**Structure Determination and Refinement:** Single crystals of complexes **2** (blue block), **8** (blue block), **10** (green block) and **11** (blue block) suitable for X-ray diffraction studies were obtained by slow diffusion of diethyl ether onto an acetone solution (**10**, **11** and **2**) or by slowly evaporation of the reaction solution (**8**) of the complex. Crystals were selected and mounted on a glass fibre for data collection. Diffraction data were measured with a Bruker SMART APEX by using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Crystallographic data are summarized in Table 5. The diffraction frames were integrated by using the SAINT package[44] and corrected for absorption with SADABS.[45] The raw intensity data were converted (including corrections for Lorentz and polarization effects) to structure amplitudes and their esd by using the SAINT program. The structures were solved by direct methods[46] and refined[46] by full-matrix least-squares techniques by using anisotropic thermal parameters for non-hydrogen atoms. Hydrogen atoms were set at calculated positions. CCDC-645172 (for **2**), -645173 (for **8**), -645174 (for **10**) and -645175 (for **11**) contain the supplementary crystallographic data for this paper. These data can be obtained free of

# Methylation of a Terdentate Schiff Base Ligand *NNO*-Coordinated to Palladium with Nitromethane

**Ana M. Arnaiz,[a] Arancha Carbayo,[a] José V. Cuevas,*[a] Virginia Diez,[a] Gabriel García-Herbosa,[a] Roberto González,[a] Abigail Martínez,[a] and Asunción Muñoz[a]**

**Keywords:** Palladium / Henry reaction / Nucleophilic attack / Nitroaldol / Schiff bases

The reaction of the complex [Pd(κ$^3$-NN′O)CH$_3$] [NN′O = 2-Py-CH=N-(*o*-C$_6$H$_4$)O$^-$] (**1a**) with nitromethane affords a mixture of **2a** and **2b**. In this reaction methylation of the ligand takes place. These complexes display exchange equilibrium in solution. The methylation reaction is proposed to occur through nucleophilic attack of the nitronate anion on the iminic carbon atom. DFT calculations are presented in order to support a part of the mechanism and these calculations show that the participation of water in the migration of a proton is important. The crystal structure of the derivative product after spontaneous release of methane (**3**) is presented as well. Attempts to extend the reaction to other nitroalkanes resulted in a mixture of complexes that was not easy to characterize.

## Introduction

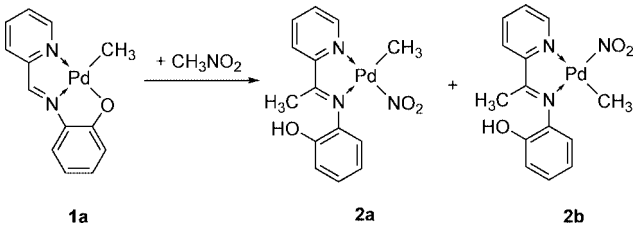
There has been increasing interest in the inorganic and organometallic chemistry of nitroalkanes. Nitroaldol (Henry) condensation is a highly versatile carbon–carbon bond formation reaction, which allows the synthesis of a huge number of interesting molecular frameworks.[1,2] In recent years considerable efforts have been devoted to developing asymmetric versions of the Henry reaction.[3] The work of Palomo et al.[3] highlights the advances in stereocontrol in these reactions that have been achieved by the use of catalysts such as cinchona alkaloids, guanidine bases, quaternary ammonium salts, or complexes of copper, zinc, or lithium/lanthanum. Recent advances on complexes of copper,[4–11] lanthanum,[12] cobalt,[13] or zinc,[11] which can act as catalysts for the asymmetric nitroaldol reaction, have been reported.

It is proposed that the metal-catalyzed nitroaldol reaction occurs through a mechanism involving *O* coordination of monodentate nitronate to the metal center.[14,15] To the best of our knowledge there are only two complexes that have a nitronate ligand coordinated to a metallic center in this way.[16] Additionally, Evans et al. reported that weakly Lewis acidic metal complexes bearing moderately basic, charged ligands may facilitate the deprotonation of nitroalkanes.[4]

In previous works of our group we have studied the dynamic behavior and the catalytic activity of palladium complexes with bi- and tridentate nitrogen donor ligands.[17,18] Those complexes have pyridine–imine donor ligands. Pelagatti et al.[19] have reported the synthesis of a palladium complex very similar to the complexes that we have studied, incorporating an additional coordination position with basic character, which could be a good candidate to catalyze the Henry reaction. In this work we report the behavior of the nitronate as a nucleophilic reagent towards this palladium complex.

## Results and Discussion

The deep purple solution of complex **1a** in nitromethane at room temperature afforded a yellow precipitate that was characterized as **2** where the *N*,*N*′,*O* tridentate ligand became only *N*,*N*′ bidentate and was methylated at the iminic carbon (see Scheme 1). For complex **2** it is possible to propose two isomers, labeled in Scheme 1 as **2a** and **2b**.



**1a** **2a** **2b**

Scheme 1.

The $^1$H NMR characterization of the reaction products was carried out in [D$_6$]DMSO because of their low solubility in other less coordinating solvents. This NMR spectrum shows two signals belonging to methyl groups bonded to

palladium at $\delta$ = 0.60 and 0.14 ppm, which is consistent with the presence of both isomers in solution. In the analysis of the values of the integrals, the isomer where the methyl group appears at $\delta$ = 0.14 ppm is ten times more abundant than the other isomer. The comparison of these chemical shifts with the values reported for similar palladium–methyl complexes with pyridine–imine ligands[20] indicates that the signal of the palladium–methyl group located in *cis* position to the pyridine ring appears downfield when compared with the same signal in the complex with the methyl group in *trans* position to the pyridine ring. Therefore, in this case, the values of the integrals indicate that the dominant isomer is **2b**. Furthermore, isomers **2a** and **2b** undergo a dynamic equilibrium in solution. A NOESY experiment (see Figure 1) shows that the signal appearing at $\delta$ = 0.14 ppm has peaks out of the diagonal; the signals belong to the $H^6$ of the pyridine ring and the *ortho*-hydrogen of the phenyl ring, which is consistent with such equilibrium. The EXSY phase of the same experiment (see Figure 2) shows peaks out of the diagonal for the signals appearing at $\delta$ = 0.14 and 0.60 ppm, also indicating the presence of the equilibrium between **2a** and **2b**.

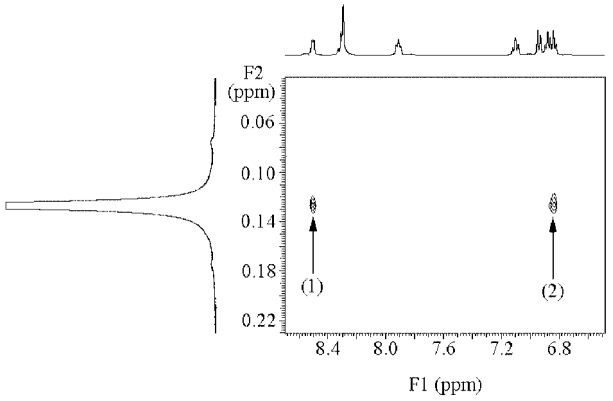

Figure 1. Expansion of the NOESY spectrum for mixture of complexes **2a** and **2b**. (1) Peak out of diagonal of the peak Pd–Me in **2b** with the $H^6$ signal of the pyridine ring. (2) Peak out of diagonal of the peak Pd–Me in **2b** with the *ortho*-hydrogen of the phenyl.

At first glance, the product of the reaction is similar to a Henry reaction product,[1,2] but there are some important differences. In our case, the bond between the nitrogen atom and the methyl carbon is broken, and the resulting nitro group is coordinated to the palladium atom. The other important difference is that the bond between the carbonylic carbon and the nitrogen atom remains as a double bond and is not transformed into a single bond as occurs in Henry reactions. For the process that we have found, the acid/base equilibrium of nitromethane can be taken into account.[21,22] This equilibrium generates a nitronate carbanionic nucleophile and a proton. We suggest that in the first step the proton attacks the phenoxide to generate the phenolic group, as shown in Scheme 2. The next step, which can be simultaneous to the previous step, is the attack of the nucleophile on the carbonylic carbon of the coordinated imine. Nucleophilic attacks on coordinated imines are

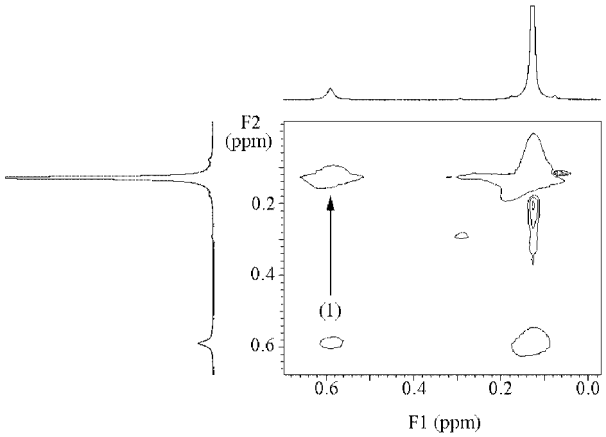

Figure 2. Expansion of the NOESY spectrum for mixture of complexes **2a** and **2b**. (1) EXSY signal out of the diagonal showing the exchange between Pd–Me groups in isomers **2a** and **2b**.

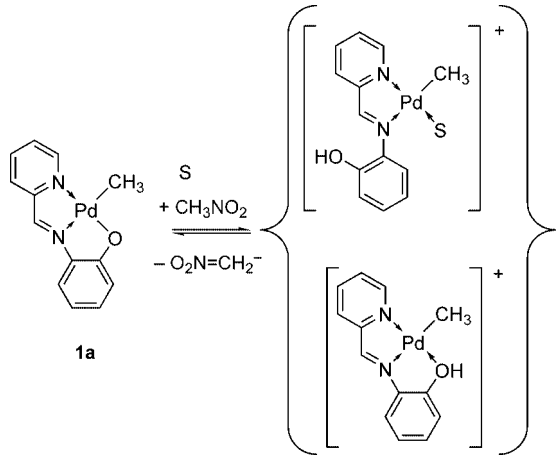
known,[23–27] and the nucleophilic behavior of nitronates has been reported as well;[14,28,29] even the nitronate attack on an imine coordinated to cobalt has been reported.[30] In our proposed mechanism, this nucleophilic attack is followed by the breaking up of the C–N bond of the nitronate fragment in an analogous way to that described for a cobalt[23] or a nickel complex[31] (see Scheme 3).

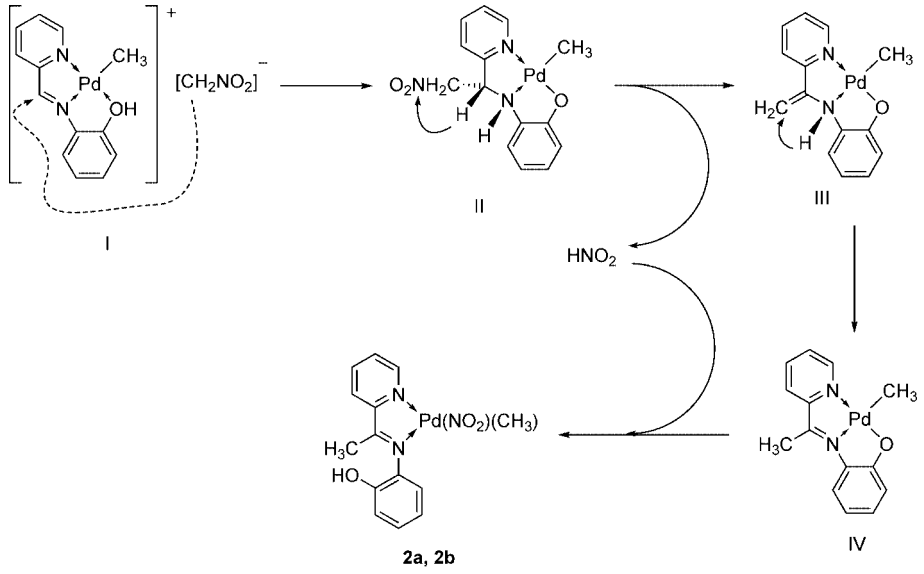


Scheme 2.

In this process, the nucleophilic attack of the carbanion on the iminic carbon atom generates the compound with structure II. This compound can release nitrous acid to afford the compound of structure III. Next, the hydrogen atom bonded to the aminic nitrogen atom "jumps" to the methylenic carbon to generate the complex with structure IV in a process of imine–enamine tautomerism. This migration of the proton has to be aided by a molecule of water, as we have found in theoretical calculations (see below). The process without water displays high activation barriers, as we will discuss later. Finally, the protonation of structure IV with the nitrous acid released earlier affords the observed products **2a** and **2b**.

In order to support this proposed mechanism, we carried out $^1$H NMR measurements of **1a** dissolved in $CD_3NO_2$

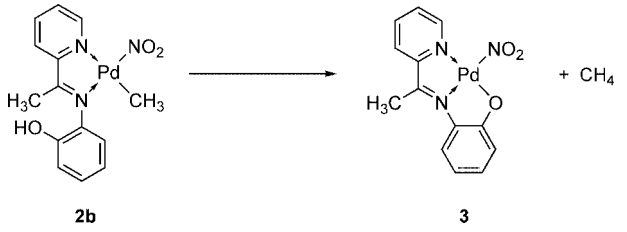
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3.

and in $CD_3NO_2/D_2O$, and $^1H$ NMR measurements of the products of these reactions dissolved in [$D_6$]DMSO, but they did not shed light on the proposal.

The slow evaporation of the mother liquors of the reaction for the preparation of complexes **2** afforded a crystal suitable for structural X-ray analysis, but not enough crystals for spectroscopic characterization. The structure of the crystal is not the structure proposed for complexes **2a** or **2b** but a complex **3** in which one molecule of methane has been lost by deprotonation of the phenolic proton, (see Scheme 4). The acidity of the phenolic proton seems to be sufficient to cause such slow methane elimination.[19,32]



Scheme 4.

## Structure of Complex 3

The molecular structure of complex **3** is shown in Figure 3, and selected bond lengths, bond angles, and torsion angles are given in Table 1. The chelating ligand binds to the metal through a pyridyl donor N(1), secondary imine donor N(2), and aryloxide oxygen O(1). The N(1)–Pd(1)–N(2) bond angle is 81.25(13)° and the N(2)–Pd(1)–O(1) bond angle is 84.95(12)°. The pyridyl donor makes a slightly larger bond to the metal than the imine does. The torsion angles N(1)–C(5)–C(6)–N(2) and N(2)–C(8)–C(13)–O(1) are close to planarity, with values of 5.0(5)° and 0.9(5)° respectively. The nitro group is out of the coordination plane of the palladium as the torsion angle O(1)–Pd(1)–N(3)–O(3) is –136.5(3)°.

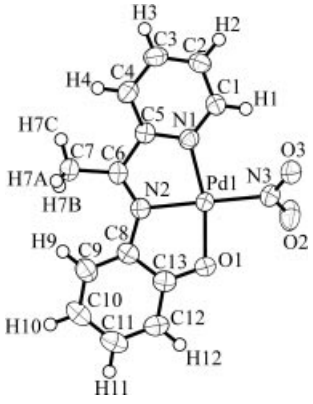


Figure 3. Molecular geometry for complex **3**.

Table 1. Selected bond lengths [Å] and angles [°] for compound **3**.

| Distances [Å] | | Angles [°] | |
|---|---|---|---|
| Pd(1)–N(2) | 1.979(3) | N(2)–Pd(1)–O(1) | 84.95(12) |
| Pd(1)–O(1) | 1.997(3) | N(2)–Pd(1)–N(3) | 178.06(11) |
| Pd(1)–N(3) | 2.011(3) | O(1)–Pd(1)–N(3) | 94.41(13) |
| Pd(1)–N(1) | 2.013(3) | N(2)–Pd(1)–N(1) | 81.25(13) |
| N(1)–C(5) | 1.355(5) | O(1)–Pd(1)–N(1) | 166.17(12) |
| N(2)–C(6) | 1.293(5) | N(3)–Pd(1)–N(1) | 99.40(13) |
| N(3)–O(2) | 1.229(4) | O(2)–N(3)–O(3) | 119.3(3) |
| N(3)–O(3) | 1.247(4) | | |
| O(1)–C(13) | 1.321(5) | N(1)–C(5)–C(6)–N(2) | 5.0(5) |
| C(5)–C(6) | 1.489(5) | N(2)–C(8)–C(13)–O(1) | 0.9(5) |
| | | O(1)–Pd(1)–N(3)–O(3) | –136.5(3) |
| | | N(1)–Pd(1)–N(3)–O(3) | 43.1(3) |

The packing of the crystal is built up through hydrogen bonds and π–π interactions. There are two weak intermolecular hydrogen bonds between the oxygen atoms of the nitro group and several hydrogen atoms of the ligand of neighbor complexes. The oxygen atom labeled as O(2) es-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tablishes bifurcated hydrogen bonds to the methyl group and arylic hydrogen atoms. The oxygen atom labeled as O(3) establishes trifurcated hydrogen bonds to the methyl group and arylic hydrogen atoms. The values of these hydrogen bonds are displayed in Table 2 and they are in good agreement with the values reported in the literature.[33–35] Additionally, there is a π–π interaction between the π systems of couples of molecules, with a separation between parallel planes (defined by the aromatics systems of the ligand) of 3.385 Å.[36] The combination of all these interactions packs the molecules in columns, as shown in Figure 4.

Table 2. Distances and angles of weak interactions in complex **3**.

| Hydrogen bonds | | | |
|---|---|---|---|
| O(2), bifurcated | | O(3), trifurcated | |

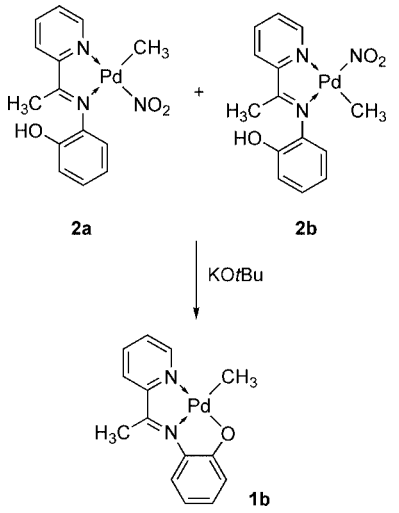
Figure 4. Packing of the molecules of complex **3** forming columns. The weak interactions are displayed.

## Deprotonation of 2

The presence of the O–H group in complexes **2** encouraged us to explore its deprotonation. Thus, as shown in Scheme 5, the reaction of the mixture of compounds **2a** and **2b** with KO*t*Bu afforded the expected O–H deprotonation to yield a new compound, **1b**, which is garnet in color. This compound has been characterized by spectroscopic techniques. The $^1$H NMR spectrum shows the presence of the two different methyl groups, a singlet at $\delta$ = 0.51 ppm (belonging to the palladium-bonded methyl) and another singlet at $\delta$ = 2.54 ppm (belonging to the carbonylic methyl).



Scheme 5.

The synthesis of complex **1b** was also attempted following an alternate pathway, like that reported for **1a**.[19] However, we were unable to synthesize the *N*,*N*′,*O* tridentate ligand through the conventional condensation of 2-acetylpyridine with 2-aminophenol using Dean–Stark equipment in the presence of a catalytic amount of *p*-toluenesulfonic acid.

## DFT Calculations

In order to rationalize the observed results, DFT quantum chemical calculations were carried out on a model of complex **1a**. The positions of nucleophilic attack should display positive charge. The process starts with the protonation of complex **1a**. It is reasonable to think that the protonation occurs on the oxygen atom, as the NBO analysis[37,38] displays a negative charge on that atom (–0.67). Although the oxygen atom is not the most negatively charged atom (we have found that the methyl carbon atom bonded to the metal has a charge of –0.90), the participation of the $p_z$ atomic orbital of the oxygen in the HOMO and the nonparticipation of any atomic orbital of the carbon atom reinforces this proposal. In addition to the protonation of the oxygen atom, there is a nucleophilic attack of the nitronate anion on the iminic carbon atom. An NBO analysis displays a positive charge on the iminic carbon (0.016). Although this value is not the most positive value (palladium atom has a value of 0.690), there is strong participation of the orbitals of the π system in the LUMO of the complex and the iminic carbon atom is a place for nucleophilic attack analogous to that observed for the Henry reaction,[1,2] accounting for the observed reaction of the nitromethane.

We have modeled the migration of the hydrogen atom from the nitrogen atom to the carbon atom, as depicted in steps III–IV in Scheme 3. This process was proposed by other authors[23,31] on similar systems. The compound with structure III comes from the compound with structure II through the loss of nitrous acid. We have found that glob-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

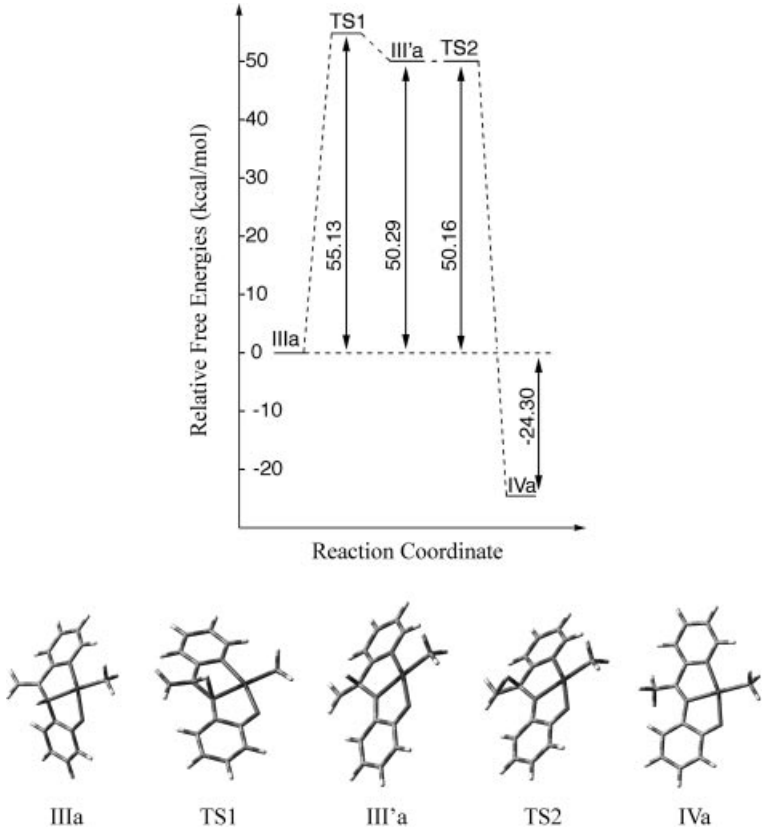


Figure 5. Calculated reaction pathway in the migration of the hydrogen atom without any molecule of water.

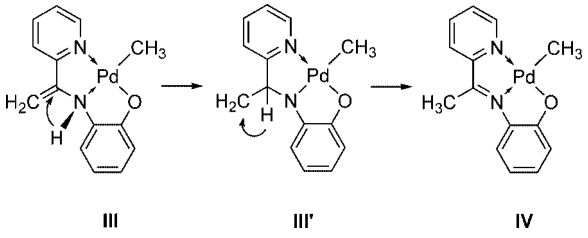
ally this process is an imine–enamine tautomerism through two steps. The first step is the migration of the aminic hydrogen atom from the nitrogen to the adjacent carbon atom (structure III′ in Scheme 6). This first step is highly endothermic (50.3 kcal/mol), with a high activation energy (55.1 kcal/mol). The second step of the tautomerism is a new migration of the hydrogen atom to generate the methyl and the double bond C=N (structure IV in Scheme 3; see Figure 5). This step has an activation energy very close to 0 kcal/mol, and the complete process is exothermic (–24.3 kcal/mol), taking as reference the energy of structure III.



Scheme 6.

The high value of the activation energy makes this mechanism unreliable. We thought that perhaps a molecule of water could help the migration of the proton. The addition of a molecule of water to structure III (see Scheme 3) established a hydrogen bond with the oxygen atom of the aryloxide fragment, stabilizing the structure. A second molecule of water established a hydrogen bond with the amine hydrogen atom, and this molecule is the carrier of the hydrogen atom to the carbon atom (see Figure 6). In

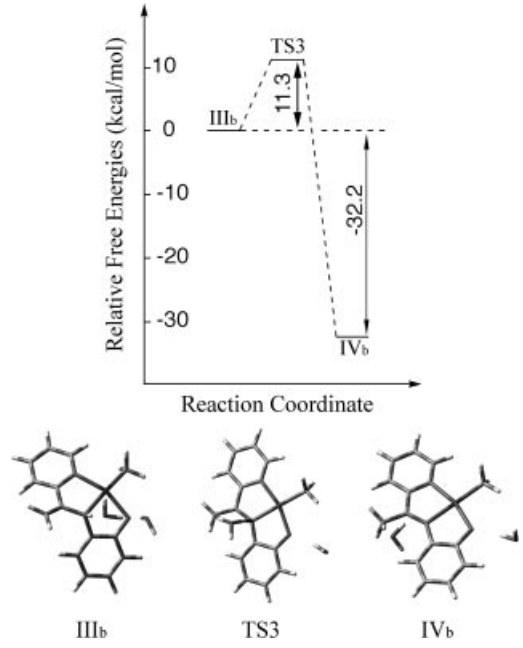


Figure 6. Calculated reaction pathway in the migration of the hydrogen atom assisted by molecules of water.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

this mechanism the molecule of water takes the proton bonded to the amine nitrogen and gives another proton to the carbon. Intrinsic reaction coordinate (IRC) calculations[39] verified this process. This process is exothermic, with a free energy of –32.2 kcal/mol and activation energy of 11.3 kcal/mol.

## Experimental Section

**General:** Elemental analyses (C,H,N) were performed with a LECO CHNS-932 apparatus. Infrared spectra were recorded with a Nicolet Impact 410 FTIR spectrophotometer in the 4000–400 $cm^{-1}$ range, as KBr disks. $^1H$ NMR spectra were obtained on a Varian Unity Inova 400-MHz spectrometer with $SiMe_4$ as internal standard at 25 °C. Complex **1a** was synthesized as reported in the literature.[19] Nitromethane and potassium *tert*-butoxide were commercial grade and were used without further purification.

**[$C_{14}H_{15}N_3O_3Pd$] (2):** Complex **1a** (50 mg, 0.157 mmol) was dissolved in nitromethane (3.5 mL). The mixture was stirred for 20 h. During this time the initial purple color disappeared and a yellow precipitate was formed. The solid was filtered off, washed with diethyl ether, and then dried under vacuum. Yield: 45.4 mg (76%). $^1H$ NMR (signals of complex **2b**) (400 MHz, [$D_6$]DMSO, 20 °C): $\delta$ = 9.73 (s, 1 H, O-H), 8.52 (d, $^3J_{H,H}$ = 4.6 Hz, 1 H, 6-H py), 8.31 (m, 2 H, 4-H, 3-H py), 7.92 (m, 1 H, 5-H py), 7.13 (dd, $^3J_{H,H}$ = 7.4, $^3J_{H,H}$ = 7.4 Hz, 1 H, 4-H Ar), 6.95 (d, $^3J_{H,H}$ = 8.2 Hz, 1 H, 3-H Ar), 6.88 (m, 2 H, 5-H, 6-H Ar), 2.28 [s, 3 H, C**H$_3$**-C(py)=N], 0.14 (s, 3 H, C**H$_3$**-Pd) ppm. IR: $\tilde{\nu}$ = 1660 [m (C=N)] $cm^{-1}$. $C_{14}H_{15}N_3O_3Pd$ (379.69): calcd. C 44.28, H 3.98, N 11.07; found C 43.96, H 3.92, N 11.13.

**[$C_{14}H_{14}N_2OPd$] (1b):** Complex **2** (30 mg, 0.079 mmol) was dissolved in dichloromethane (10 mL), and potassium *tert*-butoxide (8.9 mg, 0.079 mmol) was added. The mixture was stirred for 45 min. The solvent of this red solution was removed under vacuum and the residue was dissolved in dichloromethane, filtered through Celite, and concentrated under vacuum. The addition of hexanes affords a purple solid that was filtered off, washed with cold diethyl ether, and then dried under vacuum. Yield: 19.2 mg (73%). $^1H$ NMR (400 MHz, $CDCl_3$, 20 °C): $\delta$ = 8.14 (d, $^3J_{H,H}$ = 5.3 Hz, 1 H, 6-H py), 7.80 (m, 1 H, 4-H py), 7.50 (d, $^3J_{H,H}$ = 8.1 Hz, 1 H, 3-H py), 7.22 (m, 1 H, 5-H py), 7.10 (m, 1 H, 6-H Ar), 6.96 (m, 1 H, 4-H Ar), 6.72 (d, $^3J_{H,H}$ = 8.5 Hz, 1 H, 3-H Ar), 6.36 (m, 1 H, 5-H Ar), 2.54 [s, 3 H, C**H$_3$**-C(py)=N], 0.51 (s, 3 H, C**H$_3$**-Pd) ppm. IR: $\tilde{\nu}$ = 1627 [m (C=N)] $cm^{-1}$. $C_{14}H_{14}N_2OPd$: calcd. C 50.54, H 4.24, N 8.42; found C 49.80, H 4.47, N 8.82.

**X-ray Structure Determination:** Crystallographic data for compound **3** were collected on a Bruker SMART CCD area-detector diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å).[40] Intensities were integrated[41] from several series of exposures, each exposure covering 0.3° in $\omega$, and the total dataset being a sphere. Absorption corrections were applied, based on multiple and symmetry-equivalent measurements.[42] The structure was solved by direct methods and refined by least-squares on weighted $F^2$ values for all reflections (see Table 3).[43] All non-hydrogen atoms were assigned anisotropic displacement parameters and refined without positional constraints. All hydrogen atoms were constrained to ideal geometries and refined with fixed isotropic displacement parameters. Refinement proceeded smoothly to give the residuals shown in Table 3. Complex neutral-atom scattering factors were used.[44]

CCDC-645201 contains the supplementary crystallographic data for **3**. These data can be obtained free of charge from The Cam-

**Computational Study:** DFT calculations were performed with the hybrid method known as B3LYP, in which the Becke three-parameter exchange functional[45] and the Lee–Yang–Parr correlation functional were used,[46] implemented in the Gaussian 03 (Revision B.04) program suite.[47] The effective core potentials (ECPs) of Hay and Wadt with a double-ζ valence basis set (Lanl2DZ)[48] adding polarization functions ($\zeta_f$ = 1.472)[49] were used in describing Pd. The basis set for the main group elements was split-valence and included polarization functions in all atoms [C, N, O, and H, abbreviated as 6-31G(d,p)].[50] The structures were optimized at the level B3LYP/Lanl2DZ and transition states were confirmed by a vibrational analysis (one imaginary frequency) and IRC calculations.[39] Energies of the structures were calculated with the specific basis sets.

# On the Mechanism of Palladium-Catalyzed Cross-Coupling of Diazonium Salts with Aryltrifluoroborates: A Combined ESI-MS/NMR Study

**Nicola Taccardi,[a] Rossella Paolillo,[a] Vito Gallo,[a] Piero Mastrorilli,*[a] Cosimo F. Nobile,[a] Minna Räisänen,[b] and Timo Repo[b]**

**Keywords:** Homogeneous catalysis / Metallacycles / Mass spectrometry / Cross-coupling / Diazo compounds

A combined ESI-MS/NMR mechanistic study on the palladium-catalysed cross-coupling reaction between aryldiazonium salts and aryltrifluoroborates with bis(μ-acetato)bis(4,4′-difluoroazobenzene-$C^2$,$N$)dipalladium(II) (**4**) as the precatalyst is reported. The reaction follows a $Pd^0/Pd^{II}$ cycle after reduction of **4** to a molecular $Pd^0$ species (**I**), which according to the combined ESI-MS and $^{19}F$ NMR studies, bears an arylated azobenzene ligand. Oxidative addition by the diazonium salt generates the arylpalladium(II) intermediate (**II**), which was also detected in solution. The catalytic cycle is completed with a transmetallation between **II** and the organoborate, which is followed by fast reductive elimination of the cross-coupling product to restore the molecular $Pd^0$ species **I**. A concurrent activation path was also observed which consists of the formation of (4,4′-difluoroazobenzene-$C^2$,$N$)dipalladium(II) tetrafluoroborate (**7**) by the reaction of **4** with the diazonium salt and subsequent reduction by the aryltrifluoroborate to give **I**.

## Introduction

An innovative route to biaryls by palladium-catalysed cross-coupling between diazonium salts and aryltrifluoroborates has been proposed recently.[1] This protocol, which is an improved modification of the more popular Suzuki cross-coupling reaction,[2] does not require either temperatures higher than ambient or the addition of a base.

We have recently published a paper on the title reaction carried out in IL/methanol (IL = ionic liquid) mixtures where several (zero- and divalent) palladium complexes were used as precatalysts.[3] In this framework it was found that palladacycles of general formula $[(C^{\frown}N)Pd(\mu\text{-}OAc)]_2$ (see Scheme 1) were outstanding in terms of activity and selectivity of the reaction.

Our preliminary mechanistic investigations of this reaction demonstrated that the catalysis is molecular and is influenced by the ligand on palladium. Moreover, we found that an excess of diazonium salt (but not of aryltrifluoroborate) allowed the catalytic solutions to be recycled.[3]

In this paper we report a combined ESI-MS and $^{19}F$ NMR mechanistic study on the title reaction using $KPhBF_3$ and $p\text{-}XC_6H_4N_2BF_4$ (X = $CH_3$ or F) as substrates, [bis(μ-acetato)bis(4,4′-difluoroazobenzene-$C^2$,$N$)dipalladium(II)] (**4**) as a precatalyst and methanol as solvent (Scheme 2).

The rationale for the use of the fluorinated substrate and precatalyst resides in the possibility of monitoring the reaction progress by $^{19}F$ NMR spectroscopy, while methanol was used instead of IL/MeOH mixtures in order to simplify the experimental procedures.[4] ESI-MS, which is used here as a complementary analytical method, is a rapidly emerging technique for mechanistic investigations due to the possibility of easily revealing all species present in an actual catalyst solution.[5] The classical Suzuki cross-coupling[6] and other palladium-catalyzed reactions,[7] for example, have recently been studied by means of ESI-MS.[8]

In order to ascertain the effect of fluorine substitution of the azobenzene moiety in complex **3** on the catalysis, we preliminarily checked the catalytic activity of **4** in methanol using *p*-tolyldiazonium tetrafluoroborate ($p\text{-}CH_3C_6H_4N_2BF_4$) and $KPhBF_3$. Precatalyst **4** (1% mol) gave an 81% yield after 80 min while the non-fluorinated analogue **3** gave a 55% yield after 15 min[3] (the reactions were stopped when quantitative conversions were reached). The effect of the fluorine substitution on the ligand further confirms the molecular nature of the catalysis.

## Results and Discussion

The commonly accepted catalytic cycle for a $Pd^{II}$-initiated Suzuki cross-coupling is depicted in Scheme 3.[2] It consists of a preliminary reduction of $Pd^{II}$ to $Pd^0$ followed by the oxidative addition of the electrophile ArX (where X is typically a halide or triflate), subsequent transmetallation

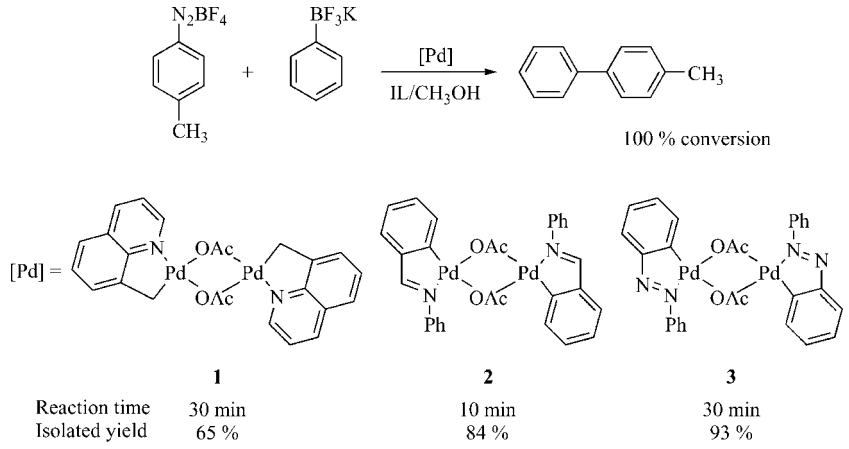
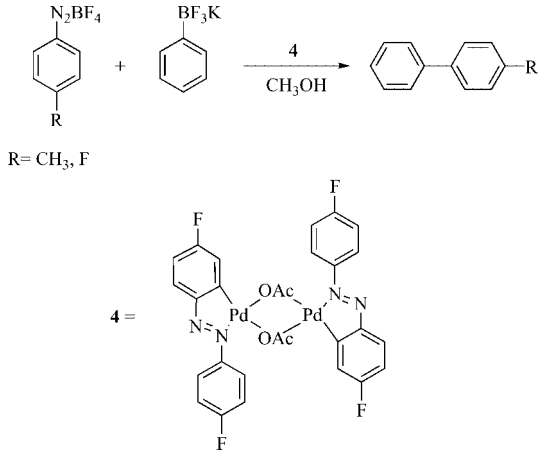
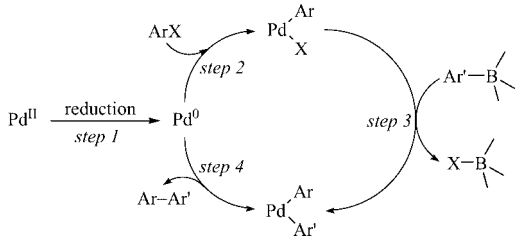


Scheme 1. Examples of highly active palladacycles for the cross-coupling reaction.[3] IL = 1-*n*-butyl-3-methylimidazolium tetrafluoroborate.



Scheme 2. Cross-coupling reaction with a fluorinated substrate and precatalyst **4**.

of the organoborate and reductive elimination leading to the cross-coupling product and regeneration of the $Pd^0$ species, which restarts the catalytic cycle.



Scheme 3. General catalytic cycle for the Suzuki cross-coupling leading to biaryls.

In order to verify whether such a cycle also holds when ArX is replaced by an aryldiazonium salt and the organoboron compound is changed to $KPhBF_3$, every single step shown in Scheme 3 was examined.

### Reaction of the Precatalyst with $KPhBF_3$

The reaction mixture comprised of **4** and $KPhBF_3$ in methanol was monitored by $^{19}F$ NMR spectroscopy at room temperature (Figure 1). The lack of signals attributable to **4** is due to its poor solubility in methanol.

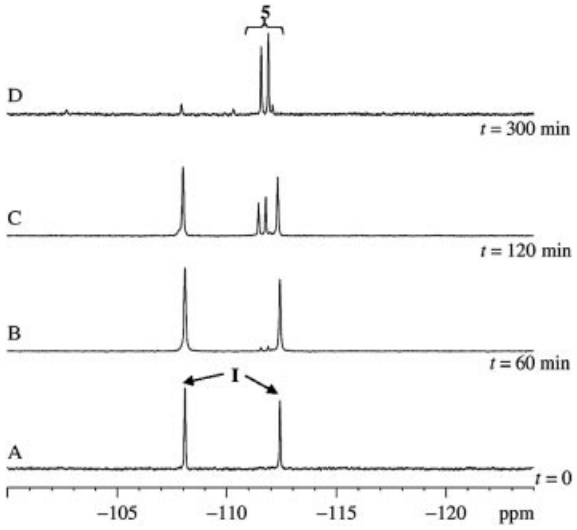


Figure 1. $^{19}F$ NMR spectroscopic monitoring of reaction mixtures of **4** and $KPhBF_3$ in methanol as a function of time (Pd:$KPhBF_3$ = 1:15 mol/mol).

It is apparent that a new species **I** with $^{19}F$ NMR resonances at $\delta$ = –108.1 and –112.4 ppm forms immediately upon mixing $KPhBF_3$ with azapalladacycle **4**. The signals assigned to **I** progressively decrease in intensity over 5 h, with concomitant appearance of two new signals at $\delta$ = –111.7 and –111.9 ppm and formation of palladium black. These latter signals belong to 4,4′-difluoro-2-phenylazobenzene (**5**), which was isolated and fully characterized. The formation of Pd black and **5** indicates two possible struc-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tures for **I**, one of which is a $Pd^{II}$ complex in which the bridging acetate of **4** has been replaced by a σ-bonded phenyl group and the other of which consists of already formed ligand **5** bonded to $Pd^0$ (Scheme 4; in this and in the following structures the solvent molecules possibly bound to palladium are omitted).

High resolution ESI-MS (HRMS) analysis of the solution showed an intense peak at *m/z* 419 (negative ion mode). This peak represents the fluoride adduct of **I** (exact mass = 400.00 daltons), as confirmed by the simulation of its isotopic pattern (Figure 2). The presence of other anions at *m/z* 399 $[M - HF]^-$ and 293 $[M - Pd - HF]^-$ in the MS/MS spectrum provided the basis to discriminate between the two structures depicted in Scheme 4. The latter ion, which corresponds to the deprotonated form of **5**, clearly indicates that species **I** seen in the $^{19}F$ NMR spectrum is a $Pd^0$ complex of **5**.

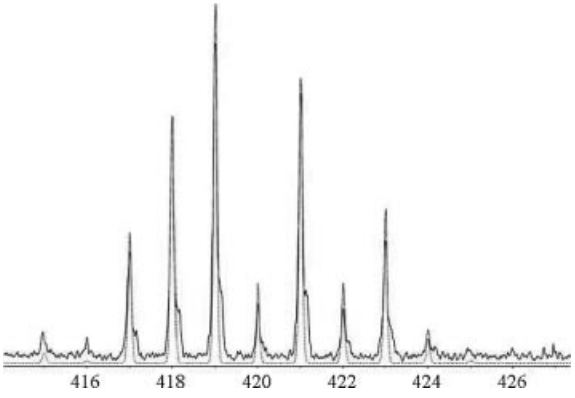

Figure 2. Experimental (solid line) and simulated (dotted line) HRMS(–) spectrum of **I** as its fluoride adduct. The error between simulated and observed isotopic patterns is –1.72 ppm.

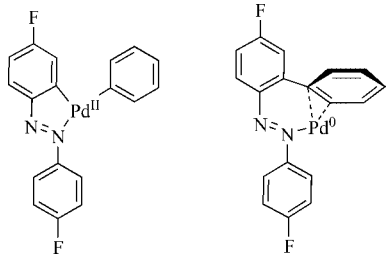
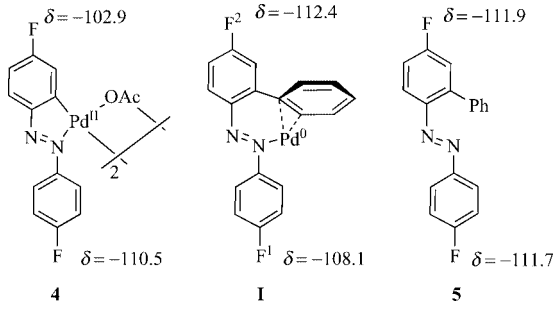


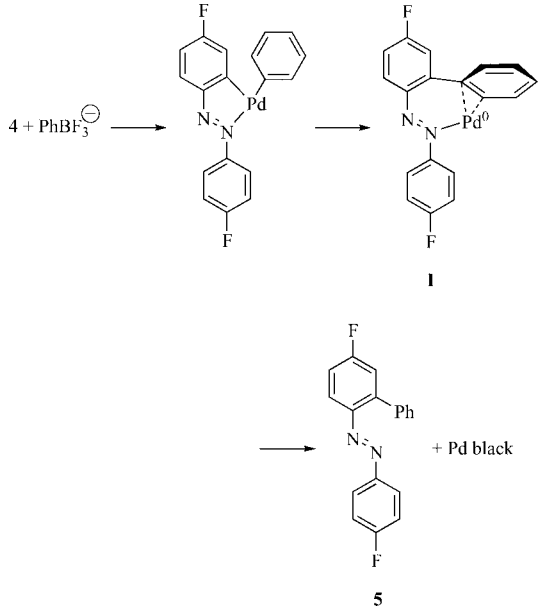
Scheme 4. Two possible structures for species **I**.

Although different structures with the same molecular formula (e.g. coordination of the other N atom, $\eta^2$ coordination of the N=N moiety or different coordination modes for the dangling phenyl) cannot be definitively ruled out,[9] the $^{19}F$ NMR resonances of **I** are in agreement with the structure depicted in Scheme 5. As suggested by a comparison of the $^{19}F$ NMR signals of **I** with those of **4**[10] and **5**, the signal at $\delta$ = –108.1 ppm in **I** can be attributed to $F^1$ while that at $\delta$ = –112.4 ppm, which is compatible with a fluorine on a 2-phenylated aryl ring in **5**, can be attributed to $F^2$.



Scheme 5. $^{19}F$ NMR features of **4**, **I** and **5**. All the chemical shifts are given for the species in methanol.

The formation of **I** and its subsequent decomposition, as shown in Figure 1, are depicted in Scheme 6. Such a process is not unexpected for a $Pd^0$ species such as **I** and has already been suggested for analogous palladacycles.[11]



Scheme 6. Reaction of **4** with phenyltrifluoroborate generates $Pd^0$ complex **I**, which slowly decomposes to **5**.

## Reaction of I with Diazonium Salts

The addition of a slight excess of diazonium salt to the catalyst solution caused the disappearance of **I** and concomitant formation of coupling products (GLC analysis) and **5** ($\delta$ = –111.7 and –111.9 ppm). Depending on the applied diazonium salts (in this case *p*-$FC_6H_4N_2BF_4$ and *p*-$CH_3C_6H_4N_2BF_4$), two new species were also formed (see parts B in Figures 3 and 4).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

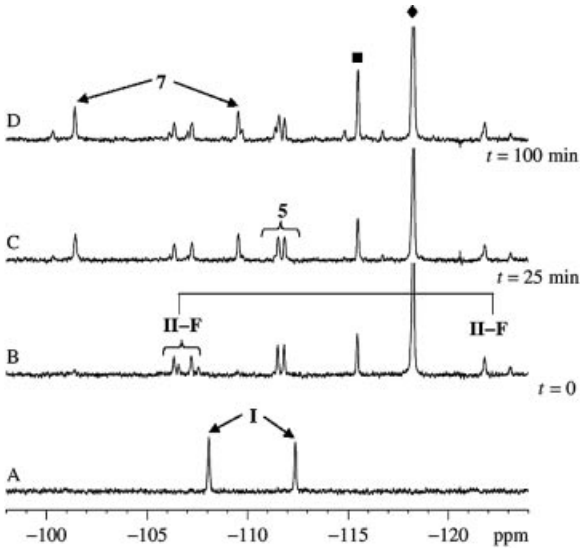


Figure 3. $^{19}F$ NMR monitoring of the reaction mixture of **4**/$KPhBF_3$ and *p*-$FC_6H_4N_2BF_4$ in methanol. A: **4**/$KPhBF_3$; B: immediately after addition of *p*-$FC_6H_4N_2BF_4$; C and D: after 25 and 100 min, respectively. ■ = 4,4′-difluorobiphenyl; ♦ = 4-fluorobiphenyl. Pd/diazonium/$KPhBF_3$ molar ratio of 1:18:15.

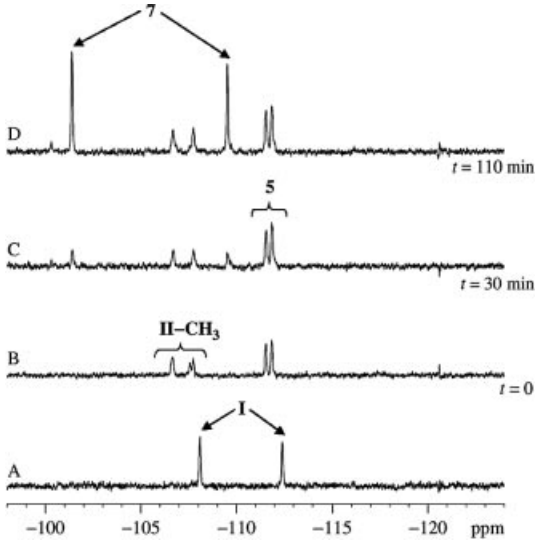

Figure 4. $^{19}F$ NMR monitoring of the reaction mixture of **4**/$KPhBF_3$ and *p*-$CH_3C_6H_4N_2BF_4$ in methanol. A: **4**/$KPhBF_3$; B: immediately after addition of *p*-$CH_3C_6H_4N_2BF_4$; C and D: after 30 and 110 min, respectively. Pd/diazonium/$KPhBF_3$ molar ratio of 1:18:15.

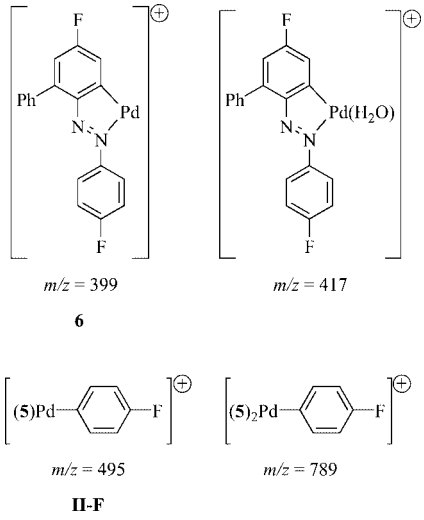
The new species formed in the case of *p*-fluorobenzenediazonium (**II-F**) shows three broad signals at $\delta$ = –106.4, –107.2 and –121.8 ppm that integrate in a 1:1:1 ratio (Figure 3), while that formed with *p*-tolyldiazonium (**II-CH$_3$**) shows only two broad signals at $\delta$ = –106.7 and –107.8 ppm that integrate in a 1:1 ratio (Figure 4).

HRMS(+) analysis of a solution containing **II-F** (that of Figure 3, B) revealed the presence of species with *m*/*z* values of 399, 417, 495 and 789. Analysis of the isotopic pattern of these peaks indicated the structures depicted in Scheme 7.



Scheme 7. $Pd^{II}$ species detected by HRMS(+) in the reaction mixture of **4**/$KPhBF_3$ after the addition of *p*-$FC_6H_4N_2BF_4$.

As already mentioned, the $^{19}F$ NMR signals of intermediate **II-F** at $\delta$ = –106.4, –107.2 and –121.8 ppm integrate in a 1:1:1 ratio and can therefore be assigned to the three fluorine atoms of the structure with *m*/*z* 495 (see Supporting Information),[12] with the downfield ones being due to the fluorine atoms of coordinated **5** and the upfield one being due to the fluorine of the σ-bonded *p*-fluorophenyl group.[13]

A structure similar to **II-F**, but with a *p*-tolyl ligand in the place of *p*-fluorophenyl, can be attributed to **II-CH$_3$**. Complexes **II-F** and **II-CH$_3$** are the products of oxidative addition of *p*-fluorophenyldiazonium and *p*-tolyldiazonium salts, respectively, to **I**.

When the reaction between **I** and *p*-$FC_6H_4N_2BF_4$ was carried out in the presence of an excess of $KPhBF_3$ (Pd/$KPhBF_3$/diazonium molar ratio of 1:18:15) the same intermediates as in Figure 3 were detected (Figure 5). However, addition of the diazonium salt did not result in the immediate disappearance of **I**, as shown in part B of Figure 5, and

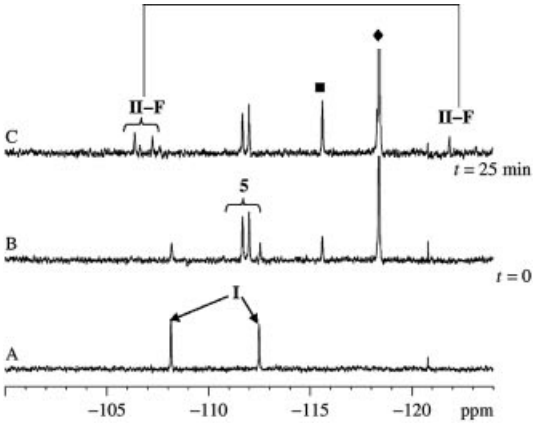


Figure 5. Reaction of **4** with excess $KPhBF_3$ and *p*-$FC_6H_4N_2BF_4$. A: **4**/$KPhBF_3$; B: immediately after addition of *p*-$FC_6H_4N_2BF_4$; C after 25 min. ■ = 4,4′-difluorobiphenyl; ♦ = 4-fluorobiphenyl. Pd/diazonium/$KPhBF_3$ molar ratio of 1:15:18.

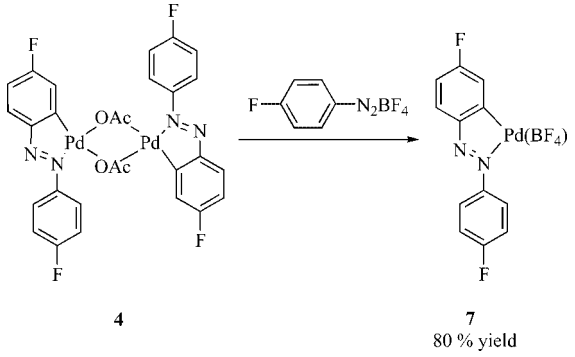
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the signals of **II-F** appeared only after consumption of **I** (Figure 5, C). Accordingly, HRMS analysis of the solution resulting from the addition of *p*-$FC_6H_4N_2BF_4$ (Figure 5, B) did not show the cations with *m*/*z* 399, 417, 495 and 789 whereas anions with *m*/*z* 419 ([**I** + F]$^-$), 399 ([**I** – H]$^-$), 487 ([**I** + $BF_4$]$^-$) and 499 ([**I** + $BF_3OMe$]$^-$) were detected in negative ion mode.

### Concurrent Activation of the Precatalyst

$^{19}F$ NMR analysis of the reaction solutions prepared from **4**, $KPhBF_3$ and diazonium salt in excess showed the formation of a new Pd complex (**7**; $\delta$ = –101.3 and –109.5 ppm) which after 1.5 h is the main Pd species in solution (see parts D in Figures 3 and 4).

Complex **7** was characterized as (4,4′-difluoroazobenzene-$C^2$,*N*)palladium(II) tetrafluoroborate, which arises from the reaction of *p*-fluorobenzenediazonium tetrafluoroborate with residual **4** (Scheme 8). Pure **7** was isolated in 80% yield from the reaction between **4** and *p*-$FC_6H_4N_2BF_4$ (1:1 Pd:diazonium salt molar ratio) in methanol at room temperature. The formation of **7** results from the abstraction of the bridging acetate of **4** by the diazonium salt[14] rather than simple metathesis of the acetate ligands with tetrafluoroborate, as demonstrated by the lack of reaction between **4** and $NaBF_4$ or [bmim]$BF_4$ (bmim = 1-*n*-butyl-3-methylimidazolium). Related (azobenzene-$C^2$,*N*)palladium(II) tetrafluoroborates have been previously synthesized by Heck starting from bis(μ-chloro)bis(azobenzene-$C^2$,*N*)-dipalladium(II) and $AgBF_4$.[15]



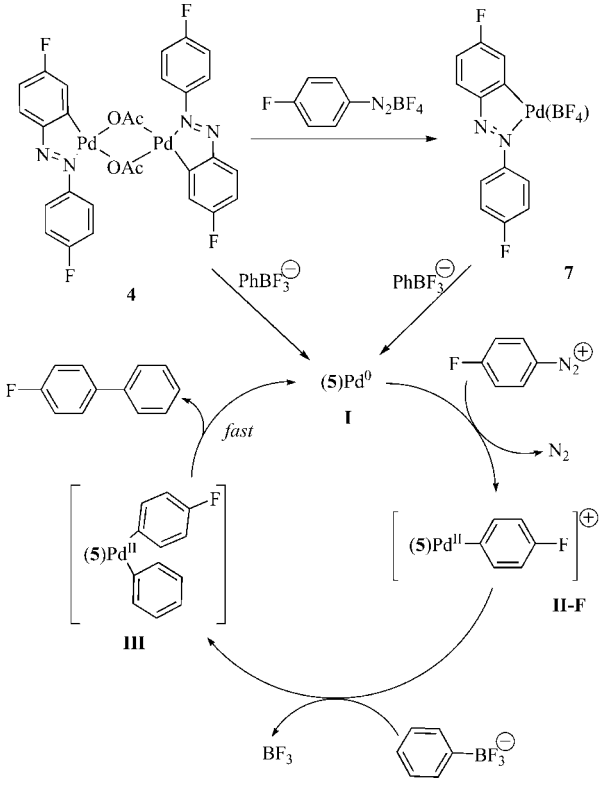
Scheme 8. Formation of complex **7**.

Complex **7** was found to be catalytically active. Thus, when **7** was used as precatalyst in the cross-coupling reaction between *p*-$CH_3C_6H_4N_2BF_4$ and $KPhBF_3$ in methanol an 88% yield of 4-methylbiphenyl was obtained in 15 min. A similar yield was obtained with the parental complex **4** only after 80 min. The higher activity of **7** compared with that of **4** can be explained by two considerations: i) complex **4** is poorly soluble in the reaction medium, while **7** is completely soluble, and ii) complex **7** is a coordinatively unsaturated species and therefore highly reactive towards prereduction reaction with $KPhBF_3$. In fact, the quantitative conversion of **7** into **I** and the subsequent slow decomposition of the latter into **5** and palladium black could be observed when following the reaction between **7** and $KPhBF_3$ by $^{19}F$ NMR spectroscopy. Thus, complex **7** can contribute to the formation of **I** and accumulates only when the aryltrifluoroborate has been consumed.

The fact that **7** survived the work-up procedures suggests that it could be responsible for the aforementioned recyclability of the catalytic solutions for reactions carried out in IL/MeOH mixtures in the presence of excess diazonium salt.[3]

### Catalytic Cycle

On the basis of the experimental data described above, the catalytic cycle shown in Scheme 9 can be proposed for palladium-catalyzed cross-coupling of diazonium salts with aryltrifluoroborates.



Scheme 9. Proposed catalytic cycle for the palladium-catalyzed cross-coupling of diazonium salts with aryltrifluoroborates.

The catalyst precursor **4** reacts with the trifluorophenylborate to give the $Pd^0$ species **I**, which is responsible for the observed catalytic activity. This species undergoes oxidative addition of the aryldiazonium salt to give the cationic arylpalladium(II) complex **II-F**, which bears the azobenzene **5** as a ligand. The catalytic cycle is completed by a transmetallation reaction between **II-F** and the organoborate to give the neutral compound **III**, which is followed by reductive elimination of the cross-coupling product. Compound **I** can also be formed from the reaction between **7** (formed from **4** and the aryldiazonium salt) and $PhBF_3^-$.

No transmetallation intermediates were detected, which indicates that the reductive elimination step from **III** is very

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fast.[16] The $^{19}F$ NMR spectroscopic data (Figure 4) allowed us to extend this mechanism to the reaction with a *p*-tolyldiazonium salt, where an intermediate analogous to **II-F** was detected.

## Conclusions

We have demonstrated that the cross-coupling between aryltrifluoroborates and diazonium salts facilitated by the acetato(azobenzene-$C^2$,*N*)palladium(II) complex **4** follows a catalytic cycle involving $Pd^0$ and $Pd^{II}$ species. The active species is a $Pd^0$ complex (**I**) bearing an arylated azobenzene as a ligand that can form by two different pathways, namely direct reaction of **4** with the arylborate or by arylation of (azobenzene-$C^2$,*N*)Pd($BF_4$) (**7**), which is generated by action of the diazonium salt on **4**. The $Pd^0$ complex **I** undergoes addition of the diazonium salt to give the cationic arylpalladium(II) complex **II** which, upon transmetallation with organoborate and fast reductive elimination, restores the active species **I**.

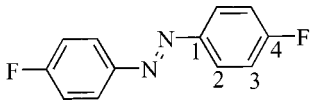
A combination of $^{19}F$ NMR and ESI-MS data has therefore allowed us to detect both intermediates **I** and **II** from the actual catalyst solutions.

## Experimental Section

**General:** Unless otherwise specified, all manipulations were carried out in air. Potassium phenyltrifluoroborate,[1] *p*-tolyldiazonium tetrafluoroborate[17] and *p*-fluorobenzenediazonium tetrafluoroborate[17] were synthesized according to literature methods. All the other reagents were commercial and used as received. All the solvents were HPLC grade and were purified by standard techniques. Flash chromatography was performed on $SiO_2$ Kieselgel (230–400 mesh). The NMR spectra were recorded with a Bruker AX400 spectrometer (400 MHz for $^1H$) at 295.0 K; chemical shifts are reported in ppm relative to $SiMe_4$ for $^1H$ and $^{13}C$, and $CFCl_3$ for $^{19}F$; $^1H$ and $^{13}C$ signals were attributed by means of $^{13}C\{^1H\}$APT, $^{13}C\{^1H\}$DEPT, $^1H$ COSY, $^1H$-$^{13}C$ HMQC and $^1H$-$^{13}C$ HMBC experiments. Deuterated solvents were purchased from Aldrich or Acros and used as received. Mass spectrometric analyses were performed using an ion-trap mass spectrometer equipped with an electrospray ion source (Bruker Esquire3000$^{plus}$). All analyses were carried out in both positive- and negative-ion modes. The sample solutions were introduced by continuous infusion with the aid of a syringe pump at a flow-rate of 180 μL min$^{-1}$. The instrument was operated in the positive-ion mode ($ESI^+$) with an end-plate offset of –500 V and a capillary offset of –4000 V. The nebuliser pressure was 0.8 bar ($N_2$) and the drying gas ($N_2$) flow 7 L h$^{-1}$. The capillary exit and skimmer 1 voltages were 90 and 30 V, respectively. The drying gas temperature was set at 200 °C. The mass spectrometric parameters in the negative ion mode ($ESI^-$) were as follows: end-plate offset: –500 V; capillary: –4000 V; capillary exit: –120 V; skimmer 1: –50 V; nebulizer pressure: 0.4 bar; drying gas flow: 5 L h$^{-1}$; drying gas temperature: 200 °C. All the samples for mechanistic studies were prepared and handled in air using HPLC-grade methanol. The software used for the simulations was Bruker Daltonics DataAnalysis (version 3.3).

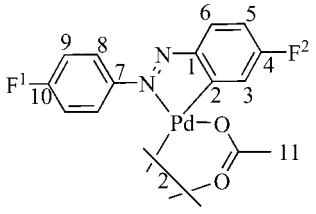
C, H, N elemental analyses were carried out with a Carlo Erba EA1108 CHNS-O elemental analyzer. Pd analyses were performed with a Perkin–Elmer SIMAA6000 atomic absorption spectrometer. The IR spectra were recorded with a Bruker Vector 22 FT-IR spectrometer. GLC analyses were performed on an HP5890 instrument equipped with a Supelco SPB-1 capillary column (30 m × 320 μm × 0.25 μm). GC-MS analyses were performed on an HP6890-HP5973MSD instrument equipped with an HP-5MS capillary column (30 m × 250 μm × 0.25 μm).

**Synthesis of 4,4′-Difluoroazobenzene**[18]



Sodium perborate (10.86 g, 0.109 mol) was added to a solution of 4-fluoroaniline (12.51 g, 0.113 mol) in 150 mL of glacial acetic acid. The system was heated at 50 °C under vigorous stirring and the reaction monitored by TLC. When the aniline has been completely consumed the system was cooled and the reaction mixture poured into a beaker containing 500 mL of cold water. The resulting suspension was neutralized with sodium carbonate and extracted with diethyl ether (3 × 150 mL). The organic phases were collected and washed with saturated sodium hydrogen carbonate (2 × 150 mL), water (2 × 250 mL) and brine (2 × 250 mL) then dried with anhydrous sodium sulfate, filtered and the solvents evaporated. The crude material was purified by column chromatography with petroleum ether (boiling range 40–70 °C) as eluent. Yield 2.46 g (20%) ppm. MS (70 eV, EI): *m*/*z* 218 (53) [$M^+$], 123 (28), 95 (100), 75 (34). $C_{12}H_8F_2N_2$ (218.20): calcd. C 66.05, H 3.70, N 12.84; found C 65.98, H 3.78, N 12.60. IR (KBr): $\tilde{\nu}$ = 430, 462, 540, 643, 668, 721, 755, 840, 951, 1008, 1093, 1141, 1201, 1232, 1288, 1302, 1415, 1499, 1593, 1653, 1896, 3061 cm$^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 7.2 (m, 4 H, $H^3$), 7.9 (m, 4 H, $H^2$) ppm. $^{13}C$ NMR (101 MHz, $CDCl_3$): $\delta$ = 116.1 (d, $^2J_{C,F}$ = 23 Hz, $C^3$), 124.9 (d, $^3J_{C,F}$ = 9 Hz, $C^2$), 149.0 (d, $^4J_{C,F}$ = 2 Hz, $C^1$), 164.4 (d, $^1J_{C,F}$ = 252 Hz, $C^4$) ppm. $^{19}F$ NMR (376 MHz, $CD_3OD$): $\delta$ = –111.6 ppm (m).

**Synthesis of Bis(μ-acetato)bis(4,4′-difluoroazobenzene-$C^2$,*N*)dipalladium(II) (4)**



Palladium acetate (0.450 g, 0.0020 mol) and 4,4′-difluoroazobenzene (0.436 g, 0.0020 mol) were dissolved in glacial acetic acid (50 mL) and the mixture was stirred at 50 °C. Once the 4,4′-difluoroazobenzene had been completely consumed (TLC monitoring) the system was cooled down to room temperature and methanol (200 mL) added to precipitate **4** as a black microcrystalline solid. This solid was filtered off, washed with diethyl ether (10 mL) and pentane (3 × 10 mL) and air-dried. Yield 0.629 g (82%). ESI-MS ($CH_2Cl_2$/$CH_3CN$): exact mass calcd. for $C_{28}H_{20}F_4N_4O_4Pd_2$: 763.95; found 364.0 [M/2 – OAc + $CH_3CN$]$^+$. $C_{28}H_{20}F_4N_4O_4Pd_2$ (765.32): calcd. C 43.94, H 2.63, N 7.32, Pd 27.81; found C 43.69, H 2.58, N 7.20, Pd 27.95. IR (KBr): $\tilde{\nu}$ = 436, 470, 534, 685, 779, 810, 844, 877, 1101, 1153, 1184, 1234, 1246, 1320, 1348, 1416, 1501, 1560, 1597, 3077 cm$^{-1}$. $^1H$ NMR (400 MHz, $CDCl_3$): $\delta$ = 2.1 (s, 6 H, $H^{11}$), 6.1 (m, 2 H, $H^3$), 6.8 (m, 2 H, $H^5$), 7.0 (m, 4 H, $H^9$), 7.4 (m, 4 H, $H^8$), 7.7 (m, 2 H, $H^6$) ppm. $^{13}C$ NMR (101 MHz, $CDCl_3$):

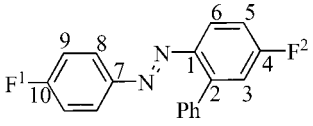
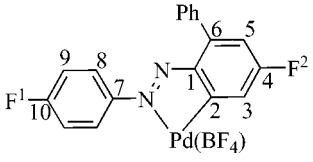
$\delta$ = 24.5 (s, $C^{11}$), 113.2 (d, $^2J_{C,F}$ = 25 Hz, $C^5$), 115.1 (d, $^2J_{C,F}$ = 23 Hz, $C^9$), 119.5 (d, $^2J_{C,F}$ = 21 Hz, $C^3$), 125.4 (d, $^3J_{C,F}$ = 9 Hz, $C^8$), 130.5 (d, $^3J_{C,F}$ = 10 Hz, $C^6$), 146.9 (d, $^4J_{C,F}$ = 3 Hz, $C^7$), 158.2 (d, $^3J_{C,F}$ = 7 Hz, $C^2$), 159.9 (d, $^4J_{C,F}$ = 3 Hz, $C^1$), 162.2 (d, $^1J_{C,F}$ = 264 Hz, $C^4$), 164.1 (d, $^1J_{C,F}$ = 253 Hz, $C^{10}$), 181.4 (s, COO) ppm. $^{19}$F NMR (376 MHz, $CD_3OD$): $\delta$ = –110.5 (m, $F^1$), –102.9 (m, $F^2$) ppm.

**Synthesis of 4,4′-Difluoro-2-phenylazobenzene (5)**



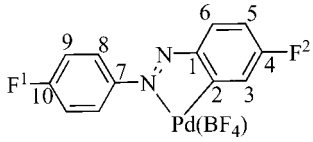
Complex **4** (0.380 g, 0.50 mmol), potassium phenyltrifluoroborate (0.250 g, 1.4 mmol) and potassium carbonate (0.225 g, 1.6 mmol) were suspended in methanol (10 mL). The system was refluxed for 1 h, then cooled and the methanol evaporated. The residue was extracted with diethyl ether (4 × 25 mL), then the organic fractions were collected and washed with water (2 × 50 mL) and brine (2 × 50 mL), dried with anhydrous sodium sulfate, filtered and the solvents evaporated. The crude product was purified by column chromatography with petroleum ether (boiling range 40–70 °C) as eluent. Yield 0.073 g (25%). MS (70 eV, EI): *m*/*z* 293 (99) [$M^+$ – 1], 184 (14), 170 (100), 151 (12), 123 (12), 95 (66), 75 (18). $C_{18}H_{12}F_2N_2$ (294.30): calcd. C 73.46, H 4.11, N 9.52; found C 73.69, H 4.28, N 9.30. IR (KBr): $\tilde{\nu}$ = 461, 542, 698, 737, 762, 781, 843, 880, 893, 1109, 1136, 1186, 1271, 1444, 1477, 1570, 1594 cm$^{-1}$. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 6.9–7.0 (m, $H^9$, $H^5$), 7.1 (m, $H^3$), 7.2 (m, Ph), 7.5–7.6 (m, $H^8$, $H^6$) ppm. $^{13}$C NMR (101 MHz, $CDCl_3$): $\delta$ = 115.2 (d, $^2J_{C,F}$ = 23 Hz, $C^5$), 116.0 (d, $^2J_{C,F}$ = 22 Hz, $C^9$), 117.2 (d, $^2J_{C,F}$ = 22 Hz, $C^3$), 118.0 (d, $^3J_{C,F}$ = 9 Hz, $C^6$), 125.1 (d, $^3J_{C,F}$ = 9 Hz, $C^8$), 127.7 (s, CH), 127.8 (s, CH), 130.7 (s, CH), 137.7 (d, $^4J_{C,F}$ = 2 Hz; 1 C), 143.6 (d, $^3J_{C,F}$ = 9 Hz, $C^2$), 145.8 (d, $^4J_{C,F}$ = 3 Hz, $C^1$), 149.2 (d, $^4J_{C,F}$ = 3 Hz, $C^7$), 164.0 (d, $^1J_{C,F}$ = 252 Hz, $C^4$), 164.2 (d, $^1J_{C,F}$ = 252 Hz, $C^{10}$) ppm. $^{19}$F NMR (376 MHz, $CD_3OD$): $\delta$ = –112.0 (m, $F^2$), –111.7 (m, $F^1$) ppm.

**Synthesis of (4,4′-Difluoro-6-phenylazobenzene-*C*$^2$,*N*)palladium(II) Tetrafluoroborate (6)**



$PdCl_2$ (36 mg, 0.2 mmol) and **5** (60 mg, 0.2 mmol) were placed in a centrifuge tube and dmso (1 mL) was added. The system was heated to 140 °C for 10 min, then cooled to room temperature. Methanol (3 mL) was added to the resulting deep red solution to precipitate an orange solid, which was centrifuged, washed with methanol (3 × 3 mL) and diethyl ether (3 × 3 mL) and vacuum dried. A 25-mg portion of this solid was placed in an NMR tube and a solution of $AgBF_4$ (12 mg, 0.06 mmol) in $CD_3OD$ (0.5 mL) was added. The NMR tube was sonicated briefly and the resulting suspension allowed to settle before analysis. $^1$H NMR (400 MHz, $CD_3OD$): $\delta$ = 6.8 (m, 1 H), 7.2 (m, 1 H), 7.3 (m, 2 H, $H^9$), 7.5 (m, 3 H, Ph), 7.6 (m, 2 H, Ph), 7.7 (m, 2 H, $H^8$) ppm. $^{13}$C NMR (101 MHz, $CD_3OD$): $\delta$ = 116.0 (d, $^2J_{C,F}$ = 24 Hz, CH), 117.1 (d, $^2J_{C,F}$ = 24 Hz, $C^9$), 119.3 (d, $^2J_{C,F}$ = 23 Hz, CH), 126.5 (d, $^3J_{C,F}$ = 9 Hz, $C^8$), 129.3 (s, CH), 130.0 (s, CH), 131.2 (s, CH), 138.8 (C), 148.0 (d, $^3J_{C,F}$ = 10 Hz, 1 C), 148.9 (C), 157.9 (d, $^3J_{C,F}$ = 7 Hz, 1 C), 158.9 (C), 163.8 (d, $^1J_{C,F}$ = 265 Hz, 1 C), 165.7 (d, $^1J_{C,F}$ = 252 Hz, 1 C) ppm. $^{19}$F NMR (376 MHz, $CD_3OD$): $\delta$ = –109.9 (m, $F^1$), –100.4 (m, $F^2$) ppm.

**Synthesis of (4,4′-Difluoroazobenzene-*C*$^2$,*N*)palladium(II) Tetrafluoroborate (7)**



Complex **4** (0.380 g, 0.50 mmol) and *p*-fluorobenzenediazonium tetrafluoroborate (0.210 g, 1.0 mmol) were suspended in dry methanol (10 mL) at room temperature under nitrogen. The suspension was vigorously stirred and the gas (dinitrogen) evolved monitored by means of a gas burette. Once the diazonium salt had completely reacted (approx. 24 mL of gas) the methanol was evaporated. The residue was treated with dry dichloromethane (3 × 10 mL) and the resulting suspension was filtered under $N_2$ through a Celite® pad. The filtrate was concentrated to about one third and dry *n*-hexane (50 mL) added to precipitate **7** as an orange powder. The product was decanted, washed with small portions of *n*-hexane and dried under vacuum. Yield 0.330 g (80%). ESI-MS ($CH_3CN$): exact mass calcd. for $C_{12}H_7BF_6N_2Pd$: 322.96; found 323.0 [M]$^+$. $C_{12}H_7BF_6N_2Pd$: 409.96; found 323.0 [M – $BF_4$]$^+$. $C_{12}H_7BF_6N_2Pd$ (410.42): calcd. C 35.12, H 1.72, N 6.83, Pd 26.93; found C 35.02, H 1.69, N 6.49, Pd 26.81. IR (nujol): $\tilde{\nu}$ = 470, 593, 779, 845, 1064, 1154, 1193, 1257, 1499, 1568, 1583, 2050 cm$^{-1}$. $^1$H NMR (400 MHz, [$D_6$]dmso): $\delta$ = 7.1 (m, 1 H, $H^3$), 7.3 (m, 1 H, $H^5$), 7.5 (m, 2 H, $H^9$), 7.9 (m, 2 H, $H^8$), 8.1 (m, 1 H, $H^6$) ppm. $^{13}$C NMR (101 MHz, [$D_6$]dmso): $\delta$ = 114.3 (d, $^2J_{C,F}$ = 24 Hz, $C^5$), 116.1 (d, $^2J_{C,F}$ = 23 Hz, $C^9$), 119.2 (d, $^2J_{C,F}$ = 23 Hz, $C^3$), 126.0 (d, $^3J_{C,F}$ = 9 Hz, $C^8$), 132.3 (d, $^3J_{C,F}$ = 10 Hz, $C^6$), 147.1 (d, $^4J_{C,F}$ = 3 Hz, $C^7$), 156.3 (d, $^3J_{C,F}$ = 7 Hz, $C^2$), 160.5 (d, $^4J_{C,F}$ = 3 Hz, $C^1$), 161.8 (d, $^1J_{C,F}$ = 263 Hz, $C^4$), 163.6 (d, $^1J_{C,F}$ = 250 Hz, $C^{10}$) ppm. $^{19}$F NMR (376 MHz, $CD_3OD$): $\delta$ = –154.6 (br. s, $BF_4$), –109.6 (br. s, $F^1$), –101.6 (br. s, $F^2$) ppm.

**Catalysis with Precatalyst 4:** $KPhBF_3$ (221 mg, 1.2 mmol) and *p*-$CH_3C_6H_4N_2BF_4$ (206 mg, 1.0 mmol) were added, with vigorous stirring, to a suspension of **4** (7.65 mg, 0.010 mmol) in methanol (4 mL) in a 10-mL Schlenk tube. At the end of the reaction (80 min) the mixture was diluted with water (100 mL) and the products were extracted with diethyl ether (3 × 25 mL); the organic phases were collected and dried with $Na_2SO_4$. The products were purified by flash chromatography and characterized by GC-MS. The yield was determined by GLC using naphthalene as an internal standard.

**Reaction of 4 with Potassium Phenyltrifluoroborate:** HPLC-grade methanol (0.5 mL) was added to a vial containing complex **4** (7 mg, 9 μmol) and potassium phenyltrifluoroborate (25 mg, 137 μmol) and the mixture shaken for half a minute. The resulting suspension was transferred into an NMR tube containing an internal insert of $CDCl_3$ for the deuterium lock. A 0.05-mL aliquot of the same suspension was diluted to 5 mL with HPLC-grade methanol and used in ESI-MS experiments.

**Reaction of Complex 4 with Potassium Phenyltrifluoroborate and Diazonium Salts:** HPLC-grade methanol (0.5 mL) was added to a vial containing complex **4** (7 mg, 9 μmol) and potassium phenyltrifluoroborate (25 mg, 137 μmol) and the mixture shaken for half a minute. A solution of diazonium salt (165 μmol) in HPLC-grade methanol (0.5 mL) was added to the resulting suspension and the

# Fine-Tuning Ligands for Catalysis Using Supramolecular Strategies

Vincent F. Slagt,[a][‡] Patrick Kaiser,[b] Albrecht Berkessel,[b] Mark Kuil,[a] Alexander M. Kluwer,[a] Piet W. N. M. van Leeuwen,[a] and Joost N. H. Reek*[a]

**Keywords:** Supramolecular catalysts / Self-assembly / Ligand effects / Phosphorus ligands / Porphyrinoids

Coordinative bonds have been used to prepare *supramolecular ligands* leading to well-defined catalysts formed by assembly. The construction of these ligands is based on selective metal–ligand interactions between nitrogen donor atoms of phosphorus-nitrogen building blocks and various zinc(II) porphyrins. The major advantage of this supramolecular approach of catalyst preparation is the simplification of ligand variation enabling straightforward modification of steric, electronic and chiral properties of the supramolecular ligand. A large number of new ligands becomes accessible by this modular variation of the building blocks. The ligand assembly based on pyridyl phosphites and zinc(II) porphyrin with electron-withdrawing substituents led to a twelve-fold increase in activity and an increase in enantioselectivity from 17 to 50 % in the rhodium-catalyzed hydrogenation of dimethyl itaconate. The first examples of assemblies based on non-chiral ligands and chiral zinc(II) porphyrin template molecules show, as proof of principle, an enantiomeric excess up to 18 % in the asymmetric palladium-catalyzed allylic alkylation.

## Introduction

In the past three decades, the exploration of ligand effects in transition-metal catalysis has proven to be a very powerful tool in homogeneous catalysis. Variation of steric[1] and electronic properties,[2] as well as the "natural bite angle"[3] for bidentate ligands, has been used to optimize many catalytic reactions. These ligand parameters have proven to control key features of catalysts, like activity, selectivity and stability, and systematic variation has resulted in better understanding of ligand effects in catalysis.[1–14] For example, electron-withdrawing substituents on the aryl ring of the phosphorus donor atom of mono- and bidentate phosphane ligands increases the activity and selectivity of the catalyst in the rhodium-catalyzed hydroformylation of 1-octene.[15] In the palladium-catalyzed arylation of alkenes, bulky phosphorus amidite ligands yielded very fast catalysts.[16] Both electronic and steric parameters of these ligands were found to be extremely important. The ligand has to be sufficiently bulky to impose formation of monoligated palladium complexes as active catalysts, but ligands that are too large retard the reaction rate.

Recently, we[17,18] and others[19] have introduced a new class of bidentate ligands that are formed by a self-assembly process of two monodentate ligands. We demonstrated that the SUPRAphos[18b,18e,18f] concept – bringing two monodentate ligands together via zinc(II)–porphyrin–pyridyl interactions to form bidentate ligands – provides easy access to large bidentate ligand libraries, and that these ligands can successfully be applied to various reactions including the rhodium-catalyzed asymmetric hydrogenation. High-throughput screening of a part of the library revealed a catalyst that hydrogenates a trisubstituted cyclic enamide, a notoriously difficult substrate, with the highest enantioselectivity known to date.[18f] This unambiguously shows that the supramolecular approach to create bidentate ligands is a very powerful tool that brings about new catalysts with properties that surpass those already known. In addition, from the library of 64 SUPRAphos ligands that was investigated, only one provided a catalyst that induced high *ee* values, stressing the point that for challenging asymmetric conversion such as the hydrogenation of the trisubstituted cyclic enamide, large ligand libraries are required. One of the advantages typical of supramolecular ligands is the easy access to these large libraries. After the successful exploration of our SUPRAphos[18b,18e,18f] library based on porphyrin-appended ligands we have extended our approach to urea-based homo-bidentate ligands[20] and chiral analogues thereof for the use in asymmetric conversions.[21] This class of supramolecular bidentate ligands are easily accessible, in large variety and at an industrially interesting scale.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

Although the preparation of monodentate ligands[22] is much easier than bidentate ligands,[23] a novel supramolecular strategy could also facilitate the preparation of large libraries of monodentate ligands. Here we report such a supramolecular strategy to change the electronic and steric properties of ligands that are equipped with pyridine and amine functional groups for the assembly of phosphorus ligands on zinc(II) porphyrin template molecules (Figure 1). The typical binding motif was previously used in the SUPRAphos concept and for the encapsulation of transition metal catalysts[24] by assembly of zinc(II) porphyrin building blocks.[25] By using the same binding motif we now show that we can vary the steric and electronic properties of phosphorus ligands by the association of the zinc(II) porphyrin templates. In this way, a series of new supramolecular ligands is prepared by just mixing the components. NMR, IR, and UV/Vis spectroscopy have been used to study the selective metal–ligand interactions and to quantify the steric and electronic properties of these supramolecular ligands. The supramolecular ligands control the activity and (enantio)selectivity of the transition metal catalysts as observed in rhodium-catalyzed hydroformylation, asymmetric hydrogenation, and asymmetric palladium-catalyzed allylic alkylation. The approach is extended to the assembly of a chiral environment around a non-chiral catalyst.

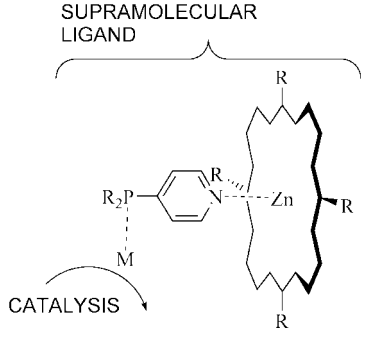

Figure 1. Schematic representation of the assembly of a phosphorus ligand on a zinc(II) porphyrin template molecule.

## Results and Discussion

### The Assembly of Phosphorus Ligands and Zinc(II) Porphyrin Building Blocks

For the preparation of supramolecular ligands with different steric and electronic properties, we synthesized several phosphorus ligands functionalized with a nitrogen donor atom and zinc(II) porphyrins (Figure 2). The phosphite ligands **2**–**4** were obtained in high yields by a reaction of the phosphor chloridite[26] with 3-hydroxypyridine. Zinc(II) *meso*,*meso*,*meso*,*meso*-tetraphenylporphyrin (**1a**) was prepared according to standard procedures.[27,28] All new compounds were fully characterized with $^{1}$H NMR, $^{31}$P-NMR and $^{13}$C-NMR spectroscopy, elemental analysis and mass spectrometry.

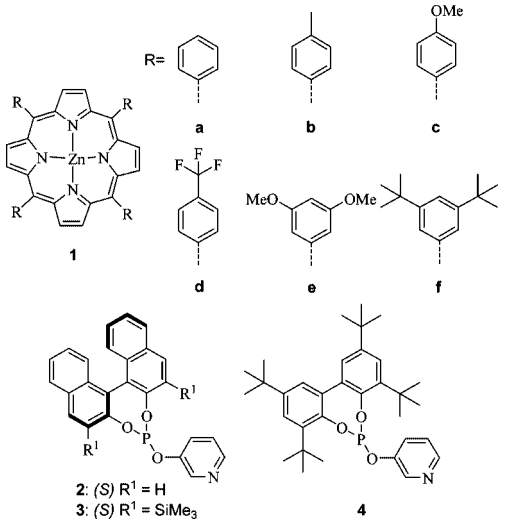

Figure 2. Various building blocks used to construct supramolecular ligands.

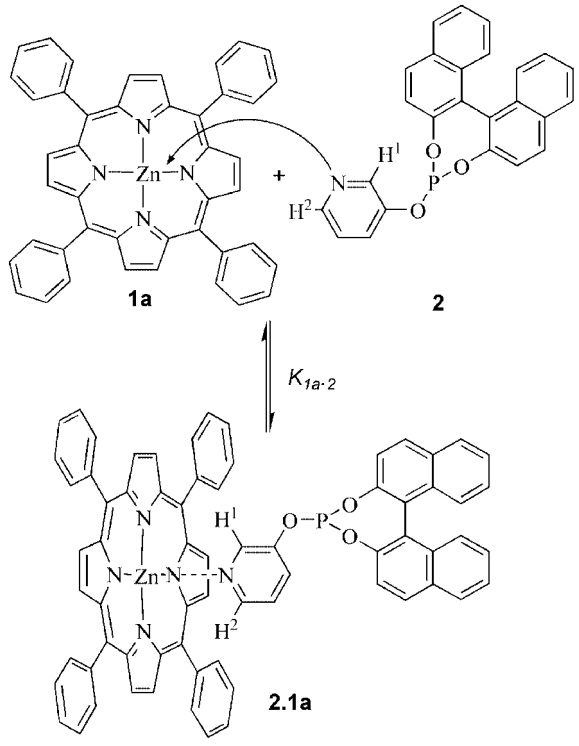
The coordination behavior of the pyridine phosphorus ligands **2** to **1a** has been studied using NMR and UV/Vis spectroscopy.[29,30] The addition of **1a** to a solution of **2** resulted in large upfield shifts of the protons on the pyridyl ring in $^{1}$H NMR spectroscopy ($\Delta\delta^{H1}$ = 5.7 ppm, $\Delta\delta^{H2}$ = 5.8 ppm), which is typical of axial binding of pyridine ligands to zinc(II) porphyrins (Scheme 1).[24,25] Also in $^{31}$P



Scheme 1. Assembly of (*S*)-(1,1′-binaphthyl-2,2′-diyl) (3-pyridyl) phosphite (**2**) on zinc(II) *meso*,*meso*,*meso*,*meso*-tetraphenylporphyrin (**1a**).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

NMR spectroscopy, a large shift to higher field ($\Delta\delta^P$ = 4.6 ppm) was observed on binding of **2** to the complex **1a**. In the UV/Vis spectrum of **1a** the typical red-shift of the Q-bands of the porphyrin on the addition of **2** was observed, indicating axial coordination of the pyridine to the zinc, and the associated binding constant determined by UV titrations was found to be high ($K_{1a.2} = 1.3 \times 10^3$ M$^{-1}$).

The binding of zinc(II) porphyrin building blocks through the nitrogen donor atom is very selective and therefore the phosphorus atom is available for coordination to transition metals that potentially can act as catalysts. Mixing two equivalents **1a** (with respect to the complex and one equivalent with respect to the ligand) with in situ formed [Rh(acac)(**2**)$_2$] yielded an assembly in which the transition metal is embedded between the two porphyrin building blocks [Rh(acac)(**2**·**1a**)$_2$], as was evident from the shifts in NMR spectroscopy. In the $^{31}$P NMR spectra the addition of the porphyrin **1a** resulted in an interestingly large upfield shift of the phosphite signals, from $\delta$ = 151.3 ppm (doublet, $J_{P-Rh}$ = 303 Hz) to $\delta$ = 144.5 ppm (doublet, $J_{P-Rh}$ = 304 Hz) (Figure 3). The large shift of $\Delta\delta^P$ = 6.8 ppm is attributed to a combination of effects: changes in the electronic and steric properties of the phosphite and the ring-current effect of the nearby complexed zinc(II) porphyrin **1a**.

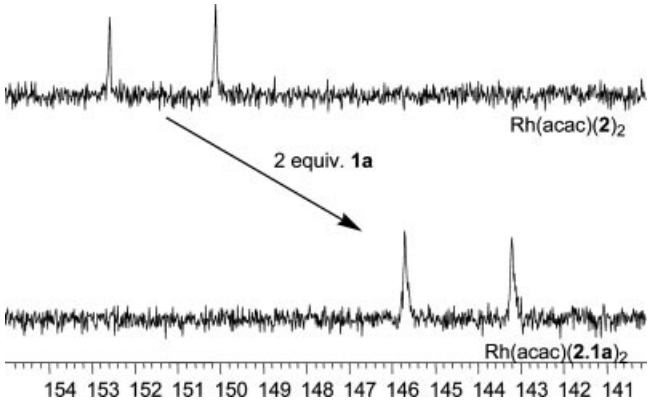


Figure 3. $^{31}$P NMR spectra before (above) and after (below) addition of two equivalents of zinc(II) *meso*,*meso*,*meso*,*meso*-tetraphenylporphyrin (**1a**) to the complex [Rh(acac)(**2**)$_2$].

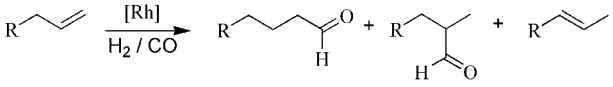
## Assemblies of Zinc(II) Porphyrin and Phosphorus Ligands in Transition-Metal Catalysis

The supramolecular complexes based on the zinc(II) porphyrin **1a** and pyridyl phosphite ligands **2** and **4** were studied in the rhodium-catalyzed hydroformylation of 1-octene (Scheme 2).[9,31] The experiments were carried out in toluene under 20 bar of syngas ($H_2$/CO = 1:1) and the results are summarized in Table 1. The catalyst formed by ligand **2** yielded a moderate activity and reasonable selectivity in the hydroformylation of 1-octene at 120 °C, and the isomerization side reaction resulted in 25% internal alkenes. The assembly based on the zinc(II) porphyrin **1a** and **2** did not influence the catalytic behavior and similar activity, selectivity and isomerization were observed.[32] The more bulky ligand **4** yielded a catalyst with different properties; an increase in activity and decrease in selectivity (linear-branched ratio, l/b = 2.1) was observed for this system compared to ligand **2**. These differences are explained by the formation of monoligated rhodium phosphite complexes, as previously observed for other bulky phosphite ligands.[33] Upon using assembly **4**·**1a** an increase in activity and isomerization was observed, showing that the assembly of zinc(II) porphyrin templates to ligands with nitrogen donor atoms influences the performance of the transition metal catalyst based on these ligands, which stimulated further studies on these assembled ligand systems.



Scheme 2. The rhodium-catalyzed hydroformylation leading to the linear and branched aldehyde.

Table 1. Rhodium-catalyzed hydroformylation of 1-octene using assemblies of pyridyl phosphite and zinc(II) porphyrins template as ligands.[a]

| Ligand[b] | Temp. [°C] | T.O.F.[c] | l/b[d] | % 2-Octene[e] |
|---|---|---|---|---|
| **2** | 120 | $1.2 \times 10^3$ | 6.0 | 24.6 |
| **2**·**1a** | 120 | $1.3 \times 10^3$ | 7.0 | 19.8 |
| **4** | 80 | $2.3 \times 10^3$ | 2.1 | 21.6 |
| **4**·**1a** | 80 | $3.0 \times 10^3$ | 2.0 | 26.0 |

[a] [Rh(acac)(CO)$_2$] = 0.084 mmol/L in toluene, pressure: 20 bar (CO/$H_2$ = 1:1), 1-octene/rhodium = 5160. [b] [Phosphorus ligand **2** or **4**] = 2.1 mmol/L, [porphyrin] = 2.1 mmol/L. [c] T.O.F. = average turn over frequency: (mol aldehyde)(mol Rh)$^{-1}$ h$^{-1}$, the reaction was stopped after 1 h. [d] l/b = linear/branched. [e] Percent isomerization to 2-octene (and some 3- and 4-octene).

## Changing the Electronic Properties of Phosphorus Ligands

To study these new self-assembled ligands based on selective nitrogen–zinc interactions in more detail, several zinc(II) porphyrins **1a**–**d** were synthesized with different electron-withdrawing and -donating substituents.[27,28] The binding constants of zinc(II) porphyrins **1a**–**d** to diphenyl(4-pyridyl)-phosphane (**7**) (Figure 4) in toluene were determined using UV/Vis spectroscopy. It was found that the porphyrin with the most electron-withdrawing substituents yielded the highest binding constant (Table 2) and a linear relation between binding constants and the Hammett values[34] was observed, with a corresponding electronic dependence value of $\rho$ = 0.285 (Figure 5).

[a] Measured in dichloromethane, carbonyl region.

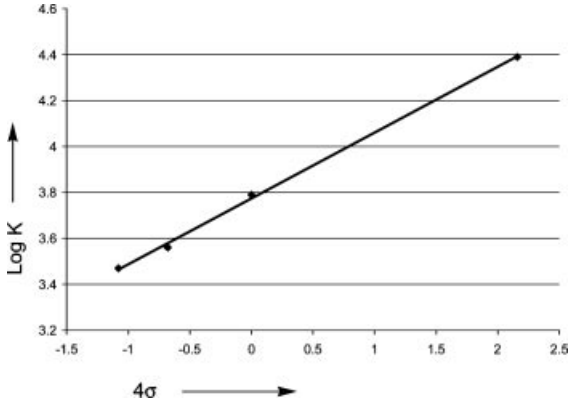

Figure 5. Plot log $K$ vs. 4σ (sigma *para*) for the assembly of zinc(II) porphyrin complexes **1a**–**d** and diphenyl(4-pyridyl)phosphane (**7**).

The substituents on the zinc(II) porphyrin template **1a**–**d** change the π back bonding of the zinc(II) metal ion to the porphyrin macrocycle, hence influencing the electron density of the pyridine moiety ring fragment.[35] Therefore, also an effect in electron density on the phosphorus donor atom is expected. Zinc(II) porphyrins containing more electron-withdrawing substituents will increase the electron-withdrawing capacity of the pyridine ring, which will result in a lower basicity of the phosphorus donor atom. (Diphenyl)(4-pyridyl)phosphane (**7**) and [Rh(CO)$_2$(Cl)]$_2$ were mixed in a 4:1 ratio to form in situ [Rh(**7**)$_2$(CO)Cl] and subsequently a stoichiometric amount of zinc(II) porphyrin **1a**–**d** was added.[36] The IR spectra of these assembled rhodium complexes show that addition of zinc(II) porphyrin changes the shift of the carbonyl ($\tilde{\nu}_{CO}$ = 1982 cm$^{-1}$) of [Rh(**7**)$_2$(CO)Cl] to higher wave numbers (up to $\tilde{\nu}_{CO}$ = 1986 cm$^{-1}$). The $\tilde{\nu}_{CO}$ band shows a gradual shift with decreasing phosphane basicity (Table 2). The lower electron density on the rhodium leads to a decrease in back bonding from the rhodium to the carbonyl ligand and hence higher CO stretching frequencies are observed. For comparison, when the strongly electron-withdrawing tris(4-α,α,α-trifluorotoluyl)phosphane is used, the $\tilde{\nu}_{CO}$ band is at 1990 cm$^{-1}$, which is a shift of 12 cm$^{-1}$ compared to triphenylphosphane, ($\tilde{\nu}_{CO}$ = 1978 cm$^{-1}$).[36,37] These results show that the effects induced by the zinc(II) porphyrin templates **1a**–**d** are significant. For phosphane **7**, the pyridine is directly attached to the phosphorus, and therefore changes on the nitrogen donor atom were expected to change the basicity of the phosphorus. Upon using a different spacer between the phosphorus and the nitrogen one can envisage that electronic effects on the phosphorus caused by the assembly of zinc(II) porphyrin templates **1a**–**d** will be different. Indeed, the use of diphenyl(3-pyridylmethyl)phosphane (**8**), a similar building block as **7** but with a spacer that has changed from 4-pyridine to 3-methylpyridine, shows that the carbonyl peak in the infrared spectrum of complex [Rh(**8**)$_2$(CO)Cl] hardly changes upon assembling the zinc(II) porphyrin templates **1a**–**d** ($\tilde{\nu}_{CO}$ = 1979–1980 cm$^{-1}$). Thus, these experiments show that electron-withdrawing substituents on the zinc(II) porphyrin that is used as a template can modify the electronic properties of the phosphane ligands, depending on the spacer between the nitrogen and phosphorus donor atom of the ligand building block.

The electronic effect of zinc(II) porphyrin templates **1a**–**d** on diphenyl(4-pyridyl)phosphane (**7**) and diphenyl(3-pyridylmethyl)phosphane (**8**) were studied in the rhodium-catalyzed hydroformylation of 1-octene (Table 3). The assemblies of zinc(II) porphyrin **1a**–**d** and **7** show a small but distinct trend in activity (**7**·**1c**<**7**·**1b**<**7**·**1a**<**7**·**1d**). The assemblies based on more electron-withdrawing zinc(II) porphyrin templates and **7** show a small increase in conversion in the rhodium-catalyzed hydroformylation of 1-octene. From the infrared spectra we know that this effect is caused by the lower basicity of the phosphane donor atoms. In the literature a similar trend has been reported for systems in which the electronic properties of the ligands were varied in a covalent manner.[15] For the various ligand assemblies based on phosphane **8** and zinc(II) porphyrin **1a**–**d** the differences in activity are negligible. This is in line with the almost identical infrared CO stretching frequencies observed for the rhodium complexes. The catalytic results obtained for the assemblies based on zinc(II) porphyrin **1a**–**d** and ligands **7** and **8** show that the spacer between the nitrogen and phosphorus donor atoms is of great importance for the small but distinct electronic influences on the phosphorus induced by the assembly process.

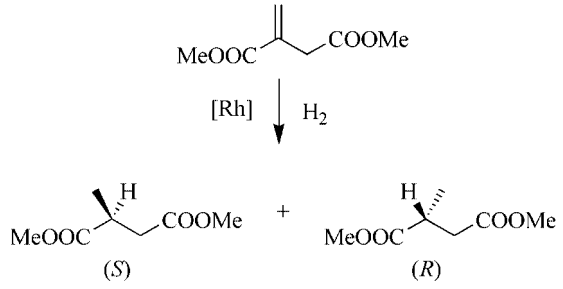
## Application of Supramolecular Ligands in Asymmetric Hydrogenation

The supramolecular ligands were used in the asymmetric rhodium-catalyzed hydrogenation[49] of dimethyl itaconate to dimethyl methylsuccinate (Scheme 3). The ligands were based on the assembly of (*S*)-[3,3′-bis(trimethylsilyl)-1,1′-binaphthyl-2,2′-diyl] (3-pyridyl) phosphite (**3**) and zinc(II) porphyrins **1a**–**f**. Ligand **3** shows low conversion and enantioselectivity in the hydrogenation of dimethyl itaconate (Table 4). In contrast, the assemblies based on zinc(II) porphyrin template **1a**–**d** and ligand **3** give higher conversion and enantioselectivity. Electron-withdrawing substituents on the zinc(II) porphyrin **1a**–**d** have a positive effect on the activity, a twelve-fold increase for the most electron-withdrawing zinc(II) porphyrin **1d** was observed. Interestingly, the ligand based on the assembly of **1d** and **3** increases the enantioselectivity from 16% to 50% (*R*).



Scheme 3. The rhodium-catalyzed hydrogenation of dimethyl itaconate.

After having observed a clear electronic effect, we decided to look at the effect of the size of various ligand assemblies in catalysis by changing the substituents on the zinc(II) porphyrin **1a**–**d**. The ligand assemblies **3·1a**–**3·1d** and the more bulky ligand assemblies **3·1e** and **3·1f** were tested in the rhodium-catalyzed hydrogenation of dimethyl itaconate. The different substituents on the aryl groups of the zinc(II) porphyrins **1e** and **1f** not only change the size of the ligand, but also lead to different electronic properties of the assembled ligand system. The assembled **3·1e** yielded

Table 4. Hydrogenation of dimethyl itaconate using different rhodium catalyst assemblies: variation of the zinc(II)porphyrin template.[a]

| Ligand[b] | % Conversion[c] | % *ee*[d] |
|---|---|---|
| **3** | 1.6 | 16 (*R*) |
| **3·1a** | 8.1 | 33 (*R*) |
| **3·1b** | 6.2 | 21 (*R*) |
| **3·1c** | 4.3 | 31 (*R*) |
| **3·1d** | 18.8 | 50 (*R*) |
| **3·1e** | 2.5 | 2 (*R*) |
| **3·1f** | 3.1 | 40 (*R*) |

[a] [$Rh(nbd)_2(BPh_4)$] = 1.0 mmol/L, [dimethyl itaconate] = 100 mmol/L, pressure: 5 bar hydrogen, $T$ = 40 °C. [b] [phosphite] = 3.0 mmol/L, [porphyrin] = 3.0 mmol/L. [c] The reaction was stopped after 17 h. [d] *ee* = enantiomeric excess.

no enantioselectivity, and a low conversion was detected in the hydrogenation. The low conversion is explained by the strong electron-donating capacity of the methoxy groups of **1e**. The more bulky ligand **3·1f** resulted in a catalyst that gave an enantiomeric excess of 40% (*R*), but at low activity.

The use of selective metal–ligand interactions to change ligand properties can be extended easily to bidentate ligands (Figure 6). The chiral (2*S*,4*S*)-(–)-4-(diphenylphosphanyl)-2-(diphenylphosphanylmethyl)pyrrolidine (**9**)[38] binds to zinc(II) porphyrins by axial coordination of the nitrogen donor atom in the pyrrolidine ring to the zinc(II) ion. $^1$H NMR spectroscopy in [D]chloroform showed a large shift for the pyrrolidine protons of **9** on addition of one equivalent of zinc(II) porphyrin **1a**, as is typical of this type of binding. Also in the $^{31}$P NMR spectra a change in chemical shifts was observed, $\Delta\delta$P(2*S*) = 4.3 ppm (Figure 7).

### Application of Supramolecular Ligands in Asymmetric Hydroformylation

The zinc(II) porphyrins **1a**, **1e** and **1f** were used to form new ligand assemblies with the diphosphane **9**, which were applied in the asymmetric rhodium-catalyzed hydroformylation[9,50] of styrene (40 °C, toluene, 20 bar $CO/H_2$). As is shown in Table 5, the catalyst based on the bidentate ligand **9** resulted in moderate enantioselectivity [19% *ee*, (*S*)-product] and activity in the hydroformylation of styrene. The ligand assembly based on zinc(II) porphyrin **9·1a** resulted in small increase in enantioselectivity and a decrease in activity. Electronic changes on phosphorus caused by the assembly of the zinc(II) porphyrin template are considered to be very small, because the use of the zinc(II) *meso*-*p*-$CF_3$-phenylporphyrin **1d** yielded similar results as **1a**. Increasing the bulk of the porphyrin building block by using **1f**, the enantioselectivity further improved to 29% (*S*), at the cost of a lower activity and lower branched to linear ratio. These results indicate that variation of steric bulk around the catalyst introduced by supramolecular interactions using different porphyrin building blocks modifies the ligand properties and the catalytic performance of their metal complexes, both for mono- and bidentate ligands.

Table 5. Hydroformylation of styrene using assemblies based on the chiral diphosphane **9**: variation of the zinc(II) porphyrin template.[a]

| Ligand[b] | % Conversion[c] | T.O.F.[d] | b/l[e] | % *ee*[f] |
|---|---|---|---|---|
| **9** | 54 | 14.2 | 5.2 | 19 (*S*) |
| **9·1a** | 25 | 6.7 | 5.6 | 23 (*S*) |
| **9·1e** | 15 | 4.0 | 3.9 | 26 (*S*) |
| **9·1f** | 9 | 2.3 | 2.4 | 29 (*S*) |

[a] [Rh] = 0.33 mmol/L in toluene, pressure: 20 bar ($CO/H_2$ = 1:1), $T$ = 40 °C, styrene/rhodium = 1750, in none of the reactions hydrogenation was observed. [b] [phosphane] = 1.67 mmol/L, [porphyrin] = 1.67 mmol/L. [c] Percent conversion, the reaction was stopped after 66.5 h. [d] T.O.F. = average turn over frequency: (mol aldehyde)(mol Rh)$^{-1}$h$^{-1}$. [e] b/l = branched/linear. [f] *ee* = enantiomeric excess.

### Introducing a Chiral Environment around a Non-Chiral Catalyst

In the previous section we described the fine-tuning of catalyst properties by the introduction of steric bulk around a chiral catalyst by supramolecular interactions. An even greater challenge would be the introduction of a chiral environment around a non-chiral catalyst via a selective assembly process, resulting in a chiral catalyst assembly for asymmetric catalysis. Towards this goal, chiral zinc(II) porphyrin building blocks based on octahydro-1,4:5,8-dimethanoanthracene **12a**–**12d** were synthesized (Figure 8).[39] This type of porphyrin is known to be very selective in the ruthenium- or manganese-catalyzed epoxidation[39,40] and cyclopropanation[41] of alkenes. The crystal structure[39] of the zinc(II) porphyrin **12a** shows that the chiral moieties are highly symmetrically positioned around the core of the porphyrin and molecular modeling[42] suggests that there is enough space for axial ligand coordination to the zinc metal (Figure 9).

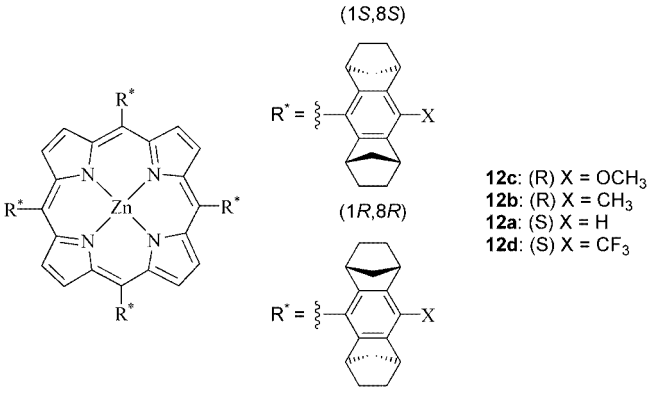

Figure 8. Various chiral porphyrin building blocks used to construct supramolecular ligands.

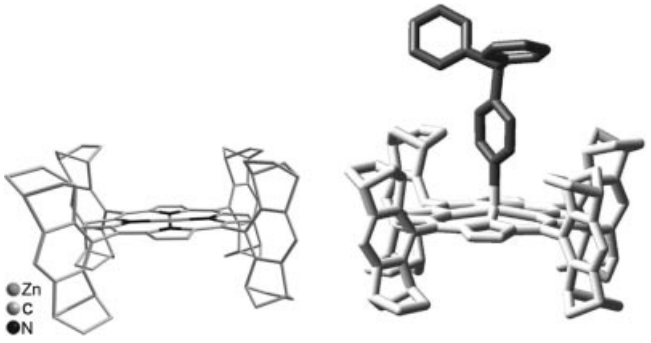

Figure 9. Crystal structure of the zinc(II) complex of *meso*,*meso*,-*meso*,*meso*-tetrakis(octahydro-1,4:5,8-dimethanoanthryl)porphyrin (**12a**) (left) and modeled structure of the assembly of **12a** (white) and diphenyl(4-pyridyl)phosphane (**7**) (dark gray, right).

Upon mixing the ligands **6**–**8** in a 1:1 ratio with the zinc(II) porphyrin **12a** supramolecular complexes were formed by complexation of the nitrogen donor atom to the axial position of zinc(II). Binding constants were determined with UV/Vis spectroscopy titrations in toluene (Table 6). Phosphane **7** has the strongest affinity for **12a** ($K$ = $3.5 \times 10^3$ M$^{-1}$) and the binding constant of phosphane **6** is approximately three times smaller ($K = 8.7 \times 10^2$ M$^{-1}$).

Table 6. Binding constants of various pyridylphosphane ligands to zinc(II) porphyrin template **12a** (and **1a** for comparison) measured by UV/Vis titrations in toluene.

| Ligand | $K$ [M$^{-1}$] | Ligand | $K$ [M$^{-1}$] |
|---|---|---|---|
| **6·12a** | $0.87 \times 10^3$ | **6·1a** | $2.3 \times 10^3$ |
| **7·12a** | $3.5 \times 10^3$ | **7·1a** | $6.1 \times 10^3$ |
| **8·12a** | $1.6 \times 10^3$ | **8·1a** | $4.0 \times 10^3$ |

A similar trend for these ligands was already observed with the complexation to the zinc(II) porphyrin **1a**, and the small differences observed for **6**–**8** are likely due to electronic effects. Titrations monitored with UV/Vis spectroscopy to determine binding constants between chiral zinc(II) porphyrins **12a**–**12d** and **7** in toluene showed that electron-withdrawing substituent X on the porphyrin resulted in higher binding constant ($OMe < Me < H < CF_3$) (Table 7), which corroborates the results obtained for **7** and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

zinc(II) porphyrin **1a**–**1d**. A similar linear relation between binding constants and the Hammett values is observed, with a corresponding electronic dependence value of $\rho$ = 0.201 (Figure 10), which is comparable with results reported in literature.[43]

Table 7. Binding constants $K$ of diphenyl(4-pyridyl)phosphane (**7**) to various zinc(II) porphyrin templates **12a**–**12d** measured by UV/Vis titrations.

| Porphyrin | $K$ [M$^{-1}$] | log $K$ | 4σ |
|---|---|---|---|
| (*R*)-$OCH_3$-porphyrin-Zn, **12c** | $2.2 \times 10^3$ | 3.346 | –1.08 |
| (*R*)-$CH_3$-porphyrin-Zn, **12b** | $2.8 \times 10^3$ | 3.444 | –0.68 |
| (*S*)-H-porphyrin-Zn, **12a** | $3.5 \times 10^3$ | 3.545 | 0 |
| (*S*)-$CF_3$-porphyrin-Zn, **12d** | $10.0 \times 10^3$ | 4.000 | 2.16 |

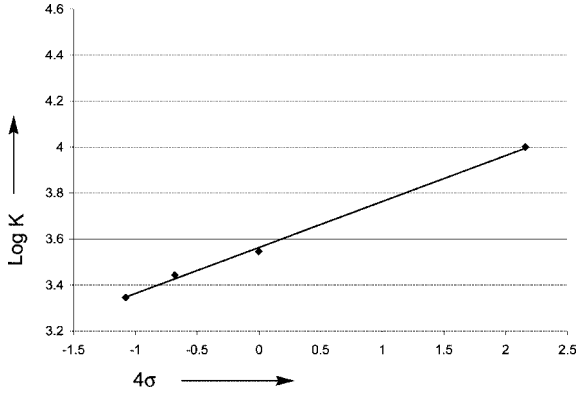

Figure 10. Plot log $K$ vs. 4σ for the reaction of zinc(II) porphyrins **12a**–**d** and diphenyl(4-pyridyl)phosphane (**7**).

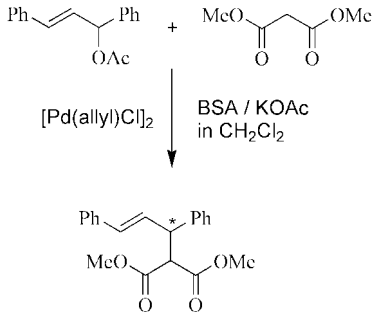
To study the effect of the "associated" chiral environment, assemblies based on zinc(II) porphyrin **12a** and **4**–**8** were tested as ligands in the asymmetric palladium-catalyzed allylic alkylation[51] using 1,3-diphenylallyl acetate as the substrate and dimethyl malonate as the nucleophile (Scheme 4). Table 8 shows that the chiral zinc(II) porphyrin **12a** was not active in the palladium-catalyzed allylic alkylation and that the palladium complexes based on triphenylphosphane (**5**) in the presence of enantiopure **12a** did not induce enantioselectivity. The assembly of the pyridine phosphite ligand **4** and chiral zinc(II) porphyrin **12a** resulted in an enantioselectivity of 8% (*S*) and a concomitant low activity. The activity was much higher upon using pyridylphosphane **6**–**8** as ligands for the assembly with **12a** and complete conversion was observed for all phosphane-based catalysts. The enantiomeric excesses for the assemblies of zinc(II) porphyrin **12a** and phosphane ligands **6**–**8** are found to be comparable with the result obtained for the assembly **4·12a**. The electronic properties of the ligand assembly were varied with the use of zinc(II) porphyrin building blocks **12a**–**12d** and phosphane **7**, but this did not affect the enantioselectivity in the palladium-catalyzed allylic alkylation. The use of the assemblies based on the other enantiomer (*R*) as zinc(II) porphyrin template (**7·12b** and **7·12c**) yields indeed the other enantiomeric product in excess. Although the chiral inductions in palladium-catalyzed allylic alkylation found for the assemblies based on monodentate phosphorus ligands **4**–**8** on the chiral zinc(II) porphyrins **12a**–**12d** do not exceed 10% yet, these first results do show that it is *possible* to create a chiral catalyst by nearby complexation of a chiral co-factor.



Scheme 4. Palladium-catalyzed allylic alkylation.

Table 8. Palladium-catalyzed allylic alkylation of 1,3-diphenylallyl acetate, using various ligand assemblies based on chiral zinc(II) porphyrin templates.[a]

| Ligand[b] | % Conversion[c] | % *ee*[d] |
|---|---|---|

| **8·12** (*S*) | >99 | 5 (*S*) |
| **10·12d** (*S*) | >99 | 18 (*S*) |
| **11·12d** (*S*) | >99 | 12 (*S*) |

[a] [[Pd(allyl)Cl]$_2$] = 0.100 mmol/L, $T$ = 25 °C. [b] [phosphite] = 0.6 mmol/L, [porphyrin] = 0.6 mmol/L. [c] The reaction was stopped after 24 h. [d] *ee* = enantiomeric excess.

This approach has also been used for bidentate phosphorus ligands with nitrogen donor atoms, i.e. ligands **10** and **11** (Figure 6).[44,45] These bidentate phosphorus ligands have been assembled on zinc(II) porphyrin template **12d** with associated binding constants of ($K_{10\cdot12d}$ = 515 M$^{-1}$) and ($K_{11\cdot12d}$ = 150 M$^{-1}$), as determined by UV/Vis spectroscopy titrations in toluene. Although the binding constants are not sufficiently high to prevent the formation of non-templated ligand under the reaction conditions, these ligand assemblies were tested in the palladium-catalyzed asymmetric allylic alkylation. It was found that the supramolecular ligands **10·12d** and **11·12d** resulted in moderate enantioselectivities, up to 18%. Attempts to increase the *ee* by shifting the equilibrium from free **11** to fully assembled **11·12d**, by adding excess of **12d**, failed due to the limited solubility of this porphyrin.

## Conclusions

A new class of supramolecular monodentate ligands is reported, which is based on selective metal–ligand interactions. The supramolecular ligands are obtained by just mixing simple building blocks, typically zinc(II) porphyrin tem-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

plate molecules and phosphorus ligands containing nitrogen donor atoms. These unique supramolecular ligand systems provide a new tool to modify key catalyst properties, such as activity and selectivity, in a very simple manner. The major advantage of this supramolecular approach is the ease of ligand variation and accessibility of a large number of new ligand systems by variation of template molecules and phosphorus nitrogen building blocks. In the rhodium-catalyzed hydroformylation of 1-octene small but distinct changes have been observed, upon using different electron-donating and withdrawing zinc(II) porphyrin building blocks for the catalyst assemblies. Interesting changes have also been observed in the enantioselective rhodium-catalyzed hydrogenation of dimethyl itaconate. The ligand assemblies based on zinc(II) porphyrin with electron-withdrawing substituents led to a twelve fold increase of activity and an increase of enantioselectivity from 17 to 50%. We also have used, for the first time, assemblies based on non-chiral ligands and chiral zinc(II) porphyrin template molecules and used these as ligands in the asymmetric palladium-catalyzed allylic alkylation. Although the enantioselectivities observed so far are rather low (up to 18%), it demonstrates that with a chiral template a chiral environment around the metal center can be obtained. In general, the use of coordinative binding in order to construct supramolecular ligands simplifies the preparation of new (chiral) ligand systems, which enables novel (chiral) catalyst systems. We are currently expanding the scope of ligands and template molecules of which the results will be reported in due time.

## Experimental Section

**General Procedures:** Unless stated otherwise, reactions were carried out under argon using standard Schlenk techniques. THF, hexane and diethyl ether were distilled from sodium benzophenone ketyl; $CH_2Cl_2$, 2-propanol and methanol were distilled from $CaH_2$ and toluene was distilled from sodium under nitrogen. NMR spectra ($^1H$, $^{31}P$ and $^{13}C$) were measured with a Bruker DRX 300 MHz and Varian Mercury 300 MHz. $CDCl_3$ was used as a solvent, if not further specified. Mass spectra were recorded with a JEOL JMS SX/SX102A four sector mass spectrometer; for FAB-MS 3-nitrobenzyl alcohol was used as matrix. Elemental analyses were obtained with an Elementar Vario EL apparatus. Gas chromatographic analyses were run with an Interscience HR GC Mega 2 apparatus (split/splitless injector, J&W Scientific, DB-1 J&W 30 m column, film thickness 3.0 μm, carrier gas 70 kPa He, FID Detector) equipped with a Hewlett–Packard Data system (Chrom-Card). Chiral GC separations were conducted with a Chirasil-L-Val capillary column (0.25 mm × 25 m). Chiral HPLC analyses were carried out using a Daicel Chiralcel-OD column (0.46 × 25 cm).

**Materials:** With exception of the compounds given below, all reagents were purchased from commercial suppliers and used without further purification. Diisopropylethylamine and triethylamine were distilled from $CaH_2$ under argon. 1-Octene was filtered through a plug of alumina. The following compound were synthesized according to published procedures: zinc(II) porphyrins **1a**–**f**,[27,28] binaphthyl or biphenyl phosphorochloridites,[26] chiral zinc(II) porphyrin **a**–**d**,[39] pyridylphosphanes **6**–**8**[46,47] and diphosphanes **9**–**11**.[38,44–45]

**Synthesis of (*S*)-(1,1′-Binaphthyl-2,2′-diyl) (3-Pyridyl) Phosphite (2):** 3-Hydroxypyridine (1.44 g, 15.1 mmol), azeotropically dried with toluene (3 × 5 mL), and triethylamine (2.3 mL, 16.6 mmol) were dissolved in THF (40 mL) and the solution was cooled to –40 °C. Freshly prepared (*S*)-2,2′-binaphthyl phosphorochloridite (5.3 g, 15.1 mmol) was dissolved in THF (20 mL) and added dropwise. The cooling bath was removed and the solution was warmed to room temperature, stirring was continued for 1 h. The reaction mixture was filtered and the solvent evaporated. A mixture of toluene/hexane, 1:3 (40 mL) was added to extract the product. After filtration the solvent was removed in vacuo, giving **2** (5.4 g, 13.2 mmol, 87%) as a white solid. $^1H$ NMR (300 MHz): $\delta$ = 8.54 (d, $J$ = 2.4 Hz, 1 H), 8.40 (d, $J$ = 4.2 Hz, 1 H), 8.02 (d, $J$ = 8.7 Hz, 1 H), 7.95 (d, $J$ = 8.7 Hz, 1 H), 7.92 (d, $J$ = 8.7 Hz, 2 H), 7.56–7.16 (m, 10 H) ppm. $^{31}P$ NMR (121.5 MHz): $\delta$ = 143.05 ppm. $^{13}C$ NMR (75.465 MHz): $\delta$ = 148.88 (d, $J_{cp}$ = 6.1 Hz), 147.52 (d, $J_{cp}$ = 4.8 Hz), 146.84 (d, $J_{cp}$ = 1.4 Hz), 145.80 (s), 142.71 (d, $J_{cp}$ = 7.3 Hz), 133.02 (s), 132.75 (s), 132.01 (s), 131.55 (s), 130.97 (s), 130.36 (s), 129.29 (s), 128.67 (d, $J_{cp}$ = 4.8 Hz), 128.48 (s), 127.945 (s), 127.83 (s), 127.28 (s), 127.19 (s), 126.80 (s), 126.67 (s), 125.68 (s), 125.49 (s), 124.49 (s) 121.77 (s), 121.59 (s) ppm. HRMS (FAB+): *m*/*z* calcd. for $C_{25}H_{17}NO_3P$ [$MH^+$]: 410.0946; obsd. 410.0952. $C_{25}H_{16}NO_3P$ (409.09): calcd. C 73.35, H 3.94, N 3.42; found C 73.20, H 4.16, N 3.25.

**Synthesis of (*S*)-(3,3′-Bis(trimethylsilyl)-1,1′-binaphthyl-2,2′-diyl) (3-Pyridyl) Phosphite (3):** This compound was prepared as described for **2**, using freshly prepared (*S*)-3,3′-bis(trimethylsilyl)-2,2′-binaphthyl phosphorochloridite. Yield (66%) as a white solid. $^1H$ NMR (300 MHz): $\delta$ = 8.30 (d, $J$ = 2.7 Hz, 1 H), 8.27 (d, $J$ = 5.1 Hz, 1 H), 8.08 (d, $J$ = 2.7 Hz, 2 H), 7.92 (dd, $J$ = 2.7, 8.1 Hz, 2 H), 7.45–7.40 (m, 2 H), 7.39–7.31 (m, 1 H), 7.26–7.09 (m, 5 H), 0.43 (s, 9 H), 0.38 (s, 9 H) ppm. $^{31}P$ NMR (121.5 MHz): $\delta$ = 138.99 ppm. HRMS (FAB+): *m*/*z* calcd. for $C_{31}H_{33}NO_3PSi_2$ ([$MH^+$]): 554.1737; obsd. 554.1725. $C_{31}H_{32}NO_3PSi_2$ (553.2): calcd. C 67.24, H 5.82, N 2.53; found C 67.18, H 5.89, N 2.42.

**Synthesis of (3,3′-5,5′-Tetra-*tert*-butyl-1,1′-biphenyl-2,2′-diyl) (3-Pyridyl) Phosphite (4):** 3-Hydroxypyridine (0.95 g, 10 mmol), azeotropically dried with toluene (3 × 2 mL), and triethylamine (1.4 mL, 10 mmol) were dissolved in THF (20 mL) and the solution was cooled to 0 °C. Freshly prepared 3,3′,5,5′-tetra-*tert*-butyl-1,1′-biphenyl phosphorochloridite (4.75 g, 10 mmol) was dissolved in THF (20 mL) and added dropwise, stirring was continued for 10 min. The cooling bath was removed and the solution was warmed to room temperature, stirring was continued for 1 h. The reaction mixture was filtered and the solvent evaporated. A mixture of toluene/hexane, 1:3 (40 mL) was added to extract the product. After filtration the solvent was removed in vacuo, giving **4** (3.4 g, 6.4 mmol, 64%) as a white solid. $^1H$ NMR (300 MHz): $\delta$ = 8.39 (d, $J$ = 2.4 Hz, 1 H), 8.31 (dd, $J$ = 2.4, 4.2 Hz, 1 H), 7.45 (d, $J$ = 2.7 Hz, 2 H), 7.22–7.19 (m, 1 H), 7.18 (d, $J$ = 2.7 Hz, 2 H), 7.16–7.12 (m, 1 H), 1.47 (s, 18 H), 1.35 (s, 18 H) ppm. $^{31}P$ NMR (121.5 MHz): $\delta$ = 137.49 ppm. $^{13}C$ NMR (75.465 MHz): $\delta$ = 147.34 (C), 145.72 (CH), 142.92 (CH), 140.37 (C), 132.86 (C), 127.95 (CH), 127.90 (C), 126.94 (CH), 125.29 (CH), 124.74 (C), 124.16 (CH), 35.66 (C), 34.93 (C), 31.75 (CH), 31.39 (CH) ppm. HRMS (FAB+): *m*/*z* calcd. for $C_{33}H_{45}NO_3P$ ([$MH^+$]): 534.3137; obsd. 534.3147; $C_{33}H_{44}NO_3P$ (533.3): calcd. C 74.27, H 8.31, N 2.62; found C 74.35, H 8.27, N 2.75.

**Catalysis:** The hydroformylation experiments were performed as follows. A stainless steel 25 mL autoclave, equipped with a Teflon stirring bar, was charged with 0.42 μmol of [Rh(acac)$(CO)_2$], 10.4 μmol of phosphane (and 1 equiv. of porphyrin template) and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

0.017 mL of diisopropylethylamine, as a base, in 4.0 mL of toluene. The solution was stirred for 1 h under 20 bar $CO/H_2$ (1:1) at 80 °C. The pressure was reduced to 1 bar and a mixture of 0.34 mL 1-octene (styrene) and 0.17 mL of decane in 0.67 mL of toluene was added. Subsequently the $CO/H_2$ pressure was adjusted to 20 bar. The mixture was stirred for 1 h (80 °C or 120 °C) and 18 h (40 °C). Then the autoclave was cooled to 0 °C in ice and the pressure was reduced to 1.0 bar. The products were analyzed by GC. A sample was taken and the conversion was checked by GC measurement of the crude product after filtration through a plug of silica to remove the catalyst. In none of the reactions hydrogenated side-products were observed. The crude product mixture of styrene was subjected to reduction with $NaBH_4$ by stirring in 5.0 mL methanol for 30 min. Quenching with water, extraction with a mixture of ethyl acetate/hexane = 1:1, drying of the organic layer, filtrations and removal of solvent gave the corresponding alcohols, for which the enantiomeric purities were determined by chiral GC (Cyclosil-B, isothermal; $T$ = 90 °C, $t_R$ (*R*) = 63.5 min. and $t_S$ (*S*) = 64.8 min.).

The allylic alkylation experiments were performed as follows. Under Schlenk conditions 0.50 μmol of $[Pd(allyl)Cl]_2$, 3.0 μmol phosphite and 3.0 μmol phosphane were dissolved in 5.0 mL of $CH_2Cl_2$ and stirred for 30 min. Then 50 μmol of 1,3-diphenylallyl acetate, 150 μmol of dimethyl malonate, 150 μmol of BSA and 50 μmol of decane and a catalytic amount of KOAc were added. The mixture was stirred for 24 h at 25 °C and the reaction was subsequently stopped by adding saturated aq. ammonium chloride. Subsequently, 5.0 mL of petroleum ether was added and the solution was washed once more with a saturated $NH_4Cl$ solution. The organic phase was dried with $Na_2SO_4$, filtered and the conversion was checked by GC measurement. The solution was chromatographed ($SiO_2$; petroleum ether/$CH_2Cl_2$ = 1:1) to give analytically pure products.[48] Enantiomeric purities were determined by chiral HPLC (OD column, eluent 0.5% 2-propanol in hexane $t_R$ (*R*) = 33.2 min. and $t_S$ (*S*) = 34.9 min.).

Asymmetric hydrogenation reactions were performed as follows. A 150-mL stainless-steel autoclave, equipped with 15 vessels and teflon stirring bars, was charged with 0.5 μmol of $[Rh(nbd)_2(BPh_4)]$, 1.5 μmol of phosphane, 1.5 μmol of porphyrin, 1.0 μL of dipea, 50 μmol dimethyl itaconate and 50 μmol of decane in 0.5 mL of toluene. The $H_2$ pressure was adjusted to 5 bar and the mixture was stirred, for 17 h at 40 °C. Then the autoclave was cooled to 0 °C and the pressure was reduced to 1.0 bar. The conversion was checked by GC measurement of the crude product after filtration through a plug of magnesium sulfate and subsequently silica. Enantiomeric purities were determined by chiral GC (Chirasil-L-Val, isothermal; $T$ = 70 °C, $t_R$ (*R*) = 34.4 min. and $t_S$ (*S*) = 35.2 min.).

# Synthesis and Characterization of Bis(dithiolene) Tungsten(VI), -(V), and -(IV) Complexes and Their Reactivities in Coupled Electron–Proton Transfer: A New Series of Active Site Models of Tungstoenzymes

**Hideki Sugimoto,*[a] Makoto Tarumizu,[a] Hiroyuki Miyake,[a] and Hiroshi Tsukube[a]**

**Keywords:** Bioinorganic chemistry / Enzyme models / Molybdenum / S ligands / Tungsten

New tungsten(VI), -(V), and -(IV) complexes containing 3,6-dichloro-1,2-benzenedithiolate ($bdtCl_2$), $(Et_4N)_2[W^{VI}O_2(bdtCl_2)_2]$ {$(Et_4N)_2$[**1**]}, $(Et_4N)[W^{V}O(bdtCl_2)_2]$ {$(Et_4N)$[**2**]}, and $(Et_4N)_2[W^{IV}O(bdtCl_2)_2]$ {$(Et_4N)_2$[**3**]} were synthesized and characterized as active site models of tungstoenzymes. $(Et_4N)_2$[**1**] was prepared in high yield by the reaction of $WO_2Cl_2$ with $2bdtCl_2$ at low temperature, and its crystal structure was determined. Isomerization between octahedral structures (Δ and Λ forms) of the tungsten center of $(Bu_4N)_2$[**1**] was characterized by variable-temperature $^1H$ NMR (VT $^1H$ NMR) spectral analysis, which offers the first example of six-coordinate bis(dithiolene) tungsten(VI) complexes. The isomerization of the molybdenum center of $(Bu_4N)_2[Mo^{VI}O_2(bdtCl_2)_2]$ {$(Bu_4N)_2$[**4**]} was similarly characterized. A comparison of their activation energies indicated that the tungsten center underwent slower isomerization than that of the molybdenum one. $(Et_4N)_2$[**1**] underwent an irreversible reduction at –2.1 V vs. SCE in $CH_3CN$ by a coupled electron–proton transfer (CEPT) process to yield $(Et_4N)_2$[**3**], while $(Et_4N)_2$[**3**] underwent an irreversible oxidation by a CEPT process at –0.27 V in the presence of 2 equiv. of $Et_4NOH$ in $CH_3CN$ to yield $(Et_4N)_2$[**1**]. $(Et_4N)$[**2**] disproportionated into 0.5 equiv. of $(Et_4N)_2$[**1**] and 0.5 equiv. of $(Et_4N)_2$[**3**] when treated with 1 equiv. of $Et_4NOH$ in $CH_3CN$.

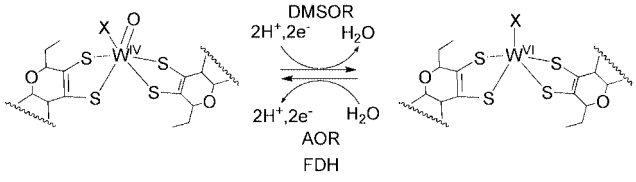
## Introduction

Since the characterization of tungstoenzymes by crystallographic and EXAFS studies,[1] many coordination chemists have paid much attention to intriguing coordination structures of their catalytic centers.[2] Mononuclear tungsten complexes containing two pyranopterin dithiolenes occur as the catalytic centers of the aldehyde ferredoxin oxidoreductase (AOR) family and the formate dehydrogenase (FDH) family, varying the oxidation number between +6, +5, and +4 and the coordination structure between that of a trigonal prism and a square pyramid (Scheme 1).[1,3] Therefore, synthetic tungsten(VI), -(V), and -(IV) complexes with identical dithiolenes are of special interest as active site models of these families.[2] However, such a series of tungsten complexes is still limited.[2] A number of six-coordinate bis(dithiolene) tungsten(VI) complexes have been prepared and structurally characterized.[2] The tungsten(VI) centers of the previously reported six-coordinate complexes were best described as octahedrons, rather than trigonal prisms, in the solid state, while their solution structures have rarely been reported. In contrast, a large number of $[WX(dithiolene)_2]^{2-/-}$ (X = monodentate ligand) complexes containing a square-pyramidal tungsten(IV) center have been reported.[2]



Scheme 1. Active site structures of DMSOR, AOR, and FDH families and their CEPT processes (X = O, OR, SR, SeR, etc.).

From the viewpoint of the functions of the AOR and the FDH families, a coupled electron–proton transfer (CEPT) process is essentially involved in the catalytic reactions, where the five-coordinate tungsten(IV) center changes to the six-coordinate tungsten(VI) center and a water molecule is utilized as the source of an oxygen atom, protons, and electrons.[1,3] A similar structural change of a tungsten center by the CEPT process is involved in tungsten-substituted DMSO reductase, where the six-coordinate tungsten(VI) center changes to the five-coordinate tungsten(IV) center, converting a net oxygen atom of DMSO to water.[3] The CEPT process is further involved in the catalytic reaction mediated by molybdenum containing arsenite oxidase.[1] Until now, no involvement of the bis(dithiolene) tungsten

complex in a CEPT process has been reported. We recently demonstrated that the CEPT process enabled the conversion from $(Et_4N)_2[MoO_2(bdtCl_2)_2]$ {$(Et_4N)_2$[**4**]} to $(Et_4N)_2$-$[MoO(bdtCl_2)_2]$ {$(Et_4N)_2$[**5**]} and its back reaction from $(Et_4N)_2$[**5**] to $(Et_4N)_2$[**4**].[5,6] Our crystallographic study on a series of $(X)_2[M(bdtCl_2)_3]$ (X = $Et_3NH$, $Et_4N$, $Ph_4P$; M = Mo, W) complexes revealed that the metal centers can adopt both trigonal-prismatic and octahedral structures depending on the size of the counter cations.[7] A similar conversion between a trigonal prism and an octahedron was not observed in other $(X)_2[M(dithiolene)_3]$ (M = Mo and W) complexes.

We herein report the synthesis and characterization of the novel $(Et_4N)_2[WO_2(bdtCl_2)_2]$ {$(Et_4N)_2$[**1**]}, $(Et_4N)[WO(bdtCl_2)_2]$ {$(Et_4N)$[**2**]}, and $(Et_4N)_2[WO(bdtCl_2)_2]$ {$(Et_4N)_2$-[**3**]} complexes. The structural isomerization of the tungsten center of $(Bu_4N)_2$[**1**] in [$D_8$]THF is characterized using the variable-temperature $^1H$ NMR (VT $^1H$ NMR) spectroscopic technique. Conversions between $(Et_4N)_2$[**1**] and $(Et_4N)_2$[**3**] by a CEPT process are described. The UV/Vis, IR, and EPR spectroscopic studies of the reaction of $(Et_4N)$[**2**] with $Et_4NOH$ indicate that $(Et_4N)$[**2**] disproportionated into 0.5 eqiv. $(Et_4N)_2$[**1**] and 0.5 equiv. $(Et_4N)_2$[**3**] and that the disproportionation is involved in the conversion of $(Et_4N)_2$[**3**] to $(Et_4N)_2$[**1**]. Since $(Et_4N)_2$[**1**] and $(Et_4N)_2$[**3**] are isostructural complexes of $(Et_4N)_2$[**4**] and $(Et_4N)_2$[**5**], the present study is useful for understanding roles of the tungsten centers of the AOR and the FDH families (Figure 1).

## Results and Discussion

### Preparation of $W^{VI}O_2$ and $W^{IV}O/W^{V}O$ Complexes of $bdtCl_2$

Three synthetic methods have been established for bis(dithiolene) $W^{VI}O_2$ complexes. In the synthesis of $(Bu_4N)_2$-$[WO_2(mnt)_2]$, $Na_2WO_4$, starting compound, was treated with $Na_2$mnt and $NaHSO_3$ at pH 5.5 (yield 59%).[2a] Several bis(dithiolene) $W^{VI}O_2$ complexes of bdt and its derivatives were obtained in modest yields (1–15%) by several steps {$WCl_6 \rightarrow [WOCl_3(THF)_2] \rightarrow [WO(SC_6H_5)_4]^- \rightarrow [WO(SC_6H_5)_4]^{2-} \rightarrow [WO(benzendithiolates)_2]^{2-} \rightarrow [WO_2$-$(benzendithiolates)_2]^{2-}$}.[8,9] The yields of bis(dithiolene) $W^{VI}O_2$ complexes of aliphatic dithiolenes were also modest (20–30%) because the following reactions were required {$[Ni(dithiolene)_2] \rightarrow [W(CO)_2(dithiolene)_2] \rightarrow [WO(dithiolene)_2]^{2-} \rightarrow [WO_2(dithiolene)_2]^{2-}$}.[10] Here, we directly synthesized the bis(dithiolene) $W^{VI}O_2$ complex of $bdtCl_2$ from commercially available reagents. When $WO_2Cl_2$ was treated with 2 equiv. of $H_2bdtCl_2$ and 2 equiv. of $Et_4NI$ or $Bu_4NBr$ in the presence of 4 equiv. of $Et_3N$ at –40 °C, a red microcrystalline powder of $(Et_4N)_2$[**1**] or $(Bu_4N)_2$[**1**] precipitated in 65% yield. $(Et_4N)$[**2**] and $(Et_4N)_2$[**3**] were prepared according to literature procedures by Nakamura et al. and Holm et al.[8,11]

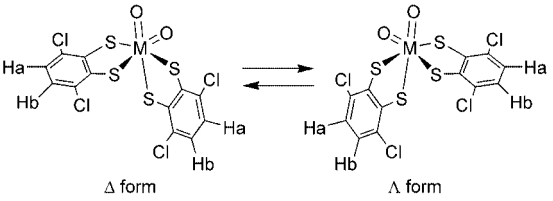
in Table 1. The tungsten center was coordinated by two oxo groups in a *cis* position and four sulfur atoms from the two $bdtCl_2$ ligands in a similar fashion to that observed for $(Et_4N)_2$[**4**].[5] The geometry around the metal centers of $(Et_4N)_2$[**1**] and $(Et_4N)_2$[**4**] is described as a distorted-octahedral structure on the basis of the torsion angles[4a] made by the four sulfur atoms {S2–S1–S3–S4, 101.1° for $(Et_4N)_2$[**1**] and 100.4° for $(Et_4N)_2$[**4**]}. The W=O bond lengths [1.749(7) Å and 1.741(6) Å] of $(Et_4N)_2$[**1**] are not significantly different from those of $(Et_4N)_2$[**4**]. The W–S2 and W–S3 distances [2.563(2) Å and 2.592(2) Å, respectively] of $(Et_4N)_2$[**1**] are longer than the W–S1 and W–S4 distances [2.443(2) Å and 2.426(2) Å, respectively] due to the *trans* influence of the two W=O bonds. The long W–S (2 and 3) bond lengths and the short W–S (1 and 4) bond lengths affect the S–C bond lengths of $(Et_4N)_2$[**1**]. The S1–C1 and S4–C8 bonds [1.762(9) Å and 1.766(8) Å, respectively] are longer than the S2–C2 and S3–C7 bonds [1.72(1) Å and 1.707(9) Å, respectively].

### VT $^1$H NMR Spectroscopic Study of $[MO_2(bdtCl_2)_2]^{2-}$ (M = W and Mo)

As described in the crystal structural study, the tungsten center of $[WO_2(bdtCl_2)_2]^{2-}$ ([**1**]$^{2-}$) offers two distinguishable S atoms in one $bdtCl_2$ ligand, consequently, two protons on one $bdtCl_2$ ligand, Ha and Hb, are not equivalent in the crystal structure. Unexpectedly, the $^1$H NMR spectra of $(Bu_4N)_2$[**1**] at 25 °C in [$D_6$]acetone, [$D_3$]acetonitrile, and [$D_8$]THF show one singlet at $\delta$ = 6.61 ppm in the aromatic region, revealing that the Ha and Hb protons are apparently equivalent in solution.[12] This singlet broadens as the [$D_8$]THF solution temperature decreases from +40 °C to –60 °C. Two separate peaks are observed at –70 °C and each peak is further divided into two peaks at –90 °C (Figure 3). The singlet from $bdtCl_2$ of $(Bu_4N)_2$[**4**] similarly broadens at low temperature and is divided into two peaks at –110 °C (Figure 3). When the temperature of the [$D_8$]THF solutions of $(Bu_4N)_2$[**1**] and $(Bu_4N)_2$[**4**] was again increased to +40 °C their original $^1$H NMR spectra at +40 °C were regenerated. Since these VT $^1$H NMR spectral changes are independent of the complex concentrations, $(Bu_4N)_2$[**1**] and $(Bu_4N)_2$[**4**] exhibit structural isomerisation between the octahedral structures (50% Δ and 50% Λ forms, Scheme 2) without dissociation of the M–S bonds in solution. The trigonal-prismatic structures probably occur in the transition states where the structural isomerization of the metal center of $(Bu_4N)_2$[**1**] and $(Bu_4N)_2$[**4**] is faster than the NMR timescale at high temperatures.



Scheme 2. Structural isomerization of anions of $(Bu_4N)_2$[**1**] and $(Bu_4N)_2$[**4**].

Δ*G* values for the isomerizations of $(Bu_4N)_2$[**1**] and $(Bu_4N)_2$[**4**] were calculated to be 43.2 and 36.4 kJ mol$^{-1}$, respectively, which are similar to the energy difference (37.2 kJ mol$^{-1}$) between the octahedron and the trigonal prism of $[Mo^{VI}(OCH_3)(OSMe_2)(S_2C_2Me_2)_2]^-$.[4a] The fact that the value of Δ*G* calculated for $(Bu_4N)_2$[**1**] is larger than that for $(Bu_4N)_2$[**4**] means that the tungsten center is kinetically more stable than the molybdenum one. This is consistent with the fact that the AOR family of tungsten enzymes belongs to the hyperthermophilic archaea.

### Redox Properties of $[W^{VI}O_2(bdtCl_2)_2]^{2-}$ and $[WO(bdtCl_2)_2]^{-/2-}$

Figure 4 shows a cyclic voltammogram of $(Et_4N)_2$[**1**] in $CH_3CN$. $(Et_4N)_2$[**1**] undergoes one irreversible reduction at $E_{pc}$ = –2.1 V vs. SCE, indicating that the octahedral structure of the tungsten center is unstable below –2.1 V. The coulometric measurement during the electrolysis at –2.2 V indicated that 2.3 electrons were consumed for the completion of the electrolysis. The electrolysis at –2.2 V caused the color to change from orange to pale yellow. Since the resulting pale yellow species exhibited an identical absorption spectrum and CV to those of $(Et_4N)_2$[**3**], $(Et_4N)_2$-[**1**] was suggested to change to $(Et_4N)_2$[**3**] by a two-electron-reduction coupled process accompanied by $H_2O$ production, with contaminant protons arising from the $CH_3CN$ solution (Scheme 3).

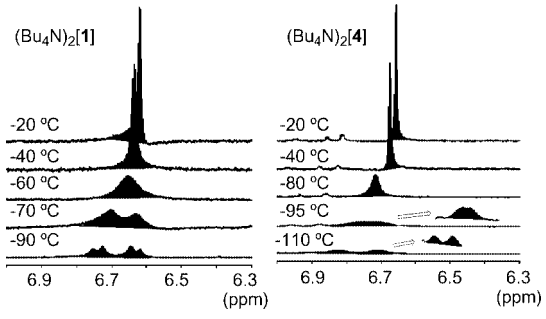


Figure 3. VT $^1$H NMR spectra of $(Bu_4N)_2$[**1**] (4.1 mM, left) and $(Bu_4N)_2$[**4**] (4.1 mM, right) in [$D_8$]THF.

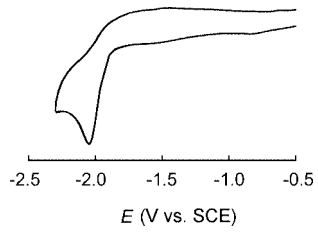

Figure 4. Cyclic voltammogram of $(Et_4N)_2$[**1**] (0.1 mM, 100 mV s$^{-1}$) in 0.1 M $TBAPF_6$ containing $CH_3CN$.

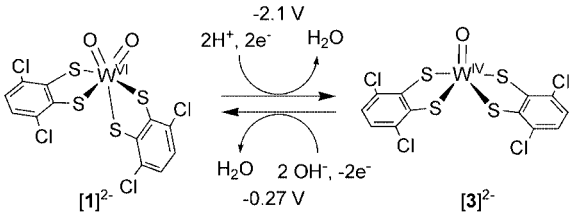

Scheme 3. Reversible structural change between $(Et_4N)_2$[**1**] and $(Et_4N)_2$[**3**] via CEPT processes.

$(Et_4N)_2$[**3**] shows one reversible oxidation wave at –0.27 V [Figure 5 (solid line)] in $CH_3CN$, which is assigned to the $[WO(bdtCl_2)_2]^{2-/-}$ process. The redox potential is more positive than those of $[WO(bdt)_2]^{2-/-}$ (–0.63 V) and $[WO(naphthalenedithiolate)_2]^{2-/-}$ (–0.52 V),[8,9] suggesting that the Cl atoms attached to the benzene ring decrease the S → W electron donations. Because the isostructural $Mo^{IV}O$ complex, $(Et_4N)_2$[**5**], changes to the $Mo^{VI}O_2$ complex, $(Et_4N)_2$[**4**], in the presence of 2 equiv. of $OH^-$ under oxidative conditions,[6] the CV change of $(Et_4N)_2$[**3**] was investigated. The reversible $W^{V/IV}$ couple at –0.27 V became an irreversible wave upon addition of $Et_4NOH$ to the $CH_3CN$ solution of $(Et_4N)_2$[**3**], increasing the current intensity of the $E_{pa}$ while decreasing that of the $E_{pc}$. The CV change depended on the added amount of $Et_4NOH$, and was completed when 2 equiv. of $Et_4NOH$ and 1 equiv. of $[WO(bdtCl_2)_2]^{2-}$ was added to the solution (dashed line in Figure 5). The absorption spectrum of the orange solution obtained after electrolysis of $(Et_4N)_2$[**3**] at –0.1 V in the presence of 2 equiv. of $Et_4NOH$ was identical to that of $(Et_4N)_2$[**1**]. The coulometric measurement taken during the electrolysis indicated that 1.9 electrons were consumed for the completion of the electrolysis. Thus, $(Et_4N)_2$[**3**] was revealed to be converted to $(Et_4N)_2$[**1**] by the CEPT process as in the case of the isostructural molybdenum complex, $(Et_4N)_2$[**5**]. Since $(Et_4N)_2$[**3**] was also changed to $(Et_4N)_2$[**1**] by the CEPT process, the tungsten center coordinated with two $bdtCl_2$ ligands was demonstrated to be convertible between the six-coordinate $W^{VI}O_2$ structure, $(Et_4N)_2$[**1**], and the five-coordinate $W^{IV}O$ structure, $(Et_4N)_2$[**3**], by CEPT processes (Scheme 3).

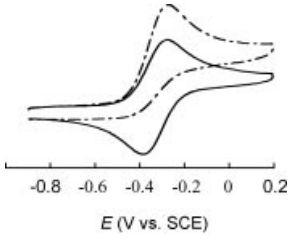

Figure 5. Cyclic voltammograms of $(Et_4N)_2$[**3**] (0.1 mM, 100 mV $s^{-1}$): complex only (solid line) and complex + 2 equiv. of $Et_4NOH$ (dashed line) in 0.1 M $TBAPF_6$ containing $CH_3CN$.

The absorption spectrum of $(Et_4N)_2$[**3**] in $CH_3CN$ remained the same when 2 equiv. of $Et_4NOH$ was added, indicating that the tungsten(IV) center does not bind $OH^-$. Whereas $(Et_4N)$[**2**] reacted with $Et_4NOH$. When $Et_4NOH$ was added to the $CH_3CN$ solution of $(Et_4N)$[**2**] the absorption band at 600 nm decreased while the bands at 470 nm and 421 nm increased (Figure 6). The plots of absorbance at 600 nm and 421 nm against the equivalence of the added $Et_4NOH$ per $(Et_4N)$[**2**] indicated that $(Et_4N)$[**2**] reacted with 1 equiv. of $OH^-$ (Figure 6, inset). The anisotropic EPR signal at $g_{av}$ = 1.96 for $(Et_4N)$[**2**] completely disappeared when 1 equiv. of $Et_4NOH$ was added. In the IR spectrum of $(Et_4N)$[**2**] the $\nu(W^{5+}{=}O)$ stretching band at 953 $cm^{-1}$ also disappears with the appearance of three new bands at 911, 892, and 848 $cm^{-1}$ when 1 equiv. of $Et_4NOH$ is added. The band at 911 $cm^{-1}$ is identical to the $\nu(W^{4+}{=}O)$ stretching band of $(Et_4N)_2$[**3**] and the other two bands are identical to the $\nu(W^{6+}{=}O)_{sym}$ and $\nu(W^{6+}{=}O)_{asym}$ stretching bands of $(Et_4N)_2$[**1**] (Figure 7). Thus, it is concluded that the disproportionation of $(Et_4N)$[**2**], when treated with 1 equiv. of $Et_4NOH$ in $CH_3CN$, yields 0.5 equiv. of $(Et_4N)_2$[**1**] and 0.5 equiv. of $(Et_4N)_2$[**3**] [Equation (1)], where $(Et_4N)_2[W^{V}O(OH)(bdtCl_2)_2]$ was proposed as an intermediate involved in the conversion process from $(Et_4N)_2$[**3**] to $(Et_4N)_2$[**1**].

$$2[W^{V}O(bdtCl_2)_2]^- + 2OH^- \rightarrow [W^{VI}O_2(bdtCl_2)_2]^{2-} + [W^{IV}O(bdtCl_2)_2]^{2-} + H_2O \quad (1)$$

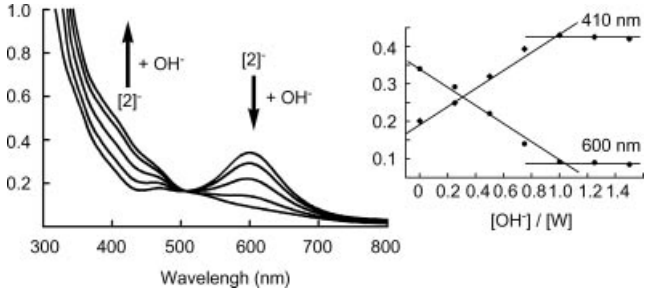

Figure 6. Absorption spectral changes of $(Et_4N)$[**2**] ($1.7 \times 10^{-4}$ M) upon addition of *n* equiv. of $Et_4NOH$ in $CH_3CN$ (left). Titration plots of the absorbance at 410 and 600 nm (right) against the *n* values.

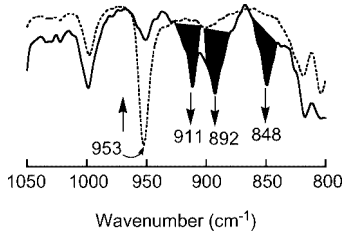

Figure 7. IR spectra of $(Et_4N)$[**2**] (dashed line) and an equimolar mixture (solid line) of $(Et_4N)$[**2**] and $Et_4NOH$.

## Conclusion

Tungsten(VI), -(V), and -(IV) complexes with two $bdtCl_2$ ligands were synthesized and characterized as a new series of active site models of tungstoenzymes as well as tungsten-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

substituted DMSO reductase. The tungsten center of $(Et_4N)_2$[**1**] adopted an octahedral structure and underwent isomerization between the Δ and Λ forms. This is the first observation involving six-coordinate bis(dithiolene) tungsten(VI) complexes. Its isomerization rate was slower than that of the isostructural molybdenum(VI) complex, [**4**]$^{2-}$. $(Et_4N)_2$[**1**] changed to $(Et_4N)_2$[**3**] by the CEPT process below –2.1 V vs. SCE, whereas $(Et_4N)_2$[**3**] was similarly converted to $(Et_4N)_2$[**1**] above –0.27 V in the presence of 2 equiv. of $Et_4NOH$. $(Et_4N)_2[W^VO(OH)(bdtCl_2)_2]$ was suggested to be an intermediate in the CEPT process from $(Et_4N)_2$[**3**] to $(Et_4N)_2$[**1**].

## Experimental Section

**General:** All reagents and solvents were used as received unless otherwise noted. $CH_3CN$ was dried with $CaH_2$ and then $P_2O_5$, and distilled under nitrogen prior to use. All manipulations were carried out under argon in Schlenk tubes. $(Bu_4N)_2[MoO_2(bdtCl_2)_2]$ {$(Bu_4N)_2$[**4**]} was synthesized by a procedure that was reported in the literature.[5,6]

**$(Et_4N)_2[WO_2(bdtCl_2)_2]$ {$(Et_4N)_2$[1]}:** $WO_2Cl_2$ (87 mg, 0.3 mmol) was added to an ethanol solution (15 mL) containing $H_2bdtCl_2$ (126 mg, 0.60 mmol), $Et_3N$ (169 μL, 1.2 μmol), and $Et_4NI$ (231 mg, 0.9 mmol) at –40 °C. After stirring for 10 h at 0 °C, the orange solution that was obtained was concentrated to 3 mL. An orange microcrystalline powder precipitated, which was collected and dried in vacuo. Yield: 174 mg (65%). $C_{28}H_{44}Cl_4N_2O_2S_4W$ (894.59): calcd. C 37.59, H 4.96, N 3.13; found C 37.64, H 4.85, N 3.07. ESI-mass: *m*/*z* = 764 [(M + $Et_4N)^-$], 634 [$(M)^-$]. UV/Vis spectrum ($CH_3CN$): λ (ε, $dm^3\,mol^{-1}\,cm^{-1}$) = 470 (sh, 1320), 421 (2820), 344 (sh, 13300) nm. IR (KBr): $\tilde{\nu}_{max}$ = 892 [$\nu(W{=}O)_{sym}$] and 848 [$\nu(W{=}O)_{asym}$] $cm^{-1}$. Raman (solid): $\tilde{\nu}_{max}$ = 893 [$\nu(W{=}O)_{sym}$] and 848 [$\nu(W{=}O)_{asym}$] $cm^{-1}$.

**$(Bu_4N)_2[WO_2(bdtCl_2)_2]$ {$(Bu_4N)_2$[1]}:** The synthesis was carried out in the same manner as that of $(Et_4N)_2$[**1**] using $Bu_4NBr$ instead of $Et_4NI$. The UV/Vis and IR spectral profiles based on the anion were consistent with those of $(Et_4N)_2$[**1**].

**$(Et_4N)[WO(bdtCl_2)_2]$ {$(Et_4N)$[2]}:** The synthesis was carried out by a similar procedure to that of $(Et_4N)[WO(bdt)_2]$ reported by Holm et al.[11] A $CH_3CN$ solution (5 mL) of 3,6-dichloro-1,2-benzenedithiol (55 mg, 0.26 mmol) and $Et_3N$ (73 μL, 0.52 mmol) was slowly added to a $CH_3CN$ solution (5 mL) of $(Et_4N)[WO(benzenethiol)_4]$ (100 mg, 0.13 mmol) at –40 °C. The temperature of the solution was increased to 25 °C and the resultant solution was stirred for 1 h. The deep blue solution that was obtained was reduced to a volume of 1 mL. Diffusion of ether into the solution gave a black powder, which was collected by filtration and dried in vacuo. Yield: 66 mg (68%). $C_{20}H_{24}Cl_4NOS_4W$ (748.34): calcd. C 32.10, H 3.23, N 1.87; found C 32.21, H 3.38, N 2.04. ESI-mass: *m*/*z* = 618 [$(M)^-$]. UV/Vis spectrum ($CH_3CN$): λ (ε, $dm^3\,mol^{-1}\,cm^{-1}$) = 600 (2050), 468 (1070) nm. IR (KBr): $\tilde{\nu}_{max}$ = 953 [$\nu(W{=}O)$] $cm^{-1}$.

**$(Et_4N)_2[WO(bdtCl_2)_2]$ {$(Et_4N)$[3]}:** A $CH_3CN$ solution (2 mL) of $Et_4NBH_4$ (4 mg, 0.027 mmol) was added to a THF solution (10 mL) of $(Et_4N)_2$[**2**] (20 mg, 0.027 mmol). After the solution was stirred for 30 min a white yellow powder precipitated out of the solution, which was collected by filtration and dried in vacuo. Yield: 19 mg (82%). $C_{28}H_{44}Cl_4N_2OS_4W$ (878.60): calcd. C 38.28, H 5.05, N 3.19; found C 38.50, H 4.95, N 3.20. ESI-mass: *m*/*z* = 748 [M + $Et_4N^+]^-$, 618 $[M]^-$. UV/Vis spectrum ($CH_3CN$): λ (ε, $dm^3\,mol^{-1}\,cm^{-1}$) = 415 (1200), 330 (11100) nm. IR (KBr): $\tilde{\nu}_{max}$ = 911 [$\nu(W{=}O)$] $cm^{-1}$.

**Other Measurements:** $^1H$ NMR spectra were measured with a JEOL-Lambda 300. IR and Electronic spectra were recorded with a Perkin–Elmer Spectrum One and a Shimazu-U2550 spectrometer at room temperature. CV measurements and bulk electrolyses were performed with a Hokuto HZ-3000, and the working and counter electrodes were a glassy-carbon disk and a platinum wire, respectively. The complex solutions of 1.0 mM (complexes = 0.01 mmol) were deoxygenated with a stream of nitrogen gas. The reference electrode that was used was SCE. The coulometric measurements performed during the electrolyses were recorded with a Hokuto HF-201 coulomb/ampere meter.

**Calculation of Activation Free Energies ($\Delta G^{\ddagger}$ Values):** The values were calculated according to the equation $\Delta G/RT_c = 22.96 + \ln(T_c/\delta\nu)$, where $T_c$ and $\delta\nu$ are the coalescence point and the frequency difference between sites in the exchange system, respectively.[13] $T_c$ = –65 and $\delta\nu$ = 32.5 for $(Bu_4N)$[**1**], and $T_c$ = –95 and $\delta\nu$ = 34.4 for $(Bu_4N)$[**4**] were employed.

**X-ray Crystallographic Study:** A single crystal of $(Et_4N)$[**1**] was recrystallized from acetonitrile/ether and mounted on top of a glass fiber. X-ray data of the crystal were collected with graphite-monochromated Mo-$K_\alpha$ radiation with a Rigaku/MSC Mercury CCD diffractometer at –130 °C. The structure was solved by direct methods (SIR-97)[14] and expanded using the program DIRDIF 99.[15] The structure was refined anisotropically by full-matrix least-squares on $F^2$. The non-hydrogen atoms in the structure were attached at the idealized positions on carbon atoms and not refined. The structure converted in the final stages of the refinement showed no movement in the atom positions. All calculations were performed using Single-Crystal Structure Analysis Software, Ver. 3.6.0.[16] Further crystal data and agreement factors are listed in Table 2.

# Evidence for Ligand-Centered Reactivity of a 17e Radical Cationic 2*H*-Azaphosphirene Complex

**Holger Helten,[a] Christoph Neumann,[b] Arturo Espinosa,[c] Peter G. Jones,[b] Martin Nieger,[d] and Rainer Streubel*[a]**

**Keywords:** Ligand-centered reactivity / Phosphorus heterocycles / Electron transfer

Reactions of 2*H*-azaphosphirene complex **1** with electron-rich nitrile derivatives **2a–e** in the presence of substoichiometric amounts of ferrocenium hexafluorophosphate yielded regioselectively 2*H*-1,4,2-diazaphosphole complexes **3a–e** under mild conditions. The dependence of the reaction on the amount of ferrocenium hexafluorophosphate is discussed. In the reactions of **1** with electron-poor nitrile derivatives HCN (**2f**), EtOC(O)CN (**2g**), and $C_6F_5CN$ (**2h**), byproducts possessing a P–F bond are formed, which indicates that the hexafluorophosphate anion is involved in the reaction course. Apart from NMR spectroscopic (**3a–f**) and X-ray data (**3b**, **3d–e**), a detailed DFT study is included that provides first insight into the reaction pathway.

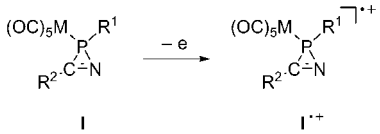
## Introduction

The generation of radical cationic intermediates has emerged as a useful synthetic tool in organic[1–4] and organometallic chemistry.[5] Oxidation of closed-shell organic molecules by single-electron transfer (SET) results in strongly destabilized odd-electron species that very often tend to fragment. Thus, upon pulse radiolysis or $^{60}Co$ γ radiolysis, phenylaziridines either form transient radical cations with retention of the closed ring structure or undergo ring opening with formation of radical cationic azomethine ylides depending on their substitution patterns.[6] Although the spin density of most organometallic radicals is localized mainly at the metal center, organometallic radicals can show both metal-centered and/or ligand-centered reactivity, whereas 17e cationic complexes often show the latter behavior.[7] For the generation of radical cations in solution four major routes are currently in use: (1) anodic oxidation, (2) photoinduced electron transfer (PET), (3) oxidation by radicals generated by pulse or γ radiolysis, and (4) chemical oxidation.[1,2] In this work, ferrocenium salts are used as mild single-electron oxidants, which have the further advantage that they are more easily recycled than most other heavy metal oxidants. Ferrocenium salts have been successfully applied in organic[8] and organometallic syntheses.[5] Recently, they were employed in the oxidation of N-heterocyclic carbenes.[9]

In the course of our studies concerning the applicability of 2*H*-azaphosphirene metal complexes **I**[10] (Scheme 1) in heterocyclic ligand syntheses,[11] we discovered that **I** undergoes P–N bond-selective ring-expansion reactions in the presence of substoichiometric amounts of typical single-electron oxidants such as tetracyanoethylene[12] and/or ferrocenium hexafluorophosphate.[13]



I  I•+

Scheme 1. 2*H*-Azaphosphirene complexes **I** and radical cationic 2*H*-azaphosphirene complexes $\mathbf{I}^{\bullet+}$ (M = Cr, Mo, W; $R^1$, $R^2$ = ubiquitous organic substituents).

Preliminary studies showed that these reactions require polar solvents such as dichloromethane or carbonitriles, reactants with a π system having a lone pair of electrons at one terminus, and substituents that are not (too) bulky. In all ferrocenium hexafluorophosphate induced ring expansions, the formation of small amounts of ferrocene is observed,[13b,13c] which indicates the transient formation of radical cationic species such as $\mathbf{I}^{\bullet+}$ (Scheme 1). Further evidence for the intermediate formation of $\mathbf{I}^{\bullet+}$ was obtained by the finding that reaction rates are reduced if *ortho*-phenyl-

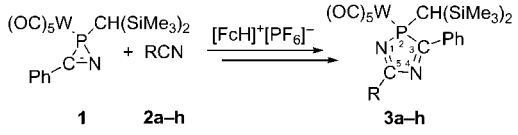
substituted 2*H*-azaphosphirene complexes with electron-donating substituents were employed.[13b] Despite all these indications, fundamental questions remained open regarding reaction pathways, for example, at which stage does the three-membered ring open and/or do transition-metal coordination spheres increase during the reactions.

Here, reactions of 2*H*-azaphosphirene complex **1** with nitriles of varying donor abilities under SET conditions are reported. A detailed DFT study on the reaction pathway is included.

## Results and Discussion

Reactions of 2*H*-azaphosphirene complex **1**[10] with dimethylcyanamide (**2a**) and electron-rich five-membered heterocyclic nitrile derivatives RCN (**2b**–**e**; Scheme 2) in the presence of substoichiometric amounts (0.05 equiv.) of ferrocenium hexafluorophosphate ([FcH]$PF_6$) at ambient temperature regioselectively yielded 2*H*-1,4,2-diazaphosphole complexes **3a**–**e** (Scheme 2). The molecular structures of **3a**–**e** were unambiguously established by multinuclear NMR spectroscopic experiments and mass spectrometry.



Scheme 2. Synthesis of 2*H*-1,4,2-diazaphosphole complexes **3a**–**h** (**a**: R = $NMe_2$; **b**: R = 1,5-dimethyl-2-pyrryl; **c**: R = 2-furyl; **d**: R = 2-thienyl; **e**: R = 3-thienyl; **f**: R = H; **g**: R = $CO_2Et$; **h**: R = $C_6F_5$).[14]

We monitored the ring expansion reaction of **1** + **2d** → **3d** (Scheme 2) at different concentrations of [FcH]$PF_6$ by using $^{31}P\{^1H\}$ NMR spectroscopy (Figure 1). These series revealed that the reaction progression depends strongly on the amount of [FcH]$PF_6$, but it can be reduced to 0.03 equiv. (0.01 mol $L^{-1}$) without a significant decrease in the conversion. If only 0.02 equiv. of [FcH]$PF_6$ was used, the conversion leveled off at around 80%; in the presence of 0.01 equiv. of [FcH]$PF_6$ even after 3 d the ratio of **3d** did not exceed 18%, and in the absence of [FcH]$PF_6$ no conversion of **1** was detected within 10 d (not shown). For ratios ≥0.02 equiv. of [FcH]$PF_6$, the curves show a steep ascending slope after a comparably flat trend at the start, and again a flattening at the end. As no resonances other than those of **1** and **3d** were detected by $^{31}P\{^1H\}$ NMR spectroscopic monitoring during the reaction course, the time dependent decrease of **1** follows the same trend as the increase of **3d**. Because we were interested in understanding the start of the reaction, we decided to monitor the reaction of **1** with **2d** with 0.025 equiv. of [FcH]$PF_6$ at more frequent time intervals (Figure 2).

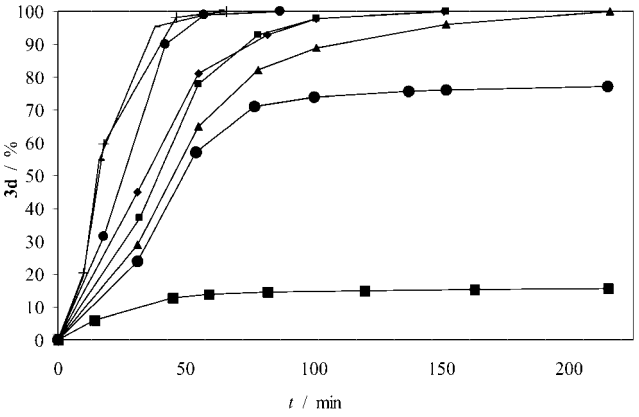


Figure 1. Ratio of **3d** over reaction time for the reaction of **1** with **2d** in the presence of varying amounts of [FcH]$PF_6$: ■ 0.01, ● 0.02, ▲ 0.03, ■ 0.04, ♦ 0.05, · 0.10, + 0.15, - 0.20 equiv.

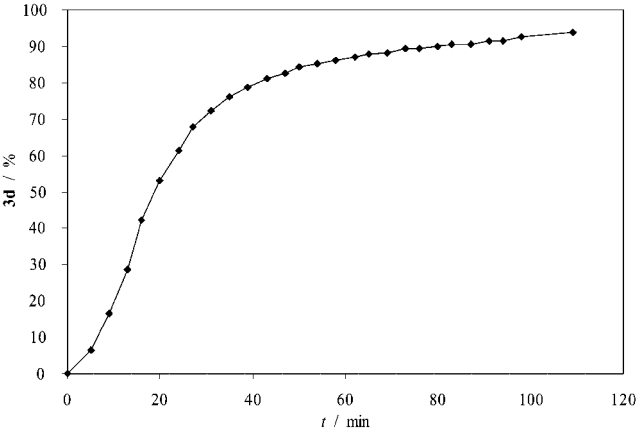

Figure 2. Ratio of **3d** over reaction time for the reaction of **1** with **2d** in the presence of 0.025 equiv. of [FcH]$PF_6$. The reaction is complete after 1 d.

The flat trend at the start is quite obvious. The fastest increase in the amount of **3d** is recorded between 29 and 42% conversion. It should be noted that a flat trend at the start of the reaction is characteristic for autocatalytic reactions, and in reactions with a very low starting concentration of the autocatalytic species the peak of the reaction rate is recorded at around 50% conversion.[15]

On the basis of these results and the finding that ferrocene is formed during the reaction, we suppose a radical cation chain reaction mechanism initiated by oxidation of **1** by the ferrocenium cation with formation of radical cation $\mathbf{1}^{\cdot+}$ and ferrocene (Scheme 3).[16]

The observed acceleration in the reaction rate at the start (Figures 1 and 2) can be explained by assuming slow oxidation of **1** followed by a fast ring-expansion reaction of highly reactive radical cation $\mathbf{1}^{\cdot+}$ with nitrile **2a**–**e**. The cycle is closed by reduction of radical cationic 2*H*-1,4,2-diazaphosphole complexes $\mathbf{3}^{\cdot+}$**a**–**e** by **1** to yield **3a**–**e** and $\mathbf{1}^{\cdot+}$, which then can restart the chain reaction. In consequence, the generation of $\mathbf{1}^{\cdot+}$ causes its multiplication, and it may be regarded as the autocatalytic species of this cycle. If

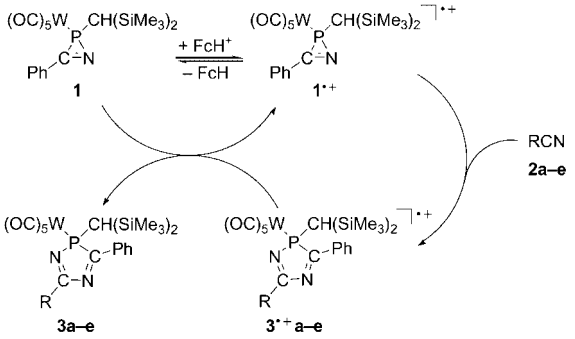

Scheme 3. Proposed chain reaction of 2*H*-azaphosphirene complex **1** with nitrile derivatives **2a**–**e** initiated by the ferrocenium cation $[FcH]^+$.

0.02 equiv. of $[FcH]PF_6$ was employed (Figure 1), the chain reaction was terminated at some point. Obviously, 0.01 equiv. of $[FcH]PF_6$ is not sufficient for the successful initiation of the chain reaction (Figure 1).

In contrast to **2a**–**e**, the reaction of **1** with HCN (**2f**) proceeded much more slowly and was unselective. Reaction monitoring showed that even after a short time (1.5 h) a variety of $^{31}P$ NMR spectroscopic resonances was detected, including a resonance at $\delta$ = 105.5 ppm (Table 1) with a tungsten–phosphorus coupling constant of 225.1 Hz and a phosphorus–hydrogen coupling constant of 34.3 Hz, which revealed the formation of **3f** (ca. 16%). Even though an excess of **2f** (2.6 equiv.) was employed, after 4 d the reaction solution still contained 16% (ratio estimation by $^{31}P\{^1H\}$ NMR spectroscopic resonance integration) of unreacted **1** and only 20% of **3f**, besides numerous unidentified byproducts. Some of the latter showed large phosphorus–fluorine coupling constants (see Experimental Section), thus revealing that the hexafluorophosphate anion, which is usually regarded as weakly coordinating, had taken part in the reaction course. As reported recently, highly electrophilic cationic species are able to abstract fluoride from the hexafluorophosphate anion.[17] Byproducts bearing a P–F bond were also found in the reaction of **1** with electron-poor nitrile derivative **2g** (see below and Experimental Section). After 6 d, 41% of **1** remained unreacted, and a product with a $^{31}P$ NMR spectroscopic resonance at $\delta$ = 110.7 ppm (21%) was observed that featured a tungsten–phosphorus coupling constant of 227.6 Hz. These data are too close to those of **3b**–**e** and, therefore, an assignment to **3g** is not supported; even more vexing is the finding that in the reaction of **1** with **2f** a byproduct having analogous $^{31}P\{^1H\}$ NMR spectroscopic data was detected. Reaction of **1** with **2h** showed a similar behavior to that of **1** with **2g**, and again, a product with a $^{31}P$ NMR spectroscopic resonance at $\delta$ = 110.7 ppm with a tungsten–phosphorus coupling constant of 228.9 Hz was observed (12% after 6 d) as well as numerous byproducts, some of which showed large phosphorus–fluorine coupling constants (see Experimental Section). Even after 6 d, 48% of **1** − and the entire amount of **2h** [by $^{19}F\{^1H\}$ NMR spectroscopy] − remained unreacted, thus indicating that **2h** had not reacted at all even though an excess of 6.4 equiv. was employed. The $^{19}F\{^1H\}$ NMR spectroscopic resonance of the hexafluorophosphate anion decreased in the course of the reaction, and after 6 d its $^{31}P\{^1H\}$ NMR spectroscopic resonance was no longer detected.

Table 1. $^{31}P\{^1H\}$ NMR spectroscopic data of **3a**–**f**.

| | **3a**[a] | **3b**[a] | **3c**[a] | **3d**[a] | **3e**[a] | **3f**[b] |
|---|---|---|---|---|---|---|
| $\delta$ / ppm | 102.1 | 108.4 | 110.6 | 110.5 | 109.1 | 105.5 |
| $^1J_{W,P}$ / Hz | 240.3 | 233.9 | 230.6 | 229.5 | 229.8 | 225.1 |

[a] In $CDCl_3$. [b] In $CH_2Cl_2$.

The $^{31}P\{^1H\}$ NMR spectroscopic data of **3b**–**e**, displayed in Table 1, are similar, and each complex has a resonance at about 110 ppm. Concerning the magnitudes of the tungsten–phosphorus coupling constant, a definite trend can be seen: $^1J_{W,P}$ constants increase with increasing donor ability[18] of the substituent at C-5 in the order: 3-thienyl ≈ 2-thienyl < 2-furyl < 1,5-dimethyl-2-pyrryl. The tungsten–phosphorus coupling constant of complex **3a**, which has a very strong electron-donating substituent ($NMe_2$) attached to C-5, is about 6 Hz larger than that of complex **3b**, whereas the $^{31}P$ NMR spectroscopic resonance is shifted by around 6 ppm to higher field. Consequently, the smallest tungsten–phosphorus coupling constant ($^1J_{W,P}$ = 225.1 Hz) was exhibited by complex **3f**, which has no substituent in the C-5 position, which lends further support to the assignment made beforehand. A further consequence can be expected from this trend: for **3g** and **3h** even lower values are expected.

To examine the aforementioned formation of products with a P–F bond, we investigated the role of the counteranion. In the reaction of **1** with **2d** we exchanged hexafluorophosphate for the weaker nucleophilic counteranion tetraphenylborate, which could not serve as a fluoride source. The outcome was a clean reaction yielding complex **4d** (by $^{31}P$ NMR spectroscopy), which also indicated that the counteranion did not play a crucial role for the ring expansions of **1** as induced by ferrocenium salts. So, the products bearing a P–F bond in the reaction of **1** with **2f** and **2g** do not constitute intermediates of the ring-expansion reaction pathway. Instead, these should be regarded as byproducts emerging from the reaction of transiently formed highly electrophilic species with hexafluorophosphate through fluoride transfer. To elucidate further the effect that $[FcH]BPh_4$ might have on reactions of **1**, we looked again at the reactions with electron-poor nitrile derivatives **2f**–**h** by using this SET reagent. Under these conditions, **1** was treated with **2f** to afford the product (again) having a $^{31}P\{^1H\}$ NMR spectroscopic resonance at $\delta$ = 110.6 ppm ($^1J_{W,P}$ = 227.6 Hz; ca. 15%) and at $\delta$ = 105.5 ppm ($^1J_{W,P}$ = 225.1 Hz: ca. 5%) that we assign to **3f** and traces of unidentified byproducts; ca. 66% of **1** remained unreacted, which did not change significantly within 4 d. Reactions of **1** with **2g** and **2h** in the presence of $[FcH]BPh_4$ showed almost no conversion of **1** within 1 d. Nevertheless, the $^{31}P\{^1H\}$ NMR spectroscopic resonance at $\delta$ = 110.6 ppm ($^1J_{W,P}$ = 227.6 Hz) slowly increased after sev-

and the particular cyclic substituent and the torsion angles between the planes of the cyclic substituents are given in Table 2. The smallest deviation from planarity is found in complex **3b**. Bond lengths and angles in the diazaphosphole ring systems of **3b** and **3d**–**e** are almost identical.

Table 2. Torsion angles of ring planes[a] for **3b** and **3d**–**e**.

| | Diazaphosphole / 5-Ph | Diazaphosphole / 3-hetaryl | 3-Hetaryl / 5-Ph |
|---|---|---|---|
| **3b** | 6.68(17) | 1.88(22) | 5.25(20) |
| **3d** | 4.29 | 3.47 / 9.96[b] | 3.52 / 7.63[b] |
| **3e** | 4.24(8) | 2.79(8) | 2.26(9) |

[a] Torsion angles with respect to least square planes; all atoms of particular ring system involved. [b] Molecule is disordered in the crystal. Values are given for both conformations.

## Theoretical Approach

The stationary points of a plausible ring-expansion pathway were calculated by DFT methods [B3LYP/TZVP//ECP-60-MWB (W)] on a model system for complex **1**, i.e. **4**. For the nitrile component, three model compounds were used, which might be classified according to their nucleophilicity: (1) medium (**2f**: R = H), (2) strong (**2i**: R = $NH_2$), and (3) weak (**2j**: R = CN). The influence of the solvent was taken into account by employing the COSMO approach with $\varepsilon$ = 8.93 to mimic dichloromethane. It was shown that this approach is appropriate.[21] In consequence, computed relative free energies (Tables 3 and 4) for reactions in solution are discussed hereafter; computed stationary points are shown in Schemes 4 and 5. All relative energies, enthalpies, and free energies are available in the Supporting Information.

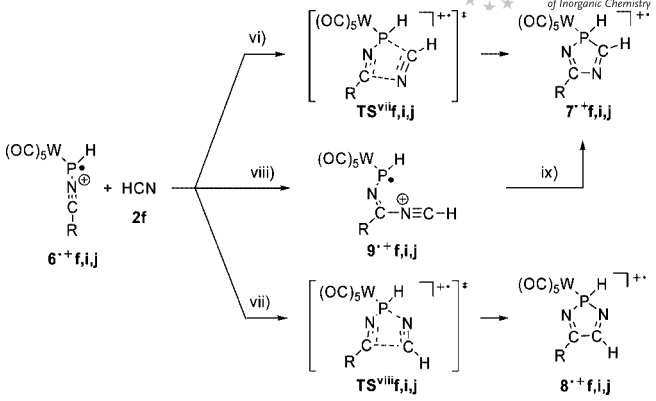
[a] Transition state could not be located. [b] The activation barrier was not calculated. We assume an outer sphere mechanism.

The overall free energy balance for net ring-expansion reactions is exergonic (cf. Schemes 4 and 5; **4** + **2f** → **7f**: $\Delta_R G_{298}$ = –104 kJ mol$^{-1}$, **4** + **2i** → **7i**: $\Delta_R G_{298}$ = –124 kJ mol$^{-1}$, and **4** + **2j** → **7j**: $\Delta_R G_{298}$ = –114 kJ mol$^{-1}$). Upon oxidation of **4**, 17e cationic complex **4**$^{\cdot+}$ is predicted to retain a closed-ring structure (Scheme 4); an isomer with a broken P–N bond could not be localized as an energy minimum. The oxidation by the ferrocenium cation (Scheme 4, reaction i) is predicted to be highly endergonic ($\Delta_R G_{298}$ = +139 kJ mol$^{-1}$), which may be due to simplification resulting from the replacement of $CH(SiMe_3)_2$ and



Scheme 5. Calculated pathways for the reactions of radical cationic nitrilium phosphane ylide complexes **6**$^{\cdot+}$**f,i,j** with HCN (**2f**) (**f**: R = H, **i**: R = $NH_2$, **j**: R = CN).

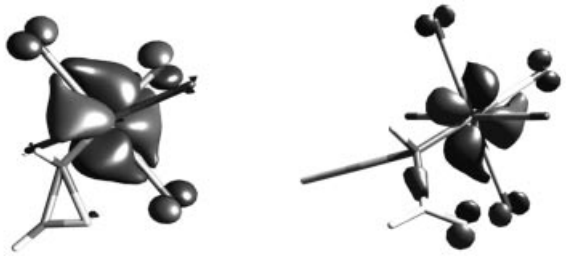


Figure 6. Highest singly occupied molecular orbitals (α-SOMO) of **4**$^{\cdot+}$ (left) and **5**$^{\cdot+}$**f** (right).

phenyl in **1** by a hydrogen atom, and thus radical cation **4**$^{\cdot+}$ is destabilized with respect to **4**. We also expect the free energy for the real system (compound **1**) to be somewhat lower but still endergonic, so the equilibrium between **1** and **1**$^{\cdot+}$ may support a low concentration of radical cation **1**$^{\cdot+}$. Most synthetically applicable radical cation chain reactions require an endergonic SET preequilibrium to initiate selective follow up reactions of highly electrophilic radical cations.[1] To save computing time we investigated the hypersurface of radical cationic model system **4**$^{\cdot+}$ by assuming that all stationary points of the reaction are affected in approximately the same way.

The highest singly occupied molecular orbital (α-SOMO) of 17e complex **4**$^{\cdot+}$, depicted in Figure 6, is mainly localized at the metal center. Only a minor participation of the nitrogen atom is apparent. An intermediate heptacoordinated tungsten complex, however, bearing one of the nitriles **2f,i,j** as ligand could not be located as an energy minimum. This ruled out a metal-centered reactivity of **4**$^{\cdot+}$ towards nitriles. Instead, a plausible pathway is the ring opening of **4**$^{\cdot+}$ by nucleophilic attack of nitriles **2f,i** with formation of intermediates **5**$^{\cdot+}$**f,i** (Scheme 4, reaction ii). The highest singly occupied molecular orbital of **5**$^{\cdot+}$**f** (Figure 6, right) also has a large contribution of the metal center, whereas a certain contribution of the nitrogen atom is apparent. This can be rationalized by the resonance structure given in Scheme 4. The barrier **TS**$^{\mathbf{ii}}$**f** for the formation of **5**$^{\cdot+}$**f** (R = H) is $\Delta G_{298}^{\neq}$ = +60 kJ mol$^{-1}$. For R = $NH_2$ no transition state

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

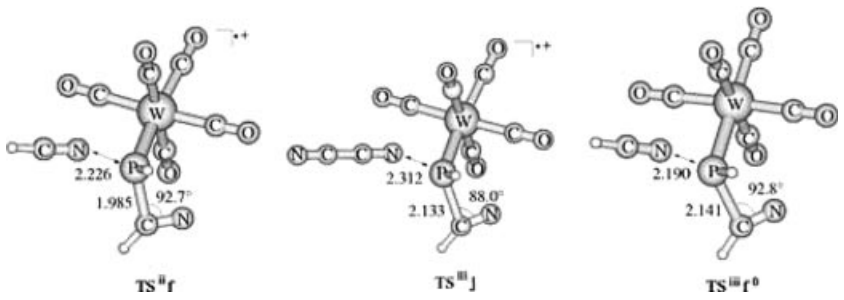

Figure 7. Transition states of the nucleophilic attack of **2f** on $\mathbf{4}^{\bullet+}$ ($\mathbf{TS}^{\mathbf{ii}}\mathbf{f}$, left), on **4** ($\mathbf{TS}^{\mathbf{iii}}\mathbf{f}^{\mathbf{0}}$, right) and of **2j** on $\mathbf{4}^{\bullet+}$ ($\mathbf{TS}^{\mathbf{iii}}\mathbf{j}$, middle).

could be located even in a constrained search, which indicates a very flat barrier. The formation of $\mathbf{5}^{\bullet+}\mathbf{f}$ is slightly endergonic ($\Delta_R G_{298}$ = +24 kJ mol$^{-1}$), whereas the formation of $\mathbf{5}^{\bullet+}\mathbf{i}$ is slightly exergonic ($\Delta_R G_{298}$ = –13 kJ mol$^{-1}$). With **2j** (R = CN), no intermediate $\mathbf{5}^{\bullet+}\mathbf{j}$ could be located. The binding of NCCN (through N) to the phosphorus center of $\mathbf{4}^{\bullet+}$ is associated with dissociation of the HCN moiety of $\mathbf{4}^{\bullet+}$ and exergonic formation of radical cationic nitrilium phosphane ylide complex $\mathbf{6}^{\bullet+}\mathbf{j}$ (Scheme 4, reaction iii; $\Delta_R G_{298}$ = –40 kJ mol$^{-1}$). The dissociation of HCN is indicated in transition state $\mathbf{TS}^{\mathbf{iii}}\mathbf{j}$ (Figure 7, middle) by the imaginary frequency, a 0.15 Å longer P–C distance and a 4.7° smaller P–C–N angle relative to ring-opening transition state $\mathbf{TS}^{\mathbf{ii}}\mathbf{f}$ (Figure 7, left). For the one-step substitution of HCN from $\mathbf{4}^{\bullet+}$ by nucleophilic attack of **2j**, the free activation energy $\mathbf{TS}^{\mathbf{iii}}\mathbf{j}$ was determined as $\Delta G_{298}^{\neq}$ = +75 kJ mol$^{-1}$. A further interesting question was to clarify the outcome of the nucleophilic attack of nitriles at the phosphorus atom of neutral 2*H*-azaphosphirene complex **4**. As indicated in the transition state, denoted as $\mathbf{TS}^{\mathbf{iii}}\mathbf{f}^{\mathbf{0}}$ (Figure 7, right), dissociation of HCN occurs also from neutral **4** upon attack of **2f**, and this reaction is also exergonic ($\Delta_R G_{298}$ = –15 kJ mol$^{-1}$) but the barrier is significantly higher ($\Delta G_{298}^{\neq}$ = +92 kJ mol$^{-1}$) than for corresponding radical cation $\mathbf{4}^{\bullet+}$. This, together with steric factors for real system **1**, might be the reason why 2*H*-azaphosphirene complex **1** does not react with nitriles in the absence of single-electron oxidants at ambient temperature.

Compound $\mathbf{5}^{\bullet+}\mathbf{i}$ (R = $NH_2$) can undergo cyclization to $\mathbf{7}^{\bullet+}\mathbf{i}$, a process that is predicted to be exergonic (Scheme 4, reaction iv; $\Delta_R G_{298}$ = –103 kJ mol$^{-1}$) and proceeding over a barrier with $\mathbf{TS}^{\mathbf{iv}}\mathbf{i}$ ($\Delta G_{298}^{\neq}$ = +22 kJ mol$^{-1}$). For $\mathbf{5}^{\bullet+}\mathbf{f}$ (R = H), transition state $\mathbf{TS}^{\mathbf{iv}}\mathbf{f}$ for the cyclization could not be located. A constrained decrease in the CN distance is associated with the breaking of the P–C bond. The dissociation of HCN from $\mathbf{5}^{\bullet+}\mathbf{f}$ proceeds over a very flat barrier $\mathbf{TS}^{\mathbf{v}}\mathbf{f}$ ($\Delta G_{298}^{\neq}$ = –2 kJ mol$^{-1}$, $\Delta E_{298}^{\neq}$ = +13 kJ mol$^{-1}$) yielding HCN and radical cationic nitrilium phosphane ylide complex $\mathbf{6}^{\bullet+}\mathbf{f}$ (Scheme 4, reaction v; $\Delta_R G_{298}$ = –96 kJ mol$^{-1}$). For $\mathbf{6}^{\bullet+}\mathbf{i}$ (R = $NH_2$), the HCN dissociation constitutes a competing pathway to the cyclization (Scheme 4, reaction iv). Calculated free activation energy for $\mathbf{TS}^{\mathbf{v}}\mathbf{i}$ is $\Delta G_{298}^{\neq}$ = +5 kJ mol$^{-1}$, and the free reaction energy is $\Delta_R G_{298}$ = –88 kJ mol$^{-1}$. In summary, the association of NCCN to $\mathbf{4}^{\bullet+}$ is simultaneously associated with a substitution of HCN, and on the other hand, upon the attack of HCN or $H_2NCN$ on $\mathbf{4}^{\bullet+}$ the HCN substitution can proceed in two steps, that is, under intermediate formation of $\mathbf{5}^{\bullet+}\mathbf{f,i}$. Alternatively, for $\mathbf{5}^{\bullet+}\mathbf{i}$ (R = $NH_2$), cyclization to $\mathbf{7}^{\bullet+}\mathbf{i}$ is feasible.

In the highest singly occupied molecular orbital (α-SOMO) of $\mathbf{6}^{\bullet+}\mathbf{f}$ (Figure 8, left) a significant contribution of the phosphorus atom is clear (as represented by the resonance structure in Scheme 4), which is in accord with the interpretation that $\mathbf{6}^{\bullet+}\mathbf{f}$ lacks one electron of the lone pair that is assigned to phosphorus in neutral nitrilium phosphane ylide complexes.[22] In 17e cationic 2*H*-1,4,2-diazaphosphole complex $\mathbf{7}^{\bullet+}\mathbf{f}$, the α-SOMO is almost exclusively located at the metal center (Figure 8, right).

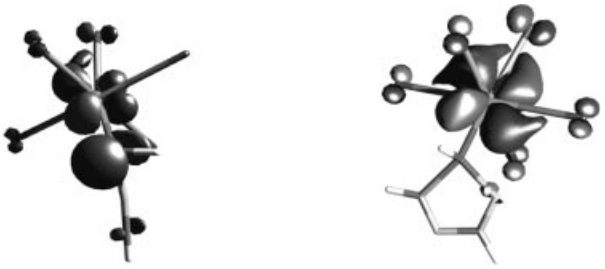

Figure 8. Highest singly occupied molecular orbitals (α-SOMO) of $\mathbf{6}^{\bullet+}\mathbf{f}$ (left) and $\mathbf{7}^{\bullet+}\mathbf{f}$ (right).

In all reactions of $\mathbf{4}^{\bullet+}$ with the three model nitrile derivatives there are plausible pathways leading to the formation of $\mathbf{6}^{\bullet+}\mathbf{f,i,j}$ with release of HCN, which in turn can (in principle) react with $\mathbf{6}^{\bullet+}\mathbf{f,i,j}$ in two regiochemically different [3+2] cycloaddition reactions, that is, with formation of radical cationic 2*H*-1,4,2-diazaphosphole complexes $\mathbf{7}^{\bullet+}\mathbf{f,i,j}$ (Scheme 5, reaction vi) or radical cationic 2*H*-1,3,2-diazaphosphole complexes $\mathbf{8}^{\bullet+}\mathbf{f,i,j}$ (Scheme 5, reaction vii). All reactions are exergonic (Table 4) and 2*H*-1,3,2-diazaphosphole complexes $\mathbf{8}^{\bullet+}\mathbf{f,i,j}$ are ca. 20–30 kJ mol$^{-1}$ more stable than corresponding 2*H*-1,4,2-diazaphosphole complexes $\mathbf{7}^{\bullet+}\mathbf{f,i,j}$. For the reactions of $\mathbf{6}^{\bullet+}\mathbf{f,i}$ (R = H and R = $NH_2$) with HCN the barriers $\mathbf{TS}^{\mathbf{vi}}\mathbf{f,i}$ for the formation of $\mathbf{7}^{\bullet+}\mathbf{f,i}$ are 18 and 14 kJ mol$^{-1}$ lower than those for the formation of $\mathbf{8}^{\bullet+}\mathbf{f,i}$ ($\mathbf{TS}^{\mathbf{vii}}\mathbf{f,i}$). For the reactions of $\mathbf{6}^{\bullet+}\mathbf{j}$ (R = CN) with HCN the barriers $\mathbf{TS}^{\mathbf{vi}}\mathbf{j}$ and $\mathbf{TS}^{\mathbf{vii}}\mathbf{j}$ are approximately equal.

For the reaction of $\mathbf{6}^{\bullet+}\mathbf{f,i,j}$ with HCN a further alternative pathway is plausible, namely a stepwise mechanism starting with the addition of HCN to $\mathbf{6}^{\bullet+}\mathbf{f,i,j}$, which leads to the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

formation of a C–N bond to yield intermediates **9**$^{\cdot+}$**f**,**i**,**j** (Scheme 5, reaction viii), with subsequent cyclization to **7**$^{\cdot+}$**f**,**i**,**j** (Scheme 5, reaction ix). The barriers for C–N bond formation **TS**$^{\mathbf{viii}}$**f**,**j** ($\Delta G_{298}^{\neq}$ = +90 kJ mol$^{-1}$ for the reaction of HCN with **6**$^{\cdot+}$**f** and $\Delta G_{298}^{\neq}$ = +77 kJ mol$^{-1}$ for the reaction with **6**$^{\cdot+}$**j**) are slightly lower than those for the corresponding direct [3+2] cycloaddition **TS**$^{\mathbf{vi}}$**f**,**j**, whereas the barriers for the second step **TS**$^{\mathbf{ix}}$**f**,**j** are almost negligible ($\Delta G_{298}^{\neq}$ = +29 kJ mol$^{-1}$ for **9**$^{\cdot+}$**f** and $\Delta G_{298}^{\neq}$ = +32 kJ mol$^{-1}$ for **9**$^{\cdot+}$**j**). The formation of **9**$^{\cdot+}$**f**,**i**,**j** (Scheme 5, reaction viii) is predicted to be endergonic for our three model reactions, that is, for the reaction of HCN with **6**$^{\cdot+}$**f** $\Delta_R G_{298}$ = +75 kJ mol$^{-1}$, for the reaction with **6**$^{\cdot+}$**j** $\Delta_R G_{298}$ = +50 kJ mol$^{-1}$, and especially for the reaction with **6**$^{\cdot+}$**i** $\Delta_R G_{298}$ = +109 kJ mol$^{-1}$.

Once **7**$^{\cdot+}$**f**,**i**,**j** are formed, the cycle is closed by the oxidation of 2*H*-azaphosphirene complex **4** by **7**$^{\cdot+}$**f**,**i**,**j** (for **7**$^{\cdot+}$**f**: $\Delta_R G_{298}$ = –13 kJ mol$^{-1}$, for **7**$^{\cdot+}$**i**: $\Delta_R G_{298}$ = –8 kJ mol$^{-1}$, for **7**$^{\cdot+}$**j**: $\Delta_R G_{298}$ = –22 kJ mol$^{-1}$) to yield 2*H*-1,4,2-diazaphosphole complexes **7f**,**i**,**j** and **4**$^{\cdot+}$, which then can restart the chain reaction (Scheme 3).

## Conclusions

A combined experimental and theoretical investigation on the ring expansion of 2*H*-azaphosphirene complex **1** with a wide variety of electronically different nitriles revealed that electron-rich nitrile derivatives **2a**–**e** furnish regioselectively 2*H*-1,4,2-diazaphosphole complexes **3a**–**e** in the presence of substoichiometric amounts of ferrocenium hexafluorophosphate. The reaction course shows characteristics of an autocatalytic reaction and is interpretable in terms of a ligand-centered reactivity of an organometallic radical cation (**1**$^{\cdot+}$). In contrast, reactions of complex **1** with **2f**–**h** proceeded differently. With HCN (**2f**) complex **3f** was formed slowly and not selectively; byproducts having a P–F bond were also formed. This provides the first strong evidence that transiently formed highly electrophilic phosphorus-containing species had reacted with hexafluorophosphate through fluoride transfer. In reactions of complex **1** with weak nucleophilic nitrile derivatives **2g**,**h**, byproducts bearing a P–F bond were also formed, but the formation of 2*H*-1,4,2-diazaphosphole complexes **3g**,**h** could not be detected.

The computational results can be summarized as follows: The barrier of the nucleophilic attack of the nitrile at radical cationic complex **4**$^{\cdot+}$ depends strongly on its nucleophilicity. As a result of steric factors in the real system of **1**, this step may be crucial. The further course of the ring expansion with strong nucleophilic nitrile derivatives[23] can proceed by direct cyclization of the intermediately formed complex **5**$^{\cdot+}$ or with moderately nucleophilic nitrile derivatives by formation of complex **6**$^{\cdot+}$ accompanied by the release of nitrile and subsequent [3+2] cycloaddition. Because the reactions are performed at ambient temperature, the kinetically controlled pathway proceeding via the more favorable transition state may be preferred, which yields regioselectively 2*H*-1,4,2-diazaphosphole complexes **7**$^{\cdot+}$. As experimentally shown, complex **1** reacts with weak nucleophilic nitrile derivatives **2g**,**h** in the presence of ferrocenium salts neither to 2*H*-1,4,2-diazaphosphole complexes **3g**,**h** nor to 2*H*-1,3,2-diazaphosphole complexes **8g**,**h**. If hexafluorophosphate is present, products bearing a P–F bond are formed. So, in the presence of weak nucleophilic nitrile derivatives a completely different reaction course is taken, which proceeds with the participation of the hexafluorophosphate anion.

## Experimental Section

**General Procedures:** All reactions and manipulations were carried out under an atmosphere of deoxygenated, dried nitrogen or argon by using standard Schlenk techniques with conventional glassware. Solvents were dried according to standard procedures. 2*H*-Azaphosphirene complex **1** was synthesized according to the method described in the literature.[10d] NMR spectra were recorded with a Bruker AC-200 spectrometer or a Bruker Avance 300 spectrometer with [D$_6$]benzene or [D]chloroform as solvent and internal standard; shifts are given relative to external tetramethylsilane ($^1$H, $^{13}$C), neat $CFCl_3$ ($^{19}$F), and 85% $H_3PO_4$ ($^{31}$P). Mass spectra were recorded with a Finnigan MAT 8430 (70 eV) or a Kratos Concept 1H spectrometer (FAB+, *m*NBA); apart from *m*/*z* values of the molecule ions, only *m*/*z* values having intensities more than 10% are given. Infrared spectra were recorded with a Biorad FTIR 165 (selected data given) or a Bruker FTIR IFS113V spectrometer. UV/Vis spectra were recorded with a Shimadzu UV-1650 PC spectrometer. Melting points were obtained with a Büchi 535 capillary apparatus or a Büchi apparatus Type S. The values are not corrected. Elemental analyses were performed using a Carlo Erba analytical gas chromatograph or an Elementar VarioEL instrument.

**General Procedure for the Synthesis of 3a–e:** To a solution of 2*H*-azaphosphirene complex **1** (617 mg, 1.00 mmol) in $CH_2Cl_2$ (3 mL) was added the appropriate nitrile (**2a**: 122 μL, 1.50 mmol; **2b**: 120 mg, 1.00 mmol; **2c**: 180 μL, 2.06 mmol; **2d**: 94 μL, 1.01 mmol; **2e**: 94 μL, 1.03 mmol) and ferrocenium hexafluorophosphate (17 mg, 0.05 mmol). The reaction mixture was stirred for 6 h at ambient temperature [reaction monitoring by $^{31}$P{$^1$H} NMR spectroscopy]. After the solvent was removed in vacuo, the product was separated and purified by column chromatography ($SiO_2$, –10 °C, petroleum ether ether/$Et_2O$, 97.5:2.5).

**Complex 3a:** Yield: 406 mg (0.59 mmol, 59%). Yellow solid, recrystallized from *n*-pentane. M.p. 122 °C. $^1$H NMR (300.13 MHz, $C_6D_6$, 30 °C): $\delta$ = –0.22 (s, 9 H, $SiMe_3$), 0.50 (s, 9 H, $SiMe_3$), 1.01 [d, $^2J_{P,H}$ = 5.8 Hz, 1 H, C*H*($SiMe_3$)$_2$], 2.78 (s, 3 H, NMe), 2.92 (s, 3 H, NMe), 7.11 (m$_c$, 3 H, *meta*, *para* Ph), 8.17 (m$_c$, 2 H, *ortho* Ph) ppm. $^{13}$C{$^1$H} NMR (75.5 MHz, $C_6D_6$, 30 °C): $\delta$ = 3.1 [d, $^3J_{P,C}$ = 1.6 Hz, Si($CH_3$)$_3$], 4.1 [d, $^3J_{P,C}$ = 2.6 Hz, Si($CH_3$)$_3$], 22.0 [d, $^1J_{P,C}$ = 5.8 Hz, *C*H($SiMe_3$)$_2$], 37.6 (s, $NCH_3$), 37.6 (s, $NCH_3$), 128.8 (s, *para* Ph), 131.6 (d, $^3J_{P,C}$ = 1.9 Hz, *ortho* Ph), 132.8 (d, $^2J_{P,C}$ = 20.7 Hz, *ipso* Ph), 133.3 (s, *meta* Ph), 165.0 (s, PNC), 198.6 (d$_{sat}$, $^2J_{P,C}$ = 6.5 Hz, $^1J_{W,C}$ = 126.7 Hz, *cis* CO), 199.6 (d, $^2J_{P,C}$ = 22.3 Hz, *trans* CO), 200.3 (d, $^{[1+4]}J_{P,C}$ = 25.5 Hz, PCN) ppm. $^{31}$P{$^1$H} NMR (121.5 MHz, $C_6D_6$, 30 °C): $\delta$ = 101.8 (s$_{sat}$, $^1J_{W,P}$ = 241.6 Hz) ppm. IR (KBr): $\tilde{\nu}$ = 2068 (CO), 1980 (CO), 1922 (CO) cm$^{-1}$. **Investigation of the Dependence of the Reaction Progression of 1 with 2d on the Amount of Ferrocenium Hexafluorophosphate:** To a solution of 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) in $CH_2Cl_2$ (0.6 mL) was added 2-thiophene carbonitrile **2d** (19 μL, 0.20 mmol) and the appropriate amount of ferrocenium hexafluorophosphate (0.7 mg, 0.002 mmol; 1.3 mg, 0.004 mmol; 2.0 mg, 0.006 mmol; 2.6 mg, 0.008 mmol; 3.3 mg, 0.010 mmol; 6.6 mg, 0.020 mmol; 9.9 mg, 0.030 mmol; 13.2 mg, 0.040 mmol). Product ratios were estimated by $^{31}$P{$^1$H} NMR spectroscopic resonance integration (30 °C, 100 scans each, measurement duration 159 s, recorded reaction time corresponds to the end of the respective measurement). For the investigations corresponding to Figure 2, a solution of $[FcH]PF_6$ (1.6 mg, 0.005 mmol) and 2-thiophene carbonitrile **2d** (19 μL, 0.20 mmol) in $CH_2Cl_2$ was added to 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) to ensure that the entire amount of $[FcH]PF_6$ was diluted at the start of the reaction. Product ratios were estimated by $^{31}$P{$^1$H} NMR spectroscopic resonance integration (30 °C, 32 scans each, measurement duration 56 s).

**Attempted Synthesis of Complex 3f with the Use of Ferrocenium Hexafluorophosphate:** To a solution of 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) in $CH_2Cl_2$ (0.6 mL) was added hydrogen cyanide **2f** (20 μL, 0.51 mmol) and ferrocenium hexafluorophosphate (12 mg, 0.04 mmol). The reaction mixture was stirred at ambient temperature [reaction monitored by $^{31}$P{$^1$H} NMR spectroscopy]. After 4 d the reaction mixture containing unidentified products **A**–**F** and **3f** was analyzed by $^{31}$P{$^1$H} NMR and $^{19}$F{$^1$H} NMR spectroscopy at 30 °C [ratio estimation by $^{31}$P{$^1$H} NMR resonance integration]. $^{31}$P{$^1$H} NMR (121.5 MHz, $CH_2Cl_2$): $\delta$ = 206.9 [d, $^1J_{P,F}$ = 855.8 Hz, **A** (1%)], 206.2 [d, $^1J_{P,F}$ = 841.8 Hz, **B** (3%)], 197.3 [d, $^1J_{P,F}$ = 824.0 Hz, **C** (9%)], 191.2 [d, $^1J_{P,F}$ = 989.3 Hz, **D** (4%)], 161.2 [$s_{sat}$, $^1J_{W,P}$ = 289.9 Hz, **E** (6%)], 110.7 [$s_{sat}$, $^1J_{W,P}$ = 227.6 Hz, **F** (5%)], 105.5 [$s_{sat}$, $^1J_{W,P}$ = 225.1 Hz, **3f** (20%)], –109.9 [$s_{sat}$, $^1J_{W,P}$ = 293.7 Hz, **1** (16%)], –143.5 [sept, $^1J_{P,F}$ = 714.0 Hz, $PF_6^-$ (3%)] ppm. $^{19}$F{$^1$H} NMR (282.4 MHz, $CH_2Cl_2$): $\delta$ = –31.0 [d, $^1J_{P,F}$ = 991.8 Hz, **D** (4%)], –72.5 [d, $^1J_{P,F}$ = 713.6 Hz, $PF_6^-$ (3%)], –109.1 [d, $^1J_{P,F}$ = 841.5 Hz, **B** (3%)], –111.4 [d, $^1J_{P,F}$ = 854.9 Hz, **A** (1%)], –117.2 [d, $^1J_{P,F}$ = 823.5 Hz, **C** (9%)] ppm.

**Attempted Synthesis of Complex 3g with the Use of Ferrocenium Hexafluorophosphate:** To a solution of 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) in $CH_2Cl_2$ (0.6 mL) was added ethyl cyanoformate **2g** (30 μL, 0.30 mmol) and ferrocenium hexafluorophos-

phate (12 mg, 0.04 mmol). The reaction mixture was stirred at ambient temperature [reaction monitored by $^{31}P\{^1H\}$ NMR spectroscopy]. After 6 d, the reaction mixture was analyzed by $^{31}P\{^1H\}$ NMR and $^{19}F\{^1H\}$ NMR spectroscopy at 30 °C [ratio estimation by $^{31}P\{^1H\}$ NMR resonance integration]. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CH_2Cl_2$): $\delta$ = 197.3 [d, $^1J_{P,F}$ = 822.7 Hz, **A** (12%)], 177.2 [d, $^1J_{P,F}$ = 967.7 Hz, **B** (2%)], 160.8 [$s_{sat}$, $^1J_{W,P}$ = 284.8 Hz, **C** (6%)], 110.7 [$s_{sat}$, $^1J_{W,P}$ = 227.6 Hz, **D** (21%)], 18.5 [d, $^1J_{P,F}$ = 1044.0 Hz, **E** (3%)], –110.1 [$s_{sat}$, $^1J_{W,P}$ = 293.7 Hz, **1** (41%)], –143.8 [sept, $^1J_{P,F}$ = 714.0 Hz, $PF_6^-$ (6%)] ppm. $^{19}F\{^1H\}$ NMR (282.4 MHz, $CH_2Cl_2$): $\delta$ = –66.7 [d, $^1J_{P,F}$ = 1046.8 Hz, **E** (3%)], –73.8 [d, $^1J_{P,F}$ = 712.5 Hz, $PF_6^-$ (6%)], –74.4 [d, $^1J_{P,F}$ = 968.3 Hz, **B** (2%)], –117.2 [d, $^1J_{P,F}$ = 823.5 Hz, **A** (12%)] ppm.

**Attempted Synthesis of Complex 3h with the Use of Ferrocenium Hexafluorophosphate:** To a solution of 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) in $CH_2Cl_2$ (0.6 mL) was added 2,3,4,5,6-pentafluorobenzonitrile **2h** (160 μL, 1.27 mmol) and ferrocenium hexafluorophosphate (12 mg, 0.04 mmol). The reaction mixture was stirred at ambient temperature [reaction monitored by $^{31}P\{^1H\}$ NMR spectroscopy]. After 6 d the reaction mixture containing unidentified products **A**–**F**, **1**, and **2h** was analyzed by $^{31}P\{^1H\}$ NMR and $^{19}F\{^1H\}$ NMR spectroscopy at 30 °C [ratio estimation by $^{31}P\{^1H\}$ NMR resonance integration]. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CH_2Cl_2$): $\delta$ = 197.4 [d, $^1J_{P,F}$ = 824.0 Hz, $^1J_{W,P}$ = 286.1 Hz, **A** (11%)], 183.1 [s, **B** (5%)], 176.3 [s, **C** (5%)], 160.9 [$s_{sat}$, $^1J_{W,P}$ = 282.3 Hz, **D** (5%)], 110.7 [$s_{sat}$, $^1J_{W,P}$ = 228.9 Hz, **E** (12%)], 18.4 [d, $^1J_{P,F}$ = 1041.4 Hz, **F** (3%)], –110.4 [$s_{sat}$, $^1J_{W,P}$ = 293.7 Hz, **1** (48%)] ppm. $^{19}F\{^1H\}$ NMR (282.4 MHz, $CH_2Cl_2$): $\delta$ = –67.6 [d, $^1J_{P,F}$ = 1041.2 Hz, **F** (3%)], –75.5 (d, $^1J_{P,F}$ = 713.6 Hz, $PF_6^-$), –117.6 [d, $^1J_{P,F}$ = 823.5 Hz, **A** (11%)], –134.0 ($m_c$, **2h**), –144.7 ($m_c$, **2h**), –160.6 ($m_c$, **2h**) ppm.

**Synthesis of 3d with the Use of Ferrocenium Tetraphenylborate:** To a solution of 2*H*-azaphosphirene complex **1** (62 mg, 0.10 mmol) in $CH_2Cl_2$ (0.3 mL) was added 2-thiophene carbonitrile **2d** (10 μL, 0.11 mmol) and ferrocenium tetraphenylborate (9 mg, 0.02 mmol). The reaction mixture was stirred for 8 h at ambient temperature, and the complete formation of **3d** was evidenced by analysis of the reaction mixture by $^{31}P\{^1H\}$ NMR spectroscopy.

**Attempted Synthesis of Complex 3f with the Use of Ferrocenium Tetraphenylborate:** To a solution of 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) in $CH_2Cl_2$ (0.6 mL) was added hydrogen cyanide **2f** (20 μL, 0.51 mmol) and ferrocenium tetraphenylborate (18 mg, 0.04 mmol). The reaction mixture was stirred at ambient temperature [reaction monitored by $^{31}P\{^1H\}$ NMR spectroscopy]. After 4 d the reaction mixture containing unidentified products **A**–**D** and **1** was analyzed by $^{31}P\{^1H\}$ NMR spectroscopy at 30 °C [ratio estimation by $^{31}P\{^1H\}$ NMR resonance integration]. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CH_2Cl_2$): $\delta$ = 110.6 [$s_{sat}$, $^1J_{W,P}$ = 227.6 Hz, **A** (13%)], 105.5 [$s_{sat}$, $^1J_{W,P}$ = 223.8 Hz, **3f** (3%)], 20.7 [$s_{sat}$, $^1J_{W,P}$ = 236.5 Hz, **B** (3%)], 13.2 [$s_{sat}$, $^1J_{W,P}$ = 236.5 Hz, **C** (8%)], –68.9 [$s_{sat}$, $^1J_{W,P}$ = 242.9 Hz, **D** (17%)], –109.9 [$s_{sat}$, $^1J_{W,P}$ = 293.7 Hz, **1** (37%)] ppm.

**Attempted Synthesis of Complex 3g with the Use of Ferrocenium Tetraphenylborate:** To a solution of 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) in $CH_2Cl_2$ (0.6 mL) was added ethyl cyanoformate **2g** (30 μL, 0.30 mmol) and ferrocenium tetraphenylborate (18 mg, 0.04 mmol). The reaction mixture was stirred at ambient temperature [reaction monitored by $^{31}P\{^1H\}$ NMR spectroscopy]. After 6 d the reaction mixture containing unidentified products **A**–**G** and **1** was analyzed by $^{31}P\{^1H\}$ NMR spectroscopy at 30 °C [ratio estimation by $^{31}P\{^1H\}$ NMR resonance integration]. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CH_2Cl_2$): $\delta$ = 204.9 [**A** (1%)], 184.5 [**B** (1%)], 163.3 [**C** (1%)], 110.7 [**D** (1%)], 97.4 [**E** (1%)], 54.5 [**F** (1%)], 34.1 [**G** (10%)], –110.1 [$s_{sat}$, $^1J_{W,P}$ = 293.7 Hz, **1** (81%)] ppm.

**Attempted Synthesis of Complex 3h with the Use of Ferrocenium Tetraphenylborate:** To a solution of 2*H*-azaphosphirene complex **1** (123 mg, 0.20 mmol) in $CH_2Cl_2$ (0.6 mL) was added 2,3,4,5,6-pentafluorobenzonitrile **2h** (160 μL, 1.27 mmol) and ferrocenium hexafluorophosphate (18 mg, 0.04 mmol). The reaction mixture was stirred at ambient temperature [reaction monitored by $^{31}P\{^1H\}$ NMR spectroscopy]. After 6 d the reaction mixture containing unidentified products **A**–**H** and **2h** was analyzed by $^{31}P\{^1H\}$ NMR and $^{19}F\{^1H\}$ NMR spectroscopy at 30 °C [ratio estimation by $^{31}P\{^1H\}$ NMR resonance integration]. $^{31}P\{^1H\}$ NMR (121.5 MHz, $CH_2Cl_2$): $\delta$ = 183.0 [$s_{sat}$, $^1J_{W,P}$ = 254.3 Hz, **A** (9%)], 176.2 [$s_{sat}$, $^1J_{W,P}$ = 277.2 Hz, **B** (3%)], 172.5 [$s_{sat}$, $^1J_{W,P}$ = 309.0 Hz, **C** (6%)], 126.1 [**D** (1%)], 110.7 [**E** (1%)], 95.5 [$s_{sat}$, $^1J_{W,P}$ = 277.2 Hz, **F** (3%)], 54.4 [$s_{sat}$, $^1J_{W,P}$ = 270.8 Hz, **G** (1%)], 40.0 [**H** (1%)], –110.4 [$s_{sat}$, $^1J_{W,P}$ = 295.0 Hz, **1** (69%)] ppm. $^{19}F\{^1H\}$ NMR: $\delta$ = –134.0 ($m_c$, **2h**), –144.7 ($m_c$, **2h**), –160.6 ($m_c$, **2h**) ppm.

**Theoretical Methods:** DFT calculations were carried out with the TURBOMOLE V5.8 program package.[24] For optimizations the gradient corrected exchange functional by Becke[25] (B88) in combination with the gradient corrected correlation functional by Lee, Yang, and Parr[26] (LYP) with the RI approximation[27] and the valence-double-ζ basis set SV(P)[28] was used. For tungsten the effective core potential ECP-60-MWB[29] derived from the Stuttgart-Dresden group was used. The influence of the polar solvent was taken into account by employing the COSMO approach[30] with $\varepsilon$ = 8.93. For cavity construction the atomic radii of Bondi[31] were used, which are obtained from crystallographic data. For tungsten the atomic radius was set to 2.2230 Å. The stationary points were characterized by numerical vibrational frequencies calculations by using the SNF 3.3.0 program package.[32] Single point calculations were carried out by using the Three Parameter Hybrid Functional Becke3[33] (B3) in combination with the LYP correlation functional[26] and the valence-triple-ζ basis set TZVP[34] and ECP-60-MWB for tungsten.

**Supporting Information** (see footnote on the first page of this article): Relative energies, enthalpies, and free energies for the reactions depicted in Schemes 4 and 5.

[19] X-ray crystallographic analysis of **3d**: Suitable yellow single crystals of **3d** were obtained from a concentrated *n*-pentane solution upon decreasing the temperature from ambient temperature to +4 °C. Data were collected with a Nonius KappaCCD diffractometer equipped with a low-temperature device (Cryostream, Oxford Cryosystems) at 123 K by using graphite monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structure was solved by Patterson methods (SHELXS-97)[20a] and refined by full-matrix least-squares on $F^2$ (SHELXL-97).[20b] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were included isotropically by using the riding model on the bound atoms. The thiophene substituent is disordered [occupancy: 0.81(1): 0.19(1)]. Semiempirical absorption correction was carried out from equivalents (min./max. transmissions = 0.27295/0.61685). $C_{24}H_{27}N_2O_5PSSi_2W$; crystal size 0.45 × 0.30 × 0.12 mm, triclinic, $P\bar{1}$ (No.2), $a$ = 10.9114(2) Å, $b$ = 12.1675(2) Å, $c$ = 13.1114(2) Å, $\alpha$ = 96.695(1)°, $\beta$ = 110.108(1)°, $\gamma$ = 109.554(1)°, $V$ = 1486.63(4) Å$^3$, $Z$ = 2, $\rho_{calcd.}$ = 1.623 Mg m$^{-3}$, $2\theta_{max}$ = 55°, collected (independent) reflections = 14224 (6590), $R_{int}$ = 0. 0716, $\mu$ = 4.124 mm$^{-1}$, 318 refined parameters, 51 restraints, $R_1$ [for $I > 2\sigma(I)$] = 0. 0361, $wR_2$ (for all data) = 0.0935, max./min. residual electron density = 2.745/–3.017 e Å$^{-3}$. X-ray crystallographic analysis of **3b**, **3e**: Crystals were obtained from a concentrated *n*-pentane solution. Data were collected with a Bruker SMART 1000 CCD diffractometer equipped with a low-temperature device. Structure solution and refinement as above. **3b**: $C_{26}H_{32}N_3O_5PSi_2W$; crystal size 0.19 × 0.14 × 0.06 mm, triclinic, $P\bar{1}$ (No.2), $a$ = 10.823(2) Å, $b$ = 12.207(2) Å, $c$ = 13.395(3) Å, $\alpha$ = 96.101(6)°, $\beta$ = 110.126(6)°, $\gamma$ = 107.666(6)°, $V$ = 1538.7(5) Å$^3$, $Z$ = 2, $\rho_{calcd.}$ = 1.592 Mg m$^{-3}$, $2\theta_{max}$ = 60°, collected (independent) reflections = 30876 (8933), $R_{int}$ = 0.0501, $\mu$ = 3.92 mm$^{-1}$, 351 refined parameters, 63 restraints, $R_1$ [for $I > 2\sigma(I)$] = 0. 0451, $wR_2$ (for all data) = 0.1125, max./min. residual electron density = 3.80/–5.13 e Å$^{-3}$. **3e**: $C_{24}H_{27}N_2O_5PSSi_2W$; crystal size 0.35 × 0.23 × 0.16 mm, triclinic, $P\bar{1}$ (No. 2), $a$ = 10.8501(12) Å, $b$ = 12.2138(12) Å, $c$ = 13.1138(14) Å, $\alpha$ = 96.171(3)°, $\beta$ = 110.016(3)°, $\gamma$ = 110.191(3)°, $V$ = 1481.5(3) Å$^3$, $Z$ = 2, $\rho_{calcd.}$ = 1.629 Mg m$^{-3}$, $2\theta_{max}$ = 61°, collected (independent) reflections = 24334 (8967), $R_{int}$ = 0. 0250, $\mu$ = 4.14 mm$^{-1}$, 331 refined parameters, 31 restraints, $R_1$ [for $I > 2\sigma(I)$] = 0. 0179, $wR_2$ (for all data) = 0.0455, max./min. residual electron density = 1.417/–1.308 e Å$^{-3}$. # Organometallic and Classical Coordination Sites in Highly Preorganized Pyrazolate-Based Hybrid Systems: The Mn/Ni Case

**Huaxin Zhang,[a] Sebastian Dechert,[a] Michael Linseis,[b] Rainer F. Winter,[b] and Franc Meyer*[a]**

**Keywords:** Bridging ligands / Cyclopentadienyl ligands / Manganese / Nickel / Heterometallic complexes

A series of unsymmetric heterodinuclear Mn/Ni complexes is reported in which an organometallic $CpMn(CO)_2$ fragment and a classical Werner-type nickel(II) subunit are arranged in close proximity by means of a bridging pyrazolate. The two metalloligand scaffolds (**1** and **2**) employed differ in the chelate size of the tripodal tetradentate $\{N_4\}$ binding site for nickel. Molecular structures have been determined for ($\mathbf{1}_{-H}$)-Ni($NO_3$) (**3**), ($\mathbf{2}_{-H}$)Ni($NO_3$) (**4**), and ($\mathbf{2}_{-H}$)Ni(OAc) (**5**). Comparison with the molecular structures of the related Mn/Mn, Mn/Co, and Mn/Zn systems confirms that structural flexibility is greater for the complexes based on ligand **2** due to the longer chelate arms. According to IR and UV/Vis spectroelectrochemistry, oxidation of the heterobimetallic systems is highly localized at the organometallic manganese site. Structural and spectroscopic features as well as trends for the redox potentials of the $Mn^I/Mn^{II}$ couple suggest that ligand variations at the nickel(II) Werner-type subunit exert only a small influence on the properties of the organometallic part. In contrast, reduction occurs at the nickel site and is strongly dependent on the anion present. The effects at the organometallic $CpMn(CO)_2$ subunit upon reduction of the proximate nickel ion are most pronounced for **5**.

## Introduction

The pyrazolate heterocycle is a well established and useful bridging unit in bimetallic complexes.[1] Further preorganization of the two metal ions as well as modulation of their structural and electronic properties can be achieved by attaching chelating side arms to the 3- and 5-positions of the heterocycle.[2,3] The majority of such pyrazolate-derived dinucleating ligand scaffolds are symmetric, which means that these scaffolds provide two identical coordination pockets and favor the formation of homobimetallic complexes. Unsymmetrical pyrazolate ligands that allow the targeted assembly of heterobimetallic complexes, despite the intriguing metal ion cooperativity that can be expected for those systems,[4] are relatively scarce due to their more laborious synthesis.[5] An interesting situation with respect to the mutual effects of the proximate metal ions arises when the distinction between the two binding sites becomes very pronounced, such as in hybrid systems that contain an organometallic subunit next to a classical Werner-type subunit.

We have recently reported a series of unsymmetrical homo- and heterobimetallic complexes of type **A** that formally combine an organometallic $CpMn(CO)_2$ fragment **B** and a classical subunit of type **C** (Scheme 1).[6–8] The latter is reminiscent of the tripodal tetradentate tris(pyridylmethyl)amine systems that are well established in mononuclear coordination chemistry.[9] Manganese(II), cobalt(II), or zinc(II) ions with different co-ligands X can be accommodated in the Werner-type compartment of complexes **A**, with only subtle changes of the spectroscopic and redox properties of the organometallic site.[6–8] It appears that the two metal ions in these complexes are electronically quite independent. In contrast, strong electronic coupling was observed in the symmetric dimanganese complex **D**, which was shown to undergo two sequential metal-centered one-electron oxidations with fast intramolecular thermal electron transfer ($k_{ET} \approx 2.6 \times 10^{10}\ s^{-1}$ at 298 K) in the mixed-valent $Mn^IMn^{II}$ species, which has a formal low-spin $d^5d^6$ electronic configuration.[10] The coincidence of the π plane of the heterocycle with the mirror plane of the $Mn(CO)_2$ moiety in **D** is an ideal arrangement for Mn-pyrazolate π-interactions and hence for electronic communication between the two Mn centers.[10–12]

In the present work we have now investigated a series of new heterobimetallic complexes of type **A** with nickel(II) in the tripodal tetradentate $\{N_4\}$ coordination site and different counteranions Y. A large separation of the metal-centered redox potentials was anticipated for this particular combination since oxidation of the manganese ion might

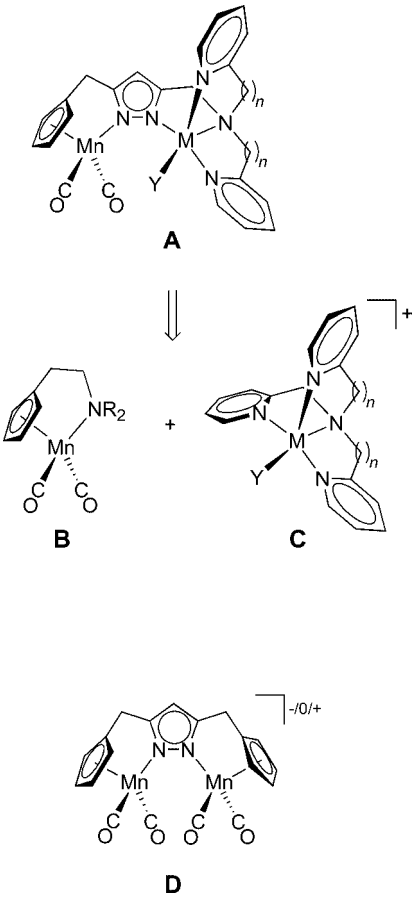


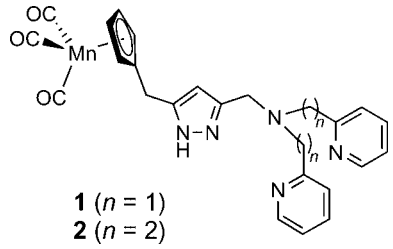
Scheme 1.

occur easily while nickel(I) or nickel(III) should be much harder to access. It therefore appeared interesting to probe whether one-electron redox processes would be strictly confined to one site and to what extent a mutual influence of the adjacent metal ions might be discernible for the Mn/Ni case.

## Results and Discussion

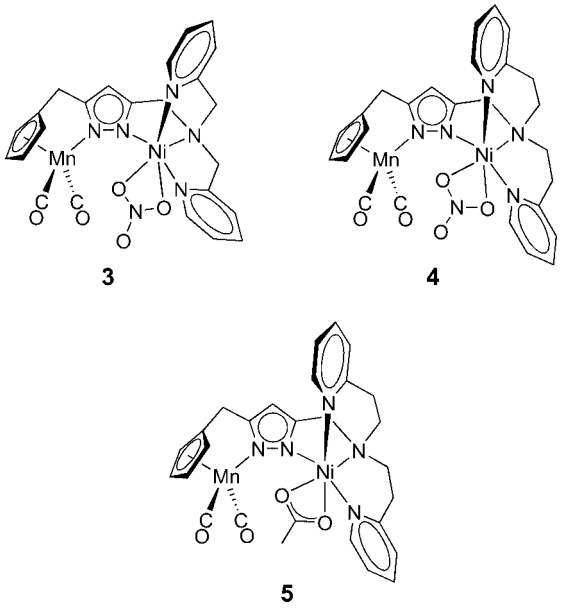
### Synthesis and Structural Characterization of the Complexes

Cymantrene derivatives **1** and **2** are the basic scaffolds for this particular class of heterobimetallic complexes (Scheme 2). They were prepared in several steps from simple pyrazole derivatives as reported previously,[6] with different lengths of the pyridylalkyl side-arms appended to the pyrazole heterocycle. The latter variation allows us to probe the effect of small changes of the Werner-type $\{N_4\}$ binding pockets on the properties of the bimetallic array. Photolysis of **1** or **2** with a high pressure mercury lamp in a quartz tube at –40 °C leads to CO release and intramolecular coordination of the pyrazole nitrogen atom to manganese, and subsequent deprotonation with one equivalent of KO*t*Bu followed by addition of the appropriate nickel salt [$Ni(NO_3)_2 \cdot 6H_2O$ or $Ni(OAc)_2 \cdot 4H_2O$] fills the $\{N_4\}$ donor compartment. This synthetic sequence is best carried out as a one-pot reaction.



Scheme 2.

Single crystals of **3**·dmf, **4**, and **5** were obtained by slow diffusion of $Et_2O$ into dmf solutions of the products (Scheme 3), and details of the constitution of all three complexes were elucidated by X-ray crystallography. The molecular structures are depicted in Figures 1, 2, and 3, together with selected interatomic distances and bond angles.



Scheme 3. Heterobimetallic Mn/Ni complexes.

The pyrazolate bridges the two metal ions in all three complexes **3**–**5** and the nickel(II) is hosted in the classical $\{N_4\}$ coordination site, as anticipated. Only complex **3** features crystallographically imposed mirror symmetry. Sixfold coordination of the nickel ion is completed by (slightly asymmetric) bidentate coordination of either a nitrate (**3**, **4**) or acetate anion (**5**), which results in a strongly distorted octahedral environment of the metal center. The metal–metal separation depends strongly on the length of the ligand side-arms. Thus, a larger Mn···Ni distance of around 4.50 Å is induced by the longer chelate arms in **4** and **5** whereas a distinctly shorter distance of 4.25 Å is observed for **3**. This variation is accompanied by different chelate arrangements of the Werner-type site: in the case of the shorter side-arms (**3**) the pyridyl nitrogens are located *trans* to each other and a nitrate oxygen is *trans* to the pyrazolate

plexes with the same pyrazole-based ligands.[6,8] The binding mode of the acetate or nitrate co-ligand (chelating, semi-chelating, or monodentate) depends on the radii and the particular stereoelectronic preferences of the metal ion in the $\{N_4\}$ binding pocket.

The Ni–O/N bond lengths of **3**–**5** lie within the range usually reported for octahedral nickel(II) complexes with a comparable $N_4O_2$ coordination sphere.[13] In particular, embedding of the nickel ion in the $\{N_4\}$ pocket is reminiscent of the situation found for a mononuclear nickel(II) acetate complex of type **C** with the tripodal tetradentate tris(pyridylmethyl)amine (TPA) ligand **E**.[14] This is in line with the description of complexes **3**–**5** as hybrids of an organometallic type **B** and a classical type **C** subunit. In the case of **E**, however, the acetate co-ligand is only monodentate and the remaining coordination site is occupied by a water molecule.

| CO–Mn–N | 96.0–102.2 | 94.8–102.7 | 99.5–104.1 | 94.6–101.4 | 95.9–104.9 |

Mn/Co, and Mn/Mn complexes, as well as complexes where the $\{N_4\}$ site is unoccupied, reveals that the choice of metal in the classical Werner-type site seems to have only a small influence on the bonding parameters of the organometallic $CpMn(CO)_2$ site (Table 1). Only the CO–Mn–N angles appear to be somewhat flexible and span a range from 94.8° to 104.1° (Table 1).

In order to visualize the extent of preorganization and the flexibility of the dimetallic arrangement based on **1** and **2**, a superposition of the pyrazolate-bridged cores of all Mn/Mn, Mn/Co, Mn/Ni, and Mn/Zn dinuclear complexes with either short or long chelate arms is shown in Figure 4. Structural variations should reflect the conformational freedom of the pyrazolate-centered dimetallic array, with the metal ions swinging above and below the heterocyclic plane. It seems that the range of displacements out of the plane of the pyrazolate heterocycle that is accessible to the two metal ions is greater in the case of the longer (and more flexible) side-arms at the $\{N_4\}$ compartment. The maximum angle between the pyrazolate plane and the N1–Mn bond is 11.1° for systems derived from **1** and 22.5° for systems derived from **2**; the maximum angle between the pyrazolate plane and the N2–M bond is 14.5° for systems derived from **1** and 17.9° for systems derived from **2**.

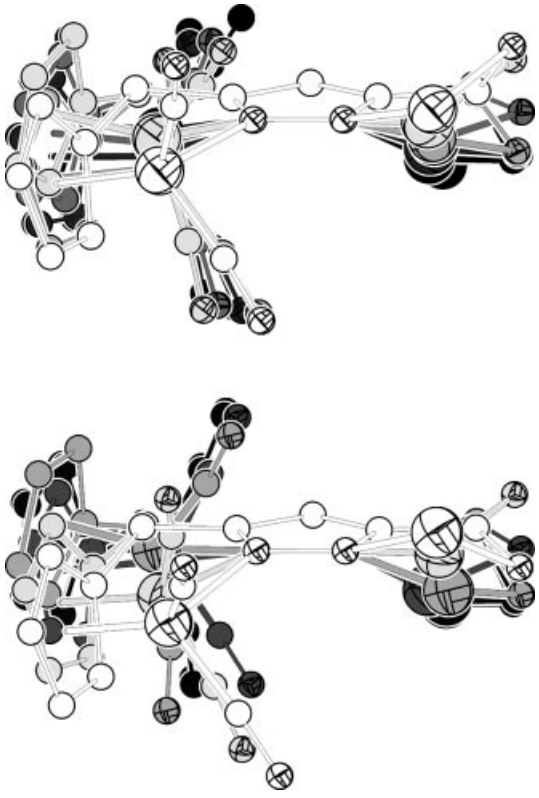

Figure 4. Overlay of the pyrazolate-bridged heterobimetallic arrangements for the series of Mn/Mn, Mn/Co, Mn/Ni, and Mn/Zn complexes based on **1** (short chelate arms; top) or **2** (long chelate arms; bottom). The appended chelate arms and the co-ligands at the Werner-type site have been omitted for clarity.

### Spectroscopic and Electrochemical Trends

All Mn/Ni complexes show two strong IR bands of similar relative intensities for the $\nu_{as}(CO)$ and $\nu_s(CO)$ vibrations of the $\{Mn(CO)_2\}$ fragment at around 1900 and 1825 $cm^{-1}$, respectively (Table 2). Neither the chelate ring size of the $\{N_4\}$ ligand compartment (**3** vs. **4**) nor the co-ligand at nickel (nitrate in **4** vs. acetate in **5**) seem to have any considerable effect on the energies of the CO stretches. Complex **5** features strong bands at 1550 and 1447 $cm^{-1}$ that are absent in the spectrum of **4** and are thus assigned to the acetate ligand. The small difference between $\nu_{as}(COO)$ and $\nu_s(COO)$ is in accordance with bidentate acetate coordination.[15]

Table 2. IR absorptions [$cm^{-1}$] in the CO stretching range.

[a] dce = 1,2-dichloroethane.

Cyclic voltammograms in MeCN (**3**) or dmf (**4**, **5**) solution feature a reversible redox wave in the range $E_{1/2}$ = –0.50 to –0.66 V and an irreversible reduction at much lower potential (Table 3).[16] The cyclic voltammograms of **4** and **5** depicted in Figures 5 and 6, respectively, show that variations in the co-ligand at nickel (nitrate in **4** vs. acetate in **5**) barely influence the first redox process at around –0.6 V but have a pronounced effect on the reduction at lower potential. The former is thus assigned to the $Mn^I/Mn^{II}$ couple while the latter process likely corresponds to the $Ni^{II} \rightarrow Ni^I$ reduction. Potentials for the $Mn^I/Mn^{II}$ interconversions of $[CpMn(CO)_2L]$ complexes are known to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

vary over a potential range of more than 2 V, depending of the nature of the ligand L.[11,12,17] The rather low oxidation potentials of **3**–**5** indicate significant stabilization of the $Mn^{II}$ state by the anionic pyrazolate ligand and reflect the high nucleophilicity of the nitrogen heterocycle in these heterobimetallic species.[17] Small influences of the ligand chelate ring size (**3** vs. **4**) or of the co-ligand at nickel (**4** vs. **5**) on the $Mn^{I}/Mn^{II}$ redox potential suggest a certain degree of electronic communication between the proximate metal ions. For example, the oxidation wave of the nitrate complex with shorter chelate arms at nickel (**3**) is shifted anodically by 60 mV with respect to the congener with longer chelate arms (**4**), and the more electron-donating acetate at nickel facilitates oxidation of the manganese site by 100 mV (**5** vs. **4**). These trends are in good agreement with findings for the related Mn/Mn, Mn/Co, and Mn/Zn systems.[6–8]

Table 3. Formal potentials for the $Mn^{I}/Mn^{II}$ couple in MeCN/0.1 M $n$Bu$_4$NClO$_4$ (**3**) or dmf/0.1 M $n$Bu$_4$NPF$_6$ (**4**, **5**).[16]

| **5** | –0.66 | –2.72[a] |

[a] Peak potentials for irreversible reduction process at 100 mV s$^{-1}$.

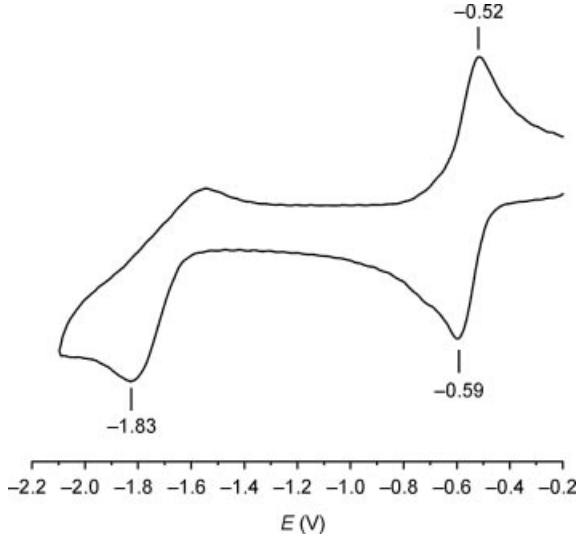

Figure 5. Cyclic voltammogram of **4** recorded with a platinum electrode in dmf containing approximately 0.1 M $n$Bu$_4$NPF$_6$; scan speed: 100 mV s$^{-1}$; potentials are given in volts vs. the Fc/Fc$^+$ couple.

IR and UV/Vis spectroelectrochemistry have proven valuable for establishing the site of redox processes in such heterobimetallic complexes and to characterize the resulting species. Oxidation of the Mn/Ni systems **3**–**5** in 1,2-dichloroethane (dce) was thus followed by IR and UV/Vis spectroscopy in an OTTLE cell (Figures 7 and 8, and Figures S1–S4 in the Supporting Information). The intensity of the pair of CO stretching vibrations at around 1905 and 1825 cm$^{-1}$ decreases at the expense of two new bands at around 2030 and 1950 cm$^{-1}$ upon gradual electrolysis, thus confirming the structural integrity of the $CpMn(CO)_2$ frag-

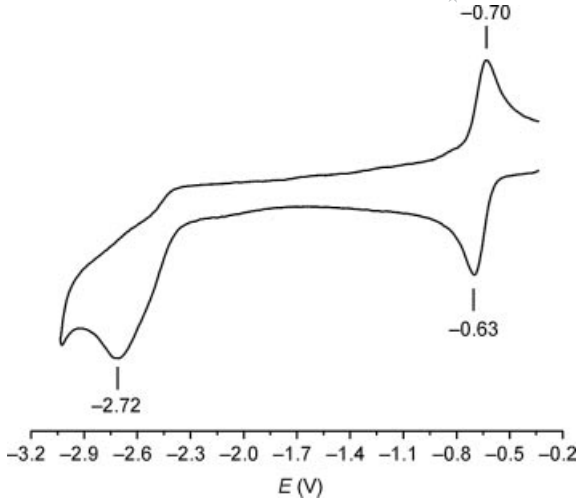

Figure 6. Cyclic voltammogram of **5** recorded with a platinum electrode in dmf containing approximately 0.1 M $n$Bu$_4$NPF$_6$; scan speed: 100 mV s$^{-1}$; potentials are given in volts vs. the Fc/Fc$^+$ couple.

ment upon generation of the oxidized species **3**$^+$–**5**$^+$. The slightly lower intensity of the new bands is in agreement with our expectations since spectral intensities in M–CO moieties usually decrease with increasing oxidation state.[18] The shift of about 125 cm$^{-1}$ to higher frequencies is very similar to the shift observed in the corresponding Mn/Zn, Mn/Co and Mn/Mn complexes.[6–8] It is typical for a one-unit increase in the oxidation state of the metal ion and reflects the diminished backbonding ability in the oxidized $CpMn^{II}(CO)_2$ subunit. This confirms that the anodic process in the present Mn/Ni systems is fully localized at the organometallic site, which means that nickel remains in the +II oxidation state. The presence of several isosbestic points confirms clean conversion between the $Mn^{I}Ni^{II}$ and $Mn^{II}$-$Ni^{II}$ species. However, the original spectra of the starting materials **3**–**5** are not fully restored upon re-reduction. Furthermore, the intensities of the CO stretching vibrations

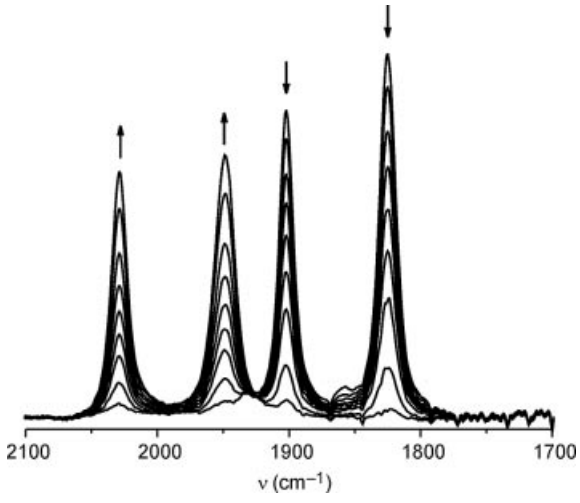

Figure 7. IR spectroscopic changes during the gradual oxidation of **3** in dce/$n$Bu$_4$PF$_6$ solution in an OTTLE cell.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

are somewhat lower than their original values, which suggests that the oxidized complexes have only limited stabilities in solution. Accordingly, attempts to crystallize the $Mn^{II}Ni^{II}$ complexes after chemical oxidation have so far proved unsuccessful.

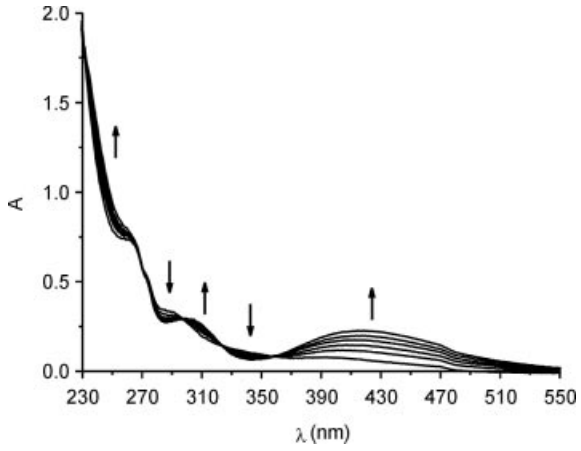

Figure 8. UV/Vis spectroscopic changes during the gradual oxidation of **3** in dce/$n$Bu$_4$PF$_6$ solution in an OTTLE cell.

The oxidation of **3**–**5** is accompanied in UV/Vis spectroelectrochemistry by the appearance of a new band peaking in the range 395–421 nm (**3**: 415 nm; **4**: 396 nm; **5**: 421 nm, Figure 8 and S3, S4). The rise of a similar band at about 400 nm has also been observed upon oxidation of the corresponding Mn/Zn, Mn/Co and Mn/Mn systems[6–8] and can thus be safely assigned to the π(pyrazolate)→CpMn$^{II}$-(CO)$_2$ LMCT transition, which is obviously relatively insensitive to the identity of the metal ion within the adjacent Werner-type {N$_4$} compartment.

According to IR spectroelectrochemistry, reduction of **4** is also an almost reversible process. Shifts to lower energy in the CO stretching range are only minor (Figures 9 and 10; 1906/1829→1902/1827 cm$^{-1}$ for **4**; 1906/1829→1896/1819 cm$^{-1}$ for **5**), in accordance with the idea that reduction occurs within the nickel subunit. It is interesting to note, however, that the CO stretches are clearly more affected in **5**, where a noticeable shift of 10 cm$^{-1}$ is observed compared to an almost negligible shift of about 3 cm$^{-1}$ for **4**. Since **4** and **5** are derived from the same pyrazolate-based ligand scaffold, this distinction must stem solely from the different anion at nickel (nitrate vs. acetate). Re-oxidation of **5**$^-$ does not reproduce the original spectrum but gives rise to a new species with two IR bands that are shifted by 18 cm$^{-1}$ to lower energy with respect to the CO absorptions of **5**. While the typical pattern of two CO stretches suggests that the integrity of the CpMn(CO)$_2$ subunit is retained, the chemical reaction that apparently follows upon electrochemical reduction may involve a ligand exchange at nickel or ligand fragmentation at the Werner-type site. The rather different behavior of **4** and **5** upon reduction is in accordance with the strongly different reduction potentials determined electrochemically for these two complexes (compare Figures 5 and 6).

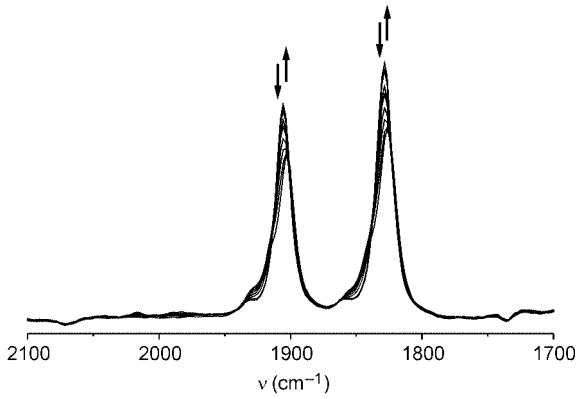

Figure 9. IR spectroscopic changes during the gradual reduction of **4** in dce/$n$Bu$_4$PF$_6$ solution in an OTTLE cell.

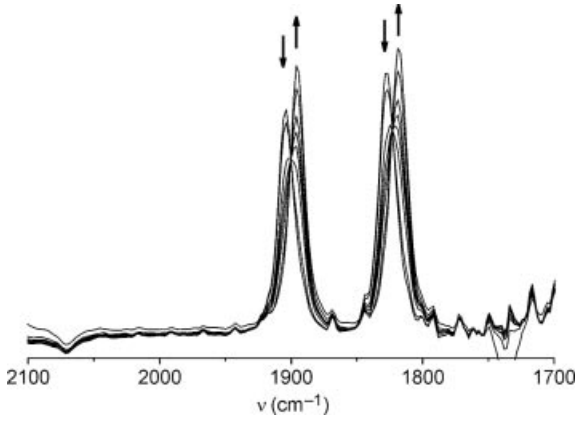

Figure 10. IR spectroscopic changes during the gradual reduction of **5** in dce/$n$Bu$_4$PF$_6$ solution in an OTTLE cell.

## Conclusions

The present set of Mn/Ni complexes complements a series of unique heterobimetallic systems in which an organometallic CpMn(CO)$_2$ fragment is bridged via a pyrazolate to a nearby metal ion ($Mn^{2+}$, $Co^{2+}$, $Ni^{2+}$, $Zn^{2+}$) that is nested in a classical Werner-type compartment with an {N$_4$} donor set. The pronounced asymmetry of the bimetallic array results in strong localization of redox events in those systems: oxidation occurs at relatively low potential and is strictly confined to the organometallic site, while reduction (in the case of $Mn^{2+}$, $Co^{2+}$, or $Ni^{2+}$ as the second metal ion) appears to occur solely within the Werner-type subunit, with very little mutual interaction. Ligand variations at the {N$_4$} compartment (such as different lengths of the chelate arms or different co-ligands) exert only minor influences on the CpMn(CO)$_2$ fragment, but have a clear effect on the properties of the second metal ion, as expected. Further modifications of the Werner-type subunit, including donor sets other than the tripodal tetradentate {N$_4$} motif of the present complexes, should allow us to shift the redox potential of the second metal ion closer to that of the organometallic Mn site. It will be interesting to monitor the changes of intermetallic communication that might accompany such modifications and to probe the co-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

operative redox transformation of substrates that bind to the second metal but exploit the strong reduction potential of the nearby organometallic site.

## Experimental Section

**General Procedures and Methods:** Manipulations were carried out under an atmosphere of dry nitrogen by employing standard Schlenk techniques. Complexes **1** and **2** were prepared as reported previously.[6] Solvents were dried according to established procedures. All other chemicals were obtained from commercial sources and used as received. IR spectra were recorded for KBr pellets with a Digilab Excalibur. ESI mass spectra were measured with a Finnigan MAT LCQ spectrometer. Elemental analyses were performed by the analytical laboratory of the Institut für Anorganische Chemie der Universität Göttingen using a Heraeus CHN-O-RAPID instrument. Cyclic voltammetry was carried out with a Perkin–Elmer Model 263A potentiostat/galvanostat with glassy carbon working electrode and platinum reference and counter electrodes, in 0.1 M $n$Bu$_4$NClO$_4$/CH$_3$CN or 0.1 M $n$Bu$_4$NPF$_6$/dmf; ferrocene (the potential in dmf being 0.45 V against SCE)[19] was used as internal standard. Spectroelectrochemistry (IR and UV/Vis) was performed with a self-constructed OTTLE cell comprising a Pt-mesh working and counter electrode and a silver wire as pseudeo-reference electrode sandwiched in between the $CaF_2$ windows of a conventional liquid IR cell. The working electrode is positioned in the center of the spectrometer beam with all other parts of the cell made non-transparent to the incident beam by means of an absorbing tape.[20]

**Synthesis of Complex 3:** A solution of **1** (0.256 g, 0.52 mmol) in thf (200 mL) was irradiated with a high-pressure mercury lamp in a quartz tube at –40 °C. Within one hour the color of the solution had changed from light yellow to yellow. The solution was then warmed to room temperature and KO$t$Bu (0.058 g, 0.52 mmol) and Ni(NO$_3$)$_2$·6H$_2$O (0.151 g, 0.52 mmol) were added. The reaction mixture was stirred overnight to produce a yellow precipitate, which was separated by filtration, washed with light petroleum ether, and dried under vacuum. Single crystals were obtained after several days by slow diffusion of diethyl ether into a concentrated dmf solution of the crude product. The crystals were separated by filtration, washed with diethyl ether, and dried under vacuum. Yield: 31 mg (9%). IR (KBr): $\tilde{\nu}$ = 2929 (w), 2869 (w), 1902 (vs), 1822 (vs), 1672 (m), 1605 (m), 1479 (m), 1384 (m), 1287 (m), 1157 (w), 1097 (w), 1056 (w), 1024 (w), 958 (w), 884 (w), 818 (w), 771 (m), 653 (w), 611 (w), 588 (w), 512 (w), 474 (w), 427 (w) cm$^{-1}$. $C_{27}H_{28}MnN_7NiO_6$ (660.2): calcd. C 49.12, H 4.27, N 14.85; found C 49.27, H 4.44, N 13.98.

**Synthesis of Complex 4:** A solution of **2** (0.230 g, 0.44 mmol) in thf (200 mL) was irradiated with a high pressure mercury lamp in a quartz tube at –40 °C. Within about one hour the color of the solution had changed from light yellow to yellow. The solution was then warmed to room temperature and KO$t$Bu (0.049 g, 0.44 mmol) and Ni(NO$_3$)$_2$·6H$_2$O (0.128 g, 0.44 mmol) were added. The reaction mixture was stirred overnight to produce a yellow precipitate, which was separated by filtration, washed with light petroleum, and dried under vacuum. Single crystals were obtained after several days by slow diffusion of diethyl ether into a concentrated dmf solution of the crude product. The crystals were separated by filtration, washed with diethyl ether, and dried under vacuum. Yield: 40 mg (15%). IR (KBr): $\tilde{\nu}$ = 2963 (w), 2916 (w), 2864 (w), 1906 (vs), 1822 (vs), 1662 (w), 1607 (m), 1578 (w), 1487 (m), 1451 (m), 1387 (m), 1340 (w), 1276 (m), 1155 (w), 1105 (m), 1052 (w), 1022 (m), 950 (w), 807 (w), 765 (m), 656 (w), 591 (w), 528 (w), 474 (w), 432 (w) cm$^{-1}$. HR-MS (ESI+, MeCN): $m/z$ calcd. for $C_{26}H_{25}MnN_6NiO_5$ [M]$^+$: 614.06149; found 614.06132. $C_{26}H_{25}MnN_6NiO_5$ (615.2): calcd. C 50.77, H 4.10, N 13.66; found C 49.50, H 4.27, N 13.62.

**Synthesis of Complex 5:** A solution of **2** (0.200 g, 0.38 mmol) in thf (200 mL) was irradiated with a high pressure mercury lamp in a quartz tube at –40 °C. Within about one hour the color of the solution had changed from light yellow to yellow. The solution was

then warmed to room temperature and KO*t*Bu (0.043 g, 0.38 mmol) and $Ni(CH_3COO)_2 \cdot 4H_2O$ (0.095 g, 0.38 mmol) were added. The reaction mixture was stirred overnight to produce a yellow precipitate, which was separated by filtration, washed with light petroleum, and dried under vacuum. Single crystals were obtained after several days by slow diffusion of diethyl ether into a concentrated dmf solution of the crude product. The crystals were separated by filtration, washed with diethyl ether, and dried under vacuum. Yield: 36 mg (16%). IR (KBr): $\tilde{\nu}$ = 2964 (w), 2917 (m), 2861 (w), 1890 (vs), 1823 (vs), 1666 (m), 1607 (m), 1550 (m), 1478 (m), 1447 (m), 1335 (m), 1259 (m), 1208 (w), 1148 (w), 1107 (m), 1052 (m), 1021 (m), 950 (w), 896 (w), 812 (m), 771 (m), 668 (w), 608 (w), 528 (w), 467 (w), 433 (w), 410 (w) $cm^{-1}$. HR-MS (ESI+, MeCN): *m*/*z* calcd. for $C_{28}H_{28}MnN_5NiO_4$ $[M]^+$: 611.08698; found 611.08634. $C_{28}H_{28}MnN_5NiO_4$ (612.2): calcd. C 54.93, H 4.61, N 11.44; found C 53.91, H 4.70, N 11.36.

**X-ray Crystallography of Complexes 3–5:** X-ray data were collected with a STOE IPDS II diffractometer (graphite-monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) using the ω-scans technique at –140 °C (Table 4). The structures were solved by direct methods and refined on $F^2$ using all reflections with SHELX-97.[21] The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions and assigned an isotropic displacement parameter of 0.08 $Å^2$. Face-indexed absorption corrections were performed numerically with the program X-RED.[22] The geometrical aspects of the structures were analyzed with the PLATON program.[23] The dmf solvent molecule in **3**·dmf was found to be disordered about a center of inversion and was refined at half occupancy.

CCDC-638867 (for **3**·dmf), -638868 (for **4**), and -638869 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Environmentally Friendly Growth of Layered $K_4Nb_6O_{17}$ Crystals from a KCl Flux

**Katsuya Teshima,*[a] Yuki Niina,[a] Kunio Yubuta,[b] Takaomi Suzuki,[a] Nobuo Ishizawa,[c] Toetsu Shishido,[b] and Shuji Oishi[a]**

**Keywords:** Flux growth / Environmental chemistry / Layered compounds / Photocatalyst

Environmentally friendly, high-quality layered $K_4Nb_6O_{17}$ crystals were easily grown by two different flux methods involving supersaturation, that is, flux evaporation and cooling of the solution. To fabricate them, potassium chloride (KCl) was chosen as the flux. Transparent and colorless plate-like layered crystals of $K_4Nb_6O_{17}$ were prepared with well-developed {010} faces of the orthorhombic system. The crystal sizes obviously depended on the evaporation loss (evaporation method), the holding temperature, and the cooling rate (cooling method). Transmission electron microscopy (TEM) images showed that the grown plate-like crystals were of a very good crystallinity. The major constituents were homogeneously distributed throughout them. The crystals exhibited good photocatalytic activity under ultraviolet light irradiation. Potassium chloride was found to be a very suitable flux for the environmentally friendly growth of photocatalytic $K_4Nb_6O_{17}$ crystals.

## Introduction

A variety of metal oxide compounds were studied for use as semiconductor photocatalysts, such as degradation of toxic substances, decomposition of pure water, and photoactive electrodes for dye-sensitized solar cells.[1–5] Photoinduced decomposition of pure water on $TiO_2$ electrodes was first reported in 1972.[4a] After this discovery, $TiO_2$ was widely studied, and has now became one of the most well-known semiconductor photocatalysts. Titanium(IV) oxide has several advantages, for example, it is harmlessness to the environment, it has a low cost, and it is highly stable. It, however, does not work efficiently as a photocatalyst under visible light irradiation, because it has a relatively wide bandgap of 3.0–3.2 eV.[4] Numerous attempts have, therefore, been made to improve its performance under visible light irradiation. In a few decades, several kinds of metal oxides, such as titanates, niobates, tantalates, and multioxides have also been found to exhibit photocatalytic performance.

The crystal of potassium hexaniobate ($K_4Nb_6O_{17}$), which is one kind of metal niobate, is orthorhombic with the space group $P2_1nb$.[6a] $K_4Nb_6O_{17}$ was reported to have lattice parameters of $a$ = 0.783 nm, $b$ = 3.321 nm, and $c$ = 0.646 nm, and a density of 3.898 g cm$^{-3}$.[3,6a] The congruent melting point of this compound is 1163 °C.[7] From a crystal structure viewpoint, $K_4Nb_6O_{17}$ is unique in that it is layered (Figure 1),[6b] and it consists of negatively charged sheets of linked $NbO_6$ octahedral units with potassium ions between the sheets. A variety of characteristics of the layered $K_4Nb_6O_{17}$ crystals, such as their ability to undergo ion exchange and photocatalysis, as well as their intercalation properties, are attributed to their unique crystal structure (layered structure).

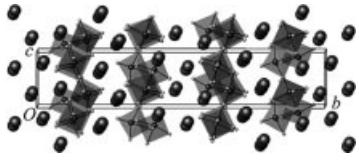

Figure 1. Schematic representation of the layered structure of $K_4Nb_6O_{17}$.

There have been many studies on $K_4Nb_6O_{17}$ crystallite syntheses and single crystal growth including flux growth, the Czochralski method, and solid-state reactions.[1,5a,8,9] Among these techniques, flux growth is an environmentally friendly process[10] and can produce $K_4Nb_6O_{17}$ crystals at temperatures below the melting point of the solute. In previous research, the following fluxes were used successfully: $K_2CO_3$, $K_2MoO_4$, and $K_2WO_4$.[5a,8] For the $K_2CO_3$ flux, however, detailed results such as the optimal growth conditions, crystal structure, size, and photocatalytic activity have not been described.[8] In our previous study,[5a] $K_4Nb_6O_{17}$

crystals were grown from $K_2MoO_4$ and $K_2WO_4$ fluxes, and their photocatalytic and adsorption properties were examined in detail. Here we report the growth of high-quality $K_4Nb_6O_{17}$ plate-like crystals from a KCl flux at a growth temperature much less than the melting point of $K_4Nb_6O_{17}$. Furthermore, their photocatalytic properties were also evaluated. Potassium chloride has some advantages for the growth of $K_4Nb_6O_{17}$ crystals; its melting point (776 °C) is much lower than those of $K_2CO_3$ (891 °C), $K_2MoO_4$ (about 930 °C), and $K_2WO_4$ (921 °C) fluxes.[11–13] In addition, it has a common cation ($K^+$) with the solute. It is abundant in nature and is also harmless to human beings and the environment, much like NaCl. Furthermore, KCl is easily soluble in warm water. Until now, no report on the growth of $K_4Nb_6O_{17}$ crystals from a KCl flux has been published.

## Results and Discussion

Photocatalytic, layered, transparent, and colorless plate-like crystals of $K_4Nb_6O_{17}$ were grown from the KCl flux (Table 1, all growth runs). In addition, byproduct crystals of $KNbO_3$ (bulk) and $K_2Nb_8O_{21}$ (whisker) were also grown in runs 1 and 10, and in run 4, respectively. The typical $K_4Nb_6O_{17}$ crystals (Table 1, run 1, solute concentration = 1 mol-%, holding temperature = 1100 °C) grown by the evaporation of the KCl flux isothermally are shown in Figure 2. Well-developed layered crystals of $K_4Nb_6O_{17}$ were clearly observed, and printed characters beneath the crystals were obviously readable. Moreover, numerous small plate-like crystals were relatively regularly layered on the well-developed surface, and the growth process was implied on the grown $K_4Nb_6O_{17}$ surface (Figure 2b). The SEM photographs of typical layered $K_4Nb_6O_{17}$ crystals are shown in Figure 3. The holding temperatures are, respectively, (a) 900 (Table 1, run 6), (b) 1000 (Table 1, run 5), and (c) 1100 °C (Table 1, run 3). The grown crystals gradually adopted rounded corners with decreasing holding temperatures as clearly shown in Figure 3. The evaporation loss of the KCl flux increased with the holding temperatures. The crystal sizes were obviously dependent on the flux evaporation ratio (and the holding temperature). In general, flux evaporation had a considerable influence on crystal growth. In the case where the holding temperature was 900 °C, the flux evaporation loss and the median diameter (D50) were, respectively, only approximately 34 wt.-% and 11.2 μm. However, they drastically increased with holding temperature, reaching about 86 wt.-% and 30.3 μm at 1000 °C, and 96 wt.-% and 27.6 μm at 1100 °C. The crystals grown at the holding temperature of 1000 °C might be slightly larger than those grown at 1100 °C, because the evaporation rate of the KCl flux at 1000 °C was smaller than that at 1100 °C. In general, crystals could grow large when the evaporation rate was suitable. When the holding temperature was 900 °C or below, the driving force for crystal growth could not distinguish between flux evaporation and solution cooling (rapid cooling) after a power supply cut of the furnace, as the evaporation loss was sufficiently low.

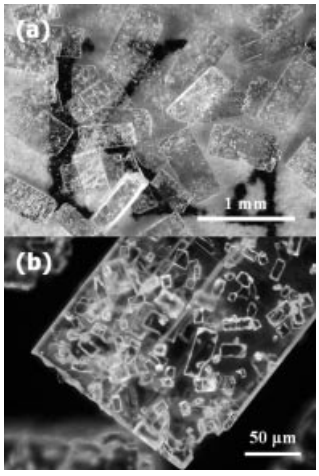

Figure 2. Optical micrographs showing plate-like $K_4Nb_6O_{17}$ crystals grown by the evaporation of a KCl flux: (a) low magnification and (b) high magnification.

Figure 4 shows the typical $K_4Nb_6O_{17}$ crystals grown by the cooling of the KCl flux (Figure 4a and b, Table 1, run 11; Figure 4c and d, Table 1, run 12). Like the $K_4Nb_6O_{17}$ crystals grown by the evaporation method (Figures 2 and 3), their basic form was a well-developed thin plate. There were a great number of the small plate-like crystals in the

SEM images showing typical layered plate-like $K_4Nb_6O_{17}$ crystals grown by the rapid cooling of a KCl flux: (a) low magnification and (b) high magnification (Table 1, run 11, holding temperature 800 °C and cooling rate 300 °C $h^{-1}$), (c) low magnification and (d) high magnification (Table 1, run 12, 800 °C and quenching).

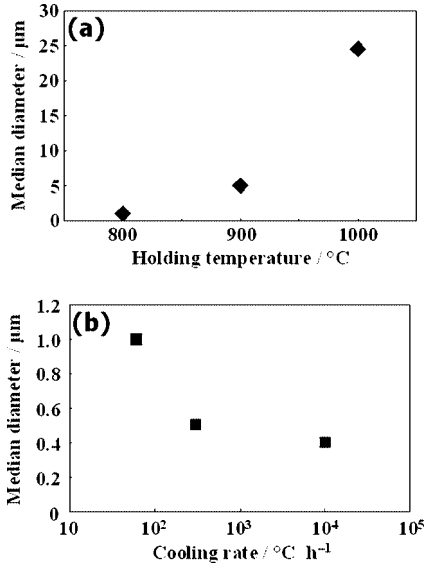

Figure 5. Variation in the median diameter of the $K_4Nb_6O_{17}$ crystals with (a) holding temperatures (solute content 20 mol-%, cooling rate 60 °C $h^{-1}$) and (b) cooling rates (solute content 20 mol-%, holding temperature 800 °C).

SEM image, although only a few of the relatively large crystals (>1 μm) were observed. However, relative to the evaporation method, the median diameters decreased drastically. Figure 5 shows the variation in the median diameter of the $K_4Nb_6O_{17}$ crystals grown by the cooling of the KCl flux with (a) the holding temperature and (b) the cooling rate. The cooling rate and the holding temperature were fixed at 60 °C $h^{-1}$ and 800 °C in Figure 5a and b, respectively. Small crystals with D50 = 1.0 μm were grown at a holding temperature of 800 °C (Figure 5a). The D50 values gradually increased with increasing holding temperatures, and they reached about 5.0 μm (900 °C) and 24.5 μm (1000 °C). In contrast, the median diameter gradually decreased with an increase in the cooling rate, and it reached 0.5 μm at 300 °C $h^{-1}$ and 0.4 μm at quenching (Figure 5b). In the previous studies, $K_4Nb_6O_{17}$ crystals were grown from a $K_2CO_3$ flux and by the Czochralski method at temperatures in excess of their melting points, or from $K_2MoO_4$ and $K_2WO_4$ fluxes at temperatures in excess of 1100 °C (in our laboratory). In this study, however, high-quality $K_4Nb_6O_{17}$ crystals were successfully grown from a KCl flux at temperatures from 800 to 1100 °C. To make environmentally functional materials, it is very important to reduce the environmental load. A low-temperature/rapid-cooling process is more environmentally friendly than other high-temperature flux ones[8] and our previous slow cooling one.[5a]

Figure 6 shows the XRD profiles of data for the well-developed layered crystals grown by the evaporation method (Figure 6a), pulverized crystallites grown by the evaporation method (Figure 6b) and by the cooling method (Figure 6c), and $K_4Nb_6O_{17}$ ICDD PDF[6] (Figure 6d). Both the grown crystals had approximately the same XRD pattern as ICDD PDF,[6] and they were identified as $K_4Nb_6O_{17}$. Byproduct crystals of $KNbO_3$ and $K_2Nb_8O_{21}$ were also identified by powder XRD patterns.[14,15] In our previous study,[5a] layered $K_4Nb_6O_{17}$ crystals were bound by two basal and eight sided faces. The indices of well-developed basal faces were {010}. In this study, the XRD patterns of oriented plate-like crystals showed that the diffraction intensity of the (040) plane was predominant, and the indices were the same as our previous study. Figure 7a and b show a bright field TEM image and the corresponding selected area diffraction (SAD) pattern of a typical crys-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tal grown by the flux evaporation method (Table 1, run 2). In Figure 7a, the existence of some facets, which are related to the *a* and *c* planes, is evidently observed at the upper, lower, and right regions. The SAD pattern indicated that the crystal has orthorhombic symmetry with lattice parameters $a$ = 0.769 nm and $c$ = 0.639 nm, which are in good agreement with those found in the previous study.[6] Because the incident electron beam is parallel to the [010] direction, the lattice parameter *b* cannot be measured by only this incident beam. The crystal planes in the SAD pattern were confirmed to be in accordance with a $K_4Nb_6O_{17}$ layered structure. The lattice image obtained from a $K_4Nb_6O_{17}$ crystal is shown in Figure 7c, which was taken with the incident beam along the [010] direction. The crystal was of very good crystallinity because no defects were observed in this image. From these TEM observations, the development of the *a*–*c* plane was clearly observed. With the consideration of the lattice parameters (extremely long *b* axis), it seems reasonable to develop the plane, and moreover, this is in good agreement with previous research[5a] and the XRD results as mentioned above. Additionally, the EDS data showed that potassium and niobium atoms were homogeneously distributed in the crystals. Chlorine atoms from the flux were not detected in the crystals.

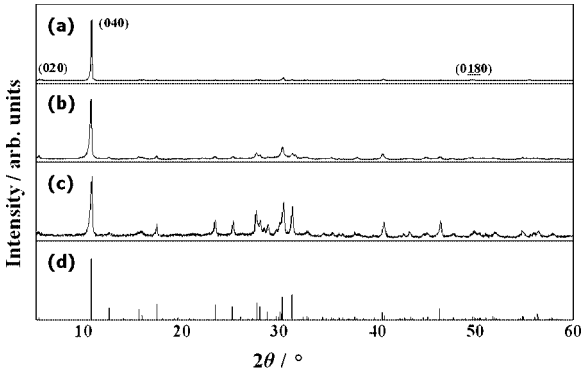

Figure 6. X-ray diffraction patterns (Cu-$K_\alpha$) of $K_4Nb_6O_{17}$ crystals: (a) plate-like crystals of which well-developed faces were laid in parallel with the holder plate (Table 1, run 4), (b) pulverized crystallites (evaporation method; Table 1, run 3), (c) pulverized crystallites (cooling method; Table 1, run 9), and (d) $K_4Nb_6O_{17}$ ICDD PDF.[6a]

The UV/Vis diffuse reflectance spectrum of the $K_4Nb_6O_{17}$ crystals was investigated. The spectrum (Figure 8) shows the onset wavelength of absorption at around 365 nm and a maximum at around 250 nm. Typical absorption spectra of $TiO_2$ (anatase) powders and $Na_2Ti_6O_{13}$ whiskers shift, respectively, to longer wavelength by about 35 and 15 nm at the onset. This result is in fair accord with that of our previous studies.[5a,5b] Furthermore, the $K_4Nb_6O_{17}$ layered crystals acted efficiently as a photocatalyst under UV light irradiation, and the characteristic colors of organic dyes (e.g., methylene blue and methyl orange) faded by the photocatalytic effect. For example, the pulverized $K_4Nb_6O_{17}$ crystals (0.5 g) and methylene blue

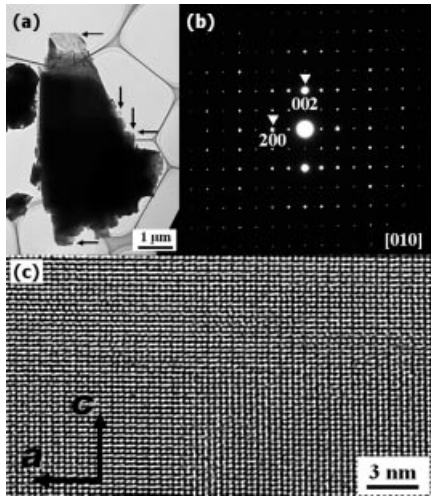

Figure 7. (a) TEM micrograph, (b) diffraction pattern, and (c) lattice image of a typical plate-like $K_4Nb_6O_{17}$ crystals.

(0.25 mg) were placed in distilled water (100 $cm^3$). The suspension was irradiated with UV light for 0–9 h. In this case, the color of the suspension decolorized gradually with an increase in irradiation time and finally changed from blue to colorless. The color of the suspension irradiated with UV light for 9 h was unchanged by the addition of any acid or base. When no $K_4Nb_6O_{17}$ crystal was added, the color of the methylene blue solution with UV light for 9 h remained unchanged.

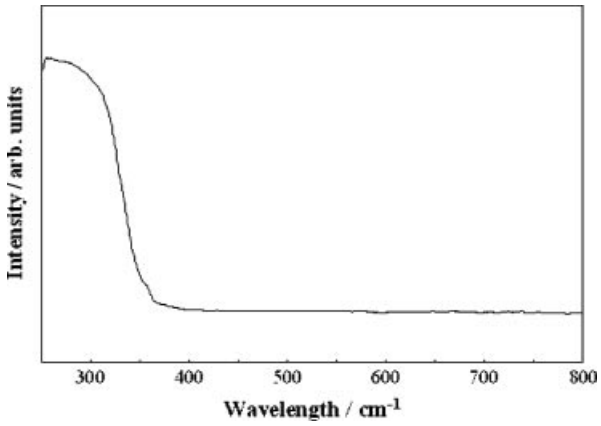

Figure 8. UV/Vis diffuse reflection spectrum of $K_4Nb_6O_{17}$ crystals.

## Conclusions

Highly crystalline photocatalytic crystals of $K_4Nb_6O_{17}$ were successfully grown by the evaporation or the rapid cooling of KCl used as the flux. Furthermore, this low holding temperature (ca. 800 °C)/rapid cooling (≥300 °C $h^{-1}$) technique is more environmentally friendly than other high-temperature flux techniques[8] and our previous slow cooling method.[5a] The layered $K_4Nb_6O_{17}$ crystals were trans-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

parent and colorless, and they were plate-like in form with well-developed {010} faces (XRD analysis and TEM observation). The crystal sizes were dependent on the holding temperature and the cooling rate. In the case of the flux evaporation, the crystal sizes decreased gradually with a decrease in evaporation rate, and they reached 11.2 μm at 34 wt.-%. In contrast, for flux cooling, the crystal size drastically decreased with a decrease in holding temperature and gradually decreased with an increase in cooling rate, and the size was reduced to 0.4 μm (holding temperature of 800 °C and quenching). The obtained crystals had no defects (TEM observation) and major components were homogeneously distributed in the crystals (EDS analysis). Furthermore, plate-like layered $K_4Nb_6O_{17}$ crystals exhibited photocatalytic properties for organic dye decolorization. In our growth technique of functional oxide crystals, environmental damages (e.g., by exhausting greenhouse gases) and product costs are thought to be reduced greatly. In the future, it will become more and more important to develop various functional materials (including crystals) with the use of environmentally friendly processes.

## Experimental Section

Potassium hexaniobate layered crystals were grown by a cooling method and an evaporation method of the KCl flux. Reagent grade $K_2CO_3$ (Wako Pure Chemical Industries, Ltd.), $Nb_2O_5$ (99.9%, Wako Pure Chemical Industries, Ltd.), and KCl (Wako Pure Chemical Industries, Ltd.) were used for the growth of the $K_4Nb_6O_{17}$ crystals. A stoichiometric mixture of $K_2CO_3$ and $Nb_2O_5$ powders and KCl were, respectively, used as a solute and flux. The typical growth conditions are given in Table 1.

**Flux Evaporation Method:** The solute concentration was varied from 1 to 40 mol-% of the KCl flux. These masses of the reagents were kept at approximately 25 g for all growth runs (Table 1, runs 1–6). Each of the mixtures was put into platinum crucibles of 30-$cm^3$ capacity. After the lids were loosely closed, the crucibles were placed in an electric furnace. The crucibles were heated to 900, 1000, or 1100 °C at a rate of 45 °C $h^{-1}$ and then held at each temperature for 60 h. Subsequently, the electric power was turned off, and the crucible was cooled quickly to room temperature in the furnace.

**Cooling Method:** The crucibles containing each mixture (Table 1, runs 7–12) were heated to 700, 800, 900, or 1000 °C at a rate of 45 °C $h^{-1}$ and held at each temperature for 5 h. The crucibles were then cooled to 500 °C at a rate of 60, 300, or >10000 (quenching) °C $h^{-1}$. The cooling rates of 60 and 300 °C $h^{-1}$ were controlled by the cooling program, and the crucibles were cooled to room temperature in the furnace. The cooling rate of >10000 °C $h^{-1}$ was not able to be attained by the cooling program in the furnace. For >10000 °C $h^{-1}$, the crucibles were held at 800 °C for 5 h, and then removed from the furnace and cooled rapidly to room temperature (quenching in air). In both cases (flux evaporation and cooling), the crystal products were separated from the remaining flux in warm water.

The obtained crystals were observed by an optical microscope and field emission scanning electron microscope (FE-SEM, JEOL, JSM-7000F). Phases and elongated directions of the crystals were studied by X-ray diffraction (XRD, SHIMADZU, XRD-6000). An energy-dispersive X-ray spectrometer (EDS, HORIBA, EMAX-5770Q) was used to study any variation in the concentration of the major constituents in the grown crystals. The presence of impurities from the KCl flux and platinum crucible was also observed. The high-resolution transmission electron microscopy (HRTEM) and electron diffraction observations were carried out with JEM-2010 (JEOL) and JEM-2000EXII (JEOL) instruments operated at 200 kV to analyze the crystallinity and elongated direction of the grown crystals. The average sizes were measured with a laser diffraction particle size analyzer (SHIMADZU, SALD-300V). The ultraviolet/visible (UV/Vis) light diffuse reflectance spectrum of the grown crystals was obtained with a spectrophotometer (SHIMADZU, UV3150). Photocatalytic properties of the grown crystals were examined by the photodecolorization of aqueous organic dyes under an atmosphere.[5a,5b] The UV light source employed in this study was a commercial black light (15 W × 2). The center wavelength of the UV light was 352 nm.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** an example of combined organometallic and enzymatic catalysis in aqueous solution. The rhodium complex $[(C_5Me_5)Rh(phenanthroline)Cl]^+$ continuously regenerates NADH from $NAD^+$ by using formate as hydrogen source, and the enzyme alcohol dehydrogenase from *Rhodococcus erythropolis* enantioselectively reduces the ketone to the corresponding alcohol by means of the NADH formed. This work illustrates the increasing interest in enantioselective catalysis with the environmentally friendly water as solvent. Details are discussed in the article by G. Süss-Fink et al. on p. 4736ff.

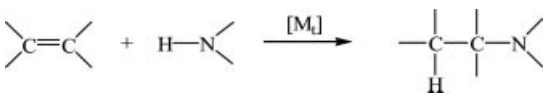
## MICROREVIEW

### Pt Intermolecular Hydroamination

**J.-J. Brunet,* N.-C. Chu, M. Rodriguez-Zubiri* ..... 4711–4722**

Platinum-Catalyzed Intermolecular Hydroamination of Alkenes: Halide-Anion-Promoted Catalysis

**Keywords:** Alkenes / Homogeneous catalysis / Intermolecular hydroamination / Ionic liquids / Platinum



Tetraalkylphosphonium halides play the role of "promoters" for the $Pt^{II}$-catalyzed hydroamination of alkenes. The promoting effect of these "cocatalysts" depends only upon their anionic moiety. The $Pt^{II}$/$n$Bu$_4$PBr system exhibits an unprecedented catalytic activity (aerobic conditions) for the hydroamination of ethylene and 1-hexene (regioselectivity > 95%, Markovnikov).

## Organometallic–Enzymatic Catalysis

Water-soluble (chlorido)(cyclopentadienyl)rhodium and -iridium complex cations, accessible from dinuclear precursors and phenanthroline derivatives, catalyse the transfer hydrogenation of $NAD^+$ to NADH in aqueous solution by using HCOONa as hydrogen source. The combination of an alcohol dehydrogenase with this NADH-regenerating system for the chemoenzymatic reduction of prochiral ketones results in *ee* values up to 98 % under biological conditions.

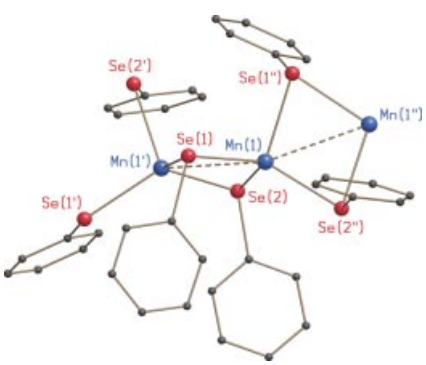
Synthesis, Structure and Magnetic Behaviour of Manganese(II) Selenolate Complexes $^1_\infty[Mn(SePh)_2]$, $[Mn(SePh)_2(bipy)_2]$ and $[Mn(SePh)_2(phen)_2]$ (bipy = bipyridyl, phen = phenanthroline)

**Keywords:** Transition-metal complexes / Manganese / X-ray structure analysis / Magnetism



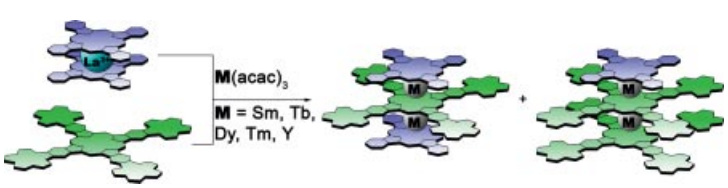
The manganese selenolate complexes $^1_\infty[Mn(SePh)_2]$ and $[Mn(SePh)_2(L)_2]$ (L = 2,2′-bipy, 1,10-phen) have been prepared and their structures characterised by X-ray analysis. The magnetic and optical properties have been investigated.

## Heteroleptic Tris(phthalocyaninates)

**A. G. Martynov, O. V. Zubareva, Yu. G. Gorbunova,* S. G. Sakharov, S. E. Nefedov, F. M. Dolgushin, A. Yu. Tsivadze ..... 4800–4807**

Diphthalocyaninatolanthanum as a New Phthalocyaninato-Dianion Donor for the Synthesis of Heteroleptic Triple-Decker Rare Earth Element Crown-Phthalocyaninato Complexes

**Keywords:** Rare earths / Macrocyclic ligands / Phthalocyanines / Sandwich complexes / Heteroleptic complexes



A new source of phthalocyaninato-dianion – diphthalocyaninatolanthanum – has been discovered. Its reaction with tetra-15-crown-5-phthalocyanine and rare-earth element (REE) acetylacetonato complexes leads to heteroleptic triple-decker phthalocyaninato complexes (Pc)M[(15C5)$_4$-Pc]M(Pc) and [(15C5)$_4$Pc]M[(15C5)$_4$Pc]-M(Pc) both of which are potential components of new supramolecular materials.

# Platinum-Catalyzed Intermolecular Hydroamination of Alkenes: Halide-Anion-Promoted Catalysis

**Jean-Jacques Brunet,*[a] Ngoc-Chau Chu,[a] and Mireia Rodriguez-Zubiri*[a]**

**Keywords:** Alkenes / Homogeneous catalysis / Intermolecular hydroamination / Ionic liquids / Platinum

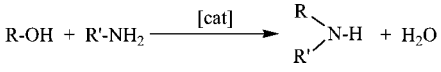
Tetraalkylphosphonium halides play the role of "promoters" for the previously unknown $Pt^{II}$-catalyzed hydroamination of alkenes. The promoting effect of these "cocatalysts" depends only upon their anionic moiety. The $Pt^{II}/nBu_4PBr$ system exhibits an unprecedented catalytic activity (aerobic conditions) for the hydroamination of ethylene and 1-hexene (regioselectivity > 95 %, Markovnikov).

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Amines are important chemicals for both industry and everyday life.[1–4] Since the discovery of ammonia,[5] chemists have developed synthetic methods for the production of amines, and many methods are available.[6] However, most of them are unsuitable for industrial purposes, mainly because they involve very expensive starting materials, reagents, or purification steps. The condensation of ammonia [Equation (1)] or amines [Equation (2)] with alcohols in the presence of various catalysts, first pointed out by Sabatier et al. in 1909,[7,8] is nowadays the main method for the industrial production of light amines. This reaction is also used in some cases for the production of fatty amines or diamines.[2]

(1)



(2)

With the exception of methanol and ethanol, most primary alcohols are industrially produced from alkenes (hydroformylation–hydrogenation sequence).[9,10] It is thus obvious that the direct transformation alkene → amine would be a more economic process since it would suppress at least one step (Scheme 1) and would avoid the coproduction of water [Equations (1) and (2)].

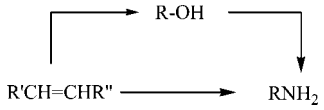
*Jean-Jacques Brunet was born in Clermont-Ferrand, France, in 1945. He attended the Faculté des Sciences and the Ecole Nationale Supérieure de Chimie de Clermont-Ferrand, where he received his Chemical Engineering degree in 1968. He obtained his PhD (Thèse d'Etat) in 1972 at the University of Nancy under the supervision of Pr P. Caubère. In 1985, he joined the Laboratoire de Chimie de Coordination of the CNRS (Toulouse), where he is one of the group leaders. Starting from organic synthesis and the study of reaction mechanisms, his current research interest lies now in organometallic chemistry and homogeneous catalysis directed towards organic synthesis, with some emphasis on carbonylation reactions and on the functionalization of alkenes by hydroamination.*

*Ngoc-Chau Chu was a PhD student at the Laboratoire de Chimie de Coordination du CNRS (Toulouse) from 2000 to 2005 and returned to Vietnam in 2006.*

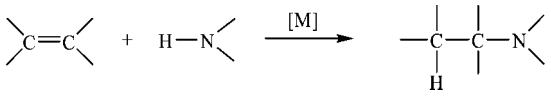
*Mireia Rodríguez i Zubiri, born in Spain (1975), studied Chemistry at the University of Valencia in Spain (1993–1998) and completed her MSc in the group of Prof. J. Reedijk at the University of Leiden (1999). After her PhD studies with Prof. J. D. Woollins and Prof. D.J. Cole-Hamilton at the University of St. Andrews (1999–2002), she moved to France where she had a postdoctoral position in the group of Dr. P. Braunstein (2003–2004). In 2004, she joined the group of Prof. Y. Fort as assistant professor. In 2005, she became a CNRS Researcher in the team of J-J. Brunet at the Laboratoire de Chimie de Coordination in Toulouse. Her research interests include the development of new catalytic systems based on transition-metal precursors for the intermolecular hydroamination of nonactivated olefins, the mechanistic and kinetic aspects of this reaction, and the use of ionic liquids, aqueous media or supercritical fluids in this reaction.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1. From alkenes to amines.

The necessity to develop atom-economic reactions is often highlighted. The direct addition of the N–H bond of ammonia or amines on carbon–carbon multiple bonds (hydroamination) belongs to this desired class of reactions,[11] especially in the case of alkenes [Equation (3)], the subject of this review.



(3)

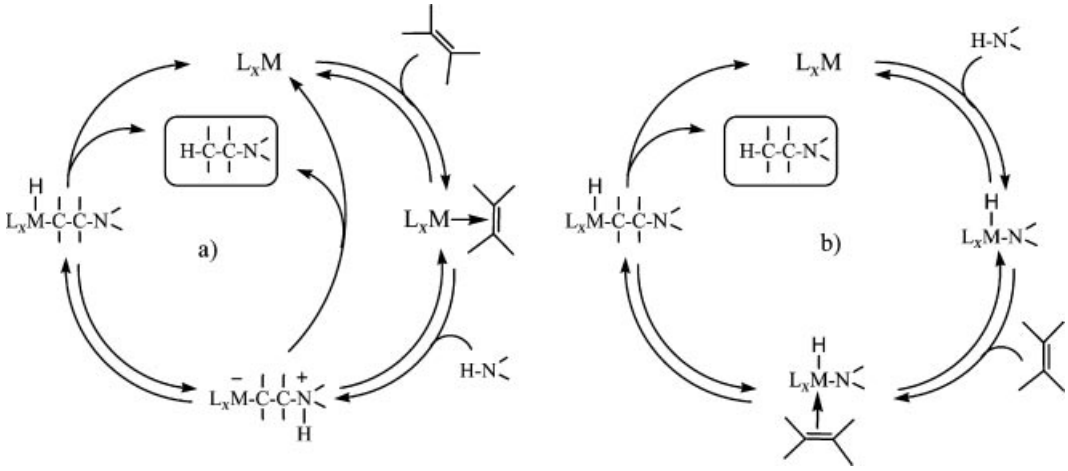
Consequently, intense efforts have long been devoted to the hydroamination of different kinds of multiple carbon–carbon bonds, alkenes, alkynes, vinylarenes, and dienes by intramolecular and intermolecular additions. Several reviews have been published since 1983.[12–23] The main conclusion that can be given (in 2006) is that significant progress has been made for the hydroamination of vinylarenes[24] and dienes,[25] which includes the inter- and intramolecular versions of this reaction. The hydroamination of vinylarenes must be highlighted since catalysts that allow fully regioselective additions (Markovnikov or anti-Markovnikov) and enantioselective Markovnikov additions have been designed.[26] In the case of nonactivated alkenes, several efficient catalytic systems have been reported for *intramolecular* hydroamination, which include highly enantioselective reactions.[22,23,27] In contrast, the *intermolecular* hydroamination of alkenes with *amines* is much less developed. Exceptions include the industrial production (BASF) of $t$BuNH$_2$ by addition of ammonia to isobutene (zeolite catalyst),[21] the organolanthanide-catalyzed (neodymium, 20% catalyst) hydroamination of 1-pentene with $n$PrNH$_2$ (fully regioselective Markovnikov addition),[27n] and the Li-catalyzed hydroamination of ethylene.[27p] This review is devoted to results developed in our group since 2002 for the platinum-catalyzed *intermolecular* hydroamination of nonactivated alkenes (some previous results with Rh catalysts are also included).

First, it is important to recall that the addition of ammonia or amines to ethylene is thermodynamically feasible (Table 1).[28] It is also noteworthy that the entropy term is highly negative, which means that very high temperatures would favor the reverse reaction and thus make the desired reaction impossible. However, this thermodynamic data gives no information on the activation barrier. It is conceivable that the approach of the nitrogen atom lone pair to the electron density of the carbon–carbon double bond of the alkene induces an electrostatic repulsion that corresponds to a high-energy barrier. The objective is thus to lower this energy barrier. Two possibilities can be considered:[14] (1) activation of the alkene (to make it more "electrophilic") and (2) activation of the amine (to make it more "nucleophilic"). The mechanisms corresponding to these two possibilities are represented in Scheme 2.[16]

Table 1. Thermodynamic data for the hydroamination of ethylene ($T$ = 298 K, $P$ = 101325 Pa).

| Reaction | $\Delta G°$ [kJ mol$^{-1}$] | $\Delta H°$ [kJ mol$^{-1}$] | $\Delta S°$ [J mol$^{-1}$ K$^{-1}$] |
|---|---|---|---|
| $C_2H_4 + NH_3 \rightarrow EtNH_2$ | –14.4 | –52.4 | –127.4 |
| $C_2H_4 + EtNH_2 \rightarrow Et_2NH$ | –33.3 | –78.6 | –152.1 |
| $C_2H_4 + Et_2NH \rightarrow Et_3N$ | –29.9 | –79.5 | –166.2 |

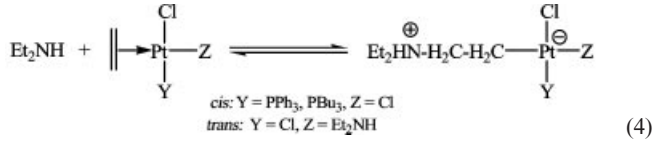
The most significant results on the *homogeneously* catalyzed *intermolecular* hydroamination of nonactivated alkenes have already been reviewed.[21] However, in view of the subject of this article, it is interesting to note that intense efforts have been devoted to the addition of amines to alkenes coordinated to transition metals, especially Pt$^{II}$ and Pd$^{II}$. In the case of Pt$^{II}$ alkene complexes,[29–34] attack by sufficiently basic amines (p$K_a$ of conjugated acid > 5) has been shown to afford zwitterionic complexes [Equation (4)], one of which could be characterized by X-ray dif-



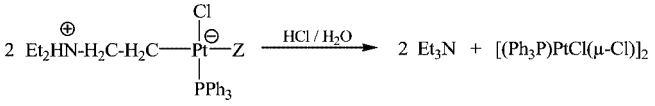
Scheme 2. a) Hydroamination by alkene activation; b) hydroamination by N–H activation.[16]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

fraction study.[30d] However, liberation of the alkylated amine by cleavage of the carbon–platinum bond needs a further step (reaction with HCl or $NaBH_4$) [Equation (5)],[30–33] so that the hydroamination reaction is only *stoichiometric*.[34]



(4)



(5)

Soon after the publication of our paper on the Pt-catalyzed *hydroamination* of ethylene with aniline in ionic liquids (see below),[35] Widenhoefer et al. reported that the dinuclear $Pt^{II}$ complex $[PtCl_2(C_2H_4)]_2$, associated with $PPh_3$, is an active catalyst for the intermolecular *hydroamidation* of ethylene with *carboxamides*.[36] Extension to the hydroamidation of alkenes with poorly basic *sulfonamides* catalyzed by $[PtCl_2(C_2H_4)]_2/[AgBF_4]$ has also been reported recently.[37]

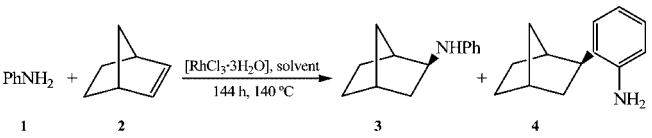
## 2. New Catalytic Systems for the Intermolecular Hydroamination of Alkenes

After our contribution on anionic $Rh^I$ anilido species as possible hydroamination catalysts,[38–41] we were tempted to take advantage of our simultaneous involvement[42] in the use of molten salts or ionic liquids as possible candidates to replace classical organic solvents – an important aspect in the development of "greener" chemical processes.[43–46]

Examination of the patent by Coulson[47] on the $Rh^{III}$-catalyzed hydroamination of ethylene with secondary amines showed that highly polar solvents, such as hexamethylphosphoramide (HMPA), have a positive effect on the reaction. We showed that some ionic solvents apparently exhibit properties similar to those of the well-known but more hazardous (carcinogenic) dipolar aprotic solvents such as DMF or HMPA.[42]

### 2.1. Hydroamination of Norbornene by Aniline in Ionic Liquids

The above results led us to examine the $Rh^{III}$-catalyzed hydroamination of alkenes in ionic solvents. The hydroamination of norbornene with aniline was selected [Equation (6)], (see Table 2).



(6)

Table 2. $[RhCl_3{\cdot}3H_2O]$-catalyzed hydroamination of norbornene with aniline in ionic solvents.[a]

| Run | Solvent | Reaction products: TON | | |
|---|---|---|---|---|
| | | **3** | **4** | Total (**3** + **4**) |
| 1 | thf (7.5 mL) | 0 | 0 | 0 |
| 2 | [EMIM][Cl] (3.0 g) | ≈0 | ≈0 | ≈0 |
| 3 | [BMIM][Cl] (3.6 g) | ≈0 | ≈0 | ≈0 |
| 4 | [BMIM][Cl] (7.2 g) | ≈0 | ≈0 | ≈0 |
| 5 | [BMIM][$PF_6$] (6 g) | 5.1 | 2.6 | 7.7 |
| 6 | [BMIM][Br] (5.7 g) | 8.3 | 1.5 | 9.8 |
| 7 | [HMIM][Br] (7.1 g) | 10.1 | 1.9 | 12 |
| 8 | $n$Bu$_4$PBr (7.1 g) | 7.7 | 2.5 | 10.2 |

[a] 144 h at 140 °C, $[RhCl_3{\cdot}3H_2O]$: 0.13 mmol, norbornene: 13 mmol, aniline: 45 mmol.

As expected,[47,48] no reaction was observed when thf was used as solvent (run 1, Table 2). The use of different imidazolium chlorides resulted in only traces of reaction products (runs 2 and 3). In contrast, the replacement of the chloride ion by [$PF_6^-$] led to the formation higher-than-stoichiometric amounts of both **3** and **4** (run 5). A higher catalytic activity was obtained when imidazolium bromides were used (runs 6 and 7). Finally, the positive effect of the bromide ions was confirmed when $n$Bu$_4$PBr (mp = 100–103 °C) was used as solvent (run 8).

Thus, the reaction of norbornene with aniline, catalyzed by $[RhCl_3{\cdot}3H_2O]$, does not occur in thf, but it can occur in the presence of imidazolium or phosphonium *bromides* as solvents. It is also worthy to note that the above ionic solvents allow the $Rh^{III}$-catalyzed hydroamination by a weakly basic amine ($pK_a$ = 4.63).

In the early 2000s, Togni et al. published a very interesting theoretical study of the hydroamination through alkene activation and subsequent nucleophilic attack by the amine.[49] They considered $d^8$ transition-metal complexes of the type $[MCl(PH_3)_2]^{z+}$ {M = Co, Rh, Ir [$z$ = 0] and M = Ni, Pd, Pt [$z$ = 1]} for the hydroamination of ethylene with ammonia. For group 9 metals, nucleophilic attack was identified as the rate-determining step, while cleavage of the M–C bond was the rate-determining step for group 10 metals. Overall, metals from group 10 are more efficient than those from group 9 (lower activation barriers), and $Ni^{II}$ precursors appeared to be the best candidates. These results led us to examine the catalytic activity of group 10 transition-metal precursors in combination with $n$Bu$_4$PBr as solvent. For comparison, the reaction of aniline with norbornene under the same experimental conditions as those used for the $Rh^{III}$ catalysts was considered.

The results reported in Table 3[50] show that group 10 transition-metal precursors exhibit some activity for the test reaction. However, contrary to that expected from the cal-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

culations by Togni and coworkers, the best results were clearly obtained with the $Pt^{II}$ catalysts. The latter gave catalytic activities and chemoselectivities similar to those observed with [$RhCl_3 \cdot 3H_2O$] (Table 2).

Table 3. Hydroamination of norbornene with aniline in $n$Bu$_4$PBr: catalysis by group 10 transition metals.[a]

| Run | Catalytic precursor [mmol] | Reaction products: TON **3** | **4** | Total (**3** + **4**) |
|---|---|---|---|---|
| 9 | [$NiBr_2$] (0.40) | 1.0 | 0 | 1.0 |
| 10 | [$PdBr_2$] (0.17) | 2.5 | 1.6 | 4.1 |
| 11 | [$PtBr_2$] (0.13) | 8.6 | 1.0 | 9.6 |
| 12 | [$PtCl_2$] (0.13) | 8.2 | 2.0 | 10.2 |
| 13 | [$PtI_2$] (0.13) | 9.8 | 1.2 | 11.0 |

[a] 144 h at 140 °C, norbornene: 13 mmol, aniline: 45 mmol, $n$Bu$_4$PBr: 7 g.

The nature of the halide ion associated with the platinum precursor plays a minor role (runs 11–13, Table 3). This is not surprising since the [$PtX_2$]/$n$Bu$_4$PBr ratio is 1:150, and this implies that the bromide ions are by far the main halogen ligands. Under these conditions, the platinum salts are soluble in the ionic solvent and can be considered as $[PtBr_4]^{2-}$ species [Equation (7)].[51]

$$[PtBr_2] + 2\,n\mathrm{Bu_4PBr} \rightleftharpoons [PtBr_4]^{2-} + 2\,[n\mathrm{Bu_4P}]^{+} \quad (7)$$

The above results were particularly exciting because, as previously noted, no platinum-catalyzed alkene hydroamination had been reported until then. Since extensive information is available on the reactivity of $Pt^{II}$–ethylene complexes with amines,[29–34] we were prompted to examine the possible catalytic hydroamination of ethylene with aniline in the presence of the newly developed [$PtBr_2$]/$n$Bu$_4$PBr system.

### 2.2. Hydroamination of Ethylene by Aniline in Ionic Liquids

Our first experiments were aimed at comparing the influence of the nature of the solvent on the reaction of aniline with ethylene (25 bar at room temperature) in the presence of catalytic amounts (0.3%) of [$PtBr_2$]. In all cases, the reaction leads to the hydroamination product, *N*-ethylaniline (**6**) (with traces of *N*,*N*-diethylaniline, **7**), together with minor amounts of 2-methylquinoline (**8**) [Equation (8)].

The results in Table 4 show that, contrary to literature data, the hydroamination reaction is catalyzed by [$PtBr_2$] in aniline or thf with significant TONs (runs 14 and15). It should be noted that no zwitterionic complex has ever been evidenced from the reaction of aniline with any $Pt^{II}$–ethylene complex.[29–33] This fact was explained by the insufficient basicity of aniline ($pK_a$ = 4.63), relative to that of, for example, diethylamine ($pK_a > 10$) for which the zwitterionic addition complex had been fully characterized.[30d] We tentatively suggest that the addition of aniline to a $Pt^{II}$–ethylene complex occurs to a very small extent and that the equilibrium is displaced toward the right because the zwitterionic complex evolves at high temperatures (150 °C) to liberate *N*-ethylaniline.

Table 4. Hydroamination of ethylene with aniline: influence of the nature of the solvent.[a]

| Run | Solvent | Reaction products: TON PhNHEt | $PhNEt_2$ | "2-Me-quinoline" |
|---|---|---|---|---|
| 14 | aniline (10 mL) | 23 | 1 | 3 |
| 15 | thf (7.5 mL) | 34 | 1 | 4 |
| 16 | $n$Bu$_4$PBr (7 g) | 80 | 1 | 11 |

[a] [$PtBr_2$]: 0.13 mmol, ethylene: 25 bar at room temperature, aniline: 45 mmol, 10 h at 150 °C.

The beneficial effect of $n$Bu$_4$PBr is again highlighted: under nonoptimized conditions, the highest catalytic activity ever reported for the hydroamination of ethylene (TON = 80) was obtained.

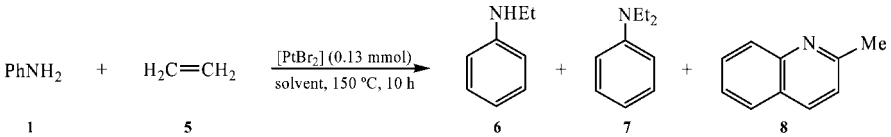
On the basis of the above observations, we briefly examined the influence of some classical reaction parameters.

The reaction temperature is an important parameter: at 150 °C, the TON was nearly twice that obtained at 120 °C (from 80 to 43 catalytic cycles after 10 h of reaction). Higher temperatures (180 °C) did not significantly improve the catalytic activity. Thus, further experiments were conducted at 150 °C.

The influence of the ethylene pressure was considered in the range 10–50 bar. By increasing the ethylene pressure from 10 to 50 bar, the formation of *N*-ethylaniline (TON from 73 to 90 after 10 h of reaction) was slightly increased. In contrast, the formation of the quinoline derivative was significantly favored by a high ethylene pressure (TON from 8 to 20).[52]

The next parameter that we examined was the amount of aniline used, whilst keeping all other parameters as stated in Table 4 (run 16An increase in the TON for the two main reaction products (TON for *N*-ethylaniline: from 30 to 99; TON for 2-methylquinoline: from 4 to 15) was observed by increasing the amount of aniline.

The evolution of the reaction with time was also considered. Runs were performed with different reaction times (1–10 h). The turnover frequency (TOF) for the formation of *N*-ethylaniline reached 37 $h^{-1}$ for the first hour, which is apparently the highest TOF reported for ethylene hydroamination. The reaction rate then decreased, and the average



1 5 6 7 8 (8)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

TOF for 10 h was 8 $h^{-1}$. In order to verify the possible poisoning by either of the two main reaction products, new runs were performed under the same conditions but in the presence of added 2-methylquinoline (1.5 mmol) or *N*-ethylaniline (15 mmol). After 10 h at 150 °C and in the presence of 2-methylquinoline, there was no significant difference in the reaction, whereas for the reaction conducted in the presence of added *N*-ethylaniline, a TON of less than 40 cycles was reached. Even more convincing is the following observation. A [$PtBr_2$]/aniline/*N*-ethylaniline (1:350:100 mmol) mixture was preheated (in the absence of ethylene) for 10 h at 150 °C. Ethylene was then added (25 bar at room temperature). This procedure resulted in a relatively inactive system for the production of **6**, but still active for the formation of **8** (9 cycles after 10 h). These results confirm that during the hydroamination reaction [Equation (8)], the increase in the concentration of *N*-ethylaniline induces a gradual poisoning of the catalyst.

Therefore, it was decided to perform the reaction in a biphasic medium consisting of *n*$Bu_4PBr$ and a high-boiling-point nonmiscible hydrocarbon. By performing the hydroamination of aniline with ethylene under the same conditions but in the presence of decane (4.5 mL for 7.2 g of *n*$Bu_4PBr$), higher TONs (**6**: 115 cycles, **7**: 2 cycles and **8**: 17 cycles) were effectively reached.[53]

Finally, the possible influence of a proton source was examined. When the hydroamination of ethylene [Equation (8)] was performed in the presence of anilinium sulfate (3 equiv. per mol of [$PtBr_2$]), the TON increased from 80 to 130. Under biphasic conditions (*n*$Bu_4PBr$/decane), the presence of anilinium sulfate led to an increase in the TON for *N*-ethylaniline from 115 to 145, the highest TON observed in the present work for the hydroamination of ethylene with aniline. Similar results were obtained when using $CF_3SO_3H$ (3 equiv. per mol of [$PtBr_2$]) instead of anilinium sulfate.

As already mentioned, the reaction of amines with coordinated ethylene in [$Pt(C_2H_4)Cl_2L$] complexes is only stoichiometric and, furthermore, is limited to amines of sufficient basicity ($pK_a > 5$). We have pointed out that aniline ($pK_a = 4.63$) reacts catalytically with ethylene in the presence of the [$PtBr_2$]/*n*$Bu_4PBr$ system. Consequently, it seemed interesting to explore the scope of the reaction with regard to the basicity of the arylamine. Thus, anilines bearing different substituents were treated with ethylene under the conditions of [Equation (8)]. The results are reported in Table 5.

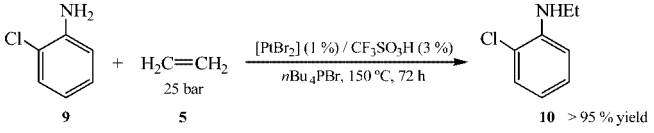
The results from Table 5 indicate that the lower the basicity of the arylamine, the higher the TON for the formation of the ArNHEt derivative. This observation is in contrast with that been reported for the stoichiometric reaction of amines with ethylene coordinated to $Pt^{II}$ centers (see above). It must be noted, however, that the observed dependence of the TON on the basicity of the arylamine may be the result of several effects, such as an increase in reactivity of the expected zwitterionic intermediate (see below), and a reduction in the poisoning ability of the ArNHEt derivative (the lower the basicity of $ArNH_2$, the lower the poisoning effect of ArNHEt). Interestingly, hydroamination of ethylene with 2-chloroaniline was fully chemoselective (run 22).

Table 5. Hydroamination of ethylene:[a,b] influence of the basicity of arylamines.[c]

| Run | Ar ($ArNH_2$) | $pK_a$ | Reaction products: TON | | |
|---|---|---|---|---|---|
| | | | PhNHEt | $PhNEt_2$ | "2-Me-quinoline" |
| 17 | 4-$MeOC_6H_4$ | 5.34 | 22 | ≈1 | 11 |
| 18 | 4-$MeC_6H_4$ | 5.08 | 55 | ≈1 | 17 |
| 19 | $C_6H_5$ | 4.63 | 80 | ≈1 | 11 |
| 20 | 2-$MeC_6H_4$ | 4.44 | 85 | ≈1 | 11 |
| 21 | 4-$ClC_6H_4$ | 4.15 | 93 | ≈1 | 11 |
| 22 | 2-$ClC_6H_4$ | 2.65 | 110 | – | – |

[a] [$PtBr_2$]: 0.13 mmol, *n*$Bu_4PBr$: 7.2 g. [b] 25 bar at room temperature, 10 h at 150 °C. [c] 45 mmol.

Finally, hydroamination of ethylene with 2-chloroaniline was performed by using the [$PtBr_2$]/*n*$Bu_4PBr$ system in the presence of $CF_3SO_3H$ (3 equiv. per mol of the Pt species). The reaction selectively afforded *N*-ethyl-2-chloroaniline with a TON of 250 after 10 h, corresponding to a 70% yield based on 2-chloroaniline. A nearly quantitative conversion of 2-chloroaniline was observed when using 1% of the catalyst system ([$PtBr_2$]/$3H^+$) in *n*$Bu_4PBr$ for 72 h at 150 °C [Equation (9)].



**9** **5** **10** > 95 % yield (9)

These results show, for the first time, that the platinum-catalyzed hydroamination of ethylene with arylamines is possible. The best results have been obtained for the hydroamination of ethylene with 2-chloroaniline by using a [$PtBr_2$]/*n*$Bu_4PBr$/3 $CF_3SO_3H$ system as catalyst. Such unprecedented catalytic performances for the hydroamination of ethylene led us to examine the catalytic activity of [$PtBr_2$]/*n*$Bu_4PBr$ systems for the hydroamination of higher alkenes.

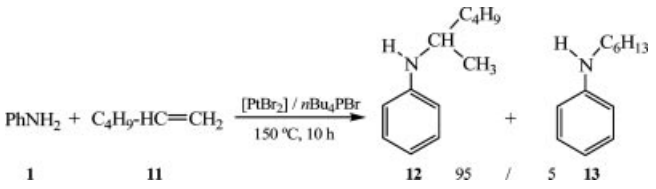
### 2.3. Hydroamination of Higher Alkenes

The literature indicates that, in most cases, systems that exhibit activity for the hydroamination of ethylene fail when applied to higher olefins.[48,54,55] Thus, it was interesting to consider the [$PtBr_2$]/*n*$Bu_4PBr$ system for the hydroamination of a higher alkene such as 1-hexene. Furthermore, it was important to determine the regioselectivity of this reaction, in view of possible enantioselective intermolecular hydroamination reactions of simple alkenes.[22,23]

The first experiment was performed by reacting aniline with 1-hexene in the presence of [$PtBr_2$] in *n*$Bu_4PBr$ (150 equiv. per mol of the Pt species) for 10 h at 150 °C [Equation (10)]. The major product formed was the Markovnikov-type addition product *N*-(2-hexyl)aniline (**12**). The other regioisomer (anti-Markovnikov-type), *N*-(*n*-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

hexyl)aniline (**13**), formed in much lower amounts (**12/13** ≈ 95:5).[56] Other side-products were identified as 2-propylquinoline (**14**, trace amounts)[57] and *N*-(2-hexenyl)aniline (**15**).

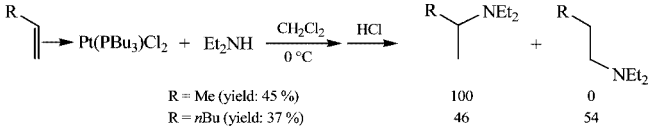


(10)

As expected, the reaction conducted in $n$Bu$_4$PBr was more efficient (10 cycles) than that conducted in thf (<1 cycle, control experiments). As for the hydroamination of ethylene (see above), the influence of the 1-hexene/Pt ratio was considered.

When the amount of 1-hexene was increased, the TON for (**12** + **13**) increased up to a maximum of 42 for a 1-hexene/Pt ratio of about 700. Higher ratios tended to decrease the TON. The regioselectivity of **12/13** is 95:5 (±1%), irrespective of the amount of 1-hexene used.

The very high regioselectivity (Markovnikov/anti-Markovnikov) was rather unexpected. Indeed, although no literature data is available on the stoichiometric addition of *aniline* to alkenes coordinated to $Pt^{II}$ complexes, it has been reported that the *Markovnikov* addition of other amines is favored only when steric factors do not interfere. This conclusion was drawn from the study of *stoichiometric* reactions of $Et_2NH$ with *cis*-[Pt(olefin)($PBu_3$)$Cl_2$] complexes [Equation (11)].[30b]



(11)

These literature data reveal a great difference in regioselectivity between the (stoichiometric) hydroaminations of propene (100% Markovnikov) and 1-hexene (46% Markovnikov, 54% anti-Markovnikov).[30b] The catalytic hydroamination of 1-hexene with our $Pt^{II}$ system thus appears remarkable, both from the point of view of catalytic efficiency and regioselectivity.

Considering now the ratio of the reagents for the best results in terms of TON, we were interested in better understanding the role of $n$Bu$_4$PBr. For the experiment, 7 g of $n$Bu$_4$PBr for 4.1 mL of aniline and 11.5 mL of 1-hexene was used. Under these conditions, $n$Bu$_4$PBr cannot truly be considered as a solvent. We therefore studied the influence of the amount of $n$Bu$_4$PBr for reactions conducted with a 1-hexene/aniline/[$PtBr_2$] ratio of 700:350:1. When the amount of $n$Bu$_4$PBr was increased from 0 to 65 equiv. per mol of [$PtBr_2$], an increase in the hydroamination TON for (**12** + **13**) from ca. 1 to 57 was observed. The TON slightly decreased to 42 when using higher $n$Bu$_4$PBr/[$PtBr_2$] ratios. The regioselectivity **12**:**13** is unchanged, irrespective of the $n$Bu$_4$PBr/[$PtBr_2$] ratio used.

These experiments confirm that $n$Bu$_4$PBr has a promoting role on the catalytic activity of the [$PtBr_2$] precursor. Furthermore, they show that the phosphonium bromide has also a limiting effect when used in larger amounts. This observation may suggest the participation of the bromide ions of $n$Bu$_4$PBr in an equilibrium implicating the active platinum species (vide infra).

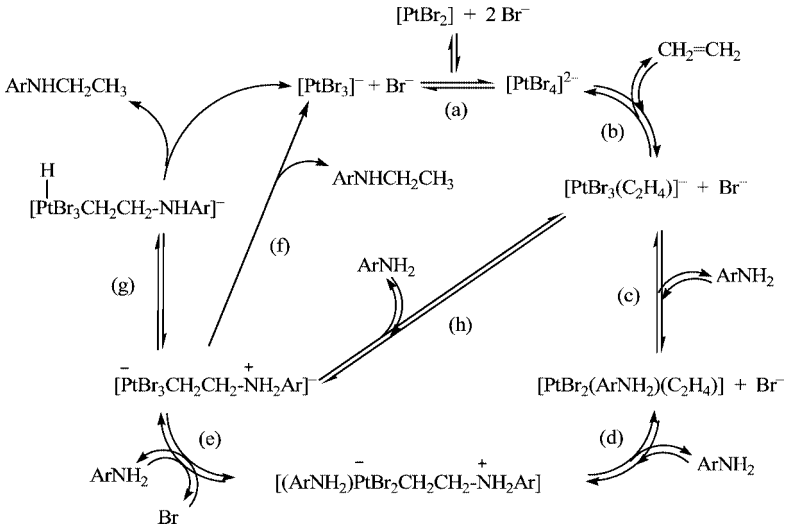
On the basis of these promising results, we examined the evolution of the reaction with time under the best conditions determined so far. This study was intended to detect possible catalyst poisoning. The results indicate some activity decrease with time, but this is much less pronounced than that for the corresponding hydroamination of ethylene. This observation may be due to several facts. Firstly, the main reaction product, *N*-(2-hexyl)aniline is much more sterically demanding than *N*-ethylaniline, which results in the retarded formation of the inactive bis(*N*-alkylaniline)platinum(II) species. Secondly, this decrease in activity could simply be due to the decrease in the 1-hexene concentration, which was shown to be an important parameter (see above). Finally, this observation could also be due to the isomerization of 1-hexene. Hence, the composition of the alkene fraction was examined at the end of several runs ($^1$H NMR spectroscopic analysis). The results indicate that the [$PtBr_2$]/$n$Bu$_4$PBr system is a poor isomerization catalyst (irrespective of the reaction pathway).[58]

The promoting effect of $n$Bu$_4$PBr for the [$PtBr_2$]-catalyzed hydroamination of alkenes was thus confirmed, but remained to be explained. The study of the hydroamination of norbornene with aniline (vide supra) indicates that for a given cationic moiety, ionic solvents associated with a bromide ion give a higher catalytic efficiency than those associated with a chloride ion. This observation was confirmed for the hydroamination of 1-hexene with aniline. Indeed, replacement of $n$Bu$_4$PBr by $n$Bu$_4$PCl resulted in the formation of (**12** + **13**) with a TON of 5 (instead of 57). It is thus clear that the anionic part of the phosphonium salt plays an important role: in contrast to chloride ions, bromide ions strongly enhance the catalytic activity. Such halide ion effects have already been observed, but are generally poorly understood,[59–61] except in some cases.[62]

A possible explanation for the promoting role of $n$Bu$_4$PBr is outlined below (Scheme 3). For simplicity, the alkene considered is ethylene and the [$n$Bu$_4$P]$^+$ cation has been omitted.

Equilibria (a) and (b) represent the solubilization of [$PtBr_2$] in phosphonium bromide and the coordination of ethylene. These steps are analogous to the formation of the Zeise's salt from $K_2$[$PtCl_4$] and ethylene in water.[29] Note that the platinum–olefin bond in [$PtBr_3(C_2H_4)$]$^-$ is known to be stronger than that in the chlorido equivalent.[63] In such complexes, the ethylene ligand is displaced by halide ions at high concentrations,[29] which could be the reason for the decrease in activity when very large amounts of $n$Bu$_4$PBr are present (vide supra).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. $Pt^{II}$-catalyzed hydroamination of ethylene promoted by bromide ions.

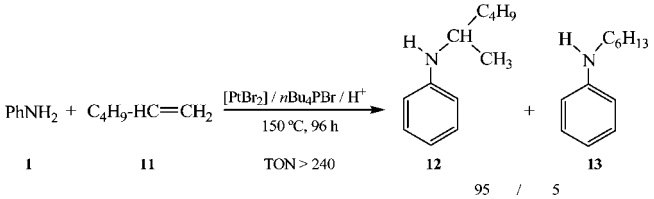
Equilibrium (c) represents the displacement of a halide ligand by aniline, similar to that involved in the formation of e.g. *trans*-$[PtCl_2(C_2H_4)(amine)]$ by reaction of $K[PtCl_3(C_2H_4)]$ with an amine.[64] This equilibrium may be shifted to the left in the presence of a very large excess of bromide ions.

Equilibrium (d) corresponds to the *external*[30c] nucleophilic attack of aniline on the neutral $[PtBr_2(C_2H_4)(C_6H_5NH_2)]$ complex to generate the corresponding zwitterionic complex. However, as indicated above, zwitterionic complexes derived from the attack of aniline have never been observed in detectable quantities (NMR spectroscopy), a failure attributed to the insufficient basicity of aniline. Nevertheless, from our work, the hydroamination of 1-hexene by aniline conducted at *150 °C* with $[PtBr_2]$ in the *absence* of $nBu_4PBr$ afforded (**12** + **13**) in nearly stoichiometric amounts. This confirms that the attack of aniline on an alkene coordinated to $[PtBr_2]$ is possible, provided that the reaction is conducted at high temperature. This result may be due to a temperature-promoted evolution of the zwitterionic complex by a further proton-transfer step (vide infra).

DFT calculations by Togni et al. strongly suggest that the platinum–carbon bond cleavage by protonolysis should be the determining step for the *catalytic* hydroamination of ethylene with ammonia.[49] In our opinion, this proton transfer should be facilitated by two parameters: the acidity of the N–H proton (ammonium part) and the basicity of the platinum center. The acidity of the proton is inversely related to the basicity of the aniline: the less basic the starting arylamine, the easier the proton transfer to the negative center. This hypothesis seems to be confirmed by our observation that the less basic aniline gave the highest TONs for the hydroamination of ethylene. For the basicity of the platinum center in the zwitterionic complex, the intervention of equilibrium (e) may possibly explain the promoting role of the bromide ions (generation of a platinum center bearing *formally* two negative charges). Note that the direct addition of aniline to $[PtBr_3(C_2H_4)]^-$ should lead to the same highly reactive zwitterionic complex [equilibrium (h)]. The liberation of the alkylated aniline proceeds either by direct protonolysis of the platinum–carbon bond [path (f)] or via a platinum hydride, followed by reductive elimination [path (g)].

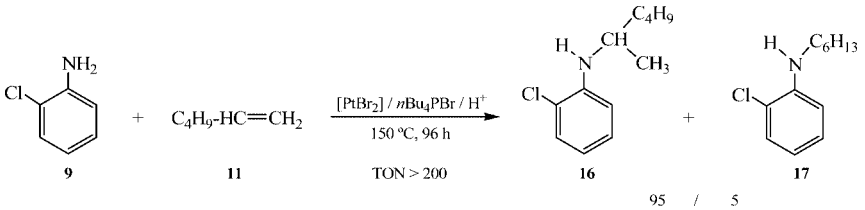
Another point has to be considered. During the *catalytic* hydroamination of ethylene with aniline, a gradual poisoning effect was observed, which could be attributed to the reaction product *N*-ethylaniline. Apparently, the possible poisoning by aniline itself is not significant, and the poisoning effect of *N*-ethylaniline does not prohibit catalysis, at least to some extent (TON = 80). It is tentatively proposed that the poisoning effect by the alkylated aniline is attenuated by the presence of an excess of bromide ions. The latter may prevent the competitive formation of catalytically inactive species by keeping the platinum species in the forms involved in equilibria (a)–(c). A more complete study of the effect of the halide ions on hydroamination reactions has recently been carried out and is presented further on in this review.

Finally, the role of an added catalytic source of protons was examined. Reactions performed under standard conditions, except for the additional presence of anilinium sulfate (3 equiv. per mol of the Pt species), allowed the formation of (**12** + **13**) with 70 cycles for a reaction time of 10 h, 180 cycles after 48 h, and finally 243 cycles after 96 h [Equation (12)] (70% yield based on aniline). Interestingly,



(12)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



(13)

under the above conditions, the formation of the side-products **14** and **15** is limited to only traces (TON < 1).

Control experiments showed that, in the *absence* of $n$Bu$_4$PBr, the [PtBr$_2$]/H$^+$ system allowed the formation of (**12** + **13**) with a TON of about 10, thus evidencing that the major activation is induced by $n$Bu$_4$PBr. Furthermore, in the absence of [PtBr$_2$], the $n$Bu$_4$PBr/H$^+$ system yielded (**12** + **13**) with a TON of 2 (vs. H$^+$ catalyst), which indicates that simple Brønsted catalysis is not significant.

Lastly, the hydroamination of 1-hexene with 2-chloroaniline, catalyzed by the [PtBr$_2$]/$n$Bu$_4$PBr/CF$_3$SO$_3$H system, afforded the expected alkylated chloroanilines (**16** + **17**) with TON = 200 and a 95% Markovnikov selectivity [Equation (13)].

From a practical point of view, it is very important to note that the above *Pt$^{II}$-catalyzed hydroamination reactions can be conducted under aerobic conditions without loss in yield*. To the best of our knowledge, the ligandless, cheap and nontoxic [PtBr$_2$]/$n$Bu$_4$PBr/H$^+$ system is the most efficient ever reported (up to the end of 2006) for the catalytic *intermolecular* hydroamination of an α-olefin such as 1-hexene.

### 2.4. Platinum-Catalyzed Transformation of Anilines into 2-Alkylquinolines

During the above studies, some unexpected observations involving the formation of quinoline derivatives were noticed. These have been examined in more detail, which allows the very interesting properties of Pt$^{II}$-based catalysts for different C–H activation processes to be highlighted.[65] Although these studies are beyond the scope of this paper, we have evidenced, for the first time, that 2-alkylquinolines are formed by a multistep, platinum(II)-catalyzed, in situ transformation of *N*-alkylanilines (Scheme 4).[66] In other words, quinoline derivatives originate from the primary hydroamination products. This new, platinum(II)-catalyzed transformation is strongly favored by the presence of an alkene (hydrogen acceptor) and compares favorably with the recently reported ruthenium-catalyzed formation of 2-alkylquinoline from aniline and trialkylamines.[67]

### 2.5. The Promoting Effect of Halide Ions for the Pt$^{II}$-Catalyzed Hydroamination of Alkenes

In the early stages of this work, ionic liquids and molten salts were first considered as solvents. The beneficial effect of some of them, especially $n$Bu$_4$PBr, was identified for the hydroamination of norbornene and ethylene. However, for the hydroamination of 1-hexene, it was pointed out that the catalytic efficiency depended upon both the $n$Bu$_4$PX/[PtBr$_2$] ratio and the nature of the anion (Br$^-$ >> Cl$^-$). This is obviously the heart of the matter since, under classical conditions, the reaction of amines with Pt$^{II}$–alkene complexes leads to stable zwitterionic species.[30d]

In order to deepen our understanding, we investigated the influence of the $n$Bu$_4$PX/[PtBr$_2$] ratio as well as that of the nature of the associated halide anion X$^-$ on the hydroamination of ethylene with aniline. For this study, experiments were conducted without the H$^+$ cocatalyst in order to better observe, if possible, the influence of the phosphonium halides.

At first, it was verified that in the absence of [PtBr$_2$] no reaction occurred between aniline (45 mmol) and ethylene (25 bar, ca. 100 mmol) over 96 h at 150 °C. For these control experiments, the presence of $n$Bu$_4$PBr (ca. 7 g) had no effect. In contrast, [PtBr$_2$]-based systems exhibited catalytic activity for the formation of hydroamination products. Two parameters have been considered: the nature of the halide anion X$^-$ associated with the phosphonium salt $n$Bu$_4$PX and the $n$Bu$_4$PX/[PtBr$_2$] ratio. The most general reaction is represented by [Equation (14)].

Compounds **6** and **7** are direct hydroamination products. Since the formation of **8** was shown to occur in situ from 2 equiv. of **6** (vide supra), the activity of the catalytic system is best represented by the total TON calculated for the amount of **6** initially formed (Table 6, see footnote [b]).[68]

As shown in Table 6, the three phosphonium halides enhance the catalytic activity. For $n$Bu$_4$PCl, the maximum activity was obtained using 65 equiv. of phosphonium halide, whereas for both $n$Bu$_4$PBr and $n$Bu$_4$PI, the maximum catalytic activity was reached with a $n$Bu$_4$PX/[PtBr$_2$] ratio of approximately 10. It is quite clear that these phosphonium halides, first intended to play the role of ionic solvents,[50,53]

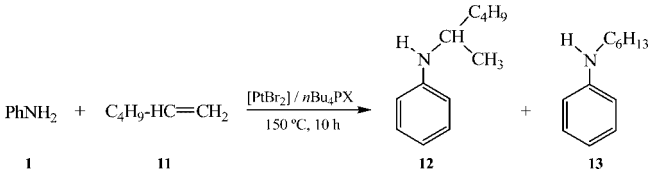
[a] Aniline: 45 mmol, ethylene: 25 bar at room temperature (ca. 100 mmol), 150 °C, 10 h. [b] Turnover number, TON calculated as $TON_6 + TON_7 + 2\ TON_8$.

must rather be considered as promoters or cocatalysts. However, very large quantities of these "promoters" decrease their positive effect, so that their role is difficult to rationalize. The "promoting" order of the $nBu_4PX$ salts for the hydroamination of ethylene seems to be $Br^- > I^- > Cl^-$.

The $[PtBr_2]/nBu_4Br$ system is the only efficient catalyst reported so far for the hydroamination of 1-hexene with aniline. Since this reaction occurs with a particularly promising regioselectivity (95% Markovnikov), it was interesting to compare the activating ability of several $nBu_4PX$ salts associated with $[PtBr_2]$ with their possible influence on the regioselectivity [Equation (15)]. The most significant results are summarized in Table 7.[68]



1 11 12 13 (15)

As may be seen from Table 7,[68] $[PtBr_2]$ alone did not catalyze the hydroamination of 1-hexene with aniline (run 36). In the same way, association of $[PtBr_2]$ with either $nBu_4PPF_6$ or $nBu_4PCl$ (runs 37 and 38) resulted in very low TONs. In contrast, as already found, association with $nBu_4PBr$ promoted a significant catalytic activity (TON = 57, run 39). An even higher activity was obtained with the $[PtBr_2]/nBu_4PI$ system, for which a TON of 83 was reached (run 40). For Equation (15), the "promoting" effect of the

Table 7. Hydroamination of 1-hexene with aniline catalyzed by $[PtBr_2]/nBu_4PX$ systems.[a]

| Run | Catalytic system | Total TON (**12** + **13**) | Regioselectivity (**12**/**13**) |
|---|---|---|---|
| 36 | $[PtBr_2]$ | 1 | n.d. |

| 38 | $[PtBr_2]/nBu_4PCl$ | 5 | n.d. |
| 39 | $[PtBr_2]/nBu_4PBr$ | 57 | 95:5 |
| 40 | $[PtBr_2]/nBu_4PI$ | 83 | 95:5 |
| 41 | $[PtBr_2]/nBu_4PBr/I_2$[b] | 115 | 95:5 |

[a] Aniline: 45 mmol, 1-hexene: 90 mmol, $[PtBr_2]$: 0.13 mmol, $nBu_4PX$: 8.45 mmol, 150 °C, 10 h. [b] $I_2$: 0.13 mmol.

phosphonium halides varies as $I^- > Br^- >> Cl^-$. The nature of the halide anion has no effect on the regioselectivity.

Iodide effects in transition-metal-catalyzed reactions are well known, and in some cases their role has been rationalized.[62] The beneficial effect of molecular iodine (generally used in large amounts) has also been observed in some transition-metal-catalyzed reactions.[69] This proved to be the case also for the $Pt^{II}$-catalyzed hydroamination of 1-hexene. With the new $[PtBr_2]/nBu_4PBr/I_2$ system (1:65:1 ratio), an even higher activity (TON = 115, run 41) than that obtained with the $[PtBr_2]/nBu_4PBr$ system (TON = 57, run 39) was reached. The use of higher amounts of iodine (vs. $[PtBr_2]$) had no beneficial effect on the TON.

These results agree with the general mechanism proposed (see Scheme 3), but suggest that the halide anions also play a role in other step(s) of the catalytic cycle, such as the coordination of the alkene and the attack of aniline on the coordinated alkene, or even by postponing poisoning effects.

Drent et al. recently reported a detailed study of the halide-anion-promoted palladium-catalyzed hydroformylation of internal alkenes to linear alcohols.[70] In the case of the [(bcope)Pd(OTf)$_2$] complex [bcope = bis(cyclooctyl)phosphinoethane], they found that the use of substoichiometric amounts (vs. Pd) of added halide anions strongly promoted the reaction rate. Most of their observations were rationalized in a qualitative way. However, it is clear that the halide-anion-promoting effect pointed out in the present work is different (no phosphorus ligand), and further detailed studies are required to gain a complete insight into these phenomena.

We have nevertheless shown that $nBu_4PX$ salts (X = $Cl^-$, $Br^-$, $I^-$) have a strong promoting effect on the $Pt^{II}$-catalyzed hydroamination of ethylene and 1-hexene with aniline. In the case of ethylene, $nBu_4PBr$ is the most efficient activator, whereas $nBu_4PI$ is more efficient than $nBu_4PBr$ in the case of 1-hexene. A special effect of molecular iodine has also been pointed out.[68]

### 2.6. $Pt^{IV}$ Salts Also Allow the Hydroamination Reaction!

In the course of the above studies, we examined the properties of $Pt^{IV}$ salts as catalytic precursors for the hydroamination of ethylene with aniline [see Equation (14)]. To the best of our knowledge, no hydroamination reaction, neither stoichiometric nor catalytic, has ever been reported by using $Pt^{IV}$ precursors.[21,29] The first results of this study are summarized in Table 8. Both $Pt^{IV}$ salts and $Pt^{IV}/n$Bu$_4$X systems (1:65 ratio) have been considered.

Table 8. Hydroamination of ethylene with aniline catalyzed by $Pt^{IV}$-based systems.[a]

| Run | $Pt^{IV}$ system | $n$Bu$_4$PX/[PtBr$_2$] ratio | Total TON[b] | Reaction products:% 6 | 7 | 8 |
|---|---|---|---|---|---|---|
| 42 | [PtBr$_4$] | – | 50 | 89 | 4 | 7 |
| 43 | [PtBr$_4$]/$n$Bu$_4$PCl | 65 | 75 | 84 | 14 | 2 |
| 44 | [PtBr$_4$]/$n$Bu$_4$PBr | 65 | 135 | 85 | 6 | 7 |
| 45 | [PtBr$_4$]/$n$Bu$_4$PI | 65 | 110 | 84 | 2 | 13 |
| 46 | [PtCl$_4$] | – | 15 | 100 | – | – |
| 47 | [PtCl$_4$]/$n$Bu$_4$PCl | 65 | 45 | 98 | 2 | – |
| 48 | [PtCl$_4$]/$n$Bu$_4$PBr | 65 | 120 | 90 | 3 | 7 |
| 49 | [PtCl$_4$]/$n$Bu$_4$PI | 65 | 110 | 86 | 2 | 11 |

[a] Aniline: 45.5 mmol, ethylene: 25 bar at room temperature (ca. 100 mmol), [PtX$_4$]: 0.13 mmol, 150 °C, 10 h. [b] Turnover number, TON calculated as $TON_6 + TON_7 + 2\,TON_8$.

The first and most important feature that emerges from Table 8 is that $Pt^{IV}$ bromide and chloride are shown for the first time to exhibit a catalytic activity for the hydroamination reaction: [PtBr$_4$] (run 42) is even more active than [PtBr$_2$] (run 24, Table 6).[71] Secondly, association of $n$Bu$_4$PX with these catalytic precursors promotes a significant increase in the catalytic activity. Although the role of the $n$Bu$_4$PX/$Pt^{IV}$ ratio has not yet been studied, the most efficient "promoter" seems to be $n$Bu$_4$PBr, as was the case for the $Pt^{II}$ systems (see above). For both $Pt^{II}$ and $Pt^{IV}$ catalytic precursors, the promoting ability exhibited by the phosphonium halide seems to follow the order $Br^- > I^- >> Cl^-$. It is again tentatively suggested that this unusual order is indicative that these halide anions play a role in different steps of the catalytic cycle.

## Conclusions

In the previous sections, we have described our progress in the study of the catalytic hydroamination of *nonactivated* alkenes with arylamines. Starting from the idea that molten salts or ionic liquids may be used as solvents for such reactions, we managed to show that tetraalkylphosphonium halides, in fact, play the role of "promoters", especially $n$Bu$_4$PBr and $n$Bu$_4$PI. It has been clearly evidenced that the promoting effect of these "cocatalysts" depends only upon their anionic moiety. The role of these anions is difficult to rationalize at the present time. Nevertheless, we succeeded in designing catalytic $Pt^{II}$- and $Pt^{IV}/n$Bu$_4$PX systems that are the most active catalysts reported to date for the hydroamination of ethylene with amines, especially weakly basic amines such as anilines. The $Pt^{II}/n$Bu$_4$PBr combination exhibits an unprecedented catalytic activity for the hydroamination of a higher alkene such as 1-hexene. In addition, the hydroamination of α-olefins has been found to occur with a very high regioselectivity (> 95%, Markovnikov), which opens the possibility to study an enantioselective version of this reaction. The interest in these promising catalytic systems for possible applications is heightened by the fact that the reactions can be conducted under aerobic conditions without loss of yield.

## Acknowledgments

The Centre National de la Recherche Scientifique (France) is acknowledged for financial support. The authors gratefully acknowledge Dr. F. Malbosc (Solvionic) for helpful discussions.

[34] Venanzi et al.[32] reported a platinum-promoted cyclization of aminoalkenes (e.g. 1-pentenylamine) that may appear catalytic in character. However, as noted by the authors, the reaction rates are so low that "its synthetic exploitation would not represent a significant improvement over existing stoichiometric processes".

# The First Example of a Bis(trifluoromethyl)carbene Transition-Metal Complex and Its Reduction to a Perfluoroallene Complex

**Jian Yuan,[a] Russell P. Hughes,*[a] and Arnold L. Rheingold[b]**

*Dedicated to Dr. Robert M. Ross on the occasion of his 90th birthday*

**Keywords:** Carbene / Iridium / Fluorine / Ligands / Structure

Na/Pb alloy reduction of the (perfluoroisopropyl)iridium complex Cp*(CO)IrI[CF(CF$_3$)$_2$] afforded the first example of a bis(trifluoromethyl)carbene complex, Cp*(CO)Ir=C(CF$_3$)$_2$, which has been crystallographically characterized. Further reduction of this carbene complex with $KC_8$ yielded the perfluoroallene iridium complex Cp*Ir(CO)($\eta^2$-CF$_2$CCF$_2$).

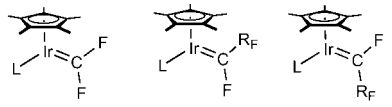
## Introduction

Transition-metal complexes with carbene ligands have been known for more than four decades,[1,2] and they have been extensively utilized in organic synthesis and catalysis.[3,4] Other than compounds of the parent methylene ligand,[5] all such complexes isolated to date contain at least one carbene substituent (alkyl, aryl, heteroatom) that is electron-donating in a σ- or π-sense. Recently we reported a simple reductive conversion of primary (perfluoroalkyl)-iridium complexes to difluorocarbene complexes **1** and **2**. The (difluorocarbene)iridium complexes are stable, crystalline solids, unlike the $CH_2$ analogue of **1**, which can only be observed spectroscopically at low temperatures,[6] even though other terminal methylene complexes of iridium are stable enough for isolation.[7,8] Similarly, fluoro(perfluoroalkyl)carbene complexes **3**–**6** can be isolated by using sodium naphthalenide (NaNp), potassium graphite ($KC_8$), or magnesium graphite [$C_{16}Mg(KCl)_2$] as electron sources.[9,10] While compounds **3**–**6** contain one perfluoroalkyl substituent, which is an exclusively electron-withdrawing group,[11–14] the other fluorine substituent at the carbene carbon is still capable of π-donation. Here we report the first example of a complex with a carbene ligand bearing two electron-withdrawing trifluoromethyl substituents, which can be isolated as a stable, sublimable solid.



**1** L = PMe$_3$
**2** L = CO

**3a–6a** **3b–6b**

**3a,b** L = PMe$_3$, R$_F$ = CF$_3$
**4a,b** L = CO, R$_F$ = CF$_3$
**5a,b** L = PMe$_3$, R$_F$ = CF$_2$CF$_3$
**6a,b** L = CO, R$_F$ = CF$_2$CF$_3$

## Results and Discussion

Careful two-electron reduction of perfluoroisopropyl complex **7**[15] in thf by using Na/Pb alloy (Na ca.10%) afforded bis(trifluoromethyl)carbene complex **8** in 87% yield as a yellow, crystalline, sublimable, air-stable compound, unambiguously characterized by a single-crystal X-ray diffraction study. An ORTEP is shown in Figure 1 (Figure 1). The Ir–C double bond length of 1.928(7) Å is significantly shorter than the Ir–C single bond in **7** [2.11(3) Å][15] and slightly longer than the double bond in its difluorocarbene analogue **2** [1.855(13) Å].[10] Not unexpectedly, the CF$_3$–Ir–CF$_3$ angle in **8** [110.0(6)°] is substantially larger than the F–C–F angle in **2** [103.5(10)°].[10]

Complex **8** represents the first unambiguously characterized compound of a carbene ligand bearing two perfluoroalkyl groups; an early attempt by others to prepare such a compound by reaction of *trans*-(Ph$_2$MeP)$_2$Ir(CO)Cl with the diazo precursor (CF$_3$)CN$_2$ gave a poorly characterized product in which it was not possible to distinguish between structure **9a** or **9b** (L = PMePh$_2$).[16] Notably, a terminal methylene analogue of **9b** can be isolated in a similar reaction by using diazomethane.[7]

While the mono(perfluoroalkyl)carbene analogues **3**–**6** are inert to further reduction, the new bis(trifluoromethyl)-

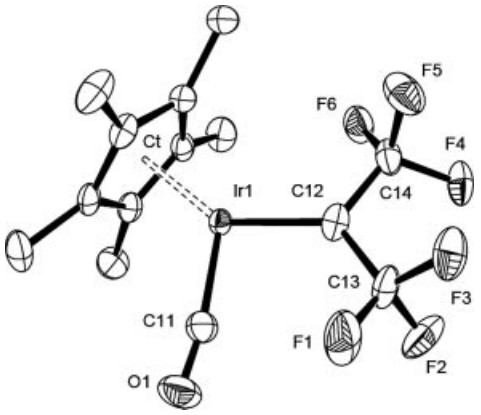

Figure 1. ORTEP diagram of the non-hydrogen atoms of **8**, showing the partial atom-labeling scheme. Thermal ellipsoids are shown at the 30% level. Selected bond lengths [Å] and angles [°]: Ir1–C11 1.860(7), Ir1–C12 1.928(7), Ir1–Ct 1.889(6), C12–C14 1.481(11), C12–C13 1.489(10), O1–C11 1.129(8); Ct–Ir1–C12 140.5(3), Ct–Ir1–C11 124.9(3), C11–Ir1–C12 94.7(3), C14–C12–C13 110.0(6), C14–C12–Ir1 123.6(5), C13–C12–Ir1 126.4(6).

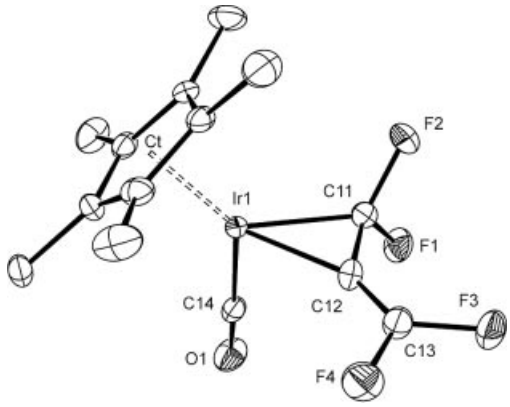

Figure 2. ORTEP diagram of the non-hydrogen atoms of **10** showing the partial atom-labeling scheme. Thermal ellipsoids are shown at the 30% level. Selected bond lengths [Å] and angles [°]: Ir1–C11 2.035(7), C11–F1 1.381(8), C11–F2 1.362(8), Ir1–C12 2.030(7), C11–C12 1.426(10), C12–C13 1.281(10), C13–F3 1.337(8), C13–F4 1.340(9), Ir1–C14 1.862(6), C14–O1 1.133(7); Ir1–C11–C12 69.3(4), Ir1–C12–C11 69.6(4), C12–Ir1–C11 41.1(3), C11–C12–C13 138.8(7), C13–C12–Ir1 151.3(6).

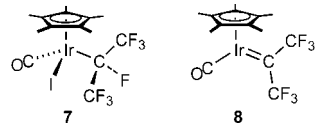
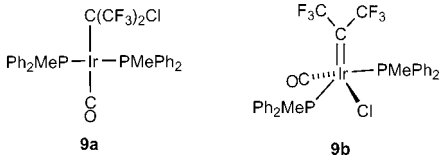
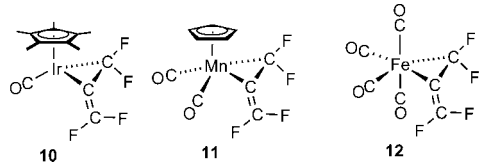




carbene complex **8** is more reactive, undergoing reduction by $KC_8$ to eliminate two more fluorides and afford (perfluoroallene)iridium complex **10** in 60% yield as a white crystalline compound. It was also possible to synthesize **10** from the direct reduction of **7** with excess $KC_8$. The structure is also unambiguously defined by means of a single-crystal X-ray diffraction study; an ORTEP representation of the structure is shown in Figure 2. As expected, the allene ligand is bent with a C–C–C angle of 138.8(7)°, and the coordinated alkene [1.426(10) Å] is longer than the uncoordinated one [1.281(10) Å]. This is only the third example of a structurally characterized perfluoroallene complex and differs from its first-row metal analogues **11**[17] and **12**[18] in that the two Ir–C distances [2.035(7) Å and 2.030(7) Å] are equal within experimental error. In compounds **11** and **12**, the distance of the metal to the internal allene carbon is significantly shorter than that to the terminal carbon. Observation of four well-resolved doublet of doublet of doublet signals in the solution $^{19}F$ NMR spectrum indicate that there is a high barrier to propeller rotation of the allene ligand in **10**; propeller rotation on the NMR timescale would interconvert the resonances of F1 and F2. All four resonances were unambiguously assigned by means of a $^{19}F\{^1H\}$ HOESY experiment.



## Conclusions

This methodology illustrates that the presence of donor substituents other than H is not a requirement for stability in transition-metal carbene complexes. In addition, it demonstrates that reductive inner-sphere construction of unsaturated fluorocarbon ligands like tetrafluoroallene and the previously reported example of tetrafluorobutatriene[19] represent useful alternative methods for their synthesis as opposed to the direct ligand substitution required when starting with the free fluorocarbon,[18,20,21] which itself can be difficult to prepare and handle. Further experimental and computational studies of the structures and reactivity of this new class of carbene complexes will be reported in due course.

## Experimental Section

**Complex 8:** To a Schlenk flask containing Na/Pb alloy (353 mg, 10 equiv.) and thf (6 mL) was added $Cp^*Ir(CO)(I)[CF(CF_3)_2]$ (100 mg, 0.154 mmol) as a solid, and the mixture was stirred at room temperature for 3 h. The solvent was removed, and the product was extracted into hexanes. Removal of solvent gave a yellow solid (68 mg, 87%). Crystals were obtained by sublimation (5 Torr, 70 °C). $C_{14}H_{15}F_6IrO$ (505.46): calcd. C 33.27, H 3.00; found C 33.19, H 3.45. IR (hexanes): ν(CO) = 2017 $cm^{-1}$. $^1H$ NMR (500 MHz, $C_6D_6$, 21 °C): $\delta$ = 1.51 (s, $C_5Me_5$) ppm. $^{19}F$ NMR (470.31 MHz, $C_6D_6$, 21 °C): $\delta$ = –54.5 (q, $^5J_{FF}$ = 8 Hz, 3 F, $CF_3$), –57.1 (q, $^5J_{FF}$ = 8 Hz, 3 F, $CF_3$) ppm. $^{13}C\{^1H\}$ NMR (125.7 Hz, $C_6D_6$, 21 °C): $\delta$ = 9.5 (q, $^5J_{CF}$ = 1.2 Hz, $C_5Me_5$), 100.7 (s, $C_5Me_5$),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

134.6 (qq, $^1J_{CF}$ = 275, $^3J_{CF}$ = 5 Hz, $CF_3$), 137.0 (qq, $^1J_{CF}$ = 275, $^3J_{CF}$ = 6 Hz, $CF_3$), 177.9 (qq, $^4J_{CF}$ = 5, $^3J_{CF}$ = 1 Hz, CO), 182.1 (qq, $^2J_{CF}$ = $^2J_{CF}$ = 32 Hz, IrC) ppm. Crystal data for **8**: $C_{14}H_{15}F_6IrO$, $M_r$ = 505.46, triclinic, space group $P\bar{1}$, $V$ = 783.8(4) Å$^3$, $a$ = 8.457(2) Å, $b$ = 8.686(3) Å, $c$ = 11.577(3) Å, $\alpha$ = 85.951(5)°, $\beta$ = 76.850(6)°, $\gamma$ = 71.198(5)°, $Z$ = 2, $T$ = 208(2) K, Mo-$K_\alpha$ = 0.71073 Å. GOF = 1.079. The final $R1(F^2)$ was 0.0343 for 3450 reflections $I > 2\sigma(I)$.

**Complex 10:** *Method A:* To a Schlenk flask containing $KC_8$ (183 mg, 1.35 mmol, 10 equiv.) and thf (6 mL) was added a solution of **8** (68 mg, 0.135 mmol) in thf (2 mL). The suspension was stirred at room temperature for 2 h. The solvent was removed, and the product was extracted into hexanes. Removal of solvent gave an off-white solid, (38 mg, 60%). *Method B:* To a Schlenk flask containing $KC_8$ (311.5 mg, 2.30 mmol, 10 equiv.) and thf (6 mL) was added. Cp*Ir(CO)(I)[$CF(CF_3)_2$] (150 mg, 0.230 mmol) as a solid. The suspension was stirred at room temperature for 2 h. The solvent was removed, and the product was extracted into hexanes. Removal of solvent gave an off-white solid (65 mg, 61%). Crystals were obtained from diffusion of neopentane into an ethyl isopropyl ether solution. $C_{14}H_{15}F_4IrO$ (467.49): calcd. C 35.97, H 3.23; found C 36.07, H 3.15. IR(hexane): ν(CO) = 2017 cm$^{-1}$, ν(C=$CF_2$) = 1787 cm$^{-1}$. $^1$H NMR (500 MHz, $C_6D_6$, 21 °C): $\delta$ = 1.56 (s, $C_5Me_5$) ppm. $^{19}$F NMR (470.31 MHz, $C_6D_6$, 21 °C): $\delta$ = –55.3 (ddd, $^2J_{FF}$ = 61, $^4J_{FF}$ = 9, $^4J_{FF}$ = 8 Hz 1 F, $CF_2$), F3; –84.7 (ddd, $^2J_{FF}$ = 133, $^4J_{FF}$ = 9, $^4J_{FF}$ = 9 Hz, 1 F, Ir$CF_2$), F1; –93.8 (ddd, $^2J_{FF}$ = 61, $^4J_{FF}$ = 9, $^4J_{FF}$ = 9 Hz, 1 F, $CF_2$), F4; –101.1 (ddd, $^2J_{FF}$ = 133, $^4J_{FF}$ = 9, $^4J_{FF}$ = 8 Hz, 1 F, Ir$CF_2$), F2 ppm. $^{13}$C{$^1$H} NMR (125.7 Hz, $C_6D_6$, 21 °C): $\delta$ = 9.1 (s, $C_5Me_5$), 45.0 (dddd, $^2J_{CF}$ = 51, $^2J_{CF}$ = 12, $^2J_{CF}$ = 7, $^2J_{CF}$ = 5 Hz, IrC), 99.1 (s, $C_5Me_5$), 97.4 (tdd, $^1J_{CF}$ = 316, $^3J_{CF}$ = 21, $^3J_{CF}$ = 2 Hz, C=$CF_2$), 148.5 (ddt, $^1J_{CF}$ = 294, $^1J_{CF}$ = 274, $^3J_{CF}$ = 2 Hz, Ir$CF_2$), 169.7 (dd, $^3J_{CF}$ = 11, $^3J_{CF}$ = 2 Hz, CO) ppm. Crystal data for **10**: $C_{14}H_{15}F_4IrO$, $M_r$ = 467.46, orthorhombic, space group *Pbca*, $V$ = 2949.4(5) Å$^3$, $a$ = 14.3156(13) Å, $b$ = 13.9844(13) Å, $c$ = 14.7327(13) Å, $\alpha = \beta = \gamma$ = 90°, dummy 90°, 90 °C, 90 °C, (2)°, (2)° dummy $Z$ = 8, $T$ = 208(2) K, Mo-$K_\alpha$ = 0.71073 Å. GOF = 1.040. The final $R1(F^2)$ was 0.0482 for 3554 reflections $I > 2\sigma(I)$.

CCDC-655232 (**8**) and CCDC-655233 (**10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic data Centre via http://www.ccdc.uk/data_request/cif.

# Hybrid Organic/Inorganic Supramolecular Conductors $D_2[Au(CN)_4]$ [D = Diiodo(ethylenedichalcogeno)tetrachalcogenofulvalene], Including a New Ambient Pressure Superconductor

**Tatsuro Imakubo,*[a] Takashi Shirahata,[a] Megumi Kibune,[a] and Hiroko Yoshino[a]**

**Keywords:** Supramolecular chemistry / Conducting materials / Iodine / Superconductors / Selenium heterocycles

Five diiodo(ethylenedichalcogeno)tetrachalcogenofulvalenes, DIEDSS {2-(5,6-dihydro[1,3]diselenolo[4,5-*b*][1,4]diselenin-2-ylidene)-4,5-diiodo-1,3-dithiole}, DIET-STF {2-(4,5-diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,3]dithiolo[4,5-*b*][1,4]dithiine}, DIEDS-STF {2-(4,5-diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,4]diselenino[2,3-*d*][1,3]dithiole}, DIETSe {2-(4,5-diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,3]diselenolo[4,5-*b*][1,4]dithiine}, and DIEDSSe {2-(4,5-diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,3]diselenolo[4,5-*b*][1,4]diselenine}, have been synthesized without the use of the highly toxic reagent $CSe_2$, and their $Au(CN)_4$ salts have been prepared by electrochemical oxidation. Characteristic I···N iodine bonds are constructed in all crystals, and their packing motifs are classified into two groups by the difference in the space group symmetry. The salt of DIEDSS crystallizes in the monoclinic *C*2/*c* space group and a novel helical supramolecular architecture is constructed by the strong and directional I···N iodine bond. On the other hand, the rest of the four salts crystallize in the triclinic $P\bar{1}$ space group and their donor packing motifs belong to the so-called β-type. Conducting properties of the β-type salts strongly depend on the number and positions of the selenium atoms on the donor molecule. The salts based on the diselenadithiafulvalene (DSDTF) derivatives, DIET-STF and DIEDS-STF, show metal–semiconductor transition and the salt of fully selenated π-donor DIEDSSe shows stable metallic behavior down to 1.6 K. On the other hand, $(DIETSe)_2[Au(CN)_4]$ is semimetallic down to low temperature and the superconducting transition occurs at around 2 K (onset).

## Introduction

The development of novel organic conductors based on tetrathiafulvalene (TTF) derivatives, which show interesting physical properties, depends not only on the design and synthesis of an independent donor molecule but also on the design of crystal structure, which is strongly related to the bulk physical properties. For designing crystal structures of organic conductors from the viewpoint of crystal engineering,[1] we have proposed the introduction of the iodine bond,[2–6] which is a special case of the halogen bond.[7] A large number of supramolecular conductors based on the iodinated TTFs have been synthesized,[8,9] and one of them, θ-$(DIETS)_2[Au(CN)_4]$ {DIETS = 2-(4,5-diiodo-1,3-dithiol-2-ylidene)-5,6-dihydro[1,3]diselenolo[4,5-*b*][1,4]dithiine}, shows superconductivity under uniaxial strain applied along the I···N iodine bond.[3c] It is well known that replacement of the sulfur atom in the TTF skeleton by the selenium atom is an effective method of increasing electrical conductivity and the development of organic superconductors.[10] Recently, we have reported a new $CSe_2$-free synthesis of 1,3-diselenole-2-thione, which may be a good alternative to 1,3-diselenole-2-selone, together with its applications to the synthesis of 4,5-diiodo-1,3-diselenole-2-one[5] and 4,5-alkylenedichalcogeno-1,3-diselenole-2-ones.[6] Cross-coupling reactions using these 1,3-diselenole-2-ones provide a number of selenium analogues of DIETS, i.e., DIEDSS {2-(5,6-dihydro[1,3]diselenolo[4,5-*b*][1,4]diselenin-2-ylidene)-4,5-diiodo-1,3-dithiole}, DIET-STF {2-(4,5-diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro-[1,3]dithiolo[4,5-*b*][1,4]dithiine}, DIEDS-STF {2-(4,5-diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,4]diselenino-[2,3-*d*][1,3]dithiole}, DIETSe {2-(4,5-diiodo-1,3-diselenol-2-

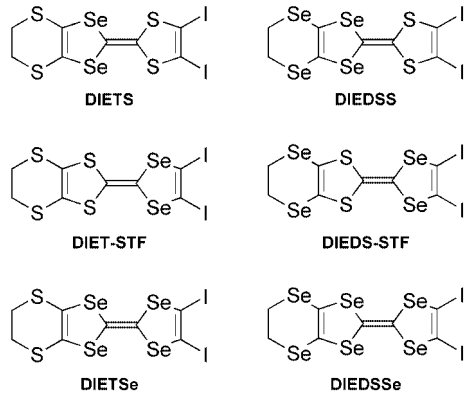

Figure 1. Molecular structure of iodinated TTFs.

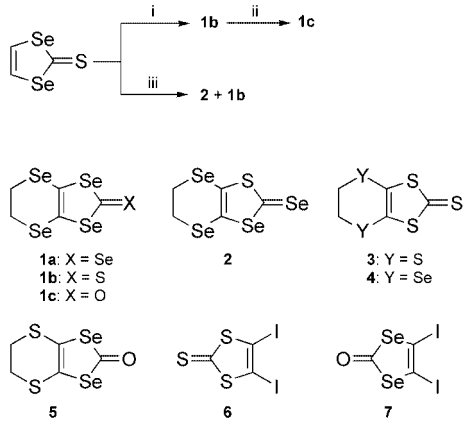
ylidene)-5,6-dihydro[1,3]diselenolo[4,5-*b*][1,4]dithiine}, and DIEDSSe {2-(4,5-diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,3]diselenolo[4,5-*b*][1,4]diselenine}, and these organic π-donors are suitable candidates for the exploration of novel supramolecular organic conductors and superconductors. In this article, we report on the synthesis, crystal structure, and physical properties of novel supramolecular organic conductors $D_2[Au(CN)_4]$ (D = organic π-donors mentioned above, see Figure 1) together with the details of the synthesis of the neutral π-donors.

## Results and Discussion

### Donor Synthesis

The first synthesis of 4,5-ethylenediseleno-1,3-diselenole-2-selone (**1a**) was accomplished by the electrochemical reduction of $CSe_2$.[11] However, the reduction process of $CSe_2$ is dangerous and not ideal from the viewpoint of a safe laboratory environment. A modified synthesis of **1a** using bis(selenocyanato)ethane as the electrophile was reported by Otsubo et al.,[12] however $CSe_2$ is still indispensable for the synthesis of the starting material 1,3-diselenole-2-selone.[13] Recently, we have reported a $CSe_2$-free synthesis of 1,3-diselenole-2-thione, which seems to be a good starting material for the synthesis of the thione **1b**. At first, we applied the same reaction conditions for the synthesis of **1a** from 1,3-diselenole-2-selone to the synthesis of **1b** from 1,3-diselenole-2-thione. However, the main product of the reaction was the 1,3-thiaselenole-2-selone **2** (20%) and the desired thione **1b** was obtained in only 3% yield. To avoid the unfavorable transformation of 1,3-diselenole-2-thione to 1,3-thiaselenole-2-selone, we changed the reaction sequence as well as the iodination of 1,3-diselenole-2-thione,[5] that is, LDA was added last to a solution of 1,3-diselenole-2-thione and 1,2-bis(selenocyanato)ethane. This inverted sequence afforded **1b** without a selenium–sulfur exchange side reaction in a yield of under 5%. The low yield of **1b** was improved under the diluted conditions, which avoided the polymerization of the intermediate anions. In the optimized reaction conditions, the yield of **1b** exceeded 20%, and about 40% of the starting material 1,3-diselenole-2-thione, which can be recycled for the same reaction, was recovered. The thione **1b** was easily converted into the corresponding ketone **1c** (89%) by the conventional $Hg(OAc)_2/CHCl_3$ method. Phosphite-mediated cross-coupling reactions between the 1,3-dichalcogenole units in Scheme 1 gave diiodo(ethylenedichalcogeno)tetrachalcogenofulvalenes, DIEDSS, DIET-STF, DIEDS-STF, DIETSe,[4] and DIEDSSe. The results of the cross-coupling reactions and the redox potentials of a series of DIETS analogues are summarized in Table 1. These π-donors show two reversible waves and their donor abilities mainly depend on the inner fulvalene skeleton. The diselenadithiafulvalene (DSDTF) derivatives, DIETS, DIEDSS, DIET-STF, and DIEDS-STF, show lower $E_1^{1/2}$ than tetraselenafulvalene (TSeF) derivatives, DIETSe and DIEDSSe. On the other hand, the smaller $\Delta E$ values of TSeFs suggest the smaller on-site Coulombic repulsion thanks to the introduction of larger selenium atoms, which extend the highest occupied molecular orbital (HOMO).



Scheme 1. Reagents and conditions: (i) 1,2-bis(selenocyanato)ethane (1.2 equiv.), then LDA (2.5 equiv.), –78 °C; (ii) $Hg(OAc)_2$, $AcOH/CHCl_3$; (iii) LDA (2.2 equiv.) then 1,2-bis(selenocyanato)ethane (1.6 equiv.), –78 °C.

### Preparation of the $Au(CN)_4$ Salts

Single crystals of the $Au(CN)_4$ salts were prepared by the galvanostatic oxidation of a $CH_2Cl_2$ solution containing DIEDSS, DIET-STF, DIEDS-STF, DIETSe, or DIEDSSe and tetrabutylammonium tetracyanoaurate as the supporting electrolyte. The five cation radical salts, $(DIEDSS)_2[Au(CN)_4]$ (**8**), $(DIET\text{-}STF)_2[Au(CN)_4]$ (**9**), $(DIEDS\text{-}STF)_2[Au(CN)_4]$ (**10**), $(DIETSe)_2[Au(CN)_4]$ (**11**), and $(DIEDSSe)_2[Au(CN)_4]$ (**12**), are classified into two groups according to the difference in their space group symmetry. The salt **8**

based on DIEDSS, which contains a 4,5-diiodo-1,3-dithiole unit, crystallizes in the monoclinic *C*2/*c* space group, whereas the salts **9**–**12** based on the π-donors containing the 4,5-diiodo-1,3-diselenole unit crystallize in the triclinic $P\bar{1}$ space group (Table 2).

## Crystal Structure

The salt **8** crystallizes in the monoclinic *C*2/*c* space group (Table 2) and its crystal structure is shown in Figure 2. The donor/anion ratio is 2:1 and one crystallographically independent donor molecule stacks uniformly in a head-to-head manner along the crystallographic *b* axis. The gold atom of the $Au(CN)_4$ anion is located on the twofold axis and the almost planar $Au(CN)_4$ anion also stacks along the crystallographic *b* axis. The molecular packing motif of **8** basically resembles that of θ-$(DIETS)_2[Au(CN)_4]$,[3c] which is also based on the π-donor containing the 4,5-diiodo-1,3-dithiole unit. However, the donor columns A and B (A′ and B′) solid-cross along the side-by-side direction (Figure 3a). On the other hand, the donor columns A and A′ (B and B′) are parallel and they correspond to a part of the so-called β"-type structure, as shown in Figure 3b. Differences in the crystal structure between θ-$(DIETS)_2[Au(CN)_4]$ and **8** originate from the external form of the donor molecule. The steric hindrance between the donor molecules along the side-by-side direction in the crystal of **8** is larger than that in θ-$(DIETS)_2[Au(CN)_4]$ because DIEDSS contains a larger ethylenediseleno group than DIETS, which contains a smaller ethylenedithio group. A solid-crossing molecular arrangement of the DIEDSS molecule seems favorable for

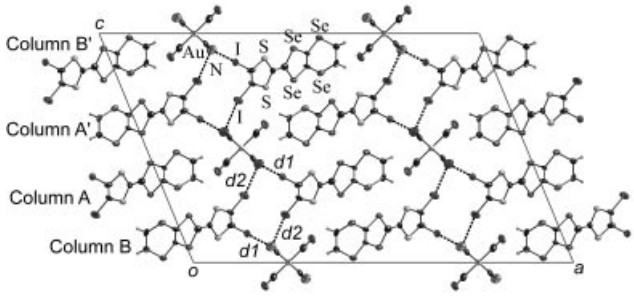

Figure 2. Crystal structure of **8** viewed along the crystallographic *b* axis. The dotted lines indicate I···N iodine bonds [*d*1 = 2.99(2), *d*2 = 3.28(1) Å].

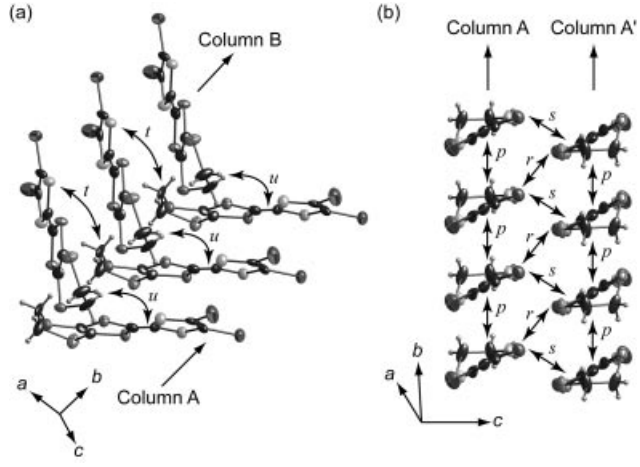

Figure 3. Molecular arrangement of the donor molecule of **8**: (a) solid-crossing arrangement for Column A and B viewed along the side-by-side direction of the donor molecule of Column A; (b) β"-type arrangement for Column A and A′ viewed along the long molecular axis of DIEDSS. The calculated overlap integrals ($\times 10^{-3}$) are *p* = –1.49, *r* = 1.41, *s* = –11.34, *t* = 0.17, *u* = 2.55.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

avoiding steric repulsion between the larger ethylenediseleno groups.

As well as the other organic conductors based on iodinated TTFs, strong I···N iodine bonds are observed in **8**. The I···N distances are $d1$ = 2.99(2) Å and $d2$ = 3.28(1) Å and they are 7–15% shorter than the sum of the van der Waals radii (3.53 Å).[14] Along the crystallographic $b$ axis, there is a helix of ···I–C=C–I···N···I–C=C–I···N··· and the helices are connected along the $c$ axis through the $Au(CN)_4$ anions, as shown in Figure 4.

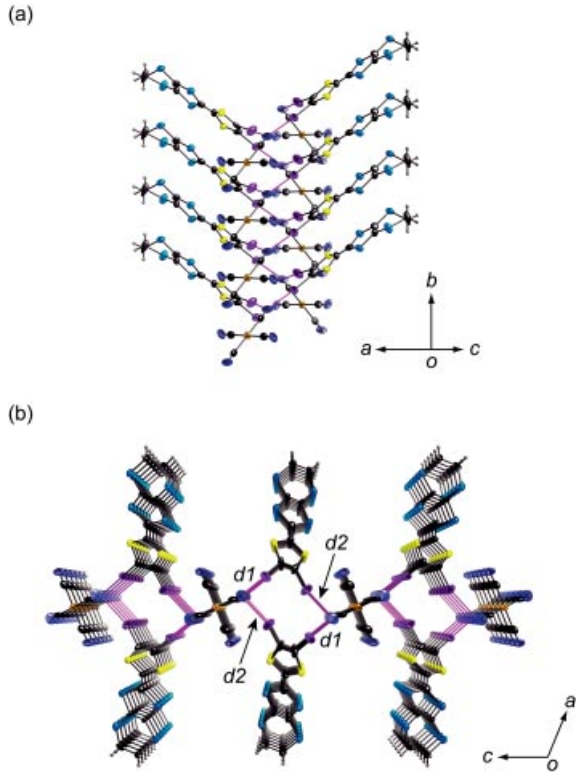

Figure 4. Helical supramolecular architecture in **8** constructed by the iodine bond (a) viewed along the $a + c$ axis; (b) projection onto the $ac$ plane. The pink lines indicate I···N iodine bonds [$d1$ = 2.99(2), $d2$ = 3.28(1) Å].

On the other hand, the $Au(CN)_4$ salts **9**–**12** based on the π-donors containing the 4,5-diiodo-1,3-diselenole unit, DIET-STF, DIEDS-STF, DIETSe, and DIEDSSe, are isostructural and crystallize in the triclinic $P\bar{1}$ space group (Table 2). The crystal structure of **11** is shown in Figure 5 as a representative of the isomorphic salts **9**–**12**. The unit cell contains two donor molecules and one $Au(CN)_4$ anion, and the donor/anion ratio is 2:1. The donor molecules stack in a head-to-tail manner along the crystallographic $b$ axis and the so-called β-type structure is constructed within the $ab$ plane. Short I···N iodine bonds ($d3$ = 2.83–2.86 Å, see the last row of Table 2), which are 19–20% shorter than the sum of the van der Waals radii, are observed.

Three types of iodine bonds, $d1$ and $d2$ for **8**, and $d3$ for **11** as the representative of the β-type salts **9**–**12**, are depicted in Figure 6 together with the lowest unoccupied molecular orbitals (LUMOs) of DIEDSS and DIETSe. In the

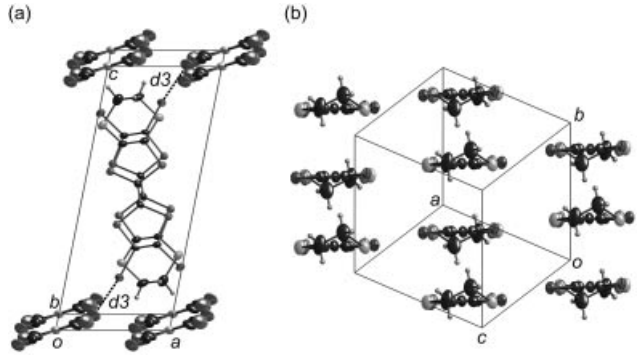

Figure 5. Crystal structure of **11**. (a) A projection onto the $ac$ plane. The dotted lines indicate I···N iodine bonds [$d3$ = 2.83(1) Å] shorter than the sum of the van der Waals radii. (b) Molecular arrangement of the donor molecule viewed along the long molecular axis of DIETSe.

case of $d1$, the donor molecule and the $Au(CN)_4$ anion are almost parallel, which is similar to the situation in θ-$(DIETS)_2[Au(CN)]_4$,[3c] and nearly orthogonal arrangements of the donor molecule and the $Au(CN)_4$ anion are observed in the cases of $d2$ and $d3$. From the viewpoint of the relationship between the molecular structure and the geometrical conformation of the iodine bond, the chalcogen element of the dichalcogenole ring on the iodine-bonded side of the molecule seems essential. A "parallel" arrangement like $d1$ is observed only in the salts based on the donor molecules containing the 4,5-diiodo-1,3-dithiole unit, that is, **8** and θ-$(DIETS)_2[Au(CN)]_4$. On the other hand, an "orthogonal" arrangement is preferred in the salts **9**–**12**, which are based on the donor molecules containing the 4,5-diiodo-1,3-diselenole unit. According to the calculated coefficients of the LUMOs on the 4,5-diiodo-1,3-dichalcogenole

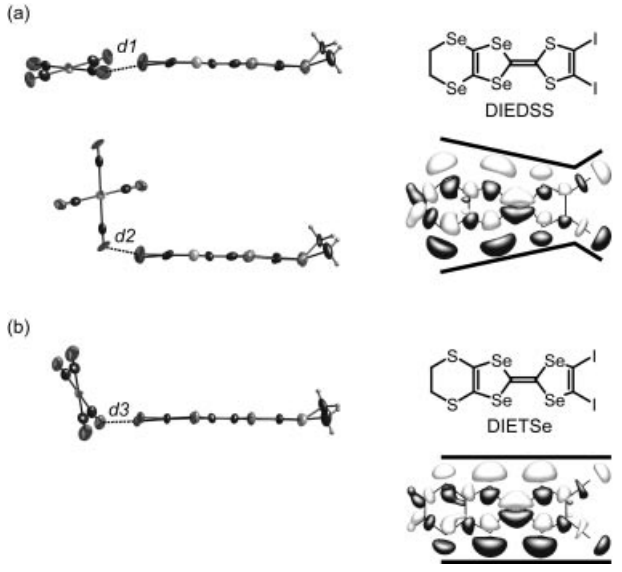

Figure 6. Three types of iodine bond, $d1$, $d2$, and $d3$, and LUMO of DIEDSS and DIETSe calculated by the MNDO–PM3 method;[15] (a) $d1$ and $d2$ for the salt **8** and LUMO of DIEDSS; (b) $d3$ for the salt **11** and LUMO of DIETSe. The solid lines are a guide for the eyes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

unit, the coefficients of the LUMO on the sulfur atoms of the 4,5-diiodo-1,3-dithiole unit are clearly smaller than those of the selenium atoms on the 4,5-diiodo-1,3-diselenole unit. Therefore, the differences in the geometrical conformation of the iodine bonds seem to be related not only to the external form of the donor molecules but also to the spatial extent of the frontier molecular orbitals around the 4,5-diiodo-1,3-dichalcogenole unit. In the salt **8**, there are two types of iodine bond, that is, "parallel" *d*1 and "orthogonal" *d*2, and the coexistence of these two types of iodine bond is essential to the helical supramolecular architecture.

## Band Calculation

Intermolecular overlap integrals for the salt **8** calculated by the extended Hückel method[16] are shown in Figure 3. The overlap integral *s* is considerably larger than the other overlap integrals *p*, *r*, *t*, and *u*, and the donor molecules are strongly dimerized along the side-by-side direction. The calculated band dispersion and the Fermi surfaces for **8** based on the tight-binding approximation using these overlap integrals are shown in Figure 7. There are four bands built from the HOMOs of the four donor molecules within the primitive cell [$a_p = (a + b)/2$, $b_p = b$, $c_p = c$] and they are separated by a gap in the upper and lower bands because of the strong dimerization mentioned above. Although the calculated Fermi surfaces are warped and quasi-one-dimensional, the calculated bandwidth of the upper band (ca. 0.08 eV) is much smaller than those of the usual organic conductors based on TTFs, and the strong electron correlation must be disadvantageous to achieving the metallic conductivity.

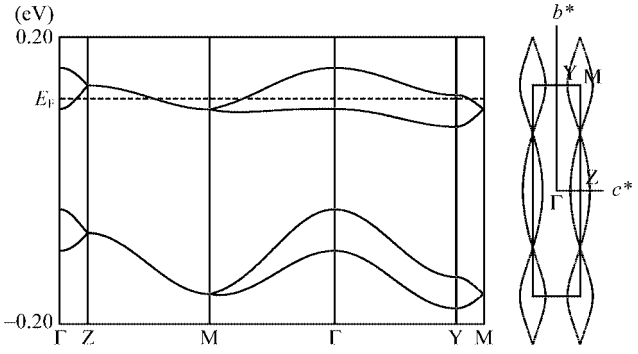

Figure 7. Calculated electronic band dispersion (left) and Fermi surfaces (right) for **8**.

Figure 8 shows a schematic view of the molecular arrangement within the donor layer for the β-type salts **9**–**12**, and the calculated overlap integrals are listed in Table 3. Differences in the intrastack overlap integrals between *p* and *q* are small enough to be regarded as a regular column structure. The interstack overlap integrals *r*, *s*, and *t* are about 1/7–1/19 of the intrastack overlap integrals *p* and *q*, and the quasi-one-dimensional character of the electronic band structure is suggested. The enhancement of the overlap integrals for **9** and **10** compared with those of **11** and **12** is accomplished by the replacement of sulfur atoms on the DSDTF skeleton with selenium atoms. On the other hand, the calculated overlap integrals of the side-by-side direction *s* and *t* for **9** based on the ethylenedithio derivative are slightly larger than those of **10** based on the ethylenediseleno derivative. There is a similar relationship between **11** and **12**, indicating that the overlap integrals *s* and *t* for the salts **10** and **12** are reduced by the steric repulsion of the larger ethylenediseleno group. The calculated band dispersion and the Fermi surfaces for **11** are shown in Figure 9 as a representative of the β-type salts **9**–**12**. There are two

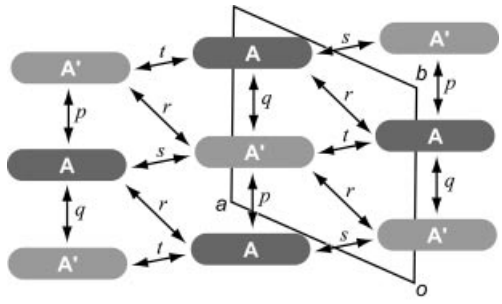

Figure 8. Schematic view of the donor layer for **9**–**12**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

bands built from the HOMOs of the two donor molecules within the unit cell, and there is no gap between the upper and lower bands. This is consistent with the regular column structure of the donor molecule. The calculated Fermi surfaces are quasi-one-dimensional along the *b* axis, which is the stacking direction of the donor molecule. The Fermi surfaces and electronic band dispersions for the salts **9**–**12** are almost the same except for the calculated bandwidth, and thanks to the TSeF skeleton, the bandwidths of **11** and **12** (about 0.7–0.8 eV) are larger than those of **9** and **10** (about 0.6 eV), and **11** and **12** are expected to have a stable metallic nature.

### Conducting Property

The single crystal of the salt **8** is a semiconductor with a small activation energy ($E_a$ = 98 meV) and the room temperature resistivity is 2.3 Ω cm. There are a few examples of helical architecture in organic crystals based on TTFs, however they are insulators.[17] To the best of our knowledge, the salt **8** is the first example of a highly conductive crystal that has helical architecture based on TTFs.

The room-temperature resistivities of the single crystals of the β-type salts **9**–**12** are $1.8 \times 10^{-2}$, $1.7 \times 10^{-2}$, $1.4 \times 10^{-2}$, and $1.6 \times 10^{-2}$ Ω cm, respectively. Figure 10 shows the temperature dependence of the resistivities for **9**–**12**. The conducting behavior of **9**–**12** strongly depends on the number and the positions of the selenium atoms on the donor molecule. The salts **9** and **10** based on the DSDTF derivatives show metal–semiconductor transition at 85 K for **9** and at 155 K for **10**. The metallic state of **9** based on the ethylenedithio derivative DIET-STF is more stable than that of **10** based on the ethylenediseleno derivative DIEDS-STF. It is consistent with the band calculation mentioned above, that is, the ethylenediseleno group reduces the overlap integrals of the side-by-side direction because of the steric repulsion and lowers the dimensionality of the electronic band structure.

The salt **12** based on the fully selenated π-donor DIEDSSe shows metallic behavior down to 1.6 K and the stable metallic nature is derived from the full replacement of the sulfur atoms in the diiodo(ethylenedichalcogeno)tetrachalcogenofulvalene with selenium atoms. On the other hand, the salt **11** shows semimetallic behavior down to 2 K and then a distinct resistivity drop, which is characteristic of the onset of superconductivity, was observed for several crystals (Figure 10b). Complete superconductivity with zero resistivity has not been confirmed because of its low transition temperature and the limit of the measurement apparatus. In spite of the identical crystal morphology among samples 1–4, there is a sample dependency of the onset temperature of the superconducting transition ($T_c$): 1.8 K for samples 1–3 and 2.1 K for sample 4. The crystals of **11** are fragile and the sample dependence of the $T_c$ may be affected by cracks in the crystals. Resistivity jumps were observed in all samples at higher temperatures, that is, at around 80 K for sample 1, 60 K for sample 2, 90 K for sample 3, and 100 K for sample 4. Samples 1 and 2 were harvested from the same crystallization cell (Batch A), and samples 3 and 4 were obtained from a different experiment (Batches B and C, respectively). The conditions of electrochemical oxidation for Batches A and B are almost the same and no clear relationship was observed between the conditions of crystal preparation and the $T_c$ of superconductivity.

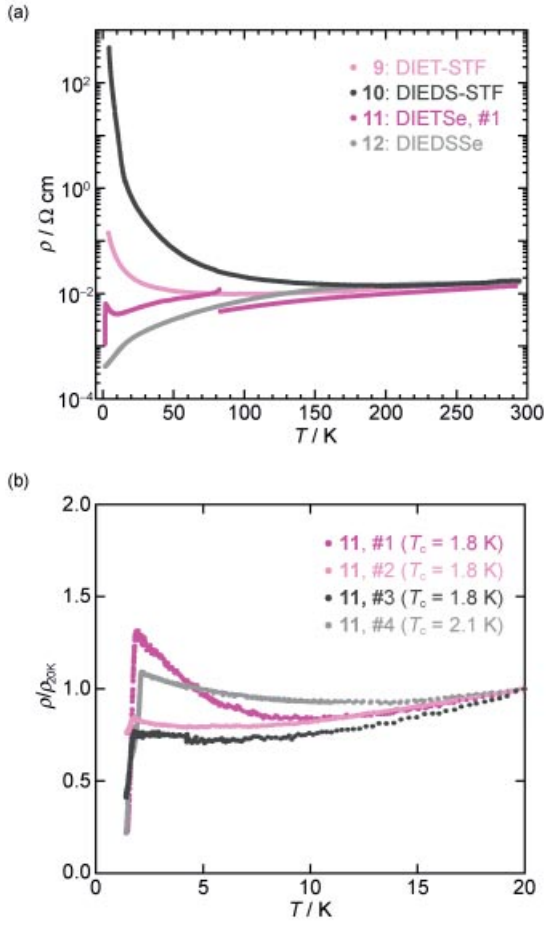

Figure 10. (a) Temperature dependence of the resistivities for **9** (light magenta), **10** (dark grey), **11** (sample 1, dark magenta), and **12** (light grey). (b) Normalized resistivities for **11** in the low-temperature region (samples 1: dark magenta, 2: light magenta, 3: dark grey, 4: light grey).

Figure 11 shows the temperature dependence of the DC magnetizations for the crystals of **11** obtained from Batches A, B, and C, which include samples 1 and 2, 3, and 4, respectively. The onset of the diamagnetic transition occurred at 1.8 K for Batches A and B, and at 1.9 K for Batch C. The higher transition temperature of Batch C is consistent with the resistivity measurement for sample 4. Owing to the very low applied field of 10 Oe and the low $T_c$, absolute values of magnetic susceptibility ($\chi$) and the volume fraction of superconductivity cannot be calculated, however the appearance of the diamagnetic transition is clear evidence for the superconducting transition of the salt **11**. The inset of Figure 11 shows the temperature dependence of the magnetic susceptibility for **11** under an applied field of 50 kOe. Magnetic susceptibility $\chi$ is almost independent of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

temperature above $T_c$ and shows Pauli paramagnetism. It is also confirmed that the jumps of resistivity at 60–100 K are not intrinsic but result from the fragility of the crystals.

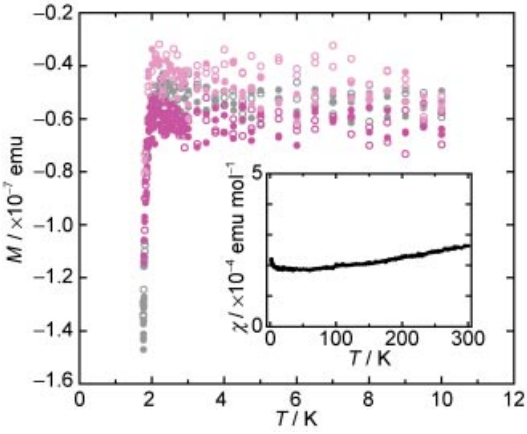

Figure 11. Temperature dependence of ZFC (filled circles) and FC (open circles) DC magnetizations for **11** (raw data). The dark magenta circles are data on Batch A including samples 1 and 2 in Figure 10b, the light magenta circles are data on Batch B including sample 3 in Figure 10b, and the light grey circles are data on Batch C including sample 4 in Figure 10b under an applied field of 10 Oe. The inset shows the temperature dependence of the magnetic susceptibility for **11** under an applied field of 50 kOe.

## Conclusions

We have synthesized five selenium-rich π-donors, DIEDSS, DIET-STF, DIEDS-STF, DIETSe, and DIEDSSe, without the use of $CSe_2$, and the crystal structure and electronic properties of their $Au(CN)_4$ salts were systematically investigated. The chalcogen element of the 4,5-diiodo-1,3-dichalcogenole unit of the donor molecule is essential to the packing motif of the crystals. The $Au(CN)_4$ salt of DIEDSS, which contains the 4,5-diiodo-1,3-dithiole unit, includes a novel helical architecture tailored by two types of the characteristic iodine bond. This salt is also the first example of a highly conductive crystal that has helical architecture based on TTFs. On the other hand, the crystal structure of the $Au(CN)_4$ salts based on donor molecules containing the 4,5-diiodo-1,3-diselenole unit, DIET-STF, DIEDS-STF, DIETSe, and DIEDSSe, is of the so-called β-type. Their conducting behavior strongly depends on the number and positions of the selenium atoms on the donor molecule and varies from semiconductor to superconductor. Among the four β-type crystals, the salt of DIETSe shows superconducting transition at around 2 K (onset), and this is the first ambient pressure organic superconductor based on halogenated TTFs. These results indicate that a combination of supramolecular architecture based on the iodine bond and enhancement of electrical conductivity by sulfur–selenium replacement is a promising method for the stepwise development of new organic superconductors.

## Experimental Section

**General:** All chemicals and solvents were of reagent grade. All reactions were conducted under argon except for the oxidation reactions using $Hg(OAc)_2$. Dehydrated THF and 4,5-ethylenedithio-1,3-dithiole-2-thione (**3**) were purchased from Kanto Chemical Co., Inc. and Tokyo Chemical Industry Co., Ltd., respectively, and used without further purification. A THF solution of LDA was prepared from diisopropylamine with an *n*-hexane solution of *n*BuLi prior to use. Column chromatography was carried out with silica gel (Kanto Chemical Co., Inc., 100–210 μm). Preparative gel permeation chromatography (GPC) was performed on a Japan Analytical Industry Co., Ltd. LC-908W equipped with a JAI-GEL 1H, 2H column assembly. $^1$H NMR spectra were recorded with a JEOL JNM-Excalibur 270 spectrometer. The chemical shifts are given in $\delta$ ppm, downfield from internal $Me_4Si$. Mass spectra were taken in the EI mode with ionization energy of 70 eV, using a Shimadzu QP-5050A quadrupole mass spectrometer. The melting points were determined from the TG-DTA analyses using a SII EXSTAR6000 analyzer. IR spectra were recorded with a Shimadzu FTIR-8100M spectrometer with a PIKE MIRacle diamond ATR. Elemental analyses were performed at the Advanced Development & Supporting Center, RIKEN. Cyclic voltammetry measurements were performed under argon using a BAS ALS-model610A analyzer.

**4,5-Ethylenediseleno-1,3-diselenole-2-thione (1b):** A THF solution of LDA (0.40 M, 2.8 mL, 1.1 mmol) was slowly added to a mixture of 1,3-diselenole-2-thione[5] (102 mg, 0.45 mmol) and 1,2-bis(selenocyanato)ethane[13] (129 mg, 0.54 mmol) in dehydrated THF (100 mL) at –78 °C for a period of 5 min. The reaction mixture was stirred for 1 h at –78 °C, then quenched by addition of $H_2O$/THF (1 mL, v:v = 1:1) and warmed to room temperature. After stirring overnight at room temperature, the resulting reddish brown solution was poured into dichloromethane (100 mL), washed with water (100 mL, three times), dried with $MgSO_4$, and then concentrated under reduced pressure. The residue was subjected to silica-gel column chromatography. The first yellow fraction eluted with $CS_2$/*n*-hexane (4:1) was **1b** (39 mg, 21%) as an ocher powder upon concentration, and the second yellow band gave the recovered 1,3-diselenole-2-thione (44 mg, 43%) as a yellow-brown solid upon concentration. Analytically pure **1b** was obtained by further purification by preparative GPC. M.p. 130 °C. MS (EI, 70 eV): *m*/*z* = 414 [$M^+$ for $C_5H_4S^{78}Se^{80}Se_3$], 370 [$M^+$ – C=S]. $^1$H NMR (270 MHz, $CDCl_3$): $\delta$ = 3.47 (s, 4 H) ppm. IR (neat): $\tilde{\nu}$ = 1001 (s), 1024 (s), 1096 (w), 1130 (w), 1217 (w), 1262 (m), 1395 (m), 1416 (w), 1458 (w), 1509 (w), 1522 (w) cm$^{-1}$. $C_5H_4SSe_4$ (411.99): calcd. C 14.58, H 0.98; found C 14.34, H 0.82.

**4,5-Ethylenediseleno-1,3-diselenol-2-one (1c):** Acetic acid (5 mL) was added to a suspension of **1b** (209 mg, 0.51 mmol) and $Hg(OAc)_2$ (339 mg, 1.06 mmol) in chloroform (25 mL), and the resulting suspension was then stirred for 5 h at room temperature. The resulting yellow-white suspension was filtered through Celite and washed with dichloromethane. The combined filtrate was washed with aqueous $NaHCO_3$ (100 mL, three times) and water (100 mL, twice), dried with $MgSO_4$, and then concentrated under reduced pressure. The residue was subjected to silica-gel column chromatography eluted with dichloromethane and pure **1c** was obtained as a cream powder (179 mg, 89%). The analytical data are identical to the reported data.[12]

**4,5-Ethylenediseleno-1,3-thiaselenol-2-selone (2):** A THF solution of LDA (0.75 M, 1.2 mL, 0.92 mmol) was added to a solution of 1,3-diselenole-2-thione[5] (96 mg, 0.42 mmol) in THF (100 mL) at –78 °C, and the resulting solution was stirred for 1 h at the same temperature. 1,2-Bis(selenocyanato)ethane[13] (157 mg, 0.66 mmol)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was added to this reaction mixture in one portion. After 15 min, the mixture was warmed to room temperature, then the resulting dark red solution was poured into dichloromethane (200 mL), washed with water (100 mL, four times), dried with $MgSO_4$, and then concentrated under reduced pressure. The residue was subjected to silica-gel column chromatography. The first yellow fraction eluted with $CS_2$ was **1b** (6 mg, 3%) as an ocher powder upon concentration, and the second orange band eluted with $CS_2$ gave **2** (35 mg, 20%) as a purplish-brown crystal upon concentration. M.p. 170 °C (dec.). MS (EI, 70 eV): $m/z$ = 414 [$M^+$ for $C_5H_4S^{78}Se^{80}Se_3$]. $^1H$ NMR (270 MHz, $CDCl_3$): $\delta$ = 3.44 (m, 2 H), 3.45 (m, 2 H) ppm. IR (neat): $\tilde{\nu}$ = 922 (s), 939 (m), 1021 (w), 1086 (w), 1136 (w), 1223 (w), 1258 (m), 1402 (m), 1453 (m) $cm^{-1}$. $C_5H_4SSe_4$ (411.99): calcd. C 14.58, H 0.98; found C 14.59, H 0.91.

**2-(5,6-Dihydro[1,3]diselenolo[4,5-*b*][1,4]diselenin-2-ylidene)-4,5-diiodo-1,3-dithiole (DIEDSS):** $P(OEt)_3$ (2.8 mL) was added dropwise over a period of 10 min to a refluxing solution of **6**[3b,8a] (154 mg, 0.40 mmol) and **1c** (128 mg, 0.26 mmol) in toluene (20 mL), followed by stirring under reflux for 30 min. After cooling to room temperature, the solution was evaporated under reduced pressure to eliminate the solvent and excess phosphite. The residue was subjected to silica-gel column chromatography. The second violet fraction eluted with $CS_2$ was collected, and DIEDSS was obtained as orange-brown crystals (114 mg, 48%). M.p. 157 °C (dec.). MS (EI, 70 eV): $m/z$ = 736 [$M^+$ for $C_8H_4I_2S_2{}^{78}Se^{80}Se_3$]. $^1H$ NMR (270 MHz, $CDCl_3$): $\delta$ = 3.37 (s, 4 H) ppm. IR (neat): $\tilde{\nu}$ = 1092 (s), 1136 (m), 1219 (w), 1262 (s), 1399 (m), 1416 (m), 1480 (w), 1507 (w) $cm^{-1}$. $C_8H_4I_2S_2Se_4$ (733.90): calcd. C 13.09, H 0.55; found C 13.14, H 0.53.

**2-(4,5-Diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,3]dithiolo[4,5-*b*]-[1,4]dithiine (DIET-STF):** $P(OEt)_3$ (3.7 mL) was added dropwise over a period of 5 min to a refluxing solution of **7**[5] (100 mg, 0.22 mmol) and **3** (58 mg, 0.26 mmol) in benzene (20 mL), followed by stirring under reflux for 1.5 h. The same procedure as for DIEDSS was adopted for the separation of the products. Evaporation of the second red-orange fraction afforded purplish-brown crystals of DIET-STF (104 mg, 76%). M.p. 175 °C (dec.). MS (EI, 70 eV): $m/z$ = 642 [$M^+$ for $C_8H_4I_2S_4{}^{80}Se_2$]. $^1H$ NMR (270 MHz, $CDCl_3$): $\delta$ = 3.30 (s, 4 H) ppm. IR (neat): $\tilde{\nu}$ = 1125 (s), 1173 (m), 1258 (m), 1283 (s), 1404 (m), 1499 (m), 1509 (m) $cm^{-1}$. $C_8H_4I_2S_4Se_2$ (640.11): calcd. C 15.01, H 0.63; found C 14.96, H 0.53.

**2-(4,5-Diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,4]diselenino[2,3-*d*]-[1,3]dithiole (DIEDS-STF):** $P(OEt)_3$ (3.7 mL) was added dropwise over a period of 3 min to a refluxing solution of **7**[5] (100 mg, 0.22 mmol) and **4**[18] (82 mg, 0.26 mmol) in benzene (20 mL), followed by stirring under reflux for 3 h. The same procedure as for DIEDSS was adopted for the separation of the products. Evaporation of the second red-orange fraction afforded orange-brown crystals of DIEDS-STF (112 mg, 71%). M.p. 154 °C (dec.). MS (EI, 70 eV): $m/z$ = 736 [$M^+$ for $C_8H_4I_2S_2{}^{78}Se^{80}Se_3$]. $^1H$ NMR (270 MHz, $CDCl_3$): $\delta$ = 3.35 (s, 4 H) ppm. IR (neat): $\tilde{\nu}$ = 1088 (m), 1132 (m), 1217 (m), 1223 (m), 1260 (s), 1399 (s), 1416 (m), 1480 (w), 1507 (w) $cm^{-1}$. $C_8H_4I_2S_2Se_4$ (733.90): calcd. C 13.09, H 0.55; found C 13.16, H 0.50.

**2-(4,5-Diiodo-1,3-diselenol-2-ylidene)-5,6-dihydro[1,3]diselenolo[4,5-*b*]-[1,4]diselenine (DIEDSSe):** $P(OEt)_3$ (3.0 mL) was added dropwise over a period of 3 min to a refluxing solution of **7**[5] (58 mg, 0.12 mmol) and **1b** (63 mg, 0.15 mmol) in toluene (10 mL), followed by stirring under reflux for 80 min. The same procedure as for DIEDSS was adopted for the separation of the products except for the eluent of the silica-gel column chromatography [$CS_2$/*n*-hexane (9:1)]. Evaporation of the second orange fraction afforded orange-red crystals of DIEDSSe (22 mg, 21%). M.p. 167 °C (dec.). MS (EI, 70 eV): $m/z$ = 830 [$M^+$ for $C_8H_4I_2{}^{78}Se_2{}^{80}Se_4$]. $^1H$ NMR (270 MHz, $CDCl_3$): $\delta$ = 3.38 (s, 4 H) ppm. IR (neat): $\tilde{\nu}$ = 1092 (m), 1132 (m), 1223 (m), 1260 (s), 1399 (s), 1416 (m), 1507 (w) $cm^{-1}$. $C_8H_4I_2Se_6$ (827.69): calcd. C 11.61, H 0.49; found C 11.71, H 0.44.

**Crystal Preparation:** Single crystals of the salts **8**–**12** were prepared by the electrochemical oxidation (4–6 d) of a $CH_2Cl_2$ (20 mL) solution containing the corresponding donor molecule (3–6 mg) and $nBu_4NAu(CN)_4$ as a supporting electrolyte (15–39 mg). Platinum electrodes (1.0 mm diameter wire or $1.0 \times 2.0$ $mm^2$ rectangular pillar-shaped) and standard H-shaped cells were employed, and a constant current of 0.5 μA was applied at 20 °C for **8**, **10**–**12** and at 5 °C for **9**. Details of the conditions of Batch A for **11** are as follows: DIETSe (6 mg, 6.8 μmol) and $nBu_4NAu(CN)_4$ (39 mg, 72 μmol) in a standard H-shaped cell were dissolved by $CH_2Cl_2$ (50 mL) and a small amount of remaining crystals of DIETSe were placed at the side of the anode. Black elongated plate-like crystals (typical size: $0.40 \times 0.06 \times 0.01$ $mm^3$) grew on the platinum rectangular pillar-shaped electrode under an applied current of 0.5 μA at 20 °C after 5 d.

**Crystal Structure Analysis:** The diffraction data were collected with a Bruker AXS SMART-APEX CCD system with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) (Table 2). Raw frame data were integrated using SAINT[19] and face-indexed absorption corrections[20] were applied. The structures were solved by the direct method (SHELXS-97[21]) and refined by full-matrix least-squares on $F^2$ with the program package SHELXTL.[22]

CCDC-642673 (for **8**), -642674 (for **9**), -642670 (for **10**), -642671 (for **11**), and -642672 (for **12**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Electronic Band Calculations:** Intermolecular overlap integrals were calculated using HOMOs of the donor molecules obtained by the extended Hückel MO calculations using semiempirical parameters for the s and p Slater-type atomic orbitals listed in Table 4. The electronic band dispersions and Fermi surfaces were calculated using the intermolecular overlap integrals under the tight-binding approximation.[16]

Table 4. Semiempirical parameters for Slater-type orbitals.

| Orbitals | $\zeta$ | $I_P$/Ryd |
|---|---|---|
| I 5s | 2.681 | –1.713 |
| I 5p | 2.322 | –0.809 |
| Se 4s | 2.44 | –1.40 |
| Se 4p | 2.07 | –0.74 |
| S 3s | 2.122 | –1.47 |
| S 3p | 1.827 | –0.79 |
| C 2s | 1.625 | –1.573 |
| C 2p | 1.625 | –0.838 |
| H 1s | 1.30 | –1.0 |

**Electrical Resistivity:** The electrical resistivities were measured using the standard four-probe method in the temperature range of 1.6–300 K. Gold wires (10 or 18 μm) were attached to a single crystal using carbon paste, and silver paste was used for wiring the sample to the measurement substrate.

**Magnetic Susceptibility:** The magnetic properties for **11** were measured with a Quantum Design SQUID magnetometer (MPMS-XL5) for randomly oriented samples operating in the temperature range of 1.8–300 K with a DC magnetic field of 10 Oe or 50 kOe.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The absolute value of molar magnetic susceptibility $\chi$ cannot be calculated because of the low applied field of 10 Oe and the discussions of the diamagnetic transition are based on raw data of the magnetization without subtraction of the diamagnetism of the sample holder, DIETSe, and $Au(CN)_4$ anion. The absolute value of $\chi$ is obtained by the measurement under the field of 50 kOe. The diamagnetism of the sample holder and DIETSe were obtained from blank experiments under the same conditions as those for the sample measurements. The diamagnetic core susceptibility of the $Au(CN)_4$ anion was evaluated with Pascal's table.

# Water-Soluble Phenanthroline Complexes of Rhodium, Iridium and Ruthenium for the Regeneration of NADH in the Enzymatic Reduction of Ketones

Jérôme Canivet,[a] Georg Süss-Fink,*[a] and Petr Štěpnička[b]

**Keywords:** Cationic complexes / Cofactor regeneration / Chemoenzymatic catalysis / Enantioselective catalysis / Transfer hydrogenation

The nicotinamide coenzyme NADH, consumed in enantioselective reduction of ketones catalysed by alcohol dehydrogenases, needs to be regenerated in order to maintain enzymatic activity. We therefore studied the catalytic potential of the cationic complexes $[(\eta^5\text{-}C_5Me_5)Rh(N\cap N)Cl]^+$ (**1**: N∩N = 1,10-phenanthroline; **2**: N∩N = 5-nitro-1,10-phenanthroline; **3**: N∩N = 5-amino-1,10-phenanthroline), $[(\eta^5\text{-}C_5Me_5)Ir(N\cap N)Cl]^+$ (**4**: N∩N = 5-nitro-1,10-phenanthroline) and $[(\eta^6\text{-}C_6Me_6)Ru(N\cap N)Cl]^+$ (**5**: N∩N = 5-nitro-1,10-phenanthroline), isolated as the water-soluble chloride salts, for transfer hydrogenation of $NAD^+$ to give NADH in aqueous solution. The best results were obtained with rhodium complex **1**, which gave catalytic turnover frequencies up to 2000 $h^{-1}$ in aqueous solution at pH 7 and 60 °C with sodium formate as the hydrogen source. When this NADH-regenerating catalytic system is combined with NADH-dependent enzymes, it is possible to chemoenzymatically reduce prochiral ketones such as acetophenone or 4-phenylbutan-2-one with high enantioselectivity. Combination of horse liver alcohol dehydrogenase (HLADH) or alcohol dehydrogenase from *Rhodococcus sp.* (S-ADH) with **1**/formate as the NADH-regenerating system resulted in *ee* values up to 98%, depending on the nature of the substrate and the enzyme. In order to explain the different catalytic activities, the electrochemical behaviour of complexes **1**–**5** has been studied.

## Introduction

There is an increasing demand for enantiopure biologically active compounds and their precursors.[1] The transition-metal-based enantioselective hydrogenation or transfer hydrogenation of ketones in organic solvents[2–10] as well as in aqueous solutions[11–21] is one of the most commonly used synthetic approaches. Biotransformations of organic substrates by various enzymes have also found widespread applications, particularly because of their capability to efficiently perform enantioselective transformations. The use of redox enzymes for synthetic purposes, however, has been limited by the need of cofactor regeneration.[22] Therefore, practical methods for the regeneration of coenzyme 1,4-NADH, the reduced form of nicotinamide adenine dinucleotide ($NAD^+$), are still of significant importance in the field of biocatalysis.

Conversion of $NAD^+$ to NADH by enzymatic,[23–26] photo- or electrochemical[27–29] methods has been extensively studied in order to increase the rate of cofactor regeneration while maintaining the necessary 1,4-dihydro regioselectivity. More than ten years ago Steckhan et al. introduced the dicationic (aqua)(bipyridine)rhodium complex $[(\eta^5\text{-}C_5Me_5)Rh(bipy)(OH_2)]^{2+}$ as a catalyst for the regeneration of NADH by using the formate anion as the hydrogen source in aqueous solution.[30,31] In a pioneering paper, Fishpp et al. extensively studied kinetic and mechanistic details of regioselective catalytic reduction by using a variety of 3-pyridinium $NAD^+$ models in the presence of $[(\eta^5\text{-}C_5Me_5)Rh(bipy)(OH_2)]^{2+}$.[32–35] This NADH-regenerating catalytic system was applied to the coupled chemoenzymatic enantioselective transfer hydrogenation of ketones in aqueous solution by combining NADH regeneration by an organorhodium complex and enantioselective ketone reduction performed by an alcohol dehydrogenase (ADH). Steckhan et al. described the transfer hydrogenation of 4-phenylbutan-2-one to the corresponding alcohol using ADH from horse liver with enantiomeric excesses up to 96%.[22] More recently, Schmid et al. reported a system based on ADH from *Thermus sp.* coupled with $[(\eta^5\text{-}C_5Me_5)Rh(bipy)(OH_2)]^{2+}$-promoted regeneration of NADH, which allowed the reduction of 3-methylcyclohexanone with an enantiomeric excess up to 97%.[1]

In this paper we report a series of water-soluble rhodium, iridium and ruthenium complexes containing 1,10-phenanthroline or its 5-substituted analogues as chelating *N*,*N*-donor ligands and the catalytic potential of these complexes for the regeneration of NADH in the chemoenzymatic re-

duction of ketones. The electrochemical behaviour of the complexes is also discussed.

## Results and Discussion

### Synthesis of Phenanthroline Complexes

Complexes $[(\eta^5\text{-}C_5Me_5)MCl_2]_2$ (M = Rh, Ir) react at room temperature in dichloromethane solution with 1,10-phenanthroline (phen) or with its 5-nitro or 5-amino derivatives to afford quantitatively the cationic complexes $[(\eta^5\text{-}C_5Me_5)M(N\cap N)Cl]^+$ (**1**: M = Rh, N∩N = phen; **2**: M = Rh, N∩N = 5-$NO_2$-phen; **3**: M = Rh, N∩N = 5-$NH_2$-phen; and **4**: M = Ir, N∩N = 5-$NO_2$-phen) [Equation (1)]. These cations are easily isolated as their chloride salts.

$$\tfrac{1}{2}[(\eta^5\text{-}C_5Me_5)MCl_2]_2 + N\cap N \rightarrow [(\eta^5\text{-}C_5Me_5)Rh(N\cap N)Cl]^+ + Cl^- \quad (1)$$

The chloride salts of **1**–**4** are yellow-orange solids that have a high solubility in water, a property that is used to remove unreacted starting material after the synthesis. As there is a risk of slow hydrolysis in water, the aqueous solutions are immediately filtered, and the filtrates are concentrated to dryness to give the analytically pure salts [**1**–**4**]Cl. All compounds have been characterised by $^1H$ and $^{13}C$ NMR spectroscopy, mass spectroscopy and elemental analysis.

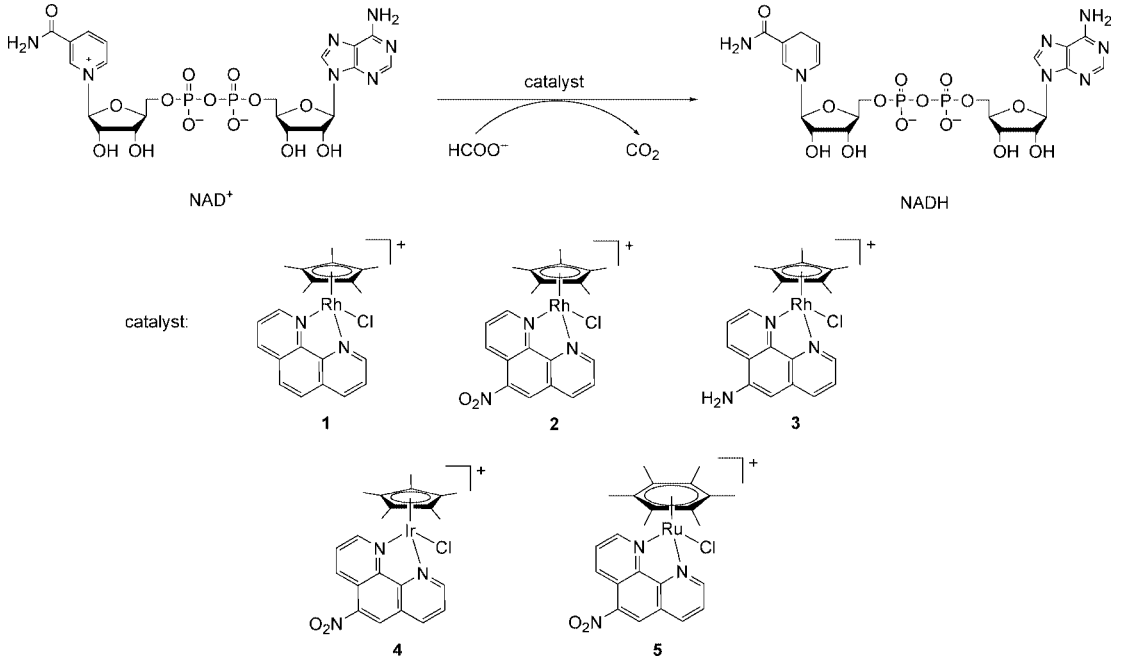
In all cases, the phenanthroline ligand is coordinated in the *N*,*N*-chelating fashion to the metal centre. In contrast to the known, symmetrical 1,10-phenanthroline complex **1**,[36] the new 5-nitro- and 5-amino-1,10-phenanthroline cations **2**, **3** and **4** are chiral, and compounds [**2**]Cl, [**3**]Cl and [**4**]Cl are produced as racemic mixtures.

### Catalytic Reduction of $NAD^+$ to NADH in Aqueous Solution

Inspired by the pioneering studies of Steckhan[30] and Fish[33] on the use of ($\eta^5$-cyclopentadienyl)rhodium bipyridine complexes as catalysts for the regioselective reduction of $NAD^+$ models with the formate anion as the hydrogen source in aqueous solution, we studied this reaction catalysed by cations **1**–**4** as well as by the previously described complex $[(\eta^6\text{-}C_6Me_6)Ru(5\text{-}NO_2\text{-phen})Cl]^+$ (**5**),[37] which is known to be active for the reduction of ketones in water (Scheme 1).

Cations **1**–**5** were found to promote the reduction of $NAD^+$ to NADH in aqueous solution with sodium formate as the hydrogen donor (Table 1). The best results were obtained with rhodium complexes **1**–**3**, which led to TOFs ranging from 1500 to 2000 $h^{-1}$ at 60 °C and pH = 7. In comparison with the analogous bipy complex $[(\eta^5\text{-}C_5Me_5)Rh(bipy)Cl]^+$ (TOF = 875 $h^{-1}$), commonly used as a catalyst for this reaction, phen analogue **1** is more than twice as active (TOF = 2000 $h^{-1}$) under the same conditions.

Ruthenium complex **5** shows a catalytic activity fifteen times lower than that observed with the related rhodium complex **2** (entries 6 and 21). The low activity of the ruthenium complex observed in this study is similar to the results recently published by Sadler et al. describing the use of (arene)(ethylenediamine)ruthenium complexes for the reduction of $NAD^+$ to NADH in aqueous solution at 37 °C



Scheme 1. Transfer hydrogenation of $NAD^+$ to NADH in aqueous solution catalysed by cationic chlorido complexes **1** to **5** by using the formate anion as the hydrogen source.

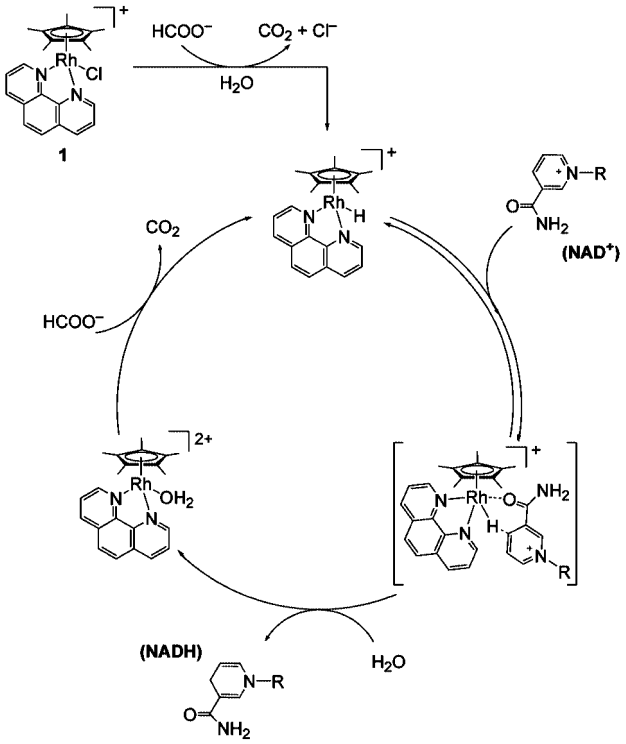
[a] Conditions: [$NAD^+$] = 8 mM, [$NaHCO_2$] = 350 mM; reactions carried out in 1 mL of phosphate buffer (pH 7). [b] Mol of substrate per mol of catalyst. [c] Determined by UV-absorption at 340 nm. [d] Turnover frequencies determined after 30 minutes and expressed in mol of product/(mol of metal·h). [e] Reactions carried out in phthalate buffer.



Scheme 2. Postulated catalytic cycle, based on the work of Fish, for the reduction of $NAD^+$ to NADH in aqueous solution with **1** as the catalyst.

and pH = 7.2.[38] Iridium complex **4** is also two times less active than the rhodium analogue **2** under the same conditions (entries 6 and 16). The results with varied pH demonstrate that the catalytic activity does not show any significant pH dependence.

According to the mechanistic scheme proposed by Fish et al. for the analogous bipy complexes,[33] cationic complex **1** is supposed to react with the formate anion to afford the corresponding hydrido complex, which can reduce $NAD^+$ to NADH (Scheme 2). The postulated catalytic cycle involves a transition state for hydride transfer from the rhodium centre to the pyridinium group, in which the $NAD^+$ and the metal hydride form a kinetically stable six-membered ring.

## Electrochemical Behaviour of the Phenanthroline Complexes

The electrochemical behaviour of complexes **1**–**4** has been studied by cyclic voltammetry at a stationary platinum disc and by voltammetry at a rotating platinum disc electrode (RDE) by using acetonitrile solutions (analyte concentration: ca. $5 \times 10^{-4}$ M) containing $Bu_4N[PF_6]$ (0.1 M) as the supporting electrolyte. Relevant data together with the parameters for the related Ru complexes[39] are summarised in Table 2.[40]

The redox response of phenanthroline complex **1** is shown in Figure 1. The first reduction occurs as a two-electron irreversible process (up to 500 $mV\,s^{-1}$), which is, however, fast and diffusion controlled ($i_{pa} \propto v^{1/2}$, $i_{lim} \propto \omega^{1/2}$). The associated oxidative peak (B) retains the diffusion control ($i_p \propto v^{1/2}$) but shows a peak current lower than that of the corresponding reduction wave (A). Such behaviour parallels that of the related cations $[L_nMCl(bipy)]^+$ [$L_nM$ = $(\eta^5\text{-}C_5Me_5)Rh$, $(\eta^5\text{-}C_5Me_5)Ir$ and $(\eta^6\text{-arene})Ru$; bipy =

Table 2. Summary of the electrochemical data.[a]

| Compound | $E_p$[V] | Reference |
|---|---|---|
| $[(\eta^5\text{-}C_5Me_5)RhCl(phen)]^+$ (**1**) | –1.32 (A), –1.10 (B), ≈ +0.64 (C) | this work |
| $[(\eta^5\text{-}C_5Me_5)RhCl(5\text{-}NO_2\text{-}phen)]^+$ (**2**) | –1.01/–0.93 ($NO_2$),[b] –1.43 (A), ≈ +0.64 (C) | this work |
| $[(\eta^5\text{-}C_5Me_5)RhCl(5\text{-}NH_2\text{-}phen)]^+$ (**3**) | –1.28 (A), –1.16 (B) | this work |
| $[(\eta^5\text{-}C_5Me_5)IrCl(phen)]^+$ (**4**) | –0.99 (A), –0.90 (B), ≈ +0.64 (C) | this work |
| $[(\eta^6\text{-}C_6Me_6)RuCl(phen)]^+$ (**5**) | –1.59 (A) | [39] |
| $[(\eta^6\text{-}C_6Me_6)RuCl(5\text{-}NO_2\text{-}phen)]^+$ | –0.99 ($E^{\circ\prime}$ for $NO_2$) | [39] |
| $[(\eta^6\text{-}C_6Me_6)RuCl(5\text{-}NH_2\text{-}phen)]^+$ | –1.58 (A) | [39] |

[a] The potentials are given relative to the ferrocene/ferrocenium reference (see the Experimental Section for details). Peak potentials for irreversible processes were obtained at a scan rate of 100 mV s$^{-1}$. Definitions: $E^{\circ\prime} = \frac{1}{2}(E_{pa} + E_{pc})$, $\Delta E_p = E_{pa} - E_{pc}$. [b] $E_{pc}/E_{pa}$ for the reversible reduction of the nitro group.

2,2′-bipyridine] and $[(\eta^5\text{-}C_5Me_5)MCl(bpym)]^+$ (M = Rh and Ir; bipym = 2,2′-bipyrimidine)[41–43] and can be explained by reductive removal of the chlorido ligand as shown in Equation (2).

$$[(\eta^5\text{-}C_5Me_5)M(phen)Cl]^+ + 2e^- \rightarrow [(\eta^5\text{-}C_5Me_5)M(phen)] + Cl^- \quad (2)$$

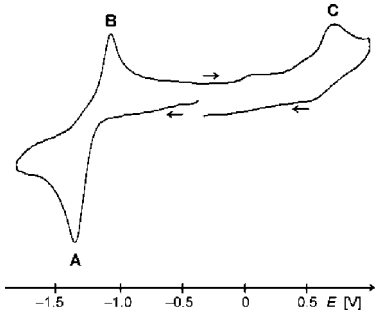

Figure 1. Cyclic voltammogram of **1** as recorded at a platinum disc electrode in acetonitrile solution at 100 mV s$^{-1}$ scan rate. The potentials are given relative to the ferrocene/ferrocenium reference.

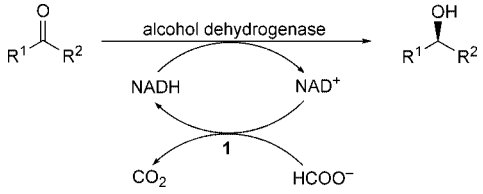
The neutral electrogenerated species $[(\eta^5\text{-}C_5Me_5)M(phen)]$ is probably rather unstable and becomes oxidised in a single step, giving rise to wave B. A broad wave (C), observed in the anodic region, can be attributed to oxidation of some decomposition product(s). However, the exact nature of this redox process remains unclear.

The presence of an amino group at the phenanthroline ligand in **3** has only a minor influence on the electrochemical behaviour, manifested mainly by a slight shift of the A and B waves to higher potentials and also by a diminished A–B separation. On the contrary, substitution with a nitro group markedly changes the redox response, as the nitro group is reduced first in a reversible, one-electron process ($–NO_2 + e^- \rightleftarrows –NO_2^{-\cdot}$), the potential of which is independent of the metal (Rh vs. Ir). Such an "inserted" redox step naturally influences the following one(s).

In the case of **2**, the metal-centred reduction occurs at –1.44 V (wave A), while for **5** only a broad wave at around –1.6 V could be detected. The associated counterwave (if any) is difficult to detect. This could explain the higher activity of rhodium catalyst **2** as compared with that found for ruthenium catalyst **5** in the reduction of $NAD^+$ to NADH described above, the more difficult-to-reduce species being less catalytically active.

## Chemoenzymatic Enantioselective Reduction of Ketones

In light of the findings by Steckhan[22] and Schmid[1] on organometallic NADH regeneration for enzymatic ketone reductions, we studied the chemoenzymatic enantioselective transfer hydrogenation of 4-phenylbutan-2-one and acetophenone in aqueous solution. We used the NADH-dependent enzymes horse liver alcohol dehydrogenase (HLADH) or alcohol dehydrogenase from *Rhodococcus sp.* (S-ADH) and **1** as the NADH-regenerating catalyst with the formate anion as the hydrogen source (Scheme 3).



Scheme 3. Organometallic NADH regeneration for the stereoselective reduction of ketones with alcohol dehydrogenase.

The NADH-regenerating catalytic system with **1** as the catalyst was found to be active in combination with the two enzymes used (HLADH and S-ADH) for the enantioselective reduction of the test substrates (Table 3). The reaction proceeds with good to excellent enantioselectivity, producing predominantly the *S* enantiomer.

The results show the enantioselectivities to be similar to those found without the organometallic NADH regeneration catalyst with *ee* values up to 92 and 98%. However, the enzymatic activity with NADH regeneration is somewhat lower relative to enzymatic ketone reduction with excess NADH. This could be explained by a deactivation of the organometallic catalyst during the reaction, probably due to coordination of functional enzyme groups to the rhodium centre.

The mechanistic aspects of the combined organometallic–enzymatic catalysis are summarised in Scheme 4, which is a combination of Scheme 2 and Scheme 3. The organometallic intermediates $[(\eta^5\text{-}C_5Me_5)Rh(phenanthroline)H]^+$ and $[(\eta^5\text{-}C_5Me_5)Rh(phenanthroline)(OH_2)]^{2+}$ work hand-in-hand with the coenzyme intermediates $NAD^+$ and NADH to perform the enantioselective reduction of a ketone to give the corresponding alcohol, with aqueous sodium formate as hydrogen source and a dehydrogenase enzyme as chiral inducer.

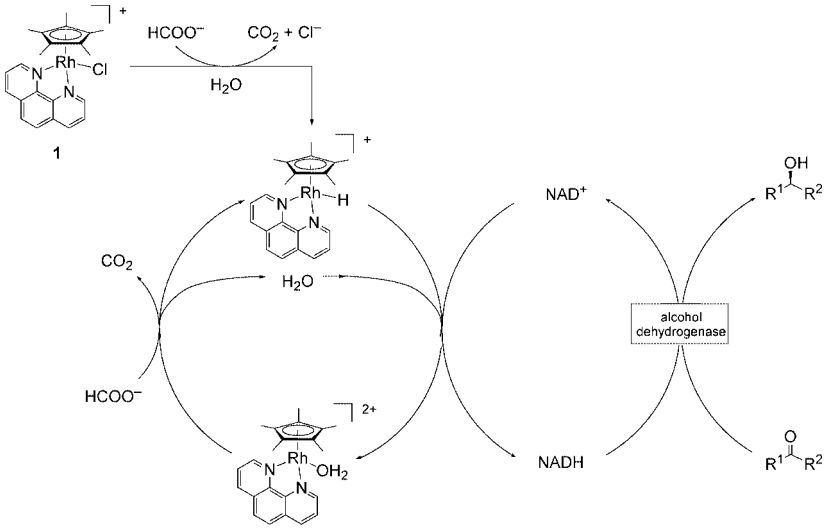
[a] Conditions: [$NAD^+$] = 1 mM, [$NaHCO_2$] = 100 mM, [ketone] = 33 mM, reactions carried out with 1 unit of alcohol dehydrogenase in 1 mL of phosphate buffer (pH 7) at 37 °C. [b] Determined by chiral HPLC analysis. [c] Conditions: [NADH] = 40 mM, [$NaHCO_2$] = 100 mM, [ketone] = 33 mM, reactions carried out with 1 unit of alcohol dehydrogenase in 1 mL of phosphate buffer (pH 7) at 37 °C. [d] Reaction carried out without HLADH or S-ADH and $NAD^+$.



Scheme 4. Catalytic cycle for the chemoenzymatic enantioselective transfer hydrogenation of ketones with **1** as NADH regenerating catalyst in aqueous solution.

## Conclusions

In conclusion, we report here a series of five water-soluble rhodium, iridium and ruthenium complexes containing 1,10-phenanthroline and derivatives thereof as chelating ligands. All these complexes were found to catalyse the 1,4-regioselective reduction of $NAD^+$ to NADH in aqueous solution. TOF values up to 2000 $h^{-1}$ have been obtained by using [($\eta^5$-$C_5Me_5$)Rh(phen)Cl]$^+$ (**1**) as a catalyst at 60 °C and pH = 7. Furthermore, rhodium catalyst **1** has been found to be active as an NADH-regenerating catalyst for the chemoenzymatic enantioselective transfer hydrogenation of ketones in aqueous solution. Under biological conditions (37 °C, pH = 7), this system, which combines organometallic NADH regeneration and enzymatic reduction in aqueous solution, converts ketones into the corresponding chiral alcohols with good activities and enantioselectivities.

## Experimental Section

**General:** All manipulations were carried out with freshly distilled solvents. The 5-amino-1,10-phenanthroline[44] and [($\eta^6$-$C_6Me_6$)-Ru(5-$NO_2$-phen)Cl]$^+$ (**5**)[37] were prepared according to the published methods. All other reagents were commercially available and were used without further purification. NMR spectra were recorded with a Bruker 400 MHz spectrometer by using sodium 2,2-dimethyl-2-silapentane-5-sulfonate in $D_2O$ as an internal standard. Electrospray mass spectra were obtained in the positive-ion mode with an LCQ Finnigan mass spectrometer. Microanalyses were carried out by the Laboratoire de Chimie Pharmaceutique, Université de Genève (Switzerland).

Electrochemical measurements were carried out with a multipurpose polarograph PA3 interfaced to a Model 4103 XY recorder (Laboratorní přístroje, Prague) at room temperature by using a standard three-electrode cell with a rotating platinum disc electrode (RDE; 1 mm diameter) as the working electrode, platinum wire as

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the auxiliary electrode and a saturated calomel electrode (SCE) as the reference electrode. The reference electrode was separated from the analysed solution by a salt bridge (0.1 M $Bu_4N[PF_6]$ in acetonitrile). The samples were dissolved in acetonitrile (Riedel-de Haën, purissimum p.a.), to give an analyte concentration of $5 \times 10^{-4}$ M, and in 0.1 M $Bu_4N[PF_6]$ (Fluka, purissimum for electrochemistry). The solutions were purged with argon prior to the measurement and then kept under an argon blanket. Cyclic voltammograms were recorded at a stationary platinum disc electrode (scan rates 50–500 mV/s), while the voltammograms were obtained at a RDE (1000–2500 rpm, scan rate 20 mV/s). The redox potentials are given relative to the ferrocene/ferrocenium reference.

**Preparation of Chlorido Complexes $[(\eta^5\text{-}C_5Me_5)M(N\cap N)Cl]^+$ (M = Rh, Ir and N∩N = phen, 5-$NO_2$-phen, 5-$NH_2$-phen):** Two equivalents (0.30 mmol) of the appropriate phenanthroline donor were added to a suspension of $[(\eta^5\text{-}C_5Me_5)MCl_2]_2$ (M = Rh, Ir; 0.15 mmol) in dichloromethane (30 mL). The mixture was stirred for 3 h at room temperature, while the colour changed from dark orange to yellow-orange. After concentration to dryness, the residue was dissolved in water. This solution was filtered, and the filtrate was concentrated to dryness, which gave the product as a yellow powder in good yield.

**Catalytic NADH Regeneration:** The reduction of $NAD^+$ (8 mM) catalysed by complexes [**1**–**5**]Cl with sodium formate (350 mM) as the hydrogen source was carried out in phosphate buffer (1 mL, pH 7) or in phthalate buffer (1 mL, pH 4). The conversion was determined by UV absorption at 340 nm. The pH was monitored with a pH meter (Mettler Toledo InLab® 413). Turnover frequencies were calculated for all the catalytic reactions from the conversions observed after 30 min for the hydrogenation reaction of $NAD^+$ to NADH. The results are summarised in Table 1.

**Chemoenzymatic Hydrogenation of Ketones:** The enzymatic transfer hydrogenation reactions of acetophenone or 4-phenylbutan-2-one (33 mM) were carried out in phosphate buffer (1 mL, pH 7) at 37 °C with 1 unit of alcohol dehydrogenase S-ADH or HLADH respectively, in the presence of $NAD^+$ (1 mM) and [**1**]Cl as NADH-regenerating catalyst and $NaHCO_2$ (100 mM) as the hydrogen source. The reactions without rhodium catalyst were performed with NADH instead of $NAD^+$ (40 mM), and the reactions without enzymatic reduction were performed without enzyme and $NAD^+$. The products were extracted with diethyl ether, filtered through silica and identified (and conversion and enantiomeric excess were determined) by HPLC on a Chiracel OD-H capillary column (hexane/2-propanol 9:10, 0.7 mL min$^{-1}$, 215 nm). The pH was monitored with a pH meter (Mettler Toledo InLab® 413).

# Copper Bis(1-methyl-5-nitriminotetrazolate): A Promising New Primary Explosive

**Georg Geisberger,[a] Thomas M. Klapötke,*[a] and Jörg Stierstorfer[a]**

**Keywords:** Primary explosives / Copper / Nitrogen heterocycles / Pyrotechnics / X-ray

Copper bis(1-methyl-5-nitriminotetrazolate) (**1**) was synthesized and investigated as a new primary explosive. Compound **1** was obtained by dehydration of diaquabis(1-methylnitriminotetrazolato)copper(II) dihydrate (**2**) or diaquabis(1-methylnitriminotetrazolato)copper(II) (**3**) at 120 °C. Complexes **2** and **3** are easily formed by the reaction of 1-methyl-5-nitrimino-1,2,3,4-tetrazole (**4**) with copper(II) nitrate in aqueous solution in high yields. Single crystals of **1** were obtained by recrystallization from dry methanol, whereas wet methanol favors the yield of diaquabis(1-methyl-nitriminotetrazolato)copper(II) dimethanolate (**5**). Compound **1** was characterized by using single-crystal X-ray diffraction, IR spectroscopy, elemental analysis, and differential scanning calorimetry (DSC). The sensitivities were investigated by using the BAM drophammer and friction tests, and the heat of formation was calculated on the basis of electronic energies at the B3LYP/SDD level of theory. Compound **1** shows an impact sensitivity that is five times higher and a friction sensitivity that is ten times lower than that of lead azide, which is appropriate. In addition, the long-term stability of **1** at higher temperatures was tested by using isothermal safety calorimetry (TSC). Compounds **2** and **3** were characterized by single-crystal X-ray diffraction, IR spectroscopy, elemental analysis, DSC, bomb calorimetry, and BAM sensitivity tests. In addition, compound **5** was characterized by single-crystal X-ray diffraction and elemental analysis. The dehydration of **2** was determined by using thermal gravimetry (TG) to occur by the loss of crystal water in one discrete step.

## Introduction

Commonly used primary explosives[1,2] still include poisonous and polluting compounds (illustrated in Figure 1) like lead azide $[Pb(N_3)_2]$,[3–5] and lead styphnate (2,4,6-trinitroresorcinate),[6] which replaced mercury fulminate $[Hg(CNO)_2]$[7] early in the last century. Primary explosives are highly sensitive and are characterized by detonation velocities of 3500–5500 $ms^{-1}$. The discovery of suitable new substitutes for lead-containing primary explosives is an important aspect of current energetic materials research. Primary explosives consisting only of C, N, and H such as tetrazene,[8] which is used as a sensitizer, exist but are often difficult to synthesize.

A recently employed idea is the formation of nontoxic metal complexes containing zinc or copper instead of toxic heavy metals.[9] Because several tetrazoles[10,11] and tetrazolates[12,13] are known to be promising energetic compounds[14] with appropriate properties such as high densities, a positive heat of formation, and a high nitrogen content, one possible alternative for the development of new primary explosives is the use of copper tetrazole complexes.[15–17]

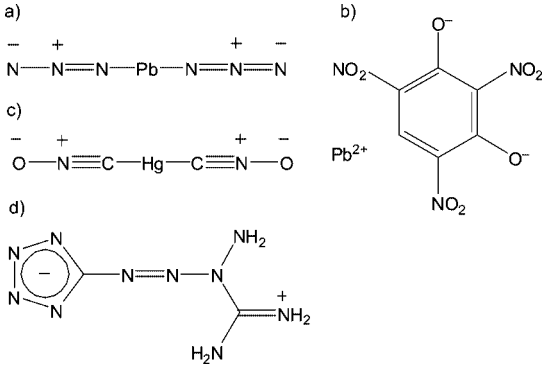

Figure 1. Common primary explosives: (a) lead azide, (b) lead styphnate, (c) mercury fulminate, and (d) tetrazene.

Copper tetrazole complexes are also suitable materials for modern pyrotechnical compositions. Common pyrotechnic compositions are nonexplosive combustible mixtures consisting of fuels and oxidizers, which generate bright-colored light, heat, or acoustic effects.[18] High-nitrogen materials have been investigated for use in pyrotechnic compositions in order to reduce smoke production.[19] A low-smoke pyrotechnic composition should include a nitrogen-rich energetic material (e.g. tetrazoles) with a low carbon content, an oxidizer, and a colorant. Copper(II) 1-

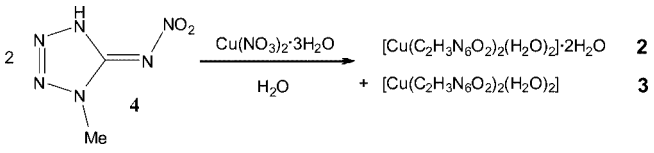
methyl-5-nitriminotetrazolates **2** and **3** are suitable new compounds for use as green-coloring pyrotechnic materials acting as substitutes for toxic barium salts.

## Results and Discussion

### Synthesis

The copper complexes $[Cu(C_2H_3N_6O_2)_2(H_2O)_2]\cdot 2H_2O$ (**2**) and $[Cu(C_2H_3N_6O_2)_2(H_2O)_2]$ (**3**) were synthesized according to Scheme 1 by the addition of an aqueous solution of copper nitrate trihydrate to an aqueous solution containing two equivalents of 1-methyl-5-nitriminotetrazole (**4**)[20] at 80 °C. Compound **2** was observed as the main product (85% yield), whereas **3** was obtained when the mother liquor was allowed to stand for a few days. Compound **4** was synthesized by the nitration of 1-methyl-5-aminotetrazole[21,22] by using fuming $HNO_3$.



Scheme 1. Synthesis of compounds **2** and **3**.

The highly explosive $[Cu(C_2H_3N_6O_2)_2]$ (**1**), which does not contain crystal water, was obtained by dehydration of **2** by using high vacuum ($1 \times 10^{-2}$ bar) at 120 °C for two hours (Scheme 2). To remove the four water molecules, heating to 120 °C is sufficient but it requires twice the time. Single crystals of **1** were obtained by recrystallization of **1** from dry methanol, whereas recrystallization from wet methanol led to the formation of crystals of compound **5**, which contains two coordinated water molecules and two free methanol molecules.

Scheme 2. Synthesis of **1** by dehydration of **2** or **3**.

### Molecular Structures

The single-crystal X-ray diffraction data were collected with an Oxford Xcalibur3 diffractometer with a Spellman generator (voltage 50 kV, current 40 mA) and a KappaCCD detector. Data collection was undertaken by using the CrysAlis CCD software,[23] and the data reductions were performed with the CrysAlis RED software.[24] The structures were solved by using SIR-92[25] and refined with SHELXL-97[26] and finally checked with PLATON.[27] In the structures, the hydrogen atoms were located and refined. The absorptions of **1**, **2**, **3**, and **5** were corrected by using the SCALE3 ABSPACK multiscan method.[28] Selected data from the X-ray data collections and refinements are given in Table 3. Further information regarding crystal structure determination was deposited with the Cambridge Crystallographic Data Centre.[29]

Primary explosive **1** crystallizes in the monoclinic space group $P2_1/c$ with 2 molecules in the unit cell and a density of 2.067 g cm$^{-3}$. The copper cations lay on the center of inversion and are coordinated in a distorted octahedral arrangement by two nitrogen atoms [$d$(Cu–N4) = 1.923(2) Å], which is also found in copper nitrogen complexes such as $[Cu(NH_3)_4(NO_3)_2]$,[30] and four oxygen atoms [$d$(Cu–O1) = 1.974(2) Å, $d$(Cu–O4$^i$) = 2.589(2) Å (i: 2 –$x$, –0.5 + $y$, 1.5 – $z$)]. The shorter coordination distances Cu–N4 and Cu–O1 are between one chelating 1-methyl-5-nitriminotetrazolato ligand, whereby a longer coordination to the other oxygen atom of the nitro group is also observed, which is longer than in typical Jahn–Teller distorted d$^9$ copper complexes (see structures of **2**, **3**, and **5**). Accordingly, every nitro group participates in coordination with two copper centers, which results in an endless 3-dimensional network. The extended molecular structure of **1**, which illustrates the coordination of the nitro groups in the crystalline state, is shown in Figure 2.

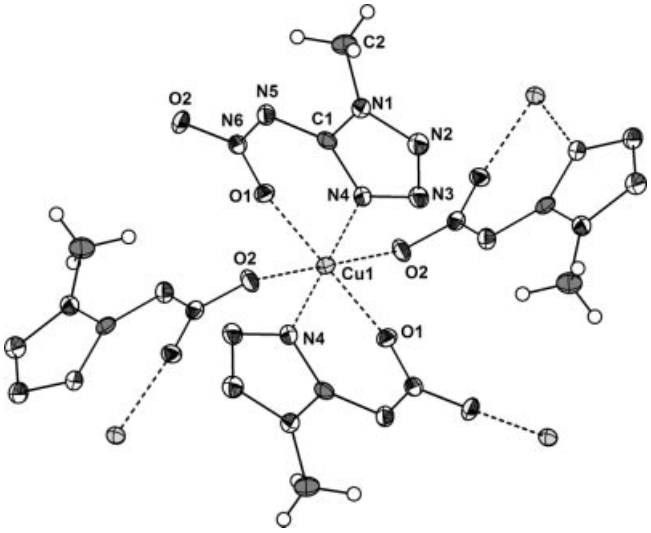


Figure 2. Crystal structure of **1** showing an extended molecular unit and atom-labeling scheme. Ellipsoids represent 50% probability.

The reaction of ligand **4** with copper(II) nitrate yields two different compounds {$[Cu(C_2H_3N_6O_2)_2(H_2O)_2]\cdot 2H_2O$ (**2**) and $[Cu(C_2H_3N_6O_2)_2(H_2O)_2]$ (**3**)}, which can be easily distinguishable by their color. Blue-colored main product **2** is characterized by the inclusion of two water molecules that do not participate in the coordination sphere. In these two structures, the effects of the inclusion of water can clearly be seen for example in the variation of the density (**2** 1.870 g cm$^{-3}$, **3** 2.035 g cm$^{-3}$). Both compounds crystallize with two molecules in the unit cell in the monoclinic crystal system: **2** in the space group $P2_1/c$ and **3** in the alternative

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

setting $P2_1/n$. The coordination geometry of the copper cations is characterized by an elongated octahedral arrangement due to the Jahn–Teller effect. This coordination geometry is typical for transition-state metals with $d^9$ valence electron configurations distorted by the Jahn–Teller[31] effect and is similar to those found for other complexes of both 2-substituted and 1-substituted tetrazoles.[32] The Cu–N bond lengths show considerable variation. Whereas a typical Cu–N4 distance of 1.997(1) Å is found in **2**, which is comparable to complexes with ligand systems such as 1,10-phenanthroline,[33] in compound **3** the distance Cu–N4 of 1.919(2) Å is importantly shorter. The differences in the Cu–O bond lengths are, however, less significant [**2**: *d*(Cu–O3) = 1.971(1) Å, *d*(Cu–O1) = 2.393(1) Å, **3**: *d*(Cu1–O1) = 2.048(2) Å, *d*(Cu1–O3) = 2.337(2) Å]. The geometries of the 1-methyl-5-nitriminotetrazolate moieties in **2** and **3** are essentially unaffected by the inclusion of water in **3**. In Figures 3 and 4 the molecular moieties of complexes **2** and **3** are shown.

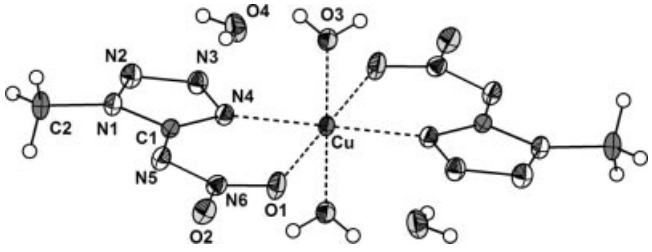

Figure 3. Crystal structure of **2** showing the molecular unit and atom-labeling scheme. Ellipsoids represent 50% probability.

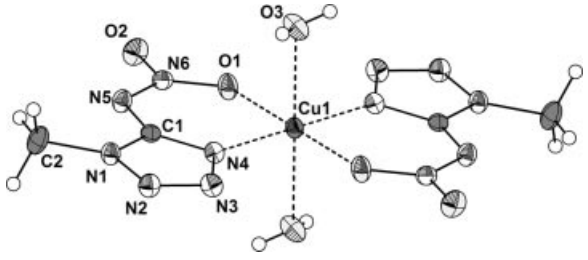

Figure 4. Crystal structure of **3** showing the molecular unit and atom-labeling scheme. Ellipsoids represent 50% probability.

Compound **5** crystallizes in the monoclinic space group $P2_1/c$ with two molecules in the unit cell and the lowest density of 1.74 g cm$^{-3}$ observed in this work. The structure is analogues to that of **2**; however, instead of two water molecules in **2**, two methanol molecules complete the packing of compound **5**. The methanol is not coordinated to any copper centers; therefore, it is not further discussed. The molecular structure of **5** in the crystalline state is shown in Figure 5.

The bond lengths and bond lengths of the discussed crystal structures **1**, **2**, **3**, and **5** are given in Table 1.

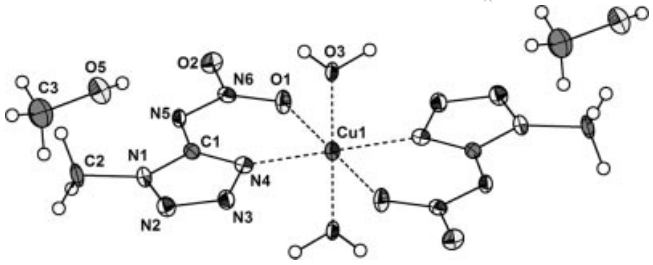

Figure 5. Crystal structure of **5** showing the molecular unit and atom-labeling scheme. Ellipsoids represent 50% probability.

## Thermogravimetry

Thermogravimetry was used to investigate the dehydration step and was performed with a Setaram TG-DTA 92-16[34] under a helium atmosphere with a heating rate of 1° min$^{-1}$ to a maximum temperature of 350 °C. For the measurement, 5.351 mg of a pulverized sample in an aluminum oxide pan was used. The TG curve as well the DTA curve are shown in Figure 6, and they show that the loss of water occurs over a wide range that starts before 50 °C and ends at about 85 °C. The loss of water depends on the heating rate and occurs at higher temperatures when higher heating rates are used (see DSC measurements). The loss of 0.878 mg weight corresponds to the loss of all four water molecules in compound **2**, and therefore, it was not possible to stop the dehydration at compound **3**. In the second step

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

at about 245 °C, a mass of 3.932 mg was lost, which is more than the expected mass for the remaining copper(II) oxide as solid residues. Through the explosion that releases a huge amount of nitrogen, some of the $Cu^{II}O$ must be removed from the open setup.

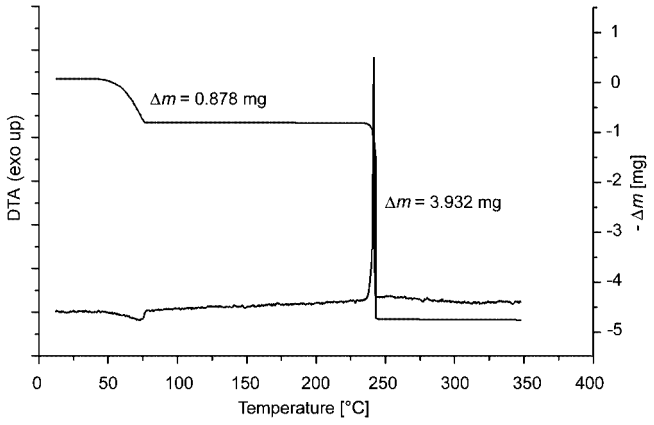

Figure 6. Thermogravimetry plot of compound **2** showing the loss of mass (right axis) and the DTA curve (left axis).

## Energetic Properties

### Differential Scanning Calorimetry (DSC)

DSC measurements used to determine the thermal behavior of the copper(II) 1-methyl-5-nitriminotetrazolate complexes were performed in covered Al containers with a nitrogen flow of 20 mL min$^{-1}$ with a Perkin–Elmer Pyris 6 DSC,[35] which was calibrated by standard pure indium and zinc at a heating rate of 5 °C min$^{-1}$. Compound **1** decomposes at a temperature of 252 °C at a heating rate of 5° min$^{-1}$ and at 248 °C at a heating rate of 2° min$^{-1}$. The DSC plots in Figure 7 show the thermal behavior of ca. 1.5 mg of **1**–**3** in the temperature range from 50 to 300 °C. Interestingly, the deprotonation in combination with the coordination to the copper(II) centers results in a substantial increase in the decomposition points in relative to neutral ligand **4**, which decomposes at temperatures above 125 °C.

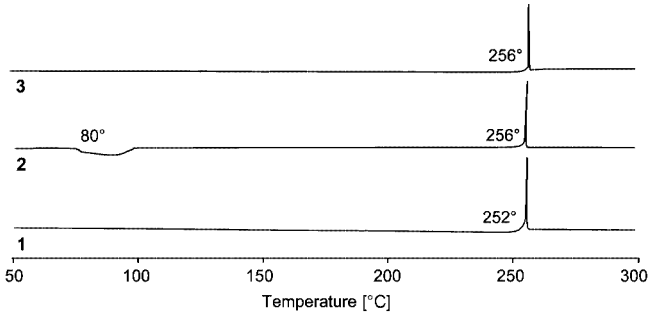

Figure 7. DSC plots of compounds **1**, **2**, and **3** (heating rate 5° min$^{-1}$).

To determine the heats of decomposition, a Linseis DSC PT10[36] instrument was used. Three samples (ca. 1 mg) were heated with a heating rate of 2° min$^{-1}$ and a fixed nitrogen flow of 5 L h$^{-1}$ over the decomposition peaks. The surface was integrated by using Linseis software, and the average of three measurements was used to calculate the heats of decomposition: for **1** $\Delta_{dec.}H_m°$ = 2739 J g$^{-1}$ (958 kJ mol$^{-1}$) and for **2** $\Delta_{dec.}H_m°$ = 2218 J g$^{-1}$ (936 kJ mol$^{-1}$).

### Bomb Calorimetry

As a result of its explosive character, it was not possible to combust compound **1** completely in the bomb calorimeter; therefore, only complex **2** was investigated by using bomb calorimetry (Scheme 3). For the calorimetric measurements of **2**, a Parr 1356 bomb calorimeter (static jacket) equipped with a Parr 1108CL oxygen bomb for the combustion of highly energetic materials was used.[37] The reported value of the energy of combustion $\Delta U_c$ = –1610 cal g$^{-1}$ (–2841 kJ mol$^{-1}$) is the average of three single measurements. The calorimeter was calibrated by combustion of certified benzoic acid (SRM, 39i, NIST) under an oxygen atmosphere at a pressure of 3.05 MPa. The standard molar enthalpy of combustion ($\Delta_c H°$) was derived from $\Delta_c H° = \Delta U_c + \Delta nRT$ [$\Delta n = \Delta n_i$ (products, g) – $\Delta n_i$ (reactants, g); where $\Delta n_i$ is the total molar amount of gases in the products or reactants]. The enthalpy of formation, $\Delta_f H°$, of –904 kJ mol$^{-1}$ for **2** was calculated at 298.15 K by using the Hess thermochemical cycle and the combustion reaction outlined in Scheme 3. After combustion, only a brown compound was left in the bomb, which was identified as copper(II) oxide.

Scheme 3. Combustion equation of **2**.

To estimate the heat of formation of solid $[Cu(C_2H_3N_6O_2)_2]$ (**1**), we calculated[38] the electronic energies of all species involved in the gas-phase reaction (Scheme 4) at the B3LYP/SDD level of theory to be $\Delta E^{el}$(**1**) = –1859 kJ mol$^{-1}$.

Scheme 4. Gas-phase combustion equation of **1**.

This gas-phase electronic energy was converted after correction for the work term and the vibrational, translational, and rotational corrections into the gas-phase enthalpy of $\Delta H$(**1**) = –1883.4 kJ mol$^{-1}$.

With the known enthalpy of sublimation for CuO of $\Delta H_{sub.}$(CuO) = 462.7 kJ mol$^{-1}$[39] and the estimated heat of sublimation for **1** of $\Delta H_{sub.}$(**1**) = 175.9 kJ mol$^{-1}$ [this value was taken to be equal to the enthalpy of sublimation of the Cu(salen) complex,[40] the enthalpy of combustion of **1** according to the equation in Scheme 5 could be calculated to be $\Delta H_{comb.}$(**1**,s) = –2169.3 kJ mol$^{-1}$.

Scheme 5. Combustion equation of solid **1**.

The enthalpy of formation was then calculated by using the known literature[41] values for the enthalpies of formation of water [$\Delta H°_f(H_2O,g) = -242\ kJ\,mol^{-1}$] and carbon dioxide [$\Delta H°_f(CO_2,g) = -393\ kJ\,mol^{-1}$] to be $\Delta H°_f$ (**1**,s) = $-83.7\ kJ\,mol^{-1}$.

### Sensitivities

For initial safety testing, the impact and friction sensitivities were tested according to BAM methods[42,43] with the "BAM Fallhammer" and "BAM friction tester". Compound **1** is very sensitive towards impact (0.7 J) and friction (40 N), and because the value is comparable with lead azide, it should be considered to be a primary explosive; it should therefore only be handled with appropriate precautions. Compounds **2** and **5** are not sensitive towards impact (<100 J) and friction (<360 N). Compound **3** shows only a very low impact sensitivity (>55 J) and is not sensitive towards friction.

### Comparison with Lead Azide

Because lead azide is still used in modern priming charges and the U. S. army alone consumes more than 1000 lbs of it,[9] a comparison of its properties with those of compound **1** is shown in Table 2.

Table 2. Energetic properties of **1** and lead azide.

| | **1** | Lead azide |
|---|---|---|
| Impact sensitivity | >0.7 J | 2.5–4.0 J (pure)<br>3.0–6.5 J (techn.) |
| Friction sensitivity | >40 N | 0.1–1 N |
| Decomposition temperature | 252 °C | >315 °C |

### Long-Term Stability Tests

The long-term stability test of **1** was performed with a Systag FlexyTSC[44] (thermal safety calorimetry) in combination with a RADEX V5 oven and the SysGraph software. The test was undertaken as long-term isoperibolic evaluations in glass test vessels at atmospheric pressure with 500 mg of the compound. It was shown that tempering the substance for 48 h at 40 °C below the decomposition point results in storage periods that are over 50 years at room temperature. Initially, for **1** a temperature of 210 °C was chosen and possible occurrences of exo- or endothermic behavior were investigated over period of 48 h (Figure 8). Compound **1** was not stable for 48 h at a temperature of 210 °C. After 25 h there was an explicit increase in the temperature that was passed again after a few hours. After 48 h the compound in the test vessel was mainly brown-colored $Cu^{II}O$. The second test was performed at a temperature of 190 °C, and the compound was completely stable during this period. It can therefore be reasoned that the compound shows long-term stability even at higher temperatures, which is a basic requirement for possible applications.

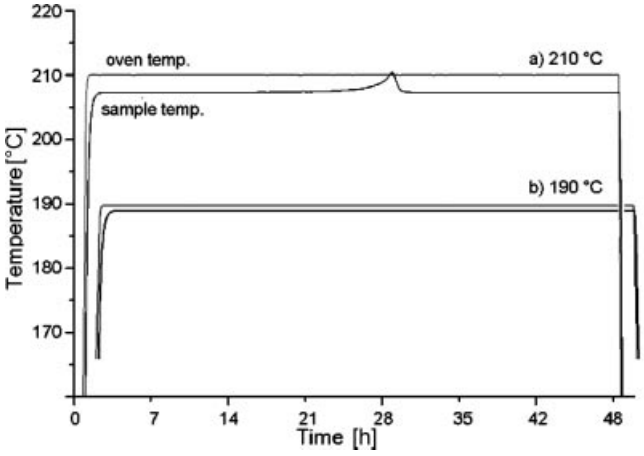

Figure 8. TSC plots of compound **1** over a period of 48 h at (a) 210 °C and (b) 190 °C (the upper curve represents the oven temperature, the curve below the sample temperature).

## Conclusions

From this experimental study the following conclusions can be drawn: (1) 1-Methyl-5-nitriminotetrazole can be used as a bidentate ligand in novel copper complexes forming compounds with different amounts of crystal water depending on the reaction conditions. The crystal water can be completely removed at higher temperatures to form highly explosive bis(1-methyl-5-nitriminotetrazolate) copper(II) (**1**). The dehydration proceeds in discrete steps and is determined by differential thermo gravimetry. (2) Bis(1-methyl-5-nitriminotetrazolato) copper(II) is a primary explosive due to its high sensitivity towards impact (0.7 J), but it shows a lower sensitivity towards friction (40 N) relative to common primary explosives. It is stable up to 250 °C and even shows long-term stability when tested at a temperature of 190 °C. In comparison with the commonly used lead azide, it shows suitable properties, in particular, its friction and impact sensitivities and its lower toxicity. The thermal decomposition provides a heat of decomposition of $2730\ J\,g^{-1}$, which was measured by using differential scanning calorimetry. (3) The crystal structures presented show common copper coordinations that are characterized by a Jahn–Teller distorted elongated octahedral coordination sphere.

## Experimental Section

All reagents and solvents were used as received (Sigma–Aldrich, Fluka, Acros Organics) if not stated otherwise. Melting points were measured with a Perkin–Elmer Pyris6 DSC apparatus by using a heating rate of $5°\,min^{-1}$. Otherwise, melting points were determined with a Büchi melting point B-450 apparatus and are not corrected.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Infrared (IR) spectra were recorded with a Perkin–Elmer Spectrum One FTIR instrument. Elemental analyses were performed with a Netsch STA 429 simultaneous thermal analyzer. Bomb calorimetry was done with a Parr 1356 bomb calorimeter with a Parr 1108CL oxygen bomb. The sensitivity data were performed with a BAM drophammer and a BAM friction tester.

***CAUTION!***

*Compounds **1** and **4** are highly energetic materials that show increased sensitivities towards various stimuli. Proper protective measures (safety glasses, face shield, leather coat, earthened equipment and shoes, Kevlar gloves and ear plugs) should be used when handling these compounds, especially when compound **1** is prepared on a larger scale.*

**$[Cu(C_2H_3N_6O_2)_2]$ (1):** The highly explosive copper complex **1** was obtained by dehydration of powdered **2** at 120 °C and reduced pressure ($1 \times 10^{-2}$ mbar) for 2h. Single crystals suitable for X-ray diffraction were grown from dry methanol. M.p. 252 °C (dec.). IR (KBr): $\tilde{\nu}$ = 3498 (m), 3456 (m), 3223 (m), 2861 (m), 2926 (m), 2346 (w), 1618 (m), 1528 (m), 1494 (m), 1477 (m), 1438 (m), 1384 (m), 1339 (s), 1303 (s), 1245 (m), 1229 (m), 1120 (m), 1037 (w), 1001 (m), 873 (m), 776 (w), 733 (w), 698 (w), 588 (w), 512 (w) $cm^{-1}$. $C_4H_6CuN_{12}O_4$ (349.71): calcd. C 13.74, H 1.73, N 48.06; found C 13.77, H 1.83, N 48.29.

**$[Cu(C_2H_3N_6O_2)_2(H_2O)_2]\cdot(H_2O)_2$ (2):** Copper(II) nitrate trihydrate (240 mg, 1.0 mmol) was dissolved in hot water (2 mL) and combined with a hot solution of 1-methyl-5-nitriminotetrazole (288 mg, 2 mmol) in water (15 mL) and heated at reflux for 5 min. After cooling to room temperature and standing for 24 h, blue crystals of **2** started to precipitate (299 mg, 71%). After filtration, the mother liquid was left, whereby green crystals of **3** were obtained (39 mg, 10%). M.p. 256 °C (dec.). IR (KBr): $\tilde{\nu}$ = 3504 (m), 3461 (m), 3220 (m), 2963 (m), 2148 (w), 1801 (w), 1662 (w), 1526 (m), 1476 (s), 1398 (m), 1384 (m), 1339 (s), 1305 (s), 1256 (m), 1120 (m), 1037 (m), 1010 (w), 929 (w), 887 (w), 859 (w), 776 (w), 737 (w), 654 (w), 585 (w) $cm^{-1}$. $C_4H_{14}CuN_{12}O_8$ (421.78): calcd. C 11.39, H 3.35, Cu 15.07, N 39.85, O 30.35; found C 11.32, H 3.38, N 39.69.

**$[Cu(C_2H_3N_6O_2)_2(H_2O)_2]$ (3):** M.p. 251 °C (dec.). IR (KBr): $\tilde{\nu}$ = 3481 (m), 2963 (w), 1798 (w), 1628 (m), 1539 (m), 1487 (m), 1417 (s), 1404 (s), 1385 (s), 1339 (m), 1298 (s), 1247 (m), 1125 (m), 1030 (m), 877 (w), 772 (w), 757 (w), 734 (m), 701 (m), 537 (w) $cm^{-1}$. $C_4H_{10}CuN_{12}O_6$ (385.75): calcd. C 12.45, H 2.61, Cu 16.47, N 43.57; found C 12.28, H 2.71, N 43.11.

**4:** 1-Methyl-5-nitriminoterazole was obtained by the nitration of 1-methyl-5-aminotetrazole by using fuming $HNO_3$. The nitration reaction was quenched with ice water, and the solvent was removed by using high vacuum until the product started to precipitate.

**$[Cu(C_2H_3N_6O_2)_2(H_2O)_2]\cdot(MeOH)_2$:** The light-blue colored methanol containing complex **5** was obtained by recrystallization of **1** from a wet methanol solution. $C_6H_{18}CuN_{12}O_8$ (449.83): calcd. C 16.02, H 4.03, N 37.37; found C 15.8, H 3.92, N 37.65.

Table 3 contains the parameters and data obtained from the single-crystal X-ray determinations.

**Keywords:** Density functional calculations / Magnetic properties / Nitrogen heterocycles / Radical anions / Sulfur / Selenium

A new heterocyclic system, namely [1,2,5]selenadiazolo[3,4-*c*][1,2,5]thiadiazole (**1**), has been prepared in 60 % yield by the 1:1 condensation of 3,4-diamino-1,2,5-thiadiazole (**4**) with $SeCl_4$ in the presence of pyridine. The structures of **1** and its 1:1 complex with pyridinium chloride (**5**) have been elucidated by X-ray diffraction (XRD). The reversible electrochemical reduction of **1**, as well as its chemical reduction with $PhS^-$ anion, provide the long-lived [1,2,5]selenadiazolo[3,4-*c*][1,2,5]thiadiazolidyl radical anion (**2**), which has been isolated in the form of the thermally stable salt [K(18-crown-6)][**2**] (**3**) in 75 % yield. The experimental structural and spectral characteristics of **1** and **2** agree fairly well with those obtained from density functional (DFT) calculations. The salt **3** has been characterized by ESR spectroscopy (in the solid state and in solution) and XRD. The radical anion **2** acts as a bridging ligand in crystalline **3**. Magnetic measurements on salt **3** reveal weak antiferromagnetic interactions ($J = -1.65$ cm$^{-1}$). The magnetic structures of **3** and its disulfur congener **11** have been analyzed in terms of dimeric exchange integrals calculated by spin-unrestricted broken-symmetry DFT and post-HF methods.

## Introduction

Chalcogen-nitrogen chemistry[1] has begun to play an increasingly important role in the design and synthesis of molecular materials, especially conducting, superconducting and magnetic materials, during the past two decades.[2–7] In particular, numerous spin-carrying chalcogen-nitrogen compounds, mostly neutral and positively charged heterocyclic thiazyl radicals (radical cations), have been carefully explored as molecular magnets and/or conductors. Related negatively charged systems (radical anions) have been less studied as they are much rarer.[1–6]

We have recently described the preparation and X-ray diffraction (XRD) and ESR characterization of thermally stable salts of the [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazolidyl radical anion.[8] This π-delocalized radical anion might be of interest in materials science as a building block for molecular ion-based magnets and/or conductors.[8–10] Indeed, the results of magnetic susceptibility ($\chi$) measurements on its salts in the temperature range 2–300 K have revealed low-temperature antiferromagnetic ordering of their spin systems. Investigation of the electrical properties of the salts is in progress. One of the directions of further development in this field relates to the Se analogue of [1,2,5]-thiadiazolo[3,4-*c*][1,2,5]thiadiazolidyl, namely [1,2,5]selenadiazolo[3,4-*c*][1,2,5]thiadiazolidyl.

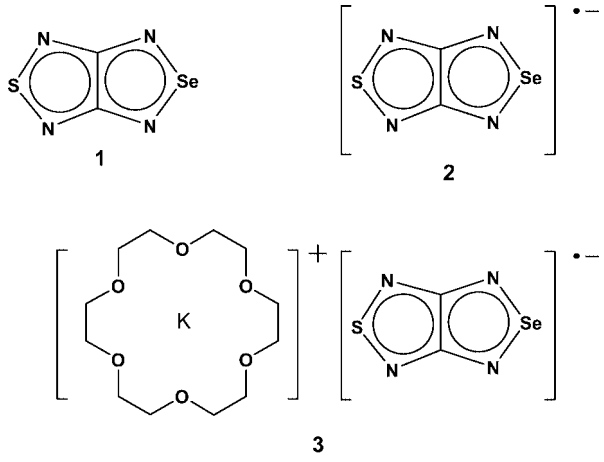
Herein we report on the synthesis of [1,2,5]selenadiazolo[3,4-*c*][1,2,5]thiadiazole (**1**) and its electrochemical and chemical reduction to [1,2,5]selenadiazolo[3,4-*c*][1,2,5]thiadiazolidyl (**2**), which is isolated in the form of the thermally stable salt [K(18-crown-6)][**2**] (**3**; Scheme 1). The crystal and molecular structures of **1** and **3** are elucidated by XRD and the radical anion **2** is characterized by ESR spectroscopy in solution. The salt **3** is also characterized by ESR spectroscopy as well as by magnetic susceptibility measurements in the temperature range 2–300 K. The experimental structural and spectral characteristics of **1** and **2** and the magnetic properties of **3** are compared with those calculated by density functional (DFT) and post-Hartree–Fock (HF) techniques.



Scheme 1.

It should be noted that beyond the field of chalcogen-nitrogen chemistry, π-delocalized radical anions suitable as spin-carrying units for molecular materials are also very rare and are represented mainly by those derived from nitrogen heterocycles, such as tetrazines,[11] cyanocarbons, such as tetracyanoethylene and 7,7,8,8-tetracyanoquinodimethane,[12] and semiquinones.[13]

## Results and Discussion

### Preparation and Characterization of [1,2,5]Selenadiazolo[3,4-*c*][1,2,5]thiadiazole (1)

An initial attempt to prepare compound **1** by treating 3,4-diamino-1,2,5-thiadiazole (**4**) with $SeOCl_2$ in the presence of pyridine was unsuccessful. The reaction product was described as an unstable solid with no reported characteristics (even melting point) other than a low-resolution mass spectrum.[14]

In this work, compound **1** is synthesized in 60% yield by the 1:1 condensation of diamine **4** with $SeCl_4$ in the presence of pyridine (Scheme 2). This approach is an extension of the chalcogen tetrahalide based methodology, previously suggested for the synthesis of 2,1,3-benzochalcogenadiazoles, to non-benzoid systems (chalcogen tetrahalides are $SF_4$, $SeCl_4$, and $TeCl_4$).[15] Unexpectedly, compound **1** was isolated from the reaction mixture in the form of a 1:1 complex with pyridinium chloride (**5**; Scheme 2). Pure **1**, which was obtained by decomposition of complex **5** with water, was found to be thermally stable and stable to air in both the solid state and in solution.

The structures of **1** and **5** were confirmed by XRD (Figures 1 and 2, respectively). The pyridinium cation in the crystal of **5** is disordered over two positions in each of which the N atom is also disordered over two positions (Figure 2). In the crystal of **1**, the molecules lie in the crystallographic *m* plane. Only half a molecule is crystallographically independent since the crystallographic $C_2$ axis passes through the center of the C–C bond, which means that either S or Se atoms can be placed in the same position. The best refinement was achieved with occupation factors (SOF) of 0.25 for both S and Se (Figure 1). As a result, the experimental accuracy of the molecular geometry of **1** is higher in the case of its co-crystal with pyridinium chloride **5** than in the case of its homo-crystal (see Figures 1 and 2). The experimental geometry of **1** in complex **5** agrees well with its geometry calculated at the DFT/B3LYP/6-31G(d) level of theory (Figure 2).

Bond lengths [pm] and angles [°]: Se1–N1 177.6(9), Se1–N2 182.1(9), S1–N2 158(2), S1–N1 165(2), N2–C1 134.1(8), N1–C1A 130.9(8), C1–C1A 148.9(13); N1–Se1–N2 93.0(4), N2–S1–N1 107.8(9), C1–N2–S1 101.4(8), C1–N2–Se1 107.4(5), C1A–N1–S1 100.7(8), C1A–N1–Se1 109.6(5), N1A–C1–N2 129.7(6), N1A–C1–C1A 115.4(8), N2–C1–C1A 114.6(8) [symmetry transformation used: $-x$, $y$, $-z + 2$].

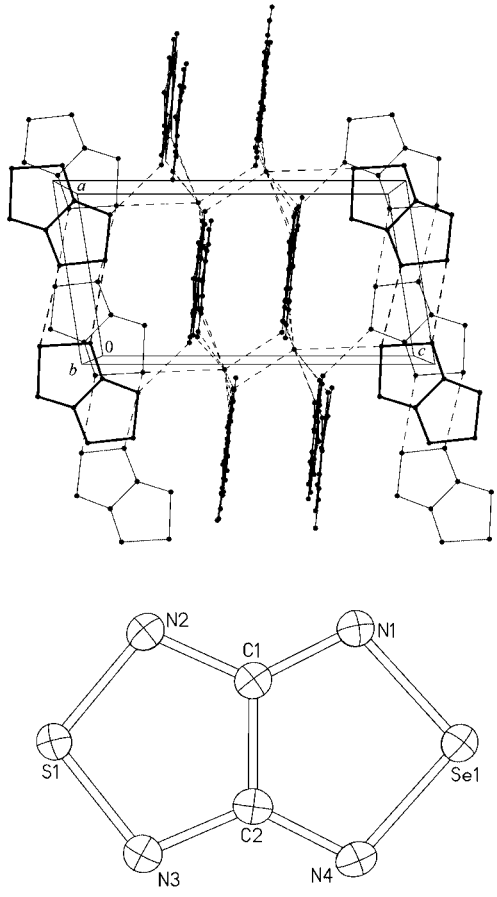

Figure 2. Top: structure of compound **5** (dotted lines show shortened intermolecular contacts). Bottom: compound **1** (XRD numbering is used) moiety in **5**; bond lengths [pm] and angles [°]: Se1–N1 179.0(4), Se1–N4 179.7(4), N1–C1 133.2(6), N4–C2 133.0(6), C1–C2 144.7(6), S1–N2 163.0(5), S1–N3 162.6(4), N2–C1 135.3(6), N3–C2 136.0(6); N1–Se1–N4 95.74(18), Se1–N1–C1 105.0(3), N1–C1–C2 117.3(4), C2–C1–N2 114.2(4), C1–N2–S1 104.9(3), N2–S1–N3 102.5(2), S1–N3–C2 105.2(3), N3–C2–C1 113.3(4), C1–C2–N4 117.0(4), C2–N4–Se1 105.0(3). Bond lengths [pm] and angles [°] of the same moiety obtained from DFT/B3LYP/6-31G(d) calculations: Se1–N1 (Se1–N4) 179.5, N1–C1 (N4–C2) 133.0, C1–C2 147.0, S1–N2 (S1–N3) 163.0, N2–C1 (N3–C2) 135.0; N1–Se1–N4 97.4, Se1–N1–C1 104.1, N1–C1–C2 117.3, C2–C1–N2 113.6, C1–N2–S1 (S1–N3–C2) 104.7, N2–S1–N3 102.9, N3–C2–C1 113.5, C1–C2–N4 116.8, C2–N4–Se1 104.6.

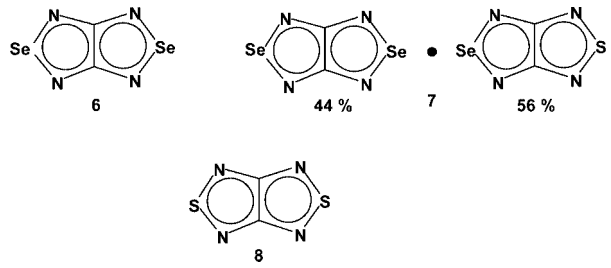
The formation of [1,2,5]selenadiazolo[3,4-*c*][1,2,5]selenadiazole (**6**) as a minor by-product in the preparation of **1** was observed by mass spectrometry and confirmed by XRD characterization in the form of a statistically disordered co-crystal of **1** with **6** ("compound" **7**; Scheme 3, Figure 3). The best refinement was achieved with occupation factors (SOF) in the S2/Se2 position of 0.56 for S and 0.44 for Se (Figure 3). As a result, the experimental accuracy was relatively low, which makes a correct comparison of the changes in molecular geometry on going from the archetypal [1,2,5]thiadiazolo[3,4-*c*][1,2,5]thiadiazole (**8**)[8b] to **1** and **6** impossible.



Scheme 3.

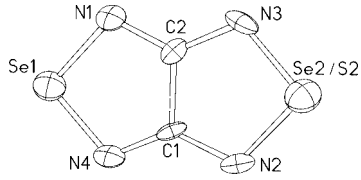


Figure 3. Structure of complex **7** between **1** and **6** (56:44). Bond lengths [pm] and angles [°]: Se1–N1 178(1), Se1–N4 175(1), Se2/S2–N2 169(1), Se2/S2–N23 166(1), N1–C2 132(2), N2–C1 132(2), N3–C2 132(2), N4–C1 131(2), C1–C2 146(2); N1–Se1–N4 94.5(5), N2–Se2/S2–N3 98.0(5), Se1–N1–C2 107.0(9), Se2/S2–N2–C1 107.6(9); Se2/S2–N3–C2 107.0(8), Se1–N4–C1 107.8(8), N4–C1–C2 115.9(12), N1–C2–C1 114.8(11), N2–C1–C2 112.2(11), N3–C2–C1 115.2(12).

A comparison of the spectroscopic properties of **1** and **8** showed the expected similarities. Thus, the maximum absorption wavelength ($\lambda_{max}$) of the long-wave band in the electronic absorption spectra (EAS) of **1** and **8** (DME solutions) is found at 353 and 319 nm, respectively. The theoretical EAS of **1** and **8**, calculated at the TD-DFT/B3LYP/6-31+G(d) level of theory, reveal two $\pi \rightarrow \pi^*$ transitions at 359 ($f$ = 0.0430) and 310 nm ($f$ = 0.3203) in the case of **1** and at 331 ($f$ = 0.0522) and 285 nm ($f$ = 0.3361) in the case of **8** ($f$ is the oscillator strength). These theoretical transitions appear as one unresolved band in the experimental EAS of both compounds (Figure 4). In the NMR spectra, the $^{13}C$ chemical shift of **1** is only 3 ppm downfield from that of **8**.[8b]

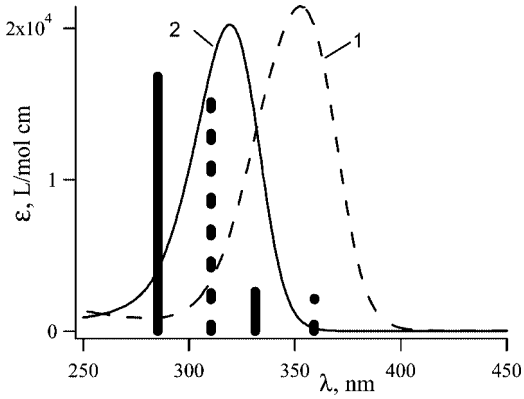

Figure 4. Experimental (curves) EAS of **1** (1) and **8** (2) and theoretical (bars) spectra of **1** (dotted bars) and **8** (solid bars) calculated at the TD-B3LYP/6-31+G(d) level of theory.

### Preparation and Characterization of the [1,2,5]Selenadiazolo[3,4-*c*][1,2,5]thiadiazolidyl Radical Anion (2) and the Salt [K(18-crown-6)][2] (3)

Cyclic voltammetry (CV) of a solution of **1** in MeCN in the potential range from 0 to –2.5 V revealed two diffusion-controlled one-electron reduction peaks (1C and 2C, Figure 5) corresponding to consecutive transformations of **1** into the radical anion **2** (peak 1C) and the dianion **9** (peak 2C; Scheme 4). The oxidation peak 1A, which is observed

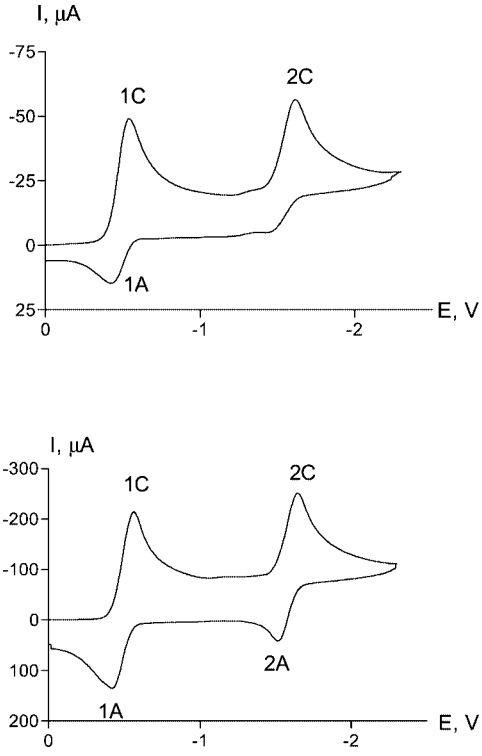

Figure 5. CV of **1** at scan rates of 100 mV s$^{-1}$ (top) and 2 V s$^{-1}$ (bottom).

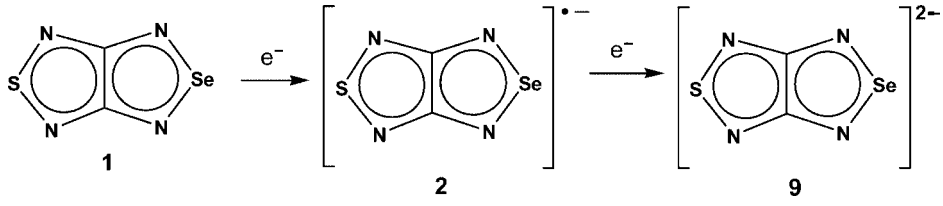

Scheme 4.

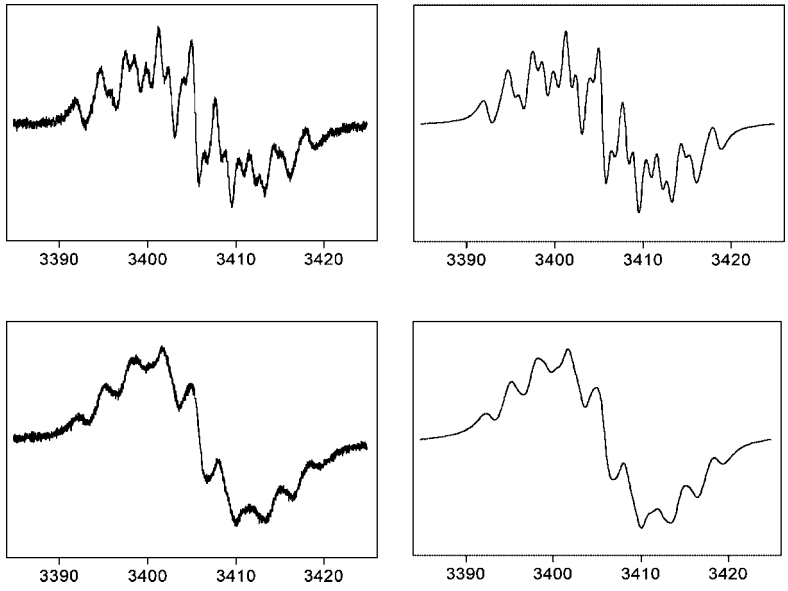

Figure 6. Experimental (in MeCN, left) and simulated (right) ESR spectra of **2** at 223 K (top) and 243 K (bottom). $|H| = 10^{-4}$ T.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

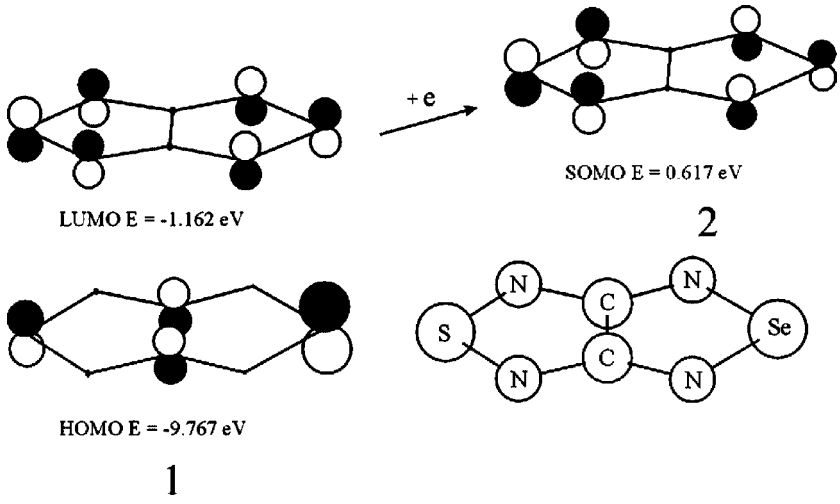

Figure 7. The frontier MOs of **1** and the SOMO of **2** obtained from the HF/6-31G(d) and ROHF/6-31G(d) calculations, respectively, for the molecular geometries optimized at the (U)B3LYP/6-31G(d) level.

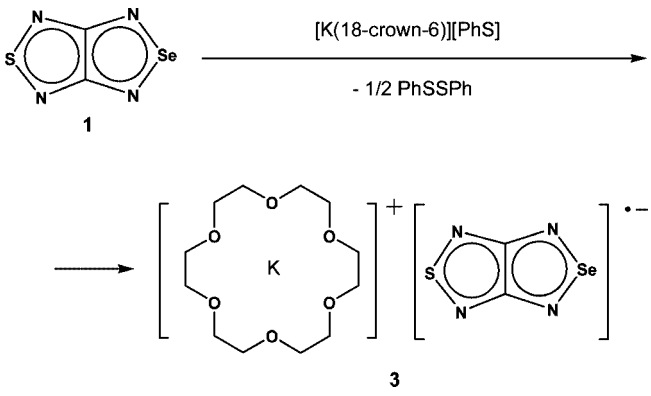
even at low scan rates (approx. 10 mV s$^{-1}$), proves that **2** is a rather long-lived species. The peak potential of reduction 1C in **1** ($E_p^{red}$ = –0.53 V) is only 0.03 V less than the corresponding peak potential of its analog **8**.[8b] Reversibility of the 2C peak of **1** is observed only at scan rates >1 V s$^{-1}$ (Figure 5), which implies that dianion **9** is less stable under the CV conditions than the dianion of **8**.[8b]

The formation of **2** was confirmed by variable-temperature ESR spectroscopy (Figure 6). For **2**, two hfc constants $a(^{14}N \times 2)$ are 0.379 and 0.269 mT, whereas for [1,2,5]thiadiazolo[3,4-*c*][1,2,5] thiadiazolidyl (**10**) $a(^{14}N \times 4)$ is 0.314 mT.[8b] The theoretical hfc constants of **2** calculated at the DFT/UB3LYP/6-31G(d) level of theory [$a(^{14}N_1, ^{14}N_4)$ = 0.360 and $a(^{14}N_2, ^{14}N_3)$ = 0.309 mT] are close to the experimental values.

The ESR spectrum of **2** is temperature-dependent (Figure 6). In the range of 223–295 K it reveals lines broadening with increasing temperature (decreasing solvent viscosity), and at 295 K the spectrum is an unresolved singlet. This behavior is rather uncommon as the inverse situation is normally observed due to better averaging of the anisotropy of both the hfc and the *g*-tensor at higher temperatures. It is not, however, unprecedented, as a similar behavior has been reported for 1,2,3-benzodithiazolyls,[16a] which are neutral thiazyl radicals related to **2**, and explained by spin-rota-



Scheme 5.

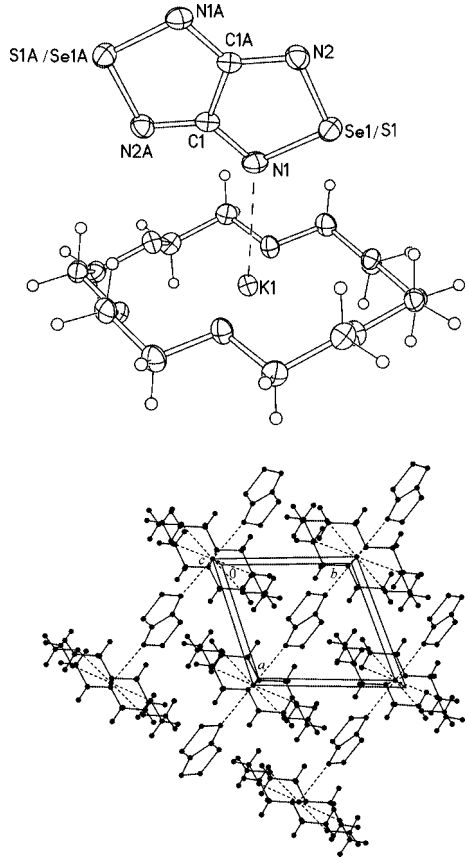


Figure 8. The structure (top) and crystal packing (bottom) of salt **3**. Bond lengths [pm] and bond angles [°] of radical anion **2**: Se1/S1–N1 175.6(4), Se1/S1–N2 174.1(4), N1–C1 133.4(6), N2–C1A 133.8(6), C1–C1A 147.2(8); N1–Se1–N2 97.72(18), Se1–N1–C1 105.3(3), N1–C1–N2A 128.4(4), N1–C1–C1A 115.7(5), N2–C1–C1A115.9(5), C1A–N2–Se1 105.4(3) [symmetry transformation used: –*x* + 1, –*y* + 1, –*z*].

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tional relaxation,[16a] which gives an inversely proportional dependence of linewidth on viscosity.[17]

On the basis of the ESR data, the half-life of the electrochemically generated radical anion **2** can be estimated as $\tau_{1/2}$ = 930 s at 243 K and $\tau_{1/2}$ = 750 s at 295 K.

Figure 7 depicts the frontier MOs of **1** and the SOMO of **2** obtained from the HF/6-31G(d) and ROHF/6-31G(d) calculations, respectively, with geometries optimized at the DFT/(U)B3LYP/6-31G(d) level of theory. As usual, the SOMO of **2** is very similar to the LUMO of its neutral precursor **1**.

The thermally stable salt [K(18-crown-6)][**2**] (**3**) was obtained in 75% yield by chemical reduction of **1** with [K(18-crown-6)][PhS] (Scheme 5; see also ref.[8a]).

The structure of salt **3** was confirmed by XRD (Figure 8). As in the case of **1**, either S or Se atoms can be placed in the same position. The best refinement was achieved with occupation factors (SOF) of 0.50 for both S and Se (Figure 8). The crystal packing of **3** is very similar to that of [K(18-crown-6)][**10**][8b] (**11**) and reveals chains along the (01$\bar{1}$) crystallographic direction formed by uniform N···K contacts of 286.7 pm (288.5 pm in salt **11**).[8b] Thus, reduction of the molecular symmetry (disappearance of the inversion center) and the resulting appearance of a dipole moment on going from **10** to **2** essentially does not affect the crystal packing of salts **3** and **11**.

The solid-state ESR spectrum of salt **3**, with an unresolved hyperfine structure and $g_\perp$ = 2.0163 and $g_\parallel$ = 1.9971, is shown in Figure 9. The solution ESR spectrum of **3** in dmf is rather different to the spectrum of the electrochemically generated **2** in MeCN as the spectrum in dmf reveals two hfc constants [$a(^{14}N)$ = 0.380 and $a(^{14}N \times 3)$ = 0.292 mT; Figure 9] with $g$ = 2.001. This difference can be tentatively explained by the reduced molecular symmetry of **2** in the dmf solution of salt **3** (cf., for example, the data for the 2,2′-bipyrimidinyl radical anion in high- and low-symmetry complexes[16b]). The reduced symmetry can be proposed, for example, for a non-dissociated complex [K(18-crown-6)(dmf)][**2**] featuring $K^+$···**2** coordination similar to that observed in the solid state (Figure 8) and additional coordination of dmf to $K^+$ (instead of a second molecule of **2** as in the solid state).

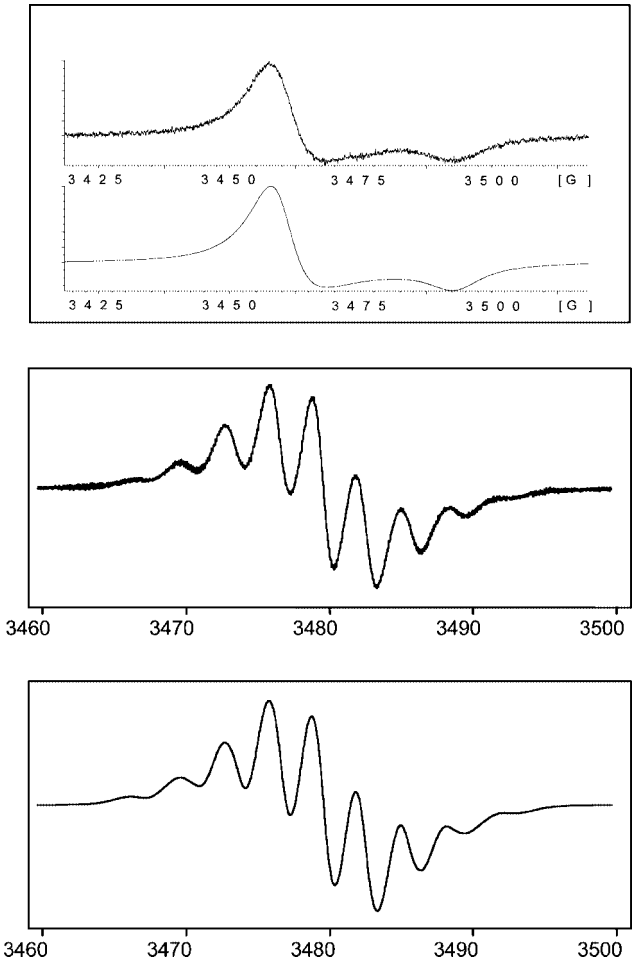

Figure 9. ESR spectra of **3** in the solid state (top: experimental and simulated) and dmf solution (center: experimental; bottom: simulated) at 295 K. $|H|$ $10^{-4}$ T.

## Magnetic Properties of [K(18-crown-6)][2] (3) in Comparison with Those of [K(18-crown-6)][10] (11)

The crystal lattices of salts **3** (this work) and **11**[8a] are very similar; therefore some similarity in their magnetic properties is to be expected. Indeed, the magnetic susceptibility, $\chi$, increases steadily for both salts with a decrease in temperature in the range 300–2 K (Figure 10). The experimental data are best fitted by the Bonner–Fisher uniform chain model[18] with exchange parameters, $J$, of $-1.65 \pm 0.03$ cm$^{-1}$ ($R_2$ = 0.997) for **3** and $-1.22 \pm 0.10$ cm$^{-1}$ ($R_2$ = 0.9997) for **11**.[8a] Thus, within this model, replacement of sulfur by selenium strengthens the antiferromagnetic exchange interactions in the discussed radical anion salts by 35%.

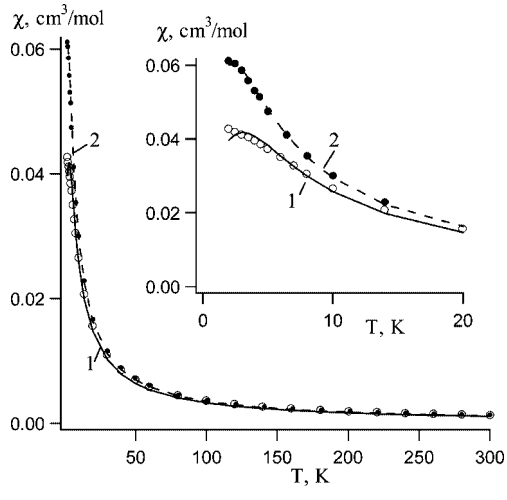

Figure 10. Temperature dependence of $\chi$ in the temperature ranges 2–300 K and 2–20 K (inset) for salts **3** (open circles) and **11** (black circles). Theoretical curves: Bonner–Fisher uniform chain model with $J$ = –1.65 cm$^{-1}$ for **3** (1) and $J$ = –1.22 cm$^{-1}$ for **11** (2).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Disordered salt **3** is less suitable for a theoretical analysis of the magnetic properties than salt **11**. Additionally, the symmetry of the radical anion **2** is lower than that of the radical anion **10**, therefore a detailed analysis of the pair exchange interactions ($J_{AB}$) based on the spin-unrestricted broken-symmetry DFT/UB3LYP/6-31+G(d) calculations was first performed for salt **11**. All radical anions **10** in the crystal of **11** are structurally equivalent. It is therefore possible to select a radical anion and calculate the $J_{AB}$ values with all first-nearest neighbors and then with the closest second-nearest neighbors.

Figure 11 demonstrates that every radical anion **10** has ten first-nearest neighbors, two of which are separated from it by $[K(18\text{-crown-6})]^+$ cations. These ten first-nearest neighbors give only five unique pairs (r1–r5, Figure 11) with the calculated $J_{AB}$ values presented in Table 1. This table also displays the shortest S···S (N···N for r4) distances in the pairs. Only for three of these five pairs are the calculated $J_{AB}$ values higher than the given accuracy of the calculations (0.04 $cm^{-1}$). All $J_{AB}$ values with closest second-nearest neighbors were found to be less than 0.04 $cm^{-1}$.

The influence of $[K(18\text{-crown-6})]^+$ cations separating radical anions **10**, as well as that of their 18-crown-6 fragments, on the values of the calculated $J_{AB}$ was estimated in the context of superexchange interactions. $J_{AB}$ was found to be zero for the "bare" r4 pair as well as for r4 pair divided by the $[K(18\text{-crown-6})]^+$ cation (Figure 11). Calculations for the clusters containing pairs r1–r3 and fragments of 18-crown-6 showed a noticeable change of the $J_{AB}$ values

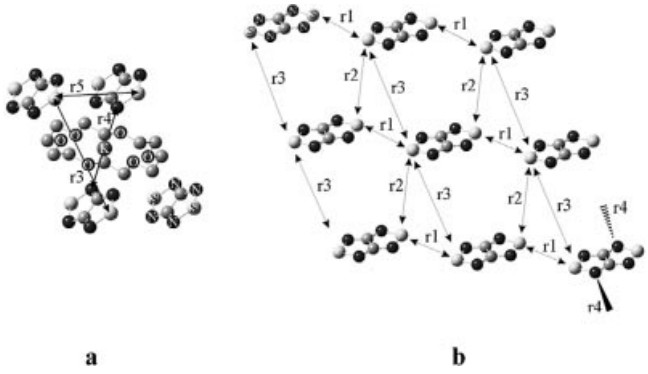

Figure 11. Crystal packing of salt **11** analyzed in terms of shortest intermolecular distances between radical anions **10**: (a) along the $(01\bar{1})$ crystallographic direction (hydrogen atoms of 18-crown-6 are omitted); (b) in the plane perpendicular to this direction.

(Table 1). Figure 12 displays the cluster containing the r3 pair together with two fragments of 18-crown-6 as an example.

Figure 12. Structure of the cluster containing the r3 pair and two fragments of 18-crown-6.

On the whole, the calculations demonstrate that the full magnetic structure of salt **11** is three-dimensional, although $J_{AB}$ for the r1 pair is much larger than all the others (Table 1, Figure 11). The magnetic motif for this salt can therefore be described approximately as a linear spin chain. This is why the $\chi(T)$ dependence is very well fitted by the Bonner–Fisher uniform chain model.[8a] At the same time, the experimentally estimated value of $J$ ($-1.22 \pm 0.01$ $cm^{-1}$) is about twice as small as $J_{AB}$ calculated for the r1 pair using the spin-unrestricted broken-symmetry approach at the DFT/UB3LYP/6-31+G(d) level of theory.

The HF and post-HF calculations of $J_{AB}$ for the r1 pair, with the same basis set as above, revealed (Table 1) that the UHF and UMP2 calculations considerably underestimate $J_{AB}$. Note that similar results were recently obtained for model systems such as H···H and H···He···H, where the $J_{AB}$ values were overestimated more than twice with the spin-polarized DFT approach and underestimated by the UHF method; only the UMP4 results agreed well with the data of high-level calculations such as full-CI ones.[19]

As mentioned above, the case of salt **3** is rather complicated since there are three different mutual orientations of the radical anions **2** in the selected pairs (Figure 13). The influence of these orientations on $J_{AB}$ was tested (Table 2). A comparison of Tables 1 and 2 clearly demonstrates that the $J_{AB}$ values for **3** are considerably larger than those for **11**. This observation agrees qualitatively with the difference in the exchange parameter ($J$) values obtained from the fitting of the $\chi(T)$ dependencies for salts **3** and **11**. At the same time, Table 2 shows that the obtained theoretical mag-

netic motif for salt **3** cannot be correctly described as a uniform spin-chain since three different $J_{AB}$ values alternate along the chain. Indeed, although the experimental $\chi(T)$ dependence for **3** can be fairly well fitted by the Bonner–Fisher uniform chain model, the agreement is not as good as for **11** (see above).

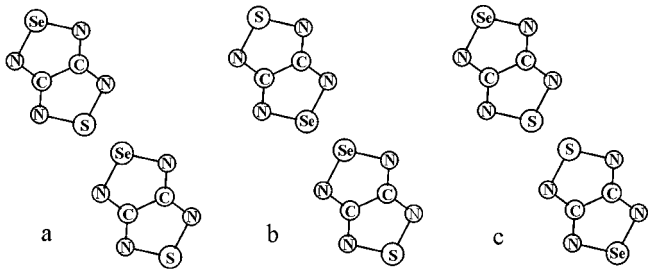

Figure 13. Different mutual orientations of the radical anions **2** reveal the highest $J_{AB}$ values in crystals of salt **3**.

Table 2. Spin-unrestricted broken-symmetry results obtained at the UB3LYP/6-31+G(d) level for the dimeric exchange interaction ($J_{AB}$) of the radical anion **2** with first-nearest neighbors in the crystal of salt **3** at different mutual orientations (Figure 13).

## Conclusions

A new heterocyclic system, namely [1,2,5]selenadiazolo[3,4-*c*][1,2,5]thiadiazole (**1**), has been prepared and characterized by XRD. The reversible electrochemical reduction of **1**, as well as its chemical reduction with the PhS$^-$ anion, provide the long-lived [1,2,5]selenadiazolo[3,4-*c*]-[1,2,5]thiadiazolidyl radical anion (**2**), which has been characterized by ESR spectroscopy and isolated in the form of the thermally stable salt [K(18-crown-6)][**2**] (**3**). According to the XRD data, the radical anion **2** acts as a bridging ligand in salt **3**. Magnetic measurements on salt **3** have revealed weak antiferromagnetic interactions ($J$ = –1.65 cm$^{-1}$). A comparison of **3** with its disulfur congener **11** assuming the Bonner–Fisher uniform chain model has shown that replacement of sulfur by selenium in these radical anion salts enhances the antiferromagnetic exchange interactions by 35%. Theoretical calculations of the exchange interactions in crystals of **3** and **11** have confirmed this trend. At the same time, these calculations demonstrate that the genuine magnetic structures of salts **3** and **11** are three-dimensional. In the case of salt **11**, the exchange interaction ($J_{AB}$) calculated for one particular type of radical anion pair in the solid state is much larger than for all the others, therefore the theoretical magnetic motif for this salt can be approximately described as a uniform spin chain. The obtained theoretical magnetic motif for salt **3** cannot be correctly described as a uniform spin chain since three different $J_{AB}$ values alternate along the chain.

## Experimental Section

**General:** 3,4-Dichloro-1,2,5-thiadiazole, $SeCl_4$, 18-crown-6, and Ph–S–$SiMe_3$ were used as received from Aldrich, whereas K*t*BuO was sublimed in vacuo before use. 3,4-Diamino-1,2,5-thiadiazole (**4**) was synthesized from the 3,4-dichloro derivative by a known procedure[14] and purified by vacuum sublimation. The complex [K(18-crown-6)][*t*BuO] was prepared as described previously.[20] The syntheses described below were performed under argon in absolutely dry solvents. The $^1$H and $^{13}$C NMR spectra were measured with a Bruker DRX-500 spectrometer at frequencies of 500.13 and 125.76 MHz, respectively, for solutions in $CDCl_3$, with TMS as standard. High-resolution mass spectra (EI, 70 eV) were recorded with a Finnigan MAT MS 8200 mass spectrometer. API-ES mass spectra were recorded with an Agilent 1100 Series LC/MSD instrument. The GC-MS measurements were performed with a Hewlett–Packard G1800A GCD device for solutions in $CH_2Cl_2$. EAS spectra were recorded with a Hewlett–Packard 8453 instrument for solutions in 1,2-dimethoxyethane (DME). The CV measurements on **1** were performed at 298 K under argon for a $2 \times 10^{-3}$ M solution of depolarizer in absolute MeCN at a stationary platinum electrode with 0.1 M $Et_4NClO_4$ as supporting electrolyte, with potential scan rates of 0.01–100 V s$^{-1}$. Both the 1C and 2C peaks were diffusion-controlled ($I_p^c v^{-1/2}$ = const, where $I_p$ is a current value in the peak and $v$ is a scan rate). Peak potentials are quoted relative to a saturated calomel electrode. The solid-state and solution ESR spectra were recorded with a Bruker ESP-300 spectrometer (MW frequency: 9.7641 GHz; MW power: 265 mW; modulation frequency: 100 kHz; modulation amplitude: 0.005 mT) equipped with a rectangular double resonator and a BST-100/700 temperature control unit. Electrochemical generation of the radical anion **2** from the neutral precursor **1** was performed with a $5 \times 10^{-3}$ M solution in MeCN (supporting electrolyte: 0.1 M $Et_4NClO_4$) with a standard cell for variable-temperature ESR measurements under anaerobic conditions. Simulations of the experimental solution ESR spectra were carried out with the Winsim 32 program using the Simplex algorithm of many-parameter optimization for hfc and linewidths. The accuracy in calculating $a$ values is ±0.0001 mT. The solid-state ESR spectrum of salt **3** was simulated with the Simfonia program in the $x$, $y$ and $z$ directions. Anisotropic hyperfine effects due to the $^{14}$N nuclei affect the general linewidth and do not appear directly in the spectrum (Figure 9). The half-life ($\tau_{1/2}$) of the electrochemically generated radical anion **2** in MeCN solution was calculated from the time dependency of the integral intensities of the ESR signals in the absence of an applied potential using the first-order kinetic equation for radical anion decay ($I = Ae^{(-kt)} + B$, $\tau_{1/2} = 0.69\ k^{-1}$). Because of the low solubility of salt **3** in MeCN, its ESR spectrum was recorded in dmf. The $g$ factors of salt **3** in the solid state and dmf solution were measured using a double resonator and MnO standard (six-line spectrum) with an accuracy of ±0.0002. The magnetic measurements were carried out with an MPMS-XL Quantum Design SQUID magnetometer in the temperature range 2–300 K in a magnetic field of 5000 Oe. The molar magnetic susceptibility, $\chi$, of salt **3** was calculated using the standard diamagnetism correction.

**Calculations:** The quantum chemical calculations were performed with the GAUSSIAN98 program suite.[21] The geometries of the closed-shell compounds and their radical anions were fully opti-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

mized at the DFT/(U)B3LYP/6-31G(d) level of theory.[22] The hfc constants were calculated by the same method. The HOMO and LUMO of the closed-shell species and the SOMO of the radical anions were characterized at the HF and ROHF levels of theory, respectively. The EAS were calculated by the TD-DFT/B3LYP/6-31+G(d) technique.[23] For the theoretical analysis of the magnetic structures of **3** and **11**, the exchange integrals ($J_{AB}$) between selected pairs of radical anions (**2** or **10**, respectively) were calculated using the spin-unrestricted broken-symmetry approach.[24] The $J_{AB}$ values were obtained from the following equation:

$$J_{AB} = E^{S}_{BS} - E^{T}$$

where $E^T$ is the energy of the triplet state of the pair of radical anions and $E^S_{BS}$ is the energy of the open-shell singlet state within the broken-symmetry approach.[24] In all cases the $<S^2>$ value for the broken-symmetry singlet state was about 1.02. The $E^T$ and $E^S_{BS}$ values were calculated using the DFT (UB3LYP), HF (UHF), and post-HF (UMP2) methods with the 6-31+G(d) basis set. The accuracy of the energy calculations was chosen to be $10^{-7}$ H, which provided values for $J_{AB}$ with an accuracy of 0.04 $cm^{-1}$.

**Crystallographic Analysis:** The XRD data (Table 3) for **1**, **3**, **5**, and **7** were collected with a Siemens P4 diffractometer using graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 71.073 pm) radiation. The structures were solved by direct methods using the SHELXS-97 program[25] and refined by the least-squares method in the full-matrix anisotropic (isotropic for H atoms) approximation using the SHELXL-97 program.[25] The structures obtained were analyzed for shortened contacts between non-bonded atoms with the PLATON program.[26] CCDC-645192 (for **1**), -644966 (for **3**), -644965 (for **5**), and -645193 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Synthesis of Compound 1:** A solution of $SeCl_4$ (1.11 g, 0.005 mol) in 15 mL of DME was added dropwise during 10 min to a refluxed and stirred solution of **4** (0.58 g, 0.005 mol) and pyridine (1.58 g, 0.02 mol) in 15 mL of the same solvent. The reaction mixture was refluxed and stirred for an additional 30 min, then filtered hot and cooled to 20 °C. The complex **1**·[$C_5H_5NH$][Cl] (**5**) was obtained as transparent light-yellow needles (yield: 1.04 g, 68%). M.p. (sealed capillary): 155–157 °C (dec.). $C_7H_6ClN_5SSe$ (306.64): calcd. C 27.42, H 1.97, Cl 11.56, N 22.84; found C 27.27, H 1.82, Cl 11.43, N 22.79. Complex **5** was subsequently treated with $H_2O$, EtOH, and $Et_2O$, and the residue was dried under vacuum at 20 °C followed by sublimation at 90 °C/0.1 Torr. According to the API-ES and GC-MS data, the sublimed product was compound **1** ($m/z$ = 191.9 [$C_2N_4S^{80}Se$]) containing approx. 5% of [1,2,5]selenadiazolo[3,4-*c*][1,2,5]selenadiazole (**6**; $m/z$ = 239.8 [$C_2N_4{}^{80}Se_2$]). The

product was recrystallized from toluene to give compound **1** as small yellow crystals (yield: 0.57 g, 60%). M.p. (sealed capillary): 231–233 °C. MS: calcd. for $C_2N_4S^{80}Se$ 191.9009; found 191.9028. $^{13}C$ NMR ($CDCl_3$): $\delta$ = 173.6 ppm. EAS (DME): $\lambda_{max}$ (log $\varepsilon$) = 353 nm (4.33). $C_2N_4SSe$ (191.08): calcd. C 12.57, N 29.32; found C 12.49, N 29.28. The use of $Et_3N$ instead of pyridine led to a mixture of unidentified products. The single crystal of **1** suitable for XRD was obtained by slowly concentrating a DME solution at ambient temperature. The single crystal of **7** (molecular complex between **1** and **6**) was found in the same sample.

**Synthesis of Salt 3:** A solution of Ph–S–$SiMe_3$ (0.182 g, 0.001 mol) in 2 mL of thf was added to a solution of [K(18-crown-6)][*t*BuO] (0.376 g, 0.001 mol) in 5 mL of the same solvent at –30 °C. The solution was warmed to 20 °C, stirred for 1 h, and the solvent distilled off under vacuum to give a white crystalline residue. Compound **1** (0.191 g; 0.001 mol) and 10 mL of MeCN were then added at –30 °C, and the wine-red solution obtained was warmed to 20 °C, stirred for 1 h, filtered, and the solvents were evaporated under vacuum. The residue was washed with 10 mL of thf, then dissolved in 5 mL of boiling MeCN under normal pressure of argon and the solution cooled to 20 °C. The solvent was removed with a syringe and the crystals that had formed were washed with 10 mL of thf and dried under vacuum. Salt **3** forms transparent ruby plates, Yield: 0.371 g (75%). M.p. (sealed capillary): 138 °C (dec.). $C_{14}H_{24}KN_4O_6SSe$ (494.50): calcd. C 34.00, H 4.89, N 11.33; found C 34.09, H 4.71, N 11.36. Concentration of the initially obtained thf solution gave PhSSPh (98%), as identified by GC-MS techniques by comparison with an authentic sample.

## Acknowledgments

The authors are grateful to Prof. Yuri N. Molin and Dr. Leonid A. Shundrin for valuable discussions, to Dr. Alexander Yu. Makarov and Mr. Peter Brackmann for their assistance in the preparative and XRD experiments, respectively, and to the Deutsche Forschungsgemeinschaft (grant 436 RUS 113/486/0-3 R), the Russian Foundation for Basic Research (grants 06-03-32229, 06-03-32742, and 07-03-00467), and the Siberian Division of the Russian Academy of Sciences (interdisciplinary project No. 25) for financial support of this work. N. G. gratefully acknowledges the Ohio Supercomputing Center, USA, for providing computational facilities.

# [(Tmp)$Co_2$L] Complexes through Preassembly on 2,6-Diformyl- and 2,6-Bis(benzylimino)-4-methylphenolate Templates

**Alok Ranjan Paital,[a] Mrinal Sarkar,[a] Masahiro Mikuriya,[b] and Debashis Ray*[a]**

**Keywords:** Cobalt complexes / Bridging ligands / Template synthesis / Imidazolidine / Magnetic properties

The reaction of the dinucleating ligand $H_3L$ {2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine} with $Co(OAc)_2{\cdot}4H_2O$ and $NaN_3$ in MeOH produces the methoxide-bridged dicobalt complex [$Co^{III}_2$(μ-OMe)L$(N_3)_2$] (**1**) under aerobic conditions. If the reaction occurs in the presence of either 2,6-diformyl-4-methylphenolate ($dfp^-$) or 2,6-bis(benzyliminomethyl)-4-methylphenolate ($bip^-$), a preassembly of the [$Co^{II}_2(OPh)]^{3+}$ units takes place on these templates before coordination with $L^{3-}$ in [$Co^{II}_2$(μ-dfp)L]·$3H_2O$ (**2**·$3H_2O$) and [$Co^{II}_2$(μ-bip)L]·$3H_2O$ (**3**·$3H_2O$), respectively. Incorporation of these coligands into the structure leads to stabilization of 3+ and 2+ oxidation states of the cobalt. In complex **2**, the $Co^{II}$ ions are engaged in a weak antiferromagnetic interaction.

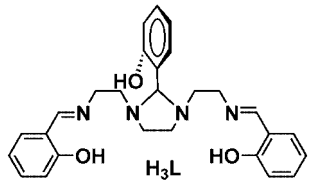
## Introduction

Dinuclear high-spin cobalt(II) complexes have been the subject of recent investigations in molecular magnetism and magnetic analysis.[1] These high-spin cobalt(II) complexes show interesting magnetic properties, where the ground term possesses an orbital angular moment.[2] Cobalt can also give rise to mixed-valent complexes because of its ready access to 2+ and 3+ oxidation states. These complexes have attracted attention because of their fascinating magnetic properties as well as their biological relevance. They can serve as synthetic models of dimetallic biosites, such as in methionine aminopeptidase,[3] and can show DNA cleavage activity.[4] This type of metallohydrolase is known to require two or more metal ions for hydrolysis of phosphate ester and peptide bonds.[5] Recently, Love and co-workers have used a binucleating macrocycle to prepare low-spin square-planar $Co^{II}Co^{II}$ diporphyrin complexes having a pacman-like cleft showing interesting dioxygen reduction chemistry.[6] Because of these various interesting features of cobalt ions, we studied their reactivity toward imidazolidinyl ligands.[7] We and others have been exploring the dinucleating properties of the ligand $H_3L$ (Scheme 1) {2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine}[8] and its close derivative $H_3L'$ {2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-4-methyl-3-azabut-3-enyl]-2-methyl-1,3-imidazolidine}[9] for various reasons, including their importance in coordination chemistry, molecular magnetism, and catalysis.[9–16]



Scheme 1.

During the course of these investigations, we have observed that in certain conditions, complexation reactions with $Mn^{III}$, $Fe^{III}$, $Co^{III}$, or $Cu^{II}$ led to the hydrolysis of the imidazolidine ring[17,18] and even the destruction of one of the imine linkages of the hexadentate proligand.[19] We have also investigated the hydrolysis of $H_3L$ as triggered by $Co^{III}$ and isolated the mononuclear complex resulting from the hydrolyzed ligand.[7] Previously Fondo et al. showed that this type of ligand leads to either $Co^{III}_2$ or mixed-valent $Co^{III}Co^{II}$ complexes[20] by spontaneous oxidation of $Co^{II}$ salts in air. The main objectives of the present investigation are (i) to scrutinize the role of the different ligand templates in inhibition of the coordination-induced hydrolysis of the imidazolidine ring of the trisphenolate ligands, (ii) to synthesize a new $Co_2$ complex of this ligand incorporating template ligands, and (iii) to stabilize the 2+ oxidation states of cobalt in phenolate environments. We have successfully achieved our goal by using 2,6-diformyl-4-methylphenol (Hdfp) and 2,6-bis(benzyliminomethyl)-4-methylphenol (Hbip) as coligands (Scheme 2).

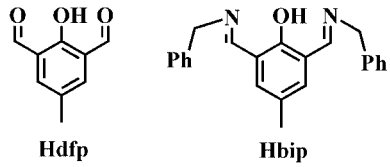


Scheme 2.

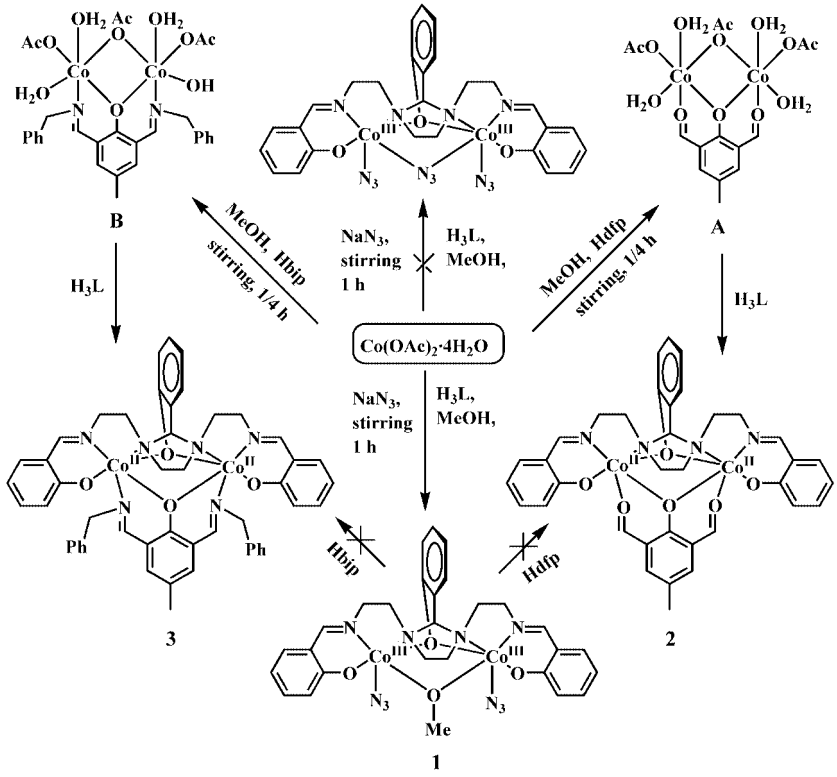
These coligands not only inhibit hydrolysis of $L^{3-}$ but also serve as templates to stabilize the metal ions in 2+ oxidation states in two new [$Co_2$] complexes. Hydroxy carboxaldehydes of this type have been used extensively as precursors in the preparation of more complicated ligands,[21] however their use as exogenous bridging ligands is very uncommon.[22] While exploring the metal ion coordination processes toward $L^{3-}$, we found that the reactions of a particular metal salt control the production of the desired complex in the presence and absence of externally added or solvent-derived template bridges. Herein complexes [$Co^{III}_2$(μ-OMe)L($N_3$)$_2$] (**1**), [$Co^{II}_2$(μ-dfp)L]·3$H_2O$ (**2**·3$H_2O$), and [$Co^{II}_2$(μ-bip)L]·3$H_2O$ (**3**·3$H_2O$) derived from ligand $H_3L$ following two different (solvent-derived or external) template routes are reported. Complexes **1** and **2**·3$H_2O$ were crystallographically characterized and the magnetic properties of **2**·3$H_2O$ were also studied.

## Results and Discussion

### Syntheses, Reactivity, and Spectroscopic Characterizations

The ligand $H_3L$ {2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine} (Scheme 1) was prepared according to a literature procedure[8] and its reaction with cobalt(II) salts has been investigated, as shown in Scheme 3.

In MeOH, the reaction of $Co(OAc)_2$·4$H_2O$ and $NaN_3$ followed by addition of a methanolic solution of $H_3L$ in a 2:2:1 molar ratio yields brown [$Co^{III}_2$(μ-OMe)L($N_3$)$_2$] (**1**) in 75% yield while stirring in air at room temperature (300 K). Complex **1** could be isolated in high purity and shows aerial oxidation of metal centers. It has also been observed that use of excess $NaN_3$ up to a molar ratio of 1:6 could not substitute the bridging $MeO^-$ group by $N_3^-$ and afforded **1** exclusively. In a previous report, we noticed that in solution $H_3L$ is unstable during reactions with cobalt(II) salts and produced crystals of the mononuclear complex cations [CoL′]$^+$ in low yield ($H_2L'$ is the hexadentate proligand formed from the imidazolidine ring hydrolysis of $H_3L$).[7] As an *o*-formylphenolate moiety is generated from the hydrolysis of $L^{3-}$, which indicates that the ligand decomposition is possibly inhibited by this. Therefore the solution stability of $L^{3-}$ as part of new [$Co_2$] complexes could be enhanced with the introduction of diformyl- and bis(benzylimino)phenolates as template ligands. 2,6-Diformyl-4-meth-



Scheme 3.

ylphenol (Hdfp)[21] and 2,6-bis(benzyliminomethyl)-4-methylphenol (Hbip)[23] have been synthesized following the methods previously described and satisfactorily characterized by elemental analysis, IR, and $^1$H NMR spectroscopy. Binucleating ligands based on this dialdehyde as introduced by Robson[24] and Okawa[25] have been extensively studied for the preparation of different dimetal complexes. The process of ligand hydrolysis, however, was inhibited completely if Hdfp or Hbip had previously been mixed with the solution of $Co(OAc)_2{\cdot}4H_2O$. Presumably this led to the formation of intermediate **A** or **B** (Scheme 3), to result in the formation of complexes **2** and **3**, after addition of $H_3L$ where the deprotonated dicarbonyl phenolate ($dfp^-$) and bis(benzylimino)phenolate ($bip^-$) behave as bisdidentate bridging ligands stabilizing the $Co^{II}_2$ complexes. The formulation of all the complexes is consistent with the elemental and metal analysis, and solution electrical conductivity data in $CH_3CN$. The red complex **2** forms in 80% yield whilst stirring in MeOH at 300 K. Similarly, compound **3** was isolated in 75% yield as a red powder. All the compounds are insoluble in water and separate directly from the reaction mixture following the completion of the reactions in air at room temperature. Stabilization of the metal oxidation states within these $Co_2$ complexes is template-ligand-dependent. Template interconversions within this family of the complexes are not possible in the presence of external oxidizing and reducing agents. This clearly identifies that the templates are present as an integral part within these assemblies.

### Infrared Spectroscopy

The sharp peak in the FTIR spectra of complexes **1**, **2**·3$H_2O$, and **3**·3$H_2O$, at 1629, 1625, and 1624 $cm^{-1}$ respectively, are characteristic of the C=N functionality of the ligand $L^{3-}$. The C=N stretching frequency of the free Hbip ligand is shifted from 1636 $cm^{-1}$ to 1601 $cm^{-1}$ in **3**·3$H_2O$. Broad medium bands at 3396 and 3422 $cm^{-1}$ are observed corresponding to $\nu$(OH) vibrations from lattice water molecules in complexes **2**·3$H_2O$ and **3**·3$H_2O$, respectively. In addition, complex **1** shows a very strong sharp band at 2025 $cm^{-1}$ for the $\nu_{as}(N_3^-)$ stretching[26] and the $\nu_s(N_3^-)$ appears at 1322 $cm^{-1}$. The position of this band is consistent with terminal azide coordinations, as observed in other cobalt(III) complexes.[27] Complex **2** also shows a sharp band at 1597 $cm^{-1}$ due to the coordinated $\nu$(C=O) functionality of the $dfp^-$ ligand.

### Electronic Spectroscopy

In MeCN solution, the brown compound **1** shows a band at 639 nm ($\varepsilon$ = 470 $L\,mol^{-1}\,cm^{-1}$) and is characteristic of the octahedral cobalt(III) environment ($^1A_{1g} \rightarrow {}^1T_{1g}$) in the d–d spectra. The charge transfer transitions ($L \rightarrow Co^{III}$ and intraligand) occur at 349 nm ($\varepsilon$ = 4600 $L\,mol^{-1}\,cm^{-1}$) and 271 nm (7600 $L\,mol^{-1}\,cm^{-1}$) with an overlapping contribution of $^1A_{1g} \rightarrow {}^1T_{2g}$ in the former. Complex **2** shows d–d transition at 562 nm ($\varepsilon$ = 310 $L\,mol^{-1}\,cm^{-1}$) and charge transfer transitions at 375 and 271 nm with molar extinction coefficients of 2400 and 12500 $L\,mol^{-1}\,cm^{-1}$. Similarly, complex **3** shows d–d transition at 591 nm ($\varepsilon$ = 361 $L\,mol^{-1}\,cm^{-1}$) and charge transfer transitions at 401 (2100 $L\,mol^{-1}\,cm^{-1}$) and 274 nm (8700 $L\,mol^{-1}\,cm^{-1}$). In a reported octahedral $Co^{II}$ compound, observation of the three bands around 450, 550, and 850 nm are assigned to spin-allowed excitations from the $^4T_{1g}$(F) ground state.[28] So for compounds **2** and **3** the bands at 562 and 591 nm may be assigned to the spin-allowed transitions from $^4T_{1g}$(F) to $^4A_{2g}$.

### The Role of Template Anions in the Stabilization of the Ligand Imidazolidine Ring

Earlier we showed that expulsion of 1 mol of 2-hydroxybenzaldehyde molecules takes place when cobalt ions react with the ligand $H_3L$ in aqueous MeOH solution in air, which is different from the selective imidazolidine ring-opening reaction for a different ligand system with no loss of aldehyde molecule.[29] In the presence of solvent-generated $MeO^-$ template and terminal $N_3^-$ coordination, a similar situation did not arise leading to imidazolidine ring hydrolysis. Thus the presence of both $MeO^-$ and $N_3^-$ stabilizes the imidazolidine ring and cobalt ions in 3+ oxidation states. Also terminal double $N_3^-$ coordination did not provide any tetranucleation through *cis*-1,3-$N_3^-$ bridges. In exactly the same fashion 2,6-diformyl- and 2,6-bis(benzylimino)-4-methylphenolate templates (Tmp) stabilize the $L^{3-}$ against imidazolidine ring hydrolysis and 2+ oxidation states of cobalt ions in a new family of $Co_2$ complexes. The nature of the final reaction product is greatly influenced by the ligands used in different steps, the solvent system, and the sequence of addition of reactants.

### X-ray Crystallographic Procedures for 1 and 2·3$H_2O$

The intensity data of complexes **1** and **2** were collected on a Nonius CAD4 X-ray diffractometer using single-crystal graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) by the $\omega$-scan method. Data were collected at 293 K. Information concerning X-ray data collection and structure refinement of the compound is summarized in Table 1. For complex **1**, a total of 4926 reflections were recorded with Miller indices $h_{min}$ = –11, $h_{max}$ = 0, $k_{min}$ = 0, $k_{max}$ = 24, $l_{min}$ = –16, and $l_{max}$ = 16. For complex **2**, a total of 6861 reflections were recorded with Miller indices $h_{min}$ = 0, $h_{max}$ = 23, $k_{min}$ = 0, $k_{max}$ = 23, $l_{min}$ = 0, and $l_{max}$ = 21. In the final cycles of full-matrix least-squares on $F^2$ all non-hydrogen atoms were assigned anisotropic thermal parameters. The positions of the H atoms bonded to C atoms were added (C–H distance 0.97 Å) in the riding model. The structure was solved using the SHELX-97[30] program system.

## Description of Structures

Single crystals suitable for X-ray structure determinations were obtained by slow evaporation of a MeOH/$CH_3CN$ (1:1) solution of **1** and a MeOH solution of **2**·3$H_2O$ after a week. The atom labeling scheme and molecular views (ORTEP) of the complexes are shown in Figures 1, 2, 3, and 4. Selected interatomic distances and angles are collected in Tables 2 and 3.

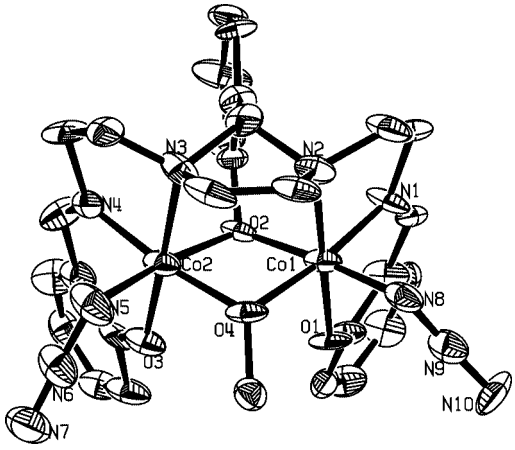

Figure 1. ORTEP representation of [$Co^{III}_2$(μ-OMe)L($N_3$)$_2$] (**1**) at the 40% probability level. Hydrogen atoms are omitted for clarity. Only independent non-carbon atoms are labeled.

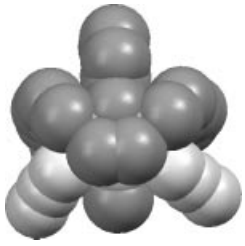

Figure 2. The ψ-like shape of the ligand covers the Co(μ-OMe)Co unit of **1** in a space-filling model when viewed along one intermediate axis (deep grey: ligand carbon; light grey: nitrogen).

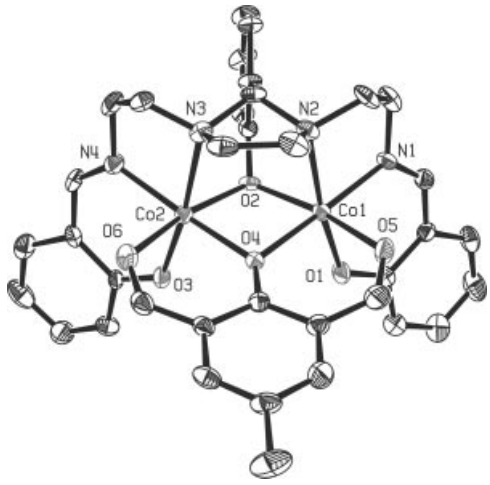

Figure 3. ORTEP representation of [$Co_2$(μ-dfp)L] (**2**) at the 30% probability level. Hydrogen atoms are omitted for clarity. Only independent non-carbon atoms are labeled.

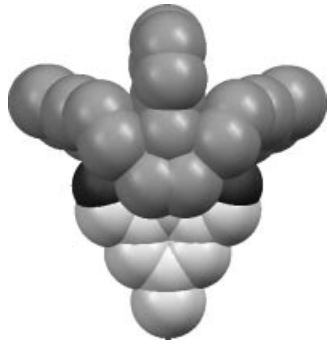

Figure 4. The template ligand in an "ice-cream cone" shape holds the Co(μ-OPh)Co unit in a space-filling model when viewed along one intermediate axis (light grey: template carbon; dark grey: ligand carbon; black: oxygen).

### *[$Co^{III}_2$(μ-OMe)L($N_3$)$_2$] (1)*

Complex **1** (Figure 1) is a neutral aggregate of two $Co^{III}$ ions linked by the template action of solvent-derived $MeO^-$ and capping coordination of the heptadentate ligand $L^{3-}$.

The unit cell of **1** consists of [$Co^{III}_2$(L)(μ-OMe)($N_3$)$_2$] neutral molecules, without any solvent of crystallization. Each tetradentate $N_2O_2$ pocket binds $Co^{III}$ ions in *cis* fashion; *facial* coordination involves bridging phenolate O, imidazolidine, and imine N atoms. The bridging function is accomplished by the central imidazolidine group (NCN group) and phenolate moiety (one μ-O) of $L^{3-}$, while the imine N-atom and the phenoxide O-donor at each side of the ligand saturate two additional coordination sites of each $Co^{III}$ center. The $MeO^-$ group, in preference to the $N_3^-$ group, contributes to the bridging within the complex and functions as a template in the absence of any externally added chelating exogenous template ligand. tion around each Co ion is achieved through terminal binding of two $N_3^-$ ions. Each Co atom is thus coordinated in a distorted octahedral $N_3O_3$ environment in which the two octahedra sharing the edge are defined by the bridging phenolate and methoxide O atoms (Scheme 4 with N5 and N8). The planes intersecting at this edge form an angle of 162.95°, as a result of the folding imposed by the imidazolidine ring [N2···N3 distance of 2.342(4) Å]. The geometric restrictions resulting from $L^{3-}$ also cause the Co–O–Co angles to be different [96.2(4)° and 99.1(4)°] for endogenous phenolate and exogenous methoxide oxygen atoms, respectively. The sums of the angles around the oxygen atoms of the central phenolate and methoxide bridges are 330.37° and 342.03° and demonstrate that the pyramidal distortion is more pronounced in the case of phenolate O atom because of a folding of the ligand $L^{3-}$ around the imidazolidine backbone. The intramolecular Co···Co distance is 2.869(3) Å. The O–Co–O angles [81.4(4)° and 80.4(4)°] within the metallacyclic $Co_2(\mu\text{-}O)_2$ diamond core indicate distortions at the metal ion octahedra. The degree of distortion from an ideal octahedral (90°) geometry is reflected in the *cisoid* [95.4(4)–80.4(4)°] and the *transoid* [179.0(5)–172.3(5)°] angles. The bridging Co–O(phenolate) distances [1.955(9) Å] are longer than the terminal distances (av. 1.859 Å).

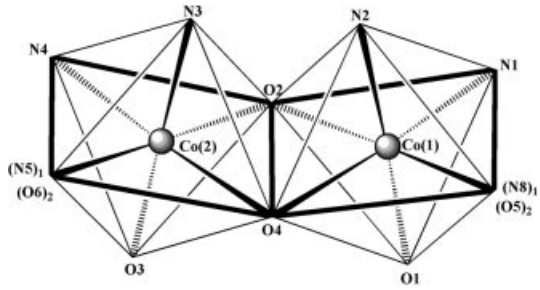

Scheme 4.

The Co–N(imidazolidine) [2.031(11) and 2.032(11) Å] and Co–N(imine) [1.871(11) and 1.879(15) Å] distances are clearly different. The terminal Co–N(azide) distances [1.883(15) and 1.930(13) Å] are intermediate between the above two distances.[31] The azide terminals are almost linear, with N–N–N angles 172.6(19)–172.8(17)°. The nonlinear monodentate coordination of $N_3^-$ is reflected in the Co–N–N angles of 121.0(11) and 118.0(10)°. Perfect covering of the Co(μ-OMe)Co unit by a ψ-like appearance of the ligand in a space-filling model is shown in Figure 2.

In crystal packing no H-bonding network is present because of the absence of solvate molecules within the crystal lattice. The crystal-packing diagram is shown in Figure S1 (see Supporting Information).

### *[$Co^{II}_2$(μ-dfp)L]·3$H_2O$ (2·3$H_2O$)*

The unit cell of **2**·3$H_2O$ consists of a dinuclear complex [$Co_2$(μ-dfp)L] (**2**) (Figure 3) along with three water molecules. Complex **2** is a neutral aggregate of $Co^{II}$ ions bridged and chelated by the ligand $L^{3-}$ in the same manner as in complex **1**. The bridging and hexacoordination of both metals is completed by a symmetric 2,6-diformylphenolate ($dfp^-$) ligand that terminally binds both metals through each of its carbonyl groups, while linking them through the central phenolate μ-O. This type of exogenous bridging coordination mode of the 2,6-diformyl-4-methylphenolate anion is quite unusual. The bridging bisdidentate ligand $dfp^-$ naturally binds the edges offered by the $[Co_2L]^+$ moiety (Scheme 4), therefore the exchange of two $N_3^-$ and $MeO^-$ ions for $dfp^-$ in going from **1** to **2** does not introduce significant changes to the overall metric parameters of the complex. Each Co atom is thus coordinated in a distorted octahedral $N_2O_4$ environment in which the two octahedra

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sharing the edge are defined by the bridging phenolate oxygen atoms of different origin (Scheme 4 with O5 and O6). The planes intersecting at this edge form an angle of 160.94° as a result of the folding imposed by the imidazolidine ring (N2···N3 distance of 2.303 Å). The geometric restrictions resulting from $L^{3-}$ also cause the Co–O–Co angles to be different [97.0(3)° and 95.8(4)°] for endogenous and exogenous phenolate O atoms, respectively. The sums of the angles around the oxygen atoms of the central endogenous and exogenous phenolates are 333.28° and 359.16°, indicating the pyramidal and planar nature of phenolate oxygen atoms of different origin. The Co···Co separation at 3.073 Å is longer than 2.869(3) Å in **1** and is due to the different oxidation levels of cobalt ions in octahedral geometries. The O–Co–O angles [82.0(3) and 82.7(3)] within the metallacyclic $Co_2(\mu\text{-}O)_2$ diamond core indicate distortions at the metal ion octahedra.

The degrees of distortion from an ideal octahedral (90°) geometry are reflected in the *cisoid* [102.7(4)–82.0(3)°] and the *transoid* [173.0(4)–167.0(3)°] angles. Compared to $Cu_2$ binding[9,19] in *meridional* mode with apical $AcO^-$ or $N_3^-$ bridging, the $dfp^-$ template in the present case forces a *facial* binding [chelate bite angles are 102.7(4), 87.0(3), and 82.2(4)° around Co1 and 102.1(4), 87.1(3), and 81.6(5)° around Co2] of the O(central phenolate)N(imidazolidine)-N(imine) part of $L^{3-}$.

Earlier we showed that in $Cu_2$ complexes each tetradentate $N_2O_2$ pocket endorses either square-pyramidal or distorted trigonal-bipyramidal geometry. Now we report its potential to accommodate $Co^{II}$ ions in octahedral geometries that have *facial* coordination involving the bridging phenolate O, and imidazolidine and imine nitrogen atoms. The bridging Co–O(phenolate) distances [av. 2.050 Å] are longer than terminal distances (av. 1.979 Å). The Co–N-(imidazolidine) [2.254(11) to 2.261(10) Å] and Co–N(imine) [2.019(10) to 2.026(12) Å] distances are clearly different. The terminal Co–O(carbonyl) distances [2.103(9) and 2.144(9)] are intermediate between the above two distances and the angle between the chelate rings of $dfp^-$ is 160.94°. The template ligand in an "ice-cream cone" shape holds the Co(μ-OPh)Co unit in a space-filling model of the complex (Figure 4). Intramolecular hydrogen bonding was found between lattice water molecules and terminal phenolate oxygen atoms of ligand $L^{3-}$ (Figure S2). A crystal-packing diagram along the *c* axis is shown in Figure S3.

### Magnetochemistry of $[Co^{II}_2(\mu\text{-dfp})L]\cdot 3H_2O$ ($2\cdot 3H_2O$)

The magnetic property of complex $2\cdot 3H_2O$ was investigated by means of bulk magnetization methods. Measurements were collected under a constant magnetic field of 0.5 T in the 4.5–300 K temperature range. The effective magnetic moment at 300 K of **2** is measured to be $6.24\mu_B$ against $5.38\mu_B$ at 4.5 K per molecule of the complex. The temperature dependence of the magnetic moment was analyzed by the expression $\chi_M = f(T)$[32] derived from the Van Vleck equation, where

$$\chi_M = \frac{2Ng^2\beta^2}{kT}\left[\frac{14 + 5\exp(-6J/kT) + \exp(-10J/kT)}{7 + 5\exp(-6J/kT) + 3\exp(-10J/kT) + \exp(-12J/kT)}\right]$$

The results for the complex are represented in Figure 5 in the form of $\chi_M$ and $\mu_{eff}$ versus *T* plots ($\chi_M$ is the molar paramagnetic susceptibility and $\mu_{eff}$ is the effective magnetic moment). The parameters emerging from this fit are $J = -0.38\ cm^{-1}$ and $g = 2.27$, and *Na* was set to $0\ cm^3\ mol^{-1}$. The experimental behavior clearly shows that the intramolecular coupling is antiferromagnetic, leading to a ground state $S = 3/2{:}3/2$ dimer model applicable because the distortion from octahedral symmetry is so large.[2a] So the small antiferromagnetic intramolecular coupling might be ascribed to the $Co^{II}$–O–$Co^{II}$ angles formed by the phenolate bridges (between 95.79° and 97°), which are within the range predicted to lead to antiferromagnetic interactions in $Co^{II}_2$ systems.[33]

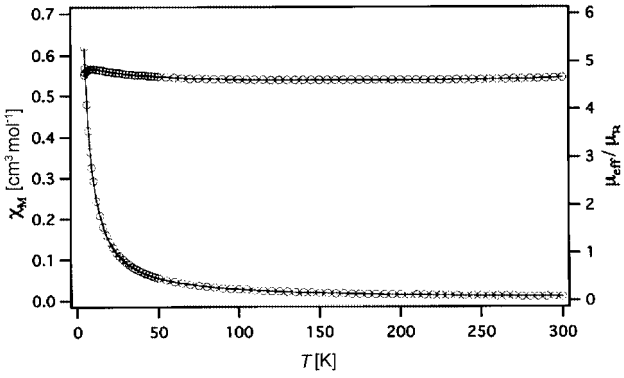

Figure 5. Plot of the temperature dependence of $\chi_M$ and $\mu_{eff}$ for complex $2\cdot 3H_2O$.

## Conclusions

We have shown that both solvent-derived and externally added templates control the synthesis of a new family of $Co^{III}Co^{III}$ and $Co^{II}Co^{II}$ complexes using a binucleating imidazolidinyl ligand $H_3L$. As part of the interesting chemistry of the ligand $L^{3-}$ with $Co^{II}$ and $Co^{III}$, we have shown that in situ generation of methoxide in the presence of $N_3^-$ and external addition of diformylphenolate and bis(benzylimino)phenolate to the system inhibit the imidazolidine ring hydrolysis of the $L^{3-}$ and lead to the high-yield formation of the assemblies $[Co^{III}_2(\mu\text{-OMe})L(N_3)_2]$ (**1**), $[Co^{II}_2(\mu\text{-dfp})L]\cdot 3H_2O$ ($2\cdot 3H_2O$), and $[Co^{II}_2(\mu\text{-bip})L]\cdot 3H_2O$ ($3\cdot 3H_2O$). The crystal structure of **1** shows that aerial oxidation in the presence of anions yields the $Co_2$ complex in 3+ oxidation state, whereas this oxidation is prevented when bisdidentate bridging template ligands are used. Interconversion of the templates within this family of the complexes is not permissible, which in turn identifies the templates as an integral part of these assemblies. Magnetic measurements indicate that complex **2** exhibits weak antiferromagnetic coupling between the $Co^{II}$ centers bridged by two phenolate groups of different origin. We are currently working to exploit the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

asymmetry induced by external bridges in this reaction system in order to induce the formation of heterometallic and high nuclearity complexes.

## Experimental Section

**Materials and Physical Measurements:** The chemicals used were obtained from the following sources: Triethylenetetramine, sodium azide, and cobalt acetate tetrahydrate from S.D. Fine Chem. (India) and 2-hydroxybenzaldehyde from SRL (India). 2,6-Diformyl-4-methylphenol (Hdfp) and 2,6-bis(benzyliminomethyl)-4-methylphenolate (Hbip) were prepared by the literature procedures.[21,23] All other chemicals and solvents were reagent-grade materials and were used as received without further purification. The elemental analyses (C,H,N) were performed with a Perkin–Elmer model 240C elemental analyzer. FTIR spectra were recorded with a Perkin–Elmer RX1 spectrometer. The solution electrical conductivity and electronic spectra were obtained using a Unitech type U131C digital conductivity meter with a solute concentration of about $10^{-3}$ M and a Shimadzu UV 3100 UV/Vis/NIR spectrophotometer respectively. The room-temperature magnetic susceptibilities in the solid state were measured using a home-built Gouy balance fitted with a Polytronic d.c. power supply. The experimental magnetic susceptibilities were corrected for the diamagnetic response using Pascal's constants. Magnetic measurements were carried out on polycrystalline samples (about 30 mg) using a Quantum Design MPMS-5S SQUID magnetometer operating at a constant magnetic field of 5000 G between 4.5 and 300 K. The experimental magnetic moment was corrected for the diamagnetic contribution from the sample holder and the diamagnetic response from the sample, which was evaluated from Pascal's constants.

**General:** All experimental procedures were carried out under air at room temperature. The ligand $H_3L$ {2-(2′-hydroxyphenyl)-1,3-bis[4-(2-hydroxyphenyl)-3-azabut-3-enyl]-1,3-imidazolidine} was prepared according to a literature procedure.[8]

**Synthesis of Complexes:** One single high-yield method was followed for the synthesis and isolation of complexes **1**–**3**. For complex **1**, a nontemplate procedure was followed in which the methoxide template was generated in solution, while for **2** and **3** prior addition of template ligands was necessary. In the absence of these templates and in the presence of azides, only **1** is isolated exclusively. Details are given below for the representative cases.

**$[Co^{III}_2(\mu\text{-}OMe)L(N_3)_2]$ (1):** $NaN_3$ (0.13 g, 2.00 mmol) in MeOH was added dropwise to the methanolic solution (20 mL) of $Co(OAc)_2{\cdot}4H_2O$ (0.5 g, 2.00 mmol) and stirred for 15 min. Methanolic solution (15 mL) of ligand $H_3L$ (0.458 g, 1.00 mmol) was then added dropwise to the above solution, and stirring was continued in air for 1 h leading to the oxidation of both the metal ions to $Co^{III}$. After evaporation of the reaction mixture a brown solid was obtained (about 75% yield). The reaction in the presence of up to 6 mmol of $NaN_3$ yields complex **1** exclusively, with no sign of azido bridging. The solid was isolated, washed with cold methanol, and dried under vacuum over $P_4O_{10}$. $C_{28}H_{30}Co_2N_{10}O_4$ (688.48): calcd. C 48.84, H 4.39, N 20.34; found C 48.76, H 4.28, N 20.08. Selected FTIR bands (KBr): $\tilde{\nu}$ = 2025 (vs), 1629 (vs), 1531 (m), 1451 (s), 1322 (m), 1264 (m), 1146 (m), 1093 (m), 949 (m), 755 (m) $cm^{-1}$. Molar conductance, $\Lambda_M$ ($CH_3CN$ solution): 6 $ohm^{-1}cm^2mol^{-1}$. UV/Vis spectra ($CH_3CN$ solution): $\lambda_{max}$ ($\varepsilon$, $L\,mol^{-1}cm^{-1}$) = 639 (470), 349 (4600), 275 (7600) nm.

***Caution!*** Metal azide complexes are potential explosives. Only a small amount of material should be prepared and handled with caution.

**$[Co^{II}_2(\mu\text{-}dfp)L]{\cdot}3H_2O$ (2·3H$_2$O):** 2,6-Diformyl-4-methylphenol (Hdfp) (0.164 g, 1.00 mmol) in MeOH was added dropwise to a methanolic solution (50 mL) of $Co(OAc)_2{\cdot}4H_2O$ (0.5 g, 2.00 mmol) for 15 min whilst stirring. Ligand $H_3L$ (0.458 g, 1.00 mmol) in hot methanol (20 mL) was added to the resulting solution and the mixture was stirred for another 1 h. The resulting solution was filtered and left undisturbed to slowly evaporate. After 4 d, a red crystalline product was obtained (about 80% yield). The solid was isolated, washed with cold methanol, and dried under vacuum over $P_4O_{10}$. $C_{36}H_{39}Co_2N_4O_9$ (789.59): calcd. C 54.76, H 4.97, N 7.09; found C 54.66, H 4.88, N 6.92. Selected FTIR bands (KBr): $\tilde{\nu}$ = 3396 (b), 1625 (s), 1597 (s), 1528 (s), 1443 (s), 1397 (m), 1341 (m), 1230 (m), 1185 (m), 1146 (m), 1034 (m), 988 (m), 756 (m) $cm^{-1}$. Molar conductance, $\Lambda_M$ ($CH_3CN$ solution): 6 $ohm^{-1}cm^2mol^{-1}$. UV/Vis spectra ($CH_3CN$ solution): $\lambda_{max}$ ($\varepsilon$, $L\,mol^{-1}cm^{-1}$) = 562 (310), 375 (2400), 271 (12500) nm.

**$[Co^{II}_2(L)(\mu\text{-}bip)]{\cdot}3H_2O$ (3·3H$_2$O):** 2,6-Bis(benzyliminomethyl)-4-methylphenolate (Hbip) (0.342 g, 1.00 mmol) was added dropwise to a methanolic solution (50 mL) of $Co(OAc)_2{\cdot}4H_2O$ (0.5 g, 2.00 mmol) for 15 min whilst stirring. Ligand $H_3L$ (0.458 g, 1.00 mmol) in hot methanol (20 mL) was added to the resulting solution and the mixture was stirred for another 1 h. The resulting solution was filtered and left undisturbed to slowly evaporate. After 7 d, a red crystalline product was obtained (about 75% yield). The solid was isolated, washed with cold methanol, and dried under vacuum over $P_4O_{10}$. $C_{50}H_{54}Co_2N_6O_7$ (968.88): calcd. C 61.98, H 5.61, N 8.67; found C 61.88, H 5.54, N 8.48. Selected FTIR bands (KBr): $\tilde{\nu}$ = 3422 (b), 1624 (vs), 1601 (s), 1560 (s), 1451 (vs), 1400 (m), 1320 (m), 1233 (m), 1028 (m), 754 (m) $cm^{-1}$. Molar conductance, $\Lambda_M$ ($CH_3CN$ solution): 8 $ohm^{-1}cm^2mol^{-1}$. UV/Vis spectra ($CH_3CN$ solution): $\lambda_{max}$ ($\varepsilon$, $L\,mol^{-1}cm^{-1}$) = 591 (361), 401 (2100), 274 (8700) nm.

CCDC-644647 (for **1**) and -644648 (for **2**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Coordination Behaviour of Bis-Terdentate N-Donor Ligands: Double- and Single-Stranded Helicates, Mesocates, and Cyclic Oligomers

**Nawal K. Al-Rasbi,[a] Harry Adams,[a] Lindsay P. Harding,[b] and Michael D. Ward*[a]**

**Keywords:** Chelating ligands / Coordination chemistry / Helical structures / Self-assembly

Three new ligands have been prepared in which two terdentate chelating pyrazolyl-bipyridine units are connected by a central aromatic spacer via methylene "hinges": the spacers are *o*-phenylene ($L^{Ph}$), 2,6-pyridine-diyl ($L^{Py}$) and 2,3-naphthalenediyl ($L^{naph}$). The ligands act as potentially hexadentate bridging ligands, with the central pyridyl N atom of $L^{Py}$ not involved in coordination. The following complexes were prepared and structurally characterised: $[M_2(L^{Ph})_2][ClO_4]_4$ (M = Ni, Cu), which are dinuclear double helicates; $[Ag_2(L^{Ph})(MeCN)_2][BF_4]_2$, a dinuclear complex with an Ag···Ag bond in which the ligand adopts a helical twist around the pair of metal ions; $[Ni_2(L^{Py})_2][BF_4]_4$, an achiral "mesocate" with a box-like structure and a face-to-face arrangement of ligands; $[Ag_3(L^{naph})_2](BF_4)_3$, which contains a linear trinuclear array of $Ag^I$ ions with the two ligands arranged in a shallow helical twist, each ligand spanning one terminal and the central metal ion; and $[Cd_6(L^{naph})_6](ClO_4)_{12}$, a cyclic hexanuclear helicate with a perchlorate anion in the central cavity. Both $[Cu_2(L^{Ph})_2][ClO_4]_4$ and $[Cd_6(L^{naph})_6](ClO_4)_{12}$, which have architecturally similar bridging ligands, show evidence by electrospray mass spectrometry for formation of a range of cyclic oligomers in solution up to 11-mers for the $Cd^{II}/L^{naph}$ system.

## Introduction

Complexes with double or triple helical structures ("helicates") have been of interest in the field of coordination chemistry for many years. These assemblies have elegantly demonstrated how the formation of architecturally complex systems is directed by the interplay between simple parameters such as the stereoelectronic preference of the metals ion and the disposition of the binding sites in the ligand.[1]

Despite that the fact that very many helical complexes are known, the field remains as popular as ever because of the development of new research areas which involve them. These are remarkably diverse as some very recent examples will illustrate. Hannon and co-workers have shown how relatively simple dinuclear helicates bind to DNA and stabilise a triple junction.[2] Rice and co-workers have prepared ligands in which the degree of twist between the two binding domains can be controlled by allosteric means, allowing the assembly of helicate complexes to be controlled by an external perturbation.[3] A double helical ligand array has been used as a scaffold for a dinuclear $Cu^I/Cu^{II}$ complex which shows unusual electronic delocalisation behaviour.[4] Piguet has used polynuclear helicate complexes to understand and illustrate the phenomenon of cooperativity in self-assembly processes,[5] and has used heterodinuclear d/f helicates for studies on photoinduced energy-transfer between d-block and f-block luminophores.[6] Nitschke has used structurally relatively simple dinuclear $Cu^I$ helicates with different combinations of ligands to probe the concept of "valence frustration" which plays an important role in controlling self-assembly processes.[7] Triple helicates with a pendant hydrogen-bonding group attached to each ligand have been found to bind anions in the resultant pocket, and such anion binding can control the orientation of the three ligands in the helical scaffold.[8] Williams and co-workers showed how dinuclear helicates can display unusual stepwise spin-crossover properties, associated with mechanical coupling between the two metal centres.[9] Certain anions can template formation of cyclic helicates in which the anion occupies the central cavity, and the size of the anion dictates the size of the metal/ligand circular helical array around it.[10]

We report here the preparation and coordination chemistry of a set of three new bis-tridentate ligands $L^{Ph}$, $L^{py}$, and $L^{naph}$ (Scheme 1), in which two terdentate arms, each based on a pyrazolyl–pyridyl–pyridyl sequence of donors, are connected to various different aromatic spacers (*o*-phenylene, pyridine-2,6-diyl, and 2,3-naphthalenediyl, respectively). Flexibility in the ligand backbone is provided by the methylene "hinges" which connect the terdentate arms to the central spacer. These belong to a general class of bridging

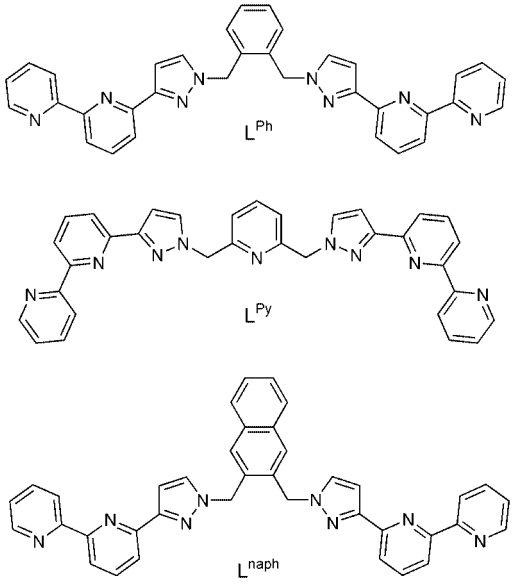
ligand that we have studied extensively in the last few years and which have proven to be particularly effective at providing polynuclear complexes with elaborate and often unexpected structures.[10b,11]



Scheme 1.

## Results and Discussion

### Ligand Syntheses

The new ligands (Scheme 1) were prepared by the reaction of two equivalents of 6-(pyrazol-3-yl)-2,2′-bipyridine[12] with the appropriate bis(bromomethyl)-substituted organic spacer, in the presence of hydroxide ion under phase-transfer conditions, according to the method we have used for related ligands in this series.[13] All of the spectroscopic and analytical data were consistent with the formulation of the ligands. Needles of $L^{Ph}$ suitable for X-ray analysis were obtained by slow evaporation of a dilute dichloromethane solution of the ligand. The crystal structure is presented in Figure 1. Individual bond lengths and angles within the ligand are unremarkable. The crystal packing shows an extensive combination of weak CH···N hydrogen bonds and π–π stacking interactions between adjacent molecules.

### Complexes with $L^{Ph}$

Reaction of $L^{Ph}$ with perchlorate salts of $Ni^{II}$ or $Cu^{II}$ in MeCN afforded crystalline products of empirical formula $M(L^{ph})(ClO_4)_2$ by elemental analysis, that is 1:1 $M^{2+}/L^{Ph}$ stoichiometry. X-ray quality crystals could be grown for M = Cu and Ni by diffusion of diethyl ether vapour into MeCN solutions of the complexes.

Both complexes $[M_2(L^{Ph})_2][ClO_4]_4$ (M = Ni, Cu) proved to be dinuclear double helicates with two ligands wrapped around two metal ions; each ligand donates one terdentate site to each metal ion, and each metal ion is six-coordinate from coordination by two terdentate fragments, one from each ligand. Their gross structures are very similar (Figure 2), with minor differences arising from the distorted coordination environment around $Cu^{II}$ due to the Jahn–Teller effect. Thus the $Ni^{II}$ complex has fairly regular coordination around the $Ni^{II}$ ions, with the Ni–N(pyridine) bond lengths in the range 2.00–2.10 Å and the Ni–N(pyrazole) distances being slightly longer at 2.12–2.18 Å. The angles between the two Ni(NNN) planes at Ni(1) and Ni(2) are 92.5° and 94.2°, respectively (Table 1). Areas of overlap between aromatic rings on adjacent ligands are clear, resulting in some degree of stabilisation of the structure by π-stack-

ing. In the $Cu^{II}$ complex in contrast the coordination geometry about the $Cu^{II}$ ions is more distorted (Table 2). Cu(1) has a *trans*-related pair of Cu–N bonds from the same ligand (using a terminal pyridyl ring and the pyrazolyl ring) and that are significantly longer than the other four; for Cu(2) in contrast the distortion is expressed as an elongation of both Cu–N(pyrazolyl) bonds, which are *cis* to one another.

Electrospray mass spectra of both complexes revealed several peaks at the *m*/*z* values expected for the dinuclear complexes (see Experimental section). However in both cases there are very weak peaks identifiable whose *m*/*z* values are consistent with formation of higher oligomers. For redissolved crystals of $[Cu_2(L^{Ph})_2][ClO_4]_4$ for example, the ES mass spectrum has a weak peak at *m*/*z* 979.1, assigned as $\{Cu_4(L^{Ph})_4(ClO_4)_5\}^{3+}$; and redissolved crystals of $[Ni_2(L^{Ph})_2][ClO_4]_4$ show numerous weak peaks at high *m*/*z* values of which those at 972.4 and 1508.1 can be assigned as belonging to $\{Ni_4(L^{Ph})_4(ClO_4)_5\}^{3+}$ and $\{Ni_4(L^{Ph})_4(ClO_4)_6\}^{2+}$ respectively. Thus, both complexes which were isolated as dinuclear species in the solid state show evidence for traces of a tetrameric (presumably, cyclic helical) species existing in solution.[10]

Reaction of $L^{Ph}$ with $AgBF_4$ in MeCN, followed by diffusion of diisopropyl ether vapour into the solution, afforded crystals of $[Ag_2(L^{Ph})(MeCN)_2][BF_4]_2$ (Figure 3) which, in contrast to the two structures above, is a dinuclear *single* stranded helicate. The hexadentate ligand $L^{Ph}$ is arranged in a shallow spiral which is wound around a central axis of two $Ag^{I}$ ions; the two metals end up close enough together to be considered as having an argentophilic bond between them [Ag(1)···Ag(2), 3.07 Å]. Somewhat surprisingly, the two $Ag^{I}$ ions are in markedly different coordination environments. It might be expected [cf. the structures

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

with $Cu^{II}$ and $Ni^{II}$, above] that $L^{Ph}$ would donate a terdentate pyrazolyl-bipyridine arm to each $Ag^{I}$ ion. Instead the partitioning of the ligand into two binding sites occurs within one of the terdentate units, such that one terdentate arm of the ligand donates only a bipyridyl unit to Ag(1), with the adjacent pyrazolyl donor [N(51)] closer to Ag(2) (2.43 Å) than to Ag(1) (2.78 Å). Such ambiguous bridging interactions of a single N-donor ligand to a pair of $Ag^{I}$ ions is known in other cases.[14] The remaining terdentate arm of the ligand is bound in its entirety to Ag(2). Thus, $L^{Ph}$ acts as a "2+4"-dentate donor [or, possibly, a "2.5+3.5" donor if N(51) is considered as genuinely bridging] to the two $Ag^{I}$ centres, each of which also has one MeCN ligand. The differences in coordination number of Ag(1) and Ag(2) are reflected in significantly longer average Ag–N bond lengths around Ag(2) (see Table 3).

A consequence of the single-stranded helical structure is that the bipyridyl groups at each end of the ligand are overlapping and π-stacked with each other. This is emphasised in Figure 3(b). These two bipyridyl groups are near-parallel, and the separation between them is ca. 3.3 Å. It is convenient that the separation between the two $Ag^{I}$ ions is almost exactly that required for aromatic ligands coordinated to them to have an optimal π-stacking separation.

## $Ni^{II}$ Complex with $L^{Py}$

Reaction of $L^{Py}$ with $Ni(BF_4)_2$ in a 1:1 ratio in nitromethane afforded, after crystallisation, $[Ni_2(L^{Py})_2][BF_4]_4$ which has the structure of a box-like achiral complex, sometimes called a "*meso*-helicate" or "mesocate",[15] in which the two ligands are side-by-side rather than twisted around one another (Figure 4, Table 4). This suits the coordination preference of $Ni^{II}$ for octahedral geometry as it allows the

two Ni(NNN) planes to be essentially perpendicular to one another (89° between them), and also allows a region of overlap between parallel and overlapping ligand fragments in the space between the two metal ions, involving the pyrazolyl ring of one ligand [N(51)–C(55)] and the non-coordinated central pyridyl ring of the other [N(41A)–C(46A)], whose mean planes are separated by ca. 3.3 Å. The Ni–N bonds to the two pyrazolyl donors (average 2.16 Å) are slightly longer than to the four pyridyl donors (average 2.05 Å). Notably, the central pyridyl ring of each ligand [containing N(41)] does not participate in coordination but acts like a *meta*-phenylene spacer such that the ligand coordinated only via its terdentate pyrazolyl-bipyridine arms.

### Complexes with $L^{naph}$

This ligand is architecturally similar to $L^{Ph}$ in that it has the same geometry spacer (an *ortho*-disubstituted six-membered aromatic ring) separating the two fragments. However, replacement of the 1,2-phenylene spacer by 2,3-naphthalenediyl spacer results in formation of some quite different structural types.

Reaction of $L^{naph}$ with $AgBF_4$ in MeCN afforded a clear solution, from which X-ray quality crystals were obtained following slow diffusion of diethyl ether vapour into the solution. The peak at the highest *m*/*z* value in the ES mass spectrum was at 1691.2, consistent with the 3:2 Ag/L fragment $\{[Ag_3(L^{naph})_2][BF_4]_2\}^+$, implying that the neutral complex should be $[Ag_3(L^{naph})_2](BF_4)_3$. This was confirmed by X-ray crystallography; the structure is in Figure 5, and shows some interesting similarities to that of the simpler complex $[Ag_2(L^{Ph})(MeCN)_2][BF_4]_2$. The trinuclear complex cation has $C_2$ symmetry, and consists of a linear sequence of three $Ag^I$ ions with two ligands each spanning two of them. Thus one ligand presents four of its six donor atoms (one entire tridentate arm, and the pyrazolyl donor of the next arm) to the terminal $Ag^I$ ion, and the remaining two (a bipyridyl unit) to the next $Ag^I$ at the centre of the array. We are seeing again how each ligand is partitioned into a "4 + 2-dentate" coordination mode rather than the more natural "3 + 3" mode which might be expected. The central $Ag^I$ ion [Ag(1)] is therefore in a four-coordinate environment, connected to a terminal bipyridyl fragment from each of the two ligands; the terminal $Ag^I$ ions are also four coordinate with all four donors coming from the same ligand (see Table 5). As with $[Ag_2(L^{Ph})(MeCN)_2][BF_4]_2$, each ligand adopts a shallow monohelical twist such that the bipyridyl units at each end of a given ligand overlap with one another. The $C_2$ symmetry of the complex cation means that both ligands have the same helical arrangement as one another, so the complex superstructure contains a pair of mono-helical ligands with the same configuration.

The Ag···Ag separations are considerably higher than in dinuclear $[Ag_2(L^{Ph})(MeCN)_2][BF_4]_2$, where it was 3.07 Å. Actually Ag(2) at the end of the sequence (and its symmetry equivalent at the other end) is disordered over two closely

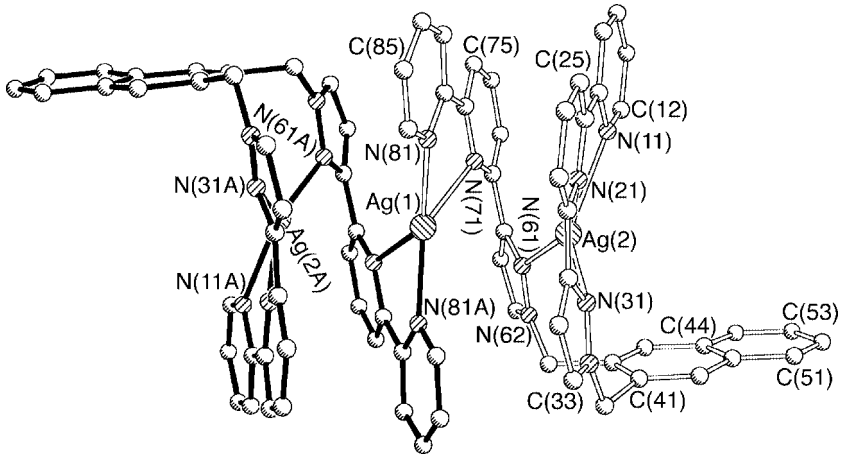

Figure 5. Structure of the complex cation of $[Ag_3(L^{naph})_2](BF_4)_3 \cdot 2MeCN$, with the two ligands shaded differently for clarity.

spaced sites, with the Ag(1)···Ag(2) separation being 3.35 Å and Ag(1)···Ag(2′) being 3.88 Å, such that argentophilic interactions are clearly much less significant than for $[Ag_2(L^{Ph})(MeCN)_2][BF_4]_2$. The structure of this complex may be compared with those of other linear polynuclear complexes of $Ag^I$ with polypyridine-type ligands.[16]

Reaction of $L^{naph}$ with $Cd(ClO_4)_2$ in MeCN (1:1 ratio), followed by diffusion of diethyl ether vapour into the resultant solution, afforded X-ray quality colourless needles. On the basis of the common preference of $Cd^{II}$ for six-coordinate geometry, we were expecting a dinuclear double helicate to form similar to what we observed for $[M_2(L^{Ph})_2][ClO_4]_4$ (M = Ni, Cu). Instead however the structure is that of a circular hexanuclear helicate $[Cd_6(L^{naph})_6](ClO_4)_{12}$ (Figure 6), in which the 1:1 ratio of metal ions to ligands ensures that each $Cd^{II}$ centre is in a six-coordinate geometry (Cd–N separations lie in the range 2.21–2.41 Å, see Table 6). There are two significant non-covalent interactions involved, beyond the metal-ligand bonding, which appear to play a significant role in the structure. Firstly, each of the six naphthyl units is sandwiched between two pyridylpyrazole chelating units (from different ligands) to form a three-layer π-stack with separations of ca. 3.5 Å between the approximately parallel layers. Secondly, there is a perchlorate ion inside the ring which is involved in numerous short O···HC contacts with H atoms from the ligands. The anion is not actually centrally located in the cavity because the ring is not planar but slightly bowl-shaped; a view of the structure emphasising this is in Figure 6 (b).

Circular helicates have been reported by several groups[10,17] and, in addition to their appealing structures, can have two features of interest. Firstly, there is often an anion located in the centre of the cavity which has acted as a template to induce assembly of the metal/ligand array around it. Thus, use of a differently-sized templating anion can lead to a larger circular helicate containing more metal ions and more ligands in the peripheral assembly to accommodate a larger anion in the central cavity. Secondly, there can be a dynamic equilibrium in solution between differently-sized assemblies ($M_3L_3$, $M_4L_4$, $M_5L_5$ etc.), even if a single component crystallises preferentially such that solid-state studies indicate that only a single product has formed. Accordingly we examined the $^1H$ NMR spectrum and electrospray mass spectra of redissolved crystals of $[Cd_6(L^{naph})_6](ClO_4)_{12}$. The $^1H$ NMR spectrum in $CD_3CN$ showed no evidence for a mixture of species being present, with a clean spectrum being observed indicative of a structure with all ligands in a chiral twofold symmetric environment, viz. half of the ligand being unique, and the two $CH_2$ protons being inequivalent (diastereotopic) and coupled to one another (AB doublets) as a consequence of the chirality of the helicate.

The ES mass spectrum however reveals more complicated behaviour in solution that is not apparent from the $^1H$ NMR spectrum (Figure 7). The most intense peak at *m*/*z* 809.1 is ascribable to the mononuclear fragment $\{Cd(L^{naph})(ClO_4)\}^+$, implying either that dissociation of the complex occurs in solution, or that fragmentation occurs under mass spectroscopic conditions. The latter explanation is likely to be correct as the $^1H$ NMR spectrum shows that the main species in solution is chiral, i.e. at least a $[Cd_2(L^{naph})_2]^{4+}$ dinuclear double helicate. More interestingly, at higher *m*/*z* values are numerous much weaker peaks (< 2% of intensity of the main peak at *m*/*z* 809.1) whose *m*/*z* values match exactly to a range of oligomers ranging from a dimer [the peak at *m*/*z* 1717.2 corresponds to $\{Cd_2(L^{naph})_2(ClO_4)_3\}^{4+}$, presumably a double helicate] up to an 11-mer [the peak at *m*/*z* 3229.2 corresponds to $\{Cd_{11}(L^{naph})_{11}(ClO_4)_9\}^{2+}$, presumably a large cyclic helical assembly of the same nature as the crystal structure]. Altogether, peaks corresponding to $\{Cd(L^{naph})\}_n$ oligomers with $n$ = 2, 4, 5, 7, 8, 10, 11 can be identified unambiguously; and a peak at *m*/*z* 2624.2 could correspond to either the $n$ = 3 species $\{Cd_3(L^{naph})_3(ClO_4)_5\}^+$ or the $n$ = 6 species $\{Cd_6(L^{naph})_6(ClO_4)_{10}\}^{2+}$ (or both, superimposed). It is clear that in solution an equilibrium mixture of cyclic helicates species exists.[10b] The fact that this is not apparent in the NMR spectrum implies either that they all have essentially

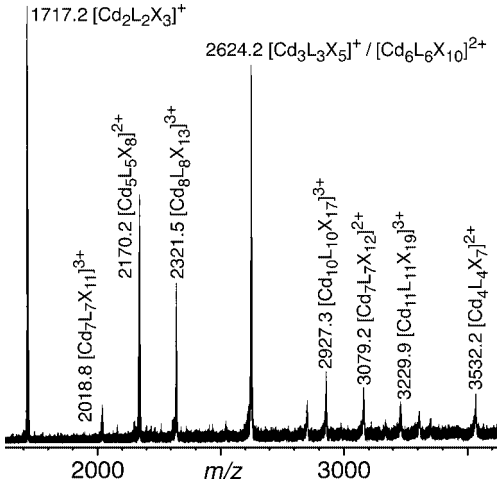

Figure 7. Part of the electrospray mass spectrum of redissolved crystals of $[Cd_6(L^{naph})_6](ClO_4)_{12}$, showing the presence of a range of cyclic oligomers in solution.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

identical NMR spectra, or that one species is present in abundance and dominates the NMR spectrum, with the minor components being invisible. Either possibility is perfectly plausible.

A final interesting point about these complexes of $L^{naph}$ is their luminescence spectra. The free ligand has a characteristic intense naphthalene-based fluorescence band at 347 nm. For the $Ag^{I}$ complex $[Ag_3(L^{naph})_2](BF_4)_3$ in MeCN solution, the fluorescence is reduced in intensity by about 90% but remains at exactly the same wavelength. In $[Cd_6(L^{naph})_6](ClO_4)_{12}$ in MeCN solution however the fluorescence is significantly red-shifted, to 363 nm (Figure 8). We ascribe this to the extensive aromatic stacking of the emissive naphthyl units between pyridyl/pyrazolyl units of adjacent ligands in the cyclic helical array (see Figure 6), which results in stabilisation of the naphthyl-based π-π* excited state and hence a red-shift of the emission.[18] Even if other cyclic oligomers are present in solution, as the ES mass spectrum suggests, similar structures are plausible in which this type of stacking is retained. Thus the red-shifted luminescence of the ligand is indicative of the nature of the self-assembled structure formed in solution.

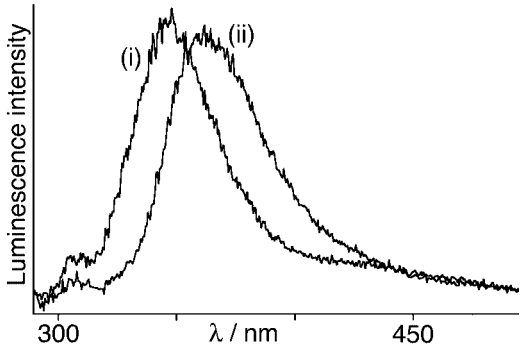

Figure 8. Luminescence spectra of solutions of (i) $[Ag_3(L^{naph})_2](BF_4)_3$ and (ii) $[Cd_6(L^{naph})_6](ClO_4)_{12}$ in MeCN, concentration ca. $10^{-6}$ M; the solutions had the same optical density at the excitation wavelength.

## Conclusions

This series of relatively simple bridging ligands has generated a range of structures in which the ligands all span two metal ions – an essential prerequisite for formation of polynuclear assemblies – resulting in double helicates, a mesocate, some single-stranded helicates based on $Ag^{I}$, and a cyclic hexanuclear helicate based on $Cd^{II}$. In some cases there are obvious factors controlling the structures, such as the presence of Ag···Ag interactions in the $Ag^{I}$ complexes. In other cases apparently very similar metal/ligand combinations generate quite different structures, cf. the difference between the dinuclear double helicates $[M_2(L^{Ph})_2][ClO_4]_4$ (M = Ni, Cu) and the cyclic hexanuclear helicate $[Cd_6(L^{naph})_6](ClO_4)_{12}$; both of these structural types have arisen from combination of bis-terdentate ligands (with similar spacers separating the binding sites) with six-coordinate metal ions. Significant factors favouring the formation of $[Cd_6(L^{naph})_6](ClO_4)_{12}$ could include the aromatic π-stacking between the naphthyl units, and the ability of $Cd^{II}$ to tolerate a more highly distorted coordination environment than $Cu^{II}$ or $Ni^{II}$ on stereoelectronic grounds.

However, although it is tempting to try and rationalise such structural variations in a facile manner, it is not appropriate to over-do this for two reasons. Firstly, the number of variables involved is large: some of the more obvious factors include the charge and radius of the metal cation; stereoelectronic preferences arising from partially filled d-shells [for $Cu^{II}$ and $Ni^{II}$]; the presence of attractive Ag···Ag interactions in the $Ag^{I}$ complexes; the nature of the anion, which may exert a templating effect in the hexanuclear $Cd^{II}$ circular helicate; and the presence of other supramolecular interactions such as aromatic π-stacking between ligands. Secondly, the solid-state structures are not necessarily thermodynamic minima but may represent kinetically stable assemblies which happened to crystallise well; for example the ES mass spectroscopic data for $[Cd_6(L^{naph})_6](ClO_4)_{12}$ clearly shows that there is a mixture of oligomers in solution. Rationalising the appearance of one kinetic product in the solid state therefore does not tell the whole story.

## Experimental Section

**General Details:** 6-Acetyl-2,2′-bipyridine,[19] 6-(pyrazol-3-yl)-2,2′-bipyridine,[12] 2,6-bis(bromomethyl)pyridine,[20] and 2,3-bis(bromomethyl)naphthalene[21] were prepared as described previously. Other organic reagents and metal salts were obtained from Aldrich and Avocado and used as received. Instrumentation used for spectroscopic analysis were as follows: $^1$H NMR spectra, a Bruker AC 250 spectrometer. EI mass spectra, a VG AutoSpec magnetic sector instrument; ES mass spectra, a Bruker MicroTOF instrument in positive ion mode, with capillary exit and first skimmer voltages of 30 V and 60 V respectively. UV/Vis absorption spectra, a Cary 50 spectrophotometer, using MeCN solutions of the complexes.

### Syntheses of Ligands

**$L^{Ph}$:** A mixture of 1,2-bis(bromomethyl)benzene (0.539 g, 2.04 mmol), 6-(pyrazol-3-yl)-2,2′-bipyridine (0.852 g, 3.84 mmol), 10 M aqueous NaOH (3 $cm^3$), $NBu_4OH$ (3 drops of 40% aqueous solution) and toluene (15 $cm^3$) was heated with vigorous stirring to 85 °C for 24 h. After cooling, the organic layer was washed with water and then dried with $MgSO_4$. The solvent was removed to afford a pale yellow solid which was purified by column chromatography (5:95 EtOAc/$CH_2Cl_2$ on alumina) to give 0.861 g (65%) of $L^{Ph}$ as a white powder. EI MS: *m*/*z* (%) = 546 (3) [$M^+$] and 324 (35) [$M^+$ – pzbpy]. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 8.67 (d, 2 H, bpy $H^{6'}$), 8.57 (d, 2 H, bpy $H^{3'}$), 8.33 (dd, 2 H, bpy $H^3$), 8.01 (dd, 2 H, bpy $H^5$), 7.76–7.85, (m, 4 H, bpy $H^{5'}$ and $H^{4'}$), 7.37 (d, 2 H, pz $H^5$), 7.24–7.33 (m, 4 H, bpy $H^4$ and phenyl $H^3$ and $H^4$), 7.17 (m, 2 H, phenyl $H^2$ and $H^5$), 7.07 (d, 2 H, pz $H^4$) and 5.49 (s, 4 H, $CH_2$) ppm. $C_{34}H_{26}N_8$ (546.63): calcd. C 74.7, H 4.8, N 20.5; found C 74.9, H 4.7, N 20.3.

**$L^{py}$:** A mixture of 2,6-bis(bromomethyl)pyridine (0.602 g, 2.27 mmol) and 6-(pyrazol-3-yl)-2,2′-bipyridine (1.00 g, 4.50 mmol) were reacted in exactly the same manner as described above for the synthesis of $L^{Ph}$. The crude product was purified by column chromatography (1% MeOH in $CH_2Cl_2$, on alumina) to give 0.593 g (47%) of $L^{py}$ as yellow foam. EI MS: *m*/*z* (%) = 547

(5) [M$^+$] and 325 (100) [M$^+$ – pzbpy]. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 8.66 (d, 2 H, bipy H$^{6\prime}$), 8.58 (d, 2 H, bpy H$^{3\prime}$), 8.32 (dd, 2 H, bpy H$^3$), 8.02 (dd, 2 H, bpy H$^5$), 7.83 (t, 4 H, bpy H$^{4\prime}$ and H$^{5\prime}$), 7.61–7.52 (m, 3 H, py H$^3$, H$^4$ and H$^5$), 7.33 (t, 2 H, bpy H$^4$), 7.11 (d, 2 H, pz H$^5$), 6.93 (d, 2 H, pz H$^4$) ppm. $C_{33}H_{25}N_9 \cdot H_2O$ (565.63): calcd. C 70.1, H 4.8, N 22.3; found C 70.5, H 4.6, N 22.4.

**L$^{naph}$:** A mixture of 2,3-bis(bromomethyl)naphthalene[9] (0.314 g, 1.00 mmol) and 6-(pyrazol-3-yl)-2,2′-bipyridine were reacted in the same manner as described above for the synthesis of L$^{Ph}$. The crude solid was purified by column chromatography (0.5% MeOH in $CH_2Cl_2$, on alumina) to give 0.390 g (69%) of yellow powder. EI-MS: *m*/*z* (%) = 596 (5) [M$^+$], 374 (100) M$^+$ – pzBipy]. $^1$H NMR (250 MHz, $CDCl_3$): $\delta$ = 8.65 (d, 2 H, bipy H$^{6\prime}$), 8.56 (d, 2 H, bipy H$^{3\prime}$), 8.33 (dd, 2 H, bipy H$^3$), 8.04 (dd, 2 H, bipy H$^5$), 7.71–7.85, (m, 6 H, bipy H$^{5\prime}$, H$^{4\prime}$and naphthyl H$^5$/H$^8$), 7.59 (s, 2 H, naphthyl H$^1$/H$^4$) 7.43–7.47 (m, 2 H, naphthyl H$^6$/H$^7$), 7.43 (d, 2 H, pz H$^5$), 7.24 (t, 2 H, bipy H$^4$), 7.10 (d, 2 H, pz H$^4$) and 5.56 (s, 4 H, $CH_2$) ppm. $C_{38}H_{28}N_8$ (596.69): calcd. C 76.5, H 4.7, N 18.8; found C 76.1, H 4.7, N 18.4.

### Syntheses of Complexes

Complexes were prepared by the reaction of the ligand (0.05 g) with the appropriate metal salt [in a 2:1 metal/ligand ratio for Ag$^I$ complexes and in a 1:1 ratio for the Ni$^{II}$, Co$^{II}$, Cu$^{II}$, and Cd$^{II}$ complexes] in nitromethane or acetonitrile. Diffusion of diisopropyl ether vapour into the resulting solutions afforded single crystals suitable for X-ray crystallography and other analyses. Characterisation data for the complexes are as follows.

**[Ni$_2$L$^{Ph}_2$](ClO$_4$)$_4$:** Yield: 0.050 g (68%). UV/Vis (MeCN): $\lambda_{max}$/nm ($\varepsilon$, dm$^3$mol$^{-1}$cm$^{-1}$) = 245 (32400), 260 (32600), 327 (18800), 340 (16700), 548 (29), 848 (71). ESMS: *m*/*z* = 704.1 {[Ni$_2$L$^{Ph}_2$](ClO$_4$)$_2$}$^{2+}$, 436.4 {[Ni$_2$L$^{Ph}_2$](ClO$_4$)}$^{3+}$, 302.6 {[Ni$_2$L$^{Ph}_2$]}$^{4+}$. $Ni_2C_{68}H_{52}N_{16}Cl_4O_{16} \cdot 2H_2O$ (1644.48): calcd. C 49.7, H 3.4, N 13.6; found C 49.3, H 3.5, N 13.6.

**[Cu$_2$L$^{Ph}_2$](ClO$_4$)$_4$:** Yield 0.046 g (62%). UV/Vis (MeCN): $\lambda_{max}$/nm ($\varepsilon$, dm$^3$mol$^{-1}$cm$^{-1}$) = 210 (67600), 245 (23000), 686 (69). ES MS: *m*/*z* = 1518.1 {[Cu$_2$L$^{Ph}_2$](ClO$_4$)$_3$}$^+$, 979.1 {[Cu$_4$L$^{Ph}_4$](ClO$_4$)$_5$}$^{3+}$, 709.1 {[Cu$_2$L$^{Ph}_2$](ClO$_4$)$_2$}$^{2+}$, 439.7 {[Cu$_2$L$^{Ph}_2$](ClO$_4$)}$^{3+}$, 305.1 {[Cu$_2$L$^{Ph}_2$]}$^{4+}$. $Cu_2C_{68}H_{52}N_{16}Cl_4O_{16} \cdot 2H_2O$ (1654.19): calcd. C 49.4, H 3.4, N 13.5; found C 48.3, H 3.3, N 13.3.

**[Ag$_2$L$^{Ph}$(MeCN)$_2$](BF$_4$)$_2$:** Yield 0.051 g (55%). $^1$H NMR (250 MHz, $CD_3CN$): $\delta$ = 8.06 (d, 2 H, bpy H$^{6\prime}$), 7.90–7.97 (m, 4 H, bpy H$^{3\prime}$, H$^3$), 7.75 (d, 2 H, bpy H$^5$), 7.68 (d, 2 H, bpy H$^{5\prime}$), 7.56 (d, 4 H, phenyl H$^2$, H$^3$), 7.53 (d, 2 H, pz H$^5$), 7.44 (m, 2 H, py H$^{4\prime}$), 7.12 (dt, 2 H, py H$^4$), 6.95 (d, 2 H, pz H$^4$), 5.32 (s, 4 H, $CH_2$) ppm. UV/Vis (MeCN): $\lambda_{max}$/nm ($\varepsilon$, dm$^3$mol$^{-1}$cm$^{-1}$) = 238 (40000), 265 (sh), 310 (19400). ES MS: *m*/*z* = 849.0 {[Ag$_2$L$^{Ph}$][BF$_4$]}$^+$, 380.0 {[Ag$_2$L$^{Ph}$]}$^{2+}$. $C_{38}H_{32}Ag_2B_2F_8N_{10}$ (1018.07): calcd. C 44.8, H 3.2, N 13.8; found C 44.5, H 2.9, N 13.4.

**[Ni$_2$L$^{py}_2$](BF$_4$)$_4$:** Yield 0.035 g (49%). UV/Vis (MeCN): $\lambda_{max}$/nm ($\varepsilon$, dm$^3$mol$^{-1}$cm$^{-1}$) = 247 (54800), 326 (19600), 845 (83). ES MS: *m*/*z* = 692.2 {[Ni$_2$L$^{py}_2$](BF$_4$)$_2$}$^{2+}$, 433.1 {[Ni$_2$L$^{py}_2$](BF$_4$)}$^{3+}$, 302.6 {[Ni$_2$L$^{py}_2$]}$^{4+}$. This sample was hygroscopic and gave variable elemental analyses consistent with the presence of several molecules of water per complex.

**[Ag$_3$(L$^{naph}$)$_2$](BF$_4$)$_3$:** Yield 0.034 g (46%). UV/Vis (MeCN): $\lambda_{max}$/nm ($\varepsilon$, dm$^3$mol$^{-1}$cm$^{-1}$) = 227 (160000), 260 (89500), 310 (37100). ES MS: *m*/*z* = 1691.2 {[Ag$_3$(L$^{naph}$)$_2$][BF$_4$]$_2$}$^+$, 899.1 {[Ag$_2$(L$^{naph}$)][BF$_4$]}$^+$. $C_{76}H_{56}Ag_3B_3F_{12}N_{16} \cdot 2H_2O$ (1813.42): calcd. C 50.3, H 3.3, N, 12.4; found C 50.3, H 3.0, N 12.3.

**[Cd$_6$(L$^{naph}$)$_6$](ClO$_4$)$_{12}$:** Yield 0.032 g (42%). $^1$H NMR (250 MHz, $CD_3CN$): $\delta$ = 8.44 (d, 2 H, bipy H$^{6\prime}$), 8.43 (br, 2 H, bipy H$^3$), 8.29 (m, 2 H, bipy H$^{3\prime}$), 8.28 (m, 2 H, bipy H$^5$), 8.13 (s, 2 H, naphthyl H$^1$/H$^4$), 7.99 (t, 2 H, bipy H$^{5\prime}$), 7.95 (d, 2 H, naphthyl H$^5$/H$^8$), 7.90 (d, 2 H, pz H$^5$), 7.65–7.68 (2 H, naphthyl H$^6$/H$^7$), 7.52 (dt, 2 H, bipy H$^{4\prime}$), 7.31 (dt, 2 H, bipy H$^{4\prime}$), 7.27 (dt, 2 H, pz H$^4$), 5.38 (d, 2 H, $CH_2$), 5.76 (d, 2 H, $CH_2$) ppm. UV/Vis (MeCN): $\lambda_{max}$/nm ($\varepsilon$, dm$^3$mol$^{-1}$cm$^{-1}$) = 320 (22800), 268 (30200), 226 (55700). ES MS: *m*/*z* = 809.1 {[Cd(L$^{naph}$)](ClO$_4$)}$^+$, 1717.2 {[Cd$_2$(L$^{naph}$)$_2$](ClO$_4$)$_3$}$^+$, 2624.2 {[Cd$_3$(L$^{naph}$)$_3$](ClO$_4$)$_5$}$^+$, 3532.2 {[Cd$_4$(L$^{naph}$)$_4$](ClO$_4$)$_7$}$^+$, 1717.2 {[Cd$_4$(L$^{naph}$)$_4$](ClO$_4$)$_6$}$^{2+}$, 2170.2 {[Cd$_5$(L$^{naph}$)$_5$](ClO$_4$)$_8$}$^{2+}$, 2624.2 {[Cd$_6$(L$^{naph}$)$_6$](ClO$_4$)$_{10}$}$^{2+}$, 3079.2 {[Cd$_7$(L$^{naph}$)$_7$](ClO$_4$)$_{12}$}$^{2+}$,

**Crystallography**

X-ray crystallographic data are summarised in Tables 7 and 8. In each case a suitable crystal was coated with hydrocarbon oil and attached to the tip of a glass fibre and transferred to a Bruker APEX-2 CCD diffractometer (graphite-monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å) under a stream of cold $N_2$. After collection and integration the data were corrected for Lorentz and polarisation effects and for absorption by semi-empirical methods (SADABS) based on symmetry-equivalent and repeated reflections.[22] The structures were solved by direct methods or heavy atom Patterson methods and refined by full-matrix least-squares methods on $F^2$. Hydrogen atoms were placed geometrically and refined with a riding model and with $U_{iso}$ constrained to be 1.2 (1.5 for methyl groups) times $U_{eq}$ of the carrier atom. Structures were solved and refined using the SHELX suite of programs.[23] Significant bond lengths and angles for the structures of the metal complexes are in Tables 1–6. Particular problems associated with the refinements are as follows.

The complex cation of $[Ni_2(L^{Py})_2][BF_4]_4\cdot 2MeNO_2$ lies on an inversion centre with only one metal ion in the asymmetric unit. Crystals of $[Cd_6(L^{naph})_6](ClO_4)_{12}$ scattered relatively weakly and only data with $2\theta \leq 50°$ were used in the final refinement. Several of the perchlorate anions showed disorder of the oxygen atoms which were in many cases disordered over two sites. Extensive use of geometric restraints was required to keep the Cl–O distances and the geometries of the perchlorate anions reasonable. Areas of electron density which presumably corresponded to disordered solvent molecules, but which could not be modelled as anything reasonable, were removed using the SQUEEZE command in PLATON. In $[Ag_3(L^{naph})_2](BF_4)_3\cdot 2MeCN$ the complex cation lies on a twofold rotation axis which passes through Ag(1) and B(2). The "terminal" ion is disordered over two closely spaced sites [Ag(2), 58% site occupancy; Ag(3), 42% site occupancy]; only Ag(2) is shown in Figure 5. Some of the F atoms of the tetrafluoroborate ions are disordered over two positions with the same fractional occupancies (0.58/0.42). None of the other structural determinations presented any significant problems.

CCDC-653275 to -653281 contain the supplementary crystallographic information for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis of Flexible Bis-Intercalating Ruthenium(II) Complexes

**Craig R. Brodie[a] and Janice R. Aldrich-Wright*[a]**

**Keywords:** Ruthenium(II) / Synthesis / Chiral resolution / TRISPHAT / Dinuclear complexes / Bis-intercalators

We report the synthesis, resolution and characterisation of a number of novel ruthenium(II) complexes. Four mononuclear complexes, $[Ru(dpq)_2(3\text{-Br-phen})]^{2+}$, $[Ru(dpq)_2(4\text{-Cl-phen})]^{2+}$, $[Ru(dpq)_2(5\text{-Cl-phen})]^{2+}$ and $[Ru(dpq)_2(phen)]^{2+}$ were synthesised (dpq = dipyrido[3,2-*d*:2′,3′-*f*]quinoxaline, phen = 1,10-phenanthroline, 3-Br-phen = 3-bromo-1,10-phenanthroline, 4-Cl-phen = 4-chloro-1,10-phenanthroline, 5-Cl-phen = 5-chloro-1,10-phenanthroline). These complexes were resolved using the chiral TRISPHAT anion, [tris(tetrachlorocatecholato)phosphate(V)]$^-$. Racemic mononuclear complexes were used in the synthesis of the racemic dinuclear complexes, $[\{Ru(dpq)_2\}_2\mu\text{-(phen-}n\text{-SOS-}n\text{-phen)}]^{4+}$ (SOS = 2-mercaptoethyl ether, $n$ = 3, 4 or 5). Resolved mononuclear complexes were used to synthesise stereoselectively the ΔΔ- and ΛΛ-enantiomers of their respective dinuclear complexes. All metal complexes were characterised by $^1$H NMR, ESI-MS, UV/Vis and luminescence spectroscopy. Resolved metal complexes were further characterised using CD spectroscopy and chiral $^1$H NMR titrations.

## Introduction

The widespread interest in ruthenium(II) complexes as DNA probes was initially sparked by the study of these complexes as potential anticancer agents.[1] Since then, ruthenium(II) complexes have displayed potential as medical diagnostic tools through their ability to act as "molecular light switches"; complexes which exhibit fluorescence only in the presence of DNA,[2–4] while others have been shown to induce the breakage of DNA strands by photocleavage.[5–9] By incorporating certain ligands, such as dipyrido[3,2-*d*:2′,3′-*f*]quinoxaline (dpq), it is possible to produce ruthenium(II) complexes that display some measure of DNA sequence selectivity,[8,10] enantioselectivity[11–14] and/or preference for DNA base mismatches.[15]

Mononuclear ruthenium(II) complexes are relatively small, can only span 2–4 DNA base pairs, and bind to the double helix over a range of $K_b \approx 10^4$–$10^6$ M$^{-1}$, depending on the intercalating ligand such as dpq $K_b = 5.9 \times 10^4$,[16] dpqc $K_b = 8.5 \times 10^4$[17] and dppz $K_b > 10^6$.[8,18] Researchers have theorised that it may be possible to increase the DNA binding affinity, and therefore biological efficacy of ruthenium complexes, by producing complexes of higher nuclearity. There have been relatively few examples, however, of the application of dinuclear complexes as DNA probes.

Flexibly linked dinuclear ruthenium(II) complexes incorporating 1,10-phenanthroline (phen) and 2,2′-bipyridine (bpy) ligands bind to DNA with a ca. 50-fold increase in $K_b$ compared to the mononuclear analogues of these complexes.[19,20] The length of the linking chain was found to be a critical factor in determining binding strength,[21] with $n$ = 7 being the optimal chain length. Nordén et al.[22–27] have focused on metal complexes derived from $[Ru(phen)_2(dppz)]^{2+}$ (dppz = dipyrido[3,2-*a*:2′,3′-*c*]phenazine). The two-component metal-based units are linked through an intercalating dppz ligand and their DNA binding was found to be extremely strong (ca. $10^{11}$–$10^{13}$ M$^{-1}$).[26,28] Other dinuclear ruthenium complexes, where the metal centre is linked by a rigid bridge,[29] such as 2,2′-bipyrimidine,[30–33] display modest affinity for DNA bulge sites,[33] with significant enantioselectivity being observed between the three stereoisomeric forms ΔΔ, ΛΛ and *meso* (ΔΛ = ΛΔ).[30–33]

We have synthesised flexibly linked dinuclear complexes incorporating the intercalating ligand, dpq, in the hope of achieving high DNA binding strength and some measure of sequence selectivity (Figure 1). The dpq ligand is known to possess some purine-purine base specificity,[10] and adding flexibility to dinuclear intercalators may enhance the DNA binding ability of the complexes as they will be better able to fit within the DNA grooves. While only one intercalating ligand (dpq) per complex may be needed to increase the DNA affinity, two dpq ligands may allow for a more effective intercalation geometry given the specific orientation of each metal complex to DNA is not known. It is anticipated that these resolved dinuclear intercalating complexes, linked by a flexible linker and with a 4+ charge, will bind with a higher binding affinity than a mononuclear

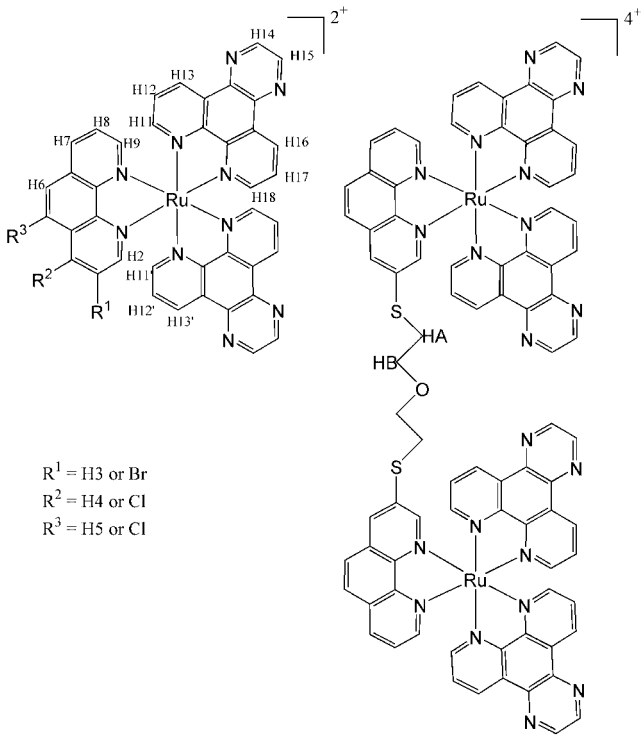

Figure 1. $[Ru(dpq)_2(R\text{-phen})]^{2+}$ and $[\{Ru(dpq)_2\}_2\mu\text{-(phen-3-SOS-3-phen)}]^{4+}$ showing the proton numbering scheme used in $^1H$ NMR assignments. Anions have been omitted for clarity.

complex.[34] It is also possible that the presence of additional intercalating ligands could cause unfavourable steric hindrance when the metal complex is bound to DNA. Varying the position of linker attachment (3-, 4- or 5-position on the phenanthroline ligand) causes subtle variations in the distance between the metal centres and complex geometry, which may affect the nature of the DNA adduct formed and the overall binding affinity.

Herein we expand an earlier communication[34] on the DNA binding of *rac*-$[\{Ru(dpq)_2\}_2\mu\text{-(phen-}n\text{-SOS-}n\text{-phen)}]^{4+}$ ($n$ = 3, 4 or 5, SOS = bis(2-mercaptoethyl) ether). We now report the synthesis of the mononuclear precursors to these complexes, the synthsis of *rac*/*meso* dinuclear complexes, the resolution of the mononuclear precursors and the stereo-retentive synthesis of the dinuclear complexes as their ΔΔ- and ΛΛ-enantiomers (see Figures 1, 2 and 3).

## Results and Discussion

### Synthesis of Mononuclear Complexes

**Synthesis and Characterisation of $[Ru(dpq)_2(pp')](PF_6)_2$.** $[Ru(dpq)_2(pp')]^{2+}$ (pp′ = phen, 3-Br-phen, 4-Cl-phen or 5-Cl-phen) were synthesised by refluxing $[Ru(dpq)_2Cl_2]$ with pp′ in water. Purification was achieved using silica gel and alumina chromatography. Assignment of the $^1H$ NMR

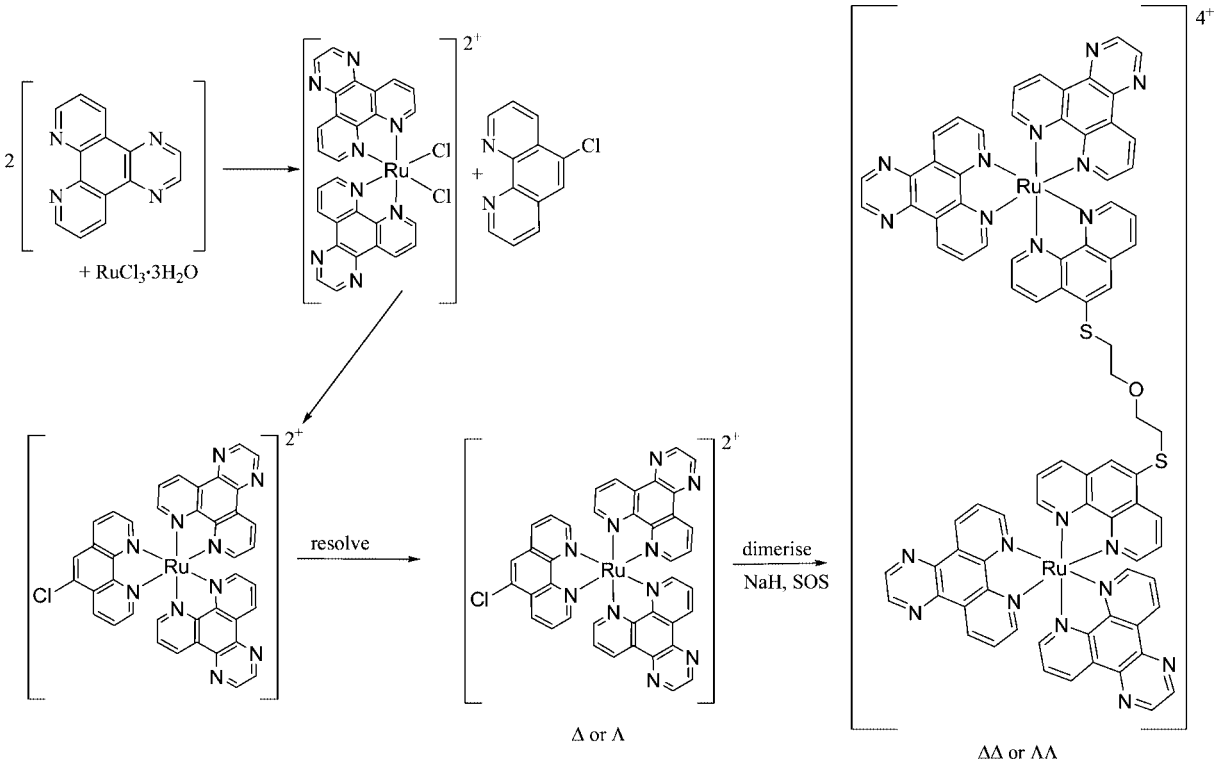

Figure 2. Synthetic route for the synthesis of dinuclear complexes of $[\{Ru(dpq)_2\}_2(\mu\text{-phen-5-SOS-5-phen})]^{4+}$. The same Scheme was also applied to synthesise $[\{Ru(dpq)_2\}_2(\mu\text{-phen-3-SOS-3-phen})]^{4+}$ and $[\{Ru(dpq)_2\}_2(\mu\text{-phen-4-SOS-4-phen})]^{4+}$. The resolution is described further in Figure 3.

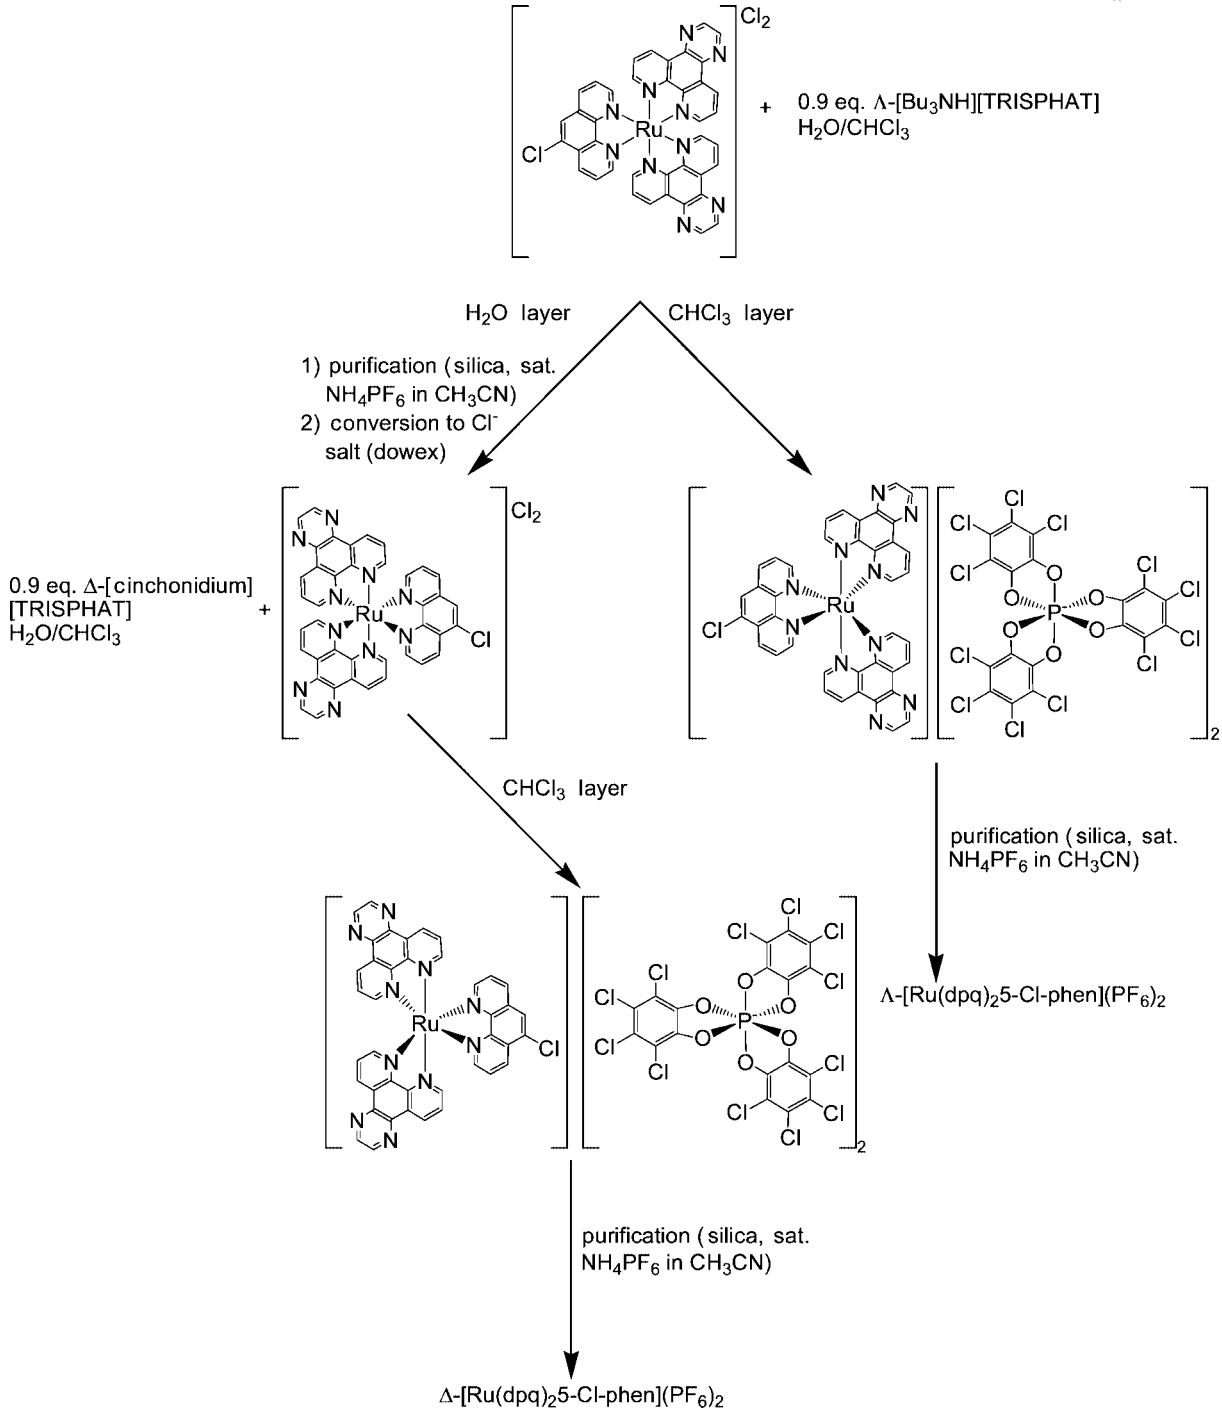

Figure 3. Resolution of $[Ru(dpq)_2(5\text{-Cl-phen})](PF_6)_2$ using the TRISPHAT anion.

spectra of the mononuclear complexes was made using NOESY and g-DQCOSY experiments. Each of the metal complexes exhibit similar resonances with comparative chemical shifts and splitting patterns observed for protons at the same relative positions. $[Ru(dpq)_2(phen)]^{2+}$ is an octahedral complex with two different types of bidentate ligands, and as such it belongs to point group $C_2$. This complex exhibits the simplest $^1H$ NMR spectrum of all the mononuclear complexes due to the presence of the $C_2$ axis. Since the halide substituent occupies the 3-, 4- and 5-position in the 3-Br-phen, 4-Cl-phen and 5-Cl-phen ligands, the complexes of these ligands feature $C_1$ symmetry (i.e. are dissymmetric) and the spectra for $[Ru(dpq)_2(pp')]^{2+}$ are slightly more complicated (see Supporting Information).

**Resolution of Mononuclear Complexes.** Attempts to resolve the $[Ru(dpq)_2(pp')]^{2+}$ complexes using solvent recycled chromatography employing SP-Sephadex® as the stationary phase and the chiral anions *O*,*O*′-dibenzoyl-L-tar-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

taric acid and *O*,*O*′-ditoluoyl-L-tartaric acid by the methods of Rutherford et al.[35] were unsuccessful. Likewise, fractional recrystallisation employing (+)- and (–)-antimonyl tartrate was also unsuccessful.

The method of [(tris(tetrachlorocatecholato)phosphate(V))]$^-$ (TRISPHAT) extraction was developed from the technique of Lacour et al.[36] for analogous ruthenium(II) complexes. $[Ru(dpq)_2(pp')]Cl_2$ in water was added to a solution of $[Bu_3NH][\Lambda$-TRISPHAT] (0.9 equiv.) in chloroform. The solutions were stirred to allow complete equilibration to occur and the layers separated, with the organic layer containing $[Ru(dpq)_2(pp')][(\Lambda$-TRISPHAT$)_2]$. The reaction was subsequently repeated on the remaining aqueous layer using [cinchonidium][Δ-TRISPHAT] to give $[Ru(dpq)_2(pp')][(\Delta$-TRISPHAT$)_2]$.

The CD spectrum of each sample was obtained and the Δε values calculated as a means of characterising the optical properties of the metal complexes. The assignment of the absolute configurations of the resolved complexes in this study is based on CD and comparison with similar complexes whose absolute configuration has been determined by X-ray crystallography, such as the complex $[Ru(phen)_2(dpq)](PF_6)_2$.[35] In this work, relative enantiomeric purity of the chloride salt was determined by CD to be 99.0–93.3% for the monomers (Tables 1 and 2). The CD spectra for Δ- and Λ-$[Ru(dpq)_2(5\text{-Cl-phen})](PF_6)_2$ are shown in Figure 4 and those of Δ,Λ-$[Ru(dpq)_2(phen)]^{2+}$, Δ,Λ-$[Ru(dpq)_2(3\text{-Br-phen})]^{2+}$ and Δ,Λ-$[Ru(dpq)_2(4\text{-Cl-phen})]^{2+}$ are shown in the Supporting Information. As expected for a pair of enantiomers, there is a mirror–image relationship between the CD curves of the Δ- and Λ-enantiomers as well as the presence of isosbetic points, where the spectra of the Δ- and Λ-enantiomers intercept on the *x*-axis.

The enantiopurity of the samples was also confirmed by the use of a $^1$H NMR TRISPHAT titration.$^1$H NMR experiments using chiral shifting agents have been applied previously[37] and were necessary in order to confirm that complete resolution had been achieved. The TRISPHAT anion has previously been shown to be a successful chiral shift reagent, specifically with complexes such as $[Ru(phen)_3]$.[38,39] The TRISPHAT titration was performed initially on *rac*/*meso* mixtures of the metal complexes to demonstrate that selective resonance shifts would be induced in the $^1$H NMR spectrum of each metal complex. As can be

Table 1. CD data obtained for the metal complexes. All measurements conducted in $CH_3CN$ at 25 °C.

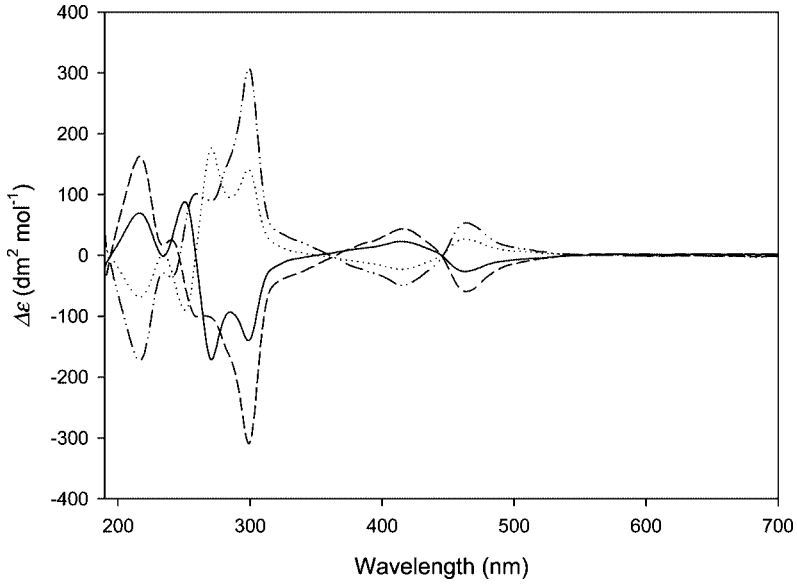

Figure 4. CD spectra ($CH_3CN$) of Δ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ (solid line), Λ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ (dotted line), ΔΔ-[{Ru(dpq)$_2$}$_2$-μ-(phen-5-SOS-5-phen)](PF$_6$)$_4$ (dashed line) and ΛΛ-[{Ru(dpq)$_2$}$_2$μ-(phen-5-SOS-5-phen)](PF$_6$)$_4$ (dashed and dotted line).

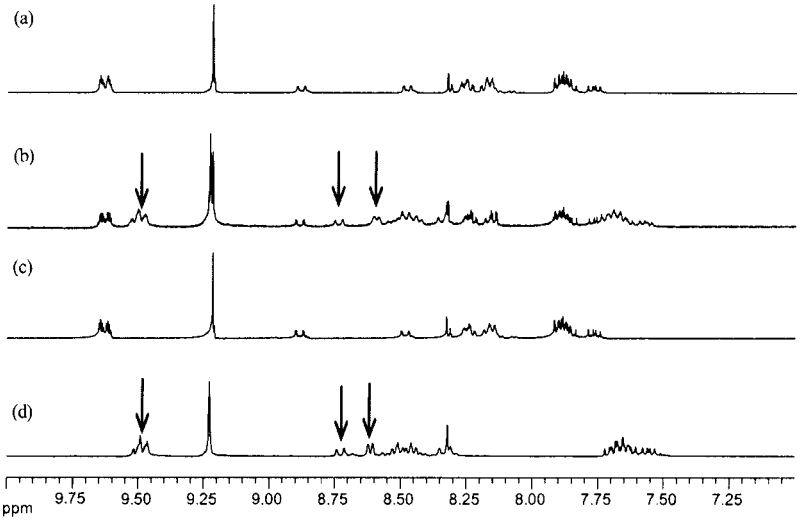

Figure 5. $^1$H NMR ($CD_3CN$, 25 °C) titration of [Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ with [Bu$_3$NH][Λ-TRISPHAT]. Arrows indicate the splitting and shifting of the Δ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ proton resonances from the Λ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ proton resonances; (a) *rac*-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$, (b) *rac*-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ + 1 mol-equiv. of [Bu$_3$NH][Λ-TRISPHAT], (c) Δ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ + 1 mol-equiv. of [Bu$_3$NH][Λ-TRISPHAT] and (d) Λ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ + 1 mol-equiv. of [Bu$_3$NH][Λ-TRISPHAT].

seen in Figure 5, the addition of 1 mol-equiv. of [Bu$_3$NH][Λ-TRISPHAT] to *rac*-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ causes the resonances for the metal complex to broaden and split into two groups – one complete set of resonances for each enantiomer.

The three most downfield resonances, corresponding to the H13/16, H14/15 and H4 protons are the signals most easily used for the assessment of optical purity, because each of them is isolated from other overlapping resonances. The resonance for H13/16 splits into two multiplets, one resonance (due to Δ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$) remains at $\delta$ = 9.63 ppm while the resonance for Λ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ shifts upfield to 9.50 ppm. Similarly, the H14/15 and H4 resonances also split, with separations of 0.01 ppm and 0.15 ppm, respectively, observed between the Δ- and Λ-resonances. The addition of 1 mol-equiv. of [Bu$_3$NH][Λ-TRISPHAT] does not induce any change in the $^1$H NMR spectrum of Δ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$, while the addition of [Bu$_3$NH][Λ-TRISPHAT] to Λ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ induces chemical shift changes in all resonances of the metal complex.

The results from the chiral $^1$H NMR titration experiment shown in Figure 5 agree with those published previously for [Ru(4,7-Me$_2$phen)$_3$]$^{2+}$ and [Ru(Me$_2$bpy)$_3$]$^{2+}$, where it was shown that Λ-TRISPHAT will interact more strongly with the Λ-enantiomer of a metal complex than with the Δ-en-

antiomer of the same metal complex.[35] The TRISPHAT titrations were repeated for all the resolved metal complexes and similar results were observed for each.

The mononuclear metal complexes were also analysed using electrospray ionisation mass spectrometry (ESI-MS) as an additional method of characterisation (Table 3). Although the parent ions, [M(PF$_6$)$_2$ + H]$^+$ were not observed, peaks were generally observed for the [M(PF$_6$)]$^+$ and [M]$^{2+}$ ions of each complex (e.g. Δ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$ ([M(PF$_6$)]$^+$ *m*/*z* calcd. 925.2, found 924.7); ([M]$^{2+}$ *m*/*z* calcd. 390.1, found 390.0)), confirming the molecular weights of the metal complexes. The isotopic splitting patterns observed agree closely with those calculated. The peak due to the [M(PF$_6$)]$^+$ ion was approximately twice the intensity of that due to the [M]$^{2+}$ ion, and this ratio was observed for all the mononuclear complexes studied.

## Dinuclear Complexes

**Synthetic Method Development:** Synthesising [{Ru(dpq)$_2$}$_2$μ-(phen-*n*-SOS-*n*-phen)](PF$_6$)$_4$ (*n* = 3, 4 or 5) by reacting the bridging SOS linker with the mononuclear complexes (DMF, $N_{2(g)}$, NaH, 25 °C) resulted in a number of side-products, in addition to the required complex. The impurities were characterised by TLC and $^1$H NMR spectroscopy. The simplest component in the mixture was the unreacted mononuclear complex [Ru(dpq)$_2$(5-Cl-phen)]$^{2+}$. A mononuclear ruthenium complex with a non-bridging dithiol linker attached, that had not dimerised with a second monomer of [Ru(dpq)$_2$(phen-*n*-SOS-H)]$^{2+}$ was also identified. A third species was also found in which the linker had reacted with itself forming a dinuclear ruthenium(II) complex, bridged by a disulfide-bonded linker, forming a 14 unit chain instead of the desired seven. The desired dinuclear ruthenium(II) complexes were isolated from solution by precipitation with diethyl ether followed by silica gel chromatography.

In the initial method development the synthesis of the dinuclear metal complexes using racemic (unresolved) mononuclear precursors was tried and it was expected that this would afford a mixture consisting of 25% of each of the two homochiral enantiomers, ΔΔ and ΛΛ, and 50% of the *meso* (ΔΛ/ΛΔ) diastereoisomer. The $^1$H NMR spectra of the ΔΔ- and ΛΛ-enantiomers of the metal complexes are

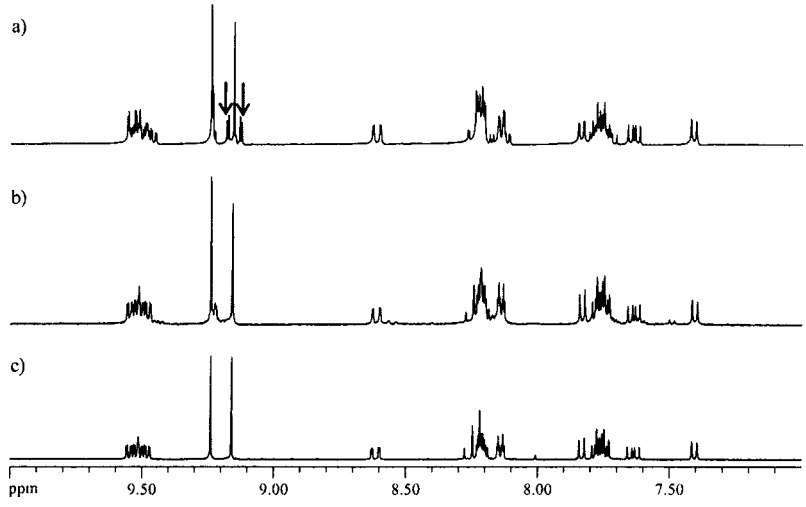

Figure 6. $^1$H NMR spectra ($CD_3CN$, 25 °C) of the stereoisomers of [{Ru(dpq)$_2$}$_2$μ-(phen-4-SOS-4-phen)](PF$_6$)$_4$; (a) *rac*/*meso* (ΔΔ/ΛΛ/ΔΛ/ΛΔ-), (b) ΔΔ- and (c) ΛΛ- showing the presence of the *meso* (ΔΛ/ΛΔ-) complex (indicated by arrows).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

slightly different from those of the *meso* (ΔΛ/ΛΔ)-diastereoisomer, giving rise to overlapping resonances due to the chemically identical ΔΔ- and ΛΛ- enantiomers with the *meso* (ΔΛ/ΛΔ) form. Due to resonance overlap, it was not possible to determine the ratio of the enantiomers formed in these experiments.

When the dinuclear metal complexes were synthesised using enantiopure starting materials, resonances due to the *meso* diastereoisomer were absent from the $^1$H NMR spectra of the ΔΔ- and ΛΛ complexes (Figure 6).

**UV/Vis:** The extinction coefficients for ΔΔ- and ΛΛ-[{Ru(dpq)$_2$}$_2$μ-(phen-3-SOS-3-phen)]$^{4+}$ exhibited an increase in intensity of 220% compared to *rac*-[Ru(dpq)$_2$(3-Br-phen)]$^{2+}$. The extinction coefficients for the ΔΔ- and ΛΛ-[{Ru(dpq)$_2$}$_2$μ-(phen-4-SOS-4-phen)]$^{4+}$ and ΔΔ- and ΛΛ-[{Ru(dpq)$_2$}$_2$μ-(phen-5-SOS-5-phen)]$^{4+}$ complexes also increased by 180 and 200%, respectively, compared to their mononuclear analogues ([Ru(dpq)$_2$(4-Cl-phen)]$^{2+}$ and [Ru(dpq)$_2$(5-Cl-phen)]$^{2+}$). Three main peaks were observed in the UV/Vis spectra of the metal complexes, in the ranges of 206–217 nm, 256–258 nm and 447–452 nm. For the mononuclear metal complexes, the transitions observed in the region of 447–452 nm are attributed to metal-to-ligand charge transfer (MLCT). For both the mono- and dinuclear metal complexes, the bands in the region of 206–256 are attributed predominantly to overlapping π→π* transitions. In the spectrum of each of the dinuclear complexes, the MLCT bands were observed at slightly higher wavelength (lower energy) than the MLCT bands of the analogous mononuclear complexes.

**Luminescence Quantum Yields:** The luminescence quantum yields of the complexes were determined and are shown in Table 2. Excitation at 450 nm of the metal complexes in $CH_3CN$ at 25 °C results in an emission maximum at 600 ± 10 nm (depending on the position of substitution shown in Table 2) and is due to both the phen and dpq ligands. The luminescence quantum yields of the mononuclear metal complexes are in the range of $\Phi = 4.2 \times 10^{-2}$ to $5.9 \times 10^{-2}$ and for the dinuclear complexes are in the range of $\Phi = 4.8 \times 10^{-2}$ to $6.2 \times 10^{-2}$. It is not expected that the excitation and emission maxima and $\Phi$ would vary significantly between the mono- and dinuclear complexes (as was the case with $\varepsilon_{max}$). The metal centres in the dinuclear complexes are separated by a relatively long aliphatic linker and therefore the electronic configuration of the ruthenium(II) centres is not significantly changed upon dimerisation.

**Circular Dichroism:** The CD spectrum of each of the resolved dinuclear metal complexes was obtained and the Δε values calculated as a means of characterising the optical properties of the complexes (see Tables 1 and 2, Figure 4 and Supporting Information). The relative enantiomeric purity of the chloride salt of each of the complexes was determined by CD spectroscopy to be 99.9–85.1% for the dimers. Each pair of enantiomers shows a mirror–image relationship between the CD curves of the ΔΔ and ΛΛ enantiomers and the presence of isosbetic points, but when compared with the spectra of the corresponding mononuclear complex subtle differences are observed.

The main CD features for the mononuclear complexes Δ-[Ru(dpq)$_2$(phen)]$^{2+}$, Δ-[Ru(dpq)$_2$(4-Cl-phen)]$^{2+}$ and Δ-[Ru(dpq)$_2$(5-Cl-phen)]$^{2+}$ are two sets of bisignate curves due to the excition coupling of the π–π* transitions of the diimine chromophores that are centred around 250 nm. The two bands between 200–250 nm are positive, the two bands between 250–350 nm are negative and the intensities between the monomeric complexes are comparable. The CD spectra of Δ-[Ru(dpq)$_2$(4-Cl-phen)]$^{2+}$ and Δ-[Ru(dpq)$_2$(5-Cl-phen)]$^{2+}$ show very slight differences, about 10% in intensity in peaks at ca. 265, 247 and 216 nm. Δ-[Ru(dpq)$_2$(3-Br-phen)]$^{2+}$ has a similar CD spectrum, however, the intensities are significantly reduced for the peaks (% reduction) at 275 (58%), 247 (42%) and 219 (70%) nm when compared with Δ-[Ru(dpq)$_2$(phen)]$^{2+}$.

Telfer et al.[29] have shown that the energy ordering of the positive and negative Cotton effects is related directly to the absolute configuration of the metal centre. The contribution of intranuclear excition coupling to the CD spectra is dependent strongly upon the length of the bridging ligand and is not simply double the intensity of the appropriate mononuclear complex, as one might expect, even though a flexible linker connects the two metal complexes in this case. The CD spectra that are produced are uniquely different for each of the dimers indicating that although the linker does not rigidly orientate the molecules there must be some coupling between the chromophores and that the resulting CD spectra are not simply additive.

The CD spectrum of Δ-[Ru(dpq)$_2$(phen)]$^{2+}$ contains four intraligand π–π* transitions, between 190–300 nm (216, 248, 265 and 298 nm at Δε = 73, 109, –190, and –140 respectively), while the weak band at 462.5 nm is most likely to be an MLCT transition. The intense CD bands at ca. 298 and 265 nm (long-axis polarization transition) for Δ-[Ru(dpq)$_2$(phen)]$^{2+}$ is strongly negative and the CD bands at higher energy (ca. 247 and 216 nm) positive, confirming the assignment as the Δ-enantiomer.[35] As expected, the CD spectrum of Λ-[Ru(dpq)$_2$(phen)]$^{2+}$ exhibits peaks of opposite intensity.

The CD spectra of Δ- and Λ-[Ru(dpq)$_2$(5-Cl-phen)](PF$_6$)$_2$, and ΔΔ- and ΛΛ-[{Ru(dpq)$_2$}$_2$μ-(phen-5-SOS-5-phen)](PF$_6$)$_4$ are shown in Figure 4. The spectra of both the mono- and dinuclear metal complexes are characterised by the peak wavelengths and their intensity in the 190 to 500 nm region. The two peaks at higher wavelength (465 to 415 nm), due to the MLCT, are similar in shape for both the mono- and dinuclear metal complexes and the peaks are approximately double (2.26 and 1.89 times intensity respectively) the intensity for the dinuclear metal complexes compared to the mononuclear complexes. The peaks at 299 and 216 nm also are approximately double (2.21 and 2.35 times intensity respectively) however, the peaks at 261 and 241 nm are considerably less (0.59 and 0.29 times intensity, respectively) than the mononuclear complex.

The CD spectra of Δ- and Λ-[Ru(dpq)$_2$-(4-Cl-phen]$^{2+}$, ΔΔ- and ΛΛ-[{Ru(dpq)$_2$}$_2$μ-(phen-4-SOS-4-phen)]$^{4+}$ are provided in the Supporting Information. For ΔΔ-[{Ru(dpq)$_2$}$_2$μ-(phen-4-SOS-4-phen)]$^{4+}$ the two peaks at higher

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

wavelength (468 to 418 nm), due to the MLCT, are similar in shape for both the mono- and dinuclear metal complexes and the peaks are 1.68 and 1.54 the intensity, respectively, for the dinuclear metal complexes compared to the mononuclear complexes. The peaks at 289, 263 and 247 nm have all similarly increased in intensity (1.57, 1.67 and 1.71 times, respectively) whereas the peak at 213 nm is the only peak which is approximately double (2.50 times) in intensity when compared to Δ-$[Ru(dpq)_2$-(4-Cl-phen)$]^{2+}$.

The CD spectra of Δ- and Λ-$[Ru(dpq)_2$-(3-Br-phen)$]^{2+}$, ΔΔ- and ΛΛ-$[\{Ru(dpq)_2\}_2\mu$-(phen-3-SOS-3-phen)$]^{4+}$ are provided in the Supporting Information. For ΔΔ-$[\{Ru(dpq)_2\}_2\mu$-(phen-3-SOS-3-phen)$]^{4+}$ the two peaks at higher wavelength (463 to 415 nm), due to the MLCT, are similar in shape for both the mono- and dinuclear metal complexes and the peaks are more than double (2.21 and 2.35) the intensity, respectively, for the dinuclear metal complexes compared to the mononuclear complexes. The peaks at 299, 260 and 212 nm are also about double the intensity (2.04, 1.98 and 2.38 times intensity, respectively) whereas the peak at 242 nm is 4.63 times the intensity when compared to Δ-$[Ru(dpq)_2$-(3-Br-phen)$]^{2+}$.

These differences in the CD spectra indicate that the location of the flexible linker attachment in the 3-, 4- or 5-positions on the phenanthroline ligand contribute differently to internuclear excitation coupling. The transitions at ca. 216 and 299 nm and the intensity of the MLCT band for all of the complexes are about double that of the mononuclear complex indicating that the linker position has a limited effect on these transitions. The transitions at ca. 241 and 261 nm are particularly sensitive to the orientation of the coordinated ligands when the linker attachment is in the 3- (0.29 and 0.29 times the mononuclear respectively), 4- (1.71 and 1.67 times the mononuclear respectively) or 5- (4.65 and 1.98 times the mononuclear respectively) positions.

For ΔΔ- and ΛΛ-$[\{Ru(dpq)_2\}_2\mu$-(phen-3-SOS-3-phen)$]^{4+}$ the distance between the complexes and the orientation with respect to one another is sufficient for all of the transitions to be additive and in the case of the transition at 242 nm four times. For ΔΔ- and ΛΛ-$[\{Ru(dpq)_2\}_2\mu$-(phen-4-SOS-4-phen)$]^{4+}$ the internuclear excitation coupling is 1.5–2 for all transitions indicating that in this case each of the observed transitions for the complexes is almost independent. In the case of ΔΔ- and ΛΛ-$[\{Ru(dpq)_2\}_2\mu$-(phen-5-SOS-5-phen)$]^{4+}$ the distance between the complexes appears to be adequate to produce a reduction in the band intensity which is accompanied by a wavelength shift of –10 nm for the dinuclear complex at 240 nm (the mononuclear complex peak occurs at 250 nm).

**ESI-MS:** As with the mononuclear complexes, the racemic and resolved dinuclear complexes were also characterised by ESI-MS (Table 3). The parent ions, $[M(PF_6)_4 + H]^+$ were not observed for any of the complexes. In the case of ΔΔ-$[\{Ru(dpq)_2\}_2\mu$-(phen-5-SOS-5-phen)$](PF_6)_4$, the mass spectrum displayed $[M(PF_6)_2]^{2+}$ (*m*/*z* calcd. 957.8, found 958.4), $[M(PF_6)]^{3+}$ (*m*/*z* calcd. for 590.2, found 590.7) and $[M]^{4+}$ (*m*/*z* calcd. 406.4, found 406.9). The intensity of the peaks increased as the charge on the metal complexes increased, such that the order of intensity was $[M]^{4+} > [M(PF_6)]^{3+} > [M(PF_6)_2]^{2+}$ (100%, 50% and 18%, respectively). The other dinuclear metal complexes also exhibited isotopic patterns for the $[M(PF_6)_2]^{2+}$, $[M(PF_6)]^{3+}$ and $[M]^{4+}$ ions, in similar ratios to those observed for ΔΔ-$[\{Ru(dpq)_2\}_2\mu$-(phen-5-SOS-5-phen)$](PF_6)_4$. The *m*/*z* values and isotopic ratios for the peaks observed in the ESI-MS of all the metal complexes are in close agreement with the calculated values.

## Conclusions

Here we have demonstrated that the mononuclear complexes Δ,Λ-$[Ru(dpq)_2$(3-Br-phen)$]^{2+}$, Δ,Λ-$[Ru(dpq)_2$(4-Cl-phen)$]^{2+}$, Δ,Λ-$[Ru(dpq)_2$(5-Cl-phen)$]^{2+}$ and Δ,Λ-$[Ru(dpq)_2$-(phen)$]^{2+}$ can be used to produce enantiomerically pure dinuclear complexes ΔΔ- and ΛΛ-$[\{Ru(dpq)_2\}_2\mu$-(phen-3-SOS-3-phen)$]^{4+}$, ΔΔ- and ΛΛ-$[\{Ru(dpq)_2\}_2\mu$-(phen-4-SOS-4-phen)$]^{4+}$ and ΔΔ- and ΛΛ-$[\{Ru(dpq)_2\}_2\mu$-(phen-5-SOS-5-phen)$]^{4+}$. The resolution of the mononuclear complexes could only be achieved using the chiral TRISPHAT anion, as column chromatography and classical resolution techniques were not effective in this case. Resolution of the mononuclear metal complexes was confirmed by CD and chiral $^1$H NMR titrations using the TRISPHAT anion. The production of the enantiomerically pure dinuclear complexes was assessed by CD. When compared to the monomeric form, the intensity of the peaks in the CD spectra the dinuclear complexes were not simply double that of their mononuclear analogues. This suggests that the position of attachment of the flexible linker affects the internuclear excitation coupling between the chromophores located on each of the metal centres differently. Binding studies using the dinuclear metal complexes are under way for these potential DNA probes.

## Experimental Section

**Materials** Dowex® 1X8–200 ($Cl^-$ form), 1,10-phenanthroline, lithium chloride, 5-chloro-1,10-phenanthroline, aluminium oxide (activated, neutral, Brockman I), potassium hexafluorophosphate, ammonium hexafluorophosphate, anhydrous *N*,*N*′-dimethylformamide (99.9%), NaH, $KNO_3$ and silica gel (TLC grade) were all obtained from the Aldrich chemical company. Ruthenium trichloride $(RuCl_3)\cdot xH_2O$ was purchased from Precious Metals Online. Silica gel 60 (0.040–0.063 mm) for column chromatography was obtained from Merck. Bis(2-mercaptoethyl) ether was purchased from Lancaster. Deuterated solvents, [$D_2O$ (99.9% D), $CD_2Cl_2$ (99.8% D) and $CD_3CN$ (99.8% D)] were purchased from Cambridge Isotope Laboratories. 3-Br-phen was made by the method of Tzalis et al.,[40] 4-Cl-phen was made by the method of Snyder and Freier,[41] dpq was made by the method of Collins et al.[17] Tetrachlorocatechol was made by the method of Renner and Hopfer,[42] TRISPHAT was synthesised and resolved by the methods of Favarager et al.[43] and $[Ru(dpq)_2Cl_2]$ was synthesised by the method of Anderson et al.[44] as for the analogous bpy complex. All general reagents and solvents were used as received (unless specifically stated) and were of analytical reagent grade or higher.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**NMR Spectroscopy:** Routine NMR was carried out on a 300-MHz Varian Mercury spectrometer equipped with a variable temperature accessory. For one-dimensional $^1$H spectra, a spectral width of 4500 Hz was used with 18000 data points and relaxation delay of 1 s, with the temperature kept constant at 25 °C. The spectra were referenced internally to the solvent resonances. Two dimensional NOESY spectra were accumulated using a 4200 Hz spectral width with 256 increments in the $t_1$ dimension, 2048 points in the $t_2$ dimension and mixing times of 300–800 ms. Two dimensional g-DQCOSY experiments were recorded over a spectral width of 4200 Hz using 256 increments in the $t_1$ dimension, 2048 points in the $t_2$ dimension and a pulse repetition delay of 1.5–2.0 s.

**ESI-MS:** Electrospray ionisation mass spectrometry was carried out by the mass spectroscopic service provided by the Research School of Chemistry, Australian National University.

**Circular Dichroism:** Circular dichroism spectra were recorded using a Jasco J-810 CD spectropolarimeter at room temperature. Samples of metal complexes (approx. 0.22 mg) were weighed directly into a 1-cm cell. The samples were dissolved by the addition of $CH_3CN$ (3.000 mL) then diluted so that the absorbance maximum was in the range $2.2 \pm 0.2$ absorbance units. The spectrum of each sample was then reacquired (in the range of 190–700 nm), the data pitch was set at 0.5 nm, the scan speed at 500 nm/min and the response time at 1 s. Spectra are shown as an average of 20 accumulations. The value of the molar absorptivity ($\Delta\varepsilon$) was calculated according to Equation (1).[45]

$$\Delta\varepsilon = \frac{\theta}{32.982 \times c \times l} \quad (1)$$

**TRISPHAT Titrations:** Samples of metal complexes $[Ru(dpq)_2(pp')]^{2+}$ (pp′ = phen, 3-Br-phen, 4-Cl-phen or 5-Cl-phen) (approx. $4.4 \times 10^{-4}$ mmol) were weighed out and dissolved in $CD_2Cl_2$ (650 μL) in NMR tubes. A solution of [$Bu_3NH$][Λ-TRISPHAT] was also prepared in $CD_2Cl_2$ at such a concentration that 25 μL of this solution would be 1 equiv. of the metal complex. $^1$H NMR spectra were acquired for each sample before and after the addition of [$Bu_3NH$][Λ-TRISPHAT].

**UV/Vis:** Absorption spectra were measured at 25 °C in the range 200–800 nm using a Varian Cary 300 Bio UV/Vis double-beam spectrophotometer referenced to $H_2O$. Extinction coefficients were determined by repeated measurements of the absorbance of aqueous metal complex solutions of known concentration. The solutions were serially diluted so that for all peaks, three measurements within the range 0.3–0.8 were obtained. The gradient of the lines of best fit of a plot of concentration vs. absorbance at each $\lambda_{max}$ gave the extinction coefficients, $\varepsilon_{max}$.

**Radiative Quantum Yield:** Radiative quantum yield ($\Phi$) measurements were performed using an adaptation of the method of Damrauer et al.[46] UV spectra were recorded on a Varian Cary 300-Bio spectrophotometer equipped with temperature controller set at 298 K. Luminescence spectra were recorded on a Varian Cary Eclipse fluorescence spectrophotometer, also equipped with a temperature controller at 298 K. All metal complexes were used as $PF_6^-$ salts in $CH_3CN$. Values of $\Phi$ are reported relative to $[Ru(bpy)_3]^{2+}$ in $CH_3CN$ ($\Phi_r = 0.062$)[47] and were calculated using Equation (2),[48] where $\Phi_{unk}$ is the radiative quantum yield of the sample, $\Phi_{std}$ is the radiative quantum yield of the standard, $I_{unk}$ and $I_{std}$ are the integrated emission intensities of the sample and standard, respectively. $A_{unk}$ and $A_{std}$ are the absorbance of the sample and standard, respectively, at the wavelength of excitation (450 nm). $\eta_{unk}$ and $\eta_{std}$ are the indices of refraction of the sample and standard solutions, respectively. Values of $\eta$ corresponding to the pure solvent are generally used. Since all measurements were conducted in the same solvent, $\eta_{unk}/\eta_{std} = 1$.

$$\Phi_{unk} = \Phi_{std}\left(\frac{I_{unk}}{A_{unk}}\right)\left(\frac{A_{std}}{I_{std}}\right)\left(\frac{\eta_{unk}}{\eta_{std}}\right)^2 \quad (2)$$

## Metal Complex Synthesis

**Synthesis of $[Ru(dpq)_2(pp')](PF_6)_2$ (pp′ = phen, 3-Br-phen, 4-Cl-phen or 5-Cl-phen):** In a typical experiment, $[Ru(dpq)_2Cl_2]$ (1.0 g, 1.58 mmol) was suspended in $H_2O$ (800 mL) and the solution heated to reflux (30 min). The ligand pp′ (1.16 mmol) was dissolved in $CH_3CH_2OH$ (200 mL) and added dropwise over a period of 1 h. The mixture was kept at reflux for another 48 h, during which time it changed colour from black to deep red. After cooling, the solution was reduced in volume to ca. 100 mL before the addition of saturated $KPF_6$ solution (3 mL), which caused precipitation of the complex. The suspension was extracted with $CH_2Cl_2$ ($5 \times 200$ mL), into which the orange complex redissolved and the combined extracts were dried with anhydrous $Na_2SO_4$. The solution was evaporated to dryness to give the crude product as a red solid, which was purified on silica gel (eluent: 89% $CH_3CN$, 1% saturated $KNO_3$ solution, 10% $H_2O$). The fractions containing pure $[Ru(dpq)_2(pp')](PF_6)_2$ were identified by $^1$H NMR, combined and extracted with $CH_2Cl_2$. The compound was dissolved in acetone and then precipitated by the addition of $H_2O$. The complex was collected by vacuum filtration, washed with diethyl ether and air-dried. The complex was subsequently purified by column chromatography on alumina, eluting with $CH_3CN$. The single fraction was collected and the solvents evaporated to dryness to yield the product as an orange solid.

***rac*-$[Ru(dpq)_2(phen)](PF_6)_2$:** Yield 0.11 g (30%). UV ($CH_3CN$): $\lambda_{max}$ ($\varepsilon \times 10^4$, $mol^{-1}\,dm^3\,cm^{-1}$) = 447 (1.7), 290 (4.6), 258 (10.6), 206 (6.7) nm. ESI-MS $CH_3CN$ $m/z$ calcd. for $C_{40}H_{23}ClF_6N_{10}PRu$ $[M(PF_6)]^+$, 925.2, found 925.6, $m/z$ calcd. for $C_{40}H_{23}ClN_{10}Ru$ $[M]^{2+}$, 390.1, found 390.2.

**Resolution of Mononuclear Complexes:** TRISPHAT extraction was carried out using modifications of the methods of Lacour et al.[36] In a typical experiment, [Ru(dpq)$_2$(pp′)](PF$_6$)$_2$ pp′ = phen, 3-Br-phen, 4-Cl-phen or 5-Cl-phen) (approx. 0.83 mmol, 1 equiv.) was suspended in $H_2O$ (1.8 L) and the solution stirred with Dowex® 1X8–200 (2.0 g) for 4 h to convert the metal complex to a chloride salt. The solution was filtered to remove the resin and [$Bu_3NH$][Λ-TRISPHAT] (approx. 0.75 mmol, 0.9 equiv.) in chloroform (600 mL) was added. The solution was stirred in darkness for 4 h, and then filtered to remove any precipitate. The organic layer was removed, dried with anhydrous $MgSO_4$ and the solvents evaporated to dryness to give an orange solid (first isolate, Λ-[Ru(dpq)$_2$(pp′)](Λ-TRISPHAT)$_2$).

To the remaining aqueous layer was added saturated $KPF_6$ (5 mL), causing the formation of an orange precipitate which was subsequently extracted with $CH_2Cl_2$ (3 × 250 mL). The extracts were dried with anhydrous $MgSO_4$ and the solvents evaporated to dryness to give an orange solid (Δ-[Ru(dpq)$_2$(pp′)](PF$_6$)$_2$) (pp′ = phen, 3-Br-phen, 4-Cl-phen or 5-Cl-phen). This complex was dissolved in $CH_3CN$ and purified on silica gel using saturated $NH_4PF_6$ in $CH_3CN$ as eluent. A single orange band was collected and the solvents evaporated to dryness (intermediate isolate).

The intermediate isolate was suspended in $H_2O$ (900 mL) and converted into the chloride salt by stirring with Dowex® 1X8–200 (1.0 g) for 4 h. The solution was filtered to remove the resin and a suspension of [cinchonidium][Δ-TRISPHAT] (approx. 0.75 mmol, 0.9 equiv.) in chloroform (600 mL) was added. The solution was stirred in darkness for 4 h, and then filtered to remove any precipitate. The organic layer was separated, dried with anhydrous $MgSO_4$ and the solvents evaporated to dryness to give an orange solid (second isolate, Δ-[Ru(dpq)$_2$(pp′)](Δ-TRISPHAT)$_2$).

The removal of TRISPHAT counterions and conversion of the metal complexes back to $PF_6^-$ salts was achieved using flash chromatography. The two isolates were separately pre-absorbed onto silica gel (5 g) using $CH_2Cl_2$ (50 mL). The $CH_2Cl_2$ was removed under reduced pressure prior to dry loading each of the fractions onto separate pre-prepared columns of silica gel equilibrated with $CH_3CN$. The complexes were eluted from the columns as a single orange band in each case using saturated $NH_4PF_6$ in $CH_3CN$. $H_2O$ (50 mL) was added to each fraction and the $CH_3CN$ was removed under reduced pressure to precipitate the complex as a finely divided orange solid. The solid was collected under vacuum, washed with diethyl ether (50 mL) and air dried. The first isolate was found to contain Λ-[Ru(dpq)$_2$(pp′)](PF$_6$)$_2$ while the second isolate contained Δ-[Ru(dpq)$_2$(pp′)](PF$_6$)$_2$. The information gained from the characterisation of Δ- and Λ-[Ru(dpq)$_2$(pp′)](PF$_6$)$_2$ (where pp′ = phen, 3-Br-phen, 4-Cl-phen or 5-Cl-phen) is detailed below.

**Δ-[Ru(dpq)$_2$(phen)](PF$_6$)$_2$:** Yield 36 mg, (13%). $^1H$ NMR (300 MHz, $CD_3CN$): $\delta$ = 9.57 (dddd, $J$ = 1.5, 3.0, 5.3, 9.0 Hz, 3 H, H13/16), 9.26 (s, 2 H, H14/15), 9.25 (s, 2 H, H14/15), 8.89 (d, $J$ = 1.9 Hz, 1 H, H2), 8.65 (dd, $J$ = 1.3, 8.3 Hz, 1 H, H7), 8.33 (d, $J$ = 8.9 Hz, 1 H, H6), 8.24 (m, 4 H, H11/18), 8.24 (s, 1 H, H4), 8.22 (d, $J$ = 2.6 Hz, 1 H, H5), 8.13 (ddd, $J$ = 1.3, 3.9, 5.2 Hz, 1 H, H9), 8.09 (dd, $J$ = 1.3, 5.4 Hz, 1 H, H13′), 7.80 (m, 3 H, H12/17), 7.81 (d, $J$ = 8.5 Hz, 1 H, H12′) 7.68 (dd, $J$ = 5.3, 8.3 Hz, 1 H, H8) ppm. **Synthesis of Racemic Dinuclear Complexes:** In a typical experiment, anhydrous $(CH_3)_2NCOH$ was de-aerated prior to use by bubbling with $N_{2(g)}$ for 10 min in a round-bottomed flask fitted with a rubber septum. *rac*-[Ru(dpq)$_2$(pp′)](PF$_6$)$_2$ (pp′ = 3-Br-phen, 4-Cl-phen or 5-Cl-phen, 0.10 mmol) was dissolved in de-aerated anhydrous $(CH_3)_2NCOH$ (2 mL). In a separate vessel NaH (70% dispersion in mineral oil, 0.0024 g, 0.10 mmol) was suspended $(CH_3)_2NCOH$ (2 mL) and the solution was purged by bubbling with $N_{2(g)}$ for 5 min. Under a strong stream of $N_{2(g)}$, bis(2-mercaptoethyl) ether (SOS) (5.6 μL, 0.05 mmol) in $(CH_3)_2NCOH$ (100 μL) was added to the solution by micropipette. The solution of SOS/NaH was allowed to stir under $N_{2(g)}$ to complete dissolution of the NaH, at which point the solution went clear (c.a. 2 min). The separate solutions containing the monomer and linker were mixed using cannulation at which time the solution underwent a rapid colour change from deep red to black. The solution was allowed to stir under $N_{2(g)}$ for a further 5 min before $(CH_3CH_2)_2O$ (50 mL) was added causing a black precipitate to form. The solution was stored at 0 °C for 2 h before the product was collected under vacuum and washed with copious amounts of $(CH_3CH_2)_2O$.

The crude mixture was purified using flash chromatography on silica gel (20 × 2.5 cm, eluent: 89% $CH_3CN$, 10% $H_2O$, 1% saturated aqueous $KNO_3$). The fractions containing pure [{Ru(dpq)$_2$}$_2$μ-(phen-*n*-SOS-*n*-phen)]$^{4+}$ ($n$ = 3, 4 or 5, SOS = –S–$CH_2$–$CH_2$–O–$CH_2$–$CH_2$–S–) were identified by TLC (silica gel, $CH_3CN$/$H_2O$/saturated $KNO_3$, 45:5:2) and were combined. Saturated $KPF_6$ (1 mL) was added before extraction with $CH_2Cl_2$ (3 × 50 mL) to remove the $KNO_3$. The extracts were dried with anhydrous $MgSO_4$, filtered and the solvent removed under reduced pressure. The complex was purified a second time on silica gel, (20 × 2.5 cm, eluent:saturated $NH_4PF_6$ in $CH_3CN$), and the single orange band was collected and the solvents evaporated to dryness under reduced pressure. The resultant orange solid was dissolved in a minimum volume of $CH_3CN$ and precipitated by the addition of $H_2O$. The complex was collected by vacuum filtration, washed with $(CH_3CH_2)_2O$ and air dried. The yields and characterisation data of the dinuclear complexes synthesised are given below.

# Synthesis, Structure and Magnetic Behaviour of Manganese(II) Selenolate Complexes $^1_\infty$[Mn(SePh)$_2$], [Mn(SePh)$_2$(bipy)$_2$] and [Mn(SePh)$_2$(phen)$_2$] (bipy = bipyridyl, phen = phenanthroline)

**Andreas Eichhöfer,*[a] Paul T. Wood,[b] Raghavan Viswanath,[a] and Richard A. Mole[c]**

**Keywords:** Transition-metal complexes / Manganese / X-ray structure analysis / Magnetism

The manganese selenolate complex $^1_\infty$[Mn(SePh)$_2$] has been prepared by reaction of Mn(OOCCH$_3$)$_2$ with 2 equiv. PhSeSiMe$_3$ in thf. In the crystal structure, the compound forms one-dimensional chains, and the bridging selenolate ligands result in relatively short metal–metal contacts of about 3 Å. Reaction with two equivalents of the Lewis bases 2,2′-bipyridine and 1,10-phenanthroline yielded the monomeric octahedral complexes [Mn(SePh)$_2$(2,2′-bipy)$_2$] and [Mn(SePh)$_2$(1,10-phen)$_2$], respectively. The magnetic and optical properties of these complexes have been investigated.

## Introduction

Metal chalcogenolato complexes have attracted interest because of their rich structural chemistry,[1–3] their potential use as precursors for M/Se materials[4,5] and their relevance as models for active sites of chalcogen-containing metalloproteins.[6,7] Manganese, for example, plays a role as a dopant for 12–16 semiconductor films and nanocrystals, referred to as dilute magnetic semiconductors (DMS),[8,9] as well as in some manganese–oxido cluster complexes such as [Mn$_{12}$O$_{12}$(O$_2$CCH$_3$)$_{16}$][10] and [Mn$_{84}$O$_{72}$(O$_2$CMe)$_{78}$(OMe)$_{24}$(MeOH)$_{12}$(H$_2$O)$_{42}$(OH)$_6$],[11] which are known as single-molecule magnets (SMMs). With respect to manganese chalcogenolato complexes, two synthetic approaches have been widely used. The reaction of a manganese(II) halide with NaEPh (E = S, Se, Te) in the presence of quarternary ammonium or phosphonium salts yields anionic monomeric and oligomeric complexes {for example, [Mn(EPh)$_4$]$^{2-}$ (E = S, Se, Te),[12,13] [Mn$_2$(SPh)$_6$]$^{2-}$[14] and [Mn$_4$(SPh)$_{10}$]$^{2-}$[12]}. In contrast, a few neutral complexes containing bulky organic groups, such as [Mn{N(SiMe$_3$)$_2$}-(μ-SeC$_6$H$_2$-2,4,6-*i*Pr$_3$)(THF)],[15] [Mn(SeMes*)$_2$C$_4$H$_8$O] (Mes* = C$_6$H$_2$-2,4,6-*t*Bu$_3$), [Mn(SeC$_6$H$_3$-2,6-Mes$_2$)$_2$] (Mes = C$_6$H$_2$-2,4,6-Me$_3$)[16] and $^1_\infty$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$],[17] have been synthesised by reaction of [Mn{N(SiMe$_3$)$_2$}$_2$] with the corresponding selenol RSeH (R = organic group).

Reported here is the organometallic synthesis of three manganese selenolate complexes by reaction of manganese acetate with PhSeSiMe$_3$. Structural characterization and investigation of the magnetic and optical properties of these complexes is also presented.

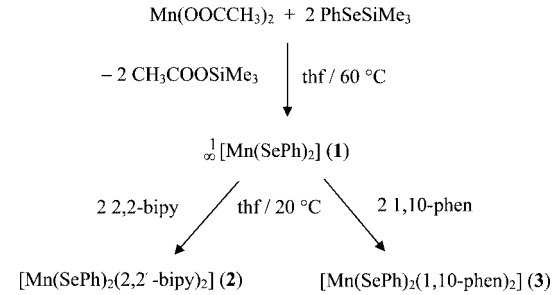
## Results and Discussion

### Synthesis and Structure

The manganese selenolate complex $^1_\infty$[Mn(SePh)$_2$] (**1**) was prepared by reaction of anhydrous Mn(OOCCH$_3$)$_2$ with 2 equiv. PhSeSiMe$_3$ in thf, as shown in Scheme 1. Reaction of **1** with 2 equiv. of the Lewis bases 2,2′-bipyridine and 1,10-phenanthroline yielded dark red crystals of the monomeric octahedral complexes [Mn(SePh)$_2$(2,2′-bipy)$_2$] (**2**) and [Mn(SePh)$_2$(1,10-phen)$_2$] (**3**), respectively.



Scheme 1.

Compound **1** crystallises in the tetragonal space group $I4_1/a$. In the crystal structure of **1**, the manganese atoms are μ$_2$-bridged in one dimension by the phenylselenolato ligands to form infinite chains (Figure 1). The Mn–Se distances of 254.7(1) and 257.3(1) pm are comparable to those found in similar compounds such as [Mn(SePh)$_4$]$^{2-}$ (average 256.7 pm)[13] and $^1_\infty$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$] (259.0 pm);[17]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the latter compound also forms a one-dimensional chain structure in the crystal lattice. However, different orientations of the phenyl rings in the structures of **1** and $^{1}_{\infty}$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$] results in different coordination geometries around the manganese atoms. In **1**, four selenium atoms [Se(1), Se(2), Se(1′) and Se(2′)] of the phenylselenolato ligands form a distorted tetrahedral coordination environment around the manganese atom with five similar Se–Mn–Se bond angles [104.63(3)° for Se(1)–Mn(1)–Se(1′), 106.0° for Se(2′)–Mn(1)–Se(1′), 105.88(3)° for Se(1)–Mn(1)–Se(2), 107.97° for Se(2′)–Mn(1)–Se(2) and 105.42° for Se(1′)–Mn(1)–Se(2)] and only one distinctly larger angle of 125.4(1)° for Se(1)–Mn(1)–Se(2′). The $Mn_2Se_2$ four-membered rings in **1** have a much more rhombic–like shape [angles of 73.0(1)° for Mn(1)–Se(1)–Mn(1′) and 72.9(1)° for Mn(1)–Se(2)–Mn(1′)] than in [Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$], where the manganese and selenium atoms form nearly planar quadratic rings (Mn–Se–Mn 88.0°, Se–Mn–Se 92.0°). In addition, the ring in **1** is twisted by 18.24° from ideal planarity to form a butterfly-type shape. This reduces the distance between the manganese atoms in the one dimensional chains distinctly from 359.3 pm in $^{1}_{\infty}$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$] to 304.6 pm in **1**, which is closer to the distance between the metal atoms in [Mn(CO)$_5$]$_2$ (290.4 pm).[18]

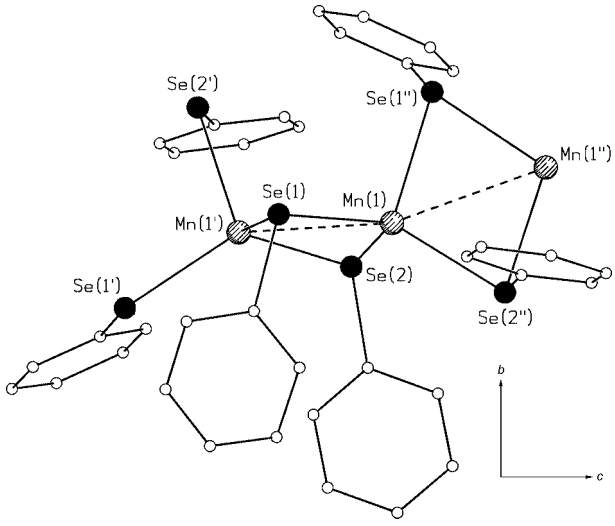


Figure 1. Section of the one-dimensional chain structure of $^{1}_{\infty}$[Mn(SePh)$_2$] (**1**) viewed down *a*. Symmetry transformation for generation of equivalent atoms: ′: *y* – 3/4, –*x* + 5/4, *z* + 1/4 ": –*y* + 5/4, *x* + 3/4, *z* – 1/4. Selected bond lengths [pm] and angles [°]: Se(1)–Mn(1) 254.7(1), Se(1)–Mn(1′) 257.3(1), Se(2)–Mn(1′) 254.8(1), Se(2)–Mn(1) 257.8(1), Mn(1)–Mn(1") 304.6(1). Mn(1)–Se(1)–Mn(1′) 73.01(3), Mn(1′)–Se(2)–Mn(1) 72.93(3), Se(1)–Mn(1)–Se(2) 105.88(3), Se(1)–Mn(1)–Se(2") 125.39(4), Se(1)–Mn(1)–Se(1") 104.63(3), Se(2′′)–Mn(1)–Se(1") 106.00(3), Se(2")–Mn(1)–Se(2) 107.97(3), Se(1")–Mn(1)–Se(2) 105.42(4), Mn(1")–Mn(1)–Mn(1′) 151.86(3).

The monomeric compound **2** crystallises in the monoclinic space group $P2_1/c$ (Figure 2) and exhibits a distorted octahedral coordination sphere around the manganese atom. The coordination sphere involves four nitrogen atoms [N(1), N(2), N(3), N(4)] from the two bidentate bipyridine ligands and two selenium atoms [Se(1), Se(2)] from the phenylselenolato ligands, which coordinate in a *cis* geometry. The Mn–Se distances are 265.3 pm and 265.5 pm, which are slightly longer than in **1**. The Mn–N distances [224.6–231.9(4) pm] as well as the N–Mn–N bite angle [N(1)–Mn(1)–N(2): 71.9(2)°, N(3)–Mn(1)–N(4): 71.5(2)°] are comparable to those in related transition-metal complexes.

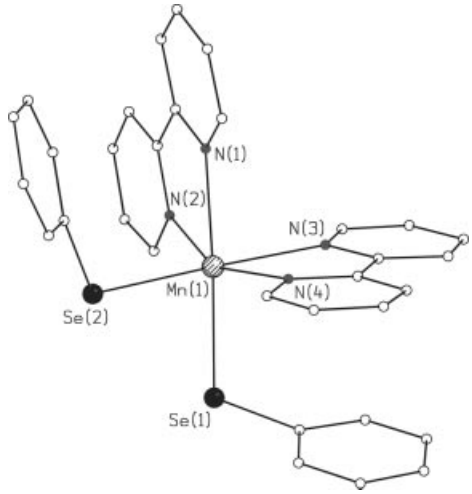

Figure 2. Molecular structure of [Mn(SePh)$_2$(2,2′-bipy)$_2$] (**2**). Selected bond lengths [pm] and angles [°]: Se(1)–Mn(1) 265.3(1), Se(2)–Mn(1) 265.5(1), Mn(1)–N(4) 224.6(4), Mn(1)–N(2) 228.3(4), Mn(1)–N(1) 228.9(4), Mn(1)–N(3) 231.9(5). N(4)–Mn(1)–N(1) 91.06(15), N(2)–Mn(1)–N(1) 71.91(16), N(4)–Mn(1)–N(3) 71.54(16), N(2)–Mn(1)–N(3) 88.81(16), N(1)–Mn(1)–N(3) 86.22(16), N(4)–Mn(1)–Se(1) 98.69(11), N(2)–Mn(1)–Se(1) 97.49(12), N(3)–Mn(1)–Se(1) 92.81(11), N(4)–Mn(1)–Se(2) 100.32(12), N(2)–Mn(1)–Se(2) 98.92(13), N(1)–Mn(1)–Se(2) 93.71(12), Se(1)–Mn(1)–Se(2) 88.74(4).

Complex **3** crystallises in the acentric space group *Cc* and is isostructural to **2**, with only slight differences in the bond lengths and bond angles.

## Magnetic Properties

The magnetic behaviour of chain compounds such as **1** is well understood.[19] For materials with an antiferromagnetic exchange interaction there should be a broad maximum in the temperature dependence of the susceptibility that is typical of short-range order found in low dimensional materials. The temperature at which the maximum occurs is dependent on the size of the *intra*chain exchange coupling, *J*. For small spins, the susceptibility is normally well modelled by the approach of Bonner and Fisher,[20] which was subsequently modified by Weng.[21] For $Mn^{II}$ chains, the larger $S = 5/2$ spin is usually better modelled[22] by the classical approach of Fisher.[23] In the case of compound **1**, the magnitude of the susceptibility is much lower than expected (the susceptibility of an array of non-interacting $S = 5/2$ ions at 300 K should be approximately 0.015 cm$^3$ mol$^{-1}$, almost an order of magnitude larger than the observed value) and it decreases smoothly down to 25 K (Figure 3). This is indica-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tive of very strong superexchange as the broad maximum must occur at a temperature far higher than 300 K. Strong exchange is expected for bridging ligands that have heavy donor atoms, although this does not seem to always be the case.[19] However, sulfur-mediated superexchange has recently been shown to give strong exchange and relatively high magnetic ordering temperatures.[24]

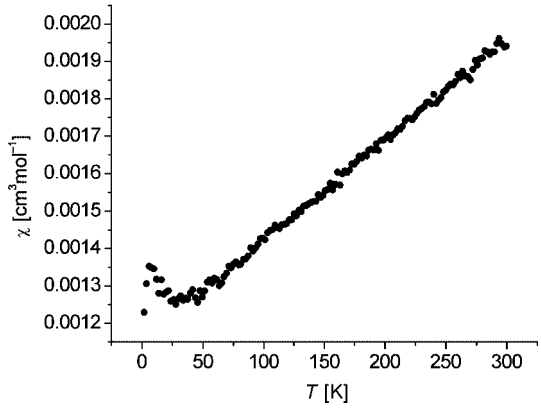

Figure 3. Susceptibility versus temperature for $^{1}_{\infty}$[Mn(SePh)$_2$] (**1**).

At the suggestion of a referee we prepared the previously reported compound $^{1}_{\infty}$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$][17] and measured its magnetic susceptibility (Figure 4). The presence of the broad maximum centred close to 100 K shows that the exchange is strong, but not as strong as that in **1**. Fits to the Weng (Equation 1) and Fisher (Equation 2) equations give satisfactory agreement for the position of the maximum, but fail to model the low-temperature data. Fits obtained by using the Weng equation are superior to those obtained from the Fisher equation, which is surprising given the way these functions were derived (see above). These fits give values for $J$ of –13.50(5) K and –11.2(3) K, respectively. Below 25 K there is a discontinuity in the susceptibility for both **1** and $^{1}_{\infty}$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$], which we ascribe to the onset of long-range order.

MnSe has an analogous structure to sodium chloride and orders antiferromagnetically at 249 K,[25] which indicates that coupling is strong in this compound. In compound **1**, the Mn–Se–Mn bridging angle is approximately 73° in comparison with 90° in MnSe and 88° in $^{1}_{\infty}$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$]. As the strength of the superexchange is dependent on the bridging angle, it is reasonable that the ordering temperatures for these three compounds should be different. Whilst there has been much study of the variation in exchange coupling with bridging angle for angles of 90° and greater, the lack of compounds with more acute bridges has meant that there has been no equivalent study for angles less than 90°. Selenolate bridges appear to favour more acute bridging angles than either alkoxide or thiolate ligands, hence further study of how the selenolate-mediated exchange interaction varies with angle would be useful. For compound **1** it is also important to remember that the Mn–Mn distance is very small, and we cannot rule out some contribution from direct exchange.

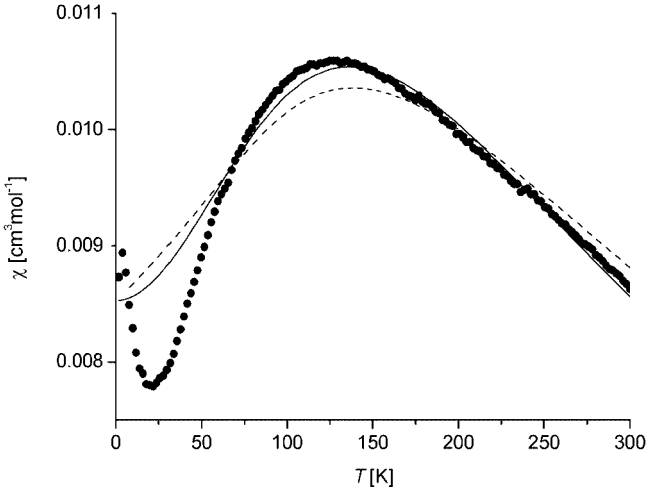

Figure 4. Susceptibility versus temperature for $^{1}_{\infty}$[Mn(SeC$_6$H$_2$-2,4,6-CH$_3$)$_2$] (dotted line). The fits according to either the Weng (straight) or Fisher (dashed) equation (see text).

For the spin Hamiltonian $\hat{H} = -2J\sum_i S_i \cdot S_{i+1}$, these equations, Equation (1) and Equation (2), have the form:

$$\chi = \frac{Ng^2\beta^2}{kT}\left(\frac{2.9167 + 208.04(J/kT)^2}{1 + 15.543(J/kT) + 2707.2(J/kT)^3}\right) \quad (1)$$

$$\chi = \frac{Ng^2\beta^2 S(S+1)}{3kT}\left(\frac{1+u}{1-u}\right)$$
$$u = \coth[2JS(S=1)/kT] - kT/[2JS(S+1)] \quad (2)$$

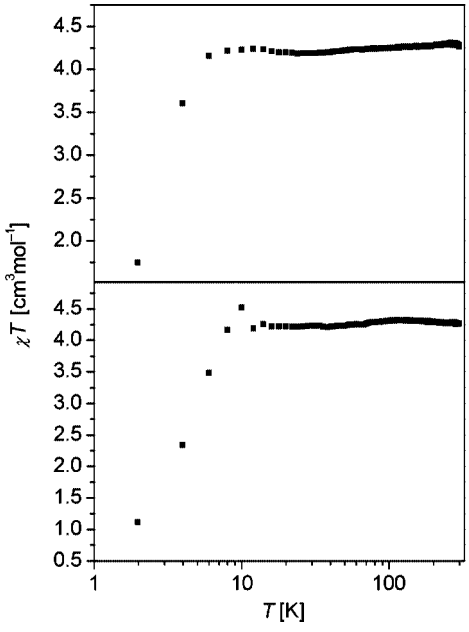

Figure 5. Graph of $\chi T$ vs. $T$ for [Mn(SePh)$_2$(2,2′-bipy)$_2$] (**2**) (bottom) and for [Mn(SePh)$_2$(1,10-phen)$_2$] (**3**) (top).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Compounds **2** and **3** are both well-isolated octahedral molecules with somewhat distorted coordination environments. They both obey the Curie law at temperatures above 10 K to give Curie constants of 4.27(8) and 4.31(1) $cm^3 mol^{-1} K$, respectively, in comparison to the expected value of 4.375 $cm^3 mol^{-1} K$ for $g = 2$ (Figure 5). Below 10 K, both compounds exhibit a local maximum in $\chi$, followed by a sharp decrease. The single ion anisotropy of a high spin $d^5$ ion may be modelled according to ref.[19], however, this approach alone does not successfully model the low temperature data for either compound. We therefore suggest that the low temperature behaviour is a combination of very weak single ion anisotropy and dipolar coupling.

## Optical Properties

Crystals of **1** appear red-brown in compact form but turn light rose-red when ground to a powder. The UV/Vis spectrum of **1** dissolved in thf is displayed in the lower part of Figure 6. The spectrum shows three distinct regions of absorption features, which differ significantly in their absorption intensity. The broad and intense band centred around 260 nm ($\varepsilon = 2.4 \times 10^4$ $M^{-1} cm^{-1}$), which comprises a weakly resolved shoulder, can be assigned to π–π* transitions of the phenylselenolato ligands. In the region between 340 and 400 nm, two additional weakly resolved shoulders with extinction coefficients between 200 and 400 $M^{-1} cm^{-1}$ can be thought to originate from ligand-to-metal charge transfer transitions, although they are relatively low in intensity, as well as from d–d transitions in $Mn^{2+}$ ions. Between 400 and 700 nm one observes one sharp band at 431 nm ($\varepsilon = 12$ $M^{-1} cm^{-1}$) followed by two shoulders at 476 and 552 nm, which can be assigned because of their low intensity as d–d transitions in $Mn^{2+}$ [$^4T_1(G) \leftarrow {}^6A_1$ 552 nm (18116 $cm^{-1}$), $^4T_2(G) \leftarrow {}^6A_1$ 476 nm (21008 $cm^{-1}$), $^4E(G) \leftarrow {}^6A_1$ 431 nm (23202 $cm^{-1}$)].[26] The solid-state spectrum as a nujol mull (Figure 6, upper part) displays, in principle, similar absorption features as observed in solutions of **1**, although the bands differ slightly in intensity, position and shape. The strong band of the π–π* transitions of the $SePh^-$ ligands is shifted to 243 nm, and the intensity of the shoulder is reduced. Bands for the transitions at 378 and 357 nm observed in the solution spectrum are obscured by a broad band centred around 324 nm in the solid-state spectrum. A shoulder is visible at 400 nm in the solid-state spectrum, which has no equivalent in the solution spectrum. In the region of the d–d transitions, the solid-state spectrum shows a weakly resolved maximum at 436 nm, a shoulder at 464 nm and a comparatively strong band at 481 nm. The shoulder in the solution spectrum at 552 nm is only visible in the solid-state spectrum as a tail of the absorption at 481 nm. The differences observed between the solution and solid-state spectra, which are due in part to the non-validity of the Lambert–Beer law for the solid-state spectra, might also indicate different coordination geometries of the $Mn^{2+}$ ions in thf and in the solid state. In the crystal structure of **1**, the $Mn^{2+}$ ions are coordinated by four selenium atoms of the phenylselenolato ligands in a tetrahedrally distorted arrangement. In solution, the one-dimensional polymeric structure might be destroyed with additional coordination of thf solvent molecules, which can either result in a tetrahedral or octahedral geometry or a mixture of both.

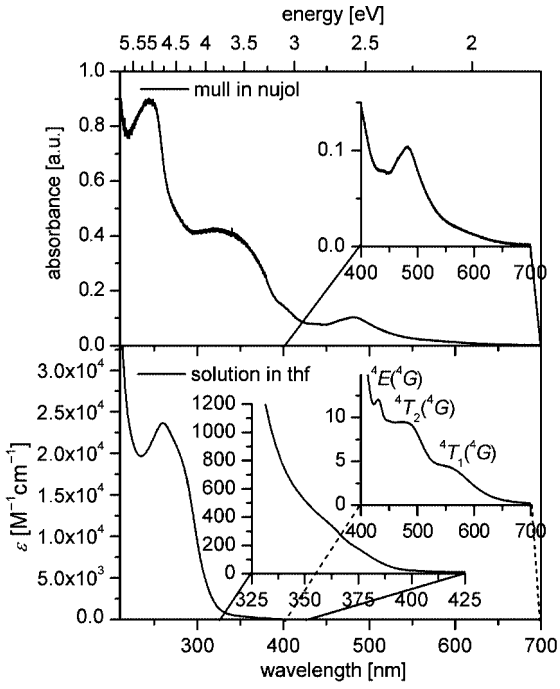

Figure 6. UV/Vis spectra of $^1_\infty$[Mn(SePh)$_2$] (**1**) in thf.

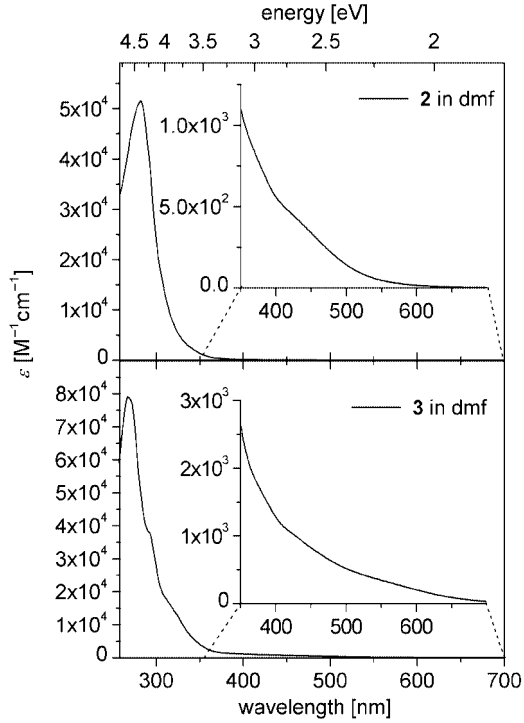

Figure 7. UV/Vis spectra of [Mn(SePh)$_2$(2,2′-bipy)$_2$] (**2**) (top) and [Mn(SePh)$_2$(1,10-phen)$_2$] (**3**) (bottom) in dmf.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The dark red crystals of **2** and **3** mostly keep their colour when ground to a powder. In dmf solutions, **2** and **3** display strong absorption features at 284 nm and 267 nm, respectively, which can be assigned to π–π* transitions of either the bidentate amine ligands or the $PhSe^-$ ligands, or a mixture of both (Figure 7). The UV/Vis spectrum of **3** displays several shoulders at 292, 313 and 322 nm. Apart from the strong absorption, weakly resolved shoulders between 350 and 600 nm (**2**), and 350 and 700 nm (**3**) could originate from metal-to-ligand charge transfer transitions into low-lying, empty π* orbitals of the bipyridyl and phenanthroline ligands, respectively. An assignment as d–d transitions seems to be unlikely because of extinction coefficients in the region between 500 and 2000 $M^{-1}cm^{-1}$. These transitions are most probably obscured by the charge-transfer bands.

## Experimental Section

**Synthesis:** Standard Schlenk techniques were employed throughout the syntheses by using a double manifold vacuum line with high-purity dry nitrogen. The solvents thf and diethyl ether were dried with sodium benzophenone and distilled under nitrogen. Anhydrous dimethylformamide (dmf) ($H_2O < 0.005\%$) obtained from Aldrich was degassed, freshly distilled and stored over molecular sieves under nitrogen. $Mn(OOCCH_3)_2$, 2,2′-bipyridine and 1,10-phenanthroline were purchased from Aldrich. $PhSeSiMe_3$ was prepared according to a literature procedure.[27]

**$^1_\infty$[Mn(SePh)$_2$] (1):** An ultrasonic bath was used to suspend $Mn(OOCCH_3)_2$ (0.42 g, 2.45 mmol) in thf (45 mL) for 45 min. $PhSeSiMe_3$ (0.98 mL, 5.1 mmol) was then added, and the mixture was stirred overnight to give an orange solution. Careful addition of diethyl ether (50 mL) resulted in the crystallisation of dark red needles of $^1_\infty$[Mn(SePh)$_2$] (**1**). Filtration of the crude product, and further addition of diethyl ether to the filtrate resulted in a total yield of 90% (0.81 g) of **1**. $C_{12}H_{10}MnSe_2$ (367.1): calcd. C 39.3, H 2.8; found C 39.8, H 3.1.

**[Mn(SePh)$_2$(2,2′-bipy)$_2$] (2):** $^1_\infty$[Mn(SePh)$_2$] (0.15 g, 0.41 mmol) was dissolved in thf (25 mL ) to give an orange-brown solution. A solution of 2,2′-bipyridine (0.13 g, 0.83 mmol) in thf (6 mL) was then added, and the mixture immediately turned dark red. Overnight, a dark red crystalline precipitate of [Mn(SePh)$_2$(2,2′-bipy)$_2$] (**2**) was formed from this solution with a total yield of 79% (0.22 g). Compound **2** was insoluble in thf and could be recrystallised for purification from dmf/thf. $C_{32}H_{26}MnN_4Se_2$ (679.4): calcd. C 56.6, H 3.7, N 8.3; found C 56.4, H 4.1, N 8.1. Crystals suitable for single-crystal X-ray analysis were grown by layering dmf solutions of **2** with diethyl ether.

**[Mn(SePh)$_2$(1,10-phen)$_2$] (3):** $^1_\infty$[Mn(SePh)$_2$] (0.081 g, 0.22 mmol) was dissolved in thf (20 mL) to give an orange-brown solution. A solution of 1,10-phenanthroline (0.083 g, 0.46 mmol) in thf (5 mL) was then added, which led to the immediate formation of [Mn(SePh)$_2$(1,10-phen)$_2$] (**3**) as a cherry red crystalline precipitate with a total yield of 84% (0.15 g). $C_{36}H_{26}MnN_4Se_2{\cdot}C_3H_7NO$ (800.6): calcd. C 58.6, H 4.2, N 8.8; found C 58.7, H 4.2, N 8.7. Crystals suitable for single-crystal X-ray analysis were grown by layering dmf solutions of **3** with diethyl ether.

**Crystallography:** Crystals suitable for single-crystal X-ray diffraction were taken directly from the reaction solution of the compound and then selected under perfluoroalkylether oil. Single-crystal X-ray diffraction data of compounds **1**–**3** were collected by using graphite-monochromatised Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) on a STOE IPDS II (Imaging Plate Diffraction System) equipped with a Schneider rotating anode. Raw intensity data were collected and treated with the STOE X-Area software Version 1.27. Data for all compounds were corrected for Lorentz and polarisation effects. The structures were solved with the direct methods program SHELXS[28] of the SHELXTL PC suite programs and were refined with the use of the full-matrix least-squares program SHELXL.[28] Molecular diagrams were prepared with SCHAKAL 97.[29]

All Mn, Se, N and C atoms, with the exception of the C atoms of thf in **1**, were refined with anisotropic displacement parameters, whilst H atoms were calculated in fixed positions (Table 1).

Table 1. Crystallographic data for $^1_\infty$[Mn(SePh)$_2$] (**1**), [Mn(SePh)$_2$(2,2′-bipy)$_2$] (**2**) and [Mn(SePh)$_2$(1,10-phen)$_2$] (**3**).

CCDC-603930(**1**), -603931(**2**) and -603932(**3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Physical Measurements:** Field-cooled SQUID measurements were performed at 1 T with an extraction magnetometer (Quantum Design PPMS) in DC extraction mode, and the response to the vertical movement of the sample (10 $ms^{-1}$) through the detection coils was recorded, under a dry helium environment. The samples were contained in high-precision quartz glass sample holders owing to the high degree of moisture sensitivity of the compounds. The data were corrected for the sample holder and for diamagnetism using Pascal's constants.[19] UV/Vis absorption spectra of cluster molecules in solution were measured on a Varian Cary 500 spectrophotometer in quartz cuvettes. Solid-state reflection spectra were measured as micron-sized crystalline powders between quartz plates with a Labsphere integrating sphere.

# Diphthalocyaninatolanthanum as a New Phthalocyaninato-Dianion Donor for the Synthesis of Heteroleptic Triple-Decker Rare Earth Element Crown-Phthalocyaninato Complexes

**Alexander G. Martynov,[a,b] Olga V. Zubareva,[a] Yulia G. Gorbunova,*[a,b] Sergey G. Sakharov,[b] Sergey E. Nefedov,[b] Fedor M. Dolgushin,[c] and Aslan Yu. Tsivadze[a,b]**

**Keywords:** Rare earths / Macrocyclic ligands / Phthalocyanines / Sandwich complexes / Heteroleptic complexes

A novel synthetic approach towards heteroleptic triple-decker crown-phthalocyaninato complexes $[(15C5)_4Pc]$-M$[(15C5)_4Pc]$M(Pc) and (Pc)M$[(15C5)_4Pc]$M(Pc) [where $(15C5)_4Pc^{2-}$ = 2,3,9,10,16,17,24,25-tetrakis(15-crown-5)-phthalocyaninato dianion; $Pc^{2-}$ = phthalocyaninato dianion; M = Sm, Tb, Dy, Tm and Y] has been developed. It utilises the application of diphthalocyaninatolanthanum, $La(Pc)_2$, as a new source of the phthalocyaninato dianion instead of well known $Li_2(Pc)$. In contrast to the highly hygroscopic $Li_2(Pc)$, $La(Pc)_2$ is quite air-stable and its use allowed a significant decrease in reaction times. All the synthesised complexes were characterised by UV/Vis and $^1H$ NMR spectroscopy as well as MALDI TOF mass spectrometry. The X-ray structure of heteroleptic triple-decker crown-phthalocyaninato (Pc)-Sm$[(15C5)_4Pc]$Sm(Pc) was determined. These new heteroleptic phthalocyaninato complexes are interesting because of their potential as components in new supramolecular materials.

## Introduction

The development of novel supramolecular devices requires both an understanding of the supramolecular interactions between individual molecules and also the possibility of tuning the structure of the supramolecular aggregates which determine the device performance.[1]

Tetrapyrrolic macrocycles (porphyrins, phthalocyanines, etc.) exhibit highly delocalised π electron systems and are thus prominent components of novel supramolecular materials with unique optical, electrochemical and magnetic properties. When tetrapyrrolic ligands are held in close proximity by metal ions in sandwich-type double- and triple-decker complexes, there exist strong intramolecular π-π interactions between macrocycles which results in the characteristic features of this class of compound. These interactions depend both on the nature of the ligand and the metal ion and can be tuned by the synthesis of heteroleptic and heteronuclear complexes.[2]

The intermolecular stacking π-π interactions are the main driving force of the formation of supramolecular assemblies by tetrapyrrolic compounds.[3a] The introduction of functional groups into the periphery of the macrocycles provides an opportunity for obtaining supramolecules of various architectures based on ionic interactions,[3b] hydrogen bonds[3c] etc. The introduction of crown-ether substituents enables the formation of supramolecular assemblies by the addition of alkali metal ions. In the case of the double-decker lutetium crown-phthalocyaninato $Lu[(15C5)_4Pc]_2^0$, the formation of a 1D oligomeric supramolecular aggregate $\{Lu[(15C5)_4Pc]_2 \cdot 4K^+\}_n$, $M_w = 8.1 \times 10^5$ g mol$^{-1}$, was identified by UV/Vis studies,[4a] light scattering measurements[4b] and atom force microscopy.[4c]

The heteroleptic double-decker 15-crown-5-phthalocyaninato complexes $[(15C5)_4Pc]$M(Pc) were synthesised previously for studying the intermolecular interactions between double-decker complexes.[5] The raise-by-one-story method was applied in the cases of the Sm, Dy and Tm complexes, whereas for the La complex a new synthetic approach was developed. This was based on the synthesis of the intermediate heteroleptic triple-decker complex $[(15C5)_4Pc]$La(Pc)-La(Pc) by means of the interaction between $H_2[(15C5)_4Pc]$, $La(Pc)_2$ and $La(acac)_3 \cdot nH_2O$. It was shown that $[(15C5)_4Pc]$-La(Pc)La(Pc) undergoes decomposition with the formation of the heteroleptic double-decker complex $[(15C5)_4Pc]$-La(Pc) due to the low stability of triple-decker lanthanum complexes.[6]

The formation of the intermediate heteroleptic heteronuclear triple-decker complexes $[(15C5)_4Pc]M(Pc)La(Pc)$ was assumed to occur as a result of the reaction between $H_2[(15C5)_4Pc]$, $La(Pc)_2$ and acetylacetonato complexes of the other lanthanides. Unexpectedly, there were isolated two types of heteroleptic homonuclear triple-decker phthalocyaninato species. Thus, we herein report the novel synthetic approach towards heteroleptic triple-decker phthalocyaninato compounds which enabled us to obtain, at first, (Pc)M[(15C5)$_4$Pc]M(Pc) and [(15C5)$_4$Pc]M[(15C5)$_4$Pc]M(Pc).

It was previously demonstrated that amphiphilic heteroleptic triple-decker complexes [(15C5)$_4$Pc]M[(15C5)$_4$Pc]M[$(C_8H_{17}O)_8$Pc] [M = Eu, Ho, Lu] form Langmuir–Blogett films which can been fabricated into field-effect transistor devices with almost the highest carrier mobilities achieved thus far for all LB film-based organic field-effect transistors.[7a] The mixed ligand triple-decker complex [(15C5)$_4$Pc]Eu[(15C5)$_4$Pc]Eu(TPP) forms well-ordered monolayers on an Au(111) surface. The molecular orientation of the complex is reversed during the electrochemical redox reaction.[7b] Thus, we suppose, that the heteroleptic tris(phthalocyaninato) complexes reported herein could be important components of new supramolecular materials.

## Results and Discussion

### Synthesis of (Pc)M[(15C5)$_4$Pc]M(Pc) and [(15C5)$_4$Pc]M-[(15C5)$_4$Pc]M(Pc)

We performed the reactions between $H_2[(15C5)_4Pc]$, $La(Pc)_2$ and $M(acac)_3{\cdot}H_2O$ [M = Sm, Tb, Dy, Tm and Y] in 1-chloronaphthalene at reflux. It was expected that the intermediate heteroleptic heteronuclear complex [(15C5)$_4$Pc]M(Pc)La(Pc) would eliminate the $La(Pc)^+$ fragment with the formation of the target heteroleptic double-decker complexes. Indeed, chromatographic separation of the reaction mixture afforded the corresponding [(15C5)$_4$Pc]M(Pc) complex although the yield was low (<5%). Unexpectedly, the major products were heteroleptic homonuclear triple-decker complexes, viz. (Pc)M[(15C5)$_4$Pc]M(Pc) and [(15C5)$_4$Pc]-M[(15C5)$_4$Pc]M(Pc) which contained no lanthanum ions (Scheme 1). The progress of the reaction was monitored by UV/Vis spectroscopy. The bands of the initial material $La(Pc)_2$ disappeared immediately after the reaction mixture started to reach reflux and the band of intermediate monophthalocyaninato species was observed. We suppose that the decomposition of $La(Pc)_2$ with the formation of the $Pc^{2-}$ species may occur under the synthetic conditions used. $Pc^{2-}$ reacts with metal acetylacetonato complexes and $H_2[(15C5)_4Pc]$ with the formation of heteroleptic triple-decker complexes. Free lanthanum ions remain in solution and do not participate in subsequent reactions as was demonstrated by MALDI TOF mass spectrometry. The reaction time decreased from 1 h in the case of M = Tm and Y to 30 min for Tb and Dy and to 10 min for Sm. The complexes (Pc)M[(15C5)$_4$Pc]M(Pc) form with lower yield for M = Y and Tm (10–12%) in comparison with M = Sm, Tb and Dy (19–25%). The yields of the [(15C5)$_4$Pc]M[(15C5)$_4$-Pc]M(Pc) complexes do not significantly change with a decrease in the ionic radii (39–46%) (Table 1). Previously, the related heteroleptic triple-decker complexes (Pc)M-[$(C_8H_{17}O)_8$Pc]M(Pc) and [$(C_8H_{17}O)_8$Pc]M[$(C_8H_{17}O)_8$Pc]M-(Pc) were prepared using a wide range of metals.[8] Phthalocyaninatodilithium $Li_2(Pc)$ was used as a soluble donor of $Pc^{2-}$ and the reactions were carried out over more than 12 h. The authors carried out the reaction between $M[(C_8H_{17}O)_8Pc]_2$ and (Pc)M(acac) which was generated in situ from $Li_2Pc$ and $M(acac)_3{\cdot}nH_2O$.

The partial decomposition of sandwich complexes under the synthetic conditions and the formation of scrambling products are common in the preparation of heteroleptic compounds. Previously[8] it was demonstrated that in the synthesis of [$(C_8H_{17}O)_8$Pc]M[$(C_8H_{17}O)_8$Pc]M(Pc), the formation of the scrambling product (Pc)M[$(C_8H_{17}O)_8$Pc]-M(Pc) occurs due to decomposition of the starting double-decker complex $M[(C_8H_{17}O)_8Pc]_2$. The contraction of the rare-earth element (REE) ion along the investigated series of elements leads to an increase of the target compound yield and a decrease in the formation of side products.

Lanthanum has the biggest covalent radius in the series of REEs and so its complexes are less stable than those of middle and late REEs. Unsubstituted diphthalocyaninato-

[a] Average *m/z* are given. [b] $[M]^+$ calculated for $C_{128}H_{104}M_2N_{24}O_{20}$. [c] $[M]^+$ calculated for $C_{160}H_{160}N_{24}O_{40}M_2$.

lanthanum should be even less stable towards the decomposition process than M[$(C_8H_{17}O)_8$Pc]$_2$ [M = Pr–Tm] and liberate $Pc^{2-}$ under the synthetic conditions utilised. Comparative studies of the chemical behaviour of other M(Pc)$_2$ complexes in this reaction will be reported elsewhere.

The low stability of some early lanthanide sandwich phthalocyaninato complexes, which has been mentioned previously,[9] makes them prospective donors of phthalocyaninato-dianions for the synthesis of more stable complexes. However, this feature has never been utilised for the synthesis of sandwich complexes with other metals by means of the metal exchange reaction. This reaction is comparatively rarely applied in the chemistry of tetrapyrrolic compounds in contrast to reactions of direct metallation and template synthesis. The above mentioned phthalocyaninatolithium was also used for the synthesis of REE monophthalocyaninato complexes.[10] Magnesium complexes can be transmetallated in acidic media[11] and cadmium ions in porphyrin complexes can be exchanged by cobalt or zinc ions in polar solvents.[12] However, REE exchange was never reported previously. Thus, the reaction described herein is also interesting in relation to the development of the coordination chemistry of tetrapyrrolic compounds.

Thus, we have proposed the alternative $Pc^{2-}$ donor – diphthalocyaninatolanthanum La(Pc)$_2$ – for the synthesis of heteroleptic triple-decker complexes. In contrast to highly hygroscopic Li$_2$(Pc), La(Pc)$_2$ is quite air-stable and its application allowed us to significantly decrease the reaction times in comparison with the synthesis of the related heteroleptic trisphthalocyaninato complexes (Pc)M[$(C_8H_{17}O)_8$Pc]M(Pc) and [$(C_8H_{17}O)_8$Pc]M[$(C_8H_{17}O)_8$Pc]M(Pc).[8]

## Spectroscopic Characterisation

All the synthesised heteroleptic complexes were isolated by column chromatography on neutral alumina using gradient elution with CHCl$_3$/MeOH mixtures and were subsequently characterised by various physical and chemical methods.

No elemental analyses were performed because the complexes undergo sublimation under the experimental conditions without complete decomposition and combustion.

Moreover, crown-ethers can contain solvent molecules which can affect the results of elemental analyses. However, these new complexes gave satisfactory MALDI-TOF mass spectra (Table 1) and the observed average *m*/*z* values and isotopic distribution patterns are in good agreement with simulated spectra. It should be pointed out that in the MALDI TOF mass spectra there were no peaks observed which could correspond to the lanthanum complexes.

The position and the shape of the Q-band in the UV/Vis spectra are mainly determined by the metal ion. It hypsochromically shifts and splits into two components upon a decrease in the metal ion's radius. It is noteworthy that the shape of the Soret band is lanthanide independent and is determined by the number and position of the crown-ether substituents (Table 2, Figure 1). The increase of the number of electron-donating crown-ether substituents leads to a bathochromic shift of the Soret band and to an increase in the relative intensity of the N-band at 292 nm.

$^1$H NMR spectra for all the heteroleptic triple-decker complexes were recorded in $CDCl_3$ and the data are collected in Table 3. Hydrazine-hydrate was added to the solutions to suppress their possible partial air oxidation so that well-resolved NMR spectra could be obtained

The positions the of signals are strongly affected by the lanthanide induced shift (LIS) effect[13] in the case of paramagnetic lanthanides. LIS depends both on the lanthanide

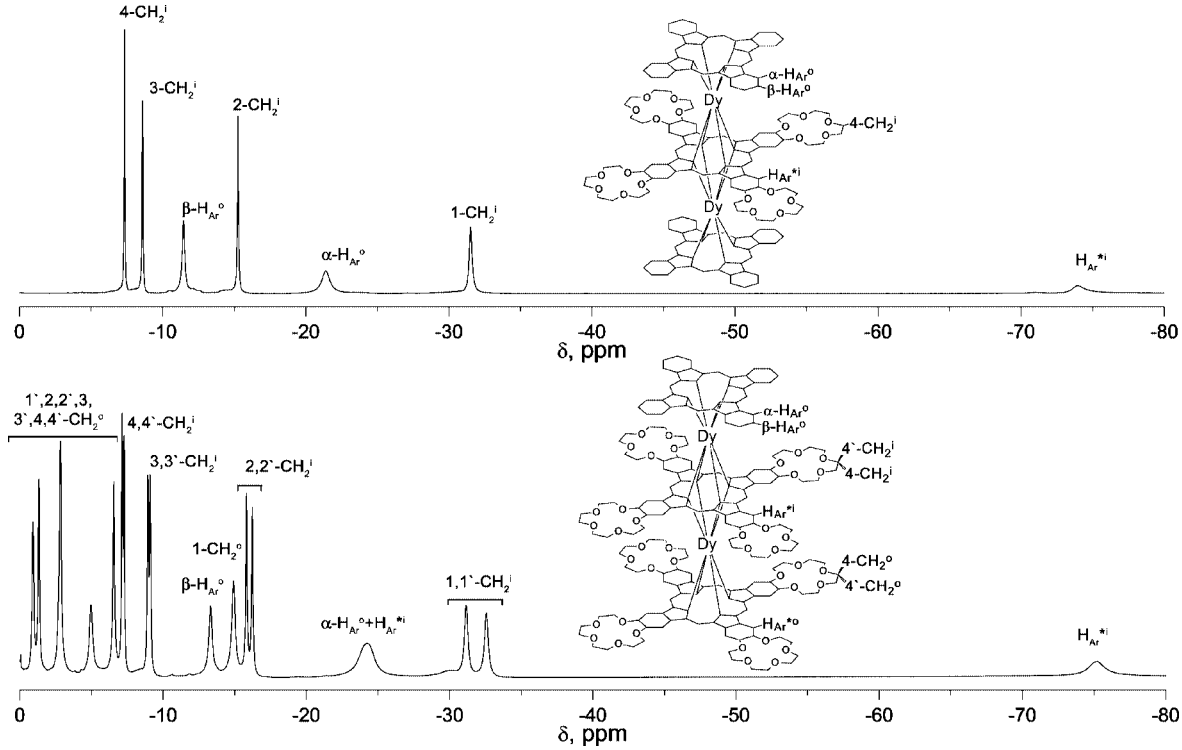

Figure 2. $^1$H NMR spectra of (Pc)Dy[(15C5)$_4$Pc]Dy(Pc) and [(15C5)$_4$Pc]Dy[(15C5)$_4$Pc]Dy(Pc) in $CDCl_3$.

ion and on the orientation of the proton relative to the paramagnetic nuclei. For Dy and Tb complexes, a strong upfield shift can be observed resulting in negative values for the chemical shifts of all resonance signals. Sm causes a slight upfield shift whereas Tm leads to a strong downfield shift of the resonance signals. Because of the paramagnetic broadening, the spin-spin coupling constants cannot be observed in the case of the Tb, Dy and Tm complexes. In the spectra of the Sm and Y complexes the multiplets, which correspond to the resonance signals of the unsubstituted ligands, are well resolved. The attribution of signals can be made using the previously reported assignment of signals in the $^1$H NMR spectra of (Pc)M[($C_8H_{17}O)_8$Pc]M(Pc) and [($C_8H_{17}O)_8$Pc]M[($C_8H_{17}O)_8$Pc]M(Pc).[13a]

In the NMR spectra of (Pc)M[(15C5)$_4$Pc]M(Pc), the resonance signals from the α- and β-aromatic protons of the outer unsubstituted rings (α- and β-$H_{Ar}$º), the aromatic protons of the inner crown-substituted ligands ($H_{Ar}$*$^i$) and the methylene protons of crown-ether macrocycles can be observed. Two protons at each $CH_2$ group are equivalent resulting in four resonance signals (Figure 2).

Along with the resonance signals of α- and β-$H_{Ar}$º and $H_{Ar}$*$^i$ there can also be observed a signal for the aromatic protons of the outer crown-substituted ligand $H_{Ar}$*$^o$ in the NMR spectra of [(15C5)$_4$Pc]M[(15C5)$_4$Pc]M(Pc). Due to lower the symmetry of the molecules, two protons at each methylene-group of the crown-ethers are nonequivalent with respect to the neighbouring ligands (*exo* and *endo*). This significantly complicates the aliphatic region of $^1$H NMR spectra of [(15C5)$_4$Pc]M[(15C5)$_4$Pc]M(Pc) in comparison with (Pc)M[(15C5)$_4$Pc]M(Pc) (Figure 2).

## Structural Studies

The molecular structure of (Pc)Sm[(15C5)$_4$Pc]Sm(Pc) was determined by single-crystal X-ray analysis. Although the structures of some heteroleptic trisphthalocyaninato complexes have been determined previously,[14] no structural data on heteroleptic triple-decker crown-phthalocyaninato complexes have been reported so far. Moreover, to date,[15a] no binuclear samarium phthalocyaninato complexes have been structurally characterised with the exception of ($\eta^2$-dpm)$_4$Sm$_2$(μ-Pc) (dpm = 2,2,6,6-tetramethylheptane-3,5-dionato ion).[15b]

According to the X-ray analysis of (Pc)Sm[(15C5)$_4$Pc]-Sm(Pc), each Sm atom is sandwiched between an outer Pc ring and the inner [(15C5)$_4$Pc] ring giving a symmetrical structure (see Figures 3 and 4). Two Sm atoms are located at a nonbonding Sm···Sm distance of 3.5111(4) Å. They are linked with four nitrogen atoms from the central bridging crown-substituted macrocycle [Sm–N(9) 2.613(3) Å, Sm–N(11) 2.599(3) Å] and each of them is linked with four isoindole nitrogen atoms of the outer Pc ligands [(Sm–N(1) 2.372(3) Å, Sm–N(3) 2.385(3) Å, Sm–N(5) 2.397(3) Å, Sm–N(7) 2.395(3) Å)]. Each metal adopts a distorted square antiprismatic geometry with an average twist angle of 43°. The inequality of the Sm–N distances and the significant decrease in the Sm–$N_{outer}$ distance compared with the Sm–$N_{inner}$ distance is in agreement with the previously reported data for the homoleptic lutetium phthalocyaninato $Lu_2$[Pc(15C5)$_4$]$_3$[16] and the heteroleptic triple-decker complexes (Pc)M[($OC_8H_{17})_8$Pc]M′(Pc)[14a] and [(α-$OC_5H_{11})_4$-Pc]M(Pc)M(Pc)[14b] (Table 4).

Table 4. Comparison of M–$N_{iso}$ for different lanthanide trisphthalocyaninates.

| Complex | M–$N_{outer}$ / Å | M–$N_{inner}$ / Å | Ref. |
|---|---|---|---|
| (Pc)Sm[(15C5)$_4$Pc]Sm(Pc) | 2.372(3)–2.397(3) | 2.599(3)–2.613(3) | present work |
| $Lu_2$[(15C5)$_4$Pc]$_3$ | 2.297(7)–2.323(7) | 2.538(8)–2.587(7) | [16] |
| (Pc)Er[(OC$_8$H$_{17}$)$_8$Pc]Er(Pc) | 2.332 | 2.573 | [14a] |
| (Pc)Lu[(OC$_8$H$_{17}$)$_8$Pc]Lu(Pc) | 2.283 | 2.507 | [14a] |
| (Pc)Er[(OC$_8$H$_{17}$)$_8$Pc]Lu(Pc) | 2.30 | 2.55 | [14a] |
| [(α-OC$_5$H$_{11}$)$_4$Pc]Gd(Pc)Gd(Pc) | 2.364, 2.386 | 2.634, 2.654 | [14b] |
| [(α-OC$_5$H$_{11}$)$_4$Pc]Lu(Pc)Lu(Pc) | 2.297, 2.307 | 2.588 | [14b] |

The Sm···Sm distance of 3.5111(4) Å in (Pc)Sm[(15C5)$_4$Pc]Sm(Pc) is different from the metal–metal separation in the binuclear complex [($\eta^2$-dpm)$_4$Sm$_2$(μ-Pc)] [Sm···Sm 3.627(3) Å].[15] This can be explained both by the nature of the axial ligands and the phthalocyanine bridge. The Sm–$N_{outer}$ distance (2.37–2.39 Å) is close to the Sm–N distance in the double-decker ionic phthalocyaninato complexes [Sm(Pc$^{2-}$)$_2$]$^-$(NBu$_4$)$^+$ (Sm–N 2.452–2.471 Å)[17a] and [Sm(Pc$^{\cdot-}$)$_2$]$^+$Br$^-$ (Sm–N 2.457 Å).[17b] It is also significantly shorter than in [Sm(Pc$^{\cdot-}$)$_2$]$^+$(ClO$_4$)$^-$ (Sm–N 2.607 Å).[17b] It is noteworthy that eight solvated $CHCl_3$ molecules are present in the crystallographic cell. The hydrogen atoms of 6 molecules form very weak contacts with the oxygen atoms of the crown-ether substituents, notwithstanding affecting their conformation [H(1SA)···O(8),O(9) 2.66 Å, H(2SA)···O(1) 2.59 Å, H(2SA)···O(5) 2.22 Å, H(4SA)··· O(7) 2.14 Å]. The molecules adopt a brick wall type packing arrangement.

## Conclusions

A simple methodology for preparing a series of heteroleptic crown-substituted REE(III) triple-decker phthalocyaninato complexes (Pc)M[(15C5)$_4$Pc]M(Pc) and [(15C5)$_4$Pc]M[(15C5)$_4$Pc]M(Pc) [M = Sm, Tb, Dy, Tm and Y] has been developed. This method involves the application of the diphthalocyaninatolanthanum La(Pc)$_2$ as a new Pc$^{2-}$ donor species. The advantages of this method are that it results in the complexes being formed in high yield under mild conditions and a significant decrease in the reaction times. All the complexes were fully characterised by MALDI TOF mass spectrometry as well as UV/Vis and $^1$H NMR spectroscopy. The molecular structure of (Pc)Sm[(15C5)$_4$Pc]Sm(Pc) was also determined and it represents the first structure reported for a heteroleptic triple-decker crown-phthalocyaninato complex.

## Experimental Section

The compounds H$_2$[(15C5)$_4$Pc],[18a] La(Pc)$_2$[5] and M(acac)$_3$·H$_2$O[18b] were prepared according to published procedures. 1-Chloronaphthalene was used as received (1-ClN, Acros Organics). Chloroform was dried with anhydrous $CaCl_2$ followed by distillation over $CaH_2$. Methanol was dried with 4 Å molecular sieves. Column chromatography was carried out on neutral alumina (Merck, 0.063–0.200 mm, activity II–III according to Brockmann).

The electronic (UV/Vis) spectra were recorded on a Cary-100 spectrophotometer (Varian) in $CHCl_3$ in quartz cells (1–10 mm). MALDI-TOF mass spectra were recorded on an Ultraflex mass spectrometer (Bruker Daltonics) with nicotinic acid as a matrix. Sonication was performed in an ElmasonicS70H ultrasonic bath (Elma) at 37 kHz. $^1$H NMR spectra were recorded on Bruker Avance-400 spectrometer (400 MHz) in $CDCl_3$ solution in the presence of 10 μL of a 1% solution of $N_2H_4$·$H_2O$ in [D$_6$]DMSO. Chemical shifts, $\delta$ values, are reported in ppm relative to the internal standard (residual $CHCl_3$, $\delta$ = 7.25 ppm) at $T$ = 298 K.

**Preparation of Heteroleptic Triple-Decker Complexes:** A mixture of La(Pc)$_2^0$ (15.0 mg, 12 μmol), H$_2$[(15C5)$_4$Pc] (16.4 mg, 12 μmol) and M(acac)$_3$·$H_2O$ (36 μmol) (M = Sm, Tb, Dy, Tm, Y) was dissolved in 1-ClN (4 mL) with sonication and heated to reflux until no further changes in the UV/Vis spectrum of the reaction mixture were observed. The resultant blue solution was subsequently cooled. The reaction mixture treated with hexane to bring about precipitation and was then filtered. The precipitate was dissolved in $CHCl_3$ and chromatographed on neutral alumina. $CHCl_3$ was used to remove M(Pc)$_2^{0\cdot}$ and M$_2$(Pc)$_3$. The complexes (Pc)M[(15C5)$_4$Pc]M(Pc) were eluted with a mixture of $CHCl_3$ and 0.75 vol.-% MeOH. The complexes [(15C5)$_4$Pc)M[(15C5)$_4$Pc]M(Pc) were eluted with a mixture of $CHCl_3$ and 1.25 vol.-% MeOH. The physical and chemical data and yields for all the complexes are summarised in Tables 1, 2 and 3.

**X-Ray Crystallographic Analysis of (Pc)M[(15C5)$_4$Pc]M(Pc):** Single crystals of (Pc)M[(15C5)$_4$Pc]M(Pc)·8$CHCl_3$ were grown by slow diffusion of heptane into a chloroform solution of the complex. The crystals ($C_{136}H_{112}Cl_{24}N_{24}O_{20}Sm_2$, $M$ = 3554.00, crystal size 0.07 × 0.08 × 0.40 mm) are triclinic, space group $P\bar{1}$, $a$ = 13.2279(9), $b$ = 15.5561(11), $c$ = 19.0738(14) Å, $\alpha$ = 69.145(1), $\beta$ = 74.402(1), $\gamma$ = 89.489(2)°, $V$ = 3516.2(4) Å$^3$, $Z$ = 1, $\rho_{calcd.}$ = 1.678 g cm$^{-3}$, $\mu$(Mo-$K_\alpha$) = 13.60 cm$^{-1}$. The intensities of 39384 reflections (16902 independent reflections, $R_{int}$ = 0.0616) were measured on a Bruker SMART APEX II diffractometer (graphite monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, $\omega$-scan technique, $2\theta_{max}$ = 56°, $T$ = 100 K). The APEX II software[19] was used for collecting frames of data, indexing reflections, determination of lattice constants, integration of intensities of reflections, scaling and absorption correction ($T_{min}/T_{max}$ = 0.707/0.911) and SHELXTL[20] was used for space group and structure determination, refinements, graphics and structure reporting. The structure was solved by direct methods and refined by the full-matrix least-squares technique against $F^2$ with the anisotropic temperature factors for all non-hydrogen atoms. All hydrogen atoms were placed geometrically and included in the structure factor calculations in the riding motion approximation. The refinement converged to $wR_2$ = 0.1085 and a $GOF$ = 0.994 for all independent reflections [$R_1$ = 0.0463 was calculated against $F$ for 12032 observed reflections with $I > 2\sigma(I)$], 936 refined parameters.

CCDC-641195 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# A Tris-Cyclometalated Iridium(III) Complex of 2-(5,5-Dioxido-dibenzothiophen-3-yl)pyridine: Synthesis, Structural, Redox and Photophysical Properties

**Mustafa Tavasli,[a] Sylvia Bettington,[a] Igor F. Perepichka,[a,b] Andrei S. Batsanov,[a] Martin R. Bryce,*[a] Carsten Rothe,[c] and Andrew P. Monkman[c]**

**Keywords:** Dibenzothiophene *S*,*S*-dioxide / Iridium / Cyclometalation / Luminescence / Electrochemistry

The first cyclometalated dibenzothiophene *S*,*S*-dioxide derivative, namely [*fac*-2-(5,5-dioxidodibenzothiophen-3-yl)-pyridine]iridium(III) (**3**) has been synthesised in high yield and characterised by X-ray crystallography, solution electrochemistry, absorption and emission spectroscopy. The Ir atom has a *fac*-octahedral coordination with three chelating ligands (*A, B* and *C*); each Ir–N bond is in *trans* position to an Ir–C bond. In cyclic voltammetry experiments in dichloromethane, complex **3** undergoes a reversible metal-centred $Ir^{III}/Ir^{IV}$ oxidation at $E_{1/2}^{ox}$ = +1.04 V vs. $Ag/Ag^+$ reference electrode. Complex **3** exhibits bright green photoluminescence ($\lambda_{max}$ = 525 nm in toluene) from mixed $^3MLCT/^3\pi\rightarrow\pi^*$ states with quantum yield ($\Phi_{PL}$) of 0.26 in toluene solution. The phosphorescence emission decay follows first order kinetics, with a lifetime of 4.9 μs. A comparison of complex **3** with analogues **1** and **2**, where the dibenzothiophene *S*,*S*-dioxide unit is replaced by 9,9-dihexylfluorene and *N*-hexylcarbazole respectively, establish that the substituent *para* to the Ir metal atom, i.e. $CR_2$ in **1**, NR in **2** and $SO_2$ in **3**, has a major influence on the redox and emission properties in this series. Organic light-emitting diodes (OLEDs) were fabricated by spin-coating techniques using a polyspirobifluorene copolymer (PSBF) as a host and complex **3** as dopant. In a single-layer blend configuration ITO/PEDOT:PSS/PSBF:**3**(8 wt.-%)/Ba/Al OLEDs showed pale blue/white light emission (CIE coordinates: x = 0.29, y = 0.31) arising from a combination of fluorescence from the host copolymer ($\lambda_{max}$ = 450 nm) and phosphorescence from **3** ($\lambda_{max}$ = 530 nm).

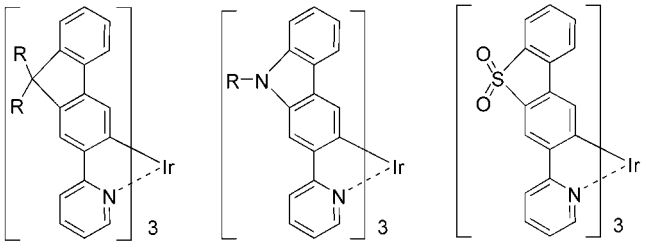
## Introduction

Since Baldo et al.[1] first reported an organic light-emitting diode (OLED) with *fac*-tris(2-phenylpyridine)iridium [$Ir(ppy)_3$] as an emitting guest in a blend with a host material, a variety of transition metal–ligand complexes have been studied from the viewpoint of their fundamental photophysical properties and for their optoelectronic applications. Mixing of the electrogenerated singlet and triplet excited states by intersystem crossing removes the spin-forbidden nature of the radiative relaxation of the triplet excited state so singlet and triplet excited states both contribute to light emission. Additionally, the triplet-state lifetime is shortened, thereby suppressing triplet–triplet annihilation. Particular emphasis has been placed on tris-cyclometalated *CN* iridium(III) complexes with their emission colours spanning the blue, green and red regions.[2–5] Colour tuning in these complexes is achieved either by the peripheral functionalisation[2,3] of the parent 2-phenylpyridine with electron-withdrawing/donating substituents, or through variation of the cyclometalating ligands.[2,4] With regard to the latter, 2-(9,9-dialkylfluoren-2-yl)pyridine-based iridium(III) complexes **1** (alkyl = *n*-hexyl[6,7] or methyl[8]) and 2-(*N*-alkylcarbazol-2-yl)pyridine-based iridium(III) complexes **2** (alkyl = hexyl[9] or ethyl[10]) have been explored by us and others.



**1** **2** **3**

We were interested in incorporating a new unit, namely dibenzothiophene *S*,*S*-dioxide (DBThD), into the ligands of cyclometalated complexes. This moiety is of current interest in the field as linearly-conjugated co-oligomers and

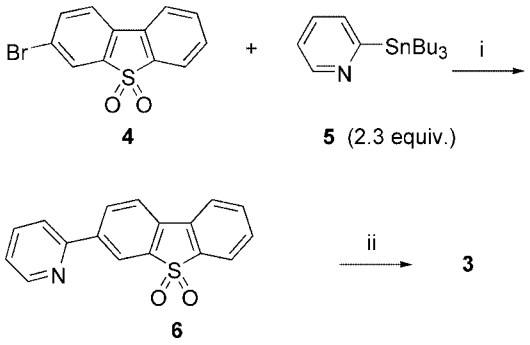
copolymers incorporating DBThD and 9,9-dialkylfluorene units are bright blue emitters in OLEDs, with the DBThD units imparting high stability, high fluorescence quantum yields and increased electron-transporting properties.[11,12] Other small-molecule DBThD derivatives have been used as an efficient electron-transporting layer (not the emitter) in OLEDs.[13]

We now report the synthesis of the first cyclometalated DBThD derivative, namely the *fac*-2-(5,5-dioxidodibenzothiophen-3-yl)pyridine iridium(III) complex (**3**), along with its structural, electrochemical and photophysical properties. Complex **3** is an analogue of complexes **1** and **2**, from which it differs in terms of the bridging group being $SO_2$, instead of $CR_2$ in **1** or NR in **2** . These complexes constitute an interesting series for comparative redox and photophysical studies.

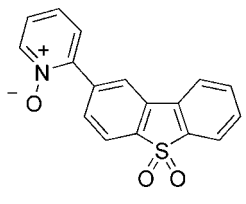
## Results and Discussion

### Synthesis

Ligand **6** was readily prepared by Stille[14] reaction of 3-bromodibenzothiophene *S*,*S*-dioxide **4**[15] with commercially available 2-tris(*n*-butyl)stannylpyridine (**5**)[16] in moderate yield (58%). An excess of ligand **6** was then treated with $Ir(acac)_3$ in glycerol at 220 °C[17] to give the *fac*-tris-cyclometalated iridium(III) complex **3** in 82% yield. The TGA analysis showed that complex **3** exhibits good thermal stability with a very high $T_d$ value of 490 °C (estimated at 5% weight loss temperature), which is ca. 75–100 °C higher than for complexes **1** and **2** and for $Ir(ppy)_3$.[8] The synthesis and X-ray molecular structure of the related 2-(5,5-dioxidodibenzothiophen-2-yl)pyridine *N*-oxide (**7**) is given in the Supporting Information (see footnote on the first page of this article). This compound was prepared during unsuccessful attempts to obtain an isomer of complex **3** (Scheme 1).



Scheme 1. Reagents and conditions: i) $Pd(PPh_3)_2Cl_2$ (13% equiv.), toluene, 110 °C, 48 h (58% yield); ii) $Ir(acac)_3$, glycerol, 220 °C, 48 h (82% yield).



### X-ray Crystal Structures of Iridium Complex 3 and Its Precursor Ligand 6

Crystallisation of **3** from $CH_2Cl_2$/MeOH yielded three pseudo-polymorphs, containing different (non-stoichiometric) amounts of disordered solvents, of which the triclinic form **3a** gave the most precise structure (Figure 1). The asymmetric unit comprises one molecule of **3** and an intermolecular void of ca. 80 Å$^3$ shared by a DCM molecule and a methanol molecule (modeled with occupancies 0.2 and 0.8, respectively), the latter hydrogen-bonded to a sulfone group. The Ir atom has a *fac*-octahedral coordination with three chelating ligands (*A, B* and *C*); each Ir–N bond is in a *trans* position to an Ir–C bond. Lengths of these bonds (Table 1) agree with X-ray studies of *fac*-$Ir(ppy)_3$[1b] and its derivatives.[6,18,19] The X-ray crystal structure of the free ligand **6** (Figure 2) revealed a practically planar molecule (except for the two oxygen atoms) with *cis* disposition of the N atom and the sulfone group. Upon coordination in complex **3**, the pyridine substituent adopts the opposite (*trans*) orientation, although the ligands are not entirely planar, as indicated by the dihedral angles between the pyridine ring and the two benzene rings (Table 1). Interestingly,

the looser is the molecular packing in a pseudo-polymorph of **3** (see the Experimental Section) the more planar are the ligands.

## Solution Electrochemical Properties

The cyclic voltammogram (CV) of complex **3** in dichloromethane displayed a reversible one-electron oxidation wave at $E_{1/2}^{ox}$ = +1.04 V vs. $Ag/Ag^+$ reference (internal $Fc/Fc^+$ reference gave +0.28 V vs. $Ag/Ag^+$ in these conditions). DFT calculations predict that dibenzothiophene *S*,*S*-dioxide has a LUMO energy level of 1.04 eV lower than that of 9,9-dialkylfluorene[11] and the substantial increase in oxidation potential of **3**, compared to complexes **1** and **2** ($E_{1/2}^{ox}$ = +0.40 V[7] and + 0.14 V,[9] respectively), indicates that the bridging $SO_2$ group has dramatically reduced the electron density on the iridium centre. On the contrary, the carbazole nitrogen of **2** donates electron density to the Ir centre and hence the ease of oxidation in the series is **2** > **1** > **3**. Generally, oxidation processes which involve an Ir–aryl moiety are considered as a metal-centered couple,[20] i.e. $Ir^{III}/Ir^{IV+}$ in the present series. Similar to complexes **1** and **2**, complex **3** shows good chemical and electrochemical reversibility in CV experiments. The half-wave oxidation potentials ($E_{1/2}^{ox}$) of the complexes **1**, **2** and **3** and ferrocene are summarised in Table 2; CV traces are shown in Figure 3.

Table 2. Summary of the half-wave oxidation potentials ($E_{1/2}^{ox}$/V) obtained by cyclic voltammetry for complexes **1**, **2** and **3** and ferrocene (Fc) vs. $Ag/Ag^+$ reference electrode.[a]

## Solution-State Photophysical Properties

### *Absorption*

The absorption spectrum of complex **3** in toluene solution is shown in Figure 4. Ligand **6** showed no absorption at all in the region of $\lambda$ = 360 to 600 nm; for complex **3** the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 3. Absorption and emission spectra data for complexes **1**, **2**, and **3**, and ligand **6** in toluene.

| Compound | Absorption, $\lambda_{max}$ (nm) [$\varepsilon$ (L mol$^{-1}$ cm$^{-1}$)] | Emission, $\lambda_{max}$ (nm) |
|---|---|---|
| **1** | 335 [55000], 350 [51000], 368 [48500], 445 [13500] | 546, 583 |
| **2** | 313 sh [85000], 324 [111000], 340 [91000], 402 [26000], 448 [10500], 475 sh [6700] | 587, 640 sh |
| **3** | 300.5 [97500], 316 [98000], 331 sh [60000], 385 [19500], 434 [7500], 455 sh [4500] | 525, 567, 610 sh |
| **6** | 313 [43500], 330 sh [20000] | |

strong peaks below 360 nm are therefore assigned to spin-allowed ligand-centered $^1\pi$–$\pi^*$ transitions, whereas the less intense absorption features seen above 360 nm are attributed to the metal-to-ligand charge-transfer (MLCT) transitions. As evident from their relative extinction coefficients, the absorption bands seen at around 385 nm and 450 nm are assigned to spin-allowed $^1$MLCT ($\lambda$ = 385 nm, $\varepsilon$ = 19500 M$^{-1}$ cm$^{-1}$) and spin-orbit coupling enhanced mixed $^3$MLCT-$^3$LC ($\lambda$ = 455 sh nm, $\varepsilon \approx$ 4500 M$^{-1}$ cm$^{-1}$) transitions, respectively (Table 3). The whole spectrum of **3** is blue shifted compared to analogous fluorene and carbazole complexes **1**[7] and **2**,[9] indicating that the bridging $SO_2$ group lowers the highest occupied molecular orbital (HOMO) energy level by withdrawing electrons from the system. These assignments were made on the basis of the literature data reported for other iridium complexes.[21]

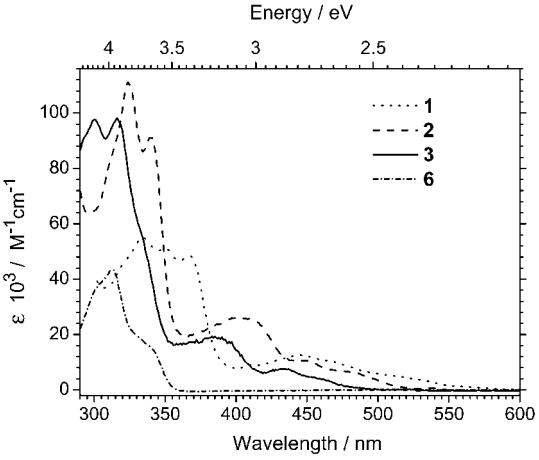

Figure 4. The absorption spectra of ligand **6** and its complex **3** in toluene at room temperature. Spectra of analogous complexes **1** and **2** have also been shown for comparison.

### *Emission*

The photoluminescence (PL) spectrum of complex **3** obtained from degassed solutions in toluene (excitation at 400 nm) is shown in Figure 5, along with comparative spectra for **1** and **2**. The PL of complex **3** is characterised by a structured spectrum with two emission peaks around $\lambda$ = 525 and 567 nm (vibronic progression of 1410 cm$^{-1}$) with a shoulder around $\lambda$ = 610 nm (Table 3). The highest energy emission peak is blue-shifted by ca. 21 nm and 62 nm from those of the complexes **1** ($\lambda_{em}$ = 546 nm)[7] and **2** ($\lambda_{em}$ = 587 nm),[9] respectively. The blue-shift in **3** is again attributed to the presence of $SO_2$ group, which increases the HOMO–LUMO energy gap by withdrawing electrons from the iridium centre. The emission intensities, upon degassing, increased without any change in the spectral profiles. Its sensitivity towards oxygen and long lifetime observed in the microsecond (4.9 μs) region both suggest that the emitting state has a triplet character.[22] The well-resolved vibronic structure, a large Stokes' shift (difference between the $^3$MLCT absorption and emission bands) and longer lifetime indicates that complex **3** emits from mixed $^3$MLCT/$^3\pi\rightarrow\pi^*$ states, with a substantial $^3\pi\rightarrow\pi^*$ contribution to the emitting states.[23]

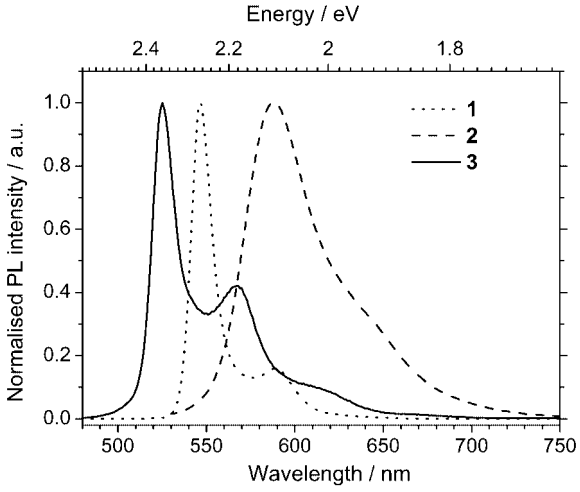

Figure 5. Photoluminesence (PL) spectra for complex **3** (PL of analogous complexes **1** and **2** are also shown) in degassed toluene at room temperature, $\lambda_{ex}$ = 400 nm.

### Phosphorescence Lifetimes and Photoluminescence Quantum Yields

Time-resolved luminescence decay measurements for the complex **3** (OD < 0.1 at $\lambda_{ex}$ = 355 nm) were performed at 298 K in degassed toluene. The emission was collected at $\lambda_{max}$ and the phosphorescence decay was found to follow first order kinetics, with a lifetime ($\tau_p$) of 4.9 μs. This lifetime is comparable with the values for **1** (2.8 μs)[7] and **2** (3.2 μs).[9] The phosphorescent quantum yield ($\Phi_{PL}$) of **3** is 0.26, measured at 298 K in thoroughly degassed toluene solution using Ir(ppy)$_3$ ($\lambda_{ex}$ = 450 nm, $\Phi_{PL}$ = 0.40 in toluene)[8,19] as the standard. This value is comparable with those for **1** ($\Phi_{PL}$ = 0.24)[7] and **2** ($\Phi_{PL}$ = 0.28).[9]

### Organic Light Emitting Devices

Preliminary studies of OLEDs have been performed for single-layer devices with spin-coated PSBF:**3** layer, in the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

following configuration: ITO/PEDOT:PSS/PSBF:**3**(8 wt.-%)/Ba/Al (PSBF is the host polyspirobifluorene copolymer; full details are given in the Supporting Information). Turn-on voltages were ca. 3 V. At driving voltages of 5–10 V, the diodes emit a pale blue/white light (CIE coordinates: $x$ = 0.29, $y$ = 0.31); the electroluminescence (EL) spectrum (Figure 6) demonstrates emission both from the host PSBF polymer around $\lambda_{max}$ = 450 nm and the characteristic emission of guest emitter (complex **3**) peaking at $\lambda_{max}$ = 530 nm. The latter phosphorescence is very similar in spectral shape to the emission spectrum of **3** in dilute solution (Figure 5) but is red shifted by ca. 5 nm in the devices. At ca. $0.9 \times 10^6$ V cm$^{-1}$ the light output of the device reached a maximum of 300 cd/m$^2$, which however, is accompanied by large currents, reducing the luminance efficiency to $< 1$ cd/A. Thus, both the luminance and the luminance efficiency are lower than complexes **1** (25000 cd/m$^2$ and 7.0 cd/A)[7] and **2** (4500 cd/m$^2$ and 1.7 cd/A).[9] The reason for this reduced performance of **3** is likely to be a combination of unbalanced charge injection and the inefficient excitation confinement at the guest emitter. Considering the latter, the triplet energies of both guest and host are of order of 2.3 eV.[24] Also, complex **3** has a high oxidation potential (HOMO level) compared to the other, better performing, complexes. Considering this, the holes may be less confined at the guest sites, implying that charge carrier recombination takes place at the host rather than the guest. This also explains the significant contribution of the host to the emission of the diode even at very low driving voltages. After exceeding ca. 0.9 V/cm the diode emission irreversibly changes from pale blue to orange with most of the host fluorescence now being quenched (Figure 6). At the same time, the guest emission becomes significantly broader and shifts to slightly lower energies. These simultaneous spectral changes indicate the formation of a new radiative site between guest emitter and host polymer.

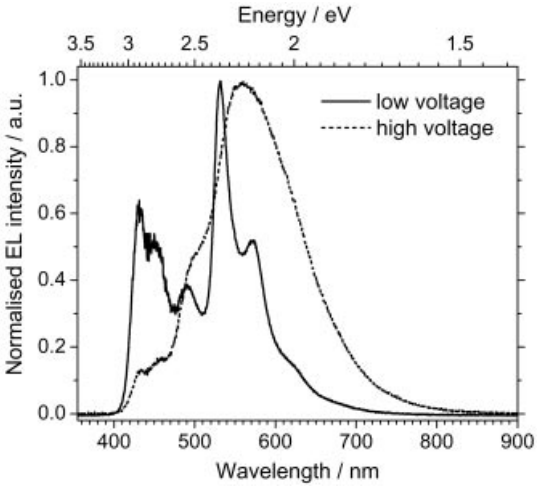

Figure 6. Electroluminescence (EL) spectrum of complex **3**, blended into polyspirobifluorene copolymer host. Device structure: ITO/PEDOT:PSS/PSBF:**3**(8 wt.-%)/Ba/Al. The spectra were taken at low (5 V) and high (15 V) applied voltage.

## Conclusions

The first cyclometalated dibenzothiophene *S*,*S*-dioxide derivative, namely *fac*-2-(5,5-dioxidodibenzothiophen-3-yl)-pyridine iridium(III) **3** has been synthesised in high yield. The structure of the homoleptic $C\widehat{N}$ $Ir^{III}$ complex **3** has been confirmed by X-ray crystallography. The complex exhibits good thermal stability with a very high $T_d$ value of 490 °C. The electron-withdrawing DBThD unit, with its $SO_2$ unit *para* to the Ir centre, significantly raises the oxidation potential of complex **3** ($Ir^{III}/Ir^{IV}$ transition; $E_{1/2}^{ox}$ = +1.04 V vs. $Ag/Ag^+$ reference) compared to the fluorene (**1**) and carbazole (**2**) analogs (+0.40 V and +0.14 V, respectively). Complex **3** displays green photoluminescence ($\lambda_{max}$ = 525 nm) attributed to mixed $^3$MLCT/$^3\pi\rightarrow\pi^*$ states, which is blue shifted compared to fluorene and carbazole complexes **1** and **2**. The phosphorescent quantum yield of **3** is $\Phi_{PL}$ = 0.26 in toluene solution; the decay followed first order kinetics, with a lifetime of 4.9 μs. Single-layer organic light-emitting diodes (OLEDs) were fabricated from a blend of complex **3** as a guest and polyspirobifluorene copolymer as a host demonstrated pale blue/white light emission (CIE coordinates: $x$ = 0.29, $y$ = 0.31) arising from a combination of fluorescence from the host copolymer ($\lambda_{max}$ = 450 nm) and phosphorescence from **3** ($\lambda_{max}$ = 530 nm). Future work will involve variations on the chemical structure of the 2-(5,5-dioxidodibenzothiophen-3-yl)pyridine ligand to form new homoleptic and heteroleptic complexes, with the aim of tuning their photophysical properties, probing deeper into the fundamental properties of this fascinating class of materials and exploiting them as emitters in electrophosphorescent devices.

## Experimental Section

**2-(5,5-Dioxidodibenzothiophen-3-yl)pyridine (6):** A mixture of 3-bromodibenzothiophene *S*,*S*-dioxide (**4**, 0.70 g, 2.73 mmol), LiCl (1.0 g, 22.5 mmol), 2-tris(-*n*-butyl)stannylpyridine (**5**, 2.6 g, 6.36 mmol) and anhydrous toluene (50 mL) was placed in a flame-dried flask and purged with argon for 30 min at room temperature. Subsequently, $[Pd(PPh_3)_2Cl_2]$ (0.22 g, 13 mol.%) was added and the mixture was heated at 110 °C for 48 h. The warm reaction mixture was passed through a sinter and the remaining black residue was washed repeatedly ($5 \times 30$ mL) with hot toluene. The combined filtrates were evaporated to dryness to give a pale orange solid. The crude product was column chromatographed [silica gel; eluent DCM to remove fast running impurities and then eluted with a mixture of DCM/EtOAc (95:5 v/v)] to give **6** which was finally washed with *n*-hexane to obtain a white solid (0.70 g, 58%), $R_f$ = 0.74 (EtOAc), m.p. 245–246 °C. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 8.71 (d, $J$ = 5.0 Hz, 1 H), 8.44 (d, $J$ = 1.5 Hz, 1 H), 8.36 (dd, $J$ = 6.0 Hz, 1 H), 7.87 (d, $J$ = 8.0 Hz, 1 H), 7.84–7.76 (m, 4 H), 7.64 (td, $J$ = 8.0 Hz, 1 H), 7.53 (td, $J$ = 7.5 Hz, 2 H), 7.30 (m, 1 H) ppm. $^{13}$C NMR (125 MHz, $CDCl_3$): $\delta$ = 155.0, 150.3, 142.0, 138.8, 138.5, 137.6, 134.3, 132.7, 132.2, 131.7, 130.8, 123.6, 122.6, 122.3, 122.2, 120.8, 117.3 ppm. MS (ES+): $m/z$ = 294.2 $[M + H]^+$. $C_{17}H_{11}NO_2S{\cdot}0.2H_2O$: calcd. C 68.76, H 3.87, N 4.72; found C 68.50, H 3.76, N 4.60. Crystals for X-ray analysis were grown from chloroform.

***fac*-2-(5,5-Dioxidodibenzothiophen-3-yl)pyridine Iridium(III) Complex (3):** A mixture of **6** (0.35 g, 1.19 mmol), Ir(acac)$_3$ (97%, 0.12 g, 0.23 mmol) and glycerol (10 mL) were heated to 220 °C under argon for 48 h. The mixture was cooled to room temperature and water (20 mL) was added. The suspension was extracted with DCM (4 × 30 mL) and the solvents evaporated to dryness giving an orange-brown solid. The crude material was column chromatographed [$SiO_2$; eluent EtOAc, then toluene/EtOAc (8:2 v/v)] to give **3** as a bright orange solid (0.20 g, 82%), $R_f$ = 0.42 (EtOAc). M.p. ca. 230 °C (broad). $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 8.13 (s, 3 H), 8.04 (d, $J$ = 8.0 Hz, 1 H), 7.83 (t, $J$ = 5.0 Hz, 1 H), 7.77 (d, $J$ = 8.0 Hz, 1 H), 7.50–7.47 (m, 2 H), 7.43–7.40 (m, 2 H), 7.32 (s, 1 H), 7.10 (t, $J$ = 6.5 Hz, 1 H) ppm. $^{13}$C NMR (125 MHz, $CDCl_3$): $\delta$ = 169.7, 164.1, 147.6, 146.3, 138.9, 138.2, 133.9, 132.6, 133.3, 131.2, 130.4, 129.3, 124.2, 122.8, 122.0, 120.4, 117.6 ppm. MALDI-ToF $m/z$ = 1069.2 (M)$^+$. $C_{51}H_{30}IrN_3O_6S_3H_2O$: calcd. C 56.34, H 2.97, N 3.86; found C 56.49, H 2.68, N 3.79. Single crystals for X-ray analysis were grown from a mixture of methanol and dichloromethane.

**X-ray Crystallography:** Single-crystal X-ray diffraction data were collected with Bruker 3-circle diffractometers with 1 K (for **3b**) or 6 K CCD area detectors, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and Cryostream (Oxford Cryosystems) open-flow $N_2$ cryostats, and corrected for absorption by numerical integration based on crystal face-indexing. The structures were solved by direct methods and refined by full-matrix least-squares against $F^2$ of all data, using SHELXTL software.[25] Crystal data and other experimental details are listed in Table 4. CCDC-645913 to -645917 contain the supplementary crystallographic data for this paper, which can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Crystallisations of **3** from DCM/MeOH produced three pseudo-polymorphs, always containing one molecule of the complex per asymmetric unit, but differing by the (non-stoichiometric) amounts of disordered solvents. In the triclinic form **3a** a closed intermolecular void of ca. 80 Å$^3$ is shared by DCM and methanol molecules (with estimated occupancies of 0.2 and 0.8, respectively), so that the methyl carbon of the latter coincides with a chlorine atom of the former. The guest methanol is hydrogen-bonded to a sulfone group of **3**.

Two orthorhombic (space group *Pbca*) pseudo-polymorphs, **3b** and **3c**, crystallize in broadly similar unit cells with similar positions of the host molecules, which are packed in layers along the $z$ = 0 and $z$ = 1/2 planes, and leave in each unit cell four large voids, of ca. 630 Å$^3$ (**3b**) or 565 Å$^3$ (**3c**) each, filled with chaotically disordered solvents, for which no meaningful model could be found. The total volume of these voids amounts to ca. 25% and 23% of the crystal volume, respectively (cf. 7% in **3a**). From these volumes and the amount of residual electron density (much higher in **3b** than in **3c**) the compositions can be tentatively estimated as **3**·2$CH_2Cl_2$·2MeOH (**3b**) and **3**·$CH_2Cl_2$·3MeOH (**3c**). The crystallization of **3b** and **3c** in fact precedes that of **3a**, in agreement with Ostwald's rule of stages. The structures of **3b** and **3c** were refined using the back-Fourier transformation of the continuous density found in a masked region of the difference map,[26] to account for the missing solvent.

**Supporting Information** (see also the footnote on the first page of this article): General details of procedures and equipment used in this work. # Synthesis and Structure of Self-Complementary {2}-Metallacryptates and Their Linear or Meandering Infinite Arrangements in the Solid State[‡]

**Rolf W. Saalfrank,*[a] Nicolai Mooren,[a] Andreas Scheurer,[a] Harald Maid,[a] Frank W. Heinemann,[a] Frank Hampel,[b] and Walter Bauer[b]**

*Dedicated to Professor Herbert Mayr on the occasion of his 60th birthday*

**Keywords:** Metallacryptate / Coordination polymers / O ligands / X-ray diffraction / Chirality

Reaction of bis(1,3-diketone) $H_2L^1$ in the presence of cesium acetate with magnesium acetate yielded crystalline one-dimensional coordination polymer *rac*-(**2**)$_n$. The {2}-metallacryptand core $[Mg_2(L^1)_3]^{2-}$ is composed of two magnesium centres linked through three bis(1,3-diketo) dianions $(L^1)^{2-}$. These {2}-metallacryptands are homochiral with either (Δ,Δ)-*fac* or (Λ,Λ)-*fac* stereochemistry at the magnesium centres, and they are capable to host a cesium ion in the cavity. Charge compensation of the thus formed {2}-metallacryptates $\{Cs\subset[Mg_2(L^1)_3]\}^-$ is achieved through extra external cesium ions to give the neutral self-complementary building blocks [{Cs⊂[(Δ,Δ)/(Λ,Λ)-$Mg_2(L^1)_3$]}Cs], which aggregate end-on across the external cesium ions to give the *homochiral* one-dimensional strings [{Cs⊂[(Δ,Δ)-$Mg_2(L^1)_3$]}Cs]$_n$ [Δ-(**2**)$_n$] and [{Cs⊂[(Λ,Λ)-$Mg_2(L^1)_3$]}Cs]$_n$ [Λ-(**2**)$_n$], which are packed in the crystal in alternating homochiral layers. However, reaction of bulkier phenyl-substituted bis(1,3-diketone) $H_2L^2$ instead of methyl-substituted $H_2L^1$ with cesium or rubidium acetate and magnesium, cobalt or zinc acetate yielded the meandering polymer *meso*-{[({$M^1\subset[(\Delta,\Delta)$-$M^2{}_2(L^2)_3$]}$M^1{}_{end}$)({$M^1\subset[(\Lambda,\Lambda)$-$M^2{}_2(L^2)_3$]}$M^1{}_{side}$)][({$M^1\subset[(\Lambda,\Lambda)$-$M^2{}_2(L^2)_3$]}$M^1{}_{end}$)({$M^1\subset[(\Delta,\Delta)$-$M^2{}_2(L^2)_3$]}$M^1{}_{side}$)]}$_n$ [*meso*-(**3**)$_n$] ($M^1$ = $Cs^+$, $Rb^+$; $M^2$ = $Mg^{2+}$, $Co^{2+}$, $Zn^{2+}$). In this case, the {2}-metallacryptates $\{M^1\subset[(\Delta,\Delta/\Lambda,\Lambda)\text{-}M^2{}_2(L^2)_3]\}^-$ are linked by only one cesium ion end-on to give the fragments *meso*-[({$M^1\subset[(\Delta,\Delta)$-$M^2{}_2(L^2)_3$]}$M^1{}_{end}$)({$M^1\subset[(\Lambda,\Lambda)$-$M^2{}_2(L^2)_3$]}$M^1{}_{side}$)], which are connected by the second cesium ions side-on. The one-dimensional meander strands of isostructural *meso*-(**3**)$_n$ are packed in the crystal in parallel. Reaction of 4 equiv. of zinc acetate and 1 equiv. of cesium or rubidium acetate with 2 equiv. of $H_2L^2$ afforded the {$M^1\subset[Zn_2(L^2)_2OAc]$} cryptates **4a**,**b** ($M^1$ = $Cs^+$, $Rb^+$).

## Introduction

In earlier work, we demonstrated that hexacoordinate nickel(II) in the presence of cesium ions reacts with bis(1,3-diketo) dianion $(L^1)^{2-}$ to yield the neutral {2}-metallacryptate [{Cs⊂[$Ni_2(L^1)_3$]}Cs] with either (Δ,Δ)-*fac* or (Λ,Λ)-*fac* stereochemistry at the nickel centres. These building blocks are self-complementary and aggregate across the external cesium ions alternately *end-on* to yield in the solid state the one-dimensional coordination polymer *meso*-[({Cs⊂[(Δ,Δ)-$Ni_2(L^1)_3$]}Cs)({Cs⊂[(Λ,Λ)-$Ni_2(L^1)_3$]}Cs)]$_n$ [*meso*-(**1**)$_n$] (Figure 1).[2]

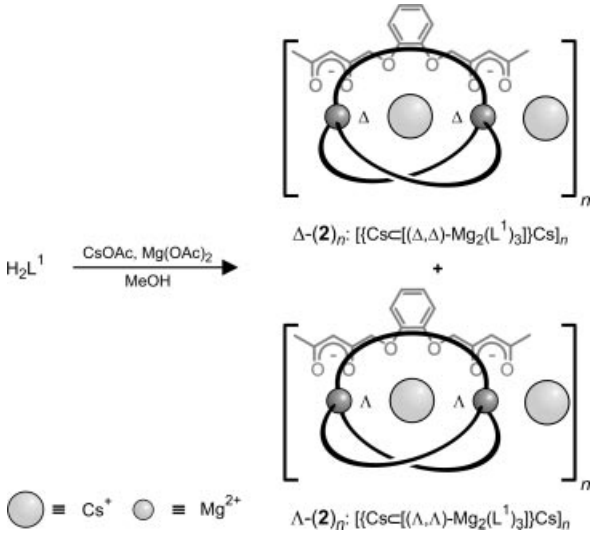
## Results and Discussion

In the course of our ongoing studies on supramolecular coordination chemistry with nickel(II)[2] and copper(II),[2–4] we focused on the development of new oligonuclear complexes by self-assembly[5] with the bis(1,3-diketo) dianion $(L^1)^{2-}$. To this end, we treated $H_2L^1$ with magnesium acetate in the presence of cesium acetate in methanol. As in the nickel case, the cesium ions function as templates for the formation of crystalline one-dimensional coordination polymer *rac*-(**2**)$_n$ (Scheme 1). Cuboids obtained by vapour diffusion of diethyl ether into a solution of the reaction product in acetonitrile were subjected to X-ray crystal analysis, which revealed that Δ/Λ-(**2**)$_n$ crystallizes in the triclinic space group $P\bar{1}$ (Table 1).[6] In Δ/Λ-(**2**)$_n$, the {2}-metallacryptand $[Mg_2(L^1)_3]^{2-}$ core is composed of two magnesium centres linked through three hexadentate catecholate-spacered bis(1,3-diketo) dianions $(L^1)^{2-}$. Therefore, each magnesium ion is coordinated octahedrally by six diketo oxygen donors. The resulting {2}-metallacryptands are homochiral with either (Δ,Δ)-*fac* or (Λ,Λ)-*fac* stereochemistry at the magnesium centres and capable to host a cesium ion in the cavity, which is coordinated by six carbonyl and six catecholate oxygen donors each. Charge compensation of the thus formed enantiomers $\{Cs\subset[(\Delta,\Delta)/(\Lambda,\Lambda)\text{-}Mg_2(L^1)_3]\}^-$ is achieved through extra external cesium ions to give the neutral self-complementary building blocks $[\{Cs\subset[(\Delta,\Delta)/(\Lambda,\Lambda)\text{-}Mg_2(L^1)_3]\}Cs]$. However, contrary to *meso*-(**1**)$_n$, these building blocks aggregate in the solid state end-on across the external cesium ions to give the *homochiral* strings $[\{Cs\subset[(\Delta,\Delta)\text{-}Mg_2(L^1)_3]\}Cs]_n$ [Δ-(**2**)$_n$] and $[\{Cs\subset[(\Lambda,\Lambda)\text{-}Mg_2(L^1)_3]\}Cs]_n$ [Λ-(**2**)$_n$],[6] which are packed in the crystal in alternating homochiral layers (Figure 2). In Δ/Λ-(**2**)$_n$, the coupling external cesium ions are coordinated by two sets of three peripheral carbonyl oxygen donors and two acetonitrile molecules. An additional noncoordinating acetonitrile molecule per monomer unit, trapped in the crystal, leads to the final overall stoichiometry Δ/Λ-(**2**·3MeCN)$_n$. Therefore, the stereogenic metal centres are controlled, simply by varying hexacoordinate $Ni^{II}$ in *meso*-(**1**)$_n$ to $Mg^{II}$ in Δ/Λ-(**2**)$_n$.

To suppress the formation of self-complementary monomers and their aggregation in the solid state by making the external pockets of the cryptates too small to host the external cesium ions, we used $H_2L^2$ with bulkier phenyl groups instead of $H_2L^1$ with methyl substituents at the end. For that purpose, the reaction of stoichiometric amounts of $H_2L^2$, cesium or rubidium acetate and magnesium, cobalt or zinc acetate in acetonitrile was performed, and we isolated microcrystalline materials after vapour diffusion of diethyl ether into a solution of the reaction products (Scheme 2).

Single crystals obtained for *meso*-(**3b**,**e**)$_n$ were subjected to X-ray crystal analyses (Table 1).[6] According to these analyses, *meso*-(**3b**,**e**)$_n$ are isostructural and crystallize in the monoclinic space group $P2_1/n$. Therefore, only the structure of *meso*-(**3e**)$_n$ is discussed in detail. Contrary to our expectation, a strand *meso*-(**3e**)$_n$ was obtained in the solid state.



Scheme 1. Synthesis and schematic presentation of the repeating units of the homochiral strings Δ-(**2**)$_n$ and Λ-(**2**)$_n$ [= *rac*-(**2**)$_n$].

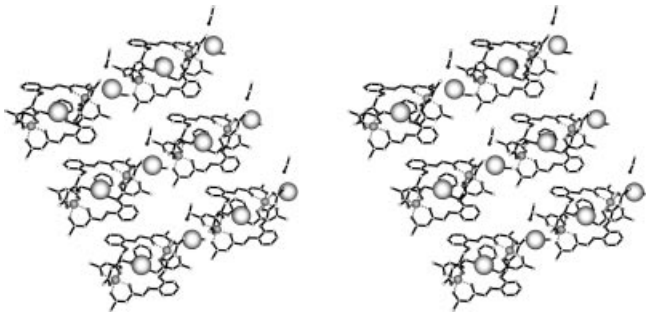


Figure 2. Stereo presentation (POVRAY) of a layer of Λ-(**2**)$_n$ in the crystal together with the coordinating acetonitrile solvent molecules. Mg grey, Cs light grey.

In *meso*-(**3e**)$_n$, two enantiomers $\{Cs\subset[(\Delta,\Delta/\Lambda,\Lambda)\text{-}Co_2(L^2)_3]\}^-$ are linked by only one cesium ion *end-on* and a second one is coordinated *side-on* to connect these units to finally give *meso*-$\{[(\{Cs\subset[(\Delta,\Delta)\text{-}Co_2(L^2)_3]\}Cs_{end})(\{Cs\subset[(\Lambda,\Lambda)\text{-}Co_2(L^2)_3]\}Cs_{side})][(\{Cs\subset[(\Lambda,\Lambda)\text{-}Co_2(L^2)_3]\}Cs_{end})(\{Cs\subset[(\Delta,\Delta)\text{-}Co_2(L^2)_3]\}Cs_{side})]\}_n$ [*meso*-(**3e**)$_n$]. Therefore, the $Cs_{end}$ links two enantiomers $\{Cs\subset[(\Delta,\Delta/\Lambda,\Lambda)\text{-}Co_2(L^2)_3]\}^-$, whereas the $Cs_{side}$ links the *meso*-$[(\{Cs\subset[(\Delta,\Delta)\text{-}Co_2(L^2)_3]\}Cs_{end})(\{Cs\subset[(\Lambda,\Lambda)\text{-}Co_2(L^2)_3]\}Cs_{side})]$ fragments across their homochiral {2}-metallacryptate halves. The explanation for the formation of this structure is the fact that when an external cesium splits the {2}-metallacryptate building block at one end, the pocket at the other end is compressed and incapable to host another $Cs_{end}$. The $Cs_{side}$ ion is coordinated to eight oxygen donors of four ligands $(L^2)^{2-}$ (one carbonyl oxygen donor of one ligand and one carbonyl oxygen donor together with two catecholate oxygen donors of another ligand of one cryptate each) and to two acetonitrile molecules. The meander strands of isostructural *meso*-(**3b**,**e**)$_n$ are packed in the crystal in parallel. The repetitive unit of the structure in the crystal is therefore

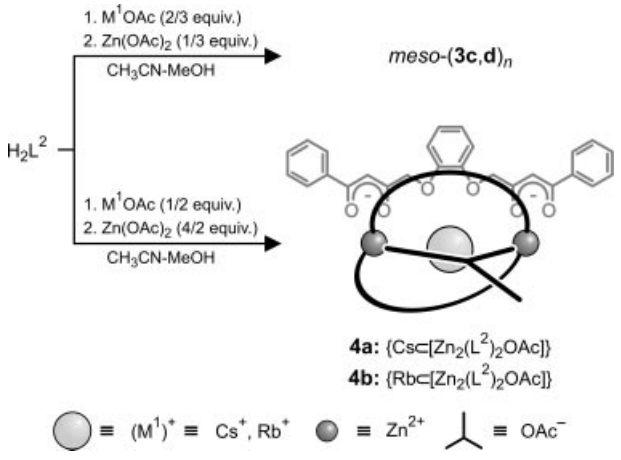
Surprisingly, when stoichiometric amounts of $H_2L^2$, zinc acetate and cesium acetate were combined, a mixture of two compounds was generated. However, both components can be synthesized separately by using the appropriate stoichiometry (Scheme 3). The reaction of 1 equiv. of zinc acetate and 2 equiv. of cesium acetate with 3 equiv. of $H_2L^2$ in a mixture of acetonitrile and methanol (3:1) yielded one-dimensional meander polymer *meso*-(**3c**)$_n$. In contrast, the reaction of 4 equiv. of zinc acetate and 1 equiv. of cesium acetate with 2 equiv. of $H_2L^2$ afforded {Cs⊂[Zn$_2$($L^2$)$_2$OAc]} cryptate **4a**, which readily crystallized from a mixture of acetonitrile and methanol (3:1) (Scheme 3, Figure 5). Analogously, supramolecular *meso*-(**3d**)$_n$ as well as metallacryptate **4b** are accessible with rubidium (Schemes 2 and 3). Metallacryptate **4a** crystallizes in space group $P2_1/c$ and has idealized $C_{2v}$ molecule symmetry (Table 1).[6] Two hexadentate bis(1,3-diketo) dianions $(L^2)^{2-}$ together with an encapsulated cesium ion formally create a {2}-metallacoronate that is folded by an acetate bridge. In the heteroleptic cryptate, one acetate oxygen atom functions as a $\mu_1$-donor to one zinc ion and the other as a $\mu_2$-donor to the other zinc ion, but also to the cesium ion. In **4a**, the cesium ion at one side is coordinatively unsaturated and, therefore, two molecules of **4a** form a dimer due to cation–π interaction of neighboring phenyl groups (Figure 5 bottom).[7]



Scheme 3. Synthesis of one-dimensional meandering polymers *meso*-(**3c**,**d**)$_n$ and heteroleptic {2}-cryptates **4** (schematic presentation).

To prove the existence of the supramolecular cryptate monomers of crystalline *rac*-(**2**)$_n$ and *meso*-(**3**)$_n$ also in solution, we carried out $^1$H and $^{13}$C NMR spectroscopic studies of diamagnetic *rac*-(**2**)$_n$ and *meso*-(**3a**–**d**)$_n$. It turned out that the spectra of all five compounds were not very significant [5 $^1$H and 8 $^{13}$C NMR signals for *rac*-(**2**)$_n$ and 7 $^1$H and 11 $^{13}$C NMR signals for *meso*-(**3a**–**d**)$_n$]. We were unable to detect an AB pattern for the diastereotopic $OCH_2$ protons, even by using variable temperature techniques.[8] The compounds *meso*-(**3a**)$_n$ and *meso*-(**3c**)$_n$ are identical except for the metal ions magnesium or zinc. Exemplarily, their spectra are discussed here in detail. They differ only slightly in their chemical shifts. To evaluate the intermolecular exchange processes, we also recorded a $^{13}$C NMR spectrum

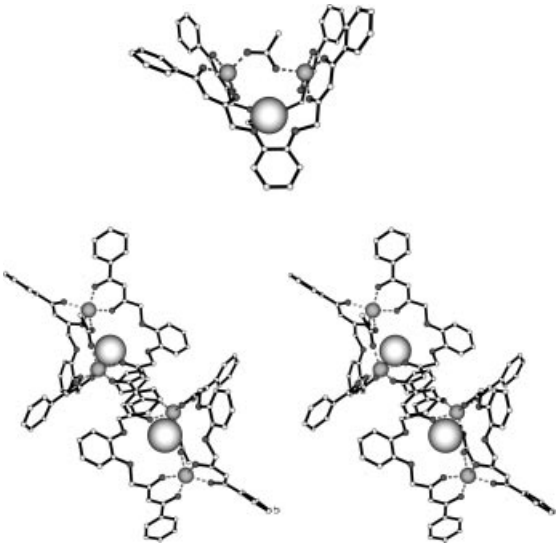


Figure 5. Structure of heteroleptic cryptate **4a** (top) and stereo presentation (POVRAY) of the dimer of **4a** (bottom). Zn grey, Cs light grey.

of a 1:1 mixture of *meso*-(**3a**)$_n$ and *meso*-(**3c**)$_n$ in [$D_6$]acetone. A total of 22 signals was detected, which is twice the number of signals for each individual compound. We thus concluded that any Mg/Zn exchange process must be extremely slow on the NMR timescale. Unequivocally, we observed intact cryptate monomers also in solution. For convenience, we present only the carbonyl $^{13}$C NMR signals for cryptates *meso*-(**3a**)$_n$ and *meso*-(**3c**)$_n$ and their 1:1 mixture in [$D_6$]acetone (Figure 6).

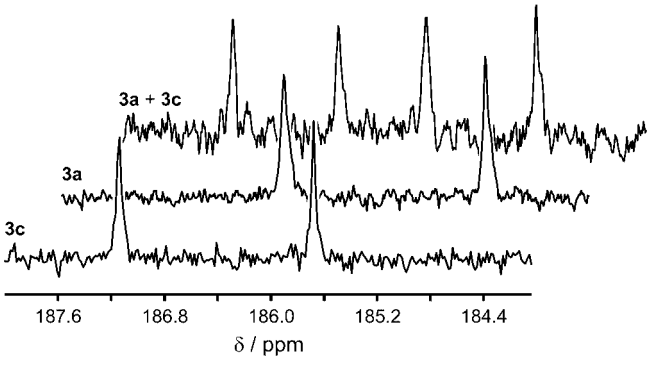

Figure 6. $^{13}$C NMR signals for the carbonyl atoms of *meso*-(**3a**)$_n$ and *meso*-(**3c**)$_n$ and their 1:1 mixture in [$D_6$]acetone at ca. 25 °C.

The number of $^{13}$C NMR signals found for *meso*-(**3a**)$_n$ and *meso*-(**3c**)$_n$ observed in solution (11 each) suggests that a homochiral (Δ,Δ/Λ,Λ) monomeric species exists as proposed from the X-ray data. However, the $^{13}$C NMR spectroscopic data would also match a heterochiral (Δ,Λ) monomeric species. The monomeric homochiral species represents the racemate, the heterochiral species is a monomeric *meso* compound. Therefore, provided that there are only minute chemical shift differences between the racemate and *meso* compounds, there might be a mixture of both diastereomers present. Normal $^{13}$C NMR spectroscopic pro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cessing yields only a single set of signals. However, we are currently exploring whether these signals can be resolved further. This requires $^{13}C$ NMR spectroscopic data with very high signal-to-noise ratios and resolution enhancement techniques. We will report in forthcoming papers on these results.

## Conclusions

We presented the synthesis of the homochiral linear one-dimensional polymers $[\{Cs\subset[(\Delta,\Delta)\text{-}Mg_2(L^1)_3]\}Cs]_n$ [$\Delta$-(**2**)$_n$] and $[\{Cs\subset[(\Lambda,\Lambda)\text{-}Mg_2(L^1)_3]\}Cs]_n$ [$\Lambda$-(**2**)$_n$] and the one dimensional meander polymers *meso*-$\{[(\{M^1\subset[(\Delta,\Delta)\text{-}M^2{}_2(L^2)_3]\}M^1{}_{end})(\{M^1\subset[(\Lambda,\Lambda)\text{-}M^2{}_2(L^2)_3]\}M^1{}_{side})][(\{M^1\subset[(\Lambda,\Lambda)\text{-}M^2{}_2(L^2)_3]\}M^1{}_{end})(\{M^1\subset[(\Delta,\Delta)\text{-}M^2{}_2(L^2)_3]\}M^1{}_{side})]\}_n$ [*meso*-(**3**)$_n$] ($M^1$ = $Cs^+$, $Rb^+$; $M^2$ = $Mg^{2+}$, $Co^{2+}$, $Zn^{2+}$). The structures of complexes **1**–**4** were solved by the combination of mass spectroscopy, single-crystal X-ray analyses and $^1H$ and $^{13}C$ NMR spectroscopy. Most importantly, the $^{13}C$ NMR spectrum of a mixture of *meso*-(**3a**,**c**) unequivocally proved the existence of the intact cryptates $\{Cs\subset[Mg_2(L^2)_3]\}^-$ of *meso*-(**3a**)$_n$ and $\{Cs\subset[Zn_2(L^2)_3]\}^-$ of *meso*-(**3c**)$_n$ in solution.

## Experimental Section

**General Techniques:** All solvents used were purified according to standard procedures. All reagents employed were commercially available, high-grade purity materials and used as supplied (Fluka, Aldrich and Acros). Melting points were determined with a WAGNER-MUNZ apparatus and are uncorrected. IR spectra were recorded as powder films with a ASI React IR-1000 spectrometer. NMR spectra were obtained from dilute solutions in $CDCl_3$, unless stated otherwise, and recorded with a JEOL EX400 or a BRUKER Avance 300 spectrometer. The residual solvent signals were used as internal standards: $CDCl_3$ ($^1H$ 7.27 ppm, $^{13}C$ 77.0 ppm); [D$_6$]acetone ($^1H$ 2.05 ppm; $^{13}C$ 29.85 ppm).[9] The resonance multiplicity is indicated as s (singlet), d (doublet) and m (multiplet). MS (FAB) spectra were recorded with a Micromass ZAB-Spec ($Cs^+$) spectrometer with *m*-NBA as matrix. Elemental analyses were performed with a Carlo Erba EA1110 CHN instrument and with a HERAEUS CHN-Mikroautomat.

**General Procedure for $H_2L^{1,2}$:**[2,10] To a suspension of sodium amide (7.8 g, 200 mmol) in THF (200 mL) was added a solution of the corresponding methyl ketone (100 mmol) in THF (20 mL) by a dropping funnel. After 15 min, a solution of ester 1,2-bis(methylacetoxy)benzene[11] (12.71 g, 50 mmol) in THF (20 mL) was added. After heating at reflux for 4 h, cooling to room temp. and the addition of water (5 mL), the mixture was concentrated under reduced pressure. The residue was taken up in water (100 mL) and acidified with concentrated HCl (30 mL). Extraction of the aqueous phase with chloroform (3 × 100 mL), drying (over sodium sulfate) and evaporation of the combined organic phases yielded the crude reaction product, which was further purified by recrystallization. In solution, the ligands $H_2L^{1,2}$ are present as a tautomeric mixture of the diketo, monoenol and bisenol species. Below, only signals of the dominating bisenol form are listed.

**$H_2L^1$:** Acetone (7.34 mL). Yield: 5.5 g (36%), bright-beige crystals (methanol). M.p. 92 °C. $^1H$ NMR (300.1 MHz): $\delta$ = 15.26 (br. s, 2 H, O*H*), 6.98–6.95 (m, 2 H, Ar-*H*), 6.89–6.86 (m, 2 H, Ar-*H*), 5.98 (s, 2 H, C*H*), 4.65 (s, 4 H, C$H_2$), 2.10 (s, 6 H, C$H_3$) ppm. $^{13}C$ NMR (75.5 MHz): $\delta$ = 191.88 (2 *C*-OH), 190.50 (2 *C*=O), 148.04 (2 Ar-*C*-O), 122.57 (2 Ar-*C*-H, *m*-$C_6H_4$), 114.69 (2 Ar-*C*-H, *o*-$C_6H_4$), 97.44 (2 *C*H), 70.24 (2 *C*$H_2$), 24.47 (2 *C*$H_3$) ppm. IR: $\tilde{\nu}$ = 2922, 1609, 1589, 1509, 1225, 1124 cm$^{-1}$. MS: *m*/*z* (%) = 307 (100) [M + H]$^+$, 222 (9) [M – $COCH_2COMe$]$^+$. $C_{16}H_{18}O_6$ (306.32): calcd. C 62.74, H 5.92; found C 62.85, H 6.04.

**$H_2L^2$:** Acetophenone (11.67 mL). Yield: 10.3 g (48%), colorless cotton-like crystals (methanol). M.p. 117 °C. $^1H$ NMR (300.1 MHz): $\delta$ = 15.87 (br. s, 2 H, O*H*), 7.78–7.76 (m, 4 H, Ar-*H*, *o*-$C_6H_5$), 7.41–7.36 (m, 2 H, Ar-*H*, *p*-$C_6H_5$), 7.30–7.25 (m, 4 H, Ar-*H*, *m*-$C_6H_5$), 6.93–6.86 (m, 4 H, Ar-*H*, $C_6H_4$), 6.66 (s, 2 H, C*H*), 4.72 (s, 4 H, C$H_2$) ppm. $^{13}C$ NMR (75.5 MHz): $\delta$ = 193.70 (2 *C*-OH), 182.75 (2 *C*=O), 147.95 (2 Ar-*C*-O), 133.90 (2 Ar-*C*-C=O), 132.67 (2 Ar-*C*-H, *p*-$C_6H_5$), 128.62 (4 Ar-*C*-H, $C_6H_5$), 127.11 (4 Ar-*C*-H, $C_6H_5$), 122.54 (2 Ar-*C*-H, *m*-$C_6H_4$), 114.68 (2 Ar-*C*-H, *o*-$C_6H_4$), 93.44 (2 *C*H), 70.73 (2 *C*$H_2$) ppm. IR: $\tilde{\nu}$ = 3050, 2890, 2830, 1610, 1575, 1509, 1262, 1227, 1127 cm$^{-1}$. MS: *m*/*z* (%) = 431 (100) [M]$^+$. $C_{26}H_{22}O_6$ (430.46): calcd. C 72.55, H 5.15; found C 72.19, H 5.13.

**$\Delta/\Lambda$-(2)$_n$:** A solution of cesium acetate (25 mg, 131 μmol) in MeOH (1 mL) was added to a solution of ligand $H_2L^1$ (40 mg, 131 μmol) in MeOH (3 mL). The mixture was heated to boiling. Then a solution of $Mg(OAc)_2{\cdot}4H_2O$ (19 mg, 87 μmol) in MeOH (1 mL) was prepared at boiling heat and added dropwise. After cooling and filtration of the resulting mixture, the crude product was obtained in the form of microcrystals by vapour diffusion of diethyl ether into the filtrate. Recrystallisation from acetonitrile by vapour diffusion of diethyl ether gave colourless crystals of $\Delta/\Lambda$-(**2**·3$CH_3CN$)$_n$, suitable for X-ray structure determination. Yield: 25 mg (47%) of $\Delta/\Lambda$-(**2**)$_n$ after drying for 8 h under reduced pressure ($10^{-3}$ mbar). M.p. >260 °C (decomp). $^1H$ NMR (300.1 MHz, XXXX): $\delta$ = 6.76 (br. s, 6 H, Ar-*H*), 6.46 (br. s, 6 H, Ar-*H*), 4.75 (br. s, 6 H, C*H*), 4.03 (br. s, 12 H, C$H_2$), 1.78 (br. s, 18 H, C$H_3$) ppm. $^{13}C$ NMR (100.5 MHz, XXXX): $\delta$ = 191.66 (6 *C*=O), 183.23 (6 *C*=O), 146.42 (6 Ar-*C*-O), 120.67 (6 Ar-*C*-H), 111.67 (6 Ar-*C*-H), 95.11 (6 *C*H), 68.24 (6 *C*$H_2$), 28.21 (6 *C*$H_3$) ppm. IR: $\tilde{\nu}$ = 3065, 2910, 1613, 1521, 1235, 1127, 1054 cm$^{-1}$. MS: *m*/*z* (%) = 1359 (15) [Cs⊂$Mg_2L_3$ + 2Cs]$^+$, 1227 (22) [Cs⊂$Mg_2L_3$ + Cs]$^+$, 789 (100) [$Mg_2L_2$ + Cs]$^+$, 691 (16) [$Mg_2L_2$ + Cs – $CH_2COCHCOCH_3$]$^+$. $C_{48}H_{48}Cs_2Mg_2O_{18}$ (1227.40): calcd. C 46.97, H 3.95; found C 46.47, H 4.13.

**General Procedure for *meso*-(3a,b,e)$_n$:** A solution of cesium or rubidium acetate (77 μmol) in MeOH (1 mL) was added to a solution of ligand $H_2L^2$ (50 mg, 116 μmol) in acetonitrile (3 mL). The mixture was heated to boiling. Then a solution of $M^2(OAc)_2{\cdot}xH_2O$ (77 μmol) in MeOH (1 mL) was prepared at boiling heat and added dropwise. After cooling and filtration of the resulting mixture, the product was obtained in the form of crystals by vapour diffusion of diethyl ether into the filtrate.

***meso*-(3a)$_n$:** CsOAc (15 mg) and $Mg(OAc)_2{\cdot}4H_2O$ (17 mg). Yield: 38 mg (62%), colorless crystals after drying for 8 h under reduced pressure ($10^{-3}$ mbar). M.p. >220 °C (decomp). $^1H$ NMR (300.1 MHz, [D$_6$]acetone): $\delta$ = 7.88–7.85 (m, 12 H, Ar-*H*, *o*-$C_6H_5$), 7.41–7.31 (m, 18 H, Ar-*H*, *m*- and *p*-$C_6H_5$), 6.61–6.58 (m, 6 H, Ar-*H*, $C_6H_4$), 6.33–6.30 (m, 6 H, Ar-*H*, $C_6H_4$), 5.63 (br. s, 6 H, C*H*), 4.33 (br. s, 12 H, C$H_2$) ppm. $^{13}C$ NMR (75.5 MHz, [D$_6$]acetone): $\delta$ = 186.32 (6 *C*=O), 184.80 (6 *C*=O), 147.65 (6 Ar-*C*-O), 142.54 (6 Ar-*C*-C=O), 130.71 (6 Ar-*C*-H, *p*-$C_6H_5$), 128.64 (12 Ar-*C*-H, $C_6H_5$), 128.16 (12 Ar-*C*-H, $C_6H_5$), 121.41 (6 Ar-*C*-H, *m*-$C_6H_4$), 112.57 (6 Ar-*C*-H, *o*-$C_6H_4$), 92.30 (6 *C*H), 69.60 (6 *C*$H_2$) ppm. IR:

C 57.28, H 3.84; found C 56.82, H 3.91.

**Single Crystal X-ray Structure Analyses:** Details of crystal data, data collection and refinement are given in Table 1. X-ray data for Δ/Λ-(**2**)$_n$, *meso*-(**3e**)$_n$, **4a** and **4b** were collected with a Nonius Kappa CCD area detector by using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods with SHELXS-97[12] and refined with full-matrix least-squares against $F^2$ using the SHELXL-97 program system.[13] All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were fixed in ideal positions (riding model) and were included without refinement and with fixed isotropic *U*. Data for *meso*-(**3b**)$_n$ were collected with a Bruker-Nonius KappaCCD dif-

fractometer by using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å), and a graphite monochromator. The structure was solved by direct methods; full-matrix least-squares refinements were carried out on $F^2$ using SHELXTL NT 6.12.[14] A semiempirical absorption correction based on multiple scans (SADABS)[15] was performed. All non-hydrogen atoms were refined anisotropically. The H atoms were geometrically positioned with isotropic displacement parameters being either 1.2 U(eq) or 1.5 U(eq) of the proceeding C atom. Disorder: Two of the aromatic rings (C99–C104 and C125–C130) are disordered with 42.6(5) and 57.4(5)% and 47.8(4) and 52.2(4)%, respectively. In the crystal structure two huge cavities are present that are occupied by different disordered solvent molecules. Attempts to solve this disorder did not lead to reasonable results and therefore the SQUEEZE algorithm was employed to treat the rest electron density in this part of the structure.[16]

# Size-Controlled Water-Soluble Ag Nanoparticles

José M. Domínguez-Vera,*[a] Natividad Gálvez,[a] Purificación Sánchez,[a] Antonio J. Mota,[a] Susana Trasobares,[b] Juan C. Hernández,[b] and Jose J. Calvino*[b]

**Keywords:** Silver / Nanoparticles / Apoferritin / Water-soluble particles

Ag nanoparticles of two different sizes (1 and 4 nm) were prepared within an apoferritin cavity by using an $Ag^+$-loaded apoferritin as a nanoconfined environment for their construction. The initial amount of $Ag^+$ ions injected in the apoferritin cavity dictates the size of the final Ag particles. The protein shell prevents bulk aggregation of the metal particles, which renders them water soluble and extremely stable.

## Introduction

Metallic nanoparticles are attracting considerable attention for their intriguing properties and potential applications. Because of their small size, the nanoparticles exhibit magnetic, electrical, optical, and chemical properties that cannot be achieved by bulk materials. Advances in the study of the properties of nanoparticles and in their technological applications depend on the development of new methods that are able to control the size and chemical stability of the nanoparticles. In this sense, it must be considered that traditional methods often restrict the flexibility in the preparation of small-size particles (<10 nm).[1] On the other hand, the chemical stability of the nanoparticles is crucial to avoid degradation processes such as partial oxidation or agglomeration. This is one of the reasons why noble metals have been the more usual candidates to be prepared and studied at the nanometer regimen. Among noble metals, Au and Ag exhibit a strong UV/Vis absorption band that is not present in the spectrum of the bulk metals. This absorption band results when the incident photon frequency is resonant with the collective excitation of the conduction electrons and is known as the surface plasmon resonance (SPR).[2] The SPR can be tuned by changing particle size, shape, as well as the surrounding dielectric medium. This tunability confers to Au and Ag nanoparticles potential applications for surface-enhanced spectroscopy,[3] optical filters,[4] and plasmonic devices[5] and sensors.[6] This potentiality is exploited more in the case of Au nanoparticles than it is for Ag nanoparticles despite the known fact that Ag nanoparticles exhibit higher efficiency of plasmon excitation.[2] However, the propensity of pure Ag nanoparticles to undergo oxidative corrosion[7] and aggregation in electrolytic solutions[8] limit their usage, especially for biological applications. The oxidative corrosion and aggregation of Ag nanoparticles can be attenuated or eliminated with a protective layer, such as organic cap ligands or inorganic coatings, which allow stable nanoparticle solutions to exist even at high NaCl concentrations and over a wide range of pH values. An alternative route for avoiding the agglomeration of the particles is the use of a preorganized molecular matrix as a chemical and spatial nanocage for building the Ag nanoparticle. An example of this underexploited route is the use of genetically engineered apoferritin expressing a silver-binding peptide.[9] Native apoferritin consists of a spherical protein shell surrounding an aqueous cavity of about 8 nm.[10] It was reported that apoferritin binds or concentrates metal ions in its cavity[11] and that, interestingly, the loaded metal ions can be chemically reduced to form the corresponding zero-valent cluster, which remains encapsulated.[12] Moreover other inorganic nanoparticles (especially oxides and hydroxides) can be prepared within the apoferritin cavity by using different strategies.[13] The final particle size should be directly determined by the number of metal ions previously encapsulated. However, size tuning by metal ion loading control was only reported for native ferritin, which was prepared with a different iron content.[14] We herein report the preparation of apoferritin-encapsulated silver nanoparticles, and we demonstrate that the initial amount of $Ag^+$ ions injected in the apoferritin capsule dictates the size of the resulting Ag particles.

## Results and Discussion

Sodium chloride free horse spleen apoferritin was incubated with $AgNO_3$ at two different stoichiometries (500 and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim InterScience 

5000 $Ag^+$ per apoferritin) to afford homogeneous solutions that were chromatographed (Sephadex G-25). Every collected fraction was added to a $NaBH_4$ solution and the apoferritin and Ag concentrations were then measured (see Experimental Section). The elution profile does not change with the $Ag^+$/apoferritin stoichiometry. As an example, the elution profile of the solution corresponding to the experiment of higher $Ag^+$/apoferritin is shown in Figure 1. The Ag-associated apoferritin peak (fractions 4–7) was separated from free Ag (fractions 10–12), which trailed well behind (Figure 1). The coelution was an indication that Ag was attached to apoferritin. In fact, fraction 4–7 contained water-soluble particles of sizes smaller than the apoferritin cavity (see below) whereas fractions 10–12 consisted of insoluble and heterogeneous larger Ag particles (20–80 nm).

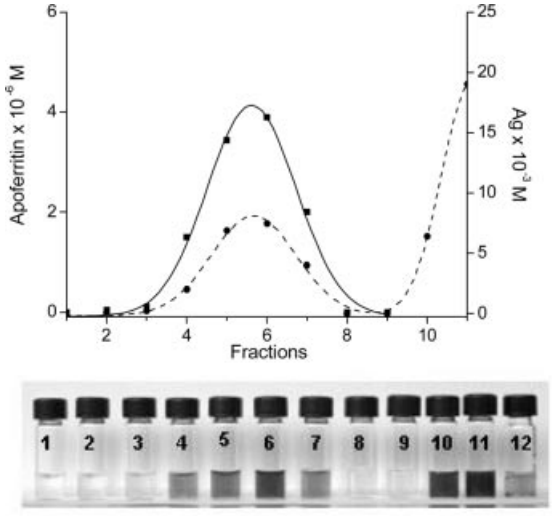

Figure 1. Elution profile of Ag-containing apoferritin. Protein (solid line) was measured by UV/Vis spectroscopy and Ag (dashed line) by atomic absorption spectroscopy.

The solutions corresponding to fractions 5–7 were dialyzed against water at 4 °C and then examined by transmission electron microscopy (TEM). A typical image obtained from the material corresponding to the experiments made in a 5000:1 $Ag^+$/apoferritin stoichiometry shows discrete electron-dense cores, which are spherical in shape (Figure 2). The mean diameter was statistically measured to be $(4 \pm 0.5)$ nm. X-ray energy dispersive spectroscopy (EDS) confirmed that the particles contained Ag (Figure 2d), which was not detected outside the particles. TEM images of samples negatively stained with uranyl acetate (to visualize the protein shell) confirmed that the particles were actually produced within the apoferritin interior (Figure 2b). The presence of the apoferritin coat prevents irreversible aggregation of the Ag particles and their precipitation. For this reason, apoferritin-free Ag particles (fractions 10 and 11) resulted in bulk precipitation.

The use of the apoferritin cavity as a nanoreactor to build the Ag particle allows initial control over the size, because the particles cannot be larger than the cavity (approximately 8 nm). In fact, particles from fractions 5–7 are smaller than 8 nm, whereas those of the apoferritin-free ones (fractions 10–12) are significantly larger (20–80 nm). However, more exhaustive control over the particle size is possible: the initial amount of $Ag^+$ injected in the apoferritin cavity plays a key role in dictating the size of the particles and then the size may be tuned by changing the molar ratio of $Ag^+$/apoferritin. Thus, with a lower $Ag^+$/apoferritin ratio (500:1) and the use of the same experimental procedure (incubation time, chromatography, and dialysis), particles of smaller size were obtained. The detection and structural characterization of these smaller particles requires the use of alternative electron microscopy techniques. Given the large difference in atomic number between Ag ($Z$ = 47) and C ($Z$ = 6), high angle annular dark field imaging (HAADF) was used, which extends the detection limit below the nanometer range. Figure 3a shows a representative HAADF image of the $Ag^+$/apoferritin (500:1) sample. Bright spot contrasts correspond to the high atomic number component, namely, the silver particles. As shown in Figure 3a, a large number of nanosized Ag particles can be detected in the HAADF images.

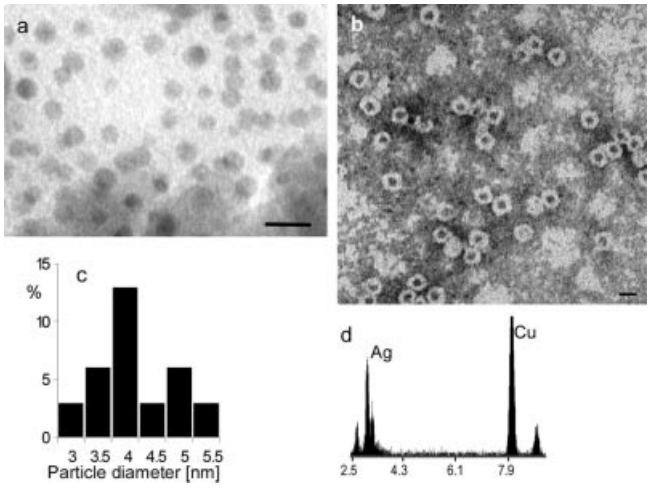

Figure 2. (a) TEM image of Ag nanoparticles prepared in a Ag/apoferritin stoichiometry of 5000:1; (b) negatively stained TEM image showing the metallic core surrounded by the apoferritin shell (scale bars are 10 nm); (c) size-distribution in nm; and (d) representative EDS recorded inside the particles. Cu peaks are due to the sample grid.

EDS obtained from locations inside these particles by using a finely focused 0.5-nm electron probe (Figure 3b) confirm the presence of Ag in these bright areas. From the particle size histogram established from HAADF images (Figure 3c) an average Ag particle size of $(1 \pm 0.1)$ nm can be estimated in this sample.

The structure of the small particles containing Ag was further investigated by means of high-resolution electron microscopy (HREM). Figure 4 shows some representative HREM images. Measurements of lattice spacings and interplanar angles on the diffractograms of these images (included as insets) confirm that the particles are fcc Ag. Some

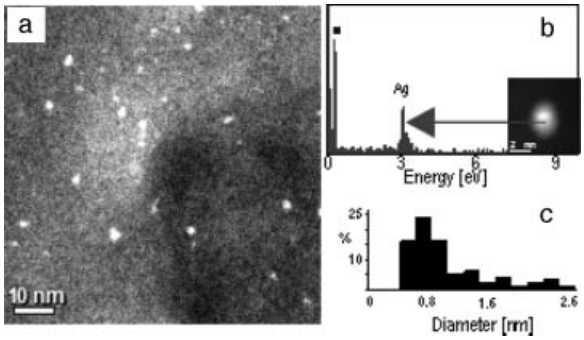

Figure 3. (a) STEM-HAADF image of the 500:1 $Ag^+$/apoferritin sample; (b) X-EDS spectrum obtained from inside one of the particles (shown as inset); (c) particle diameter histogram of this sample established from a collection of HAADF images.

of them are monocrystalline domains (Figure 4a,b), whereas in some other cases they are made of several singly or multiply twinned smaller fcc domains (Figure 4c,d). In the diffractograms of the former, {002} reflections at 0.204 nm, {022} at 0.14 nm, and {111} at 0.235 nm can be clearly identified. Twinning on the {111} planes complicates the appearance of the diffractograms in the case of the latter, but these same reflections can still be clearly identified. Note that the size of the domains in these twinned particles is smaller than 1 nm.

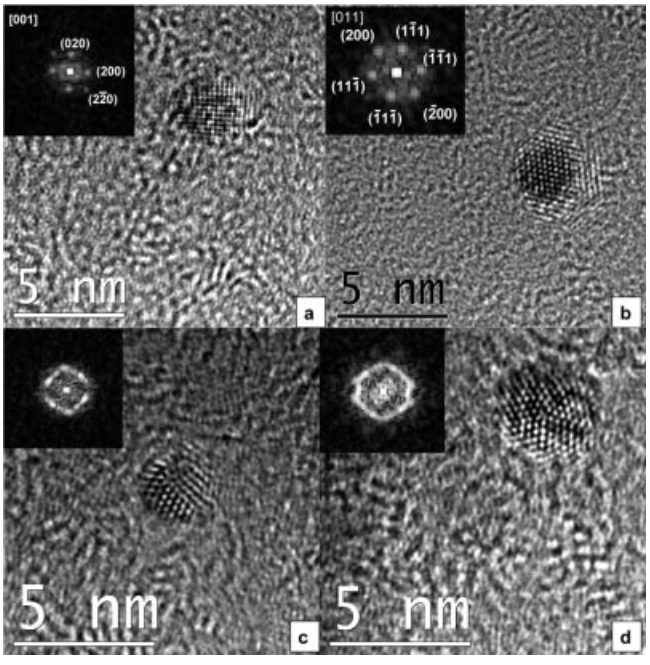

Figure 4. HREM images recorded of the 500:1 $Ag^+$/apoferritin sample: (a) shows a fcc Ag particle down the [001] zone axis; (b) Ag particle down the [110] zone axis; (c) and (d) correspond to multiply twinned Ag particles. Diffractograms are included as insets. Multiply-twinned particles illustrate the structure of larger particles.

These results demonstrate that $Ag^+$-apoferritin acts as a reactor because the trapped $Ag^+$ ions are able to react with a chemical reagent that is small enough to traverse the apoferritin channels to build a new material. Thus, $Ag^+$ ions are reduced with $NaBH_4$ to yield zero-valent silver. As a result of the reduction, the UV/Vis spectrum of the solution dramatically changed and showed the typical absorption band attributable to the SPR of the Ag particles. The position of the SPR can be tuned by changing the particle size and shape, as well as the surrounding dielectric medium. In Figure 5, the UV/Vis spectra of the solution corresponding to the particles of 1 and 4 nm show the presence, in both cases, of the SPR at 392 and 434 nm, respectively. This significant shift must be a direct consequence of the different particle sizes[15] and/or their different dielectric surrounding media: the lower the Ag particle size, the less contact with the apoferritin takes place. In fact, particles of 1 nm exhibit a SPR (392 nm) that is typical for uncoated Ag nanoparticles, whereas that (434 nm) of the 4-nm sized particle is more characteristic of Ag particles surrounded with a high refractive index shell.[16]

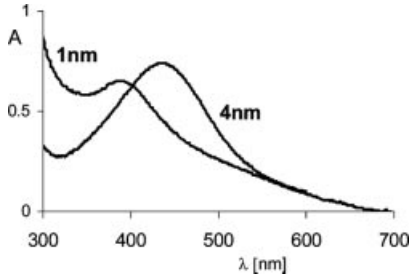

Figure 5. UV/Vis spectra of the Ag particles. The SPR showed a redshift with a reduced particle size.

Stability is a key point for silver nanoparticles. Previous studies showed that silver nanoparticles were often unstable in solution and easily aggregated at high concentration of the particles or NaCl. The apoferritin-encapsulated Ag nanoparticles we have prepared exhibited excellent stability in solution and no significant UV/Vis spectral changes were observed over one month at room temperature. Likewise, the addition of NaCl to reach a 0.1 M concentration did not produce either precipitation or UV/Vis spectral change. Moreover, the solution can be lyophilized and the particles kept in the solid state under ambient conditions for months without showing significant changes on the basis of X-ray powder diffraction analysis.

## Conclusions

Ag nanoparticles were prepared by using the apoferritin cavity as a nanoreactor to reduce the $Ag^+$ ions. The size of the nanoparticles can be tuned by changing the $Ag^+$ loading. The presence of the apoferritin coat is responsible for the water solubility and stability of these particles.

## Experimental Section

Horse spleen apoferritin (53 mg mL$^{-1}$) was exhaustively dialyzed for 3 d with several changes of the milli-Q water at 4 °C to remove NaCl. After this treatment, apoferritin (5.3 mg mL$^{-1}$) was incubated with $AgNO_3$ at two different concentrations (6 and 60 mM) at room temperature, which corresponds to 500 and 5000 $Ag^+$/apoferritin stoichiometries. No precipitation of AgCl occurred. After 1 d, the resulting solutions were dialyzed against water for 15 min and then passed through a 1.5 cm × 5.5 cm column of Sephadex G-25 equilibrated with water. Fractions were collected every minute, and then, the concentrations of apoferritin and Ag were obtained by the absorbance values at 280 nm ($\varepsilon^{280} \approx 468000$ M$^{-1}$) and atomic absorption spectroscopy, respectively. In a parallel experiment, the chromatographed fractions were directly added to a water solution containing $NaBH_4$ (4.5 mg mL$^{-1}$). The samples used for electron microscopy (TEM) studies were prepared by diluting the dialyzed solutions of particles with milli-Q water and then placing a drop onto a carbon-coated Cu grid and drying it in a glove box. To record images in high-resolution electron microscopy (HREM) and high angle annular dark field (HAADF) modes, the samples were deposited onto holey carbon Cu grids. The average particle sizes and the standard deviations were estimated from measurements of diameters performed either with TEM or HAADF images of a statistically adequate number of particles (about a hundred). Electron micrographs were recorded with two different microscopes: a Philips CM-20 HR analytical electron microscope operating at 200 keV (TEM) and a JEOL 2010F (HREM, HAADF) working also at 200 kV. Structural resolution of the last instrument was 0.19 nm, which allowed structural analysis of noble metals as it is the case of silver. Moreover operating this instrument in scanning transmission electron microscopy mode (STEM) allows forming electron probes with diameters as small as 0.2 nm, which opens the possibility, in combination with X-EDS detectors, to perform chemical analysis with a spatial resolution better than 1 nm.

# Synthesis, Structure and Magnetic Properties of a Novel Hexanuclear Copper Methylsiloxane Complex

Larissa Zherlitsyna,[a] Norbert Auner,*[a] Michael Bolte,[a] Yulia Pozdniakova,[b] Olga Shchegolikhina,[b] Konstantin Lyssenko,[b] Vladimir Pashchenko,*[c] Bernd Wolf,[c] Michael Lang,[c] Florian Schütz,[d,e] Marcus Kollar,[f] Francesca Sauli,[d] and Peter Kopietz[d]

**Keywords:** Copper / Cluster compounds / Sandwich complexes / Magnetic properties

A new hexanuclear copper(II) sandwich complex based on two 12-membered macrocyclic methylsiloxanolate ligands, $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$, was synthesized and characterized by single-crystal X-ray diffraction analysis and magnetic measurements. The cluster compound crystallizes in the monoclinic system, space group $P2_1/n$ (No. 14), with $a$ = 13.3728(5) Å, $b$ = 15.4281(7) Å, $c$ = 17.4335(7) Å, $\beta$ = 98.932(3)° and $Z$ = 2. The unit cell contains two identical molecular clusters, each consisting of six interacting $Cu^{2+}$ ($S$ = ½) ions. Within the cluster the six oxygen-bridged $Cu^{2+}$ ions are arranged in an almost regular hexagon. An analysis of the high-temperature part of the magnetic susceptibility reveals that the complex has a strong average ferromagnetic Cu–Cu exchange interaction of $|J_{av}/k_B|$ = (50.4 ± 1) K with a high-spin $S$ = 3 ground state. A satisfactory fit for the magnetic susceptibility and the magnetization in the whole accessible temperature range is obtained from a Heisenberg model with nonuniform exchange couplings within a ring, corresponding to a system of two weakly coupled trimers with a ferromagnetic intratrimer exchange coupling of $|J/k_B|$ = 72.5 K and a ferromagnetic intertrimer exchange coupling of $|J'/k_B|$ = 7 K.

## Introduction

Because of their unusual physical properties, large metal clusters have attracted much attention during the past two decades.[1,2] In particular, the ability of transition-metal clusters to form single-molecule magnets has stimulated the research community to synthesize new compounds with various exchange interactions between the magnetic ions within a cluster.[1–3] In addition, different spin configurations within a cluster, together with possible magnetic exchange between neighbouring clusters, are of interest in molecular and low-dimensional magnetism because these systems may play an important role in future applications.

From a widespread series of molecular polymetallaorganosiloxane complexes, we have concentrated our interest on the family $[M_N\{(RSiO_2)_N\}_2]\cdot N$(Ligand) (where M = Ni, Mn, Co, Cu,…; $N$ = 6, 8, 10,…; R = Et, Ph, Me,…; Ligand = EtOH, DMF,…), having a sandwich-like molecular structure. In the past decades, some representatives of this family have been obtained and their molecular structures have been established by single-crystal X-ray analysis.[4–8] These clusters are composed of two 2$N$-membered ($N$ Si + $N$ O) cycloorganosiloxanolate fragments linked together through $N$ metal atoms. These polymetallaorganosiloxane complexes offer the potential to study the magnetic properties of molecular quantum rings experimentally. It should be noted that in a subfamily of copper-containing organosiloxanes with $N$ = 6, only three representatives of hexanuclear copper(II) siloxanes with phenyl substituents at silicon atoms, $[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6EtOH$, $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6DMF\}\cdot 4DMF$ and $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 5BuOH\}\cdot 3^nBuOH$, have been described in the literature.[4,6,8] For the previously reported ring-shaped molecular complex $[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6EtOH$,[9] it was demonstrated that the six copper ions within the ring are ferromagnetically coupled ($J/k_B$ = –60 K) with a total spin $S_{tot}$ = 3 ground state. The complex $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 5BuOH\}\cdot 3^nBuOH$ also has a high-spin $S_{tot}$ = 3 ground state, but its magnetic data indicate a strong nonequivalence of exchange pathways

within the ring ($J_1/k_B$ = –89.2 K, $J_2/k_B$ = –15.3 K).[8] For more detailed investigations on the mechanisms leading to the formation of a high-spin ground state and the influence of various substituents and/or ligands of the molecule on the magnetic behaviour of the quantum ring, we have attempted to expand the existing class of copper-containing molecular magnets by the synthesis of new isostructural molecular complexes.

Here we report on the synthesis, structure and magnetic properties of a novel sandwich-like hexacopper hexamethylcyclohexasiloxane complex, $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$. In contrast to the phenyl analogues previously reported,[4,6,8] the present complex has methyl groups as substituents at the silicon atoms. Preliminary results of this work have been published in ref.[10], in which the high-temperature susceptibility of this complex has been analyzed and an initial comparative investigation of the structural and magnetic properties has been carried out.

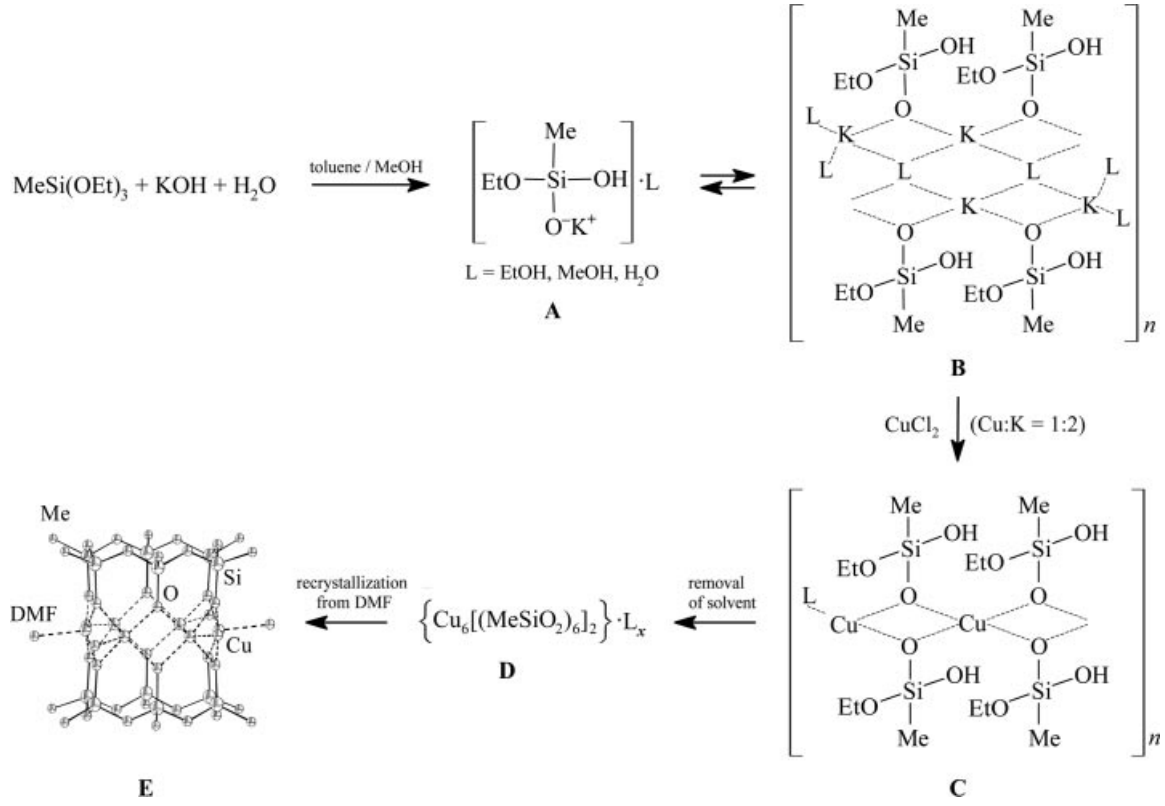
## Results and Discussion

The synthesis of sandwich-like polyhedral metallaorganosiloxanes containing transition metals is commonly based on an exchange reaction of alkali-metal organosiloxanolates[11] with transition-metal chlorides in alcohol-containing media.[4–6,12,13]

Similarly, the novel copper methylsiloxane $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ (**E**) has been obtained in a two-step reaction (Scheme 1). The first step involves an alkaline hydrolysis of methyltriethoxysilane $MeSi(OEt)_3$ (Si/KOH ratio of 1:1) in a toluene/methanol mixture generating in situ a potassium methylsiloxanolate intermediate **A**. A spontaneous association of potassium methylsiloxanolate intermediates **A** leads to the formation of aggregates **B**, in which an ionic network containing alcohol and water molecules is surrounded by organosilicon species with functional groups. In a second step, the addition of a methanolic solution of $CuCl_2$ (Cu/K ratio of 1:2) initiates an irreversible exchange reaction that substitutes the potassium ions with copper ions. Consequently, potassium chloride precipitates from the reaction. Thus, aggregates **B**, originally containing only alkali metals, are reorganized into new aggregates **C**, now possessing only copper atoms. Finally, condensation of EtO– and OH– functional groups at silicon results in the formation of the cyclic siloxane fragments.

After filtration of precipitated KCl, complete evaporation of the solvent from aggregates **C** gives a greenish-blue product **D** with a yield up to 82.5%. A powder X-ray diffraction analysis (XRD) of the obtained product **D** proved that the product was in the crystalline state. However, the crystals were too small for single-crystal X-ray analysis.

To identify product **D**, we used a well-known approach applied in organosilicon chemistry, preparing the trimethylsilyl-substituted derivative of the functional system. This general route was optimized for the treatment of metallaorganosiloxanes.[13] According to Scheme 2, the cyclic siloxane fragments of the starting metallaorganosiloxanes were isolated as a trimethylsiloxy derivative with retention of the



Scheme 1.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

size and configuration of the rings. Consequently, the correspondence of crystalline **D** to the formula $[Cu_6\{(MeSiO_2)_6\}_2]\cdot L_x$ was confirmed by its trapping reaction with $Me_3SiCl$ and subsequent NMR spectroscopy investigations on the resulting product.

$$\left\{Cu_6[(MeSiO_2)_6]_2\right\}\cdot L_x + Me_3SiCl \xrightarrow[-\,CuCl_2]{\text{py, hexane}} \left[MeSi(O)(OSiMe_3)\right]_6$$

Scheme 2.

The $^1H$ NMR spectrum of $[MeSi(O)(OSiMe_3)]_6$ exhibits two nonequivalent signals for the methyl groups: one singlet at 0.11 ([–$SiMe_3$]) and one singlet at $\delta$ = 0.03 ppm ([MeSi–]), with an integrated intensity ratio of 3:1.

The $^{29}Si$ NMR spectrum of $[MeSi(O)(OSiMe_3)]_6$ shows two signals: one singlet at $\delta$ = 8.50 ppm corresponds to the [–$OSiMe_3$] groups and the second one at –68.18 ppm ([Me-$SiO_3$–]) to the Si atoms in the hexamethylcyclohexasiloxanolate ring $[MeSi(O)O^-]_6$.

As the dried product **D** is insoluble in methanol, toluene or ethanol, DMF was used as a solvent for recrystallization, giving greenish-blue crystals **E** after a few months. X-ray analysis on suitable single crystals proved the product to be $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$. It should be noted that the crystals are very unstable in air because the desolvating occurs within a short time period, thereby reducing the properties of the crystal transparency.

### Crystal Structure of $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$

In accordance with the single-crystal X-ray analysis, the complex $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ crystallizes in the monoclinic system, space group $P2_1/n$ (no. 14) with $a$ = 13.3683(14) Å, $b$ = 15.388(2) Å, $c$ = 17.4383(14) Å, $\beta$ = 98.88(7)° and $Z$ = 2.

The complex $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ exhibits a ring-shaped sandwich-like structure (Figure 1). The molecule consists of two hexamethylcyclohexasiloxanolate ligands, $[(MeSiO_2)_6]^{6-}$, sandwiched by six $Cu^{2+}$ ions. Within the ring, the adjacent $Cu^{2+}$ ions are linked by pairs of siloxanolate oxygen atoms, which provide the main magnetic exchange path for the copper $S$ = 1/2 spins. The overall molecular building topology is analogous to that of the hexacopper(II) cyclohexaphenylsiloxanolates $[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6EtOH$,[4] $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6DMF\}\cdot 4DMF$[6] and $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 5BuOH\}\cdot 3^nBuOH$[8] described earlier.

It is important to note that the molecular structure of $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ is centrosymmetric, with a crystallographic inversion centre at the midpoint of the molecule. The molecules of the complexes $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6DMF\}\cdot 4DMF$ and $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 5BuOH\}\cdot 3^nBuOH$ also contain a crystallographic centre of inversion, while the complex $[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6EtOH$ shows a higher local symmetry of the molecules (trigonal symmetry $C_3$), giving only two symmetry-independent positions for copper atoms.

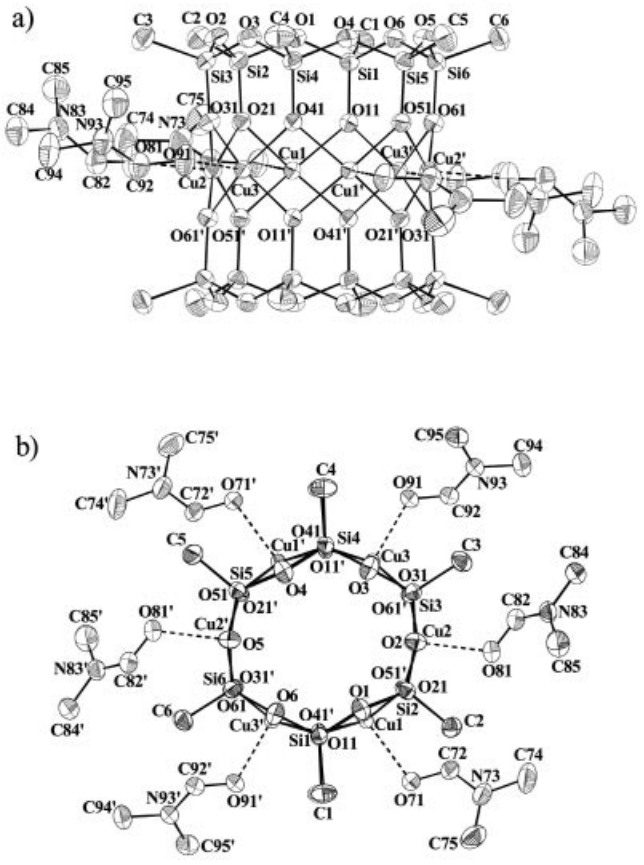


Figure 1. Side view (a) and top view (b) of the molecular structure of the complex $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ with the atomic labelling. The hydrogen atoms have been omitted for clarity. The dashed bonds indicate the apical coordination of the copper atoms. Displacement ellipsoids are drawn at the 50% probability level.

The hexamethylcyclohexasiloxanolate ligands have an *all-cis* configuration; the olate groups are directed towards the plane of the Cu atoms. The two 12-membered siloxanolate $(Si–O)_6$ rings are coaxial and parallel to each other. The Si–O(Si) bond lengths vary in the range of 1.624–1.636 Å and the Si–O–Si angles in the range of 133.98–136.64°, which are usual for this class of compounds.[4,5,7] The standard deviations of the Si and O atoms from the mean planes do not exceed 0.0004 Å and 0.0012 Å, respectively. The Si–O(Cu) bond lengths are significantly shorter (1.609–1.613, av. 1.611 Å) than the corresponding Si–O(Si) bond lengths in the hexasiloxane macrocycle. The Si–O–Si sections of the siloxanolate ring are nearly perpendicular to the mean plane of the Si atoms (dihedral angles 74.3–89.3°). The methyl group, attached to each of the $2\times 6$ Si atoms, points away from the molecule.

A metal group of the six $Cu^{II}$ atoms is arranged as an almost flat (standard deviation from the mean plane is 0.0002 Å) hexagon. In contrast to the complex $[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6EtOH$,[4] which has a high (trigonal) crystal symmetry, the hexagon in the complex $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ is slightly distorted. However, this distortion of the hexahedron is significantly smaller compared with the observed one in the complex

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

{[$Cu_6${$(PhSiO_2)_6$}$_2$]·6DMF}·4DMF.[6] In all cases the Cu, Si, O skeleton approaches 6/*mmm* symmetry. In the complex [$Cu_6${$(MeSiO_2)_6$}$_2$]·6DMF the nonbounded Cu–Cu distances are 2.816, 2.841 and 2.861 Å (av. 2.839 Å) and the distance between opposite copper atoms varies between 5.495(7) and 5.820(6) Å (av. 5.677 Å).

The coordination surrounding of the copper atoms in the complex [$Cu_6${$(MeSiO_2)_6$}$_2$]·6DMF is a slightly distorted oxygen square-pyramidal (SP) configuration. It should be noted that, similarly to the known sandwich-like complexes,[4,6,8] the copper–oxygen moiety is organized in the cyclic form by the oxygen atoms of the siloxanolate ligands and the SP configuration arises from the apical oxygen bonding with the solvent molecules. In the further discussion, the oxygen atoms of the siloxanolate ligands bound to the copper atoms will be indicated as equatorial, whereas the others, belonging to the DMF solvent, will be mentioned as apical or axial.

The equatorial Cu–O bonds in the complex vary in the range of 1.946–1.974 Å (av. 1.957 Å), which is close to the expected values for copper atoms with a square-pyramidal coordination environment. In the recently reported copper-containing siloxanolate complexes,[4,6,8] it was demonstrated that the average Cu–O bond lengths in the basal plane for SP (av. 1.96 Å) and in the case of square-planar configuration (av. 1.90 Å) are significantly different. The Cu–O–Cu angles at the bridging equatorial oxygen atoms, which mainly determine the magnetochemical behaviour of polynuclear clusters, vary in the range 91.26–94.59°, which is typical for other copper-containing sandwich-like organosiloxanes.[4,6,8] The average value of the Cu–O–Cu angle is about 93.02°.

All copper atoms are shifted from the mean planes of the slightly distorted basal squares of the equatorial oxygen atoms by 0.324 (for Cu1), 0.290 (Cu2) and 0.323 Å (Cu3) towards the external axially coordinated oxygen of DMF molecules. In the close analogues [$Cu_6${$(PhSiO_2)_6$}$_2$]·6EtOH and {[$Cu_6${$(PhSiO_2)_6$}$_2$]·6DMF}·4DMF, the shifts are 0.285(Cu1)–0.290(Cu2) and 0.345(Cu1)–0.288(Cu2)–0.349(Cu3) Å, respectively.

The six apical positions of all copper polyhedra in the complex $Cu_6[(MeSiO_2)_6]_2$·6DMF are occupied by the DMF oxygen atoms and the corresponding Cu–O bonds are always significantly longer than the equatorial ones. The apical Cu–O bonds vary in the range of 2.229(3)–2.322(6) Å (av. 2.273 Å).

Selected bond lengths and bond angles are summarized in Table 1.

Interestingly, in contrast to the complex {[$Cu_6${$(PhSiO_2)_6$}$_2$]·6DMF}·4DMF described earlier,[6] which was also recrystallized from DMF, the crystal structure of [$Cu_6${$(MeSiO_2)_6$}$_2$]·6DMF does not contain any additional solvate molecules within the intermolecular space.

It should be noted that the central cavity of the molecule contains a relatively large empty inner channel, suitable for small molecules or ions to enter the interior of the complex. The estimated diameter of the free cross-section is about 2.5 Å. Despite the similarity in the overall molecular building topology, the presence of an additional small anion, occupying the central cavity, was observed only for non-copper-containing metallasiloxanes (with Ni, Co, Mn).[5,7]

### Magnetic Properties of $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF

Magnetic susceptibility and magnetization measurements were performed on polycrystalline samples of $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF. The data were corrected for the contribution of the sample holder and for the diamagnetic core contribution. Notably, the temperature-independent contribution of $\chi_0 = -3.29 \times 10^{-3}$ cm$^3$/mol, determined by analyzing the high-temperature magnetic behaviour, is in reasonable agreement with the sum of the sample holder contribution of $\chi_{sholder} \approx -1.9 \times 10^{-3}$ cm$^3$/mol and the core contribution of $\chi_{core} = -1.37 \times 10^{-3}$ cm$^3$/mol calculated by using tabulated values for Pascal's constants.[14]

Figure 3 shows the molar magnetic susceptibility $\chi(T) = M(T)/B$ of complex $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF, where $M$ denotes the magnetic moment of the sample per mole. The data were found to be reversible upon cooling and heating, with no indications for hysteretic behaviour. Moreover, no sign of long-range magnetic ordering was observed in the temperature range under investigation. From isothermal magnetization measurements in dc fields from 0 to 5 T at varying temperatures (see Figure 6), we have also extracted the data for the differential magnetic susceptibility $[dM(T)/dB]_{B\to 0}$, which are indicated as the solid star symbols in Figure 3. The collapse of the susceptibility data onto a single curve shows that no significant field dependence occurs over the whole temperature (2–350 K) and field (0.01–0.2 T) range under investigation.

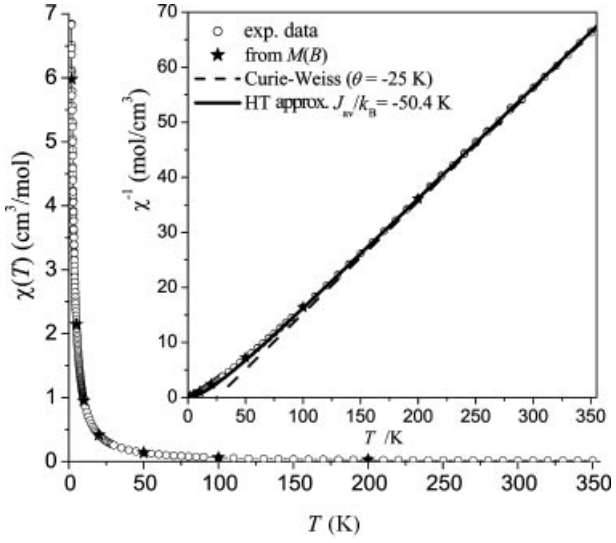

Figure 3. Temperature dependence of the magnetic susceptibility of complex $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF for temperatures 2–350 K. The data have been taken at magnetic fields of 0.01–0.2 T. Star symbols denote the susceptibility data extracted from isothermal magnetization measurements. The inset shows the inverse magnetic susceptibility. The solid line corresponds to the best fit using the high-temperature approximation Equation (2) with the parameter $J_{av}/k_B = (-50.4 \pm 1)$ K in the range 100–350 K. The dashed line corresponds to the calculated curve by using a simple Curie–Weiss law $\chi(T) = C/(T + \theta)$ for the six-site ring ($S = 1/2$; $g = 2.10$) with $\theta = -25$ K.

The analysis of the magnetic properties of the complex $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF was performed in the following three steps. First, in the high-temperature range, we used a Curie–Weiss law to obtain preliminary information on the sign and average magnitude of the exchange interactions between the six $Cu^{2+}$ ($S = 1/2$) ions inside the molecule. Next, in analogy to what has been done for other ring-shaped complexes,[8,9] we attempted to analyze the obtained experimental data within the framework of a model with uniform exchange couplings between nearest-neighbour spins within the ring. We found that this uniform exchange coupling model, even with the possible extensions such as significant intermolecular interactions, weakly anisotropic intramolecular exchange interactions or next-nearest neighbour exchange couplings, is not capable of satisfactorily reproducing the low-temperature part of the magnetic behaviour of this compound. In a third step, taking into account the structural symmetry properties of the molecule, we thus considered the most general Heisenberg model for the six-site ring with three a priori nonequivalent exchange couplings. This nonuniform nearest-neighbour exchange model, which has a parameter set corresponding to a pair of weakly coupled trimers with a strong ferromagnetic intratrimer coupling and a weak ferromagnetic intertrimer coupling, yields a satisfactory agreement with the observed experimental data.

### Magnetic Susceptibility at High Temperatures

In a first attempt at setting up a simple model capable of describing the main features of the magnetic susceptibility of the complex $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF at high temperatures, the magnetic behaviour can be assigned to a Curie–Weiss-like temperature dependence $\chi(T) = C/(T + \theta)$ with a Curie constant $C$ and a Weiss temperature $\theta$. In the temperature range 100–350 K, the best fit yields $C = 5.041$ cm$^3$ K/mol and $\theta = -17.7$ K. The obtained Curie constant is consistent with the presence of six $Cu^{2+}$ ions per molecule (two molecules per unit cell) yielding a spin-only value of $C_{theory} = 4.914$ cm$^3$ K/mol. The latter number is based on an average spectroscopic $g$-value of $2.10 \pm 0.02$, as determined by our high-temperature ESR measurements operated at X- and Q-band frequencies. It should be noted that all known ring-shaped copper complexes[4,6,8] have a similar square-pyramidal oxygen configuration of the nearest environment of the copper ions, therefore a quite close value of the average spectroscopic $g$-factor for the local magnetic centre is expected. For the recently reported phenyl analogues,[8,9] it was found that the average $g$-values of the $Cu^{2+}$ ions are in the range 2.11–2.12. The negative Weiss constant $\theta$ indicates a dominant ferromagnetic spin–spin interaction. It should be noted that a simple Curie–Weiss law implies a temperature-independent effective moment of the magnetic centres, which results in a strictly linear behaviour of the inverse magnetic susceptibility. As can be seen in the inset of Figure 3, the inverse magnetic susceptibility of the complex exhibits a weak nonlinearity over the entire high-temperature region and an appropriate microscopic magnetic model would be desirable.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

In search of a minimal microscopic model, we first assume isotropic Heisenberg exchange between nearest-neighbour spins in the ring, ignoring possible complications such as next-nearest neighbour couplings or anisotropic exchange interactions. Because of the inversion centre of the molecule (see Figure 1, b), bonds on opposite sites of the ring that are mapped onto each other by the symmetry transformation are equal and the most general Heisenberg model is given by Equation (1)

$$H = J_1(\mathbf{S}_1 \cdot \mathbf{S}_2 + \mathbf{S}_4 \cdot \mathbf{S}_5) + J_2(\mathbf{S}_2 \cdot \mathbf{S}_3 + \mathbf{S}_5 \cdot \mathbf{S}_6) + J_3(\mathbf{S}_3 \cdot \mathbf{S}_4 + \mathbf{S}_6 \cdot \mathbf{S}_1) - g\mu_B B \sum_{i=1}^{6} S_i^z \quad (1)$$

with three a priori nonequivalent exchange couplings, $J_1$, $J_2$ and $J_3$, which, from the molecular structure, might be expected to be close in magnitude. However, this expectation turns out not to be justified, as we will discuss in the next section. In Equation (1), $\mathbf{S}_i$ are spin-1/2 operators located at the Cu sites of the ring, $\mu_B$ is the Bohr magneton and $g$ is an average spectroscopic $g$-value of $Cu^{2+}$ ions.

A first estimate of the strength of the exchange couplings can be obtained from a high-temperature expansion of the magnetic susceptibility. The first terms are given by Equation (2)

$$\chi|_{h=0} = \frac{N\mu_B^2 g^2}{k_B} \frac{3}{2T}\left\{1 - \frac{J_{av}}{2k_B T} + O\left(\frac{Ji^2}{T^2}\right)\right\} \quad (2)$$

where $J_{av} = (J_1 + J_2 + J_3)/3$ is the average exchange interaction within the ring.[10,15] In Equations (2)–(4), $N$ is the number of spins and $k_B$ is the Boltzmann constant. For uniform exchange couplings $J_1 = J_2 = J_3$, we have compared this high-temperature approximation with results of a complete numerical diagonalization for spin $S = 1/2$ rings with $N = 6$ and concluded that this is in satisfactory agreement with the exact solution for temperatures above $3/2 \cdot J_{av}$.

In the inset of Figure 3 the solid line shows the best fit of the high-temperature expansion Equation (2) to the experimental data with the parameter $J_{av}/k_B = (-50.4 \pm 1)$ K. It should be noted that at high temperatures, the leading terms in the high-temperature expansion agree with the Curie–Weiss law, where, by expanding the latter in powers of $1/T$, one obtains $J_{av}/k_B = 2\theta$.

### Magnetic Behaviour at Low Temperatures

Before starting the discussion of the low-temperature part, a few interesting peculiarities of the low-temperature magnetic behaviour of the present complex observed in the experiment should be underlined. At $T = 2$ K, the product $\chi(T) \cdot T$ reaches a value of approximately 12 $cm^3/mol\,K$, which is close to what would be expected for two effective spins $S = 3$ per unit cell, but with an effective spectroscopic $g$-value $g = 2.00$, yielding $\chi \cdot T = 12.004\ cm^3/mol\,K$. Of course, this can be due to the fact that at the given temperature ($T = 2\ K \approx \frac{1}{25}|J_{av}/k_B|$) the system has not yet frozen into the state with full ferromagnetic alignment and a tendency toward the higher value of $2 \times (S = 3;\ g = 2.10) \rightarrow 13.234\ cm^3/mol\,K$ is observable (see the inset of Figure 4). Note that Figure 4 shows the normalized square of the effective moment $\chi \cdot T/(N\mu_B^2 g^2/k_B)$ of the complex $[Cu_6\{(MeSiO_2)_6\}_2] \cdot 6DMF$ (where we set $g = 2.10$) as a function of normalized temperature $T/J_{av}$. Additionally, the experimentally observed magnetization $M(B)$ of the complex at $T = 2$ K can be nicely reproduced by a Brillouin function for an effective spin $S = 3$, again with $g = 2.00$ (see the dashed line in Figure 6). The reason for this "high symmetry" isotropic behaviour of the effective $g$-tensor of the magnetic molecular cluster is not clear.

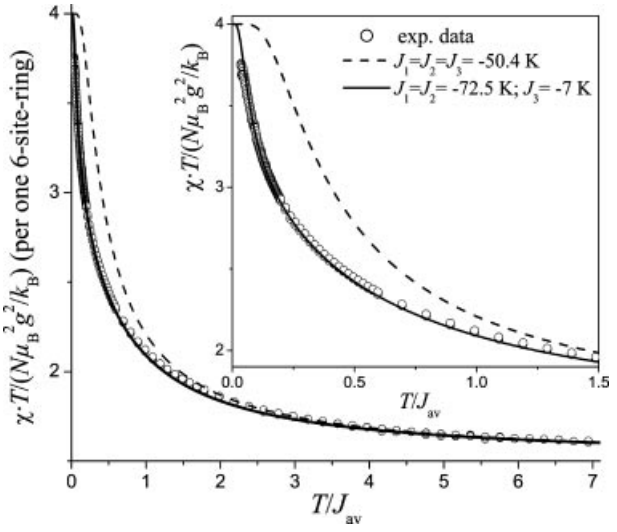

Figure 4. The product $\chi \cdot T/(N\mu_B^2 g^2/k_B)$ as a function of normalized temperature $T/J_{av}$. The inset shows the low-temperature behaviour on expanded scales. The dashed line indicates the theoretical result of a complete numerical diagonalization for uniform ferromagnetic exchange couplings within the ring. The solid line corresponds to the best fit for a nonuniform exchange coupling model.

In the case of uniform ferromagnetic couplings $J_1 = J_2 = J_3$ within the ring (as well as in the presence of weak anisotropy of these interactions), the parameter $J_{av}/k_B = -50.4$ K strictly determines the initial structure of the energy spectrum and, therefore, the quantitative characteristics of the crossover (the temperature evolution of the effective magnetic moment of the molecular cluster) from a low-temperature plateau of width $\sim\Delta/2 = \frac{1}{4}|J_{av}/k_B| = 12.6$ K to the $1/T$ behaviour at high temperatures discussed in the previous section. Here, $\Delta = |J| \cdot [1 - \cos(2\pi/N)] = |J|/2$ is the finite-size gap of spin-wave excitations above the high-spin ferromagnetic ground state corresponding to the splitting between the lowest two levels. The lowest levels of the resulting energy-level scheme for a model with uniform exchange couplings with $J_{av}/k_B = -50.4$ K are sketched in Figure 5 (left part). In Figure 4, the numerical result for the product $\chi \cdot T/(N\mu_B^2 g^2/k_B)$ for the uniform-exchange model with $J_{av}/k_B = -50.4$ K is shown as a black dashed line. A

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

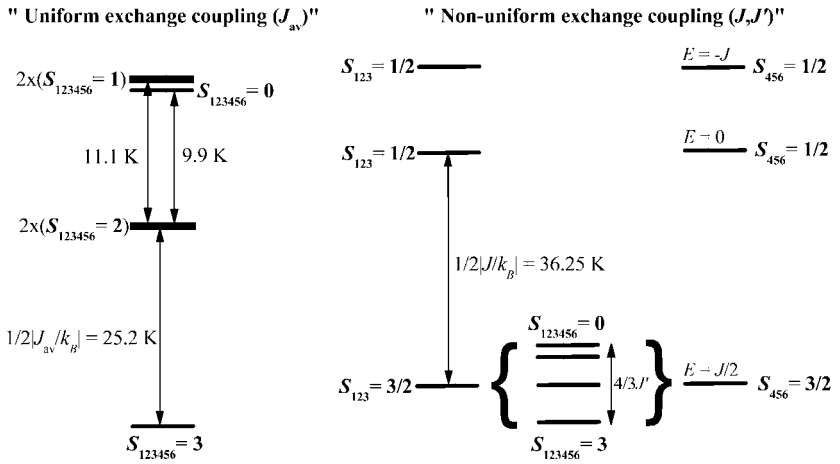

Figure 5. Energy-level schemes for a uniform ferromagnetically coupled ring (left part) with $J_{av}$ and for two weakly coupled trimers (right part) with a strong ferromagnetic intratrimer coupling $J$ and a weak ferromagnetic intertrimer coupling $J'$. Only the splitting of the high-spin ground state of the complex due to the coupling $J'$ is considered, as the splitting of excited states is not relevant for the thermodynamic quantities in the temperature and field range considered here.

closer look at the experimental data in Figure 4 reveals that $\chi \cdot T/(N\mu_B{}^2g^2/k_B)$ does not show a low-temperature plateau in the accessible temperature range. This indicates that the ground state of the magnetic cluster might be composite, and the presence of other energy levels at a distance of a few Kelvin from the ground $S_{123456} = 3$ multiplet is possible. Furthermore, Figure 4 reveals that significant deviations of the experimental data from the results for the uniform-exchange model with $J_{av}/k_B = -50.4$ K become visible at temperatures below approximately 100 K. A comparison to the total width of the spectrum of $|E_{FM} - E_{AFM}| = 8.6 \times 50.4/2 \approx 217$ K for this case already hints at the fact that to account for these deviations a significant adaptation of the model is required.

In order to fix further the parameters of the microscopic model, we analyzed the low-temperature behaviour of the magnetic susceptibility more carefully. To this end, the Hamiltonian in Equation (1) can easily be diagonalized numerically, as the dimension of the largest subspace to be considered is only 20 using the conservation of the $z$ component of the total spin. For uniform exchange couplings $J_1 = J_2 = J_3$, even analytic results can be obtained exploiting translational invariance.[16] For convenience, we will only use numerical results here, as well as a perturbative treatment for $J_1 = J_2 \equiv J$ and $J_3 \equiv J'$, $|J'| << |J|$. In Figure 4 the presentation of the product $\chi \cdot T/(N\mu_B{}^2g^2/k_B)$ as a function of normalized temperature $T/J_{av}$ has been chosen in order to simplify the comparison of the data with various theoretical predictions. Note also that the set of exchange coupling parameters $\{J_1, J_2, J_3\}$, extracted for a particular model, always have to be in agreement with the average value $J_{av}/k_B = -50.4$ K obtained from the high-temperature fit in the previous section.

The absence of a sizeable finite-size gap above the high-spin ferromagnetic ground state might be attributed to intermolecular interactions, either of dipolar or exchange type. However, rather large intermolecular distances and the absence of an apparent exchange path between neighbouring molecules lead us to search for intramolecular mechanisms to explain the low-temperature behaviour. As candidates, we have envisioned anisotropic intramolecular exchange and next-nearest neighbour exchange, as well as a nonuniform exchange.

Our low-temperature ESR measurements show a zero-field splitting in the order of 1 K, so that it seems natural to analyze the influence of anisotropies on the low-temperature behaviour of the susceptibility. Microscopically, such anisotropies can arise from anisotropic exchange interactions as well as intramolecular dipolar interactions. In the high-spin low-energy subspace they lead to an effective single-ion anisotropy term of the form $H = D(S^z_{tot})^2$, where $\mathbf{S}_{tot} = \mathbf{S}_1 + \ldots + \mathbf{S}_6$ and $D$ can in principle be obtained as an average over the microscopic anisotropic exchange parameters. Yet, a quantitative analysis of such anisotropy terms reveals that the angular average of the susceptibility is only changed below a temperature scale in the order of $D$. Furthermore, $\chi \cdot T$ is reduced for $T \rightarrow 0$ and shows a maximum at a temperature $\sim D$. This behaviour is clearly not observed in the experiment and we conclude that the anisotropies seen in ESR measurements are too small to be relevant to thermodynamic quantities in the temperature range under consideration.

From a numerical treatment of next-nearest-neighbour exchange we find a slightly better fit to the experimental data than with just the nearest-neighbour exchange. Yet, the agreement is not satisfactory, as the functional form with a very steep decrease of $\chi \cdot T$ at low temperatures does not correspond to the experimentally observed curve.

To analyze nonuniform exchange, we consider $J_1 = J_2 = J$ and $J_3 = J'$, which might correspond, for example, to the following exchange links between the Cu1–Cu2, Cu2–Cu3 and Cu3–Cu1′ atoms, respectively. It turns out that for $|J'| << |J|$ a good fit of the experimental data can indeed be achieved. The model then reduces to two weakly coupled

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

trimers with a strong ferromagnetic intratrimer coupling $J$ and a weak ferromagnetic intertrimer coupling $J'$. The solid line in Figure 4 shows the best fit of the effective magnetic moment with nonuniform exchange couplings, yielding $J/k_B$ = –72.5 K and $J'/k_B$ = –7 K. For these parameters, a perturbative treatment of the intertrimer coupling is possible. The resulting level scheme is sketched in Figure 5 (right part). The energy spectrum of an isolated ferromagnetic trimer consists of a quartet ground state separated from two excited doublets by an energy gap $|J/2|$ and $|3J/2|$, respectively. The ground-state splitting $4/3|J'|$ of two ferromagnetic trimers within the molecule is due to ferromagnetic intertrimer coupling. For the magnetization and the magnetic susceptibility, only the splitting of the high-spin ground state due to the intertrimer coupling $J'$ is relevant and we can obtain analytic formulas, for example, the magnetic susceptibility is given by Equation (3)

$$\chi(T) = \frac{N\mu_B^2 g^2}{k_B}\,\frac{1}{2T}\,\frac{x^{-6}\left(1+x^2+2x^3\right)\left(1+x^2+10x^3\right)+\left(14y^9+5y^{-3}+y^{-11}-20\right)}{x^{-6}\left(1+x^2+2x^3\right)^2+\frac{1}{4}\left(7y^9+5y^{-3}+3y^{-11}+y^{-15}-16\right)} \tag{3}$$

where $x = \exp[-(J/2k_BT)]$ and $y = \exp[-(J'/18k_BT)]$. Equation (3) can be checked by comparison with numerical diagonalization for the full model. At least up to $|J'/J| \leq 0.1$, we obtain excellent agreement with the exact result. Note that for $J' \to 0$ Equation (3) results as expected in twice the susceptibility of an isolated ferromagnetic trimer. In contrast to the antiferromagnetically coupled trimer model described earlier,[3] the influence of $J'$ on the magnetic susceptibility is rather strong and the deviations from the pure ferromagnetic trimer model become visible even at relatively high temperatures. This can be understood by noting that the saturation value of the product $\chi T|_{J' \to 0,\ T \to 0} = 5/2$ for two isolated trimers within a molecule is significantly reduced compared to $\chi T|_{J' \neq 0,\ T \to 0} = 4$ for the high-spin $S = 3$ ground state.

### Magnetization Curves

The magnetization of the complex $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ at various temperatures is shown in Figure 6 as a function of the applied magnetic field. In order to check the main result obtained from the analysis of the magnetic susceptibility, we have also calculated the isothermal magnetization curves for the above-discussed models of a uniform ferromagnetically coupled ring with $J_{av}/k_B$ = –50.4 K and nonuniform exchange couplings with $J/k_B$ = –72.5 K and $J'/k_B$ = –7 K. The uniform-exchange model progressively departs from the experimental data below 100 K (calculated curves are not shown). On the other hand, a very good description, except for the data taken at the lowest temperature of 2 K, can be achieved by the model with nonuniform exchange couplings.

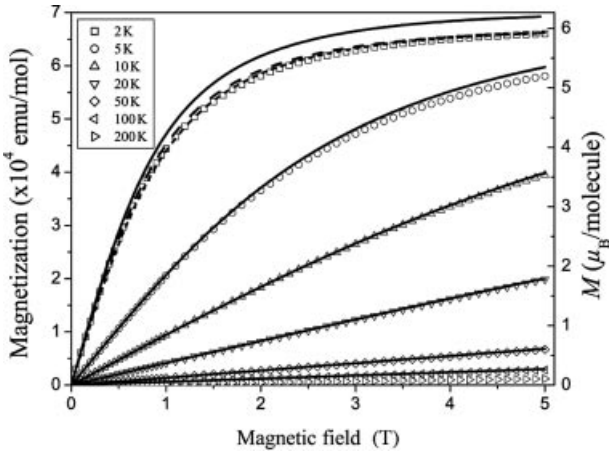

Figure 6. Isothermal magnetization measurements in dc fields from 0 to 5 T at varying temperatures as indicated in the figure. The right scale of the main panel is given in units of $\mu_B$ per molecule. The solid lines indicate the theoretical results for a nonuniform exchange coupling model with $J/k_B$ = –72.5 K and $J'/k_B$ = –7 K ($g$ = 2.10). The dashed and short dashed lines correspond to the calculated magnetization curve (Brillouin function) at $T$ = 2 K for isolated magnetic quasiparticles with $S$ = 3 and $g$ = 2.00 and for the above-mentioned nonuniform coupling model with $g$ = 2.00, respectively.

For the model with nonuniform exchange couplings, we can obtain a perturbative analytic expression for the magnetization in Equation (4)

$$M(T,h) = N\mu_B g \cdot \frac{2x^{-6}\left(Z'_{½}+Z'_{½}x^2+Z'_{½}x^3\right)\left(Z_{½}+Z_{½}x^2+Z_{½}x^3\right)+\left(Z'_3y^9+Z'_2y^{-3}+Z'_1y^{-11}-2Z'_{½}Z_{½}\right)}{x^{-6}\left(Z_{½}+Z_{½}x^2+Z_{½}x^3\right)^2+\left(Z_3y^9+Z_2y^{-3}+Z_1y^{-11}+y^{-15}-Z_{½}^2\right)} \tag{4}$$

where $h = \frac{g\mu_B}{k_B}B$, $Z_s(t) = \frac{\sinh(t[s+1/2])}{\sinh(t/2)}$ is the partition function of a single half-integer spin $s$ as a function of the dimensionless magnetic field $t = \frac{h}{T}$, and its derivative is given by

$$Z'_s(t) = (s+1/2)\frac{\cosh(t[s+1/2])}{\sinh(t/2)} - \frac{\sinh(t[s+1/2])\cosh(t/2)}{2\sinh^2(t/2)}.$$

$x$ and $y$ are defined below Equation (3). The approximate result in Equation (4) can again be checked against the complete numerical solution yielding very good agreement for at least $|J'/J| \leq 0.1$ for all relevant temperatures.

The calculated magnetization curves for a model with nonuniform exchange couplings with $J/k_B$ = –72.5 K and $J'/k_B$ = –7 K ($g$ = 2.10) are shown in Figure 6 as solid lines. As shown in Figure 6, we have obtained a very satisfactory agreement with the experimental data for the complex $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ over the whole temperature range under investigation, except for data taken at $T$ = 2 K. The deviations between theory and experiment become visible below 5 K. However, we should note once more that the magnetization curve at $T$ = 2 K can be nicely simulated

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

by using a Brillouin function for isolated particles with $S$ = 3 and $g$ = 2.00 (dashed line) or by using our nonuniform exchange model with an effective $g$-value of 2.00 (short dashed line). We would like to point out however that the same conceptual problem arises in ref.[8]: The low-temperature magnetization of the complex $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 5BuOH\}\cdot 3^nBuOH$ also shows a saturation value expected for $S$ = 3 with $g$ = 2.00.

## ESR Measurements

In two papers reported only recently,[8,9] high-frequency ESR (HF-ESR) techniques were used to investigate polycrystalline powder samples of $[Cu_6\{(PhSiO_2)_6\}_2]\cdot 6EtOH$ and $\{[Cu_6\{(PhSiO_2)_6\}_2]\cdot 5BuOH\}\cdot 3^nBuOH$ to study the nature of the ground spin state of ferromagnetic rings and to obtain the effective magnetic anisotropy parameters of paramagnetic clusters. It was demonstrated that two sets of the equally spaced resonances at high exciting frequency might be attributed to the parallel and perpendicular transitions of an anisotropic paramagnet with an effective $S$ = 3 spin and unresolved rhombicity ($E$ = 0). The sign of the zero-field splitting parameter $D > 0$ corresponds to a hard-axis type anisotropy. The molecular $g$-tensor shows an axial symmetry with an unusual feature of "reversed" $g$-values ($g_\parallel < g_\perp$), which is not in accordance with the expected correlation ($g_\parallel > g_\perp$) for the local $g$-tensor with a square-pyramidal environment of the copper centres. Notably, there are still two small questions in the interpretation of magnetic data based on a uniform/nonuniform microscopical model, which the HF-ESR measurements on polycrystalline powder samples did not answer. (i) The reported magnetic anisotropy parameters $D$ (0.3 and 0.308 $cm^{-1}$) are quite similar, showing that the initial splitting of the $S$ = 3 manifold remains almost insensitive to the anisotropy of exchange interactions within the ring (uniform and nonuniform exchange cases). (ii) The absence of additional transitions to the variable-temperature HF-ESR polycrystalline spectra in the temperature range up to 100 K may indicate that the ground $S$ = 3 state of a molecular cluster is well thermally isolated from the other excited multiplets.

Performing the resonance measurements on single crystals of $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$, a more complicated situation than that described in the literature was found. Single-crystal ESR spectra were recorded using the cavity technique in the frequency range 26–56 GHz with an opportunity of a sample rotation in three mutually perpendicular planes. The ESR spectra at 38.816 GHz ($T$ = 1.5 K) for two different directions of the magnetic field are shown in parts a and b of Figure 7. Each spectrum consists of up to 20 well-resolved absorption lines (ESR active) with an average line width in the order of 28 mT. The angular dependence of the resonance line positions shows the strong magnetic anisotropy. The appearance of the spectrum with multicomponent structure may be interpreted as follows: (1) The energy spectrum of individual clusters is strongly anisotropic; consequently the presence of two nonequivalent molecules in the unit cell with an angle of 51.5° between the local axial axis might double the ESR spectrum (in the literature[8,9] this effect is not observed or discussed for polycrystalline powder samples). (2) According to a nonuniform model, the excited states ($S$ = 2, 1, 0) of the molecular cluster of $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ are close to each other and to the ground multiplet $S$ = 3 (in the distance of a few Kelvins); all of the states are split, consequently the extra transitions between different sublevels inside and/or between different multiplets are possible.

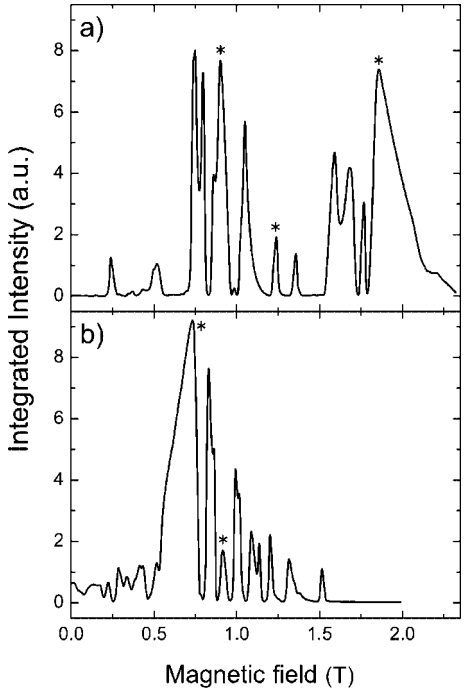

Figure 7. ESR spectra recorded on a single-crystal sample of $[Cu_6\{(MeSiO_2)_6\}_2]\cdot 6DMF$ at 38.816 GHz ($T$ = 1.5 K). (a) Parallel and (b) perpendicular to the axial axis of a molecule.

In the case of a few close multiplets, the ESR spectra for a $S$ = 3, 2 or 1 system can be interpreted separately for each manifold by the effective spin Hamiltonian

$$H = D[S_x^2 - 1/3S(S+1)] + E(S_x^2 - S_y^2) + \mu_B \mathbf{S}\cdot\mathbf{g}\mathbf{B},$$

in which each set of anisotropic parameters $D$, $E$, $\mathbf{g}$ will correspond to the given effective spin $S$ = 3, 2 or 1. It should be stressed that $D$, $E$, $g_\parallel$, $g_\perp$ are effective parameters for an effective spin $S$, and they cannot be used directly in the microscopic model (1). A single ion anisotropy is not possible for a spin $S$ = 1/2 ($Cu^{2+}$ ions) and only an effective anisotropy term $D$ of the complete molecule can arise from an anisotropy of the exchange interactions within the ring. The molecular $g$-tensor for a given geometry is related in a complicated way to the local $g$-tensors of individual Cu sites.

Analysis of the resonance data reveals that some lines of the spectrum (marked by * symbols in Figure 7) might be attributed to transitions for the split $S$ = 3 multiplet with unresolved rhombicity, as reported for polycrystalline pow-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

der measurements.[8,9] The magnetic anisotropic parameters obtained for the split $S = 3$ multiplet are: $g_{\parallel} = 2.05$, $g_{\perp} = 2.22$, $D = 14.5$ GHz (0.48 $cm^{-1}$) and $E = 0$. The value of the zero-field splitting parameter $D$ is in good agreement with the estimation obtained from the single-crystal X-band spectra of $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF. Single-crystal ESR measurements have confirmed an unchangeable character of the molecular $g$-tensor with good accuracy for polymetallaorganosiloxane complexes. It should be noted that the larger magnitude of the effective anisotropy parameter $D$ of the $S = 3$ manifold for the given complex indicates the larger anisotropy of exchange interactions within the ring compared to the previously reported analogues.[8,9]

A weak ferromagnetic intertrimer coupling $|J'/k_B| = 7$ K produces the total energy splitting of $4/3|J'/k_B| = 9.33$ K between idealized (non-split) $S = 3$ and $S = 0$ states (see energy-level scheme for the coupling of two "effective $S = 3/2$ spins" in Figure 5). Note, the energy interval to the nearest excited state $S = 2$ takes half of this value and is 4.67 K. For the obtained effective parameter $D = 14.5$ GHz the expected total splitting of the $S = 3$ state is 6.26 K. Thus, if we assume that all close states $S = 3, 2, 1$ are split by anisotropy of exchange interactions within the ring then the energy overlap or superposition of the different sublevels associated with the different manifolds is expected. According to this complication, a classification of all detected resonances in the frame of all possible transitions for excited and ground states was avoided. We consider that the other ESR-active lines, which are not marked in Figure 7, might be associated to the sublevel transitions for the split $S = 2$ and $S = 1$ states and their satellites arising from a second independent molecule. The slightly different values of the effective anisotropy parameter $D$ for the $S = 2$ and $S = 1$ states compared with the corresponding value for the $S = 3$ state are expected.

## Conclusions

This paper reports on the synthesis, X-ray crystal structure and magnetic properties of a new oxygen-bridged hexanuclear copper(II) hexamethylcyclohexasiloxane complex, $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF. In contrast to the known phenyl analogues, the present complex has methyl groups as substituents at the silicon atoms. This compound has a sandwich-like molecular structure. The molecule contains a planar ring of six oxygen-bridged $Cu^{II}$ atoms arranged in an almost regular hexagon and sandwiched by two hexamethylcyclohexasiloxanolate ligands.

Investigations of the magnetic properties in the high-temperature region have shown that the molecular complex has a strong average ferromagnetic Cu–Cu exchange interaction of $|J_{av}/k_B| = (50.4 \pm 1)$ K, which produces a high-spin $S = 3$ molecular ground state. Yet, at temperatures below about 100 K, significant deviations between the experimental susceptibility data and the theory for a model with uniform nearest-neighbour exchange couplings become visible. Because of rather large intermolecular distances and the absence of an apparent exchange path, intermolecular interactions of either dipolar or exchange type do not seem likely. Attempts to modify the uniform-exchange model by including weakly anisotropic intramolecular exchange terms (because of slight distortions of copper–oxygen exchange bridges) or next-nearest neighbour exchange do not lead to a satisfactory agreement with the experimentally observed curve either. However, good fits for the magnetic susceptibility and the magnetization in the whole accessible temperature and field range can be obtained from an isotropic Heisenberg model that has nonuniform nearest-neighbour exchange couplings corresponding to weakly coupled trimers with a strong ferromagnetic intratrimer exchange coupling of $|J/k_B| = 72.5$ K and a weak ferromagnetic intertrimer exchange coupling of $|J'/k_B| = 7$ K.

Such dramatic variations in the magnitude of the exchange couplings within the ring might seem surprising in light of the almost regular hexagonal arrangement of the $Cu^{2+}$ ions. However, it is well known that small variations in the bonding angles of oxygen exchange bridges can significantly influence the exchange couplings. For the family of the ring-shaped polynuclear $Cu^{II}$ cyclomethylsiloxanolate complexes, the critical bonding angle of the oxygen bridge Cu–O–Cu for a transition between ferromagnetic and antiferromagnetic exchange is approximately 96°.[10] Yet, it seems plausible that the highest bonding angles of about 94° (see Table 1) might be close enough to the critical angle that the corresponding exchange coupling is significantly reduced compared to the other two. Our results thus seem to suggest that the magnetic properties of quantum rings are very susceptible to small structural infringements of symmetry, which at once effectively split the ring as a whole into a system with simpler blocks: poorly cooperating trimers or dimers.

## Experimental Section

**General Remarks:** All chemicals used were of high quality and purchased from Aldrich. The solvents were dried and distilled prior before use. Calculations on KOH were made based on the content of KOH (85%, Aldrich).

**Synthesis of $[Cu_6\{(MeSiO_2)_6\}_2]$·6DMF:** $MeSi(OEt)_3$ (10 mL, 0.05 mol), KOH (3.3 g, 0.05 mol), water (0.9 mL, 0.05 mol) and MeOH (80 mL) were added to toluene (80 mL) under vigorous stirring. The reaction mixture was stirred for 45 min at room temperature and then heated up to the boiling point. A solution of $CuCl_2$ (3.4 g, 0.025 mol) in MeOH (80 mL) was added dropwise. The reaction mass was refluxed for 10 min and filtered. The solution was evaporated and dried in vacuo (1 Torr, at 80 °C). A greenish-blue crystalline product **D** (see Scheme 1) was obtained. Yield: 4.43 g (82.5%). This product was dissolved in DMF (50 mL) under heating and left to crystallize. The recrystallization process took a few months and transparent greenish-blue crystals, suitable for the X-ray structure analysis, were obtained. $C_{30}H_{78}Cu_6N_6O_{30}Si_{12}$ (1721.30): C 20.93, H 4.57, N 4.88; found C 20.19, H 4.53, N 4.58.

**Trimethylsilylation of Product D:** A mixture of product **D** (1.5 g, 1.2 mmol) and pyridine (3.5 mL, 43.2 mmol) was slowly stirred for 15 min. $Me_3SiCl$ (7.28 mL, 7.6 mmol) was added while slowly stirring. The reaction mixture was stirred for another 10 min at room

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

temperature and then hexane (30 mL) was added. The solution was heated and refluxed for 55 min. The mixture was cooled to room temperature, washed with water to remove $Cl^-$, dried with $Na_2SO_4$ and the solvent was evaporated. A viscous colourless product was obtained after drying in vacuo (1 Torr, at 50 °C, 1 h). Yield: 0.56 g (53.57%). $^1$H NMR: $\delta$ = 0.11 (s, 9 H, –OSiMe$_3$), 0.03 (s, 3 H, MeSiO$_3$–) ppm. $^{29}$Si NMR: $\delta$ = 8.50 (s, –OSiMe$_3$), –68.18 (s, MeSiO$_3$–) ppm.

**Single-Crystal X-ray Crystallography:** A single crystal (greenish-blue block with dimensions $0.52 \times 0.49 \times 0.37$ mm) was measured on a Stoe-IPDS-II diffractometer in $\omega$-scan mode. An empirical absorption correction was performed using the MULABS option[17] in PLATON.[18] Structure solution was performed by direct methods using SHELXS-97[19] and structure refinement by full-matrix least-squares on $F^2$ with SHELXL-97.[20] Hydrogen atoms were placed at ideal positions and refined with fixed isotropic displacement parameters using a riding model.

Detailed crystal data and experimental parameters are given in Table 2.

CCDC-630857 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Magnetic Susceptibility and Magnetization Measurements:** Variable-temperature magnetic susceptibility measurements in the temperature range 2–350 K and magnetic fields 0.01–0.2 T were carried out on a polycrystalline sample ($m$ = 97.85 mg) using a Quantum Design SQUID magnetometer MPMS-XL. These measurements were complemented by isothermal magnetization runs at temperatures between 2 and 200 K for fields up to 5 T.

**NMR Measurements:** $^1$H and $^{29}$Si NMR spectra were recorded with a Bruker Avance 400 spectrometer ($^1$H, 400.13 MHz; $^{29}$Si, 79.495 MHz) at 30 °C in $CDCl_3$. Chemical shifts ($\delta$, ppm) were measured relative to TMS ($\delta$ = 0.00 ppm).

**ESR Measurements:** Powder and single-crystal ESR spectra of the compound [Cu$_6${(MeSiO$_2$)$_6$}$_2$]·6DMF were recorded employing various spectrometers operating on different fixed frequencies in the range 9.5–134 GHz equipped with a variable-temperature Oxford cryostat with an accessible temperature range of 1.4–300 K.

**Supporting Information** (see also footnote on the first page of this article): View of the crystals (Figure S1), comparison of the magnetic susceptibility data with calculations for alternative models (Figures S2, S3 and S4) and the calculated magnetization curves for uniform and nonuniform models (Figure S5).

# Dinuclear Titanium(IV) Complexes Bearing Phenoxide-Tethered N-Heterocyclic Carbene Ligands with *cisoid* Conformation through Control of Hydrolysis

**Dao Zhang*[a]**

**Keywords:** Titanium / Carbene ligands / Phenoxides

In situ generated N-heterocyclic carbene salt derivative $Na_2(L)$ of 1,3-bis(4,6-di-*tert*-butyl-2-hydroxybenzyl)imidazolium bromide, $[H_3(L)]Br$, reacted with 1 equiv. of $TiBr_4$ at –78 °C to give a titanium complex of the composition $[(L)TiBr_2(thf)]$ (**1**), while the reaction in a 2:1 ratio under the same conditions afforded bisligand titanium complex $[(L)_2Ti]$ (**2**). Two oxygen-bridged titanium dimers, $\{[(L)TiBr]_2(\mu\text{-}O)\}$ (**4**) and $\{[(L)Ti(\mu\text{-}O)]_2\}$ (**5**), were obtained by control of hydrolysis of **1** and $[(L)Ti(CH_2Ph)_2]$ (**3**) in tetrahydrofuran and diethyl ether. The molecular structures of **2**, **4**, and **5** have been confirmed by X-ray single-crystal analysis. The phenoxide-functionalized NHC ligand adopts *transoid* conformation in mononuclear complex **2** but rare *cisoid* conformation in dinuclear complexes **4** and **5**.

## Introduction

N-Heterocyclic carbene (NHC) ligands are heterocycles that bind as soft, two-electron donors through the NCN carbon atom, and are now used widely as strongly basic phosphane analogs, to support transition-metal complexes.[1] The overwhelming majority of NHCs are functionalized (with respect to the N and N′ substituents) by incorporating neutral donor or anionic groups such as pyridyl, phosphane, NHC, amide, alkoxide, and cyclopentadienyl.[1–14] In contrast, the diversity of NHC ligands found in high-oxidation-state transition-metal chemistry and homogeneous catalysis is conspicuously absent in early transition-metal NHC systems because of the ease of dissociation of the NHC ligand from the electron-deficient metal center, which makes it difficult to study the chemistry of NHCs in early transition metals and f-elements.[2–8]

In recent years, we have been investigating the use of aryl oxides linked to the NHC donor by a $C_1$ alkyl chain to generate asymmetric, heterobidentate and symmetric, heterotridentate ligands (Scheme 1) through which we can explore the NHC binding to *s*-block and early transition metal cations.[8] Earlier we reported the application of the bisphenoxy-substituted NHC ligand $(L)^{2-}$ – $[H_3(L)]Br$ = 1,3-bis(4,6-di-*tert*-butyl-2-hydroxybenzyl)imidazolium bromide) – and its corresponding aryloxy–NHC IVB metal complexes $[(L)MX_2]$ (M = Ti, Zr; X = Cl, $CH_2Ph$).[8a,8c] Among these complexes, the dichloride titanium complex has been proven to be a highly active procatalyst (up to $10^5$ g PE $mol^{-1}$ Ti $h^{-1}$) for polymerization of ethylene under methylaluminoxane (MAO) activation.[8c] The X-ray crystallography analysis of these Ti and Zr compounds revealed that only *transoid* conformation ligands were observed (Scheme 2). Herein, we wish to describe the synthesis and structural characterization of the first dinuclear titanium complexes supported by phenoxide-tethered N-heterocyclic carbene ligands, the tridentate chelate bianionic $(L)^{2-}$ with *cisoid* conformation (Scheme 3).

## Results and Discussion

The bromide titanium complex [(L)$TiBr_2$(THF)] (**1**) is easily prepared in 76% yield by the in situ reaction at low temperature of 3 equiv. of $NaN(SiMe_3)_2$ with [$H_3$(L)]Br, followed by addition to $TiBr_4$ in 1:1 ratio in THF. The temperature-dependent NMR spectroscopic features of **1** are similar to those of the reported [(L)$TiCl_2$(THF)].[8c] $TiBr_4$, a more expensive reagent than $TiCl_4$, was also chosen to study the influence of different halide ions on the solid-state structures of titanium complexes. Unfortunately the poor quality of the orange-red crystals of **1** prevented us from carrying out X-ray analysis to determine its molecular structure.

Attempts to prepare the titanium complex [$(L)_2$Ti] (**2**), a NHC phenoxide titanium derivative analogous to [$(L)_2$Zr],[8a] were successful by the reaction of $TiCl_4(THF)_2$ or $TiBr_4$ with 2.0 equiv. of in situ generated $Na_2$(L) in THF. The structure of **2** was determined crystallographically (Figure 1). The selected bond lengths and angles of **2** are listed in Table 1, which includes the data of zirconium complex [$(L)_2$Zr][8a] for comparison. The titanium center shows a slightly distorted octahedral geometry and features two meridionally coordinated tridentate $(L)^{2-}$ ligands, each with mutually *trans* NHC donors [C8–Ti–C25, 179.9(2)°; O1–Ti–O2, 177.3(1)°; O3–Ti–O4, 176.6(1)°]. The molecule has approximate $C_2$ symmetry and the ligands adopt a *transoid* conformation. The Ti–C(carbene) [2.2053(4) and 2.196(4) Å] and Ti–O(phenoxide) distances [average 1.909 Å] are comparable to the corresponding distances found in [(L)$TiCl_2$(THF)].[8c]

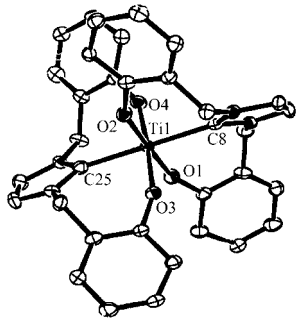

Figure 1. The molecular structure of **2**. All *t*Bu groups, solvent molecules, and hydrogen atoms are omitted for clarity.

The NMR spectroscopic data of **2** in [$D_1$]chloroform are consistent with the solid-state structure, and signals for only a single $D_2$ symmetric bis(phenoxide)–NHC ligand environment are seen, although the slight broadening of signals assigned to the N–$CH_2$ protons at $\delta$ = 3.88 and 6.42 ppm indicates some fluxional process at room temperature. The *tert*-butyl groups appear as two singlets at $\delta$ = 1.11 and 1.42 ppm, and the NHC ring protons are observed as a singlet at $\delta$ = 6.18 ppm. In the $^{13}C\{^1H\}$ NMR spectrum, the NHC carbon is observed at $\delta$ = 182.4 ppm.

Table 1. Selected bond lengths [Å] and bong angles [°] of **2** and $[(L)_2Zr]$.[8a]

| Bond lengths | $[(L)_2Zr]$ | **2** | Bond angles | $[(L)_2Zr]$ | **2** |
|---|---|---|---|---|---|
| M–C8(carbene) | 2.385(30) | 2.205(4) | C8–M–C25 | 160.23(10) | 179.9(2) |
| M–C25(carbene) | 2.381(3) | 2.196(4) | O1–M–O2 | 161.85(8) | 177.3(1) |
| M–O1 | 2.028(1) | 1.910(3) | O3–M–O4 | 161.00(8) | 176.6(1) |
| M–O2 | 2.041(2) | 1.914(3) | C8–M–O1 | 84.57(9) | 89.2(1) |
| M–O3 | 2.018(2) | 1.912(3) | C8–M–O2 | 80.05(9) | 88.3(1) |
| M–O4 | 2.035(2) | 1.898(3) | C25–M–O3 | 83.79(9) | 88.3(1) |
| | | | C25–M–O4 | 79.82(9) | 88.5(2) |

Complex $[(L)Ti(Ch_2Ph)_2]$ (**3**) has been prepared from $[(L)TiCl_2(thf)]$ by salt metathesis in toluene at room temperature and characterized by X-ray analysis, but a lower yield (30%) was obtained with this method.[8a] We modified this method by changing the reaction solvent and temperature. Reaction of **1** with 2 equiv. of $PhCH_2MgCl$ in $Et_2O$ at –78 °C (Scheme 1) affords an orange microcrystalline solid of alkyl derivatives **3** in high yield (>88%) after washing with hexamethyldisiloxane (HMDSO), in which they are insoluble. As we previously reported, these derivatives are air- and moisture-sensitive and soluble in common organic solvents, including benzene, toluene, and dimethyl ether.

Hydrolysis of **1** with 0.5 equiv. of water in THF affords a dinuclear titanium complex $\{[(L)TiBr]_2(\mu\text{-}O)\}$ (**4**) with the release of 1 equiv. of hydrogen bromide (Scheme 1). The proton resonances of N–$CH_2$–Ar appeared at $\delta$ = 4.27 and 6.00 ppm as two broad signals and $^{13}C\{^1H\}$ NMR spectra revealed the coordinated carbene carbon signal at $\delta$ = 185.0 ppm.

The X-ray single-crystal analysis of needle crystals of **4** showed that the titanium center binds to the carbene–phenoxide ligand, a bromide, and a bridged oxygen atom to form a pseudo-trigonal-bipyramidal geometry in the solid state (see Figures 2 and 4a). The aryloxy–NHC ligands are bound in a meridional fashion; the phenoxide donors occupy axial positions and two tops are occupied by bromide and carbene carbon. The most notable feature of this structure is that each carbene–phenoxide ligand coordinated to titanium favors *cisoid* conformation, but not *transoid* conformation. Bond lengths Ti–Br [2.5759(7) Å] and Ti–O(phenoxide) [1.822(3)–1.810(5) Å] (Table 2) are longer than those in monomeric aryl oxide complexes $[Ti(OC_6H_3Ph_2)_2Br_2]$ [2.3719(4) Å; 1.746(2) Å][15] and $[Ti(ebmp)Br_2]$ [ebmp = (3-*t*Bu-5-Me-2-O-$C_6H_2CH_2$)$_2$] [2.372(2), 2.363(2) Å; 1.754(4), 1.747(4) Å].[16]

Alkyl titanium complex **3** reacts with 1.0 equiv. of $H_2O$ in $Et_2O$ to afford $\{[(L)Ti]_2(\mu\text{-}O)_2\}$ (**5**) as a light yellow solid in almost quantitative yield. Its $^1H$ NMR spectrum exhibits

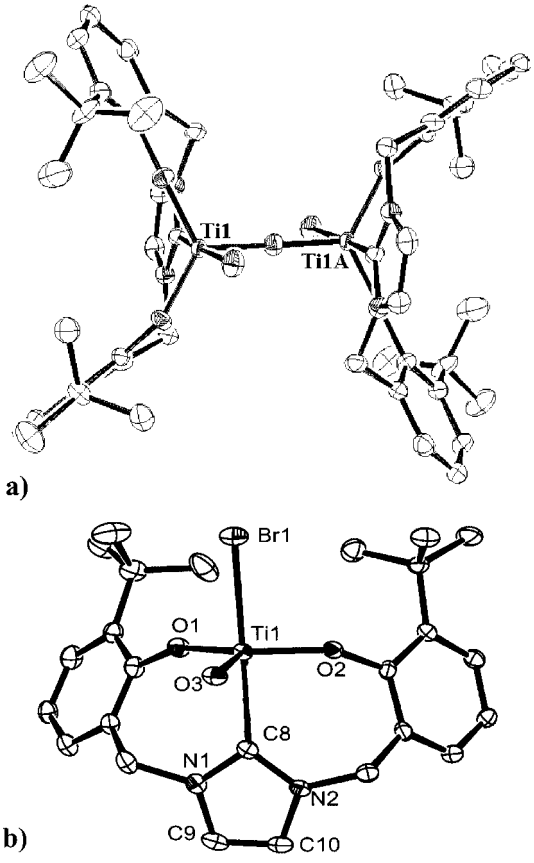

Figure 2. The molecular structure of **4**. All *t*Bu groups, solvent molecules, and hydrogen atoms are omitted for clarity. (a) The side view of the whole molecule; (b) one of the two symmetrically related Ti units.

resonances at 3.98 and 6.06 ppm attributable to the N–$CH_2$–Ar protons of the carbene–phenoxide ligand.

Light yellow single crystals of **5** suitable for X-ray diffraction were obtained by recrystallization from hexane/THF at –20 °C. X-ray analysis of **5** revealed the dinuclear

Table 2. Selected bond lengths [Å] and angles [°] of **4** and **5**.

| Bond lengths | **4** | **5** | Bond angles | **4** | **5** |
|---|---|---|---|---|---|
| Ti1–C8 | 2.208(5) | 2.250(5) | C8–Ti1–O3A | | 177.0(2) |
| Ti1–O1 | 1.822(4) | 1.862(3) | C8–Ti1–Br | 176.4(1) | |

titanium structure to be linked by two μ-oxygen atoms; the geometry around the titanium atom is distorted trigonal-bipyramidal (Figures 3 and 4b). Each aryloxy–NHC ligand coordinated to titanium favors *cisoid* conformation, as titanium complex **4** does. The coordinated dianionic [Ti(μ-O)$_2$-Ti] core strongly compresses the carbene–phenoxide ligand to *cisoid* conformation. The titanium–carbene distance [2.249(5) Å] is obviously longer than those in other titanium complexes bearing a *transoid* conformation ligand because of the presence of two bridged $O^{2-}$ groups that strongly bind to the titanium centers. A similarly short Ti···Ti distance of 2.704(8) Å has been observed in other titanium compounds where the dianionic groups such as oxo, imido, or alkylidene bridge the $d^0$ metals. Examples include [{$C_5H_2(SiMe_3)_3$}ClTi(μ-O)$_2$TiCl {$C_5H_2(SiMe_3)_3$}] 2.7071(4) Å,[17] [(2,6-$Me_2C_6H_3$)$_2$Ti(μ-N*t*Bu)$_2$Ti(O$C_6H_3Me_2$-2,6)$_2$] 2.7909(7) Å,[18] [(cb)$_2$ClTi(μ-CHSi$Me_3$)$_2$Ti(cb)$_2$] (Hcb = carbazole) 2.9504(8) Å,[19] and [($Cy_2N$)$_2$ClTi(μ-$CH_2$)$_2$-Ti($NCy_2$)$_2$] 2.934(2) Å.[20]

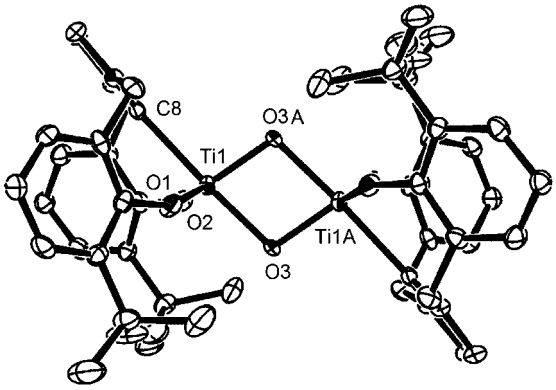

Figure 3. The molecular structure of **5**. All *t*Bu groups, solvent molecules, and hydrogen atoms are omitted for clarity.

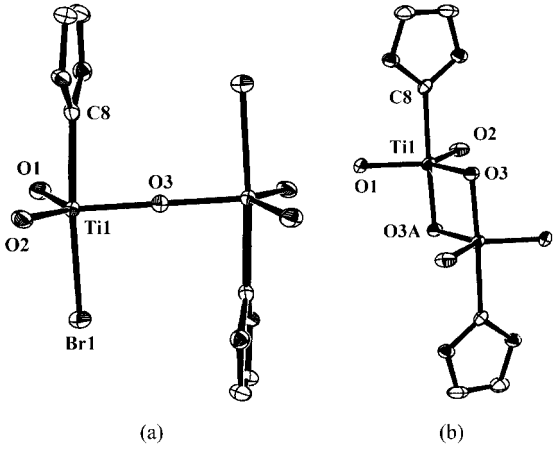

Figure 4. The coordinate sphere of dinuclear titanium complexes **4** (a) and **5** (b) with trigonal-bipyramidal geometry around the metal centers.

Compounds **1**, **4**, and **5** were found to catalyze the polymerization of ethylene at ambient temperature to give polyethylene with MAO as cocatalyst (Table 3). Compared with **1** and previously reported [(L)TiCl$_2$(thf)],[8a] which reveal high activity up to $10^5$ g PE mol$^{-1}$ Ti h$^{-1}$, the dinuclear complexes **4** and **5** show very low activities for polymerization of ethylene. The catalytic activity in the polymerization of ethylene decreases in the order of **1** > **4** > **5**. We are not convinced there is any relationship between conformation (*cisoid* or *transoid*) of the auxiliary carbene ligand and activity in polymerization reactions, because the ground-state conformation of the procatalysts is largely irrelevant to what happens following the addition of a MAO cocatalyst. We tried but failed to obtain information from theory calculation to support this idea. A possible reason for this is that the oxo compounds **4** and **5** are less reactive than **1** following MAO activation.

Table 3. Results of polymerization of ethylene.[a]

| Complex | *T* [°C] | Polymer [g] | Activity[b] |
|---|---|---|---|
| [(L)TiCl$_2$(thf)][c] | 30 | – | 290 |
| **1** | 25–35 | 2.3 | 164 |
| **4** | 25–35 | 0.5 | 39 |
| **5** | 25–35 | 0.3 | 21 |

[a] Polymerization conditions: 2 μmol of titanium, activated by MAO (Al/Ti = 1000), 1 h, 250 mL of toluene, 7 bar. [b] kg PE mol$^{-1}$ Ni h$^{-1}$ bar$^{-1}$. [c] See ref.[8a], 1 L of toluene, 0.5 h, 9 bar.

## Conclusions

In summary, the present work demonstrated that two unique dinuclear titanium phenoxide-tethered N-heterocyclic carbene compounds, **4** and **5**, could be synthesized by control of the hydrolysis of **1** and **2** with the right amount of water. The phenoxide-functionalized NHC ligand adopts *transoid* conformation in mononuclear complexes but rare *cisoid* conformation in dinuclear complexes. This synthetic strategy may be applied to the preparation of other early transition-metal complexes. We are currently working on the synthesis of multinuclear macrocyclic metal compounds with a similar phenoxide-functionalized carbene ligand.

## Experimental Section

**General Considerations:** All manipulations were carried out under dry oxygen-free argon using standard Schlenk techniques. Solvents were dried by refluxing with appropriate drying agents (sodium/benzophenone for toluene, diethyl ether, THF, and hexane; $CaH_2$ for dichloromethane) and distilled under argon prior to use. $CDCl_3$ and $C_6D_6$ were distilled from $CaH_2$ or K and degassed by three freeze–pump–thaw cycles prior to use. The chemicals $TiBr_4$, NaN($SiMe_3$)$_2$ (1.1 M in THF), and $C_6H_5CH_2MgCl$ (1.0 M in diethyl ether) were obtained commercially and used as received. Ligand [$H_3$(L)]Br and complexes [(L)TiCl$_2$(thf)] and [(L)Ti($CH_2Ph$)$_2$] were prepared according to the literature.[8] $^1$H and $^{13}$C{$^1$H} NMR spectra were recorded with a JEOL Lambda-500 spectrometer. Chemical shifts are reported in parts per million. Elemental analyses were measured using Yanaco MT-6 and MSU-32 microanalyzers.

**Synthesis of [(L)TiBr$_2$(THF)] (1):** Complex **1** was prepared using $TiBr_4$ instead of $TiCl_4(THF)_2$ according to a similar way of preparing [(L)TiCl$_2$(THF)].[8a] A 200-mL round-bottomed flask was

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

charged with $[H_3L]Br$ (1.930 g, 3.3 mmol). THF (50 mL) was added and the mixture was cooled to –78 °C. A solution of 3.0 equiv. $NaN(SiMe_3)_2$ (9.9 mmol) in THF (1.0 M, 9.9 mL) was added drop by drop using a syringe. The reaction mixture was kept at –78 °C and stirred for another 30 min to afford the suspended solution of sodium salt of the ligand $Na_2[L]$. The obtained sodium salt was slowly transferred to a suspension of $TiBr_4$ (1.237 g, 3.3 mmol) in THF (50 mL) at –78 °C by cannula. The dark red solution was slowly warmed to room temperature and stirred for another 12 h. The metathesis reaction was evident by the formation of NaBr; all volatile compounds were removed under vacuum, and the crude product was extracted with toluene (50 mL) and filtered through a layer of Celite to remove NaBr. The extracts were concentrated to 10 mL and hexane (30 mL) was added. Filtration followed by drying in vacuo gave an orange-red solid, **1** (0.958 g). The mother liquid was cooled to –30 °C overnight to yield a second crop of **1** (1.023 g). Yield 75.8%. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.27 (s, 18 H, $CH_3$ of *t*Bu), 1.52 (s, 18 H, $CH_3$ of *t*Bu), 1.85 (m, 2 H, $CH_2$ of THF), 3.76 (m, 2 H, $CH_2$ of THF), 4.5–6.0 (br. m, 4 H, Ar–$CH_2$–N), 6.93 (br. s, 2 H, Ar-H), 7.10 (br. s, 2 H, N–CH=), 7.27 (br. s, 2 H, Ar-H) ppm. $^{13}$C{$^1$H} NMR (127 MHz, $CDCl_3$): $\delta$ = 24.8 ($CH_2$ of THF), 31.0 ($CH_3$ of *t*Bu), 34.2, 35.10 ($CMe_3$), 52.2 (N–$CH_2$–Ar), 67.5 (O–$CH_2$ of THF), 119.4 (CH of imidazol), 123.7, 124.3, 124.9, 128.6, 137.8, 145.3, 164.8 (NCN) ppm. $C_{37}H_{54}Br_2N_2O_3Ti$ (782.51): calcd. C 56.79, H 6.96, N 3.58; found C 56.84, H 7.04, N 3.61.

**Synthesis of [(L)$_2$Ti] (2):** $TiBr_4$ (0.187 g, 0.50 mmol) in THF (20 mL) was slowly added by channel transfer to a suspended solution of sodium salt $Na_2(L)$ obtained from the reaction of $[H_3(L)]$-Br (0.587 g, 1.0 mmol) with $NaN(SiMe_3)_2$ (3.3 mL, 1.1 M in THF) at –78 °C. The mixture was warmed to room temperature and stirred for another 12 h. The residue was evaporated to dryness and extracted with hexane/toluene (30 mL/20 mL), and the salt was removed by centrifugation. The light yellow solution was concentrated to dryness, washed with HMDSO and dried in vacuo to give a yellow solid of **2** in 73% yield. $^1$H NMR (500 MHz, $CDCl_3$): $\delta$ = 1.11 (s, 36 H, $CH_3$ of *t*Bu), 1.42 (s, 36 H, $CH_3$ of *t*Bu), 3.88 (d, 4 H, $CH_2$), 6.18 (s, 4 H, CH), 6.41 (d, 4 H, $CH_2$), 6.96 (s, 4 H, ArH), 7.46 (s, 4 H, Ar-H) ppm. $^{13}$C{$^1$H} NMR (127 MHz, $CDCl_3$): $\delta$ = 30.4, 31.8 ($CH_3$ of *t*Bu), 34.1, 34.9 ($CMe_3$), 53.7 ($CH_2$), 119.5 (CH of imidazol), 123.1, 123.7, 124.4, 136.2, 138.0, 161.8, 182.4 (NCN) ppm. $C_{66}H_{94}N_4O_4Ti$ (1055.34): calcd. C 75.11, H 8.98, N 5.31; found C 75.05, H 8.92, N 5.47.

**Synthesis of [(L)Ti(CH$_2$Ph)$_2$] (3):** Complex **3** was prepared from [(L)$TiBr_2$(thf)] (**1**) instead of [(L)$TiCl_2$(thf)] using a modified method. Benzylmagnesium chloride (1.4 mL, 1.0 M in diethyl ether, 1.4 mmol) was added dropwise to a precooled suspension of **1** (0.536 g, 0.69 mmol) in $Et_2O$ (30 mL) at –78 °C. The mixture was slowly warmed to 0 °C and stirred for another 4 h at 0 °C. The solvent was removed under vacuum, and $CH_2Cl_2$ (20 mL) was added to the solid residue. The suspension was centrifuged to remove the formed salt and the upper clear solution was evacuated to dryness. The orange-red crude product was washed with HMDSO (5 mL) and dried in vacuo, yielding an orange solid, **3** (0.439 g). Yield 88%. $C_{47}H_{60}N_2O_2Ti$ (732.86): calcd. C 77.03, H 8.25, N 3.82; found C 76.87, H 8.33, N 3.91.

**Synthesis of {[(L)TiBr]$_2$(μ-O)} (4):** Water (1.0 M in $Et_2O$) (193 μL, 0.193 mmol) was added dropwise to a THF solution (20 mL) of **1** (0.300 g, 0.386 mmol) with an ice–water bath. The mixture was stirred overnight at room temperature and was evaporated to dryness. The crude mixture was recrystallized from THF/hexane to give red plate microcrystals (0.206 g). Yield 84%. $^1$H NMR (500 MHz, $C_6D_6$): $\delta$ = 0.88 (t, $CH_3$ of hexane), 1.24 (m, $CH_2$ of hexane), 1.28 (s, 18 H, $CH_3$ of *t*Bu), 1.41 (m, $OCH_2CH_2$ of THF), 1.75 (s, 18 H, $CH_3$ of *t*Bu), 3.57 (m, $OCH_2CH_2$ of THF), 4.27 (br. s, 2 H, N–$CH_2$–Ar), 6.00 (br. s, 1 H, N–$CH_2$–Ar), 6.93 (br. s, 2 H, N–CH=), 7.17 (s, overlapped by 7.15 of $C_6D_6$), 7.49 (d, $J$ = 6.4 Hz, 2 H, H-Ar) ppm. $^{13}$C{$^1$H} NMR (127 MHz, $C_6D_6$): $\delta$ = 14.3 ($CH_3$ of hexane), 23.0 ($CH_2$ of hexane), 25.8 ($OCH_2CH_2$ of THF), 31.4, 32.7 ($CH_3$ of *t*Bu), 31.9 ($CH_2$ of hexane), 34.5, 35.8 ($CMe_3$), 53.2 (N–$CH_2$–Ar), 67.8 ($OCH_2CH_2$ of THF), 119.2 (CH of imidazol), 124.8, 124.9, 125.6, 127.9, 128.1, 128.3, 138.4, 143.5 (arom.), 164.0 (Ti–O–C), 185.0 (NCN) ppm. $C_{66}H_{94}Br_2N_4O_5Ti_2$ (1279.02): calcd. C 61.98, H 7.41, N 4.38; found C 61.41, H 7.12, N 3.89.

**Synthesis of {[(L)Ti(μ-O)]$_2$} (5):** $H_2O$ (1 M $Et_2O$) (0.35 mL, 0.35 mmol) was added dropwise to a THF solution (20 mL) of **3** (0.350 mmol) with an ice–water bath. The mixture was stirred over-

**Ethylene Polymerization:** A 500-mL autoclave was charged with 240 mL of toluene under argon and a mixture of titanium complex/MAO (the molar ratio of Al:Ti was 1000) in 10 mL toluene was added. After three ethylene gas exchanges, the ethylene pressure was raised to 7 bar and maintained for 1 h. The polymerization was terminated by the addition of methanol and diluted HCl (10%). The solid polyethylene was filtered, washed with methanol, and dried at 40 °C in vacuo.

**X-ray Crystal Structure Determination:** A suitable crystal was immersed in mineral oil and mounted on a nylon loop in a random orientation under a cold stream of dry nitrogen (Rigaku GNNP low-temperature device). Diffraction experiments were performed with Mo-$K_\alpha$ radiation ($\alpha$ = 0.71070 Å) on a Rigaku CCD diffractometer. The data were collected in a hemisphere of data in 720 frames with 20–40-s exposure times. The data sets were collected ($4.0 < 2\theta < 45$–$55°$). The data were processed using CrystalClear (Rigaku) Processing packages.[21] The structures were determined by routine heavy-atom and Fourier methods by using SHELXS-97[22] and refined by full-matrix least-squares. The non-hydrogen atoms were refined with anisotropic parameters and the hydrogen atoms with fixed isotropic thermal parameters of 0.07 Å by means of the SHELXL-97[23] program. The hydrogen atoms were partially located from difference electron-density maps and the rest were fixed at predetermined positions. Scattering factors were from common sources. Some details of data collection and refinement are given in Table 4.

CCDC-639449, -639453, and -639454 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## COVER PICTURE

**The cover picture shows** one of donor-stabilized phosphenium compounds which have been obtained by direct addition of chlorophosphanes to the 1,3-dimethylimidazolium-2-carboxylate without any further purification step. Their stronger π-acceptor character similar to phosphites and their ionic nature render these ligands very promising in the development of new continuous-flow catalytic processes. Details of phosphorylation mechanisms of imidazolium-2-carboxylate as well as the electronic and steric properties of these adducts are discussed in the article by J. Andrieu et al. on p. 4877 ff.

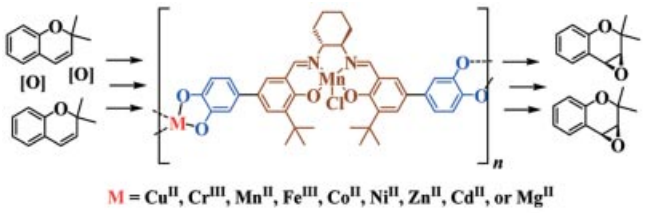
## SHORT COMMUNICATION

### Heterogeneous Asymmetric Catalysts

**S.-H. Cho, T. Gadzikwa, M. Afshari, S. T. Nguyen,* J. T. Hupp* .... 4863–4867**

[Bis(catechol)salen]$Mn^{III}$ Coordination Polymers as Support-Free Heterogeneous Asymmetric Catalysts for Epoxidation

**Keywords:** Asymmetric catalysis / Heterogeneous catalysis / Manganese / Salen ligands / Coordination polymers



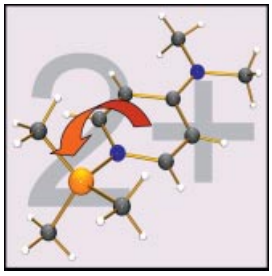
Amorphous coordination polymers, formed by the linkage of [bis(catechol)salen]$Mn^{III}$ units, function as recyclable heterogeneous asymmetric epoxidation catalysts.

### Phosphorus Cations

**J. J. Weigand,* N. Burford,* A. Decken, A. Schulz ..... 4868–4872**

Preparation and Characterization of a Ligand-Stabilized Trimethylphosphane Dication

**Keywords:** Phosphane dication / Donor–acceptor complexes



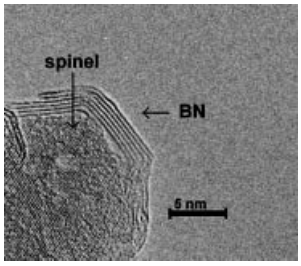
Chlorotrimethylphosphonium triflate reacts with 4-(dimethylamino)pyridine (DMAP) in the presence of trimethylsilyltriflate to give the DMAP-stabilized trimethylphosphane dication as a ditriflate salt. The new salt is also formed from DMAP-dimethylphosphenium triflate by reaction with methyltriflate. Ligand exchange of DMAP for $PMe_3$ yields the hexamethyldiphosphonium dication.

### Turbostratic Boron Nitride

**S. K. Klitgaard, K. Egeblad, M. Brorson, K. Herbst, C. H. Christensen* ..... 4873–4876**

Turbostratic Boron Nitride Coated on High-Surface Area Metal Oxide Templates

**Keywords:** Boron nitride / Turbostratic / Metal oxide templates / Catalyst support material / Nanostructure



Boron nitride coatings on high-surface area $MgAl_2O_4$ and $Al_2O_3$ have been synthesized and characterized by TEM and by X-ray powder diffraction. The metal oxide templates were coated with BN using a simple nitridation in a flow of ammonia starting from ammonium borate adsorbed onto $MgAl_2O_4$ or $\gamma$-$Al_2O_3$. This procedure resulted in the formation of a turbostratic boron nitride film with a thickness of a few individual BN layers.

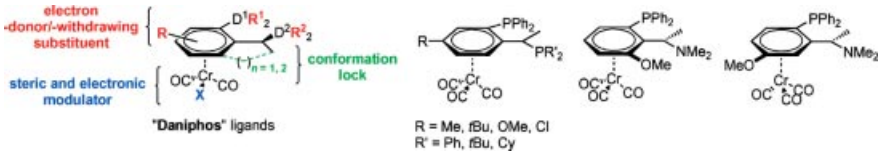
**Keywords:** N,P ligands / Phosphane ligands / Asymmetric catalysis / Arene complexes / Chromium



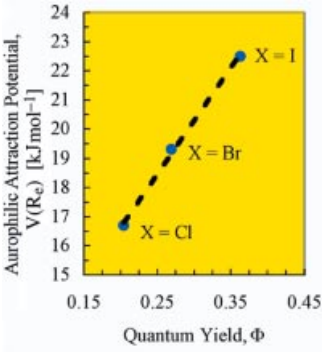
New P∩P- and P∩N-ligands have been synthesised whose core structure is an [(η⁶-arene)Cr(CO)₃] unit. These new ligands, which expand the range of "Daniphos" ligands, are endowed with central and planar chirality and have been prepared by a stereoselective synthetic strategy from optically pure benzylamines bearing a second substituent on the arene other than the benzyldimethylamino group.

## Gold Photochemistry

**J. B. Foley,* S. E. Gay, M. J. Vela, B. M. Foxman, A. E. Bruce, M. R. M. Bruce* ..... 4946–4951**

Structure and Photochemical Isomerization of the Dinuclear Gold(I) Halide Bis(diphenylphosphanyl)ethylene Complexes: Correlation Between Quantum Yield and Aurophilicity

**Keywords:** Aurophilicity / Metal–metal interactions / Gold / Photochemistry / Olefin isomerization / Quantum yield



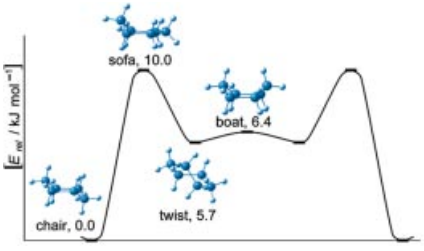
The quantum yields for the photochemical isomerization of *cis*-$(Ph_2PCH{=}CHPPh_2)(AuX)_2$, $\Phi_{(cis\rightarrow trans)}$, were measured (for X = Cl, Br, and I, respectively) and found to correlate with the aurophilic attraction potential $V(R_e)$. The crystal structures for *cis*-$(Ph_2PCH{=}CHPPh_2)(AuI)_2$ and *trans*-$(Ph_2PCH{=}CHPPh_2)(AuI)_2$ are also reported.

## Conformations of Cyclohexagermanes

**M. Hölbling, M. Flock, J. Baumgartner, K. Hassler* ..... 4952–4957**

$Ge_6Me_{12}$ and $Ge_6H_{12}$ Cyclohexagermanes: Conformer Equilibria Studied by Raman Spectroscopy and Quantum Chemical Calculations

**Keywords:** Cyclohexagermanes / Conformational analysis / Raman spectroscopy / X-ray structure / Ab initio calculations



The conformational equilibria of cyclohexagermanes have been investigated with ab initio calculations. Two stable conformers were located on the potential energy surface for $Ge_6H_{12}$, whereas three were located for $Ge_6Me_{12}$. With the aid of Raman spectroscopy, two conformers were detected for $Ge_6Me_{12}$, a chair and an averaged twist/boat conformer, with an enthalpy difference of 2.4 kJ mol$^{-1}$ between them.

# [Bis(catechol)salen]Mn$^{III}$ Coordination Polymers as Support-Free Heterogeneous Asymmetric Catalysts for Epoxidation

So-Hye Cho,[a] Tendai Gadzikwa,[a] Mitra Afshari,[a] SonBinh T. Nguyen,*[a] and Joseph T. Hupp*[a]

**Keywords:** Asymmetric catalysis / Heterogeneous catalysis / Manganese / Salen ligands / Coordination polymers

The formation of coordination polymers by the reaction of [bis(catechol)salen]Mn$^{III}$ with several di- and trivalent metal ions is reported. These polymers are insoluble in a wide range of organic solvents and water but can be dissolved upon addition of excess pyrocatechol. They function as enantioselective heterogeneous epoxidation catalysts and exhibit catalytic activity comparable to that of the homogeneous [bis(catechol)salen]Mn$^{III}$ building block alone when used for the enantioselective epoxidation of 2,2-dimethyl-2*H*-chromene. After catalysis, catalyst isolation from the reaction mixture can be readily achieved by centrifugation and decantation. Under practical oxidant concentrations, the catalyst can be recycled up to ten times with little loss of activity and no loss of enantioselectivity.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Porous coordination polymers – especially crystalline ones – have recently received much attention for their potential applications in the areas of heterogeneous catalysis, separations, and gas storage.[1,2] Although the coordination polymerization of chiral homogeneous catalysts has been suggested as a strategy to obtain practically useful heterogeneous asymmetric catalysts,[3] to date there are only a few demonstrations of this approach.[4] Among these are heterogenized catalysts for the addition of $ZnEt_2$ to aromatic aldehydes[4a] and for enantioselective Michael addition.[4b] In addition, coordination polymers have been used in asymmetric Lewis acid catalysis.[4c,4d] Examples of coordination polymers in chiral oxidative catalysis are scarcer. Suslick and co-workers have reported that a porphyrin-based material catalyzes organic oxidations;[4e] however, this system is not chiral. To the best of our knowledge, our recent report of the enantioselective epoxidation of 2,2-dimethyl-2*H*-chromene by a microporous, crystalline metal–organic framework (MOF) material constitutes the first example of chiral oxidation catalyzed by a coordination polymer.[5] While this work successfully illustrates the translation of a homogeneous chiral (salen)Mn$^{III}$ catalyst into the heterogeneous realm, the (salen)Mn-based MOF material has limited recyclability. Specifically, fragmentation of MOF particles and loss of the catalyst (4 to 7% per cycle) can occur during each batch reaction, reflecting the inherent weakness of the Zn$^{II}$–N(pyridine) bond. The required usage of zinc or similar divalent ions as framework nodes in these particular MOFs also limits the diversity of functional materials that can potentially be obtained by this approach.

If the requirement of crystallinity were relaxed, however, stronger chelate-type metal–ligand linkages (such as metal–catecholate or –semiquinone links) could be used, and the resulting amorphous coordination polymers may still exhibit heterogeneous catalytic competency.[6] Previously, we reported the immobilization of mono-catechol-functionalized (salen)Mn$^{III}$ complexes on alumina membranes.[7] The modified membranes functioned well as heterogeneous asymmetric epoxidation catalysts, achieving high one-pass conversion and excellent turnover numbers, albeit with moderate recyclability due to catalyst leaching. We hypothesized that a more permanent approach to heterogenization would be coordination polymerization of [bis(catechol)-salen]Mn (**1**). By combining **1** with various soluble metal ions, linear and/or branched coordination polymers should form, ideally as isolable solids that can be used as catalysts. While there is no precedent for the use of catechol-based coordination polymers in heterogeneous catalysis, catechol has long been known as an effective bidentate ligand for many metal ions.[8] The redundantly chelating (salen)Mn moieties in the polymer networks might well display reduced leaching and higher stability/recyclability compared to the alumina-supported species. Herein, we report that a series of exceptionally stable enantioselective heterogeneous epoxidation catalysts can be made by the coordination po-

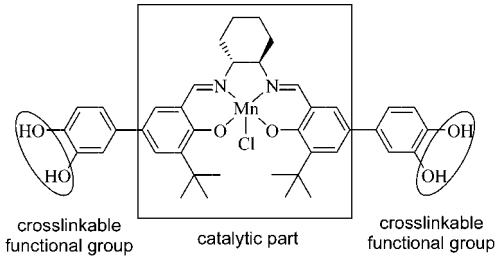
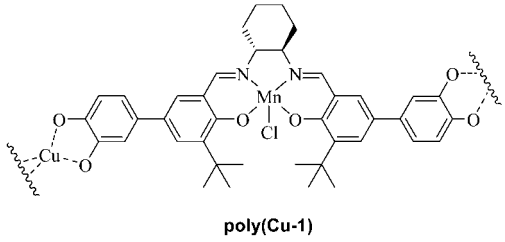
lymerization of **1** and several metal ions. These catalysts can be recycled numerous times with minimal leaching and no loss of enantioselectivity.



**1**

## Results and Discussion

The bis(catechol)-functionalized salen ligand of **1** can be prepared easily from (1*R*,2*R*)-diaminocyclohexane (see Supporting Information). Metalation with $MnCl_2$ under an $N_2$ atmosphere, followed by oxidation in air, afforded complex **1** in good yield. Coordination polymerization of **1** with $Cu^{II}$ was accomplished under an $N_2$ atmosphere by adding $CuCl_2$ to a 1:4 mixture of compound **1** and triethylamine (TEA) dissolved in deoxygenated dimethylformamide (DMF). Vigorous stirring of the resulting reaction mixture led to a spontaneous formation of precipitates, which were then filtered and thoroughly washed with DMF to afford the Cu-linked (salen)Mn polymer **poly(Cu-1)** as a brown solid (Figure 1).[9]



**poly(Cu-1)**

Figure 1. A schematic drawing of the coordination polymer formed between $Cu^{II}$ and [bis(catechol)salen]$Mn^{III}Cl$ [**poly(Cu-1)**].

**Poly(Cu-1)** is insoluble in a wide range of organic solvents (toluene, methanol, DMF, and dimethyl sulfoxide) and water. Inductively coupled plasma (ICP) mass spectrometric measurements performed on **poly(Cu-1)** yielded a Mn/Cu ratio of approximately 1:1.1, suggesting that **poly(Cu-1)** exhibits a quasi-one-dimensional structure, in which **1** is connected by bis(catecholate)copper linkages. The formation of **poly(Cu-1)** can be reversed: addition of excess pyrocatechol to a DMF slurry of **poly(Cu-1)** dissolves the particles within a few hours. Electrospray ionization mass spectrometry conducted on the resulting solution clearly showed mass peaks associated with the (salen)Mn building block ($[M - Cl]^+$ = 703.92 and $[M - Cl + DMF]^+$ = 776.56, see Supporting Information).

Thermal gravimetric analysis (TGA) performed on the as-synthesized **poly(Cu-1)** revealed a weight loss of ca. 18% between 25–200 °C, followed by several additional losses up to 700 °C (see Supporting Information). We attribute the initial weight loss to the liberation of DMF and water and the latter ones to the decomposition of the polymer. As further evidence for the initial solvent loss, TGA of a sample polymer that had been evacuated (30 mTorr) for 18 h at 80 °C showed only ca. 2% weight loss in the temperature range of 25–200 °C. The TGA trace of an evacuated polymer sample that was then resolvated showed a lower loss of solvent than the as-synthesized product (8% vs. 18%), suggesting that **poly(Cu-1)** may have undergone further aggregation upon evacuation and become less porous than freshly prepared samples. However, it still has moderate porosity (total BET surface area = 72 $m^2 g^{-1}$) and an amorphous structure as evidenced by scanning electron microscopy (SEM; Figure 2) and by the absence of peaks in powder X-ray diffraction measurements.

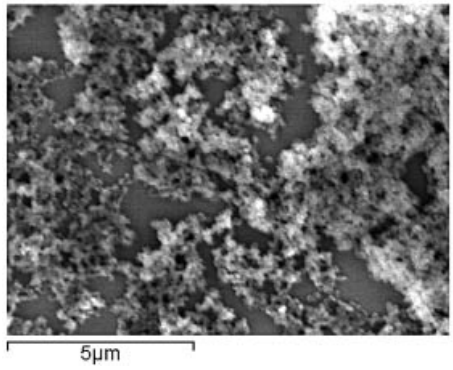


Figure 2. SEM image of **poly(Cu-1)**.

Catalytic epoxidations of 2,2-dimethyl-2*H*-chromene were carried out in dichloromethane[10] solution under ambient conditions with **poly(Cu-1)** by using 2-(*tert*-butylsulfonyl)iodosylbenzene as the oxidant [Equation (1)]. For comparison, [bis(dimethoxyphenyl)salen]$Mn^{III}Cl$ (**2**), the protected soluble analogue of **poly(Cu-1)**, was also tested for epoxidation activity.[11] Although a slightly lower enantioselectivity was observed for **poly(Cu-1)** relative to **2** [76% *ee* for **poly(Cu-1)** vs. 86% *ee* for **2**], their epoxidation activities were comparable (Table 1, entries 1 and 2). As reduced enantioselectivity is often seen with homogeneous catalysts immobilized in constrained environments such as cross-linked polymers and zeolites,[12] this slight decrease in enantioselectivity may be attributed to structural constraints resulting from the immobilization. Indeed, when **poly(Cu-1)** is dissolved in the presence of pyrocatechol (vide supra) and used as a catalyst for reaction (1), its enantioselectivity (82%) becomes quite close to that of free **1**.

| 10 | **poly(Cu-1)** | 9th | 69 | 75 | not detectable |
| 11 | **poly(Cu-1)** | 10th | 70 | 76 | not detectable |

[a] Molar ratio olefin/oxidant/catalyst = 100:150:1. [b] GC yield after 2 h with undecane as an internal standard. [c] Determined by using a Supelco β-DEX 120 chiral GC column. [d] Measured by ICP mass spectrometry.

Encouraged by the persistence of catalytic activity for **poly(Cu-1)**, we examined its recyclability. Samples of **poly(Cu-1)** were easily recovered by centrifugation after catalysis and rinsed with dichloromethane and acetone before being used again for epoxidation. Remarkably, **poly(Cu-1)** can be recycled up to ten times with little loss in activity (79% → 70% yield) and no loss in enantioselectivity (75–76% *ee*) (Table 1, entries 2–11). Evaluation of the product solutions by ICP mass spectrometry, after removing the catalyst particles, showed that 3.1% of the manganese and 4.7% of the copper initially leached out during the first two cycles (Table 1, entries 2 and 3). However, this metal loss quickly decreased during the next four cycles (Table 1, entries 4–7), and no leaching was detected in the last stages of recycling (Table 1, entries 10 and 11). Together with the retention of activity and selectivity mentioned above, it is conceivable that the initial leaching could have arisen from Cu$^{II}$ ions and **1** that were weakly bound or entrapped in **poly(Cu-1)**. As **poly(Cu-1)** undergoes successive recycling, these weakly bound or entrapped ions and compounds are removed, leading to a substantial decrease in leaching after the second cycle.

Figure 3 compares the epoxidation activity of **poly(Cu-1)** to that of compound **2** in dichloromethane solution over a 3-h period under high-oxidant conditions (ca. 13 times the concentration used for the experiments in Table 1). As is often observed for homogeneous epoxidation catalysts, **2** is initially highly effective; however, it loses much of its activity after the first few minutes, followed by complete deactivation in less than 0.5 h. In contrast, the insoluble catalyst **poly(Cu-1)** exhibits a lifetime that is significantly greater ($> 3$ h) than that of **2**.[13] In addition, the enantioselectivity of **poly(Cu-1)** stays consistent throughout the reaction, indicating that it is inherent to the nature of the system and that the Cu-coordinated **1** is probably more stable than **1** itself during the epoxidation. Although the rate of catalysis by **poly(Cu-1)** is slower than that by **2**, presumably because of the biphasic nature of its reaction, a total turnover number (TON) greater than 2000 can be obtained within 3 h. Employing a filtered homogeneous reaction mixture as catalyst in the epoxidation of chromene provides no significant TON, suggesting that the catalysis occurs heterogeneously. Interestingly, use of the recovered **poly(Cu-1)** under the same high-oxidant conditions only affords about 600 turnovers in the 3-h period and with a slightly lower *ee* (ca. 60%). These data suggest that although **poly(Cu-1)** is highly stable under practical synthetic laboratory scale (0.17 M), it is not immortal and can eventually be degraded under highly oxidative environments.

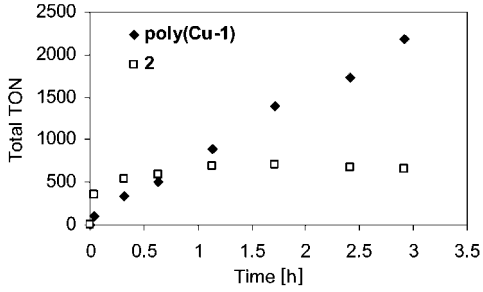

Figure 3. Plots of total turnover number (TON) vs. time for the epoxidation of 2,2-dimethyl-2*H*-chromene catalyzed by **poly(Cu-1)** (diamonds) and **2** (empty squares).

The catechol-based coordination-polymer-formation strategy is general for a wide range of metal ions, including Cr$^{III}$, Mn$^{II}$, Fe$^{III}$, Co$^{II}$, Ni$^{II}$, Zn$^{II}$, Cd$^{II}$, and Mg$^{II}$. Similar to the procedure for the formation of **poly(Cu-1)**, separately prepared solution mixtures of compound **1** and TEA were exposed to deoxygenated DMF solutions of $CrCl_3$, $MnCl_2$, $FeCl_3$, $CoCl_2$, $NiCl_2$, $ZnCl_2$, $Cd(NO_3)_2{\cdot}4H_2O$, or $MgCl_2$. All mixtures yielded spontaneous precipitation of the desired **poly(M-1)** products as dark brown solids except for the polymer derived from Fe$^{III}$ [**poly(Fe-1)**], which was red brown.

The catalytic activities of **poly(M-1)** were also examined through the asymmetric epoxidation of 2,2-dimethyl-2*H*-chromene with 2-(*tert*-butylsulfonyl)iodosylbenzene as the oxidant. As shown in Table 2, all **poly(M-1)** compounds catalyzed this epoxidation but to varying extents. Polymers assembled with Cr$^{III}$, Mn$^{II}$, Cd$^{II}$, and Mg$^{II}$ nodes gave the highest yields ($> 70$%; Table 2, entries 1–4) followed by those with Co$^{II}$ and Zn$^{II}$ (Table 2, entries 5 and 6). While enantioselectivities for **poly(Cr-1)**, **poly(Cd-1)**, **poly(Mg-1)**, and **poly(Zn-1)** were the same as that of **poly(Cu-1)** (76% *ee*), **poly(Mn-1)** and **poly(Co-1)** gave slightly lower *ee* values (60 and 52%, respectively). ICP mass spectrometric analysis for Mn was also performed for each epoxidation to estimate the extent of catalyst leaching. Similar to **poly(Cu-1)**, polymers assembled with Cr$^{III}$, Mn$^{II}$, Cd$^{II}$, Mg$^{II}$, Co$^{II}$, and Zn$^{II}$ exhibited ca. 1–3% catalyst leaching during catalysis.

Polymers assembled from Fe$^{III}$ and Ni$^{II}$ afforded poor epoxide yields (Table 2, entries 7 and 8). These low activities are accompanied by low enantioselectivities (48% and 20% *ee*), which suggests either potential competing oxidation from the added linker ions or that the Mn-based catalytic sites of **poly(Fe-1)** and **poly(Ni-1)** are damaged or inaccessible. Notably, a large amount of manganese (19%) was

| 5 | **poly(Co-1)** | 49 | 52 | 2.6 |
| 6 | **poly(Zn-1)** | 66 | 76 | 2.2 |
| 7 | **poly(Fe-1)** | 22 | 48 | 19 |
| 8 | **poly(Ni-1)** | 31 | 20 | 0.5 |

[a] Molar ratio olefin/oxidant/catalyst = 100:150:1. [b] GC yield after 2 h with undecane as an internal standard. [c] Determined by using a Supelco β-DEX 120 chiral GC column. [d] Measured by ICP mass spectrometry. [e] Combined amount of Mn leached from complex **1** and the catechol complex.

found to leach from **poly(Fe-1)**, conceivably as a result of the displacement of $Mn^{III}$ by $Fe^{III}$. A color change from dark brown to red brown [the color of (salen)$Fe^{III}$ complexes, which are known to give lower *ee* than (salen)$Mn^{III}$ in epoxidation][15] during polymerization also supports this argument. Interestingly, **poly(Ni-1)** exhibited substantially less Mn leaching than the other polymers, suggesting that its Mn-based catalytic sites are not as readily accessible, which in turn may explain its low activity and selectivity.

## Conclusion

We have demonstrated that heterogeneous asymmetric catalysts can be formed by the coordination polymerization of chiral [bis(catechol)salen]$Mn^{III}$ catalysts and any of several di- or trivalent metal ions. These catalysts show catalytic activity comparable to their homogeneous counterpart, complex **1**, when used for epoxidation and exhibit great potential as recyclable catalysts. This polymerization approach provides a facile and efficient strategy for support-free heterogenization of molecular catalysts.

## Experimental Section

**Materials and Methods:** Please see Supporting Information.

**Preparation of poly(M-1):** In a 20-mL vial equipped with a magnetic stir bar were combined **1** (30 mg, $4.1 \times 10^{-2}$ mmol), TEA (19.0 mg, 0.16 mmol), and degassed DMF (10 mL) under a nitrogen atmosphere. In another vial was prepared a DMF solution of corresponding metal salts (0.10 M). To the DMF solution of **1** was added the salt solution in appropriate amount ([**1**]/[salts] = 1:1 for dicationic salts or [**1**]/[salts] = 3:2 for tricationic salts) over 10 min with vigorous stirring. Precipitates formed instantaneously, and the resulting slurry was left to stir for an additional 2 h under a nitrogen atmosphere. The solids were collected by filtration in air, washed with DMF ($3 \times 10$ mL), and dried under vacuum overnight. The samples were stored under $N_2$ prior to being used.

**General Procedure for the Asymmetric Epoxidation of 2,2-Dimethyl-2*H*-chromene:** To a 2-mL conical vial were added 2,2-dimethyl-2*H*-chromene (17.6 mg, $1.1 \times 10^{-4}$ mol), undecane (9.8 mg), and dichloromethane (1 mL). Catalyst ($1.1 \times 10^{-6}$ mol) was next placed in the vial along with a micro magnetic stir bar. The oxidant, 2-(*tert*-butylsulfonyl)iodosylbenzene (18.7 mg, $5.5 \times 10^{-5}$ mol), was then added as a solid to the mixture to start the reaction. The same quantity of oxidant was added twice more at 20-min intervals (total amount added = $1.7 \times 10^{-4}$ mol). Aliquots (40 μL) of the reaction mixture were taken, filtered through a silica gel plug (120 mg), and washed with $CH_2Cl_2$ (5 mL). The combined filtrate was analyzed by GC and chiral GC for yield and enantioselectivity, respectively.

**General Procedure for Recycling of poly(Cu-1):** After being used for the catalytic reaction, the mixture was centrifuged on a Hermle Z230MA centrifuge at 12,000 rpm for 1 min. The supernatant solution was decanted for analysis by GC. The remaining solid was washed with acetone ($3 \times 1$ mL) followed by dichloromethane ($3 \times 1$ mL) before being dried in air for 0.5 h prior to being reused.

**General Procedure for the Asymmetric Epoxidation of 2,2-Dimethyl-2*H*-chromene under High-Oxidant Conditions:** To a 3.7-mL screw-threaded vial (15 mm × 45 mm) were added a dichloromethane solution of 2,2-dimethyl-2*H*-chromene (2.25 mM, 2 mL, $5.5 \times 10^{-3}$ mol) and undecane (100 mg) as an internal standard. The catalyst ($1.1 \times 10^{-6}$ mol) was next placed in the vial along with a micro magnetic stir bar. The oxidant, 2-(*tert*-butylsulfonyl)iodosylbenzene (136 mg, $4.0 \times 10^{-4}$ mol), was then added as a solid to the reaction mixture to start it. The same quantity of oxidant was added 10 more times at 10 min intervals (total amount added = $4.4 \times 10^{-3}$ mol). Aliquots (20 μL) of the reaction mixture were taken periodically over 3 h, filtered through a silica gel plug (60 mg), and washed with $CH_2Cl_2$ (5 mL). The combined filtrate was analyzed by GC and chiral GC for yield and enantioselectivity, respectively.

**Supporting Information** (see footnote on the first page of this article): Synthetic procedures and characterization data for **1** and **2**; ESI-MS, FTIR, TGA, and BET isotherm data for **poly(Cu-1)**; ICP mass spectroscopic analysis of **poly(M-1)**; and procedure for catalyst dissolution.

# Preparation and Characterization of a Ligand-Stabilized Trimethylphosphane Dication

**Jan J. Weigand,*[a] Neil Burford,*[a] Andreas Decken,[b] and Axel Schulz[c]**

*In memoriam of Prof. Dr. Nils Wiberg*

**Keywords:** Phosphane dication / Donor–acceptor complexes

The ditriflate salt of the DMAP-stabilized trimethylphosphane dication is formed from the reaction of chlorotrimethylphosphonium triflate with DMAP (4-dimethylaminopyridine) in the presence of trimethylsilyltriflate and also from the reaction of DMAP-dimethylphosphenium triflate with methyltriflate. The coordinative nature of the DMAP–phosphorus bond is demonstrated by a ligand exchange of DMAP for $PMe_3$ to give the hexamethyldiphosphonium dication.

## Introduction

Phosphorus exhibits a broad range of bonding environments and coordination numbers, and the chemistry of phosphorus is further diversified by the ability of compounds to accommodate negative or positive charges. Nevertheless, new electronic and structural arrangements for phosphorus are regularly reported. The Lewis acceptor properties of phosphorus have recently provided new synthetic approaches to new bonding environments.[1] Cations of phosphorus are the most versatile acceptors as classified in Figure 1 according to the coordination number and the charge.

Also summarized in Figure 1 are generic examples of donor–acceptor complexes that have been structurally characterized for monocations of type **A**,[2–8] **B**,[9–13] **C**,[1,14–18] **D**,[19–21] **E**[22,23] and **F**.[24] Complexes of a phosphorus dication of type **G** have been proposed on the basis of spectroscopic and chemical analysis data,[25–28] but solid-state structures have been confirmed for only two examples.[6,14,18] There are no structural reports of complexes involving cations of the type **H**, **I**, **J**, **K**, **L** or **M**.

We now report the preparation and isolation of complex **1** representing a 4-(dimethylamino)pyridine (DMAP) ligand on the dication of trimethylphosphane, the first example of a ligand-stabilized bonding environment **H**. Two preparative reactions demonstrate synthetic versatility and the solid-state structure provides fundamental comparisons with the DMAP complex of the isoelectronic group 13 Lewis acid $AlMe_3$.

Reaction of $[Me_3PCl][OTf]$ (OTf = trifluoromethanesulfonate; **2**[OTf], $\delta^{31}P$ = 94.0 ppm, $[D_3]$MeCN, room temp.) with DMAP in the presence of $Me_3SiOTf$ (Scheme 1, a) results in quantitative formation (isolated 93%) of the new salt **1**$[OTf]_2$ ($\delta^{31}P$ = 89.0 ppm, $[D_3]$MeCN, room temp.). The reaction represents a chloride ion displacement or ligand (neutral DMAP for chloride ion) exchange from monocation **2** (OTf = trifluoromethanesulfonate). Compound **1**$[OTf]_2$ is also formed quantitatively (isolated 95%) from the DMAP-phosphenium complex cation in **3**[OTf] ($\delta^{31}P$ = 91.3 ppm, $[D_3]$MeCN, room temp.) by reaction with MeOTf in the absence of solvent (Scheme 1, b). As illustrated in part c of Scheme 1, DMAP·$AlMe_3$ (**4**) was prepared quantitatively by reaction of $AlMe_3$ with DMAP in hexane.

The solid-state structure of **2**[OTf] (Figure 2) exhibits weak inter-ion contacts that give strands of alternating cations and anions along the *c* axis. The P–Cl distance [1.990(1) Å] is slightly shorter than that in $[Ph_3P–Cl\cdots Cl\cdots Cl–PPh_3]Cl·2CH_2Cl_2$ [2.015(9)].[29] The position of O1 [O1–P–Cl 178.33(5)°, P–O cation–anion contact 3.355(2) Å; cf. sum of the van der Waals radii $r_w(P) + r_w(O)$ = 3.32 Å][30] is envisaged as the associative site for DMAP in an $S_N2$ displacement of chloride. The cation in the solid-state structure of **3**(OTf) is shown in Figure 3, and is comparable to that of the previously reported $(DMAP·PPh_2)(OTf)$.[15]

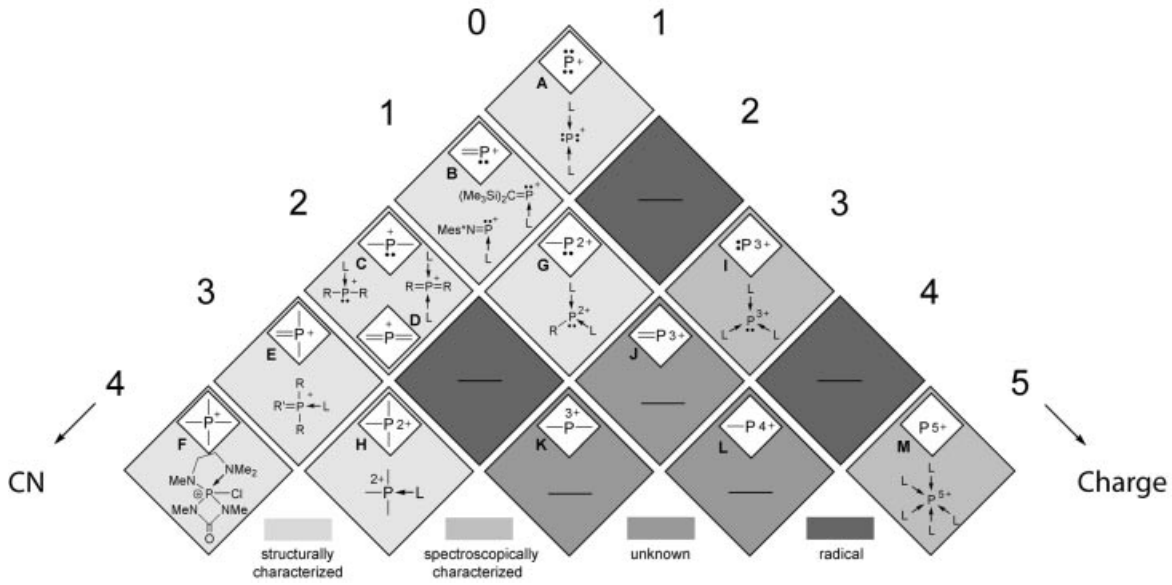

Figure 1. Bonding environments of cationic phosphorus centers and generic representations of isolated complexes.

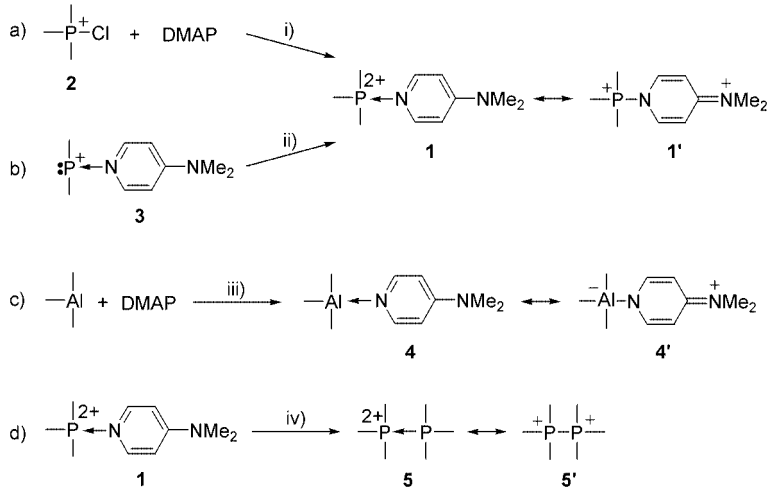

Scheme 1. Preparative routes to **1**[OTf]$_2$, **4**, and **5**[OTf]$_2$ [i) $Me_3SiOTf$, MeCN, – $Me_3SiCl$; ii) MeOTf; iii) hexane; iv) excess. $PMe_3$, – DMAP, MeCN].

Figure 4 shows the $^{31}P$ and $^{1}H$ NMR spectra for **1**[OTf]$_2$ as well as the bandshape analysis.[31] The phosphorus-coupled $^{1}H$ NMR spectrum exhibits a doublet centered at $\delta$ = 2.60 ppm assigned to the methyl groups attached to the phosphorus atom and the complex patterns at $\delta$ = 8.19 ppm and 7.13 ppm have been fitted as an AA′BB′$M_9X$ spin system. The $^{1}H$ and $^{13}C$ NMR signals for the *ortho* positions are upfield shifted, while those for the *meta* position are downfield shifted with respect to free DMAP (cf. $\delta^{1}_{H}$ = 8.21 and 6.46 ppm, [$D_3$]MeCN, room temp.).[32]

The solid-state structure of the dication in **1**[OTf]$_2$ is compared in Figure 3 with the structures of the monocation in **3**[OTf] and the neutral compound **4**. Selected bond lengths for DMAP,[33] **1**[OTf]$_2$, **2**[OTf], **3**[OTf] and **4** are listed in Table 1. The distinctly pyramidal geometry at phosphorus in monocation **3** is comparable with that in the diphenyl derivative, as is the P–N distance [**3**(OTf), 1.801(2) Å; ($Ph_2$P·DMAP)$^+$, 1.789(1) Å[15]]. The tetrahedral geometry of the phosphorus center in **1**[OTf]$_2$ is less distorted than that for the Al center in **4** (Figure 3). The DMAP ligand in all three complexes exhibits minimal structural adjustments with respect to free DMAP.[33] The Al–N distance [2.005(2) Å] in **4** is in the typical range for four-coordinate nitrogen-atoms involved in a donor–acceptor bond to an aluminium center (1.93–2.13 Å).[34] The P–N distance in **1**[OTf]$_2$ [1.720(3) Å] is significantly shorter than those in other DMAP complexes of phosphorus acceptors,[13,15,35] including **3**[OTf] [1.801(2) Å]. In addition, the P–C bonds in **1**[OTf]$_2$ [1.777(3), 1.772(3), 1.774(3) Å] are significantly shorter than those in **3**[OTf] [1.824(3), 1.826(3) Å] and in **4** [1.975(2), 1.971(2), 1.978(2) Å] (Table 1), all consistent with the greater positive molecular charge in **1**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

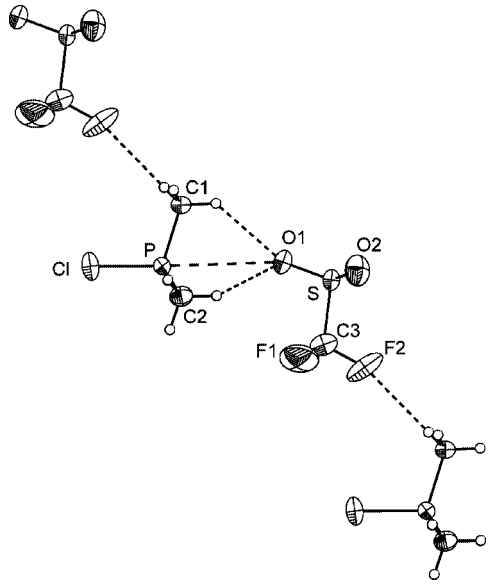

Figure 2. ORTEP view of a portion of the solid-state structure for **2**[OTf] along the *c* axis. Atoms Cl, P, C1, C3, S and F2 lie on a mirror plane, and atoms C2′, F1′ and O2′ are not shown. Amplitude displacement ellipsoids are depicted at 50% probability and hydrogen atoms with arbitrary radii.

The quinoidal character of the pyridine framework (Scheme 1, **1**′ and **4**′) is demonstrated in Table 1, by the C2–C3, C5–C6 and C4–N7 bonds being shorter in all complexes than in the free ligand. The trend in length for these bonds is **1** < **3** < **4** < DMAP, which we correlate with the relative strength of the N–E (E = P or Al) interaction in the complexes. Moreover, the N–E bond is shortest in the dicationic **1** and longest in **4**.

NBO analyses[36] and MO analyses of **4**, **3**, **1**, $AlMe_3$, $PMe_2^+$ and $PMe_3^{2+}$ at the B3LYP/6-31+G(d,p)[37] level provide charge-transfer and charge-distribution values that are summarized in Table 2. The donor–acceptor NP bond in **1** is purely σ in character and is strongly polarized (N: 75%, P: 25%) with a partial charge of 1.806 *e* at phosphorus, representing a substantial increase with respect to neutral $PMe_3$ (0.734 *e*). The calculated charge at phosphorus in the free $PMe_3^{2+}$ dication is 1.906 *e* (cf. 1.539 *e* at Al in $AlMe_3$) so that formation of **1** effects only a slight decrease in charge at phosphorus in the complex, although polarization of the P–C bonds in the $PMe_3$ fragment (P: 42%, C: 58%) contributes to the positive charge on phosphorus. The total charge transfer $Q_{CT}$ (from DMAP to acceptor, Table 2) in dication **1** (0.540 *e*) is significantly greater than that in **4** (0.158 *e*) and only slightly greater than that in **3** (0.411 *e*) consistent with the relative positive charge in each acceptor.

Reaction of **1** in MeCN with an excess of $PMe_3$ results in the displacement of DMAP and formation of **5**$[OTf]_2$ ($\delta^{31}P$ = 28.4 ppm, [D$_3$]MeCN, room temp.; isolated by $Et_2O$ diffusion into the reaction mixture)[38] (Scheme 1, d), which is understood in terms of a ligand exchange of DMAP in **1** by $Me_3P$.

## Summary

Compound **1**$[OTf]_2$ has been prepared by two methods and represents a ligand-stabilized $PMe_3^{2+}$, which is compared with the isoelectronic group 13 analog $AlMe_3$. The synthetic versatility of the first phosphane dication bodes well for the discovery and development of a series of ligand-stabilized multiply-charge phosphorus cations.

CCDC-650300 (for **1**$[OTf]_2$), -650302 (for **2**[OTf]), -650299 (for **3**[OTf]) and -650301 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Turbostratic Boron Nitride Coated on High-Surface Area Metal Oxide Templates

Søren K. Klitgaard,[a] Kresten Egeblad,[a] Michael Brorson,[b] Konrad Herbst,[b] and Claus H. Christensen*[a]

**Keywords:** Boron nitride / Turbostratic / Metal oxide templates / Catalyst support material / Nanostructure

Boron nitride coatings on high-surface area $MgAl_2O_4$ and $Al_2O_3$ have been synthesized and characterized by transmission electron microscopy and by X-ray powder diffraction. The metal oxide templates were coated with boron nitride using a simple nitridation in a flow of ammonia starting from ammonium borate adsorbed on $MgAl_2O_4$ or $\gamma$-$Al_2O_3$. This procedure resulted in the formation of a turbostratic boron nitride film with a thickness of a few individual BN layers.

## Introduction

The importance of boron nitride (BN) as a ceramic material, a lubricant, and for other industrial purposes is increasing. Whereas boron nitride in many respects is similar to carbon because of the isoelectronic relation, some important differences between the properties of the two materials remain. On one hand, boron nitride, like carbon, exists in several allotropic forms, including a diamond-like cubic structure and a graphite-like hexagonal layer structure. Even boron nitride nanotubes[1] and an intriguing boron nitride nanomesh[2] were recently reported. On the other hand, white hexagonal BN (occasionally referred to as "white graphite") is a good insulator with a bandgap around ca. 5.3 eV,[3] whereas black graphite is a semimetallic conductor. Both materials are resistant towards most reagents, but boron nitride is slightly less so due to its more polarized bonds. However, boron nitride is superior to carbon when it comes to thermal stability, in air and also in hydrogen. This has led to numerous studies on the use of boron nitride as a non-oxide ceramic material.[4–6] Due to the excellent stability of boron nitride at high temperatures and under harsh chemical conditions it has found application as a support material for heterogeneous catalysts.[7–12] The growing interest in using boron nitride as a catalyst support material, in particular for reactions where carbon is not stable, has increased the need for simple ways of synthesizing high-surface area boron nitride – an undertaking that normally involves considerable technical difficulties.[3,13] Very recently, the use of organic-inorganic block copolymers have been used to produce BN and BCN nanostructured ceramics with very high-surface areas.[14]

## Results and Discussion

Here we present a simple, versatile procedure for the formation of high-surface area turbostratic boron nitride by high-temperature nitridation of ammonium borate adsorbed on high-surface area $MgAl_2O_4$ or $\gamma$-$Al_2O_3$ with ammonia.

Previously, reports of BN thin films on different substrates have appeared in the literature.[3,7,15,16–19] Paine et al. showed that large $Al_2O_3$, $TiO_2$ and MgO single crystals could be covered by BN thin films using pyrolysis of a solid polymer formed by cross-linking chloroborazenes with hexamethyldisilazane.[4,16] Also, the preparation of BN films on metallic surfaces obtained by thermal decomposition of borazine or related compounds have been reported.[17,18]

In the present work, BN was synthesized by impregnating high-surface area $MgAl_2O_4$ and $Al_2O_3$ with aqueous precursor solutions of ammonium borate, using readily available boric acid as the source of boron, followed by high temperature nitridation in a flow of ammonia.[15,20] One advantage of the present procedure is its simplicity and the fact that it can be easily modified to control the extent of BN coverage on the metal oxide. $Al_2O_3$ and $MgAl_2O_4$ was chosen as the templates because they are considered completely inactive in redox processes and both known as inert support materials from the literature.[21,22] Given the stability, a removal of the metal oxides has not been attempted here even though new interesting structures could be envis-

aged. Other templating approaches to produce high-surface area BN have been reported recently. For instance, a soft-template approach involving surfactant assembly[23] and also a hard-template method involving the use of carbon as mesopore hard-template for making boron nitride and boron carbon nitride, BCN, using $B_2O_3$ as precursor was reported.[19] These materials were prepared by reaction with $N_2$ which require very high reaction temperatures (1500–1750 °C) due to the thermodynamic stability of $N_2$. By conducting the nitridation with ammonia the reaction temperature can be lowered.

The boron content of all the samples was determined by elemental analysis using Inductively Coupled Plasma (ICP) analysis. Prior to ICP analysis, the boron nitride coated samples were pretreated with aqua regia in a microwave oven leading to decomposition of boron nitride and its dissolution as boric acid. As shown in Table 1, the measured boron contents are in good agreement with those calculated. Table 1 also lists the surface areas measured at liquid-nitrogen temperature with a Micromeritics ASAP 2020, and calculated using the BET (Brunauer–Emmett–Teller) method.[24] As seen in Table 1, the BET surface areas of all the samples are moderate to high, though not as high as the parent metal oxide templates. The surface area of the boron nitride is very much dependent on the choice of metal oxide. By choosing a high-surface area metal oxide it will give a high-surface area boron nitride. Not surprisingly, a further decrease in the surface area is observed with successive BN coatings of the $MgAl_2O_4$ sample. This can be interpreted as encapsulation of the individual metal oxide crystals into larger agglomerates giving an overall smaller surface area.

Figure 1 shows a representative high-resolution transmission electron microscopy (TEM) image of the prepared BN-coated $MgAl_2O_4$, impregnated once with the precursor solution. The images were obtained by means of a JEM 2000FX microscope operated at an accelerating voltage of 300 kV. For sample preparation, ground powders were dispersed in ethanol and deposited on a 300 mesh copper grid coated with a holey carbon film. Figure 1 shows $MgAl_2O_4$ particles coated with a thin film of BN. The BN films, which coat and apparently fully encapsulate the metal oxide particles, have thicknesses between 0.5 and 3 nm. These films consist of 2 to 6 individual BN sheets. Judged from Figure 1, the thickness of a stack of 6 sheets is estimated to be ca. 1.8 nm resulting in an interlayer distance between the sheets of ca. 0.3 nm. This distance compares well with the 0.333 nm interlayer distance of bulk hexagonal BN.[3] The composition of the BN film was qualitatively confirmed by elemental analysis using energy-dispersive X-ray (EDX) analysis. TEM analyses of the samples with higher BN content, i.e. samples impregnated two or three times with precursor solution, showed BN coating of agglomerates of metal oxide particles already coated with BN (see electronic supporting information, Figure S1).

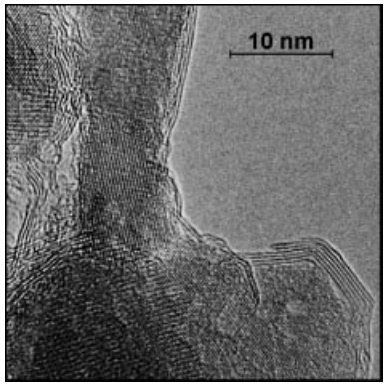

Figure 1. TEM image of BN on $MgAl_2O_4$ impregnated once. A thin film of BN encapsulates the $MgAl_2O_4$ particles. The film consists of 2–6 layers of BN.

Figure 2 shows a TEM image of BN-coated $Al_2O_3$ obtained by impregnating once with the precursor solution. $Al_2O_3$ is encapsulated by BN in a manner very similar to that of $MgAl_2O_4$, as 2–6 BN layers are formed. Multiple impregnations of $Al_2O_3$ are expected to show a similar behaviour as those of $MgAl_2O_4$.

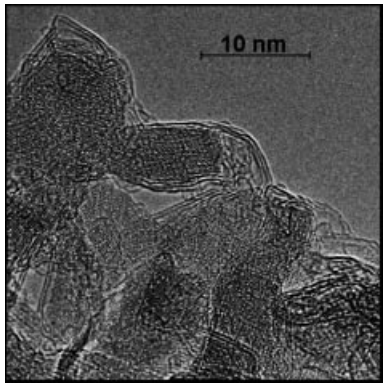

Figure 2. TEM image of BN on $Al_2O_3$. The $Al_2O_3$ particles are coated with a thin BN film.

Table 1. Boron contents and BET surface areas.

| Support material | Number of impregnations | Boron content measured [wt.-%] | Boron content calculated [wt.-%] | BET Surface area [$m^2/g$] |
|---|---|---|---|---|
| $MgAl_2O_4$ | 0 | 0 | 0 | 72 |
| $MgAl_2O_4$ | 1 | 4.67 | 4.49 | 39 |
| $MgAl_2O_4$ | 2 | 7.77 | 8.13 | 27 |
| $MgAl_2O_4$ | 3 | 10.70 | 11.16 | 14 |
| $Al_2O_3$ | 0 | 0 | 0 | 228 |
| $Al_2O_3$ | 1 | 4.30 | 4.49 | 175 |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

X-ray powder diffraction (XRPD) patterns of all samples were recorded after nitridation. Figure 3 shows the XRPD patterns of the $MgAl_2O_4$ sample coated (a) twice and (b) three times with BN; the remaining XRPD patterns are available as supplementary information (Figures S2–S3). In the XRPD patterns of BN-coated $MgAl_2O_4$ and $Al_2O_3$ samples that were impregnated once with precursor solution, only the parent metal oxide templates are observed, whereas the BN films are X-ray amorphous. This is because the BN film is too thin to give rise to any diffraction showing that all BN in the samples is present as film and that no bulk BN is present. However, when increasing the BN content by impregnating a second or third time, the BN phase appears as broad diffraction peaks at $2\theta$ ca. 26° and 43° in the diffraction pattern of BN-coated $MgAl_2O_4$. These diffraction maxima can be assigned to a boron nitride phase which has previously been described in the literature as turbostratic BN.[25] Turbostratic materials are characterized by having a structure of roughly parallel layers, these layers, however, showing random rotation and translation about the layer normal.[26] In an X-ray diffraction pattern, turbostratic BN can be indexed on the basis of the diffraction maxima of well-defined hexagonal BN, although some reflections of hexagonal BN alter their shape and other reflections are missing. The most characteristic changes caused by the layer disorder in turbostratic relative to hexagonal BN are seen in a broadening of the (002) reflection at $2\theta$ = 26.4°, the appearance of a two-dimensional (10) reflection at $2\theta$ = 42.4° merged from the (100) and (101) reflections and the disappearance of higher indexed reflections (102), (004) and (103) above $2\theta$ = 45°.[25] These features, although partially covered by the diffraction maxima of the spinel phase, are most clearly visible in the diffraction pattern shown in Figure 3, (b).

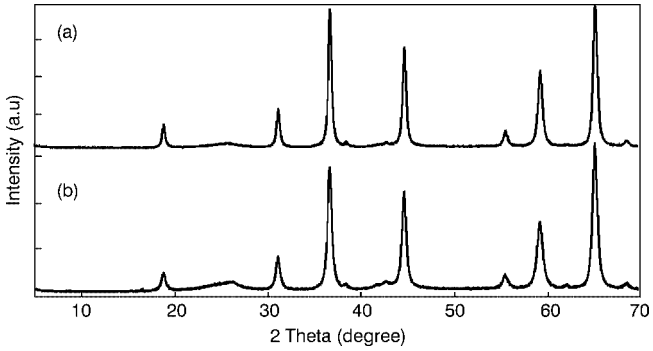

Figure 3. XRPD patterns of the BN samples coated (a) twice and (b) three times on $MgAl_2O_4$. The turbostratic BN phase appears at $2\theta$ ca: 26° and 43°.

Both diffraction maxima of turbostratic boron nitride can be used for the calculation of the particle size, although different information is obtained from the three-dimensional (002) reflection and the two-dimensional (10) reflection. The (002) reflection renders information about the crystallite size along the *c* axis, i.e. the thickness $L_c$ of the crystallite. From the (002) reflections in Figure 3, (a) and (b), $L_c$ parameters of 2.5 and 2.2 nm, respectively, can be determined. The interlayer spacings $d_{(002)}$, obtained from the exact position of the (002) peak maxima, are 0.344 nm in Figure 3, (a) and 0.339 nm in Figure 3, (b). This means that the BN film is, on average, 7 individual layers of BN thick confirming the impression from the TEM image shown in Figure S1. The slightly higher value for the *d* spacing in samples containing turbostratic BN compared to well-ordered hexagonal BN is consistent with the layer disorder in these samples, and several subpolytypes of turbostratic BN have been discussed in the literature.[27] On the other hand, the two-dimensional (10) reflection can be used to calculate the width of the crystallite layer. However, in the diffraction patterns of the BN-coated $MgAl_2O_4$ samples, the (10) reflection at $2\theta$ ca. 43° is partially covered by the (400) reflection of spinel, preventing an unambiguous determination of the line width of the (10) reflection.

The presence of a turbostratic boron nitride phase implies the presence of boron oxynitride ($BN_xO_y$) and amorphous boric oxide zones interconnecting the peripheries of the hexagonal planar boron nitride networks.[27–29] On the other hand, no indication for the presence of crystalline boric oxide with diffraction peaks at $2\theta$ = 13.58° and 27.98° is seen in the diffraction patterns shown in Figure 3. A removal of the oxygen impurities, coinciding with the growth and ordering of the BN layers to form crystalline BN, requires temperatures above 1350 °C.[29,30]

The diffraction pattern of BN coated on alumina (Figure S3) shows a mixture of two alumina phases, γ-alumina and θ-alumina, the latter being obtained by thermal degradation of γ-alumina at temperatures above 800 °C. Remarkably, no indication was found in the diffraction pattern for the formation of the thermodynamically stable α-alumina during the nitridation process, despite the thermal treatment of the coated material at 1100 °C for 24 h.

## Conclusions

In summary, composite materials of turbostratic boron nitride coated in various concentrations on high-surface area metal oxides, $MgAl_2O_4$ and $Al_2O_3$, were prepared by nitridation of ammonium borate with ammonia. This provides a simple way for the synthesis of high-surface area BN which could be an ideal support material for many heterogeneous catalytic applications.

## Experimental Section

In a typical synthesis of BN, a precursor solution was prepared by suspending $H_3BO_3$ (5.72 g, containing 1 g of boron) in $H_2O$ (7 mL) whilst stirring, followed by addition of aqueous $NH_3$ (3 mL, 24 wt.-%) resulting in a clear solution. Aqueous $NH_3$ was used to raise the solubility of $H_3BO_3$. The BN precursor solution (0.5 mL) was impregnated once onto high-surface area powders of $MgAl_2O_4$ or γ-$Al_2O_3$ (1 g) to incipient wetness, giving boron loads of ca. 4.5 wt.-% in each of the final the samples after the formation of boron nitride. Prior to nitridation, all samples were dried for at least 30 min at 100 °C. Nitridation was performed by passing a gentle flow of ammonia over the samples at 1100 °C for 24 h. Attempts

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to lower the reaction temperature for nitridation resulted in incomplete BN coverage of the metal oxide particles. In order to increase the amount of boron nitride, samples obtained by first impregnation were dried for 30 min at 100 °C and then impregnated a second and third time.

**Supporting Information** (see also the footnote on the first page of this article): Figure S1 shows a TEM image of BN on $MgAl_2O_4$ impregnated three times (boron content ca. 11 wt.-%). Figure S2 and S3 show XRPD patterns of BN coated on $MgAl_2O_4$ and $Al_2O_3$ impregnated once.

# Straightforward Synthesis of Donor-Stabilised Phosphenium Adducts from Imidazolium-2-carboxylate and Their Electronic Properties

Michèle Azouri,[a] Jacques Andrieu,*[a] Michel Picquet,[a] Philippe Richard,[a] Bernard Hanquet,[a] and Igor Tkatchenko[a]

**Keywords:** Carboxylates / Phosphanes / Electronic properties / Synthesis / Coordination modes

Cationic imidazolium-2-phosphanes were obtained by the addition of a chlorophosphane ($R_2PCl$, R = Ph, *i*Pr or Cy) to 1,3-dimethylimidazolium-2-carboxylate without the need for a purification step. An additional anion exchange reaction with $KPF_6$ led to the corresponding halide-free ligands in excellent yields. The molecular structure of one of them was examined both in the solid state and in solution. The lone pair of electrons on the phosphorus atom is not delocalised to the imidazolium fragment and thus remains available for further metal coordination. As such compounds can be described as phosphenium cations stabilised by a N-heterocarbene donor base, the electronic properties of the Lewis acceptor phosphorus centre was evaluated upon nickel tricarbonyl coordination, and the properties are surprisingly similar to those found for phosphites. The stronger π-acceptor character of these imidazolium-2-phosphanes relative to that of neutral tertiary phosphanes can thus explain the higher catalytic activities observed with the corresponding rhodium complexes in styrene hydroformylation reactions. Additionally, a preliminary study of platinum coordination chemistry indicated that the steric demand of 1,3-dimethylimidazolium-2-phosphanes is comparable to mixed arylalkylphosphanes.

## Introduction

Imidazolium-functionalised phosphanes, when compared to neutral phosphane ligands, represent an interesting opportunity to decrease strongly the metal leaching in homogeneous polyphasic catalysis, especially with the use of an ionic liquid phase.[1–3] However, if the C-2 position of the imidazolium ring is unprotected, this type of cationic ligand can sometimes decrease the activity of the catalyst and/or the enantioselectivity of the reaction because of the production of zerovalent metals[4,5] induced by the formation of the corresponding chelating N-heterocarbene phosphane.[6] To overcome such a limitation, we thus focused our investigations on imidazolium-2-phosphanes. Moreover, these particular structures represent rare examples of "base donor, P acceptor complexes" involving an electron rich $P^{III}$ centre as the Lewis acceptor.[7] It is also noteworthy that a simple change in the substituent on the nitrogen atom can easily tune their electronic and steric properties.

There are few examples of imidazolium-2-phosphanes in the literature.[8] They are obtained either by selective N alkylation of the corresponding free[9] or metal-coordinated[10] neutral imidazolyl-2-phosphane or by the addition of chlorodiphenylphosphane to isolated[11] or in situ generated imidazol-2-ylidenes from the related imidazolium salts in the presence of a strong base.[1] However, all these preparations require several steps, most of which are quite difficult due to the air-sensitive phosphorus intermediates or the use of strong alkyllithium bases. Thus, we developed a short and easy synthetic method allowing the obtention of the expected products on a large scale. Our synthetic approach is thus based on the use of 1,3-dimethylimidazolium-2-carboxylate (**1**) as a N heterocarbene source,[12] as it was reported in the preparation of N heterocarbene metal complexes[13,14] or ionic liquids,[15,16] as well as in the study of its reactivity towards several chlorophosphanes.

## Results and Discussion

### Synthesis and Characterisation of Imidazolium-2-phosphanes

The chlorophosphanes $Ph_2PCl$ and $iPr_2PCl$ react smoothly with **1** to afford pure imidazolium-2-phosphanes **2a** and **2b**, respectively (see Experimental Section) after 4 h (Scheme 1). When the more sterically hindered chloroalkylphosphane $Cy_2PCl$ was used, complete conversion leading to cationic ligand **2c** was achieved after a longer period (ca. 8 h), which also favoured the formation of small amounts of 1,3-dimethylimidazolium chloride [MMIM]Cl as a result of the competitive hydrolysis of the chlorophosphane by trace amounts of water in the solution and the subsequent protonation–decarboxylation of **1** with HCl.[15,16] This side reaction is, however, inhibited by the addition of molecular

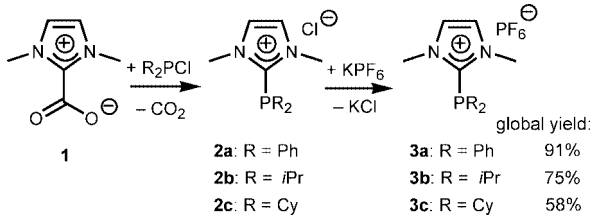
sieves. It is noteworthy that the bulky chlorodialkylphosphane $t$Bu$_2$PCl does not react with imidazolium-2-carboxylate at room temperature even after 24 h.



Scheme 1.

An anion exchange reaction of **2a**–**c** with $KPF_6$ in $CH_2Cl_2$, which can be done in a one-pot synthesis, led to the corresponding halide free ligands **3a**–**c** in excellent yields. Compounds **3a** and **3c** could be crystallised from dichloromethane/pentane as white plates in poor quality and as a white crystalline powder, respectively, which were therefore unsuitable for crystallographic studies. However, suitable crystals for X-ray structure determination were obtained for compound **3b** (Figure 1) from the same mixture of solvents.

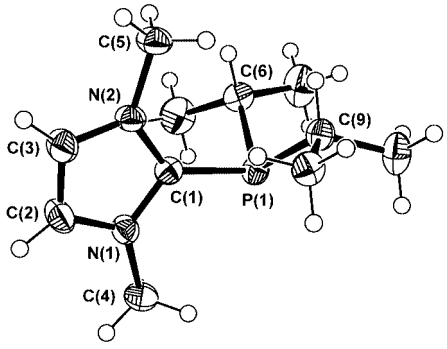


Figure 1. Molecular structure of **3b** with thermal ellipsoids presented at the 50% probability level. The $PF_6^-$ anion is omitted for clarity.

The ORTEP view shows that the P(1)–C(1) bond length of 1.840(3) Å (Table 1) is similar to that found in the 1,3-diisopropyl-4,5-dimethylimidazolium-2-phosphane analogue (1.813 Å)[11] obtained from the reaction of $Ph_2PCl$ and the corresponding imidazol-2-ylidene.

Table 1. Selected bond lengths [Å] and bond angles [°] for **3b**.

| | | | |
|---|---|---|---|
| P(1)–C(1) | 1.840(3) | P(1)–C(6) | 1.859(3) |
| P(1)–C(9) | 1.855(3) | C(1)–N(1) | 1.344(4) |
| C(1)–N(2) | 1.354(4) | C(4)–N(1) | 1.476(4) |
| C(5)–N(2) | 1.474(4) | C(2)–C(3) | 1.341(5) |
| N(1)–C(1)–N(2) | 105.6(3) | N(1)–C(1)–P(1) | 121.3(2) |
| N(2)–C(1)–P(1) | 133.0(2) | C(1)–P(1)–C(9) | 102.47(15) |
| C(1)–P(1)–C(6) | 98.96(15) | C(9)–P(1)–C(6) | 105.58(16) |
| C(9)–P(1)–C(1)–N(2) | 51.8(4) | C(6)–P(1)–C(1)–N(2) | –56.5(4) |

The imidazolium heterocycle is in the bisector plan of the C(9)–P(1)–C(6) angle [dihedral angles C(6,9)–P(1)–C(1)–N(2), Table 1], analogously to the structure of the above-mentioned cationic compound, possibly because of the strong steric hindrance of the methyl groups in the solid state. In $CDCl_3$ solution, we observed two different signals for the C(6,9)–$CH_3$ methyl groups. To obtain more information, an additional 1D-NMR NOE experiment was recorded at 298 K. Figure 2 shows a strong Overhauser effect of 2.5% between the irradiated N–Me groups and the C(6,9)H protons. This effect decreases from 1 to <0.2% for the C(6,9)Me$_{endo}$ and C(6,9)Me$_{exo}$ methyl groups, respectively. Such a difference in the Overhauser effect observed for the latter fragments proves that the spatial organisation of the isopropyl groups observed in the solid state is maintained in solution. However, the unique signals obtained at

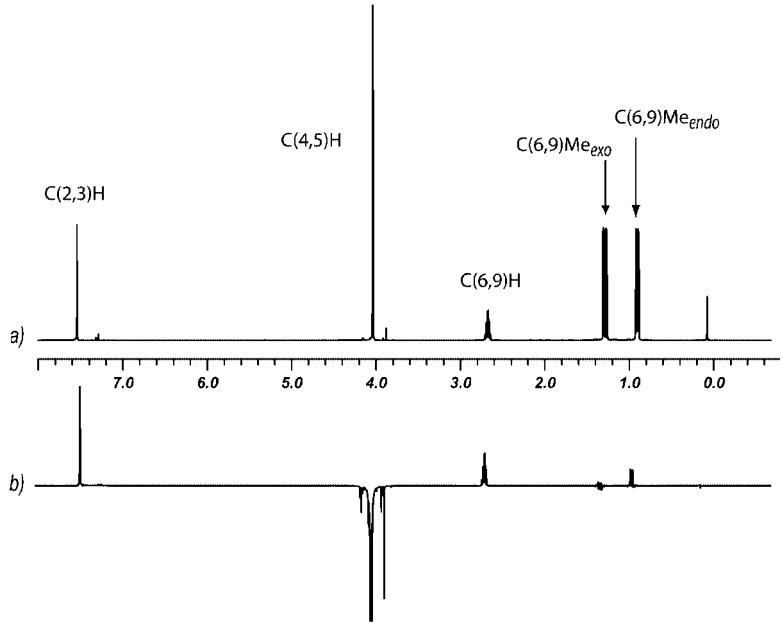

Figure 2. (a) $^1$H NMR spectrum and (b) NOE difference spectrum of **3b** in $CDCl_3$ at room temperature.

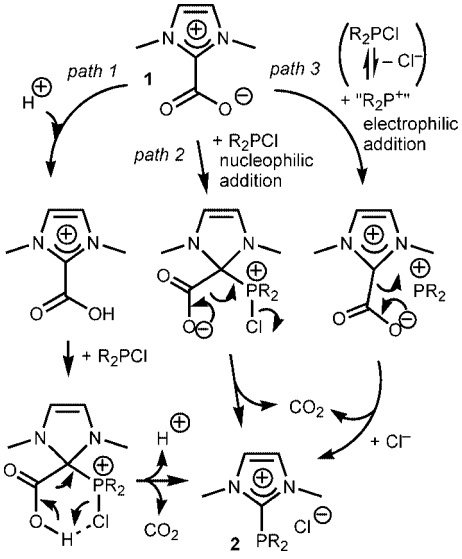
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

298 K for the N–Me group and for the olefinic CH moiety of compound **2** in the $^1$H and $^{13}$C NMR spectra (for example Figure 2, spectrum a) seemed to indicate free rotation of the imidazolium ring. Indeed, VT-NMR spectroscopic experiments in $CD_2Cl_2$ solutions were investigated at lower temperature and differentiation between the two N–Me signals and between the two olefinic CH was found at 193 K in the $^1$H and $^{13}$C NMR for **2a**, whereas the same phenomena was observed at 273 K for **2b**. These observations show unambiguously that the cationic fragment rotates around the P(1)–C(1) bond at room temperature, whereas the isopropyl groups do not rotate around the P–C(6,9) bonds. In addition, and in line with previous calculations,[7] this easy rotation of the imidazolium ring confirms that the lone pair of electrons on the P centre remains selectively localised on the phosphorus atom, which thus makes it available for further metal coordination.

## Mechanistic Aspects in the Formation of Imidazolium-2-phosphane

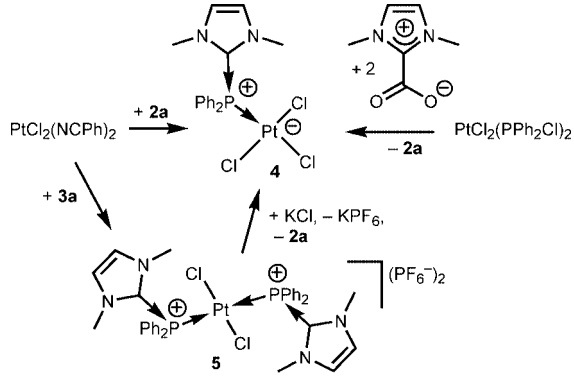
As our phosphorylation reaction contrasts other preparations of imidazolium-2-phosphanes because it does not involve the use of additional alkyllithium for the formation of the N heterocyclic carbene intermediate, different mechanistic pathways can reasonably be proposed to explain the formation of **2** (Scheme 2).



Scheme 2. Possible phosphorylation mechanisms of the imidazolium-2-carboxylate.

A first kinetic experiment in $CH_2Cl_2$ solution with $Ph_2PCl$ showed that the addition of a stoichiometric amount of $K_2CO_3$ did not prevent the formation of **2a**, although an increased reaction time from 4 to 14 h was needed to reach complete conversion. This observation is more consistent with the strong stabilizing interaction observed in our laboratory between **1** and alkali metals[17] rather than with an acid-catalysed mechanism. A second experiment based on the direct addition of $Ph_2PCl$ to the pure carboxylic acid form [MMIM-2-$CO_2H$]($BF_4$)[15,17] of **1** in a $CH_2Cl_2/C_6D_6$ mixture did not proceed even after 18 h at room temperature. Both observations exclude the possibility of an acid-catalysed phosphorylation reaction.

Notably, a mechanism involving the formation of a P–O bond followed by P migration to the N–C–N carbon atom can also be excluded, as no adduct was observed after the addition of $t$Bu$_2$PCl to the imidazolium-2-carboxylate. Therefore, two alternative mechanisms both involving the direct addition of $R_2PCl$ were examined (Scheme 2, paths 2 and 3); these mechanisms differ in their nucleophilic and electrophilic nature. To distinguish between them, we envisioned the use of a chlorophosphane reagent in which the nucleophilic character would be masked by metal coordination. The reactivity of imidazolium-2-carboxylate towards *cis*-$PtCl_2(PPh_2Cl)_2$ was then investigated in $CD_2Cl_2$ solution. $^{31}$P NMR spectroscopic analysis of the crude product performed after 2 d showed the absence of a signal at $\delta$ = 71.4 ppm, which is due to the platinum starting material, and the presence of two new peaks at $\delta$ = –26.9 and 2.2 ppm; the latter peak showed a $^1J_{Pt,P}$ value of 3420 Hz. This spectrum indicates that the *cis*-$PtCl_2(PPh_2Cl)_2$ complex had totally disappeared while free ligand **2a** and a new monophosphane platinum complex were formed. The latter complex was assigned to the [$PtCl_3$(**2a**)] complex **4**, which was independently prepared by treating [$PtCl_2(NCPh)_2$] with one equivalent of compound **2a** (Scheme 3), and by using reaction conditions similar to those described for a platinum analogue complex.[18] Because the imidazolium-2-phosphane was formed in the above experiment in spite of the platinum coordination, which masks the lone pair of electrons on the phosphorus atom in chlorodiphenylphosphane, we can suggest that $PR_2Cl$ likely reacts as an electrophilic reagent[19] toward imidazolium-2-carboxylate (Scheme 2, path 3). This assumption is supported by the lack of reactivity when the less electron rich carboxylic acid [MMIM-2-$CO_2H$]($BF_4$) is used under the conditions described for imidazolium-2-carboxylate (Scheme 2, path 1). Nevertheless, the presence of free ligand **2a** could also be the result of the direct addition of imidazolium-2-carboxylate to free $PPh_2Cl$, which thus illustrates the electrophilic character of compound **1**. However, the release of $Ph_2PCl$



Scheme 3.

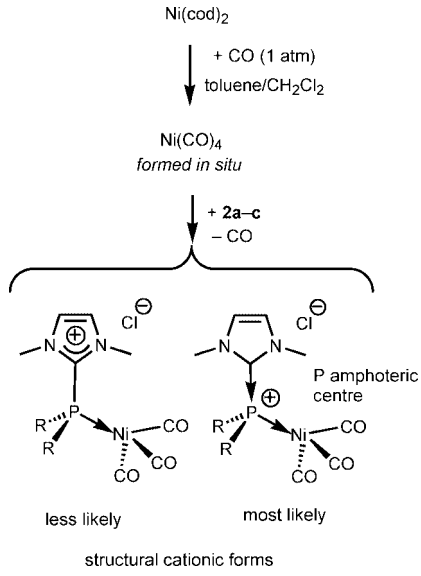
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

from *cis*-$PtCl_2(PPh_2Cl)_2$ is unlikely at room temperature, as the reaction would then induce *cis*/*trans*-$PtCl_2(PPh_2Cl)_2$ isomerisation, which was shown to require higher temperatures.[20] Therefore, in our case the presence of free ligand **2a** in solution seems to be the consequence of imidazolium-2-phosphane displacement by a chloride anion, which leads to more stable complex **4**.

### Electronic Properties of the Ligands and Catalytic Properties

As mentioned in the introduction, there is only one report of the use of imidazolium-2-phosphanes in homogeneous catalysis.[1] In that paper, the authors observed that the presence of a *para*-phenylene spacer between the phosphorus atom and the imidazolium fragment decreased the TOF from 552 to 51 $h^{-1}$ for rhodium catalysts in hydroformylation reactions of 1-octene and also decreased the *n:i* aldehyde ratio.[1] Besides, terminal alkenes are hydroformylated at higher rates when bulky phosphites[21] or arylphosphanes containing electron-withdrawing substituents[22] are used instead of triphenylphosphane. All results agree with the fact that the nature of the phosphorus ligand plays an important role in the stabilisation of the active species in hydroformylation reactions and the associated kinetic behaviour (alkene coordination vs. hydrogenolysis step), which drastically modify the conversion rate and selectivity in the catalytic reaction.[23] However, recent calculations performed on imidazolium-2-phosphanes describe these compounds as nonmetal complexes with a coordination bond between the electron rich N–C–N carbon and the P acceptor centre instead of a P–C covalent bond.[7] Therefore, we thought that the different hydroformylation experiments performed with an imidazolium-2-phosphane could be correlated with its specific σ-donor/π-acceptor character, which should certainly be different to those of the unmodified $PPh_3$, although the lone pair of electrons on the phosphorus atom is not delocalised (see above). The electronic/donor properties of the P atom was then evaluated by measurement of the $A_1$ symmetric stretching frequency of nickel complexes prepared in situ by replacement of a CO group in $[Ni(CO)]_4$ by phosphane **2a**. Although less-toxic compounds than $Ni(CO)_4$ {prepared in situ from $[Ni(cod)_2]$} are now more commonly used to characterise the electronic properties of phosphanes {for example, the $[Rh(CO)_2Cl]_2$ dimer}, we opted to prepare a nickel–carbonyl complex to compare easily the imidazolium-2-phosphane complex parameters directly with the large database tabulated by Tolman for adducts of the $Ni(CO)_3$ moiety.[24] We thus reacted **2a** with an equimolar amount of $Ni(CO)_4$ to afford [$Ni(CO)_3$(**2a**)] (Scheme 4).

The new nickel complex was not isolated but was recognised by its characteristic $\nu_{CO}(A_1)$ carbonyl stretching mode in the infrared spectrum of the crude mixture, which was found at 2082 $cm^{-1}$ in a toluene/$CH_2Cl_2$ solution. This value classifies **2a** as less electron-donating than the common arylphosphanes [$\nu_{CO}(A_1)$ = 2069 $cm^{-1}$ with $PPh_3$]. The



Scheme 4.

replacement of the aryl groups by isopropyl or cyclohexyl substituents in imidazolium-2-phophanes **2b** and **2c** led to new stretching frequencies at 2075 and 2078 $cm^{-1}$, respectively, in the infrared spectra for the corresponding phosphane–nickel tricarbonyl complexes. The latter values are slightly shifted to lower frequencies owing to the presence of better electron-donating alkyl groups. Nevertheless, the electronic parameters of compounds **2a**–**c** are wedged in the range of strong π-acceptor ligands such as phosphites, from $P(OiPr)_3$ [with $\nu_{CO}(A_1)$ = 2076 $cm^{-1}$] and $P(OPh)_3$ ligands [with $\nu_{CO}(A_1)$ = 2085 $cm^{-1}$][24] and clearly illustrate the strong acceptor properties of a donor-stabilised phosphenium cation reinforced by the presence of its positive charge (Scheme 4).

In addition to the above electronic properties studied, a preliminary determination of the steric demands of imidazolium-2-phosphanes was investigated in platinum dichloride complexes with the smallest ligand. So, the addition of one (or two) equivalent(s) of ligand **2a** to $PtCl_2(NCPh)_2$ in $CH_2Cl_2$ solution at room temperature led selectively to the formation of [$PtCl_3$(**2a**)] complex **4**. When the same reaction was performed under similar conditions with two equivalents of related halide-free ligand **3a**, the selective formation of new [$PtCl_2$(**3a**)$_2$] complex **5** was observed with a typical $^1J_{Pt,P}$ value of 2785 Hz for a P *trans* geometry around the metal centre (Scheme 3). Additionally, the $^{31}P\{^1H\}$ NMR spectrum of **5** recorded in $CH_2Cl_2/C_6D_6$ after introduction of KCl in a 1:1 ratio showed the presence of complex **4** and free ligand **2a**. This observation confirms the higher stability of the latter platinum trichloride complex **4**, and noteworthy is the phosphane decoordination from the platinum centre by halide addition (Scheme 3).

It is interesting to note that the nature of the counter anion perfectly controls the metal/ligand ratio in the metal–imidazoliumphosphane complexes. Nevertheless, the latter reaction contrasts those with other tertiary phosphanes $Ph_2PR$ (R = Ph, Cl, OMe or $NEt_2$[20]), which selectively

lead, under similar mild conditions, to the corresponding *cis*-[$PtCl_2(Ph_2PR)_2$] isomers. The results seem to indicate that compound **2a** behaves as a bulky phosphane like the mixed arylalkylphosphanes. Other investigations on the electronic and steric properties of the cationic imidazolium-2-phosphanes, as well as their catalytic properties, are currently in progress.

## Conclusions

In this paper, we report that imidazolium-2-carboxylate is an interesting starting material in the simple and straightforward synthesis of imidazolium-2-phosphanes, and the reaction could easily be extended to large-scale preparation. The synthesis of other base-stabilised phosphenium cation complexes, in addition to their optically pure forms, are currently in progress in our laboratory. Moreover, the measurements of the $A_1$ symmetric stretching frequency of related $Ni(CO)_3$(imidazolium-2-phosphane) complexes have shown that such compounds behave as stronger π-acceptor ligands like phosphites. The result seems to be the consequence of the C→P bond present in imidazolium-2-phosphanes, which displaces the positive charge from the imidazolium ring to the phosphorus centre. This electronic property combined with the ionic nature of the compounds renders these ligands very promising in the development of new continuous-flow catalytic processes that are currently being investigated.

## Experimental Section

**General Procedures:** All reactions were performed in Schlenk-type flasks under an argon atmosphere. Solvents were purified and dried by conventional methods and distilled under an argon atmosphere. With the exception of compound **1** and the *trans*-$PtCl_2$(**3a**)$_2$ complex, all $^1H$, $^{31}P\{^1H\}$ and $^{13}C\{^1H\}$ NMR spectra were recorded with a Bruker Avance 300 instrument at 298 K. Complete assignment was achieved by COSY, DEPT and HMQC experiments. All chemical shifts are reported relative to $SiMe_4$ ($^1H$ and $^{13}C$ NMR) and 85% $H_3PO_4$ ($^{31}P$ NMR) and are given in ppm. Electrospray spectra were performed with a Bruker micrOTOF-Q instrument. The IR instrument was calibrated with solutions of $Ni(CO)_3(PPh_3)$, for which the $A_1$ $\nu_{CO}$ stretching band was reported to be 2068.9 $cm^{-1}$.[24] Elemental analyses were performed with a Fisons EA 1108 apparatus at the ICMUB in Dijon. The chlorophosphanes $Ph_2PCl$, *i*$Pr_2PCl$ and $Cy_2PCl$ were commercial products from Aldrich and Ni(1,5-cod)$_2$ was a commercial product from Strem, and all were used as received. 1,3-Dimethylimidazolium-2-carboxylate (**1**) and the $PtCl_2(NCPh)_2$ complex were prepared according to the literature.[15,17,25] Nickel tetracarbonyl $Ni(CO)_4$ was prepared from Ni(1,5-cod)$_2$ and CO according to the literature;[26] however, owing to its highly toxic nature, this preparation was handled with extreme care in a dedicated facility (CECUB, Université de Bourgogne).

**Compound 2a:** To a mixture of **1** (0.164 g, 1.17 mmol) and $Ph_2PCl$ (0.258 g, 1.17 mmol) was added $CH_2Cl_2$ (5 mL). The mixture was stirred for 4 h at room temp. The solvent was then removed under vacuum to afford a white powder (359 mg, 97%) that was dried for 3 h under vacuum. M.p. 200 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.46 (s, 2 H, CH=), 7.42–7.23 (m, 10 H, aromatics), 3.78 (d, $J_{P,H}$ = 7.2 Hz, 6 H, $NCH_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): $\delta$ = 142.24 (d, $J_{P,C}$ = 52.1 Hz, 1 C, NCN), 132.74–130.95 (m, 12 C, aromatics), 128.52 (s, 2 C, CH=), 37.71 (d, $^3J_{P,C}$ = 9.1 Hz, 2 C, $NCH_3$) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = –27.31 (s) ppm. $C_{17}H_{18}N_2PCl$ (316.76): calcd. C 64.46, H 5.73, N 8.84; found C 64.23, H 5.78, N 8.84.

**Compound 2b:** Prepared in an analogous manner to **2a** and obtained as white powder (250 mg, 86%). M.p. 133 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.50 (s, 2 H, CH=), 4.18 (s, 6 H, $NCH_3$), 2.62 (hept., $^3J_{H,H}$ = 6.6 Hz, 2 H, PCH), 1.23 (dd, $^3J_{H,H}$ = 6.6 Hz, $^3J_{P,H}$ = 12.6 Hz, 6 H, $CCH_3$ *exo*), 0.83 (dd, $^3J_{H,H}$ = 6.9 Hz, $^3J_{P,H}$ = 7.2 Hz, 6 H, $CCH_3$ *endo*) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): $\delta$ = 145.07 (d, $J_{P,C}$ = 60.4 Hz, 1 C, NCN), 127.17 (s, 2 C, CH=), 37.86 (d, $^3J_{P,C}$ = 9.1 Hz, 2 C, $NCH_3$), 24.07 (d, $^3J_{P,C}$ = 10.6 Hz, 2 C, PCH), 21.33 (d, $^3J_{P,C}$ = 27.2 Hz, 4 C, $CH_3$ *exo*), 20.75 (d, $^3J_{P,C}$ = 9.1 Hz, 4 C, $CH_3$ *endo*) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = –9.44 (s) ppm. $C_{11}H_{22}N_2PCl$ (248.73): calcd. C 53.12, H 8.91, N 11.26; found C 53.05, H 8.71, N 11.70.

**Compound 2c:** Prepared in an analogous manner to **2a** over molecular sieves and obtained as a white powder (277 mg, 72%). $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 8.61 (s, 2 H, CH=), 4.14 (s, 6 H, $NCH_3$), 2.33 (m, 1 H, PCH), 1.77 (m, 8 H, $CH_2$), 1.24 (m, 10 H, $CH_2$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): $\delta$ = 144.5 (d, $J_{P,C}$ = 60.4 Hz, 1 C, NCN), 127.4 (s, 2 C, CH=), 37.79 (s, 2 C, $NCH_3$), 33.99 (d, $J_{P,C}$ = 11.3 Hz, 2 C, PCH), 31.85 (d, $^2J_{P,C}$ = 24.2 Hz, 2 C, $CH_2$), 30.39 (d, $^2J_{P,C}$ = 6.0 Hz, 2 C, $CH_2$), 26.33 (d, $^3J_{P,C}$ = 8.3 Hz, 2 C, $CH_2$), 26.08 (d, $^3J_{P,C}$ = 15.1 Hz, 2 C, $CH_2$), 25.51 (s, 2 C, $CH_2$) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = –19.77 (s) ppm. $C_{17}H_{30}N_2PCl$ (328.86): No satisfactory elemental analysis was obtained for **2a** owing to its strong hygroscopic character.

**Compound 3a:** To a solution of **2a** (0.380 g, 1.20 mmol) in acetone (5 mL) was added $KPF_6$ (0.277 g, 1.50 mmol), and the resulting suspension was stirred for 2 d at room temp. The solvent was removed under vacuum at 50 °C for 2 h. The residue was dissolved in $CH_2Cl_2$ (5 mL), and the resulting solution was filtered. Evaporation of solvent under vacuum afforded compound **3a**, which was crystallised from $CH_2Cl_2$/pentane as white plates (481 mg, 94%). M.p. 176 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.49 (s, 2 H, CH=), 7.45–7.24 (m, 10 H, aromatics), 3.57 (s, 6 H, $NCH_3$) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): $\delta$ = 143.08 (d, $J_{P,C}$ = 54.3 Hz, 1 C, NCN), 133.06–130.07 (m, 12 C, aromatics), 127.00 (s, 2 C, CH=), 37.65 (d, $^3J_{P,C}$ = 7.6 Hz, 2 C, $NCH_3$) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = –25.89 (s, $P_{phosphane}$), –144.14 (hept., $J_{P,F}$ = 712 Hz, $PF_6^-$) ppm. $C_{17}H_{18}N_2P_2F_6$ (426.27): calcd. C 47.90, H 4.25, N 6.57; found C 47.80, H 4.08, N 6.49.

**Compound 3b:** Prepared in an analogous manner to **3a** and obtained as white solid (374 mg, 87%). M.p. 154 °C. $^1H$ NMR (300 MHz, $CDCl_3$): $\delta$ = 7.46 (s, 2 H, CH=), 3.96 (s, 6 H, $NCH_3$), 2.60 (hept., $^3J_{H,H}$ = 6.9 Hz, 2 H, PCH), 1.20 (dd, $^3J_{H,H}$ = 6.9 Hz, $^3J_{P,H}$ = 12.3 Hz, 6 H, $CCH_3$ *exo*), 0.82 (dd, $^3J_{H,H}$ = 6.9 Hz, $^3J_{P,H}$ = 7.20 Hz, 6 H, $CCH_3$ *endo*) ppm. $^{13}C\{^1H\}$ NMR (75 MHz, $CDCl_3$): $\delta$ = 145.89 (d, $J_{P,C}$ = 62.4 Hz, 1 C, NCN), 126.14 (s, 2 C, CH=), 37.35 (d, $^3J_{P,C}$ = 9.8 Hz, 2C, $NCH_3$), 23.88 (d, $J_{C,P}$ = 10.5 Hz, 2 C, PCH), 21.16 (d, $^3J_{P,C}$ = 27.2 Hz, 4 C, $CH_3$ *exo*), 20.46 (d, $^3J_{P,C}$ = 9.8 Hz, 4 C, $CH_3$ *endo*) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = –8.57 (s, $P_{phosphane}$), –144.40 (hept., $J_{P,F}$ = 712 Hz, $PF_6^-$) ppm. $C_{11}H_{22}N_2P_2F_6$ (358.24): calcd. C 36.88, H 6.19, N 7.82; found C 36.39, H 6.08, N 7.54.

**Compound 3c:** Prepared in an analogous manner to **3a** and obtained as white solid (421 mg; 80%). M.p. 193 °C. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.51 (s, 2 H, CH=), 3.95 (s, 6 H, $NCH_3$), 2.37 (m, 2 H, PCH), 1.75 (m, 8 H, $CH_2$), 1.23 (m, 10 H, $CH_2$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CDCl_3$): $\delta$ = 144.53 (d, $J_{P,C}$ = 62.6 Hz, 1 C, NCN), 125.6 (s, 2 C, CH=), 36.57 (s, 2 C, $NCH_3$), 32.86 (d, $J_{P,C}$ = 11.3 Hz, 2 C, PCH), 30.87 (d, $^2J_{P,C}$ = 24.2 Hz, 2 C, $CH_2$), 29.33 (d, $^2J_{P,C}$ = 6.8 Hz, 2 C, $CH_2$), 25.22 (d, $^3J_{P,C}$ = 8.3 Hz, 2 C, $CH_2$), 25.02 (d, $^3J_{P,C}$ = 15.1 Hz, 2 C, $CH_2$), 24.56 (s, 2 C, $CH_2$) ppm. $^{31}$P{$^1$H} NMR (121 MHz, $CDCl_3$): $\delta$ = –18.89 (s, $P_{phosphane}$), –144.33 (hept., $J_{P,F}$ = 712 Hz, $PF_6^-$) ppm. $C_{17}H_{30}N_2P_2F_6$ (438.37): calcd. C 46.58, H 6.90, N 6.39; found C 44.99, H 7.54, N 6.05.

**Formation of [Ni(CO)$_3$(2a–c)]:** $Ni(CO)_4$ was prepared by treating a solution of [Ni(1,5-cod)$_2$] (50.1 mg, 0.182 mmol) in toluene (1 mL) with CO at 0 °C for 5 min, followed by the addition of **2a** (0.0545 mg, 0.172 mmol) in $CH_2Cl_2$ (1 mL). The mixture was stirred for 15 min. A light-green solution was obtained, which was analysed by infrared spectroscopy. IR (toluene/$CH_2Cl_2$): $\nu_{CO}$ = 2082 ($A_1$), 2013 cm$^{-1}$ (E). The formation of the analogous [Ni(CO)$_3$(**2b**)] and [Ni(CO)$_3$(**2c**)] complexes was performed under similar conditions. IR (toluene/$CH_2Cl_2$): $\nu_{CO}$ = 2075 ($A_1$), 2051 cm$^{-1}$(E) for [Ni(CO)$_3$(**2b**)] and $\nu_{CO}$ = 2078 ($A_1$), 2005 cm$^{-1}$ (E) for [Ni(CO)$_3$(**2c**)].

**Platinum Complex 4:** To a mixture of **2a** (60.1 mg, 0.19 mmol) was added $PtCl_2(PhCN)_2$ (86.6 mg, 0.19 mmol) in $CH_2Cl_2$ (2 mL), and the mixture was stirred for 7 h. A yellow suspension was obtained. The suspension was filtered off, and the yellow solid was washed with diethyl ether and dried under vacuum to afford $PtCl_3$(**2a**) (94 mg, 85%). M.p. >200 °C (dec.). $^1$H NMR (300 MHz, [D$_6$]acetone): $\delta$ = 7.56–7.78 (m, 12 H, aromatics and CH=), 2.03 (s, 6 H, $NCH_3$) ppm. $^{31}$P{$^1$H} NMR (121 MHz, [D$_6$]acetone): $\delta$ = 2.24 (s, $J_{Pt,P}$ = 3425 Hz, $P_{phosphane}$) ppm. MS: *m*/*z* = 510.060 [M – Cl – HCl]$^+$. $C_{17}H_{18}Cl_3N_2PPt$ (582.76): calcd. C 35.04, H 3.11, N 4.81; found C 35.51, H 2.78, N 4.26.

**Platinum Complex 5:** To a mixture of **3a** (0.0396 mg, 0.093 mmol) was added $PtCl_2(PhCN)_2$ (0.0224 mg, 0.049 mmol) in $CH_2Cl_2$ (1.5 mL), and the mixture was stirred for 12 h. A yellow suspension was obtained. The suspension was filtered off, and the yellow solid was dried under vacuum to afford *trans*-$PtCl_2$(**3a**)$_2$ (100 mg, 95%). M.p. 216 °C. $^1$H NMR (300 MHz, [D$_6$]acetone): $\delta$ = 8.43–7.80 (m, 20 H, aromatics), 7.97 (s, 4 H, CH=), 3.75 (s, 12 H, $NCH_3$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, [D$_6$]acetone): $\delta$ = 141.64 (d, $J_{P,C}$ = 7.5 Hz, 2 C, NCN), 139.51–127.09 (m, 24 C, aromatics), 126.68 (s, 4 C, CH=), 44.04 (s, 4 C, $NCH_3$) ppm. $^{31}$P{$^1$H} NMR (121 MHz, [D$_6$]acetone): $\delta$ = 17.83 (s, $J_{Pt,P}$ = 2785 Hz, $P_{phosphane}$), –139.08 (hept, $J_{P,F}$ = 712 Hz, $PF_6^-$) ppm. $C_{34}H_{48}Cl_2F_{12}N_4P_4Pt$ (1130.64): calcd. C 36.12, H 4.28, N 4.96; found C 36.30, H 3.86, N 4.66.

**Crystal Structure Determination for 3b:** Crystal data and refinement figures are reported in Table 2. The data set was collected with an Enraf–Nonius Kappa CCD diffractometer at 110 K with Mo-$K_\alpha$ radiation. The structure was solved by direct methods and refined with full-matrix least-squares methods[27] based on $|F^2|$ with the aid of the WINGX program.[28] All non-hydrogen atoms were refined with anisotropic thermal parameters. The positions of the hydrogen atoms were either calculated or located on final Fourier difference maps and refined, after idealization, with a riding model. CCDC-649689 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 2. Crystallographic and refinement data for complex **3b**.

# $V^{IV}O$ Complexes of Bis(imidazol-2-yl) Derivatives: A Potentiometric, Spectroscopic and DFT Study

Katalin Várnagy,[a] Timea Csorba,[a] Dóra Kiss,[a] Eugenio Garribba,*[b] Giovanni Micera,*[b] and Daniele Sanna[c]

**Keywords:** Vanadium / Bioinorganic chemistry / pH potentiometry / EPR spectroscopy / Density functional calculations

The complexation of the $V^{IV}O$ ion with four amino acid derivatives of bis(imidazol-2-yl)methylamine [*N*-glycyl-bis(imidazol-2-yl)methylamine = Gly-BIMA, *N*-α-aspartyl-bis(imidazol-2-yl)methylamine = α-Asp-BIMA, *N*-α-glutamyl-bis(imidazol-2-yl)methylamine = α-Glu-BIMA and *N*-histidyl-bis(imidazol-2-yl)methylamine = His-BIMA] was studied in aqueous solution through the combined application of potentiometric and spectroscopic (UV/Vis and EPR) techniques. For comparison, the complexing capability of three simple bis(imidazol-2-yl) derivatives [bis(imidazol-2-yl)methane = BIM, bis(imidazol-2-yl)methylamine = BIMA and bis(imidazol-2-yl)-nitromethane = BINM] and two benzyloxycarbonyl (Z) derivatives (Z-Gly-BIMA and Z-Ala-BIMA) was reported. Mono- and bis-chelated species with the ($N_{im}$, $N_{im}$) donor set were formed in both acid and neutral pH conditions, with the bis-chelated complexes being characterised by a *cis-trans* isomerism. In the basic pH range the complexation process continues with the formation of a mono-hydroxo *cis*-$VOL_2H_{-1}$ complex in systems with BIM, BIMA and BINM, and with the deprotonation and coordination of the amide nitrogen to give $VOLH_{-1}$ and $VOLH_{-2}$ in those with Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA and His-BIMA. The results demonstrate that the bis(imidazol-2-yl)methyl residue is an anchoring group of intermediate strength, capable of avoiding extensive hydrolysis of the $V^{IV}O$ ion in the presence of a slight excess of ligand (L/M from 3:1 to 5:1). DFT calculations with progressively more complex basis sets were performed in order to obtain information on the structure of the $VOLH_{-1}$ and $VOLH_{-2}$ complexes. Finally, a discussion on the $^{51}V$ anisotropic parallel hyperfine coupling constant ($A_{\parallel}$) of $VOLH_{-1}$ and $VOLH_{-2}$ and on the EPR properties connected to the V–$N^-$(amide) bond in $V^{IV}O$ complexes is presented.

## Introduction

Vanadium plays a number of roles in biological systems.[1] It is accumulated by tunicates (ascidians or sea squirts)[2] and the fan worm *Pseudopotamilla occelata*,[3] and by some species of the mushroom genus *Amanita*.[4] Vanadium is also present in two enzymes, vanadium-dependent haloperoxidases,[5] and nitrogenase.[6] In the human organism it elicits a number of physiological responses, for example, the inhibition of phosphate-metabolising enzymes,[7] such as phosphatases, ribonuclease and ATPases, and its compounds show insulin-mimetic activity.[8]

The presence of vanadium in all these systems suggests it interacts with biomolecules. Among the biomolecules present in intra- and extra-cellular fluids, proteins and peptides have a special importance because of their high amount in the cellular environment and their possible interaction with the metal ions through a number of donor groups. For instance, glutathione is believed to play an important role in the processes of reduction of $V^V$ to $V^{IV}O$ and in the subsequent complexation reactions.[9]

The interaction of vanadium, mainly in the oxidation states +IV and +V, with different proteins and enzymes has been reported in the literature.[10] Of special importance is interaction with human transferrin (hTF) and human serum albumin (HSA), since they could be involved in the transport of vanadium and insulin-mimetic compounds towards physiological target sites.[11–16]

Oligopeptides are the most closely related models for proteins; they may mimic specific metal ion binding sites, for example, GlyGlyHis for serum albumin.[17] Detailed studies on synthetic models of the vanadium–protein interaction can greatly contribute to the knowledge of its biological activity. Oligopeptides can interact with a metal ion through the terminal amino and carboxylate groups, intermediate peptide bond and side-chain donors, but all these groups are not strong enough to keep metal ions in solution at the physiological pH. However, they can play the role of "anchoring group" and promote the deprotonation of the

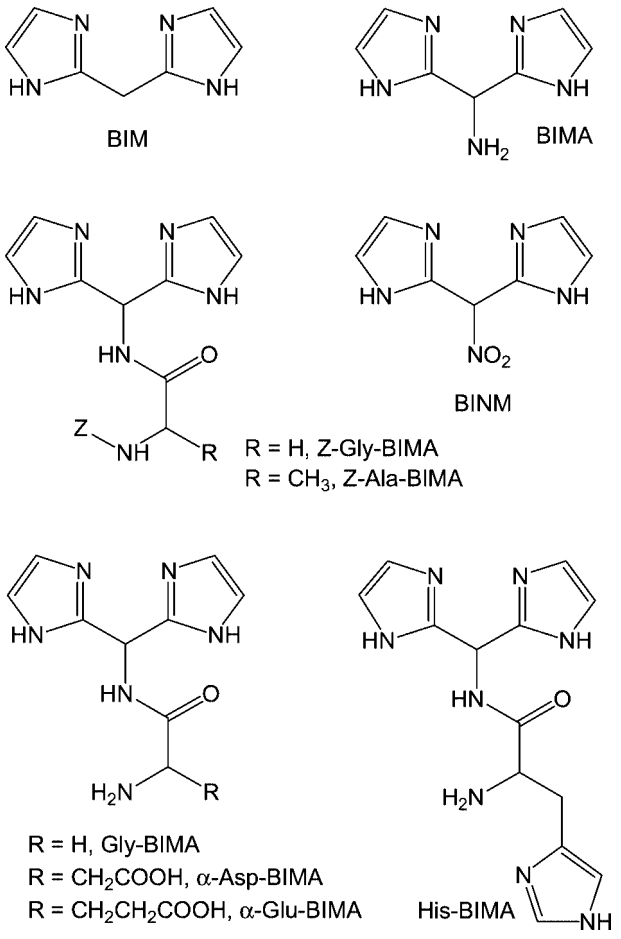
amide bond and its coordination in the $–N^-$ form, as proved with $Pt^{II}$, $Pd^{II}$, $Cu^{II}$, $Ni^{II}$, $Zn^{II}$ and $Co^{II}$.[18]

Recently, the role of the anchoring groups was studied with $V^{IV}O$ and it was found that their effectiveness in promoting peptide amide deprotonation and coordination follows the order: phenolate-$O^-$ > alcoholate-$O^-$ > thiolate-$S^-$ > carboxylate-$COO^-$ > amino-$NH_2$.[19] Subsequent results demonstrated that a histidyl residue in the *N*-terminal position can act as a valid anchor because the coordination of the amino group is assisted by the imidazole nitrogen of the side-chain.[20] Many examples of $V^{IV}O$ complexes containing a V–$N^-$(amide) bond, both in solution and in the solid state, have been characterised in the last few years.[19–21]

A particularly interesting case of anchoring group is represented by the bis(imidazol-2-yl)methyl moiety, in which two imidazole rings are linked via a methylene group, since it can potentially mimic the binding sites and catalytic activities of the metal-enzymes with the binding of imidazole nitrogen donors belonging to histidine residues (for example, copper and zinc enzymes).[22] It has been proved that amino acid derivatives containing the bis(imidazol-2-yl)-methyl residue form very stable complexes with $Cu^{II}$, $Zn^{II}$, $Ni^{II}$ and $Co^{II}$ ions, promoting the deprotonation and coordination of the amide nitrogens.[23]

In this work, we report the complexation of the $V^{IV}O$ ion with four amino acid derivatives of bis(imidazol-2-yl)-methylamine: *N*-glycyl-bis(imidazol-2-yl)methylamine (Gly-BIMA), *N*-α-aspartyl-bis(imidazol-2-yl)methylamine (α-Asp-BIMA), *N*-α-glutamyl-bis(imidazol-2-yl)methylamine (α-Glu-BIMA) and *N*-histidyl-bis(imidazol-2-yl)methylamine (His-BIMA). In addition, two protected benzyloxycarbonyl (Z) derivatives were considered, where the terminal amino group of glycine and alanine was transformed into a Ph–$CH_2$–O–C(O)–NH– function: Z-Gly-BIMA and Z-Ala-BIMA. This allows us to evaluate how the transformation of an amino into a carbamate function, which can be considered as an analogue of the peptide group, modifies the complexation process. Bis(imidazol-2-yl)methane (BIM), bis(imidazol-2-yl)methylamine (BIMA) and bis(imidazol-2-yl)nitromethane (BINM) were studied for comparison. The structure of all the examined ligands is reported in Scheme 1. The study was performed through the combined application of potentiometric and spectroscopic (UV/Vis and EPR) techniques. DFT calculations were used to obtain information on the structure of $V^{IV}O$ complexes containing a V–$N^-$(amide) bond.



Scheme 1. Structure of the ligands (Z = benzyloxycarbonyl).

## Results and Discussion

### BIM, BIMA, BINM, Z-Gly-BIMA and Z-Ala-BIMA

All these ligands have two titrable protons in water and can be indicated in the fully protonated form as $H_2L$. The two protons belong to the two imidazole rings except for BIMA, for which the higher p$K_a$ refers to the deprotonation of the ammonium group $–NH_3^+$. Protonation constants of the ligands are reported in Table 1. The measured p$K_a$ values are comparable with those already reported for BIM and BIMA.[23a] As previously observed, the interaction between the two aromatic rings decreases the first p$K_a$ value in the bis(imidazol-2-yl)methyl moiety with respect to imidazole.[23a] Substitution at the methylene group has a marked effect on the p$K_a$ values of the ligands; the positive charge on the ammonium group results in a further decrease in the basicity of the aromatic nitrogens and the first p$K_a$ of BIMA cannot be determined. In the case of BINM an increase of acidity of one imidazole group can be observed [p$K_{a1}$ = log$\beta$($H_2L$) – log$\beta$(HL) is 4.00 for BINM and 4.72 for BIM]; the formation of the hydrogen bond between the two aromatic nitrogens, however, results in a decrease of acidity of the second imidazole group.

If the amino group of BIMA is transformed into an amide nitrogen the decrease of p$K_a$ values is smaller than for BIMA itself, but the imidazole nitrogens are still less basic than those of BIM. This is well reflected by the p$K_a$ of the two imidazole nitrogens of the bis(imidazol-2-yl)methyl moiety of Z-Gly-BIMA and Z-Ala-BIMA (Table 1). Their values, however, are in good agreement with those of peptide derivatives of the bis(imidazol-2-yl)methyl group with a protected terminal amino group (e.g. Ac-ProLeuGly-BIMA).[23a]

All the five ligands show analogous complexing behaviour, different from that of the derivatives of amino acids (see below). Stability constants of the $V^{IV}O$ complexes are

reported in Table 1. From these data, the distribution curves of the species as a function of pH can be obtained; as an example, the distribution diagram for the system with BIM with a ligand-to-metal molar ratio of 5:1 is represented in Figure 1.

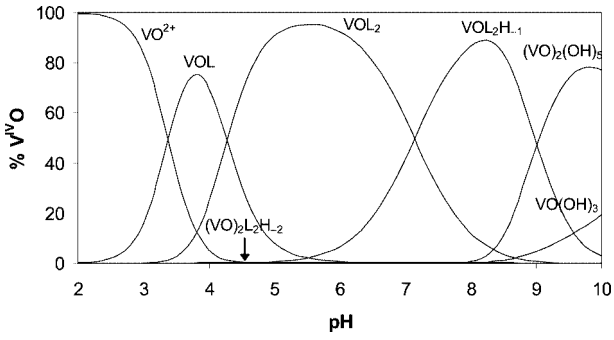

Figure 1. Species distribution for the $V^{IV}O$/BIM system as a function of pH with a ligand-to-metal molar ratio of 5:1 and a $V^{IV}O$ concentration of 1 mM.

In all the systems a mono-chelated VOL complex in acid solution, a bis-chelated $VOL_2$ in the pH range 4–7, and a mono-hydroxo $VOL_2H_{-1}$ species above pH 7 are formed. With BIMA, besides VOL and $VOL_2$, VOLH and $VOL_2H_2$ exist, because of the presence of one and two additional protons on the amino group (Table 1). $(VO)_2L_2H_{-2}$ is probably an EPR-silent dimeric di-μ-hydroxo complex with antiferromagnetic coupling between the two $V^{IV}O$ ions.[24]

The complexation reactions can be followed by EPR spectroscopy, since the anisotropic hyperfine coupling constant along the $z$ axis ($A_\parallel$) between the unpaired electron and the nucleus of $^{51}V$ in tetragonal complexes of the $V^{IV}O$ ion is particularly sensitive to the donors coordinated in the equatorial plane. $A_\parallel$ can be calculated from the sum of the contribution of each equatorial donor function, according to the "additivity rule" proposed by Wüthrich,[25] and subsequently developed by Chasteen, see Equation (1).[26]

$$A_\parallel = \sum_{i=1}^{4} A_\parallel(\text{donor i}) = A_\parallel(\text{donor 1}) + A_\parallel(\text{donor 2}) + A_\parallel(\text{donor 3}) + A_\parallel(\text{donor 4}) \quad (1)$$

This is an empirical rule that allows one to correlate $A_\parallel$ to the number and type of ligands present in the equatorial plane of the $V^{IV}O$ ion and has been proved and accepted in a large number of subsequent works.[27] The contribution to $A_\parallel$ is approximately inverse to the electron donor capacity of the ligand, with the most donating ligands contributing the least to the hyperfine coupling constant $A_\parallel$. Usually, the experimental $A_\parallel$ falls in the range of ca. $3 \times 10^{-4}$ $cm^{-1}$ with respect to the calculated value.[26,27]

EPR parameters for the complexes formed by BIM, BIMA, BINM and Z-Gly-BIMA are listed in Table 2. Anisotropic EPR spectra, recorded on frozen samples as a function of pH, for the system with BIM are displayed in Figure 2.

According to the potentiometric data (Figure 1), with a total $V^{IV}O$ concentration of 4 mM and a total BIM concentration of 20 mM, the first species is recognised between pH 3 and 4 as the mono-chelated complex VOL. Spectral parameters support a [($N_{im}$, $N_{im}$); $H_2O$; $H_2O$] equatorial donor set (Scheme 2).[26]

At pH values higher than 4, the appearance of two new sets of resonances attributable to a complex with $VOL_2$ stoichiometry is detected (Figure 2). Since in the pH range 4.5–7.5 we observe the same EPR spectra with the presence of two species with an almost identical relative amount, it is obvious to suppose that these are the two isomeric *cis* and *trans* forms of the species $VOL_2$.

In bis-chelated $V^{IV}O$ complexes, *cis* species are hexacoordinate with one solvent molecule coordinated in the fourth equatorial position; *trans* species can be penta- or hexacoordinate according to the absence or presence of a solvent molecule weakly bound in the axial position, which can be revealed through the combined application of IR and UV/Vis spectroscopy.[28] As usual, because of the higher contri-

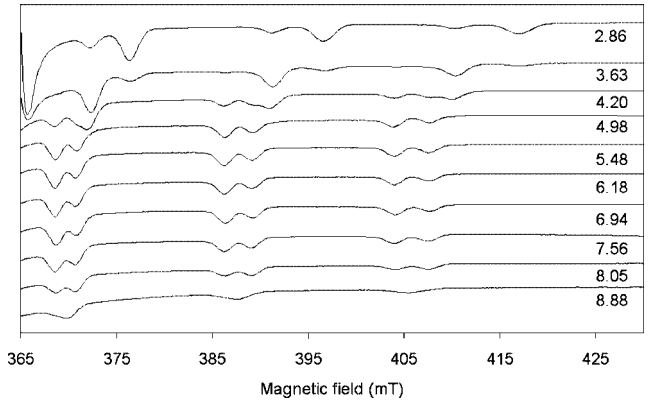

Figure 2. High field region of the X-Band anisotropic EPR spectra recorded at 140 K as a function of pH for an aqueous solution of the $V^{IV}O$/BIM system with a ligand-to-metal molar ratio of 5:1 and a $V^{IV}O$ concentration of 4 mM.

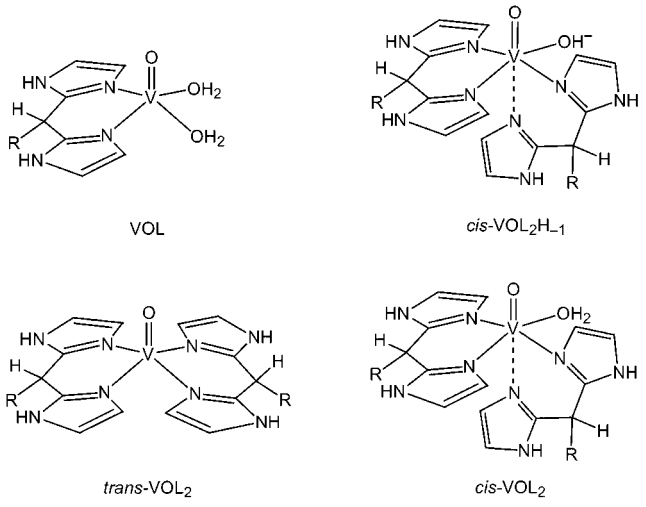

Scheme 2. Structure of the $V^{IV}O$ complexes formed by BIM (R = H), BIMA (R = $NH_2$), BINM (R = $NO_2$), Z-Gly-BIMA (R = Z-Gly) and Z-Ala-BIMA (R = Z-Ala). *Trans*-$VOL_2$ complex does not form with BINM, and *cis*-$VOL_2H_{-1}$ with Z-Gly-BIMA and Z-Ala-BIMA.

bution of water to $A_\parallel$ than the other donor functions, the *cis* complex corresponds to the species with the higher $A_\parallel$ value and the *trans* to that with the lower $A_\parallel$ (Table 2). Their structure is proposed in Scheme 2. The donor set is [($N_{im}$, $N_{im}$); ($N_{im}$, $N_{im}^{ax}$); $H_2O$] for the *cis*, and [($N_{im}$, $N_{im}$); ($N_{im}$, $N_{im}$)] for the *trans* isomer. Only the system with BINM constitutes an exception, since only the *cis* isomer for $VOL_2$ is observed.

*cis*-*trans* isomerism is not unusual for $V^{IV}O$ complexes and, of course, is due to the comparable stability of the two species. To date, many examples of such an isomerism have been reported in the literature.[28,29] The relative stability of the two isomers is influenced by a number of factors, including the ligand bite, the size of the chelate ring, the basicity and the steric requirements of the ligands, the hydrophobicity of the complexes; usually, large ligand bites, six-membered chelate rings, strong ligands and hydrophobicity of the complexes favour the *trans* isomer.[29,30] To the best of our knowledge, this is the first example of *cis*-*trans* isomerism with bidentate ligands forming six-membered chelate rings provided with only nitrogen donors.

In the systems with BIM, BIMA and BINM, potentiometry suggests a further deprotonation process above pH 7 and the species formed has been identified as $VOL_2H_{-1}$. p$K$ values for the deprotonation of $VOL_2$ to give $VOL_2H_{-1}$ fall in the range 6.97–7.76 (Table 1). As previously observed, a water molecule bound in the equatorial position of a *cis* complex with $VOL_2$ stoichiometry is more

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

acid than the bulk water,[28,30,31] and can be easily deprotonated to form the corresponding mono-hydroxo complex, *cis*-$VOL_2H_{-1}$ or *cis*-$VOL_2(OH)$. This transformation can be followed by EPR spectroscopy, since the replacement of a water molecule with a hydroxo ion implies a marked decrease of $A_{\parallel}$. In fact, with BIM, BIMA and BINM, above pH 7.5 EPR spectra change considerably, suggesting the transformation of *cis*-$VOL_2$ into *cis*-$VOL_2H_{-1}$ species (Figure 2); the decrease of the $A_{\parallel}$ value from 163.0–164.3 × $10^{-4}$ $cm^{-1}$ of *cis*-$VOL_2$ to 159.1–161.0 × $10^{-4}$ $cm^{-1}$ of *cis*-$VOL_2H_{-1}$ (Table 2) is that expected on the basis of the "additivity rule",[26] and is similar to what has been previously observed in the literature.[30,31]

It is worth noting that Z-Gly-BIMA and Z-Ala-BIMA, even if they have a carbamide group in their structure, behave like the simple BIM, BIMA or BINM derivatives, with the only difference being that they do not form the hydroxo complex $VOL_2H_{-1}$ (Table 1). The binding of the two bis(imidazol-2-yl)methyl moieties does not promote the deprotonation and the subsequent coordination of the (carb)amide nitrogen, unlike Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA or His-BIMA (see below); this seems to be due to the lack of a third strong donor in the ligand chain, able to close a second chelate ring after the coordination of the amide nitrogen-$N^-$.

### Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA, His-BIMA

Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA, and His-BIMA can be considered as amino acid derivatives of BIMA, in which the carboxylic group of the amino acid forms an amide bond with the amino group of BIMA (Scheme 1).

Gly-BIMA in the fully protonated form has three titrable protons, α-Glu-BIMA and His-BIMA four (i.e. the formula is $H_3L$ for Gly-BIMA, and $H_4L$ for α-Glu-BIMA and His-BIMA), as reported in Table 3. The p$K_a$ values of imidazole nitrogens are similar to those of other amino acid and peptide derivatives of the bis(imidazol-2-yl)methyl group; the highest value corresponds to the deprotonation of the ammonium group of the amino acid residue. The additional deprotonation process measured for α-Glu-BIMA and His-BIMA is due to the carboxylic group and to the imidazole nitrogen of the amino acid side-chain, respectively. The p$K_a$ values recalculated in this work are in good agreement with those previously reported by some of the present authors.[23b,23d,23g]

For this group of ligands, the complexation scheme derived from the potentiometric and spectroscopic studies is similar to that of BIM, BIMA, BINM, Z-Gly-BIMA and Z-Ala-BIMA in the acid and neutral solution, but includes two different species at pH >7, $VOLH_{-1}$ and $VOLH_{-2}$, in which the amino and deprotonated amide group take part in the coordination. The stability constants of the complexes are presented in Table 3. The distribution curves for the $V^{IV}O$/Gly-BIMA system with a ligand-to-metal molar ratio of 5:1 are shown in Figure 3 as an example.

The EPR analysis allows us to confirm the results of the potentiometric titrations. Anisotropic EPR spectra recorded as a function of pH for the system with Gly-BIMA are displayed in Figure 4, and EPR parameters are listed in Table 2.

Table 3. Stability constants (log$\beta$) of proton and $V^{IV}O$ complexes for Gly-BIM, α-Glu-BIMA, His-BIMA at 25.0 ± 0.1 °C and $I$ = 0.2 M (KCl).[a]

| p$K$(VOL)[b] | 6.48 | 6.67 | 5.80 |
| p$K$($VOLH_{-1}$)[c] | 7.05 | 7.23 | 7.96 |

[a] The uncertainties (σ values) of the protonation and stability constants are given in parentheses. [b] p$K$(VOL) = log$\beta$(VOL) – log$\beta$($VOLH_{-1}$). [c] p$K$($VOLH_{-1}$) = log$\beta$($VOLH_{-1}$) – log$\beta$($VOLH_{-2}$).

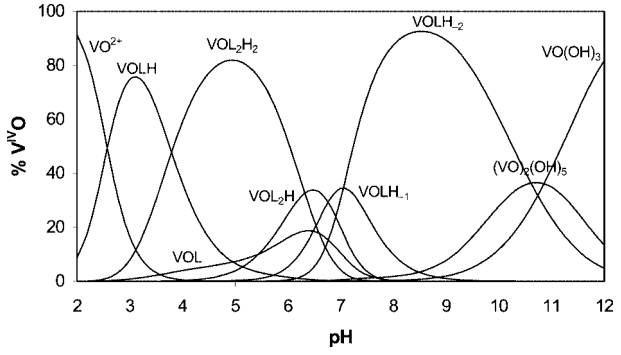

Figure 3. Species distribution for the $V^{IV}O$/Gly-BIMA system as a function of pH with a ligand-to-metal molar ratio of 5:1 and a $V^{IV}O$ concentration of 1 mM.

In all the systems we can identify two mono-chelated species with the compositions VOLH and VOL, with similar EPR parameters, $A_{\parallel}$ = 168.7–170.3 × $10^{-4}$ $cm^{-1}$, and equatorial donor set [($N_{im}$, $N_{im}$); $H_2O$; $H_2O$]; the only difference is the protonation of the terminal amino group, $–NH_3^+$ in VOLH and $–NH_2$ in VOL. For α-Glu-BIMA and His-BIMA, the additional species $VOLH_2$ has the carboxylate or the imidazole nitrogen of the amino acid residue protonated.

At excess of ligand, a number of $VOL_2H_x$ (with $x$ = 1–4) complexes predominate if pH >4 (Table 3). They are characterised by the same donor set and a *cis*-*trans* isomer-

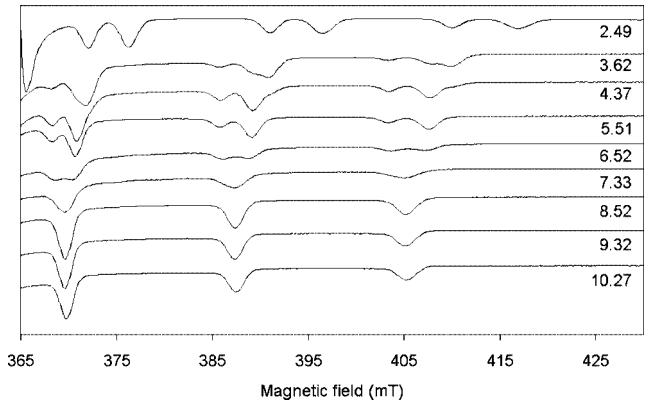

Figure 4. High field region of the X-Band anisotropic EPR spectra recorded at 140 K as a function of pH for an aqueous solution of the $V^{IV}O$/Gly-BIMA system with a ligand-to-metal molar ratio of 5:1 and a $V^{IV}O$ concentration of 4 mM.

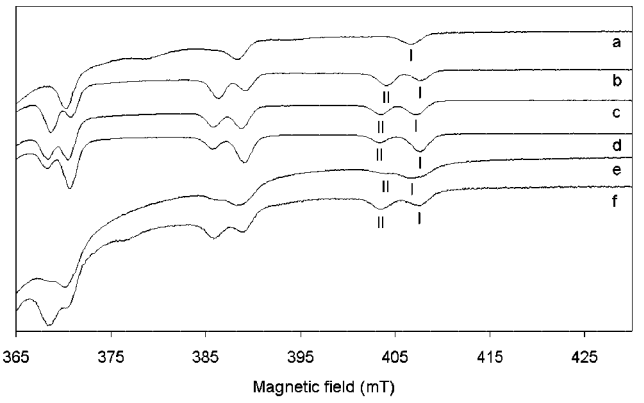

Figure 5. High field region of the X-Band anisotropic EPR spectra of the bis-chelated complexes formed by BINM, BIM, BIMA, GlyBIMA, α-Glu-BIMA and HisBIMA recorded in aqueous solutions at 140 K with a $V^{IV}O$ concentration of 4 mM: a) BINM: L/M = 1, pH = 7.20; b) BIM: L/M = 5, pH = 6.95; c) BIMA: L/M = 5, pH = 6.60; d) Gly-BIMA: L/M = 5, pH = 5.50; e) α-Glu-BIMA: L/M = 3, pH = 5.65; f) HisBIMA: L/M = 3, pH = 6.60. I and II denote *cis* and *trans* species, respectively.

ism similar to that discussed for BIM, BIMA, BINM and Z-Gly-BIMA (Table 2). The difference is the protonation degree of the ligands (for example, $VOL_2H_2$ and $VOL_2H$ species formed by Gly-BIMA have two and one non-coordinating amino group protonated, respectively). Analogously to the previous systems, the *cis* complexes are characterised by a higher $A_{\parallel}$ value ($A_{\parallel}$ = 163.7–165.2 × $10^{-4}$ $cm^{-1}$) and a [($N_{im}$, $N_{im}$); ($N_{im}$, $N_{im}^{ax}$); $H_2O$] donor set, whereas the *trans* species shows lower $A_{\parallel}$ values ($A_{\parallel}$ = 158.2–158.4 × $10^{-4}$ $cm^{-1}$), as expected on the basis of the "additivity rule",[26] and a [($N_{im}$, $N_{im}$); ($N_{im}$, $N_{im}$)] donor set. The relative amount of the two isomers does not change in the pH range 4–7 for a given ligand, but it can vary depending on the ligand; in particular, the relative amount of the *cis* isomer with respect to the *trans* increases in the order: His-BIMA < Gly-BIMA < α-Glu-BIMA ≈ α-Asp-BIMA.

In Figure 5 a comparison between the EPR spectra for a number of bis-chelated complexes formed by bis(imidazol-2-yl)methyl ligands is shown. As mentioned above, some of the present authors recently demonstrated that for ligands with the same bite, basicity and size of the chelate ring, the hydrophilicity of the complexes is the critical factor in determining the relative amount of the *cis* and *trans* species in water; particularly, hydrophilic complexes prefer the *cis* arrangement.[29] This could also explain the results displayed in Figure 5: the hydrophilic bis-chelated complexes formed by BIMA, Gly-BIMA, α-Glu-BIMA and His-BIMA prefer *cis* arrangement, whereas the most hydrophobic complex formed by BIM prefer the *trans* one. With this rule in mind, the reason for which BINM forms only a *cis* bis-chelated complex can be rationalised: BINM is the most hydrophilic ligand, because of the presence of a formal positive charge on the nitrogen and a formal negative charge on one of the oxygen atoms for each of the two $–NO_2$ groups.

Differently from the BIM, BIMA, BINM, Z-Gly-BIMA and Z-Ala-BIMA systems, above pH 7 the formation of two new species, with the composition $VOLH_{-1}$ and $VOLH_{-2}$, is observed. These species cannot be confused at all with the hydroxo complexes $VOL_2H_{-1}$ present in the previously examined systems because they exist in a wider pH range and are characterised by a higher intensity of the EPR signals, indicating a different coordination mode. Moreover, the formation of these complexes is accompanied by a new absorption maximum in the UV/Vis spectra around 390 nm, as demonstrated by an examination of Figure 6, where the distribution curves of $V^{IV}O$/His-BIMA species and the variation of molar absorptivity of the system at 386 nm are depicted as a function of pH. The appearance of this new band suggests the coordination of a "strong" donor atom, as a consequence of the deprotonation and coordination of the amide nitrogen. Similar changes in the electronic spectra were observed in the case of the $V^{IV}O$/SalGly system (SalGly = salicylglycine), where simultaneously to the deprotonation and coordination of the amide-$N^-$ a new absorption band is observed around 400 nm.[21f]

For Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA and His-BIMA, in contrast with Z-Gly-BIMA and Z-Ala-BIMA, the presence of a terminal amino group allows the deprotonation and coordination of the amide nitrogen, with the closure of two five-membered chelate rings; this possibility results in the formation of $VOLH_{-1}$ and $VOLH_{-2}$ with [($N_{im}$, $N^-$, $NH_2$); $H_2O$] and [($N_{im}$, $N^-$, $NH_2$); $OH^-$] donor sets. Their structure is represented in Scheme 3. As noted above, with Z-Gly-BIMA and Z-Ala-BIMA, the second chelate ring does not form because the amino group is involved in a "carbamate-like" bond with the benzyloxycarbonyl group. For α-Asp-BIMA and α-Glu-BIMA, the formation of the final species $VOLH_{-2}$ takes place at higher pH values with respect to Gly-BIMA and His-BIMA, probably because of the presence of a negative charge on the carboxylate group which prevents the deprotonation of the amide nitrogen.

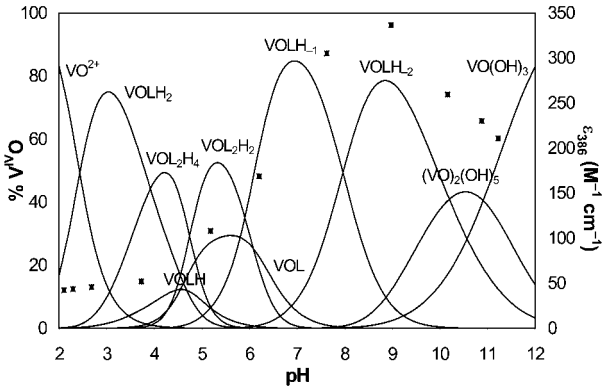

Figure 6. Species distribution for the $V^{IV}O$/His-BIMA system as a function of pH with a ligand-to-metal molar ratio of 4:1 and a $V^{IV}O$ concentration of 1 mM. The superimposed squares show the variation of molar absorptivity $\varepsilon$ at 386 nm.

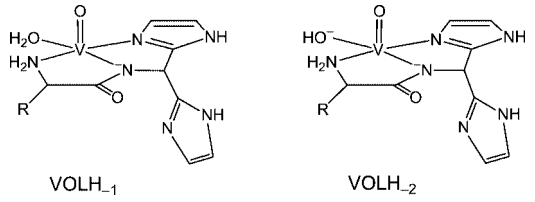

Scheme 3. Structure of the $VOLH_{-1}$ and $VOLH_{-2}$ complexes formed by Gly-BIMA (R = H), α-Asp-BIMA (R = $CH_2COO^-$), α-Glu-BIMA (R = $CH_2CH_2COO^-$) and His-BIMA (R = 4-$CH_2$-imidazole).

Since Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA and His-BIMA display a comparable complexing scheme, this allows us to rule out the participation of the side-chain of α-Asp, α-Glu or His amino acids to the coordination.

As a final comment, we propose some observations on the differences between the behaviour at basic pH values of BIM, BIMA, BINM, Z-Gly-BIMA and Z-Ala-BIMA which form *cis*-$VOL_2H_{-1}$ on the one hand, and Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA, His-BIMA which form $VOLH_{-2}$ on the other hand: (i) *cis*-$VOL_2H_{-1}$ undergoes hydrolytic reactions to give $[(VO)_2(OH)_5]^-$ and $[VO(OH)_3]^-$ above pH 9, whereas $VOLH_{-2}$ exists in a rather wide pH range (7.0–11.0), suggesting the coordination of stronger donors like the deprotonated amide nitrogen; (ii) UV/Vis electronic absorption spectra recorded at pH >7 on equimolar solutions of $V^{IV}O$ ions and His-BIMA are characteristic of a limpid solution: this allows us to rule out the presence of a 1:2 complex, which should result in the precipitation of the remaining part of the $V^{IV}O$ ion as $VO(OH)_2$, and supports the formation of 1:1 species like $VOLH_{-1}$ and $VOLH_{-2}$; (iii) the linewidth of the EPR signal due to $VOLH_{-2}$ is notably narrower than *trans*-$VOL_2$, indicating a lower number of nitrogen atoms coordinated (three instead of four): indeed, the nitrogen atoms on the equatorial plane increase the linewidth of the EPR signal because of the superhyperfine coupling between the unpaired electron on the $V^{IV}O$ ion and the $^{14}N$ nucleus ($I$ = 1).

## Density Functional Calculations of the $VOLH_{-1}$ and $VOLH_{-2}$ Structures

An optimised geometry of the $VOLH_{-1}$ and $VOLH_{-2}$ complexes formed by Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA and His-BIMA was calculated by performing Density Functional Theory (DFT) calculations with the Gaussian 03 program.[32] In the last few years, there has been growing use of DFT methods because they give rather good results in the optimisation of the geometries of transition-metal complexes.[33] The functional B3LYP,[34,35] which has been demonstrated to yield good agreement with the experimental structures for many vanadium compounds,[33d,36] and the mixed basis set 6-311g for vanadium and 6-31g(d) for the other elements were used. With this latter set, differences of 0.023 Å in V–C and 0.010 Å in C–O bond lengths are obtained for $[V(CO)_6]^-$ and of 0.001 Å in Cr–C and 0.009 Å in C–O distances for $[Cr(CO)_6]$.[36a]

Attempts to simulate the structure of $VOLH_{-1}$ and $VOLH_{-2}$ complexes with the second imidazole ring coordinated in the axial position, in *trans* to the oxo group of the V=O unit, were unsuccessful. Therefore, in order to speed up the calculation time, we simulated the structure of $VOLH_{-1}$ and $VOLH_{-2}$ by replacing one imidazole ring with a hydrogen atom and abbreviating with Gly-IMA the obtained ligand *N*-glycyl-(imidazol-2-yl)methylamine. The results are listed in Table 4. The structure of the $VOLH_{-2}$ complex with Gly-IMA, simulated with the mixed 6-311g/6-31g(d) basis set, is displayed in Figure 7.

From an examination of Table 4 it can be noticed that beginning from the 6-31g basis set comparable results are obtained, suggesting that also simple sets can provide a satisfactory agreement with a real structure, whereas more complete basis sets supply only a marginal improvement in the geometric parameters. The distance of V=O(oxo) bond ranges were between 1.588 and 1.622 Å, that of V–N(amino) between 2.150 and 2.163 Å, that of V–$N^-$(amide) between 2.009 and 2.021 Å, that of V–N(imidazole) between 2.112 and 2.140 Å and that of V–O(hydroxo) between 1.860 and 1.882 Å.[37] An important structural parameter, which will be used for estimating the $A_\parallel$ value for $VOLH_{-1}$ and $VOLH_{-2}$ species, is the dihedral angle $\theta$, defined by the vanadyl oxo, the vanadium atom, the coordinated imidazole N and the carbon atom that bridges the two imidazole nitrogen atoms.[27,38] From an examination of Table 4, it can be noticed that it falls in the range 111.1–112.8°, suggesting an almost perpendicular arrangement of the imidazole ring with respect to the V=O bond.[27,38] The structural data of our simulations are comparable with those of the [VO(Gly-L-Val)(phen)]·$H_2O$ complex (see Table 4), characterised by a similar equatorial donor set: [($NH_2$, $N^-$, $COO^-$); ($N_{pyr}$, $N_{pyr}^{ax}$)].[21] A shorter V–O(hydroxo) distance (1.785 Å) has been measured for the complex *cis*-[VO(OH)(4,4′-dtbipy)$_2$]-$BF_4$·1.2$H_2O$ (Table 4).[36c] We have no explanation for this.

For the complex $VOLH_{-1}$, simulated with Gly-IMA with a water molecule replacing the $OH^-$ ion, bond lengths of 1.567, 2.155, 1.948, 2.091 and 2.130 Å are obtained for V=O(oxo), V–N(amino), V–$N^-$(amide), V–N(imidazole)

[a] Gly-IMA is *N*-glycyl-(imidazol-2-yl)methylamine. [b] O belonging to an $OH^-$ ion or to a $H_2O$ molecule. [c] Defined by the vanadyl oxo, the vanadium atom, the coordinated imidazole nitrogen and the carbon atom that bridges the two imidazole nitrogens.[27,38] [d] [VO(Gly-L-Val)(phen)]·$H_2O$, where Gly-L-Val is glycyl-L-valinato and phen is 1,10-phenanthroline.[21l] [e] *cis*-[VO(OH)(4,4′-dtbipy)$_2$]-$BF_4$·1.2$H_2O$, where 4,4′-dtbipy is 4,4′-di-*tert*-butyl-2,2′-bipyridine.[36c] [f] Mean values.

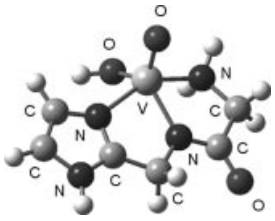

Figure 7. Simulated structure of the complex [VO(Gly-IMA)(OH)] calculated by the DFT method using the 6-311g basis set for vanadium and 6-31g(d) for the other elements (see Table 4). Gly-IMA is *N*-glycyl-(imidazol-2-yl)methylamine.

and V–O(water), respectively.[39] The dihedral angle $\theta$ is 105.9° (Table 4).[39] As expected, V–N$^-$(amide) becomes shorter as the length of the bond in the *trans* position increases; thus, V–N$^-$(amide) in VOLH$_{-1}$ is shorter than in VOLH$_{-2}$ (1.948 vs. 2.021 Å)[39] because $H_2O$ replaces the $OH^-$ ion.

### Effect of the V–N$^-$(amide) Bond on the $A_\parallel$ Value

By continuing the discussion of a previous work,[20] we would now analyse the bond between a deprotonated amide-N$^-$ and a vanadyl ion and its effect on the $^{51}V$ anisotropic parallel hyperfine constant of $V^{IV}O$ complexes. The latter is indicated with $A_\parallel$ or $A_z$, depending on the symmetry of the complexes, axial or rhombic (here we consider only axial species with two $g$, $g_\parallel$ and $g_\perp$, and two $A$, $A_\parallel$ and $A_\perp$, values). For the $^{51}V$ nucleus, $A_\parallel$ can be expressed as shown in Equation (2).[40]

$$A_{\parallel} = P_d\left[\beta^2\left(-\kappa-\frac{4}{7}\right)+(g_{\parallel}-2.0023)+\frac{3}{7}(g_{\perp}-2.0023)\right] \quad (2)$$

In this equation $P_d = g_N\beta_N g\beta\langle r^{-3}\rangle$ is the dipolar interaction between the unpaired electron and the $^{51}V$ nucleus and is determined by the spatial distribution of the *d* electron,[40] $\kappa$ is the Fermi contact term and measures the unpaired *s*-electron spin density at the nucleus, and $\beta^2$ is, to a good approximation, the population of the ground state *d* orbital containing the unpaired spin (for $V^{IV}O$ species with $C_{2v}$ symmetry or higher, it measures the population of the $d_{xy}$ orbital). Pecoraro assumed the terms $\kappa$ and $P_d$ as constants and reported a value of 0.85 for $\kappa$ and of $128\times10^{-4}$ cm$^{-1}$ for $P_d$.[38] A similar value for $P_d$ ($125\times10^{-4}$ cm$^{-1}$) has been used by Deligiannakis and Kabanos.[21h] Mabbs and Collison report a significantly higher value ($173.5\times10^{-4}$ cm$^{-1}$).[41]

In the "additivity rule",[26] Chasteen estimated $A_\parallel$ or $A_z$ of a $V^{IV}O$ species from the contribution of each of the four equatorial donor groups, see Equation (1).[26] The contribution of the various groups to $A_\parallel$ is listed in Table 5.

The rule provides a valid criterion for the identification of the equatorial donor atoms. Additions or corrections concerning the contribution of N(imino),[20] $Cl^-$ and $SCN^-$,[21j] CO(carbonyl)[42] and $COO^-$,[21m] appeared subsequently in the literature. Pecoraro and co-workers proposed that for imidazole the overlap of the π orbitals of the aromatic ring with the $d_{xy}$ vanadium atomic orbital bearing the unpaired electron would increase the covalence of the metal–ligand bond and produce a decrease of the $\beta^2$ value and of the contribution of an imidazole nitrogen to $A_\parallel$, see Equation (2).[27,38] They determined an empiric equation to calculate the value of $A_\parallel$(imidazole) as a function of the dihedral $\theta$ angle, see Equation (3) where $x = 42.72\times10^{-4}$ cm$^{-1}$ and $y = 2.96\times10^{-4}$ cm$^{-1}$.[27,38]

$$A_\parallel(\text{imidazole}) = x + y\sin(2\theta - 90) \quad (3)$$

With the data reported in Table 5, an expected value of $A_\parallel$ for the complexes VOLH$_{-1}$ and VOLH$_{-2}$ formed by Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA and His-BIMA can be calculated. The values of $32.7\times10^{-4}$ cm$^{-1}$ and $35.3\times10^{-4}$ for $A_\parallel$(amide) in VOLH$_{-1}$ (total equatorial charge of –1, Table 5) and VOLH$_{-2}$ (total equatorial charge of –2, Table 5), and of $45.2\times10^{-4}$ and $44.8\times10^{-4}$ cm$^{-1}$ for $A_\parallel$(imidazole) in VOLH$_{-1}$ and VOLH$_{-2}$ calculated with the dihe-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dral $\theta$ angles obtained from DFT simulations (Table 4) were used.[39] $A_{\parallel}$ of $163.6 \times 10^{-4}$ cm$^{-1}$ for $VOLH_{-1}$ and $158.9 \times 10^{-4}$ cm$^{-1}$ for $VOLH_{-2}$ are derived, comparable to the experimental ones (Table 2).

Table 5. Contribution of the various groups to $^{51}$V hyperfine coupling constants $A_{\parallel}$.[a]

| Donor group[b] | Contribution to $A_{\parallel}$[c] | Ref. |
|---|---|---|
| $H_2O$ | 45.6 | [26] |
| $COO^-$ | 42.1 | [21m] |
| CO | 43.5 | [42] |
| $OH^-$ | 38.7 | [26] |
| $O_{aromatic}^-$ ($O_{ar}^-$) | 38.9 | [26] |
| $RO^-$ | 35.3 | [26] |

| $RS^-$ | 31.9 | [26] |
| $NH_2$ | 40.1 | [26] |
| $N_{imino}$ | 41.6 | [20] |
| $N_{imidazole}$ ($N_{im}$) | $42.72 + 2.96 \cdot \sin(2\theta - 90)$[d] | [27,38] |
| $N_{pyridine}$ ($N_{pyr}$) | 40.7 | [26] |
| $N_{amide}$ ($N^-$) | 32.7 (–1), 35.3 (–2), 38.6 (–3), 40.9 (–4)[e] | [20] |
| $Cl^-$ | 44.2 | [21j] |
| $SCN^-$ | 43.2 | [21j] |

[a] Contribution measured in $10^{-4}$ cm$^{-1}$. [b] Between round brackets are given the symbols used in Table S1 of the electronic supporting information and in other parts of the text. [c] In many parts of the text the contribution of each donor group to $A_{\parallel}$ is also indicated with $A_{\parallel}$(donor). [d] $\theta$ is the dihedral angle defined by the vanadyl oxo, the vanadium atom, the coordinated imidazole nitrogen and the carbon atom that bridges the two imidazole nitrogen atoms.[27,38] [e] Between round brackets, the total charge present in the equatorial plane of the $V^{IV}O$ ion (including that of the amide nitrogen).

Concerning the amide contribution to $A_{\parallel}$, $A_{\parallel}$(amide), it was found to be sensitive to the total charge of the donor atoms in the equatorial plane; in particular, its value decreases with a decrease in the total equatorial charge.[20,21b,21h] By taking into account the $A_{\parallel}$(amide) values for 37 $V^{IV}O$ compounds with a V–N$^-$(amide) bond, we recently calculated 35.5, 38.3 and $40.9 \times 10^{-4}$ cm$^{-1}$ for the contribution to $A_{\parallel}$ when the total equatorial charge is –4, –3 or –2 (including that of the amide nitrogen) and by extrapolation $32.7 \times 10^{-4}$ cm$^{-1}$ for the –1 equatorial charge (Table 5),[20] in good agreement with the results of Tasiopoulos et al.[21h]

On the basis of the methods reported in the literature for rationalising some cases of anomalous EPR behaviour displayed by $V^{IV}O$ complexes, three different hypotheses could be advanced to explain the unusual reduction of $A_{\parallel}$(amide) with the total equatorial charge:

(i) Two limit resonance structures for a deprotonated amide group coordinated through nitrogen, one "amide-like" with the nitrogen atom negatively charged and a double bond between the carbon and oxygen atoms of the carbonyl group, and another "imine-like" with the carbonyl oxygen negatively charged and a double bond between the carbon and nitrogen atoms, can be assumed.[21b] With a decrease in the total equatorial charge around vanadium the importance of the "amide-like" arrangement should increase, to which a lower $A_{\parallel}$(amide) contribution corresponds.[21b] This explanation would result in a change in C–N, C=O and V–N distances as a function of $A_{\parallel}$(amide), but is not supported by the data of the structures resolved through a single-crystal X-ray diffraction analysis for which EPR parameters are reported.[20]

(ii) A reduction of the $P_d$ parameter, which should decrease the electron density on the metal ion and hence the V=O bond length, could be proposed. A similar explanation was put forward by Kabanos and co-workers to explain the reduction of $A_{\parallel}$ by about 10%, relative to the value predicted with the "additivity rule", for the complexes [VOX(capca)], where Hcapca is *N*-{2-[(2-pyridylmethylene)amino]phenyl}pyridine-2-carboxamide and $X^-$ is an anion ($Cl^-$, $SCN^-$, $CH_3COO^-$ or $PhCOO^-$) occupying the axial position.[21j] This mechanism can be ruled out for $V^{IV}O$ complexes involving a V–N$^-$(amide) bond, because no correlation between the $A_{\parallel}$(amide) values and V=O length is observable.[20] According to the theoretic treatment of Mabbs and Collison,[41] to Pecoraro and co-workers[27,38] and to a previous paper of Deligiannakis and Kabanos,[21h] we believe that the value of $P_d$ can be assumed to be constant.

(iii) An overlap between the π orbitals of the ligand and $d_{xy}$ atomic orbital of vanadium, which increases the covalence of the V–N$^-$(amide) bond and decreases $\beta^2$ and $A_{\parallel}$ values [see Equation (2)] could be suggested, i.e. a mechanism similar to that proposed by Pecoraro and co-workers to justify the reduction of $A_{\parallel}$(imidazole) when the aromatic ring is perpendicular to the V=O group.[27,38] However, this possibility is not applicable to the V–N$^-$(amide) bond if the amide group remains perpendicular to the V=O group, because the delocalised π system is not in a favourable position to overlap with the $d_{xy}$ orbital.

The question arising is: why only the V–N$^-$(amide) bond (and not the other V-donor bonds) should compensate a lower electronic density in the equatorial plane of a $V^{IV}O$ complex through an increase of the covalence? In order to evaluate the effect of the total equatorial charge on $A_{\parallel}$, we re-analysed the EPR parameters of the structures containing a V–N$^-$(amide) bond (see Table S1 in the electronic supporting information). We compared several couples of $V^{IV}O$ structures, in which the only variable is the equatorial charge; in particular, we examined four couples which only differ in one donor and in one unit of the total equatorial charge (two couples with –4/–3 and two with –3/–2 equatorial charge), two couples which differ in one donor but two units of equatorial charge (–4/–2) and, for comparison, six couples which differ in one donor but not in equatorial charge (two couples with –4/–4, two with –3/–3 and two with –2/–2). To avoid taking into account the influence of the donor which changes going from higher to lower equatorial charge, for each couple we considered the experimental $A_{\parallel}$ value ($A_{\parallel}$ exp.) for the complex with higher equatorial charge and, from it, calculated $A_{\parallel}$ ($A_{\parallel}$ calcd.) for the complex with lower charge by subtracting the contribution of the donor which is replaced and adding that of the donor which replaces it (indicated in bold in Table S1 of Supporting Information), with the contribution of several donors taken from Table 5.[43] If $A_{\parallel}$ was only dependent on the do-

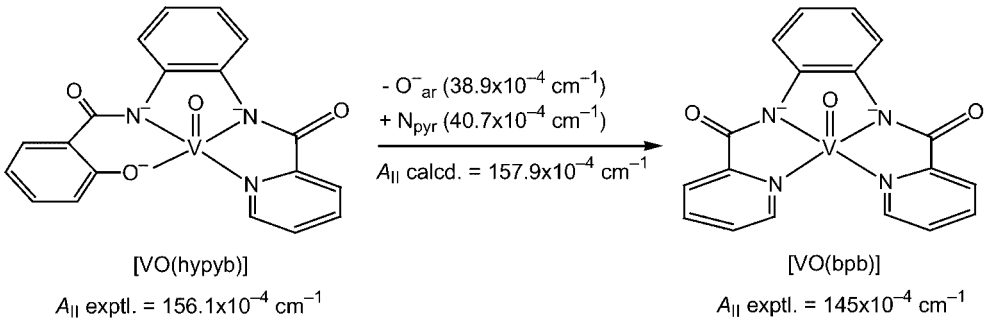

Scheme 4. Methods for calculating $A_{\parallel}$ ($A_{\parallel}$ calcd.) for a $V^{IV}O$ complex containing a V–$N^{-}$(amide) bond from the experimental $A_{\parallel}$ value ($A_{\parallel}$ exp.) of the species with higher total equatorial charge. $H_3$hypyb = 1-(2-hydroxybenzamido)-2-(2-pyridinecarboxamido)benzene,[21e] and $H_2$bpb = 1,2-bis(2-pyridinecarboxamido)benzene.[21i]

nor functions bound to the $V^{IV}O$ ion and not on the equatorial charge, we should expect an almost exact coincidence between $A_{\parallel}$ calcd. and $A_{\parallel}$ exp. for the species with lower charge; every difference between the two values can be attributable only to the decrease of the equatorial charge. This is illustrated in Scheme 4.

The conclusion is that the decrease of the equatorial charge always results in a decrease of the $A_{\parallel}$ value for a $V^{IV}O$ complex, whereas if the equatorial charge remains the same no significant changes in the $A_{\parallel}$ value can be observed. In particular, in the two couples with –4/–3 equatorial charge, in the two with –3/–2 and in the two with –4/–2 a reduction in the range 3.0–3.8, 3.2–8.9 and 7.6–10.2% is observed, respectively; on the other hand, in the six couples with the same equatorial charge the maximum difference (negative or positive) is 1.2%. It is worth noting that the most marked reduction is observed when changing the equatorial charge from –4 to –2. The comparison between the $VOLH_{-2}$ complex studied in this work (total equatorial charge of –2) and two $V^{IV}O$ species with a charge of –3 and –2 follows the same trend.

It is obvious that, if the contribution to $A_{\parallel}$ of all the donor functions is considered constant, the decrease in $A_{\parallel}$ for $V^{IV}O$ complexes containing a V–$N^{-}$(amide) bond must be entirely attributed to the decrease of $A_{\parallel}$(amide). However, analysing the 14 couples of $V^{IV}O$ complexes in Table S1 of the electronic supporting information, the hypothesis that all the donors participate in the reduction of $A_{\parallel}$ could be advanced, i.e. all the contributions of the four equatorial donors could decrease with a decrease in the total equatorial charge. Of course, this reduction can be almost negligible; for example, in the couple **I** in Table S1 of the supporting information it is enough if the contribution of every donor to $A_{\parallel}$ decreases by 3.0% to obtain an agreement with the calculated value, i.e. the contribution of phenolate ($O_{ar}^{-}$) will be of $37.7 \times 10^{-4}$ cm$^{-1}$ instead of $38.9 \times 10^{-4}$ cm$^{-1}$. This effect is not evident when bis-chelated complexes of bidentate ligands (often with the same donor function),[44] like those analysed by Chasteen in formulating the "additivity rule", are considered.[26] However, this difference falls within the uncertainty of ca. $3 \times 10^{-4}$ cm$^{-1}$ for the $A_{\parallel}$ value estimated by Chasteen and Pecoraro.[26,27] Therefore, we would stress that the "additivity rule" is respected; what should be taken into account in its application is that the contribution of the various donor functions could vary in a narrow range, probably centred around the value reported in Table 5, depending on the type of $V^{IV}O$ complex under examination.

Since the $\kappa$ and probably $P_d$ terms can be considered constant for vanadyl complexes,[21h,38,41] a reduction of $A_{\parallel}$ could be only connected to a reduction of coefficient $\beta^2$ in Equation (2). By following the discussion of Ballhausen and Gray, in a square pyramidal $V^{IV}O$ complex the $d_{xy}$ atomic orbital with $b_{2g}$ symmetry which bears the unpaired electron can covalently interact with the ligand orbitals only through a π bond, see Equation (4).[45]

$$\psi(b_{2g}) = \beta d_{xy} + (\gamma_1\pi_{x1} + \gamma_2\pi_{y2} - \gamma_3\pi_{x3} - \gamma_4\pi_{y4}) \quad (4)$$

where $\beta$ is the coefficient of the $d_{xy}$ vanadium atomic orbital, see Equation (2), and $\gamma_i$ are the coefficients of the ligand orbitals $\pi_i$ with suitable symmetry to overlap with $d_{xy}$.[46] A value of 1 for $\beta^2$ indicates that the unpaired electron is localised exclusively on the vanadium $d_{xy}$ orbital and that there is no delocalisation onto the ligands; on the other hand, a value of $\beta^2$ lower than 1 indicates that a $(1–\beta^2)$ fraction of the spin density is delocalised onto the ligands, causing a decrease of $A_{\parallel}$ value through Equation (2).

By analysing the data reported in Table S1 of the electronic supporting information, we think that it can not be excluded that the reduction of $A_{\parallel}$ is due to an increase of the covalence of all or part of the four equatorial V-donor bonds through a π interaction between the $d_{xy}$ orbital of vanadium and the π wavefunction of the ligands with $b_{2g}$ symmetry in the $C_{4v}$ group (for example, p atomic orbitals of oxygen in $O_{aromatic}^{-}$, $RO^{-}$, $OH^{-}$, $COO^{-}$, and of sulfur in $S_{aromatic}^{-}$, $RS^{-}$, or π aromatic orbitals of phenols, thiols, imidazole and pyridine rings, imino groups with suitable orientation to overlap with the $d_{xy}$ orbital). Probably, such a π interaction is necessary when the total equatorial charge around vanadium diminishes and the four σ bonds are not sufficient to neutralise the +2 charge of the vanadyl ion. We do not believe that the decreased contribution of the deprotonated $N^{-}$(amide) function to $A_{\parallel}$ is the only reason for the decrease in $A_{\parallel}$. Further studies are, however, necessary to clarify this topic.

## Conclusions

Simple amino acid derivatives of bis(imidazol-2-yl)-methylamine coordinate the $V^{IV}O$ ion at acid pH values and keep it in solution until the deprotonation and the coordination of the amide group occurs. A ligand-to-metal molar ratio between 3:1 and 5:1 is enough to avoid the hydrolysis of $V^{IV}O$ solutions; on the other hand, for ligands with weaker anchoring groups higher ratios are required: for example 10:1 for HisGlyGly provided with the ($NH_2$, CO, $N_{im}^{ax}$) donor set,[21o] and 15:1 for GlyGlyHis and GlyGlyCys with the ($COO^-$, CO) set.[21o] This suggests that the bis(imidazol-2-yl)methyl residue is an anchoring group of intermediate strength, weaker than phenolate-$O^-$ or thiolate-$S^-$ but stronger than amino-$NH_2$ or carboxylate-$COO^-$.

The presence of a free terminal amino group seems to be a necessary condition to promote the deprotonation of the amide bond through the closure of a second chelate ring besides that formed by imidazole and deprotonated amide nitrogens; its absence, like with Z-Gly-BIMA and Z-Ala-BIMA, stops the complexation to the $VOL_2$ complex.

The identical complexing behaviour of Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA and His-BIMA indicates that the side-chain of the α-Asp, α-Glu or His residues does not take part in the coordination. This is not too surprising because the carboxylate group of α-Asp-BIMA and α-Glu-BIMA should close seven- and eight-membered chelate rings, and the imidazole nitrogen of His-BIMA a seven-membered ring. Moreover, the lower affinity of the $V^{IV}O$ ion for nitrogen atoms with respect to $Cu^{II}$ hinders the formation of the dinuclear structures observed for α-Asp-BIMA,[23g] α-Glu-BIMA[23g] and His-BIMA.[23b]

Also with Gly-BIMA, α-Asp-BIMA, α-Glu-BIMA and His-BIMA the "additivity rule" for calculating the $^{51}V$ anisotropic parallel hyperfine coupling constant ($A_\parallel$) is followed,[20,21j,21m,26,27,38,42] but only attributing a reduced contribution to $A_\parallel$(amide) when the total equatorial charge around the vanadyl ion decreases.[20,21b,21h] This simplification allows us to obtain a good agreement between the calculated and experimental $A_\parallel$ values,[20,21o] but is justified only if the contribution of all the other donors is considered constant so that the reduction of $A_\parallel$ can be entirely attributed to a reduction of $A_\parallel$(amide). In this work we present the new idea that all four equatorial donors could contribute to reducing the positive charge of the vanadyl ion when a decrease in the total equatorial charge is considered; the mechanism could be based on an increase of the covalence of V-donor bonds through π interactions involving the overlap of the ligand orbitals with $d_{xy}$ bearing the unpaired electron, which in turn results in a decrease of the $A_\parallel$ value, according to Equation (2). However, further experimental data must be collected to confirm this hypothesis.

## Experimental Section

**Syntheses:** The synthetic procedures for preparation of simple amino acid derivatives containing the bis(imidazoly-2-yl)methyl moiety have already been reported.[23b,47] The purities of products were checked by $^1H$ NMR and concentrations were determined by potentiometric titration. $V^{IV}O$ solutions were prepared following literature methods.[48]

**Potentiometric Measurements:** The stability constants of proton and $V^{IV}O$ complexes were determined by pH-potentiometric titrations on 3–10 mL of samples. The ligand-to-metal molar ratio was between 1:1 and 5:1 and $V^{IV}O$ concentration was 0.001–0.004 M. Titrations were performed from pH 2.0 until precipitation or very extensive hydrolysis by adding carbonate-free KOH of known concentration (ca. 0.2 M KOH).[49] The pH was measured with a Metrohm 6.0234.100 combined electrode, calibrated for hydrogen concentration by the method of Irving et al.[50] Measurements were carried out at 25.0 ± 0.1 °C and at a constant ionic strength of 0.2 M KCl with a Radiometer ABU91 automatic titration system or MOLSPIN pH-meter equipped with a digitally operated syringe (1.00 mL) controlled by a computer. Purified argon was bubbled through the samples to ensure the absence of oxygen. The number of experimental points was 50–100 for each titration curve and the reproducibility of the points included in the evaluation was within 0.005 pH units in the whole pH range examined. The stability of the complexes, reported as the logarithm of the overall formation constant $\beta_{pqr} = [VO_pL_qH_r]/[VO]^p[L]^q[H]^r$, where VO stands for the $V^{IV}O$ ion, L is the deprotonated form of the ligand and H is the proton, was calculated with the aid of the SUPERQUAD[51] and PSEQUAD programs.[52] Standard deviations were calculated by assuming random errors. Conventional notation was used: negative indices for protons indicate either the dissociation of groups which do not deprotonate in the absence of $V^{IV}O$ coordination, or hydroxo ligands. Hydroxo complexes of $V^{IV}O$ were taken into account and the following species were assumed: $[VO(OH)]^+$ ($\log\beta_{10-1} = -5.94$), $[(VO)_2(OH)_2]^{2+}$ ($\log\beta_{20-2} = -6.95$), with stability constants calculated from the data of Henry et al.[53] and corrected for the different ionic strengths by use of the Davies equation,[54] $[VO(OH)_3]^-$ ($\log\beta_{10-3} = -18.0$) and $[(VO)_2(OH)_5]^-$ ($\log\beta_{20-5} = -22.0$).[55]

**Spectroscopic Measurements:** Anisotropic EPR spectra were recorded for aqueous solutions with an X-band (9.35 GHz) Bruker EMX spectrometer in the temperature range 120–140 K. As usual for low temperature measurements, a few drops of DMSO were added to the samples to ensure good glass formation. The spectra were simulated with the computer program Bruker WinEPR SimFonia.[56] Although the temperature is different during the potentiometric and EPR measurements, according to the data in the literature the same stoichiometry and coordination mode of the main species can be supposed.[19] Electronic spectra were recorded with Perkin–Elmer Lambda 25 or 35 spectrophotometers in the same concentration range as used for potentiometry. All operations were performed under a purified argon atmosphere in order to avoid oxidation of the $V^{IV}O$ ion.

**Computational Details:** All calculations presented in this paper were performed using the Gaussian 03 program (revision C.02)[32] and DFT methods.[57] The hybrid exchange-correlation functional B3LYP was employed.[34,35] Several basis functions were used for the calculations: 3-21g, 6-31g, 6-31g(d), 6-31+g, 6-31g(d,p) and 6-311g; finally, the mixed set with 6-311g for vanadium and 6-31g(d) for the other elements was chosen. Full geometry optimisations were carried out on the $VOLH_{-1}(H_2O)$ and $VOLH_{-1}(OH)$ complexes (i.e. $VOLH_{-1}$ and $VOLH_{-2}$), using the ligand L in which one imidazole ring of the bis(imidazol-2-yl) residue was replaced by a hydrogen atom [L = *N*-glycyl-(imidazol-2-yl)methylamine, Gly-IMA]. Minima were verified through frequency calculations.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Minimisations of the structures formed by Gly-BIMA with the second imidazole ring coordinated in the axial position of the $V^{IV}O$ ion were unsuccessful.

**Supporting Information** (see also the footnote on the first page of this article): Details of DFT calculations. Comparison between the experimental and calculated $A_{\parallel}$ values for $V^{IV}O$ complexes containing a V–$N^{-}$(amide) bond, characterised by different and same total equatorial charge (Table S1).

[43] For example, in the couple **III** of Table S1 $A_{\parallel}$ calcd. for [VO(bpb)] [equatorial donor set ($N_{pyr}$, $N^-$, $N^-$, $N_{pyr}$) and total equatorial charge –2] has been obtained from $A_{\parallel}$ exptl. of [VO(hypyb)] [$156.1 \times 10^{-4}$ cm$^{-1}$ [21e]], equatorial donor set ($N_{pyr}$, $N^-$, $N^-$, $O_{ar}^-$) and total equatorial charge –3] with this formula: $A_{\parallel}$ calcd.([VO(bpb)]) = {$A_{\parallel}$ exptl.([VO(hypyb)]) – $A_{\parallel}(O^-_{ar})$ + $A_{\parallel}(N_{pyr})$} = {$156.1 \times 10^{-4}$ cm$^{-1}$ – $38.9 \times 10^{-4}$ cm$^{-1}$ + $40.7 \times 10^{-4}$ cm$^{-1}$} = $157.9 \times 10^{-4}$ cm$^{-1}$. Subsequently, $A_{\parallel}$ calcd. ($157.9 \times 10^{-4}$ cm$^{-1}$) has been compared with $A_{\parallel}$ exptl. ($145 \times 10^{-4}$ cm$^{-1}$).[21b,21i] The reduction is 8.9%.
[44] For example, Chasteen calculated the contribution to $A_{\parallel}$ for $NH_2$ and $O_{ar}^-$ from the experimental $A_{\parallel}$ value of $[VO(en)_2]^{2+}$ and $[VO(cat)_2]^{2-}$ complexes, where en = ethylenediamine and cat = catecholate, and for $H_2O$ from experimental $A_{\parallel}$ of aqua ion $[VO(H_2O)_5]^{2+}$[26].

# Synthesis, Spectroscopic and Structural Systematics of Complexes of Germanium(IV) Halides ($GeX_4$, X = F, Cl, Br or I) with Mono-, Bi- and Tri-Dentate and Macrocyclic Nitrogen Donor Ligands

**Fei Cheng,[a] Martin F. Davis,[a] Andrew L. Hector,[a] William Levason,*[a] Gillian Reid,[a] Michael Webster,[a] and Wenjian Zhang[a]**

**Keywords:** Germanium / Nitrogen ligands / Fluorido complexes

The six-coordinate adducts *cis*-[$GeX_4$(L–L)] (L–L = 2,2′-bipyridyl, 1,10-phenanthroline, or $Me_2NCH_2CH_2NMe_2$, X = F, Cl or Br) have been synthesised and characterised by IR and VT $^1H$ and $^{19}F\{^1H\}$ NMR spectroscopy. X-ray crystal structures reveal distorted octahedral geometries and the trends in *d*(Ge–N) with halide are interpreted in terms of varying Lewis acidity within the series. The *trans*-[$GeX_4(py)_2$] were similarly characterised. In contrast, $GeI_4$ does not form similar adducts, although it appears to co-crystallise with some of the ligands, and the structure of $GeI_4 \cdot (1,10\text{-phenH})_3 \cdot I_3$ which contains phenanthrolinium cations, iodide anions and tetrahedral $GeI_4$ molecules is reported. Multidentate nitrogen donor ligands including cyclam (1,4,8,11-tetraazacyclotetradecane) and $Me_4$-cyclam (1,4,8,11-tetramethyl-1,4,8,11-tetraazacyclotetradecane) react with [$GeF_4(MeCN)_2$] to form insoluble compounds [{$GeF_4$}$_2$(macrocycle)] ($F_4N_2$ donor sets). In contrast, $Me_3$[9]ane$N_3$ (1,4,7-trimethyl-1,4,7-triazacyclononane) forms the cation [$GeF_3${$Me_3$[9]ane$N_3$}]$^+$ with a facial geometry ($N_3F_3$ donor set) which is the first example of displacement of fluoride from $GeF_4$ by a neutral ligand.

## Introduction

The coordination chemistry of tin(IV), especially complexes derived from the three tetrahalides, $SnX_4$ (X = Cl, Br or I), is among the most extensive of the *p*-block elements.[1–5] Tin(IV) fluoride has been much less studied (see ref.[4,5] and citations therein), but is a very strong Lewis acid. In marked contrast, the coordination chemistry of the lighter analogue germanium(IV) is little known. Surveys in the 1950–1960s established that germanium(IV) halides exhibited modest Lewis acidity, markedly less than that of the tin(IV) analogues, but provided little detail.[6] A few more examples have been reported in the intervening years,[7–13] but data on series of complexes, solution speciation studies or even establishment of the boundaries of complex formation are elusive. We have begun a detailed examination of the coordination chemistry of germanium(IV), and have recently reported a series of phosphane oxide adducts of the tetrahalides,[14] including *trans*-[$GeF_4(R_3PO)_2$] (R = Me, Et or Ph), *trans*-[$GeCl_4(Et_3PO)_2$], *fac*-[$GeCl_3(Me_3PO)_3$]$_2$-[$GeCl_6$], and *cis*-[$GeX_2(Me_3PO)_4$]$X_2$ (X = Cl or Br). The ability of $R_3PO$ to displace Cl or Br from the $GeX_4$ to form the cationic complexes was unexpected and is unknown in the corresponding tin(IV) systems. Similarly, whilst $GeF_4$ forms *trans*-[$GeF_4(Ph_3AsO)_2$] on reaction with the arsane oxide, reaction of $Ph_3AsO$ or $Me_3AsO$ with $GeCl_4$ leads to the corresponding $R_3AsCl_2$, again contrasting with the tin(IV) systems.[14]

This present study focuses on nitrogen donor ligands of a variety of architectures and denticities, especially the complexes with $GeF_4$. A more limited range of examples with $GeCl_4$ and $GeBr_4$ were examined for comparison purposes.

## Results and Discussion

### Mono- and Bi-Dentate Nitrogen Donor Ligands

The germanium(IV) halides and their complexes are moisture sensitive to varying degrees and all syntheses were carried out using rigorously anhydrous conditions. $GeF_4$ is a gas (sub. 236 K) and inconvenient to handle in this form, and the nitrile adduct, [$GeF_4(MeCN)_2$][14] is a more convenient precursor. The reaction of [$GeF_4(MeCN)_2$] with the bidentate N-donors 2,2′-bipyridyl, 1,10-phenanthroline and $Me_2N(CH_2)_2NMe_2$ (L–L) in anhydrous MeCN solution afforded white solid [$GeF_4$(L–L)] complexes which were unaffected by exposure to moist air and stable in solution in dry MeCN or $CH_2Cl_2$. The $^{19}F\{^1H\}$ NMR spectra in $CH_2Cl_2$ or MeCN each show two triplets consistent with the presence of *cis* isomers ($^2J_{FF}$ = 55–65 Hz), and the IR spectra show several strong bands in the region 590–660 cm$^{-1}$ assigned as ν(Ge–F) (theory: 4 IR-active stretches $2a_1 + b_1 + b_2$). The $^1H$ NMR spectra are also simple showing resonances only due to the coordinated ligands. In contrast the

monodentates, pyridine and $Et_3N$ (L) give $[GeF_4(L)_2]$ which exhibit singlet $^{19}F\{^1H\}$ NMR resonances in $CDCl_3$ solution consistent with *trans* isomers. The $^1H$ NMR spectra of solutions of $[GeF_4(NEt_3)_2]$ in $CH_2Cl_2$ at 298 K shows broad $\delta$(Me) and $\delta(CH_2)$ resonances with no couplings, but on cooling four resonances appear, two quartets and two triplets ($^3J_{HH} \approx 7$ Hz) with approximately equal intensities in each case, assigned from their chemical shifts to $[GeF_4(NEt_3)_2]$ and free $NEt_3$, showing significant ligand dissociation in solution. The presence of only the *trans* isomer contrasts with the behaviour found for $[GeF_4(R_3PO)_2]$ where varying amounts of *cis* and *trans* isomers were found in solution in chlorocarbons.[14]

The structure of $[GeF_4(2,2'\text{-bipy})]$[9] is the only literature structure of a $GeF_4$ adduct with a bidentate N-donor ligand. We have determined the structures of $[GeF_4$-(1,10-phenanthroline)] and $[GeF_4(Me_2NCH_2CH_2NMe_2)]$ (Table 1, Figures 1 and 2) which show close to octahedral coordination at the Ge with F–Ge–F angles slightly greater than 90° and F–Ge–N slightly smaller than 90°, and with N–Ge–N 80.0(2)° and 85.2(3)° respectively. The Ge–$F_{trans F}$ are typically longer than Ge–$F_{trans N}$, with the *trans* F–Ge–F unit bent towards the neutral ligand, as is usually found in compounds of this type.[5,9] The structure of $[GeF_4(py)_2]$ in contrast, is of a *trans* isomer, a centrosymmetric molecule, with unexceptional bond lengths (Table 2, Figure 3).

In contrast to the fluorides, the complexes of $GeCl_4$ and $GeBr_4$ are hydrolytically very sensitive and must be handled in a glove box and in dry solvents. The complexes $[GeX_4$-(L–L)] (X = Cl or Br; L–L = 2,2′-bipy, 1,10-phen, $Me_2NCH_2CH_2NMe_2$) were obtained as white powders by combining the constituents in dry $CH_2Cl_2$ solution, and in several cases, as colourless crystals on recrystallisation from dry MeCN in a freezer. The structures of $[GeCl_4(2,2'$-bipy)][12] and $[GeCl_4(Me_2NCH_2CH_2NMe_2)]$[8] have been reported previously, and we report here the structures of $[GeX_4$(1,10-phenanthroline)], $[GeBr_4(2,2'$-bipy)] and $[GeBr_4$-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

($Me_2NCH_2CH_2NMe_2$)] (Tables 3, 4, and 5, Figures 4, 5, 6, and 7). The structural features generally mimic those discussed above for the fluorides, with X–Ge–X angles rather greater than 90° and X–Ge–N angles rather less. The N–Ge–N angles are 79.5(1)° [$GeCl_4$(1,10-phenanthroline)], 78.8(3)° [$GeBr_4$(1,10-phenanthroline)], 79.0(2)° [$GeBr_4$-(2,2′-bipy)] and 82.3(2)° [$GeBr_4(Me_2NCH_2CH_2NMe_2)$], reflecting the slightly different ligand bites. The availability of the present data combined with that in the literature permits a detailed comparison of structural features within the [$GeX_4$(L–L)] series as a function of X and hence an examination of the Lewis acidity of the $GeX_4$. The trends reflect two major contributions, the strength of the Ge–N bond

[a] There are two molecules in the asymmetric unit. The first line refers to the Ge1 centred molecule.

and the reorganisation energy necessary to convert the tetrahedral $GeX_4$ to the four-coordinate fragment of the octahedron produced on bonding the Lewis base. For comparison the key bond lengths are summarised in Table 6.

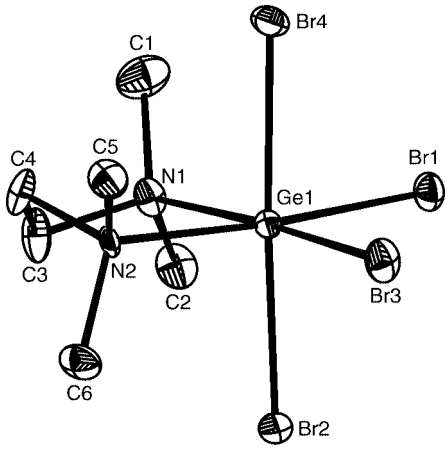

Figure 7. Structure of [$GeBr_4(Me_2NCH_2CH_2NMe_2)$] showing the atom labelling scheme. The H atoms have been omitted for clarity and the atom displacement ellipsoids are drawn at the 40% probability level.

The Ge–X bonds are all longer than in the parent (tetrahedral) $GeX_4$ {X = F, 1.661(1) Å at 133 K; X = Cl, 2.082(7) Å; X = Br, 2.262(2), 2.269(1) Å}[15–17] reflecting the increased coordination number. Looking at the [$GeX_4(Me_2NCH_2CH_2NMe_2)$] series there is a very clear lengthening of Ge–N as the halide changes F → Cl → Br, showing reduced Lewis acidity in this order. There is a corresponding small decrease in the N–Ge–N angle along the series. For the diimine series the Ge–N are markedly shorter in the fluorido complexes, but the differences are small between the chlorides and bromides (although marginally longer in the latter), possibly reflecting the effects of the rigid ligand skeleton in 1,10-phenanthroline and to a lesser extent 2,2′-bipyridyl (the two rings are essentially co-planar in the bipy complexes and the angles N–Ge–N change by ≤ 1° between the three complexes in each series). The two independent molecules in the unit cell of [$GeCl_4$(1,10-phenanthroline)] show small but significant differences and this is presumably attributable to packing,[18] and effects of a similar magnitude in other cases could mask trends in Ge–N distances with changing halogen co-ligands. The decreasingly strong binding of the nitrogen ligands as the halide becomes heavier is also reflected in the solution properties. Thus, whilst the fluorides show simple spectra due to coordinated ligand with high frequency shifts for the resonances in the $^1$H NMR spectra at 295 K in $CDCl_3$ or $CD_3CN$, the diimine bromide complexes show evidence for both coordinated and "free" ligand, indicative of partial dissociation in solution at ambient temperatures. The $^1$H NMR spectrum of [$GeBr_4(Me_2NCH_2CH_2NMe_2)$] at 295 K shows broad features consistent with fast exchange, whilst at low temperatures separate resonances are seen for coordinated and "free" diamine as exchange slows. The chlorides are intermediate in properties with the [$GeCl_4$(1,10-phenanthroline)] showing sharp resonances for the coordinated ligand only, but [$GeCl_4$(2,2′-bipy)] shows both "free" and coordinated ligand resonances.

The older literature contains a few reports of brown or red complexes derived from $GeI_4$ and nitrogen donor ligands[19] mostly characterised only by (partial) microanalytical data. We have obtained similar products in a number of cases. The IR spectra show the presence of the nitrogen ligand (protonated in some examples) and a strong band at 250 ± 5 $cm^{-1}$ which corresponds to the $t_2$ vibration of tetrahedral $GeI_4$, but are otherwise uninformative, and since extensive dissociation is expected in solution, NMR spectroscopic data are of little help. For the 1,10-phenanthroline/$GeI_4$ system in $CH_2Cl_2$, a few good quality crystals were obtained, the structure revealed the composition to be $GeI_4$·(1,10-phenH)$_3$·$I_3$, presumably formed by trace hydrolysis (Table 7). This contained tetrahedral $GeI_4$, 1,10-phenanthrolinium cations, and iodide ions. Two of the three protonated 1,10-phenanthrolines were involved in N–H···I H-bonding and one $I^-$ (I5) showed a weak interaction to an iodine atom of $GeI_4$ (3.483 Å), rather shorter than that found in $Et_4NI$·2$GeI_4$ (3.660–3.792 Å).[20] The unit cell is

shown in Figure 8. In our work on the $GeI_4/R_3PO$ systems[14] we also obtained crystals of $GeI_4$ and $R_3POH^+ I_3^-$, but no adducts from reactions of $GeI_4$ with the ligands, and there appear to be no structurally authenticated examples of $GeI_4$ complexes with neutral ligands.

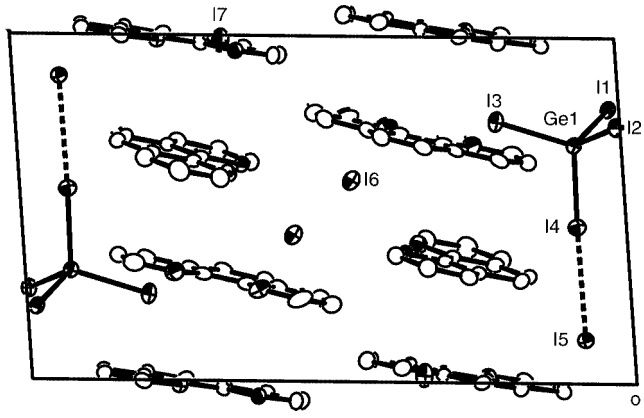

Figure 8. Unit cell packing diagram of $GeI_4 \cdot 3[C_{12}H_9N_2] \cdot 3I$ viewed along the *a* direction. The H atoms have been omitted for clarity, only Ge and I are labelled with C drawn as boundary ellipsoids, and the atom displacement ellipsoids are drawn at the 50% probability level. The weak I···I interaction is shown as a dotted bond. I6 and I7 are involved in N–H···I H-bonds (not shown). The origin is in the lower right corner with *c* along the horizontal direction and *b* near vertical. The packing consists of nearly parallel 1,10-phenanthrolinium cations ($C_{12}H_9N_2$) lying in the *ac* plane. The cations stack to form a sheet in the *ab* plane $\{[(C_{12}H_9N_2)_3I_2]^+\}$ interleaved with a sheet of composition $[(GeI_4) \cdot I]^-$.

## Polydentate and Macrocyclic N-Ligands

Polydentate N-donor macrocycles displace halide from the appropriate $GeX_4$ (X = Cl or Br) in forming $[GeCl_3\{Me_3[9]aneN_3\}]^+$ and $[GeBr_3(1,3,5\text{-trimethyl-}1,3,5\text{-triazacyclohexane})]^+$,[7] and it was therefore of interest to establish if it was possible to displace fluoride from $GeF_4$ by similar ligands. The reaction of $Me_3[9]aneN_3$ with $[GeF_4(MeCN)_2]$ in $CH_2Cl_2$ produced a white solid identified as $[GeF_3\{Me_3[9]aneN_3\}]_2[GeF_6]$ by microanalysis, which was insoluble in MeCN or chlorocarbons. The IR spectrum showed two strong broad features at 629 and 602 $cm^{-1}$ attributable to the ν(Ge–F) stretching modes of the cation and anion respectively, and a strong feature at 340 $cm^{-1}$ which is δ(Ge–F) of the anion. Unfortunately crystals of this salt could not obtained due to insolubility in common solvents, but a few crystals were isolated by slow evaporation of an MeCN extract of the white solid from the preparation and were found to be (Figure 9, Table 8) $[GeF_3\{Me_3[9]aneN_3\}]Cl$. The adventitious chloride anion is believed to arise from the displaced fluoride ion reacting with the chlorocarbon solvent.[21] The structure shows the expected facial geometry for the cation with Ge–N 2.043(3) Å which may be compared with 2.106(2)–2.125(2) Å in the chloride analogue $[GeCl_3\{Me_3[9]aneN_3\}]^+$.[7] The N–Ge–N angle in the former is 85.53(13)° compared to 82.59(8)–83.17(8)° in the latter. The Ge–F distance in the cation is 1.767(2) Å not significantly different from that in the $[GeF_4(diimine)]$ complexes despite the cation charge. This complex is the first example in which fluoride has been displaced from $GeF_4$ by a neutral ligand.

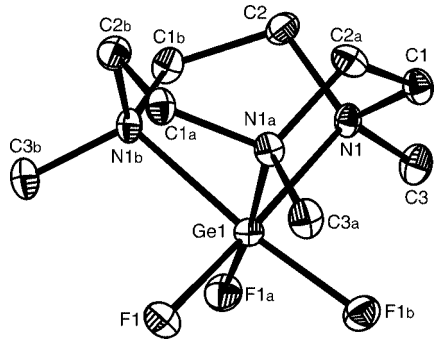

Figure 9. Structure of the cation of $[GeF_3(Me_3[9]aneN_3)]Cl$ showing the atom labelling scheme. The H atoms have been omitted for clarity and the atom displacement ellipsoids are drawn at the 50% probability level. The cation has threefold crystallographic symmetry. Symmetry operations: $a = 1 - y, x - y, z$; $b = 1 - x + y, 1 - x, z$.

Table 8. Selected bond lengths [Å] and angles (°) for $[GeF_3(Me_3[9]aneN_3)]Cl$.[a]

[a] Symmetry operations: $a = 1 - y, x - y, z$; $b = 1 - x + y, 1 - x, z$.

The reactions of cyclam (1,4,8,11-tetra-azacyclotetradecane) and $Me_4$-cyclam (1,4,8,11-tetramethyl-1,4,8,11-tetra-azacyclotetradecane) with $[GeF_4(MeCN)_2]$ in $CH_2Cl_2$ in either a 1:1 or 1:2 molar ratio, precipitated white powders which were identified by microanalysis as $[(GeF_4)_2(\text{azamacrocycle})]$. The solids are air-stable and the IR spectra reveal the presence of the macrocycle and terminal Ge–F modes. The isolated solids are insoluble in chlorocarbons and MeCN, precluding NMR studies, but the $^{19}F\{^1H\}$ NMR spectra of the reaction mixtures (in situ) show a number of resonances in the regions expected for $\delta F_{trans F}$ and $\delta F_{trans N}$ and on cooling the solutions these show t or d,t patterns consistent with *cis* octahedral-$GeF_4$ units with $\kappa^2$ coordination to the macrocycles (depending upon the rate of pyramidal inversion at N or reversible dissociation, resonances due to the presence of *meso* and DL forms of the $\kappa^2$ coordinated macrocycle may be expected). Notably absent were any features attributable to $[GeF_6]^{2-}$ $\{\delta(^{19}F) = -139\}$ or significant amounts of $F^-$, which would be present if fluoride had been displaced from the germanium centre. Confirmation of the $\kappa^2$-bonding mode came from the crystal structure of $[GeF_4(Me_4\text{-cyclam})]$, a few crystals of which were obtained from the filtrate of the 1:1 reaction mixture after removal of the precipitated 2:1 complex. The crystals were very small and the data quality modest, but the structure (Figure 10, Table 9) shows $[GeF_4(\kappa^2\text{-}Me_4\text{-cyclam})]$ with the *meso* conformation at the coordinated nitrogens, and the other two N-donors bent away from and not interacting with the germanium. The failure of the cyclam type ligands

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

to form cationic complexes is rationalised in that they are not well suited to $\kappa^3$ coordination (in contrast to $Me_3$[9]-ane$N_3$), and the displacement of two fluorides to form $[GeF_2(\kappa^4\text{-cyclam})]^{2+}$ is probably energetically unfavourable. Reaction of 2,2′,6′,2′′-terpyridyl with $[GeF_4(MeCN)_2]$ in $CH_2Cl_2$ gave a white solid of composition $[(GeF_4)_3(2,2',6',2''\text{-terpy})_2]$ which was insoluble in MeCN or chlorocarbons. The IR spectrum showed terpy and terminal Ge–F stretches at similar frequencies to the $[GeF_4(diimine)]$ complexes. The insolubility prevented further study, but it seems likely that the terpy is $\kappa^2$ coordinated to one $GeF_4$ residue and $\kappa^1$ to a second $GeF_4$, producing oligomers with six-coordinate germanium centres ($F_4N_2$ coordinated).

## Conclusions

This study has shown that $GeF_4$ forms robust complexes with a variety of neutral nitrogen donor ligands, all but one example containing six-coordinate germanium with $F_4N_2$ donor sets. The exception, $[GeF_3\{Me_3[9]aneN_3\}]^+$ reflects the strong pre-organisation in the macrocycle for $\kappa^3$ coordination which in this case achieves the displacement of one fluorido ligand. The complexes are generally only slightly moisture sensitive, whereas the corresponding complexes with $GeX_4$ (X = Cl or Br) are very sensitive to moisture, and often partially dissociated in solution. Structural studies confirm that Lewis acidity decreases along the series $GeF_4 >> GeCl_4 > GeBr_4$. There is no evidence that simple N-donor complexes form with $GeI_4$. The much stronger acceptor ability of $GeF_4$ may well mean that an extensive coordination chemistry is accessible, including complexes with other neutral donor types, e.g. tertiary phosphanes, thio- or seleno-ethers (none of which form simple adducts with $GeCl_4$)[10,22] and work is underway in our laboratory to explore this possibility.

## Experimental Section

The germanium(IV) halides $GeF_4$, $GeBr_4$ and $GeI_4$ were obtained from Aldrich and used as received. $GeCl_4$ (Aldrich) was distilled from a mixture of $CaCl_2/Na_2CO_3$, which removes traces of water and HCl. MeCN and $CH_2Cl_2$ were dried by distillation from $CaH_2$. All reactions were conducted using Schlenk, vacuum line and glove-box techniques and under a dry dinitrogen atmosphere. $Me_3$[9]ane$N_3$ was made as described.[23] 2,2′-Bipyridyl, 1,10-phenanthroline, 2,2′,6′2′′-terpyridyl and cyclam and $Me_4$-cyclam were dried by heating in vacuo. Pyridine was dried by distillation from potassium, and $Me_2N(CH_2)_2NMe_2$ and $NEt_3$ by distillation from BaO. $[GeF_4(MeCN)_2]$ was made as described.[14]

Infrared spectra were recorded as Nujol mulls on a Perkin–Elmer PE 983G spectrometer, $^1$H NMR spectra in $CDCl_3$, $CD_2Cl_2$ or $CD_3NO_2$ solutions on a Bruker AV300, $^{19}F\{^1H\}$ NMR spectra on a Bruker DPX400 and referenced to $CFCl_3$. Microanalytical measurements on new complexes were performed by the microanalytical service at Strathclyde University. Representative syntheses of the complexes are given below.

Yields of the complexes were at least 80% based upon germanium.

**$[GeF_4(2,2'\text{-bipy})]$:** 2,2′-Bipyridyl (0.04 g, 0.25 mmol) was added to a solution of $[GeF_4(MeCN)_2]$ (0.057 g, 0.25 mmol) in MeCN (10 mL) at room temperature with stirring, which led to the slow formation of a white precipitate. After stirring for 20 min, the solvent was removed in vacuo to leave a white solid. Air-stable colourless crystals were obtained by vapour diffusion of diethyl ether into solution of the compound in MeCN. $C_{10}H_8F_4GeN_2$ (304.8): calcd. C 39.4, H 2.7, N 9.2; found C 39.6, H 2.6, N 9.2. $^1$H NMR ($CD_3CN$, 295 K): $\delta$ = 9.03 (d, 2 H), 8.52 (m, 2 H), 8.37 (m, 2 H), 7.89 (m, 2 H) ppm. $^{19}F\{^1H\}$ NMR ($CDCl_3$, 295 K): $\delta$ = –116.2 (t, $^2J_{F,F}$ = 58 Hz, 2 F), –151.2 (t, 2 F) ppm. IR (Nujol): $\tilde{\nu}$ = 635 (sh), 618 (s), 605 (sh) ν(Ge–F) cm$^{-1}$.

**$[GeF_4(1,10\text{-phenanthroline})]$:** Was made analogously to the 2,2′-bipyridyl complex. $C_{12}H_8F_4GeN_2{\cdot}0.5MeCN$ (350.8): calcd. C 44.5, H 3.2, N 10.0; found C 44.5, H 2.7, N 10.0. $^1$H NMR ($CD_3CN$, 295 K): $\delta$ = 9.26 (d 2 H), 8.89 (d,d 2 H), 8.24 (s, 2 H), 8.15 (m 2 H) ppm. $^{19}F\{^1H\}$ NMR ($CDCl_3$, 295 K): $\delta$ = –115.7 (t, $^2J_{F,F}$ = 62 Hz, 2 F), –150.1 (t, 2 F) ppm. IR (Nujol): $\tilde{\nu}$ = 664 (s), 618 (s), 597 (s) ν(Ge–F) cm$^{-1}$.

**$[GeF_4(Me_2NCH_2CH_2NMe_2)]$:** Was made similarly to the 2,2′-bipyridyl complex and the white solid obtained was washed with diethyl ether and dried in vacuo. $C_6H_{16}F_4GeN_2$ (264.8): calcd. C 27.2, H 6.1, N 10.6; found C 27.3, H 5.9, N 10.1. $^1$H NMR ($CDCl_3$, 295 K): $\delta$ = 2.97 (m, 1 H) 2.83 (t, 3 H) ppm. $^{19}F\{^1H\}$ NMR ($CDCl_3$, 295 K): $\delta$ = –132.7 (t, $^2J_{F,F}$ = 60 Hz, 2 F), –150.9 (t, 2 F) ppm. IR (Nujol): $\tilde{\nu}$ = 619 (vs), 605 (s), 590 (sh) ν(Ge–F) cm$^{-1}$.

**$[GeF_4(py)_2]$:** Was made similarly to the 2,2′-bipyridyl complex using a 2:1 molar ratio of pyridine to $[GeF_4(MeCN)_2]$ in $CH_3CN$ solution. $C_{10}H_{10}F_4GeN_2$ (306.8): calcd. C 39.2, H 3.3, N 9.1; found C 39.0, H 2.7, N 9.1. $^1$H NMR ($CD_3CN$, 295 K): $\delta$ = 8.89 (m, 2 H),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

8.29 (m, 1 H), 7.81 (s, 2 H) ppm. $^{19}F\{^1H\}$ NMR ($CDCl_3$, 295 K): $\delta$ = –125.7 (s) ppm. IR (Nujol): $\tilde{\nu}$ = 617 (vs) ν(Ge–F) $cm^{-1}$.

**[$GeF_4(NEt_3)_2$]:** Triethylamine (0.020 g, 0.20 mmol) was added to a solution of [$GeF_4(MeCN)_2$] (0.023 g, 0.10 mmol) in $CH_2Cl_2$ (15 mL) at room temperature with stirring. After stirring for 10 min, the volatiles were evaporated slowly from the static solution which gave colourless crystalline solid. $^1H$ NMR ($CD_2Cl_2$, 295 K): $\delta$ = 1.2 (s, 3 H) 3.0 (s, 2 H) ppm; (253 K): $\delta$ = 1.10 (t, $^3J_{HH}$ = 6 Hz, 3 H), 1.27 (t, $^3J_{HH}$ = 6 Hz, 3 H), 2.98 (q, 2 H), 3.11 (q, 2 H). $^{19}F\{^1H\}$ NMR ($CD_2Cl_2$, 295 K): $\delta$ = –129 (br); 253 K $\delta$ = –118.5 (s) ppm. IR (Nujol): $\tilde{\nu}$ = 602 ν(Ge–F) $cm^{-1}$.

**[$GeCl_4$(2,2′-bipy)]:** $GeCl_4$ (0.22 g, 1.0 mmol) and 2,2′-bipyridyl (0.15 g, 1.0 mmol) were combined in dry dichloromethane (20 mL) producing an immediate white precipitate. The solvent was removed in vacuo and the white solid recrystallised from MeCN (20 mL). Colourless crystals were obtained by keeping the filtrate in a freezer for 3 d. $C_{10}H_8Cl_4GeN_2$ (370.6): calcd. C 32.4, H 2.2, N 7.6; found C 31.7, H 2.1, N 7.2. $^1H$ NMR ($CDCl_3$, 295 K): $\delta$ = 8.85 (br., H), 8.80 (br., H), 8.38 (m, H), 8.15 (m, H); (273 K): $\delta$ = 9.01 (d, $J$ = 8 Hz, 1 H), 8.92 (m, 1 H), 8.40 (m, 1 H), 8.20 (m, 1 H) ppm. IR (Nujol): $\tilde{\nu}$ = 335, 317, 295 ν(Ge–Cl) $cm^{-1}$.

**[$GeCl_4$(1,10-phenanthroline)]:** The complex was prepared analogously to the 2,2′-bipyridyl analogue. Colourless crystals were obtained from the MeCN filtrate after several days in a freezer. $C_{12}H_8Cl_4GeN_2$ (394.6): calcd. C 36.5, H 2.0, N 7.1; found C 36.6, H 1.9, N 7.2. $^1H$ NMR ($CD_3CN$, 295 K): $\delta$ = 10.17 (d, 2 H), 9.08 (d, 2 H), 8.42 (br., 2 H), 8.36 (m, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 357, 332, 320 (sh), 275 ν(Ge–Cl) $cm^{-1}$.

**[$GeCl_4(Me_2NCH_2CH_2NMe_2)$]:** The complex was made similarly to the 2,2′-bipyridyl analogue. $C_6H_{16}Cl_4GeN_2$ (330.6): calcd. C 21.8, H 4.9, N 8.5; found C 22.4, H 5.2, N 8.2. $^1H$ NMR ($CDCl_3$, 295 K): $\delta$ = 2.90 (s, 3 H), 3.05 (s, 1 H) (little change at 220 K) ppm. IR (Nujol): $\tilde{\nu}$ = 324, 303, 282 ν(Ge–Cl) $cm^{-1}$.

**[$GeCl_4(py)_2$]:** Pyridine (0.16 g, 1.0 mmol) was added to a solution of $GeCl_4$ (0.11 g, 0.5 mmol) in $CH_2Cl_2$ (20 mL) resulting in an immediate white precipitate, which was isolated by filtration and dried in vacuo. $C_{10}H_{10}Cl_4GeN_2$ (372.6): calcd. C 32.2, H 2.7, N 7.5; found C 31.9, H 2.5, N 7.2. $^1H$ NMR ($CDCl_3$, 295 K): $\delta$ = 8.71 (d, 2 H), 8.54 (m, 1 H), 8.01 (m, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 323 (vbr) ν(Ge–Cl) $cm^{-1}$.

**[$GeBr_4$(2,2′-bipy)]:** Was made similarly to the chloride as pale yellow crystals. $C_{10}H_8Br_4GeN_2$ (548.4): calcd. C 21.9, H 1.5, N 5.1; found C 22.1, H 1.7, N 5.2. $^1H$ NMR ($CDCl_3$, 295 K): $\delta$ = 8.92 (m, 2 H), 8.20 (m, H), 7.69 (m, H); (253 K): $\delta$ = 9.01 (d. H), 8.90 (d, $J$ = 8 Hz, 1 H), 8.32 (m, 1 H), 7.70 (m, 1 H) ppm. IR (Nujol): $\tilde{\nu}$ = 284 (s), 237 (s), 218 (s) ν(Ge–Br) $cm^{-1}$.

**[$GeBr_4$(1,10-phenanthroline)]:** Was made similarly to the 2,2-bipy complex. $C_{12}H_8Br_4GeN_2$ (572.4): calcd. C 25.2, H 1.4, N 4.9; found C 25.5, H 1.9, N 5.3. $^1H$ NMR ($CD_3CN$, 298 K): $\delta$ = 10.33 (d, 2 H), 9.10 (d, 2 H), 8.45 (s, 2 H), 8.40 (m, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 247 (s), 232 (s), 203 (sh), ν(Ge–Br) $cm^{-1}$.

**[$GeBr_4(Me_2NCH_2CH_2NMe_2)$]:** The diamine (0.06 g, 0.50 mmol) was added to a solution of $GeBr_4$ (0.19 g, 0.50 mmol) in $CH_2Cl_2$ (10 mL) at room temperature with stirring, which lead to an immediate colour change to pale yellow and slow precipitation of a yellow solid. After stirring for 10 min the solution was filtered and the pale yellow solid was dried in vacuo. Pale yellow crystals were obtained from a concentrated solution in MeCN in the freezer. $C_6H_{16}Br_4GeN_2$ (508.4): calcd. C 14.2, H 3.2, N 5.5; found C 14.5, H 3.8, N 5.7. $^1H$ NMR ($CDCl_3$, 298 K): $\delta$ = 2.46 (s, 3 H), 2.75 (s, H); (235 K): $\delta$ = 2.45 (s, 1 H), 2.63 (s, 1 H), 3.00 (s, 3 H), 3.12 (s, 1 H) ppm. IR (Nujol): $\tilde{\nu}$ = 238 (sh), 216 (s), ν(Ge–Br) $cm^{-1}$.

**[$GeBr_4$(py)$_2$]:** Was made similarly to the chloride analogue above, as a pale yellow powder. $C_{10}H_{10}Br_4GeN_2$ (540.4): calcd. C 21.8, H 1.8, N 5.1; found C 22.0, H 2.6, N 5.2. $^1H$ NMR ($CDCl_3$, 295 K): $\delta$ = 8.71 (d, 2 H), 8.33 (m, 1 H), 7.83 (m, 2 H) ppm. IR (Nujol): $\tilde{\nu}$ = 237 (vbr) ν(Ge–Br) $cm^{-1}$.

**[$(GeF_4)_3$(2,2′,6′,2′′-terpy)$_2$]:** Was made analogously to the 2,2′-bipyridyl complex, using $MeCN/CH_2Cl_2$ solvent mixture. $C_{30}H_{22}F_{12}Ge_3N_6{\cdot}0.5CH_2Cl_2$ (954.7): calcd. C 38.4, H 2.4, N 8.8; found C 38.2, H 2.3, N 9.1. IR (Nujol): $\tilde{\nu}$ = 645 (br., s), 580 (s) ν(Ge–F) $cm^{-1}$.

**[$(GeF_4)_2$($Me_4$-cyclam)]:** $Me_4$-cyclam (0.025 g, 0.10 mmol) was added to a solution of [$GeF_4(MeCN)_2$] (0.046 g, 0.20 mmol) in $CH_2Cl_2$ (20 mL) at room temperature with stirring, which led to slow precipitation of a white solid. After stirring for 15 min the white precipitate was separated by filtration and dried in vacuo. $C_{14}H_{32}F_8Ge_2N_4{\cdot}0.5CH_2Cl_2$ (596.1): calcd. C 29.2, H 5.5, N 9.4; found C 28.4, H 5.3, N 9.2. IR (Nujol): $\tilde{\nu}$ = 615 (vbr, s), 590 (sh) ν(Ge–F) $cm^{-1}$. A small number of colourless crystals of [$GeF_4$($Me_4$-cyclam)] were obtained by slow evaporation of the solvent from the filtrate.

**[$(GeF_4)_2$(cyclam)]:** Cyclam (0.020 g, 0.10 mmol) was added to a solution of [$GeF_4(MeCN)_2$] (0.046 g, 0.20 mmol) in $CH_2Cl_2$ (20 mL) at room temperature with stirring which lead to immediate precipitation of a white solid. After stirring for 15 min the white precipitate was separated by filtration and dried in vacuo. $C_{10}H_{24}F_8Ge_2N_4$ (497.5): calcd. C 24.1, H 4.8, N 11.3; found C 25.5, H 4.7, N 11.7. IR (Nujol): $\tilde{\nu}$ = 3100 (br) ν(N–H), 1650 (br) δ(N–H), 624 (br., s), 572 (br., s) ν(Ge–F) $cm^{-1}$.

**[$GeF_3${$Me_3$[9]aneN$_3$}]$_2$[$GeF_6$]:** $Me_3$[9]aneN$_3$ (0.018 g, 0.10 mmol) was added to a solution of [$GeF_4(CH_3CN)_2$] (0.035 g, 0.15 mmol) in $CH_2Cl_2$ (20 mL) at room temperature with stirring which lead to the precipitation of a white solid. After stirring for 30 min the white precipitate was separated by filtration and washed with diethyl ether. A few crystals of [$GeF_3$($Me_3$[9]aneN$_3$)]Cl were obtained by extracting the crude solid in $CH_3CN$ with heating followed by filtration and slow evaporation of the filtrate at room temperature. $C_{18}H_{42}F_{12}Ge_3N_6{\cdot}CH_2Cl_2$ (873.3): calcd. C 26.1, H 5.1, N 9.6; found C 26.6, H 5.1, N 10.1. IR (Nujol): $\tilde{\nu}$ = 629 (s), 602 (s) ν(Ge–F), 340 δ(Ge–F) $cm^{-1}$.

**X-ray Crystallography:** Details of the crystallographic data collection and refinement parameters are given in Table 10. Crystals were mostly obtained directly from the preparations as described. Data collections used a Bruker-Nonius Kappa CCD diffractometer fitted with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) and with the crystals held at 120 K in a nitrogen gas stream. Structure solution and refinement were straightforward[24–27] with H atoms introduced into the models in calculated positions using the default C–H distance.

CCDC-652869 [for F/N(phen)], -652870 [for F/N(diamine)], -652871 [for F/N(py)], -652872 (for Cl/N), -652873 [for Br/N(phen)], -652874 [for Br/N(bipy)], -652875 [for Br/N(diamine)], -652876 [for F/N(cyclam)], -652877 (*I*), and -652878 ($F_3N_3$) contain the supplementary crystallographic data for this paper (the atoms in parentheses indicate the species bonded to Ge in the compound). These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Stepwise Assembly of Nanoparticles, -tubes, -rods, and -wires in Reverse Micelle Systems

Yun Chen,[a] Qingsheng Wu,*[a] and Yaping Ding[b]

**Keywords:** Stepwise-assembly synthesis / Nanomaterials / $CaSO_4 \cdot 2H_2O$ / Reverse micelles

A traditional facile method was used for the stepwise-assembly synthesis of $CaSO_4 \cdot 2H_2O$ nanoparticles, -tubes, -rods, and -wires. Sizes of these nanostructures vary from tens of nanometers to tens of microns. The key point of the stepwise-assembly process is the reaction time. The growth process was studied as a function of the reaction time and this was used to guide the synthesis of other one-dimensional nanomaterials in reverse micelle systems. The results showed that this growth process is somewhat universal in synthesizing inorganic salts with zero/one-dimensional and solid/hollow structures in reverse micelle systems. The growing mechanism was also explored and it was believed to be an assembly-based growth in association and concurrent with the surfactant-templating mechanism.

## Introduction

The reverse micelle or microemulsion system is a traditional synthesis method that has been widely used to prepare nanomaterials because of its facility, speediness, and efficiency. Being a soft template system with affluent diversification, reverse micelles were used to fabricate nanomaterials with different novel morphologies.[1–14] However, it is the variety that makes it difficult to effectively control the morphology. Thus, how to regulate the shapes and structures effectively in reverse micelle systems has become the target that most scientists seek. Although considerable efforts have been made to control the synthesis at will in reverse micelle systems,[15–19] to date no one has achieved the successful synthesis of a series of different nanostructures in one reverse micelle system. Somewhat controllable methods are involved such as changing surfactant concentration, reactant concentration, $\omega_0$, and using different surfactants.[20–22] In these methods it is found that the structures of the micelle templates are changed fundamentally to tune nanostructures. However, the structures and behavior of micelle templates are still not clear so much uncertainty is involved in these methods. Consequently there is an urgent need to explore the entire picture of the growth process in such a system.

The development of nanoscience and -technology over the last two decades shows that some interesting new nanostructures can be fabricated based on the mechanism called "oriented attachment".[23–24] In this mechanism, inorganic nanocrystals are the fundamental building blocks for the creation of highly ordered extended nanostructures. Although there are now feasible ways for the formation of low-dimensional complex nanostructures using nanoparticles as building blocks,[25] the challenge for the organization of nanoparticles into higher dimensional structures still remains. Nanotubes are higher structures constructed by initial nano building blocks and are thought to be a sort of the most promising nanomaterials.[26–27] However, most of the obtained nanotubes are oxides or have graphite-like structures:[28–32] noncarbon, nonoxide, and nonlaminated nanotubes are difficult to fabricate through ordinary methods.[33–34] The simple and easy way to make nanotubes at room temperature described in this paper can offer more opportunities for the research of noncarbon, nonoxide, and nonlaminated nanotubes.

Reaction time was investigated as an impact factor in the microemulsion system and its main role is believed to be to control the crystal growth and crystallinity.[5,35] However, after many trials other important functions of aging time were discovered. It can control the dimension, morphology, and structure of the products under certain circumstances. In this work, by controlling reaction time step by step, according to the characteristics of different inorganic salts, stepwise-assembly synthesis of non-oxide ionic-crystal nanomaterials from nanoparticles to nanotubes, nanorods, and nanowires is successfully realized for the first time in reverse micelle soft-template systems. Thus this study provides a new route in selectively synthesizing low-dimensional nanomaterials in identical reverse micelle systems. It can also bring new vitality to this traditional facile synthesis method.

## Results and Discussion

### Results

The phase composition and phase structure of the samples were examined by X-ray powder diffraction (XRD). Because samples with different shapes all have the same composition, only the XRD pattern of the nanotubular products was given. The products were deposited on a glass base when characterized by XRD. As shown in Figure 1, all of the peaks can be perfectly indexed to a pure monoclinic phase (space group $C2/c$[15]) of $CaSO_4 \cdot 2H_2O$ with lattice constants (a) 6.286 Å, (b) 15.213 Å, and (c) 5.678 Å (JCPDS card No. 33–0311). No other impurities have been detected in the synthesized products. The broad peak between 10 and 30° ($2\theta$) is caused by the amorphous-phase glass base on which the product deposited.

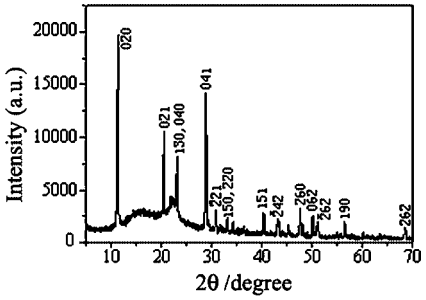

Figure 1. XRD curve of $CaSO_4 \cdot 2H_2O$ obtained in the reverse micelle system.

The morphologies of the synthesized products were examined by transmission electron microscopy (TEM). Figure 2 shows the typical TEM images of the sample prepared in $C_{12}E_9$ reverse micelles with different reaction times. $\omega_0$ of the reverse micelle was 8 when the concentration of $CaCl_2$ and $Na_2SO_4$ was 0.1 M. Tunable shapes of $CaSO_4$ nanocrystals can be readily produced at different reaction times.

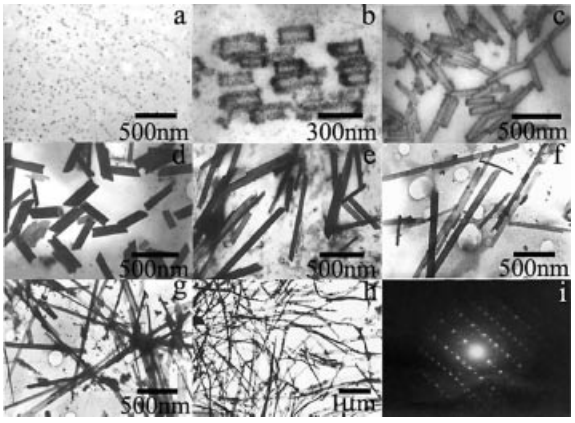

Figure 2. TEM and SAED images of $CaSO_4 \cdot 2H_2O$ at different aging times: (a) 1 min, (b) 3 min, (c) 5 min, (d) 40 min, (e) 3 h, (f) 12 h, (g) 36 h, (h) 108 h, (i) SAED image.

As shown in Figure 2 (a), the products are primarily nanoparticles with a diameter of about 15 nm when the reaction time is 1 min; there are some signals showing nanoparticles tending to form a one-dimensional morphology. This trend is realized when the reaction time extends to 3 min. Nanotubes with a diameter of about 50 nm and a length of nearly 200 nm are formed as shown in part b of Figure 2. From further observations it can be seen that the walls of the nanotubes are composed of nanoparticles, and that the walls become solid when the reaction time is 5 min. But there are few changes in the size of the nanotubes (see Figure 2, c). This process can be described as the assembly from nanoparticles to nanotubes and the increase in the firmness of the nanotubes. The simple method reported in this paper can produce inorganic salt nanotubes at room temperature, which provides a contribution to the research on nanotubes.

Interestingly, when the reaction time is prolonged to 40 min well-dispersed short rods are observed (Figure 2, d), and the growth of the rods keeps for tens of hours as revealed in parts d and g of Figure 2. With the extension of the reaction time both the length and the diameter increased and the increment in length was much larger than that in diameter. When the reaction time is long enough rods grow into wires and the lengths reach nearly 100 μm as shown in part h of Figure 2. The Selected Area Electron Diffraction (SAED) image (Figure 2, i) taken from a single nanotube shown in Figure 2 (c) exhibits single-crystalline diffraction dots that can be indexed to the monoclinic structure of $CaSO_4 \cdot 2H_2O$, which is in good agreement with the XRD result presented above.

The experimental results above demonstrate the possibility of synthesizing nanoparticles, nanotubes, nanorods, and nanowires under certain circumstances in reverse micelle systems. Furthermore, it is found that the reaction time has a significant effect on the morphologies and dimensions of the final products. The effect of the reaction time on the shape and size of the nanomaterials is shown in Figure 3. The size becomes larger with an increase in the reaction time, and the curve reveals that the increase in length is much bigger than that in diameter. Thus the aspect ratio is enhanced when the reaction time becomes longer. The size can vary from tens of nanometers to tens of microns.

By tracking the observed results, the growth process shows that nanoparticles assemble to nanotubes, nanorods, and then to nanowires in a step-by-step fashion as the reaction time increases. The aspect ratio increases along with the reaction time. In order to justify this deduction another two inorganic salts have been synthesized by the same method. The results are shown in Figure 4 and Figure 5. Firstly, Pb(OH)Cl was prepared in the same reverse micelle system ($C_{12}E_9$, *n*-pentanol, cyclohexane and $Pb^{2+}$, $Cl^-$ water solution) as $CaSO_4$. TEM pictures taken at different reaction times are shown in Figure 4. The results demonstrate that the deduced growth process is reasonable. Another experiment was carried out in a different reverse micelle system to justify the growth process. In this system, $C_{12}E_9$ was replaced by Triton X-100 and CdS nanoparticles, -tubes,

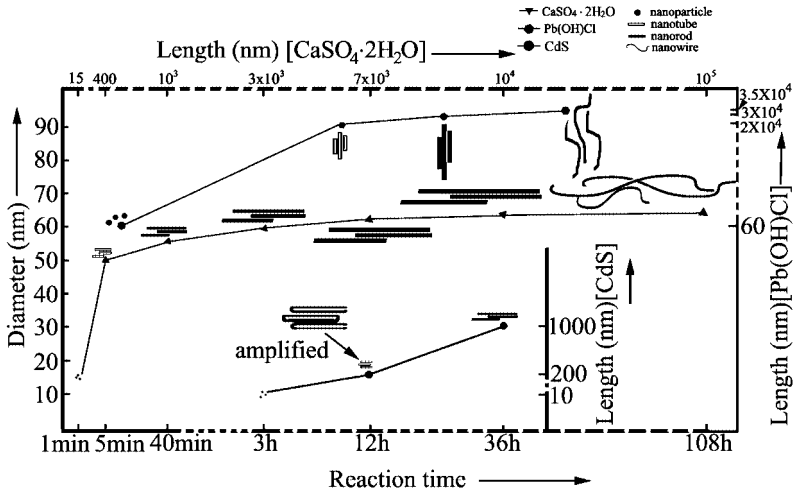

Figure 3. The effect of reaction time on the shape and size of nanomaterials obtained in the reverse micelle systems.

and -rods were prepared stepwise with reaction times becoming longer (as shown in Figure 5). It indicates that the deduction could be used to guide the stepwise-assembly formation in different reverse micelle systems.

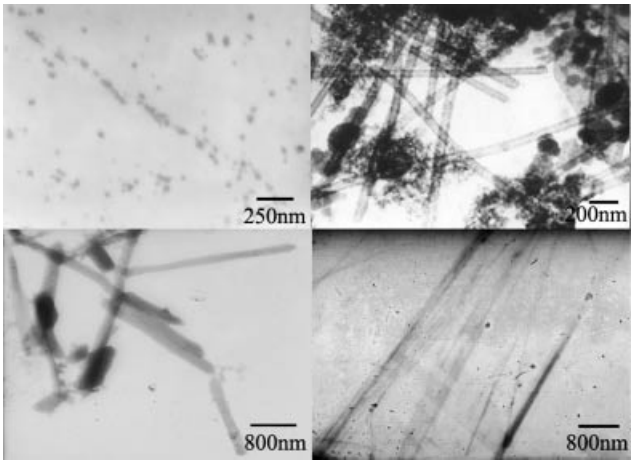

Figure 4. TEM images of as-obtained Pb(OH)Cl nanomaterials in the reverse micelles ($C_{12}E_9$ as surfactant) at different reaction times.

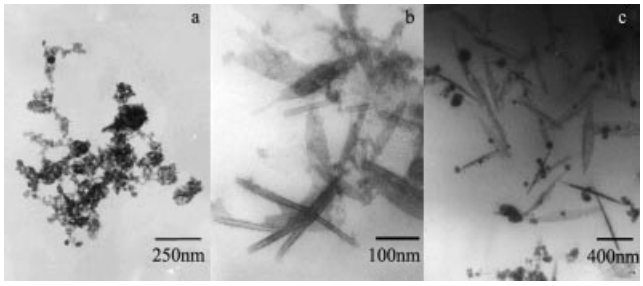

Figure 5. TEM images of CdS obtained in the reverse micelle systems (Triton X-100 as surfactant) at different reaction times: (a) 3 h, (b) 12 h, (c) 36 h.

Similar to the synthesis of CdS, ZnS, and $Ag_2S$ nanoparticles, nanotubes, and nanorods are also synthesized using sulfocarbamide as the sulfur source in the reverse micelle system (see Supporting Information). All results obtained above show that the stepwise-assembly synthesis has universality in preparing inorganic salts in reverse micelle systems. What is important is that ZnS and $Ag_2S$ nanotubes and nanorods synthesized by this method have never been reported before.

## Discussion

The mechanism of stepwise-assembly synthesis is discussed according to the results. The surfactant used in this system is AEO ($C_{12}E_9$), which is a long-chain molecule. It contains two indented hydrophobic and hydrophilic chains, which can easily form a one-dimensional template.[36] The products obtained in such reverse micelles are commonly one-dimensional materials. The mechanism diagram of the growth procedure is shown in Figure 6.

When two reverse micelle solutions are mixed only micelles containing two different reactants have effective collisions. These effectively collided reverse micelles then fuse and inorganic ions filter to form nucleation. These nuclei grow up to form nanoparticles with micelles attached to the surface. The nanotubes are then assembled in association and concurrent with the self-organization of stacked micellar aggregates (see Figure 7, Figure 2, a and b). It is clearly seen that incompact particles are assembling into wandering tubes, which indicates that nanoparticles are firstly formed and then assembled into tubes. Because these nanotubes are surfactant coated, micelles containing different ions can be absorbed onto the faces by the interaction between the hydrophobic tails of AEO.[37] When the micelles attach to the surface the surface tension is broken and the ions enter the nanotubes through the interstices of nanoparticles in the wall of the nanotube. Thus different ions react to form $CaSO_4$ nuclei inside nanotubes. These nuclei then grow bigger and the hollow tubes are filled. Lateral growth can still take place since the surfactant-$CaSO_4$ particles are not depleted.[38] The fact that the size of the nanotubes becomes larger in both length and width is evidence

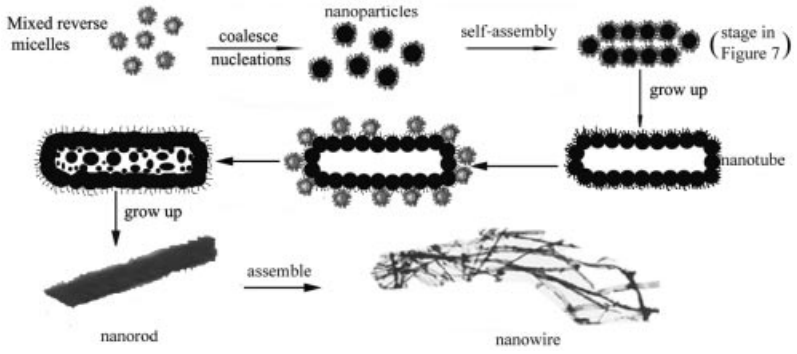

Figure 6. Formation mechanism diagram of stepwise-assembly synthesis.

for this process (Figure 2, b and c). After enough growth nanorods are obtained (Figure 2, d). These short rods coated with surfactant can also assemble into long nanowires with an extension of the aging time (Figure 2, e and f). Thus stepwise-assembly synthesis of nanoparticles, nanotubes, nanorods, and nanowires is successfully realized.

## Conclusions

In conclusion, a facile reverse micelle method for the stepwise preparation of $CaSO_4$ nanoparticles, -tubes, -rods, and -wires in one reverse micelle system is described. By controlling the reaction time in a certain reverse micelle system, $CaSO_4$ nanocrystals with tunable shapes and sizes are presented. The growth process in this system is deduced to be a stepwise-assembly-growth process. This deduction is demonstrated by several experimental results. This deduction can perceptibly make a contribution not only to the research on inorganic salt nanotubes, nanorods, and nanowires, but also to the application of reverse micelles or micoremulsions in fabricating one-dimensional nanomaterials. The products obtained in this work also have potential applications in many fields, such as nanoreactors and drug carriers.

## Experimental Section

**Reagents:** Anhydrous calcium chloride, sodium sulfate, *n*-pentanol, and cyclohexane used in this work were A.R. reagents purchased from Shanghai Chemical Reagent Factory, China. They were used without any pretreatment. $C_{12}E_9$ (AEO) [polyoxyethylene (9) dodecyl ether] was used as received from Henkel.

**Stepwise Synthesis of $CaSO_4$ Nanoparticles, Nanotubes, Nanorods, and Nanowires:** In a typical procedure a calculated amount of 0.1 M $CaCl_2$ solution was first placed in a conical flask, and then certain amounts of $C_{12}E_9$, *n*-pentanol, and cyclohexane were added in turn to form a reverse micelle when stirred vigorously. Another reverse micelle system was prepared through the same method except that the $CaCl_2$ solution was replaced by a 0.1 M $Na_2SO_4$ solution. The corresponding volume ratio of $Ca^{2+}/SO_4^{2-}$/AEO is 1:1:0.3. Thereafter, the above two reverse micelle solutions were mixed quickly. The mixture was stirred for a few minutes, and then a slightly viscous and optically transparent single-phase liquid was formed. This liquid was then aged for 1 min, 3 min, 5 min, 40 min, 3 h, 12 h, 36 h, and 108 h statically at 30 °C. The solid products were separated by centrifugation and repeatedly washed with anhydrous ethanol. These products were then kept in anhydrous ethanol for further characterization.

**Characterization of $CaSO_4$ Nanomaterials with Different Morphologies:** X-ray powder diffraction (XRD) analyses of the products were carried out with a Rigaku D/mx2550 X-ray diffractometer with Cu-$K_\alpha$ radiation ($\lambda$ = 1.5418 Å). Transmission electron microscopic (TEM) images were recorded using a Hitachi-800 transmission electron microscope. And the TEM images were obtained on thin films deposited on Cu gauze from a dilute ethanol solution of as-prepared products.

**Supporting Information** (see also the footnote on the first page of this article): Stepwise synthesis of ZnS and $Ag_2S$ nanoparticles, nanotubes and nanorods. Two figures with transmission electron microscopy images (ZnS at different reaction times and $Ag_2S$ after different aging times).

# Vibrational Spectrum and Electronic Structure of the $[B_{11}H_{11}]^{2-}$ Dianion

**Elena G. Kononova,[a] Larissa A. Leites,*[a] Sergey S. Bukalov,[a] Irina V. Pisareva,[a] Igor T. Chizhevsky,[a] John D. Kennedy,[b] and Jonathan Bould[b]**

**Keywords:** Boron / Cage compounds / Vibrational spectra / Electronic structure / Fluxionality

The vibrational spectrum, geometrical structure and electron-density distribution (EDD) of the formally *closo* (2*n*+2)-electron cluster species $[B_{11}H_{11}]^{2-}$ have been studied. The presence of two low-frequency vibrational modes is evidence of cluster nonrigidity. A rationale for this lies in the results of EDD calculations which show that the polyhedron lacks two-centre edge-localized B–B bonds of the 6**k**–5**k** type and that its surface exhibits two six-membered rings with low electron density. Thus, the polyhedron does not consist of deltahedral faces only and therefore does not have a genuine *closo* structure. The data obtained also allow further elucidation of the "diamond-square-diamond" mechanism as commonly applied to the fluxionality of $[B_{11}H_{11}]^{2-}$ in solution.

## Introduction

The eleven-vertex *closo* boranes and *closo* carbaboranes differ from their twelve-vertex and ten-vertex *closo* congeners in that (i) their cages contain a boron atom with the highest cluster connectivity of six, designated 6**k** in Williams' notation,[1] and in that (ii) they exhibit unusual NMR spectroscopic and chemical properties.[2–7]

Recently we studied the vibrational spectra of two representatives of the eleven-vertex *closo*-carbaborane family, namely the neutral molecule 2,3-$C_2B_9H_{11}$ (**1**) and the [2-$CB_{10}H_{11}]^-$ anion (**2**) (see Figure 1 for atom numbering), and showed that both species exhibited two low-frequency large-amplitude vibrational modes, at ca. 200 and ca. 300 $cm^{-1}$.[8,9] In this regard they contrast to all of the previously studied[10–12] unsubstituted twelve-, ten-, and six-vertex *closo*-boranes and *closo*-carbaboranes, which exhibit **no** normal modes with frequencies lower than 450 $cm^{-1}$. This lack of low-frequency modes is a consequence of the rigidity of the latter polyhedral cages. The cage rigidity, when present, permits the treatment of a *closo*-carbaboranyl moiety as a *pseudo*-atom, "Cb", and this model approach has worked well for the interpretation of the vibrational spectra of Cb–Cb and Cb–X molecules.[10,13,14]

By contrast, the presence of the low-frequency "soft modes" in the vibrational spectra of both **1** and **2** suggested cage nonrigidity, which, we surmised, was associated with the 6**k** feature. Based on the analysis of the published experimental and computed data on interboron distances in the structures of **1** and **2**, together with the results of the topological analysis of the electron-density distribution in both species, we thence concluded[8,9] that each of the polyhedra **1** and **2** does not actually have the deltahedral *closo* structure traditionally associated with them by the formal [2*n*+2] electron-count.[1,15]

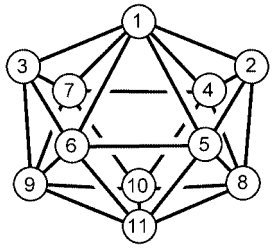

Figure 1. A traditional representation of the $\{B_{11}\}$ *closo* polyhedron depicting the atom numbering.

It was of interest similarly to investigate the other principal representative of the eleven-vertex *closo* polyhedral class, the $[B_{11}H_{11}]^{2-}$ boron cluster dianion (**3**), of which a well-known and interesting characteristic is its very simple, averaged $^{11}B$ NMR spectrum in solution, which was first reported by Tolpin and Lipscomb in 1973,[2] and which arises from a fluxionality due to a rapid polyhedral rearrangement.[2,6]

In this paper we present the Raman and IR spectra of **3** as its di-$K^+$ and di-$Cs^+$ salts and the Raman data on an aqueous solution of the di-$Cs^+$ salt. These vibrational spectra of **3** are previously unreported. Quantum-chemical DFT B3LYP calculations of the geometry of the undistorted dianion **3** and its vibrational mode frequencies and eigenvec-

tors are also reported, and the electron density distribution (EDD) in **3** has been reconstructed using Bader's theory of "atoms in molecules" (AIM),[16] based on the optimized structure arising from DFT calculations. The results are related to the mechanism of the fluxionality of the anion.

## Results and Discussion

### Synthesis

A sample of $K_2[B_{11}H_{11}]$ (**3a**) was synthesized essentially according to a literature method.[6] The cation exchange reaction, substituting $Cs^+$ for $K^+$, between **3a** and a solution in methanol of CsCl, did not lead to $Cs_2[B_{11}H_{11}]$ (**3b**) but to a mixed salt of which the elemental analysis was consistent with the formulation $Cs_2[B_{11}H_{11}]$·CsCl (**3c**). Here it may be noted that an analogous double salt has been obtained for the $[B_{12}H_{12}]^{2-}$ dianion.[17] Subsequent attempts to prepare the simple di-$Cs^+$ salt of **3** using CsCl were made by variation of the concentrations of the reagents and by changing the order of reagent addition, but, in both cases, only the mixed salt **3c** with a 1:1 $Cs_2[B_{11}H_{11}]$: CsCl ratio was obtained. Use of CsF, however, did yield $Cs_2[B_{11}H_{11}]$ (**3b**). The Raman spectra of both $Cs^+$ salts **3b** and **3c** were almost identical, as were the IR spectra; the presence of $Cl^-$ anions in **3c** resulted only in small shifts of several bands in the spectrum of solid **3c** (Table 1).

### Vibrational Spectra and Electronic Structure

The undistorted dianion $[B_{11}H_{11}]^{2-}$ belongs to the $C_{2v}$ symmetry point group; its 60 normal modes are distributed among the symmetry species as follows:

$\Gamma = 19\ A_1 + 11\ A_2 + 16\ B_1 + 14\ B_2$

The vibrations of the $A_1$, $B_1$ and $B_2$ species are both IR-active and Raman-active, whereas the $A_2$ ones are only Raman-active. The spectra obtained are given in Figure 2 and Table 1. The latter also presents the calculated, unscaled harmonic frequencies and IR intensities of some normal modes, along with band assignment. The assignment was based on the Raman and IR activities, depolarization ratios of the Raman lines and on the results of normal-coordinate analysis. Previously, the low-resolution IR spectrum of the Nujol mull of the di-$Cs^+$ salt has been presented as a picture in ref.[18], where its Raman spectrum was also mentioned, but no particularly specific data were reported.

As is seen from Figure 2 and Table 1, the number of spectral features is much less than the theoretical value of 60. This observation can be rationalized in terms of the results of the normal-coordinate analysis, which shows that the frequencies of some normal modes, having close displacement eigenvectors but belonging to different symmetry species, nearly coincide (Table 1). An analogous situation was also observed for the spectra of both **1** and **2**.[8,9] It is of interest that the calculation for **3** reproduces the frequencies of ν(BH) stretching vibrations quite well without any scaling, unlike in the cases of the carbaboranes **1** and **2**, for which the computed ν(BH) frequencies were highly overvalued.

The vibrational spectrum of **3** is as specific as those of **1** and **2** in that it also exhibits two low-frequency modes at about 200 and 300 $cm^{-1}$. The exact frequency values of these modes depend slightly on the nature of the cation. The normal-coordinate analysis for the free anion **3** reproduces these low-frequency modes, but with somewhat lowered frequencies compared to the experimental values, as if they are now free from cation influences. Notably, by contrast, in the spectra of the two rigid-cage species $[B_{12}H_{12}]^{2-}$ and $[B_{10}H_{10}]^{2-}$ there are no frequencies lower than 588 $cm^{-1}$ [19] and 515 $cm^{-1}$,[20] respectively. However, all the rest of the salient spectral features, for example the ν(BH) frequencies or the cage breathing modes, are very much alike for all three borane dianions $[B_nH_n]^{2-}$, where $n$ is 12, 11 and 10.[10] There are two totally symmetric cage vibrations in the spectra of all of the salts of **3**, to which very intense Raman lines at ca. 725 $cm^{-1}$ and ca. 750 $cm^{-1}$ correspond.

The incidence of low frequencies in the spectrum of **3**, as for those of **1** and **2**, is explained by the nonrigidity of the cage that is caused by the peculiarities of geometrical and electronic structure of the eleven-vertex polyhedron. To the best of our knowledge, three molecular structures, as determined by X-ray crystallography, are available for salts containing $\{B_{11}\}$ cluster anions. These are for $A_2[B_{11}H_{11}]$, where A is $[Li(thp)_3]$ (**4**) or $[NBzlEt_3]$ (**5**),[6b] and for $[NEt_4][4\text{-}(SMe_2)B_{11}H_{10}]$ (**6**).[21] Short interionic contacts in the crystal structure of **4** strongly distort the symmetry of the anion from regular $C_{2v}$. However, the less interactive ammonium cations in **5** and **6** leave the geometry of the anion closer to the idealized one. Dimensions derived by X-

[a] The corresponding B–B interatomic distances in **5** and **6** are crystallographically non-equivalent as well as being subject to differing cation and substituent influences.

ray crystallography for **5** and **6**,[6b,21] as well as the results of geometry optimization for the undistorted **3**, both as reported previously[6a,22,23] and as obtained in this study, are given in Table 2. Both the experimental data and the computed data show that the interatomic distances between the B(1) and the B(4), B(5), B(6) and B(7) boron atoms, that average at 2.02 Å, are anomalously long for B–B bonds in *closo*-boranes, which typically vary from 1.58 to 1.99 Å.[22] Analogously long 6**k**–5**k** distances are similarly observed for **1** and **2**.[8,9] It is pertinent to mention here that Wade estimated the 6**k**–5**k** type of B–B interatomic distance to be 1.95 Å on the basis of fractional bond order.[15b] Long interboron connectivities have been recognized in some "disobedient" *closo* clusters to be typical for "fragile" structures.[24]

Explanation for these peculiar properties of the eleven-vertex *closo* polyhedra can be attempted by means of a topological analysis of the electron-density function according to Bader's "atoms in molecules" (AIM) approach.[16] This method has proven to be a useful and successful tool in understanding several other electron-deficient borane and carbaborane structures.[25,26] The results of such calculations for the $[B_{11}H_{11}]^{2-}$ anion **3** are given in Table 2. The corresponding molecular graph is presented in Figure 3, where the bond critical points are indicated and denoted by small circles.

The electron density values $\rho_b(\mathbf{r})$ for the (3,–1) critical points [i.e. bond critical points (BCPs)] of the BH and BB two-centre bonds lie in the intervals 0.166–0.162 and 0.142–0.108 a.u., respectively. These values are close to those obtained for the $[B_{12}H_{12}]^{2-}$ dianion.[25a] The electron-density values $\rho_r(\mathbf{r})$ for the (3,+1) critical points [i.e. ring critical points (RCPs)] that characterize the three-membered rings are as follows: for the eqivalent B(3,9,6) = B(3,9,7) = B(2,5,8) = B(2,4,8) faces: 0.116 a.u., for the equivalent B(6,9,11) = B(5,8,11) = B(4,8,10) = B(7,9,10) faces: 0.109 a.u., for the equivalent B(9,10,11) = B(8,10,11) faces: 0.105 a.u.

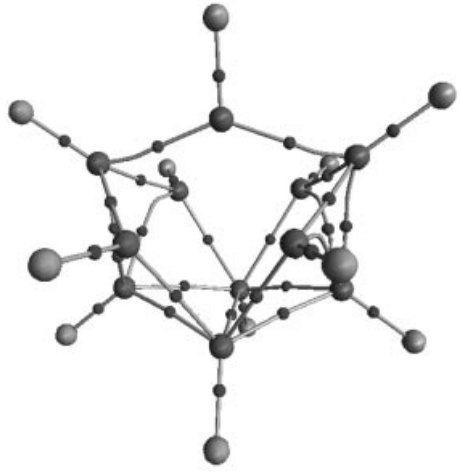

Figure 3. Molecular graph of the $[B_{11}H_{11}]^{2-}$ dianion **3** obtained as a result of the AIM topological analysis of electron-density distribution.

It is evident from these data that the $\rho_r(\mathbf{r})$ values for the above-mentioned three-membered rings in the structure of **3** are of comparable magnitude to those of $\rho_b(\mathbf{r})$ for the pairwise B–B interactions (Table 2). This is typical for boron polyhedra[25,26] and shows that the three-centre bonding plays almost the same role as the two-centre bonding; in other words, stabilization of the cage is attained both by the accumulation of electron density along the edge-localized bond paths and by its delocalization over the triangular polyhedral faces. There is a (3,+3) critical point in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the cage interior: this is consistent with the essentially closed volume of **3**. The electron density value $\rho_c(\mathbf{r})$ in the centre of the cage **3** is low, at 0.0196 a.u., close to those[8,9] of the other eleven-vertex cages, for **1** at 0.0211 a. u. and for **2** at 0.0195 a.u.

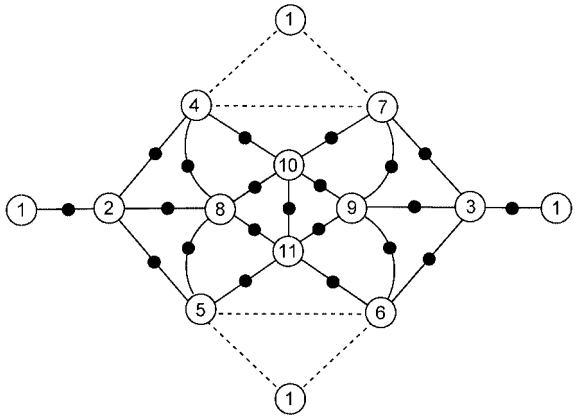
However, the results also show that there are no (3,–1) BCPs between members of each of the following pairs of boron atoms: B(1)–B(4), B(1)–B(5), B(1)–B(6) and B(1)–B(7); that is, there are no edge-localized two-centre 6**k**–5**k** bonds in the bonding network of **3**. This obviously leads to the longer interatomic distances from the B(1) atom to B(4), B(5), B(6) and B(7). Also, however, no BCPs were found between the B(5) and B(6) atoms, or between the B(4) and B(7) atoms, for which the interboron distances, which average at 1.86 Å, are significantly shorter than the 1.99 Å upper limit mentioned above, although elongated compared to the typical expected value of 1.79 Å[15b] for a 5**k**–5**k** cluster interboron linkage. The reason for this is not clear yet; the atoms in each of the B(4)–B(7) and B(5)–B(6) pairs would seem to be drawn together by the whole delocalized bonding system of the cage **3**. An analogous situation occurs for the *closo*-1,5-$C_2B_3H_5$ molecule, for which the AIM treatment, both theoretical[25a] and experimental,[26b] reveals no B–B bond paths, although the corresponding experimental B–B interatomic distances are also of closely similar magnitude, at 1.853 Å.

Thus, according to the analysis of the topology of electron density with AIM, six of the 27 edges of the octadecahedron of **3**, specifically B(1)–B(4), B(1)–B(5), B(1)–B(6) and B(1)–B(7), together with B(5)–B(6) and B(4)–B(7), do not correspond to two-centre bond paths. The absence of these leads to the presence in the structure of **3** of two equivalent six-membered rings encompassing the B(1,2,5,11,6,3) and B(1,2,4,10,7,3) atoms. These rings are characterized by two (3,+1) RCPs with low values for the electron density $\rho_r(\mathbf{r})$ of 0.070 a.u. The $\rho_r(\mathbf{r})$ values for the RCPs of the three-membered rings are much higher (see above), all being greater than 0.105 a.u. Thus in the structure of **3**, multicentre bonding in the six-membered rings is significantly weakened. These rings can therefore be regarded to some extent as "open faces", although it is pertinent to mention here that, according to our computations, the $\rho_r(\mathbf{r})$ value for a conventionally recognized five-membered open face, as in the *nido*-dicarbaborane anion [7,8-$C_2B_9H_{12}]^-$, is much lower, at 0.020 a.u.

The weaker bonding interaction between the B(1) and the B(4), B(5), B(6) and B(7) atoms (compared to those between other pairs of boron atoms) inevitably gives a freer mobility to these atoms, and thus accounts for the low frequencies and large amplitudes of the corresponding vibrational "soft modes" that involve this set of boron atoms. The normal-coordinate analysis shows that the mode at ca. 200 $cm^{-1}$ is of the $A_2$ type and involves mainly displacements of equivalent B(4), B(5), B(6) and B(7) atoms. During this vibration, atoms B(4) and B(6) are approaching B(1) whereas atoms B(5) and B(7) are moving away from it. The mode at ca. 300 $cm^{-1}$ of the $B_2$ type is a wagging of the 6**k** B(1) atom in the B(2)B(1)B(3) "handle" back and forth in the symmetry plane defined by the B(1), B(10) and B(11) atoms.

Hence, all the data presented here and in the previous papers on 2,3-$C_2B_9H_{11}$ (**1**) and $[2\text{-}CB_{10}H_{11}]^-$ (**2**)[8,9] suggest that the formally closed eleven-vertex polyhedra **1**, **2** and **3** are **not formed by triangular faces only**, and therefore do not have genuine *closo* structures, in spite of having (2*n*+2) skeletal bonding electrons. It is obvious that they can be regarded as belonging to a category of "disobedient skeletons".[24]

It is of interest to attempt to reconcile the molecular graph that emerges from Bader's AIM approach with a more familiar Lipscomb-type "semi-localised" bonding diagram, which is based on two-electron two-centre and two-electron three-centre bonds. A schematic as in **I** (Scheme 1) below may be sketched as a representation of the bond paths and bond critical points of the molecular graph presented in Figure 3. In this diagram the hatched lines from B(1) to the B(4), B(7), B(5) and B(6) atoms, as well as from the B(4) to B(7) and from the B(5) to B(6) atoms, correspond to the "missing" two-centre bond paths and point to the thinning of the bonding "electronic glue" layer in these regions of the cage surface.



Scheme 1.

This schematic **I** can be supplemented by a schematic **II** (Scheme 2) to approximately reflect the rings and ring critical points of the molecular graph.

A corresponding classical Lipscomb-type semi-localized diagram, which seems to be a reasonable approximation of the electron density in terms of a factorization into localised two-electron bonding units, may be sketched as in schematic **III** (Scheme 3): this accommodates the 2*n*+2 cluster electrons required for a formal *closo* cluster-electron count if the dotted lines among the B(1), B(4), B(7), B(5) and B(6) atoms are taken to account for an overall total two-electron bonding interaction between B(1) and the B(4)B(7)B(5) B(6)B(10)B(11) region of the molecule.

The bonding representations involving the hatched lines, between B(2), B(4) and B(8), and also at the other three equivalent sites, B(2)B(5)B(8), B(3)B(6)B(9), and B(3)B(7) B(9), represent Lipscomb's semi-localised "partial-three-

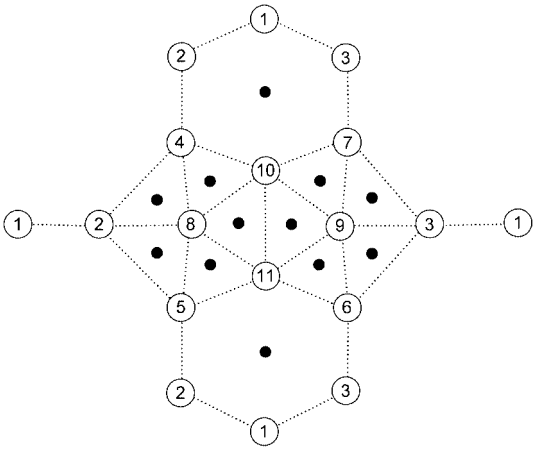
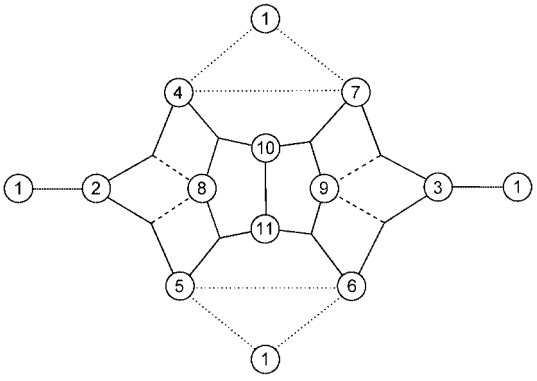


Scheme 2.



Scheme 3.

centre bonds". Which of these two approaches to a description of the bonding is adopted is a matter of taste and habit.

The data obtained also shed new light on the long-recognized phenomenon of the very facile fluxionality of anion **3**, which mutually "scrambles" all the cluster vertices. A Lipscomb diamond-square-diamond (*dsd*) mechanism is reasonably established for the dynamic framework rearrangements in the 11-vertex *closo* polyhedra.[3a,6] Repeated *dsd* processes, involving the B(1)B(2)B(5)B(6) quadrangle or one of the three other equivalent units, lead to the time-average equivalence of all the boron atoms in **3** in the $^{11}$B NMR spectrum in solution.[2,3,6] On the presumption that each of the quadrangles consists of two deltahedral faces, the *dsd* mechanism requires that, in its initiating diamond-to-square stage, a 6**k**–5**k** linkage [e.g. B(1)–B(5)] be broken, thus generating a square face, and then the nearest boron atoms undergo a slight rotation, and in the final square-to-diamond stage a new interboron linkage is formed, between B(2) and B(6). The B(6) atom thereby becomes a 6**k** vertex [instead of B(1)], and by repetition of this process, the 6**k** and all the 5**k** and 4**k** positions move over the whole polyhedron. However, the present results suggest that 6**k**–5**k** two-centre edge-localized bonds from B(1) to the B(4), B(5), B(6) and B(7) atoms are in fact absent, and, further, that multicentre bonding between B(1) and the B(4)B(5)B(6)B(7) quartet is weak. This bonding perception, together with the vibrational analysis, indicates that the process for the permutation of the 6**k** position can be regarded as being initiated simply via large-amplitude vibrations entailing the B(1) and the B(4), B(5), B(6), and B(7) atoms. Hence there is no need for a "*deus ex machina*" initially to "break" a (non-existent) 6**k**–5**k** linkage in the process of this cluster rearrangement.

These factors imply a very low activation energy for this process. Indeed, Paetzold and co-workers have calculated this value as 9.1 kJ mol$^{-1}$.[6] Incidental to this present work we have also obtained a similarly low calculated activation energy. This low value is clearly in accord with the experimental finding that fluxionality cannot be slowed sufficiently for individual resonances to be observed in the solution-state $^{11}$B NMR spectrum down to 200 K,[2] which implies an experimental activation energy upper limit of ca. 30 kJ·mol$^{-1}$. The low activation energy adds further to the perception that distortions away from the $C_{2v}$ ideal should be frequently observable in solid-state structures, since asymmetric crystal packing forces of even a few kJ mol$^{-1}$ will easily force distortions along the *dsd* rearrangement coordinate. This last phenomenon is manifested, for example, in the crystallographically determined square-open-faced structure of the interesting fluxional eleven-vertex formally *closo* $[B_{11}H_9(Se_3)]^{2-}$ anion.[27]

## Conclusions

Two low-frequency large-amplitude modes (at ca. 200 cm$^{-1}$ and ca. 300 cm$^{-1}$) in the vibrational spectra of the salts of the $[B_{11}H_{11}]^{2-}$ anion **3** have been found, and these are shown by normal coordinate analysis to involve the 6**k** B(1) and the neighbouring 5**k** B(4), B(5), B(6) and B(7) atoms. A critical review of the published experimental and computed data on the geometry of $[B_{11}H_{11}]^{2-}$ species reveals that the interboron distances between the 6**k** and the 5**k** atoms are greater than the generally accepted interboron bonding limit of 2.0 Å. Calculations of the electron-density distribution in **3**, performed according to Bader's approach and grounded on DFT results, show that there are no two-centre bond paths between the 6**k** B(1) and 5**k** B(4), B(5), B(6), and B(7) atoms; nor are there any between the members of each of the B(4)–B(7) and B(5)–B(6) pairs. Hence the cage of the $[B_{11}H_{11}]^{2-}$ anion **3** contains two six-membered rings with low electron density. These consistent data lead to the conclusion that the eleven-vertex polyhedron of $[B_{11}H_{11}]^{2-}$, although possessing $2n+2$ skeletal bonding electrons, is not in fact a pure deltahedron and not a straightforward *closo* cluster. A similar conclusion was made previously for the two corresponding eleven-vertex carbaboranes: the neutral 2,3-$C_2B_9H_{11}$ molecule **1** and the [2-$CB_{10}H_{11}]^-$ monoanion **2**.[8,9] The terminology "*quasi-closo*-polyhedron" has been suggested as a nomenclature to be associated with this interesting phenomenon.[9] Molecules **1**, **2** and **3** can therefore be placed in a category of "disobe-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dient skeletons".[24] The data obtained also allow a refinement of the interpretation of the "diamond-square-diamond" mechanism as commonly applied to the fluxionality of anion **3** in solution.

Overall the results well illustrate the important general point that an allegedly triangulated deltahedron does not necessarily merit such a description when the actual bonding is considered in appropriate detail. More generally, it is important to recognise that the bonding within any cluster may often be much less uniform than a simple consideration of the polyhedral shape of the cluster may be taken to imply.

## Experimental Section

**Preparation of $Cs_2[B_{11}H_{11}]\cdot CsCl$ (3c). Procedure A:** A filtered solution of $K_2[B_{11}H_{11}]$ (0.083 g, 0.4 mmol; prepared essentially as in ref.[6]) in absolute MeOH (2 mL) was added in drops to a stirred solution of CsCl (0.2 g, 1.2 mmol) in the same solvent (5 mL). After 10 min of vigorous stirring, the mother liquid was removed with a pipette from the white precipitate formed. The residue was washed with MeOH (2 × 3 mL) and thoroughly dried in vacuo, affording the mixed salt $Cs_2[B_{11}H_{11}]\cdot CsCl$ (**3c**) (0.15 g, 68%). $B_{11}H_{11}ClCs_3$ (564.20): calcd. B 21.06, H 1.95, Cl 6.29, Cs 70.69; found: B 21.02, H 2.08, Cl 5.76, Cs 70.27.

**Procedure B:** Analogous to procedure A, but with an inverse order of reagent addition, the same mixed salt $Cs_2[B_{11}H_{11}]\cdot CsCl$ (**3c**) was obtained in 56% yield. $B_{11}H_{11}ClCs_3$ (564.20) calcd. B 21.06, H 1.95, Cl 6.29, Cs 70.69; found: B 21.55, H 2.04, Cl 5.65, Cs 69.21.

**Preparation of $Cs_2[B_{11}H_{11}]$ (3b):** The salt $Cs_2[B_{11}H_{11}]$ was obtained in the same manner, but using CsF in EtOH instead of CsCl in MeOH.

**Vibrational Spectra:** Raman spectra for the solid salts sealed in capillaries, and also for a saturated aqueous solution of the salt **3c**, were recorded in the region 30–3500 $cm^{-1}$ using LabRAM and U-1000 Jobin–Yvon laser Raman spectrometers. The spectra were excited by the 632.8 nm line of a He-Ne laser and the 514.5 nm line of an $Ar^+$ laser (Spectra Physics 2020). Depolarization ratios of the Raman lines in the spectrum of the aqueous solution of **3c** were estimated qualitatively. IR spectra in the region 150–3500 $cm^{-1}$ for the salts **3b** and **3c** pressed with polyethylene, and for their Nujol mulls and KBr pellets, were obtained using a M-82 Carl Zeiss spectrophotometer and a Nicolet Magna-750 FTIR spectrometer.

**Computational Details:** Geometry optimization and calculations of the vibrational-mode frequencies and eigenvectors for the isolated anion **3** were carried out at the DFT B3LYP/6-31++G(d,p) level, using the G94W program suite.[28] Topological analysis of the theoretical electron-density distribution (based on the results of the DFT calculation) was accomplished using the AIMpac program package.[29] Calculations for the rearrangement process were carried out at the B3LYP/6-31G* level using the Gaussian 98 and Gaussian 03 packages,[30,31] and gave a value of 9.3 kJ $mol^{-1}$, comparable to the result of 9.1 kJ $mol^{-1}$ reported from a higher-level B3LYP/6-31++G(d,p) calculation.[6]

# Syntheses, Characterizations, and X-ray Single-Crystal Structures of 1,8-Bis(trimethylsilylamino)naphthalene Aluminum Hydride and the Methyl Derivative

**Zhi Yang,[a] Xiaoli Ma,[a] Herbert W. Roesky,*[a] Ying Yang,[b] Víctor Manuel Jiménez-Pérez,[a] Jörg Magull,[a] Arne Ringe,[a] and Peter G. Jones[c]**

*Dedicated to Professor K. Mach*

**Keywords:** Aluminum / Arene ligands / Structure elucidation

The reaction of 1,8-bis(trimethylsilylamino)naphthalene ($LH_2$) (**1**) with *n*BuLi yields the dilithium compound [1,8-$(Me_3SiN)_2C_{10}H_6$]$(Li)_2(thf)_3$ (**2**). Compound **1** reacts with $H_3Al{\cdot}NMe_3$ with elimination of hydrogen gas to produce [1,8-$(Me_3SiN)_2C_{10}H_6$]$AlH(NMe_3)$ (**3**), and the reaction of **2** with $MeAlCl_2$ leads to [1,8-$(Me_3SiN)_2C_{10}H_6$]Al(Me)thf (**4**). Compounds **3** and **4** are the first two aluminum mononuclear compounds to contain the 1,8-diaminonaphthalene ligand. These compounds were characterized by elemental analysis, NMR and IR spectroscopy, MS, and single-crystal X-ray structural analysis.

## Introduction

Aluminum hydrides and their alkyl derivatives are involved in many aluminum-containing reactions, and thus are extraordinarily important in aluminum chemistry. Aluminum hydrides are good reducing agents and are used in a wide range of inorganic and organic transformations.[1] In addition, they are excellent precursors in the synthesis of alumoxanes by controlled hydrolysis,[2] and they can be used in the preparation of carbaalane clusters in conjunction with acetylenes or substituted acetylenes[3,4] and for the generation of amidoalane clusters from organic nitriles.[5] Recent research in our group showed that they can be used as very efficient starting materials in the preparation of aluminum chalcogenides[6–10] and also in the preparation of aluminum-containing heterocycles[11] by the elimination of $H_2$ gas. Alkylaluminum compounds are important cocatalysts used in polymerization reactions for the production of polypropylene, medium-to-low pressure polyethylene, and polybutadiene. They can also be converted into aluminum halides or oxides. A series of aluminum oxides and hydroxides was synthesized by the hydrolysis of alkylaluminum compounds,[12] and a very important product is methylaluminum oxide (MAO). MAO is a highly active cocatalyst for group 4 metallocenes and catalyzes ethylene and propylene polymerization.[13,14]

A bulky organic ligand is usually employed to stabilize the aluminum center both electronically and sterically. The introduction of a bulky organic ligand at the Al center can efficiently reduce the condensation of the resulting products. In recent years, a number of aluminum compounds with monovalent bulky chelating ligands have been reported, although there are not many aluminum compounds known that are supported by bivalent bulky ligands. In 1998, a series of new bivalent bulky 1,8-diaminonaphthalene ligands was synthesized.[15–19] The interest in these ligands is currently growing as a result of their specific steric and electronic properties, and these properties can efficiently control the geometry at the metal center. The known complexes containing these ligands, or naphthalene-based substrates, include main group (Al, Ge, In, Li, Na, Mg, Si, Sn, Tl) and transition-metal (Ni, Ti, Zr, Zn) derivatives.[16,20–27] Previously, aluminum mononuclear complexes were unknown, but herein we report the synthesis and characterization of bulky 1,8-bis(trimethylsilylamino)naphthalene (L) aluminum monohydride and its aluminum monomethyl derivative.

## Results and Discussion

The reaction of 1,8-bis(trimethylsilylamino)naphthalene ($LH_2$) (**1**) with *n*BuLi leads to the starting material [1,8-

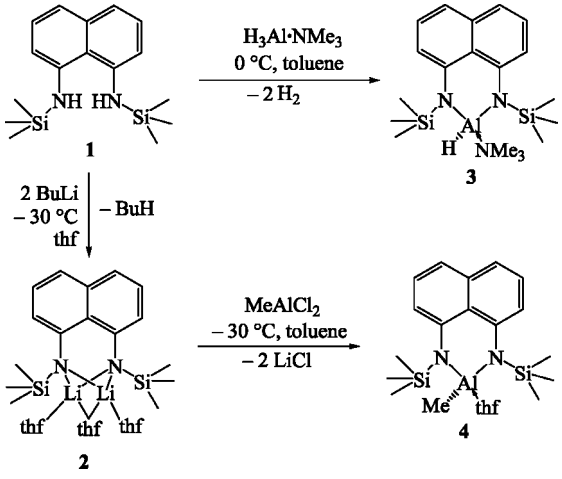
$(Me_3SiN)_2C_{10}H_6](Li)_2(thf)_3$ (**2**). Synthesis of [1,8-$(Me_3SiN)_2$-$C_{10}H_6$]AlH($NMe_3$) (**3**) was accomplished by the reaction of $LH_2$ (**1**) with $H_3Al{\cdot}NMe_3$ at 0 °C in high yield. The compound [1,8-$(Me_3SiN)_2C_{10}H_6$]Al(Me)thf (**4**) was prepared from the reaction of **2** in situ with $MeAlCl_2$ at –30 °C. Compounds **3** and **4** (Scheme 1) are both mononuclear aluminum compounds containing the 1,8-diaminonaphthalene ligand (L). Only one aluminum compound of the form $L(AlMe_2)_2$ is known to contain the 1,8-diaminonaphthalene ligand,[25] and it is a binuclear compound synthesized by the reaction of $LH_2$ (**1**) with $AlMe_3$. We found, whether in a ratio of 1:1 or 1:2, the reaction of compound **1** with $AlMe_3$ always leads to $L(AlMe_2)_2$. Mononuclear LAlMe compounds are unknown. This is explained by the fact that after the formation of the $LH(AlMe_2)$ intermediate, the second Me group at the same Al center is not reactive enough to interact with the other proton of the ligand to eliminate another molecule of methane. In the reaction of **1** with $H_3Al{\cdot}NMe_3$, only mononuclear LAlH($NMe_3$) (**3**) was obtained independently whether the reaction was conducted in the ratio of 1:1 or 1:2. This is due to the reactivity of the second hydride at the same Al center, which is high enough to interact with the other proton of the ligand to result in the elimination of $H_2$ gas. Consequently, the question as to whether it is possible to prepare the mononuclear methylaluminum compound of the general form LAlMe is raised. To prepare LAlMe, we used $LLi_2(thf)_3$ (**2**) and $MeAlCl_2$ as the starting materials. This reaction involved the elimination of two molecules of LiCl, and we successfully prepared the mononuclear methylaluminum compound LAl(Me)thf (**4**). The lithium salt **2** was prepared in situ at –30 °C, and the reaction with $MeAlCl_2$ was conducted also at –30 °C. Compounds **3** and **4** are soluble in common solvents such as toluene, dichloromethane, and tetrahydrofuran, and they can be kept in the glove box for several months without decomposition.



Scheme 1. Preparation of compounds **3** and **4**.

Compounds **3** and **4** were characterized by multinuclear NMR and IR (for **3**) spectroscopy, MS (EI), and elemental analysis. The presence of an Al–H bond in **3** is evident from the analysis of the IR spectrum. The broad IR band around 1869 $cm^{-1}$ was assigned to the Al–H stretching frequency, which compares well with the known value of 1860 $cm^{-1}$.[28] In the $^1H$ NMR spectra of compounds **3** and **4**, resonances in the ranges from $\delta$ = 6.6 to 7.2 ppm and $\delta$ = 0.3 to 0.1 ppm in the ratio of 6:18 are present, which were assigned to the $C_{10}H_6$ and $SiMe_3$ groups, respectively. They confirm the existence of the backbone of the 1,8-bis(trimethylsilylamino)naphthalene ligand. In the $^1H$ NMR spectrum of **3**, the resonance at $\delta$ = 2.66 ppm suggests the existence of the $NMe_3$ group. In the $^1H$ NMR spectrum of **4**, the resonances at $\delta$ = 3.79 and 1.57 ppm in a ratio of 1:1 were assigned to the thf molecule coordinated to the aluminum center, and the resonance at $\delta$ = –0.55 ppm indicates the existence of the Al–Me bond in the molecule. The $^{13}C$ NMR spectra of **3** and **4** for the arene part exhibit almost the same resonances for both compounds.

Compounds **3** (Figure 1) and **4** (Figure 2) crystallize in the orthorhombic system *Ama*2 and in the monoclinic system $P2_1/n$, respectively. In both structures, the aluminum centers have a tetrahedral environment. The tetrahedral aluminum center in **3** indicates the existence of an H atom. Compounds **3** and **4** have almost the same Al–N bond lengths (av. 1.828 Å for **3** and 1.830 Å for **4**), whereas the Al–N bonds in the binuclear compound $L(AlMe)_2$ are much longer (av. 2.00 Å). The Al centers in $L(AlMe_2)_2$ are much more crowded than those in mononuclear **3** and **4**.[25] Thus, the two Al centers in $L(AlMe_2)_2$ are in close proximity, which results in the longer bond lengths of the Al–N bonds in $L(AlMe_2)_2$ in comparison to those in **3** and **4**. In the binuclear structure of $L(AlMe_2)_2$, it is obvious that the two Me groups at the same aluminum atom have different chemical environments. One Me group is near the naphthalene ligand and the other Me group is positioned away from the arene ring ($\delta$ = –0.11 and –1.14 ppm).[25] There is only one Me group at the aluminum atom in mononuclear **4**, which results in only one chemical shift. The Al→N2 bond

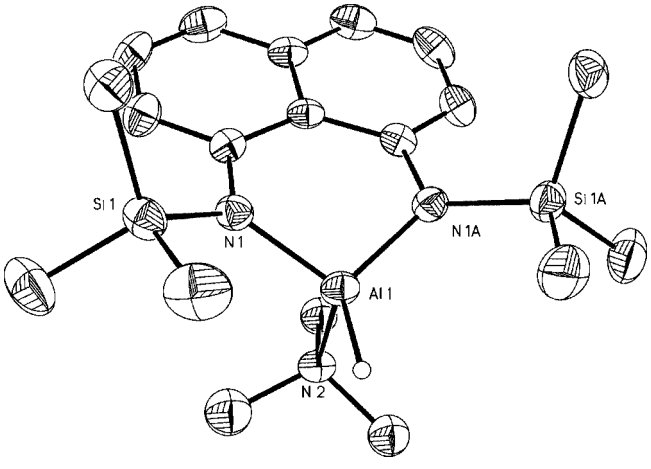


Figure 1. Molecular structure of **3**. Thermal ellipsoids are drawn at the 50% probability level and the hydrogen atoms are omitted for clarity, while the hydrogen atom on the aluminum atom was set. Selected bond lengths [Å] and angles [°]: Al1–N1 1.828(2), Al1–N1A 1.828(2), Al1–N2 2.021(3), N1–Si1 1.744(2); N1–Al1–N1A 102.95(13), N1–Al1–N2 106.85(8), N1A–Al1–N2 106.86(8).

length (2.021 Å) in **3** and the Al→O bond length (1.920 Å) in **4** are longer than the normal σ bonds of compounds containing Al–N and Al–O moieties.

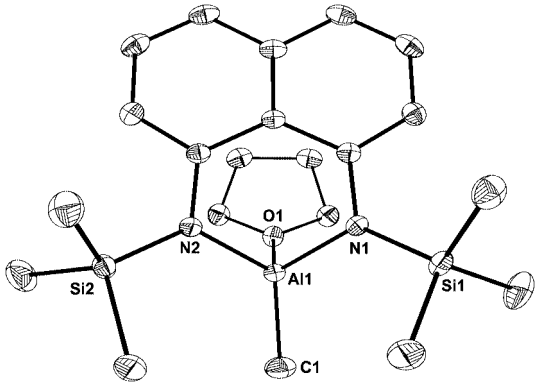

Figure 2. Molecular structure of **4**. Thermal ellipsoids are drawn at the 50% probability level and the hydrogen atoms are omitted for clarity. Selected bond lengths [Å] and angles [°]: Al1–N1 1.8298(13), Al1–N2 1.8311(12), Al1–O1 1.9202(11), Al1–C1 1.9482(16); N1–Al1–N2 100.82(6), N1–Al1–O1 101.88(5), N2–Al1–O1 100.33(5), N1–Al1–C1 121.37(7), N2–Al1–C1 125.87(7), O1–Al1–C1 102.09(7).

## Conclusions

Herein, we described the syntheses, characterizations, and X-ray structures of aluminum hydride and methyl compounds supported by the 1,8-bis(trimethylsilylamino)naphthalene ligand. The resulting compounds are interesting precursors for the preparation of new aluminum compounds.

## Experimental Section

**[1,8-(Me$_3$SiN)$_2$C$_{10}$H$_6$]AlH(NMe$_3$) (3):** To a solution of [1,8-(Me$_3$SiNH)$_2$C$_{10}$H$_6$] (3.02 g, 10 mmol) in toluene (40 mL) at 0 °C was added dropwise H$_3$Al·NMe$_3$ (1 M in toluene, 10 mL, 10 mmol). The resulting solution was stirred and warmed to room temperature. After additional stirring for 2 h, the solution was evaporated to dryness in vacuo, and the residue was washed with cold *n*-hexane (2 × 5 mL) to yield crystalline **3** (3.29 g, 85%). M.p. 213 °C. $^1$H NMR (500.13 MHz, CDCl$_3$, 298 K): $\delta$ = 0.30 (s, 18 H, Si-*Me*), 2.66 (s, 9 H, N*Me*$_3$), 6.70 (m, 2 H, C$_{10}$*H*$_6$), 7.25–7.45 (m, 4 H, C$_{10}$*H*$_6$) ppm. $^{13}$C NMR (125.77 MHz, CDCl$_3$, 298 K): $\delta$ = 2.91 (Si-*Me*), 47.60 (N*Me*$_3$), 116.19 (*C*H, *C*$_{10}$H$_6$), 118.54 (*C*H, *C*$_{10}$H$_6$), 125.32 (*C*, *C*$_{10}$H$_6$), 137.98 (*C*H, *C*$_{10}$H$_6$), 144.75 (*C*, *C*$_{10}$H$_6$), 150.64 (*C*N, C$_{10}$H$_6$) ppm. $^{29}$Si NMR (99.36 MHz, CDCl$_3$, 298 K): $\delta$ = –0.55 ppm. IR (KBr, plate): $\tilde{\nu}$ = 1869 (m, AlH) cm$^{-1}$. MS (EI): *m*/*z* (%) = 387 (16) [M]$^+$, 328 (100) [M – NMe$_3$]$^+$. C$_{19}$H$_{34}$AlN$_3$Si$_2$ (387.64): calcd. C 58.87, H 8.84, N 10.84; found C 57.76, H 8.62, N 10.44.

**[1,8-(Me$_3$SiN)$_2$C$_{10}$H$_6$]Al(Me)thf (4):** To a solution of [1,8-(Me$_3$SiNH)$_2$C$_{10}$H$_6$] (3.02 g, 10 mmol) in thf (40 mL) at –30 °C was added dropwise *n*BuLi (2.5 M, 8 mL, 20 mmol). The mixture was stirred and warmed to room temperature. After additional stirring for 1 h, all volatiles were removed in vacuo and toluene (40 mL) was added to the solid residue. The solution was cooled to –30 °C and MeAlCl$_2$ (1 M, 10 mL, 10 mmol) was added. The resulting solution was warmed to room temperature and stirred for 2 h. After workup, the insoluble LiCl was removed by filtration, and the residue was dried in vacuo and washed with cold *n*-hexane (2 × 5 mL) to yield solid **4** (2.94 g, 71%). M.p. 154–155 °C. $^1$H NMR (500.13 MHz, CDCl$_3$, 298 K): $\delta$ = –0.55 (s, 3 H, Al-*Me*), 0.23 (s, 18 H, Si-*Me*), 1.57 [m, 4 H, O(CH$_2$C*H*$_2$)$_2$], 3.79 [m, 4 H, O(C*H*$_2$CH$_2$)$_2$], 6.63 (m, 2 H, C$_{10}$*H*$_6$), 7.01–7.05 (m, 4 H, C$_{10}$*H*$_6$) ppm. $^{13}$C NMR (125.77 MHz, CDCl$_3$, 298 K): $\delta$= 2.70 (Si-*Me*), 24.93 [O(CH$_2$*C*H$_2$)$_2$], 69.78 [O(*C*H$_2$CH$_2$)$_2$], 116.68 (*C*H, *C*$_{10}$H$_6$), 118.21 (*C*H, *C*$_{10}$H$_6$), 125.17 (*C*, *C*$_{10}$H$_6$), 137.66 (*C*H, *C*$_{10}$H$_6$), 144.15 (*C*, *C*$_{10}$H$_6$), 151.01 (*C*N, C$_{10}$H$_6$) ppm. $^{29}$Si NMR (99.36 MHz, CDCl$_3$, 298 K): $\delta$ = –1.12 ppm. MS (EI): *m*/*z* (%) = 342 (100) [M – thf]$^+$. C$_{21}$H$_{35}$AlN$_2$OSi$_2$ (414.67): calcd. C 60.83, H 8.51, N 6.76; found C 58.94, H 7.99, N 6.93. The slight difference in the found and calculated analytical data is due to the extreme moisture sensitivity of the product.

**X-ray Structure Determination of 3 and 4:** Suitable crystals of **3** and **4** were mounted on a glass fiber and coated with paraffin oil. Data for **3** was obtained with a STOE-IPDS II image-plate diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data for **4** was collected with a Bruker SMART 1000 CCD diffractometer. The structures were solved by direct methods by using SHELXS-97[29] and refined against $F^2$ on all data by using full-matrix least-squares with SHELXL-97.[30] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms connected to carbon atoms were included at geometrically calculated positions and refined by using a riding model (Table 1).

CCDC-645712 (**3**) and -644929 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free

# Expanding the Range of "Daniphos"-Type P∩P- and P∩N-Ligands: Synthesis and Structural Characterisation of New [(η⁶-arene)Cr(CO)₃] Complexes

**Elisabetta Alberico,*[a] Wolfgang Braun,[b] Beatrice Calmuschi-Cula,[b] Ulli Englert,[b] Albrecht Salzer,*[b] and Daniel Totev[b]**

**Keywords:** N,P ligands / Phosphane ligands / Asymmetric catalysis / Arene complexes / Chromium

New P∩P- and P∩N-ligands have been synthesised whose core structure is an [(η⁶-arene)Cr(CO)₃] unit. These new ligands, which extend the range of "Daniphos" ligands, are endowed with central and planar chirality and have been prepared through a stereoselective synthetic strategy from optically pure benzylamines bearing a second substituent on the arene other than the benzyldimethylamino group. Because the two faces of unsymmetrically 1,2- and 1,3-disubstituted benzylamine are diastereotopic, which means that diastereomeric complexes arise upon coordination of the Cr(CO)₃ fragment to either of these two faces, the synthetic plan has been adjusted by exploiting the trimethylsilyl group as a temporary steric modulator in order to access both complexes with high diastereoselectivity.

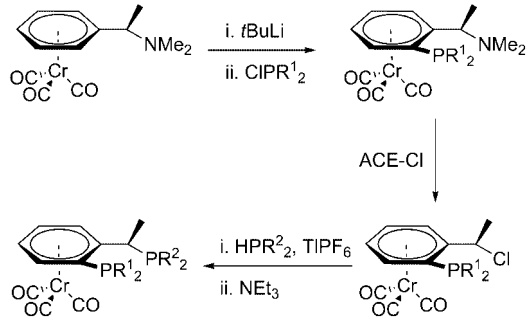
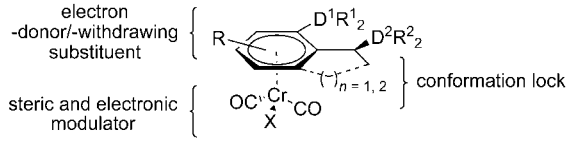
## Introduction

"Daniphos" ligands are a class of ligands suitable for application in catalysis whose core structure is an [(η⁶-arene)Cr(CO)₃] unit. A stereoselective synthetic strategy developed recently in our laboratories has provided these ligands with a modular and tunable character (Scheme 1).[1] Daniphos ligands are usually prepared from commercially available optically pure benzylamines and are characterised by the presence of a stereogenic plane and a stereocentre. Planar chirality is introduced by means of a diastereoselective directed orthometallation (DOM) assisted by the benzylic amino group and subsequent electrophilic substitution on the arene ring. Central chirality is preserved by the stereoselective replacement of the dimethylamino group for a chloride by treatment with chloroethyl chloroformate (ACE-Cl) and subsequent stereoselective nucleophilic substitution of the chloro substituent for a different nucleophile. A library of ligands, which comprises mono- and bidentate P∩N and P∩P ligands, has been prepared following this approach.[1–3] The steric and/or electronic properties of these ligands can be easily tuned by varying the $R^1$/$R^2$ substituents on the donor atoms D or by reducing their conformational flexibility by tethering the donor atoms to an annelated framework[3e] (Scheme 2). These ligands have been tested in a number of enantioselective homogeneous catalytic processes such as hydrogenation,[3] hydroamination,[3a] allylic sulfonation,[3a] hydrovinylation,[1b] transfer hydrogenation[4] and, more recently, nucleophilic asymmetric ring opening (ARO) of oxabenzonorbornadienes.[5]



Scheme 1. General synthetic strategy for the preparation of "Daniphos"-like diphosphanes. ACE-Cl = 1-chloroethyl chloroformate.



Scheme 2. Accessibility of a modular ligand architecture based on [(η⁶-arene)Cr(CO)₃] complexes.

As shown in Scheme 2, a further possibility for altering the basic structure of Daniphos ligands is to introduce a substituent R onto the arene ring. Such substituents might be important in modulating the electronic properties of the donor atoms D and, depending on their location on the arene, also their steric properties. Such substituents can be introduced at the stage of complexation of the arene to the

$Cr(CO)_3$ moiety as a range of chiral amines related to 1-phenylethylamine that already bear the R substituent are commercially available. In this paper we detail the synthesis of these complexes and explore the influence of the R group on the outcome of some steps of our established synthetic strategy. The X-ray structures of some intermediates and some of the target ligands are also provided, which, in cases of uncertainty, serve to define the stereochemical outcome of a reaction.

## Results and Discussion

The amines used to prepare the "Daniphos" ligands reported in this paper are shown in Figure 1. The corresponding primary benzylamines were reductively methylated with formaldehyde and formic acid following the Eschweiler–Clarke procedure.[6] Protection of the amino group prior to complexation to the $Cr(CO)_3$ moiety is necessary in order to reduce its coordinating ability towards chromium as this might lead to incomplete complex formation. The diphosphanes P∩P were prepared from the *para*-substituted benzylamines (*S*)-**1**, (*S*)-**2**, (*R*)-**3** and (*R*)-**6** while the bidentate P∩N ligands were prepared from *ortho*- and *meta*-methoxy-substituted benzylamines (*S*)-**4** and (*S*)-**5**.

### Preparation of Daniphos Diphosphanes P∩P

The coordination of amines (*S*)-**1**, (*S*)-**2**, (*R*)-**3** and (*R*)-**6** was accomplished by thermolysis with $Cr(CO)_6$ (Scheme 3). The reactions weren carried out under the conditions reported by Mahaffy and Pauson.[7] The protected benzylamine and $Cr(CO)_6$ were heated (temperature of the oil bath: 140 °C) in an 8:1 mixture of di-*n*-butyl ether and tetrahydrofuran until the evolution of CO ceased or onset of decomposition was observed. The best yield was obtained with the *para*-*tert*-butyl-substituted benzylamine (*S*)-**2**. It is known that π-electron-withdrawing groups (e.g. CHO or COOH) slow down complexation and are best protected before complexation, while electron-donating arene substituents accelerate complexation.[8a,8b] Complexation of (*R*)-**3** to the $Cr(CO)_3$ moiety gave a modest 43% yield of the expected complex. In this case, decomposition during the reaction, as indicated by formation of a grey-green precipitate, was difficult to avoid. This appears to be progressive and the reaction had to be stopped. The poor yield might also be due to reductive dehalogenation.[9]

Scheme 3. Yields obtained in the complexation of protected *para*-substituted benzylamines with $Cr(CO)_6$.

DOM of complexes (*S*)-**7**, (*S*)-**8**, (*R*)-**9** and (*R*)-**10** was carried out according to a general procedure consisting of treatment with *t*BuLi in diethyl ether at –78 °C for 1.5 h, subsequent quenching with $ClPPh_2$, and warming to room temperature overnight. The relative amounts of products formed were calculated based on integration of the corresponding $^{31}P$ NMR signals in the spectra of crude reaction mixtures in all cases. The diastereomeric excesses reported in the schemes were calculated in a similar manner. Products of very high purity were obtained by flash chromatography.

Coordination of the $Cr(CO)_3$ group to the arene enhances the kinetic acidity of the ring C–H bonds due to the strong electron-withdrawing character of the $Cr(CO)_3$ moiety,[8c] therefore direct lithiation of the arene ring occurs more easily than that of the parent chromium-free arene. Because of the presence of a heteroatom-containing functionality, lithiation can be extremely selective towards the *ortho* position due to specific coordination of the base through its lithium counterion.[10]

The two hydrogen atoms *ortho* to the ethylamino group in complexes (*S*)-**7**, (*S*)-**8**, (*R*)-**9** and (*R*)-**10** are diastereotopic because of the α-stereogenic centre, which means that preferential replacement of either of them gives rise to unequal amounts of two molecules endowed with the same central chirality but opposite planar chirality.[11] When the related complex [{(*R*)-*N*,*N*-dimethyl-1-phenylethylamine}$Cr(CO)_3$] is treated with *tert*-butyllithium in diethyl ether at –78 °C, the ortholithiated species derived from preferential abstraction of the $H_S$ proton is formed with 96% diastereoselectivity (Figure 2).[12] The origin of this high diastereoselectivity stems from a preferential average solution-state conformation in which both the α-methyl and α-dimethylamino groups lie above the plane of the arene ring, opposite the bulky $Cr(CO)_3$ unit (Figure 2, a). This "sensible" spatial arrangement has been inferred by deuterium-labelling and difference NOE $^1H$ NMR experiments. According to these data, it can be expected that the *ortho*-directing dimethylamino group preferentially directs a precoordinated lithium base towards the closest $H_S$ proton (Figure 2, b). Removal of the $H_R$ proton would force the benzylic methyl group below the plane of the arene, thereby causing an unfavourable steric interaction with the tricarbonylchromium unit. The absolute configuration of the α-stereogenic centre dictates the relative planar chirality, thus

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

indicating that the sense of asymmetric induction is determined in the deprotonation step. The greater discrimination between the two diastereotopic hydrogens achieved with a sterically more demanding base such as *t*BuLi is consistent with this assumption. In fact, although high *ortho* diastereoselectivity has been demonstrated with both *n*BuLi and *t*BuLi, only the latter allows for complete transfer of side-chain chirality on to the arene ring.

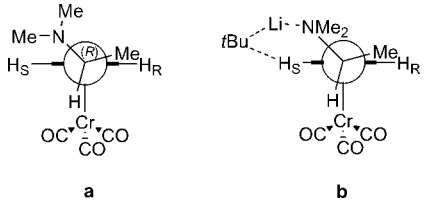

Figure 2. (a) Average solution-state conformation of the benzylic side chain of [{(*R*)-*N*,*N*-dimethyl-1-phenylethylamine}$Cr(CO)_3$] as inferred from NOEDS. (b) Newman projection of the possible directed orthometallation intermediate along the $C_\alpha$–$C_{ipso}$ bond.

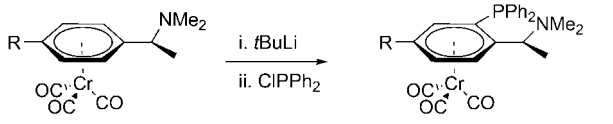
Uemura and Hayashi prepared the first ever reported P,N ligand of the "Daniphos" type by diastereoselective lithiation of [{(*R*)-*N*,*N*-dimethyl-1-phenylethylamine}$Cr(CO)_3$] and subsequent reaction with chlorodiphenylphosphane.[13]

DOM of (*S*)-**7** and (*S*)-**8** proceeds with high diastereoselectivity to give the expected products (*S*,*R*p)-**11** and (*S*,*R*p)-**12**, respectively (Scheme 4). No competitive α-proton abstraction was observed in the *ortho* functionalisation of (*S*)-**7** either from the dimethylaminoethyl group or from



R = Me (*S*)-**7** (*S*,*R*p)-**11** *de* = 92% (90%)

R = *t*Bu (*S*)-**8** (*S*,*R*p)-**12** *de* > 99% (78%)

Scheme 4. Products obtained in the *ortho*-functionalisation of (*S*)-**7** and (*S*)-**8**.

the *para*-substituted methyl group − α-proton abstraction from [($\eta^6$-arene)$Cr(CO)_3$] complexes is in fact the thermodynamically favoured process and the high yield of ring-substituted products clearly demonstrates that proton abstraction by *tert*-butyllithium is kinetically controlled.[14]

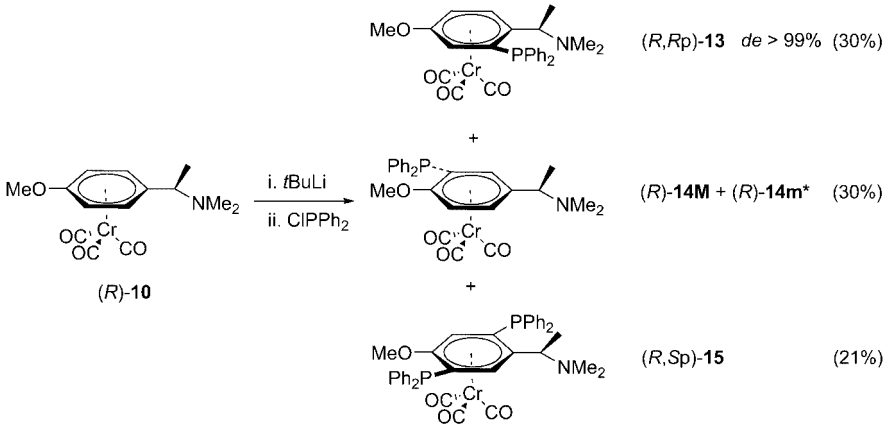
*ortho*-Functionalisation of [{$\eta^6$-(*R*)-1-(4-methoxyphenyl)-*N*,*N*-dimethylethylamine}$Cr(CO)_3$] [(*R*)-**10**] according to the procedure described above affords a mixture of products due to the presence of two coordinating substituents (Scheme 5).

A very useful study has demonstrated that the substituent effects on regioselectivity in the deprotonation of free arenes are distinctly different from those found for [$Cr(CO)_3$]-complexed arenes.[15] A series of *para*-disubstituted arenes were complexed and deprotonated, and the ratio of the two possible products in each case allowed a reactivity series to be generated. The following ratio of *ortho*-directing abilities of functional groups was deduced:

$F > CONHR > NHCOR > CH_2NR_2 \approx OMe >> CH_2OMe$

According to this study, when lithiation is performed at –78 °C with *s*BuLi for 1.5 h and is followed by electrophilic quenching with $Me_3SiCl$, the relative kinetic acidity of a ring proton takes precedence over simple base coordination by a heteroatom in the substituent group as the principal factor in determining the site of metallation in disubstituted arene complexes. The chromium complex of *p*-methoxy-*N*,*N*-dimethylbenzylamine provides a comparison of the directing effect of the OMe and $CH_2NMe_2$ groups. In this case, the two effects, namely OMe-induced labilisation of the *ortho* proton by electron withdrawal and $CH_2NMe_2$ coordination of the incoming base, are almost exactly balanced. In line with this result, D*O*M of (*R*)-**10** produces similar amounts of products in which lithiation has occurred *ortho* to the benzylic amino group and *ortho* to the methoxy group.

The products reported in Scheme 5 were separated by means of flash chromatography, although (*R*)-**14M** (the more abundant isomer) and (*R*)-**14m** (the less abundant iso-



Scheme 5. Products obtained in the *ortho*-functionalisation of (*R*)-**10**. Yields of isolated products are reported in parentheses. * This notation indicates the two regioisomeric products bearing a diphenylphosphanyl group *ortho* to the OMe substituent; the absolute configurations, however, could not be assigned.

mer), which are the two regioisomeric products bearing a diphenylphosphanyl group *ortho* to the -OMe substituent, could not be separated and were collected as a single fraction.

The identity of the products was assigned based on the mass, $^1H$ and $^{31}P$ NMR, and 2D NMR spectra (Table 1). The location of the diphenylphosphanyl group *ortho* to the dimethylethylamino group was easily inferred from the $^1H$ NMR spectrum due to the phosphorus-hydrogen coupling, which further splits the signal of the α-hydrogen compared to the corresponding signal in complex (*R*)-**10**. Furthermore, this resonance is shifted nearly 2 ppm to lower field due to the proximity of the phenyl groups and their "ring current" effect. This is observed both in the spectrum of the desired (*R*,*R*p)-**13** [its diastereomeric product (*R*,*S*p)-**13** could not be detected in the $^1H$ NMR spectrum of the crude reaction mixture] and in the spectrum of disubstituted (*R*,*S*p)-**15**. The chemical shift of the α-hydrogen signal is nearly unchanged and no H-P coupling is detected in the spectrum of (*R*)-**14M** or (*R*)-**14m**, which were identified as the species in which lithiation has occurred *ortho* to the OMe group. The two regioisomers are formed in a 72:28 ratio, thereby suggesting a possible influence of the remote stereogenic centre; the absolute planar chirality was not assigned.

Formation of complex (*R*,*S*p)-**15** might proceed via a dianion stabilized by the strongly electron-withdrawing Cr(CO)$_3$ moiety, which could mean that the mono-lithiated arene ring is sufficiently acidic to allow a second deprotonation or the second deprotonation is faster than the first one.[16] Unfortunately, to the best of our knowledge, there is no reliable structural and spectroscopic information on lithiated [(η$^6$-arene)Cr(CO)$_3$] complexes which would make it possible to determine whether the electronic effect of Li as a substituent does or does not deactivate the aromatic ring towards further H-abstraction. The existence of an intermediate polycarbanion has been postulated recently in a detailed investigation of multiple substitution of [(η$^6$-arene)Cr(CO)$_3$] complexes.[17] The treatment of representative complexes such as [{η$^6$-1-(*tert*-butyl-sulfonyl)-benzene}Cr(CO)$_3$], [(η$^6$-anisole)Cr(CO)$_3$] and [(η$^6$-*N*,*N*-dimethylbenzylamine)Cr(CO)$_3$] with three equivalents of 2,2,6,6-tetramethylpiperidyllithium (LiTMP), followed by electrophilic quenching with Me$_3$SiCl, provided a series of di- and trisilylated complexes. Deuteration studies using lithium diisopropylamide (LDA) as the base and deuteroacetic acid as the electrophile led to the observation of a trideuterated species presumably derived from a trianionic species formed during the reaction. Alternatively, complex (*R*,*S*p)-**15** might arise from successive deprotonation/trapping/deprotonation processes enabled by the unreacted *t*BuLi. This would imply that electrophilic trapping of the base itself is rather slower than deprotonation of the arene complex, although the isolation of *t*BuPPh$_2$ as a by-product in some cases suggests that this might not be the case.

The stereochemistry of complex (*R*,*S*p)-**15** was tentatively assigned based on the most stable charge arrangement of the intermediate dianion considering that both the dimethylethylamino group and the methoxy group favour the formation of the corresponding *ortho* anion and that the dimethylethylamino group stereoselectively promotes abstraction of the pro-$S_P$ *ortho* H atom.

Lithiation of [{η$^6$-(*R*)-1-(4-chlorophenyl)-*N*,*N*-dimethylethylamine}Cr(CO)$_3$] [(*R*)-**9**] with *t*BuLi followed by treatment of the lithiated species with ClPPh$_2$ afforded the expected *ortho*-functionalised diastereomeric complexes (*R*,*S*p)-**16** and (*R*,*R*p)-**16** and the product of metal/halogen exchange [(*R*)-**17**; Scheme 6]. According to the $^{31}P$ NMR spectrum of the crude reaction mixture, the relative ratio of (*R*,*S*p)-**16** and (*R*,*R*p)-**16** is 94:6, which corresponds to an 88% diastereoselectivity of the ortholithiation reaction (Table 2). Pure (*R*,*S*p)-**16** was obtained by flash chromatography. A second fraction contained (*R*,*R*p)-**16** as the main product. Attempts to further purify this complex failed, however, and its structure was assigned based on its $^1H$ NMR spectrum, where the diagnostic H-P coupling and shift of the -C*H*(Me)NMe$_2$ signal to lower field are observed. Although directed orthometallation is predominant, competitive chloride/lithium exchange leads to the formation of complex (*R*)-**17**. Interestingly, no lithiation *ortho* to the chloro substituent was detected.

Because lithium amides enable metallation to be achieved in preference to metal/halogen exchange,[18a] lithiation of (*R*)-**9** was repeated with LDA under otherwise identical conditions. However, only the two diastereoisomers corresponding to lithiation *ortho* to the chloro substituent were detected in a nearly 1:1 ratio (Scheme 6). The steric bulk of the base most likely prevents coordination by the ethyldimethylamino group and the electron-withdrawing effect of the chloro substituent prevails in dictating the regiochemis-

[d] The two diastereomeric products (*R*)-**18M** and (*R*)-**18m** could not be separated by flash chromatography and were isolated as a single fraction (see text).

try of deprotonation.[18b] These complexes could not be separated by flash chromatography and the regiochemistry of lithiation was assigned based on the $^1$H NMR spectrum of the mixture of the two diastereoisomers. The two compounds, the absolute planar chirality of which could not be defined, are labelled as the major [(*R*)-**18M**] and minor [(*R*)-**18m**] diastereoisomers in Table 2.

After the first phosphorus donor has been introduced into the *ortho* position, a second one has to be appropriately placed in the benzylic position for subsequent metal chelation. This was achieved in two steps, both of which are highly stereoconservative (Scheme 7). The first step involves transformation of the phosphanylamino complex into a chlorobenzyl derivative by treatment of the former with an excess of 1-chloroethyl chloroformate (ACE-Cl). This procedure, which has been developed in our laboratory,[1a] relies on the ability of chloroformates to promote the mild debenzylation of tertiary amines.[19] Replacement of the dimethylamino group by chloride takes place with retention of configuration and no evidence of epimerisation was observed. All the desired α-chloro derivatives were obtained in good yields after purification by flash chromatography except the *para*-chloro one [(*R*,*S*p)-**22**], which readily decomposes while adsorbed on silica gel. The reported yield of (*R*,*S*p)-**22** therefore refers to the crude product after the removal of excess ACE-Cl and carbamate by-product.

The new $C_1$-symmetric diphosphane ligands were finally prepared by treatment of the corresponding benzyl chloride complexes with a slight excess of a secondary phosphane (HPR′$_2$) in acetone at room temperature in the presence of $TlPF_6$, which acts as a chloride scavenger by precipitation of highly insoluble TlCl. The $^{31}$P NMR spectra of all ligands display two doublets − one for each non-equivalent phosphorus atom − whose splitting is due to coupling to the other phosphorus atom in the molecule (Table 3). Large low-field shifts are observed upon changing the substituent on the α-phosphorus atom from phenyl to cyclohexyl and, to a larger extent, to *tert*-butyl. This downfield shift with increasing steric bulk at phosphorus can be explained by a concomitant change in the hybridisation at phosphorus.[20] However, within the same set of diphosphanes having the

same substituents on the phosphorus donors, replacing a hydrogen on the arene directly complexed to chromium with either a methoxy, methyl, *tert*-butyl or chloro substituent does not bring about any meaningful change in the properties of the phosphorus donors, as measured by the corresponding chemical shifts. This means that the influence of the $Cr(CO)_3$ moiety on the electron richness of the arene, either as an aryl substituent on the phosphorus directly attached to the arene or a benzyl substituent on the α-phosphorus, is too strong and levels out any electronic contribution due to substituents on the arene.

[a] NMR spectra recorded in $C_6D_6$. [b] These data, which are provided for comparison, have been taken from ref.[3a].

The diphosphanes are characterised by large four-bond phosphorus-phosphorus coupling constants whose values increase from 11–26 Hz in $PPh_2/PPh_2$ diphosphanes to 54–68 Hz in $PPh_2/PtBu_2$ ones. A similar trend has been reported for the analogous ferrocene-based ligands.[21] The two phosphorus donors are bound to an allylic fragment (P–$C_o$=$C_{ipso}$–$C_\alpha$–P) and π-systems usually lead to unexpectedly large long-range couplings.[22] The large value of the $^4J_{P,P}$ coupling might stem from "through-space" nuclear spin-spin coupling made possible by partial overlap of the two phosphorus lone pairs.[23a] The steric crowding provided by the substituents on phosphorus locks the molecule in a preferred time-average conformation in solution which, by keeping the substituents on the *ortho*- and α-donors far apart, brings the lone pairs into close proximity. The X-ray structure of ligand (*S*,*R*p)-**23b** supports this hypothesis (Figure 3).[24a] The larger values observed for the derivatives bearing bulky cyclohexyl and *tert*-butyl groups compared to those which only possess phenyl substituents might reflect the further restricted conformational freedom caused by the former substituents, although formal hybridisation of the coupled nuclei and the electronegativity of their substituents also play a role.[22,23b]

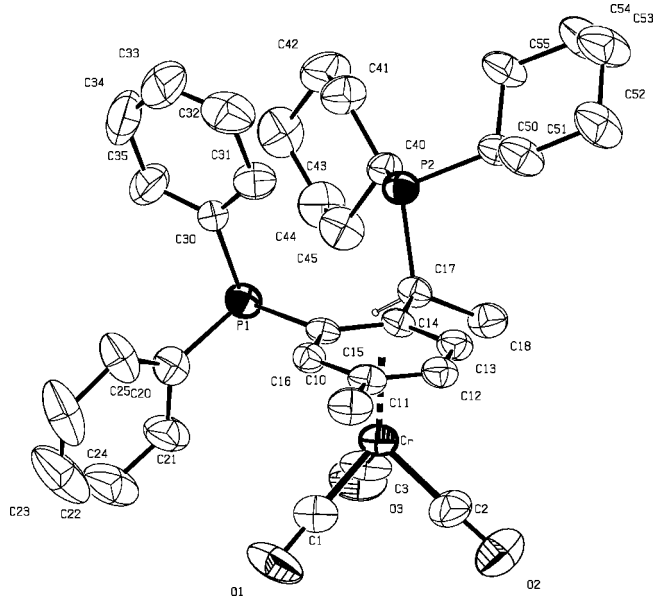

Figure 3. Displacement ellipsoids plot (PLATON) of (*S*,*R*p)-**23b**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

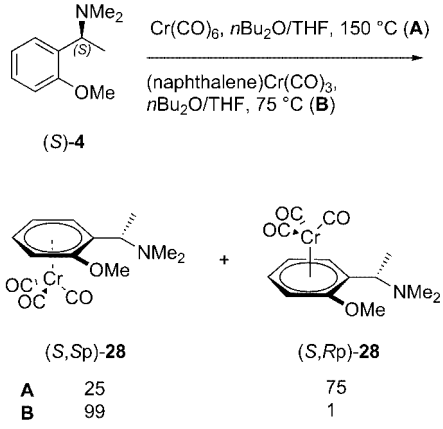
The diphosphanes were tested in a variety of hydrogenations in comparison with the complexes without R substituents. Some of the results of these studies have already been published elsewhere.[3c] In most reactions there was a general trend in that the more electron-rich *para*-substituted ligands gave better *ee* values in enantioselective hydrogenations.

## Synthesis of Daniphos N∩P Ligands

The two faces of unsymmetrically 1,2- and 1,3-disubstituted benzylamine (*S*)-**4** and (*S*)-**5**, respectively, are diastereotopic, which means that diastereomeric complexes arise upon coordination of the $Cr(CO)_3$ fragment to either of these two faces.[25]

When complexation of (*S*)-**4** is carried out under harsh conditions [$Cr(CO)_6$, $nBu_2O$/thf, 150 °C] the isomer (*S*,*R*p)-**28** is preferentially formed with a diastereoselectivity of 50% (Scheme 8). An excellent diastereoselectivity in favour of the other diastereoisomer (*S*,*S*p)-**28** is achieved when complexation is carried out using Kündig's reagent [(naphthalene)$Cr(CO)_3$]. The latter is a good starting material for the mild synthesis of other [(arene)$Cr(CO)_3$] compounds by $Cr(CO)_3$ fragment transfer.[26] The absolute configuration of complex (*S*,*S*p)-**28** was confirmed by X-ray crystallographic analysis (Figure 4).



Scheme 8. Relative amounts of diastereomeric complexes obtained in the complexation of (*S*)-**4** under thermodynamic (A) and kinetic (B) conditions.

These results can be explained on the basis of the preferred average conformation adopted by (*S*)-**4** in solution at room temperature (Figure 5a), which was inferred by difference NOE/$^1$H NMR experiments. Thus, a much greater NOE enhancement of the α-$CH_3$ signal is observed compared to the α-H signal upon irradiation of the *ortho*-hydrogen, thus suggesting that, in order to minimize non-bonding interactions between the α-substituents and the *ortho* OMe group, the dimethylamino group is preferentially located below the pro-*R*p face of the arene. Under thermodynamic conditions, the $Cr(CO)_3$ fragment coordinates to the less crowded pro-$S_P$ face of the arene; under milder conditions, it is delivered to the pro-*R*p face due to temporary coordination by the amino group.

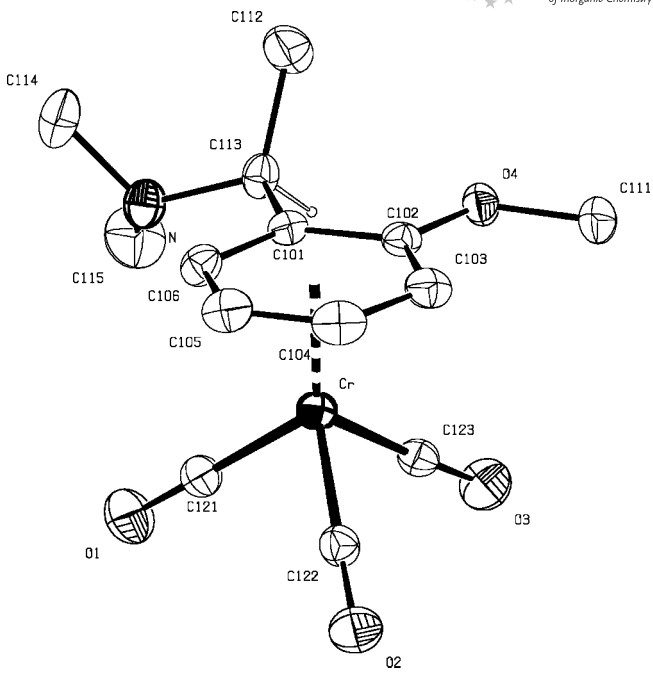


Figure 4. Displacement ellipsoids plot (PLATON) of (*S*,*S*p)-**28**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

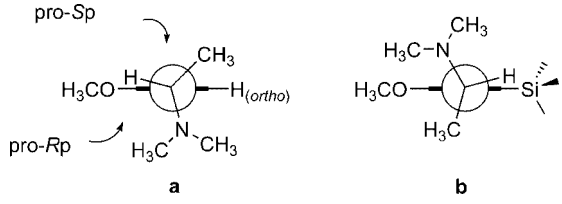

Figure 5. (a) Preferred average conformation adopted by (*S*)-**4** in solution at room temperature as inferred by difference NOE/$^1$H NMR experiments. (b) Preferred conformation in the presence of a bulky $–SiMe_3$ group in the *ortho* position.

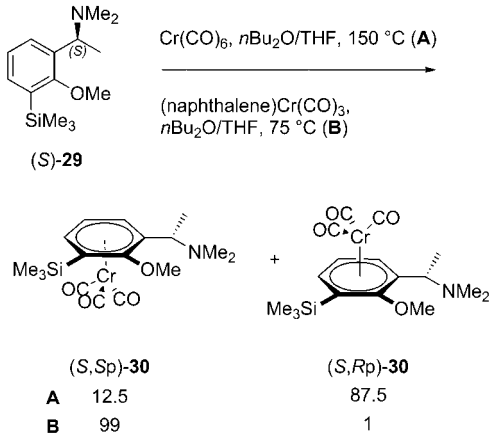
Because flash chromatography and fractional crystallisation failed to provide the (*S*,*R*p)-**28** isomer in acceptable yield and purity, an alternative synthetic strategy was devised in order to obtain it as a single diastereoisomer. This strategy is based on the direct complexation of a benzylamine derivative in which a sterically bulky and easily removable trimethylsilyl group has been temporarily introduced at the *ortho* position of the 1-*N*,*N*-dimethylaminoethyl group in (*S*)-**4**.[27] The presence of this group should restrict rotation of the benzylic group at high temperature and favour a conformation which, while limiting interaction of the α-Me with the $SiMe_3$ group, preferentially confines the dimethylamino group to the "upper" face, thus enhancing the diastereoselectivity of the complexation (Figure 5b). However, treatment of (*S*)-**4** with *t*BuLi at –50 °C followed by quenching with $ClSiMe_3$ afforded benzylamine (*S*)-**29** in which lithiation has taken place at the most acidic site of the molecule *ortho* to the methoxy group, instead.[10b,28]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

As shown in Scheme 9, the presence of an $SiMe_3$ group improves the diastereoselectivity of the complexation which, however, is still not satisfactory in the (*S*,*R*p)-**30** isomer, the absolute configuration of which was unambiguously assigned based on an X-ray crystallographic analysis (Figure 6).



Scheme 9. Relative amounts of diastereomeric complexes obtained in the complexation of (*S*)-**29** under thermodynamic (A) and kinetic (B) conditions.

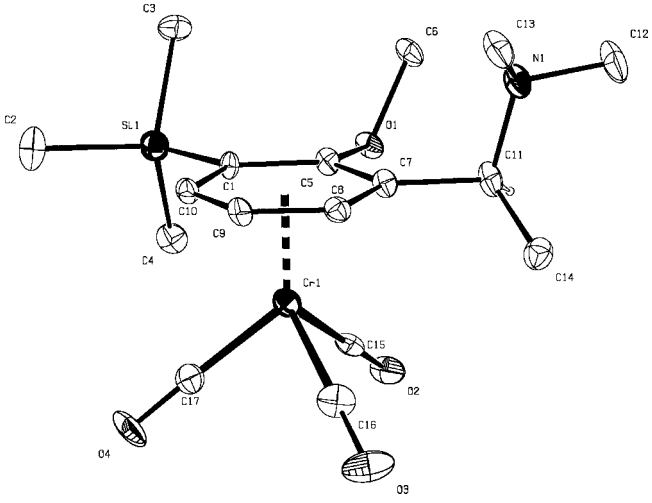


Figure 6. Displacement ellipsoids plot (PLATON) of one independent molecule of (*S*,*R*p)-**30**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

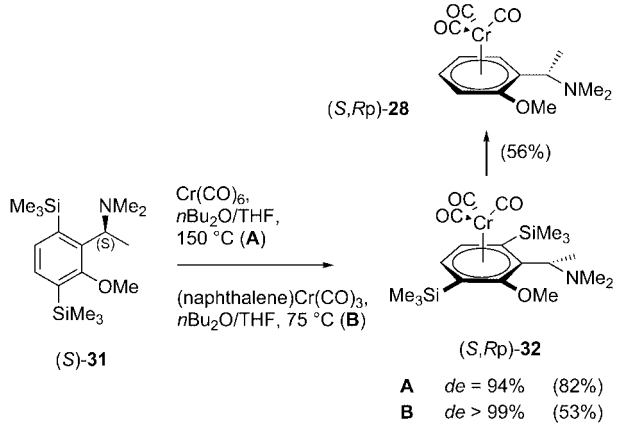
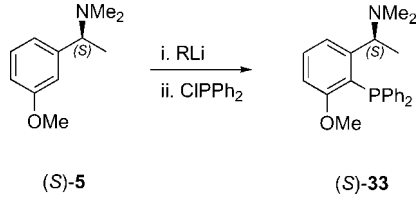
Complexation of (*S*)-**31**, in which a second $SiMe_3$ group has been introduced *ortho* to the benzylamino group by lithiation and subsequent electrophilic quenching of (*S*)-**29** with $ClSiMe_3$, turned out to be highly selective for the desired isomer (*S*,*R*p)-**32** (Scheme 10).[24b] Notably, the (*S*,*R*p) isomer is formed preferentially even under the rigorous conditions of the thermal complexation due to hampered rotation of the amino group around the benzylic bond. The $SiMe_3$ groups are easily removed by treatment with $Bu_4NF$, thereby opening a stereoselective route to (*S*,*R*p)-**28**.



Scheme 10. Stereoselective route to (*S*,*R*p)-**28**.

Complexation of the *meta*-substituted benzylamine (*S*)-**5** to the $Cr(CO)_3$ moiety gives rise to equal amounts of the two possible diastereomers whatever the method of complexation. The same approach used for (*S*)-**4** was therefore applied to (*S*)-**5** by introduction of an $SiMe_3$ group as steric modulator. According to a previous report, metallation of the related compound *m*-methoxy-*N*,*N*-dimethylbenzylamine occurs exclusively at the position mutually *ortho* to both the methoxy and the amine side chain.[27] This was explained by assuming that the combined *ortho*-directing effects of both coordinating substituents and inductive electron withdrawal by the methoxy group serve to stabilize metallation at the position mutually *ortho* to these two substituents. In the case of (*S*)-**5**, optimisation of the metallation conditions was carried out using $ClPPh_2$ as electrophile since this compound allows an easy monitoring of the reaction course by $^{31}P$ NMR spectroscopy (Scheme 11). Table 4 summarises the relative amounts of products formed when lithiation was carried out using different RLi reagents under different reaction conditions.



Scheme 11. Lithiation and subsequent electrophilic quenching of (*S*)-**5**.

Treatment of (*S*)-**5** with *t*BuLi at –78 °C for 4 h in $Et_2O$ and subsequent quenching of the Li salt formed with $ClPPh_2$ did not provide the expected product (*S*)-**33** (Table 4, entry 5) – $tBuPPh_2$ and unreacted (*S*)-**5** were isolated instead. The bulkiness of the $tBu^-$ anion might hamper its access to the *ortho* position between the two coordinating groups in (*S*)-**5**. However, the use of *n*BuLi both at –78 °C and –50 °C (Table 4, entries 1 and 2, respectively) was also unsuccessful. Formation of (*S*)-**33** was observed when either *s*BuLi or *t*BuLi were used at –50 °C (Table 4, entries 3 and 6, respectively). A further temperature increase up to room temperature favoured formation of a side

| 8 | | room temp. | 4 | n.d. | 1 | 1 |

[a] The ratio of the three products was calculated based on integration of the areas of the corresponding $^{31}P$ NMR signals of the crude reaction mixture: (*S*)-**33**: $\delta_{31P}$ = –24 ppm; *n*BuPPh$_2$: $\delta_{31P}$ = –17.8 ppm; *s*BuPPh$_2$: $\delta_{31P}$ = –0.8 ppm; *t*BuPPh$_2$: $\delta_{31P}$ = 16.8 ppm; other unidentified product: $\delta_{31P}$ = 115 ppm. [b] n.d. = non detected. [c] The best reaction conditions are printed in bold.

product ($\delta_{31P}$ = 115 ppm) which, unfortunately, could not be identified (Table 4, entries 4 and 8, respectively). The best selectivity and yield for the desired *ortho*-substituted product (*S*)-**33** were achieved by carrying out the metallation with *t*BuLi at –50 °C for 24 h (Table 4, entry 7). The identity of this product was unambiguously assigned by X-ray crystallographic analysis (Figure 7).

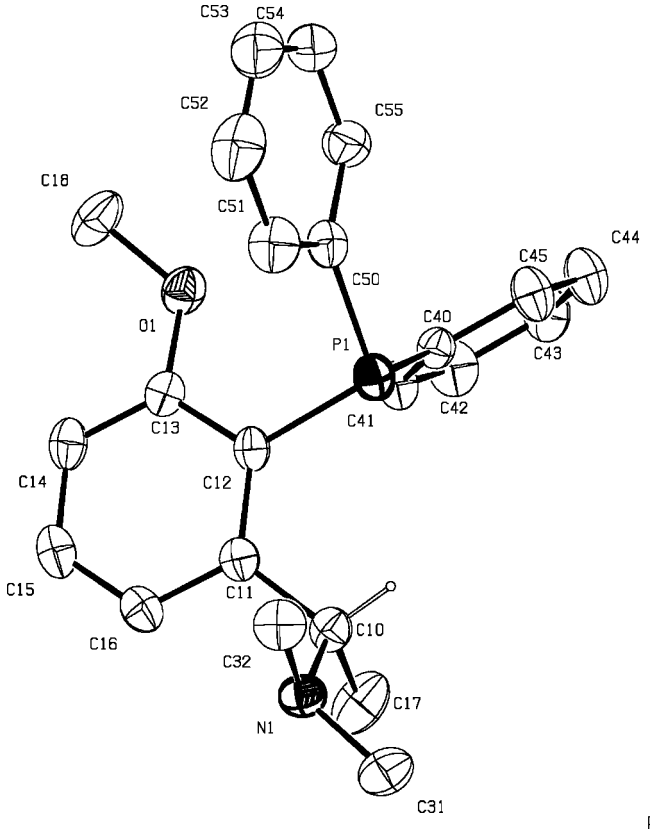

Figure 7. Displacement ellipsoids plot (PLATON) of one independent molecule of (*S*)-**33**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

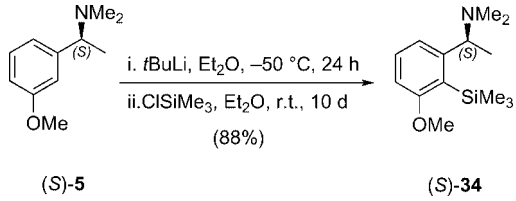
The optimised conditions were applied to the preparation of (*S*)-**34** (Scheme 12), although a large excess of $ClSiMe_3$ had to be used and the electrophilic trapping following metallation required ten days at room temperature.



Scheme 12. Synthesis of (*S*)-**34**.

Complexation of (*S*)-**34** to $Cr(CO)_3$ was carried out using Kündig's reagent under mild conditions (Scheme 13). The diastereoselectivity was 86% in favour of the (*S*,*R*p)-**35** isomer, as established from the NMR spectra of the crude reaction mixture. This complex could be obtained as a single diastereoisomer after flash chromatography [the other diastereoisomer (*S*,*S*p)-**35** was not isolated]. Desilylation of (*S*,*R*p)-**35** afforded complex (*S*,*S*p)-**36**, the absolute configuration of which was confirmed by X-ray crystallographic analysis (Figure 8).

(*S*,*S*p)-**37** was obtained by treatment of complex (*S*,*S*p)-**28** with *t*BuLi at –78 °C for four hours and then with $ClPPh_2$ (Scheme 14). The site of ortholithiation was confirmed by an X-ray crystallographic analysis (Figure 9). The NMR spectrum of the crude reaction mixture did not show the formation of other regioisomers. This result is surprising because the OMe group and the $CH_2NMe_2$ group have a similar *ortho*-directing ability in [($\eta^6$-arene)$Cr(CO)_3$] complexes.[15c] Lithiation of the diastereomeric complex (*S*,*R*p)-**28** with opposite planar chirality under analogous conditions failed and was also unsuccessful at higher temperatures or when using the less bulky base *n*BuLi. Directed orthometallation adjacent to the OMe group might be expected in (*S*,*R*p)-**28**, as is the case for (*S*,*S*p)-**28**, whereas lithiation adjacent to the $CH(Me)NMe_2$ group is hampered due to steric reasons. Removal of the *ortho* proton by a lithium base pre-coordinated by the amino group would

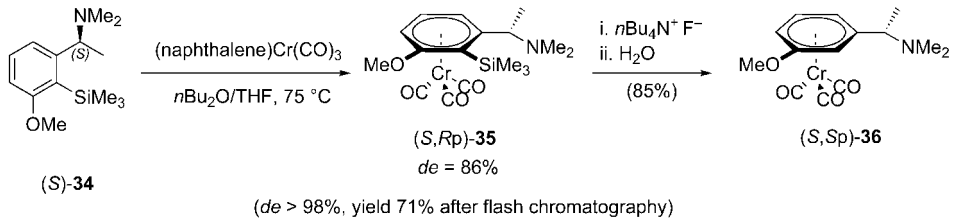

Scheme 13. Stereoselective route to (*S*,*S*p)-**36**.

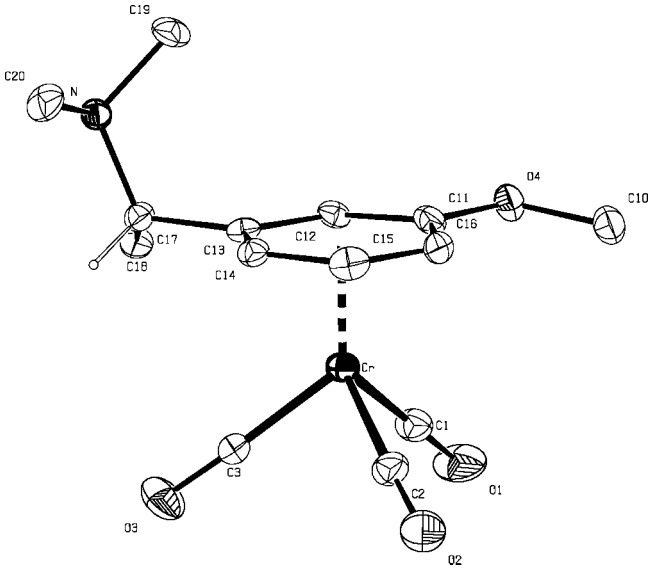

Figure 8. Displacement ellipsoids plot (PLATON) of (*S*,*S*p)-**36**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

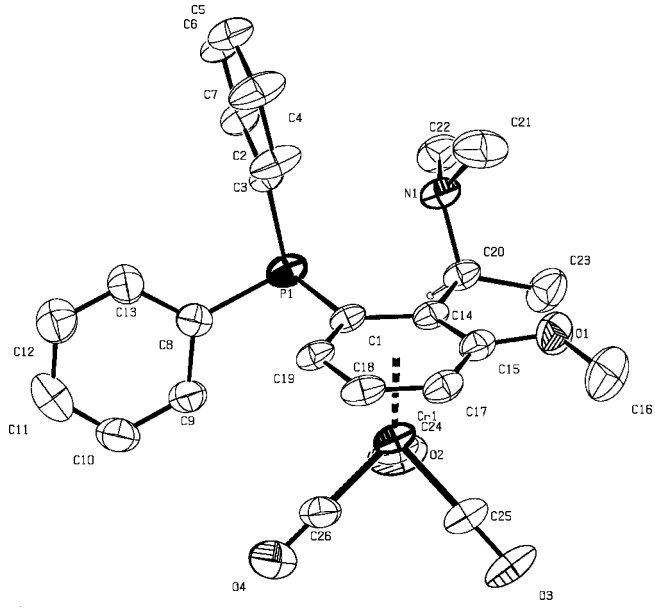

Figure 9. Displacement ellipsoids plot (PLATON) of (*S*,*S*p)-**37**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

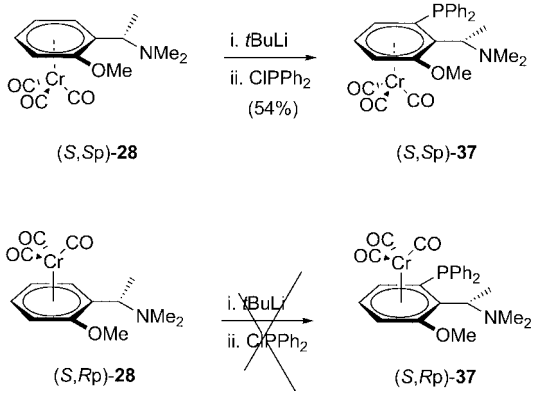
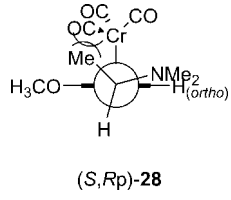
force the benzylic methyl group below the plane of the arene, thereby causing unfavourable steric interaction with the $Cr(CO)_3$ unit (Figure 10).



Scheme 14. Lithiation of diastereomeric complexes (*S*,*S*p)-**28** and (*S*,*R*p)-**28** and subsequent electrophilic quenching with $ClPPh_2$. The latter complex fails to react (see text for experimental conditions).

The inertness of (*S*,*R*p)-**28** towards *ortho*-functionalisation was advantageously exploited to separate the diastereomeric mixture of (*S*,*S*p)-**28** and (*S*,*R*p)-**28** obtained in



(*S*,*R*p)-**28**

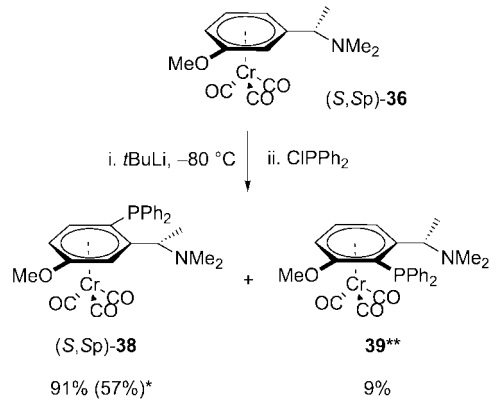
Figure 10. Conformation of (*S*,*R*p)-**28** required for ortholithiation assisted by the benzylic dimethylamino group.

the thermal complexation of (*S*)-**4** with $Cr(CO)_6$. Thus, after treatment of this mixture with *t*BuLi and $ClPPh_2$, (*S*,*S*p)-**37** and unreacted (*S*,*R*p)-**28** were easily separated and purified by flash chromatography.

When complex (*S*,*S*p)-**36** was treated with *t*BuLi and then with $ClPPh_2$, the $^{31}P$ NMR spectrum of the crude reaction mixture indicated the formation of two products in a 10:1 ratio, as established from the areas of the corresponding NMR signals [81 MHz, $CDCl_3$; (*S*,*S*p)-**38**: $\delta$ = –16.74 ppm; **39**: $\delta$ = –12.67 ppm; Scheme 15]. An X-ray crystallographic analysis of the major product (*S*,*S*p)-**38**

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

indicated that lithiation had occurred *ortho* to the benzylic amino group and *para* to the methoxy group (Figure 11). The minor product **39** could not be isolated in a pure form.



Scheme 15. Lithiation of (*S*,*S*p)-**36** and subsequent electrophilic quenching with $ClPPh_2$. * Yield of isolated products. ** The structure of complex **39** is only a proposal.

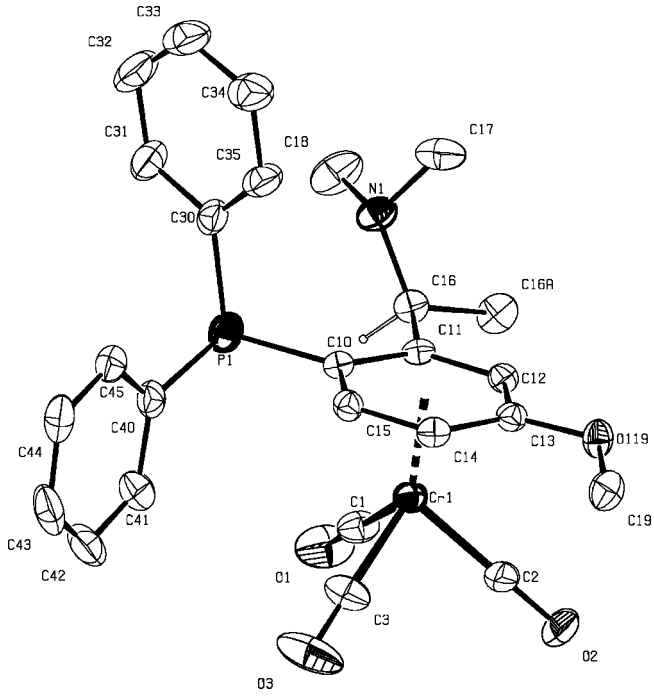


Figure 11. Displacement ellipsoids plot (PLATON) of one independent molecule of (*S*,*S*p)-**38**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

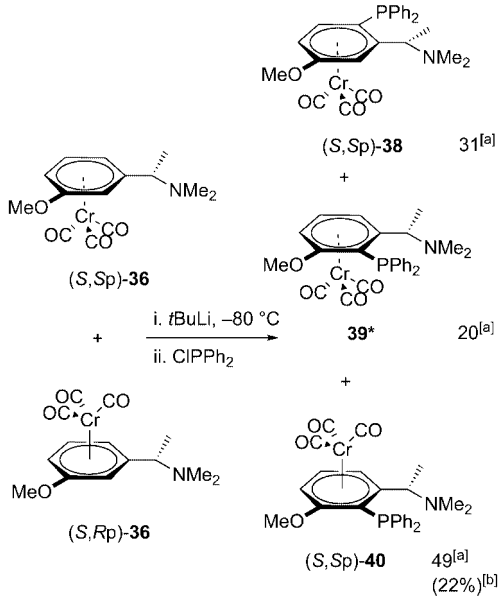
Because (*S*,*R*p)-**36** was not available in a pure form, the 1:1 diastereomeric mixture of (*S*,*S*p)-**36** and (*S*,*R*p)-**36** was lithiated instead (Scheme 16). A third product [(*S*,*S*p)-**40**] was detected along with (*S*,*S*p)-**38** and **39** in the $^{31}P$ NMR spectrum of the crude product [(*S*,*S*p)-**40**: $\delta = -10.70$ ppm]. This complex was isolated and its structure confirmed by an X-ray crystallographic analysis (Figure 12). (*S*,*S*p)-**40** is formed from (*S*,*R*p)-**36** by selective abstraction of the proton *ortho* to both substituents on the arene. The relative amounts of (*S*,*S*p)-**38**, **39** and (*S*,*S*p)-**40** depend on the temperature at which lithiation is carried out. Thus, at 0 °C and at room temperature (*S*,*S*p)-**38** is not detected and **39** and (*S*,*S*p)-**40** are formed in equal amounts. This might suggest that **39** is the product derived from (*S*,*S*p)-**36** when the dimethylamino group can overcome restricted rotation



Scheme 16. Products arising from *ortho*-functionalisation of a 1:1 diastereomeric mixture of (*S*,*S*p)-**36** and (*S*,*R*p)-**36**. * The structure of complex **39** is only a proposal. [a] Relative amounts of products as inferred from the $^{31}P$ NMR spectrum of the crude reaction mixture. [b] Yield after flash chromatography; only this product was isolated.

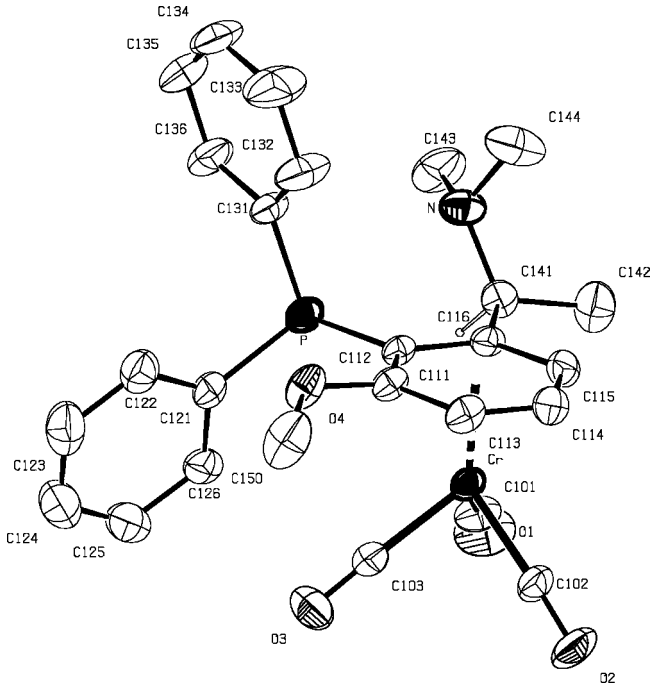


Figure 12. Displacement ellipsoids plot (PLATON) of (*S*,*S*p)-**40**. Ellipsoids are shown at the 30% probability level. The H-atom attached to the stereogenic centre is shown with arbitrary radius; other H-atoms have been omitted for clarity.

around the benzylic bond at higher temperature and the base is delivered to the other *ortho* proton through chelation by both substituents on the arene.

Some of the complexes containing P∩N ligands coordinated to the $Cr(CO)_3$ moiety have been successfully tested by us in asymmetric transfer hydrogenation. The results of these studies have been reported elsewhere.[4]

## Conclusions

The range of "Daniphos" ligands has been expanded to include N∩P and P∩P ligands bearing a substituent R on the arene of the [($\eta^6$-arene)$Cr(CO)_3$] unit, which might serve to modulate the steric and electronic properties of the donor atoms. The stereoselective synthetic strategy originally devised for the preparation of this class of ligands has been successfully applied to their preparation. In the case of N∩P ligands derived from 1,2- and 1,3-disubstituted benzylamines, because the two faces of such amines are diastereotopic and diastereomeric complexes arise from the coordination of the $Cr(CO)_3$ fragment to either of the two faces, the synthetic plan has been adjusted by exploiting the trimethylsilyl group as a temporary steric modulator in order to access both complexes with high diastereoselectivity.

## Experimental Section

**Materials and Methods:** All reactions involving air- and moisture-sensitive compounds, and their subsequent workup, were carried out under nitrogen using Schlenk and syringe techniques. Reactions were monitored by analytical TLC using either Merck silica gel 60 F 254 or Merck aluminium oxide F 254 aluminium cards. The chromatograms were visualized with UV light. Solutions of crude reaction mixtures were filtered through a short bed of the filter aid Fluka Celite 535. The solvent was then evaporated. Flash chromatography of the crude products was performed either on silica gel 60 [Merck; particle size: 0.063–0.200; pH 7.0 (0.5)] or aluminium oxide 90 II–III [Merck; particle size: 0.063–0.200; pH 9.0 (0.5)]. Solvents were dried and deoxygenated by standard procedures. NMR spectra were recorded with a Varian Mercury 200 spectrometer operating at 200 (for $^1H$), 50 (for $^{13}C$) or 81 MHz (for $^{31}P$), a Varian Unity 300 spectrometer operating at 300 (for $^1H$), 75.5 (for $^{13}C$) or 121.5 MHz (for $^{31}P$), a Varian Mercury Plus spectrometer operating at 400 (for $^1H$), 100.5 (for $^{13}C$) or 162 MHz (for $^{31}P$), or a Varian Unity 500 spectrometer operating at 500 (for $^1H$), 125 (for $^{13}C$) or 202 MHz (for $^{31}P$) at ambient temperature. Chemical shifts ($\delta$) are given in ppm relative to TMS ($^1H$, $^{13}C$) or 85% $H_3PO_4$ as external standards ($^{31}P$). IR spectra were recorded with a Perkin–Elmer FT-IR Model 1720-X spectrometer. Optical rotations were measured in 1-dm cells with a Perkin–Elmer Model 341 polarimeter at ambient temperature. Mass spectra were obtained by electron impact (EI) or chemical ionisation (CI) with isobutane with a Finnigan MAT 95 spectrometer. Elemental analyses were performed with a Carlo Erba Strumentazione Element Analyzer (Model 1106). Generous loans of chiral amines were kindly provided by BASF GmbH. [($\eta^6$-naphthalene)$Cr(CO)_3$]. was prepared according to published procedure.[9,26] All other chemicals were purchased and used without further purification.

**General Methods**

**A. Methylation of Amines:** Benzylamines were methylated according to the Eschweiler–Clarke procedure with formic acid and formaldehyde.[6] Formaldehyde (37% aqueous solution, $d$ = 1.090, 3 equiv.) and formic acid (98% aqueous solution, $d$ = 1.220, 5 equiv.) were added dropwise to the amine (1 equiv.) at 0 °C. The solution was heated at 80 °C for the reported time, then cooled and acidified with 10 N HCl. The solution was extracted with diethyl ether and then basified with 50% aqueous NaOH. The basic aqueous phase was extracted three times with diethyl ether and the combined ether extracts were washed with water and dried with $MgSO_4$. Diethyl ether was evaporated and the crude product finally distilled under reduced pressure.

**B. Synthesis of [($\eta^6$-Arene)$Cr(CO)_3$] Complexes by Thermolysis with $Cr(CO)_6$:** [($\eta^6$-arene)$Cr(CO)_3$] complexes were prepared according to the Pauson–Mahaffy procedure.[7] $Cr(CO)_6$ (1.2 equiv.) and the protected benzylamine (1 equiv.) were refluxed (bath temperature: 140 °C) in an 8:1 di-*n*-butyl ether/thf mixture ([Cr] = 0.36 M) for the reported time. The solution was cooled and filtered through a short pad of Celite on a sintered glass filter, which was then washed with some additional solvent. The solvents were distilled off on a rotary evaporator from a water bath held at 60 °C (an oil pump was required to remove the solvents completely). The crude product was purified by column chromatography and crystallised from suitable solvents.

**C. Directed Orthometallation and Functionalisation of [($\eta^6$-arene)-$Cr(CO)_3$] Complexes:** The appropriate [($\eta^6$-arene)$Cr(CO)_3$] complex (1 equiv.) was dissolved in dry diethyl ether ([Cr] = 0.05 M). The solution was cooled to –78 °C and *tert*-butyllithium (1.7 M in pentane, 1.14 equiv.) was added dropwise with a syringe. After 1.5 h, chlorodiphenylphosphane (1.14 equiv.) was added dropwise. The reaction mixture was warmed slowly to room temperature overnight and then filtered through a short pad of Celite on a sintered glass filter. The solvent was distilled off on a rotary evaporator and the crude product purified by column chromatography.

**D. Replacement of $NMe_2$ with Cl:** The appropriate [($\eta^6$-arene)-$Cr(CO)_3$] complex (1 equiv.) was dissolved in dry thf ([Cr] = 0.05 M). The solution was cooled to –40 °C and 1-chloroethyl chloroformate ($d$ = 1.312, 4 equiv.) was added dropwise. The reaction mixture was warmed up to room temperature overnight. The course of the reaction was monitored by $^{31}P$ NMR spectroscopy on a small sample of the crude reaction mixture dissolved in $C_6D_6$. The solvent and unreacted 1-chloroethyl chloroformate were distilled off. The residue was redissolved in diethyl ether and the solution filtered through a short pad of Celite on a sintered glass filter to eliminate the insoluble by-product [$(CH_3)_2NC(O)CHClCH_3$]. The crude product was purified by column chromatography after removal of the solvent.

**E. Replacement of Cl with $PR_2$:** The appropriate [($\eta^6$-arene)Cr-$(CO)_3$] complex (1 equiv.) was dissolved in dry acetone and $HPR_2$ (1.1 equiv.) was added. A suspension of $TlPF_6$ (1.1 equiv.) in dry acetone (final concentration of Cr in acetone = 0.05 M) was added dropwise to this solution very slowly. A fine white precipitate consisting of TlCl formed immediately. The solution was stirred at room temperature overnight. $NEt_3$ (1.5 mL per millimol of Cr) was added, the solution stirred for a further 15 min and then filtered through a short pad of Celite on a sintered glass filter to remove TlCl. The solvent and excess $NEt_3$ were distilled off and the crude product purified by column chromatography.

**(*S*)-*N*,*N*-Dimethyl-1-(*p*-tolyl)ethylamine [(*S*)-1]:** This compound was prepared according to general procedure A from formaldehyde

Thermolysis with Cr(CO)$_6$:** Reaction of (*S*)-**4** (4.00 g, 22.00 mmol) and $Cr(CO)_6$ (6.00 g, 27.00 mmol) in a 8:1 mixture of di-*n*-butyl ether and thf (81 mL) for 50 h according to general procedure B afforded (*S*,*S*p)-**28** and (*S*,*R*p)-**28** in a 25:75 ratio (Scheme 8). The two diastereomers were collected as a single fraction after flash chromatography (aluminium oxide; diethyl ether). Yield 4.65 g (66%).

**Arene Exchange with [(η$^6$-Naphthalene)Cr(CO)$_3$]:** (*S*,*S*p)-**28** was prepared in a high-pressure Schlenk tube from (*S*)-**4** (0.86 g, 4.78 mmol) and [(η$^6$-naphthalene)$Cr(CO)_3$] (1.50 g, 5.68 mmol) in di-*n*-butyl ether (25 mL). After all reagents and the solvent had been mixed, a catalytic amount of thf (0.53 g, 7.35 mmol) was added, the reaction mixture was degassed by means of ultrasound and three freeze-pump-thaw cycles and then heated in the dark at 75 °C for 95 h. The reaction mixture was then filtered through a short pad of Celite, the solvent was distilled off on a rotary evaporator and the residue was taken up in diethyl ether and purified by flash chromatography (aluminium oxide; diethyl ether/hexane = 1:10→1:2). A yellow crystalline product was isolated after evaporation of the solvents. Crystals suitable for X-ray analysis were grown by slow diffusion of hexane into a solution of the compound in diethyl ether at –30 °C. Yield 0.91 g (60%).

(N*Me*$_2$), 55.08 (O*Me*), 58.98 (d, $J_{C,P}$ = 14.4 Hz, α-*C*H), 73.95 ($C_{Ar}$), 79.62 ($C_{Ar}$), 99.61 ($C_{Ar}$), 100.33 (d, $J_{C,P}$ = 24.0 Hz, $C_{Ar,ipso}$), 120.88 (d, $J_{C,P}$ = 21.1 Hz, $C_{Ar,ipso}$), 128.75 (d, $J_{C,P}$ = 5.8 Hz $C_{PPh_2}$), 129.18 ($C_{PPh_2}$), 132.31 (d, $J_{C,P}$ = 20.1 Hz, $C_{PPh_2}$), 135.24 (d, $J_{C,P}$ = 21.1 Hz, $C_{PPh_2}$), 137.62 (d, $J_{C,P}$ = 14.4 Hz, $C_{PPh_2}$), 139.00 (d, $J_{C,P}$ = 6.7 Hz, $C_{PPh_2}$), 142.94 ($C_{Ar,ipso}$), 233.01 (*C*O) ppm. $^{31}$P NMR (81 MHz, $CDCl_3$): $\delta$ = –16.74 ppm. IR (hexane): $\nu_{CO}$ = 1972, 1908 cm$^{-1}$. $C_{26}H_{26}NO_4PCr$ (499.46): calcd. C 62.52, H 5.21, N 2.80; found C 62.78, H 5.54, N 2.89.

**[{η$^6$-(*S*,*Sp*)-*N*,*N*-Dimethyl-1-[2-(diphenylphosphanyl)-3-methoxyphenyl]ethylamine}Cr(CO)$_3$] [(*S*,*Sp*)-40]:** A 1:1 mixture of (*S*,*Sp*)-**36** and (*S*,*Rp*)-**36** (4.20 g, 13.33 mmol, 1 equiv.) was dissolved in diethyl ether (250 mL). The solution was cooled to –80 °C and *tert*-butyllithium (1.7 M in pentane; 8.94 mL, 15.20 mmol, 1.14 equiv.) was added dropwise (Scheme 16). After stirring for 4 h at –80 °C, chlorodiphenylphosphane (3.35 g, 15.20 mmol, 1.14 equiv.) was added dropwise. The reaction mixture was warmed to room temperature overnight, filtered through a short pad of celite to remove LiCl and the solvent removed in vacuo. Three compounds were detected in the NMR spectrum of the crude product: (*S*,*Sp*)-**38**, **39** and (*S*,*Sp*)-**40** in a 31:20:49 ratio. The crude product was purified by column chromatography (aluminium oxide; diethyl ether/hexane, 1:7). Only (*S*,*Sp*)-**40** was isolated and further purified by column chromatography on silica gel. Yield yellow crystals (0.64 g, 22%). Crystals suitable for X-ray analysis were grown by slow diffusion of hexane into a solution of the complex in diethyl ether at –30 °C. $^1$H NMR (200 MHz, $C_6D_6$): $\delta$ = 0.85 (d, $J$ = 6.3 Hz, 3 H, α-Me), 1.69 (s, 6 H, N*Me*$_2$), 2.59 (s, 3 H, O*Me*), 3.87 (d, $J$ = 7.3 Hz, 1 H, $H_{Ar}$), 4.20 (d, $J$ = 7.3 Hz, 1 H, $H_{Ar}$), 4.83 (m, 1 H, α-C*H*), 4.97 (t, $J$ = 7.3 Hz, 1 H, $H_{Ar}$), 7.07–7.31 (m, 8 H, $H_{PPh_2}$), 7.79 (t, $J$ = 8.3 Hz, 2 H, $H_{PPh_2}$) ppm. $^{13}$C NMR (125 MHz, $CDCl_3$): $\delta$ = 5.80 (α-Me), 38.03 (N*Me*$_2$), 54.51 (O*Me*), 58.88 (d, $J_{C,P}$ = 22.1 Hz, α-*C*H), 71.48 ($C_{Ar}$), 82.47 ($C_{Ar}$), 94.03 ($C_{Ar}$), 121.98 (d, $J_{C,P}$ = 8.6 Hz, $C_{Ar,ipso}$), 123.60 (d, $J_{C,P}$ = 25.9 Hz, $C_{Ar,ipso}$), 127.41–135.83 (10 C, $C_{PPh_2}$), 137.60 (d, $J_{C,P}$ = 14.2 Hz, 1 C, $C_{PPh_2}$), 139.90 (d, $J_{C,P}$ = 6.5 Hz, 1 C, $C_{PPh_2}$), 146.80 ($C_{Ar,ipso}$), 233.24 (*C*O) ppm. $^{31}$P NMR (81 MHz, $C_6D_6$): $\delta$ = –10.70 ppm. IR (hexane): $\nu_{CO}$ = 1971, 1903 cm$^{-1}$.

**X-ray Structure Determination:** Crystal data and details of the structure determinations are listed in Tables 5 and 6. Data collection was performed with a Bruker Smart CCD (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, graphite monochromator) fitted with an area detector for (*S*,*Sp*)-**28**, (*S*,*Rp*)-**30**, (*S*)-**33**, and (*S*,*Sp*)-**40** and an Enraf Nonius CAD4 diffractometer (Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, graphite monochromator) for (*S*,*Rp*)-**23b**, (*S*,*Sp*)-**36**, (*S*,*Sp*)-**37** and (*S*,*Sp*)-**38**. The unit-cell parameters were obtained by least-squares refinement of up to 8096 reflections for the area detector and 25 reflections for the CAD4 point detector. The structures were solved by direct methods (SHELXS-97)[29] and refined by full-matrix least-squares procedures based on $F^2$ with all measured reflections (SHELXL-97).[29] The SADABS[30] program was used for absorption correction of the structures. All non-hydrogen atoms were refined anisotropically. All H-atoms were introduced at their idealised positions and were refined using a riding model. The absolute configuration was confirmed by evaluation of the Flack[31] parameter. Displacement ellipsoid plots were obtained with PLATON.[32]

# Structure and Photochemical Isomerization of the Dinuclear Gold(I) Halide Bis(diphenylphosphanyl)ethylene Complexes: Correlation Between Quantum Yield and Aurophilicity

**Janet B. Foley,*[a] Stanley E. Gay,[b] Michael J. Vela,[c] Bruce M. Foxman,[c] Alice E. Bruce,[b] and Mitchell R. M. Bruce*[b]**

**Keywords:** Aurophilicity / Metal–metal interactions / Gold / Photochemistry / Olefin isomerization / Quantum yield

The crystal structures for *cis*-$(Ph_2PCH{=}CHPPh_2)(AuI)_2$ and *trans*-$(Ph_2PCH{=}CHPPh_2)(AuI)_2$ are reported. The structure of *cis*-$(Ph_2PCH{=}CHPPh_2)(AuI)_2$ reveals a short intramolecular Au–Au distance of 2.9526(5) Å, while the structure of *trans*-$(Ph_2PCH{=}CHPPh_2)(AuI)_2$ shows intermolecular Au–Au distances of 3.2292(7) Å. Structural data for the iodide complexes are compared to previously reported crystal structural data for *cis*- and *trans*-$(Ph_2PCH{=}CHPPh_2)(AuCl)_2$ and dppbz$(AuCl)_2$. The quantum yields for the photochemical isomerization of *cis*-$(Ph_2PCH{=}CHPPh_2)(AuX)_2$ with 334-nm light, $\Phi(_{cis\rightarrow trans})$, are 0.204, 0.269, and 0.363 for X = Cl, Br, and I, respectively. Prior results from ab initio calculations on the model *cis*- and *trans*-$Au_2X_2C_2H_2(PH_2)_2$ complexes aid in the interpretation of the correlation between the quantum yield for isomerization and the calculated aurophilic attraction potential $V(R_e)$.

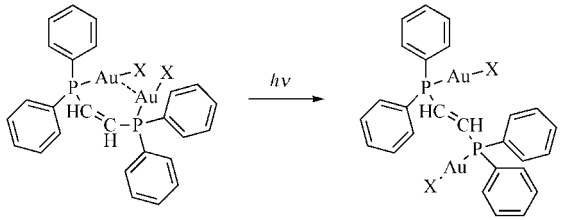
## Introduction

In the 1980s, the X-ray structures of the *cis*- and *trans* isomers of dppee$(AuCl)_2$ (dppee: $Ph_2PCH{=}CHPPh_2$) were reported by Jones,[1] and Eggleston, McArdle, and Zuber,[2] respectively. The crystal structure of *cis*-dppee$(AuCl)_2$ ($\mathbf{1}_{cis}$) reveals short intramolecular Au–Au interactions of 3.05(1) Å, whereas *trans*-dppee$(AuCl)_2$ ($\mathbf{1}_{trans}$) shows only intermolecular Au–Au interactions of 3.043(1) Å. In the structure for $\mathbf{1}_{cis}$ reported in 1980, Jones comments that "radiation damage, the exact nature of which is uncertain, causes the cell constants to increase." Subsequently, it was shown by Foley et. al that the series of *cis* complexes involving X = Cl, Br, I, and thiolate [Equation (1)] are photochemically reactive in solution, which results in a clean isomerization to the *trans* isomers.[3] In addition, the *cis* complexes show changes in crystal morphology upon exposure to room light, which suggests the interesting possibility of solid-state photochemical reactivity,[4] consistent with Jones' observations noted above.



$\mathbf{1}_{cis}$ (X = Cl)
$\mathbf{2}_{cis}$ (X = Br)
$\mathbf{3}_{cis}$ (X = I)

$\mathbf{1}_{trans}$ (X = Cl)
$\mathbf{2}_{trans}$ (X = Br)
$\mathbf{3}_{trans}$ (X = I) (1)

The photochemical conversions depicted in Equation (1) are rapid and efficient. For example, photolysis of a 2.1 mM solution of *cis*-(dppee)$(AuI)_2$ in $CDCl_3$ with a 300 W Hg arc lamp ($\lambda \geq 320$ nm) results in complete conversion of the *cis* isomer to the *trans* isomer within 3 min [as monitored by $^{31}P(^1H)$ NMR spectroscopy].[3] The quantum yields for isomerization of $\mathbf{1}_{cis}$–$\mathbf{3}_{cis}$ to the respective *trans* complexes were estimated to be greater than 0.1, and control reactions establish that the isomerization process is not thermally activated.

In contrast, the free *cis*- and *trans*-dppee ligands do not undergo photochemical isomerization under similar conditions or when light of higher energy ($\lambda \geq 220$ nm) is used.[3] In addition, the *trans*-dppee gold complexes $\mathbf{1}_{trans}$–$\mathbf{3}_{trans}$ do not photochemically convert into the *cis*-dppee gold complexes. The photochemical reactivity of $\mathbf{3}_{trans}$ appears to be limited to a decomposition pathway that is consistent with release of $I_2$.[4]

The *cis*- and *trans*-dppee ligands have been used extensively to prepare metal complexes, and examples are reported for nearly every transition metal.[5] In addition, there are a few reports of thermal isomerization processes involving dppee. For example, *cis*-dppee isomerizes to *trans*-dppee in the presence of $GaBr_3$, $GaCl_3$, and $AlBr_3$ at elevated temperatures in a catalytic process that is correlated with Lewis acidity.[6] The *cis*-dppee disulfide and *cis*-dppee dioxide also thermally isomerize to the *trans* isomers in refluxing thf in the presence of $PCl_3$.[7] However, photochemical reactivity for dppee is rare, and to date, as far we are aware the photoisomerization of dppee has been reported only for the gold(I) complexes $\mathbf{1}_{cis}$–$\mathbf{3}_{cis}$. These observations suggest a pivotal role for gold atoms in photoisomerization. In this report, we present the crystal structures for $\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$, details of the quantum yield measurements for the photoisomerization reactions of $\mathbf{1}_{cis}$–$\mathbf{3}_{cis}$ to $\mathbf{1}_{trans}$–$\mathbf{3}_{trans}$, and the correlation between quantum yield and aurophilicity.[8]

## Results and Discussion

### Structural Characterization of $3_{cis}$ and $3_{trans}$ Complexes

Selected bond lengths and angles for $\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$ are presented in Tables 1, 2, and 3, and ORTEP diagrams are shown in Figure 1. In both $\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$, the dppee ligands bridge two gold atoms and the Au–P (average = 2.25 Å) and Au–I (average = 2.55 Å) bond lengths are typical for gold(I).[9–13] The P–Au–I angles are approximately linear.

Table 1. Selected bond lengths [Å] and angles [°] for compound $\mathbf{3}_{cis}$.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Au1–Au2 | 2.9526(5) | Au1–I1 | 2.5629(9) |
| Au1–P1 | 2.256(3) | Au2–I2 | 2.5385(9) |
| Au2–P2 | 2.253(2) | P1–C1 | 1.81(1) |
| P1–C11 | 1.81(1) | P1–C31 | 1.82(1) |
| P2–C2 | 1.831(11) | P2–C21 | 1.82(1) |
| P2–C41 | 1.832(9) | C1–C2 | 1.332(14) |
| **Bond Angles [°]** | | | |
| Au2–Au1–I1 | 90.24(2) | Au1–P1–C31 | 112.8(4) |
| Au2–Au1–P1 | 94.21(6) | C1–P1–C31 | 98.9(5) |
| I1–Au1–P1 | 174.80(7) | C11–P1–C31 | 107.6(4) |
| Au1–Au2–I2 | 105.40(3) | Au2–P2–C2 | 115.1(3) |
| Au1–Au2–P2 | 82.30(6) | Au2–P2–C21 | 116.3(3) |
| I2–Au2–P2 | 170.36(7) | C2–P2–C21 | 105.0(5) |
| Au1–P1–C1 | 119.1(3) | Au2–P2–C41 | 110.2(3) |
| Au1–P1–C11 | 113.3(3) | C2–P2–C41 | 102.0(4) |
| C1–P1–C11 | 103.7(5) | C21–P2–C41 | 106.9(4) |

In $\mathbf{3}_{cis}$, the *cis* orientation of the rigid phosphane ligand promotes formation of an intramolecular Au–Au bond of 2.9526(5) Å. The Au–Au distance in $\mathbf{3}_{cis}$ is 0.1 Å shorter than that found in the related complex $\mathbf{1}_{cis}$ and 0.05 Å shorter than the intramolecular Au–Au distance in the *cis*-dppbz$(AuCl)_2$[14] (Table 3). These distances all fall within the accepted values for aurophilic interactions, which range from 2.8 Å (strong interaction) to 3.5 Å (weak interaction).[15] The two P–Au–I arms in $\mathbf{3}_{cis}$ "cross" at the Au centers with an I–Au···Au–I torsion angle of 63.61°. The structure of $\mathbf{3}_{trans}$ is very similar to that reported for the related complex $\mathbf{1}_{trans}$.[2] Both crystallize in the centrosymmetric space group *C*2/*c* with an inversion center at the midpoint of the ethylene backbone. Only one half of each *trans* molecule is crystallographically unique. In $\mathbf{3}_{trans}$, a partially disordered dichloromethane molecule is also present. The intermolecular Au–Au interactions in $\mathbf{3}_{trans}$ [3.2292(7) Å] are 0.19 Å longer than in $\mathbf{1}_{trans}$.

Table 2. Selected bond lengths [Å] and angles [°] for compound $\mathbf{3}_{trans}$.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Au1–Au1 | 3.2292(7) | Au1–I1 | 2.5435(8) |
| Au1–P1 | 2.250(2) | P1–C1 | 1.811(9) |
| P1–C2 | 1.812(9) | P1–C8 | 1.796(9) |
| C1–C1 | 1.309(17) | | |
| **Bond Angles [°]** | | | |
| Au1–Au1–I1 | 83.51(2) | C1–P1–C2 | 104.1(4) |
| Au1–Au1–P1 | 101.42(6) | Au1–P1–C8 | 115.9(3) |
| I1–Au1–P1 | 174.81(6) | C1–P1–C8 | 103.7(4) |
| Au1–P1–C1 | 113.3(3) | C2–P1–C8 | 104.4(4) |
| Au1–P1–C2 | 114.1(3) | P1–C1–C1 | 123.5(9) |

### Electronic Spectra of dppee Gold Complexes and Quantum Yield Measurements

The *cis*- and *trans*-dppee$(AuX)_2$ complexes (X = Cl, Br, I) exhibit featureless, broad absorptions above 300 nm. The bands for each *cis* complex are slightly redshifted relative to that of its *trans* isomer. Quantum yield measurements were carried out at 334 nm where the molar absorptivities of the *cis* complexes range from $0.9–3.0 \times 10^3\ M^{-1}\,cm^{-1}$ and those of the *trans* complexes are near zero.[3] The quantum yields for disappearance, $\Phi_{disappearance}$, of the *cis*-dppee$(AuX)_2$ complexes measured at 334 nm are: $\Phi(\mathbf{1}_{cis,disappearance}) = 0.204 \pm 0.062$; $\Phi(\mathbf{2}_{cis,disappearance}) = 0.269 \pm 0.092$; $\Phi(\mathbf{3}_{cis,disappearance}) = 0.363 \pm 0.055$. Because

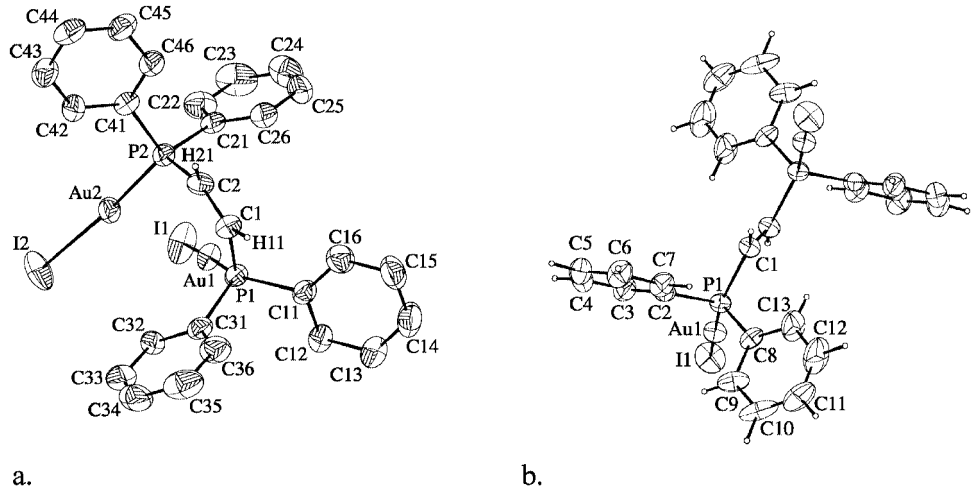

Figure 1. ORTEP drawings of a) $\mathbf{3}_{cis}$ and b) $\mathbf{3}_{trans}$ at the 50% probability level.

the photochemical isomerization processes are clean and appear to be irreversible, the quantum yields are reasonable estimates of the relative photoefficiencies of the *cis* to *trans* isomerizations, e.g. $\Phi(\mathbf{1}_{cis,\text{disappearance}}) = \Phi(\mathbf{1}_{cis} \rightarrow \mathbf{1}_{trans})$.

It is interesting to note that the increase in quantum yield in this series is correlated with an increase in the aurophilic attraction potential[16] (Figure 2). The quantum yield is also correlated with a decrease in electronegativity of the halide ligand X[16] (not shown). Both correlations give linear correlation coefficients above 0.99. The aurophilic attraction potential is a measure of the energy of interaction between a dimer and a pair of monomers and has been calculated[16] as well as estimated experimentally. Experimental values for the aurophilic attraction potential, $V(R_e)$, have been reported in the range 29–42 kJ mol$^{-1}$.[15,17–22] The ligand dependence on aurophilic attraction has been studied on the interacting, perpendicular X–Au–$PH_3$ monomer by using 19-valence electron quasirelativistic pseudopotentials for gold.[16] The study estimates that in interacting X–Au–$PH_3$ monomers, the aurophilic potentials, $V(R_e)$, are 16.7, 19.3, and 22.5 kJmol$^{-1}$ for X = Cl, Br, and I, respectively. Thus, the aurophilic potential increases as the electronegativity of X decreases.

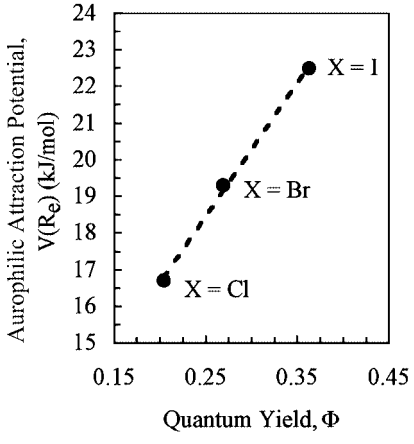

Figure 2. Correlation between aurophilic attraction potential[14] and quantum yield for isomerization of $\mathbf{1}$–$\mathbf{3}_{cis}$ to $\mathbf{1}$–$\mathbf{3}_{trans}$.

## Photochemical Isomerization of Alkenes – Direct and Photosensitized

The direct and triplet sensitized photochemical isomerization of alkenes and polyenes has been extensively studied and reviewed. The ground state of the *cis* olefin is usually slightly higher in energy than that of the *trans* isomer, and photochemical processes have been shown to proceed through either discrete singlet or triplet pathways. For many organic dienes, e.g. stilbenes or 1,2-diphenylpropenes, photoisomerization originating from either the *cis* or *trans* isomer produces a photostationary state as a result of direct photolysis or photolysis with the addition of a triplet sensitizer.[23]

While the molar absorptivity of the two isomers at a particular wavelength affects the direct population of the *cis** and *trans** excited states, it is the shape of the excited state potential surface that is often critical for understanding the mechanism and photoefficiency of isomerization.[24–29] The research of Hammond and coworkers in the 1960s laid the groundwork for an explosion of interest in this field by illustrating how suitable photosensitizers could be used to understand reactivity that ensues after photoexcitation.[28]

To explain the basic photochemical phenomena, we have included Figure 3, which shows *cis* and *trans* olefin ground states, and an excited state potential surface reached by photoexcitation. This is a generic diagram similar to many diagrams used to discuss olefin photoisomerization,[26–28] and precise details of energy changes of the ground state as a function of olefin twist angle have been omitted. Excitation, according to the Franck–Condon principle, produces vertical transitions and initial excited states possess identical geometries as in the ground state. Three critical points are important to keep in mind: (a) excitation of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

either isomer populates a common potential surface, (b) the energy of the excited state is a function of the degree of olefin twist, and (c) deactivation pathways (e.g. thermal relaxation, luminescence) as well as the lifetime of the excited state dictate how far the excited state travels along the excited state potential surface. The excited state perpendicular geometry, *p**, with a twist angle of 90° may be thought of ideally as the state from which it is equally possible to convert to either isomer (see Figure 3). In the diagram in Figure 3, the excited states *trans** or *p** occur at local minima while *cis** is found at a transient position. However, the actual shape of the process under consideration varies and has a significant effect on the ensuing chemistry.

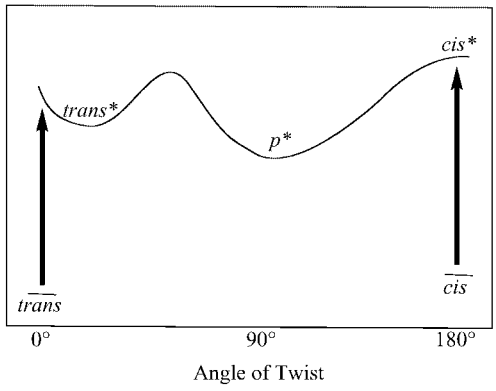

Figure 3. Relative energy of ground and excited states as a function of the angle of twist around the C–C olefin bond.

We may also consider photolysis of a system that contains a photosensitizer. In this case, photolysis produces an excited state sensitizer that must either become covalently attached or is pre-complexed to the olefin in order for photoisomerization to occur. Examples of sensitizers in both categories exist. In order for the sensitizer to influence the olefin, energy transfer must occur. If the excited state lifetimes are short compared to processes involving rotation about the carbon–carbon double bond or if rotation is hindered, the excited state will undoubtedly relax with little or no photoisomerization. However, if the lifetime is sufficiently long for either a system involving a sensitizer or for direct photolysis of an olefin, then the shape of the excited state potential surface and the energy available to the excited state complexes will dictate the process that occurs.

### The Photochemical Process and Quantum Efficiency

To consider why the quantum yield for photoisomerization of $\mathbf{1}_{cis}$–$\mathbf{3}_{cis}$ is correlated with the aurophilic potential, it is useful to consider the overall photoisomerization as occurring in distinct steps involving absorption of a photon by a ground state molecule, the creation of an excited state complex, rotation about the C=C bond, and relaxation to various isomers. The gold complexes may be thought of as an assembly involving a chromophore (X–Au) that is covalently attached to the olefin through phosphorus atoms in the dppee ligand [see Equation (1)]. Thus, the ground state, excited state, and mixing of X, Au, and C=C orbitals all play important roles in the observed photoisomerization reaction.

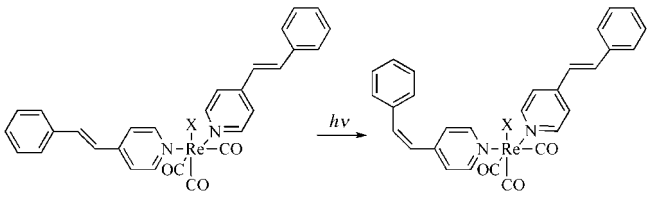
Ab initio MP2 calculations on the model complexes *cis*- and *trans*-$Au_2X_2C_2H_2(PH_2)_2$ were previously reported and the excited states were investigated by the CIS (configuration interaction with single excitations only) and CAS-LMP2 procedures.[30] The results show that in the *cis* compounds the degree of aurophilic interaction increases with an increase in the softness of the ligand. Thus, $\mathbf{3}_{cis}$ would be expected to have a greater aurophilic interaction than $\mathbf{1}_{cis}$. The aurophilic interactions stabilize the ground state of the *cis* complexes relative to that of the *trans* complexes. In addition, the aurophilic interactions stabilize the first excited state, which leads to a red shift and an increased transition moment for the *cis* complexes, in contrast to that observed for the *trans* complexes. While the overall effect lowers the energy needed for promotion into the first excited state of the $\mathbf{1}_{cis}$–$\mathbf{3}_{cis}$ complexes (i.e. the red shift), it does not explain the increase in photoefficiency, since quantum yield measures the ratio of the number of *cis* molecules that isomerize relative to those that absorb light, regardless of what the energy gap is at 334 nm.

The stabilization of the first excited state was found to be critically dependent on the intramolecular Au–Au distance. The CIS calculations produce results that suggest that the HOMO–LUMO transitions (as well as the first few singlet excitations) are primarily halide to gold [Au(5d6s6p)] charge transfer transitions. However, there were significant admixtures from a variety of other orbitals. For both the *cis* and *trans* complexes, phosphorus p orbital character is found in the LUMO orbitals. In addition, for the *cis* complexes, the HOMO has some gold character, and in the LUMO, there is significant ethylene π* character. Population of an orbital with ethylene π* character in the *cis* complexes would be predicted to weaken the carbon–carbon double bond. The shorter Au–Au bond length in $\mathbf{3}_{cis}$ than in $\mathbf{1}_{cis}$ may indicate a higher degree of aurophilic interaction. Although the ab initio calculations do not easily permit quantification of orbital mixing, it seems reasonable to suggest that the aurophilic interaction in the *cis* complexes facilitates mixing of ethylene π* character in the excited states. Thus, it may be inferred that $\mathbf{3}_{cis}$ would have a greater degree of ethylene π* character in the excited state than $\mathbf{1}_{cis}$.

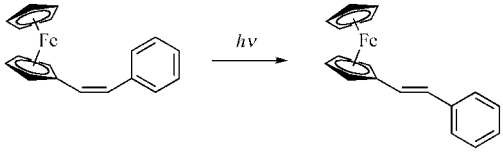
The relatively high quantum yield for photoisomerization of $\mathbf{1}_{cis}$–$\mathbf{3}_{cis}$ suggests that the HOMO–LUMO transition directly populates an orbital with sufficient ethylene π* character to weaken the C=C bond and permit rotation. Our results can be compared to the $ReX(CO)_3L_2$ complexes {see [Equation (2)]; X = Cl, Br; L = *trans*-4-styrylpyridine} whose IL transitions involve a spin-allowed π–π* transition, which directly weakens the C=C bond, permitting rotation and high quantum yields ($\Phi$ = 0.49–0.64). In this case, the quantum yields are very similar to that of the free ligand.[31] In contrast, the quantum yield for photoisomerzation of *cis*-styrylferrocene [Equation (3)] is ca. 0.001. The inef-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ficiency of this isomerization is attributed to rapid deactivation of the triplet *cis* excited state by the heavy atom effect.[26,32]



(2)



(3)

We are continuing to explore the correlation between quantum yield and aurophilic potential as a function of the ligands attached to gold. Preliminary results indicate that substitution of thiolate ligands for halides increases the photoefficiency, while substitution of arsenic for phosphorus in dppee decreases the photoefficiency.

## Summary

The crystal structure of the *cis*-$(AuI)_2$dppee shows a shorter gold–gold distance than the analogous chloride and bromide complexes. This is consistent with the assertion, made by Pyykkö and others, that soft ligands should increase the gold–gold interaction. We have demonstrated that the quantum yield for the photoisomerization of *cis*-$(AuX)_2$dppee to the *trans*-$(AuX)_2$dppee [X = Cl($\Phi$ = 0.204); Br($\Phi$ = 0.269); I($\Phi$ = 0.363)] increases as the aurophilic attraction potential increases. We suggest that the increase in quantum yield is indicative of increased ethylene π* character in the first excited state of the iodide complex ($\mathbf{3}_{cis}$) relative to that in the chloride complex ($\mathbf{1}_{cis}$). This experimental approach allows a quantitative comparison of the effect of different ligands on the strength of gold–gold interactions.

## Experimental Section

**General Procedures:** Methylene chloride (spectral grade) was obtained from Aldrich and used as received. Complexes $\mathbf{1}_{cis}$–$\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$ were synthesized and purified as previously reported.[3,4] The following abbreviations are used: dppee = 1,2-bis(diphenylphosphanyl)ethylene; dppbz = 1,2-bis(diphenylphosphanyl)benzene.

**Quantum Yield Measurements:** A 200-W Oriel mercury arc lamp was used for quantum yield measurements. The wavelengths for the experiments were isolated by using a model 77250 Oriel monochrometer with 6-mm gratings. Ferrioxalate actinometry was used for determining lamp flux for quantum yield calculations.[33] The flux for the 200-W lamp had an average value of $6.12 \times 10^{15}$ photons/Ls. Gold(I) complexes were dissolved in dichloromethane, and the solutions were protected from light while transferring them to a dark room for quantum yield experiments. No attempts were made to exclude oxygen from the solutions. Previous studies confirmed that the presence of oxygen does not affect the photochemical isomerization reaction.[4] Solutions were irradiated at room temperature in 1-cm quartz cells and were stirred during irradiation. Absolute quantum yield measurements for the *cis* to *trans* isomerization were made by monitoring the decrease in absorbance for the *cis* complexes at 334 nm (X = I, Br, Cl). Absorbances were measured by using a Beckman DU spectrophotometer. Quantum yield measurements were replicated 4–6 times for each complex.

**Crystal Structure Determination:** Details of the X-ray experiments and crystal data for $\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$ are summarized in Table 4. Crystals of $\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$ were grown from $CH_2Cl_2$/$Et_2O$. Crystals of $\mathbf{3}_{trans}$ turned opaque when exposed to the atmosphere owing to loss of solvent, and no longer diffract X-rays. In order to prevent loss of solvent, crystals of $\mathbf{3}_{trans}$ were coated with a thin film of epoxy. Crystals of $\mathbf{3}_{cis}$ did not require any special treatment.

Table 4. Crystallographic data for compounds $\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$·$2CH_2Cl_2$.

| | $\mathbf{3}_{cis}$ | $\mathbf{3}_{trans}$·$2CH_2Cl_2$ |
|---|---|---|
| Chemical formula | $C_{26}H_{22}Au_2I_2P_2$ | $C_{28}H_{26}Au_2Cl_4I_2P_2$ |

| *a* [Å] | 12.6165(15) | 11.7391(14) |
| *b* [Å] | 14.505(1) | 20.3363(16) |
| *c* [Å] | 15.2955(9) | 15.634(3) |
| $\beta$ [°] | 103.457(7) | 108.255(17) |
| *V* [Å$^3$] | 2722.3(4) | 3544.6(9) |
| *Z* | 4 | 4 |
| *T* [°C] | 21 | 21 |
| $\lambda$ [Å] | 0.71073 | 0.71073 |
| $\rho_{calcd.}$ [g cm$^{-1}$] | 2.547 | 2.267 |
| $\mu$ [cm$^{-1}$] | 13.164 | 10.419 |
| *R*[a] | 0.0476 | 0.0380 |
| $R_w$[b] | 0.0548 | 0.0379 |

[a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$. [b] $R_w = [\Sigma w(|F_o| - |F_c|)^2/\Sigma w|F_o|^2]^{1/2}$.

Data on $\mathbf{3}_{cis}$ and $\mathbf{3}_{trans}$ were collected with an Enraf–Nonius CAD4-Turbo diffractometer at Brandeis University by using the Enraf–Nonius EXPRESS program with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The structures were solved by direct methods by using SHELXS-86 and refined with the Oxford CRYSTALS package. Drawings were made (50% probability ellipsoids) with the Oxford CAMERON program. All non-hydrogen atoms were located from successive difference-Fourier syntheses for both structures. Final refinement of positional and anisotropic displacement parameters for all non-hydrogen atoms in compound $\mathbf{3}_{cis}$ led to $R$ = 0.0476 and $R_w$ = 0.0548 by using 4602 data for which $I > 1.96\sigma(I)$. For compound $\mathbf{3}_{trans}$, final refinement of positional and isotropic displacement parameters for all non-hydrogen atoms [anisotropic displacement parameters for Au, P, I, C(1), C(2), and C(8), a total of 77 parameters] led to $R$ = 0.0380 and $R_w$ = 0.0379 by using 2272 data for which $I > 1.96\sigma(I)$. Attempts to refine all non-hydrogen atoms by using anisotropic displacement parameters led to unsatisfactory values. Hence the non-*ipso* carbon atoms in each of the phenyl rings were refined by using isotropic displacement parameters. The hydrogen atoms were placed in calculated positions ($d_{C-H}$ = 0.95 Å) in both structures.

For the solvent molecule present in $\mathbf{3}_{trans}$, only atom Cl(1) was refined by using an anisotropic displacement parameter, while the other atoms in the solvent molecule were refined by using isotropic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

displacement parameters. The $CH_2Cl_2$ solvent was found to be partially disordered over two sites with the major component occupancy equal to 0.67(2). The Cl–C distances and the Cl–C–Cl angles were restrained to be at 1.75(5) Å and 111.0(5)°. Occupancy constraints were also applied to the disordered atoms in the solvent molecule.

**Supplementary Crystallographic Data:** CCDC-646580 and -646581 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.ac.uk/data_request/cif.

# $Ge_6Me_{12}$ and $Ge_6H_{12}$ Cyclohexagermanes: Conformer Equilibria Studied by Raman Spectroscopy and Quantum Chemical Calculations

**Margit Hölbling,[a] Michaela Flock,[a] Judith Baumgartner,[a] and Karl Hassler*[a]**

**Keywords:** Cyclohexagermanes / Conformational analysis / Raman spectroscopy / X-ray structure / Ab initio calculations

In the first experimental study of rotational isomerism of a compound possessing a fourth row element backbone, the totally symmetric Ge–Ge stretching mode of dodecamethylcyclohexagermane ($Ge_6Me_{12}$), which is the most intense Raman band in the range 200–300 $cm^{-1}$, was analyzed with temperature-dependent vibrational Raman spectroscopy in both the crystalline and solution states. Below 50 °C, the Raman spectrum of the solid shows a single band at 232 $cm^{-1}$ originating from the chair conformer. Between 50 and 60 °C, a shoulder at 227 $cm^{-1}$ appears, which is associated with a twisted conformer. In solution, the band attributed to the chair conformer displays a shoulder arising from an averaged twist/boat conformer, even at –80 °C. The intensity of the shoulder increases with temperature. By using the van't Hoff relationship, an enthalpy difference of 2.4 kJ $mol^{-1}$ between chair and twist/boat conformers was obtained. An improved X-ray crystal structure of $Ge_6Me_{12}$ was also obtained, and an average Ge–Ge bond length of 242 pm was found, about 5 pm longer than previously reported. With the help of quantum chemical DFT and MP2 calculations, the geometries and energies of the conformers of $Ge_6Me_{12}$ and of the parent $Ge_6H_{12}$ compound were investigated thoroughly by employing 6-31+G*, D95V and aug-cc-pVTZ basis sets, as well as SDD and aug-cc-pVTZ-PP pseudopotentials on the Ge atoms. B3LYP/aug-cc-pVTZ calculations predict two conformers for $Ge_6H_{12}$, chair and twist, with zero-point vibrational energy (ZPVE) corrected relative energies of 0.0 and 5.7 kJ $mol^{-1}$, respectively. They predict three conformers, chair (0.0), twist (5.2) and boat (9.2), for $Ge_6Me_{12}$. They also give reasonable geometry parameters, relative energies and barriers for the conformer interconversion.

## Introduction

In the early days of stereochemistry, which at the time was essentially carbon chemistry, it was assumed that rotation about single bonds was free. Yet by the middle of the third decade of the twentieth century, the idea that rotation around the C–C bond in ethane and related carbon compounds was not free had been widely accepted. In 1936, Kemp and Pitzer[1] calculated the barrier for the internal rotation in ethane to be 13.2 kJ $mol^{-1}$ from entropy data, a value which is very similar (±10%) to the most recent results (12.1–12.3 kJ $mol^{-1}$).[2] About forty years later, the barrier for disilane, $Si_2H_6$, was determined to be 5.1 kJ $mol^{-1}$.[3] The barrier for $Ge_2H_6$ was estimated with the aid of vibrational spectroscopy to be about 6 kJ $mol^{-1}$.[4] However, no experimental data for $Sn_2H_6$ and $Pb_2H_6$ are available as they have not even been prepared.

With the availability of quantum chemical calculations, the origin of these barriers could be investigated. Schleyer et al. analyzed the barriers for $X_2H_6$ (X = C, Si, Ge, Sn and Pb) in detail.[5] In the natural bond orbital (NBO) picture, the stabilizing vicinal σ(XH)→σ*(XH) delocalization is responsible for the more stable staggered rather than eclipsed conformation, and decreased overlap due to longer X–X bonds is responsible for the smaller rotational barriers of the heavier species.[5] These results contradict the long and widely held belief that the steric repulsion of X–H bonds is responsible for hindered rotation. The debate is ongoing; for instance a more recent ab initio valence bond (VB) study by Mo et al. [HF/6-31G(d) and HF/6-311G(d,p)] reinstated that the barrier for ethane and its congeners is overwhelmingly dominated by steric repulsion.[2a–2d]

In disubstituted ethane-like molecules such as $FH_2XXH_2F$, the conformer stabilities are influenced by the relative magnitudes of σ(XH) and σ(XF) delocalization into the antibonding σ*(XH) and σ*(XF) orbitals. For instance, in $FH_2CCH_2F$, the gauche form is preferred even in the gas phase, despite the repulsive dipole–dipole interactions.

Of course, steric effects due to the increasing size of the pendant groups will increasingly dominate the conformational potential. While conformer stabilities and equilibria due to hindered rotation about C–C bonds have been determined for a huge number of compounds and various pendant groups, experimental data for Si–Si bonds remain

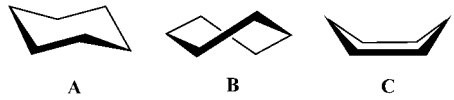
scarce.[6] Generally, not only barrier heights but also energy differences between conformers decrease from carbon- to silicon-containing molecules, and this is accompanied by a considerable decrease in the conformer mean lifetimes. The increased rate constants for conformer interconversion make NMR spectroscopy − so successful in organic chemistry − an inadequate method for the monitoring of many silicon compounds. The NMR time scale of $10^{-1}$ to $10^{-9}$ seconds demands temperatures as low as –160 °C or lower to slow down reaction rates sufficiently for conformer observation. For instance, the splitting of the $^{13}C$ resonances of the methyl groups of $Si_6Me_{12}$ as a result of them being in axial and equatorial positions was observed at –165 °C, and a ring inversion barrier of ca. 20 kJ mol$^{-1}$ was deduced. However, the signals were barely detectable due to low solubility.[7]

So far, no experimental studies of hindered rotation about Ge–Ge, Sn–Sn or Pb–Pb bonds have been reported in the literature. Surely NMR spectroscopy is not a suitable method for exploring these systems, and the question arises whether vibrational spectroscopy, possessing a time scale which on average is six orders of magnitudes smaller (about $10^{-13}$ seconds) than that of NMR spectroscopy, might be able to resolve these fast processes. If vibrational transitions originating from two different conformers are separated by 10 cm$^{-1}$ or by a frequency difference $\Delta\nu$ of $3 \times 10^{11}$ Hz, the lifetime of the conformers has to be longer than $\Delta\nu^{-1}$ to give resolved vibrational spectra. By using the theory of the activated complex, a barrier height of about 4 kJ mol$^{-1}$ or larger is estimated for this to occur at 300 K.[8,9] Alternatively, it can be argued that the barrier must be noticeably larger than the Boltzmann energy *RT*, which is 2.5 kJ mol$^{-1}$ at 300 K.

Recent ab initio calculations for digermane predict a barrier of 3.1 to 3.6 kJ mol$^{-1}$; this result is dependent on the methods and basis sets that were used.[2b,10] These results support the expectation that the conformer equilibria of digermanes and oligogermanes will be borderline cases as far as the use of vibrational spectroscopy is concerned. We have therefore set out to investigate some germanes that are expected to possess at least two conformational minima on the potential energy surface (PES) by employing Raman spectroscopy combined with quantum chemical ab initio calculations. Here we report on cyclohexagermane studied by quantum chemical calculations and on dodecamethylcyclohexagermane studied by both theory and Raman spectroscopy. Results for 1,2-dichlorotetramethyldigermane, tetramethyldigermane, and hexamethyldigermane will be published elsewhere.[11]

We were led to choose $Ge_6Me_{12}$ because, by analogy with $C_6Me_{12}$ and $Si_6Me_{12}$, we expected the barriers for the chair-to-chair and chair-to-twist interconversions to be larger than the barrier in digermane itself. Dynamic NMR spectroscopic studies for $C_6Me_{12}$ and $Si_6Me_{12}$ gave barriers for the chair-to-chair interconversion of 70 kJ mol$^{-1}$ and 20 kJ mol$^{-1}$, respectively.[7,12] In two Raman spectroscopic studies of $Si_6Me_{12}$ and $Si_6Me_{11}X$ (X = H, F, Cl, Br and I), we were able to identify chair and twist conformers and to determine their enthalpy differences.[13,14] It turned out that boat conformations also represent minima for these cyclohexasilanes, and that the boat-to-twist interconversion is fast even on the timescale of Raman spectroscopy. Therefore, a three-conformer equilibrium between chair (**A**), twist (**B**) and boat (**C**) must also be expected for $Ge_6Me_{12}$.



Generally, reports of experimental studies of conformer equilibria for molecules composed of fourth or higher row elements (group 14: Ge, Sn, Pb; group 15: As, Sb, Bi; group 16: Se. Te) are virtually absent from the literature. To the best of our knowledge, group 14 and group 16 elements have not been studied at all. Of the group 15 elements, tetramethyldistibane has been examined by photoelectron spectroscopy, and the existence of *gauche* and *anti* conformers in the gas phase was observed. No enthalpy data or barrier heights were given.[15] A gas-phase electron diffraction study of tetrakis(trifluoromethyl)diarsane showed quite a different behaviour: only the trans conformer was present.[16]

## Results and Discussion

### Cyclohexagermane, $Ge_6H_{12}$

$Ge_6Me_{12}$ was prepared by known methods.[17] It is now well established by extensive calculations on $Ge_2H_6$ (and also $SiH_3GeH_3$) that experimental geometrical parameters are reproduced well at correlated levels by employing triple-zeta basis sets augmented with f polarization functions on the heavy atoms.[10b,18] The calculated Ge–Ge distance was 0.013 Å longer than the experimental value at the CISD/TZP(f) level. MP2 and DFT calculations, which may be used for larger molecules, performed satisfactorily in computing geometries and vibrational spectra. The Ge–Ge distances were longer than the experimental value by about 0.030–0.035 Å, and consequently, the barriers were generally about 10% too small.

DFT calculations for $Ge_6H_{12}$ employing the B3LYP functional and all-electron basis set 6-31+G* predict three conformers, chair, twist and boat, with relative energies of 0.0, 10.2 and 12.1 kJ mol$^{-1}$, respectively. DFT and MP2 calculations with SDD predict only two conformers, chair and twist, with relative energies of 4.4 and 4.2 kJ mol$^{-1}$, respectively. Finally, B3LYP/aug-cc-pVTZ calculations also led to two conformers, again chair and twist, with respective energies of 0.0 and 5.7 kJ mol$^{-1}$. The boat turned out to be a transition structure for the twist-to-twist interconversion with a relative energy of 6.4 kJ mol$^{-1}$.

We know from calculations of the ring inversion barriers of cyclohexasilanes $Si_6H_{12}$ and $Si_6Me_{12}$ that sofa and half-chair transition structures have almost the same energy.[13]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

To obtain a representative value for the barrier of $Ge_6H_{12}$, we calculated the energy of the sofa transition structure to be 10.0 kJ mol$^{-1}$, and we anticipated that it would not differ significantly from that of the half-chair. The energy profile for ring inversion at the B3LYP/aug-cc-pVTZ level is depicted in Figure 1. It is of some note that B3LYP/6-31+G* calculations gave an energy of 40 kJ mol$^{-1}$ for the half-chair transition structure, thus predicting a ring inversion barrier that is considerably larger than that found for $Si_6H_{12}$ (15 kJ mol$^{-1}$) and $Si_6Me_{12}$ (16 kJ mol$^{-1}$). This large value can be explained with the shorter Ge–Ge bonds and the much larger Ge–Ge–Ge–Ge dihedral angles (up to 70°) obtained by using nonrelativistic basis sets on the Ge atoms. Even when the small SDD quasi-relativistic basis set for Ge is used, this barrier is more appropriately estimated [7.4/7.6 kJ mol$^{-1}$ (DFT/MP2)]. However, the large-core effective core pseudopotential (ECP) in the SDD basis sets is known to result in bond lengths that are too long. The aug-cc-pVTZ basis set with the small-core ECP gives more accurate bond lengths. Nevertheless, it is obvious that relativistic effects in the Ge atom have to be taken into consideration, and to this purpose the ECP approximation seems to be satisfactory.

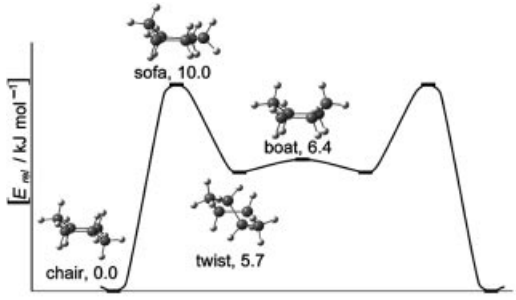


Figure 1. Calculated minima and transition structures of $Ge_6H_{12}$ at the B3LYP/aug-cc-pVTZ level of theory. All relative energies are ZPVE-corrected.

### Dodecamethylcyclohexagermane, $Ge_6Me_{12}$

#### *X-ray Structure Determination*

A first crystal structure of dodecamethylcyclohexagermane obtained at 298 K with $R$ = 0.131 was published in 1975; an average Ge–Ge bond length of 2.37 Å was reported.[19] In the present work, an improved structure ($R$ = 0.101) determined at 100(2) K is presented and is depicted in Figure 2.[20] The average Ge–Ge bond length is found to be 2.42 Å, which is 5 pm longer than that previously reported, whereas the Ge–Ge–Ge angles are the same. Other structural parameters do not differ significantly from the parameters determined for $Si_6Me_{12}$.[21] The average Ge–Ge–Ge–Ge dihedral angle is ±52.97°, the same as that in the silicon ring (53.4°). Further, the average Ge–Ge–Ge angle of 112.0° is only 0.1° smaller than the average Si–Si–Si angle of 111.9°.

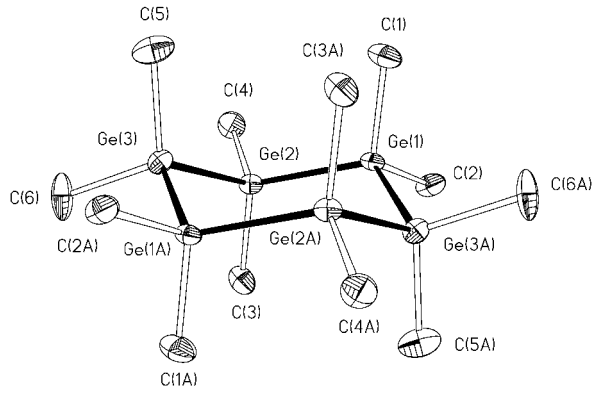

Figure 2. ORTEP plot (30% probability) of the molecular structure of $Ge_6Me_{12}$, including numbering of the atoms. Hydrogen atoms have been omitted for clarity. Selected bond lengths [Å] and bond angles [°] (with standard deviations): Ge(1)–Ge(2) 2.4094(19), Ge(1)–Ge(3A) 2.4242(17), Ge(2)–Ge(3) 2.4300(16), Ge(1)–C(1) 1.971(11), Ge(1)–C(2) 1.979(11), Ge(2)–C(3) 1.994(11), Ge(2)–C(4) 1.969(11), Ge(3)–C(5) 1.987(11), Ge(3)–C(6) 1.982(13), Ge(1)–Ge(2)–Ge(3) 111.13(6), Ge(2)–Ge(3)–Ge(1A) 111.56(6), Ge(2)–Ge(1)–Ge(3A) 113.32(6), C(1)–Ge(1)–Ge(2) 109.0(4), C(1)–Ge(1)–Ge(3A) 106.7(4), C(1)–Ge(1)–C(2) 108.4(5), C(1)–Ge(1)–Ge(2)–Ge(3) –65.2(4), C(2)–Ge(1)–Ge(2)–Ge(3) 177.0(3), Ge(3A)–Ge(1)–Ge(2)–Ge(3) 53.45(8), Ge(1)–Ge(2)–Ge(3)–Ge(1A) –52.49(8).

For comparison, the Ge–Ge bond length in $Ge_6Ph_{12}$ was determined to be 2.466 Å, and the dihedral angles to be 49.16° and –48.92° ($R$ = 7.1%, r.t.).[22] In $Ge_2Ph_6$, this bond length is 2.437 Å ($R$ = 3.3%, r.t.).[23] A shorter Ge–Ge bond of 2.419 Å was found in $Ph_3GeGeMe_3$ ($R$ = 3.6%, r.t.).[24] The longest Ge–Ge bond of 2.713 Å was detected in $Ge_2(t\text{Bu})_6$ ($R$ = 2.8%, r.t.).[25]

#### *Ab Initio Calculations*

As observed for $Ge_6H_{12}$, the optimized geometry parameters for $Ge_6Me_{12}$ also strongly depend on the basis sets employed. We will therefore present results for B3LYP/aug-cc-pVTZ calculations only. Additional results are summarized in the Supporting Information (Figure S1, Tables S1–S4). Three minima closely related to those of $Si_6Me_{12}$,[13] chair, twist and boat, with ZPVE-corrected relative energies of 0.0, 5.2 and 9.2 kJ mol$^{-1}$, respectively, were found. Table 1 summarizes the most important geometry parameters for the conformers of both $Ge_6Me_{12}$ and $Ge_6H_{12}$, including the wavenumbers and Raman intensities of the symmetric ring-breathing modes. As can be seen from Table 1, the calculations overestimate Ge–Ge bond lengths by about 5 pm relative to those obtained from the X-ray results, but agree reasonably well with experimental bond angles and dihedral angles.

In order to assign the vibrational spectra, calculations of the Raman and infrared intensities were also performed. In the range expected for Ge–Ge stretching vibrations between 200 and 300 cm$^{-1}$, where rotational isomerism is expected to show up most clearly, the symmetric Ge–Ge stretch possessing the smallest wavenumber (henceforth denoted as the ring-breathing mode) has by far the largest Raman intensity for all the conformers. Although the absolute wavenumbers

Table 1. Calculated relative energies, wavenumbers and Raman intensities of the ring-breathing modes, and selected geometry parameters for the conformers of $Ge_6H_{12}$ and $Ge_6Me_{12}$ obtained at the B3LYP/aug-cc-pVTZ level.

| | $Ge_6H_{12}$ | | $Ge_6Me_{12}$ | | |
|---|---|---|---|---|---|
| | Chair | Twist | Chair | Twist | Boat |
| $E_{rel}$ [kJ mol$^{-1}$] | 0.0 | 5.7 | 0.0 | 5.2 | 9.2 |
| $\nu_s$(Ge–Ge) [cm$^{-1}$] | 198.4 | 197.8 | 214.7 | 209.4 | 211.5 |
| Raman intensity [Å$^4$ amu$^{-1}$] | 51 | 52 | 18 | 16 | 14 |
| av. $r$(Ge–Ge) [Å] | 2.450 | 2.453 | 2.473 | 2.475 | 2.477 |
| av. ∠(Ge–Ge–Ge) [°] | 111.2 | 111.6 | 112.3 | 113.1 | 113.9 |
| av. ∠(Ge–Ge–Ge–Ge) [°] | ±55.5 | ±63.3/±30.5 | ±52.2 | ±57.5/±27.8 | ±0.1/±46.7 |

of the modes shift depend on the basis set and method used, the wavenumber differences between the various conformers remain almost constant. Table 1 includes the most important predictions, and further details of the calculations can be retrieved from the Supporting Information. As we will show shortly, the chair conformer can be distinguished experimentally from the twist and boat conformers by a close examination of the ring-breathing mode. It is noteworthy that the calculations also show that the $CH_3$-group vibrations $\nu_s$, $\nu_{as}$, $\delta_s$, $\delta_{as}$, $\rho(CH_3)$ and $\nu_s$, $\nu_{as}$, $\delta$, $\gamma$, $\tau$, $\rho(GeC_2)$ cannot be used for this purpose.

To estimate the ring inversion barrier of $Ge_6Me_{12}$, the energy of the half-chair structure was calculated at the B3LYP/SDD level to be 10.1 kJ mol$^{-1}$. For cyclohexasilanes it is known that the calculated barriers are almost the same for both $Si_6H_{12}$ (ca. 15 kJ mol$^{-1}$) and $Si_6Me_{12}$ (ca. 16 kJ mol$^{-1}$).[13,14,26] Therefore, a calculation at the aug-cc-pVTZ level was not performed for $Ge_6Me_{12}$ in the interest of conserving time (the barrier is 10.0 kJ mol$^{-1}$ for $Ge_6H_{12}$ at the B3LYP/aug-cc-pVTZ level). The predicted barrier for the twist-to-chair interconversion of about 10 kJ mol$^{-1}$ for $Ge_6Me_{12}$ is realistic when compared with $C_6Me_{12}$ (70 kJ mol$^{-1}$) and $Si_6Me_{12}$. This value is considerably larger than $RT$ (2.5 kJ mol$^{-1}$ at 300 K) and supports the expectation that the chair and twist conformers will give separate Raman spectra.

### *Solid-State Raman Spectra*

For $Si_6Me_{12}$, a phase transition in the solid state from a crystalline phase containing only the chair conformer into a plastic phase with chair and twist conformers has been reported. The transition occurs between 70 and 80 °C.[7] A similar transition was also detected for $Ge_6Me_{12}$ between 50 and 60 °C. Figure 3 shows the ring-breathing mode of crystalline $Ge_6Me_{12}$ for different temperatures. At 60 °C, a shoulder suddenly appears at lower wavenumbers, certainly originating from a second conformer, which can be either twist or boat in nature. However, a detailed investigation of its nature was not performed in this work.

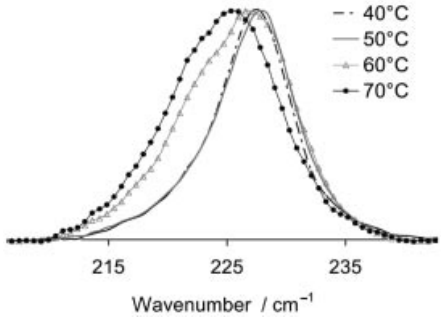

Figure 3. Shape of the ring-breathing mode of crystalline $Ge_6Me_{12}$ for different temperatures.

### *Solution Raman Spectra*

With a band shape closely resembling that in the solid state, a second band on the low-wavenumber side of the ring-breathing mode of the chair conformer is observed in thf solution. On the basis of quantum chemical calculations, it is identified as the signal for the twist or the averaged twist/boat conformer. At –80 °C, the band is barely observed as a small shoulder separated by about 5 cm$^{-1}$, and it gains intensity with increasing temperature. At room temperature, it is more intense than the band of the chair conformer. The band shapes for two temperatures as well as the relevant deconvolutions are shown in Figure 4.

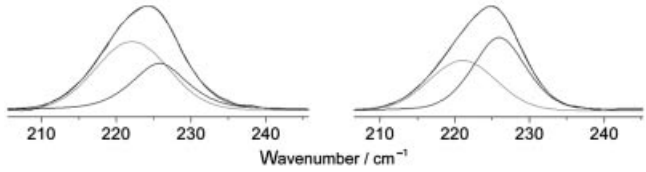

Figure 4. Appearance and deconvolution of the ring-breathing mode of $Ge_6Me_{12}$ in the Raman spectrum of a thf solution for 0 °C (left) and –40 °C (right).

According to Boltzmann statistics, the population of two conformational states varies with temperature. To analyze temperature-dependent Raman spectra of a compound possessing two conformational minima, I and II, the van't Hoff relation is used. The simple formula, $\ln(A_I/A_{II}) = -\Delta H/RT$ + constant, can be derived by assuming that $\Delta H$ and the ratio of Raman scattering coefficients, $a_I$ and $a_{II}$, are temperature independent ($a_I$, $a_{II}$ and $\Delta S$ are incorporated into the constant term). $A_I$ and $A_{II}$ are the intensities of the lines originating from conformers I and II (either band areas or band heights resulting from deconvolution may be used). The enthalpy difference, $\Delta H$, can then be obtained from the slope of a plot of $\ln(A_I/A_{II})$ against $T^{-1}$.

The calculated wavenumber difference between the chair and the averaged twist conformations is only ca. 5 cm$^{-1}$. To get the line intensities $A$, a band deconvolution was per-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

formed. First, peak positions were obtained by calculating the second derivative, which clearly indicates the presence of two overlapping peaks. Deconvolution was then achieved by free peak fitting using Lorentzian band shapes, and an enthalpy difference of 2.4 kJ mol$^{-1}$ was obtained between the chair and the averaged twist/boat conformer. A graphical reproduction of the resulting van't Hoff plot is shown in Figure 5. The statistical errors of the experimental results are not given here because the standard deviation obtained from van't Hoff analysis certainly underestimates the actual error of the method, which originates, amongst other things, from the assumptions made in the van't Hoff analysis[27] and from ambiguities in the band deconvolution. The overall accuracy of the experimental method is estimated to be no better than ± 20%.

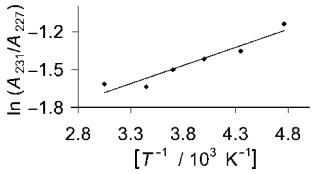

Figure 5. van't Hoff plot for the 231/227 cm$^{-1}$ band pair of $Ge_6Me_{12}$ in thf solution.

As the quantum chemical calculations refer to the isolated molecule in the gas phase, the calculated enthalpy values of 4–5 kJ mol$^{-1}$, which depend on the method and basis set used, compare fairly well with the experimental $\Delta H$ value of 2.4 kJ mol$^{-1}$.

## Conclusions

Third and higher row $E_6H_{12}$ and $E_6Me_{12}$ ring systems behave somewhat differently from cyclohexanes because the ring inversion barriers and the energy differences between stable conformers are considerably larger in the cyclohexanes. By using quantum chemical calculations, two minima, belonging to chair and twist conformations, were located on the PES for $Ge_6H_{12}$, and three minima, belonging to chair, twist, and boat conformations, were found for $Ge_6Me_{12}$. Relativistic effects have to be taken into account for the Ge atoms.

As in the case for $Si_6Me_{12}$, an averaged twist/boat conformer was observed in the Raman spectrum of $Ge_6Me_{12}$ in solution in addition to the most stable chair conformer, even at low temperatures. In the spectrum of the solid, a phase transition was observed between 50 and 60 °C. It should be noted though that $Ge_6Me_{12}$ represents a borderline case for the successful application of temperature-dependent Raman spectroscopy in terms of conformational analyses. Substituted digermanes with fairly small substituents, such as H, Me or Cl, which possess smaller rotational barriers between stable conformers, cannot be detected separately in a Raman spectrum. As we will report elsewhere, they must be investigated with the faster gas-phase electron diffraction technique.

## Experimental Section

**Synthesis:** $Ge_6Me_{12}$ was synthesized as described by Carberry et al.[17] by a coupling reaction of dimethyldichlorogermane with excess Li granulate in thf and was purified by recrystallization from acetone. The purity of the compound was checked with $^1$H NMR spectroscopy, GC-MS and Raman spectroscopy. Data were compared with literature data.[17]

**Quantum Chemical Calculations:** Geometry optimizations were initiated by using the previously published structures of $Si_6H_{12}$ and $Si_6Me_{12}$ as a starting point.[13] All geometry optimizations and minimum energy calculations, as well as the calculations of vibrational frequencies and intensities, were performed with the Gaussian03 program package at the DFT and MP2 levels of theory.[28] MP2 and B3LYP[29] density functional with the 6-31+G*[30] basis sets were employed to scan the potential energy surface, as well as the combination of D95V[31] basis sets for the C and H atoms and the quasi-relativistic Stuttgart Dresden large-core pseudopotentials (ECP28MWB[32]) for the Ge atoms. This combination is incorporated in Gaussian03 and is denoted as SDD. Geometry optimizations for located stationary points of $Ge_6H_{12}$ and $Ge_6Me_{12}$ were performed by using B3LYP with the aug-cc-pVTZ[33,34] basis set for the H atoms and aug-cc-pVTZ-PP,[35] a small-core relativistic pseudopotential correlation consistent basis set, for the Ge atoms. However, in the interest of reduced computational costs, the 6-31+G* basis set was used for the C and H atoms in $Ge_6Me_{12}$. In order to simplify the discussion, both of these methods are referred to as B3LYP/aug-cc-pVTZ.. The minima possess all real frequencies, while the transition structures have one single imaginary frequency. No symmetry restraints were employed to ensure a full investigation of the PES.

**X-ray Structure Determination:** For X-ray structure analyses, the crystals were mounted onto the tip of glass fibers, and data collection was performed with a BRUKER-AXS SMART APEX CCD diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation (0.71073 Å). The data were reduced to $F^2_o$ and corrected for absorption effects with SAINT[36] and SADABS,[37] respectively. The structures were solved by direct methods and refined by the full-matrix least-squares method (SHELXL97).[38] All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydrogen atoms were located in calculated positions to correspond to standard bond lengths and angles. CCDC-642005 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Raman Spectroscopy:** Raman spectra were recorded with a Jobin Yvon T64000 spectrometer equipped with a triple monochromator and a CCD camera. The samples were transferred into 1-mm glass capillary tubes and irradiated with the green 532-nm line of a frequency-doubled Nd-YAG laser (Coherent DPSS model 532–20, 20 mW). Spectra were recorded for both solid samples and solutions in thf. For high-temperature measurements, a metal block of copper with filament heating, on which the capillary was mounted, and a thermocouple for temperature monitoring were used. A continuous-flow cryostat (Oxford Instruments OptistatCF™ using liquid nitrogen for cooling) was employed for the low-temperature measurements.

**Supporting Information** (see footnote on the first page of this article): Due to space limitations, a compilation of geometric parameters for the chair, twist and boat conformers of $Ge_6H_{12}$ and $Ge_6Me_{12}$ obtained with various basis sets at the MP2 and B3LYP levels is presented.

# Open Platinum Aggregate Frameworks with Overhead Dithiolate Bridges

Siew Huay Chong,[a] William Henderson,[b] and T. S. Andy Hor*[a]

**Keywords:** Platinum / Sulfide / Aggregate / Alkylation / Dithiolate

A convenient method has been developed to bring together two discrete moieties of $[Pt_2(\mu\text{-}S)_2(PPh_3)_4]$ to give an open $Pt_4$ aggregate of $Pt_2\cdots(spacer)\cdots Pt_2$, as exemplified in the isolation of $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SRS)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ [R = *m*-$CH_2C_6H_4CH_2$, *p*-$CH_2C_6H_4CH_2$, $CH_2C_{10}H_6CH_2$, and $CH_2(C_6H_4)_2CH_2$]. The spacer is a dithiolate with an extended skeletal backbone formed from the alkylation of sulfide with a suitable dibromo-organic compound. This synthetic methodology can tolerate a range of conformationally contrasting thiolate substituents with different chemical functionalities. Shorter or stereochemically more restrictive spacers could opt to be an intramolecular bridge over the $Pt_2$ core, as given in $[Pt_2(\mu\text{-}S\text{-}o\text{-}CH_2C_6H_4\text{-}C_6H_4CH_2S)(PPh_3)_4](PF_6)_2$. A few representative complexes have been characterized by single-crystal X-ray diffraction analysis.

## Introduction

Owing to the rich nucleophilicity of the $\{Pt_2(\mu\text{-}S)_2\}$ core, the $[Pt_2(\mu\text{-}S)_2(P\text{-}P)_2]$ (P-P = diphosphane or $2\times PR_3$) (**1**) complexes have evolved to be a versatile metalloligand[1] and an efficacious thio-template for organic reactions.[2] The well-developed metallation chemistry of **1** has resulted in a large number of homo-, hetero-, and intermetallic polynuclear structures, which are best described as metal aggregates, not clusters, as they generally do not have active and direct M–M bonds. One of the objectives for this type of supramolecular assembly is to construct a mega-aggregate framework using sub-aggregates as building blocks. Parallel to this development is the use of organic moieties, instead of metal species, to connect the aggregate and build up the nuclearity. Conceptually, this can be viewed as an application of the growing alkylation chemistry of $[Pt_2(\mu\text{-}S)_2(P\text{-}P)_2]$.[1c,3–4] The nuclearity growth is controlled by the electronic and geometric features of the spacer. Adjusting the nucleophilicity of both sulfide centers could help to control the mono- or dialkylation selectivity, as evidenced from our recent study of the alkylation and arylation chemistry of $[Pt_2(\mu\text{-}S)_2(PPh_3)_4]$ (**1a**) using Electrospray Ionization Mass Spectrometry (ESI-MS).[3a] While simple monohalides predominantly give monoalkylated products of the type, $[Pt_2(\mu\text{-}SR)(\mu\text{-}S)(PPh_3)_4]^+$ (**2**), reactive halides, dimethyl sulfate, and α,ω-dialkylating agents result in dialkylated products, such as $[Pt_2(\mu\text{-}SR)_2(PPh_3)_4]^{2+}$ (**3**) and $[Pt_2(\mu\text{-}S_2R)(PPh_3)_4]^{2+}$ (**4**). Of particular interest here is the use of α,ω-dialkylating agents, with more rigid spacers; the spacer length between the alkylating groups [typically halides (X), e.g. XRX] determines the extent of functionalization in **1a**. For example, with a spacer containing up to four carbons, the end product of the reaction is the bridged complex (**4**), but with a longer separation, monoalkylation tends to dominate, resulting in complexes of the type $[Pt_2(\mu\text{-}SRX)(\mu\text{-}S)(PPh_3)_4]^+$ (**5**). In the case where the dihalides have a hydrocarbon chain which is too long to fit into the overhead S···S bridge, they can opt to intermolecularly bridge two sulfides, thus resulting in $Pt_4$ dications.[3a]

We herein present a synthetic application of our earlier ESI-MS study by preparing, isolating, and characterizing the tetranuclear platinum ($Pt_4$) sulfide aggregates $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SRS)(\mu\text{-}S)Pt_2(PPh_3)_4]^{2+}$ (**6**), which up to now have only been observed spectroscopically.[3a] This type of high-nuclearity platinum complex, in which the metal centers interact through ligand bridges, has attracted attention for their structural diversity,[5] luminescent[6] and redox[7] properties, electronics,[8] catalysis,[7] and as molecular precursors for inorganic materials under mild conditions,[9] as possible models in redox-active metalloproteins,[10] and as anti-cancer agents.[11]

## Results and Discussion

### Constructing Linkages to Build Platinum Sulfide Aggregates

The use of dihalides (XRX) of an appropriate spacer length to cross both sulfur atoms in $[Pt_2(\mu\text{-}S)_2(P\text{-}P)_2]$ (**1**) has provided the first solution to stable dialkylated derivatives of **1**.[2,3b] Early alkylation studies of $[Pt_2(\mu\text{-}S)_2(PPh_3)_4]$ (**1a**) demonstrate that while monoalkylation is facile, dialky-

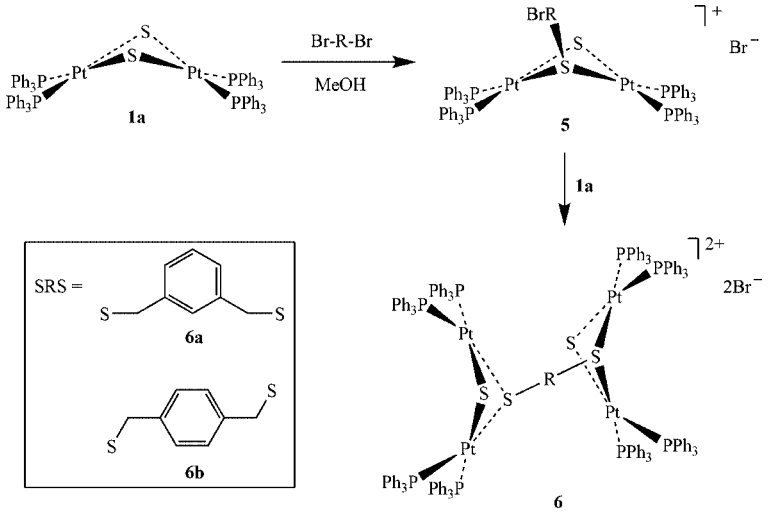

Scheme 1. Formation of a $Pt_4$ aggregate (**6**) through the linkage of two moieties of **1a**.

lation is elusive since the second sulfide is deactivated upon alkylation of the first in the initially formed monocation, $[Pt_2(\mu\text{-}SR)(\mu\text{-}S)(PPh_3)_4]^+$ (**2**)[3a–3b] or disintegration of the $\{Pt_2(\mu\text{-}S)_2\}$ core that follows dialkylation with $CH_2Cl_2$[4a–4c] and protic acids.[12] This method of sulfide functionalization in **1** leads to the isolation of stable overhead-bridged dialkylated products, such as $[Pt_2(\mu\text{-}SC_nH_{2n}S)(PPh_3)_4](PF_6)_2$ ($n$ = 2 and 4)[3b] and $[Pt_2(\mu\text{-}S\text{-}o\text{-}CH_2C_6H_4CH_2S)(P\text{-}P)_2](PF_6)_2$ [P-P = 2 × $PPh_3$ and $Ph_2PC_3H_6PPh_2$ (dppp)].[2a] The latter complex has been shown to be a useful precursor in the catalytic-like preparation of dithiacyclophanes.

As mentioned previously, dihalides with a hydrocarbon chain which is too long or insufficiently flexible to fit into the overhead S···S bridge will lead to monoalkylation, giving $[Pt_2(\mu\text{-}SRX)(\mu\text{-}S)(PPh_3)_4]^+$ (**5**).[3a–3b] By taking advantage of the dehalogenation capability of $\{Pt_2(\mu\text{-}S)_2\}$[3d] to displace the halide in **5**, $Pt_4$ dications of the type, $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SRS)(\mu\text{-}S)Pt_2(PPh_3)_4]^{2+}$ (**6**) can be readily obtained (Scheme 1). Initial alkylation of **1a** with one equivalent of α,α′-dibromo-*m*-xylene gives the stable monoalkylated $[Pt_2(\mu\text{-}S\text{-}m\text{-}CH_2C_6H_4CH_2Br)(\mu\text{-}S)(PPh_3)_4]^+$ (**5a**) (*m*/*z* 1687, 100%), followed by the formation of $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}S\text{-}m\text{-}CH_2C_6H_4CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (**6a**) upon addition of another equivalent of **1a**, and metathesis with $NH_4PF_6$. Single-crystal X-ray diffraction analysis of **6a** (Figure 1) reveals two $\{Pt_2(\mu\text{-}S)_2\}$ butterflies joined together by -$CH_2C_6H_4CH_2$- at each of their sulfides, resulting in a "coat hanger-like" structure. Similarly, in the case of the *para* isomer (α,α′-dibromo-*p*-xylene), the two $\{Pt_2(\mu\text{-}S)_2\}$ butterflies are connected at both ends of the xylyl bridge (Figure 2) to give the intermolecularly bridged complex, $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}S\text{-}p\text{-}CH_2C_6H_4CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (**6b**). It is expected that the dihedral angles in each of the $\{Pt_2(\mu\text{-}S)_2\}$ moieties would be the same within the same molecule, and that is observed in the case of complex

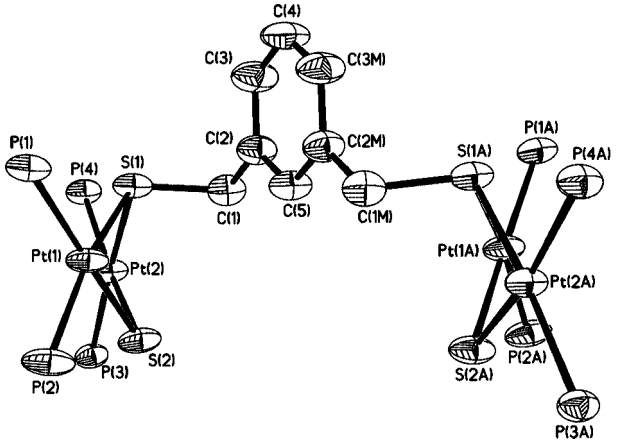

Figure 1. A 50% thermal ellipsoid representation of the cation of $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}S\text{-}m\text{-}CH_2C_6H_4CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (**6a**). The phenyl rings of $PPh_3$ and hydrogen atoms are omitted for clarity.

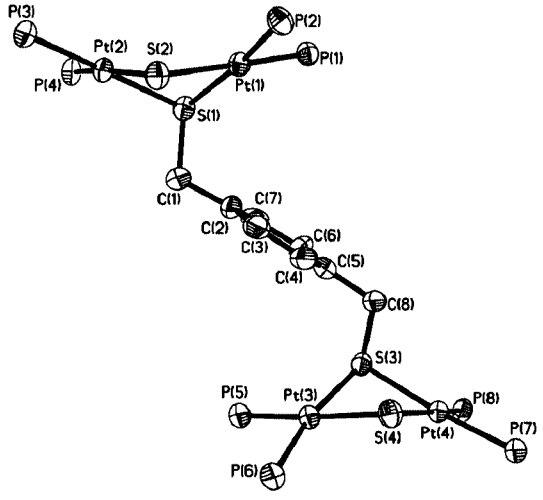

Figure 2. A 50% thermal ellipsoid representation of the cation of $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}S\text{-}p\text{-}CH_2C_6H_4CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (**6b**). The phenyl rings of $PPh_3$ and hydrogen atoms are omitted for clarity.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**6a** where both $\{Pt_2(\mu\text{-}S)_2\}$ rings are hinged with the dihedral angle of 132°. Interestingly, each of the $\{Pt_2(\mu\text{-}S)_2\}$ rings in complex **6b** are hinged to a slightly different extent – the moiety with the Pt(1)–S(1)–S(2)–Pt(2) core has a dihedral angle of 133° while the one with the Pt(3)–S(3)–S(4)–Pt(4) core has a dihedral angle of 138°. The slight difference in the dihedral angles is a result of having two noncrystallographically related $\{Pt_2(\mu\text{-}S)_2\}$ rings in **6b**. In contrast, the asymmetric unit for complex **6a** is half a molecule, so the two $\{Pt_2(\mu\text{-}S)_2\}$groups are symmetry-related and must therefore have exactly the same dihedral angle.

The $^{31}P\{^1H\}$ NMR characteristics of the two complexes are similar. The two sets of phosphanes have very similar chemical shifts and are differentiated by the different Pt-P couplings; a multiplet due to the overlap of the two phosphane signals at $\delta_P$ 23.2–23.8 ppm ($^1J_{Pt,P(1)}$ = 3292, $^1J_{Pt,P(2)}$ = 2627 Hz) and $\delta_P$ 23.3–23.6 ppm ($^1J_{Pt,P(1)}$ = 3293, $^1J_{Pt,P(2)}$ = 2591 Hz) for **6a** and **6b**, respectively. The thiolate ligand, $SCH_2C_6H_4CH_2S$ has a lower *trans* influence than a sulfido ligand, so the Pt–P bond *trans* to thiolate is shorter and has a larger $J_{Pt,P}$ coupling.

Isolation of complexes **6a** and **6b** suggested that we could conveniently control the directionality of the aggregate alignment by adjusting the geometry effect of the spacer. This synthetic methodology opens up the opportunity for the preparation of platinum sulfide aggregates that can be linked by a variety of organic alkyl or aryl chains. Application of this technique to two other dihalides: 2,6-bis(bromomethyl)naphthalene and 4,4′-bis(chloromethyl)-1,1′-biphenyl results in similar $Pt_4$ aggregates; $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SCH_2C_{10}H_6CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (**6c**) and $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SCH_2(C_6H_4)_2CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (**6d**). $^{31}P\{^1H\}$ NMR confirms successful syntheses and displays a multiplet from the overlap of the two phosphane signals at $\delta_P$ 23.5–24.2 ppm ($^1J_{Pt,P(1)}$ = 3289, $^1J_{Pt,P(2)}$ = 2630 Hz) and $\delta_P$ 23.7–24.4 ppm ($^1J_{Pt,P(1)}$ = 3282, $^1J_{Pt,P(2)}$ = 2628 Hz) for **6c** and **6d**, respectively.

**6d**

## From Linker to a Bridge

An unexpected overhead-bridged dialkylated complex, $[Pt_2(\mu\text{-}S\text{-}o\text{-}CH_2C_6H_4\text{-}C_6H_4CH_2S)(PPh_3)_4](PF_6)_2$ (**7**) with a long ($C_6$) spacer between the alkylating groups has been successfully isolated using 2,2′-bis(bromomethyl)-1,1′-biphenyl as the difunctional alkylating agent. Prior to this, dihalides with a spacer more than four C–C bonds long impeded dialkylation significantly and resulted predominantly in monoalkylation (**6**).[2] Despite the long $C_6$ distance that would normally result in monoalkylation of **1a**, dialkylation occurs rapidly and is completed within 2 h. Any signal corresponding to monoalkylation is absent in the ESI mass spectrum of the reaction monitored in MeOH. The bridging nature of the dithiolate ($\mu$-S-*o*-$CH_2C_6H_4\text{-}C_6H_4CH_2S$) ligand as opposed to the expected monothiolate ($\mu$-$SCH_2C_6H_4\text{-}C_6H_4CH_2Br$) ligand is confirmed by the single-crystal X-ray diffraction analyses of

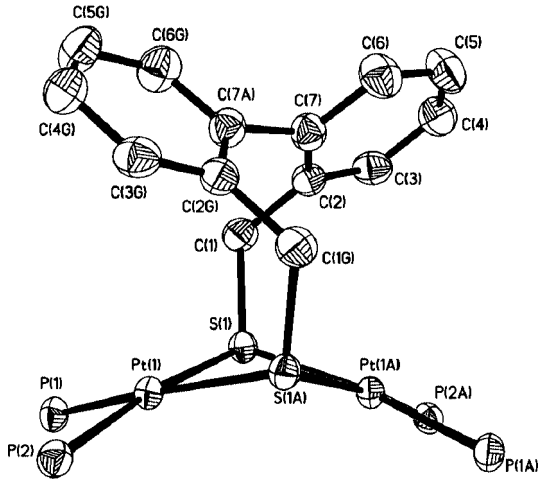

Figure 3. A 50% thermal ellipsoid representation of the cation of $[Pt_2(\mu\text{-}S\text{-}o\text{-}CH_2C_6H_4\text{-}C_6H_4CH_2S)(PPh_3)_4](PF_6)_2$ (**7**). The phenyl rings of $PPh_3$ and hydrogen atoms are omitted for clarity.

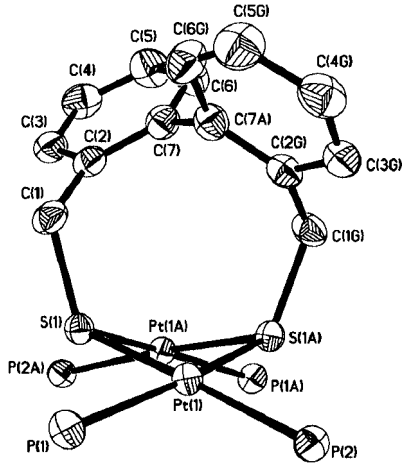

Figure 4. View along the Pt(1)–Pt(1A) axis. A 50% thermal ellipsoid representation of the cation of $[Pt_2(\mu\text{-}S\text{-}o\text{-}CH_2C_6H_4\text{-}C_6H_4CH_2S)(PPh_3)_4](PF_6)_2$ (**7**). The phenyl rings of $PPh_3$ and hydrogen atoms are omitted for clarity.

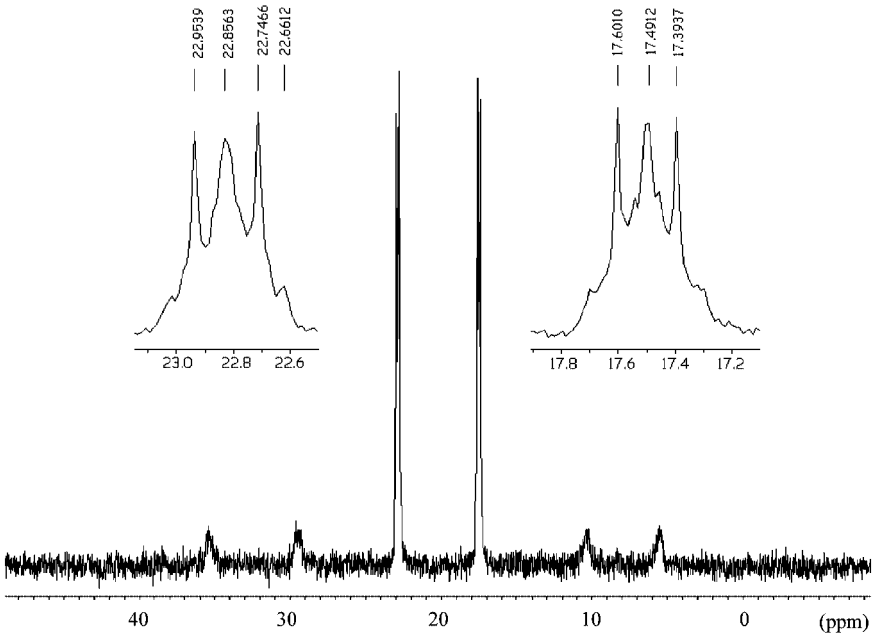

Figure 5. $^{31}P\{^{1}H\}$ NMR spectrum of $[Pt_2(\mu\text{-}S\text{-}o\text{-}CH_2C_6H_4\text{-}C_6H_4CH_2S)(PPh_3)_4](PF_6)_2$ (**7**) in $[D_6]$DMSO.

complex **7** in Figures 3 and 4. When viewed along the S(1A)–S(1) axis (Figure 3), the two phenyl groups which are joined at the C(7A)–C(7) bond are pointing away from one another as they are bent about the $\{S_2C_2\}$ plane. The conformationally flexible C(7A)–C(7) bond appears almost perpendicular to the S(1)–C(1) and S(1A)–C(1G) bonds, which are in a *syn-exo* conformation, pointing away from the sterically bulky triphenylphosphanes. These conformational features allow the flexible $C_6$ chain to fit into the S···S bridge. When viewed along the Pt(1)–Pt(1A) axis (Figure 4), complex **7** shows a unique and unusual bicyclic nine-membered metallosulfur-carbon ring. Its structure has a bent $\{Pt_2(\mu\text{-}S)_2\}$ ring and a dihedral angle of 147°. The dissymmetry created by the bridge generated two sets of inequivalent phosphanes that give two discrete resonances at $\delta_P$ = 17.5 (m, $^1J_{Pt,P}$ = 2923, $^2J_{P,P}$ = 13 Hz) and 22.9 ppm (m, $^1J_{Pt,P}$ = 3043, $^2J_{P,P}$ = 13 Hz) in its $^{31}P\{^{1}H\}$ NMR spectrum (Figure 5). Such NMR characteristics have been observed in the xylyl dithiolato-bridged complex, $[Pt_2(\mu\text{-}S\text{-}o\text{-}CH_2C_6H_4CH_2S)(PPh_3)_4](PF_6)_2$.[2a]

## Conclusions

The isolation of tetranuclear platinum sulfide aggregates that can be linked by a variety of organic chains marks an extension to the scope of alkylation chemistry in the $\{Pt_2(\mu\text{-}S)_2\}$ systems. The choice of appropriate alkylating agents coupled with the excellent dehalogenation capability of the sulfide centers in $[Pt_2(\mu\text{-}S)_2(PPh_3)_4]$ (**1a**) makes the preparation possible. In principle, all dibromo-organic compounds with an extended skeleton can function as an overhead bridge across the sulfide centers. If it is stereochemically too restrictive to serve as an intramolecular bridge within the $Pt_2$ core, it could be switched to the intermolecular mode and interlink two $Pt_2$ cores, giving $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}SRS)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (**6**). Our next synthetic target is to activate the unsubstituted sulfide atoms of the aggregate. The strategies used could be adapted from the method we recently developed for the alkylation of the $[Pt_2(S)(SR)]^+$ core to $[Pt_2(SR)_2]^{2+}$.[13] The success of such a synthesis would pave the way to stepwise alignment of Pt aggregates ···$Pt_2$···$Pt_2$···$Pt_2$··· with sole dithiolate spacers.

## Experimental Section

### Materials and Methods

All manipulations were carried out at room temperature under an atmosphere of dinitrogen. Solvents used were generally of analytical grade (Tedia) and were dried and deoxygenated before being used. The complex $[Pt_2(\mu\text{-}S)_2(PPh_3)_4]$ (**1a**) was synthesized by metathesis of *cis*-$[PtCl_2(PPh_3)_2]$ with $Na_2S{\cdot}9H_2O$ (Riedel-de Haën) in benzene. Complex **1a** was obtained in 86% yield {ESI-MS (80% MeOH/20% $H_2O$): *m*/*z* 1504 (100%) $[M + H]^+$}. The following chemicals were used as supplied from Aldrich: α,α′-dibromo-*m*/*p*-xylenes, 2,2′-bis(bromomethyl)-1,1′-biphenyl, 2,6-bis(bromomethyl)naphthalene, 4,4′-bis(chloromethyl)-1,1′-biphenyl, and ammonium hexafluorophosphate ($NH_4PF_6$).

Electrospray mass spectra were obtained in the positive-ion mode with a Finnigan/MAT LCQ mass spectrometer coupled with a TSP4000 HPLC system and the crystal 310 CE system. The mobile phase was 80% methanol/20% $H_2O$ (flow rate: 0.4 mL min$^{-1}$). The capillary temperature was 150 °C. Peaks were assigned from the *m*/*z* values and from the isotope-distribution patterns. The charge(s) on the species could be confirmed by comparing the experimental and calculated isotope-distribution patterns. Elemental analyses were performed with a Perkin–Elmer PE 2400 CHNS elemental analyzer. $^1H$ NMR spectra were recorded at 25 °C with a Bruker ACF 300 spectrometer (at 300 and 75.47 MHz, respectively) with $Me_4Si$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

as internal standard. The $^{31}P$ NMR spectra were recorded at 25 °C and 121.50 MHz with 85% $H_3PO_4$ as external reference. The $^{31}P$ NMR spectra of **6a**–**d** and **7** obtained are generally higher-order spectra which were treated with first-order approximations. Detailed analysis of similar six-spin systems ($4\times{}^{31}P + 2\times{}^{195}Pt$) has been reported.[4d]

**Syntheses**

**$[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}S\text{-}m\text{-}CH_2C_6H_4CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (6a):** Compound **1a** (29.6 mg, 0.020 mmol) and a stoichiometric amount of α,α′-dibromo-*m*-xylene (5.0 mg, 0.019 mmol) in methanol (15 mL) was stirred for 2 h, followed by the addition of a slight excess of **1a** (36.2 mg, 0.024 mmol, 1.2 equiv.). The yellow suspension was stirred for a further 2.5 h and filtered to remove any unreacted **1a**. Excess $NH_4PF_6$ (20.0 mg, 0.123 mmol) was added to give a yellow suspension. Deionized water (40 mL) was then used to complete the precipitation. A yellow powder of **6a** (56.2 mg, 76%) was obtained by washing with deionized water (100 mL) and diethyl ether (100 mL) using vacuum suction filtration. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta_P$ = 23.6 ppm (m, $^1J_{Pt,P(1)}$ = 3292, $^1J_{Pt,P(2)}$ = 2627 Hz). $^1H$ NMR ($CD_2Cl_2$): $\delta_H$ = 3.84 (br. s, 4 H, 2 $SCH_2$), 5.82–5.85 (d, $J$ = 8.0 Hz, 2 H, $CH_2C_6H_4CH_2$), 6.49 (b t, $J$ = 7.7 Hz, 1 H, $CH_2C_6H_4CH_2$), 6.76 (s, 1 H, $CH_2C_6H_4CH_2$), 7.03–7.43 ppm (m, 120 H, 24 $C_6H_5$). ESI-MS (MeOH/$H_2O$): *m*/*z* (%) = 1555 (100) $[M]^{2+}$. $C_{152}H_{128}F_{12}P_{10}Pt_4S_4$ (3400.94): calcd. C 53.68, H 3.79, S 3.77; found C 53.65, H 3.76, S 3.98. Yellow crystals of $[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}S\text{-}m\text{-}CH_2C_6H_4CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ suitable for X-ray crystallographic analysis were obtained from dichloromethane/benzene (1:1).

**$[(PPh_3)_4Pt_2(\mu\text{-}S)(\mu\text{-}S\text{-}p\text{-}CH_2C_6H_4CH_2S)(\mu\text{-}S)Pt_2(PPh_3)_4](PF_6)_2$ (6b):** A procedure similar to that used above was employed. A stoichiometric amount of α,α′-dibromo-*p*-xylene (6.8 mg, 0.026 mmol) was introduced into an orange suspension of compound **1a** (40.0 mg, 0.027 mmol) in methanol (20 mL). The mixture changed from an orange suspension to a yellow solution in 2 h. Another 40.5 mg (0.027 mmol) of **1a** was added, resulting in a yellow suspension. The mixture was stirred for a further 2 h, and the resultant suspension was filtered, followed by the addition of excess $NH_4PF_6$ (20.0 mg, 0.123 mmol). Deionized water (50 mL) was used to complete the precipitation. A yellow powder of **6b** (64.2 mg, 71%) was obtained by washing with deionized water (100 mL) and diethyl ether (100 mL) using vacuum suction filtration. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta_P$ = 23.5 ppm (br. s, $^1J_{Pt,P(1)}$ = 3293, $^1J_{Pt,P(2)}$ = 2591, $^2J_{P(1)-P(2)}$ = 18 Hz). $^1H$ NMR ($CD_2Cl_2$): $\delta_H$ = 3.39 (br. s, 4 H, 2 $SCH_2$), 6.12 (s, 4 H, $CH_2C_6H_4CH_2$), 6.99–7.43 ppm (m, 120 H, 24 $C_6H_5$). pension of compound **1a** (30.5 mg, 0.020 mmol) in methanol (15 mL). The mixture was stirred for 3.5 h followed by the addition of another 30.6 mg (0.020 mmol) of **1a**. The resultant yellow suspension was left to stir overnight. The suspension was then filtered, followed by the addition of excess $NH_4PF_6$ (20.0 mg, 0.123 mmol). Deionized water (30 mL) was used to complete the precipitation. A yellow powder of **6d** (45.8 mg, 66%) was obtained by washing with deionized water (100 mL) and diethyl ether (100 mL) using vacuum suction filtration. $^{31}P\{^1H\}$ NMR ($CD_2Cl_2$): $\delta_P$ = 23.7–24.4 ppm (m, $^1J_{Pt,P(1)}$ = 3282, $^1J_{Pt,P(2)}$ = 2628 Hz). $^1H$ NMR ($CD_2Cl_2$): $\delta_H$ = 3.73 (br. s, 4 H, 2 $SCH_2$), 6.65–7.45 (m, 8 H, 2 $C_6H_4$), 6.65–7.45 ppm (m, 120 H, 24 $C_6H_5$). ESI-MS (MeOH/$H_2O$): *m*/*z* (%) = 1592 (100) $[M]^{2+}$. $C_{158}H_{132}F_{12}P_{10}Pt_4S_4$ (3477.03): calcd. C 54.58, H 3.83, S 3.69; found C 54.57, H 3.36, S 3.40.

**[$Pt_2$(μ-S-*o*-$CH_2C_6H_4$-$C_6H_4CH_2$S)($PPh_3$)$_4$]($PF_6$)$_2$ (7):** 2,2′-Bis(bromomethyl)-1,1′-biphenyl (32.3 mg, 0.095 mmol, 3 equiv.) and compound **1a** (48.7 mg, 0.032 mmol) in methanol (20 mL) gave a pale yellow solution in 15 min and was left to stir for 2 h. Excess $NH_4PF_6$ (20.0 mg, 0.123 mmol) was then added, resulting in an off-white suspension. Deionized water (40 mL) was used to complete the precipitation. A cream-colored powder of **7** (58.7 mg, 92%) was obtained by washing with deionized water (100 mL) and diethyl ether (100 mL) using vacuum suction filtration. $^{31}P\{^1H\}$ NMR ([D$_6$]DMSO): $\delta_P$ = 17.5 (m, $^1J_{Pt,P}$ = 2923, $^2J_{P,P}$ = 13 Hz), 22.9 ppm (m, $^1J_{Pt,P}$ = 3043, $^2J_{P,P}$ = 13 Hz). $^1H$ NMR ([D$_6$]DMSO): $\delta_H$ = 3.32 (s, 4 H, 2 $SCH_2$), 6.85–6.88 (d, *J* = 7.6 Hz, 2 H, $C_6H_4$-$C_6H_4$), 6.76–6.78 (d, *J* = 7.4 Hz, 2 H, $C_6H_4$-$C_6H_4$), 7.86 (t, *J* = 7.4 Hz, 2 H, $C_6H_4$-$C_6H_4$), 7.56 (t, *J* = 6.8 Hz, 2 H, $C_6H_4$-$C_6H_4$), 6.99 (br. s, 12 H, 12 $C_6H_5$), 7.15 (br. s, 24 H, 12 $C_6H_5$), 7.43 ppm (br. s, 24 H, 12 $C_6H_5$). ESI-MS (MeOH/$H_2O$): *m*/*z* (%) = 842 (100) $[M]^{2+}$, 1827 (10) $[[M]^{2+}[PF_6]^-]$. $C_{86}H_{74}F_{12}OP_6Pt_2S_2$ (1991.62): calcd. C 51.86, H 3.74, S 3.22; found C 51.85, H 3.49, S 3.59. Pale yellow crystals of [$Pt_2$(μ-S-*o*-$CH_2C_6H_4$-$C_6H_4CH_2$S)($PPh_3$)$_4$]($PF_6$)$_2$ suitable for X-ray crystallographic analysis were obtained from dichloromethane/ethanol (1:1).

**X-ray Crystal Structure Determination and Refinement**

Selected bond lengths and angles for complexes **6a**, **6b**, and **7** are given in Table 1. All measurements were made with a Bruker AXS SMART APEX diffractometer equipped with a CCD area detector by using Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The software SMART[14] was used for the collection of data frames, for indexing reflections, and to determine lattice parameters; SAINT[14] was used for the integration of the intensity of the reflections and for scaling; SADABS[15] was used for empirical absorption correction; and SHELXTL[16] was used for space group and structure determination, refinements, graphics, and structure reporting. The structure was refined by full-matrix least-squares on $F^2$ with anisotropic thermal parameters for non-hydrogen atoms. A summary of crystallographic parameters for the data collections and refinements is given in Table 2.

For **6a**, the asymmetrical unit contains half a titled cation, two halves of the $PF_6^-$ counteranion, one benzene, and one and a half dichloromethane molecules. The whole of the molecule can be generated by a twofold symmetry. One of the half $PF_6^-$ counteranions is at a special position and the other is disordered. The disordered $PF_6^-$ counteranion is refined only with isotropic thermal parameters. The half dichloromethane molecule is also disordered. For **6b**, the asymmetric unit contains one titled cation, two counter $PF_6^-$ counteranions, seven dichloromethane solvent molecules, and one disordered water molecule. One of the dichloromethane molecules is slightly disordered. The phenyl rings are refined as fixed hexagon rings with anisotropic thermal parameters. For **7**, the asymmetrical unit contains one half of the titled cation, two halves of $PF_6^-$, and two disordered dichloromethane molecules.

CCDC-646073 (for **6a**), -646074 (for **6b**), and -646075 (for **7**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Azolium Salts Functionalized with Cyanomethyl, Vinyl, or Propargyl Substituents and Dicyanamide, Dinitramide, Perchlorate and Nitrate Anions

Ye Gao,[a] Haixiang Gao,[b] Crystal Piekarski,[a] and Jean'ne M. Shreeve*[a]

**Keywords:** Energetic salts / Density / Heat of formation / Thermal stability

A series of functionalized imidazolium and 1,2,4-triazolium salts with cyanomethyl, vinyl and propargyl substituents coupled with energetic anions, viz., perchlorate, nitrate, dicyanamide and dinitramide were prepared and characterized by NMR and IR spectroscopy, and elemental analyses. Since some melt < 100 °C, they can be classed as ionic liquids. Their densities range between 1.25–1.76 g cm$^{-3}$. The standard enthalpies of formation of the salts were calculated by using the computationally feasible DFT(B3LYP) and MP2 methods in conjunction with an empirical approach based on calculated densities of the salts. These values range from $\Delta H°_f$ = –56 (**12a**) to 851 (**21c**) kJ mol$^{-1}$. Of the salts synthesized, the dicyanamides exhibit the highest positive heats of formation, but also the lowest densities.

## Introduction

Ionic liquids have been extensively studied, e.g., as novel solvents,[1] in separation processes,[2] in electrochemistry,[3] and as lubricants.[4] The introduction of functional groups into the azolium cation modifies the properties of the salt which enables the enhancement of certain characteristics which may be tailored to particular applications.[1g–1i]

Syntheses of energetic materials continue to attract considerable interest. Salt-based energetic materials often possess some advantage over molecular compounds since they tend to have lower vapor pressures and higher densities.[5–7] Many new members of heterocyclic-based energetic, low-melting salt families have been reported. Theoretical calculations of enthalpies of formation of salts, based on the heats of formation of cation, anion, and lattice energy, show that when $\Delta H_f$ for analogous species with various functional groups are determined, the values decrease CN > $NO_2$ > $NH_2$ > H.[8a–8d] Initially, this appears to suggest that introduction of the nitrile moiety would give rise to the most energetic species, i.e., a compound with the highest detonation pressure and velocity. However, nearly invariably and not surprisingly, the density of the nitrile is less than that of the nitro or amino-substituted salt and thus detonation properties are diminished given that the detonation pressure is dependent on the square of the density and detonation velocity is proportional to the density. Calculations show that $\Delta H°_f$ for the vinyl group is also slightly higher than that of hydrogen; $\Delta H°_f$ for ethylene is 52.4 kJ mol$^{-1}$; and $\Delta H°_f$ for acetylene is 226.7 kJ mol$^{-1}$.[8d] Therefore, $\Delta H°_f$ for propargyl is expected to be higher than vinyl.

This paper describes the synthesis and characterization of a series of azolium salts with cyanomethyl-, vinyl- and propargyl-substituted imidazolium and 1,2,4-triazolium cations coupled with energetic inorganic anions – nitrate, perchlorate, dicyanamide and dinitramide. Their thermal properties were determined and the standard enthalpies of formation calculated.

## Results and Discussion

1-Substituted 1,2,4-triazoles, **1**, **2**, and **19**, were obtained by reacting sodium triazolate with methyl iodide, chloroacetonitrile and propargyl bromide. The remaining starting materials, 4-amino triazole, 1-vinyl imidazole, 1-methyl imidazole, 1-methyl triazole are commercially available. Compounds **3**, **4**, **7**, **9**, **10**, **11**, **15**, **16**, and **20** were obtained via quaternization reactions between the azole and the corresponding halide. These were then metathesized with silver nitrate, silver perchlorate, silver dicyanamide[9] or silver dinitramide[10] to give salts **5**, **6**, **8**, **12**, **13**, **14**, **17**, **18**, or **21** (Scheme 1).

Phase-transition temperatures (midpoints of melting points, $T_m$, or glass transition temperature, $T_g$) for all the salts were determined using differential scanning calorimetry (DSC) (Table 1). Most of the phase-transition temperatures are lower than 100 °C, and some of the salts are room temperature ionic liquids. With a common cation, phase-transition temperatures recorded for perchlorates > nitrates (with the exception of **8** and **12**) > dicyanamides > dinitra-

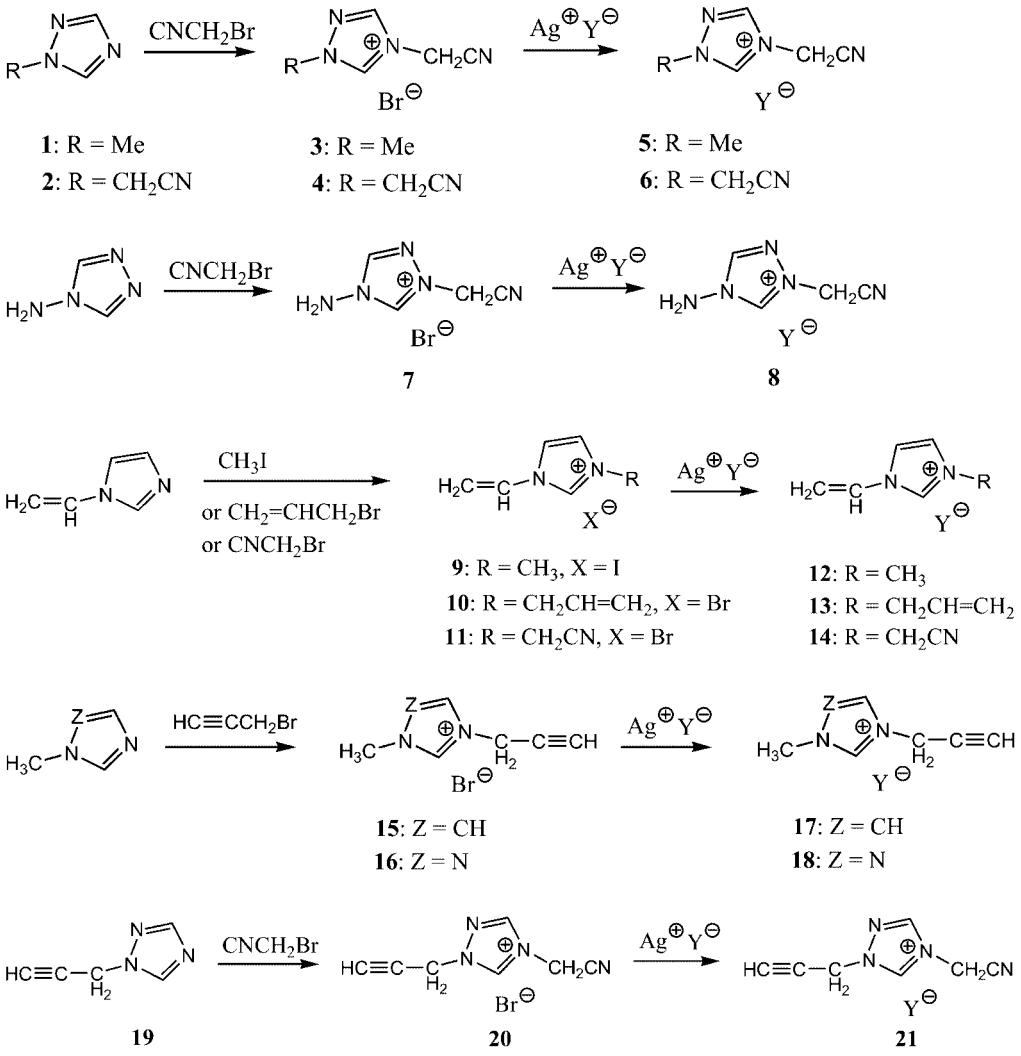

Scheme 1.

mides (with the exception of **8** and **17**). Invariably the perchlorate salts are the most thermally stable, sometimes by > 100 °C and with thermal decomposition temperatures ≥ 200 °C. Comparing compounds **5**, **6**, and **8** that have common anions, the melting points or phase transition points ($T_m$/$T_g$) of the triazolium salts substituted with two cyanomethyl ($CNCH_2$-) groups were highest (**6a**–**d**). When the substituents were one $CNCH_2$– group and 1-methyl (**5a**–**d**) or 4-amino (**8a**–**d**), the $T_m$/$T_g$ decreased, and the latter two sets were similar (except **8b**). For vinyl imidazolium salts, **14a**–**d** with a $CNCH_2$– substituent exhibit the highest $T_m$/$T_g$ followed by the salts with a methyl group (**12a**, **d**), and finally the allyl-substituted salts (except **12b**). Similar relationships were observed for propargyl-substituted salts **18** and **21**.

When comparing densities, it is seen that the 1-methylcyano-4-aminotriazolium salts (**8a**–**d**) exhibit the highest values, from perchlorate (1.76 g cm$^{-3}$) to dicyanamide (1.43 g cm$^{-3}$).[11–13] Not surprisingly, the presence of the amino-substituted cation with its enhanced proclivity to form hydrogen bonds gives rise to higher density followed by $CNCH_2^- > CH_3$. Similar ordering is observed in moving from **14a**–**d** > **12a**,**b**,**d** > **13a**–**d** as the cation substituent changes from $CNCH_2^-$ to $CH_3$ to allyl. Densities of **21a**–**c** exceed those of **18a**–**d** due to the presence of the dicyanomethyl vis-à-vis methyl. The densities of **18a**–**d** > **17a**–**d** because, in general, the densities of triazolium salts are higher than imidazolium. Regardless of the cation, with few exceptions, the density order is $ClO_4^- > N(NO_2)_2^- > NO_3^- > N(CN)_2^-$.

One of the purposes of this work is to compare the energetic properties of salts that contain the dicyanamide anion with their dinitramide analogues. As predicted,[8] the calculated heats of formation for the dicyanamide salts are invariably more positive than those of the analogous dinitramide salts, and, in fact, the dicyanamides have values higher than any of their counterparts in this study followed by dinitramides > perchlorates > nitrates in each of the cation

families. As is usually the case, the nitrate salts have the lowest heats of formation.

However, the performance of energetic materials is measured by detonation pressure and detonation velocity where the former is dependent on the square of the density and the latter is proportional to the density.[14] Some of these values (based on the traditional Chapman–Jouget thermodynamic detonation theory) were obtained by using CHEETAH 4.0 (Table 2).[15]

As is shown in Table 1, the dicyanamide salts exhibit the lowest densities of the anion salts studied. The importance of density in performance is easily seen since in every case, while the dinitramide is more dense and exhibits a lower heat of formation than its dicyanamide counterpart, it displays an appreciably higher detonation pressure and velocity. It should be noted that **5d**, **6d**, **8d**, **18d**, and **21d** have performance characteristics resembling those of TNT. None of the dicyanamides approaches this value.

Comparing the heats of formation of **5**, **6**, and **8**, it can be seen that the $CNCH_2$– group contributes most, greater than $NH_2$ with the $CH_3$ substituent contributing least. From **12**–**14**, the order of the heats of formation is **14** > **13** > **12**, once again indicating that the $CNCH_2$-substituent contributes most, greater than allyl with $CH_3$– last. Based on **17**, **18**, and **21**, the results further indicate that the 1,2,4-triazolium cation contributes more positively to the heat of formation of a salt than imidazolium does, and again the $CNCH_2$– group is a stronger contributor than methyl.

Table 2. Comparison of detonation pressures and velocities for dicyanamide and dinitramide salts with common cations.[a]

| Compd. | Anion | Detonation pressure[b] | Detonation velocity[c] |
|---|---|---|---|
| **5c** | $N(CN)_2^-$ | 11.60 | 6.21 |
| **5d** | $N(NO)_2^-$ | 21.53 | 7.51 |
| **6c** | $N(CN)_2^-$ | 11.64 | 6.21 |
| **6d** | $N(NO)_2^-$ | 21.38 | 7.44 |
| **8c** | $N(CN)_2^-$ | 14.83 | 6.88 |
| **8d** | $N(NO)_2^-$ | 24.82 | 7.85 |

## Thermochemistry

Computations were performed with the Gaussian 03 (Revision D.01) suite of programs.[16] The geometric optimization of the structures based on single-crystal structures, where available, and frequency analyses are carried out by using B3LYP functional with 6-31+G** basis set,[17] and single energy points were calculated at the MP2(full)/6-311++G** level.[18,19] All of the optimized structures were characterized to be true local energy minima on the potential energy surface without imaginary frequencies. Based on Born–Haber energy cycles, the heats of formation of an ionic salt can be simplified by the formula:

$$\Delta H_f^\circ \text{ (ionic salt, 298 K)} = \Delta H_f^\circ \text{ (cation, 298 K)} + \Delta H_f^\circ \text{ (anion, 298 K)} - \Delta H_L$$

where $\Delta H_L$ is the lattice energy of the ionic salt which can be predicted by the formula suggested by Jenkins[20] as:

$$\Delta H_L = U_{POT} + [p(n_M/2 - 2) + q(n_X/2 - 2)]RT$$

where $n_M$ and $n_X$ depend on the nature of the ions $M_p^+$ and $Xq^-$, respectively, and are equal to 3 for monatomic ions, 5 for linear polyatomic ions, and 6 for nonlinear polyatomic ions. The equation for lattice potential energy $U_{POT}$ has the form

$$U_{POT}/\text{kJ mol}^{-1} = \gamma\,(\rho_m/M_m)^{1/3} + \delta$$

where $\rho_m$ [g/cm$^3$] density, $M_m$ [g] is the chemical formula mass of the ionic material, and the coefficients $\gamma$ [kJ/mol cm] and $\delta$ [kJ/mol] take the values from the literature.[20]

For $NO_3^-$, $ClO_4^-$, and $N(NO_2)_2^-$, the proton affinities (PA) were taken from literature results calculated by using the G2 or G3 method.[21] For $N(CN)_2^-$, the PA was calculated by using G2. The heats of formation of $NO_3^-$, $ClO_4^-$, $N(NO_2)_2^-$, and $N(CN)_2^-$ were calculated to be –308, –278, –162, and 113 kJ mol$^{-1}$, respectively. Thus with a common

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cation, the heats of formation of these salts (positive to negative) is $N(CN)_2^- > N(NO_2)_2^- > ClO_4^- > NO_3^-$.

## Conclusions

A series of imidazolium and 1,2,4-triazolium salts functionalized with vinyl, propargyl and cyanomethyl substituents and paired with nitrate, perchlorate, dicyanoamide, and dinitroamide anions have been prepared and characterized. Some of them melt at less than 100 °C and can be classified as ionic liquids. The densities of these salts range between 1.25–1.76 g cm$^{-3}$ with those of the dicyanamides being the lowest. The heats of formation for these salts which were calculated with the Gaussian 03 (Revision D.01) suite of programs indicate that the dicyanamides have the highest values. However, they unfortunately show the least promise for useful applications since they have the lowest energetic performance characteristics which are primarily a function of density.

## Experimental Section

***Caution:*** While we have experienced no difficulties with shock and friction sensitivity of these compounds that have high nitrogen content and rather high heats of formation, they must be synthesized in mmol amounts and handled with extreme care.

**General Methods:** $^1$H and $^{13}$C NMR spectra were recorded on a 300 MHz (Bruker AMX 300) spectrometer operating at 300.1 and 75.5 MHz, respectively. Chemical shifts are reported in parts per million relative to the appropriate standard ($Me_4Si$ for $^1$H and $^{13}$C NMR spectra). Phase-transition temperatures and decomposition temperatures were determined by using a differential scanning calorimeter (DSC, TA Instruments TA10) at a scan rate of 10 °C min$^{-1}$. IR spectra (BioRad FTS 3000 Excalibur series infrared spectrometer) were measured by using KBr pellets. Elemental analyses were carried out by using a CE-440 elemental analyzer (EAI Exeter Analytical). In some cases the experimental values for nitrogen are lower than the required values. This is sometimes observed for compounds with large amounts of nitrogen.

1-Substituted 1,2,4-triazoles, **1**, **2** and **19**, were obtained by reacting sodium triazolate with methyl iodide, chloroacetonitrile and propargyl bromide. The remaining starting materials, 4-aminotriazole, 1-vinylimidazole, 1-methylimidazole, 1-methyltriazole are commercially available. Compounds **3**, **4**, **7**, **9**, **10**, **11**, **15**, **16**, and **20** were obtained via quaternization reactions between the azole and the corresponding halide. These were then metathesized with silver nitrate, silver perchlorate, silver dicyanamide[9] or silver dinitramide[10] to give salts **5**, **6**, **8**, **12**, **13**, **14**, **17**, **18**, or **21**.

Sodium hydride (25 mmol, 1.00 g, 60% yield) in dry THF (40 mL) was added to a two-necked round-bottomed flask (100 mL) maintained under $N_2$ and containing a magnetic stir bar. 1,2,4-Triazole (25 mmol, 1.70 g) in THF (5 mL) was then added slowly to the stirring solution and the mixture was refluxed for 12 h and then cooled to room temp. Chloroacetonitrile (40 mmol, 3.12 g) was added and the mixture was refluxed for 12 h. Then the mixture was cooled to room temp. filtered. The filtrate was concentrated under vacuum then isolated by chromatography (silica gel column), eluted by hexane/ethyl acetate (80:20). The light brown solid **2** was obtained (1.9 g, 70% yield), $T_m$ = 60 °C.

Sodium 1,2,4-triazolate (25 mmol) was prepared as above. Propargyl bromide (40 mmol, 4.72 g) was added and the mixture was refluxed for 12 h. Workup was similar to above. A light brown liquid **19** (1.6 g, 60% yield), $^1$H NMR ($CHCl_3$): $\delta$ = 2.60 (t, $J$ = 2.6 Hz, 1 H), 5.40 (d, $J$ = 2.6 Hz, 2 H), 7.97 (s, 1 H), 8.30 (s, 1 H) ppm. $^{13}$C NMR ($CHCl_3$): $\delta$ = 153.2, 143.6, 76.7, 75.8, 40.3 ppm.

A typical preparation of an iodide salt was to dissolve **1** (10 mmol, 0.83 g) and methyl iodide (20 mmol, 2.8 g) in ethyl acetate (5 mL) in a Pyrex glass tube (20 mL) that was subsequently evacuated, sealed, and stirred at 60 °C for 24 h. The precipitate was washed with ethyl acetate (3 × 5 mL) and dried under vacuum for 24 h to give the colorless solid 3-cyanomethyl-1-methyl-1,2,4-triazolium iodide (**3**) (1.8 g, 80% yield), $T_m$ = 168 °C. IR (KBr): $\tilde{\nu}$ = 3062, 2953, 2906, 1580, 1402, 1227, 1163, 1070 cm$^{-1}$. $^1$H NMR ($D_2O/H_2O$): $\delta$ = 4.22 (s, 3 H), 5.67 (s, 2 H), 9.10 (s, 1 H), 10.10 (s, 1 H) ppm. $^{13}$C NMR ($D_2O/H_2O$): $\delta$ = 145.7, 144.4, 114.2, 40.5, 37.1 ppm. $C_5H_7BrN_4$ (203.04): calcd. C 29.58, H 3.47, N 27.59; found C 29.53, H 3.33, N 26.80.

**1,4-Bis(cyanomethyl)-1,2,4-triazolium Bromide (4):** 1.6 g, 70% yield, grey solid; $T_m$ = 184 °C. IR (KBr): $\tilde{\nu}$ = 3113, 2965, 2918, 1788, 1570, 1537, 1421, 1382, 1342, 1231, 1155, 1035, 1003 cm$^{-1}$. $^1$H NMR ($H_2O/D_2O$): $\delta$ = 5.78 (s, 2 H), 5.89 (s, 2 H), 9.33 (s, 1 H), 10.50 (s, 1 H) ppm. $^{13}$C NMR ($H_2O/D_2O$): $\delta$ = 146.2, 145.6, 113.4, 113.1, 41.4, 37.1 ppm. $C_6H_6BrN_5$ (228.05): calcd. C 31.60, H 2.65, N 30.71; found C 31.54, H 2.54, N 30.84.

**1-Cyanomethyl-1,2,4-triazolium Bromide (7):** 1.8 g, 90% yield, colorless solid; $T_m$ = 102 °C. IR (KBr): $\tilde{\nu}$ = 3107, 2932, 2071, 1638, 1560, 1520, 1406, 1287, 1162, 1034, 998 cm$^{-1}$. $^1$H NMR ([D$_6$]-DMSO): $\delta$ = 5.92 (s, 2 H), 7.22 (s, 2 H), 9.35 (s, 1 H), 10.37 (s, 1 H) ppm. $^{13}$C NMR (DMSO): $\delta$ = 147.2, 145.3, 115.1, 41.7 ppm. $C_4H_6BrN_5$ (204.03): calcd. C 23.55, H 2.96, N 34.33; found C 23.45, H 2.86, N 34.43.

**3-Methyl-1-vinylimidazolium Iodide (9):**[22] 2.3 g, 96% yield, light yellow liquid, $T_m$ = 75 °C.

**3-Allyl-1-vinyl-imidazolium Bromide (10):** 1.8 g, 85% yield, orange solid, $T_m$ = 253 °C. IR (KBr): $\tilde{\nu}$ = 3124, 3065, 2994, 1651, 1549, 1423, 1370, 1308, 1172 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 4.97 (d, $J$ = 6.2 Hz, 2 H), 5.33–5.49 (m, 3 H), 6.01 (dd, $J$ = 2.7, $J$ = 15.6 Hz, 1 H), 6.10 (tdd, $J$ = 6.2, $J$ = 10.3, $J$ = 17.0 Hz, 1 H), 7.39 (dd, $J$ = 8.7, $J$ = 15.6 Hz, 1 H), 7.67 (t, $J$ = 1.8 Hz, 1 H), 8.02 (t, $J$ = 1.8 Hz, 1 H), 10.06 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 136.3, 131.5, 129.5, 123.7, 122.0, 120.6, 109.9, 52.4 ppm. $C_8H_{11}BrN_2$ (215.09): calcd. C 44.67, H 5.15, N 13.02; found C 44.40, H 5.03, N 12.34.

**3-Cyanomethyl-1-vinylimidazolium Bromide (11):** 1.5 g, 70% yield, colorless solid, $T_m$ = 148 °C. IR (KBr): $\tilde{\nu}$ = 3103, 3063, 3034, 2983, 1647, 1555, 1406, 1177 cm$^{-1}$. $^1$H NMR ($D_2O/H_2O$): $\delta$ = 5.53 (dd, $J$ = 3.0, $J$ = 8.7 Hz, 1 H), 5.55 (s, 2 H), 5.89 (dd, $J$ = 3.0, $J$ = 15.5 Hz, 1 H), 7.20 (dd, $J$ = 8.7, $J$ = 15.5 Hz, 1 H), 7.79 (t, $J$ = 1.8 Hz, 1 H), 7.91 (t, $J$ = 1.8 Hz, 1 H), 9.31 (s, 1 H) ppm. $^{13}$C NMR ($D_2O/H_2O$): $\delta$ = 136.6, 128.9, 124.1, 121.4, 114.5, 111.9, 38.3 ppm. $C_7H_8BrN_3$ (214.06): calcd. C 39.28, H 3.77, N 19.63; found C 39.19, H 3.68, N 19.31.

**1-Methyl-3-propargylimidazolium Bromide (15):** 1.8 g, 90% yield, colorless solid, $T_m$ = 68 °C. IR (KBr): $\tilde{\nu}$ = 3196, 3086, 2126, 1627, 1570, 1437, 1342, 1164 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 3.23 (t, $J$ = 2.6 Hz, 1 H), 3.95 (s, 3 H), 5.33 (d, $J$ = 2.6 Hz, 2 H), 7.63 (s, $J$ = 1.8 Hz, 1 H), 7.72 (s, $J$ = 1.8 Hz, 1 H), 9.54 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 137.6, 124.9, 122.9, 78.4, 75.9, 40.0, 37.1 ppm. $C_7H_9BrN_2$ (201.06): calcd. C 41.82, H 4.51, N 13.93; found C 41.31, H 4.50, N 13.42.

**4-Cyanomethyl-1-propargyl-1,2,4-triazolium Bromide (20):** 1.4 g, 62% yield, light brown solid, $T_m$ = 179 °C. IR (KBr): $\tilde{\nu}$ = 3123, 2965, 2117, 1570, 1412, 1379, 1341, 1231, 1152, 1069 cm$^{-1}$. $^1$H NMR ($D_2O/H_2O$): $\delta$ = 3.23 (t, $J$ = 2.6 Hz, 1 H), 5.40 (d, $J$ = 2.6 Hz, 2 H), 5.69 (s, 2 H), 9.18 (s, 1 H), 10.36 (s, 1 H) ppm. $^{13}$C NMR ($D_2O/H_2O$): $\delta$ = 146.0, 144.3, 113.8, 80.0, 73.7, 43.9, 36.9 ppm. $C_7H_7BrN_4$ (227.06): calcd. C 37.03, H 3.11, N 24.67; found C 37.38, H 3.04, N 24.44.

All metathesis reactions were carried out by using halide salts (1 mmol) reacted with silver nitrate or silver perchlorate or silver dicyanoamide or silver dinitroamide (1 mmol) in water (10 mL) in a test tube (100 mL). The mixture was filtered, the water pumped off, and the remaining residue dried under vacuum at 40 °C for 24 h. The yields were essentially quantitative.

**4-Cyanomethyl-1-methyl-1,2,4-triazolium Nitrate (5a):** Colorless solid, $T_m$ = 115 °C. IR (KBr): $\tilde{\nu}$ = 3059, 2952, 2395, 1761, 1580, 1380, 1163 cm$^{-1}$. $^1$H NMR ($D_2O/H_2O$): $\delta$ = 4.21 (s, 3 H), 5.66 (s, 2 H), 9.09 (s, 1 H), 10.08 (s, 1 H) ppm. $^{13}$C NMR ($D_2O/H_2O$): $\delta$ = 145.7, 144.4, 114.2, 40.4, 36.9 ppm. $C_5H_7N_5O_3$ (185.14): calcd. C 32.44, H 3.81, N 37.83; found C 32.46, H 3.67, N 38.01.

**4-Cyanomethyl-1-methyl-1,2,4-triazolium Perchlorate (5b):** Colorless solid, $T_m$ = 140 °C. IR (KBr): $\tilde{\nu}$ = 3059, 2951, 2904, 1578, 1466, 1363, 1072 cm$^{-1}$. $^1$H NMR ([D$_6$]acetone): $\delta$ = 4.12 (s, 3 H), 5.40 (s, 2 H), 8.81 (s, 1 H), 9.59 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]-acetone): $\delta$ = 145.2, 144.0, 113.7, 40.5, 37.0 ppm. $C_5H_7ClN_4O_4$ (222.59): calcd. C 26.98, H 3.17, N 25.17; found C 27.09, H 3.14, N 24.49.

**4-Cyanomethyl-1-methyl-1,2,4-triazolium Dicyanamide (5c):** Colorless solid, $T_m$ = 66 °C. IR (KBr): $\tilde{\nu}$ = 3082, 3019, 2239, 2198, 2136, 1582, 1418, 1318, 1161, 1071 cm$^{-1}$. $^1$H NMR ([D$_6$]acetonitrile): $\delta$ = 4.12 (s, 3 H), 5.47 (s, 2 H), 8.89 (s, 1 H), 9.82 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]acetonitrile): $\delta$ = 145.3, 144.1, 120.7, 113.8, 40.4, 37.0 ppm. $C_7H_7N_7$ (189.18): calcd. C 44.44, H 3.73, N 51.83; found C 43.88, H 3.65, N 49.59.

**4-Cyanomethyl-1-methyl-1,2,4-triazolium Dinitramide (5d):** Colorless liquid, $T_g$ = –45 °C. IR (KBr): $\tilde{\nu}$ = 3091, 2997, 1584, 1518, 1434, 1182, 1013 cm$^{-1}$. $^1$H NMR ([D$_6$]acetonitrile): $\delta$ = 4.11 (s, 3 H), 5.44 (s, 2 H), 8.87 (s, 1 H), 9.75 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]-acetonitrile): $\delta$ = 145.2, 144.1, 113.7, 40.3, 36.8 ppm. $C_5H_7N_7O_4$ (229.15): calcd. C 26.21, H 3.08, N 42.79; found C 25.45, H 2.85, N 42.92.

**1,4-Bis(cyanomethyl)-1,2,4-triazolium Nitrate (6a):** Colorless solid, $T_m$ = 133 °C. IR (KBr): $\tilde{\nu}$ = 3101, 3003, 2957, 2378, 2264, 1755, 1574, 1355, 1073, 934 cm$^{-1}$. $^1$H NMR ($H_2O/D_2O$): $\delta$ = 5.70 (s, 2 H), 5.82 (s, 2 H), 9.25 (s, 1 H), 10.44 (s, 1 H) ppm. $^{13}$C NMR ($H_2O$/$D_2O$): $\delta$ = 146.1, 145.5, 113.3, 113.0, 41.1, 36.8 ppm. $C_6H_6N_6O_3$ (210.15): calcd. C 34.29, H 2.88, N 39.99; found C 34.46, H 2.70, N 39.83.

**1,4-Bis(cyanomethyl)-1,2,4-triazolium Perchlorate (6b):** Colorless solid, $T_m$ = 147 °C. IR (KBr): $\tilde{\nu}$ = 3116, 2925, 2364, 1572, 1419, 1386, 1068 cm$^{-1}$. $^1$H NMR ([D$_3$]acetone): $\delta$ = 5.93 (s, 2 H), 6.04 (s, 2 H), 9.51 (s, 1 H), 10.53 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetone): $\delta$ = 146.4, 146.3, 113.4, 112.9, 41.3, 37.2 ppm. $C_6H_6ClN_5O_4$ (247.61): calcd. C 29.11, H 2.44, N 28.29; found C 29.12, H 2.15, N 27.72.

**1,4-Bis(cyanomethyl)-1,2,4-triazolium Dicyanamide (6c):** Colorless solid, $T_m$ = 114 °C. IR (KBr): $\tilde{\nu}$ = 3121, 2991, 2245, 2201, 2139, 1576, 1318, 1161, 1069 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 5.53 (s, 2 H), 5.64 (s, 2 H), 9.05 (s, 1 H), 10.09 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 146.1, 145.5, 120.6, 113.4, 113.0, 41.5, 37.3 ppm. $C_8H_6N_8$ (214.19): calcd. C 44.86, H 2.82, N 52.32; found C 44.43, H 3.01, N 51.98.

**1,4-Bis(cyanomethyl)-1,2,4-triazolium Dinitramide (6d):** Colorless liquid, $T_g$ = –22 °C. IR (KBr): $\tilde{\nu}$ = 3135, 3080, 2997, 1578, 1518, 1433, 1337, 1179, 1015 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 5.56 (s, 2 H), 5.66 (s, 2 H), 9.06 (s, 1 H), 10.11 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 146.1, 145.7, 113.3, 112.9, 41.5, 37.2 ppm. $C_6H_6N_8O_4$ (254.16): calcd. C 28.35, H 2.38, N 44.09; found C 27.87, H 2.21, N 44.09.

**4-Amino-1-cyanomethyl-1,2,4-triazolium Nitrate (8a):** Colorless solid, $T_m$ = 93 °C. IR (KBr): $\tilde{\nu}$ = 3201, 3103, 2988, 1701, 1626, 1562, 1366, 1166, 1071 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 5.61 (s, 2 H), 6.60 (s, 2 H), 8.81 (s, 1 H), 10.16 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]-acetonitrile): $\delta$ = 146.8, 145.6, 113.4, 41.3 ppm. $C_4H_6N_6O_3$ (186.13): calcd. C 25.81, H 3.25, N 45.15; found C 25.62, H 3.12, N 45.00.

**4-Amino-1-cyanomethyl-1,2,4-triazolium Perchlorate (8b):** Colorless liquid, $T_g$ = –23 °C. IR (KBr): $\tilde{\nu}$ = 3345, 3140, 2962, 2023, 1634, 1567, 1418, 1360, 1171, 1095 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 5.49 (s, 2 H), 6.10 (s, 2 H), 8.76 (s, 1 H), 9.59 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 147.2, 145.4, 113.4, 41.7 ppm. $C_4H_6ClN_5O_4$ (223.57): calcd. C 42.87, H 4.11, N 28.56; found C 43.05, H 3.94, N 28.37.

**3-Cyanomethyl-1-vinylimidazolium Perchlorate (14b):** Colorless solid, $T_m$ = 130 °C. IR (KBr): $\tilde{\nu}$ = 3154, 3098, 3063, 2983, 1652, 1555, 1406, 1368, 1177, 1104 cm$^{-1}$. $^1$H NMR ([D$_3$]acetone): $\delta$ = 5.57 (dd, $J$ = 3.1, $J$ = 8.7 Hz, 1 H), 5.77 (s, 2 H), 6.10 (dd, $J$ = 3.1, $J$ = 15.5 Hz, 1 H), 7.46 (dd, $J$ = 8.7, $J$ = 15.5 Hz, 1 H), 8.09 (t, $J$ = 1.8 Hz, 1 H), 8.24 (t, $J$ = 1.8 Hz, 1 H), 9.66 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetone): $\delta$ = 137.6, 129.6, 124.5, 121.3, 114.2, 111.0, 38.2 ppm. $C_7H_8ClN_3O_4$ (233.61): calcd. C 35.99, H 3.45, N 17.99; found C 35.89, H 3.32, N 17.60.

**3-Cyanomethyl-1-vinylimidazolium Dicyanamide (14c):** Colorless solid, $T_m$ = 73 °C. IR (KBr): $\tilde{\nu}$ = 3105, 2239, 2197, 2135, 1653, 1557, 1425, 1313, 1175 cm$^{-1}$. $^1$H NMR ($D_2O/H_2O$): $\delta$ = 5.59 (dd, $J$ = 3.0, $J$ = 8.7 Hz, 1 H), 5.60 (s, 2 H), 5.95 (dd, $J$ = 3.0, $J$ = 15.5 Hz, 1 H), 7.26 (dd, $J$ = 8.7, $J$ = 15.5 Hz, 1 H), 7.85 (t, $J$ = 1.8 Hz, 1 H), 7.98 (t, $J$ = 1.8 Hz, 1 H), 9.36 (s, 1 H) ppm. $^{13}$C NMR ($D_2O/H_2O$): $\delta$ = 136.7, 129.0, 124.2, 121.5, 120.9, 114.5, 112.0, 38.3 ppm. $C_9H_8N_6$ (200.20): calcd. C 53.99, H 4.03, N 41.98; found C 53.70, H 4.01, N 41.82.

**3-Cyanomethyl-1-vinylimidazolium Dinitramide (14d):** Colorless solid, $T_m$ = 70 °C. IR (KBr): $\tilde{\nu}$ = 3144, 3075, 2996, 1652, 1557, 1515, 1434, 1336, 1182, 1011 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 5.45 (s, 2 H), 5.48 (dd, $J$ = 2.8, $J$ = 8.8 Hz, 1 H), 5.88 (dd, $J$ = 2.8, $J$ = 15.6 Hz, 1 H), 7.20 (dd, $J$ = 8.8, $J$ = 15.6 Hz, 1 H), 7.74 (t, $J$ = 1.8 Hz, 1 H), 7.85 (t, $J$ = 1.8 Hz, 1 H), 9.21 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 137.0, 129.2, 124.2, 121.2, 114.1, 111.5, 38.3 ppm. $C_7H_8N_6O_4$ (240.19): calcd. C 35.01, H 3.36, N 34.99; found C 34.37, H 3.15, N 34.74.

**1-Methyl-3-propargylimidazolium Nitrate (17a):** Colorless solid, $T_m$ = 63 °C. IR (KBr): $\tilde{\nu}$ = 3222, 3151, 3104, 1570, 1378, 1164 cm$^{-1}$. $^1$H NMR ($D_2O/H_2O$): $\delta$ = 3.17 (t, $J$ = 2.6 Hz, 1 H), 3.97 (s, 3 H), 5.14 (d, $J$ = 2.6 Hz, 2 H), 7.54 (t, $J$ = 1.8 Hz, 1 H), 7.64 (t, $J$ = 1.8 Hz, 1 H), 8.93 (s, 1 H) ppm. $^{13}$C NMR ($D_2O/H_2O$): $\delta$ = 137.1, 124.9, 123.0, 78.5, 75.7, 40.0, 36.9 ppm. $C_7H_9N_3O_3$ (183.16): calcd. C 45.90, H 4.95, N 22.94; found C 45.04, H 4.93, N 22.53.

**1-Methyl-3-propargylimidazolium Perchlorate (17b):** Colorless solid, $T_m$ = 74 °C. IR (KBr): $\tilde{\nu}$ = 3268, 3150, 2984, 1607, 1566, 1442, 1387, 1355, 1165, 1093 cm$^{-1}$. $^1$H NMR ([D$_6$]acetone): $\delta$ = 3.35 (t, $J$ = 2.6 Hz, 1 H), 4.10 (s, 3 H), 5.30 (d, $J$ = 2.6 Hz, 2 H), 7.76 (t, $J$ = 1.8 Hz, 1 H), 7.81 (t, $J$ = 1.8 Hz, 1 H), 9.13 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 137.7, 125.2, 123.2, 78.6, 75.8, 39.8, 36.9 ppm. $C_7H_9ClN_2O_4$ (220.61): calcd. C 38.11, H 4.11, N 12.70; found C 37.85, H 4.02, N 12.62.

**1-Methyl-3-propargylimidazolium Dicyanamide (17c):** Colorless liquid, $T_m$ = 17 °C. IR (KBr): $\tilde{\nu}$ = 3233, 3106, 2236, 2195, 2135, 1570, 1440, 1312, 1164 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 3.16 (t, $J$ = 2.6 Hz, 1 H), 3.88 (s, 3 H), 5.07 (d, $J$ = 2.6 Hz, 2 H), 7.47 (t, $J$ = 1.8 Hz, 1 H), 7.55 (t, $J$ = 1.8 Hz, 1 H), 8.84 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 137.2, 125.0, 123.0, 120.4, 78.6, 75.5, 40.0, 37.0 ppm. $C_9H_9N_5$ (187.20): calcd. C 57.74, H 4.85, N 37.41; found C 58.28, H 4.89, N 38.27.

**1-Methyl-3-propargylimidazolium Dinitramide (17d):** $T_m$ = 62 °C. IR (KBr): $\tilde{\nu}$ = 3258, 3153, 2978, 1515, 1434, 1339, 1183, 1008 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 3.10 (t, $J$ = 2.6 Hz, 1 H), 3.87 (s, 3 H), 5.05 (d, $J$ = 2.6 Hz, 2 H), 7.44 (t, $J$ = 1.8 Hz, 1 H), 7.52 (t, $J$ = 1.8 Hz, 1 H), 8.76 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 137.4, 125.1, 123.1, 78.5, 75.6, 40.0, 37.1 ppm. IR (KBr): $\tilde{\nu}$ = 3258, 3153, 2978, 1515, 1434, 1339, 1183, 1008 cm$^{-1}$. $C_7H_9N_5O_4$ (227.18): calcd. C 37.01, H 3.99, N 30.83; found C 36.43, H 3.97, N 30.78.

**1-Methyl-4-propargyl-1,2,4-triazolium Nitrate (18a):** Colorless solid, $T_m$ = 74 °C. IR (KBr): $\tilde{\nu}$ = 3267, 3085, 2994, 2395, 2130, 1757, 1577, 1375, 1155, 1070 cm$^{-1}$. $^1$H NMR ($D_2O/H_2O$): $\delta$ = 3.16 (t, $J$ = 2.6 Hz, 1 H), 4.14 (s, 3 H), 5.21 (d, $J$ = 2.6 Hz, 2 H), 8.95 (s, 1 H), 9.91 (s, 1 H) ppm. $^{13}$C NMR ($D_2O/H_2O$): $\delta$ = 145.0, 143.4, 79.2, 74.4, 39.7, 38.9 ppm. $C_6H_8N_4O_3$ (184.15): calcd. C 39.13, H 4.38, N 30.42; found C 39.15, H 4.34, N 29.58.

**1-Methyl-4-propargyl-1,2,4-triazolium Perchlorate (18b):** Colorless solid, $T_m$ = 98 °C. IR (KBr): $\tilde{\nu}$ = 3289, 3102, 2988, 1573, 1439, 1373, 1153, 1096 cm$^{-1}$. $^1$H NMR ([D$_6$]acetone): $\delta$ = 3.39 (t, $J$ = 2.6 Hz, 1 H), 4.26 (s, 3 H), 5.37 (d, $J$ = 2.6 Hz, 2 H), 9.09 (s, 1 H), 9.94 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 144.9, 143.8, 79.6,

74.7, 39.9, 38.8 ppm. $C_6H_8ClN_3O_4$ (221.60): calcd. C 32.52, H 3.64, N 18.96; found C 32.52, H 3.45, N 18.89.

**1-Methyl-4-propargyl-1,2,4-triazolium Dicyanamide (18c):** Colorless liquid, $T_g$ = –54 °C. IR (KBr): $\tilde{\nu}$ = 3252, 3067, 2237, 2196, 2135, 1580, 1440, 1314, 1158, 1069 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 3.21 (t, $J$ = 2.6 Hz, 1 H), 4.10 (s, 3 H), 5.17 (d, $J$ = 2.6 Hz, 2 H), 8.83 (s, 1 H), 9.77 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 144.7, 143.3, 120.4, 79.3, 74.5, 39.9, 39.0 ppm. $C_8H_8N_6$ (188.19): calcd. C 51.06, H 4.28, N 44.66; found C 51.35, H 4.33, N 43.88.

**1-Methyl-4-propargyl-1,2,4-triazolium Dinitramide (18d):** Colorless liquid, $T_g$ = –59 °C. IR (KBr): $\tilde{\nu}$ = 3265, 3091, 1582, 1518, 1437, 1184, 1012 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 3.13 (t, $J$ = 2.6 Hz, 1 H), 4.11 (s, 3 H), 5.18 (d, $J$ = 2.6 Hz, 2 H), 8.80 (s, 1 H), 9.68 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 144.8, 143.5, 79.3, 74.6, 40.1, 39.1 ppm. $C_6H_8N_6O_4$ (228.17): calcd. C 31.58, H 3.53, N 36.83; found C 30.97, H 3.42, N 37.22.

**4-Cyanomethyl-1-propargyl-1,2,4-triazolium Nitrate (21a):** Colorless solid, $T_m$ = 112 °C. IR (KBr): $\tilde{\nu}$ = 3135, 2951, 1683, 1569, 1347, 1151, 1070 cm$^{-1}$. $^1$H NMR (D$_2$O/H$_2$O): $\delta$ = 3.18 (t, $J$ = 2.6 Hz, 1 H), 5.36 (d, $J$ = 2.6 Hz, 2 H), 5.64 (s, 2 H), 9.13 (s, 1 H), 10.31 (s, 1 H) ppm. $^{13}$C NMR (D$_2$O/H$_2$O): $\delta$ = 146.1, 144.5, 113.9, 80.0, 73.9, 44.0, 36.9 ppm. $C_7H_7N_5O_3$ (209.16): calcd. C 40.20, H 3.37, N 33.48; found C 40.10, H 3.45, N 33.68.

**4-Cyanomethyl-1-propargyl-1,2,4-triazolium Perchlorate (21b):** Colorless solid, $T_m$ = 125 °C. IR (KBr): $\tilde{\nu}$ = 3271, 3135, 2988, 1574, 1423, 1348, 1100 cm$^{-1}$. $^1$H NMR ([D$_6$]acetone): $\delta$ = 3.45 (t, $J$ = 2.6 Hz, 1 H), 5.57 (d, $J$ = 2.6 Hz, 2 H), 5.87 (s, 2 H), 9.40 (s, 1 H), 10.45 (s, 1 H) ppm. $^{13}$C NMR ([D$_6$]acetone): $\delta$ = 146.0, 144.7, 113.6, 79.5, 74.2, 43.5, 36.9 ppm. $C_7H_7ClN_4O_4$ (246.61): calcd. (246.61) C, 34.09; H, 2.86; N, 22.72. Found: C, 34.14; H, 2.49; N, 21.99.

**4-Cyanomethyl-1-propargyl-1,2,4-triazolium Dicyanamide (21c):** Colorless liquid, $T_g$ = –23 °C. IR (KBr): $\tilde{\nu}$ = 3126, 2985, 2239, 2131, 1673, 1574, 1428, 1317, 1154 cm$^{-1}$. $^1$H NMR ([D$_3$]acetonitrile): $\delta$ = 3.18 (t, $J$ = 2.6 Hz, 1 H), 5.31 (d, $J$ = 2.6 Hz, 2 H), 5.48 (s, 2 H), 8.97 (s, 1 H), 10.03 (s, 1 H) ppm. $^{13}$C NMR ([D$_3$]acetonitrile): $\delta$ = 145.9, 144.3, 121.5, 113.7, 79.7, 74.0, 43.9, 37.2 ppm. $C_9H_7N_7$ (213.20): calcd. C 50.70, H 3.31, N 45.99; found C 50.16, H 3.04, N 44.10.

**4-Cyanomethyl-1-propargyl-1,2,4-triazolium Dinotramide (21d):** Colorless solid, $T_m$ = 100 °C. IR (KBr): $\tilde{\nu}$ = 3140, 2955, 1697, 1570, 1349, 1152, 1071 cm$^{-1}$. $^1$H NMR (D$_2$O/H$_2$O): $\delta$ = 3.12 (t, $J$ = 2.6 Hz, 1 H), 5.30 (d, $J$ = 2.6 Hz, 2 H), 5.59 (s, 2 H), 9.08 (s, 1 H), 10.26 (s, 1 H) ppm. $^{13}$C NMR (D$_2$O/H$_2$O): $\delta$ = 145.9, 144.2, 113.6, 79.7, 73.6, 43.7, 36.7 ppm. $C_7H_7N_7O_4$ (253.17): calcd. C 33.21, H 2.79, N 38.73; found C 33.07, H 2.73, N 37.52.

## Acknowledgments

The authors gratefully acknowledge the support of the Air Force Office of Scientific Research (AFOSR) (F49 620-03-1-0209), the National Science Foundation (NSF) (Grant CHE0315 275), and the Office of Naval Research (ONR) (Grant N00014-06-1-1032). We are grateful to Dr. Alex Blumenfeld for NMR analyses.

# On the Influence of "Arm-on, Arm-off" Processes on Alkene Hydrogenation Catalysed by a Rhodium Triphos Complex

**Adrian B. Chaplin[a] and Paul J. Dyson*[a]**

**Keywords:** Rhodium / Homogeneous catalysis / Hydrogenation / Tripodal ligands / Phosphane ligands

The influence of phosphane "arm-on, arm-off" association/dissociation in rhodium catalysed alkene hydrogenation using [Rh(COD)($\kappa^3$-triphos)]$PF_6$ {**1**, COD = cyclooctadiene, triphos = 1,1,1-tris(diphenylphosphanylmethyl)ethane} has been investigated by comparison of the activity of **1** to mixtures of the related diphosphane complex, [Rh(COD)($\kappa^2$-dppp)]$PF_6$ {**2**, dppp = 1,3-bis(diphenylphosphanyl)propane} and triphenylphosphane (THF, 50 °C, 1 bar $H_2$). These investigations are supplemented by a demonstration of the $\kappa^2$–$\kappa^3$ fluxionally of the triphos coordination in **1** by reversible reaction with $[RuCl_2(p\text{-cymene})]_2$ at room temperature in $CH_2Cl_2$. The product of this reaction, the bimetallic complex [(*p*-cymene)$Cl_2$Ru{($PPh_2CH_2$)CMe($CH_2PPh_2$)$_2$}Rh(COD)]$PF_6$, was isolated and fully characterized, including determination of the solid-state structure by X-ray diffraction analysis. Despite this evidence for facile arm-off dissociation of the triphos ligand in **1**, complex **2**, with or without triphenylphosphane, was found to be more efficient for the hydrogenation of styrene and cyclohexene. Notably, use of triphenylphosphane together with **2** was found to have beneficial effects – increasing the rate of styrene hydrogenation (in some cases) and helping to stabilise the metal center during cyclohexene hydrogenation. These observations are supported by mercury poisoning experiments and reactivity experiments with **2** in medium pressure sapphire NMR tubes.

## Introduction

Tripodal triphosphane ligands have found widespread application in inorganic and organometallic chemistry.[1] Among these ligands, the $C_3$ symmetric 1,1,1-tris(diphenylphosphanylmethyl)ethane (triphos) and it's derivatives are among the most extensively investigated, forming a large variety of transition metal complexes, many of which have found applications in catalysis.[1,2] Bianchini and co-workers, in particular, have pioneered the use of this ligand in transition metal catalysis, using platinum group metals for a number of processes, including hydrogenation and hydroformylation of alkenes,[3] oxidation of catechols,[4] coupling reactions of alkynes,[5] and the hydrogenation, hydrogenolyis and hydrodesulfurisation of thiophenes.[6] Functionalisation of the triphos ligand by derivation of the bridgehead atom with appropriate moieties has allowed the formation of metallo-dendrimers[7] or immobilisation of metal complexes on silica[8] or into biphases;[9] facilitating catalyst reuse or modifying reactivity. Such immobilization is complemented by the tridentate nature of the ligand, stabilising the metal center during catalysis and reducing leaching.

Although commonly found in a tridentate ($\kappa^3$) coordination mode,[1] $\kappa^2$-coorindination of triphos is also observed in a number of transition metal complexes.[10] The interconversion between these $\kappa^2$ and $\kappa^3$ coordination modes by "arm-on, arm-off" association/dissociation of one of the phosphane arms has been implicated in the reactivity and catalytic activity of triphos complexes, particularly those of rhodium.[10c,11] Notably, Kiss and Hováth demonstrated a reversible arm-off dissociation in [Rh(CO)H($\kappa^3$-triphos)], an active hydroformylation catalyst,[3a] and addition of CO under hydroformylation conditions at room temperature by high pressure IR and $^{31}$P NMR spectroscopy (Scheme 1).[12] Caulton and co-workers have further affirmed the importance of this arm-off mechanism in hydroformylation catalysis by reactions of related hydride, alkyl and acetyl rhodium triphos complexes.[13] During their investigation of rhodium triphos, and related tripodal phosphane complexes, Huttner and co-workers suggested that the $\kappa^3$-coordination of the phosphane hinders hydrogenation,[14] and

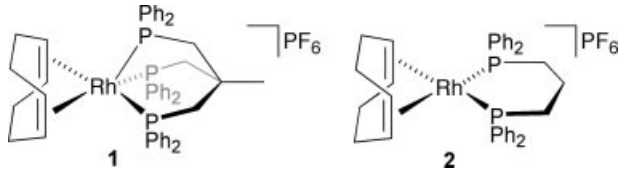
they demonstrated that related diphosphane complexes are significantly more active for the hydrogenation of (*Z*)-α-*N*-acetamidocinnamic acid.[15] Burk and co-workers have also reported similar behaviour for other rhodium tripodal phosphane systems.[16]

To further investigate the importance of phosphane arm-on, arm-off processes in the hydrogenation activity of rhodium triphos complexes, we report here a comparison of the activity of [Rh(COD)(κ$^3$-triphos)]$PF_6$ (**1**) with mixtures of the related diphosphane complex, [Rh(COD)(κ$^2$-dppp)]-$PF_6$ (**2**), and triphenylphosphane (Scheme 2).[14a,15] To complement these investigations, relevant in situ reactivity studies are also presented together with the demonstration of the κ$^2$–κ$^3$ interconversion in complex **1** using a ruthenium complex.

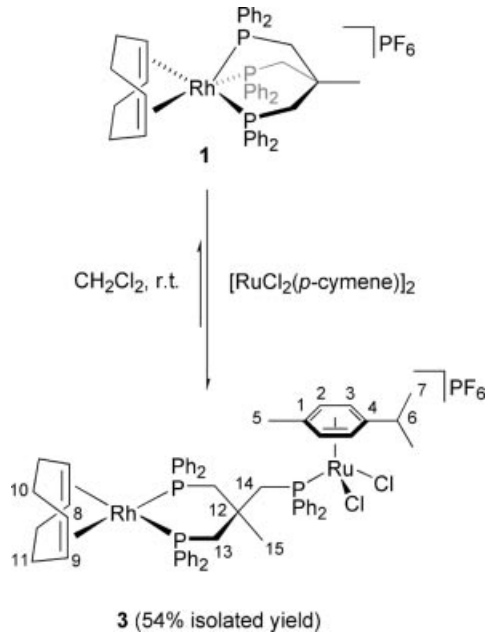


Scheme 2.

## Results and Discussion

### 1. Reaction of 1 with [$RuCl_2$(*p*-cymene)]$_2$

To probe the presence of an arm-on, arm-off process, **1** was reacted at room temperature with the dinuclear ruthenium complex [$RuCl_2$(*p*-cymene)]$_2$, well known to react rapidly with phosphane ligands,[17] in an attempt to trap the κ$^2$-coordination mode of the triphos ligand. After 30 minutes, analysis of the reaction solution by $^{31}$P NMR spectroscopy revealed the formation of the bimetallic complex, [(*p*-cymene)$Cl_2$Ru{($PPh_2CH_2$)CMe($CH_2PPh_2$)$_2$}-Rh(COD)]-$PF_6$ **3**, identified by the presence of characteristic singlet and doublet ($^1J_{RhP}$ = 141 Hz) resonances at $\delta$ = 16.6 and 13.1 ppm, respectively, in a 1:2 ratio together with a small quantity of **1** (Scheme 3). Subsequently, **3** was isolated, albeit in moderate yield (54%), following recrystallisation and the structure was further verified by $^1$H and $^{13}$C NMR spec-



Scheme 3. Formation and equilibrium of complex **3** (with NMR numbering scheme).

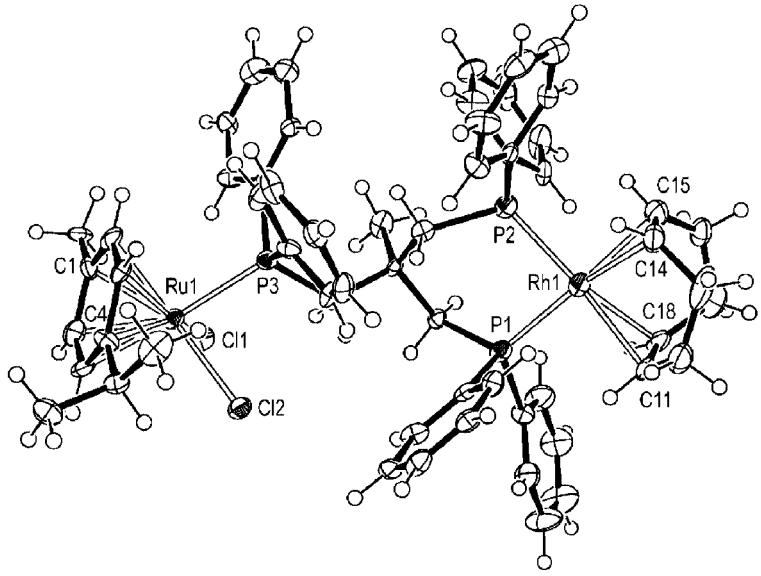


Figure 1.ORTEP representation of **3**; thermal ellipsoids drawn at 50%. Solvent molecules and counter anion omitted for clarity. Key bond lengths [Å] and angles [°]: Ru1–Cl1 2.420(3), Ru1–Cl2 2.421(2), Ru1–P3 2.356(3); Cl1–Ru1–Cl2 88.23(8), Cl1–Ru1–P3 88.37(9), Cl2–Ru1–P1 83.78(8); Ru1–C1 2.200(9), Ru1–C4 2.227(9), Ru1–$C_{avg}$ 2.21(2), Rh1–P1 2.287(3), Rh1–P2 2.286(3); P2–Rh1–P3 88.06(10); Rh1–C11 2.274(8), Rh1–C18 2.263(9), Rh1–C14 2.217(10), Rh1–C15 2.226(10).

troscopy and electrospray ionization mass spectrometry (ESI-MS). Furthermore, the solid-state structure of **3** has been established by X-ray diffraction analysis – depicted in Figure 1. The bonding parameters about the Ru center are similar to related [$RuCl_2$($\kappa^1$-phosphane)(*p*-cymene)] (Ru–P ≈ 2.4 Å)[18] complexes, while those about the Rh center are similar to [Rh(COD)($\kappa^2$-dppp)]$BF_4$ {**1**·$BF_4$, Rh–P 2.311(2), 2.319(2) Å; P–Rh–P 90.81(4)°},[19] although the Rh–P bond length and P–Rh–P angle are slightly contracted in **3** in comparison to **1**·$BF_4$ {Rh1–P1, 2.287(3) Å; Rh1–P2, 2.286(3) Å; P1–Rh–P2, 88.06(10)°}. In $CD_2Cl_2$ solution at room temperature, **3** undergoes a slow equilibration reaction ($t_{1/2}$ = 22 ± 3 h) in which dissociation of the phosphane from the ruthenium-arene moiety results in an mixture of **1**, **3**, and [$RuCl_2$(*p*-cymene)]$_2$ with a equilibrium constant, *K*, of approximately 2, demonstrating the reversible nature of the triphos coordination.

## 2. Catalytic Activity

The catalytic activity of **1** and solutions of **2** containing various quantities of triphenylphosphane were first investigated for the hydrogenation of styrene. The hydrogenation experiments were carried out in THF, a weakly coordinating solvent,[20] at 50 °C under 1 bar of $H_2$ with a substrate to catalyst (S/C) ratio of 200:1; **2** was investigated with 0, 0.5, 1, 2, and 5 equiv. of triphenylphosphane. Conversion was monitored by GC during the reaction and results are listed in Table 1 with selected data depicted in Figure 2. Both complexes were found to exhibit incubation periods, consistent with previously reported kinetic studies on diphosphane rhodium complexes containing the COD ligand (attributed to hydrogenation of the diene).[21] From the hydrogenation curves (Figure 2) it is apparent that **1** is significantly less active than **2** under these conditions. Catalytic runs carried out with **2** in the presence of added triphenylphosphane showed enhanced rates of hydrogenation at 50% conversion in comparison to **2** alone – most pronounced with 1 equiv. of the phosphane. However, in the presence of excess triphenylphosphane significant reductions in the rate of hydrogenation with **2** are observed close to complete conversion (> 90%), resulting in longer reactions times than in the absence of triphenylphosphane (see insert in Figure 2). Addition of mercury, a selective poison for heterogeneous catalysis, did not inhibit catalytic activity for **2** + *n*$PPh_3$ (*n* = 0 or 1) significantly.[22]

Table 1. Hydrogenation of styrene using **1** and **2** + *n*$PPh_3$.[a]

| | *n* | 50% Conversion Time/h | TOF[b]/$h^{-1}$ | > 99% Conversion Time/h |
|---|---|---|---|---|
| **1** | | 2.83 | 32 | 10 |
| **2** | 0 | 1.72 | 68 | 3.5 |
| **2**[c] | 0 | 1.81 | 62 | 4.5 |
| **2** | 0.5 | 1.63 | 74 | 3.5 |
| **2** | 1 | 1.50 | 80 | 3.0 |
| **2**[c] | 1 | 1.49 | 80 | 3.5 |
| **2** | 2 | 1.65 | 72 | 4.0 |
| **2** | 5 | 1.65 | 70 | 4.5 |

[a] Conditions: $2.6 \times 10^{-5}$ mol pre-catalyst, S/C = 200:1, 20 mL of THF, 0.1 mL of octane (internal standard), 1 bar $H_2$. Conversion determined by GC analysis of reaction aliquots. [b] Calculated at 50% conversion from hydrogenation progress. [c] 0.1 mL of Hg added.

In comparison to styrene, the initial rate of cyclohexene hydrogenation using **2** is significantly reduced by the addition of 1 equiv. of triphenylphosphane (Figure 3). However, mercury poisoning experiments suggest a significant degree of heterogeneous character to the active species for **2** alone, whereas, with 1 equiv. of triphenylphosphane there is no significant change in activity in the presence of mercury (Figure 3 and Table 2). This difference is also apparent to some degree by significant darkening of the reaction solution after ca. 90 min in the absence of triphenylphosphane, whereas with 1 equiv. of triphenylphosphane the solution remains yellow throughout the reaction. For **1**, the initial rate of hydrogenation is comparable to **2** with 1 equiv. of triphenylphosphane, although activity is gradually reduced and is accompanied by the reaction solution becoming green/brown – consistent with decomposition into inactive molecular species.

Together, these results are consistent with the ability of the triphos ligand to undergo reversible phosphane arm-off coordination during catalysis. While the catalytic activity of

| **2** | 0 | 2.81 | 24 |
| **2**[d] | 0 | 8.78 | 6 |
| **2** | 1 | 4.36 | 22 |
| **2**[d] | 1 | 4.59 | 26 |

[a] Conditions: $2.6 \times 10^{-5}$ mol pre-catalyst, S/C = 200:1, 20 mL of THF, 0.1 mL of octane (internal standard), 1 bar $H_2$. Conversion determined by GC analysis of reaction aliquots. [b] Calculated at 50% conversion from hydrogenation progress. [c] Conversion < 50%. [d] 0.1 mL of Hg added.

**1** is attributed to the ability of the triphos ligand to undergo an arm-off dissociation process, leading to active species containing the $\kappa^2$-coordinated ligand and a vacant coordination site (i.e. becoming directly analogous to **2**), the adoption of the $\kappa^3$-mode during catalysts is suggested to complete with substrate significantly during catalysis resulting in significantly lower activity than **2**. This suggestion is supported by similar reductions in activity observed for the hydrogenation of styrene with **2** and excess triphenylphosphane, but only near reaction completion, when substrate concentration is low. The reduced effect of triphenylphosphane coordination in comparison to the arm-on, arm-off process in **1** is presumably due to the absence of the chelate effect and the bulky nature of triphenylphosphane. (*Note:* no reaction with **2** and triphenylphosphane can be detected in THF cf. $\kappa^3$-coordination of the triphos ligand in **1**.) The failure of **1** to hydrogenate cyclohexene to completion may also be rationalised by the tendency of the triphos ligand in **1** to adopt a $\kappa^3$-coordination mode. This feature together with the more hindered nature of cyclohexene could be responsible for the decomposition observed with this substrate in comparison with styrene.

While the arm-on coordination appears to be detrimental the catalytic activity of **1**, the addition of triphenylphosphane, in an attempt to mimic this behaviour,[23] during catalysis with **2** had a number of beneficial outcomes. For example, in the hydrogenation of cyclohexene with **2**, addition of triphenylphosphane appeared to stabilise the metal center, i.e. by reversible coordination, preventing decomposition with only a minor decrease in activity. For styrene, addition of, for example, one equivalent of triphenylphosphane noticeably increased the rate of hydrogenation. As Osborn-type rhodium and iridium complexes are known to react with arenes under hydrogenation conditions to form inactive species of the type, $[M(\eta^6\text{-arene})L_2]^+$,[20] reversible coordination of triphenylphosphane may help prevent the formation of species of this nature and thus enhance the rate of hydrogenation. This possibility was thus investigated further (see below).

### 3. Effect of Triphenylphosphane on the Formation of $[Rh(\eta^6\text{-toluene})(\kappa^2\text{-dppp})]^+$

To further investigate the enhancement of catalytic activity of **2** with triphenylphosphane for styrene hydrogenation, reactions of **2** with hydrogen (ca. 12 bar) in the presence of toluene (ca. 80 equiv.) and triphenylphosphane were carried out in medium pressure sapphire NMR tubes.[24,25] In the absence of triphenylphosphane, following COD hydrogenation, $[Rh(\eta^6\text{-toluene})(\kappa^2\text{-dppp})]^+$ **4** is formed quantitatively.[26] However, in the presence of 5 equiv. of triphenylphosphane **4** cannot be detected and instead a species assigned to *cis*-$[RhH_2(PPh_3)_2(\kappa^2\text{-dppp})]^+$ **5** is observed in ca. 94% yield.[27] The identity and geometry of this species is deduced primarily from the $^{31}P\{^1H\}$ NMR spectrum, which exhibits four distinct phosphorus resonances with characteristic multiplicity and coupling constants (Figure 4). Notably, those centred at $\delta$ = 31.3 and 18.3 ppm exhibit large $^2J_{PP}$ coupling constants of 318 Hz, suggesting a *trans* arrangement of two of the phosphane moieties,[28] and $^1J_{RhP}$ coupling constants of ca. 100 Hz. The other phosphorus resonances, centred at 21.6 and –3.6 ppm, have smaller $^1J_{RhP}$ coupling constants (82 and 85 Hz) consistent with phosphane moieties *trans* to hydride ligands.[29] The remaining $^2J_{PP}$ coupling constants, ca. 20 Hz, are typical for *cis*-coordinated phosphane ligands.[28] Furthermore, the $^1H$ NMR spectrum exhibits two broad doublets at –10.55 and –11.33 ppm with $^2J_{PH}$ coupling constants of 132 and 136 Hz, respectively. A similar species, containing instead a tetradentate phosphane, has been reported by Bianchini and co-workers.[30]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

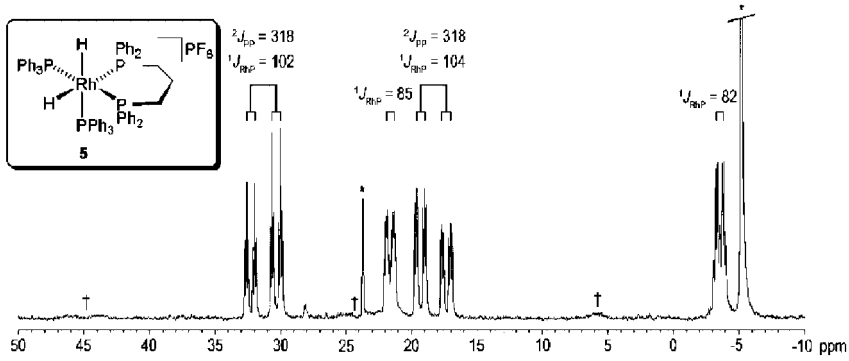

Figure 4. $^{31}P\{^1H\}$ NMR spectrum of **5**. * $PPh_3$ ($\delta \approx 5$ ppm) and $OPPh_3$ ($\delta \approx 24$ ppm), † denotes complex **6**.

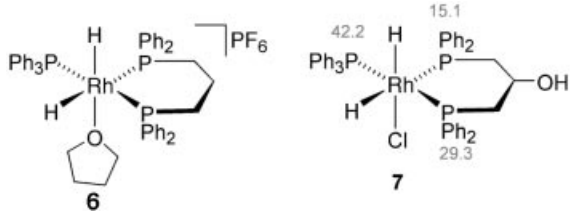
In the presence of 1 equiv. of triphenylphosphane **4** is formed, although only in modest yield (ca. 24%), together with a new species, exhibiting two broad doublets of doublets at 45.0 ($^2J_{PP}$ = 340 Hz, $^1J_{RhP}$ = 112 Hz) and 24.0 ppm ($^2J_{PP}$ = 340 Hz, $^1J_{RhP}$ = 112 Hz) and a broad resonance at 5.8 ppm (ca. 54%), and a small amount of **5** (ca. 12%). This new species is tentatively assigned as *cis*-$[RhH_2(THF)(PPh_3)(\kappa^2\text{-dppp})]^+$ (**6**, Scheme 4) on the basis of these data and their good agreement with that of the known complex *cis*-$[RhH_2Cl(PPh_3)(\kappa^2\text{-}\{PPh_2CH_2\}_2CHOH)]$ **7** (Scheme 4).[27,31] A small quantity of this complex is also observed during the reaction with 5 equiv. (ca. 4%).



Scheme 4. Proposed structure of **6** and the known compound **7** {annotated with $^{31}P$ NMR spectroscopic data ([$D_8$]toluene / ppm)}.[31]

Combined these data are consistent with the ability of triphenylphosphane to hinder the coordination of arene substrates or products under catalytic conditions, supporting the observation of enhanced activity on addition of triphenylphosphane during hydrogenation of styrene with complex **2**.

## Concluding Remarks

The influence of the phosphane arm-on, arm-off process in rhodium triphos complexes for hydrogenation catalysis has been further established by comparison to related dppp systems with added triphenylphosphane. Despite further evidence for facile dissociation of one of the triphos arms in these systems, by the reaction of **1** with $[RuCl_2(p\text{-cymene})]_2$, the tendency of this ligand to adopt a $\kappa^3$-coordination appears to significantly encumber catalytic activity by competing with the substrate for vacant coordination sites on the metal. In comparison, in an attempt to mimic the $\kappa^3$-coordination motif in the triphos complex, added triphenylphosphane results in the enhancement of the rate of catalytic activity during the hydrogenation of styrene with **2**, although with excess triphenylphosphane, reduction in the hydrogenation rate close to completion is observed – upholding the proposed reduction of activity by $\kappa^3$-coordination of the triphos ligand in **1**. The enhanced rate of styrene hydrogenation is attributed to the ability of triphenylphosphane to prevent the coordination of the substrate or product (by weak and reversible coordination) during catalysis, and this hypothesis is supported by medium pressure in situ reactions of **2** with $H_2$, toluene and different quantities of triphenylphosphane. The use of triphenylphosphane with **2** also has the beneficial effect of stabilizing the metal center towards decomposition during catalysis as demonstrated in the hydrogenation of cyclohexene.

## Experimental Section

**General:** All organometallic manipulations were carried out under a nitrogen atmosphere using standard Schlenk techniques. Solvents ($CH_2Cl_2$, THF, toluene) were dried catalytically under dinitrogen using a solvent purification system, manufactured by Innovative Technology Inc. All other solvents were p.a. quality and saturated with nitrogen prior to use. Styrene and cyclohexene were saturated with nitrogen and stored over activated molecular sieves. $[Rh(COD)(\kappa^3\text{-triphos})]PF_6$ (**1**),[15] $[Rh(COD)(\kappa^2\text{-dppp})]PF_6$ (**2**),[14a] and $[RuCl_2(p\text{-cymene})]_2$[32] were prepared as described elsewhere. All other chemicals are commercial products and were used as received. NMR spectra were recorded with a Bruker Avance 400 spectrometer at room temperature, unless otherwise stated. Chemical shifts are given in ppm and coupling constants (*J*) in Hz. The NMR labelling for complex **3** is given in Scheme 3. ESI-MS were recorded on a Thermo Finnigan LCQ DecaXP Plus quadrupole ion trap instrument according to a literature protocol;[33] $CH_2Cl_2$ was used as the solvent for all experiments with a capillary temperature of 80 °C and spray voltage of 5.0 kV.

**Preparation of $[(p\text{-Cymene})Cl_2Ru\{(PPh_2CH_2)CMe(CH_2PPh_2)_2\}Rh(COD)]PF_6$ (3):** A solution of $[Rh(COD)(\kappa^3\text{-triphos})]PF_6$ (0.070 g, 0.071 mmol) and $[RuCl_2(p\text{-cymene})]_2$ (0.022 g, 0.036 mmol) in $CH_2Cl_2$ (10 mL) was stirred at room temp. for 30 min. The solution was then concentrated to ca. 5 mL and hexane (ca. 10 mL) added precipitating out a small amount of a un-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

identified brown impurity, which was removed by filtration. The product was obtained as a microcrystalline orange solid from the filtrate upon standing at –20 °C. Yield 0.049 g (54%). Crystals suitable for X-ray diffraction were obtained from a $CH_2Cl_2$/hexane solution of the complex at –20 °C. $^1$H NMR ($CD_2Cl_2$): $\delta$ = 7.26–7.92 (m, 30 H), 5.12 (d, $^3J_{HH}$ = 6.1, 2 H, H$^3$), 5.07 (d, $^3J_{HH}$ = 5.7, 2 H, H$^2$), 4.74–4.84 (m, 2 H, H$^8$), 4.01–4.11 (m, 2 H H$^9$), 3.00–3.10 (m, 2 H, H$^{13}$), 2.70–2.78 (m, 2 H, H$^{14}$), 2.59 (sept, $^3J_{HH}$ = 6.9, 1 H, H$^6$), 2.41–2.50 (m, 2 H, H$^{10}$), 2.30–2.41 (m, 2 H, H$^{10'}$), 2.06–2.21 (m, 4 H, H$^{11}$), 1.83–1.96 (m, 2 H, H$^{13'}$), 1.78 (s, 3 H, H$^5$), 1.05 (d, $^3J_{HH}$ = 7.0, 6 H, H$^7$), –0.09 (s, 3 H, H$^{15}$) ppm. $^{13}$C{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = 127–135 (m), 109.6 (s, C$^4$), 104.4–104.9 (m, C$^9$), 98.8–99.3 (m, C$^8$), 95.3 (s, C$^1$), 89.9 (d, $^2J_{PC}$ = 3, C$^2$), 86.3 (d, $^2J_{PC}$ = 6, C$^3$), 45.0–45.7 (m, C$^{14}$), 39.7 (d, $^2J_{PC}$ = 6, C$^{12}$), 36.2–36.9 (m, C$^{13}$), 31.4 (s, C$^{15}$), 30.3 (s, C$^6$), 30.0 (s, C$^{10}$), 29.9 (s, C$^{11}$), 21.4 (s, C$^7$), 17.1 (s, C$^5$) ppm. $^{31}$P{$^1$H} NMR ($CD_2Cl_2$): $\delta$ = 16.6 (s, 1 P, Ru*P*Ph$_2$), 13.1 (d, $^1J_{RhP}$ = 141, 2 P, Rh*P*Ph$_2$), –144.4 (sept, $^1J_{PF}$ = 711, 1 P, *P*F$_6$) ppm. ESI-MS ($CH_2Cl_2$, 80 °C, 5 kV) positive ion: *m*/*z*, 834 (30%) [M –RuCymeneCl$_2$]$^+$, 1141 [M]$^+$. ESI-MS$^2$ (+1141): *m*/*z*, 834 [M – RuCymeneCl$_2$]$^+$. $C_{59}H_{65}Cl_2F_6P_4RhRu$ (1286.94 g mol$^{-1}$): calcd. C 55.07, H 5.09; found C 55.14, H 5.11.

**Medium Pressure NMR Experiments:** Reactions of **2** (9 mg) with $H_2$ (12 bar) and toluene (0.1 mL, ca. 80 equiv.) were carried out in 10 mm sapphire NMR tubes in THF (2.5 mL) with the appropriate quantity of triphenylphosphane. All samples were prepared under nitrogen. Reaction progress was followed by $^{31}$P NMR spectroscopy until complete consumption of **2** was observed, typically < 5 h (no further change in product distributions were observed). Selected $^1$H and $^{31}$P{$^1$H} NMR spectroscopic data for **5** and **6** follow; referenced externally to TMS and 85% $H_3PO_4$, respectively. $^1$H NMR (**5**, THF, hydride region): $\delta$ = –10.55 (br. d, $^2J_{PH}$ = 132, 1 H), –11.33 (br. d, $^2J_{PH}$ = 136, 1 H) ppm. $^{31}$P{$^1$H} NMR (**5**, THF): $\delta$ = 31.3 (ddt, $^2J_{PP}$ = 318, $^1J_{RhP}$ = 102, $^2J_{PP}$ = 21, 1 P), 21.6 (dq, $^1J_{RhP}$ = 85, $^2J_{PP}$ = 20, 1 P), 18.3 (dddd, $^2J_{PP}$ = 318, $^1J_{RhP}$ = 104, $^2J_{PP}$ = 26, $^2J_{PP}$ = 16, 1 P), 3.6 (dq, $^1J_{RhP}$ = 82, $^2J_{PP}$ = 23, 1 P) ppm. $^{31}$P{$^1$H} NMR (**6**, THF): $\delta$ = 45.0 (br. d, $^2J_{PP}$ = 340, $^1J_{RhP}$ = 112, 1 P), 24.0 (br. d, $^2J_{PP}$ = 340, $^1J_{RhP}$ = 112, 1 P) 5.8 (br., 1 P) ppm. The hydride region of the $^1$H NMR spectrum of **6** was broad and uninformative.

**Catalytic Evaluations:** Catalytic experiments were conducted in a 50 mL three-necked round-bottomed flask equipped with a 2.0 L latex balloon (Dräger/2165694) connected via a 6 cm reflux condenser and gas tap, a septum cap and gas adaptor. Following pressurisation of the balloon with hydrogen (1 bar), via successive vacuum hydrogen cycles, the flask was charged with pre-catalyst ($2.6\times10^{-5}$ mol) and magnetic stirring bar and placed under an inert atmosphere. THF (20 mL), octane (0.1 mL), substrate ($5.2\times10^{-3}$ mol) and, for the poisoning experiments, mercury (0.1 mL) were then added via syringe through the septum cap. The system was then placed under $H_2$ by three vacuum/$H_2$ cycles and then heated at 50 °C. The hydrogenation was followed by sampling the reaction solution at *t* = 10, 20, 30, 60, 90, 120, 180, 210, 240, 270, 300 min and every successive hour up to *t* = 12 h by GC (Varian chrompack CP-3380 gas chromatograph) or until reaction completion. Full hydrogenation data is given in the supplementary material.

**Crystallography:** Relevant details for the structure refinement are given in Table 3 and selected geometrical parameters for **3** are found in caption of Figure 1. Data collection for the X-ray structure determination was performed on a KUMA CCD diffractometer system using graphite monochromated Mo-$K_\alpha$ radiation (0.71073 Å) and a low-temperature device [140(2) K]. Data reduction was performed using CrysAlis RED.[34] The structure was solved using SIR97,[35] and refined (full-matrix least-squares on $F^2$) using SHELXTL.[36] An absorption correction was applied to the data set (empirical, DELABS).[37] All non-hydrogen atoms were refined anisotropically, with hydrogen atoms placed in calculated positions using the riding model. The occupancy of one of the $CH_2Cl_2$ molcules was refined to 66% and it was necessary to retrain the displacement parameters of some atoms. The graphical representation of **3** was made with ORTEP3.[38]

Table 3. Crystal data and details of the structure determinations of **3**.

| Formula | $C_{59}H_{65}Cl_2F_6P_4RhRu\cdot4.66\,CH_2Cl_2$ |
|---|---|
| *M* | 1682.81 |
| Crystal system | triclinic |
| Space group | $P\bar{1}$ |
| *a* /Å | 11.8544(10) |
| *b* /Å | 16.506(2) |
| *c* /Å | 19.485(2) |
| *α* /° | 105.563(10) |
| *β* /° | 90.054(8) |
| *δ* /° | 100.954(9) |
| *V* /Å$^3$ | 3600.5(7) |
| *Z* | 2 |
| Density /g cm$^{-3}$ | 1.552 |
| *μ* /mm$^{-1}$ | 1.002 |
| *θ* range /° | $3.09 < \theta < 25.25$ |
| Measured reflections | 21093 |
| Unique reflections | 11146 [$R_{int}$ = 0.0832] |
| Number of data/restraints/parameters | 11146/126/798 |
| *R*1, *wR*2 [$I > 2\sigma(I)$][a] | *R*1 = 0.0622, *wR*2 = 0.1122 |
| Largest diff. peak and hole /e Å$^{-3}$ | 1.377 and –0.975 [rms = 0.112] |
| GoF[b] | 0.819 |

[a] $R1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, $wR2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$. [b] $GoF = \{\Sigma[w(F_o^2 - F_c^2)^2]/(n-p)\}^{1/2}$ where *n* is the number of data and *p* is the number of parameters refined.

CCDC-645738 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

[23] This approach is inherently limited owing to the different possible coordination geometries that could be obtained and the chelate effect. For example, the triphos ligand adopts a *fac*-coordination geometry, while in the dppp-$PPh_3$ system the *mer*-geometry is more likely (see section 3). However, despite these limitations similar impacts on catalytic activity could be expected with high concentrations of $PPh_3$.
[24] No reactions of **2** with $PPh_3$ where observed before pressurisation with $H_2$.

# Combined Studies on the Surface Coordination Chemistry of Benzotriazole at the Copper Electrode by Direct Electrochemical Synthesis and Surface-Enhanced Raman Spectroscopy

**Ya-Xian Yuan,[a] Ping-Jie Wei,[a] Wei Qin,[a] Yong Zhang,[a] Jian-Lin Yao,*[a] and Ren-Ao Gu[a]**

**Keywords:** Benzotriazoles / Copper / Surface coordination / Electrochemistry / Raman spectroscopy

The surface coordination chemistry of benzotriazole (BTAH) on a Cu electrode was investigated by electrochemical synthesis of surface complexes and in situ electrochemical surface-enhanced Raman spectroscopy (SERS) in nonaqueous solution. Two different surface complexes were prepared in solution with or without triphenylphosphane ($PPh_3$). A new mixed-valence Cu–N cluster compound containing BTAH was synthesized by direct electrochemical oxidation of Cu in nonaqueous solutions with $PPh_3$. The final product, $Cu_5Cl(BTA)_5(PPh_3)_4$ was crystallized and characterized by microanalysis and Raman spectroscopy together with X-ray crystallographic determinations. The complex crystallized in a monoclinic space group ($P2_1/n$) with lattice parameters $a$ = 16.739(2) Å, $b$ = 18.919(2) Å, $c$ = 31.042(4) Å, $\beta$ = 103.194(3)°, $V$ = 9571.0(19) Å$^3$, $R_1$ = 0.0704, $wR_2$ = 0.1643. The results showed that the complex was a pentanuclear compound. The central $Cu^{II}$ atom is coordinated to four equatorial and one axial $BTA^-$ ligands to form a distorted tetragonal pyramidal coordination polyhedron, whereas each surrounding $Cu^I$ ion is in a distorted tetrahedral environment. The in situ SERS studies revealed that the $BTA^-$ ion was coordinated to a Cu surface through its two N atoms of the triazole ring to form a surface polymer complex of $[Cu(BTA)]_n$, which suppressed the dissolution and oxidation of Cu effectively. The introduction of $PPh_3$ blocked the surface coordination of BTAH with the electrode, and a complex of $BTA^-$ and $PPh_3$ with Cu was formed in the bulk solution.

## Introduction

The coordination chemistry of metal surfaces exposed to a corrosion medium has attracted considerable attention from the coordination chemists and surface scientists because of its economic importance.[1–5] For example, some organic molecules adsorbed on particular metal surfaces form a compact complex layer that can inhibit the corrosion of the surface effectively.[6–12] Despite the importance of special organic inhibitors, little attention has been paid to the investigation of how they bind or coordinate to the metal surfaces or as to why seemingly minor modifications in the structures of the active organic compounds can have a profound effect on their efficiency. Therefore, investigation into the interaction or the coordination chemistry of organic ligands with metal surfaces could be beneficial to obtain deeper insight into the adsorption behavior of ligands and their relevant surface coordination processes.

Generally, the deduction of the surface reaction mechanisms that include strong chemisorption or the formation of films (surface complexes) should be based on the known habits of the components and the structures of the surface complexes. One reliable and direct way to obtain such components is by the preparation of the corresponding surface complexes under conditions similar to those of the electrode surface. So far, many methods have been used to synthesize the relevant surface complexes. For example, the soluble metal salt and the ligands can simply be mixed in aqueous/nonaqueous solutions to produce the corresponding complexes, or the metal salt and the ligand solid powders can be mixed to form the complexes, a so-called solid-phase synthesis.[13] However, the direct electrochemical synthesis performed for the first time by Tuck and coworkers has exhibited several advantages for providing the comparable conditions of the surface.[14–21] This method consists in oxidizing a sacrificial metal anode in the nonaqueous solution with one or more appropriate kinds of ligands. Therefore, the synthetic conditions, including the bulk metal electrode, applied potential/current, solution (aqueous or nonaqueous), and electrolyte resemble the real electrode reaction system. As a consequence, on the basis of the interactions and chemical bonding between the ligand and the metal, it is reasonable to deduce the surface adsorption processes with the participation of some ligands on the electrode in the complex prepared by the electrochemical synthetic

method. Moreover, no oxidant or reductant is introduced into the system of the electrochemical synthesis, and this avoids the possible complicated processes resulting from redox reactions. Alternatively, the oxidation of the metal electrode and the reduction of the ligands were carried out by the "clean" electron, which was removed or added on the anode and cathode by the applied potential/current. This dramatically decreased the contamination due to extraneous chemicals not only in the reaction processes but also in the separation of the final products. Most importantly, the adjustable applied potential/current made the reaction become highly selective, and thus enabled us to obtain the expected final products. However, the introduction of supporting electrolytes might be found in the final product in the form of anions or cations. In low concentrations, the appropriate amount of supporting electrolyte can, to some extent, minimize its negative effect on the complexes. Therefore, the direct electrochemical synthetic technique provided an effective way to simulate the electrochemical adsorption and reaction on the electrode surface, which allowed the structure and composition of the surface species to be obtained.

However, information on the dynamic and mechanistic aspects of the surface processes was not obtained by the above-mentioned techniques. Information about the processes that occur on the electrode surface can be gained by several modern surface techniques, such as scanning tunneling microscopy (STM), X-ray photoelectron spectroscopy (XPS), electron energy loss spectroscopy (EELS), sum frequency generation (SFG), and infrared and Raman spectroscopy.[10,11,22–25] Among them, Raman spectroscopy is a powerful tool for the investigation of the surface chemistry of adsorbed molecules involving adsorption and coordination at the liquid–solid interface, provided that the surface Raman signals are sufficiently enhanced.[26,27] In particular, surface-enhanced Raman scattering (SERS) has been shown to be a good method for determining the structure of molecules adsorbed on electrode surfaces.[28–34] Furthermore, unlike EELS and XPS, SERS can yield detailed surface information free from the interference of the bulk phase even at metal–liquid interfaces, and it has been widely used to investigate the dynamic and mechanisms of surface processes in situ.

To date, most coatings for metals have contained corrosion inhibitors as key constituents, and their activity was dependent on the surface coordination chemistry of the inhibitor. Benzotriazole (BTAH) is one of the most effective inhibitors for Cu and its alloys. Since the pioneering work of Cotton and coworkers,[35] the adsorption/coordination behavior and bonding structure between BTAH and a Cu substrate have been extensively studied by many authors by using various techniques, including electrochemical, surface analytical, and spectroscopic techniques.[36–40] Most of the previous work revealed that BTAH inhibited the corrosion of Cu in a wide pH range and potential region. For example, in different potential regions, BTAH can form a chemisorbed layer or a multilayer polymerized structural film with a larger thickness that increases the inhibition of corrosion significantly. The details of the mechanism by which the film forms and protects the metal are the subject of much investigation and debate.

Therefore, a powerful in situ technique with high surface sensitivity that is able to provide specific molecular information on metal surfaces has long been desired. Many researchers reported studies on the inhibition effect of BTAH by electrochemical SERS in aqueous solutions. To the best of our knowledge, there is no report on the studies of the adsorption/coordination chemistry and film formation of inhibitors in nonaqueous solutions. However, nonaqueous solvents are extremely important in both pure and applied electrochemistry, particularly as a component of the electrolyte that is in contact with the electrodes. Moreover, the involved organic molecules or inorganic ions can exhibit different inhibition efficiencies.[40,41] For example, the introduction of $I^-$ ions into solutions containing BTAH makes the inhibition efficiency for both the anodic and cathodic processes become even more remarkable,[42,43] which thus indicates the existence of a synergetic effect between the $I^-$ ions and benzotriazole on the inhibition. However, some organic ligands might play a negative role in the inhibition when it coexists with BTAH. For example, the introduction of ligands such as β-diketonate, acetylacetone, and triphenylphosphane ($PPh_3$) can result in remarkable differences in the structures of metal complexes with BTAH, specifically, the transformation of single metal nuclear to multinuclear complexes.[1,44–49] Therefore, it is worth investigating the inhibition of BTAH in nonaqueous solutions containing some organic molecules that might play an important role in the formation of surface complex films. In contrast, it is highly desirable to extend SERS studies directly to wider applications in surface science, not only for the various processes of corrosion and inhibition, but also for the surface coordination chemistry of BTAH together with other ligands. Triphenylphosphane is one of the most commonly used ligands in organometallic and coordination chemistry, and it is one of the most common ligands found in homogeneous transition-metal catalysts for the binding and transformation of organic substrates.[50–53] Phosphanes in general have been mainly used as protecting groups in organic synthesis as well as in catalytic processes, in which they were responsible for the decisive reaction step.[54] For this reason, $PPh_3$ was chosen as the second metal-binding domain in studying the surface coordination chemistry of BTAH on a Cu electrode.

In the present work, the adsorption behavior and film formation of BTAH were investigated by in situ electrochemical SERS on the surface of a Cu electrode in nonaqueous solution and by the coordination chemistry between the Cu surface and BTAH with and without $PPh_3$. Meanwhile, for the determination of the compositions and structures of the surface complexes, two kinds of complexes of BTAH and Cu with and without $PPh_3$ were synthesized by direct electrochemical synthesis and characterized by microanalysis, X-ray crystallographic measurements, and Raman spectroscopy. The modes of inhibitor on the Cu surface in nonaqueous solution were proposed.

## Results and Discussion

### Electrochemical Synthesis of the Complex

The electrochemical oxidation of Cu provided a convenient route to its coordination compound with the title ligands in a "one pot" procedure. One of the advantages of these techniques is that the metal in the product is frequently in a low oxidation state as the starting point is the element itself. It should be noted that the deposited layer on the anode resulted in its low conductivity. Thus, a mild voltage was applied to the system to maintain electrolysis. However, the electrochemical reaction potential was less than the applied voltage and the current density was maintained with a small value of about 5–8 $mA\,cm^{-2}$ during the electrolytic procedures. Therefore, the conditions used in the direct electrochemical synthesis were comparable to those at the Cu electrode surface, which was studied by in situ SERS. Complexes 1 and 2, which were synthesized by the electrochemical method, were expected to have the same composition as the Cu electrode surface in the electrochemical system for the in situ SERS investigation.

The stoichiometry of the electrochemical reaction is indicated by the electrochemical efficiency outlined in Equations (1) and (2), where $m$ is the weight lost at the Cu anode, $M$ is the molar mass of Cu, $z$ is the valence of the Cu ion, $i$ is the applied current, $t$ is the electrolysis time, and $F$ is Faraday constant; the value $\int_t^0 idt$ is determined by the silver coulomb meter, which is linked into the circuit, and is defined as the number of moles of metal dissolved from the anode per Faraday of charge. In the present study, the value of $E_f$ of $0.99\,mol\,F^{-1}$ and $0.98\,mol\,F^{-1}$ implied that the monovalent $Cu^I$ complex was formed on the electrode surface at the initial stage in solutions without/with $PPh_3$, respectively. The electrochemical systems can be represented as Pt(–)|$CH_3CN$, BTAH, electrolyte|Cu(+) and Pt(–)|$CH_3CN$, $PPh_3$, BTAH, electrolyte|Cu(+), respectively. The electrode reactions are outlined in Equations (3) and (4).

$$E_f = (m/M)F/\int_0 \mathrm{idt}(\mathrm{mol}/F) \quad (1)$$

$$z = 1/E_f = M\int_0^t \mathrm{idt}/mF \quad (2)$$

$$\text{cathode: } BTAH + e \rightarrow BTA^- + 1/2H_2 \quad (3)$$

$$\text{anode: } Cu \rightarrow Cu^+ + e \quad (4)$$

For the solution without $PPh_3$, the $BTA^-$ anion coordinated to the $Cu^+$ ion immediately to form a compact film that attached itself to the electrode surface. Actually, at the initial stage of the electrochemical synthesis, to be exact, as soon as the electrolytic current was applied, a yellow precipitate was produced that attached itself to the Cu electrode surface. At last, a dark yellow product was obtained after separation of the precipitate from the solution. Unfortunately, no crystal of the final product was obtained because of its poor solubility in most solvents. Elemental microanalysis of the sample gave a composition of C 61.35, H 4.18, N 11.47 (CuBTA: calcd. C 59.74, H 4.15, N 10.55) and revealed that the molar ratio of Cu to the $BTA^-$ anion was 1:1. Previous investigations of BTAH adsorbed on Cu electrodes showed that compact polymer films of $(CuBTA)_n$ were attached to the surface and inhibited the corrosion of Cu effectively in the aqueous solution;[12,29,40] this is in agreement with the synthesized sample that was prepared by mixing the $Cu^+$ compound with the BTAH solution. Therefore, it is reasonable to assume that the formula of the present sample was $(CuBTA)_n$ (complex 1). The overall reaction at the electrode surface is depicted in Equation (5). On the basis of previous experimental results, its structure was proposed as that shown in Figure 1.

$$nBTAH + nCu \xrightarrow{\text{electrolysis}} (CuBTA)_n + n/2H_2\uparrow \quad (5)$$

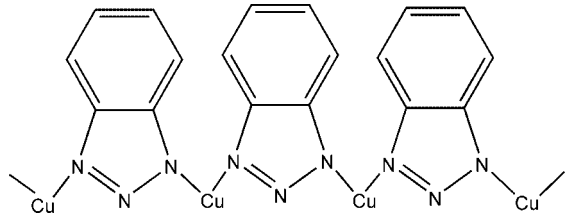

Figure 1. Proposed structure of the $(CuBTA)_n$ polymer complex.

The normal Raman spectrum of $(CuBTA)_n$ was presented with in situ SERS studies. The large blueshift of the triazole and benzene ring mode indicated the coordination of the $BTA^-$ ion with Cu. The detailed structure information will be discussed in the next section.

After the addition of $PPh_3$, no precipitation was observed on the Cu electrode surface or in the solution at the initial stage of the electrolytic reaction. With an increase in the electrolysis time, a brown-yellow precipitate was formed at the bottom of the flask. The absence of precipitation at the beginning of the electrochemical synthesis in the $CH_3CN$ solution with BTAH and $PPh_3$ indicated that no film was attached to the surface or that the prepared complex might be soluble in the $CH_3CN$ solution (normally, with a low solubility). To separate the precipitate, the nonaqueous solution was transferred into the fridge and yellow crystals were formed. Both the $BTA^-$ and $PPh_3$ signals were detected together in the normal Raman measurement of the crystal. The frequency of the triazole and benzene ring mode of $BTA^-$ was shifted to 1031 $cm^{-1}$, which is an indication of the coordination of the $BTA^-$ ion to the Cu electrode. This result revealed that both the $BTA^-$ ion and the $PPh_3$ ligand coordinate to the Cu ion. The final molecular formula and structure of this crystal should be deduced from its X-ray crystal structure.

### Crystal Structure of $Cu_5(BTA)_5(PPh_3)_4Cl$

Selected bond lengths and angles of the $Cu_5(BTA)_5(PPh_3)_4Cl$ complex are listed in Table 1. The $Cu_5(BTA)_5$-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$(PPh_3)_4Cl$ complex crystallizes as a pentanuclear complex, and its molecular structure is illustrated in Figure 2. Because the benzotriazolate ion has a charge of –1, the pentacopper complex is a mixed-valent material that contains four $Cu^I$ ions and one $Cu^{II}$ ion. The central $Cu^{II}$ ion is surrounded by four tetrahedrally coordinated $Cu^I$ ions held by bridging $BTA^-$ ligands. In the title complex, each tridentate $BTA^-$ ligand bridges two $Cu^I$ ions in two sides and coordinates to the central $Cu^{II}$ ion through its central nitrogen atom. The central $Cu^{II}$ ion is coordinated to four equatorial and one axial $BTA^-$ ligands at the N2, N5, N8, N11, and N14 positions, and it has a distorted tetragonal pyramidal coordination geometry with average distances of $Cu^{II}$–$N_{eq}$ 2.050(1) Å and $Cu^{II}$–$N_{ax}$ 2.294(3) Å. These values are comparable to the $Cu^{II}$–N bond lengths (2.08 and 2.29 Å, respectively) in the related $Cu_5(BTA)_6(tfpbd)_4$ complex (tfpdb = 4,4,4-trifluoro-1-phenyl-1,3-butanedione).[47] Each surrounding $Cu^I$ ion is four-coordinate with two types of coordination environments. For example, Cu3 (or Cu4) is in a distorted tetrahedral ($CuN_3P$) environment and is bound to three nitrogen atoms from different BTA ligands and a phosphorus atom in $PPh_3$. The $Cu^I$–N lengths Cu3–N9, Cu3–N3, and Cu3–N13 are about 2.061 Å and are close to those values in the complex [CuL($PPh_3$)] {L = bis(2-pyridyl)[2-(6-methoxy)pyridyl]methoxymethane} with the similar core of $CuN_3P$.[55] In addition to Cu1 (or Cu2) being coordinated to two nitrogen atoms in two different $BTA^-$ ligands and a phosphorus atom in $PPh_3$, it is also coordinated to a chloride ion that bridges two Cu centers with a Cu···Cu separation of 4.822 Å. The average value of all $Cu^I$–P bond lengths (about 2.1766 Å) is a little shorter than the value in $[Cu_4(BTA)_3(PPh_3)_4][Cu(PPh_3)_3](BF_4)_2$ [2.200(5) Å],[49] whereas the $Cu^I$–Cl bond lengths [Cu1–Cl1 2.4456(13) Å, Cu2–Cl1 2.4619(13) Å] are close to the value of about 2.455(1) Å in the $Cu_2Cl_2(PPh_3)_3$ complex together with a bridging chloride ion.[56]

Table 1. Selected bond lengths and bond angles of the $Cu_5(BTA)_5(PPh_3)_4Cl$ complex.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Cu1–N1 | 2.041(3) | Cu3–N9 | 2.060(4) |

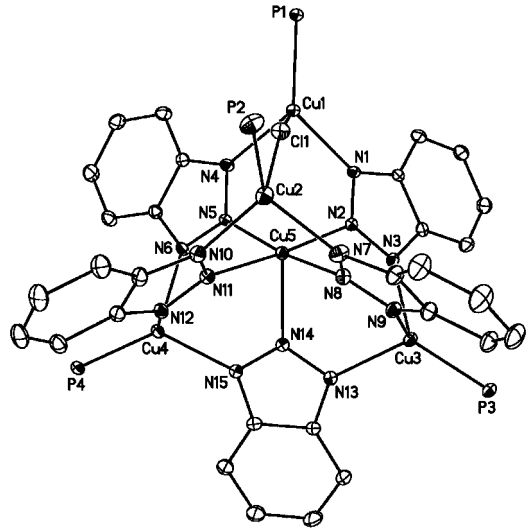

Figure 2. ORTEP drawing of the $Cu_5Cl(BTA)_5(PPh_3)_4$ complex. Hydrogen atoms are omitted for clarity.

For the $Cu^I$ ion bridged by the axial benzotriazolate anion and the chloride ion, the average distance between the surrounding $Cu^I$ ion is 5.315 Å and the distance increases to about 5.886 Å for the $Cu^I$ ion bridged by the equatorial benzotriazolate anions, whereas the average distance of about 3.500 Å between the surrounding $Cu^I$ and central $Cu^{II}$ ions is much shorter than the above-mentioned value. The structure of the complex bears resemblance to that of $Cu_5(BTA)_6(t\text{-}C_4H_9NC)_4$,[44] where the latter contains an extra $BTA^-$ group instead of the bridging chloride ion.

### In Situ Electrochemical SERS Investigation

Figure 3 presents a set of potential-dependent SERS spectra of BTAH from a roughened Cu electrode in a wide potential range in acetonitrile solution with or without $PPh_3$ together with the normal Raman spectra of two complexes prepared by an electrochemical method for comparison. The series of spectra on the right side of Figure 3 unambiguously demonstrate the change in spectral features over a narrow range. Because the surface coordination of the $BTA^-$ ion to the Cu electrode occurs in a positive potential range irreversibly, which was proven by relevant SERS studies in aqueous solution,[8,12] the potential-dependent spectra were recorded stepwise starting from a negative limit potential to more positive potentials so that all the ad-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sorption and surface coordination processes could be observed. It can be seen that the SERS spectra changed significantly with the applied potential not only in the intensity, but also in the frequency of the relevant bands. The spectra showed a similar spectral feature to that of the BTAH solid in the extremely negative potential region both in solution with or without $PPh_3$. For example, the surface spectra at –0.9 V without $PPh_3$ and at –1.0 V with $PPh_3$ exhibited the same frequency as the free BTAH for the triazole and benzene ring mode at 1022 $cm^{-1}$, respectively. This normally can serve as direct evidence for the determination of the coordination configuration of BTAH on the metal surface, although in this sample this band broadened significantly because of the complicated surface structure of the Cu electrode (as shown in Figure 3, right).[12] Our previous results indicated that the $BTA^-$ ion of the surface complex film showed a blueshift to ca. 1040 $cm^{-1}$ for this band. Therefore, the high similarity of the SERS spectra of BTAH on the surface to that from the bulk solution revealed the existence of an adsorption adlayer of BTAH molecules in the relative negative potential region in both solutions.

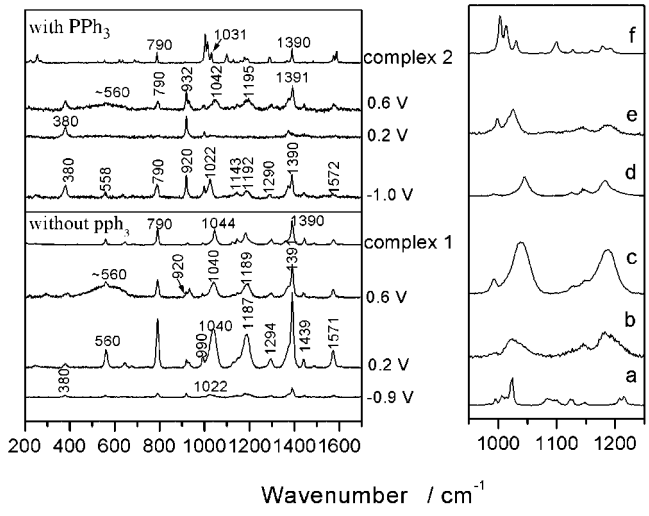

Figure 3. Potential dependent SERS spectra of BTAH adsorbed on the Cu electrode in acetonitrile solution without (bottom) and with 0.01 mol $dm^{-3}$ $PPh_3$ (upper) together with the normal Raman spectra of two surface complexes (left). The figure presented on the right is for comparison in the range from 950 to 1250 $cm^{-1}$: (a) BTAH solid; (b) without $PPh_3$ at –0.9 V; (c) 0.2 V; (d) complex 1; (e) with $PPh_3$ at –1.0 V; and (f) complex 2.

By moving the potential positively, the signal intensity also increased greatly and the frequency of the triazole and benzene ring mode shifted to 1040 $cm^{-1}$ at 0.2 V in the solution without $PPh_3$. Moreover, the surface spectrum at 0.2 V exhibited the same spectral features as that of the electrochemically synthesized $[Cu(BTA)]_n$ (complex 1; Figure 3, right). Most interestingly, the color of the electrode surface changed from brown to gray after the positive potential excursion, and the SERS measurement on the electrode in air without potential control exhibited similar spectral features to those in solution in the positive potential region. It was reported by many researchers that the $BTA^-$ ion can adsorb onto the Cu surface to form an irreversible compact polymer film of $[Cu(BTA)]_n$, which increases the inhibition efficiency dramatically in a certain potential region in aqueous solutions.[8,9,12,35–37] Therefore, it is reasonable to assume that the observed surface Raman spectrum at 0.2 V comprised contributions from this irreversible polymer film attached to the Cu surface in a wide potential range, that is, the BTAH was adsorbed on the surface by the coordination of N atoms with Cu atoms. In the extremely positive potential region, the signal of the film decreased remarkably. This occurred mainly because of the following two reasons: (1) the disappearance of or decrease in the SERS activity of the Cu surface owing to the oxidation of the Cu surface and (2) the partial breakage of the polymer film due to the formation of Cu oxide. At 0.6 V, the intensities of the bands decreased and a broad band at ca. 560 $cm^{-1}$ was detected with a sharp band at 560 $cm^{-1}$. The broad band was assigned to the stretching vibrational mode of Cu–O and the sharp band was assigned to the triazole ring torsion mode. Therefore, the observation of broad bands revealed the formation of Cu oxide in this potential region.

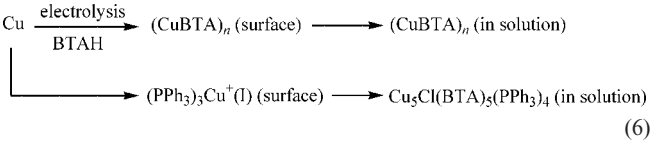
It is reasonable to assume that the surface complex (surface film) has the same composition as the synthesized complex. Therefore, on the basis of the fact that the potential-dependent adsorption behavior in nonaqueous solutions was similar to that in aqueous solutions, one can assume that BTAH adsorbs in the form of neutral BTAH molecules onto the Cu surface to form an adsorption layer in the negative potential region and in the form of $BTA^-$ ions to form a compact polymer film of the type $[Cu(BTA)]_n$ in the positive potential region; the polymer film partially breaks in the most positive potential region. The formation of a surface complex film results in a more compact barrier layer, which leads to a higher inhibition effect. Most interestingly, when a small amount of $PPh_3$ (the same concentration as BTAH) was introduced into the solution as above and the same experimental processes were performed, significant spectral changes were found. For example, the Raman signal of BTA/BTAH was not detected at 0.2 V, and the observed bands in this spectrum could be assigned to the vibrational modes of $CH_3CN$ and $PPh_3$. Therefore, the detected Raman signal in fact comes mainly from the bulk solvent rather than from the surface species. The great differences in the spectral features in this potential region might be caused by the differences in the compositions of the surface films on the surface, that is, the $PPh_3$ might play an important role in the formation of the surface film and it may modify the properties of the surface complex.

### The Role of $PPh_3$ in the Surface Coordination Chemistry of BTAH

It is well known that $PPh_3$ serves as a common ligand in metal coordination chemistry. On the basis of the hard–soft acid–base theory, low-valent metal ions (e.g. $Cu^+$) are a class of soft Lewis acids, whereas $PPh_3$ is a typical soft base.[57] Therefore, stabilization of the low-valent $Cu^+$ metal

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ion was increased by the interaction of $PPh_3$ with the metal ion, which resulted in an increase in the softness by increasing the electron density on the metal ion. Generally, more than one $PPh_3$ molecule coordinated with one $Cu^+$ ion to form a $Cu(PPh_3)_n^+$ cation.[58–60] Therefore, this cation is a soft acceptor ion that can accommodate a wide range of coordination anions to form air-stable complexes.[61] In the direct electrochemical synthesis, the electrochemical efficiency $E_f$ value of ca. 1.0 mol $F^{-1}$ for both cases indicated that the Cu metal was oxidized to the $Cu^+$ ion in the electrochemical reaction. As a consequence, the central metal ion was $Cu^+$, which was quickly stabilized by the soft neutral $PPh_3$ ligand. Following that, the $BTA^-$ anion that was generated at the cathode participated to form a stable complex. In the final product, the separation of crystalline $Cu(PPh_3)_3Cl$ indicated the formation of $Cu(PPh_3)_3^+$ (Figure 4). However, the structure of the final product in the latter case of $Cu_5Cl(BTA)_5(PPh_3)_4$ indicated that the central $Cu^{II}$ was coordinated to four equatorial and one axial $BTA^-$ ligands to form a distorted tetragonal pyramidal coordination polyhedron, whereas each surrounding $Cu^I$ ion was in a distorted tetrahedral environment and coordinated with one $PPh_3$ ligand. It revealed that one $Cu^I$ ion was oxidized to $Cu^{II}$ after the electrochemical reaction, and some of the $PPh_3$ ligands that were coordinated to $Cu^I$ in the initial stage of the electrochemical procedure were exchanged by $BTA^-$ ligands in solution. The proposed surface coordination chemistry of BTAH is presented in Equation (6).



(6)

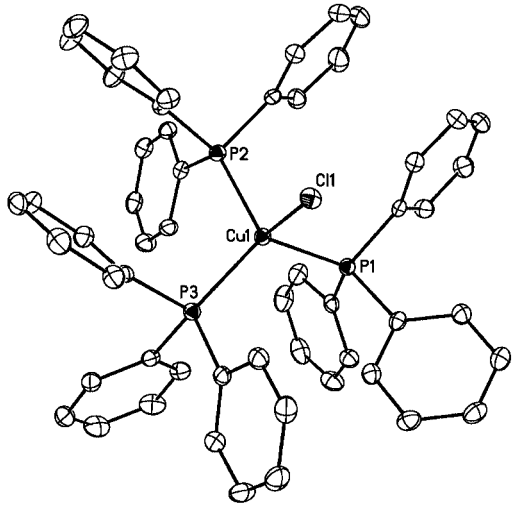


Figure 4. ORTEP drawing of the $Cu_3Cl(PPh_3)_3$ complex. Hydrogen atoms are omitted for clarity.

The in situ SERS measurements were in agreement with the processes of electrochemical synthesis, namely, the soluble $Cu(PPh_3)_3^+$ cation was firstly formed on the surface and then the complex was secondly formed in solution. Thus, the fact that no BTAH film covered the electrode surface resulted in the absence of an SERS signal at +0.2 V. There are two effects that can be attributed to the disappearance of the surface Raman signal of BTAH/$BTA^-$ at +0.2 V: (1) no compact film was formed on the electrode surface and (2) the decrease in the SERS activity because of the dissolution of Cu to form the $Cu(PPh_3)_3^+$ layer in the specific potential region. When the potential was increased again to the severe oxidization region, the surface atoms of the electrode were oxidized to $Cu^{2+}$ which were located at the borderline between being a hard acid and a soft acid. Conversely, because of the increase in the valence of Cu, an increase in the coordination numbers produces steric hindrance that hinders the participation of a large ligand such as $PPh_3$ in the coordination process. Therefore, the observation of the SERS signal from the $BTA^-$ ion and the absence of the SERS signal from the $PPh_3$ ligand in the potential region of 0.4 to 0.6 V revealed that the $Cu^{2+}$ ion could be coordinated by the $BTA^-$ anion directly to form a film on the surface again. At +0.6 V, a broad band at ca. 560 $cm^{-1}$ was detected, which was similar to that obtained in the solution without $PPh_3$. Therefore, it is reasonable to assume that the $BTA^-$ anion showed a similar adsorption or coordination behavior in the most positive potential region, specifically, the formation of surface complex film together with the Cu oxide.

The formation of longchains of the insoluble polymer $[Cu(BTA)]_n$ is suppressed because the neutral $PPh_3$ ligand participates in the formation of the complex and shows a strong stabilization effect on the complexes. As a consequence, the cation of $Cu(PPh_3)_3^+$ dissolves into $CH_3CN$ quickly and hence no strong signal of BTAH from the surface could be detected in a specific potential region. In fact, it accelerates the dissolution of the Cu electrode rather than strengthening the inhibition efficiency in that potential region; explicitly, the existence of $PPh_3$ plays a negative role in the inhibition of BTAH at the Cu surface.

## Conclusions

The surface coordination of BTAH onto the Cu surface was deduced to involve chemically adsorbed layers, a $BTA^-$ polymer film, and $PPh_3$-assisted surface dissolution. BTAH exhibits different adsorbed and filmed behaviors in different potential regions in solution. In the extremely negative potential region, the neutral BTAH molecules were adsorbed onto the Cu surface in acetonitrile solutions with or without $PPh_3$. BTAH also formed an attached polymer film on the surface in the medium without $PPh_3$, whereas a crystalline complex formed in solutions containing $PPh_3$. Our preliminary experiment showed that electrochemical synthesis combined with SERS studies could provide the surface coordination mechanism at the molecular level.

## Experimental Section

**Physical Measurements:** BTAH and $PPh_3$ (Aldrich) were used as received. Solvents were purified by standard methods. C and H

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

elemental analysis was performed with an Italy Carlo Erba MOD-1106 microanalysis instrument. Raman spectra were measured with a micro-Raman system of LabRam I with a low power He–Ne laser source.

**Electrochemical Synthesis of $(CuBTA)_n$, $Cu_5Cl(BTA)_5(PPh_3)_4$:** The electrosynthesis of the metal complex was carried out in acetonitrile by using Pt as the cathode and Cu as a sacrificial anode according to the technique described in our previous work.[21] The BTAH ligand (0.2374 g), with or without $PPh_3$ (0.5230 g), was dissolved in $CH_3CN$ (30 mL) containing a small amount of $Et_4NClO_4$ as the supporting electrolyte. The electrodes were treated with $HNO_3$, and washed and dried before use. All operations were carried out under the protection of dry Ar with rigorous exclusion of air by using standard vacuum line techniques. The voltage was regulated to obtain an initial current of 20 mA. As soon as the current flowed in the cell, bubbles of hydrogen gas were visible at the cathode. Five minutes later, pale yellow solids precipitated around the anode piece. After two hours of electrolysis, the Cu piece was rinsed, dried, and weighed to determine the electrochemical efficiency ($E_f$). A black powder was obtained in the solution without $PPh_3$ and defined as complex 1. For the system with $PPh_3$, the solid was isolated by filtration, and then dissolved in a mixture of acetonitrile/chloroform (1:1; complex 2). One week later, brown crystals of $Cu_5(BTA)_5(PPh_3)_4Cl{\cdot}2CH_3CN$ were separated out from the solution in a yield of ca. 63%. A little quantity of $Cu(PPh_3)_3Cl$ was separated from the final product and its structure was determined.

**X-ray Structure Determination:** $C_{106}H_{86}ClCu_5N_{17}P_4$ (2075.04): calcd. C 61.35, H 4.18, N 11.47; found C 59.74, H 4.15, N 10.55. A brown crystal having approximate dimensions of $0.60 \times 0.36 \times 0.35$ mm was selected and mounted on a glass fiber. All measurements were made with a Rigaku Mercury CCD diffractometer equipped with graphite-monochromated Mo-$K_\alpha$ ($\lambda$ = 0.71070 Å) radiation by using an $\omega$ scan mode in the range $3.02 < \theta < 27.48°$ at 193(2) K. A total of 99572 reflections were collected, of which 17353 with $I > 2\sigma(I)$ out of 21901 were unique ones ($R_{int}$ = 0.0512) were considered as observed. All of the calculations were performed by using the SHELXS-97package.[62] The structure was solved by direct methods and refined by full-matrix least-squares techniques on $F^2$. All non-hydrogen atoms were refined anisotropically, whereas the hydrogen atoms included in the final cycle of refinement were located on the calculated positions boned to their carrier atoms. The weighting scheme was $w = 1/[\sigma^2(F_o^2) + (0.0739P)^2 + 24.2198P]$, where $P = (F_o^2 + 2F_c^2)/3$, $S$ = 1.069. The final $R$ indices $R_1$ = 0.0704, $wR_2$ = 0.1643[$I > 2\sigma(I)$]. The crystallographic data is summarized in Table 2, and the crystal structure is presented in Figure 2. CCDC-283457 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**The In Situ Electrochemical SERS Measurements:** Raman spectra were recorded with a confocal micro-Raman system (LabRam I from Dilor). The microscope attachment was based on an Olympus BX40 system and used a 50× long working length objective (≈ 8 mm) so that the objective would not be immersed into the solution. All the experiments were performed with the excitation line of 632.8 nm from an internal He–Ne laser with a power of 4 mW on the electrode surface. The electrochemical cell for the SERS measurement was made by Teflon with a quartz window for introducing the laser and collecting the Raman signal. The working electrode was a Cu disk with a geometric area of 0.1 $cm^2$ embedded in a Teflon rod. It was polished successively with 1 and 0.05 μm alumina powder and sonicated in triply distilled water. Consequently, a double potential step from –0.4 to + 0.4 V (vs. SCE) was applied to the electrode in 0.1 M KCl solution for about 2 min followed by a potential excursion at –0.4 V for 1 min, and then, it was rinsed thoroughly and dried with nitrogen to remove traces of water on the surface. A large Pt ring served as the counter electrode. The reference electrode was a solid Ag/AgCl electrode, which was prepared by electrochemical oxidation of an Ag wire with a constant anodic current of 0.4 $mA\,cm^{-2}$ in a 0.1 M HCl solution for 30 min. A detailed description of the spectroelectrochemical measurements is given elsewhere.[9,40] All experiments were performed at room temperature. All the chemicals used were analytical reagent grade. The solutions were prepared by using acetonitrile, which was pretreated to remove water.

# Cyclodiphosphazane *cis*-{(*o*-$MeOC_6H_4O$)P(μ-N*t*Bu)}$_2$ as a Bridging Bidentate Ligand: Synthesis, Structures of Heterometallic Complexes, and Halogen Exchange Between Rh–Cl and Cu–X (X = Br, I)

**P. Chandrasekaran,[a] Joel T. Mague,[b] Ramalingam Venkateswaran,[a] and Maravanji S. Balakrishna*[a]**

**Keywords:** Heterometallic complexes / Cyclodiphosphazanes / P,N ligands / Halogen exchange / Rhodium

The mononuclear rhodium complexes of cyclodiphosphazane [(cod)RhCl{L-κP}] (**1a**) (L = *cis*-{(*o*-$MeOC_6H_4O$)P(μ-N*t*Bu)}$_2$) and *trans*-[Rh(CO)Cl{L-κP}$_2$] (**1b**) react in a 1:1 molar ratio with [AuCl($SMe_2$)] to form the heteronuclear complexes [(cod)RhCl{μ-L-κP,κP}AuCl] (**2**) and *trans*-[Rh(CO)Cl{μ-L-κP,κP}$_2$(AuCl)$_2$] (**7**), respectively, in quantitative yield. The reaction between **1a** and CuCl afforded a tetranuclear complex [(cod)RhCl{μ-L-κP,κP}Cu(μ-Cl)]$_2$ (**3**). Under similar reaction conditions **1** reacts with 2 equiv. of CuX (X = Br, I) to produce the heteronuclear complexes [(cod)RhBr{μ-L-κP,κP}Cu(μ-Br)]$_2$ (**4**) and [((cod)RhI{μ-L-κP,κP})$_2$Cu(μ-X)$_2$Cu] (X ≈ 1:1 mixture of Cl and I disordered over both sites) (**5**), respectively, in which two molecules of **1a** are bridged by the rhombic, disordered, mixed halide [Cu(μ-X)$_2$Cu] (**5**: X = Br; **6**: X = Cl, I) unit. The crystal structures of **4** and **5** confirm the halogen exchange between the Rh–Cl and CuX (X = Br, I) moieties which leads to the formation of Rh–Br and Rh–I bonds. The heterodinuclear $Rh^I/Pd^{II}$ complex [(cod)RhCl{μ-L-κP,κP}PdCl($\eta^3$-$C_3H_5$)] (**6**) was synthesized by the reaction of **1a** with [PdCl($\eta^3$-$C_3H_5$)]$_2$ in a 2:1 ratio. Reaction of **1b** with CuI leads to the formation of the tetranuclear complex [Rh(CO)I{μ-L-κP,κP}$_2$Cu(μ-I)]$_2$ (**8**) containing two terminal uncoordinated phosphorus(III) centers irrespective of reactant ratio and reaction conditions. Halogen exchange reaction which leads to the formation of the Rh–I bond was also observed during the preparation of complex **8**.

## Introduction

The cooperativity or synergism present in heterometallic complexes gives remarkable chemical and biological properties compared to homonuclear complexes.[1] These heteromultinuclear complexes have applications in the formation of new materials with useful physicochemical properties,[2] and as polyfunctional catalysts for organic transformations.[3] The ligand design is important for the synthesis of heteronuclear complexes because the dimensionality and topology of the final structures are predominantly controlled by the location of donor sites in the ligand and their coordination preferences towards different metal centers.[4] Several phosphane ligands have been utilized for the synthesis of heterometallic complexes; however, in many cases formation of homonuclear complexes was observed along with the expected heterometallic complexes, due to the competition between different metal centers for the coordination sites and also due to the symmetric nature of bis(phosphanes). Preparation of heterometallic complexes can be made easier by choosing robust bidentate ligands which can perform as monodentate ligands under mild reaction conditions to give mononuclear complexes containing one or two free phosphorus(III) sites. These metalloligands containing uncoordinated phosphorus(III) centers can be conveniently treated with appropriate metal centers to form a variety of heterometallic complexes. In this context, cyclodiphosphazanes containing saturated four-membered $P_2N_2$ rings are interesting since they often exhibit monodentate coordination with several metal reagents under mild reaction conditions as shown in Scheme 1.[5,6] These mononuclear complexes containing uncoordinated phosphorus centers can be utilized to form heterometallic complexes. Such complexes can be of importance in homogeneous catalysis to promote

more than one type of catalysis and also for exploring the catalytic activity of multimetallic systems.[7] As a continuation of our work on transition metal chemistry of phosphorus-based ligands and their catalytic applications,[8] we describe in this article the synthesis and molecular structures of several heterometallic complexes of cyclodiphosphazanes.

## Results and Discussion

### Synthesis of Heterometallic Complexes

The rhodium(I) complex containing monocoordinated cyclodiphosphazane, [(cod)RhCl{L-κP}] (**1a**), chosen for the construction of heterometallic complexes was synthesized by treating *cis*-{(*o*-MeOC$_6$H$_4$O)P(μ-N*t*Bu)}$_2$ (L) with [Rh(cod)Cl]$_2$ as described previously.[6] The reaction of **1a** with 1 equiv. of [AuCl(SMe$_2$)] in dichloromethane at room temperature affords the heterodimetallic Rh$^I$/Au$^I$ complex **2** in good yield as shown in Scheme 2. The $^{31}$P NMR spectrum of **2** consists of two sets of doublets of doublets centered at δ = 104.7 and 94.1 ppm, respectively, for Au-coordinated and Rh-coordinated centers of the cyclodiphosphazane together with a low-intensity singlet at $\delta$ = 107.9 ppm attributable to the presence of a small amount of [ClAu{(*o*-MeOC$_6$H$_4$O)P(μ-N*t*Bu)}$_2$AuCl].[9] The formation of the dinuclear complex may be due to the replacement of the RhCl(cod) moiety present in **2** by [AuCl(SMe$_2$)] which was used in slight excess quantity for the complete conversion of **1a** into **2**. In order to confirm this metathesis reaction between Au and Rh centers, we carried out an NMR-tube reaction between [(cod)RhCl{L-κP}] (**1a**) and 2 equiv. of [AuCl(SMe$_2$)] in CDCl$_3$. We observed complete conversion of **1a** into dinuclear gold complex [ClAu{(*o*-MeOC$_6$H$_4$O)P(μ-N*t*Bu)}$_2$AuCl] as indicated by its $^{31}$P NMR spectrum which shows a single resonance at $\delta$ = 107.9 ppm. The gold-bound phosphorus center of **2** shows $^2J_{PP}$ and $^3J_{RhP}$ couplings of 30 and 5.5 Hz, respectively. The magnitude of $^3J_{RhP}$ is comparable with literature values,[10] while the rhodium-coordinated phosphorus atom shows a $^1J_{RhP}$ coupling of 247 Hz along with $^2J_{PP}$. However, compound **1a** did not show any $^2J_{PP}$ coupling and the $^1J_{RhP}$ coupling (229 Hz) was smaller than that of **2** (Table 1). The mass spectrum of **2** exhibits a peak at *m*/*z* = 893.21 which corresponds to the [M – Cl] ion (Figure 1).

Table 1. $^{31}$P{$^1$H} NMR spectroscopic data for complexes **1**–**7**.

| Compound | $\delta$(RhP) [ppm] | $^1J_{RhP}$ [Hz] | $\delta$(MP) [ppm] (other *J* values [Hz]) |
|---|---|---|---|
| **1a** | 102.8 (d) | 229 | 131.7 (s)[a] |
| **1b** | 112.5 (d) | 187 | 130.8 (s)[a] |
| **2** | 94.1 (dd) | 247 | 104.7 (dd, $^2J_{PP}$ = 30, $^3J_{RhP}$ = 5.58)[b] |
| **3** | 93.2 (d) | 227 | 93.8 (br. s)[c] |
| **4** | 93.0 (d) | 236 | 92.3 (br. s)[c] |
| **5** | 91.0 (d) | 259 | 90.2 (br. s)[c] |
| **6** | 94.1 (dd) | 240 | 130.6 (d, $^2J_{PP}$ = 37)[d] |
| **7** | 104.8 (d) | 219 | 106.8 (s)[b] |

[a] M = lone pair. [b] M = Au. [c] M = Cu. [d] M = Pd.

The equimolar reaction of **1a** with CuCl in CH$_3$CN/CH$_2$Cl$_2$ produces the tetranuclear, dimetallic complex **3**. The $^{31}$P NMR spectrum of **3** exhibits a doublet at $\delta$ = 93.2 ppm for the rhodium-coordinated phosphorus atom of the cyclodiphosphazane, while the signal due to the copper-coordinated phosphorus atom appears as a broad singlet at $\delta$ = 93.8 ppm. Reaction of 2 equiv. of CuX (X = Br, I) with **1a** leads to the formation of heterotetranuclear derivatives [(cod)RhBr(μ-L-κP,κP)Cu(μ-Br)]$_2$ (**4**) and [{(cod)RhI(μ-L-κP,κP)}$_2$Cu(μ-X)$_2$Cu] (**5**), respectively. The rhombic [Cu(μ-X)$_2$Cu] unit in complex **5** contains a ca. 1:1 mixture of Cl and I disordered over both sites as indicated by X-ray dif-

fraction studies. Complexes **3**–**5** show a slight increase in their $^{1}J_{RhP}$ values as the halide varies from chloride to iodide (**3**: 227; **4**: 236; **5**: 259 Hz). Similar variations in $^{1}J_{RhP}$ have been seen in complexes containing the $[RhXP_3]$ unit depending on the nature of the anionic ligand X situated *cis* to the phosphorus atom in question[11] although the range is smaller than observed here. However, the remaining ligand set on Rh here is two C=C moieties which are weaker σ-donors than the two P atoms in the other examples and since the magnitude of $^{1}J_{MP}$ is sensitive to the *s*-orbital character in the M–P bond,[12] there should be more *s*-orbital character to share between Rh and X in the present case. Thus, a larger variation in the *s*-orbital character of the Rh–P bond with the nature of the halide ligand might be expected. The X-ray crystal structure of **5** reveals the presence of an Rh–I bond instead of the Rh–Cl bond present in the starting complex as well as the presence of a rhombic $[Cu(\mu\text{-}X)_2Cu]$ unit which clearly contains a mixture of chloride and iodide but because the unit sits on a crystallographic center of symmetry, the two halides are disordered over the two bridging sites. This result was unexpected since CuI was used in the reaction and suggests that the halogen exchange reaction occurs between the Rh–Cl bond present in **1a** and CuI to form the Rh–I derivative with concomitant formation of CuCl, which later coordinates to the uncoordinated phosphorus center of cyclodiphosphazane to produce a tetranuclear complex **5**. This indicates that the halogen exchange reaction occurs prior to the formation of Cu–P bonds. The formation of Rh–X (X = Br, I) through the halogen exchange between Rh–Cl and CuX (X = Br, I) as well as the preference for CuI over CuCl in coordination with phosphorus can be explained on the basis of the HSAB principle.[13]

The reaction of **1a** with $[PdCl(\eta^3\text{-}C_3H_5)]_2$ in dichloromethane in a 2:1 ratio produces the heterodinuclear complex $[(cod)RhCl(\mu\text{-}L\text{-}\kappa P,\kappa P)PdCl(\eta^3\text{-}C_3H_5)]$ (**6**) in good yield. The $^{31}P$ NMR spectrum of **6** exhibits a doublet centered at $\delta$ = 130.6 ppm with $^{2}J_{PP}$ = 37 Hz for the palladium-coordinated phosphorus atom, whereas the signal corresponding to the rhodium-coordinated phosphorus atom appears as a doublet of doublets centered at $\delta$ = 94.1 ppm ($^{1}J_{RhP}$ = 240 Hz, $^{2}J_{PP}$ = 37 Hz). Compounds **2**–**6** are stable solids and soluble in $CH_2Cl_2$, $CHCl_3$, and THF.

The complex *trans*-$[Rh(CO)Cl(L\text{-}\kappa P)_2]$ (**1b**)[6] containing two uncoordinated phosphorus centers from two *trans*-disposed cyclodiphosphazanes, when treated with 2 equiv. of $[AuCl(SMe_2)]$ in dichloromethane, afforded trinuclear complex **7** in quantitative yield (Scheme 3). The $^{31}P$ NMR spectrum of **7** consists of a singlet at $\delta$ = 106.8 ppm, which is assigned to the gold-coordinated phosphorus centers. The doublet appearing at $\delta$ = 104.8 ppm ($^{1}J_{PRh}$ = 218 Hz) is due to the rhodium-coordinated phosphorus centers. The IR spectrum of **7** shows $\nu_{CO}$ at 2019 $cm^{-1}$.

The slow addition of 2 equiv. of copper(I) iodide dissolved in acetonitrile to a dichloromethane solution of **1b** affords complex **8** containing two $Rh^{I}$ and two $Cu^{I}$ centers

along with two uncoordinated P$^{III}$ ends. Complex **8** crystallizes from the mother liquor at room temperature and the X-ray quality yellow crystals obtained are insoluble in most organic solvents, thus preventing solution spectroscopic characterization. The IR spectrum of **8** shows a strong $\nu_{CO}$ band at 2021 cm$^{-1}$ which is slightly lower than that of the parent compound **1b**.[6] The analytical data for **8** indicate the formation of a 1:1 complex between **1b** and CuI, and also the presence of an Rh–I bond. The structure of **8** was confirmed by low-temperature X-ray diffraction studies. Surprisingly, only one of the two dangling phosphorus(III) centers of complex **1b** coordinates to CuI with the resulting dimetallic Rh/Cu complex dimerizing through the formation of a rhombic [Cu(μ-I)$_2$Cu] unit, leaving the other phosphorus(III) center uncoordinated. Since phosphorus prefers the softer CuI for coordination over the CuCl which is generated from the halogen exchange reaction, we carried out the reaction between **1b** and CuI in a 1:3 ratio to force coordination of CuI to the heretofore uncoordinated phosphorus atom in anticipation of the formation of a heteronuclear metallopolymer containing rhodium(I) and [Cu(μ-I)$_2$Cu] units bridged by the cyclodiphosphazane. However, we observed exclusive formation of complex **8** in this reaction as well as under various other conditions.

## Molecular Structures of 2, 4, 5, 7, and 8

Molecular structures of complexes **2**, **4**, **5**, **7**, and **8** with atom numbering schemes are shown in Figures 2, 3, 4, 5, and 6, respectively. Crystallographic information and the details of the structure determination are summarized in Table 6. The pertinent bond lengths and bond angles are listed in Tables 2, 3, and 4. A compilation of Cremer–Pople puckering parameters[14] for the cyclodiphosphazane rings in **2**, **4**, **5**, **7**, and **8** appears in Table 5.

X-ray quality crystals of **2** were grown from a 1:1 solution of $CH_2Cl_2$/$Et_2O$ at –30 °C. In complex **2**, the cyclodiphosphazane bridges the rhodium(I) and gold(I) moieties in a *cis* fashion through P-coordination. As noted in the previous section, the crystal used for the structure determination proved to contain about 3.8% of cocrystallized [ClAu{(*o*-MeOC$_6$H$_4$O)P(μ-N*t*Bu)}$_2$AuCl], but this impurity appears to have no effect on the derived structural parameters for **2**. Previously, Krishnamurthy and co-workers have reported[15] the crystal structure of a heterodimetallic Mo$^0$/W$^0$ complex containing μ-cyclodiphosphazane, *cis*-[(*p*-MeC$_6$H$_4$O)P(μ-NPh)]$_2$, which is the only structurally characterized heterometallic complex of cyclodiphosphazanes to date. The geometry around the gold center in complex **2** is linear with a P2–Au–Cl2 angle of 178.36(3)°, whereas the rhodium center is in a distorted square-planar environment. The P1–Rh bond length is 2.2269(8) Å, which is considerably shorter than that in the parent compound **1** [2.2439(9) Å]. The Rh–Cl and Rh–C bond lengths are almost equal in both the complexes [Rh–Cl 2.3605(5) Å for **1b**, 2.3612(9) Å for **2**]. The presence of a shorter Rh–P bond in **2** is also reflected in its $^{31}$P NMR spectrum, which shows a large $^1J_{RhP}$ coupling of 247 Hz, whereas that in complex **1** is 229 Hz. The Au–P2 bond length in **2** is 2.2084(8) Å, which is comparable to that found in the mononuclear gold complex [ClAu{(*o*-MeOC$_6$H$_4$O)P(μ-N*t*Bu)}$_2$] [2.210(1) Å].[9] Assessment of these bond parameters suggests a stronger metal–ligand interaction in the heterodimetallic complex **2** as compared to the homodimetallic complex. The exocyclic phenyl substituents on the phosphorus centers are arranged in an *exo*,*endo* manner. The P$_2$N$_2$ ring present in **2** is unevenly puckered (see Table 5) with the sum of the angles around N1 and N2 being 359.00(18)° and 355.46(12)°, respectively. The crystal structure of **2** contains a molecule of dichloromethane in the lattice which forms a weak C–H···Cl hydrogen bond with the chlorido ligand on the rhodium atom (C21–H31A···Cl1 153°; H31A···Cl1 2.56 Å which is significantly less than the 2.88 Å average normalized distance determined previously for this type of interaction[16]). The other hydrogen atom on this solvent molecule (H31B) makes a contact of less than the sum of the van der Waals radii with the chlorido ligand on the gold atom (Cl2), but the C–H···Cl angle is too small for this to be considered a hydrogen bond.

| P2–O3 | 1.607(2) | P2–O3–C16 | 125.7(2) |
| N1–C1 | 1.494(4) | P1–N1–C1 | 131.32(20) |
| N2–C5 | 1.496(4) | P2–N1–C1 | 131.48(20) |

Crystals of **4** and **5** suitable for X-ray structure determination were obtained by slow evaporation of dichloromethane from respective 1:1 $CH_3CN/CH_2Cl_2$ solutions at room temperature. The core structures of **4** and **5** consist of a rhombic [Cu(μ-X)$_2$Cu] [X = Br (**4**) and X = apparent equimolar mixture of Cl and I (**5**)] unit bridging the two [(cod)RhX] (X = Br, I) moieties through two cyclodiphosphazanes as shown in Figures 3 and 4, respectively. Because the [Cu(μ-X)$_2$Cu] unit in **5** sits on a crystallographic center of symmetry, the bridging chlorido and iodido ligands are necessarily disordered, so it is not possible to say whether each molecule actually has a discrete [Cu(μ-Cl)(μ-I)Cu] unit at its center or if a more random distribution of Cl and I is present. The best model for refinement proved to be one in which Cl and I were given the same atomic coordinates and displacement parameters after which refinement of occupancy factors converged at ca. 0.5 for each atom type. Copper complexes containing mixed halide bridges are rare but in a copper(I) complex containing a mixed halide [$Cu_4Br_2Cl_2$] unit of distorted cubane geometry a 50:50 occupancy of all bridging halide sites was used as the model for refinement of the structure as we have done here. A similar disorder model was used in refining the structures of a series of $[Cu_2Cl_{6-x}Br_x]^{2-}$ ($x$ = 0.70–4.78) salts.[17] Copper centers adopt a distorted trigonal-planar geometry in both the molecules **4** and **5**. The bromo derivative **4** shows larger P2–Cu–Br [136.71(6)°] and short Br–Cu–Br$^i$ angles [99.50(4)°] compared with **5** [P2–Cu–X$^i$ 130.59(4)°, X–Cu–X$^i$ 103.79(2)°]. In structure **4**, the OMe groups present on exocyclic phosphorus substituents show strong interaction with the copper center [Cu···O4 2.691(4) Å], and this interaction leads to the formation of a boat-shaped six-membered ring around each copper center. However, complex **5** does not show such Cu···O interactions. The rhodium centers in **4** and **5** are located in the center of a distorted square-planar environment with the corners being occupied by iodido, phosphorus, and 1,5-cyclooctadiene ligands. The Rh–P1 bond lengths in **4** and **5** are 2.243(1) and 2.232(1) Å,

[a] For the P3–N3–P4–N4 ring. [b] Dihedral angle P3–N3–N4 vs. P3–N4–P4. [c] Dihedral angle P3–N3–P4 vs. P3–P4–N4.

respectively, which is slightly shorter than that in the parent complex **1a**. The Cu···Cu$^{i}$ separation of 3.082(1) and 3.057(1) Å, respectively, in complexes **4** and **5**, indicate the absence of cuprophilicity.[18] The two rhodium moieties present in **4** and **5** are arranged in a *trans* disposition with respect to the [Cu(μ-X)$_2$Cu] plane; however, the molecules maintain the *cis* disposition of substituents on the phosphorus atom with respect to the $P_2N_2$ plane as was found in the molecular structure of **1a**.

Single crystals of **7** were grown by slow diffusion of hexane into a dichloromethane solution of the complex at room temperature. Complex **7** contains two gold centers bridged by rhodium-bound cyclodiphosphazanes to form a trinuclear complex with a conformation very similar to that of the parent complex **1b**. The geometry around the rhodium center is slightly distorted square-planar with *cis* angles varying from 88.80(2) (P1–Rh–Cl1) to 91.12(2)° (P1–Rh–C1). The gold centers are dicoordinated and have a linear geometry with a P2–Au–Cl2 angle of 179.70(3)° which is more linear than that in the monometallic complex of the same ligand [176.83(2)°] but comparable with that in $Ph_3PAuCl$ [179.63(2)°].[19] The Rh–P1 distance in **7** is 2.2687(7) Å, which is shorter than those in the parent compound [**1b**: 2.2784(6), 2.2863(6) Å] – a situation comparable to that in the Rh$^{I}$/Au$^{I}$ complex **2**. The Au–P2 bond length is 2.1968(7) Å which is slightly shorter than that in **3** but much shorter than that in the mononuclear gold complex of the same ligand, [AuCl({(*o*-MeOC$_6$H$_4$O)P(μ-N*t*Bu)}$_2$-κP)].[11] The phenyl substituents on the phosphorus centers are arranged in an *exo*,*endo* manner.

Crystals of **8** suitable for X-ray diffraction studies were obtained from a $CH_2Cl_2$/$CH_3CN$ solution at room temperature. The core structure of **8** consists of two *trans*-Rh(P$_2$N$_2$)$_2$ moieties that are bridged by a [Cu(μ-I)$_2$Cu] unit to form a heterometallic complex containing two Rh$^{I}$ and two Cu$^{I}$ centers along with an uncoordinated P$^{III}$ site at each end. These two *trans*-Rh(P$_2$N$_2$)$_2$ moieties are oriented in a *trans* manner with respect to the plane of the rhombic [Cu(μ-I)$_2$Cu] unit and gives the molecule an overall S-shape. The rhodium centers are in distorted square-planar geometries, whereas the copper centers are in trigonal-planar environments. The Rh–P2 bond [2.288(2) Å] is shorter than the Rh–P3 distance [2.302(2) Å] while the distance between the two copper atoms (Cu···Cu$^{i}$) is 3.085 Å at 100 K, which indicates the absence of metal–metal interactions in complex **8**. This stands in contrast to the low-temperature structure of (Cy$_3$P)Cu(μ-I)$_2$Cu(PCy$_3$) in which the Cu···Cu separation is 2.893(2) Å.[20] Interestingly, the molecular structure of **8** shows a weak interaction between the copper and iodine atoms to form two six-membered rings based on the observation that the Cu···I2 distance is 3.262 Å, which is distinctly shorter than the sum of the van der Waals radii for the two atoms (3.38 Å).[21] There are no unusually short intermolecular contacts apparent that would flex the molecule so as to cause I2 to approach Cu more closely than a van der Waals contact, but since the distance is much longer than normal bonding distances [2.525(4)–2.640(2) Å],[22] it is a weak attractive interaction at best. There also appears to be a distinct C–H···I hydrogen bond between the aromatic hydrogen atom H27 and I1 (H27···I1 2.993 Å; C27–H27···I1 156.05°) as the H27···I1 distance is less than the 3.15 Å mean H···I1 distance considered indicative of a C–H···I hydrogen bond.[16]

## Conclusions

Several heterodi-, -tri-, and -tetrametallic complexes [Cu$^{I}$/Rh$^{I}$ (3d/4d), Pd$^{II}$/Rh$^{I}$ (4d/4d), and Au$^{I}$/Rh$^{I}$ (5d/4d)] containing cyclodiphosphazanes are described. The selective mono- and bidentate coordination modes exhibited by cyclodiphosphazane with a range of metal precursors gives

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a facile synthetic approach for construction of heterometallic systems. The halogen exchange reaction was observed for the first time between Rh–Cl and Cu–X (X = Br, I) during the synthesis of Cu$^{I}$/Rh$^{I}$ derivatives. Formation of rhombic [Cu(μ-X)$_2$Cu] units increases the nuclearity and can be utilized for the synthesis of a series of heterometallic coordination polymers. The work in this direction is currently underway in our laboratory.

## Experimental Section

**General:** All manipulations were performed under rigorously anaerobic conditions using high-vacuum manifolds and Schlenk techniques. All the solvents were purified by conventional procedures and freshly distilled and degassed prior to use.[23] Compounds *cis*-{(*o*-MeOC$_6$H$_4$O)P(μ-N*t*Bu)}$_2$ (L), [(cod)RhCl{L-κP}] (**1a**), *trans*-[Rh(CO)Cl{L-κP}$_2$] (**1b**),[6] [AuCl(SMe$_2$)],[24] CuX (X = Cl, Br)[25], and [PdCl(η-C$_3$H$_5$)]$_2$[26] were prepared according to published procedures. CuI was purchased from commercial sources and used as received.

**Instrumentation:** $^1$H and $^{31}$P{$^1$H} NMR (δ in ppm) spectra were recorded with a Varian Mercury Plus spectrometer operating at the appropriate frequencies using TMS and 85% $H_3PO_4$ as internal and external references, respectively. IR spectra of KBr disks were recorded with a Nicolet Impact 400 FT-IR instrument. Microanalyses were performed with a Carlo Erba Model 1112 elemental analyzer. Mass spectrometry experiments were carried out with a Waters Q-Tof micro-YA-105 instrument. Melting points were recorded in capillary tubes and are uncorrected.

**Synthesis of [(cod)RhCl{μ-L-κP,κP}AuCl] (2):** A dichloromethane solution (5 mL) of [AuCl(SMe$_2$)] (22.2 mg, 0.075 mmol) was added dropwise to a well-stirred dichloromethane solution (7 mL) of [(cod)RhCl{L-κP}] (**1a**) (52.5 mg, 0.075 mmol) at room temperature. The resulting yellow reaction mixture was stirred for 4 h. The solution was concentrated to 5 mL under reduced pressure, diluted with 5 mL of Et$_2$O and stored at –30 °C for 1 d to give the product as yellow crystals (62.4 mg, 89%). M.p. 222–224 °C (dec). $C_{30}H_{44}AuCl_2N_2O_4P_2Rh$ (929.4): calcd. C 38.76, H 4.77, N 3.01; found C 38.50, H 4.74, N 3.22. $^1$H NMR (400 MHz, CDCl$_3$, 25 °C): δ = 7.78–6.79 (m, 8 H, Ph), 5.77, 4.33 (br. s, 4 H, CH), 3.85 (s, 3 H, OMe), 3.82 (s, 3 H, OMe), 2.49–2.24 (m, 8 H, CH$_2$), 1.66 (s, 18 H, *t*Bu) ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, CDCl$_3$, 25 °C): δ = 104.7 (dd, $^2J_{PP}$ = 30 Hz, $^3J_{RhP}$ = 5.58 Hz, 1 P, PAu), 94.1 (dd, $^1J_{PRh}$ = 247 Hz, 1 P, PRh) ppm. MS (EI): *m*/*z* = 893.21 [M – Cl].

**Synthesis of [(cod)RhCl{μ-L-κP,κP}Cu(μ-Cl)]$_2$ (3):** Copper(I) chloride (4.5 mg, 0.045 mmol), dissolved in acetonitrile (5 mL), was added dropwise to a well-stirred $CH_2Cl_2$ solution (10 mL) of [(cod)RhCl{L-κP}] (**1a**) (31.1 mg, 0.045 mmol) at room temperature. The resulting yellow reaction mixture was stirred for 6 h. The solution was concentrated to 5 mL under reduced pressure, diluted with Et$_2$O (5 mL) and stored at –30 °C for 1 d to afford yellow crystals of the product (33.9 mg, 61%). M.p. 228–230 °C (dec). $C_{60}H_{88}Cl_4Cu_2N_4O_8P_4Rh_2$ (1519.9): calcd. C 45.26, H 5.57, N 3.51; found C 45.53, H 5.39, N 3.44. $^1$H NMR (400 MHz, CDCl$_3$, 25 °C): δ = 7.89–6.84 (m, 16 H, Ph), 5.72, 4.32 (s, 8 H, CH), 3.93 (s, 6 H, OMe), 3.81 (s, 6 H, OMe), 2.48–2.22 (m, 16 H, CH$_2$), 1.57 (s, 36 H, *t*Bu) ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, CDCl$_3$, 25 °C): δ = 93.8 (br. s, 2 P, CuP), 93.2 (d, $^1J_{PRh}$ = 227 Hz, 2 P, RhP) ppm.

**Synthesis of [(cod)RhBr{μ-L-κP,κP}Cu(μ-Br)]$_2$ (4):** The synthesis was the same as that for **3**, using copper(I) bromide (18.4 mg, 0.128 mmol) and [(cod)RhCl{L-κP}] (**1a**) (44.9 mg, 0.064 mmol). Yield: 74% (42.07 mg). M.p. 236–238 °C (dec). $C_{60}H_{88}Br_4Cu_2N_4O_8P_4Rh_2$ (1769.7): calcd. C 40.71, H 5.01, N 3.16; found C 40.94, H 5.17, N 3.24. $^1$H NMR (400 MHz, CDCl$_3$, 25 °C): δ = 7.94–6.84 (m, 16 H, Ph), 5.78, 4.44 (m, 8 H, CH), 3.93 (s, 6 H, OMe), 3.82 (s, 6 H, OMe), 2.41–2.19 (m, 16 H, CH$_2$), 1.55 (s, 36 H, *t*Bu) ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, CDCl$_3$, 25 °C): δ = 93.0 (d, $^1J_{PRh}$ = 236 Hz, 2 P, RhP), 92.3 (br. s, 2 P, CuP) ppm.

**Synthesis of [((cod)RhBr{μ-L-κP,κP})$_2$Cu(μ-Cl,I)Cu] (5):** The synthesis was the same as that for **3**, using copper(I) iodide (27.5 mg, 0.144 mmol) and [(cod)RhCl{L-κP}] (**1a**) (50.3 mg, 0.072 mmol). Yield: 85% (57.10 mg). M.p. 224–226 °C (dec). $C_{60}H_{88}ClCu_2I_3N_4O_8P_4Rh_2$ (1866.3): calcd. C 38.61, H 4.75, N 3.00; found C 38.83, H 4.81, N 3.07. $^1$H NMR (400 MHz, CDCl$_3$, 25 °C): δ = 7.98–6.87 (m, 16 H, Ph), 5.87, 4.67 (br. s, 8 H, CH), 3.82 (s, 6 H, OMe), 3.81 (s, 6 H, OMe), 2.47–2.01 (m, 16 H, CH$_2$), 1.53 (s, 36 H, *t*Bu) ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, CDCl$_3$, 25 °C): δ = 91.0 (d, $^1J_{PRh}$ = 259 Hz, 2 P, RhP), 90.2 (br. s, 2 P, CuP) ppm.

**Synthesis of [(cod)RhCl{μ-L-κP,κP}PdCl(η$^3$-C$_3$H$_5$)] (6):** A dichloromethane solution (5 mL) of [PdCl(η$^3$-C$_3$H$_5$)]$_2$ (16.9 mg, 0.046 mmol) was added dropwise to a well-stirred dichloromethane (10 mL) solution of [(cod)RhCl{L-κP}] (**1a**) (64.6 mg, 0.093 mmol) at room temperature. The reaction mixture was stirred for 6 h, concentrated to 5 mL under reduced pressure, diluted with diethyl ether (5 mL) and stored at –30 °C for 1 d to give a yellow crystalline solid (61.3 mg, 75%). M.p. 160–162 °C (dec). $C_{33}H_{49}Cl_2N_2O_4P_2PdRh$ (879.9): calcd. C 45.04, H 5.61, N 3.18; found C 45.31, H 5.82, N 3.37. $^1$H NMR (400 MHz, CDCl$_3$, 25 °C): δ = 7.79–6.76 (m, 8 H, Ph), 5.60 (br. s, 1 H, allyl CH), 5.73, 4.32 (s, 4 H, cod CH), 4.66, 3.65 (m, 4 H, allyl CH$_2$), 3.84 (s, 3 H, OMe), 3.82 (s, 3 H, OMe), 2.46–2.25 (m, 8 H, CH$_2$), 1.57 (s, 18 H, *t*Bu) ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, CDCl$_3$, 25 °C): δ = 130.6 (d, $^2J_{PP}$ = 37 Hz, 1 P, PPd), 94.1 (dd, $^1J_{PRh}$ = 240 Hz, 1 P, PRh) ppm.

**Synthesis of *trans*-[Rh(CO)Cl{μ-L-κP,κP}$_2$(AuCl)$_2$] (7):** To a suspension of *trans*-[Rh(CO)Cl{L-κP}$_2$] (**1b**) (100 mg, 0.093 mmol) in acetonitrile (5 mL), a dichloromethane solution (10 mL) of [AuCl(SMe$_2$)] (55.1 mg, 0.187 mmol) was added dropwise at room temperature. The reaction mixture was stirred for 4 h, concentrated to 10 mL under reduced pressure, and diluted with hexane (5 mL). Storing the resulting clear yellow solution overnight afforded a crystalline product (132 mg, 93%). M.p. 236–238 °C. $C_{45}H_{64}Au_2Cl_3N_4O_9P_4Rh$ (1532.1): calcd. C 35.27, H 4.21, N 3.65; found C 35.02, H 4.10, N 3.88. IR (KBr disk): $\tilde{\nu}$ = 2019 [ν(C≡O)] cm$^{-1}$. $^1$H NMR (400 MHz, CDCl$_3$, 25 °C): δ = 7.31–6.91 (m, 16 H, Ph), 3.93 (s, 6 H, OMe), 3.91 (s, 6 H, OMe), 1.73 (s, 36 H, *t*Bu) ppm. $^{31}$P{$^1$H} NMR (161.9 MHz, CDCl$_3$, 25 °C): δ = 106.8 (s, 2 P, PAu), 104.8 (d, $^1J_{PRh}$ = 218.5 Hz, 2 P, PRh) ppm.

**Synthesis of [Rh(CO)I{μ-L-κP,κP}$_2$Cu(μ-I)]$_2$ (8):** Copper(I) iodide (0.019 g, 0.101 mmol) in $CH_3CN$ (5 mL) was added dropwise to a well-stirred dichloromethane solution (10 mL) of *trans*-[Rh(CO)Cl{L-κP}$_2$] (**1b**) (0.054 g, 0.051 mmol) at room temperature. The reaction mixture was stirred for 6 h. Upon standing at room temperature for 3 d, the yellow solution afforded compound **8** as dark yellow crystals (47.5 mg, 69%). M.p. 248–250 °C (dec). $C_{90}H_{128}Cu_2I_4N_8O_{18}P_8Rh_2$ (2698.3): calcd. 40.06, H 4.78, N 4.15; found C 40.38, H 4.42, N 4.27. IR (KBr disk): $\tilde{\nu}$ = 2021 [ν(C≡O)] cm$^{-1}$.

**X-ray Crystallography:** Crystals of **2**, **4**, **5**, **7**, and **8** were mounted in a CryoLoop with a drop of Paratone oil and placed in the cold nitrogen stream of the Kryoflex attachment of the Bruker APEX CCD diffractometer (Table 6). For each, a full sphere of data was collected using a protocol of 400 scans in ω (0.5° per scan) at φ =

0, 90, and 180° plus 800 scans in $\phi$ (0.45° per scan at $\omega$ = –30 and 210° for **2**, **4**, and **5**) and one of 606 scans in $\omega$ (0.3° per scan) at $\phi$ = 0, 120, and 240° for **7** and **8** using the SMART software package.[27] The raw data were reduced to $F^2$ values using the SAINT+ software[28] and global refinements of unit cell parameters employing 8555–9267 reflections chosen from the full data set were performed. Multiple measurements of equivalent reflections provided the basis for empirical absorption correction as well as a correction for any crystal deterioration during the data collection (SADABS[29]). The structures were solved by direct methods and refined by full-matrix least-squares procedures using the SHELXTL program package.[30] Hydrogen atoms were placed in calculated positions [C–H 0.95 Å (aromatic rings) or 0.98 Å (methyl groups)] and included as riding contributions with isotropic displacement parameters 1.2 (aromatic rings) or 1.5 (methyl groups) times those of the attached non-hydrogen atoms. Near the end of the refinement of the structure of **2**, two significant peaks were observed in a difference map near the rhodium atom which formed a linear unit with P1. These were treated as the second Au and Cl atoms of the [ClAu{(*o*-$MeOC_6H_4O$)P(μ-N*t*Bu)}$_2$AuCl] impurity which had been identified by NMR spectroscopy in the original sample and which presumably had cocrystallized with **2**. Addition of these to the model significantly improved the refinement and resulted in a refined occupancy of the digold complex impurity of 0.038. CCDC-642038 (**2**), -642039 (**4**), -642040 (**5**), -642041 (**7**), and -642042 (**8**) contain the supplementary crystallographic data for this paper. This can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** how a novel tetranuclear $Ni^{II}$ complex $[Ni_4L_4^1(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]\cdot 2C_2H_5OH\cdot CH_3OH\cdot 3H_2O$ [$L^1$ = *N*-(3-aminopropyl)-5-bromosalicylaldimine] acts as an active catalyst for the partial oxidation of cyclohexene into its epoxide product when it is immobilized over a network of hexagonal mesoporous silica. Herein the catalytic sites allow the formation of epoxide over their surfaces. *tert*-Butyl hydroperoxide acts as an oxidant for the partial oxidation process. A dinuclear unit is formed, in which the $Ni^{II}$ is bridged by a phenolato group, and two such units are connected through a terephthalate moiety to form a tetranuclear nickel(II) complex. The tetranuclear units are connected to each other by another terephthalate moiety in its bis(monodentate) mode to form one-dimensional networks. Details are described in the article by P. Banerjee et al. on p. 5033 ff. The artwork was designed by Mr. Jishnunil Chakraborty and Mr. Gopal Das.

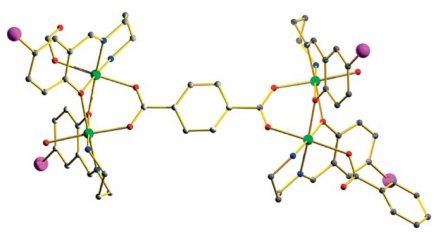
### Nickel Epoxidation Catalysts

**J. Chakraborty, M. Nandi, H. Mayer-Figge, W. S. Sheldrick, L. Sorace, A. Bhaumik, P. Banerjee*** ..... **5033–5044**

Nickel Complexes with $N_2O$ Donor Ligands: Syntheses, Structures, Catalysis and Magnetic Studies

**Keywords:** Nickel / N,O ligands / Epoxidation / Heterogeneous catalysis / Magnetic properties



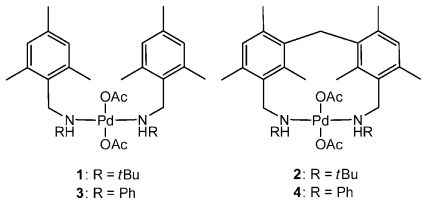
The terephthalato-bridged tetranuclear polymeric $Ni^{II}$ complexes $[Ni_4L_4^1(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]\cdot 2C_2H_5OH\cdot CH_3OH\cdot 3H_2O$ (**1**) and $[Ni_4L_4^2(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]\cdot 3H_2O$ (**2**) are synthesized along with the dicyanoargentate-bridged polymeric complexes $[Ni^{II}(L^1)(H_2O)\{Ag(CN)_2\}]_\alpha$ (**3**) and $[Ni^{II}(L^3)(MeOH)\{Ag(CN)_2\}]_\alpha$ (**4**). All four complexes are effective catalysts for the epoxidation of alkenes. Variable-temperature magnetic susceptibility measurements of complex **1** show a medium-strength antiferromagnetic coupling between the $Ni^{II}$ centers.

## Square-Planar Palladium Complexes

**L. Chahen, B. Therrien, G. Süss-Fink* 5045–5051**

Square-Planar Diacetatopalladium Complexes with *trans*-Configured Secondary Amine Ligands that Avoid Orthometalation: Ligand Synthesis, Coordination, Molecular Structure and Catalytic Potential for Suzuki Cross-Coupling Reactions

**Keywords:** Cross-coupling / Palladium / N ligands / Amines / Homogeneous catalysis



*trans*-Configured square-planar palladium complexes have been synthesized by treating palladium acetate with the amines or diamines. All complexes are found to catalyze Suzuki cross-coupling reactions of deactivated and even sterically hindered arene substrates.

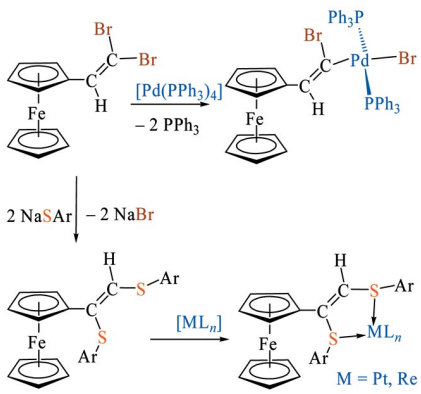
## Heterodimetallic Ferrocene Complexes

**S. Clément, L. Guyard, M. Knorr,* F. Villafañe, C. Strohmann, M. M. Kubicki ..... 5052–5061**

(2,2-Dibromovinyl)ferrocene as a Building Block for the Assembly of Heterodinuclear Complexes – Preparation of an σ-Alkenylpalladium Complex and Dimetallic Dithioether Complexes

**Keywords:** Oxidative addition / Thioether ligands / Platinum / Rhenium / Palladium / Electrochemistry

The oxidative addition of (2,2-dibromovinyl)ferrocene to $[Pd(PPh_3)_4]$ yields the σ-alkenyl complex *trans*-[{Pd(Br)-$(PPh_3)_2$}–C(Br)=C(H)–Fc]. Nucleophilic attack of NaSR on $[Br_2C=C(H)–Fc]$ produces the π-conjugated dithioether compounds [(RS)CH=C(SR)–Fc], which react with $[Re(thf)(CO)_3(\mu\text{-}Br)]_2$ or $[PtCl_2(PhCN)_2]$ to afford heterodinuclear dithioether complexes.



## Iron-Only Hydrogenase Models

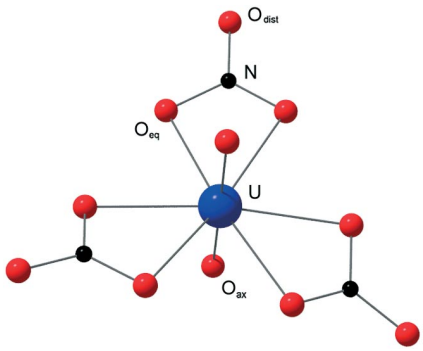
## Speciation of Uranyl Nitrate

Complex formation between the uranyl ion and nitrate ions is investigated in acetonitrile and the ionic liquid [$C_4$mim][$Tf_2$N] at room temperature by optical absorption, magnetic circular dichroism and EXAFS spectroscopy. The sharp peaks in the absorption spectrum are characteristic of a $[UO_2(NO_3)_3]^-$ species with $D_{3h}$ coordination symmetry. No evidence is found for the formation of uranyl nitrato complexes in aqueous solution.



**K. Servaes, C. Hennig,* I. Billard, C. Gaillard, K. Binnemans, C. Görller-Walrand, R. Van Deun* ..... 5120−5126**

Speciation of Uranyl Nitrato Complexes in Acetonitrile and in the Ionic Liquid 1-Butyl-3-methylimidazolium Bis(trifluoromethylsulfonyl)imide

**Keywords:** EXAFS spectroscopy / Ionic liquids / Uranium / UV/Vis spectroscopy / X-ray absorption spectroscopy

## Cyclopentadienylcobalt Complexes

Chelation by the amino-functionalised side chain occurred when the Cp′-cobalt(I) dicarbonyl complexes were oxidised by iodine, resulting in the corresponding Cp′-cobalt(III) chelates via diiodocarbonyl intermediates. The stabilities of the intermediates were found to correlate with the I−Co−I angles and the repulsive force from the amino-functionalised groups in the chelates. Complex **6′** was reduced to **6** by the CO released upon chelation. Its $PPh_3$-substituted $CH_2CH_2$ solvate shows a strong N−H···I hydrogen bond.

Synthesis and Reactivity of Cobalt Complexes with Pendant Nitrogen Functional Groups

**Keywords:** Cyclopentadienylcobalt complexes / Carbonylcobalt complexes

## Inorganic Reaction Mechanisms

The process $AuCl_3$(3R-py) + $Cl^-$ → $AuCl_4^-$ + 3R-py (3R-py = *meta*-substituted pyridines) was studied in methanol at 25 °C and the data were compared with those found for *para*-substituted pyridines (4R-py). Until now the two groups of bases have been considered to behave in the same manner in their displacement reactions but, on the contrary, the reactivity of the two classes of N donors is slightly different and follows the order: 4R-py > 3R-py. This kinetic result is explained on the basis of an energetic difference between the frontier orbitals of the $AuCl_3$(3R-py) and $AuCl_3$(4R-py) derivatives.

# Electron Transfer and Molecular Recognition in Metallocene-Containing Dendrimers

**Angel E. Kaifer*[a]**

*Dedicated to the late Professor Moisés Morán*

**Keywords:** Metallocenes / Dendrimers / Electrochemistry / Molecular recognition / Supramolecular chemistry

This manuscript provides a summary of the relatively large body of research on the preparation and characterization of dendrimers containing (1) multiple copies of metallocene residues on their surfaces or (2) a single metallocene residue at their core. Special emphasis is placed on dendrimers functionalized with either ferrocene or cobaltocenium groups, because their reversible electrochemistry makes them particularly attractive to the author's group. Dendrimers containing multiple, peripheral metallocene residues are of interest to develop multivalent interactions with suitable receptors or receptor assemblies. With dendrimers containing a single metallocene at their cores, the key questions relate to the effects of the dendritic mass on their properties and degree of encapsulation or site isolation. We focused our work on the electrochemical properties of these dendrimers as well as on their use as guests in molecular recognition processes with freely diffusing hosts.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Dendrimers[1] are highly branched macromolecules spanning from a central core and containing a series of layers, structurally and synthetically distinct, which are usually referred to as "generations". Whereas the initial interest in dendrimers was basically related to the synthetic and structural characterization challenges that they pose, their fractal geometries, high molecular weights, and nanometer-range sizes, a little more than a decade ago many groups started to focus on their functionalization. In very simplistic terms, one can look at a functionalized dendrimer as one or more functional residues attached to a large dendritic mass that defines the shape, size, and other properties of the macromolecule. In some cases, the dendritic mass also has a pronounced influence on the chemical or physical properties of the functional residue. There are two general ways to approach dendrimer functionalization. First, one can attach many copies of a functional residue on the surface of the dendrimer (peripheral functionalization). Second, one can grow dendritic mass branching out from a functional residue (core functionalization). Both styles of functionalization (see Figure 1 for schematic drawings) have different advantages and target various purposes. Peripheral functionalization is advantageous to develop multivalent interactions with dendrimers or to achieve chemical amplification. Core functionalization is more suitable when the main interest revolves around site isolation of the residue and/or the concomitant alteration of its properties.

*Angel E. Kaifer was born in Madrid, Spain, where he completed his undergraduate studies in chemistry at Universidad Autónoma. He earned his Ph.D. (with Luis Echegoyen) in 1984 at the University of Puerto Rico, Rio Piedras, and did postdoctoral work (with Allen Bard) at the University of Texas, Austin. In 1985 he joined the faculty of the University of Miami, where he is now Professor of Chemistry. His research interests focus on the electrochemistry of supramolecular systems, with current emphasis on functionalized dendrimers, molecular capsules, hydrogen-bonded systems, and the binding properties of cucurbit[n]uril hosts.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

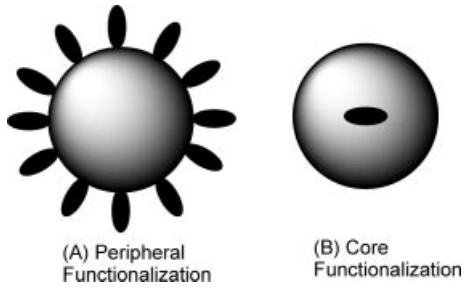

Figure 1. Main approaches to dendrimer functionalization.

In this manuscript, research work on dendrimers functionalized with metallocene residues is described, placing significant emphasis on the work done by my research group, without relegating the very important work done by other groups, from which we have gained inspiration and a healthy measure of competition. From the standpoint of my own group, reversible electrochemical properties are quite desirable, and, thus, we have mostly focused our efforts on dendrimers functionalized with either ferrocene [bis(cyclopentadienyl)iron(II)] or cobaltocenium [bis(cyclopentadienyl)-cobalt(III)] centers. Both metallocene residues are stable, 18-electron systems, which differ on the charge of their most accessible oxidation states: zero for ferrocene and +1 for cobaltocenium. Ferrocene undergoes fast one-electron oxidation to the positively charged ferrocenium form, whereas cobaltocenium exhibits fast one-electron reduction to produce the neutral cobaltocene. Both electrochemical processes take place at accessible potentials and usually maintain fast kinetics (*reversibility* in electrochemical jargon) in ferrocene- and cobaltocenium-containing compounds.

## Dendrimers Containing Multiple Peripheral Metallocene Residues

Our initial interest in this type of system was sparked by the elegant work of Cuadrado and Morán, at Universidad Autónoma de Madrid, who were among the pioneering groups reporting the preparation of dendrimers with multiple, peripheral metallocene centers.[2] Our long-standing interest on the binding interactions between water-soluble ferrocene derivatives (see compound **1** as an example) and cyclodextrins, naturally led to the investigation of the supramolecular interactions between dendrimers **2** and **3** with cyclodextrin hosts[3] (see Figure 2).

The binding interactions between **1** and β-cyclodextrin (βCD) were studied by using $^1$H NMR spectroscopy in 0.1 M NaCl/$D_2O$. An equilibrium association constant ($K$) of 1230 $M^{-1}$ was measured by using this technique.[4] The formation of inclusion complex **1**·βCD was also evident from cyclic voltammetric data. The binding interactions between dendrimers **2** and **3**, as guests, and the βCD host were harder to study, as these dendrimers are quite insoluble in aqueous media. We observed, however, that the solubility of the dendrimers in aqueous solution containing 6.0 mM βCD was substantially higher.[4] In fact, our solubility measurements suggested that a minimum number of ferrocene residues per dendrimer must be CD bound for solubilization to take place. Competition experiments with a second guest (2-naphthalenesulfonate) and voltammetric experiments revealed that all the ferrocene residues in dendrimers **2** and **3** are accessible to βCD for formation of the inclusion complexes. On the other hand, a larger dendrimer (compound **4**, structure not shown) containing 16 ferrocenyl groups on its surface, shows signs of steric peripheral congestion, as not all the ferrocene groups are accessible for βCD complexation under our experimental conditions.

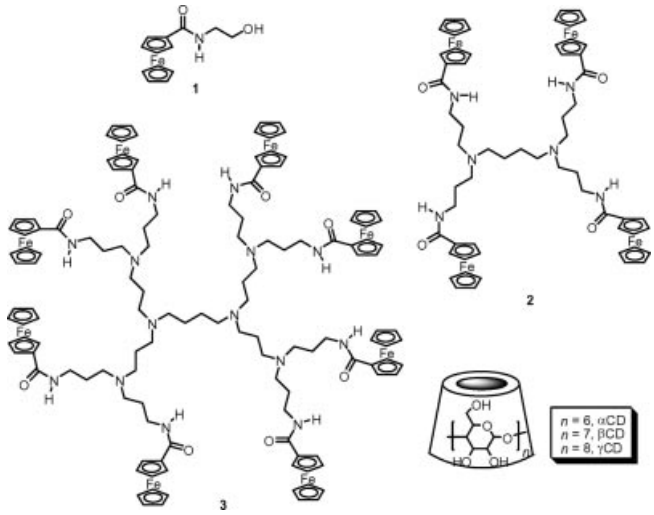

Figure 2. Structures of model compound **1**, dendrimers **2** and **3**, and the cyclodextrin hosts.

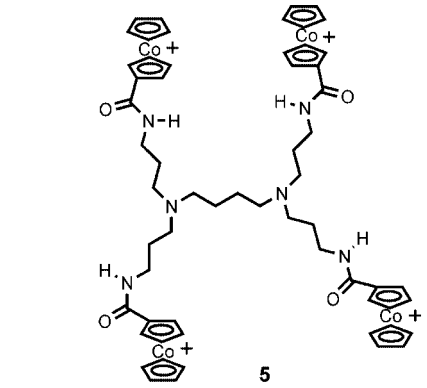
Conceptually, these dendrimers serve as three-dimensional templates for the organization of the CD receptors on their peripheries, giving rise to large supramolecular assemblies. For instance, the molecular weight of the octameric inclusion complex formed by the interaction of dendrimer **3** and excess βCD exceeds 11 kDa.[4] In addition to this, the one-electron oxidation of the ferrocene derivatives provides a reversible mechanism to release the CD receptors from these supramolecular complexes, as it is well known that the binding affinity of a ferrocene–βCD inclusion complex decreases by approximately two orders of magnitude upon oxidation of the ferrocene guest, effectively going from a $K$ value in the range $1 \times 10^3$ to $5 \times 10^3$ $M^{-1}$ to less than 50 $M^{-1}$.[5]

Our joint work with the Madrid group quickly moved to the exploration of the binding interactions between a similar series of dendrimers containing multiple cobaltocenium units on their surfaces and cyclodextrin hosts.[6] The simplest structures (dendrimers **5** and **6**) within this dendrimer series are shown in Figure 3. Unlike their ferrocene counterparts, these dendrimers have excellent aqueous solubility due to their polycationic character. Previous work from my group on the binding interactions between βCD and simple cobaltocenium revealed that the positively charged, oxidized form does not interact significantly with the CD host.[7] However, one-electron reduction leads to the formation of a stable inclusion complex between the neutral co-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

baltocene form and βCD. These binding interactions have a strong effect on the shape of the current–potential voltammetric curves for cobaltocenium. In the absence of βCD, one-electron reduction gives rise to extensive precipitation on the electrode surface of the neutral, hydrophobic cobaltocene, which results in a distorted, very sharp peak for its reoxidation process back to cobaltocenium.[7] The sharpness of this peak is strongly related to the stripping nature of the electrochemical process, as material deposited onto the electrode surface is redissolved back into the solution as a result of the electron-transfer reaction. Not surprisingly, similar cyclic voltammograms were observed with dendrimers **5** and **6** (Figure 4), strongly suggesting that the same βCD binding mechanism operates on them as it does on simple cobaltocenium derivatives. The lack of binding interactions between βCD and the fully oxidized, cationic forms of the dendrimers was verified by $^1$H NMR spectroscopic data.[6] When comparing the behavior of ferrocene- and cobaltocenium-containing dendrimers, it is clear that dendrimers **5** and **6** interact with the cyclodextrin host only after one-electron reduction of the cobaltocenium units, whereas in the case of the ferrocene dendrimers (**2** and **3**, for instance) the binding interactions are disrupted by one-electron oxidation of the electroactive peripheral units. Whereas the behavior is similar in the sense that the neutral metallocene forms are complexed by βCD and the cationic forms are not, we must recognize that the ferrocene dendrimers are bound in their most stable and accessible oxidation state, and the cobaltocenium dendrimers are only bound after electrochemical stimulation. Therefore, electrochemical stimulation has opposite effects on these two types of dendrimers; it leads to the disassembly of the supramolecular complexes in the case of the ferrocene dendrimers and to supramolecular association for the cobaltocenium dendrimers.



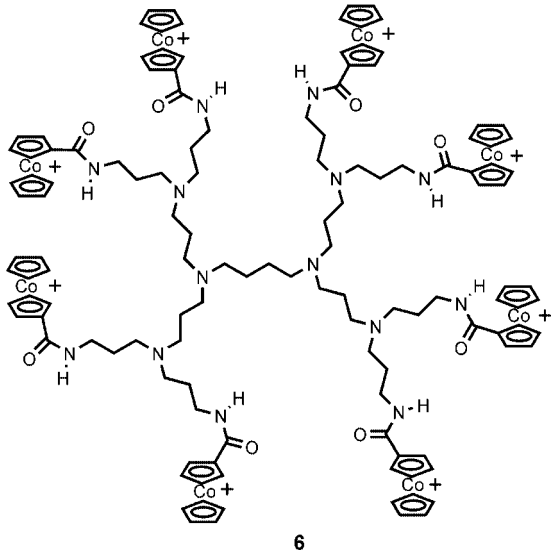


Figure 3. Representative structures of dendrimers containing multiple cobaltocenium units on their surfaces.

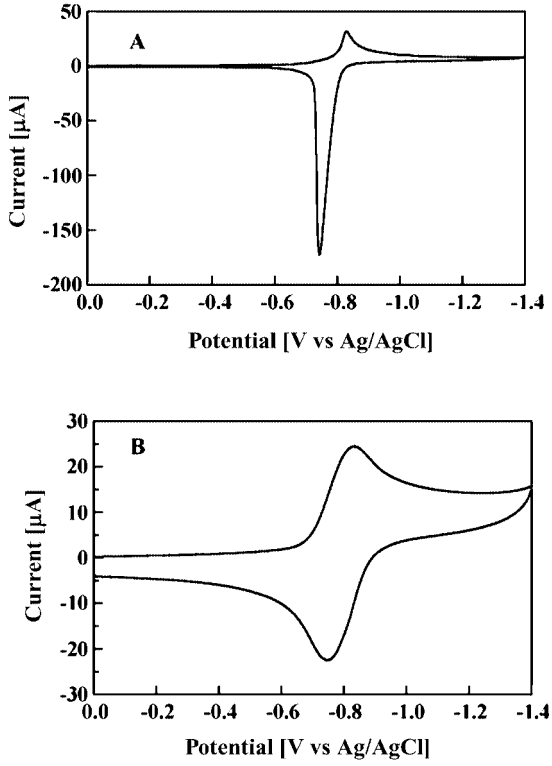

Figure 4. Cyclic voltammetric behavior on glassy carbon (0.08 cm$^2$) of a solution containing **5** (0.5 mM) and NaCl (0.1 M) (A) in the absence and (B) in the presence of βCD (7.0 mM).

We noted early that dendrimers with multiple copies of a metallocene unit on their surfaces could be interesting to express chemical amplification and or multivalency properties.[4] However, we did not explore this kind of phenomena. Reinhoudt and coworkers started to investigate the interactions between dendrimers containing multiple peripheral copies of adamantyl units with βCD and were able − by decreasing substantially the pH of the solution − to solubilize these dendrimers in aqueous media and investigate their CD binding interactions in more detail.[8] Whereas we observed limitations on the number of βCD hosts that can interact with dendrimers containing 16 peripheral ferrocene groups or more, their experimental conditions led to more open dendrimer structures that can interact easily with larger number of cyclodextrin hosts, even if considerable steric crowding is expected on the dendrimer surface. This group moved on to perform a series of elegant studies on

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the interaction between dendrimers containing multiple surface guest units, such as adamantyl or ferrocenyl, and gold surfaces covered with self-assembled monolayers prepared with complementary host (βCD) monomers.[9] These are multivalent interactions involving several guest units from an individual dendrimer that interact simultaneously with several binding cavities in the cyclodextrin monolayer. The multivalent aspect of the interaction adds considerable thermodynamic stability to the assembly, leading to the robust immobilization of the dendrimers on the monolayer-covered surfaces. These multivalent dendrimer–monolayer interactions constitute the supramolecular basis for the development of a new class of soft nanolithographic patterning methods.

The βCD binding properties of cobaltocenium and ferrocene units were combined in a single compound (**7**), which exhibits three oxidation states that we can represent as $Fc^+$–$Cob^+$, Fc–$Cob^+$ and Fc–Cob (see Figure 5).[10] The first form ($Fc^+$–$Cob^+$) does not interact with βCD, the second forms a 1:1 inclusion complex (Fc included, $Cob^+$ not bound), and the third oxidation state interacts with two βCD hosts (both Fc and Cob units are bound). The group of Cuadrado and Morán has also prepared dendrimers containing multiple ferrocene and cobaltocenium residues,[11] but their binding interactions with βCD were not investigated.

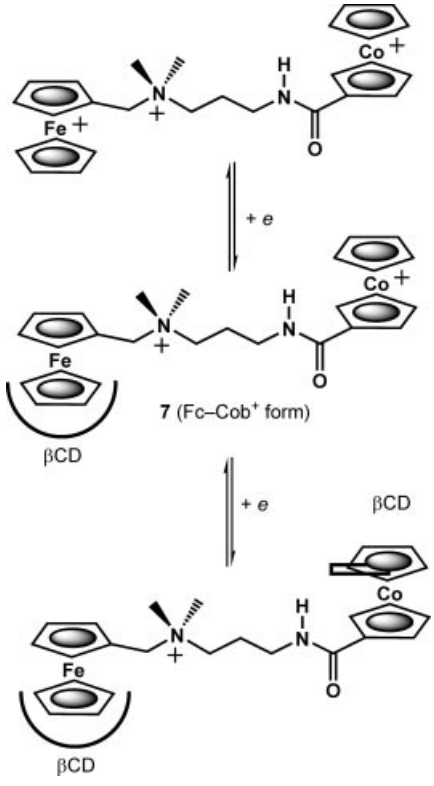

Figure 5. The three oxidation states of compound **7** and their respective binding sites for βCD.

The group of Astruc has pioneered a large amount of work with dendrimers having multiple ferrocenyl and other organometallic residues on their surfaces. Among many other goals, this group has emphasized the possible use of these systems in anion binding/sensing applications.[12] Furthermore, they have also utilized gold nanoparticles as the scaffold to assemble a multiple set of peripheral metallocene subunits for anion recognition.[13] Inspired by this work, we decided to modify the structure of our ferrocene dendrimers, such as **2** and **3**, to enhance the binding of biologically relevant anions, of which phosphate is one of the most significant examples. The preparation of **2** and **3** relies on the reaction of commercially available amine-terminated, poly(propylene imine) (PPI) dendrimers with chlorocarbonylferrocene (**8**).[2b] The final dendrimer products have multiple ferrocenyl centers covalently attached to the dendrimer through amide functional groups. Whereas amides are known to hydrogen bond to anions, ureido groups are typically more effective for this purpose. Therefore, we treated the amine-terminated PPI dendrimers with isocyanatoferrocene, which was prepared from **8** via formation of the acyl azide derivative as an intermediate.[14] We obtained a series of novel dendrimers terminated in 4, 8, 16 or 32 ferrocenyl–ureido termini (see Figure 6 for an example). These dendrimers exhibit a voltammetric behavior in DMSO solution that is quite sensitive to the presence of hydrogenphosphate anions. The addition of hydrogenphosphate (1 equiv.) shifts the observed half-wave potential for ferrocene oxidation 112 mV to less positive values, whereas hydrogensulfate and chloride cause much smaller potential shifts (40 and 16 mV, respectively). Furthermore, the selectivity of the ferrocenyl–urea dendrimers for hydrogenphosphate was excellent as judged by the potential shifts observed in the presence of anion mixtures.[14] A particularly interesting aspect of this work is that the anion binding interactions and their voltammetric sensing were performed in a relatively polar solvent (DMSO), affording a reasonable measure of optimism for the development of structur-

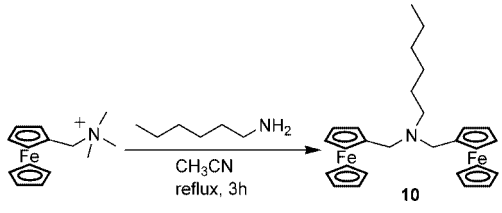
ally related systems that might have similar operational characteristics in aqueous environments.

When discussing the electrochemistry of dendrimers such as **2**, **3**, **5**, **6**, **9**, and related compounds having an even larger number of metallocene units on their surfaces, it is important to clearly point out that their electrochemical behavior is characterized by a single voltammetric wave (anodic in the case of ferrocene systems and cathodic for cobaltocenium dendrimers). This wave may be distorted due to precipitation effects, because these dendrimers suffer a large change in their hydrophilic/hydrophobic nature as a result of electron-transfer reactions. However, the individual oxidation of all the ferrocene centers (or reduction of all the cobaltocenium units) takes place at rather similar potentials. In other words, all metallocene units undergo electron transfer independently and no significant degree of electronic coupling among them can be discerned. This is so in spite of the spatial proximity between adjacent metallocenes forced by the crowding on the dendrimer surface. Even dendrimer systems with 64 peripheral ferrocenes, thus located very close to one another, exhibit a single, albeit relatively broad, oxidation wave.[15] In other words, the electrochemical behavior of these dendrimers clearly suggests that through space communication between adjacent metallocenes does not seem to be very effective in these systems.

A few years ago we prepared a new class of dinuclear ferrocene compounds containing a $–CH_2–N(R)–CH_2–$ bridge between the two ferrocenyl residues.[16] These compounds could be readily synthesized by thermal decomposition in polar solvents of (ferrocenylmethyl)trimethylammonium in the presence of a primary amine (Scheme 1). Interestingly, we observed that the level of electronic coupling between the two ferrocenyl residues was dependent on the state of protonation of the central nitrogen atom in the bridge. For instance, unprotonated amine **10** showed a modest level of electronic coupling between the ferrocene centers, as reflected by the measurable difference between the two half-wave potentials ($\Delta E_{1/2}$ = 82 mV), but the protonated compound exhibited a $\Delta E_{1/2}$ value of 46 mV, which was barely above that expected for fully independent redox centers. Alkylation of the bridge nitrogen atom had an effect similar to protonation on the level of communication between the two ferrocene centers.[16]



Scheme 1. The preparation of dinuclear ferrocene compound **10**.

Intrigued by these observations, we decided to express this dinuclear ferrocene motif on dendritic surfaces. By allowing the thermal decomposition of ferrocenyltrimethylammonium in the presence of amine-terminated PPI dendrimers, we successfully prepared a series of small dendrimers shown in Figure 7.[17] Unfortunately, the modest level of electronic communication existing in simple ferrocene dinuclear compounds bridged by $–CH_2–N(R)–CH_2–$ linkages is not observable on the surface of these dendrimers. However, their voltammetric behavior was interesting in a different way. For simplicity, let us discuss first the behavior of compound **13**. Our experiments were recorded in an 80:20 v/v mixture of $CH_2Cl_2/CH_3CN$, in order to minimize precipitation problems associated with the electron transfer reactions. In this solvent system the electrochemical behavior of **13** is characterized by a single reversible oxidation at a half-wave potential of 0.45 V vs. Ag/AgCl. However, the addition of HCl leads to the observation of two distinct oxidation waves at 0.45 and 0.61 V vs. Ag/AgCl. The addition of an excess amount of acid eliminates the first redox couple at 0.45 V and develops the second wave (at 0.61 V) to maximum current levels.[17] Clearly, protonation of one of the two tertiary nitrogen atoms of the compound shifts the half-wave potential of the two attached ferrocene centers to more positive values, and thus, the voltammetric behavior reveals the presence of protonated and unprotonated nitrogen centers on the periphery of the compound. This was further verified by partial methylation of one of the peripheral tertiary nitrogen atoms, leading to compound **14**, which we also prepared and characterized. The voltammetric behavior of **14** shows two oxidation processes at 0.48 and 0.67 V vs. Ag/AgCl. Protonation of **14** eliminates the redox couple at 0.48 V and leads to a single oxidation wave at the higher half-wave potential. These experiments suggest that the protonation (or methylation) of each of the peripheral nitrogen atoms leads to an anodic shift of the half-wave potential corresponding to the oxidation of the two ferrocenyl units covalently attached to it. One would expect, therefore, that the behavior of larger dendrimer **11**, containing four pairs of ferrocenyl units on its surface, would be similar. In fact, this expectation was fully realized. The voltammetric response of **11** in the absence of acid shows a single redox couple at 0.50 V vs. Ag/AgCl, which corresponds to the oxidation of eight ferrocene centers. The addition of HCl gives rise to a new redox wave at 0.61 V, which grows at the expense of the original wave as more acid is added to the solution. Eventually, upon addition of ca. 10 equiv. of HCl, the first wave disappears and the second wave at 0.61 V reaches full development.[17] This behavior reveals that it is possible to control − by the addition of suitable concentrations of acid − the relative population of the two types of ferrocene centers attached to protonated or unprotonated nitrogen atoms, which are characterized by different half-wave potentials. It is interesting to point out that compound **12** was isolated during the preparation of **11**. This defective compound (missing one ferrocenyl group in comparison to **11**) affords an interesting example on the poor diagnostic power of elemental analysis with some types of dendrimers. Both **11** and **12** gave experimental elemental compositions (C, H) that agree with the calculated compositions of both **11** and **12** within accepted error margins. This highlights the importance of mass spectrometry for the unequivocal confirmation of dendritic structures.

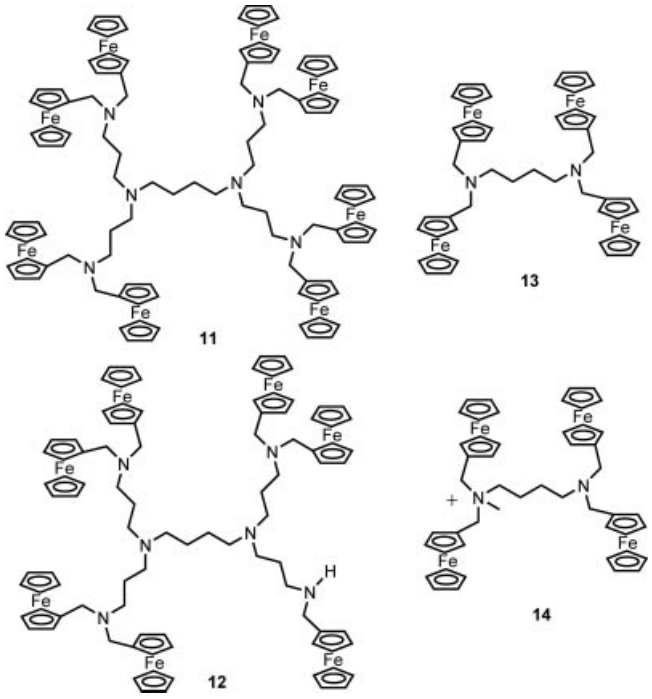

Figure 7. Small dendrimers containing Fc–$CH_2$–N(R)–$CH_2$–Fc units on their surfaces.

Dendrimers with multiple metallocene centers on their surfaces are interesting systems from the standpoint of their electrochemical properties and their possible use as guests in multivalent interactions, either in new nanolithographic surface patterning methods or in their potential applications as anion sensors.

## Dendrimers with a Single Metallocene Unit at Their Focal Positions

As discussed in the Introduction, dendrimer functionalization can take many forms. Whereas we first became interested in dendrimers with multiple metallocene units on their surfaces, our interests evolved and eventually focused on the properties of metallocene core dendrimers, that is, dendrimers containing a single metallocene residue covalently attached to one or more dendrons. Dendron growth may give rise to site isolation, that is, the partial or complete encapsulation of the metallocene unit by dendrimer mass. These dendritic systems are interesting for a number of reasons. Primarily, site isolation leads to new and intriguing properties for the dendrimer-surrounded metallocene residue, which may exhibit very different electrochemical and optical properties relative to those of the free metallocene. This has some biological overtones because in redox proteins the electrochemical reactivity of the prosthetic redox active group is often modulated by its partial encapsulation in the polypeptide framework. Therefore, we decided to start a research program to prepare and characterize dendronized metallocenes, that is, dendrimers containing a single metallocene unit attached to their focal points.

Our molecular design relies on the use of three dendrimer building blocks based on the branching architecture of a triester amine (Behera's amine, compound **15** in Figure 8) first reported by Newkome and coworkers.[18] We modified slightly the synthetic procedures published by this group and prepared Behera's amine, as well as its second and third generation analogs[19] (Figure 8). Once these amine dendrons are available, we can easily tap into the reactivity of the focal amine groups to covalently attach a variety of electroactive and fluorescent groups to the dendrons. Our group has taken advantage of this chemistry to prepare dendrimers with ferrocene,[19,20] dansyl,[21] pyrene,[22] viologen,[23] cobaltocenium,[24] and hydrogen-bonding ureidopyrimidine[25] groups attached to the focal position of the dendron. In this review, we will obviously focus our attention on the properties of dendronized ferrocene and cobaltocenium compounds, but will use some of the data obtained with other functional groups to support specific conclusions along the way.

## Dendronized Ferrocenes: Electrochemistry

These compounds were readily prepared by reaction of the amine dendrimer building blocks (compounds **15**, **16**, and **17**) with chlorocarbonylferrocene.[19] The amidation reaction worked well and led to the dendronized ferrocenes in reasonable yields (31–49%). These dendrimers (Figure 9), having 3, 9 and 27 *tert*-butyl esters on their surfaces, were characterized by $^1$H and $^{13}$C NMR spectroscopy, MALDI-TOF mass spectrometry, UV/Vis and IR spectroscopy, and electrochemical data.

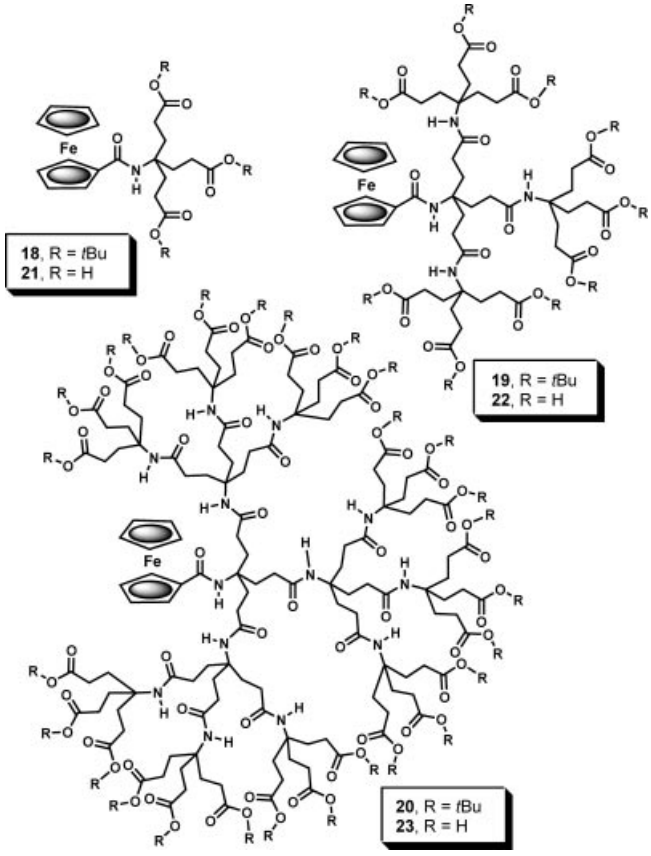

Figure 9. Hydrophobic (**18**, **19**, and **20**) and hydrophilic (**21**, **22**, and **23**) series of dendronized ferrocenes.

The anodic voltammetric behavior in dichloromethane solution is characterized by the one-electron oxidation of the ferrocenyl group. Table 1 gives the relevant electrochemical parameters obtained in voltammetric experiments. Generally, ferrocene derivatives exhibit fast (reversible) electrochemical kinetics in their one-electron oxidation processes. In agreement with this expectation, the first generation ferrocene dendrimer (compound **18**) shows reversible electrochemical behavior, characterized by a reasonably fast heterogeneous electron transfer rate constant ($k°$). However, the $k°$ values decrease quickly as the size of the attached dendron increases,[19] which is consistent with the findings of other groups who have investigated electrochemical kinetics with core dendrimers.[26] These results are understood as a straightforward effect of molecular size. As the dendrimer grows, its diffusion coefficient decreases, which leads to lower current levels due to slower mass transport of electroactive molecules to the electrode surface. However, the decrease in the $k°$ value represents an intrinsic slowdown of the electrochemical kinetics and is thought to be associated with the distance between the redox center and electrode surface when the interfacial electron transfer takes place. As electroactive molecules move towards the electrode surface, they reach a point of maximum approach, which is defined by the so-called outer Helmholtz plane (OHP). The larger the molecule, the further away from the electrode the OHP will be located. Therefore, if one considers all possible rotational orientations for the dendrimer, it is clear that the average distance between the ferrocene center and the electrode surface should increase with the molecular size. The electron transfer rate is well known to decrease exponentially with distance,[27] thus explaining the general trend observed with most core dendrimers and the $k°$ values reported in Table 1.

Table 1. Molecular weights and electrochemical parameters (0.2 M $TBA^+PF_6^-$ in $CH_2Cl_2$ at 25 °C) for the dendronized ferrocenes.

| Dendrimer | MW[a] [amu] | $E_{1/2}$ [V vs. Ag/AgCl] | $D_o$[b] [$10^6 \times cm^2 s^{-1}$] | $k°$[b] [$10^3 \times cm\,s^{-1}$] |
|---|---|---|---|---|

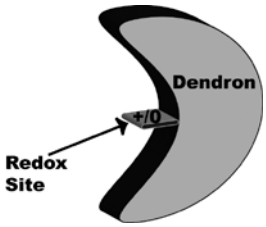
[a] Calculated and verified by MALDI-TOF mass spectrometry. [b] Determined from digital simulations of the voltammetric data obtained on glassy carbon electrodes (0.078 $cm^2$).

The data in Table 1 also shows a very interesting trend in the variation of the half-wave potentials for ferrocene oxidation, which tend to decrease with increasing size of the attached dendron. When we first reported this data, a similar trend had been reported by Diederich and coworkers for porphyrin-core dendrimers.[28] Our data clearly indicate that, in dichloromethane solution, Newkome dendrimer growth differentially stabilizes the positively charged, oxidized ferrocenium form. Although Smith and coworkers demonstrated a different trend in half-wave potentials for dendronized ferrocenes with unrelated architecture,[29] we investigated the half-wave potentials of dendrimers of the same architecture containing a single, electroactive 4,4′-bipyridinium (viologen) residue at their apical positions.[23] These dendronized viologens have more favorable solubility properties, allowing the exploration of their electrochemistry in a variety of solvents, with a large range of polarities. The results provide a very clear picture in which the variation of the half-wave potential as a function of dendron size can be rationalized by the balance of polarities between the bulk solution and the inner phase of the dendrimer. Basically, as the dendron grows, it starts to affect the microenvironment of the redox center attached to the apical position (Scheme 2). If the inner phase of the dendrimer is more polar than the bulk solution, dendrimer growth is expected to differentially stabilize the more highly charged form of the redox couple. This is why the positively charged ferrocenium form is differentially stabilized versus neutral ferrocene by the growth of the attached Newkome dendron −

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

containing polar amide groups − in a low polarity solvent, such as dichloromethane. Therefore, the half-wave potential decreases as the dendrimer size increases, as seen in Table 1.



Scheme 2. Cartoon representation of the effect of dendron growth on the microenvironment of the apical redox center.

One of the advantages of our dendrimer architecture is that the set of peripheral *tert*-butyl esters can be easily hydrolyzed to yield dendrimers with multiple carboxylic acid groups on their surfaces.[19b] In fact, hydrolysis transforms a series of hydrophobic dendrimers (**18**–**20**), soluble in low polarity solvents, such as chloroform and dichloromethane, into a series of hydrophilic dendrimers (**21**–**23**, see structures in Figure 9) with moderate solubility in aqueous solution. The presence of multiple carboxylic acids on the surface immediately suggests the possibility of endowing these dendrimers with considerable negative charge (up to a maximum of 27 negative charges in the case of **23**). Charge development on these dendrimers was of interest to us because we assumed that the negative charges could favor specific dendrimer orientations at the electrode solution interface. Titration experiments with these dendrimers revealed that their p$K_a$ values are in the range 4.5–6.[20] Therefore, we started to focus our attention on a comparison of properties between solutions in the pH range 3–4, where the dendrimers are protonated and uncharged, and solutions in the pH range 7–8, in which the dendrimers are extensively deprotonated and negatively charged. Electrochemical experiments on bare gold electrodes did not show any significant differences on the electrochemical parameters measured for ferrocene oxidation in the 3–8 pH range. Faced with these initial results, we hypothesized that the surface density of positive charge on the electrode surface was probably not high enough to enforce specific dendrimer orientations at the interface. Therefore, we decided to derivatize the gold electrode surface by preparing a self-assembled monolayer (SAM) with a protonated amine in order to increase the positive charge surface density on the electrode. For simplicity, we selected cystamine as the monomer for SAM formation, as it is known that it stays protonated in the pH range 3–7, and it forms a relatively disorganized, albeit thin SAM, which is suitable for our purposes.

On gold electrodes covered with cystamine SAMs, the voltammetric behavior of the second generation dendrimer **22** was found to be extremely pH dependent.[20] At low pH (3–4) the reversible, one-electron oxidation of the ferrocene group was clearly detected, whereas at high pH (7–8) the oxidation wave basically disappeared. Similarly pronounced pH-induced changes in the voltammetric response were observed with the third generation dendrimer **23**. However, the first generation dendrimer **21** (a much smaller molecule) showed only small changes in its voltammetric response as the solution pH was changed from 3 to 8. The square wave voltammograms recorded in all these cases could be fitted to digital simulations in which the variable degree of voltammetric response could be rationalized by dramatic changes in the heterogeneous electron transfer rate constants. For instance, the $k°$ values for dendrimer **22** on cystamine-covered gold electrodes were found to decrease from $(8 \pm 1) \times 10^{-3}$ cm s$^{-1}$ at pH 4 to $(1.5 \pm 0.1) \times 10^{-5}$ cm s$^{-1}$ at pH 7.[20] This considerable decrease is completely gradual and reversible, as the measured $k°$ values oscillate between quasireversible to irreversible electrochemical behavior as the pH of the solution is titrated back and forth. What could be responsible for the pronounced change in electrochemical kinetics as the pH of the solution oscillates between these two extremes? Our interpretation of the data relies on the presence of a large negative charge on the dendrimer surface. The anionic form of the dendrimer, present at high pH, experiences strong electrostatic forces with the positively charged electrode surface, enforcing orientations in which the ferrocene group faces away from the electrode surface. Conversely, at low pH, the uncharged form of the dendrimer is free from these electrostatic forces and no specific interfacial orientations are favored, thus allowing free rotation of the dendrimer. These two extreme situations are represented in Scheme 3. When the dendrimer reaches the OHP and becomes ready for electron transfer, the average distance between the electrode surface and the ferrocene residue is larger at high pH than at low pH. Thus the electrochemical kinetics is considerably faster in the latter situation, as free rotation allows the electrode surface to sample dendrimers in which the ferrocene residue is facing it. As the pH increases, negative charge develops on the dendrimer, restricting free rotation and forcing the electrode surface to sample dendrimers in which the redox active center is facing towards the bulk solution. Therefore, dendrimers **22** and **23** are synthetic macromolecular compounds exhibiting strong pH-induced, orientational effects on their interfacial electron transfer reactions. In this sense, both dendrimers show similar electrochemical behavior to that exhibited by a number of redox proteins, providing an interesting kind of validation for our molecular design.

An aspect of these experiments that should not go unnoticed is the possible effect that surface ionization may have on the solution conformation of the dendrimers. In the polyelectrolyte field, it is well known that charge development in a polymer chain usually leads to remarkable conformational changes, as the polymer goes from a random coil arrangement to a fully extended chain, in which the charges are well solvated and separated from one another. Similarly, we could anticipate that surface ionization of the dendrimer should lead to a more expanded conformation, particularly in comparison with the more collapsed structure expected for the neutral, uncharged macromolecule. Quite recently, we looked at this issue by doing careful diffusion coefficient measurements on these dendrimers[30] with the use of pulse gradient stimulated echo (PGSE)

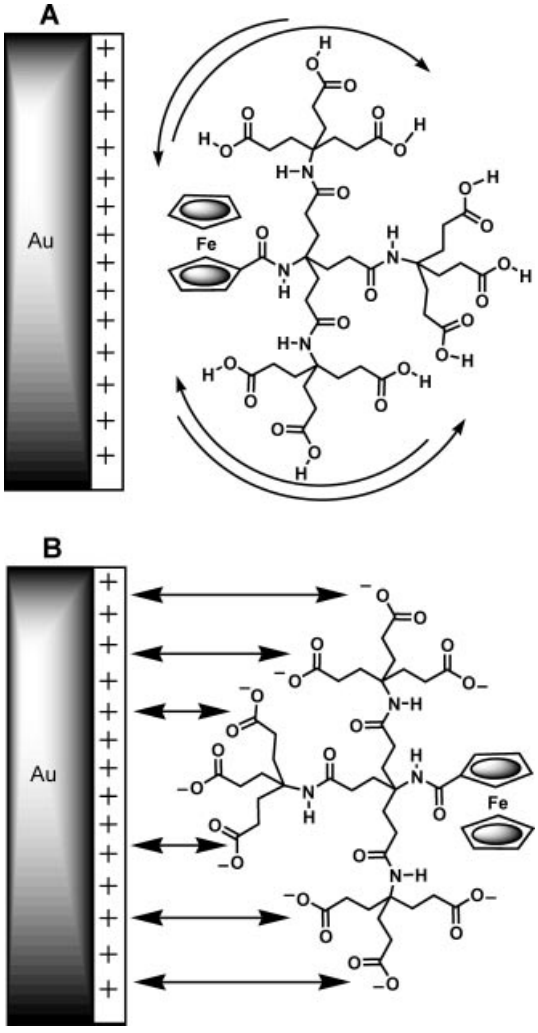

Scheme 3. Interfacial orientation of dendrimer **22** as it approaches the OHP next to a gold electrode covered by a positively charged SAM of cystamine in aqueous solution at (A) pH 3–4 and (B) pH 7–8.

NMR techniques. The data (Table 2) shows that the diffusion coefficient of any of these dendrimers is always smaller in pH 7 solution than in pH 2, which is consistent with the electrostatically expanded conformation anticipated for the ionized dendrimer. However, we must point out that these conformational changes by themselves cannot be responsible for the observed changes in electrochemical kinetics, as shown by the essentially pH independent electrochemical behavior obtained on bare gold electrodes.

Table 2. Approximate radii and diffusion coefficients at 25 °C for water-soluble dendronized ferrocenes.

| Dendrimer | Radius[a] [Å] | $D_o$ at pH 2 [$cm^2 s^{-1}$] | $D_o$ at pH 7 [$cm^2 s^{-1}$] |

## Dendronized Cobaltocenium Derivatives: Electrochemistry

The attachment of cobaltocenium units to the Newkome dendrons shown in Figure 8, can be readily accomplished by reaction of their apical amine groups with cobaltocenium carboxylic acid (as its chloride salt) in dry DMF by using *O*-(7-azabenzotriazol-1-yl)-*N*,*N*,*N*′,*N*′-tetramethyluronium hexafluorophosphate (*n*-HATU) to promote amide coupling.[24] As it is the case with the ferrocene derivatives, the dendrimers are initially prepared with *tert*-butyl ester peripheries (hydrophobic series, **24**–**26**) but hydrolysis with formic acid led to their water-soluble forms (hydrophilic series, **27**–**29**, see Figure 10 for structures). As expected, the cathodic electrochemical behavior of the dendrimers is dominated by the reversible one-electron reduction of cobaltocenium. The corresponding electrochemical parameters obtained in voltammetric experiments and the diffusion coefficients measured in PGSE NMR experiments are given in Table 3.

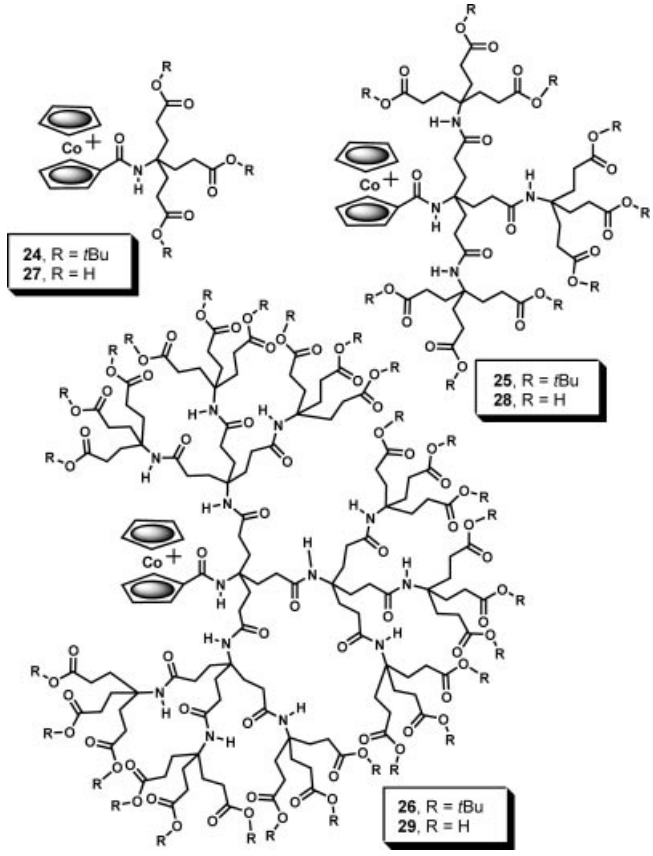

Figure 10. Hydrophobic (**24**, **25**, **26**) and hydrophilic (**27**, **28**, **29**) series of cobaltocenium-containing dendrimers.

The data in Table 3 generally follow the trends discussed before with dendronized ferrocenes. For instance, within the hydrophobic series of dendrimers (**24**–**26** surveyed in dichloromethane solution), $k°$ values and diffusion coefficients decrease with dendrimer size, as expected. The half-

| **27** | –0.91[b] | $1.4 \times 10^{-2}$[b] | 4.1[d] |
| **28** | –0.92[b] | $8.0 \times 10^{-3}$[b] | 3.2[d] |
| **29** | –0.95[b] | $6.0 \times 10^{-3}$[b] | 2.1[d] |

[a] Measured in $CH_2Cl_2$ with 0.1 M $TBAPF_6$. [b] Measured in pH 7 phosphate buffer. [c] Measured in $CD_2Cl_2$ at 25 °C. [d] Measured in $D_2O$ buffered at pH 7 (phosphate) at 25 °C.

wave potential for the one-electron reduction of cobaltocenium shifts to more negative values as the dendron grows. This potential variation is consistent with the differential stabilization of the charged member of the redox couple (the positively charged cobaltocenium) by the inner phase of the dendrimer. The hydrophilic dendrimers were investigated in aqueous solution buffered at pH 7. The $k°$ values and diffusion coefficients again decrease as the size of the dendrimer grows. The half-wave potentials for cobaltocenium reduction show minor changes as the dendron size increases. However, for the third generation dendrimer (**29**) the $E_{1/2}$ value is about 30 mV more negative than in the first generation dendrimer (**27**). Because these experiments were run in a very polar, aqueous solution, we cannot attribute this small potential variation to the inner phase of the dendrimer having greater polarity than the bulk solution. We believe that this unusual potential trend may be associated to electrostatic interactions between the cobaltocenium unit and some of the carboxylate groups on the surface of the dendrimer.

## Guest Behavior of Dendronized Metallocenes

One of the most interesting aspects of these metallocene dendrimers is that their structures are "unsymmetric" in the sense that they offer two very different directions of approach for a species capable of reacting with the metallocene unit. Of course, this unsymmetric character was used to advantage in our demonstration of strong pH-induced, orientation effects on the electron transfer reactions between the dendronized ferrocene residue and a properly derivatized electrode surface.[20] Because of our long-standing interest in host–guest interactions, we decided to investigate the guest properties of dendronized metallocenes with freely diffusing hosts. These macromolecules can be used as guests because the metallocene unit is accessible to a free host that approaches the dendrimer near the apical site, where the metallocene is located. Basically, the driving force for this research work is to understand the effects of dendron size on the thermodynamic binding affinity between the partially buried, dendronized guest and the free host. We recently published a review of our research work on dendrimers as guests in molecular recognition phenomena.[31] Thus, we will limit ourselves here to provide a brief account of some of the most recent data involving dendronized metallocenes.

We started this research by investigating the binding interactions between the βCD host and dendronized ferrocenes **21**, **22**, and **23** in aqueous solution (0.1 M NaCl) buffered at pH 7 with 0.05 M tris.[19b] The complexation phenomena was monitored by using cyclic voltammetric experiments, as our group has considerable experience analyzing voltammetric data to extract information on chemical reactions, such as complexation by βCD, involving electroactive species, such as ferrocene derivatives. Fitting of the experimental current–potential curves by using digital simulation techniques is a powerful methodology to extract thermodynamic and/or kinetic parameters for the host–guest reactions coupled to the electron transfer processes. The addition of βCD to a solution containing any of the dendronized ferrocenes has two major effects on the voltammetric response: (1) the apparent half-wave potential for the one-electron oxidation of the ferrocene center shifts to more positive values and (2) the overall current levels of the voltammetric peaks decrease. The CD-induced, anodic potential shift reflects the differential stabilization of ferrocene relative to ferrocenium. This is consistent with the strong thermodynamic preference for the neutral ferrocene versus the positively charged ferrocenium of the host, which reflects the well-known selectivity of CD hosts for hydrophobic guests.[3] The CD-induced current decrease is readily explained by the lower diffusion coefficient of the ferrocene derivative due to its binding interactions with the bulky CD host. By optimizing the fitting of digitally simulated voltammograms to the experimental ones at variable βCD concentrations, we obtained 950, 250, and 50 M$^{-1}$ as the $K$ values for the βCD association with **21**, **22**, and **23**, respectively. The binding constant between the first generation dendrimer (**21**) with βCD is at the lower end of the usual range (1000–5000 M$^{-1}$) for binding of this host with small, water-soluble ferrocene derivatives. However, the binding constant comes down quite rapidly as the dendron size increases. By the third generation dendrimer, the host–guest binding interaction is almost completely quenched by the presence of the dendron.

What causes such a rapid decrease in the $K$ values as the dendron grows from first to third generation? Clearly, the larger dendron hinders the host approach towards the unsubstituted cyclopentadienyl ring of the ferrocene group, which is the main βCD binding site (Scheme 4). We also know that dendron growth leads to changes in the microenvironment around the ferrocene residue. In aqueous solution, dendrimer growth should decrease the polarity of the environment, which is expected to decrease the strength of the βCD–ferrocene binding interaction. In any instance, the effect of dendron growth on the stability of the inclusion complex formed between βCD and the dendronized ferrocenes is quite pronounced. The key question that must be asked upon examination of these data concerns the possible extrapolation of these effects to other host–guest systems.

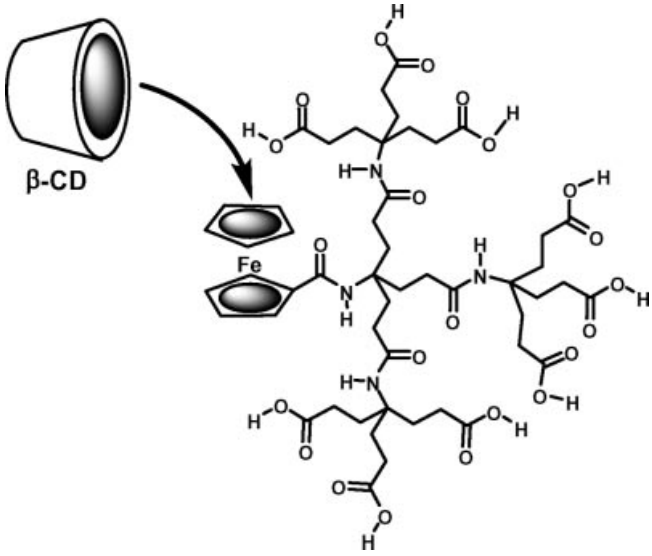

Scheme 4. Complexation of dendrimer **22** by the βCD host.

The cucurbit[*n*]urils[32] are a family of molecular receptors that can be prepared by the acid-catalyzed condensation of glycoluril with formaldehyde. Recent work on expanded cucurbiturils ($n \geq 6$) was sprung by their first isolation, reported by Kim and coworkers.[33] Whereas the cavity size of cucurbit[6]uril (CB6) is similar to αCD, cucurbit[7]-uril (CB7) resembles βCD, and the similarities between these two host families are more superficial than real.[34] CB hosts are known to be much more sensitive to guest charge, charge distribution, and shape than CD hosts. Therefore, the CBs are capable of achieving higher levels of binding selectivity. In optimal cases, CB hosts reach extremely high levels of binding affinities ($K > 10^{10}$ M$^{-1}$), which are completely unimaginable with unmodified cyclodextrins. The binding interactions between the simple ferrocene derivatives (**30**, **31**, and **32**) with βCD and CB7 provide an excellent illustration of these differences. All these ferrocene derivatives, regardless of their charge, form stable inclusion complexes with βCD, with *K* values in the range 1–$5 \times 10^3$ M$^{-1}$, as mentioned before. In contrast to this, CB7 forms a very stable complex with **30** ($K = 3 \times 10^9$ M$^{-1}$) and even more so with **31** ($K = 2 \times 10^{12}$ M$^{-1}$), but does not bind anionic **32** at all.[34] The complete lack of binding between **32** and CB7 is understood to result from the electrostatic repulsion between the carboxylate group of the guest and the negative charge density accumulated on the carbonyl oxygen-laced portals of the host (Figure 11).

As a result of our interest in cucurbit[*n*]uril chemistry, we decided to investigate the interactions between CB7 and dendrimers **21**–**23**. In this case the binding constants are readily obtained in $^1$H NMR spectroscopic experiments in which the dendronized ferrocene and a reference guest compete for a limited amount of the CB7 host.[30] The corresponding binding constants are given in Table 4. Measurements were made at two solution pH values (2 and 7) to ascertain the magnitude of the electrostatic effects between the anionic carboxylate charges on the dendrimer surface

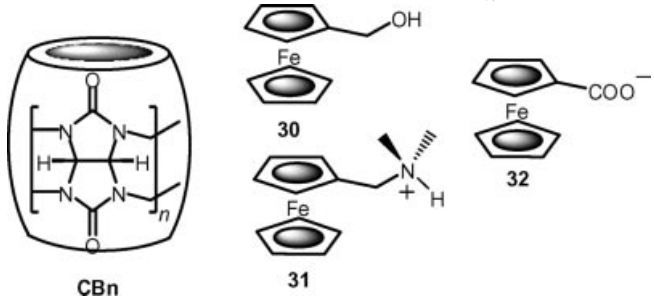

Figure 11. Structures of the cucurbituril hosts (CBn) and ferrocene derivatives **30**–**32**.

and the negatively charged portal openings on the host. These electrostatic effects are clearly evidenced by the lack of binding observed between ionized **21** (at pH 7) and CB7, in analogy with the absence of binding interactions between **32** and this host.[34] However, dendrimer growth decreases the intensity of the electrostatic repulsions opposing host–guest association, as evidenced by the measured binding constants at pH 7 with the dendronized guests **22** and **23**. In these larger macromolecules, the average distance between the peripheral carboxylates and the ferrocene site is sufficiently long for binding to take place. At pH 2, the binding constant between neutral **21** and CB7 is moderately high. Similarly the *K* value measured for neutral **22** is larger than that determined for anionic **22** (at pH 7) due to the lack of coulombic repulsion in the former case. In general terms, however, the trends observed in the *K* values with CB7 are quite different from what was observed with βCD, as dendrimer growth does not decrease the binding affinity in the quick and pronounced way that was observed with the latter host.

Table 4. Equilibrium association constants (*K*) at 25 °C measured in aqueous media between dendronized metallocenes and the CB7 host.

| Dendrimer | *K* [L mol$^{-1}$] at pH 2 | *K* [L mol$^{-1}$] at pH 7 |
|---|---|---|
| **21** | $3.9 \times 10^4$ | n.b.[a] |
| **22** | $4.2 \times 10^6$ | $3.8 \times 10^5$ |
| **23** | Insol.[b] | $7.7 \times 10^5$ |
| **27** | $3.2 \times 10^5$ | $1.0 \times 10^4$ |
| **28** | $1.1 \times 10^7$ | $3.4 \times 10^6$ |
| **29** | $4.0 \times 10^5$ | $4.0 \times 10^5$ |

[a] No binding detected. [b] Insoluble under these conditions.

We also investigated the binding interactions between CB7 and cobaltocenium-containing dendrimers[24] **27**–**29** (Table 4). The *K* values offer many similarities to those obtained with the dendronized ferrocenes. Perhaps the key difference between the two data sets is that the first generation dendrimer **27**, in its ionized form at pH 7, does form a stable complex with CB7. This is in clear contrast with unprotonated **21**. Clearly, the positive charge on the metallocene nucleus plays an important role in neutralizing the coulombic repulsions between the CB7 portal and the peripheral carboxylates on the dendrimer. In general terms, the *K* values with the cobaltocenium systems are slightly larger than the corresponding values with the dendronized

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ferrocenes, probably a reflection of the positive charge on the cobaltocenium residue.

The differences observed in the host–guest binding interactions between our dendronized metallocenes and the hosts βCD and CB7 are part of a growing body of data,[31] which will eventually allow us to rationalize the effect of dendron size on the thermodynamic binding affinity. So far, the observed effects have proven to be very specific to the particular host–guest system under examination, and extended generalizations cannot be made at this time.

## Hybrid Dendrimers Containing Newkome and Fréchet Dendrons

Whereas all the work discussed so far on single metallocene dendrimers used Newkome-type dendrons, we recently reported a new class of dendrimers containing a single ferrocene group and two different dendrons (Newkome and Fréchet) covalently attached to a triazine nucleus.[35] Some examples are shown in Figure 12.

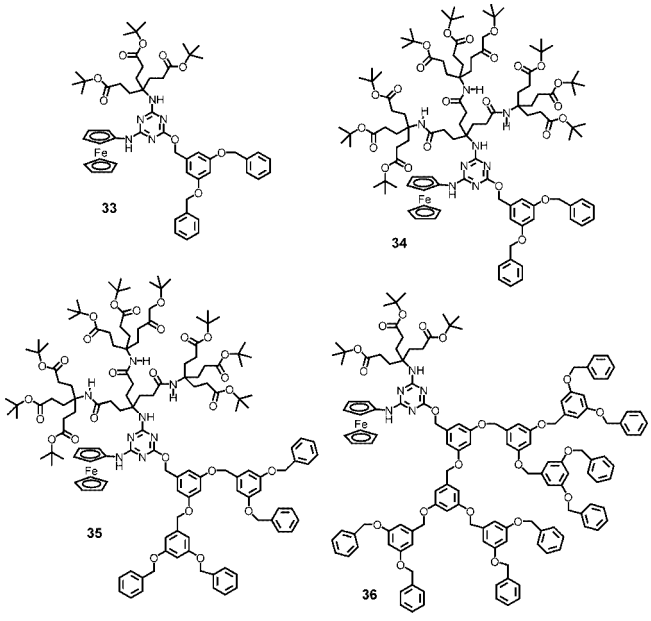

Figure 12. Hybrid dendrimers containing a ferrocene unit and Newkome and Fréchet dendrons attached to a central triazine nucleus.

This new series of dendrimers offers the possibility of comparing on the same molecule the relative effects of two different types of dendritic architectures. Because of their synthetic availability and widespread use by various research groups, we decided to use $AB_3$ Newkome-type, ester-terminated dendrons[18] and $AB_2$ Fréchet-type, aromatic ether dendrons.[36] Initially, we focused our attention on comparative dendron effects on the electrochemical parameters of the ferrocene residue and on the diffusion coefficients of the macromolecules.[35] Our preliminary data suggest that the Fréchet dendrons expand as wedges away from the core, whereas the Newkome dendrons are more effective at changing the polarity of the microenvironment around the ferrocene residue. This is probably a reflection of the more highly branched $AB_3$ architecture of the Newkome dendrons and their greater flexibility.

## Conclusions

This manuscript has addressed many aspects of the research work done by the authors' group on metallocene dendrimers. Whereas most of our work has focused on electrochemical processes and host–guest interactions in which the dendrimers act as mono- or multivalent guests, these systems also have tremendous potential as nanoscale objects for surface patterning, sensors, and other interesting applications. Furthermore, it is important to realize that the synthetic degree of sophistication of these systems is still in its infancy. Most of the synthetic work described here is based on the straightforward functionalization of existing dendritic architectures with metallocene units. More elaborate synthetic schemes, such as those leading to hybrid dendrimers **33**–**36**, may yield macromolecules with more complex structures and yet unexplored and, hopefully, exciting properties. The exploration of these novel structures and their properties is one of the major goals of our continuous research work in this field.

## Acknowledgments

The author is grateful to the U.S. National Science Foundation for continuous and generous support. This work would have been impossible without the effort and dedication of all the coworkers named in the references. A special mention should go to Claudia Cardona, who prepared the first series of dendrimers in my group. Her persistence and extraordinary ability as a chemist were crucial for the initial development of this work. Many thanks to all my friends at Universidad Autónoma de Madrid for their willingness to collaborate on these research problems and for making me feel very welcome as an Iberdrola Visiting Professor. The support of our collaborative efforts by NATO and the U.S.–Spain Fulbright Commission is also gratefully acknowledged.

# Reductive Nitrosation of Peptides Ligated to High-Valent Metal Cations

**Dror Shamir,[a] Israel Zilbermann,*[a] Eric Maimon,[a] Gary Gellerman,[b] Haim Cohen,[b] and Dan Meyerstein*[c,d]**

**Keywords:** Nitrosation / Peptides / NO / High-valent transition metals

NO reacts with $M^{III}$–(glycylglycylglycine), M = Fe; Ni and Cu, to form the terminal *N*-nitrosated peptide complex. This reaction proceeds by a radical mechanism.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

The role of NO in a variety of physiological processes renders its reaction mechanisms with species present in biological media of importance. Of special interest are nitrosation processes that are involved in signaling[1–2] and pathological[2] processes as well as in buffering the concentration of NO in the cell.[1,3–6] Two transition-metal-initiated reductive nitrosation mechanisms were reported:

(1) Ligation of NO to the central cation, which induces a partial positive charge on the nitrogen atom and thus enables attack of a nucleophile at the nitrogen atom[7–10] [Reaction (1)].

$$M^{n+1}L_n \xrightarrow[-L]{NO} L_{n-1}M^{n+1}\text{–}NO \xrightarrow[L]{:B} M^nL_n + BNO^- \quad (1)$$

In water: B is usually $H_2O$ or $OH^-$ and the product is $NO_2^-$.

(2) Reaction of NO with a ligand bound to the central cation with a lone electron pair on the atom ligated to the cation. This process often requires proton loss to form the lone pair. Recently,[11] it was suggested that this is a radical process as outlined in Reactions (2)–(4).

$$M^{n+1}\text{–}E(H)R_m \rightleftharpoons M^{n+1}\text{–}\ddot{E}R_m + H^+ \quad (2)$$

$$M^{n+1}\text{–}\ddot{E}R_m \rightleftharpoons M^n\text{–}\dot{E}R_m \quad (3)$$

$$M^n\text{–}\dot{E}R_m + NO \longrightarrow M^n + R_mENO \quad (4)$$

Where E = N, S and plausibly O.

Reactions of this type were previously attributed to attack of NO on the lone pair followed by electron transfer.[7–10] However, as NO does not react with strong nucleophiles, for example, $OH^-$, it is reasonable that the radical mechanism is the occurring one. As the mechanism described by Reactions (2)–(4) was observed for $E(H)R_m$ = $CH_3NH_2$, it seemed of interest to check whether it took place also for $E(H)R_m$ = peptides. The present study proves that indeed peptide *N*-nitrosations of the terminal amine occur by this mechanism.

The first peptide investigated in this study was glycylglycylglycine (glyglygly). The complexes $Ni^{III}$–(glyglygly) and $Cu^{III}$–(glyglygly) were prepared by a known procedure,[12,13] and the complex $Fe^{III}$–(glyglygly) was prepared by slow addition of 0.3 M tris buffer to a solution containing $Fe(ClO_4)_3$ and 10–20% excess of tripeptide. The solutions containing the complexes were saturated with Ar and mixed with NO saturated aqueous solutions at the same pH. By using stopped flow, the kinetic results, Figure 1, confirm that these complexes react with NO in reactions obeying pseudo-first-order rate laws. The observed rates depend linearly on the concentrations of NO and $OH^-$, Figures 2 and 3, respectively. The observed rate constants at pH 6.0 are summed up in Table 1. The pH dependence of the rate con-

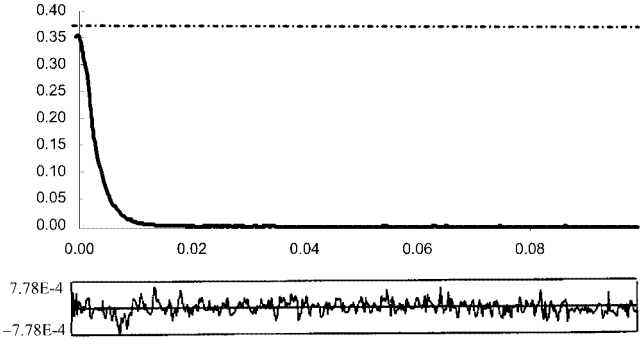

Figure 1. Kinetics of reaction of $Ni^{III}$–(glyglygly) at pH 7.0 with NO measured at 332 nm. Solution composition: (——) $Ni^{III}$ 0.0005 M, glyglygly 0.0011 M, (50% saturated NO); (-·-·-·) $Ni^{III}$ 0.0005 M, glyglygly 0.0011 M (saturated Ar).

stants, Figure 3, suggests that these reactions occur with an alkaline form of the complexes [the results suggest a p$K_a \geq 7$ for $Cu^{III}$–(glyglygly); $\geq 9$ for $Ni^{III}$–(glyglygly) and ca. 10 for $Fe^{III}$–(glyglygly)] (for the Cu and Ni complexes, measurements could not be performed at higher pH values, as they are faster than the mixing time of the stopped flow). The p$K_a$ values of the amide nitrogen atoms of these complexes are $\leq 6.0$.[14–17] Thus, the results suggest that the reactions observed require the loss of a proton from the terminal amine of the peptide.

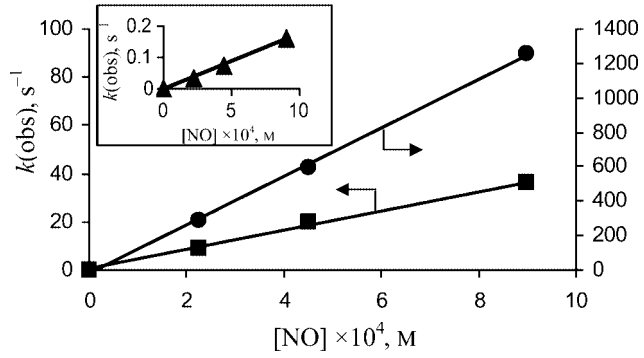

Figure 2. Dependence of the observed rate constants on [NO]. Solution composition: A: $k$(obs.) vs. [NO] pH 6.0, [bis tris buffer] = $5 \times 10^{-5}$ M, [$M^{III}$] = 0.005 M, [glyglygly] = $1.1 \times 10^{-3}$ M; (●) = $Cu^{III}$; (▲) = $Fe^{III}$; (■) = $Ni^{III}$.

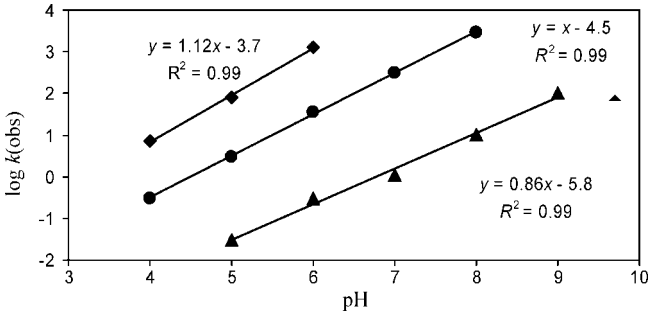

Figure 3. Dependence of the observed rate constants on pH. Solution composition: (●) $Ni^{III}$ 0.0005 M, glyglygly 0.0011 M, (■) $Cu^{III}$ 0.0005 M, glyglygly 0.0011 M, (▲) $Fe^{III}$ 0.0005 M, GGG 0.0011 M, NO 50% saturated.

Table 1. Observed rate constants at pH 6.0.

| $M^{III}$ | $K_{obs.}$, $M^{-1} s^{-1}$ (alaglygly) | $k_{obs.}$, $M^{-1} s^{-1}$ (glyglygly) |
|---|---|---|
| $Cu^{III}$ | 880 | 1260 |
| $Ni^{III}$ | 21 | 36 |
| $Fe^{III}$ | 0.090 | 0.16 |

The pH dependence of the observed rate constants of the reactions (Figure 3) suggests that the site of the nitrosation of the ligand is the terminal amine of the peptide. The observed rate constants (Table 1 and Figure 3) decrease along the series $Cu^{III} > Ni^{III} > Fe^{III}$. This result is in accord with expectations as the redox potentials vs. NHE of $M^{III/II}$–(glyglygly) complexes are 0.92,[18,19] 0.83[19,20] and –0.21 V [this study] for M = Cu, Ni and Fe, respectively. Though the rate constants decrease with the decrease in the oxidation potential of the complexes, one would expect a larger difference between the $Ni^{III}$ and $Fe^{III}$ complexes. The source of this observation is not clear although it might be due to a higher p$K_a$ of the bound terminal amine in the $Ni^{III}$ complex. Analysis of the final products was performed by the following techniques: (1) Ion chromatography, which proved that $NO_2^-$ is not a product of the reactions studied. (2) ESI MS (Supporting Information, Figure S1), which detected a product with $m/z$ = 219 in solutions that contained $M^{III}$–(glyglygly) and NO (Ar saturated and acidified to pH 3.0 after the nitrosation). This peak is absent in a blank experiment that contained Ar-saturated solutions of $M^{II}$–(glyglygly), which were then acidified. A mass of 219 fits the adduct glyglyglyH-NO, namely, the reductive nitrosation product, which as expected is obtained by adding NO to solutions containing the three $M^{III}$–(glyglygly) complexes. (3) Determination of pH − the pH dependence of the rate constants suggests that the nitrosation occurs on the terminal amine. In order to verify this assumption the $^{13}C$ NMR spectra of the peptides before and after the nitrosation reactions were measured [deaerated $D_2O$ solutions of $M^{II}$–(glyglygly) and of $M^{III}$–(glyglygly) were treated with NO then Ar saturate in order to inhibit nitrite formation, and acidified to pH 3.0 in order to release the peptide from the paramagnetic cation].

The results (Supporting Information, Figures S2, S3) show that the glyglygly peptide has $^{13}C$ NMR signals at 176.4, 170.8 and 167.7 ppm for the carboxylate and amide carbons and at 43.1, 42.3 and 40.4 ppm for the $CH_2$ carbons. For the nitrosation product, signals at 173.3, 173.2, 172.8, 50.0, 42.1 and 41.7 ppm and an additional weak signal at 41.0 ppm are observed. These results are in accordance with those obtained by approximate simulation by using the semiempirical simulation − CS ChemDraw Ultra program − for the different plausible nitrosation sites (Table 2). Comparison of the experimental results with the simulations points out that the nitrosations do not occur on the $CH_2$ groups. However, the results do not enable a decision regarding which nitrogen is nitrosated.

Table 2. Simulations of the $^{13}C$ NMR data of glyglygly, and the different plausible nitrosation products.

| Nitrosation Site | $C^1$ | $C^2$ | $C^3$ | $C^4$ | $C^5$ | $C^6$ |
|---|---|---|---|---|---|---|
| None | 43.0 | 171.1 | 42.9 | 171.1 | 42.7 | 173.2 |
| $N^1$ | 43.4 | 171.1 | 42.7 | 171.0 | 48.7 | 173.2 |
| $N^2$ | 42.8 | 171.0 | 49.1 | 171.1 | 42.7 | 173.2 |
| $N^3$ | 48.4 | 171.2 | 42.9 | 171.1 | 42.7 | 173.2 |

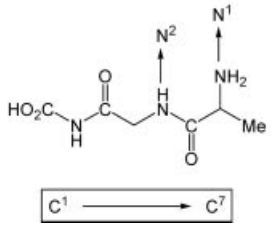
In order to resolve this dilemma, the experiments were repeated with the peptide alaglygly, as the $^{13}C$ NMR spectroscopic simulation (Table 3) clearly demonstrates that *N*-nitrosation at the terminal amine and the amide N adjacent to the alanine residue will have significantly different $^{13}C$ NMR spectra. The results (Supporting Information, Figures S4, S5) point out signals for the alaglygly peptide at 176.4, 171.3, 170.6, 49.0, 43.3, 42.3 and 16.2 ppm and for the nitrosation product signals at 178.9, 176.8, 170.7, 57.2, 43.1, 42.2 and 9.8 ppm and additional very weak signals 16.9 and 10.4 ppm. Comparison of the results with the simulation clearly points out that the signal of the $CH_3$ group is shifted to higher field from 16.2 to 9.8 ppm in perfect accord with the simulation results for nitrosation of the terminal amine group. In contrast, the simulation of the nitrosation product on $N^2$ predicts that the signal due to the $CH_3$ group will be shifted to a lower field. The kinetics of the reaction of the $M^{III}$–(alaglygly) with NO are very similar to those observed for the $M^{III}$–(glyglygly) complexes. The observed rate constants at pH 6.0 (Table 1) are slightly lower than those for the $M^{III}$–(glyglygly) complexes. This result is tentatively attributed to the fact that the terminal amine of alaglygly is a slightly stronger base than that of glyglygly. The corresponding p$K_a$ values are 8.16 and 7.95,[21] respectively. The stronger base is expected to stabilize better the $M^{III}$ oxidation state and probably to increase the p$K_a$ value of the terminal amine; both these effects are expected to lower the rate constant of the nitrosation reactions.

Table 3. Simulations of the $^{13}C$ NMR spectra of alaglygly and the different plausible nitrosation products.

| Nitrosation Site | $C^1$ | $C^2$ | $C^3$ | $C^4$ | $C^5$ | $C^6$ | $C^7$ |
|---|---|---|---|---|---|---|---|
| None | 173.2 | 42.7 | 171.1 | 43.2 | 172.1 | 49.3 | 20.5 |
| $N^1$ | 173.2 | 42.7 | 171.1 | 43.2 | 172.1 | 56.1 | 15.7 |
| $N^2$ | 173.2 | 42.7 | 171.1 | 49.4 | 176 | 49.1 | 21.1 |



It is of interest to note that nitrosations do not occur at the amide sites although a lone electron pair is also available at these sites even at the lowest pH values used in the this study. This observation is attributed to the higher energy of the orbital of the lone pair of the terminal amine than that of the amide groups.

Finally one should consider whether the ·NO attacks the lone pair of the $M^{III}$–N̈HR group followed by an electron transfer or the NO attacks the radical isomer of this species:

$$M^{III}-\ddot{N}HR \rightleftharpoons M^{II}-\dot{N}HR$$

As the lone pair in $M^{III}$–N̈HR is a weaker base than $OH^-$ and NO does not react with the latter, it is suggested that the nitrosations proceed by a radical mechanism. This suggestion is also attractive as it suggests that the nitrosation of E(H)R and the release of NO from ON–ER[7,22,23] proceed through the same mechanism: a radical mechanism. Finally as *N*-nitroso compounds are carcinogenic[2] this mechanism of reductive *N*-nitrosation might be of biological importance.

**Supporting Information** (see footnote on the first page of this article): Mass spectra and $^{13}C$ NMR spectra of pertinent solutions studied.

# Nickel Complexes with $N_2O$ Donor Ligands: Syntheses, Structures, Catalysis and Magnetic Studies

**Jishnunil Chakraborty,[a] Mahasweta Nandi,[b] Heike Mayer-Figge,[c] William S. Sheldrick,[c] Lorenzo Sorace,[d] Asim Bhaumik,[b] and Pradyot Banerjee*[a]**

**Keywords:** Nickel / N,O ligands / Epoxidation / Heterogeneous catalysis / Magnetic properties

Two new terephthalato-bridged tetranuclear polymeric $Ni^{II}$ complexes, namely $[Ni_4L_4^1(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]\cdot 2C_2H_5OH\cdot CH_3OH\cdot 3H_2O$ (**1**) and $[Ni_4L_4^2(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]\cdot 3H_2O$ (**2**) [$L^1$ = *N*-(3-aminopropyl)-5-bromosalicylaldimine and $L^2$ = *N*-(3-aminopropyl)salicylaldimine], are reported along with the syntheses and structures of the dicyanoargentate-bridged polymeric complexes $[Ni(L^1)(H_2O)\{Ag(CN)_2\}]_\alpha$ (**3**) and $[Ni(L^3)(MeOH)\{Ag(CN)_2\}]_\alpha$ (**4**) [$L^3$ = *N*-(3-amino-2,2-dimethylpropyl)-5-bromosalicylaldimine]. All four complexes are found to be effective heterogeneous catalysts for the epoxidation of alkenes such as styrene, α-methylstyrene and cyclohexene in the presence of *tert*-butyl hydroperoxide. The variable-temperature magnetic susceptibility measurements (300–2 K) of complex **1** show a fair degree of antiferromagnetic coupling between the $Ni^{II}$ centers.

## Introduction

Low-dimensional coordination polymers, including one-dimensional (1D) chain-like and two-dimensional (2D) layer-like structures, have received much attention in recent years owing to their intriguing structural features and unique electroconductive, nonlinear optical, and magnetic properties, which differ from those of three-dimensional (3D) coordination polymers.[1] A great variety of low-dimensional coordination polymers based on d-block transition metal ions and organic ligands have been prepared to date, many of which have potential applications in the field of functional materials.[2–6] The organic components containing N- or O- donors in the framework offer great potential for chemical and structural diversity.[7]

Organic aromatic polycarboxylates are some of the most widely employed multidentate O-donor ligands for the preparation of such coordination polymers with multidimensional networks. In this respect, terephthalate (tp) has been studied extensively as a rigid and versatile bridging ligand[8] as it contains multiple bridging moieties that lead to a variety of connection modes with transition metal centers and provide abundant structural motifs. Furthermore, it can act not only as a hydrogen-bond donor but also as an acceptor due to the existence of protonated and/or deprotonated carboxylate groups. The terephthalate ligand is therefore regarded as an excellent candidate for the construction of multidimensional coordination frameworks.

The introduction of another kind of both N- and O-donor chelating ligand, such as a tridentate Schiff base, in the {M/tp} (M = transition metal) system may induce new structural evolution as the introduction of N-donor chelating ligands into the metal sites may inhibit the expansion of the polymeric frameworks and lead to the desired low-dimensional coordination polymers. However, the synthesis of complexes containing mixed ligands is expected to be more difficult to control than that of complexes containing one ligand for several reasons, such as the different solubility of the organic ligands and competition between these ligands to coordinate the transition metal. In order to gain insight into the parameters that control these variables we have synthesized two new terephthalate-bridged tetranuclear polymeric $Ni^{II}$ complexes, namely $[Ni_4L_4^1(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]\cdot 2C_2H_5OH\cdot CH_3OH\cdot 3H_2O$ (**1**) and $[Ni_4L_4^2(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]\cdot 3H_2O$ [**2**; $L^1$ = *N*-(3-aminopropyl)-5-bromosalicylaldimine and $L^2$ = *N*-(3-aminopropyl)salicylaldimine]. $Ni^{II}$ forms a phenolate-bridged binuclear unit in these complexes and two such units are connected by a terephthalate moiety to form a tetranuclear nickel(II) complex. The crystal structure of complex **1** shows that the tetranuclear units are connected to each other by the terephthalate moiety in a bis(monodentate) mode to form a one-dimensional network. The variable-

temperature magnetic behavior of complex **1** is also investigated.

Like terephthalate, cyanometalate anions have been extensively used as building blocks in supramolecular coordination polymers.[9,10] Compared to the higher coordination counterparts of various transition metals, there has been considerably less investigation of two-coordinate linear cyanometalate building blocks for the construction of coordination polymers. We have chosen to examine the ability of the linear dicyanoargentate ion $[Ag(CN)_2]^-$ to form supramolecular frameworks. The syntheses and structures of two dicyanoargentate-bridged polymeric networks, namely $[Ni(L^1)(H_2O)\{Ag(CN)_2\}]_\alpha$ (**3**) and $[Ni(L^3)(MeOH)\{Ag(CN)_2\}]_\alpha$ [**4**; $L^3$ = *N*-(3-amino-2,2-dimethylpropyl)-5-bromosalicylaldimine], are therefore also included in this paper.

Intrigued by a recent study concerning the use of (salen)-$Ni^{II}$ complexes as homogeneous/heterogeneous epoxidation catalysts,[11] we extended our study to the epoxidation of alkenes such as styrene, α-methylstyrene and cyclohexene in the presence of *tert*-butyl hydroperoxide heterogeneously catalyzed by complexes **1**–**4**.

## Results and Discussion

### Synthesis

The monocondensed ligands $L^1$–$L^3$ were prepared as their nickel complexes $Ni(L^1)_2$, $Ni(L^2)_2$, and $Ni(L^3)_2$ by treating 5-bromosalicylaldehyde or salicylaldehyde with $Ni(OAC)_2{\cdot}4H_2O$ and the corresponding amine (see Experimental Section). Complex **1** was prepared by the reaction of $Ni(L^1)_2$ with equimolar amounts of $Ni(ClO_4)_2{\cdot}6H_2O$ and the disodium salt of terephthalic acid in EtOH/MeOH/$H_2O$ to produce the $\mu_2$-phenolate and terephthalate-bridged tetranuclear complex $[Ni_4L_4{}^1(\mu\text{-tp-}\kappa_4\text{-O})(H_2O)_2(\mu\text{-tp-}\kappa_2\text{-O})]{\cdot}2C_2H_5OH{\cdot}CH_3OH{\cdot}3H_2O$ (Scheme 1). Complex **2** was prepared in the same way as described for complex **1** but with salicylaldehyde for the Schiff base condensation instead of 5-bromosalicylaldehyde. Complex **3** was prepared by the reaction of $Ni(L^1)_2$ with equimolar amounts of $Ni(ClO_4)_2{\cdot}6H_2O$ and $[NaAg(CN)_2]$ in MeOH/$H_2O$ to produce the argentocyanide-bridged heterobinuclear polymeric complex $[Ni(L^1)(H_2O)\{Ag(CN)_2\}]_\alpha$ (Scheme 2). Complex **4** was syn-

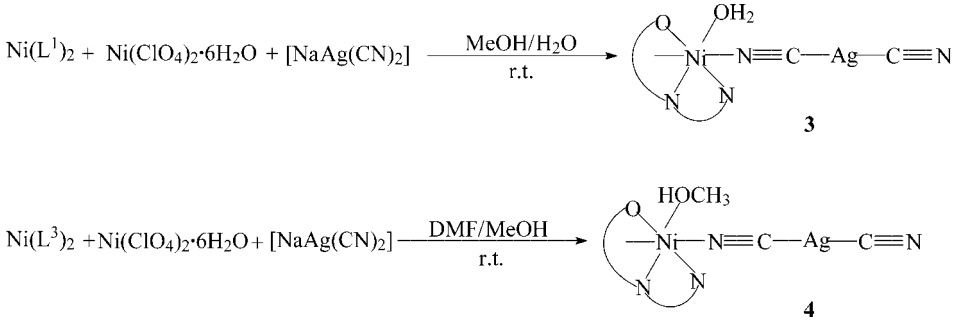

Scheme 2. Synthetic routes to complexes **3** and **4**.

thesized in dmf/MeOH by treating $Ni(L^3)_2$ with equimolar amounts of $Ni(ClO_4)_2·6H_2O$ and $[NaAg(CN)_2]$ to yield the argentocyanide-bridged polymeric species $[Ni(L^3)(MeOH)\{Ag(CN)_2\}]_\alpha$.

## IR Spectra

The IR spectra of **1** and **2** show a broad absorption band in the range 3321–3504 $cm^{-1}$ which can be assigned to the O–H stretching vibrations of the coordinated and noncoordinated water molecules and noncoordinated MeOH and EtOH molecules in the case of complex **1**. The strong band in the range 1637–1645 $cm^{-1}$ can be assigned to $\nu(CN_{iminic})$, which suggests coordination of the ligands to the metal centers through the imine nitrogen atoms. The tp unit coordinates the metal ions in both complexes in both its bis(monodentate) and bis(bidentate) coordination modes. The values of $\Delta\nu$, indicating the difference between the asymmetric stretching $\nu_a(COO^-)$ and the symmetric stretching $\nu_s(COO^-)$, for **1** are 148 and 29 $cm^{-1}$, whereas those for complex **2** are 142 and 27 $cm^{-1}$.

The strong band at 2162 $cm^{-1}$ in the IR spectrum of complex **3** is due to the $\nu(CN)$ absorption of the N-bonded argentocyanide unit and the band at 3346 $cm^{-1}$ is due to the water molecule coordinated to the $Ni^{II}$ center. Complex **4** also exhibits a strong band at 2164 $cm^{-1}$ due to the N-bonded argentocyanide unit. The broad band at 3437 $cm^{-1}$ is assigned to an O–H stretching vibration, thereby confirming the presence of the coordinated $CH_3OH$ molecule. The strong band in the range 1585–1602 $cm^{-1}$ observed for all complexes is due to the $\nu(CO)$ absorption of the phenolate-containing ligands.

## Structure of Complex 1

A view of **1** is shown in Figure 1 and key bond lengths and angles are listed in Table 1. The crystal structure of this complex shows that the asymmetric unit contains a tetranuclear molecule of the type $[Ni_4L_4^1(\mu\text{-}O_2CC_6H_4CO_2)(H_2O)_2(O_2CC_6H_4CO_2)]$ in addition to two ethanol, one methanol, and three water molecules. The tetranuclear unit is formed by two $Ni^{II}$ atoms (Ni1 and Ni2) bridged by two $\mu_2$-phenolato oxygen atoms (O1 and O2) of the Schiff-base ligands and a terephthalato ligand in its bis(bidentate) mode that connects the four $Ni^{II}$ centers. The tridentate ligand $L^1$ provides an $N_2O_2$ donor set around each metal atom. The basal $NiN_2O_2$ plane for the Ni1 center is formed by the two nitrogen atoms (N1 and N2) and the two oxygen atoms (O1 and O2) of the bridging phenolato ligands while the basal plane of the Ni2 center is formed by two different nitrogen atoms (N3 and N4) of another $L^1$ ligand and the same phenolate oxygens (O1 and O2). The O3 atom of the terminal water molecule and the O5 atom of the bridging bis(bidentate) terephthalato ligand occupy the axial positions of the Ni1 center. The coordination environment of the Ni2 center is somewhat different to that of the Ni1 center. Thus, for

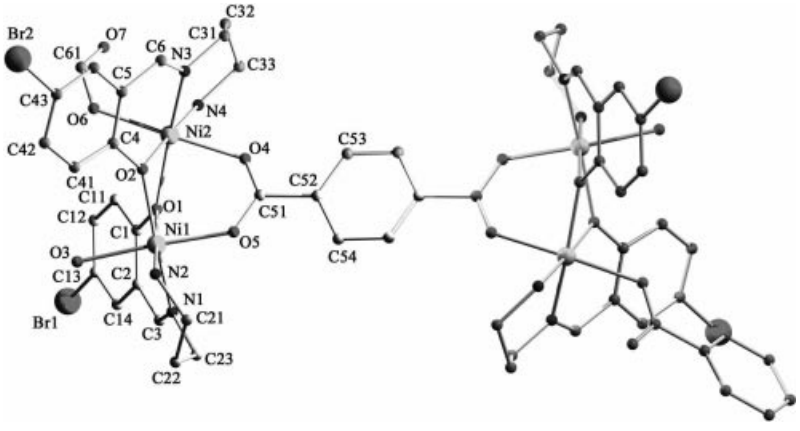

Figure 1. A view of the molecule of complex **1**.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the Ni2 center the axial positions are occupied by the O4 atom of the bridging terephthalato ligand and the O6 atom of another bridging terephthalato ligand in its bis(monodentate) coordination mode. Each nickel atom has a distorted octahedral environment. The phenolate-bridged nickel atoms are separated by 3.076 Å with two Ni1–O1–Ni2 and Ni1–O2–Ni2 bridging angles of 97.4(4)° and 96.5(3)°, respectively; two $Ni_2N_4O_2$ moieties are separated from each other by 10.996 Å. The basal bond lengths around Ni1 are within the range 2.020(8)–2.089(10) Å while those around Ni2 are in the range 2.044(8)–2.092(10) Å. The apical Ni1–O3, Ni1–O5, Ni2–O4, and Ni2–O6 bond lengths are 2.143(6), 2.077(8), 2.091(6), and 2.133(8) Å, respectively. The O3–Ni1–O5 bond angle is 176.8(3)° while that for O4–Ni2–O6 is 177.8(3)°. The Ni–$O_{tp}$ bond lengths are similar to those found in other terephthalate-bridged nickel complexes.[12,13]

The packing diagram of complex **1** (Figure 2) shows that the tetranuclear $Ni^{II}$ units are joined to each other by the terephthalate moiety in its bis(monodentate) mode to form an infinite one-dimensional network where symmetry-related O6 terephthalato-oxygen atoms bind two Ni2 centers in a zig-zag structure along the *a*-axis The simultaneous presence of two terephthalate ligands with different bridging modes gives rise to an unprecedented coordination chain. It is interesting to note that the adjacent layers are not parallel when viewed along the *c*-axis but are inclined to each other with an angle of 39.17° (Figure 3). The dihedral angle formed between the anion and the equatorial plane is 62.14°, and the carboxylate group O6/C61/O7 deviates from coplanarity with the phenyl ring (11.65°). This deviation is uniform throughout the chain. The Ni···Ni separation within a linear chain is 11.296 Å. This distance is

shorter than in other terephthalate-bridged nickel complexes such as $[Ni(pyrazole)_4(tp)]_n$ [11.446(2) Å],[14] $[Ni(C_{12}H_{30}N_6O_2)(C_8H_4O_4)]_n{\cdot}4nH_2O$ [11.514(1) Å],[12] where $n$ is ∞, and [(μ-terephthalato){Ni(dca)(dpt)($H_2O$)}$_2$] [11.379(10) Å].[15] The one-dimensional chains are connected together by intermolecular hydrogen-bonding interactions between the oxygen atom of uncoordinated methanol and the coordinated amine of the Schiff base [N2···O300 3.33(3) Å]. In addition, one lattice ethanol molecule takes part in hydrogen bonding with another coordinated amine group of the Schiff base [N4···O200 3.12(3) Å]. There is also an intramolecular hydrogen bond connecting an amine group with a bis(monodentate) terephthalato oxygen atom [N4···O7 2.889(14) Å]. The two C–O bond lengths of the carboxylate group are practically identical even though one is coordinated to the Ni2 center [1.253(16) Å] and the other is not [1.253(19) Å]. In general, the C–O bond lengths of coordinated carboxylate groups fall in the range 1.266–1.279 Å and are longer than the free carbonyl C–O bonds (1.226–1.255 Å) when terephthalate coordinates a metal ion in a monodentate fashion.[12]

### Structure of Complex 3

The coordination environment of the $Ni^{II}$ ion in complex **3** is shown in Figure 4 along with the atom-numbering scheme. Key bond lengths and angles are listed in Table 2. The coordination environment for each nickel center is best described by a distorted octahedral geometry. Two nitrogen atoms, a phenolate oxygen atom of the tridentate Schiff-base ligand $L^1$, and an oxygen atom of the coordinated water molecule, with Ni1–N1, Ni1–N2, Ni1–O1, and Ni1–O2 distances of 2.045(4), 2.076(5), 2.015(4), and 2.152(4) Å, respectively, define the equatorial plane around the nickel atom. The axial sites are occupied by two nitrogen atoms of the bridging argentocyanide moiety with Ni1–N3 and Ni1–N4 bond lengths of 2.115(5) and 2.101 Å, respectively. The central nickel atom lies slightly above the equatorial plane (0.048 Å).

Table 2. Selected bond lengths [Å] and angles [°] in complex **3**.

| Bond lengths [Å] | | | |
|---|---|---|---|
| Ni1–O1 | 2.015(4) | N3–C8 | 1.142(9) |
| Ni1–O2 | 2.152(4) | Ag1–C8 | 2.064(7) |
| Ni1–N1 | 2.045(4) | Ag1–C9 | 2.065(7) |
| Ni1–N2 | 2.076(5) | N4–C9 | 1.139(9) |
| Ni1–N3 | 2.115(5) | | |
| **Bond angles [°]** | | | |
| O1–Ni1–O2 | 87.66(16) | O1–Ni1–N1 | 89.90(18) |
| O1–Ni1–N2 | 175.28(17) | O1–Ni1–N3 | 86.61(19) |
| O2–Ni1–N1 | 175.72(19) | O2–Ni1–N2 | 87.91(17) |
| O2–Ni1–N3 | 84.29(17) | N1–Ni1–N2 | 94.42(19) |
| N1–Ni1–N3 | 92.05(19) | N2–Ni1–N3 | 91.4(2) |
| C8–Ag1–C9 | 176.4(3) | | |
| **Hydrogen bonds [Å, °]** | | | |
| D–H–A | D···A | H···A | ∠D–H···A |
| O2–H2···O1 | 2.608(6) | 1.78(5) | 176(7) |

The crystal packing of complex **3** (Figure 5) shows that the $[Ag(CN)_2]^-$ units display an almost linear coordination [C8–Ag1–C9 176.4(3)°] with Ag1–C8 and Ag1–C9 bond lengths of 2.064(7) and 2.065(7) Å, respectively, and form endless one-dimensional chains involving the $[NiL^1(H_2O)]^+$ moiety. These chains lie parallel to each other with diagonal distances $a$ and $b$ of 8.12 and 5.95 Å, respectively, and an Ag···Ag distance of about 10.6 Å. The minimum Ag···Ag distance found between two successive layers is 4.514 Å, which is greater the van der Waals diameter of silver (3.44 Å)[16] and hence no direct Ag···Ag interactions are present. In addition to the argentocyanide bridging, there

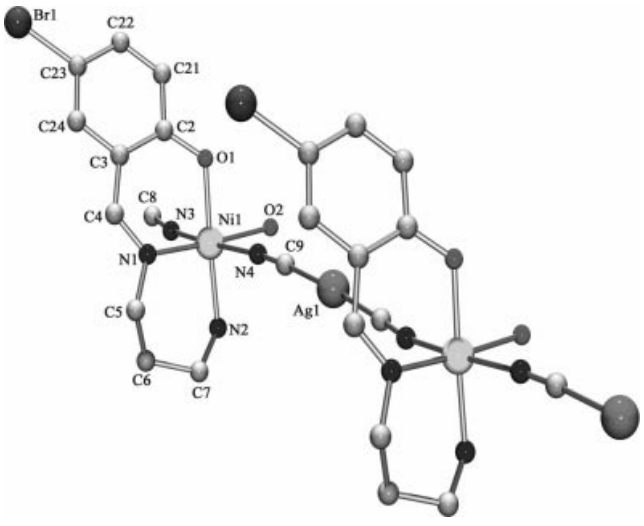

Figure 4. A view of the molecule of complex **3**.

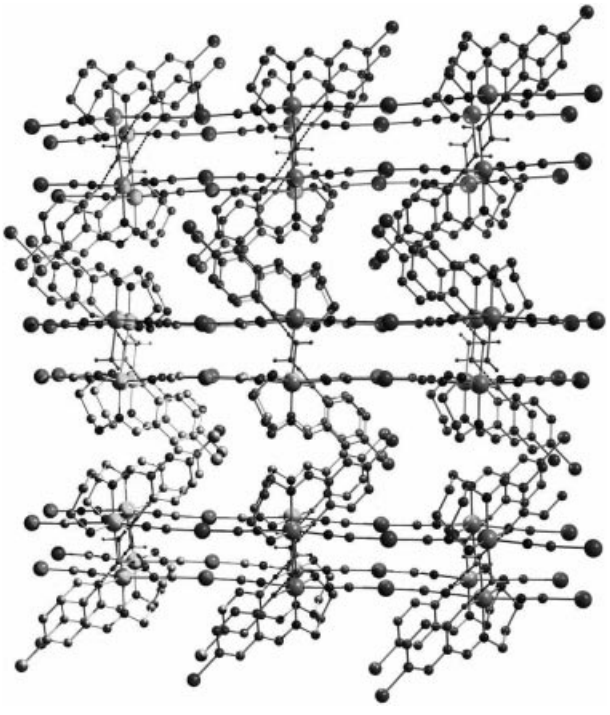

Figure 5. Packing diagram of complex **3**.

are intermolecular hydrogen-bonding interactions between the phenolate oxygen of the $L^1$ moiety in one layer and the coordinated water oxygen of the next layer which form stable eight-membered rings [O2···O1 2.608(6) Å; ∠O2–H20···O1 176(7)°] in an extended two-dimensional ladder-like network (Figure 6).

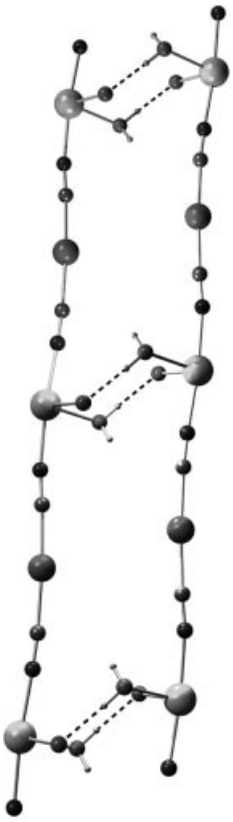

Figure 6. Packing fragment of complex **3** showing the ladder-like network.

### Structure of Complex 4

A perspective view of **4** together with the atom-labeling scheme is shown in Figure 7. Each nickel site is coordinated by two nitrogen atoms, a phenoxo oxygen atom of the tridentate $L^2$ ligand, an oxygen atom of the methanol molecule, and two bridging nitrogen atoms of the $[Ag(CN)_2]^-$ moiety. The average Ni–N bond length is 2.069 Å and the $Ni–O_{phenolato}$ and $Ni–O_{methanol}$ bond lengths are 2.0316(18) and 2.1135(19) Å, respectively. The N(O)–Ni–O(N) bond angles range from 86.77(9)° to 178.07(8)° (see Table 3), which means that the nickel centers display a distorted octahedral coordination geometry. The argentocyanide ion acts as a bridging ligand that connects the $[NiL^3(MeOH)]^+$ moieties to form endless one-dimensional chains. The Ni···Ni separation within a chain is 10.414 Å, whereas the Ni···Ni separation between two successive chains is 5.052 Å. This distance is uniform throughout two successive layers. Moreover, adjacent chains are connected together through non-covalent interactions between the two coordinated phenolato oxygen atoms (O1) in one layer and the methanol oxygen atom (O2) in the adjacent layer (O1···O2 2.586 Å) to form a 2D supramolecular network (Figure 8). It is noteworthy that this network adopts a wavelike layer (Figure 9) due to greater deviation of the bond angles [∠Ni1–N3–C8 166.4(2)° and ∠Ni1_a–N4–C9 166.6(2)°] from planarity in the bridging argentocyanide moieties along the *b*-axis. The same bond angles in complex **3** are close to planarity, which means that the formation of a wavelike network can be ruled out and a chainlike network is obtained instead.

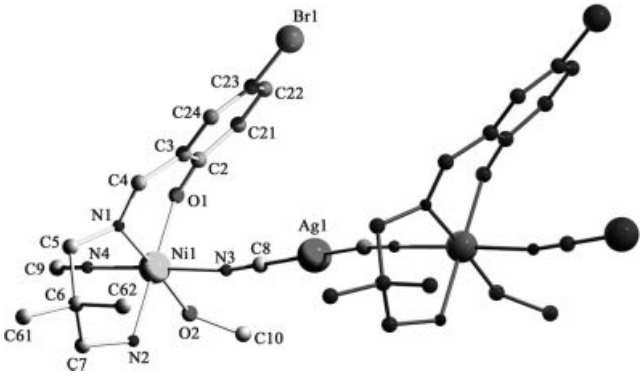

Figure 7. A view of the molecule of complex **4**.

## Heterogeneous Catalysis

The use of nickel complexes with cyclam and salen ligands as active catalysts in the epoxidation of alkenes[17–22] has been reported in the literature. Some examples include the use of (salen)Ni-type complexes in faujasites for the oxidation of phenol with $H_2O_2$,[23] the epoxidation of cyclohexene and 1-hexene by NaOCl,[24,25] as well as the use of [Ni(salen)] immobilized on several solid supports as a catalyst for hydrogenation reactions.[26] More recently, Ferreira et al.[11] have carried out an extensive study of (salen)$Ni^{II}$ complexes as homogeneous catalysts and, after immobilization in zeolites (X and Y; following the "ship-in-a-bottle" procedure), as heterogeneous catalysts in the epoxidation of *trans*-β-methylstyrene by NaOCl (considered to be environmentally more friendly).

The heterogeneous oxidation reactions were carried out using 1.0 g of substrate and 0.200 g of loaded catalyst (0.050 g of solid complex in the case of complex **2**) in 10 mL of $CH_3CN$ whilst stirring in a two-necked, round-bottomed flask fitted with a water condenser in an oil bath at 333 K. *tert*-Butyl hydroperoxide (equimolar with respect to the substrate) was added immediately before the start of the reaction. The products were collected from the reaction mixture after different time intervals and analyzed by gas chromatography. They were identified by comparison with known standards.

Tables 4, 5, and 6 show the results obtained with for the various Ni complexes immobilized on silica. Acetonitrile was used as the solvent in all cases. The major products of the reactions are epoxides and the selectivities for these compounds are very high. The very high TONs obtained for the oxidation of styrene, α-methylstyrene, and cyclohexene suggest a very high catalytic efficiency for the nickel hydroperoxo species that could form in the presence of *tert*-butyl hydroperoxide. Small amounts of the corresponding diols were also obtained for all substrates.

Complex **2** is insoluble in all common solvents therefore instead of immobilizing it on mesoporous silica this pure complex was used as a solid catalyst. Our experimental results show that the TONs obtained with the immobilized catalysts are better than the pure nickel complex **2** for all the olefin substrates and that among these substrates cyclohexene shows the highest conversion and TON; the epoxide selectivities for styrene and α-methylstyrene are also very good.

Table 4. Epoxidation of styrene[a] catalyzed by complexes **1**–**4**.

| Entry | Catalyst | Conversion [%][b] | Epoxide selectivity | TON[c] |
|---|---|---|---|---|
| 1 | **1** | 39 | 81 | 121 |
| 2 | **2** | 56 | 82 | 36 |
| 3 | **3** | 41 | 91 | 127 |
| 4 | **4** | 66 | 83 | 205 |

[a] Solvent: $CH_3CN$; temperature: 333 K; complex **2** was used as a solid catalyst whereas the other catalysts were impregnated on a 2D hexagonal mesoporous silica. [b] Reaction time: 24 h; conversion and TON were measured by GC using *n*-decane as internal standard. [c] TON: mol of substrate converted per mole of $Ni^{II}$ present in catalyst used for the reaction.

Table 5. Epoxidation of α-methylstyrene[a] catalyzed by complexes **1**–**4**.

| Entry | Catalyst | Conversion [%][b] | Epoxide selectivity | TON[c] |
|---|---|---|---|---|

[b] Reaction time: 24 h; conversion and TON were measured by GC using *n*-decane as internal standard. [c] TON: mol of substrate converted per mole of $Ni^{II}$ present in catalyst used for the reaction.

Table 6. Epoxidation of cyclohexene[a] catalyzed by complexes **1**–**4**.

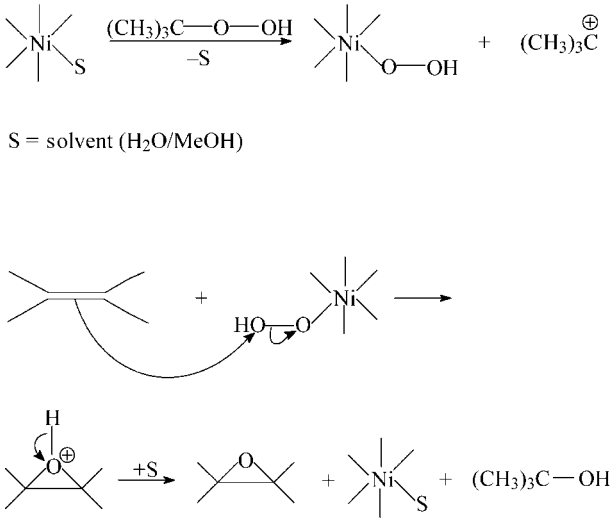
| Entry | Catalyst | Conversion [%][b] | Epoxide selectivity | TON[c] |
|---|---|---|---|---|
| 1 | **1** | 82 | 82 | 323 |
| 2 | **2** | 89 | 82 | 72 |
| 3 | **3** | 81 | 87 | 319 |
| 4 | **4** | 89 | 84 | 350 |
| 5 | **4** | 87 | 79 | |
| 6 | **4** | 33 | 29 | |

[a] Solvent: $CH_3CN$; temperature: 333 K; complex **2** was used as a solid catalyst whereas the other catalysts were impregnated on a 2D hexagonal mesoporous silica. [b] Reaction time: 24 h; conversion and TON were measured by GC using *n*-decane as internal standard. [c] TON: mol of substrate converted per mole of $Ni^{II}$ present in catalyst used for the reaction.

Microporous and mesoporous titanium silicates have been widely employed in the epoxidation of aromatic and alicyclic unsaturated compounds[27] in the presence of dilute aqueous $H_2O_2$ as oxidant. The intermediate titanium hydroperoxo species formed play a crucial role in catalyzing the epoxidation reaction. The water molecules present in **1**–**3** and the methanol moiety in **4** could help the Ni complex to form such Ni hydroperoxide species in presence of $H_2O_2$, similar to the titanium silicate surface, and this could help in the catalysis of these epoxidation reactions (Scheme 3).

One control experiment was carried out for cyclohexene over immobilized catalyst **4** to check the efficiency of subsequent catalytic cycles and whether Ni leaches from these catalysts (Table 6, entry 4). After the initial experiment the catalyst was washed thoroughly with acetonitrile and then

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 3. Proposed mechanism for the partial oxidation of styrene, α-methylstyrene, and cyclohexene by *tert*-butyl hydroperoxide with complexes **1**–**4** as catalyst.

treated with 0.1 M HCl solution in EtOH for 8 h at 343 K and finally dried at 373 K for 2 h. It was then re-used as catalyst for a second experiment (Table 6, entry 5). The catalytic activity was found to remain practically the same, with only a marginal difference in the epoxide selectivity. This suggests that there is almost no Ni leaching into the liquid phase from these immobilized catalysts. A blank reaction of the oxidation of cyclohexene in the absence of any solid catalyst under otherwise identical reaction conditions was also carried out (Table 6, entry 6). The results show very poor conversion and epoxide selectivity in this case, thereby confirming the catalytic role of the Ni complex and the immobilized catalysts in these epoxidation reactions.

Figures 10, 11, and 12 show bar diagrams for the epoxidation of the alkenes over different immobilized catalysts at 333 K. It is clear from these figures that all the $Ni^{II}$ complexes act as efficient epoxidation catalysts in the presence of *tert*-butyl hydroperoxide as oxidant. Figure 13 shows the alkene conversion as a function of reaction time for the epoxidation of styrene catalyzed by the four $Ni^{II}$ complexes. The conversions follow a sigmoid curve and reach maximum conversion after 24 h. It is apparent from these experimental observations that immobilized Ni complex **4** is most

reactive for the epoxidation of all three substrates with high TONs (205, 167, and 350 for styrene, α-methylstyrene, and cyclohexene, respectively).

### Magnetic Behavior of 1

The temperature dependencies of $\chi_M T$ and $\chi_M$ for complex **1** are plotted in Figure 14. The value of $\chi_M T$ observed at room temperature (4.54 $cm^3 mol^{-1} K$ at 300 K) is typical for four uncoupled $Ni^{II}$ ions with $g > 2.00$, as expected. On lowering the temperature the $\chi_M T$ product decreases smoothly, reaching 0.05 $cm^3 mol^{-1} K$ at 2 K. This behavior clearly points to the existence of moderate antiferromagnetic interactions between the $Ni^{II}$ centers, which result in a diamagnetic ground state. This is confirmed by the shape of the $\chi_M$ vs. $T$ curve, which passes through a maximum at around 22 K.

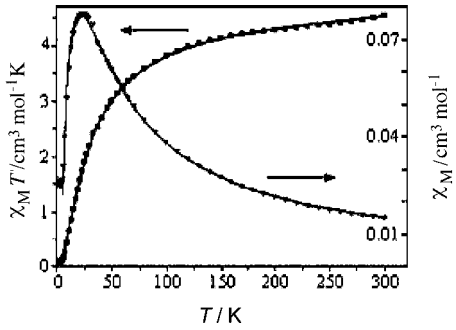

Figure 14. Temperature-dependence of $\chi_M T$ (left scale, full squares) and $\chi_M$ (right scale, full triangles) for **1** and best fit curves obtained with the parameters reported in the text. The theoretical curves calculated with the two different models cannot be discerned.

An initial quantitative analysis of the results obtained was performed using a simple isotropic Hamiltonian that considers all the possible exchange interactions in the tetramer [Equation (1)].

$$\hat{H} = J(S_1S_2 + S_3S_4) + J'(S_1S_3 + S_1S_4 + S_2S_3 + S_2S_4) + g\beta SH \quad (1)$$

where $J$ is the exchange coupling within each dinuclear moiety, in other words the exchange interactions transmitted by the two phenolato bridges and the carboxylato one, and $J'$ describes the coupling through the terephthalato bridging ligand. The fit was implemented using the CLUMAG package,[28] including a temperature-independent paramagnetism term ($N_\alpha = (8 \pm 2) \times 10^{-4}$ emu $mol^{-1}$), which yields the best fit parameters $J = 14.5 \pm 0.6$ $cm^{-1}$, $J' = 3.8 \pm 1.2$ $cm^{-1}$, and $g = 2.15 \pm 0.02$. This set of parameters results in a diamagnetic ground state, as expected, with the first triplet lying 14.5 $cm^{-1}$ higher in energy. This is in fair agreement with the $M$ vs. $H$ curve (Figure 15), which shows the beginning of a singlet–triplet field induced transition at the highest measured field.

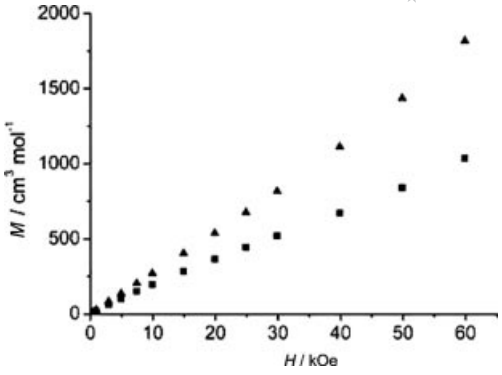

Figure 15. $M$ vs. $H$ curve for **1** measured at 2.7 (squares) and 5.1 K (triangles).

The obtained value of $J'$ appears to be relatively large and higher than would be expected on the basis of literature data.[29] This might, in principle, be due to the neglecting of the single-ion zero-field-splitting terms that affect the shape of the calculated temperature dependence of the susceptibility curve in the same way as an intermolecular coupling.[30] We therefore fitted the data by including these terms using the Ginsberg formula for dinuclear $Ni^{II}$ centers with interdimer interactions.[30,31] The best fit parameters obtained with this approach were $J = 14.5 \pm 0.2$ $cm^{-1}$, in perfect agreement with the simple isotropic approach, $2zJ' = 3.4 \pm 0.6$ $cm^{-1}$, $N_\alpha = (4.5 \pm 2) \times 10^{-4}$ emu $mol^{-1}$, $g = 2.17 \pm 0.02$, and $D = 1$–$8$ $cm^{-1}$, with the latter parameter having only a weak effect on the calculated curve. We can conclude on the basis of the two fits that the Ni–Ni interaction in each dinuclear moiety is close to 14.5 $cm^{-1}$ and that a non-negligible interaction is transmitted by the terephthalato ligand, in contrast to what is normally assumed.[32] The value of the Ni–Ni coupling constant in the dinuclear moiety is somewhat larger than would be expected on the basis of simple magnetostructural correlations derived for centrosymmetric bis(phenolate)-bridged dinuclear nickel complexes derived by Thompson's group[33] [Equation (2)].

$$J = +7.27\theta - 704.06 \quad (2)$$

where $\theta$ is the bridging Ni–O–Ni angle. Using the average value of the bridging angle (96.94°) for $\theta$ would result in a predicted value of $J = 0.8$ $cm^{-1}$ for **1**, far from what is observed experimentally. We attribute this discrepancy to the effect of the carboxylato ligand, which bridges the two nickel ions in a *syn-syn* fashion and provides an additional pathway for the antiferromagnetic coupling between the two centers.[34] Finally, we note that the importance of the interdimer exchange coupling provided by the terephthalato ligand lies in the large π-connectivity it may provide, thus providing a relatively efficient pathway whilst keeping the interacting metal centers far apart.

## Conclusions

We have prepared four polymeric nickel(II)/Schiff-base complexes with terephthalate and argentocyanide as bridg-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ing moieties. Complex **1** is tetranuclear and its X-ray crystal structure shows that each tetranuclear unit contains both phenolate and terephthalate bridges. These tetranuclear units are connected together by the terephthalate units in a bis(monodentate) coordination mode to form an infinite 1D network. Variable-temperature magnetic measurements show that this complex exhibits moderate antiferromagnetic coupling. Complex **2** has the same structure as complex **1**, although we were unable to obtain crystals suitable for X-ray diffraction. Both complexes **3** and **4** form 2D polymeric networks utilizing the bridging argentocyanide units and strong noncovalent interactions.

Alkene epoxidation studies have been performed with all the complexes as active heterogeneous catalysts. Styrene, α-methylstyrene, and cyclohexene are all efficiently converted into their corresponding epoxides. The experimental results show that immobilized Ni complex **4** is the most active catalyst for the epoxidation of all three substrates (TON values of 205, 167, and 350 for styrene, α-methylstyrene, and cyclohexene, respectively).

## Experimental Section

**Starting Materials:** Salicylaldehyde, 5-bromosalicylaldehyde, 1,3-diaminopropane, 1,3-diamino-2,2-dimethylpropane, terephthalic acid, and $Ni^{II}$ salts were purchased form commercial sources and used as received. Sodium terephthalate was readily prepared by the reaction of terephthalic acid with a stoichiometric amount of NaOH in water. All other chemicals (sodium hydroxide, $AgNO_3$, and NaCN) were of reagent grade. Ethanol, methanol, and dmf were of reagent grade and used without further purification. Doubly distilled water was used throughout. The acetonitrile used in the epoxidation reaction was of HPLC grade. *tert*-Butyl hydroperoxide purchased form Aldrich was used as oxidant. The substrates styrene, α-methylstyrene, and cyclohexene were also obtained from Aldrich.

**Physical Measurements:** Microanalyses (CHN) were performed with a Perkin–Elmer 240C elemental analyzer. FT-IR spectra were obtained on a Nicolet, MAGNA-IR 750 spectrometer with samples prepared as KBr pellets. A Perkin–Elmer 2380 AAS was used for wet chemical analysis. GC analysis was carried out with an Agilent Technologies 6890N network GC system equipped with a fused silica capillary column (30 m × 0.32 mm) and a FID detector. The column temperature was increased from 80 °C (4 min) to 220 °C at a rate of 5 °C $min^{-1}$. The injection temperature was 200 °C. The solid-state electronic spectra were measured with a Shimadzu UV 2401PC spectrophotometer using a $BaSO_4$ pellet as background standard. Magnetic measurements were performed with a Cryogenic SQUID S600 magnetometer operating between 2 and 300 K with applied magnetic fields of up to 65 kOe. Raw data were corrected for diamagnetic contribution of the sample holder and the intrinsic diamagnetism of the sample estimated by Pascal's constants.

**General Procedure for the Preparation of the Immobilized Catalysts:** For the synthesis of the mesoporous silica,[35] the cationic surfactant cetyl trimethylammonium bromide (2.96 g) was mixed with an aqueous solution containing sodium dodecyl sulfate (0.47 g) and vigorously stirred at room temperature for 30 min. Gel formation occurred immediately leading to a viscous suspension. Tetraethyl orthosilicate (3.5 g) was added to this suspension with continuous stirring for 30 min. After 2 h constant stirring, tetraethylammonium hydroxide was added dropwise until the color of the solution turned white. The pH value of the final mixture was about 11.0. The resultant mixture was aged overnight whilst stirring at room temperature and then transferred into a polypropylene bottle and heated at 80 °C for 72 h without stirring. The solid produced was recovered by filtration, washed several times with water, and dried at room temperature. The resulting powder was calcined at 703 K to remove the organic surfactants. The molar ratio of the various constituents was TEOS/CTAB/SDS/$H_2O$ = 50:25:5:4500. For loading of the $Ni^{II}$ complexes, 1.0 g of the calcined solid was suspended in 50 mL of dmf containing 0.2 g of complex. The mixture was stirred for 4 h at room temperature, then filtered off and washed several times with dmf and dried in vacuo at ambient temperature. The loading (immobilization) of the Ni complexes on the mesoporous host was confirmed by UV/Vis solid state spectroscopy.

**Bis(3-aminopropyl-5-bromosalicylideneiminato)nickel(II) [Ni($L^1$)$_2$]:** This complex was prepared following the method of Elder.[36] Thus, a solution of 1,3-diaminopropane (8.88 g, 120 mmol) in ethanol was heated at 60 °C and a solution of 5-bromosalicylaldehyde (4.02 g, 20 mmol) in ethanol added dropwise with stirring for 30 min. After the addition was complete, solid $Ni(CH_3COO)_2 \cdot 4H_2O$ (2.49 g, 10 mmol) was added at once. The solid dissolved rapidly to give a dark solution, which was refluxed for 20 min at 60 °C. The green precipitate that formed was filtered off, washed with a small amount of ethanol and diethyl ether, and dried in air.

**Bis(3-aminopropylsalicylideneiminato)nickel(II) [Ni($L^2$)$_2$]:** This complex was also prepared by the method described by Elder.[36]

**Bis(3-aminopropyl-5-bromo-2,2-dimethylsalicylideneiminato)nickel(II) [Ni($L^3$)$_2$]:** This complex was prepared in a similar manner to Ni($L^1$)$_2$. Thus, a solution of 1,3-diamino-2,2-dimethylpropane (6.13 g, 60 mmol) in ethanol was heated at 60 °C and a solution of 5-bromosalicylaldehyde (2.01 g, 10 mmol) in ethanol was added dropwise with stirring for 30 min. The deep yellow precipitate obtained dissolved after the addition of solid $Ni(CH_3COO)_2 \cdot 4H_2O$ (1.25 g, 5 mmol) at once. The solid dissolved rapidly to give a dark brown solution, which was refluxed for 30 min at 60 °C. The green precipitate obtained was filtered off, washed with a small amount of ethanol and diethyl ether, and dried in air.

**[$Ni_4L^1_4$(μ-tp-κ$_4$-O)($H_2O$)$_2$(μ-tp-κ$_2$-O)]·2$C_2H_5OH$·$CH_3OH$·3$H_2O$ (1):** A solution of [Ni($L^1$)$_2$] (0.057 g, 0.1 mmol) in 10 mL of hot ethanol was added to a methanolic solution (5 mL) of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.036 g, 0.1 mmol) with constant stirring. The color of the solution turned deep green. An aqueous solution of $Na_2tp$ (0.021 g, 0.1 mmol) was then added to this mixture. The resulting solution was stirred for 30 min, then filtered. Slow evaporation at room temperature yielded green crystals of **1** suitable for X-ray analysis after 4 d. Yield: 0.040 g (45%). $C_{61}H_{82}Br_4N_8Ni_4O_{20}$ (1800.8): calcd. C 40.65, H 4.55, N 6.22; found C 39.40, H 4.70, N 6.40.

**[$Ni_4L^2_4$(μ-tp-κ$_4$-O)($H_2O$)$_2$(μ-tp-κ$_2$-O)]·3$H_2O$ (2):** A solution of [Ni($L^2$)$_2$] (0.083 g, 0.2 mmol) in 10 mL of hot ethanol was added to a methanolic solution (5 mL) of $Ni(ClO_4)_2 \cdot 6H_2O$ (0.073 g, 0.2 mmol) with constant stirring. The color of the solution turned deep green. An aqueous solution of $Na_2tp$ (0.042 g, 0.2 mmol) was then added to this mixture. The resulting solution was stirred for 30 min, then filtered. This solution yielded dark green crystals of **2** on standing at room temperature for 3 d. Unfortunately, it was not possible to grow single crystals of X-ray diffraction quality. Yield: 0.085 g (63%). $C_{56}H_{70}N_8Ni_4O_{17}$ (1360.8): calcd. C 49.38, H 5.14, N 8.23; found C 49.29, H 5.06, N 8.17.

| $\lambda$ [Å] | 0.71073 (Mo-$K_\alpha$) | 0.71073 (Mo-$K_\alpha$) | 0.71073 (Mo-$K_\alpha$) |
| $\theta_{min}$–$\theta_{max}$ [°] | 2.2–25.0 | 2.1–30.0 | 3.4–27.6 |
| Reflections collected | 6266 | 5787 | 9565 |
| Independent reflections | 6093 | 4857 | 4287 |
| Observed data [$I > 2\sigma(I)$] | 3140 | 2516 | 3373 |
| Data/restraints/parameters | 6093/0/429 | 4857/2/196 | 4287/0/220 |
| Goodness-of-fit on $F^2$ | 0.889 | 0.922 | 0.927 |
| Final $R$ indices [$I > 2\sigma(I)$] | $R_1$ = 0.0828 | $R_1$ = 0.0566 | $R_1$ = 0.0286 |
| | $wR_2$ = 0.1480 | $wR_2$ = 0.1145 | $wR_2$ = 0.0635 |
| $R$ indices (all data) | $R_1$ = 0.2370 | $R_1$ = 0.1145 | $R_1$ = 0.0392 |
| | $wR_2$ = 0.1872 | $wR_2$ = 0.1324 | $wR_2$ = 0.0656 |

**$[Ni(L^1)(H_2O)\{Ag(CN)_2\}]_\alpha$ (3):** A methanolic solution (5 mL) of $Ni(ClO_4)_2{\cdot}6H_2O$ (0.036 g, 0.1 mmol) was added to a methanolic solution (10 mL) of $[Ni(L^1)_2]$ (0.057 g, 0.1 mmol) and the resulting green solution stirred for 10 min. An aqueous solution (5 mL) of $Na[Ag(CN)_2]$ (0.018 g, 0.1 mmol) was then added to this mixture and the solution stirred for 20 min. The solution was filtered to remove any suspended material and kept at room temperature. Slow evaporation of solvents yielded deep green crystals suitable for X-ray analysis after 7 d. Yield: 0.018 g (73%). $C_{12}H_{14}AgBrN_4NiO_2$ (492.76): calcd. C 29.22, H 2.84, N 11.36; found C 29.16, H 2.79, N 11.23.

**$[Ni(L^3)(MeOH)\{Ag(CN)_2\}]_\alpha$ (4):** A methanolic solution (5 mL) of $Ni(ClO_4)_2{\cdot}6H_2O$ (0.036 g, 0.1 mmol) was added to a methanolic solution (10 mL) of $[Ni(L^3)_2]$ (0.057 g, 0.1 mmol) and the resulting green solution stirred for 10 min. A dmf solution (5 mL) of $Na[Ag(CN)_2]$ (0.018 g, 0.1 mmol) was then added to this mixture and the solution stirred for 20 min. It was then filtered and kept at room temperature. Slow evaporation of the solvents yielded green crystals suitable for X-ray analysis after 5 d. Yield: 0.021 g (40%). $C_{15}H_{20}AgBrN_4NiO_2$ (534.83): calcd. C 33.66, H 3.74, N 10.47; found C 33.59, H 3.70, N 10.41.

**Crystal-Structure Determination:** Single crystals of complex **1** were grown from EtOH/MeOH/$H_2O$ and those of complexes **3** and **4** were grown from MeOH/$H_2O$ and dmf/MeOH medium, respectively. The X-ray single-crystal data for complexes **1** and **3** were collected with a Siemens P4 four-circle diffractometer whereas those of complex **4** were collected on an Oxford Instruments Sapphire2-CCD diffractometer. Crystal size: $0.18 \times 0.21 \times 0.51$, $0.30 \times 0.31 \times 0.52$, and $0.08 \times 0.17 \times 0.22$ mm$^3$ for complexes **1**, **3**, and **4** respectively. Unit cell dimensions and intensity data were measured at 294 K for **1** and **3** and 108 K for **4**. The crystallographic data, conditions used for the intensity data collection and some features of the structure refinement are listed in Table 7. Graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) was used to collect the data sets. Accurate unit-cell parameters for **1**, **3**, and **4** were determined from automatic centering of 14, 15, and 5214 reflections, respectively, and refined by least-square methods. 6266 Reflections were collected for **1** in the range $2.2° < \theta < 25.0°$, 5787 reflections were collected in the range $2.1° < \theta < 30.0°$ for **3**, and 7224 reflections were collected in the range $3.4° < \theta < 27.6°$ for **4**. A total of 3140, 2516, and 3373 reflections were assumed as observed [$I > 2\sigma(I)$] for complexes **1**, **3**, and **4** respectively. All calculations for data reduction, structure solution and refinement were performed using standard procedures with SHELXS-97[37] and SHELXL-97.[38] All non-hydrogen atoms were refined anisotropically by full-matrix least-squares techniques on $F^2$. The H atoms were constrained to idealized positions and refined isotropically using a riding model.

CCDC- 645841 (for **1**), -645842 (for **3**), and -645843 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Square-Planar Diacetatopalladium Complexes with *trans*-Configured Secondary Amine Ligands that Avoid Orthometalation: Ligand Synthesis, Coordination, Molecular Structure and Catalytic Potential for Suzuki Cross-Coupling Reactions

**Ludovic Chahen,[a] Bruno Therrien,[a] and Georg Süss-Fink*[a]**

**Keywords:** Cross-coupling / Palladium / N ligands / Amines / Homogeneous catalysis

The *trans*-configured square-planar palladium complexes $[Pd(OAc)_2(LN{t}Bu)_2]$ (**1**), $[Pd(OAc)_2(\eta^2\text{-}LN\cap N{t}Bu)]$ (**2**), $[Pd(OAc)_2(LNPh)_2]$ (**3**), and $[Pd(OAc)_2(\eta^2\text{-}LN\cap NPh)]$ (**4**), have been synthesized by treating palladium acetate with the amines $NH{t}BuCH_2\text{-}2,4,6\text{-}Me_3C_6H_2$ (LN*t*Bu) or $NHPhCH_2\text{-}2,4,6\text{-}Me_3C_6H_2$ (LNPh) or with the diamines $NH{t}BuCH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}NH{t}Bu$ (LN∩N*t*Bu) or $NHPh\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}NHPh$ (LN∩NPh). The single-crystal X-ray structure analysis of complexes **1**–**3** confirms a *trans* arrangement of the two acetato groups and of the two nitrogen atoms. Orthometalation leading to palladacycles is impossible in all cases as the *ortho* positions in the benzylic rings are blocked by methyl substituents. All complexes are found to catalyze Suzuki cross-coupling reactions of deactivated and even sterically hindered arene substrates.

## Introduction

The Suzuki cross-coupling reaction is one of the most important methods for the selective assembly of biaryls in the synthesis of natural products, pharmaceuticals, and advanced materials.[1] Although many palladium(II) or palladium(0) complexes catalyze this coupling reaction, significant efforts have been made to design ligands that can increase the catalytic activity of the palladium center. Some of the most widely studied Suzuki catalysts are palladium phosphane complexes that are susceptible to orthometalation or palladacycle formation.[2] However, the most efficient catalysts so far reported are palladium phosphane complexes that cannot undergo orthometalation.[3] These very active phosphane complexes require rigorous exclusion of air and water, however, due to the air sensitivity of the phosphane ligands, which is the main reason for the growing interest in Ncoordinating ligands for Suzuki catalysts. Indeed, many N-based ligands have been reported to be efficient for the Suzuki cross-coupling reactions, especially tertiary amines and imines.[4] These ligands are air-stable and are therefore easier to synthesize and handle. Boykin et al. have screened several simple and commercially available amines as ligands with palladium acetate in the Suzuki cross-coupling reaction and found that bulky primary and secondary amines appear to be better ligands than comparable tertiary amines that do not form stable complexes with palladium acetate.[5] Although these catalytic systems are efficient at low temperature and under aerobic conditions, a significantly higher amount of palladium acetate (2 mol-%) is needed compared to the molar ratio generally required with phosphane ligands (0.01 mol-%) in order to afford similar turnover numbers.

Our laboratory has recently designed new ligands that impose a *trans* geometry at the metal center, thereby preventing orthometalation.[6] As the palladium complex *trans*-$[PdCl_2(P\cap P)]$, which contains the diphosphane ligand $PPh_2CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}PPh_2$ (P∩P) is an active Suzuki catalyst for the cross-coupling of deactivated or hindered aryl bromides, we decided to synthesize the analogous amine ligands $NH{t}Bu\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H_2$ (LN*t*Bu), $NHPh\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H_2$ (LNPh), $NH{t}Bu\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}NH{t}Bu$ (LN∩N*t*Bu), and $NHPh\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}2,4,6\text{-}Me_3\text{-}C_6H\text{-}CH_2\text{-}NHPh$ (LN∩NPh) in order to study their coordination to palladium acetate as well as the catalytic potential of these complexes for Suzuki reactions.

## Results and Discussion

### Synthesis and Characterization of New Secondary Amine Ligands

The secondary amines $NH{t}Bu\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H_2$ (LN*t*Bu), $NH{t}Bu\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}NH{t}Bu$ (LN∩N*t*Bu), and $NHPh\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}2,4,6\text{-}Me_3C_6H\text{-}CH_2\text{-}NHPh$ (LN∩NPh) are accessible in one step from the corresponding bromide and the corre-

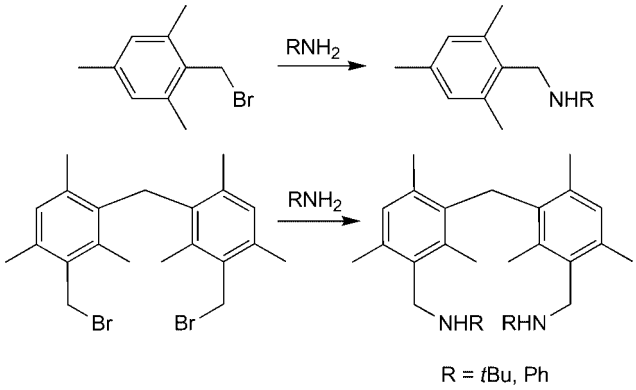
sponding amine (Scheme 1). The synthesis of (2,4,6-trimethylbenzyl)aniline (LNPh) has been described previously.[7]

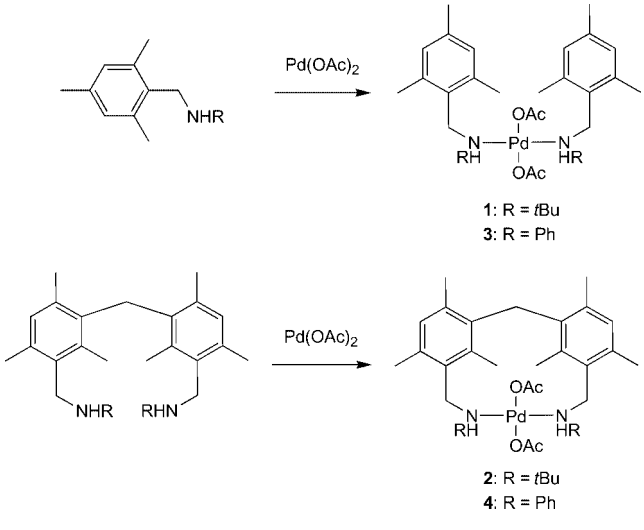


Scheme 1. Synthesis of the secondary amines LN*t*Bu, LNPh, LN∩N*t*Bu, and LN∩NPh.

All new compounds were characterized by NMR ($^1$H, $^{13}$C) spectroscopy, mass spectrometry, and elemental analysis.

## Synthesis and Molecular Structure of *trans*-Palladium Complexes

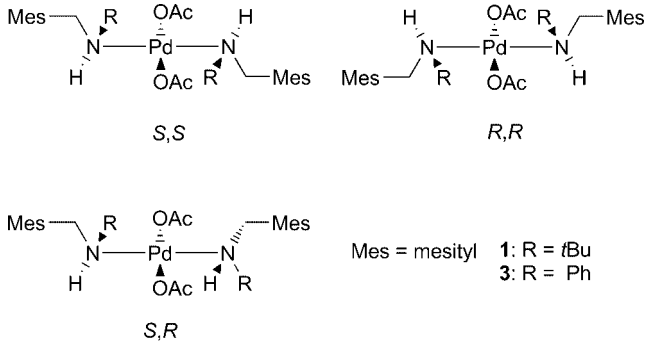
The *trans*-palladium complexes [Pd(OAc)$_2$(LN*t*Bu)$_2$] (**1**), [Pd(OAc)$_2$($\eta^2$-LN∩N*t*Bu)] (**2**), [Pd(OAc)$_2$(LNPh)$_2$] (**3**), and [Pd(OAc)$_2$($\eta^2$-LN∩NPh)] (**4**) were synthesized by treating [Pd(OAc)$_2$] with the corresponding amines or diamines in toluene at 50 °C and simple workup of the reaction mixture (Scheme 2).



Scheme 2. Synthesis of the palladium complexes *trans*-[Pd(OAc)$_2$(LN*t*Bu)$_2$](**1**), *trans*-[Pd(OAc)$_2$($\eta^2$-LN∩N*t*Bu)](**2**), *trans*-[Pd(OAc)$_2$(LNPh)$_2$] (**3**), and *trans*-[Pd(OAc)$_2$($\eta^2$-LN∩NPh)] (**4**).

The question of stereochemistry needs to be addressed for complexes containing secondary amine ligands with three different substituents as the nitrogen atom is stereogenic (asymmetric tetrahedral geometry) due to coordination to the metal center. This problem has been solved by NMR spectroscopy and X-ray crystallography for complexes **1**–**4**.

The two asymmetric nitrogen centers in the bis-amine complexes **1** and **3** give rise, in principle, to three isomers − a pair of enantiomers (*R*,*R* and *S*,*S*) and a *meso* isomer (*R*,*S*), as shown in Scheme 3. In both cases, all three isomers are indeed formed upon coordination of LN*t*Bu or LNPh to [Pd(OAc)$_2$] as the NMR spectra show the expected signals of both diastereoisomers.



Scheme 3. Representation of the stereoisomeric configurations of complexes **1** and **3**.

While it did not prove possible to separate the three isomers of complex **3**, we succeeded in separating the diastereoisomers of **1** by extraction with diethyl ether. However, the separated diastereoisomers (*R*,*R*)/(*S*,*S*)-**1** and (*R*,*S*)-**1** were found to isomerize in solution over a period of several minutes so it was only possible to record $^1$H NMR spectra of diastereomerically pure **1a** and **1b**, but not the $^{13}$C{$^1$H} NMR spectra. Crystallization from chloroform gave only the *meso* isomer (*R*,*S*) for both complexes **1** and **3**.

The single-crystal X-ray structure analysis of **1** and **3** revealed that, in contrast to solutions of these complexes, which contain all isomers, the crystals isolated in both cases represent only the *meso* isomer. The molecular structures of **1** and **3** show the palladium atom to be in a square-planar geometry surrounded by two acetato ligands and two nitrogen atoms in a *trans* coordination geometry (Figures 1 and 2, respectively).

There are intramolecular hydrogen bonds in the crystal structures of **1** and **3** between the NH of the amino function and the C=O group of the acetato ligands [N–O 2.846(5) Å, N–H···O 141.7° in **1** and N–O 2.714(3) Å, N–H···O 150.4° in **3**; Figure 3]. The N···O distances and N–H···O angles are similar to those observed in analogous *trans* acetato(amino)-palladium complexes.[5a,8]

The rigid diamine backbone in the diamine complexes **2** and **4** generates an additional chirality upon coordination, with two enantiomers (*P* and *M*) being generated depending on the sense of helicity. Complexes **2** and **4** therefore possess three chiral elements (two chiral nitrogen atoms and a helical chirality element) and thus eight stereoisomeric species can theoretically be obtained (Scheme 4).

(i = –*x*, –*y*, 1 – *z*).

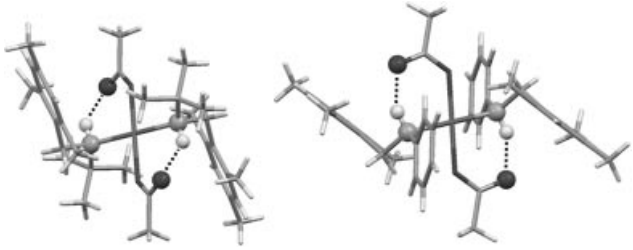

Figure 3. Intramolecular hydrogen-bonded systems in **1** (left) and **3** (right).

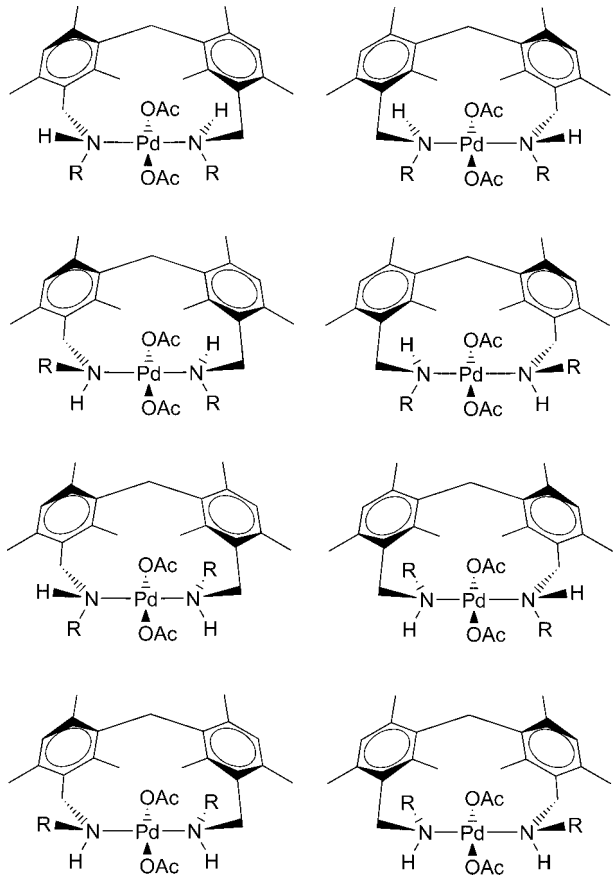
However, as suggested by $^{1}$H NMR spectroscopy and confirmed by the X-ray structure analysis of **2**, only one pair of enantiomers is observed for **2** and **4**.



Scheme 4. Representation of the possible stereoconfigurations of complexes **2** and **4**.

Despite the high number of theoretically possible isomers, the $^{1}$H NMR spectra of complexes **2** and **4** are not complex and show only the expected signals for the ligands, thereby suggesting that only one isomer or pair of enantiomers is present in solution. As neither **2** nor **4** shows a signal in its CD spectrum, it can be assumed that both complexes exist as a pair of enantiomers. The single-crystal X-ray structure analysis of **2** confirmed this hypothesis since it reveals a racemic crystal containing two enantiomers, with the square-planar palladium center being *trans* coordinated to two acetato ligands and to the two nitrogen atoms of the diamine ligand (Figure 4).

The coordination of the chelating diamino ligand in **2** imposes a slight distortion of the planar geometry. Thus, unlike in **1** and **3**, where the O–Pd–O and N–Pd–N axes are perfectly linear by symmetry, the corresponding angles in **2** are 179.1(4)° and 178.8(4)°, respectively. A strong distortion is imposed on the diphenylmethane spacer such that the angle between the two planes of the phenyl rings is much more acute (56.4°; Figure 5) than the corresponding angle in diphenylmethane[9] (80.5°), the analogous *trans*-diphosphane complex [$PdCl_2$(P∩P)][6] (65.9°), and in the structurally constrained dinuclear chromium complex [($\mu_2$-$\eta^6$,$\eta^6$-di-

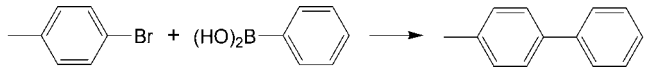
## Catalytic Activity of Complexes 1–4 for Suzuki Cross-Coupling Reactions

The *trans*-palladium complexes **1**–**4** were studied as catalyst precursors for Suzuki cross-coupling reactions. As we wanted to study the real influence of the ligands and the geometry they impose, we decided to compare the results of these four complexes with the ligand-free compound [$Pd(OAc)_2$], which is suspected to catalyze the Suzuki cross-coupling due to nanoparticle formation, depending on the catalyst concentration.[11]

We studied two Suzuki-type reactions, namely the cross-coupling of phenylboronic acid with 4-bromotoluene, which is a deactivated bromo derivative, and the cross-coupling of phenylboronic acid with 1-bromo-2,4,6-trimethylbenzene, which is both deactivated and sterically hindered. The cross-coupling of phenylboronic acid with aliphatic bromides, which was recently reported to occur with [$Pd(OAc)_2$] in the presence of sterically hindered phosphanes,[12,13] does not work with our complexes [<5% of product formation with $CH_3(CH_2)_{11}Br$; catalyst/substrate ratio: 1:20; dioxane, *t*BuOK, 30–90 °C].



The results summarized in Table 1 show that the efficiency of the catalysts depends mainly on the temperature. Thus, at 90 °C the highest catalytic turnover number (86000) is achieved with [$Pd(OAc)_2$], which is not surprising given that recent work has shown [$Pd(OAc)_2$] to be an excellent source of highly active palladium nanoparticles during cross-coupling reactions.[14] However, at 60 °C complexes **1** and **2** are more efficient than [$Pd(OAc)_2$] and the other complexes, thereby indicating that the ligands have a strong influence on the catalytic performance − the electronic and steric effect of the *tert*-butyl groups on secondary amines is stronger than that of phenyl groups. Finally, this sequence changes again at 30 °C, since complex **2** becomes the least efficient one. This is due to the rigidity of the ligand, which means that the complex requires more energy to perform the catalytic reaction.

Table 1. Catalytic turnover numbers (TON), indicating the mol of product formed per mol of catalyst used after 18 h, for the Suzuki cross-coupling of 4-bromotoluene and phenylboronic acid catalyzed by **1**–**4** and [$Pd(OAc)_2$]. Solvent: toluene; base: $K_2CO_3$; reaction time: 18 h. Average of two runs.

| *T* [°C] | Catalyst/substrate | **1** | **2** | **3** | **4** | [$Pd(OAc)_2$] |
|---|---|---|---|---|---|---|
| 30 | 1:1000 | 410 | 250 | 130 | 230 | 240 |
| 30 | 1:10000 | 2700 | 0 | 600 | 900 | 460 |
| 60 | 1:1000 | 620 | 960 | 360 | 390 | 1000 |
| 60 | 1:10000 | 4800 | 6200 | 2300 | 2200 | 3800 |
| 60 | 1:100000 | 36000 | 38000 | 7000 | 12000 | 21000 |
| 90 | 1:1000 | 800 | 1000 | 710 | 710 | 1000 |
| 90 | 1:10000 | 6200 | 9100 | 4000 | 4900 | 9600 |
| 90 | 1:100000 | 45000 | 58000 | 28000 | 29000 | 86000 |

Nevertheless, as the TONs of the four complexes have the same order of magnitude as that of [$Pd(OAc)_2$], we compared complex **2** and [$Pd(OAc)_2$] kinetically at 60 °C with a catalyst/substrate ratio of 1:10000.

Figure 6 shows that the two precursors behave differently during the catalytic reaction. Thus, whereas [$Pd(OAc)_2$] shows a relatively constant activity, complex **2** undergoes an induction period of almost one hour, thereby indicating that it is also only a precatalyst. As we cannot exclude nanoparticle formation in the case of **2**, we performed poisoning tests with metallic mercury using a catalyst/substrate ratio of 1:1000. At 60 °C, **2** attains a TON of 300 after 1 h, while it is 960 after 18 h. When 400 equiv. of mercury is added at the beginning of the reaction, the TON falls to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

480 after 18 h, and if mercury is added after one hour of reaction the TON is 660 after 18 h. Under the same conditions, the catalytic turnover of $[Pd(OAc)_2]$ drops to 84 or 267 if 400 equiv. of mercury is added at the beginning or after 1 h, respectively. Since the catalytic activity of metallic palladium nanoparticles should be suppressed completely by metallic mercury, we can conclude that the molecular catalysis pathway dominates for complex **2** while in the case of palladium acetate the nanoparticle pathway is dominant.

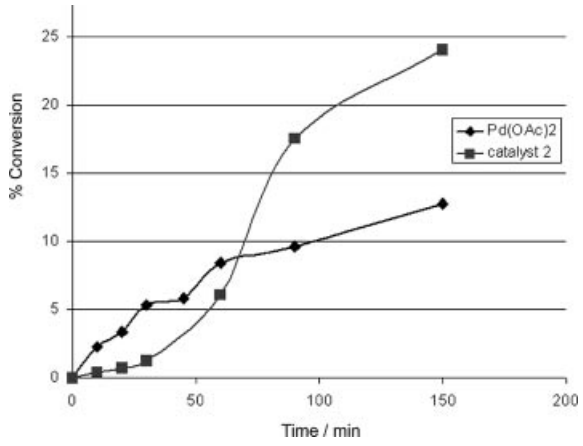


Figure 6. Kinetic comparison of complex **2** and $[Pd(OAc)_2]$ at 60 °C with a ratio of 1:10000.

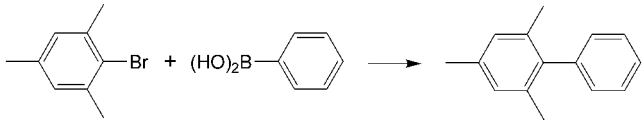

The results of the Suzuki cross-coupling of 1-bromo-2,4,6-trimethylbenzene with phenylboronic acid are summarized in Table 2. As expected with a sterically hindered and deactivated bromide, the TONs are lower than those observed for the previous reaction. Complex **2** is less active than **1** at 30 °C because of the rigidity of the ligand backbone. However, at temperatures above 60 °C complex **2** shows the best catalytic performance for sterically hindered substrates.

Table 2. Catalytic turnover numbers (TON) indicating the mol of product formed per mol of catalyst used after 18 h for the Suzuki cross-coupling of 2,4,6-trimethylphenyl bromide and phenylboronic acid catalyzed by **1**–**4** and $[Pd(OAc)_2]$. Solvent: toluene; base: $K_2CO_3$; reaction time: 18 h. Average of two runs.

| *T* [°C] | Catalyst/ substrate | **1** | **2** | **3** | **4** | $[Pd(OAc)_2]$ |
|---|---|---|---|---|---|---|
| 30 | 1:1000 | 297 | 66 | 18 | 60 | 86 |
| 60 | 1:1000 | 430 | 620 | 80 | 160 | 200 |
| 60 | 1:10000 | 2790 | 2900 | 300 | 900 | 420 |
| 90 | 1:1000 | 550 | 730 | 140 | 140 | 270 |
| 90 | 1:10000 | 3200 | 4900 | 800 | 1000 | 1300 |

## Conclusions

The *trans*-secondary amino complexes **1**–**4**, in which orthometalation is impossible because of the methyl substituents in the *ortho*-positions, catalyze the Suzuki cross-coupling of 4-bromotoluene and even of 2,4,6-trimethylphenyl bromide with phenylboronic acid. Whereas the TONs of the four complexes show the same order of magnitude as $[Pd(OAc)_2]$ in both reactions, it seems that the new ligands give rise to the formation of catalytically active molecular species rather than to metallic nanoparticles. Furthermore, we have shown that, at temperatures above 60 °C, the rigidity of the ligand backbone and the *tert*-butyl substituents increase the catalytic performance in the Suzuki cross-coupling of sterically hindered and deactivated bromides.

## Experimental Section

**General:** All reactions were carried out under argon using standard Schlenk techniques. Thf was distilled from sodium benzophenone under $N_2$ to avoid water and oxygen contamination. Toluene, *n*-hexane, and diethyl ether were purchased from Merck (puriss., pro analysi) and, along with distilled water, were saturated with argon prior to use. Dichloromethane was distilled from $CaH_2$ and saturated with $N_2$. $[Pd(OAc)_2]$ was purchased from Aldrich and used as received. Deuterated chloroform was used as received, and all NMR spectra were performed with a Bruker spectrometer [400 MHz for $^1H$ and 100 MHz for $^{13}C\{^1H\}$]. All GC analyses were performed using a GC DANI 86.10 equipped with a fused-silica capillary column OPTIMA $\delta$-3 (0.5 μm, 30 m × 0.25 mm) and an SP-4400 integrator.

**Synthesis of NH*t*Bu-$CH_2$-2,4,6-$Me_3C_6H_2$ (LN*t*Bu):** *tert*-Butylamine (2.11 mL, 20 mmol) was added to a suspension of 1-(bromomethyl)-2,4,6-trimethylbenzene (1.278 g, 6 mmol) and $K_2CO_3$ (2.76 g, 20 mmol) in toluene (20 mL). The mixture was refluxed for 15 h, then cooled to room temperature, and filtered through filter pulp. The filtrate was evaporated to dryness to give 793 mg of an oil (yield 64%). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 6.91 (s, 2 H), 3.75 (s, 2 H), 2.44 (s, 6 H), 2.32 (s, 3 H), 1.27 (s, 9 H) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 136.74, 136.09, 134.25, 128.95, 50.43, 40.37, 28.89, 20.84, 19.21 ppm. EI-MS: *m*/*z* 206 $[M + H]^+$. $C_{14}H_{23}N$ (205.34): calcd. C 81.89, H 11.29, N 6.82; found C 81.95, H 11.34, N 6.75.

**Synthesis of NH*t*Bu-$CH_2$-2,4,6-$Me_3C_6H$-$CH_2$-2,4,6-$Me_3C_6H$-$CH_2$-NH*t*Bu (LN∩N*t*Bu):** *tert*-Butylamine (2.11 mL, 20 mmol) was added to a suspension of bis[3-(bromomethyl)-2,4,6-trimethylphenyl]methane (1.313 g, 3 mmol) and $K_2CO_3$ (2.76 g, 20 mmol) in toluene (20 mL) and the mixture refluxed for 15 h. The solution was then filtered through filter pulp at room temperature and the filtrate dried in vacuo (yield 80%). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 6.78 (s, 2 H), 4.02 (s, 2 H), 3.63 (s, 4 H), 2.32 (s, 6 H), 2.08 (s, 12 H), 1.15 (s, 18 H) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 136.41, 135.87, 135.15, 135.13, 133.99, 130.54, 50.46, 41.07, 32.39, 28.90, 21.07, 19.37, 15.74 ppm. $C_{29}H_{46}N_2$ (422.69): calcd. C 82.40, H 10.97, N 6.63; found C 82.56, H 11.04, N 6.57.

**Synthesis of NHPh-$CH_2$-2,4,6-$Me_3C_6H$-$CH_2$-2,4,6-$Me_3C_6H$-$CH_2$-NHPh (LN∩NPh):** Phenylamine (2 mL, 20 mmol) was added to a suspension of bis[3-(bromomethyl)-2,4,6-trimethylphenyl]methane (1.313 g, 3 mmol) and $K_2CO_3$ (2.76 g, 20 mmol) in toluene (20 mL) and the mixture refluxed for 24 h. The solution was then filtered through filter pulp at room temperature and the filtrate dried in vacuo. The white residue was washed with *n*-hexane (20 mL) to remove an excess of phenylamine (yield 968 mg, 70%). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.35–7.24 (m, 4 H), 6.91 (s, 2 H),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

6.88–6.69 (m, 6 H), 4.22 (s, 4 H), 4.15 (s, 2 H), 2.38 (s, 6 H), 2.19 (s, 6 H), 2.16 (s, 6 H) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 148.20, 136.48, 136.22, 134.77, 133.09, 130.68, 129.25, 129.01, 128.20, 125.28, 117.42, 115.16, 112.62, 43.15, 32.36, 21.09, 19.53, 16.12 ppm. EI-MS: *m*/*z* 463 $[M + H]^+$. $C_{33}H_{38}N_2$ (462.67): calcd. C 85.67, H 8.28, N 6.05; found C 85.89, H 8.46, N 5.90.

**Synthesis of $[Pd(OAc)_2(LNtBu)_2]$ (1):** A solution of LN*t*Bu (102.5 mg, 0.5 mmol) in toluene (40 mL) was added to a suspension of $[Pd(OAc)_2]$ (56 mg, 0.25 mmol) in toluene (40 mL) and the mixture stirred at 50 °C for 3 h. The red solution became clear after 20 min, although towards the end of the reaction it became slightly cloudy again. After 3 h the cloudy solution was concentrated in vacuo to 40 mL and then filtered through filter pulp to remove the solid precipitate. The filtrate was evaporated to dryness and the residue washed with *n*-hexane (40 mL) to give analytically pure **1** as a mixture of isomers (total yield 65%). Complex **1** was separated into two diastereoisomers by extraction with diethyl ether (40 mL). After stirring at room temperature for 10 min, the diethyl ether extract was filtered through a cannula equipped with filter paper and the solvents evaporated to dryness to give isomer **1a**; diastereoisomer **1b** remained as a solid.

**1a:** $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.60 (br. d, $^3J_{H,H}$ = 9.6 Hz, 2 H, NH), 6.87 (s, 4 H), 3.69 (dd, $^3J_{H,H}$ = 12.8, 9.6 Hz, 2 H), 3.05 (dd, $^3J_{H,H}$ = 12.8, 2.2 Hz, 2 H), 2.40 (s, 6 H), 2.19 (s, 12 H), 1.80 (s, 6 H), 1.63 (s, 18 H) ppm. $C_{32}H_{52}N_2O_4Pd$ (635.19): calcd. C 63.72, H 8.69, N 4.64; found C 63.96, H 8.85, N 4.44.

**1b:** $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.11 (br. d, $^3J_{H,H}$ = 10.6 Hz, 2 H, NH), 6.90 (s, 4 H), 3.64 (t, $^3J_{H,H}$ = 10.6 Hz, 2 H), 3.00 (dd, $^3J_{H,H}$ = 12.8, 2.0 Hz, 2 H), 2.45 (s, 12 H), 2.32 (s, 6 H), 1.70 (s, 6 H), 1.41 (s, 18 H) ppm. $C_{32}H_{52}N_2O_4Pd$ (635.19): calcd. C 63.72, H 8.69, N 4.64; found C 63.88, H 8.78, N 4.50.

**Synthesis of $[Pd(OAc)_2(\eta^2\text{-}LN\cap NtBu)]$ (2):** A solution of LN∩N*t*Bu (105 mg, 0.25 mmol) in toluene (50 mL) was added to a suspension of $[Pd(OAc)_2]$ (56 mg, 0.25 mmol) in toluene (50 mL) and the mixture stirred at 50 °C for 15 h. The red solution became clear after 20 min. After 15 h the solvent was evaporated to dryness to give a yellow powder, which was washed with diethyl ether (10 mL). Yield 80%. $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 7.71 (d, $^3J_{H,H}$ = 10.6 Hz, 2 H), 6.86 (s, 2 H), 4.16 (s, 2 H), 3.61 (dd, $^3J_{H,H}$ = 12.3, 10.6 Hz, 2 H), 2.93 (d, $^3J_{H,H}$ = 12.6 Hz, 2 H), 2.51 (s, 6 H), 3.32 (s, 6 H), 1.72 (s, 6 H), 1.67 (s, 18 H), 1.66 (s, 6 H) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 180.16, 140.47, 138.95, 136.26, 135.70, 132.40, 129.94, 59.47, 42.90, 32.39, 28.85, 24.80, 21.48, 20.59, 18.46 ppm. $C_{33}H_{52}N_2O_4Pd$ (647.20): calcd. C 61.24, H 8.10, N 4.33; found C 61.48, H 8.28, N 4.28.

**Synthesis of $[Pd(OAc)_2(LNPh)_2]$ (3):** A solution of LNPh (225 mg, 1 mmol) in toluene (50 mL) was added to a suspension of $[Pd(OAc)_2]$ (112 mg, 0.5 mmol) in toluene (50 mL) and the mixture stirred at 50 °C for 3 h. The red solution became clear after 20 min, although towards the end of the reaction the solution became slightly cloudy again. After 3 h the cloudy solution was concentrated in vacuo to 50 mL and then filtered through filter pulp to remove the solid precipitate. The filtrate was evaporated to dryness and the residue washed with diethyl ether (20 mL) to give analytically pure **3** as a mixture of isomers (total yield 60%). $^1H$ NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 9.35 (m), 9.06 (m), 7.22–7.07 (m), 6.82 (s), 6.78 (s), 4.41–4.20 (m), 3.79 (dd, $^3J_{H,H}$ = 13.4, 4.6 Hz), 3.63 (dd, $^3J_{H,H}$ = 13.4, 4.7 Hz), 2.37 (s), 2.33 (s), 2.28 (s), 1.81 (s), 1.76 (s) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 180.78, 147.21, 138.35, 137.87, 129.52, 129.42, 129.20, 129.08, 128.90, 125.61, 122.96, 122.26, 50.78, 49.84, 29.32, 24.22, 23.15, 21.27, 20.39, 20.26 ppm. $C_{36}H_{44}N_2O_4Pd$ (675.17): calcd. C 61.20, H 6.10, N 4.46; found C 61.48, H 6.12, N 4.42.

**Synthesis of $[Pd(OAc)_2(\eta^2\text{-}LN\cap NPh)]$ (4):** A solution of LN∩NPh (230 mg, 0.5 mmol) in toluene (50 mL) was added to a suspension of $[Pd(OAc)_2]$ (112 mg, 0.5 mmol) in toluene (50 mL) and the mixture stirred at 50 °C for 15 h. The red solution became clear after 20 min, although towards the end of the reaction the solution became slightly cloudy again. After 15 h the cloudy solution was con-

centrated in vacuo to 50 mL and then filtered through filter pulp to remove the solid precipitate. The filtrate was evaporated to dryness and the residue washed with diethyl ether (20 mL) to give **4** (yield 60%). $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 10.34 (d, $^3J_{H,H}$ = 10.0 Hz, 2 H, NH), 7.35–7.31 (m, 4 H), 7.27–7.15 (m, 6 H), 6.98 (s, 2 H), 4.39 (dd, $^3J_{H,H}$ = 12.1, 10.0 Hz, 2 H), 4.23 (s, 2 H), 3.08 (d, $^3J_{H,H}$ = 12.1 Hz, 2 H), 2.56 (s, 6 H), 2.28 (s, 6 H), 1.90 (s, 6 H), 1.79 (s, 6 H) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CDCl_3$, 25 °C): $\delta$ = 181.20, 148.43, 140.28, 138.23, 136.90, 136.23, 131.37, 130.18, 129.44, 125.37, 121.29, 49.00, 32.38, 25.34, 21.62, 19.67, 18.59 ppm. $C_{37}H_{44}N_2O_4Pd$ (687.18): calcd. C 64.67, H 6.45, N 4.08; found C 64.90, H 6.59, N 3.99.

**X-ray Crystallographic Study:** Crystals of **1**–**3** were mounted on a Stoe Image Plate Diffraction system equipped with a $\phi$ circle goniometer and a Mo-$K_\alpha$ graphite-monochromated radiation source ($\lambda$ = 0.71073 Å). Data were collected in the $\phi$ range 0–200°, in increments of 1.0°, 1.2°, and 1.0°, respectively, with the 2$\theta$ range 2.0–26° and $D_{max}$–$D_{min}$ = 12.45–0.81 Å. The structures were solved by direct methods using the program SHELXS-97.[15] Refinement and all further calculations were carried out using SHELXL-97.[16] The H-atoms were included in calculated positions in all complexes and treated as riding atoms using the SHELXL default parameters. The non-H atoms were refined anisotropically using weighted full-matrix least-squares on $F^2$. Crystallographic details are summarized in Table 3. Figures 1, 2, and 4 were drawn with ORTEP[17] and Figures 3 and 5 with MERCURY.[18]

CCDC-647487 (for **1**), -647488 (for **2**), and -647489 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Catalytic Reactions:** The catalyst was added (in the molar ratio given in Tables 1 and 2) to a solution of $K_2CO_3$·1.5$H_2O$ (138 mg, 0.8 mmol), phenylboronic acid (91 mg, 0.75 mmol), and the aryl bromide (0.5 mmol) in toluene (5 mL) in a Schlenk tube and the mixture heated to the desired temperature (Tables 1 and 2) and stirred for 18 h. After cooling, the solution was filtered through a small silica gel column then the silica gel was eluted with diethyl ether (20 mL). The filtrate was combined with the ether washings and the solution obtained analyzed by GC.

# (2,2-Dibromovinyl)ferrocene as a Building Block for the Assembly of Heterodinuclear Complexes – Preparation of an σ-Alkenylpalladium Complex and Dimetallic Dithioether Complexes

**Sébastien Clément,[a] Laurent Guyard,[a] Michael Knorr,*[a] Fernando Villafañe,[b] Carsten Strohmann,[c] and Marek M. Kubicki[d]**

**Keywords:** Oxidative addition / Thioether ligands / Platinum / Rhenium / Palladium / Electrochemistry

The oxidative addition of (2,2-dibromovinyl)ferrocene [$Br_2C$=C(H)–Fc] (**1**) to [$Pd(PPh_3)_4$] yields the heterodinuclear σ-alkenyl complex *trans*-[{$Pd(Br)(PPh_3)_2$}–C(Br)=C(H)–Fc] (**2**). Nucleophilic attack of sodium thiolates on **1** unexpectedly affords the vinyl thioether derivatives (*Z*)-[(RS)(H)C=C(H)–Fc] (**4a**: R = Ph; **4b**: R = *t*Bu; **4c**: R = Et). Complexes **4a** and **4c** can also be prepared by addition of NaSR across the triple bond of Fc–C≡C–H (**3**). Addition of an excess of NaSR to **1** affords the dithioether derivatives (*Z*)-[(RS)(H)C=C(SR)–Fc] (**5a**: R = Ph; **5b**: R = *p*-tolyl; **5c**: R = Et). An addition/elimination sequence is suggested to account for this surprising result. The yield of **5c** is very low due to a competing formation of ethynylferrocene (**3**). Reaction of **5b** with [Re(thf)$(CO)_3$-(μ-Br)]$_2$ and [$PtCl_2(PhCN)_2$] leads to the heterodinuclear chelate complexes [Fc{C(S–*p*-tolyl)=C(H)(S–*p*-tolyl)}Re(Br)-$(CO)_3$] (**6**) and [Fc{C(S–*p*-tolyl)=C(H)(S–*p*-tolyl)}$PtCl_2$] (**7a**), respectively. Metathesis of the fluxional compound **7a** in the presence of NaI affords [Fc{C(S–*p*-tolyl)=C(H)(S–*p*-tolyl)}$PtI_2$] (**7b**). The electrochemical properties of some of these complexes have been studied by means of cyclic voltammetry, and the molecular structures of **1**, **2**, **3**, **4b**, **4c** and **6** have been determined by X-ray diffraction.

## Introduction

Ethynylferrocene[1] is increasingly being used as building block for the construction of di- and polymetallic organometallic systems[2–5] due to the presence of an electrochemically active ferrocenyl unit. In contrast, only a few examples of the preparation of polymetallic arrays starting from alkenylferrocenes have been reported in the literature.[6–9] In addition to a covalent connection to other metal centres, vinylferrocene has also been used as side-on bound π-ligand for the synthesis of dimetallic compounds of the type [$M(CO)_5$\{$\eta^2$-$H_2C$=C(H)Fc\}] (M = Cr, Mo, W).[10] For the past few years, we have been interested in the assembly of homo- and heterodinuclear transition metal complexes and the evaluation of their physicochemical properties (electrochemistry, luminescence).[11] Indeed, we recently published the synthesis of (dibromovinyl)[2.2]paracyclophane and investigated its reactivity towards [$M(PPh_3)_4$] (M = Pd, Pt).[11c] For comparison, we embarked on a study on the reactivity of (2,2-dibromovinyl)ferrocene (**1**), which shares some common features with (dibromovinyl)[2.2]paracyclophane such as planar chirality, redox activity and potential applications in materials science. We now wish to report the use of **1** for the synthesis of a functionalised vinylpalladium(II) complex, the reactivity of **1** towards various thiolates (NaSR) and the subsequent rearrangement reactions that lead to vinylic thioether compounds, which may also serve as ligands in coordination chemistry. This work also includes electrochemical investigations and several crystal structure determinations.

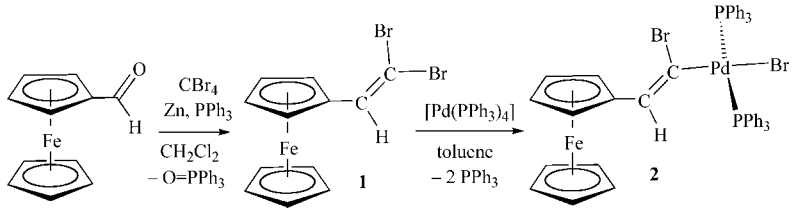
## Results and Discussion

### Oxidative Addition of (2,2-Dibromovinyl)ferrocene (1) to [$Pd(PPh_3)_4$]

The starting material **1** was prepared according to a literature procedure under Corey–Fuchs conditions by treatment of ferrocenecarbaldehyde with $CBr_4$ in the presence of zinc dust and $PPh_3$ (Scheme 1).[12,13] An X-ray diffraction study (Figure 1) revealed that, in contrast to (dibromovinyl)[2.2]paracyclophane,[11c] the alkenyl unit and the cyclopentadienido ring are almost parallel, with an interplanar angle of only 10.43°.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1.

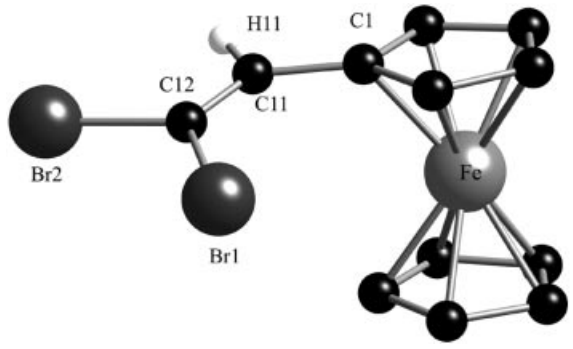


Figure 1. Ball-and-stick view of the molecular structure of **1**. Selected bond lengths [Å] and angles [°]: C(12)–Br(2) 1.892(2), C(12)–Br(1) 1.873(3), C(12)–C(11) 1.318(4), C(11)–C(1) 1.445(4); Br(1)–C(12)–Br(2) 113.56(15), Br(2)–C(12)–C(11) 120.7(2), Br(1)–C(12)–C(11) 125.7(2), C(12)–C(11)–C(1) 130.8(2).

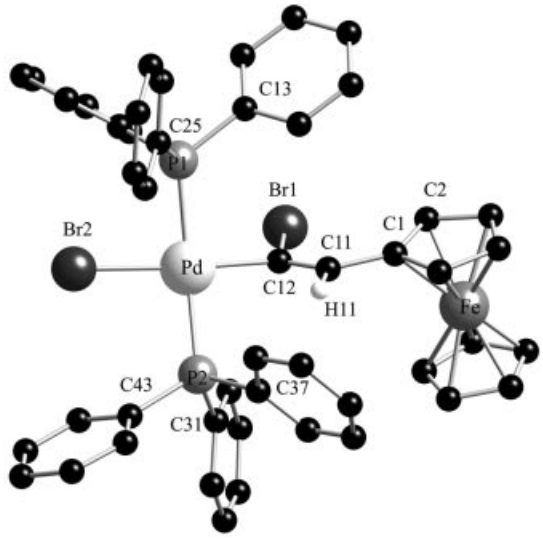

Figure 2. Ball-and-stick view of the molecular structure of **2**. For clarity, only the vinylic hydrogen atom is shown. Selected bond lengths [Å] and angles [°]: Pd–P(1) 2.3375(17), Pd–P(2) 2.3185(18), Pd–Br(2) 2.4479(8), Pd–C(12) 2.037(6), C(12)–Br(1) 1.952(6), C(12)–C(11) 1.272(9), C(11)–C(1) 1.481(8); P(1)–Pd–P(2) 166.74(5), Br(2)–Pd–C(12) 173.86(16), P(1)–Pd–C(12) 92.66(17), P(2)–Pd–C(12) 90.21(17), P(1)–Pd–Br(2) 84.76(4), P(2)–Pd–Br(2) 93.61(4), Br(1)–C(12)–Pd 108.8(3), Pd–C(12)–C(11) 120.4(5), C(12)–C(11)–C(1) 135.2(6).

Several experimental and theoretical studies have shown that the oxidative addition of vinyl halides to low-valent $Pd^0$ centres leads to $Pd^{II}$ complexes bearing a σ-alkenyl ligand.[14–18] For example, treatment of $[Pd(PPh_3)_4]$ with β-bromostyrene results in the formation of *trans*-$[PdBr(CH{=}CHPh)(PPh_3)_2]$.[18] The vinyl bromide **1** adds oxidatively to $[Pd(PPh_3)_4]$ at 60 °C in toluene solution in a similar manner to produce the heterodinuclear σ-alkenyl complex *trans*-[PdBr{C(Br)=C(H)–Fc}$(PPh_3)_2$] (**2**) in 76% yield (Scheme 1). The *trans* geometry of the $PPh_3$ ligands is evidenced by the presence of a single resonance at $\delta$ = 22.7 ppm in the $^{31}P\{^1H\}$ NMR spectrum. Unfortunately, the reaction with $[Pt(PPh_3)_4]$ under identical conditions led mainly to the formation of *cis*-$[PtBr_2(PPh_3)_2]$.

The X-ray structure of **2**, which is shown in Figure 2, reveals a slightly deformed square-planar coordination around Pd consisting of two *trans* $PPh_3$ residues, a terminal bromo ligand and a vinylferrocene moiety. The C(11)–C(12) double bond in **2** is shorter than in **1** [1.318(4) vs. 1.272(9) Å]. The latter ligands are placed almost linearly, with a Br(2)–Pd–C(12) angle of 173.86(16)°. Due to a stereoselective activation of the Br(2)–C(12) bond during the oxidative addition process, the stereochemistry about the vinylic C(11)=C(12) double bond is *anti* (*E*) with respect to the ferrocene unit and the Pd centre, with a C(1)–C(11)–C(12)–Pd dihedral angle of 164.7°.

### Reactivity of 1 Towards Various Thiolates

In the context of our work on the development of new dithioether ligands and their coordination chemistry,[19–21] we recently demonstrated that the nucleophilic attack of various thiolates on the π-conjugated 2-azabutadiene $[Cl_2C{=}C(H)N{=}CPh_2]$ in dmf affords the functionalised derivatives $[(RS)_2C{=}C(H){-}N{=}CPh_2]$ (R = Ph, *i*Pr) by replacement of the two vinylic chloro substituents by $SR^-$.[22] If the reaction with sodium thiophenolate is carried out in a 1:1 ratio, the monosubstituted product $[(PhS)(Cl)C{=}C(H){-}N{=}CPh_2]$ can be isolated. Unexpectedly, treatment of **1** with thiolates was less straightforward. Thus, when **1** is treated with just 1 equiv. of thiophenolate the reaction is incomplete and leads to the formation of a mixture of **1**, the substitution product **4a** and some ethynylferrocene (**3**). Treatment of **1** with a slight excess of NaSPh in dmf allowed us to isolate the vinylic thioether **4a** as an orange-red solid. However, the elemental analysis and NMR spectroscopic
