research in this field has resulted in some interesting compounds.[2e,3g]

In the present work, with the intention of preparing new quaternary host–guest compounds based on the mercury-pnicogen framework, we selected divalent cadmium cation as the coordination center of the octahedral guest anions and changed the halogen and pnicogen atoms from Cl to I, and P to Sb, respectively. We succeeded in synthesizing a new series of supramolecular complexes, $(Hg_6As_4)(CdCl_6)$-$Hg_{0.5}$ (**1**), $(Hg_6As_4)(HgCl_6)Hg_{0.5}$ (**2**), $(Hg_6As_4)(CdBr_6)$ (**3**), and $(Hg_6Sb_4)(CdI_6)Hg_{0.6}$ (**4**). Herein, we report the syntheses, crystal and band structures, and properties of these new supramolecular inorganic complexes. These band structure and optical and thermal studies are the first to be reported for supramolecular complexes based on mercury pnictide halides, which are also the major interest for us.

## Results and Discussion

The present compounds are all stable in air. Their crystal structures were determined by means of single-crystal X-ray diffraction. All these compounds have a similar structural organization. Their crystal structures feature a 3D cationic host framework and discrete different guest anions. The 3D cationic network is built up of linearly coordinated mercury and tetrahedrally coordinated pnicogen atoms to form distorted $As_2Hg_6$ or $Sb_2Hg_6$ octahedra. The distorted octahedra corner-share with each other to form a perovskite-like 3D cationic framework that possess two types of closed cavities with different sizes (Figure 1).

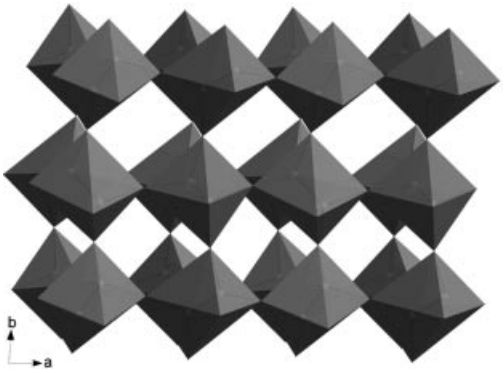

Figure 1. The perovskite-like 3D cationic framework built from corner-sharing distorted octahedra viewed along the *c* axis.

The octahedral guest anions $(CdCl_6)^{4-}$, $(HgCl_6)^{4-}$, and $(CdI_6)^{4-}$ are embedded in the larger cavities of the host framework in **1**, **2**, and **4**, respectively, whereas the smaller cavities trap the excess mercury atoms with 50%, 50%, and 60% site occupancy for **1**, **2**, and **4**, respectively (Figure 2). Partial occupancy of the smaller cavities by mercury atoms has been reported previously in the literature, particularly for $(Hg_6As_4)(HgCl_6)Hg_{0.4}$, which is nearly same as **2** except for the different occupancy of the discrete mercury atom.[2b,3b] Like the ternary compounds $(Hg_6P_4)(HgBr_6)$[3b] and $(Hg_6Sb_4)(HgBr_6)$,[6a] in which the larger cavities of the host framework are filled with the octahedral guest anions $(HgX_6)^{4-}$ with the smaller cavities remaining empty, compound **3** is the first quaternary compound with this structural feature in metal pnictide halides (see Figure S1 in the Supporting Information).

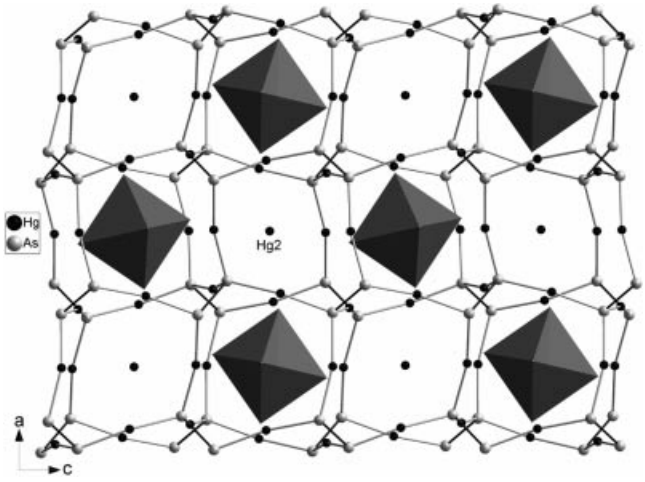

Figure 2. View of the structure of **1**, **2**, and **4** along the *b* axis. The $(CdCl_6)^{4-}$, $(HgCl_6)^{4-}$, and $(CdI_6)^{4-}$ octahedra are drawn in grey.

The Hg1–As, Hg1–Sb, and As–As bond lengths in the cationic moieties in the present compounds range from 2.496(2) to 2.531(2), 2.686(2) to 2.693(2), and 2.389(7) to 2.428(6) Å, respectively, all of which lie in the normal ranges for Hg–Z and As–As bond lengths in known mercury pnictide halides.[2–6] The Sb–Sb bond length of 2.790(5) Å is also in good agreement with those found in various mercury antimonide halides.[3f,6a] The Hg3–Cl [2.70(1) Å] and Cd–X [Cd–Cl 2.636(7), Cd–Br 2.806(3), Cd–I 3.006(2) Å] bond lengths in the guest anions are all close to the those in mercury and cadmium pnictide halides.[2e,2f]

The distances between the hosts and anionic guests in the present compounds are significantly longer than the expected values for covalent bonding, thus suggesting the typical supramolecular interactions between them.[1b] The interatomic distance between the chlorine atoms of the guest anions and the mercury atoms in the host framework range from 2.95 to 3.30, 2.93 to 3.30, 3.02 to 3.28, and 3.20 to 3.58 Å for **1**, **2**, **3**, and **4**, respectively, all of which are much longer than the Hg–X covalent bond lengths but shorter than the sum of the van der Waals radii of Hg and X. Therefore, host–guest supramolecular interactions are present in the crystal structures and these fix the octahedral guest anions to their specific positions so that no positional or rotational disorder is observed. This situation has also been reported in the literature.[2b,2d,2h]

As for the monatomic guests, the discrete mercury atoms have similar environments in **1**, **2**, and **4**. In the first coordination sphere, each Hg atom displays a coordination number of 14 [(6 Hg + 2 As + 6 Cl) in **1** and **2** and (6 Hg + 6 I + 2 Sb) in **4**]. The distances between the hosts and monatomic guests fall in the ranges 3.50–3.68 Å for **1**, 3.55–3.70 Å for **2**, and 3.68–3.92 Å for **4**. With such coordination, the monatomic guests can be regarded as being clath-

rated with an oxidation state of zero, similar to the case found in $(Hg_6As_4)(HgCl_6)Hg_{0.4}$[3b] and $(Hg_6As_4)(FeBr_6)$-$Hg_{0.6}$,[2b] where the zero oxidation state of the guest mercury was confirmed by means of solid-state $^{199}Hg$ NMR spectroscopy.

As shown in Figure 3, the diffuse reflectance spectra of the present compounds reveal the presence of an optical gap of 2.05, 2.01, 1.94, and 1.23 eV for **1**–**4**, respectively, which suggests that the compounds are semiconductors and is consistent with their colors. The bandgaps are shifted to lower energies in the order Cl > Br > I, which is similar to other cases reported in the literature.[8] The bandgap of **4** is close to those of CdTe (1.44 eV), GaAs (1.43 eV), and $CuInS_2$ (1.55 eV), all of which are highly efficient photovoltaic materials.[9] Thus, we suppose that this compound may find a use for the efficient absorption of solar radiation in solar cell applications. The IR spectra of the present compounds show no obvious absorptions in the range of 4000–400 $cm^{-1}$ (see Figures S2–S5 in the Supporting Information) which, in combination with their good thermal stability (see Figure S6–S9 in the Supporting Information), may make them useful as window materials for laser delivery media and infrared transmitters for optical fiber applications in telecommunications.[10]

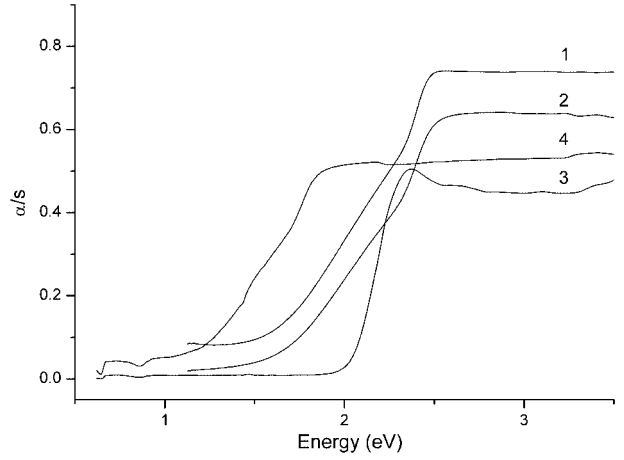

Figure 3. Diffuse reflectance spectra of **1**–**4**.

The calculated band structures of the present compounds along the high symmetry points of the first Brillouin zone are plotted in Figure 4a–d for **1**–**4**, respectively. It can be seen that the valence bands (VBs) and conduction bands (CBs) are both disperse. All four compounds show semiconductor character: the lowest *k*-point of the CBs and the highest *k*-point of the VBs are both localized at the G point and the direct bandgaps are about 1.86, 1.72, and 1.89 eV for **1**–**3**, respectively. For **4**, the lowest *k*-point of the CBs and the highest *k*-point of the VBs are not localized at the same point, which indicates that compound **4** has indirect semiconductor character, with a bandgap of 1.33 eV. The calculated energy gaps for the present compounds are similar to their experimental values. The bands can be assigned according to total and partial densities of states (DOS), as plotted in parts a–d of Figure 5 for **1**–**4**, respectively. In **1**

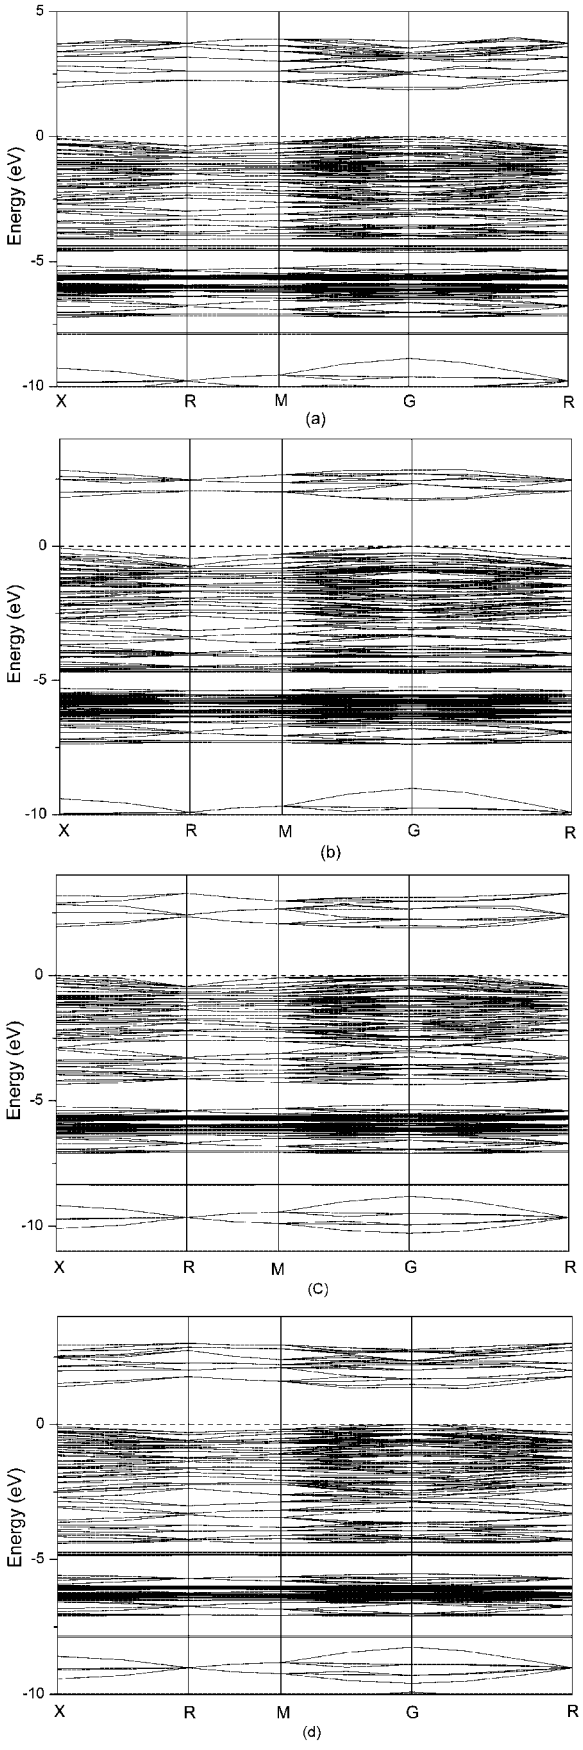

Figure 4. The band structures of **1** (a), **2** (b), **3** (c), and **4** (d). The Fermi level is set at 0 eV.

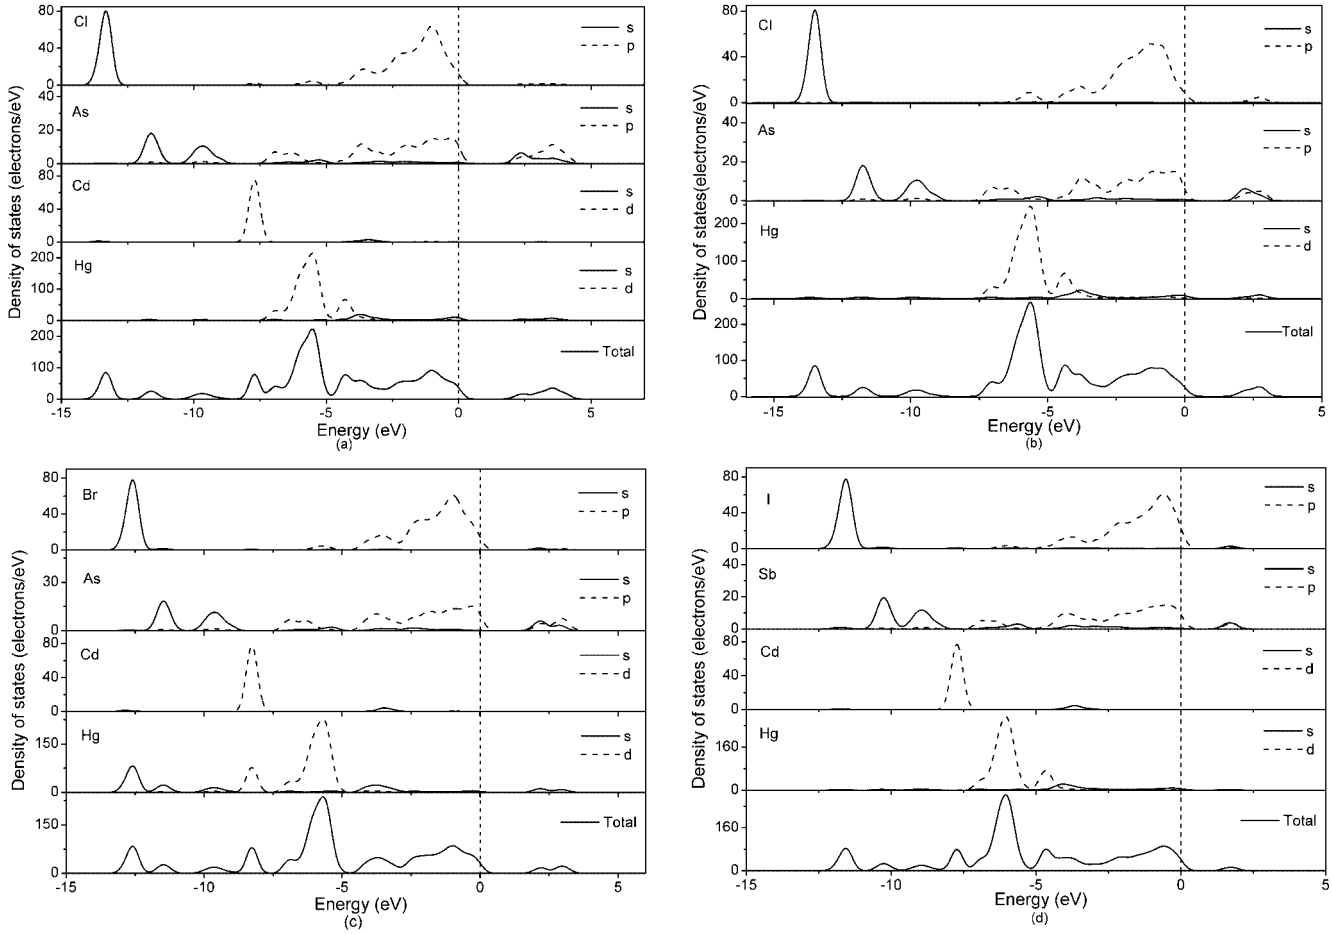

Figure 5. Total and partial density of states for **1** (a), **2** (b), **3** (c), and **4** (d). The Fermi level (vertical dotted line) is set at 0 eV.

and **2**, the VBs between –15.0 and –5.0 eV are mostly formed by the Hg 5d and Cd 4d states mixing with small Cl 3s and As 4s states, and the VBs lying about between –5.0 eV and the Fermi level (0.0 eV) are the main contributions from the Cl 3p and As 4p states mixing with a small amount of Hg 5d state, while the CBs between 1.7 and 5.0 eV are due to the Hg 6s, As 4s, and As 4p states. In addition, comparing the partial DOS of the different types of mercury atoms in **1** and **2** (parts a,b in Figure 6), the DOS of Hg1 6s state is seen to be much higher than that of the Hg2 6s state at the bottom of the CBs in **1**, and the DOS of the Hg1 6s and Hg3 6s states are much higher than that of the Hg2 6s state at the bottom of the CBs in **2**. This shows that electron transitions mostly come from the s orbital of the mercury atoms in the host framework or the octahedral guest anions rather than from the s orbital of the monoatomic mercury to Cl 3p and As 4p states. Therefore, the optical absorption is mainly ascribed to the charge transitions from Cl 3p and As 4p to Hg1 6s states for **1**, and Cl 3p and As 4p to Hg1 6s and Hg3 6s states for **2**.

Similarly, the VBs between –15.0 and –5.0 eV are mostly formed by the Hg 5d and Cd 4d states mixing with small Br 4s, As 4s, and Hg 6s, and I 5s and Sb-5s states for **3** and **4**, respectively. The VBs between –5.0 eV and the Fermi level (0.0 eV) are mostly formed by Br 4p and As 4p states for **3**, and I 5p and Sb 5p states for **4**, hybridized with a small amount of the s orbital of the transition metals, whereas the CBs between 1.3 and 5.0 eV are made from the Hg 6s state mixed with the s and p orbitals of the pnicogen atoms. Thus, it can be concluded that the optical absorption can be mainly assigned to the charge transitions from Br 4p and As 4p to Hg 6s states for **3**. As shown in Figure 6 (c), the partial DOS of the different type of mercury atoms in **4** shows that the DOS of the Hg1 6s state is much higher than that of the Hg2 6s state at the bottom of the CBs, which indicates that the electron transitions arise mostly from the Hg1 6s rather than Hg2 6s to I 5p and Sb 5p states. Therefore, the optical absorption is mainly ascribed to the charge transitions from I 5p and Sb 5p to Hg1 6s.

In addition, we calculated the atomic site and angular momentum projected DOS of the present compounds to elucidate the nature of the electronic band structures and chemical bonds. As shown in Figure 5, we observed that the density and shape of the p orbital of the pnicogen atoms states are similar to that of the Hg 6s state between –5.0 and –2.5 eV, while the DOS of the p orbital of the halogen atoms states are higher than that of the Cd 5s state (Hg 6s state for **2**) for each compound. Accordingly, we can conclude that there are strongly covalent Hg1–As and Hg1–Sb

interactions in the host cations and weakly covalent Cd–Cl, Hg3–Cl, Cd–Br, and Cd–I interactions in the guest anions for **1**–**4**, respectively.

Semi-empirical population analyses allow for a more quantitative bond analyses. The calculated bond orders of **1**–**4** within a unit cell are listed in Table 1; the bond order of a purely covalent single bond is generally 1.0 e. As can be seen, except for the Z–Z bond in **4**, the covalent interactions of the bonds are in the order Hg1–X < M–X < Z–Z < Hg1–Z (M = Hg3 for **2** and Cd for **1**, **3**, **4**) for each compound. This indicates that the covalent interactions of the Hg–Z bonds are stronger than those of the M–X bonds, which is in agreement with the results from the DOS analyses. The Hg1–X bond is the weakest of all four types of bonds, which is consistent with the existence of supramolecular interactions between the host framework and guest anions.

Table 1. Calculated bond orders (e) of **1**–**4** within the unit cell.

## Conclusions

In summary, a series of quaternary supramolecular $[Hg_6Z_4](MX_6)Hg_y$ complexes has been synthesized and structurally characterized. Their main structural feature is that they all consist of discrete guest anions and a perovskite-like 3D cationic framework composed of corner-sharing distorted $As_2Hg_6$ or $Sb_2Hg_6$ octahedra that possesses two types of closed cavities with different sizes. The octahedral guest anions $(MX_6)^{4-}$ are embedded in the larger cavities, while the smaller cavities trap the excess mercury atoms or remain empty. The present compounds, which have a bandgap range of 1.2–2.1 eV and are transparent over a broad range of IR frequencies, may have applications as efficient photovoltaic materials and IR window materials. The calculations of the electronic band structures and density of states (DOS) indicate that their optical absorption mainly originates from the charge transitions from the p orbital of the pnicogen and halogen atoms to the Hg1 6s states for **1**, **3**, and **4**, and to Hg1 6s and Hg3 6s for **2**.

## Experimental Section

**Materials and Measurement:** All chemicals were analytically pure (>99.99%) and used without further purification. The powder X-ray diffraction patterns were collected with a Rigaku DMAX2500 diffractometer at 40 kV and 100 mA for Cu-$K_\alpha$ radiation ($\lambda$ = 1.5406 Å) with a scan speed of 5° per minute at room temperature. The simulated patterns were produced using the Mercury program and single-crystal reflection data. Thermogravimetric analysis (TGA) and differential scanning calorimetry were performed on a Netzsch Sta449C thermoanalyzer under a $N_2$ atmosphere in the range 30–800 °C at a heating rate of 10 °C min$^{-1}$. IR spectra were recorded with a Magna 750 FT-IR spectrometer as KBr pellets in the range 4000–400 cm$^{-1}$. Optical diffuse reflectance spectra were measured with a PE Lambda 35 UV/Vis spectrophotometer for **1** and **2**, and a 900 UV/Vis spectrophotometer for **3** and **4** equipped with an integrating sphere at 293 K, and the $BaSO_4$ plate was used as the reference. The absorption spectra were calculated from reflection spectra by the Kubelka–Munk function:[11] $\alpha/S = (1 - R)^2/2R$, where $\alpha$ is the absorption coefficient, $S$ is the scattering coefficient, which is practically wavelength independent when the particle size is larger than 5 μm, and $R$ is the reflectance. The energy gap was determined as the intersection point between the energy axis at the absorption offset and the line extrapolated from the linear portion of the absorption edge in the $\alpha/S$ vs. $E$ (eV) plot. Microprobe elemental analysis on Hg, Cd, Sb, As, Cl, Br, and I for the present compounds were performed with a field-emission scanning electron microscope (FESEM, JSM6700F) equipped with an energy dispersive X-ray spectroscope (EDS, Oxford INCA).

**Synthesis of $(Hg_6As_4)(CdCl_6)Hg_{0.5}$ (1):** Yellow crystals of **1** were initially prepared by the solid-state reaction of a mixture of $HgCl_2$ (1.5 mmol, 407 mg), Cd (0.5 mmol, 56 mg), $CdCl_2$ (0.5 mmol, 91 mg), and As (1.0 mmol, 75 mg) at 450 °C for 120 h. Microscope element analysis on several single crystals of **1** confirmed the presence of Hg, Cd, As, and Cl in the approximate molar ratio 6.5:1.0:3.9:6.1, which is in good agreement with that obtained from structural analysis. After structural analysis, a yellow crystalline sample of **1** was obtained quantitatively by the reaction of a mixture of $Hg_2Cl_2$, Hg, Cd, and As in a 6:1:2:8 molar ratio at 450 °C for 120 h. The TGA curve of **1** shows no weight change up to 310 °C (see Figure S6 in the Supporting Information). The purity of the yellow crystalline sample was confirmed by XRD powder diffraction (see Figure S10 in the Supporting Information). The powder diagram of **1** shows some splitting of the reflections, which indicates there is a lower symmetry in **1**.

**Synthesis of $(Hg_6As_4)(HgCl_6)Hg_{0.5}$ (2):** Yellow crystals of **2** were initially prepared by the reaction of a mixture of $Hg_2Cl_2$ (1.0 mmol, 472 mg), Cd (0.5 mmol, 56 mg), and As (1.0 mmol, 75 mg) at 320 °C for 120 h in an attempt to obtain the new phase $(Hg_6As_4)(CdCl_6)$. The results of the single-crystal X-ray diffraction analysis indicated the absence of Cd. Microscope element analysis on several single crystals of **2** confirmed the presence of Hg, As, and Cl in the approximate molar ratio 7.4:4.0:5.9, which is in good agreement with that obtained from structural analysis. After structural analysis, a yellow crystalline sample of **2** was then obtained quantitatively by the reaction of a mixture of $Hg_2Cl_2$, Hg, and As in a 6:3:8 molar ratio at 320 °C for 120 h. The TGA curve of **2** shows no weight change up to 320 °C (see Figure S7 in the Supporting Information). The purity of the yellow crystalline sample was confirmed by XRD powder diffraction (see Figure S11 in the Supporting Information). The powder diagram of **2** shows some splitting of the reflections, which indicates there is a lower symmetry in **2**.

**Synthesis of $(Hg_6As_4)(CdBr_6)$ (3):** Red crystals of **3** were prepared by the reaction of a mixture of $HgBr_2$ (1.0 mmol, 361 mg), Cd (0.5 mmol, 56 mg), and As (1.0 mmol, 75 mg) at 350 °C for 120 h. Microscope element analysis on several single crystals of **3** confirmed the presence of Hg, Cd, As, and Br in the approximate molar ratio 5.9:1.0:3.9:5.8, which is in good agreement with that obtained from structural analysis. After structural analysis, a red crystalline sample of **3** was then obtained quantitatively by the reaction of a mixture of $Hg_2Br_2$, Cd, and As in a 3:1:4 molar ratio at 350 °C for 120 h. The TGA curve of **3** shows no weight change up to

280 °C (see Figure S8 in the Supporting Information). The purity of the red crystalline sample was confirmed by XRD powder diffraction (see Figure S12 in the Supporting Information).

**Synthesis of $(Hg_6Sb_4)(CdI_6)Hg_{0.6}$ (4):** Black crystals of **4** were prepared by the reaction of a mixture of $Hg_2I_2$ (0.6 mmol, 393 mg), Cd (0.3 mmol, 34 mg), and Sb (0.9 mmol, 110 mg) at 350 °C for 120 h. Microscope element analysis on several single crystals of **4** confirmed the presence of Hg, Cd, Sb, and I in the approximate molar ratio 6.5:1.0:4.2:6.1, which is in good agreement with that obtained from structural analysis. After structural analysis, a mixture of liquid mercury and a black crystalline sample of **4** was then obtained quantitatively by the reaction of a mixture of $Hg_2I_2$, Hg, Cd, and Sb in a 3:1:1:4 molar ratio at 350 °C for 120 h. The TGA curve of **4** shows no weight change up tol 260 °C (see Figure S9 in the Supporting Information). The purity of the black crystalline sample was confirmed by XRD powder diffraction (see Figure S13 in the Supporting Information).

**X-ray Crystallographic Studies:** Single crystals of **1**–**4** suitable for X-ray analysis were mounted at the apex of a glass fiber for data collection. Data sets for **1**, **2**, and **4** were collected with a Rigaku AFC7R diffractometer, and that for **3** was collected with Rigaku Mercury CCD, both of which were equipped with a graphite-monochromated Mo-$K_\alpha$ radiation source ($\lambda$ = 0.71073 Å) from a rotating anode generator at 293 K. The intensity data were collected with the $\omega$-scan technique and corrected for Lorentz polarization factors. All the structures were solved by direct methods and difference Fourier synthesis and refined by full-matrix least-squares techniques using the Siemens SHELXTL™ version 5 crystallographic software package.[12] All atoms were refined anisotropically. Crystallographic data for **1**–**4** are listed in Table 2 and selected bond lengths and angles are given in Table 3. Further details of the crystal structure investigation can be obtained from the Fachinformationzentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany, on quoting the depository number CSD-417040, -417038, -417039, and -417037 for **1**–**4**, respectively.

**Computational Details:** The X-ray crystallographic data of the present compounds were used to calculate their electronic band structures. The calculations of electronic band structures along with density of states (DOS) were carried out using density functional theory (DFT) with one of the three nonlocal gradient-corrected exchange-correlation functionals (GGA-PBE) and performed with the CASTEP code,[13] which uses a plane wave basis set for the valence electrons and norm-conserving pseudopotential[14] for the core electrons. The number of plane waves included in the basis was determined by a cutoff energy, $E_c$, of 450 eV for **1**, **3**, and **4**, and 400 eV for **2**. Pseudo-atomic calculations were performed for Cl $3s^23p^5$, Br $4s^24p^5$, I $5s^25p^5$, As $4s^24p^3$, Sb $5s^25p^3$, Cd $4d^{10}5s^2$, and Hg $5d^{10}6s^2$. The parameters used in the calculations and convergence criteria were set by the default values of the CASTEP code.[13]

**Supporting Information:** (see also the footnote on the first page of this article): Experimental and simulated powder X-ray diffraction patterns, TG and DTA curves, and IR spectra of compounds **1**–**4**.

# Zinc Thiolate Complexes $[ZnL_n(SR)]^+$ with Azamacrocyclic Ligands, Part III: The Influence of the Ligand $L_n$ on the Reactivity of Zinc-Bound Thiolate[‡]

**Johannes Notni,[a] Wolfgang Günther,[a] and Ernst Anders*[a]**

**Keywords:** Zinc / Sulfur ligands / Kinetics / Density functional calculations / Enzyme models

In this study, we focus on the structure–reactivity relationship of cationic zinc thiolate complexes with the general formula $[Zn(L_n)(SR)]ClO_4$ ($L_n$: *n*-dentate azamacrocyclic ligand; R = phenylmethyl). The complexes feature macrocyclic ligands with ring sizes varying from 11 to 16 atoms and possess three or four nitrogen donors (three of them containing one tertiary nitrogen). Thiol methylations with methyl iodide have been performed in order to determine the relative reactivities, because this reaction has been used before to investigate zinc thiolate reactivity and therefore allows comparison of our results with literature data. The kinetic behaviour was investigated in nitromethane and dichloromethane and was found to be second order in all cases. The observed rate constants vary in the range of $k_2$ = 2.46–55.28×$10^{-3}$ $M^{-1}s^{-1}$ in nitromethane and $k_2$ = 0.23–7.35×$10^{-3}$ $M^{-1}s^{-1}$ in dichloromethane at 300 K. Furthermore, the structures of all thiolate complexes were optimised at the B3LYP/6-311+G(d) level of theory. Natural bond orbital (NBO) analyses were performed to obtain information on partial charges of the heteroatoms and energies of a lone pair in a p-type orbital at the zinc-bound sulfur. In order to elucidate which parameters determine reactivity, selected structural and electronic parameters were correlated with the experimental rate constants. As a result, we found that the reaction is controlled predominantly by frontier orbital energy in dichloromethane and by charge in nitromethane. However, we observed that electronic reactivity control can be overridden by the degree of steric obstruction of the zinc ion, which directly depends on ring size and configuration of the ring nitrogens. The complex $[Zn(cyclen)(SR)]ClO_4$ (**5**) can therefore not be included in any of the correlations; steric constraint imposed by the comparably small ring system causes an extraordinarily increased reactivity. In turn, this finding provides a new rationale for the high reactivity reported for the cyclen complex $[Zn(cyclen)(OH)]^+$, which has been used as a model for carbonic anhydrase in previous studies.

## Introduction

Methylation is of outstanding importance for biosystems.[2] Irregularities in this process are implicated in the development of the most severe diseases such as cancer, cardiac diseases and neural tube defects. Currently, about 150 methyl transferases (EC 2.1.1.*n*) are known, of which approximately 140 use *S*-adenosylmethionine (SAM) as a methyl donor.[3] As the SAM precursor methionine is produced (regenerated) by methylation of the thiol function of homocysteine, thiol-methylating enzymes such as the cobalamine-dependent/independent methionine synthases[4,5] play a crucial role for biological methylation in general. Both require zinc(II) as a cofactor. Other thiol-alkylating enzymes that also feature a zinc centre in their catalytic domain are the Ada DNA repair protein,[6] farnesyl transferase,[7] methanol-CoM-methyltransferase[8] and betaine-homocysteine *S*-methyltransferase.[9]

The biological importance of the reactions catalysed by these enzymes led to the development of a variety of zinc(II) complexes as functional model compounds in order to gain better understanding of the reaction mechanism. They all feature at least one zinc-thiolate linkage and one or more additional ligands that are responsible for the overall charge of the complex and the reactivity of the thiolate ligand. For a long time, the mechanism of methylation has been subject to debate. Two substantially different reaction modes have been proposed: an attack of free thiolate after prior dissociation of the complex, and an associative mechanism that includes a four-centre transition structure. The first path would show a first-order kinetic behaviour and the latter is expected to be second-order. However, the observed kinetic behaviour cannot finally prove a proposed mechanism because of possible perturbation effects, which could influence the observed reaction order. In the following, a brief survey of selected important studies on this subject is given.

Wilker and Lippard employed the dianionic tetrathiolate $[Zn(SPh)_4]^{2-}$ as a functional model for Ada.[10] They found that methylation of the complex by $(MeO)_3PO$ yielded

PhSMe and postulated a dissociative reaction mechanism. This seems particularly plausible as the reaction was carried out in a polar solvent, thus facilitating the dissociation of the thiolate from the highly charged complex anion. Vahrenkamp et al. studied the methylation of tris(pyrazolyl)-boratozinc(II) thiolates $Tp^{R,R}ZnSR$ in chloroform. Investigation of the kinetics provided strong evidence that these reactions occur intramolecularly, featuring a four-centre transition structure.[11–13] A similar conclusion has been drawn by Carrano et al., who investigated the methylation of a series of scorpionate zinc thiolates.[14–16] Darensbourg et al. studied alkylations of a zinc complex with a bis-thiolate $[N_2S_2]^{2-}$ chelate ligand.[17] They also obtained the thioether derivatives, but did not discuss the mechanism. Riordan and co-workers investigated the reactivity of zinc thiolates with a borato ligand,[18] focusing in particular on the influence of additional hydrogen bonds to the thiolate.[19] They found that hydrogen bonding considerably lowers the nucleophilicity of the thiolates. Similar to the results by Vahrenkamp et al., an associative mechanism is proposed because of the observed second-order kinetic behaviour of the reactions. However, in a recent contribution by Vahrenkamp and co-workers, which covers a comparison of methylation rates of zinc thiolates with $N_3$, $N_2S$, $NS_2$ and $S_3$ tripod ligands, evidence is given that a "sulfur-rich" coordination environment is likely to promote a dissociative mechanism.[20]

In all preceding studies of complexes $[ZnL_nSR]$, much attention is paid to the influence of the reactive thiolate ligand on alkylation mechanism and reactivity, or their dependence on different N/S ligations of the zinc ion. In contrast, we focus exclusively on *N*-ligated zinc thiolates. Our interest lies mainly in the coordination geometry and electronic properties of the complexes as reactivity-determining factors. Thus, we address the following questions: What is the actual contribution of $L_n$ to the nucleophilicity of a given thiolate ligand? Is it possible to derive a quantitative relation between structure and reactivity? Which, if any, structural and/or electronic parameters are suitable for the prediction of reactivity?

Recently, we introduced a series of novel zinc thiolate complexes[1] that are ideally suited for these investigations for several reasons: 11 different compounds meeting the experimental requirements are currently available; they feature both $N_3S$ and $N_4S$ coordination environments for zinc(II); all compounds are fully characterised by X-ray crystallography; they are insensitive to the influence of air and moisture; reactions with electrophiles (e.g., methyl iodide, benzyl bromide, acetyl and benzoyl chloride, and carbon disulfide[21]) were found to occur cleanly and on a convenient time scale; they comprise a sufficiently small number of non-hydrogen atoms to be suited for investigation by high-level density functional calculations. The latter instance offers the possibility to reveal the effect especially of electronic parameters that are only accessible by computation, for example, orbital energies and partial charges. This discloses a lot of new perspectives for the interpretation of the reactivity of such complexes.

## Results and Discussion

### Starting Materials

The alkylation experiments were performed using a series of 11 zinc(II) thiolate complexes with azamacrocyclic ligands of the general formula $[ZnL_n(S–CH_2–C_6H_5)]ClO_4$ (see Figure 1, Table 1). Their syntheses and structures have been reported in detail before.[1] They contain 11–16-membered azamacrocycles with three (**1**–**4**) and four (**5**–**11**) secondary nitrogen donors. In three of them, namely compounds **2**, **4** and **9**, one tertiary nitrogen is incorporated.

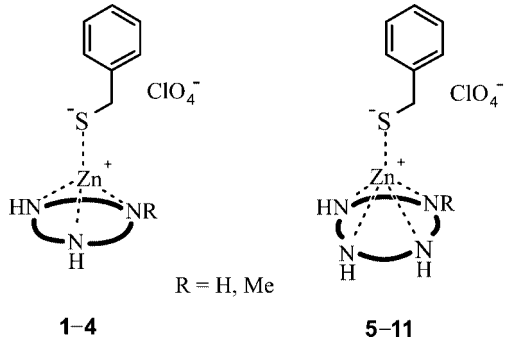

Figure 1. Generic structures of compounds **1**–**11**. Bold lines indicate alkyl bridges.

Table 1. Macrocyclic ligands of complexes **1**–**11**, with the general formula $[ZnL_n(S–CH_2–C_6H_5)]ClO_4$.

| Compound | $L_n$ abbreviated names | $L_n$ IUPAC names |
|---|---|---|
| **1** | [11]aneN$_3$ | 1,4,8-triazacycloundecane |
| **2** | methyl-[11]aneN$_3$ | 8-methyl-1,4,8-triazacycloundecane |
| **3** | [12]aneN$_3$ | 1,5,9-triazacyclododecane |
| **4** | methyl-[12]aneN$_3$ | 1-methyl-1,5,9-triazacyclododecane |
| **5** | [12]aneN$_4$ (cyclen) | 1,4,7,10-tetraazacyclododecane |
| **6** | [13]aneN$_4$ | 1,4,7,11-tetraazacyclotridecane |
| **7** | [14]aneN$_4$ (cyclam) | 1,4,8,11-tetraazacyclotetradecane |
| **8** | *i*[14]aneN$_4$ (*iso*-cyclam) | 1,4,7,11-tetraazacyclotetradecane |
| **9** | methyl-*i*[14]aneN$_4$ | 11-methyl-1,4,7,11-tetraazacyclotetradecane |
| **10** | [15]aneN$_4$ | 1,4,8,12-tetraazacyclopentadecane |
| **11** | [16]aneN$_4$ | 1,5,9,13-tetraazacyclohexadecane |

### Methylation Kinetics

For the determination of the reactivities we used the standard model reaction, methylation with methyl iodide, which yielded the corresponding iodide complexes and phenyl methyl sulfide [Equation (1)].

$$[ZnL_n(SCH_2Ph)]^+ + MeI \rightarrow [ZnL_nI]^+ + MeSCH_2Ph \quad (1)$$

At 300 K, the reactions come to completion within times of hours up to several days. No evidence for the formation of any byproducts was detected. Reaction monitoring could thus easily be performed using NMR spectroscopy. However, this required sufficiently concentrated solutions (0.02 M). In this respect, the varying solubilities of the model complexes proved to be a problem, as rate constants are only suited for direct comparison in case reactions are carried out in the same solvent. We initially intended to investigate the methylation in a nonpolar solvent in order to rule out a dissociative reaction mechanism. This was found to be unfeasible as only five compounds were soluble in chloroform and seven in dichloromethane. However, the semipolar solvent nitromethane could be used for all complexes. Second-order kinetic behaviour was observed in each case (with correlation coefficients of $R^2 > 0.99$ for all fit curves), thus indicating only associated reactions as proposed previously. In this work, we focus on kinetic data obtained from reactions in [$D_3$]nitromethane and [$D_2$]-dichloromethane solution.

Table 2 shows the experimentally determined second-order rate constants of methylation according to Equation 1. As expected, in the more polar solvent nitromethane the reactions proceed several times faster. The factor of acceleration by the solvent varies by about 3 for compound **11** and about 21 for **4**. We currently cannot give an explanation for this remarkable difference. However, the observed rate constants exhibit an even more pronounced dependence on the nature of the azamacrocycle. The fastest reaction in nitromethane was observed for complex **5**, which reacted more than 22 times faster than its slowest competitor, compound **2**. This effect is even more pronounced in dichloromethane; complex **11** reacts faster than **4** by a factor of 32. Because compound **5** is insoluble in this solvent, these data are of limited significance. Hence, a straightforward comparison of the two data sets is not possible in this way.

Table 2. Second-order rate constants of the methylation of compounds **1**–**11** at 300 K. Values are given in $10^{-3}$ $M^{-1}$ $s^{-1}$.

| Compound | In $CD_3NO_2$ | In $CD_2Cl_2$ |
|---|---|---|
| **1** | 4.71 | – |
| **2** | 2.46 | 0.28 |
| **3** | 7.05 | – |
| **4** | 4.92 | 0.23 |
| **5** | 55.28 | – |
| **6** | 29.03 | – |
| **7** | 21.60 | 1.52 |
| **8** | 13.93 | 1.00 |
| **9** | 8.66 | 0.53 |
| **10** | 16.69 | 2.81 |
| **11** | 23.12 | 7.35 |

A more expressive representation is given in Figure 2. It shows a comparison of the rate constants of all complexes that could be measured in both solvents. Again it is obvious that the absolute acceleration factor by a more polar solvent is not constant. Rather, a trend is reproduced, and compound **7** is the single exception. An explanation could be the following: The macrocycle cyclam ([14]aneN$_4$), which is featured in complex **7**, forms particularly stable tetracoordinate zinc complexes. The ring size of 14 atoms and the configuration of the *N*-bound hydrogen atoms in the complex enable the placement of the zinc ion in the plane of the four nitrogens[22] (a structural representation of **7** is given in the literature[1]). In the case of other ligands, a displacement is rather unavoidable. This renders the Zn–S bond of **7** less stable than in the other compounds regarded in this study. A similar conclusion can also be drawn from the mass spectra of the complexes.[1] In a polar solvent such as nitromethane, the Zn–S bond of **7** is weakened above average (without an actual dissociation taking place) and the reaction receives particular acceleration. Thus we conclude that the observed order of reaction rates obviously arises from a superposition of ligand and solvent control, but the macrocyclic ligand has the predominant influence on the reactivity of the thiolate. In addition, we found that the complexes with a tertiary nitrogen (**2**, **4** and **9**) exhibit a slightly reduced rate constant (by about 30–50%) compared to the analogue compounds without the methyl groups (**1**, **3** and **8**, respectively; see Table 2). The effect can be observed for both solvents.

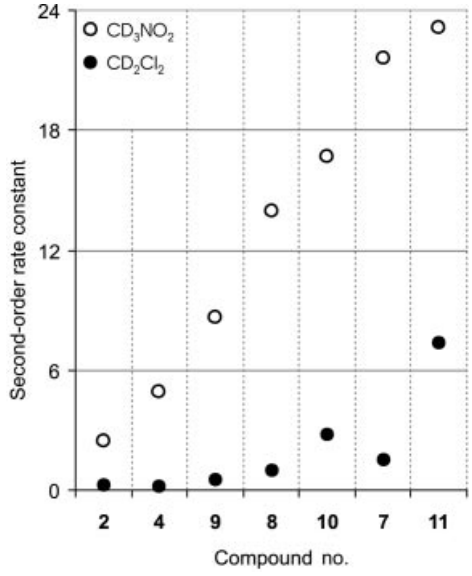

Figure 2. Comparison of second-order rate constants (given in $10^{-3}$ $M^{-1}$ $s^{-1}$) of the reactions with methyl iodide in $CD_2Cl_2$ and $CD_3NO_2$. Only the data of compounds that are soluble in both solvents are plotted.

### Density Functional Calculations

Different methods can be applied to obtain structural information, such as spectroscopy, computation or X-ray crystallography. However, the structural information pro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vided by the latter is only of restricted use for the interpretation of processes in solution. In most cases, spectroscopical methods can be applied to solutions as well, but the structural information it provides is restricted to certain parameters and of limited generality. The search for parameters suitable to correlate to the experimentally determined reaction rates requires detailed information on the nature of the zinc–sulfur bond and the electronic properties of the sulfur atom that is not accessible by either spectroscopy or crystallography. Thus, quantum mechanical calculation is the method of choice to obtain structural and electronic data for correlation purposes. A comparable approach has been successfully applied by Halfen, Brunold et al., who investigated the electronic structure of 4-methylphenylthiolate and some transition-metal complexes thereof by density functional calculations in order to obtain an explanation for the observed nucleophilicities.[23]

An investigation that provided an accurate description of the observed reactivities would require more than gas-phase optimisations of the starting material complexes. Rather, a calculation of the transition state of the nucleophilic attack, including the modelling of solvent effects, had to be performed for the methylation reaction of every single compound. However, such calculations would by far push the boundary of the currently available computational resources. In addition, all our previous attempts to locate the transition states failed because of the extremely flat potential energy hypersurface. Thus, only gas-phase structures could be calculated at a sufficient level of theory, that is, one that includes polarised and diffuse functions, which are necessary for the correct description of coordination compounds. We were thus searching for a simple but effective means of characterising the observed reactivities using only the available structural and electronic data derived from gas-phase calculations. At least, we do not expect problems concerning the geometries obtained. According to our own experience, in the case of azamacrocycle-zinc(II) complexes, there are generally only minute differences between the structures obtained by calculations in the gas phase and in the presence of solvents.

We decided to use density functional theory because it is also applicable to larger molecules. All structures were optimised in the gas phase at the B3LYP/6-311+G(d) level of theory, with the molecular structures derived from X-ray diffraction[1] as starting geometries. The experimental and computational structures are in reasonable accordance. As expected, minor deviations in bond lengths and differences in the conformations (e.g., rotations about the Zn–S bond) were observed. Natural bond orbital (NBO)[24] analyses were performed for all structures to obtain information on orbital energies and partial charges on the metal and the heteroatoms. The energy of a specific lone pair orbital at the sulfur atom was determined, the reason for this being the following: In a previous study, it has been shown that a zinc-bound oxygen atom in complexes $[LZn–OH]^+$ possesses three lone pairs: two of sp hybridisation and one of pure p characteristic.[25] The latter one is the orbital with the highest energy, and because of its orientation, it is responsible for nucleophilic attack. A higher energy implicates a smaller energy gap between this orbital and the LUMO of an electrophilic substrate, thus facilitating orbital interaction and lowering transition-state energy. A comparable configuration was found for the zinc thiolate complexes. There are three localised orbitals at the zinc-bound sulfur atom, two with sp and one with a pure (>99%) p character, which also possesses the highest energy. Its strictly localised character has been proven for all structures regarded in this study. No significant overlap with other orbitals that would indicate multicentre bonding could be detected. It is thus reasonable to assume that the energy of this "localised HOMO" could be a controlling factor for the nucleophilic reactivity.

## Correlations

In the following consideration, we focus on possible correlations of computed parameters with the experimentally determined rate constants. We thus refer to three parameters based on gas-phase calculations that are likely to correlate with thiolate reactivity: the Zn–S bond length, the S atom partial charge and the above-mentioned S lone pair orbital energy.

As the Zn–S bond length reflects how tightly the thiolate is bound and how much its reactivity is lowered by zinc(II) complexation, one would expect it to be a good measure for reactivity. Figure 3 depicts the result, the rate constants of methylation plotted against the computed Zn–S bond lengths. There is apparently only a very loose correlation, which is certainly not sufficient for a quantitative description of reactivity. (Two points that correspond to compounds **5** and **6** are highlighted by means of square shaping in this and other charts; this is of importance and will be explained below.)

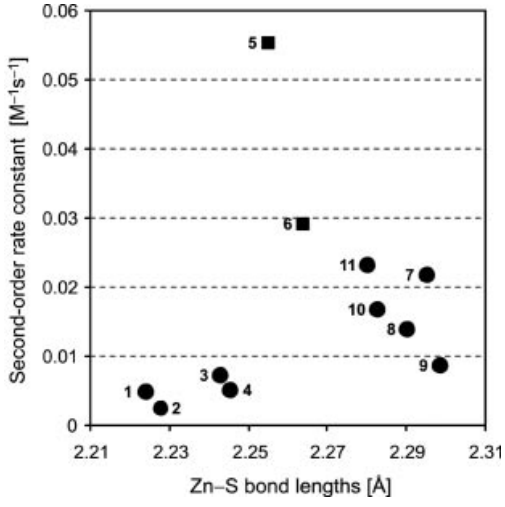

Figure 3. Second-order rate constants of thiolate methylation, plotted against the Zn–S bond lengths; solvent: nitromethane.

A much more promising situation is found for the plots of the sulfur's partial charge (see Figure 4). The data points for the reaction in nitromethane (with exception of **5** and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**6**) are found on a steady curve. In principle, this allows a prediction of reactivity: A larger absolute value of partial charge implicates an increased nucleophilic reactivity. The line that indicates this dependency is a spline curve, simply chosen by an obviously visible regularity of the data points. Of course, its existence does not permit any conclusions beyond the fact that there is a systematic relation between the two parameters regarded. It is also obvious that in the less polar solvent dichloromethane, such a correlation does not exist.

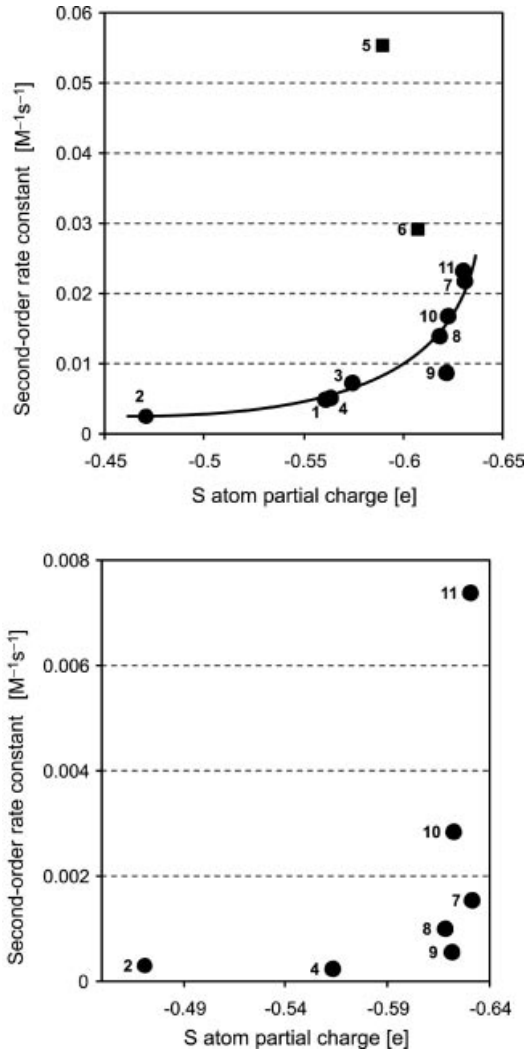

Figure 4. Second-order rate constants of thiolate methylation, plotted against partial charges of the sulfur atom. Upper diagram: solvent nitromethane; lower diagram: solvent dichloromethane.

The energy of the *p*-type lone pair seems to be a good measure for thiolate reactivity in both solvents (although again two exceptions, **5** and **6**, are encountered). As can be seen in Figure 5, the regularity is more pronounced in dichloromethane. The LP energy is the only parameter that allows a correlation with the rate constants for this solvent at all.

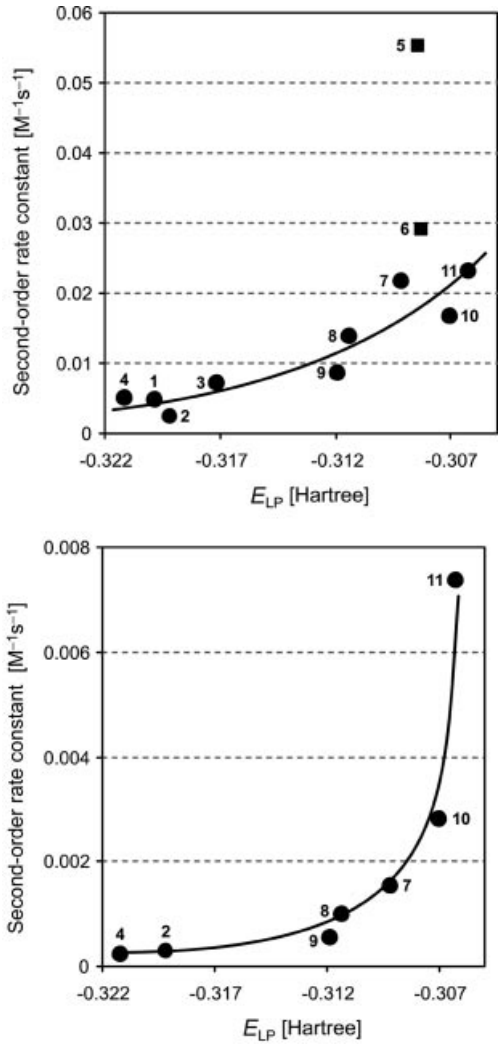

Figure 5. Second-order rate constants of thiolate methylation, plotted against energies of the sulfur's *p*-type lone pair. Upper diagram: solvent nitromethane; lower diagram: solvent dichloromethane.

All these findings allow some interesting conclusions: (1) Justifying solely from structural parameters (bond lengths), it is not possible to draw conclusions regarding the reactivity; one has to employ other sources of data, such as quantum mechanical calculation. (2) Obviously, the reaction can be biased towards charge or orbital control, depending on the polarity of the solvent. In nitromethane, both parameters (partial charge and orbital energy) are useful to describe the reactivity; in dichloromethane, the reaction is predominantly orbital-controlled. (3) The observed regularities include both $N_3S$ and $N_4S$ systems. The concept is obviously not restricted to a specific coordination environment of zinc(II) but is apparently valid for zinc thiolates in general.

However, we would like to emphasise that the correlations discussed herein are not supported by any equations or a stringent theory. This would of course not be permissible, as the results of gas-phase calculations are used in combination with data obtained from experiments in solu-

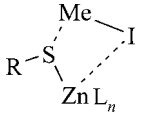
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tion. Notwithstanding this background, some fundamental conclusions can be drawn, as will be demonstrated in the following.

### Steric Influences

Until now, we have not discussed the rate constants obtained for compounds **5** and **6**, which are indicated by squares in Figure 3, Figure 4 and Figure 5 (a structural representation of their calculated geometries is given in Figure 7, see below). Their reactivities differ significantly from those of the other complexes. They exhibit the largest rate constants whilst showing only average values for the structural and electronic parameters. Thus, we conclude that reactivity is also controlled by another important factor.

Regarding the reaction mechanism, we share the predominant viewpoint from the literature, the assumption that the methylation reaction involves an attack of the zinc-bound thiolate and features a four-centre intermediate (Scheme 1).[12–15,26,27] In this case, the methylation (as well as any other reaction) is restricted to occur at the thiolate side of the complex cation. As the coordination of the reacting molecules to $Zn^{II}$ implicates a steric demand, the degree of obstruction of the zinc(II) ion by the macrocycle should have a pivotal influence on the geometry of the transition state.



Scheme 1. Assumed four-centred transition state of the methylation of zinc-bound thiolate.

In case of planar chelate ligands, the degree of surface obstruction of a metal ion caused by complexation can easily be characterised by the bite angle; in case the ligand's donor atoms and the metal ion form a four-sided pyramid, one rather has to consider the solid angle at the Zn vertex. It is usually given in steradian [*sr*] and represents a measure for the extent to which the zinc ion is displaced out of the plane (or near-plane) of the four N atoms. In theory, values can vary between 0 *sr* (for infinite Zn–N distance) and 2π *sr* (for in-plane location of $Zn^{2+}$).[28] The results of these considerations are summarised in Figure 6, which also shows calotte model representations in order to illustrate the varying degree of steric demand of the macrocyclic ligands.

With regard to the comparably small solid angle of 0.95π *sr* associated to compound **5**, it is obvious that its coordination geometry can be assessed as being quite distorted in comparison to the other $N_4Zn$ systems (Figure 7). The calotte model drawings also show that the zinc ion in **5** is a lot more exposed. However, in the case of compound **6**, the solid angle is comparable to other $N_4$ complexes. As the corresponding calotte drawing still indicates a substantial degree of exposition of the metal ion, there is apparently another structural factor that affects the steric situation: the

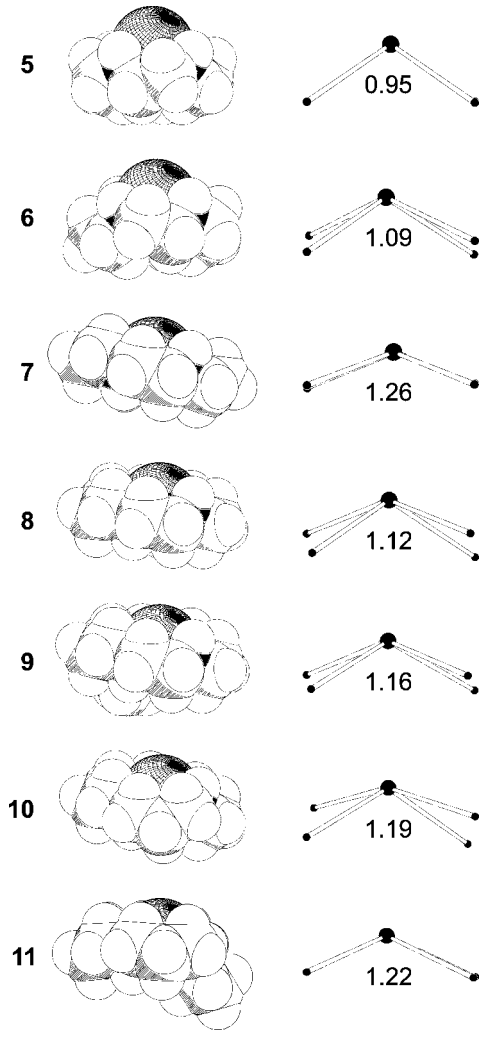


Figure 6. Left column: calotte model drawings of the cations of compounds **5**–**11**, thiolate ligands omitted. Right column: $N_4Zn$ coordination polyhedra and solid angles at the Zn vertex [π *sr*] of the same molecules; the perspective of vision corresponds to the drawings in the left column. All representations are derived from the calculated structures (see computational details).

configuration of the nitrogen atoms of the macrocycle. (In a previously published study, we discussed this aspect in detail, and structural representations of complexes **1**–**11** are given therein.[1]) Of the $N_4$ systems **5**–**11**, compounds **5** and **6** are the only examples in which all *N*-bound hydrogen atoms are located at the thiolate side [the (+)-side] of the molecule [the so-called (+ + + +)-configuration, see also Figure 7]. This characteristic accessorily accounts for a smaller degree of steric hindrance, as a hydrogen atom on the (+)-side obstructs the zinc(II) ion to a lesser extent than an alkyl bridge.

As a result of a superposition of both the ring size and configuration effects, complex **5** exhibits a markedly superior reactivity, while the just slightly increased reactivity of compound **6** is mainly based on the all-(+) configuration of the macrocycle. Moreover, a plausible mechanistic interpretation can be given for this acceleration: Given a more exposed zinc(II) ion, formation of a four-centred transition

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

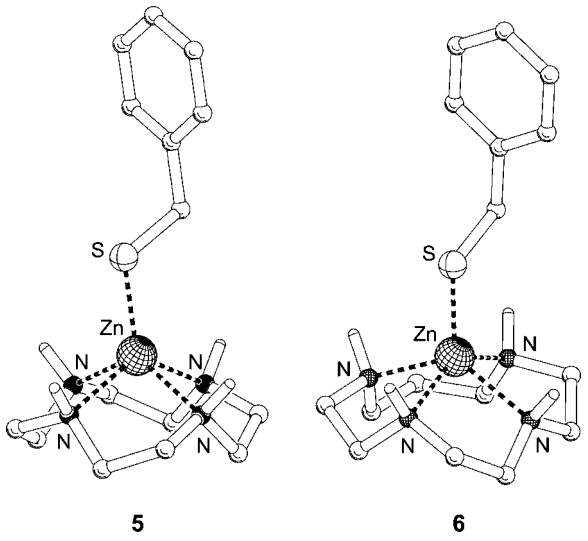

Figure 7. Structures of compounds **5** and **6**, calculated at the B3LYP/6-311+G(d) level of theory. Hydrogen atoms on carbon atoms are omitted for clarity of presentation. Note the good correlation of the values of the critical Zn–S bond lengths obtained by experimental and DFT calculation [for **5**: exp. 2.266(2) Å, calcd. 2.25 Å; for **6**: exp. 2.2853(9) Å, calcd. 2.26 Å].

state is facilitated rather than in the case of highly obstructed zinc(II), as illustrated in Figure 8. The latter would promote the formation of a more linear transition state that entails separation of the resulting iodide anion from the cationic centre, thus leading to a higher energy barrier for the overall reaction. Nevertheless, we do not expect this difference to amount to more than a couple of kilocalories per mole. However, as a small decrease of transition-state energy of 1.5 kcal mol$^{-1}$ already results in an increase of reaction velocity of about one order of magnitude, this allows for a sound explanation of the observed differences in reaction velocity.

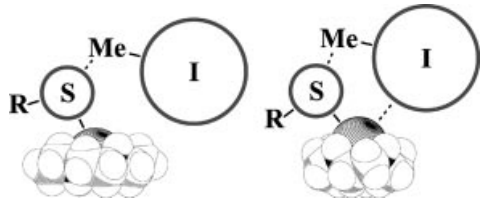

Figure 8. Illustration of possible differences in transition-state geometries for the nucleophilic attack of zinc-bound thiolate on methyl iodide. As examples, calotte model drawings of the $ZnL_n$ moieties of **7** (left) and **5** (right) were utilised. Ion radii of S and I are not exactly fitted to the ion radii of the calotte models.

## Conclusions

### General Remarks

The thiolate complexes have proven to be suitable functional models for thiolate-methylating enzymes. As expected, a clean second-order methylation reaction was found. The observed acceleration of the reaction in a polar environment comes as no surprise; neither do the general results concerning charge and orbital control in the different solvent systems. Similar observations have been reported by many other work groups (see above). However, an important improvement provided by our work is the presented way of analysing experimental reactivity data by correlation to electronic parameters obtained from gas-phase density functional calculations. It enabled us to elucidate to what extent certain geometry factors can influence reactivity and override electronic and/or orbital control. With regard to the rapidly increasing availability of computing power, this technique could generally prove to be a valuable tool in exploring structure–reactivity relationships and catalyst tailoring. However, we are aware that our procedure is only a coarse approximation. As mentioned above, an exact treatment of the subject would require DFT calculations of the transition states of the methyl iodide reactions for all investigated complexes, a task that we found to be unfeasible. We believe, however, that even though our approach is quite coarse, it provides interesting insight into the chemistry of nucleophilic cationic complexes.

### Implications Concerning CA Model Compounds

The unexpected reactivities of compounds **5** and **6** (Figure 7) allow some additional conclusions of high interest. Although it may not seem that this work relates to the enzyme carbonic anhydrase (CA), it nevertheless provides fundamentally enhanced insight into the chemistry of CA model compounds.

Carbonic anhydrases (CA) are a family of zinc enzymes that accelerate the reversible hydration of $CO_2$ by a factor of up to $10^7$ as compared to the uncatalysed reaction.[29,30] The catalytic domain consists of a zinc(II) ion that is bound to three histidine residues and bears an additional water molecule or hydroxide ligand (dependent from pH). The properties of this structural motif have been elucidated using a variety of monodentate zinc hydroxide complexes.[31–35] In addition, numerous experimental[36–38] and computational studies provided detailed insight into the reaction mechanism.[39–42]

In 1995, van Eldik and co-workers[43] published a study addressing the reaction rates of several functional CA model complexes of the general formula $[ZnL_n(OH)]^+$ with $CO_2$, according to Equation (2).

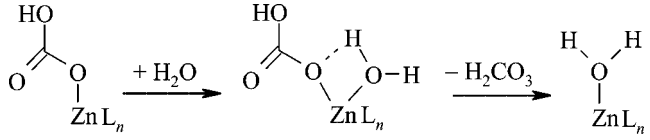
$$[ZnL_n(OH)]^+ + CO_2 \leftrightarrows [ZnL_n(OCO_2H)]^+ \quad (2)$$

They investigated complexes of various chelate ligands $L_n$, of which two macrocycles with four nitrogen donors are of particular interest. One is 14-membered (comparable to the ligand in compound **8**), and the other is cyclen as in compound **5**. They found that the $CO_2$ hydration velocity of the latter exceeds that observed for the first by a factor of approximately 15. However, no explanation for this remarkable variation is given. With regard to the results of the present work, we would like to propose a rationale for these observations, as, because of the close structural relationship of the ligands, we assume the steric situation for

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

those hydroxo complexes is comparable to compounds **8** and **5**, respectively.

In a previous study, some of us have shown that the aquation of zinc hydrogencarbonato complexes involves an intramolecular proton transfer as depicted in Scheme 2.[42] It involves the initial coordination of a water ligand to the zinc centre, which then protonates the hydrogen carbonate. Subsequently, carbonic acid is expelled (which, under normal conditions, will immediately be deprotonated in the reaction medium) and the hydroxo complex $[ZnL_n(OH)]^+$ is obtained. In the course of this mechanism, only uncharged molecules dissociate from the metal centre. However, with an increasing steric demand of the chelate ligand, the aquation may as well afford a preliminary dissociation of hydrogen carbonate, followed by addition of water, which is subsequently deprotonated. This dissociative reaction pathway necessarily includes a separation of electrical charges, which is very likely to result in an increased reaction barrier. In practice, one will normally encounter hybrid forms of both idealised mechanism types that are more or less biased to one side. We thus assume, by analogy with the results of the present work, that in the case of aquation of the two hydrogencarbonato complexes, the exposed placement of the zinc ion in the cyclen complex is much more likely to promote the associated reaction mechanism, thereby lowering the reaction barrier and increasing the aquation rate. We therefore conclude that the unique combination of properties united by the zinc(II) complexes of the ligand cyclen, that is, a small solid angle of the coordination polyhedron *and* the all-(+) configuration of the *N*-bound hydrogen atoms, results in an extraordinarily increased reactivity of additional monodentate ligands.



Scheme 2. Calculated mechanism of the aquation of zinc(II) hydrogencarbonato complexes.[41]

## Experimental Section

**General:** The thiolate complexes were prepared according to our published procedure.[1] Deuterated solvents were obtained from eurisotop. NMR spectra were recorded with a BRUKER AC 400 spectrometer at a temperature of 300 K.

**Methylation Kinetics:** The complex (0.1 mmol) was dissolved in deuterated solvent (5 mL) ($CD_2Cl_2$ or $CD_3NO_2$). Methyl iodide (0.1 mmol) was added with a microlitre syringe. After short stirring, a sample of the solution was placed in a sealable NMR tube and inserted into the spectrometer. $^1$H NMR spectra were recorded every 30 min for dichloromethane and every 15 min for nitromethane solutions. For determination of the rate constants of nitromethane solutions of **6**, **7** and **10**, the decreasing integral of the methyl peak of methyliodide was utilised. For all other measurements, the signals assigned to benzylic protons of the zinc-bound thiolate were used for integration. In all cases, the integral of all aromatic peaks was taken as a reference, as it was assumed to be constant. Thus, concentration data for kinetic analysis could be obtained directly from the standardised integral values. Under the condition that the reaction proceeds according to Equation (1) and the reactants are present in equal concentrations, a special case of a second-order kinetic law can be applied [Equation (3)].

$$1/c - 1/c_0 = k_2 t \quad (3)$$

In this equation, $c_0$ represents the initial concentration of any reactant and $c$ is the concentration of any reactant at a given time $t$. Accordingly, the obtained concentration data were plotted against $t$ and a linear function was obtained by regression analysis. Linear correlations were found in all cases, exhibiting correlation coefficients of $R > 0.995$. The second-order rate constants were obtained from the slopes of these fit functions.

**Computational Details:** Full geometry optimisations, that is, without constraints, were carried out using the Gaussian98[44] program package (Rev. A11/4). All optimisations were performed using the hybrid B3LYP[45] density functional method, which includes the use of a term that accounts for the effect of dynamic electron correlation (Coulomb hole).[46] Geometries were optimised in the gas phase using the standard 6-311+G(d) basis set. All structures were rigorously characterised as true minima. NBO analyses[24,47] were carried out using version 5.0 of the NBO program[48] as patched in Gaussian 98. A search for three-centre, four-electron hyperbonds using the keyword 3CHB yielded no evidence of nonlocalised orbitals. The partial charges of the heteroatoms were obtained by natural population analysis. Orbital energies were taken from the Natural Bond Orbital Summary Table.

**Supporting Information** (see also the footnote on the first page of this article): Mathematical details on calculation of the solid angle, a table with absolute energies (SCF energies, $\Delta U$, $\Delta G$) and cartesian coordinates in *xyz* format of all computed structures are given.

## Acknowledgments

Financial support of this work by the Deutsche Forschungsgemeinschaft, SFB 436 "Metal Mediated Reactions Modeled after Nature" is gratefully acknowledged. We particularly thank Prof. Dr. M. Westerhausen (FSU Jena) for an enlightening discussion, Dr. Stephan Schenk (ETH Zürich) for his advice concerning computational problems, and Steffen Kluge (FSU Jena) for his assistance in mathematics.

# Syntheses, Properties and Structures of $[\{(C_5Me_5)_2Nb\}_2NiTe_4]$ and $[(tBuC_5H_4Nb)_2Ni_5Te_7(Ph_2PCH_2PPh_2)_2]$: The Quest for Tetratelluronickelate Clusters

**Martin Brandl,[a] Alexander Ebner,[a] Marek M. Kubicki,[b] Yves Mugnier,[b] Joachim Wachter,*[a] Estelle Vigier-Juteau,[b] and Manfred Zabel[a]**

**Keywords:** Niobium / Nickel / Tellurium / Electrochemistry / Density functional calculations

The reaction of $[Ni(COD)_2]$ with $[Cp^*_2NbTe_2H]$ (**1**; $Cp^*$ = $\eta$-$C_5Me_5$) in the presence of $Ph_2PCH_2PPh_2$ (dppm) in boiling toluene gives black-violet $[(Cp^*_2Nb)_2NiTe_4]$ (**3**). If $[Cp'_2NbTe_2H]$ (**2**; Cp′ = $tBuC_5H_4$) is used under similar conditions dark-brown $[(Cp'Nb)_2Ni_5Te_7(dppm)_2]$ (**4**) is formed. The structures of **3** and **4** have been determined crystallographically. Complex **3** contains a severely distorted $NiTe_4$ tetrahedron to which two niobocene groups are coordinated. Density functional analysis of the electronic structure of the $NiTe_4$ building block shows that it is best described as an $[Ni(\eta^2\text{-}Te_2)_2]^{2-}$ fragment. The structure of **4** reveals the presence of two $Ni_5$ and $Te_5$ tetragonal pyramids stacked into each other in an opposite way. Six of the Te bridges form two triangular faces, each of which is capped by a Cp′Nb fragment. Additionally, two dppm ligands bridge the long Ni–Ni edges of the $Ni_4$ bases. Oxidation of **3** with $[(C_5H_5)_2Fe]BPh_4$ gives paramagnetic $[(Cp^*_2Nb)_2NiTe_4]BPh_4$ (**6**), whereas oxidation with $[(C_5H_5)_2Fe]PF_6$ proceeds with fluoride transfer to give $[Cp^*_2NbF_2]PF_6$ (**5**). Electrochemical studies of **3** reveal the existence of the redox couples $[\mathbf{3}]^{2+}/[\mathbf{3}]^{+}/[\mathbf{3}]^{0}/[\mathbf{3}]^{-}/[\mathbf{3}]^{2-}$. Density functional calculations carried out on the different oxidation states of **3** reveal the following main features: the persistent presence of Nb–Ni bonds and the retention of Te–Te bonds in cationic and neutral species and their breaking off in reduced forms. Irrespective of the initial site of electrochemical attack, the Te atoms and Cp rings are principally affected in the final products.

## Introduction

The idea of employing tetrachalcogeno metallate anions $[MX_4]^{2-}$ as ligands for the synthesis of heterodimetallic chalcogenido clusters was first elaborated by Müller et al. with M = V, Mo, and W and X = S and Se.[1] Such compounds are of interest as building blocks in extended structures that possess nonlinear optical properties.[2] Little is known about telluro metallates with coordination number four, however.[3] Whereas bis(niobocene)tetrathio and -seleno metallates of formula $[(Cp^*_2Nb)_2MX_4]$ (M = Cr, Mo, Fe, Co; X = S, Se) are easily formed in the reaction between $[Cp^*_2NbE_2H]$ derivatives and the corresponding metal carbonyls,[4,5] $[\{(Cp'_2Nb)_2WTe_4\}W(CO)_4]$ has been synthesised only recently from $W(CO)_6$ and $[Cp'_2NbTe_2H]$ (**2**; Cp′ = $tBuC_5H_4$). This complex contains the hitherto unknown $[WTe_4]^{2-}$ moiety.[6] The versatile abilities of $[Cp^*_2NbTe_2H]$ (**1**) and **2** to serve as tellurium transfer reagents towards transition metal carbonyls has already been reviewed.[7] In this work, we report on the reactions of **1** and **2** with $[Ni(COD)_2]$ in the presence of $Ph_2PCH_2PPh_2$ (dppm). The structures and properties of the mixed early-late transition metal telluride clusters obtained are investigated and the electronic structure of the hitherto elusive $NiTe_4$ structural moiety is investigated in a theoretical study.

## Results and Discussion

### Syntheses, Properties and Structural Characterisation

Addition of **1** to a yellow solution of $[Ni(COD)_2]$ and half an equivalent of dppm in toluene at room temperature results in an immediate darkening. Attempts to isolate a well-defined product from this solution failed. After refluxing the solution for 18 h black-violet $[(Cp^*_2Nb)_2NiTe_4]$ (**3**) was isolated in 20% yield after chromatographic work-up. The analogous reaction of **2** with $[Ni(COD)_2]$/dppm in boiling toluene gave brown crystals of $[(Cp'Nb)_2Ni_5Te_7(dppm)_2]$ (**4**) after filtration and cooling to –24 °C in a total yield of 11%.

The field desorption (FD) mass spectrum of **3** exhibits the parent ion along with another peak at *m*/*z* 619 (intensity ratio 3:10), which may be attributed to the $[Cp^*_2NbTe_2]$ fragment. The composition of compound **3** is in agreement

with the elemental analysis. The $^1$H NMR spectrum of **3** shows a singlet at $\delta$ = 1.89 ppm ($C_6D_6$) for the $C_5Me_5$ rings. Complex **4** was characterised by means of elemental analysis, FD-MS, and X-ray crystallography. The FD mass spectrum shows the molecular peak of **4** after focussing the scan range at 2380 ± 50 amu. This was necessary to avoid decomposition during routine registration and to increase the sensitivity of the detector (Figure 1). No satisfactory NMR spectra were obtained because of the low solubility of the cluster.

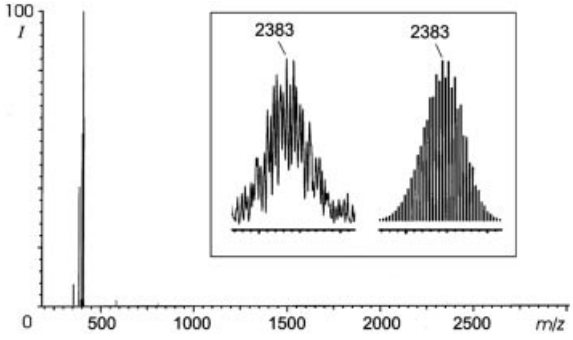

Figure 1. FD mass spectrum of **2** in $CH_2Cl_2$ (scan range up to 3000 amu). The inset shows the experimental (left) and simulated (right) spectra for a scan range of M ± 50 amu.

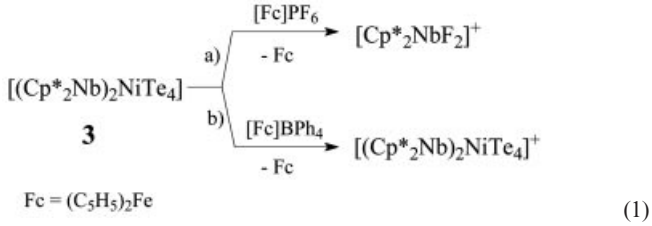
Oxidation of **3** with excess $[(C_5H_5)_2Fe]PF_6$ in thf gave yellow $[Cp^*_2NbF_2]PF_6$ (**5**) [Equation (1), path a] according to the FD mass spectrum and elemental analysis. The closely related salt $[(C_5Me_4Et)_2NbF_2]PF_6$ has been prepared previously from $[(C_5Me_4Et)_2NbCl_2]$ by reduction with Na/Hg and subsequent reaction with $HPF_6$.[8] Similar fluoride-transfer reactions from hexafluorophosphate anion to reactive niobocene derivatives are known.[8,9]



(1)

Reaction of **3** with $[(C_5H_5)_2Fe]BPh_4$, which contains the large and non-coordinating tetraphenylborate anion, was therefore attempted. Black-green $[(Cp^*_2Nb)_2NiTe_4]BPh_4$ (**6**) was formed in 37% yield in thf at room temperature [Equation (1), path b]. The composition was determined by elemental analysis and ESI-MS. The $^1$H NMR spectrum exhibits a broad singlet at $\delta$ = 11.15 ppm, which is in agreement with the expected paramagnetic nature of the new compound. Three multiplets at $\delta$ = 7.31, 7.03, and 6.88 ppm may be assigned to the tetraphenylborate anion. Attempts to measure an ESR signal were not successful due to a delocalisation of the unpaired electron over the trimetallic core including the telluride bridges (see below). Unfortunately, single crystals of **6** could not be obtained either.

In another experiment we tried to methylate the Te bridges of **3** with MeI, but $[Cp^*_2NbI_2]$ was obtained as the only product. This means that the lone pairs of the Te bridges are less accessible for methyl electrophilic attack than those in the dinuclear complex $[Cp'_4Nb_2(\mu\text{-}Te)_2]$, which gives $[Cp'_4Nb_2(\mu\text{-}CH_3Te)_2]^{2+}$ upon methylation.[10]

### *Structure of [Cp*$_4$Nb$_2$NiTe$_4$] (3)*

Compound **3** crystallises as monoclinic black rods. Its molecular structure contains a distorted $NiTe_4$ tetrahedron to which two mutually perpendicular niobocene units are coordinated (Figure 2). Thus, complex **3** is one of the extremely rare coordination compounds incorporating an $MTe_4$ structural unit and is the first tetratelluronickelate derivative. Another example of a tetratelluro metallate complex is $[(Cp'_2Nb)_2WTe_4{\cdot}W(CO)_4]$,[6] in which a central $WTe_4$ tetrahedron is surrounded by two niobocene fragments. Interestingly, tetrathionickelates like $[Ni(MoS_4)_2]$[11] and $[Ni(WS_4)_2]$[1] prefer a square-planar arrangement of the sulfur ligands around $Ni^{2+}$.

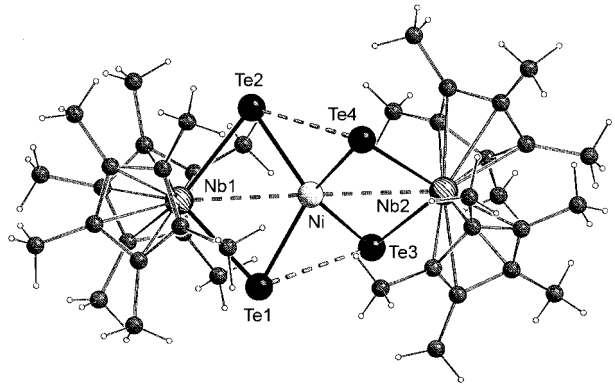


Figure 2. Structure of $[(Cp^*_2Nb)_2NiTe_4]$ (**3**). Selected bond lengths [Å] and angles [°]: Ni–Te 2.470(1)–2.481(1), Nb–Te 2.757(1)–2.766(1), Te1–Te3 3.122(1), Te2–Te4 3.201(1), Ni···Nb1 3.100(4), Ni···Nb2 3.147(4), Te1···Te2 4.212(1), Te3···Te4 4.169(1); Te1–Nb1–Te2 99.2(1), Te1–Ni–Te2 116.4(1), Te1–Ni–Te3 78.2(1), Te2–Ni–Te4 80.5(1), Te1–Ni–Te4 138.2(1), Nb1–Ni–Nb2 178.6(1).

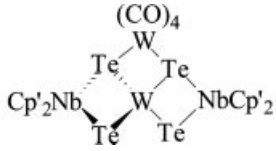
The core of the molecule is characterised by a nearly linear Nb–Ni–Nb arrangement. The Ni–Te distances range from 2.467(1) to 2.481(1) Å and the Nb–Te distances are between 2.757(1) and 2.774(1) Å (see Table S1 in the Supporting Information). The Te–Te distances around Ni merit a more detailed discussion. Taking into account that two $NbTe_2Ni$ rings are linked together by nickel one may distinguish sets of two short and four long Te–Te distances. The latter range between 4.190 and 4.632 Å and are typical of nonbonding intra- and interannular interactions. However, it is striking that the short distances (mean: 3.161 Å) are found between (interannular) Te1 and Te3 and Te2 and Te4 of two different rings.

The geometrical parameters found in both $Cp'_2NbTe_2$ moieties of **3** differ considerably from those observed in $[Cp'_2Nb(Te_2)H{\cdot}Cr(CO)_5]$.[10] The Te–Nb–Te angle in this compound is contracted to 55.4(1)° and the distance of 2.695(1) Å corresponds well to those reported for side-on terminal $\eta^2$-$Te_2$ ligands in mononuclear complexes for which a Te–Te bond order of between 1 and 2 has been suggested.[12]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The Te–Te distances considered as bonding interactions in a series of complexes comprising the $NiTe_2Ni$ unit vary from 2.802(1) Å in $[\{(triphos)Ni\}_2(\mu\text{-}Te)_2]$[13] to 3.052(5) Å in $[\{(C_5H_iPr_4)Ni\}_2(\mu\text{-}Te)_2]$[14] and even up to 3.28 Å in $[\{CpNi\}_2(\mu_3\text{-}Te)_2\{Ni(PPh_3)Cp\}_2]$.[15] Consequently, the short interannular Te–Te distances observed close to 3.161 Å in the structure of **3** may be considered as long single Te–Te bonds. The question of coupling of two Te atoms coming from two different fragments (interannular) through $Ni^{2+}$ will be discussed in the calculations section below.



### *Structure of [(Cp′Nb)$_2$Ni$_5$Te$_7$(dppm)$_2$] (4)*

Compound **4** crystallises directly from the filtered reaction mixture as dark prisms. The molecular structure contains a tetragonal pyramid of five nickel atoms at its centre, the basal plane of which is formed by two short (av. 2.637 Å) and two long (av. 3.540 Å) Ni–Ni linkages (Figure 3, Table 1). Six edges of the nickel pyramid are bridged by Te ligands such that they form two triangular faces that serve as tridentate chelate ligands for the coordination of both niobium centres (Figure 4). Another tellurium ligand (Te1) bridges the nickel base in a $\mu_4$-fashion and thus serves as the top of a tetragonal $Te_5$ pyramid which is inverted with respect to the $Ni_5$ pyramid. The molecule is completed by two dppm ligands that bridge the long Ni–Ni edges of the rectangular nickel base. The axial phenyl rings of these ligands are arranged in two parallel pairs. The loss of one of the $t$BuC$_5$H$_4$ ligands from the niobocene unit in this reaction is not new as it has been observed previously during the thermal conversion of $[(Cp'_2NbS_2)_2(\mu\text{-}S_5)]$ into $[Cp'_3Nb_3S_{12}]$.[16]

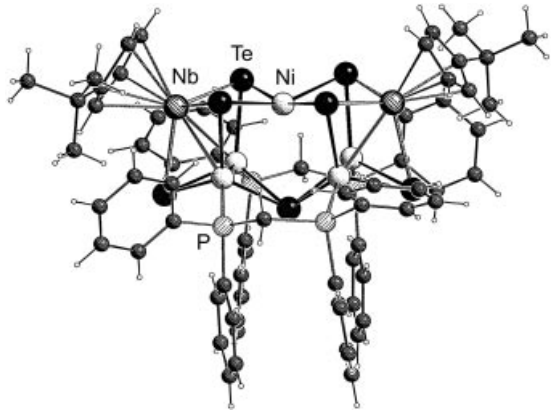


Figure 3. Structure of $[(Cp'Nb)_2Ni_5Te_7(dppm)_2]$ (**4**).

The combination of niobium and nickel atoms together in a polymetallic architecture such as that in **4** is, to the best of our knowledge, unique. The structural motif of the tetragonal d$^{10}$-metal pyramid is extremely rare; it has been realised previously only in $[Pd_5Se_5(PPh_3)_5]$[17] and $[Ni_5S_4(CH_3CO_2)(PPh_3)_5]^+$.[18]

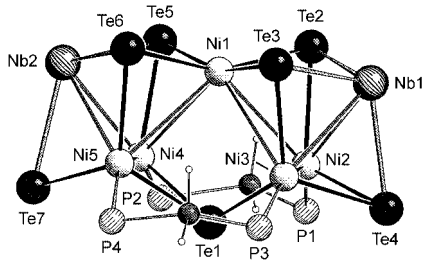

Figure 4. The $Nb_2Ni_5Te_7(P_2CH_2)_2$ core of **4** with labelling scheme.

The cluster core of **4** contains three different ranges of Ni–Ni distances around 2.64 (Ni2–Ni3, Ni4–Ni5), 2.80 (Ni1–Ni2–5), and 3.53 (Ni2–Ni4, Ni3–Ni5) Å. A wide range of Ni–Ni distances (2.49–2.87 Å) of more or less bonding character has been described in the literature, for example in $Ni_{10}$ and $Ni_{11}$ polyhedra.[19] Due to the small covalent radius of nickel (1.15 Å), no bonding interactions are to be expected between Ni2–Ni4 and Ni3–Ni5. On the other hand, the Ni–Nb distances (2.80 Å mean) may be short enough to exhibit a bonding character. Consequently, considering six Ni–Ni and four Ni–Nb metal–metal contacts, each metal centre formally fulfils the 18-electron rule,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

although a delocalised bonding situation may be envisaged. Density functional calculations are planned in order to elucidate the electronic structure within the cluster core.

### Electrochemical Investigations

The trimetallic sulfido and selenido compounds $[(Cp^*_2Nb)_2MX_4]$ are distinguished by a pronounced redox activity.[4,5] Therefore, and in order to understand the chemical oxidation of **3** by ferricinium salts (see above), we examined the electrochemical behaviour of **3** and **6** in thf solution by rotating disk electrode (RDE) voltammetry, cyclic voltammetry and electrolysis.

The RDE voltammogram of **3** (thf/$NBu_4PF_6$) exhibits two oxidation waves E′ ($E_{1/2}$ = –0.22 V) and F′ ($E_{1/2}$ = +0.420 V) and three reduction waves A, B, and C (–1.61, –2.12 and –2.25 V, respectively). The heights of waves E′, F′, A and B are nearly equal, whereas wave C is twice as high as B (Figure 5).

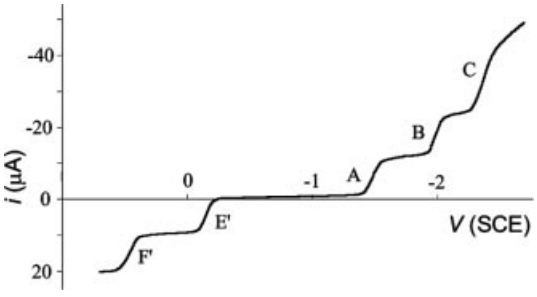

Figure 5. RDE voltammogram of **3** (thf/$NBu_4PF_6$) at a carbon electrode vs. SCE.

Three reversible systems A/A′, E/E′ and F/F′ are observed at room temperature by cyclic voltammetry (Figure 6). The current ratio $i_{p,a}/i_{p,c}$ for each system is equal to unity (or very close to it) for sweep rates $v$ between 20 and 200 mV s$^{-1}$ and the peak current increases linearly with $v^{1/2}$. The half-wave potential scan rate and the peak shape are characterised by $|E_{p,a} - E_{p,c}| \approx 60$ mV, in agreement with a one-electron transfer controlled by diffusion.[20,21]

Peak B is not reversible at room temperature and an oxidation peak appears at –1.74 V during the anodic scan. At 0 °C a low reversibility (system B/B′) is observed and the intensity of peak B′ increases with the scan rate. These results indicate that the species electrogenerated by one- ($[\mathbf{3}]^+$) or two-electron oxidation ($[\mathbf{3}]^{2+}$) and one-electron reduction ($[\mathbf{3}]^-$) are stable, whereas the product obtained by two-electron reduction ($[\mathbf{3}]^{2-}$) is relatively unstable.

Electrolysis at –1.8 V (plateau of wave A) consumes more than one electron equivalent. After reduction with two electrons the RDE voltammogram of the resulting solution shows the reduction waves A and B and the oxidation waves A′, E′ and F′ (Figure 7, b). After reduction with two and a half electrons wave A decreases and oxidation wave A′ increases (Figure 7, c). It is interesting to note that waves F′, A, A′ and B are nearly as high as the corresponding initial waves, whereas wave E′ is higher. No ESR signal is detected during the electrolysis. The solution shows a slow evolution towards partial regeneration of **3** from $[\mathbf{3}]^-$ upon standing under argon. This means that wave A increases while wave A′ decreases and the height of oxidation wave E′ grows considerably (Figure 7, d). It is still unclear why the formation of $[\mathbf{3}]^-$ consumes more than 1 F. It may well be that this reduction concerns one of the Nb atoms, which means that the anionic charge can be transferred by an intramolecular process to a ligand atom (probably tellurium). Consequently, subsequent oxidation at the potential of wave E′ may give rise to an increase of the height of the concerned oxidation wave.

When oxidative electrolysis is performed at –0.1 V (plateau of wave E′) the current drops to zero after a quantity of electricity of 0.2 F. The RDE voltammogram shows oxidation wave F′ and reduction waves E, A and B (Figure 8). Whereas these waves are in agreement with the formation of the cation $[\mathbf{3}]^+$, two additional reduction waves $E_1$ and $A_1$ are observed at –0.86 and –1.86 V, respectively. A similar result has been obtained in $CH_2Cl_2$/$NBu_4PF_6$ solution. Under these conditions, 0.2 F was consumed and a 0.2-V shift to more negative potentials is observed for all waves.

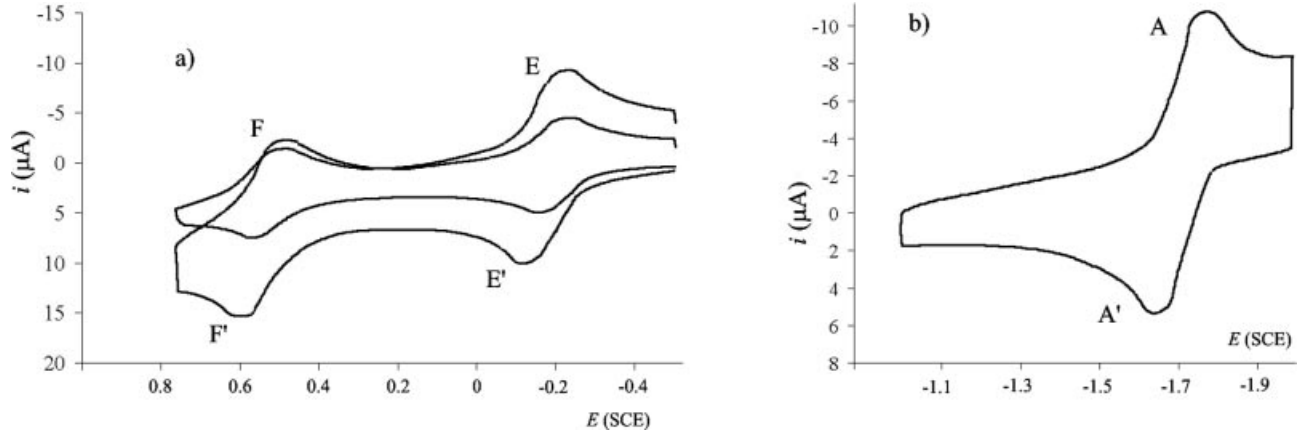

Figure 6. Cyclic voltammogram of **3** (thf/$NBu_4PF_6$): a) starting potential: –0.5 V; sweep rate: 20 and 100 mV s$^{-1}$; b) starting potential: –1 V; sweep rate: 50 mV s$^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

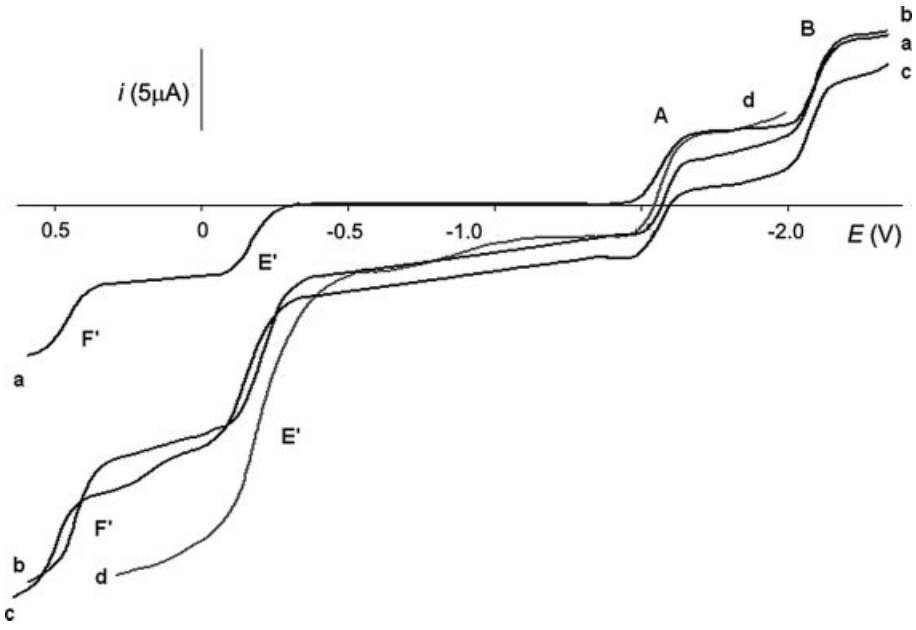

Figure 7. RDE voltammogram of **3** (thf/$NBu_4PF_6$): a) before electrolysis; b) after two-electron reduction at –1.8 V; c) after consumption of 2.5 F; d) evolution of the reduced solution at room temperature after 1 h.

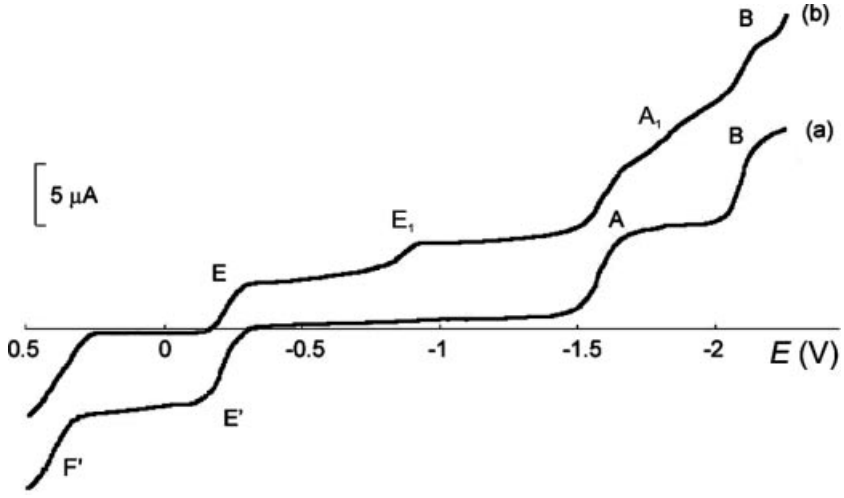

Figure 8. RDE voltammogram of **3** (thf/$NBu_4PF_6$): a) before electrolysis; b) after oxidation at –0.1 V and consumption of 0.2 F.

It is still unclear why the electrolysis of **3** at –0.1 V consumes 0.2 F instead of the required amount of 1 F for the formation of $[(Cp^*_2Nb)_2NiTe_4]^+$. However, if the oxidation is carried out at +0.35 V ($CH_2Cl_2$/$NBu_4PF_6$), 2 F are consumed and the subsequent cyclic voltammograms exhibit two new reversible systems $E_1/E_1'$ and $F_1/F_1'$ at 0.28 and –0.45 V, respectively. These systems may be assigned to the redox couples $[Cp^*_2NbF_2]/[Cp^*_2NbF_2]^+/[Cp^*_2NbF_2]^{2+}$. The first oxidation potential of $[(C_5Me_4Et)_2NbF_2]$ in $CH_2Cl_2$ has been determined to be $E_{1/2}$ = –0.38 V.[8]

The electrochemical behaviour of $[(Cp^*_2Nb)_2NiTe_4]BPh_4$ (**6**), which contains the cation [**3**]$^+$, was also studied. RDE voltammetry ($CH_2Cl_2$/$NBu_4PF_6$) gave the expected oxidation wave F′ at +0.28 V and the reduction wave E at –0.42 V. An additional reduction wave $E_1$ at –0.86 V is present, as in the case of the electrogenerated cation [**3**]$^+$. The heights of waves F′ and E are nearly equal and are twice as high as wave $E_1$ (see Figure S1 in the Supporting Information). Two reversible systems F′/F and E/E′ are observed in the cyclic voltammogram.

## Density Functional Calculations

The X-ray structure analysis of **3** shows that, contrary to the nearly tetrahedral $WTe_4^{2-}$ bridging fragment in $[\{(Cp'_2Nb)_2WTe_4\}W(CO)_4]$, the $NiTe_4$ moiety is highly distorted with short and long Te–Te distances. It is evident that the nickel atom is unable to reach the formal oxidation state +6 that is plausible for group 6 metals. In order to get an insight into the electronic structure of **3** and of its cationic and anionic species we have carried out DFT calcula-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tions with the Gaussian03 package by using the B3PW91/3-21G (SDD for Nb and Te) functional/basis set couple.[22] The molecular geometries of all systems studied were optimised first and then frequency calculations were performed to confirmation that the optimised geometries correspond well to energy minima. Cp ($C_5H_5$) replaces Cp* as a ligand in the models.

A preliminary analysis of the electronic properties of $[Cp_2NbTe_2]^-$ and the hypothetical $[NiTe_4]^{2-}$ anionic fragments derived from **3** will be useful for understanding the nature of **3**, and, in particular, why two pairs of Te atoms from two different niobocene ditelluride fragments form Te–Te bonds in the presence of $Ni^{2+}$.

Formally, complex **3** is built from $Ni^{2+}$ and two chelating $[Cp^*_2NbTe_2]^-$ anions. The electronic structures of bent metallocenes are well known.[23] We should recall, however, the main features of $[Cp_2NbTe_2]^-$ together with the shapes of the frontier molecular orbitals depicted in Figure 9. HOMO–5 to HOMO–3 are responsible for the σ and π Nb–Te bonds based on classical $1a_1$, $b_2$ and $2a_1$ bent metallocene molecular orbitals,[23] respectively, while HOMO–2 to HOMO are representative of Te lone pairs. Both LUMOs contain a large contribution from Nb atomic orbitals. All depicted orbitals may be involved in Te–Ni and Nb–Ni interactions upon formation of the trimetallic complex **3**. The optimised Nb–Te (2.722 Å), Te–Te (4.193 Å, labelled *intra*annular in **3**) and Te–Nb–Te (101.6°) parameters for $[Cp_2NbTe_2]^-$ are close to the corresponding values found in the crystal structure of **3**.

As shown above, the central $[NiTe_4]^{2-}$ moiety in the structure of **3** is severely distorted. In an attempt to clarify this feature we looked at the behaviour of the hypothetical $[NiTe_4]^{2-}$ anion in planar ($D_{4h}$ and $D_{2h}$), tetrahedral ($T_d$) and distorted tetrahedral ($D_{2d}$) symmetries in the singlet (s) and triplet (tr) spin states. The $D_{4h}$ initial geometry was ruled out because no convergence could be reached upon its optimisation. Remember that the $[NiX_4]^{n-}$ moiety (X = chalcogen) is extremely electron rich and is not known in classical mineral salts. Its stabilisation may occur with electron-withdrawing counterions like selected organometallic buffers. A niobocene seems to be a good candidate, as shown in this paper. $Ni^{2+}$ may exhibit its spin flexibility in distorted polyhedra, which is why both the singlet and triplet states were calculated. The geometry optimisations led to slightly $C_{3v}$ distorted (singlet) and to severely distorted $C_1$ (triplet) symmetries starting from tetrahedral $T_d$, and to approximately $D_2$-symmetric structures starting from $D_{2h}$ and $D_{2d}$ for both the singlet and triplet states. The total energies of the four main species obtained from geometry optimisations increase in the order $D_2$(tr) (0) < $C_1$(tr) (0.71) < $D_2$(s) (1.98) < $C_{3v}$(s) (2.84 eV). The triplet paramagnetic states are therefore more stable than the diamagnetic singlets. Due to the lack of experimental (e.g. magnetic) data for hypothetical $[NiTe_4]^{2-}$ we did not look at the nature of its singlet and triplet states and can therefore only state that the metal (Ni) must be responsible for them. In fact, in both the singlet and triplet $D_2$ optimised structures there are two short Te–Te bonding distances [mean: 2.970 (singlet) and 2.987 Å (triplet)] corresponding to the short *inter*annular ones in **3** and two sets of long separations (mean: 4.482/5.138 Å and 5.038/5.137 Å for singlet and triplet, respectively) that correspond to pairs of two long *inter*- and of two *intra*annular Te–Te distances in **3**. Thus, we can conclude that there are two ditelluride ($Te_2^{2-}$) ligands bound to the $Ni^{2+}$ centre in $[NiTe_4]^{2-}$.

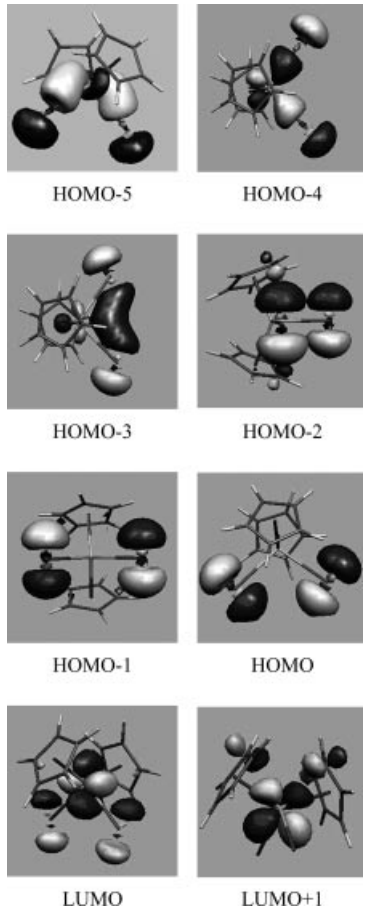

Figure 9. Shapes of significant molecular orbitals of the $[Cp_2NbTe_2]^-$ anion.

Such an intrinsic property of the $[NiTe_4]^{2-}$ anion, which is better described as bis(ditelluro)nickelate $[Ni(Te_2)_2]^{2-}$, in either the singlet or triplet spin state corroborates well the crystal structure of **3**. Selected molecular orbitals of $[Ni(Te_2)_2]^{2-}$ (singlet) are shown in Figure 10. The HOMO–11 and HOMO–3 are the Te–Te bonding orbitals, whereas the HOMO–7 and HOMO–2 may be considered as the non-bonding lone pairs of the Te atoms. Their shapes correspond to the HOMO–2 and HOMO–1 of the $[Cp_2NbTe_2]^-$ anion (Figure 9).

What do we know about the covalency of the Te–Te interaction in pertelluride ($Te_2^{2-}$)? X-ray data suggest a range of 2.67 to 3.05 Å for Te–Te bonds in $Te_2^{2-}$,[12–14,24] and covalent Te–Te bonds in the range of 2.74 to 2.93 Å have been reported from theoretical studies carried out on $H_2Te_2$ and $Me_2Te_2$.[25–27] We have calculated (B3WP91/SDD functional/basis set used in this paper) the Te–Te bond lengths for the singlet (2.946 Å) and triplet (3.364 Å) states of free

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

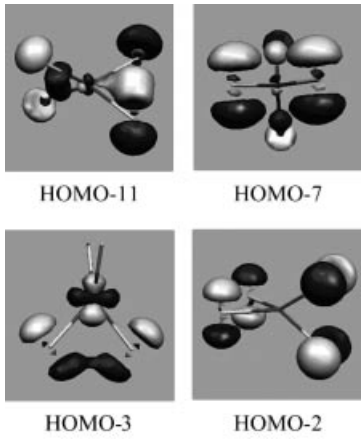

Figure 10. Shapes of selected molecular orbitals of $[Ni(Te_2)_2]^{2-}$.

ditelluride $Te_2^{2-}$. The triplet state consists of excitation of one electron from a π* antibonding to the high energy σ* orbital of $Te_2^{2-}$. The calculated Te–Te distance of 2.946 Å in the free diamagnetic molecule increases slightly to 2.970 Å in the diamagnetic complex $[Ni(Te_2)_2]^{2-}$ (vide supra) and up to 3.16 Å in trimetallic **3** (X-ray). In such a trimetallic environment of $Te_2^{2-}$ a lengthening and weakening of the Te–Te bond with retention of its covalent nature is acceptable for **3**. However, one may easily formulate a doubt about its existence at the distances (as long as 3.36 Å) calculated for the triplet state of free $Te_2^{2-}$ and the $[\mathbf{3}]^-$ anion (3.34 Å; vide infra). We checked this last question in the frame of Bader's AIM theory[28] for $Te_2^{2-}$ singlet and triplet states by using a full electron polarised 3-21G* basis set (needed for topological analysis of the wave function) coupled with the B3WP61 functional. The new optimised Te–Te distances are 2.865 (singlet) and 3.400 Å (triplet). Local topological properties such as electron density ($\rho$, e Å$^{-3}$), laplacian ($\nabla^2\rho$, e Å$^{-5}$), density of total energy $H$ ($H_a$, Å$^{-3}$) and derived "bond degree" $-H/\rho$ ($H_a$/e) at bond critical points (BCP) are useful for our purpose. In a simplified approach the covalent interaction needs accumulation of $\rho$ and a negative value of $H$ at the BCP. The $\nabla^2\rho$ may be negative (pure covalent shared–shared interaction) or positive [partially covalent shared–closed interaction; the closed–closed one (H positive) is of a van der Waals or ionic nature]. All considerations of atom–atom interactions need the detection of a BCP. This is the case for both the singlet and triplet states of $Te_2^{2-}$. The numerical values of $\rho$, $\nabla^2\rho$, $H$ and $-H/\rho$ at BCPs for the singlet/triplet are 0.37/0.17, –0.02/+0.72, –0.105/–0.012 and 0.28/0.07, respectively. These values also suggest a clearly covalent Te–Te bond in the singlet as some of its covalent nature is retained at a distance as long as 3.4 Å.

The initial geometry obtained from the DFT calculations on $[\mathbf{3}]^0$ is that of the X-ray structure of **3**. The optimisation of $[\mathbf{3}]^{2-}$ leads to one imaginary frequency (excited transition state) and will be only briefly mentioned below. The fact that we were not able to optimise the geometry of the ground state for $[\mathbf{3}]^{2-}$ agrees with the electrochemical evidence for its relative instability. Some metric, charge and energy data for the optimised structures of **3** in different oxidation states are given in Table S2 (see Supporting Information). On comparing the calculated and experimental metric parameters one can clearly see that the $NbTe_2Ni$ rings in $[\mathbf{3}]^0$ are compressed along the Nb–Ni vector by some 0.4 Å and stretched by 0.35 Å along the Te–Te *inter*annular vector with respect to **3** (X-ray). Thus, the direct Nb–Ni bonding interaction is favoured in the isolated molecule over the same molecule packed in the crystal. The shape of the HOMO–4 of **3**, which is clearly an Nb–Ni bonding orbital, is shown in Figure 11. The differences of other heavy atom distances between the calculated $[\mathbf{3}]^0$ and experimental **3** (X-ray) structures are close to 0.05 Å for mean values.

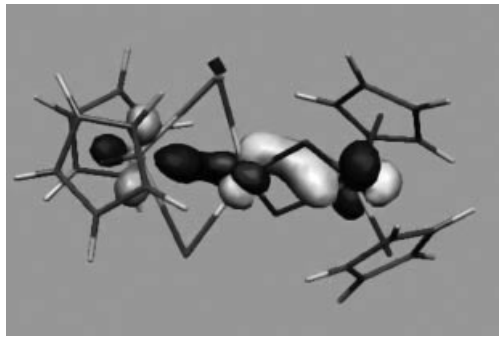

Figure 11. Shape of the HOMO–4 (Nb–Ni–Nb bonding) in the neutral complex **3**.

In the optimised $[\mathbf{3}]^n$ ($n$ = +2, +1, 0, –1) structures the calculated Nb–Ni, Nb–Te, Ni–Te, Te–Te (*intra*) and long Te–Te (*inter*) distances vary in an irregular manner, whereas the short Te–Te (*inter*) (ditelluride $Te_2^{2-}$) bonds increase regularly on going from $[\mathbf{3}]^{2+}$ to $[\mathbf{3}]^-$. A smooth increase is also observed for cationic and neutral species (mean values of 2.961, 3.040 and 3.105 Å), while a spectacular lengthening of the Te1–Te3 distance up to 3.908 Å is calculated for the anion. Note that the second *inter*annular (Te2–Te4) bond in $[\mathbf{3}]^-$ is also elongated, but "only" to 3.328 Å (Figure 12).

In all $[\mathbf{3}]^n$ species the Nb atoms bear a high positive charge, while the Ni atoms are negatively charged (except in $[\mathbf{3}]^+$). However, the variations of these charges (like those of metric parameters including Nb and Ni) do not correlate with the overall charges. It is, however, worth noting that the sums of metallic charges for all $[\mathbf{3}]^n$ ($n$ = +2, +1, 0, –1) species cover a narrow range of 2.38 ($[\mathbf{3}]^+$) to 2.08 Å ($[\mathbf{3}]^0$). On the other hand, the evolution of Mulliken charges on four Te atoms and four Cp rings follows the overall charges of $[\mathbf{3}]^{2+}$ to $[\mathbf{3}]^-$ species well. This is not surprising for the rings because of their well-known buffer properties. In the case of Te atoms, the observed trend strongly suggests that, whatever the first site of redox processes, the Te atoms are most affected in the final reduced or oxidised structure. Such an overview of the main metric and charge properties of $[\mathbf{3}]^n$ species argues well for the presence of two ditelluride $Te_2^{2-}$ ligands in complexes with $n$ = +2, +1 and 0, where

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

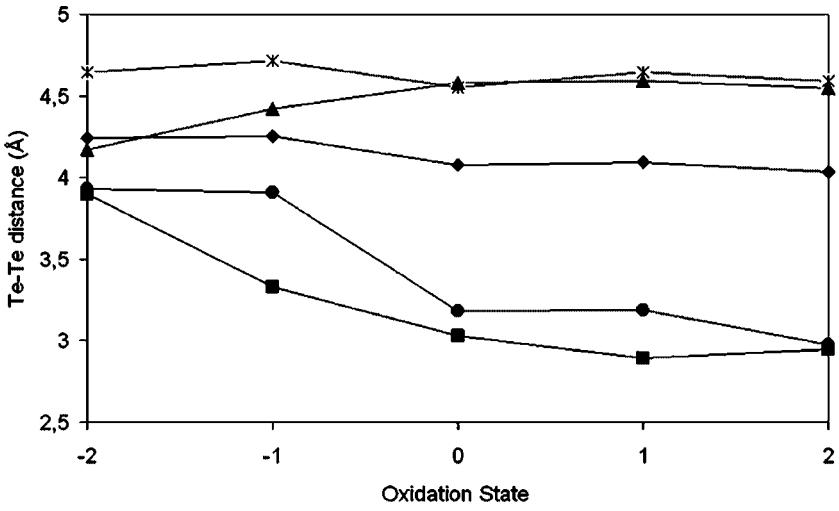

Figure 12. Evolution of the Te–Te distances in differently charged **3**: ■ Te2–Te4 *inter*annular short; ● Te1–Te3 *inter*annular short; ▲ mean of two *inter*annular long (Te1–Te4 and Te2–Te4); ♦ mean of all six Te–Te; × mean of two *intra*annular (Te1–Te2 and Te3–Te4).

the calculated Te–Te distances range between 2.894 and 3.186 Å. The presence of one ditelluride (calculated 3.328 Å) is also expected in the reduced $[\mathbf{3}]^-$ anion from both the tendencies observed in Figure 12 and from the AIM calculations. It is worth noting that the shortest Te–Te distances calculated for the transition state of doubly reduced $[\mathbf{3}]^{2-}$ are 3.896 and 3.929 Å, thus excluding any covalent Te–Te bonding interaction.

Electrochemical studies have revealed the presence of the redox-couples $[\mathbf{3}]^{2+}/[\mathbf{3}]^+$, $[\mathbf{3}]^+/[\mathbf{3}]$ and $[\mathbf{3}]/[\mathbf{3}]^-$ with $E_{1/2}$ potentials of +0.42, –0.22 and –1.61 V, respectively. These values should correlate with the energies (total, HOMO, LUMO) of the implied species. Taking the total energy of neutral $[\mathbf{3}]^0$ as the origin, those of $[\mathbf{3}]^{2+}$, $[\mathbf{3}]^+$ and $[\mathbf{3}]^-$ are equal to +13.979, +4.614 and –1.761 eV, respectively. There is a very good linear correlation between the total energy difference, $\Delta E_{tot}$, values (+9.365, +4.614 and –1.761 eV) and $E_{1/2}$ potentials (linear regression $R^2 = 0.997$) for the three redox systems. On the other hand, the linear correlation does not hold too well for $E_{1/2}$ or the energies of the HOMOs (oxidation, three points, $[\mathbf{3}]^+$, $[\mathbf{3}]^0$, $[\mathbf{3}]^-$, $R^2 = 0.927$) or the LUMOs {reduction, four points, $[\mathbf{3}]^{2+}$, $[\mathbf{3}]^+$, $[\mathbf{3}]^0$ and $[\mathbf{3}]^-$ (with $E_{1/2}$ $[\mathbf{3}]^-/[\mathbf{3}]^{2-} = -2.12$ V), $R^2 = 0.953$}. This may suggest that the one-electron oxidation of $[\mathbf{3}]^0$ does not necessarily operate on its HOMO similar to the one-electron reduction on its LUMO. Other occupied or empty orbitals may contribute to redox processes.

## Conclusions

The novel heterometallic telluride clusters $[(Cp^*_2Nb)_2NiTe_4]$ (**3**) and $[(Cp'Nb)_2Ni_5Te_7(dppm)_2]$ (**4**) have been obtained by the reaction of $[Ni(COD)]_2$ with $[Cp^*_2NbTe_2H]$ and $[Cp'_2NbTe_2H]$, respectively. Whereas the presence of the chelating phosphane dppm seems to increase the yields of **3**, it is essential for the formation of cluster **4**. The structure of the latter compound is characterised by two tetragonal $Ni_5$ and $Te_5$ pyramids stacked into each other.

Complex **3** is the first example of the trimetallic series $[(Cp^*_2Nb)_2MX_4]$ to contain a formally electron-rich tetratelluronickelate bridge. Contrary to some other experimentally observed tetrahedral $MX_4$ systems (M = Mo, W; X = S, Se, Te), the DFT calculations provide evidence for the presence of ditelluride ligands as an intrinsic property of the $[NiTe_4]^{2-}$ anion. The calculated Te–Te single bond lengths cover the range from 2.946 to 3.186 Å for $[\mathbf{3}]^{2+}$, $[\mathbf{3}]^+$ and $[\mathbf{3}]^0$, and are as high as 3.328 Å for the $[\mathbf{3}]^-$ anion. It follows from these calculations that the neutral complex **3** does not result from a simple chelation of two $[Cp^*_2NbTe_2]^-$ anions by $Ni^{2+}$. Instead, its formation is assisted by direct Nb–Ni interactions and bonding Te–Te interactions between both $[Cp^*_2NbTe_2]^-$ anions (*inter*annular bonds). A good linear correlation between the $E_{1/2}$ redox potentials and total energies of different oxidation states of **3** indicates that the electronically delocalised heavy atom core governs these reactions. However, the Te–Te bonding is most affected and thus plays a crucial role in redox processes involving **3**.

## Experimental Section

All manipulations were carried out under inert atmosphere using Schlenk line and/or glovebox techniques and dry solvents. Elemental analyses were performed at the Mikroanalytisches Laboratorium, University of Regensburg. IR spectra were obtained with a Mattson Genesis Series FTIR instrument; ESI mass spectra and FD mass spectra were measured with Finnigan TSQ 7000 and MAT 95 instruments, respectively. The $^1$H- NMR spectra were recorded with a Bruker ARX 250 instrument. $[Cp^*_2NbTe_2H]$ (**1**),[29] $[Cp'_2NbTe_2H]$ (**2**),[10] $[Ni(COD)_2]$[30] and $[(C_5H_5)_2Fe]BPh_4$[31] were prepared as described in the literature. Electrochemical experiments were carried out as described previously.[10]

**Synthesis of $[(Cp^*_2Nb)_2NiTe_4]$ (3):** $[Ni(COD)_2]$ (110 mg, 0.4 mmol) and dppm (80 mg, 0.2 mmol) were dissolved in toluene (120 mL) and a solution of **1** (250 mg, 0.4 mmol) in 15 mL of toluene, was added. The resulting mixture was stirred for 18 h at 110 °C. After cooling, the solvent was evaporated and the dark residue dissolved

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in toluene/pentane (2:1, 15 mL). Chromatography on $SiO_2$ (column: 15 cm; diameter: 3 cm) gave an orange band containing some **1** upon elution with toluene/pentane (2:1) and then a broad black-violet band containing **3** (100 mg, 20% yield) with toluene. Recrystallisation from toluene/pentane (1:1) gave black crystals. Complex **3**: $C_{40}H_{60}Nb_2NiTe_4{\cdot}C_7H_8$ (1387.98): calcd. C 40.67, H 4.94; found C 40.94, H 4.96. FD-MS (from toluene): *m*/*z* 1296.7 (centre; $M^+$). $^1H$ NMR ($C_6D_6$): $\delta$ = 1.89 (s) ppm.

**Synthesis of $[(Cp'Nb)_2Ni_5Te_7(dppm)_2]$ (4):** A solution of **2** (160 mg, 0.27 mmol) in toluene (20 mL) was added to a yellow solution of $[Ni(COD)_2]$ (150 mg, 0.55 mmol) and dppm (104 mg, 0.27 mmol) in toluene (100 mL). The dark mixture was stirred for 18 h at 110 °C. After cooling, the solution was concentrated to 20 mL and filtered through a frit charged with dry kieselguhr. Then filtrate was then layered carefully with pentane (20 mL). Crystallisation at –20 °C gave several crops of black crystals with a total yield of 11%. Complex **4**: $C_{68}H_{70}Nb_2Ni_5P_4Te_7{\cdot}2C_7H_8$ (2567.94): calcd. C 38.35, H 3.38; found C 37.54, H 3.34. FD-MS (from $CH_2Cl_2$): *m*/*z* 2383.4 (centre; $M^+$).

**Reaction of 3 with $[Cp_2Fe]PF_6$:** A solution of **3** (200 mg, 0.15 mmol) in thf (20 mL) was mixed with a suspension of $[(C_5H_5)_2Fe]PF_6$ (100 mg, 0.30 mmol) in 15 mL of thf. After stirring for 2 h at room temperature a black precipitate separated from the yellow solution. After evaporation of the solvent the residue was suspended in toluene, transferred to a frit charged with Celite® and washed several times with toluene. Dissolving the residue in thf and evaporation of the solvent gave 40 mg (24%) of yellow $[Cp^*_2NbF_2]PF_6$ (**5**). The product is identical with a sample prepared from $[Cp^*_2NbCl_2]$ by reduction with Na/Hg and subsequent reaction with $HPF_6$.[8] Complex **5**: $C_{20}H_{30}F_8NbP$ (546.32): calcd. C 43.97, H 5.53; found C 43.83, H 5.43. FD-MS (from $CH_2Cl_2$): *m*/*z* 401.3 $[Cp^*_2NbF_2]^+$. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 2.13 (s) ppm.

**Synthesis of $[(Cp^*_2Nb)_2NiTe_4]BPh_4$ (6):** Complex **3** (250 mg, 0.24 mmol) was dissolved in thf (50 mL) and then added to a suspension of $[(C_5H_5)_2Fe]BPh_4$ (250 mg, 0.49 mmol) in 40 mL of thf. During the reaction the colour changed from black-violet to black-green. After stirring for 4 h at room temperature the solvent was removed. The residue was then washed with toluene (20 mL) to remove $[(C_5H_5)_2Fe]$ (50 mg, 0.27 mmol). The black residue was suspended in thf, filtered and the solvents evaporated to dryness to give 120 mg (37%) of **6**. Repeated recrystallisation from thf gave only microcrystalline material. Complex **6**: $C_{64}H_{80}BNb_2NiTe_4$ (1615.06): calcd. C 47.60, H 5.00; found C 47.31, H 4.84. ESI-MS (from $CH_2Cl_2$): Positive ion ESI: *m*/*z* 1295.7 $[\mathbf{6}]^+$; negative ion ESI: *m*/*z* 319.0 $[BPh_4]^-$. $^1H$ NMR ($CD_2Cl_2$): $\delta$ = 11.15 (br. s, 60 H, $C_5Me_5$), 7.31 (m, 8 H, $C_6H_5$), 7.03 (m, 8 H, $C_6H_5$), 6.88 (m, 4 H, $C_6H_5$) ppm.

### Crystal Structure Determination

**Complex 3:** Black rods were grown from a toluene solution at –24 °C. Data were collected at 173 K on a STOE imaging plate diffraction system (IPDS) using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Crystallographic details are listed in Table 2. The structure was solved by direct methods and refined by full-matrix least-squares (SHELXL-97) with all reflections. All non-hydrogen atoms were refined with anisotropic displacement parameters. The H atoms were calculated geometrically and a riding model was used during the refinement process.

**Complex 4:** Crystal data were collected at 123 K on a STOE IPDS instrument using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Crystallographic details are listed in Table 2. The space group determination following systematic extinction rules for the reflections together with the orthorhombic lattice constants led to space group *Pccn* (no. 56). First attempts to solve the structure by direct methods (SIR-97) immediately showed all heavy atoms. Searching for the carbon atoms by difference Fourier synthesis (SHELX-97) revealed that the chosen symmetry was too high. Inspection of the systematic absence violations of the reflections showed that all violations concern *h*0*l* reflections. Therefore, all following calculations were carried out in the acentric space group $Pc2_1n$, the unconventional setting of $Pna2_1$ (no. 33). In this space group there was no problem to locate all atoms by difference Fourier synthesis. Due to the high degree of pseudo-centrosymmetry and the fact that the crystal was an inversion twin with a ratio of 44:56, the correlation factors between a great number of atomic parameters made several constraints during the refinement calculations necessary. All carbon rings were fitted by the suitable AFIX instruction to a regular hexagon or pentagon, respectively. In particular, the C–C distances of one *tert*-butyl group had to be fixed. Despite including a damping factor during the least-squares refinements, all carbon atoms had to be refined with isotropic displacement factors. In addition, the solvent molecules showed severe positional disorder and could only be refined as a cloud of electron density. The shape of that cloud and the found electron numbers suggested that the solvent molecules are toluene. Despite these difficulties a reliable structure determination was obtained but with slightly increased estimated standard deviations for the interatomic distances.

Table 2. Crystal data for compounds **3** and **4**.

# Transition Metal-Assisted Hydrolysis of Pyrazole-Appended Organooxotin Carboxylates Accompanied by Ligand Transfer

**Vadapalli Chandrasekhar,*[a] Pakkirisamy Thilagar,[a] and Tapas Senapati[a]**

**Keywords:** Organotin carboxylates / Organooxotin / Organostannoxane / Heterobimetallics / Supramolecular chemistry / Transition metals

The reaction of the potentially multi-site coordination ligands $[\{n\text{Bu}_2\text{SnO}_2\text{CL}\}_2\text{O}]_2$ (**1**), $[\{n\text{Bu}_2\text{SnO}_2\text{CL}'\}_2\text{O}]_2$ (**2**), $[n\text{BuSn(O)O}_2\text{CL}]_6$ (**3**), and $[n\text{BuSn(O)O}_2\text{CL}']_6$ (**4**), (L = $(\text{Pz})_2$CH-); L′ = $(3,5\text{-Me}_2\text{Pz})_2$CH-; Pz = pyrazolyl) with hydrated metal salts leads to the hydrolysis of the organotin carboxylates accompanied by the formation of insoluble organotinoxide/hydroxides and metal complexes. The in situ generated LCOO and L′COO ligands bind to the metal ions. The complexes $[\text{Cu(LCOO)}_2(\text{NO}_3)_2(n\text{Bu}_2\text{Sn}((\text{H}_2\text{O})_2)]_n[\text{Cu(LCOO)}_2]$ (**5**), $[\text{Mg(L′COO)}_2]$ (**6**), $[\text{Cu(LCOO)}_2]$ (**7**), and $[\{(\text{Cu(L′COO)}_2(\text{Cu(MeOH)})_3\}\{\text{ClO}_4\}_2]_n$ (**8**) were isolated and structurally characterized. The solid-state structure of **5** reveals that two discrete molecules are present in the same asymmetric unit; a heterobimetallic coordination polymer, $[\text{Cu(LCOO)}_2(\text{NO}_3)_2(n\text{Bu}_2\text{Sn}((\text{H}_2\text{O})_2)]_n$ and a discrete coordination complex, $[\text{Cu(LCOO)}_2]$. The cationic portion of the heterobimetallic compound contains alternate six-coordinate $\text{Sn}^{\text{IV}}$ and $\text{Cu}^{\text{II}}$ centers bridged by the carboxylate oxygen atoms of the LCOO ligand.

## Introduction

Synthetic polymers in spite of their many attractive features[1–2] suffer from a serious disadvantage.[1–2] Even in well-controlled polymerization pathways the chain lengths as well as the molecular structure of the various individual chains present in a given macromolecule are not the same. *Dendrimers* or *Star-burst* molecules are hyperbranched macromolecules with high surface area and structural symmetry which retain the advantages of the macromolecules while avoiding the structural imprecision found in the latter.[3–5] We and others have been pursuing the possibility of using inorganic cores for building star-burst-type molecules.[6–14] Thus, inorganic rings such as cyclophosphazenes,[6,8] cyclosiloxanes,[9] and borazines[10] have been used recently as supports for the preparation of novel compounds which contain a central inorganic core and a periphery of judiciously placed functional substituents. Other inorganic rings and cages that contain Al–N or Al–C units have been similarly investigated.[11]

We have been interested in organostannoxanes for some time now and have recently shown the utility of these compounds to support hexa-ferrocene[12] and hexa-porphyrin[13] architectures. Encouraged by the success in the use of stannoxanes as inert cores for supporting a functional periphery we have turned our attention to the possibility of building multi-site coordination ligands based on stannoxane cores. Accordingly we have recently reported a series of multi-site coordination ligands containing a central stannoxane core which is decorated by a periphery of bis-pyrazolyl groups.[14] By a one-step synthetic protocol involving the reaction of bis(pyrazol-1-yl)acetic acid, LCOOH, (L = $(\text{Pz})_2$CH-) or bis(3,5-dimethylpyrazol-1-yl)acetic acid, L′COOH (L′ = $(3,5\text{-Me}_2\text{Pz})_2$CH-) with various organooxotin precursors potentially multi-site coordination ligands $[\{n\text{Bu}_2\text{SnO}_2\text{CL}\}_2\text{O}]_2$ (**1**), $[\{n\text{Bu}_2\text{SnO}_2\text{CL}'\}_2\text{O}]_2$ (**2**), $[n\text{BuSn(O)O}_2\text{CL}]_6$ (**3**), and $[n\text{BuSn(O)O}_2\text{CL}']_6$ (**4**), were prepared.[14] The number of coordination units assembled on the stannoxane periphery depends on the type of stannoxane assembled. Metalation reactions of **1**–**4** with hydrated metal salts resulted, in all the cases, in the transfer of the bis(pyrazolyl)acetate unit from the tin to the transition/alkaline earth metal ion. In one instance involving the interaction between $[\{n\text{Bu}_2\text{SnO}_2\text{CL}\}_2\text{O}]_2$ (**1**) (L = $(\text{Pz})_2$CH-; Pz = pyrazolyl) and $\text{Cu(NO}_3)_2\cdot 3\text{H}_2\text{O}$ we isolated $[\text{Cu(LCOO)}_2(\text{NO}_3)_2(n\text{Bu}_2\text{Sn}(\text{H}_2\text{O})_2)]_n$ $[\text{Cu(LCOO)}_2]$ (**5**). The crystal structure of the latter reveals that its asymmetric unit contains two independent chemical entities viz., a heterobimetallic coordination polymer $[\{\text{Cu(LCOO)}_2\}\{n\text{Bu}_2\text{Sn}(\text{H}_2\text{O})_2\}]_n$ (**5a**) and a discrete six-coordinate copper complex $[\text{Cu(LCOO)}_2]$ **5b**. The structure of the heterobimetallic complex provides the clue that the transfer of the ligand from

the organotin compound to the transition metal ion is probably initiated and accompanied by a hydrolysis reaction.

## Results and Discussion

**Synthesis:** Compounds **5**–**8** were obtained in the reactions of the organotin precursors **1**–**4** with various hydrated metal salts (Scheme 1 and Supporting Information). In all these cases an insoluble colorless solid presumably a mixture of organotinoxide/hydroxides, was also isolated. For example, in the reaction of **3** with $Cu(ClO_4)_2 \cdot 6H_2O$ the insoluble material, **7b**, was obtained. The powder XRD of **7b** matches very closely that of *n*BuSn(O)OH based on its powder XRD (Figure S1, Supporting Information). Similarly the solid-state IR spectrum of **7b** also is in agreement with the spectrum of the authentic *n*BuSn(O)OH sample (Supporting Information, Figure S2). The insoluble product obtained in the reaction of metal salts with $Cu(NO_3)_2 \cdot 3H_2O$ and $Mg(NO_3)_2 \cdot 6H_2O$ has a powder XRD pattern similar to that of $nBu_2SnO$ (Supporting Information Figure S3–S4). These results imply that the organotin carboxylate cores of **1**–**4** decompose upon interaction with metal salts releasing hydrated organotin cations (Scheme 2) which can self-condense to afford organotin oxides/oxide hydroxides. In the process, the carboxylate ligand originally bound to the tin center is transferred to the interacting transition metal ion. Compound **5** is obtained in the reaction of **1** and Cu-

$(NO_3)_2 \cdot 3H_2O$ (Scheme 1) and is probably an intermediate on the way to the fully hydrolyzed products. One of the molecules present in the crystal structure of **5a** is a heterobimetallic coordination polymer containing both tin and copper atoms (Figure 1). We were unable to obtain a $^{119}Sn$ NMR for this compound because of the strong paramagnetic relaxation of $Cu^{II}$.

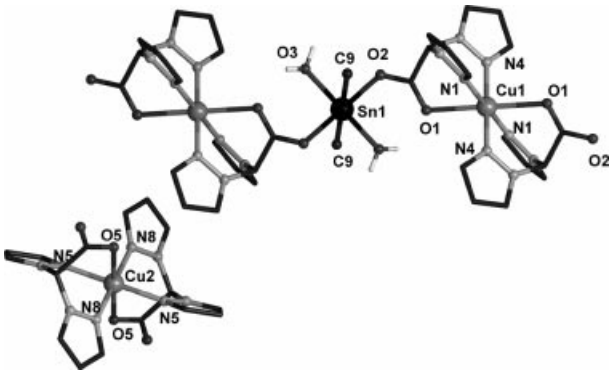

Figure 1. Independent crystallographic components of compound **5** with atom numbering. Heterobimetallic coordination polymer (top) and discrete mononuclear $Cu^{II}$ complex (bottom). Only the alpha carbon of the *n*-butyl group is shown. The other carbon atoms of the butyl group and the hydrogen atoms of the pyrazolyl rings are removed for the sake of clarity.

### X-ray Crystal Structure of 5

The X-ray structure of **5** is discussed herein. The structures of **6**–**8** along with their description and supramolecular structures are given in supporting information.

The crystal structure of **5** is quite unusual. Its asymmetric unit contains two independent chemical entities viz., a heterobimetallic coordination polymer $[\{Cu(LCOO)_2\}\{n Bu_2Sn(H_2O)_2\}]_n$ (**5a**) and a discrete six-coordinate copper complex $[Cu(LCOO)_2]$ **5b**. However, these two chemical entities are intimately related as discussed vide infra.

Complex **5a** is a coordination polymer containing alternately two sub-units. One of these is $Cu(LCOO)_2$ while the other is $[n Bu_2Sn(H_2O)_2]$. These are interlinked to each other to afford a one-dimensional helical polymer chain (Figure 1). Such a heterobimetallic coordination polymer is unprecedented among organotin compounds. The geometry around both of the metal ions found in **5a** can be described as distorted octahedral (Figure 2). The dihedral angle between the two square planes around $Cu^{II}$ and $Sn^{IV}$ is 16.322(5)°. The equatorial plane around $Cu^{II}$ is formed by four pyrazole nitrogen atoms derived from two LCOO moieties. The apical positions are occupied by two carboxylate oxygen atoms (O1 and O1′). The two uncoordinated oxygen atoms (O2 and O2′) of the $[Cu(LCOO)_2]$ unit assist in forming the coordination polymer by bridging two $[n Bu_2Sn(H_2O)_2]$ units (Figure 2). As a result the immediate coordination environment around $Sn^{IV}$ consists of two *n*-butyl groups (C9 and C9′), two water molecules (in the equatorial plane) and two oxygen atoms (O2 and O2′) in the axial sites. The two *n*-butyl groups are arranged in a *trans* manner with respect to each other. In spite of two different oxygen donors the Sn–O bond lengths in **5a** are nearly similar (Sn1–O2, 2.219(1); Sn1–O3, 2.207(1) Å). In the case of the copper sub unit of **5a** the Cu1–O1 distance is 2.381(1) Å. Interestingly, all the metric parameters found for the copper subunit in **5a** are very similar to that found in **5b**. The formation of **5a** can be readily rationalized as follows. Hydrolysis of the organotin carboxylate **1** leads to the formation of $[n Bu_2Sn(H_2O)_4]^{2+}$ and $Cu(LCOO)_2$. Interaction of these two entities results in the expulsion of two water molecules (that are *trans* to each other) from the former leading to the assembly of the heterobimetallic coordination polymer **5a** (Scheme 2). The presence of **5b**, fortuitously co-crystallizing with **5a**, strongly supports this supposition. Further, we have previously isolated $[n Bu_2Sn(H_2O)_4]^{2+}$, albeit in a different reaction.[15]

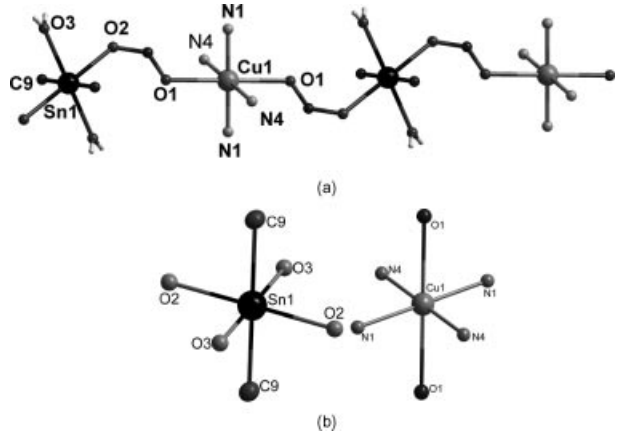

Figure 2. (a) Helical structure of compound **5** with atom numbering. The unlabeled atoms are generated by a symmetry relationship with the labeled atoms. (b) Coordination environment around Cu1 and Sn1. Important bond lengths [Å] and bond angles [°] in the monomer portion of the heterobimetallic polymer. Sn1–C9 2.133(2), Sn1–O3 2.207(1), Sn1–O2 2.219(1), Cu1–N4 1.995(1), Cu1–N1 2.013(1), Cu1–O1 2.381(1), C9–Sn1–C9 180, C9–Sn1–O3 86.137(7), O3–Sn1–O3 180, O2–Sn1–O2 180, N4–Cu1–N4 180, N4–Cu1–N1 91.355(6), N4–Cu1–O1 97.162(6), N1–Cu1–N1 180.0(6), N1–Cu1–O1 81.755(6), O1–Cu1–O1 180.

It must be mentioned that **1** itself does not undergo hydrolysis (Experimental Section). This means that the interaction of the metal ion with the coordination periphery of the organostannoxane ligand **1** accentuates the electrophilicity of the tin center and renders them susceptible to attack by water. Transfer of the bis(pyrazolylcarboxylate) ligand to the transition metal ion is also helped by the pincer-like coordination action of the released LCOO tripodal ligand resulting in the formation of two chelating five-membered rings arising from the coordination of the carboxylate oxygen atom to the metal center (Scheme 2).

**Supramolecular Structure of 5:** The crystal structures of **5**–**8** show rich supramolecular architectures mediated by intermolecular C-H---O, C-H---N, and O-H---O interactions. Only the case of **5** is discussed here. The remaining supramolecular structures are given in the Supporting Information (Figures S8–S12). The crystal structure of **5** shows interesting supramolecular interactions between **5a**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

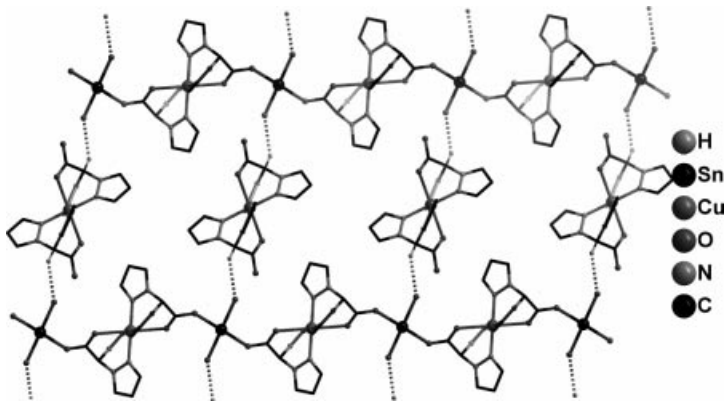

Figure 3. The 2D layer structure of compound **5** as a result of intermolecular C-H---O interactions [C19–H19···O13 2.673(1) Å and C19-H19---O13 134.747(11)°].

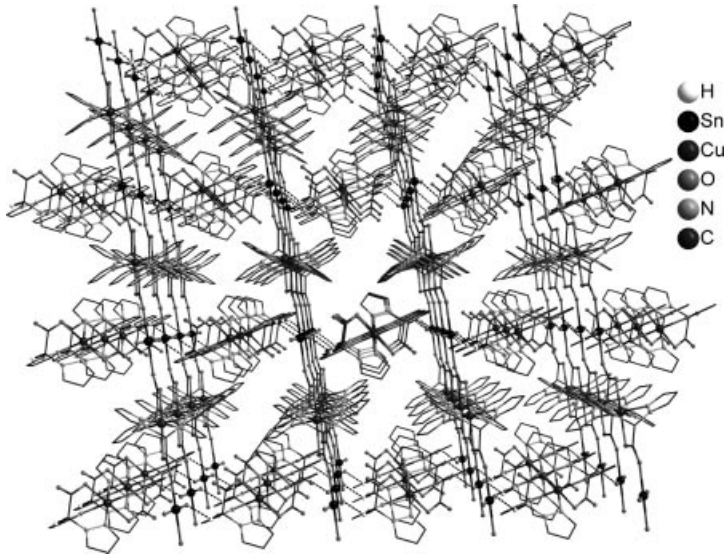

Figure 4. The 3D structure of **5**.

and **5b**. An intermolecular C-H---O interaction between the $Pz_2$-C-*H*-COO- of **5b** and an oxygen atom (belonging to a water molecule coordinated to tin) leads to the generation of a two-dimensional layer structure (Figure 3). Further intermolecular C-H---O interactions between the C-H′s of pyrazolyl ring of **5b** and the oxygen atoms of the nitrate anions leads to the elaboration of the supramolecular structure into a three-dimensional structure (Figure 4).

## Conclusions

In conclusion, we report in this contribution, the hydrolytic sensitivity of the organostannoxane cages $[\{n\mathrm{Bu_2SnO_2CL}\}_2\mathrm{O}]_2$ (**1**), $[\{n\mathrm{Bu_2SnO_2CL'}\}_2\mathrm{O}]_2$ (**2**), $[n\mathrm{BuSn(O)O_2CL}]_6$ (**3**), and $[n\mathrm{BuSn(O)O_2CL'}]_6$ (**4**), (L = $(Pz)_2$CH-); L′ = $(3,5\text{-}Me_2Pz)_2$CH-; Pz = pyrazolyl) upon interaction with hydrated metal salts. Interestingly, compounds **1**–**4** themselves do not hydrolyze in the absence of hydrated transition metal salts. This suggests that the coordination of the peripheral pyrazole arms of the organostannoxanes **1**–**4** renders the tin atoms electron deficient and therefore susceptible to nucleophilic attack by water leading to the collapse of the organostannoxane cores and the transfer of the ligands LCOO or L′COO to the metal ions. Another reason for the ligand transfer may be traced to the facile chelation that occurs *after* the ligand breaks off from the stannoxane and coordinates to the added metal ion. One of the ways of limiting this would be to insulate the tin atoms of the stannoxane core from the coordinating units by means of appropriate spacer groups. The delineation of this hypothesis is under progress.

## Experimental Section

**General:** All solvents were dried and purified by standard procedures. $Cu(NO_3)_2{\cdot}3H_2O$, $Cu(ClO_4)_2{\cdot}6H_2O$, and $Mg(NO_3)_2{\cdot}6H_2O$ were purchased from Aldrich and used without further purification. Melting points were measured with a JSGW melting point apparatus and are uncorrected. Elemental analyses were carried out by using a Thermo-quest CE instruments model EA/110 CHNS-O elemental analyzer. IR spectra were recorded as KBr pellets with a Bruker Vector 22 FT IR spectrophotometer operating from 400 to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

4000 $cm^{-1}$. Compounds **1**–**4** were synthesized according to procedures published by us recently.[14]

**Synthesis of $[Cu(LCOO)_2(NO_3)_2(nBu_2Sn(H_2O)_2)]_n[Cu(LCOO)_2]$ (5):** To a solution of **1** (0.2 mmol, 345 mg) in dichloromethane (100 mL) was added $Cu(NO_3)_2{\cdot}3H_2O$ (0.4 mmol, 93 mg). The reaction mixture was stirred for 2 h at room temperature. An insoluble white solid (**5′**) was removed by filtration. The white solid **5′** has a powder XRD pattern similar to $[nBu_2SnO_2]_n$. The blue filtrate was concentrated to half of its volume and kept for crystallization. Blue crystals started to form after about a week. The crystals were collected, washed with diethyl ether, and dried. Total yield of the blue crystals: 34% (150 mg), m.p. 192–195 °C (d). IR (KBr): $\tilde{\nu}$ = 3341.0 (b), 3154.2–3124.7 (s, d), 2999.5 (w), 2959.2 (s), 2926.2 (s), 2863 (w), 1663.1 (s), 1515.1 (s) 1470.7 (s) 1410.4 (s), 1375.9 (s), 1291.6 (s), 1200.6 (w) 1102.2 (s), 1070.0 (w), 940.3 (w), 773.9 (s) and 749.9 (w) $cm^{-1}$.

A blank experiment was also performed to check if **1** underwent hydrolysis in the absence of the metal salt. Compound **1** (0.10 mmol, 0.18 g) was dissolved in methanol (35 mL), to this was added 2 mL of water. The reaction mixture was stirred for 3 h at room temperature. It was observed that **1** could be fully recovered. This was confirmed by the $^{119}Sn$ NMR [$CDCl_3$: δ = –172.1 (s), –195.5 (s) ppm] of **1** before and after performing the hydrolysis experiment.

Synthetic procedures for compounds **6**–**8**, IR and powder XRD traces for fully hydrolyzed products and their corresponding organooxotin precursors, molecular and supramolecular description for compounds **6**–**8** are given in the Supporting Information.

**X-ray Crystallography:** The crystal data for **5**–**8** were collected with a Bruker Smart diffractometer. All the structures were solved by direct methods using SHELXS-97[16] and refined by full-matrix least-squares on $F^2$ using SHELXL-97. All hydrogen atoms were included in idealized positions, and a riding model was used. Non-hydrogen atoms were refined with anisotropic displacement parameters. The asymmetric unit of compound **5** contains two independent structural entities. (1) A portion of a coordination polymeric chain with one copper (Cu1) and one tin (Sn1). (2) Half of the molecule of a mononuclear copper complex. All the metals in the asymmetric unit (Cu1, Sn1, and Cu2) have 0.5 occupancy. The asymmetric unit of compound **6** contains half of the molecule with two lattice water molecules (O3 and O4). The magnesium atom (Mg1) has 0.5 occupancy in the asymmetric unit and the oxygen atom (O4) of the lattice water molecule is disordered over two positions with 0.5 occupancies. The asymmetric unit of compound **7** contains half of the molecule with one copper center (Cu1) and the copper atom has 0.5 occupancy. The asymmetric unit of **8** contains two perchlorate molecules and a fraction of polymeric chain with three copper centers Cu1, Cu2, and Cu3. The atoms Cu1 and Cu3 have 0.5 occupancy in the asymmetric unit. Two of the perchlorate oxygen atoms (O11 and O14) are disordered. O11 is disordered over two positions with occupancies of 0.5 (O11a) and (O11b) and refined anisotropically. O14 is disordered over three positions with occupancies 0.4(O14a), 0.3 (O14b), and 0.3 (O14c), and are refined isotropically. Because of the inadequate quality of data we were unable to fix the hydrogen atoms on the oxygen atoms of the methanol molecules (O5, O6, and O7).

CCDC-608022, -608024, and -608027 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Figures 1–4 were obtained from the DIAMOND 3.0 software package.

# Tripyrrinatocadmium Complexes: Enforcing Supramolecular Aggregation by a Large Ion

Martin Bröring,*[a] Serguei Prikhodovski,[a] Esther Cónsul Tejero,[a] and Silke Köhler[a]

**Keywords:** Tripyrrin / Cadmium / Porphyrinoids / Supramolecular chemistry

A newly developed method for the preparation of free base tripyrrin ligands HTrpy by cyanide-promoted demetalation of nickel chelates TrpyNiNCO was used in order to explore the chemistry of cadmium tripyrrins TrpyCdX with a variety of anionic co-ligands X. The introduction of the large $Cd^{II}$ ion into the tripyrrin $N_3$ coordination site was accomplished by the use of cadmium acetate as the metal precursor. Ligand exchange experiments using sodium salts of different anions disclose a marked tendency for pentacoordination, which is achieved either by the formation of chelates or of 1D coordination polymers that form as a consequence of the size of the central metal. The attempted introduction of chlorido, iodido, or cyanato ligands thus leads mainly to decomposed material, while the use of 1,1,1-trifluoracetylacetonate, salicylate, and acetate ligands results in stable, pentacoordinate and monomeric complexes with the external ligand bound as a four- or six-membered *O,O*-chelate ring. With the pseudohalogenido ligands thiocyanate, selenocyanate, and azide as well as with the weakly coordinating trifluoroacetate 1D coordination polymers with a variety of chain structures were obtained and investigated by X-ray diffraction studies. Interestingly $TrpyCdN_3$ is present in the crystal as a coordinatively and hydrogen-bonded methanol adduct with a dimeric repeating subunit.

## Introduction

The $Cd^{II}$ ion has only recently been recognized as a useful species in porphyrinoid chemistry. In a series of ring-exchanged porphyrinoids like *m*-benziporphyrin, *S*-confused thiaporphyrin and the like (Figure 1) the spin-active nuclei of $^{111}Cd$ and $^{113}Cd$ ($I = 1/2$) have been used to detect unusual metal–ligand interactions through the observation of $^{1}H$-Cd and $^{13}C$-Cd scalar couplings (so-called "through-space couplings") in the NMR spectra.[1] This approach makes the $Cd^{II}$ ion a unique probe, that allows the direct spectroscopic investigation of nonbonding metal–ligand interactions for diamagnetic ions. Cadmium complexes of porphyrins are also known,[2] but have only scarcely been used[3] due to their pronounced solvolytic lability. The problem appears to be the size of the $Cd^{II}$ ion, which is too large to allow a proper adaptation of the porphyrin macrocycle. This results in largely domed structures with open sites for solvent attack. As has been shown in 1998 flexible open-chain tetrapyrroles with more than four donor atoms are much more effective in providing a suitable coordination sphere for cadmium, which obviously prefers a coordination number of larger than four in a porphyrinoid environment (Figure 1).[4]

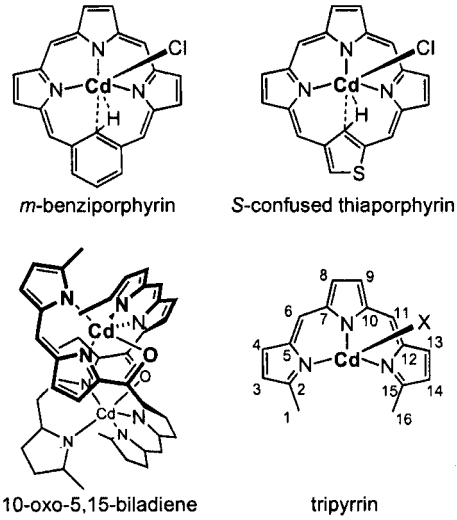

Figure 1. Selected tri- and tetrapyrrolic cadmium chelates.

The tripyrrin ligand HTrpy is formally derived from the macrocyclic parent porphyrin by the loss of one of the four $C_4N$ rings.[5] Chemically, however, the Trpy ligand differs largely from the porphyrin and from other macrocyclic porphyrinoids with respect to ligand stability and the open *cis*-situated coordination site at the central ion. The presence of two terminal methyl moieties, which is currently one of the synthetic limitations of tripyrrin ligand synthesis, leads to an effective shielding of the one coordination site situated in the $N_3M$-plane of a given complex.[6] Earlier studies

have shown, that as a result of this steric constraint palladium(II) complexes of Trpy ligands are always distorted from a square-planar geometry[7] and that tetracoordinate tripyrrinatonickel(II) complexes display a sterically induced HS ground state despite an intermediately strong ligand field.[8]

The presence of two terminal methyl groups at the tripyrrin ligand framework limits the maximum coordination number of all metallotripyrrins described so far to five. The association of a fifth donor L to a four-coordinate compound TrpyMX can in principle occur from either side of the tripyrrin plane, resulting in two different coordination geometries **A** and **B** (Figure 2). In this regard tripyrrins differ largely from the structurally similar, but more flexible bis(arylimino)isoindolines (BAI), which have been shown in the recent past to adopt nonplanar conformations and nonmeridonal tridentate binding modes in several instances.[9] Complexes of type **A** are of particular interest due to their propensity to form 1D- and 3D coordination polymers with a large structural variety. However, the number of ions that have been shown to form five-coordinate metallotripyrrins is almost limited to one, i.e. $Ni^{II}$.[10] In addition, two examples of mononuclear pentacoordinate palladium(II)-tripyrrin complexes and one example for an extremely labile pentacoordinate cobalt(II)-tripyrrin complex have been unravelled.[11] In this contribution we describe our successful attempt to employ the large ion $Cd^{II}$ in order to enforce the formation of 1D coordination polymers from TrpyCd subunits.

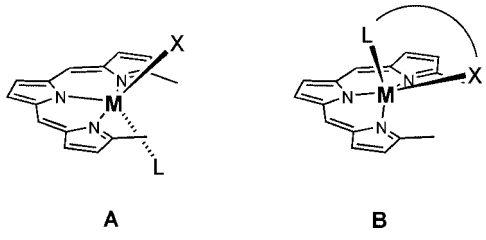

Figure 2. Generalized structures **A** and **B** for pentacoordinate metallotripyrrins.

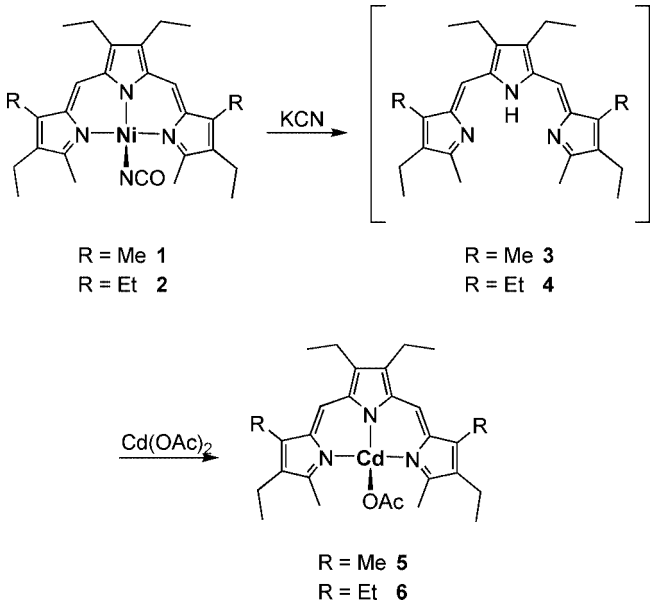
## Results and Discussion

*Preparation and spectroscopic characterization*. During our studies on ligand exchange procedures of TrpyNi complexes we recently realized that the attempted ligand exchange of the isocyanates TrpyNiNCO **1** and **2**[10a] with excess cyanide results in the demetalation of the chelate complexes, which is indicated by an immediate color change from dark green to red. The red solutions of the putative free base tripyrrins **3** and **4**, which were obtained after washing with water and phase separation, proved very unstable over time. The advent of the free base ligands **3** and **4**, however, opens the desired possibility to obtain more sensitive tripyrrin complexes like TrpyCdX, which are unavailable by other means. For the metalation of the free base tripyrrins a two-phase system with the ligand in the ethereal phase and $Cd(OAc)_2$ in the aqueous one was applied. Some methanol was added to ensure the interpenetration of the two layers and thus to enhance the metalation rate. No additional base is necessary to drive the metalation to completion. Since the removal of the solvent often leads to the decomposition of sensitive metallotripyrrins the product solutions of **5** and **6** were used directly in ligand exchange reactions without further purification. Only for TrpyCdOAc **5** an attempt to isolate and characterize the compound was undertaken (Scheme 1).



Scheme 1. Preparation of tripyrrinatocadmium complexes **5** and **6** via free base tripyrrins **3** and **4**.

The composition TrpyCdOAc was confirmed for the new complex **5** by elemental analysis and by EI mass spectrometry, which shows two peaks at $m/z$ = 561 and 501 for the $M^+$ and $[M - OAc]^+$ ion, respectively. The UV/Vis spectrum is dominated by two absorptions at 350 and 650 nm from ligand-based transitions and resembles those of other metallotripyrrins.[10,11] Spectroscopically, the new complex shows $A_2X_3$ systems for two chemically distinct ethyl substituents in addition to four singlets for the methyl groups at C-2,15 ($\delta$ = 2.50 ppm), C-4,13 ($\delta$ = 2.20 ppm) and at the acetate ($\delta$ = 1.87 ppm) as well as for the *meso* protons at C-6,11 ($\delta$ = 6.86 ppm). The spectrum is almost indistinguishable from those of TrpyZnX species[12] and contains no information for the coordination mode of the acetato ligand. From IR data the acetate coordination can be assigned to a bidentate binding mode. The $\nu_{CO}$ stretching band is found at 1553 $cm^{-1}$ and therefore below the value for the free acetate ion. For monodentate acetate ligands stretching frequencies of >1600 $cm^{-1}$ are typical.[13] TrpyCdOAc **5** can therefore be regarded as a pentacoordinate species, presumably of type **B**.

Ligand exchange reactions were carried out on **5** and **6** under biphasic standard conditions using different monoanionic halide, pseudohalide, and *O*,*O*-chelate ligands as their sodium salts (Scheme 2). The use of chlorido-, bromido-, iodido-, and cyanato ligands resulted in labile material which decomposed to a large extent upon the attempted

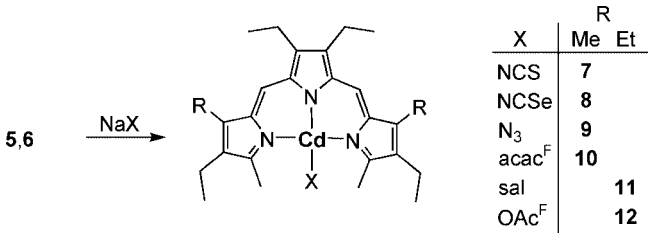
isolation. For X = NCS, NCSe, $N_3$, sal, 1,1,1-trifluoracetylacetonate ($acac^F$), and trifluoroacetate ($OAc^F$), however, pure complexes TrpyCdX **7**–**12** were obtained in good yield (the azido derivative **9** was obtained as a methanol adduct) and characterized by means of elemental analyses and mass spectra.



| X | R: Me | Et |
|---|---|---|
| NCS | **7** | |
| NCSe | **8** | |
| $N_3$ | **9** | |
| $acac^F$ | **10** | |
| sal | | **11** |
| $OAc^F$ | | **12** |

Scheme 2. Anion metathesis reactions on tripyrrinatocadmium complexes **5** and **6**.

All new complexes form violet crystals with a metallic sheen. In solution intense green colors are observed throughout. The solubility, however, differs strongly with the anionic ligand. The pseudohalide derivatives TrpyCdNCS **7**, TrpyCdNCSe **8**, and TrpyCd$N_3$(MeOH) **9** are almost insoluble in nondonor solvents, while the compounds with the *O*,*O*-chelate ligands TrpyCdacac$^F$ **10**, TrpyCdsal **11**, and TrpyCdOAc$^F$ **12** dissolve readily in, for example, dichloromethane. From UV/Vis data **7**–**12** can be divided into two groups. Thiocyanate **7** and selenocyanate **8** yield optical spectra with two major maxima at about 345 and 630 nm, while the *O*,*O*-chelated species **10**–**12** and the methanol-azido compound **9** yield spectra similar to that of the acetato complex **5** with maxima at about 350 and 650 nm. $^1$H and $^{13}$C NMR spectra of **7**–**12** are also very similar to the one discussed in detail for **5** and differ mainly by the signals for the respective anionic coligands. Characteristic shifts for the coordination number or type were not found for the diamagnetic cadmium chelates (Figure 3).

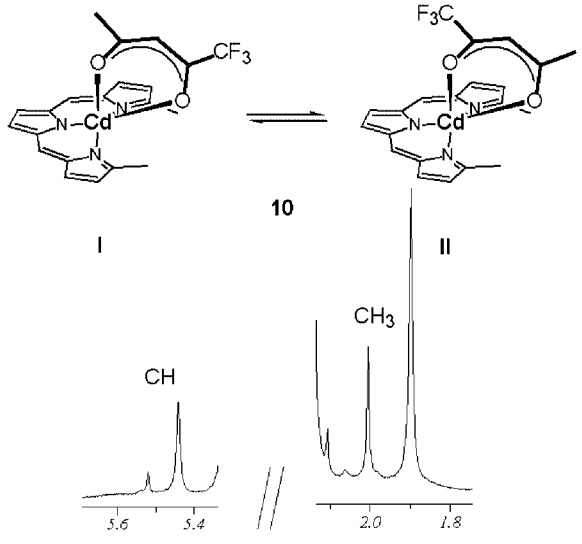


Figure 3. Details of the $^1$H NMR spectra of TrpyCdacac$^F$ (**10**) (230 K, $CD_2Cl_2$) and schematic representations of isomers I and II (β-alkyl groups omitted).

Dynamic behavior was observed in the proton NMR spectra of the 1,1,1-trifluoroacetoacetato derivative TrpyCdacac$^F$ **10**. At ambient temperature, the resonance signals of the $acac^F$ ligand appear extremely broadened and split into two pairs of singlets with a ratio of 5:2 at low temperature (Figure 3). At 230 K, the peaks for the major form are found at 1.90 ($CH_3$) and 5.44 (CH) ppm, while those for the minor form are recorded low field at $\delta$ = 2.00 and 5.52 ppm. This dynamic process of **10** can be interpreted in terms of the interconversion of two isomers I and II (Figure 3). The attempted assignment of I and II to major and minor form by a ROESY experiment, however, failed.

IR spectroscopy is a particularly well-suited tool in order to determine the binding mode (i.e. terminal or bridging) of the anion in complexes with pseudohalide ligands, and thus to assign the degree of complex association. Typical of monomeric omplexes with *N*-bound terminal NCS and NCSe ligands are $\nu_{as}$ vibrations with wavenumbers well below 2100 cm$^{-1}$.[13] For TrpyCdNCS (**7**) and TrpyCdNCSe (**8**), however, the band for this vibration is found at 2103 and 2115 cm$^{-1}$, respectively. In combination with the low solubility of these species this finding points to the presence of bridging pseudohalide ligands for **7** and **8** and thus of coordination polymers in the solid state. The thiocyanate ion has frequently been reported as a bridging ligand in coordination polymers,[14,15] as has been for the homologous selenocyanate, although reports about the use of this nonconventional pseudohalide are rather rare.[15,16]

In the IR spectra of the azido complex TrpyCd$N_3$(MeOH) (**9**) two equally intense bands are found in the region for the $N_3$ vibrations at 2090 and 2067 cm$^{-1}$. As before these values are higher than those expected for complexes with terminal monodentate azido ligands. In addition, the splitting into two bands indicates, that the azide is situated in a bridging coordination mode. From this data it remains open, whether an *end-on* ($\mu_{1,1}$) or an *end-to-end* ($\mu_{1,3}$) coordination is realized for **9**.[17] The $\nu_s$ bands at about 1300 cm$^{-1}$, which are characteristic for the distinction between these two binding modes, overlap severely with bands from the tripyrrin backbone and cannot be assigned unambiguously. For sterical reasons, however, the *end-to-end* ($\mu_{1,3}$) coordination is favored and thus the formation of a polymeric structure of TrpyCd$N_3$(MeOH) (**9**).

*X-ray crystallographic characterization*. Single crystal X-ray diffraction studies were undertaken on suitable crystals of the pseudohalide species TrpyCdNCS (**7**), TrpyCdNCSe (**8**), and TrpyCd$N_3$(MeOH) (**9**) as well as on the *O*,*O*-chelate complexes TrpyCdacac$^F$ (**10**), TrpyCdsal (**11**), and TrpyCdOAc$^F$ (**12**) and will be discussed below. Details for the structure solutions and refinements are summarized in Table 1.

TrpyCdNCS and TrpyCdNCSe crystallize isotypically by slow evaporation of respective solutions in toluene/methanol in the monoclinic system, space group *C*2/c, with *Z* = 4 and very similar unit cell metrics [**7**: *a* = 26.972(3), *b* = 11.7933(9), *c* = 18.827(2) Å, *β* = 95.564(13)°; **8**: *a* = 27.073(2), *b* = 11.9547(9), *c* = 18.7485(16) Å, *β* = 95.391(10)°]. In both cases one half molecule of a severely

disordered toluene molecule per formula unit is present in the cell. As expected from the IR spectroscopic results both compounds indeed form 1D coordination polymers (Figure 4; Table 2).

TrpyCdNCS (**7**) and TrpyCdNCSe (**8**) form type **A** metallotripyrrins in the solid state. The coordination environment of the $Cd^{II}$ ion in 7 and **8** can be assigned to distorted trigonal bipyramids with N1 and N3 in the apices and N2, N4, and S or Se, respectively, in the equatorial positions. The assignment is based mainly on the N–Cd–N and N–Cd–S/Se angles which deviate less than 11° from the ideal 90°, 120°, or 180° for this polyhedron. The combination of the large ionic radius of cadmium and the coordination number of 5 results in the longest M–$N_{Trpy}$ bonds of 2.217–2.274 Å observed so far in the chemistry of the tripyrrins. The typical relation, that the central M–N2 bond is shorter than the terminal N1–M and N3–M bonds, is found for type **A** cadmium tripyrrins, too. The tripyrrin backbones C2–C15 of both compounds display slight helical distortions, which appears necessary in order to accommodate the large cadmium atom in the ligand N,N,N planes [deviation ("doming") for **7**: 0.0799(2), for **8**: 0.1545(3) Å]. As a result the methyl termini C1 and C16 are as far apart from each other as 5.570(6) (**7**) and 5.596(6) Å (**8**) and leave much space for the binding of N4 and S/Se. In fact, despite the size of the S or Se donor the arrangement at the open sites of the TrpyCd moieties is almost unstrained, and the distance between the N4 and S/Se donor on one hand and the terminal methyl groups C1, C16 on the other undercuts the sum of the van der Waals distances by only 4.5 (**7**) and 5.8% (**8**). For comparison, this value is of the same magnitude as for most tetracoordinate metallotripyrrins, and is increased to almost 20%, if the metal enforces a square-planar coordination mode like in TrpyNiCN.[10a]

Repeating units of TrpyCdNCS (**7**) (top left) and TrpyCdNCSe (**8**) (top right) from X-ray crystallographic analyses, and representation of the isotypical single chain arrangements of **7** (left) and **8** (right; ellipsoids set at 50% probability; hydrogen atoms omitted for clarity).

As mentioned above, **7** and **8** form isotypical 1D coordination polymers that propagate in the direction of the crystallographic *b* axis. The TrpyCd plates are organized with a Cd···Cd distance of 6.184 (**7**) and 6.230 Å (**8**), and arrange

almost vertical with an angle of 97.2 (**7**) and 93.4° (**8**) towards each other. This arrangement is a result of the size (NCS: 2.805; NCSe: 2.948 Å) and binding angles Cd–N4–C27 and Cd–S/Se–C27 of the almost linear pseudohalide ligands (NCS: 177.86; NCSe: 176.84°). As depicted in Figure 4, the coordination of the pseudohalide ligand via the *N*-donor end is rather straight with 166.98 for **7** and 169.42° for **8**, while the chalcogeno donors coordinate at angles as steep as 98.61 (**7**) and 94.14° (**8**). This relaxed arrangement still allows a tight intrastrand packing of the monomers, with minimum distances between methyl carbon atoms of one unit and the $sp^2$ system of the next of 3.283 (7) and 3.254 Å, and without losing the rather weak Cd–S and Cd–Se coordination.

The pillars consisting of the 1D polymeric strands of **7** and **8** pack more tightly in the crystallographic *c* than in the *a* direction, forming layers of pillars with interdigitated alkyl groups in the solid state. These layers are glued together by disordered toluene molecules that occupy the clefts and thus stabilize the structures of **7** and **8** (Figure 5).

The azido ligand deviates from the above pseudohalides by a reduced size. This change in metrics leads to a different solid-state arrangement for **9** and to the necessity to introduce methanol into the coordination of the cadmium ion. After crystallization of freshly prepared $TrpyCdN_3$ from a toluene/methanol mixture the 1D coordination polymer **9** was obtained, which displays chains of methanol and H-bridge linked $TrpyCdN_3$ dimers. The chain structure of **9**, a detailed view of the dimeric building block and a representation of the layer-like structure formed by the individual chains are presented in Figure 6. Crystallographic data

Figure 5. for **9** and selected molecular parameters can be found in Table 1 and Table 2.

The dinuclear $(TrpyCd)_2N_3$ fragment of the coordination polymer **9** consists of two nonequivalent cadmium tripyrrin units TrpyCd1 and TrpyCd2. In order to adapt sterically to the voluminous $Cd^{II}$ ions the tripyrrin ligands of both TrpyCd units show a slight helical distortion known as "ruffling" in porphyrin chemistry[20] with mean deviations from planar $C_{14}N_3$ frameworks of 0.105 and 0.089 Å for TrpyCd1 and TrpyCd2, respectively. The coordination geometry at the cadmium ions can be described in both cases as distorted trigonal bipyramidal with N1,N2 and N4,N6

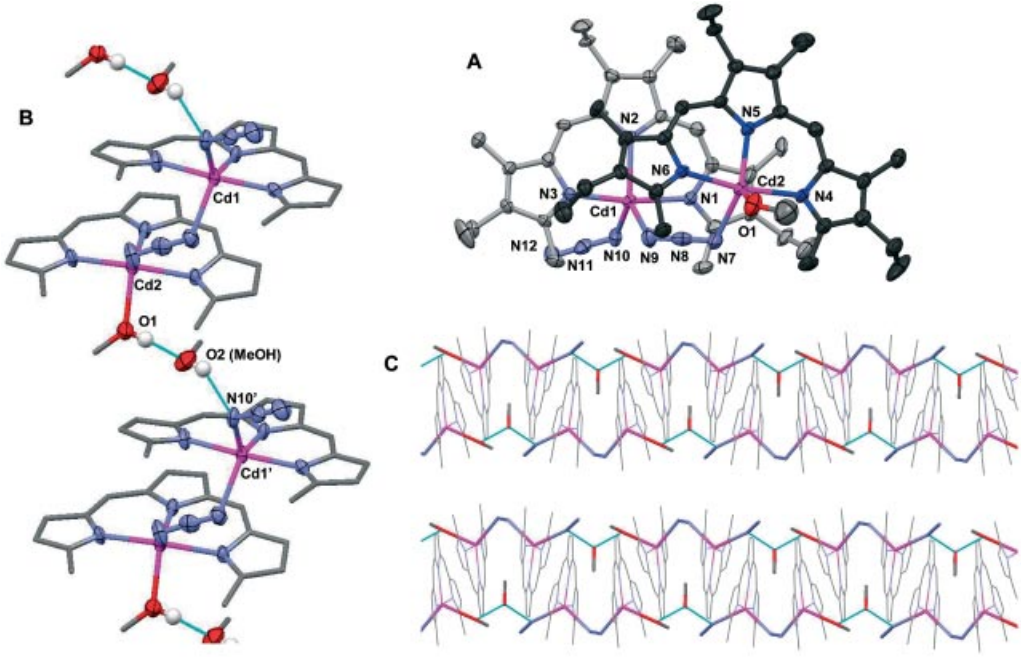

Figure 6. Presentation of the dimeric asymmetric unit (**A**, ellipsoids at 50% probability), the MeOH and H-bond initiated chain formation (**B**, ball-and-stick representation) and the sheet structure (**C**) of coordination polymer $[TrpyCdN_3(MeOH)]_n$ (**9**) [hydrogen atoms (A–C) and β-alkyl substituents (B,C) omitted for clarity].

in the apical positions, and with N2,N9,N10 and N5,N7,O1 in the equatorial ones. The deviation from an ideal geometry is particularly large for the TrpyCd2 subunit, where angles N7–Cd2–O1 and N4–Cd2–N6 are found at 107.2(3) and 168.9(2)° instead of the ideal 120 and 180°, respectively. Cd1 and Cd2 are bridged by a linear $\mu_{1,3}$ azido ligand [N7–N8–N9: 178.6(9)°], which coordinates to both metal ions in a bent fashion [Cd1–N9–N8: 118.2(6)°, Cd2–N7–N8: 116.2(5)°] and with a torsion Cd1–N9–N7–Cd2 of 75.2(5)°. The Cd–N bonds to the $\mu_{1,3}$ azido ligand are longer for Cd1–N9 than for Cd2–N7 [2.356(8) vs. 2.294(8) Å], which results in slightly asymmetric N–N bonds within the azide anion of N7–N8: 1.215(12) and N8–N9: 1.192(12) Å. The mean planes of the $C_{14}N_3$ frameworks of the tripyrrin subunits are arranged almost coplanar with an angle of 13.57(11)°, and are rotated against each other by 14.4(2)° as indicated by the N2–Cd1–Cd2–N5 torsion angle. The cadmium ions Cd1 and Cd2 of the dimeric unit are separated by 5.2139(12) Å.

A second azido ligand is coordinated to Cd1 with a Cd1–N10 distance of 2.296(8) Å and a Cd1–N10–N11 angle of 120.1(6)°. Cd2, on the other hand, is coordinated to the oxygen atom O1 of a methanol molecule as the fifth donor in a distance of 2.356(7) Å. The N10- and O1′ atoms of neighboring dimeric fragments are connected to each other by H-bonds to a second molecule of methanol at O1′–O2 and O2–N10 distances of 2.623(8) and 2.748(8) Å, respectively. This H-bond network results in the formation of a 1D-coordination polymer (**B** in Figure 6) with the Cd atoms of neighboring dimers Cd1 and Cd2′ situated 8.154(6) Å apart from each other. From a structural point-of-view the second azido anion N10N11N12 should be assigned as a $\mu_{1,1}$ bridging ligand rather than as a terminal azide. As for **7** and **8** before the single chains of the 1D coordination polymer **9** organize to 2D sheets in the crystal lattice, but in this case without interlayered solvent (**C** in Figure 6).

From a dichloromethane/*n*-hexane solution a single crystal of **10** was grown. The X-ray crystallographic analysis proofs the chelate character of the $acac^F$ ligand in the solid state (Figure 7). From the possible isomers only form I (see Figure 3) is present in the crystal. One of the six ethyl groups as well as the $CF_3$ group of the $acac^F$ ligand were found disordered and treated as such in the structure refinement. Selected molecular parameters of **10** are summarized in Table 3.

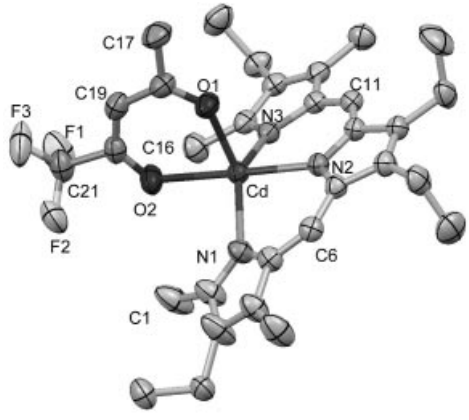

Figure 7. Molecular structure of $TrpyCdacac^F$ (**10**) (ellipsoids at 50% probability; hydrogen atoms omitted for clarity).

The crystallographic analysis identifies **10** as a monomeric molecule of type **B** with a $\kappa^2$ coordinated $acac^F$ li-

gand. The coordination of the tripyrrin ligand to the voluminous cadmium atom demands a doming of 0.7639(1) Å and an additional distortion of the ligand backbone similar to the *saddling* conformation of the porphyrins.[20] The Cd$^{II}$ ion is bound to the three nitrogen donors at distances of 2.21–2.26 Å. Perpendicular to the TrpyCd subunit the anionic acac$^F$ ligand forms a six-membered chelate ring with an O1–Cd–O2 angle of 80.18(6)° and Cd–O1 and Cd–O2 distances of 2.2873(15) and 2.2613(16) Å, respectively. The $CdN_3O_3$ core forms a distorted trigonal bipyramidal structure with N2 and O2 in the apices. With respect to the ideal values the angle N1–Cd–N3 of 140.13(6)° shows the largest deviation. Surprisingly, the distance between O2 and the methyl termini C1 and C16 of **29** is found up to 11.5% below the sum of the van der Waals radii, producing a significant amount of intramolecular strain. A six-membered chelate ring thus appears too large for a strainless coordination of two donor centers from one side of a TrpyM subunit.

Single crystals from TrpyCdsal (**11**) were obtained from dichloromethane/*n*-hexane solutions. For **11** one half molecule of dichloromethane per formula unit is present in the crystal lattice. A disorder model with two orientations for the solvent was successfully applied in the solution and refinement of the structure. The results of the crystallographic determination proves the preferential formation of a four-membered over a possible six-membered ring chelate, as observed before in a related nickel(II)-tripyrrin.[10a] The molecular structure of **11** is shown in Figure 8. Table 3 contains selected molecular parameters.

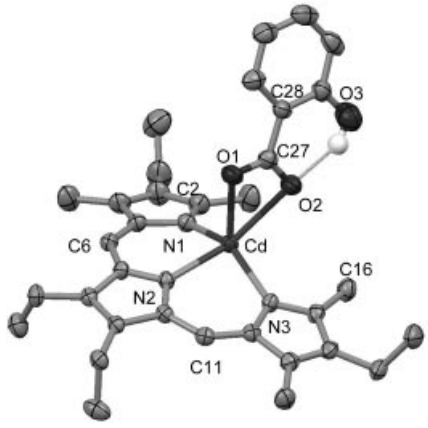

Figure 8. Molecular structure of the salicylato complex TrpyCdsal (**11**) (ellipsoids at 50% probability; CH hydrogen atoms omitted for clarity).

TrpyCdsal can be assigned to a pentacoordinate metallotripyrrin of type **B**. A noticeable feature of the molecular structure of **11** is the severely distorted $C_{14}N_3$ perimeter of the trpyrrin ligand which has a maximum deviation from the mean tripyrrin plane of 0.307(6) Å as compared to only 0.165(3) Å for the related nickel derivative.[10a] The Cd–N bonds of **11** are 2.199(3)–2.221(4) Å long and therefore at the short end of those observed in this series of cadmium complexes. The sal ligand of **11** is coordinated via both carboxylate oxygen atoms to the metal ions with M–O1 being the smaller distance. The aromatic ring of the salicylato ligands and the four-membered $CO_2M$ ring are oriented towards each other in a coplanar fashion, and the sal ligand of **11** is tilted by about 20° from a perpendicular arrangement with the tripyrrin. This finding is caused by an intermolecular π-stacking interaction of the sal group with a $C_4N$ subunit of a neighboring molecule of **11**. The sal complex shows an intramolecular H-bridge from the hydroxy functionality of the salicylato ligands, which binds to O2 with an O2–O3 distance of 2.564(6) Å. This is different from the above-mentioned nickel chelate, where the aryl group is rotated by 180° so as to form a H-bridge with O1. With respect to the O2–$C_{term}$ distance and the *out-of-plane* distortion of the tripyrrin ligand the structure of complex **11** with the four-membered *O*,*O* chelate appears to be more relaxed than that of the six-membered ring chelate TrpyCdacac$^F$ **10**. This finding emphasizes the preference of four- vs. six-membered ring chelate formation on sterically hindered TrpyM fragments.

A different scenario is provided by the structure of the trifluoroacetate **12** (Figure 9, Table 3). The donor strength of the weak OAc$^F$ ligand appears too small to compensate for the strain of a four-membered ring chelate. Therefore, this ring opens at the Cd–O2 bond up to a distance between these atoms of 3.333(3) Å. At the same time, the O2′ donor atom of an adjacent TrpyCdOAc$^F$ molecule coordinates to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the free site at the Cd central atom in a distance of 2.346(3) Å. Similar to the NCS/NCSe and the azido/methanol derivatives **7**–**9** a chain structure from coordinatively connected pentacoordinate TrpyCd fragments results. Complex **12** thus escapes the strained situation of a four-membered ring by the formation of a typical coordination polymer with type **A** metallotripyrrin fragments.

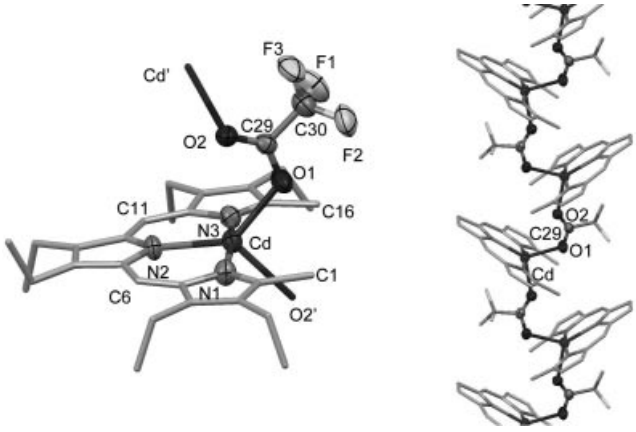

Figure 9. Crystallographically determined structure of the monomeric unit (left; ellipsoids at 50% probability) and the polymeric chain arrangement (right) of TrpyCdOAc$^F$ (**12**) (hydrogen atoms and ethyl groups omitted for clarity).

The trifluoroacetate in **12** functions as a nonsymmetrical bridging ligand. O1 is bound with greater strength to the central metal atom than O2 as indicated by a shorter Cd–O1 bond ($\Delta$ = 0.083 Å) and a longer O1–C29 bond ($\Delta$ = 0.049 Å). The coordination geometry at the cadmium atom can best be described as distorted trigonal bipyramidal with O1, O2, and N2 at the equatorial and N1, N3 at the apical positions. The distortion is particularly strong at the O1–Cd–O2 angle, which is found to be as narrow as 95.76(11)° instead of the ideal 120°. The monomeric units are organized with a Cd···Cd′ distance of 5.541(2) Å and thus further apart than for the dimeric unit of **9** although the O1···O2 distance is as short as 2.222(3) Å. Other than in the azido case **9** the TrpyCd fragments of **12** are not in a near-coplanar orientation but are found to be bent towards each other by 67.39(17)° and additionally rotated by 172.40(19)°, similar to that found for the pseudohalide species **7** and **8**. The markedly planarized tripyrrin ligand of **12** and the O–$C_{term}$ distances of only 8.8% or less below the sum of the van der Waals radii prove the polymeric form as a largely strain-free assembly and an alternative for cases with weakly bound *O*,*O* chelate ligands. The individual pillars are densely packed in all directions and leave no inner space between the isolated chains. The formation of layers, which was seen in **7**–**9**, is also not detected in this case.

## Conclusions

We have shown for a series of pseudohalide and *O*,*O*-chelate ligands that the size of the cadmium(II) ion leads to the formation of tripyrrinatocadmium(II) complexes TrpyCdX with a high propensity for pentacoordination. It appears, that complexes containing the TrpyCd fragment seem to be insufficiently shielded with only four donors at the metal ion and tend to form the desired larger associates. Most of the crystallographically determined molecular structures of these new complexes display coordination polyhedra, which deviate significantly from ideal geometries. The structures are determined by steric factors alone and can be understood on the basis of van der Waals radii and intramolecular interactions. The two limiting geometries **A** and **B** typically obtained for pentacoordinate metallotripyrrins have both also been observed in the case of $Cd^{II}$.

In all 1D-coordination polymers formed from the TrpyCd fragment the external donor atoms bind from opposite sites of the TrpyCd plane, i.e. in type **A**. Unstrained complexes with almost planar Trpy ligands result from this arrangement. *O*,*O*-Chelating co-ligands, however, usually bind with both oxygen donor atoms from the same side of the TrpyCd unit (type **B**). The presence of two donor atoms in the same segment of the coordination sphere results in additional intramolecular strain. The stresses are compensated for by a shortening of the $O_{donor}\cdots CH_{3term}$ distances and by nonplanar tripyrrin conformations. The weak donor ligand trifluoroacetate in the complex TrpyCdOAc$^F$ (**12**) is not capable of keeping up the strained situation of geometry **B**. In this case a strain-driven polymerization with transformation of the coordination environment to geometry **A** is observed.

To summarize, we have achieved the first general description of the syntheses, spectroscopic properties, and structures of sterically hindered tripyrrinatocadmium(II) complexes.

## Experimental Section

**General:** All reagents were purchased from commercial sources and used as received. Solvents were dried by standard protocols and distilled prior to use. TrpyNiNCO **1** and **2**[10a] and sodium 1,1,1-trifluoroacetylacetonate[21] were prepared according to literature procedures. NMR spectra were obtained with a Bruker AMX 400 spectrometer. Chemical shifts ($\delta$) are given in ppm relative to residual protio solvent resonances ($^1$H spectra), chloroform ($^{13}$C), or $CFCl_3$ ($^{19}$F). Mass spectra were recorded with a Finnigan 90 MAT (EI, FAB), Finnigan-MAT 95S (ESI), or the Bruker Biflex IV instrument (MALDI-TOF); *m*/*z* values are given for the most abundant isotopes only. IR spectra were recorded with a Bruker Vector 22 spectrometer in Nujol paste. UV data were collected with a Hitachi U-3200 spectrophotometer. For X-ray crystallographic measurements an IPDS-1 or IPDS-2 instrument from STOE was used.

**Preparation of Complexes**

**Acetato(tripyrrinato)cadmium Complexes 5 and 6 (TrpyCdOAc) from Free Base Tripyrrins. General Procedure:** Complexes **1** or **2** of type TrpyNiNCO (0.1 mmol) was dissolved in diethyl ether (40 mL) and treated with a saturated KCN solution (10 mL) at ambient temperature in an ultrasonic bath for 2 h. During this time the color of the mixture changes from green to red. After phase separation the organic layer was washed with water (2 × 20 mL) and dried with sodium sulfate, which resulted in a red ethereal solution of **3** or **4**. These solutions were treated with water (30 mL) and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a saturated solution of cadmium(II) acetate in methanol (5 mL). Upon stirring of this mixture for 30 min at ambient temperature the color changes to blue-green. The phases were separated and the organic layer was washed with water (2 × 10 mL) and dried with sodium sulfate. The resulting solution of cadmium complex **5** or **6** can directly be used for further reactions. For **5** an attempt to isolate the compound was performed by reducing the volume of the solution to 5 mL and adding ice-cold pentane. Violet microcrystals of **5** precipitated overnight. Yield: 43.1 mg (77%). $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.08 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.19 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.87 (s, 3 H, OAc), 2.20 (s, 6 H, 2× $CH_3$), 2.42 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 2.50 (s, 6 H, 2× $CH_3$), 2.62 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 6.86 (s, 2 H, 2× $H_{meso}$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CD_2Cl_2$): $\delta$ = 10.0, 14.3, 17.4, 17.5, 17.9, 18.2, 21.5, 120.1, 136.0, 139.2, 143.3, 144.6, 145.4, 171.4, 180.3 ppm. MS (70 eV, EI): $m/z$ (%) = 561 ($M^+$), 501 ([M – OAc]$^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 279 (18000), 350 (69000), 413 (11000), 610 sh (35000), 648 nm (60000 mol$^{-1}$ dm$^3$ cm$^{-1}$). IR (Nujol): $\nu$ = 1597 ($\nu_{C=C}$), 1553 ($\nu_{C=O}$) cm$^{-1}$. $C_{28}H_{37}CdN_3O_2$ (560.023): calcd. C 60.05, H 6.66, N 7.50; found C 59.82, H 6.79, N 7.60.

**Ligand Exchange by Treatment with Aqueous Salt Solutions. General Procedure:** The solution of acetato cadmium complex TrpyCdOAc **5** or **6** (0.1 mmol based on 100% yield) in diethyl ether (30 mL) was treated with a saturated NaY solution (15 mL; Y = anionic ligand) with intense stirring for 16 h. The ether was removed from the mixture in vacuo, and the product was filtered off the aqueous phase and washed with additional water. If the solubility was sufficiently low, the residue was washed with cold pentane or methanol and dried in vacuo.

**Thiocyanato-(3,8,9,14-tetraethyl-2,4,13,15-tetramethyltripyrrinato)-cadmium(II) (TrpyCdNCS, 7):** Yield: 48.1 mg (86%). $^1$H NMR (400 MHz, [D$_6$]acetone): $\delta$ = 1.07 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.15 (t, $J$ = 7.6 Hz, 6 H, 2×$CH_2CH_3$), 2.19 (s, 6 H, 2× $CH_3$), 2.43 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 2.56 (s, 6 H, 2× $CH_3$), 2.65 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 6.92 (s, 2 H, 2× $H_{meso}$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, [D$_6$]acetone): $\delta$ = 11.3, 16.2, 18.4, 19.3, 19.7, 20.0, 121.7, 138.6, 141.3, 144.6, 146.6, 147.7, 173.4 ppm. MS (70 eV, EI): $m/z$ (%) = 560 ($M^+$), 501 ([M – SCN]$^+$). UV/Vis (acetone): $\lambda_{max}$ ($\varepsilon$) = 345 (58000), 401 (9000), 600 sh (34700), 630 nm (61100 mol$^{-1}$ dm$^3$ cm$^{-1}$). IR (Nujol): $\nu$ = 2103 ($\nu_{NCS}$), 1595 cm$^{-1}$ ($\nu_{C=C}$). $C_{27}H_{34}CdN_4S$ (559.06): calcd. C 58.01, H 6.13, N 10.02; found C 58.36, H 6.46, N 9.69.

**Selenocyanato-(3,8,9,14-tetraethyl-2,4,13,15-tetramethyltripyrrinato)cadmium(II) (TrpyCdNCSe, 8):** Yield: 54.5 mg (90%). $^1$H NMR (400 MHz, [D$_6$]acetone): $\delta$ = 1.05 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.16 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 2.19 (s, 6 H, 2× $CH_3$), 2.42 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 2.55 (s, 6 H, 2× $CH_3$), 2.66 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 6.94 (s, 2 H, 2× $H_{meso}$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, [D$_6$]acetone): $\delta$ = 10.2, 15.0, 17.8, 18.2, 18.6, 18.9, 120.6, 134.1, 137.3, 140.2, 145.4, 150.1, 172.1 ppm. MS (70 eV, EI): $m/z$ (%) = 606 ($M^+$), 501 ([M – SeCN]$^+$). UV/Vis (acetone): $\lambda_{max}$ ($\varepsilon$) = 345 (60000), 403 (9000), 595 sh (35000), 631 nm (62000 mol$^{-1}$ dm$^3$ cm$^{-1}$). IR (Nujol): $\nu$ = 2115 ($\nu_{NCSe}$), 1596 cm$^{-1}$ ($\nu_{C=C}$). $C_{27}H_{34}CdN_4Se$ (605.96): calcd. C 53.51, H 5.66, N 9.25; found C 53.33, H 5.91, N 8.86.

**Azido-(3,8,9,14-tetraethyl-2,4,13,15-tetramethyltripyrrinato)-cadmium(II)·MeOH (TrpyCdN$_3$·MeOH, 9):** Purified by recrystallization from methanol/toluene. Yield: 47.1 mg (82%). $^1$H NMR (400 MHz, $CD_3OD$): $\delta$ = 1.09 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.18 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 2.16 (s, 6 H, 2× $CH_3$), 2.43 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 2.45 (s, 6 H, 2× $CH_3$), 2.64 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 6.78 (s, 2 H, 2× $H_{meso}$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, [D$_6$]DMSO): $\delta$ = 9.6, 14.4, 15.3, 16.2, 17.3, 17.6, 17.7, 119.1, 136.0, 138.6, 141.5, 143.7, 144.8, 170.8 ppm. MS (70 eV, EI): $m/z$ (%) = 501 ([M – MeOH – SeCN]$^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 270 (14000), 335 sh (26000), 350 (51000), 413 (10000), 564 sh (14000), 610 sh (24000), 649 nm (41000 mol$^{-1}$ dm$^3$ cm$^{-1}$). IR (Nujol): $\nu$ = 2090, 2067 ($\nu_{NNN}$), 1594 cm$^{-1}$ ($\nu_{C=C}$). $C_{27}H_{38}CdN_6O$ (575.041): calcd. C 56.39, H 6.66, N 14.61; found C 56.67, H 6.53, N 14.35.

**Salicylato-(3,8,9,14-tetraethyl-2,4,13,15-tetramethyltripyrrinato)-cadmium(II) (TrpyCdsal, 10):** Yield: 42.1 mg (66%). $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.05 (t, $J$ = 7.5 Hz, 6 H, 2× $CH_2CH_3$), 1.20 (t, $J$ = 7.5 Hz, 6 H, 2× $CH_2CH_3$), 2.19 (s, 6 H, 2× $CH_3$), 2.39 (q, $J$ = 7.5 Hz, 4 H, 2× $CH_2CH_3$), 2.51 (s, 6 H, 2× $CH_3$), 2.62 (q, $J$ = 7.5 Hz, 4 H, 2× $CH_2CH_3$), 6.88 (s, 2 H, 2× $H_{meso}$), 6.73–6.78, 6.80–6.82, 7.27–7.33, 7.81–7.83 (4m, 4 H, $H_{Ar}$), 12.21 (br., 1 H, O$H$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CD_2Cl_2$): $\delta$ = 10.0, 14.3, 17.4, 17.6, 18.0, 18.2, 116.5, 118.3, 120.0, 131.6, 133.8, 136.1, 139.3, 143.4, 144.5, 145.4, 161.4, 171.3 ppm. MS (70 eV, EI): $m/z$ (%) = 501 ([M – sal]$^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 278 (18000), 350 (69000), 413 (12000), 600 sh (33000), 648 nm (60000 mol$^{-1}$ dm$^3$ cm$^{-1}$). IR (Nujol): $\nu$ = 3384 ($\nu_{OH}$), 1595 cm$^{-1}$ ($\nu_{C=C}$, $\nu_{C=O}$). $C_{33}H_{39}CdN_3O_3$ (638.092): calcd. C 62.12, H 6.16, N 6.59; found C 61.91, H 6.07, N 6.34.

**1,1,1-Trifluoroacetylacetonato-(3,8,9,14-tetraethyl-2,4,13,15-tetramethyltripyrrinato)cadmium(II) (TrpyCdacac$^F$, 11):** Yield: 39.2 mg (60%). $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.06 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.20 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.93 (br., 3 H, $CH_3$ [acac$^F$]), 2.18 (s, 6 H, 2× $CH_3$), 2.40 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 2.47 (s, 6 H, 2× $CH_3$), 2.64 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 5.46 (br., 1 H, C$H$ [acac$^F$]), 6.86 (s, 2 H, 2× $H_{meso}$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CD_2Cl_2$): $\delta$ = 10.0, 14.3, 17.1, 17.3, 18.0, 18.2, 29.8, 120.0, 136.1, 138.9, 143.2, 144.5, 146.0, 172.3 ppm. $^{19}$F{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = –76.2 ppm. MS (70 eV, EI): $m/z$ (%) = 501 ([M – acac$^F$]$^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 276 (18000), 351 (69000), 410 (11000), 605 sh (30000), 652 nm (61000 mol$^{-1}$ dm$^3$ cm$^{-1}$). IR (Nujol): $\nu$ = 1636, 1612 ($\nu_{C=O}$), 1594 cm$^{-1}$ ($\nu_{C=C}$). $C_{31}H_{38}CdF_3N_3O_2$ (654.059): calcd. C 56.93, H 5.86, N 6.42; found C 56.59, H 5.81, N 6.25.

**Trifluoracetato-(3,4,8,9,13,14-hexaethyl-2,15-dimethyltripyrrinato)-cadmium(II) (TrpyCdOAc$^F$, 12):** Yield: 43.0 mg (67%). $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.10 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.19 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 1.20 (t, $J$ = 7.6 Hz, 6 H, 2× $CH_2CH_3$), 2.42 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 2.51 (s, 6 H, 2× $CH_3$), 2.62 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 2.63 (q, $J$ = 7.6 Hz, 4 H, 2× $CH_2CH_3$), 6.87 (s, 2 H, 2× $H_{meso}$) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CD_2Cl_2$): $\delta$ = 14.8, 17.0, 17.4, 17.8, 17.9, 18.2, 18.4, 120.2, 135.4, 139.5, 144.1, 144.6, 150.2, 171.5 ppm. $^{19}$F{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = –74.1 ppm. MS (70 eV, EI): $m/z$ (%) = 529 ([M – OAc$^F$]$^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ ($\varepsilon$) = 276 (16000), 350 (65000), 403 (12000), 596 sh (33000), 656 nm (59000 mol$^{-1}$ dm$^3$ cm$^{-1}$). IR (Nujol): $\nu$ = 1602, 1597 cm$^{-1}$ ($\nu_{C=C}$, $\nu_{C=O}$). $C_{30}H_{38}CdF_3N_3O_2$ (642.048): calcd. C 56.12, H 5.97, N 6.54; found C 55.93, H 6.02, N 6.29.

CCDC-625800 to -625805 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.request/cif.

**Supporting Information** (see also the footnote on the first page of this article): UV/Vis spectra of **8** in acetone and in MeOH.

# Polymer-Supported Dioxido-Mo$^{VI}$ Complexes as Truly Functional Molybdenum Oxotransferase Model Systems

**Katja Heinze*[a] and Andreas Fischer[a]**

**Keywords:** Enzyme models / Immobilised complexes / Molybdenum / Nitrogen ligands / Oxygen transfer

A truly functional model system for molybdenum oxotransferases provides evidence for all biologically realistic intermediates, namely mononuclear Mo$^{VI}$, Mo$^{V}$ and Mo$^{IV}$ species. Dinucleation to EPR-silent [Mo$^{V}_2$O$_3$] species prevailing in homogeneous solution is suppressed by immobilising the active species to a polymeric support by two-point attachment.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Currently there is a great interest in structural and functional biomimetic models for active sites of metalloenzymes which mimic the primary coordination sphere (number and nature of ligating atoms) as well as the secondary coordination sphere (protein environment, site isolation, substrate selectivity, entatic state, secondary interactions with substrates, etc.).[1] Mononuclear molybdenum enzymes catalyse the net transfer of an oxygen atom between substrate and water [Equation (1)] shuttling between Mo$^{VI}$, Mo$^{V}$ and Mo$^{IV}$ states.[2,3]

$$X + H_2O \Leftrightarrow XO + 2H^+ + 2e^- \quad (1)$$

$$XO + Y \rightarrow X + YO \quad (2)$$

$$L_nMo^{VI}O_2 + L_nMo^{IV}O \rightarrow L_{2n}Mo^{V}_2O_3 \quad (3)$$

$$2\,L_nMo^{V}(OH)O \rightarrow L_{2n}Mo^{V}_2O_3 + H_2O \quad (4)$$

The primary oxo atom transfer (OAT) from/to molybdenum model compounds to/from substrates [Equation (2)] has been extensively investigated by Holm, Wedd, Young, Enemark, Basu and many others and is well understood.[4–7] The most successful model systems are based on enedithiolate ligands mimicking the natural sulfur ligation,[8–12] multidentate N/S ligands[13–17] and substituted hydrotris(pyrazolyl)borate ligands (Tp*, Tp$^{iPr}$).[18–21] Especially the latter family, although bearing no structural resemblance to natural enzymes, has been exceptionally useful for identifying mononuclear Mo$^{V}$ species which are essential to the enzymatic catalytic cycle involving OAT and CEPT reactions (CEPT = coupled electron proton transfer). In these model systems the inherent tendency of molybdenum oxido complexes to form dinuclear species with a [Mo$_2$O$_3$] core via comproportionation [Equation (3)] or condensation [Equation (4)] is reduced due to steric hindrance. In molybdenum enzymes, the active site is located in the interior of the protein matrix and the substrate approaches the catalytic centre through a "funnel".[2,6] Of course dinucleation does not occur in natural systems.

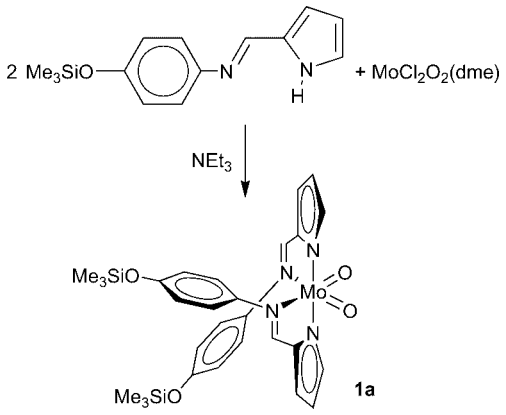
## Results and Discussion

The present report describes a different solution to the dinucleation problem, namely immobilisation of an active complex on a polymer support. In order to improve site-isolation and minimise leaching, the Mo complexes are immobilised onto the support via two-point fixation with two chelating 2-imino-pyrrolato ligands. The twofold attachment to the support parallels the incorporation of molybdenum in oxotransferases by pterin dithiolene and cysteinato ligands (e.g. sulfite oxidase or DMSO reductase).[2–7] Different EPR-active states have been observed in natural systems depending on preparation and environment.[2,3] The artificial system described below also shows several EPR-active Mo$^{V}$ states during full biomimetic catalytic turnover [OAT and CEPT; Equation (1)]. First we introduce a sterically unencumbered model system, investigate the chemistry in homogeneous solution, and finally we describe our results for the immobilised system.

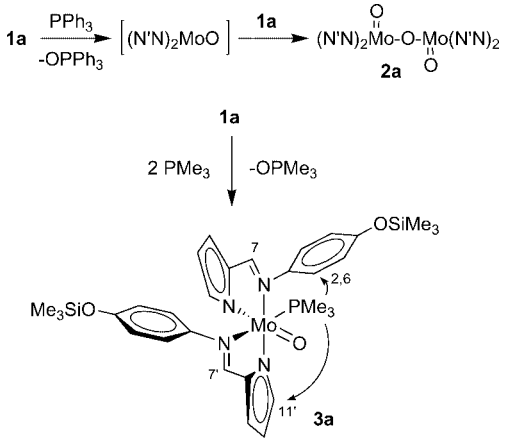
The soluble 2-imino-pyrrole ligand cleanly forms the bis(chelate) dioxido Mo$^{VI}$ complex **1a** with MoCl$_2$O$_2$(dme) (Scheme 1). **1a** was fully characterised by NMR, IR and UV/Vis spectroscopic methods as well as mass spectrometric and elemental analysis (see Exp. Sect.). Reduction of **1a** with tertiary phosphanes results in OAT from the Mo$^{VI}$ complex to the substrate giving the corresponding phosphane oxide (Scheme 2). Stoichiometric reaction with one

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

equivalent $PPh_3$ only produces 0.5 equiv. $OPPh_3$ even after prolonged reaction times as shown by time-dependent $^{31}P\{^1H\}$ NMR spectroscopy (Figure 1). Similar observations are made with $PMe_3$ as substrate albeit OAT proceeds faster in this case.[22] Thus comproportionation of $Mo^{VI}$ and initially formed $Mo^{IV}$ species to the diamagnetic μ-oxo species **2a** (Scheme 2) significantly slows down full conversion to $Mo^{IV}$. Complex **2a** has been analysed by mass spectrometry as well as NMR, IR and UV/Vis spectroscopy (see Exp. Sect.). The FAB and HR-FAB mass spectra confirm the dinuclear nature of the complex. A strong absorption band can be observed around 548 nm in the UV/Vis spectrum which is assigned the characteristic π-π* transition of the Mo–O–Mo unit. The antisymmetric Mo=O stretching vibration of the [O=Mo–O–Mo=O] core appears at 960 $cm^{-1}$.



Scheme 1.



Scheme 2.

Full reduction of **1a** is achieved by using excess $PMe_3$ in THF at elevated temperature giving a green solution of the highly air-sensitive $PMe_3$ complex **3a** (Scheme 2). Coordination of $PMe_3$ to $Mo^{IV}$ is shown by multinuclear two-dimensional NMR spectroscopy [$\delta(^{31}P) = 2.4$; $^2J_{PH} = 8.5$ Hz to methyl protons and $^4J_{PH} = 2.8$, <2 Hz to protons $H^{7'}$ and $H^7$ of the chelate ligands; Figure 2] and LIFDI mass spectrometry (*m*/*z* = 704, molecular ion peak[23]). In the NOESY spectrum NOE cross peaks are observed between

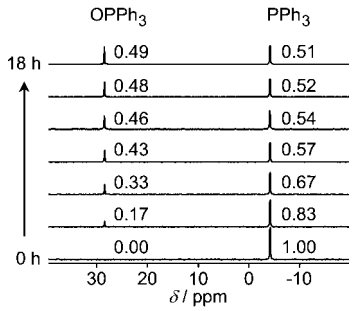


Figure 1. $^{31}P\{^1H\}$ NMR spectra of **1a** and 1 equiv. $PPh_3$ at 25 °C.

methyl protons of the $PMe_3$ ligand and protons of both chelate ligands ($H^{2,6}$ and $H^{11'}$) compatible with $PMe_3$ coordination *trans* to an imine nitrogen donor atom of one chelate ligand and *cis* to the imine nitrogen of the other (Scheme 2). Thus a second substrate can coordinate to molybdenum in the +IV state during OAT. Precedence for such a behaviour was only recently reported using a bis($\eta^2$-pyrazolate)$MoO_2$ complex.[24]

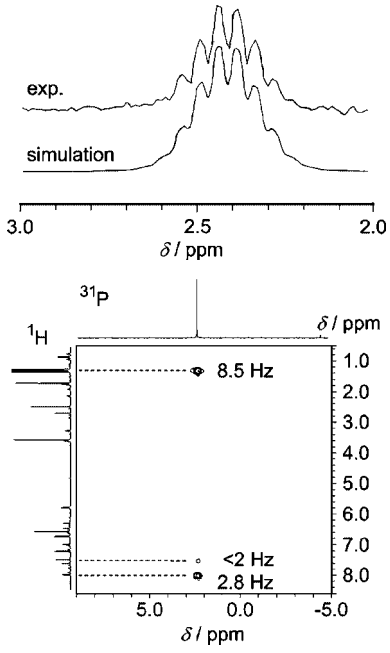

Figure 2. $^{31}P$ NMR spectrum and simulation (top) and PH-COSY spectrum of **3a** (bottom).

Re-oxidation of **3a** with DMSO as oxygen donor at 50 °C under single-turnover conditions yields dinuclear **2a** after 20 min and **1a** after 24 h. Thus a full OAT cycle [Equation (2)] from DMSO to $PMe_3$ has been accomplished with complex **1a**, however, with intermediate formation of dinuclear **2a** via comproportionation.

The reaction of **1a** with excess $PMe_3$ in THF (Scheme 2) was monitored UV-spectrophotometrically at 548 nm where **2a** possesses an absorption maximum (π-π* transition). Numerical simulation[25,26] of the data (Figure 3, top) yielded rate constants *k* for the rate-determining step (attack of $PMe_3$ at one oxido ligand of **1a**) and equilibrium constants *K* for the comproportionation [Equation (3)]. An Eyring

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

analysis yielded $\Delta H^{\neq}$ = 53 kJ mol$^{-1}$ and $\Delta S^{\neq}$ = –82 J mol$^{-1}$ K$^{-1}$ (Figure 3, bottom). The negative activation entropy agrees with the associative transition state in the bimolecular reaction between **1a** and $PMe_3$.[4–7]

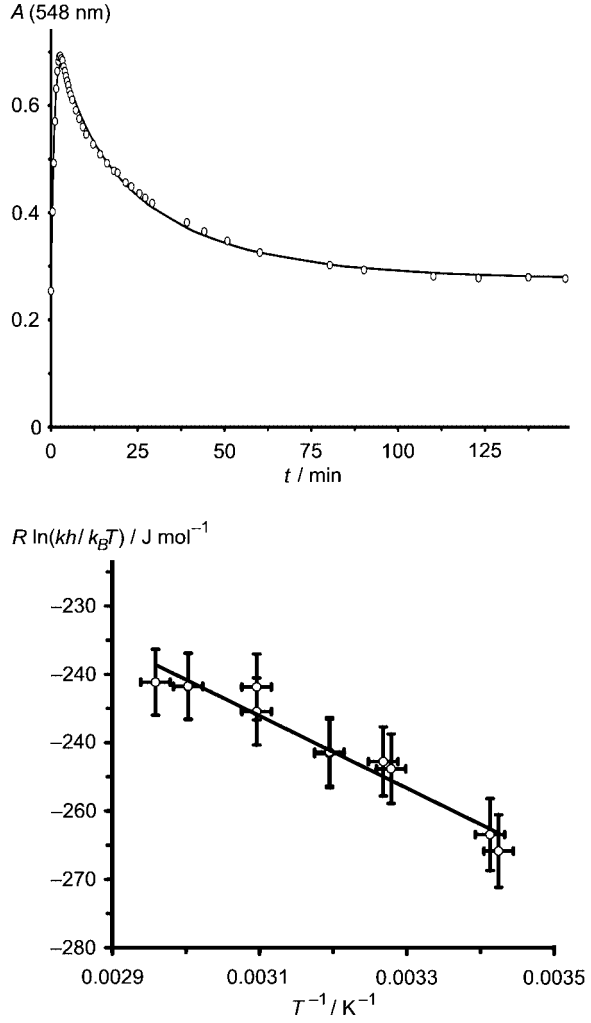

Figure 3. *A* vs. *t* plot of the reaction of **1a** and 100 eq $PMe_3$ at 60 °C (top) and Eyring plot (bottom).

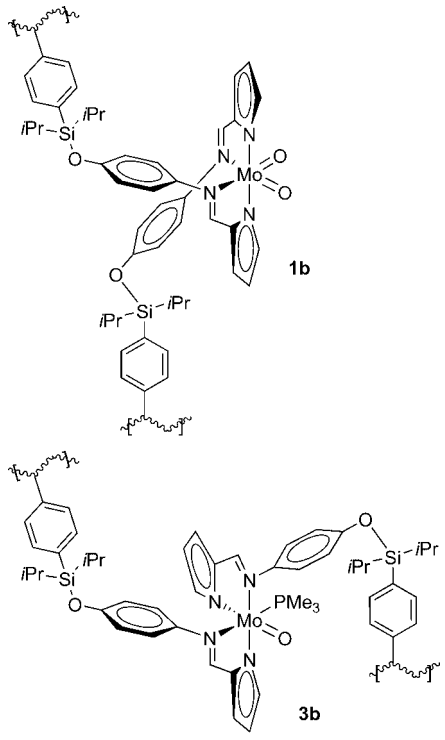
So far it has been shown that oxo transfer chemistry (OAT) is possible with the system **1a/3a**. However, all attempts to observe mononuclear $Mo^V$ species in homogeneous solution by EPR spectroscopy failed due to the high stability of EPR-silent **2a** towards disproportionation ($K_{dis} \approx 5 \cdot 10^{-6}$) and hydrolysis. To suppress (or at least diminish) formation of dinuclear species the doubly anchored versions of **1a/3a** are investigated (Scheme 3).

The immobilised bis(chelate) complex **1b** is prepared analogously to **1a** employing polymer-supported chelate ligands (Scheme 1 and Scheme 3; ligand loading 0.6–0.8 mmol g$^{-1}$ polymer; polymer = polystyrene/2% divinylbenzene).[27–32] The amount of molybdenum incorporated by **1b** is compatible with the required 2:1 ligand/metal stoichiometry as shown by molybdenum uptake measurements.[23] Thus the molybdenum complexes are anchored to the polymeric backbone by two attachment points which should guarantee the desired site isolation effect (at least



Scheme 3.

for some sites within the polymer). Cleaving the Si–O bonds of **1b** with fluoride ions releases the hydroxy analogue of **1a** into solution confirming the correct formation of **1b**.[27–32]

$PMe_3$ is oxidised by **1b** to $OPMe_3$ as shown by $^{31}P\{^1H\}$ NMR spectroscopic analysis of the solution. The reduction product of **1b** is the immobilised $PMe_3$ complex **3b** (Scheme 3) characterised by its CP MAS $^{31}P\{^1H\}$ NMR signal at $\delta$ = 2.4 which fits to that observed for the soluble complex **3a** (Figure 2 and Figure 4).

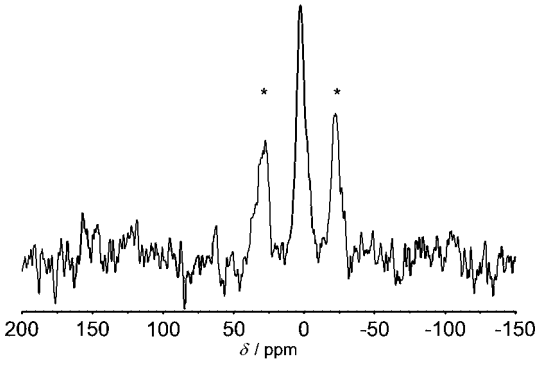


Figure 4. CP MAS $^{31}P\{^1H\}$ NMR spectrum (4 kHz) of **3b** (* denote rotational side bands).

The anchored $Mo^{VI}$ and $Mo^{IV}$ complexes **1b** and **3b** were subjected to one-electron reduction and oxidation, respectively (CEPT chemistry). Reaction of **1b** with cobaltocene $Co(C_5H_5)_2$[33] gave polymer **4b** which is EPR-active. Anisotropic EPR spectra ($g_1$ = 1.9544, $g_2$ = 1.9388, $g_3$ = 1.9111; **1b** and **3b** are EPR-silent) both in the solid and the THF gel-phase of the polymer are observed at room temperature (Figure 5). We have previously shown that singly polymer

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

attached $Cu^{II}$ complexes give isotropic EPR spectra under gel-phase conditions suggesting that a single-point attachment allows for sufficient mobility.[34] However, two-point fixation seems to decrease the mobility of the anchored complexes **4b** resulting in anisotropic EPR spectra even in the gel-phase at room temperature.[35] In addition this finding proves that the molybdenum species are still bound to the support as otherwise isotropic signals for soluble species would have been observed.

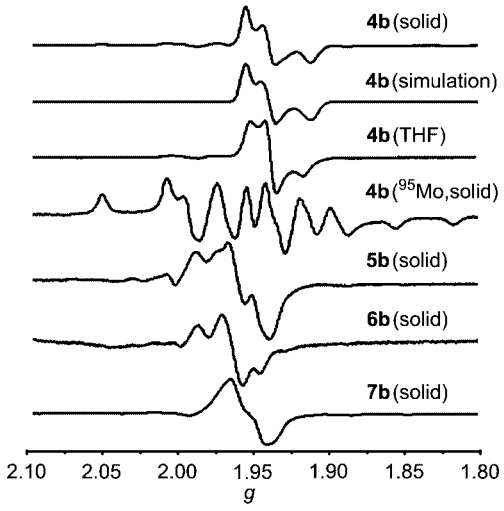

Figure 5. EPR spectra of **4b**–**7b** (295 K, 9.4 GHz).

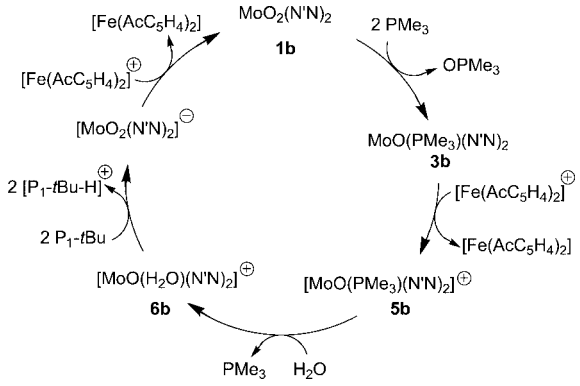
All *g*-values observed for **4b** are well below 2.0 typical for $Mo^{V}$ species with non-thiolate donor atoms. Further confirmation of mononuclear $Mo^{V}$ present is provided by using $^{95}$Mo-enriched precursors (98%; $I = {}^{5}/_{2}$). The isotopically enriched polymer **4b** displays characteristic anisotropic hyperfine coupling to the $^{95}$Mo nucleus in the EPR spectrum (Figure 5). Upon one-electron reduction of **1b** an anionic dioxido-$Mo^{V}$ species should be formed initially. For $[MoO_2(NCS)Tp^*]^-$ an anisotropic spectrum (*g*-values of 1.9939, 1.9277, 1.8350) is observed at 77 K, while the corresponding protonated complex MoO(OH)(NCS)Tp* displays signals at $g = 1.966$, 1.944 and 1.922 much more similar to the values observed for **4b**.[21] Addition of a proton source ($HBF_4$) to the reduced polymer **4b** had no influence on the EPR spectrum, suggesting that **4b** has already captured a proton. However, if protonation to the hydroxo complex occurred during reduction split signals due to coupling to the hydroxo proton are expected which is not observed for **4b**.[21] The protonation state of **4b** remains ambiguous at the moment.

One-electron oxidation of the anchored $Mo^{IV}$ complex **3b** with $[Fe(C_5H_5)_2][PF_6]$[33] yields polymer **5b**. Again $^{95}$Mo labelling proves the presence of $Mo^{V}$ species.[23] The EPR pattern of **5b** differs from that of **4b** as additional coupling to an $I = {}^{1}/_{2}$ nucleus is observed ($g_1 = 1.9812$, $g_2 = 1.9528$, $g_3 = 1.9415$; $A_1 = 23$ G, $A_2 = 27$ G, $A_3 = 23$ G; Figure 5). Thus it is suggested that $PMe_3$ ($^{31}$P: $I = {}^{1}/_{2}$) is still bound to molybdenum in the +V state. $PMe_3$ coordinated to $Mo^{V}$ should only be weakly bound so that ligand displacement reactions should be possible.

Indeed, reaction of **4b** with water displaces the phosphane and generates the $Mo^{V}$-containing polymer **6b**. The EPR spectrum of **6b** could only be reasonably simulated with two equivalent $I = {}^{1}/_{2}$ nuclei present ($g_1 = 1.9868$, $g_2 = 1.9624$, $g_3 = 1.9440$; $A_1 = 30$ G, $A_2 = 7$ G, $A_3 = 28$ G; Figure 5).[23] We tentatively assign these nuclei to two protons of a coordinated water molecule (or less likely to two hydroxo ligands). Substitution of $PMe_3$ is also possible with chloride ions ($[nBu_4N]Cl$) giving polymer **7b**. The EPR spectrum of **7b** can be simulated with coupling to one Cl nucleus ($^{35,37}$Cl: $I = {}^{3}/_{2}$; $g_1 = 1.9680$, $g_2 = 1.9522$, $g_3 = 1.9362$; $A_1 = 7$ G, $A_2 = 10$ G, $A_3 = 8$ G; Figure 5).[39] Thus different ligands (substrate, water, chloride) can occupy the free coordination site at $Mo^{V}$ as suggested by the different EPR spectra – similar to the situation assumed in molybdenum enzymes.[2] Remarkably, no evidence for leaching was observed during all these operations (reduction, oxidation, ligand exchange).

A full catalytic cycle (OAT and CEPT) involving $PMe_3$ as oxygen acceptor, $[Fe(AcC_5H_4)_2][BF_4]$ as one-electron oxidant,[33] water as oxygen donor and phosphazene base $P_1$-*t*Bu[36] as proton acceptor is finally attempted. $[Fe(AcC_5H_4)_2][BF_4]$ is employed instead of $[Fe(C_5H_5)_2][BF_4]$ because of its higher oxidation potential.[33] A suggested mechanism is depicted in Scheme 4. In fact, under these conditions **1b** catalysed the production of 25 equiv. $OPMe_3$ from $PMe_3$, water and oxidant within 48 h as shown by $^{31}P\{^{1}H\}$ NMR spectroscopy (Figure 6). With $^{18}$O-enriched water the label is incorporated into $OPMe_3$ as shown by mass spectrometric analysis. This proves that water is the source of the oxygen atom in the phosphane oxide product as required [Equation (1)].[23]



Scheme 4.

Although the present system definitely does not represent a structural model (Mo enzymes prefer sulfur coordination[2]) it is a truly functional model providing evidence for all biologically realistic mononuclear intermediates, namely $Mo^{VI}$, $Mo^{V}$ and $Mo^{IV}$ species. Dinucleation to EPR-silent $[Mo^{V}_2O_3]$ species prevailing in homogeneous solution and inhibiting CEPT chemistry is largely suppressed when the active species are doubly bound to a polymeric support. Double anchoring of active pre-catalysts to polymeric matrices with the aim to detect reactive interme-

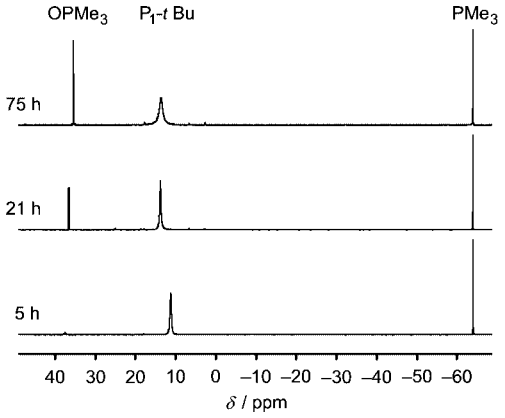

Figure 6. Selected $^{31}P\{^{1}H\}$ NMR spectra during catalysis.

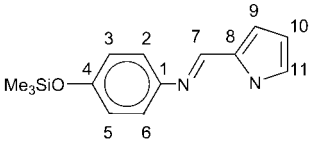
diates of catalytic cycles will be further developed in our laboratories.

## Experimental Section

Unless noted otherwise, all manipulations were carried out under anaerobic conditions by means of standard Schlenk techniques. For the solid-phase reactions a flask with a nitrogen inlet and a fritted glass filter with large pores that allows addition and removal of reagents and solvents without exposure of the resin to the atmosphere was used. All solvents were dried by standard methods and distilled under anaerobic conditions prior to use.

NMR: Bruker Avance DPX 200 at 200.15 MHz and Varian Unity Plus 400 at 399.89 MHz ($^{1}H$); chemical shifts ($\delta$) in ppm with respect to residual solvent peaks as internal standard: $[D]_8THF$ ($^{1}H$: $\delta$ = 1.73, 3.58; $^{13}C$: $\delta$ = 25.5, 67.7) or with respect to external 85% $H_3PO_4$ ($^{31}P$: $\delta$ = 0 ppm). CP MAS NMR: Bruker Avance 400 NMR with a 4 mm MAS probe head. IR: BioRad Excalibur FTS 3000 spectrometer using CsI disks. EI-MS, FAB-MS: Finnigan MAT 8400 spectrometer. – LIFDI-MS: JEOL JMS-700 double-focusing magnetic sector mass spectrometer.[37] UV/Vis: Perkin–Elmer Lambda 19, 0.2-cm cells (Hellma, suprasil). – Melting points: Gallenkamp capillary melting point apparatus MFB 595 010. – Elemental analyses: Microanalytical Laboratory of the Organic Chemistry Department, University of Heidelberg. – EPR: Bruker ELEXSYS E500 spectrometer (X-band). Xsophe, version 1.0.2β was used for simulation of the spectra using the following parameters: isotope $^{98}Mo$ ($I$ = 0; 100%), $^{31}P$, $^{1}H$, $^{35,37}Cl$ natural isotope distribution; $g$- and $A$-strain Gaussian line shape model; matrix diagonalisation; 25 theta orientations; 5 field segments; orthorhombic symmetry. No attempts have been made for simulation of $^{95}Mo$ spectra or $^{95}Mo$ satellites.

**Synthesis of 1a:** The ligand (1.67 g, 6.5 mmol) dissolved in THF (10 mL) was added to a suspension of $MoCl_2O_2$(dme) (0.94 g, 3.24 mmol) in THF (40 mL) and triethylamine (0.9 mL, 6.5 mmol) was added. The red mixture was stirred at 25 °C for 1 h and heated under reflux for 2 h. After cooling to room temperature the mixture was filtered and the solvent was removed in vacuo. Toluene (40 mL) was added, covered with hexanes and the solution was cooled to 4 °C. The red precipitate was collected by filtration and dried. Yield 55% (2.31 g, 3.6 mmol); m.p. 168 °C; calcd. for $C_{28}H_{34}MoN_4O_4Si_2$ (642.7) C 52.33, H 5.33, N 8.72; found C 52.55, H 5.40, N 8.74. MS (EI): $m/z$ (%) = 644 (98) $[M]^+$, 387 (11) $[M - C_{14}H_{17}N_2OSi]^+$, 257 (100) $[C_{14}H_{17}N_2OSi]$. HR-MS (EI): calcd. for $^{98}Mo$ 644.1177, found 644.1217; calcd. for $^{96}Mo$ 642.1176, found 642.1129; calcd. for $^{95}Mo$ 641.1181, found 641.1144. IR (CsI): $\tilde{\nu}$ = 2961 $cm^{-1}$ (w), 1605 (m), 1585 (s), 1526 (m), 1499 (m), 1251 (s, C–O), 930 (m, Mo=O), 902 $cm^{-1}$ (m, Mo=O). UV (THF): $\lambda_{max}$ = 303 nm (43260 $M^{-1}cm^{-1}$), 440 nm (6130 $M^{-1}cm^{-1}$). $^{1}H$ NMR ($[D_8]$THF): $\delta$ = 7.94 (s, 1 H, $H^7$), 7.25 (s, 1 H, br. s, $H^{11}$), 6.97 (d, 2 H, $^{3}J$ = 8.5 Hz, $H^{2,6}$), 6.60 (d, 2 H, $^{3}J$ = 8.5 Hz, $H^{3,5}$), 6.39 (dvd, 1 H, $^{3}J$ = 3.4 Hz, 1.0 Hz, $H^9$), 6.11 (dvd, 1 H, $^{3}J$ = 3.4 Hz, 2.4 Hz, $H^{10}$), 0.23 (s, 9 H, $CH_3$); $^{13}C\{^{1}H\}$ NMR ($[D_8]$THF): $\delta$ = 158.1 (s, $C^7$), 153.8 (s, $C^4$), 148.6 (s, $C^1$), 142.9 (s, $C^{11}$), 139.4 (s, $C^8$), 123.1 (s, $C^{2,6}$), 120.3 (s, $C^{3,5}$), 119.6 (s, $C^9$), 114.8 (s, $C^{10}$), –0.35 (s, $CH_3$); assignments are based on 2D NMR spectra.



**Synthesis of 2a:** Complex **1a** (0.643 g, 1 mmol) was dissolved in THF (20 mL) and $PMe_3$ (1 M in THF, 0.6 mL, 0.6 mmol) was added. The reaction mixture was maintained at 50 °C for 12 h. The solvent was removed in vacuo and the residue was washed with diethyl ether giving a brown product. Yield 95% (0.60 g, 0.48 mmol). MS (FAB): $m/z$ (%) = 1268 (3) $[M]^+$, 1011 (2) $[M - C_{14}H_{17}N_2OSi]^+$, 628 (72) $[M - C_{28}H_{34}MoN_4O_4Si_2]^+$. HR-MS (FAB): calcd. for $^{98}Mo/^{98}Mo$ 1272.2396, found 1272.2418; calcd. for $^{96}Mo/^{98}Mo$ 1270.2389, found 1270.2380; calcd. for $^{96}Mo/^{96}Mo$ 1268.2414, found 1268.2393. IR (CsI): $\tilde{\nu}$ = 2960 $cm^{-1}$ (w), 1604 (s), 1581 (s), 1509 (s), 1493 (s), 1253 (s, C–O), 960 $cm^{-1}$ (m, Mo=O). UV (THF): $\lambda_{max}$ = 300 (81850 $M^{-1}cm^{-1}$), 468 (20990 $M^{-1}cm^{-1}$) 548 nm (11150 $M^{-1}cm^{-1}$). $^{1}H$ NMR ($[D_8]$THF): $\delta$ = 7.86 (s, 1 H, $H^7$), 7.73 (s, 1 H, $H^{7'}$), 7.63 (br. s, 1 H, $H^{11'}$), 7.12 (d, 2 H, $^{3}J$ = 8.5 Hz, $H^{2',6'}$), 6.98 (d, 2 H, $^{3}J$ = 8.5 Hz, $H^{2,6}$), 6.59 (d, 2 H, $^{3}J$ = 8.5 Hz, $H^{3,5}$), 6.54 (d, 2 H, $^{3}J$ = 8.5 Hz, $H^{3',5'}$), 6.43 (d, 1 H, $^{3}J$ = 3.1 Hz, $H^{9'}$), 6.37 (d, 1 H, $^{3}J$ = 3.1 Hz, $H^9$), 6.32 (dvd, 1 H, $H^{10'}$), 6.08 (br. s, 1 H, $H^{11}$), 5.80 (dvd, 1 H, $H^{10}$), 0.21 (s, 9 H, $CH_3$), 0.20 (s, 9 H, $CH_3$); assignments are based on 2D NMR spectra; low solubility prevented acquisition of $^{13}C$ NMR spectroscopic data.

**Synthesis of 3a:** Complex **1a** (0.643 g, 1 mmol) was dissolved in THF (20 mL) and $PMe_3$ (1 M in THF, 2 mL, 2 mmol) was added. The reaction mixture was maintained at 50 °C for 12 h. The solvent was removed in vacuo and the residue was washed with diethyl ether giving a green product. Yield 80% (0.562 g, 0.80 mmol); LIFDI-MS: $m/z$ (%) = 704 (100) $[M]^+$, 627 (30) $[M - PMe_3]^+$. IR (CsI): $\tilde{\nu}$ = 2961 $cm^{-1}$ (w), 2906 (w), 1604 (m), 1572 (s), 1506 (vs), 1266 (vs, C–O), 1253 (vs, C–O), 954 $cm^{-1}$ (m, Mo=O). UV (THF): $\lambda_{max}$ = 294 (26090 $M^{-1}cm^{-1}$), 345 (27970 $M^{-1}cm^{-1}$), 410 nm (sh, 9060 $M^{-1}cm^{-1}$), 478 (sh, 3170 $M^{-1}cm^{-1}$), 629 (1050 $M^{-1}cm^{-1}$). $^{1}H$ NMR ($[D_8]$THF): $\delta$ = 7.98 (d, 1 H, $^{4}J_{PH}$ = 2.8 Hz, $H^7$), 7.61 (br. s, 1 H, $H^{11}$), 7.50 (br. s, 1 H, $H^{7'}$), 7.22 (d, 2 H, $^{3}J$ = 8.8 Hz, $H^{3,5}$), 7.00 (d, 1 H, $^{3}J$ = 3.4 Hz, $H^9$), 6.73 (d, 2 H, $^{3}J$ = 8.8 Hz, $H^{2,6}$), 6.57 (s, 4 H, $H^{2',6',3',5'}$), 6.49 (dvd, 1 H, $H^{10}$), 6.30 (d, 1 H, $^{3}J$ = 3.4 Hz, $H^{9'}$), 5.80 (br. s, 1 H, $H^{11'}$), 5.78 (dvd, 1 H, $H^{10'}$), 1.29 (d, 9 H, $^{2}J_{PH}$ = 8.5 Hz, $PMe_3$), 0.29 (s, 9 H, $CH_3$), 0.24 (s, 9 H, $CH_3$); $^{13}C\{^{1}H\}$ NMR ($[D_8]$THF): $\delta$ = 158.0 (s, $C^7$), 150.6 (s, $C^{7'}$), 147.3 (s, $C^{11}$), 137.8 (s, $C^{11'}$), 158.0 (s, $C^7$), 125.0 (s, $C^{3,5}$), 124.1 (s, $C^{3',5'}$), 120.3 (s, $C^{2',6'}$), 119.9 (s, $C^{2,6}$), 118.9 (s, $C^9$), 115.2 (s, $C^{9'}$), 114.5 (s, $C^{10}$), 113.1 (s, $C^{10'}$), 16.2 (d, $^{1}J_{PC}$ = 23.3 Hz, $PCH_3$), 0.40 (s, $CH_3$), 0.39 (s, $CH_3$); assignments are based on 2D NMR spectra; low solubility prevented observation of $C^1$, $C^4$, $C^8$; $^{31}P\{^{1}H\}$ NMR ($[D_8]$THF): $\delta$ = 2.41 (s). $^{31}P$ NMR ($[D_8]$THF): $\delta$ = 2.41 (m, $^{2}J_{PH}$ = 8.5 Hz, $^{4}J_{PH}$ = 2.8 Hz).

**Determination of Activation Parameters for OAT between 1a and $PMe_3$:** In a typical experiment a UV cell containing a known amount of **1a** in THF was thermostatted at the desired temperature and 100 eq $PMe_3$ (1 M in THF) were added. The time dependence of the absorbance was measured at 548 nm.

**Synthesis of 1b:** The immobilised ligand (1.0 g, 0.8 mmol) was suspended in THF (30 mL) and $MoCl_2O_2$(dme) (116 mg, 0.4 mmol) was added as a solid. After 10 min triethylamine (0.28 mL, 2 mol) was added. The suspension was stirred at 25 °C for 1 h and heated under reflux for 2 h. After cooling to room temperature the mixture was filtered and washed successively with THF and diethyl ether giving a bright red resin. The isotopically enriched samples were prepared starting from $^{95}MoO_3$ (98% $^{95}$Mo) via $Na_2{}^{95}MoO_4$ and $^{95}MoCl_2O_2$(dme).

**Determination of Mo Uptake:** 1.0 g (0.80 mmol) of immobilised ligand was treated as above with $MoCl_2O_2$(dme) (103.8 mg, 0.36 mmol). All washing solutions were collected, evaporated to dryness and dissolved in ethanol (50 mL). 4 mL of this solution were treated with a $3.3\cdot10^{-3}$ M solution of 5,7-dibromo-8-hydroxyquinoline (1 mL), 0.5 M $H_2SO_4$ (1 mL) and ethanol (4 mL). The solution was diluted with $H_2O$ to 10 mL. Absorbance was measured at 400 nm and molybdenum content was determined using a calibration graph.[23] $A$(400 nm) = 1.432122 corresponds to 32.1 mg (0.11 mmol) $MoCl_2O_2$(dme), i.e. 0.25 mmol molybdenum was immobilised onto the polymer.[38]

**Cleavage with [$n$Bu$_4$N]F:** To resin **1b** (500 mg, 0.13 mmol Mo) suspended in THF (10 mL) was added [$n$Bu$_4$N]F·3H$_2$O (107 mg, 0.34 mol) dissolved in THF (10 mL). The solution immediately became coloured. The solution was collected by filtration and the solvents evaporated to dryness. The residue was washed with diethyl ether (to remove ammonium salts and free ligand) giving a red product. $^1$H NMR ([D$_8$]THF): $\delta$ = 11.0 (br. s, 1 H, OH), 8.05 (s, 1 H, H$^7$), 7.13 (s, 1 H, br. s, H$^{11}$), 7.10 (d, 2 H, $^3J$ = 8.5 Hz, H$^{2,6}$), 6.66 (d, 2 H, $^3J$ = 8.5 Hz, H$^{3,5}$), 6.45 (d, 1 H, $^3J$ = 2.5 Hz, H$^9$), 6.15 (pt, 1 H, H$^{10}$).

**Synthesis of 3b:** To resin **1b** (300 mg, 0.08 mmol Mo) suspended in THF (10 mL) was added $PMe_3$ (1 M in THF, 0.2 mL, 0.2 mmol) and the mixture was held at 40 °C for 4 h. The $OPMe_3$ formed was detected by $^{31}$P NMR spectroscopy. The resulting resin was washed with THF and diethyl ether giving a dark coloured resin. $^{31}$P{$^1$H} CP-MAS NMR: $\delta$ = 2.4.

**Reduction of 1b with Co($C_5H_5$)$_2$:** To resin **1b** (300 mg, 0.08 mmol Mo) suspended in THF (10 mL) was added Co($C_5H_5$)$_2$ (19 mg, 0.1 mmol) and the mixture was held at 40 °C for 5 h. The resulting resin was washed with THF and diethyl ether giving a dark coloured resin **4b**. EPR (solid, 295 K): $g_1$ = 1.9544, $g_2$ = 1.9388, $g_3$ = 1.9111.

**Oxidation of 3b with [Fe($C_5H_5$)$_2$][$BF_4$]:** To resin **3b** (300 mg, 0.08 mmol Mo) suspended in THF (10 mL) was added [Fe($C_5H_5$)$_2$][$PF_6$] (33 mg, 0.1 mmol) and the mixture was held at 40 °C for 5 h. The resulting resin was washed with THF and diethyl ether giving a dark coloured resin **5b**. EPR (solid, 295 K): $g_1$ = 1.9812, $g_2$ = 1.9528, $g_3$ = 1.9415; $A_1$($^{31}$P) = 23 G, $A_2$($^{31}$P) = 27 G, $A_3$($^{31}$P) = 23 G.

**Reaction of 5b with $H_2O$:** To resin **5b** (300 mg, 0.08 mmol Mo) suspended in THF (10 mL) was added $H_2O$ (0.1 mL, 5.6 mmol) and the mixture was held at 25 °C for 18 h. The resulting resin was washed with THF and diethyl ether giving a dark coloured resin **6b**. EPR (solid, 295 K): $g_1$ = 1.9868, $g_2$ = 1.9624, $g_3$ = 1.9440; $A_1(2\times{}^1H)$ = 30 G, $A_2(2\times{}^1H)$ = 7 G, $A_3(2\times{}^1H)$ = 28 G.

**Reaction of 5b with [$n$Bu$_4$N]Cl:** To resin **5b** (80 mg, 0.02 mmol Mo) suspended in THF (5 mL) was added [$n$Bu$_4$N]Cl (28 mg, 0.1 mmol) and the mixture was held at 25 °C for 18 h. The resulting resin was washed with THF and diethyl ether giving a dark coloured resin **7b**. EPR (solid, 295 K): $g_1$ = 1.9680, $g_2$ = 1.9522, $g_3$ = 1.9362; $A_1$($^{35,37}$Cl) = 7 G, $A_2$($^{35,37}$Cl) = 10 G, $A_3$($^{35,37}$Cl) = 8 G.[39]

**Catalytic Experiments with 1b:** To resin **1b** (50 mg, 0.013 mmol Mo) suspended in THF/$CH_3CN$ (5 mL, 1 mL) was added $PMe_3$ (1 M in THF, 1 mL, 1 mmol), $P_1$-$t$Bu (0.5 mL, 2 mmol), $H_2O$ (0.030 mL, 1.6 mmol) and [Fe($AcC_5H_4$)$_2$][$BF_4$] (714 mg, 2 mmol) and the mixture was held at 35 °C. $^{31}$P{$^1$H} NMR spectra of the solution indicated selective formation of $OPMe_3$. The $^1$H NMR spectrum of the solution after 126 h displays signals for $OPMe_3$ ($\delta$ = 1.35 ppm, d, $^2J_{PH}$ = 13.1 Hz), residual $PMe_3$ ($\delta$ = 0.90 ppm, d, $^2J_{PH}$ = 2.2 Hz), $P_1$-$t$Bu ($\delta$ = 2.63, 2.59, 1.17 ppm), $H_2O$ ($\delta$ = 2.80 ppm) and Fe($AcC_5H_4$)$_2$ ($\delta$ = 4.71, 4.46, 2.22 ppm).

The EI mass spectra of the dried residue show signals for Fe($AcC_5H_4$)$_2$ ($m/z$ = 270, 255, 227, 199, 163), $P_1$-$t$Bu ($m/z$ = 234, 219) and $OPMe_3$ ($m/z$ = 92, 77). Using $^{18}$O-labeled water (95% $^{18}$O) the EI mass spectra display peaks for $^{18}OPMe_3$ ($m/z$ = 94, 79). Additionally the mass spectra indicate incorporation of the $^{18}$O label into Fe($AcC_5H_4$)$_2$ ($m/z$ = 272 [single $^{18}$O; 36.10%], 274 [double $^{18}$O, 6.1%]), probably by hydrating the ketone groups and dehydrating the geminal diol. This reduces the fraction of $H_2{}^{18}O$ present during catalysis from 95% to 40 ± 12% as calculated from the amount of $^{16}$O released from Fe($AcC_5H_4$)$_2$, the amount of $^{16}$O present in the catalyst and in the water employed. The fraction of $^{18}OPMe_3$ was calculated as 33.1% from the mass spectroscopic analysis agreeing within error with the expected value.

**Supporting Information** (see also the footnote on the first page of this article): The Supporting Information contains the LIFDI-MS spectrum of **3a** and molecular ion peak, the UV/Vis absorption spectra of **1a** and 100 eq $PMe_3$ at 60 °C, the calibration graph for Mo uptake, the EPR spectrum of **5b** at 295 K and simulation, the EPR spectrum of **6b** at 295 K and simulation, the EPR spectrum of **7b** at 295 K and simulation, the conversion vs. time plot, the $^1$H NMR spectrum after 126 h and the partial EI mass spectra of the reaction products.

# Structural Studies of Keggin-Type Polyoxotungstates by Extended X-ray Absorption Fine Structure Spectroscopy

**M. Salete S. Balula,[a] Isabel C. M. S. Santos,[a] José A. F. Gamelas,[a] Ana M. V. Cavaleiro,*[a] Norman Binsted,[b] and Walkiria Schlindwein[c]**

**Keywords:** Polyoxometalates / Keggin / EXAFS spectroscopy

Extended X-ray absorption fine structure spectroscopy (EXAFS) was used to characterize several Keggin-type polyoxotungstates (tetrabutylammonium salts) in the solid state and in acetonitrile solution. The polyoxometalates studied were $[PW_{12}O_{40}]^{3-}$ (the parent Keggin anion), $[PW_{11}O_{39}]^{7-}$ (a lacunary anion), $[PW_{11}M(H_2O)O_{39}]^{4-}$, M = Fe, Ru, and $[XW_{11}Mn^{III}(H_2O)O_{39}]^{n-}$, X = P, Si, B (transition-metal-substituted anions). The role of multiple-scattering contributions was evaluated for $[PW_{12}O_{40}]^{3-}$ for which an accurate structure determination was available. The results from the multiple-scattering analyses were compared with the single-scattering method. The average W-shell inter-atomic distances were determined in relation to a selected tungsten atom ($W_c$) by W $L_{III}$ edge transmission analysis. Several shells of up to 3.8–4.0 Å were identified. For the anion $[PW_{12}O_{40}]^{3-}$, the obtained inter-atomic distances in the solid sample and in acetonitrile were identical but for the lacunary anion the EXAFS spectrum of the solid was different from that in solution (the number of atoms coordinated to $W_c$ in $[PW_{11}O_{39}]^{7-}$ was the same in both cases, but the calculated distances for the shells were slightly different). Metal-substituted anions were studied by W $L_{III}$ edge transmission and by Fe, Mn, or Ru *K* edge fluorescence analysis. The average coordination sphere of tungsten was affected by the replacement of a W=O by a M–$OH_2$ group. The EXAFS results indicate that on average the $MnO_6$ octahedron is larger than $FeO_6$ or $RuO_6$ and also larger than the average of all $WO_6$ octahedra in $[PW_{11}M(H_2O)O_{39}]^{4-}$. This was attributed to the occurrence of the Jahn–Teller effect in the coordination sphere of $Mn^{III}$. A comparison of the W $L_{III}$ edge analysis EXAFS data for three $Mn^{III}$-substituted anions (X = P, Si, B) suggested that the average size of the $W_3O_{13}$ groups did not depend on X.

## Introduction

Keggin-type polyoxometalates[1–4] have been continuously studied in the last decade due to their interesting properties and possible applications in various fields, like catalysis,[5,6] materials science,[7] and medicine.[8] The Keggin-type polyoxotungstates include a large number of anions structurally related to the parent Keggin anions, α-$[XW_{12}O_{40}]^{n-}$, X = P, Si, B, etc., namely the lacunary, α-$[XW_{11}O_{39}]^{n-}$, and the metal-monosubstituted polyoxotungstates, α-$[XW_{11}M(H_2O)O_{39}]^{n-}$, M = transition or p-block metal, among others.[1,9]

The structure of the α isomer of $[PW_{12}O_{40}]^{3-}$ ($PW_{12}$) has been known since 1933[10] and is presented in Figure 1 (a). The twelve $WO_6$ octahedra, arranged in four corner shared $W_3O_{13}$ groups, surround a central tetrahedral $PO_4$ group, forming a tungsten–oxygen cluster with overall $T_d$ symmetry. Each $W_3O_{13}$ group comprises three edge-sharing $WO_6$ octahedra. This structure was found for a variety of other $[XMo_{12}O_{40}]^{n-}$ and $[XW_{12}O_{40}]^{n-}$ anions.[1] Only the α-isomers will be considered in this paper and the prefix will be omitted hereafter.

Only a few crystallographic studies are known for simple salts of the lacunary and monosubstituted Keggin-type polyoxotungstates.[1,9] The disorder observed for the $XO_4$ central group and also for the substituting $MO_6$ group (over twelve positions) usually precludes the determination of the structures with acceptable refinement parameters and no information can be given for the structural environment around M. Exceptions were found for a few compounds, namely $[Et_3NH]_5[XW_{11}Co^{II}O_{39}]\cdot 3H_2O$ (X = P, As),[11] $(ET)_8[PW_{11}Mn^{II}O_{39}]\cdot 2H_2O$,[12,13] and $(ET)_8[PW_{11}Ni^{II}(H_2O)O_{39}]\cdot 2H_2O$,[13] in which the metals M were disordered over two positions, $[Co(dpa)_2(H_2O)_2]_2[Hdpa][PW_{11}Co^{II}O_{39}]$,[14] $(Hpbpy)_5[PW_{11}Co^{II}(pbpy)O_{39}]\cdot 2H_2O$,[15] and $[Ni(DETA)_2]_3[SiW_{11}Ni^{II}O_{39}]\cdot 2.5H_2O$[16] [ET = bis(ethylenedithio)tetrathiafulvalene, dpa = di(2-pyridyl)amine, pbpy = 5-phenyl-2-(4-pyridinyl)pyridine, DETA = diethylenetriamine]. The formation of chains of linked heteropolyanions was observed for most of these compounds.

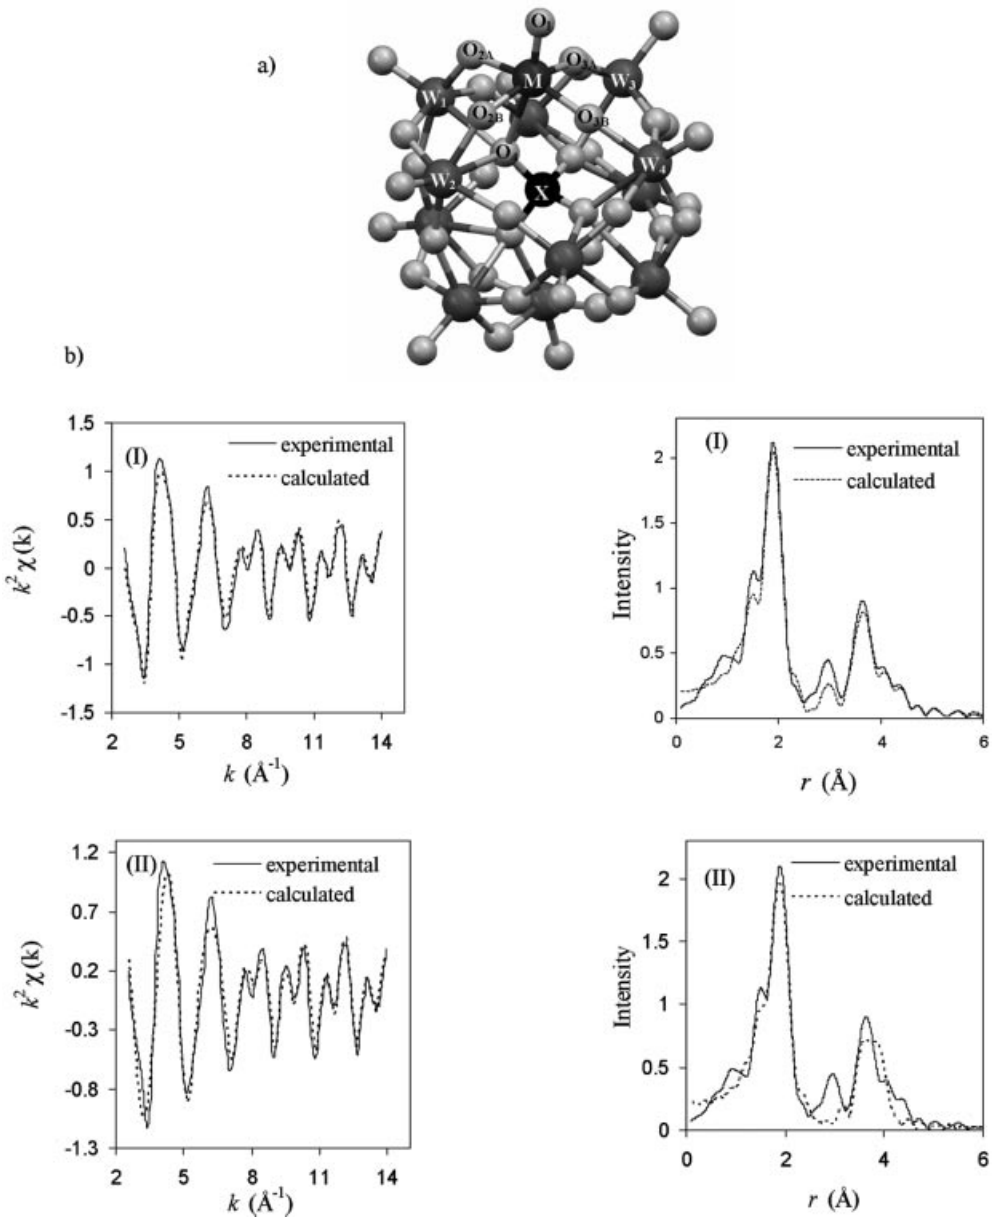

Figure 1. (a) The structure of the Keggin-type polyoxoanions (M = W, Fe, Mn, Ru). (b) EXAFS fit to $k^2\chi(k)$, and Fourier transform of $[PW_{12}O_{40}]^{3-}$: (I) multiple scattering calculation using crystallographic coordinates[25] with refined Debye–Waller factors, $E_f$ and AFAC; (II) using refined shell parameters.

An approach to the solution of the problem created by the disorder of X-ray crystal structures can be given by the use of extended X-ray absorption fine structure (EXAFS) spectroscopy. Information regarding the coordination sphere of W, the substituting metal M (first shell), and other longer-distance interactions (farther shells), up to about 4 Å, is, in many cases, possible. Besides, the EXAFS technique has the advantage that the measurements can be made in solids as well as in solution. Polyoxometalates have already been studied by EXAFS and related techniques. Particularly, studies on Keggin-type heteropolyanions, the majority performed in the solid state, have been published. Evans et al. used EXAFS to characterize the structure of $[PMo_{12}O_{40}]^{3-}$ and $[PW_{12}O_{40}]^{3-}$.[17] Previous studies in this area have been performed by Watanabe and coworkers.[18] Zhang and Pope investigated the nature of the ligand (L) coordinated to the Mn atom within the $[ZnW_{11}Mn^{IV}(L)O_{39}]^{6-}$ and $[ZnW_{11}Mn^{II}(L)O_{39}]^{8-}$ heteropolyanions.[19] EXAFS was used to determine the local structure of tetrahedral $Co^{III}$ in $[CoW_{12}O_{40}]^{5-}$.[20] Other published studies concerned supported $[PW_{12}O_{40}]^{3-}$ (mainly to confirm the presence of the anion) and vanadium-substituted tungstophosphates.[21] Studies of Keggin polyoxomolybdates that are related to their use in heterogeneous catalysis (e.g. formation of the anions on supports, thermal stability, environment of substituting metals) are also found.[22,23] Studies

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

referring to non-Keggin heteropolyanions were also reported.[24] In general, it can be summarized that EXAFS and related techniques were used to probe the coordination geometry or oxidation states of different metals encapsulated, coordinated, or supported by the polyoxometalates and the formation or stability of the heteropolyanions (mostly heteropolymolybdates) on heterogeneous catalysts. In spite of the importance of Keggin-type anions in homogeneous oxidative catalysis,[5] no studies in solution in conditions used in homogeneous catalysts have been reported so far.

In this work, EXAFS results are reported regarding the structural aspects of W and M in the tetrabutylammonium (TBA) salts of the Keggin-type anions $[PW_{11}O_{39}]^{7-}$ ($PW_{11}$), $[PW_{11}M(H_2O)O_{39}]^{4-}$ ($PW_{11}M$), M = Fe, Ru, and $[XW_{11}Mn^{III}(H_2O)O_{39}]^{n-}$ ($XW_{11}M$), X = P, Si, B. The role of multiple scattering contribution was evaluated for $[PW_{12}O_{40}]^{3-}$ ($PW_{12}$) for which an accurate structure was available that was determined by neutron diffraction.[25] The average inter-atomic distances in the series of anions formed when one tungsten atom of dodecatungstophosphate is removed to create a vacancy or is substituted isomorphically by a transition metal, $M^{III}$ = Fe, Mn, and Ru, are compared in the solid state and in acetonitrile solution. Structural data for the majority of these compounds are given for the first time. Some of these salts have been found to be good catalysts for the oxidation of cycloalkanes and other organic comounds with hydrogen peroxide in acetonitrile[26–28] and this prompted us to use this solvent in our studies with the aim of obtaining results that may be used in future studies on the stability of Keggin anions in homogeneous catalytic conditions.

## Results and Discussion

### The Keggin Heteropolyanion, $[PW_{12}O_{40}]^{3-}$ – Multiple versus Single Scattering Analysis

Multiple scattering (MS) generally makes a significant contribution to XAFS.[29] At low energy covalent clusters may give a massive contribution to the "white line", associated with resonant scattering of a photoelectron. The significance of these paths is such that unless the near edge region is entirely avoided the effect will be seen even in the Fourier transform of the first shell. At higher energies the paths will certainly make large contributions where the forward scattering path angles are 150° or more. Other paths may or may not give significant effects. Quite often, the main effect is a phase change over all or part of the spectrum, which may be especially conspicuous near a scattering minimum associated with an $l > 1$ final state. However, these are only general rules and for any specific structure it is necessary to compare results with and without multiple scattering before presuming to adopt the single-scattering approximation.

The role of MS was evaluated for $[PW_{12}O_{40}]^{3-}$, for which an accurate structure was available determined by neutron diffraction.[25] This allowed the EXAFS data to be fitted with no adjustable parameters other than a small number of Debye–Waller terms (for groups of shells of similar type and distance), the energy zero $E_f$, and the overall amplitude AFAC. The result, using a cluster of 6 Å radius, with 3796 MS paths to the fifth order, is shown in Figure 1 (b, I). The *R* factor obtained was 19%, which is considered good given that no structural variables were involved. Most of the error actually appears to be involved in residual low-frequency background contributions rather than any intrinsic inaccuracy in the technique. Multiple scattering makes an important contribution, but this is dominated by a small number of paths: principally the W–O–W second and third order paths with bond angles close to 120 or 150°. The number of structural parameters required to describe this cubic phase is small, but this is not the case for the lacunary or monosubstituted compounds, for which published structures show a low symmetry with several different metal sites, and oxygen polyhedra of $C_1$ or $C_2$ symmetry. For these, a simplified model is required using a reduced number of shells and without multiple scattering, which requires the addition of more parameters to describe the bond angles. To test the validity of this we repeated the analysis using only seven shells, and without multiple scattering. The fit, shown in Figure 1(b, II), gave an *R* factor of 26%, which is considered acceptable, and although the distances are different they differ by no more than 0.03 Å. The results are shown in Table 1. Given that this is only an approximate structural model, errors of this magnitude can be expected, and we believe that the results obtained are sufficient to draw the conclusions we do concerning the nature of the oxygen octahedra and metal–metal distances in the cluster. This approach was therefore used throughout this paper.

Table 1. Theoretical EXAFS best-fit parameters for $[PW_{12}O_{40}]^{3-}$ with and without multiple scattering. Data obtained from neutron diffraction.[25] $E_f$ is the edge position relative to the photoelectron wavevector (eV); $R_x$ refer to the distances (in angstroms) and *A* are the Debye–Waller Factor terms (in Å$^2$); the *R* factor gives a meaningful indication of the quality of the fit in *k* space (in%).

Data were collected for solid $TBA_3[PW_{12}O_{40}]$ as well as in acetonitrile solution. The fitted results of the EXAFS experimental data are presented in Table 2. The average W-shell inter-atomic distances are determined in relation to a selected tungsten atom referred here as $W_c$. Results for the solid sample are in good agreement with those of the previous EXAFS study by Evans et al.[17] and with the reported diffraction data.[25] They are presented here for comparison with results obtained for $[PW_{12}O_{40}]^{3-}$ in solution and for the other Keggin-type anions. From the results in Table 2 it can be seen that the structure of the $[PW_{12}O_{40}]^{3-}$ anion does not change when the compound is dissolved in acetonitrile. The differences in bond lengths and Debye–Waller factors for the shells fitted in both cases (solid and in acetonitrile solution) are within the standard deviation. These results parallel those observed previously for the related $[PMo_{12}O_{40}]^{3-}$ anion.[17]

In agreement with the known Keggin structure, six oxygen atoms were found around $W_c$ (only five had been detected by Evans et al.[17]). For the solid sample, the shortest observed bond length between tungsten and oxygen, attributed to the terminal oxygen atoms ($O_1$, Figure 1, a, M = $W_c$), was 1.697 Å. Four bridging oxygen atoms ($O_{2a}$, $O_{2b}$, $O_{3a}$, $O_{3b}$) were found at a distance of 1.915 Å from $W_c$ and the oxygen of the central $PO_4$ tetrahedron ($O_4$) at a distance of 2.304 Å. Each oxygen atom from the central $PO_4$ tetrahedron belongs to one of the four $W_3O_{13}$ groups. Two tungsten atoms at a distance of 3.459 Å probably belong to the same $W_3O_{13}$ group as $W_c$ ($W_1$ and $W_2$, Figure 1, a), whereas two tungsten atoms at a distance of 3.733 Å must be located in different $W_3O_{13}$ groups in relation to $W_c$ ($W_3$ and $W_4$, Figure 1, a). The distance between $W_c$ and the phosphorus atom of the central $PO_4$ tetrahedron is 3.545 Å. The inclusion of one phosphorus atom improved the *R* value; however, the improvement was even more significant when tungsten atoms were introduced at 3.733 Å. The results obtained for the dodecatungstophosphate in the solid state and in acetonitrile solution (Table 2) are very similar.

### The Lacunary Polyoxoanion, $[PW_{11}O_{39}]^{7-}$

The lacunary anion $[PW_{11}O_{39}]^{7-}$ has a Keggin structure from which one W=O group was removed. In this case not all W atoms are equivalent because four of the eleven W atoms have two terminal oxygen atoms. Figure 2 shows the EXAFS spectrum and the Fourier transform for the $PW_{11}$ anion. In this case the spectrum of the solid was different from that obtained in solution. The fit of the EXAFS results is presented in Table 3. The average number of atoms coordinated to $W_c$ (average of all tungsten atoms presented in the structure) was the same in both cases, but the calculated distances for the shells are slightly different. The structure of the lacunary anion is globally less rigid than that of the parent $PW_{12}$. This may be the reason that different distance values were observed for the anion in the solid state and in $CH_3CN$ solution, reflecting different environments in each case, contrary to what was observed for $PW_{12}$.

Table 3. EXAFS best-fit parameters for the lacunary heteropolyanion in $TBA_4H_3[PW_{11}O_{39}]$ (W $L_{III}$ edge transmission mode). Parameters as defined in Table 1.

| R7 (1 × P) | 3.346 (0.028) | 3.220 (0.012) |
| R9 (2 × W) | 3.919 (0.029) | 3.765 (0.016) |
| *A*[1] | 0.008 (0.001) | 0.019 (0.004) |
| *A*[2–3] | 0.015 (0.002) | 0.010 (0.002) |
| *A*[4] | 0.015 (0.005) | 0.004 (0.002) |
| *A*[7] | 0.023 (0.008) | 0.005 (0.002) |
| *A*[5,9] | 0.023 (0.007) | 0.012 (0.004) |
| $E_f$ (eV) | 10.2 | 13.5 |
| *R* (%) | 22.5 | 21.8 |

From the EXAFS fit of the lacunary anion four shells of oxygen atoms were deduced in the first coordination sphere of $W_c$. In the solid state the shortest oxygen–tungsten bond length was 1.641 Å and corresponds to the average of the W–O distance to the oxygen atoms protruding from the anion. The value of 1.761 Å is possibly the average of terminal (oxygen atoms surrounding the lacuna) and bridging W–O bond lengths. This is a consequence of the fact that each of the W atoms surrounding the lacuna is bound to two monocoordinated oxygen atoms. Other bridging oxygen atoms are located at a distance of 2.205 Å. Finally, the W–O distance to the oxygen of the central $PO_4$ group was found to be 2.412 Å. These values are comparable to those reported for $[PW_{11}O_{39}]^{7-}$[30] and $[SiW_{11}O_{39}]^{8-}$,[31] obtained by X-ray crystallography. In these studies the position of the vacancy could not be located with certainty.[30,31]

### W $L_{III}$ Edge Analysis of Monosubstituted Polyoxoanions, $[PW_{11}M(H_2O)O_{39}]^{4-}$, M = Fe and Mn

It is commonly accepted that the Keggin structure is maintained when one W=O group from the anion $[PW_{12}O_{40}]^{3-}$ is substituted by $M^{III}–OH_2$, M = transition metal, to form $[PW_{11}M(H_2O)O_{39}]^{4-}$ and the results here presented for M = Fe, Mn are in agreement with this fact. Figure 3 shows the W $L_{III}$ edge EXAFS spectrum and the Fourier transform for the solid samples of TBA salts of $PW_{11}Mn$ and $PW_{11}Fe$. The results from the curve fitting are presented in Table 4. For these anions, the EXAFS data obtained from the W $L_{III}$ edge analysis are the average of the eleven tungsten atoms in an octahedral coordination.

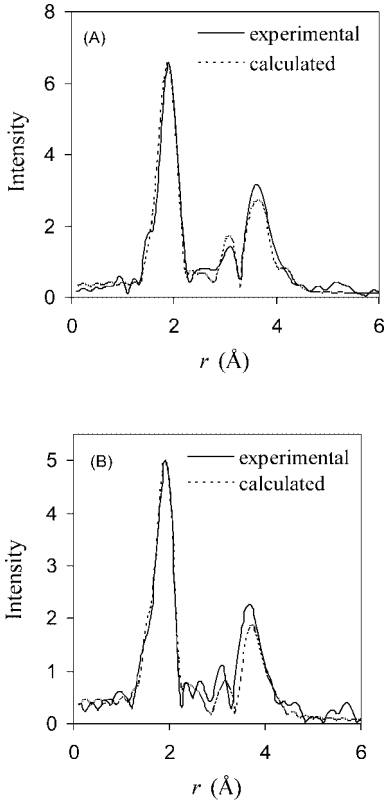

Figure 3. W $L_{III}$ edge Fourier transform for $[PW_{11}Fe(H_2O)O_{39}]^{4-}$ (a) and $[PW_{11}Mn(H_2O)O_{39}]^{4-}$ (b) in solid state TBA salts.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As found for $PW_{12}$ and $PW_{11}$, the $W_c$ atom of $PW_{11}Fe$ has six oxygen atoms in the first coordination sphere with bond lengths of 1.628 Å, 1.944 Å, and 2.131 Å (Table 4). These average distances do not differ much from those of the $PW_{12}$ unit. The Fe atom was located at a distance of 2.994 Å from $W_c$ and the nearest W atom at a distance of 3.234 Å. These distances are close enough to suggest that the W is localized within a $W_cWFeO_{13}$ group. The shortest W–$W_c$ distance obtained for $PW_{12}$ was 3.459 Å (Table 2). These values seem to indicate that when Fe replaces one W atom from a $W_cW_2O_{13}$ unit (in $PW_{12}$) it stays closer to $W_c$ than the replaced W was in the $PW_{12}$ structure. Also, the distance from $W_c$ to the four coordinated oxygen atoms of the $W_c$–O–P bridge is shorter in the iron anion than in $PW_{12}$. Therefore, even if the structure of the polyoxoanion is not globally altered the coordination sphere of tungsten is affected by the change of the W atom (with its terminal oxygen) for Fe, possibly with a terminal water molecule as a ligand.

For the $[PW_{11}Mn(H_2O)O_{39}]^{4-}$ polyoxoanion, the $W_c$–O bond lengths within the $W_cO_6$ octahedron (Table 4) were similar to the analogous bond lengths for $PW_{12}$. The terminal oxygen is at a distance of 1.705 Å from $W_c$, and the bridging oxygen atoms are at distances in the range of 1.931–2.225 Å. One tungsten atom from a $W_cWMnO_{13}$ group ($W_2$, 3.034 Å) and two other from a different $W_3O_{13}$ group ($W_3$ and $W_4$, 3.730 Å) are also at a close distance to the $W_c$ atom.

In the case of the $PW_{12}$ anion the four equatorial $W_c$–O(–W) bond lengths have the same value. This is not the case for $PW_{11}Fe$ and $PW_{11}Mn$, for which one of these distances was found to be longer than the other three, reflecting the loss of symmetry associated with the replacement of tungsten by a different transition metal.

The average of the W–O bond lengths around $W_c$ in $PW_{12}$, $PW_{11}Fe$, and $PW_{11}Mn$ are 1.94, 1.95, and 1.95 Å, respectively. However, the Mn seems to be closer (2.564 Å) to the $W_c$ atom than the Fe (2.994 Å) in the structure of $PW_{11}Fe$. These differences may be related to a higher distortion of the $W_cWMO_{13}$ group in the case of Mn, possibly as a consequence of the Jahn–Teller effect of the $Mn^{III}$ ion.

### Fe *K* Edge Analysis of $[PW_{11}Fe(H_2O)O_{39}]^{4-}$

Polyoxoanions like $PW_{11}Fe$ and $PW_{11}Mn$, with two different transition metals in their structure, have the advantage of providing two different elements for EXAFS studies. Curve-fitting results for the Fe *K* edge fluorescence EXAFS data for $PW_{11}Fe$ in the solid state and in $CH_3CN$ solution are presented in Figure 4 and Table 5. It was assumed for all M substituted anions that no replacement of the coordinated water of the M–$OH_2$ group by acetonitrile occurred. The results indicate that the structures around Fe are very similar in both media. On comparing the distances of the six oxygen atoms to Fe in the $FeO_6$ octahedron (values for the solid state and in solution are in the range 1.943–2.512 and 1.976–2.522 Å, respectively, Table 5) with those of the six oxygen–tungsten bonds in the $WO_6$ octahedra of the parent Keggin anion (1.697–2.318 Å, first three shells in

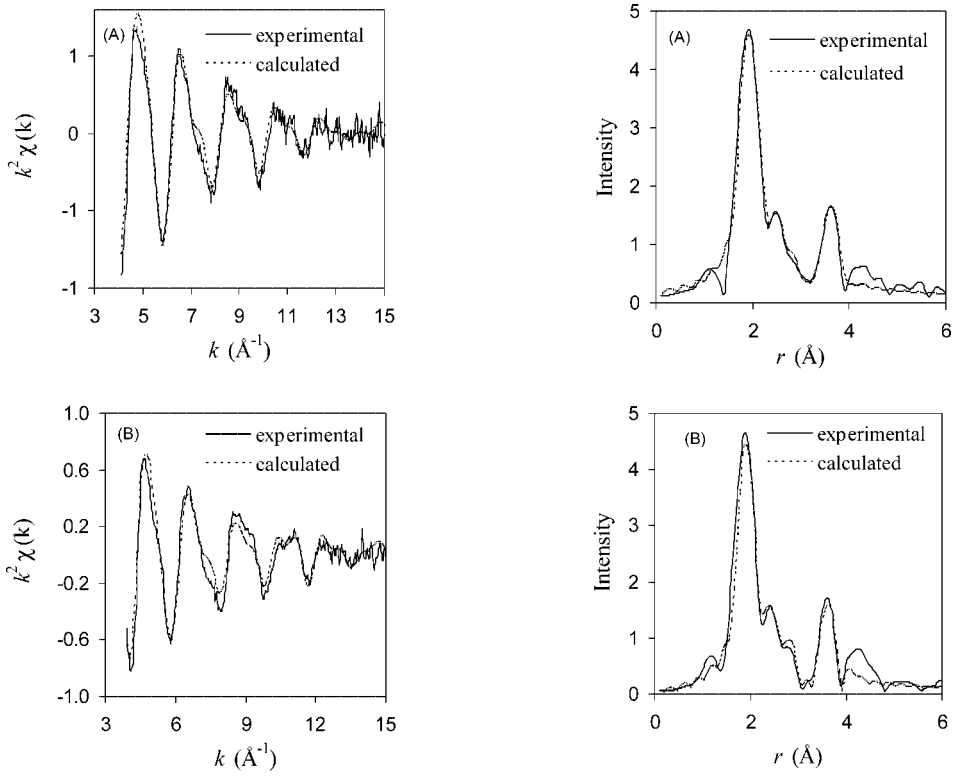

Figure 4. Fe *K* edge EXAFS spectrum and Fourier transform for $[PW_{11}Fe(H_2O)O_{39}]^{4-}$ in solid state TBA salt (a) and in $CH_3CN$ solution (b).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 2), it can be noticed that the $FeO_6$ octahedron is larger than the $WO_6$ that it has substituted. It is also larger than the nearest $WO_6$ octahedra (Table 4).

Polyoxotungstophosphates with $Fe^{III}$ have been structurally characterized by Li et al.[32] and by Hill and collaborators.[33] The former determined the structure of the dimeric $[Fe_4(OH)_4(PW_{10}O_{37})_2]^{10-}$, whereas the latter studied the sandwich anions $[Fe_4(H_2O)_2(PW_9O_{34})_2]^{6-}$ and $[Fe_4(H_2O)_2(P_2W_{15}O_{56})_2]^{12-}$. Structures of multi-iron polyoxotungstates (tungstosilicates, tungstogermanates and others) and of the anion $[Fe_4(H_2O)_2(FeW_9O_{34})_2]^{10-}$ were also reported.[34,35] The Fe–$O(H_2)$ bond lengths in the sandwich-type iron polyoxotungstophosphates were found to be around 2.00 Å.[33] Other values reported, for polyoxometalates or iron complexes, fall in the range 2.02–2.19 Å.[34,36] The average value reported for hexaaquairon(III) countercations in Keggin-type molybdophosphate compounds, obtained from EXAFS data, was 1.98 Å.[23] Thus, the Fe–O bond length corresponding to the oxygen from the terminal water molecule for the $PW_{11}Fe$ anion is possibly 1.943 Å in the solid sample and 1.976 Å in the $CH_3CN$ solution. With this assumption the average value of the equatorial Fe–O distances is 2.29 Å. The iron–oxygen distances found for the sandwich and the dimeric anions with P were in the range 1.88–1.99 Å for Fe–O–W and 2.18–2.40 Å in the Fe–O–P bridges.[32,33] In all cases the iron was octahedrally coordinated, but the arrangements of atoms around the $FeO_6$ octahedra in those anions are different from that of the monosubstituted $PW_{11}Fe$. The results obtained by EXAFS reported in this paper seem to indicate a larger and more distorted $FeO_6$ for $PW_{11}Fe$ than for the dimeric or the sandwich anions, which is obviously related to the difference in the structural arrangements, in which the possibility of an increase in Fe–O distances is higher for the less rigid $PW_{11}Fe$ anion. It is interesting to note that the Fe in $PW_{11}Fe$ is at a closer distance from the phosphorus heteroatom (3.105 Å in the solid, 3.156 Å in solution) than the W in the Keggin, lacunary, and iron-monosubstituted structures (3.545, 3.346, and 3.583, respectively, for solid samples). The enlargement of the $FeO_6$ octahedron is possibly accompanied by a rearrangement of the whole $FeW_2O_{13}$ group. Nevertheless, results from infrared spectroscopy suggest that there is not a significant distortion of the central $PO_4$ group.[37] The infrared spectrum, between 1000–1100 $cm^{-1}$, of the TBA salt of the $PW_{11}Fe$ anion has only one band,[38] assigned to the $\nu_{as}$(P–O) at 1069 $cm^{-1}$. The corresponding value for the $PW_{12}$ anion is 1080 $cm^{-1}$. The splitting of the $\nu_{as}$(P–O) is usually less pronounced for TBA than for K salts,[38] with the possible exception of the TBA salt of the $PW_{11}$ anion, for which the infrared spectrum shows two bands in this region at 1107 $cm^{-1}$ and 1054 $cm^{-1}$.[39]

### Mn *K* Edge Analysis of $[PW_{11}Mn(H_2O)O_{39}]^{4-}$

The Mn *K* edge analysis of $PW_{11}Mn$ indicated that there are six oxygen atoms in the first coordination sphere of Mn (Figure 5) with distances in the range of 1.981–2.626 Å (Table 6). The two W atoms in the same $W_2MnO_{13}$ group are at an average distance of 3.243 Å from Mn. The longest bond length was attributed to the Mn–O in the Mn–O–P group. This long Mn–O(–P) distance was considered to be evidence of Jahn–Teller tetragonal distortion of the octahedron around the high spin $Mn^{III}$ ion. One oxygen atom at 2.140 Å was attributed to the Mn–$O(H_2)$ group from a comparison with values reported by Zhang et al.[40] The average Mn–O bond lengths found in the EXAFS spectroscopic study described here are larger than the usual $Mn^{III}$–O bond lengths reported in the literature either in polyoxometalates[40,41] or otherwise.[42] As a consequence of the

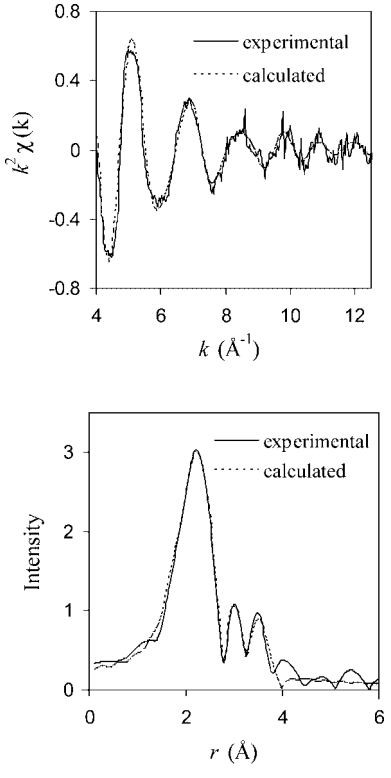

Figure 5. Mn *K* edge EXAFS spectrum and Fourier transform for $[PW_{11}Mn(H_2O)O_{39}]^{4-}$ in solid state TBA salt.

Jahn–Teller effect, the $Mn^{III}$ ion is possibly slightly out of the polyoxometalate vacancy of the $PW_{11}$ ligand, and this may be the reason for the long Mn–O bond length values found in this study. It may be noted, comparing the data in Table 4, Table 5, and Table 6, that the average of the M–O bond lengths in the $MO_6$ octahedra for M = Mn, Fe, (2.30 Å and 2.27 Å, respectively) are larger than the average W–O distances in $PW_{11}M$.

### $[PW_{11}Ru(H_2O)O_{39}]^{4-}$, Ru *K* Edge Analysis

Table 7 shows the distances from the shells to the Ru atom. The distance from the Ru atom to the first six oxygen atoms average 2.23 Å in the solid state (2.056–2.413 Å) and 2.35 Å in acetonitrile solution (2.106–2.603 Å). The two W atoms from the same $W_2RuO_{13}$ group ($W_1$ and $W_2$, Figure 1, a) are localized at 3.361 Å in the solid state and 3.410 Å in $CH_3CN$ solution (Table 7). Thus the structure of $PW_{11}Ru$ seems to be approximately the same in the solid compound and in solution. The phosphorus atom was found at a longer distance from ruthenium for the $PW_{11}Ru$ in acetonitrile than in the solid state (3.781 Å and 3.571 Å, respectively), and this is the only important difference when we compare these two environments (Table 7 and Figure 6).

| *R* (%) | 26.5 | *R* (%) | 20.7 |

By comparing the EXAFS data of $PW_{11}Ru$ with $PW_{11}Fe$ it may be noted that the results suggested that the size of

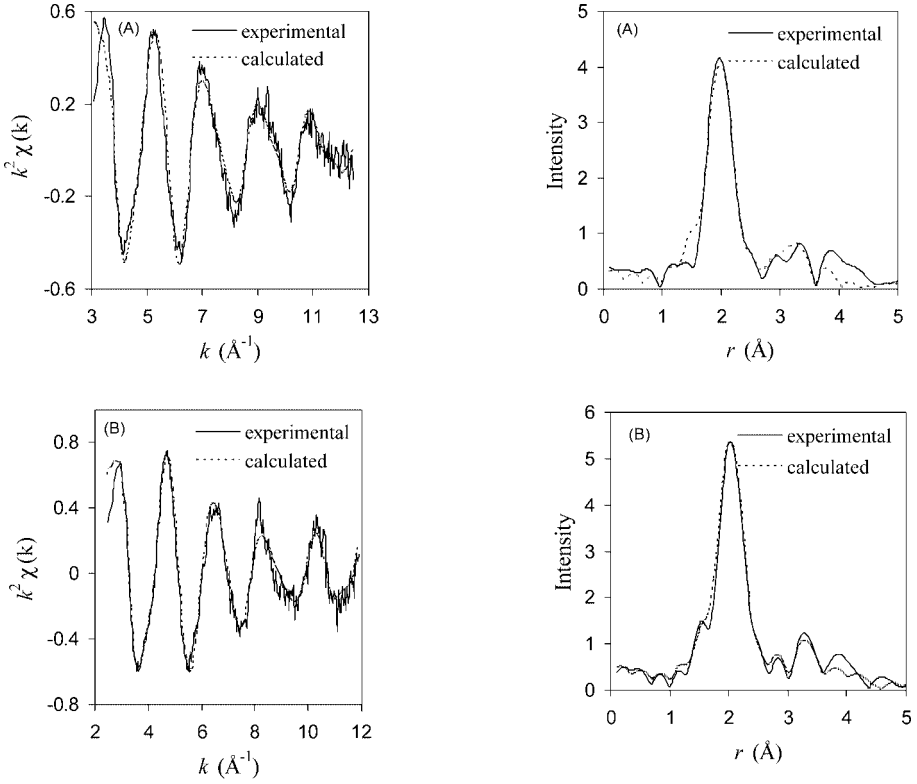

Figure 6. Ru *K* edge EXAFS spectrum and Fourier transform for $[PW_{11}Ru(H_2O)O_{39}]^{4-}$ in solid state TBA salt (a) and in $CH_3CN$ solution (b).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the $FeO_6$ and the $RuO_6$ octahedra were not very different. The Ru atom is at a longer distance from the heteroatom P than it is from Fe. Also, the size of the group $W_2RuO_{13}$ seems to be bigger than $W_2FeO_{13}$ because the distance from the Ru atom to the closest two W atoms, Ru–W, is larger than for Fe–W. The two other W atoms (outside the $W_2RuO_{13}$ unit) are at a distance from the Ru atom of 3.584 Å in the solid state and at 3.564 Å in the $CH_3CN$ solution.

The crystal structure of a salt of the anion $[SiW_{11}Ru^{III}(S\text{-}DMSO)O_{39}]^{5-}$ was reported recently.[43] This was the first Ru-monosubstituted Keggin ion in which the ruthenium center was not crystallographically disordered. The Ru–O bond lengths averaged 2.04 Å in this anion.[43];7

### Effect of Changing the Central Heteroatom X (P, Si, and B)

The effect of changing the central heteroatom (X) on the structure of polyoxotungstates was studied by comparing EXAFS data resulting from W $L_{III}$ edge analysis for $PW_{11}Mn^{III}$, $SiW_{11}Mn^{III}$, and $BW_{11}Mn^{III}$ (Figure 7 and Table 8). Because of the possible occurrence of the Jahn–Teller effect the environment of the Mn ion was expected to be more distorted than for other substituting metals. Thus, the ability of the $W_{11}Mn(H_2O)O_{39}$ unit to accommodate different heteroatom sizes of varying formal oxidation states could be studied in the solid compounds.

Table 8. EXAFS best-fit parameters for solid $TBA_4H[SiW_{11}Mn(H_2O)O_{39}]\cdot H_2O$ and $TBA_4H_2[BW_{11}Mn(H_2O)O_{39}]\cdot 2H_2O$ (W $L_{III}$ edge transmission mode). Parameters as defined in Table 1.

| *R* (%) | 18.8 | *R* (%) | 20.1 |

The six oxygen atoms from the first coordination sphere $WO_6$ were localized in the range 1.717–2.277 Å for X = Si and 1.714–2.272 Å for X = B (Table 8). It can be noticed that the average W–$O_4$ distance (Figure 1, a) in the $WO_6$ octahedra are slightly smaller for the polyanion with X = P (Table 4). Contrary, the distance between the Mn atom and $W_c$ is bigger for X = P than for X = Si and B.

No relationship between the average bond lengths and the size of the central atom could be deduced (in line with published results for the parent Keggin anions[44,45]). Glob-

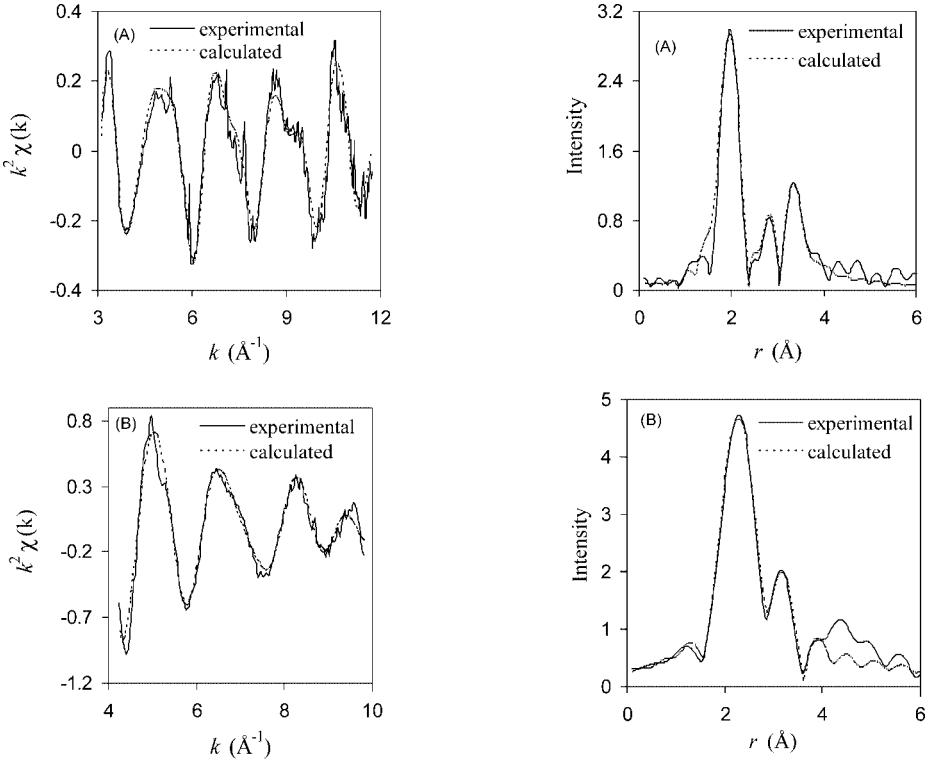

Figure 7. W $L_{III}$ edge EXAFS spectrum and Fourier transform for $[SiW_{11}Mn(H_2O)O_{39}]^{5-}$ (a) and $[BW_{11}Mn(H_2O)O_{39}]^{6-}$ (b) anions in solid state compounds.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ally, the size of the $W_3O_{13}$ groups seems to be independent of X because of the similarity between all X = P, Si, and B anions.

## Conclusions

EXAFS spectroscopy was used to characterize several tetrabutylammonium Keggin-type polyoxotungstates in the solid state and in acetonitrile solution. With this technique the local average environment around W and other substituting metals (Fe, Mn, Ru) was revealed in the lacunary and metal-substituted tungstophosphates $[PW_{11}O_{39}]^{7-}$ and $[PW_{11}M(H_2O)O_{39}]^{4-}$, M = Fe, Mn, Ru, and compared with that of the parent Keggin anion $[PW_{12}O_{40}]^{3-}$. These are compounds with interesting catalytic properties and the detailed knowledge of their structure, particularly around the lacunae or of the substituting metals, has unquestionable relevance. The average structure of W in the series $[XW_{11}Mn^{III}(H_2O)O_{39}]^{n-}$, X = P, Si, B was also obtained and compared. Of those anions, only the structure of $[PW_{12}O_{40}]^{3-}$ and $[PW_{11}O_{39}]^{7-}$ are known from crystallographic studies.[25,30] For the different anions EXAFS data allowed the determination of bond lengths and other interatomic distances in the vicinity of target atoms. The influence of the lacuna or of substituting metals on the W–O bond lengths was not, in general, very large, but could be noticed. The substituting metals (Fe, Mn, Ru) were coordinated by six oxygen atoms, but the coordination octahedron around Mn was found to be larger and more distorted than for the other metals. This was considered to be evidence of Jahn–Teller distortion.

For most cases little change in EXAFS and in the determined parameters occurred upon dissolution of the compounds in acetonitrile. The lacunary anion was, however, the most affected. EXAFS spectroscopy may be used to monitor the stability of the polyoxometalates in solution. The structure of the polyoxoanions in the presence of $H_2O_2$ will be described in a forthcoming paper. In this context, the results presented here may open a way of studying the fate of polyoxometalates in homogeneous catalysis in acetonitrile.

In conclusion, this EXAFS study allowed (1) the determination of structural information and details of metal coordination in these anions, not obtained to date by other techniques, in view of the natural difficulties introduced by the structural disorder, and (2) the comparison of the interatomic distances in different heteropolyanions of the same family in the solid state and in solution. This is the first systematic structural study using EXAFS of lacunary or metal-monosubstituted Keggin-type anions.

## Experimental Section

**Materials:** All reagents were used as received. Acetonitrile (Panreac, for instrumental analysis) and boron nitride (Aldrich) were used. The following compounds were prepared and purified as reported previously: $TBA_3[PW_{12}O_{40}]$,[46] $TBA_4H_3[PW_{11}O_{39}]$,[26] $TBA_4[PW_{11}M(H_2O)O_{39}]$, M = Fe[26] and Mn,[47] $TBA_4H[SiW_{11}Mn(H_2O)O_{39}]$,[47] and $TBA_4H_2[BW_{11}Mn(H_2O)O_{39}]\cdot H_2O$.[27] IR spectra of $PW_{11}Mn$ [$cm^{-1}$]: $\nu_{as}$(P–$O_a$) 1086, 1074 (s), $\nu_{as}$(W–$O_d$) 962 (vs), $\nu_{as}$(W–$O_b$–W) 881 (s), $\nu_{as}$(W–$O_c$–W), 804 (vs) ($O_d$, terminal oxygen, $O_b$, $O_c$, bridging oxygens, and $O_a$, central oxygen atom[46]). The general procedure used for the TBA salt of $PW_{11}Fe$[26] was adapted to prepare $TBA_4[PW_{11}Ru(H_2O)O_{39}]\cdot 4H_2O$:[48] aqueous solutions of $RuCl_3$ (Fluka) and $PW_{11}$, prepared in situ, were mixed at 90 °C; the solid obtained after the addition of aqueous TBABr was filtered and recrystallized in acetonitrile. Analytical data (%) with calculated values in parenthesis: C: 18.93 (20.03), H: 3.79 (4.05), N: 1.82 (1.46). The IR spectrum shows characteristic peaks attributed to $\nu_{as}$(W–$O_d$) at 945 $cm^{-1}$, $\nu_{as}$(W–$O_b$–W) at 892 $cm^{-1}$, $\nu_{as}$(W–$O_c$–W) at 820 $cm^{-1}$, and $\nu_{as}$(P–$O_a$) at 1080 and 1045 $cm^{-1}$.

**Data Collection and Analysis:** The extended X-ray absorption spectra associated with Fe (7.112 keV) or Mn (6.539 keV) *K* edges were collected in the fluorescence mode on stations 7.1 [double crystal Si (111) order-sorting monochromator] and with the Ru *K* edge (22.117 keV) on station 9.2 [double crystal Si (220) order-sorting monochromator]. W $L_{III}$ edge (10.207 keV) was collected in transmission mode on station 7.1. Both stations are located at Daresbury Laboratory (Synchrotron Radiation Source-SRS). The energy of the storage ring is 2 GeV and during the experiments the average current was 150 mA. Solid samples of polyoxotungstates were diluted when necessary with boron nitride and pressed into self supporting pellets with a typical thickness of 0.3 mm. Liquid samples of polyoxotungstates (10 mM) were prepared by direct dissolution of the compound in acetonitrile and placed in liquid cells that were 2 mm in thickness. The measurements were carried out at room temperature.

EXCALIB,[49] SPLINE,[50] and EXCURV98[51] were the programs used to process and analyze the EXAFS data. For each sample at least six scans were averaged. Curve-fitting analyses by least-squares refinement of the non-Fourier filtered $k^2$-weighted EXAFS data were carried out with the EXCURV98 program.[51] The calculations were performed using single scattering. The coordination number of each shell was fixed according to literature values. EXAFS refinements were performed in the *R* space. The number of parameters ($N_i$) was calculated for each refinement and this number indicates the number of parameters that can be refined. The number of shells that were fitted depended on the number of parameters determined. $N_i$ was quantified considering the distance range in the Fourier transform ($\Delta r$) and the energy range in EXAFS oscillations ($\Delta k$), $N_i = 2\Delta r\Delta k/\pi$. The number of parameters refined for each sample was smaller than $N_i$.

The analysis of the W $L_{III}$ edge structure of the Keggin anion $[PW_{12}O_{40}]^{3-}$ was done using as reference the published structural data.[25] For the lacunary $[PW_{11}O_{39}]^{7-}$ and for the substituted anions, $[XW_{11}M^{III}(H_2O)O_{39}]^{n-}$, X = P, M = Fe, Mn, Ru, and X = Si, B, M = Mn, this was done using the X-ray single crystal data of the similar lacunary anion $[SiW_{11}O_{39}]^{8-}$,[31] and of the $[PW_{11}Co(H_2O)O_{39}]^{5-}$ polyanion,[11] respectively.

## Acknowledgments

Thanks go to Daresbury Laboratory (synchrotron Radiation source-SRS) for the EXAFS analysis and to Fundação para Ciência e Tecnologia (FCT) and the University of Aveiro for the financial support of this work. M. S. B. is grateful to FCT and FEDER for her PhD grant.

## COVER PICTURE

**The cover picture shows** the one-dimensional polymeric iron(II) spin crossover material, $Fe(NCX)_2$-(cddt)·*n*(guest) (X = S or Se) containing the ligand 2-chloro-4,6-bis(dipyrid-2-ylamino)-1,3,5-triazine. The thiocyanate analogue undergoes a "half" spin crossover, illustrated at the bottom, where at low temperatures there are alternating, crystallographically distinct, high spin (yellow) and low spin (red) iron(II) centres (as can be seen in the structural diagram). The selenocyanate material undergoes a full spin crossover illustrated at the base of the image. Further characterisation of the thiocyanate material has been carried out by powder X-ray diffraction using synchrotron radiation; a representative image is shown in the background of the picture. Details are discussed in the article by K. S. Murray et al. on p. 1073 ff.

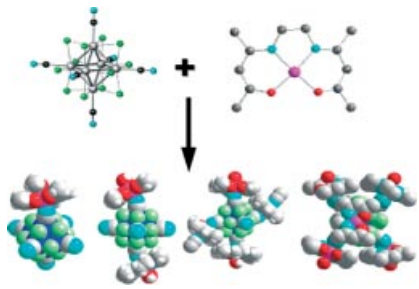
## MICROREVIEW

### Cluster-Based Materials

**H. Zhou, A. Lachgar* ..... 1053–1066**

Octahedral Metal Clusters $[Nb_6Cl_{12}(CN)_6]^{4-}$ as Molecular Building Blocks: From Supramolecular Assemblies to Coordination Polymers

**Keywords:** Metal clusters / Self-assembly / Supramolecular Chemistry / Coordination polymers



Reactions between octahedral niobium cyanochloride metal clusters and coordinatively unsaturated metal complexes in different solvents led to the formation of supramolecular moieties with different sizes and different charges. Judicious choice of the synthetic conditions led to the preparation of either supramolecules that are hydrogen bonded, or to coordination polymers with 1D, 2D, and 3D frameworks built from cluster anions and metal complexes linked by CN ligands.

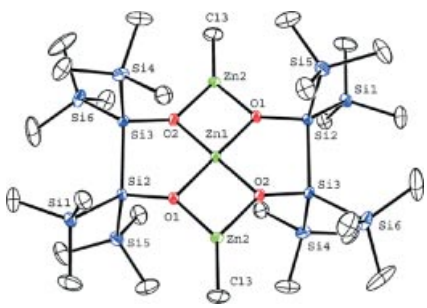
## SHORT COMMUNICATION

### Zinc Siloxides

**C. Krempner,* H. Reinke, K. Weichert ..... 1067–1071**

Synthesis and Structure of Cyclic Trinuclear Zinc Disiloxides

**Keywords:** Oligosilanes / Zinc / Siloxides / Clusters



The synthesis of three new cyclic trinuclear zinc disiloxides has been reported from reactions of $ZnMe_2$ with various vicinal silanediols. The solid-state structure of one of the zinc siloxides (see Figure) reveals unusual square-planar coordination geometry of the inner $Zn^{2+}$ ion, which is enforced by steric interactions of the silyl groups.

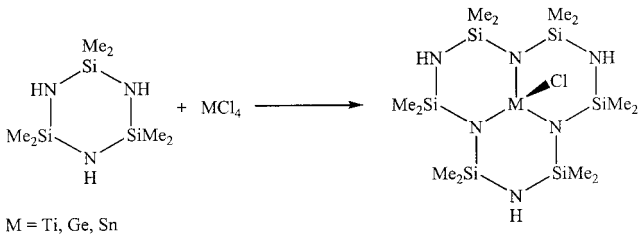
## Silazane Complexes



M = Ti, Ge, Sn

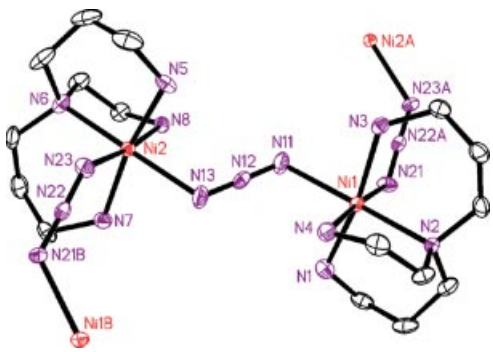
**C. Lehnert, J. Wagler, E. Kroke, G. Roewer* ..... 1086–1090**

Synthesis and Characterization of Novel Titanium, Germanium, and Tin Silazane Complexes Bearing a Cyclohexasilazane-triido Ligand

Novel titanium, germanium and tin silazane complexes can be synthesized by the reactions of 1,1,3,3,5,5-hexamethylcyclotrisilazane $H_3$(HMCTS) with the corresponding metal tetrachloride under various reaction conditions. The molecular structures of these complexes exhibit a new dodecamethylcyclohexasilazane system with the Ti, Ge, and Sn atom in the center. The metal atoms are coordinated by one chlorine atom and three nitrogen atoms that are part of three six-membered heterosilazane rings.

**Keywords:** Heterometallic complexes / N ligands / Titanium / Germanium / Tin / Cyclohexasilazane complexes

## Bridged Azido – Nickel(II) Complexes



**S. S. Massoud,* F. A. Mautner, R. Vicente, A. A. Gallo, E. Ducasse ..... 1091–1102**

Dinuclear and Polynuclear Bridged Azido–Nickel(II) Complexes: Synthesis, Structure Determination, and Magnetic Properties

A new series of azido–$Ni^{II}$ complexes $[Ni_2(trpn)_2(\mu_{1,3}\text{-}N_3)_2](ClO_4)_2$ (**1**), 1D *cis*-$[Ni(abap)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n$ (**2**), 1D *cis*-$[Ni(Me_6trien)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n{\cdot}nH_2O$ (**3a**), and $[Ni(Me_6trien)(N_3)]ClO_4$ (**3b**) were synthesized and structurally characterized by spectroscopic techniques, X-ray crystallography, and magnetic measurements.

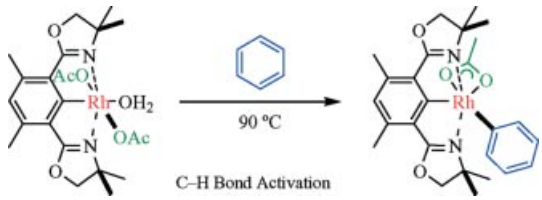
## C−H Activation

**J. Ito, H. Nishiyama* ..... 1114−1119**

Carbon−Hydrogen Bond Activation of Arenes by a [Bis(oxazolinyl)phenyl]rhodium(III) Acetate Complex

**Keywords:** C−H activation / Arenes / Rhodium / Substituent effects



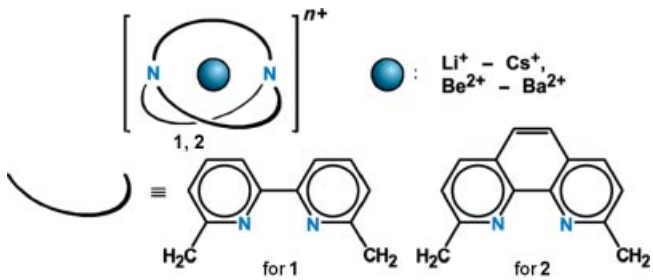
Thermolysis of a [bis(dimethyloxazolinyl)-phenyl]rhodium(III) acetate complex in the presence of various arenes results in the formation of the corresponding aryl complexes by intermolecular C−H bond activation assisted by the acetato ligand as a proton acceptor.

## Host−Guest Complexes

**R. Puchta,* R. van Eldik ..... 1120−1127**

Host−Guest Complexes of Oligopyridine Cryptands: Prediction of Ion Selectivity by Quantum Chemical Calculations

**Keywords:** Density functional calculations / Semiempirical calculations / Cryptands / Host−guest systems / Cation selectivity



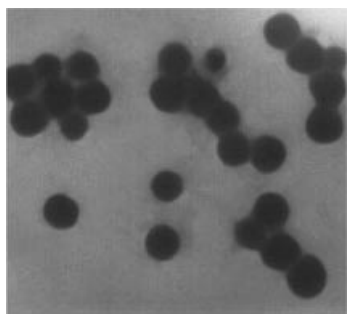
Quantum chemical investigations of endohedral ion complexation by the cryptands **1** and **2** predict a favourable binding of $K^+$, $Ca^{2+}$ and $Sr^{2+}$ by **1** and $Na^+$, $Ca^{2+}$ and $Sr^{2+}$ by **2**. To obtain the best coordination mode for each cation, the cryptands fold around the ions by twisting their torsion angles.

## Nanomaterials

**L. B. Yang, Y. H. Shen,* A. J. Xie, J. J. Liang, J. M. Zhu, L. Chen ..... 1128−1134**

Synthesis of Controllable-Size Core−Shell Se@Ag and Se@Au Nanoparticles in UV-Irradiated TSA Solution

**Keywords:** Nanostructures / Photochemistry / Core−shell structures / Selenium



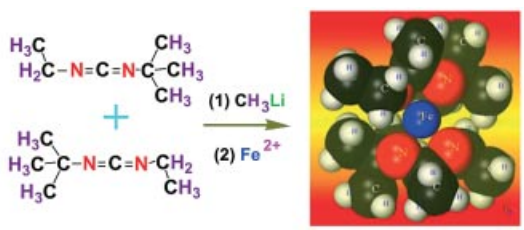
The formation of Se-core−Au-shell and Se-core−Ag-shell nanoparticles by using photochemically reduced tungstosilicate Keggin ions has been described. With this method, the core size and the shell thickness can be controlled by varying the conditions.

## A Volatile Iron Amidinate

**X.-G. Li,* Z. Li, H. Li, R. G. Gordon* ..... 1135−1142**

Synthesis and Sublimation Kinetics of a Highly Volatile Asymmetric Iron(II) Amidinate

**Keywords:** Asymmetric iron(II) amidinate / Bridging ligands / Metathesis / Sublimation kinetics / Thermochemistry



Iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate), was synthesized and characterized for the first time by NMR spectroscopy, MS, IR spectroscopy and TG techniques. The activation energy of the sublimation is 105 kJ $mol^{-1}$. The optimal starting iron (II) compound and reaction medium are iron (II) acetylacetonate and diethyl ether, respectively. The combination offers the highest yield, the greatest volatilizability of 98%, and thus the purest product.

# Octahedral Metal Clusters $[Nb_6Cl_{12}(CN)_6]^{4-}$ as Molecular Building Blocks: From Supramolecular Assemblies to Coordination Polymers

**Huajun Zhou[a] and Abdessadek Lachgar*[a]**

*This microreview is dedicated to the memory of Ekatherina Anokhina*

**Keywords:** Metal clusters / Self-assembly / Supramolecular Chemistry / Coordination polymers

There are considerable advantages for using metal clusters as building units of supramolecular materials because of their unique structural, chemical, and physical properties, all of which fall in between normal valence compounds and the metals. In this microreview, we describe the synthetic methodology and structural properties of recent findings in the use of octahedral niobium hexacyanochloride anions as building units of assemblies of different size, charge, and dimensionality. We focus on the use of a metal-directed approach to prepare cluster-based supramolecular assemblies and coordination polymers with one-, two-, and three-dimensional frameworks. The materials described herein are all built from diamagnetic cyanochloride cluster anions $[Nb_6Cl_{12}(CN)_6]^{4-}$ and coordinatively unsaturated metal complexes such as $[Mn(salen)]^+$ and their derivatives. The overall structures are largely determined by the number of coordination sites available for linkage to the cluster unit and coordination preferences of the metal complexes.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Supramolecular chemistry "chemistry beyond the molecule" focuses on the rational design and preparation of supramolecular structures through self-assembly processes in which building units are linked through noncovalent forces such as hydrogen bonding, coordination bonds, electrostatic and charge-transfer attractions, and aromatic π-π stacking interactions.[1,2] It is fundamentally related to the field of crystal engineering which focuses on the organization of molecular or ionic building units into functional crystalline materials with desired structures and properties.[3]

*Abdou Lachgar graduated from the University of Nantes, France in 1982 and obtained his Ph.D. degree in materials science and solid state chemistry from the Institute of Materials Jean Rouxel in Nantes in 1987. He joined the group of John Corbett at Iowa State University (1988–1990) to pursue his postdoctoral studies and investigated the chemistry of reduced zirconium and scandium iodides. In 1990, he joined the University of Washington in Seattle, as a research fellow with James Mayer. He concentrated on the synthesis of extended solids from molecular precursors by using electrochemical processes. In 1991, he joined the Department of Chemistry at Wake Forest University as an Assistant Professor. He was promoted to Associate Professor in 1996 and then to Professor in 2002. His teaching and research interests are in the area of materials chemistry with a focus on the use of the molecular building block approach for the rational preparation of hybrid inorganic–organic materials. He was awarded visiting faculty fellowships from the Japanese Government in 1997 and 1998, and he was a visiting Professor at the Institute of Materials Jean Rouxel in 2003 and the institute Gallile in Paris in 2006.*

*Huajun Zhou obtained his B.S in chemistry from Beijing University (China) in 1999. After conducting research on Li-ion batteries as a research scientist for two years at BYD Co. Ltd (China), he joined Professor Lachgar's group at Wake Forest University in 2002. His current research focuses on strategies used in crystal engineering for the preparation of supramolecular materials built from octahedral cyanochloride clusters and metal ions/metal complexes as building units and the correlation of their structures with their observed properties.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Progress in supramolecular chemistry has led to the use of more complex molecular building units to prepare materials with novel structures and properties. Inspired by the success of using hexacyanometalate anions $[M(CN)_6]^{n-}$ as building units to construct functional solids with diverse structures,[4] several groups are actively exploring the use of their expanded analogues, such as octahedral transition metal clusters, as building units to investigate the effect of the metal–metal bonds on their physicochemical properties. Octahedral transition metal clusters based on an $M_6$ octahedron in which six metal atoms are linked to each other through metal–metal bonds and $\mu_2$ or $\mu_3$ ligands to give a $M_6L_{12}$ or $M_6L_8$ cluster core (Figure 1) have received considerable interest since the discovery of the Chevrel phases which consist of 3D frameworks based on the 6–8 type clusters.[5] Different synthetic methodologies have been developed to excise these clusters from their solid-state precursors through solution chemistry routes.[6] The cluster core $[M_6L_{12}]^{n+}$ or $[M_6L_8]^{n+}$ has an atom- or ion-like behavior. It is larger in size compared with mononuclear metal complexes, has versatile electronic structures, multiple coordination sites, and potential catalytic properties that make them promising candidates as building units of supramolecular structures.[7] Face-capped octahedral cluster units $[W_6S_8(CN)_6]^{6-}$ and $[Re_6Q_8(CN)_6]^{n-}$ (Q = S, Se and Te) have been used as building units of supramolecular structures, some of which show functional properties such as catalysis and molecular sieves.[8]

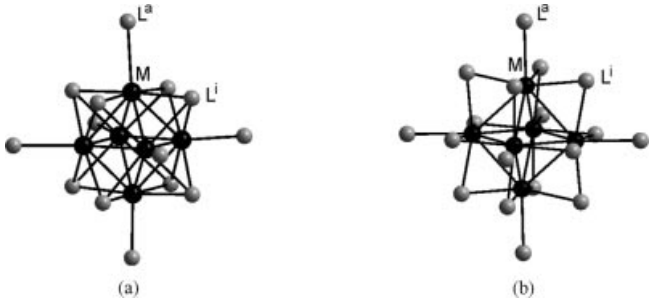

Figure 1. (a) The structure of the cluster $[(M_6L_8^i)L_6^a]$ common for M = Mo, W, Re; L = halides, S, Se, Te. (b) The structure of the cluster $[(M_6L_{12}^i)L_6^a]$ common for M = Nb, Ta; L = Cl, Br, O; and M = Zr; L = halides.

The use of edge-capped octahedral niobium halide clusters as building units remains largely unexplored compared with the extensive work that has been reported on octahedral face-capped rhenium and tungsten clusters. These two cluster types differ from each other not only in terms of the coordination mode of inner ligands, but also by the number of valence electrons available for metal–metal bonding (VEC). The use of the cyanochloride cluster $[Nb_6Cl_{12}(CN)_6]^{n-}$ as building units should, in principle, lead to the formation of supramolecular materials with new structures and properties. This microreview describes our recent results in the use of $[Nb_6Cl_{12}(CN)_6]^{4-}$ and metal complexes as building units of supramolecular structures by using the cyanide ditopic coordination ability and the coordination requirement of the metal complexes.

## 2. Synthetic Strategy

The cluster anion $[Nb_6Cl_{12}(CN)_6]^{4-}$ can be considered as an expanded analogue of $[Fe(CN)_6]^{4-}$ in which $Fe^{2+}$ is replaced by an $[Nb_6Cl_{12}]^{2+}$ cluster core. As in the case of $[Fe(CN)_6]^{4-}$, the cyanochloride cluster reacts with virtually all hydrated $[M(H_2O)_6]^{2+}$ ions to afford compounds that are expanded analogues of the iron-based Prussian-blue.[9] Their crystal structure is based on edge-bridged $[Nb_6Cl_{12}]^{2+}$ clusters and $M^{2+}$ ions bridged by cyanide ligands to form a cubic face centered anionic framework $[MNb_6Cl_{12}(CN)_6]^{2-}$ in which all tetrahedral sites are occupied by the cations $[Me_4N]^+$, which act as charge compensating templates.

After investigating the interaction between the cyanochloride cluster and simple metal ions, we focused on the use of the "directional-bonding" approach first cited by Stang and coworkers and systematized by coordination chemists to prepare supramolecular species.[10,11] The fundamental principle of this approach is the use of coordinatively unsaturated metal complexes as building units. These complexes have specific coordination sites available for ligands from other building units located at appropriate angles to "direct" the formation of desired supramolecular structures. For instance, *cis*-$[Ni(bpy)_2(\mu_{1,3}\text{-}N_3)](PF_6)$[12] and *trans*-$[Ni(N\text{-}Eten)_2(\mu_{1,3}\text{-}N_3)](PF_6)$[13] have been used to prepare 1D coordination polymers with different structural features because of different angles between the two coordination sites available for the incoming azide ligand. Similar strategies have been developed for metal clusters where site-differentiated clusters $[Re_6Se_8(PEt_3)_n(MeCN)_{6-n}]^{2+}$ have been used as building units of supramolecular assemblies.[14]

The reactivity between coordinatively unsaturated metal complexes and $[Nb_6Cl_{12}(CN)_6]^{4-}$ equipped with six cyanide ligands was studied. Two types of metal complexes have been investigated: 1) complexes with tetradentate salen-type ligands (*L1–L3*) (Figure 2) chosen for their potential catalytic properties,[15] and 2) complexes coordinated by one or two chelating diamine ligands (phen and en) that block two or four coordination sites, respectively. This leaves different numbers of coordination sites available depending on the nature of the metal ions. The structures of the compounds obtained can be, to a certain extent, predicted from the coordination requirements of the metal complexes. However, the competition between different geometries with similar stoichiometries does not allow complete predictability without considering the effect of solvent, counterions, and stability of the complexes.[16] This review intends to highlight some basic structures to illustrate the use of the concept of "metal complex directed assembly" to build supramolecular structures with versatile geometrical and topological features. Investigations into the combination of metal complexes such as $[Mn(salen)]^+$ with $Re_6$ clusters resulted in the synthesis of extended framework materials, whereas the use of metal porphyrins with $Re_6$ clusters led to discrete supramolecular units that have shown excellent catalytic activity toward the epoxidation of olefins.[17,8d]

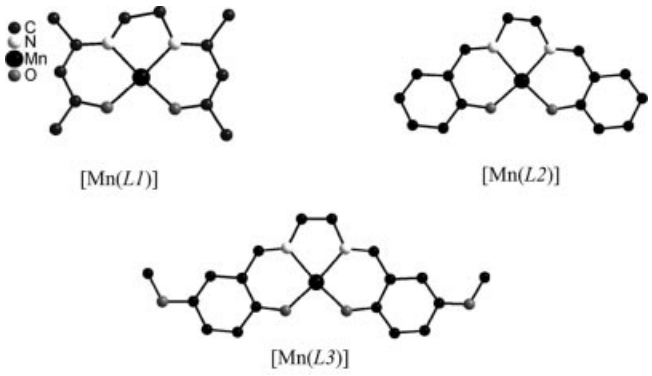

Figure 2. Molecular structures of $Mn^{III}$ complexes with tetradentate salen-type ligands used in the present study. $L1^{2-}$ = bis(acetylacetonato)ethylenediamine; $L2^{2-}$ = bis(salicylidene)ethylenediaminato; $L3^{2-}$ = bis(5-methoxysalicylidene)ethylenediaminato.

## 3. Synthesis of the $[Nb_6Cl_{12}(CN)_6]^{4-}$ Building Unit

The clusters are prepared following a three-step procedure. Firstly, solid-state precursors containing the chloride cluster $[Nb_6Cl_{12}]^{2+}$ are prepared from reactions between Nb metal, $NbCl_5$, and chloride salts that provide the cations as needed. The reactants are sealed in silica containers under vacuum and heated at 700–900 °C.[18] The second step involves dissolving the solid state precursor in a common polar solvent to excise the chloride cluster. In the third step, substitution of all outer chloride ligands by cyanides is performed. $Li_2Nb_6Cl_{16}$ was used as the solid-state precursor because of its ease of preparation, high yield, and ease of solubility in different solvents. The complete procedure is described by the chemical equations given in steps 1–3.

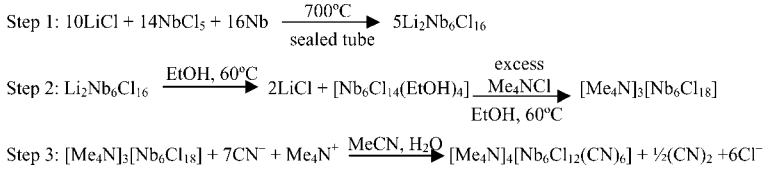
Scheme 1 shows the use of $Li_2Nb_6Cl_{16}$ as the solid state precursor for the preparation of $[Nb_6Cl_{12}(CN)_6]^{4-}$. $Li_2Nb_6Cl_{16}$ features a 2D framework in which each $[Nb_6Cl_{18}]^{4-}$ cluster is connected to four neighboring clusters by sharing four outer chloride ligands. $[Me_4N]_3[Nb_6Cl_{18}]$ (**1**), which contains the 15-electron cluster $[Nb_6Cl_{18}]^{3-}$, was obtained by dissolving $Li_2Nb_6Cl_{16}$ in EtOH and adding excess $Me_4NCl$.[9] The reaction time was substantially reduced to 30 min when these two steps were performed at 60 °C. Addition of excess KCN to a solution of **1** in $MeCN/H_2O$ followed by recrystallization from MeOH/ether results in the formation of $[Me_4N]_4[Nb_6Cl_{12}(CN)_6]$ (**2**).[19] The compounds were characterized by single-crystal XRD. The average Nb–Nb [2.983(5) Å], Nb–$Cl^i$ [2.441(6) Å], and Nb–$Cl^a$ [2.53(1) Å] bond lengths in **1** are close to those reported for compounds containing the 15-electron cluster $[Nb_6Cl_{18}]^{3-}$.[20] The average bond lengths of Nb–Nb [2.927(4) Å] and Nb–$Cl^i$ [2.464(7) Å] in **2** are the same as those observed in $Li_2Nb_6Cl_{16}$ [Nb–Nb: 2.919(6) Å; Nb–$Cl^i$: 2.46(2) Å], which contains the 16-electron cluster $[Nb_6Cl_{18}]^{4-}$. The bond lengths Nb–C [2.282(1) Å] and C≡N [1.131(6) Å] are close to those observed in other compounds containing $[Nb_6Cl_{12}(CN)_6]^{4-}$.[21,22] The stretching frequency for the C≡N group appears at 2126 $cm^{-1}$ in the IR spectrum, which is higher than that observed in $K_4[Fe(CN)_6]$ (2044 $cm^{-1}$) but close to that found in $K_3[Cr(CN)_6]$ (2129 $cm^{-1}$).[23] The Nb–C≡N linkages are almost linear [∠ Nb–C≡N = 178.3(6)°].

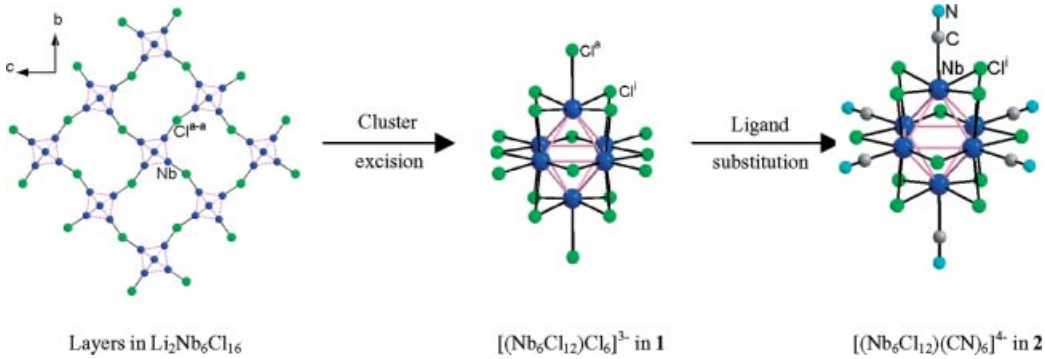
$[Et_4N]_4[Nb_6Cl_{12}(CN)_6]$ was prepared through a cation metathesis reaction in which an aqueous solution of $Et_4NBr$ was added to an aqueous solution of **2**.

$[Me_4N]_4[Nb_6Cl_{12}(CN)_6]$ (aq.) + $4Et_4NBr$ (aq.) → $[Et_4N]_4[Nb_6Cl_{12}(CN)_6]$ (s) + $4Me_4NBr$ (aq.)

## 4. Supramolecular Assemblies and Their Hydrogen-Bonded Frameworks

Supramolecular assemblies in which the cluster is coordinated by a different number of metal complexes have been isolated and investigated. For a clearer description, we con-





Scheme 1.

sider each cluster as an entity and follow the nomenclature that is widely used for assemblies built from hexacyanometalates and metal complexes.[24,25] For example, supramolecular assemblies with two metal complexes attached to one cluster will be referred to as heterotrimers.

In compounds **3**, **4**, and **6**, each cluster is coordinated by one, two, or four manganese complexes to give di-, tri-, and pentamers. Each cluster in **5** is coordinated by two $[Ca(phen)_2(H_2O)_3]^{2+}$ to give neutral trimeric units, whereas **7** is built from a combination of cationic heptamers and anionic trimers. In all these compounds, the supramolecular assemblies are held together through significant hydrogen bonding to form one-, two-, and three-dimensional frameworks.

### 4.1 Anionic Heterodimers

Reactions between methanolic solutions of **2** and [Mn(*L1*)]Cl afforded $[Me_4N][Mn(L1)(MeOH)_2]_2\{[Mn(L1)(MeOH)][Nb_6Cl_{12}(CN)_6]\}$ (**3**).[26] In **3**, each cluster is coordinated by one $[Mn(L1)(MeOH)]^+$ through a Nb–C≡N–Mn linkage to give anionic heterodimers $\{[Mn(L1)(MeOH)][Nb_6Cl_{12}(CN)_6]\}^{3-}$ (Figure 3a). Only one of the six CN ligands is bridging, whereas the other five are involved in extensive hydrogen bonding. The bond length of the bridging C≡N ligand [1.150(7) Å] is significantly longer than those for nonbridging CN ligands [1.133(7) Å]. IR spectra show a broad unsymmetrical absorption band at 2134 $cm^{-1}$, which corresponds to the CN bond stretching frequency. The Mn–C≡N linkage is significantly bent [∠Mn–N≡C = 150.3(4)°] because of the electronic structure of the metal complex. The heterodimers are connected to each other through strong hydrogen bonds between the $CN^-$ ligand and the coordinated MeOH molecule. The dimers are further connected to each other by two solvated metal complexes $[Mn(L1)(MeOH)_2]^+$ through hydrogen bonding between the $CN^-$ ligand and the coordinated MeOH to afford hybrid tubular-like chains (Figure 3b). The manganese adopts distorted octahedral coordination environments ($MnN_3O_3$ in the dimer and $MnN_2O_4$ in the cations). The chains lie on top of each other when viewed along the crystallographic *a* axis to form layers within which the chains are parallel to each other and separated by solvent molecules and cations. The layers are related to each other by an inversion center. Analogous dimers built from hexacyanometalates and $Mn^{III}$ Schiff-base complexes were found in $[Et_4N]_2\{[Mn(saldmen)(H_2O)][Fe(CN)_6]\}$ (**I**).[27]

The anionic charge of the heterodimer is balanced by two solvated Mn complex cations, which leads to an $Mn:Nb_6$ ratio of 3:1; however, **3** also formed even when the starting ratio $Mn:Nb_6$ was increased to 6:1. Interestingly, direct mixing of the two solutions followed by vigorous stirring led to slow formation of the Prussian-blue analogue $[Me_4N]_2[MnNb_6Cl_{12}(CN)_6]$[9] probably because of slow decomposition of the manganese complex in methanol followed by further hydrolysis to afford $Mn^{2+}$ ions.[28]

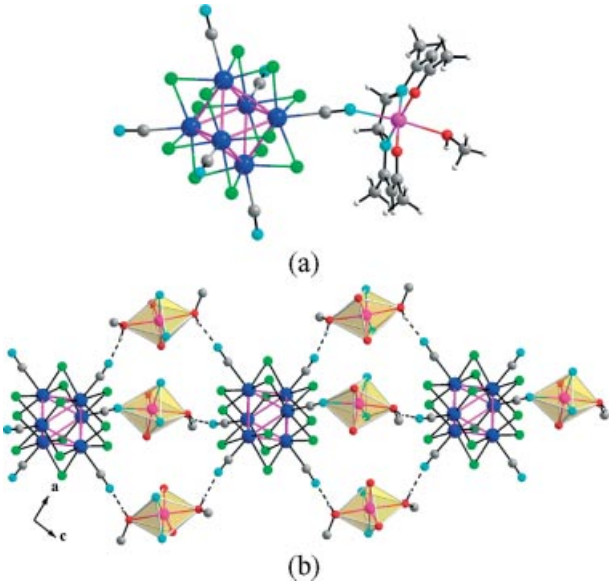

Figure 3. (a) The anionic heterodimeric unit $\{[Mn(L1)(MeOH)][Nb_6Cl_{12}(CN)_6]\}^{3-}$. (b) The anionic tubular-like chain built through extensive hydrogen bonding. *L1* ligands except $N_2O_2$ atoms, and all hydrogen atoms except those involved in hydrogen bonding are omitted for clarity. Hydrogen bonding is represented as dashed lines. The Mn complexes are shown as $\{MnN_3O_3\}$ and $\{MnN_2O_4\}$ octahedra.

### 4.2 Anionic Heterotrimers

Reactions between $[Et_4N]_4[Nb_6Cl_{12}(CN)_6]$ and $[Mn(L2)](ClO_4)\cdot 2H_2O$ in methanol led to precipitation of $[Et_4N]_2\{[Mn(L2)(MeOH)]_2[Nb_6Cl_{12}(CN)_6]\}$ (**4**).[19] In **4**, each cluster is *trans*-coordinated by two $[Mn(L2)(MeOH)]^+$ complexes to afford anionic heterotrimers $\{[Mn(L2)(MeOH)]_2[Nb_6Cl_{12}(CN)_6]\}^{2-}$ (Figure 4a). The cluster core $[Nb_6Cl_{12}]^{2+}$ in **4** is similar to that found in **3** in terms of its bond lengths and angles. Of the six CN ligands, two link the cluster to Mn complexes, and four have their N atom involved in hydrogen bonding. The bond lengths of the bridging C≡N ligand [1.143(5) Å] are not significantly different from those found for the nonbridging ones [1.146(5) Å]. Only one band at 2131 $cm^{-1}$ in the IR spectrum was observed for the C≡N stretching frequency. The bond angle Mn–C≡N [157.2(3)°] is slightly larger than that in **3** because of the differences between the salen-type ligands. The heterotrimers are connected to each other through hydrogen bonds between coordinated MeOH molecules and $CN^-$ ligands to afford chains along the crystallographic *a* axis (Figure 4b). The chains run parallel to each other and are separated by solvent molecules and ammonium ions.

Analogous trimeric units built from $[M(CN)_6]^{3-}$ (M = Fe, Cr) *trans*-coordinated by two Mn Schiff-base (SB) complexes have been previously reported.[29–31] For instance, in $K\{[Mn(5\text{-}Br\text{-}salen)(H_2O)]_2[Fe(CN)_6]\}\cdot 2H_2O$ (**II**) each $[Fe(CN)_6]^{3-}$ anion is coordinated by two solvated Mn complexes to afford the units $\{[Mn(5\text{-}Br\text{-}salen)(H_2O)]_2[Fe(CN)_6]\}^-$.

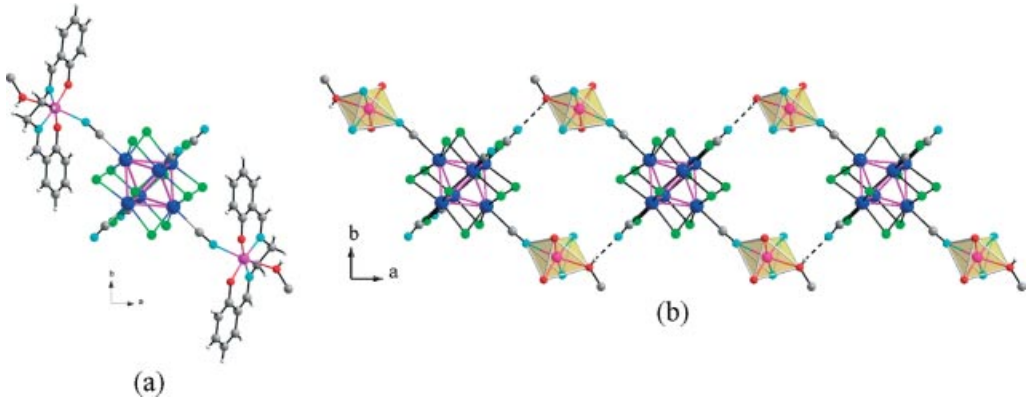

Figure 4. (a) The anionic heterotrimeric unit $\{[Mn(L2)(MeOH)]_2[Nb_6Cl_{12}(CN)_6]\}^{2-}$ in which each cluster is coordinated by two $[Mn(L2)(MeOH)]^+$ complexes in a *trans* fashion. (b) The anionic chain along the *a* axis in which the heterotrimeric units are connected to each other through hydrogen bonds. All hydrogen atoms except those involved in hydrogen bonding are omitted.

### 4.3 Neutral Heterotrimers

$\{[Ca(phen)_2(H_2O)_3]_2[Nb_6Cl_{12}(CN)_6]\}$ (**5**) was obtained by mixing a solution of $Ca(NO_3)_2$ and phen (mol ratio = 1:2) in $H_2O$/EtOH with an aqueous solution of $[Me_4N]_4[Nb_6Cl_{18}]$ and KCN.[32] In **5**, each cluster is *trans*-coordinated by two $[Ca(phen)_2(H_2O)_3]^{2+}$ complexes through Nb–C≡N–Ca linkages to form neutral trimeric units $\{[Ca(phen)_2(H_2O)_3]_2[Nb_6Cl_{12}(CN)_6]\}$ (Figure 5a). Each Ca ion is coordinated by four N atoms from two phen ligands, one N atom from the cyanide ligand, and three O atoms from water molecules to give an overall eight coordination environment (distorted square antiprism) that is common for calcium.[33–35] For the cyanide ligands coordinated to Ca ions, the C≡N bond length is 1.149(9) Å, whereas for nonbridging cyanide ligands the bond lengths range from 1.11(1) to 1.15(1) Å. Only one absorption band at

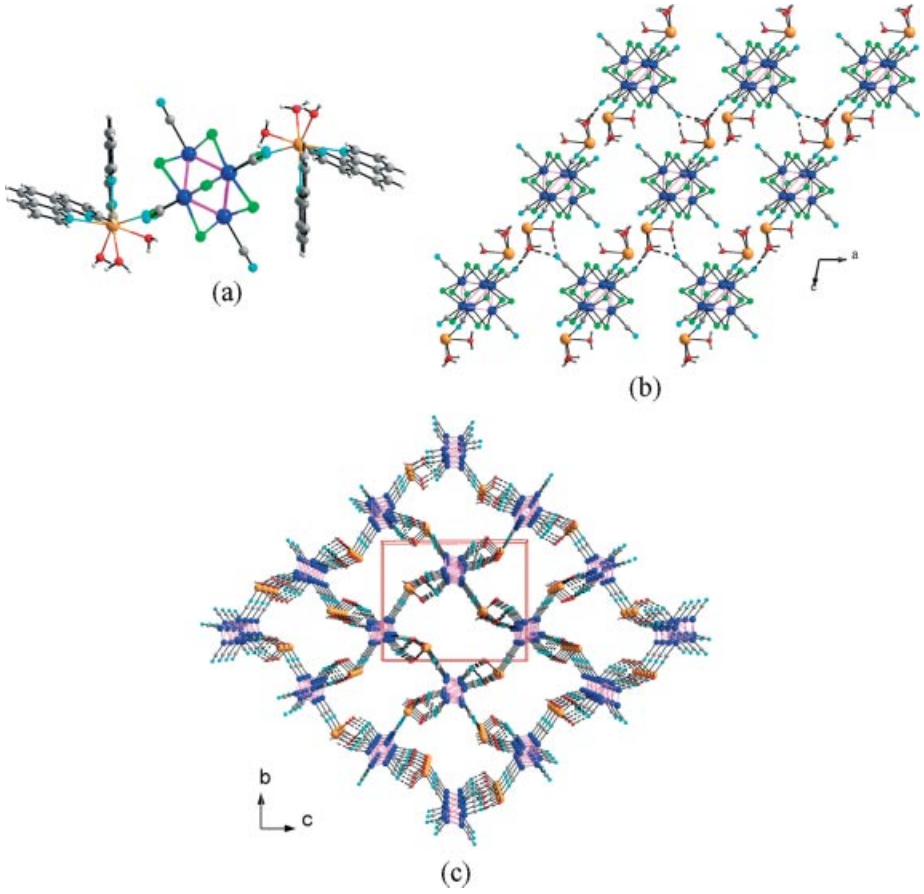

Figure 5. (a) The neutral trimeric unit $\{[Ca(phen)(H_2O)_3]_2[Nb_6Cl_{12}(CN)_6]\}$ in which each cluster is coordinated by two $[Ca(phen)(H_2O)_3]^{2+}$ complexes in a *trans* fashion. (b) Projection along the *b* axis of the neutral layer in which each trimeric unit links four trimeric units through hydrogen bonding. phen Ligand and all hydrogen atoms except those involved in hydrogen bonding are omitted. (c) Perspective view along the *a* axis, which shows the 3D framework of **5**. Inner chloride ligands are omitted.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2128 $cm^{-1}$ was observed for the C≡N stretching frequency. Each trimer is linked to four neighboring trimers by hydrogen bonds between the aqua ligand in $[Ca(phen)_2(H_2O)_3]^{2+}$ and the cyanide ligands to afford layers (Figure 5b). The layers are further connected by hydrogen bonds between calcium complexes and cluster units from neighboring layers to form a 3D framework (Figure 5c). Hydrogen-bonded frameworks built from similar trimeric units in which mononuclear hexacyanometalates such as $[Fe(CN)_6]^{3-}$ and Ca-phen complexes have been reported, as is the case in {$[Ca(phen)_2(H_2O)_2][Fe(CN)_6][Ca(phen)_2(H_2O)(NO_3)]$}- (**III**).[36,37]

### 4.4 Heteropentamers

Slow evaporation of a solution of $[Me_4N]_4[Nb_6Cl_{12}(CN)_6]$ and a sixfold excess of [Mn(*L1*)]Cl in partially dried acetonitrile resulted in crystals of {$[Mn(L1)(MeCN)]_2[Mn(L1)(H_2O)]_2[Nb_6Cl_{12}(CN)_6]$} (**6**).[26] In **6**, each cluster uses four CN ligands to connect to four solvated manganese complexes: two $[Mn(L1)(MeCN)]^+$ complexes and two $[Mn(L1)(H_2O)]^+$ complexes to form neutral heteropentamers (Figure 6a). The complexes are located opposite to each other across the cluster and are related by an inversion center. The average bond length of the bridging cyanide ligands is 1.148(4) Å, which is close to that of nonbridging cyanide ligands [1.145(5) Å]. In the IR spectrum, only one broad absorption band at 2142 $cm^{-1}$ is observed. The bond length $Mn–N_{CN}$ [2.26(2) Å] is slightly shorter than that found in **3** and **4**. The pentamers link to each other through hydrogen bonds between the cyanide and aqua ligands from adjacent assemblies and form chains (Figure 6b) that run parallel to each other and interact through acetonitrile solvent molecules.

Pentameric units of this type have been found in compounds built from hexacyanometalate and Mn Schiff-base complexes such as $\{[Mn(saltmen)(H_2O)]_4[Fe(CN)_6]\}(ClO_4)$[27] in which the pentamers are hydrogen bonded to each other, and $\{[Mn_2(saltmen)_2]_2[Fe(CN)_6]\}(ClO_4)\cdot H_2O$ (**IV**)[29] which is a 2D coordination polymer built from the pentamers $\{[Mn(saltmen)]_4[Fe(CN)_6]\}^+$ linked through phenoxo bridges between the manganese complexes.

In the synthesis of **6**, it was observed that a small amount of water in the acetonitrile plays an important role in its formation. When dry acetonitrile was used and extra care was taken to reduce inadvertent exposure to moisture, a 3D coordination polymer $[Me_4N]\{[Mn(L1)]_3[Nb_6Cl_{12}(CN)_6]\}$ (**12**) was obtained (vide infra).[38] Despite the availability of two cyanide ligands, attempts to increase the nuclearity of the supramolecular assemblies by using a tenfold excess of [Mn(*L1*)]Cl were not successful. Only when the reaction was performed in a $MeOH/H_2O$ mixture were heptameric assemblies containing a cluster connected to six manganese complexes isolated (vide infra).

### 4.5 Heteroheptameric and Heterodimeric Supramolecules

When **2** was mixed with [Mn(*L1*)]Cl in a $MeOH/H_2O$ mixture, $\{[Mn(L1)(H_2O)]_4[Mn(L1)]_2[Nb_6Cl_{12}(CN)_6]\}\{[Mn(L1)]_2[Nb_6Cl_{12}(CN)_6]\}$ (**7**) was isolated. Its structure consists of the heptamers $\{[Mn(L1)(H_2O)]_4[Mn(L1)]_2[Nb_6Cl_{12}(CN)_6]\}^{2+}$ (Figure 7a) and trimers $\{[Mn(L1)]_2[Nb_6Cl_{12}(CN)_6]\}^{2-}$ (Figure 7b). The cation assembly consists of $[Nb_6Cl_{12}(CN)_6]^{4-}$ linked to six Mn complexes by way of Nb–C≡N–Mn linkages. Two complexes are pentacoordinate, two oxygen atoms and two nitrogen atoms from the Schiff-base ligand and one nitrogen atom from the cyanide ligand, which leads to a distorted square-pyramidal coordination geometry. The complexes are related to each other by an inversion centre. The other four manganese ions are coordinated by two oxygen atoms and two nitrogen atoms from the tetradentate ligand, one nitrogen from the cyanide ligand, and one oxygen from the solvent molecule, which leads to the formation of a distorted octahedral environment. The overall shape of the heptameric cation can be described as a large flattened sphere with a diameter of about 2.1 nm. The anionic trimer is built from $[Nb_6Cl_{12}(CN)_6]^{4-}$ complexes coordinated by two pentacoordinate manganese complexes that are similar to those observed in the heptamer. The trimers are similar to those found in **4** except that the manganese ions in **4** are hexacoordinate because of the presence of a solvent molecule as a ligand. Hydrogen bonds between the $CN^-$ ligand from the

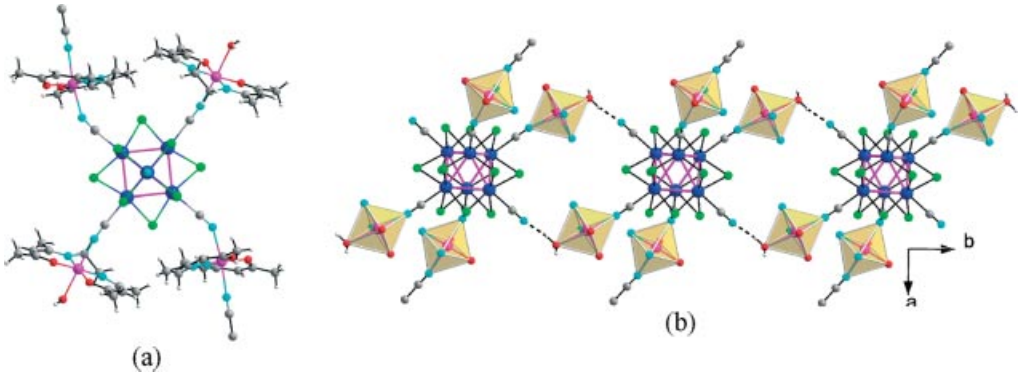

Figure 6. (a) The heteropentamers $\{[Mn(L1)(MeCN)]_2[Mn(L1)(H_2O)]_2[Nb_6Cl_{12}(CN)_6]\}$ in which each cluster is coordinated by two $[Mn(L1)(MeCN)]^+$ complexes and two $[Mn(L1)(H_2O)]^+$ complexes. (b) Neutral chains extending along the *b* axis in which heteropentameric units are connected to each other through hydrogen bonding.

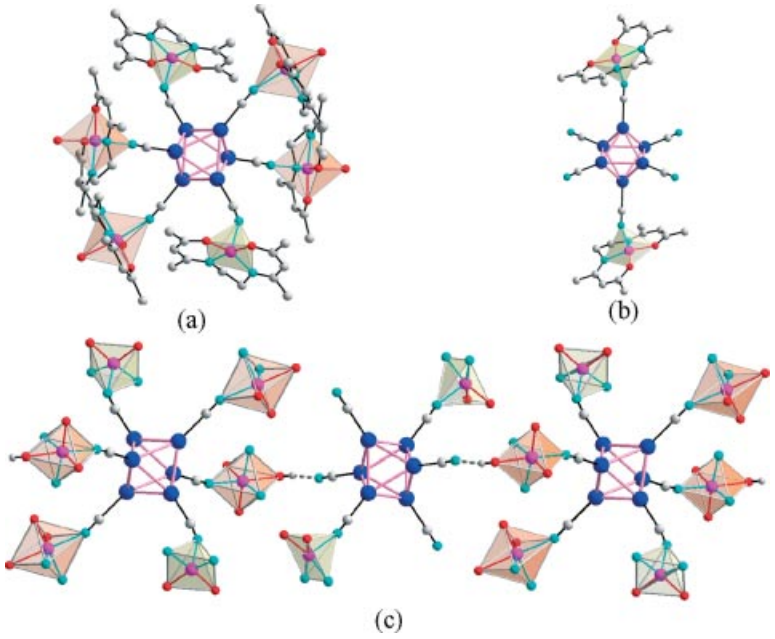

Figure 7. (a) The heteroheptamer $\{[Mn(L1)(H_2O)]_4[Mn(L1)]_2[Nb_6Cl_{12}(CN)_6]\}^{2+}$ complex where each cluster is coordinated by four $[Mn(L1)(H_2O)]^+$ complexes and two $[Mn(L1)]^+$ complexes. (b) The heterotrimer $\{[Mn(L1)]_2[Nb_6Cl_{12}(CN)_6]\}^{2-}$ where each cluster is linked to two $[Mn(L1)]^+$ complexes in the *trans* position. (c) Chains built from hydrogen bonding between coordinated water molecules from cations and cyanide ligands from anions.

anions and the coordinated $H_2O$ molecules from the cations lead to the formation of chains (Figure 7c). The C≡N bond length [1.146(4) Å] for the ligands coordinated to the hexacoordinate Mn complex is longer than that for the CN ligand coordinated to the pentacoordinate manganese [1.137(4) Å]. The average bond length of $Mn–N_{CN}$ for the pentacoordinate Mn complex [2.150(3) Å] is significantly shorter than that found in the hexacoordinate Mn complex [2.287(3) Å] as a result of the solvent coordination effect.

The structure of compound **7** is interesting in terms of the coexistence of the cationic heteroheptamers and anionic heterotrimers as well as penta- and hexacoordinate Mn ions. However, both penta- and hexacoordinate Mn ions have been observed in $[Mn(L2)]_4[Re_6Te_8(CN)_6]$[17a] in which two $[Mn(L2)]^+$ complexes bridge the cluster units to give a 2D framework whereas two other complexes are attached to one cluster unit only through the $N_{CN}$ atom. Similar cationic–anionic assemblies have been observed in compounds containing hexacyanometalates $[M(CN)_6]^{3-}$ (M = $Fe^{3+}$, $Cr^{3+}$) as building units.[39,40] For example, $\{[Mn(L2)(H_2O)]_6[Fe(CN)_6]\}[Fe(CN)_6]$ (**V**)[41] is built from $[Fe(CN)_6]^{3-}$ complex anions coordinated by six solvated $[Mn(L2)(H_2O)]^+$ complex cations to form the heptamer $\{[Mn(L2)(H_2O)]_6[Fe(CN)_6]\}^{3+}$.

## 5. Coordination Polymers Built from $[Nb_6Cl_{12}(CN)_6]^{4-}$ and Metal Complexes

The species described in Section 4 can be described as octahedral clusters ligated by one, two, four, and six metal complexes to form larger supramolecular assemblies. In most cases, the solvent completes the preferred octahedral coordination environment for $Mn^{III}$, which prevents the formation of coordination polymers. Judicious choice of the synthetic conditions such as cations, solvents, stoichiometries, metal complexes, and salen-type ligands led to the preparation of coordination polymers with 1D, 2D, and 3D frameworks. The framework dimension depends on the cluster/metal complex ratio and the connectivity mode between the two building units. The clusters in all the coordination polymers are similar to those found in supramolecular assemblies in terms of bond lengths and angles.

### 5.1 One-Dimensional Coordination Polymers

Two coordination polymers with one-dimensional frameworks built from $[Nb_6Cl_{12}(CN)_6]^{4-}$ and $[Mn(L)]^+$ connected by cyanide ligands have been characterized. The salen-type ligand and the solvent system determine which one of these two compounds forms.

$[Me_4N]_3\{[Mn(L1)][Nb_6Cl_{12}(CN)_6]\}$ (**8**) cocrystallized with $[Me_4N]_2[MnNb_6Cl_{12}(CN)_6]$ from the reaction of equimolar amounts of **2** and $[Mn(L1)]Cl$ in dry MeCN. It crystallizes in the tetragonal symmetry (space group: $I4_1/a$) and is formed from two sets of chains related to each other by a $4_1$ screw axis (Figure 8a). In **8**, each cluster is coordinated by two $[Mn(L1)]^+$ complex cations through Nb–C≡N–Mn linkages, and each $[Mn(L1)]^+$ complex connects two clusters to give anionic zigzag chains $\{[Mn(L1)][Nb_6Cl_{12}(CN)_6]\}_\infty^{3-}$ (Figure 8b) that extend along the crystallographic *a* and *b* axes. The chains are bent with ∠Mn–N≡C of 152.9(2)° and 156.5(3)°. The Nb–C bond length associated with the bridging cyanide ligands [2.301(3) Å] is larger than that of a nonbridging cyanide ligand [2.268(3) Å]. The bond length for a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

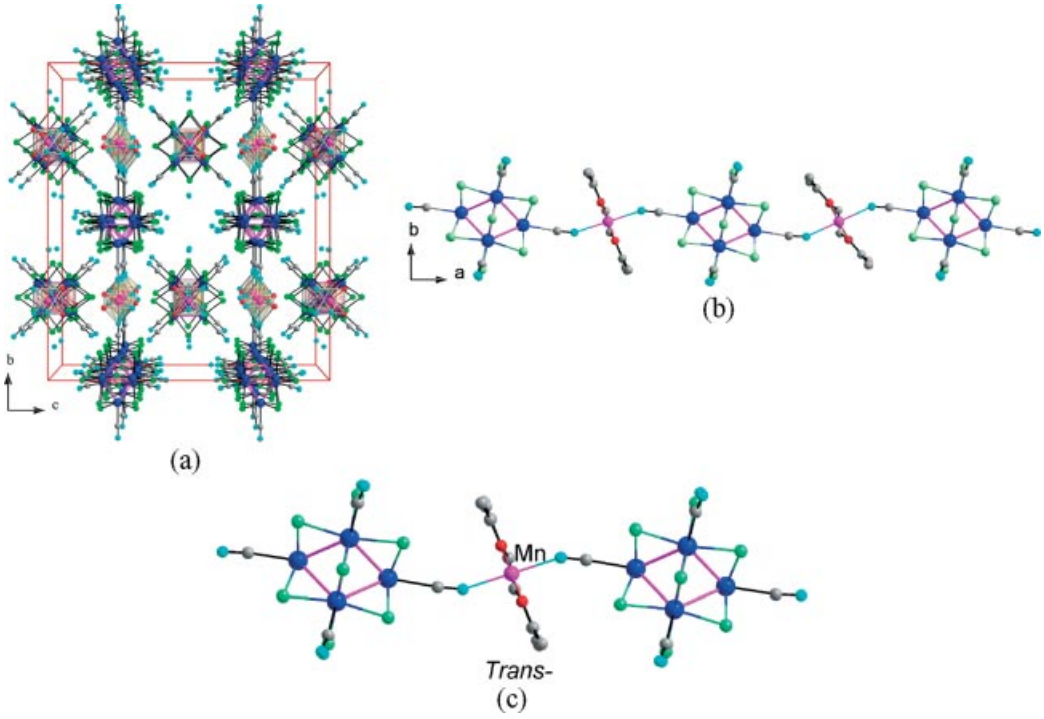

Figure 8. (a) Perspective view of the 1D coordination polymer $[Me_4N]_3\{[Mn(L1)]\ [Nb_6Cl_{12}(CN)_6]\}$ (**8**); (b) The anionic zigzag chain extending along the *a* axis. (c) Each Mn complex is coordinated by two cluster units in a *trans* conformation. The Mn complexes are shown as $\{MnN_4O_2\}$ octahedra.

bridging C≡N ligand [1.145(4) Å] is slightly longer than that for a nonbridging C≡N group [1.139(4) Å]. Two Mn–$N_{CN}$ bond lengths are observed [2.332(3) and 2.382(3) Å] and they are longer than those found in all supramolecular assemblies described above. The chains belong to the 2,2-TT type because each cluster is *trans* coordinated by two Mn complexes and each Mn complex is connected to two clusters in a *trans* conformation (Figure 8c).[42] The chains are stacked parallel to each other along the *ac* and *ab* planes and are separated by solvent molecules and ammonium ions (Figure 8a).

$[Me_4N]_3\{[Mn(L3)][Nb_6Cl_{12}(CN)_6]\}$ (**9**) was obtained from reaction of **2** with $[Mn(L3)(MeOH)](ClO_4)$ in methanol (mol ratio $[Nb_6Cl_{12}(CN)_6]^{4-}$:$[Mn(L3)]^+ \approx 1.0$).[38] It is a 1D coordination polymer with the same cluster complex connectivity as that observed for **8**. Each cluster is connected to two complexes through two cyanide ligands on opposite sides, and each complex connects two clusters to afford anionic zigzag chains $\{[Mn(L3)][Nb_6Cl_{12}(CN)_6]\}_\infty^{3-}$ that extend along the crystallographic *c* axis. The chains stack parallel to each other along the *a* axis (Figure 9a) to form layers parallel to the *ac* plane. Ammonium ions and solvent molecules are located between the chains. The Nb–C bond lengths for the bridging C≡N ligands are 2.278(8) and 2.288(8) Å, slightly larger than those for nonbridging CN ligands [2.25(1)–2.271(9) Å]. The bond lengths of the bridging C≡N ligand [1.129(9) and 1.126(9) Å] are significantly smaller than those for nonbridging cyanide ligands [1.15(1) Å]. Yet only one broad asymmetric band is observed in the IR spectrum at 2128 $cm^{-1}$. The Mn–N≡C

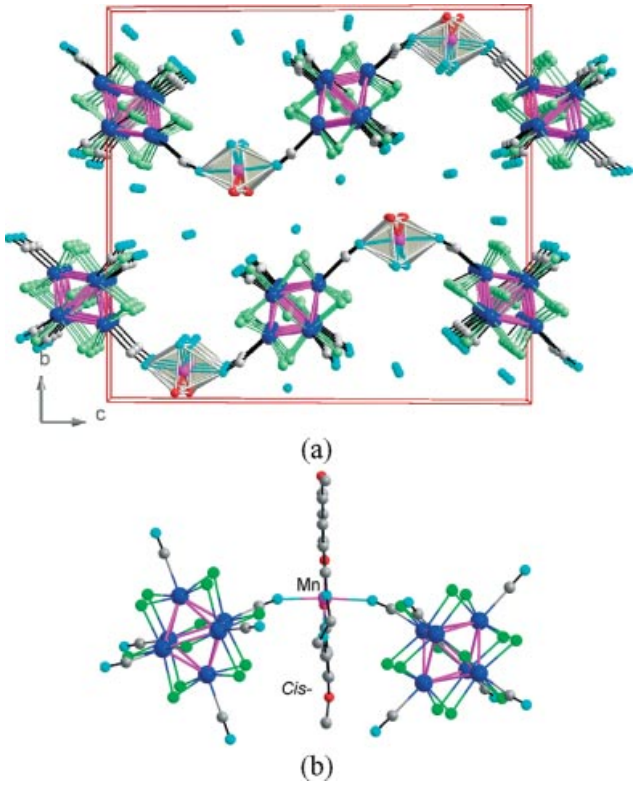

Figure 9. (a) Perspective view of the structure of 1D coordination polymer $[Me_4N]_3\{[Mn(L3)]\ [Nb_6Cl_{12}(CN)_6]\}$ (**9**) along the crystallographic *a* axis; (b) each Mn complex is coordinated by two cluster units in the *cis* conformation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

linkage [∠Mn–N≡C = 148.59(8)°] is bent to a greater extent than in **8**. The $N_{CN}$–Mn–$N_{CN}$ linkage [∠$N_{CN}$–Mn–$N_{CN}$ = 174.2(2)°] is also slightly more bent compared to that observed in **8**. The geometric conformation of the metal complex dictates the topology of the chains in **8** and **9**. In **8**, each manganese is linked to two clusters located on opposite sides of the $N_{CN}$–Mn–$N_{CN}$ axis (*trans* conformation), whereas in **9**, each Mn complex is linked to two clusters located on the same side of the $N_{CN}$–Mn–$N_{CN}$ axis (*cis* conformation) (Figure 9b). Complex **9** is an expanded analogue of $[Et_4N]_2\{[Mn(L1)][Fe(CN)_6]\}$ (**VI**) in which $[Mn(L1)]^+$ and $[Fe(CN)_6]^{3-}$ are linked by CN ligands to afford chains.[43]

Reactions between $[Et_4N]_3[Fe(CN)_6]$ and $[Mn(L3)(H_2O)]^+$ in methanol led to the formation of $[Et_4N]\{[Mn_2(L3)_2][Fe(CN)_6]\}$ built from phenoxo-bridged dimers $[Mn_2(L3)_2]^{2+}$ and $[Fe(CN)_6]^{3-}$ linked by the cyanide ligand to form one dimensional coordination polymers.[44] The formation of the dimeric Mn complexes is most likely due to the relative stability of the monomer versus the dimer, which depends on the solvent used.

### 5.2 Two-Dimensional Coordination Polymers

Direct mixing of dilute methanolic solutions of **2** and $[Mn(L2)](ClO_4)$ (mol ratio complex:cluster = 2) led to quantitative formation of $[Me_4N]_2\{[Mn(L2)]_2[Nb_6Cl_{12}(CN)_6]\}$ (**10**).[19] Polymer **10** can be obtained as a microcrystalline powder when the molar ratio $[Mn(L2)]^+$:$[Nb_6Cl_{12}(CN)_6]^{4-}$ ranges from 1.0 to 4.0. In **10**, each cluster is coordinated by four $[Mn(L2)]^+$ complexes through Nb–C≡N–Mn linkages and each $[Mn(L2)]^+$ complex connects two $[Nb_6Cl_{12}(CN)_6]^{4-}$ anionic complexes to generate anionic layers $\{[Mn(L2)]_2[Nb_6Cl_{12}(CN)_6]\}_\infty^{2-}$ that are parallel to the *bc* plane (Figure 10b). The Nb–C bond lengths associated with bridging cyanide ligands are about 2.29 Å and longer than those associated with nonbridging cyanides (2.27 Å). In contrast, the C≡N bond lengths are all about 1.13 Å, which is consistent with the observation of only one absorption band in the IR spectrum at 2134 $cm^{-1}$ for the C≡N stretch. The Mn–$N_{CN}$ bond lengths are significantly different from each other and vary between 2.23 and 2.36 Å owing to the bowl-shaped salen-type ligand *L2* with the longer Mn–$N_{CN}$ linkages on the concave side of the ligand. The Mn–N≡C bond angles are also significantly different, 144.2(3) and 155.0(3)°, respectively. The two phenyl groups of the *L2* ligand in **10** are located in a *cis* fashion with respect to the basal $N_2O_2$ plane; in contrast, the phenyl groups in $[Mn(L2)](ClO_4)$[45], which is used as a precursor, are located in a *trans* fashion.[46] The layers are stacked in a staggered fashion along the crystallographic *a* axis and are separated by ammonium ions that are found in the vicinity of the uncoordinated cyanide ligands (Figure 10a). Similar layers have been observed in $[Mn(L2)]_4[Re_6Te_8(CN)_6]$[17a] in which $Re_6$ clusters are coordinated by six [Mn(*L2*)], two of which are dangling. Polymer **10** represents a cluster-expanded analogue of the compound $[Et_4N]\{[Mn(L2)]_2[Fe(CN)_6]\}$ (**VII**)[47] in which each $[Fe(CN)_6]^{3-}$ is linked to four complexes and each complex links two ferricyanides to form anionic layers that stack perfectly on top of each other contrary to the stacking in **10**.

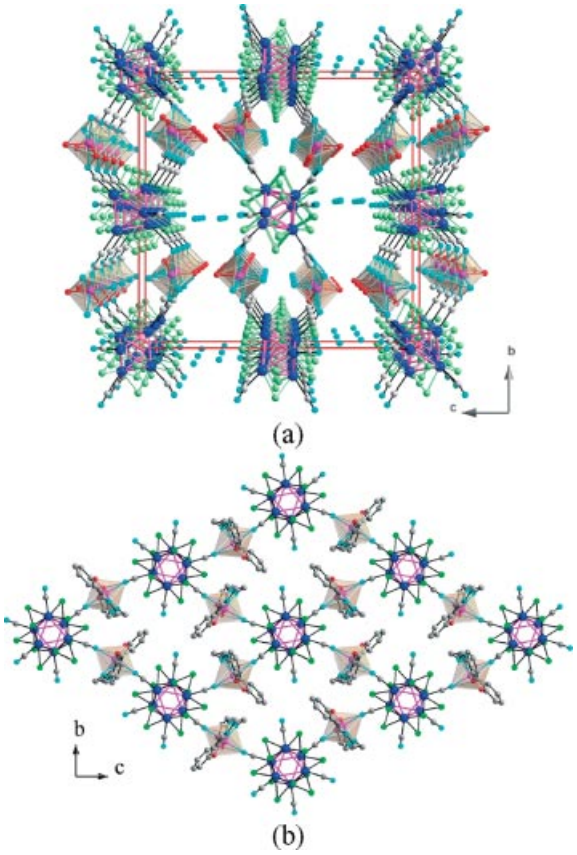

Figure 10. (a) Perspective view of the structure of 2D coordination polymer $[Me_4N]_2\{[Mn(L2)][Nb_6Cl_{12}(CN)_6]\}$ (**10**) along the crystallographic *a* axis; (b) A projection of the anionic layer parallel to the crystallographic *bc* plane along the *a* axis.

### 5.3 Effect of the Metal Complex Coordination Requirements: The Layered Framework of $[Zn(en)]_2[Nb_6Cl_{12}(CN)_6]$

The topology, dimension, and properties of frameworks built from clusters and metal complexes presumably depend on the metal complex and the coordination preferences of the metal ion. The use of $[Zn(en)]^{2+}$ and the cluster as building units led to the formation of $[Zn(en)]_2[Nb_6Cl_{12}(CN)_6]$ (**11**) which has a layered framework and was obtained from the reaction between an aqueous solution of $Na_4[Nb_6Cl_{12}(CN)_6]$ and an ethanolic solution containing equimolar amounts of $Zn(ClO_4)_2{\cdot}6H_2O$ and en.[48] The structure of **11** consists of neutral layers in which each cluster $[Nb_6Cl_{12}(CN)_6]^{4-}$ is coordinated by six $[Zn(en)]^{2+}$ complexes through Nb–C≡N–Zn linkages and each $[Zn(en)]^{2+}$ is connected to three cluster units to afford layers parallel to the *ab* plane (Figure 11a). Although the C≡N bond lengths are all found at ca. 1.15 Å, not much different

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

from that observed in **10**, the C≡N IR bond stretch frequency appears at 2167 $cm^{-1}$, which is much higher than that observed for **10**. The Zn–N bond length [2.051(8) Å] is shorter than that of the Mn–N bond found in compounds containing supramolecular assemblies and coordination polymers and reflects the smaller ionic radius of $Zn^{2+}$. The Zn–N≡C bond angle is 172.5(9)°, which is close to those found for Ca–N≡C in **5** [172.9(8)°] but larger than the Mn–N≡C bond angles in **3**, **4**, and **6**–**9** [144.2(3)–165.8(3)°]. The layers stack on top of each other along the *c* axis and are held together only through weak Van der Waals interactions. Projection along the crystallographic *b* axis indicates that [Zn(en)] complexes are alternatively located above and below the plane (Figure 11b).

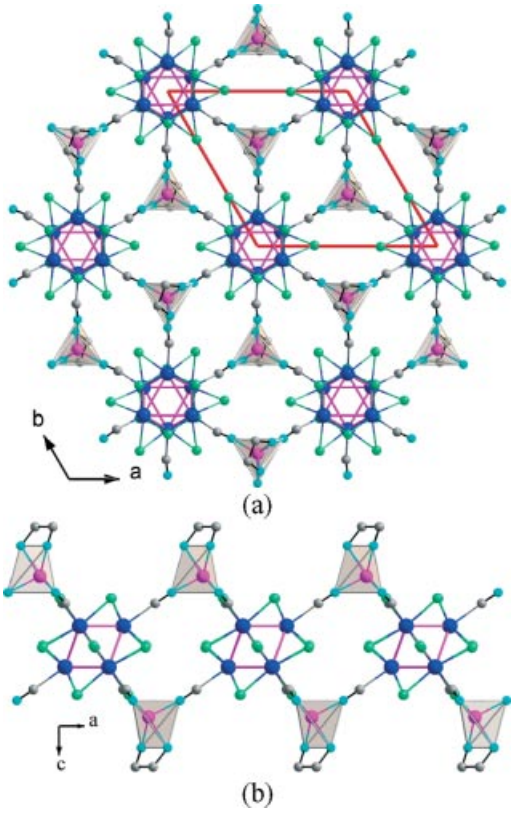

Figure 11. (a) A projection of the layer in $[Zn(en)]_2[Nb_6Cl_{12}(CN)_6]$ (**11**) along the *c* axis. (b) A projection of the layer along the crystallographic *b* axis, which shows that the [Zn(en)] complexes are alternatively located above and below the plane.

Similar layers have been observed in $[Zn(H_2O)]_2[Fe(CN)_6]$[49] and in $[Zn(H_2O)]_2[Re_6Se_8Fe(CN)_6]$.[8k] However, in contrast to **11** where $Zn^{2+}$ is coordinated by two N atoms from the chelating en ligand and three $N_{CN}$ atoms from three different clusters to form a distorted square pyramid $ZnN_5$, in the latter compounds $Zn^{2+}$ is coordinated by one oxygen atom from the aqua ligand and three $N_{CN}$ atoms, which leads to the formation of distorted $ZnN_3O$ tetrahedra. The layers in **11** can be considered as expanded layers of the $CdCl_2$ or $CdI_2$ structure types[50,51] in which the $[Nb_6Cl_{12}]^{2+}$ cluster core takes the place of $Cd^{2+}$, and the complex anion $[Zn(en)(CN)_3]^-$ takes the place of the halide; thus the chemical formula can be written as $[Nb_6Cl_{12}][Zn(en)(CN)_3]_2$. However, the layers are stacked on top of each other in **11**, whereas in $CdCl_2$ and $CdI_2$, the layers are staggered.

### 5.4 Three-Dimensional Coordination Polymers

$[Me_4N]\{[Mn(L1)]_3[Nb_6Cl_{12}(CN)_6]\}$ (**12**) was obtained from the reaction of **2** with [Mn(*L1*)]Cl (8 equiv.) in dry acetonitrile.[38] In the presence of even trace amounts of water in acetonitrile, compound **7** was obtained instead. In **12**, each cluster is coordinated by six $[Mn(L1)]^+$ complexes and each complex links two cluster units to give an overall 3D framework (Figure 12a). The structure consists of identical but symmetry independent layers parallel to the *bc* plane with the same cluster complex connectivity as that found in **10** (Figure 12b). The layers are linked to each other through manganese complexes, which leads to the formation of cavities where the cation and acetonitrile molecules are located. The C≡N bond lengths range between 1.14 and 1.16 Å and only one peak at 2142 $cm^{-1}$ was observed for the C≡N vibrational stretching frequency. This value is larger than that found in the starting materials (2126 $cm^{-1}$) and 2D coordination polymer **10** built from [Mn(*L2*)] (2134 $cm^{-1}$). Two symmetry independent manga-

(a) Projection of the structure of the 3D coordination polymer $[Me_4N]\{[Mn(L1)][Nb_6Cl_{12}(CN)_6]\}$ (**12**) along the crystallographic *b* axis; (b) A projection along the *a* direction of two adjacent layers (one is bold and the other is faded), which shows the staggered packing of the layers along the *a* axis. The layers are further connected to each other through an additional set of Mn complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nese complexes are used to connect the clusters within the layers with bond lengths $Mn–N_{CN}$ = 2.34 Å, whereas a third manganese complex links the layers together to form the 3D framework with an average bond length $Mn–N_{CN}$ = 2.296 Å. The compound $Na\{[Mn(L2)]_3[Re_6Se_8(CN)_6]\}$[17a] also features a 3D coordination polymer in which each $Re_6$ cluster is surrounded by six Mn complexes.

The overall structure can be considered a 3D framework in which layers found in **10** are connected to each other through additional Mn complexes by using the two remaining CN ligands. The compound has been shown to lose almost all solvent molecules after being washed or when evacuated at room temperature without loss of crystallinity. Careful structural analysis reveals that solvent molecules are not involved in hydrogen bonding.

### 5.5 Effect of the Metal Complex: The 3D Framework of $[Ba(phen)_2(H_2O)]_2[Nb_6Cl_{12}(CN)_6]$ (13)

This compound was synthesized in a one-pot reaction by mixing a solution of $BaCl_2$ and phen (mol ratio = 1:2) in $H_2O$/EtOH with an aqueous solution containing $[Me_4N]_4[Nb_6Cl_{18}]$ and KCN.[32] The cyanochloride cluster was generated in situ. The structure of **13** is a neutral 3D framework built from $[Nb_6Cl_{12}(CN)_6]^{4-}$ and $[Ba(phen)_2(H_2O)]^{2+}$ (Figure 13a). Each cluster unit is linked to six barium complexes through cyanide ligands and each Ba complex links three clusters. Two crystallographically independent Ba complexes are present and arranged in a *mer* conformation around the cluster. Each set of Ba complexes links the cluster units to form ladder-like chains along the *c* and *b* axis (Figure 13b); this generates channels along the crystallographic *a* axis in which the phen ligands are located. The bond length of C≡N is about 1.14 Å yet two C≡N stretches were observed in the IR spectrum (2122, 2131 $cm^{-1}$). In addition to three N atoms from the cyanide ligands, each barium is additionally coordinated by four N atoms from two phen ligands and one O atom from a water molecule. Extended frameworks containing Ba-phen complexes and hexacyanometalates as building units have been reported. For instance, $\{[Ba_2(phen)_4(H_2O)_6][Fe(CN)_6]\}Cl$ (**VIII**)[52] is built from dimeric unit $[Ba_2(phen)_4(H_2O)_6]^{4+}$ and $[Fe(CN)_6]^{3-}$ and they are connected to each other by CN ligands to form chains. The dimers $[Ba_2(phen)_4(H_2O)_6]^{4+}$ are built from monomers $[Ba(phen)_2(H_2O)_2]^{2+}$ that are connected to each other by two water molecules through Ba–O–Ba linkages. Ba ions are nine-coordinate by four N atoms from two phen ligands, four O atoms from water molecules, and one N atom from a cyanide ligand.

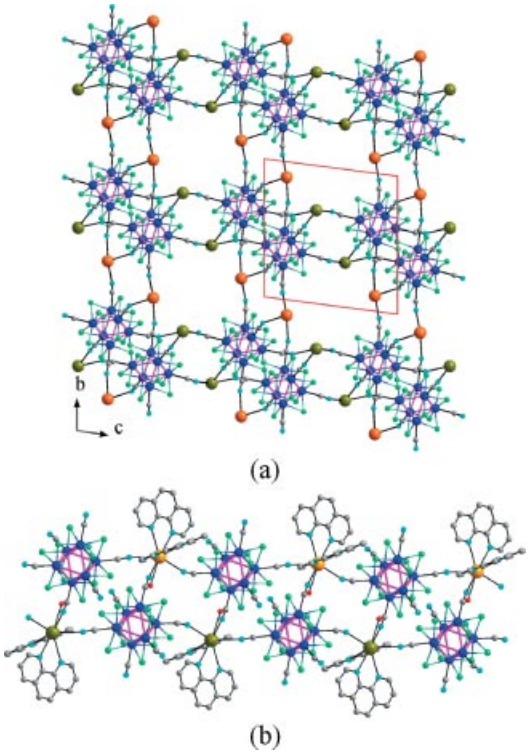

Figure 13. (a) Projection of the 3D framework found in $[Ba(phen)_2(H_2O)]_2[Nb_6Cl_{12}(CN)_6]$ (**13**) along the *a* direction. Water molecules and phen ligands located within the cavities have been omitted for clarity. (b) Ba complexes link cluster units to afford ladder chains along the *c* direction.

## 6. Properties

### 6.1 Thermal Stability

The thermal stability of compounds built from cluster units and Mn complexes depends on the nature of their framework. Thus, when heated to 200 °C in air-flow, materials built from supramolecular assemblies lose their crystallinity after losing all solvent molecules essential to the formation of the hydrogen-bonded frameworks. Figure 14 shows typical TGAs for materials based on supramolecular assemblies and coordination polymers. The stability of the

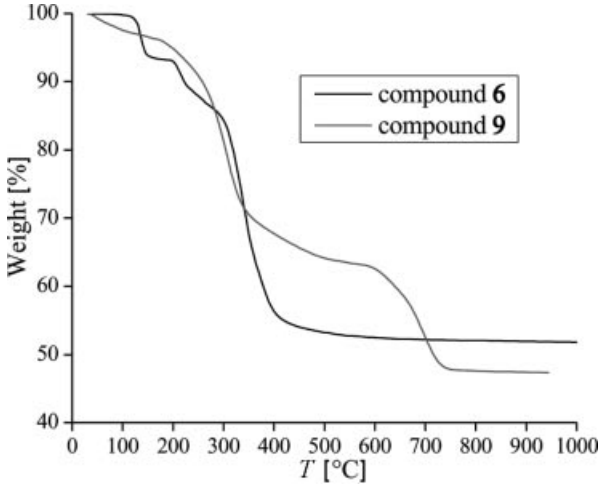

Figure 14. TGA of **6** built from supramolecular assemblies and **9** characteristic of coordination polymer heated from 30 °C to 950 °C at 5 °C /min under air-flow (40 mL/min).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coordination polymers is different because the solvent molecules are not involved in building the frameworks. When heated in air-flow, the product obtained after 700 °C is generally a mixture of metal oxides with compositions determined by the ratio of Mn:$Nb_6$ in the initial material. When the ratio Mn:$Nb_6$ = 1 or 2, the product is a mixture of $MnNb_2O_6$ and $Nb_2O_5$, and when Mn/$Nb_6$ = 3, only $MnNb_2O_6$ is observed. The thermal decomposition can be described by the following chemical equation:

$\{[Mn(L)]_n[Nb_6Cl_{12}(CN)_6]\} + [(15 + n)/2 + n]O_2 \rightarrow nMnNb_2O_6 + (3 - n)Nb_2O_5$ ($n$ = 1, 2, 3)

It is worth noting that the columbite $MnNb_2O_6$ forms in the temperature range 400–750 °C, much lower than the temperatures (800–1400 °C) at which $MnNb_2O_6$ is prepared through conventional mixed oxide route.[53]

### 6.2 Magnetic Properties

In all compounds described above, the Nb–Nb bond lengths are characteristic of diamagnetic 16-electron clusters.[18] The effective magnetic moment in **6**, **10**, and **12** are characteristic of high-spin $Mn^{III}$ ions. For example, for **12** the $\mu_{eff}$ value at 300 K is 5.17 $\mu_B$, close to the calculated value of the spin-only effective moment of the high-spin $Mn^{3+}$ ion (4.90 $\mu_B$). As the compound is cooled from 300 K to 20 K, the effective magnetic moment remains almost the same and then decreases slowly. The data were fitted with the Curie–Weiss relation $\chi(T) = \chi_0 + C/(T - \theta)$ to give C = 3.36 emu K $mol^{-1}$ and $\theta$ = –2.02 K (Figure 15). No evidence of magnetic exchange coupling between the $Mn^{III}$ centers was observed even for the 3D framework of **12**. This is different from the case of the Prussian-blue $Fe^{III}_4[Fe^{II}(CN)_6]_3 \cdot 14H_2O$ in which the $Fe^{III}$ ions are separated from each other by diamagnetic $Fe^{II}$ ions, yet ferromagnetic coupling ($T_c$ = 5.6 K) was observed.[54] Two reasons can account for this: 1) the large size of the cluster units, which separate two $Mn^{III}$ ions, results in a Mn interdistance of 15.1(2) Å for **12**, and 2) the electronic structure of the diamagnetic 16-electron cluster.

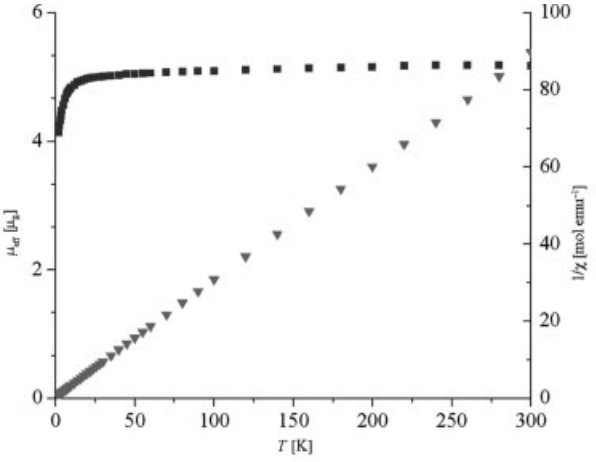

Figure 15. Plot of $\mu$ (left) and $1/\chi$ (right) versus $T$ of **12** measured under a 1 kG magnetic field.

## 7. Conclusion

Octahedral niobium cyanochloride clusters and coordinatively unsaturated metal complexes have been successfully used as components of larger assemblies. Two types of assemblies have been obtained depending on the metal complex chosen, the solvent system, and the molar ratios used. Table 1 summarizes the most important bond lengths and angles, as well as the $\nu$(C≡N) bond stretching frequency of the compounds described here and their analogues based on $[Fe(CN)_6]^{3-}$. The following observations can be made: 1) Supramolecular assemblies in which the cluster is progressively coordinated by one, two, four, and six metal complexes have been obtained. The size of these supramolecules increases from 1.5 to 2.4 nm as the number of metal complexes per cluster increases. The cluster-based supramolecules are about 0.5 to 0.8 nm larger than analogous species built from $[Fe(CN)_6]^{3-}$ and metal complexes, which is consistent with the fact that the size of $[Nb_6Cl_{12}(CN)_6]^{4-}$ is about 0.5 nm larger than $[Fe(CN)_6]^{3-}$. 2) The functionalization of the cluster unit by attaching a different number of metal complexes led to the formation of different species with different charges. 3) The dimension and topology of coordination polymers built from clusters and metal complexes are dictated by the coordination requirements of the metal complex and the connectivity mode between the metal complex and the cluster. Thus, $Mn^{III}$ Schiff-base complexes containing two free coordination sites are used to build 1D, 2D, and 3D coordination polymers as the cluster uses two, four, and six CN ligands to link to the metal complex and the Mn:$Nb_6$ ratio increases from 1 to 3. Both $[Zn(en)]^{2+}$ and $[Ba(phen)_2(H_2O)]^{2+}$ use three coordination sites to build either 2D and 3D coordination polymers because of the availability of three coordination sites. 4) Though similarities between the compounds reported here and their counterparts that are built from $[Fe(CN)_6]^{3-}$ or $Re_6$ clusters are observed, the compounds differ from each other in terms of their structural features and properties. The reactivity of $[Nb_6Cl_{12}(CN)_6]^{4-}$ towards metal complexes is also different from that of $[Fe(CN)_6]^{3-}$ and $Re_6$ clusters. 5) The formation of supramolecular assemblies results from the substitution of ammonium ions with coordinatively unsaturated metal complexes. Di-, tri-, and pentameric supramolecules are formed as the number of Mn complexes attached to the cluster increases. The process can be represented by the following chemical equation:

$[Me_4N]_4[Nb_6Cl_{12}(CN)_6] + n[Mn(L)]+ \rightarrow [Me_4N]_{4-n}\{[Mn(L)]_n[Nb_6Cl_{12}(CN)_6]\} + n[Me_4N]+ (0 \leq n \leq 4)$

6) The formation of 1D, 2D, and 3D coordination polymers is governed by the same chemical equation as above. As $n$ increases from 1 to 3, 1D, 2D, and 3D frameworks are obtained. These coordination polymers can be viewed as supramolecular units connected to each other by additional clusters. Thus, the 1D polymer can be described as being formed from heterotrimers connected to cluster units to form chains, the 2D material can be described as heteropen-

[a] Compounds **I**–**VIII** are based on $[Fe(CN)_6]^{3-}$ as building units and were used to compare compounds based on mononuclear hexacyanides to their cluster analogues.

tamers linked by way of cluster units, whereas the 3D framework consists of heteroheptamers connected by cluster units.

Further studies are necessary to advance our understanding of this system and to allow the preparation of materials with tailored structural features and properties. The stability of the supramolecular assemblies in solution is of interest in order to study their potential use as larger building units for the preparation of materials with more complex structures. More important are the opportunities these assemblies present in terms of their functionalization by use of different metal complexes and different ligands. The rate-limiting step of advances in this field, as in many other areas of synthesis, is the preparation of single-crystals suitable for structural characterization. The use of powder XRD to solve and refine the crystal structure is in most cases of little use as PXRD patterns are generally dominated by four or five peaks. For instance, in the case of the Prussian-blue analogues, the structure initially determined from PXRD was significantly different from that determined later from single-crystal XRD. Magnetic studies of supramolecular assemblies and coordination polymers show that no magnetic coupling was observed between the cluster units and the metal ions or between the metal ions through cluster units, possibly a result of the diamagnetism and large size of the metal cluster. Oxidation–reduction of the cluster and its use as a building unit may lead to modification of the physical properties of the materials obtained. Recently, the 15-electron cluster $[Nb_6Cl_{12}(CN)_6]^{3-}$ was isolated, and it is being investigated as a building unit in complexes to determine its effect on magnetic properties.

# Synthesis and Structure of Cyclic Trinuclear Zinc Disiloxides

Clemens Krempner,*[a] Helmut Reinke,[a] and Katja Weichert[a]

**Keywords:** Oligosilanes / Zinc / Siloxides / Clusters

The synthesis and structure of the new disilane-1,2-diol $[(Me_3Si)_2SiOH]_2$ (**2b**) and the trinuclear zinc disiloxides of the formula $[Me_2Si\{(Me_3Si)_2SiO\}_2]_2Zn_3Me_2$ (**3a**), $[\{(Me_3Si)_2SiO\}_2]_2Zn_3Me_2$ (**3b**) and $[E\text{-}\{Me(Me_3Si)_3SiSiO\}_2]_2Zn_3Me_2$ (**3c**) are reported. Compounds **3a**–**c** were prepared by reactions of the corresponding silanedioles **2a**–**c** with $ZnMe_2$. The results of an X-ray structure analysis of **3b** reveal an almost perfectly planar spirocyclic $Zn_3O_4$ core with a square-planar geometry of the inner $Zn^{2+}$ ion, whereas in **3a**,**c** the inner zinc ions are distorted tetrahedral. Upon treatment with $B(C_6F_5)_3$, compounds **3b**,**c** have been converted quantitatively into the complexes $[\{(Me_3Si)_2SiO\}_2]_2Zn_3(C_6F_5)_2$ (**4b**) and $[E\text{-}\{Me(Me_3Si)_3SiSiO\}_2]_2Zn_3(C_6F_5)_2$ (**4c**).

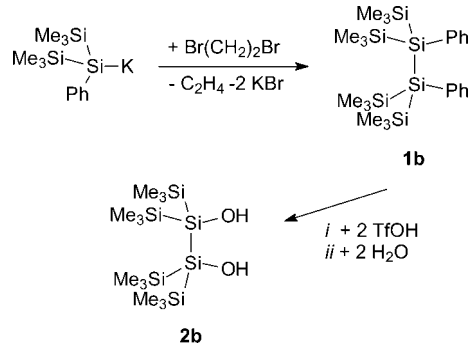
## Introduction

There has been a considerable interest in recent years in the chemistry and structures of zinc siloxides as the steric hindrance of the ligand ($R_3SiO^-$) in such compounds can lead to novel structural features and unusual reactivity.[1] For example, some structurally well-defined zinc compounds have been found application as soluble precursors for zinc oxides and silicates.[2] Significant synthetic and structural studies of a variety of mainly monodentate zinc siloxides are reported from the Driess group. They could demonstrate that the degree of aggregation of the central $(ZnO)_n$ core decreases as the bulkiness of the attached siloxide ligand increases.[3] Bidentate cyclic zinc siloxides, however, are rare and the only example has been reported from the reaction of $ZnMe_2$ with $Ph_2Si(OH)_2$, which under self-condensation of the silanol affords a remarkable polycyclic hexanuclear zinc complex with two $Zn_3O_4$ cores.[4]

We have a long-term interest in the synthesis and structural characterization of cyclic five- and six-membered metal disiloxides, as these highly strained cycles might be useful for the selective ring insertion of metal species, which may form novel hetero- and homobimetallic complexes as we have shown recently for a dinuclear titanium disiloxide derived from a mononuclear cyclic species.[5] In this contribution we describe the preparation of a new disilane-1,2-diol and we report on the synthesis of polycyclic trinuclear zinc disiloxides from reactions of $ZnMe_2$ with various sterically congested vicinal silanediols together with their solid-state structures.

## Results and Discussion

A rather straightforward strategy for the design of vicinal silanediols with an oligosilane backbone involves the use of phenyl-substituted metal silanides in salt metathesis reactions. In analogy to the synthesis of the trisilane-1,3-diol **2a** previously reported,[5] treatment of $Ph(Me_3Si)_2Si\text{-}K$ with $BrCH_2CH_2Br$ provides easy access to the diphenyl oligosilane **1b** in high yields.[6] This compound was treated with two equivalents of trifluoromethanesulfonic acid (TfOH) and subsequently hydrolyzed to give almost quantitatively the silanediol **2b** as a colorless solid (Scheme 1). The compound slowly decomposes at room temperature within several days and must be stored in a freezer at ca. –40 °C. However, the structure of **2b** was unambiguously established by standard spectroscopic methods and elemental analysis. The synthesis of the racemic disilane-1,2-diol **2c** has been reported elsewhere.[7]



Scheme 1. Synthesis of **2b**.

As reported recently, differently aggregated zinc silanolates can be prepared by acid–base reactions of silanols $R_3SiOH$ (R = Me, Et, *i*Pr, Ph) with $ZnR_2$ (R = Me, Et).

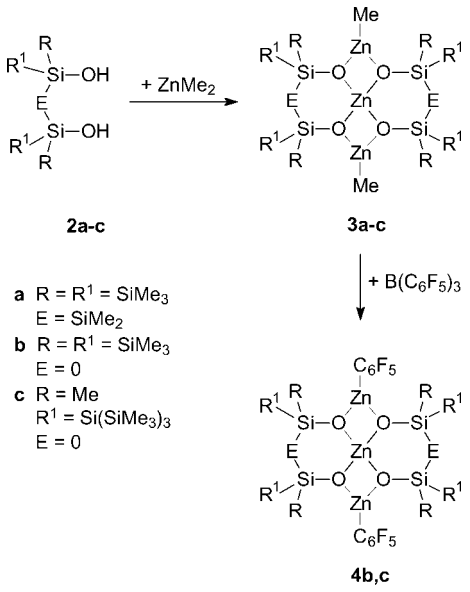
Employing $ZnMe_2$ as the reagent the trinuclear zinc complexes **3a**–**c** have been synthesized in good yields as outlined in Scheme 2. The NMR and MS data and the results of elemental analysis have confirmed the proposed structures of **3a**–**c**. The NMR ($^1H$, $^{13}C$, $^{19}Si$) spectra of all complexes are rather straightforward and show roughly the same features as observed for the corresponding free ligands **2a**–**c**. For example, the $^1H$ and $^{13}C$ NMR spectra of **3a** exhibit only one signal for the $SiMe_3$ and $SiMe_2$ groups, respectively, and also the $^{29}Si$ NMR spectra showed only one signal for the $SiMe_3$ silicon atoms.



Scheme 2. Synthesis of **3a**–**c** and reaction behavior toward $B(C_6F_5)_3$.

In addition, the solid-state structures of **3a**–**c** have been determined by X-ray crystallography; suitable single crystals were grown from pentane solutions at room temperature. The molecular structures along with selected bond lengths and bond angles are shown in Figure 1, 2, 3, and 4. Compounds **3a**–**c** crystallize in the triclinic space group $P\bar{1}$. All structures consist of fused polycyclic ring systems with central trinuclear $Zn_3O_4$ cores, which are coordinated in a chelate fashion by two diolate ligands, respectively. The coordination of the ligand to the inner zinc ion in **3a** results in the formation of a six-membered ring system with a distorted chair conformation. In **3b** and **3c**, however, five-membered rings are formed, which are either strongly twisted [**3b**; dihedral angle O1–Si2–Si3–O2 32.05(6)°] or almost planar [**3c**; dihedral angle O1–Si3–Si4–O2 2.70(10)°]. The outer zinc atoms of **3a** and **3c** are three-coordinate with trigonal-planar ligand environments, while the inner $Zn^{2+}$ ions are four-coordinate with distorted tetrahedral geometries. Overall, the observed distorted geometries of the $Zn_3O_4$ cores are in good agreement with those of the monodentate zinc siloxides $[(iPr_3SiO)_4Zn_3Me_2]$ (**5**),[2a] $[(Ph_3SiO)_4Zn_3Me_2]$ (**6**)[4] and $[(OSiPh_2OSiPh_2O)(OSiPh_2)OZn_2Me_2 \cdot THF]_2$ (**7**)[4] (see Table 1).

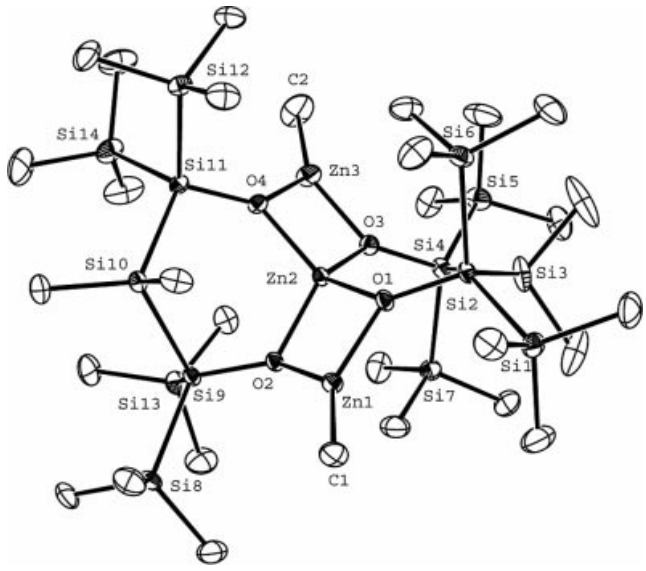


Figure 1. Molecular structure of **3a** in the crystal. The thermal ellipsoids correspond to 30% probability (hydrogen atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Zn1–C1 1.942(4), Zn3–C2 1.934(5), Zn2–O1 1.975(2), Zn2–O2 1.968(2), Zn2–O3 1.959(2), Zn2–O4 1.973(2), Zn1–O1 1.952(2), Zn1–O2 1.954(2), Zn3–O3 1.953(2), Zn3–O4 1.959(2), Si2–O1 1.673(2), Si4–O3 1.673(2), Si9–O2 1.678(2), Si11-O4 1.679(2), Si2–Si3 2.3597(14), Si3–Si4 2.3775(14), O3–Zn2–O2 135.37(10), O3–Zn2–O4 85.50(9), O2–Zn2–O4 112.70(9), O3–Zn2–O1 110.92(9), O2–Zn2–O1 84.63(9), O4–Zn2–O1 135.80(10), O1–Zn1–O2 85.64(9), O3–Zn3–O4 86.03(9), C1–Zn1–O1 137.17(14), C2–Zn3–O3 140.12(19), Zn2–O3–Si4–Si3 45.43(18), O3–Si4–Si3–Si2 14.59(12), Si4–Si3–Si2–O1 23.79(12), Si3–Si2–O1–Zn2 43.74(19), Si2–O1–Zn2–O3 21.8(2), O1–Zn2–O3–Si4 34.34(19).

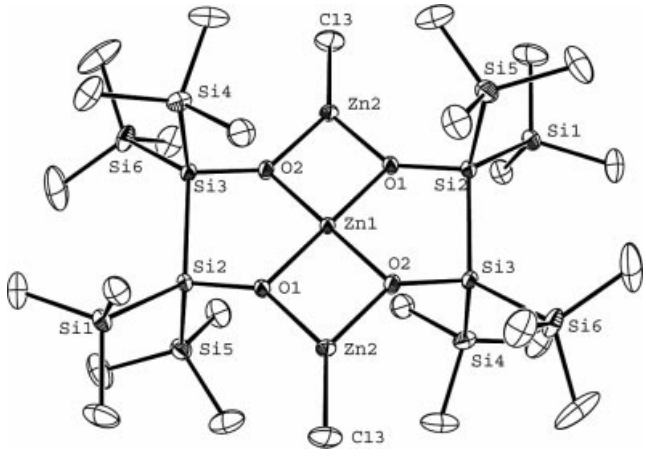

Figure 2. Molecular structure of **3b** in the crystal. The thermal ellipsoids correspond to 30% probability (hydrogen atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Zn2–C13 1.9223(16), Zn1–O1 1.9721(9), Zn1–O2 1.9831(10), Zn2–O2 1.9438(10), Zn2–O1 1.9403(10), Si2–O1 1.6744(11), Si3–O2 1.6763(10), Si2–Si3 2.3832(5), O1–Zn1–O2 96.88(4), O1–Zn1–O1A 180.0, O1–Zn1–O2A 83.12(4), O2–Zn2–O1A 84.99(4), O1A–Zn2–C13 137.63(8).

The most remarkable feature of the zinc siloxide **3b**, however, is the unusual square-planar coordination geometry of the inner $Zn^{2+}$ ion. To the best of our knowledge, this is the first completely planar structure with a spirocyclic

Selected bond lengths [Å] and angles [°]: Zn2–C2 1.934(3), Zn3–C1 1.933(3), Zn1–O1 1.9665(17), Zn1–O2 1.9650(16), Zn1–O3 1.9677(16), Zn1–O4 1.9650(16), Zn2–O1 1.9687(17), Zn2–O3 1.9588(16), Zn3–O2 1.9644(16), Zn3–O4 1.9664(16), Si3–O1 1.6672(17), Si4–O2 1.6650(17), Si13–O3 1.6653(17), Si14–O4 1.6685(17), Si3–Si4 2.4229(9), Si13–Si14 2.4003(9), Si2–Si3 2.3891(10), O2–Zn1–O4 86.64(7), O2–Zn1–O1 101.54(7), O4–Zn1–O1 151.34(8), O2–Zn1–O3 147.62(7), O4–Zn1–O3 100.93(7), O1–Zn1–O3 86.84(7), O3–Zn2–O1 87.02(7), O2–Zn3–O4 86.62(7), C2–Zn2–O3 135.32(12), C2–Zn2–O1 137.66(12), C1–Zn3–O4 134.97(11), O1–Si3–Si4–O2 2.70(10), O3–Si13–Si14–O4 10.53(10).

$Zn_3X_4$ core (X = S, O, N, P). Apart from three planar mononuclear zinc complexes with bidentate phenolate type ligands,[8] only in porphyrin complexes the zinc ion has an almost perfect square-planar coordination environment. A view along the Si2–Si3 axis in **3b** (Figure 3) clearly reveals this arrangement to be mainly enforced by the steric repulsion of the adjacent trimethylsilyl groups. In fact, the steric interactions of the trimethylsilyl groups can be significantly minimized by adopting a staggered conformation along the Si2–Si3 axis, which results in the formation of a planar spirocyclic $ZnO_2ZnO_2Zn$ core. This is not evident for **3a**, because the $SiMe_2$ spacer group, which reduces steric repulsions within the molecule, separates the vicinal trimethylsilyl groups. Consequently the bulky trimethylsilyl groups can adopt an eclipsed conformation, which enables the inner zinc ion to be coordinated in the energetically preferred tetrahedral geometry.

Table 1. Selected average bond lengths [Å] and angles [°] for trinuclear zinc disiloxides.

| Compound | **3a** | **3b** | **3c** | **5**[a] | **6**[b] | **7**[c] |
|---|---|---|---|---|---|---|

[a] $[(iPr_3SiO)_4Zn_3Me_2]$. [b] $[(Ph_3SiO)_4Zn_3Me_2]$. [c] $[(OSiPh_2OSiPh_2O)(OSiPh_2)OZn_3Me_2{\cdot}THF]_2$.

For comparison, a summary of selected average distances and angles together with those of the complexes recently reported by Driess et al. is given in Table 1. As expected, the Zn–O distances and O–Zn–O angles of the inner zinc ions and also the Zn–C distances in all these complexes are rather similar to each other. It is worthy to note, however, that the Si–O distances in **3a**–**c** are markedly longer and the Zn–O distances for the outer zinc ions are shorter than those of the closely related complexes **5–7**. The longer Si–O distances can be attributed to the specific electronic situation in **3a**–**c**, in which the central silicon atoms possess electropositive silyl groups. These electron-donating groups clearly diminish the capability of silicon to act as strong π acceptor for oxygen, which gives rise to stronger electrostatic oxygen–zinc interactions and consequently to shorter Zn–O distances as compared to **5–7**.

Furthermore, we have investigated the reactivity of the highly strained trinuclear zinc complexes **3b**,**c** towards the Lewis acid $B(C_6F_5)_3$ that is known to abstract alkyl groups from the metal center to form cationic metal species. The reactions were performed at room temperature in a J-Young NMR tubes using [D$_6$]benzene as solvent, and the course of the reaction was monitored by $^1$H NMR spectroscopy. The complexes **3b**,**c** reacted cleanly with $B(C_6F_5)_3$ (molar ratio 1:1) within minutes, resulting in the formation of $[\{(Me_3Si)_2SiO\}_2]_2Zn_3(C_6F_5)_2$ (**4b**) and $[E\text{-}\{Me(Me_3Si)_3SiSiO\}_2]_2Zn_3(C_6F_5)_2$ (**4c**), the quantitative products of a rapid $C_6F_5$ group transfer, as evidenced by multinuclear NMR spectroscopic data. The compounds **4b**,**c** could be isolated in a larger scale and the spectroscopic data obtained were identical to those from the NMR experiments (Scheme 2). Solutions of **4b**,**c** in $C_6D_6$ proved to be fairly stable over a prolonged period of time, and even at higher temperature no substantial decomposition occurred. Similar $C_6F_5$ transfer reactions have been observed for the reaction of $ZnMe_2$.[9] The fact that the $C_6F_5$ groups have re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

placed both methyl groups rapidly is somewhat surprising; however, it indicates an increased electrophilicity of the zinc centers caused by the electron-withdrawing disiloxide ligands.

## Experimental Section

**General Remarks:** All manipulations of air- and/or moisture-sensitive compounds were carried out under argon using standard Schlenk and Glove Box techniques. THF, *n*-heptane and *n*-pentane were distilled under argon from alkali metals prior to use. $CH_2Cl_2$ was distilled from $CaH_2$ and stored over molecular sieves. [$D_6$]Benzene was dried with activated molecular sieves and stored in the glove box. $B(C_6F_5)_3$ was prepared as described previously.[10] NMR: Bruker AC 250, Bruker ARX 300. IR: Nicolet 205 FT-IR. MS: Intectra AMD 402, chemical ionization with isobutane as the reactant gas.

**2,3-Dihydroxy-1,1,1,4,4,4-hexamethyl-2,3-bis(trimethylsilyl)tetrasilane (2b):** Freshly distilled TfOH (0.97 mL, 0.011 mol) was added at –40 °C to a stirred solution of **1b** (2.51 g, 0.005 mol) in $CH_2Cl_2$ (25 mL) and the mixture was warmed to room temp. within 2 h. After changing the solvent from $CH_2Cl_2$ to diethyl ether, an aqueous solution of $NH_4COONH_2$ (10 mL, 1 M) was added dropwise and stirring was continued for 30 min. The organic phase was separated, dried with $MgSO_4$, and the solvent was evaporated. Drying under high vacuum afforded 1.76 g (92%) of the title compound, which was kept in a freezer. $^1$H NMR ($C_6D_6$, 250 MHz): $\delta$ = 0.72 (br. s, OH, 2 H), 0.29 [s, $Si(CH_3)_3$, 36 H] ppm. $^{13}$C NMR ($C_6D_6$, 62.9 MHz): $\delta$ = 0.1 [$Si(CH_3)_3$] ppm. $^{29}$Si-INEPT ($C_6D_6$, 59.6 MHz): $\delta$ = 8.1 (SiOH), –15.0 [$Si(CH_3)_3$] ppm. MS (70 eV): *m*/*z* (%) = 383 (8) [$M^+$], 279 (8) [$M^+$ – 2Me – $SiMe_3$], 205 (20) [$M^+$ – Me – 2$SiMe_3$ – OH], 131 (42) [$M^+$ – Me – 3$SiMe_3$ – OH]. $C_{12}H_{38}O_2Si_6$ (382.94): calcd. C 37.64, H 10.00; found C 37.49, H 9.98. IR (Nujol): $\tilde{\nu}_{OH}$ = 3394.4 cm$^{-1}$ (assoc.), 3641.6 cm$^{-1}$ (non-assoc.).

**[$Me_2Si${$(Me_3Si)_2SiO$}$_2$]$_2Zn_3Me_2$ (3a):** Solid **2a** (2.0 g, 4.5 mmol) was added to a vigorously stirred solution of $ZnMe_2$ (2 M, 3.6 mL, 7.2 mmol) in *n*-pentane (20 mL) at –78 °C. After stirring for 2 h at room temp., the solvent was removed under vacuum. Crystallization of a concentrated *n*-pentane solution in a freezer at –40 °C afforded the title compound as colorless crystals. Yield 1.75 g (65%). M.p. 115–117 °C. $^1$H NMR ($C_6D_6$, 250 MHz): $\delta$ = 0.43 [s, $Si(CH_3)_2$, 12 H], 0.34 [s, $Si(CH_3)_3$, 72 H], –0.04 (s, $ZnCH_3$, 6 H) ppm. $^{13}$C NMR ($C_6D_6$, 75.5 MHz): $\delta$ = 1.2 [$Si(CH_3)_3$], –0.4 [$Si(CH_3)_2$], –10.8 ($ZnCH_3$) ppm. $^{29}$Si NMR ($C_6D_6$, 59.6 MHz): $\delta$ = 14.8 (SiOZn), –16.1 [$Si(CH_3)_3$], –37.1 [$Si(CH_3)_2$] ppm. $C_{30}H_{90}O_4Si_{14}Zn_3$ (1104.40): calcd. C 32.63, H 8.21; found C 32.47, H 8.24.

**[{$(Me_3Si)_2SiO$}$_2$]$_2Zn_3Me_2$ (3b):** A heptane solution of **2b** (0.5 g, 1.31 mmol) was added to a vigorously stirred solution of $ZnMe_2$ (2 M, 0.8 mL, 1.6 mmol) in *n*-pentane (20 mL) at –78 °C. After stirring for 2 h at room temp., the solvent was removed under vacuum. Crystallization of a concentrated *n*-pentane solution in a freezer at –40 °C afforded the title compound as colorless crystals. Yield 0.41 g (63%). M.p. 169–171 °C. $^1$H NMR ($C_6D_6$, 250 MHz): $\delta$ = 0.30 [s, $Si(CH_3)_3$, 72 H], –0.13 (s, $ZnCH_3$, 6 H) ppm. $^{13}$C NMR ($C_6D_6$, 75.5 MHz): $\delta$ = 0.1 [$Si(CH_3)_3$], –15.1 ($ZnCH_3$) ppm. $^{29}$Si NMR ($C_6D_6$, 59.6 MHz): $\delta$ = 1.2 (SiOZn), –16.4 [$Si(CH_3)_3$] ppm. $C_{26}H_{78}O_4Si_{12}Zn_3$ (988.09): calcd. C 31.60, H 7.96; found C 31.42, H 7.84.

**[E-{$Me(Me_3Si)_3SiSiO$}$_2$]$_2Zn_3Me_2$ (3c):** A heptane solution of **2c** (0.5 g, 0.81 mmol) was added to a vigorously stirred solution of $ZnMe_2$ (2 M, 0.6 mL, 1.2 mmol) in *n*-heptane (15 mL) at –78 °C. After warming to room temp., the suspension was stirred overnight and refluxed until the colorless precipitate fully dissolved. Crystallization of the solution at room temp. afforded the title compound as colorless crystals. Yield 0.45 g (75%). M.p. 161–164 °C. $^1$H NMR ($C_6D_6$, 250 MHz): $\delta$ = 0.94 (s, $SiCH_3$, 12 H), 0.41 [s, $Si(CH_3)_3$, 108 H], 0.04 (s, $ZnCH_3$, 6 H) ppm. $^{13}$C NMR ($C_6D_6$, 75.5 MHz): $\delta$ = 11.0 ($SiCH_3$), 4.6 [$Si(CH_3)_3$], –10.3 ($ZnCH_3$) ppm. $^{29}$Si NMR ($C_6D_6$, 59.6 MHz): $\delta$ = 15.8 (SiOZn), –10.0 [$Si(CH_3)_3$], –127.1 ($Si$$Si_4$) ppm. MS (70eV): *m*/*z* (%) = 1438 (2) [$M^+$ – Me], 1207 (22) [$M^+$ – $Si(SiMe_3)_3$], 1110 (8) [$M^+$ – $Si(SiMe_3)_3$ – 2Me – Zn], 247 (35) [$Si(SiMe_3)_3$]. $C_{42}H_{126}O_4Si_{20}Zn_3$ (1453.33): calcd. C 34.71, H 8.74; found C 34.51, H 8.74.

**Reaction of 3b,c with $B(C_6F_5)_3$ in $C_6D_6$:** An NMR tube (equipped with J. Young valve) was charged in the glove box with **3b** or **3c** and $B(C_6F_5)_3$ (molar ratio 1:1) and dissolved in $C_6D_6$ (0.5 mL). The progress of the reaction was monitored by $^1H$ NMR spectroscopy and complete conversion of the starting materials into **4b** and **4c** and a mixture of the boranes $MeB(C_6F_5)_2$ ($\delta$ = 1.35 ppm), $Me_2BC_6F_5$ ($\delta$ = 0.98 ppm) and $BMe_3$ ($\delta$ = 0.74 ppm) was observed within 2 h at room temperature, according to the $^1H$ , $^{29}Si$ , $^{11}B$ and $^{19}F$ NMR spectra.

**Isolation of 4b,c:** A stirred mixture of $B(C_6F_5)_3$ and **3b** or **3c** (molar ratio 1:1) was dissolved in *n*-pentane at ca. –20 °C and stirring was continued for 2 h at room temperature. Crystallizations of concentrated solutions in a freezer afforded colorless crystals of the title compounds.

**$[\{(Me_3Si)_2SiO\}_2]_2Zn_3(C_6F_5)_2$ (4b):** Compound **3b** (0.15 g, 0.15 mmol), $B(C_6F_5)_3$ (0.08 g, 0.15 mmol) and *n*-pentane (10 mL). Yield 0.1 g (67%). $^1H$ NMR ($C_6D_6$, 250 MHz): $\delta$ = 0.24 [s, $Si(CH_3)_3$, 72 H] ppm. $^{13}C$ NMR ($C_6D_6$, 75.6 MHz): $\delta$ = –0.1 [$Si(CH_3)_3$], 135.4–150.6 ($C_6F_5$) ppm. $^{29}Si$ NMR ($C_6D_6$, 59.6 MHz): $\delta$ = 7.9 (SiO), –16.0 [$Si(CH_3)_3$] ppm. $^{19}F$ NMR ($C_6D_6$, 235.4 MHz): $\delta$ = –169.5, –140.2, –116.2 (*o*-, *p*-, *m*-F, $C_6F_5$) ppm. $C_{36}H_{72}F_{10}O_4Si_{12}Zn_3$ (1292.11): calcd. C 33.46, H 5.62; found C 33.09, H 5.44.

**$[E\text{-}\{Me(Me_3Si)_3SiSiO\}_2]_2Zn_3(C_6F_5)_2$ (4c):** Compound **3c** (0.15 g, 0.1 mmol), $B(C_6F_5)_3$ (0.05 g, 0.1 mmol) and *n*-pentane (10 mL). Yield 0.09 g (61%). $^1H$ NMR ($C_6D_6$, 250 MHz): $\delta$ = 1.00 (s, $SiCH_3$, 12 H), 0.31 [s, $Si(CH_3)_3$, 72 H] ppm. $^{13}C$ NMR ($C_6D_6$, 75.6 MHz): $\delta$ = 4.5 [$Si(CH_3)_3$], 10.9 ($SiCH_3$), 136.1–151.2 ($C_6F_5$) ppm. $^{29}Si$ NMR ($C_6D_6$, 59.6 MHz): $\delta$ = 21.0 (SiO), –9.9 [$Si(CH_3)_3$], –125.4 ($SiSi_4$) ppm. $C_{52}H_{120}F_{10}O_4Si_{20}Zn_3$ (1757.35): calcd. C 35.54, H 6.88; found C 35.18, H 6.79.

Crystal data collection see Table 2 for **3a**, **3b** and **3c** are deposited in the Cambridge Crystallographic Data Centre. CCDC-622651 (for **3a**), -622650 (for **3b**) and -622649 (for **3c**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Spin-Crossover Studies on a Series of 1D Chain and Dinuclear Iron(II) Triazine-Dipyridylamine Compounds

**Suzanne M. Neville,[a] Ben A. Leita,[a] Daniel A. Offermann,[a] Martin B. Duriska,[a] Boujemaa Moubaraki,[a] Karena W. Chapman,[b] Gregory J. Halder,[c] and Keith S. Murray*[a]**

**Keywords:** Iron / N ligands / Spin crossover / 1D chains / Dinuclear / Magnetic properties

Four isostructural one-dimensional polymeric iron(II) spin crossover materials containing the ligand 2-chloro-4,6-bis(dipyrid-2-ylamino)-1,3,5-triazine (cddt) have been synthesised and magnetically and structurally characterised. The polymeric material $Fe(NCS)_2(cddt)\cdot n(guest)$ (**1**), self assembles into three crystallographically distinct phases; the compounds **1b** and **1c**, $[Fe(NCS)_2(cddt)]\cdot 2(CH_3OH)$, are polymorphs, however, **1a**, $[Fe(NCS)_2(cddt)]\cdot 1/2(CHCl_3)\cdot(H_2O)$ contains a different solvent system. Each phase shows very different magnetic behaviour; phases **1a** and **1b** remain high spin over all temperatures, whilst phase **1c** undergoes a "half" spin crossover between 225 and 125 K. The structural consequences of the spin transition in **1c** have been followed using variable temperature synchrotron powder X-ray diffraction techniques. Variation of the chalcogenide ligand in the complex $[Fe(NCSe)_2(cddt)]\cdot 2(CH_3OH)$, **2**, leads to a full one-step spin crossover with a $T_{1/2}$ of 200 K. Structural analysis of **1c** below the transition temperature reveals alternating, crystallographically distinct, HS and LS iron(II) centres (HS: high spin, LS: low spin) along the chain, and structural analysis of **2** below the transition temperature reveals all LS iron(II) centres. Also reported are the structural characterisations of two dinuclear materials, containing the ligand 2,4,6-tris(dipyridin-2-ylamino)-1,3,5-triazine (tdt), of the formula $[Fe(tdt)(X)_2]_2\cdot(ClO_4)\cdot$(solvent) (X = $H_2O$, $Cl^-$ for **3a**, **3b**) which are analogous to those recently reported by Gamez et al. In addition, the structural characterisations are described for dinuclear materials, containing the ligand cddt, of the formula $[Fe(cddt)(Cl)(X)]_2\cdot(Y)_2\cdot n$(solvent) (X: $H_2O$ or $NCCH_3$, Y: $ClO_4^-$, $BF_4^-$ **4a**, **4b** and **4d**) and for a cobalt(II) analogue, $[Co(cddt)(Cl)(H_2O)]_2\cdot(BF_4)_2\cdot n$(solvent) (**4c**).

## Introduction

The recent papers of Gamez, Roubeau and coworkers[1,2] dealing with exchange coupling and spin crossover (SCO) in dinuclear iron(II) complexes of triazine-based bridging ligands prompts us to report our contemporaneous studies using the same ligand, and a related one. Similarities and differences in the two studies are emphasised, with a series of 1D (one-dimensional) chain SCO species being reported here for the first time. Our work forms part of a wide investigation into the synthesis, structures and magnetism of dinuclear,[3–7] and higher nuclearity,[8–14,19] iron(II) SCO compounds. We[15] and others[16] are interested in probing fundamental questions dealing with, for example, the synergy, if any, between exchange coupling and SCO, and the possible increase in cooperativity [e.g. thermal hysteresis of the spin transition(s)] in dinuclear and polynuclear SCO materials when compared to mononuclear. A range of structural designs of the bridging geometry and of the chemical nature of the bridging ligands has been employed in order to attempt to answer some of these questions.[17] The ligand common to both studies is 2,4,6-tris(dipyrid-2-ylamino)-1,3,5-triazine (labelled dpyatriz by Gamez et al.[1–2] and tdt herein, Figure 1) while the other ligand is 2-chloro-4,6-bis(dipyridin-2-ylamino)-1,3,5-triazine (labelled cddt, Figure 1).

There have been several reports recently of ligands based on dipyrid-2-ylamine (dpa) being incorporated into mono- and dinuclear systems.[1–2,4,18] The mononuclear complex $Fe(dpa)_2(NCS)_2$ containing *cis*-coordinated thiocyanate ligands, recently reported by Real et al., undergoes an incomplete one-step spin crossover with a $T_{1/2}$ of 88 K.[18] The mononuclear complex *trans*-$Fe(tdt)_2(NCS)_2$ recently reported by Gamez et al.,[2] undergoes a complete one-step spin crossover with a $T_{1/2}$ of 200 K. This was the first report for an iron(II) dpa-style material containing *trans*-thiocyanate ligands.[2] We recently reported the dinuclear complex

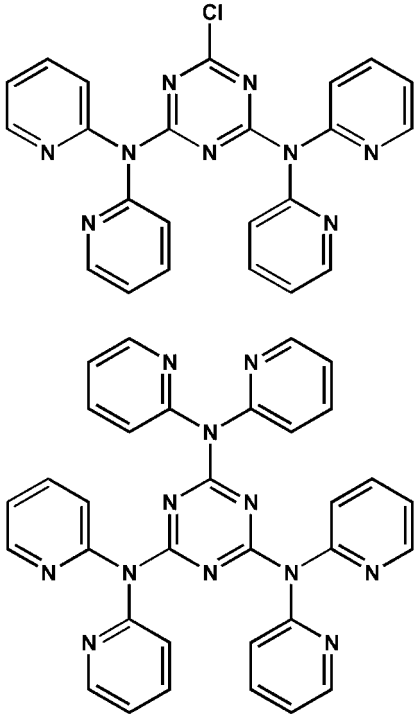

Figure 1. The ligands 2-chloro-4,6-bis(dipyrid-2-ylamino)-1,3,5-triazine (cddt) and 2,4,6-tris(dipyrid-2-ylamino)-1,3,5-triazine (tdt).

[*cis*-Fe(ddpp)$(NCS)_2$]$_2$·4$(CH_2Cl_2)$ [ddpp = 2,5-bis(dipyrid-2-ylamino)pyridine], which undergoes a two-step spin crossover influenced by the number and type of solvent molecules present.[4] This material uniquely shows structural resolution of a "trapped" [HS-LS] state dinuclear complex (HS = high spin, LS = low spin). Here, we present a new series of 1D polymeric species containing the ligand cddt, $[Fe(NCS)_2(cddt)]\cdot 1/2(CHCl_3)\cdot(H_2O)$ (**1a**), the polymorphs $[Fe(NCS)_2(cddt)]\cdot 2(CH_3OH)$ (**1b** and **1c**) and $[Fe(NCSe)_2(cddt)]\cdot 2(CH_3OH)$ (**2**). **1c** undergoes a half spin crossover and **2** undergoes a complete spin crossover. We also report a series of dinuclear materials similar to those reported by Gamez et al.[1–2] containing the ligand tdt, $[Fe(tdt)(Cl)]_2(ClO_4)_2\cdot(C_2H_5OH)\cdot 2(CHCl_3)$ (**3a**) and $[Fe(tdt)(H_2O)]_2(ClO_4)_4\cdot 6(H_2O)$ (**3b**), and a series of dinuclear complexes containing the ligand cddt, $[Fe(cddt)(H_2O)Cl]_2(ClO_4)_2\cdot 2(C_2H_5OH)\cdot(H_2O)$ (**4a**), $[Fe(cddt)(H_2O)Cl]_2(BF_4)_2\cdot 2(C_2H_5OH)\cdot 2(H_2O)$ (**4b**), $[Co(cddt)(H_2O)Cl]_2(BF_4)_2\cdot 2(C_2H_5OH)\cdot 2(H_2O)$ (**4c**) and $[Fe(cddt)(NCCH_3)(H_2O)]_2(ClO_4)_4\cdot(NCCH_3)$ (**4d**). All attempts to incorporate the tdt ligand into polymeric iron(II) systems have thus far resulted in the formation of the monomeric spin crossover material reported by Gamez et al.[1–2]

Structural analysis on two-step/half spin crossover materials reveal that there are two ways which the octahedral environments of the iron(II) centres can be observed at the plateau temperature below the transition temperature. Firstly, it can be observed as an average Fe–N bond length between HS and LS where there is no ordering (trapping) of the LS and HS states, and secondly, as two crystallographically distinct iron(II) centres where 50% are HS and 50% LS (indeed these are the same possibilities for systems where a half spin crossover is observed). The former is by far the most commonly observed and much effort is currently being invested in understanding the two modes of crossover, in particular for dinuclear systems where two-step and half crossovers are commonly observed.[3–7] In the case of polynuclear systems, there have been relatively few examples where two-step spin crossovers are observed[8,19] and few have shown ordering of HS and LS iron(II) at the plateau region of the temperature between the two spin transitions. Here, the polymeric material $[Fe(cddt)(NCS)_2]\cdot 2(CH_3OH)$ (**1c**) undergoes a spin crossover and, at low temperatures, alternating HS and LS iron(II) centres have been observed for the first time in a 1D chain.

Initially, the present polynuclear iron(II) systems were synthesised with the intention of observing the magnetic influence of incorporating dpa style ligands into extended materials. However, the unexpected synthesis of three different crystalline phases of **1**, $[Fe(cddt)(NCS)_2]\cdot 1/2(CHCl_3)\cdot(H_2O)$ (**1a**) and $[Fe(cddt)(NCS)_2]\cdot 2(CH_3OH)$ (**1b** and **1c**), of which two are polymorphs, presents one of the first cases of polymorphism in a polymeric SCO species and as such offers a valuable opportunity to directly compare intra- and intermolecular structural effects on materials where metal centres are linked. There have been two previous reports of polymorphism in polymeric spin crossover materials, namely, $\{Fe(pmd)_2[Ag(CN)_2]_2\}$ (pmd = pyrimidine) and $\{Fe(3\text{-}CNpy)[Au(CN)_2]_2\}\cdot n(H_2O)$ (3-CNpy = 3-cyanopyridine).[20,21] The majority of reports of polymorphism have been in mononuclear iron(II) species,[22–26] in particular, the compounds [*cis*-$Fe(phen)_2(NCS)_2$][22] and [*cis*-$Fe(bipy)_2(NCS)_2$][23] (phen = 1,10-phenanthroline, bipy = 2,2-bipyridyine) exist as polymorphs and have received a large amount of interest over many years. More recently, the material $[Fe(dppa)_2(NCS)_2]$ [dppa = (3-aminopropyl)bis(pyrid-2-ylmethyl)amine] was reported[25] which forms as three crystallographically distinct polymorphs; **A**: triclinic, **B**: monoclinic and **C**: orthorhombic. The **A** phase displayed a gradual SCO, the **B** phase remained high spin and the **C** phase had an abrupt SCO with hysteresis and structurally it was tentatively explained in terms of the presence of an array of intermolecular contacts in **C** that led to more cooperativity. Guionneau et al.[26] have further investigated the structural features between two polymorphs of the compound $[Fe(PM\text{-}BiA)_2(NCS)_2]$ (PM = *N*-pyrid-2-ylmethylene and BiA = 4-aminobiphenyl) that crystallised in the same symmetry, however, they displayed gradual and abrupt spin transitions, respectively. They found a direct correlation between the abruptness of a transition and a set of structural parameters that reflected the inter- and intramolecular interactions. While it is now clearly established that intermolecular interactions, such as hydrogen bonding and π-π interactions influence spin transitions, it appears that, from one chemical example to the next, little correlation exists. Certainly, for spin crossover materials to become useful in devices, understanding the governing factors that drive cooperativity is very important. In this context, the present study compares the structural features of a series of poly-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

meric spin crossover materials which reveal the presence of π-π interactions to be the primary characteristic influencing the spin transition.

## Results and Discussion

### Syntheses

In synthesising the 1D complexes $[Fe(NCS)_2(cddt)]\cdot n(guest)$ (**1**) [guest: $1/2(CHCl_3)(H_2O)$ for **1a**, $2(CH_3OH)$ for **1b** and **1c**] direct addition of $Fe(NCS)_2$ to cddt in the relevant solvent systems, resulted in immediate precipitation of yellow powders. In order to obtain structural information, single crystals of each phase were grown by slow diffusion techniques by using a vial for multiple solvent systems and a H-shaped tube for single solvent systems. For the materials **1b** and **1c** it was found that by using 2:4:1 ratios of Fe:NCS:cddt crystals of both phases grew together. By altering the Fe:NCS:cddt ratio to 1:2:1 it was found that that crystals of the spin crossover material **1c** could be grown with only a ca. 10% impurity of the **1b** phase. Furthermore, allowing the slow diffusion of **1c** to proceed at <5 °C the **1c** phase formed in isolation. Crystals of **1b** formed as light yellow blocks whereas crystals of **1c** formed as dark yellow-orange clumps of inter-grown crystals.

The synthesis of the dinuclear complex $[Fe(tdt)(Cl)]_2(ClO_4)_2\cdot(C_2H_5OH)\cdot 2(CHCl_3)$ (**3a**) containing the ligand tdt was carried out by slow diffusion methods in a H-tube. Single crystals of **3a** contain bound $Cl^-$, however, the synthesis was not carried out in the presence of chloride ions. Three possible chloride ion sources are; trace amounts from the tdt ligand synthesis, $Fe(ClO_4)_2\cdot 6(H_2O)$ and chloroform solvent. Gamez et al.[2] commented, in their synthesis of the analogous material, that the addition of stoichiometric amounts of chloride salt reduced the product yield compared to limited amounts, here whichever the chloride source is, it would be in small amounts and potentially drive the formation of the observed dinuclear. In addition, the synthesis of **3a** was carried out in the presence of $NaNCBH_3$, intended to be bound to the metal via the terminal nitrogen group, but has not been incorporated in the dinuclear material. Microanalysis of **3a** revealed a hydrated product.

The synthesis of the dinuclear complex $[Fe(tdt)(H_2O)]_2(ClO_4)_4\cdot 6(H_2O)$ (**3b**) was carried out in a mixed solvent system of methanol and acetonitrile, in air. Structural analysis revealed water molecules to be both bound to the metal, and as a solvate, and would originate from the solvent methanol and the metal salt.

The syntheses of dinuclear complexes containing the ligand cddt, $[Fe(cddt)(Cl)(X)]_2\cdot(Y)_2\cdot n(solvent)$ (X: $H_2O$ or $NCCH_3$, Y: $ClO_4^-$, $BF_4^-$ **4a**, **4b** and **4d**) and $[Co(cddt)(Cl)(H_2O)]_2\cdot(BF_4)_2\cdot n(solvent)$ (**4c**), as with **3a** did not contain any free $Cl^-$. The possible chloride ion sources are; trace amounts from the cddt ligand synthesis, from decomposition of the ligand and, for **4a**, from $Fe(ClO_4)_2\cdot 6(H_2O)$. While it is unclear where the chloride salt arises from it is likely from the cddt ligand. Microanalysis revealed hydrated species for each of these materials.

### Magnetic Studies

The complex **1a** remains high spin over all temperatures and the $\chi_M T$ vs. temperature plot is shown in Figure S11 (see Supporting Information). The $\chi_M T$ values remain constant at 3.29 $cm^3 mol^{-1}$ K down to ca. 15 K, followed by a small decrease due to a combination of weak antiferromagnetic coupling and zero field splitting. A sufficient amount of sample of **1b** for carrying out magnetism studies was unfortunately not obtained, as it grows as an impurity in the synthesis of **1c**, and, as such, no magnetic measurements were made on this phase. However, the crystal structure of **1b** at 123(2) K revealed all iron(II) centres to be in the high spin state, and upon quench cooling of the sample in liquid nitrogen, no colour change occurred in the yellow crystals, indicating that a spin transition probably did not occur.

Plots of $\chi_M T$ vs. temperature for polycrystalline samples of **1c** and **2** are shown in Figure 2. Compound **1c** undergoes an incomplete spin crossover with what appears to be a subtle, two-step nature. At temperatures above 240 K the material is in the fully high spin state with a maximum $\chi_M T$ of 3.38 $cm^3 mol^{-1}$ K. Between 240 and 200 K there is a gradual drop in $\chi_M T$ to ca. 2.66 $cm^3 mol^{-1}$ K. Below 200 K the transition becomes even more gradual with a lowest $\chi_M T$ of 1.64 $cm^3 mol^{-1}$ K attained below 70 K, which corresponds to 50% of the iron(II) centres being in the high spin state. From 200 K to low temperatures, slow kinetics or a structural effect may prevent the completion of the spin transition.

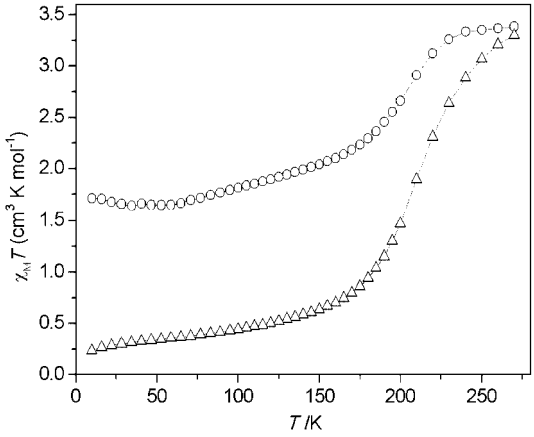

Figure 2. $\chi_M T$ vs. temperature for $[Fe(NCS)_2(cddt)]\cdot 2(CH_3OH)$ (**1c**) (o) and $[Fe(NCSe)_2(cddt)]\cdot 2(CH_3OH)$ (**2**) (Δ).

The selenocyanate analogue **2**, undergoes a full one-step spin crossover with a $T_{1/2}$ of ca. 220 K. At 270 K, a $\chi_M T$ value of 3.29 $cm^3 mol^{-1}$ K is attained corresponding to the majority of iron(II) centres being in the high spin state. The $\chi_M T$ values have not reached the LS plateau as between 270 and 170 K there is a gradual decrease in $\chi_M T$. Below 170 K

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a plateau $\chi_M T$ value of 0.23 $cm^3 mol^{-1}$ K is observed corresponding to all the iron(II) centres being in the low spin $t_{2g}^6$ state. The non-zero magnitude of $\chi_M T$ at low temperature is a common occurrence in iron(II) spin crossover LS states and is due to second order Zeeman effects. No thermal hysteresis occurred in either **1c** or **2**.

The $T_{1/2}$ values observed for **1c** and **2** are similar in size to that observed by Gamez et al.[1,2] for Fe(dpyatriz)$_2$(NCS)$_2$, ca. 200 K. Each of these materials contains the *trans*-Fe(DPA)$_2$(NCS)$_2$ coordination environment and the similar $T_{1/2}$ values and lack of abrupt transitions and thermal hysteresis suggest that incorporation into a polymeric, covalently linked species does not increase the communication between spin crossover centres. Further detailed structural comparisons of the materials are discussed below.

The dinuclear compounds **3a**, **3b**, **4a**, **4b**, **4c** and **4d** contain iron(II) and cobalt(II) coordination environments that involve $Cl^-$ and $H_2O$ groups and are thus expected to be HS-HS. Some interesting magnetic results were reported, however, for dinuclear systems by Gamez et al.[1] For example, [Fe(tdt)(NCCH$_3$)(H$_2$O)]$_2$(ClO$_4$)$_4$ displayed a gradual, partial spin crossover with a $T_{1/2}$ of ca. 280 K. This is unusual for iron(II) [FeN$_5$O] coordination environments. The replacement of acetonitrile by $H_2O$ by exposure to air led to HS-HS magnetic behaviour, as expected, and similar to that noted for [Fe(tdt)(H$_2$O)(CH$_3$OH)]$_2$(BF$_4$)$_4$, also having [$Fe^{II}N_4O_2$] coordination.[1] A very small $J$ value of –0.37 $cm^{-1}$ was obtained for the latter, possibly with a zero-field splitting parameter of ca. 4 $cm^{-1}$, rather than $J$, being responsible for the rapid decrease in $\mu_{eff}$ being observed below 50 K.

Interestingly, the triazine *N*-bonded example [Fe(tdt)(Cl)]$_2$(CF$_3$SO$_3$)$_2$ was reported to show weak ferromagnetic coupling between the $S$ = 2 $Fe^{II}$ centres.[1] However, care has to be taken to exclude crystallite torquing effects as being the cause of increases in $\mu_{eff}$ in such $^5T_{2g}$ (parent) single-ion states and dispersal of the powder in Vaseline is the way to check for such effects. The magnetic behaviour of the present analogue [Fe(tdt)(Cl)]$_2$(ClO$_4$)$_2$·(C$_2$H$_5$OH)·2(CHCl$_3$) (**3a**) unfortunately could not be measured due to insufficient and impure amounts of bulk sample.

The cddt analogue [Fe(cddt)(NCCH$_3$)(H$_2$O)]$_2$(ClO$_4$)$_4$·(CH$_3$CN) (**4d**) contains the same iron(II) [FeN$_5$O] coordination environment as [Fe(tdt)(NCCH$_3$)(H$_2$O)]$_2$(ClO$_4$)$_4$ which, as discussed above, undergoes a gradual SCO. Here, the complex **4d** remains HS over all temperatures and the $\chi_M T$ vs. temperature plot is shown in Figure S12. The $\chi_M T$ values remain constant at 3.49 $cm^3 mol^{-1}$ K down to ca. 15 K, followed by a small decrease due to a combination of weak antiferromagnetic coupling and zero field splitting.

## One-Dimensional Chain Complexes

### *General. [Fe(NCS)$_2$(cddt)]·n(guest) (1)*

Crystal data and refinement details for the complexes **1a**, **1b** and **1c** can be found in Table 2. Three crystallographically distinct materials of the general formula [Fe(NCS)$_2$(cddt)]·*n*(guest) (**1**) have been synthesised and crystallised by slow diffusion techniques. All three phases are composed of one-dimensional (1D) chains which differ in their crystal packing and the number and type of solvent molecules. The general structures of **1a**, **1b** and **1c** are the same. However, as seen above, these three phases display vastly different magnetic properties [see part (a) of Figure 2 and Figure S11 in the Supporting Information]; **1a** and **1b** are HS and **1c**

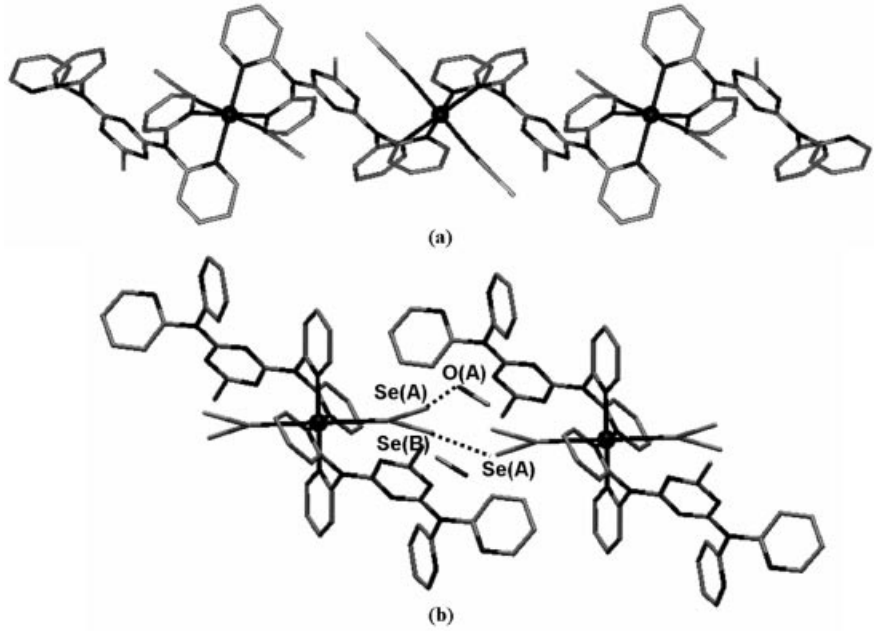

Figure 3. The general polymeric 1D chain structure observed in the materials (a) **1a**, **1b**, **1c** and (b) **2** illustrating the A and B positions of the disordered selenium atoms, the Se(A)···Se(B) interactions between adjacent chains and the Se(A)···O interactions are shown with dotted lines. Iron(II) centres are shown as black spheres, hydrogen atoms have been omitted.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

undergoes a spin transition. The iron(II) environments and extended structure of these materials are, nevertheless, isostructural. These systems are highly relevant for making structural comparisons in order to attempt to determine both the intra- and inter-chain structural influence on the magnetism.

$[Fe(NCS)_2(cddt)]\cdot 1/2(CHCl_3)\cdot(H_2O)$ (**1a**) is grown as a pure crystalline phase by slow diffusion in methanol and chloroform. The two phases **1b** and **1c** are polymorphs, $[Fe(NCS)_2(cddt)]\cdot 2(CH_3OH)$, and grow simultaneously but they differ in their crystal symmetries (**1b**: monoclinic and **1c**: triclinic); **1c** is the major product. By subtle variation in the stoichiometry of reactants, **1c** can be grown in isolation, as indicated above. There have previously been in-depth studies into understanding the differences in spin crossover behaviours observed in polymorphic species;[20–24] here we will continue this, further, through detailed structural comparisons between each of the materials **1b** and **1c**.

All three phases, **1a**, **1b** and **1c** consist of iron(II) coordinated by *trans*-thiocyanate ligands bound through the terminal nitrogen and two half cddt ligands, the full ligands generated by symmetry [Figure 3 (a)]. The cddt ligands bridge two metal centres, binding via the terminal pyridyl groups of the bis(2-pyridyl)amine moiety. Each alternate ligand is rotated *ca*. 180° such that the triazine chlorine atom is directed up or down. This extends to form infinite 1D chains. Following are detailed structural descriptions of each of the three phases of **1**. The octahedral distortion parameter $\Sigma$ has been calculated for each of the materials **1a**, **1b** and **1c**, smaller $\Sigma$ values are associated with stronger crystal fields and stabilisation of the LS state.[27]

### *[Fe(NCS)$_2$(cddt)]·1/2(CHCl$_3$)·(H$_2$O) (1a)*

Structural analysis of **1a** revealed a tetragonal symmetry with all iron(II) centres equivalent and with Fe–N distances typical of the HS iron(II) state (Table 1). The 1D chains are stacked parallel and run along the *c*-axis [Figure 4 (a)]. In the *ac*- and *bc*-planes the adjacent 1D chains are rotated by 90° [Figure 5 (a)]. Located between the chains are two types of alternating 1D channels along the *c*-axis which account for 23.4% of the unit cell volume [Figure 4 (a)]. The first type of channel is lined by the chlorine atoms from the cddt ligand and is filled with chloroform molecules. The second type of channel is lined by aromatic ligand rings and is filled by a 1D chain of water molecules. Neither the water or chloroform molecules interact with the 1D chains. It was surprising that since this material was synhesised in a mixed solvent system consisting of methanol and chloroform, no

Table 1. Selected bond lengths for **1a**, **1b**, **1c** and **2** obtained at 123 K.

| Bond [Å] | **1a** | **1b** | **1c** | **2** |
|---|---|---|---|---|
| Fe(1)–N(CS) | 2.083(9) | 2.082(9) | 1.953(5) | 1.969(5) |
| Fe(1)–N(py) | 2.223(9) | 2.232(7) | 1.995(4) | 2.007(4) |

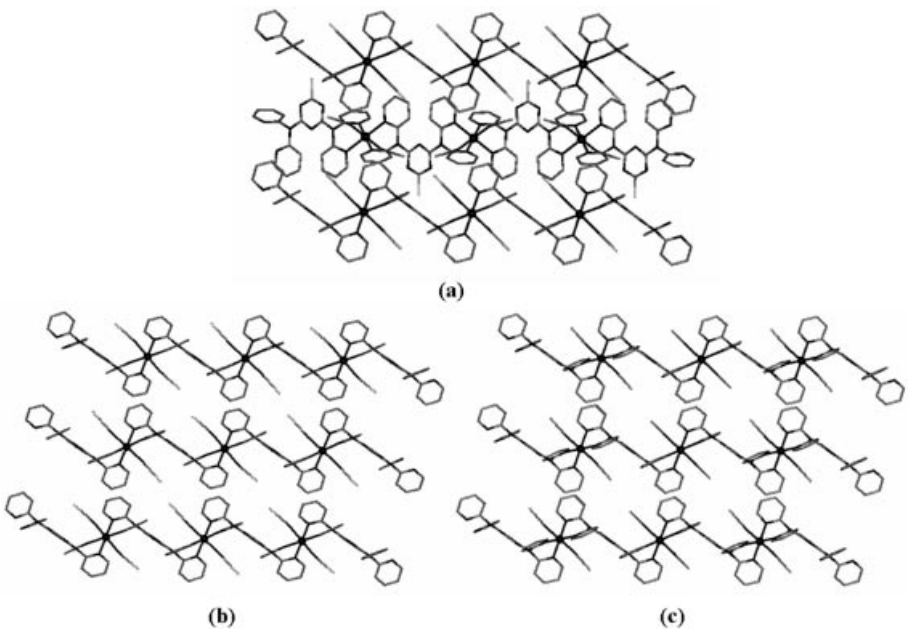

Figure 5. Illustration of the crystal packing of adjacent 1D chains in the *ab*-plane (a) **1a** (b) **1b** and (c) **1c**. Hydrogen atoms and solvent molecules have been omitted. Iron(II) atoms as black spheres and 1D chains as sticks.

methanol has been incorporated into the crystalline material. The chlorine atoms on the cddt ligand are involved in Cl···Cl interactions with adjacent chains [Cl···Cl: 3.204(10) Å]. Analysis of the geometry of the iron(II) centre revealed an octahedral distortion parameter $\Sigma$ of 45.6° which is comparable to other $[Fe(N)_4(NCS)_2]$ centres in the HS state.[4,18,27] The Fe···Fe separation within each chain is 9.345(3) Å and this is similar to that between chains 9.258(2) Å.

### *[Fe(NCS)$_2$(cddt)]·2(CH$_3$OH) (1b)*

The complex **1b** has different stacking of the 1D chains to that seen in both **1a** and **1c** [Figure 4 (b)]. Structural analysis of **1b** revealed a monoclinic symmetry with two iron(II) centres in the asymmetric unit which are both in the HS state at 123(2) K with average Fe–N bond lengths for Fe1 and Fe2 of 2.176(6) and 2.169(5) Å, respectively (Table 1). There are two crystallographically distinct thiocyanate ligands in the asymmetric unit; the sulfur atom of the thiocyanate ligand bound to Fe1 is disordered over two sites, **A** and **B** (Figure S2). The 1D chains are parallel packed in the *ab*-plane, where adjacent chains within the same *ab*-plane are generated by a translation along either the *a*- or *b*-axis [Figure 5 (b)]. The chains in the next *ab*-plane are rotated by 90° [Figure 4 (b)]. The Fe···Fe separation within each chain is 9.584(6) Å and smaller between chains, 8.717(6) Å. There are two solvent methanol molecules present in the asymmetric unit; one of the methanol molecules is hydrogen bonded to a sulfur atom of the **A** component of the disordered thiocyanate ligand [O2···S2A: 3.193(3) Å, Figure 5]. This thiocyanate ligand is also involved in a S···S interaction with its symmetry equivalent atom on an adjacent chain [S2A···S2A: 3.029(11) Å]. Neither the **B** component of the other thiocyanate ligand are involved in any significant O···S or S···S interactions. The most obvious distinction between the two iron(II) centres in the asymmetric unit is their hydrogen bonding interactions. However, further analysis of the metal centre geometries revealed that the iron(II) centre involved in the hydrogen bonding interaction, Fe1, is in a less distorted octahedral environment than is the other iron(II) centre, Fe2, thus, $\Sigma$(Fe1): 34.4 and $\Sigma$(Fe2): 44.8°.[27] The distortion parameter of Fe1 is considerably lower than Fe2 which is often indicative of the LS state being stabilised. However, while we do not have magnetic data, both iron(II) centres are in the HS state down to 123 K. The average Fe–N bond lengths for both Fe1 and Fe2 are indicative of high spin iron(II). Notably, the Fe2–N(CS) bond length is 2.108(8) Å, which is longer than the ca. 2.0 Å usually observed for iron(II). It is well known that weak intermolecular interactions can strongly influence the observed spin crossover features,[26] comparison of such features with **1c** will be discussed in the following section.

### *[Fe(NCS)$_2$(cddt)]·2(CH$_3$OH) (1c)*

Structural analysis of **1c** at 123(2) K revealed a triclinic symmetry with two iron(II) centres in the asymmetric unit [Figure 4 (c)]. At 123(2) K, Fe1 is in the LS state and Fe2 is in the HS state with average Fe–N bond lengths of 1.983(3) and 2.171(4) Å, respectively (Table 1). This is a most unusual situation to have alternating HS and LS centres along the chains. In contrast, a recent iron(III) 1D system has been reported which contains isolated alternating HS and LS chains.[29]

The 1D chains in **1c** run along the *c*-axis, where adjacent chains are generated by a translation along either the *a*- or

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

*b*-axis as seen in **1b** [Figure 5 (c)]. In contrast to **1b**, all of the 1D polymer chains in **1c** run in the same direction, i.e., along the *c*-axis [Figure 4 (c)]. The Fe···Fe separation within each chain is 9.512(3) Å and between chains is 8.818(4) Å, which is similar to that observed for **1b**. There are two solvent methanol molecules present per metal centre and one of these molecules is hydrogen bonded to a sulfur atom of a thiocyanate [O2···S1: 3.267(5) Å]. In addition, there is a π-π interaction between a pyridyl ring coordinated to Fe1 and its symmetry generated ring on an adjacent chain, 3.699(2) Å. One of the pyridyl rings attached to Fe2 is also in the correct orientation for a π-π interaction with its symmetry equivalent however the distance of 4.699(2) Å is too long to be a significant interaction. It is well known that intramolecular π-π interactions influence spin transitions[28] and indeed the presence of such interactions in **1c**, but not in **1b**, is likely to determine whether spin crossover behaviour will be observed.

As discussed above, smaller octahedral distortion parameters generally suggest a more stabilised LS state.[27] Further analysis of the geometries of the two metal centres in **1c** revealed that the iron(II) centre involved in this hydrogen bonding interaction is in a less distorted octahedral environment than the other iron centre, $\Sigma$(Fe1): 32.28 and $\Sigma$(Fe2): 42.76° which has been observed previously for materials in an intermediate [HS-LS] state.[4,18,27] Interestingly, $\Sigma$ is comparable for Fe1 and Fe2 in **1b** and **1c**, where only **1c** undergoes a spin transition. This suggests that the interplay between intermolecular interactions, as discussed above and metal coordination environments are influencing these systems greatly.

### *Variable-Temperature Powder X-ray Diffraction of 1c*

Some difficulties were encountered in preparing phase pure bulk sample of **1c**, such as required for SQUID magnetometry, with up to ca. 10% impurity of **1b** typically observed. Consequently, it was necessary to confirm the nature of the (two-step) spin transition identified in this way. This was achieved using variable-temperature diffraction methods whereby the structural perturbations accompanying the changes in Fe–N bond length associated with the spin transition are evident as pronounced changes in the lattice dimensions. Typically a contraction in unit cell volume of 10% is observed for a full transition from high to low spin. While this approach can be applied to both single crystal[4,8,26] and powdered samples,[30] the latter probes bulk samples allowing the temperature dependence of lattice parameters of individual phases to be monitored and the component(s) undergoing structural transitions to be identified. Moreover, crystals of **1c** are typically twinned which would complicate single-crystal studies.

Here, variable temperature powder diffraction methods have been applied to study the structural and spin transition in **1c**. Powder diffraction data were collected at 3 K intervals upon cooling of the sample from 250 to 85 K, the temperature region in which the spin transition was observed. The lattice parameter of the majority phase was refined using a single phase Le Bail fit to the data (Figure S13) based on the crystal symmetry and lattice parameters determined in single crystal structural studies of **1c**.[40] The adequacy of the single phase refinement confirms the phase purity of the bulk sample used here.

The relative changes in the refined lattice parameters for **1c** upon cooling from 250 to 85 K are shown in Figure 6. Two sets of non-linear features evident in the temperature dependence of the lattice parameters for **1c** (at 250–200 K and ca. 125 K) support the two-step nature of the spin transition in this phase. The sharp contraction in the unit cell volume (ca. 2%) in the range 250–200 K correlates directly with the sharp decrease observed in the magnetic susceptibility at 250–200 K associated with a partial spin transition. This contraction was highly anisotropic, with different temperature dependent behaviour observed along the *a*-, *b*- and *c*-axes (Figure 6). A more gradual contraction in the unit cell volume (ca. 1.5%) occurs upon further cooling between 200 and 100 K, which corresponds to the second more gradual spin transition observed in the magnetic susceptibility. The magnitude of the volume contraction observed over the entire temperature range studied (ca. 3.5%), and those attributed to each step are consistent with the degree of spin transition indicated by the magnetic susceptibility measurements with a total volume contraction of 3–5% anticipated for this "half" spin-crossover phase. Although the intrinsic thermal expansion of the framework would also contribute to a contraction of the lattice with decreasing temperature, the non-linearity of the observed behaviour supports the existence of additional phenomena. This non-linearity is most evident for the individual cell axes. In particular, the *c*-axis, along which the 1D chains are oriented, is most directly sensitive to the spin transition and associated changes in the Fe–N bond length. This axis shows pronounced non-linear behaviour (a minimum) at ca.

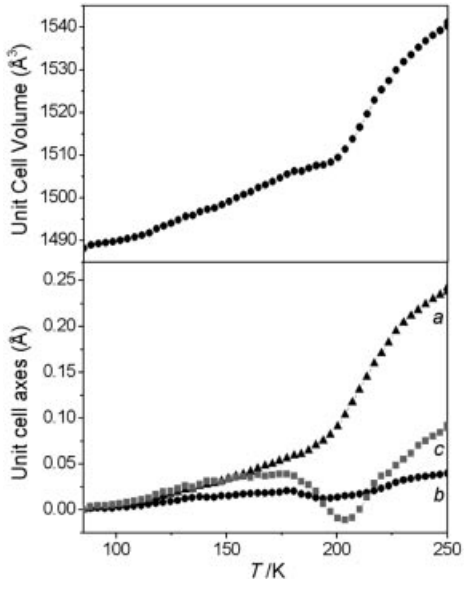

Figure 6. Unit cell volume (top) and axes (bottom) evolution vs. temperature for the spin transition in **1c** over the range 85–250 K obtained by synchrotron powder diffraction.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

200 K and a more subtle non-linearity at ca. 125 K. Non-linear thermal expansion behaviour was also evident along the *a*- and *b*-axes which is associated with the contraction of Fe–N bonds oriented in the *ab*-plane, and structural perturbations which propagate via intermolecular interactions including the π-π interactions present in this phase.

### *[Fe(NCSe)$_2$(cddt)]·2(CH$_3$OH) (2)*

Crystal data and refinement details of complex **2** can be found in Table 2. Structural analysis of **2** revealed a monoclinic symmetry, isomorphous to **1b**, with two iron(II) centres in the asymmetric unit. The selenocyanate sulfur atom attached to Fe2 is disordered over two crystallographically distinct sites, **A** and **B** (50:50 site occupancies). There is a Se···Se interaction between adjacent chains from the part **A** of the disordered selenocyanate to part **B** [Se···Se: 3.369(2), Figure 3 (b)]. The Se atoms associated with Fe1 are not involved in any interactions. There are two solvent molecules in the asymmetric unit, however one is only present 50% of the time and is associated with the **B** part of the disordered selenocyanate [Figure 3 (b)]. There are no π-π interactions present in this compound which is converse to the case in the thiocyanate analogue **1c**. The Fe···Fe separation within each chain is 9.330(2) Å and between chains is 8.988(2) Å, similar to that of **1b** and **1c**. Further analysis of the geometries of the two metal centres revealed octahedral distortion parameters for Fe1 and Fe2 of $\Sigma$: 30 and 26.04°, respectively.[27] Firstly, it can be seen that Fe1 is slightly more distorted than Fe2 in agreement with the presence of two crystallographically distinct metal centres in the asymmetric unit. Secondly, the distortion parameters for Fe1 and Fe2 are of the same magnitude and similar to the distortion parameter observed in **1c** for Fe1, i.e. 32.28°. Of great interest, here, is the large difference in octahedral distortion of the iron(II) centres between the isomorphous materials **1b** and **2**, which highlights the influence of the stronger ligand field of the $NCSe^-$ ligand. As discussed above, the π-π interactions observed in **1c** are thought to play a major role in influencing the spin transition, no such interactions are observed in **2**, however, the stronger ligand field strength of the $NCSe^-$ ligand compared to the $NCS^-$ ligand would contribute towards the spin state of iron(II) and the observed crossover in **2**.

## Dinuclear Fe$^{II}$ and Co$^{II}$ Complexes of tdt and cddt

### *General*

Crystal data and refinement details for the dinuclear complexes **3a**, **3b**, **4a**, **4b**, **4c** and **4d** are summarised in Table 3. **3a** and **3b** contain the ligand tdt and their two kinds of dinuclear structures have been reported recently by Gamez et al.,[1] differing only in the anion and solvent present and so will not be discussed here in detail. **4a**, **4b**, **4c** and **4d** contain the ligand cddt and consist of isostructural dinuclear moieties that differ in their metals, associated anions and solvents.

### *[Fe(tdt)(Cl)]$_2$(ClO$_4$)$_2$·(C$_2$H$_5$OH)·2(CHCl$_3$) (3a)*

The dinuclear complex **3a** consist of two iron(II) centres coordinated by two tdt ligand and two chloride ligands (Figure S5). The metal centres are in a distorted octahedral environment consisting of five Fe–N bonds from two tdt ligands, including a triazine N donor, and one terminal Fe–Cl bond. The average Fe–Cl and Fe–N bond lengths are 2.3386(18) and 2.2114(5) Å, respectively (Table S1), and correlated well with those of HS iron(II) and those reported by Gamez et al. for [Fe(tdt)(Cl)]$_2$·($CF_3SO_3$).[1] The iron(II) centres are in an extremely distorted octahedral environment illustrated by the octahedral distortion parameters of 66.65°.[27] The Fe···Fe separation within the dinuclear moiety is 8.384(2) Å.

### *[Fe(tdt)(H$_2$O)$_2$]$_2$(ClO$_4$)$_4$·6(H$_2$O) (3b)*

The dinuclear complex **3b** consists of two iron(II) centres coordinated by two tdt ligands and four terminal water molecules. The triazine nitrogen atoms do not coordinate. The average Fe–O and Fe–N bond lengths are 2.161(3) and 2.174(4) Å, respectively (Table S1), and correlated well with those of HS iron(II) and those reported by Gamez et al. for [Fe(tdt)($H_2O$)($CH_3OH$)]$_2$($BF_4$)$_4$.[1] Here, however, we observed the coordination of two water molecules rather than one water and one methanol by Gamez et al.[1] The Fe···Fe separation within the dinuclear molecule is 9.215(2) Å.

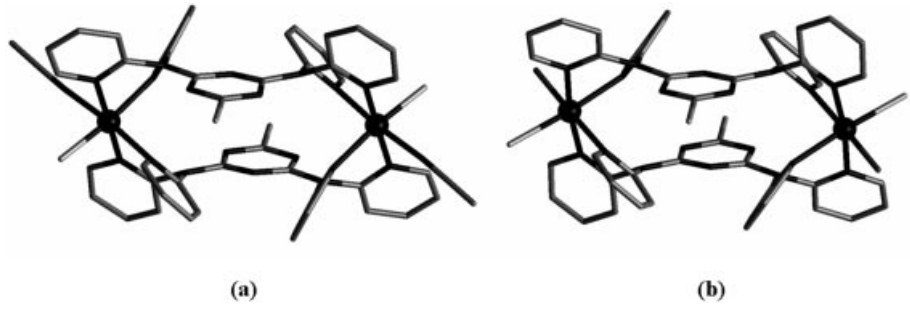

Figure 7. Structural representations of the dinuclear complexes containing the ligand cddt (a) **4a**, **4b**, **4c** and (b) **4d**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### *[M(cddt)(H$_2$O)Cl]$_2$(X)$_2$·n(C$_2$H$_5$OH, H$_2$O) [M: Fe, X: ClO$_4$ (4a), M: Fe, X: BF$_4$ (4b), M: Co, X: BF$_4$ (4c)]*

The dinuclear structures of **4a**, **4b** and **4c** generally consists of two metal(II) centres each in a distorted octahedral environment, two cddt ligands and terminal water and chlorine atoms [Figure 7 (a)]. Each cddt ligand is bound to two metal centres through both pyridyl groups of each di(pyrid-2-yl)amine, as seen in **3b**. The chlorine atoms of the cddt ligand are not involved in any interactions within the metal coordination sphere or any hydrogen bonding interactions. However, hydrogen bonding interactions are present between the metal coordinated chlorine atoms and the solvent water molecule [Cl···O: 3.149(4) (**4a**), 3.150(6) (**4b**) and F···O: 3.331(13) Å (**4c**)] and between the metal coordinated water molecules and the solvent ethanol [O···O: 2.703(5) Å (**4a**), 2.688(7) (**4b**) and 2.704(9) Å (**4c**)]. The Fe–N or Co–N bond lengths for each of these compounds are indicative of HS iron(II) or cobalt(II) (Table S1). The average Fe–Cl, Fe–O and Fe–N bond lengths for **4a** are 2.3954(13), 2.174(3) and 2.207(4) Å, respectively. The average Fe–Cl, Fe–O and Fe–N bond lengths for **4b** are 2.389(2), 2.164(5) and 2.206(5) Å, respectively. The average Co–Cl, Co–O and Co–N bond lengths for **4c** are 2.400(2), 2.136(5) and 2.160(6) Å, respectively. The Fe···Fe separations for **4a**, **4b** and **4c** within the dinuclears are 9.479(7), 9.459(9) and 9.351(5) Å, respectively.

### *[Fe(cddt)(NCCH$_3$)(H$_2$O)]$_2$(ClO$_4$)$_4$·(CH$_3$CN) (4d)*

The general structure of **4d** is a dinuclear complex that is isostructural to **4a**, **4b** and **4c**, however, the coordinated chloride atoms are replaced here by acetonitrile molecules bound through the terminal nitrogen [Figure 7 (b)]. **4d** crystallises in the monoclinic space group $P2_1/n$ whereas **4a**, **4b** and **4c** crystallise in the monoclinic space group $C2/c$ (Table 3), resulting in a different packing of the dinuclear units within their respective unit cells. The average Fe–O and Fe–N bond lengths are 2.123(2) and 2.173(2) Å, respectively, and are indicative of HS iron(II) (Table S1). This same coordination environment was observed for the dinuclear complex [Fe(tdt)(NCCH$_3$)(H$_2$O)]$_2$(BF$_4$)$_4$·(CH$_3$CN) reported by Gamez et al.[1] and was observed to undergo a one step spin transition. Here the Fe–N and Fe–O bond lengths are comparable, but we observed no spin crossover. The Fe···Fe separation within the dinuclear is 9.068(2) Å, this distance is shorter both to that observed in **4a** and **4b** and in [Fe(tdt)(NCCH$_3$)(H$_2$O)]$_2$(BF$_4$)$_4$·(CH$_3$CN).[1]

## Conclusions

Structural and magnetic studies of a range of polynuclear compounds using the dipyrid-2-ylamine containing ligands tdt and cddt have been carried out on a series of 1D polymers of the type [Fe(NCS)$_2$(cddt)$_2$]·*n*(guest) (**1a**, **1b**, and **1c**) and [Fe(NCSe)$_2$(cddt)$_2$]·*n*(guest) (**2**). A combination of such measurements has revealed the role of crystal packing and symmetry on the observed magnetic properties. Three crystal phases of **1** were obtained and exist in tetragonal (**1a**), monoclinic (**1b**) and triclinic (**1c**) symmetries, with only the triclinic phase displaying a thermally induced spin transition. Full structural comparisons of **1a**, **1b**, **1c** and **2** revealed very similar iron(II) coordination environments and extended 1D chain structures. Each of the compounds **1a**, **1b**, **1c** and **2** contain S···S or Se···Se interactions and solvent···S or Se hydrogen bonds, respectively. However, **1c** contains additional π-π interactions which are thought to be the major influence on the observed spin transition. The complex **2** does not contain any π-π interactions but undergoes a spin transition that is probably due to the increase ligand field strength of the NCSe$^-$ ligand compared to the NCS$^-$ ligand in **1c**.

**1c** displays a one-step half spin crossover with a slight two-step character at low temperatures. To differentiate between the presence of a second step or the possibility of sample impurity (due the possibly presence of three crystal phases), further structural characterisation was carried out by monitoring the unit cell evolution of **1c** at temperatures over the spin transition. All the crystals of **1c** grow twinned, hence single crystal techniques for this experiment were not viable so powder diffraction using synchrotron radiation was utilised. This technique has scope to be used, in future, to desolvate and resolvated powder samples, in situ, and monitor such influences on any spin transition observed.

The most celebrated iron(II) SCO chains are the triply-bridged 1,2,4-triazole complexes of type [Fe(4-R-1,2-triazole)$_3$](anion)$_2$.[31] These materials display abrupt spin transitions near to room temperature, with wide hysteresis widths, the $T_{1/2}$ and $\Delta T$ values varying with R and anion. No crystal structures have been obtained but they are assumed similar to the structurally characterised Cu$^{II}$ 1D species.[32] They would possibly benefit from synchrotron powder XRD measurements of the kind given in Figure 6 to ascertain their phase purity and to see if hysteresis occurred in the structural data. In comparison to the present 1D compounds [Fe(NCS)$_2$(cddt)$_2$]·*n*(guest), **1c** and [Fe(NCSe)$_2$(cddt)$_2$]·*n*(guest), **2**, the tris-triazole complexes form more rigid *facially* bridging motifs, with Fe···Fe separations less than in the cddt systems. On this basis, it would appear that such rigidity would favour the strong cooperativity noted, compared to the weak cooperativity observed here in the more flexibly-bridged cddt species. This still begs the question of how, as the HS to LS transition occurs, all the Fe$^{II}$ centres along the tris-$\mu$-triazole chains are able to structurally adjust to accommodate the smaller coordination spheres existing in the LS state, be it in "an all at once" or a sequential process. Such readjustment should be more facile in the present systems. The inter-chain effects upon the Fe$^{II}$ sites, modulated by anions or solvate molecules are, of course, very difficult to define.

Two dinuclear materials containing the ligand tdt have been structurally characterised that are isostructural to those recently reported by Gamez et al.[1] but with different counter anions and solvent molecules. Complex **3a** involves triazine N–Fe coordination, while complex **3b** does not. A similar series of dinuclear materials **4a**, **4b**, **4c** and **4d** containing the ligand cddt, of the **3b** structure type, have been

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structurally characterised and shown to contain the same general dinuclear structure but differ in their counter anions and solvent molecules. Each of the dinuclear compounds containing either tdt or cddt ligands were intended to have both a $FeN_6$ coordination sphere through incorporation of the *N*-donor ligand thiocyanate, and display spin transitions. However, even though such a situation is sterically possible it is apparent that coordination of chloride atoms and/or water molecules is much more favourable. In the paper by Gamez et al.[1] it was suggested that extended framework materials incorporating the ligand tdt were possible, however all attempts, here, to synthesise such materials, using $NCS^-$ as co-ligand, have resulted in the formation of the mononuclear spin crossover complex $Fe(NCS)_2(tdt)_2$ already reported.[2] The present direct synthesis contrasts with the report that it could only be made from dinuclear precursors.[2]

There are some interesting similarities and differences noted between the present dinuclear iron(II) compounds and the analogues described by Gamez et al.[1] If the effects of intermoleculear interactions in crystals are ignored, and the ligand-field around each iron(II) is assumed dominant, then the following conclusions can be made about the ligand-field and the spin state on the iron(II) centres. The complexes possessing a triazine N-donor $[Fe(tdt)(Cl)]_2(ClO_4)_2{\cdot}(C_2H_5OH){\cdot}2(CHCl_3)$ (**3a**) here, and the complex $[Fe(tdt)(Cl)]_2(CF_3SO_3)_2$ in Gamez et al.,[1] have a $[FeN_5Cl]$ coordination set and are both HS-HS. The other dinuclear type, not displaying triazine coordination are $[Fe(cddt)(NCCH_3)(H_2O)]_2(ClO_4)_4{\cdot}(CH_3CN)$ (**4d**) and the complex $[Fe(tdt)(NCCH_3)(H_2O)]_2(ClO_4)_4$ in Gamez et al.,[1] both with $[Fe_5NO]$ coordination. The SCO behaviours observed in the tdt system contrasts with the HS-HS behaviour in **4d** and, thus, tdt provides a stronger ligand-field contribution than does cddt.

## Experimental Section

**General:** All the reagents and solvents were used as commercially available and used as received. The ligands tdt and cddt were prepared by literature methods.[33] Infrared spectra were recorded on single crystals mounted on a Low-e microscope slide using a Varian FTS7000 FT-IR spectrometer with a VMA600 microscope in reflectance mode. CHN analyses were performed by Campbell Microanalytical Laboratory, Department of Chemistry, University of Otago, Dunedin, New Zealand.

**Magnetic Susceptibility Measurements:** Magnetic susceptibility data were collected using a Quantum Design MPMS 5 SQUID magnetometer under an applied field of 1 T. The powder samples were placed in a quartz tube and great care was taken to avoid any solvent loss and/or torquing of crystallites of these potentially anisotropic HS iron(II) species, the latter by dispersal of the powder in a Vaseline mull. Care was also taken to allow long thermal equilibration times at each temperature point.

**Crystallographic Data Collection and Refinement (Tables 2 and 3):** Crystallographic data and parameters for all materials are summarised in Tables 2 and 3. Single crystal diffraction data for all structures were collected on a Bruker APEX X8 diffractometer using Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) radiation and equipped with an Oxford Instruments nitrogen gas cryostream. Crystals were mounted on a MiTeGen MicroMounts fibre in a small amount of oil. Crystals were quench-cooled to 123(2) K for all data sets.

Diffraction data analysis was performed using SAINT+ within the APEX2 software package.[34] Empirical absorption corrections were applied to all data using SADABS.[35] The structures were solved using SHELXS and refined using SHELXL-97 within WINGX.[34,36] All non–hydrogen atoms in the structures were refined anisotropically and hydrogen atoms were generated using the riding model. The data set for the material **1c** was merohedrally twinned over two orientations related by a 179.9° rotation about the reciprocal axis 010. Initial indexing for the two components was carried out using CELL NOW within the APEX2 software package.[34] Multi-component integration was carried out using SAINT+.[34] Scaling and empirical absorption corrections were then applied using TWINABS.[34] The structure was solved as above using a HKLF 5 command with a resulting BASF parameter of 0.3477.

CCDC-625487 to -625496 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

**Powder Synchrotron X-ray Diffraction:** A pulverised sample of $[Fe(NCS)_2(cddt)]\cdot 2(CH_3OH)$ (**1c**) was loaded in a polyimide capillary of 0.8 mm diameter and kept in an inert helium atmosphere for the duration of the experiments.[37] The X-rays (20.02 keV, 0.61915 Å) available at the 1-BM beamline at the Advanced Photon Source at Argonne National Laboratory were used in combination with a MAR-345 imaging plate (IP) detector to record diffraction patterns. The sample temperature was controlled using an Oxford Cryosystems Cryostream 700 and data were collected in 1 s exposures upon continuous cooling from 250 K to 85 K at 100 Kh$^{-1}$. This corresponds to the collection of diffraction images at 3 K intervals. The raw images were processed using Fit-2D.[38–39] The sample-to-detector distance and tilt of the IP relative to the beam were refined using a $LaB_6$ standard. Le Bail analyses of the variable-temperature diffraction data were performed within GSAS.[40] Details of the refinements are included in the Supporting Information.

**$[Fe(cddt)(NCS)_2]\cdot 1/2(CHCl_3)\cdot(H_2O)$ (1a):** A 5 mL solution of cddt (45 mg, 0.1 mmol) in chloroform was placed at the base of a test tube onto which an 8 mL 50:50 mixture of methanol/chloroform was carefully layered. A 5 mL solution of $Fe(ClO_4)_2\cdot 6(H_2O)$ (25 mg, 0.1 mmol) and NaNCS (16 mg, 0.2 mmol) in methanol was then layered on-top and the test tube stoppered. After two weeks bright yellow needle shaped crystals formed (61 mg, 88%). IR: ν = 3445 (br), 2062 (s), 1604 (m), 1554 (m), 1466 (s), 1261 (m), 658 (w). $C_{51}H_{32}Cl_5Fe_2N_{22}O_2S_4$ (1402): calcd. C 39.97, H 2.71, N 19.72; found C 39.69, H 3.15, N 17.85.

**$[Fe(cddt)(NCS)_2]\cdot 2(CH_3OH)$ (1b):** A 2 mL solution of cddt (22 mg, 0.05 mmol) in methanol was placed at the base of one arm of an H-shaped tube. A 2 mL solution of $Fe(ClO_4)_2\cdot 6(H_2O)$ (25 mg, 0.1 mmol) and NaNCS (16 mg, 0.2 mmol) was placed in the other arm of the H-shaped tube. Solvent methanol was carefully layered to fill the tube, which was then stoppered. After one week yellow block shaped crystals formed (yield: unknown forms as a mixed product with **1c** ca. 10%). IR: ν = 3440 (br), 2063 (s), 1598 (m), 1550 (m), 1465 (m), 1264 (m), 668 (w).

**$[Fe(cddt)(NCS)_2]\cdot 2(CH_3OH)$ (1c):** A 2 mL solution of cddt (45 mg, 0.1 mmol) in methanol was placed at the base of one arm of an H-shaped tube. A 2 mL solution of $Fe(ClO_4)_2\cdot 6(H_2O)$ (25 mg, 0.1 mmol) and NaNCS (16 mg, 0.2 mmol) was placed in the other arm of the H-shaped tube. Solvent methanol was carefully layered to fill the rest of the tube, which was then stoppered. After one week yellow block shaped crystals formed (60 mg, 87%). IR: ν = 3440 (br), 2057 (s), 1603 (m), 1552 (m), 1399 (s), 1229 (m), 670 (w). $C_{27}H_{24}ClFeN_{11}O_2S_2$ (689): calcd. C 47.9, H 2.58, N 24.62; found C 47.6 H 2.73, N 24.48.

**$[Fe(cddt)(NCSe)_2]\cdot 2(CH_3OH)$ (2):** A 5 mL solution of cddt (45 mg, 0.1 mmol) in methanol was placed at the base of one arm of an H-tube. A 2 mL solution of $Fe(ClO_4)_2\cdot 6(H_2O)$ (25 mg, 0.1 mmol) and

# Synthesis and Characterization of Novel Titanium, Germanium, and Tin Silazane Complexes Bearing a Cyclohexasilazanetriido Ligand

Christian Lehnert,[a] Jörg Wagler,[a] Edwin Kroke,[a] and Gerhard Roewer*[a]

**Keywords:** Heterometallic complexes / N ligands / Titanium / Germanium / Tin / Cyclohexasilazane complexes

Novel heterometallic silazane complexes were synthesized by the reaction of 1-lithio-2,2,4,4,6,6-hexamethylcyclotrisilazane Li(HMCTS)$H_2$ with the tetrachloride salts of titanium and germanium as well as by the reaction of 1,1,3,3,5,5-hexamethylcyclotrisilazane $H_3$(HMCTS) with tin tetrachloride and excess triethylamine. The products [$H_3$(DMCHS)TiCl] (**1**), [$H_3$(DMCHS)GeCl] (**2**), and [$H_3$(DMCHS)SnCl] (**3**) {$H_3$(DMCHS) = 2,2,4,4,6,6,8,8,10,10,12,12-dodecamethylcyclohexasilazane-1,5,9-triido} were characterized by $^1$H-, $^{13}$C-, $^{14}$N-, and $^{29}$Si NMR spectroscopy, elemental analyses and single-crystal X-ray structure analyses. The complexes have a surprising and interesting structure, that of a new dodecamethylcyclohexasilazane system with the Ti, Ge, or Sn atom in the center. These metal atoms are coordinated by one chlorine atom and three nitrogen atoms. The metal centers are part of three six-membered hetero-silazane rings.

## Introduction

Silazanes offer promising ligand properties in reactions with metal chlorides because of their reactive N–H and Si–N bonds.[1–3] Especially, the cyclic silazane 1,1,3,3,5,5-hexamethylcyclotrisilazane $H_3$(HMCTS) shows striking reactivity patterns. In addition to substitution reactions, isomerizations of the cyclotrisilazane system into cyclodisilazanes and ring coupling reactions were observed, which led to an assortment of structurally diverse compounds.[4–10]

Silazanes are widely used as precursors for silicon-based non-oxide ceramic materials with outstanding thermal, mechanical, and chemical properties, which make them uniquely applicable under extreme conditions.[11–13] Furthermore, silazane derivatives of Ti, Zr, Fe, B, Al, and Ge are used for the synthesis of multinary ceramics. The incorporation of these elements provides access to new classes of ceramic materials and to the development of new applications. For example, the integration of boron can improve the thermal stability of silicon-based ceramic materials up to 2000 °C because of the suppression of recrystallization processes.[14] The incorporation of iron leads to magnetic ceramics.[15] The germanium(II) precursor, Ge[N(SiMe$_3$)$_2$]$_2$, has been employed to obtain germanium nanocrystals by thermal decomposition of the complex.[16]

These developments encouraged us to examine reactions between $H_3$(HMCTS) and $TiCl_4$, $GeCl_4$, and $SnCl_4$ in order to combine the interesting chemistry of cyclic silzanes and the synthesis of metal-atom-containing Si–C–N molecules. In this paper, we report the ring-isomerization of $H_3$(HMCTS) with formation of novel Ti-, Ge-, and Sn-centered tricyclic silazane frameworks.

## Results and Discussion

1-Lithio-2,2,4,4,6,6-hexamethylcyclotrisilzane [Li(HMCTS)$H_2$] was prepared by treating a toluene solution of $H_3$(HMCTS) with an equimolar amount of a solution of *n*-butyllithium in hexane. The subsequent reaction of Li(HMCTS)$H_2$ with $TiCl_4$ or $GeCl_4$ in a molar ratio of 2:1 should produce Ti- or Ge-containing silazane compounds and LiCl as by-product (Scheme 1, route A). Surprisingly, the $^{29}$Si NMR spectra of the products exhibit only one resonance signal. This fact and also the result of the elemental analyses were not in accord with any structures derived from simple substitutions or ring contractions of the cyclotrisilazane system. Fortunately, we were able to obtain crystals of both products, and the nature of the new complexes **1** and **2** could easily be clarified by crystal structure analysis (Scheme 1, route B).

Both complexes **1** and **2** exhibit the same cyclohexasilazane ring system with the titanium or germanium atom in the center of the ring system. When the reaction conditions were varied and $H_3$(HMCTS), titanium tetrachloride, and excess triethylamine were used, the same titanium complex **1** formed, with only a small difference in the yield. Furthermore, the reaction pathway was almost unaffected by the type of solvent used. The reaction of Li(HMCTS)$H_2$ with tin tetrachloride in a ratio of 2:1 yields the substitution product dichlorobis(2,2,4,4,6,6-hexamethylcyclotrisilazano)-stannane, as we reported recently (Scheme 2, route A),[17] but a complex analogous to **1** or **2** was not found. Complex

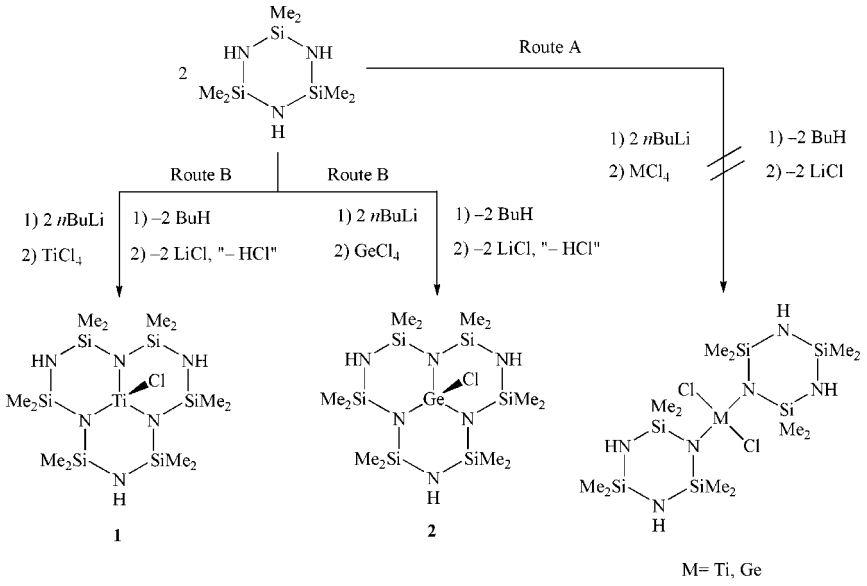
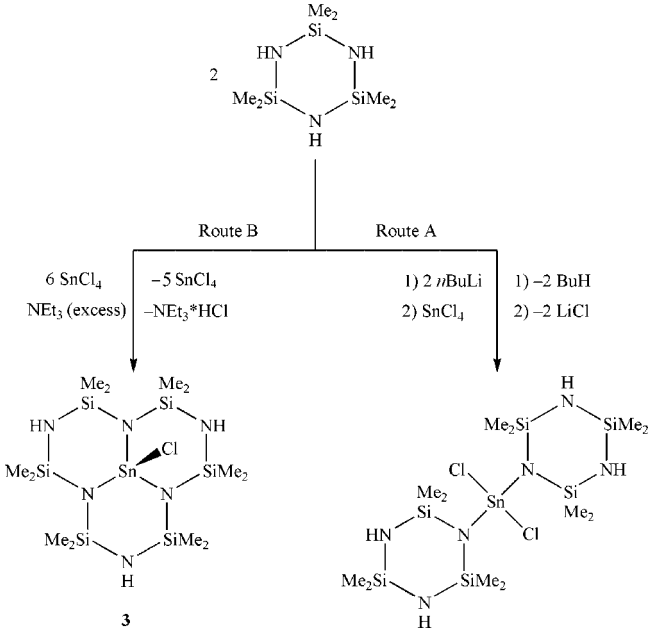


Scheme 1. Synthesis of titanium and germanium cyclohexasilazane complexes by reaction of lithiated $H_3$(HMCTS) with $TiCl_4$ and $GeCl_4$.

**3**, which exhibits the same molecular structure as **1** and **2**, was synthesized by reacting $H_3$(HMCTS) with 3 equiv. $SnCl_4$ and excess triethylamine (Scheme 2, route B).



Scheme 2. Formation of the tin cyclohexasilazane complex **3** by reaction of $H_3$(HMCTS) with $SnCl_4$ and $Et_3N$.

The formation of **3** deserves specific attention because of the different starting material molar ratios from those used in the reactions of Li(HMCTS)$H_2$ with $TiCl_4$ and $GeCl_4$. The NMR spectroscopic data of **1**, **2**, and **3** are presented in Table 1.

Table 1. $^1$H, $^{13}$C, $^{14}$N, $^{29}$Si, $^{49}$ Ti, and $^{119}$Sn NMR spectroscopic data for the new complexes **1**, **2**, and **3**.

| Compound | $^1$H Si–Me | N–H | $^{13}$C | $^{14}$N M–N | N–H | $^{29}$Si | $^{49}$Ti, $^{73}$Ge or $^{119}$Sn |
|---|---|---|---|---|---|---|---|
| **1** | 0.20, 0.26 | 0.56 | 1.9, 4.5 | –85 | –343 | –7.0 | –137 |
| **2** | 0.28, 0.35 | 0.61 | 2.5, 5.3 | –83 | –349 | –3.8 | not obtained |
| **3** | 0.21, 0.33 | 0.58 | 3.3, 4.6 | –71 | –350 | –3.9 | –169 |

The $^{29}$Si NMR spectra of the heterometallic complexes exhibit one resonance signal each, which is located at –7 ppm for **1** and at ca. –4 ppm for **2** and **3**. Therefore, the chemical shifts are nearly identical with that of $H_3$(HMCTS) [$\delta$($^{29}$Si) = –4.3 ppm].

Time-dependent $^{29}$Si NMR studies of the reaction between $H_3$(HMCTS) and $TiCl_4$ provided valuable data from which a possible reaction pathway can be proposed, although the overall reaction mechanism is not clear so far. The $^{29}$Si resonance of the silazane starting material quickly disappears after the start of the reaction, and new resonance signals ranging from 10 to 15 ppm arise in the spectra. They can be assigned to silicon atoms of $(Si–N)_2$ rings[17] and indicate cyclodisilazanes as intermediates in the formation of the dodecamethylcyclohexasilazane ring, which is found in complexes **1**–**3**. During the reaction, the intensities of the resonance signals between 10 and 15 ppm decrease, and simultaneously, the $^{29}$Si resonance of the titanium complex **1** appears at $\delta$ = –7 ppm.

Compound **1** has a $^{49}$Ti NMR signal at $\delta$ = –137 ppm, and compound **3** a $^{119}$Sn resonance at $\delta$ = –169 ppm, but no $^{73}$Ge signal was measured for compound **2** because of the quadrupolar momentum of this nucleus and the unsym-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

metrical substitution pattern of the germanium atom in **2**. The methyl moieties at each silicon atom are diastereotopic as indicated by two signals for the methyl groups in both the $^{1}H$- and $^{13}C$ NMR spectra of complexes **1**–**3**. The $^{14}N$ NMR spectra exhibit a broad resonance signal at around –350 ppm, which results from the nitrogen atoms bearing one hydrogen atom. The location of this signal is similar to that of the chemical shift of the silazane starting material [$\delta(^{14}N)$ = –360 ppm]. Additionally, a sharp signal is detected between –85 and –70 ppm, which indicates the deprotonated nitrogen atom that is bonded to the titanium, germanium, and tin atoms.

Crystals suitable for X-ray diffraction analysis were easily obtained in the case of compound **1** by crystallization from hexane. The reaction of $GeCl_4$ with $Li(HMCTS)H_2$ primarily gave a clear, colorless oil. However, storage of this oil at –20 °C for several days produced white crystals. In case of the tin complex **3**, crystals were obtained by sublimation ($T$ = 120 °C, $p$ = 5 Torr) of the crude product. The molecular structures of compounds **1**, **2**, and **3** are illustrated in Figures 1, 2, and 3, respectively. Crystal data collection parameters and structure refinement details are given in the Experimental Section (Table 2).

The single-crystal X-ray structure analysis of **1** shows that the titanium complex crystallizes in two different modifications (trigonal $P31c$; hexagonal $P6_3$) with two molecules in each unit cell. Both modifications exhibit analogous molecular conformations and similar cell dimensions. The corresponding bond lengths and angles of **1** in the two modifications are identical within the range of standard error. The titanium atom is coordinated by three nitrogen atoms and one chlorine substituent. Thus, the coordination sphere exhibits a tetrahedral geometry (Figure 1). The angles N1–Ti–N1* [109.6(1)°] and N1–Ti–Cl [109.3(1)°] in **1** ($P6_3$) perfectly match this coordination pattern. Si–N bond lengths in **1** are in the typical range 1.72–1.75 Å. In both modifications, the Ti–Cl bond is situated on a threefold axis of rotation. Therefore, the asymmetric unit consists of one third of a molecule of **1**.

The germanium complex **2** crystallizes in the same trigonal space group $P31c$ as found for one modification of **1** with two molecules in the unit cell. The germanium atom in **2** has a slightly distorted tetrahedral coordination sphere with a N1–Ge–N1* angle of 111.6(1)° and a N1–Ge–Cl angle of 107.3(1)° (Figure 2).

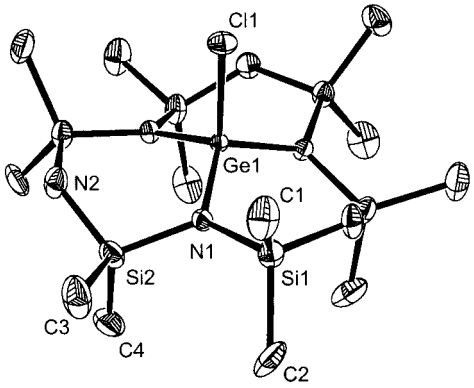


Figure 2. ORTEP plot of one molecule of **2** (thermal ellipsoids at the 50% probability level). Selected bond lengths [Å] and angles [°]: **2**: Ge–N1 1.823(4), Ge–Cl 2.192(2), Si1–N1 1.735(4), Si2–N1 1.761(5), Si1–N2 1.720(5), Si2–N2 1.722(5), N1–Ge–N1* 111.6(1), N1–Ge–Cl 107.3(1), N1–Si1–N2 105.0(2), N1–Si2–N2 107.4(2), Si1–N1–Si2 122.0(3), Si1–N2–Si2 125.8(3).

The tin complex **3** crystallizes in the hexagonal space group $P6_3$ with two molecules in the unit cell and is isomorphic with one modification of **1**. The tin atom in the center of the complex is almost tetrahedrally coordinated by the ligands, with bond angles of 110.1° and 108.8° for N1–Sn–N1* and N1–Sn–Cl, respectively (Figure 3). Despite the different metal atoms, the corresponding bond lengths and angles in **2** and **3** are similar to those in **1** with only minor differences that can arise as a result of the different atomic radii of Ti, Ge, and Sn.

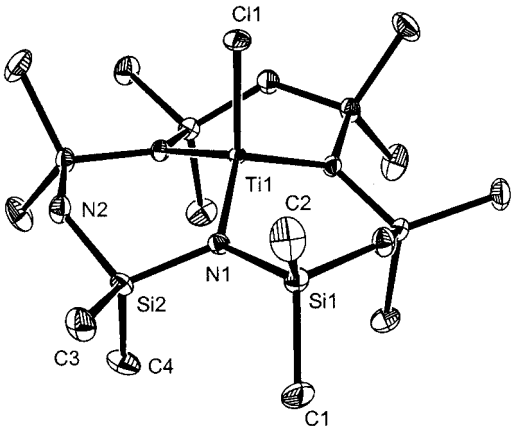

Figure 1. ORTEP plot of one molecule of **1** in space group $P6_3$ (thermal ellipsoids at the 50% probability level). Selected bond lengths [Å] and angles [°]: **1** ($P6_3$): Ti–N1 1.899(1), Ti–Cl 2.276(1), Si1–N1 1.740(1), Si2–N1 1.751(1), Si2–N2 1.717(1), N1–Ti–N1* 109.6(1), N1–Ti–Cl 109.3(1), N1–Si1–N2 105.8(1), N1–Si2–N2 107.4(1), Si1–N1–Si2 123.0(1), Si1–N2–Si2 127.7(1).

## Conclusions

For the first time, titanium, germanium, and tin complexes exhibiting a dodecamethylcyclohexasilazano ligand have been synthesized by reactions starting from $H_3$(HMCTS) and $MCl_4$ (M = Ti, Ge, Sn). In contrast to conversions of $TiCl_4$ and $GeCl_4$ with Li(HMCTS)$H_2$ to the new compounds **1** and **2**, respectively, the analogous reaction with $SnCl_4$ leads to the substitution product $Cl_2Sn[(HMCTS)H_2]_2$. However, the tin complex **3** that features the same molecular structure of **1** and **2** is obtained by using $NEt_3$/$H_3$(HMCTS) instead of Li(HMCTS)$H_2$ as starting materials. The formation of the novel cyclohexasilazane framework in **1**–**3** emphasizes the striking reactivity patterns of $H_3$(HMCTS) in reactions with metal chlorides to mark a new reaction pathway in addition to the well-known ring-contraction reactions and substitution reactions of the cyclotrisilazane system. The titanium and germanium complexes **1** and **2** are potentially good candidates to act as single-source precursors for ceramic materials of the quaternary SiCNTi and SiCNGe systems, respectively. All new compounds represent valuable synthons for further reactions because of their reactive M–Cl bonds. Further investigation of derivatization reactions of **1**–**3** and of the reaction mechanism of the overall formation reaction are to be undertaken now.

## Experimental Section

All manipulations were carried out under an inert atmosphere of argon by using a standard Schlenk line, a glovebox, and syringe techniques. $H_3$(HMCTS) was purchased from ABCR GmbH, and *n*BuLi, $SiCl_4$, $GeCl_4$, and $SnCl_4$ from Acros Organics. Toluene and hexane were distilled from over sodium/benzophenone and stored over sodium wire. NMR spectra were recorded at 400.13 MHz ($^1$H NMR), 100.62 MHz ($^{13}$C NMR), 28.91 MHz ($^{14}$N NMR), 79.49 MHz ($^{29}$Si NMR), 22.56 MHz ($^{49}$Ti NMR), and 149.21 MHz ($^{119}$Sn NMR) with a BRUKER DPX 400 instrument. Elemental analyses were performed on a Foss Heraeus CHN-O-Rapid apparatus. X-ray structure data were recorded with a Bruker-Nonius-X8-APEX2-CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), and semi-empirical correction (SADABS) was applied. The structures were solved with direct methods (SHELXS-97) and refined by full-matrix least-squares methods (refinement of $F^2$ against all reflections with SHELXS-97). All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in idealized positions and refined isotropically. Merohedral twinning was found for **1** in both modifications as well as for **2** (about 50:50 ratio in each case). The crystal of **3** exhibited neither merohedral nor racemic twinning. Selected data for the structure determination and refinement are summarized in Table 2. CCDC-621166 (**1** *P*31*c*), CCDC-621165 (**1** $P6_3$), CCDC-621164 (**2**), and CCDC-621163 (**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Chlorido-2,2,4,4,6,6,8,8,10,10,12,12-dodecamethylcyclohexasilazane-1,5,9-triidotitanium (1):** A solution of *n*-butyllithium (3.7 mL of a 2.5-M solution, 9.2 mmol) in hexane was slowly added to an ice-cooled solution of 1,1,3,3,5,5-hexamethylcyclotrisilazane (2.0 g, 9.1 mmol) in toluene (25 mL). The resulting clear, colorless solution was allowed to reach room temperature and was stirred for 1 h. A solution of $TiCl_4$ (0.86 g, 4.5 mmol) in toluene (25 mL) was then added dropwise to the resulting solution of 1-lithio-2,2,4,4,6,6-hexamethylcyclotrisilazane. This procedure led to a

slight warming of the reaction mixture. After 24 h of stirring at room temperature, the color of the solution became yellow-orange. The solvents were removed under reduced pressure, and the residue was dissolved in hexane and filtered to give a clear yellow solution. After reducing the filtrate volume by evaporation of the solvent, yellow crystals were obtained, which were filtered off and dried in vacuo. Yield: 2.94 g (62%). $C_{12}H_{39}ClN_6Si_6Ti$ (519.38): calcd. C 27.74, H 7.57, N 16.18; found C 27.37, H 7.38, N 16.03. $^1$H NMR (400.13 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.20 (s, 12 H, Si–Me), 0.26 (s, 12 H, Si–Me), 0.56 (s, 3 H, N–H) ppm. $^{13}$C NMR (100.62 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.9 (Si–Me), 4.5 (Si–Me) ppm. $^{14}$N NMR (28.91 MHz, $CDCl_3$, 25 °C): $\delta$ = –85 (Ti–N), –343 (N–H) ppm. $^{29}$Si NMR (79.49 MHz, $CDCl_3$, 25 °C): $\delta$ = –7.0 ppm. $^{49}$Ti NMR (22.56 MHz, $CDCl_3$, 25 °C): $\delta$ = –137 ppm.

**Chlorido-2,2,4,4,6,6,8,8,10,10,12,12-dodecamethylcyclohexasilazane-1,5,9-triidogermanium (2):** The synthesis was carried out as described for **1** with a solution of *n*-butyllithium (5.5 mL of a 2.5-M solution, 13.8 mmol) in hexane, 1,1,3,3,5,5-hexamethylcyclotrisilazane (3.0 g, 13.7 mmol) in toluene (25 mL), and $GeCl_4$ (1.46 g, 6.8 mmol) in toluene (25 mL) as reagents. After removal of the solvents, dissolution of the residue in hexane, and filtration, the hexane was removed from the filtrate under vacuum to give a clear, colorless oil. Storage of the oil at –20 °C for several days led to the formation of white crystals, which were dried in vacuo. Yield: 2.56 g (69%). $C_{12}H_{39}ClGeN_6Si_6$ (544.05): calcd. C 26.49, H 7.22, N 15.45; found C 26.52, H 7.37, N 15.37. $^1$H NMR (400.13 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.28 (s, 12 H, Si–Me), 0.35 (s, 12 H, Si–Me), 0.61 (s, 3 H, N–H) ppm. $^{13}$C NMR (100.62 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.5 (Si–Me), 5.3 (Si–Me) ppm. $^{14}$N NMR (28.91 MHz, $CDCl_3$, 25 °C): $\delta$ = –83 (Ti–N), –349 (N–H) ppm. $^{29}$Si NMR (79.49 MHz, $CDCl_3$, 25 °C): $\delta$ = –3.8 ppm.

**Chlorido-2,2,4,4,6,6,8,8,10,10,12,12-dodecamethylcyclohexasilazane-1,5,9-triidotin (3):** At room temperature, a solution of $SnCl_4$ (7.04 g, 27.0 mmol) in toluene (20 mL) was added dropwise to a solution of 1,1,3,3,5,5-hexamethycyclotrisilazane (2.0 g, 9.1 mmol) and triethylamine (3.0 g, 29.7 mmol) in toluene (40 mL). The resulting yellow reaction mixture was stirred for 24 h. Precipitated $NEt_3$·HCl was filtered off, and the solvent as well as the excess triethylamine were removed from the filtrate under reduced pressure to give a brownish solid product. Subsequent sublimation ($T$ = 120 °C, $p$ = 5 Torr) yielded white crystals of compound **3**. Yield: 1.47 g (54.7%). $C_{12}H_{39}ClN_6Si_6Sn$ (590.17): calcd. C 24.42, H 6.66, N 14.24; found C 24.28, H 6.58, N 14.11. $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 0.21 (s, 12 H, Si–Me), 0.33 (s, 12 H, Si–Me), 0.58 (s, 3 H, N–H) ppm. $^{13}$C NMR (100.62 MHz, $CDCl_3$, 25 °C): $\delta$ = 3.3 (Si–Me), 4.6 (Si–Me) ppm. $^{14}$N NMR (28.91 MHz, $CDCl_3$, 25 °C): $\delta$ = –71 (Ti–N), –350 (N–H) ppm. $^{29}$Si NMR (79.49 MHz, $CDCl_3$, 25 °C): $\delta$ = –3.9 ppm. $^{119}$Sn NMR (149.21 MHz, $CDCl_3$, 25 °C): $\delta$ = –169 ppm.

# Dinuclear and Polynuclear Bridged Azido–Nickel(II) Complexes: Synthesis, Structure Determination, and Magnetic Properties

**Salah S. Massoud,*[a] Franz A. Mautner,[b] Ramon Vicente,[c] August A. Gallo,[a] and Elodie Ducasse[a]**

**Keywords:** Nickel / Azido bridges / Crystal structure / Magnetic properties

Azido–$Ni^{II}$ complexes of dinuclear, $[Ni_2(trpn)_2(\mu_{1,3}\text{-}N_3)_2](ClO_4)_2$ (**1**), and monodimensional structures *cis*-$[Ni(abap)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n$ (**2**) and *cis*-$[Ni(Me_6trien)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n \cdot nH_2O$ (**3a**) as well as the monomer $[Ni(Me_6trien)(N_3)]ClO_4$ (**3b**) {trpn = tris(3-aminopropyl)amine; abap = *N*-(2-aminoethyl)-*N*,*N*-bis(3-aminopropyl)amine; $Me_6$trien = 1,1,4,7,10,10-hexamethyltriethylene tetramine} were synthesized and structurally characterized by spectroscopic techniques, X-ray crystallography, and variable-temperature magnetic measurements. In the complexes **1**–**3a**, the $ClO_4^-$ groups are counterions and the $Ni^{2+}$ centers are bridged by the azido ligands in an end-to-end bonding fashion. The coordination geometry around the $Ni^{II}$ ions is six-coordinate with a distorted octahedral environment achieved by the four N atoms of the tetradentate amines and two terminal N atoms of the azide groups. Complex **1** consists of dinuclear units with doubly bridged azido groups whereas in **2** and **3a**, a polymeric 1D chain is formed in which the adjacent azido groups link the $Ni^{II}$ centers in a *cis* arrangement. In complex **2**, the structural parameters of the two adjacent azido bridging ligands are different and an alternating 1D system with two different end-to-end azido bridges is produced. Complex **3a** is a uniform 1D system where the strong steric hindrance imposed by the methyl groups of the $Me_6$trien ligand [diagonal N(azide)–Ni–N(amine) bond angles] causes pronounced deviation from the ideal octahedral geometry. Complex **3b** exhibits a distorted square pyramidal geometry. The complexes **1**–**3a** show antiferromagnetic coupling. In complex **1**, the exchange coupling constant was $J = -64(1)$ cm$^{-1}$, whereas in the polynuclear species **2** and **3a**, the calculated values were $J_1 = -63.7(2)$ ($\alpha = 0.52$) and $J = -26.8(1)$ cm$^{-1}$, respectively. The magnetic parameters have been correlated to the structural data.

## Introduction

The pseudohalides and especially the azido bridging ligands have been reported to be efficient transmitters for propagating magnetic interaction between paramagnetic divalent metal centers ($Mn^{2+}$, $Co^{2+}$, $Cu^{2+}$, $Ni^{2+}$)[1] This property makes the metal complexes derived from these ligands an attractive topic for materials scientists and for physicists,[2] and for the same reason this class of compounds was considered to be one of the most extensively studied systems in the last three decades.[3–28] This was attributed to the distinct possibilities of magnetic coupling interactions through the azide bridge and the versatility of the ligand when it binds metal ions.[4–28] In general, two different coordination modes were established in the azido/$M^{2+}$ systems: end-to-end coordination ($\mu_{1,3}$-$N_3$) and end-on coordination ($\mu_{1,1}$-$N_3$).[4–24] Restricting our discussion to azido $Ni^{II}$ complexes derived from amines and/or amine derivatives as blocking ligands, the azido ligand generates a variety of bonding modes ranging from discrete molecules,[4–6] dinuclear ($\mu_2$-1,3-$N_3$ and $\mu_2$-1,1-$N_3$)[7–18] and even polynuclear species ($\mu_3$-1,1,1-$N_3$, $\mu_3$-1,1,3-$N_3$, $\mu_4$-1,1,1,1-$N_3$ and $\mu_4$-1,1,3,3-$N_3$)[19–21] to polymeric molecules with different dimensionality ranging from 1D[22–26] to 2D[27] networks. Moreover, many 1D polymers containing alternate chains with the same or two different bonding modes (end-to-end: $\mu_{1,3}$-$N_3$ and end-on: $\mu_{1,1}$-$N_3$) were also reported.[1,26] Azido compounds with 3D network structures were separated out and characterized in the case of $Mn^{II}$ systems.[28] The different modes of coordination of the azide group to $Ni^{2+}$ are illustrated in Scheme 1.

In general, the end-to-end coordination mode results in antiferromagnetically coupled compounds,[1,8–13] whereas the end-on coordination gives ferromagnetically coupled compounds.[1,14,16,17] However, deviation may exist in certain cases for example in the single end-to-end bridged azido 1D compound $[Ni(5\text{-methylpyrazole})_4(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n$ ferromagnetic coupling with an exchange coupling constant $J = 6.5$ cm$^{-1}$ was reported.[15] In alternating 1D

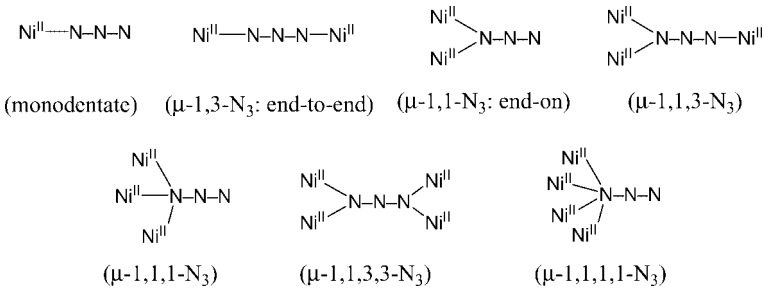

Scheme 1.

systems containing double azido bridging ligands in end-to-end and end-on coordination alternatively, two *J* values were obtained; ferromagnetic coupling with a positive *J* value corresponding to end-on azido bridging and an antiferromagnetic coupling with a negative *J* value for the end-to-end coordination.[1,26] Moreover there exists also alternating 1D systems containing single azido bridging ligands in the same end-to-end coordination mode due to the alternation in the structural parameters associated with the bridging azido environment.[1] A number of factors were addressed to correlate the magnetic behavior of the metal–azido complexes to their structural parameters. These include the intradimer M···M and M···N(azido) distances and, in the end-to-end coordination mode, the M–N–N(azido) angle and the dihedral angle, $\tau$ (the angle between the mean planes M–N1–N2–N3 and N1′–N2′–N3′–M′), in the singly bridged azido complexes or the dihedral angle, $\delta$ (the angle between the plane defined by the six *N*-azido atoms and the N1–M–N3′ plane), in the doubly bridged complexes, and also the M–($N_3$)–M angle in the end-on bonding mode.[1]

The 1D *trans*-Ni($\mu_{1,3}$-$N_3$) systems containing one azido bridging ligand between the two nickel atoms have been widely studied from the point of view of the magnetostructural correlations.[1] However, a few studies have been reported on the corresponding *cis*-Ni($\mu_{1,3}$-$N_3$) systems.[1] Therefore, in an effort to shed light on the 1D *cis*-Ni($\mu_{1,3}$-$N_3$) systems, we have selected the tripod tetradentate amines tris(3-aminopropyl)amine (trpn), *N*-(2-aminoethyl)-*N*,*N*-bis(3-aminopropyl)amine (abap), and the sterically hindered linear tetradentate amine 1,1,4,7,10,10-hexamethyltriethylenetetramine ($Me_6$trien) as blocking ligands to enforce the formation of complexes of *cis*-Ni($\mu_{1,3}$-$N_3$) geometry. With abap and $Me_6$trien amines, the reactions afforded the desired 1D compounds *cis*-[Ni(abap)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$ (**2**) and *cis*-[Ni($Me_6$trien)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$·*n*$H_2O$ (**3a**), but with the trpn ligand, the dinuclear compound [$Ni_2$(trpn)$_2$($\mu_{1,3}$-$N_3$)$_2$]($ClO_4$)$_2$ (**1**) was produced. The magnetic properties of these complexes were measured and correlated to their structural parameters.

## Results and Discussion

### Synthesis and IR Spectra

The blue azido bridged dinuclear complexes [$Ni_2$(trpn)$_2$($\mu_{1,3}$-$N_3$)$_2$]($ClO_4$)$_2$ (**1**), and the 1D polymeric chain *cis*-[Ni(abap)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$ (**2**), and the anhydrous green complex [Ni($Me_6$trien)($N_3$)]$ClO_4$ (**3b**) were prepared in a reasonably good yield (74–81%) by dropwise addition of $NaN_3$ dissolved in $H_2O$ to a hot aqueous solution containing equimolar amounts of Ni($ClO_4$)$_2$·6$H_2O$ and the polyamine ligand. Crystals suitable for X-ray analysis were obtained by slow evaporation of dilute aqueous solutions of the complexes at room temperature or in the refrigerator. However, it should be noted that a solid sample of the monomer [Ni($Me_6$trien)($N_3$)]$ClO_4$ (**3b**) slowly absorbs water at ambient temperature to form the polymeric species [Ni($Me_6$trien)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$·*n*$H_2O$ (**3a**) without losing its crystallinity (see the X-ray section). The synthesized complexes were characterized by elemental analysis and IR and UV/Vis spectroscopy.

The IR spectra of the two bridged azido complexes **1** and **2** displayed a single very strong absorption band over the range 2075–2094 $cm^{-1}$, whereas the fresh anhydrous [Ni($Me_6$trien)($N_3$)]$ClO_4$ revealed the band at a relatively lower frequency, 2060 $cm^{-1}$. The strong absorption observed in this region is attributable to the asymmetric stretching of the coordinated azido group, $\nu(N_3^-)$. The strong stretching absorption of $\nu$(Cl–O) assigned to the noncoordinated $ClO_4^-$ group was observed over the 1082–1092 $cm^{-1}$ region. Interestingly, the IR spectrum of the **3b** sample which was used for the X-ray analysis and was measured after about two months of the synthesis displayed a new broad band of medium intensity centered at 3449 $cm^{-1}$ due to the $\nu$(O–H) of lattice water. Moreover, the azido band which was located at 2060 $cm^{-1}$ in the parent complex disappeared, two strong bands at 2125 and 2092 $cm^{-1}$ were detected instead, and the strong $\nu$(Cl–O) of the perchlorate ion was slightly shifted from 1082 to 1090 $cm^{-1}$. On the basis of these data and the X-ray structural determination (see next section), the formula [Ni($M_6$trien)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$·*n*$H_2O$ (**3a**) was proposed.

### Description of the Structures

#### *[Ni(trpn)(μ$_{1,3}$-N$_3$)]$_2$(ClO$_4$)$_2$ (1)*

A labeled ORTEP plot for compound **1** is shown in Figure 1 and selected bond parameters are given in Table 1. The structure of the compound consists of centrosymmetric [$C_{18}H_{48}N_{14}Ni_2$]$^{2+}$ dinuclear units in which the nickel atoms are bridged by two azide ions in a $\mu_2$-1,3 end-to-end (EE)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fashion and $ClO_4^-$ counterions. Each nickel atom has distorted octahedral coordination geometry. The octahedron around the $Ni^{2+}$ center is achieved by the four N atoms of the tetradentate amine, trpn, and the two terminal N atoms of the azide groups. The Ni–N(trpn) bond lengths are in the range 2.072(4)–2.162(4) Å, and the Ni–N($N_3$) bond lengths are Ni(1)–N(11) = 2.180(4) and Ni(1)–N(13) = 2.169(5) Å. The largest deviation of *cisoid* and *transoid* N–Ni–N bond angles from the ideal geometry is 8.6(2)°, whereas the N(11)–Ni(1)–N(13) bond angle is 87.3(2)°. The bond lengths of the EE-bridging azide group are N(11)–N(12) = 1.182(6) and N(12)–N(13A) = 1.163(6) Å. The Ni(1)–N(11)–N(12), Ni(1)–N(13)–N(12A), and N(11)–N(12)–N(13A) bond angles in the bridge are 119.9(3), 149.3(4), and 177.5(5)°, respectively. The Ni(1)–N(11)···N(13A)–Ni(1A) torsion angle is –19.2(7)°. The six atoms of the $N_3^-$ bridging ligands are in one plane, and the dihedral angle between this plane and the N(11)–Ni(1)–N(13) plane is 8.3(3)°; i.e. the eight-membered $Ni_2(N_3)_2$ ring adapts a flat "chair conformation". The Ni(1)···Ni(1A) intradinuclear distance is 5.4310(16) Å, and the shortest Ni(1)···Ni(1B) interdimer distance is 5.9657(17) Å. The shortest hydrogen bond of type N–H···O (Table 4) is observed between N(3) and the perchlorate oxygen atom O(1) [2 – *x*, 1 – *y*, –*z*], with a separation of 3.121(6) Å.

$[Ni(abap)(N_3)]_n^{n+}$ chains in which the nickel atoms are bridged by means of single $\mu_2$-1,3 EE azide groups in *cis* arrangement, and $ClO_4^-$ counterions. Within the chains two different crystallographic nickel(II) centers exist with similar distorted octahedral coordination geometry. Each $NiN_6$ chromophore is achieved by the four N atoms of the tetradentate abap blocking ligand, and two terminal N atoms of azide groups adopting the *cis* arrangement. The Ni–N(abap) bond lengths are in the range 2.082(4)–2.135(4) Å, and the Ni–N($N_3$) bond lengths are in the range 2.103(4)–2.199(4) Å. The largest deviation of *cisoid* and *transoid* N–Ni–N bond angles from the ideal geometry is 11.0(2)°, whereas the N(11)–Ni(1)–N(21) and N(13)–Ni(2)–N(23) bond angles are 92.8(2) and 93.4(2)°, respectively. The bond lengths of the EE-bridging azide groups vary from 1.176(5) to 1.181(6) Å and the Ni–N–N bond angles from 116.0(3) to 131.9(3)°. The N(11)–N(12)–N(13) and N(23)–N(22)–N(21B) bond angles are 179.1(5) and 177.9(5)°, respectively. The Ni(1)–N(11)···N(13A)–Ni(1A) and Ni(1)–N(21)···N(23A)–Ni(2A) torsion angles are 171.0(2) and –64.3(4)°, respectively. The Ni(1)···Ni(2) and Ni(1)···Ni(2A) intrachain distances are 5.820(2) and 5.340(2) Å, whereas the shortest Ni···Ni interchain distance is 8.088(3) Å. The arrangement of the Ni–azido chain may be described as a compressed helix (Figure 2, bottom), extended along the *a* axis of the orthorhombic unit cell. Hydrogen bonds of type N–H···O and N–H···N (Table 4) form a supramolecular network.

### *cis-[Ni(Me$_6$trien)($\mu_{1,3}$-N$_3$)]$_n$(ClO$_4$)$_n$·nH$_2$O (3a)*

An ORTEP drawing for **3a** together with the atom labeling scheme is illustrated in Figure 3 (top), and selected bond parameters are given in Table 3. The structure of **3a** consists of cationic $[Ni(Me_6trien)(N_3)]_n^{n+}$ chains in which the nickel atoms are bridged by means of single $\mu_2$-1,3 EE azide groups in *cis* arrangement, $ClO_4^-$ counterions, and lattice water molecules. The nickel atoms have distorted octahedral coordination geometry. Similar as in **2**, each $NiN_6$ chromophore is achieved by the four N atoms of the $Me_6$-trien ligand and two terminal N atoms of azide groups adopting *cis* arrangement. The Ni–N(Me$_6$trien) bond lengths are in the range 2.183(3)–2.234(3) Å, and the corresponding Ni–N(azide) bond lengths, Ni(1)–N(11) and Ni(1)–N(21) are 2.088(3) and 2.101(3) Å, respectively. As a

consequence of the bulky $Me_6$trien blocking ligand, the N–Ni–N bond angles deviate up to 17.3(2)° from the ideal octahedral geometry, the N(11)–Ni(1)–N(21) bond angle is 96.90(13)°. The central nitrogen atoms of the two EE-bridging azide groups are located at inversion centers where the azide groups are symmetric [N(11)–N(12) = 1.174(3), N(21)–N(22) = 1.175(3) Å] and linear [N–N–N = 180°]. The Ni(1)–N(11)–N(12) and Ni(1)–N(21)–N(22) bond angles are 138.8(2) and 135.8(2)°, respectively. The Ni(1)–N(11)···N(11A)–Ni(1A) and Ni(1)–N(21)···N(21B)–Ni(1B) torsion angles both are 180°. The Ni(1)···Ni(1A) and Ni(1)···Ni(1B) intrachain distances are 6.1412(16) and 6.1110(15) Å, respectively, whereas the shortest Ni···Ni interchain distance is 8.619(2) Å. The Ni–azide "zigzag" chain extends along the *a* axis of the orthorhombic unit cell (Figure 3 bottom). Lattice water molecules form hydrogen bonds (Table 4) of the type O–H···O to oxygen atoms O(3) of perchlorate counterions [with O···O distances of 2.956(6) and 3.337(6) Å].

Table 4. Selected hydrogen bonds in $[Ni_2(trpn)_2(\mu_{1,3}\text{-}N_3)_2](ClO_4)_2$ (**1**), *cis*-$[Ni(abap)\text{-}(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n$ (**2**), and *cis*-$[Ni(Me_6trien)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n{\cdot}nH_2O$ (**3a**).

### *[Ni(Me$_6$trien)(N$_3$)]ClO$_4$ (3b)*

An ORTEP drawing for **3b** together with the atom labeling scheme is illustrated in Figure 4, and selected bond parameters are given in Table 5. The structure of **3b** consists of monomeric $[Ni(Me_6trien)(N_3)]^+$ complex cations and $ClO_4^-$ counterions. The $NiN_5$ chromophore may be described as a distorted square pyramid ($\tau$ = 0.117)[29] with N(11) of the azide group, N(1), N(2), and N(3) of the $Me_6$-trien ligand in basal sites and N(4) or N(5) of the partially disordered tetramine ligand at the apical site. The Ni(1)–N bond lengths range from 1.997(2) to 2.135(2) Å. In contrast to the symmetric EE azide bridges in **3a**, the monodentate azido group has asymmetric bond parameters [N(1)–N(2) = 1.189(3), N(2)–N(3) = 1.159(3) Å, N(11)–N(12)–N(13) =

### Electronic Spectra

The UV/Vis spectra of the azido–nickel(II) complexes under investigation were recorded in the solid state and in $H_2O$. In addition the polymer [Ni($Me_6$trien)($\mu_{1,3}$-$N_3$)]$_n$-($ClO_4$)$_n$·$n$$H_2O$ (**3a**) and its monomer (**3b**) were also measured in different organic solvents, and the data are collected in Table 6. The solid and the aqueous solution spectra of [$Ni_2$(trpn)$_2$($\mu_{1,3}$-$N_3$)$_2$]$^{2+}$ and [Ni(abap)$_2$($\mu_{1,3}$-$N_3$)]$_n^{n+}$ display two bands over 360–370 and 570–590 nm, and a shoulder or broad band over 770–1000 nm range. Similarly, the electronic diffuse reflectance spectrum of **3a**, [Ni($Me_6$-trien)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$·$n$$H_2O$ reveals the presence of the three absorption bands at 367, 655, and ca. 900 nm. These spectral features are consistent with six-coordinate octahedral geometry for $Ni^{II}$ complexes and the spectrum of the complex ions of **1**, **2**, or **3a** is adequately explained by d-d transitions in the $Ni^{2+}$ ion in a distorted octahedral environment where the last two maxima observed in the visible region result from $^3A_{2g}$→$^3T_{1g}$(F) and $^3A_{2g}$→$^3T_{2g}$(F) transitions, respectively, and the high energy band from the $^3A_{2g}$→$^3T_{1g}$(P) transition. When the spectra of **1** were measured in organic solvents ($CH_3CN$, $CH_3NO_2$, dmso, dmf), the positions of $\lambda_{max}$ did not show any significant change and were almost independent of the nature of the solvent used. The insolubility and/or the very low solubility of complex **2** prohibit measuring its spectrum in organic solvents. The reflectance spectra of the complexes **1**–**3a** showed low resolution and the fact that the low energy broad band was detected at higher wavelengths ($\lambda_{max} \geq 900$ nm) compared to that observed in $H_2O$ or other solvent may be attributed to the contribution of the vibrational transitions in this region. Interestingly, these findings in solutions and in the solid state were consistent with the distorted octahedral geometry around the $Ni^{2+}$ ion as determined by X-ray.

The electronic diffuse reflectance spectrum of the complex [Ni($Me_6$trien)($N_3$)]$ClO_4$ (**3b**) displays two bands at 659 nm and a shoulder at 477 nm besides a very broad band at ca. 960 nm (Table 6). Although this spectrum was not completely conclusive, it is most likely consistent with the presence of a five-coordinate environment around the $Ni^{2+}$ center where the first two bands could be assigned to $^3B_1$ (F)→$^3E$ (F) and $^3B_1$ (F)→$^3A_2$, $^3E$ (P) transitions, respectively.[30] When the spectra of the complex were measured in different coordinated solvents, the dissolution was associated with color change and the visible spectrum exhibits strong dependence on the nature of the solvent used. The spectra reveal the presence of the three bands typical for distorted octahedral $Ni^{II}$ complexes as indicated above. The six-coordinate geometry in **3b** was achieved by the addition of a solvent molecule to the coordinatively unsaturated nickel(II) center to form [Ni($Me_6$trien)($N_3$)(solv)]$^+$ where the ligand field strength increases in the order: $CH_3NO_2$ < dmf < $H_2O$ < $CH_3CN$ < dmso. Similar spectral dependence was also observed for the corresponding polymer [Ni-($Me_6$trien)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$·$n$$H_2O$ (**3a**) in $CH_3CN$ and in dmso (Table 6) which clearly demonstrates the octahedral geometry for the central $Ni^{2+}$ ion. The fact that in the same solvent, the monomer **3b** and the polymer **3a** gave absorption bands which are different in position and intensity might rule out the formation of the same six-coordinate species and instead a different octahedral $Ni^{II}$ species is

produced in solution from the polymer **3a**. Upon dissolution, the complex $[Ni(Me_6trien)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n{\cdot}nH_2O$ undergoes solvolysis via bond rupture of the bridged Ni–N(azido) bonds and displacement of one of the azido ligands with a solvent molecule to form the dimeric six-coordinate species, $[(solv)(Me_6trien)Ni(\mu_{1,3}\text{-}N_3)Ni(Me_6trien)(solv)]^{3+}$. The interaction of the solvent molecules with $[Ni(Me_6trien)(\mu_{1,3}\text{-}N_3)]_n^{n+}$ is not surprising in terms of the strong steric hindrance imposed by the methyl groups of $Me_6$trien in $[Ni(Me_6trien)(\mu_{1,3}\text{-}N_3)]_n^{n+}$ where the two diagonal N(azido)–Ni–N(amine) bond angles namely N(21)–Ni(1)–N(3) and N(11)–Ni(1)–N(2) deviate from the ideal octahedral geometry by 17.3 and 13.1°, respectively. Therefore, the Ni–N(azido) bond rupture and an azide displacement with solvent molecule seems to reduce the magnitude of crowding. A similar solvent effect was also observed in the dinuclear doubly bridged end-to-end azido complex $[Cu(Et_2dien)(\mu_{1,3}\text{-}N_3)]_2(ClO_4)_2$, where $Et_2$dien = *N*,*N*-diethyldiethylenetriamine.[3a] However, it is difficult to propose with certainty any nuclearity for the species in solution without measuring the electrical conductivity.

## Magnetic Properties

The molar magnetic susceptibility, $\chi_M$, for polycrystalline samples of **1**, **2**, and **3a** were measured as a function of temperature and the plots of $\chi_M$ vs. $T$ are illustrated in Figure 5, Figure 6, and Figure 7, respectively. At room temperature compound **1** exhibits a $\chi_M$ value of $7.6\times10^{-3}$ cm$^3$mol$^{-1}$. This value increases as the temperature decreases, reaching a broad maximum of $14.2\times10^{-3}$ cm$^3$mol$^{-1}$ at ca. 70 K. Below this temperature, the molar magnetic susceptibility decreases continuously and reaches a minimum value of $6.77\times10^{-3}$ cm$^3$mol$^{-1}$ at 2 K. Careful inspection of the graph in Figure 5 clearly indicates a small change in the slope of the curve around 25 K which can be attributed to a little structural change. The susceptibility data in the range 25–300 K for **1** were fitted to the expression [Equation (1)] for the magnetic susceptibility of isotropically coupled S = 1 dinuclear compounds, derived from the Hamiltonian $H = -JS_1S_2$:

$$\chi_M = [0.375g^2/(T-\theta)]\{[2\exp(x) + 10\exp(3x)]/[1 + 3\exp(x) + 5\exp(3x)]\} \quad (1)$$

A Weiss $\theta$ parameter was introduced in the formula to take into consideration the possible antiferromagnetic interactions between the dinuclear molecules. The results of the best fit, shown as the solid line in Figure 5, were $J$ = –64(1) cm$^{-1}$, $g$ = 2.34(1), and $\theta$ = 14(1) K. Dinuclear complexes with core formula $[Ni_2(\mu_{1,3}\text{-}N_3)_2]^{2+}$ are known to develop a magnetostructural relationship between the exchange coupling constant, $J$, and the structural parameters.[1,9a] The main factor determining the $|J|$ value is the [Ni–$(\mu_{1,3}\text{-}N_3)_2$–Ni] dihedral angle, $\delta$; the more planar the structure ($\delta$ is close to 0°) the more antiferromagnetic the interaction and hence the higher $|J|$.[1,9a] In this compound, the small dihedral angle $\delta$ (8.3°) should account for the relatively high observed $|J|$ value (64 cm$^{-1}$).

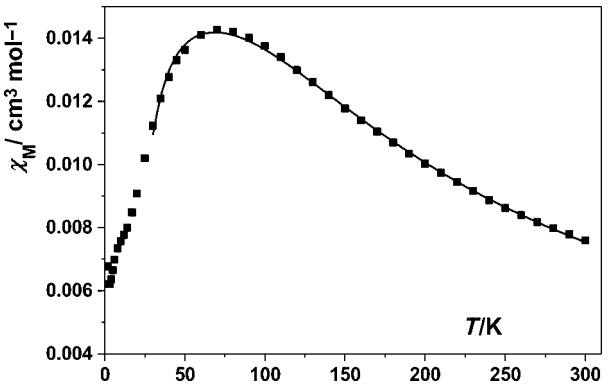

Figure 5. Plot of $\chi_M$ vs. $T$ in the 300–2 K temperature range for $[Ni_2(trpn)_2(\mu_{1,3}\text{-}N_3)_2](ClO_4)_2$ (**1**) measured on cooling under an external magnetic field of 0.7 T. The solid line shows the best fit as a dinuclear compound (see text).

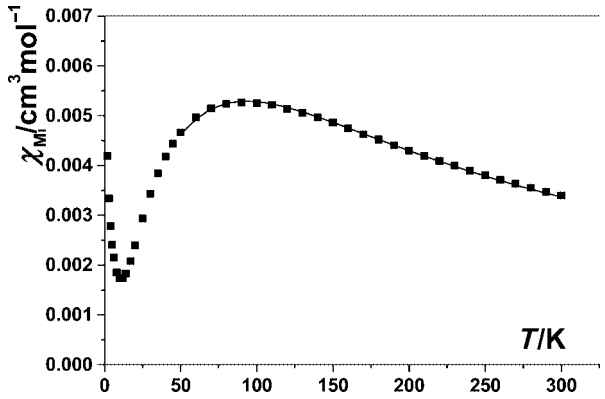

Figure 6. Plot of $\chi_M$ vs. $T$ in the 300–2 K temperature range for *cis*-$[Ni(abap)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n$ (**2**) measured on cooling under an external magnetic field of 0.7 T. The solid line shows the best fit as an alternating antiferromagnetic chain (see text).

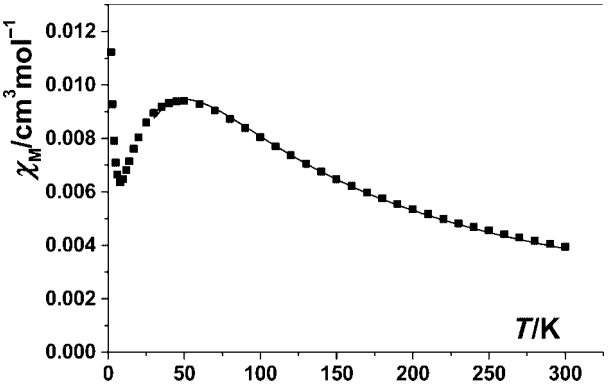

Figure 7. Plot of $\chi_M$ vs. $T$ in the 300–2 K temperature range for *cis*-$[Ni(Me_6trien)(\mu_{1,3}\text{-}N_3)]_n(ClO_4)_n{\cdot}nH_2O$ (**3a**) measured on cooling under external magnetic field of 0.7 T. The solid line shows the best fit as a uniform antiferromagnetic chain (see text).

For compound **2**, the $\chi_M$ value at room temperature ($3.48\times10^{-3}$ cm$^3$mol$^{-1}$) increases as the temperature decreases, reaching a broad maximum of $5.35\times10^{-3}$ cm$^3$mol$^{-1}$ at ca. 90 K (Figure 6). This high temperature maximum clearly indicates strong antiferromagnetic coupling between the $Ni^{II}$ ions through the azido brid-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ges. Below this temperature, the molar magnetic susceptibility decreases continuously and reaches a minimum value of $1.82 \times 10^{-3}$ cm$^3$ mol$^{-1}$ at 10 K. Beyond this temperature, $\chi_M$ increases sharply to a value of $4.28 \times 10^{-3}$ cm$^3$ mol$^{-1}$ at 2 K, most likely due to the presence of paramagnetic impurities.

In a first approach, experimental data were fitted up to near the maximum to the Weng equation[31] for uniform chains based on the Hamiltonian $H = -J\sum_i S_i \cdot S_{i+1}$, where the nickel ion and the exchange interaction are isotropic. The fitting is only possible up to near the maximum (in our case up to 90 K) because neither the zero-field splitting nor the Haldane gap are taken into account.[32] The best parameters so obtained were $J = -49.4(1)$ cm$^{-1}$ and $g = 2.40(2)$. The high $J$ value indicates a good superexchange pathway. When the alternating chain structure of compound **2** was taken into account, the coupling parameters were optimized up to 50 K by using Equation (1) for an alternating chain[33] based on the Hamiltonian $H = -J_1[\Sigma^N_{i=1} S_{2i}S_{2i+1} + \alpha\Sigma^N_{i=1} S_{2i}S_{2i-1}]$ [Equation (2)]:

$$\chi_M = (2Ng^2\mu_B^2/3kT)/(X_r T_r) \quad (2)$$

in which [Equation (3)]:

$$X_r T_r = (AT_r^2 + BT_r + C)/(T_r^3 + DT_r^2 + ET_r + F) \quad (3)$$

with $T_r = kT/|J_1|$, $X_r = 3\chi_M|J_1|/2N_A g^2\mu_B$, and $\alpha = |J_2|/|J_1|$. A–F are polynomial expressions of the $\alpha$ alternance parameter. There are two sets of polynomial expressions in the regions of $\alpha \leq 0.5$ and $\alpha \geq 0.5$. This equation can reproduce the experimental data up to the value of $kT/J \approx 0.4$. The values corresponding to minimum in the regression are $J_1 = -63.7(2)$ cm$^{-1}$, $J_2 = -33.4(2)$ cm$^{-1}$ ($\alpha = 0.52$), and $g = 2.35(1)$ in the $\alpha \leq 0.5$ region. This result with $\alpha > 0.5$ indicates that the set of polynomial expressions to be used in the regression are those corresponding to $\alpha \geq 0.5$. But in the region where $\alpha \geq 0.5$ the values corresponding to the minimum in the regression are $J_1 = -49(2)$ cm$^{-1}$, $J_2 = -48(2)$ cm$^{-1}$ ($\alpha = 0.97$), and $g = 2.37(1)$, which means to a practically uniform 1D $\mu_{1,3}$-azido chain with a similar $J$ value to that obtained by using the Weng equation.[31] In fact, this was not the case because of the presence of two sets of alternating $\mu_{1,3}$-azido bridging ligands. One of them is associated with Ni–N–N angles of 116.0 and 117.0°, and a Ni–N···N–Ni torsion angle of 171.02° and the second set with Ni–N–N angles of 131.9 and 126.4°, and a Ni–N···N–Ni torsion angle of –64.3°. By taking this into consideration and the fact that the value of $\alpha = 0.52$ is very close to the upper limit of the region, we believe physically more coherent are the parameters $J_1 = -63.7(2)$ cm$^{-1}$, $J_2 = -33.4(2)$ cm$^{-1}$ ($\alpha = 0.52$), and $g = 2.35(1)$ in the $\alpha \leq 0.5$ region.

The second point is the assignment of the $J$ values of –63.7(2) and –33.4(2) cm$^{-1}$ to the two sets of structurally different alternating $\mu_{1,3}$-azido bridging ligands. To do so, we checked the literature for magnetostructural correlations in closely related monobridged 1D *cis*-Ni-($\mu_{1,3}$-$N_3$)–Ni systems[1,9b,34–37] and the data are collected in Table 7. These systems have been fairly well studied and it can be concluded[1,34] that in a correlation between the $|J|$ coupling values and the structural parameters in the bridging region, the bond parameters that must be taken into account are in the order: the bond angles Ni–N–N, the Ni–N···N–Ni torsion angle, and finally the bond lengths Ni–N(azido bridging).[1,33] Maximum coupling was found for a Ni–N–N angle of 108° and decreases when Ni–N–N increases. Also, for fixed Ni–N–N angles $|J|$ is maximum for a Ni–N···N–Ni torsion angle of 180° (or 0°) and decreases when Ni–N···N–Ni increases from 0 to 90°. On the basis of this experimental finding, the highest $|J|$ value of –63.7(2) cm$^{-1}$ calculated for compound **2** is assigned to the superexchange pathway created by the $\mu_{1,3}$-azido bridging ligands with the set of parameters Ni–N–N angles of 116.0 and 117.0°, and a Ni–N···N–Ni torsion angle of 171.02° whereas the lowest $|J|$ value of –33.4 cm$^{-1}$ is assigned to the superexchange pathway created by the $\mu_{1,3}$-azido bridging ligands with the set of parameters Ni–N–N angles of 131.9 and 126.4°, and a Ni–N···N–Ni torsion angle of –64.3°. Also, it should be

Table 7. Structural and magnetic parameters for 1D *cis*-Ni-($\mu_{1,3}$-$N_3$)–Ni systems: Ni–Nα–Nβ and Ni′–Nγ–Nβ angles, $\tau$ dihedral angles [°]; $J$ [cm$^{-1}$]; $\tau'$ = interplanar angle Ni–Nα···Nγ and Ni′–Nγ···Nα.

noted that for one of the two sets of the structural parameters compound **2** reveals the highest reported $|J|$ value (Table 7). This high $J$ value, as has been stated above, is in accordance with the nearest Ni–N–N angles to 108° and Ni–N···N–Ni torsion angle to 180°.

For compound **3a**, the $\chi_M$ value at room temperature ($3.94 \times 10^{-3}$ cm$^3$ mol$^{-1}$) increases as the temperature decreases, reaching a broad maximum of $9.40 \times 10^{-3}$ cm$^3$ mol$^{-1}$ at ca. 50 K (Figure 7). This temperature maximum clearly indicates moderate antiferromagnetic coupling between the Ni$^{II}$ ions through the azido bridges. Below this temperature, the molar magnetic susceptibility decreases continuously and reaches a minimum value of $6.51 \times 10^{-3}$ cm$^3$ mol$^{-1}$ at 8 K. After this temperature, $\chi_M$ increases rapidly to a value of $11.38 \times 10^{-3}$ cm$^3$ mol$^{-1}$ at 2 K due to the presence of paramagnetic impurities.

Thus, taking into account that compound **3a** is structurally a uniform chain, experimental data were fitted up to near the maximum (50 K) to the Weng equation for uniform chains.[31] The best parameters so obtained were $J$ = –26.8(1) cm$^{-1}$ and $g$ = 2.36(1). The $J$ value indicates a moderate superexchange pathway. The set of parameters related with the antiferromagnetic superexchange pathway in **3a** are Ni–N–N angles of 138.8 and 135.8° and a Ni–N···N–Ni torsion angle of 180°.

Finally, it should be mentioned that the *cis* 1D Ni$^{II}$–azido complexes **2** and **3a** can be used as examples of low-dimensional magnetic systems to calculate the Haldane gap: for 1D systems containing integer values of the spin, $S$, Haldane predicted that they will exhibit a singlet ground state separated from the first triplet excited state by an energy gap $E_g$ (Haldane gap), whereas for half-odd integer spin, this gap would not exist.[38] As a consequence in the 1D compounds at $T$ = 0 K, $\chi_M$ has a zero value for integer spin systems and finite values for half-odd integer spin systems.[38] Thus, the integer $S$ 1D systems with low interchain coupling are considered to be good candidates to measure the Haldane gap[39] and several well-isolated *trans* 1D azido-bridged Ni$^{II}$ systems have been studied to demonstrate this phenomenon.[40,41] The two *cis* 1D azido-bridged Ni$^{II}$ complexes **2** and **3a** should add further examples that potentially can serve to calculate the Haldane gap.

For the monomer compound [Ni(Me$_6$trien)(N$_3$)]ClO$_4$ (**3b**), the $\chi_M T$ vs. $T$ plot is illustrated in Figure 8. The calculated room temperature $\chi_M T$ value of 1.29 cm$^3$ mol$^{-1}$ K was found to be larger than the spin only value of 0.99 cm$^3$ mol$^{-1}$ K for $S$ = 1 in mononuclear compounds. The $\chi_M T$ value decreases slowly with decreasing temperature and at ca. 50 K the decrease is becoming too fast, reaching a $\chi_M T$ value of 0.20 cm$^3$ mol$^{-1}$ K at 2 K. The experimental susceptibility data were fitted using Equation (4):[42]

$$\chi_M = (2Ng^2\beta^2/3kT)[2x^{-1} - 2\exp(-x)x^{-1} + \exp(-x)]/[1 + 2\exp(-x)] \quad (4)$$

where $x = D/kT$ and $D$ is the Zero field splitting parameter. This equation considers only noninteracting $S$ = 1 ions in the presence of single ion anisotropy. The best fit is given by the parameters $D$ = 19 cm$^{-1}$, $g$ = 2.22. The $D$ value is related to the geometry around the nickel(II) ion; the high anisotropy for the pentacoordinate nickel(II) ions implies high $D$ values.[43] The high value reported here for **3b** (19 cm$^{-1}$) is comparable with the high $D$ values of 14.7 and 14.8 cm$^{-1}$ found in similar pentacoordinate Ni$^{II}$ compounds [Ni(Me$_5$dien)(NCS)$_2$] and [Ni(Me$_4$Etdien)(NCS)$_2$], respectively where Me$_5$dien = 1,1,4,7,7-pentamethyldiethylenetriamine and Me$_4$Etdien = 4-ethyl-1,1,7,7-tetramethyldiethylenetriamine.[43]

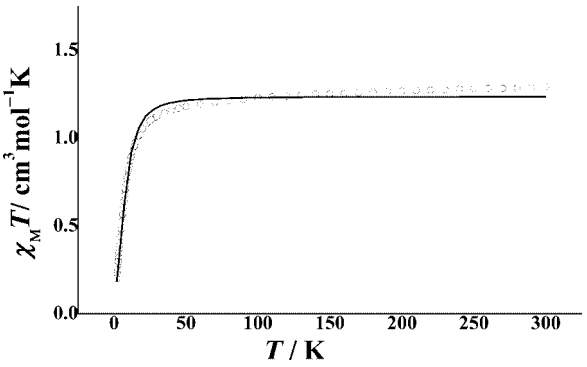

Figure 8. Plot of $\chi_M T$ vs. $T$ in the 300–2 K temperature range for [Ni(Me$_6$trien)(N$_3$)]ClO$_4$ (**3b**) measured on cooling under an external magnetic field of 0.7 T. The solid line shows the best fit as a uniform antiferromagnetic chain (see text).

## Conclusions

Bridged azido–Ni$^{II}$ complexes have been synthesized by using tetradentate amine ligands where the Ni$^{2+}$ centers are linked by the azido ligands in end-to-end-bond fashion. With the tripod amine trpn = N(CH$_2$CH$_2$CH$_2$NH$_2$)$_3$, dinuclear doubly bridged azido complex, [Ni$_2$(trpn)$_2$($\mu_{1,3}$-N$_3$)$_2$](ClO$_4$)$_2$ (**1**) was obtained. A small alteration in the trpn ligand skeleton to produce the corresponding tripod abap = N(CH$_2$CH$_2$CH$_2$NH$_2$)$_2$(CH$_2$CH$_2$NH$_2$), afforded the polynuclear 1D chain *cis*-[Ni(abap)($\mu_{1,3}$-N$_3$)]$_n$(ClO$_4$)$_n$ (**2**) in which the two azido groups adopt a *cis* arrangement. Surprisingly, when the tripod ligands were replaced with the linear tetradentate amine Me$_6$trien = [Me$_2$NCH$_2$CH$_2$N(Me)CH$_2$-CH$_2$N(Me)CH$_2$CH$_2$NMe$_2$], a 1D polynuclear species *cis*-[Ni(M$_6$trien)($\mu_{1,3}$-N$_3$)]$_n$(ClO$_4$)$_n$·$n$H$_2$O (**3a**) was also obtained with a distorted octahedral structure similar to **2**, in which the Ni–azide is extended in a zigzag chain. In complex **3a** strong steric hindrance imposed by the methyl groups of Me$_6$trien causes pronounced deviations for the two diagonal N(azide)–Ni–N(amine) bond angles from the ideal octahedral geometry. The magnetic behavior of **1**–**3a** is consistent with antiferromagnetic coupling. Compound **2** is a magnetically alternating 1D *cis* Ni($\mu_{1,3}$-N$_3$) compound, and one set of the structural parameters shows the high reported $|J|$ value. Complex **3a** is a magnetically uniform 1D *cis* Ni($\mu_{1,3}$-N$_3$) compound.

## Experimental Section

**Materials and Physical Measurements:** 1,1,4,7,10,10-hexamethyltriethylenetetramine ($Me_6$trien) and *N*-(2-*b*romoethyl)phthalimide were purchased from Aldrich Chem. Co., whereas tris(3-aminopropyl)amine (trpn) was obtained from TCI-America. All other materials were reagent grade quality. Infrared spectra were recorded with a JASCO FT/IR-480 plus spectrometer as KBr pellets. Electronic spectra of the complexes in solutions were recorded with the JASCO V-550 UV/Vis. spectrophotometer and the solid spectra (diluted with $BaSO_4$) were measured by the BECKMAN DK 2A spectrophotometer using $BaSO_4$ as a standard. Elemental analyses were carried out by Atlantic Microlaboratory, Norcross, Georgia, U.S.A. Magnetic susceptibility measurements under several magnetic fields in the range 2–300 K and magnetization measurements in the field range 0.4–1 T were performed with a Quantum Design MPMS-XL SQUID magnetometer at the Magnetochemistry Service of the University of Barcelona. All measurements were performed on polycrystalline samples. Pascal's constants were used to estimate the diamagnetic corrections, which were subtracted from the experimental susceptibilities to give the corrected molar magnetic susceptibilities.

***Caution:*** *Salts of perchlorate and azide as well as their metal complexes are potentially explosive and should be handled with great care and in small quantities.*

**Synthesis of the Compounds**

***N*-(2-Aminoethyl)-*N*,*N*-bis(3-aminopropyl)amine Tetrahydrochloride Trihydrate (abap·4HCl·3$H_2O$):** This ligand was prepared according to the literature method[44] by fusing 3,3-diphthalimidodipropylamine (observed m.p. 136–138 °C, lit. m.p. 136–137 °C) with *N*-(2-bromoethyl)phthalimide and the product, *N*-(2-phthalimidoethyl)-*N*,*N*-bis(3-phthalimidopropyl)amine, was hydrolyzed in HCl (8 M). $C_8H_{32}Cl_4N_4O_3$ (374.18): calcd. C 25.68, H 8.62, N 14.97; found C 25.54, H 8.49, N 14.55.

**[$Ni_2$(trpn)$_2$($\mu_{1,3}$-$N_3$)$_2$]($ClO_4$)$_2$ (1):** Nickel(II) perchlorate hexahydrate (0.365 g, 1.0 mmol) dissolved in $H_2O$ (5 mL) was added to tris(3-aminopropyl)amine (0.190 g, 1.0 mmol) in $H_2O$ (10 mL). The mixture was then heated on a steam bath for 5 min, followed by dropwise addition of an aqueous solution of $NaN_3$ (10 mL, 0.130 g, 2 mmol). The resulting solution was heated for another 10 min and then filtered through Celite. Slow evaporation at ambient temperature afforded mauve-blue crystals suitable for X-ray analysis. These crystals were collected by filtration, washed with cold ethanol (10 mL), ether, and air dried (yield: 0.286 g, 74%). $C_9H_{24}ClNiN_7O_4$ (388.50): calcd. C 27.82, H 6.23, N 25.24; found C 28.11, H 6.24, N 24.88. Selected IR bands (KBr): ν($N_3^-$) stretching 2092 (vs); ν(Cl–O) ($ClO_4^-$) centered at 1092 (vs); ν(N–H) stretching at 3328 (m) and 3288 (m) $cm^{-1}$.

***cis*-[Ni(abap)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$ (2):** To abap·4HCl·3$H_2O$ (0.372 g, 1 mmol) dissolved in $H_2O$ (10 mL) and four equivalents of NaOH (0.160 g) was added $Ni(ClO_4)_2$·6$H_2O$ (0.375 g, 1.0 mmol) in $H_2O$ (10 mL). The solution was heated for 15 min and then an aqueous solution of $NaN_3$ (0.0720 g, 1.1 mmol in 10 mL $H_2O$) was added, drop by drop. The resulting blue solution was heated on a steam bath for 15 min, followed by filtration through Celite and allowed to crystallize at room temperature. After one week, the blue crystals which separated out were collected by filtration, washed with ethanol and ether and air dried (overall yield: 0.29 g, 77%). Crystals of X-ray quality were obtained from a dilute solution that was kept at room temperature. $C_8H_{22}ClNiN_7O_4$ (370.02): calcd. C 25.62, H 5.96, N 26.14; found C 25.78, H 6.00, N 26.32. Selected IR bands (KBr): ν($N_3$), 2075 (vs); ν(Cl–O) ($ClO_4^-$), 1091 (vs); ν(N–H) stretching, 3334 (m) and 3288 (m) $cm^{-1}$.

**[Ni($Me_6$trien)($N_3$)]$ClO_4$ (3b):** The complex was prepared by a procedure similar to that described for **1** and then allowed to crystallize in the refrigerator. After two weeks, the complex was separated out as green crystals (yield: 0.348 g, 81%). Single crystals were obtained from dilute solutions. $C_{12}H_{30}ClNiN_7O_4$ (430.57): calcd. C 33.47, H 7.02, N 22.71; found C 33.48, H 7.22, N 22.77. Selected IR bands (KBr): ν($N_3^-$) stretching 2060 (vs); ν(Cl–O) ($ClO_4^-$) 1082 (vs) $cm^{-1}$.

***cis*-[Ni($Me_6$trien)($\mu_{1,3}$-$N_3$)]$_n$($ClO_4$)$_n$·*n*$H_2O$ (3a):** When the solid sample of [Ni($Me_6$trien)($N_3$)]$ClO_4$ (**3b**) was allowed to stand at room temperature for about two months, it absorbed water without losing its crystallization shape. $C_{12}H_{32}ClNiN_7O_5$ (448.59): calcd. C 32.13, H 7.19, N 21.86; found C 32.55, H 7.16, N 21.79. The IR spectrum of the hydrated sample, which was then used for single-crystal X-ray structure determination, exhibited a new band centered at 3449 $cm^{-1}$ (mb) attributable to the ν(O–H) of lattice water and two strong bands for the azido groups at 2125 and 2092 $cm^{-1}$. The strong ν(Cl–O) of the perchlorate ion was detected at 1090 $cm^{-1}$.

**Crystal Structure Analyses:** The single-crystal X-ray data of compounds **1**, **2**, and **3b** were collected with a modified STOE four-circle diffractometer and that of compound **3a** with a Bruker-AXS SMART APEX CCD diffractometer. The crystallographic data, conditions retained for the intensity data collection, and some features of the structure refinements are listed in Table 8. Crystal size: 0.30 × 0.20 × 0.06 mm for **1**, 0.42 × 0.32 × 0.20 mm for **2**, 0.42 × 0.34 × 0.22 mm for **3a**, and 0.36 × 0.27 × 0.14 mm for **3b**. Intensities were collected with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å). Total of 3117 (**1**), 5926 (**2**), 3788 (**3a**), and 4069 (**3b**) reflections were nonequivalent by symmetry, and observed reflections by applying the condition $I > 2\sigma(I)$ were 2278 for **1**, 4288 for **2**, 3498 for **3a**, and 3153 for **3b**. Lorentz polarization and absorption corrections using the SADABS computer program[45] were made for **3a**, and DIFABS program[46] for **1**, **2**, and **3b**. The structures were solved by direct methods using the SHELXS-86 computer program,[47] and refined by full-matrix least-squares methods on $F^2$, using the SHELXL-93 program[48] incorporated in the SHELXTL/PC V 5.03 program package.[49] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were assigned with isotropic displacement factors and included in the final refinement cycles by use of geometrical restraints ($C_{ar}$–H = 0.93 Å; $C_{Me}$–H = 0.96 Å; N–H = 0.90 Å; O–H = 0.82 Å). In the case of **1**, split occupancy of 0.79(2) and 0.21(2), was applied to the disordered methylene group with atoms C(2) and C(52), respectively. In the case of **3b**, split occupancy of 0.50 was applied to atoms N(4), N(5),C(1), C(2), C(9), C(10), C(12), and C(21)–C(24) of disordered $Me_6$trien, respectively. The final *R* (on *F*) factors were 0.0589, 0.0572, 0.0592, and 0.0430 for the four compounds, respectively, whereas the corresponding *wR* (on $F^2$) were 0.1468 for **1**, 0.1504 for **2**, 0.1267 for **3a**, and 0.0986 for **3b**. Numbers of refined parameters were 210, 379, 250, and 278 for **1**, **2**, **3a**, and **3b**, respectively. Maximum and minimum peaks in the final difference Fourier syntheses were 0.556 and –0.628 e Å$^{-3}$, respectively, for **1**, 1.074 and –0.733 e Å$^{-3}$, respectively, for **2**, 0.721 and –0.593 e Å$^{-3}$, respectively, for **3a**, and 0.347 and –0.413 e Å$^{-3}$, respectively, for **3b**. The molecular plots were obtained by using the ORTEP-32 program.[50] CCDC-609516–CCDC-609518 for **1**–**3a** and CCDC-628117 for **3b** contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# (Pentabenzylcyclopentadienyl)molybdenum Complexes: Synthesis, Structures and Redox Properties

Sónia Namorado,[a] Jinlan Cui,[a] Cristina G. de Azevedo,[a] M. Amélia Lemos,[b] M. Teresa Duarte,[a] José R. Ascenso,[a] Alberto R. Dias,[a] and Ana M. Martins*[a]

**Keywords:** Molybdenum / Tungsten / Cyclopentadienyl ligands / Half-sandwich complexes / Cyclic voltammetry

[MCpBz(CO)$_3$]$_2$ (M = Mo **3**, W **4**; CpBz = pentabenzylcyclopentadienyl) complexes were prepared by reaction of Li[MCpBz(CO)$_3$] [M = Mo (**1**), W (**2**)] with Fe$^{III}$. [MoCpBz(CO)$_2$]$_2$ (**5**) can be prepared by thermal elimination of CO from **3** and also by reaction of **1** with C$_3$H$_5$Br. The steric bulk of the CpBz ligands causes all the dimers to exist either in the solid state or in solution as the *trans* isomers. The hydrido complexes [MH(CpBz)(CO)$_3$] [M = Mo (**6**), W (**7**)] were prepared by reactions of **1** and **2** with H$^+$. Cyclic voltammetry and controlled potential coulometry of **5** in CH$_2$Cl$_2$, thf and CH$_3$CN were performed and mechanisms for the redox behaviour are proposed.

## Introduction

The thermodynamic and kinetic properties of transition metal complexes are strongly dependent on the interplay of the ligands' stereochemical and electronic features. For metallocene complexes, the importance of cyclopentadienyl (Cp) substituents is extensively documented, with current practice being to tune the metal centres' reactivity through the choice of appropriate Cp ligands. In this context, we recently became interested in pentabenzylcyclopentadienyl (CpBz) derivatives with the aim of assessing the influence of the five bulky benzyl groups on the structures and properties of half-sandwich Mo and W complexes. Preliminary studies with [MoCpBz(O)$_2$Cl] have shown an enhanced performance in the catalytic epoxidation of cyclooctene. A comparison of [MoCp′(O)$_2$Cl] (Cp′ = Cp, Cp*, Cp*i*Pr$_4$, CpBz) complexes showed that the CpBz derivative leads to the most active and stable catalyst system when activated with *t*BuOOH.[1] Moreover, chlorination reactions of low oxidation-state (CpBz)carbonylmolybdenum and -tungsten complexes also differ from those of their Cp and Cp* analogues. In particular, the reactions of [MoCpBz(CO)$_3$(CH$_3$)] with PCl$_5$ or PhICl$_2$ have been observed to proceed by different routes leading to the formation of [MoCpBz{$\eta^2$-C(O)CH$_3$}Cl$_3$] or [MoCpBzCl$_4$], respectively.[2] Among the extremely varied reactivity of half-sandwich molybdenocene and tungstocene complexes, the application of hydrido complexes of general formula [MCp(CO)$_2$L(H)] (M = Mo, W; L = CO, PR$_3$) as hydrogenation catalysts of ketones and aldehydes has recently been reported.[3,4]

The results presented here are part of our ongoing interest in (pentabenzylcyclopentadienyl)molybdenum and -tungsten reactivity. To determine the influence of the benzyl substituents on the metal electronic features, we performed electrochemical studies of the dimer [MoCpBz(CO)$_2$]$_2$.

## Results and Discussion

All new complexes are represented in Scheme 1. Li[MCpBz(CO)$_3$] [M = Mo (**1**), W (**2**)] are readily prepared in thf or dmf solution, respectively, by treating M(CO)$_6$ with LiCpBz.[5] Treatment of **1** and **2** with Fe$^{III}$ in CH$_3$COOH at 0 °C leads to the formation of [MCpBz(CO)$_3$]$_2$ [M = Mo (**3**), W (**4**)], which precipitate from their solution as red and orange solids, respectively.

The IR spectrum of **3** in KBr pellets shows three bands at 1932, 1901 and 1876 cm$^{-1}$ for the carbonyl ligands. In **4**, the three carbonyl bands appear at 1928, 1897 and 1868 cm$^{-1}$. These values are lower than those reported for similar [MCp(CO)$_3$]$_2$ complexes (Mo: 1966, 1922, 1914 cm$^{-1}$; W: 2012, 1952, 1905 cm$^{-1}$).[6,7]

The $^1$H NMR spectra of [MCpBz(CO)$_3$]$_2$ in CD$_2$Cl$_2$ display only one resonance for the benzyl protons at $\delta$ = 3.88 ppm for **3** and $\delta$ = 3.92 ppm for **4**. This means that there are no constraints on the free rotation of the pentabenzylcyclopentadienyl ligands around the metal–C$_{5ring}$ and the C$_{5ring}$–CH$_2$Ph bonds and, considering the arrangement of the CpBz ligands in relation to the metal–metal bonds,

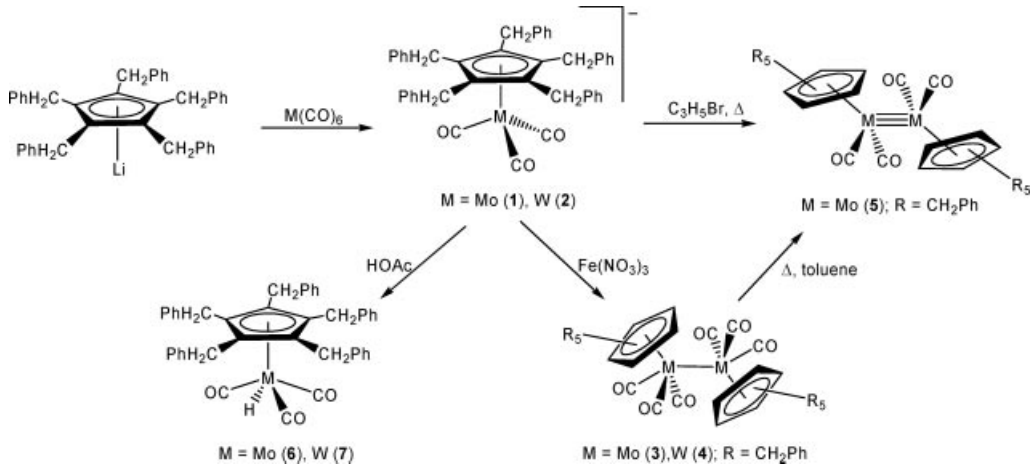
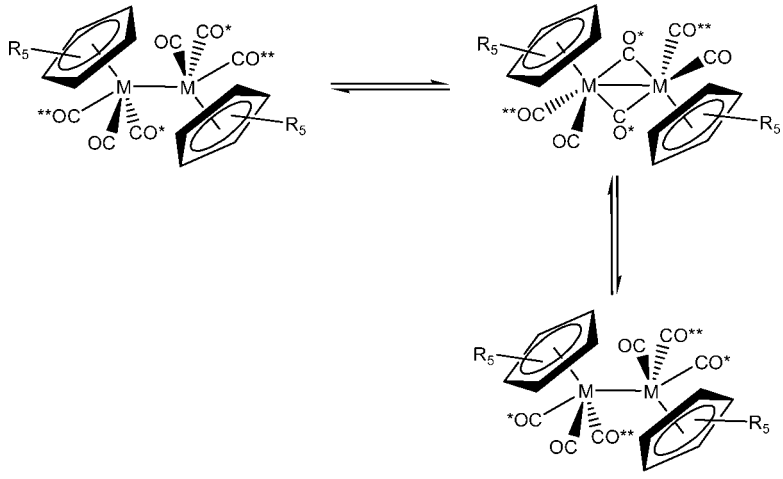


Scheme 1.



Scheme 2. The asterisks on the CO groups denote inequivalent carbonyl ligands.

is indicative of the presence of only one isomer in solution. The $^{13}C$ NMR spectra of **3** and **4** corroborate this result and also show that there is a fluxional process in solution that renders the six carbonyl groups equivalent, which gives rise to only one resonance at $\delta$ = 234.7 ppm (Mo) and $\delta$ = 224.3 ppm (W). The mechanism that accounts for this process is a rapid scrambling of the CO ligands among the six positions available at the two metal centres that involves CO-bridged intermediates, as represented in Scheme 2.[8]

Attempts to block the CO scrambling process by lowering the temperature did not produce any modifications in the NMR spectra down to –80 °C. This behaviour also indicates that *cis*/*trans* isomerisation is not operative, which might be expected on stereochemical arguments, and that the unique isomers in solution are *trans*-$[MCpBz(CO)_3]_2$ for both molybdenum and tungsten complexes. Thus, in contrast to their Cp analogues, *cis*/*trans* isomerisation processes in **3** and **4** are hampered.[6,9]

Treatment of $Li[MoCpBz(CO)_3]$ with an excess of $C_3H_5Br$ led to the dimer $[MoCpBz(CO)_2]_2$ (**5**; Scheme 1). This complex was isolated in 76% yield upon recrystallisation from diethyl ether as orange-red single crystals that were suitable for X-ray diffraction. It is clear that the reaction of $C_3H_5Br$ with **1** is not an elementary process. The formation of $[MoCpBz(CO)_2]_2$ probably results from an outer-sphere redox reaction between the anion $[MoCpBz(CO)_3]^-$ and $C_3H_5Br$, leading to the radical $[MoCpBz(CO)_3]$, which, upon dimerisation and a thermally induced Mo–CO bond cleavage,[10] finally gives $[MoCpBz(CO)_2]_2$. By analogy with the formation of $[MoCpBz(CO)_3Me]$ from **1** and MeI, $[MoCpBz(CO)_3(\sigma\text{-}C_3H_5)]$ would be the expected product. An allyl radical elimination from the putative $Mo^{II}$ intermediate $[MoCpBz(CO)_3(\sigma\text{-}C_3H_5)]$ may, however, be excluded, as it goes against the usual reactivity trend that affords π-allyl coordination by thermal or photochemical activation of σ-allyl precursors.[11,12] The formation of $[MoCpBz(CO)_3]_2$ as an intermediate in the synthesis of **5** was confirmed by the quantitative formation of the latter from a toluene solution of **3** under reflux (Scheme 1).

The IR spectrum of **5** shows characteristic peaks due to CpBz and peaks ascribed to the carbonyl ligands at 1878 and 1821 $cm^{-1}$. These values, which are notably lower than those reported for the Cp ($\nu_{CO}$: 1900 and 1850 $cm^{-1}$) and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Cp* ($\nu_{CO}$: 1940, 1907, 1874 and 1846 $cm^{-1}$) analogues,[10,13] should reflect extensive Mo–CO backbonding. The $^1H$ and $^{13}C$ NMR spectra display one set of CpBz resonances, consistent with the free rotation of the ligand in solution. The magnetically equivalent CO ligands give rise to a resonance at $\delta$ = 239.3 ppm.

Li[Mo(CpBz)$(CO)_3$] does not react with other electrophiles like $Me_3CCH_2Br$, as attested by the essentially quantitative recovery of the starting material. This result is probably dictated by stereochemical constraints that prevent the coordination of the neopentyl ligand.

The hydrido complexes [MH(CpBz)$(CO)_3$] [M = Mo (**6**), W (**7**)] were obtained upon treatment of **1** with $CH_3COOH$ in 90% and 95% yield for **6** and **7**, respectively. The IR spectrum of **6** displays carbonyl stretching vibrations at 2008 (vs), 1928 (vs) and 1822 $cm^{-1}$ (m) and that of **7** shows carbonyl peaks at 2008 (vs) and 1901 $cm^{-1}$ (vs). The lower CO vibration values displayed by **6** and **7** with respect to their Cp and Cp* counterparts are, once more, indicative of a more extensive metal–carbonyl backbonding in the CpBz derivatives.[14,15] The hydrido resonances in **6** appear at $\delta$ = –4.85 ppm and in **7** at $\delta$ = –6.31 ppm.

Crystals suitable for X-ray analysis of compound **4** were grown from a toluene solution at –20 °C. The molecular structure is shown in Figure 1 and selected bond lengths and angles are listed in Table 1.

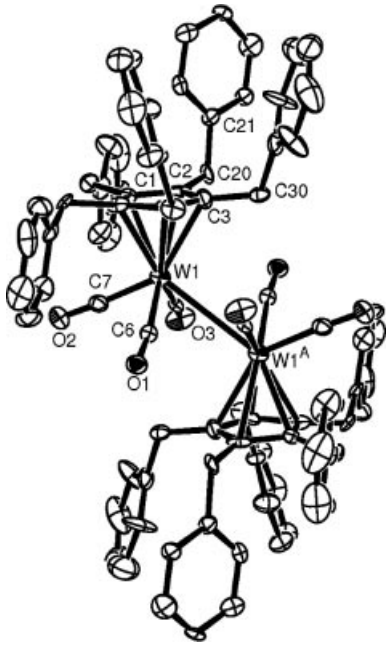


Figure 1. Molecular structure of complex **4**. H atoms have been excluded for clarity. Thermal ellipsoids are shown at the 50% probability level.

The tungsten coordination geometry is best described as a distorted four-legged piano-stool with a CpBz(CT)–W(1)–W(1A) angle of 125.06(19)° and CpBz(CT)–W(1)–C(*n*) angles of 125.5(4), 114.2(4) and 124.2(4) for C(6), C(7) and C(8), respectively [CpBz(CT) = centroid of the cyclopentadienyl ring]. The spatial arrangement of the cyclopentadienyl substituents displays three benzyl groups directed opposite to the metal atom and the other two slightly bent towards it. The relative conformation of the phenyl rings is characterised by the torsion angles of the pendent benzyl arms, defined as M–C(CpBz)–C($CH_2$)–$C_{ipso}$ in Table 1. As a whole, the molecular structure of **4** parallels those previously reported for related dimers.[9,16–19] Two carbonyl ligands of each tungsten atom bend over the metal–metal bond, whereas the remaining carbonyl groups are mutually *trans* in relation to the metal–metal bond and their structural features are typical of linear terminal CO ligands. These carbonyl groups point towards the middle region between the two CpBz benzyl groups that point down towards the tungsten centres. The steric bulk requirements of the CpBz ligands are responsible for elongated metal–metal and metal–CpBz(CT) bond lengths, when compared with analogous complexes [3.215 < W–W < 3.287 Å; 1.995 < W–Cp′(CT) < 2.029 Å].[9,16–19] Short-contact distances have been found between carbonyl oxygen atoms and the methylenic protons of the benzyl groups pointing down and belonging to the other half of the molecule [O(1)···H(20) 2.383, O(3)···H(40) 2.489 Å]. The most peculiar feature of

the structure of $[WCpBz(CO)_3]_2$ is related to the cyclopentadienyl ring. The C–C bond lengths deserve a comment as two are longer (1.46 and 1.49 Å) than the other three, which are in accordance with the usual average C–C distances in $\eta^5$-Cp ligands (1.41 Å).[16] This difference reflects an asymmetry in the metal–ring bonding that is reminiscent of an $\eta^3+\eta^2$ coordination.[20–23]

The molecular structure of $[Mo(CpBz)(CO)_2]_2$ is depicted in Figure 2 and some selected distances and angles are listed in Table 1.

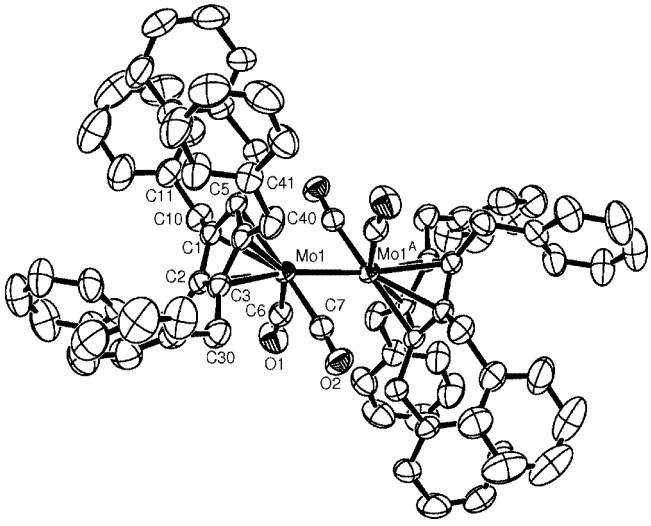

Figure 2. Molecular structure of complex **5**. H atoms have been excluded for clarity. Thermal ellipsoids are shown at the 50% probability level.

The molybdenum coordination is best described as a distorted piano-stool geometry with basal angles ranging between 71.43(8) and 87.93(11)° and CpBz(CT)–Mo(1)–X angles [X = C(6), C(7), Mo(1A)] varying from 116.95(8) to 119.31(8)°. The CpBz(CT)–Mo(1)–Mo(1A) angle [161.54(8)°] is more acute than that reported for $[MoCp(CO)_2]_2$, which displays a linear Cp–Mo–Mo arrangement,[13] but close to the values reported for the majority of $[MCp'(CO)_2]_2$ complexes [M = Cr, Mo, W; Cp′ = $C_5H_5$, $C_5Me_5$, Ind, $C_5H_4COOEt$, $C_5H_3tBu_2$, $C_5Me_4(CH_2)_2NMe_2$].[13,24–28] The Mo(1)–Mo(1A) distance [2.5198(8) Å] is compatible with a metal–metal triple bond, although it is longer than in $[MoCp'(CO)_2]_2$ [Cp′ = $C_5H_5$ 2.448(1) Å, $C_5Me_5$ 2.488(3) Å].[13,28] As generally observed for $[MoCp'(CO)_2]_2$ complexes, the carbonyl ligands in **5** are linear semi-bridging.[24,25] The Mo(1)–C(6) [1.950(3) Å] and Mo(1)–C(7) [1.948(3) Å] bond lengths are thus identical to those of similar compounds,[13,25–28] and much shorter than in $[MoCp(CO)_2]_2$ [2.14(2) and 2.52(2) Å]. All the CpBz phenyl rings in **5** point away from the metal atom and define torsion angles of between 148.2(2) and 176.37(18)°.

The relative orientation of the cyclopentadienyl rings towards the metal–metal bonds in $[Cp'M(CO)_2]_2$ complexes (M = Cr, Mo; Cp′ = $C_5H_5$, $C_5Me_5$), which results in linear or bent arrangements, has been attributed to electronic rather than stereochemical reasons. The combination of ring orbitals with σ or π* metal–metal orbitals was taken as the determining factor for the Cp(CT)–M–M angle values whilst pointing out that the metal–ring and metal–metal bonds are strongly interdependent, that is, the Cp rings may be thought of as conjugated with the M≡M system.[26] In the case of bent Cp(CT)–M–M arrangements, since σ* metal–metal orbitals are involved, the weakening (and thus the lengthening) of the metal–metal bond is more pronounced.

The molecular structures of **6** and **7** are represented in Figures 3 and 4, respectively, and selected bond lengths and angles are listed in Table 2.

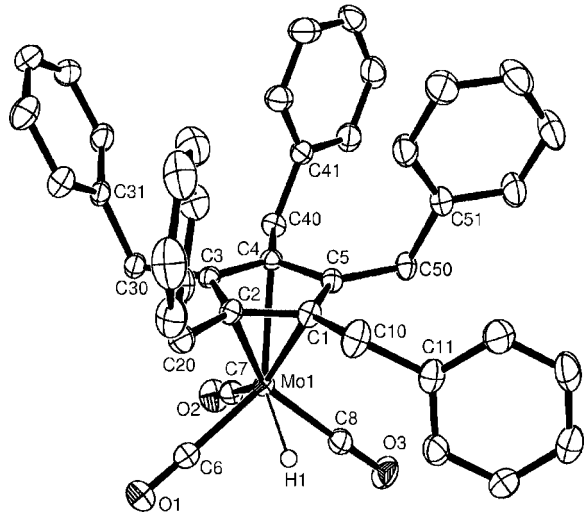

Figure 3. Molecular structure of complex **6**. H atoms have been excluded for clarity, except the hydride ion. Thermal ellipsoids are shown at the 50% probability level.

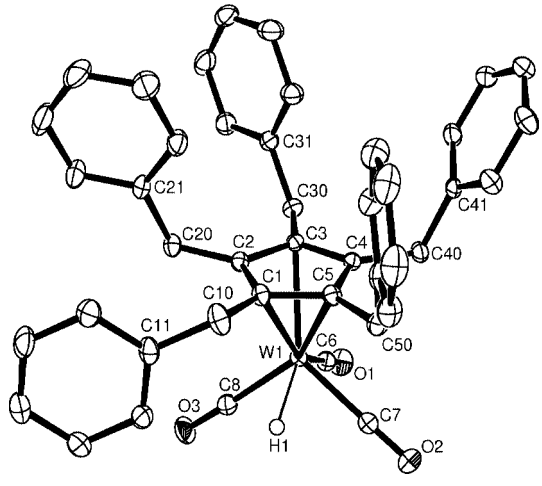

Figure 4. Molecular structure of complex **7**. H atoms have been excluded for clarity, except the hydride ion. Thermal ellipsoids are shown at the 50% probability level.

Complexes **6** and **7** have similar four-legged piano-stool metal coordination geometries, as also reported for analogous metal hydride complexes.[29–32] The structural parameters displayed are consistent with the data found in the literature for this class of compounds and will not be discussed further. The M–CpBz(CT)–C($CH_2$)–$C_{ipso}$ torsion angles are similar to those observed for complex **4**, although in **6** and **7** only one phenyl ring approaches the metal atoms.

## Electrochemical Studies

The electrochemical behaviour of [Mo(CpBz)(CO)$_2$]$_2$ (**5**) was investigated by means of cyclic voltammetry (CV) and controlled-potential coulometry (CPC). The CV results in thf, $CH_2Cl_2$ and $CH_3CN$, using $Bu_4NBF_4$ or $Bu_4NPF_6$ as electrolyte, measured at 200 mV s$^{-1}$, are summarised in Table 3 (Figures S1–S3 in the Supporting Information show the voltammograms of **5** in the three solvents with different electrolytes at different scan rates).

Table 3. Electrochemical data [$E_p^{ox}$(V) vs. FcH] for **5**.

| Solvent | $CH_2Cl_2$ | THF | $CH_3CN$ |
|---|---|---|---|
| $Bu_4NPF_6$ | 0.49 | – | 0.26 (I)<br>0.52 (II) |
| $Bu_4NBF_4$ | – | 0.56 | 0.26 (I)<br>0.54 (II) |

In thf and $CH_2Cl_2$, **5** exhibits one irreversible oxidation process at $E_p^{ox}$ = 0.56 and 0.49 V, respectively (Figure S1, Supporting Information). A different behaviour was observed in $CH_3CN$ (Figure 5), where a new irreversible anodic wave appears at a significantly lower oxidation potential of $E_p^{ox}$(I) = 0.26 V. A second oxidation process occurs in $CH_3CN$ at $E_p^{ox}$(II) = 0.52 V or $E_p^{ox}$(II) = 0.54 V, depending on the electrolyte. The relative intensity of the two waves varies with the scan rates. Thus, the ratio between the intensity of the second and first oxidation waves increases when the scan rate decreases from 200 to 20 mV s$^{-1}$ (Figure S2, Supporting Information). This behaviour suggests that the oxidation process taking place at the higher potential is related to the product formed at the first oxidation potential by an ECE-type mechanism (ECE = heterogeneous electron transfer, homogeneous chemical reaction and heterogeneous electron transfer, in sequence). Furthermore, the second wave is much higher when $Bu_4NPF_6$ is used instead of $Bu_4NBF_4$ (Figure S3, Supporting Information). This dependence on the electrolyte is suggestive of a chemical reaction that requires its participation and, assuming that the two oxidation waves are linked by an ECE-type mechanism, the rate of the intermediate chemical reaction must be much higher in the case of $PF_6^-$ than in the case of $BF_4^-$. Moreover, the lower potential at which the first redox process occurs in $CH_3CN$, in comparison with the other solvents, indicates that the first oxidation process should be supported somehow by the solvent.

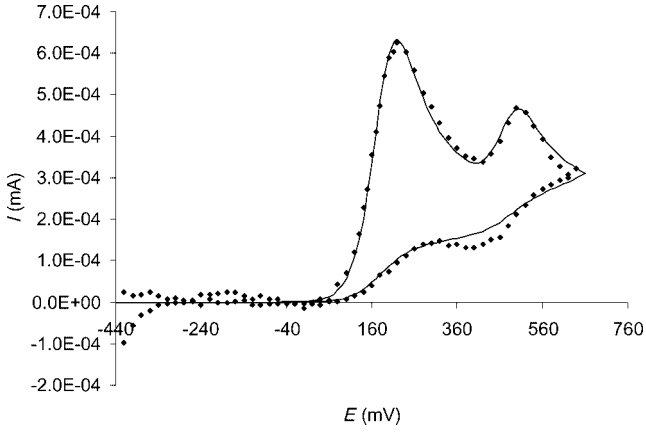

Figure 5. Voltammogram of a solution of **5**, at a Pt disc electrode, at a scan rate of 20 mV s$^{-1}$ in $CH_3CN$ with $Bu_4NBF_4$ as supporting electrolyte. The line corresponds to simulation using Scheme 3 with the parameters shown in Table 4.

Controlled-potential coulometry of **5** in $Bu_4NPF_6$/$CH_2Cl_2$, at a potential of 0.56 V, reveals a complex pattern of current vs. time (Figure S5, Supporting Information) that is compatible with the concomitant occurrence of a redox process involving the exchange of four electrons per molecule and a chemical reaction. On the other hand, coulometry of **5** in $CH_3CN$, performed at the first wave potential (0.26 V), reveals an exchange of two electrons independently of the electrolyte used (Figure S4, Supporting Information).

The experimental results described above may be interpreted as follows. The much lower potential observed for the transfer of the first two electrons in $CH_3CN$ suggests the participation of the solvent, which, as it is a better donor than $CH_2Cl_2$ and thf, makes the metal centre more electron-rich. Based on literature reports, it would be plausible

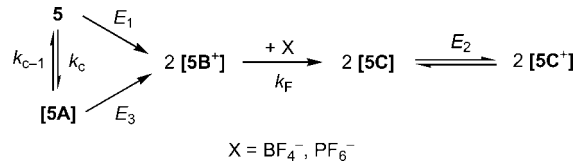
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to consider acetonitrile coordination to **5**, leading to the formation of an adduct. This type of compound has been described by Curtis et al., who have reported the addition of soft nucleophiles to $[MoCp(CO)_2]_2$ to give products in which the metal–metal π bonds have been displaced.[33] On the other hand, studies on the oxidation of $[MoCp(CO)_3]_2$ and $[MoCp(CO)_3]^-$ have shown that the cleavage of the dimer occurs with $CH_3CN$ coordination to afford the 19-electron species $[MoCp(CO)_3(CH_3CN)]^{\cdot}$, which are oxidized to $[MoCp(CO)_3(CH_3CN)]^+$ at a lower potential than would be observed for non-stabilized 17-electron species.[34–36] However, efforts to identify a solvent adduct by NMR and IR spectroscopy have proved unsuccessful, and the nature of the interaction with the solvent remains unclear, although it is probable that the oxidation of **5** results in metal–metal bond cleavage and the formation of the cation $[MoCpBz(CO)_2(CH_3CN)_2]^+$.

The intensity of the second oxidation wave observed in $CH_3CN$ depends on the electrolyte counterion. Thus, it is likely that, despite the high dielectric constant of the solvent, ion pairs are formed between the cation $[MoCpBz(CO)_2(CH_3CN)_2]^+$ and the anions $BF_4^-$ or $PF_6^-$, which are present in a large excess in solution. The rate of formation of these species, which are oxidized at the higher potentials (0.52 or 0.54 V), is reflected in the different peaks' intensity (Figure S3, Supporting Information). Considering the molar amount of **5**, the number of electrons involved in this process is two, which corresponds to one electron per molybdenum centre.

In $CH_2Cl_2$ and thf a global transfer of four electrons occurs at a unique potential (0.54 or 0.56 V). Taking into consideration this higher potential, it can be assumed that the first oxidation process is not assisted by solvent coordination. This assumption is consistent with the poorer donor ability of these solvents in comparison with $CH_3CN$. The oxidative cleavage of the metal–metal bond would afford 2 equiv. of $[MoCpBz(CO)_2(L)_2]^+$ (L = $CH_2Cl_2$, thf). At this potential, two electrons are exchanged in succession. As proposed to occur in $CH_3CN$, ion-pair formation and subsequent oxidation attest for the exchange of the remaining two electrons of the overall transfer. Ruiz et al. have reported that the two-electron oxidation of $[M_2Cp_2(CO)_4(\mu\text{-}PPh_2CH_2PPh_2)]$ (M = Mo, W) with $[FeCp_2]X$ (X = $BF_4$, $PF_6$) is followed by reactions with the counterions, which lead to different reaction pathways.[37] Further support for this interpretation is provided by Bullock and co-workers, who reported the formation of M–$FBF_3$ complexes in their mechanistic studies of hydride-transfer reactions of transition metal hydrides,[38] and by our own results on the analogous CpBz systems for which $[MoCpBz(CO)_3(CH_2Cl_2)]^+$ and $[MoCpBz(CO)_3(FBF_3)]$ have been identified and by the CV of $[MoCpBz(CO)_3(FBF_3)]$ in $NBu_4BF_4$/THF, which shows an irreversible anodic wave at 0.54 V.[39]

Simulation of the controlled-potential coulometry results in $CH_2Cl_2$ and $CH_3CN$ and of the voltammograms obtained in $CH_3CN$, using $Bu_4NBF_4$ as electrolyte, has been performed according to Scheme 3. The fittings obtained for the potential coulometry results are presented in the Supporting Information (Figures S4 and S5) and the estimated kinetic parameters in $Bu_4NBF_4$/$CH_3CN$ are listed in Table 4. Figures 5 and S6 (Supporting Information) depict the fittings obtained for this system at three different scan rates.



Scheme 3.

Table 4. Kinetic rate constants for the electrochemical behaviour of **5** in $Bu_4NBF_4$/$CH_3CN$, at a Pt disc electrode, based on Scheme 3.

| Electron transfer | Heterogeneous standard rate constant $k_{het}$ [cm s$^{-1}$] | Formal potential $E^{0\prime}$ [V] | Transfer coefficient $\alpha$ |
|---|---|---|---|
| $E_1$ | $1 \times 10^{-2}$ | 0.38 | 0.5 |
| $E_2$ | $1 \times 10^{-2}$ | 0.49 | 0.5 |
| $E_3$ | $1 \times 10^{-2}$ | 0.23 | 0.5 |
| Homogeneous rate constants [s$^{-1}$] | | | |
| $k_{c1}$ | 2 | $k_{c-1}$ | 0.2 |
| $k_F$ | 5.8 | | |

The first issue to be addressed is the difference in behaviour between the voltammograms obtained in $CH_3CN$ and those displayed in $CH_2Cl_2$ and thf. It is clear that the performance in the two latter solvents is similar, thus indicating that a series of electron transfers occurs, followed by some sort of chemical reaction that generates a non-electroactive species since the oxidation wave is irreversible for all scan rates studied. Although the second wave in $CH_3CN$ is significantly coincident with the wave observed in the other two solvents, another wave at lower potential is observed. The best fittings of the simulation to the experimental results obtained in $CH_3CN$ require the acceptance of an equilibrium that converts complex **5** into a new species (**5A**) that undergoes oxidation in the first wave. As discussed above, this species should result from an unidentified interaction with the solvent. The apparent first-order rate constant (the solvent concentration is incorporated in the rate constant value) was estimated as $k_{c1} = 2$ s$^{-1}$, a much lower value than those found for the coordination of acetonitrile to the $[CpMo(CO)_3]^{\cdot}$ radical[35] (ranging from $6.3 \times 10^5$ to $6.0 \times 10^8$ s$^{-1}$) and to the iron centre in $[Fe(\eta^5\text{-}C_6H_7)(CO)_3]^+$[40] ($8.0 \times 10^2$ s$^{-1}$). This first wave involves the sequential exchange of two electrons. It was simulated by an ECE sequence and a homogeneous rate constant for the chemical step in-between the two electron-transfer processes of more than 500 s$^{-1}$ was estimated. In $CH_2Cl_2$ and thf, although it is likely that a similar ECE pattern involving the transfer of two electrons is taking place, the available data is not good enough to estimate the rate constant for the chemical step. However, due to the shape of the voltammetric wave, it is not possible to consider that the two electrons are exchanged in a single step.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The voltammograms obtained in $CH_3CN$ also reveal some additional aspects. During the voltammetric experiment, if the scan rate is sufficiently low, all **5A** is oxidised and, during this period, the equilibrium between **5** and **5A** is displaced towards the latter, which is oxidised in a typical CE mechanism (CE = homogeneous chemical reaction preceding heterogeneous electron transfer). At higher scan rates this interconversion has no time to occur and thus, after oxidation of the initial amount of **5A** present, compound **5** is oxidised at the second wave in the same way as in dichloromethane or thf. This explains why the second wave does not disappear, although it remains relatively small, even at very high scan rates. This second wave has, then, two components that result from the oxidation of **5** and from the oxidation of the ion pair formed by the interaction with the electrolyte counterions, as explained above.

The simulation of the voltammograms obtained in $Bu_4NPF_6/CH_3CN$ may be explained using the same set of parameters listed in Table 4, with the exception of the reaction rate constant for the anion. In this case the value obtained is $k_F = 30\ s^{-1}$, which is significantly higher than that obtained in $Bu_4NBF_4/CH_3CN$ (only $5.8\ s^{-1}$). The cationic species $\mathbf{5B}^+$ and $\mathbf{5C}^+$ are considered to decompose through a first-order chemical reaction with estimated constants of $k_{d1} = 12$ and $k_{d2} = 1.5\ s^{-1}$ ($Bu_4NBF_4/CH_3CN$) and $k_{d2} = 10\ s^{-1}$ ($Bu_4NPF_6/CH_3CN$). The simulation results are depicted in Figures 5 and S6 (see Supporting Information).

Previous electrochemical studies on related carbonyl group 6 metal dimers have been dominated by complexes of general formula $[MCp'(CO)_3]_2$, where Cp′ = Cp,[41–43] Cp*,[44] CpR (CpR = $\eta^5$-$C_5H_4R$),[41,45] Fv [Fv = ($\eta^5$:$\eta^5$-$C_5H_4)_2$][45,46] and M = Mo and W. Even though the electron-transfer processes in the hexacarbonyl dimers involve the disruption of the dinuclear unit,[35,41–43,45,46] as proposed for **5**, and the anodic wave at around 0.5 V compares well with those reported for $[MoCp'(CO)_3]_2$, the cathodic shift observed for the first oxidation wave at 0.26 V in $CH_3CN$ has no parallel in the hexacarbonyl dimers' oxidation, and the irreversibility of the redox process for **5** contrasts with the reversible processes reported for $[MoCp'(CO)_3]_2$.

## Conclusion

As a final comment, we conclude that the set of reactions depicted in Scheme 3 explains all the available CV and CPC data, as can be seen from the good fittings obtained at several scan rates. It should be noted, however, that, although this may not be the only possible combination of reaction steps, it is probably the simplest one that fulfils all the experimental observations in agreement with the reported studies found in the literature for analogous systems.

## Experimental Section

**General Procedures and Starting Materials:** All manipulations were carried out under dry nitrogen using standard Schlenk techniques. Solvents were dried and distilled by the usual methods prior to use. Deuteriated solvents were dried with molecular sieves (4 Å), degassed and stored under nitrogen. NMR spectra were recorded at room temperature with a Varian Unity 300 and referenced to the proton and carbon resonances of the residual protonated solvents. Infrared spectra were obtained with a Perkin–Elmer 577 spectrophotometer. Elemental analyses were performed by the Laboratório de Análises do I.S.T., Lisbon, with a Fisons Instruments 1108. The compound HCpBz was prepared according to the described procedure.[5] All other reagents were of commercial grade and used without further purification, except $Bu_4NBF_4$ and $Bu_4NPF_6$, which were of electrochemical grade.

**$[Mo(CpBz)(CO)_3]_2$:** HCpBz (1.01 g, 1.96 mmol) was dissolved in thf (20 mL) and a 1.6 M solution of BuLi in hexanes (1.30 mL, 2.08 mmol) was slowly added at –5 °C. The resulting light-yellow solution was stirred for 1 h and then added to a suspension of $Mo(CO)_6$ (0.88 g, 3.34 mmol) in thf (10 mL) and the yellow solution obtained was refluxed overnight. The red mixture formed was cooled to room temperature and a solution of $Fe(NO_3)_3{\cdot}9H_2O$ (3.00 g) and acetic acid (2 mL) in water (10 mL) was added dropwise. By the end of the addition, a red precipitate had formed and the mixture was stirred at –5 °C for 2 h. The solution was filtered off and the red precipitate was washed with diethyl ether (10 mL). Yield: 95% (1.29 g, 0.93 mmol). $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 7.03–6.89 (m, 15 H, *p*-$C_6H_5$, *m*-$C_6H_5$), 6.78–6.71 (m, 10 H, *o*-$C_6H_5$), 3.88 (s, 10 H, C$H_2$Ph) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, –80 °C): $\delta$ = 234.7 (*C*O), 138.6 (*i*-$C_6H_5$), 128.1 (*o*-$C_6H_5$), 127.7 (*m*-$C_6H_5$), 125.6 (*p*-$C_6H_5$), 109.5 [$C_5(CH_2Ph)_5$], 31.3 (*C*$H_2$Ph) ppm. IR (KBr pellet): $\nu_{C\equiv O}$ = 1932, 1901, 1876 $cm^{-1}$. $C_{86}H_{70}Mo_2O_6$ (1391.4): calcd. C 74.24, H 5.07; found C 74.13, H 5.35.

**$[WCpBz(CO)_3]_2$:** HCpBz (1.07 g, 2.07 mmol) was dissolved in thf (25 mL) and a 1.6 M solution of BuLi in hexanes (1.30 mL, 2.08 mmol) was slowly added at –5 °C. The resulting light yellow solution was stirred for 1 h and was then added to a suspension of $W(CO)_6$ (0.78 g, 2.19 mmol) in thf (10 mL). The yellow solution obtained was refluxed overnight and then cooled to room temperature. A solution of $Fe(NO_3)_3{\cdot}9H_2O$ (3.55 g) and acetic acid (2 mL) in water (10 mL) was added dropwise at –10 °C. The mixture was stirred for 3 h and a precipitate formed. The solution was filtered off and the precipitate washed with diethyl ether (10 mL). The orange solid obtained was separated by filtration and dried. Yield: 31% (0.50 g, 0.32 mmol). Crystals suitable for X-ray diffraction were obtained from a toluene solution. $^1H$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 7.01–6.99 (m, 15 H, *p*-$C_6H_5$, *m*-$C_6H_5$), 6.71–6.70 (m, 10 H, *o*-$C_6H_5$), 3.92 (s, 10 H, C$H_2$Ph) ppm. $^{13}C\{^1H\}$ NMR ($CD_2Cl_2$, 25 °C): $\delta$ = 224.3 (*C*O), 139.3 (*i*-$C_6H_5$), 129.3 (*o*-$C_6H_5$), 128.4 (*m*-$C_6H_5$), 126.5 (*p*-$C_6H_5$), 109.2 [$C_5(CH_2Ph)_5$], 32.8 (*C*$H_2$Ph) ppm. IR (KBr pellet): $\nu_{C\equiv O}$ = 1928, 1897, 1868 $cm^{-1}$. $C_{86}H_{70}O_6W_2$ (1567.2): calcd. C 65.91, H 4.50; found C 65.89, H 4.76.

**$[MoCpBz(CO)_2]_2$:** A solution of $Li[MoCpBz(CO)_3]$ (1.81 g, 2.57 mmol) in thf was treated with $CH_2{=}CHCH_2Br$ (0.27 mL, 3.08 mmol) and heated overnight at 50 °C, whereupon the initial red-brown solution turned red. The volatiles were removed in vacuo to give an oily material, which was extracted with $Et_2O$. The solution was concentrated and cooled to –20 °C, which led to the formation of orange-red crystals in 76% yield (1.30 g, 0.97 mmol). In an alternative procedure, $[Mo(CpBz)(CO)_3]_2$ (1.76 g, 1.26 mmol) was refluxed overnight in toluene (40 mL) and the solution was then cooled to room temperature and filtered. Solvent removal afforded a red microcrystalline solid in 91% yield (1.54 g, 1.15 mmol). $^1H$ NMR ($C_6D_6$): $\delta$ = 6.85–6.84 (m, 15 H, *p*-$C_6H_5$, *m*-$C_6H_5$), 6.70–6.69 (m, 10 H, *o*-$C_6H_5$), 4.16 (s, 10 H, C$H_2$ Ph) ppm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$^{13}C\{^1H\}$ NMR ($C_6D_6$, 25 °C): $\delta$ = 239.3 (*C*O), 139.4 (*i*-$C_6H_5$), 129.3 (*o*-$C_6H_5$), 128.3 (*m*-$C_6H_5$), 126.3 (*p*-$C_6H_5$), 109.3 [$C_5(CH_2Ph)_5$], 32.2 ($CH_2Ph$) ppm. $^1H$ NMR ($CDCl_3$): $\delta$ = 6.95–6.92 (m, 15 H, *p*-$C_6H_5$, *m*-$C_6H_5$), 6.63–6.60 (m, 10 H, *o*-$C_6H_5$), 3.87 (s, 10 H, $CH_2Ph$) ppm. $^{13}C\{^1H\}$ NMR ($CDCl_3$, 25 °C): $\delta$ = 238.6 (*C*O), 138.9 (*i*-$C_6H_5$), 128.8 (*o*-$C_6H_5$), 128.0 (*m*-$C_6H_5$), 126.0 (*p*-$C_6H_5$), 108.6 ($C_5\{CH_2Ph\}_5$), 31.5 ($CH_2Ph$) ppm. IR (KBr pellet): $\nu_{C\equiv O}$ = 1878 (s), 1821 (s) $cm^{-1}$. $C_{84}H_{70}Mo_2O_4$ (1335.3): calcd. C 75.55, H 5.28; found C 75.05, H 5.44.

**[MoH(CpBz)(CO)$_3$]:** A 1.6 M solution of BuLi in hexanes (1.4 mL, 2.24 mmol) was added dropwise, at –5 °C, to a solution of HCpBz (1.10 g, 2.13 mmol) in thf (25 mL). The reaction mixture was stirred for 1 h and added to a suspension of $[Mo(CO)_6]$ (0.68 g, 2.57 mmol) in thf (10 mL) and the mixture was refluxed for 24 h. After cooling to room temperature, glacial acetic acid (1 mL; 11 mmol) was added and the solution was stirred for 12 h. The solvent was removed under vacuum and the brown solid obtained extracted with diethyl ether and filtered. Concentration and cooling to 4 °C yielded yellow crystals. Yield: 98% (1.47 g). $^1H$ NMR ([$D_8$]-toluene): $\delta$ = 6.90 (m, 15 H, *p*-$C_6H_5$, *m*-$C_6H_5$), 6.72 (m, 10 H, *o*-$C_6H_5$), 3.66 (s, 10 H, $CH_2Ph$), –4.85 (s, 1 H, Mo-*H*) ppm. $^{13}C\{^1H\}$ NMR ([$D_8$]toluene): $\delta$ = 228.5 (*C*O), 140.1 (*i*-$C_6H_5$), 128.9 (*o*-$C_6H_5$), 128.3 (*m*-$C_6H_5$), 126.4 (*p*-$C_6H_5$), 111.4 [$C_5(CH_2Ph)_5$], 32.6 ($CH_2Ph$) ppm. IR (KBr pellet): $\nu_{C\equiv O}$ = 2008 (s), 1928 (s) $cm^{-1}$. $C_{43}H_{36}MoO_3$ (696.7): calcd. C 74.13, H 5.21; found C 74.11, H 5.82.

**[WH(CpBz)(CO)$_3$]:** A 1.6 M solution of BuLi in hexanes (1.2 mL; 1.92 mmol) was added dropwise, at –5 °C, to a solution of HCpBz (1.00 g, 1.94 mmol) in thf (20 mL). The reaction mixture was then stirred for 1 h and the solvent was removed. After the addition of dmf (20 mL), the resulting solution was added to a suspension of $[W(CO)_6]$ (0.71 g, 2.00 mmol) in dmf (10 mL). The mixture was then heated at 80 °C for 24 h and cooled to room temperature. Glacial acetic acid (1 mL, 11 mmol) was then added and the solution stirred overnight. The volatiles were removed under vacuum and the brown solid obtained extracted with diethyl ether to give a yellowish solution, which was filtered and the solvents were evaporated to dryness. Yield: 95% (1.47 g). $^1H$ NMR ([$D_8$]toluene): $\delta$ = 6.88 (m, 15 H, *p*-$C_6H_5$, *m*-$C_6H_5$), 6.68 (m, 10 H, *o*-$C_6H_5$), 3.69 (s, 10 H, $CH_2Ph$), –6.31 (s, 1 H, W-*H*) ppm. $^{13}C\{^1H\}$ NMR ([$D_8$]-toluene): $\delta$ = 219.4 (*C*O), 139.9 (*i*-$C_6H_5$), 128.9 (*o*-$C_6H_5$), 128.3 (*m*-$C_6H_5$), 126.5 (*p*-$C_6H_5$), 109.9 [$C_5(CH_2Ph)_5$], 32.7 ($CH_2Ph$) ppm. IR (KBr pellet): $\nu_{C\equiv O}$ = 2008 (s), 1901 (s) $cm^{-1}$. $C_{43}H_{36}O_3W$ (784.6): calcd. C 65.82, H 4.62; found C 65.92, H 4.80.

**General Procedures for X-ray Crystallography:** Pertinent details for the individual compounds can be found in Tables 5 and 6. Crystallographic data for compounds **4**, **6** and **7** were collected using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å) with a Bruker AXS-KAPPA APEX II area detector diffractometer equipped with an Oxford Cryosystem open-flow nitrogen cryostat; data were collected at 150 K for compounds **4** and **6** and at 130 K for compound **7**. Cell parameters were retrieved using the Bruker

SMART software and refined using SAINT with all observed reflections. Absorption corrections were applied using SADABS. Data for compound **5** were collected at room temperature with a MACH3-Bruker Nonius diffractometer equipped with an Mo-$K_\alpha$ radiation ($\lambda$ = 0.71069 Å) source. Data were corrected for Lorentz and polarisation effects but not for absorption. Cell dimensions were determined from the setting angles of 25 reflections, within $\theta$ values of 15–17°. The structures were solved by direct methods using either SHELXS-97[47] or SIR 97[48] and refined using full-matrix least-squares refinement against $F^2$ using SHELXL-97.[47] All programs are included in the package of programs WINGX, version 1.64.05.[49] All non-hydrogen atoms were refined anisotropically and all hydrogen atoms except the hydride ions were inserted in idealised positions and allowed to refine as riding on the parent carbon atom. The molecular structures were produced with ORTEP3 for Windows,[50] included in the software package. CCDC-616390, -617703, -616388 and -616389 for complexes **4**, **5**, **6** and **7**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**General Procedures for Electrochemistry:** Cyclic voltammetric and controlled-potential coulometry measurements were carried out using a Radiometer DEA 101 Digital Electrochemical Analyser interfaced with an IMT 102 Electrochemical Interface. For cyclic voltammetry measurements, a three-electrode cell with a total volume of around 5 mL was used. A platinum disc electrode was used as working electrode, the counter-electrode was a Pt wire and a silver wire was used as a pseudo-reference electrode; this electrode was kept in a separate compartment and connected to the main compartment by a Luggin capillary. The ferrocene/ferrocenium couple was used as internal standard to measure wave potentials, according to IUPAC recommendations.[51] The controlled-potential coulometry electrochemical cell had a three-compartment design. A large platinum gauze electrode was employed as working electrode, the pseudo-reference electrode was similar to the one used for cyclic voltammetry measurements and it was also connected to the main compartment by a Luggin capillary. The counter electrode was also a platinum gauze electrode and it was kept in a different compartment which was connected to the main compartment by a sintered-glass separation disk. Concentrations of around 0.2 M were used for cyclic voltammetry and 0.3 M for electrolysis experiments. Concentrations in the range $1.1–1.3 \times 10^{-3}$ M were used for the complexes studied. All experiments were carried out at 25 °C in the absence of oxygen. Dry nitrogen was bubbled through the solution in the cell before measurements.

**Cyclic Voltammetry Simulation:** Digital simulation of cyclic voltammograms was carried out using a custom-made program, developed in Turbo Pascal 6 (© Borland Inc.) and run on a Pentium IV computer at 2.4 GHz. The solution of the partial differential equations describing the reaction ion-diffusion processes of all the species involved in the mechanism was performed by the method of lines, using a non-uniform space grid.[52] Space discretisation was performed upon a diffusion layer ($\delta$) computed according to the formula $\partial = \sqrt{(\pi D \tau)}$, where D is the diffusion coefficient and $\tau$ is the duration of each scan.[53] The time-course integration of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

differential equations resulting from the semi-discretisation process of the space coordinate was carried out using a fourth-order Runge–Kutte method. Parameter estimation was performed by visual fitting of simulated data to a series of base-line-corrected experimental voltammograms, using a single set of model parameters. In this procedure, the parameters involved in the model were systematically varied so as to obtain the best possible agreement between the simulated and the experimental values. Various mechanisms were tried, starting from a simple ECE scheme, which was refined so that the most relevant features of the voltammetric response were explained, resulting in the proposed scheme.

**Controlled-Potential Coulometry:** Digital simulation of the experiments was carried out in Excel (© Microsoft Corporation). The relevant differential equations were solved using the Euler method and the parameters were estimated by least-squares regression using the Solver utility to minimize the sum of the square of the residuals.

**Supporting Information** (see footnote on the first page of this article): Voltammograms of **5** in different solvents (thf, $CH_2Cl_2$ and $CH_3CN$) at different scan rates and with $Bu_4NBF_4$ or $Bu_4NPF_6$ as supporting electrolyte; graphics of current vs. time for controlled potential coulometry of **5**; simulation curves of CV and CPC results.

## Acknowledgments

The authors would like to thank the Fundação para a Ciência e a Tecnologia, Portugal for funding this work (research project POCI/QUI/55744/2004 and research grant SFRH/BD/13374/2003).

# Carbon–Hydrogen Bond Activation of Arenes by a [Bis(oxazolinyl)phenyl]-rhodium(III) Acetate Complex

**Jun-ichi Ito[a] and Hisao Nishiyama*[a]**

**Keywords:** C–H activation / Arenes / Rhodium / Substituent effects

Thermolysis of the rhodium(III) complex [(*dm*-Phebox-*dm*)-$Rh(OAc)_2(H_2O)$] [**1**; *dm*-Phebox-*dm* = 2,6-bis(4,4-dimethyloxazolinyl)phenyl] in various arenes results in the formation of the corresponding aryl complexes [(*dm*-Phebox-*dm*)Rh(Ar)($\kappa^2$-OAc)] [Ar = $C_6H_5$ (**2**), 3,5-$Me_2C_6H_3$ (**3**), 3,4-$Me_2C_6H_3$ (**4**), $C_6H_4Me$ (**5**), $C_6H_4CF_3$ (**6**), $C_6H_4OMe$ (**7**), $C_6H_4COMe$ (**8**), $C_6H_4Cl$ (**9**)]. The reaction of **1** with monosubstituted benzenes such as toluene, anisole, acetophenone, trifluorotoluene, and chlorobenzene produces a mixture of *meta*- and *para*-activated complexes, the ratio of which depends on the substituents on the benzene ring. The relative rate of the reaction of **1** with monosubstituted benzenes $C_6H_5X$ was determined to be: X = OMe (1.8) > COMe (1.6) > $CF_3$ (1.2), Cl (1.2) > $CH_3$ (1). The acetato ligand of **1** appears to be essential for C–H bond activation of arenes as no reaction of the $Rh^{III}$ complex [(*dm*-Phebox-*dm*)$RhCl_2(H_2O)$] is observed in chlorobenzene at 120 °C. The first-order rate constants obtained by thermolysis of **1** in [$D_8$]toluene at 97.1–116.5 °C yielded the following activation parameters: $\Delta H^{\ddagger}$ = 22(2) kcal mol$^{-1}$, $\Delta S^{\ddagger}$ = –24(5) cal mol$^{-1}$ K$^{-1}$. The kinetic isotope effect for the C–H bond activation of toluene by **1** was determined to be $k_H/k_D$ = 5.4 at 100 °C. These data suggest that the rate-determining step involves the C–H bond cleavage with a rigid, cyclic transition structure.

## Introduction

Intermolecular C–H bond activation has been considered to be an essential step for functionalization of unreactive hydrocarbons due to their relatively high dissociation energies.[1] Such transformations are attractive from a synthetic point of view due to the possibility of using simple and naturally abundant compounds to provide more useful and complex products.[2] Thus far, a number of studies have focused on the mechanism involving oxidative addition, σ-bond metathesis, 1,2-addition, and electrophilic activation.[3] Recently, electron-deficient Pd complexes bearing acetato ligands have been found to be reactive for inter- and intramolecular C–H bond activation and have been applied to a suitable precursor for catalytic reactions.[4] Furthermore, computational studies of the C–H bond activation by $Pd(OAc)_2$ and related complexes have suggested a mechanism whereby the acetato ligand assists the heterolytic cleavage through a six-membered cyclic transition state, as shown in Scheme 1.[5] Although Rh and Ir complexes have been known to undergo oxidative addition to the electron-rich metal center for some time,[3] only very recently have Periana and co-workers reported the C–H bond cleavage of arenes by the action of the alkoxy ligands of the $Ir^{III}$ complexes [$Ir(acac)_2(OR)L$].[6] Similarly, Davies and co-workers have reported the intramolecular C–H bond activation of {Cp*M} (M = Rh, Ir) species.[7] Such base-assisted C–H bond activation is very attractive as an alternative mechanism to oxidative addition. In this context, the $Rh^{III}$ complexes [(Phebox)$Rh(OAc)_2(H_2O)$] [Phebox = 2,6-bis(oxazolinyl)phenyl],[8] which possess an $Rh^{III}$ center and meridional stereochemistry, could be expected to combine the functions of a Lewis acid for coordination of the substrate and a base to act as a proton acceptor during the C–H bond cleavage step (Scheme 2). The $Rh^{III}$ acetate complex would therefore provide different information regarding the coordination chemistry in the meridional reaction field compared with the structurally related Rh and Ir complexes having a phosphane-based ligand (PCP- and PNP-type li-

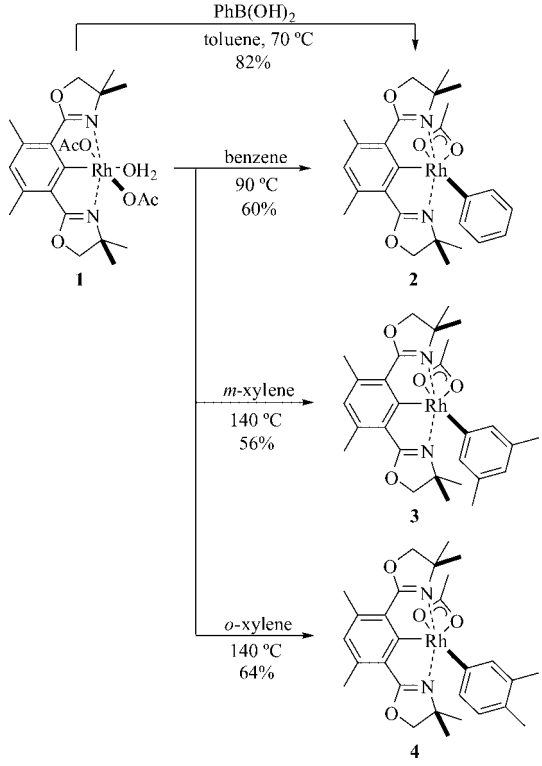
gands).[9] We report herein an intermolecular C–H bond activation reaction of simple arenes to a (Phebox)$Rh^{III}$ acetate complex.

## Results and Discussion

When a solution of the $Rh^{III}$ acetate complex [(*dm*-Phebox-*dm*)$Rh(OAc)_2(H_2O)$] [**1**; *dm*-Phebox-*dm* = 2,6-bis(4,4-dimethyloxazolinyl)phenyl][8b] in benzene was heated at 90 °C for 144 h, C–H bond activation took place to produce the novel phenylrhodium(III) complex [(*dm*-Phebox-*dm*)-Rh(Ph)($\kappa^2$-OAc)] (**2**) in 60% isolated yield (Scheme 3). Thermolysis of **1** in *m*- and *o*-xylenes also gave the corresponding arylRh$^{III}$ complexes [(*dm*-Phebox-*dm*)Rh(Ar)($\kappa^2$-OAc)] [Ar = 3,5-$Me_2C_6H_3$ (**3**), 3,4-$Me_2C_6H_3$ (**4**)] in 56% and 64% yields, respectively (Scheme 3). Since products arising from *ortho*-C–H bond activation of xylenes were not detected, the regioselectivity of the reactions must be strongly affected by the steric hindrance in the coordination environment of the Phebox ligand. The authentic phenyl complex **2** could be synthesized in 82% yield by treating **1** with $PhB(OH)_2$.



Scheme 3.

An X-ray analysis of **3** confirmed its structure as an arylRh$^{III}$ complex (Figure 1). The orientation of the aryl ligand is perpendicular to the Phebox plane [C(1)–Rh(1)–C(19) 91.81(9)°]. The difference in angles around the *ipso*-carbon atom of the aryl ligand [C(20)–C(19)–Rh(1) 128.83(17), C(24)–C(19)–Rh(1) 113.55(17)°] indicates that the aryl ring is bent slightly towards the acetato ligand, probably due to steric repulsion with the Phebox ligand. The Rh(1)–C(19) bond length of 1.993(2) Å is comparable to those in other arylRh$^{III}$ complexes.[10] The $\kappa^2$-acetato ligand makes the Rh center saturated.

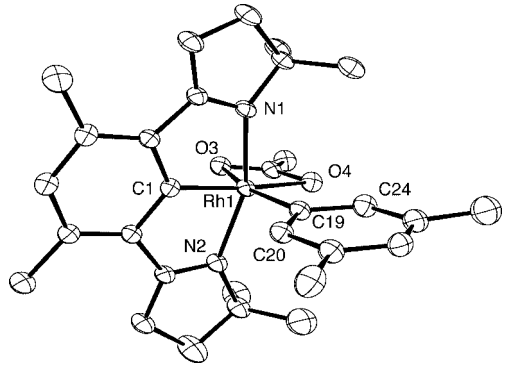


Figure 1. Molecular structure of **3** with ellipsoids at the 40% probability level (one of the molecules in the unit cell has been omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh(1)–C(1) 1.919(2), Rh(1)–C(19) 1.993(2), Rh(1)–O(3) 2.2687(16), Rh(1)–O(4) 2.2673(16), Rh(1)–N(1) 2.0753(18), Rh(1)–N(2) 2.0580(18); N(2)–Rh(1)–N(1) 158.72(7), C(20)–C(19)–Rh(1) 128.83(17), C(24)–C(19)–Rh(1) 113.55(17).

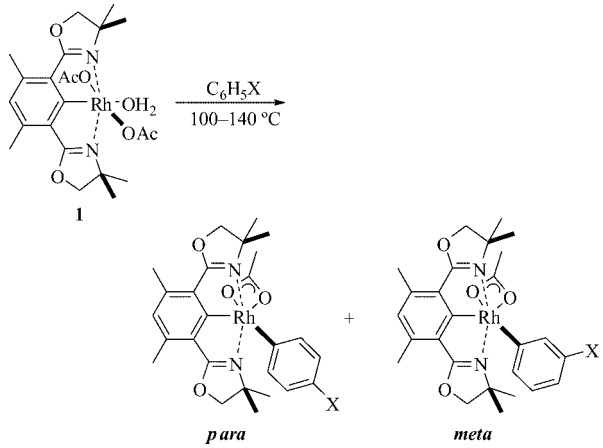
Since the substituent on the benzene ring has been shown to affect the selectivity of C–H bond activation, we examined the reactivity of **1** toward the monosubstituted benzenes $C_6H_5X$ (X = Me, $CF_3$, OMe, COMe, Cl; Scheme 4). Thermolysis of **1** in toluene resulted in the formation of *para*- and *meta*-tolyl complexes **5p** and **5m** in 64% isolated yield in a 1:1.4 ratio, respectively. We did not detect the *ortho*-C–H activated product, as observed in the reaction of xylenes. We also prepared the authentic tolyl complex **5p** as a single isomer by the reaction of **1** with *p*-tolylboronic acid (Figure 2). A similar C–H bond activation of electron-deficient $C_6H_5CF_3$ took place to produce a 1:7.8 mixture of **6p** and **6m**, respectively, in 76% yield. In the cases of anisole and acetophenone, the formation of *para*- and *meta*-activated complexes was observed. This suggests that precoor-



Scheme 4.

dination of the carbonyl and methoxy groups to the Rh center is not important for the selectivity of the C–H bond activation.[11] Reaction of **1** with $C_6H_5Cl$ produced the *para*- and *meta*-activated complexes **9p** and **9m**. The C–Cl bond-activated complex was not detected in the (Phebox)-Rh system.[12] Selectivity for the *para* position in preference to the *meta* position was observed for electron-rich toluene and anisole, whereas the inverse selectivity was observed for electron-deficient trifluorotoluene and acetophenone. This tendency is due to electrophilic aromatic substitution reactions. It is noteworthy that interconversion between **5p** and **5m** is inhibited, as shown by no observation of isomerization of **5p** in toluene at 120 °C for 24 h.

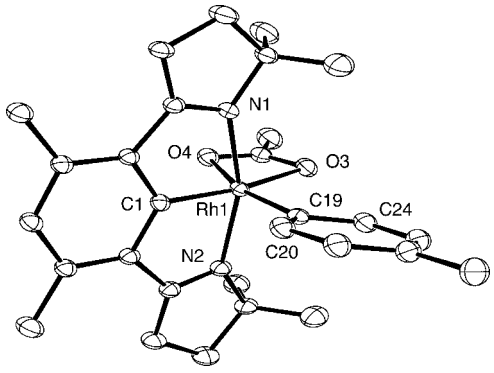

Figure 2. Molecular structure of **5p** with ellipsoids at the 40% probability level (one of the molecules in the unit cell has been omitted for clarity). Selected bond lengths [Å] and angles [°]: Rh(1)–C(1) 1.912(2), Rh(1)–C(19) 2.005(2), Rh(1)–O(3) 2.2843(17), Rh(1)–O(4) 2.2328(18), Rh(1)–N(1) 2.0526(19), Rh(1)–N(2) 2.0592(19); N(1)–Rh(1)–N(2) 159.00(8), C(20)–C(19)–Rh(1) 128.69(19), C(24)–C(19)–Rh(1) 113.81(19).

The substituent effect for C–H bond activation of monosubstituted benzenes was determined by competition reactions between two different aromatic compounds. The relative rate of reaction of **1** with $C_6H_5X$ decreased in the following sequence: OMe (1.8) > COMe (1.6) > $CF_3$ (1.2), Cl (1.2) > $CH_3$ (1); no correlation with Hammett's σ values was observed. This result is inconsistent with electrophilic C–H bond activation, where the $\rho$ values have been determined in the cases of $PtCl_6^{2-}$ and [(OEP)RhCl] (OEP = octaethylporphyrinato).[13,14]

Thermolysis of **1** in a 1:1 mixture of toluene and [$D_8$]-toluene at 100 °C resulted in formation of the C–H- and C–D-activated complexes **5** and [$D_7$]**5**. $^1$H NMR analysis revealed that the kinetic isotope effect is 5.4. This large value suggests that the C–H bond cleavage is the rate-determining step. Additionally, the rate constants obtained in the range of 97.1–116.5 °C yielded the following activation parameters: $\Delta H^{\ddagger} = 22 \pm 2$ kcal mol$^{-1}$ and $\Delta S^{\ddagger} = -24 \pm 5$ cal mol$^{-1}$ K$^{-1}$. The relatively large and negative value of the activation entropy suggests a rigid transition state.[15]

We also checked the reaction of the $Rh^{III}$ complex [(*dm*-Phebox-*dm*)$RhCl_2(H_2O)$] with chlorobenzene. When a solution of the complex in chlorobenzene was heated at 120 °C for 40 h, no reaction was observed. This result clearly indicates that the acetato ligand in **1** is essential for C–H bond activation.

The proposed mechanism for C–H bond activation of arenes by **1** is illustrated in Scheme 5. We have demonstrated previously that the coordination site of $H_2O$ in [(Phebox)$RhCl_2(H_2O)$] plays the role as the Lewis acidic position.[16] We therefore presume that a coordinatively unsaturated intermediate **A** with a vacant site can be formed by dissociation of $H_2O$. According to the final geometry of the aryl complexes, isomerization to **B** might be important to accept the arene molecule. The negative activation entropy suggests that the C–H bond of arenes is cleaved though a rate-determining six-centered transition state **C**.[5,7b] However, we cannot rule out mechanisms involving σ-bond metathesis and oxidative hydrogen migration, which require the four-centered transition state **D**.[3,17]

## Conclusion

We have found intermolecular C–H bond activation of various arenes by the structurally well-defined $Rh^{III}$ acetate complex **1**, where the acetato ligand acts as a proton acceptor. A large kinetic isotope effect and negative entropy were found in this system. X-ray analysis of **3** has revealed a molecular structure with the aryl ligand at the apical position and a $\kappa^2$-acetato ligand. Further detailed mechanistic and derivatization studies of arenes are in progress.

## Experimental Section

**General Procedures:** $^1$H and $^{13}$C NMR spectra were obtained at 25 °C with a Varian Mercury 300 spectrometer. $^1$H NMR chemical shifts are reported relative to the singlet at $\delta$ = 7.26 ppm for chloroform or $\delta$ = 7.16 ppm for benzene. $^{13}$C NMR spectra are reported in terms of chemical shifts relative to the triplet at $\delta$ = 77.0 ppm for $CDCl_3$ or $\delta$ = 128.0 ppm for $C_6D_6$ as an internal standard. IR spectra were recorded with a JASCO FT/IR-230 spectrometer. Elemental analysis was performed with a Perkin–Elmer 2400II. [(*dm*-Phebox-*dm*)Rh(OAc)$_2$(H$_2$O)] (**1**) and [(*dm*-Phebox-*dm*)Rh(Cl)$_2$(H$_2$O)] were prepared according to a literature procedure.[8b]

**Reaction of 1 with Benzene:** Complex **1** (27 mg, 0.050 mmol) was dissolved in benzene (5 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 90 °C for 144 h. After removal of the solvent, the yellow residue was purified by column chromatography on silica gel with ethyl acetate/MeOH (10:1) as eluent to give [(*dm*-Phebox-*dm*)Rh(Ph)($\kappa^2$-OAc)] (**2**; 17 mg, 62%) as a yellow solid. Complex **2** was alternatively synthesized by treatment of **1** (54 mg, 0.10 mmol) with PhB(OH)$_2$ (27 mg, 0.22 mmol) in toluene (2 mL) at 70 °C for 46 h. Workup as described above gave **2** (44 mg, 0.082 mmol, 82%). $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.97 (s, 6 H, Phebox-*Me*), 1.39 (s, 6 H, Phebox-*Me*), 2.07 (s, 3 H, O*Ac*), 2.56 (d, $J_{H,H}$ = 0.6 Hz, 6 H, 3,5-*Me*), 4.23 (d, $J_{H,H}$ = 8.2 Hz, 2 H, Phebox-C$H_2$), 4.33 (d, $J_{H,H}$ = 8.2 Hz, 2 H, Phebox-C$H_2$), 6.69–6.79 (m, 6 H, $C_6H_5$ and 4-*H*) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.08, 24.45 (OAc), 27.01, 27.19, 65.18, 81.87, 121.5, 125.3, 126.1, 126.7, 134.1, 139.7, 146.0 (d, $J_{Rh,C}$ = 31.9 Hz, $C_{ipso}$), 171.0 (d, $J_{Rh,C}$ = 5.2 Hz), 183.5 (OAc), 196.5 (d, $J_{Rh,C}$ = 29.6 Hz) ppm. $C_{26}H_{31}N_2O_4Rh$ (538.44): calcd. C 58.00, H 5.80, N 5.20; found C 58.11, H 5.67, N 5.07.

**Reaction of 1 with *m*-Xylene:** Complex **1** (54 mg 0.10 mmol) was dissolved in *m*-xylene (10 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 140 °C for 60 h. The reaction mixture was purified by column chromatography on silica gel with ethyl acetate as eluent to give [(*dm*-Phebox-*dm*)Rh(3,5-Me$_2$C$_6$H$_3$)($\kappa^2$-OAc)] (**3**; 32 mg, 56%) as a yellow solid. $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 1.00 (s, 6 H, Phebox-*Me*), 1.38 (s, 6 H, Phebox-*Me*), 2.05 (s, 3 H, OAc), 2.06 (s, 6 H), 2.55 (s, 6 H), 4.24 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 4.33 (d, $J_{H,H}$ = 8.4 Hz, 2 H, Phebox-C$H_2$), 6.32 (s, 1 H, $C_6H_3Me_2$), 6.38 (s, 2 H, $C_6H_3Me_2$), 6.68 (s, 1 H, 4-*H*) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.08, 21.52, 24.47 (OAc), 27.06, 27.14, 65.23, 81.84, 123.6, 126.0, 126.7, 131.6, 131.6, 133.9, 139.5, 145.6 (d, $J_{Rh,C}$ = 31.4 Hz, $C_{ipso}$), 170.9 (d, $J_{Rh,C}$ = 5.7 Hz), 183.3 (OAc), 196.7 (d, $J_{Rh,C}$ = 29.6 Hz) ppm. $C_{28}H_{35}N_2O_4Rh$ (566.49): calcd. C 59.37, H 6.23, N 4.95; found C 59.34, H 6.33, N 4.46.

**Reaction of 1 with *o*-Xylene:** Complex **1** (27 mg 0.050 mmol) was dissolved in *o*-xylene (2 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 140 °C for 36 h. The reaction mixture was purified by column chromatography on silica gel with ethyl acetate as eluent to give [(*dm*-Phebox-*dm*)Rh(3,4-Me$_2$C$_6$H$_3$)($\kappa^2$-OAc)] (**4**; 24 mg, 86%) as a yellow solid. $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 1.01 (s, 6 H, Phebox-*Me*), 1.38 (s, 6 H, Phebox-*Me*), 2.06 (m, 9 H, OAc and $C_6H_3Me_2$), 2.55 (d, $J_{H,H}$ = 0.6 Hz, 6 H), 4.23 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 4.33 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 6.17 (d, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_3Me_2$), 6.48 (d, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_3Me_2$), 6.68 (m, 1 H, 4-*H*), 6.76 (s, 1 H, $C_6H_3Me_2$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.05, 19.08, 19.90, 24.52 (OAc), 27.17, 65.19, 81.84, 125.9, 126.7, 126.8 (d, $J_{Rh,H}$ = 1.1 Hz), 129.1, 131.4, 133.0, 134.9 (d, $J_{Rh,C}$ = 1.1 Hz), 139.5 (d, $J_{Rh,C}$ = 1.1 Hz), 141.2 (d, $J_{Rh,C}$ = 32.0 Hz, $C_{ipso}$), 170.9 (d, $J_{Rh,C}$ = 5.7 Hz), 183.4 (OAc), 196.8 (d, $J_{Rh,C}$ = 29.6 Hz) ppm. $C_{28}H_{35}N_2O_4Rh$ (566.49): calcd. C 59.37, H 6.23, N 4.95; found C 58.75, H 6.19, N 4.28.

**Reaction of 1 with Toluene:** Complex **1** (27 mg 0.050 mmol) was dissolved in toluene (10 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 115 °C for 144 h. The reaction mixture was purified by column chromatography on silica gel with ethyl acetate as eluent to give [(*dm*-Phebox-*dm*)Rh($C_6H_4Me$)($\kappa^2$-OAc)] (**5**; 22 mg, 78%) as a yellow solid. The $^1$H NMR spectrum of the crude product revealed the formation of **5p** and **5m** in a 1.0:1.4 ratio. Complex **5p** was alternatively synthesized by treatment of **1** (54 mg, 0.10 mmol) with (*p*-$C_6H_4Me$)B(OH)$_2$ (30 mg, 0.20 mmol) in toluene (2 mL) at 90 °C for 16 h. Workup as described above gave complex **5p** (36 mg, 65%). **5p:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.99 (s, 6 H, Phebox-*Me*), 1.37 (s, 6 H, Phebox-*Me*), 2.06 (s, 3 H, O*Ac*), 2.14, (s, 3 H, $C_6H_4Me$), 2.55 (s, 3,5-*Me*), 4.23 (d, $J_{H,H}$ = 8.4 Hz, 2 H, Phebox-C$H_2$), 4.33 (d, $J_{H,H}$ = 8.4 Hz, 2 H, Phebox-C$H_2$), 6.57 (d, $J_{H,H}$ = 8.0 Hz, 2 H, $C_6H_4$Me), 6.61 (d, $J_{H,H}$ = 8.0 Hz, 2 H, $C_6H_4$Me), 6.69 (s, 1 H,4-*H*) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.09, 20.67 ($C_6H_4Me$), 24.48 (OAc), 27.11, 27.23, 65.18, 81.87, 122.4–139.6, 140.8 (d, $J_{Rh,H}$ = 31.9 Hz, $C_{ipso}$), 170.9 ($J_{Rh,C}$ = 5.2 Hz), 183.5 (O*Ac*), 196.7 ($J_{Rh,C}$ = 29.6 Hz) ppm. **5m:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.99 (s, 6 H, Phebox-*Me*), 1.38 (s, 6 H, Phebox-*Me*), 2.06 (s, 3 H, *OAc*), 2.13, (s, 3 H, $C_6H_4Me$), 2.55 (s, 3,5-Me), 4.23 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 4.33 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 6.27 (d, $J_{H,H}$ = 7.6 Hz, 1 H, $C_6H_4$Me), 6.50 (d, $J_{H,H}$ = 7.6 Hz, 1 H, $C_6H_4$Me), 6.60 (t, $J_{H,H}$ = 7.6 Hz, 1 H, $C_6H_4$Me), 6.69 (s, 1 H), 6.87 (s, 1 H, $C_6H_4$Me) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.09, 21.67 ($C_6H_4Me$), 24.48 (OAc), 27.05, 27.17, 65.21, 81.87, 122.4–139.60, 145.8 (d, $J_{Rh,C}$ = 31.4 Hz, $C_{ipso}$), 170.9 (d, $J_{Rh,C}$ = 5.2 Hz), 183.5 (OAc), 196.6 (d, $J_{Rh,C}$ = 29.6 Hz) ppm. $C_{27}H_{33}N_2O_4Rh$ (552.47): calcd. C 58.70, H 6.02, N 5.07; found C 58.83, H 5.98, N 4.96.

**Reaction of 1 with α,α,α-Trifluorotoluene:** Complex **1** (27 mg 0.050 mmol) was dissolved in α,α,α-trifluorotoluene (3 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 100 °C for 140 h. The reaction mixture was purified by column chromatography on silica gel with ethyl acetate as eluent to give [(*dm*-Phebox-*dm*)Rh($C_6H_4CF_3$)($\kappa^2$-OAc)] (**6**; 23 mg, 76%) as a yellow solid. The $^1$H NMR spectrum of the crude products revealed the formation of **6p** and **6m** in a ratio of 1:7.8. **6p:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.94 (s, 6 H, Phebox-*Me*), 1.39 (s, 6 H, Phebox-*Me*), 2.06 (s, 3 H, O*Ac*), 2.57 (s, 3,5-*Me*), 4.25 (d, $J_{H,H}$ = 8.4 Hz, 2 H, Phebox-C$H_2$), 4.35 (d, $J_{H,H}$ = 8.4 Hz, 2 H, Phebox-C$H_2$), 6.74 (s, 1 H, 4-*H*), 6.77–6.97 (4 H, $C_6H_4CF_3$) ppm. **6m:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.94 (s, 6 H, Phebox-*Me*), 1.39 (s, 6 H, Phebox-*Me*), 2.06 (s, 3 H, O*Ac*), 2.57 (s, 3,5-*Me*), 4.25 (d, $J_{H,H}$ = 8.4 Hz, 2 H, Phebox-C$H_2$), 4.35 (d, $J_{H,H}$ = 8.4 Hz, 2 H, Phebox-C$H_2$), 6.74 (s, 1 H, 4-*H*), 6.77–6.97 (3 H, $C_6H_4CF_3$), 7.18 (s, 1 H, $C_6H_4CF_3$) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.11, 24.45 (OAc), 26.99, 27.23, 65.23, 81.94, 118.5 (q, $J_{C,F}$ = 4.1 Hz), 124.4 (q, $J_{C,F}$ = 269.9 Hz), 127.0 (q, $J_{C,F}$ = 31.4 Hz), 130.4 (q, $J_{C,F}$ = 2.9 Hz), 134.3, 140.1, 147.4 (d, $J_{Rh,C}$ = 31.9 Hz, $C_{ipso}$), 171.1 (d, $J_{Rh,C}$ = 5.1 Hz), 184.1 (OAc), 195.6 (d, $J_{Rh,C}$ = 29.1 Hz) ppm. $C_{27}H_{30}F_3N_2O_4Rh$ (606.44): calcd. C 53.47, H 4.99, N 4.62; found C 54.13, H 5.27, N 3.85.

**Reaction of 1 with Anisole:** Complex **1** (27 mg 0.050 mmol) was dissolved in anisole (3 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 120 °C for 44 h. The reaction mixture was purified by column chromatography on silica gel with ethyl acetate as eluent to give [(*dm*-Phebox-*dm*)Rh($C_6H_4OMe$)($\kappa^2$-OAc)] (**7**; 20 mg, 70%) as a yellow solid. The $^1$H NMR spectrum

of the crude products revealed the formation of **7p** and **7m** in a 1:1 ratio. **7p:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.98 (s, 6 H, Phebox-*Me*), 1.38 (s, 6 H, Phebox-*Me*), 2.05 (s, 3 H, OAc), 2.55 (s, 3,5-Me), 3.64 (s, 3 H, OMe), 4.23 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 4.33 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 6.42 (d, $J_{H,H}$ = 7.8 Hz, 2 H, $C_6H_4$OMe), 6.60 (d, $J_{H,H}$ = 7.8 Hz, 2 H, $C_6H_4$OMe), 6.69 (s, 1 H, 4-*H*) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.10, 24.47 (OAc), 27.03, 27.23, 55.07 (O*Me*), 65.16, 81.88, 111.5, 126.0, 126.7, 133.3 (d, $J_{Rh,C}$ = 33.1 Hz, $C_{ipso}$), 133.9, 139.6, 155.6, 170.9 (d, $J_{Rh,C}$ = 5.3 Hz), 183.6 (O*Ac*), 196.6 (d, $J_{Rh,C}$ = 29.0 Hz) ppm. **7m:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.99 (s, 6 H, Phebox-*Me*), 1.38 (s, 6 H, Phebox-*Me*), 2.05 (s, 3 H, OAc), 2.54 (s, 3,5-*Me*), 3.61 (s, 3 H, O*Me*), 4.23 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 4.33 (d, $J_{H,H}$ = 8.1 Hz, 2 H, Phebox-C$H_2$), 6.01 (m, 1 H, $C_6H_4$OMe), 6.27 (d, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_4$OMe), 6.69 (t, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_4$OMe), 6.69 (s, 1 H, 4-*H*), 6.77 (d, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_4$OMe) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.10, 24.47 (OAc), 27.03, 27.23, 54.82 (O*Me*), 65.21, 81.88, 106.5, 120.0, 124.8, 126.2, 126.6, 127.0, 139.7, 148.0 (d, $J_{Rh,C}$ = 31.4 Hz, $C_{ipso}$), 156.4, 170.9 (d, $J_{Rh,C}$ = 5.2 Hz), 183.6 (O*Ac*), 196.3 (d, $J_{Rh,C}$ = 29.7 Hz) ppm. $C_{27}H_{33}N_2O_5Rh$ (568.47): calcd. C 57.05, H 5.85, N 4.93; found C 56.85, H 5.76, N 4.72.

**Reaction of 1 with Acetophenone:** Complex **1** (27 mg 0.050 mmol) was dissolved in acetophenone (3 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 140 °C for 24 h. The reaction mixture was purified by column chromatography on silica gel with ethyl acetate as eluent to give [(*dm*-Phebox-*dm*)-Rh($C_6H_4$COMe)($\kappa^2$-OAc)] (**8**; 23 mg, 78%) as a yellow solid. The $^1$H NMR spectrum of the crude products revealed the formation of **8p** and **8m** in a 1:4.5 ratio. **8p:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.95 (s, 6 H, Phebox-*Me*), 1.39 (s, 6 H, Phebox-*Me*), 2.07 (s, 3 H, OAc), 2.44 (s, 3 H, -CO*Me*), 2.57 (s, 3,5-*Me*), 4.24 (d, $J_{H,H}$ = 8.5 Hz, 2 H, Phebox-C$H_2$), 4.35 (d, $J_{H,H}$ = 8.5 Hz, 2 H, Phebox-C$H_2$), 6.74 (s, 1 H, 4-*H*), 6.96 (d, $J_{H,H}$ = 8.0 Hz, 2 H), 7.31 (d, $J_{H,H}$ = 8.0 Hz, 2 H) ppm. **8m:** $^1$H NMR (300 MHz, $CDCl_3$, room temp.): $\delta$ = 0.95 (s, 6 H, Phebox-*Me*), 1.39 (s, 6 H, Phebox-*Me*), 2.07 (s, 3 H, OAc), 2.39 (s, 3 H, -CO*Me*), 2.57 (s, 3,5-*Me*), 4.24 (d, $J_{H,H}$ = 8.5 Hz, 2 H, Phebox-C$H_2$), 4.35 (d, $J_{H,H}$ = 8.5 Hz, 2 H, Phebox-C$H_2$), 6.74 (s, 1 H, 4-*H*), 6.84 (t, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_4$COMe), 7.15 (d, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_4$COMe), 7.23 (s, 1 H, $C_6H_4$COMe), 7.31 (d, $J_{H,H}$ = 7.8 Hz, 1 H, $C_6H_4$COMe) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$, room temp.): $\delta$ = 19.11, 24.52 (OAc), 26.70 (CO*Me*), 27.06, 27.33, 65.20, 81.92, 121.8, 125.1, 126.5, 126.6, 133.3, 139.5, 140.1, 146.7 (d, $J_{Rh,C}$ = 31.9 Hz, $C_{ipso}$), 171.1 (d, $J_{Rh,C}$ = 5.7 Hz), 184.0 (OAc), 195.9 (d, $J_{Rh,C}$ = 29.7 Hz), 199.0 (*C*OMe) ppm. $C_{28}H_{33}N_2O_5Rh$ (580.48): calcd. C 57.93, H 5.73, N 4.83; found C 57.68, H 5.60, N 4.64.

**Reaction of 1 with Chlorobenzene:** Complex **1** (27 mg 0.050 mmol) was dissolved in chlorobenzene (5 mL) in a 20-mL Schlenk tube under argon and the solution was stirred at 120 °C for 50 h. The reaction mixture was purified by column chromatography on silica gel with ethyl acetate as eluent to give [(*dm*-Phebox-*dm*)-Rh($C_6H_4$Cl)($\kappa^2$-OAc)] (**9**; 23 mg, 80%) as a yellow solid. The $^1$H NMR spectrum of the crude products revealed the formation of **9p** and **9m** in a 1:2.2 ratio. **9p:** $^1$H NMR (300 MHz, $C_6D_6$, room temp.): $\delta$ = 0.78 (s, 6 H, Phebox-*Me*), 1.17 (s, 6 H, Phebox-*Me*), 2.16 (s, 3 H, OAc), 2.48 (s, 6 H, 3,5-*Me*), 3.43 (d, $J_{H,H}$ = 8.7 Hz, Phebox-C$H_2$), 3.55 (d, $J_{H,H}$ = 8.7 Hz, Phebox-C$H_2$), 6.49 (s, 1 H, 4-*H*), 6.91 (d, $J_{H,H}$ = 8.3 Hz, 2 H, $C_6H_4$Cl), 7.08 (d, $J_{H,H}$ = 8.3 Hz, 2 H, $C_6H_4$Cl) ppm. $^{13}$C NMR (75 MHz, $C_6D_6$, room temp.): $\delta$ = 19.35, 25.04 (OAc), 27.10, 27.34, 65.45, 81.90, 122.5–140.0, 145.2 (d, $J_{Rh,C}$ = 32.5 Hz, $C_{ipso}$), 171.4 (d, $J_{Rh,C}$ = 4.5 Hz), 184.1, 198.3 (d, $J_{Rh,C}$ = 28.0 Hz) ppm. **9m:** $^1$H NMR (300 MHz, $C_6D_6$, room temp.): $\delta$ = 0.81 (s, 6 H, Phebox-*Me*), 1.16 (s, 6 H, Phebox-*Me*), 2.16 (s, 3 H, OAc), 2.45 (s, 6 H, 3,5-*Me*), 3.40 (d, $J_{H,H}$ = 8.1 Hz, Phebox-C$H_2$), 3.52 (d, $J_{H,H}$ = 8.1 Hz, Phebox-C$H_2$), 6.47 (s, 1 H, 4-*H*), 6.61 (t, $J_{H,H}$ = 7.8 Hz, 2 H, $C_6H_4$Cl), 6.84 (d, $J_{H,H}$ = 7.8 Hz, 2 H, $C_6H_4$Cl), 6.97 (d, $J_{H,H}$ = 7.8 Hz, 2 H, $C_6H_4$Cl), 7.46 (s, 1 H, $C_6H_4$Cl) ppm. $^{13}$C NMR (75 MHz, $C_6D_6$, room temp.): $\delta$ = 19.35, 25.04 (OAc), 27.04, 27.34, 65.45, 81.90, 122.5–140.1, 150.4 (d, $J_{Rh,C}$ = 32.6 Hz, $C_{ipso}$), 171.5 (d, $J_{Rh,C}$ = 5.2 Hz), 184.1, 198.1 (d, $J_{Rh,C}$ = 28.0 Hz) ppm. $C_{26}H_{30}ClN_2O_4Rh$ (572.89): calcd. C 54.51, H 5.28, N 4.89; found C 54.66, H 5.18, N 4.72.

**Competition Reaction:** Complex **1** (16 mg, 0.030 mmol) was dissolved in a 1:1 molar mixture (4 mL) of toluene and $C_6H_5X$ (X = OMe, COMe, $CF_3$, or Cl) under argon. The solution was stirred at 100 °C for 24 h and then passed through a short column. The relative ratio of products was determined on the basis of the $^1$H NMR spectra in $CDCl_3$.

**Reaction of 1 with [D$_8$]Toluene/Toluene:** Complex **1** (11 mg 0.020 mmol) was dissolved in a 1:1 mixture of [$D_8$]toluene and toluene (1 mL) in a 20-mL Schlenk tube under argon. The solution was stirred at 100 °C for 40 h and then the solvent was removed under reduced pressure. The $^1$H NMR spectrum of the resulting residue revealed the formation of [$D_7$]**3** and **3** in a 5.4:1 ratio.

**Monitoring the Reaction of 1 with [D$_8$]Toluene:** Complex **1** (16.0 mg, 0.030 mmol) was dissolved in [$D_8$]toluene (3 mL) under argon. The solution (0.6 mL) was placed into an NMR tube and then the tube was flame-sealed. The four samples were maintained in oil baths at 97.1, 105.0, 111.3, and 116.5 °C. The reaction was monitored by $^1$H NMR spectroscopy by recording the signal of the methyl group. The rate constants were estimated as $2.48(5)\times10^{-6}$ (97.1 °C), $4.13(5)\times10^{-6}$ (105.0 °C), $7.12(9)\times10^{-6}$ (111.3 °C), and $1.21(1)\times10^{-5}$ s$^{-1}$ (116.5 °C). The Eyring plot gave the following activation parameters: $\Delta H^{\ddagger}$ = 22 ± 2 kcal mol$^{-1}$ and $\Delta S^{\ddagger}$ = –24 ± 5 cal mol$^{-1}$ K$^{-1}$.

**X-ray Diffraction Study:** Single crystals of **3** and **5p** suitable for an X-ray diffraction study were obtained from hexane/$CH_2Cl_2$ solutions at room temperature. The diffraction data were collected with a Bruker SMART APEX CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). An empirical absorption correction was applied with SADABS. The structure was solved by direct methods and refined by full-matrix least squares on $F^2$ using SHELXTL. All non-hydrogen atoms of the rhodium complex were refined with anisotropic displacement parameters. All hydrogen atoms were located at calculated positions and refined as rigid groups. Refinement details for **3**: empirical formula: $C_{29.50}H_{38.50}N_2O_4Rh$; $M_r$ = 588.03; temperature: 153(2) K; crystal system: triclinic; space group: $P\bar{1}$; $a$ = 11.2915(5), $b$ = 13.4972(7), $c$ = 19.5574(9) Å, $\alpha$ = 96.8790(10), $\beta$ = 103.3450(10), $\gamma$ = 101.8940(10)°, $V$ = 2793.7(2) Å$^3$, $Z$ = 4, $\rho_{calcd.}$ = 1.398 Mg m$^{-3}$, $\mu$ = 0.648 mm$^{-1}$, $F$(000) = 1226, crystal size = 0.40 × 0.40 × 0.30 mm, $\theta$ range = 1.74–27.53°; index ranges: $-14 \le h \le 14$, $-16 \le k \le 17$, $-25 \le l \le 21$; reflections collected: 19914; independent reflections: 12803 [$R$(int) = 0.0187], completeness to $\theta$ = 27.53°: 99.2%; max/min transmission: 1.000000/0.788581; data/restraints/parameters: 12803/0/673; goodness-of-fit on $F^2$: 1.030; final $R$ indices [$I > 2\sigma(I)$]: $R1$ = 0.0343, $wR2$ = 0.0844; $R$ indices (all data): $R1$ = 0.0438, $wR2$ = 0.0895; largest diff. peak/hole: 0.946/–0.363 e Å$^{-3}$. # Host–Guest Complexes of Oligopyridine Cryptands: Prediction of Ion Selectivity by Quantum Chemical Calculations[‡]

**Ralph Puchta*[a,b] and Rudi van Eldik[b]**

**Keywords:** Density functional calculations / Semiempirical calculations / Cryptands / Host–guest systems / Cation selectivity

The structures and complex-formation energies for the cryptands 6,6′,6′′,6′′′,6′′′′,6′′′′′-bis[nitrilotri(methylene)]tris(2,2′-bipyridine) (**1**) and 2,2′,2′′,9,9′,9′′-bis[nitrilotri(methylene)]tris(1,10-phenanthroline) (**2**) with alkali and alkaline-earth cations are obtained by PM3/SPASS and density functional (B3LYP/LANL2DZp) calculations and the results used to predict the ion selectivity. Both cryptands **1** and **2** have a cavity size similar to [2.2.2] and prefer $Ca^{2+}$ and $Sr^{2+}$, while **1** has a preference for $K^+$ and **2** favours $Na^+$ and $K^+$. The cryptand flexibility for **1** is attributed mainly to the bipyridine building block and that for **2** to the groups neighbouring the bridgehead nitrogen atoms.

## Introduction

The selective complexation of guest molecules and ions is an essential prerequisite for the proper functioning of enzymes and receptors in biological and technical systems, and it has therefore been investigated over several decades.[1,2] In order to mimic the geometric and electronic requirements necessary for selective complexation as observed in nature, many different model compounds with cavities of variable size and structure have been studied experimentally and computationally.[3–5] Examples are the well-known calixarenes,[6,7] crown ethers,[8] cryptands,[9,10] and their inclusion complexes, along with the corresponding metallatopomers, which are easily accessible by self-organisation.[11]

The synthesis of 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane, which was reported by Dietrich, Lehn and Sauvage in 1969, today well known as [2.2.2] and traded as Kryptofix 222, led to a wide range of applications, although other cryptands with similar topology have hardly been explored. It was immediately recognized that [2.2.2] and its derivatives have an outstanding potential to selectively bind guests, in particular alkali and alkaline-earth metal ions. Today, cryptands and cryptates like [2.2.2] and their different derivatives are widely applied, for example in phase-transfer catalysis,[12,13] studies on Zintl phases,[14] selective complexation of radioactive or toxic ions in medicine[15] and elsewhere,[16,17] as chelates for MRI contrast agents,[18] and as models for carrier-antibiotics such as Valinomycin and enzyme inhibitors.[19] In contrast, the cryptands 6,6′,6′′,6′′′,6′′′′,6′′′′′-bis[nitrilotri(methylene)]tris-(2,2′-bipyridine) (**1**) and 2,2′,2′′,9,9′,9′′-bis[nitrilotri(methylene)]tris(1,10-phenanthroline) (**2**) are systems that have only been partially investigated (see Figure 1).

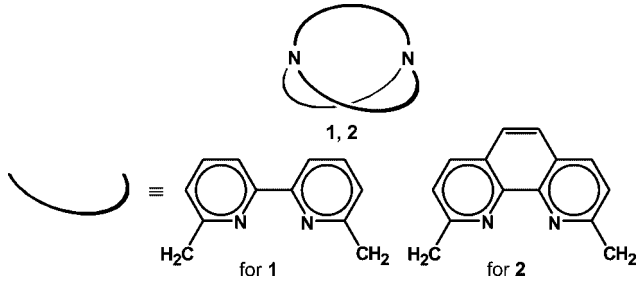

Figure 1. 6,6′,6′′,6′′′,6′′′′,6′′′′′-Bis[nitrilotri(methylene)]tris(2,2′-bipyridine) (**1**) and 2,2′,2′′,9,9′,9′′-bis[nitrilotri(methylene)]-tris(1,10-phenanthroline) (**2**).

In the 1984 report on the first synthesis of cryptands, two project aims for these newly designed polypyridine cryptands were expressed: (i) as ligand systems with novel metal-ion binding properties and (ii) special photophysical/photochemical properties for electron-transfer processes.[20] In the following years much research has been focused on their photophysics and photochemistry,[21] and the lanthanide complexes $[Ln\subset\mathbf{1}]^{3+}$ and $[Ln\subset\mathbf{2}]^{3+}$ were found to be efficient luminophores for converting UV light into visible light.[22,23] These properties can be utilized in fluorescent markers,[24] for example for detecting or locating nucleic acids,[25] or in other labelling techniques.[26] With the help of NMR techniques, the water exchange of $[Gd(H_2O)_3\subset\mathbf{1}]^{3+}$ has been investigated by Merbach et al., who tested $[Gd(H_2O)_3\subset\mathbf{1}]^{3+}$ as a potential contrast agent for magnetic

resonance imaging.[27] However, for the first proposed aim and application involving the selective ion binding of **1** and **2**, only two studies on the separation of $Am^{3+}$ and $Eu^{3+}$ have appeared.[28,29] This is surprising since different cryptand/cryptate or crown ether-solvent combinations have been investigated,[30–34] especially with respect to their transport properties[35] or ion conductivity and potential applications in batteries and capacitors,[36] while parallel alkali and alkaline-earth ion complexes with phenanthroline and bipyridine moieties have also been studied.[37]

In a recent report we demonstrated that ion selectivity can be studied by quantum chemical methods for [2.2.2] and smaller homologues. The calculated complex-formation energy is a reliable value to conclude which ion fits best.[38] In this study we will tie up with the first report by Lehn et al., where **1** and **2** were synthesised as $[Na\subset\mathbf{1}]^+$ and $[Na\subset\mathbf{2}]^+$ (see Figures 2 and 3).[20] We have calculated the complex-formation energies for the alkali and alkaline-earth metal ions to determine which ions fit best into **1** and **2**. In addition, we have investigated how the host responds to the different guest ions.

## Quantum Chemical Methods

We performed B3LYP/LANL2DZp hybrid density functional calculations, with pseudo-potentials on the heavy elements and the valence basis set augmented with polarisation functions.[39,40] During the optimisation of the structures no constraints other than symmetry were applied. In addition, the resulting structures were characterised as minima, transition structures, etc., by computation of their vibrational frequencies. The relative energies were corrected for zero-point vibrational energies (ZPE). The Gaussian suite of programs was used for all calculations.[41]

Semiempirical PM3 calculations[42] for $Li^+$[43], $K^+$[44] and $Ca^{2+}$[45] were performed using VAMP.[46] The PM3/

SPASS[38,47] calculations for all other alkali and alkaline-earth ions not included in PM3 were performed using MOPAC 6.0.[48]

## Results and Discussion

In contrast to [2.2.2], for which X-ray structures of all alkali and alkaline-earth metal cryptate complexes have been published, only the structures of [Na **1**]$^+$e$^-$[49] and [Na⊂**2**]Br[50] have been published for **1** and **2**. The cryptatium species [Na⊂**1**]$^+$e$^-$ is an electride[49] and therefore cannot be taken into consideration. The structural parameters for the calculated (Table 2) and published X-ray structure of [Na⊂**2**]$^+$ are in satisfactory agreement (the mean X-ray bond length between Na and the sp$^2$-hybridized pyridine nitrogen (Na–$N_{sp^2}$) is 2.70 Å, and that between Na and the amine nitrogen ($N_{sp^3}$) is 2.79 Å),[50] as expected. Further selected data for the calculated structures (metal–$N_{sp^2}$ and metal–$N_{sp^3}$ distances and the twist angle) are summarised in Tables 1 and 2.

The $Li^+$ and $Be^{2+}$ ions seem to be too small for **1** and **2** as the calculated $D_3$ structures of [Li⊂**1**]$^+$ and [Li⊂**2**]$^+$ as well as [Be⊂**1**]$^{2+}$ and [Be⊂**1**]$^{2+}$ are not local minima on the potential hypersurface. The $D_3$ structures of all endohedral complexed $Li^+$ and $Be^{2+}$ are transition states for the movement of the metal ion inside the cavity of **1** and **2**. This motion leads from one $N_{sp^3}$ to the other. Whereas [Li⊂**1**]$^+$ shows a clear barrier of 3.3 kcal mol$^{-1}$ for this movement, the $C_3$ and $D_3$ conformers of [Li⊂**2**]$^+$ have no barrier, indeed $D_3$ is even slightly negative (–0.1 kcal mol$^{-1}$). The $Be^{2+}$ ion is significantly smaller than $Li^+$ and therefore the barriers are higher: [Be⊂**1**]$^{2+}$ 22.4 kcal mol$^{-1}$ and [Be⊂**2**]$^{2+}$

11.6 kcal mol$^{-1}$. The lower barriers in both cryptates based on **2** can be attributed to the rigidity of the phenanthroline moieties.

Interestingly, the quality of the structures calculated applying the simple PM3/SPASS method, in which the metal cation is modelled by a "sparkle" (a charged pseudo-atom), is very satisfactory, although the metal–sp$^2$-nitrogen distances are somewhat too short and the metal–sp$^3$-nitrogen interactions are somewhat too long compared to the DFT data.

The main goal of this work was to investigate the selective complexation of alkali and alkaline-earth metal ions by the cryptands **1** and **2**. As demonstrated in our earlier contributions,[11d,38] one can inspect two properties in order to predict whether or not an ion will be complexed. The bond length between the metal ion and the donor atoms in the cryptate can be compared with those computed for a metal ion complexed by solvent molecules like acetonitrile or ammonia. This method only seems to be of value if the donor atoms coordinating to the metal ions are the same in the cryptand and have the same hybridisation as in the solvent, and was therefore not followed further in this work. Alternatively, the energy of the model reactions shown in Equations (1) and (2) can be evaluated. Note that, for the sake of consistency, sixfold coordination is adopted for all cations. The lithium[51] and sodium cations prefer four- and fivefold coordination, respectively, with additional water molecules hydrogen-bonded in the second coordination sphere instead of being coordinated to the cation. However, in the gas phase $[Li(OH_2)_6]^+$ and $[Na(OH_2)_6]^+$ are local minima.

$$[M(H_2O)_6]^{n+} + \mathbf{1} \rightarrow [M\subset\mathbf{1}]^{n+} + 6H_2O \quad (1)$$

$$[M(H_2O)_6]^{n+} + \mathbf{2} \rightarrow [M\subset\mathbf{2}]^{n+} + 6H_2O \quad (2)$$

The complexation energies computed in this way are plotted against the ionic radii in Figures 4, 5, 6 and 7. The most stable endohedral complexes of **1** with the alkali-metal ions are formed for $K^+$ followed by $Na^+$ and with the alkaline-earth ions $Ca^{2+}$ and $Sr^{2+}$, followed by $Ba^{2+}$. Cryptand **2** prefers to bind $Na^+$ followed by $K^+$ of the alkali-metal ions, and $Ca^{2+}$ and $Sr^{2+}$ followed by $Ba^{2+}$ of the alkaline-earth ions. Therefore, we conclude that the cavity sizes of **1** and **2** are of the same order as the cavity size of [2.2.2], and that the cavity of **1** is slightly larger than that of **2**.

The same trend can be qualitatively found by application of semiempirical methods, in this case PM3/SPASS. (see Figures 5 and 7) In the semiempirical series, $[Ca\subset\mathbf{1}]^{2+}$ and $[Ca\subset\mathbf{2}]^{2+}$ and, to a lesser extent, $[K\subset\mathbf{2}]^{+}$ and $[K\subset\mathbf{2}]^{+}$, are computed to be too stable. Previous studies on the endohedral complexation of $Ca^{2+}$[38] and calculations on $[Ca(H_2O)_n]^{2+}$ and $[Ca(NH_3)_n]^{2+}$ confirm that the calcium PM3 parameters do not describe Ca–N and Ca–O interactions correctly. The semiempirical structures of $[Mg\subset\mathbf{1}]^{2+}$ and $[Mg\subset\mathbf{2}]^{2+}$ lead to a clear fourfold-coordinated $C_3$ structure and therefore show a larger energy gap than in the DFT case, although the qualitative result is not affected.

A comparison of the M–N distances (Tables 1 and 2) shows an increase in the metal–donor bond lengths with increasing size of the guest ion. This behaviour is clearly attributed to the different contributions of the guest ions, but it is also a distinct hint that the investigated cryptands show some flexibility. An essential prerequisite for flexibility is that the molecular moieties can undergo twisting and tilting. While in $[M\subset\mathbf{1}]^{n+}$ every molecular bar has two N–$CH_2$(pyridine) motifs adjacent to the N bridgehead and a conformationally nearly unhampered C–C bond bridging the two pyridine rings, $[M\subset\mathbf{2}]^{n+}$ has only two such pyridine motifs adjacent to the N bridgehead, and the two pyridine rings in phenanthroline are stiffened by a third, weaker aromatic[52] six-membered ring. A descriptor for the twist and tilt of these moieties is the torsion angle $N_{sp^2}$–C···C–$N_{sp^2}$ between the aromatic pyridine groups and the $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$ angle between the aliphatic methylene building blocks (see Tables 1 and 2).

Both sorts of torsion angles show a qualitative linear behaviour that mainly depends on the ion size (see Figures 8, 9, 10 and 11). The $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$ angle covers a wide range in both host–guest systems [96° for $[M\subset\mathbf{1}]^{n+}$ (see Figure 8)[53] and 83° for $[M\subset\mathbf{2}]^{n+}$ (see Figure 10)[53]]. Throughout the series, all cryptates show the same stereochemistry, which is easily derivable from the algebraic sign (here minus, and therefore λ). As expected, there are more drastic differences in the series of $N_{sp^2}$–C···C–$N_{sp^2}$ angles. Whereas the bipyridine building block shows a 1/3 higher value for the twist (123°)[53] (see Figure 9) compared to $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$, the phenanthroline moiety is inflexible and only shows a three times lower angle (25°)[53] (see Figure 11) than $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$. Interestingly, both coordinating systems use the same principle to improve the

interactions between donor and guest ion: in order to get more tilted and closer to the ion, the puckered ring formed by the pyridine moieties and guest ions interconvert their stereochemistry. Therefore, small ions like $Li^+$, $Be^{2+}$ and $Ca^{2+}$ have a λλ arrangement as both torsion angles show negative algebraic signs, whereas the larger ions $K^+$, $Rb^+$, $Cs^+$, $Sr^{2+}$ and $Ba^{2+}$ have a λδ arrangement since $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$ is negative and $N_{sp^2}$–C···C–$N_{sp^2}$ is positive. The sodium cation is a special case. Thus, whereas $[Na\subset\mathbf{1}]^+$ is clearly λλ, the stiffened cryptand $[Na\subset\mathbf{2}]^+$ is only just λλ since the $N_{sp^2}$–C···C–$N_{sp^2}$ angle is only –0.2°.

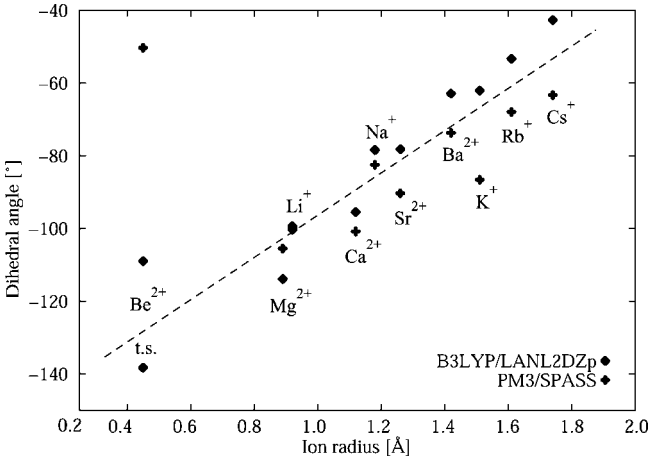

Figure 8. RB3LYP/LANL2DZp and PM3/SPASS torsion angle $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$ of $[M\subset\mathbf{1}]^{n+}$ plotted against the ionic radius of $M^{n+}$ (dashed line represents observed trend).

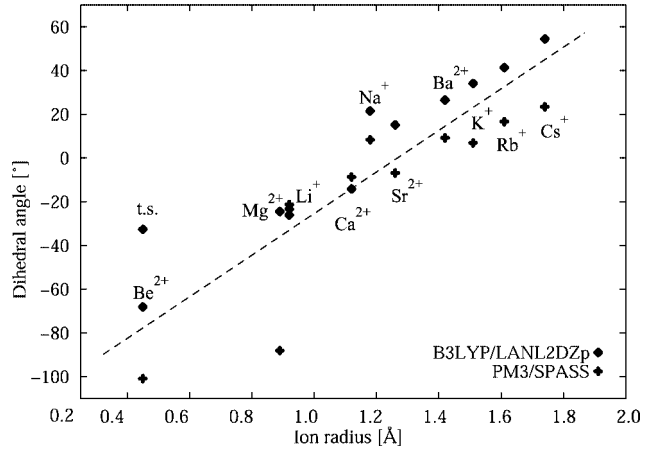

Figure 9. RB3LYP/LANL2DZp and PM3/SPASS torsion angle $N_{sp^2}$–C···C–$N_{sp^2}$ of $[M\subset\mathbf{1}]^{n+}$ plotted against the ionic radius of $M^{n+}$ (dashed line represents observed trend).

## Conclusions

Density functional theory and PM3/SPASS suggest that **1** and **2** have similar-sized cavities to [2.2.2]. According to our calculations and introduced model reactions, the investigated cryptands prefer $Ca^{2+}$ and $Sr^{2+}$ as alkaline-earth ions, whereas $K^+$ is preferred by **1** and **2** binds $Na^+$ and $K^+$ equally well. The flexibility, which is important for selective

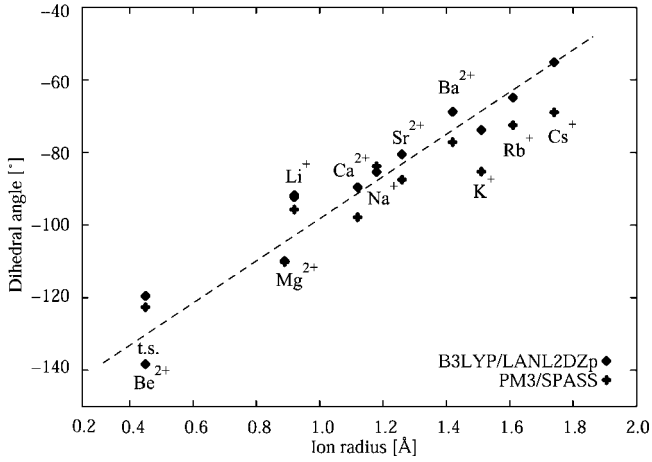

Figure 10. RB3LYP/LANL2DZp and PM3/SPASS torsion angle $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$ of $[M\subset\mathbf{2}]^{n+}$ plotted against the ionic radius of $M^{n+}$ (dashed line represents observed trend).

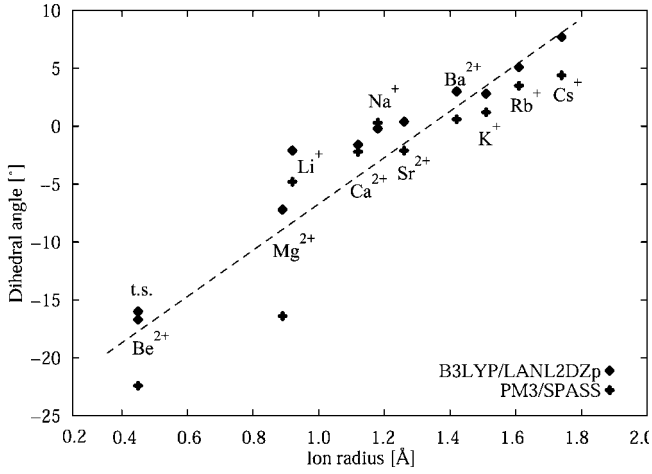

Figure 11. RB3LYP/LANL2DZp and PM3/SPASS torsion angle $N_{sp^2}$–C···C–$N_{sp^2}$ of $[M\subset\mathbf{2}]^{n+}$ plotted against the ionic radius of $M^{n+}$ (dashed line represents observed trend).

host binding, is dominated in **1** by the flexibility of the pyridine–pyridine connection, whereas in the more rigid **2** the $CH_2$–$N_{sp^3}$···$N_{sp^3}$–$CH_2$ motif contributes the main part. The stereo-arrangement of the molecular cage axis fixed at the bridgehead nitrogen is identical in all host–guest systems investigated and does not change during the calculations. On the contrary, the stereochemistry of the coordinating bipyridine and phenanthroline moieties can change depending on the size of the guest ion.

# Synthesis of Controllable-Size Core–Shell Se@Ag and Se@Au Nanoparticles in UV-Irradiated TSA Solution

**Liangbao Yang,[a] Yuhua Shen,*[a,b] Anjian Xie,[a,b] Jianjun Liang,[a] Jinmiao Zhu,[a] and Long Chen[a]**

**Keywords:** Nanostructures / Photochemistry / Core–shell structures / Selenium

The formation of Se-core–Au-shell and Se-core–Ag-shell nanoparticles by using photochemically reduced tungstosilicate Keggin ions has been described. The Se core structure serves both as a chemical and a physical template for the coating of Au and Ag. With this method, the core size and the shell thickness can be controlled by varying the conditions. With this strategy, it is possible to realize a large combination of core–shell nanostructures with potential application in engineered nanomaterials and catalysis by using Keggin ions.

## Introduction

For many years, considerable effort has been made to design, fabricate and manipulate nanostructured systems with functional properties.[1] This knowledge, together with effective strategies towards the fabrication of nanostructures, has inspired the design and development of new composites for advanced applications. Core–shell structures provide a useful means to modify the properties of nanoparticles.[2] Such core–shell nanoparticles have become attractive because of the advantages offered by the combination of the properties of different compositions and of the shelled structures. They are used as building blocks for photonic crystals,[3] as heterogeneous catalysts,[4] in multienzyme biocatalysis,[5] and in surface-enhanced Raman scattering[6] and drug-delivery applications.[7] Most studies on the core–shell particles have focused on composites that are typically composed of solid or liquid cores surrounded by shells of polymers, inorganic compounds, or biomacromolecules. They provide the possibility of enhanced functionality and multifunctional properties, which is in contrast with their more-limited, single-component counterparts.

Semiconductor-metal core–shell structures are most interesting because of the bifunctional properties of the metal and the semiconductor.[8–10] In this work, we report a facile, one-pot synthesis of Se@Au and Se@Ag composite colloids in UV-irradiated TSA solution. Such Se@Au(Ag) nanocomposite colloids are expected to be useful in biotechnology, as Se is an essential trace element for humans. Further, Se is an important elemental semiconductor, because of its many intriguing photoelectrical properties as well as its applications in semiconductor rectifiers, solar cells, photographic exposure meters, and xerography.[11] Silver or gold exhibits high-temperature and high-pressure stability and resistance to acids, bases, and solvents.[12] Combination of the two nanomaterials of Se and Au or of Se and Ag provides a model structure for the further understanding of the core–shell heterostructures and their properties. The composite colloids produced are also expected to have potential applications in electronics, photonics, catalysis, and sensors. Metal-based materials with nanoscale hollow interiors exhibit promising properties for diverse applications.[13] As reported previously,[14] the Se-core composites can be used as precursors to yield hollow capsules by subsequent removal of the sacrificial Se cores; this is because Se exhibits high solubility in various solvents (e.g. $CS_2$ and $N_2H_4$) and a relatively low melting point (≈ 217 °C).[11]

Experimental procedures for the synthesis of core–shell nanostructures are rather cumbersome and involve several steps. Generally, growth of core–shell structures can be accomplished by the successive reduction of one metal ion over the core of another.[15–18] Keggin ions have a special structure, which may be reduced photochemically.[19,20] Sastry and co-workers have demonstrated that bimetallic nanoparticles can be synthesized by using Keggin ions as a UV-switchable reducing agent.[21,22] In this paper, we use a strategy that involves the immobilization of a reducing agent such as tungstosilicate acid (TSA) in the solution of the core, which, when exposed to the second metal ions, can selectively reduce them on the surface to lead to phase-pure

core–shell structures. An advantageous feature of this approach for obtaining phase-pure core–shell nanoparticle structures could be a reducing agent bound to the surface of the core nanoparticle that can be selectively activated (i.e. whose reducing capability can be switched off and on at will). The mechanism is also discussed. Presented below are details of the investigation.

## Results and Discussion

Figures 1A and B show the UV/Vis spectra of the Se-core–Au-shell and Se-core–Ag-shell nanoparticle solutions, respectively, at different stages of preparation. Curve 1 in Figure 1 corresponds to the spectrum of a 1 mM TSA/1 mM $H_2SeO_3$ aqueous solution. It can be observed that there is no absorption in the visible region of the electromagnetic spectrum. The UV/Vis absorption spectrum recorded after UV irradiation of the TSA/$H_2SeO_3$ solution for 5 h is shown as curve 2 in Figure 1. It can be clearly seen that an absorption band starts to form from ca. 655 nm. This absorption band may arise as a result of excitation of the surface plasmon vibrations in the Se nanoparticles.[23] The TSA/Se nanoparticle solution was further irradiated with UV light for 3 h; this UV/Vis spectrum is shown as curve 3 in Figure 1. At this stage, the color of the solution changed from orange to bluish-red; these changes are reflected as an increase in absorption at 760 nm in the spectrum. This increase in absorption at long wavelengths clearly indicates that the TSA ions have been reduced.[20] Curve 4 in Figure 1 corresponds to the UV/Vis spectra of the UV-irradiated TSA/Se nanoparticle solution after addition of $HAuCl_4$ (Figure 1A) and $AgNO_3$ solutions (Figure 1B). Strong absorption bands at ca. 540 nm and ca.410 nm are observed. These absorption bands arise from excitation of the surface plasmon vibrations in the Au[20,21,24] and Ag[20,21] nanoparticles. Curve 5 in Figure 1 corresponds to the TSA/Se solution without further UV irradiation (sample 2) with the addition of $10^{-3}$ M aqueous solutions of $HAuCl_4$ (Figure 1A) and $AgNO_3$ (Figure 1B). When curves 4 and 5 in Figures 1A and B are compared, large changes in both the UV/Vis absorption spectra of the gold and silver nanoparticle solutions are observed. Thus, the photochemical charging of the TSA molecules is the most crucial step in the protocol, which sets this protocol apart from other bimetallic nanoparticle core–shell synthesis protocols that employ reducing agents present uniformly in the reaction media. That the reducing capability of the TSA ions can be switched on by irradiation with UV light is an additional feature that enhances the versatility of this technique.

The XRD pattern recorded from a drop-coated film of the UV-irradiated TSA solution after addition of $H_2SeO_3$ on a glass substrate is shown in Figure 2, curve 1. All of the strong and sharp reflection peaks can readily be indexed to a single phase of trigonal-structured selenium (indicated by "*", JCPDS Cards No. 86-2246). Curve 2 in Figure 2 shows the XRD pattern recorded from a drop-coated film of the UV-irradiated TSA/Se solution after addition of $HAuCl_4$ (Figure 2A) and $AgNO_3$ (Figure 2B) solutions. The (111), (200), and (220) Bragg reflections of face-centered cubic gold and silver are clearly observed. The background is most likely caused by Brownian motion of the particles during the scan, solvent scattering, or the short-range order of the solvation cage around the particles. The results, obtained from XRD, indicate that the products of Se and Au/Ag are crystalline and have a high purity.

To confirm the presence of Se, Au, and Ag in Se–Au- and Se–Ag-core–shell nanoparticles, a chemical analysis of these samples was performed by using XPS. The Se 3d core level spectra recorded from the Se-core–Au-shell and Se-core–Ag-shell nanoparticles at various stages of preparation are shown in Figure 3A and Figure 3B, respectively, while the Au 4f core level spectrum from the Se-core–Au-shell sample and the Ag 3d core level spectrum from the Se-core–Ag-shell nanoparticles are shown in Figure 3C and Figure 3D, respectively. The binding energy at 53.61 eV (Figure 3A) or 54.32eV (Figure 3B), corresponding to Se 3d, is the characteristic peak for elemental selenium,[25,26] which

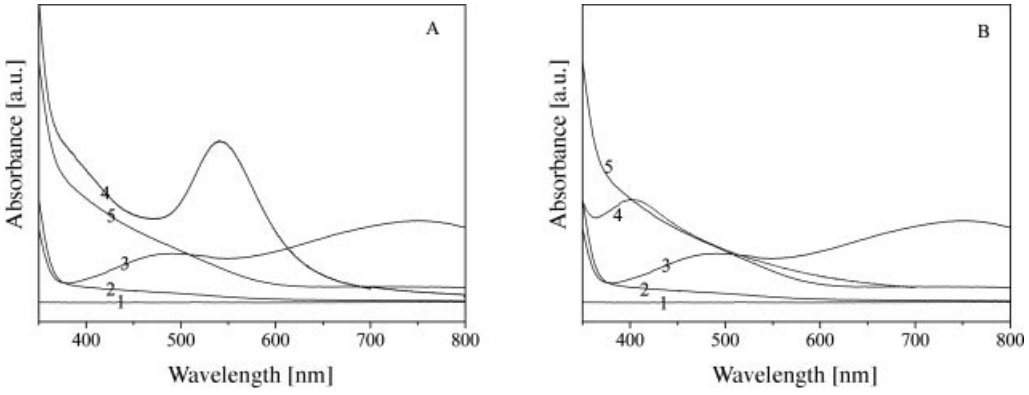

Figure 1. (A) and (B) show the UV/Vis spectra of the Se-core–Au/Ag-shell nanoparticle solutions at different stages of reaction. Curve 1 in (A) and (B): $10^{-3}$ M TSA/$10^{-3}$ M $H_2SeO_3$ aqueous solution before UV irradiation; curve 2 in (A) and (B): TSA/$H_2SeO_3$ solution (sample 1) after UV irradiation for 5 h.; curve 3 in (A) and (B): further UV irradiation of sample 2 (for 3 h); curve 4: addition of $10^{-3}$ M $HAuCl_4$ (A) and $AgNO_3$ (B) solutions to sample 3; curve 5: addition of $10^{-3}$ M aqueous solutions of $HAuCl_4$ (A) and $AgNO_3$ (B) to sample 2 (no further UV irradiation).

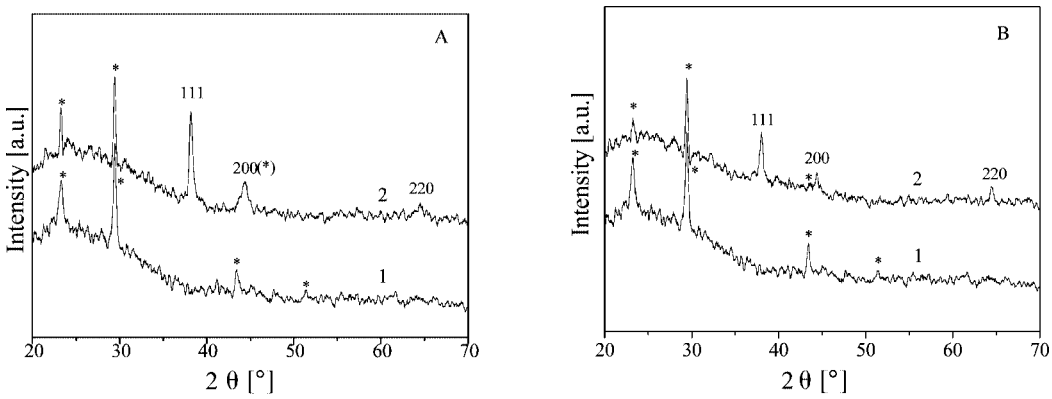

Figure 2. (A) and (B) show the XRD patterns recorded from drop-coated films on glass substrates of the Se-core–Au/Ag-shell nanoparticle solutions at different stages of reaction. Curve 1 in (A) and (B): UV-irradiated TSA solution after addition of $10^{-3}$ M $H_2SeO_3$; Curve 2: UV-irradiated TSA/Se solution after addition of $10^{-3}$ M $HAuCl_4$ (A) and $AgNO_3$ (B) solutions. The Bragg reflections marked * correspond to Se.

implies that the valence of selenium in the core is zero. The Au 4f core level spectrum recorded from the Se–Au-core–shell nanoparticle sample could be resolved into a single spin-orbit pair (spin-orbit splitting ≈ 3.71 eV) with a $4f_{7/2}$ binding energy (BE) of 83.68 eV (Figure 3C). This BE is characteristic of Au in the fully reduced state.[27] The Ag 3d spectrum (Figure 3D) resolves into two spin-orbit components. The Ag $3d_{5/2}$ and $3d_{3/2}$ peaks occur at a BE of 367.8 and 373.8 eV, respectively, and correspond to metallic silver.[28] This result demonstrates that only one form of Ag is present in solution, in the form of $Ag^0$.

Figure 4 shows a representative TEM image of the Se nanoparticle solution. From the TEM image, it can clearly be seen that the nanoparticles, with an average size in diameter of 40 nm, are spherical colloids. Figure 5A and Figure 6A display the SEM images of Se@Au- and Se@Ag-

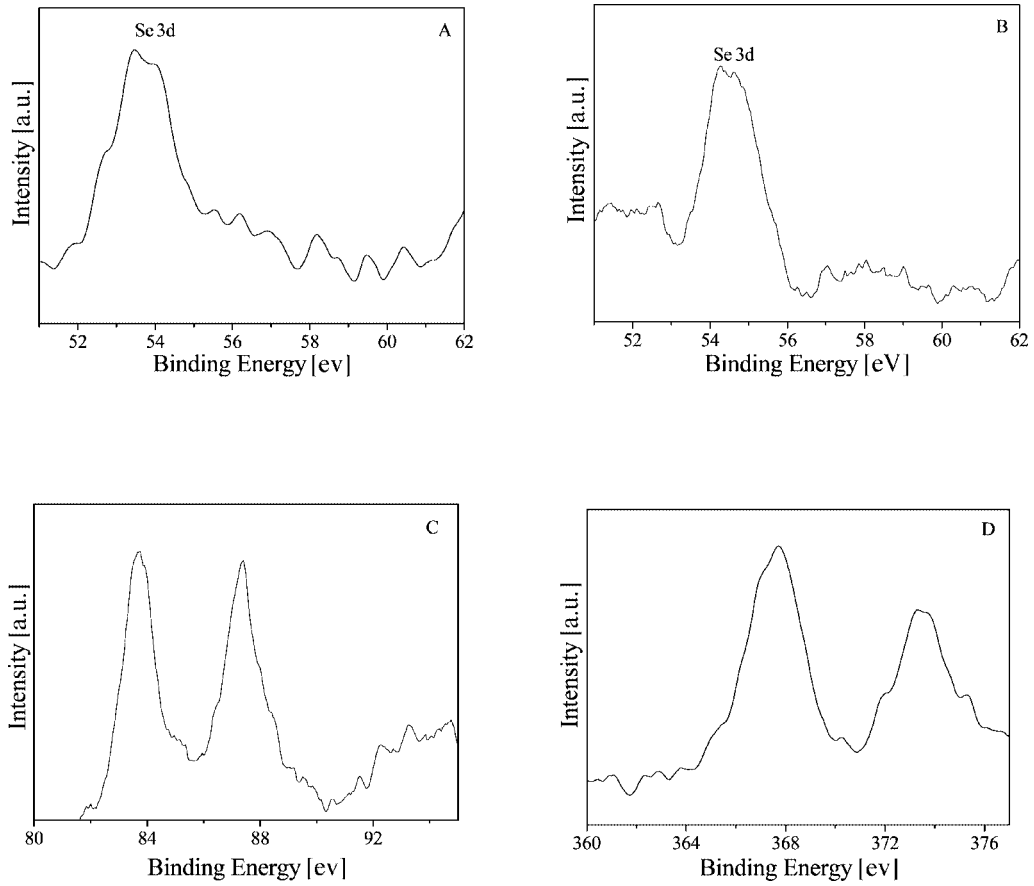

Figure 3. Se 3d core level spectra recorded from Se–Au- (A) and Se–Ag-core–shell nanoparticles (B). Au 4f (C) and Ag 3d (D) core level spectrum recorded from Se–Au- and Se–Ag-core–shell nanoparticles, respectively.

core–shell colloids formed by sequential reduction by a UV-irradiated TSA solution. Such core–shell colloids were quite uniform and could be obtained in copious quantities. Figure 5B and Figure 6B show the TEM images of the same samples of Figure 5A and Figure 6A, respectively, which reveal the smoothness and uniformity of these spheres with sizes in diameter of 51 nm and 99 nm, respectively. Again, the Se cores could selectively be removed by chemical or thermal means.[14] When the Se@Au and Se@Ag nanoparticles (Figures 5A,B and 6A,B) are compared with the Se nanoparticles (Figure 4), it can be seen that the particles are quite monodisperse and show a small increase in size (ranging from 40 nm to 51 nm and to 99 nm, respectively).

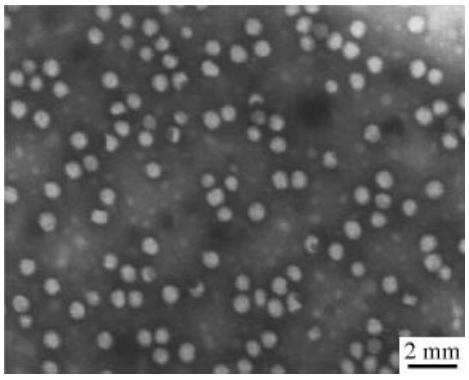

Figure 4. TEM image of Se nanoparticles reduced by UV-irradiated TSA solution.

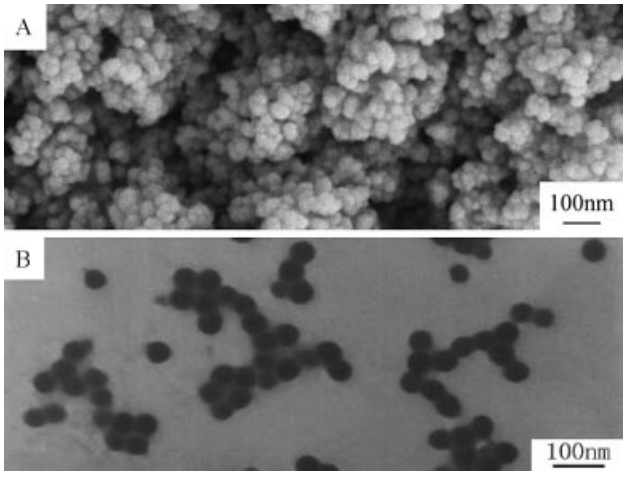

Figure 5. (A) SEM of Se@Au-core–shell colloids formed by sequential reduction of selenium and gold ions by UV-irradiated TSA solution. (B) TEM of the same sample.

Figure 7 shows the TEM image of Au nanoparticles reduced by a UV-irradiated TSA solution. From Figure 7, it can clearly be seen that the gold nanoparticles are very different from those covering the templates of Se. This control experiment thus clearly shows that the template in the nucleation step facilitates the formation of the coating on the template. From Figures 5 and 6, we notice that the t-Se templates are well coated by the Au and Ag nanoshells. In our study, we believe that the Se structures serve as both chemical and physical templates.[14a] The coating of Se templates

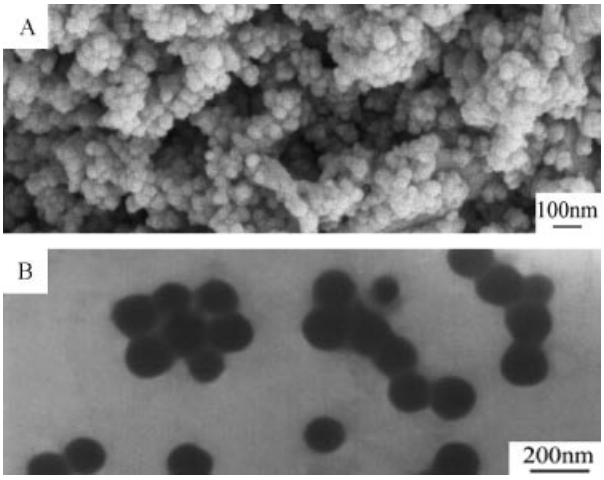

Figure 6. (A) SEM of Se@Ag-core–shell colloids formed by sequential reduction of selenium and gold ions by UV-irradiated TSA solution. (B) TEM of the same sample.

with Au and Ag is believed to occur through two distinct reduction reactions: (i) the initial reduction of the $Au^{III}$ or $Ag^{I}$ salt by the Se template itself at the interface, which is similar to the method described in the literature[29], and (ii) the reduction of the $Au^{III}$ or $Ag^{I}$ salt by the UV-irradiated TSA solution. The galvanic reduction of $Au^{III}$ or $Ag^{I}$ by a Se template can continue until the surface is completely covered. Subsequent deposition of the Au- or Ag coating is dominated by the UV-irradiated TSA solution. The engagement of the template in the nucleation step facilitates the formation of homogeneous, uniform coating on the template. This is also the major reason why Se is such a good template for the coating by metals relative to inert structures such as polystyrene beads or silica spheres. On the other hand, we believe that such spontaneous "landing" of the small nanoparticles of Au or Ag on the backbone of the Se nanoparticles followed by self aggregation rather than aggregation with the Se nanoparticles can be related to the "contact epitaxy" mechanism proposed by Averback et al.[30,31] The driving force for this spontaneous, oriented attachment is substantial reduction in the surface free energy (from a thermodynamic viewpoint) that arises as a result of the elimination of pairs of high energy surfaces.[32,33] The

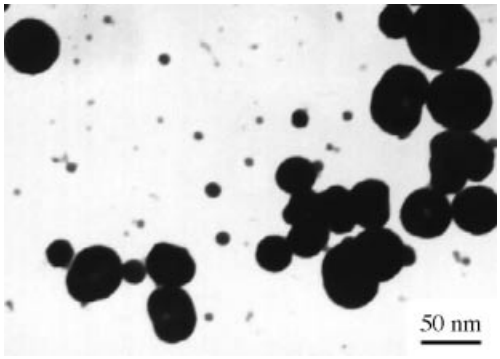

Figure 7. TEM image of Au nanoparticles reduced by UV-irradiated TSA solution.

initial randomly oriented nanocrystals can align epitaxially with the substrate (the Se nanoparticles in this case), which can be explained by the rotation of the nanoparticles within the aggregates that is driven by short-range interactions between adjacent surfaces.[30,31]

Figures 8A and B show the dependence of the diameters of the Se–Au- and Se–Ag-core–shell nanoparticles, respectively, on pH. In Figure 8 a, b, c, and d four samples with pH of 1.5, 2.5, 3.5, and 4.5, respectively, are represented. In Figure 8A, the mean diameters of the four samples of the Se-core–Au-shell are 59.5 nm, 51.1 nm, 48 nm, and 47.4 nm, respectively. From Figure 8A, it can clearly be seen that the diameter of the particles continuously decreases with increasing pH from 1.5 to 4.5. However, the rate at which the diameter decreases diminishes gradually, and when the pH is >4, the decrease in the diameter of the Se-core–Au-shell nanoparticles is minimal. In Figure 8B, the mean diameters of the four samples of the Se-core–Ag-shell are 95.6 nm, 99.3 nm, 125.5 nm, and 128 nm. From Figure 8B, it can clearly be seen that the diameter of the particles continuously increases with increasing pH from 1.5 to 4.5. In the regions between 1.5 and 2.5 and between 3.5 and 4.5, the increase in the diameter of the Se-core–Ag-shell nanoparticles is slight; however, there is a great increase in the region between pH 2.5 and 3.5. Comparing Figures 8A and B, we notice that the diameter of the Se-core–Au-shell nanoparticles decreases with increasing pH, while that of the Se-core–Ag-shell nanoparticles increases.

We also study the relationship between the diameter of the core shell nanoparticles and temperature, which is shown in Figures 9A (Se–Au) and B (Se–Ag). In Figure 9 a, b, c, and d four samples the- core–shell nanoparticles having different diameters at 20, 40, 60, and 80 °C, respectively, are represented. The mean diameters of the four typical samples of the Se-core–Au-shell are 52.3 nm, 60.3 nm, 66.3 nm, and 69.1 nm, respectively. As demonstrated in Figure 9A, the size of these colloids can conveniently be controlled by simply varying the reaction temperature, i.e. the diameter continuously increases with an increase in the temperature. In Figure 9B, the mean diameters of the four samples of the Se-core–Ag-shell are 105 nm, 99 nm, 69.2 nm, and 47.2 nm. It can clearly be seen from Figures 9A and B that the diameter of Se-core–Au-shell nanoparticles increases with increasing temperature, while that of Se-core–Ag-shell nanoparticles decreases. The reasons for the above phenomena are not clear yet.

Since the size of these core–shell nanoparticles can conveniently be controlled by simply varying the pH of the reaction solution and the reaction temperatures, it is believed that the procedure described here should provide an effective route to produce Se@Au and Se@Ag nanoparticles with controllable size. In this current investigation in which

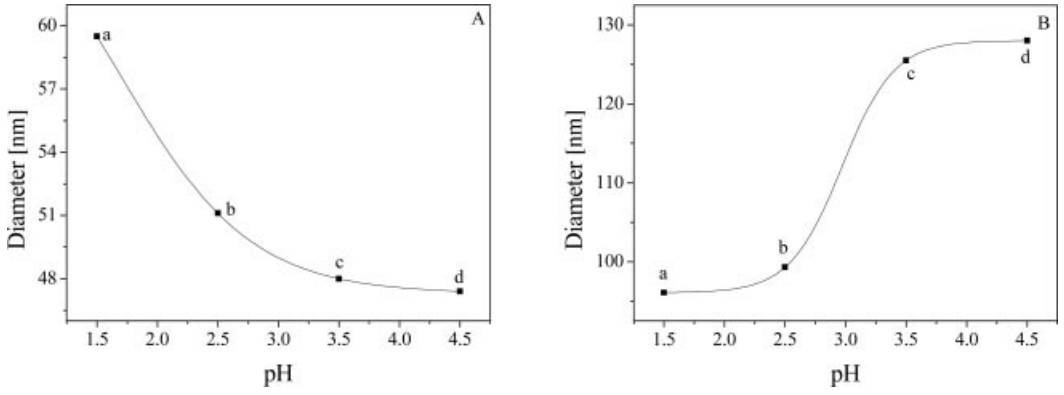

Figure 8. (The dependence of the diameter of the Se–Au- (A) and Se–Ag-core–shell nanoparticles (B) on pH. a, b, c, and d correspond to a pH value of 1.5, 2.5, 3.5, and 4.5, respectively. (Conditions: temperature, ca. 25 °C; the diameter of the Se core, ca.40 nm).

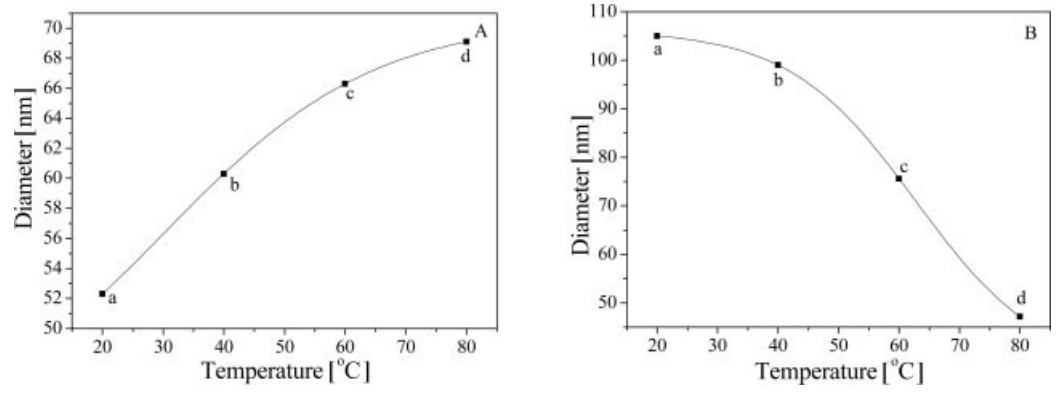

Figure 9. The dependence of the diameter of the Se–Au- (A) and Se–Ag-core–shell nanoparticles (B) on temperature. a, b, c, and d correspond to 20, 40, 60, and 80 °C. (Conditions: pH, ca. 2.5; the diameter of the Se core, ca.40 nm).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

we studied the formation of the nanoparticles as a function of temperature, the size of the t-Se colloids could conveniently be controlled by simply varying the reaction temperature, which ranged from 20 to 80 °C; the diameter increased from about 44.7 to about 83.3 nm. We can therefore control the size of the core and the thickness of the shell. In principle, this procedure can be extended to several other noble metal shells that have been prepared as nanocomplexes by reduction with TSA-ion particles.

## Conclusions

In summary, we have demonstrated the use of t-Se colloids as templates in forming controllable-size Se-core–Au/Ag-shell nanoparticle structures. It is also worth mentioning that the Se templates are not limited to the randomly dispersed nanostructures shown in this work. It has been demonstrated that the Se nanowires and colloids could be organized into ordered structures such as networks (or meshes) and crystalline lattices.[34] These templates are expected to play an increasingly important role in fabricating metal nanostructures with complex (yet controllable) morphologies. In addition, the monodisperse shells of Au/Ag will be suitable as a new class of building blocks to fabricate colloidal crystals that are expected to exhibit improved photonic bandgap properties.[35]

## Experimental Section

Tungstosilicate acid [$H_4(SiW_{12}O_{40})$, TSA], selenious acid ($H_2SeO_3$), silver nitrate ($AgNO_3$), chloroauric acid ($HAuCl_4$), and 2-propanol [$CH_3CH(OH)CH_3$] were all A.R. grade and obtained from Shanghai reagent Co. All the reagents in the experiment were used as received. Doubly distilled water was used throughout to prepare the solutions.

In a typical experiment, an aqueous, deaerated solution of tungstosilicate acid (30 mL of a 1 mM solution), an aqueous, deaerated solution of $H_2SeO_3$ (30 mL of a 1 mM solution), and propan-2-ol (2 mL) were placed in a test tube. This mixture was irradiated with UV light (Pyrex filter, >280 nm, 450 W Hanovia medium pressure lamp) for 5 h. UV irradiation leads to the in situ reduction of $H_2SeO_3$ by the electron-rich $[SiW_{12}O_{40}]^{5-}$ ions {formed by the photochemical reduction of $[SiW_{12}O_{40}]^{4-}$ ions}, which can clearly be seen by the appearance of an orange solution. The above solution was further irradiated with UV light for 3 h, and the color of the solution changed from orange to bluish-red. To this solution (15 mL) were added aqueous solutions of $HAuCl_4$ and $AgNO_3$ (15 mL of 1 mM solution, each) separately whilst stirring. The color of the solutions changed from bluish-red to pink and light brown, which indicates the formation of gold and silver nanoparticles, respectively.

UV/Vis spectroscopic measurements of the samples were carried out with a TU-1901 model UV/Vis double beam spectrophotometer (Beijing Purkinje General Instrument Co., Ltd, China) operated at a resolution of 2 nm. XRD analyses of drop-coated films of the Se solution and Se@Ag and Se@Au on glass substrates were carried out with a MAP18AHF instrument (Japan MAC Science Co.). XPS measurements of the Se nanoparticles were carried out with a VG ESCALAB MKII instrument at a pressure $>10^{-6}$ Pa. The general scan and Se core-level spectra were recorded with non-monochromatized Mg–$K_\alpha$ radiation (photon energy = 1253.6 eV). The core-level binding energies (BEs) were aligned with respect to the $C_{1s}$ BE of 285 eV. Samples for TEM analysis were prepared by drop-coating films of the Se solution and Se@Ag and Se@Au solutions on carbon-coated copper TEM grids and allowing the grid to stand for 2 min following which the extra solution was removed using blotting paper. The above TEM analysis was carried out with a JEM model 100SX electron microscope instrument (Japan Electron Co.) operated at an accelerating voltage at 80 kV. SEM measurements were carried out with a Leica Stereoscan-440 instrument equipped with a Phoenix energy dispersive analysis of X-rays (EDAX) attachment. The size distribution of the nanoparticles was measured by PCS on the Zetasizer $3000HS_A$ instrument (Malvern Instruments Limited).

# Synthesis and Sublimation Kinetics of a Highly Volatile Asymmetric Iron(II) Amidinate

Xin-Gui Li,*[a,b] Zhengwen Li,[a] Huazhi Li,[a] and Roy G. Gordon*[a]

**Keywords:** Asymmetric iron(II) amidinate / Bridging ligands / Metathesis / Sublimation kinetics / Thermochemistry

A highly volatile asymmetric iron(II) amidinate, iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate), was synthesized for the first time by systematically changing starting iron(II) compounds such as acetylacetonate, acetate, and chloride, in different media such as diethyl ether, toluene, and tetrahydrofuran. The amidinate has been characterized and compared with the symmetric iron(II) bis(*N*,*N*′-diisopropylacetamidinate) by NMR spectroscopy, MS, IR spectroscopy, and dynamic and isothermal thermogravimetric techniques. Different amidinates from three starting compounds exhibit almost the same NMR, MS, and IR spectra, a melting point of 85 °C, and the same solution color in the same solvents, but quite different synthetic yields, volatilities, and colors in different solvents. This implies that the amidinates show an interesting solvatochromism. In particular, the asymmetric iron(II) amidinates obtained should be a mixture of paramagnetic and diamagnetic compounds. The thermostability and sublimation kinetics of the iron(II) amidinates have been investigated in detail. It is found that the average activation energy of 106 kJ mol$^{-1}$ for the nonisothermal sublimation is slightly higher than the average activation energy of 104 kJ mol$^{-1}$ determined from the isothermal thermogravimetric experiments. The sublimation is a diffusion-controlled process because the temperature and the rate of the sublimation depend strongly on the sublimation level and the sample size. The optimal iron(II) starting compound and reaction medium should be iron(II) acetylacetonate and diethyl ether, respectively, because the combination offers the highest yield, the greatest volatilizability of 98 %, and thus the purest product.

## Introduction

Metal amidinate complexes with intriguing structural diversity and novel properties have been the subject of intense investigations in chemistry, electronics, optics, energy, and materials science.[1–4] Great interest has been focused on the applicability of the complexes as single-source precursors of advanced functional materials,[5] efficient homogeneous catalysts in olefin and caprolactone polymerizations,[6–7] initiators for the stereospecific and degenerative transfer living Ziegler–Natta polymerization of alpha-olefins with an extremely high level of stereoselectivity,[8] and activators for the polymerization of *rac*-lactide to produce heterobiased polylactides.[9] Metal-based amidinate complexes that are of particular relevance to this paper have been used as highly volatile precursors for atomic layer deposition of films with novel multifunctionalities and a wide variety of applications in modern high technology, including semiconductor microelectronics, high-resolution displays, optical filters, magnetic information storage, and catalysis.[10–12]

The precursors need to be designed in such a way that the compounds are volatile and thermally stable at growth temperatures.[10,13] Generally, the more volatile the better the precursors are. The synthesis and characterization of numerous metal compounds with amidinate ligands have been reported in the literature.[10,12–14] The volatility and thermal stability of symmetric amidinates of transition metals and lanthanum with oxidation states of one (Cu, Ag, Au),[15] two (Mg, Mn, Fe, Co, Ni),[16] three (Ti, V, Y, Al, Ga, La),[17] and four (Ru, Hf)[8] have been reported. Note that the symmetric metal amidinates usually exhibit a lower volatility than asymmetric metal amidinates with the same molar mass because there is relatively disordered molecular aggregation and hence a lower molecular interaction among the asymmetric amidinates. However, no studies on the synthesis, characterization, and volatility of asymmetric iron(II) amidinates were found to the best of our knowledge.

Herein we describe a facile synthesis of a highly volatile asymmetric iron(II) amidinate, iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate). The effect of starting iron(II) compounds and amidination solvents on the synthetic yield, molecular structure, and properties of the iron(II) amidinate was studied. The NMR spectral characteristics of various iron(II) amidinates obtained under different synthetic

conditions were carefully compared. In particular, the thermostability, volatility, and sublimation kinetics were investigated in detail for the first time.

## Results and Discussion

### Synthesis of Iron(II) Amidinates

All iron amidinate compounds listed in Table 1 were synthesized by the metathesis reactions of starting iron compounds with corresponding equivalents of the lithium amidinates [*N*-*tert*-butyl-*N*′-ethylacetamidinate (*t*Bu-Et-MeAMD) and *N*,*N*′-diisopropylacetamidinate (*i*Pr-MeAMD)] in various solvents. Lithium amidinates were prepared in situ from the corresponding carbodiimide with methyllithium and not isolated. Compounds **1**–**3** and **6**–**7** are all solids at room temperature but compounds **4**–**5** look like semisolids at room temperature. The synthetic yield and physical properties are summarized in Table 1. It appears that the starting iron(II) compounds and acetamidination solvents influence the synthesis and properties of the final iron complexes.

In the solvent diethyl ether it is found that the yield increases and product color darkens when changing the starting iron(II) materials from iron(II) acetate to iron(II) chloride to iron(II) acetylacetonate. This phenomenon should be attributed to the solubility difference of the three iron compounds in diethyl ether. Iron(II) acetate is almost insoluble in diethyl ether and iron(II) chloride is slightly soluble in diethyl ether. However, iron(II) acetylacetonate is nearly completely soluble in diethyl ether. As a result the highest yield achieved with iron(II) acetylacetonate as the starting material should be ascribed to its best solubility in diethyl ether. Note that the three iron amidinate products obtained have similar melting points and sublimation temperatures.

In addition, the synthetic yield increases steadily when changing the acetamidination solvent from toluene to THF to diethyl ether by using a fixed starting iron(II) material of iron(II) acetylacetonate, which could result from an increased solubility of iron(II) acetylacetonate in toluene to THF to diethyl ether. The product obtained in THF has the lowest melting point. A similar variation of the yield and melting point with changing solvent from THF to diethyl ether is observed with a fixed starting iron(II) material of iron(II) chloride. It can then be concluded that a combination of iron(II) acetylacetonate and diethyl ether is better for the synthesis of the asymmetric iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s giving a higher yield. On the contrary, this combination produces a symmetric iron(II) bis(*N*,*N*′-diisopropylacetamidinate) with a lower yield but higher melting point than the asymmetric iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s. The different colors of the final solid products could be ascribed to different spatial arrangements of atoms from different starting materials or acetamidination solvents regardless of their same molecular structure.

### Molecular Structure of the Iron(II) Amidinates

The asymmetric iron(II) amidinates were systematically characterized by $^1$H NMR, IR and MS methods. It seems that the NMR spectra of the compounds do not display a high resolution, possibly because of the presence of a very small amount of impurity resulting from their light sensitivity. Just like other paramagnetic iron(II) amidinates,[18,19] however, the $^1$H NMR spectra of the asymmetric iron(II) amidinates in $CDCl_3$ show two series of resonance peaks over a very wide chemical shift range from –10 to +200 ppm. The first series of resonance peaks at 8.6 ppm (sharp, $NCH_2CH_3$), 3.5 ppm (sharp, $N_2CCH_3$), 1.5 ppm [broad, $NC(CH_3)_3$], and 0.3 ppm (sharp triplet, $NCH_2CH_3$) are typically attributed to the diamagnetic fraction. The second series of resonance peaks at $\delta$ = 199.5 ppm (broad, $NCH_2CH_3$), 56.7–111 ppm (sharp, $N_2CCH_3$), 29.7 ppm [broad, $NC(CH_3)_3$], and –6.1 ppm (sharp triplet, $NCH_2CH_3$) are ascribed to the paramagnetic fraction because of their much higher chemical shift. Therefore, the area ratio, calculated from the resonance peaks at 29.7 over 1.5 ppm, could be used to estimate the paramagnetic percentage, as listed in Table 1. As shown in Figure 1, $^1$H NMR spectra of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) in $CDCl_3$ look almost the same regardless of the change of starting iron(II) materials from iron(II) acetate and $FeCl_2$ to iron(II) acetylacetonate for the synthesis of the asymmetric iron(II) amidinate. This implies that the three iron(II) amidinates that were obtained should have

the same molecular structure. Note that their paramagnetic percentages and sublimation behavior (as discussed below) are slightly different. It is seen from Table 1 that the highest paramagnetic percentage, up to 60%, could be found in the amidinate made from iron(II) acetate.

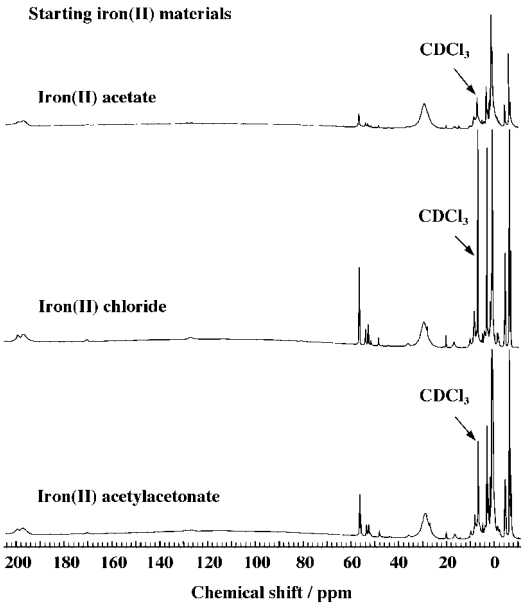

Figure 1. The $^1$H NMR spectra of the resulting iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s obtained with iron(II) acetate, chloride, and acetylacetonate as starting iron(II) materials, respectively.

However, the $^1$H NMR spectra of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) vary significantly with the amidination media and NMR testing solvent used in the synthesis of the iron(II) amidinates, regardless of whether the other conditions are kept constant, as shown in Figure 2 and Figure 3. It is found from Figure 2 that the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained in diethyl ether exhibits nearly the same $^1$H NMR spectral characteristics as that obtained in THF, signifying that the molecular structure of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s obtained in diethyl ether and THF should be very similar. Note that the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained in toluene displays quite a different spectrum with a chemical shift range of 10–205 ppm compared with those obtained in diethyl ether and THF. In addition, their paramagnetic percentages and sublimation behavior (as discussed below) are distinctly different. Table 1 reveals that the paramagnetic percentage in the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained from the same iron(II) acetylacetonate consistently increases from 37 to 47 to 55% when changing the amidination solvent from toluene to THF to diethyl ether. A similar situation is also discovered for the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained from the same $FeCl_2$. This structure difference might be attributable to the different structural characteristics of the solvents used. Toluene is an aromatic hydrocarbon with a low dielectric constant (2.3), whereas diethyl ether and THF are aliphatic ether solvents with relatively high dielectric constants (4.2 and 7.4, respectively). That is to say, acetamidination solvents will significantly influence the synthesis of the target iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate), notwithstanding the other conditions. Hence, the acetamidination solvents should be carefully selected for the synthesis of an ideal asymmetric iron(II) amidinate. The ether could be an optimal acetamidination solvent for the synthesis of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate).

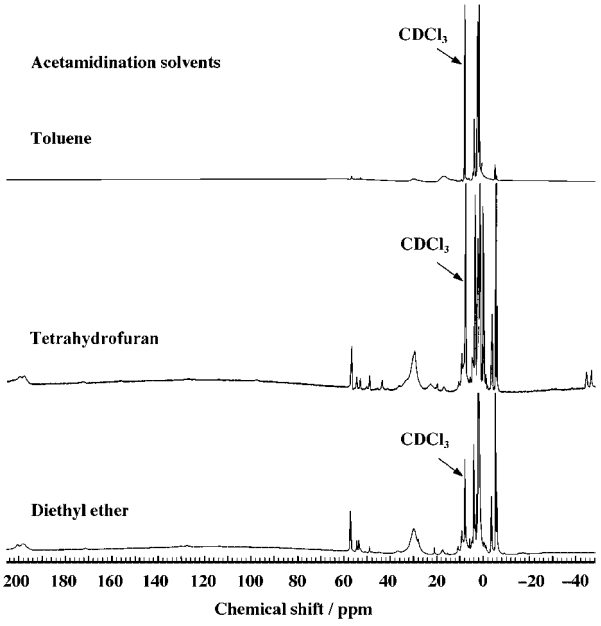

Figure 2. The effect of the acetamidination solvent on the $^1$H NMR spectra of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s with iron(II) acetylacetonate as the same starting iron(II) material.

Figure 3 reveals that the same iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained in diethyl ether exhibits totally different NMR spectra if NMR testing solvents were changed from $C_6D_6$ to $CDCl_3$ to $C_5D_5N$ with dielectric constants of 2.3, 4.8, and 13.3, respectively. This should result from different interactions between the iron amidinate and solvent molecules with different characteristics. In particular, the NMR spectrum obtained in $C_6D_6$ suggests the lowest paramagnetism, whereas the NMR spectrum in $C_5D_5N$ suggests the highest paramagnetic content of up to 60%, implying that the paramagnetism of the iron(II) amidinates depends on the solvent characteristics. It appears that the paramagnetism of the complexes in the solvent with the highest dielectric constant is higher. The diversification of the NMR spectra with changing NMR testing solvents from $CDCl_3$ to $C_6D_6$ to $C_5D_5N$ is also observed for the same iron(II) bis(*N*,*N*′-diisopropylacetamidinate) in this study. Therefore, NMR testing solvents should be carefully chosen for the obtainment of an ideal NMR spectrum of the paramagnetic materials. The deuterated solvent with a high dielectric constant could be optimal for the NMR spectroscopic analysis.

IR spectra of iron(II) complexes obtained show the expected and very strong absorptions at 1651–1653 and 548 cm$^{-1}$ attributable to the delocalized –N⋯C⋯N– and Fe–

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

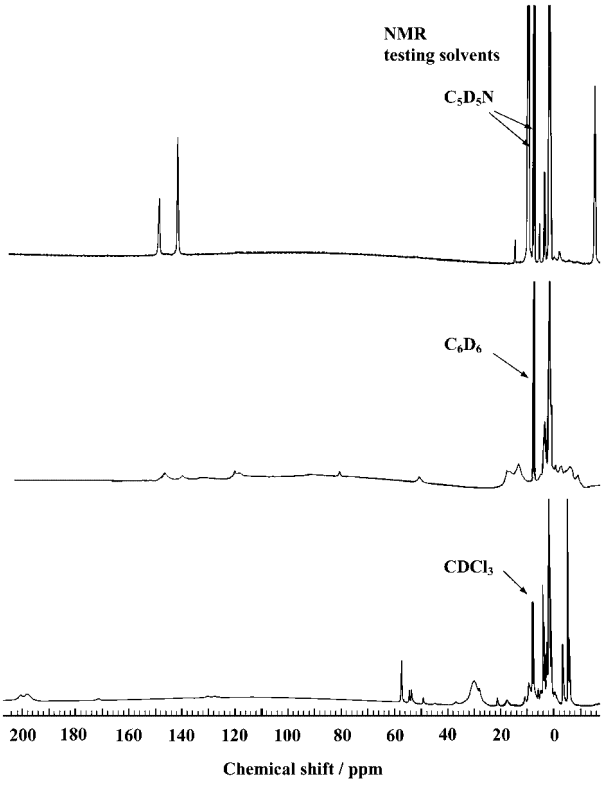

Figure 3. The effect of the NMR testing solvent on the $^1$H NMR spectra of the same iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) with iron(II) acetylacetonate as a starting iron(II) material in diethyl ether.

N stretching modes, respectively, but no characteristic absorptions at 3436 and 2100 cm$^{-1}$ due to the amidine $\phi_{NH}$ and free carbodiimide $\upsilon_{N=C=N}$ stretching modes are observed.[20,21] These results strongly suggest the formation of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate).

In the mass spectra, all the amidinate complexes are characterized by a loss of the methyl and *tert*-butyl groups from the ions.[18] The ligand bonds between N and Fe break the most easily. It seems that the breaking mode of the complexes does not change with elevating MS testing temperatures from 120, 150, to 300 °C. However, the MS spectra indeed vary if 10% water is added to MCN or when changing starting iron(II) materials from acetylacetonate to acetate to chloride. These results also significantly indicate a successful synthesis of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate).

### Sublimation and Volatility of the Iron(II) Amidinates

TG and derivative thermogravimetry (DTG) curves of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s obtained from three starting iron(II) compounds in diethyl ether are given in Figure 4. Sublimation or thermal decomposition occurs clearly in one step at a lower temperature (110–170 °C)[10,13] with a lower residual mass of 3%, that is, a higher volatility of 97%. The low sublimation temperature of iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) might be ascribed to the weak intermolecular forces, which are due to its spherical shape (Scheme 1). The weaker intermolecular forces of iron(II) bis(*N*,*N*′-diisopropylacetamidinate) can also be used to explain the fact that its sublimation temperature (Table 1) is lower than that of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate), which has the same molecular mass, because the iron(II) bis(*N*,*N*′-diisopropylacetamidinate) molecule should be more spherical and more symmetric. The iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s obtained with iron(II) acetate and chloride as starting iron(II) materials exhibit the same sublimation or volatile characteristics, which are different from that of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained with iron(II) acetylacetonate. The iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained with iron(II) acetylacetonate begins to sublimate at a higher temperature with a further residual weight of 2% lower than the other two. In other words, the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained with iron(II) acetylacetonate possesses the highest volatilizability of 98%.

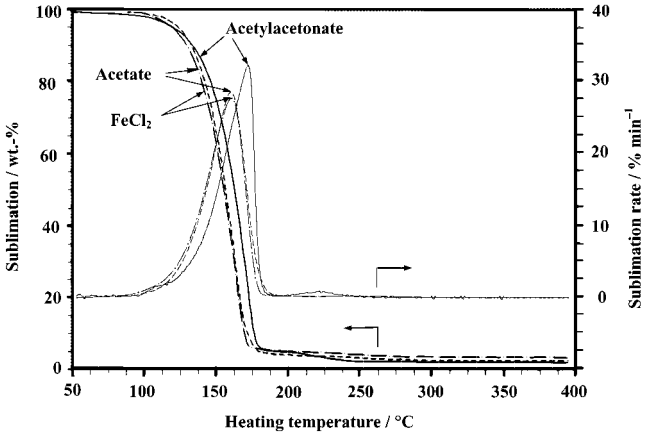

Figure 4. The effect of the starting iron(II) compounds on the sublimation of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained in diethyl ether at a heating rate of 10 °C/min.

The TG sublimation thermograms of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s vary significantly with iron(II) amidination solvents despite the same synthetic conditions being used, as shown in Figure 5. It is found that the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained in diethyl ether exhibits nearly the same major sublimation characteristics as that obtained in THF, suggesting that the two iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s obtained in diethyl ether and THF should be very similar. However, the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained in THF displays a much higher residual weight percentage or lower volatilizability than that obtained in diethyl ether, implying that the latter is much purer in composition. Note that the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained in toluene displays quite a different TG thermogram as compared with those obtained in diethyl ether and THF, indicative of the iron(II) amidinates having different molecular structures. This is corroborated by the NMR results discussed above. The

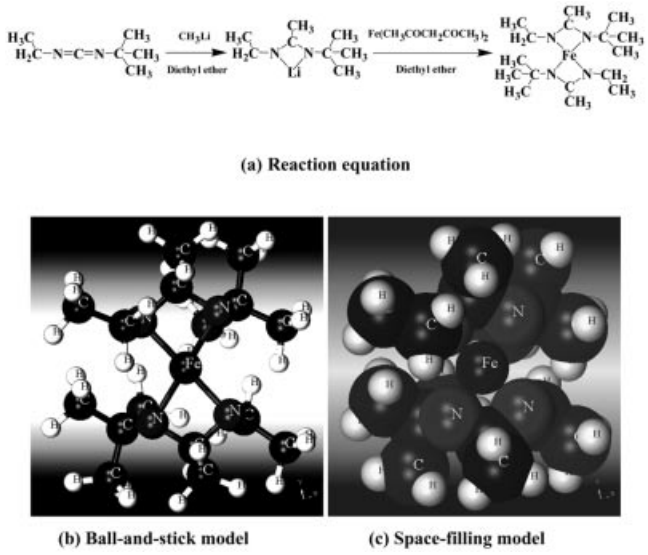

Scheme 1. The synthesis of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) and its structural models at the minimum energy.

iron(II) bis(*N*,*N*′-diisopropylacetamidinate) obtained with iron(II) acetylacetonate as the iron(II) source exhibits a much lower sublimation temperature (150 °C) at the maximal-sublimation rate than that (225 °C) of the iron(II) bis(*N*,*N*′-diisopropylacetamidinate) obtained with $FeCl_2$ as the iron(II) source.[10] This suggests that iron(II) acetylacetonate could be a better starting iron(II) material for the synthesis of the iron(II) amidinates with higher volatility at a much lower temperature than $FeCl_2$.

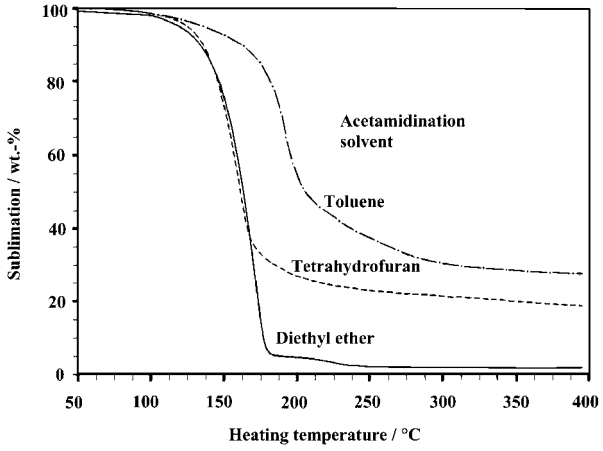

Figure 5. The effect of the amidination solvent on the sublimation of the iron(II) amidinate complex from iron(II) acetylacetonate at a heating rate of 10 °C/min.

## Sublimation Kinetics of the Iron(II) Amidinates

A strong and regular effect of the heating rate on the nonisothermal TG and DTG curves of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained with iron(II) acetylacetonate as a starting iron(II) source in diethyl ether is shown in Figure 6. The isothermal TG and DTG curves of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained with iron(II) acetylacetonate and acetate as the starting iron(II) sources in diethyl ether are shown in Figure 7. According to Equations (1)–(3) of the Flynn–Wall technique the activation energy of sublimation for iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s and bis(*N*,*N*′-di-

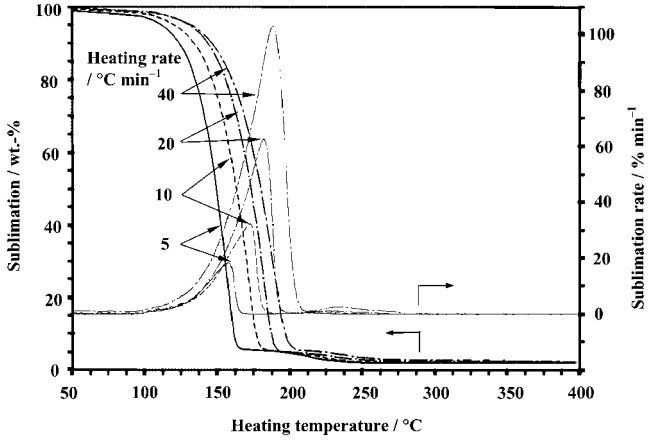

Figure 6. The effect of the heating rate on the the TG and DTG curves of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained with iron(II) acetylacetonate as a starting iron(II) source in diethyl ether.

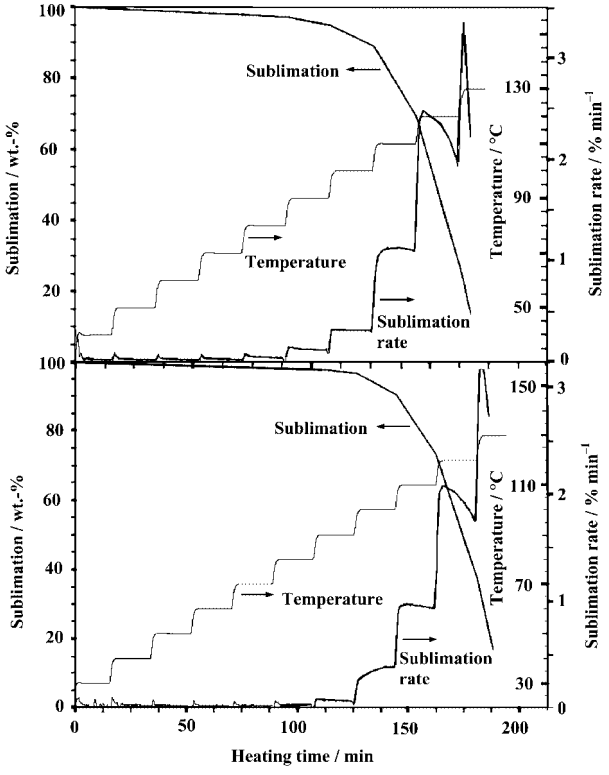

Figure 7. Multiple-stage isothermal TG and DTG curves of the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) obtained with iron(II) acetylacetonate (top) and iron(II) acetate (bottom) as starting iron(II) sources in diethyl ether.

isopropylacetamidinate) is summarized in Figure 8 and Table 2. Figure 8 discloses that the activation energy decreases with an increase in the sublimation level, indicating that a variation in the thermal sublimation kinetics, from diffusion-controlled kinetics to sublimation-controlled kinetics, is occurring. Under a large sample size at an early sublimation step the heat diffusion across the whole sample may be slow, leading to a diffusion control. As listed in Table 2, a larger sample size will result in a higher activation energy of the isothermal sublimation for sample No. **4**. It is also seen from Table 2 that two kinds of nonisothermal techniques, Flynn–Wall and Kissinger, afford similar activation energies of sublimation for the five iron(II) amidinates. However, the activation energy of the isothermal sublimation is different from that of the nonisothermal sublimation. In particular, the activation energy of the isothermal sublimation over a lower temperature range between 40 and 80 °C is much lower. In addition, the variation of the sublimation activation energy calculated by nonisothermal techniques for the iron(II) amidinates **1** to **7** is different from that calculated by isothermal techniques. These signify that the sublimation characteristics could vary with the heating method and temperature range. Nevertheless, it is interesting that the average activation energy (106 kJ mol$^{-1}$) for the nonisothermal sublimation at 127–198 °C is almost the same as the average activation energy (104 kJ mol$^{-1}$) determined from the isothermal thermogravimetric experiments at 80–130 °C.

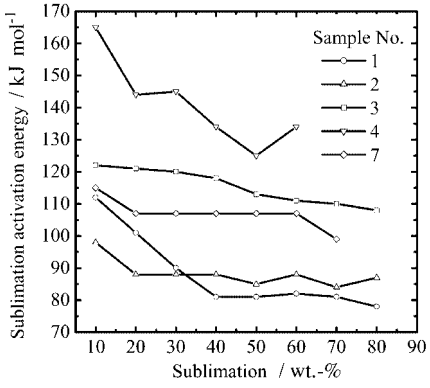

Figure 8. The variation of the sublimation activation energy with sublimation level based on the Flynn–Wall plot of ln (heating rate) against the reciprocal temperature for the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) and bis(*N*,*N*′-diisopropylacetamidinate).

### Solubility and Solvatochromism of the Iron(II) Amidinates

All dark solid iron(II) amidinates will immediately become red upon exposure in air or water because of their fast decomposition over several seconds. That is to say, the iron(II) amidinates are highly air and moisture sensitive. Solubility of the iron(II) amidinates is investigated in several representative solvents with different dielectric constants in a nitrogen atmosphere. It is found that almost all the iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate)s and bis(*N*,*N*′-diisopropylacetamidinate) are readily soluble in most organic solvents like chloroform, benzene, pyridine, toluene, hexane, pentane, diethyl ether, and THF with dielectric constants between 1.9 and 13.3 but except for methanol with a high dielectric constant of 32.4. It is of interest that a variation of the amidinate solution color with the solvents is observed, i.e., a novel solvatochromism. The solution of the same amidinate exhibits different colors within various solvents. The black solid iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) becomes blue in chloroform, purple in pyridine, and brown in benzene, toluene, hexane, pentane, diethyl ether, and THF. Similarly, dark-blue solid iron(II) bis(*N*,*N*′-diisopropylacetamidinate) becomes blue in chloroform, bluish black in benzene, and brown in pyridine. This indicates that the amidinate molecules may have different conformations and hence different solvates in different solvents, induced by the different interactions between the amidinate and the solvent molecules with different dielectric constants and polarity. In other words, the solvatochromism might be adjusted by changing the amidinate structure and choosing the solvent. However, there is no regular variation of the amidinate solvatochromism with the solvent dielectric constant. Similar solvatochromism has also been observed for the intrinsically conducting copolymers from orthanilic acid and aniline.[22]

## Conclusions

A highly volatile and paramagnetic asymmetric iron(II) amidinate, iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate), was successfully synthesized. The optimal starting iron(II) compound and reaction solvent should be iron(II) acetylacetonate and diethyl ether, respectively, because the combination offers the highest yield, the strongest volatilizability of 98%, and the purest product. The NMR spectra of the iron(II) amidinates depend strongly on the deuterated sol-

Table 2. The activation energy (kJ mol$^{-1}$) of the sublimation of the iron bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) and bis(*N*,*N*′-diisopropylacetamidinate).

| No. | Nonisothermal sublimation activation energy | | Isothermal sublimation activation energy at a sample size of 2.1–3.0 mg | |
|---|---|---|---|---|
| | Flynn–Wall (average) | Kissinger | 80–130 °C | 40–80 °C |
| **1** | 88 | 90 | 114 | 25 |
| **2** | 88 | 91 | 111 | 37 |
| **3** | 115 | 107 | 104 | 11 |
| **4** | 141 | 127 | 87(90)[a] | 25(41)[a] |
| **7** | 107 | 97 | 79 | 48 |

vent used. It seems that deuterated chloroform is the optimal solvent for the structure characterization of the paramagnetic iron(II) amidinates. The different iron(II) amidinates from various starting iron(II) compounds exhibit almost the same NMR, MS, and IR spectra, a melting point of 85 °C (with an exception in THF around 25 °C), and solution color in the same solvents but different synthetic yields, paramagnetic fractions, volatilizabilities, and colors in different solvents. This implies that the iron(II) amidinates exhibit interesting variable paramagnetism and solvatochromism. The iron(II) bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) demonstrates an average activation energy of 106 kJ mol$^{-1}$ for the nonisothermal sublimation, which is very close to the average activation energy of 104 kJ mol$^{-1}$ calculated on the basis of the isothermal sublimation. The sublimation is a diffusion-controlled process because the temperature and rate of the sublimation depend strongly on the sublimation level and sample size. Great volatilizability at a lower temperature is a special feature of the asymmetric iron(II) amidinates compared with other related compounds.

## Experimental Section

**General:** All reactions, manipulations, and characterizations were conducted under a nitrogen atmosphere using an inert atmosphere box. Tetrahydrofuran (THF), diethyl ether, toluene, and hexane were dried by using an innovative solvent purification system and stored over 0.4-nm molecular sieves. Methyllithium, 1-*tert*-butyl-3-ethyl-carbodiimide, 1,3-diisopropylcarbodiimide, anhydrous $FeCl_2$, iron(II) acetylacetonate[$Fe(CH_3COCH_2COCH_3)_2$], and iron(II) acetate (Aldrich) were used after vacuum treatment in nitrogen.

**Iron(II) Bis(*N*-*tert*-butyl-*N*′-ethylacetamidinate) ([Fe(*t*Bu-Et-Me-AMD)$_2$]):** A solution of methyllithium (1.6 M in diethyl ether, 3.8 mL, 6 mmol) in diethyl ether was added dropwise to a solution of 1-*tert*-butyl-3-ethyl-carbodiimide (0.9 g, 7 mmol) in diethyl ether (20 mL) at –30 °C. The mixture was warmed to room temperature and stirred for 4 h. This colorless mixture solution was then added to a solution of iron(II) acetylacetonate (0.9 g, 35 mmol) in diethyl ether (10 mL). The reaction mixture was stirred for 24 h. After all the volatiles were removed under reduced pressure the resulting solid was extracted with hexane (30 mL). The hexane extract was filtered through a pad of Celite on a glass frit to afford a dark solution. Subsequent sublimation afforded pure dark products (42%). Sublimation: 80 °C at 30 mTorr. The whole reaction procedure for the synthesis of the iron(II) complex is depicted in Scheme 1. The iron(II) bis(*N*,*N*′-diisopropylacetamidinate) was prepared in the same manner as described above. The iron(II) amidinate synthesized from iron(II) acetylacetonate in diethyl ether exhibits the following spectra: $^1$H NMR ($CDCl_3$, 25 °C): 199.5 (broad, N$CH_2$CH$_3$), 56.7–111 (very broad, $N_2CCH_3$), 29.7 [broad, NC($CH_3$)$_3$], –6.1 (sharp triplet, $NCH_2CH_3$) ppm for paramagnetic iron(II) amidinate; 8.6 (sharp, N$CH_2$CH$_3$), 3.5 (sharp, $N_2CCH_3$), 1.5 [broad, NC($CH_3$)$_3$], 0.3 (sharp triplet, $NCH_2CH_3$) ppm for non-paramagnetic (diamagnetic) iron(II) amidinate. On the basis of the area ratio of the resonance peaks at 29.7 over 1.5 ppm it could be estimated that 55% of the product is paramagnetic. $^1$H NMR ($C_5D_5N$, ([D$_5$]pyridine), 25 °C): 147.5 (sharp, N$CH_2$CH$_3$), 140.6 (sharp, $N_2CCH_3$), 9.1 (broad, NC($CH_3$)$_3$), –15.9 (sharp, $NCH_2CH_3$) ppm for paramagnetic iron(II) amidinate; 4.7 (sharp, N$CH_2$CH$_3$), 2.8 (sharp, $N_2CCH_3$), 1.1 [broad, NC($CH_3$)$_3$], 0.79 (sharp, $NCH_2CH_3$) ppm for diamagnetic iron(II) amidinate. The product could be 60% paramagnetic on the basis of the area ratio of the resonance peaks at 9.1 over 1.1 ppm. IR absorbances: 3268 (vw), 2968 (s), 2922 (s), 2854 (m), 1651 (vs), 1543 (m), 1457 (m), 1374 (m), 1288 (w), 1220 (m), 1157 (vw), 1031 (vw), 686 (s), and 548 (s) cm$^{-1}$. ES-MS at 120 °C: *m*/*z* [fragment, relative intensity (%)] = 331 [M – $(CH_3)_2$ + Na$^+$, 16], 321 [M – $(CH_3)_2$ + acetonitrile(MCN)$^+$, 7], 297 [M – $(CH_3)_2$–$C_2H_5$ + $NH_4^+$, 6], 269 [M – $(CH_3)_2$–$C(CH_3)_3$ + $NH_4^+$, 42], 207 [$FeNC(CH_3)NC(CH_3)_3$ + K$^+$, 6], 143 [$C_2H_5NC(CH_3)NC(CH_3)_3$ + 2H$^+$, 100]. The iron(II) amidinate from iron(II) acetate displays the following $^1$H NMR ($CDCl_3$, 25 °C): 196.8 (broad, N$CH_2$CH$_3$), 56.3–114.5 (very broad, $N_2CCH_3$), 29.4 [broad, NC($CH_3$)$_3$], –5.6 (sharp, $NCH_2CH_3$) ppm for paramagnetic iron(II) amidinate; 8.8 (sharp, N$CH_2$CH$_3$), 3.6 (sharp, $N_2CCH_3$), 1.2 [broad, NC($CH_3$)$_3$], 0.4 (broad, $NCH_2CH_3$) ppm for diamagnetic iron(II) amidinate. On the basis of the area ratio of the resonance peaks at 29.4 over 1.2 ppm it could be calculated that 60% of the product should be paramagnetic. IR absorbances: 3250 (vw), 3043 (vw), 2962 (s), 2922 (s), 2856 (m), 1653 (vs), 1559 (m), 1510 (m), 1457 (m), 1374 (m), 1288 (w), 1220 (m), 1157 (vw), 1030 (vw), 687 (s), and 548(s) cm$^{-1}$. ES-MS at 120 °C: *m*/*z* [fragment, relative intensity (%)] = 350[M – $C_2H_5$ + MCN$^+$, 4], 331 [M – $(CH_3)_2$ + Na$^+$, 21], 321[M – $(CH_3)_2$ + MCN$^+$, 9], 281 [M – $C(CH_3)_3$, 4], 269 [M – $(CH_3)_2$–$C(CH_3)_3$ + $NH_4^+$, 8], 143 [$C_2H_5NC(CH_3)NC(CH_3)_3$] + 2H$^+$, 100]. The iron(II) amidinate synthesized from $FeCl_2$ in diethyl ether demonstrates the following: $^1$H NMR ($CDCl_3$, 25 °C): 196.8 (broad, N$CH_2$CH$_3$), 56.3–115 (very broad, $N_2CCH_3$), 29.8 [broad, NC($CH_3$)$_3$], –5.8 (sharp, $NCH_2CH_3$) ppm for paramagnetic iron(II) amidinate; 8.8 (sharp, N$CH_2$CH$_3$), 3.6 (sharp, $N_2CCH_3$), 1.4 [broad, NC($CH_3$)$_3$], 0.6 (broad, $NCH_2CH_3$) ppm for diamagnetic iron(II) amidinate. It is evaluated based on the area ratio of the resonance peaks at 29.8 over 1.4 ppm that 58% of the product could be paramagnetic. ES-MS at 120 °C: *m*/*z* [fragment, relative intensity (%)] = 350 [M – $C_2H_5$ + MCN$^+$, 50], 349 [M – $C_2H_5$ + H$^+$ + K$^+$, 25], 348 [M – $(CH_3)_2$ + H$^+$ + K$^+$, 100], 339 [M + H$^+$, 16], 338 [M, 55], 331 [M – $(CH_3)_2$ + Na$^+$, 13], 324 [M – $CH_3$ + H$^+$, 17], 323 [M – $CH_3$, 87], 322 [M – $(C_2H_5)_2$ + MCN$^+$, 53]. The iron(II) amidinate synthesized from iron(II) acetylacetonate in toluene shows the following: $^1$H NMR ($CDCl_3$, 25 °C): 56 (N$CH_2$CH$_3$), 29.2 (broad, $N_2CCH_3$), 16.2 [broad, NC($CH_3$)$_3$], –5.8 (sharp, $NCH_2CH_3$) ppm for paramagnetic iron(II) amidinate; 8.6 (N$CH_2$CH$_3$), 3.2 (sharp, $N_2CCH_3$), 1.4 [broad, NC($CH_3$)$_3$], 1.1 (broad, $NCH_2CH_3$) ppm for diamagnetic iron(II) amidinate. The paramagnetic fraction calculated based on the area ratio of the resonance peaks at 16.2 over 1.4 ppm is 37%.

**Measurements:** $^1$H NMR spectra of the iron(II) amidinate solutions in test tubes filled with nitrogen were recorded with a Bruker AM-500 spectrometer. Melting points were obtained in a sealed capillary using optical microscopy. Infrared spectra were obtained with a Nicolet FT-IR 7000 spectrometer with sample solutions in diethyl ether in a nitrogen atmosphere. Mass spectra of the sample in THF were recorded with a Micromass LCT time-of-flight Mass Spectrometer operating in electrospray mode. Solution samples of the respective complexes in diethyl ether or THF were rapidly introduced by a direct inlet technique with acetonitrile as a mobile phase at a source temperature of 120–300 °C. Thermogravimetry (TG) was performed with a TGA Q50 V6.2 Build 187 thermogravimetric analyzer. Conventional constant heating-rate TG measurements were run at 5 °C, 10 °C, 20 °C, and 40 °C min$^{-1}$ in nitrogen with a sample size of 1–3 mg to provide a control set of values for thermal sublimation parameters. Isothermally programmed TG analyses

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were carried out at 40, 50, 60, 70, 80, 90, 100, 110, 120, and 130 °C in nitrogen at a flow rate of 40 mL min$^{-1}$ with a sample size of 2–3 mg. The furnace was quickly heated at a heating rate of 60 °C min$^{-1}$ to the selected temperature after the sample was inserted in the furnace. There are several techniques for the kinetic evaluation of the TG thermal weight-loss data, and they have been discussed in an earlier publication.[23] The thermal sublimation kinetics were examined by the following three evaluating techniques [Equation (1)], [Equation (2)], and [Equation (3)].

**Flynn–Wall Technique**[24]

$$\ln(\text{Heating rate}) = \ln(ZE/R) - \ln[F(a)] - E/(RT) \quad (1)$$

$$\ln(\text{Heating rate}/T_{sm}^2) = \ln[n(1-\alpha_m)^{n-1}ZR/E] - E/(RT_{sm}) \quad (2)$$

$$\ln(d\alpha/dt)_m = \ln Z + n\ln(1-\alpha_m) - E/(RT) \quad (3)$$

The activation energy, $E$, can be calculated from a plot of ln (heating rate) against $1/T$ (absolute temperature) at a fixed weight loss since the slope of such a line is given by $E/R$ (gas constant 8.314 J mol$^{-1}$K$^{-1}$).

**Kissinger Technique**[25]

Where $T_{sm}$ and $\alpha_m$ are the absolute temperature and sublimation, respectively, at the maximum sublimation rate $(d\alpha/dt)_m$. The slope of ln (Heating rate/$T_{sm}^2$) vs. $1/T_{sm}$ is equal to $-E/R$.

**For an Isothermal TG Measurement at Several Isothermal Temperatures**[23]

The $E$ value of isothermal degradation was calculated from the slope of the plot of the maximum weight-loss rate ln $(d\alpha/dt)_m$ vs. the reciprocals of the several isothermal temperatures ($1/T$).

# Control of Intramolecular Ether-Oxygen Coordination in the Crystal Structure of Copper(II) Complexes With Dipicolylamine-Based Ligands

**Yuji Mikata,*[a] Tomomi Fujimoto,[b] Yuko Sugai,[b] and Shigenobu Yano[b]**

**Keywords:** N,O ligands / Copper / Coordination modes / Ligand effects

Thirteen crystal structures of copper(II) complexes with a series of dipicolylamine (DPA)-derived ligands, *N*-(2-methoxyethyl)-*N*,*N*-bis(2-pyridylmethyl)amine (**L1**), *N*-[2-(2-hydroxyethyloxy)ethyl]-*N*,*N*-bis(2-pyridylmethyl)amine (**L2**) and *N*-(3-methoxypropyl)-*N*,*N*-bis(2-pyridylmethyl)amine (**L3**), have been determined and the factors that control the coordination of the ether-oxygen atom of these ligands to the copper centre are discussed. Complexes that have +1 or +2 charges exhibit coordination of the ether-oxygen atom, whereas neutral complexes in which two anions are bound to the copper(II) centre tend to lose the oxygen coordination. Upon chelation of the oxygen atom, **L3** forms a six-membered chelate ring with respect to the 3-aminopropyl ether moiety whereas **L1** and **L2** form a five-membered chelate. This difference, especially in the nitrate and bromide complexes, determines whether the ether-oxygen atom chelates to the metal centre to give a monocationic complex, or the second anion coordinates to the metal centre to form the ether-free, neutral complex. The terminal anchor hydroxy group of **L2** facilitates the ether-oxygen coordination via a hydrogen bond interaction to the donor atom located *trans* to the aliphatic nitrogen atom in the basal plane.

## Introduction

Weak interatomic interactions with noncovalent bonds, including hydrogen bonds and electrostatic and van der Waals interactions, are essential elements not only in life sciences but also in chemistry in general.[1–3] Cooperative binding by multipoint interactions, which are often called cluster effects in glycoscience, makes weak interactions strong and specific.[3–5] On/off switching of such noncovalent interactions is another important process, and triggers of such switching include conformational changes induced by remote sites as well as redox changes in the metal centre.[6] It is therefore important to regulate these weak interatomic interactions both in solution and in the solid state.

In this report, we will focus on the coordination of ether-oxygen atoms to metal ions. Although multipoint coordination of ether-oxygen atoms, such as those found in crown ethers, can exhibit strong metal-binding, an isolated oxygen atom has only a moderate to weak binding ability to the metal centre.[7–9] Sigel et al. have been extensively studying the solution chemistry of intramolecular ether-oxygen coordination to metal centres using phosphate-pendant alkyl ether derivatives.[10,11] Recently, by employing the sugar-pendant dipicolylamine (DPA) ligand, we reported that the oxygen atom in an asymmetric ether is capable of becoming a stereogenic centre upon coordination to a copper(II) ion.[12,13] Strong binding of the DPA unit to the copper(II)[14–19] assists the asymmetric coordination of the anomeric oxygen atom of the sugar unit to the metal centre in the crystal and in solution.

In this study, in order to gain general information about intramolecular ether-oxygen chelation, the factors that promote the oxygen atom coordination to the copper(II) centre in the solid state are investigated by means of X-ray crystallography with a series of DPA-derived ligands, namely *N*-(2-methoxyethyl)-*N*,*N*-bis(2-pyridylmethyl)amine (**L1**),[20–24] *N*-[2-(2-hydroxyethyloxy)ethyl]-*N*,*N*-bis(2-pyridylmethyl)amine (**L2**)[25] and *N*-(3-methoxypropyl)-*N*,*N*-bis(2-pyridylmethyl)amine (**L3**).[21] The anion of the metal salt as well as the ligand structure control the ether-oxygen coordination to the copper(II) centre in these complexes.

## Results and Discussion

### Preparation and Structure Determination of the Complexes

Single crystals of complexes of **L1** with $Cu(NO_3)_2$ {$[Cu(\mathbf{L1})(NO_3)_2]$ (**1**) and $[Cu(\mathbf{L1})(NO_3)](ClO_4)$ (**2**)}, **L3** with $Cu(NO_3)_2$ {$[Cu(\mathbf{L3})(NO_3)_2]$ (**3**) and $[Cu(\mathbf{L3})(NO_3)(ClO_4)]$ (**4**)}, **L1** with $Cu(ClO_4)_2$ {$[Cu(\mathbf{L1})(ClO_4)(CH_3OH)](ClO_4)$ (**5**) and $[Cu(\mathbf{L1})(CH_3CN)(H_2O)](ClO_4)_2$ (**6**)}, **L2** with $Cu(ClO_4)_2$ ($[Cu(\mathbf{L2})(ClO_4)(CH_3OH)](ClO_4)$ (**7**)], **L1** with $CuCl_2$ {$[Cu(\mathbf{L1})Cl](ClO_4)$ (**8**)}, **L2** with $CuCl_2$

{[Cu(**L2**)Cl]($ClO_4$) (**9**)}, **L3** with $CuCl_2$ {[Cu(**L3**)Cl]($ClO_4$) (**10**)}, **L1** with $CuBr_2$ {[Cu(**L1**)Br]($ClO_4$) (**11**)}, **L2** with $CuBr_2$ {[Cu(**L2**)Br]($ClO_4$) (**12**)} and **L3** with $CuBr_2$ {[Cu(**L3**)$Br_2$] (**13**)} were prepared from methanol solutions of the ligand and metal salt by slow diffusion of diethyl ether into these solutions; in some cases sodium perchlorate was added. The complex numbers and metal salt/ligand combinations are summarised in Table 1. Complexes **3** and **10** afforded crystals from methanol/diethyl ether of insufficient quality for X-ray analysis and were therefore recrystallised from acetonitrile/diethyl ether, which resulted in good quality crystals. Complex **6** was prepared in acetonitrile and crystals were grown by ether diffusion. The crystallographic data and X-ray diffraction conditions for complexes **1**–**13** are summarised in Tables S1–S4 (see Supporting Information). ORTEP diagrams of these complexes with 50% probability ellipsoids are shown in Figures 1 (**1**), 2 (**2**), 3 (**3**), 4 (cation of **6**), 5 (cation of **7**), 6 (cation of **9**) and 7 (cation of **10**). The remainder are given as Supporting Information (Figures S1–S6). Selected bond lengths and the coordination geometries, including $\tau$ values,[26] ether oxygen atom coordination, complex charges and hydrogen-bond interactions, for the copper centres in complexes **1**–**13** are summarised in Tables 2 and 3.

Table 1. Preparation of copper(II) complexes **1**–**13**.[a]

| | Ligand | | |
|---|---|---|---|
| Metal salt | **L1** | **L2** | **L3** |
| $Cu(NO_3)_2$ | **1**, **2**[b] | _[c] | **3***, **4**[b] |
| $Cu(ClO_4)_2$ | **5**, **6*** | **7** | _[d] |
| $CuCl_2$ + $NaClO_4$ | **8*** | **9** | **10** |
| $CuBr_2$ + $NaClO_4$ | **11** | **12** | **13** |

[a] Crystals were grown from the reaction mixture in methanol by diffusion of diethyl ether vapour except for those indicated with asterisks (*), which were obtained by recrystallisation from $CH_3CN$/diethyl ether. [b] In the presence of one equivalent of $NaClO_4$. [c] Reported in ref.[25] [d] No single crystals suitable for X-ray analysis were obtained.

The crystal structure for the complex of **L2** with $Cu(NO_3)_2$ has already been reported.[25] In spite of extensive crystallisation trials, the mixture of **L3** and $Cu(ClO_4)_2$ in methanol did not afford single crystals suitable for X-ray crystallography, although the formation of a metal–ligand complex was confirmed by UV/Vis spectral changes and ESI mass spectrometry (data not shown). All structures exhibit meridional coordination geometries for the DPA unit.[14–20,23–25] Among them, [Cu(**L1**)($NO_3$)]($ClO_4$) (**2**),

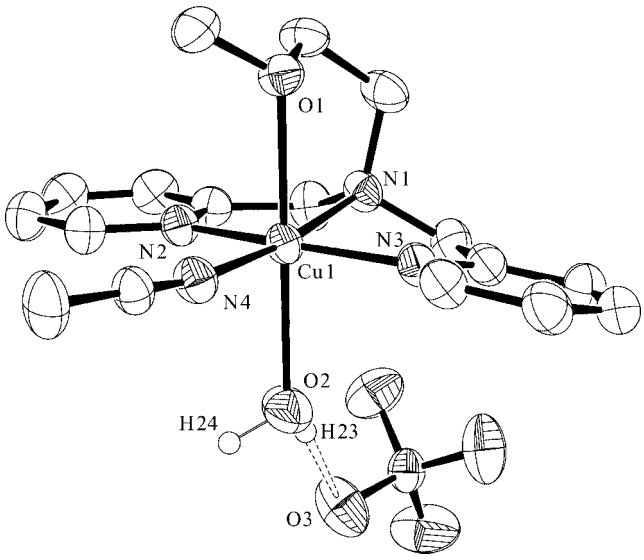

Figure 4. ORTEP plot of the cation of [Cu(**L1**)($CH_3CN$)($H_2O$)]-($ClO_4$)$_2$ (**6**). Both hydrogen atoms of the coordinated water molecule (H23 and H24) are hydrogen bonded to the oxygen atoms of perchlorate ion (O3 and O4).

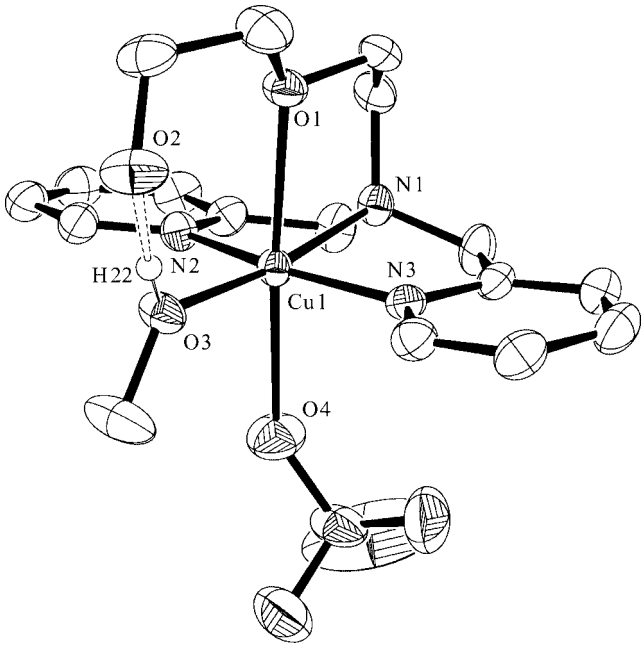

Figure 5. ORTEP plot of the cation of [Cu(**L2**)($ClO_4$)($CH_3OH$)]-($ClO_4$) (**7**).

[Cu(**L1**)($ClO_4$)($CH_3OH$)]($ClO_4$) (**5**), [Cu(**L1**)($CH_3CN$)-($H_2O$)]($ClO_4$)$_2$ (**6**), [Cu(**L2**)($ClO_4$)($CH_3OH$)]($ClO_4$) (**7**), [Cu(**L1**)Cl]($ClO_4$) (**8**), [Cu(**L2**)Cl]($ClO_4$) (**9**), [Cu(**L3**)Cl]-($ClO_4$) (**10**), [Cu(**L1**)Br]($ClO_4$) (**11**) and [Cu(**L2**)Br]($ClO_4$) (**12**) are mono- or dicationic complexes with coordination of the ether-oxygen atom to the copper centre. The ether-oxygen atom in these structures occupies the apical position of a Jahn–Teller-distorted copper(II) centre with Cu–O bond lengths of between 2.329 and 2.453 Å.

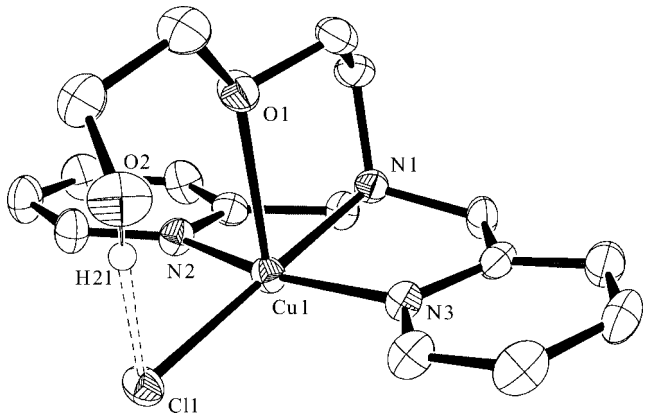

Figure 6. ORTEP plot of the cation of [Cu(**L2**)Cl]($ClO_4$) (**9**).

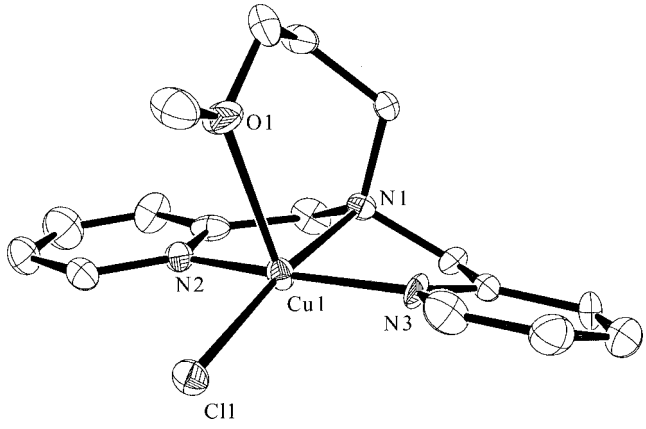

Figure 7. ORTEP plot of the cation of [Cu(**L3**)Cl]($ClO_4$) (**10**).

### Nitrate Complexes

Metzler-Nolte and co-workers have already reported the structures of $Ni^{II}$, $Cu^{II}$, $Co^{II}$ and $Zn^{II}$ nitrate complexes of **L2**.[25] In all cases, the ether-oxygen atom in **L2** coordinates to the metal centre. In contrast to the Ni, Co and Zn complexes in which the hydroxy group of **L2** is directly coordinated to the metal centre, the hydroxy group in the Cu-**L2** complex no longer binds to the metal centre. This is due to the elongated Cu–$O_{ether}$ distance (2.562 Å) resulting from the Jahn–Teller effect of the $d^9$ copper(II) centre. As a consequence, the hydroxy group of **L2** in the complex is separated from the metal coordination sphere and hydrogen-bonded to the metal-coordinated water molecule located in the basal plane containing copper and three DPA nitrogen atoms.

The present study shows that the absence of the hydroxy anchor group results in the dissociation of the ether-oxygen atom from the copper(II) centre in the nitrate complexes (see Figures 1 and 3). Complex **1** adopts a five-coordinate, slightly distorted square-pyramidal geometry ($\tau$ = 0.11) and is ligated by DPA and two nitrate anions. Weak chelation to the sixth site by the oxygen atom of the coordinated nitrate ion [Cu–O3 = 2.721(2) Å] is also observed. The coor-

[a] sqp: square pyramidal; oh: octahedral; tbp: trigonal bipyramidal.

dination geometry of pentacoordinate complex **3** is more distorted ($\tau$ = 0.28) and is close to a trigonal-bipyramidal geometry. For complex **3**, taking the weak intramolecular chelations [Cu–O6 = 2.646(3), Cu–O3 = 2.805(6) Å] into account, this structure can be regarded as seven-coordinate with a pentagonal bipyramidal geometry. This steric hindrance of chelated nitrate may remain during the crystallisation process, and, in combination with the neutral nature of the complexes, prevent the coordination of the ether side chain in **L1** and **L3** in the crystal structures.

In contrast, the addition of sodium perchlorate to the reaction solution of **L1** with $Cu(NO_3)_2$ affords the ether-bound complex **2** (Figure 2). Perchlorate ion is considered to promote crystallisation of monocationic complexes, giving rise to the oxygen-coordinated complex. On the other hand, for the **L3**/$Cu(NO_3)_2$/$NaClO_4$ system, a perchlorate anion coordinates to the copper centre together with a nitrate ion to give the neutral, ether-free complex **4** (Figure S1 in the Supporting Information). This difference could originate from the preferred formation of a five-membered chelate ring over a six-membered ring by the aminoalkyl ether system.

## Perchlorate Complexes

Copper(II) perchlorate complexes were subsequently examined. Unfortunately, single crystals of the Cu/**L3** complex could not be obtained but the other two ligands afforded crystals suitable for X-ray analysis, resulting in the structures of the cationic portions of [Cu(**L1**)$(ClO_4)$-$(CH_3OH)$]$(ClO_4)$ (**5**), [Cu(**L1**)$(CH_3CN)(H_2O)$]$(ClO_4)_2$ (**6**) and [Cu(**L2**)$(ClO_4)(CH_3OH)$]$(ClO_4)$ (**7**) shown in Figures S2 (see Supporting Information), 4 and 5, respectively.

In complexes **5** and **7**, which were crystallised from methanol, the copper centre adopts an $N_3O_3$ hexacoordinate, slightly distorted octahedral geometry ligated by the tridentate DPA, methanol, perchlorate and the ether-oxygen atom

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in the ligand. Since the bond length for the sixth site of complex **5** occupied by the perchlorate oxygen atom is very long [Cu–O = 2.672(5) Å], the geometry of this complex could also be described as a distorted square-pyramid ($\tau$ = 0.14). The Cu–$O_{ether}$ bond lengths of these two complexes are similar [2.427(5) Å for **5** and 2.453(3) Å for **7**] and are significantly different from that in the $Cu(NO_3)_2$/**L2** complex (2.562 Å).[25]

For complex **6**, which was crystallised from acetonitrile, the perchlorate anion is no longer coordinated to the copper centre; instead, acetonitrile and water molecules occupy the basal and apical positions, respectively. The weak coordination ability and superior crystallising ability of the perchlorate complex promotes the formation of a dicationic complex that facilitates the ether-oxygen coordination to the copper centre. The bond length between copper and the ether-oxygen atom (O1) in this six-coordinate complex is very short (2.367 Å) but slightly longer than that of the five-coordinate, monocationic complex **2** (2.329 Å). Both hydrogen atoms of the copper-bound water molecule in complex **6** are hydrogen-bonded to perchlorate anions, which increases the donor ability of this metal-coordinated water oxygen atom. Thus, the Cu–$O_{water}$ bond length [2.385(3) Å] is very short and is close to those seen for anion coordination distances in the apical position [2.237(2) Å for **1**, 2.321(4) Å for **3** and 2.408(5) Å for **4**]. This strong water coordination to the copper centre makes the Cu–O1 bond relatively weak for dicationic complex **6** compared to that in monocationic complex **2**.

### Chloride Complexes

Chloride anion, in combination with sodium perchlorate, is found to facilitate ether-oxygen coordination to the copper centre for all ligands (see Figure S3 in the Supporting Information and Figures 6 and 7). Complexes **8**–**10** comprise one copper(II) ion, one ligand molecule and one chloride ion in five-coordinate complexes with distorted square-pyramidal geometries ($\tau$ = 0.14–0.24). The copper-bound chloride ions occupy the site *trans* to the aliphatic nitrogen atom of DPA, which reduces the steric hindrance around the metal centre. For the perchlorate-bound, ether-coordinated complexes **5** and **7**, the weakly coordinating perchlorate anion occupies the Jahn–Teller-elongated apical position that allows solvent methanol to coordinate to the metal centre from the basal plane, which satisfies the steric requirements for ether-oxygen binding. For the ether-free neutral complexes **1**, **3** and **4**, the moderate coordination strength and steric hindrance of the nitrate anion located at the equatorial site prevent ether-oxygen binding to the metal centre. Chloride anion has enough coordination ability to occupy the equatorial ordinate and less steric bulk, which gives rise to ether-coordinated complexes for all ligands. In complex **9**, the hydroxy group is hydrogen-bonded to the metal-coordinated chloride atom.

In the absence of sodium perchlorate, the reaction mixture of **L1** and $CuCl_2$ afforded a complex formulated as $[Cu(\mathbf{L1})Cl]_2[CuCl_4]$ (data not shown). The structure of the cationic portion of this complex is almost the same as complex **8**. Ligands **L2** and **L3** did not afford any precipitates in the absence of sodium perchlorate.

### Bromide Complexes

Bromide ion as the counterion also has an effect on the coordination sphere (see Figures S4–S6 in the Supporting Information). Complex **13** crystallises directly from the ligand/metal solution mixture, but addition of sodium perchlorate was found to be effective for crystallisation of complexes **11** and **12**. Even in the presence of perchlorate anion, the reaction mixture of **L3** with $CuBr_2$ in methanol affords the dibromide complex **13**. From these results, **L3** seems to exhibit weaker ether-oxygen coordination than **L1** and **L2**, thus forming an ether-free, neutral complex. This difference again highlights the preferred formation of a five-membered chelate over a six-membered ring, although the superior crystallising ability of complex **13** might be important. This complex adopts a distorted trigonal-bipyramidal geometry ($\tau$ = 0.59) due to the bulkiness of two copper-bound bromide ions. Complexes **11** and **12** exhibit five-coordinate, distorted square-pyramidal geometries ($\tau$ = 0.19 and 0.28) similar to the chloride complexes, but for **12**, the hydroxy group of the ligand is no longer hydrogen-bonded to the copper-bound bromide atom.

### Solution Studies

The electronic absorption spectra, cyclic voltammetry and EPR spectra were examined for complexes **1**–**13** to investigate the solution structure. In methanol solution, all complexes exhibit a copper d–d transition band around 640–710 nm ($\varepsilon$ = 80–200). No specific relationship between absorption maxima and ligand/complex structure was observed. For cyclic voltammetry in acetonitrile, the reduction potentials were significantly altered by ligand structure. Thus, the complexes ligated by **L3** exhibit positive-shifted reduction potentials that indicate a strong electron requirement for the copper centre. The EPR spectra in acetonitrile at room temperature exhibit well-resolved $^{63/65}$Cu hyperfine splitting in the range of 7–8 mT, except for complexes **7** and **13**, which show broad signals. $^{79/81}$Br hyperfine splitting in the range of 3 mT was also observed for complexes **11**–**13**, and this could be responsible for broadness of the signals for the dibromide complex **13**. Further studies of the solution structures of these complexes are in progress in our laboratory.

## Conclusions

As summarised in Table 3, the ligand structure and the anion of the starting metal salt play crucial roles in the ether-oxygen coordination in metal complexes in the crystal structure. The difference in chelate ring size determines the ether-oxygen coordination to the metal centre. The steric

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bulk of the chelating nitrate ion prevents ether-oxygen coordination whereas chloride ion promotes it. As a consequence, complexes that have +1 or +2 charges exhibit coordination of the ether-oxygen atom, whereas neutral complexes in which two anions are bound to the copper(II) centre tend to dissociate the ether-oxygen atom. The strong electron-withdrawing character of the metal centre in cationic complexes requires ether-oxygen coordination. However, stronger electron demand would require more efficient coordination by anion binding. Compensating balance between enthalpy gain and entropy loss caused by the coordination of the external anion, as well as crystallising ability of the complex, controls the choice of formation of intramolecular ether-oxygen binding to afford cationic complexes or intermolecular anion binding leading to neutral complexes. The hydroxy group of **L2** does not coordinate to the copper centre but promotes the ether-oxygen coordination by hydrogen bonding to the oxygen or chloride atom located *trans* to the aliphatic nitrogen in the basal plane. The present information provides an important strategy to regulate the coordination of an oxygen atom to the metal centre in the solid state.

## Experimental Section

**Materials:** *N*-(2-Methoxyethyl)-*N*,*N*-bis(2-pyridylmethyl)amine (**L1**),[21] *N*-[2-(2-hydroxyethyloxy)ethyl]-*N*,*N*-bis(2-pyridylmethyl)-amine (**L2**)[25] and *N*-(3-methoxypropyl)-*N*,*N*-bis(2-pyridylmethyl)-amine (**L3**)[21] were prepared from the corresponding amine by refluxing with two equivalents of 2-chloromethylpyridine hydrochloride in the presence of potassium carbonate in acetonitrile (75–84% yield). The spectroscopic data of **L1**–**L3** are in good agreement with those reported in the literature. Copper(II) nitrate trihydrate, copper(II) perchlorate hexahydrate (Wako Pure Chemical Industries, Ltd.), copper(II) chloride dihydrate, copper(II) bromide (Nacalai Tesque), sodium perchlorate monohydrate and all solvents (Wako Pure Chemical Industries, Ltd.) were used as received.

**Preparation of Complexes:** A methanolic solution of the ligands (0.03–0.25 mmol) was mixed with 1 equiv. of copper(II) salt in the same solvent at room temperature (total methanol volume: 0.4–2.0 mL), then diethyl ether vapour was introduced at 4 °C. In case crystallisation or precipitation did not occur, 1 equiv. of sodium perchlorate was added to the reaction mixture before ether diffusion. In most cases, single crystals suitable for X-ray crystallography were obtained directly from the reaction mixture. Complexes **3** and **8** precipitated from the reaction mixture and were recrystallised from acetonitrile/diethyl ether to obtain satisfactory single crystals. Single crystals of complex **6** were prepared from the ligand/metal mixture in acetonitrile under ether diffusion conditions. Table 1 summarises the preparation conditions, metal salt/ligand combinations and complex numbers.

***CAUTION:*** *Perchlorate salts of metal complexes with organic ligands are potentially explosive. All due precautions should be taken.*

**[Cu(L1)(NO$_3$)$_2$] (1):** Starting from **L1** (64.3 mg, 0.25 mmol), 72.5 mg of complex was obtained (65% yield). $C_{15}H_{19}CuN_5O_7$ (**1**) (444.89): calcd. C 40.50, H 4.30, N 15.74; found C 40.52, H 4.40, N 15.66.

**[Cu(L1)(NO$_3$)](ClO$_4$) (2):** Starting from **L1** (12.9 mg, 0.05 mmol), 14.9 mg of complex **2** was obtained (62% yield). $C_{15}H_{19}ClCuN_4O_8$ (482.34): calcd. C 37.35, H 3.97, N 11.62; found C 37.57, H 4.07, N 11.66.

**[Cu(L3)(NO$_3$)$_2$] (3):** Starting from **L3** (40.7 mg, 0.15 mmol), 29.3 mg of complex **3** was obtained (41% yield). $C_{16}H_{23}CuN_5O_8$ (**3**·$H_2O$; 476.93): calcd. C 40.29, H 4.86, N 14.68; found C 40.48, H 4.77, N 14.83.

**[Cu(L3)(NO$_3$)(ClO$_4$)] (4):** Starting from **L3** (8.1 mg, 0.03 mmol), 10.3 mg of complex **4** was obtained (69% yield). $C_{16}H_{21}ClCuN_4O_8$ (496.36): calcd. C 38.72, H 4.26, N 11.29; found C 38.22, H 4.52, N 11.37.

**[Cu(L1)(ClO$_4$)(CH$_3$OH)](ClO$_4$) (5):** Starting from **L1** (18.0 mg, 0.07 mmol), 27.6 mg of complex **5** was obtained (69% yield). $C_{16}H_{25}Cl_2CuN_3O_{11}$ (**5**·$H_2O$; 569.84): calcd. C 33.72, H 4.42, N 7.37; found C 33.94, H 4.39, N 7.56.

**[Cu(L1)(CH$_3$CN)(H$_2$O)](ClO$_4$)$_2$ (6):** Starting from **L1** (12.9 mg, 0.05 mmol), 17.8 mg of complex **6** was obtained (62% yield). $C_{17}H_{24}Cl_2CuN_4O_{10}$ (578.85): calcd. C 35.27, H 4.18, N 9.68; found C 34.77, H 4.36, N 9.25.

**[Cu(L2)(ClO$_4$)(CH$_3$OH)](ClO$_4$) (7):** Starting from **L2** (14.4 mg, 0.05 mmol), 15.6 mg of complex **7** was obtained (52% yield). $C_{17}H_{27}Cl_2CuN_3O_{12}$ (**7**·$H_2O$; 599.87): calcd. C 34.04, H 4.54, N 7.00; found C 34.28, H 4.23, N 7.27.

**[Cu(L1)Cl](ClO$_4$) (8):** Starting from **L1** (7.7 mg, 0.03 mmol), 5.0 mg of complex **8** was obtained (34% yield). $C_{16}H_{23}Cl_2CuN_3O_6$ (**8**·$CH_3OH$; 487.83): calcd. C 39.39, H 4.75, N 8.61; found C 39.02, H 4.34, N 8.90.

**[Cu(L2)Cl](ClO$_4$) (9):** Starting from **L2** (14.4 mg, 0.05 mmol), 15.5 mg of complex **9** was obtained (62% yield). $C_{16}H_{23}Cl_2CuN_3O_7$ (**9**·$H_2O$; 503.83): calcd. C 38.14, H 4.60, N 8.34; found C 38.09, H 4.43, N 8.47.

**[Cu(L3)Cl](ClO$_4$) (10):** Starting from **L3** (21.7 mg, 0.08 mmol), 27.9 mg of complex **10** was obtained (71% yield). $C_{16}H_{23}Cl_2CuN_3O_6$ (**10**·$H_2O$; 487.83): calcd. C 39.39, H 4.75, N 8.61; found C 39.60, H 4.53, N 8.34.

**[Cu(L1)Br](ClO$_4$) (11):** Starting from **L1** (12.9 mg, 0.05 mmol), 17.9 mg of complex **11** was obtained (71% yield). $C_{15}H_{19}BrClCuN_3O_5$ (500.24): calcd. C 36.02, H 3.83, N 8.40; found C 36.04, H 3.78, N 8.34.

**[Cu(L2)Br](ClO$_4$) (12):** Starting from **L2** (8.6 mg, 0.03 mmol), 11.2 mg of complex **12** was obtained (71% yield). $C_{16}H_{21}BrClCuN_3O_6$ (530.26): calcd. C 36.24, H 3.99, N 7.92; found C 36.37, H 4.09, N 7.88.

**[Cu(L3)Br$_2$] (13):** Starting from **L3** (8.1 mg, 0.03 mmol), 10.3 mg of complex **13** was obtained (65% yield). $C_{17}H_{25}Br_2CuN_3O_2$ (**13**·$CH_3OH$; 526.76): calcd. C 38.76, H 4.78, N 7.98; found C 38.45, H 4.36, N 7.97.

**X-ray Crystallography:** Single crystals of **1**–**13** were covered by paraffin oil and mounted on a glass fibre. All data were collected at 173 K on a Rigaku Mercury CCD detector, with monochromatic Mo-$K_\alpha$ radiation, operating at 50 kV/40 mA. Data were processed with a PC using CrystalClear Software (Rigaku). Structures were solved by direct methods (SIR-97, SIR-92 or SHELXS-97) and refined by full-matrix least-squares methods on $F^2$ (SHELXS-97).

CCDC-612373 to -612385 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.request/cif.

# Metal–Organic Hybrids of 1,3,5-Tris(4-pyridylsulfanylmethyl)-2,4,6-trimethylbenzene with Mercuric Halides

**Jayarama PrakashaReddy[a] and Venkateswara Rao Pedireddi*[a]**

**Keywords:** Metal–organic hybrids / Supramolecular chemistry / Crystal engineering / Fluxional thio ligands / Mercuric halides

Synthesis and solid-state structure elucidation of metal–organic hybrids of 1,3,5-tris(4-pyridylsulfanylmethyl)-2,4,6-trimethylbenzene with $Hg^{II}$ halides ($HgCl_2$, $HgBr_2$, and $HgI_2$) are reported. In the metal-hybrids of **L¹**, a reaction with $HgCl_2$ in dmso as well as in dmf gave host–guest complexes, **1a** and **1b**, respectively, with the corresponding solvent of crystallization as the guests, while a reaction with $HgI_2$ gave open-frame network structures without any solvent of crystallization from both dmso and dmf (**1c**). However, reaction with $HgBr_2$ gave crystals of two different morphologies from each solvent dmso and dmf (**1d**–**1f**), which corresponds to the structures with and without solvent of crystallization that resemble the related structures formed by $HgCl_2$ and $HgI_2$, respectively. Three-dimensional structures of all the compounds were characterized by single-crystal X-ray diffraction methods. While **1a** and **1b** crystallize in triclinic $P\bar{1}$ space groups **1a**: $a$ = 9.049(2), $b$ = 13.646(4), $c$ = 16.298(4) Å, $\alpha$ = 111.99(1), $\beta$ = 90.43(1), $\gamma$ = 101.57(1)°, $Z$ = 2, $V$ = 1820.6(8) Å$^3$; **1b**: $a$ = 8.979(3), $b$ = 13.611(5), $c$ = 16.355(5) Å, $\alpha$ = 111.57(1), $\beta$ = 92.37(1), $\gamma$ = 101.07(1)°, $Z$ = 2, $V$ = 1810.05(11) Å$^3$, complexes **1c**–**1f** crystallize into monoclinic space groups [**1c**: $C2/c$, $a$ = 27.661(7), $b$ = 18.821(4), $c$ = 15.786(4) Å, $\beta$ = 113.13(1), $Z$ = 4, $V$ = 7558(3) Å$^3$, **1d**: $P2_1/c$, $a$ = 17.950(5), $b$ = 9.031(2), $c$ = 22.200(6) Å, $\beta$ = 113.62(1), $Z$ = 4, $V$ = 3297.3(15) Å$^3$, **1e**: $C2/c$, $a$ = 26.753(15), $b$ = 18.415(10), $c$ = 14.940(7) Å, $\beta$ = 109.50(1), $Z$ = 4, $V$ = 6938(6) Å$^3$, **1f**: $P2_1/n$, $a$ = 17.697(10), $b$ = 9.224(5), $c$ = 21.933(12) Å, $\beta$ = 112.50(1), $Z$ = 4, $V$ = 3308(3) Å$^3$].

## Introduction

Design and synthesis of coordination polymers with exotic supramolecular architectures in the solid state are of current research interest because of the potential applications of the assemblies in the areas of separation technology, catalysis, gas storage devices, etc.[1–5] Thus, there are numerous reports of a myriad of supramolecular assemblies of coordination polymers utilizing different types of organic ligands possessing varied functionalities like carboxylates, aza-donor groups, etc., in recent literature.[6,7] In general, most of the assemblies known in the literature, however, were synthesized by utilizing organic moieties as rigid, spacer entities.[8] Thus, the crucial role of organic ligands with respect to the geometry and position of the functional groups was demonstrated in the formation of the desired topology. Also, another important feature of organic ligands is their conformational flexibility, which has been utilized in metal–organic framework structures in recent studies.[9] In this process, taking into account the well-established synthetic routes for the preparation of the required fluxional organic molecules, novel thio-based ligands with multi-armed, tripodal geometry, such as pyridylsulfanylmethyl derivatives, were synthesized, and these ligands demonstrated their significance in the supramolecular studies.[10]

Because of our continued interest in both molecular and supramolecular synthesis,[11] we were motivated to study the influence of such thio-based, flexible-armed molecules in the creation of assemblies with tailor-made geometries that possess cavities, channels, etc., and subsequently to evaluate possible applications. Thus, we have synthesized a pyridylsulfanyl compound 1,3,5-tris(4-pyridylsulfanylmethyl)-2,4,6-trimethylbenzene (**L¹**) and prepared its host–guest complexes in the form of metal–organic hybrid assemblies in which solvents are incorporated in the channels. Thus, in this manuscript, we report on coordination polymers of **L¹** with different halides of $Hg^{II}$ obtained by carrying out supramolecular synthesis from different solvents as illustrated in Scheme 1.

## Results and Discussion

### Solid-State Structure of Complex $[Hg(L^1)Cl_2]\cdot(dmso)_2$ (1a)

Crystallization of a precipitate of **L¹** and $HgCl_2$ from dmso gave single crystals that were suitable for analysis by

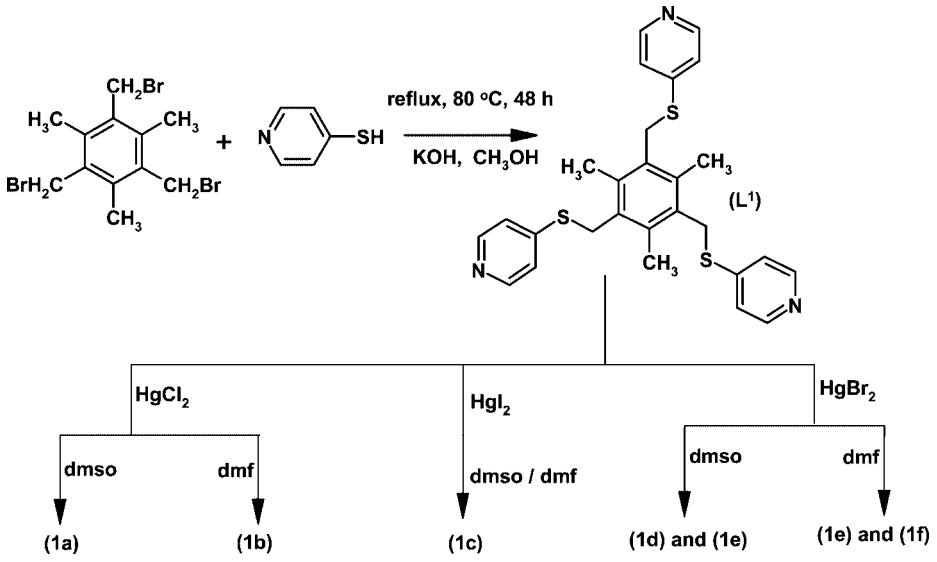

Scheme 1.

X-ray diffraction methods. The crystal structure determination reveals that, as expected, the pyridyl N atoms of $\mathbf{L^1}$ form coordination bonds with $Hg^{II}$ (Figure 1). The observed Hg–N bond distances (2.457–2.479 Å) are in agreement with distances presented in the literature.[12] Further, each $Hg^{II}$ is connected to two halide ions to form Hg–Cl bonds with distances of 2.458 and 2.491 Å. The pertinent coordination bonds and angles are given in Table 1. Thus, each $Hg^{II}$ with pentacoordination has a square-pyramidal geometry. This interaction results in the formation of a cavity of dimension $9 \times 12$ Å$^2$ and each cavity is created by two molecules of $\mathbf{L^1}$ and $Hg^{II}$ as shown in Figure 2a. The cavities are further aligned in a three-dimensional arrangement to yield channels (see Figure 2b), which are occupied by dmso molecules (solvent of crystallization) that exist in both ordered and disordered forms. Furthermore, both types of dmso molecules exist as dimers independently through the formation of C–H···O hydrogen bonds (see insets in Figure 2a).

### Solid-State Structure of Complex $[Hg(L^1)Cl_2]\cdot(dmf)_2$ (1b)

A precipitate of ligand $\mathbf{L^1}$ with $HgCl_2$ from dmf gave solvent-incorporated crystals as confirmed by X-ray diffraction methods, and each $Hg^{II}$ is connected to ligand $\mathbf{L^1}$ in exactly the same mode as that observed in **1a** (Figure 3a). The Hg–N distances are in the range 2.464–2.515 Å, and the Hg–Cl distances are 2.430 and 2.451 Å.

Thus, in the crystals of **1b**, dmf molecules are present in the cavities like the dmso molecules in **1a**, but both the dmf molecules are disordered in **1b**. Further, the symmetry-independent dmf molecules interact with each other through C–H···O hydrogen bonds with C···O distances of 3.07 and 3.13 Å. A typical hydrogen-bonding network between the dmf molecules is shown in the inset of Figure 3b. However, unlike in **1a**, no interaction exists between symmetry-dependent molecules.

### Supramolecular Structure of $[Hg(L^1)I_2]$ (1c)

A precipitate of ligand $\mathbf{L^1}$ and $HgI_2$ (used in a ratio of 2:3) from dmso gave **1c**. Crystallographic details of **1c** are given in Table 2. In this structure, ligand $\mathbf{L^1}$ forms coordination bonds with $Hg^{II}$ with Hg–N distances of 2.353–2.440 Å. Furthermore, $Hg^{II}$ forms Hg–I coordination bonds with distances in the range 2.623–2.661 Å (Figure 4).

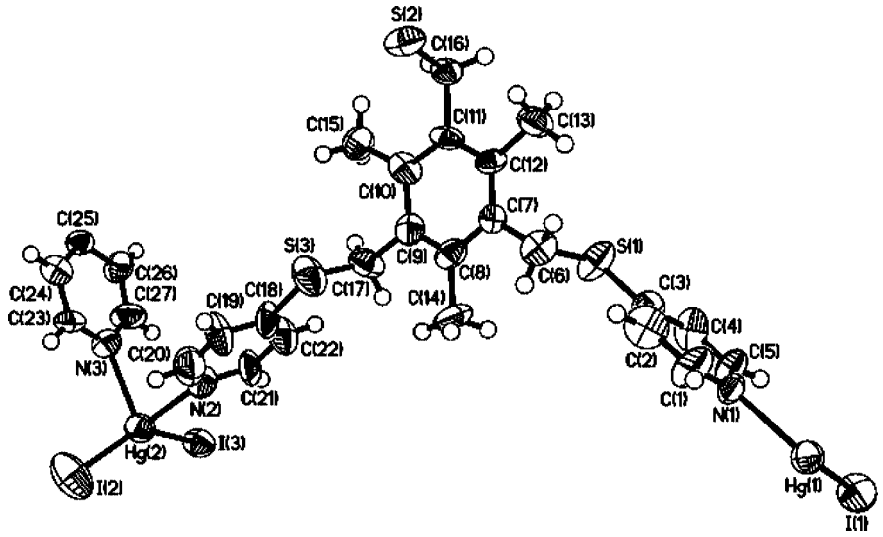

Figure 4. ORTEP drawing of the coordination geometry in the crystal structure of **1c**.

Further, the coordination geometry around $Hg^{II}$ in **1c** is distorted tetrahedral and differs from the square pyrimidal geometry observed in **1a** and **1b**. Thus, the coordination moieties in **1c** yield a polymer network comprising interconnected square grids with cavities (Figure 5a, b). However, the cavities could not be translated into channels in a three-dimensional arrangement as the void space is filled by moieties from adjacent chains as shown in Figure 5c.

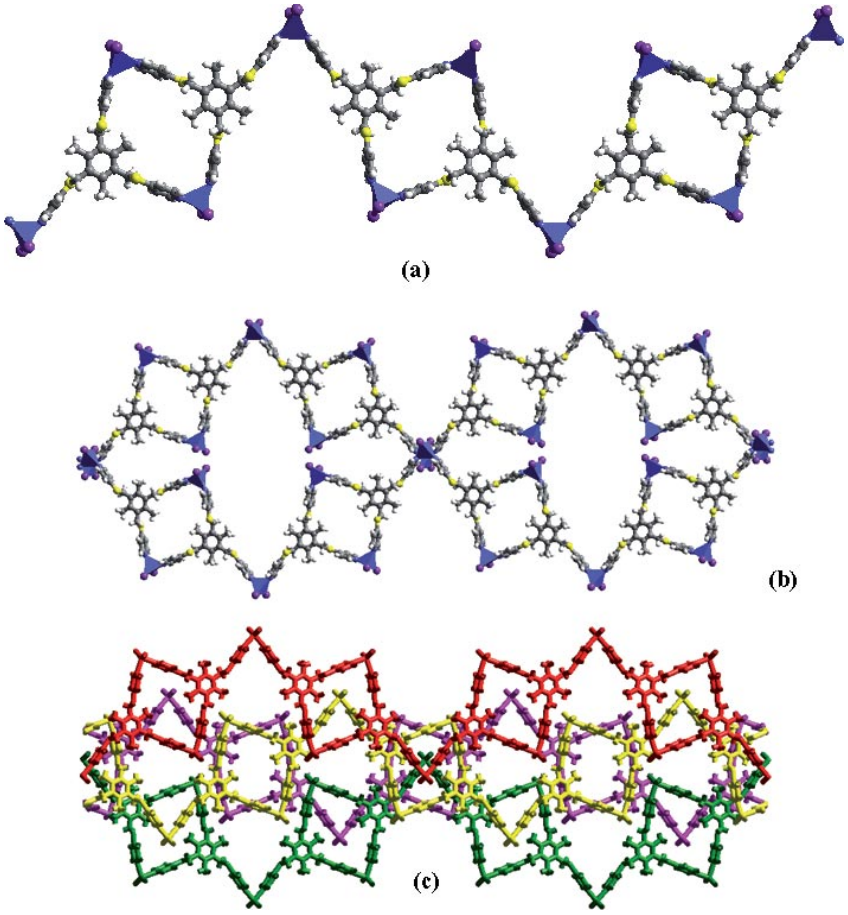

Figure 5. (a) Square-grid network mediated coordination polymers in the crystal structure of **1c**. (b) Arrangement of two adjacent polymer networks. (c) The three-dimensional arrangement of the coordination polymers. Each polymer network is shown in different colors.

### Solid-State Structures of Complexes of $L^1$ with $HgBr_2$ (1d–1f)

The complexes formed by $HgBr_2$ are quite intriguing and in fact further reinforce the systematic changes generally observed in the halogen series. Crystallization of a solid mixture of $\mathbf{L^1}$ and $HgBr_2$ from dmso and dmf gave concomitant crystals of two different morphologies from each solvent. Structure analysis reveals that, while one of the morphologies from each solvent [**1d** (dmso) and **1f** (dmf)] corresponds to a solvated structure such as for $HgCl_2$ (**1a** and **1b**, respectively), the other morphologies gave structures without a solvent of crystallization (**1e**) like **1c** formed by $HgI_2$.

Although **1d** and **1f** have similar unit cell parameters, they are not isomorphous, as they crystallize in different space groups, $P2_1/c$ and $P2_1/n$, respectively. The full crystallographic details are given in Table 2. However, structure analysis reveals that both **1d** and **1f** are isostructural with the formation of identical three-dimensional arrangements. In a typical interaction, as shown in Figure 6, the ligand $\mathbf{L^1}$ interacts with $Hg^{II}$ by forming Hg–N bonds (Table 1) to yield an infinite coordination polymer chain.

Figure 6. Coordination polymer formed between $\mathbf{L^1}$ and $HgBr_2$ yielding a chain.

Thus, out of the available three pyridyl moieties only two interact with $Hg^{II}$. Also, each $Hg^{II}$ is bonded to two Br atoms (Table 1). Thus, in **1d** and **1f**, the coordination geometry around each $Hg^{II}$ atom is also distorted tetrahedral as shown in Figure 6. Such adjacent chains are held together by C–H···N hydrogen bonds with H···N distances of 2.66–2.89 Å, as observed in the structure of the free ligand (Supporting Information) and form cavities of dimension $11 \times 16$ Å$^2$ (Figure 7), which are aligned in a three-dimensional arrangement to yield channels. The channels are occupied by the solvent molecules dmso and dmf in **1d** and **1f**, respectively. Thus, **1d** and **1f** show some similarities with **1a** and **1b** in the formation of an open-frame network. However, the metal coordination and geometry around each $Hg^{II}$ in **1d** and **1f** has a close resemblance to that of **1c**. Further, the solvent molecules present in the channels of the structures **1d** and **1f** do not interact with each other but are bound to the host lattice through numerous intermolecular interactions.

However, complex **1e**, obtained as concomitant crystals along with **1d** and **1f**, crystallizes in the monoclinic space group $C2/c$. Further, packing analysis reveals that the structure of **1e** is identical to that formed by $HgI_2$ (**1c**) in all respects except for the difference of the halogen atoms. A typical structural arrangement in complex **1e** is shown in Figure 8 for purposes of comparison with the structure of **1c**.

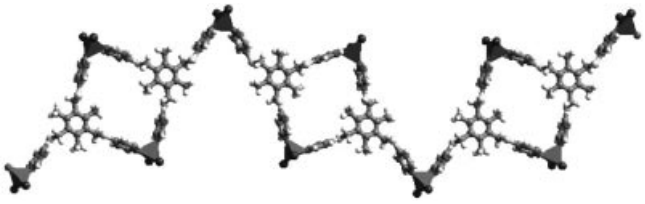

Figure 8. Square-grid network found in the solid-state structure of complex **1e**.

By comparing the crystal structures of the metal complexes described herein, it is clearly evident that the structures obtained are in agreement with the proposition of

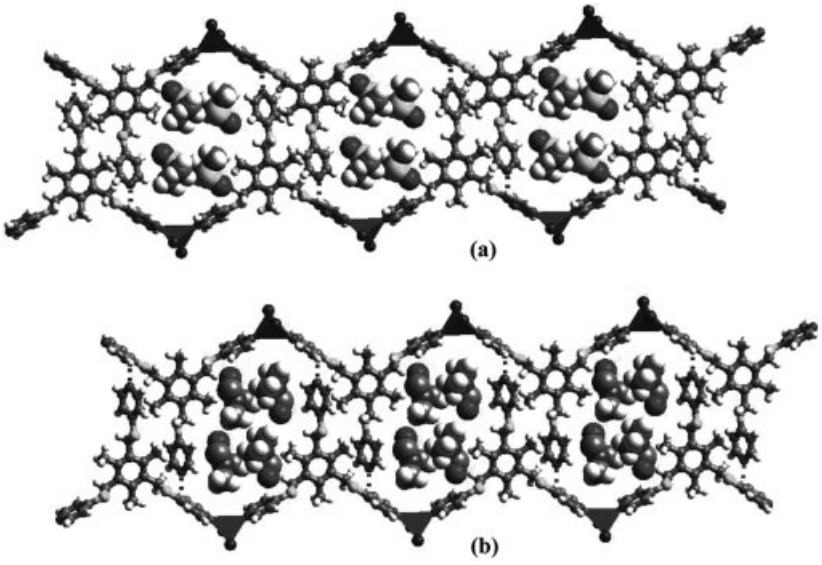

Figure 7. Representation of cavities formed by the interaction of the adjacent polymeric chains through C–H···N hydrogen bonds in the crystal structures (a) **1d** and (b) **1f**, along with the solvent molecules dmso and dmf, respectively.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

utilization of pyridylsulfanyl ligands in the supramolecular synthesis through either dative bonds (**1a**–**1c**, **1e**) or a combination of dative bonds and hydrogen bonds (**1d** and **1f**). Another intriguing feature of these metal complexes is the systematic variation with the change in halogen. While $HgCl_2$ forms solvated structures, $HgI_2$ forms structures exclusively without solvents of crystallization.

One more interesting feature is the conformational changes in ligand $\mathbf{L^1}$ that occur when the ligand is uncoordinated and when it is in the different complexes (Figure 9). It is apparent that all the metal complexes, except **1d** and **1f**, adopt the same conformation (*cis*, *trans*, *trans*), which is different from that of the conformation observed in the pure structure of $\mathbf{L^1}$ (*cis*, *cis*, *cis*). It is well known from the literature that tripodal ligands like $\mathbf{L^1}$ show both types of conformation observed in this study, but often the conformation was attributed to the nature of the anion present in the structures.

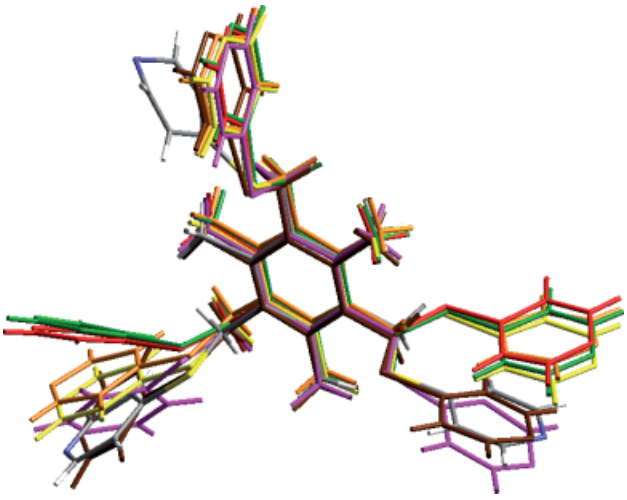

Figure 9. An overlay diagram of the molecular conformation of ligand $\mathbf{L^1}$ in its crystal structure (gray) and also in the complexes **1a**–**1f**. Brown and pink correspond to **1d** and **1f**.

However, it is apparent from this study that the coordination environment of the metal species as well as denticity of the ligands also may play a significant role in determining the conformation. In particular, the complexes formed by $HgBr_2$ are quite significant in this respect. Since, the same halogen (Br) gave structures of both conformations, which can be differentiated by the number of metal coordination centers, it may be understood that interaction with three metal ions like $Hg^{II}$ leads to strained crowding in a *cis*, *cis*, *cis* geometry, which might have forced the transformation of the conformation to *cis*, *trans*, *trans* in **1e**, whereas in **1d** and **1f**, with only two $Hg^{II}$ involved in complex formation, the conformation is retained as such, as in $\mathbf{L^1}$.

## Conclusions

In conclusion, we have reported the solid-state structures of metal–organic hybrids of conformationally flexible thio ligand $\mathbf{L^1}$ with different mercuric halides. Complexes **1a**–**1f** were prepared and the supramolecular assembly networks have been analyzed, and it is understood that all the complexes have open-frame networks with void space. In complexes **1a**, **1b**, **1d**, and **1f**, solvent of crystallization occupies the void space, while in other structures (**1c** and **1e**), the void space was filled by the self-protrusion of functional groups from adjacent molecules. In particular, the variations observed in the conformations of the ligand $\mathbf{L^1}$ are intriguing and may provide further insight in modeling experiments, especially for the evaluation of metal-hybrids as catalysts, which has increased demands under the current research themes.

## Experimental Section

**Synthesis of 1,3,5-Tris(4-pyridylsulfanylmethyl)-2,4,6-trimethylbenzene ($\mathbf{L^1}$):** 1,3,5-tris-(bromomethyl)-2,4,6-trimethylbenzene (399 mg, 1 mmol) was added to an ice-cooled solution of pyridine-4-thiol (333 mg, 3 mmol) and KOH (560 mg, 10 mmol, slight excess) in methanol whilst stirring. The mixture was heated at reflux for 48 h at 80 °C. The solution was poured into ice-cold water, the crude product was filtered and separated by column chromatography, and a colorless microcrystalline solid was obtained ($\mathbf{L^1}$) in 72% yield (m.p. 228–230 °C). Single crystals of $\mathbf{L^1}$ suitable for X-ray diffraction were obtained from methanol solution after 2–3 d.

**Preparation of Complex $[Hg(L^1)Cl_2]\cdot(dmso)_2$ (1a):** A white precipitate obtained by dissolving $HgCl_2$ (81 mg, 0.3 mmol) and $\mathbf{L^1}$ (49 mg, 0.1 mmol) in methanol was filtered and dissolved in dmso and allowed to slowly evaporate at room temperature. Within 48 h, well-grown colorless single crystals of **1a** were obtained in 36% yield (m.p. 204–206 °C).

**Preparation of Complex $[Hg(L^1)Cl_2]\cdot(dmf)_2$ (1b):** A white precipitate was obtained as described for **1a**; however dmf was used instead of dmso. After slow evaporation under ambient conditions, gave colorless single crystals of **1b** were obtained in 42% yield (m.p. 213–215 °C).

**Preparation of Complex $[Hg(L^1)I_2]$ (1c):** A solution of $HgI_2$ (135 mg, 0.3 mmol) in methanol was added to a solution of $\mathbf{L^1}$ (49 mg, 0.1 mmol) in methanol, and a white precipitate was obtained. The precipitate was filtered and dissolved in dmso to obtain colorless crystals of **1c** in 31% yield (m.p. 208–210 °C). The complex **1c** was also obtained by dissolving the precipitate in dmf and by evaporating the solution under ambient conditions.

**Preparation of Complexes $[Hg(L^1)Br_2]\cdot(dmso)$ (1d) and $[Hg(L^1)Br_2]$ (1e):** A solution of $HgBr_2$ (108 mg, 0.3 mmol) in methanol was added to a solution of $\mathbf{L^1}$ (49 mg, 0.1 mmol) in methanol. The resulting white precipitate was filtered and dissolved in dmso. Colorless crystals of two morphologies (plates **1d** and blocks **1e**) were obtained in 21 and 11% yields, respectively [m.p. 177–179 (**1d**) and 197–199 °C (**1e**)].

**Preparation of Complex $[Hg(L^1)Br_2]\cdot(dmf)$ (1f):** A solution of $HgBr_2$ (108 mg, 0.3 mmol) in methanol was added to a solution of $\mathbf{L^1}$ (49 mg, 0.1 mmol) in methanol. The white precipitate obtained

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was filtered and dissolved in dmf. Colorless crystals of two morphologies (blocks **1e**; plates **1f**) were obtained in 28 and 14% yields, respectively, (**1f**: m.p. 184–186 °C).

**Crystal Structure Determination:** Good quality, single crystals of $\mathbf{L^1}$ and **1a**–**1f**, grown as described above, were carefully chosen with the aid of a polarized optical microscope and glued to glass fiber to mount on a X-ray diffractometer goniometer equipped with a CCD area detector.[13] The data collection proceeded without any complication and was processed using the Bruker suite of software. The structures were determined and refined by using the SHELXTL suite of programs, and absorption corrections were made on all the crystals with SADABS.[14] All the non-hydrogen atoms were refined anisotropically except a few atoms in **1d** (one atom) and **1f** (nine atoms). All hydrogen atoms were placed in the calculated positions.

The structural parameters are given in Table 2. All the intra- and intermolecular distances were computed with PLATON software.[15] The packing drawings were generated either by an XP package of SHELXTL or Cerius$^2$ of Accelrys, Inc. CCDC-625087–625093 for $\mathbf{L^1}$ and **1a**–**1f**, respectively, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Discussion of the structure of $\mathbf{L^1}$ and corresponding figures, its crystallographic information and powder X-ray diffraction patterns (both experimental and simulated from crystal data) are given.

## Acknowledgments

We thank Dr. S. Sivaram (Director, NCL) and Dr. K. N. Ganesh (Head of Organic Division, NCL) for their constant support and encouragement. Also, we acknowledge the financial assistance of DST and BRNS for the ongoing projects. One of us (J. P.) thanks the Council of Scientific and Industrial Research (CSIR), New Delhi for a research fellowship.

# Neutral Yttrium Tris(amide) and Ate Complexes Coordinated by an (*R*)-*N*,*N*′-Diisopropyl-1,1′-binaphthyl-2,2′-diamido Ligand as Enantioselective Catalysts for Intramolecular Hydroamination

**David Riegert,[a] Jacqueline Collin,*[a] Jean-Claude Daran,[b] Tauqir Fillebeen,[a] Emmanuelle Schulz,[a] Dmitrii Lyubov,[c] Georgy Fukin,[c] and Alexander Trifonov*[c]**

**Keywords:** Asymmetric catalysis / N ligands / Yttrium / Hydroamination / Nitrogen heterocycles

A bis(amido)yttrium chloride coordinated by (*R*)-*N*,*N*′-diisopropyl-1,1′-binaphthyl-2,2′-diamide [Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}-Cl(thf)$_2$] has been prepared and characterized by X-ray analysis along with the corresponding yttrium ate complex [Li(thf)$_4$][Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}$_2$]. The reaction of [(*R*)-*N*,*N*′-diisopropyl-1,1′-binaphthyl-2,2′-diamido]yttrium chloride with lithium diisopropylamine leads to the formation of a neutral tris(amido)yttrium complex which was characterized by NMR spectroscopy. The new complexes [Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}-{N*i*Pr$_2$}] and [{Li(thf)$_4$}(Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}$_2$)], which contain the same enantiopure binaphthyldiamido ligand, are compared for the catalysis of several intramolecular hydroamination reactions. Both complexes provide pyrrolidines and piperidines with moderate to high enantioselectivities.

## Introduction

The intramolecular hydroamination of alkenes is an atom-economic process that leads to the formation of nitrogen heterocycles that are found in numerous biologically active compounds.[1] The pioneering work of Marks and coworkers has shown the ability of lanthanocenes to perform hydroamination/cyclization reactions.[2] More recently non-cyclopentadienido rare-earth complexes[3] as well as transition metal complexes and others[4] have been reported to catalyze the intramolecular hydroamination of alkenes. However, enantioselective hydroamination reactions have been less studied and only a few chiral asymmetric catalysts have been reported to date.[5]

Chiral catalysts that are efficient for the asymmetric cyclization of aminoalkenes are almost all prepared from lanthanides with different types of ligands and are either isolated or used in situ. The first enantioselective catalysts reported for hydroamination/cyclization were the *ansa*-lanthanocene complexes substituted by a menthyl or neomenthyl group synthesized by Marks et al. that possess two stereogenic centers (backbone and lanthanide chirality, see **A** in Figure 1).[6] Diastereomeric mixtures and diastereomerically pure precatalysts yielded the formation of pyrrolidines with identical enantiomeric excesses of up to 74% *ee*. Similar rare-earth metal complexes with an octahydrofluorenido group instead of a tetramethylcyclopentadienido group (structure **B** in Figure 1) have been isolated and have been found to be more efficient for the preparation of piperidines (up to 67% *ee*).[7] Both series of complexes were prepared in a two-step synthesis that includes the formation of a metal chloride followed by its transformation into the amido or alkyl complex. Chiral lanthanide bis(aryloxide)s and bis(naphthoxide)s have been prepared by a different route and studied for the catalysis of aminoalkene cyclization. Scott et al. have thus synthesized chiral rare-earth metal bis(aryloxide) complexes by the reaction of the ligand [a bis(phenol) with a bis(arylamine) providing the chirality, structure **C**] with the tris(amide) precursors [Ln{N(SiHMe$_2$)$_2$}$_3$(thf)$_2$].[8] The lanthanum complex was found to cyclize an aminopentene, albeit with low activity (reaction performed at 70 °C), with 61% *ee*. A similar chiral cationic zirconium complex has also been characterized and tested for the hydroamination/cyclization of secondary amines; it affords 82% *ee* for a piperidine.[9] Hultzsch et al. have synthesized various lanthanide bis(phenolate)s and bis(naphtholate)s.[10] They isolated dimeric alkyllanthanum bis(phenolate) complexes from the reaction of 3,3′-substituted bis(phenol) with [La{CH(SiMe$_3$)$_2$}$_3$] which exhibited only low enantioselectivity for hydroamination reactions.[10a] The amidoyttrium biphenolate and binaphtholate

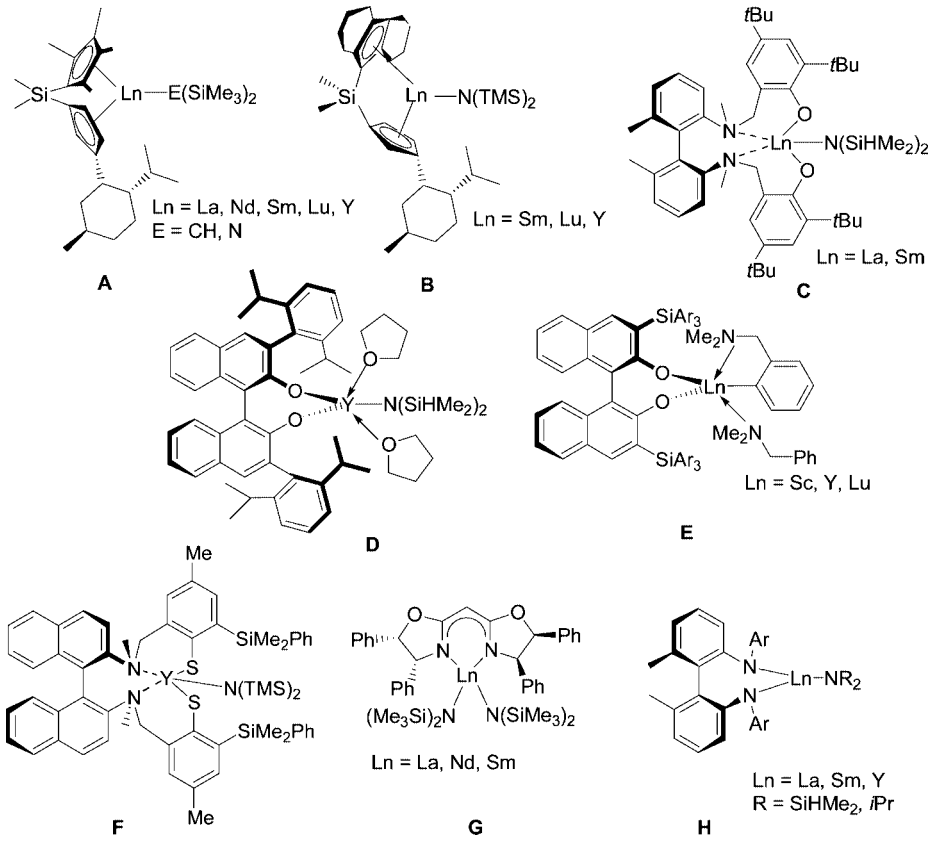

Figure 1. Complexes for intramolecular hydroamination reactions.

complexes synthesized according to a similar procedure (complex **D** in Figure 1) afforded moderate activities in these transformations, with enantiomeric excesses of up to 57%.[10b] To the best of our knowledge, the highest enantioselectivities obtained for intramolecular hydroamination are provided by chiral lanthanide 3,3′-tris(arylsilyl)binaphtholates prepared by arene, alkane or amine elimination and used in situ. The yttrium,[10c] lutetium, and scandium binaphtholates prepared from [Ln{*o*-$C_6H_4CH_2NMe_2$}$_3$] and 3,3′-bis(triarylsilyl)binaphthol (structure **E**) allow the cyclization of aminopentenes to be performed at room temperature with high turnovers and with enantiomeric excesses of up to 95%.[10d] Other enantioselective catalysts have also been prepared by the same procedure and used in situ. The amidoyttrium compounds synthesized by Livinghouse et al. from [Y{$N(TMS)_2$}$_3$] and chiral bis(thiolate) ligands (complex **F**) catalyze the cyclization of aminoalkenes at 60 °C and with enantiomeric excesses above 80% for several substrates.[11] Similarly, by the reaction of lanthanide amides with commercially available $C_2$-symmetric bis(oxazoline)s, Marks et al. have prepared enantioselective catalysts (structure **G** in Figure 1) that are active at room temperature (up to 67% *ee*).[12] A chiral, bridged aminotroponiminate complex of lutetium was very recently synthesized by Roesky[13] that shows moderate enantioselectivities for intramolecular hydroamination.

Since the pioneering work of Livinghouse et al. that showed that lanthanide tris(amide)s are active hydroamination catalysts and that the stereoselectivity and the rate of the reaction can be tuned by varying the diamine ligands,[3b,3d] the preparation of chiral lanthanide tris(amide)s for the enantioselective catalysis of hydroamination reactions has been a challenge. Interesting results have been reported by the group of Scott, who prepared precatalysts by the reaction of bis(arylamine)s possessing axial chirality with lanthanide tris(amide)s. These complexes (structure **H** in Figure 1) catalyze the cyclization of 2,2-dimethylpent-4-enylamine at 60 °C, albeit with only moderate asymmetric inductions.[14]

We have previously reported the preparation of lanthanide catalysts coordinated by chiral amido ligands for intramolecular hydroamination.[15] A new family of lanthanide ate complexes [Li(thf)$_4$][Ln{(*R*)-$C_{20}H_{12}(NR)_2$}$_2$] (Ln = Yb, Sm, Nd, Lu; **1** in Scheme 1) derived from chiral, disubstituted (*R*)-binaphthylamido ligands was studied. These compounds consist of a complex anion resulting from coordination of two (*R*)-binaphthylamine ligands to the lanthanide atom and a discrete [Li(thf)$_4$]$^+$ counterion. Both the influence of the lanthanide and of the alkyl substituent on the nitrogen groups was examined in a hydroamination test reaction. The activity and enantioselectivity of these catalysts were evaluated for the cyclization of *C*-(1-allylcyclohexyl)-methylamine. The ytterbium and lutetium complexes with bulky substituents (isopropyl, cyclohexyl) on the nitrogen atom led to the highest enantioselectivities (up to 76% *ee* for the spiropyrrolidine).

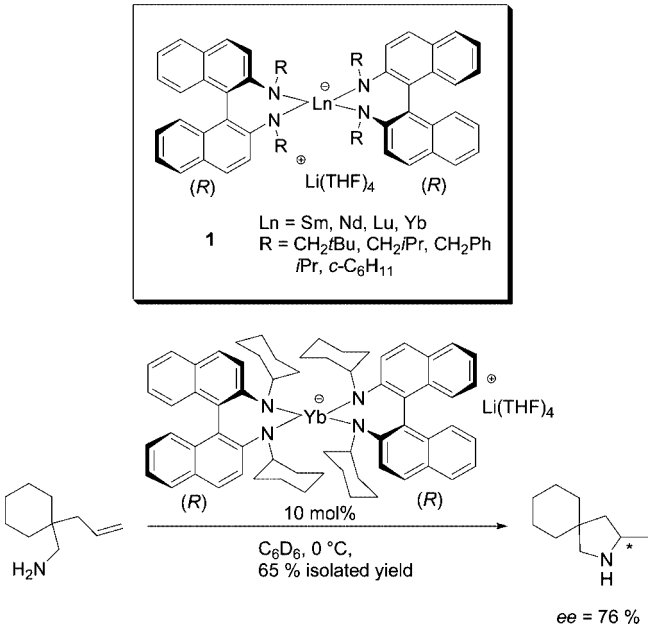


Scheme 1. Intramolecular hydroamination catalyzed by chiral lanthanide ate complexes.

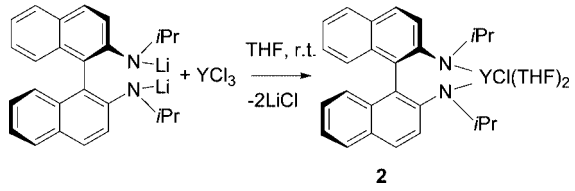
In order to gain insight into the nature of the active catalytic species for the hydroamination reaction mediated by the ionic compounds $[Li(thf)_4][Ln\{(R)\text{-}C_{20}H_{12}(NR)_2\}_2]$, we considered the synthesis of both neutral and ate complexes of the same metal coordinated with the same chiral ligand and compared their catalytic properties.

## Results and Discussion

### Preparation and Characterization of Complexes

With the aim of preparing neutral tris(amido)lanthanide complexes $[Ln\{(R)\text{-}C_{20}H_{12}(NR)_2\}\{NR'_2\}]$ with binaphthylamino ligands, we focused on the synthesis of yttrium derivatives since yttrium tris(amide)s have been already synthesized and characterized by X-ray analysis. Several lanthanide tris(amide)s have been prepared by metathesis reactions,[16] and yttrium complexes coordinated by a chiral bis(arylamido) ligand have been used as enantioselective hydrosilylation catalysts.[17]

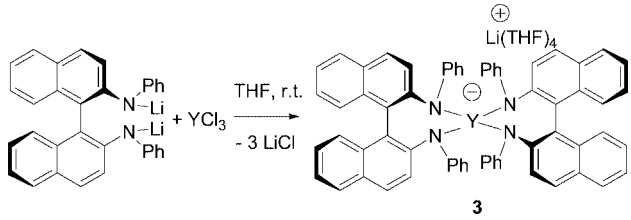
Initially, we attempted to use the amine elimination reaction as a synthetic approach to the neutral complexes $[Ln\{(R)\text{-}C_{20}H_{12}(NR)_2\}\{NR'_2\}]$ (Ln = Y, La, Sm; R = $CH_2CMe_3$, *i*Pr; R′ = $SiMe_3$). Thus, reactions of $[Ln\{N(SiMe_3)_2\}_3]$ (Ln = Y, La, Sm) with chiral diamines $(R)\text{-}C_{20}H_{12}(NHR)_2$ (R = $CH_2CMe_3$, *i*Pr) in a 1:1 molar ratio were carried out in toluene at 70 °C. However, these reactions were found to occur with complete substitution of the $N(SiMe_3)_2$ groups in the parent tris(amido) complexes since the $^1H$ NMR spectra of the solid products indicated the absence of the corresponding signals. The salt metathesis reaction of anhydrous $YCl_3$ with 1 equiv. of $Li_2\{(R)\text{-}C_{20}H_{12}(NiPr)_2\}$[18] in thf at ambient temperature allowed the isolation of the chiral diamidoyttrium chloride complex **2** in 81% yield (Scheme 2).



Scheme 2. Synthesis of the neutral yttrium complex $[Y\{(R)\text{-}C_{20}H_{12}(NiPr)_2\}Cl(thf)_2]$ (**2**).

Complex **2** was purified by extraction of the solid residue with toluene after evaporation of thf and subsequent recrystallization from thf/hexane mixtures. The $^1H$ and $^{13}C$ NMR spectra of complex **2** in $C_6D_6$ at 20 °C show the expected sets of resonances due to the (*R*)-*N*,*N*′-diisopropyl-1,1′-binaphthyl-2,2′-diamido ligand and the coordinated thf molecules.

This salt metathesis reaction turned out to be highly sensitive to the substituent on the nitrogen atom of the starting (*R*)-1,1′-binaphthyl-2,2′-diamine. Thus, the reaction of equimolar amounts of $YCl_3$ and the dilithium derivative of (*R*)-*N*,*N*′-diphenyl-1,1′-binaphthyl-2,2′-diamine under analogous conditions afforded the ate complex $[Li(thf)_4]\text{-}[Y\{(R)\text{-}C_{20}H_{12}(NPh)_2\}_2]$ (**3**) in 42% yield instead of the expected complex $[Y\{(R)\text{-}C_{20}H_{12}(NPh)_2\}Cl(thf)_n]$ (Scheme 3).



Scheme 3. Synthesis of the yttrium ate complex $[Li(thf)_4][Y\{(R)\text{-}C_{20}H_{12}(NPh)_2\}_2]$ (**3**).

Complex **3** was purified by extraction of the solid residue obtained after evaporation of thf with hot toluene. Slow cooling of hot solutions of **3** in toluene afforded crystalline samples. The $^1H$ and $^{13}C$ NMR spectra of complex **3** in $C_6D_6$ at 20 °C show the expected sets of signals corresponding to the aromatic protons of the diamido ligand and the coordinated thf molecules.

In order to synthesize the amidoyttrium complex containing a chiral ancillary ligand, we carried out the reaction of complex **2** with $LiNiPr_2$ in thf at room temperature (Scheme 4). After evaporation of thf, the crude complex $[Y\{(R)\text{-}C_{20}H_{12}(NiPr)_2\}\{NiPr_2\}\{LiCl(thf)_2\}]$ (**4**) was characterized by $^1H$ and $^{13}C$ NMR spectroscopy. According to the $^1H$ NMR spectrum, complex **4** contains two molecules of thf. Unfortunately, the experimental data did not allow us to conclude with certainty whether these thf molecules are coordinated to Y or Li. Extraction of the complex with toluene and recrystallization from thf/hexane resulted in the products of ligand-redistribution reactions. All attempts to isolate individual compounds to obtain samples suitable for

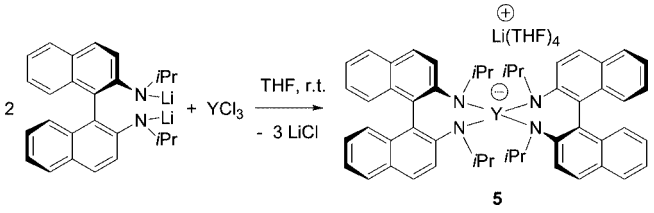
Scheme 4. Synthesis of [Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}{N*i*Pr$_2$}{LiCl(thf)$_2$}] (**4**).

X-ray analysis failed. We also tried to prepare alkylyttrium derivatives containing the (*R*)-*N*,*N*′-diisopropyl-1,1′-binaphthyl-2,2′-diamido ligand. However, reactions of **2** with the alkyllithium reagents $LiCH_2SiMe_3$ (toluene 0 °C) and MeLi ($Et_2O$, 0 °C, in the presence of a twofold molar excess of TMEDA) did not afford any tractable organoyttrium compounds.

The ate complex [Li(thf)$_4$][Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}$_2$] (**5**) was synthesized by the metathesis reaction of anhydrous $YCl_3$ with 2 equiv. of Li$_2${(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$} in thf at ambient temperature (Scheme 5).



5

Scheme 5. Synthesis of the ate complex [Li(thf)$_4$][Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}$_2$] (**5**).

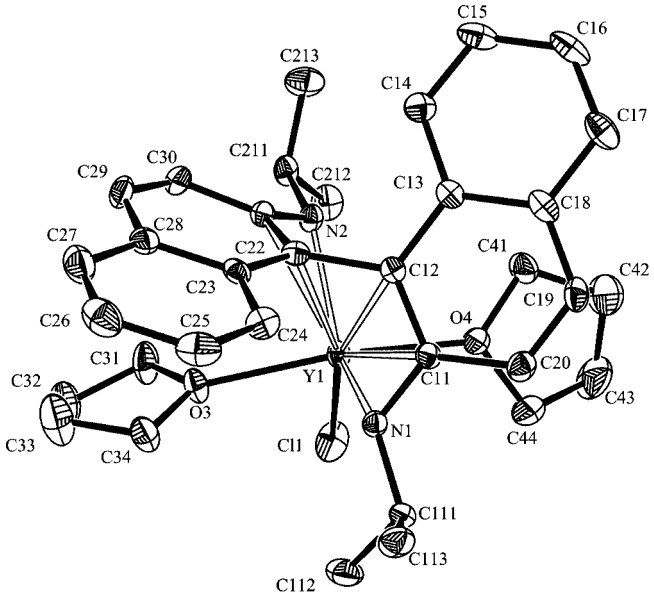


Figure 2. ORTEP drawing of complex **2** with the atom labeling scheme. Ellipsoids are drawn at the 30% probability level. The hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Y1–N1 2.254(3), Y1–N2 2.257(4), Y1–Cl1 2.5835(14), Y1–C11 2.700(4), Y1–C12 2.756(4), Y1–C21 2.717(4), Y1–C22 2.746(4); N1–Y1–N2 123.36(15), N1–Y1–Cl1 115.78(12), N2–Y1–Cl1 120.86(10).

Complex **5** was purified by extraction of the solid residue remaining after evaporation of thf with toluene and subsequent recrystallization from thf/hexane mixtures; it was isolated in 71% yield. Complexes **2**–**5** were obtained as yellow, highly air- and moisture-sensitive crystalline solids. Complexes **2**, **4**, and **5** are soluble in thf and toluene and insoluble in hexane. Complex **3** is soluble in thf and hot toluene. Clear single-crystalline samples of complex **2** suitable for X-ray investigation were obtained by slow condensation of hexane into the concentrated thf solution at room temperature. Complex **2** crystallizes in the monoclinic space group $P2_1$ with four molecules in the unit cell. The molecular structure of **2** is depicted in Figure 2, and the crystal and structural refinement data are listed in the Experimental Section. The X-ray single-crystal structure analysis showed that complex **2** adopts a monomeric structure, thus indicating a considerable steric demand of the diamido ligand.

The coordination sphere of the yttrium atom in **2** contains the two nitrogen atoms of the (*R*)-*N*,*N*′-diisopropyl-1,1′-binaphthyl-2,2′-diamido ligand, one chlorido ligand, and two oxygen atoms of two thf molecules. The formal coordination number of the metal atom is five, which is rather low for yttrium. The presence in complex **2** of short contacts between the metal atom and the carbon atoms in the *ipso* and *ortho* positions to the amido groups [Y(1)–C(211) 2.708(4), Y(1)–C(111) 2.719(5), Y(1)–C(112) 2.745(4), Y(1)–C(212) 2.758(4) Å] comparable to those reported for the yttrium π-complexes [({PhP(CH$_2$SiMe$_2$NSiMe$_2$CH$_2$)$_2$PPh}Y)$_2${η$^6$:η$^6$-($C_6H_5$)$_2$}] [2.699(1)–2.738(4) Å][19] and [Y(*o*-2,6-Ph$_2$$C_6H_3$)$_3$] [2.84(1)–3.38(1) Å][20] probably reflects an η$^2$-interaction of the yttrium atom with the aromatic rings of the binaphthyl ligand, which leads to a saturation of the coordination sphere of the yttrium atom. The Y–N bond lengths in **2** [2.254(3) and 2.257(4) Å] are very close to the length of the covalent bond reported for the amidoyttrium complexes [{[6,6′-Me$_2$-($C_6H_3$)$_2$](2,2′-NSiMe$_2$*t*Bu)$_2$}YCl(thf)$_2$] [2.247(7) and 2.252(7) Å][21] and [Cp*$_2$Y{N(SiMe$_3$)$_2$}] [2.274(1) and 2.253(1) Å].[22] The Y–Cl bond length in **2** [2.5835(14) Å] is comparable to those in [{[6,6′-Me$_2$-($C_6H_3$)$_2$](2,2′-NSiMe$_2$*t*Bu)$_2$}YCl(thf)$_2$] [2.574(2) Å][21] and [Cp*$_2$YCl(thf)] (2.579 and 2.577 Å).[23]

Clear single-crystal samples of complex **3** suitable for X-ray investigation were obtained by slow cooling of its hot toluene solution from 70 °C to room temperature. Complex **3** crystallizes in the orthorhombic space group $P2_12_12_1$ with four molecules in the unit cell. Complex **3** was isolated as a solvate containing three molecules of toluene per molecule

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

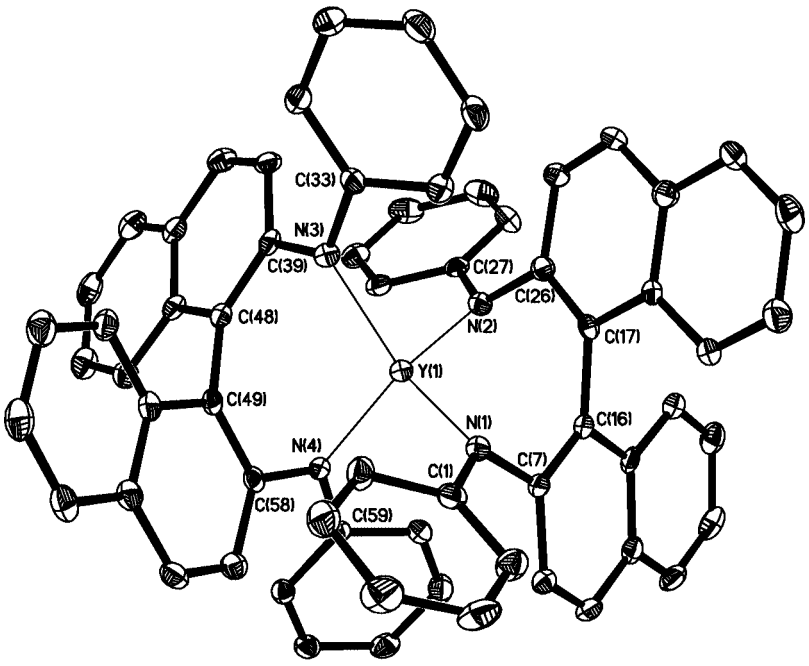

Figure 3. ORTEP drawing of complex **3** with the atom labeling scheme. Ellipsoids are drawn at the 30% probability level. The $Li(thf)_4^+$ cation and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Y1–N1 2.275(2), Y1–N2 2.267(2), Y1–N3 2.270(2), Y1–N4 2.288(2), Y1–C26 2.747(2), Y1–C16 2.849(3), Y1–C7 2.727(3), Y1–C39 2.743(3), Y1–C58 2.746(3); N1–Y1–N2 118.47(8), N1–Y1–N3 103.74(8), N2–Y1–N3 104.69(9), N1–Y1–N4 108.65(8), N2–Y1–N4 103.84(8), N3–Y1–N4 118.15(8).

of complex, i.e., $[\{Li(thf)_4\}(Y\{(R)\text{-}C_{20}H_{12}(NPh)_2\}_2)\text{-}(C_7H_8)_3]$. The molecular structure of **3** is depicted in Figure 3 and the crystal and structural refinement data are listed in the Experimental Section.

The X-ray single-crystal structure analysis revealed that compound **3** is an ionic complex containing a discrete $Li(thf)_4^+$ cation and a discrete $[Y\{(R)\text{-}C_{20}H_{12}(NPh)_2\}_2]^-$ complex anion resulting from the coordination of two diamido ligands to the trivalent yttrium atom. The Y–N bonds within the complex anion of **3** [2.267(2), 2.270(2), 2.275(2), and 2.288(2) Å] are slightly longer than the same distances in neutral complex **2** and are comparable to those in ionic $[Li(thf)_4][Y(NPh_2)_4]$ [2.244(2)–2.271(2) Å].[24] Short contacts between the yttrium atom and the carbon atoms in the *ipso* and *ortho* positions [Y(1)–C(39) 2.743(3), Y(1)–C(58) 2.746(3), Y(1)–C(26) 2.747(2), Y(1)–C(16) 2.849(3) Å] to the amido groups are also observed in complex **3**.

Crystals of **5** suitable for X-ray diffraction studies were obtained by slow condensation of hexane into concentrated thf solutions at room temperature. Complex **5** crystallizes as a thf solvate containing one molecule of thf per molecule

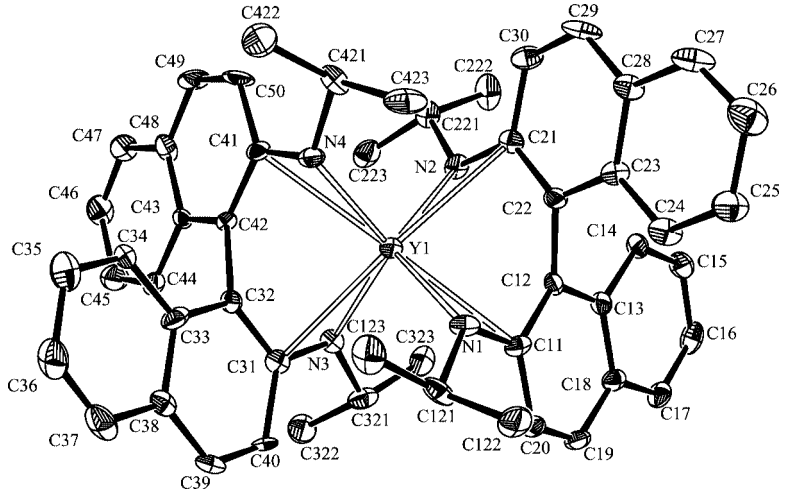

Figure 4. ORTEP drawing of complex **5** with the atom labeling scheme. Ellipsoids are drawn at the 30% probability level. The $Li(thf)_4^+$ cation and the hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and angles [°]: Y1–N1 2.297(5), Y1–N2 2.284(5), Y1–N3 2.290(5), Y1–N4 2.265(6), Y1–C11 2.712(6), Y1–C21 2.767(6), Y1–C31 2.733(7), Y1–C41 2.753(7); N1–Y1–N2 118.50(2), N1–Y1–N3 102.07(18), N2–Y1–N3 109.1(2), N1–Y1–N4 108.7(2), N2–Y1–N4 100.8(2), N3–Y1–N4 118.5(2).

of complex, i.e., $[Li(thf)_4][Y\{(R)\text{-}C_{20}H_{12}(NiPr)_2\}_2](C_4H_8O)$. The molecular structure of **5** is shown in Figure 4, and the structure refinement data are listed in the Experimental Section. Complex **5** crystallizes in the orthorhombic space group $P2_12_12_1$ with four molecules in the unit cell. The X-ray diffraction study shows that complex **5**, similarly to **3**, is an ionic complex consisting of a discrete $Li(thf)_4^+$ cation and a complex $\{Y[(R)\text{-}C_{20}H_{12}(NiPr)_2]_2\}^-$ anion. The yttrium is coordinated by the four nitrogen atoms of the two (*R*)-1,1′-binaphthyl-2,2′-diamido ligands. The Y–N bond lengths in **5** are 2.297(5), 2.284(5), 2.290(5), and 2.265(6) Å. The average value of the Y–N bond lengths in **5** [2.284(5) Å] is very similar to that found for complex **3** [2.275(2) Å].

## Catalytic Tests

We have previously reported the efficiency of an ytterbium ate complex $[Li(thf)_4][Yb\{(R)\text{-}C_{20}H_{12}(NiPr)_2\}_2]$ for the cyclization of various aminopentene derivatives to the corresponding pyrrolidines with high enantioselectivities (up to 70% *ee*).[15b] This complex requires several days of reaction at room temperature, however, to reach complete conversion. The new amidoyttrium complexes **3**, **4**, and **5** have been tested for their ability to perform enantioselective intramolecular hydroamination reactions. Complex **3** is not active for the cyclization of *C*-(1-allylcyclohexyl)methylamine (**6**), whereas **4** and **5** are efficient catalysts for several intramolecular hydroaminations (see Table 1).

The hydroamination/cyclization of **6** was initially investigated with both complexes at room temperature; the expected spiropyrrolidine (**7**) was obtained with a similar enantioselectivity (68% *ee*). It should be noted that catalyst **4** is much more active since it cyclized substrate **6** in 4 h, whereas a reaction time of 20 h was necessary for catalyst **5** to achieve the same transformation (Entries 1 and 2, Table 1). Similarly, in the cyclization of *C*-(1-allylcyclopentyl)methylamine (**8**) both catalysts afforded the spiropyrrolidine **9** with the same enantiomeric excess (Entries 3 and 4). With other substrates, however, the enantioselectivity depended on the catalyst employed. For the cyclization of 2,2-dimethylpent-4-enylamine (**10**) and 2,2-diphenylpent-4-enylamine (**12**), for example, complex **4** proved to be both more active and enantioselective than **5** – catalysts **4** and **5** afforded the pyrrolidine **11** with 68% *ee* and 40% *ee*, respectively (Entries 5 and 6), and the pyrrolidine **13** with 65% *ee* and 50% *ee* (Entries 7 and 8).

The cyclization of aminohexene derivatives into piperidines is a more difficult process, and substrate **14** could only be partially transformed into the corresponding spiropiperidine **15** within 12 d in the presence of catalyst **4** (Entry 9). This transformation was greatly accelerated at 60 °C, however, and the piperidine was obtained after only 8 h with 18% *ee* (Entry 10). Under the same reaction conditions, the aminohexene was cyclized in 17 h in the presence of complex **5**. Surprisingly, and only for this substrate, catalyst **5** gave a better enantioselectivity and product **15** was isolated with 29% *ee* (Entry 11).

The yttrium complex **4** is more stable than the ate lanthanide complexes that we prepared earlier as we performed catalytic hydroamination reactions with samples of **4** prepared two months previously with no loss of enantioselectivity. We thus investigated the possibility of reusing catalyst **4** in successive reactions. The results are given in Table 2.

Table 2. Reuse of catalyst **4** for the cyclization of aminopentene **6**.

| Reuse | Cat. ratio (mol-%) | *t* (h) | Conv. (%) | *ee* (%) |
|---|---|---|---|---|
| 0 | 8 | 4 | 100 | 69 |
| 1 | 4 | 17 | 100 | 67 |
| 2 | 3 | 14 | 100 | 65 |
| 3 | 2 | 14 | 79 | 65 |
| 4 | 1.5 | 23 | 59[a] | 62 |

[a] New substrate was added in the fourth reuse before complete consumption of the substrate in the preceding run.

The experiments were performed in an NMR tube. After the first reaction, an aliquot of the reaction mixture was separated to determine the enantiomeric excess and additional substrate in solution in $C_6D_6$ was added to the NMR tube. This procedure was repeated three times without loss of enantioselectivity. For the fourth reuse, a slight

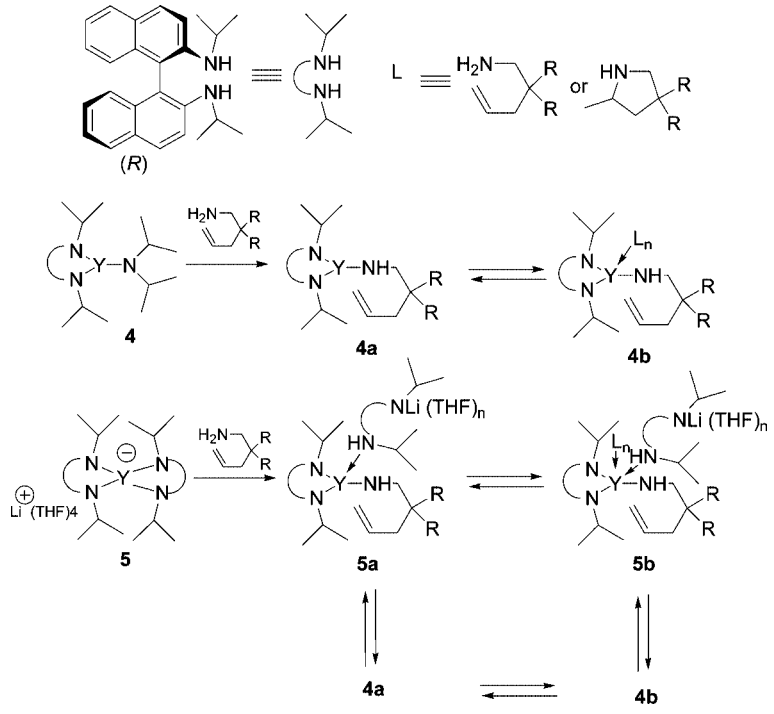
decrease of enantioselectivity was observed together with a lower rate of reaction due to the decrease in the catalytic ratio or inhibition by the reaction product.[10d,25] Nevertheless, these results indicate that this neutral, chiral yttrium complex is highly stable and active for performing enantioselective hydroamination reactions. While this work was going on, Marks et al. reported a new procedure for the reuse of nonchiral organolanthanide hydroamination catalysts.[26] Their homogeneous lanthanocene precatalyst was recycled three times in the presence of amino-derived polystyrene resins.

The reactions catalyzed by the neutral yttrium complex **4** and the yttrium ate complex **5** coordinated with the same binaphthylamine ligand do not afford the same rates and/or enantiomeric excesses for the various hydroamination reactions studied. Shibasaki has demonstrated that for enantioselective carbon–carbon bond formation promoted by heterodimetallic catalysts both lanthanide and alkali metals are involved in the reaction mechanism.[27] Hence, these results suggest that the catalytically active species are not the same in the reactions involving precatalysts **4** and **5**. A mechanism for hydroamination reactions catalyzed by lanthanocenes has been proposed by Marks.[2] In the first step, the lanthanide–carbon or lanthanide–nitrogen bond of the precatalyst is cleaved by the amino olefin to form an amidolanthanide intermediate. This proton transfer is then followed by the insertion of the double bond in the lanthanide–nitrogen bond, which is the rate-determining step. Release of the cyclized product is favored by reaction of another amino olefin. For hydroamination reactions catalyzed by *ansa*-lanthanocenes[2] or lanthanide binaphtholates,[10d] several species with different coordination numbers that are in equilibrium have been proposed to be formed after the reaction of the amino olefin with the precatalyst.

Reaction of neutral complex **4** with an amino olefin may indeed form the tris(amide) species **4a** with selective replacement of the diisopropylamido group by the unsaturated substrate as the amido ligand. One or two amino ligands arising from the substrate or the cyclized product may then coordinate to the lanthanide center to give species **4b**. As for the yttrium ate complex **5**, at least two different structures can be considered for the active species formed by reaction with the amino olefin: after the proton transfer, a binaphthylamine ligand is transformed into the corresponding monolithium salt, which can coordinate (**5a**), or not (**4a**), to the yttrium atom.[28] In the case of the complete decoordination of one binaphthlyamine ligand, the structures of the active species for the catalysis by neutral complex **4** or ate complex **5** should be identical (**4a** and **4b**, Scheme 6). Furthermore, additional amino ligands from the substrate or the product may coordinate to the yttrium atom to form species **5b**.

For reactions involving substrates **6** or **8** the same catalytic species could be involved during catalysis by complexes **4** or **5**. This is probably not the case for hydroamination reactions involving the other substrates, although further studies are required to gain insight into the mechanism of hydroamination catalyzed by lanthanide ate complexes for more precise explanations concerning the role of the second chiral ligand.



Scheme 6. Proposed structures for the intermediate catalytic species.

## Conclusion

We have prepared new asymmetric yttrium ate complexes and an asymmetric yttrium tris(amide) coordinated by *N*-substituted binaphthylamine ligands. An ate and a neutral complex coordinated with the same ligand are active catalysts for intramolecular hydroamination reactions. Comparison of the hydroamination reactions with different substrates catalyzed by both complexes has shown differences in activity and/or enantioselectivity, thus indicating that different active species are involved. Higher reaction rates and/or higher asymmetric inductions are generally observed for the formation of several pyrrolidines with the neutral yttrium tris(amide).

## Experimental Section

**General:** All procedures were performed under argon using standard Schlenk and glove-box techniques. Tetrahydrofuran (thf) was distilled from sodium benzophenone ketyl prior to use. Hexane and toluene were purified by distillation from sodium/triglyme benzophenone ketyl or $CaH_2$. Deuterated benzene was dried with sodium benzophenone ketyl and vacuum-transferred. Anhydrous $LnCl_3$ was purchased from Aldrich. The *N*,*N*′-diisopropylbinaphthyldiamine ligand and its lithium salt were prepared according to ref.[15b] The *N*,*N*′-diphenylbinaphthyldiamine ligand was prepared according to ref.[29] The substrates for the hydroamination/cyclization reactions were prepared as reported in ref.[15c] All other commercially available chemicals were used after the appropriate purification. Bruker AM 250, and Bruker DRX 400 NMR spectrometers (operating at 250 and 400 MHz, respectively) were used to record the NMR spectra. Chemical shifts for $^1H$ and $^{13}C$ NMR spectra were referenced internally with respect to the residual solvent resonances. IR spectra were recorded with a Perkin–Elmer FT-IR spectrometer as Nujol mulls. Elemental analyses were performed by the Microanalytical laboratory of the Institute of Organometallic Chemistry of RAS.

**Synthesis of [Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}Cl(thf)$_2$] (2):** $Li_2${(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$} (0.303 g, 0.799 mmol) was slowly added to a suspension of $YCl_3$ (0.156 g, 0.799 mmol) in thf (25 mL) at 20 °C with vigorous stirring. The reaction mixture was stirred for 3 h, then the thf was evaporated in vacuo and the resulting solid extracted with toluene (15 mL). The extracts were filtered, the toluene was evaporated off, and the solid residue was dissolved in thf (5 mL). Slow condensation of hexane into the thf solution at 20 °C resulted in yellow crystals of **1** (0.410 g, 81%). $C_{34}H_{42}ClN_2O_2Y$ (634.77): calcd. C 64.33, H 6.61, Y 14.00; found C 63.81, H 6.20, Y 14.11. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.07 (br. s, 8 H, β-$CH_2$, thf), 1.35 (d, $^3J_{H,H}$ = 5.8 Hz, 6 H, CHC$H_3$), 1.62 (d, $^3J_{H,H}$ = 5.8 Hz, 6 H, CHC$H_3$), 3.28, 3.40 (2 br. s, 8 H, α-$CH_2$, thf), 4.04 (br. m, 4 H, C*H*CH$_3$) 7.07–7.34 (m, 8 H, Ar), 7.64–7.74 (m, 4 H, Ar) ppm. $^{13}C$ NMR ($C_6D_6$): $\delta$ = 24.7 (β-$CH_2$, thf), 25.4, 25.2 (CH*C*H$_3$), 46.6 (*C*HCH$_3$), 70.7 (α-$CH_2$, thf), 112.7, 116.4, 121.2, 124.7, 126.7, 127.6, 128.1, 131.6, 136.4, 150.2 (Ar) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 3048 (w), 1610 (s), 1591 (s), 1541 (s), 1364 (s), 1301 (s), 1286 (s), 1249 (s), 1209 (s), 1146 (m), 1118 (w), 1036 (m), 1016 (m), 976 (w), 940 (w), 918 (m), 870 (m), 836 (w), 808 (w), 745 (s) cm$^{-1}$.

**Synthesis of [Li(thf)$_4$][Y{(*R*)-$C_{20}H_{12}$(NPh)$_2$}$_2$] (3):** $Li_2${(*R*)-$C_{20}H_{12}$(NPh)$_2$} (0.338 g, 0.756 mmol) was slowly added to a suspension of $YCl_3$ (0.147 g, 0.756 mmol) in thf (25 mL) at 20 °C with vigorous stirring. The reaction mixture was stirred for 5 h, then the thf was evaporated in vacuo and the resulting solid extracted with hot toluene (15 mL). Slow cooling of the toluene extract from 70 to 20 °C resulted in yellow crystals of **3** (0.480 g, 42%). $C_{101}H_{100}LiN_4O_4Y$ (1529.7): calcd. C 79.30, H 6.53, Y 5.81; found C 78.86, H 6.17, Y 6.00. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.08 (br. s, 16 H, β-$CH_2$, thf), 2.09 (s, 9 H, C$H_3C_6H_5$), 3.10 (br. s, 16 H, α-$CH_2$, thf), 6.58–7.99 (m, 59 H, Ar) ppm. $^{13}C$ NMR ($C_6D_6$): $\delta$ = 21.1 (C$H_3$), 24.8 (β-$CH_2$, thf), 67.9 (α-$CH_2$, thf), 117.0, 117.5, 118.3, 120.0, 122.1, 123.1, 123.7, 124.7, 125.2, 125.4, 125.6, 126.6, 127.6, 128.0, 129.0, 129.2, 129.5, 129.7, 129.9, 130.2, 130.5, 134.4, 136.1, 137.6, 140.8, 142.7, 154.7 (Ar) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 3050 (w), 1587 (m), 1348 (s), 1297 (s), 1173 (m), 1148 (m), 1079 (m), 1015 (m), 965 (m), 859 (m), 726 (s), 696 (s) cm$^{-1}$.

**Synthesis of [Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}{N*i*Pr$_2$}{LiCl(thf)$_2$}] (4):** [Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}Cl(thf)$_2$] (0.039 g, 0.061 mmol) was slowly added to a solution of LiN*i*Pr$_2$ (0.007 g, 0.061 mmol) in thf (1.5 mL) at 20 °C with vigorous stirring. The reaction mixture was then stirred for 20 h and the thf evaporated in vacuo. The complex was used without further purification as a crude yellow powder. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.06–1.14 (m, 12 H, CHC$H_3$), 1.20–1.27 (m, 6 H, CHC$H_3$), 1.28 (br. s, 8 H, β-$CH_2$, thf), 1.48–1.62 (m, 6 H, CHC$H_3$), 3.02–3.15 (m, 2 H, C*H*CH$_3$), 3.35 (br. s, 8 H, α-$CH_2$, thf), 3.88–4.13 (m, 2 H, C*H*CH$_3$), 6.62–7.84 (m, 12 H, Ar) ppm. $^{13}C$ NMR ($C_6D_6$): $\delta$ = 25.1, 25.3, 25.4, 25.52, 25.60, 25.64, 25.7, 26.0 (C$H_3$), 25.2 (β-$CH_2$, thf), 47.1, 48.3, 48.5, 67.9 (α-$CH_2$, thf), 116.0, 116.4, 117.2, 118.0, 118.8, 120.8, 121.0, 121.1, 122.7, 124.7, 126.6, 126.7, 128.9, 131.5, 131.9, 132.5, 133.2, 135.4, 150.5, 154.9 (Ar) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 3047 (m), 1610 (s), 1593 (s), 1540 (m), 1496 (s), 1421 (s), 1377 (s), 1310 (s), 1246 (s), 1171 (s), 1038 (s), 916 (m), 810 (s), 746 (s) cm$^{-1}$.

**Synthesis of [Li(thf)$_4$][Y{(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$}$_2$] (5):** $YCl_3$ (0.061 g, 0.313 mmol) was slowly added to a solution of $Li_2${(*R*)-$C_{20}H_{12}$(N*i*Pr)$_2$} (0.238 g, 0.626 mmol) in thf (15 mL) at 20 °C with vigorous stirring. The reaction mixture was stirred for 3 h, then the thf was evaporated in vacuo and the resulting solid extracted with toluene (20 mL). The extracts were filtered, the toluene was evaporated off, and the solid residue was dissolved in thf (2 mL). Slow condensation of hexane into the thf solution at 20 °C resulted in yellow crystals of **5** (0.276 g, 71%). $C_{72}H_{92}LiN_4O_5Y$ (1189.35): calcd. C 72.75, H 7.73, Y 7.47; found C 72.28, H 7.30, Y 7.81. $^1H$ NMR ($C_6D_6$): $\delta$ = 1.29–1.35 (m, 20 H, β-$CH_2$, thf), 1.37 (d, $^3J_{H,H}$ = 6.1 Hz, 12 H, CHC$H_3$), 1.41 (d, $^3J_{H,H}$ = 6.1 Hz, 12 H, CHC$H_3$), 3.30–3.50 (m, 20 H, α-$CH_2$, thf), 3.90–4.10 (m, 4 H, C*H*CH$_3$), 6.90–7.85 (m, 24 H, Ar) ppm. $^{13}C$ NMR ($C_6D_6$): $\delta$ = 24.7 (C$H_3$), 25.1 (β-$CH_2$, thf), 26.9 (C$H_3$), 45.9, 67.7 (α-$CH_2$, thf), 113.5, 115.3, 117.9, 124.9, 125.2, 125.8, 127.1, 129.1, 138.5, 155.0 (Ar) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 3036 (w), 2802 (w), 2578 (w), 1609 (s), 1590 (s), 1540 (m), 1496 (m), 1420 (s), 1364 (s), 1304 (m), 1286 (s), 1247 (m), 1208 (w), 1168 (m), 1145 (m), 1115 (w), 1043 (s), 1015 (w), 916 (m), 886 (m), 851 (w), 835 (w), 808 (s), 745 (s) cm$^{-1}$.

**General Procedure for NMR-Scale Hydroamination/Cyclization of Aminoalkenes:** In an argon-filled glove box, the appropriate aminoalkene (0.176 mmol) was dissolved in $C_6D_6$ (0.1 mL) and dried with molecular sieves (4 Å) for 2 h. Complex **4** or **5** (see Tables 1 and 2 for the corresponding catalytic ratio) was introduced into an NMR tube equipped with a Teflon screw cap, dissolved in $C_6D_6$ (0.5 mL), and the aminoalkene solution was then introduced. The hydroamination reaction was monitored by $^1H$ NMR spectroscopy by observing the decrease of the signals of the olefinic protons. After the reaction time mentioned in the tables, the reaction was quenched with $CH_2Cl_2$. Determination of the enantiomeric excesses of the products was performed as described in ref.[15c]

**X-ray Structure Determination:** A single crystal of each compound was mounted under inert perfluoropolyether at the tip of a glass fiber and cooled in the cryostream of an Oxford Diffraction XCALIBUR CCD diffractometer for **2**, **3**, and **5**. Data were collected using monochromatic Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073). Further details are provided in Table 3. The structures were solved by direct methods (SIR97)[30] and refined by least-squares procedures on $F^2$ using SHELXL-97.[31] All hydrogen atoms attached to carbon atoms were introduced in the calculation in idealized positions and treated as riding models. In compound **5**, there is one thf solvate molecule disordered over two positions. The disordered moieties were refined applying the restraints available within SHELXL-97.[32] The absolute configuration was determined by refining the Flack parameter[32] using a large number of Friedel pairs. The drawings of the molecules were produced with ORTEP32.[33] CCDC-615714, -615715 and -625520 (**2**, **3**, and **5**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## COVER PICTURE

**The cover picture shows** the disruption of amido- and alkoxo-to-metal π-donation because of a filled dπ manifold, which occurs for metal centers in low oxidation states and which renders the anionic amido, alkoxo and related ligands highly reactive. The low oxidation states decrease the predilection toward metal-center reduction and, as a result, tend to promote "even-electron" chemistry over odd-electron radical chemistry that is based on net single-electron reduction of the metal. For $Ru^{II}$ and $Cu^{I}$ complexes, evidence for the enhanced reactivity of the heteroatomic ligands is derived from acid/base reactions as well as from nucleophilic additions. The combination of a Lewis acid metal center and a basic/nucleophilic heteroatomic ligand (amido, hydroxo, alkoxo, etc.) can be exploited for the activation of substrates that possess polar and nonpolar bonds, for example for metal-mediated C−H activation and for catalytic hydroamination and hydroalkoxylation of activated olefins. Details are presented in the Microreview by T. B. Gunnoe on p. 1185 ff.

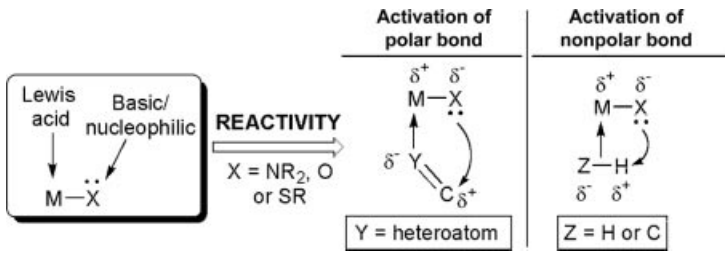
## MICROREVIEW

### Organometallic Chemistry

**T. B. Gunnoe* ..... 1185–1203**

Reactivity of Ruthenium(II) and Copper(I) Complexes that Possess Anionic Heteroatomic Ligands: Synthetic Exploitation of Nucleophilicity and Basicity of Amido, Hydroxo, Alkoxo, and Aryloxo Ligands for the Activation of Substrates that Possess Polar Bonds as well as Nonpolar C–H and H–H Bonds

**Keywords:** Nondative heteroatomic ligands / Ruthenium / Copper / C–H Activation



The coordination of amido, sulfido alkoxo, aryloxo, and hydroxo ligands to late transition-metal complexes in low oxidation states can disrupt ligand-to-metal π bonding. As a result, anionic and heteroatomic ligands coordinated to metals with high d-electron counts often exhibit highly basic and nucleophilic reactivity. The microreview summarizes the preparation, characterization, and reactivity of a series of Ru and Cu complexes with these and related ligands.

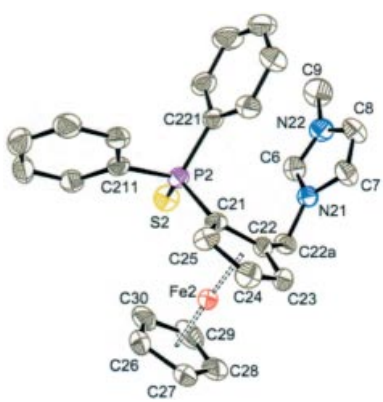
## SHORT COMMUNICATIONS

### Diaminocarbene Ligands

**A. Labande,* J.-C. Daran, E. Manoury, R. Poli* ..... 1205–1209**

New (1-Phosphanylferrocen-1′- and -2-yl)-methyl-Linked Diaminocarbene Ligands: Synthesis and Rhodium(I) Complexes

**Keywords:** Carbene ligands / Phosphane ligands / Ferrocenes / Rhodium



New, bifunctional (1-phosphanylferrocen-1′- and -2-yl)methyl-linked NHC ligands have been accessed by a general and simple method from the corresponding [1-(thiophosphanyl)ferrocen-1′- and -2-yl]methanols and used to prepare rhodium(I) complexes.

### NH,NR-Stabilized NHC Ligands

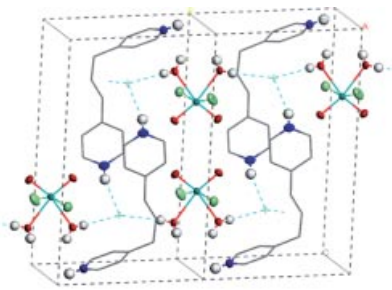
## Hydrogen-Bond Network

A new hybrid inorganic–organic $Mo^{VI}$ polymer with a two-dimensional layer structure has been synthesized and crystallographically characterized. This complex is an efficient catalyst, with $H_2O_2$ as the oxygen-source oxidant and $NaHCO_3$ as the cocatalyst, in the epoxidation of olefinic compounds under ambient conditions.



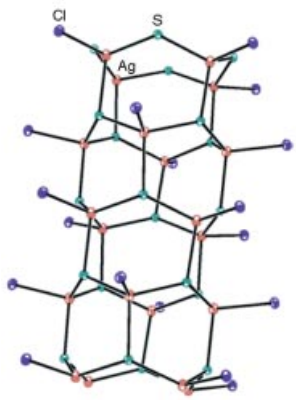
**Y. Luan, G. Wang,* R. L. Luck, M. Yang ..... 1215–1218**

A Two-Dimensional, Hydrogen-Bond-Cross-Linked Molybdenum(VI) Network Polymer with Catalytic Activity

**Keywords:** Hydrogen bonds / Crystal engineering / Hydrogen peroxide / Epoxidation / Molybdenum

## Nanotubes

Silver(I) chloride reacts with 2-mercapto-3,4,5,6-tetrahydropyrimidine ($StpmH_2$, $C_4H_8N_2S$) in DMSO with excess triethylamine to give a complex of formula $\{[Ag_4Cl_4(\mu_3\text{-}StpmH_2)_4]_n\}$ (**1**). The structure consists of octagonal $Ag_4S_4$ cores where $\mu_3$-S bonding interactions lead to an infinite nanotube assembly which exhibits quasi-aromaticity.

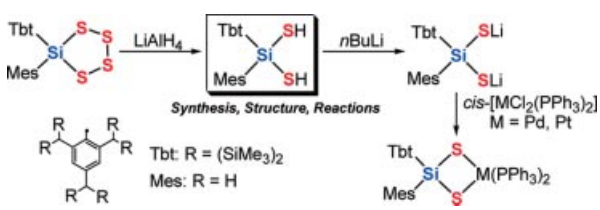


**S. Zartilas, N. Kourkoumelis, S. K. Hadjikakou,* N. Hadjiliadis,* P. Zachariadis, M. Kubicki, A. Yu. Denisov, I. S. Butler ..... 1219–1224**

A New Silver(I) Aggregate Having an Octagonal $Ag_4S_4$ Core Where $\mu_3$-S Bonding Interactions Lead to a Nanotube Assembly that Exhibits Quasiaromaticity

**Keywords:** Bioinorganic chemistry / Silver / Aromaticity / Nanotubes

## Silanedithiol



An overcrowded silanedithiol was synthesized as an air- and moisture-stable crystalline compound by the reaction of the corresponding tetrathiasilolane with $LiAlH_4$. The reaction of dilithium silanedithiolate, which was generated by the reaction of silanedithiol with *n*-butyllithium, with *cis*-$[MCl_2(PPh_3)_2]$ (M = Pd, Pt) afforded the corresponding silanedithiolato complexes quantitatively.

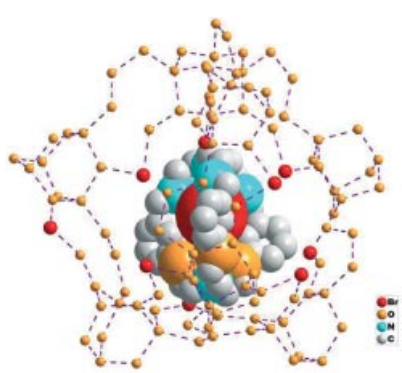
**T. Tanabe, N. Takeda, N. Tokitoh* ..... 1225–1228**

First Structural Characterization of Silanedithiol and Its Application toward the Synthesis of Silanedithiolato Complexes

**Keywords:** Silanedithiol / Silanedithiolato complexes / Silaneselenol / Group 10 transition metal complexes / X-ray crystallography

## Water Clusters

Adamantanoid water clusters H-bonded to bromide ions and other water molecules form a cage-like structure. Bromide-encapsulated aza cryptands reside within this cage to form a host-within-a-host-like structure. This adamantanoid water decamer is remarkably similar to that of cubic ice ($I_c$).



**M. C. Das, P. K. Bharadwaj* ..... 1229–1232**

Molecular Ice with Hybrid Water–Bromide Network around a Cryptand with a Bromide Ion Included in the Cavity to Form a Host-within-a-Host-Like Structure

## FULL PAPERS

### Hydrogen Bonding

**F.-M. Nie, G. Leibeling, S. Demeshko, S. Dechert, F. Meyer* ..... 1233–1239**

Intra- and Intermolecular H···Cl–Ni Bonding Patterns in a Series of Highly Pre-organized Dinuclear Nickel(II) Complexes

**Keywords:** Nickel / Dimetallic complexes / Hydrogen bonds / Pyrazolate ligands / Magnetic properties

Various Cl···H–O hydrogen-bonding motifs are identified in a series of pyrazolato-based dinickel complexes, where either the H-donor (MeOH or $H_2O$) or the H-acceptor (chlorido) or both are bound to a nickel ion.

### Heterodimetallic Complexes

**Z.-H. Ni, L. Zheng, L.-F. Zhang, A.-L. Cui, W.-W. Ni, C.-C. Zhao, H.-Z. Kou* ..... 1240–1250**

Cyanido-Bridged Dimetallic Complexes Derived from Manganese(III) Schiff Bases and Pentacyanidonitrosylchromate(I): Synthesis, Crystal Structure and Magnetic Properties

**Keywords:** Cyanide ligands / Bridging ligands / Magnetic properties / Manganese / Schiff-base ligands

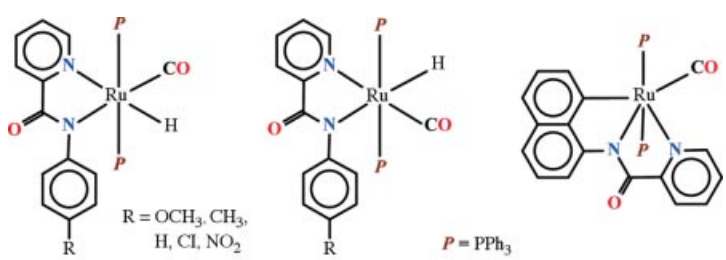
Four types of cyanido-bridged complexes derived from the $[Cr(CN)_5(NO)]^{3-}$ anion and $Mn^{III}$ Schiff-base cations have been synthesized with trinuclear, 1D chain or 2D layered molecular structures. Antiferromagnetic $Mn^{III}$–$Cr^{I}$ coupling has been exclusively observed in these complexes.

### Ruthenium Complexes

**S. Nag, R. J. Butcher, S. Bhattacharya* ..... 1251–1260**

*N*-(Aryl)picolinamide Complexes of Ruthenium: Usual Coordination and Strategic Cyclometalation

**Keywords:** Picolinamide ligands / Ruthenium complexes / Cyclometalation



**1-R** **2-R** **3**

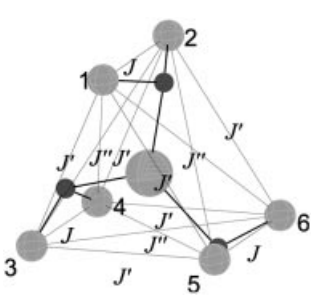
Reaction of $[Ru(PPh_3)_2(CO)_2Cl_2]$ with five *N*-(4-*R*-phenyl)picolinamides in the presence of a base affords two geometrical isomers (**1-R** and **2-R**) on N–H activation. A similar reaction with *N*-(naphthyl)-picolinamide affords complex **3** on additional C–H activation.

### Single-Molecule Studies

**Y.-Q. Zhang,* C.-L. Luo ..... 1261–1267**

A Theoretical Study of the Nearest Cu···Cu Antiferromagnetic Exchange Coupling Interactions in $[LaCu_6]$ and $[YCu_6]$

**Keywords:** Magnetic properties / Density functional calculations / Broken symmetry / Single-molecule studies



Calculation of the exchange coupling interactions between the nearest $Cu^{II}$ centers in complexes $[LaCu_6]$ and $[YCu_6]$ show that the Cu···Cu antiferromagnetic interactions increase with a decrease of the ionic radius of the central $La^{III}$ and $Y^{III}$ and the stronger antiferromagnetic interactions between the nearest $Cu^{II}$ centers in $[LaCu_6]$ than in $[YCu_6]$ are not due to the central $La^{III}$ but the structure.

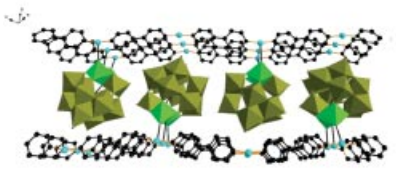
## Modified Keggin Polyoxometalates

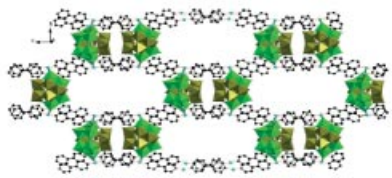
**J. Sha, J. Peng,* H. Liu, J. Chen, B. Dong, A. Tian, Z. Su ..... 1268–1274**

Keggin POMs Modified by Bonding to Multitrack Cu(bipy) Chains through Linearly Arrayed Terminal and Bridging Oxygen Atoms of the $M_3O_{13}$ Triad

**Keywords:** Polyoxometalates / N ligands / Copper / Organic–inorganic hybrids



**1**



**2**

Fully oxidized Keggin $SiMo_{12}$ and $SiW_{12}$ anions as polydentate pendant ligands covalently bonded to a multitrack Cu(bipy) chain(s) through linearly arrayed terminal and bridging oxygen atoms of the $M_3O_{13}$ triad(s) are reported for the first time. Compound **1** has a tri-chain 1D "zipper" structure, and **2** a di-chain 2D net-texture structure.

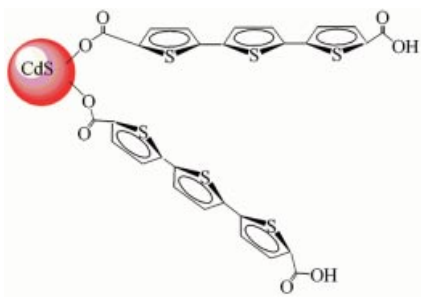
## Organic–Inorganic Nanoparticles

**T. Antoun, R. Brayner, S. Al terary, F. Fiévet, M. Chehimi, A. Yassar* ..... 1275–1284**

Facile Synthesis of Oligothiophene-Capped CdS Nanoparticles

**Keywords:** Nanoparticle synthesis / Oligothiophenes / Photovoltaics / Conjugated polymers / Nanostructures

To improve the electronic communication between nanocrystal semiconductors and conjugated molecules, we have prepared CdS-bound oligothiophenes. In such a design, the two components are in intimate contact and electron transfer is not altered by the presence of insulating surfactants.



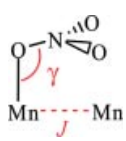
## Magneto-Structural Correlations

**G. Fernández, M. Corbella*, G. Aullón, M. A. Maestro, J. Mahía ..... 1285–1296**

New Dinuclear $Mn^{III}$ Compounds with 2-$MeC_6H_4COO$ and 2-$FC_6H_4COO$ Bridges – Effect of Terminal Monodentate Ligands ($H_2O$, $ClO_4^-$ and $NO_3^-$) on the Magnetic Properties

**Keywords:** Manganese / Magnetic properties / Ligand effects

The magnetic properties of dinuclear $Mn^{III}$ complexes with a $[Mn_2O(RCOO)_2]^{2+}$ core could be sensitive to the type and orientation of the monodentate ligand coordinated to the manganese ions.



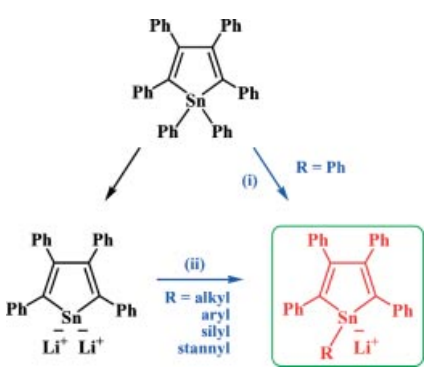
## Stannole Anions

**R. Haga, M. Saito,* M. Yoshioka ..... 1297–1306**

Synthesis and Reactions of Stannole Anions

**Keywords:** Anions / Aromaticity / Lithium / Metallacycles / Tin

Methods for the preparation of stannole anions are described: (i) the reduction of hexaphenylstannole with the proper amount of lithium, and (ii) the reaction of the stannole dianion with various halogen reagents. NMR studies on the stannole anions and their reactions are also reported.



**If not otherwise indicated in the article, papers in issue 8 were published online on March 2, 2007**

## COVER PICTURE

**The cover picture shows** the disruption of amido- and alkoxo-to-metal π-donation because of a filled dπ manifold, which occurs for metal centers in low oxidation states and which renders the anionic amido, alkoxo and related ligands highly reactive. The low oxidation states decrease the predilection toward metal-center reduction and, as a result, tend to promote "even-electron" chemistry over odd-electron radical chemistry that is based on net single-electron reduction of the metal. For $Ru^{II}$ and $Cu^{I}$ complexes, evidence for the enhanced reactivity of the heteroatomic ligands is derived from acid/base reactions as well as from nucleophilic additions. The combination of a Lewis acid metal center and a basic/nucleophilic heteroatomic ligand (amido, hydroxo, alkoxo, etc.) can be exploited for the activation of substrates that possess polar and nonpolar bonds, for example for metal-mediated C−H activation and for catalytic hydroamination and hydroalkoxylation of activated olefins. Details are presented in the Microreview by T. B. Gunnoe on p. 1185 ff.

# Reactivity of Ruthenium(II) and Copper(I) Complexes that Possess Anionic Heteroatomic Ligands: Synthetic Exploitation of Nucleophilicity and Basicity of Amido, Hydroxo, Alkoxo, and Aryloxo Ligands for the Activation of Substrates that Possess Polar Bonds as well as Nonpolar C–H and H–H Bonds

**T. Brent Gunnoe*[a]**

**Keywords:** Nondative heteroatomic ligands / Ruthenium / Copper / C–H Activation

The preparation and reactivity of late transition-metal complexes in low oxidation states with nondative-heteroatomic ligands (e.g., amido, hydroxo, alkoxo, and aryloxo ligands) are described. For such complexes the disruption of ligand-to-metal π-donation because of a filled dπ manifold can enhance the nucleophilic and/or basic reactivity at the nondative-heteroatomic ligand relative to transition-metal complexes in high oxidation states. The chemistry of five- and six-coordinate Ru complexes with amido, hydroxo, methoxo, and aryloxo ligands is described including Brønsted acid/base reactions, coordination, and activation of polar substrates toward N–C bond forming reactions and metal-mediated activation of dihydrogen and C–H bonds. The impact of ancillary ligands and Ru oxidation states ($Ru^{II}$ versus $Ru^{III}$) are discussed. In addition, the preparation and reactivity of well-defined monomeric two- and three-coordinate Cu complexes with amido, alkoxo, hydroxo, and aryloxo ligands are presented including examples of reactions to probe fundamental reactivity patterns as well as catalytic addition of N–H and O–H bonds across C=C bonds of olefins.

## Introduction

Nondative-heteroatomic fragments are a common class of ligand that formally bear anionic, dianionic, or trianionic charge. Such ligands based on nitrogen, oxygen, or sulfur, including amido, alk-/aryl-/hydr-oxo, alkyl-/aryl-/hydro-sulfido, oxide, sulfide, imido, and nitrido, have been utilized as nonreactive ancillary supports for reactive transition-metal systems as well as for *active participation* in "group transfer" and other catalytic processes. Prominent examples of the latter include olefin epoxidation and aziridination, olefin dihydroxylation, and polymerization sequences.[1–9] As part of our efforts to understand and develop the reactivity of late transition-metal complexes in low oxidation states with formally anionic heteroatomic ligands, our group has been studying the synthesis and reactivity of $Ru^{II}$ and $Cu^{I}$ systems. Herein, the scope of complexes accessed and their reactivity are reviewed with a focus on the development of new stoichiometric and catalytic reactions that are based on the nucleophilic/basic character of the nondative ligands.

Bonding between a transition metal and an anionic heteroatomic ligand results from a metal–ligand σ bond and one ligand–metal π-interaction. Thus, when the metal center possesses one or more empty orbitals of π-symmetry metal–ligand multiple bonds result.[10] On the basis of metal–X (X = OR, $NR_2$ or SR ligand) bond polarity it is anticipated that nondative-heteroatomic ligands should exhibit inherent nucleophilicity and basicity; however, ligand-to-metal π-donation can serve to delocalize electron density from the heteroatomic ligand to the metal center. As a result, the electron density centered on the heteroat-

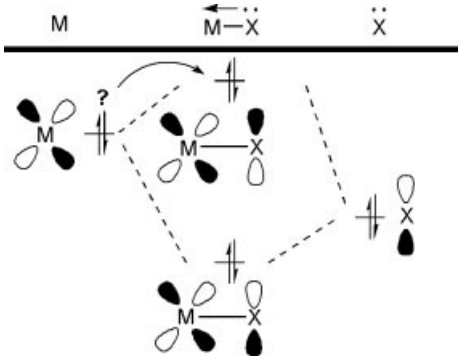
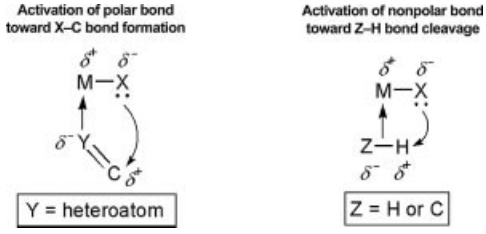
omic ligand can be attenuated and, in some cases, the heteroatomic ligand is rendered relatively inert. Schrock-type carbene complexes supported by alkoxo and imido ligands represent classic examples of unreactive anionic heteroatomic ligands. For these complexes, the formally anionic and dianionic heteroatomic ligands are reaction inert relative to the carbene moiety.[11] High oxidation states for metal centers tend to facilitate the ligand-to-metal π-bonding and, hence, serve to decrease the impact of M–X bond polarity and ligand-centered electron density and, consequently, to decrease nucleophilic and/or basic reactivity at the heteroatomic ligand. The lack of reaction of $TpOs^{IV}(Cl)_2NHPh$ with HCl (a thermodynamic effect) serves as a striking example that potentially illustrates the effect on reactivity of reduced charge density at the anionic heteroatomic ligand (due to increased ligand-to-metal π-donation).[12]

The majority of anionic heteroatomic ligands of early or middle transition elements are coordinated to relatively high oxidation state systems. In contrast, late(r) transition metals, which are more predisposed toward low oxidation states, often have high d-electron counts that disrupt ligand-to-metal π-bonding (Scheme 1). Until relatively recently, examples of anionic heteroatomic ligands coordinated to late transition-metal systems in low oxidation states were scant compared with high oxidation state complexes of the early and middle transition elements.[13–15] Recent efforts have substantially increased the number of late transition-metal complexes and revealed a wealth of interesting reactivity.[15–22] Careful studies of thermodynamic trends and reactivity indicate that the bond dissociation energies (BDEs) between heteroatom-based ligands and late transition-metal centers can be substantial, and recent bonding models suggest that these M–L bonds are relatively strong; however, the disruption of metal-to-ligand π-bonding can afford enhanced reactivity by decreasing electron delocalization from the ligand to the metal.[17]



Scheme 1. M–X (M = transition metal, X = $NR_2$, OR, SR, etc.) multiple bonding occurs if dπ orbital(s) is vacant. Filled dπ manifold results in no net π-bond.

Our group has been interested in understanding and exploiting the reactivity of late transition-metal systems with highly nucleophilic/basic heteroatom-based ligands including amido and alk-/aryl-/hydroxo ligands coordinated to $Ru^{II}$ and $Cu^{I}$.[23–38] From the perspective of catalyst development, the positioning of a nucleophilic/basic heteroatomic ligand adjacent to a Lewis acidic metal center provides opportunities for the coordination and activation of external organic substrates toward controlled bond-breaking and bond-forming reactions (Scheme 2). From a fundamental perspective, we have been studying the impact of metal identity, ancillary ligand identity, and the heteroatomic ligand identity and substituents on reactivity. Herein, we summarize results over the past five years and comment on future prospects.

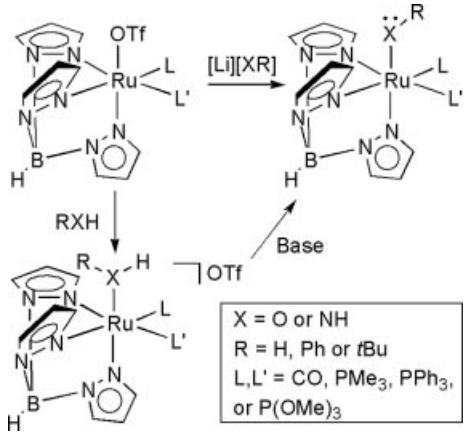


Scheme 2. Potential use of Lewis acidic metal centers with the basic anionic ligand "X" (X = $NR_2$, OR, SR, etc.) to activate substrates with polar and nonpolar bonds.

## Octahedral $TpRu^{II}$ Systems

### Preparation and Characterization

We have used the monoanionic hydridotris(pyrazolyl)borate (Tp) ligand[39] as a foundation to build octahedral Ru complexes with anionic heteroatom-based ligands.[24,26,31–36] Our strategy has been to utilize the template $[TpRu(L)(L')X]^{n+}$ (L, L′ = neutral, two-electron donor ligands, X = anionic heteroatomic ligand; $n$ = 0 or 1) to access systems with variable ancillary ligands (L/L′), heteroatomic ligands (X), and oxidation states. Two strategies have been used for syntheses: (1) coordination of amine or alcohols followed by deprotonation and (2) metathesis of the anionic heteroatomic moiety with Ru–halide or Ru–triflate linkages (Scheme 3).



Scheme 3. Two general routes used for the preparation of TpRu(L)(L′)NHR and TpRu(L)(L′)OR systems.

For the $Ru^{II}$ oxidation state, the hydroxo and parent amido complexes exhibit upfield chemical shifts between –1 and –4 ppm for the N–H/O–H resonances ($^1$H NMR spec-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

troscopy), which is indicative of electron-rich nondative-heteroatomic ligands (a hallmark of the disruption of ligand-to-metal π-donation for amido and hydroxo ligands). Upfield chemical shifts have been observed for related $Ru^{II}$ systems.[26,31,34] For the anilido complexes [TpRu(L)(L′)-NHPh], variable-temperature $^1H$ NMR spectroscopy provides a convenient means to determine the Gibbs free energy of activation for rotation around the Ru–$N_{amido}$ and the $C_{ipso}$–$N_{amido}$ bonds (Scheme 4).[33] Although the data set is limited there is an inverse correlation between the magnitudes of these two rotational barriers, a result that is consistent with anticipated Ru–N multiple-bond character in response to metal-electron density. That is, the presence of strongly electron-donating and poorly π-acidic ancillary L/L′ reduces anilido-to-Ru multiple bonding (via three-center, four-electron interactions), which most likely increases the extent of anilido-to-phenyl π* back-bonding and hence increases the $N_{amido}$–$C_{ipso}$ multiple-bond character. Using this rationale, an inverse correlation between Ru–$N_{amido}$ and $C_{ipso}$–$N_{amido}$ bond lengths is anticipated. In fact, comparing structural data for the series of octahedral $Ru^{II}$–anilido complexes [TpRu(CO)($PPh_3$)NHPh],[35] [TpRu{P-$(OMe)_3$}$_2$NHPh],[33] [($\eta^6$-$C_6Me_6$)Ru(Ph)($PMe_3$)NHPh],[40] and [$(PMe_3)_4$Ru(H)NHPh][41] reveals such a trend (Figure 1). In addition, the equilibrium constants for a series of reactions of [TpRu($PMe_3$)$_2$NHPh] with *p*-substituted anilines ($NH_2Ar$) to form [TpRu($PMe_3$)$_2$(NHAr)] (Ar = *p*-substituted phenyl) and aniline afforded a Hammett plot (using $\sigma_p^-$) with $\rho = 4.1$, which is consistent with the delocalization

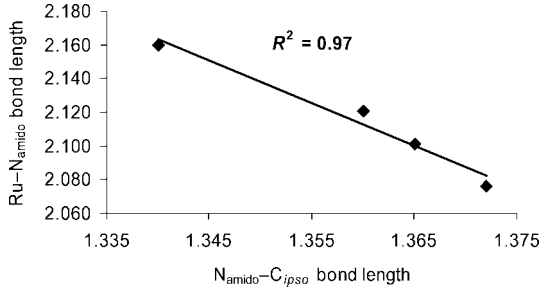


Figure 1. Plot of Ru–$N_{amido}$ and $N_{amido}$–$C_{ipso}$ bond lengths (Å), which illustrates an inverse relationship for the series of Ru–anilido complexes [TpRu(CO)($PPh_3$)NHPh],[35] [TpRu{P($OMe)_3$}$_2$-NHPh],[33] [($\eta^6$-$C_6Me_6$)Ru(Ph)($PMe_3$)NHPh],[40] and [$(PMe_3)_4$Ru-(H)NHPh].[41]

of electron density from the amido ligand to the aryl substituent.[31] This $\rho$ value is similar to the value of 3.4 obtained for Cp*Ni($PEt_3$)(NHPh)/$NH_2Ar$ reactions.[42] In contrast, a study of equilibria for four-coordinate $Re^{III}$–aryloxo complexes revealed a correlation with Hammett $\sigma$ parameters with a much smaller $\rho$ value of 0.7.[43]

## Acid–Base Reactions

The coordination of anionic heteroatomic ligands to late transition-metal complexes in low oxidation states can impart substantial basicity/nucleophilicity to the ligand, a feature that has been attributed to polar metal–ligand bonds and the disruption of ligand-to-metal π-donation. For example, Bergman et al. have demonstrated that *trans*-[$(DMPE)_2$Ru(H)$NH_2$] {DMPE = 1,2-bis(dimethylphosphanyl)ethane} forms an acid–base equilibrium upon reaction with triphenylmethane (p$K_a \approx 31.5$ in THF) to form *trans*-[$(DMPE)_2$Ru(H)$NH_3$][$Ph_3C$],[44] and related octahedral $Ru^{II}$ and $Fe^{II}$ parent amido complexes exhibit analogous reactivity.[45,46] Similarly, [TpRu(L)(L′)NHR] (R = Ph, H or *t*Bu) complexes react with weakly acidic C–H bonds. For example, the anilido complexes [TpRu(L)(L′)NHPh] form acid–base equilibria with malononitrile (p$K_a \approx 24$ in THF),[47] which is the least acidic substrate that we have found to react at room temperature with the anilido complexes (Scheme 5).[33] For [TpRu(L)(L′)NHR] (R = H or *t*Bu), the combination with phenylacetylene (p$K_a \approx 28.7$ in DMSO)[48] results in the formation of ion pairs [TpRu(L)(L′)$NH_2$R][$PhC_2$] at room temperature (Scheme 5).[31] Thus, the formal substitution of H or *t*Bu for phenyl as the amido substituent likely increases basicity by several orders of magnitude. For [TpRu($PMe_3$)$_2$-($NH_2t$Bu)][$PhC_2$], heating to 80 °C cleanly forms free $t$BuNH$_2$ and [TpRu($PMe_3$)$_2$(C≡CPh)].

Although no reaction is observed at room temperature, heating solutions of [TpRu(L)(L′)NHPh] and phenylacetylene to 80 °C forms free aniline and [TpRu(L)(L′)(C≡CPh)]; however, detailed mechanistic studies have revealed that these transformations do not likely proceed through the formation of ion pairs [TpRu(L)(L′)($NH_2$Ph)][$PhC_2$] (as do the parent amido and *t*Bu-amido systems, see above).[31] Rather, small and undetectable quantities of [TpRu(L)(L′)-

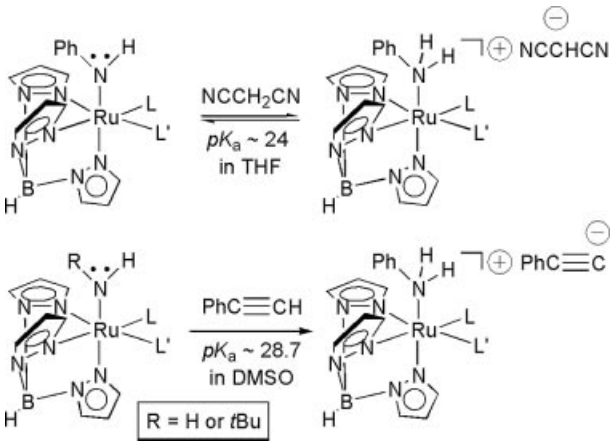
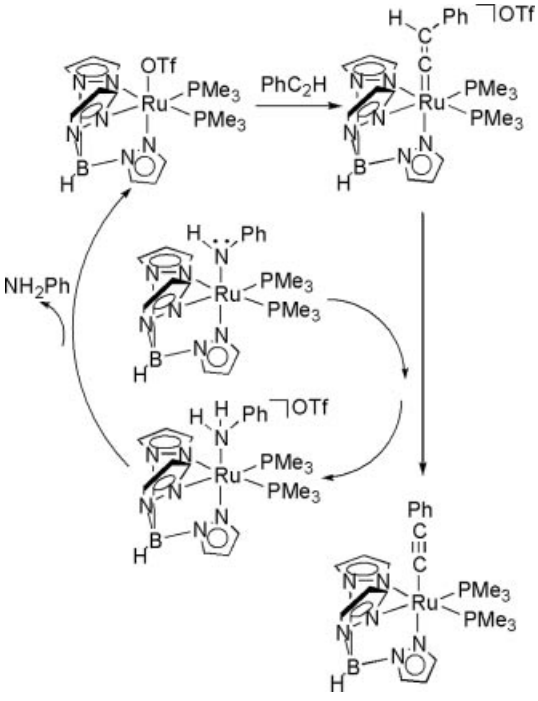


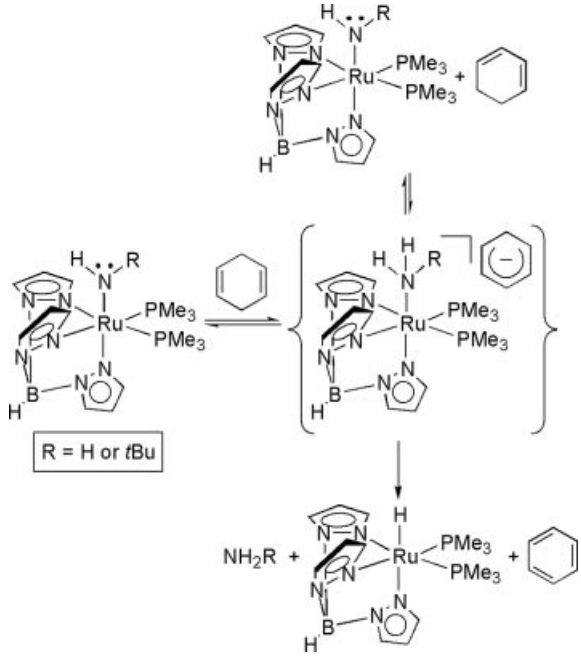
Scheme 5. Acid/base equilibria observed for [TpRu(L)(L′)NHR] (R = H, *t*Bu or Ph) systems upon treatment with malononitrile or phenylacetylene.

OTf] likely catalyze the reaction as shown in Scheme 6. For the $PMe_3$ system, late in the reaction the putative vinylidene intermediate is trapped by free aniline to form the Fischer carbene complex [$Tp(PMe_3)_2Ru{=}C(CH_2Ph)(NHPh)$], a reaction that is confirmed by independent conversion of [$Tp(PMe_3)_2Ru{=}C{=}C(H)Ph$] and aniline to [$Tp(PMe_3)_2Ru{=}C(CH_2Ph)(NHPh)$].



Scheme 6. Proposed pathway for the conversion of [$TpRu(PMe_3)_2$-NHPh] and phenylacetylene to [$TpRu(PMe_3)_2C{\equiv}CPh$], which is catalyzed by [$TpRu(PMe_3)_2OTf$].

At 80 °C, [$TpRu(PMe_3)_2NHR$] (R = H or *t*Bu) complexes react with 1,4-cyclohexadiene to ultimately form benzene, free amine, and [$TpRu(PMe_3)_2H$] with a 1:1 molar ratio of benzene and Ru–hydride.[31] Preceding the formation of benzene and Ru–hydride, the isomerization of 1,4-cyclohexadiene to 1,3-hexadiene is observed ($k_{obs}$ = $2.0 \times 10^{-5}$ $s^{-1}$ at 80 °C). The addition of free $PMe_3$ does not influence the rate of isomerization of the 1,4-cyclohexadiene. We have proposed that these reactions occur by the acid–base pathway shown in Scheme 7. Although hydrogen atom abstraction pathways are also possible and have been observed for late transition-metal complexes with heteroatomic ligands in which the metal centers are in relatively high oxidation states,[49–57] the failure of [$TpRu(PMe_3)_2$-NHPh], which is much less basic than the parent or *t*Bu-amido complexes, to react with 1,4-cyclohexadiene is consistent with the proposed acid–base pathway. Furthermore, initial hydrogen atom abstraction would form a cyclohexadienyl radical and [$TpRu^{I}(PMe_3)_2NH_2R$], which is a 19-electron $Ru^{I}$ complex that is likely to be a high-energy species. For [$TpRu(PMe_3)_2NHR$] systems, the Ru(II/I) potential is negative of –2.0 V (vs. NHE), which supports the suggestion that access to [$TpRu^{I}(PMe_3)_2NH_2R$] is most likely a high-energy process. In comparison, an octahedral $Fe^{III}$–methoxo complex that converts 1,4-cyclohexadiene to benzene by a proposed hydrogen atom abstraction pathway exhibits an Fe(III/II) potential of 0.73 V.[52,53]

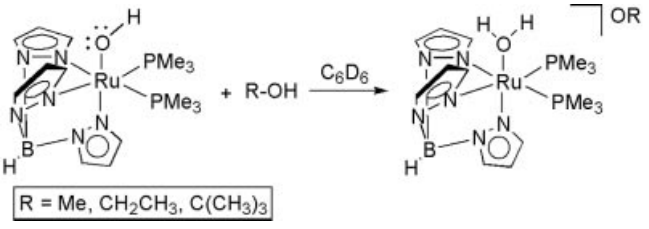


Scheme 7. Proposed pathway for isomerization of 1,4-cyclohexadiene to 1,3-cyclohexadiene by [$TpRu(PMe_3)_2NHR$] and ultimate conversion to benzene, [$TpRu(PMe_3)_2H$], and amine.

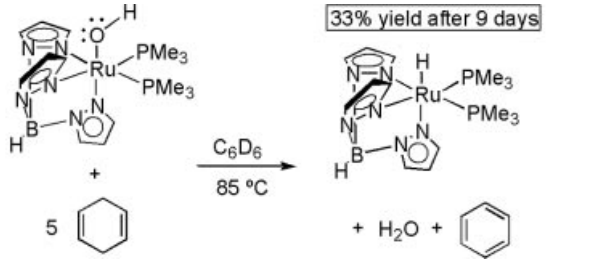
We have recently extended our studies of octahedral $Ru^{II}$ complexes to [$TpRu(PMe_3)_2OH$].[24,26,36] Similar to the amido complexes, the $Ru^{II}$–hydroxo complex is basic. For example, reactions with MeOH, EtOH, or *t*BuOH result in the formation of species whose NMR spectra are consistent with the ion pairs [$TpRu(PMe_3)_2OH_2$][OR] [R = Me, Et, or *t*Bu; Equation (1)].[36] In contrast to the parent amido complexes, [$TpRu(PMe_3)_2OH$] does not react with phenylacetylene at room temperature; however, at an elevated temperature (80 °C) [$TpRu(PMe_3)_2OH$] and phenylacetylene are converted to water and [$TpRu(PMe_3)_2(C{\equiv}CPh)$]. Sim-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ilar to the amido complexes, at 85 °C [TpRu(PMe$_3$)$_2$OH] and 1,4-cyclohexadiene are converted to benzene, water, and [TpRu(PMe$_3$)$_2$H] with a 1:1 molar ratio of benzene to Ru–H [Equation (2)]. Consistent with an acid–base pathway (see Scheme 7) and the reduced basicity of the hydroxo complex relative to the parent and *t*Bu-amido complexes, the reaction of [TpRu(PMe$_3$)$_2$OH] and 1,4-cyclohexadiene is only 33% complete after 9 days at 85 °C. In comparison, [TpRu(PMe$_3$)$_2$NH$_2$] and 1,4-cyclohexadiene produce benzene and [TpRu(PMe$_3$)$_2$H] in about 50% conversion after 3 days at 75 °C.

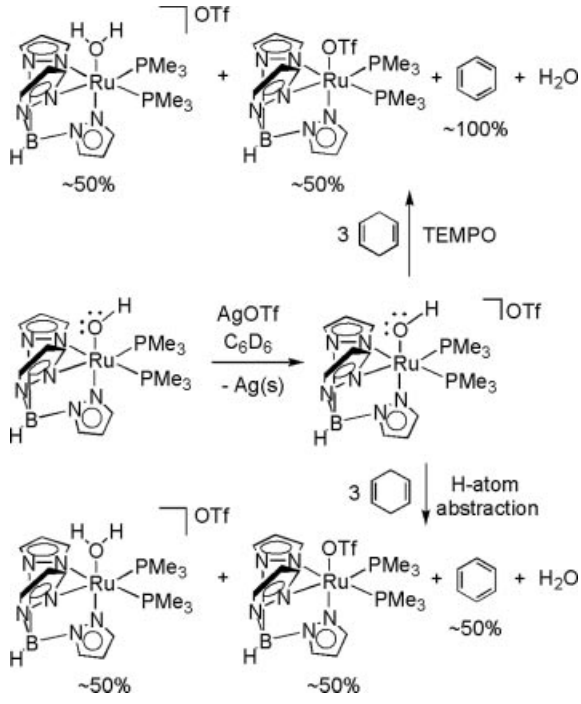


(1)



(2)

Single-electron oxidation of [TpRu(PMe$_3$)$_2$OH] yields the paramagnetic and NMR spectroscopic silent $Ru^{III}$ system [TpRu(PMe$_3$)$_2$OH]$^+$.[36] For the cationic $Ru^{III}$–hydroxo complex, Evans NMR spectroscopic experiments reveal $\mu_{eff}$ = 1.78 $\mu_B$ (room temperature), which is consistent with a single unpaired electron and close to the spin-only value of 1.73 $\mu_B$. Similar to the $Ru^{II}$–hydroxo complex [TpRu(PMe$_3$)$_2$-OH], the $Ru^{III}$ system [TpRu(PMe$_3$)$_2$OH]$^+$ converts 1,4-cyclohexadiene to benzene; however, experimental evidence points to a pathway that involves net hydrogen atom abstraction rather than even-electron acid–base chemistry (Scheme 8). In the absence of an external radical trap, [TpRu(PMe$_3$)$_2$OH]$^+$ most likely reacts with 1,4-cyclohexadiene to produce [TpRu(PMe$_3$)$_2$(OH$_2$)]$^+$ and a cyclohexadienyl radical, the latter is probably consumed rapidly by a second equivalent [TpRu(PMe$_3$)$_2$OH]$^+$ to form benzene and a second equivalent of [TpRu(PMe$_3$)$_2$(OH$_2$)]$^+$. The observed stoichiometry of products (2:1 molar ratio of [TpRu(PMe$_3$)$_2$(OH$_2$)]$^+$ and benzene) is consistent with the proposed mechanism. When the radical trap TEMPO (TEMPO = 2,2,6,6-tetramethylpiperidinyloxy) is added the cyclohexadienyl radical is trapped by TEMPO to give benzene and hence a 1:1 ratio of [TpRu(PMe$_3$)$_2$(OH$_2$)]$^+$ and benzene in the products. [TpRu(PMe$_3$)$_2$OH]$^+$ reacts with substrates that possess C–H bonds with bond dissociation energies up to ca. 335 kJ/mol. Using the approximate p$K_a$ of [TpRu(PMe$_3$)$_2$(OH$_2$)]$^+$ and the Ru(III/II) potential of [TpRu(PMe$_3$)$_2$OH] a thermodynamic cycle has been used to estimate the O–H BDE of [TpRu(PMe$_3$)$_2$OH$_2$]$^+$ to be between 343 and 356 kJ/mol, which is consistent with the experimental reactivity of the [TpRu$^{III}$(PMe$_3$)$_2$OH]$^+$ complex. Furthermore, DFT calculations of the model [(Tab)Ru(PH$_3$)$_2$(OH$_2$)]$^+$ [Tab = tris(azo)borate] reveal that the O–H BDE is 351 kJ/mol.

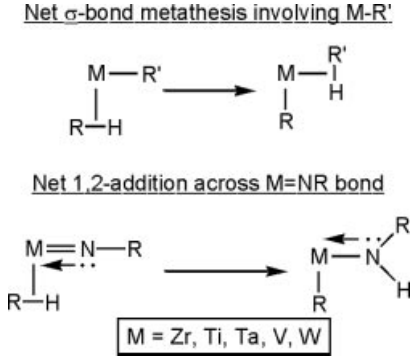


Scheme 8. The conversion of 1,4-cyclohexadiene to benzene by [TpRu(PMe$_3$)$_2$OH]$^+$ most likely proceeds by hydrogen-atom abstraction.

From a synthetic perspective, our interest in anionic heteroatomic ligands coordinated to late transition metals is derived predominantly from the positioning of a basic/nucleophilic moiety adjacent to a Lewis acidic metal center (Scheme 2). Hence, opportunities exist to coordinate substrates to the Lewis acidic metal and to activate them toward reactions with the heteroatomic ligands. For example, metal-mediated C–H activation by σ-bond metathesis pathways involve the conversion of M–R and R′–H to M–R′ and R–H via a transition state in which net $H^+$ is transferred to a basic alkyl or aryl ligand "R" (Scheme 9). We have considered that related reactions of late transition metals with nondative-heteroatomic ligands might provide facile and controlled C–H activation/functionalization. In this case, the net C–H activation might be best viewed as an intramolecular proton transfer to the basic heteroatomic ligand. In related examples, the net 1,2-additions of dihydrogen across Ru amido ligands have been implicated in enantioselective ketone hydrogenation as well as Rh and Ir catalysts.[58–62] Morris et al. have demonstrated that the reaction of a $Ru^{II}$ amido complex with dihydrogen yields a complex

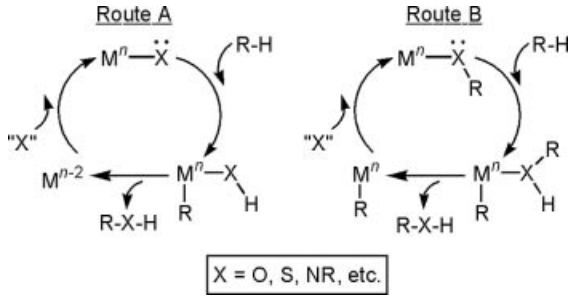
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

in which the H–H bond is intermediate between protic-hydridic and dihydrogen,[63] dihydrogen adds across an $Ir^{III}$–amido bond,[64] and the chelating amido ligand of $\{Ru(Cl)(PPh_3)[N(SiMe_2CH_2PPh_2)_2]\}$ deprotonates dihydrogen to yield $\{Ru(Cl)(H)(PPh_3)[NH(SiMe_2CH_2PPh_2)_2]\}$.[65] In addition, early transition-metal imido complexes have been demonstrated to activate C–H bonds for 1,2-addition across the M = NR moiety to yield amido and alkyl or aryl ligands (Scheme 9).[66–74] Studies have demonstrated that key factors in the imido-based C–H activation include coordination of the C–H bond to the metal center and the polar nature of the metal–imido bond.[75–77] We have been pursuing the utilization of $Ru^{II}$ systems for the activation of nonpolar bonds such as dihydrogen and carbon–hydrogen bonds.



Scheme 9. Net 1,2-addition of C–H bonds across early transition-metal imido fragments has been observed.

Several strategies exist for oxygen or nitrogen functionalization of C–H bonds via metal-mediated activation, and the net 1,2-addition of C–H bonds across metal heteroatom bonds is a potentially viable step in catalytic sequences. For example, Scheme 10 depicts two possible catalytic cycles for C–H functionalization involving the 1,2-addition of C–H bonds across M–X bonds (X = amido, imido, oxide, alkoxo, etc.). Route A illustrates C–H functionalization with three key steps: (1) 1,2-addition of a C–H bond across a metal–oxide or metal–imido bond, (2) O–C or N–C reductive elimination, and (3) formal oxidation of the metal to reform the oxide or imido complex. Although the 1,2-addition of C–H bonds across M–X bonds has been demonstrated for early transition-metal–imido complexes (see above),[66–77]



Scheme 10. Two possible routes to incorporate the net 1,2-addition of C–H bonds across transition-metal–heteroatom bonds (e.g., imido, oxide, amido, alkoxo, etc. ligands) into catalytic cycles.

the product forming reductive elimination from electropositive early transition metals is likely to be substantially unfavorable. In contrast, N–C and O–C reductive elimination reactions have been successfully incorporated into catalytic cycles involving late transition-metal systems (e.g., catalytic arylamine or aryl ether preparation).[78–82] Thus, *catalytic cycles* by Route A are potentially more viable with late transition-metal systems; however, the 1,2-addition of C–H bonds across late transition-metal–oxide or –imido bonds remains, to the best of our knowledge, unknown.

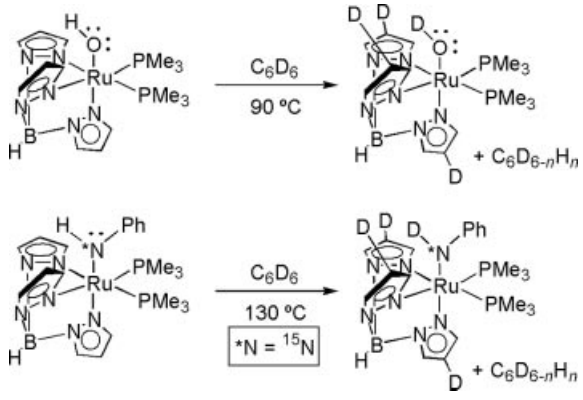
Route B (Scheme 10) illustrates an alternative catalytic cycle with three key steps: (1) the 1,2-addition of a C–H bond occurs across a metal–amido or metal–alkoxo (or aryloxo) bond, (2) dissociation of the alcohol or amine, and (3) net oxygen atom or nitrene insertion into the newly formed M–R or M–Ar bond.[83] To the best of our knowledge, prior to our work and efforts by Periana et al., evidence for the 1,2-addition of C–H bonds across the bonds of late transition metals and amido, alkoxo, and related ligands was unknown.[24,26,84] Macgregor et al. have suggested a related pathway for a C–H cyclometalation by Pd–acetate and Ir complexes.[85,86] Addition of a C–H bond across a Pt–Cl bond has been proposed as a possibility in the Shilov reaction.[87] Establishing the viability of these potential catalytic cycles requires an understanding of the metal-mediated C–H activation by late transition-metal amido, alkoxo, and related systems.

In addition to the C–H activation step, oxo or nitrogen functionalization of the M–R or M–Ar bond is a substantial challenge to the development of catalytic cycles shown in Route B. For example, insertions of metal–oxo ligands into metal–alkyl (or aryl) bonds are extremely rare, especially under nonphotolytic conditions.[88,89] However, Periana et al. have recently reported kinetically facile conversions of a $Re^{VII}$–methyl ligand and external oxidants to a Re–OMe linkage, and they have proposed that the key to the relatively low activation barriers is a mechanism that does not involve a rhenium–oxo ligand but rather resembles the classic organic Baeyer–Villiger reaction.[83] *Thus, both of the reaction steps for catalytic oxy functionalization of C–H bonds by Route B in* Scheme 10 *have been observed to be kinetically accessible under reasonably mild reaction conditions using late transition-metal systems.* With a better understanding of both reactions, it might be possible to merge the two steps with a single catalyst.

$[TpRu(PMe_3)_2OH]$ and $[TpRu(PMe_3)_2NHPh]$ provide kinetic access to aromatic C–H activation sequences that involve the net 1,2-addition of C–H(D) bonds across the Ru–OH and Ru–NHPh bonds.[24,26] For example, heating these systems in $C_6D_6$ results in H/D exchange between the deuterated benzene and the hydroxo and anilido ligands, which has been observed by both $^1H$ and $^2H$ NMR spectroscopy. In addition to the incorporation of deuterium at the heteroatomic ligand, highly regioselective H/D exchange is observed at the Tp 4-position (Scheme 11). On the basis of several experimental results including detailed kinetic studies and complementary computational studies,[24] the mechanism in Scheme 12 has been proposed. Initial dissoci-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

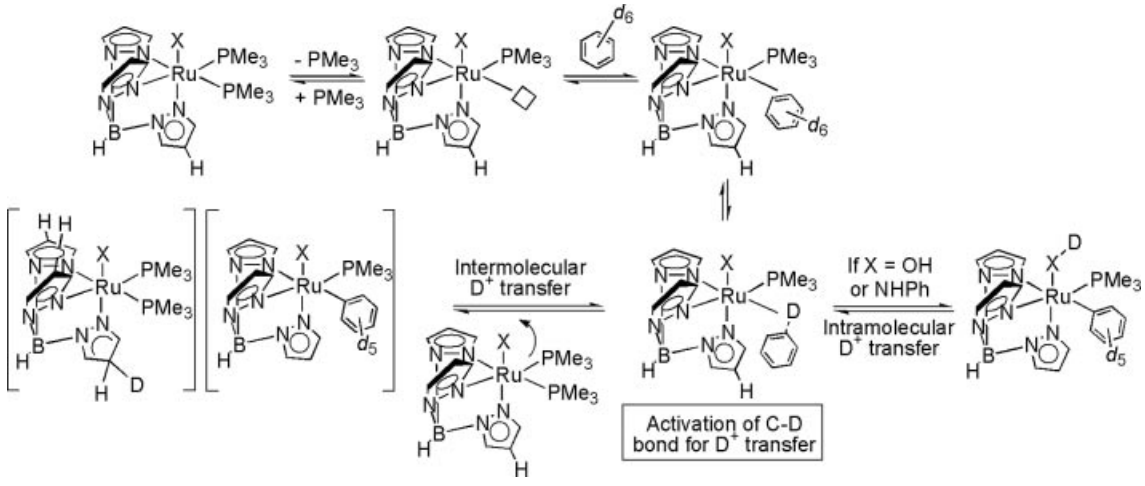
ation of $PMe_3$ provides a pathway to coordinate and activate the aromatic substrate (benzene in Scheme 12). Activation of the aromatic C–H(D) bond imparts acidic character, which results in the transfer of the "protic" hydrogen to the basic hydroxo or anilido site (intramolecular transfer) or transfer to the most basic pyrazolyl position (the 4-position, intermolecular transfer). The proposed mechanism suggests that the C–H(D) activations are thermally disfavored, and consistent with this notion heating $[TpRu(PMe_3)_2Ph]$ and aniline in $C_6D_6$ initially results in the conversion to benzene and $[TpRu(PMe_3)_2NHPh]$. In closely related work, Periana et al. have directly observed the conversion of an octahedral $Ir^{III}$–methoxo complex, which is isoelectronic to the $[TpRu(PMe_3)_2X]$ systems, and benzene to the corresponding $Ir^{III}$–phenyl and methanol.[84]



Scheme 11. Observed H/D exchange from heating $[TpRu(PMe_3)_2X]$ (X = OH or NHPh) in $C_6D_6$ (N* = isotopically labeled $^{15}N$).

DFT calculations performed by Cundari et al. using the Tp model "Tab" [Tab = tris(azo)borate] and $PH_3$ reveal the energetics for the conversion of $[(Tab)Ru(PH_3)_2OH]$ and benzene to $[(Tab)Ru(PH_3)_2Ph]$ and $H_2O$ (Scheme 13). Consistent with the experimental evidence suggesting that the 1,2-additions of the benzene C–H(D) bonds are thermally disfavored, the conversion of $[(Tab)Ru(PH_3)_2OH]$ and benzene to $[(Tab)Ru(PH_3)(OH_2)Ph]$ and free $PH_3$ is calculated to be endergonic by 77 kJ/mol, and conversion to $[(Tab)Ru(PH_3)_2Ph]$ and free $H_2O$ is calculated to be endergonic by 38 kJ/mol relative to starting materials. Similar to calculations for C–H activation by isoelectronic [TpRu(L)R] (R = alkyl) systems,[90,91] the calculated pathway for benzene C–H activation by $[(Tab)Ru(PH_3)OH]$ does not involve oxidative addition but rather more closely resembles a σ-bond metathesis reaction that is typically observed with $d^0$ metal systems (i.e., the C–H and O–H bonds are simultaneously broken and formed). The intramolecular C–H activations with Ru–X (X = OH or NHPh) are perhaps best considered as intramolecular deprotonations (see below).

While examples of C–H activation by late transition-metal complexes that involve the overall conversion of M–R + R′H to M–R′ and RH or oxidative addition of C–H bonds are relatively common,[90–110] related examples involving M–X + R–H to M–R + X–H (X = amido, alkoxo, etc.) are rare. Thus, an important fundamental aspect of the latter transformations is the relative predilection toward C–H activation for systems that possess nondative-heteroatomic ligands. *That is, what features of the metal center and ligand "X" decrease the activation barrier for the C–H activation?* Part of our efforts with late transition-metal nondative-heteroatomic complexes is directed toward elucidating such features. For example, *our preliminary results and calculations suggest that the net 1,2-addition of C–H bonds across M–X (X = anionic heteroatomic ligand) may be more facile than related reactions involving M–R bonds, which may be explained by considering the C–H activation as an intramolecular proton transfer that is facilitated by the lone pair on the hydroxo and related ligands* (Scheme 14). For example, Scheme 15 depicts benzene C–H activation by [TpRu(PMe$_3$)X] (X = OH, NHPh, or Me) fragments. The activated benzene C–H bond can either produce a net transfer of $H^+$ to the pyrazolyl ring of another Ru system ($k_{inter}$ in Scheme 15) or the intramolecular transfer of $H^+$ to X ($k_{intra}$) in Scheme 15. For X = OH and NHPh, $k_{intra}$ is more rapid than $k_{inter}$; however, for X = Me, $k_{inter}$ is more rapid that $k_{intra}$, ***results which are consistent with the presence of a lone pair on ligand X facilitating the intramolecular transfer of a proton from the activated benzene C–H(D) bond***. The



Scheme 12. Proposed mechanism for H/D exchange with $[TpRu(PMe_3)_2X]$ (X = OH or NHPh) and deuterated arene solvents.

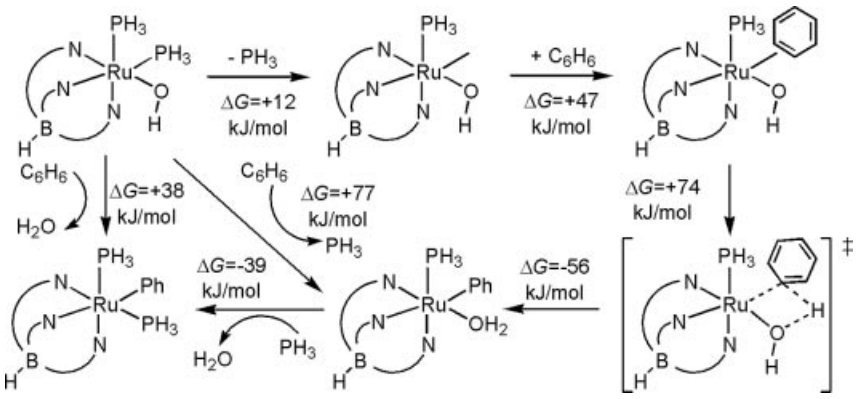
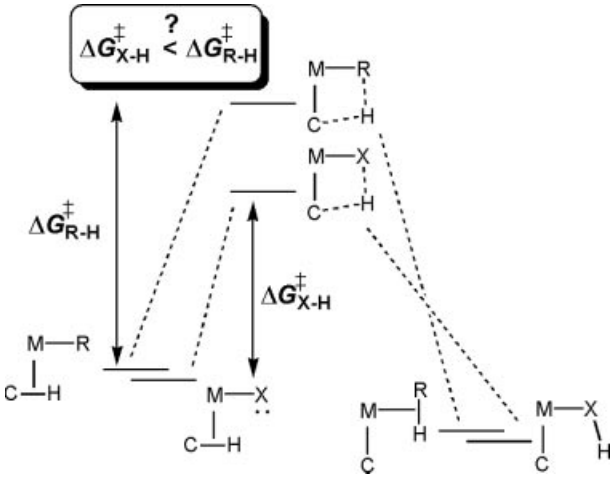


Scheme 13. Calculated energetics for benzene C–H activation using a model complex [(Tab)Ru($PH_3$)$_2$OH].

$k_{inter}$ for X = Me is an estimate based on an approximate half-life acquired in an NMR tube reaction of [TpRu($PMe_3$)$_2$Me] in $C_6D_6$ to produce [TpRu($PMe_3$)$_2$(Ph-$d_5$)] and $CH_3D$ at 130 °C.



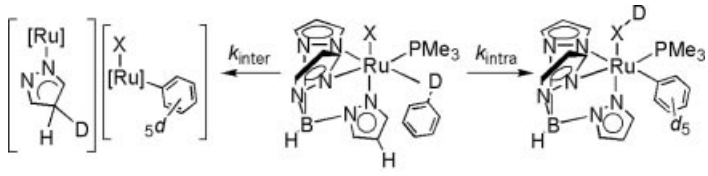
Scheme 14. For late transition-metal systems in low oxidation states the net 1,2-addition of C–H bonds across M–X (X = anionic heteroatomic ligand such as hydroxo, amido, etc.) may possess inherently lower activation barriers than analogous reactions of M–R (R = alkyl or aryl) bonds.

Clearly, more work is needed to substantiate (or disprove) this possibility as well as to understand the influence of the metal oxidation state, metal identity, identity of the nondative-heteroatomic ligand, identity of substituents on the nondative ligand, and the donating ability of the ancillary ligands. We are currently studying such details both experimentally and computationally. However, these preliminary experimental and computational results suggest that 1,2-additions of C–H bonds across M–X (X = anionic heteroatomic ligand) bonds with late transition metals in low oxidation states might be viable reactions for catalytic C–H functionalization.

## Five- and Six-Coordinate (PCP)Ru$^{II}$ Systems

### Preparation and Characterization of (PCP)Ru$^{II}$ Systems

In order to access coordinatively unsaturated Ru$^{II}$ amido complexes we employed the sterically bulky PCP ligand 2,6-($CH_2P$-$t$Bu$_2$)$_2$C$_6$H$_3$, which is strongly donating and coordinates in a meridonal fashion.[111] The addition of ammonia to the previously reported complex [(PCP)Ru(CO)Cl] results in reversible coordination of the amine to form [(PCP)Ru(CO)($NH_3$)Cl], and reactions of the Ru$^{II}$–amine complex with strong bases produce the parent amido complex [(PCP)Ru(CO)$NH_2$] (Scheme 16).[29] In contrast to the octahedral 18-electron [TpRu(L)(L′)$NH_2$] parent amido complexes (see above), the resonance arising from the amido protons appears downfield at $\delta$ = 4.36 ppm. The



| X | $k_{intra}$ | $k_{inter}$ | $k_{intra}/k_{inter}$ |
|---|---|---|---|
| OH[a] | $2.4 \times 10^{-4}$[b] | $5.2 \times 10^{-6}$ | 46 |
| NHPh[c] | $1.4 \times 10^{-5}$ | $5.6 \times 10^{-6}$ | 2.5 |
| Me[c] | $1.1 \times 10^{-6}$ | $1.1 \times 10^{-5}$ | 0.1 |

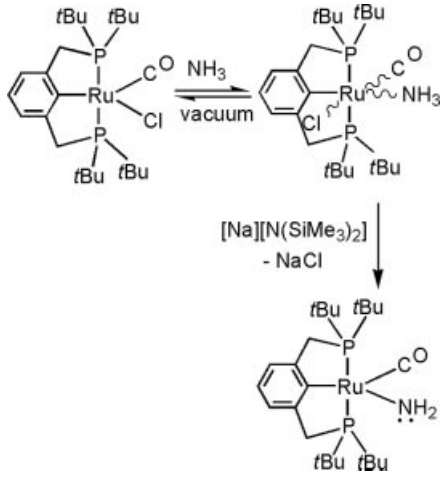
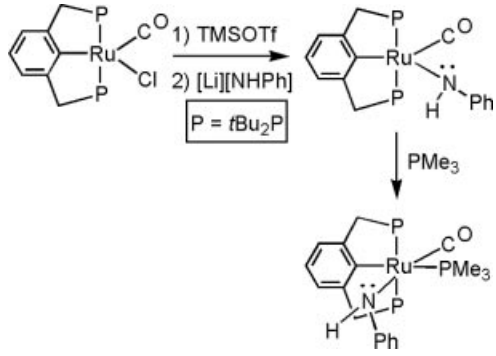
Scheme 15. downfield chemical shift most likely reflects amido-to-Ru π-donation as a result of the metal's coordinative and electronic unsaturation.

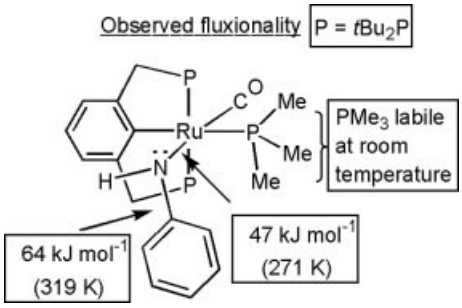


Scheme 16. Preparation of five-coordinate [(PCP)Ru(CO)$NH_2$].

The anilido complex [(PCP)Ru(CO)NHPh] has been prepared via transformation of [(PCP)Ru(CO)Cl] and TMSOTf to [(PCP)Ru(CO)OTf] followed by reaction with [Li][NHPh].[27,28] The addition of $PMe_3$ to [(PCP)Ru(CO)-NHPh] allows the isolation of the octahedral complex [(PCP)Ru(CO)($PMe_3$)NHPh] (Scheme 17). Variable-temperature $^1H$ and $^{31}P$ NMR spectroscopy of [(PCP)Ru(C-O)($PMe_3$)NHPh] reveals three fluxional processes including



Scheme 17. Preparation of [(PCP)Ru(CO)NHPh] and [(PCP)Ru(C-O)($PMe_3$)NHPh].

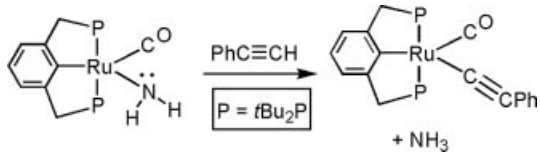


Scheme 18. Fluxional processes observed for [(PCP)Ru(CO)-($PMe_3$)NHPh] using variable-temperature NMR spectroscopy.

facile dissociation of $PMe_3$ and hindered rotation about the Ru–$N_{anilido}$ ($\Delta G^{\ddagger}$ = 47 kJ/mol at 271 K) and $N_{anilido}$–$C_{ipso}$ ($\Delta G^{\ddagger}$ = 64 kJ/mol at 319 K) bonds (Scheme 18).

### Reactivity of (PCP)$Ru^{II}$ Systems

The (PCP)$Ru^{II}$ amido complexes undergo reactions similar to the Tp$Ru^{II}$ amido complexes, but also afford access to transformations not observed with the Tp systems. For example, similar to the TpRu parent amido complexes, [(PCP)Ru(CO)$NH_2$] reacts with phenylacetylene to produce free ammonia and [(PCP)Ru(CO)(C≡CPh)]; however, in contrast to the Tp systems, the putative intermediate(s) [(PCP)Ru(CO)$NH_3$][$PhC_2$] or [(PCP)Ru(CO)($NH_3$)-(C≡CPh)] are not observed (even at –78 °C) as they apparently undergo rapid conversion to the five-coordinate acetylide complex [(PCP)Ru(CO)(C≡CPh)] (Scheme 19).

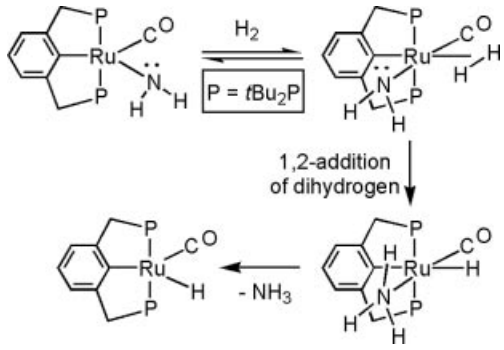


Scheme 19. Reaction of [(PCP)Ru(CO)$NH_2$] and phenylacetylene to produce [(PCP)Ru(CO)C≡CPh] and free ammonia.

The failure of the TpRu parent amido complexes to react with dihydrogen is potentially attributable to the lack of an open coordination site to bind and activate the dihydrogen. Consistent with this notion, the five-coordinate complex [(PCP)Ru(CO)$NH_2$] rapidly reacts with dihydrogen at room temperature to produce [(PCP)Ru(CO)H], and mechanistic studies suggest the pathway displayed in Scheme 20.[29] In related chemistry, Morris et al. demonstrated that the reaction of a $Ru^{II}$ amido complex with dihydrogen yields a complex in which the H–H bond is intermediate between protic-hydridic and dihydrogen bonding.[63] Fryzuk et al. have reported the 1,2-addition across a Ru–amido bond in which the amido is part of a chelated PNP ligand.[65] Rauchfuss has recently reported the addition of dihydrogen across an $Ir^{III}$–amido bond.[64] Also, the 1,2-addition of dihydrogen across Ru–amido linkages has been implicated for asymmetric hydrogenation reactions.[58,59] The conversion of [(PCP)Ru(CO)$NH_2$] and dihydrogen to [(PCP)Ru(CO)H] and ammonia suggests that nonpolar bonds can be activated with late transition metals in low oxidation states that possess anionic heteroatomic ligands.

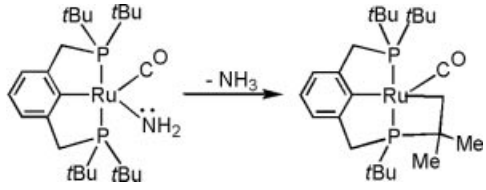
Despite the facile activation of dihydrogen by [(PCP)-Ru(CO)$NH_2$], this system does not mediate the 1,2-addition of C–H bonds of benzene or methane across the Ru–$NH_2$ bond. Rather, intramolecular C–H activation of a *t*Bu group of the PCP ligand kinetically competes with intermolecular C–H activation (Scheme 21). Fryzuk et al. have recently reported a related intramolecular cyclometalation of a triphenylphosphane ligand that involves the conversion of an amido moiety to amine coordinated to $Ru^{II}$.[112] The intramolecular C–H activation occurs for [(PCP)Ru(CO)X] (X = $NH_2$ or Me) with the rate of reaction approximately

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



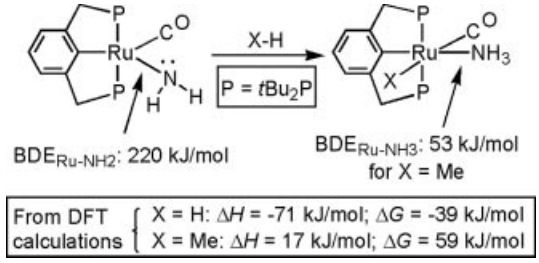
Scheme 20. Proposed pathway for the conversion of [(PCP)Ru(CO)$NH_2$] and dihydrogen to free ammonia and [(PCP)Ru(CO)H].

five times faster for the methyl complex at 50 °C. Eyring plots for both complexes over a temperature range of 30 °C revealed identical $\Delta H^{\ddagger}$ values of 75(4) kJ/mol with a $\Delta S^{\ddagger}$ value of –23(4) eu for [(PCP)Ru(CO)$NH_2$] and –18(4) eu for [(PCP)Ru(CO)Me]. Thus, the difference in the reaction rate for intramolecular 1,2-addition of C–H bonds across $Ru^{II}$–X (X = $NH_2$ or Me) bonds for these systems is predominantly due to a more ordered transition state for X = $NH_2$ than X = Me. Interestingly, the comparative rates of intramolecular C–H activation for the PCP systems with X = $NH_2$ or Me are in contrast to the more rapid 1,2-addition of benzene C–D bonds by [TpRu($PMe_3$)$_2$OH] versus [TpRu($PMe_3$)$_2$Me] (see above).



Scheme 21. Intramolecular C–H activation via 1,2-addition of the C–H bond across the Ru–$NH_2$ bond.

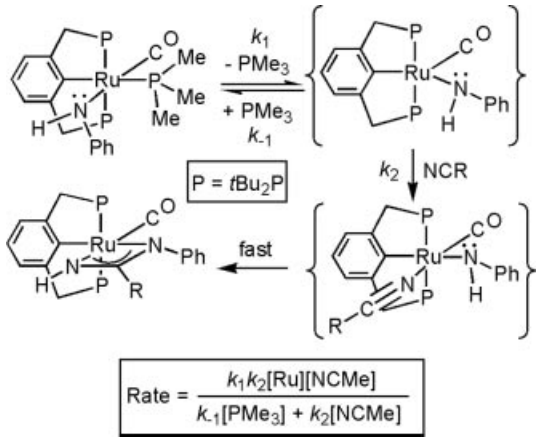
Consistent with experimental observations, DFT calculations {B3LYP/SBK(d)} by Cundari et al. suggest that the conversion of [(PCP′)Ru(CO)$NH_2$] (PCP′ = model PCP ligand with *t*Bu groups replaced with hydrogen) and dihydrogen to [(PCP′)Ru(CO)($NH_3$)H] is exothermic ($\Delta H$ = –71 kJ/mol) and exergonic ($\Delta G$ = –39 kJ/mol; Scheme 22). In contrast, the 1,2-addition of a C–H bond of methane to [(PCP′)Ru(CO)$NH_2$] to form [(PCP′)Ru(CO)($NH_3$)Me] is calculated to be both endothermic ($\Delta H$ = +17 kJ/mol) and endergonic ($\Delta G$ = +59 kJ/mol). While the calculated endergonic nature of the methane conversion is not entirely unexpected (due to consumption of gaseous methane), the endothermic nature is perhaps more difficult to rationalize. For example, the enthalpic change from the cleavage of a C–H bond of methane in combination with Ru–$C_{Me}$ and N–H bond formation is calculated to be ca. 134 kJ/mol; however, calculations also reveal that the conversion of the Ru–$NH_2$ moiety to the dative Ru←$NH_3$ bond comes at the expense of approximately 167 kJ/mol (Scheme 22)! Thus, in addition to intramolecular competition with the *t*Bu groups, the calculations reveal that the desired intermolecular C–H activation is thermally disfavored, and these results are consistent with both calculations and experimental observations for [TpRu$L_2$X] (X = amido or hydroxo) systems (see above). These results suggest that *direct observation* of the 1,2-addition of C–H bonds across the bonds of late transition-metal–heteroatomic ligands requires a more favorable change in M–X BDE. Interestingly, Periana et al. have reported that benzene C–H activation by an $Ir^{III}$–methoxo complex, which is isoelectronic to our $Ru^{II}$ systems, to form methanol and an Ir–phenyl complex is thermally favored.[84]



Scheme 22. Calculations for 1,2-addition of H–H and C–H (methane) across the Ru–$NH_2$ bond of [(PCP)Ru(CO)$NH_2$].

In addition to reactivity with nonpolar H–H and C–H bonds the combination of a Lewis acidic metal center and nucleophilic amido ligand of [(PCP)Ru(CO)NHPh] can be utilized to coordinate and activate polar bonds.[27,28] These transformations are of potential relevance to transition-metal-catalyzed polymerization of heterofunctionalized monomers such as carbodiimides, carbon dioxide, lactams, lactones, lactides, isocyanates, epoxides, and aziridines,[6,8,9,113–124] catalytic hydration of nitriles,[125] catalytic transamidation and transesterification,[126–135] and related transformations.

[(PCP)Ru(CO)($PMe_3$)NHPh] reacts with nitriles to form the amidinate complexes. Detailed kinetic studies for the reaction with NCMe are consistent with the rate law from the mechanism shown in Scheme 23, which involves dissociation of $PMe_3$, coordination of acetonitrile, and intramolecular C–N bond formation. For reactions with 10 equiv. of



Scheme 23. Proposed pathway for the conversion of [(PCP)Ru(CO)($PMe_3$)NHPh] and nitriles to amidinate complexes, and the corresponding rate law.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

acetonitrile and 10 to 25 equiv. of $PMe_3$, the rate of conversion of complex **1** and acetonitrile to the amidinate complex **2** is inverse first order in concentration of $PMe_3$, which is consistent with the term in the denominator "$k_{-1}$[$PMe_3$]" dominating the term "$k_2$[NCMe]" *under the specific conditions of these experiments* with $k_{obs}$ under pseudo-first-order conditions being equal to $k_1k_2$[NCMe]/$k_{-1}$[$PMe_3$]. A plot of $k_{obs}$ versus the concentration of NCMe for reactions with 10 equiv. of $PMe_3$ and between 10 and 50 equiv. of NCMe reveals a first-order dependence on the concentration of NCMe at low concentrations of NCMe while saturation kinetics are apparent at higher concentrations. Thus, in agreement with the observation of an inverse dependence of reaction rate on the concentration of $PMe_3$ at lower concentrations of NCMe, the term "$k_{-1}$[$PMe_3$]" is greater than "$k_2$[NCMe]" with the pseudo-first-order rate constant equal to $k_1k_2$[NCMe]/$k_2$[$PMe_3$]. At elevated concentrations of NCMe the term "$k_2$[NCMe]" becomes greater than "$k_{-1}$[$PMe_3$]" with $k_{obs}$ independent of the concentration of NCMe. Monitoring the rate of disappearance of [(PCP)Ru(CO)($PMe_3$)NHPh] in the presence of 100 equiv. of acetonitrile with 10, 15, or 20 equiv. of $PMe_3$ reveals that $k_{obs}$ is independent of the $PMe_3$ concentration and is equal to $1.29(7) \times 10^{-5}$ $s^{-1}$. For reactions that are pseudo-first order in concentration of [(PCP)Ru(CO)($PMe_3$)NHPh], rearrangement of the rate law shown in Scheme 23 indicates that a plot of $1/k_{obs}$ versus [$PMe_3$]/[NCMe] should be linear with the slope equal to $k_{-1}/k_1k_2$ and the $y$ intercept equal to $1/k_1$ [Equation (3)]. From the plot shown in Figure 2, $k_1$ was estimated to be $1.8 \times 10^{-5}$ $s^{-1}$, and using the value of $k_1$ and the slope from the plot in Figure 2, the ratio of $k_{-1}/k_2$ was calculated to be 3; however, small deviations in the slope can result in substantial deviations for the $y$ intercept.

$$1/k_{obs} = \frac{k_{-1}[PMe_3]}{k_1k_2[NCR]} + \frac{1}{k_1} \quad (3)$$

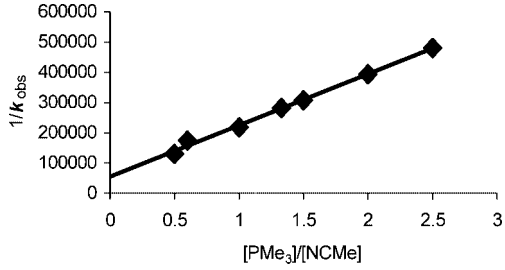


Figure 2. Plot of $1/k_{obs}$ versus [$PMe_3$]/[NCMe] for the conversion of [(PCP)Ru(CO)($PMe_3$)NHPh] and NCMe to the amidinate complex ($R^2$ = 0.99).

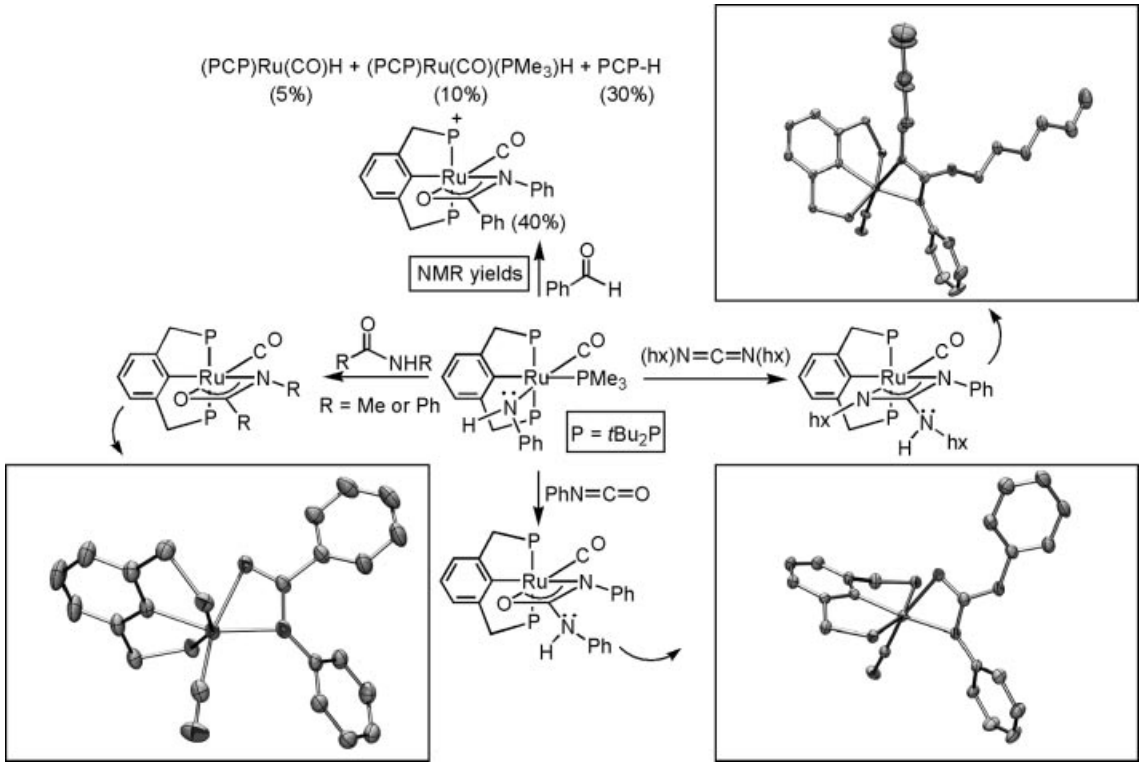
[(PCP)Ru(CO)($PMe_3$)NHPh] also reacts with carboxamides, isocyanates, carbodiimides, benzaldehyde, and water (Scheme 24). The reactions with carbodiimides, isocyanates, and benzaldehyde follow similar pathways to the reaction of [(PCP)Ru(CO)($PMe_3$)NHPh] with nitriles to form $\kappa^2$-ligands, which most likely result from intramolecular C–N bond formation. Thus, coordination of polar substrates with Lewis basic sites by the $Ru^{II}$ fragment activates the



Scheme 24. Reactions of [(PCP)Ru(CO)($PMe_3$)NHPh] including ORTEPs (30% probability) of three products (with hydrogen atoms and *t*Bu groups omitted).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

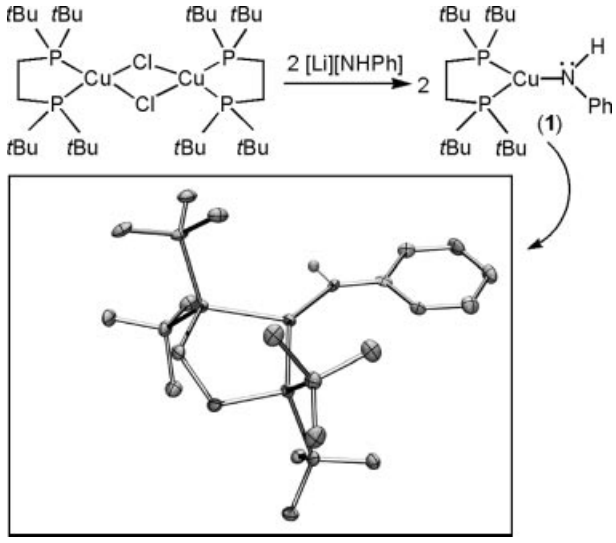
unsaturated molecules toward intramolecular nucleophilic addition by the amido ligand. For benzaldehyde, the amidate complex is isolated in only 40% yield because of side reactions that produce [(PCP)Ru(CO)H] (5%), [(PCP)-Ru(CO)($PMe_3$)H] (10%), and free PCPH (30%).

## Two- and Three-Coordinate $Cu^I$ Systems

### Preparation and Characterization of $Cu^I$ Systems

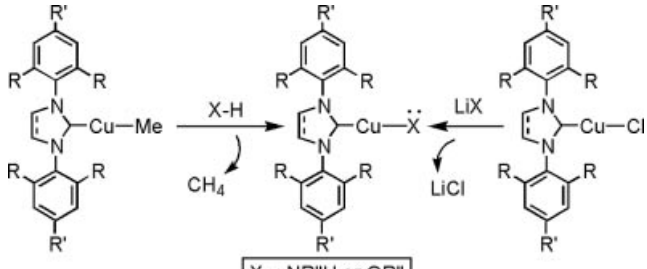
Copper has played an important role in the development of metal-mediated organic synthesis. However, despite the prevalence of anionic heteroatomic ligands with early and middle transition metals, increasing evidence for the highly reactive nature of late transition-metal complexes with anionic heteroatomic ligands and the possibility that Cu–imido complexes are intermediates in Cu-catalyzed olefin aziridination,[3,136–140] the isolation and full characterization of *monomeric* Cu amido complexes was, to the best of our knowledge, unknown prior to our efforts. Multinuclear systems with bridging-amido ligands have been reported,[141–146] including an example of a nonbridging amido that is part of a chelated ligand.[147] In addition, reports of monomeric Cu–alkoxo and Cu–aryloxo complexes are relatively scant.[148–154] Thus, we sought ligand platforms and synthetic routes that would allow the isolation of well-defined *monomeric* $Cu^I$ systems with amido, alkoxo, and related ligands. Sterically bulky ancillary ligands have been incorporated in an effort to inhibit the formation of dimeric or multinuclear Cu systems bridged by the heteroatomic ligands.

Chloride/amido metathesis between [(dtbpe)Cu(μ-Cl)]$_2$ {dtbpe = 1,2-bis(di-*tert*-butylphosphanyl)ethane} and [Li][NHPh] allows the isolation of monomeric [(dtbpe)-Cu(NHPh)] (**1**) (Scheme 25).[30] The bulky dtbpe most likely prevents the dimerization of **1** via bridging-anilido ligands, and the strongly donating nature probably prevents reduction of $Cu^I$ to $Cu^0$ by the lithium amide salt (as is observed for $Cu^I$ systems with more weakly donating aryl–phosphane ligands). The Cu–$N_{amido}$ bond length {1.890(6) Å} of **1** is shorter than that of the corresponding aniline complex [(dtbpe)Cu($NH_2$Ph)][OTf] by ca. 0.12 Å. Recently, Johnson et al. have reported a multinuclear $Cu_9$ system that possesses Cu–amido linkages.[147] The three-coordinate $d^{10}$ $Cu^I$ complex **1** has a vacant p orbital of π-symmetry with respect to the Cu–$N_{amido}$ bond, and the amido ligand is oriented for overlap with the Cu-based p orbital. For example, the P–Cu–N–$C_{ipso}$ torsion angle is about 13°, while a torsion angle of 0° would provide an orientation optimized for π-overlap (see Figure 4 below). This amido orientation is approximately perpendicular to that observed by Hillhouse and Mindiola for the closely related $d^9$ $Ni^I$ complex (dtbpe)Ni{NH(2,6-$CHMe_2$)$C_6H_3$}.[155] The phenyl substituent of **1** is also oriented for π-overlap with the amido lone pair (see Figure 4 below).



Scheme 25. Preparation of the monomeric $Cu^I$–anilido complex [(dtbpe)Cu(NHPh)] (**1**) and its ORTEP diagram (30%).

Similar to the preparation of Cu–methyl complexes by Sadighi et al,[156] we have employed NHC (NHC = N-heterocyclic carbene) ligands to stabilize monomeric two-coordinate $Cu^I$ systems with anionic heteroatomic ligands.[23,25,38] The NHC ligand has been varied between IMes {1,3-bis-(2,4,6-trimethylphenyl)imidazol-2-ylidene}, IPr {1,3-bis(2,6-diisopropylphenyl)imidazol-2-ylidene}, and SIPr {1,3-bis(2,6-diisopropylphenyl)imidazolin-2-ylidene}. Complexes with amido, alkoxo, and aryloxo ligands can be prepared upon reaction of amines or alcohols with [(NHC)-Cu(R)] (R = Me or Et) complexes or via metathesis using [(NHC)Cu(Cl)] and lithium salts of the anionic heteroatomic ligand (Scheme 26). For the conversion of [(IPr)-Cu(Me)] and aniline to methane and [(IPr)Cu(NHPh)] (**2**) studies suggest that the reaction involves the initial coordination of aniline followed by protonation of the methyl ligand.[25]



| NHC | X | NHC | X |
|---|---|---|---|

| IPr | OEt (**5**) | IPr | SPh (**11**) |
| SIPr | OEt (**6**) | SIPr | SPh (**12**) |
| IMes | OEt (**7**) | IMes | SPh (**13**) |

Scheme 26. Two routes for the preparation of [(NHC)Cu(X)] complexes (X = NHPh, OEt or OPh).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Several of these complexes have been characterized by single-crystal X-ray diffraction. In all cases the structures reveal approximately linear two-coordinate monomeric systems (Figure 3). We have structurally characterized three Cu–NHPh complexes: [(dtbpe)Cu(NHPh)], [(IPr)Cu(NHPh)], and [(SIPr)Cu(NHPh)]. In all three systems, the plane of the anilido–phenyl group is approximately coplanar with the H–N–$C_{phenyl}$ plane, which optimizes delocalization of the amido lone pair into the phenyl π* system (Figure 4). Consistent with the amido-to-phenyl electron delocalization, the $N_{amido}$–$C_{phenyl}$ bond lengths {1.351(4) Å to 1.359(3) Å} are shorter than a typical N–C single bond (1.47 Å) and shorter than the corresponding N–C bond of the aniline complex [(dtbpe)Cu($NH_2$Ph)][$PF_6$], which is 1.444(4) Å.[23,30]

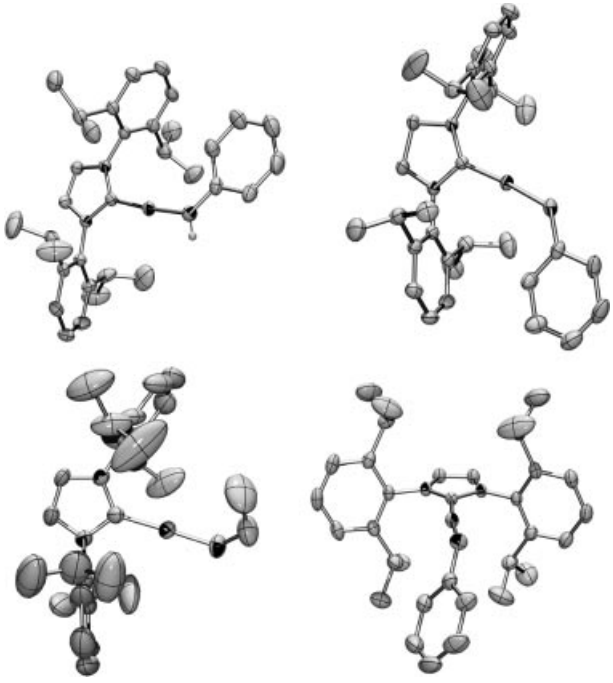

Figure 3. ORTEPs (30%) of representative examples of [(NHC)Cu(X)] (X = nondative heteroatomic ligand) complexes including [(IPr)Cu(NHPh)] (**2**), [(SIPr)Cu(NHPh)] (**3**), [(IPr)Cu(OEt)] (**5**), and [(IPr)Cu(OPh)] (**8**) (presented from left to right and top to bottom).

Consistent with the solid-state structures that suggest a negligible Cu–$N_{amido}$ π-interaction for the $Cu^{I}$ anilido complexes **1**–**4**, the calculated Kohn–Sham (KS) HOMO of these systems has little Cu character, and that which is present is Cu 3d ($p_{amido}$–$d_{Cu}$ π*) rather than 4p (Figure 5).[23] However, the KS HOMOs possess a substantial contribution from the phenyl π-system.

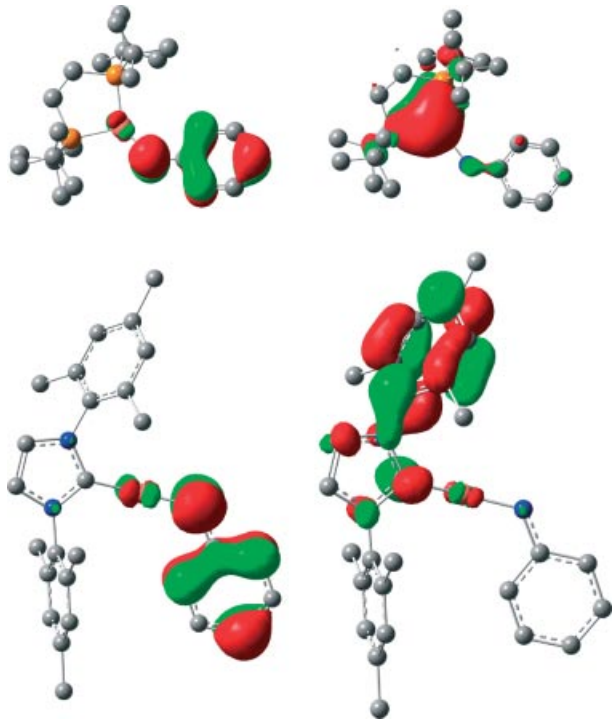

Figure 5. Highest occupied (left) and lowest unoccupied (right) Kohn–Sham orbitals for [(dtbpe)Cu(NHPh)] (**1**) (top pair) and [(IMes)Cu(NHPh)] (**4**) (bottom pair). Orbitals for other NHC $Cu^{I}$–anilido complexes are similar.

### Reactivity of $Cu^{I}$ Systems

As a straight-forward probe of nucleophilic reactivity, the rates of net $S_N2$ reactions of $Ru^{II}$– and $Cu^{I}$–anilido complexes with bromoethane to produce the corresponding metal–bromide and ethyl aniline were compared.[23] The complexes [TpRu($PMe_3$)$_2$NHPh], [(dtbpe)Cu(NHPh)] (**1**), [(IPr)Cu(NHPh)] (**2**), [(SIPr)Cu(NHPh)] (**3**), and [(IMes)Cu(NHPh)] (**4**) all react with bromoethane with the rate of reaction for Ru being considerably slower than Cu (Scheme 27 and Table 1). Using $\Delta G^{\ddagger}$ values calculated at variable temperatures and calculating rate constants at 298 K, which assumes a constant $\Delta G^{\ddagger}$, reveals that the reactions with the Cu complexes are 55000 to 250000 times more rapid than for the TpRu system. These results suggest

Figure 4. Depiction of the orientation of phenyl substituents of anilido ligands of [(SIPr)Cu(NHPh)] (**3**) (left), [(IPr)Cu(NHPh)] (**2**) (middle), and [(dtbpe)Cu(NHPh)] (**1**) (right) with most atoms removed.

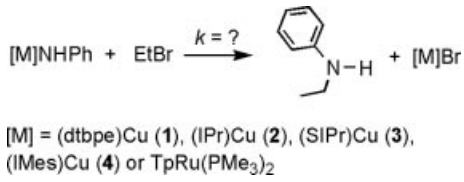
that the $L_nCu–X$ (X = anionic heteroatomic ligand) are highly reactive and indicate that they may be useful for the development of Cu-mediated catalytic organic syntheses.



Scheme 27. Nucleophilic substitution reaction of amido complexes with bromoethane.

Table 1. Kinetic data for the reaction of bromoethane with [(IPr)-Cu(NHPh)] (**2**), [(SIPr)Cu(NHPh)] (**3**), [(IMes)Cu(NHPh)] (**4**), [(dtbpe)Cu(NHPh)] (**1**), and [TpRu($PMe_3$)$_2$(NHPh)] (see Scheme 27). All reactions were carried out at room temperature except [TpRu($PMe_3$)$_2$NHPh], which was performed at 80 °C.

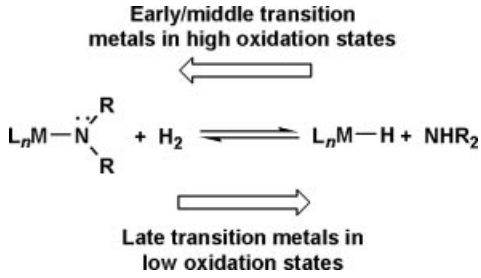
[a] Minutes. [b] kJ/mol. [c] Hours.

In general, the thermodynamics of reactions between transition-metal amido (and related) complexes and dihydrogen to form metal–hydride complexes and free amines appear to be dependent upon the identity of the metal center. Early and middle transition-metal systems in relatively high oxidation states tend to favor metal–amido/dihydrogen while late transition-metal systems in low oxidation states exhibit a trend toward the metal–hydride/free amine (Scheme 28 and see below for examples). This trend can be rationalized by increased metal–amido bond energies due to amido-to-metal π-donation for metal centers in relatively high oxidation states. For late transition-metal centers in low oxidation states the π-bonding is disrupted and the M–$N_{amido}$ BDE is presumably decreased relative to systems in which π-bonding is present. The [(NHC)Cu(NHPh)] systems exhibit reactivity that contrasts these general trends. For example, [(IPr)Cu(NHPh)] (**2**) does not react with dihydrogen, while [[(IPr)Cu(μ-H)]$_2$] rapidly reacts with aniline to form dihydrogen and complex **2** (Scheme 29), reactivity which is consistent with an *early* transition-metal system. Furthermore, [(IPr)Cu(Ph)] reacts with aniline to produce benzene and [(IPr)Cu(NHPh)] with an equilibrium constant > 1000 (Scheme 30).

Examples of systems that follow the relative thermodynamics for reactions of amido complexes and dihydrogen (see paragraph above) include the conversion of [Cp*Ru($PMe_3$)$_2$($NPh_2$)] (Cp* = pentamethylcyclopentadienyl) and dihydrogen to free amine and Ru–hydride complexes,[157] reaction of [(PCP)Ru(CO)$NH_2$] and dihydrogen to produce free ammonia and Ru–hydride complexes,[29] release of aniline and formation of a Pt–dihydride



Scheme 28. Equilibrium trends between metal–amido/dihydrogen and metal–hydride/amine based on the identity and oxidation state of the transition metal.

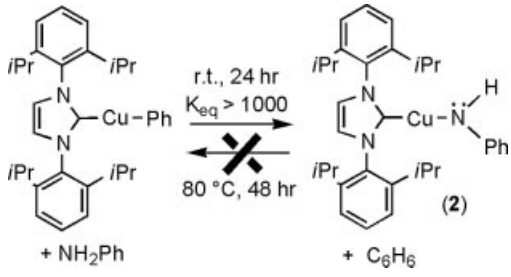

Scheme 30. Observed equilibrium for Cu–phenyl/aniline and Cu–anilido/benzene.

upon combination of *trans*-[($PEt_3$)$_2$Pt(H)NHPh] and dihydrogen,[158] and reaction of Cp*$_2$M(H)$_2$ (M = Zr or Hf) with ammonia to produce dihydrogen and the corresponding parent amido complexes.[159] In contrast to the late transition metal and low oxidation state $Ru^{II}$ and $Pt^{II}$ systems, complex **2** favors the Cu–amido and dihydrogen. The conversion of [(IPr)Cu(Ph)] and aniline to [(IPr)Cu(NHPh)] (**2**) and benzene also contrasts reactivity observed with another late transition-metal anilido complex. [(PCP)Ir(H)(Ph)] and free $NH_2Ph$ are thermally favored over [(PCP)-Ir(H)(NHPh)] and free $C_6H_6$ with $K_{eq}$ = 105.[160] In contrast, the [(IPr)$Cu^{I}$] fragment demonstrates a thermodynamic propensity for the formation of a Cu–NHPh bond and free benzene, which seems to suggest a shift in the relative magnitude of M–H/M–$N_{anilido}$ and M–$C_{phenyl}$/M–$N_{anilido}$ BDEs from established norms.

Analysis of the Cu–$N_{amido}$ BDE using B3LYP/CEP-31G(d) calculations provides a rationale for the observed equilibria. For [(IPr)Cu(NHPh)], the Cu–$N_{amido}$ BDE is

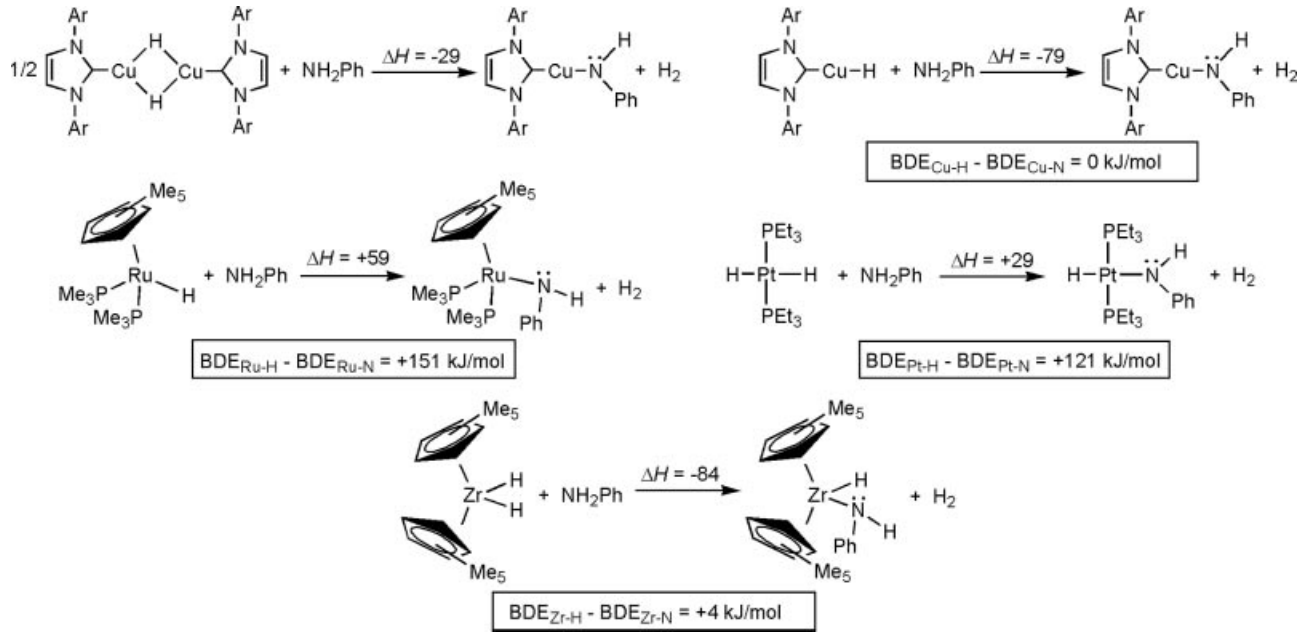

Scheme 31. DFT calculated changes in enthalpy (kJ/mol) for conversion of transition-metal–hydride complexes and aniline to transition-metal–anilido complexes and dihydrogen.

calculated to be 364 kJ/mol. In comparison, the calculated M–$N_{amido}$ BDEs of [Cp*$_2$Zr(NHPh)(H)] (284 kJ/mol; Cp* = pentamethylcyclopentadienyl), *trans*-[$(Et_3P)_2$Pt(H)(NHPh)] (180 kJ/mol), and [Cp*Ru$(PMe_3)_2$NHPh] (146 kJ/mol) are substantially weaker (Scheme 31).[23] The difference in M–$N_{amido}$ BDE for the Zr and Pt/Ru systems is easily rationalized by, at least in part, the π-bonding component of the Zr–$N_{amido}$ bond, which is likely to be negligible for $Pt^{II}$ and octahedral $Ru^{II}$. The large BDE for the Cu–$N_{amido}$ is more difficult to rationalize, and future studies will address whether this is an anomaly or a central feature of $Cu^{I}$ systems with anionic heteroatomic ligands. *At this point it can be stated that in terms of ground-state energetics the Cu–NHPh systems appear similar to early/middle transition-metal systems in high oxidation states. In contrast, the reactivity of Cu–NHPh related systems is more reminiscent of highly nucleophilic complexes in low oxidation states.*

The hydroamination or hydroalkoxylation of electron-deficient olefins under acidic or basic conditions is known; however, such reactions typically require relatively harsh conditions, including high temperatures that are often incompatible with functional groups and do not allow the control of regio-, chemo- or stereoselectivity.[161] In contrast, transition-metal-catalyzed reactions offer the promise of more ambient conditions and greater control over product selectivity. For example, both early and late transition-metal complexes as well as lanthanide systems have been developed for olefin hydroamination, with many of these systems limited to specific substrates or more facile intramolecular reactions.[162–167]

Copper catalysts for the enantioselective conjugate addition of carbon-based nucleophiles have been reported,[168] and we have become interested in related reactions for hetero-conjugate additions. $Cu(OTf)_2$ systems have been recently reported to catalyze the hydroamination of olefins.[169] The [(NHC)Cu(X)] and [(dtbpe)Cu(X)] (X = anionic heteroatomic ligand) complexes catalyze the conjugate

addition of N–H and O–H bonds across the C=C bonds of electron-deficient olefins (Table 2 and Table 3).[37] In all examples studied the reactions are regioselective for the "anti-Markovnikov" product (Scheme 32). Under conditions identical to catalysis some of the substrates undergo transformation in the absence of a Cu catalyst; however, comparison of reaction rates clearly indicates that the Cu complexes are serving as catalysts. For comparison, Table 2 and Table 3 depict results from control experiments under identical reaction conditions and times for the Cu-catalyzed transformations.

Table 3. Hydroalkoxylation and hydroaryloxylation of olefins and uncatalyzed control reactions.

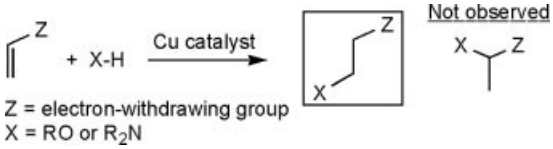
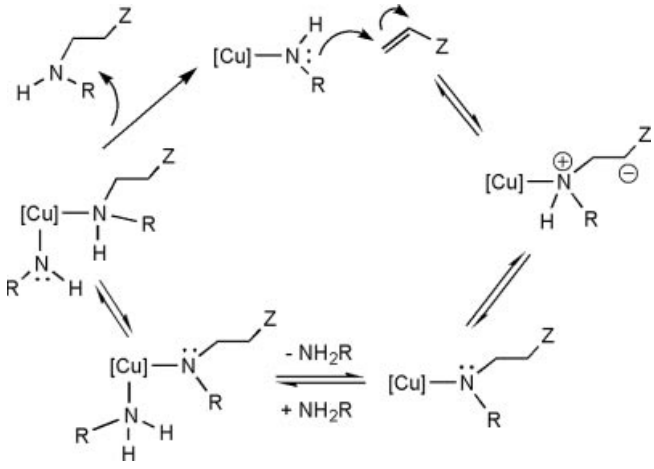
[a] All reactions performed with 5 mol-% catalyst in $C_6D_6$. [b] % Conversions determined by $^1H$ NMR spectroscopy. [c] Control experiments are reported after similar reaction times to catalyzed variants and are given in % conversion. [d] Transesterification observed. [e] Addition of *t*BuNC (1 equiv. based on EtOH) allows observation of hydroalkoxylation. [f] Approximately 10% transesterification also observed.



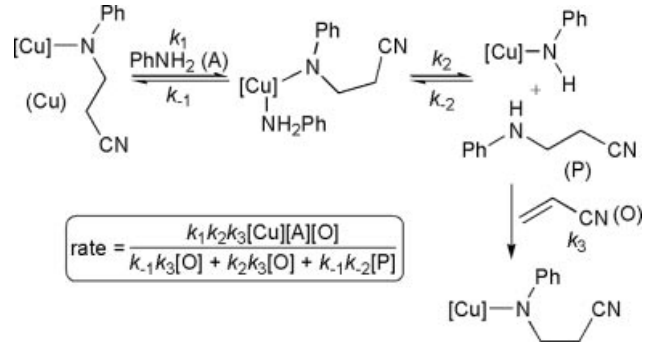
Scheme 32. Cu-catalyzed additions of N–H and O–H across C=C bonds of electron-deficient olefins are selective for the "anti-Markovnikov" products.

In general, reactions that incorporate stronger nucleophiles react more rapidly. For example, among amines and alcohols, catalysis is generally slower and less broad in scope for alcohols than for amines. Amongst a series of amines, alkylamines react more rapidly than arylamines. Table 2 shows comparative reactions for aniline and alkylamines with acrylonitrile. The exception to this generalization is the sterically bulky *t*BuNH$_2$, which reacts more slowly with acrylonitrile than aniline.

We have recently proposed a reaction mechanism for the copper-catalyzed hydroamination (and related reactions) of electron-deficient olefins in which initial intermolecular nucleophilic addition of the amido ligand to the olefin produces an unobserved zwitterionic intermediate.[38] Subsequent proton transfer yields a new copper amido complex and reaction with aniline (presumably via coordination to Cu) yields a free organic product and regenerates the original Cu system (Scheme 33). The hydroalkoxylation reactions are proposed to proceed through a similar mechanism with the exception that product formation likely originates from the zwitterionic intermediate or a linkage isomer Cu–alkyl complex. The relative rate of catalysis is consistent with a nucleophilic addition pathway. For example, reactivity decreases in the order N(H)*n*Pr > N(H)Ph > OEt > OPh for reactions with acrylonitrile. It is also possible that olefin coordination precedes N–C or O–C bond formation; however, this pathway seems unlikely as it does not necessarily account for the observed anti-Markovnikov regioselectivity. Furthermore, the addition of coordinating *t*BuNC slightly accelerates the rate of catalysis for the addition of aniline to acrylonitrile. If olefin coordination precedes N–C bond formation, competition for coordination between acrylonitrile and the isocyanide would be anticipated to re-



Scheme 33. Proposed catalytic cycle for Cu–amido catalytic hydroamination reactions.



Scheme 34. Proposed mechanism and derived rate law for addition of aniline to acrylonitrile catalyzed by [(IPr)Cu(NHPh)] {[Cu] = (IPr)Cu in scheme, A = aniline, O = acrylonitrile, P = product}.

duce the rate of catalysis. In addition, reaction of [(IPr)Cu(NHPh)] and acrylonitrile produces [(IPr)CuN(Ph)($CH_2CH_2CN$)]. Finally, kinetic studies (using initial rates) for the addition of aniline to acrylonitrile reveal that the catalysis is first order in Cu catalyst and aniline, 0.7 order in acrylonitrile, and inhibited by the presence of organic product. These results are consistent with the proposed mechanism and derived rate law shown in Scheme 34 in which the rate-determining step is the reaction with acrylonitrile.[37]

## Summary and Future Outlook

Work presented herein and reported by others have demonstrated that anionic heteroatomic ligands coordinated to metal centers in low oxidation states results in highly reactive heteroatomic ligands. Such substrates are potentially useful for catalytic polymerizations as well as transformations of small molecules. Using well-defined $Ru^{II}$ and $Cu^{I}$ systems, we have demonstrated controlled stoichiometric and catalytic N–C bond formation using polar substrates, N–C and O–C bond formation using olefins as well as metal-mediated activation of dihydrogen and carbon–hydrogen bonds. Mechanistic studies indicate that, in some cases, the combination of a Lewis acidic metal center and nucleophilic/basic heteroatomic ligand form the foundation of these transformations.

Future efforts will be directed toward continued development of catalysts using these, and related, complexes. For example, we are presently pursuing strategies to extend the scope and selectivity of Cu-catalyzed hydroamination and hydroalkoxylation reactions as well as to develop other methods of N–C and O–C bond formation using these reactive Cu systems. Furthermore, efforts toward using the 1,2-addition of C–H bonds across metal–heteroatom bonds as a key step for C–H functionalization sequences are continuing. In terms of the reactivity of anionic heteroatomic ligands, future work will be directed toward an increased understanding of the impact of ancillary ligands, metal identity, and metal oxidation state on accessible reactions.

## Acknowledgments

The National Science Foundation, the Alfred P. Sloan Foundation, the Office of Basic Energy Sciences, United States Department of Energy, and the Petroleum Research Fund administered by the American Chemical Society are gratefully acknowledged for support of this work. T. B. G. also gratefully acknowledges the efforts and dedication of the students, postdocs and collaborators who have worked on these projects.

# New (1-Phosphanylferrocen-1′- and -2-yl)methyl-Linked Diaminocarbene Ligands: Synthesis and Rhodium(I) Complexes

**Agnès Labande,*[a] Jean-Claude Daran,[a] Eric Manoury,[a] and Rinaldo Poli*[a]**

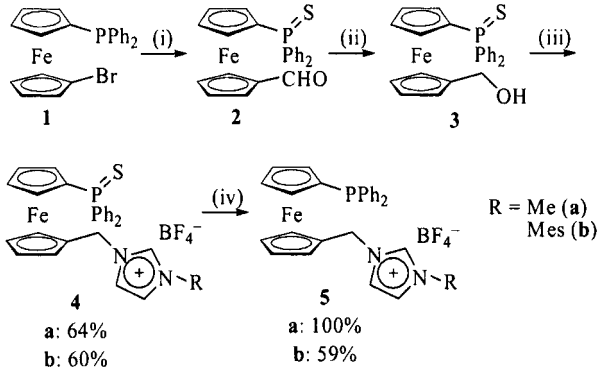
**Keywords:** Carbene ligands / Phosphane ligands / Ferrocenes / Rhodium

Two ferrocenylmethanols, [1′-(diphenylthiophosphanyl)-ferrocen-1-yl]methanol (**3**) and [2-(diphenylthiophosphanyl)-ferrocen-1-yl]methanol (**6**), have been converted in one step into the 1,1′- and 1,2-ferrocenediyl-linked thiophosphane/*N*-R-imidazolium salts **4a**,**b** and **7a**,**b** (**a**: R = Me; **b**: R = 2,4,6-$Me_3C_6H_2$ or Mes). This straightforward method allows the linkage of an imidazolium group to a ferrocene unit with a nonsubstituted methylene bridge. After desulfurisation of the phosphane group, the ligands reacted with an $Rh^I$ precursor, in the presence of *t*BuOK, to give cationic complexes **9a**,**b** and **10a**,**b**. All compounds were characterised by elemental analysis, NMR spectroscopy and mass spectrometry. The molecular structures of compounds **4a**, **7a** and **9a** were determined by X-ray crystallography.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

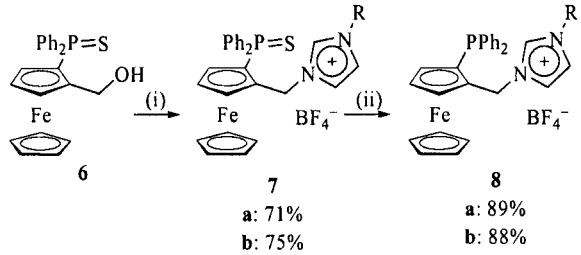
The chemistry of N-heterocyclic carbenes (NHCs) has experienced a very rapid development over the past ten years.[1] They have found many applications in catalysis, since the corresponding transition metal complexes have proven to be very active, robust and generally air-stable.[2] Ligands associating an NHC and a phosphane have also shown very interesting properties,[3] in particular for C–C coupling reactions catalysed by palladium or nickel.[4]

To date, there are only two synthetic methods allowing the preparation of ferrocenediyl-linked phosphane/NHC ligands with an aryl (or ferrocenyl) substituent on the imidazole moiety.[5,6] However, the carbon atom situated in α-position to the Cp ring has a methyl substituent in both cases. To the best of our knowledge, there is no precedent in the literature for 1,1′-disubstituted ferrocenediyl phosphane/imidazolium ligands. On the other hand, the fundamental difference between our 1,2-disubstituted ligands and previously reported ligands is that the former possess only planar chirality, whereas the latter have both planar and central chirality.[5,6] Thus, it becomes possible to study the specific effect of planar chirality in asymmetric catalytic reactions. We present here a new synthetic method for 1,1′- and racemic 1,2-disubstituted ferrocenediyl phosphane/imidazolium ligands, which are precursors of phosphane/NHCs.

The precursors for the introduction of the imidazolium moiety are alcohols **3** (Scheme 1) and **6** (Scheme 2). The synthesis of racemic (as well as enantiomerically pure) alcohol **6** is already well known.[7,8] We have adapted this method to prepare the new alcohol **3**. It was successfully obtained in two steps from known 1-bromo-1′-(diphenylphosphanyl)ferrocene,[9] with satisfactory yields.



Scheme 1. Synthesis of 1,1′-ferrocenediyl ligands. i. a) *n*BuLi, THF, –25 °C, b) dmf, –25 °C, c) $S_8$, $CH_2Cl_2$, 40 °C (70%); ii. $NaBH_4$, toluene/NaOH, 0 °C (88%); iii. a) $HBF_4$, $CH_2Cl_2$, room temp., b) *N*-R-imidazole; iv) Raney Ni, MeCN, room temp. or 80 °C.



Scheme 2. Synthesis of 1,2-ferrocenediyl ligands. i. a) $HBF_4$, $CH_2Cl_2$, room temp., b) *N*-R-imidazole; ii) Raney Ni, MeCN, room temp. or 80 °C.

Procedures for introducing an *N*-substituted imidazole ring on a ferrocenyl unit can involve the displacement of a chloride,[10] an acetate,[6,11] or a dimethylamino group.[5] Bolm et al. described the efficient conversion of ferrocenyl alcohols into corresponding imidazolium compounds by a two-step procedure.[12,13] However, this method has not been applied so far to introduce aryl or tertiary alkyl groups. Here, the imidazolium functionality has been introduced in one-pot procedure from the alcohol, according to a protocol developed earlier in our group for the introduction of various nucleophiles on 1,2-disubstituted ferrocenediyl phosphanes.[14] The α-carbocation is generated with a strong acid and reacts with the *N*-R-imidazole (**a**: R = Me; **b**: R = 2,4,6-$Me_3C_6H_2$ or Mes). This method allowed us to introduce equally well imidazolium groups bearing a primary alkyl or an aryl substituent. The reactions are clean, very rapid and high-yielding (Schemes 1 and 2).[15] The structure of the intermediates **4a** and **7a** was confirmed by X-ray diffraction methods (Figure 1). The bond lengths and angles in both compounds are all within the expected range. The imidazolium moiety is *exo* with respect to the ferrocene unit, and slightly tilted towards the diphenylphosphanyl group in the case of **7a**. In **4a**, the packing is governed by C–H···π interactions involving the H(64) atom of the imidazolium group and the centroid of the symmetry-related Cp ring bearing the imidazolium group [C(64)–H(64)···Cg2$^{i}$: C(64)–H(64) 0.95 Å; H(64)···Cg2$^{i}$ 2.74 Å; C(64)···Cg2$^{i}$ 3.562(5) Å; C(64)–H(64)···Cg2$^{i}$ 144.8°; symmetry code (i): $-x + 1, -y + 1, -z + 1$], leading to the formation of a centrosymmetric pseudo dimer. The two molecules within the asymmetric unit in **7a** are also connected through weak C–H···π interactions involving the H(14) atom of the substituted Cp ring of one molecule and the centroid of the C(211)–C(216) phenyl ring of the other one [C(14)–H(14)···Cg3: C(14)–H(14) 0.93 Å; H(14)···Cg3 3.13 Å; C(14)···Cg3 3.755(3) Å; C(14)–H(14)···Cg3 126.5°]. In **7a**, the imidazolium ring and one of the phenyl rings [C(121)–C(126); C(221)–C(226)] interact through an offset π–π stacking with a plane-to-plane distance of 3.566(2) Å [3.438(2) Å], a centroid-to-centroid distance of 3.9217(3) Å [3.6301(3) Å] and an offset angle of 24.6° [18.7°]. The sulfur atom in **7a** is pointing towards the iron atom, as has been seen with similar 1,2-disubstituted ferrocenediyl ligands.[8]

Mild reaction conditions were then required for the phosphane deprotection, compatible with the imidazolium moiety. After several attempts, we found that the use of Raney nickel in acetonitrile gave the best results.[16]

(Carbene)rhodium(I) complexes were obtained by deprotonation of the imidazolium salts in the presence of potassium *tert*-butoxide and $[RhCl(cod)]_2$ in THF, followed by chloride abstraction (Scheme 3). The latter step could be carried out with either $NaBF_4$ in $CH_2Cl_2/H_2O$, or $AgBF_4$ in $CH_2Cl_2$. The silver reagent results in a faster abstraction process while it does not oxidize the ferrocene unit. Room-temperature conditions for the deprotonation step resulted in good yields (75%) for product **9a**, but less satisfactory results were obtained in other cases (i.e. 32% for **10b**). However, carrying out the deprotonation at –78 °C raised the yield of **10b** to 77%. This shows that the bulky imidazolium substituent does not negatively affect the coordination process. Good yields (81%) were also obtained for **9b** when using the low temperature deprotonation protocol, whereas the yield of **9a** was lowered (62%). While the products with the 1,1′-disubstituted ligands, **9a**,**b**, were obtained selec-

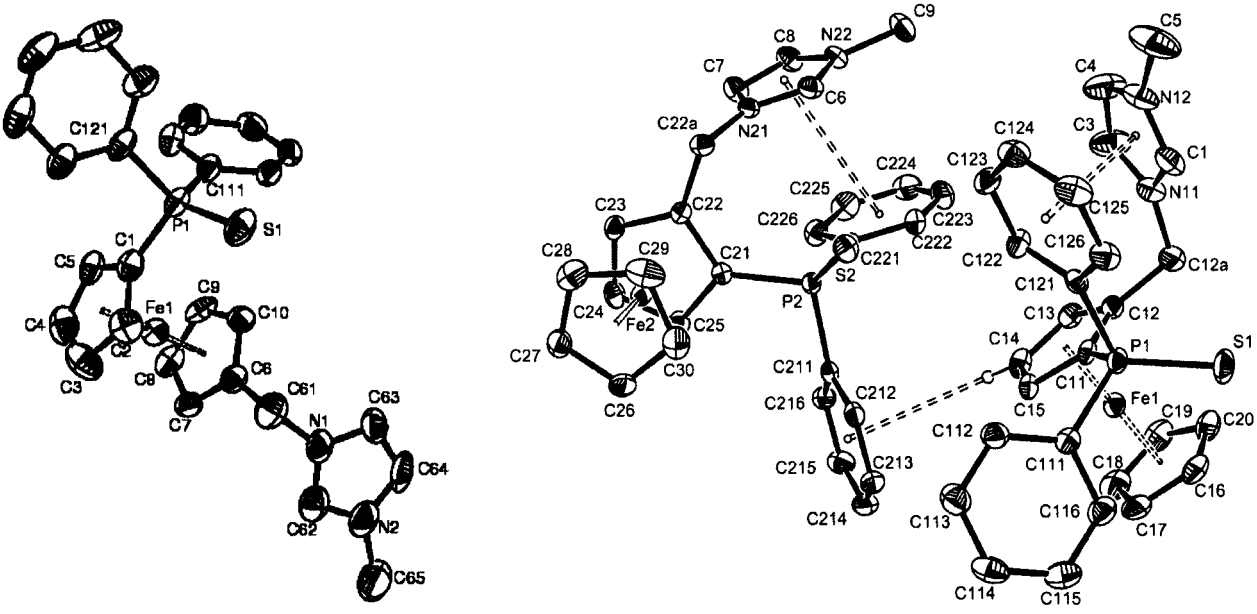

Figure 1. Molecular views of compounds **4a** (left) and **7a** (right) with atom labelling scheme. Ellipsoids are plotted at the 50% level. H atoms have been omitted for clarity. Selected bond lengths [Å] and bond angles [°]: **4a**: C(1)–P(1) 1.790(3), C(62)–N(1) 1.324(5), C(62)–N(2) 1.313(5), C(63)–C(64) 1.330(6); N(2)–C(62)–N(1) 108.6(3); **7a**: C(11)–P(1) 1.792(3), C(1)–N(11) 1.317(3), C(1)–N(12) 1.309(4), C(3)–C(4) 1.333(5); N(11)–C(1)–N(12) 109.7(3); C(21)–P(2) 1.801(3), C(6)–N(21) 1.316(3), C(6)–N(22) 1.323(3), C(7)–C(8) 1.344(4); N(21)–C(6)–N(22) 109.4(3).

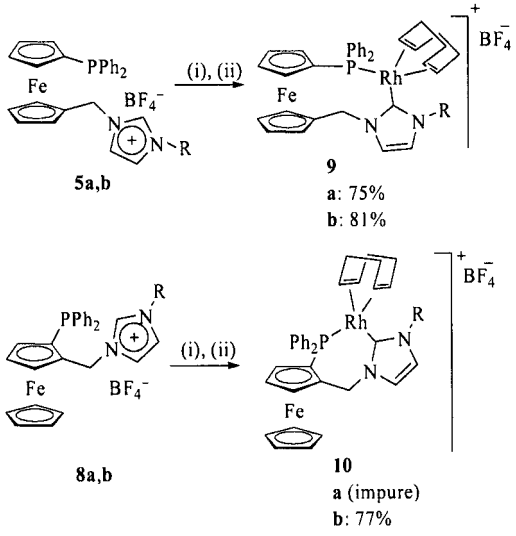
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tively, the reactions with the 1,2-disubstituted ligands yielded by-products. The selectivity for **10b** was almost total,[17] however, complex **10a** was obtained along with another carbene/phosphane complex in a 85:15 ratio.[18,19] It is reasonable to think that, in the case of 1,2-disubstituted ligands, the selectivity is affected by the steric encumbrance of the imidazolium substituent. All complexes are stable in air and could be purified by filtration through silica gel. The structure of complex **9a** was confirmed by X-ray diffraction methods (see Figure 2). The structure shows a square-planar geometry with the carbene and phosphane donors in a *cis* arrangement. The bond lengths and angles are again within the expected range for this kind of complexes. The Rh–carbene distance is in accordance with what Seo obtained with a very similar complex, although the Rh–P distance is slightly longer in our case [2.3345(8) Å instead of 2.2935(10) Å in Seo's $Rh^I$ complex, which has two NHC/phosphane ligands coordinated to the metal centre].[5] However, we do not observe any significant lenghtening of the Rh–C bonds *trans* to the carbene [Rh(1)–CG1], with respect to the other Rh–C bonds [Rh(1)–CG2], as is commonly observed for bifunctional NHC ligands.[5,13] Finally, no tilting of the Cp rings can be observed upon complexation of the ligand to the rhodium centre [the angles between the two least-squares Cp planes are 4.66(29)° for **4a** and 3.15(24)° for **9a**].



Scheme 3. Synthesis of Rh complexes. i. *t*BuOK, $[Rh(cod)Cl]_2$, THF; ii. $NaBF_4$, $CH_2Cl_2/H_2O$, room temp. or $AgBF_4$, $CH_2Cl_2$, room temp.

Preliminary tests have been carried out to evaluate the activity of complexes **9a**, **9b** and **10b** (racemic mixture) for the hydrosilylation of ketones. The reaction of diphenylsilane with acetophenone was carried out in dichloromethane or THF at room temperature, with 2 mol-% of catalyst (Table 1). The first results show that THF is a better solvent, despite the low solubility of complexes **9a** and **9b**, and that the complex bearing a 1,2-disubstituted ligand is more active. All complexes show a moderate activity, compared with other literature benchmarks.[13,20]

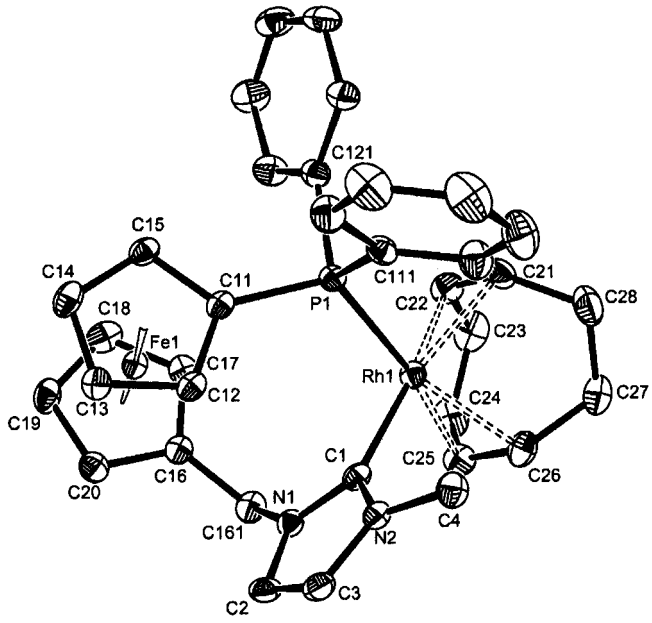


Figure 2. Molecular view of compound **9a** with atom labelling scheme. Ellipsoids are plotted at the 50% level. H atoms have been omitted for clarity. Selected bond lengths [Å] and bond angles [°]: Rh(1)–C(1) 2.047(3), Rh(1)–P(1) 2.3345(8), Rh(1)–C(21) 2.215(3), Rh(1)–C(22) 2.231(3), Rh(1)–C(25) 2.220(3), Rh(1)–C(26) 2.217(3), Rh(1)–CG1 2.1140(3), Rh(1)–CG2 2.1091(3), N(1)–C(1) 1.359(4), N(2)–C(1) 1.357(4), C(2)–C(3) 1.338(4); C(1)–Rh(1)–P(1) 90.83(8), C(1)–Rh(1)–CG1 175.91(8), C(1)–Rh(1)–CG2 90.46(8), CG1–Rh(1)–P(1) 93.26(2), CG2–Rh(1)–P(1) 174.69(2), CG2–Rh(1)–CG1 85.450(10), N(1)–C(2)–N(2) 104.5(2). CG1 and CG2 denote the C(21)–C(22) centroid and the C(25)–C(26) centroid, respectively.

Table 1. Hydrosilylation of acetophenone with diphenylsilane. Conditions: 1 equiv. of acetophenone, 1.1 equiv. of diphenylsilane, 2 mol-% of catalyst, room temperature.

| Entry | Complex | Solvent | *t* (d) | Conversion (%)[a] |
|---|---|---|---|---|
| 1 | **9a** | $CH_2Cl_2$ | 7 | 17 |
| 2 | **9a** | THF | 3 | 46 |
| 3 | **9b** | THF | 3 | 49 |
| 4 | **10b** | THF | 3 | 67 |

[a] Determined by $^1H$ NMR spectroscopy after hydrolysis of the silylated intermediate.

In conclusion, we have prepared new ferrocenediyl phosphane/imidazolium ligands by a general and effective method. Further tests will be carried out to evaluate the activity of the $Rh^I$ complexes in various catalytic reactions. Enantiomerically pure 1,2-disubstituted ligands will also be prepared and tested in the asymmetric version of the reactions. Results will be published in due course.

## Experimental Section

**General:** All reactions were carried out under dry argon using Schlenk glassware and vacuum-line techniques. Solvents for syntheses were dried and degassed by standard methods before use. *N*,*N*-Dimethylformamide (dmf) was purified by distillation from $CaH_2$. Spectra were recorded with a Bruker AM250, a Bruker AV300 or a Bruker AV500 spectrometer. All spectra were recorded in $CDCl_3$,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

unless otherwise stated. Mass spectra were obtained from acetonitrile solutions with a TSQ7000 instrument from ThermoElectron. All new compounds described were fully characterised by $^{1}H$, $^{13}C$, and $^{31}P$ NMR spectroscopy, elemental analysis and mass spectrometry. 1,1′-dibromoferrocene and 1-bromo-1′-(diphenylphosphanyl)-ferrocene were prepared according to literature procedures.[9]

**General Procedures for the Preparation of Imidazolium Salts:** To a solution of **3** (100 mg, 0.23 mmol) in degassed dichloromethane (5 mL) was quickly added $HBF_4$ (35 μL, 54 wt-% in $Et_2O$), immediately followed by an *N*-substituted imidazole (0.35 mmol). The mixture was washed with 2 M aq. HCl, water, satd. aq. $NaHCO_3$ and water again. The organic phase was dried ($MgSO_4$), filtered and concentrated in vacuo. Methyl-substituted salts: the residue was taken up in dichloromethane (1 mL), diethyl ether was added and the orange precipitate was filtered, washed with diethyl ether and dried in vacuo to give a yellow-orange solid. Mesityl-substituted salts: the residue was purified by column chromatography on silica gel (eluent: $CH_2Cl_2$/acetone, 9:1) to give a yellow-orange solid. Similar yields were obtained starting from 500 mg of **3**.

**Imidazolium Salt 4a:** 86 mg, 64% yield. Single crystals suitable for X-ray diffraction studies were obtained by slow concentration of a dichloromethane solution. $C_{27}H_{26}BF_4FeN_2PS$ (584.21): calcd. C 55.51, H 4.49, N 4.80; found C 54.98, H 4.16, N 4.55. $^{1}H$ NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 8.65 (s, 1 H, NC*H*N$^+$), 7.79–7.72 (m, 4 H, $PPh_2$), 7.59–7.47 (m, 6 H, $PPh_2$), 7.29 (s, 1 H, HC=C Im$^+$), 7.27 (s, 1 H, HC=C Im$^+$), 5.09 (s, 2 H, Cp), 4.69 (s, 2 H, Cp), 4.54 (s, 2 H, Cp or C$H_2$Im$^+$), 4.50 (s, 2 H, Cp or C$H_2$Im$^+$), 4.16 (s, 2 H, Cp), 3.88 (s, 3 H, C$H_3$Im$^+$) ppm. $^{13}C\{^{1}H\}$ NMR (75.5 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 135.5 (NCN$^+$), 134.2 (d, $J_{P,C}$ = 87.0 Hz, 2× quat. $PPh_2$), 131.55 (2× $PPh_2$), 131.53 (d, $J_{P,C}$ = 10.6 Hz, 4× $PPh_2$), 128.4 (d, $J_{P,C}$ = 12.5 Hz, 4× $PPh_2$), 123.6 (C=C Im$^+$), 121.8 (C=C Im$^+$), 80.4 (quat. Cp$^C$), 76.2 (d, $J_{P,C}$ = 96.9 Hz, quat. Cp$^P$), 74.1 (d, $J_{P,C}$ = 12.4 Hz, 2× Cp$^P$), 73.1 (d, $J_{P,C}$ = 10.0 Hz, 2× Cp$^P$), 71.7 (2× Cp$^C$), 71.3 (2× Cp$^C$), 49.1 (*C*$H_2$Im$^+$), 36.3 (*C*$H_3$Im$^+$) ppm. $^{31}P\{^{1}H\}$ NMR (81.0 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 41.0 ppm. MS (ESI): *m*/*z* (%) = 497 (70) [M$^+$], 415 (100) [M$^+$ – $C_4H_6N_2$].

**Imidazolium Salt 4b:** 96 mg, 60% yield. $C_{35}H_{34}BF_4FeN_2PS$ (688.36): calcd. C 61.07, H 4.98, N 4.07; found C 60.31, H 4.71, N 3.91. $^{1}H$ NMR (300 MHz, $CD_3CN$, 25 °C): $\delta$ = 8.54 (s, 1 H, NC*H*N$^+$), 7.80–7.73 (m, 4 H, $PPh_2$), 7.60–7.50 (m, 7 H, $PPh_2$ + HC=C Im$^+$), 7.40 (s, 1 H, HC=C Im$^+$), 7.11 (s, 2 H, Mes), 5.15 (br. s, 2 H, C$H_2$Im$^+$), 4.71 (br. s, 2 H, Cp), 4.55 (br. s, 2 H, Cp), 4.51 (br. s, 2 H, Cp), 4.18 (br. s, 2 H, Cp), 2.36 (s, 3 H, *p*-$CH_3$ Mes), 2.00 (s, 6 H, *o*-$CH_3$ Mes) ppm. $^{13}C\{^{1}H\}$ NMR (75.5 MHz, $CD_3CN$, 25 °C): $\delta$ = 141.2 (quat. Mes), 135.8 (NCN$^+$), 134.7 (2× quat. Mes), 134.4 (d, $J_{P,C}$ = 87.0 Hz, 2× quat. $PPh_2$), 131.7 (d, $J_{P,C}$ = 2.9 Hz, 2× $PPh_2$), 131.4 (d, $J_{P,C}$ = 10.7 Hz, 4× $PPh_2$), 131.0 (quat. Mes), 129.5 (2× C-H Mes), 128.5 (d, $J_{P,C}$ = 12.5 Hz, 4× $PPh_2$), 124.2 (C=C Im$^+$), 122.7 (C=C Im$^+$), 80.7 (quat. Cp$^C$), 76.1 (d, $J_{P,C}$ = 97.3 Hz, quat. Cp$^P$), 74.0 (d, $J_{P,C}$ = 12.4 Hz, 2× Cp$^P$), 73.2 (d, $J_{P,C}$ = 10.1 Hz, 2× Cp$^P$), 71.6 (2× Cp$^C$), 71.2 (2× Cp$^C$), 49.2 (*C*$H_2$Im$^+$), 20.2 (*p*-$CH_3$ Mes), 16.6 (2× *o*-$CH_3$ Mes) ppm. $^{31}P\{^{1}H\}$ NMR (121.5 MHz, $CD_3CN$, 25 °C): $\delta$ = 40.6 ppm. MS (ESI): *m*/*z* (%) = 601 (100) [M$^+$], 415 (100) [M$^+$ – $C_{12}H_{14}N_2$].

**Imidazolium Salt 7a:** 96 mg, 71% yield. Single crystals suitable for X-ray diffraction studies were obtained by slow diffusion of diethyl ether into a THF solution. $C_{27}H_{26}BF_4FeN_2PS$ (584.21): calcd. C 55.51, H 4.49, N 4.80; found C 51.53, H 3.90, N 4.32. $^{1}H$ NMR (500 MHz, $CDCl_3$, 25 °C): $\delta$ = 8.33 (s, 1 H, NC*H*N$^+$), 7.73–7.33 (m, 10 H, $PPh_2$), 6.98 (br. s, 1 H, HC=C Im$^+$), 6.87 (br. s, 1 H, HC=C Im$^+$), 6.41 (br. s, 1 H, C$H_2$Im$^+$), 5.15–5.04 (m, 2 H, C$H_2$Im$^+$ + Cp), 4.52 (br. s, 1 H, Cp), 4.41 (br. s, 5 H, Cp′), 3.81 (br. s, 1 H, Cp), 3.52 (br. s, 3 H, C$H_3$Im$^+$) ppm. $^{13}C\{^{1}H\}$ NMR (125.8 MHz, $CDCl_3$, 25 °C): $\delta$ = 135.9 (NCN$^+$), 134.0 (d, $J_{P,C}$ = 85.6 Hz, 2× quat. $PPh_2$), 132.2–131.8 (m, 5× $PPh_2$), 131.4 (d, $J_{P,C}$ = 10.1 Hz, 2× $PPh_2$), 128.7 (d, $J_{P,C}$ = 12.6 Hz, $PPh_2$), 128.45 (d, $J_{P,C}$ = 12.6 Hz, 2× $PPh_2$), 123.6 (C=C, Im$^+$), 122.4 (C=C, Im$^+$), 83.4 (d, $J_{P,C}$ = 11.3 Hz, quat. Cp), 77.5–77.0 (Cp + $CDCl_3$), 76.3 (d, $J_{P,C}$ = 11.3 Hz, Cp), 74.3 (d, $J_{P,C}$ = 94.4 Hz, quat. Cp), 71.4 (Cp′), 71.3 (Cp), 48.2 (*C*$H_2$Im$^+$), 37.0 (*C*$H_3$Im$^+$) ppm. $^{31}P\{^{1}H\}$ NMR (202.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 40.7 ppm. MS (ESI): *m*/*z* (%) = 497 (37) [M$^+$], 415 (100) [M$^+$ – $C_4H_6N_2$].

**Imidazolium Salt 7b:** 121 mg, 76% yield. $C_{35}H_{34}BF_4FeN_2PS$ (688.36): calcd. C 61.07, H 4.98, N 4.07; found C 60.34, H 4.93, N 3.98. $^{1}H$ NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 8.67 (s, 1 H, NC*H*N$^+$), 7.84–7.77 (m, 2 H, $PPh_2$), 7.58–7.28 (m, 9 H, $PPh_2$ + HC=C Im$^+$), 6.92 (s, 2 H, Mes), 6.71 (s, 1 H, HC=C Im$^+$), 6.66 (d, $J_{H,H}$ = 14.3 Hz, 1 H, C$H_2$Im$^+$), 5.58 (d, $J_{H,H}$ = 14.3 Hz, 1 H, C$H_2$Im$^+$), 5.31 (br. s, 1 H, Cp), 4.56 (br. s, 1 H, Cp), 4.35 (s, 5 H, Cp′), 3.96 (br. s, 1 H, Cp), 2.30 (s, 3 H, *p*-$CH_3$ Mes), 1.84 (br. s, 3 H, *o*-$CH_3$ Mes), 1.68 (br. s, 3 H, *o*-$CH_3$ Mes) ppm. $^{13}C\{^{1}H\}$ NMR (75.5 MHz, $CDCl_3$, 25 °C): $\delta$ = 141.2 (quat. Mes), 136.2 (NCN$^+$), 135.0 (d, $J_{P,C}$ = 86.0 Hz, quat. $PPh_2$), 134.2 (quat. Mes), 132.3 (d, $J_{P,C}$ = 87.3 Hz, quat. $PPh_2$), 132.0 (d, $J_{P,C}$ = 11.0 Hz, 2× $PPh_2$ + d, $J_{P,C}$ = 3.1 Hz, $PPh_2$), 131.7 (d, $J_{P,C}$ = 2.9 Hz, $PPh_2$), 131.4 (d, $J_{P,C}$ = 10.5 Hz, 2× $PPh_2$), 130.5 (quat. # Molecular Recognition Utilizing Complexes with NH,NR-Stabilized Carbene Ligands

Nicole Meier,[a] F. Ekkehardt Hahn,*[a] Tania Pape,[a] Carsten Siering,[b] and Siegfried R. Waldvogel*[b]

**Keywords:** Carbene ligands / Supramolecular chemistry / Hydrogen bonds / Homogeneous catalysis / N-Heterocyclic carbenes

Tungsten complex [W(NHC)(CO)$_5$] (**1**) (NHC=NH,N-ethyl-substituted benzimidazolin-2-ylidene ligand) was prepared by transmetallation of lithiated 1-ethylbenzimidazole with the pentacarbonyltungsten complex fragment. The hydrogen-bonding ability of the carbene-NH group to substrates with carbonyl groups was investigated by NMR titration. Structural analogues to **1** with a catalytically active rhodium center show a distinct substrate-selective hydrogenation behaviour.

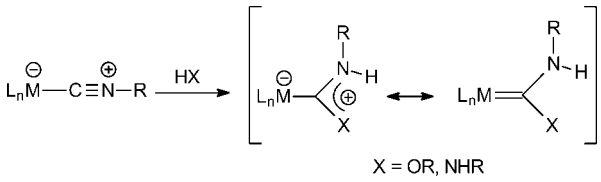
## Introduction

Complexes with NR,NR-substituted N-heterocyclic carbene ligands are important catalysts for various transformations. However, much less is known about complexes with NH,NR-substituted carbene ligands, which thus have been disregarded for catalytic applications.[1] We became interested in complexes with NH,NR-substituted carbene ligands because the NH function could act as a hydrogen-bonding donor. In a catalytically active complex bearing an NH,NR-functionalized carbene ligand this could lead to recognition and temporary binding of a substrate with a hydrogen-bonding acceptor moiety like carbonyl compounds. We report here a new one-pot synthesis of a tungsten complex with an NH,NR-stabilized carbene ligand and the observation of hydrogen bonding between the carbene-NH group and carbonyl compounds in solution.

Aminocarbenes with an NH group are obtained, when protic nucleophiles like alcohols or primary or secondary amines attack a coordinated isocyanide ligand (Scheme 1). Unintentionally and most likely unrecognized, this method was first applied as early as 1915 when Tschugajeff and Skanawy-Grigorjewa treated tetrakis(methyl isocyanide)-platinum(II) with hydrazine and isolated a red salt[2] which was very likely the first carbene complex to be synthesized in pure form, predating Fischer's seminal carbene synthesis from carbonylmetal compounds[3] by 49 years. Tschugajeff's red salt was unambiguously established as a carbene complex in 1970[4] and a number of derivatives, partially forming higher associates through hydrogen bonds, have been described recently.[5]



Scheme 1. Nucleophilic attack of a proton base HX at a coordinated isocyanide ligand.

The use of β-functionalized isocyanides, which contain both the isocyanide und the nucleophile in the same molecule, gives access to complexes with N-heterocyclic carbenes through an intramolecular 1,2-addition across the C≡N triple bond (Scheme 2). This method has been used for the preparation of a large number of complexes with NH,O-[6] and NH,NH-heterocyclic carbenes derived from aliphatic[7] and aromatic[8] isocyanides. The NH,NH-stabilized carbene ligands in **A** are easily and stepwise alkylated to give the *N*-alkyl derivatives **B** and **C** by reaction with a base and an alkyl halide.[7,8] However, the preparation of the β-functionalized isocyanides is tedious as are alternative methods for the preparation of complexes with NH,NR-stabilized carbene ligands like the metalla Ugi reaction[9] and others.[10]

## Results and Discussion

We have now found an easy one-pot synthesis leading to complexes with NH,NR-stabilized benzimidazolin-2-ylidenes which avoids the use of functionalized isocyanides. If benzimidazole is deprotonated with *n*BuLi and treated with $[W(CO)_5(THF)]$ followed by protonation, only the complex with an *N*-coordinated benzimidazole was obtained.[11] However, the reaction of 1-ethylbenzimidazole with *n*BuLi in THF yields the lithium 1-ethylbenzimidazolate which reacts exclusively under C2 metallation with freshly prepared $[W(CO)_5(THF)]$ (Scheme 3). Complex **1** was formed by protonation of the initially obtained anionic complex with $HCl/Et_2O$. The air- and moisture-stable complex **1** was obtained after column chromatography in 69% yield. The method depicted in Scheme 3 constitutes an alternative and time-saving approach to complexes with NH,NR-substituted N-heterocyclic carbene ligands compared to the intramolecular cyclization of coordinated isocyanide ligands followed by *N*-alkylation.

Complex **1** was investigated by $^1H$ NMR spectroscopy where a broad singlet at $\delta$ = 8.65 ppm was observed for the NH proton and by IR spectroscopy showing a strong absorption for the NH stretching mode at $\tilde{\nu}$ = 3422 $cm^{-1}$. The $^{13}C$ NMR spectrum shows the resonance for the carbene carbon atom at $\delta$ = 191.1 ppm which is a typical value for pentacarbonyltungsten complexes containing a benzannulated N-heterocyclic carbene.[8] The molecular structure of **1** was determined by X-ray diffraction (Figure 1) confirming the connectivity within the complex. Bond lengths and angles in **1** show no unusual features and are within the range observed previously for pentacarbonyltungsten complexes with saturated[7] or benzannulated[9] N-heterocyclic carbene ligands.

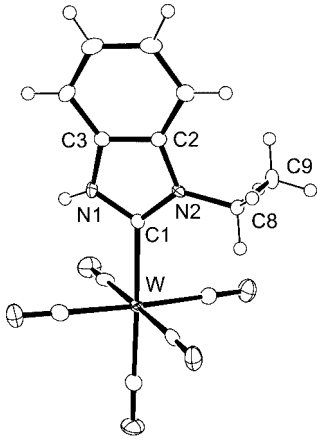

Figure 1. Molecular structure of one of the two independent, essentially identical molecules of **1** in the asymmetric unit. Selected bond lengths [Å] and angles [°] for molecule 1 [molecule 2]: W–C1 2.244(3) [2.242(3)], C1–N1 1.350(4) [1.353(4)], C1–N2 1.351(4) [1.357(4)]; W–C1–N1 123.4(2) [124.2(2)], W–C1–N2 131.1(2) [131.5(2)], N1–C1–N2 105.2(3) [104.2(3)].

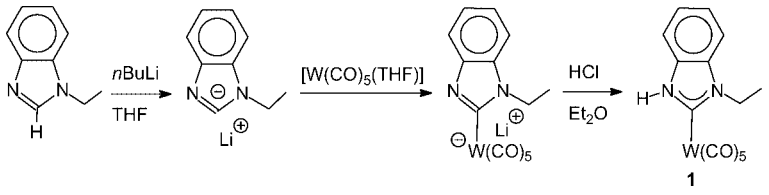
Only little is known about the hydrogen-bonding properties of complexes with N-heterocyclic carbenes exhibiting free NH functions. Hydrogen bonding between the NH group of an NH,O-stabilized carbene ligand and triphenylphosphane oxide has been described (Scheme 4).[12] We became interested in the hydrogen-bonding properties of **1**.

$^1H$ NMR techniques allowed a detailed insight into the hydrogen bonding involving the NH proton of the N-heterocyclic carbene. Complex **1** was titrated with the strong hydrogen-bond acceptor DMPU (Scheme 4) as a model for carbonyl compounds in $CDCl_3$ and the reaction was monitored by $^1H$ NMR spectroscopy (Figure 2). Since **1** involves



Scheme 3. Preparation of **1** by transmetallation of lithium 1-ethylbenzimidazolate.

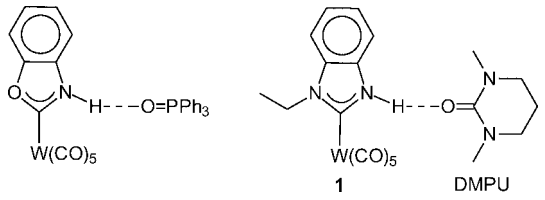

Scheme 4. Hydrogen bonds involving NH,O- and NH,NR-stabilized cyclic carbene ligands.

both a hydrogen-bond donor (NH) and acceptor ($NR_3$), self-assembly to supramolecular aggregates seemed possible. Self-aggregation of the carbene complex as well as the formation of higher aggregates could be excluded by dilution experiments. The investigated concentration range covered several orders of magnitude.[13]

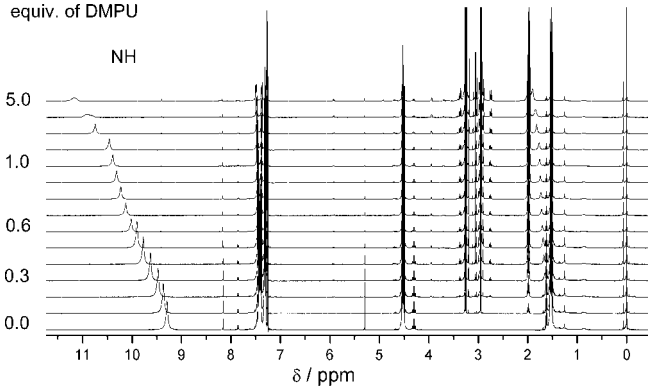

Figure 2. $^1$H NMR titration of **1** with DMPU (up to 5 equiv.).

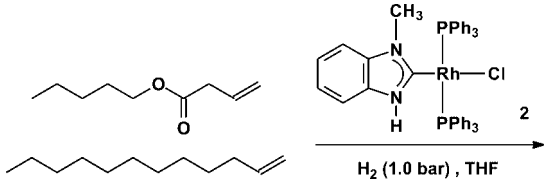
The NMR titration was carried out at 27 °C in $CD_2Cl_2$ and demonstrated a significant downfield shift of the resonance for the NH proton upon addition of DMPU, while the chemical shifts for all other protons remained essentially unchanged. Only broadening of the NH signal was observed after addition of more than 1 equiv. of DMPU (up to 5 equiv.).

The chemical shifts were fitted using standard tools.[14] Multiple experiments revealed a binding constant of about $40 \pm 10$ M$^{-1}$ for the single hydrogen bond which corresponds to $\Delta G_{ass} = 2.2$ kcal mol$^{-1}$. Investigations of the secondary interaction using optical spectroscopy failed since the high dilution required does not favour the hydrogen bonding. The hydrogen bonding is supported by chlorinated solvents and THF, whereas protic media like alcohols impede the supramolecular interaction.

The NH group of an NH,NR-stabilized carbene ligand is able to function as a supramolecular recognition site. Its close proximity to the metal center is unusual. In most described cases the supramolecular host moieties are connected to the metal center by a flexible spacer causing entropic problems.[15] Secondary interactions of the NH group with selected substrates should be suitable to direct metal-mediated conversions. In the rhodium(I)-catalyzed hydrogenation reaction of a suitably carbonyl-functionalized olefin, for example, the substrate will interact initially by multiple contacts while some attractive interactions will disappear after the catalytic transformation at the metal center (Scheme 5), which generates an interesting motif for directed transition metal catalysis.

Preliminary studies of the catalytic properties of the (carbene)rhodium(I) complex **2** (Scheme 6) yielded proof of our concept. Complex **2** is equipped with an NH,NR-stabilized carbene ligand.[16] The use of triphenylphosphane in the preparation of **2**, however, gave a mixture of complexes. Together with complex **2** (major), the complex with an *N*-coordinated methylbenzimidazole ligand (minor) were obtained, which appeared to interconvert in solution.



Scheme 6. Competitive hydrogenation experiment utilizing the substrate selectivity of the NH,NR-stabilized carbene ligand in **2**.

In the hydrogenation of 1-octene the mixture of **2** and its isomer turned out to be catalytically more active than Wilkinson's catalyst. When the mixture was treated in a

competitive hydrogenation experiment with 1-dodecene and a 3-butenoic acid ester (Figure 3), the substrate with the supramolecular recognition unit is clearly preferred. Up to a conversion of 80% a significant preference for the substrate bearing the supramolecular key was observed. Control experiments with Wilkinson's catalyst clearly eliminate the Lewis acidic properties of rhodium(I) as source for this selectivity since only a very slight preference for the oxygenated substrate was found in this case.

## Conclusions

We have described a straightforward one-pot synthesis of complex **1** bearing an N-heterocyclic carbene ligand which exhibits a free NH function. The NH group is able to act as a hydrogen-bond donor. However, hydrogen bonding does not lead to self-aggregation in the case of **1**. The NH group of an NH,NR-stabilized N-heterocyclic carbene ligands can act as a supramolecular key in the vicinity of a catalytically active rhodium center which enabled a substrate-selective hydrogenation. Currently, we are studying complexes with NH,NR-stabilized N-heterocyclic carbene ligands bound to various catalytically active metal centers with the intention of employing the supramolecular recognition of suitable substrates for selective catalytic transformations, e.g. for regioselective C–C coupling reactions.

## Experimental Section

**Analytical Data for Complex 1**: $^1$H NMR (200.1 MHz, $CDCl_3$): $\delta$ = 8.65 (br. s, 1 H, NH), 7.46–7.26 (m, 4 H, Ar-H), 4.52 (q, 2 H, $CH_2$), 1.50 (t, 3 H, $CH_3$) ppm. $^{13}$C NMR (50.3 MHz, $CDCl_3$): $\delta$ = 201.0 ($CO_{trans}$), 197.6 ($CO_{cis}$), 191.1 (NCN), 133.9, 132.9, 123.7, 123.3, 110.6, 110.3 (Ar-C), 44.5 ($CH_2$), 14.9 ($CH_3$) ppm. IR (KBr): $\tilde{\nu}$ = 3422 (s, NH), 3087–3008 (w, CH aliphatic), 3001–2877 (w, CH aromatic), 2063 (vs, CO), 1910 (vs, CO), 1859 (vs, CO) cm$^{-1}$. MS (EI): *m/z* (%) = 470 (100) $[M]^+$, 442 (50.0) $[M - CO]^+$, 414 (90.0) $[M - 2\,CO]^+$, 386 (15) $[M - 3\,CO]^+$. $C_{14}H_{10}N_2O_5W$ (470.09): calcd. C 35.77, H 2.14, N 5.96; found C 35.50, H 2.53, N 5.87.

**Crystal Data for Complex 1**: $C_{14}H_{10}N_2O_5W$, $M$ = 470.09, $T$ = 123(2) K, $\lambda$ = 0.71073 Å, monoclinic, $P2_1/c$, $Z$ = 8, $a$ = 13.257(2), $b$ = 17.566(2), $c$ = 12.853(2) Å, $\beta$ = 96.744(3)°, $V$ = 2972.4(7) Å$^3$, 33820 measured reflections, 8650 unique reflections ($R_{int}$ = 0.0481), $R$ = 0.0279, $wR$ = 0.0567 for 7446 contributing reflections [$I \geq 2\sigma(I)$], refinement against $|F^2|$with anisotropic thermal parameters for all non-hydrogen atoms and hydrogen atoms on calculated positions. CCDC-618744 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk./data/request/cif.

# A Two-Dimensional, Hydrogen-Bond-Cross-Linked Molybdenum(VI) Network Polymer with Catalytic Activity

**Yi Luan,[a] Ge Wang,*[b] Rudy L. Luck,[c] and Mu Yang[b]**

**Keywords:** Hydrogen bonds / Crystal engineering / Hydrogen peroxide / Epoxidation / Molybdenum

The new hybrid inorganic–organic polymer $[MoO_2Cl_2(H_2O)_2]\cdot(H_2dipy\text{-}pra)Cl_2$ (**1**), where dipy-pra = 1,3-bis(4-pyridyl)propane, has been synthesized and crystallographically characterized. $MoO_2Cl_2(H_2O)_2$ and the $[H_2dipy\text{-}pra]^{2+}$ cation are cross-linked by Mo–$H_2O$···Cl and $H_2$dipy-pra···Cl hydrogen bonds to form a two-dimensional layer structure. Complex **1** is an efficient catalyst, with $H_2O_2$ as the oxygen-source oxidant and $NaHCO_3$ as the cocatalyst, in the epoxidation of olefinic compounds under ambient conditions.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

The design and synthesis of metal–organic coordination polymers that is based on the strategy of crystal engineering is an emerging area, and a variety of novel supramolecular architectures have been obtained. Moreover, coordination polymers are used in areas such as magnetism,[1,2] optoelectronics,[3] guest exchangeability,[4,5] and catalysis.[6] The concept of crystal engineering was first introduced as an approach to more efficient topochemical reactions in the early 1960s.[7] However, the synthesis of coordination polymers following the principles of crystal engineering was not achieved until 1995.[8,9] Several recent reviews have described how coordination polymers ranging from one-dimensional to three dimensional can be attributed to the rapid development of crystal engineering research.[10,11] Molybdenum- and tungsten-based supramolecular networks have also been investigated.[12] Zubieta described a molybdenum-based network that employed protonated 4,4′-bipyridine as a ligand serving to buttress the inorganic layers.[13] In light of recent successes in the construction of potentially useful coordination polymers, we wanted to utilize a bidentate ligand and a dioxidomolybdenum(VI) center to yield this type of metal–organic hydrogen-bond network by crystal engineering.

Organomolybdenum reagents have been used in a variety of oxidation reactions such as epoxidation and the oxidation of alcohols and sulfides. In the past few years, dioxidomolybdenum(VI) halide complexes have been found to be efficient epoxidation catalysts.[14] We reported a series of dioxidomolybdenum(VI) halide complexes that catalyze the epoxidation of olefins with *tert*-butyl hydroperoxide (TBHP).[15,16] From both an economic and an environmental viewpoint, there is a definite need for catalytic oxidations employing hydrogen peroxide as the stoichiometric oxidant, because hydrogen peroxide is environmentally friendly, cheap, and readily available.[17] To the best of our knowledge, there is no report regarding efficient epoxidations with $H_2O_2$ by using dioxidomolybdenum(VI) halide complexes. In the present work, the synthesis, crystal structure, and characterization of $[MoO_2Cl_2(H_2O)_2]\cdot(H_2dipy\text{-}pra)Cl_2$ is reported, as well as the potential of this complex as an epoxidation catalyst with hydrogen peroxide as the oxidant.

The key to our approach was the utilization of aromatic amines such as 1,3-bis(4-pyridyl)propane. It is known that under more acidic reaction conditions protonation of the aromatic amine provides an aromatic ammonium cation. Thus, the aromatic ammonium cations of a linear bidentate ligand can serve as a structure-directing template by virtue of multipoint hydrogen bonding between the cation and the metal complex to form a new hydrogen-bond network structure. Compound **1** was synthesized by the reaction of $MoO_2Cl_2(H_2O)_2$ and protonated dipy-pra.[18] Single-crystal X-ray diffraction studies on the sample obtained from the reaction revealed its composition, $[MoO_2Cl_2(H_2O)_2]\cdot(H_2dipy\text{-}pra)Cl_2$, and an extended structure composed of the building units shown in Figure 1.

The supramolecular structure of complex **1** is shown in Figure 2. Each dipy-pra molecule is linked by H-bonds to a $H_2O$ molecule of two uncharged $MoO_2Cl_2(H_2O)_2$ units through external chloride anions. The two-dimensional polymeric structure was formed by H-bonded linkages (O2W···Cl4 = 3.087, N2···Cl4 = 3.100, O1W···Cl4 = 3.059, O2W···Cl3 = 3.125, O1W···Cl3 = 3.047, N1···Cl3 = 3.038 Å). The Mo–O(oxido) and Mo–Cl distances, and the *cis*-$MoO(oxido)_2$ and *trans*-$MoCl_2$ angles, are comparable

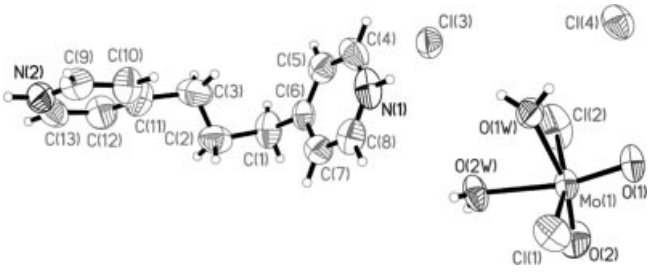

Figure 1. The building-block unit present in crystalline **1**. Thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: Mo(1)–O(2) 1.671(3), Mo(1)–O(1) 1.683(3), Mo(1)–O(1W) 2.217(3), Mo(1)–O(2W) 2.244(3), Mo(1)–Cl(1) 2.3739(13), Mo(1)–Cl(2) 2.3754(15), O(2)–Mo(1)–O(1) 105.12(16), O(1W)–Mo(1)–O(2W) 75.33(12), Cl(1)–Mo(1)–Cl(2) 162.13(6).

to those reported for other related $MoO_2Cl_2L_2$ complexes.[19] There are slight differences in the Mo–O(W) distances, and the shorter distance, i.e. Mo–O(1W) = 2.217(3) Å, correlates with a smaller O(1W)–Mo–O(2) angle of 164.07(14)° and the longer Mo–O(2W) distance of 2.244(3) Å with a larger O(2W)–Mo–O(1) angle of 166.08(14)°. This significant difference in Mo–O(W) bond lengths would appear to be related to the *trans* effect of the oxido ligand.

The catalytic property of compound **1** was then studied. With complex **1** as the catalyst, $NaHCO_3$ as the cocatalyst, and $H_2O_2$ as the oxygen source, we were able to catalyze the epoxidation of olefinic compounds. Cyclooctene was selected as a standard substrate for the optimization process with $H_2O_2$ in acetonitrile. A good yield (99%) of the epoxide was achieved with a catalytic amount of **1** (1 mol-%) and $NaHCO_3$ as cocatalyst (25 mol-%) after 1 h at room temperature (25 °C).

To evaluate the scope of this procedure, the oxidation of other alkenes was also studied (Table 1). As shown, carbocyclic alkenes were oxidized to produce the corresponding epoxy compounds in high yields (entries 1 and 2, Table 1). However, oxidation of the aromatic and linear alkenes required longer reaction times than that of the carbocyclic alkenes (entries 3 and 4, Table 1), especially 1-octene. Similarly, the allylic alcohols underwent oxidation without affecting the hydroxy group (entry 5, Table 1). Kuhn reported that dioxidomolybdenum derivatives are able to catalyze the olefin epoxidation reaction with TBHP but not with $H_2O_2$.[14]

Table 1. Epoxidation of selected olefins catalyzed by molybdenum(VI) complex **1**, with $H_2O_2$ as oxidant and hydrogencarbonate as cocatalyst.[a]

| Entry | Substrate | Time [h] | Product | Yield[b] [%] | Selectivity [%] |
|---|---|---|---|---|---|
| 1 | | 1 | | 99[c] | 99 |
| 2 | | 1.5 | | 99[c] | 99 |
| 3 |  | 4 |  | 86[c] | 99 |
| 4 |  | 4 |  | 92 | 99 |
| 5 | | 2 | | 95 | 99 |

[a] Reaction conditions: the substrate (10 mmol), catalyst **1** (0.1 mmol, 1 mol-%), $NaHCO_3$ (2.5 mmol, 25 mol-%) and 30% aqueous $H_2O_2$ (40 mmol) dissolved in acetonitrile (10 mL) at 25 °C. [b] Determined by GC by using an internal standard technique. [c] Isolated yield.

Notably, the chemoselectivity was reduced at higher temperatures. In the epoxidation of cyclic alkenes (such as cyclohexene) at 50 °C, 2,3-epoxycyclohexanone and 2-cyclohexen-1-one were obtained in addition to the desired epoxide product. When the reaction was carried out at reflux temperature, i.e. 75 °C, the efficiency was significantly reduced. To confirm whether this reduction in efficiency was due to the conversion of $NaHCO_3$ (which acts as a cocatalyst) into $Na_2CO_3$, $NaHCO_3$ was replaced by $Na_2CO_3$; this resulted in almost no oxidation products, even after 24 h.[20]

Besides our system, Burgess and Bhattacharyya demonstrated that $MnSO_4$ and $[MoO(O_2)_2(saloxH)]$ can catalyze epoxidation reactions efficiently with $NaHCO_3/H_2O_2$.[21,22] The epoxidation of alkenes in the presence of hydrogencarbonate alone was also investigated.[20,23] Interestingly, the use of complex **1** or hydrogencarbonate alone gave much lower yields of epoxides than when they were used together.[21,22] Richardson showed that a key aspect of such reactions is that hydrogen peroxide and hydrogencarbonate combine in an equilibrium process to produce peroxymonocarbonate, $HCO_4^-$.[24,25] $HCO_4^-$ may be more reactive than hydrogen peroxide and can be expected to attack the metal center or other more potent, activated groups at a much faster rate.[21] The mechanism for our epoxidation reaction is under investigation.

In conclusion, a novel 2D network material with the general formula $[MoO_2Cl_2(H_2O)_2]\cdot(dipy\text{-}praH_2)Cl_2$ has been synthesized and successfully applied to epoxidation reactions. Our current observations suggest that, under acidic conditions, the protonated $[H_2dipy\text{-}pra]^{2+}$ cation serves as a structure-directing template by using multipoint hydrogen bonding in the formation of infinite frameworks. The epoxidation of alkenes was studied with hydrogen peroxide in the presence of complex **1** to give products in high yields. This reaction provides a new environmentally friendly route for the conversion of a variety of alkenes to their respective epoxides.

[18] Experimental details: $MoO_3$ (0.826 g, 5.74 mmol) was dissolved in excess concentrated HCl by stirring at 40 °C for 4 h; a pale yellow solution was obtained. The solution was cooled in an ice bath, and a solution of a dipy-pra (1.138 g, 5.74 mmol) in ethanol (10 mL) was then added in portions. After stirring for 6 h, a yellow solution was obtained, which when left overnight at ca. 4 °C afforded the lemon yellow crystalline complex **1** in 1.48 g, 51% yield. The characterization results are as follows: $C_{13}H_{20}Cl_4MoN_2O_4$ (506.66): calcd. C 30.85, H 3.98, Mo 18.96, N 5.54, $O_2^{2-}$ 12.65; found C 30.71, H 4.11, Mo 18.91, N 5.46, $O_2^{2-}$ 12.87. IR (KBr disc; selected bands): 952, 936 ($MoO_2$, asym.), 906 ($MoO_2$, sym.) $cm^{-1}$. Crystal data for **1** at 293 K: $C_{13}H_{20}N_2O_4Cl_4Mo$, $M$ = 506.05, triclinic, space group $P\bar{1}$, yellow plate crystal (0.32 mm × 0.28 mm × 0.24 mm), $a$ = 8.6398(17), $b$ = 8.6481(17), $c$ = 13.944(3) Å, $\alpha$ = 85.33(3), $\beta$ = 83.03(3), $\gamma$ = 82.44(3)°, $V$ = 1022.9(4) Å$^3$, $Z$ = 2, $D_{calcd.}$ = 1.643 Mg/m$^3$, $\mu$ = 1.182 mm$^{-1}$, $F$(000)= 508, 10144 reflections measured, 4632 unique. # A New Silver(I) Aggregate Having an Octagonal $Ag_4S_4$ Core Where $\mu_3$-S Bonding Interactions Lead to a Nanotube Assembly that Exhibits Quasiaromaticity

**Sotiris Zartilas,[a] Nikolaos Kourkoumelis,[a] Sotiris K. Hadjikakou,*[a] Nick Hadjiliadis,*[a] Panagiotis Zachariadis,[a] Maciej Kubicki,[b] Alexey Yu. Denisov,[c] and Ian S. Butler[c]**

**Keywords:** Bioinorganic chemistry / Silver / Aromaticity / Nanotubes

Silver(I) chloride reacts with 2-mercapto-3,4,5,6-tetrahydropyrimidine ($StpmH_2$, $C_4H_8N_2S$) in DMSO with excess triethylamine to give a complex of formula $\{[Ag_4Cl_4(\mu_3\text{-}StpmH_2)_4]_n\}$ (**1**). The product was characterized by elemental analyses, FTIR far-IR, UV/Vis, and $^1H$ and $^{109}Ag$ NMR spectroscopic techniques. The $^{109}Ag$ NMR spectroscopic data of the complexes $\{[Ag_6(\mu_2\text{-}Br)_6(\mu_2\text{-}StpmH_2)_4(\mu_3\text{-}StpmH_2)_2]_n\}$ (**2**) and $\{[Ag_4(\mu_2\text{-}StpmH_2)_6](NO_3)_4\}_n$ (**3**) are also reported here for comparison. Crystal structure of complex **1** was determined by X-ray diffraction at 100(1) K. Complex **1**, $C_4H_8AgClN_2S$, crystallized in the tetragonal system, space group *P4cc*, $a$ = 15.7761(9) Å, $b$ = 15.7761(9) Å, $c$ = 6.9624(8) Å, $V$ = 1732.8(2) Å$^3$, $Z$ = 2. Each metal ion is bonded to one terminal Cl atom and three $\mu_3$-S atoms from three $StpmH_2$ ligands. Four silver ions are bridged by four sulfur atoms forming an octagonal $Ag_4S_4$ core. Each $Ag^I$ ion of one core is also bridged to an $Ag^I$ ion of another core through a sulfur atom, which forms an infinite nanotube structure. A computational study utilizing the method of nucleus-independent chemical shifts (NICS) showed that the $Ag_4S_4$ core exhibits strong quasiaromaticity at the geometric cage center. To the best of our knowledge, this is the first example of an $Ag^I$ cluster that presents quasiaromaticity and stacking interactions.

## Introduction

The research in designing infinite molecular components with specific chains and networks is a matter of current interest.[1] This self-assembly process between metal ions and ligands is known to depend on steric and interactive information stored in the ligand and governed by the metal ions through their coordination geometry demands.[1b,1c] Recently, a new type of aromaticity that results from the cyclical delocalization of electron density of d- as well as (d–p)π-type orbitals instead of the usual p orbitals on metal–ligand rings has been reported;[2] this may introduce greater stability to the higher-order structures. From this point of view, the ability of silver(I) thiolate or thionate complexes to adopt geometries with variable nuclearities and structural diversity makes the study of silver(I) chemistry very attractive.[3–4] Such silver(I) complexes with sulfur-containing ligands exhibit a wide range of applications in medicine, analytical chemistry, or the industrial preparation of polymers.[3,4] Biomedical applications and uses of silver(I) complexes are related to their antibacterial action,[5a,5b] which appears to involve interactions with DNA.[5c] The molecular design and structural characterization of silver(I) complexes is therefore an intriguing aspect of bioinorganic chemistry and metal-based drugs.[6]

A great deal of work has been devoted to the study of thioamides because of their tendency to bridge metal centers to form oligo- and polynuclear species with potential usage as functional solid materials.[7] Furthermore, 2-mercapto-3,4,5,6-tetrahydropyrimidine can coordinate up to three metal centers at short distances, which offers the possibility of studying the metal–metal interaction of $d^{10}$ systems which have attracted considerable attention.[8] Such well-defined higher-order structures of 2-mercapto-3,4,5,6-tetrahydropyrimidine have already been reported for complexes **2** and **3**.[9]

In this paper, we report the structural and spectroscopic characterization of a new silver complex with the heterocyclic thioamide 2-mercapto-3,4,5,6-tetrahydropyrimidine (Scheme 1) of formula $\{[Ag_4Cl_4(\mu_3\text{-}StpmH_2)_4]_n\}$ (**1**). Also, a computational study of the aromaticity aimed at the rationalization of the stability of this structure and its $^{109}Ag$ NMR spectroscopic data in relation to the corresponding known complexes $\{[Ag_6(\mu_2\text{-}Br)_6(\mu_2\text{-}StpmH_2)_4(\mu_3\text{-}StpmH_2)_2]_n\}$ (**2**) and $\{[Ag_4(\mu_2\text{-}StpmH_2)_6](NO_3)_4\}_n$ (**3**) is de-

tailed. To the best of our knowledge, this is the first example of an experimentally isolated silver(I) cluster that possesses (d-p)π-type quasiaromaticity.

## Results and Discussion

### General Aspects

The synthesis of complex **1** was carried out in DMSO with excess triethylamine according to the reaction shown in Equation (1).

$$4n\ AgCl + 4n\ StpmtH_2 \xrightarrow[DMSO]{Et_3N} \{[Ag_4Cl_4(\mu_3\text{-}StpmtH_2)_4]_n\} \quad (1)$$

No deprotonation of the thioamide ligand was observed in this case even though excess triethylamine was used. When 2-mercaptonicotinic acid reacted with silver(I) chloride under the same reaction conditions, a hexanuclear, water-soluble aggregate of formula $\{[Ag_6(\mu_3\text{-Hmna})_4(\mu_3\text{-mna})_2]^{2-}\cdot[(Et_3NH)^+]_2\cdot(DMSO)_2\cdot(H_2O)\}$ formed.[8d] Complex **1** has an infinite nanotube structure (vide infra) that consists of an octagonal $Ag_4S_4$ core. Four silver ions bridged by four sulfur atoms form an octagonal $Ag_4S_4$ core. Each $Ag^I$ ion of a core is also bridged to a $Ag^I$ ion of another core through a sulfur atom. Notably, the geometry around the silver(I) ions in **1** is tetrahedral.

The formula of synthesized compound **1** was first deduced from elemental analysis and spectroscopic data. Complex **1** is soluble in DMSO and DMF. The crystals of the complex were stable in air but were stored in darkness.

With the use of 3-(*tert*-butyldimethylsilyl)pyridine-2-thione, and 3,6-bis(*tert*-butyldimethylsilyl)pyridine-2-thione,[10a] 2-(triorganosilyl)thiophenols, 2,6-bis(triorganosilyl)thiophenols,[10b] and 2-(triorganosilyl)methanethione[10c] as ligands for the silver(I) ions, Zubieta et al.[10] established that the extent of the association in silver(I) ions in their clusters intimately depends on the nature of the thioamide. Thus, silver(I) ions with unbranched-chain thiolate ligands are highly polymeric as silver(I) is unprotected from the approach of additional bridging thiolate groups, whereas bulky ligands such as substituted thiolates increase the aggregation degree of the class of $[Ag(LS)]_n$ compounds.[10] In accordance with the above findings, the aggregate of formula $\{[Ag_6(\mu_3\text{-Hmna})_4(\mu_3\text{-mna})_2]^{2-}\cdot[(Et_3NH)^+]_2\cdot(DMSO)_2\cdot(H_2O)\}$[8d] was recently synthesized by using the branched substituted 2-mercaptonicotinic acid. When the unbranched, nonaromatic 2-mercapto-3,4,5,6-tetrahydropyrimidine was used for the synthesis of complexes **1**, $\{[Ag_6(\mu_2\text{-Br})_6(\mu_2\text{-StpmH}_2)_4(\mu_3\text{-StpmH}_2)_2]_n\}$ (**2**),[9] and $\{[Ag_4(\mu_2\text{-StpmH}_2)_6](NO_3)_4\}_n$ (**3**),[9] highly polymeric structures, were obtained.

### Spectroscopy

*Infrared*: The infrared spectra of complex **1** show distinct vibrational bands at 1572 and 1235 $cm^{-1}$, which were assigned as vibrations of the C–N bond (thioamide I and II bands), and at 1017 and 621 $cm^{-1}$, which were attributed to the C–S bond vibrations (thioamide III and IV bands). The corresponding thioamide bands of the free 2-mercapto-3,4,5,6-tetrahydropyrimidine ligand are given at 1557, 1206, 1067, and 644 $cm^{-1}$. The new band at 142 $cm^{-1}$ in the far-IR spectrum of complex **1** was assigned to the vibration of the Ag–S bond,[11] whereas a band appearing at 149 $cm^{-1}$ was attributed to the vibration of the Ag–Cl bond.

*NMR:* The $^1H$ NMR spectrum of a $[D_6]$DMSO solution of free ligand $StpmH_2$ shows resonance signals at $\delta$ = 7.86 ppm for the amide proton and at $\delta$ = 3.20 and 1.75 ppm for the $CH_2$ a and b protons. The band for the amide protons is shifted to 8.80 ppm in the $^1H$ NMR spectrum of complex **1**, obtained from a $[D_6]$DMSO solution, which confirms the N,S–metal coordination.

The $^{109}Ag$ NMR spectrum of complex **1** shows a signal at $\delta$ = +852 ppm. The corresponding signals for **2** and **3** are found at $\delta$ = 753 and 709 ppm, respectively. The significantly higher value of the chemical shift in the case of complex **1** relative to that of **2** and **3** could be due to the calculated aromaticity of complex **1** (see Computational Study). When the silver(I) ion is coordinated to the imine nitrogen atoms of a neutral $N_4$ donor system, as in the case of $[Ag_2\{\mu\text{-(R,S)-1,2-(6-R-py-2-CH=N)}_2Cy_2\}](OSCF_3)_2$ {where (R,S) = 1,2-(6-R-py-2-CH=N)$_2$Cy and R = H (a) or Me (b), and Cy = cyclohexane}, the chemical shift value for (a) is $\delta$ = 580 ppm and for (b) $\delta$ = 612 ppm.[12]

### Crystal and Molecular Structures of Complex $\{[Ag_4Cl_4(\mu_3\text{-}StpmH_2)_4]_n\}$ (1)

In complex **1** (Figure 1), four $\mu_3$-S atoms from the thione ligands bridge four silver(I) ions, which forms an eight-membered ring. The four $Ag^I$ ions define an $Ag_4$ plane that rises 0.826 Å from the corresponding $S_4$ plane defined by the sulfur atoms. Strong $\mu_3$-S intramolecular interactions bridge two eight-membered rings through silver(I) ions, whereas the coordination sphere of each silver ion is completed by a terminal Cl atom. The distance between two $Ag_4$ planes is 3.481 Å, which shows a stacking interaction. The same distance between two subsequent $S_4$ planes is also observed. Thus, an infinite nanotube structure is formed with strong interatomic interactions (Figure 2). A disordered solvent molecule (not identified) is also trapped inside the voids that are formed between the nanotubes.

The Ag–S bond lengths are Ag1–S2 = 2.5117(11) Å, Ag1–S2B = 2.5421(11) Å (symmetry code to equivalent position B: $1-y, -1+x, z$) and Ag1–S2A = 2.6627(13) Å (symmetry code to equivalent position A: $x, -y, z+1/2$). These values are in the range of those measured in complexes with infinite ribbon structures as in $\{[Ag_6(\mu_3\text{-pyS})_4(\mu_4\text{-pyS})_2]_n\}$[1a] [Ag–S = 2.456(5) to 2.959(5) Å], $\{[Ag_5(pyS)_4(pySH)BF_4]_n\}$[7] (Ag–S = 2.45 to 2.90 Å), $\{[Ag_6(SPh)_8](Me_4N)_2\}$[11] [Ag–S = 2.431(3) to 2.878(2) Å], and $\{[Ag(\mu_2\text{-pyS})]_n\}$[1a] [Ag–S = 2.587(4) and Ag–S(a) = 2.502 Å] (pySH = 2-mercaptopyridine).

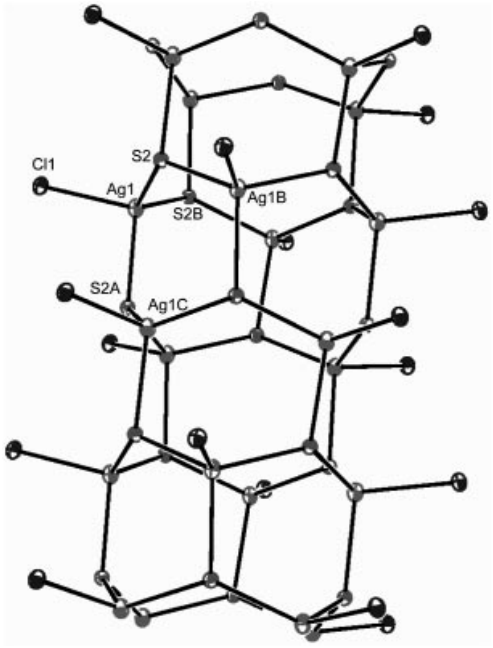

Figure 1. Molecular diagram of compound **1** together with the atomic numbering scheme (C, H, and N atoms were omitted for clarity). Symmetry codes to equivalent positions: A: 1 –*y*, –1 + *x*, *z*, B: *x*, –*y*, 1/2 + *z*, C: 1 –*y*, –1 + *x*, *z*. The displacement ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å]: Ag1–S2 = 2.5117(11), Ag1–S2B = 2.5421(11), Ag1–S2A = 2.6627(13), Ag1–Cl1 = 2.6627(13), Ag1···Ag1B = 4.4614(5). Contact across ring [Å]: S2···S2A = 4.119(1), Ag1···Ag1C = 4.3487(5). Selected angles [°]; Cl1–Ag1–S2 = 109.04(4), Cl1–Ag1–S2B = 108.82(4), Cl1–Ag1–S2A = 101.41(4), S2–Ag1–S2B = 119.26(5), S2–Ag1–S2A = 112.18(3), S2B–Ag1–S2A = 104.61(3).

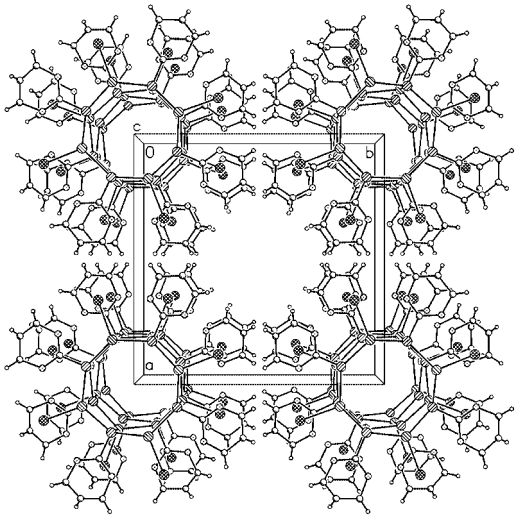

Figure 2. Unit cell of complex **1**. Strong $\mu_3$-S bonding interaction between $Ag^I$ ions of octagonal $Ag_4S_4$ cores lead to an infinite nanotube structure. The disordered guest molecule was omitted for clarity.

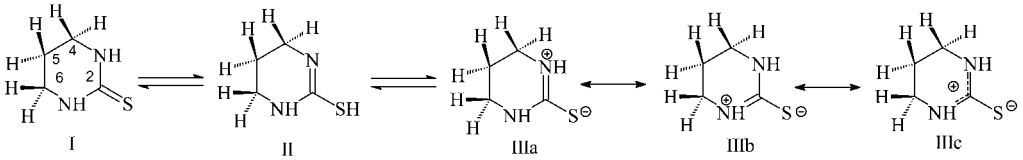
The Ag···Ag distance in the $Ag_4S_4$ ring in complex **1** is Ag1···Ag1B = 4.4614(5) Å, whereas the Ag···Ag distance between two subsequent rings is Ag1···Ag1C = 4.3487(5) Å (symmetry code to equivalent position C: 1 –*y*, –1 + *x*, *z*) and this is longer than twice the van der Waals radius for silver (3.44 Å),[6b] which indicates that there is no Ag···Ag interaction. The corresponding Ag···Ag distances in $\{[Ag_6(\mu_2\text{-}Br)_6(\mu_2\text{-}StpmH_2)_4(\mu_3\text{-}StpmH_2)_2]_n\}$ (**2**) are 3.063(1) Å and 2.963(2) Å, and they are shorter than twice the van der Waals radius for silver, which indicates that there is a strong Ag···Ag interaction, whereas in the case of complex $\{[Ag_4(\mu_2\text{-}StpmH_2)_6](NO_3)_4\}_n$ (**3**), no Ag···Ag interaction was observed because Ag1–Ag1B = 3.666(5) Å and Ag1–Ag1C = 3.954(5) Å. Other compounds presenting Ag···Ag interactions include $\{[Ag_6(\mu_3\text{-}pyS)_4(\mu_4\text{-}pyS)_2]_n\}$,[1a] with Ag···Ag = 2.959(2) Å, the neutral cluster $\{[Ag_6(\mu_3\text{-}Hmna)_6]\cdot 8DMSO\}$ ($H_2$mna = 2-mercaptonicotinic acid)[6b] with Ag···Ag = 2.911(1) Å, $\{[Ag_5(pyS)_4(pySH)BF_4]_n\}$[7] with Ag···Ag = 2.995 Å, $\{[Ag_6(\mu_3\text{-}Hmna)_4(\mu_3\text{-}mna)_2]^{2-}\cdot[(Et_3NH)^+]_2\cdot(DMSO)_2\cdot(H_2O)\}$[9] with Ag···Ag = 2.916 Å, and $\{[Ag_6(SPh)_8](Me_4N)_2\}$[11] with Ag···Ag = 2.959(1) Å. It is noteworthy that in all complexes with a short silver(I)–silver(I) distance (shorter than twice the van der Waals radius for silver) there is no halogen atom in the coordination sphere of the metal center. Complex **2** is still the only example of a silver(I) cluster containing a bromide ion in the coordination sphere of the metal center and presenting a Ag···Ag interaction.

The C–S bond length found in complex **1** is S2–C2 = 1.755(5) Å, which shows single bond character, whereas the C–N bond lengths are C2–N1 = 1.323(6) Å, C2–N3 = 1.328(5) Å, C6–N1 = 1.453(5) Å, and C4–N3 = 1.480(5) Å. Thus, in this case there are two equivalent short C–N bonds and a single C–S bond upon coordination to the silver(I) ion. These bond lengths, as well as all bond angles C–N–C and N–C–S that are around 122° [C2–N1–C6 = 123.7(4) and C2–N3–C4 = 121.8(4)°] and 119° [N1–C2–S2 = 119.9(3)° and N3–C2–S2 = 119.0(4)°], indicate that the ligand coordinates to silver(I) ion through zwitterionic form IIIc (Scheme 1).

The Ag–S–Ag bond angle in the $Ag_4S_4$ octagonal ring of complex **1** is S2–Ag1–S2B = 119.25(4)°, which is far from the ideal value of 135° of the normal octagon because of the nonplanar arrangements of the atoms, whereas the corresponding Ag–S–Ag angles formed between the octagonal



Scheme 1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rings are S2–Ag1–S2A = 112.18(4)° and S2B–Ag1–S2A = 104.57(4)°.

### Computational Study

Theoretical as well as experimental evidence of aromaticity in all-metal systems[13a] has introduced a novel category of compounds containing either an aromatic cycle completely composed of metal atoms[2c,2e,2f] or ligand-stabilized aromatic molecules with the ligands being either terminal or bridging adjacent metal atoms.[13b,13c] Furthermore, aromatic clusters involving d orbitals in pseudooctahedral and in tetrahedral three-dimensional metal cages were extensively studied by density functional methods.[2b,2e] Despite that, experimentally structurally characterized compounds containing aromatic metalloid and metal clusters play a significant role in the *metallaromaticity* concept because they verify results obtained computationally.[13d–13f] We evaluated the aromaticity of compound **1** by means of magnetic criteria and by utilizing the nucleus-independent chemical shifts (NICS) method proposed by Schleyer et al. in 1996[2a] as a precept to estimate the aromatic character of cyclic structures.

NICS indexes are defined as the negative isotropic values of the absolute magnetic shieldings calculated at the geometric ring centers (nonweighted mean of the heavy atom coordinates) and at the cage metal centers. In general, negative and positive NICS values are associated with aromatic and antiaromatic character, respectively, whereas values near zero are indicative of nonaromaticity. The use of the NICS method in 3D structures has been recently evaluated comprehensively[13g] showing the successful estimation of aromaticity. Here, the core of compound **1** adopts a $D_4$ symmetry and to assess its aromaticity we have calculated NICS values at the geometric cage center, NICS(0), and at various equal distances along the $C_4$ symmetry axis (Figure 3).

The calculated results are illustrated in Figure 4, and they should be compared with the corresponding value of –6.9 ppm obtained for benzene at the same level of theory. The NICS data of –9.7 ppm at the cage barycenter confirms the aromatic character of the structure. The shielding influence reaches its minimum value of –13.1 ppm at NICS(1.7), which is the geometric center of one of the two $D_{4h}$ four-membered metal rings, whereas NICS(–1.7) is –6.4 ppm. Both results suggest the presence of induced diatropic ring current at each of the molecular planes that is set up by four Ag and four S atoms,[13e] and it is this (d-p)π bonding that accounts for the equalization of the Ag–S bonds in the homometallic clusters. Also, induced diatropic ring current is characteristic of cyclic electron delocalization of d or (d-p)π-type orbital electron density,[13e] which causes the strong chemical shifts of the $^{109}$Ag NMR signals in the spectrum of complex **1** (see NMR Study). Consistent with the literature,[13h] the sensitivity of NICS falls considerably with distance and the values are shifted downfield as the distance from the centre is increased, which eventually is proven as a suitable position for the evaluation of aromaticity.

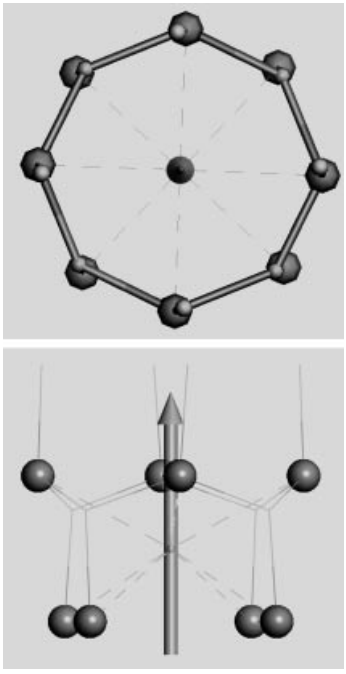


Figure 3. Geometrical representation for the core structure along and alongside the main symmetry axis.

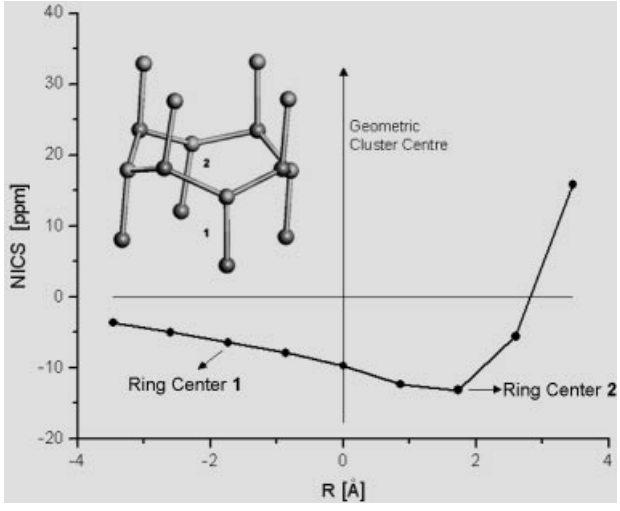

Figure 4. A plot of B3LYP/LANL2DZ NICS calculated along the $C_4$ axis for the asymmetric unit.

## Conclusions

One new $Ag^I$ aggregate was synthesized by the reaction of silver chloride and 2-mercapto-3,4,5,6-tetrahydropyrimidine. The crystal structure of complex **1** reveals that the formed $Ag_4S_4$ core exhibits strong (d-p)π-type quasiaromaticity. Stacking interactions between sequential rings are also observed. As a result, the $^{109}$Ag NMR resonance signal of complex **1** is observed at a higher positive value relative to that observed for complexes **2** and **3**. Thus, the delocal-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ization of the electron density in the (d-p)π-type orbitals, which results from quasiaromaticity, leads to deshielding of the electron density at the silver atoms.

## Experimental Section

**Materials and Instruments:** All solvents were of reagent grade. 2-Mercapto-3,4,5,6-tetrahydropyrimidine (Aldrich) was used with no further purification. Elemental analyses for C, H, N, and S were carried out with a Carlo Erba EA model 1108 elemental analyzer. Infrared were recorded with a Perkin–Elmer Spectrum GX FTIR spectrophotometer. A Jasco UV/Vis/NIR V 570 series spectrophotometer was used to obtain the electronic absorption spectra. The $^1H$ and $^{13}C$ NMR spectra were recorded with a Bruker AC 250 FTNMR instrument. Chemical shifts are given relative to internal tetramethylsilane. The $^{109}Ag$ NMR spectra were recorded with a Bruker DRX-600 spectrometer with Ag-109 resonance at 27.93 MHz at 30 °C, and $AgNO_3$ was used as a reference standard.

**Synthesis and Crystallization of $\{[Ag_4Cl_4(\mu_3\text{-}StpmH_2)_4]_n\}$ (1):** A clear DMSO solution (7 mL) of 2-mercapto-3,4,5,6-tetrahydropyrimidine (0.234 g, 2 mmol) was treated with silver(I) chloride (0.143 g, 1 mmol). After stirring for 30 min, triethylamine (0.5 mL, 3.6 mmol) was added. The resulting clear solution was then filtered, and the filtrate was kept in the dark at room temp. After a few days, colorless crystals ($0.10 \times 0.20 \times 0.30$ mm) of complex **1** that were suitable for single-crystal X-ray analysis were obtained. M.p. 190–195 °C. $^1H$ NMR (250 MHz, [D$_6$]DMSO): $\delta$ = 8.80 (s, 1 H, NH), 3.40 (t, 2 H, $J$ = 7 Hz, $C^4H_2$), 1.81 (q, $J$ = 7 Hz, 2 H, $C^5H_2$) ppm. IR (KBr): $\tilde{\nu}$ = 3199, 1572, 1235, 1017, 621 cm$^{-1}$. Far-IR (polyethylene): $\tilde{\nu}$ = 142, 149 cm$^{-1}$. UV/Vis (DMSO): $\lambda$ = 258.0 nm. $C_4H_8AgClN_2S$: calcd. C 18.51, H 3.11, N 10.79, S 12.36; found C 18.89, H 2.97, N 10.95, S 12.22.

**Computational Details:** Calculations were based on the molecular geometry acquired by X-ray diffraction methods. Magnetic shielding tensors for a ghost atom placed at different interior and near exterior positions of the metal–ligand cluster (asymmetric unit) were computed by using the gauge-independent atomic orbital (GIAO) DFT method[14a–14c] within the B3LYP level of theory. Nucleus independent chemical shift (NICS) values were estimated with the B3LYP functional by using the Los Alamos effective core potentials plus double zeta (LANL2DZ).[14d] All theoretical results reported were carried out with the Gaussian03W program package.[14e]

**X-ray Structure Determination:** Data were collected by the ω scan technique in the range $3.9° < 2\theta < 29.1°$ with a KUMA KM4CCD four-circle diffractometer[15a] equipped with a CCD detector with the use of graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) at 100(1) K. Cell parameters were determined by a least-squares fit method.[15b] All data were corrected for Lorentz-polarization effects and absorption.[15b,15c] The structure was solved with direct methods with SHELXS97[15d] and refined by full-matrix least-squares procedure on $F^2$ with SHELXL97.[15e] All non-hydrogen atoms were refined anisotropically, hydrogen atoms were located at calculated positions and refined as a "riding model" with isotropic thermal parameters fixed at 1.2 times the $U_{eq}$'s of the appropriate carrier atom.

**1**: $C_4H_8AgN_2S$, tetragonal in $P4cc$, $a$ = 15.7761(9) Å, $b$ = 15.7761(9) Å, $c$ = 6.9624(8) Å, $V$ = 1732.8(2) Å$^3$, $Z$ = 2, $T$ = 100(1) K, $\rho_{calcd.}$ = 2.166 g cm$^{-3}$, $\mu$ = 2.8 mm$^{-1}$, reflections collected: total, unique data, $R$(int) = 9927, 1824, 0.043, index range: $-21 < h < 20$, $-21 < k < 20$, $-9 < l < 7$, observed data [$I > 2.0$ sigma($I$)]: 1445, final $R$[a], $wR2$[b] [$I > 2\sigma(I)$] indices: 0.0289 and 0.0605, respectively. ([a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$; [b] $wR2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$, goodness of fit: 1.032.

CCDC-624697 (for **1**) contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# First Structural Characterization of Silanedithiol and Its Application toward the Synthesis of Silanedithiolato Complexes

Taro Tanabe,[a] Nobuhiro Takeda,[a] and Norihiro Tokitoh*[a]

**Keywords:** Silanedithiol / Silanedithiolato complexes / Silaneselenol / Group 10 transition metal complexes / X-ray crystallography

In this paper, we report the synthesis and the structural characterization of stable examples of silanedithiol [Tbt(Mes)Si(SH)$_2$ (**1**)], hydroxysilanethiol [Tbt(Mes)Si(OH)(SH) (**3**)], and hydroxysilaneselenol [Tbt(Mes)Si(OH)(SeH) (**7**)], which are kinetically stabilized by an effective combination of steric protection groups, Tbt (2,4,6-tris[bis(trimethylsilyl)methyl]phenyl) and Mes (2,4,6-trimethylphenyl). Silanedichalcogenols **1**, **3**, and **7** are suggested to exist as a monomer without any intermolecular contact such as hydrogen bonds both in the solid state and in solution as judged by X-ray structural analysis and IR spectroscopy. Treatment of **1** with 2 equiv. of butyllithium resulted in the quantitative formation of the corresponding dilithium silanedithiolate, Tbt(Mes)Si(SLi)$_2$ (**8**), the generation of which was confirmed by a trapping experiment using MeI. Furthermore, the addition of *cis*-[MCl$_2$(PPh$_3$)$_2$] (M = Pd, Pt) to a THF solution of **8** afforded the corresponding silanedithiolato complexes, [Tbt(Mes)Si(μ-S)$_2$M(PPh$_3$)$_2$] (**9a**: M = Pd; **9b**: M = Pt), respectively.

## Introduction

Controlled synthesis of (chalcogenido)metal clusters has been one of the most attractive subjects in organometallic chemistry.[1] Recently, silanethiolato or silanedithiolato complexes of late transition metals have been shown to be good precursors of (sulfido)mixed-metal clusters prepared by ligand exchange involving Si–S bond cleavage.[2,3] However, chelating silanedithiolato complexes are less common due to the limitation of appropriate synthetic methodology. That is, an excess amount of 1,3,5,2,4,6-trithiatrisilinane (SSiMe$_2$)$_3$ should be required as a sulfur transfer reagent for the synthesis of such silanedithiolato complexes.[4] On the other hand, silanedithiols, which should be a good precursor of silanedithiolato complexes, have attracted much interest from the viewpoint of their structure and properties. However, it is very difficult to isolate silanedithiols due to their high sensitivity toward moisture, and the properties remained little understood.[5] As for the analogues of main group elements having two geminal SH groups, three examples are structurally characterized, i.e., TbtB(SH)$_2$,[6] AlL(SH)$_2$,[7] and Dep(Dip)Ge(SH)$_2$[8] {Tbt = 2,4,6-tris[bis(trimethylsilyl)methyl]phenyl, L (β-diketiminato) = [N(Dip)C(Me)]$_2$CH, Dip = 2,6-diisopropylphenyl, Dep = 2,6-diethylphenyl}, where the reactive M–SH moieties are protected by bulky substituents. All of these compounds could be easily converted into the heterodimetallic sulfido clusters.[9] Thus, kinetic stabilization should be an appropriate method for the stabilization of M(SH)$_2$ species. In this paper, we present the synthesis and the first structural characterization of a silanedithiol, which is kinetically stabilized by an effective steric protection group, Tbt. In addition, its application as a building block toward the synthesis of silanedithiolato complexes will also be presented.

## Results and Discussion

Silanedithiol **1** was synthesized by the reaction of the corresponding sterically hindered tetrathiasilolane **2**[10] with 1.5 equiv. of LiAlH$_4$ at 0 °C as air- and moisture-stable crystals in 83% isolated yield (Scheme 1). When the reaction was carried out at room temperature, further reduction occurred to give a mixture of **1**, Tbt(Mes)Si(H)SH and Tbt(Mes)SiH$_2$.

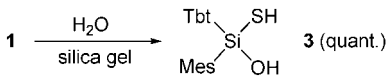
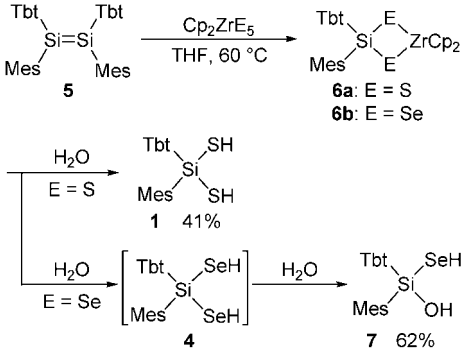
Silanedithiol **1** is stable in [$D_6$]benzene solution even in the presence of $H_2O$ for 1 d, reflecting the extreme bulkiness of the combination of Tbt and Mes groups. However, **1** underwent ready hydrolysis during preparative thin layer chromatography ($SiO_2$) to afford the corresponding hydroxysilanethiol **3** quantitatively (Scheme 2).



Scheme 2. Synthesis of **3** by hydrolysis of **1**.

The successful isolation of silanedithiol **1** prompted us to attempt the synthesis of the selenium analogue, silanediselenol, a stable example of which has been unknown. Unfortunately, tetraselenasilolane, the selenium analogue of **2**, is known to be not available.[10] Another synthetic route is required to obtain the heavier analogue. We focused our attention on the (silanedichalcogenolato)zirconium complexes, which possess reactive Zr–E (E = S, Se) bonds. When disilene **5**[10] was treated with $Cp_2ZrE_5$ at 60 °C, the corresponding silanedichalcogenolato complexes **6a**,**b** were obtained.[11] Treatment of **6a** with $H_2O$ followed by the separation afforded **1**, where the hydrolysis of the Zr–S bonds should occur selectively. Thus, the $SiS_2Zr$ ring system (**6a**) was found to be another precursor for silanedithiol **1**. The selenium analogue **6b** should be a good precursor for silanediselenol. However, the reaction of **6b** with $H_2O$ gave hydroxysilaneselenol **7**, which was probably formed by further hydrolysis of the initially generated silanediselenol **4** (Scheme 3).



Scheme 3. Reaction of **5** with $Cp_2ZrE_5$ (E = S, Se).

The molecular structures of the newly isolated silanedichalcogenols, **1**, **3**, and **7**, were fully determined by X-ray crystallographic analysis (Figure 1).[12] To the best of our knowledge, these are the first examples of the X-ray structural analyses of a silanedithiol, a hydroxysilanethiol, and a hydroxysilaneselenol.[13] The Si–E (E = O, S, Se) bond lengths of **1**, **3**, and **7** are within the range of those reported for the corresponding single bonds between silicon and chalcogen atoms. Absence of intermolecular hydrogen bonding in the solid state was suggested by the packing view, where the observed intermolecular distances between chalcogen atoms are apparently longer than the sum of the van der Waals radii.[14]

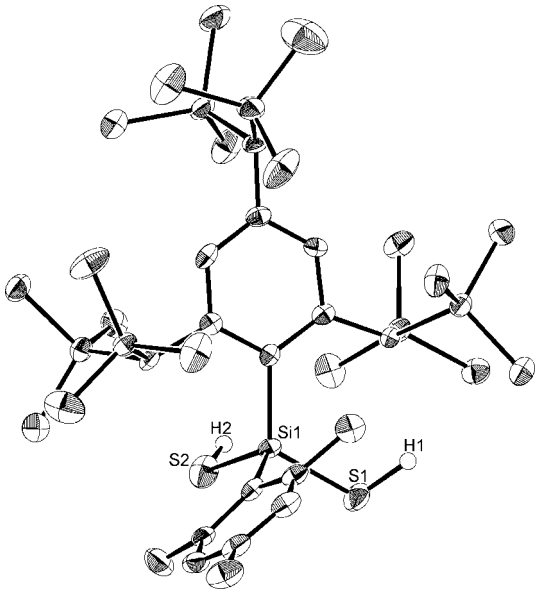


Figure 1. Crystal structure of **1** (ORTEP plot; thermal ellipsoids are shown at 50% probability; hydrogen atoms except for the S–H hydrogen atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Si(1)–S(1) 2.1576(16), Si(1)–S(2) 2.1436(15); S(1)–Si(1)–S(2) 101.73(6).

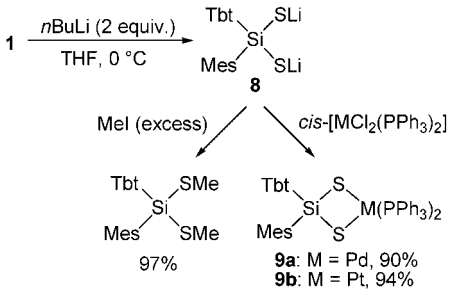
The IR spectra in the solid state for **1**, **3**, and **7** show sharp absorptions assigned to the E–H stretching vibrations [**1**: 2572 $cm^{-1}$; **3**: 2661 $cm^{-1}$, 3646 $cm^{-1}$; **7**: 2479 $cm^{-1}$, 3656 $cm^{-1}$], suggesting the absence of intra- and intermolecular interactions through hydrogen bonds.[15] No change of the IR spectra in $CCl_4$ with several concentrations indicated their monomeric structure and almost no intermolecular contact even in solution.

The generation of dilithium silanedithiolate **8** in the reaction of **1** with 2 equiv. of *n*BuLi was confirmed by a trapping experiment with MeI. Compound **8** should be applicable toward the development of a new synthetic strategy for (silanedithiolato)transition-metal complexes. Addition of *cis*-[$MCl_2(PPh_3)_2$] (M = Pd, Pt) to a THF solution of **8** resulted in the almost quantitative formation of the corresponding silanedithiolato complexes **9a**,**b**, respectively (Scheme 4).[16] The $^{29}Si$ NMR signals of the central silicon atoms in the silanedithiolato complexes **9a** ($\delta_{Si}$ = 15.3 ppm) and **9b** ($\delta_{Si}$ = 14.2 ppm), which appear in the characteristic region of silanedithiolato complex signals,[4c] are in a lower-field region than that of **1** ($\delta_{Si}$ = –1.8 ppm). The structures of **9a**,**b** were revealed by X-ray crystallography. Both of the four-membered rings consisting of Si, S, and Pd or Pt atoms have puckered structures, though the $SiS_2Pd$ ring of the reported (silanedithiolato)palladium complex, [$Me_2Si(\mu\text{-}S)_2Pd(PEt_3)_2$],[4c] has an almost planar structure. This is probably due to the steric repulsion between the extremely bulky

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Tbt group and the triphenylphosphane groups. The X-ray structural analysis of **9b**[17] is the first example of a silanedithiolato complexes of platinum (Figure 2, Scheme 4).



Scheme 4. Synthesis of silanedithiolato complexes **9**.

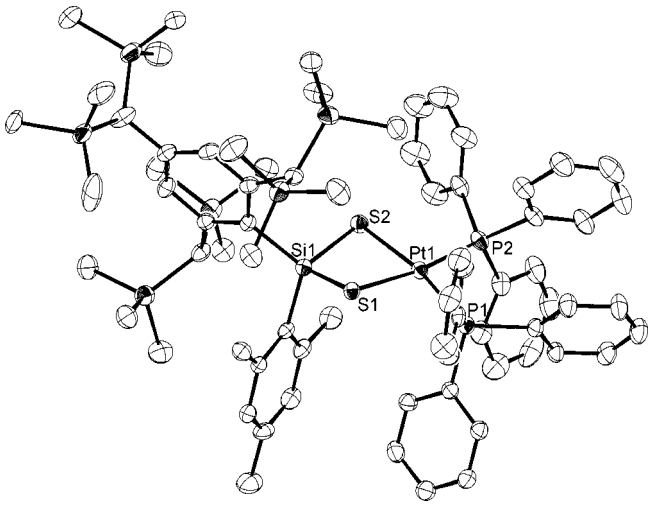


Figure 2. Crystal structure of **9b·hexane** (ORTEP plot; thermal ellipsoids are shown at 30% probability; hexane and hydrogen atoms are omitted for clarity). Selected bond lengths [Å] and angles [°]: Si(1)–S(1) 2.157(2), Si(1)–S(2) 2.115(2), Pt–S(1) 2.3667(15), Pt–S(2) 2.3333(17); S(1)–Si(1)–S(2) 94.92(9), S(1)–Pt–S(2) 84.09(6).

## Conclusions

We have succeeded in the synthesis and characterization of a stable silanedithiol **1** and its application toward the synthesis of the silanedithiolato complexes of palladium and platinum. The stable silanedithiol should be a key species as a building block for several types of (sulfido)mixed-metal clusters. Further investigation on the reactivity of **8** and related compounds are currently in progress.

## Experimental Section

**General Procedure**. All experiments were performed under anhydrous conditions under argon unless otherwise noted. All solvents used in the reactions were purified prior to use by standard methods and/or by an Ultimate Solvent System (Glass Contour Company).[18] $C_6D_6$ used as a solvent was dried with Na, then with a K mirror. $^1$H NMR (300 or 400 MHz) spectra were measured in $CDCl_3$ or $C_6D_6$ with a JEOL AL-400 or AL-300 spectrometer using residual $CHCl_3$ ($\delta$ = 7.25 ppm) or $C_6D_5H$ ($\delta$ = 7.15 ppm) as an internal standard. $^{13}$C NMR (75 MHz) spectra were recorded with a JEOL JNM AL-300 spectrometer. $^{13}$C chemical shifts are reported in ppm downfield from tetramethylsilane and referenced to the carbon signal of $CDCl_3$ ($\delta$ = 77.0 ppm) or $C_6D_6$ ($\delta$ = 128.0 ppm). The multiplicity of signals in the $^{13}$C NMR spectra was determined by the DEPT technique. The $^{29}$Si (59 MHz), $^{31}$P (120 MHz), $^{77}$Se (95 MHz), and $^{195}$Pt (64 MHz) NMR spectra were recorded with a JEOL JNM AL-300 spectrometer. IR spectra were recorded with a JASCO FT/IR-5300 spectrometer. High- and low-resolution mass spectrometric data were obtained with a JEOL JMS-700 spectrometer. Elemental analyses were carried out at the Microanalytical Laboratory of the Institute for Chemical Research, Kyoto University. All melting points were measured with a Yanaco micro melting point apparatus and are uncorrected. Wet column chromatography (WCC) and preparative thin-layer chromatography (PTLC) were performed using Wakogel C-200 and Merk Kieselgel 60 PF254, respectively. GPLC (gel permeation liquid chromatography) was performed on LC-908, LC-918 (Japan Analytical Industry Co., Ltd. Systems) equipped with JAIGEL 1H and 2H columns (eluent: toluene).

**1**: To a solution of **2** (165 mg, 238 μmol) in THF (15 mL) was added $LiAlH_4$ (13.5 mg, 356 μmol) at 0 °C. After the mixture was stirred at 0 °C for 1 h, ethyl acetate (5 mL) was added. After removal of the solvent, hexane was added to the residue. The suspension was filtered through Celite®, and the solvent was removed. The residue was separated by silica gel chromatography (*n*-hexane) to afford **1** (149.7 mg, 195.5 μmol, 83%); colorless crystals, m.p. 177–178 °C. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = –0.02 (s, 18 H), 0.00 (s, 18 H), 0.04 (s, 18 H), 1.18 (s, 2 H, S–H), 1.31 (s, 1 H), 2.22 (s, 3 H), 2.49 (s, 1 H), 2.57 (s, 6 H), 2.63 (s, 1 H), 6.24 (s, 1 H), 6.38 (s, 1 H), 6.76 (s, 2 H) ppm. $^{13}$C NMR (75 MHz, $CDCl_3$): $\delta$ = 0.9 (q), 1.6 (q), 1.9 (q), 20.9 (q), 26.4 (q), 28.0 (d), 28.3 (d), 30.6 (d), 123.3 (d), 126.3 (s),128.5 (d), 130.5 (d), 134.9 (s), 139.7 (s), 142.8 (s), 145.5 (s), 151.9 (s), 152.2 (s) ppm. $^{29}$Si NMR (59 MHz, $CDCl_3$): $\delta$ = –1.8, 1.9, 2.9, 3.0 ppm. IR (KBr): $\tilde{\nu}$ = 2572 [ν(S–H)] cm$^{-1}$. HRMS (FAB$^+$): calcd. for $C_{36}H_{72}S_2Si_7$ $[M]^+$ 764.3460, found 764.3472. $C_{36}H_{72}S_2Si_7$ (765.69): calcd. C 56.47, H 9.48, S 8.38; found C 56.51, H 9.57, S, 8.81.

**9b**: To a solution of **1** (27.8 mg, 36.3 μmol) in THF (3 mL) was added *n*BuLi (1.64 N hexane solution, 51 μL, 82.1 μmol) at 0 °C. After the mixture was stirred at 0 °C for 30 min, a THF solution (15 mL) of *cis*-bis(triphenylphosphane)platinum dichloride (43.1 mg, 54.4 μmol) was added. After removal of the solvent, benzene (3 mL) was added to the residue. The mixture was filtered through Celite®, and the solvent was removed. The residue was separated with HPLC (toluene) to afford **9b** (50.5 mg, 34.1 μmol, 94%) as a pale yellow solid. Pale yellow crystals suitable for X-ray structural analysis were grown from hexane at –20 °C; pale yellow crystals, m.p. 250–252 °C (dec.). $^1$H NMR (300 MHz, $C_6D_6$): $\delta$ = 0.21 (s, 18 H), 0.29 (s, 18 H), 0.34 (s, 18 H), 1.49 (s, 1 H), 2.11 (s, 1 H), 2.31 (s, 3 H), 2.53 (s, 1 H), 2.93 (s, 6 H), 6.50 (s, 1 H), 6.62 (s, 1 H), 6.83 (s, 2 H), 6.85–6.94 (m, 18 H, $Ph_3P$), 7.49–7.55 (m, 12 H, $Ph_3P$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $C_6D_6$): $\delta$ = 1.2 ($CH_3$), 2.1 ($CH_3$), 2.5 ($CH_3$), 21.1 ($CH_3$), 25.3 (CH), 25.6 (CH), 26.9 ($CH_3$), 30.5 (CH), 127.8 (CH), 128.3 (CH), 128.5 (CH), 128.6 [d, $^4J_{CP}$ = 1.2 Hz, CH, *p*-Ph($PPh_3$)], 131.41 [*d*, $^3J_{CP}$ = 1.9 Hz. CH, *m*-Ph($PPh_3$)], 131.42 [dd, $^1J_{CP}$ = 54.9 Hz, $^3J_{CP}$ = 6.8 Hz, C, *ipso*-Ph

# Molecular Ice with Hybrid Water–Bromide Network around a Cryptand with a Bromide Ion Included in the Cavity to Form a Host-within-a-Host-Like Structure

**Madhab C. Das[a] and Parimal K. Bharadwaj*[a]**

**Keywords:** Anion binding / Cryptands / Hydrogen bonds / Water chemistry / X-ray diffraction

A new mode of association of water molecules is described. Adamantanoid water clusters bonded to bromide ions as well as other water molecules form a cage within which bromide-encapsulated aza cryptands reside to form a host-within-a-host-like structure. The structure of this adamantanoid water decamer is remarkably similar to that of cubic ice ($I_c$). The average O···O distance is 2.78 Å, which is close to 2.75 Å present in $I_c$, and the average O···O···O angle of 109.40° is also close to the tetrahedral angle in ice $I_c$.

## Introduction

Complexation of anions by different host molecules has become an area of intense research[1] because the function of anions is essential in biological systems and in diverse enzymatic reactions. Anions are also implicated[2] in several diseases such as cystic fibrosis, Alzheimer's disease, etc. In addition, different environmental problems are associated with anions. Herein, we report the supramolecular association of ten water molecules into "molecular ice", which further connects other such units and a cluster of water and bromide ions to form a 3D cage within which lies a cryptand that encapsulates a bromide ion in its cavity. There are other cryptands also present with empty cavities.

The importance of water and its well-discussed anomalies have resulted in a large number of theoretical as well as experimental studies[3–6] that cover a broad range of topics on the structure of water. For ice, there are several crystalline[7] and amorphous[8] phases known. Phases $I_h$ and $I_c$ are the two most common forms[7a] of ice and are strikingly similar in structure. They differ only in the stacking sequence of the puckered layers relative to one another such that the interconnecting rings are in the boat conformation in ice $I_h$ whereas they assume a chair conformation in ice $I_c$. This form of ice is also called cubic ice and its formation is of utmost importance in cryobiology where formation of ice upon cooling the sample is the primary cause of cell damage. Biological samples are better preserved in $I_c$ which form tiny crystals all around and do not lead to extensive solute segregation,[9] whereas $I_h$ causes massive cell damage. Cubic ice is also likely to be present[10] in the outer spheres of some of the planets of our solar system, including earth.

## Results and Discussion

Complex **1** was isolated as colorless crystals[11] from an aqueous methanolic solution of **L**[12] (Scheme 1) in the presence of HBr in 65% yield. The asymmetric unit of **1** consists of two bridges from two different cryptand units, seven water molecules, and three bromides, where one of the bromides (Br1) sits on a crystallographic threefold symmetry axis. The atom Br1, included in the cryptand cavity, pulls the two bridgehead N atoms towards itself thereby decreasing their interatomic distance to 8.452 Å from the observed value of 9.904 Å [12] in **L**. This bromide is H-bonded with the three protonated secondary amines in the three bridges (N6···Br1, 3.278 Å; N6–H2···Br1, 148.55°) and three aromatic CH protons (C20···Br1, 3.439 Å; C20–H20···Br1, 127.73°) to complete a distorted octahedral coordination (Figure 1) geometry. The second bromide (Br2), which occupies a position outside the cryptand cavity, forms one strong N–H···Br hydrogen bond (N6···Br2, 3.286 Å; N6–

H1···Br2, 119.59°) with the bromide-encapsulated cryptand and two strong N–H···Br hydrogen bonds (N3···Br2, 3.262 Å; N3–H2···Br2, 127.55°, and N3···Br2, 3.262 Å; N3–H1···Br2, 141.85°) with the bromide-free cryptand, thereby acting as a linker among the cryptand units. Thus, each of the protonated secondary amines of the "tren" end of the bromide-encapsulated cryptand makes two contacts: one N–H···Br1 and one N–H···Br2. Each of the protonated secondary amines of the bromide-free cryptand also makes two different N–H···Br2 intermolecular contacts (Figure 2).

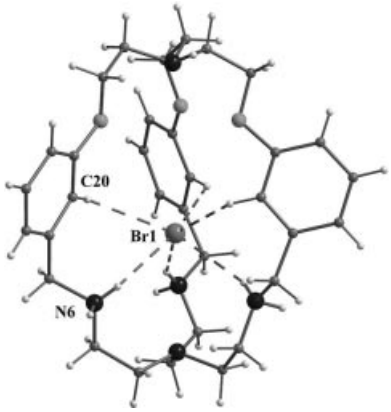

Figure 1. A perspective view showing a bromide ion (Br1) encapsulated inside the cryptand cavity.

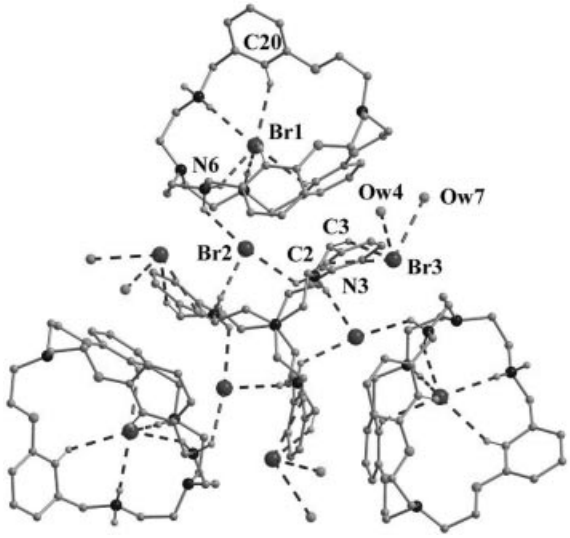

Figure 2. A view showing different hydrogen bonding interactions of the three bromide ions. Only those H atoms that are involved in H-bonding are shown.

Out of the seven water molecules present in the asymmetric unit, four are involved with other symmetry related $H_2O$ molecules to form an adamatanoid $(H_2O)_{10}$ cluster whereas the rest join these $(H_2O)_{10}$ clusters to form a layer of supramolecularly assembled water molecules. Br3 ions are H-bonded to the layer of water molecules that reinforce the structure. Overall, there are three different types of H-bonding networks associated with the adamantanoid water cluster (three Ow2···Ow7···Br3, three Ow3···Ow5···Ow6, and three Ow4···Br3···Ow7 networks). Six adamantanoid units form a 3D cage-like supramolecular network through connections with the remaining $H_2O$ molecules and Br3 ions. The bromide-encapsulated cryptand lies within this cage and assumes a host-within-a-host-like structure (Figure 3), which resembles the Russian nesting doll.[13]

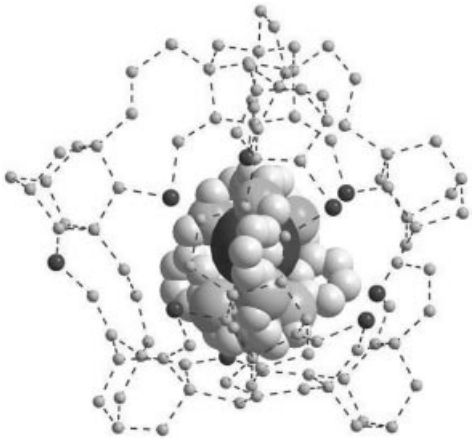

Figure 3. A view of the host within a host structure. Bromide encapsulated cryptand moiety is shown in space-filling model. Hydrogen atoms are omitted for clarity. Color code: C light grey, N medium grey, O dark grey, Br black.

Figure 4 represents the coordination environment of the adamantanoid water cluster, which consists of four different types of water molecules with respect to their noncovalent interactions. The $(H_2O)_{10}$ cluster is termed "molecular ice" because this is the smallest unit of naturally occurring cubic ice. The structure of this adamantanoid water decamer in **1** is remarkably similar to that of ice $I_c$.[14] The average O···O distance in **1** is 2.78 Å, which is close to 2.75 Å, present in $I_c$.[14] The average O···O···O angle of 109.40° in the structure is also close to the tetrahedral angle in ice $I_c$.[14] The distance across the water decamer from Ow2 to Ow4 is slightly lower [6.282(2) Å] than the value (6.35 Å) observed in $I_c$.[15] Adamantanoid $(H_2O)_{10}$ clusters detected in the voids of a

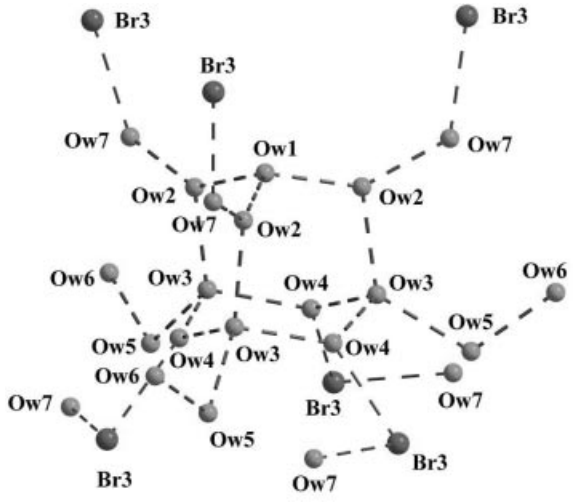

Figure 4. A close view of the adamantanoid water cluster and its environment.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cupric complex[16] or within a hydrophobic self-assembled cage[17] have comparable noncovalent parameters. Notably, the Ow6 makes three H-bonded contacts with three Ow5 and creates three fused nonameric units;[18] each nonamer contains two water molecules of one adamantanoid unit (Ow2, Ow3), two water molecules of another adamantanoid unit (Ow3, Ow4), two Ow5, and one Br3 ion. Figure 5 shows the packing diagram of the different constituent units present in **1**.

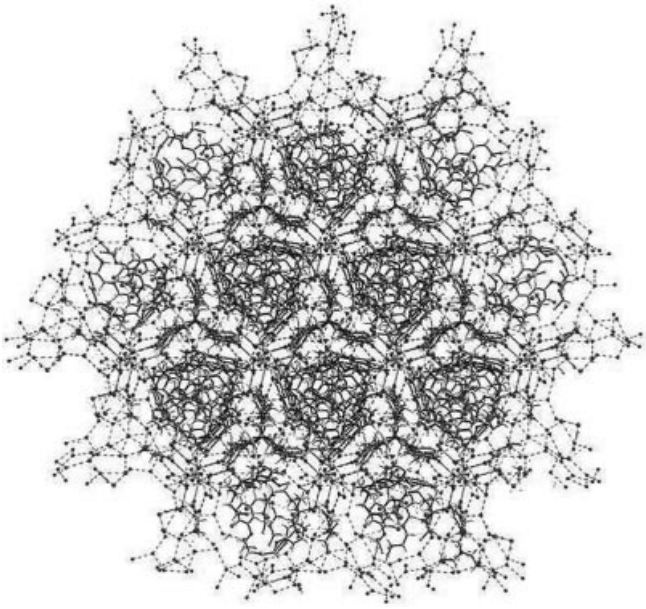

Figure 5. Packing diagram of **1** viewed along the two bridgehead N atoms of the bromide encapsulated cryptand.

Compound **1** exhibits a strong broad peak at about 3404 $cm^{-1}$ in the IR spectrum, and this peak is attributed[18] to O–H stretching pertaining to the water cluster. The O–H stretching vibration for $I_c$ appears[14] as a broad band centered around 3200 $cm^{-1}$. The difference in the stretching vibrations of **1** in comparison to $I_c$ is due to its different environment. Thermal gravimetric analysis[18] reveals that **1** loses 9.55% of weight at 120 °C, which corresponds to ca. 10 molecules of water. The rest of the water molecules are lost along with decomposition of the compound after only 250 °C, which signifies that the remaining water molecules are tightly held in the crystal lattice. After heating[18] the compound at 120 °C to remove ten molecules of water, the IR spectrum shows the broad peak characteristic of the remaining association of water molecules. Powder X-ray data taken[18] before and after heating the sample in vacuo at 120 °C for 2 h show that once the bulk of the water molecules are removed, the lattice breaks down.

## Conclusions

In conclusion, we have shown that a bromide-encapsulated cryptand is surrounded by a cage formed by connecting molecular ice-like water clusters with other water molecules and bromide ions. Thus, the structure looks like a Russian nesting doll. The understanding of three-dimensional structures of this and similar systems have profound effects in several areas, from molecular self-assembly,[19] gas clathrate hydrates,[20] to cryobiology.[9] We are presently working along these lines.

## Experimental Section

Cryptand **L** was synthesized as reported[12] previously from our lab. Complex **1** was synthesized by allowing a solution of the cryptand (84 mg, 0.15 mmol) in aqueous methanol (6 mL, 1:1, v/v) in the presence of HBr to concentrate. After a few days, crystals of $\{[H_3\mathbf{L}][H_4\mathbf{L}]\cdot(Br)_7\cdot 15H_2O\}_n$ (**1**) appeared as colorless rectangular plates in 65% yield. $C_{66}H_{127}Br_7N_{10}O_{21}$ (1956.10): calcd. C 40.52, H 6.54, N 7.16; found C 40.46, H 6.59, N 7.08.

**Supporting Information** (see footnote on the first page of this article): FTIR spectrum, TGA curve, and PXRD analysis of **1**. Additional figures that show the structure of the cryptand cage-like structure.

# Intra- and Intermolecular H···Cl–Ni Bonding Patterns in a Series of Highly Preorganized Dinuclear Nickel(II) Complexes

**Feng-Mei Nie,[a][‡] Guido Leibeling,[a] Serhiy Demeshko,[a] Sebastian Dechert,[a] and Franc Meyer*[a]**

**Keywords:** Nickel / Dimetallic complexes / Hydrogen bonds / Pyrazolate ligands / Magnetic properties

Four dinickel complexes $[L^1Ni_2(\mu\text{-}Cl)(Cl)_2]\cdot 2CH_3OH$ (**1a**), $[L^1Ni_2(\mu\text{-}Cl)(CH_3OH)](ClO_4)_2$ (**1b**), $[L^2Ni_2(\mu\text{-}Cl)Cl_2(H_2O)_2]\cdot H_2O$ (**2**) and $[L^3Ni_2Cl_2(CH_3OH)_2]Cl\cdot 2CH_3OH$ (**3**) were synthesized and structurally characterized. The ligand scaffolds have a central pyrazolato bridge and N-donor chelate arms that provide two proximate binding pockets for the nickel ions. While the longer ligand side arms in **1a**, **1b** and **2** induce Ni···Ni distances of around 4.0 Å and favour incorporation of a chlorido bridge within the dimetallic pocket, a stretched Ni···Ni separation of 4.6 Å with an unusual intramolecular Cl···H–O linkage is observed in **3**. Various Cl···H–O hydrogen-bonding motifs are identified in the solid-state structures of **1**–**3**, where either the H-donor (MeOH or $H_2O$) or the H-acceptor (chlorido) or both are bound to a nickel ion, and their relative donor–acceptor distances are discussed. Magnetic coupling mediated through the pyrazolato and chlorido bridges is rather weak and antiferromagnetic, but it is even weaker for the Cl···H–O linkage.

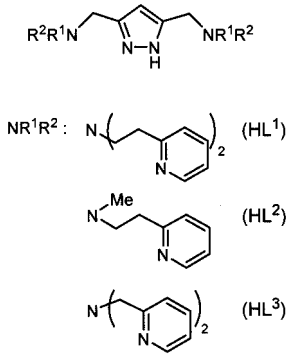
## Introduction

Hydrogen bonding to metal-bound ligands can have profound effects on fundamental properties of the metal complex, such as the metal–ligand bond lengths, redox potentials and reactivity.[1–3] Metal-bound chlorido ligands have been identified as a very good hydrogen-bond acceptor (in contrast to its organochlorine counterpart), having the potential to interact with hydrogen-bond donors in both a strong (i.e., short) and anisotropic fashion.[4,5] While hydrogen bonds to metal-bound fluorido ligands are even stronger, they also exhibit a distinct angular preference for larger H···F–M angles.[6] Intermolecular D–H···X–M (D = N, O; X = F, Cl, Br, I) interactions are increasingly applied in molecular recognition, crystal engineering and the noncovalent assembly of metallosupramolecules,[7,8] while intramolecular D–H···X–M motifs involving pendant nonligating hydrogen-bonding groups allow the stabilization of unusual ligands, such as HF, at a metal ion.[9] A particular situation arises if the hydrogen-bond donor D is itself acting as a ligand towards a second metal ion. This may enhance the acidity of the D–H unit and may induce particularly strong intramolecular D–H···X–M interactions, as was observed in some Cu–(H)O–H···F–Cu motifs with extremely short H···F distances.[10,11] In order to enforce the formation of such hydrogen bonds, the use of dinucleating ligand scaffolds that constrain the metal–metal separation appears most promising. Here we report the structural characterization of a series of pyrazolato-based dinickel chloride complexes that exhibit various hydrogen-bonding arrangements. These involve the nickel-bound chlorido ligand and water or methanol solvent molecules, comprising an unusual intramolecular Ni–(Me)O–H···Cl–Ni interaction. The set of compartmental ligands used in this work is depicted in Scheme 1.



Scheme 1. Ligands used in this work.[10]

The ligands differ by the number of side arm donor sites ($HL^1$ versus $HL^2$) or by the side arm chain length ($HL^1$ versus $HL^3$). The latter variation was previously shown to determine the preferred metal–metal distance in the resulting dimetallic complexes, with the shorter side arms in

$HL^3$ enforcing larger metal–metal distances of >4 Å.[12,13] With 3d transition-metal ions such as copper(II) and zinc(II), $\{L^1M_2\}$ scaffolds (M = Cu, Zn) allow small bridges such as a hydroxido group to span the two metal ions, while the shorter ligand side arms in $\{L^3M_2\}$ pull the metal ions back and apart. The latter situation induces incorporation of an additional solvent molecule, giving functionalities such as (H)O–H–O(H) or F–H–O(H) within the dimetallic pocket.[10,14] Similar effects are now anticipated in nickel complexes of the current pyrazolato ligands and are investigated in order to probe hydrogen-bonding patterns to nickel-bound chlorido ligands.

## Results and Discussion

### Synthesis and Structural Characterization

Dinickel complexes of $[L^1]^-$, $[L^2]^-$ and $[L^3]^-$ were readily prepared from the respective pyrazole derivative $HL^1$, $HL^2$ and $HL^3$, 2 equiv. of $NiCl_2{\cdot}6H_2O$ and a base (usually $NEt_3$). Crystalline material of the resulting complexes **1a**, **2** and **3** was obtained from methanol/diethyl ether solutions. In order to gain some insight into the structural consequences that result from the presence of fewer chlorido ligands, complex **1b** was prepared by a similar procedure starting from $HL^1$, but using 2 equiv. of $Ni(ClO_4)_2{\cdot}6H_2O$ and 1 equiv. of NaCl. FAB mass spectra of **1a**, **2** and **3** feature dominant signals for the respective $[LNi_2Cl_2]^+$ ions, while the FAB mass spectrum of **1b** shows a signal for $[L^1Ni_2Cl(ClO_4)]^+$.

The molecular structures of all four complexes are depicted in Figures 1, 2, 3 and 4, along with selected interatomic distances and bond angles. In all cases the two nickel ions are hosted within the binding pockets of the ligand scaffold, spanned by the pyrazolato ligand and coordinated by the side arm nitrogen atoms. In $[L^1Ni_2Cl_3]$ (**1a**), both nickel(II) ions are six-coordinate; the coordination environment of each nickel ion consists of four nitrogen atoms from the pyrazolato, a bridging chlorido and a terminal chlorido ligand (Figure 1). Interestingly, the chlorido ligand at Ni1 is located *trans* to the pyrazolato N1 atom, while the chlorido ligand at Ni2 is found *trans* to the pyridyl N8 atom. When only a single chlorido ligand is present per dimetallic entity in $[L^1Ni_2(Cl)(CH_3OH)](ClO_4)_2$ (**1b**), it occupies the bridging position, leaving Ni2 five-coordinate while a methanol solvent molecule fills the remaining site at Ni1 (Figure 2). Fewer ligand side arms in $[L^2Ni_2Cl_3(H_2O)_2]$ (**2**) allow for the binding of a water solvent molecule to each of the metal ions, with one of the chlorido ligands in the bridging position and the others terminally bound *trans* to the pyrazolato N atom (Figure 3). The Ni–O distances in **1b** and **2** (2.16 and 2.14 Å) are comparable to those found in other six-coordinate nickel complexes with three or four nitrogen donor atoms and one or two chlorido ligands, as for example in $[(phen)_2NiCl(H_2O)]Cl{\cdot}EtOH{\cdot}H_2O$ (2.03 Å, phen = 1,10-phenanthroline)[15] or [(1,4,8,11-tetraazaundecane)$NiCl(H_2O)$]Cl (2.18 Å).[16] Metal···metal separations in all three complexes are very similar and quite short at 4.09 (**1a**), 4.00 (**1b**) and 4.11 (**2**) Å. It should be noted that related nickel(II) chloride complexes of some pyrazolato-derived ligands bearing aliphatic N-donor side arms usually feature five-coordinate nickel atoms,[17] in contrast to the systems studied here. However, close inspection reveals that the Ni–Cl–Ni bridge in **1a** is highly asymmetric with a long Ni1–Cl2 distance (2.82 Å) and a much shorter Ni2–Cl2 bond (2.50 Å). All other Ni–Cl distances ranging from 2.36 to 2.57 Å for Ni–Cl and from 2.46 to 2.65 Å for Ni–(μ-Cl) are in agreement with expectations.[17] The slight asymmetry of the Ni–Cl–Ni bridge in **1b** [*d*(Ni1–Cl1) = 2.61 Å, *d*(Ni2–Cl1) = 2.46 Å] reflects the different coordination numbers of the metal ions. The methanol molecule bound to Ni1 in **1b** is hydrogen-bonded to one of the perchlorate counteranions [*d*(O1···O21) = 2.80 Å].

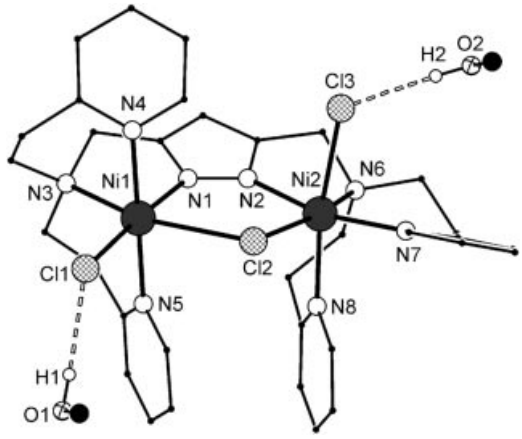

Figure 1. Plot of the molecular structure of **1a**. All hydrogen atoms except the O–H protons have been omitted for clarity. Selected interatomic distances [Å] and angles [°]: Ni1–Cl1 2.3632(6), Ni1–Cl2 2.8251(6), Ni1–N1 1.982(2), Ni1–N3 2.180(2), Ni1–N4 2.142(2), Ni1–N5 2.117(2), Ni2–Cl2 2.4947(5), Ni2–Cl3 2.5723(6), Ni2–N2 1.984(2), Ni2–N6 2.205(2), Ni2–N7 2.105(2), Ni2–N8 2.118(2), Ni1···Ni2 4.0917(6), O1–H1 0.86(3), O1···Cl1 3.184(2), O2–H2 0.82(3), O2···Cl3 3.062(2); Ni1–Cl2–Ni2 100.37(2), N1–Ni1–Cl1 175.94(4), N1–Ni1–Cl2 82.25(4), Cl2–Ni1–N3 162.44(4), N4–Ni1–N5 178.30(6), N2–Ni2–N7 166.14(6), N2–Ni2–Cl2 87.73(4), Cl3–Ni2–N8 169.42(4), O1–H1···Cl1 162(3), O2–H2···Cl3 170(3).

The terminal chlorido ligands in **1a** are involved in hydrogen bonding with methanol molecules included in the crystal lattice (Figure 1), where the Cl···O distances correlate with the Ni–Cl bond lengths; the chlorido ligand Cl1 with a short *d*(Ni1–Cl1) = 2.36 Å forms a relatively long hydrogen bond [*d*(Cl1···O1) = 3.18 Å], while the hydrogen bond of the more loosely bound Cl3 [*d*(Ni2–Cl3) = 2.57 Å] is significantly shorter at *d*(Cl3···O2) = 3.06 Å. The pyrazolato-based dinickel entities in **2** are strongly dimerized in the solid state through a series of O–H···Cl hydrogen bonds (Figure 3). In this closed hydrogen-bonding motif each nickel-bound water molecule forms two hydrogen bonds to chlorido ligands of the opposite dinickel array, giving rise to a zig-zag sequence of O–H···Cl linkages. The dimerized

arrangement is capped by hydrogen bonds to two additional water molecules included in the crystal lattice, thus preventing the formation of chains or 3D hydrogen-bonded

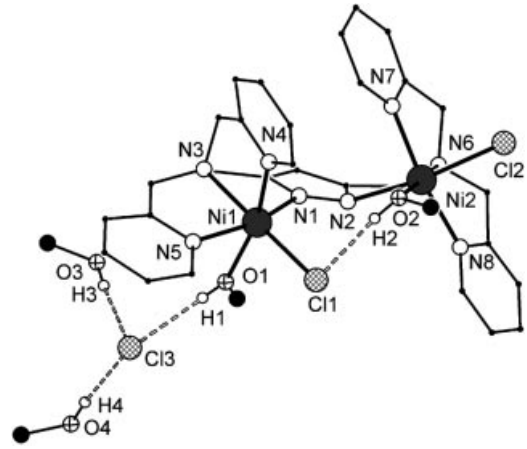

Figure 4. Plot of the molecular structure of **3**. All hydrogen atoms except the O–H protons have been omitted for clarity. Selected interatomic distances [Å] and angles [°]: Ni1–Cl1 2.3641(6), Ni1–O1 2.184(2), Ni1–N1 2.052(2), Ni1–N3 2.121(2), Ni1–N4 2.092(2), Ni1–N5 2.082(2), Ni2–Cl2 2.4522(7), Ni2–O2 2.070(2), Ni2–N2 2.144(2), Ni2–N6 2.106(2), Ni2–N7 2.066(2), Ni2–N8 2.070(2), Ni1···Ni2 4.6007(7), O1–H1 0.77(3), O1···Cl3 3.054(2), O2–H2 0.83(3), O2···Cl1 3.052(2), O3–H3 0.80(3), O3···Cl3 3.150(2), O4–H4 0.85(4), O4···Cl3 3.133(2); N1–Ni1–N5 159.32(6), N1–Ni1–Cl1 101.35(4), Cl1–Ni1–N3 177.81(5), O1–Ni1–N4 166.58(6), N2–Ni2–Cl2 171.67(4), N2–Ni2–O2 91.82(6), O2–Ni2–N6 174.73(6), N7–Ni2–N8 161.91(7), O1–H1···Cl3 167(3), O2–H2···Cl1 172(3), O3–H3···Cl3 174(3), O4–H4···Cl3 174(3).

networks. Overall, each chlorido ligand and each water molecule is involved in two hydrogen-bonding contacts. The resulting dimer of dinickel subunits in **2** is located on a centre of inversion, with each dinickel molecule having crystallographically imposed $C_s$ symmetry. As expected, O–H···Cl interactions to the bridging chlorido ligands are the longest at $d$(Cl1···O1) = 3.29 Å, but they are well within the range expected for HOH···Cl or $RCH_2OH$···Cl hydrogen bonds.[5,8]

The molecular structure of **3** that incorporates the pyrazolato ligand $[L^3]^-$ with shorter side arms differs fundamentally from those of **1a**, **1b** and **2**, since the chlorido atom Cl1 does not occupy a bridging position within the dimetallic pocket (Figure 4). Instead, a methanol molecule is inserted at Ni2 to give an unusual intramolecular Ni–Cl···H–O(Me)–Ni bridge with a short hydrogen bond [$d$(Cl1···O2) = 3.05 Å]. As a consequence, the Ni···Ni separation in **3** (4.60 Å) is considerably longer than in **1a**, **1b** and **2** (4.09, 4.00 and 4.11 Å, respectively). Ligand $[L^3]^-$ has previously been shown to favour longer metal–metal separations of around 4.5 Å because of the shorter chelate arms than those of $[L^1]^-$.[12] Observation of $[L^3Ni_2Cl_2]^+$ as the dominant ion in the FAB mass spectrum of **3** suggests, however, that the inserted methanol molecule is readily lost under reduced pressure.

Both nickel(II) ions in **3** are six-coordinate, but a major difference to the analogous complex of ligand $[L^1]^-$ (i.e., complex **1a**) is the coordination isomerism of some chlorido

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligands. In **1a** a chlorido ligand (Cl1) is terminally bound to Ni1 and forms a hydrogen bond to a lattice methanol molecule, while an inverse situation is found for **3** where the methanol molecule acts as a ligand to Ni1 and is hydrogen-bonded to the chlorido ligand Cl3 that is dissociated from the metal ion. The distance Cl3···O1 in **3** is very short and comparable to the short intramolecular Cl···H–O linkage (3.05 Å), in accordance with the idea that a dissociated chloride ion should be a better H-bond acceptor because of its larger negative charge compared with a metal-bound chlorido ligand such as in **1a** and **2**.[5] Interestingly, the "free" Cl3 in **3** forms two further hydrogen-bonding interactions to lattice methanol molecules which are significantly longer (3.13 and 3.15 Å; Figure 4) than the hydrogen bond to nickel-bound O1, thus supporting the assumption that the hydrogen-bond strength is enhanced by coordination and acidification of the H-donor methanol.

## Magnetic Properties

In order to evaluate the effect of the different structural features and bridging units of the dimetallic scaffolds on the magnetic coupling between the proximate nickel(II) ($S$ = 1) ions, magnetic susceptibility measurements were carried out for all four complexes at two different magnetic fields in a temperature range from 2.0 to 295 K. No significant field dependence was observed for any of the complexes. The temperature dependence of the magnetic susceptibility $\chi_M$ and the product $\chi_M T$ is shown in Figure 5. In all cases, the observed $\chi_M T$ values of around 2.5 $cm^3 K mol^{-1}$ (≈ 4.5 $\mu_B$) at room temperature are close to the value expected for two uncoupled nickel(II) ions ($\chi_M T$ = 2.42 $cm^3 K mol^{-1}$ for $g$ = 2.2). The $\chi_M T$ curves gradually but steadily drop with decreasing temperature and finally tend to zero, indicating an $S$ = 0 ground state. $\chi_M$ accordingly goes through a maximum, but only at very low temperatures, suggesting that the coupling is weak.

Magnetic parameters were determined using a fitting procedure to the appropriate Heisenberg spin Hamiltonian for isotropic exchange coupling. Simulation of the experimental magnetic data was performed with full-matrix diagonalization of exchange coupling and Zeeman splitting according to the Hamiltonian in Equation (1).[18]

$$H = -2J\vec{S}_1\vec{S}_2 + g\mu_B(\vec{S}_1 + \vec{S}_2)\vec{B} \quad (1)$$

Before simulation the experimental data were corrected for the underlying diamagnetism by using tabulated Pascal constants (incremental method) and for temperature-independent paramagnetism (*TIP*; included in the data representation in Figure 5). A Curie-behaved paramagnetic impurity (*PI*) with spin $S$ = 1 was included according to $\chi = (1 - PI)\chi + PI\chi_{mono}$. Satisfactory fits were obtained for all four systems, and values for $g$, $J$, *PI* and *TIP* are listed in Table 1.

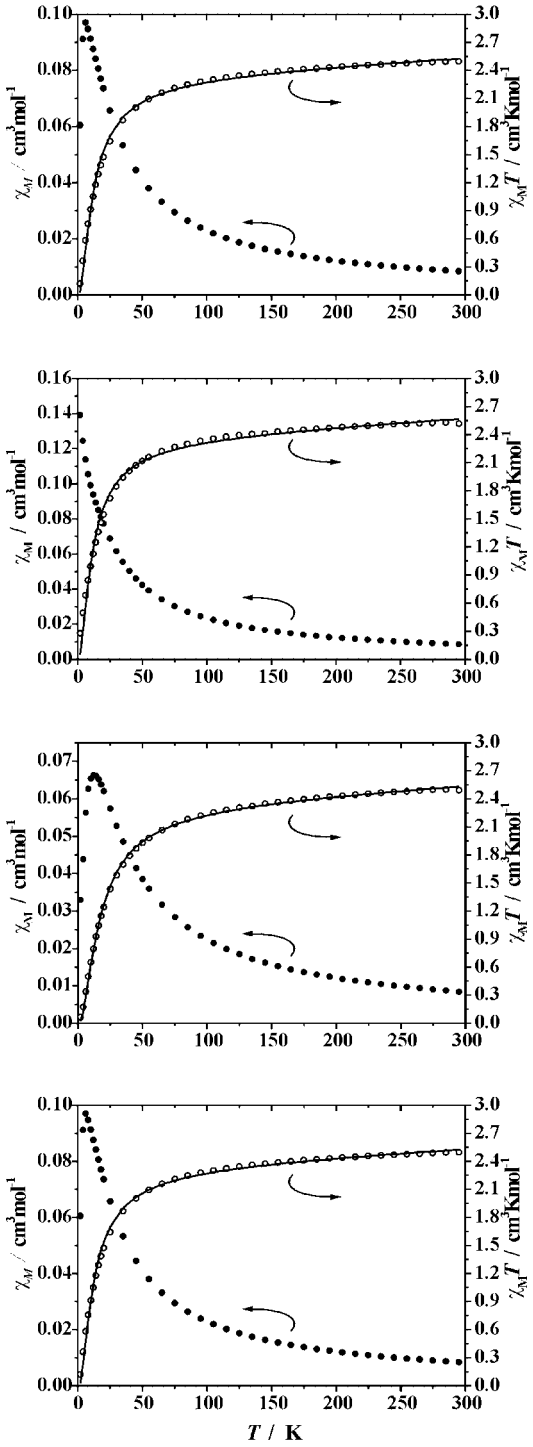

Figure 5. $\chi_M$ (solid circles) and $\chi_M T$ (open circles) vs. $T$ plot for **1a** (top), **1b** (second from top), **2** (second from bottom) and **3** (bottom) at 5000 G; the solid line represents the calculated curve fit (see text).

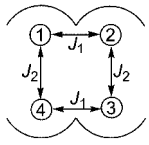
Table 1. Magnetic parameters for complexes **1a**, **1b**, **2** and **3** according to Equation (1).

| | **1a** | **1b** | **2** | **3** |
|---|---|---|---|---|
| $g$ | 2.18 | 2.20 | 2.22 | 2.20 |
| $J$ [$cm^{-1}$] | –3.6 | –3.4 | –5.1 | –1.7 |
| *PI* [%] | 0.7 | 2.0 (fixed) | 2.0 (fixed) | 1.5 |
| *TIP* [$10^{-4}$ $cm^3 mol^{-1}$] | 7.2 | 7.8 | 7.8 | 4.3 |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Since nickel(II) may exhibit significant zero-field splitting that can be similar in magnitude to the *J* values determined, data analysis was also probed with an additional term $2D[S_z^2 - 1/3S(S + 1)]$ included in Equation (1) that accounts for a local zero-field splitting parameter *D*. However, with reasonable values for *D* and *PI* this analysis did not lead to any substantial changes in the *J* values, while the decrease of $\chi_M T$ at low temperatures could not be described by considering *D* only (i.e., without exchange Hamiltonian, $J = 0$).[19]

In view of the aggregation of **2** in the solid state as described earlier, an alternative "dimer of dimer" model according to Scheme 2 has also been applied to the magnetic data analysis of this complex. This model gives a similarly good fit with $g = 2.25$, $J_1 = -3.9\ cm^{-1}$, $J_2 = -2.6\ cm^{-1}$, $PI = 2\%$ and $TIP = 8.8 \times 10^{-4}\ cm^3 mol^{-1}$. Note that assignment of $J_1$ and $J_2$ to the *intra*dimer and *inter*dimer coupling is arbitrary because of the symmetry of the Hamiltonian.



Scheme 2. Alternative coupling scheme for **2**.

Rather small negative *J* values confirm relatively weak antiferromagnetic coupling between the adjacent nickel ions in all cases, but subtle differences are discernible. The coupling is clearly weakest in **3**, while it appears to be strongest in **2**. Although the multitude of structural variations among the four complexes (coordination numbers and geometries, distortion of the nickel ions out of the pyrazolato plane, etc.) prevents any definite interpretation in terms of magnetostructural correlations, one may attribute the much lower *J* value for **3** to the lack of a chlorido bridge and to the much weaker coupling efficiency of the intramolecular Cl···H–O linkage. This also corroborates the assignment of $J_1$ and $J_2$ in the "dimer of dimer" model for **2**, since any interaction through the hydrogen bonds should be weak. The somewhat weaker coupling in **1a** and **1b** relative to the coupling within the pyrazolato-based dinickel entities of **2** may be a result of the pronounced asymmetry of the Ni–Cl–Ni bridge and the presence of a very long Ni–Cl bond in the two former systems [*d*(Ni1–Cl2) = 2.83 Å in **1a**; *d*(Ni1–Cl1) = 2.61 Å in **1b**], as such long distances provide no efficient exchange pathway. It should be emphasized, though, that additional factors such as the canting between the basal planes of the two nickel ions and the plane of the pyrazolato bridge will also play a substantial role and should contribute to the diminished coupling in **3**.

## Conclusions

The compartmental pyrazolato-based ligands $HL^1$, $HL^2$ and $HL^3$ with pyridyl side arms are obviously well suited to form dinuclear nickel(II) complexes, similar to related pyrazolato ligands with aliphatic chelate arms. Since the latter have provided useful scaffolds for synthetic models of the active site of the dinickel enzyme urease, a likewise rich chemistry is now expected for $HL^1$, $HL^2$ and $HL^3$. The current set of complexes confirms that different Ni···Ni distances and distinct coordination spheres can be obtained by proper modifications of the ligand side arms attached to the central pyrazolato bridge. Various O–H···Cl hydrogen-bonding motifs were characterized crystallographically in **1**–**3**, where either the H-donor (MeOH or $H_2O$) or the H-acceptor (chlorido) or both are bound to a metal ion, that is, nickel(II). The structural trends are in line with the following ranking of such interactions: (1) the hydrogen bond is shortened by coordination and acidification of the H-donor, *d*[Cl⁻···H(Me)O–Ni] < *d*[Cl⁻···H(Me)O]; (2) free chloride ions are better H-acceptors than metal-bound chlorido ligands, *d*[Cl⁻···H(Me)O–Ni] < *d*[Ni–Cl···H(Me)-O–Ni]; and (3) a terminal chlorido ligand is a better H-acceptor than a bridging one, *d*[Ni–Cl···H(H)O–Ni] < *d*[Ni(μ-Cl)···H(H)O–Ni]. Magnetic couplings through the chlorido and pyrazolato bridges are rather weak, but are even weaker through a Cl···H–O linkage or when the metal ions are displaced out of the plane of the pyrazolato ligand. These comparisons may prove useful for the assessment of hydrogen-bonding interactions in molecular recognition, crystal engineering and related fields.

## Experimental Section

***Caution!*** Although no problems were encountered in this work, transition metal perchlorates are potentially explosive and should be handled with care and with proper precautions.

**General:** Ligands $HL^1$, $HL^2$ and $HL^3$ were prepared as described previously.[10] All other chemicals were purchased from commercial sources and used as received. Microanalyses were performed by the Analytical Laboratory of the Inorganic Chemistry Institute at Georg-August-University Göttingen. Infrared spectra: Digilab Excalibur, recorded as KBr pellets. Mass spectra (FAB MS): Finnigan MAT 95 with nitrobenzylalcohol as the matrix.

**Synthesis of $[L^1Ni_2(\mu\text{-}Cl)(Cl)_2]\cdot 2CH_3OH$ (1a):** A solution of $HL^1$ (0.273 g, 0.5 mmol) in methanol (40 mL) was treated with 1 equiv. of $NEt_3$ (0.051 g, 0.5 mmol) and stirred for 10 min. To the reaction mixture was then added a solution of $NiCl_2\cdot 6H_2O$ (0.291 g, 1.0 mmol) in methanol (40 mL), and stirring was continued for a further 2 h. All volatile material was then evaporated under reduced pressure, the residue was taken up in methanol (10 mL) and this solution was filtered. The filtrate was layered with diethyl ether to gradually yield green crystals (203 mg, 49%) of **1a**. $C_{33}H_{37}Cl_3N_8Ni_2\cdot 2CH_3OH$ (833.5): calcd. C 50.43, H 5.44, N 13.44; found C 49.61, H 5.47, N 13.22. FAB MS: *m/z* (%) = 733 (100) $[L^1Ni_2Cl_2]^+$, 698 (60) $[L^1Ni_2Cl]^+$. IR (KBr): $\tilde{\nu}$ = 3474 (s), 3415 (s), 3267 (s), 2853 (m), 1637 (m), 1606 (s), 1567 (m), 1485 (s), 1443 (s), 1330 (s), 1314 (s), 1161 (w), 1108 (w), 1066 (w), 1045 (w), 1021 (m), 939 (w), 785 (s), 758 (s), 582 (w), 422 (w) $cm^{-1}$.

**Synthesis of $[L^1Ni_2(\mu\text{-}Cl)(CH_3OH)](ClO_4)_2$ (1b):** A solution of $HL^1$ (0.273 g, 0.5 mmol) in methanol (40 mL) was treated with 1 equiv. of $NEt_3$ (0.051 g, 0.5 mmol) and stirred for 10 min. The reaction mixture was then transferred to a solution containing 2 equiv. of $Ni(ClO_4)_2\cdot 6H_2O$ (0.365 g, 1.0 mmol) in methanol (40 mL). The re-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

action mixture was stirred for 1 h before 1 equiv. of NaCl (0.027 g, 0.5 mmol) was added, and stirring was continued overnight. All volatile material was then evaporated under reduced pressure, the residue was taken up in methanol (10 mL) and the solution was filtered. The filtrate was layered with diethyl ether to gradually yield green crystals (139 mg, 29%) of **1b**. $C_{34}H_{41}Cl_3N_8Ni_2O_9$ (929.5): calcd. C 43.94, H 4.45, N 12.06; found C 43.81, H 4.57, N 11.93. FAB MS: *m*/*z* (%) = 797 (100) $[L^1Ni_2Cl(ClO_4)]^+$, 696 (30) $[L^1Ni_2Cl]^+$. IR (KBr): $\tilde{\nu}$ = 3410 (m), 3074 (w), 2939 (w), 2902 (w), 2858 (w), 1609 (s), 1568 (m), 1488 (s), 1443 (s), 1383 (w), 1336 (w), 1310 (m), 1296 (w), 1162 (m), 1088 (vs), 1020 (s), 981 (m), 933 (m), 831 (w), 781 (m), 765 (m), 646 (w), 623 (s), 587 (w), 462 (w), 424 (m) $cm^{-1}$.

**Synthesis of $[L^2Ni_2(\mu\text{-}Cl)Cl_2(H_2O)_2]\cdot H_2O$ (2):** A solution of $HL^2$ (0.181 g, 0.5 mmol) in methanol (40 mL) was treated with 1 equiv. of $NEt_3$ (0.051 g, 0.5 mmol) and stirred for 10 min. The reaction mixture was then transferred to a solution containing 2 equiv. of $NiCl_2\cdot 6H_2O$ (0.291 g, 1.0 mmol) in methanol (40 mL) and stirred for a further 2 h. All volatile material was then evaporated under reduced pressure, the residue was taken up in methanol (10 mL) and the solution was filtered. The filtrate was layered with diethyl ether to gradually yield green crystals (0.103 g, 40%) of **2**. $C_{21}H_{33}Cl_3N_6Ni_2O_3$ (641.3): calcd. C 39.33, H 5.19, N 13.10; found C 38.99, H 5.28, N 12.69. FAB MS: *m*/*z* (%) = 551 (100) $[L^2Ni_2Cl_2]^+$. IR (KBr): $\tilde{\nu}$ = 3379 (br s), 2914 (w), 2859 (w), 2814 (w), 1632 (m), 1607 (s), 1571 (m), 1485 (m), 1444 (s), 1376 (w), 1322 (s), 1287 (w), 1246 (w), 1156 (w), 1099 (w), 1042 (m), 988 (m), 926 (w), 863 (w), 766 (s), 642 (m), 593 (m), 426 (m) $cm^{-1}$.

**Synthesis of $[L^3Ni_2Cl_2(CH_3OH)_2]Cl\cdot 2CH_3OH$ (3):** To a solution of $NiCl_2\cdot 6H_2O$ (0.291 g, 1.0 mmol) in methanol (40 mL) was added a solution of $HL^3$ (0.245 g, 0.5 mmol) and $NEt_3$ (0.051 g, 0.5 mmol) in methanol (40 mL), and the reaction mixture stirred at room temp. for 2 h. All volatile material was then evaporated under reduced pressure, the residue was taken up in methanol (10 mL) and this solution was filtered. The filtrate was layered with diethyl ether to gradually yield blue needle-like crystals (268 mg, 64%) of **3**. Upon storage in air, the methanol solvent molecules appear to be partly replaced by water, and the compound appears to be somewhat hygroscopic according to elemental analysis. $C_{31}H_{37}Cl_3N_8Ni_2O_2\cdot 4H_2O$ (849.49): calcd. C 43.83, H 5.34, N 13.19; found C 43.32, H 5.08, N 13.02. FAB MS: *m*/*z* (%) = 677 (100) $[L^3Ni_2Cl_2]^+$, 642 (20) $[L^3Ni_2Cl]^+$. IR (KBr): $\tilde{\nu}$ = 3344 (vs), 2920 (w), 1625 (m), 1605 (vs), 1573 (w), 1480 (m), 1441 (s), 1322 (m), 1287 (m), 1259 (w), 1154 (w), 1098 (m), 1052 (w), 1022 (m), 903 (w), 959 (w), 876 (w), 767 (s), 642 (w), 493 (w), 428 (w) $cm^{-1}$.

**X-ray Crystallographic Study:** X-ray data for **1a** and **3** were collected with a Bruker P4 diffractometer (graphite-monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) by use of $\omega$ scans at –140 °C and –100 °C, respectively (Table 2). Data for **1b** and **2** were collected with a STOE IPDS II diffractometer (graphite-monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) by use of $\omega$ scans at –140 °C (Table 2). The structures were solved by direct methods and refined on $F^2$ using all reflections with SHELX-97.[20] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms which were not involved in hydrogen bonding were placed in calculated positions and assigned to an isotropic displacement parameter of 0.08 $Å^2$. The positional and isotropic thermal parameters of the oxygen-bound hydrogen atoms H1 and H2 in **1a**, H1A/B in **2** and H1 to H4 in **3** were refined without any restraints or constraints. A DFIX restraint ($d_{O-H}$ = 0.82 Å) was applied for the O2–H2 distance in **2**. All other positional and isotropic thermal parameters of the hydrogen atom H2 were refined without restraints or constraints. SADABS was used to perform area-detector scaling and absorption corrections for **1a** and **3**.[21] Face-indexed absorption corrections were performed numerically with the program X-RED for **1b** and **2**.[22] Three oxygen atoms of one $ClO_4^-$ ion in **1b** are disordered about two positions [occupancy factors: 0.852(4)/0.148(4)]. SADI ($d_{Cl-O}$ and $d_{O\cdots O}$) restraints and EADP constraints were used to model the disorder and for anisotropic refinement. CCDC-616755 (**1a**), -616756 (**1b**), -616757 (**2**) and -616758 (**3**) contain the supplemen-

# Cyanido-Bridged Dimetallic Complexes Derived from Manganese(III) Schiff Bases and Pentacyanidonitrosylchromate(I): Synthesis, Crystal Structure and Magnetic Properties

Zhong-Hai Ni,[a] Lei Zheng,[a] Li-Fang Zhang,[a] Ai-Li Cui,[a] Wei-Wei Ni,[a] Chong-Chao Zhao,[a] and Hui-Zhong Kou*[a]

**Keywords:** Cyanide ligands / Bridging ligands / Magnetic properties / Manganese / Schiff-base ligands

Four cyanido-bridged $Mn^{III}$–$Cr^{I}$ heterodimetallic complexes have been synthesized by the reactions of $Mn^{III}$ Schiff-base complexes with the $[Cr(CN)_5(NO)]^{3-}$ building block. X-ray diffraction analysis reveals that $[Mn(5\text{-Cl-salen})(H_2O)_2][Mn_2(5\text{-Cl-salen})_2(H_2O)_{1.5}Cr(CN)_5(NO)]$ (**1**) has a trinuclear structure, and $[Mn_3(salen)_3(H_2O)(CH_3CN)Cr(CN)_5(NO)]\cdot 0.5CH_3CN\cdot 0.5MeOH\cdot 2H_2O$ (**2**) and $[Mn(5\text{-Br-salen})(H_2O)(CH_3OH)][Mn_2(5\text{-Br-salen})_2(CH_3OH)Cr(CN)_5(NO)]\cdot 2H_2O$ (**3**) have novel 1D chain topological structures, whereas $[\{Mn(saltmen)\}_4Cr(CN)_5(NO)]ClO_4\cdot 3H_2O$ (**4**) displays a 2D layered network structure. Magnetic measurements show that the magnetic interaction between the $Mn^{III}$ and $Cr^{I}$ ions bridged by a cyanido group is antiferromagnetic for complexes **1**–**4**. The magnetic fitting for the trinuclear complex **1** gives the magnetic coupling constant $J = -10.4(1)$ cm$^{-1}$ and $J' = -1.29(2)$ cm$^{-1}$ based on the isotropic Hamiltonian $\hat{H} = -2J\hat{S}_{Cr}[\hat{S}_{Mn(1)} + \hat{S}_{Mn(2)}] - 2J'\hat{S}_{Mn(1)}\hat{S}_{Mn(2)}$. Complex **2** exhibits 3D antiferromagnetic ordering ($T_N = 3.5$ K) with a metamagnetic character below $T_N$. Complex **3** exhibits an obvious frequency-dependent AC magnetic susceptibility below 4.0 K, which is due to the spin-glass behavior. The layered complex **4** displays 3D ferromagnetic ordering with $T_c = 6.4$ K due to the ferromagnetic interaction between the ferrimagnetic layers.

## Introduction

In the past two decades, the design and synthesis of cyanido-bridged molecule-based magnetic materials with high-$T_c$, single-molecule magnets (SMMs), single-chain magnets (SCMs), and those that exhibit spin crossover (SCO) or photomagnetic behavior has become one of the most important fields in coordination chemistry and magnetochemistry.[1–10] (Schiff base)$Mn^{III}$ complexes and hexacyanidometalate building blocks have been shown to be two intriguing precursors for the above purpose. Indeed, their combinations have successfully yielded a variety of structures, including polynuclear[3b,11–18] 1D chains[19,20] and 2D networks,[11,12,21–23] by tuning the Schiff-base ligands and the coordination numbers around the $Mn^{III}$ ion. However, much attention has been paid to the investigation of $Mn^{III}$–$Fe^{III}$ complexes derived from (Schiff base)$Mn^{III}$ complexes and $[Fe(CN)_6]^{3-}$, and only limited examples have been obtained based on (Schiff base)$Mn^{III}$ complexes and other cyanido-containing building blocks.[7,17,18,24–30] In particular, to the best of our knowledge, there is still no report on cyanido-bridged $Mn^{III}$–$Cr^{I}$ or $Mn^{III}$–$Cr^{III}$ 1D chain-like complexes and only three known $Mn^{III}$–$Fe^{III}$ 1D assemblies,[19,20,25] one $Mn^{III}$–$Mn^{III}$, and one $Mn^{III}$–$Mo^{IV}$ 1D chain complex[24,26] derived from (Schiff base)$Mn^{III}$ complexes and $[Fe(CN)_6]^{3-}$, $[Fe(bpb)(CN)_2]^{-}$, $[Mn(salen)(CN)_2]^{-}$, or $[Mo(CN)_8]^{4-}$ building blocks.

In light of our continuing interest in cyanido-bridged dimetallic complexes, we are interested in extending this system to the paramagnetic $[Cr(CN)_5(NO)]^{3-}$ building block, which has the same negative charge as $[M^{III}(CN)_6]^{3-}$ (M = Fe, Cr, Co or Mn). In addition, the unpaired electron ($d^5$, low-spin) in $Cr^{I}$ means that it has the same low spin as the $Fe^{III}$ ion ($S = 1/2$), and is different from the $Cr^{III}$ ion ($S = 3/2$). Therefore, special interest lies in comparing the magnetic properties of $[Cr(CN)_5(NO)]^{3-}$ with $[Fe(CN)_6]^{3-}$ and in the search for a new family of molecule-based magnets. To this end, we decided to investigate complexes based on $[Cr(CN)_5(NO)]^{3-}$ and (Schiff base)$Mn^{III}$ building blocks. Herein, we report the synthesis, crystal structures, and magnetic properties of four such complexes, including the trinuclear complex $[Mn(5\text{-Cl-salen})(H_2O)_2][Mn_2(5\text{-Cl-salen})_2(H_2O)_{1.5}Cr(CN)_5(NO)]$ (**1**) and two novel 1D chain complexes $[Mn_3(salen)_3(H_2O)(CH_3CN)Cr(CN)_5(NO)]\cdot 0.5CH_3CN\cdot 0.5MeOH\cdot 2H_2O$ (**2**), and $[Mn(5\text{-Br-salen})(H_2O)(CH_3OH)][Mn_2(5\text{-Br-salen})_2(CH_3OH)Cr(CN)_5(NO)]\cdot 2H_2O$ (**3**), as well as one 2D layered compound $[\{Mn(saltmen)\}_4Cr(CN)_5(NO)]ClO_4\cdot 3H_2O$ (**4**), [salen$^{2-}$ = *N*,*N*′-ethylenebis(salicylideneaminato) dianion, 5-Br-salen$^{2-}$

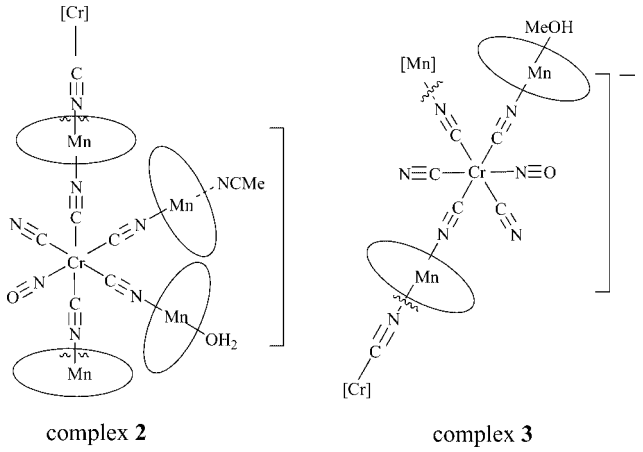
= *N*,*N*′-ethylenebis(5-bromosalicylideneaminato) dianion, 5-Cl-salen$^{2-}$ = *N*,*N*′-ethylenebis(5-chlorosalicylideneaminato) dianion, and saltmen$^{2-}$ = *N*,*N*′-(1,1,2,2-tetramethylethylene)bis(salicylideneaminato) dianion].

## Results and Discussion

### Synthesis and General Characterization

The reaction between the different (Schiff base)Mn$^{III}$ complexes {[Mn(salen)]$ClO_4$, [Mn(5-Cl-salen)]$ClO_4$, [Mn(5-Br-salen)]$ClO_4$, or [Mn(saltmen)]$ClO_4$} and $K_3Cr(CN)_5(NO)$ gave entirely different molecular structures under similar conditions. Complex **1**, for example, has an $Mn_2Cr$ trinuclear structure with a monomer (Schiff base)Mn$^{III}$ complex as the balanced cation, whereas complexes **2** and **3** have 1D topological structures (Scheme 1) with a 3:1 alternating arrangement of Mn$^{III}$ and Cr$^{I}$. Complex **4** is a 2D network in which the (Schiff base)Mn$^{III}$ complex forms an out-of-plane dimeric motif with a biphenolate bridge, which is similar to that of the previously reported complexes [{Mn(saltmen)}$_4${Fe(CN)$_6$}]$ClO_4$·$H_2O$,[12] $(Et_4N)[Mn_2(5\text{-}MeOsalen)_2Fe(CN)_6]$[20] [5-MeOsalen$^{2-}$ = *N*,*N*′-ethylenebis(5-methoxysalicylideneiminate)] and [Mn(salen)($H_2O$)$_2$]$_2$[{Mn(salen)($H_2O$)}{Mn(salen)}$_2${Mo(CN)$_8$}]·0.5$ClO_4$·0.5OH·4.5$H_2O$.[26] It is intriguing to note that the formation of different cyanido-bridged Mn$^{III}$–Cr$^{I}$ complexes is a very subtle process, which further shows that the steric effects of the Schiff-base ligands play an important role in the self-assembly of Mn$^{III}$–M (M = Fe$^{III}$, Cr$^{III}$ and Cr$^{I}$) complexes.



Scheme 1. Schematic representation of the chain-like structures in **2** and **3**. The circles represent salen$^{2-}$ and 5-Br-salen$^{2-}$ for **2** and **3**, respectively.

The IR spectra in the range 2100–2140 cm$^{-1}$ exhibit moderately sharp peaks assigned to cyanido stretching absorptions. The weak peaks at 1677–1712 cm$^{-1}$ can be attributed to the N=O stretching vibration in these complexes. For complex **4**, the strong broad peaks centered at around 1090 cm$^{-1}$ suggest the presence of $ClO_4^-$ anions in the complex.

### Crystal Structures

Complex **1** consists of two crystallographically independent trinuclear [{Mn(5-Cl-salen)}$_2$Cr(CN)$_5$(NO)]$^-$ units with two free [Mn(5-Cl-salen)($H_2O$)$_2$]$^+$ units as charge-balancing cations. The two [Mn(5-Cl-salen)]$^+$ segments are bound at the *cis* positions of the central Cr$^{I}$ ion through two *cis* cyanido groups (see Figure 1 and Table 1).

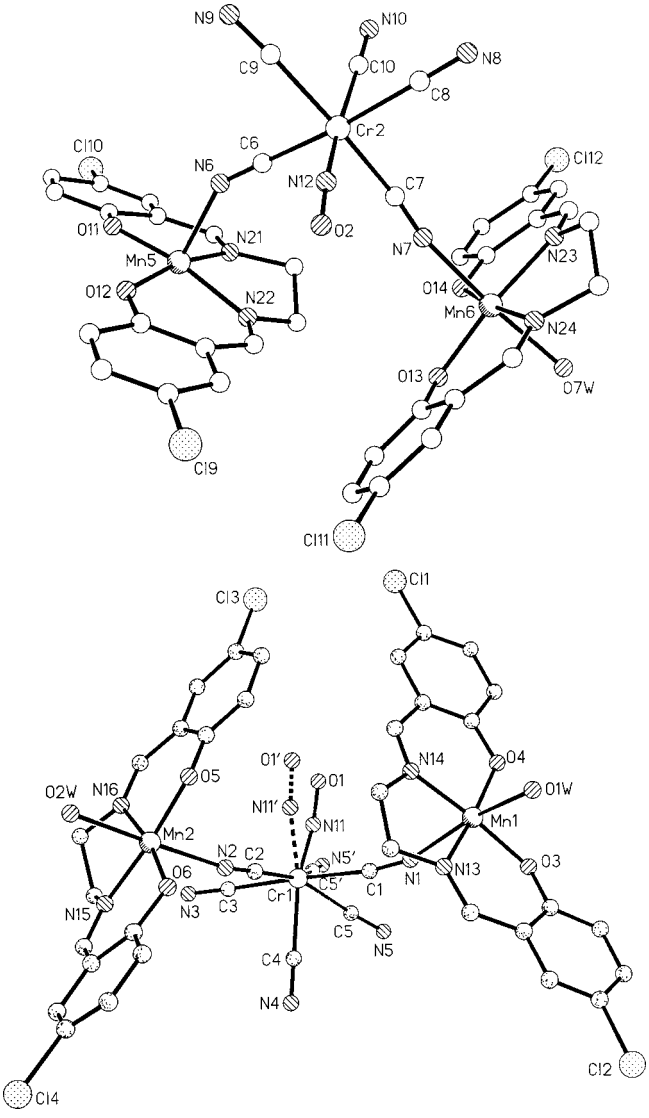


Figure 1. Structure of two $Mn_2Cr$ trinuclear anionic units in compound **1**.

Three Mn$^{III}$ ions in the trinuclear units are ligated by three nitrogen atoms from the 5-Cl-salen$^{2-}$ ligand and the cyanido bridge and three oxygen atoms from the Schiff-base ligand and the coordinated water molecule to give a distorted $MnN_3O_3$ octahedral environment. One Mn$^{III}$ ion is pentacoordinated by two Schiff-base nitrogen and two Schiff-base oxygen atoms as well as one cyanido nitrogen atom to yield a square-pyramidal $MnN_3O_2$ environment, which weakly interacts with a phenoxy oxygen atom [O(7)$^{\#}$] from an adjacent free (Schiff base)Mn$^{III}$ unit (symmetry operation: $^{\#}$ –2/3 + *x*, –1/3 + *y*, 2/3 + *z*) with an

[a] Symmetry operation: $^{\#1}$ –2/3 + *x*, –1/3 + *y*, 2/3 + *z*.

Mn(5)–O(7)$^{\#}$ bond length of 3.369(5) Å. The two discrete $Mn^{III}$ ions are coordinated by the Schiff-base ligand and two water molecules to form a distorted octahedral $MnN_2O_4$ environment. The Mn–$N_{cyanido}$ bond lengths vary from 2.131(6) to 2.264(6) Å. The Mn–N≡C bonds are bent [147.4(6)–168.3(6)°], with an average bond angle of 158.7(6)°. The shortest intramolecular Mn···Cr separation through the bridging cyanido ligand is 5.125 Å, and the shortest intermolecular metal–metal distance is 6.388 Å for Mn···Cr.

The cell-packing diagram of complex **1** (see Supporting Information) shows an H-bonding interaction between the two O atoms of one 5-Cl-salen$^{2-}$ ligand and a coordinated water molecule as well as between a cyanido nitrogen atom and a coordinated water molecule. Interestingly, the cell packing along the *c* axis is highly ordered, with many honeycomb holes in which all the chlorine atoms from the Schiff-base ligands face the center of the holes.

The structure of complex **2** consists of a neutral chain which is formed by a $[Cr(CN)_5(NO)]^{3-}$ and three $[Mn(salen)]^+$ units connected by cyanido ligands (Figure 2). Four cyanido ligands of $[Cr(CN)_5(NO)]^{3-}$ coordinate axially to the $[Mn(salen)]^+$ units. The primary chain is composed of alternate Cr(1) and Mn(1) units bridged by two *trans*-cyanido groups in $[Cr(CN)_5(NO)]^{3-}$. Two $[Mn(salen)]^+$ units [Mn(2) and Mn(3)] dangle outside the primary $Mn^{III}Cr^{I}$ chain. One dangling $[Mn(salen)]^+$ unit has a distorted octahedral environment with an acetonitrile nitrogen atom hemicoordinated [Mn(2)–N(13) 2.605(5) Å]. Each $Mn^{III}$ ion is hexacoordinate and has a distorted octahedral surrounding [$MnN_3O_3$ for Mn(2) and Mn(3), and $MnN_4O_2$ for Mn(1)] due to the Jahn–Teller effect for a high-spin $d^4$ $Mn^{III}$ ion. The Mn–$N_{cyanido}$ bonds are comparatively long, ranging from 2.206(3) to 2.333(3) Å. The $Cr^{I}$ ion lies in a compressed $CrC_5N$ octahedral geometry, as evidenced by the shorter Cr–N bond [1.695(3) Å for Cr(1)–N(6)] than the Cr–C distance [2.049(4)–2.111(3) Å], which is very different from those of the $Fe^{III}$ and $Cr^{III}$ ions in $[Fe(CN)_6]^{3-}$ and $[Cr(CN)_6]^{3-}$ building blocks, which have a standard octahedral geometry. The Cr–C≡N and Cr–N≡O bond angles are essentially linear [172.1(3)–176.7(3)°], whereas the Mn–N≡C bond angles deviate markedly from linearity [147.8(2)° for Mn(1)–N(5)–C(5), 148.0(2)° for Mn(1)$^{\#}$–N(3)–C(3) (symmetry operation: $^{\#}$ –*x* + 1/2, *y* + 1/2, –*z* + 3/2), 148.2(3)° for Mn(2)–N(2)–C(2), and 157.5(3)° for Mn(3)–N(4)–C(4)], and give rise to a wave-like chain structure (Table 2).

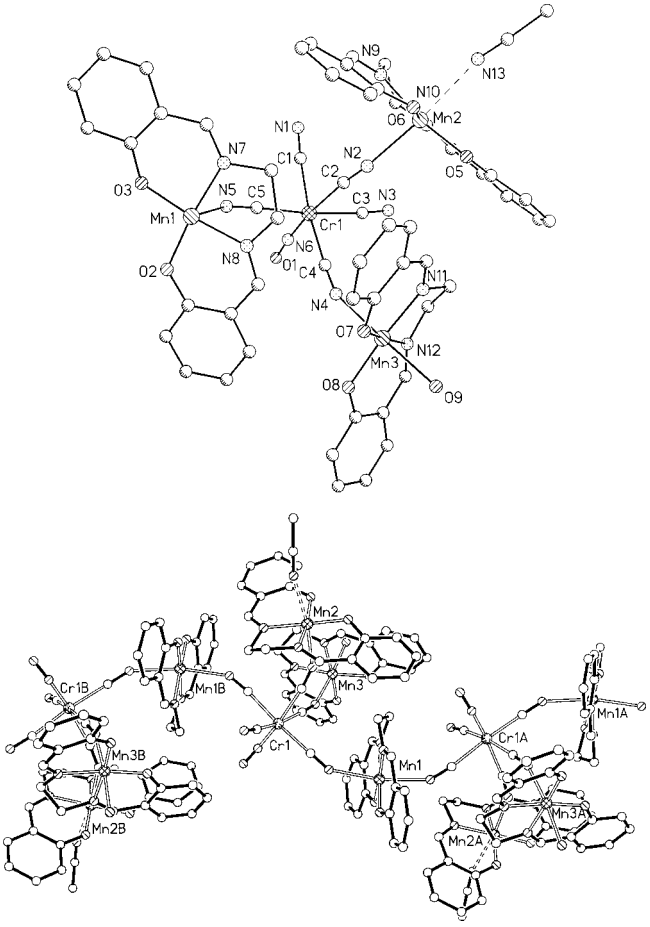

Figure 2. Tetrameric building unit (top) and the one-dimensional chain-like structure (bottom) in complex **2**.

Interestingly, two adjacent chains along the *a* axis arrange oppositely and form relatively broad cavities where the dangling $[Mn(salen)]^+$ units [Mn(2) and Mn(3)] are ac-

commodated, whereas the Mn(1) units are situated in the formed narrow cavities and afford the shortest interchain metal–metal distance of 8.040 Å (Figure 3).

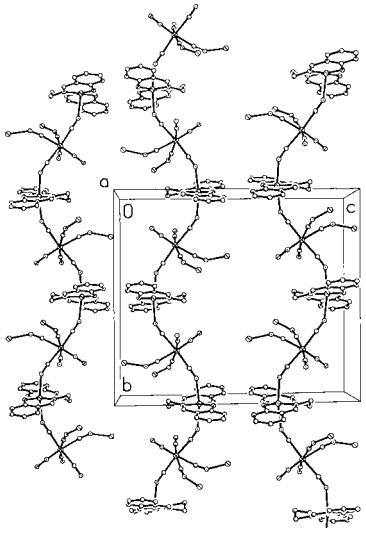

Figure 3. Cell-packing diagram of complex **2** showing the wave-like chain structure along the *a* axis [only the $Mn^{III}$ ions of the dangling Mn(salen) units are shown].

Unlike complex **2**, the structure of **3** consists of an anionic chain formed by a $[Cr(CN)_5(NO)]^{3-}$ and two $[Mn(5\text{-Br-salen})]^+$ units (see Figure 4 and Supporting Information), with a free $[Mn(5\text{-Br-salen})(H_2O)(MeOH)]^+$ moiety as the countercation. Three *mer*-cyanido groups of $[Cr(CN)_5(NO)]^{3-}$ in the chain are linked to the $[Mn(5\text{-Br-salen})]^+$ units. One $[Mn(5\text{-Br-salen})]^+$ and one $[Cr(CN)_5(NO)]^{3-}$ unit connect alternately through two *cis*-cyanido groups in $[Cr(CN)_5(NO)]^{3-}$ to give rise to a zigzag primary chain; another $[Mn(5\text{-Br-salen})(MeOH)]^+$ unit dangles outside the $Mn^{III}Cr^{I}$ chain. The free $[Mn(5\text{-Br-salen})(H_2O)(MeOH)]^+$ countercations are in the vicinity of the anionic chains. The Mn–$N_{cyanido}$ bond lengths are 2.230(11) Å for Mn(1)–N(1), 2.251(12) Å for Mn(2)–N(2), and 2.281(11) Å for Mn(2)–N(3)$^{\#}$ (symmetry operation: $^{\#}$ $-x + 1/2$, $y - 1/2$, $-z + 1/2$). The Mn–N≡C bond angles are 138.1(10)° for Mn(1)–N(1)–C(1), 160.7(12)° for Mn(2)–N(2)–C(2), and 145.6(11)° for Mn(2)$^{\#}$–C(3)–N(3) (symmetry operation: $^{\#}$ $-x + 1/2$, $y + 1/2$, $-z + 1/2$), with an average value of 148.1(11)° (Table 3).

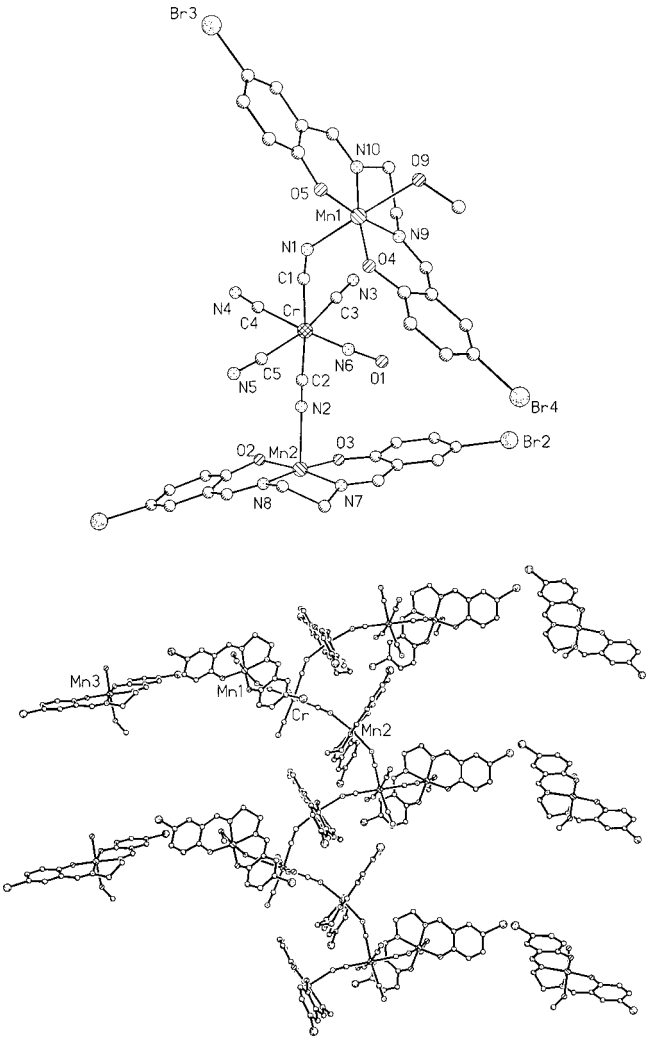

Figure 4. Top: one unit of the chain {the free $[Mn(5\text{-Br-salen})(H_2O)(CH_3OH)]^+$ block is omitted for clarity}; bottom: one-dimensional zigzag chain structure in complex **3**.

[a] Symmetry operations: $^{\#1}$ $-x + 1/2, y - 1/2, -z + 1/2$; $^{\#2}$ $-x + 1/2, y + 1/2, -z + 1/2$.

The zigzag chains form a 2D structure with alternating saddle-like squares through H-bonds between the free cyanido nitrogen atoms and the coordinated methanol oxygen atoms (see Supporting Information). This 2D layered structure is further linked by the free (Schiff base)$Mn^{III}$ units through H-bonds involving cyanido nitrogen, phenoxy oxygen, and coordinated water to form a 3D network structure. Since the adjacent chains are linked together by N···H–O H-bonds (N···O = 2.775 Å), the closest interchain metal–metal distance is only 6.722 Å for Mn–Cr, which is much shorter than that in complex **2** (8.040 Å).

The out-of-plane phenoxido-bridged dimeric $[Mn(saltmen)]_2^{2+}$ cations found in complex **4** connect $[Cr(CN)_5(NO)]^{3-}$ in a *trans* fashion to give rise to a 2D network structure with free $ClO_4^-$ as counteranion. The layered structure of **4** is very similar to that of the complex $[\{Mn(saltmen)\}_4\{Fe(CN)_6\}]ClO_4\cdot H_2O$[12] reported by Miyasaka et al. It is worth noting that a cyclic dodecanuclear square unit is formed through alternating dimeric $[Mn(saltmen)]_2^{2+}$ and $[Cr(CN)_5(NO)]^{3-}$ groups. Figure 5 shows the pentanuclear $[\{Mn(saltmen)\}_4\{Cr(CN)_5(NO)\}]^+$ moiety and the 2D network structure along the *c* axis (Table 4).

The $Mn^{III}$ ion in the complex has a distorted octahedral geometry in which the equatorial plane is occupied by $N_2O_2$ donor atoms from the saltmen$^{2-}$ ligand while the two *trans* positions are taken up by the cyanido nitrogen and the phenoxy oxygen atom [O(2)$^{\#}$] of the adjacent (Schiff base) $Mn^{III}$ unit (symmetry operation: $^{\#}$ $1/2 + x, 1/2 + y, z$). The $Mn–N_{cyanido}$ bond length is 2.166(9) Å for Mn(1)–N(1) and the corresponding Mn–N≡C bond angle is 154.6(8)° for Mn(1)–N(1)–C(1). The Mn(1)–O(2)$^{\#}$ bond length is 2.629(11) Å, comparable to those of $[\{Mn(saltmen)\}_4\{Fe(CN)_6\}]ClO_4\cdot H_2O$ [2.847(9) Å] and the dimeric precursor $[Mn(saltmen)(H_2O)]_2(ClO_4)_2$ [2.434(2) Å]. The Mn···Mn distance in the dimeric unit is 3.474(8) Å. The Mn···Cr distance through the cyanido ligand is 5.231(8) Å and the shortest interlayer metal–metal separation is 11.879(8) Å.

## Magnetic Properties

The temperature-dependence of $\chi_m T$ for **1** is shown in Figure 6. Upon cooling, the $\chi_m T$ value decreases smoothly from 300 to 40 K before increasing again. The maximum of the curve is at 20 K, with a $\chi_m T$ value of 8.380 emu K mol$^{-1}$. The origin of the decrease in $\chi_m T$ (below 20 K) may be due to the saturation effect and the zero-field-splitting (ZFS) effect of $Mn^{III}$. The magnetic susceptibilities (25–300 K) obey the Curie–Weiss law with a negative Weiss constant, $\theta$, of –8.8 K and a Curie constant, $C$, of 9.425(1) emu K mol$^{-1}$, which also confirms the presence of an overall antiferromagnetic interaction in **1**.

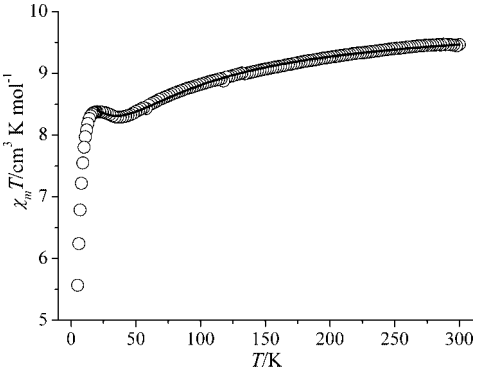

Figure 6. Temperature dependence of $\chi_m T$ for **1**. The solid line represents the theoretical results based on the parameters described in the text.

On the basis of the trinuclear model, the magnetic susceptibilities can be fitted by the expression given in Equation (1) derived from the isotropic exchange spin Hamiltonian $\hat{H} = -2J\hat{S}_{Cr}[\hat{S}_{Mn(1)} + \hat{S}_{Mn(2)}] - 2J'\hat{S}_{Mn(1)}\hat{S}_{Mn(2)}$ for an $Mn_2Cr$ trinuclear unit ($S_{Mn} = 2$, $S_{Cr} = 1/2$) by neglecting the bond-angle difference of Mn–N≡C for simplicity, where $A = 165 + 84\exp(-9J/kT) + 84\exp(-J/kT - 8J'/kT) + 35\exp(-8J/kT - 14J'/kT) + 35\exp(-2J/kT - 14J'/kT) + 10\exp(-7J/kT - 14J'/kT) + 10\exp(-3J/kT - 18J'/kT) + \exp(-6J/kT - 18J'/kT) + \exp(-4J/kT - 10J'/kT)$, and $B = 20 + 16\exp(-9J/kT) + 16\exp(-J/kT - 8J'/kT) + 12\exp(-8J/kT - 14J'/kT) + 12\exp(-2J/kT - 14J'/kT) + 8\exp(-7J/kT - 14J'/kT) + 8\exp(-3J/kT - 18J'/kT) + 4\exp(-6J/kT - 18J'/kT) + 4\exp(-4J/kT - 20J'/kT)$.

$$\chi_t = \frac{Ng^2\beta^2}{kT}\left[\frac{A}{B}\right] \quad (1)$$

The final molar magnetic susceptibility ($\chi_m/Mn_3Cr$) takes the form of Equation (2).

$$\chi_m = \chi_t + \frac{Ng_{Mn}^2\beta^2}{3kT} S_{Mn}(S_{Mn}+1) \quad (2)$$

The best-fit parameters obtained are $J = -10.4$ cm$^{-1}$, $g = g_{Mn} = 2.06$, $J' = -1.29$ cm$^{-1}$ and $R = \sum(\chi_{obsd}T - \chi_{calcd}T)^2/\sum(\chi_{obsd}T)^2 = 3.75 \times 10^{-5}$ in the temperature range 20–300 K. We note that the absolute $J$ value is much larger than that (ca. –2 cm$^{-1}$) for the antiferromagnetically coupled $Mn^{III}$–$Fe^{III}$ analogues,[11] which is indicative of the presence of a stronger magnetic interaction between $Mn^{III}$ and $Cr^{I}$.

The temperature dependence of the $\chi_m T$ product per $Mn_3Cr$ unit in the range 2–300 K for **2** is shown in Figure 7. The room-temperature $\chi_m T$ values are in good agreement with the expected value of 9.375 emu K mol$^{-1}$ (calculated by assuming $g = 2.0$) for one low-spin $Cr^{I}$ and three high-spin $Mn^{III}$ ions. Upon cooling, the $\chi_m T$ value of **2** decreases smoothly from 300 to 70 K and then increases, with a maximum value of 27.5 emu K mol$^{-1}$ at 4.3 K. The negative Weiss constant of –8.78(10) K and a Curie constant of 9.385(1) emu K mol$^{-1}$ can be obtained from the data between 5 and 300 K. These indicate that the $Mn^{III}$–$Cr^{I}$ magnetic coupling through the cyanido bridges is antiferromagnetic. The decrease in $\chi_m T$ below 4.3 K suggests the presence of interchain antiferromagnetic coupling (see below).

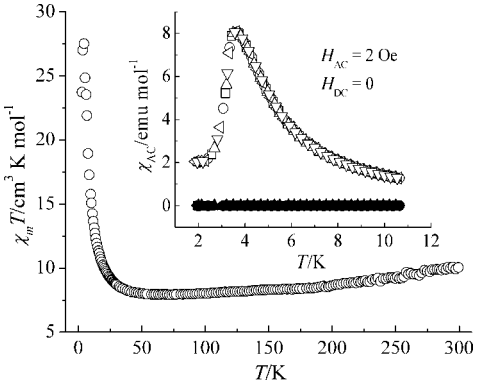

Figure 7. Temperature dependence of $\chi_m T$ for **2**. Inset: temperature dependence of the AC magnetization for **2** in zero static field and an AC field of 2 Oe at 111, 199, 355, 633 and 1111 Hz.

The field-cooled magnetization (FCM) and zero-field-cooled magnetization (ZFCM) plots for **2** (see Supporting Information) at an applied field, $H$, of 100 Oe show a maximum at around 3.6 K, which demonstrates that there is an antiferromagnetic phase transition at this temperature. The real part of the AC magnetic susceptibility displayed in the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

inset of Figure 7 also has a maximum at around 3.6 K, and the imaginary part is zero, which suggests that the critical temperature ($T_N$) is approximately 3.6 K.

The field-dependence of the magnetization and the hysteresis loop measured at 1.83 K (see Supporting Information) show a spin transition from antiferromagnetic to ferromagnetic. A critical field of 500 Oe is observed. This metamagnetic behavior is commonly observed for 2D layered antiferromagnets with short-range, intralayer ferri- or ferromagnetic ordering.[31–35]

The temperature-dependence of the $\chi_m T$ magnetic behavior of **3** is similar to that of **1** and **2**, as shown in Figure 8. Upon cooling, $\chi_m T$ decreases smoothly, reaching a minimum at 80 K, and then increases. The maximum of the curve is at 9.2 K, with a $\chi_m T$ value of 12.1 emu K mol$^{-1}$. The magnetic susceptibilities above 10 K obey the Curie–Weiss law with a negative Weiss constant of –4.98(6) K and a Curie constant of 9.257(1) emu K mol$^{-1}$, which also confirms the presence of overall antiferromagnetic interactions in **3**.

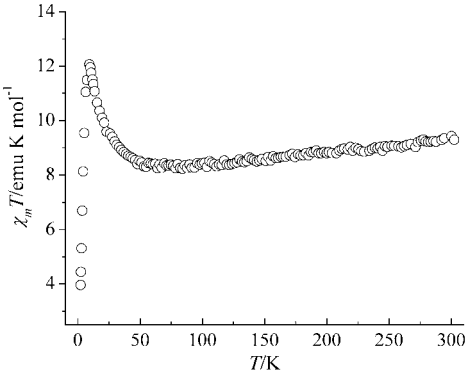

Figure 8. Temperature dependence of $\chi_m T$ for **3**.

The temperature dependence of the magnetic susceptibility in a zero DC and 3-Oe AC magnetic field for complex **3** is displayed in Figure 9. The out-of-phase AC magnetic susceptibility has nonzero values below 4.0 K and is strongly frequency-dependent. The shift of the peak temperature ($T_P$) of $\chi''$ is evaluated by the parameter $\Phi = (\Delta T_P/T_P)/\Delta(\log\omega) = 0.17$, which is larger than that for a canonical spin-glass but smaller than the normal value for a superparamagnet.[36–39] The hysteresis loop at 1.8 K shows noticeable magnetic hysteresis (Figure 10), which indicates the presence of magnetic ordering in complex **3**.

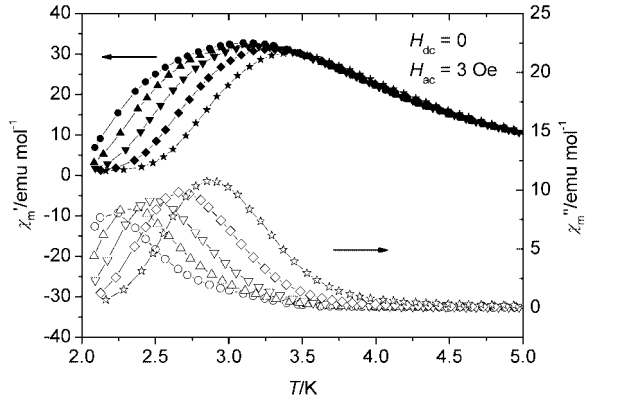

Figure 9. Temperature dependence of the AC magnetization for **3** in a zero static field and an AC field of 3 Oe at frequencies of 277 (circles), 666 (triangles tip up), 1633 (tringles tip down), 4111 (diamonds), and 9999 (stars) Hz.

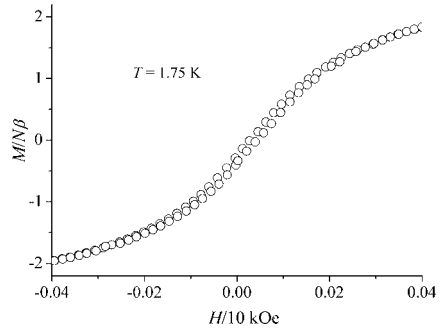

Figure 10. Magnetic hysteresis loop for **3** at 1.75 K.

The crystal data show that there is a large number of strong H-bonds in complex **3** which form a 3D network structure and that the metal···metal distance is 6.722 Å. This suggests the presence of a significant intermolecular magnetic interaction. Therefore, we tentatively attribute the slow relaxation of magnetization in **3** to a spin-glass behavior.[39] The origin of this spin-glass behavior may be due to the presence of competitive ferro- and antiferromagnetic coupling within the chains considering the presence of a wide range of cyanido bridging bond angles [138.1(10)–160.7(12)°].

The magnetic susceptibilities of complex **4** were measured in the temperature range 2–300 K in an applied magnetic field of 2000 Oe. The plot of $\chi_m T$ vs. $T$ for **4** is shown in Figure 11, where $\chi_m$ is the magnetic susceptibility per $Mn_4Cr$ unit. The room-temperature $\chi_m T$ value of 12.541 emu K mol$^{-1}$ is nearly equal to the spin-only value of 12.375 emu K mol$^{-1}$ for five uncoupled spins [four $S_{Mn}$ ($S$ = 2) and one $S_{Cr}$ ($S$ = 1/2)]. On lowering the temperature, $\chi_m T$ decreases gradually to 11.82 emu K mol$^{-1}$ at 150 K, then increases smoothly until about 50 K before rapidly reaching a maximum value of 166 emu K mol$^{-1}$ at 8 K, and then sharply decreases to 56.5 emu K mol$^{-1}$ at 2 K, which

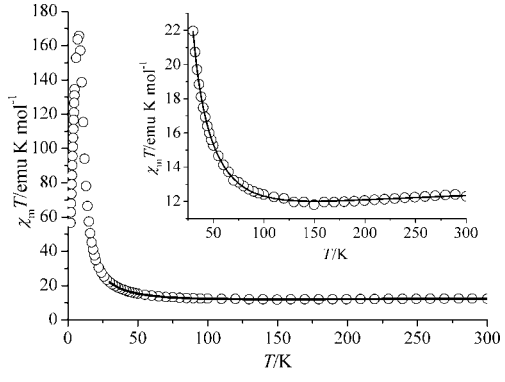

Figure 11. Temperature dependence of $\chi_m T$ for **4**. Inset: enlarged view in the temperature range 25–300 K. The solid line shows the best fit based on the parameters discussed in the text.

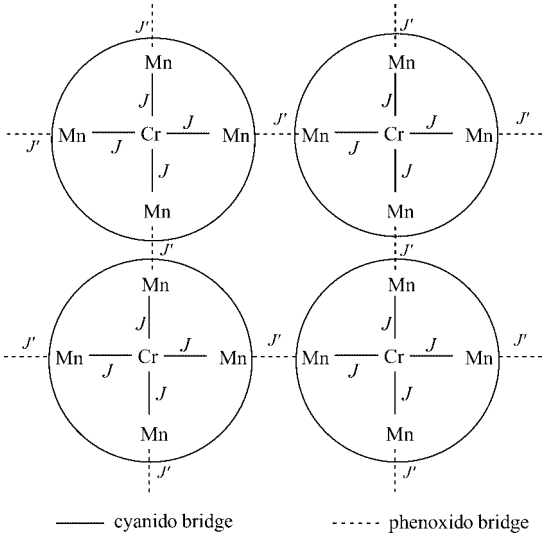
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

suggests the presence of global antiferromagnetic interactions and three-dimensional magnetic ordering in the complex. The plot of $1/\chi_m$ vs. $T$ above 150 K obeys the Curie–Weiss law with a negative Weiss constant of –12.5 K and a Curie constant of 12.4 emu K mol$^{-1}$, which suggest that antiferromagnetic coupling between $Mn^{III}$ and $Cr^{I}$ through a cyanido bridge is dominant in the high-temperature range with the $Mn^{III}$–$Mn^{III}$ ferromagnetic coupling through the phenoxido bridges superimposed. The higher temperature shift of the minimum in $\chi_m T$ for **4** (150 K) than those of complexes **1**–**3** (40 K for **1**, and 70 for **2**, and 80 K for **3**) may be due to the presence of ferromagnetic $Mn^{III}$–$Mn^{III}$ interactions through the phenoxy oxygen atoms.

To evaluate the magnitude of the intramolecular magnetic coupling, we tried to fit the magnetic susceptibilities to the model previously employed for coordination polymers.[20] The structural information shows that in complex **4** there are two different magnetic coupling pathways, namely cyanido bridges and phenoxido bridges. The layers are illustrated schematically in Scheme 2, where $J$ is for the cyanido bridges and $J'$ for the phenoxido ones. We can see from the $\chi_m T$ vs. $T$ plot that $J$ is dominant, i.e. $|J| >> |J'|$. The 2D layer can be accordingly described as weakly interacting $Mn_4Cr$ pentanuclear units in which an antiferromagnetic coupling ($J < 0$) is present.



Scheme 2. Schematic view of the layer structure of **4** showing the magnetic coupling pathways.

Based on the above considerations, the magnetic data were fitted to the Van Vleck equation for the pentanuclear unit derived from the exchange Hamiltonian $\hat{H} = -2J\hat{S}_{Cr}(\hat{S}_{Mn1} + \hat{S}_{Mn2} + \hat{S}_{Mn3} + \hat{S}_{Mn4})$.[11,15] The magnetic coupling through the phenoxido bridges was treated as an intermolecular term using the mean-field method. The final molar magnetic susceptibility ($\chi_m$) is in the form of Equation (3), where $\chi_p$ is for the $Mn_4Cr$ pentanuclear unit, $J'$ is the coupling constant between the pentanuclear units, and $z$, the number of nearest $Mn_4Cr$ neighbors, is 4. Other symbols have their usual meanings.

$$\chi_m = \chi_p/[1 - \chi_p(2zJ'/Ng^2\beta^2)] \quad (3)$$

The best-fit parameters based on the data above 30 K are $J = -17.2$ cm$^{-1}$, $zJ' = 0.17$ cm$^{-1}$, $g_{Mn} = 1.97$, and $g_{Cr} = 3.70$. The calculated solid line shown in Figure 11 agrees well with the experimental values. The calculated $J$ value is comparable to that [–10.4(1) cm$^{-1}$] for the trinuclear $Mn_2Cr$ compound **1**. The positive $J'$ value suggests a ferromagnetic $Mn^{III}$–$Mn^{III}$ coupling through the phenoxido bridges. However, this value is smaller than that for the similar $Mn_2$ complexes according to the equation $J' = 4.5724 - 1.1868x$ ($x$ is the Mn–$O_{phenoxido}$ distance [Å] in the range of 2.4–3.7 Å) proposed by Miyasaka et al.[40] This may be due to the rough approximation of the fit. Furthermore, the $g_{Cr}$ value is too large, although the use of a value less than 3.0 did not give a satisfactory fit. Nevertheless, the $g_{Cr}$ value is not reasonable, and should be considered with care.

To further confirm the magnetic phase transition, the temperature dependence of the AC magnetic susceptibility was measured at a zero DC and a 5-Oe AC field, as shown in Figure 12. The real part of the AC magnetic susceptibility has a maximum peak at about 6.4 K which is accompanied by the occurrence of a nonzero $\chi_{AC}''$, thereby suggesting that the $T_c$ of complex **4** is about 6.4 K, similar to that of the 2D analogue [{Mn(saltmen)}$_4${Fe(CN)$_6$}]-$ClO_4 \cdot H_2O$[12] (4.5 K). The hysteresis loop at 2.0 K (see Supporting Information) displays a characteristic behavior for a soft ferromagnet, with a small coercive field of 10 Oe and a remnant magnetization of about 4.0 $N\beta$.

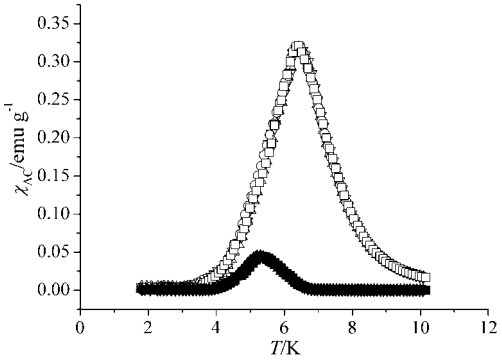


Figure 12. Temperature dependence of the AC magnetization for **4** in a zero static field and an AC field of 2 Oe at 277, 666, 1633, and 4111 Hz.

The nature of the magnetic coupling between the high-spin $Mn^{III}$ ion ($d^4$, $t_{2g}^3$, $e_g^1$) and the low-spin $Cr^{I}$ ion ($d^5$, $t_{2g}^5$) through the cyanido bridge should be similar to those of cyanido-bridged $Mn^{III}$–$Fe^{III}(CN)_6$ systems.[11,12,14] According to the GK rule,[41] ferromagnetic and antiferromagnetic contributions coexist, and the antiferromagnetic contributions that originate from the overlap of magnetic orbitals of $t_{2g}$ symmetry between $Mn^{III}$–$Fe^{III}$ and $Mn^{III}$–$Cr^{I}$ are dominant in these systems. Therefore, overall antiferromagnetic interactions between $Mn^{III}$ and $Cr^{I}$ through cyanido groups are expected for complexes **1**–**4** in this work, as is also observed in the 3D Prussian blue analogue $Mn^{III}$-$[Cr(CN)_5(NO)] \cdot H_2O$ recently reported by Liao et al.[42] In

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

addition, the bending of the Mn–N≡C angle is an important factor that affects the magnetic coupling in these systems because it diminishes the overlap of $t_{2g}$-type magnetic orbitals on adjacent metal ions and therefore weakens the antiferromagnetic contributions. It has been concluded empirically that an Mn–N≡C angle close to 150° tends to favor ferromagnetic coupling in cyanido-bridged $Mn^{III}$–$Fe^{III}$ systems.[14] However, the magnetic couplings for the cyanido-bridged $Mn^{III}$–$Cr^{I}$ systems in this work are all antiferromagnetic, with average Mn–N≡C angles in the range 148.1(11)–158.7(6)°, therefore further work needs to be done to fully elucidate the nature of the magnetic interactions in cyanido-bridged $Mn^{III}$–$Cr^{I}$ systems.

## Conclusions

Polynuclear 1D and 2D $Mn^{III}$–$Cr^{I}$ complexes have been synthesized by tuning the Schiff-base ligands around $Mn^{III}$. The complexes in the present work all show antiferromagnetic $Mn^{III}$–$Cr^{I}$ coupling, which is in contrast to the $[Fe(CN)_6]^{3-}$ analogues, which usually exhibit intermetallic ferromagnetic interactions.[11–16,19–23] In this regard, $[Cr(CN)_5(NO)]^{3-}$ is much like $[Cr(CN)_6]^{3-}$, as no ferromagnetic cyanido-bridged $Mn^{III}$–$Cr^{III}$ complexes have been found so far.[43] The present study further demonstrates that this is a good strategy for designing and assembling molecule-based magnetic materials based on (Schiff base)$Mn^{III}$ precursors and cyanido-bearing paramagnetic building blocks.

## Experimental Section

**General Remarks:** Elemental analyses for carbon, hydrogen, and nitrogen were carried out with an Elementar Vario EL. The IR spectra were recorded with a Magna-IR 750 spectrophotometer in the region 4000–650 $cm^{-1}$. Variable-temperature magnetic susceptibility measurements of **1**–**4** were performed with a Quantum Design MPMS SQUID magnetometer. The zero-field AC magnetic susceptibilities of **1**, **3**, and **4** were recorded with a MagLab 2000 magnetometer. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal's tables).

**General Procedures for the Synthesis of (Schiff Base)$Mn^{III}$ Complexes:** The precursors [Mn(salen)]$ClO_4$, [Mn(5-Br-salen)]$ClO_4$, [Mn(5-Cl-salen)]$ClO_4$, and [Mn(saltmen)]$ClO_4$ were synthesized according to the following procedure. Solid $[Mn(ClO_4)_2]\cdot 6H_2O$ (1.8 g, 5 mmol) was added to an MeOH and EtOH solution (40 mL, MeOH/EtOH = 1:1, v/v) of the Schiff base $H_2$salen (1.34 g, 5 mmol), $H_2$-5-Cl-salen (1.7 g, 5 mmol), $H_2$-5-Br-salen (2.1 g, 5 mmol), or $H_2$saltmen (1.6 g, 5 mmol), then solid NaOH (5 mmol) was added directly to the above mixture whilst stirring at room temperature. The mixture was then warmed to about 60–70 °C and kept at this temperature for about 1–3 h until the solid Schiff base had completely dissolved and the solution had become dark red/brown. After cooling and filtering, the solution was kept at room temperature for several days, which gave rise to red/brown crystals in high yield (80%).

**Synthesis of Complexes 1–3:** Red/brown crystals of **1**, **2**, and **3** were obtained at room temperature by the slow diffusion of a yellow aqueous solution (5 mL) of $K_3[Cr(CN)_5(NO)]\cdot H_2O$ (0.1 mmol, 32.9 mg) into a reddish brown mixture of [Mn(5-Cl-salen)]$ClO_4$ (0.2 mol, 98.4 mg), [Mn(salen)]$ClO_4$ (0.2 mol, 84.4 mg), or [Mn(5-Br-salen)]$ClO_4$ (0.2 mol, 116 mg) in MeOH and MeCN (5 mL) over about one week. These crystals were collected carefully and air-dried. Yield: 10–15%. IR: **1**: ν(C≡N) 2114 m, ν(N≡O) 1687 m, ν(C=N) 1628 $cm^{-1}$ vs; **2**: ν(C≡N) 2113 m, 2246 w ($CH_3CN$), ν(N≡O) 1677 s, ν(C=N) 1625 $cm^{-1}$ vs; **3**: ν(C≡N) 2009 m, ν(N≡O) 1684 s, ν(C=N), 1627 $cm^{-1}$ vs. **1**: $C_{53}H_{43}Cl_6CrMn_3N_{12}O_{10.50}$ (1445.5): calcd. C 44.04, H 3.00, N 11.63; found C 44.79, H 2.96, N 11.35; **2**: $C_{56.50}H_{54}CrMn_3N_{13.50}O_{10.50}$ (1307.0): calcd. C 51.92, H 4.16, N 14.47; found C 51.37, H 4.13, N 14.22; **3**: $Mn_3CrC_{55}H_{50}Br_6N_{12}O_{12}$ (1767.4): calcd. C 37.38, H 2.85, N 9.51; found C 37.30, H 2.86, N 8.98.

**Synthesis of Complex 4:** Thin lamellar brown single crystals of **4** suitable for X-ray structure analysis were grown at room temperature by slow evaporation of an MeOH/MeCN/$H_2O$ solution of [Mn(saltmen)]$ClO_4$ (64.9 mg, 0.2 mmol) and $K_3[Cr(CN)_5(NO)]\cdot H_2O$ (32.0 mg, 0.1 mmol) for several days. Yield: 28 mg (30% based on Mn). IR: ν(C≡N) 2114 m, ν(N≡O) 1712 s, ν(C=N) 1602 $cm^{-1}$

**X-ray Structure Determination:** Data collection for **2** was performed with a Simens Bruker P4 diffractometer, that for **3** with a Bruker Smart CCD, and that for **1** and **4** with a Rigaku Saturn70 CCD diffractometer (123 K). The structures were solved by direct methods with SHELXS-97 and refined by full-matrix least squares (SHELXL-97) on $F^2$. Hydrogen atoms were added geometrically and refined using a riding model. One free MeCN molecule in complex **2** and one $CN^-$ and one $NO^-$ group from one $[Cr(CN)_5(NO)]^{3-}$ unit in complex **1** are disordered over two sets of positions. Single crystals of **4** are thin, weakly diffracting, and give high final $R$ values: $R_1 = 0.1429$, $wR_2 = 0.2771$ (all data). Its molecular structure was further confirmed by elemental analysis and magnetism studies. Crystallographic data for complexes **1**–**4** are summarized in Table 5. CCDC-623479 to -623482 (**1**–**4**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Center via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see footnote on the first page of this article): Schematic view of the structures of **1** and **4**; cell packing diagrams for **1**–**4**; FCM and ZFCM plots, hysteresis loop, and magnetization data at 1.83 K for **2**; hysteresis loop at 2.0 K for **4**; powder XRD plot for complex **4**.

# *N*-(Aryl)picolinamide Complexes of Ruthenium: Usual Coordination and Strategic Cyclometalation

**Sumon Nag,[a] Ray J. Butcher,[b] and Samaresh Bhattacharya*[a]**

**Keywords:** Picolinamide ligands / Ruthenium complexes / Cyclometalation

Reaction of five *N*-(4-*R*-phenyl)picolinamides (R = $OCH_3$, $CH_3$, H, Cl, and $NO_2$) with $[Ru(PPh_3)_2(CO)_2Cl_2]$ in refluxing 2-methoxyethanol in the presence of a base ($NEt_3$) affords two geometrical isomers of a group of complexes (**1-R** and **2-R**), each of which contains an amide ligand coordinated to the metal center as a monoanionic bidentate *N*,*N* donor along with two triphenylphosphanes, a carbonyl, and a hydride. Similar reaction of *N*-(naphthyl)picolinamide with $[Ru(PPh_3)_2(CO)_2Cl_2]$ affords an organometallic complex, **3**, in which the amide ligand is coordinated to the metal center, by C–H activation of the naphthyl ring at the 8-position, as a dianionic tridentate *N*,*N*,*C* donor along with two triphenylphosphanes and one carbonyl. Structures of the **1-$OCH_3$**, **2-$CH_3$**, and **3** complexes have been determined by X-ray crystallography. In all the complexes the two triphenylphosphanes are *trans*. In the **1-R** complexes the hydride is *trans* to the pyridine nitrogen and in the **2-R** complexes it is *trans* to the amide-nitrogen. All the complexes are diamagnetic, and show characteristic $^1H$ NMR signals and intense MLCT transitions in the visible region. Cyclic voltammetry on all the complexes shows a $Ru^{II}$–$Ru^{III}$ oxidation within 0.71–0.93 V versus SCE. An oxidation and a reduction of the coordinated amide ligand are also observed within 1.29–1.69 V versus SCE and –1.02 to –1.21 V versus SCE respectively.

## Introduction

There has been considerable current interest in the chemistry of ruthenium complexes, largely because of their fascinating redox, photophysical, and photochemical properties.[1] As all these properties are directed primarily by the coordination environment around the metal center, complexation of ruthenium by ligands of selected types is of significant importance. In the present study, which has originated from our continued interest in the chemistry of ruthenium in different coordination environments,[2] we have selected a group of amide ligands (**$L^1$**) derived from picolinic acid and anilines with five different *para*-substituents in order to study their influence, if any, on the redox properties of the resulting ruthenium complexes.

Chemistry of the amide ligands is of particular interest with reference to their role in biological processes.[3] For example, the amide linkage plays a key role in the formation and maintenance of protein architectures, which are crucial for their performance in biological systems.[4] The selected amide ligands (**$L^1$**) are known to bind to metal ions either as neutral *N*,*O* donors (amide form, **I**) or as monoanionic *N*,*N* donors (amidate form, **II**) by loss of the amide pro-

ton.[5] Chelation in the amidate mode is known to stabilize metal ions in their high oxidation states, while that in the amide mode is reported to favor relatively lower oxidation states of a metal.[5] Interconversion between the amide (**I**) and amidate (**II**) modes of binding has been utilized to chemically manipulate redox properties of the metal center.[6] It may be mentioned here that though the chemistry of amide complexes of many transition metals has been extensively studied,[7] that of ruthenium appears to have received much less attention.[2j,8] As the source of ruthenium we have selected the $[Ru(PPh_3)_2(CO)_2Cl_2]$ complex, because of its demonstrated ability to accommodate bidentate ligands through displacement of carbonyl and chloride.[2f,2m] Reaction of the selected amides ($\mathbf{L^1}$) as well as a related ligand, viz. *N*-(naphthyl)picolinamide ($\mathbf{L^2}$), with $[Ru(PPh_3)_2(CO)_2Cl_2]$ has been found to afford interesting complexes where the amides ($\mathbf{L^1}$ and $\mathbf{L^2}$) are bound to ruthenium, as in **II** and **III** respectively. An account of the chemistry of all these complexes is presented in this report, with special reference to their formation, characterization, and spectral and electrochemical properties.

## Results and Discussion

Reactions of the *N*-(4-*R*-phenyl)picolinamides ($\mathbf{L^1}$) with $[Ru(PPh_3)_2(CO)_2Cl_2]$ proceed smoothly in refluxing 2-methoxyethanol in the presence of triethylamine. From each of these reactions two complexes were obtained, viz. a golden yellow complex and a yellow complex (**1-R** and **2-R**). The combined yield of these two complexes was reasonable.

**3**

Preliminary (microanalytical, spectroscopic, magnetic, etc.) characterizations on these complexes (vide infra) indicate the presence of an amide ligand, two triphenylphosphanes, a carbonyl, and a hydride in the coordination sphere. In order to find the stereochemistries of these complexes as well as the coordination mode of the *N*-(4-*R*-phenyl)picolinamides in them, the structure of one representative complex from each family, viz. **1-$OCH_3$** and **2-$CH_3$**, has been determined by X-ray crystallography. The structure of the **1-$OCH_3$** is shown in Figure 1 and selected bond parameters are listed in Table 1.

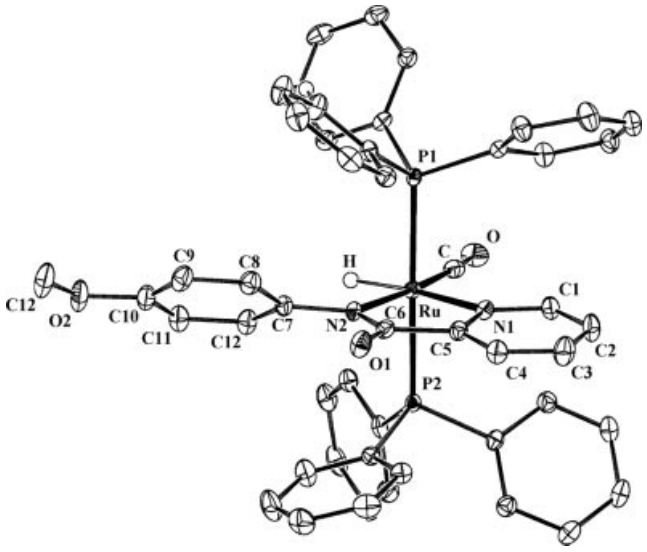

Figure 1. View of the **1-$OCH_3$** complex.

The structure shows that the *N*-(4-methoxyphenyl)picolinamide is coordinated to ruthenium, by dissociation of the acidic proton, as a monoanionic *N*,*N* donor (**II**). Two triphenylphosphanes, a hydride, and a carbonyl are also coordinated to the metal center. Ruthenium is therefore sitting in a $C_1H_1N_2P_2$ coordination environment, which is distorted octahedral in nature, as reflected in all the bond parameters around ruthenium. The coordinated picolinamide, hydride, and carbonyl constitute one equatorial plane with the metal at the center, where the hydride is *trans* to the pyridine nitrogen and the carbonyl is *trans* to the amide-nitrogen. The $PPh_3$ ligands occupy the remaining two axial positions and hence they are mutually *trans*. The observed Ru–P, Ru–C, and Ru–H distances are all quite normal,[9] and so are the bond lengths in the Ru(amide) fragment.[8b,8c] In the crystal lattice of the **1-$OCH_3$** complex, there are two water molecules present per molecule of the complex. In order to find out the link between these water molecules and the complex molecule, the packing pattern in the lattice has been scrutinized (Figure 2), which shows that a layer of water molecules lies in between two layers of complex molecules and thereby holds them together. A closer inspection into the network reveals that the methoxy-oxygen in each complex molecule is hydrogen-bonded to a phenyl hydrogen of a coordinated $PPh_3$ of an adjacent complex molecule and two such hydrogen bonds result in the formation of a dimeric unit. Four water molecules, which are interlinked by hydrogen bonds, bridge two such dimeric units by hydrogen bond formation involving the amide oxygen and a phenyl hydrogen of a $PPh_3$. These hydrogen-

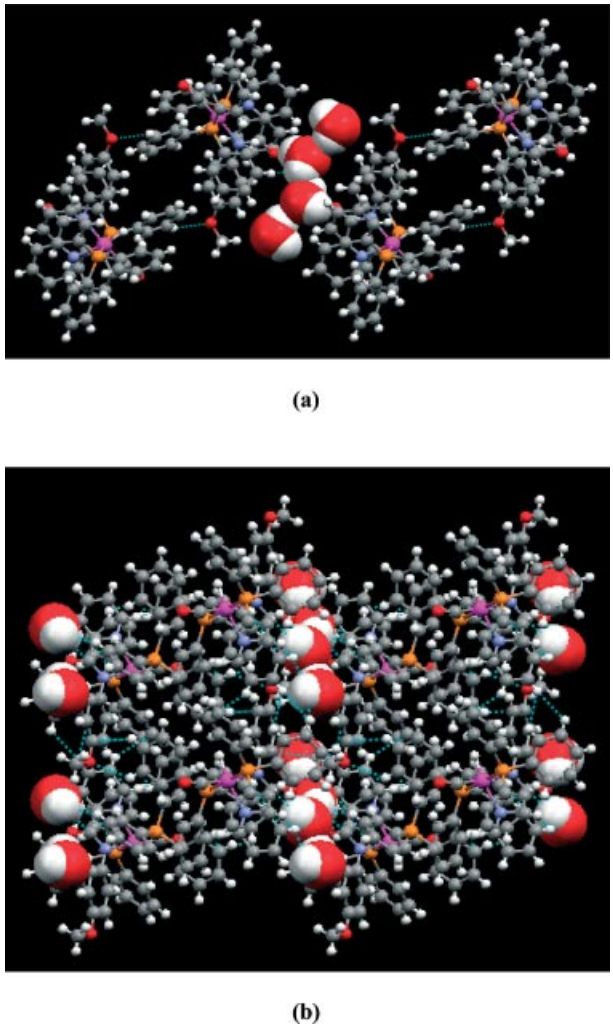

Figure 2. (a) Hydrogen bonding and (b) packing diagram (down the *b* axis) of the **1-OCH$_3$** complex.

bonding interactions in the crystal lattice appear to contribute a lot to its stability. As all the **1-R** complexes have been synthesized similarly and they show similar properties (vide infra), the other four **1-R** (R ≠ $OCH_3$) complexes are assumed to have a similar structure to the **1-OCH$_3$** complex.

The structure of the **2-CH$_3$** complex (Figure 3) shows that it is very similar to the **1-OCH$_3$** complex; the only differences are in the disposition of coordinated carbonyl and hydride with respect to the coordinated picolinamide. The hydride is *trans* to the amide-nitrogen and the carbonyl is *trans* to the pyridine nitrogen. All the bond parameters in this **2-CH$_3$** complex compare well with those observed in the **1-OCH$_3$** complex (Table 1). In the crystal lattice of **2-CH$_3$** there is one molecule of methanol per molecule of the complex. The packing pattern in the lattice shows (Figure S1, supporting information) that this methanol molecule is involved in three hydrogen-bonding interactions, two with the amide oxygen and a phenyl hydrogen of a $PPh_3$ of one

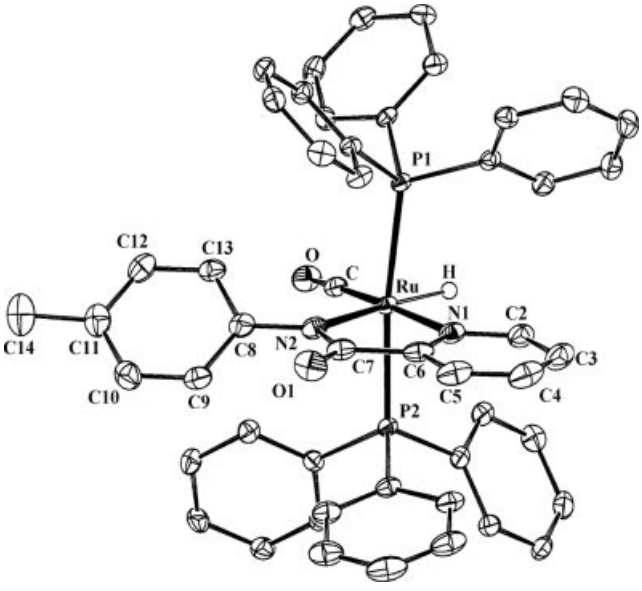

Figure 3. View of the **2-CH$_3$** complex.

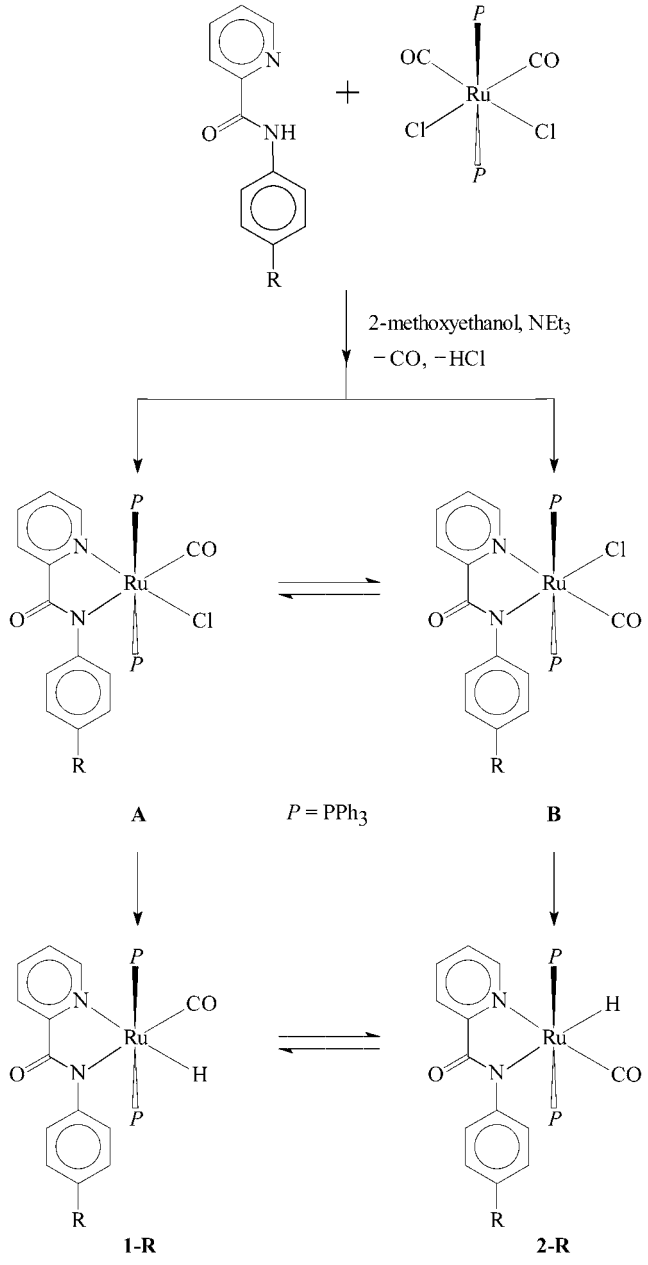
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

complex molecule, and the third with the phenyl hydrogen of a $PPh_3$ of a second complex molecule. The methanol molecules thus bridge the individual complex molecules through hydrogen bonding. Based on the similarity in their synthesis and properties (vide infra), the other four **2-R** (R $\neq$ $CH_3$) complexes are assumed to have similar structures to **2-CH$_3$**. Each **2-R** complex is therefore a geometrical isomer of the corresponding **1-R** complex. The observed elemental (C, H, N) analytical data of the **1-R** and **2-R** complexes agree well with their compositions.

Formation of the two stereoisomers (**1-R** and **2-R**) from the same reaction may be rationalized in terms of Scheme 1. Upon reaction with $[Ru(PPh_3)_2(CO)_2Cl_2]$ the amide ligands (**L$^1$**) bind to the metal center, through dissociation of the acidic N-H proton, as monoanionic *N*,*N* donors with simultaneous dissociation of a CO and a chloride from the ruthenium starting complex to generate two stereoisomers (**A** and **B**) of an intermediate. These two stereoisomers, which are believed to remain in equilibrium, are probably formed by different kinetic routes. The Ru–Cl bond in these intermediates is then converted into a Ru–H bond under the prevailing reaction condition affording the **1-R** and **2-R** complexes respectively. Such conversion of a Ru–Cl bond into a Ru–H bond in alcoholic solvent in the presence of base is well documented in the literature.[10]

Disposition of the Ru–H bond with respect to the pendent phenyl ring in **1-R** points to the possibility of a C–H activation of the aryl ring. Such an activation could not take place in the **1-R** complexes, because in them the phenyl ring is not close enough to the metal center, and had the phenyl ring undergone an orthometalation it would have resulted in the formation of a sterically unstable four-membered metallacycle. In order to undergo C–H activation the aryl fragment should be so chosen that one of its C–H bonds should come in close proximity to the Ru–H bond. With this simple strategy in mind, *N*-(naphthyl)picolinamide (**L$^2$**) has been chosen as the target ligand for the C–H activation. Reaction of *N*-(naphthyl)picolinamide with $[Ru(PPh_3)_2(CO)_2Cl_2]$ has been carried out similarly as before, which has afforded an orange complex (**3**) in good yield. Preliminary characterizations on this complex indicate the presence of an amide ligand, two triphenylphosphanes, and a carbonyl in the coordination sphere, as well as the absence of any hydride. The identity of complex **3** has been revealed by its structure determination by X-ray crystallography. The structure (Figure 4) shows that *N*-(naphthyl)picolinamide is indeed coordinated to ruthenium in the expected *N*,*N*,*C* fashion (**III**). The Ru–C(naphthyl) bond is found to be normal[2m] and the other bond parameters compare well with those observed in the earlier structures (Table 1). The absence of any solvent of crystallization in the crystal lattice of complex **3** indicates the possible existence of some noncovalent interaction(s) between the individual complex molecules. A careful inspection of the packing pattern in the lattice shows that noncovalent interactions of two different types, viz. C–H···O and C–H···π interactions, are active in the lattice (Figure S2, Supporting Information). Two phenyl protons of two $PPh_3$ ligands belonging to two adjacent complex molecules are found to be hydrogen bonded to the π-cloud of two other phenyl rings of the same two $PPh_3$ ligands. However, this hydrogen-bonding interaction is directed to an edge of the phenyl ring in an $\eta^2$ fashion. The amide oxygen of a third complex molecule is also hydrogen-bonded to two phenyl hydrogen atoms of two $PPh_3$ ligands of the first two complex molecules. These C–H···O and C–H···π interactions are extended throughout the entire lattice of **3**. The noncovalent interactions, observed in all three crystals, play a key role in the packing of the molecules in the crystals, and it may be relevant to note here that such interactions are of significant importance in molecular recognition processes as well as in crystal engineering.[11]



Scheme 1.

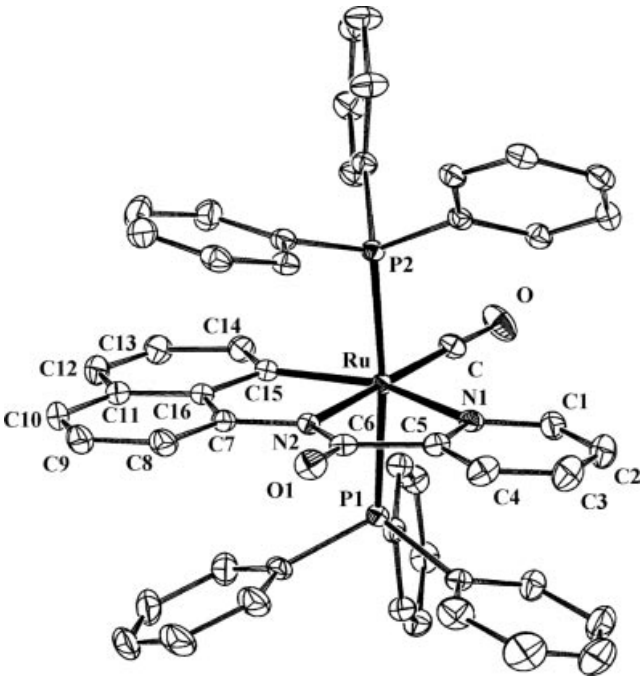

Figure 4. View of complex **3**.

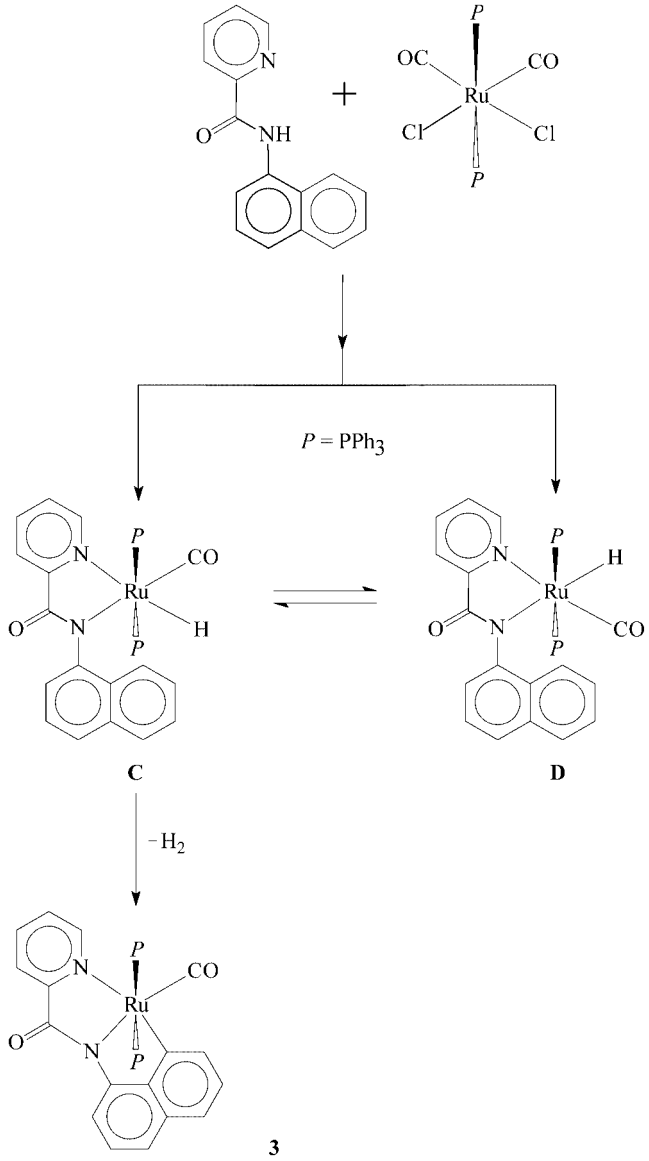

Scheme 2.

Probable sequences behind formation of the cyclometalated complex **3** are illustrated in Scheme 2. In the early stage of the synthetic reaction an equilibrium mixture of two stereoisomers (**C** and **D**) of a hydride intermediate (as shown in Scheme 1) are believed to be formed, in both of which ligand $\mathbf{L^2}$ is coordinated as a *N*,*N* donor. Isomer **C** of the intermediate then undergoes the C–H activation at the 8-position of the naphthyl ring affording the cyclometalated species **3** through elimination of molecular hydrogen.[12] As isomer **C** is irreversibly transformed into the cyclometalated species **3**, the equilibrium between the two isomers gradually shifts towards **C**, and thus only the cyclometalated species **3** is obtained as the sole product from this reaction and none of the two intermediates can be isolated.

Magnetic susceptibility measurements show that the **1-R**, **2-R**, and **3** complexes are diamagnetic, which corresponds to the +2 oxidation state of ruthenium (low-spin $d^6$, $S = 0$) in these complexes. $^1$H NMR spectra of the **1-R** complexes show broad signals within 7.1–7.7 ppm for the coordinated $PPh_3$ ligands. The hydride signal is observed as a distinct triplet, because of coupling with two magnetically equivalent phosphorus nuclei, near δ = –10.6 ppm. Most of the aromatic proton signals from the coordinated amide ligand are clearly observed in the expected region, while a few could not be detected because of their overlap with other signals in the same region. Signals for the methoxy and methyl groups in the **1-OCH$_3$** and **1-CH$_3$** complexes are observed respectively at $\delta$ = 3.67 and 2.11 ppm. In the $^1$H NMR spectra of the **2-R** complexes, the hydride signal (triplet) is observed at around δ = –12.1 ppm, and this significant shift in position, compared to the **1-R** complexes, has been useful as a diagnostic property in distinguishing this group of **2-R** complexes from their **1-R** isomers. Besides small shifts in the signal positions, the rest of the $^1$H NMR spectrum of each **2-R** complex is qualitatively similar to that of the corresponding **1-R** complex. It may be mentioned here that in $CDCl_3$ solution, each **1-R** (or **2-R**) complex is slowly and partially converted into the corresponding **2-R** (or **1-R**) isomer, which is easily recognized by the appearance of the characteristic hydride signal of the generated isomer. It may also be noted that conversion of **1-R** to **2-R** is relatively faster (takes about 6 d to reach equilibrium, where concentration ratio of **1-R** and **2-R** becomes approximately 2:1), while that of **2-R** to **1-R** is much slower (takes about 8 d to reach a concentration ratio of **1-R** and **2-R** of approximately 1:8). Except for the absence of the hydride signal and the presence of a few additional signals in the aromatic region, $^1$H NMR spectral features of complex **3** are similar to those of the **1-H** complex. $^{31}$P NMR spectra of all the **1-R** and **2-R** complexes show a single resonance

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

near 41.7 and 44.0 ppm respectively. In complex **3**, the $^{31}P$ signal is observed at $\delta$ = 31.42 ppm.

The infrared spectrum of each **1-R** complex shows many bands of different intensities in the 400–4000 $cm^{-1}$ region. Assignment of each individual band to a specific vibration has not been attempted. However, comparison with the spectra of the corresponding uncoordinated ligands shows that the N–H stretch, observed near 3140 $cm^{-1}$ in the uncoordinated ligands, is absent in the complexes. The amide C=O stretch, observed at around 1680 $cm^{-1}$ in the uncoordinated ligands, is also found to be shifted to around 1578 $cm^{-1}$ in the complexes. A strong band observed near 1900 $cm^{-1}$ in all the **1-R** complexes is due to the coordinated carbon monoxide, and three strong bands have been observed near 517, 692, and 746 $cm^{-1}$ in **1-R** complexes, indicating the presence of the coordinated $PPh_3$ ligands.[2m] Sharp bands are also observed near 1092, 1433, 1479, and 1557 $cm^{-1}$ in the **1-R** complexes, which are found to be absent in the spectrum of $[Ru(PPh_3)_2(CO)_2Cl_2]$, and hence these are attributed to the coordinated *N*-(aryl)picolinamide. Infrared spectra of the **2-R** and **3** complexes are similar to those of the **1-R** complexes. The $^1H$ NMR and IR spectroscopic data of the **1-R**, **2-R**, and **3** complexes are therefore consistent with their compositions.

The **1-R**, **2-R**, and **3** complexes are soluble in acetone, dichloromethane, chloroform, and so forth, producing bright yellow solutions. Electronic spectra of the complexes have been recorded in dichloromethane solution. All the complexes show several intense absorptions in the visible and ultraviolet regions (Table 2). The absorptions in the ultraviolet region are attributable to transitions within the ligand orbitals and those in the visible region are probably due to charge-transfer transitions. To have a better insight into the nature of the absorptions in the visible region, qualitative EHMO calculations have been performed[13] on computer-generated models of the complexes where phenyl rings of the triphenylphosphanes have been replaced by hydrogen. Partial MO diagrams of a selected **1-R** complex are shown in Figure 5 and those of a representative **2-R** and **3** complexes are deposited as supporting information (Figures S3 and S4). Compositions of selected molecular orbitals are given in Table S1 (supporting information). In the **1-R** complexes, the highest occupied molecular orbital (HOMO) and the next two filled orbitals (HOMO-1 and HOMO-2) have major contributions from the ruthenium $d_{xy}$, $d_{yz}$, and $d_{xz}$ orbitals.[14] These three occupied orbitals may therefore be regarded as the ruthenium $t_2$ orbitals. The lowest unoccupied molecular orbital (LUMO) has more than 90% contribution from the *N*-(aryl)picolinamide and is concentrated largely on the pyridine ring and the amido fragment. Among the next few vacant orbitals (LUMO+1, LUMO+2 etc.), LUMO+1 is primarily centered on the pyridine ring, while LUMO+2 is delocalized over both the pyridine ring and the pendent phenyl ring of the *N*-(aryl)picolinamide. The lowest energy absorption in the 392–420 nm region may therefore be assigned to the charge-transfer transition taking place from the highest filled ruthenium $t_2$ orbital (HOMO) to the vacant orbital delocalized over the *N*-(aryl)picolinamide (LUMO). The other intense absorptions in the visible region may be assigned to charge-transfer transitions from the ruthenium $t_2$ orbitals to the higher-energy vacant orbitals. The nature of the molecular orbitals in the **2-R** complexes is very similar to that in the **1-R** complexes, and the electronic spectral features of these two groups of complexes are also very similar. In complex **3**, however, the HOMO, HOMO-1, and HOMO-2 are found to have large contributions from the *N*-(naphthyl)picolinamide besides having significant contributions from the ruthenium $d_{xy}$, $d_{yz}$, and $d_{xz}$ orbitals. The LUMO of complex **3** is concentrated largely on the pyridine ring and the carbonamide functionality. The next two vacant orbitals (LUMO+1 and LUMO+2) are close in energy; LUMO+1 is primarily centered on the pyridine ring, while LUMO+2 is delocalized over both the naphthyl and pyridine ring of the *N*-(naphthyl)picolinamide. The absorption at 472 nm may therefore be assigned to a HOMO-to-LUMO charge-transfer transition and the other absorptions in the visible region to charge-transfer transitions from the filled orbitals to the higher-energy vacant orbitals.

[a] In dichloromethane. [b] Solvent: dichloromethane/acetonitrile, 1:9; supporting electrolyte, TBAP; reference electrode, SCE; $E_{pa}$ and $E_{pc}$ are anodic and cathodic peak potentials; scan rate, 50 $mV s^{-1}$. [c] Shoulder.

Electrochemical properties of the **1-R**, **2-R**, and **3** complexes have been studied by cyclic voltammetry in 1:9 dichloromethane/acetonitrile solution (0.1 M TBAP).[15] Each complex shows two anodic waves at positive potentials of the SCE reference electrode and a cathodic one at negative potential (Table 2). All the responses are irreversible in nature. In view of the composition of the HOMO, the first oxidation is assigned to $Ru^{II}$–$Ru^{III}$ oxidation. Simi-

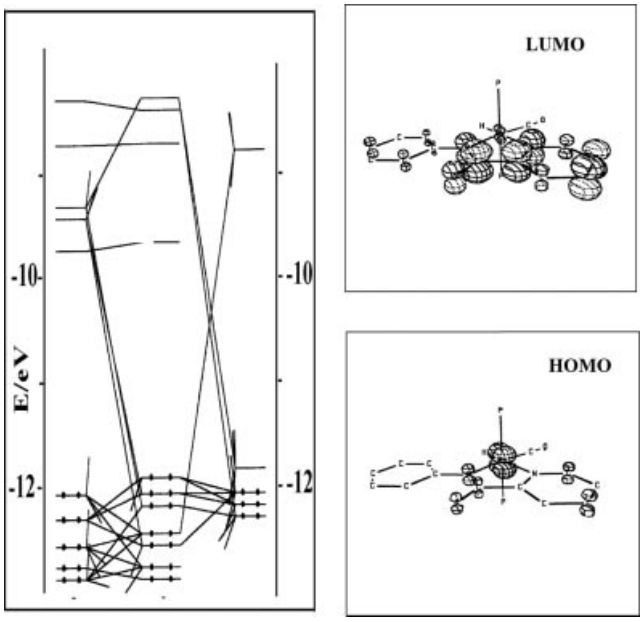

Figure 5. Partial molecular orbital diagram of the **1-H** complex.

larly based on composition of the LUMO, the reduction is assigned to reduction of the coordinated amide ligand. The second oxidation is attributed tentatively to oxidation of the coordinated amide ligand. Comparison of the potential of the $Ru^{II}$–$Ru^{III}$ couple in the **1-R** and **2-R** complexes shows that the bivalent state of ruthenium is much more stabilized in the former group of complexes, which may be attributed to the presence of carbonyl ligand *cis* to the pyridine nitrogen in the coordination sphere of ruthenium in the **1-R** complexes, favoring the back donation from the metal center to these two π-acidic ligands, rendering the ruthenium(II) state much more stable than the **2-R** complexes. In these **1-R** and **2-R** complexes, the potential of the $Ru^{II}$–$Ru^{III}$ oxidation has been observed to be sensitive to the nature of the substituent R in the *N*-(aryl)picolinamide. The potential ($E_{pa}$) increases with increasing electron-withdrawing character of the substituent R. The plots of $E_{pa}$ versus $\sigma$ [$\sigma$ = Hammett constant of R;[16] for $OCH_3$: –0.27, $CH_3$: –0.17, H: 0.00, Cl: 0.23, $NO_2$: 0.78] are linear for both the **1-R** and **2-R** complexes (see Figures S5 and S6 in the supporting information) with slopes ($\rho$) of 0.19 and 0.15 V ($\rho$ = reaction constant of this oxidation[17]) respectively. For both **1-R** and **2-R** complexes, the potential of the second oxidative response also shows linear correlation with the electron-withdrawing nature of substituent R (Figures S7 and S8, supporting information), with slopes ($\rho$) of 0.39 and 0.15 V, respectively. Potentials of the irreversible reductive response do not show any systematic variation with the nature of the substituent R.

## Conclusions

The present study shows that upon reaction with $[Ru(PPh_3)_2(CO)_2Cl_2]$ the *N*-(aryl)picolinamides (**$L^1$**) can bind to ruthenium as monoanionic *N*,*N*-donors by displacing a carbonyl and a chloride, as well as turning a Ru–Cl bond into a Ru–H bond. This study also demonstrates that the Ru–H bond can be utilized for inducing C–H activation of selective amides, such as *N*-(naphthyl)picolinamide. Utilization of the Ru–H bond for other useful reactions is currently under exploration.

## Experimental Section

**General Procedure:** Commercial ruthenium trichloride was purchased from Arora Matthey, Kolkata, India and was converted to $[Ru(PPh_3)_2(CO)_2Cl_2]$ by following a reported procedure.[18] The *N*-(aryl)picolinamides were prepared by condensing picolinic acid with *para*-substituted anilines or α-naphthylamine.[8a] Purification of dichloromethane and acetonitrile, and preparation of tetrabutylammonium perchlorate (TBAP) for electrochemical work were performed as reported in the literature.[19] All other chemicals and solvents were reagent grade commercial materials and were used as received. Microanalyses (C, H, N) were performed using a Heraeus Carlo Erba 1108 elemental analyzer. Magnetic susceptibilities were measured using a PAR 155 vibrating sample magnetometer fitted with a Walker scientific L75FBAL magnet. $^1$H NMR spectra were recorded in $CDCl_3$ solution with a Bruker Avance DPX 300 NMR spectrometer using TMS as the internal standard. IR spectra were obtained with a Shimadzu FTIR-8300 spectrometer with samples prepared as KBr pellets. Electronic spectra were recorded with a JASCO V-570 spectrophotometer. Electrochemical measurements were made using a CH Instruments model 600A electrochemical analyzer. A platinum disc working electrode, a platinum wire auxiliary electrode, and an aqueous saturated calomel reference electrode (SCE) were used in the cyclic voltammetry experiments. All electrochemical experiments were performed under dinitrogen. All electrochemical data were collected at 298 K and are uncorrected for junction potentials.

### Preparations of Complexes

The **1-R** and **2-R** complexes were obtained by following a general procedure. Specific details are given below for a particular pair of complexes.

**1-$OCH_3$ and 2-$OCH_3$:** *N*-(4-Methoxyphenyl)picolinamide (**$L^1$**, R = $OCH_3$) (30 mg, 0.13 mmol) was dissolved in warm 2-methoxyethanol (50 mL) and triethylamine (13 mg, 0.13 mmol) was added to it followed by $[Ru(PPh_3)_2(CO)_2Cl_2]$ (100 mg, 0.13 mmol). The mixture was refluxed for 24 h, whereby a yellow solution was obtained. Evaporation of this solution afforded a dark yellow solid, which was subjected to purification by thin layer chromatography on a silica plate. With 1:3 acetonitrile/benzene as the eluent, a distinct golden yellow band separated first followed by an orangish-yellow band, both of which were extracted separately with 1:3 dichloromethane/acetonitrile. Evaporation of these extracts respectively gave **1-$OCH_3$** as a crystalline golden yellow solid and **2-$OCH_3$** as a yellow crystalline solid.

C 66.40, H 4.40, N 3.16; found C 66.17, H 4.35, N 3.12. $^1$H NMR: $\delta$ = –12.16 (t, $J$ = 20.5 Hz, 1 H); 6.20 (t, $J$ = 6.3 Hz, 1 H); 6.52–6.80 (d + d, 4 H)*; 7.11–7.63 (2PPh$_3$); 7.82 (d, $J$ = 5.1 Hz, 1 H) ppm. $^{31}$P NMR: $\delta$ = 44.10 ppm. **2-NO$_2$:** Yield: 40 mg, 34%. $C_{49}H_{39}N_3O_4P_2Ru$ (896): calcd. C 65.62, H 4.35, N 3.12; found C 65.38, H 4.31, N 3.11. $^1$H NMR: $\delta$ = –12.36 (t, $J$ = 20.1 Hz, 1 H); 6.24 (t, $J$ = 6.2 Hz, 1 H); 6.93 (d, $J$ = 9.0 Hz, 2 H); 7.11–7.36 (2PPh$_3$); 7.51 (d, $J$ = 8.1 Hz, 1 H); 7.66 (d, $J$ = 8.3 Hz, 1 H); 7.70 (d, $J$ = 9.3 Hz, 2 H) ppm. $^{31}$P NMR: $\delta$ = 44.14 ppm.

**3:** *N*-(1-Naphthyl)picolinamide (**L$^2$**) (32 mg, 0.13 mmol) was dissolved in warm 2-methoxyethanol (50 mL) and triethylamine (13 mg, 0.13 mmol) was added to it followed by [Ru(PPh$_3$)$_2$(CO)$_2$Cl$_2$] (100 mg, 0.13 mmol). The mixture was refluxed for 24 h, whereby a yellow solution was obtained. Evaporation of this solution afforded an orange solid, which was subjected to purification by thin layer chromatography on a silica plate. With 1:3 acetonitrile/benzene as the eluent, a distinct orange band separated, which was extracted with 1:3 dichloromethane/acetonitrile. Evaporation of this extract gave **3** as a crystalline orange solid. Yield: 84 mg, 70%. $C_{53}H_{40}N_2O_2P_2Ru$ (899): calcd. C 71.54, H 4.49, N 3.14; found C 72.23, H 4.46, N 3.11. $^1$H NMR: $\delta$ = 6.62 (t, $J$ = 6.2 Hz, 1 H); 6.76 (t, $J$ = 7.5 Hz, 1 H); 6.82–6.90 (t + 2d, 3 H)*, 6.99–7.15 (2PPh$_3$); 7.36 (t, $J$ = 7.8 Hz, 1 H); 7.48 (d, $J$ = 6.3 Hz, 1 H); 7.69 (d, $J$ = 7.9 Hz, 1 H), 8.05–8.07 (d + d, 2 H)* ppm. $^{31}$P NMR: $\delta$ = 31.42 ppm.

**X-ray Crystallography:** Single crystals of the **1-OCH$_3$** and **3** complexes were obtained by slow evaporation of acetonitrile solutions of the respective complexes. Single crystals of the **2-CH$_3$** complex were obtained by slow evaporation of a solution of the complex in a 1:1 mixture of methanol and dichloromethane. Selected crystal data and data collection parameters are given in Table 3. Data were collected on a Bruker CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation. X-ray data reduction, and structure solution and refinement were done using SHELXS-97 and SHELXL-97 programs.[21] The structures were solved by the direct methods.

CCDC-623582, -623583, and -623584 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# A Theoretical Study of the Nearest Cu···Cu Antiferromagnetic Exchange Coupling Interactions in [$LaCu_6$] and [$YCu_6$]

**Yi-Quan Zhang*[a] and Cheng-Lin Luo[a]**

**Keywords:** Magnetic properties / Density functional calculations / Broken symmetry / Single-molecule studies

A density functional study of the exchange coupling interactions between the two nearest $Cu^{II}$ centers in [$LaCu_6$] and [$YCu_6$] is presented. Two approaches show that the Cu···Cu antiferromagnetic interactions increase with a decrease of the ionic radius of the diamagnetic central $La^{III}$ and $Y^{III}$ ions. However, the influence of the central ions on the Cu···Cu interactions is small compared to that of their structures according to our calculations. We therefore conclude that the stronger antiferromagnetic interactions between the two nearest $Cu^{II}$ centers in [$LaCu_6$] than in [$YCu_6$] are not a result of the central $La^{III}$ ion but the structure. The antiferromagnetic contributions of the direct overlap between the two nearest $Cu^{II}$ magnetic orbitals also play a major role according to the calculations of the overlap integral $S_{ij}$ based on Kahn's theory.

## Introduction

In recent years, the synthesis and study of single-molecule magnets with high total spin that can be used to store data has received much attention.[1–15] Among these single-molecule magnets, heteropolynuclear transition-metal and rare-earth mixed complexes are of great interest due to their interesting structures and magnetic properties.[14,15] In a recent experimental study, Liu et al.[10] considered that the substitution of the central $La^{III}$ ion with $Y^{III}$ will decrease the antiferromagnetic exchange coupling interactions between the two nearest $Cu^{II}$ ions in [$LaCu_6(\mu\text{-}OH)_3(HL)_2(L)_4$]($ClO_4$)$_2$·25$H_2O$[15] and [$YCu_6(\mu\text{-}OH)_3(HL)_2(L)_4$]($ClO_4$)$_2$·25$H_2O$[14] ($H_2L$ = iminodiacetic acid) clusters and that the direct overlap of Cu orbitals plays a minor role since this would enhance the antiferromagnetic coupling at shorter Cu···Cu separations. However, the above conclusions are not correct according to our calculations. Herein, we investigate the influence of the diamagnetic central ions $La^{III}$ and $Y^{III}$ and the effects of the direct overlap of Cu orbitals on the exchange coupling interactions between the two nearest $Cu^{II}$ ions in the clusters [$LaCu_6$] and [$YCu_6$] by density functional theory (DFT).

## Computational Methodology

### Description of the Complexes and Models

Complex **1-La**[15] [$LaCu_6(\mu\text{-}OH)_3(HL)_2(L)_4$] ($H_2L$ = iminodiacetic acid) contains two parallel layers, each of which is composed of three $Cu^{II}$ ions and three ligands. Six $Cu^{II}$ ions form a trigonal prism with the $La^{III}$ ion located in the center (see Figure 1). Each two nearest $Cu^{II}$ centers are connected by bridging hydroxides. The Cu–O–Cu angles are 120.7°. The nearest Cu···Cu distance is 3.383 Å and the La···Cu distance is 3.509 Å. The structure of model **1-Y** is the same as that of complex **1-La** except that its central ion is $Y^{III}$ not $La^{III}$. Complex **2-Y**[14] [$YCu_6(u\text{-}OH)_3(HL)_2(L)_4$] has a similar structure to that of **1-La** (see Figure 2). The Cu–O–Cu angles are 118.3°, the nearest Cu···Cu distance is 3.323 Å, and the Y···Cu distance is 3.447 Å. The structure of model **2-La** is the same as that of complex **2-Y** except

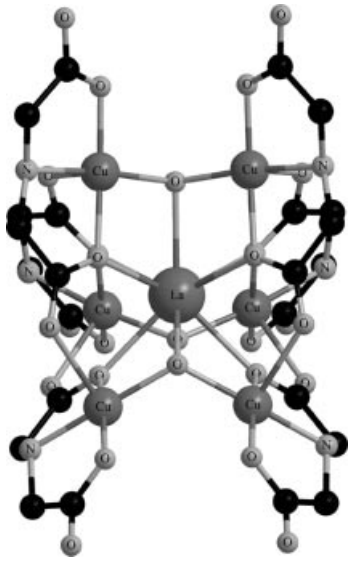

Figure 1. Structure of complex **1-La** ($LaCu_6$).

that the central ion is $La^{III}$ not $Y^{III}$. In all the complexes and models, the six $Cu^{II}$ centers are symmetry equivalent. A thorough description of the above complexes can be found in the literature.[14,15] To be able to compare our calculated coupling constants for complete structures with the experimental values, we used the experimentally determined molecular structure rather than an optimized one in our calculations because small changes to the experimental structure could result in significant deviations of the coupling constant.

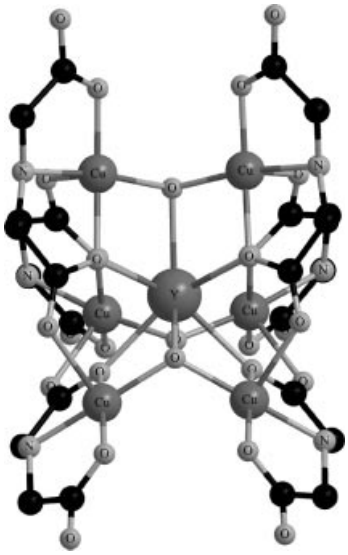

Figure 2. Structure of complex **2-Y** ($YCu_6$).

### Calculation of the Exchange Coupling Constants

There are two different approaches to calculate the exchange coupling constants for polynuclear complexes.[3–5] In all calculations, the spin-orbit coupling is not considered, so the magnetic anisotropy needs not be considered. The first approach consists of evaluating the exchange coupling constant, $J_{ij}$, between two paramagnetic metal centers *i* and *j* in the hexanuclear molecule by calculating the energy difference between the highest and broken-symmetry spin states of a model molecule in which the metal atoms, except for *i* and *j*, are substituted by diamagnetic $Zn^{II}$ cations. This approach has been used to calculate the exchange coupling interactions of hexanuclear complexes many times and has proven to give good results compared to the experimental ones.[3–5,16] The second approach is to calculate the different spin-state energies of hexanuclear complexes and use the Heisenberg Hamiltonian to obtain the exchange coupling constants between different metal centers.[3–5,16,17] This is a more rigorous approach for evaluating *J* for polynuclear complexes than the first one. How to use these two approaches will be discussed thoroughly below.

First of all we will discuss the first approach. The magnetic interactions between $Cu^{II}$ metal ions were studied on the basis of density functional theory (DFT) coupled with the broken-symmetry approach (BS).[18–20] The exchange coupling constants *J* were evaluated by calculating the energy difference between the high-spin state ($E_{HS}$) and the broken-symmetry state ($E_{BS}$) by assuming that the spin Hamiltonian is defined as shown in Equation (1).

$$\hat{H} = -2J\hat{S}_1\cdot\hat{S}_2 \quad (1)$$

If the spin-projected approach is used, the equation proposed by Noodleman[18–20] to extract the *J* value for a binuclear transition-metal complex becomes

$$J = \frac{E_{BS} - E_{HS}}{4S_1S_2} \quad (2)$$

For all the models, where $S_1 = 1/2$, $S_2 = 1/2$ for $Cu^{II}$, we derive Equation (3) from (2),

$$J = E_{BS} - E_{HS} \quad (3)$$

while with the non-projected approach[21]

$$2J = \frac{E_{BS} - E_{HS}}{2S_1S_2 + S_2} \quad (4)$$

where $S_1$ and $S_2$ are the total spins of the two interacting paramagnetic centers and $S_1$ is assumed to be greater than $S_2$ for heterodinuclear complexes.

For all the models, we derive Equation (5) from (4).

$$J = (E_{BS} - E_{HS})/2 \quad (5)$$

There are a lot of discussions as to whether Equation (4) can be used to calculate *J*.[21–27] Adamo and co-workers consider that Equation (4) corresponds strictly to the limit of complete overlap between the magnetic orbitals and such a hypothesis is not sustained,[22,23] although it can give good *J* results compared to experiment.[21,24,25] Ruiz and co-workers[26,27] think that the spin-projected approach [Equation (2)] introduces a double counting of the static correlation contributions due to the multi-determinant character of the broken symmetry solution obtained with the common functional that includes a self-interaction error. However, the non-projected approach [Equation (4)] can remove the self-interaction correction (SIC)[28] error and give better *J* values. A detailed discussion of the two approaches can be found in the literature.[21–27] In this paper, Equations (2) and (4) are both used to calculate the *J* values. The differences in the calculated *J* values using the two approaches will be discussed below.

Now we interpret the more rigorous second approach. If one neglects spin-orbit coupling effects, the Hamiltonian for a general extended structure is given by Equation (6).

$$\hat{H} = \sum_{i>j}(-2J_{ij}\hat{S}_i\hat{S}_j) \quad (6)$$

where $\hat{S}_i$ and $\hat{S}_j$ are the spin operators of the different paramagnetic centers and the $J_{ij}$ values are the coupling constants between all the paramagnetic centers. Here, we only consider the exchange interactions between nearest neighbors. This fact, together with the presence of additional symmetry elements in the structure, normally results in a reduced set of $J_{ij}$ values.

For complexes **1-La** and **2-Y**, 15 pair-wise coupling constants can in principle be calculated (see Figure 3), but these are reduced by symmetry to yield only three independent coupling constants for a symmetric structure:

$$J = J_{12} = J_{34} = J_{56};\ J' = J_{15} = J_{26} = J_{35} = J_{46} = J_{13} = J_{24};\ J'' = J_{16} = J_{25} = J_{36} = J_{45} = J_{14} = J_{23} \quad (7)$$

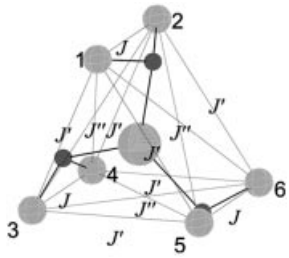

Figure 3. A sketch of the interactions between each $Cu^{II}$ center.

For the systems studied here, we only need to calculate four different spin configurations for each of the models **1-La**, **1-Y**, **2-Y**, and **2-La**, namely **A** ($S = 0$), **B** ($S = 0$), **C** ($S = 1$), and **F** ($S = 3$; see Figure 4). From the calculated relative energies of these spin configurations, we can extract exchange coupling constants by associating them to energy expressions obtained as a sum of pair-wise interactions, as introduced in the Heisenberg Hamiltonian. Given the energy differences between the four spin states, we can evaluate the exchange coupling constants *J*.

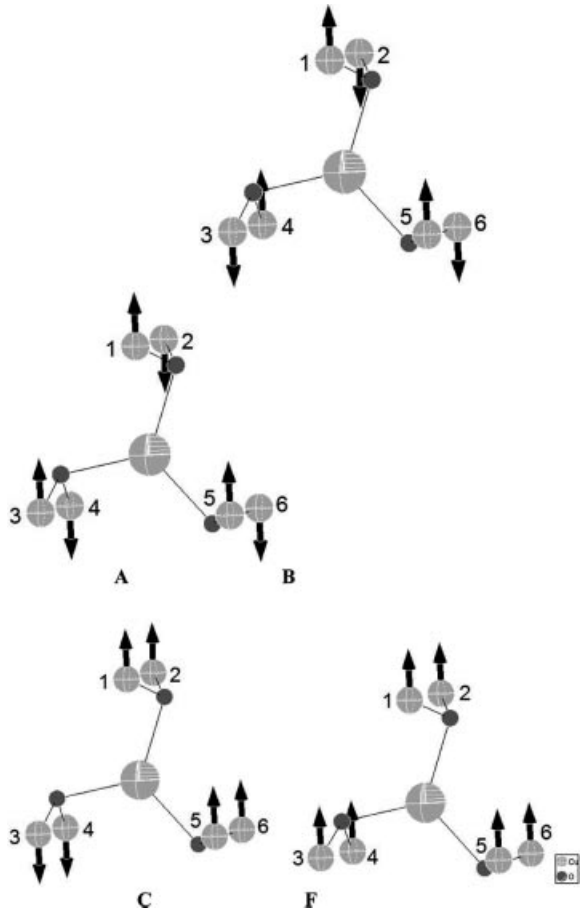

Figure 4. Four spin states: **A** ($S = 0$), **B** ($S = 0$), **C** ($S = 1$), and **F** ($S = 3$) for all the models.

$$E_A - E_F = 6J + 2(J' - J'') \quad (8)$$

$$E_A - E_B = 8(J' - J'') \quad (9)$$

$$J = \frac{(E_A - E_F)}{6} - \frac{(E_A - E_B)}{24} \quad (10)$$

Although the $J'$ and $J''$ values are very small and have no corresponding experimental equivalents, we also calculated these values using the second approach. The equations to extract $J'$ and $J''$ are:

$$J' = \frac{(E_C - E_F)}{4} + \frac{(E_A - E_B)}{16} \quad (11)$$

$$J'' = \frac{(E_C - E_F)}{4} - \frac{(E_A - E_B)}{16} \quad (12)$$

Density functional calculations were performed using the Amsterdam Density Functional (ADF, version 2004.01[29–31]) package for the four model clusters. Illas et al.[32] have shown the strong dependence of the calculated *J* with respect to the exchange-correlation functionals chosen, therefore several exchange-correlation functionals were used to evaluate *J*. In the calculations of *J* using ADF, the local density approximation (LDA) made use of the Vosko, Wilk, and Musair[33] (VWN) local correlation functional. A series of generalized gradient approximations (GGAs), namely the Perdew–Wang 1991 (PW91),[34] the Perdew–Burke–Ernzerhof (PBE),[35] and the recently developed OPTX-Perdew (OP86)[36,37] and OPTX-Perdew–Burke–Ernzerhof (OPBE)[35–37] functionals were examined. The tau-dependent meta-GGAs such as VSXC[38] and tau-HCTH[39] were also examined. For Cu and Zn, the TZV2P basis set (a basis set of triple-ξ quality[40] with two polarization functions) was applied. For La and Y, the TZV2P basis set (a basis set of triple-ξ quality[40] with one polarization function) was applied. The DZP basis set (a basis set of double-ξ quality[40] supplemented with one polarization function) was used for the other atoms (C, N, O and H). The inner core shells of C (1s), N (1s), O (1s), Cu (1s,2s,2p), Zn (1s,2s,2p), Y (1s,2s,2p,3s,3p,3d), and La (1s,2s,2p,3s,3p,3d,4s,4p,4d) were treated with the frozen core approximation. The accuracy parameter (accint) for the numerical integration grid was set to 4.0 for all complexes. The convergence standard of the system energy was set to be smaller than $10^{-6}$ eV in order to reach the precision required for the evaluation of *J*.

## Results and Discussion

### Evaluation of *J* for Each Model

The calculated and experimental values are shown in Table 1. The *J* values calculated using the first approach with Equation (2) for all the models show larger differences

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with respect to the experimental values. However, there is a good improvement in the calculated ones obtained using Equation (4). The reason for this has been mentioned above. However, we obtain the same qualitative description of the magnetostructural correlations from the *J* values calculated using both Equation (2) and Equation (4). For models **1** (**1-La** and **1-Y**), the *J* values calculated using the two approaches with all the functionals are consistent with the experimental values. However, for models **2** (**2-Y** and **2-La**), the calculated *J* values using the first approach (BS-DFT) with all functionals except for the meta-GGA tau-HCTH show a large difference from the experimental values. In the BS-DFT approach we used $Zn^{II}$ to replace the $Cu^{II}$ to calculate the *J* values and did not consider the influence of the other $Cu^{II}$ center. This approximation is acceptable for models **1** because the *J′* and *J″* values are very small compared to *J*. However, the *J′* and *J″* values for models **2** are similar to that of *J* and so the influence of the other $Cu^{II}$ cannot be ignored. The BS-DFT approach therefore gives inaccurate *J* values for models **2**, although the second approach, which considers the influence of all the $Cu^{II}$ centers, gives better ones. The second approach is therefore a more rigorous one for evaluating Cu···Cu interactions irrespective of whether they are strong or weak, as we reported in our previous papers.[41,42]

For **1-La**, the *J* values calculated with the meta-GGA VSXC are the closest to the experimental value[15] (–12.0 $cm^{-1}$). However, the VSXC functional gives poor *J* values for **2-Y**. Although the first approach gives the opposite sign for complex **2-Y**, both approaches with all the functionals show that the antiferromagnetic interactions between the two nearest $Cu^{II}$ centers in complex **1-La** are stronger than those in complex **2-Y**, which is consistent with the experimental results. It can be seen that the calculated *J* values are qualitatively correct (indeed, some are in good agreement with the experimental ones) and empirically scale the *J* with respect to experiments.

In their studies, Liu et al.[14] considered that the strength of the antiferromagnetic interactions between the two nearest $Cu^{II}$ centers for the above two complexes is due to the central ions. They concluded that the stronger antiferromagnetic interactions in complex **1-La** are because its central ion is $La^{III}$, which has a greater ionic radius, and the direct overlap of metal orbitals plays a minor role. Whether the central ions have a dominant effect on the interactions between the two nearest $Cu^{II}$ ions will be discussed in the following section.

## Effects of the Central Ions on the Interactions Between the Two Nearest $Cu^{II}$ Ions

To investigate the effects of the central ions on the interactions between the two nearest $Cu^{II}$ ions, we replaced the $La^{III}$ in complex **1-La** with $Y^{III}$ to obtain the model **1-Y** and also substituted $Y^{III}$ with $La^{III}$ in complex **2-Y** to obtain the model **2-La**. From the calculated *J* values of **1-La** and **1-Y** (Table 1), we can see that substituting $La^{III}$ with $Y^{III}$ enhances the interactions between the two nearest $Cu^{II}$ centers, which is opposite to the conclusion reached by Liu et al.[14] From the calculated *J* values of **2-Y** and **2-La**, we find that replacing $Y^{III}$ with $La^{III}$ weakens the interactions, although the first approach with the GGAs PW91, PBE, OP86, and OPBE gives almost the same *J* values for **2-Y**

Table 1. Experimental *J* and calculated *J*, *J′*, and *J″* values [$cm^{-1}$] for models **1** (**1-La** and **1-Y**) and **2** (**2-La** and **2-Y**) obtained from the two approaches (one is the BS-DFT approach and the other approach is to obtain the $J_{ij}$ by calculating the energies of several pure spin states) with several LDA, GGA, and meta-GGA functionals.

and **2-La**. In conclusion, substituting $La^{III}$ with $Y^{III}$ enhances the antiferromagnetic interactions between the two nearest $Cu^{II}$ centers and these interactions in models **1** (**1-La** and **1-Y**) are always stronger than those in models **2** (**2-Y** and **2-La**), irrespective of whether the central ions are $La^{III}$ or $Y^{III}$. Moreover, we find that the central ions $La^{III}$ and $Y^{III}$ have only a very small influence on the values of $J'$ and $J''$ and can be ignored for models **1** (**1-La** and **1-Y**) and **2** (**2-Y** and **2-La**).

From the above results, we conclude that the antiferromagnetic Cu···Cu interactions increase with a decrease of the ionic radius of the diamagnetic central ion. Irrespective of whether the central ions are $La^{III}$ or $Y^{III}$, the nearest Cu···Cu interactions in models **1** (**1-La** and **1-Y**) are all stronger than those in models **2** (**2-Y** and **2-La**), therefore their structures have a larger influence on the nearest Cu···Cu interactions. In the next section we will investigate the effects of the structural parameters on the nearest Cu···Cu interactions.

### Effects of the Structural Parameters on the Interactions Between the Two Nearest $Cu^{II}$ Ions

The nearest Cu···Cu distance decreases from 3.383 to 3.323 Å, the Ln···Cu distance decreases from 3.509 to 3.447 Å, and the Cu···O···Cu angle decreases from 120.7° to 118.4° on going from complex **1-La** to complex **2-Y**. In a recent paper,[43] Ruiz et al. calculated the value of $J$ between $Cu^{II}$ with several different Cu···O···Cu angles and Cu···Cu distances and concluded that a decrease of the Cu···O···Cu angle weakens the antiferromagnetic Cu···Cu interactions when such angles are larger than about 100° in spite of the antiferromagnetic contributions due to the decrease of the Cu···Cu distance. We can see the same from Table 2, which only gives the results calculated using the PW91 functional, namely that the decrease of the Cu···O···Cu angle weakens the antiferromagnetic Cu···Cu interactions in spite of the decrease of the Cu···Cu distance when the diamagnetic central ions are $La^{III}$. The same results are also obtained using the other functionals. When the central ions are $Y^{III}$, we obtain the same trend. The above results can also be obtained from the book written by Kahn.[44] Therefore, we can see from the calculated and experimental results in Table 1 that the absolute $J$ values in models **1** (**1-La** and **1-Y**) are all larger than those in models **2** (**2-Y** and **2-La**).

From the calculated $J'$ and $J''$ values in Table 2, the weaker Cu···Cu ferromagnetic interactions in **2-La** appear to be due to its shorter Cu···Cu distances, which enhance the antiferromagnetic interactions and therefore decrease $J'$ and $J''$. The same results can also be found for **1-Y** and **2-Y**.

That the differences between the $J$ values calculated for **1-La** and **1-Y** or **2-Y** and **2-La** are small shows that the antiferromagnetic exchange interactions between the two nearest $Cu^{II}$ centers occur mostly through the nearest exchange pathway (Cu···O···Cu) and that the long exchange pathways via $Y^{III}$ or $La^{III}$ could possibly give rise to a weak antiferromagnetic component similar to the results reported in ref.[45]

Table 2. Dependence of $J_{ij}$ values between each two $Cu^{II}$ on $d$(Cu···Cu) and Cu···O···Cu for complexes **1-La** and **2-Y** using the second approach (this approach gives $J_{ij}$ by calculating the energies of several pure spin states) with the PW91 functional.

| | | $d$(Cu···Cu) [Å] | Cu···O···Cu [°] | $J_{ij}$ [$cm^{-1}$] |
|---|---|---|---|---|
| $J$ | **1-La** | 3.383 | 120.7 | –22.5 |
| | **2-La** | 3.323 | 118.3 | –1.0 |
| $J'$ | **1-La** | 5.326 | | 6.1 |
| | **2-La** | 5.230 | | 3.1 |
| $J''$ | **1-La** | 6.310 | | 8.3 |
| | **2-La** | 6.197 | | 1.7 |

### Qualitative Analysis of the Exchange Interaction

According to the Kahn–Briatt[46,47] (KB) and Hay–Thibeault–Hoffmann[48] (HTH) models, see Equations (13) and (14), respectively.

$$(\hat{H} = -2J\hat{S}_1\cdot\hat{S}_2)$$

$$J_{ab} = K_{ab} - S_{ab}(\Delta^2 - \delta^2)^{1/2} \quad (13)$$

$$J_{ab} = K_{ab} - \frac{(\varepsilon_1 - \varepsilon_2)^2}{2(J_{aa} - J_{ab})} \quad (14)$$

Some authors[49,50] have recently shown that magnetic orbitals **a** and **b** are well represented by the localized orbitals of the broken-symmetry solution (called the BS-OMSO[51]). As usual, the changes in the $J_{AF}$ term are more important and these contributions will usually control the magnetostructural correlations, especially those whose intramolecular interactions are antiferromagnetic. Hence, we have only considered the changes in the $J_{AF}$ term. The $J_{AF}$ term is associated with the overlap integral $S_{ab}$ in the broken-symmetry spin solution between the two $e_g$ magnetic orbitals ($d_{x^2-y^2}$) (KB model) or the square of the energy gap $(\varepsilon_1 - \varepsilon_2)^2$ in the high-spin solution between the orbitals bearing the unpaired electrons (HTH model). The $S_{ab}$ and $(\varepsilon_1 - \varepsilon_2)^2$ values calculated using the first approach with the PW91 functional are shown in Table 3, where it can be seen that the values for models **1-La** and **1-Y** are almost the same, but larger than those of models **2-La** and **2-Y**. The above results show that the different diamagnetic central ions essentially do not influence the overlap integrals $S_{ab}$ and the $(\varepsilon_1 - \varepsilon_2)^2$ values, although the structures of models **1** (**1-La** and **1-Y**) and **2** (**2-La** and **2-Y**) do have an influence on them. On going from the structures of models **1** to those of **2**, the Cu···O···Cu angles decrease from 120.7° to 118.4°. According to Kahn's investigations,[44] a decrease of the Cu···O···Cu angle will bring the magnetic orbitals closer to orthogonality and so the $S_{ab}$ values for models **1** are larger than those for **2**. The stronger antiferromagnetic interactions in models **1** corresponding to the larger $S_{ab}$ values show that the direct overlap between $Cu^{II}$ orbitals also plays a major role.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 3. Calculated $S_{ab}$ (a and b denote the magnetic orbitals occupied by the unpaired electrons on two $Cu^{II}$ centers in the broken-symmetry spin solutions), $(\varepsilon_1 - \varepsilon_2)^2$ ($eV^2$) ($\varepsilon_1$ and $\varepsilon_2$ denote the energies of the orbitals bearing the unpaired electrons in the high-spin solutions), and $-(\rho^2_{HS} - \rho^2_{BS})$ values for models **1** (**1-La** and **1-Y**) and **2** (**2-La** and **2-Y**) obtained using the first approach (BS-DFT) with the PW91 functional.

| | 1-La | 1-Y | 2-Y | 2-La |
|---|---|---|---|---|
| $S_{ab}$ | 0.021 | 0.023 | 0.008 | 0.008 |
| $(\varepsilon_1 - \varepsilon_2)^2$ [$eV^2$] | 0.6464 | 0.6544 | 0.1764 | 0.1789 |
| $\rho^2_{HS} - \rho^2_{BS}$ | 0.0092 | 0.0089 | 0.0027 | 0.0028 |

Blanchet-Boiteux and Mouesca[50,52] have proposed that the antiferromagnetic part of the exchange coupling constant in di-μ-oxo-bridged binuclear $Cu^{II}$ complexes can be split into two terms, one associated with the metal d orbitals, which is always positive, and the other representing the contribution of the bridging ligand. The second term can be related to the copper spin population through the analytical expression given in Equation (15), derived from a Mulliken population analysis.[53]

$$J \propto -(\rho^2_{HS} - \rho^2_{BS}) \quad (15)$$

Bi et al.[54] have found that the $J$ values are almost linearly related to $-(\rho^2_{HS} - \rho^2_{BS})$ for a series of oxamidocopper complexes. We have also used Equation (15) to evaluate binuclear $Mo^{III}$ complexes and also found that the $J$ values are almost linearly related to $-(\rho^2_{HS} - \rho^2_{BS})$.[55] The spin populations were obtained by PW91 calculations on the basis of a Mulliken population analysis[53] using the first approach. Due to the symmetry of the structures, we only give the results for one of the $Cu^{II}$ ions (Table 3). The stronger antiferromagnetic interactions in models **1** (**1-La** and **1-Y**), which correspond to larger $(\rho^2_{HS} - \rho^2_{BS})$ values, show that Equation (15) is also valid for the systems studied here, although it cannot differentiate the relative strengths of **1-La** and **1-Y** or **2-La** and **2-Y**.

## Conclusions

From the above calculations, we conclude that the strength of the nearest Cu···Cu antiferromagnetic interactions increase with a decrease of the ionic radius of the diamagnetic central ion. However, this influence of the central ion on the exchange coupling interactions is small compared to the influence of the variation of the Cu···O···Cu angle. The weaker Cu···Cu antiferromagnetic interactions in models **2** (**2-La** and **2-Y**) compared to those in models **1** (**1-La** and **1-Y**) are because of the smaller Cu···O···Cu angles corresponding to the smaller $S_{ab}$ and $(\varepsilon_1 - \varepsilon_2)^2$ values in models **2**. KB and HTH models have been used to demonstrate that the antiferromagnetic contributions of the direct overlap between the two nearest $Cu^{II}$ centers also plays a major role and that the influence of the diamagnetic central ion on the direct overlap can be ignored.

# Keggin POMs Modified by Bonding to Multitrack Cu(bipy) Chains through Linearly Arrayed Terminal and Bridging Oxygen Atoms of the $M_3O_{13}$ Triad

**Jingquan Sha,[a,b] Jun Peng,*[a] Hongsheng Liu,[a] Jing Chen,[a] Baoxia Dong,[a] Aixiang Tian,[a] and Zhongmin Su[a]**

**Keywords:** Polyoxometalates / N ligands / Copper / Organic–inorganic hybrids

Two novel complexes based on the Keggin POMs modified by the Cu(4,4′-bipy) moiety, $\{[Cu(4,4'\text{-bipy})]_3[HSiMo_{12}O_{40}]\}\cdot 1.5H_2O$ (**1**) and $\{[Cu(4,4'\text{-bipy})]_4[SiW_{12}O_{40}]\}\cdot 3H_2O$ (**2**) (bipy = bipyridine), have been hydrothermally synthesized and characterized by routine physical methods and single-crystal X-ray diffraction. Complexes **1** and **2** represent the first examples of fully oxidized Keggin POM anions as pendant polydentate ligands covalently bonded to a multitrack Cu(bipy) polymer chain(s) through linearly arrayed $O_d\cdots O_c\cdots O_d$ ($O_d$, terminal oxygen; $O_c$, bridging oxygen) atoms of single $M_3O_{13}$ triad(s). In the crystalline lattice of **1**, the 1D chain is constructed from a α-$[SiMo_{12}O_{40}]^{4-}$ ($SiMo_{12}$) cluster as a pendant tridentate ligand covalently bonded to three $Cu^I$(4,4′-bipy) subunits, and the neighbouring polymer strands interconnect with the Keggin fragments geared like the teeth of a zipper. In compound **2**, the 2D extended layer structure is composed of a α-$[SiW_{12}O_{40}]^{4-}$ ($SiW_{12}$) cluster as a pendant hexadentate ligand covalently bonded to four $Cu^I$(4,4′-bipy) subunits and forms a 2D net-texture structure with a large vacancy ($30.9\times 10.6$ Å), and the 2D layers are arranged in a parallel staggering fashion to form a 3D framework.

## Introduction

Polyoxometalates (POMs) composed of early transition metals (V, Nb, Ta, Mo, W) have been investigated for over a century because of their intriguing structural chemistry, unexpected reactivities, and potential applications.[1] Among a wide variety of POMs, the Keggin species $[XM_{12}O_{40}]^{n-}$ (X = B, P, Si, etc.; M = Mo and W) are one of the most important research topics, especially the modified Keggin derivatives. This reflects a current interest for the following reasons: the Keggin species are viewed as soluble metal oxide analogues and can therefore be used for the modeling of catalytic reactions taking place at metal oxide surfaces; they are valuable building blocks for tailor-made inorganic and organic or metal–organic hybrid materials with attractive structures and properties.[2] The increasing attention is currently devoted to their organometallic derivatives, and their multigraft modification could prove interesting in the context of the development of multidimensional framework structures.[3] Recently, a number of Keggin POMs covalently modified by transition-metal complexes have been reported, such as the mixed-valent compounds $[\{Cu_4(terpy)_4(PO_4)(H_2O)_2\}\{W^{VI}_{10}W^{V}_{2}O_{36}(PO_4)\}]\cdot 5H_2O$ described by Zubieta et al.,[4] $[PW_{12}O_{40}\cdot Ni(2,2\text{-bipy})_2(H_2O)]^{3-}$ by Xu et al.,[5] and $(NH_4)[Cu_{24}I_{10}L_{12}][PMo^{V}_{2}Mo^{VI}_{10}O_{40}]_3$ by Wang et al.;[6] the controlled assembly from lacunary Keggin POMs has also been reported by Pope et al.[7] and Gutiérrez-Zorrilla et al.[8] All these compounds featured sufficient charge density on the Keggin anion surface atoms to coordinate the transition-metal complexes. It is believed that surface activation is achieved by reducing the metal centres or by replacing metal centre(s) with a high oxidation state by other lower-valence metal(s). However, there are only a few examples of fully oxidized Keggin POMs modified by transition-metal complexes. These examples include the unsymmetrical discrete complex $[\{Cu_2(O_2CMe)_2(5,5\text{-dimethyl-2,2-bipy})_2\}\{Cu(5,5'\text{-dimethyl-2,2'-bipy})_2\}SiW_{12}O_{40}]$,[9] the 1D framework $[Ag_3(2,4'\text{-bipy})_3PMo_{12}O_{40}]$,[10] the 3D framework complexes $[Cu_3(pz)_3(PW_{12}O_{40})]$,[11] $[Ag_3(pz)_3(PW_{12}O_{40})]$,[11] $[Ag(4,4\text{-bipy})](OH)[\{Ag(4,4\text{-bipy})\}_2\{PAgW_{12}O_{40}\}]$,[12] and $KH_2[(D\text{-}C_5H_8NO_2)_4(H_2O)Cu_3][BW_{12}O_{40}]$.[13] In the last framework, chirality was designed into the helical motif. The coordination fashions of the Keggin POMs as polydentate ligands in these complexes are graphically summarized in Scheme 1: Keggin POMs provide only a terminal oxygen atom (see Scheme 1a, e and f) or both terminal and bridging oxygen atoms (see Scheme 1b–d).

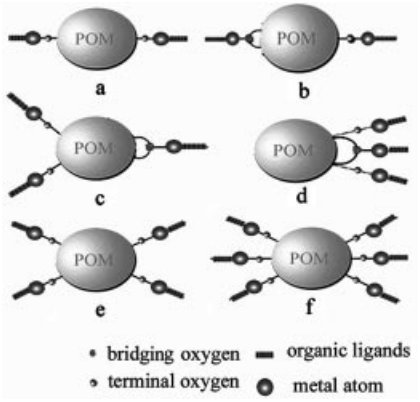

Scheme 1. Schematic representation of the coordination fashions of Keggin POMs as polydentate ligands.

It is noteworthy that most of these coordination fashions are prone to barycentre distribution of their oxo ligands, presumably because of steric crowding, with the exception of that shown in Scheme 1d, in which all the oxo ligands belong to a single $M_3O_{13}$ triad. To the best of our knowledge, the title compounds are unique examples with the coordination fashion represented in Scheme 1d. The ligand 4,4′-bipy is a rod-like molecule and is commonly used as a rigid ligand. The $d^{10}$ ions, the soft Lewis acid metal ions, generally show variable coordination numbers and tunable coordination spheres. Especially, Cu–bipy complex units have been widely used in magnetic and catalytic materials,[14] and some POM-based Cu–bipy polymers with interesting structures have been reported quite recently.[15] Hydrothermal synthesis represents a fast and excellent method to afford new POM structures. Although the hydrothermal synthesis employing the usual mixture of polyoxometalate, transition-metal salt, and nitrogen-containing ligand has been intensively extended, there is still abundant scope for the construction of intricate structures for new materials. The challenge is really to demonstrate control and expendability, to optimise the physical properties, etc. In this paper, we select the ligand 4,4′-bipy and the Cu ion to build metal–organic complex subunits in the hope of forming an extended structure of Keggin POMs modified by transition-metal complex moieties with little steric crowding, and we report the hydrothermal syntheses and crystal structures of two novel Cu(4,4′-bipy) modified Keggin derivatives, $[\{Cu(4,4'\text{-bipy})\}_3\{\alpha\text{-}HSiMo_{12}O_{40}\}]\cdot 1.5H_2O$ (**1**) and $[\{Cu(4,4'\text{-bipy})\}_4\{\alpha\text{-}SiW_{12}O_{40}\}]\cdot 3H_2O$ (**2**). They are the first examples of fully oxidized Keggin POM anions as pendant polydentate ligands covalently bonded to colinear multitrack Cu(bipy) chain(s) through $O_d\cdots O_c\cdots O_d$ atoms of $M_3O_{13}$ triad(s).

## Results and Discussion

The isolation of compounds **1** and **2** depends on the use of hydrothermal techniques. Hydrothermal reactions in the presence of organic ligand molecules have been established as a versatile method for the isolation of new materials with diverse structural architectures. Therefore, the introduction of hydrothermal techniques and the direct use of saturated Keggin POM as building blocks may produce a large number of novel organic–inorganic hybrid materials. By many parallel experiments, we found that the choice of starting materials is vital for the success of these reactions among other factors such as stoichiometry, temperature, pH and fill volume.[10,11] Transition-metal ions can greatly influence the structural formation of materials. We found that when $Cu(NO_3)_2\cdot 3H_2O$ was replaced by $Zn(NO_3)_2\cdot 6H_2O$, $NiCl_2\cdot 6H_2O$ or $MnCl_2\cdot 4H_2O$ in parallel experiments, we could not obtain the expected homologies but rather POM–4,4′-bipy supramolecular compounds. The oxidation states of the copper atoms in **1** and **2** are assigned as +1 on the basis of charge neutrality, coordination environments, valence sum calculations and XPS. A similar case of $Cu^{II}\rightarrow Cu^{I}$ was also observed in other polyoxometalates bridged by organonitrogen ligands coordinated to copper ions.[16] Additionally, the organic reductant species was also crucial for maintaining the intact skeleton of presynthesized saturated Keggin POMs. If the reducibility of the organic reductant were high, the skeleton of the saturated Keggin cluster may be inclined to decompose and reassemble into a new cluster.[17] We found that triethylamine was a good candidate.

### Structural Description of 1

Single-crystal X-ray diffraction analysis reveals that **1** consists of one $[SiMo_{12}O_{40}]^{4-}$ anion, three $[Cu(4,4'\text{-bipy})]^{+}$ moieties and one and a half water molecules (Figure 1). The heteropolyanion $[SiMo_{12}O_{40}]^{4-}$ possesses the classical α-Keggin-type structure without disorder.[18] The tetrahedrally coordinated Si is surrounded by four oxygen atoms with Si–O bonds ranging from 1.624(7) to 1.631(8) Å (mean 1.627 Å). All Mo atoms have $\{MoO_6\}$ octahedral environments. The distances of Mo–O bonds are divided into three groups: Mo–$O_a$ (centre oxygen atom), 2.316(7)–2.386(8) Å; Mo–$O_{b/c}$ (bridging oxygen atom), 1.821(8)–2.015(8) Å; Mo–$O_d$ (terminal oxygen atom), 1.660(9)–1.714(8) Å.

Each $\alpha\text{-}SiMo_{12}O_{40}$ cluster as a tridentate pendant ligand covalently bonds to three $Cu^{I}(4,4'\text{-bipy})$ complexes through

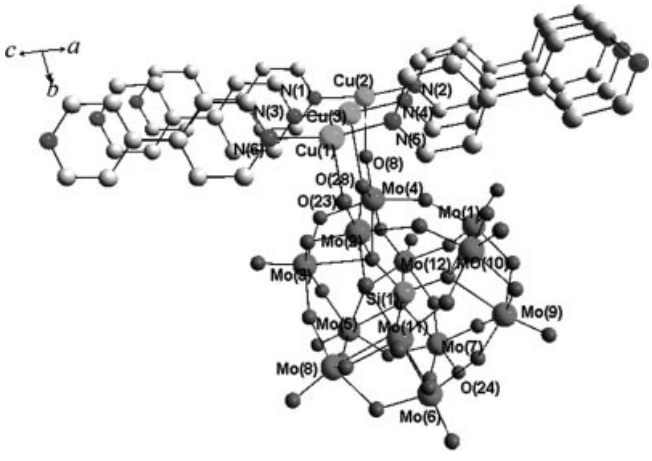

Figure 1. Representation of the molecular structure unit of **1**. The hydrogen atoms and crystal water molecules are omitted for clarity.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

linearly arrayed O23, O28 and O8 atoms of the $Mo_3O_{13}$ triad (Mo2, Mo3 and Mo4). The bond lengths around the three $Cu^I$ ions are 2.298(8) Å (Cu1–O23), 2.383(8) Å (Cu2–O8), 2.493(8) Å (Cu3–O28), 1.888–1.898 Å (Cu1–N), 1.905–1.915 Å (Cu2–N) and 1.897–1.902 Å (Cu3–N), while the N–Cu–N angles are in the range 165.4–170.2° and the N–Cu–O angles are in the range 93.9–100.3°. There are three crystallographically independent $Cu^I$ atoms, and each $Cu^I$ atom adopts a "T-type" coordination geometry established by two nitrogen atoms of two 4,4′-bipy ligands and one oxygen atom of the $[SiMo_{12}O_{40}]^{4-}$ anion, which is similar to the coordination mode of $\{Cu_3(4,4'\text{-bpy})_3(H_2O)\}[PMo_{12}O_{40}(VO)_2]\cdot 5H_2O$.[19] In this way, each 4,4′-bipy ligand links two symmetrical $Cu^I$ atoms into a one-dimensional $Cu^I$(4,4′-bipy) complex chain. Because each α-$SiMo_{12}O_{40}$ cluster bonds to three parallel $Cu^I$(4,4′-bipy) subunits, the Keggin clusters become pendants of tri-track Cu(bipy) chains, projecting towards two sides (Figure 2).

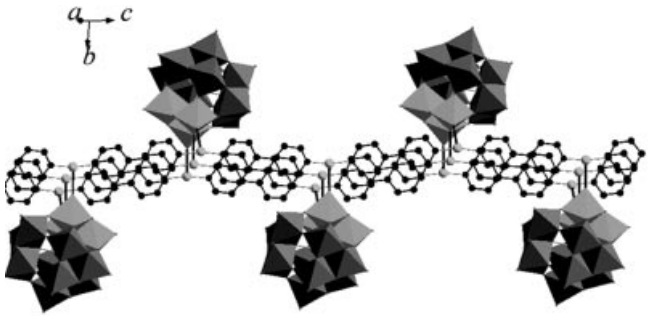

Figure 2. Combined polyhedral/wire representation of the 1D chain structure in **1**. The dark grey polyhedra represent the molybdenum polyhedra and the light grey polyhedra the $Mo_3O_{13}$ triad bound to Cu(bipy).

The tri-track chains with POM pendants are positioned relative to each other so that the POM clusters from different chains are alternatively arranged; each POM cluster joins other neighbouring clusters through hydrogen-bonding interactions. The shortest $O_d$(Mo9–O18)···$O_c$(Mo1–O16–Mo11) distance is 2.907 Å, and the distance between Cu2 and $O_d$ (O24) of the α-$SiMo_{12}O_{40}$ cluster of the neighbouring chain is 2.873 Å (Figure 3a), which is in the van der Waals interaction range. In this way, an interesting 2D structure is established in the manner of a "zipper" (Figure 3b).

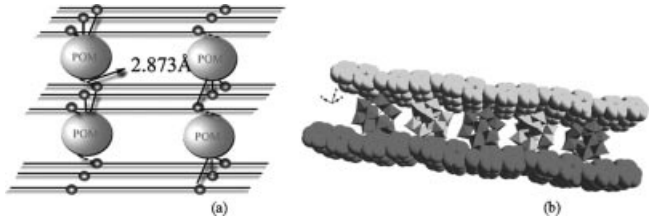

Figure 3. (a) Schematic view of part of the 2D structure in **1** with a dotted line representing the shortest distances between two adjacent chains (Cu2–O24); (b) Combined polyhedral/space filling representation of the "zipper" fashion in compound **1**. Selected bond lengths and angles for **1** are presented in Table S1.

**Structural Description of 2**

In the cell unit of complex **2**, there are four $Cu^I$ ions, four 4,4′-bipy ligands and one Keggin anion $[SiW_{12}O_{40}]^{4-}$ (Figure S1). The fully oxidized Keggin structure of $[SiW_{12}O_{40}]^{4-}$ contains four $W_3O_{13}$ units and one ordered $[SiO_4]^{4-}$ in the centre; the Si–O bonds range from 1.594(13) to 1.627(9) Å (mean 1.611 Å). The lengths of the W–O bonds can be divided into three groups: W–$O_a$ 2.320(12)–2.387(9) Å, W–$O_{b/c}$ 1.873(8)–1.908(12) Å and W–$O_d$ 1.691(12)–1.698(17) Å. Notably, the coordination fashion of the $Cu^I$(4,4′-bipy) chains to the Keggin cluster is very similar to that in complex **1** – they connect the Keggin cluster through the linearly arranged $O_d$···$O_c$···$O_d$ atoms of the $M_3O_{13}$ (W1, W2 and W6) triads. As shown in Figure 4a, there are three sets of linearly arranged $O_d$···$O_c$···$O_d$ atoms at the equatorial position that can be used as coordination atoms. We can see that the significant difference between the two compounds is that in **1** only one set of $O_d$···$O_c$···$O_d$ atoms is used (Figure 4b), while two sets of $O_d$···$O_c$···$O_d$ atoms are used in **2**. For **2**, this means that the Keggin cluster covalently bonds to four $Cu^I$(4,4′-bipy) moieties through six bridging and terminal oxygen atoms of two adjacent $W_3O_{13}$ triads at the equatorial position, which results in a rare hexadentate coordination mode in the Keggin-based coordination polymer (Figure 4c).

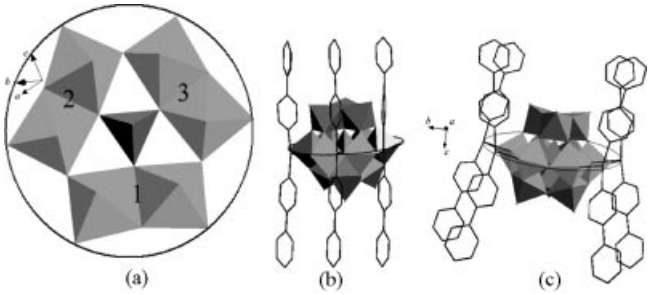

Figure 4. (a) The top view of the MO octahedra at the equatorial position; (b) Combined polyhedral/wire representation of the connection of Cu(bipy) with $SiM_{12}$ through one set of $O_d$···$O_c$···$O_d$ atoms in **1**, and (c) through two sets of $O_d$···$O_c$···$O_d$ atoms in **2**. Molybdenum octahedra of the $M_3O_{13}$ triad bound to Cu(bipy) are in light grey.

Crystal-structure analysis reveals that there are two independent $Cu^I$ centres in **2**, in which one copper centre (Cu1) is tricoordinated by two nitrogen atoms of two 4,4′-bipy ligands and one terminal oxygen atom of the $[SiW_{12}O_{40}]^{4-}$ anion, and the other (Cu2) is tetracoordinated by two nitrogen atoms of two 4,4′-bipy ligands and two oxygen atoms (terminal and bridging oxygen) of the $[SiW_{12}O_{40}]^{4-}$ anion. The bond lengths around the $Cu^I$ ions are 2.190 Å (Cu1–O11), 2.469(8) Å (Cu2–O10), 2.716(12) Å (Cu2–O3), 1.915–1.943 Å (Cu1–N) and 1.894–1.917 Å (Cu2–N), and the N–Cu–N bond angles are in the range 157.0–169.5° and the N–Cu–O angles in the range 97.2–105.3°. It is interesting that Cu1 and Cu2 are arrayed alternately in the 1D $Cu^I$ chain. In this way, each 4,4′-bpy ligand links two asymmetrical $Cu^I$ atoms into a one-dimensional $Cu^I$(4,4′-bipy) complex chain along the *c* axis direction. In contrast to compound **1**, each pair of adjacent α-$SiW_{12}O_{40}$ clusters covalently bonds to four

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Cu^{I}$ chains from opposite directions to form pendants of tetra-track Cu(bipy) chains. The two adjacent POM clusters (including the bonded Cu) present an inversed relation. Owing to POM groups linked to the $Cu^{I}$ chain with two opposite directions on the *b* axis and the inversed subunits alternately arrayed on the two sides of each pair of chains in the direction of the *c* axis, a 2D layer is extended in the [010] plane. In the 2D layer, the POM clusters and metal–organic complex chains are alternatively arranged to form a net texture with large vacancies (about $30.9 \times 10.6$ Å) (Figure 5a). The 2D layers are then stacked in a parallel staggering fashion and linked through supramolecular interactions, which lead to a 3D network frame, as shown in Figure 5b. Selected bond lengths and angles for **2** are presented in Table S2.

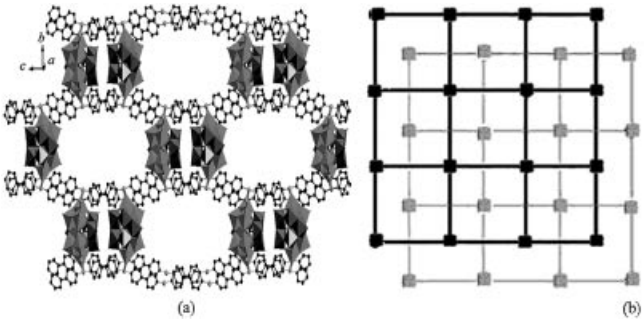

Figure 5. (a) Combined polyhedral/ball-and-stick representation of 2D layer structure in **2**. The dark grey polyhedra represent the tungsten polyhedra and the light grey polyhedra the $W_3O_{13}$ triad bound to Cu(bipy); (b) Schematic representation of the 3D network frame in **2**.

It is noteworthy that the $Cu^{I}$ ions show variable coordination numbers and present a nearly linear coordination with the nitrogen atoms in the bipyridine cationic chains, so they can easily accommodate one or two surface oxygen atoms of the POM to give a 2(N) + 1(O) T-type geometry (Cu1, Cu2 and Cu3 for **1**, and Cu1 for **2**), or a 2(N) + 2(O) distorted square-planar geometry (Cu2 for compound **2**), as shown in Figure 6. The O23, O28 and O8 atoms are coordinated to Cu1, Cu3 and Cu2 in **1** (Figure 6a) and the O11, and O10 and O3 atoms are coordinated to Cu1 and Cu2 in **2** (Figure 6b), respectively. The far distance between adjacent Cu atoms (Cu···Cu) make it possible that a Keggin POM is modified by bonding to co-parallel multichains of Cu(bipy) polymers through linearly arrayed $O_d$···$O_c$···$O_d$ atoms of the $M_3O_{13}$ triad(s). Such an unusual coordination mode has not hitherto been found in POM chemistry.

Also noteworthy are the differences in the dimension and in the number of co-parallel multichains of Cu(bipy) polymers in the two compounds, namely a tri-chain 1D structure for **1** and a di-chain 2D structure for **2**. This is perhaps due to the effect of the different volumes of the Keggin POMs. The volume of the $SiMo_{12}$ cluster is smaller than that of the $SiW_{12}$ cluster, and in compound **1**, the unit length of a Cu(bipy) chain can just accommodate a $SiMo_{12}$ cluster, which results in an array of $SiMo_{12}$ clusters side by side. Whereas, in compound **2**, the bigger $SiW_{12}$ clusters adopt an inversed face-to-face array, alternately arranged in pairs to form a 2D

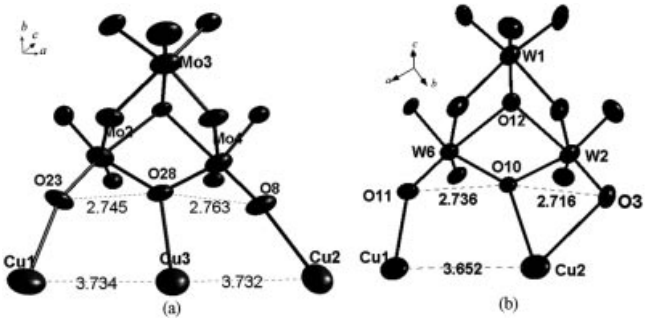

Figure 6. The view of the triad bound to multi-Cu(4,4′-bipy) with the Cu···**Cu** and $O_d$···$O_b$···$O_d$ distances [Å] for (a) **1** and (b) **2**.

net structure with large vacancies (about $30.9 \times 10.6$ Å). The micropores are occupied by water molecules, and the solvent-accessible volume of the unit cell is estimated to be 1451.1 $Å^3$ (PLATON program[20]), which is approximately 18.5% of the unit-cell volume (7844.0 $Å^3$). The contribution of the remaining solvent-accessible voids to the unit-cell volume after the guest water molecules are taken into account is 12.9% (1010.1 per unit cell). All these parameters are greater than those of **1**, in which the solvent-accessible volume of the unit cell is 224.0 $Å^3$, which is approximately 7.30% of the unit-cell volume (3068.1 $Å^3$), and the contribution of the remaining solvent-accessible voids to the unit-cell volume after the guest water molecules are taken into account is 3.7% (114.4 per unit cell).

### FTIR, XPS Spectra and TG Analyses

The IR spectra (Figure S2) exhibit prominent characteristic peaks for the α-Keggin structure at 947, 898 and 785 $cm^{-1}$ for compound **1**, and 956, 906 and 786 $cm^{-1}$ for compound **2**, which can be attributed to the $\nu_{as}$(M–$O_d$), $\nu_{as}$(Si–O) and $\nu_{as}$(M–$O_c$–M) bands (M = Mo, W), respectively.[21] The peaks in the 1410–1610 $cm^{-1}$ range are characteristic of the 4,4′-bipy ligands.

The bond valence sum calculations (BVS)[22] indicate that all the molybdenum and tungsten atoms are in the highest oxidation state (+6), while all the copper atoms are in the +1 oxidation state. Direct evidence for this is also provided by XPS measurements. The XPS spectra for both **1** and **2** (Figure S3) exhibit two peaks at 933.6 and 953.5 eV attributed to $Cu^{+}(2p_{3/2})$ and $Cu^{+}(2p_{5/2})$, respectively.[23] Two peaks at 232.1 and 235.7 eV can be attributed to $Mo^{+6}(3d_{5/2})$ and $Mo^{+6}$-$(3d_{3/2})$, respectively, for compound **1**, and a peak at 35.8 eV to $W^{+6}$ for compound **2**.[24] Hence, addition of a proton is necessary to balance the charge of **1** in the molecular formula. Calculation of the bond strength sums was used to predict the hydrogen atom positions. Possible protonation sites are the unshared oxygen atoms ($O_d$) or corner- and edge-sharing oxygen atoms ($O_{b/c}$). The calculated bond strength sums indicate that the basicity of $O_{b/c}$ is stronger than that of $O_d$. We therefore deduce that the corner- and edge-sharing oxygen atoms ($O_{b/c}$) are protonated.

Thermogravimetric analysis (TGA) also supports the chemical composition. The TGA curves show two steps of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

weight loss for compounds **1** and **2** (Figure S4). In compound **1**, the initial weight loss of 1.40% (calcd. 1.08%) from 43 °C to 236 °C corresponds to the removal of lattice water molecules, and the second weight loss of 18.1% (calcd. 18.61%) in the range 236–461 °C is ascribed to decomposition of the 4,4′-bipy ligands. The whole weight loss (19.5%) is in good agreement with the calculated value (19.73%). For compound **2**, the first weight loss of 1.60% (calcd. 1.42%) from 50 °C to 290 °C is also assigned to the removal of lattice water molecules, and the second weight loss of 15.9% (calcd. 16.4%) in the range 290–760 °C is also ascribed to decomposition of the 4,4′-bipy ligands.

### Cyclic Voltammetry

To study the redox properties of compounds **1** and **2**, we used them as modifiers to fabricate chemically modified carbon paste electrode (CPE), owing to their insolubility in water and most organic solvents. As the intact Keggin skeletons in compounds **1** and **2** are still maintained, the electrochemical properties of **1** and **2** are expected to be similar to those of the parent compounds α-$H_4[SiM_{12}O_{40}]\cdot xH_2O$ (M = Mo or W).

The cyclic voltammogram of **1**-CPE was measured in 0.1 M $Na_2SO_4$ + 0.5 M $H_2SO_4$ aqueous solution in the potential range from +800 to –150 mV. There are three pairs of reversible redox peaks at +326, +217 and +8 mV [$E_{1/2} = (E_{pc} + E_{pa})/2$] (Figure 7), which correspond to three consecutive two-electron processes for Mo.[25] The values for the peak-to-peak separation between the corresponding anodic and cathodic peaks ($\Delta E_p$) are 29 (I–I′), 38 (II–II′) and 40 mV (III–III′). These values deviate from zero, the value expected for a reversible surface redox process, perhaps because of non-ideal behaviour. It is noteworthy that the expected redox peak in the range 100–200 mV attributed to $Cu^{II}/Cu^{I}$ was not observed, perhaps because of the overlap of the $Mo^{VI}/Mo^{V}$ redox peak.

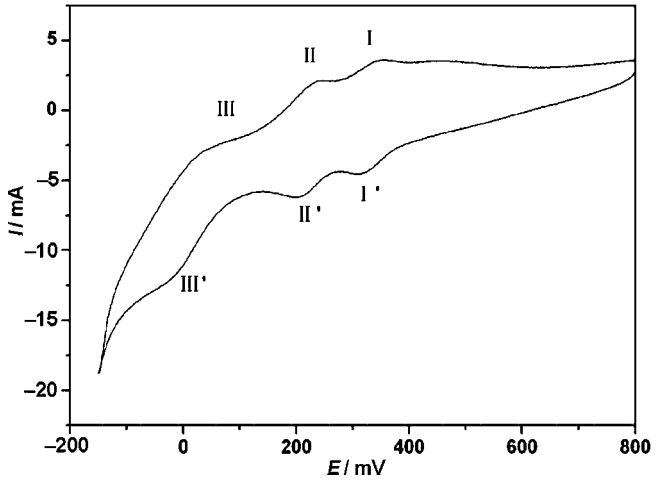

Figure 7. Cyclic voltammogram of **1**-CPE in 0.1 M $Na_2SO_4$ + 0.5 M $H_2SO_4$ aqueous solution at a scan rate of 100 mV/s.

Cyclic voltammetry on **2**-CPE was carried out in 0.1 M $Na_2SO_4$ + 0.5 M $H_2SO_4$ aqueous solution in the potential range from –700 to +300 mV. There are two pairs of reversible redox peaks at $E_{1/2}$ = –585 and –429 mV, and one irreversible peak at +131 mV (Figure 8). The values for the peak-to-peak separations between the corresponding anodic and cathodic peaks ($\Delta E_p$) are 74 (I–I′) and 80 mV (II–II′) which shows a one-electron process. The third irreversible anodic peak is assigned to the oxidation of $Cu^{I}$.

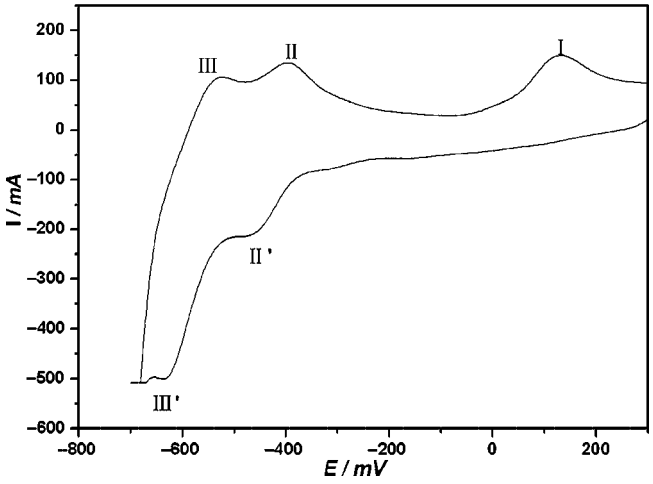

Figure 8. Cyclic voltammogram of **2**-CPE in 0.1 M $Na_2SO_4$ + 0.5 M $H_2SO_4$ aqueous solution at a scan rate of 100 mV/s.

The cyclic voltammetric behaviour of **1**-CPE as a function of scan rate (from 20 to 200 mV/s) was studied. The peak currents are proportional to the scan rates − the increase in the anodic and cathodic peak currents is almost the same, which indicates that the redox process is surface-controlled − and the exchange rate of the electrons becomes faster as the scan rate increases (Figure S5).[25b,26] The peak potentials change gradually: the cathodic peak potentials shift towards the negative direction and the corresponding anodic peak potentials towards the positive direction. The peak-to-peak separation between the corresponding cathodic and anodic peaks increases with the increasing scan rate, but the mean peak potentials do not change on the whole. In the experiment, **1**-CPE showed a higher stability than the conventional POM gel film electrode. The as-prepared electrode was stable over 300 cycle at a scan rate of 100 mV/s, and the current responses remained almost unchanged. The higher stability shows the merit of the robust POM derivatives as electrochemical active materials.

## Conclusions

We have isolated two novel Keggin derivatives by using presynthesized Keggin POMs, soft Lewis acid metal Cu ions and 4,4′-bipy ligands. In **1** and **2**, the fully oxidized Keggin clusters as pendants bond to multi-Cu(4,4′-bipy) metal–organic subunits in a unique coordination fashion: Cu(4,4′-bipy) moieties are parallelly arrayed and covalently linked to the Keggin clusters through linearly arranged $O_d\cdots O_c\cdots O_d$ atoms of single $M_3O_{13}$ triad(s). In this manner, the Keggin cluster is modified by bonding to a tri-track Cu(bipy) chain

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

through a set of linearly arrayed $O_d\cdots O_c\cdots O_d$ atoms of a single $Mo_3O_{13}$ triad in compound **1**, while the Keggin cluster is modified by bonding to di-track Cu(bipy) chains through two sets of linearly arrayed $O_d\cdots O_c\cdots O_d$ atoms of two $W_3O_{13}$ triads in compound **2**. It can be expected that there should be a Keggin POM that can be modified by bonding to multitrack Cu(bipy) chains through three sets of linearly arranged $O_d\cdots O_c\cdots O_d$ atoms from three $M_3O_{13}$ triads. The different volumes of the Keggin POMs may have a significant influence on the dimension and on the number of co-parallel multichains of Cu(bipy) polymers in the two compounds. A tri-chain 1D "zipper" structure is seen for **1** and a di-chain 2D net-texture structure for **2**, which again highlights the effect of POM units on the self-assembly of POM-based metal–organic polymer solid materials. The successful isolation of the two novel compounds shows the possibility of extending the POM family through reasonable modification of the POM clusters by selecting suitable second metals and organic ligands. The structures of these compounds should also be helpful for understanding catalytic reactions taking place at metal oxide surfaces. Design and synthesis of other Keggin POM derivatives with such coordination modes, perhaps with a higher dimension, are currently underway to obtain novel architectures and topologies and to satisfy functional demands for inorganic–organic hybrid materials.

## Experimental Section

**Materials and Methods:** All reagents were purchased commercially and used without further purification. Elemental analyses (C, H and N) were performed on a Perkin–Elmer 2400 CHN Elemental Analyzer, Cu, Mo and W analyses were determined by a Leaman inductively coupled plasma (ICP) spectrometer. The IR spectra were obtained on an Alpha Centaurt FTIR spectrometer in the 400–4000 $cm^{-1}$ region with a KBr pellet. XPS analyses were performed on a VGESCALABMKII spectrometer with a Mg-$K_\alpha$ (1253.6 eV) achromatic X-ray source. The vacuum inside the analysis chamber was maintained at $6.2\times10^{-6}$ Pa during analysis. The TG analyses were performed on a Perkin–Elmer TGA7 instrument under flowing $N_2$ with a heating rate of 10 °C/min. Cyclic voltammograms were obtained with a CHI 660 electrochemical workstation at room temperature. Platinum gauze was used as a counter electrode and Ag/AgCl electrode was used as the reference electrode. Chemically bulk-modified carbon paste electrodes were used as working electrodes.

**Synthesis**

**{[Cu(4,4′-bipy)]$_3$[α-HSiMo$_{12}$O$_{40}$]}·1.5H$_2$O (1):** The starting materials, α-$H_4[SiMo_{12}O_{40}]\cdot XH_2O$,[27] 4,4-bipy, $Cu(NO_3)_2\cdot3H_2O$, triethylamine and distilled water in a molar ratio of about 1:1:2:0.5:555, were mixed. The resulting suspension was stirred for 1 h, and the pH was adjusted to 4.3 by 1 M NaOH. The suspension was then sealed in an 18-mL Teflon-lined reactor and filled to a 60-% volume. After heating the mixture for 6 d at 160 °C, the reactor was slowly cooled to room temperature over a period of 16 h; the final pH was 4.6. Blocklike black-brown crystals of **1** were filtered, washed with water and dried at room temperature. Yield: 32% (80 mg). $C_{30}H_{28}Cu_3Mo_{12}N_6O_{42}Si$ (2507.9): calcd. C 14.36, H 1.12, Cu 7.66, Mo 45.92, N 3.35, ; found C 14.24, H 1.23, Cu 7.79, Mo 45.76, N 3.21.

**{[Cu(4,4′-bipy)]$_4$[SiW$_{12}$O$_{40}$]}·3H$_2$O (2):** Compound **2** was obtained in a manner similar to that illustrated for **1**, but the pH was adjusted to 5.26. Prismlike brown crystals of **2** were collected. Yield: 60% (228 mg). $C_{40}H_{38}Cu_4N_8O_{43}SiW_{12}$ (3807.19): calcd. C 12.61, H 0.99, Cu 6.67, N 2.94, W 58.00; found C 12.32, H 1.03, Cu 6.45, N 2.86, W 57.87.

**X-ray Crystallographic Study:** Crystal data for compounds **1** and **2** were collected on Rigaku RAXIS RAPID IP with Mo-$K_\alpha$ monochromatic radiation ($\lambda$ = 0.71073 Å) at 293 K. The structures were solved by direct methods and refined by full-matrix least-squares on $F^2$ by using the SHELXTL crystallographic software package.[28] All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms on carbon atoms were calculated theoretically. Crystallographic data are given in Table 1. CCDC-611115 (for **1**) and

-620041 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Preparation of 1- and 2-CPE: 1-/2**-modified carbon paste electrode [**1**-/**2**-CPE] was prepared as follows: graphite powder (48 mg) and **1**/**2** (8 mg) were mixed and ground together by an agate mortar and pestle to achieve a uniform mixture, and nujol (0.6 mL) was then added with stirring. The homogenized mixture was packed into a glass tube with a 1.2-mm inner diameter, and the tube surface was wiped with paper. Electrical contact was established with a copper rod through the back of the electrode.

**Supporting Information** (see footnote on the first page of this article): Tables for selected bond lengths and bond angles for compounds **1** and **2**, representation of the molecular structure unit of **2**, and XPS, IR and TG data of complexes **1** and **2**.

# Facile Synthesis of Oligothiophene-Capped CdS Nanoparticles

**Tarek Antoun,[a] Roberta Brayner,[a] Seham Al terary,[a] Fernand Fiévet,[a] Mohamed Chehimi,[a] and Abderrahim Yassar*[a]**

**Keywords:** Nanoparticle synthesis / Oligothiophenes / Photovoltaics / Conjugated polymers / Nanostructures

CdS nanoparticles functionalized by electroactive oligothiophenes, with narrow size distribution, have been prepared and characterized. The structure of the hybrid product was investigated by TEM, XRD, optical and FTIR spectroscopy. The modified nanoparticles consist of a few tens of oligothiophene units attached to the CdS core. The grafting of conjugated oligomers to nanoparticles was made possible by complexing the dangling cadmium ion on the nanoparticle surface.

## Introduction

The design of nanostructured hybrid materials, with novel physical properties, has emerged as one of the most exciting areas of scientific endeavour in this decade, in which material and chemical research are playing a dominant role.[1] Nanocrystals (NCs) have a well-documented array of properties that differ from those of the corresponding bulk materials. Surface modification was shown to optimize the intrinsic optical properties, producing highly luminescent NCs, and also serves as a means of tuning their solubility. On the other hand, π-conjugated oligomers and polymers are a relatively new class of electronic materials that are revolutionizing important technological applications including large-area electronics, owing to their compatibility with low-temperature processing, the simplicity of thin-film device fabrication and the tunability of their electronic properties.[2] The richness of the synthetic organic chemistry allows the fabrication of π-conjugated materials with a degree of control unattainable with conventional inorganic semiconductors. Grafting conjugated polymers and oligomers onto the surface of nanoparticles provides a means of controlling not only the final surface functionality of the material, as one could do also with ligands, but also of introducing new optoelectronic and enhancing charge-transport properties.[3] Such physical properties have motivated many studies on π-conjugated systems and NC composites.

The encapsulation of inorganic nanoparticles by conjugated polymers has its origin in work by Greenham et al. which dates back over one decade.[4] Although much attention has been devoted to the study of the photovoltaic properties of these materials, there have been studies reporting the elaboration and the characterization of well-organized NCs embedded in conjugated polymers, as can be seen from reports of the Lahav group who studied the organization of $(Pb_{1-x}Cd_x)S$ nanoparticles within an oligo(*p*-phenyleneethylene)dicarboxylate matrix.[5] In optoelectronic devices, inorganic semiconductor NCs have been combined with π-conjugated systems in order to take advantage of the ease of processing, characteristic of many π-conjugated polymers, and their complementary properties. The inorganic semiconductor NCs have high electron affinities and the organic semiconductors show high hole mobilities, so charge transfer occurs rapidly in such systems. Photoinduced charge transfer can result in enhancement of the photoconductivity and photovoltaic effects. A major problem which arises in the fabrication of these composites is the immiscibility of the two materials due to differences in their polarities. In composites heavily loaded with NCs, phase segregation occurs even when the NCs are stabilized by hydrophilic ligands.[4]

To overcome this problem and to obtain a three-dimensional interpenetrating network of nanocomposites, many approaches have been used, in which NCs and conjugated polymers are intimately associated. In these approaches the conjugated systems are directly connected to the quantum dot surface. Milliron et al. reported the preparation of novel soluble oligothiophene-CdSe NCs, wherein electronic interaction between functional components was facilitated by attaching the binding group directly to the conjugated backbone.[6] Mutual fluorescence quenching of oligothiophenes and CdSe NCs indicates photoinduced charge transfer, which is essential for their potential utility as an active component in photovoltaic devices. Similarly, Sun et al. have

[a] Interfaces, Traitements, Organisation et Dynamique des Systèmes, CNRS, UMR 7086, Université Diderot (Paris 7), 1 rue Guy de la Brosse, 75005 Paris, France

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

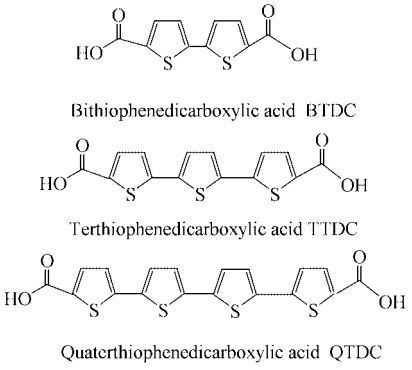
demonstrated that devices fabricated from blends of tetrapod CdSe nanoparticles and a conjugated polymer perform better than devices made from nanorod/polymer blends.[7] The authors believe that the control of the NC shape provides an additional tool to control morphology and facilitate the charge transfer process. Nanocomposites based on $TiO_2$ nanoparticles functionalized by conjugated terthiophenecarboxylic acid have been prepared and characterized by Beek et al.[8] The fluorescence of the terthiophene moiety was completely quenched due to photoinduced electron transfer from terthiophene to titanium dioxide. The quenching is believed to be predominantly static rather than dynamic.

The role of organic surfactants and morphology control have been pointed out by Liu et al.[9] In their work, they showed that an end-functional poly(3-hexylthiophene) (P3HT) enhances the performance of P3HT/CdSe nanocrystal solar cells by increasing the dispersion of CdSe without introducing insulating surfactants. Despite several reports of various NC post-functionalization procedures, much development is still needed to elaborate NC-π-conjugated systems, in which the two components are in intimate contact and electron transfer is not altered by the presence of insulating surfactants. On the basis of a survey of published accounts, CdSe and CdS quantum dots are II–VI semiconductor nanoparticles. There is no distinction that separates the two nanoparticles in terms of desirable properties for applications. CdSe nanoparticles and π-conjugated polymers have to date been the most-studied nanocomposite materials; however, one of the limitations of CdSe nanoparticle synthesis is the use of hazardous and pyrophoric compounds such as dimethylcadmium, $(CH_3)_2CdSe$, TOPO and, especially, the high temperatures (300 °C) that are required. In contrast the synthesis of CdS is safer. These reasons motivated our choice of CdS nanoparticles as models to develop a versatile one-pot method for preparing CdS NC-bound conjugated materials.

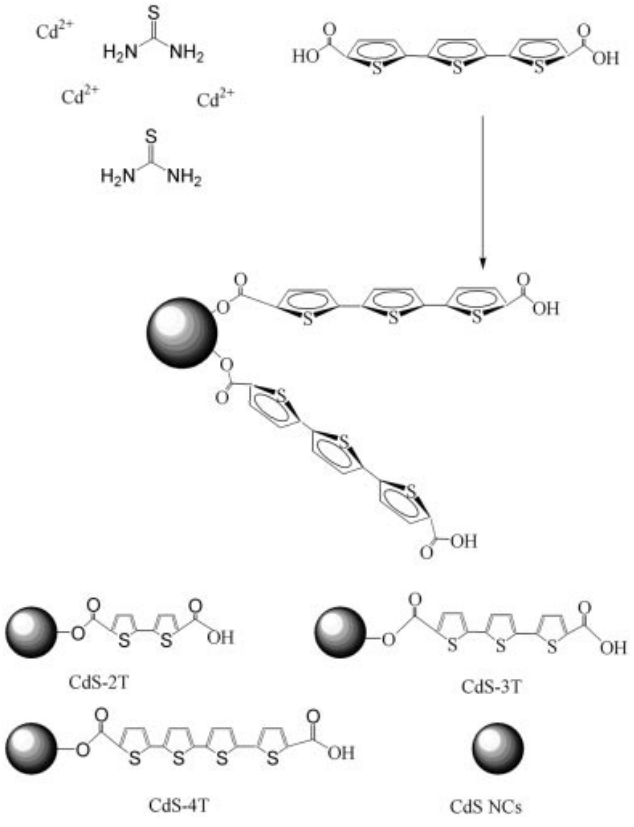
In this work we report a one-pot method for preparing CdS NC-bound oligothiophenes. Transmission electron microscopy (TEM) and X-ray diffraction powder (XRD) show that the CdS nanoparticles are monodisperse. The amount of oligothiophene and the nature of surface binding are studied in detail using X-ray photoelectron spectroscopy (XPS), IR, UV/Vis and fluorescence spectroscopy. The major advantage of this method is that we use functionalized π-conjugated electroactive systems as ligands to control NC growth. The electroactive ligand binds to the NC surface, and allows intimate contact between the NC and the conjugated oligomer backbone leading to better electronic communication between the two components. The bonding of the oligomers to the NC surface was made possible by complexing the dangling cadmium ion on the NC surface by the lone-pair electrons of the carboxylate group in the oligomer. We have also found the carboxylate function to be a versatile and stable ligating group that can be easily attached to II–VI semiconductor nanoparticle surfaces.

## Results and Discussion

Scheme 1 depicts the chemical structures of the α,ω-oligothiophene dicarboxylic acids used in this study. 2,2′-Bithiophene-5,5′-dicarboxylic acid (**I**), 2,2′;5′,2′′-terthiophene-5,5′′-dicarboxylic acid (**II**), and 2,2′;5′,2′′;5′′,2′′′-quaterthiophene-5,5′′′-dicarboxylic acid (**III**) were prepared as described in detail elsewhere.[10] CdS NCs capped with **I**, **II** and **III** (**CdS-2T**, **CdS-3T**, **CdS-4T**, respectively) were then prepared in ethylene glycol (EG) according to the polyol process;[11] see Scheme 2.



Scheme 1. Oligothiophenes used for the functionalization of CdS nanocrystals.



Scheme 2. Schematic representation of the preparation of CdS–oligothiophene by a one-pot procedure.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

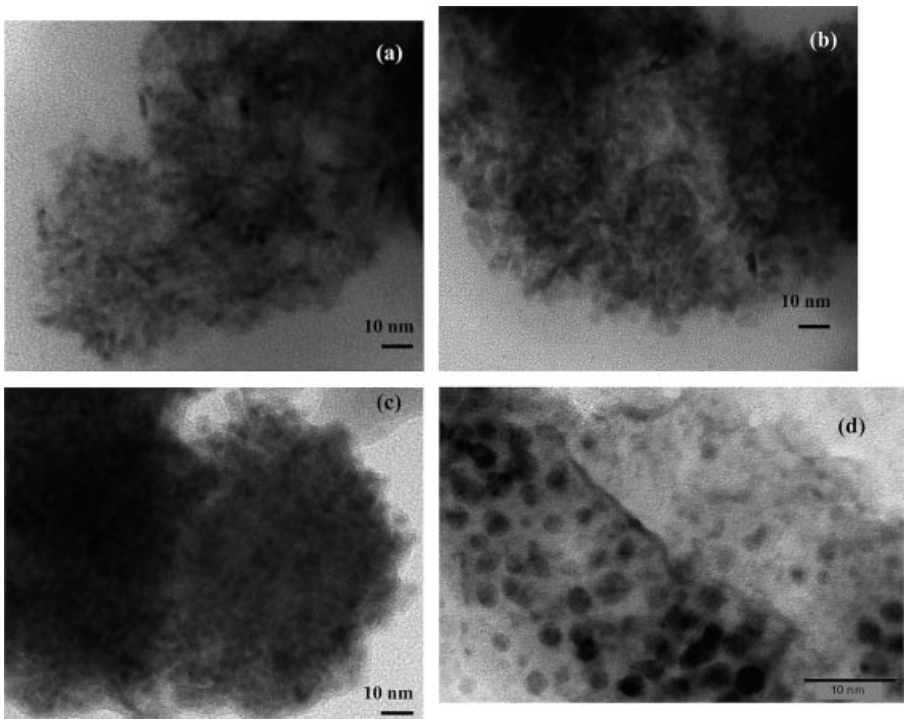


Figure 1. TEM micrographs of CdS–oligothiophene nanoparticles (a) **CdS-2T**; (b) **CdS-3T**; (c) **CdS-4T**; (d) **CdS-3T** prepared at pH = 9. The scale bar represents 10 nm in each case.

The general procedure involves addition of cadmium acetate and thiourea to a given volume of EG to obtain a concentration between $10^{-2}$ and $10^{-3}$ mol $L^{-1}$. To form CdS–oligothiophene hybrids, oligothiophenes were added to the reaction mixture in EG. The mixture was then heated with vigorous stirring to a temperature between 100 and 150 °C.

Transmission electron microscopy reveals that the oligothiophene molecules act as mediator templates towards the preparation of size-controlled spherical assemblies (50–200 nm) (Figure 1). The average individual CdS particle sizes are on the nanometer scale, 2–4 nm, depending on the conjugation length of the organic chain. In deionized water at pH = 9 CdS–oligothiophene nanoparticles are generally isolated from one another (Figure 1d). The assembly of CdS nanoparticles into nanospheres is believed to be a result of π–π interactions between conjugated systems.[12] The crystallinity of the **CdS-*n*T** samples was investigated by X-ray diffraction, as shown in Figure 2. At equilibrium reaction conditions, CdS nanoparticles present the thermodynamically stable hexagonal (wurtzite) structure. In this work, all samples can be indexed as cubic (sphalerite) in structure, showing (111), (220) and (311) peaks. This behaviour is perhaps due to the presence of oligothiophene molecules on the CdS surface. The same phase was observed by McPherson et al. for CdS synthesized in water-in-oil microemulsions using a combination of bis(2-ethylhexyl) sulfosuccinate (AOT) and the zwitterionic phospholipid L-α-phosphatidylcholine (lecithin).[13] An average size was estimated by applying Scherrer's formula. Crystallite sizes decrease with an increase in the conjugation length of the organic molecule, from 4 nm for **CdS-2T** to 2 nm for **CdS-4T**.

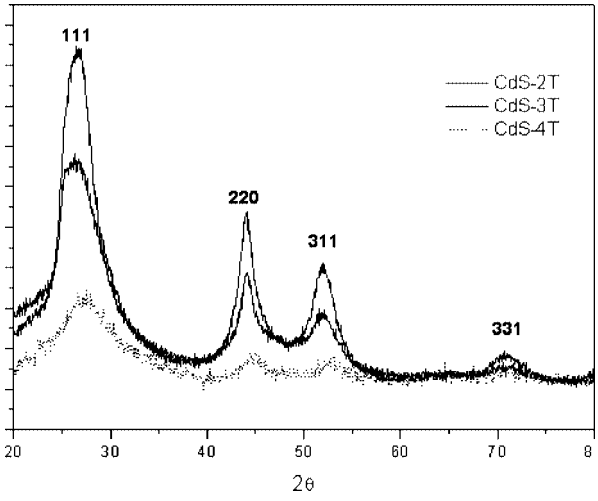

Figure 2. Powder X-ray diffraction patterns of three samples of **CdS-*n*T** nanoparticles.

The reduction of particle size with an increase in the conjugation length of the adsorbate can be understood as a passivation effect on the NC surface with longer oligomers. This result is somewhat surprising, that the steric effects are similar for the three oligomers, assuming they lie perpendicular to the NC surface. The HOMO–LUMO energy and carboxylate reactivity is an alternative explanation. In general, the smaller the HOMO–LUMO energy gap of an aromatic acid, the softer the anions. A soft base with smaller HOMO–LUMO energy will adsorb more readily on a surface. DFT calculations on the oligothiophenecarboxylates

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

show that changing the carboxylate from thiophene to bithiophene or terthiophene reduces the energy gap considerably.[14] The HOMO rises and the LUMO falls. In the light of these facts, we assume that the longer oligomers, i.e. **QTDC** and **TTDC** bind more strongly to the NC surface than **BTDC**; therefore, the longer oligomer straightforwardly passivates the NC surface and stops particle growth at an early stage of growth resulting in small nanoparticles.

FTIR spectroscopy was used to study CdS–oligothiophene core-shell structures and to reveal also the bonding mode of the organic molecule adsorbed on the NC. In the frequency region where C=C, C–C and C–S stretching vibrations are active, the infrared spectra of α,ω-oligothiophene diacids and **CdS-*n*T** show many similarities. These spectra exhibit characteristic bands of oligothiophenes that are centred at 1520, 1436, 890, 812 $cm^{-1}$, and 750 $cm^{-1}$, assigned to antisymmetric C=C, symmetric C=C, antisymmetric C–S, symmetric C–S stretching modes, and out-of-plane C–H deformation, respectively. However, we observe a slight vibration shift of the π-conjugated system upon adsorption of the oligomer on the NC surface. The $\nu_{ant}$ (C–C) and symmetric C–S modes are redshifted by 7 and 13 $cm^{-1}$, respectively. The out-of-plane deformation of C–H is blueshifted by 17 $cm^{-1}$. The change in the thiophene vibration can be attributed to the new electronic distribution of the bonded oligomers. Figure 3a, b represents typical FTIR spectra of the carboxylate region, for **BTDC**, **CdS-2T**, **TTDC** and **CdS-3T**.

The stretching band of the carbonyl group C=O, which appears at 1669 $cm^{-1}$ for **BTDC** and 1663 $cm^{-1}$ for **TTDC**, is no longer identified in the IR spectra of **CdS-*n*T**. Instead, the symmetric and asymmetric stretching vibrations of the $COO^-$ group appear distinctly at 1386 and 1560 $cm^{-1}$, respectively. The shoulder at 1617 $cm^{-1}$, observed for **CdS-2T** indicates the existence of a second coordination mode of the carboxylate group. The intensity of the latter increases and becomes a distinct band for **CdS-3T**. The presence of the $\nu_s(COO^-)$ band in the **CdS-*n*T** spectra clearly indicates that the oligothiophene binds to the CdS surface through the carboxylate group. Also, observing two types of carboxylate stretches indicates that the carboxylate group of the oligomers function in different coordination fashions, two at least. The binding mode can be determined from the carboxylate band splitting. Hence, it was established that the mode of carboxylic acid coordination in complexes or adsorbed on a surface can be determined using infrared spectroscopy. There are four common carboxylate coordination modes: monodentate, chelating bidentate, bridging bidentate and ionic interaction. The coordination mode can be distinguished by the different separations between the antisymmetric and symmetric stretching adsorption bands ($\Delta\nu$).[15] Bidentate coordination modes of the carboxylate group show a separation less than 200 $cm^{-1}$, whereas monodentate modes show a larger separation. In the present work band separations of $\Delta\nu$ = 180 and 240 $cm^{-1}$ were obtained for **CdS-3T**, indicating bidentate and monodentate coordination modes. The similarity of the **CdS-2T** spectrum and its band separations, $\Delta\nu$ = 180 and 230 $cm^{-1}$, indicates

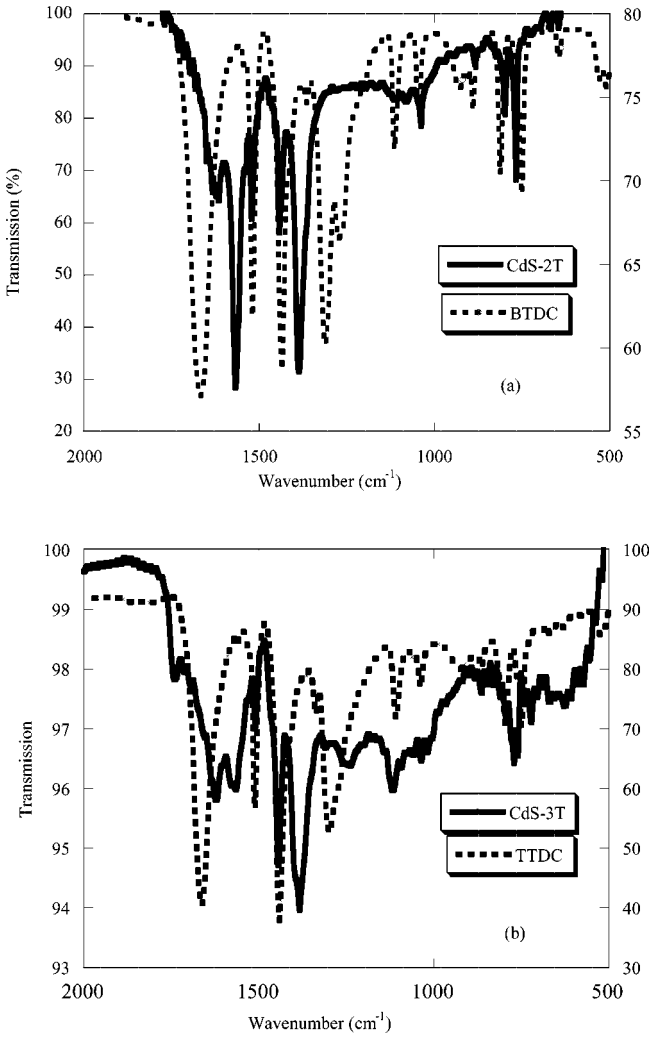

Figure 3. FT-IR spectra of (a) **BTDC** and **CdS-2T**, (b) **TTDC** and **CdS-3T**.

that a similar mode of binding occurs. The FTIR data show clearly that the final composition of the **CdS-*n*T** core shell includes both a thiophene oligomer shell and a CdS core. On the other hand, the complexation of oligothiophenecarboxylate with CdS nanoparticles occurs through strong ionic/covalent bonds. Also, the bonding of the oligomer on the NC surface deeply influences the electronic distribution of the π-conjugated system.

The elemental composition of the CdS–oligothiophene nanoparticles was analyzed by XPS. The XPS survey scan of **CdS-4T** is depicted in Figure 4, as a representative example. The main features, S2p, C1s, $Cd3d_{5/2}$ and O1s, are centred at 162, 285, 405 and 532 eV, respectively. The O1s/$Cd3d_{5/2}$ and C1s/$Cd3d_{5/2}$ intensity ratios differ markedly depending on the chemical structure of the oligomer, i.e. chain length. The high-resolution Cd3d region from **CdS-4T**, shown as an insert in Figure 4, exhibits $Cd3d_{5/2}$ and $Cd3d_{3/2}$ peaks (spin-orbit doublet) centred at 405.8 and 412.4 eV, respectively.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

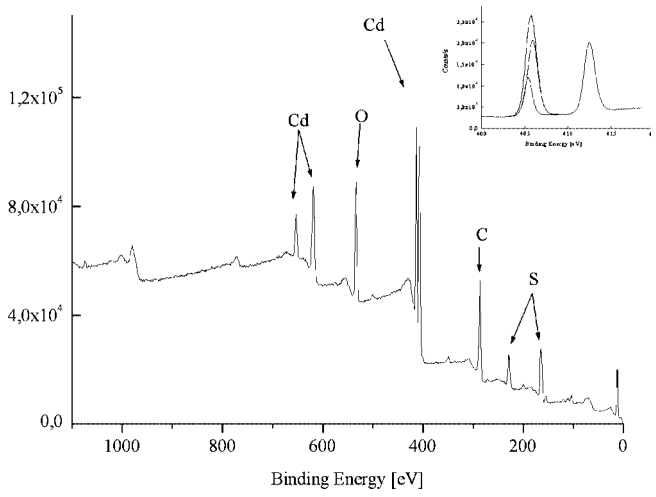

Figure 4. XPS survey scan of **CdS-4T**; the insert shows core level of $Cd3d_{5/2}$.

The $Cd3d_{5/2}$ binding energy is in line with the published data for CdS.[16] When care was taken to closely analyze the $Cd3d_{5/2}$ spectra, they were fitted with two peaks using Gaussian line shapes, which can be assigned to the bulk of Cd atoms, the second one at high binding energy, which should be attributed to surface cadmium atoms complexed to the oligomer through the carboxylate group. The surface contribution is about 20% of the total signal for **CdS-4T** and drops to 10% for **CdS-2T**. This is expected and is in agreement with literature data, which show that the surface contribution is larger for smaller NCs; the sizes of the nanoparticles are 4 and 2 nm for **CdS-2T** and **CdS-4T**, respectively.

Figure 5 compares the S2p regions of **CdS-2T** and **CdS-4T**. The spectra are fitted with three different spin-orbit split S2p doublets. The spin-orbit energy shift (ca. 1.2 eV) and the intensity ratio of 2:1 for the $S2p_{3/2}/S2p_{1/2}$ components has been taken to fit. The S2p peak-fitting parameters are reported in Table 1 for the three samples analyzed. The three components identified are attributed to sulfur in the bulk of CdS (161.9 eV), sulfur atoms from the oligothiophene (164.1 eV), the organic stabilizer bound to the nanoparticle, and a very small amount of oxidized sulfur (168.4 eV), from the oxidation of the particle surface. Table 2 reports the surface chemical composition (in percent) of the nanoparticles. Similarly, as previously observed for CdS and CdSe nanocrystals, the $Cd^{2+}/S^{2-}$ atomic ratio is nonstoichiometric,[17] showing a significant excess of cadmium atoms on the surface, with the atomic ratio of Cd/S = 1.54, 1.52 and 1.43 for **CdS-2T**, **CdS-3T** and **CdS-4T**, respectively. It is reasonable to assume that the lack of sulfur in the outermost layers of the nanoparticles is compensated by the carboxylate groups from the oligothiophene capping ligands.

The production of highly monodisperse semiconductor nanocrystals requires stabilizers such as amines, phosphanes, phosphane oxides and phosphonic acids as capping ligands. However, a few recent reports have examined in detail the binding of long-chain carboxylic capping ligands

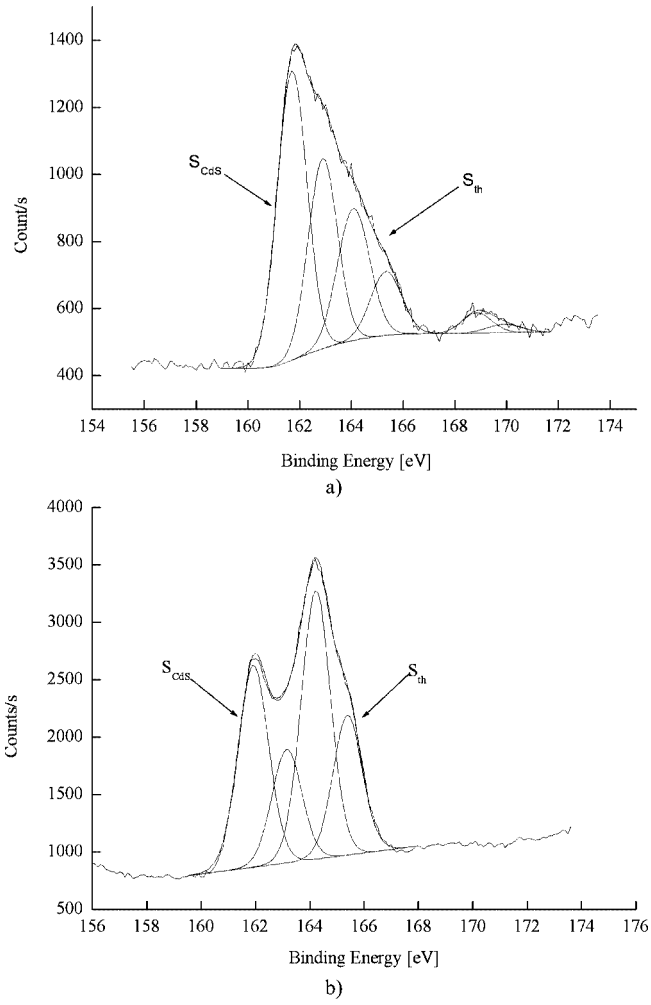

Figure 5. Core level of S2p for **CdS-4T** (top) and **CdS-2T**.

Table 1. Characteristic S2p binding energies (eV) for sulfur within different materials.[a]

| Materials | $S_{CdS}$ | | $S_{Th}$ | | $S_{ox}$ | |
|---|---|---|---|---|---|---|
| | S2p3/2 | S2p1/2 | S2p3/2 | S2p1/2 | S2p3/2 | S2p1/2 |
| **CdS-2T** | 161.7 | 162.9 | 164.1 | 165.3 | 168.4 | 169.9 |
| | 40.4 | 26.3 | 19.9 | 9.3 | 2.83 | 1.3 |

at the CdS and CdSe NC surface. Mulvany et al.[18] and Dushkin et al.[19] reported a version of the hot-matrix method for the synthesis of CdSe nanoparticles using a noncoordinating solvent and a carboxylic acid as the coordinating ligand. This new method is an adaptation of widely reported methods that use cadmium carboxylate salts as precursors for these NCs. Their synthetic approach allows one to tune the nucleation and growth of CdSe by altering the reactivities of selenium and cadmium and to probe more clearly the role of the chalcogenide and cadmium precursors on CdSe nanocrystal synthesis, as well as the role of TOPO on surface passivation. In these systems, it was shown that the usual stabilizing agent, TOPO, can be eliminated completely in favour of a fatty acid without effects on the particle size distribution or their optical properties. They claim that CdSe terminated with a long-chain carboxylate is one of the cleanest colloidal CdSe systems to date, with oleic acid as the sole stabilizer. Peng et al.[20] have developed a successful approach to synthesizing CdS in a noncoordinating solvent. Oleic acid, a natural surfactant, was chosen as the ligand for stabilizing the nanocrystals and the cationic precursors. The ability to use long-chain carboxylic acids as stabilizers was later extended to InP and InAs nanocrystals.[21]

Therefore, it is necessary to estimate the contribution of the carboxylate capping ligands to the total carbon content of the nanoparticles. Figure 6 displays a typical C1s region for **CdS-2T** fitted with five components centred at 285.0, 286.0, 287.4, 288.7 and 290.2 eV. The component centred at 288.7 eV is assigned to the carboxylate group from the oligothiophenes.[22] The contribution of the carboxylate groups to the C1s peak areas of the **CdS-2T**, **CdS-3T** and **CdS-4T** nanoparticles is 11.8, 12.1 and 9.9%, respectively, corresponding to 5.78, 4.35 and 4.88% carboxylate carbon atoms. Note that the contributions of the carboxylates to the C1s region differ slightly from those expected, due to unavoidable adventitious hydrocarbon contamination and the presence of carbonates (peak centred at ca. 290.5 eV).

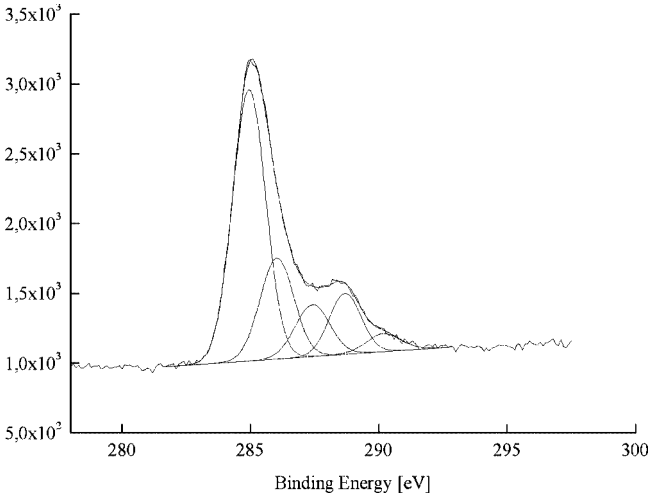

Figure 6. Narrow-scan XPS spectrum of C1s region for **CdS-2T**.

With the contribution of the carboxylates to the surface composition in hand, the $Cd/(S_{CdS}+1/2C_{COO^-})$ atomic ratio, assuming that only one carboxylate group per oligothiophene is coordinated with $Cd^{2+}$ on the particle surface, is 1.26, 1.31 and 1.07, which is in agreement with the stoichiometry of CdS. The contribution of the carboxylates to the surface chemical composition can further be related to the sulfur content due to the oligothiophenes, and the experimental $COO^-/S_T$ molar ratio compared to that expected from microanalysis. Figure 7 shows a plot of the experimental $COO^-/S_T$ molar ratio, as determined by XPS, vs. microanalysis data. The results reflect reasonably well the progressive relative concentration of the carboxylate groups within the oligothiophenes.

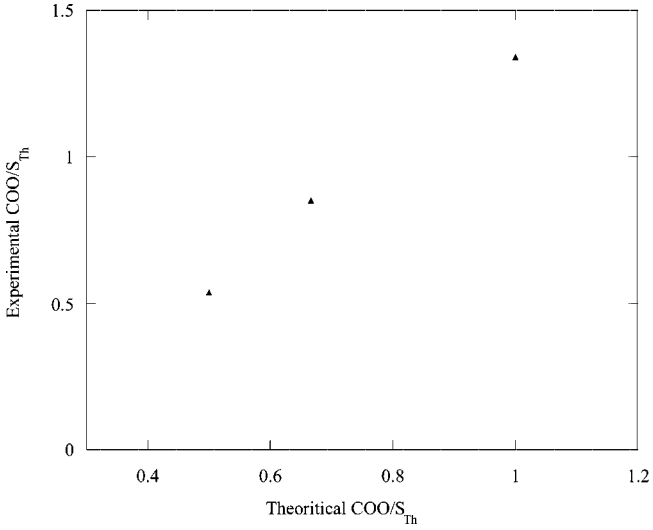

Figure 7. Plot of $COO^-/S_T$ molar ratio, as determined by XPS vs. microanalysis results.

From the surface chemical composition reported in Table 1, one can estimate the number of molecules bound per CdS particle. In this case, only the sulfur of the organic component is considered for the oligothiophenes, and the CdS nanoparticles are, to a first approximation, assumed to be stoichiometric. Because the nanoparticles have also diameters lower than the sampling depth probed by XPS, it is reasonable to assume that the apparent surface composition reflects that of the whole coated nanoparticle. For **Cd-3T** and **CdS-4T** the diameters are estimated to be 3.8 and 2 nm, respectively. Taking into account the density of CdS, and thus the number of Cd atoms per particle, one can estimate the number of bound oligothiophenes per nanoparticle using the ratio $(\%S_T/n_S)/(\%Cd/n_{Cd})$ where $\%S_T$ and %Cd are the atom percents reported in Table 2, $n_{Cd}$ the number of Cd atoms per CdS nanoparticle, and $n_S$ the number of thiophene repeat units per oligothiophene. For **CdS-3T** and **CdS-4T**, we find ca. 19 molecules of terthiophene and 18 molecules of quaterthiophene per nanoparticle.

The hybrid structures of **CdS-*n*T**, with two, three and four rings were characterized by means of absorption and emission spectroscopy. In the UV/Vis studies the structures

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

were investigated in EG and dimethyl sulfoxide. No marked differences were observed in the absorption spectra of these compounds in either solvent, the resulting spectra being essentially the additive combination of those of the two constituent parts, with slight modification. Figure 8 shows the typical spectra recorded for the CdS–oligothiophene series as well as CdS stabilized by acetate in EG. The NCs stabilized by acetate have an absorption shoulder at 440 nm corresponding to the first excitonic peak. Note that in our studies variation of the synthesis conditions was found to have no significant effect on the excitonic peak energy.

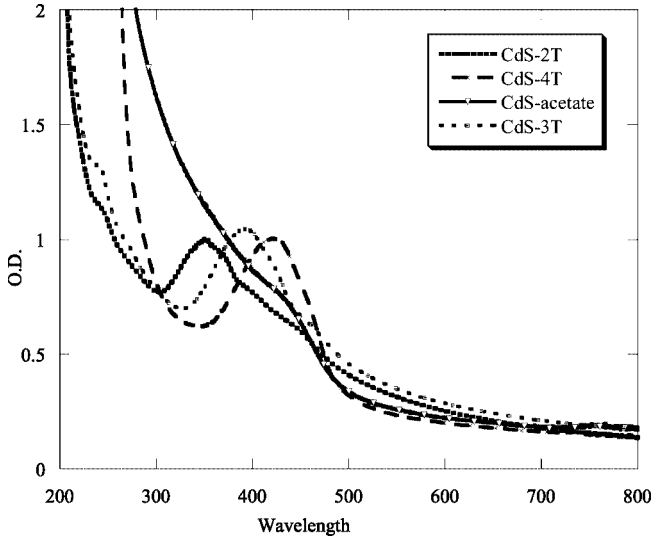

Figure 8. UV/Vis spectra of three samples of **CdS-*n*T** and **CdS-acetate**.

The spectrum of **CdS-*n*T** shows a main peak, in the visible region, due to the π–π* transition, and a weaker but well-defined shoulder at low energy attributed to NC excitonic absorption. The main peak exhibits a perfect correlation with the conjugation length, i.e. the maximum is significantly redshifted as the conjugation length of the corresponding oligothiophene shell increases. Hence, UV/Vis absorption spectra of **CdS-*n*T** show a maximum centred at 350, 395 and 428 nm for **CdS-2T**, **CdS-3T** and **CdS-4T**, respectively. All these maxima were found to be close to those observed for solutions of the oligothiophene dicarboxylates. However, when the spectra of the CdS-bound oligomers are examined carefully the absorption seems not to be a simple superposition of the two components, as can be seen in Figure 9. The easiest case is **CdS-2T**, where the two bands are separate. Additional shoulders appear at the low-energy side of the bithiophene absorption (367 and 400 nm), indicating a ground-state interaction between CdS NCs and the conjugated system. For longer oligomers, the absorption of the organic shell overlaps that of CdS, which makes discussion difficult. The structureless broad absorption observed indicates that the oligomers bound to the nanoparticle surface are relatively flexible for the formation of different conformers in the ground state.

The number of oligomers attached to the nanoparticle is fundamental to fully characterizing the **CdS-*n*T** hybrid core-shell materials. This can be calculated using the absorbance at the oligomer absorption maximum ($\lambda_{max}$), that at the CdS excitonic peak (450 nm) and their extinction coefficients. Although the determination of the NC extinction coefficient has been largely debated in the literature, recent work, has established for CdS NCs capped with oleic acid show a strong dependence of the extinction coefficient on the size of the NCs, while the nature of the ligands and the solution refractive index were shown not to have a significant effect.[23] Given the average particle size (4 nm for **CdS-2T**), $\varepsilon$ = 552820 L mol$^{-1}$ cm$^{-1}$ for the extinction coefficient of CdS NCs, and 26100 L mol$^{-1}$ cm$^{-1}$ for the extinction co-

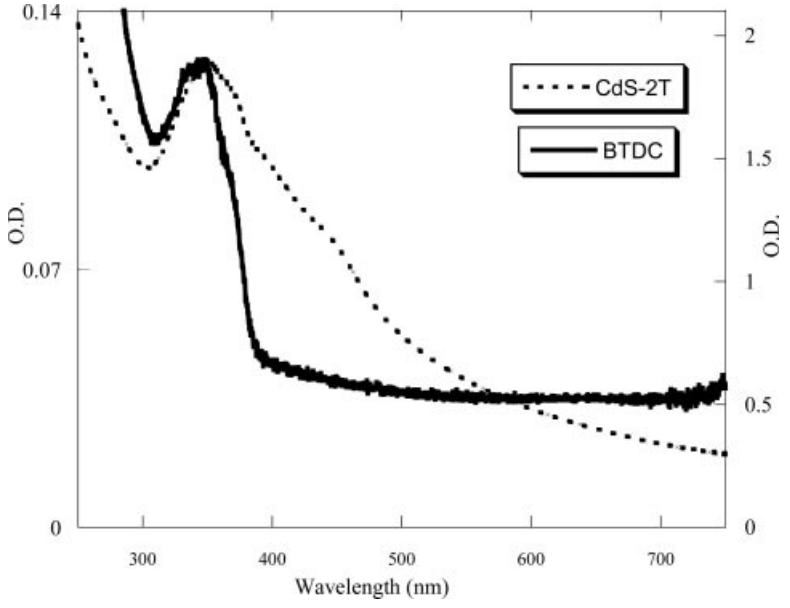

Figure 9. UV/Vis spectra of **CdS-2T** and **BTDC**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

efficient of **BTDC**, the maximum absorbance is 1.88 for **BTDC** and that for the CdS excitonic peak is 1.035. We found that each NC is embedded in 40 **BTDC** molecules. This result is consistent with the work of Milliron et al., who report 50 molecules of pentathiophene per CdSe nanocrystal.[6] Note that the value obtained is relatively low compared to the theoretical one. In fact, 200 molecules were expected to form a close-packed monolayer in a 4-nm diameter sphere. The area occupied per molecule was estimated using the following approximations. The molecule binds perpendicularly to the surface; the area occupied is the projection of the oligomer on the NC. From the known bond lengths, van der Waals atomic radii and the thickness of the oligomers, the area occupied per molecule is estimated to be 24 $Å^2$. Using the same UV/Vis procedure, an average of 18 molecules per NC was found for **CdS-3T**; this value is in good agreement with that estimated from the XPS measurements.

It is well known that the fluorescence properties of CdS NCs depend strongly on their surface states, surface passivation and size distributions. Fluorescence quench or changes in the quantum yield indicate also differences in the branching ratio between radiative and nonradiative decay and therefore might serve as a powerful probe of NC-conjugated polymer interactions. To determine the degree of electronic communication between CdS NCs and oligothiophene, we performed fluorescence measurements. Figure 10 illustrates the room-temperature fluorescence spectra of **CdS-*n*T**. The general trends observed are that the emission of CdS-bound oligothiophenes is weak and exhibits a weak Stokes shift. The intensity drops by a factor of two relative to their homologues, i.e. sodium dicarboxylates. We note also that the emission spectra of **CdS-*n*T** are redshifted relative to the oligothiophenedicarboxylates. This shift is more pronounced for the longer oligomers, i.e. **CdS-3T** and **CdS-4T**. Hence, the emission spectra of **CdS-2T** and its free ligand are similar in energy and shape, except for the low-energy side. **CdS-2T** has a long emission tail in the low-energy part of the spectrum. Quite different emission spectra were obtained for **CdS-3T** and **CdS-4T**, as seen in Figure 10b, c. Those of **TTDC** and **QTDC** sodium salts show two clearly resolved bands at 450 and 465 nm and at 480 and 500 nm, respectively, which have been identified as the vibronic replicas of the O–O transition. These emission maxima are redshifted to 490 and 530 nm for **CdS-3T** and **CdS-4T**, respectively. The intensity of the first band observed for the precursors decreases and becomes a shoulder in **CdS-*n*T**. The similarity in the appearance of the emission spectra of the precursors and CdS-bound oligothiophenes suggests that the origin of this emission is π*–π emission; no CdS NC emission is observed. Selective excitations have been undertaken to analyze the CdS NC emission. Upon excitation into the CdS excitonic absorption band (461 nm), the emission spectrum is similar to that when exciting into the main oligothiophene band, indicating a complete quench of CdS NC fluorescence. The **CdS-*n*T** excitation spectra are similar to the absorption spectra of the oligothiophene precursors.

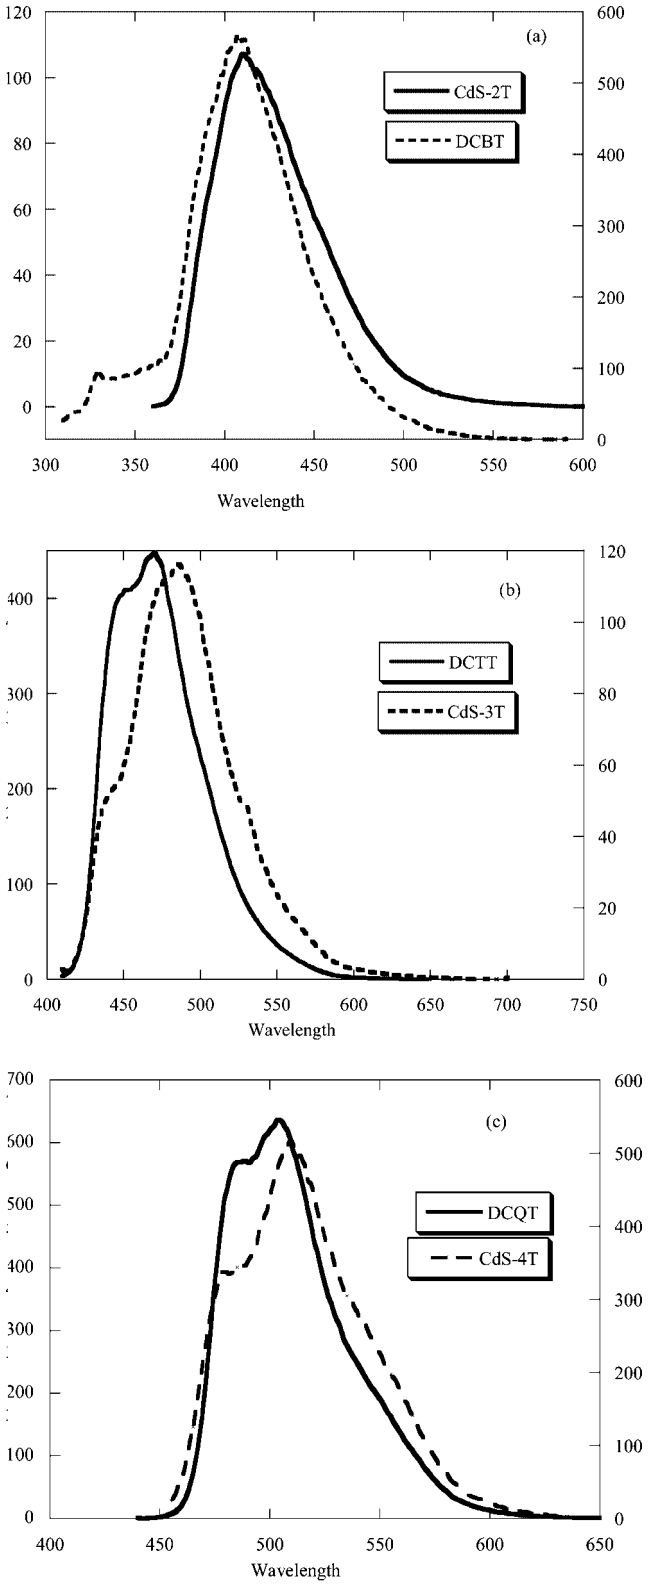

Figure 10. Fluorescence spectra of (a) **CdS-2T** and **BTDC**, (b) **CdS-3T** and **TTDC**, (c) **CdS-4T** and **QTDC**.

The fluorescence changes in the **CdS-*n*T** are in good agreement with the **ZnO-(Th)$_n$** fluorescence observed by Jiu et al. who reported a strong redshift in the precursor emis-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sion, when they were adsorbed on ZnO NC.[24] They found a 100-nm redshift emission of **ZnO-(Th)$_n$** and free precursors. Similar significant modification in the spectral distribution of fluorescence of the CdSe conjugated oligophenylene–vinylene surfactants, relative to blended films of the inorganic and organic components was recently observed by Emrick et al.[3] They attributed this effect to enhanced energy transfer between the conjugated ligand and the quantum dot facilitated by connecting the conjugated backbone directly to the quantum dot.

To help understand the fluorescence results, NC emission properties must be taken into account. Indeed, it has been established that the emission properties of NCs are very sensitive to their surface environment. In general, as-synthesized NCs have high fluorescence quantum yields approaching unity. Decrease in the quantum yield and/or change in the fluorescence shape are considered to be the result of the surface states located in the bandgap of the NCs, which act as trapping states for the photogenerated charges. These surface trapping states originate from the dangling bonds of some of the surface atoms. It has been speculated that in III–V semiconductor NCs, the nanoparticle surfaces are terminated by either cadmium or chalcogen sites. On the other hand, it is well established that an aromatic acid can be bound to a metal surface through the oxygen lone-pair electrons and aromatic carboxylates are also common O-donor ligands in cadmium coordination chemistry. In light of this evidence, and based on published reports showing that carboxylates can act as capping ligands,[18–21] we assume that the oligomer binds to a dangling cadmium ion on the NC surface through the lone-pair electrons of the carboxylate function. In this way, a monolayer of cadmium oligomer complex is formed on the surface of the CdS nanoparticles. This novel supramolecular structure composed of dangling cadmium and conjugated oligomer has more electronic delocalization, which profoundly influences the emission properties of the π-conjugated system of the oligomers. This assumption corroborates well with ab initio calculations made by Puzder et al. The authors calculated the binding energy of different organic functions to a range of the CdSe NC facets.[25] The dominant binding carboxylate interaction found is between oxygen atoms in the ligands and the dangling cadmium atoms on the NC surfaces.

## Conclusion

We have prepared a new organic–inorganic structure consisting of oligothiophenes grafted onto the surface of CdS nanocrystals, with narrow size distribution, using a one-pot reaction. The number of bound molecules and the grafting of the oligomers on the surface of the nanocrystals were investigated using XPS, IR, UV/Vis and fluorescence spectroscopy. The bonding of the oligomers to the nanocrystal surface is made possible by complexing the dangling cadmium ion on the surface with the lone-pair electrons of the carboxylate group at the end of the oligomers, leading to better electronic interaction between the two components. On the basis of the observed properties, these hybrid nanoparticles should have potential applications in optoelectronic and photovoltaic devices.

## Experimental Section

**Materials:** All chemicals used in the syntheses and the analytical grade solvents used for UV/Vis studies were purchased from Aldrich and used as received.

**Organic Synthesis:** 2,2′-Bithiophene-5,5′-dicarboxylic acid (**I**), 2,2′;5′,2″-terthiophene-5,5″-dicarboxylic acid (**II**), and 2,2′;5′,2″;5″,2‴-quaterthiophene-5,5‴-dicarboxylic acid (**III**) were prepared as described in detail elsewhere.[10] All the oligothiophenes were fully characterized by $^1$H and $^{13}$C NMR spectroscopy and elemental analysis.

**Synthesis of Oligothiophene-Functionalized CdS Nanoparticles:** CdS–oligothiophene hybrid nanoparticles were synthesized in ethylene glycol by the Polyol process.[11] Briefly, the general procedure involves addition of cadmium acetate and thiourea to a given volume of polyol to obtain a concentration between $10^{-2}$ and $10^{-3}$ mol L$^{-1}$. To form CdS–oligothiophene hybrids, oligothiophene with different conjugation lengths was added to the solution. The final oligothiophene concentration was also between $10^{-2}$ and $10^{-3}$ mol L$^{-1}$. The mixture was then heated with vigorous stirring to a temperature varying between 100 and 150 °C. Purification was achieved by adding excess methanol. The precipitate formed was centrifuged and the upper liquid layer decanted, and the isolated solid then dispersed in an appropriate solvent. The above centrifugation and isolation procedure was repeated several times.

**General Experimental Procedures:** UV/Vis spectroscopy. UV/Vis absorbance spectra were acquired with a Cary 50 spectrometer. Fluorescence spectra were recorded with a Perkin–Elmer LS50 spectrofluorometer. IR spectra were recorded on KBr pellets using a Nicolet IRTF-Magma 860. Transmission electron microscopy (TEM) observations were performed with a JEOL 100 kV JEM-100CX II microscope. The CdS-functionalized nanoparticles were deposited on the amorphous carbon membrane of the transmission electron microscope grid and the solvent then evaporated off at room temperature. The mean diameter was estimated from image analysis of a hundred particles. X-ray powder diffraction (XRD) patterns were recorded with a Philips PW1050/25 using Cu-$K_\alpha$ radiation. The diffractometer was calibrated using a standard Si sample. The counting time was 30 s per $2\theta$ step of 0.05°. The mean crystallite size was estimated using the Scherrer equation. X-ray photoelectron spectroscopy signals were recorded using a Thermo VG Scientific ESCALAB 250 system equipped with a micro-focused, monochromatic Al-$K_\alpha$ X-ray source (1486.6 eV) and a magnetic lens which increases the electron acceptance angle and hence the sensitivity. The specimens were pressed against double-sided adhesive tapes mounted on sample holders, and then pumped overnight in the fast-entry lock at ca. $5 \times 10^{-8}$ mbar before introduction into the analysis chamber. A 650-μm X-ray beam was used at a power of 13.7 mA × 15 kV. The spectra were acquired in the constant analyzer energy mode, with pass energies of 150 and 40 eV for the survey and the narrow regions, respectively. Charge compensation was achieved with an electron flood gun operated under argon flow at a partial pressure of $2 \times 10^{-8}$ mbar in the analysis chamber. Under these conditions, the surface charge was negative but perfectly uniform. Avantage software, version 2.2 (Thermo Electron), was used for digital acquisition and data processing.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Spectra were calibrated by setting the C1s peak maximum at 285.0 eV. The apparent surface compositions (in atom%) were determined by considering the integrated peak areas of the C1s, O1s, S2p and $Cd3d_{5/2}$ peaks and the manufacturer's sensitivity factors.

## Acknowledgments

The authors wish to thank the Conseil Régional d'Ile-de-France for financial support through the SESAME 2000 Scheme, and Ms. Carole Connan for her assistance with the XPS measurements, Marie-Josèphe Vaulay and Frédéric Herbst for TEM and XRD characterizations.

# New Dinuclear $Mn^{III}$ Compounds with 2-$MeC_6H_4COO$ and 2-$FC_6H_4COO$ Bridges – Effect of Terminal Monodentate Ligands ($H_2O$, $ClO_4^-$ and $NO_3^-$) on the Magnetic Properties

**Gema Fernández,[a] Montserrat Corbella,*[a] Gabriel Aullón,[a] Miguel A. Maestro,[b] and José Mahía[c]**

**Keywords:** Manganese / Magnetic properties / Ligand effects

Four new dinuclear $Mn^{III}$ complexes with the general formula $[\{Mn(bpy)L\}(\mu\text{-}RCOO)_2(\mu\text{-}O)\{Mn(bpy)L'\}]^{n+}$ (bpy = 2,2′-bipyridine) have been synthesized with RCOO = 2-$MeC_6H_4COO$ (**1**, **2**) and 2-$FC_6H_4COO$ (**3**, **4**); the counteranion could be $NO_3^-$ (**1**, **3**) or $ClO_4^-$ (**2**, **4**), and a monodentate ligand (L, L′) completes the octahedral environment of the manganese ions. For compound **1** L = $H_2O$ and L′ = $H_2O$ or $NO_3^-$; compound **2** shows two different dinuclear complexes, one of them with L = L′ = $H_2O$ and the other one with L = L′ = $ClO_4^-$; for compound **3**, L and L′ = $H_2O$ or $NO_3^-$ and for compound **4**, L = $H_2O$ and L′ = $ClO_4^-$. The characterization by X-ray diffraction shows an important disorder in the crystal for the nitrate compounds, principally for compound **3**, where each monodentate ligand could be a water molecule or a nitrate anion. The antiferromagnetic contribution to the magnetic coupling constant *J* is weaker for the nitrate compounds (**1** and **3**) than for the perchlorate compounds (**2** and **4**), and a ferromagnetic behaviour is found for compound **3**, with $J = +1.4\ cm^{-1}$. The magnetic coupling constant found for compound **1** is $J = -0.5\ cm^{-1}$ and for compounds **2** and **4** it is $-5.6\ cm^{-1}$ and $-3.5\ cm^{-1}$, respectively. Extended Hückel calculations were carried out and there is evidence that the nitrate anions coordinated to the manganese atoms act as π-acid ligands providing a means to diminish the antiferromagnetic contribution.

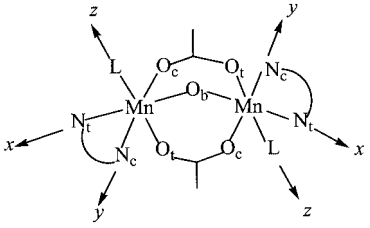
## Introduction

Interest in dinuclear $Mn^{III}$ complexes with a carboxylate ligand is due to their presence in some metalloenzymes such as the Mn-catalase. With the aim of obtaining good model compounds of this enzyme several dinuclear $Mn^{III}$ complexes with the $[Mn_2(\mu\text{-}RCOO)_2(\mu\text{-}O)]^{2+}$ core have been reported in the literature,[1–15] but only 11 of them are characterized by X-ray diffraction and magnetic studies.[5–15]

It is well known that the magnetic interaction for this kind of complex is weak and could be antiferro- or ferromagnetic[16] with *J* values between +18 and –8 $cm^{-1}$. Three possible distortions of the coordination octahedron can be observed due to the Jahn–Teller effect: (a) compression in the direction of the oxo-bridge, (b) elongation in the direction of one of the blocking ligands or (c) rhombic distortion. In general, compounds with a compressed octahedron in the direction of the oxo-bridging ligand show a ferromagnetic coupling, while complexes with an elongated octahedron (*z*) show antiferromagnetic coupling (Scheme 1). When the distortion is rhombic the magnetic interaction can be ferro- or antiferromagnetic.[5,6,16]



Scheme 1.

Tridentate amines $Me_3tacn$ (*N*,*N*′,*N*′′-trimethyl-1,4,7-triazacyclononane) and tp-tacn (trispyrrolidine-1,4,7-triazacyclononane) favour a compressed octahedron, and a significant ferromagnetic interaction was reported for $[\{Mn(Me_3tacn)\}_2(\mu\text{-}CH_3COO)_2(\mu\text{-}O)](ClO_4)_2$[11,12] ($J = +18.0\ cm^{-1}$) and $[\{Mn(tp\text{-}tacn)\}_2(\mu\text{-}CH_3COO)_2(\mu\text{-}O)](PF_6)_2$[13] ($J = +9.2\ cm^{-1}$). However, tridentate amines TMIP (tris(*N*-methylimidazol-2-yl)phosphane) and HB(pz)$_3$ (hidrotris(1-pyrazolyl)borate) lead to a rhombic distortion, (antiferromagnetic and ferromagnetic contributions are similar) and a small antiferromagnetic interaction was

found for compounds $[\{Mn(HBpz_3)\}_2(\mu\text{-}CH_3COO)_2(\mu\text{-}O)]$[14] ($J \approx -1$ cm$^{-1}$) and $[\{Mn(TMIP)\}_2(\mu\text{-}CH_3COO)_2(\mu\text{-}O)](ClO_4)_2$ ($J \approx -0.4$ cm$^{-1}$).[15]

When the blocking ligand is bpy (2,2′-bipyridine) the sixth position of the octahedron is occupied by a monodentate ligand; this situation provides a major flexibility to the coordination polyhedron and different types and degrees of distortion can be found. In this work we focused our attention on these kinds of compounds, with the aim of studying the effect of the carboxylate bridge and the monodentate ligand on the magnetic properties. We report here on four new complexes with a general formula $[\{Mn(bpy)L\}(\mu\text{-}RCOO)_2(\mu\text{-}O)\{Mn(bpy)L'\}]^{n+}$ with RCOO = 2-$MeC_6H_4COO$ (**1**, **2**) and 2-$FC_6H_4COO$ (**3**, **4**); the counteranion could be $NO_3^-$ (**1**, **3**) or $ClO_4^-$ (**2**, **4**). A monodentate ligand (L, L′) completes the octahedral environment of the manganese ions and could be $H_2O$, $NO_3^-$ or $ClO_4^-$. The coordination of the counteranion to the manganese ion enables us to study the effect of these ligands on the magnetic properties. Extended Hückel calculations were performed with the aim of clarifying the role of these ligands on the magnetic behaviour.

## Results and Discussion

### Syntheses

The synthetic method used to obtain the dinuclear $Mn^{III}$ complexes is a comproportionation reaction between $Mn^{II}$ and $MnO_4^-$ in the presence of carboxylic acid and a bidentate ligand (2,2′-bipyridine, bpy). The stoichiometry of this reaction is

$$1.6\ MnX_2 + 2\ RCOOH + 0.4\ Bu_4NMnO_4 + 2\ bpy \rightarrow [\{Mn(bpy)L\}(\mu\text{-}RCOO)_2(\mu\text{-}O)\{Mn(bpy)L'\}]X_{2-m} + 0.4\ Bu_4NX + 0.8\ HX + n\ H_2O$$

where RCOOH = 2-$MeC_6H_4COOH$, 2-$FC_6H_4COOH$, X = $NO_3$, $ClO_4$. These compounds show ionization isomerism, and the monodentate ligand (L and L′) could be $H_2O$ or the counteranion X. When both positions (L and L′) are occupied by X, a neutral complex is obtained ($m = 2$), while if L = $H_2O$ and L′ = X or $H_2O$ the complex is anionic (with $m = 1$ or 0).

The most significant difference between the four compounds synthesized here is their solubility. The perchlorate complexes **2** and **4** are very soluble in MeCN, so it is necessary to add $CH_2Cl_2$ (for **4**) or $CH_2Cl_2$ and hexanes (for **2**) to obtain good crystals. In contrast, the nitrate complexes **1** and **3** are less soluble, and subsequently it is necessary to work with dilute solutions to obtain crystalline products. In this case good crystals for X-ray diffraction are obtained directly from the mother liquor.

Infrared spectra of these compounds show two characteristics bands of the carboxylate bridging group at about 1600 and 1380 cm$^{-1}$. For compounds **1** and **3** the intense band of $NO_3^-$ appears overlapped with the carboxylate one (ca. 1380 cm$^{-1}$) and it is not possible to distinguish between the coordinated and free ion. Compounds **2** and **4** show three characteristic bands of the $ClO_4^-$ ion at ca. 1100 cm$^{-1}$. Several weak bands appear in the region between 800–400 cm$^{-1}$ corresponding to the counteranion, the Mn–O–Mn motive and the bpy ligand. The bipyridine ligand shows several bands, some of them in the range 1600–1440 cm$^{-1}$ and 780–635 cm$^{-1}$.

### Description of the Structures

The four compounds reported here display a similar structure. The cationic complex of each compound consists of a dinuclear unit with two carboxylates and one oxo group bridging the two manganese ions. The carboxylate bridging ligand is 2-$MeC_6H_4COO^-$, for **1** and **2**, and 2-$FC_6H_4COO^-$, for **3** and **4**. Each manganese ion is chelated by a bipyridine ligand (bpy), and the coordination sphere can be completed by a molecule of water or by an anion, i.e., nitrate or perchlorate. In all cases the carboxylate group and the aromatic ring of the $RCOO^-$ ligand are not in the same plane. The torsion angle $\delta(O\text{–}C_{carb}\text{–}C_{ar}\text{–}C'_{ar})$ is in the range 15.8–52.4°, however, the compounds with the 2-$FC_6H_4COO^-$ ligand (**3** and **4**) show smaller $\delta$ values than the compounds with the 2-$MeC_6H_4COO^-$ ligand (**1** and **2**). The relative orientation of the two coordination octahedrals is quite perpendicular, with the torsion angle $\tau$(L–Mn–Mn–L′) between 84.7–98.1°.

The Mn–$O_b$ distance for the compounds reported here is ca. 1.79 Å, similar to the values found for analogous compounds described in the literature.[5–15] The Mn–$O_b$–Mn angles for compounds **1**–**4** are between 121° and 125°; these values are also characteristic of these kinds of compounds. An important asymmetry in the carboxylate bridges is observed. In all these compounds, the Mn–O bond length is larger for the carboxylate oxygen atoms *trans* to the monodentate ligand than for the oxygen atoms placed in a *cis* position: $d$(Mn–$O_t$) > $d$(Mn–$O_c$). The bond lengths $d$(Mn–$O_t$) (ca. 2.16 Å) and $d$(Mn–$O_N$) (ca. 2.17 Å) are similar, while the distances $d$(Mn–$O_W$) and $d$(Mn–$O_{Cl}$) are longer (ca. 2.27 Å and ca. 2.36 Å, respectively). [$O_N$, $O_W$ and $O_{Cl}$ correspond to the oxygen atom of the L ligand coordinated to the manganese ions: nitrate, water and perchlorate, respectively.] Therefore, the monodentate ligand in these kinds of complexes produces an important effect on the coordination polyhedra of the manganese ions.

This compound shows a certain disorder in the crystal structure between one water molecule and one nitrate anion. The labile position in Mn(2) is always occupied by a water ligand, O(1s). However, in Mn(1) only in 57% of the cases is this position occupied by a water ligand, O(5s), while in the rest of the cases it is occupied by one nitrate anion, O(6). In Figure 1 it is possible to see both ligands near to Mn(1), although only one of them is present in each dinuclear unit. The most relevant distances and angles are listed in Table 1. The nitrate ligand is situated approxi-

mately perpendicular to the *z* axis, (defined in the L ligand direction as indicated above) with γ(O–*N*–O–Mn) angles of ca. 98°.

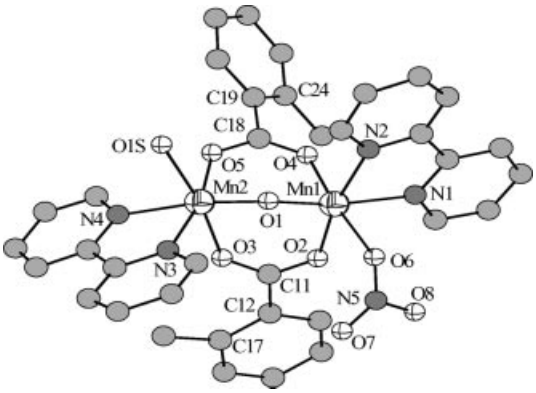

Figure 1. Drawing of the cation [{Mn(bpy)($H_2O$)}(μ-2-$CH_3C_6H_4COO$)$_2$(μ-O){Mn($NO_3$)(bpy)}]$^+$ in compound **1** showing two ligands coordinated in the same position for Mn(1): nitrate and water, corresponding to the two forms of the dinuclear unit present in the crystal.

There are hydrogen bonds between the nitrate anions and the coordinated water molecule generating a one-dimensional system. On one side, two Mn(2) ions of different dinuclear entities are bridged through the ionic nitrate anions and the coordinated water ligand, Mn(2)–O(1s)···O(10)–N–O(11)···O(1s)–Mn(2). On the other side, two Mn(1) ions of neighbour dinuclear complexes are bridged through the nitrate ion coordinated to one Mn(1) ion and the water molecule coordinated to the other Mn(1) ion, Mn(1)–O(6)–N–O(7)···O(5s)–Mn(1) (Figure 2).

### *[{Mn(bpy)($H_2O$)}$_2$(μ-2-$MeC_6H_4COO$)$_2$(μ-O)]-[{Mn($ClO_4$)(bpy)}$_2$(μ-2-$MeC_6H_4COO$)$_2$(μ-O)]($ClO_4$)$_2$·$CH_2Cl_2$ (2)*

The crystal structure of this compound shows two different dinuclear complexes. One of them is cationic, with the labile position on each manganese occupied by one water molecule, and the other one is neutral, with a perchlorate coordinated to each manganese in the labile position. Figure 3 shows the two dinuclear entities and the most important distances and angles are reported in Table 2. The cationic and neutral dinuclear complexes are bridged through hydrogen bonds between the water ligand of one entity and the perchlorate ligand of the other: Mn(3)–$O_W$···$O_{Cl}$–Mn(2). The same water ligand is also hydrogen bonded to one of the perchlorate anions.

### *[{Mn(bpy)(H$_2$O)}(μ-2-FC$_6$H$_4$COO)$_2$(μ-O){Mn(NO$_3$)(bpy)}]NO$_3$·H$_2$O (3)*

Similarly to compound **1**, a certain delocalization between the water and nitrate ligands is observed. In this case both manganese ions show disorder: in 31% of the dinuclear complexes both manganese ions present a coordinated water molecule, another 20% have one nitrate anion coordinated to each manganese and the last 49% show an asymmetric coordination (in one manganese ion the monodentate ligand is a nitrate ion, while in the other one it is a water molecule). Figure 4 shows the dinuclear complex with both possible ligands in the labile position. In comparison to compound **1**, the orientation of the nitrate ligand is different; in this case the ligand is placed quite parallel to the *z* axis, with $\gamma$(O–N–O–Mn) angles of ca. 20°. Selected interatomic bond lengths and angles are listed in Table 3. This compound shows disorder in the position of the F atoms of the carboxylate bridges: F(1) bonded to C(17) and F(1′) bonded to C(13) with an occupancy of 86% and 14%, respectively. And for the other carboxylate there is F(2) bonded to C(24) and F(2′) bonded to C(20) with an occupancy of 82% and 18%, respectively. Mn(1) and Mn(2) of neighbour complexes are bridged by hydrogen bonds between a water ligand of one dinuclear complex and a nitrate ligand of another complex, generating a 1D system.

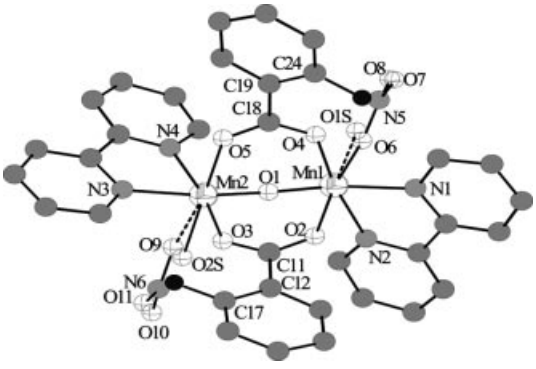

Figure 4. Drawing of the dinuclear complex of compound **3**. In the crystal the monodentate ligand attached to each manganese atom could be either nitrate or water. In the picture, both ligands are shown in each position.

Compounds **1**–**4** show intramolecular hydrogen bonds between the groups (or atoms) in the *ortho* position on the aromatic ring, the oxygen atoms of the carboxylate groups and the hydrogen atom of the bpy ligand (Figure 7). In compounds **3** and **4** the fluorine atom on the aromatic ring shows a preference for the position closest to the $O_c$ atom and the hydrogen bonds present in these compounds are F···$H_{bpy}$, $H_{Ph}$···$O_t$ and $O_c$···$H_{bpy}$. In contrast, the methyl group on the aromatic ring is placed closest to the $O_t$ atom

## Magnetic Properties

Magnetic susceptibility data were recorded for all complexes from room temperature to 4 K (or 2 K for **1** and **3**). The $\chi_M T$ product is ca. 5.6–5.9 $cm^3 mol^{-1}$ K at room temperature, which is close to the expected value for two uncoupled $Mn^{III}$ ions (6.0 $cm^3 mol^{-1}$ K). For compounds **1**, **2** and **4**, the $\chi_M T$ decreases with the temperature (very slowly for compound **1**) reaching a value of 0.4–0.8 $cm^3 mol^{-1}$ K at 4 K for compounds **2** and **4** and 4.4 $cm^3 mol^{-1}$ K for compound **1** (Figure 8). This behaviour is typical of an antiferromagnetic coupling between two $Mn^{III}$ ions. In contrast, for compound **3**, the $\chi_M T$ values increase when the temperature descends, reaching a maximum value of 6.43 $cm^3 mol^{-1}$ K at 16.5 K; at lower temperatures $\chi_M T$ decreases until 4.94 $cm^3 mol^{-1}$ K at 2 K. This behaviour is characteristic of ferromagnetic coupling. The expected value of $\chi_M T$ for a system with a ground state $S = 4$ must be 10 $cm^3 mol^{-1}$ K; the lower value found at 16.5 K and a decreasing of $\chi_M T$ below this temperature could be explained by the presence of zero-field splitting in the ground state and/or the intermolecular interactions. Magnetization measurements at 2 K, for compound **3**, show a $M/N\beta$ value of 5.5 at 50000 G, in agreement with the weak ferromagnetic interaction. For compounds **2** and **4** the $\chi_M$ vs. $T$ plot (Figure 8, inset) shows a maximum at 16.8 K ($\chi_M$ = 0.11 $cm^3 mol^{-1}$) and at 10.2 K ($\chi_M$ = 0.18 $cm^3 mol^{-1}$), respectively, indicating a major antiferromagnetic coupling for the former compound.

The spin Hamiltonian $H = -J\, S_1 \cdot S_2$ was used to fit the experimental data assuming that the two $Mn^{III}$ ions present the same $g$ value. The parameters $J$ and $g$ obtained from a least-squares fitting of the $\chi_M$ vs. $T$ data to the theoretical equation are listed below. Similar results are obtained by fitting the $\chi_M T$ vs. $T$ data. For the ferromagnetic compound (**3**), the theoretical equation was modified including the parameter of axial zero-field splitting, $D$, in the ground state $S = 4$. The Hamiltonian describing the ZFS was: $H_D = D[S_z^2 - S(S+1)/3]$. The best fits correspond to: $J = -0.5$ $cm^{-1}$ and $g = 1.98$, with $R = 5.5 \times 10^{-5}$ for **1**; $J = -5.6$ $cm^{-1}$ and $g = 1.98$, with $R = 4.1 \times 10^{-4}$ for **2**; $J = +1.4$ $cm^{-1}$, $|D| = 0.4$ $cm^{-1}$ and $g = 1.98$, with $R = 5.8 \times 10^{-5}$ for **3** and $J = -3.5$ $cm^{-1}$ and $g = 1.98$, with $R = 2.6 \times 10^{-5}$ for **4**.

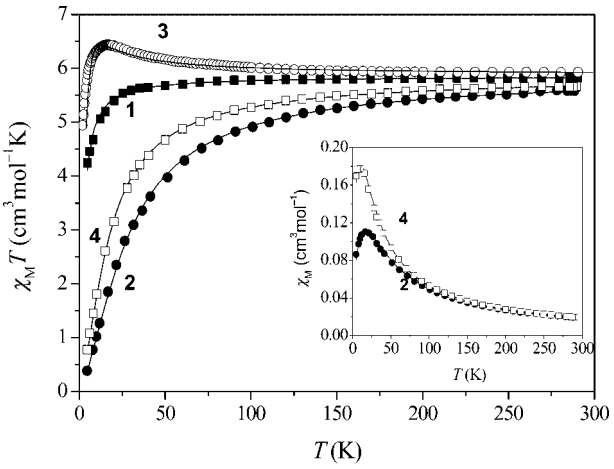

Figure 8. $\chi_M T$ vs. temperature plot for compounds **1**–**4**. The inset is the $\chi_M$ vs. $T$ plot for compounds with a perchlorate anion (**2** and **4**). The solid line is the best fit of the experimental data.

The four compounds show a moderate magnetic coupling. The strongest antiferromagnetic coupling was found for compound **2** while a ferromagnetic coupling was observed for compound **3**. As indicated in the previous section, in all cases the counteranion could be coordinated to the manganese ions. For compounds **2** and **4** the perchlorate anion is coordinated in 50% of the manganese ions, while for compounds **1** and **3**, the coordination of the nitrate anion is lower: only ca. 21% of the manganese ions show a nitrate ligand for compound **1**, while for compound **3** ca. 45% of the manganese ions show a coordinated nitrate anion. A comparison of the magnetic coupling constant of the four compounds indicates that, with the same carboxylate bridges, the perchlorate complexes show greater antiferromagnetic coupling than the nitrate complexes, with a difference of ca. 5 $cm^{-1}$. On the other hand, with the same anion, complexes with 2-$MeC_6H_4COO$ bridges show a stronger antiferromagnetic interaction than do complexes with 2-$FC_6H_4COO$ bridges, with a difference of ca. 2 $cm^{-1}$. The magnitude of the magnetic exchange interaction between the two $Mn^{III}$ ions found in compounds **1**–**4** may be compared with those reported for other dinuclear $Mn^{III}$ complexes with the general formula $[\{Mn(bpy)L\}_2(\mu\text{-}RCOO)_2(\mu\text{-}O)]^{n+}$ ($n = 2$ for neutral L ligands and $n = 0$ for anionic L ligands). Table 6 summarizes the most important structural parameters and the magnetic coupling constants for these compounds. As an example, the $Mn\text{–}O_b\text{–}Mn$ angle is in the range 122–125° and the $Mn\text{–}O_b$ distances are very similar for all compounds, since the d-orbital pointing to the oxo bridge is empty the magnitude of the magnetic interaction will not be very sensitive to this parameter.

Considering the $x$ axis in the oxo-bridge direction and the $z$ axis in the L direction (Scheme 1) we can find approximate values of the octahedron axes lengths by the addition of the Mn–ligand distances: $d(Mn\text{–}O_b) + d(Mn\text{–}N_t)$ ($x$ axis), $d(Mn\text{–}O_c) + d(Mn\text{–}N_c)$ ($y$ axis) and $d(Mn\text{–}L) + d(Mn\text{–}O_t)$ ($z$ axis). When the distance values for the $x$ and $y$ axis are similar, and smaller than the distance value found for the $z$ axis [$d(O_b\cdots N_t) \approx d(O_c\cdots N_c) < d(L\cdots O_t)$], the coordination

[a] Values using the $H = -J\ S_1 \cdot S_2$ convention. [b] See Scheme 1 for the terminology $O_c$, $O_b$, $N_t$ and $N_c$. [c] $x$, $y$ and $z$ symbolize the distances between ligands in the *trans* position, e.g., $x = O_b \cdots N_t$ is the addition of both manganese–ligand distances, $d(O_b \cdots N_t) = d(Mn\text{–}O_b) + d(Mn\text{–}N_t)$, $y = d(O_c \cdots N_c)$ and $z = d(O_t \cdots L)$. [d] $\gamma$ = ONOMn angle. All distances and angle values are the average of the two manganese centres, and for **2** it is also the average for the two complexes present in the crystal. **5** = $[\{Mn(OH)(bpy)\}(\mu\text{-}PhCOO)_2(\mu\text{-}O)\{Mn(NO_3)(bpy)\}]$;[5] **6** = $[\{Mn(N_3)(bpy)\}_2(\mu\text{-}PhCOO)_2(\mu\text{-}O)]$;[6] **7** = $[\{Mn(bpy)(H_2O)\}_2(\mu\text{-}ClCH_2COO)_2(\mu\text{-}O)](ClO_4)_2$;[8] **8** = $[\{Mn(bpy)(H_2O)\}_2(\mu\text{-}ClCH_2COO)_2(\mu\text{-}O)](NO_3)_2$.[8] **9** = $[\{Mn(bpy)(H_2O)\}_2(\mu\text{-}CH_3COO)_2(\mu\text{-}O)](PF_6)_2$;[9] **10** = $[\{Mn(Cl)(bpy)\}_2(\mu\text{-}CH_3COO)_2(\mu\text{-}O)]$;[6] **11** = $[\{Mn(bpy)(H_2O)\}_2(\mu\text{-phtha})_2(\mu\text{-}O)]$ $[\{Mn(bpy)(H_2O)\}(\mu\text{-phtha})_2(\mu\text{-}O\{Mn(bpy)(NO_3)\}](NO_3)_3$ (phtha = phthalate).[10]

polyhedron is considered elongated, while if the distance for the $x$ axis is shorter than the distances for the $z$ and $y$ axis $[d(O_b \cdots N_t) < d(O_c \cdots N_c) \approx d(L \cdots O_t)]$, the octahedron is compressed. Finally, if the distances of the three axes are different the octahedron presents a rhombic distortion. Then, we can define the distortion parameter as $(z - y)/(y - x)$, where $z = d(L \cdots O_t)$, $y = d(O_c \cdots N_c)$ and $x = d(O_b \cdots N_t)$, and the greater values of this parameter correspond to the compounds with a major antiferromagnetic coupling. For the four compounds reported here the major distortion parameter value corresponds to the complexes with perchlorate as the monodentate ligand. Figure 9 shows the distortion parameter for the compounds reported in Table 6, in front of the magnetic coupling constant. The two extreme values of the distortion parameter are found for compound **6**, with a distortion parameter close to zero, and for compound **10**, with a distortion parameter of 5.36.

Only one of the compounds collected in Table 6 shows compressed octahedra; this is the case for compound **6** $[\{Mn(N_3)(bpy)\}_2(\mu\text{-}C_6H_4COO)_2(\mu\text{-}O)]$.[6,7] As in the case of the complexes with tridentate amines[11–13] a ferromagnetic interaction is also observed for this compound. Compound **10** $[\{MnCl(bpy)\}_2(\mu\text{-}CH_3COO)_2(\mu\text{-}O)]$[7] is the compound with the most elongated octahedra and shows major antiferromagnetic coupling. The other compounds show closest distortion parameters between 1.5 and 3.5. Two compounds reported here, **2** and **4**, in which the perchlorate anion is coordinated to the manganese ions, also show elongated octahedra, and in general the magnitude of the antiferromagnetic coupling agrees with the values found for compounds **9**[9] and **10**.[7]

When the nitrate anion is coordinated to the manganese ion the Mn–L distances are shorter. Consequently, the elongation in the $z$ axis is moderate, and the distortion is intermediate between elongated and rhombic. The first

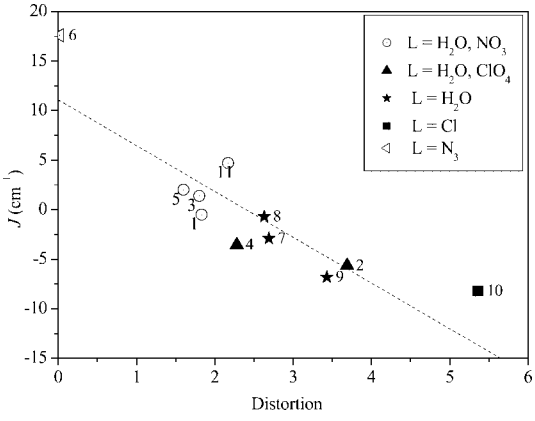

Figure 9. Correlation between the distortion around the $Mn^{III}$ ions and the magnetic interaction. The degree of distortion was measured as $(z - y)/(y - x)$, where $z = d(L \cdots O_t)$, $y = d(O_c \cdots N_c)$ and $x = d(O_b \cdots N_t)$ (See Scheme 1). The dashed line is the plot of the function $J = 11.1 - (4.6 \times \text{distortion})$, and the symbols are the experimental data.

compound of this kind described in the literature, $[\{Mn(OH)(bpy)\}(\mu\text{-}C_6H_4COO)_2(\mu\text{-}O\{Mn(NO_3)(bpy)\}]$ (**5**),[5] presents a rhombic distortion, and a ferromagnetic interaction was found. Compound **3** also shows a ferromagnetic coupling, while compound **1** is weakly antiferromagnetic. Another analogous compound reported in the literature has two different dinuclear complexes in the crystal, $[\{Mn(bpy)(H_2O)\}_2(\mu\text{-phtha})_2(\mu\text{-}O)][\{Mn(bpy)(H_2O)\}(\mu\text{-phtha})_2(\mu\text{-}O)\{Mn(bpy)(NO_3)\}](NO_3)_3$ (**11**) (phtha = phthalate),[10] one of them with two water molecules and the other with one water and one nitrate ligand. A net ferromagnetic interaction was reported for this compound, where we could expect a different degree of magnetic interaction in each dinuclear complex.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

For dinuclear $Mn^{III}$ compounds with four electrons in each manganese ion ($i$ and $j$) the magnetic coupling constant is $J = 1/16\ \Sigma\ J_{ij}$.[17] Because of the presence of one empty orbital in each manganese ion there are eight crossing interactions between each single occupied orbital and the empty orbital ($x^2$–$y^2$), and this kind of interaction is postulated as ferromagnetic.[17] The most important antiferromagnetic contribution to the magnetic behaviour is due to the $xz(1)/xy(2)$ interaction (Figure 10). The other $\pi^*$ interaction through the oxo-bridging ligand, the $xy(1)/xz(2)$ interaction, could be sensitive to the Mn–$O_b$–Mn angle. For these kinds of complexes, with $\alpha \approx 124°$, an antiferromagnetic interaction can be expected. The same occurs with the $z^2(1)/z^2(2)$ interaction: for Mn–$O_b$–Mn angles far from 90° an antiferromagnetic interaction can be expected. Other antiferromagnetic contributions are the $z^2(1)/xz(2)$ and the $xy(1)/z^2(2)$ interactions. Subsequently, there are an important number of interactions of both signs, ferro- and antiferromagnetic, and the resultant magnetic behaviour of a compound is because of the balance of these contributions.

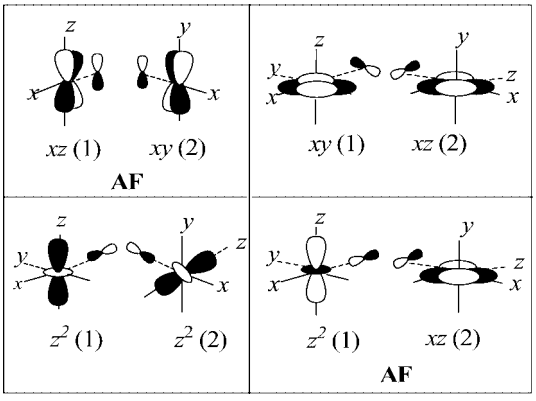

Figure 10. Schematic representation of the magnetic exchange pathway.

## Extended Hückel Calculations

In an attempt to rationalize the magnetic properties of the compounds **1**–**4**, we found that their molecular geometries can be differentiated by the following factors:

(a) the nature of the substituent of the benzoate bridge, with a $CH_3$ group for compounds **1** and **2** and an electron-withdrawing F atom for compounds **3** and **4**;

(b) the position of the F atom or the $CH_3$ group in the aromatic ring: the $CH_3$ group is on the side of the $O_t$ atom, while the F atom is placed on the side of the $O_c$ atom; (Figure 7)

(c) the nature of the monodentate ligand, which could be $H_2O$, $NO_3$ or $ClO_4$;

(d) the dihedral angle between the carboxylate group and the phenylic ring, defined by the $\delta(O_tC_1C_2C_3)$ angle (Figure 7);

(e) the relative orientation of the nitrate ligand in the environment of manganese, defined by the $\gamma$(ONOMn) angle.

With the aim of determining the effect of these factors on the magnetic properties, Extended Hückel calculations were carried out on the crystallographic coordinates of compounds **1**–**4** using the CACAO program.[18] Taking into consideration that in compounds **1** and **3** the monodentate ligand $H_2O$ could be replaced by the $NO_3$ anion, the different complexes present in the crystal, in each case, have been studied. Other calculations carried out were:

– the dihedral angle between the COO group and the aromatic ring, $\delta$, was modified from the original crystallographic coordinates and two values are considered: $\delta = 17°$ and 45°;

– the substituent on the aromatic ring, $CH_3$ or F was replaced by the other group (F or $CH_3$, respectively), in the same position as the original compound, and also, in the opposite position;

– for compounds **1** and **3** the crystallographic coordinates of the nitrate group have been modified, with $\gamma$ angles between 0–180°;

– with the aim of making comparisons with other compounds with nitrate ligands calculations with the crystallographic coordinates of compounds **5**[5] and **11**[10] have been also carried out. And the position of the nitrate ligand was also modified with $\gamma$ angles between 0–180°.

Considering the axis depicted in Scheme 1, the $x^2$–$y^2$ orbital of each manganese atom points to the $O_b$, $O_c$ of the carboxylate group and both N atoms of the bidentate ligand, and the $z^2$ orbital points to the monodentate ligand L and the $O_t$ atom. The energy diagram and the shape of the MO's are similar for all the studied compounds except for the MO with contributions from the $z^2$ orbital of the manganese ions. In all cases, the $z^2$ orbitals of the manganese ions contribute significantly to the first single occupied orbitals. The $z^2$ orbital of each manganese ion could overlap with the orbitals of the ligands in the $z$ axis (L and $O_t$), and to a lesser degree with the ligands in the equatorial plane ($O_b$, $N_t$, $N_c$ and $O_c$). The two resultant molecular orbitals are each considerably localized on one of the manganese atoms, even if a small contribution of the bridging ligands is present.

The analysis of the results shows a very small effect in the energy and composition of the MO by modification of the torsion angle between the carboxylate group and the aromatic ring, and the last with its substituent group. However, both factors modify the positive charge on the manganese ions. The clearest effect is due to the substituent in the aromatic ring: with the same crystallographic parameters the exchange $CH_3$/F slightly modifies the positive charge on the manganese ions (the methyl group, with a donor effect, decreases the positive charge on the manganese ions while the F atom, with a withdrawing effect, increases the positive charge).

The dinuclear complexes listed in Table 6 show different kinds of monodentate ligands: $H_2O$, $OH^-$, $ClO_4^-$, $Cl^-$, $NO_3^-$ and $N_3^-$. The $H_2O$, $ClO_4^-$ and $Cl^-$ ligands act as σ-donor ligands, and their HOMO's are low in energy. On the other hand, the $NO_3^-$ and $N_3^-$ ligands show two orbitals with similar energies to the d-orbitals of the manganese ions: a

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

filled nonbonding orbital with a σ-donor character and an empty π* orbital.

For the nitrate complexes with 2-$MeC_6H_4COO$ (**1**), 2-$FC_6H_4COO$ (**3**) and 2-$OOCC_6H_4COO$ (**11**) an important overlap between the empty π* orbital of the nitrate ligand and the $z^2$ of the $Mn^{III}$ ion is observed. Then, two molecular orbitals $\pi_L^* \pm z^2_{Mn}$ were found for each metallic centre. In contrast, for compound **5** [{Mn(OH)(bpy)}(μ-PhCOO)$_2$-(μ-O){Mn($NO_3$)(bpy)}][5] no contribution of the π* orbital of the nitrate ligand was found in the $z^2$ orbital. For this compound the nitrate ligand acts only as a σ-donor ligand. The energy of the $\pi_L^*$ orbital is very sensitive to the distortions in the nitrate anion. For compound **5**, the N–O distances are quite a bit shorter than those for complexes **1**, **3** and **11** (average of 1.19 Å for **5** and average of 1.25 Å for **1**, **3** and **11**) therefore the $\pi_L^*$ was found at a higher energy and no appreciable interaction with the $z^2$ of the metal was observed.

Another factor to consider is the orientation of the nitrate group. The combination $\pi_L^* \pm z^2_{Mn}$ must be sensitive to the orientation of the nitrate group in front of the $z$ axis. This orientation is related to the torsion angle $\gamma$(ONOMn). When the nitrate group is perpendicular to the $z$ axis ($\gamma$ = 90°) (Figure 11) a good overlap between the $\pi_L^*$ and the $z^2_{Mn}$ orbital can be found, while for the other extreme when the nitrate ligand is aligned to the $z$ axis ($\gamma$ = 0° or 180°) the overlap vanishes.

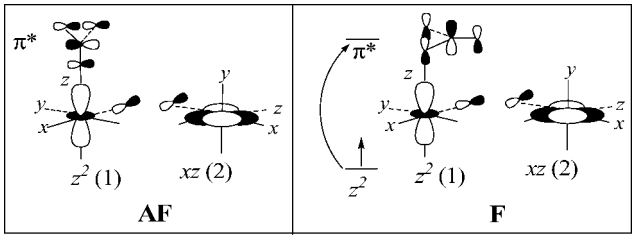

Figure 11. Schematic representation of the effect of the $NO_3^-$ ligand in the $z^2$–$xz$ antiferromagnetic contribution.

Then, for compound **5**, the small $\gamma$ angle and short N–O distances could explain that the $\pi_L^*$ orbital does not contribute to the $z^2$ orbital. In compound **1**, with 2-$MeC_6H_4$-COO bridges, the nitrate ligand shows a good overlap between the $\pi_L^*$ orbital and the $z^2_{Mn}$ orbital. The two combinations, $\pi_L^* \pm z^2_{Mn}$ show an important contribution of the nitrate and the manganese orbitals (39% Mn and 42% nitrate and 29% Mn and 63% nitrate). For compound **3**, with 2-$FC_6H_4COO$ bridges, the nitrate ligand is placed more parallel to the $z$ axis and the two MO's are more localized, one of them with a major contribution from the manganese ion (61% Mn and 23% nitrate) and the other one with a major contribution from the nitrate group (12% Mn and 82% nitrate). For the nitrate complex of compound **11** the higher energy orbital shows a major contribution from the π* of the nitrate ligand (60% of nitrate and 19% of $z^2_{Mn}$)

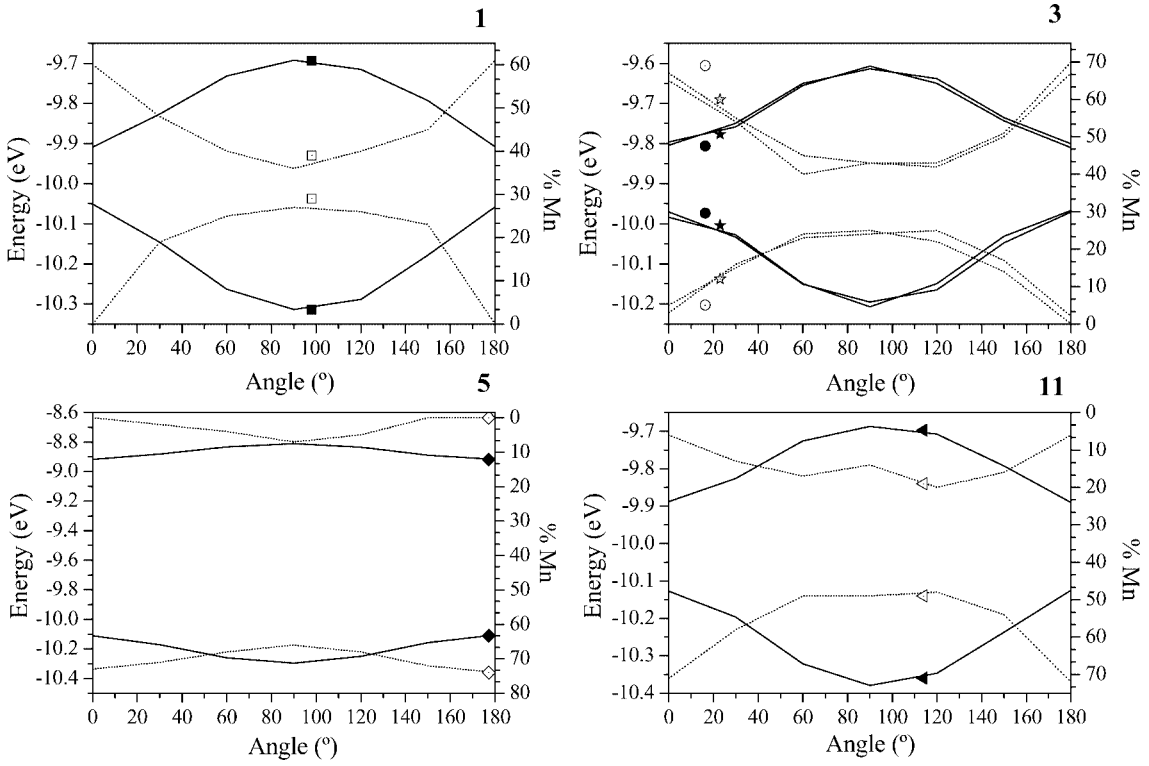

Figure 12. Energy of the $z^2 \pm \pi^*$ orbitals (solid line), and contribution of the Mn ions (%) to the MO (dotted line) as a function of the Mn–O–N–O angle ($\gamma$ angle) for compounds **1** (top, left), **3** (top, right), **5** (bottom, left) and **11** (bottom, right). The filled symbols show the energy and the dotted symbols show the composition (% Mn) of the orbitals found for the real compounds (experimental values of $\gamma$, Table 6). For compound **3** the coordination of the two nitrates is considered.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

while the lower energy orbital shows a major contribution from the $z^2_{Mn}$ orbital (49%) and 31% of the π* orbital of the monodentate ligand.

Figure 12 shows the effect in the energy and composition of the $\pi_L^* \pm z^2_{Mn}$ orbitals by the variation of the Mn–O–N–O angle ($\gamma$), between 0–180°. This variation is not appreciable for compound **5**. For compounds **1**, **3** and **11** the modification of this torsion angle has an important effect. The major energy gap between the MO $\pi_L^*+z^2_{Mn}$ and $\pi_L^*-z^2_{Mn}$ orbitals was found for $\gamma \approx 90°$, and with this orientation a similar contribution of the $\pi_L^*$ and $z^2_{Mn}$ was found in all cases. Consequently, the nitrate ligand could act as a π-acid ligand, providing a means for the delocalization of the electronic density of the manganese $z^2$ orbital onto the ligand. This situation is enhanced if the nitrate ligand is placed perpendicular to the $z$ axis. Then, the antiferromagnetic interactions $z^2(1)/xz(2)$ and $xy(1)/z^2(2)$ could diminish, and when the delocalization to the empty π* orbital of the nitrate ligand is important the ferromagnetic contribution could be increased. This could explain the minor antiferromagnetic interaction observed for the nitrate complexes **1** and **3** in comparison to their analogous compounds with perchlorate ligands.

On the other hand, the energy of the $z^2$ orbital decreases considerably by increasing the elongation in the $z$ direction, therefore the antiferromagnetic interaction $z^2(1)/xz(2)$ and $xy(1)/z^2(2)$ could be more efficient; increases the antiferromagnetic contribution resulting in a more negative value for the overall coupling, as is observed for compounds **2**, **4**, **7**, **9** and **10**.

## Conclusions

In this paper we reported the synthesis of four dinuclear $Mn^{III}$ complexes with the general formula [{Mn(bpy)L}(μ-RCOO)$_2$(μ-O){Mn(bpy)L′}]$X_{2-m}$ (RCOO = 2-$MeC_6H_4$COO and 2-$FC_6H_4$COO); these compounds show a labile position on each manganese ion, which could be occupied by different ligands: $H_2O$, $NO_3^-$ or $ClO_4^-$. The magnetic properties are sensitive to the carboxylate bridges and the counteranion/monondentate ligand: compounds with 2-$MeC_6H_4$COO show much more antiferromagnetic coupling than compounds with 2-$FC_6H_4$COO, and perchlorate complexes show more of an antiferromagnetic interaction than the nitrate complexes. Several factors are being evaluated by Extended Hückel calculations and show that that the most important effect is the coordination of the nitrate ligand and their orientation, parallel to the $z$ axis (small values of $\gamma$) or perpendicular to the $z$ axis ($\gamma$ close to 90°). This ligand could act as a π-acid ligand and then provide a new ferromagnetic means of interaction.

## Experimental Section

**Synthesis:** All manipulations were performed under aerobic conditions. Organic reagents were used as received. $Bu_4NMnO_4$ was prepared as described in the literature.[19] The yield was calculated from the total available Mn.

***Caution!*** Perchlorate salts of compounds containing organic ligands are potentially explosive. Only small quantities of these compounds should be prepared and handled behind protective shields.

**[{Mn(bpy)L}(μ-2-RC$_6$H$_4$COO)$_2$(μ-O) {Mn(bpy)L′}]X$_{2-m}$, with R = CH$_3$ and X = NO$_3^-$ (1), ClO$_4^-$ (2), R = F and X = NO$_3^-$ (3), ClO$_4^-$ (4); L and L′ = H$_2$O or X:** The four compounds were synthesized using the same procedure: 1.6 mmol of the benzoic derivative acid (0.22 g of 2-$MeC_6H_4COOH$ or 0.23 g of 2-$FC_6H_4COOH$) was added to a solution containing the $Mn^{II}$ salt (1.28 mmol) in MeCN, $Mn(NO_3)_2{\cdot}4H_2O$ (0.32 g) or $Mn(ClO_4)_2{\cdot}6H_2O$ (0.45 g). $Bu_4NMnO_4$ (0.11 g, 0.32 mmol) dissolved in MeCN was then added to the solution, which immediately turned dark brown. Finally, a MeCN solution of 2,2′-bipyridine (0.25 g, 1.6 mmol) was added and the resulting solution was stirred for some minutes. The total volume for the nitrate compounds (**1** and **3**) was 100 mL, and was 30 mL for the perchlorate compounds (**2** and **4**). Small dark crystals were obtained from the nitrate solutions when they were left undisturbed in the refrigerator for several days (compounds **1** and **3**). For the compounds with perchlorate anions suitable X-ray diffraction crystals were obtained in the presence of $CH_2Cl_2$. The compound with the 2-$MeC_6H_4COO^-$ bridging ligand crystallized from the mother MeCN solution mixed with $CH_2Cl_2$ (1:1), which was layered with hexanes and left undisturbed at room temperature. While for the compound with 2-$FC_6H_4COO^-$ bridges, the mother MeCN solution was kept inside a container with an atmosphere of $CH_2Cl_2$ and after several days at room temperature crystals of compound **4** were obtained.

**Compound 1, [{Mn(bpy)(H$_2$O)}(μ-2-MeC$_6$H$_4$COO)$_2$(μ-O){Mn(NO$_3$)(bpy)}]NO$_3$·H$_2$O:** Yield 0.38 g (ca. 56%). $C_{36}H_{32}Mn_2N_6O_{12}{\cdot}H_2O$ (868.56): calcd. 1000 G) and the magnetization (at 2 K between 0–50000 G) were measured with a SQUID magnetometer, Quantum Design Magnetometer, model MPMP. Pascal's constants were used to estimate the diamagnetic corrections for each compound. The fits were performed by minimizing the function $R = \Sigma(\chi_M \cdot T_{exp} - \chi_M \cdot T_{calcd})^2 / \Sigma(\chi_M \cdot T_{exp})^2$. All the samples were prepared by crushing the crystalline products.

**Crystallographic Measurements:** A green plate crystal ($0.50 \times 0.50 \times 0.15$ mm) of [{Mn(bpy)($H_2O$)}(μ-2-$MeC_6H_4COO)_2$(μ-O){Mn($NO_3$)(bpy)}]$NO_3 \cdot 1.5CH_3CN \cdot 2H_2O$ (**1**), a brown block crystal ($0.28 \times 0.15 \times 0.15$ mm) of [{Mn(bpy)($H_2O$)}$_2$-(μ-2-$MeC_6H_4COO)_2$(μ-O)][{Mn($ClO_4$)(bpy)}$_2$(μ-2-$MeC_6H_4COO)_2$-(μ-O)]$(ClO_4)_2 \cdot 0.5CH_2Cl_2$ (**2**), a black block crystal ($0.50 \times 0.50 \times 0.40$ mm) of [{Mn(bpy)($H_2O$)}(μ-2-$FC_6H_4COO)_2$(μ-O){Mn($NO_3$)(bpy)}]-$NO_3 \cdot H_2O$ (**3**) and a dark green block crystal ($0.50 \times 0.25 \times 0.20$ mm) of [{Mn(bpy)($H_2O$)}(μ-2-$FC_6H_4COO)_2$(μ-O){Mn($ClO_4$)(bpy)}]-$ClO_4 \cdot 2CH_2Cl_2$ (**4**) were chosen for X-ray diffraction experiments. The unit cell and intensity data were measured with a Bruker SMART CCD area detector single-crystal diffractometer with graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) operating at 50 kV and 30 mA. A total of 1271 frames of intensity data were collected over a hemisphere of the reciprocal space by a combination of three exposure sets. Each frame covered 0.3° in $\omega$ and the first 50 frames were recollected at the end of the data collection to monitor crystal decay. Absorption corrections were applied using the SADABS program.[20] The structures were solved using the Bruker SHELXTL-PC software[21] by direct methods and refined by full-matrix least-squares methods on $F^2$. Hydrogen atoms were included in calculated positions and refined in the riding mode except those of the water molecules that were located on residual density maps, and their positions were then fixed and refined in the riding mode. All non-hydrogen atoms were refined anisotropically. Crystal data collection and refinement parameters are given in Table 7. Further details, concerning disorder for example, are given in the crystallographic CIF files. CCDC-288243 to -288246 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

# Synthesis and Reactions of Stannole Anions

Ryuta Haga,[a] Masaichi Saito,*[a] and Michikazu Yoshioka[a]

**Keywords:** Anions / Aromaticity / Lithium / Metallacycles / Tin

The synthesis of stannole anions bearing various substituents on the tin atom is described. The reduction of hexaphenylstannole by the proper amount of lithium gave 1,2,3,4,5-pentaphenylstannole anion **1**. The reaction of **1** with 1,*n*-dihaloalkanes (*n* = 1, 3, 4, 5, 6) gave the corresponding 1,*n*-bis(1-stannacyclopentadien-1-yl)alkanes. In contrast, the reaction of **1** with 1,2-dihaloalkanes gave the 1,1′-bistannole. The reactions of stannole dianion **3** with an equimolar amount of bulky alkyl, aryl, silyl, and stannyl halides gave the corresponding stannole anions.

## Introduction

Metalolyl anions of heavier group 14 elements have received considerable attention in view of their potential aromatic character as heavier congeners of the cyclopentadienyl anion,[1] since the first report on the generation of a silole anion in 1958.[2] Over the past few decades, silole and germole anions have already been synthesized by deprotonation, dehalogenation, or transmetallation of the corresponding metaloles, and their structures have been discussed extensively by NMR, or X-ray structural analysis.[3–6] Boudjouk reported the first NMR characterization of a silole anion.[5] The negative charge was concluded to delocalize in the silole ring. In contrast to Boudjouk's silole anion, in some silole and germole anions, the negative charge localizes on the central atom, as evidenced by NMR[4] and/or X-ray structural analyses.[6] Although remarkable progress has been made on silicon and germanium analogues, no stannole anion had been reported before we undertook a study on such species a few years ago.[7] First, we reported the synthesis of 1,2,3,4,5-pentaphenylstannole anion **1** by the reaction of 1,1′-bistannole **2** with lithium (Scheme 1).[8] However, it was difficult to manipulate the stoichiometry or reaction conditions to produce stannole anion **1** without stannole dianion **3** from the 1,1′-bistannole **2** because no sufficient amount of **2** could be obtained in several steps from diphenylacetylene.[7–9] To investigate the chemistry of stannole anions, alternative methods for the synthesis of stannole anions using an easily accessible starting material were required. Very recently, we reported an efficient synthesis of the first tin-containing carbocyclic aromatic stannole dianion **3** by the reaction of hexaphenylstannole (**4**) with excess lithium and discussed its aromaticity by the aid of NMR studies, X-ray analysis and theoretical calculations (Scheme 2).[10,11] Furthermore, we reported the oxidation of the stannole dianion **3** to the 1,1′-bistannole dianion **5** as a novel method for the synthesis of a stannole anion.[12]

Herein we describe novel methods for the preparation of stannole anions: (i) the reduction of hexaphenylstannole (**4**) with the proper amount of lithium, and (ii) the reaction of the stannole dianion **3** with various halogen reagents. NMR studies on stannole anions and their reactions are also reported.

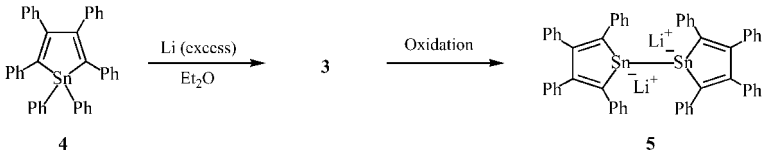
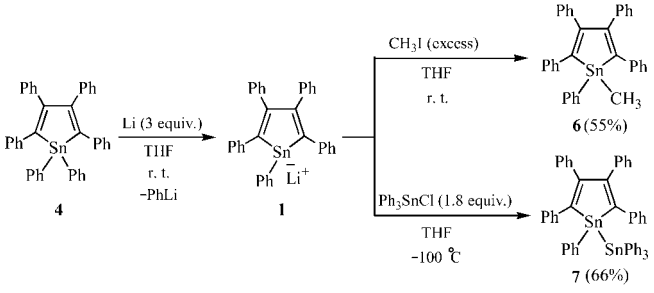


Scheme 2.

tion, suggesting the formation of an anion species. After stirring the reaction mixture for 6 h, addition of excess methyl iodide to this reaction mixture gave 1-methyl-1,2,3,4,5-pentaphenylstannole (**6**)[8] in 55% yield, indicating the effective formation of pentaphenylstannole anion **1** from **4** (Scheme 3). Treatment of **1** thus obtained with 1.8 equiv. of chlorotriphenylstannane at –100 °C gave 1-triphenylstannyl-1,2,3,4,5-pentaphenylstannole (**7**) in 66% yield.



Scheme 3.

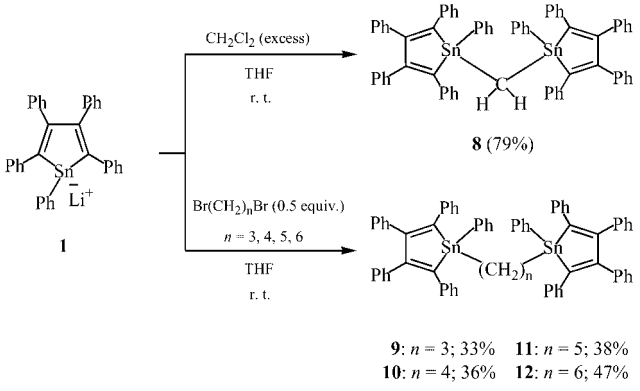
The reaction of **4** with 3 equiv. of lithium was monitored by NMR spectroscopy. In the $^{119}$Sn NMR spectrum, only one signal was observed at $\delta$ = –28.6 ppm in the same region as that in the previous synthesis from the 1,1′-bistannole **2**,[8,9] suggesting the formation of **1**. In contrast to the reduction of 1,1′-bistannole **2** to form both stannole anion **1** and the stannole dianion **3**, the $^{13}$C NMR spectrum revealed the clean formation of the stannole anion **1**. Although some unidentifiable signals were observed, the signals due to the stannole anion **1** could be completely assigned by the comparison of the chart of the mixture of the stannole anion **1** and the stannole dianion **3** obtained by the reduction of the 1,1′-bistannole **2**.[14] A phenyl group of hexaphenylstannole (**4**) was eliminated probably as phenyllithium, as in the reduction of hexaphenylstannole (**4**) to form the stannole dianion **3**,[10] although the signals due to phenyllithium were not observed in the reaction mixture. The signal assignable to the α-carbon atom in the five-membered ring was observed at $\delta$ = 176.5 ppm, judging from the large tin–carbon coupling constant of about 171 Hz. The low-field resonance of the α-carbon atom could be explained by paramagnetic contribution of a tin–carbon bond as was observed in the stannole dianion **3**.[10] In the $^{7}$Li NMR spectrum, a single resonance was observed at $\delta$ = –0.64 ppm. In contrast to the successful isolation of the stannole dianion **3**, recrystallization of the reaction mixture to purify the stannole anion **1** was not successful. Thus, the degree of aromaticity of **1** using the $^{7}$Li chemical shift could not be estimated because intermolecular exchange of lithium cations between **1** and phenyllithium could not be suppressed. Although the yield of **1** could not be estimated, the yields of the trapping products **6** and **7**, and the NMR spectra of **1**, especially the $^{119}$Sn NMR spectrum, suggest that the generation efficiency should be very high.

### *Reaction of Stannole Anion 1 with Dihaloalkanes*

Connecting two stannole skeletons with a hydrocarbon chain is a subject of interest because two stannole rings could face each other to reveal unique electronic properties resulting from through-space π-facial interactions.[15]

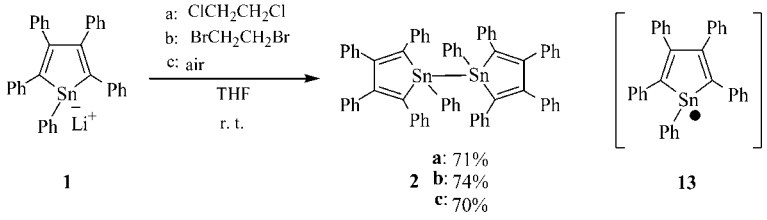
Reaction of **1** with excess dichloromethane gave bis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadien-1-yl)methane (**8**) in 79% yield (Scheme 4). Compound **8** was proved to have a symmetrical structure having an Sn–C–Sn skeleton by $^{2}J$(Sn–Sn) of 284 Hz in the $^{119}$Sn NMR spectrum. The bis(stannoles) **9**–**12**, whose two stannole rings are connected by a saturated hydrocarbon chain were also synthesized by the reaction of **1** with 0.5 equiv. of the corresponding 1,*n*-dibromoalkanes (*n* = 3–6) in moderate yields (Scheme 4). The structures of all the bis(stannoles) thus obtained were determined by NMR spectroscopy and elemental analysis. These results are similar to the formation of 1,3-bis(triphenylstannyl)propane from triphenylstannyl anion and 1,3-dibromopropane.[16]

On the other hand, reactions of the stannole anion **1** with 1,2-dihaloethanes gave bi(1,2,3,4,5-pentaphenyl-1-stannacyclopentadien-1-yl) (**2**)[8,9] in about 70% yields. Oxidation



Scheme 4.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

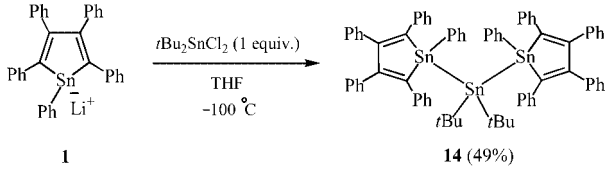


Scheme 5.

of the stannole anion **1** by air also gave **2** in high yield (Scheme 5). The formation of **2** can be reasonably interpreted in terms of the dimerization of stannole radical **13** resulting from oxidation of **1** by air or dihaloethanes. Evidently, dihaloethanes function as one-electron oxidants in these reactions.[17]

### *Reaction of Stannole Anion 1 with Di-tert-butyldichlorostannane*

Reaction of the stannole anion **1** with di-*tert*-butyldichlorostannane at –100 °C gave di-*tert*-butylbis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadien-1-yl)stannane (**14**) in 49% yield (Scheme 6). In the $^{119}Sn$ NMR spectrum, two signals are observed with an intensity ratio of 2:1, resulting from the two equivalent terminal and one central tin atoms, respectively.



Scheme 6.

### *Photophysical Properties of Bis(stannoles) 8–12 and 14*

We examined the photophysical properties of the newly obtained bis(stannoles) **8**–**12** and **14** whose two stannole rings are connected by a saturated hydrocarbon or a stannyl chain. UV/Vis absorption spectra for **4**,[16] **8**–**12**, and **14** are listed in Table 1. The absorption maxima of **8**–**12** appear at almost the same wavelength as that of **4**, reflecting the same chromophore. Namely, the absorption is derived from the π–π* transition of the stannole ring.[18] The π–π* transitions of group 14 metaloles are observed in the same region at about 360 nm because the contribution of the diene moiety to both HOMO and LUMO is more predominant than that of the metal moiety.[18] This spectral feature suggests no significant through-space interaction between the two stannole rings in solution. Compound **14** displays two shoulder absorption bands at about 310 and 370 nm. The latter band can be assigned to π–π* transition of the stannole ring. The shorter band can be assigned to the transition of σ(Sn–Sn) to π* of the diene moiety because the corresponding band is absent in other bis(stannoles), **8**–**12** with no tin–tin bond.[9]

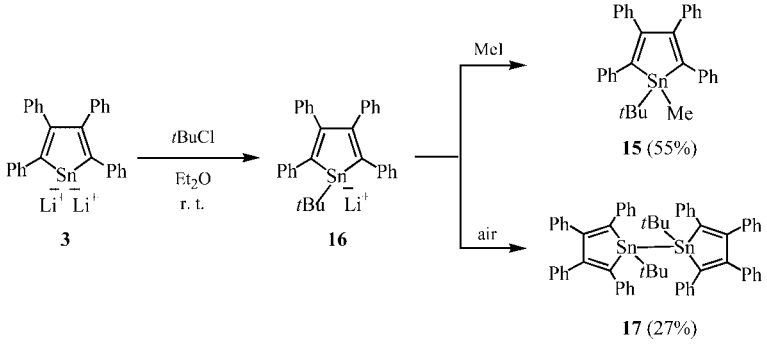
Table 1. UV/Vis absorptions of stannole **4** and bis(stannoles) **8**–**12**, **14** in $CH_2Cl_2$.

| Compound | $\lambda_{max}$/nm ($\varepsilon$) |
|---|---|
| **4** | 355 (12000) |
| **8** ($n$ = 1) | 359 (20000) |
| **9** ($n$ = 3) | 353 (10600) |
| **10** ($n$ = 4) | 353 (8800) |
| **11** ($n$ = 5) | 353 (16500) |
| **12** ($n$ = 6) | 349 (4100) |
| **14** | 315 (12000) 373 (6800) |

## Synthesis of Stannole Monoanions from Stannole Dianion 3

### *Alkylation of Stannole Dianion 3*

Because the reaction of **3** with methyl iodide gave 1,1-dimethylstannole,[8] *tert*-butyl chloride was chosen as a bulkier alkylating reagent than methyl iodide.[19] When



Scheme 7.

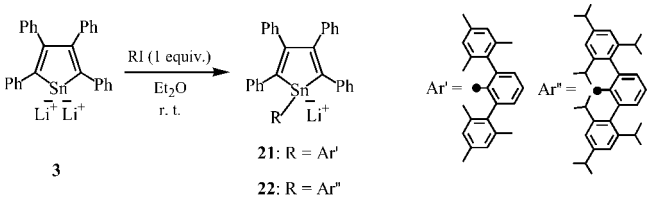
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1 equiv. of *tert*-butyl chloride was added to a diethyl ether solution of the stannole dianion **3**, the color of the reaction mixture changed from deep red to bright red. By treatment of the reaction mixture with methyl iodide, the 1-*tert*-butyl-1-methylstannole **15**[19] was obtained in 55% yield, suggesting the formation of the stannole anion **16** bearing a *tert*-butyl group on the tin atom (Scheme 7). The formation of **16** from **3** is reasonably explained by an electron-transfer mechanism, as observed in the reaction of the tributylstannyl anion with *tert*-butyl halides.[20] The reaction of **3** with *tert*-butyl chloride followed by exposure of the reaction mixture to air gave the 1,1′-bistannole **17**[8,9] in 27% yield. The formation of **17** is interpreted in terms of the dimerization of the 1-*tert*-butylstannole radical resulting from the oxidation of **16**, as was observed in the oxidation of pentaphenylstannole anion **1** (Scheme 5).

### *Arylation of Stannole Dianion 3*

Next we examined the synthesis of 1-arylstannole anions by the reaction of the stannole dianion **3** with aryl halides. Reactions with small aryl halides, however, became complicated because of the formation of mono- and disubstituted products. Thus, bromo-2,4,6-triisopropylbenzene was chosen as a bulky aryl halide. On treatment of the stannole dianion **3** with 1 equiv. of 1-bromo-2,4,6-triisopropylbenzene in diethyl ether at room temperature, the color of the reaction mixture remained deep red, indicating the existence of an anion species. After addition of methyl iodide to the reaction solution, the color of the reaction mixture changed to green. After usual workup, the 1-methyl-1-(2,4,6-triisopropylphenyl)stannole **18** was obtained in 29% yield, indicating the formation of the intermediary stannole anion **19** bearing a 2,4,6-triisopropylphenyl group on the tin atom (Scheme 8). Treatment of **3** with 1-bromo-2,4,6-triisopropylbenzene followed by exposure of the reaction mixture to air gave a complex mixture without the formation of the expected 1,1′-bistannole **20**. The dimerization of the intermediary stannole radical generated by oxidation of **19** is suppressed due to the steric congestion around the tin atom, preventing the formation of **20**.

We examined the synthesis of the stannole anions **21** and **22** having an *m*-terphenyl group, Ar′ = $C_6H_3$-2,6-$Mes_2$ (Mes = $C_6H_3$-2,4,6-$Me_3$) and Ar″ = $C_6H_3$-2,6-$Tip_2$ (Tip = $C_6H_3$-2,4,6-*i*$Pr_3$), respectively, as a more bulky group than a Tip group on the tin atom (Scheme 9). The NMR spectra of these reaction mixtures suggest the formation of **21** or **22** (vide infra), although trapping of **21** and **22** with appropriate reagents was not successful.

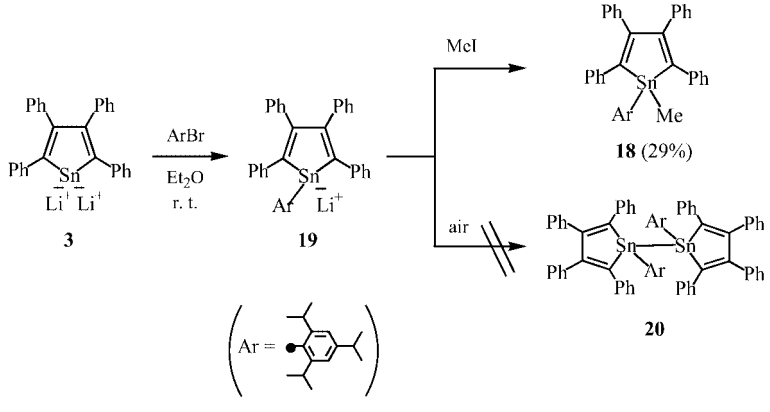


Scheme 9.

The formation of **19** from **3** can be also explained by an electron-transfer mechanism, as observed in the reaction of **3** with *tert*-butyl chloride (Scheme 7) because electrophilic substitution reactions rarely occur in simple aryl halides.

### *Silylation or Stannylation of Stannole Dianion 3*

On treatment of the stannole dianion **3** with 1 equiv. of chlorotriisopropylsilane in diethyl ether at room temperature, the color of the reaction mixture remained deep red. The NMR spectra of the reaction mixture reveal the presence of only one species which can be assigned to the 1-silyl-substituted stannole anion **23** (Scheme 10). Trapping of **23** by methyl iodide, however, gave a complex mixture. The reaction of the stannole dianion **3** with 1 equiv. of chlorotriphenylstannane in diethyl ether at room temperature gave a dark-brown solution. The formation of the 1-stannyl-substituted stannole anion **24** was evidenced by a chemical trapping reaction. Addition of methyl iodide or chlorotriphenylstannane to the solution of **24** gave the 1-methyl-1-(triphenylstannyl)stannole **25** and the 1,1-bis(triphenylstannyl)stannole **26** in 47 and 39% yields, respectively (Scheme 10).



Scheme 8.

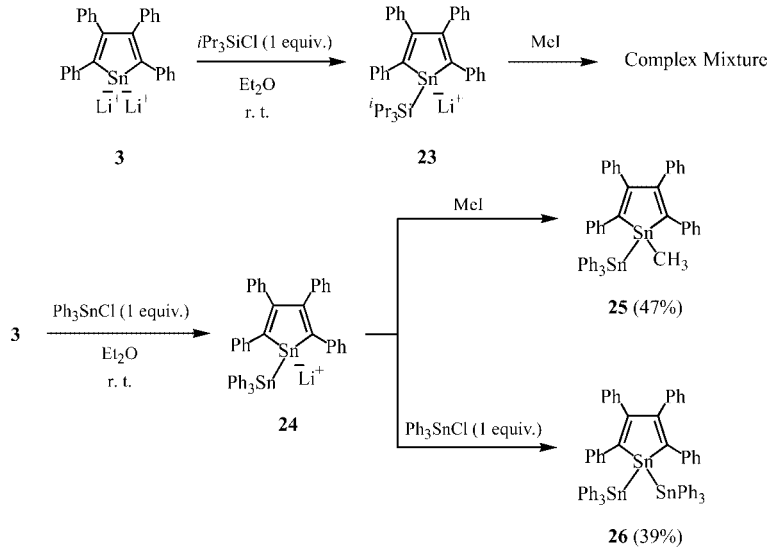
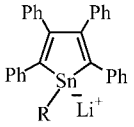


Scheme 10.

### *NMR Studies of the Newly Obtained Stannole Anions*

The structure in solution of the stannole anions was characterized by $^{1}H$, $^{13}C$, $^{119}Sn$ and $^{7}Li$ NMR spectroscopy (Table 2). In the $^{119}Sn$ NMR spectra, there appears only one signal assignable to the 1-*tert*-butyl-substituted stannole anion **16** at δ = 30.4 ppm, suggesting that the generation efficiency of **16** is relatively high, although the isolation of **16** by recrystallization was not successful. The resonance is at lower field than that of hexaphenylstannole (**4**) (δ = –88 ppm) or pentaphenylstannole anion **1** (δ = –28.6 ppm). The $^{119}Sn$ NMR signal of the stannyl anion ($t$Bu$_2$HSn–Sn$t$Bu$_2$Li) appears at low field (δ = 107.8 ppm in $D_2O$/THF).[21] Thus, the low-field shift of the stannole anion **16**

Table 2. Selected $^{13}C$, $^{119}Sn$ and $^{7}Li$ NMR chemical shifts of stannole anions (ppm).



| Compounds | δ($^{13}C_\alpha$) | δ($^{13}C_\beta$) | δ($^{7}Li$) | δ($^{119}Sn$) |
|---|---|---|---|---|
| **1** (R = Ph) | 176.47 ($J_{C, Sn}$ = 171 Hz) | 150.24 | -0.64 | -28.6 |
| **16** (R = *t*Bu) | 170.66 ($J_{C, Sn}$ = 113 Hz) | 151.78 | 0.92 | 30.4 |
| **19** (R = Tip) | 170.39 ($J_{C, Sn}$ = 90 Hz) | 148.97 | 0.95 | -49.6 |
| **21** (R = $Mes_2C_6H_3$) | 170.34 | [a] | 0.15 | –50.2 (br) |
| **22** (R = $Tip_2C_6H_3$) | 170.33 | [a] | 0.61 | –47.1 |
| **23** (R = Si*i*Pr$_3$) | 156.01 ($J_{C, Sn}$ = 190 Hz) | 145.50 | 0.48 | –218.5 ($J_{Sn, Si}$ = 380 Hz) |
| **24** (R = $SnPh_3$) | 172.03 ($J_{C, Sn}$ = 150 Hz) | 148.85 | -0.74, 0.62 | –240.5 (ring) ($J_{Sn, Sn}$ = 3800 Hz) |

[a] Not identified.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

can be explained by the substituent effect of the *tert*-butyl group on the tin atom. On the other hand, the $^{119}$Sn NMR signals of the stannole anions **19**, **21** and **22**, bearing an aryl group on the tin atom are observed at δ = –49.6 (Ar = Tip), –50.2 (Ar′ = $C_6H_3$-2,6-$Mes_2$) and –47.1 (Ar′′ = $C_6H_3$-2,6-$Tip_2$) ppm in the region similar to that of pentaphenylstannole anion **1**. Although the isolation of **19**, **21** and **22** by recrystallization was not successful, the $^{119}$Sn NMR signals due to **19**, **21** and **22** were major in each reaction mixture. Thus, the generation efficiency of **19**, **21** and **22** was estimated to be relatively high. The signal assignable to 1-silyl-substituted stannole anion **23** was observed at δ = –218 ppm with a coupling constant of 380 Hz resulting from a tin–silicon bond. The high-field resonance is characteristic of silyl-substituted stannanes.[22] Although the isolation of **23** by recrystallization was not successful, the generation efficiency of **23** was estimated to be very high, judging from the clean $^{119}$Sn, $^{13}$C, and $^{1}$H NMR spectra of the reaction mixture. The $^{119}$Sn NMR spectrum of the 1-stannyl-substituted stannole anion **24** reveals two signals at δ = –98.7 and –240.5 ppm, assignable to the triphenylstannyl and the stannole moieties, respectively. Each signal has a coupling constant of about 3800 Hz resulting from a tin–tin bond. Although hexaphenyldistannane was also generated in the reaction mixture as a minor product, probably because stannole dianion **3** functions as a reductant for triphenylstannyl chloride, the generation efficiency of **24** was estimated to be relatively high.

The $^{13}$C NMR signals due to **16**, **19**, **23** and **24** could be assigned completely. In particular, a characteristic low-field signal assignable to the α-carbon atom in **16**, **19** and **24** was observed at δ ≈ 170 ppm with a large tin–carbon coupling constant of about 90–150 Hz, as was observed in the stannole dianion **3** and pentaphenylstannole anion **1**. Interestingly, the α-carbon atom of **23** (δ = 156.0 ppm), assigned by a large tin–carbon coupling constant of about 190 Hz, appears at higher field than those of other stannole anions, probably due to the effect of the silyl group on the tin atom. The $^{13}$C NMR signals due to the α-carbon atom of **21** and **22** could be observed at δ = 170.34 ppm for **21** and δ = 170.33 ppm for **22**. Other signals in the $^{13}$C NMR spectra, however, are too complicated to be assigned, probably due to steric congestion around the tin atom. The $^{7}$Li NMR signals of all the stannole anions are observed at δ ≈ 0 ppm.

## Conclusions

We have succeeded in an efficient synthesis of pentaphenylstannole anion **1** by the reaction of hexaphenylstannole (**4**) with 3 equiv. of lithium. The stannole anion **1** reacted with 1,*n*-dihaloalkanes (*n* = 1, 3, 4, 5 and 6) to give the corresponding adducts, as do common organostannyl anions. On the other hand, 1,2-dihaloethanes reacted with **1** as one-electron oxidants. The UV/Vis spectra of the newly obtained bis(stannoles) reveal no significant interaction between the two stannole rings in solution. The synthesis of a variety of stannole anions from stannole dianion **3** could be also achieved. The formation of the anions was clearly evidenced by NMR analysis and chemical trapping reactions. The $^{7}$Li NMR signals of these stannole anions are observed at δ ≈ 0 ppm. The aromaticity of the newly obtained stannole anions can not be presently discussed by using $^{7}$Li NMR spectroscopy because of the involvement of exchange of lithium cations as well as a small possibility of $\eta^5$-coordination of a lithium cation to the stannole anion.

## Experimental Section

**General Procedures:** All experiments were performed under argon using a usual glass apparatus or a glovebox. THF, diethyl ether and [$D_6$]benzene were distilled from sodium/benzophenone or a potassium mirror. $^{1}$H (400 MHz) and $^{13}$C (101 MHz) NMR spectra were recorded with a Bruker AM-400 or a Bruker DRX-400 spectrometer in $CDCl_3$ or a mixture of THF or diethyl ether and [$D_6$]benzene. $^{119}$Sn (149 MHz) and $^{7}$Li (156 MHz) NMR spectra were recorded with a Bruker DRX-400 spectrometer in $CDCl_3$ or a mixture of THF or diethyl ether and [$D_6$]benzene. Wet column chromatography (WCC) was carried out with Kanto silica gel 60N. Preparative gel permeation chromatography (GPC) was carried out with an LC-918 (Japan Analytical Ind. Co., Ltd.) with JAIGEL-1H and -2H columns with chloroform as the eluent. All melting points were determined with a Mitamura Riken Kogyo MEL-TEMP apparatus and are uncorrected. Elemental analyses were carried out at the Microanalytical Laboratry of Molecular Analysis and Life Science Center, Saitama University.

**Synthesis of 1,2,3,4,5-Pentaphenylstannole Anion (1) from 1,1,2,3,4,5-Hexaphenylstannole (4):** A THF (4 mL) solution of hexaphenylstannole (**4**) (370 mg, 0.59 mmol) was treated with lithium (10 mg, 1.45 mmol) at room temperature. After the reaction mixture was stirred for 6 h, an aliquot (1.0 mL) of the reaction mixture was placed in an NMR tube with [$D_6$]benzene (0.2 mL) and the tube was degassed by freeze-pump-thaw cycles and sealed. **1:** $^{1}$H NMR (THF/$C_6D_6$): $\delta$ = 6.45–6.49 (m, 2 H), 6.55–6.58 (m, 2 H), 6.61–6.67 (m, 7 H), 6.70–6.74 (m, 4 H), 6.75–6.78 (m, 6 H), 6.86–6.90 (m, 3 H), 7.71–7.74 (m, 1 H) ppm. $^{13}$C NMR (THF/$C_6D_6$): $\delta$ = 121.36 (d), 123.51 (d), 124.10 (d), 126.44 (d), 126.56 (d), 126.59 (d), 128.54 (d), 131.58 (d), 138.66 (d), 145.59 (s), 150.24 (s), 150.66 (s, $J_{C,Sn}$ = 33 Hz), 161.96 (s), 176.47 (s, $J_{C,Sn}$ = 171 Hz) ppm. $^{119}$Sn NMR (THF/$C_6D_6$): $\delta$ = –28.6 ppm. $^{7}$Li NMR (THF/$C_6D_6$): $\delta$ = –0.64 ppm.

**Reaction of Pentaphenylstannole Anion 1 with Methyl Iodide:** To a THF (5 mL) solution of **1** prepared from **4** (148 mg, 0.235 mmol) and lithium (4 mg, 0.61 mmol) was added an excess amount of methyl iodide (1.0 mL, 1.61 mmol) at room temperature. After removal of volatile substances, the residue was subjected to column chromatography (hexane/ethyl acetate, 10:1) to afford 1-methyl-1,2,3,4,5-pentaphenylstannole (**6**) (80 mg, 0.13 mmol, 55%). **6:** M.p. 139–140 °C (decomp.) ($CH_2Cl_2$ + MeOH). $^{1}$H NMR ($CDCl_3$): $\delta$ = 0.86 (s, $J_{H,Sn}$ = 56 Hz, 3 H), 6.79–6.88 (m, 8 H), 6.94–7.06 (m, 12 H), 7.34–7.41 (m, 3 H), 7.51–7.67 (m, 2 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = –9.06 (q), 125.19 (d), 125.77 (d), 127.30 (d), 127.80 (d), 128.76 (d), 129.15 (d), 129.20 (d), 130.29 (d), 136.45 (d), 139.50 (s), 140.71 (s), 142.55 (s), 143.62 (s), 154.59 (s) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –38.8 ppm. $C_{38}H_{34}Sn$ (609.42): calcd. C 74.10, H 4.97; found C 73.84, H 4.96.

**Reaction of Pentaphenylstannole Anion 1 with Chlorotriphenylstannane:** To a THF (4 mL) solution of **1** prepared from **4** (178 mg, 0.28 mmol) and lithium (6 mg, 0.85 mmol) was added chlorotri-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

phenylstannane (202 mg, 0.52 mmol) at –100 °C. After being warmed to room temperature, the reaction mixture was stirred overnight. After removal of volatile substances, the residue was chromatographed (hexane/ethyl acetate, 10:1) to give 1,2,3,4,5-pentaphenyl-1-(triphenylstannyl)stannole (**7**) (169 mg, 0.19 mmol, 66%). **7:** M.p. 189 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 6.73–6.84 (m, 8 H), 6.85–6.92 (m, 6 H), 6.94–7.00 (m, 6 H), 7.25–7.38 (m, 12 H), 7.40–7.53 (m, 8 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 125.18 (d), 125.79 (d), 127.30 (d), 127.77 (d), 128.76 (d), 128.92 (d), 128.96 (d), 129.00 (d), 129.15 (d), 129.54 (d, $J_{C,Sn}$ = 21 Hz), 130.35 (d), 137.38 (d, $J_{C,Sn}$ = 9, 41 Hz), 136.15 (s), 140.80 (s), 142.57 (s), 146.97 (s), 154.23 (s) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –125.0 ($^1J_{Sn,Sn}$ = 3573 Hz), –111.5 ($^1J_{Sn,Sn}$ = 3573 Hz) ppm. $C_{52}H_{40}Sn_2$ (902.32): calcd. C 69.22, H 4.47; found C 68.81, H 4.36.

**Reaction of Pentaphenylstannole Anion 1 with Dichloromethane:** To a THF (5 mL) solution of **1** prepared from **4** (250 mg, 0.40 mmol) and lithium (7 mg, 1.05 mmol) was added excess dichloromethane (5 mL, 79 mmol) at room temperature. After removal of volatile substances, the residue was chromatographed (hexane/ethyl acetate, 10:1) to give bis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadienyl)-methane (**8**) (88 mg, 0.079 mmol, conv. 79%). The starting **4** was recovered in 50% yield. **8:** M.p. 226–228 °C (decomp.) ($CH_2Cl_2$ + EtOH). $^1$H NMR ($CDCl_3$): $\delta$ = 1.14 (s, $J_{H,Sn}$ = 64 Hz, 2 H), 6.71–6.77 (m, 16 H), 6.90–6.95 (m, 24 H), 7.28–7.33 (m, 6 H), 7.42–7.52 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = –15.37 (t, $J_{C,Sn}$ = 253, 256 Hz), 125.30 (d), 125.82 (d), 127.25 (d), 127.90 (d), 128.82 (d, $J_{C,Sn}$ = 39 Hz), 129.15 (d), 129.35 (d, $J_{C,Sn}$ = 22 Hz), 130.38 (d), 136.28 (d, $J_{C,Sn}$ = 41 Hz), 140.36 (s, $J_{C,Sn}$ = 18 Hz), 140.68 (s, $J_{C,Sn}$ = 70 Hz), 142.05 (s, $J_{C,Sn}$ = 47 Hz), 143.47 (s), 154.53 (s, $J_{C,Sn}$ = 89 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –29.5 ($^2J_{Sn,Sn}$ = 284 Hz) ppm. $C_{69}H_{52}Sn_2$(1118.61): calcd. C 74.09, H 4.69; found C 74.20, H 4.57.

**Reaction of Pentaphenylstannole Anion 1 with 1,3-Dibromopropane:** 1,3-Dibromopropane (0.03 mL, 0.30 mmol) was added to a THF (5 mL) solution of **1** prepared from **4** (350 mg, 0.56 mmol) and lithium (11 mg, 1.64 mmol) at room temperature. After removal of volatile substances, the residue was subjected to GPC to afford 1,3-bis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadienyl)propane (**9**) (104 mg, 0.091 mmol, 33%). **9:** M.p. 90–95 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 1.65–1.86 (m, 4 H), 2.10–2.35 (m, 2 H), 6.73–6.85 (m, 16 H), 6.85–7.00 (m, 24 H), 7.27–2.36 (m, 6 H), 7.40–7.60 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 13.13 (t, $^1J_{C,Sn}$ = 340, 356 Hz, $^3J_{C,Sn}$ = 70 Hz), 24.63 (t, $^2J_{C,Sn}$ = 21 Hz), 125.14 (d), 125.72 (d), 127.26 (d), 127.83 (d), 128.78 (d), 129.05 (d, $J_{C,Sn}$ = 21 Hz), 129.09 (d), 130.30 (d), 136.75 (d, $J_{C,Sn}$ = 38 Hz), 139.26 (s), 140.66 (s, $J_{C,Sn}$ = 63 Hz), 142.72 (s, $J_{C,Sn}$ = 45 Hz), 144.02 (s, $J_{C,Sn}$ = 391, 409 Hz), 154.75 (s, $J_{C,Sn}$ = 79 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –49.9 ppm. $C_{71}H_{56}Sn_2$ (1146.67): calcd. C, 74.37, H 4.92; found C 74.07, H 4.92.

**Reaction of Pentaphenylstannole Anion 1 with 1,4-Dibromobutane:** 1,4-Dibromobutane (0.019 mL, 0.16 mmol) was added to a THF (3 mL) solution of **1** prepared from **4** (200 mg, 0.32 mmol) and lithium (6 mg, 0.89 mmol) at room temperature. After removal of volatile substances, the residue was subjected to GPC to afford 1,4-bis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadienyl)butane (**10**) (66 mg, 0.057 mmol, 36%). **10:** M.p. 190 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 1.45–1.63 (m, 4 H), 1.68–1.86 (m, 4 H), 6.77–6.83 (m, 16 H), 6.90–7.01 (m, 24 H), 7.30–7.36 (m, 6 H), 7.46–7.58 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 12.71 (t, $^1J_{C,Sn}$ = 369 Hz), 30.92 (t, $^2J_{C,Sn}$ = 56 Hz, $^3J_{C,Sn}$ = 24 Hz), 125.13 (d), 125.73 (d), 127.27 (d), 127.81 (d), 128.77 (d), 129.09 (d, $J_{C,Sn}$ = 20 Hz), 129.09 (d), 130.32 (d), 136.71 (d, $J_{C,Sn}$ = 38 Hz), 139.58 (s), 140.73 (s, $J_{C,Sn}$ = 63 Hz), 142.84 (s, $J_{C,Sn}$ = 45 Hz), 144.21 (s, $J_{C,Sn}$ = 390, 408 Hz), 154.69 (s, $J_{C,Sn}$ = 81 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –47.3 ppm. $C_{72}H_{58}Sn_2$ (1160.70): calcd. C 74.51, H 5.04; found C 74.00, H 5.09.

**Reaction of Pentaphenylstannole Anion 1 with 1,5-Dibromopentane:** 1,5-Dibromopentane (0.046 mL, 0.35 mmol) was added to a THF (5 mL) solution of **1** prepared from **4** (430 mg, 0.68 mmol) and lithium (14 mg, 2.0 mmol) at room temperature. After removal of volatile substances, the residue was subjected to GPC to afford 1,5-bis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadienyl)pentane (**11**) (152 mg, 0.13 mmol, 38%). **11:** M.p. 85–87 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 1.31–1.43 (m, 2 H), 1.43–1.58 (m, 4 H), 1.58–1.77 (m, 4 H), 6.63–6.84 (m, 16 H), 6.84–7.00 (m, 24 H), 7.29–7.42 (m, 6 H), 7.42–7.63 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 13.27 (t, $^1J_{C,Sn}$ = 355, 372 Hz), 26.26 (t, $^3J_{C,Sn}$ = 24 Hz), 37.98 (t, $^2J_{C,Sn}$ = 54 Hz), 125.10 (d), 125.71 (d), 127.28 (d), 127.79 (d), 128.74 (d), 129.14 (d, $J_{C,Sn}$ = 20 Hz), 129.14 (d), 130.29 (d), 136.72 (d, $J_{C,Sn}$ = 44 Hz), 139.63 (s), 140.75 (s, $J_{C,Sn}$ = 63 Hz), 142.90 (s, $J_{C,Sn}$ = 44 Hz), 144.32 (s, $J_{C,Sn}$ = 389, 406 Hz), 154.63 (s, $J_{C,Sn}$ = 79 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –46.5 ppm. $C_{73}H_{60}Sn_2$ (1174.73): calcd.C 74.64, H 5.15; found C 74.59, H 5.15.

**Reaction of Pentaphenylstannole Anion 1 with 1,6-Dibromohexane:** 1,6-Dibromohexane (0.04 mL, 0.27 mmol) was added to a THF (4 mL) solution of **1** prepared from **4** (338 mg, 0.54 mmol) and lithium (11 mg, 1.59 mmol) at room temperature. After removal of volatile substances, the residue was subjected to GPC to afford 1,6-bis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadienyl)hexane (**12**) (151 mg, 0.13 mmol, 47%). **12:** M.p. 75–80 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 1.15–1.30 (m, 4 H), 1.51–1.75 (m, 8 H), 6.70–6.86 (m, 16 H), 6.86–7.05 (m, 24 H), 7.26–7.35 (m, 6 H), 7.45–7.63 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 13.63 (t, $^1J_{C,Sn}$ = 358, 373 Hz), 26.78 (t, $^3J_{C,Sn}$ = 24 Hz), 33.45 (t, $^2J_{C,Sn}$ = 50 Hz), 125.08 (d), 125.70 (d), 127.28 (d), 127.78 (d), 128.74 (d), 129.05 (d, $J_{C,Sn}$ = 20 Hz), 129.05 (d), 130.29 (d), 136.71 (d, $J_{C,Sn}$ = 45 Hz), 139.71 (s), 140.77 (s, $J_{C,Sn}$ = 63 Hz), 142.89 (s, $J_{C,Sn}$ = 45 Hz), 144.41 (s, $J_{C,Sn}$ = 388, 407 Hz), 154.61 (s, $J_{C,Sn}$ = 78 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –46.6 ppm. $C_{74}H_{62}Sn_2$ (1188.76): calcd. C 74.77, H 5.26; found C 75.01, H 5.39.

**Reaction of Pentaphenylstannole Anion 1 with 1,2-Dichloroethane:** Excess 1,2-dichloroethane (2 mL, 32 mmol) was added to a THF (4 mL) solution of **1** prepared from **4** (252 mg, 0.40 mmol) and lithium (9 mg, 1.30 mmol) at room temperature. After volatile substances were removed, the residue was washed with hexane to give 1,1′-bistannole **2**[8,9] (298 mg, 0.27 mmol, 71%).

**Reaction of Pentaphenylstannole Anion 1 with 1,2-Dibromoethane:** Excess 1,2-dibromoethane (0.5 mL, 5.8 mmol) was added to a THF (5 mL) solution of **1** prepared from **4** (303 mg, 0.48 mmol) and lithium (11 mg, 1.59 mmol) at room temperature. After volatile substances were removed, the residue was washed with hexane to give 1,1′-bistannole **2**[8,9] (196 mg, 0.18 mmol, 74%).

**Formation of 2 by Oxidation of Pentaphenylstannole Anion 1:** A THF (7 mL) solution of **1** prepared from **4** (408 mg, 0.65 mmol) and lithium (12 mg, 1.69 mmol) was exposed to air for a few minutes. After volatile substances were removed, the residue was washed with hexane to give 1,1′-bistannole **2**[8,9] (120 mg, 0.11 mmol, conv. 70%). The starting **4** was recovered in 20% yield.

**Reaction of Pentaphenylstannole Anion 1 with Di-*tert*-butyldichlorostannane:** A THF (4 mL) solution of **1** prepared from **4** (250 mg, 0.40 mmol) and lithium (8 mg, 1.16 mmol) was added to a THF (2 mL) solution of di-*tert*-butyldichlorostannane (121 mg, 0.40 mmol) at –100 °C. The reaction mixture was warmed to room

temperature and stirred overnight. After removal of volatile substances, the residue was subjected to GPC to afford di-*tert*-butylbis(1,2,3,4,5-pentaphenyl-1-stannacyclopentadienyl)stannane (**14**) (109 mg, 0.08 mmol, conv. 49%). The starting **4** was recovered in 16% yield. **14:** M.p. 138–140 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 1.15 (s, $J_{H,Sn}$ = 7, 77 Hz, 18 H), 6.72–6.83 (m, 24 H), 6.91–6.94 (m, 16 H), 7.25–7.34 (m, 6 H), 7.52–7.66 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 33.33 (q, $J_{C,Sn}$ = 10 Hz), 35.31 (s, $J_{C,Sn}$ = 31 Hz), 125.10 (d), 125.64 (d), 127.19 (d), 127.60 (d), 128.68 (d, $J_{C,Sn}$ = 11 Hz), 128.96 (d, $J_{C,Sn}$ = 44 Hz), 129.59 (d, $J_{C,Sn}$ = 20 Hz), 130.93 (d), 137.40 (d, $J_{C,Sn}$ = 41 Hz), 140.99 (s), 141.16 (s, $J_{C,Sn}$ = 54 Hz), 142.73 (s, $J_{C,Sn}$ = 47 Hz), 148.60 (s, $J_{C,Sn}$ = 16 Hz), 154.25 (s, $J_{C,Sn}$ = 71 Hz) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = –103.2 ($^1J_{Sn,Sn}$ = 329 Hz), –44.8 ($^1J_{Sn,Sn}$ = 329 Hz) ppm. $C_{76}H_{68}Sn_3$ (1337.54): calcd. C 68.25, H 5.12; found C 68.23, H 5.11.

**Reaction of 1-*tert*-Butylstannole Anion 16 with Methyl Iodide:** A diethyl ether (5 mL) solution of stannole dianion **3** prepared from hexaphenylstannole **4** (270 mg, 0.43 mmol) and lithium (15 mg, 2.18 mmol) was added to a diethyl ether (2 mL) solution of *tert*-butyl chloride (0.05 mL, 0.46 mmol) was added at room temperature. After being stirred for 30 min, the mixture was treated with methyl iodide (0.03 mL, 0.07 mmol). After filtration of materials insoluble in dichloromethane, the filtrate was recrystallized from dichloromethane and methanol to give 1-*tert*-butyl-1-methyl-2,3,4,5-tetraphenylstannole (**15**)[17] (130 mg, 0.24 mmol, 55%). **15:** M.p. 75–80 °C (decomp.) ($CH_2Cl_2$ + MeOH). $^1$H NMR ($CDCl_3$): $\delta$ = 0.60 (s, $J_{H,Sn}$ = 51 Hz, 3 H), 1.22 (s, $J_{H,Sn}$ = 74 Hz, 9 H), 6.77–6.79 (m, 4 H), 6.83–6.85 (m, 4 H), 6.93–6.98 (m, 8 H), 7.04–7.08 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = –10.57 (q), 29.90 (s), 30.68 (q), 124.86 (d), 125.58 (d), 127.18 (d), 127.74 (d), 129.09 (d), 130.44 (d), 141.01 (s), 143.62 (s), 145.41 (s), 154.47 (s) ppm. $^{119}$Sn NMR ($CDCl_3$): $\delta$ = 5.1 ppm. $C_{33}H_{32}Sn$ (547.35): calcd. C 72.42, H 5.89; found C 72.43, H 5.51.
