In contrast to the behaviour in neutral media, when a base such as triethylamine is added to the reaction mixtures, rapid changes occur, and for the $Zn^{II}$ systems, the $^1H$ NMR spectra indicate the presence of distinctly different species after the addition of one and two molar equivalents of the base. The effects of adding more than two equivalents are negligible, and the final spectra are in fact identical with those obtained on dissolving the structurally characterised neutral grid species (see below) obtained by precipitation from preparative mixtures of similar composition. It is thus assumed that the species present in solution are also tetranuclear grids. In the high-resolution spectra that can be obtained with the $Zn^{II}$ complexes, those at room temperature reflect a higher symmetry than would be expected for a grid having exactly the same structure as in the solid but that this is a reflection of site-exchange processes is indicated by the fact that at –40° in $CHCl_3$, the acetylhydrazone dianion complex shows aromatic resonances consistent with restricted rotation of the central (pyrimidine) phenyl group, giving rise to a distinction between "inner" and "outer" *ortho* and *meta* proton sites.[30]

### *(b) Complex Formation by Component Self-Assembly*

In the absence of any added base in moderately polar and ligating solvents such as methanol or acetonitrile, the reaction between the phenylpyrimidinedicarbaldehyde and acylhydrazines in the presence of one molar equivalent of various $M^{II}$ ions as their triflates leads commonly, as noted above, to the precipitation of the metal-free acylhydrazone. Nonetheless, the colour of the reaction medium prior to precipitation is indicative of some degree of complexation, and although the development of this colour in methanol and acetonitrile occurs over a time period similar to that required for precipitation of the acylhydrazone in the absence of the metal, in dimethyl sulfoxide it is clear that there is an efficient metal ion catalysis of hydrazone formation. When a base such as triethylamine is incorporated in the reaction mixtures, metal ion catalysis (template effect) appears to be important in all solvents, as very rapid reactions (extensive within the time of mixing) occur to give the same neutral complex species as those obtained from reactions with the preformed ligand in basic media. An advantage of performing the syntheses in this "one pot" manner is that a good solvent for all components is much more readily

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

found than for the reactions involving preformed ligands, so that precipitation of the product from a homogeneous solution occurs easily.

### 3. General Chemistry of the Grid Systems

As many of the neutral (grid) complexes show appreciable solubility in solvents in which the parent bis(acylhydrazone)s are completely insoluble, it is possible to recover the ligand from neutral complexes by their protonation upon acidification in solution. When the complex $[Zn_4(\mathbf{1})_4]$, for example, is dissolved in methanol, in which it forms an orange solution, and acetic acid is added, the colour is instantly discharged, and the neutral ligand rapidly precipitates. Significantly, the $^1$H NMR spectrum of this material is identical with that of the "preformed" ligand, indicating it to be a mixture of species and, since the crystal structure of the neutral grid shows the presence of a single isomer of the dianionic ligand, this suggests that isomerisation of the neutral ligand is very rapid. Support for this conclusion is offered by the fact that the water-soluble complex $[Zn_4(\mathbf{6})_4]$ (R = $CH_3OCH_2$), when dissolved in $D_2O$, shows two sharp singlet resonances for the methyl and methylene protons, each of which become at least three peaks when acetic acid is added.

We thus conclude that ligand isomerisation cannot constitute a kinetic barrier to the formation of complexes. (It may be noted here that attempts to separate *E*/*Z* isomers of acylhydrazones by flash chromatography have been unsuccessful.[31]) Also significant is the fact that the use of a strong acid such as HCl to protonate the neutral complexes does not lead to precipitation of the neutral ligand, but instead to its hydrolysis, indicating that it should be possible to find conditions where all components (acylhydrazine, dicarbaldehyde and metal ion complexes) are in labile equilibrium.

Although neutral grid complexes do not generally show high solubility in apolar solvents, most dissolve readily in pyridine or, to a lesser extent, both in methanol and in dimethyl sulfoxide. Interestingly, the grids are frequently more soluble in a mixed solvent (protic + aprotic) than in either of its components. Preferential solubility in particular solvents results from the appropriate choice of acyl group; for example, the heptanoylhydrazine derivatives are moderately soluble in dichloromethane, the benzoylhydrazine derivatives in acetone and the tolylhydrazine complexes in benzene (and in dichloromethane but not in toluene), while the methoxy- and methoxyethoxyacetylhydrazine derivatives show some solubility in water. Acetonitrile is a useful solvent for the syntheses, both of the ligands and of their complexes, since the reactants are generally quite soluble and the desired products insoluble (while byproducts such as triethylammonium triflate are soluble), but, as indicated in the Experimental Section, a variety of simple approaches can be used successfully, and wherever either of the solvents methanol or acetonitrile has been used, it may certainly be substituted by the other. The successful synthesis of the neutral grids depends on the facile deprotonation of the coordinated acylhydrazone, and although no direct measurements of the acidity constants of the coordinated acylhydrazones used here have been made, triethylamine, in various solvents including water, sufficed to completely deprotonate ligands $\mathbf{1}H_2$ and $\mathbf{3}H_2$–$\mathbf{7}H_2$ when bound to first-row transition-metal(II) ions, indicating that the bound ligands are significantly stronger acids than the triethylammonium ion. This deduction is supported by the fact that the use of $^1$H NMR to monitor the titration of 1:1 mixtures of $Zn^{II}$ and various ligands with triethylamine showed shifts of the triethylamine protons consistent with complete protonation up to the point of addition of a full two equivalents of the base. Independent measurements[32] on water-soluble grids formed by pyrimidinedicarbaldehyde bis(acylhydrazone) derivatives indicate that the first ligand proton is quite acidic, and that the second is removed at pH ≈ 7.

### 4. Crystal Structures of Acylhydrazone Complexes

Basic crystallographic data for all the complexes presently studied are summarised in Table 2, Table 3 and Table 4. Disorder associated with lattice solvent molecules, grid substituents and (in some cases) anions was a common problem, and not all the structures are of equivalent quality. In all cases, however, the nature of the metal aggregate has been established with certainty. Not all crystals obtained proved suitable for an X-ray structure determination, so that the following discussion is presented more in terms of identified grid types than in terms of the systematic variation of the ligands and metals, though certainly some ligand and metal effects are taken into consideration.

#### *(a) Complexes of the Non-Deprotonated Ligands*

##### *(i) $[Ni_4(4H_2)_4](ClO_4)_8$*

The reaction between acetonitrile-solvated $Ni^{II}$ perchlorate and ligand $\mathbf{4}H_2$ (R = $C_6H_5$) in nitromethane provides a crystalline complex which may be formulated on the basis of its structure determination as $[Ni_4(\mathbf{4}H_2)_4](ClO_4)_8 \cdot 8H_2O \cdot 4CH_3NO_2$. (Elemental analysis of the dried bulk material is consistent with a formulation in which only one molecule of nitromethane of solvation is present.) The cation present in the lattice (Figure 8) is a 2×2 grid species of a form very similar to those formed with neutral hydrazone ligands[8,18,33] and remarkably similar to grids formed by the deprotonated acylhydrazones described below. It is thus a useful reference point for the whole of the present discussion.

As viewed perpendicular to the mean plane of the $Ni_4$ unit, it appears that this unit is very close to a square, but in fact there is a significant distortion towards a "butterfly" form reflected in the fact that the centroids of the two Ni···Ni diagonals are separated by 0.685 Å. This can be seen largely as a consequence of the fact that the metal–donor-atom array for a given ligand unit does not have the idealised geometry[34] shown in Figure 6, but instead is such

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

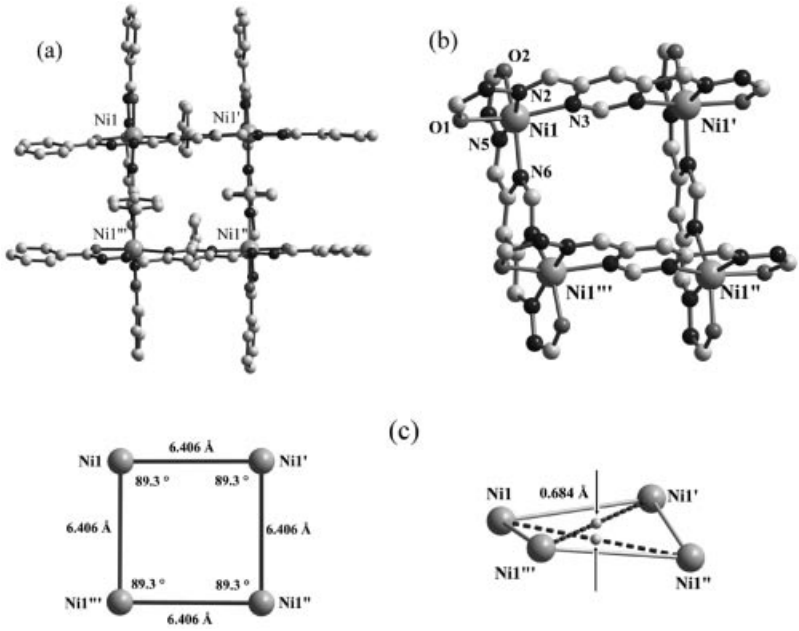

Figure 8. (a) A view of the full grid unit perpendicular to the $Ni_4$ plane and (b) a view of the grid in perspective, without phenyl substituents, to show the metal ion coordination; (c) aspects of the geometry of the $Ni_4$ unit.

that the Ni–N(hydrazide) vectors are slightly inclined to one another (here at 15°). This can be accommodated and allows six-coordination of the metal (by binding of a second ligand) by displacing two metal atoms in the same direction out of the idealised square which would be formed if the incline was 0°. As will be seen in considering other grids (see ahead), however, this is perhaps not the only factor of influence (Figure 9).

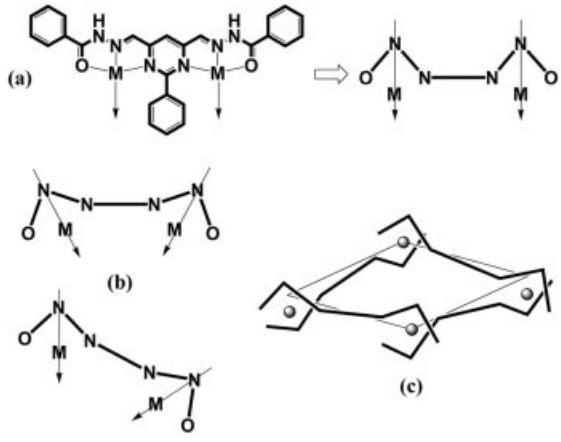

Figure 9. (a) An idealised structural representation of a metal-bound ditopic acylhydrazone and its schematic equivalent, showing parallel orientation of the M–N(hydrazide) vectors. (b) Schematic representations, with exaggerated inclination, of an actual metal-bound ditopic acylhydrazone, shown both in a form where the M···M vector is horizontal and where the O···N(inner) vector is horizontal. (c) Schematic representation of a grid formed by a real acylhydrazone, the metal atoms (grey spheres) located relative to a perfect square.

$Ni^{II}$-donor atom bond lengths (Table 1) reflect the expected weaker donor ability of the pyrimidine-*N* atom relative to the hydrazide-*N* atom, and C–N and C–O bond lengths within the hydrazide unit indicate significant delocalisation and hence an enhanced donor ability of the hydrazide-*O* atom relative to a simple carbonyl-*O* atom. While it is conceivable that the bound ligand is in fact deprotonated and that $H_3O^+$ and not $H_2O$ is present in the lattice, each uncoordinated hydrazide-*N* atom has a short contact to oxygen (ca. 2.7–3.2 Å), suggesting that it is indeed protonated, nevertheless involved in strong hydrogen bonding. The oxygen atoms involved in these contacts, interestingly, are those of perchlorate anions and not of water molecules. Unfortunately, the quality of the structure (from a twinned crystal) and disorder of both perchlorate and water entities militate against a detailed analysis of the hydrogen bonding.

When viewed down *a*, for example, the lattice can be considered to be made up of layers of cations, water and some of the perchlorate anions, alternating with layers of perchlorate anions and water. Thus, direct interactions between grid units do not give rise to a three-dimensional array, but within the sheets of cations (parallel to the *ab* plane), there is an interlocking of grid units as a result of face-to-face interactions of the terminal phenyl rings (any edge-to-face contacts being very remote). Note that, as in several analogous hydrazone complexes, each phenyl group attached to a pyrimidine ring lies within the grid and is parallel to two flanking ligand units at a distance of ca. 3.5 Å, suggesting its involvement in intramolecular stacking. The phenyl group loses its plane of symmetry perpendicular to the ring plane, so that the two *ortho* and the two *meta* protons are nonequivalent, as also seen in the solution NMR spectra of certain other complexes.[30]

Though various $Ni^{II}$ salts react with ligand $\mathbf{4}H_2$ to give isolable red complexes, not all of which prove to contain the undeprotonated ligand, with most of the other metal ions studied this is not so, and the free ligand is the material

preferentially precipitated from nearly all solutions containing equimolar amounts of $Mn^{II}$, $Fe^{II}$, $Co^{II}$ and $Zn^{II}$. With $Cu^{II}$, there is obviously complexation, but the product appears to undergo slow decomposition and no crystals suitable for structure determination were isolated. With $Zn^{II}$, a method was finally found to isolate a crystalline complex, and its structure provides an intriguing contrast with that of the $Ni^{II}$ complex described above.

### *(ii) $Zn^{II}$ Complex of $4H_2$*

The $Zn(BF_4)_2$ complex of $\mathbf{4}H_2$ may be formulated as $[Zn_8(E,E\text{-}\mathbf{4}H_2)_4(Z,Z\text{-}\mathbf{4}H_2)_4(OH_2)_2(CH_3CN)_2(BF_4)_2](BF_4)_{14}\cdot 7C_6H_6\cdot 3CH_3CN\cdot 3H_2O$. The stoichiometric unit (Figure 10) is a double grid, tetrafluoroborate anions serving as the links between two identical $Zn_4$ grid units. The grids, however, are very different from those seen in the $Ni^{II}$ complex, in that the $Zn_4$ are of a rectangular, and not square, shape each being very close to planar and involving pairs of $\mathbf{4}H_2$ in their (*E*,*E*) and (*Z*,*Z*) forms. Each metal ion is thus bound to one site of an (*E*,*E*) ligand and one site of a (*Z*,*Z*) ligand, and it is because the latter site is only didentate that the Zn centres achieve six-coordination by binding either monodentate ($H_2O$, $CH_3CN$) or bridging didentate ($[BF_4]^-$) co-ligands. (This observation raises interesting prospects for rearrangements of complexes of the ligands by changes in the oxidation state of a metal, for example, Cu, where the different oxidation states have different preferred coordination geometry.) The combination of convergent, tridentate donor sites on one ligand (*E*,*E*) with divergent, didentate sites on the other (*Z*,*Z*) presumably explains the fact that the $Zn_4$ unit here is essentially planar. The $Zn^{II}$ centres bridged by the (*Z*,*Z*) ligand are quite remote (Figure 10), indicating that paramagnetic metal ions in the same structure would be unlikely to show significant magnetic interactions.

In its (*Z*,*Z*) form, the three phenyl groups of bound $\mathbf{4}H_2$ are placed in proximity, with similar orientations away from the coordinated metal sites. In the double $Zn_4$ array of the $Zn^{II}$ complex, this means that the upper and lower surfaces parallel to the $Zn_4$ planes consist essentially of arrays of phenyl groups, since it is the (*Z*,*Z*) ligands which form the exterior faces. Unsurprisingly, there is strong interpenetration of these arrays from different double-grid units, which is consistent with the fact that π-stacking plays a significant role in the lattice assembly. Though the (*E*,*E*) ligands appear less accessible for intermolecular contacts, the fact that, in this configuration, the terminal phenyl groups project laterally rather than axially allows significant "slipped" overlap between staggered arrays of one set of these ligands, while the other set has at most remote contacts between the terminal carbon atoms but is involved in stacking with the lattice benzene molecules. The lattice water and acetonitrile molecules, as well as the $[BF_4]^-$ anions, are involved also in various contacts between themselves and with aromatic rings, so that the full gamut of weak forces appearing to be operative is highly complicated.

Although its crystal structure has not been determined, it is worth noting that a 2:1 complex of $\mathbf{4}H_2$, $Zn_2(\mathbf{4}H_2)(CF_3SO_3)_4\cdot 2H_2O\cdot CH_3CN$, is readily isolated. While it is perhaps surprising that the binding of two cations does not lead to facile acid dissociation of the ligand, it may be that repulsion between the cationic centres is relieved by adopt-

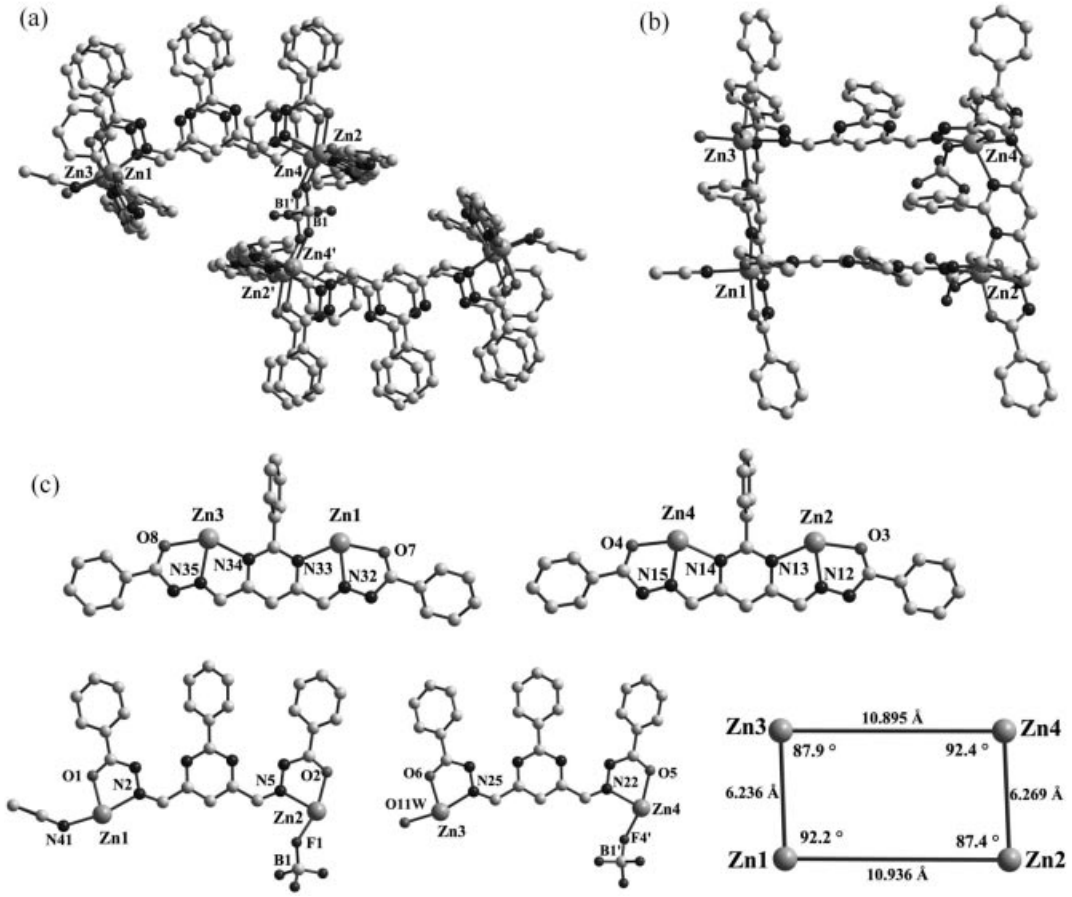

Figure 10. (a) A view of the "double-grid" unit and (b) an approximately orthogonal view of one rectangular grid; (c) geometry of the $Zn_4$ unit and views, perpendicular to the mean plane of the pyrimidine ring, of the two types of ligand unit [lower: (*Z*,*Z*); upper: (*E*,*E*)] found in each rectangle.

ing the (*E*,*E*) configuration seen in the 1:1 complex and which places the two metals at positions quite remote from one another, thus minimising the effect of the second metal on the hydrazide NH proton influenced more closely by the first metal.

### *(b) Complexes Containing Partly Deprotonated Ligands*

#### *(i) $[Co_4(\mathbf{4}H)_4](BF_4)_4$*

While rational syntheses based on monodeprotonation of the acylhydrazones are presumably possible, the first complex of this type was isolated from a reaction medium (involving ligand $\mathbf{4}H_2$) to which no base was deliberately added, a result which parallels those concerning several thioacylhydrazone analogues,[19] although it has proved difficult to reproduce. Under conditions of formally correct stoichiometry, it appears to be the complex $[Co_4(\mathbf{4})_2(\mathbf{4}H)_2](BF_4)_2$ which precipitates. The crystal selected from the initial preparation was characterised by a single-crystal X-ray diffraction study, from which the composition $[Co_4(\mathbf{4}H)_4](BF_4)_4{\cdot}7CH_3CN$ was deduced, as well as the presence of a quadruply charged $[2\times2]Co_4^{II}$ grid species (Figure 11), very similar in form, including the "butterfly" nature of the $M_4$ unit, to that seen in the complex $[Ni_4(\mathbf{4}H_2)_4](ClO_4)_8{\cdot}8H_2O{\cdot}4CH_3NO_2$ (Figure 8). While the structure is somewhat more complicated to analyse than those of related neutral $M^{II}$ complex species incorporating fully deprotonated ligands, there are some remarkable similarities between them all (see ahead). Assuming the residual proton of $\mathbf{4}H^-$ to be localised on one N-centre, isomeric forms of the grid are possible, and thus it is unfortunate that NH protons were not located in the structure solution. However, a view of the cationic grid unit shows that each ligand unit is unsymmetrical, with a significant but different twisting distortion of one hydrazide entity on each, so that the idealised isomeric form is that of $S_4$ symmetry shown also in Figure 11. The actual symmetry of the lattice is such that the grid units have no symmetry and thus all four Co atoms are nonequivalent. In agreement with the fact that the bent ends of the ligands are the sites of protonation, the Co–O bond lengths (Table 1) are greater than those for the less distorted units, though comparison (ahead) with data for fully deprotonated complexes of $Co^{II}$ indicates that the overall effect of protonation/deprotonation on bond lengths is quite slight and may not be simply related to differences in the formal charge assigned to the donor atoms. Further-

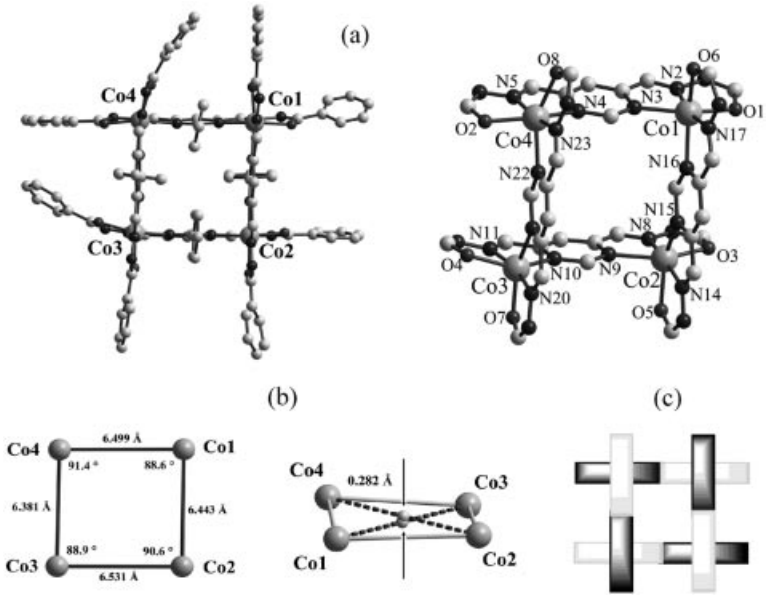

Figure 11. (a) Approximately orthogonal views of the grid unit present in $[Co_4(\mathbf{4}H)_4](BF_4)_4 \cdot 7CH_3CN$; (b) aspects of the geometry of the $Co_4$ unit and (c) the idealised representation of the grid in terms of ligand units that are unsymmetrical because of partial deprotonation.

more, given that force constants for bond stretching and bending for light elements considerably exceed those for transition-metal–donor-atom bonds,[33] it is reasonable that it is the ligand which imposes nearly a fixed coordination geometry on the metal.

A feature of the lattice of $[Co_4(\mathbf{4}H)_4](BF_4)_4 \cdot 7CH_3CN$, which is not found in that of $[Ni_4(\mathbf{4}H_2)_4](ClO_4)_8 \cdot 8H_2O \cdot 4CH_3NO_2$ presumably because of the need to accommodate a greater number of anions, is the three-dimensionality of the interactions between grids, a feature rather commonly observed in neutral grids. Every grid in the lattice of $[Co_4(\mathbf{4}H)_4](BF_4)_4 \cdot 7CH_3CN$ can be considered to be surrounded tetrahedrally by four others in a way which involves a kind of "slipped stacking" of pairs of hydrazone ligands from separate grids, so that every (grid)$(grid)_4$ unit has idealised $S_4$ symmetry (Figure 12). This extended tetrahedral interlocking of grids gives rise to a lattice which, when viewed down *c*, for example, appears to consist of columns composed of grids in alternating, inverted pairs separated by channels into which protrude the "bent" ends of the ligands and which contain partially disordered $[BF_4]^-$ anions and acetonitrile solvent as well. Some anions and solvents can also be considered to be located within the grid columns, and in both environments there are numerous contacts to aromatic entities.

### *(ii)* $[Ni_4(\mathbf{4})_{2.5}(\mathbf{4}H)_{1.5}](NO_3)_{1.5} \cdot CH_3OH \cdot 0.5(C_2H_5)_2O$

The isolation of a complex of a deprotonated thiohydrazone ligand by use of the metal nitrate in methanol has been suggested[19d] to be a consequence of the consumption of acid by a (metal-catalysed) reduction of nitrate by the solvent. Though this seems less likely for acetonitrile, the

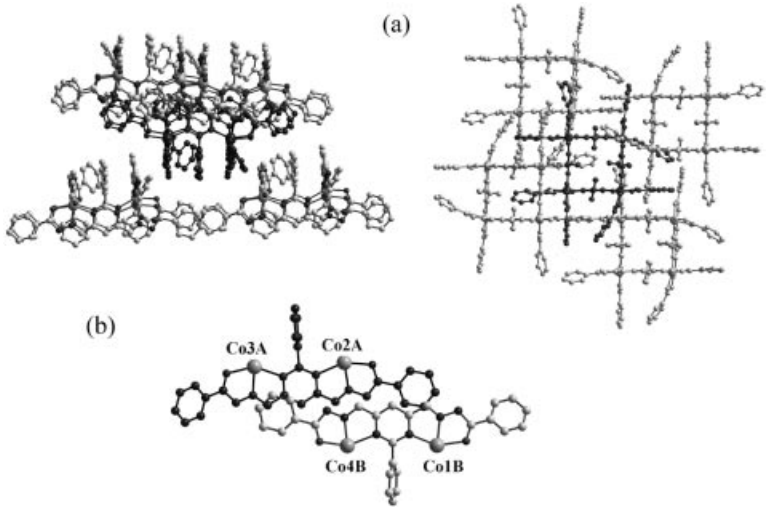

Figure 12. (a) Orthogonal views of a grid unit (atoms in black) and its environment of four other grids; (b) atom contacts within the proximal ligand units of separate grids.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

presently isolated complex of ligand $\mathbf{4}H_2$ with $Ni(NO_3)_2$ was recrystallised from methanol, and both needle and plate-like crystals were apparent in the product mass. As with the $Co^{II}$ complex above, analysis of the bulk product corresponded to a composition, $[Ni_4(\mathbf{4})(\mathbf{4}H)_3](NO_3)_3$, which is different from that deduced from solution of the crystal structure for a selected plate-like crystal. Perhaps the simplest explanation of all the present results, including the isolation of true complexes of the uncharged ligands from the most (Brønsted) acidic solvent, nitromethane, is that coordination of the ligand results in partial dissociation and the formation of multiple species related by proton loss in solution, and various species precipitate, depending upon subtle aspects of lattice interactions. The solid-state structure of the material, which was assigned the composition $[Ni_4(\mathbf{4})_{2.5}(\mathbf{4}H)_{1.5}](NO_3)_{1.5}\cdot CH_3OH\cdot 0.5(C_2H_5)_2O$ (presumably indicating it to be a mixture of different protonated forms) on the basis of its structure solution, shows various similarities to that of $[Co_4(\mathbf{4}H)_4](BF_4)_4\cdot 7CH_3CN$, including the bending of a terminal phenyl group unit (Figure 13) and the tetrahedral coordination of one grid unit by four others involving close contacts of atoms within parallel ligand planes of separate grids. Perhaps in reflection of the higher degree of ligand deprotonation, the $Ni_4$ unit is closer to a true square than that in the complex of the undeprotonated ligand.

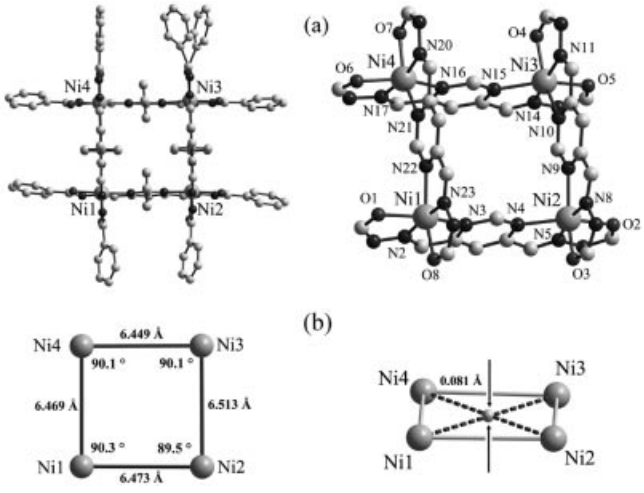

Figure 13. (a) Orthogonal views of the cationic grid unit in$[Ni_4(\mathbf{4})_{2.5}(\mathbf{4}H)_{1.5}](NO_3)_{1.5}$; (b) aspects of the geometry of the $Ni_4$ unit of the grid.

### *(c) Complexes of the Doubly Deprotonated Ligands*

Structural studies within the group of ligands presently described have been limited to the $Co^{II}$, $Ni^{II}$ and $Zn^{II}$ complexes of ligand $\mathbf{1}H_2$ and the $Fe^{II}$, $Co^{II}$, $Ni^{II}$, $Cu^{II}$ and $Zn^{II}$ complexes of ligand $\mathbf{3}H_2$. All are confirmed to be [2×2] grids, but significant variations in both the grid core and the lattice interactions are seen.

*Neutral Grids of Ligand* $\mathbf{1}^{2-}$

A common feature of the Co, Ni and Zn complexes of $\mathbf{1}^{2-}$ is the high degree of hydration of the solids.

*(i) [$Co_4(\mathbf{1})_4$] Complex:* From the structure determination, the $Co^{II}$ complex is formulated as $[Co_4(\mathbf{1})_4]\cdot 8CH_3OH\cdot 16H_2O$ and contains a familiar grid unit with a butterfly-form $Co_4$ aggregate and with Co–N and Co–O bond lengths all very similar on average to those of $[Co_4(\mathbf{4}H)_4](BF_4)_4\cdot 7CH_3CN$. There is also a similarity to this complex in that the lattice can be regarded as involving tetrahedrally connected grid units, though the slipped stacking observed here is associated also with bridging of grids by water molecules forming hydrogen bonds to hydrazide-*N* and acetyl-*O* atoms of essentially orthogonal ligands of adjacent grids. Disorder in the solvent molecule array makes any detailed interpretation of its nature difficult, but it is clear that hydrogen bonding plays a major role in the assembly of the lattice.

*(ii) [$Ni_4(\mathbf{1})_4$] Complex:* The structure of $[Ni_4(\mathbf{1})_4]\cdot \approx 18H_2O$ (Figure 14) displays several significant differences from that of the Co complex, which may be to some extent dependent upon their differences in solvation, although the grid unit is overall very similar, despite the twofold and not fourfold symmetry associated with its different space group. The distortion of the $Ni_4$ unit from planarity, as measured by the distance between the centroids of the diagonals (0.216 Å vs. 0.925 Å for the Co species) is considerably smaller, and this is associated with a packing of the grid units which reflects their twofold symmetry in that although each grid is surrounded by four others in an essentially tetrahedral array (involving, once again, "slipped stacking" of parallel ligand units), two neighbours are slightly more remote than the others, so that the lattice, when viewed down *a*, has the appearance of being built up from staggered double-layers of grids. Despite its partial disorder, the water molecule array clearly involves hydrogen bonding to all the hydrazide-*N* and acetyl-*O* atoms of every grid as well as water–water interactions (Figure 15), forming chains that link the grids additionally to any stacking, and perhaps it is the importance of this extensive set of interactions that results in the distortion of the intergrid stacking (relative to that in the Co complex). Another possible consequence is

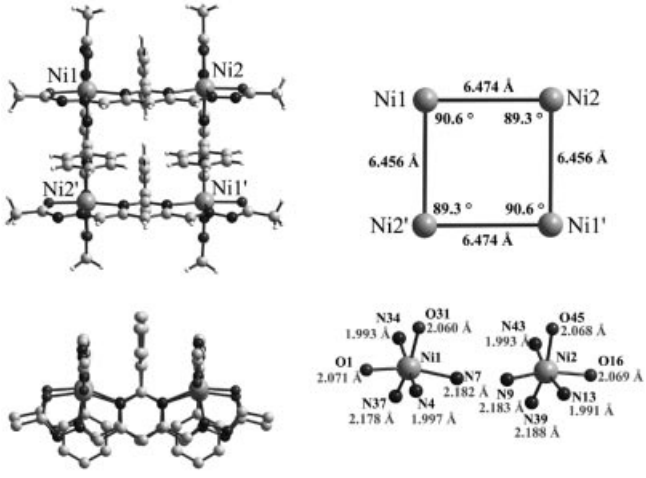

Figure 14. Structure and geometry of the grid unit present in $[Ni_4(\mathbf{1})_4]\cdot \approx 18H_2O$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the fact that grids lying along the columns seen end-on down *a* are now close enough for contacts to occur between the acetyl-$CH_3$ groups and the acetyl-*O* atoms (C···O 3.66 Å). (For coplanar grid units of the Co structure, these atoms are >4 Å apart.) Other adjacent grids in the Ni complex have acetyl-$CH_3$/acetyl-$CH_3$ and acetyl-$CH_3$/phenyl-*C* contacts of also ca. 3.7 Å.

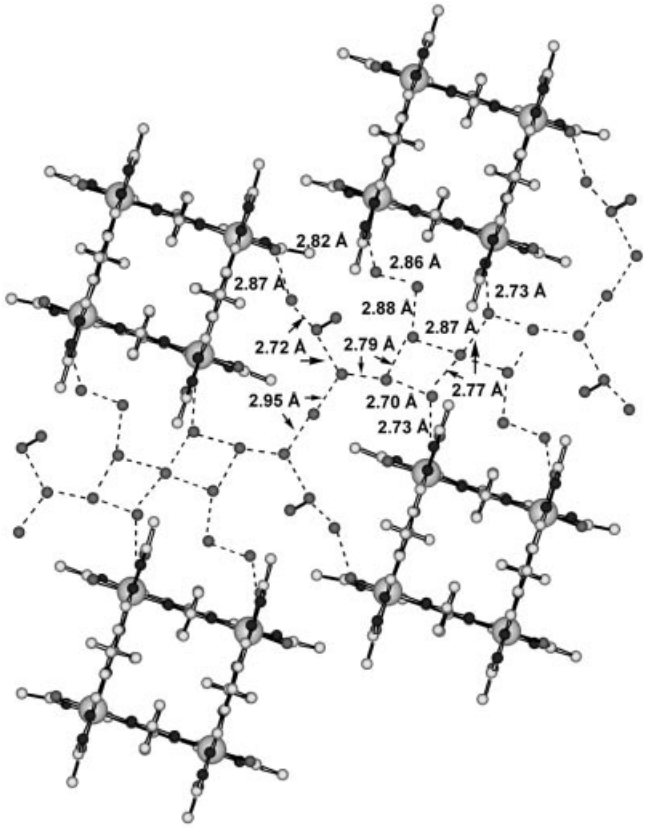

Figure 15. A partial view of the hydrogen bond network present in $[Ni_4(\mathbf{1})_4]\cdot\approx 18H_2O$.

*(iii) [$Zn_4(\mathbf{1})_4$] Complex*: The structure of $[Zn_4(\mathbf{1})_4]\cdot\approx 18H_2O$ is practically isostructural with that of its Ni analogue. Metal–donor-atom bonds are slightly longer to $Zn^{II}$ than to $Ni^{II}$, but the distortion of the $Zn_4$ unit from planarity (diagonal centroid separation 0.191 Å) is marginally smaller. Evidence for intergrid interactions is the same, so that again it appears that hydrogen bonding to the apolar grid is an important interaction.

### *Neutral Grids of Ligand $\mathbf{3}^{2-}$*

Complexes of the ligand $\mathbf{3}^{2-}$ make up the most nearly complete series of metallogrid complexes structurally characterised. All five metals (Fe, Co, Ni, Cu, Zn) studied form the expected $[2\times2]M_4^{II}$ grids, but with some significant differences in structure both within the series and between their analogues in the series formed by $\mathbf{1}^{2-}$. Introduction of a $C_7H_{15}$ "tail" in $\mathbf{3}^{2-}$ in place of the methyl group of $\mathbf{1}^{2-}$ leads to a much lower degree of hydration of the $[M_4(\mathbf{3})_4]$ series, where either tetra- (Fe, Co, Ni) or di- (Cu, Zn) hydrates are formed. The retained water molecules act in isolation to form bridges, again involving hydrazide-*N* and acyl-*O* acceptors, between grids. Across the $[M_4(\mathbf{3})_4]$ series, there is remarkably little variation in M–O and M–N(pyrimidine) distances ($Cu^{II}$ excepted – see below) and only the M–N(hydrazide) bond lengths show the variations expected on the basis of changes in effective nuclear charge across the transition-metal group. For the Co, Ni and Zn complexes of $\mathbf{3}^{2-}$ and $\mathbf{1}^{2-}$, there are no significant differences in analogous M–O and M–N bond lengths, but considerable differences are found in the distortions of the $M_4$ units from planarity. Thus, in all $[M_4(\mathbf{3})_4]$ complexes, the diagonal–centroid separations are ca. 1 Å and do not diminish dramatically across the series, as seems to be the case for the $\mathbf{1}^{2-}$ complexes. The origins of this difference are obscure, especially given that despite such an "internal" difference, "externally" all the grids (from both ligands) display similar properties in that they form very similar lattices (space group differences accommodated). A particular common feature is the tetrahedral coordination of any one grid by four others, associated in all cases with a seeming stacking of ligand units and, given its persistence, indicating that, whatever the nature of the interactions giving rise to these contacts, they are an important means of association of acylhydrazone grids.

The $Fe^{II}$, $Co^{II}$ and $Ni^{II}$ complexes of ligand $\mathbf{3}^{2-}$ are isostructural, while the analogous $Zn^{II}$ complex crystallises in a cell of lower symmetry associated with a lower degree of hydration. Useful for more detailed consideration of the $[M_4(\mathbf{3})_4]$ structures is the form of $[Cu_4(\mathbf{3})_4]\cdot 2H_2O$, which, although unique as a structurally characterised grid, provides a lattice that may be considered to be the "Rosetta Stone" for the interpretation of all the present structures. In the molecular grid unit $[Cu_4\mathbf{3}_4]$ (Figure 16), several features of the geometry differ markedly from those of the Co, Ni and Zn grids. One that does not is the geometry of the binding portion of the ligand, indicating that bond lengths and bond angles about the metals must be the primary means of adapting to any degree of metal–ligand misfit. Thus, for a ligand intended to generate grids with octahedral units by coordinating metal ions, it is unsurprising, given the well-known tendency of $Cu^{II}$ to adopt strongly tetragonally distorted octahedral geometry (and generally to readily lose one or two of its six ligands), to find that the $Cu^{II}$ coordination geometry in the present complex is very irregular (Figure 17), involving in particular considerable variation (up to ca. 0.4 Å) in the Cu–N(pyrimidine) distances.

As discussed earlier, the outer donor atoms of a given tritopic site cannot generally lie at the same distance from the metal as the central donor while also giving bond angles of π/2. Thus, distortion of some kind is inherent in grid formation, and it is certainly well-known that it can become very marked in grids larger than the [2×2] type.[8,33,35] Hence, the form of the Cu grid here may express the way in which any grid must tend to distort in order to achieve the most efficient coordination of the ligand. While all the

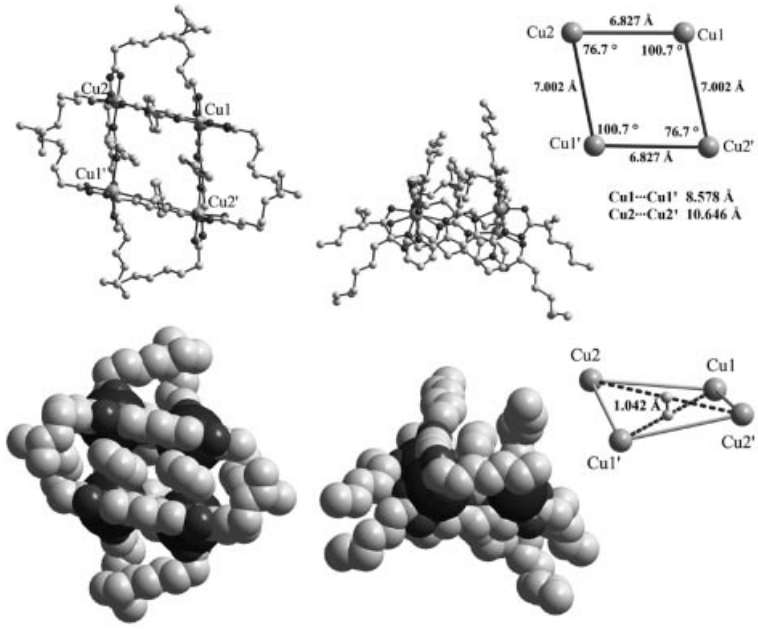

Figure 16. Views and various features of the geometry of the grid unit present in the lattice of $[Cu_4\mathbf{3}_4]\cdot 2H_2O$. The projection of the $Cu_4$ unit is given with Cu(1)···Cu(1′) along *x* and Cu(2)···Cu(2′) along *y*, although the two axes are not coplanar.

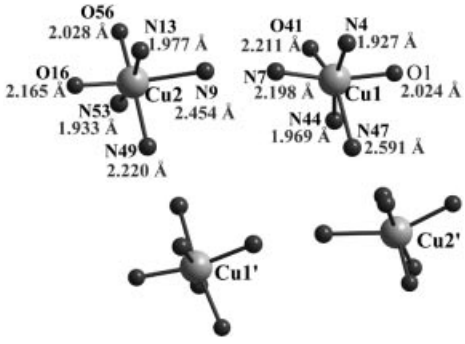

Figure 17. Donor atom distribution about the $Cu^{II}$ centres of a grid unit.

grids formed by the $C_7$-functionalised ligand involve a "butterfly" form of the $M_4$ unit, with $Cu^{II}$ this is associated also with a marked "extrusion" (Figure 16), which results in very different diagonal Cu···Cu distances (possibly influencing magnetic properties, for example). Significantly, however, even with $Cu^{II}$, there is no change in the system which is great enough to result in an apparent change in the form of the metal–ligand aggregate formed.

Thus, outside the grid units, the lattice of $[Cu_4\mathbf{3}_4]\cdot 2H_2O$ is of very similar appearance (Figure 18) to those of the other metal complexes; kinked $C_7$ substituents occupy the space between grids, each of which is surrounded tetrahedrally by four other grids. (The alkyl chain conformations differ, but this presumably corresponds to a very small energy difference.) The specific location and quantity of the lattice water in the $Cu^{II}$ complex, however, may be associated with the distorted form of the $Cu_4$ grid. It is apparent (Figure 19) that the water molecules lie essentially within the columns of grids which run parallel to *c* and they are in fact not in positions where they can bridge grids lying in separate columns, as is the case in the Co compound lattice, for example. Thus, hydrogen bond bridging of grids (Figure 20) occurs in one dimension only (i.e. along *c*), where it

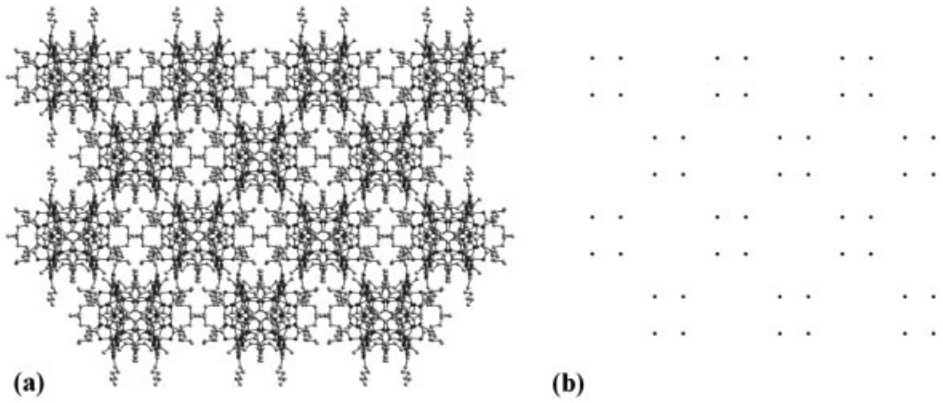

Figure 19. Partial views of the lattice of $[Cu_4\mathbf{3}_4]\cdot 2H_2O$ (down *c*) showing (a) all atoms and (b) water molecule oxygen atoms only.

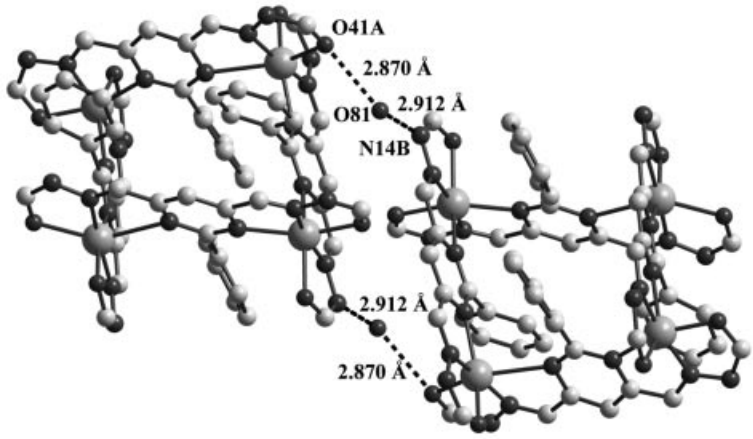

Figure 20. Adjacent $Cu_4$ grids with their shorter edges at the closest position, showing water molecules that form bridges between the two grids.

brings the shorter edges of the grid units into proximity. Longer edge pairs are also present, but their proximity does not seem to be directly assisted by hydrogen bonding. Perhaps the length of the edges keeps hydrogen-bond-acceptor sites too remote to be efficiently bridged by a single water molecule, while "aromatic–aromatic" contacts are maintained (Figure 21), which is perhaps again consistent with their provision of a more important contribution to the lattice energy and structure.

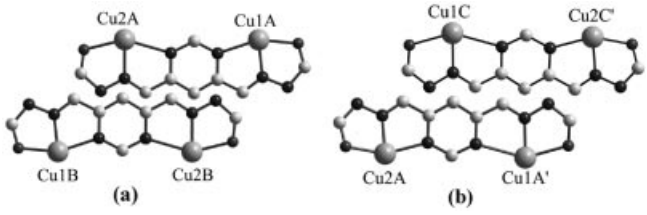

Figure 21. Atom contacts of 3.6 Å or less between ligand atoms in (a) the shorter edges of two adjacent grids and (b) the longer edges of two adjacent grids.

### *(d) Properties of the Grid Complexes*

Crucial to the extension of the chemistry of bis(acylhydrazone) ligands presently studied is the knowledge of the exact conditions under which metallogrid species are stable. Clearly, the several crystal structures obtained here inspire confidence in the belief that in the solid state, certainly with doubly deprotonated ligands, grid species are present. In solution, the situation is less certain in general, although NMR spectroscopy of $Zn^{II}$ complexes again indicates the presence of grids (at $[Zn^{II}] \approx 10^{-3}$ mol L$^{-1}$) only when the ligands are doubly deprotonated. Nonetheless, most of the neutral grid complexes can be subjected to adsorption (silica) chromatography without decomposition, indicating that all of them retain at least the grid stoichiometry in solution (in solvents such as dichloromethane containing ca. 10% methanol). The most direct evidence of the form of paramagnetic species in solution, particularly that of those for which crystal structures have not been obtained, is provided by MALDI-TOF mass spectrometry, though of course this establishes most directly the stoichiometry and not the structure. Here, in a relatively strongly coordinating solvent like tetrahydrofuran, there is evidence that the grids begin to undergo extensive dissociation at concentrations below $10^{-4}$ mol L$^{-1}$.

In regard to possible applications, the properties of grid complexes of importance include not only their redox, elec-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tronic and magnetic behaviour,[8] but also the supramolecular chemistry which may be mediated by their substituents. The crystal structures reported here show that, despite their symmetrical and thus apolar nature, neutral grids derived from acylhydrazones are good hydrogen bond acceptors, in view of the presence of charged sites in the deprotonated ligands, and are prone to stacking interactions involving the delocalised ligand entities. Differing substituents derived from the acid hydrazide moieties have a marked influence on the interactions of the grids with the medium, viz. upon their solubility, and in the particular case of the grid derived from methoxyethoxyacetohydrazide, the detection of $Na^+$ adducts by mass spectrometry indicates that metal ion coordination by appropriate side chains is possible.

Different transition-metal ions must endow their grids with different redox, spectroscopic and magnetic properties, and while detailed studies of the magnetism of the complexes are still in progress, $^1$H NMR spectroscopy shows that the $Fe^{II}$ complexes are in mixed-spin states at room temperature (in solution). Fluorescence apparent for the $Zn^{II}$ grids is quenched in all the open-shell transition-metal ion grids, though the exact mechanism of deactivation is yet to be established. All the grids show strong absorption in the visible region, with features that vary not only with the metal, but also with the acyl-unit substituents. That the acylhydrazone-derived grids may show very different redox behaviour from the grids derived from pyridylhydrazones is indicated by the difficulty experienced in obtaining a $Co^{III}$ complex of the benzoylhydrazone $\mathbf{4}H_2$. While $Co^{II}$ complexes of pyridylhydrazones are very sensitive to atmospheric oxygen under basic conditions and readily give tetra-$Co^{III}$ grids,[8] the $Co^{II}$ complex of $\mathbf{4}^{2-}$ is insensitive to oxygen or hydrogen peroxide, and appears to undergo only partial oxidation by $Ce^{IV}$ to give a mixed-valence $Co^{III}$-$Co^{II}$ grid.

## Conclusions

The grid complexes presently characterised are related to but differ significantly from those derived from both bis(hydrazone)s of 2-phenylpyrimidine-4,6-dicarbaldehyde and thiocarbonylbis(hydrazone)s. Bis(acylhydrazone)s, as neutral ligands, appear to be poorer chelators than the analogous neutral bis(hydrazone)s, but they are more easily deprotonated, enhancing their donor properties and thus providing, with $M^{II}$ ions, a family of neutral grids with lateral substituents which may be very readily varied over a wide range. Compared to thiocarbonylbis(hydrazone)s, their metal-chelating sites are considerably more widely separated [especially in their (*Z*,*Z*) form], so that different electronic and magnetic interactions within the metal ion quartet of the grids are expected.

The present structural studies show that some aspects of grid geometry, in particular the distortion of the $M_4$ unit from planarity, are remarkably sensitive to minor variations in the ligand structure. The geometry of the chelating sites of the ligands, in contrast, is insensitive to both its substituents and to the bound metal ion, and it is clear that accommodation of the requirements of a grid array is largely achieved through the flexibility of the metal ion coordination environment. A feature of nearly all the grid lattices presently studied is the association of grid units in pseudo-tetrahedral arrays, where ligands of different grids lie parallel and with numerous atom contacts $< 3.5$ Å, which is presumably indicative of a type of stacking interaction. Another common feature is hydration of the formally apolar grid units through hydrazide-*N* and acyl-*O* hydrogen bond acceptor sites. Finally, a remarkable feature resides in the efficient self-assembly of the grid structures in the presence of a base directly from their organic components and the metal ions (see also ref.[22]).

## Experimental Section

**Reagents and Equipment:** Although a literature synthesis of 2-phenylpyrimidine-4,6-dicarbaldehyde exists,[24a] the compound was presently prepared by an adaptation of an alternative literature method for partial oxidation of azaaromatic methyl groups[24b] applied to 4,6-dimethyl-2-phenylpyrimidine[36] and developed by Dr. J.-L. Schmitt. The procedure is detailed below. 1-methyl-1-propionylhydrazine was obtained as described in the literature.[37] Acetohydrazide, benzohydrazide, 4-toluohydrazide and heptanohydrazide were obtained from Aldrich Chemicals and used as received. Methoxyacetyl- and methoxyethoxyacetyl chlorides were obtained commercially (Lancaster) and converted into the hydrazides by reaction with excess hydrazine. All solvents and chemicals used in the syntheses were reagent grade and were used without further purification or drying. Dimethyl sulfoxide (dmso) solvates of metal triflates and tetrafluoroborates used as reactants in various complex ion syntheses were prepared by precipitation (at least twice) of the (commercial) anhydrous or hydrated salts from dmso by the addition of ethanol/diethyl ether. For $[Cu(dmso)_6](CF_3SO_3)_2$, the presence of the hexakis(solvent) species in the solid was confirmed by a crystal structure determination.[38] $[Ni(CH_3CN)_6](ClO_4)_2$ was prepared as described in the literature.[39] Iron(II) ascorbate was purchased from Sigma Chemicals.

Solution $^1$H (400 MHz) and $^{13}$C (100 MHz) NMR spectra were recorded with a Bruker Ultrashield Avance 400 instrument, using residual solvent proton resonances as internal references for the $^1$H NMR spectra and the solvent $^{13}$C peaks as references for the $^{13}$C NMR spectra. The atom numbering used in assignments of the NMR peaks is shown in Figure 22. Mass spectra [MALDI-TOF and electrospray (ESMS)] were provided by the Service de Spectrometrie de Masse, Université Louis Pasteur. MALDI-TOF spectra of neutral grid species in all cases provided $[M + H]^+$ peaks. Elemental microanalyses (C,H,N) were provided by the Service d'Ana-

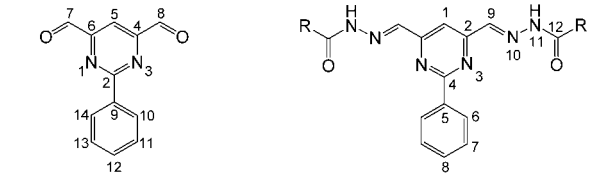

Figure 22. Atom numbering used in description of the NMR spectra.

lyses, Université Louis Pasteur, all samples being gently dried by storage in an unevacuated desiccator containing concentrated $H_2SO_4$ as desiccant for at least 3 d.

**Synthesis**

**(a) 2-Phenylpyrimidine-4,6-dicarbaldehyde:** A stirred solution of 4,6-dimethyl-2-phenylpyrimidine (5.08 g; 27.6 mmol), iodine (14.02 g; 53.2 mmol) and trifluoroacetic acid (8.0 mL; 103.8 mmol) in deoxygenated dmso (200 mL) was heated, under argon, at 150 °C for 135 min. After cooling to ambient temperature, further manipulations were conducted under the normal atmosphere. A solution of $Na_2S_2O_3{\cdot}5H_2O$ (31.6 g; 127.3 mmol) in water (100 mL) was added, causing discharge of the $I_2$ colour, after which the solution was neutralised by the addition of saturated $NaHCO_3$ solution. The product was extracted into $CH_2Cl_2$ ($6 \times 100$ mL) and the combined extracts dried with $MgSO_4$ before being taken to dryness in vacuo. The dmso remaining in the orange residue was removed by high-vacuum distillation, and the product was then crystallised from diethyl ether as pale yellow needles. Yield: 4.06 g (19.2 mmol, 80%). M.p. 123.5 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 10.18 (s, 2 H, 7,8-H), 8.60 (d, $^3J$ = 7.9 Hz, 2 H, 10,14-H), 8.12 (s, 1 H, 5-H), 7.58 (m, 3 H, 11,12,13-H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 192.13 (C-7,8), 166.76 (C-2), 160.25 (C-4,6), 135.50 (C-9), 128.60, 128.93 (C-10,14, C-11,13), 132.17 (C-12), 109.97 (C-5) ppm.

**(b) Bis(acylhydrazone)s of 2-Phenylpyrimidine-4,6-dicarbaldehyde, RCONR′N=CHC$_{10}$H$_6$N$_2$CH=NNR′COR**

**(i) R = CH$_3$, R′ = H (1H$_2$):** Solutions of 2-phenylpyrimidine-4,6-dicarbaldehyde (250 mg) in $CH_3CN$ (10 mL) and acetohydrazide (190 mg) in $CH_3CN$ (10 mL) were mixed to give a pale yellow solution. Within 30 s, the solution became turbid, and after 5 min, formation of a granular but not obviously crystalline pale yellow precipitate was extensive. After 12 h, the well-settled precipitate was separated from the colourless supernatant, washed with $CH_3CN$ and diethyl ether, and dried in vacuo. Yield: 280 mg (80%). $C_{16}H_{16}N_6O_2{\cdot}^1/_4H_2O$ (327.85): calcd. C 58.51, H 4.99, N 25.63; found C 58.7, H 4.85, N 25.2%. M.p. > 310 °C (decomp.). $^1$H NMR ([D$_6$]dmso): $\delta$ = 11.93, 11.91, 11.83 (NH), 8.41 (m, br), 8.24, 8.20, 8.17, 8.10, 8.09, 8.07, 8.05, 7.57, 2.28, 2.27, 2.04 ppm. $^{13}$C NMR ([D$_6$]dmso): $\delta$ = 172.5, 172.4, 166.3, 166.2, 163.8, 161.2, 160.8, 143.9, 143.4, 141.1, 140.6, 136.4, 131.1, 128.7, 127.8, 108.1, 107.8, 54.8, 21.7, 20.2, 19.9 ppm. ESMS: *m*/*z* (%) = 325.24 (100) [M + H]$^+$.

**(ii) R = C$_2$H$_5$, R′ CH$_3$ (2):** 2-Phenylpyrimidine-4,6-dicarbaldehyde (421 mg) and 1-methyl-1-propionylhydrazine (405 mg) were dissolved in ethanol (35 mL), and the solution was stirred at room temperature for 24 h as a yellow precipitate formed. The precipitate was collected, washed with ethanol and dried under vacuum. Yield: 443 mg (59%). The compound was recrystallised from $CHCl_3$ by addition of $CH_3CN$. M.p. 231–232 °C. $^1$H NMR ($CDCl_3$): $\delta$ = 8.49–8.46 (m, 2 H), 8.24 (s, 1 H), 7.77 (s, 2 H), 7.51–7.50 (m, 3 H), 2.93 (q, $J$ = 7.6 Hz, 4 H), 1.25 (t, $J$ = 7.6 Hz, 6 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 176.2, 165.3, 161.7, 137.2, 137.1, 131.3, 128.9, 128.5, 108.3, 28.5, 27.2, 9.6 ppm. ESMS: *m*/*z* (%) = 381.30 (100) {[M + H]$^+$ = [$C_{20}H_{24}N_6O_2$ + H]$^+$}.

**(iii) R = C$_7$H$_{15}$, R′ = H (3H$_2$):** Essentially the same procedure as described for the synthesis of **1**H$_2$ was followed, except that ethanol (20 mL) was used as solvent in the reaction of 2-phenylpyrimidine-4,6-dicarbaldehyde (273 mg) and heptanohydrazide (469 mg), the acylhydrazone precipitating as an almost white solid. Yield: 478 mg (75%). The compound was recrystallised from boiling acetonitrile (or methanol) by cooling on ice. $C_{28}H_{40}N_6O_2$ (492.66): calcd. C 68.26, H 8.18, N 17.06; found C 68.6, H 8.10, N 17.1%. M.p. 225–227 °C. $^1$H NMR ([D$_6$]dmso): $\delta$ = 11.85 (br., 2 H), 8.43 (m, 2 H), 8.25 (m, 1 H), 8.09 (m, 2 H), 7.58 (br. m, 3 H), 2.68 (m, 2 H), 2.31 (m, 2 H), 1.63 (m, 4 H), 1.32 (m, 16 H), 0.86 (m, 6 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 174.8, 169.3, 163.9, 161.3, 160.9, 143.9, 143.6, 141.0, 140.5, 136.5, 131.2 128.7, 127.8, 108.2, 107.3, 34.3, 31.8, 31.2, 28.8, 28.7, 28.5, 28.4, 24.8, 24.2, 24.0, 22.1, 13.9$_2$,13.8$_8$ ppm. ESMS: *m*/*z* (%) = 492.30 (100) [M + H]$^+$.

**(iv) R = C$_6$H$_5$, R′ = H (4H$_2$):** Solutions of 2-phenylpyrimidine-4,6-dicarbaldehyde (50 mg) in $CH_3CN$ (3 mL) and benzohydrazide (64 mg) in $CH_3CN$ (2 mL) were mixed to give a pale yellow solution. Within 2 min, deposition of pale yellow, globular material commenced, and, on continued standing, this material transformed into clusters of pale yellow needles. After 12 h, the solid was collected, washed with $CH_3CN$ and dried in air. Yield: 98 mg (93%). Use of methanol as a solvent gave essentially the same result, though initiation of the precipitation was slower (ca. 30 min). The compound was recrystallised from pyridine by addition of acetonitrile. $C_{26}H_{20}N_6O_2{\cdot}^1/_2H_2O$ (457.49): calcd. C 68.26, H 4.63, N 18.37; found C 68.4, H 4.74, N 18.1%. M.p. 286–287 °C. $^1$H NMR ([D$_6$]-dmso): $\delta$ = 12.40 (s, 2 H), 8.56 (s, 2 H), 8.45 (t, $^3J$ = 3.6 Hz, 2 H), 8.35 (s, 1 H), 7.98 (d, $^3J$ = 7.2 Hz, 4 H) 7.67–7.62 (m, 3 H), 7.62–7.53 (m, 6 H) ppm. $^{13}$C NMR ([D$_6$]dmso): $\delta$ = 164.0, 163.6, 161.3, 145.7, 136.5, 132.8, 132.3, 131.2, 128.8, 128.6, 127.9, 108.9 ppm. ESMS: *m*/*z* (%) = 449.10 (100) [M + H]$^+$.

**(v) R = 4-CH$_3$C$_6$H$_4$, R′ = H (5H$_2$):** The procedure used for ligand **3**H$_2$ was followed for the reaction of 2-phenylpyrimidine-4,6-dicarbaldehyde (223 mg) and toluohydrazide (331 mg), the acylhydrazone again precipitating as an almost white solid which was recrystallised from pyridine by addition of acetonitrile. Yield: 364 mg (73%). $C_{28}H_{24}N_6O_2$ (476.53): calcd. C 70.57, H 5.08, N 17.64; found C 70.5, H 4.69, N 17.6%. M.p. 287–288 °C. $^1$H NMR ([D$_6$]-dmso): $\delta$ = 14.59 (w), 12.39 (w), 12.34, 8.56, 8.46, 8.34, 8.22 (w), 8.21 (w), 7.90, 7.89, 7.81 (w), 7.79 (w), 7.59, 7.40, 7.38, 7.33 (w), 7.31 (w), 2.44 (w), 2.41 ppm. $^{13}$C NMR ([D$_6$]dmso): $\delta$ = 164.0, 163.4, 161.3, 158.2, 145.4, 142.5, 136.5, 136.1, 131.6, 131.2, 129.9, 129.8, 129.4, 129.2, 128.8, 128.2, 127.9, 127.7, 114.9, 108.8, 104.5, 104.4, 21.1$_3$, 21.0$_9$ ppm. ESMS: *m*/*z* (%) = 477.2 (100) [M + H]$^+$.

**(vi) R = CH$_3$OCH$_2$, R′ = H (6H$_2$):** $CH_3OCH_2CONHNH_2$ (21 mg) in $CH_3CN$ (1 mL) and 2-phenylpyrimidine-4,6-dicarbaldehyde (22 mg) in $CH_3CN$ (1 mL) were mixed to give a slightly cloudy, pale yellow solution, which was filtered (the cloudiness appearing to be due to traces of acid impurity in the hydrazide) before being mixed with a solution of $[Ga(dmso)_6](CF_3SO_3)_3$ (5 mg; ca. 0.1 molar equivalent) in $CH_3CN$ (1 mL). The colour of the mixture changed to a deeper yellow, and within 5 min, deposition of the product commenced. (In the absence of $Ga^{III}$, no precipitate forms within at least 2 h.) After 1 h, the solid was collected and washed with $CH_3CN$ and diethyl ether. Yield: 30 mg (75%). The compound was recrystallised from hot thf by addition of an equal volume of diethyl ether after cooling. $C_{18}H_{20}N_6O_4{\cdot}^1/_2H_2O$ (393.40): calcd. C 54.96, H 5.38, N 21.36; found C 54.9, H 5.1, N 21.8%. M.p. 238–239 °C. $^1$H NMR ([D$_6$]dmso): $\delta$ = 11.93 (NH) (two very weak peaks at $\delta$ = 13.86 and 12.00 ppm may also be NH resonances), 8.43 (s, br.), 8.39 (m, br.), 8.20, 8.01 (t, $^3J$ = 15 Hz), 7.55 (s, br.), 4.49, 4.08, 3.39, 3.35 ppm. $^{13}$C NMR ([D$_6$]dmso): $\delta$ = 171.6, 166.9, 164.4, 161.7, 161.1, 146.3, 146.0, 142.3, 141.6, 136.8, 131.7, 129.2, 128.3, 109.4, 108.9, 108.7, 71.5, 69.4, 59.3, 59.0 ppm. ESMS: *m*/*z* (%) = 385.29 (100) [M + H]$^+$.

**(vii) R = CH$_3$OCH$_2$CH$_2$OCH$_2$, R′ = H (7H$_2$):** The relatively high solubility of the product in most organic solvents made its direct precipitation from the volume of solvent required to dissolve the reactants rather inefficient. Hence, 2-phenylpyrimidine-4,6-dicarb-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

aldehyde (40 mg) and methoxyethoxyacetohydrazide (82 mg) were allowed react in acetonitrile (5 mL) for 2 h before the solvent was removed under vacuum. The pale yellow residue was then dissolved in the minimum volume of boiling acetonitrile and the solution cooled on ice to provide clusters of pale yellow needles. These were recrystallised similarly. Yield: 57 mg (64%). $C_{22}H_{28}N_6O_6 \cdot {}^1/_2H_2O$ (481.51): calcd. C 54.88, H 6.07, N 17.45; found C 54.8, H 6.2, N 17.6%. M.p. 165–166 °C. $^1$H NMR ($CD_3CN$): $\delta$ = 10.66, 9.82, 8.50, 8.24, 8.15, 7.92, 7.56, 4.62, 4.17, 3.74, 3.60, 3.55, 3.43, 3.33 ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 168.4, 167.9, 166.9, 164.7, 162.9, 161.0, 158.1, 147.4, 146.0, 137.7, 136.9, 136.2, 131.7, 131.1, 129.1, 128.8$_3$, 128.7$_7$, 128.6, 128.3, 124.6, 115.0, 111.3, 71.6, 71.5, 71.4, 71.1, 71.0, 70.1, 70.0, 59.1, 58.8 ppm. ESMS: *m*/*z* (%) = 473.36 (100) $[M + H]^+$.

**(c) Metal Ion Complexes of the Bis(acylhydrazone) Ligands**

**(i) R = $CH_3$, R′ = H (1H$_2$)**

**Zn$^{II}$ Complex (Zn/L 1:1) of the Doubly Deprotonated Ligand, [Zn$_4$(1)$_4$]·23H$_2$O:** Solutions of $[Zn(dmso)_6](BF_4)_2$ (730 mg) and $CH_3CONHNH_2$ (180 mg) in $CH_3CN$ (5 mL) and of 2-phenylpyrimidine-4,6-dicarbaldehyde (215 mg) in $CH_3CN$ (5 mL) were mixed to give a clear yellow solution from which no precipitate formed (cf. ligand synthesis). Addition of triethylamine (0.3 mL) caused immediate precipitation of a canary yellow solid which, after 12 h, was collected by filtration, washed with $CH_3CN$ and diethyl ether and dried in air. Yield: 424 mg (85%). The crude product was dissolved in methanol (40 mL), filtered to remove a small amount of gelatinous material and reprecipitated by the addition of diethyl ether. $[Zn_4(\mathbf{1})_4]\cdot 23H_2O\cdot CH_3OH = C_{65}H_{106}N_{24}O_{32}Zn_4$ (1997.3): calcd. C 39.09, H 5.35, N 16.83; found C 39.3, H 4.4, N 16.9%. M.p. > 250 °C (decomp.). $^1$H NMR ([D$_6$]dmso): $\delta$ = 7.60 (t, $^3J$ = 7.7 Hz, 1 H, 8-H), 7.52 (s, 1 H, 1-H), 7.51 (s, 2 H, 9,9′-H), 7.09 (t, $^3J$ = 7.7 Hz, 2 H, 7,7′-H), 6.28 (d, $^3J$ = 7.3 Hz, 2 H, 6,6′-H), 1.82 (s, 6 H, $CH_3$) ppm. (A large water peak was also observed, as expected from the high degree of hydration of the solid.) $^{13}$C NMR ([D$_6$]dmso): $\delta$ = 181.7, 165.1, 158.4, 136.1, 133.4, 130.0, 128.0, 125.2, 117.8, 22.5 ($CH_3$) ppm. MS (MALDI-TOF): *m*/*z* (%) = 1551.1 (100) $[M + H]^+$.

**Other M$^{II}$ Complexes (M/L 1:1) of the Doubly Deprotonated Ligand, [M$_4$(1)$_4$]·*n*H$_2$O:** The following synthesis illustrates an alternative to the above, in which the preformed diacylhydrazone is used as a reactant. A solution of KO*t*Bu (71 mg) in dry methanol (5 mL) was slowly added to a stirred slurry of **1**H$_2$ (99 mg) in dry $CH_2Cl_2$ (20 mL) to give a yellow solution. This was mixed with a solution of $[M(dmso)_6](CF_3SO_3)_2$ (254 mg for M = Zn, with the appropriate slightly different amounts for M = Co and Ni) in dry methanol (5 mL), causing a marked intensification of the colour (dark red-brown for Co, deep yellow-brown for Ni and orange for Zn) and some precipitation. After stirring the mixture for 1 h, the solvents were removed under vacuum and the residues crystallised from methanol as above. Yields were essentially quantitative.

**M = Co$^{II}$:** $[Co_4(\mathbf{1})_4]\cdot 23H_2O = C_{64}H_{102}Co_4N_{24}O_{31}$ (1939.4): C 39.64, H 5.30, N 17.33; found C 39.6, H 4.95, N 17.4%. M.p. >250 °C (decomp.). MS (MALDI-TOF) *m*/*z* (%) = 1526.3 (100).

**M = Ni$^{II}$:** $[Ni_4(\mathbf{1})_4]\cdot 22H_2O = C_{64}H_{100}N_{24}Ni_4O_{30}$ (1920.4): calcd. C 40.02, H 5.25, N 17.50; found C 40.1, H 5.01, N 17.8%. M.p. >250 °C (decomp.). MS (MALDI-TOF): *m*/*z* (%) = 1523.2 (100).

**(ii) R = $C_2H_5$, R′ = $CH_3$ (2):** This acylhydrazone appears to be a rather poor ligand, and no solid transition-metal complexes were readily obtained from it.

**(iii) R = $C_7H_{15}$, R′ = H (3H$_2$):** All complexes (M/L 1:1) containing the doubly deprotonated ligand were obtained as described above (for ligand **1**H$_2$) by using KO*t*Bu to deprotonate the preformed ligand. Again, yields appeared to be essentially quantitative. $[Fe(dmso)_6](CF_3SO_3)_2$ was used as the reactant for the synthesis of the Fe$^{II}$ complex.

**Fe$^{II}$ Complex [Fe$_4$(3)$_4$]·3H$_2$O:** $C_{112}H_{158}Fe_4N_{24}O_{11}$ (2240.0): calcd. C 60.05, H 7.11, N 15.00; found C 59.7, H 7.21, N 14.9%. M.p. >250° (decomp.). MS (MALDI-TOF): *m*/*z* (%) = 2187.0 (100).

**Co$^{II}$ Complex [Co$_4$(3)$_4$]·11H$_2$O:** $C_{112}H_{174}Co_4N_{24}O_{19}$ (2396.5): calcd. C 56.13, H 7.32, N 14.03; found C 56.0, H 7.03, N 13.7%. M.p. >250 °C (decomp.). MS (MALDI-TOF): *m*/*z* (%) = 2199.8 (100).

**Ni$^{II}$ Complex [Ni$_4$(3)$_4$]·11H$_2$O·2CH$_2$Cl$_2$:** $C_{114}H_{178}Cl_2N_{24}Ni_4O_{19}$ (2565.4): calcd. C 53.37, H 6.99, N 13.10; found C 53.4, H 7.33, N 13.1%. M.p. >250 °C (decomp.). MS (MALDI-TOF): *m*/*z* (%) = 2198.9 (100).

**Cu$^{II}$ Complex [Cu$_4$(3)$_4$]·2H$_2$O:** $C_{112}H_{156}Cu_4N_{24}O_{10}$ (2252.9): calcd. C 59.71, H 6.98, N 14.92; found C 60.0, H 7.04, N 15.1%. M.p. >250 °C (decomp.). MS (MALDI-TOF): *m*/*z* (%) = 2217.4 (100).

**Zn$^{II}$ Complex [Zn$_4$(3)$_4$]·4.5H$_2$O:** $C_{112}H_{161}N_{24}O_{12.5}Zn_4$ (2323.2): calcd. C 57.90, H 6.99, N 14.47; found C 57.9, H 7.07, N 14.8%. M.p. >250 °C (decomp.). $^1$H NMR ($CDCl_3$): $\delta$ = 7.62 (t, $^3J$ = 7.5 Hz, 1 H, 8-H), 7.37 (s, 2 H, 9-H), 7.13 (t, $^3J$ = 7.5 Hz, 2 H, 7,7′-H), 6.80 (s, 1 H, 1-H), 6.50 (d, $^3J$ = 6.9 Hz, 2 H, 6,6′-H), 2.19 (m, 4 H), 1.50 (m, 4 H), 1.20 (m, 16 H), 0.82 (t, $^3J$ = 6.6 Hz, 6 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 186.4, 165.9, 159.1, 137.2, 132.6, 130.5, 128.3, 126.3, 116.5, 37.2, 31.9, 29.8, 29.2, 26.9, 22.7, 14.2 ppm. MS (MALDI/TOF): *m*/*z* (%) = 2225.8 (100) $[M + H]^+$.

**(iv) R = $C_6H_5$, R′ = H (4H$_2$)**

**Attempted Synthesis of the Co$^{II}$ Complex (Co/L 1:1) of the Singly Deprotonated Ligand:** Triethylamine (10 mg, viz. 1 mL of a solution of 0.1 g of the amine in 10 mL of $CH_3CN$) was added to a yellow solution of 2-phenylpyrimidine-4,6-dicarbaldehyde (22 mg) in $CH_3CN$ (1 mL), causing the colour to become brownish, though immediate addition of a solution of benzohydrazide (27 mg) in $CH_3CN$ (1 mL) caused a return to pale yellow. Without delay, a solution of $[Co(dmso)_6](BF_4)_2$ (70 mg) in $CH_3CN$ (1 mL) was added, producing a deep brown-red solution from which small, dark red crystals began to deposit within 30 s. After 12 h, the precipitate was collected and washed on the filter with $CH_3CN$ and then diethyl ether. Yield: 18 mg (33%). The complex was recrystallised from chloroform (in which it is only moderately soluble) by the addition of acetonitrile. $[Co_4(\mathbf{4})_2(\mathbf{4H})_2](BF_4)_2 = C_{104}H_{74}B_2Co_4F_8N_{24}O_8$ (2197.3): calcd. C 56.85, H 3.39, N 15.30; found C 56.8, H 3.9, N 15.4%. Note that a single crystal drawn from the initial reaction product was found, as a result of the solution of its structure by X-ray crystallography, to have the composition $[Co_4(\mathbf{4H})_4](BF_4)_4\cdot 7CH_3CN$.

**Co$^{II}$ Complex (Co/L 1:1) of the Doubly Deprotonated Ligand:** The procedure above was repeated except that the quantity of triethylamine added (20 mg) was doubled. Here, copious precipitation of a dark red solid occurred immediately, though again 12 h was allowed for equilibration. The final precipitate was collected and washed with acetonitrile followed by diethyl ether on the filter. Yield: 48 mg (89%). The complex was recrystallised from chloroform by the addition of acetonitrile. $[Co_4(\mathbf{4})_4]\cdot 7H_2O = C_{104}H_{86}Co_4N_{24}O_{15}$ (2147.77): calcd. C 58.16, H 4.04, N 15.65; found C 58.2, H 4.2, N 15.0%. MS (MALDI/TOF): *m*/*z* (%) = 2022.2 (100) $[M + H]^+$.

**Ni$^{II}$ Complexes (Ni/L 1:1) of the Undeprotonated and Partly Deprotonated Ligand:** (a) Ligand **4**H$_2$ (42.4 mg) and $[Ni(CH_3CN)_6]$-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$(ClO_4)_2$ (47.7 mg) were stirred at room temperature with anhydrous $CH_3NO_2$ (8 mL) until a clear red solution was obtained. Stirring was continued for another 3 h before diisopropyl ether was added to cause precipitation of the red complex. $[Ni_4(\mathbf{4}H_2)_4](ClO_4)_8 \cdot CH_3NO_2 = C_{105}H_{83}Cl_8N_{25}Ni_4O_{42}$ (2885.3): calcd. C 43.70, H 2.90, N 12.13; found C 43.9, H 3.6, N 12.2%. Note that a single crystal drawn from the reaction mixture was assigned the composition $[Ni_4(\mathbf{4}H_2)_4](ClO_4)_8 \cdot 8H_2O \cdot 4CH_3NO_2$ on the basis of the solution of its X-ray structure determination. (b) $[Ni(OH_2)_6](NO_3)_2$ (29 mg) and 2-phenylpyrimidine-4,6-dicarbaldehyde (23 mg) were dissolved in $CH_3CN$ (2 mL), giving a yellow-green solution. $C_6H_5CONHNH_2$ (27 mg) in $CH_3CN$ (1 mL) was then added, an initial pale violet precipitate dissolving readily on agitation of the mixture. Within 30 s, a yellow precipitate commenced to form from the yellow solution, but on continued agitation, the solution became dark red, and the precipitate transformed into a red-brown solid. After 2 h, the solid was collected by filtration and washed with $CH_3CN$ and diethyl ether. Yield: 28 mg (48%). The complex was recrystallised from methanol by the addition of diethyl ether. Slow crystallisation by vapour diffusion of diisopropyl ether into a methanol solution provided a mixture of plate- and needle-like crystals. The synthesis can equally well be conducted in methanol, in which case no precipitates form, but a reaction time of at least 3 h is required at room temperature before the product can be precipitated by the addition of ether. Elemental analyses indicated that the complex in fact contains the ligand in both its doubly and singly deprotonated forms. $[Ni_4(\mathbf{4})(\mathbf{4}H)_3](NO_3)_3 \cdot 4CH_3OH = C_{108}H_{93}N_{27}Ni_4O_{21}$ (2339.9): calcd. C 55.44, H 4.01, N 16.16; found C 55.7, H 4.2, N 16.7%.

**$Zn^{II}$ Complex (Zn/L 1:1) of the Undeprotonated Ligand:** 2-Phenylpyrimidine-4,6-dicarbaldehyde (23 mg), $C_6H_5CONHNH_2$ (27 mg) and $Zn(BF_4)_2$ (23 mg) were dissolved in $CH_3CN$ (5 mL) to give a red solution, which was then taken to dryness under vacuum. The residue was dissolved in a mixture of $CH_3CN$ (1 mL) and $CH_3NO_2$ (2 mL), giving a deep red solution which was then diluted with benzene (10 mL). On keeping the mixture in a sealed flask, small red plates slowly deposited within a few hours, to be followed over a period of several days by yellow crystals of free ligand. One of the red crystals was selected for a crystal structure determination, from which it was assigned the composition $[Zn_8(E,E\text{-}\mathbf{4}H_2)_4(Z,Z\text{-}\mathbf{4}H_2)_4(OH_2)_2(CH_3CN)_2(BF_4)_2](BF_4)_{14} \cdot 7C_6H_6 \cdot 3CH_3CN \cdot 3H_2O$.

**$Zn^{II}$ Complex (Zn/L 2:1) of the Undeprotonated Ligand:** A filtered solution of $C_6H_5CONHNH_2$ (27 mg) and $Zn(CF_3SO_3)_2$ (75 mg) in $CH_3NO_2$ (3 mL) was mixed with a filtered solution of 2-phenylpyrimidine-4,6-dicarbaldehyde (22 mg) in $CH_3NO_2$ (2 mL), giving a bright yellow solution which developed a red-orange colour within 5 min. Slow deposition of small, red-orange crystals commenced shortly thereafter. After 48 h, the crystals were collected, washed with diethyl ether and dried in air. Yield: 65 mg (52%). The complex was recrystallised from acetonitrile by vapour diffusion of diethyl ether, forming clusters of fine, red needles. $Zn_2(\mathbf{4}H_2)(CF_3SO_3)_4 \cdot 2H_2O \cdot CH_3CN = C_{31}H_{27}F_{12}N_7O_{16}S_4Zn_2$ (1241.7): calcd. C 30.68, H 2.17, N 7.83; found C 30.7, H 3.1, N 7.8%. $^1H$ NMR ($CD_3CN$): $\delta$ = 12.58 (s, br., 2 H, NH), 8.61 (s, 2 H, 9,9′-H), 8.45 (s, 1 H, 1-H), 8.01 (d, $^3J$ = 8 Hz, 4 H), 7.76 (m, 3 H), 7.62 (t, $^3J$ = 8 Hz, 4 H), 7.49 (t, $^3J$ = 8 Hz, 2 H), 7.42 (s, br., 2 H) ppm.

**Attempted Formation of the $Zn^{II}$ Complex (Zn/L 1:1) of the Singly Deprotonated Ligand:** The procedure described above for preparation of the $Co^{II}$ analogue was repeated with $[Zn(dmso)_6](CF_3SO_3)_2$ (83 mg) substituted for $[Co(dmso)_6](BF_4)_2$. A copious, dark-red, seemingly crystalline precipitate formed immediately and 12 h at room temperature was then allowed for equilibration before the solid was collected and washed with acetonitrile and diethyl ether. Yield: 34 mg. Microscopic examination indicated contamination of this crude product with a few crystals of the bis(acylhydrazone). The complex was recrystallised from $CHCl_3$ by addition of $CH_3CN$, microanalysis then indicating that it was in fact the complex of the doubly deprotonated ligand. $[Zn_4(\mathbf{4})_4] \cdot 4H_2O = C_{104}H_{80}N_{24}O_{12}Zn_4$ (2119.5): calcd. C 58.94, H 3.80, N 15.86; found C 59.3, H 3.9, N 15.9%. M.p. >250 °C (decomp.).

**$Zn^{II}$ Complex (Zn/L 1:1) of the Doubly Deprotonated Ligand:** The procedure described above for preparation of the $Co^{II}$ analogue was repeated with $[Zn(dmso)_6](CF_3SO_3)_2$ (83 mg) substituted for $[Co(dmso)_6](BF_4)_2$. A bright red precipitate formed immediately, though again 12 h was allowed for full equilibration. The solid was collected and washed with acetonitrile and diethyl ether. Yield: 45 mg (84%). The complex was recrystallised from $CHCl_3$ by addition of $CH_3CN$. $[Zn_4(\mathbf{4})_4] \cdot 5H_2O = C_{104}H_{82}N_{24}O_{13}Zn_4$ (2137.5): calcd. C 58.44, H 3.87, N 15.73; found C 58.3, H 3.5, N 15.3%. M.p. >250 °C (decomp.). $^1H$ NMR ($CD_3OD/CD_2Cl_2$ 1:4): $\delta$ = 7.80 (m, 5 H, phenyl 2-protons superimposed on H-8); 7.73 (s, 2 H, 9-H); 7.43 (s, 1 H, 1-H); 7.40 (t, $^3J$ = 8 Hz, 2 H, phenyl 4-protons); 7.27 (t, $^3J$ = 8 Hz, 4 H, phenyl 3-protons); 7.14 (t, 2 H, 7,7′-H); 6.42 (d, $^3J$ = 8 Hz, 2 H, 6,6′-H) ppm. $^{13}C$ NMR ($C_2D_5OD/CD_2Cl_2$ 1:4): $\delta$ = 175.0, 156.8, 132.9, 132.5, 129.6, 128.4, 127.3, 126.7, 126.5, 126.4, 126.3, 123.9, 115.7 ppm. MS (MALDI-TOF): *m/z* (%) = 2048.3 (100) $[M + H]^+$.

**Other $M^{II}$ Complexes (M/L 1:1) of the Doubly Deprotonated Ligand**

**M = Fe:** $Fe^{II}$ ascorbate (43 mg, 5% excess) was dissolved in water (0.5 mL) and added to a solution of benzohydrazide (27 mg) in $CH_3CN$ (3 mL) to give a deep violet solution. 2-phenylpyrimidine-4,6-dicarbaldehyde (22 mg) in $CH_3CN$ (1 mL) was added and the mixture allowed stand for 5 min. The oily, violet precipitate which formed was redissolved by the addition of water (2 mL) before triethylamine (20 mg) was added, causing the solution to gain a deep yellow-brown colour and brown crystals to commence depositing. After 2 h, the crystals were collected and washed with water, acetonitrile and diethyl ether, then air dried. Yield: 39 mg (74%). The complex was recrystallised from ethanol/$CH_2Cl_2$ (1:10) by adding an equal volume of ethanol and allowing the $CH_2Cl_2$ to evaporate out. $[Fe_4(\mathbf{4})_4] \cdot 6H_2O = C_{104}H_{84}Fe_4N_{24}O_{14}$ (2117.4): calcd. C 59.00, H 4.00, N 15.88; found C 59.2, H 3.7, N 16.2%. MS (MALDI-TOF): *m/z* (%) = 2010.4 (100) $[M + H]^+$.

**M = Ni:** Benzohydrazide (54 mg) and $[Ni(dmso)_6](CF_3SO_3)_2$ (164 mg) were dissolved in $CH_3CN$ (2 mL), forming a blue solution. Triethylamine (40 mg) was added, followed by a solution of 2-phenylpyrimidine-4,6-dicarbaldehyde (43 mg) in $CH_3CN$ (2 mL). An amorphous, deep yellow-brown precipitate formed immediately. After 12 h, by which time the precipitate was obviously crystalline, this was collected and washed with a little acetonitrile (slightly soluble) and then ether. Yield: 82 mg (73%). The complex was recrystallised from boiling ethanol (20 mL) by cooling to room temperature, very slow deposition of small, brown, rod-like crystals ensuing. $[Ni_4(\mathbf{4})_4] \cdot 2CH_3CN \cdot 9H_2O = C_{108}H_{96}N_{26}Ni_4O_{17}$ (2265.0): calcd. C 57.27, H 4.27, N 16.08; found C 57.1, H 4.0, N 16.1%. MS (MALDI-TOF): *m/z* (%) = 2021.3 (80) $[M + H]^+$.

**M = Cu:** Benzohydrazide (54 mg) and $[Cu(dmso)_6](CF_3SO_3)_2$ (164 mg) were dissolved in $CH_3CN$ (2 mL), forming a blue solution. Triethylamine (40 mg) was added (causing a colour change to brownish-green), followed by a solution of 2-phenylpyrimidine-4,6-dicarbaldehyde (43 mg) in $CH_3CN$ (2 mL). An amorphous, dark brown precipitate formed immediately. Again, the mixture was allowed stand for 12 h before the precipitate was collected and washed with acetonitrile (slightly soluble) and ether. Yield: 88 mg

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(82%). The complex was recrystallised from ethanol/$CH_2Cl_2$ (1:10) by slow evaporation of the filtered solution. $[Cu_4(\mathbf{4})_4]\cdot 6H_2O$ = $C_{104}H_{84}Cu_4N_{24}O_{14}$ (2148.1): calcd. C 58.15, H 3.94, N 15.65; found C 58.1, H 3.7, N 15.2%. MS (MALDI-TOF): *m*/*z* (%) = 2041.3 (5) $[M + H]^+$.

**(v) R = 4-$CH_3C_6H_4$, R′ = H (5H$_2$)**

**Cu$^{II}$ Complex (Cu/L 1:1) of the Doubly Deprotonated Ligand:** $[Cu(dmso)_6](CF_3SO_3)_2$ (166 mg), 2-phenylpyrimidine-4,6-dicarbaldehyde (44 mg) and 4-$CH_3C_6H_4CONHNH_2$ (60 mg) were dissolved together in $CH_3CN$ (5 mL), the initially green solution developing a deep red colour within 60 s. Precipitation of a red-brown solid with a metallic sheen rapidly ensued but, before this was extensive, triethylamine (50 mg) was added, causing the precipitate to become a darker red and to become more voluminous. After 15 min, the precipitate was well-settled and the supernatant retained only a pale yellow colour. The precipitate was collected, washed with $CH_3CN$ then diethyl ether, and air-dried. Yield: 86 mg (75%). It was recrystallised from the minimum volume (ca. 20 mL) of EtOH/$CH_2Cl_2$ (1:10) by adding EtOH (10 mL) after filtration and allowing the $CH_2Cl_2$ to evaporate out. $[Cu_4(\mathbf{5})_4]\cdot 7H_2O$ = $C_{112}H_{102}Cu_4N_{24}O_{15}$ (2278.3): calcd. C 59.04, H 4.51, N 14.75; found C 59.1, H 4.4, N 14.8%. MS (MALDI-TOF): *m*/*z* (%) = 2153.5 (10) $[M + H]^+$.

**Zn$^{II}$ Complex (Zn/L 1:1) of the Doubly Deprotonated Ligand:** The method using the preformed ligand deprotonated by KO*t*Bu was used to provide the orange complex, which was recrystallised from a 1:1 mixture of $CH_3OH$ and $CH_2Cl_2$ by adding an equal volume of $CH_3CN$ and then allowing the $CH_2Cl_2$ to evaporate out. $C_{112}H_{152}N_{24}O_8Zn_4\cdot 12H_2O$ (2375.8): calcd. C 56.62, H 4.75, N 14.15; found C 56.3, H 4.09, N 14.2%. M.p. >250 °C (decomp.). $^1$H NMR ($CDCl_3$ + $CD_3OD$, 1:1): $\delta$ = 7.67 (t, $^3J$ = 7.3 Hz, 1 H, 8-H), 7.64 (d, $^3J$ = 8.0 Hz, 4 H, tolyl-2-protons), 7.59 (s, 2 H, 9,9′-H), 7.23 (s, 1 H, 1-H), 7.03 (t, $^3J$ = 7.7 Hz, 2 H, 7,7′-H), 7.01 (d, $^3J$ = 8.0 Hz, 4 H, tolyl-3-protons), 6.34 (d, $^3J$ = 7.3 Hz, 2 H, 6,6′-H), 2.26 (s, 6 H, $CH_3$) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 177.1, 166.3, 158.9, 152.8, 142.1, 137.6, 132.9, 131.0, 129.7, 128.2, 126.6, 116.1, 107.9, 73.5, 69.3, 32.1, 30.6, $29.9_5$, $29.9_2$, $29.8_7$, 29.8, 29.7, $29.6_4$, $29.5_6$, 29.5, $26.3_3$, $26.3_0$, 22.86, 22.9, $14.2_7$, $14.2_5$ ppm. MS (MALDI-TOF): *m*/*z* (%) = 2161.3 (100) $[M + H]^+$.

As an alternative synthesis, solutions of $Zn(BF_4)_2\cdot$6dmso (70 mg) and 4-$CH_3C_6H_4CONHNH_2$ (30 mg) in $CH_3CN$ (1 mL) and of 2-phenylpyrimidine-4,6-dicarbaldehyde (22 mg) in $CH_3CN$ (1 mL) were mixed to give an initially pale yellow solution, which developed a deep orange colour over 2 min. Triethylamine (30 mg) was then added to give immediately a red precipitate, which was collected by filtration and washed with acetonitrile and diethyl ether. Yield: 43 mg (59%). This was recrystallised by dissolution in the minimum volume (ca. 20 mL) of 1:1 ethanol/$CH_2Cl_2$, filtration and slow evaporation of the filtrate.

**(vi) R = $CH_3OCH_2$, R′ = H (6H$_2$)**

**Zn$^{II}$ Complex (Zn/L 1:1) of the Doubly Deprotonated Ligand:** $CH_3OCH_2CONHNH_2$ (42 mg) and $Zn(BF_4)_2\cdot$6dmso (120 mg) were dissolved in $CH_3CN$ (2 mL) and added to a solution of 2-phenylpyrimidine-4,6-dicarbaldehyde (43 mg) in $CH_3CN$ (2 mL) to give a clear, yellow solution. Triethylamine (50 mg, excess) was added to produce an immediate bright orange precipitate which settled within 5 min, leaving a pale yellow supernatant. After 1 h, the precipitate was collected, washed with $CH_3CN$ and diethyl ether and dried in air. Yield: 65 mg (64%). The crude product was dissolved in boiling $CH_3OH$ (10 mL), filtered to remove a small amount of brownish, gelatinous material, and the filtrate diluted with an equal volume of diethyl ether to produce small orange crystals. $C_{72}H_{72}N_{24}O_{16}Zn_4\cdot 11H_2O$ (1989.2): calcd. C 43.47, H 4.76, N 16.75; found C 43.5, H 4.4, N 16.8%. M.p. >255 °C (about this temperature, the sample shrinks and its colour lightens but there is no obvious melting). $^1$H NMR ($D_2O$): $\delta$ = 7.78 (m, br.), 7.73 (s), 7.28 (m, br.), 3.91 (s, 2 H), 3.21 (s, 3 H) ppm. $^{13}$C NMR ($D_2O$ + ca. 10% $CD_3OD$): $\delta$ = 181.6, 166.6, 159.8, 138.9, 136.7, 132.9, 130.0, 121.2, 72.1, 59.5 ppm. MS (MALDI-TOF): no peaks above *m*/*z* 897 were detectable.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

isopropyl ether into a $CH_3NO_2$ solution. A $[Zn_8(E,E\text{-}\mathbf{4}H_2)_4(Z,Z\text{-}\mathbf{4}H_2)_4(OH_2)_2(CH_3CN)_2(BF_4)_2](BF_4)_{14}\cdot 7C_6H_6\cdot 3CH_3CN\cdot 3H_2O$ crystal was selected from the mixture of products obtained as described above. A $[Co_4(\mathbf{4}H)_4](BF_4)_4\cdot 7CH_3CN$ single crystal was selected from the mass obtained on one occasion when the ligand and metal ion were subjected to reaction in the absence of any deliberately added base. $[Ni_4(\mathbf{4})_{2.5}(\mathbf{4}H)_{1.5}](NO_3)_{1.5}\cdot CH_3OH\cdot 0.5(C_2H_5)_2O$ single crystals, as a mixture of needles and plates, were grown by vapour diffusion of diethyl ether into a methanol solution of the complex. All variously solvated complexes $[M_4(\mathbf{1})_4]$, M = $Co^{II}$, $Ni^{II}$, $Zn^{II}$, were crystallised by slow evaporation of methanol solutions in air. All variously hydrated complexes $[M_4(\mathbf{3})_4]$, M = $Fe^{II}$, $Co^{II}$, $Ni^{II}$, $Cu^{II}$, $Zn^{II}$, were crystallised by liquid-liquid diffusion of $CH_3CN$ into $CHCl_3$ solutions.

**(b) Structure Determination:** The structures were determined under various conditions on various instruments in Jyväskäla, Strasbourg and Grenoble (European Synchrotron Radiation Facility). Basic information for each structure is given in Tables 2, 3 and 4.

CCDC-637552–637565 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## MICROREVIEW

### Coordination Rectangle, Prism, Tube

**C.-L. Chen, J.-Y. Zhang, C.-Y. Su* ..... 2997–3010**

Coordination Assemblies of Metallacyclic, Prismatic and Tubular Molecular Architectures Based on the Non-rigid Ligands

**Keywords:** Metallacycle / Coordination prism / Coordination tube / Non-rigid ligand / Molecular architecture

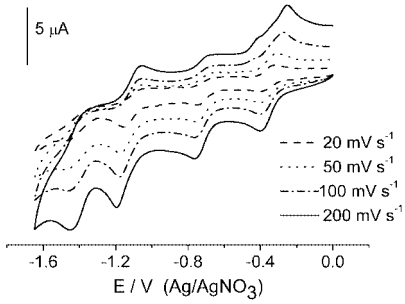
Recent progresses in self-assembly of coordination molecular architectures showing polygonal, prismatic and tubular structures on the basis of the semi-rigid or flexible ligands have been introduced. Four assembly routes depending on the symmetry interactions between specific ligands and metal ions are outlined: a) molecular clips + metal ions of $C_n$ symmetry; b) multipodal ligands + metal ions of $C_2$ symmetry; c) molecular clips + protected metal ions of restrained $C_n$ symmetry and d) multicomponent self-assembly.

## SHORT COMMUNICATION

### Osmium-Rhodium Clusters

**J. Po-Kwan Lau, Y.-J. Gu, W.-T. Wong* ..... 3011–3014**

High-Yield Synthesis of a New Layered High-Nuclearity Carbonyl Osmium-Rhodium Cluster Complex – Synthesis, Structural Characterization, and Electrochemistry of $[PPN][Os_9Rh_3(\mu\text{-}CO)_2(CO)_{26}]$



**Keywords:** Osmium / Rhodium / High-nuclearity clusters / Electrochemistry

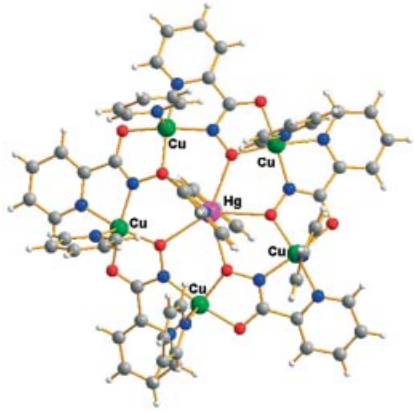
A direct and high-yield synthetic route for a novel dodecanuclear osmium-rhodium mixed-metal cluster is presented. The redox properties of the cluster were examined, and it was found that the anion behaves as an "electron reservoir".

## FULL PAPERS

### Metallacrowns

**S. H. Seda, J. Janczak, J. Lisowski* ..... 3015–3022**

Synthesis and Structural Characterisation of Copper(II) 15-Metallacrown-5 Complexes with $Pb^{II}$, $Hg^{II}$, $Ag^{I}$, $Na^{I}$ and $Y^{III}$ Central Metal Ions

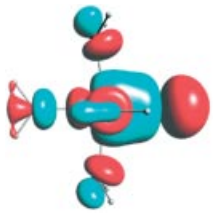


**Keywords:** Metallamacrocyles / Hydroxamic acids / Lead / Mercury / Copper / Crystal structure

New copper(II) 15-metallacrown-5 complexes $[MCu_5L_5]X_n$ {$H_2L$ is 2-picoline- or (*S*)-phenylalaninehydroxamic acid and M is the central metal ion} have been characterised. The X-ray crystal structures of the $Pb^{II}$ and $Hg^{II}$ derivatives show that the 15-metallacrown-5 ring can adopt a distorted conformation in order to adjust to the size of central metal ion.

## High-Valent Oxidoiron(IV) Systems

An empty low-lying 3σ* orbital is responsible for the catalytic activity of oxidoiron(IV) compounds in alkane hydroxylation. We study the influence of the ligand environment on the spin state and catalytic activity of simple systems, correlating these properties to the strength of the electron donation from the ligands, and in particular, we prove that systems with *weak* equatorial and axial donor ligands show superior catalytic activity.

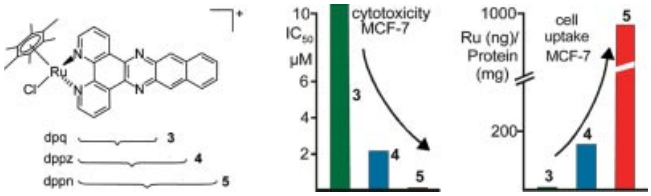


**L. Bernasconi,* M. J. Louwerse, E. J. Baerends* ..... 3023–3033**

The Role of Equatorial and Axial Ligands in Promoting the Activity of Non-Heme Oxidoiron(IV) Catalysts in Alkane Hydroxylation

**Keywords:** Density functional calculations / Fenton reaction / Alkanes / Hydroxylation / High-valent oxidoiron(IV) systems / Push effect

## Organoruthenium(II) Complexes



The DNA binding of polypyridyl (pp) complexes such as **3**–**5** has been studied by spectroscopic and viscometric techniques. Intercalation is observed for dpq and dppz complexes but not for chloro complexes with smaller (phen,tap) or larger (dppn) ligands. The cytotoxicities of the complexes correlate with the level of cellular ruthenium uptake in the order of increasing ligand size.

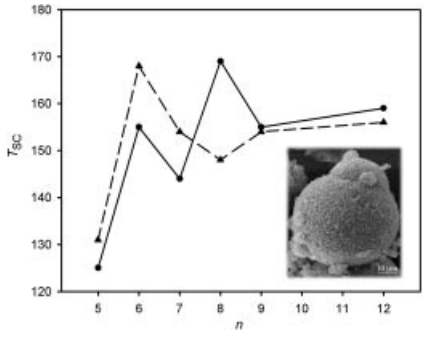
**S. Schäfer, I. Ott, R. Gust, W. S. Sheldrick* ..... 3034–3046**

Influence of the Polypyridyl (pp) Ligand Size on the DNA Binding Properties, Cytotoxicity and Cellular Uptake of Organoruthenium(II) Complexes of theType $[(\eta^6\text{-}C_6Me_6)Ru(L)(pp)]^{n+}$ [L = Cl, $n$ = 1; L = $(NH_2)_2CS$, $n$ = 2]

**Keywords:** Ruthenium / Iridium / DNA / Antitumour agents / Arene ligands

## Iron(II) Spin Crossover

Parity effect and anion influence found at the spin-crossover behaviour of iron(II) coordination polymers and visualised by systematic magnetic and magneto-optical investigations are based on structural variations.

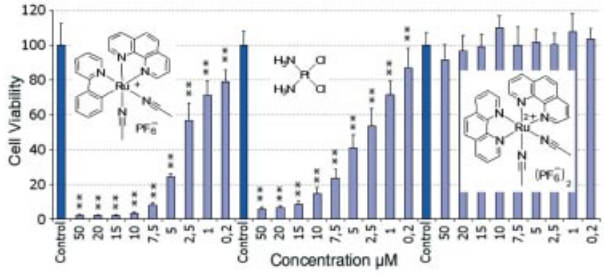


**A. Absmeier, M. Bartel, C. Carbonera, G. N. L. Jameson, F. Werner, M. Reissner, A. Caneschi, J.-F. Létard, W. Linert* ..... 3047–3054**

Mutual Influence of Spacer Length and Noncoordinating Anions on Thermal and Light-Induced Spin-Crossover Properties of Iron(II)–α,ω-Bis(tetrazol-1-yl)alkane Coordination Polymers

**Keywords:** Iron(II) / Magnetic properties / Coordination polymers / Photomagnetism / Spin crossover

## Metallacyclic Antitumour Agents



Several cycloruthenated compounds have been evaluated for their in vitro cytotoxicity against a series of human and murine tumor cells. Some of these organometallic compounds that contain a chemically stable Ru-C σ bond stabilized by intramolecular coordination of a nitrogen atom displayed interesting in vitro cytotoxic activities against tumor cells of the same order of magnitude as cisplatin.

**L. Leyva, C. Sirlin,* L. Rubio, C. Franco, R. Le Lagadec, J. Spencer, P. Bischoff, C. Gaiddon, J.-P. Loeffler, M. Pfeffer* ..... 3055–3066**

Synthesis of Cycloruthenated Compounds as Potential Anticancer Agents

**Keywords:** Bioinorganic chemistry / Ruthenium / Metallacycles / Antitumor agents

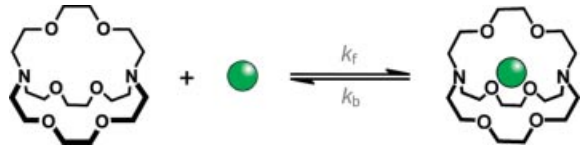
## Ion Exchange Kinetics

**E. Pasgreta, R. Puchta, A. Zahl, R. van Eldik* ..... 3067–3076**

Ligand Exchange Processes on Solvated Lithium Cations, V. Complexation by Cryptands in Acetone as Solvent

**Keywords:** Lithium / Cryptands / Acetone / Exchange mechanism



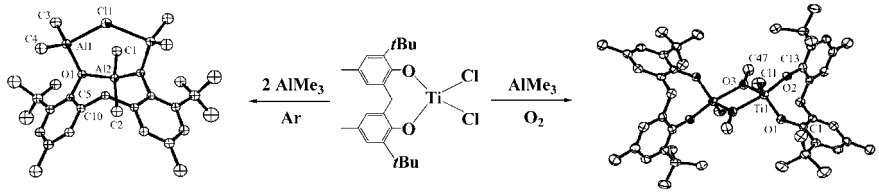
$^7$Li NMR was used to study $Li^+$ exchange between the cryptands C222 and C221 and acetone as solvent, as a function of ligand-to-metal mol ratio, temperature and pressure. The reported activation parameters suggest that the exchange reaction follows an associative interchange mechanism.

## Organometal(IV) Halides with $AlMe_3$

**D. Zhang* ..... 3077–3082**

Facile Formation of Hexacyclic $[Al_3O_2Cl]$ Aluminum and Alkoxide-Bridged Titanium Complexes: Reactions of $AlMe_3$ with $[Ti(L)Cl_2]$ [L = 2,2′-Methylenebis(6-*tert*-butyl-4-methylphenolato)]

**Keywords:** Aluminum complexes / Titanium complexes / Trimethylaluminum



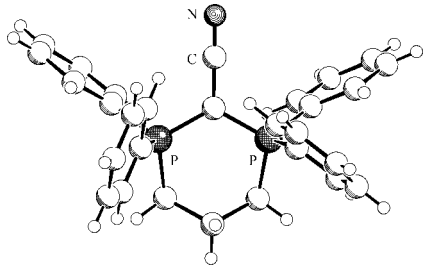
The dichloride titanium complex $[Ti(L)Cl_2]$ [L = 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato)] (**1**) reacted with $AlMe_3$ in a 1:2 ratio under argon to give the trimetallic compound $[(L)(AlMe_2)_3(\mu_2\text{-}Cl)]$ (**2**) with a symmetrical six-membered ring $[Al_3(\mu_2\text{-}O)_2(\mu_2\text{-}Cl)]$, while the reaction of 1 equiv. $AlMe_3$ under $O_2$ afforded the oxygen-insertion product $[\{(L)TiCl\}_2(\mu_2\text{-}OMe)_2]$ (**4**) with a five-coordinate metal center.

## Stabilized Ylides

**L. Braun, G. Kehr, T. Blömker, R. Fröhlich, G. Erker* ..... 3083–3090**

Preferred Phosphorus Ylide Formation Upon Alkylation of Lithiobis(diphenylphosphanyl)acetonitrile

**Keywords:** Chelates / Phosphane ligands / Carbanions / Ylides / Alkylation



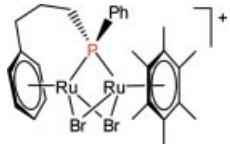
The reaction of lithiobis(diphenylphosphanyl)acetonitrile, which exhibits an unusual monomeric structure in the crystal form, with a variety of alkyl halides proceeds exclusively by alkylation at phosphorus to yield mono- or dialkylated ylidic products.

## Chiral-at-Phosphorus Complexes

**M. J.-L. Tschan, G. Süss-Fink,* F. Chérioux, B. Therrien ..... 3091–3100**

Dinuclear (Arene)ruthenium Complexes Containing a Chiral-at-Phosphorus Phosphanido Bridge

**Keywords:** Arene ligands / Ruthenium / Tethered complexes / P ligands / Hydride ligands



The cation $[(\eta^6\text{-arene})Ru_2(\mu_2\text{-}H)_3]^+$ reacts with $PPh_2(CH_2)_3Ph$ to give the phosphanido complex $[(\eta^6\text{-arene})Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ which, upon heating in bromobenzene, converts into $[(\eta^6\text{-arene})Ru_2\{\mu_2\text{-}PPh(CH_2)_3\text{-}\eta^6\text{-}Ph\}(\mu_2\text{-}Br)_2]^+$, the first chiral-at-phosphorus diruthenium complex.

# Coordination Assemblies of Metallacyclic, Prismatic and Tubular Molecular Architectures Based on the Non-rigid Ligands

**Chun-Long Chen,[a] Jian-Yong Zhang,[a] and Cheng-Yong Su*[a,b]**

**Keywords:** Metallacycle / Coordination prism / Coordination tube / Non-rigid ligand / Molecular architecture

This microreview covers recent advances in the assembly of coordination molecular architectures showing cyclic, prismatic and tubular structures based on the semi-rigid or flexible ligands. Four assembly routes are outlined depending on the symmetry interactions between specific ligands and metal ions.

## 1. Introduction

During the past decades, great attentions have been paid to control the self-assembly of metallasupramolecular species, and numerous discrete molecular architectures with different shapes and functionalities have been synthesized in an effort to approach the ambitious goal: rational prediction and design.[1] Usually, the coordination assemblies can be classified into two main branches: infinite coordination

*Chun-Long Chen was born in 1979 in Jiangxi, China. He got his Ph.D degree from Sun Yat-Sen University in 2005 under the supervision of Professor Cheng-Yong Su and Professor Bei-Sheng Kang. His research interests are mainly focused on self-assembly of coordination supramolecular species and their dynamic behavior in solution. He was a visiting scholar in Hans-Conrad zur Loye's group at University of South Carolina (Sep. 2004-Jul. 2005), where he was engaged in the design and synthesis of rigid ligands and their coordination chemistry. He is currently doing post-doctoral research with Dr. Nathaniel L. Rosi at University of Pittsburgh.*

*Jian-Yong Zhang was born in 1974 in Henan, China. He obtained his master's degree from Nankai University in 1999 with Prof. Shansheng Xu and his PhD from National University of Singapore in 2003 under the supervision of Prof. T. S. Andy Hor on rhenium complexes for nuclear medicine, followed by one-year postdoctoral experience at the Institut de Recherches sur la Catalyse – CNRS, France, with Prof. Liliane G. Hubert-Pfalzgraf on molecular precursors for inorganic materials. Further three-year post-doc experience was gained at the Queen's University of Belfast, UK, with Dr. Stuart L. James on coordination cages and polymers. He joined Sun Yat-Sen University in 2006 and is currently an associate professor. His research interests include catalysis, supramolecular chemistry and materials chemistry.*

*Cheng-Yong Su was born in 1968 in Inner Mongolia, China. He earned his Ph.D degree in Chemistry from Lanzhou University in 1996 under the supervision of Professor Min-Yu Tan in the field of Rare Earth chemistry. He joined Professor Wolfgang Kaim's group at Stuttgart University as an Alexander von Humboldt Research Fellow in 2001, and moved to the University of South Carolina in 2002 working with Professor Hans-Conrad zur Loye as a Postdoctoral Fellow for one and half years. He became Associate Professor in 1998 at Sun Yat-Sen University and was promoted to Professor in 2004. He is the author or co-author of over 100 peer reviewed publications and has research interests in coordination crystal engineering, molecular architectures and supramolecular chemistry.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

polymers and discrete molecular architectures. The field of coordination polymers continues to expand exponentially because of their potential applications in the areas of catalysis, chirality, conductivity, luminescence, magnetism, spin-transition (spin-crossover), non-linear optics (NLO) and porosity or zeolitic behaviors. On the other hand, interests in the design and construction of discrete molecular architectures have also experienced extraordinary progress not only because of their intrinsic aesthetic appeals but also due to their various potentials for being used as sensors, probes, catalysts, containers and in basic host-guest chemistry.

On the base of some well-documented strategies, such as Molecular Library Model,[1a,1b] Symmetry Interaction Model,[1c,1d] Directional-Bonding Approach,[1a] Weak-Link Synthetic Approach,[1e] and so on, various discrete molecular architectures with desired shapes and concomitant properties have been synthesized. However, most of these approaches relate to high symmetric molecules, such as polygons and polyhedra. The ligands therein used are usually rigid or specifically multifunctional, and the coordination geometry of metal center sometimes needs protecting. In contrast, using of non-rigid (semi-rigid or flexible) ligands to construct well-shaped molecular architectures is far less common, partly due to the less predictable assembly process. However, the incorporation of flexible components may endow the molecular architectures with potential advantages, for example, a "breathing" ability in the solid state and adaptive recognition properties as a functional of coexisting guest or counterions. Furthermore, flexibility of the non-rigid ligand can afford a good opportunity to investigate the details of the self-assembly process and provide more information for the directional synthesis of target supramolecular complexes. For instance, the flexibility of the ligand can lead to the formation of both discrete macrocycles and infinite polymeric structures on the basis of the conformational freedom of the connecting fragment, and the conversion between these two types of structures could be related by the concept of ring-opening isomerism.[2] Most important, deliberate design of non-rigid ditopic ligands can afford organic "molecular clips" which make it easy to construct relatively lower-symmetric molecular architectures of rectangular or prismatic shapes following a ligand-directed symmetry-interaction approach.[3]

We have long been involving in the synthesis of cyclic, tubular or cage-like metallasupramolecules through design of the specified semi-rigid or flexible ligands with benzimidazolyl or quinolyl as terminal groups and rigid arenes or flexible alkenes as spacers. Given the availability of different coordination modes provided by the designed ligands, we have synthesized a diverse array of discrete structures ranging from simple binuclear cyclic $M_2L_2$, prismatic $M_3L_2$, $M_2L_3$ or $M_2L_4$, to tubular $M_4L_4$ molecular architectures. The present microreview will mainly concentrate on recent progress in the assembly of the prismatic coordination structures by using of the non-rigid ligands, involving some related examples of macrocyclic and tubular molecules on the basis of the results from our and other groups, but avoid covering comprehensive literature examples.

## 2. Design Approaches

Several general strategies have been developed for construction of the discrete coordination molecular architectures.[1] The directional-bonding or molecular library approaches[1a,1e] are efficient for building up molecular polygons or polyhedra based on rigid ligands, the symmetry-interaction approach[1a–1d] is a powerful tool to elegant shapes and architectures like helicates, tetrahedral and adamantoid structures through multibranched chelating ligands, the molecular paneling approach is used by Fujita et al.[1b] to assemble large 3D assemblies, and the weak-link approach is mainly developed by Mirkin et al.[1e] to prepare supramolecular architectures from flexible ligands. However, none of above strategies are characteristic of prismatic structures.

In contrast to the highest symmetric polyhedral structures which possessing multiple *n*-fold rotation axes, the right prisms are composed of two regular *n*-gons perpendicular to a sole *n*-fold rotation axis, such as trigonal and tetragonal prisms, therefore, showing relatively lower symmetry. The even lower symmetric oblique prisms only contain two polygonal bases in parallel and several lateral parallelograms without actual *n*-fold rotation axis. On the other hand, a lot of dimeric cage structures possessing apparent $D_{nh}$ symmetry also show prismatic shape without the strict lateral parallelograms. The common feature of these structures is the absence of multiple *n*-fold rotation ($n \geq 3$) symmetry but having two parallel *n*-gons. If such structures are open ended (two bases of the prisms are not closed), tubular structures are formed. Similar symmetry relationship between the polyhedral and prismatic structures can also be found between polygonal and rectangular structures.

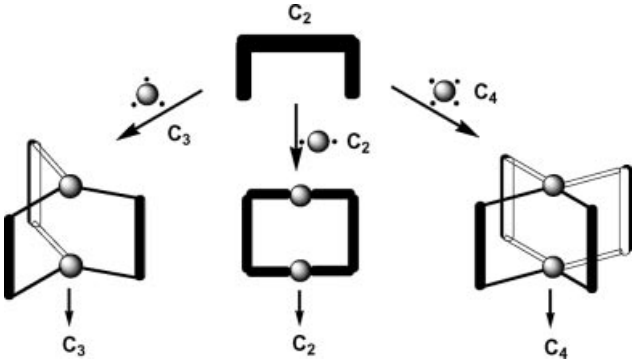
To achieve convergent assembly of molecular prisms by preventing appearance of more than one *n*-fold axes during the self-assembly process, more deliberate predesign and judicious choice of the components are required. One of constructive approaches proposed by Stang and co-workers is to design a "molecular clip": two parallel coordination sites are facing in the same direction, which allows for the assembly e.g. of a molecular rectangle by using rigid bipyridyl bridging ligands[4a,4b] or of trigonal prisms by using tritopic ligands with pyridyl subunits.[4c] Taking advantages of such a design principle, we have proposed a ligand-directed symmetry-interaction approach,[3] relying on synthesis of shape-defined "organic molecular clips" which display a coordination directing mode similar to Stang's organometallic clips, thereby facilitate modular assembly of prismatic architectures. On the basis of known examples from our and other groups, the following routes for assembly of coordination prismatic cages and related structures could be outlined:

### 2.1 Molcular Clips + Metal Ions of $C_n$ Symmetry

As shown in Scheme 1 a molecular clip can be a ditopic semi-rigid ligand possessing two coordinating arms which must take the *cis* conformation. Because the molecular clip

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

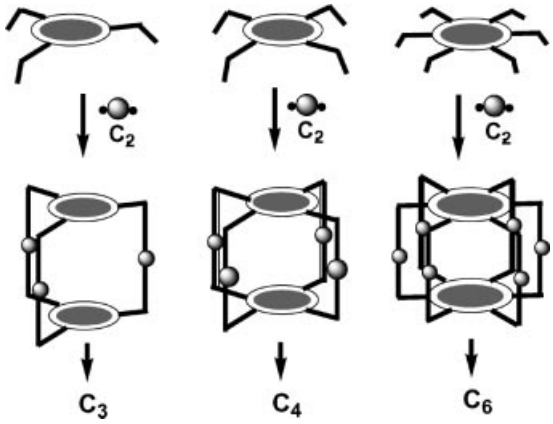
has a symmetry no higher than 2-fold, combination of the molecular clips with two axial centers will give rise to rectangle or *n*-gonal prisms determined by *n*-fold symmetry of the axial centers ($C_n$). That is, two linearly coordinating metal ions will connect two clips to form a rectangular-shaped structure, while two triangularly coordinating metal ions can lead to the formation of a trigonal prism, and further, a tetragonal prism may be generated by using two metal ions which prefer a square-planar coordination environment. The shape and size of the assembled molecules are determined by the size of the ligands and preferred coordination of the metal ions.



Scheme 1. Assembly of rectangular or prismatic structures from molecular clips and metal ions of $C_n$ symmetry.

### 2.2 Multipodal Ligands + Metal Ions of $C_2$ Symmetry

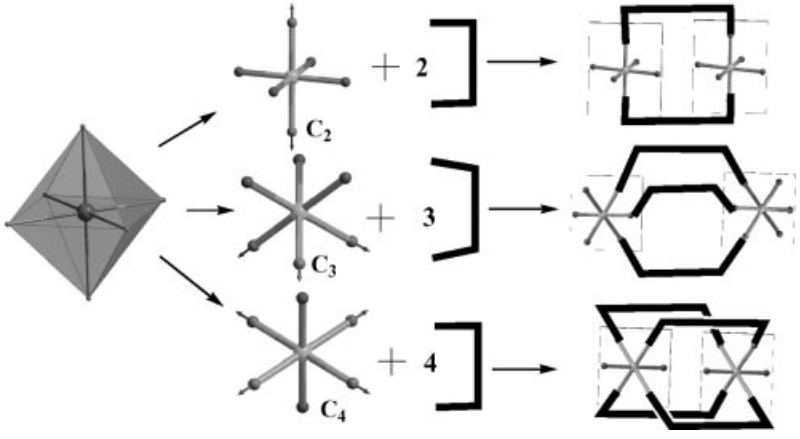
A complementary approach to construct compositionally different but topologically identical prismatic molecules compared to route 2.1 is shown in Scheme 2. In this route, a multipodal ligand which contains more than two legs connecting with the basal core and pointing in the same direction (*cis* conformation) is used to determine the *n*-fold rotation axis. In combination of the metal ions with $C_2$ symmetry, *n*-gonal prismatic structures are readily available depending on the size and shape of the ligands. One of the advantages of this route is that assembly of the coordination prisms with higher $C_n$ symmetry ($n \geq 5$) become feasible. This is hard for route 2.1 due to absence of metal ions with coordination geometry having $C_5$ or higher rotation symmetry.



Scheme 2. Assembly of prismatic structures from multipodal ligands and metal ions of $C_2$ symmetry.

### 2.3 Molcular Clips + Protected Metal Ions of Restrained $C_n$ Symmetry

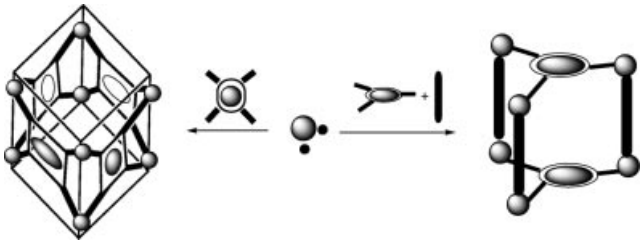
Another route to construct rectangular and prismatic molecular architectures is to use selected symmetry of metal ions with protected coordination geometry. For example, the octahedral metal ions are known to provide versatile coordination symmetry, however, it is a surprise that their potential application in construction of molecular prisms has so far been mainly realized in tetragonal prisms. As depicted in Scheme 3, the utilization of four equatorial sites can afford a $C_4$ tetragonal node, while a $C_3$ trigonal node can be produced if three *fac*-coordination sites are blocked. Even further, if only two opposite coordination sites are kept free while all other occupied, a linear node of $C_2$ symmetry is obvious. Such symmetry restrained metal ions interact with the appropriate molecular clips can lead to formation of tetragonal prism, dicapped trigonal prisms and molecular rectangles, respectively. Therefore, octahedral metal ions could become an abundant source to construct



Scheme 3. Assembly of rectangular or prismatic structures from molecular clips and blocked octahedral metal ions.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

rectangular or prismatic molecular architectures following the ligand-directed symmetry-interaction approach if their $C_n$ symmetry can be properly retained.[5] Similarly, the metal ions of square pyramidal geometry could provide $C_4$ symmetry if the apical site is blocked, and the trigonal bipyramidal geometry could give rise to $C_3$ symmetry if two axial sites are protected.



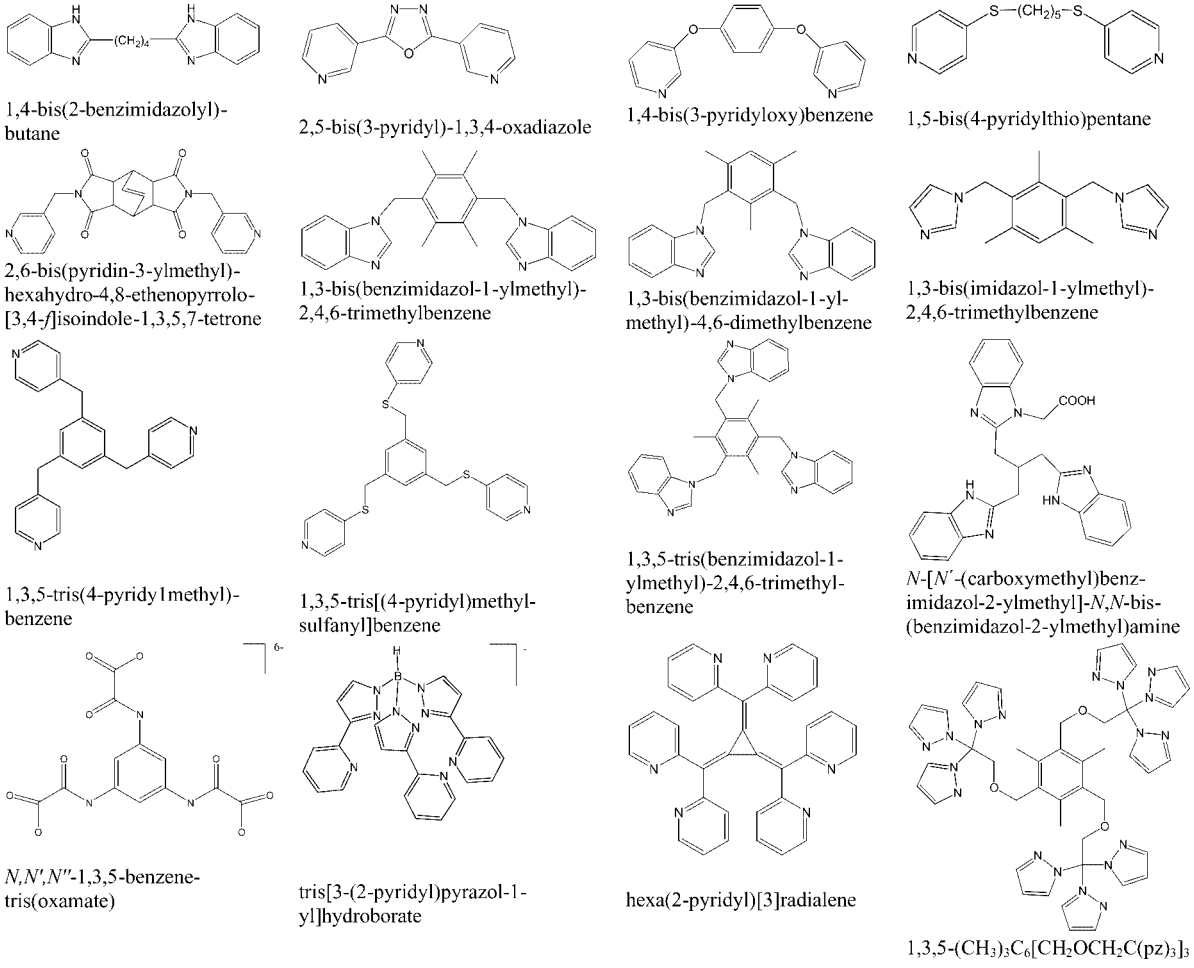
Scheme 4. Representative of multicomponent assembly of a molecular tube or a trigonal prism.

### 2.4 Multicomponent Self-Assembly

By contrast to above approaches for construction of discrete molecular architectures based on $C_n$ symmetry, deliberate design of prismatic architecture has long been achieved from multiple components self-assembly as depicted in Scheme 4.

This approach is mainly characteristic of the rigid ligands. The pioneering work in this field includes Lehn's cylindrical structures[6] assembled from tetrapyridine and hexaphenylhexaazatriphenylene derivatived multidentate compounds involving two triangular ligands and three ditopic linear ligands. However, the flexible tetrapyridine ligand containing the $CH_2CH_2$ spacer was found to be able to result in the similar trigonal structure.[6c] Fujita and co-workers have reported a series of prismatic architectures based on the self-assembly of tridentate panel-like ligand, bidentate pillar ligand and *cis*-capped $Pd^{II}$ or $Pt^{II}$ ions.[7a–7c] Because the ligands are normally "self-select",[7a,7c] the template has been found necessary for the formation of such prismatic structures. Moreover, thus constructed molecular architectures are usually kinetically stable once formed and remain stable to a certain extent even after the template was removed.

It is interesting that formation of tubular structures sometimes takes benefit from such a multicomponent assemble process.[7d] As shown in Scheme 4, if the ligands oc-



Scheme 5. Part of the mentioned ligands.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

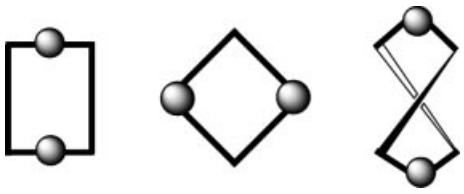
cupying the bases of the prisms are absent, the prismatic structure becomes open-ended, thus turning into tubular architectures keeping the shape of the prisms.

It should be noticed that there are other routes besides above four have also appeared in the literature. On the other hand, these approaches sometimes may also result in formation of helical structures, such as double-stranded, triple-stranded and even quadruple-stranded helicates,[1d,8] which sometimes become ambiguous to be distinguishable from the prismatic structures. However, for the molecular architectures having well-shaped structure or even possessing apparent $C_{n\mathrm{h}}$ or $D_{n\mathrm{h}}$ symmetry which incompatible with the helical sense, it is inappropriate to describe them as helicates. In this microreview, we mainly focus on apparently regular molecular architectures. A few obvious helicates are only mentioned selectively. In many cases, the structures may not possess the exact crystallographically imposed $C_n$ symmetry thus deviating from the right prisms, or only keeping the overall prismatic shapes. Part of organic ligands mentioned in the following discussion are listed in Scheme 5.

## 3. Cyclic Molecular Architectures

### 3.1 $M_2L_2$ Metallacycles and Rectangles Based on Non-Rigid Ligands

Design and synthesis of cyclic molecular architecture has attracted extensive interests in several research fields, including materials chemistry and molecular nanotechnology. Dinuclear metallacycles may represent the most productive cyclic molecular architectures, partly owing to the fact that the closed $M_2L_2$ motif is the smallest metallacyclic species hence the most thermodynamically favored one predominant over other larger species in solution. As early examples of such structures, flexible long-chain diphosphanes $Ph_2P(CH_2)_nPPh_2$ ($n \geq 3$) have been shown to generally give rise to dinuclear ring structures on reaction with equivalent amounts of silver(I) or copper(I) salts, containing terminal or bridging anions.[9] Depending on the different conformations of the non-rigid ligands, $M_2L_2$ cyclic molecules can display varied shapes like molecular rectangles, molecular rhombus and dinuclear helicates as shown in Scheme 6. Usually, when the non-rigid ligand contains two terminal coordinating arms which adopt a *cis* conformation and point to the same direction, the ligand can act as a "molecular clip" to react with metal ions to form $M_2L_2$ rectangles. While the angular ligand turning in the middle can react with two metal ions to assemble an $M_2L_2$ molecule showing rhombic structure. On the contrary, if the conformation of the non-rigid ligand is changed from *cis* to *trans*, the ligand can twist along two metal axes to form dinuclear helicate. For example, Hannon et al. designed a series of bis(pyridylimine) Schiff-base ligands from methyldianiline, which offer sufficient flexibility for two strands to wrap around the two metal centers while impose the same stereochemistry at both centers. Reaction of these ligands with $Cu^{I}$ or $Ag^{I}$ ions afforded various dinuclear helicates.[10]



Scheme 6. Schematic view of the rectangular, rhombic or dinuclear helical $M_2L_2$ metallacycles.

Compared to the well developed higher symmetric $M_4L_4$ square, molecular rectangles may be able to exhibit improved selectivity and sensitivity with respect to molecular recognition and separation.[4] However, preparation of molecular rectangles based on the rigid ligands is still challengeable, because simply mixing two ligands of different lengths and *cis*-protected metal corners usually forms two types of molecular squares instead of molecular rectangles due to the enthalpic reason.[11] Alternatively, Stang and coworkers creatively designed an organometallic "clip" which anchors two metal corners on each side of a rigid ligand and opens two labile coordination sites in a nearly parallel fashion ready for connecting the second rod-like dipotic ligand.[4a] Similarly, clever design of semi-rigid ligand possessing two co-facial directing coordination groups could provide analogous "organic molecular clips" which facilitate a ligand-directed symmetry-interaction approach[3] for fabrication of rectangular structures as demonstrated in route 2.1 and 2.3.

Early examples matching such design approach can be found in a series of cofacial dinuclear complexes formed from bis(β-diketone) and bis(β-ketoenamine) ligands.[12a–12d] The well-defined size and shape of these complexes show inner cavity where small guest molecules are able to be hosted. Latter examples include Mirkin's neutral $Re^{I}$ macrocycles of the phosphanylthioether ligands,[12e] Cotton's molecular loops composed of two dimetal *cis*-$Mo_2(DAniF)_2^{2+}$ units (DAniF = *N*,*N*′-di-*p*-anisylformamidinate) linked by two dicarboxylate dianions,[12f] Chung's $Ag^{I}$ metallosupramolecules of the flexible 2-pyridyl ligands,[12g] and Fujita's rhombic structure consisting of two angular dipyridyl ligands and *cis*-protected metal ions.[12h]

We designed a series of semi-rigid and flexible ligands containing two (benz)imidazolyl or quinolyl terminal coordinating groups.[13] The flexibility of the methylene -$CH_2$- groups endow the ligands conformational freedom and, when induced by the symmetry interaction from properly selected metal ions, they behavior as molecular "clips" to assemble dinuclear metallocycles showing the rectangular structures. The shape and size of these molecular rectangles could be adjusted by modifying the structures of the ligands, thereby imposing distinguishable nature of the cavity and ability of hosting small molecules or counterions (Figure 1).[3] In addition, many dinuclear macrocycles based on the non-rigid ligands have good solubility, thus giving a chance to investigate their solution dynamics and the potential mechanism of self-assembly by means of NMR and ESI-MS techniques. For example, in complexes

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

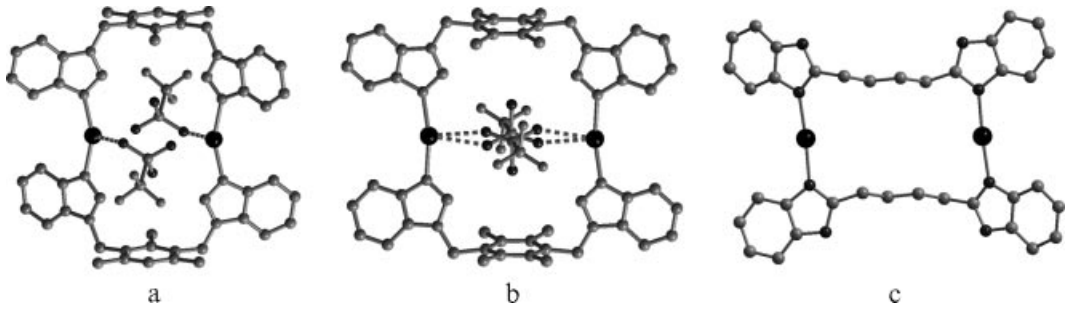


Figure 1. Rectangular structures formed in complexes (a) $[Ag_2\mathbf{L^1}_2](CF_3SO_3)_2$ [$\mathbf{L^1}$ = 1,3-bis(benzimidazol-1-ylmethyl)-2,4,6-trimethylbenzene],[3] (b) $[Ag_2\mathbf{L^2}_2](CF_3SO_3)_2$ [$\mathbf{L^2}$ = 1,4-bis(benzimidazol-1-ylmethyl)-2,3,5,6-tetramethylbenzene][3] and (c) $[Ag_2(C4BIm)_2](CF_3CO_2)_2$.[13a]

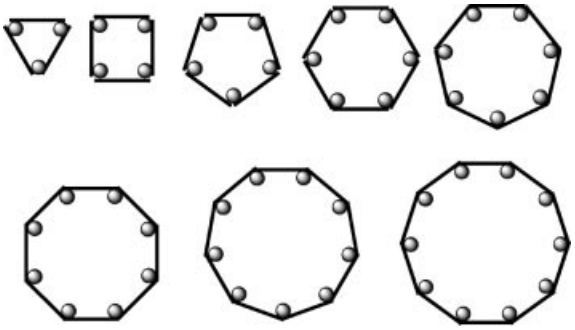
$[Ag_2(C4BIm)_2](CF_3CO_2)_2$ [C4BIm = 1,4-bis(2-benzimidazolyl)butane][13a] as shown in Figure 1, c, the solution dynamics study showed that equilibria among the $[Ag_2(C4BIm)_2]^{2+}$ dication and other potential oligomers were established via a solvent-assisted dissociative exchange mechanism. The calculated metal–ligand exchange barrier from VT-$^1$H NMR results was comparable with the energy of a strong hydrogen bond, which accounts for the reason that why the formation of $Ag^I$ complexes are very unpredictable and can be easily affected by various subtle factors and why astonishingly diversified structures and topologies could be obtained from $Ag^I$ and quite similar ligands, namely, supramolecular isomerism.[13a]

### 3.2 $M_nL_n$ ($n \geq 3$) Metallacycles Based on Non-Rigid Ligands

The directional-bonding approach has been usually used to predetermine the larger cyclic molecules, and various structures with a wide range of sizes, shapes and desirable physical properties have been obtained through careful selection of the metal starting material, coordinatively inert directing ligands or bridging ligands.[1] Theoretically, multinuclear cyclic molecular architectures can be synthesized via the systematic combination of ditopic building blocks and metals conforming to required angles as shown in Scheme 7, in which the regular models of polygons, such as triangles, squares, pentagon, hexagons an so on, could be developed.



Scheme 7. Schematic view of the metallacycles varying from triangle to decagon.

However, there are many subtle factors which can influence the final formation of the cyclic molecules based on the non-rigid ligands, so precise control of the polygonal shape and size is often difficult. Nevertheless, Puddephatt et al.[14a] reported a cationic molecular triangle [{Pt($Bu_2$-bipy)[μ-4-$NC_5H_4C(NO)NH$-4-$C_5H_4N$]}$_3$]$^{6+}$ which was assembled from the *cis*-blocked platinum(II) unit ($Bu_2$-bipy)-$Pt^{2+}$ and the unsymmetrical bis(pyridine) ligand 4-$NC_5H_4C(NO)NH$-4-$C_5H_4N$ (Figure 2, a), while a neutral molecular triangle [*cis*-$Mo_2(DAniF)_2]_3$(*trans*-1,4-$O_2CC_6H_{10}CO_2)_3$ (DAniF = *N*,*N*′-di-*p*-anisylformamidinate) containing metal–metal bound units derived from paddlewheel complexes was obtained by Cotton et al.[14b] The square $M_4L_4$ molecules are rather common for the rigid ligands, but still remain rare for the non-rigid ligands. One example can be found in a nickel(II)-based cationic molecular square $[Ni(HL)]_4^{4+}$ which was achieved via self-assembly from a pentadentate N4S ligand bis[phenyl(2-pyridyl)methanone] thiocarbazone ($H_2L$).[14c] The ligand was believed to be "conformationally rigid" and its multidentate character made it possible to use the octahedral metal ion for formation of square structure. A similar example is a zinc(II)-based square complex assembled from a linear-spacer-bridged bis(pyrrol-2-ylmethyleneamine) ligand. The structure possesses a $D_4$ geometry with two pyrrol-2-ylmethyleneamine units adopt a *trans* arrangement resulting in inner dimensions of 8.7 × 8.7 Å[14d] as shown in Figure 2, b.

It is usually believed that, for the $M_nL_n$ macrocyclic structures, when the value *n* becomes larger, the discrete macrocycles becomes more thermodynamically disfavored in solution. However, the flexibility of the ligands sometimes may facilitate formation of multinuclear macrocyclic $M_nL_n$ ($n \geq 4$) with the aid of template guest. Known examples may be found from a series of $M_6L_6$ assemblies,[15] such as the chiral $Ag_6L_6$ from a completely stereospecific self-assembly of a semi-rigid bipyridine derivative with fused pinene group,[15a] neutral molecular $Pd_6L_6$ hexagons by using of flexible carboxylic acid modified ditertiary phosphanes $\kappa^3$-$P_2O$-terdentate ligands,[15b] $Fe_6L_6$ hexameric ferric wheels from reaction of various *N*-substituted diethanolamines.[15c] Even larger metallacycles[16] include [30]-metallacrown-10 compounds $[Mn(C_{14}H_9N_2O_3)(CH_3OH)]_{10}\cdot 5CH_2Cl_2\cdot 16CH_3OH\cdot H_2O$ and $[Fe(C_{14}H_9N_2O_3)(CH_3OH)]_{10}\cdot$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

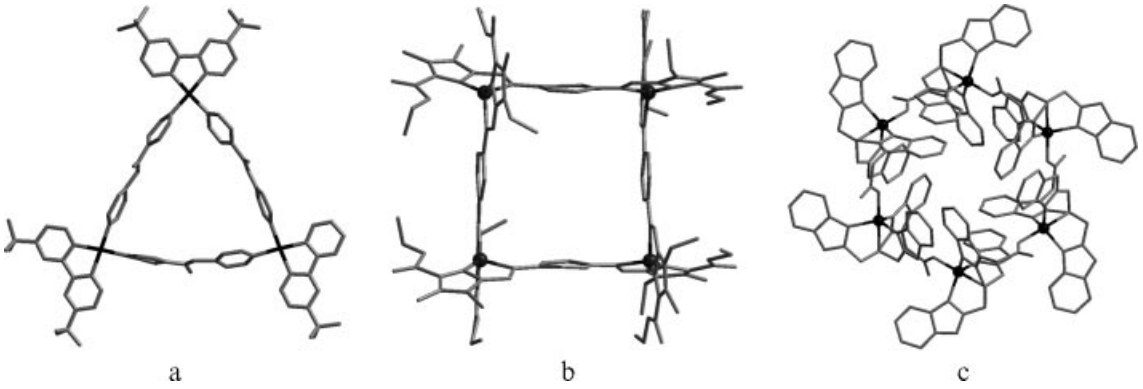


Figure 2. (a) A cationic molecular triangle $[\{Pt(Bu_2\text{-bipy})[\mu\text{-}4\text{-}NC_5H_4C(NO)NH\text{-}4\text{-}C_5H_4N]\}_3]^{6+}$,[14a] (b) a zinc(II)-based square complex assembled from a bis(pyrrol-2-ylmethyleneamine) ligand,[14d] and (c) a hexanuclear cationic metallamacrocycle $[Cu_6(Acntb)_6](ClO_4)_6\cdot 6H_2O$.[15d]

$3CH_2C_{12}\cdot 12.5CH_3OH\cdot 5H_2O$ with a pentadentate ligand *N*-phenylsalicylhydrazidate,[16a] [36]metallacrown-12 $Ni^{II}$ compound $[Ni(C_{13}H_9N_3O_2)(CH_3OH)]_{12}$ from a pentadentate Schiff-base ligand salicylaldehyde 2-pyridinecarboxylhydrazone,[16b] 36-membered dodecanuclear $Mn^{II}$ metalladiazamacrocycle $[Mn_{12}(tpeshz)_{12}(dmf)_{12}]$ (H3tpeshz = *N*-*trans*-2-pentenoylsalicylhydrazide)[16c] and $[Mn_{12}(chxshz)_{12}(MeOH)_{12}]$ (H3chxshz = *N*-cyclohexanoylsalicylhydrazide),[16d] and a chiral luminescent $Au_{16}$ ring $[(dppm)_2Au_4(pipzdtc)]_4(PF_6)_8$ assembled from achiral components dppm [bis(diphenylphosphanyl)methane] and $K_2$(pipzdtc) (piperazine-1,4-dicarbodithiolate).[16e]

We have modified a versatile $C_3$-symmetric ligand, tris(2-benzimidazolylmethyl)amine (ntb), by introducing one acetic acid group to get a new unsymmetric tripodal ligand *N*-[*N*′-(carboxymethyl)benzimidazol-2-ylmethyl]-*N*,*N*-bis(benzimidazol-2-ylmethyl)amine (HAcntb). Reaction of this ligand with $Cu(ClO_4)_2$ afforded a nanometer-sized hexanuclear cationic metallamacrocycle $[Cu_6(Acntb)_6](ClO_4)_6\cdot 6H_2O$ as shown in Figure 2, c.[15d] Each $Cu^{II}$ ion is coordinated by three imino-nitrogen atoms and the apical amino-nitrogen atom form the same ligand, and one oxygen atom of the branching methylenecarboxylate group from another ligand, thus linking six $Cu^{II}$ ions to a hexameric structure possessing a crystallographically imposed –3 symmetry.

As mentioned above, one of the disadvantages by using non-rigid ligand is the difficulty of the controlling the size of the target macrocycles. A typical example is the assembly of a series of chiral molecular polygons, ranging from triangle to octagon, with $[cis\text{-}(PEt_3)_2PtCl_2]$ and the same enantiopure 6,6′-bis(alkynyl)-1,1′-binaphthalene.[17] The limited conformational flexibility of the bridging ligand is believed the key to the facile one-pot self-assembly of six polygons of different size, which were able to be purified by silica gel column chromatography in varied yield. Another problem by using non-rigid ligand is the difficulty of determining the shape of the molecules. In many cases, so called circular helicates were obtained. For example, Steel et al. obtained an $M_3L_3$ trinuclear metallacycles[18a] by exploiting a semi-rigid ligand 1,3-bis(8-quinolyloxymethyl)-benzene to react with $AgCF_3SO_3$, and Hannon et al. reported a $Cu^{I}$ trinuclear helicate[18b] by utilizing semi-rigid bis(pyridylimine) Schiff-base ligands based on 4,4′-methylenebis(2,6-dimethylaniline). Moreover, different polygons can interconvert into each other by guest- or counterion-induced interactions which favor one over another during the assembly process. For example, Stang et al.[19a] reported an equilibrium mixture of triangular and square assemblies which was established in solution when the flexible, ditopic donor unit, *trans*-bis(4-pyridyl)ethylene, was treated with the ditopic acceptor unit, $cis\text{-}(Me_3P)_2Pt(OTf)_2$, in a 1:1 ratio. Such equilibrium is dependent on water and anions, and selective crystallization of either of the two species can be accomplished via the appropriate choice of solvents and ratio of anions. Similarly, Lehn and co-workers demonstrated that a linear trinuclear triple helicate could be converted to a pentagonal $M_5L_5$ in the presence of a template chloride anion while hexagonal $M_6L_6$ in the presence of a sulfate anion.[19b]

## 4. Prismatic Molecular Architectures

Design and assembly of prismatic molecular architectures, especially for those possessing an internal cavity capable of entrapping guest molecules, has been receiving great interests in recent years because of the prospective applications in host-guest chemistry, molecular recognition, catalysis, biology (drug delivery), and materials science (molecular devices). This section will give some examples according to the *n*-gonal bases of the prismatic structures.

### 4.1 Trigonal Prismatic Cages

#### *4.1.1 Assembled via Route 2.1*

Two three-connected metal ions locating at two bases and three ditopic ligands acting as lateral edges are required by this approach. The $Ag^{I}$ ion is a good candidate which is well known to display flexible coordination geometry vary-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

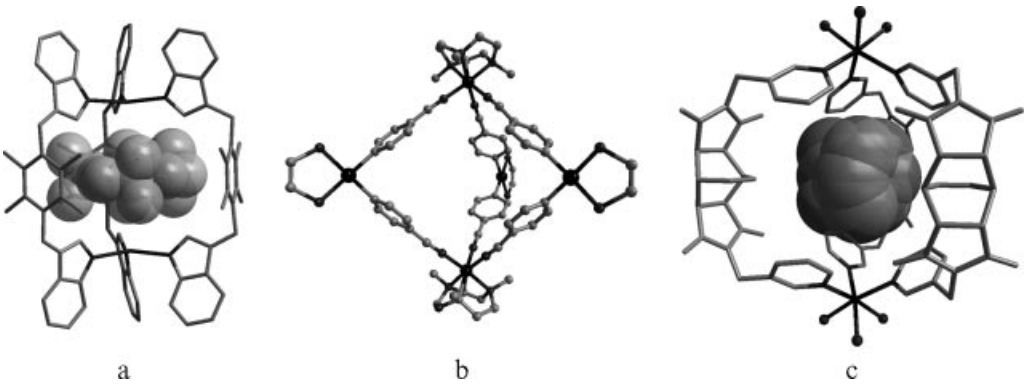

Figure 3. (a) Trigonal prismatic structures in complex $[Ag_2\mathbf{L^2}_3](CF_3SO_3)_2$,[21a] (b) trigonal-bipyramidal cage in complex $[[(Me_3tacn)Rh(CCPy)_3]_2[(DCPE)Pt]_3]$[22b] and (c) dicapped trigonal prismatic cage in complex $[Zn_2\mathbf{L^3}_3(H_2O)_6]\cdot(CF_3SO_3)_4\cdot CHCl_3$.[5] Guest molecules are shown in space-filling mode.

ing from two-coordinate linear to six-coordinate octahedral geometry.[20] When taking the triangular coordination geometry, $Ag^I$ ion can be utilized as trigonal node to assemble trigonal prisms in combination with three clip-like bis(monodentate) ligands. For example, we have prepared a ligand 1,4-bis(benzimidazol-1-ylmethyl)2,3,5,6-tetramethylbenzene (**L²**) which reacts with $AgCF_3SO_3$ in a 2:3 ratio to afforded a trigonal prismatic cage $[Ag_2\mathbf{L^2}_3](CF_3SO_3)_2$ as shown in Figure 3, a.[21a] The three ligands adopted the *cis* conformations with the nitrogen donor atoms from the benzimidazole rings pointing to the same direction, thus behaving as molecular "clip". The entire cationic prism exhibits an unusual $S_3$ symmetry. Steel et al.[21b] reported a similar structure which was described as a helicate. Another example of trigonal prism with trigonal geometric metal ions at the bases has been synthesized by Johnson and coworkers.[21c] In this case they used three dithiol ligands and two $As^{III}$ metal ions and the trigonal prism was close to a $C_{3h}$ symmetry.

### *4.1.2 Assembled via Route 2.3*

If metal ions of higher coordination numbers are used for such a purpose, the metal centers have to be protected to degrade the symmetry to $C_n$ according to the route 2.3. For instance, when the metal ions take the tetrahedral coordination geometry, one of four coordination sites has to be occupied by a monodentate anion or auxiliary ligand. By utilizing diphosphane ligand 1,2-bis(diphenylphosphanyl)-acetylene (dppa) to react with $Ag^I$ ions in a 2:3 ratio, a trigonal prism with tetrahedral geometric $Ag^I$ atoms at bases was obtained by James et al., in which the fourth coordination sites was taken by oxygen from anion $CF_3SO_3^-$ or $NO_3^-$, and the three P atoms from diphosphane ligands took the other three coordination sites.[22a] Another interesting example is the trigonal-bipyramidal supramolecular cage constructed by Youngs et al.[22b] where they used the well protected octahedral $Rh^{II}$ and square $Pt^{II}$ ions as shown in Figure 3, b. The reaction of 4-ethynyl-pyridine with the facially protected $(Me_3tacn)RhCl_3$ in the presence of *tert*-butyllithium afforded the octahedral complex $(Me_3tacn)Rh(CCPy)_3$, further reaction of this unit with three corner restricted *cis*-$(DCPE)Pt(NO_3)_2$ resulted in the mixed-metal-containing trigonal bipyramidal $[[(Me_3tacn)Rh(CCPy)_3]_2((DCPE)Pt)_3]$. From another point of view, this structure can be described as an assembly of three angular metal-containing ligands with two facially protected octahedral metal ions, showing a shape analogous to the trigonal prism.

We have prepared a semi-rigid conformational adaptive ligand, 2,6-bis(pyridin-3-ylmethyl)hexahydro-4,8-ethenopyrrolo[3,4-*f*]isoindole-1,3,5,7-tetrone (**L³**), which can react with the octahedral $Zn^{II}$ ion to afford a complex $[Zn_2\mathbf{L^3}_3(H_2O)_6]\cdot(CF_3SO_3)_4\cdot CHCl_3$[5] as shown in Figure 3, c. Two $Zn^{II}$ ions in this complex are coordinated by three different ligands and three water molecules, resulting in a N3O3 environment where three N and three O atoms are arranged in a *fac*-conformation allowing of a *3*-fold rotation symmetry $C_3$, thus the $[M_2\mathbf{L^3}_3]^{4+}$ cationic motif displays a dicapped trigonal prismatic structure (Figure 3, c) containing a trigonal cage in which a disordered $CHCl_3$ guest molecule is hosted. The molecule possesses an exact $C_{3h}$ point symmetry with a $C_3$ rotation axis passing through two $Zn^{II}$ atoms and a mirror plan bisecting the molecule.[5]

It should be noted that routes 2.1 and 2.3 are also applicable to rigid ligands providing the ligands are ditopic and exhibit the molecular clip character. For instance, Du et al.[23a] obtained a trigonal prism $[Cu_2(\mathbf{L^4})_3(CH_3CN)_2](ClO_4)_2$ [**L⁴** = 2,5-bis(3-pyridyl)-1,3,4-oxadiazole] in which one coordination site of each distorted tetrahedral $Cu^I$ center is occupied by N atom of an acetonitrile solvent, and the other three coordination sites join three different ligands acting as a 3-connecting node. Each trigonal prismatic cation hosts one water guest inside the cavity. Moreover, the bases of the trigonal prism can also be provided by different metal ions. Catalano et al. reported two mixed-metal trigonal prisms $[AuPdTl(P_2phen)_3](PF_6)_2$ and $[AuPtTl(P_2phen)_3](PF_6)_2$, where one basal site was taken by $Au^I$, and the other by $Pd^0$ or $Pt^0$. One $Tl^I$ ion was encapsulated inside via metal–metal interactions.[23b]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

A combination of two six-coordinate metal ions and three flexible bis(bidentate) ligands can also follows route 2.1 to give $M_2L_3$ molecular architecture, however, in most cases the ligands are twisted and the structures are actually dinuclear triple-stranded helicates[24] which fall out the scope of this review.

### *4.1.3 Assembled via Route 2.2*

Alternatively, the two bases of the trigonal prism can also be provided by non-metal planes. As shown in Scheme 3, tripodal ligands can be exploited in the assembly of trigonal prism following route 2.2, where the trigonal prism is generated in combination with three bridging metal ions. The tripodal ligands could be based on an aromatic ring, macrocycle, or even B atomic core having three *cis*,*cis*,*cis* conformational coordinating legs.

#### *4.1.3.1 From Tri(monodentate) Tripodal Ligands Based on Aromatic Core*

By using of the inherent $C_3$ symmetry of benzene ring, Fujita and co-workers designed one semi-rigid tripodal ligand 1,3,5-tris(4-pyridylmethyl)benzene and firstly described the formation of a trigonal prismatic structure having $M_3L_2$ components with two tripodal ligands bridged by three palladium atoms.[25] By changing the donor group 4-pyridyl to 1-imidazolyl, Sun and co-workers synthesized some new types of tripodal ligands and obtained a series of $M_3L_2$ trigonal prisms composed of two tripodal ligands and three bridging tetrahedral geometric zinc ions[25b] or linear coordinated silver ions.[25c–25e] Their results indicated that the frameworks of these prisms were mainly determined by the nature of the tripodal ligand and geometric need of the metal ions, independent of the anions and the solvents. A similar trigonal prism was also reported by Lindoy et al.,[25f] where they combine a flexible tripodal ligand 1,3,5-tris[(4-pyridyl)methylsulfanyl]benzene with three silver(I) ions affording an $M_3L_2$ prismatic structure.

Similarly, based on the inherent $C_3$ symmetry of mesitylene core, we have designed a semi-rigid tri(monodentate) tripodal ligand 1,3,5-tris(benzimidazol-1-ylmethyl)-2,4,6-trimethylbenzene with 1-benzimidazolyl as coordination donor groups. Reaction of this tripodal ligand with $AgBF_4$, $AgClO_4$ or CuI resulted in a series of $M_3L_2$ trigonal prismatic cages which comprising two *syn*-conformational tripodal ligands jointed by three linearly coordinated metal ions with six benzimidazolyl legs nearly perpendicular to the central mesitylene cores (Figure 4, a).[3,26a] It was found that the assembly processes were not significantly affected by the counteranions, metal-to-ligand ratio or the solvent used, and the guest molecules encapsulated inside the cages showed diversified shapes and sizes varying from the spherical anion $BF_4^-$, $ClO_4^-$ to the planar $Cu_2I_4^{2-}$ coordination motif. To enlarge the inner cavity, the three legs of such tri(monodentate) tripodal ligand can be elongated. Ahn et al. have prepared a ligand containing three extended 4-pyridine legs with mesitylene or 1,3,5-triethylbenzene as cores. Two homochiral trigonal prisms were obtained from two tripodal ligands bridged by three $Pd^{II}$ ions. Since these prisms had internal binding sites, the authors believed that these cages could recognize organoammonium ions, or even chiral guests.[26b]

#### *4.1.3.2 From Tri(bidentate) or Tri(tridentate) Tripodal Ligands Based on Aromatic Core*

To assemble the trigonal prismatic structures by using the tri(monodentate) tripodal ligands, three metal ions with only two free coordination sites are required, such as linear coordinated $Ag^I$ or $Cu^I$ ions. The metal ion of higher coordination number needs proper blocking. Such restriction can be released by using tri(bidentate) or tri(tridentate) tripodal ligands. Journaux et al.[27a] designed a tripodal ligands *N*,*N*′,*N*′′-1,3,5-benzenetris(oxamate) with oxamate group as coordination donor. Two ligands adopted a tris(*N*,O-bidentate) coordination mode to generate a trigonal prism in which each $Cu^{II}$ ions was coordinated by two nitrogen atoms and two oxygen atoms in the equatorial plane. Similarly, Reger et al.[27b] designed a tri(tridentate) tripodal ligand $1,3,5\text{-}(CH_3)_3C_6[CH_2OCH_2C(pz)_3]_3$ (pz = pyrazolyl ring). Since each arm of this flexible tripodal ligand has three potential coordination donors, so many metal ions with different coordination geometry can be used to assembly $M_3L_2$ trigonal prism. Reaction of this ligand with $AgBF_4$ gave rise to a trigonal prismatic cage of composition $\{[Ag_3L_2(CH_3CN)](BF_4)_3\}\cdot(CH_3CN)_4$, in which all arms take a bidentate coordination mode to join three four coordinating $Ag^I$ ions. One $CH_3CN$ guest molecule was encapsulated inside the trigonal prism (Figure 4, b).

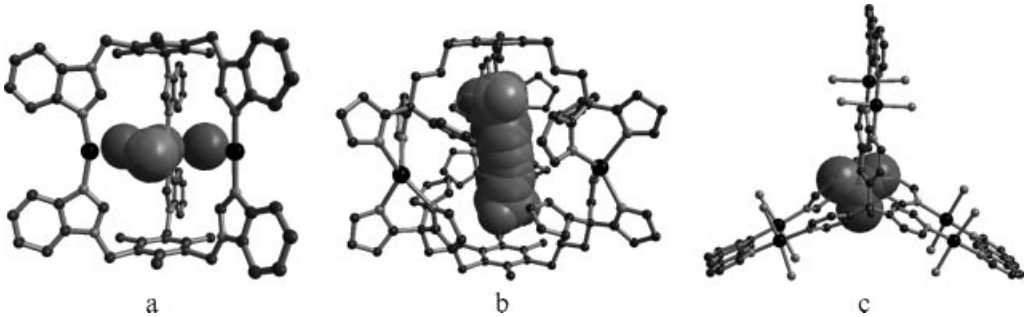

Figure 4. Representative trigonal prismatic structures assembled from (a) a tri(monodentate) tripodal ligand,[3] (b) a tri(tridentate) tripodal ligand[27b] and (c) an $sp^3$ C atom based tripodal ligand.[28d]

*4.1.3.3 From Tripodal Ligands Based on Non-Aromatic Core*

Alternatively, tripodal ligand could also contains a non-aromatic core, such as cavitand moiety, $sp^3$ C or B atoms etc.[28] Shinkai et al. obtained a trigonal prism via $Pd^{II}$-pyridine interactions when they used the tripodal ligand based on homooxacalix[3] as starting material, in which the [60] fullerene can be encapsulated inside the cavity.[28a] A variety of tripodal organic ligands or metal-containing ligands with $sp^3$ C, adamantane, Si or P=O as central cores have been synthesized by Stang and co-workers. Reaction of these ligands with predesigned metal-containing "clip" or organic "clip" afforded various trigonal structures (Figure 4, c).[28b–28d] Ward et al. synthesized an $M_3L_2$ structure by using tri-chelating hexadentate ligand tris[3-(2-pyridyl)-pyrazol-1-yl]hydroborate based on B center, in which each $Cu^I$ ion is four coordinated by two *N*,*N*′-bidentate arms from two ligands.[25e] Torres et al. also reported an $M_3L_2$ trigonal cage based on subphthalocyanine which is a 14 π-electron aromatic macrocycle combining three *N*-fused diiminoisoindole units around a boron atom.[25f]

## 4.2 Tetragonal Prismatic Cages

### *4.2.1 Assembled via Route 2.1*

Metal ions preferring square-planar coordination geometry can be utilized to assemble tetragonal prisms through route 2.1 when the four coordination sites in the same plane are taken by four bis(monodentate) ligands with *cis* conformation.[29] The $Pd^{II}$ and $Pt^{II}$ ions are the mostly used square-planar geometric metal ions in the literature, and the coordination flexible $Cu^{II}$ ion sometimes is also used in the construction of tetragonal prism when it adopts square-planar coordination geometry. One of the earliest papers in this area is reported by Steel and co-workers,[29a] where they synthesized a coordinatively saturated tetragonal cage by using the ligand 1,4-bis(3-pyridyloxy)benzene and $Pd^{II}$ ion. One hexafluorophosphate anion was encapsulated inside the cage acting as a bridging ligand via the weak Pd···F interactions. However, this structure exhibits the helical sense and described by authors as the quadruply stranded helicate. A more regular trigonal prism was fabricated by Fujita et al.[29b] when they used a rigid bis(pyridyl) ligand to react with $Pd(NO_3)_2$ at a ratio of 2:1, in which each tetragonal prismatic cage encapsulated a nitrate ion inside its cavity. An isomorphous tetragonal structure based on $Pt^{II}$ ion was reported by Chand et al. in modified reaction conditions.[29c] Similar tetragonal prism based square-planar $Pd^{II}$ ions was also assembled from a semi-rigid ligand 1,3-bis(imidazol-1-ylmethyl)-2,4,6-trimethylbenzene (bitmb), in which the two square planar geometric $Pd^{II}$ ions were bridged by four bitmb ligands in *cis*-conformation.[29d] By exploiting some bis(amidopyridine) ligands to react with $[PdCl_2(PhCN)_2]$, Puddephatt at al. obtained a series of dipalladium(II) tetragonal prisms (Figure 5, a), these prismatic complexes exhibited remarkable host–guest chemistry. The encapsulated guest molecules could vary from anions, neutral molecules to cations, depending on the conformation of the bis(amidopyridine) ligands.[30]

### *4.2.2 Assembled via Route 2.3*

The metal ions adopting the square-pyramidal or octahedral coordination geometries can be used to assemble tetragonal prisms if the apical positions were blocked by auxiliary ligands or counterions. In this route, the metal ions usually involve $Co^{II}$, $Zn^{II}$, $Ni^{II}$, $Cu^{II}$ and so on.[31] One of the early tetragonal prisms constructed following this way is the $Cu^{II}$ prism synthesized by Atwood and co-workers,[31a] in which the two octahedral $Cu^{II}$ ions are bridged by four semi-rigid bis(monodentate) ligands and two coordinated water molecules occupy the axial positions. Later they reported an isomorphous tetragonal structure by using six-coordinate $Co^{II}$ ion instead of $Cu^{II}$.[31b] From the reaction of a semi-rigid ligand 3,5-bis(benzimidazol-1-ylmethyl)-1,4-dimethoxyl-2,6-dimethylbenzene with $Co(BF_4)_2 \cdot 6H_2O$ in the presence of solvent $CH_3CN$, Amouri et al.[31c] obtained a coordinatively unsaturated cobalt-based $M_2L_4$ cage, in which each $Co^{II}$ ion adopted a square-pyramidal coordination geometry. The four equatorial positions were occupied by four benzimidazolyl arms and the solvent molecule $CH_3CN$ coordinated to $Co^{II}$ ions at the axial position. The anion $BF_4^-$ was encapsulated inside through weak interactions with the metal centers. Similar tetragonal prisms have also been synthesized by Bu et al.[31d] when they used a flexible ligand 1,5-bis(4-pyridylthio)pentane to react with $Co(ClO_4)_2 \cdot 6H_2O$ or $Zn(ClO_4)_2 \cdot 6H_2O$.

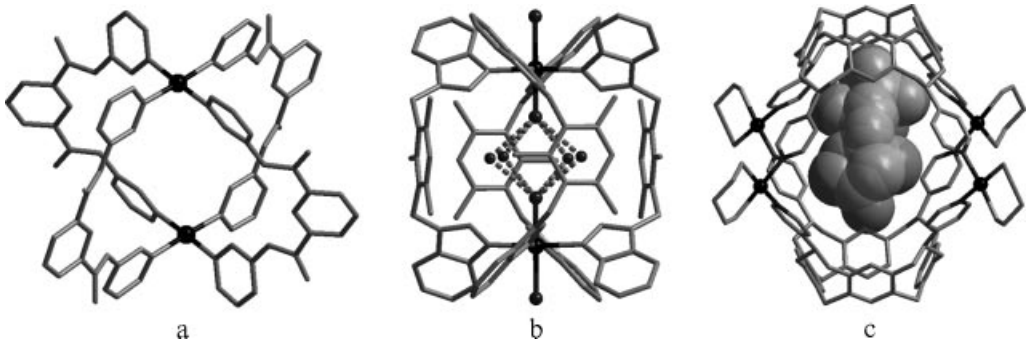

Figure 5. Representative tetragonal prismatic structures assembled with (a) square planar $Pd^{II}$ ion,[30a] (b) octahedral $Ni^{II}$ ion[3] and (c) cavitand-based tetrapodal ligand[33c] (phenyl groups are omitted).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

We have prepared a semi-rigid ligand 1,3-bis(benzimidazol-1-ylmethyl)-2,4,6-trimethylbenzene (bbimms) which reacted with $Cu(ClO_4)_2$ to afford a right prismatic cage complex.[3,21a] Four ligands take *cis* conformation to bridge two copper(II) ions to form the prism within which resides an axially disordered perchlorate anion. There is crystallographically imposed $C_4$ axis passing through the two $Cu^{II}$ atoms and a $\sigma_h$ mirror across the center of the molecule, resulting in an $S_4$ symmetry of the box. Along the $C_4$ axis the perchlorate anions are arranged alternately inside and outside the box to generate a one-dimensional multicompartmental column. Moreover, we found that metal halide compounds like $NiCl_2$ and $CoCl_2$ were good candidates for providing four open equatorial sites. The halide atoms are usually retained after metal ions coordinate with the bis(monodentate) ligands, so metal halide can be ideally used to assembly tetragonal prisms. From the reaction of mbbimb ligand with $NiCl_2{\cdot}6H_2O$, we obtained a neutral $S_4$ symmetric tetragonal prismatic cage as shown in Figure 5, b. In this complex, the two $Ni^{II}$ ions are held by the benzimidazolyl arms from four $C_4$-symmetrically arranged ligands via four equivalent Ni–N bonds with the octahedral coordination geometry completed by two axial chloride ions. There are four *4*-fold symmetrically arranged water molecules was hosted inside the cage via weak O–H···Cl hydrogen bonds. Similar tetragonal prismatic cages based on metal halide were also reported by Hong et al.[31e] when they used a flexible ligand 1,3-bis(pyrid-4-ylthio)propan-2-one to react with $CoCl_2{\cdot}6H_2O$ or $CoBr_2{\cdot}6H_2O$, where only one halide anion ligated to metal ions at the apical position to complete a distorted square-pyramidal coordination geometry.

#### *4.2.3 Assembled via Route 2.2*

Similar to trigonal prisms described above, tetragonal prismatic structures can also be assembled from two tetrapodal ligands and four bridging metal ions through route 2.2. Four legs of the tetrapodal ligand could be monodentate, bidentate or tridentate. As a consequence, four metal ions with two, four or six coordination sites available are required, respectively.

Although various tetrapodal ligands based on the aromatic ring are available in literature, successful application of route 2.2 to assembly of tetragonal prismatic structure is still rare.[32] However, Brisbois et al.[32] obtained one organometallic tetragonal complex when they used tetradentate ligand based on cyclobutadienyl core to react with ethylenediamine palladium(II) nitrate, in which the two organometallic tetrapodal ligands CpCo-tetrakis(3-pyridyl)cyclobutadiene were bridged by four *cis*-protected $Pd^{II}$ ions. On the other hand, Shinkai and co-workers[32b] have exploited porphyrin-based tetrapodal ligands containing four pyridyl donor groups to react with the *cis*-protected $Pd^{II}$ ions, leading to formation of dimeric capsules. The $^1H$ NMR spectral studies indicate that such self-assembled molecular capsules have a highly symmetrical $D_{4h}$ structure as well as a large inside cavity.

Even more tetrapodal ligands have been synthesized on the basis of cavitand or calix[4]arene moieties with substituted pyridyl or cyano groups as coordination donors.[33] The first tetragonal cage based on cavitand ligand was reported by Dalcanale et al.,[33a] in which the two tetracyanocavitand derivatives were connected by four square-planar $Pd^{II}$ or $Pt^{II}$ ions. Afterwards, a series of similar enlarged prismatic cages have been reported by them or others through design of related deepened cavitand precursors via introduction of an appropriate coordinating group on the resorcinarene skeleton (Figure 5, c).[33b–33e] Hong et al.[33f] designed cavitand ligand via introduction of four flexible 4-pyridylmethyl groups at the upper rims and assembled $Pd^{II}$ and $Pt^{II}$ cages, while Harrison et al.[33g] synthesized similar prisms by using cavitand ligand with four flexible methyliminodiacetic acids attached to its upper rims. The cage was formed from two ligands connected by four six-coordinate $Co^{II}$ ions.

### 4.3. Multigonal Prismatic Cages

The coordination prismatic structures with two bases of *n*-gons ($n \geq 5$) are heretofore rather rare. One of the reasons is that the metal ions with $C_n$ ($n \geq 5$) symmetric coordination sites locating in the same plane remain very unusual, so the routes 2.1 and 2.3 are not applicable for such a purpose. The routes 2.3 and 2.4 are potentially practicable for construction of e.g. pentagonal or hexagonal-prismatic structures, however, it was found difficult to maintain $C_n$ ($n \geq 5$) symmetry during self-assembly process. For example, pentapodal[34a] and hexapodal[27b] ligands have been prepared to react with the two-connecting metal ions, nevertheless, assembly of pentagonal or hexagonal prismatic structures were not successful due to failure to prevent intramolecular metal chelation or conformational isomerization.

One example close to a hexagonal-prismatic structure was reported by Steel and co-workers.[34b] They synthesized an $M_6L_2$ cage by using the ligand hexa(2-pyridyl)[3]radialene (**L**$^5$) to react with silver tetrafluoroborate. In this complex, two ligands both adopt a hexapodal hexadentate coordination mode, connected by six bridging $Ag^I$ ions to result in a hexapodal prismatic metallosupramolecule with an encapsulated $\mu_3$-fluorido anion (Figure 6).

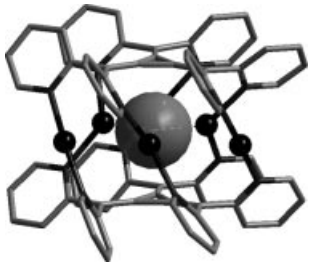

Figure 6. A representative hexagonal prismatic structure assembled with a hexapodal ligand **L**$^5$.[34b]

## 5. Tubular Molecular Architectures

In contrast to the well-developed inorganic nanotubes and organic nanotubular molecular architectures, the field of inorganic-organic hybrid coordination nanotubes remains largely unexplored in spite of the fast moving developments in the area of inorganic-organic hybrid materials. Recently, designing and constructing of tubular structures by utilizing coordination chemistry has been realized to be a useful approach, and a number of coordination polymers containing tubular channels have been synthesized.[35] However, the discrete coordination tubular molecular architectures remain rather uncommon. Depending on the deliberately protected angular coordination environments displayed by metal atoms and the judicious choice of the multidentate ligands, construction of coordination tubes via multicomponent assembly route 2.4 is feasible in the aid of template effect of the guest molecules. Initial work in this topic was reported by Fujita and co-workers.[36] They synthesized one discrete coordination tube by using rigid oligo(3,5-pyridine)s ligand and *cis*-protected $Pd^{II}$ ions, in which the four ligands were bridged by $Pd^{II}$ ions to encircle into tube, and the rod-like guests was the essential template of the formation of such coordination nanotubes (Figure 7, a). The tube dissociated into its components by the removal of the guest molecule and again re-associated by the addition of guest molecule.[36a] The length of thus formed tubes could be controlled just by elongating the ligand with increasing the numbers of pyridine nuclei.[36b] However, the solubility of the ligand became poorer when the ligand had more rigid rings, therefore they further introduced methylene ($CH_2$) groups to design flexible long tape-shape ligand, and successfully extended the length of similar coordination nanotube to 3.5 nm.[36c] Another longer coordination tube based on $Pd^{II}$ was also reported by them when they used one semi-rigid tetrapodal ligand having four terpyridines arms to react with $Pd^{II}$ ions, in which the two tetrapodal ligands were circled into a 3.0 nm open tube as a result of the coordination of terpyridines with $Pd^{II}$ ions.[36d]

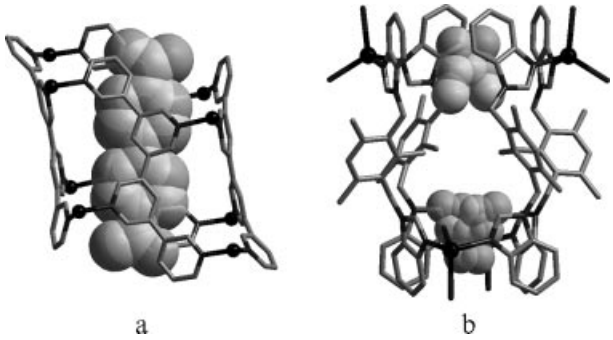

Figure 7. Tubular structures assembled with (a) a tetrakis(3,5-pyridine) ligand[36b] and (b) a *trans*-conformational ditopic semi-rigid ligand.[36e]

Based on the fact that the ditopic semi-rigid ligand is able to display either *cis*- or *trans*-conformation depending on the orientation of the two coordinating arms, we synthesized a discrete tubular tetramers $[Hg_4Cl_8(bbimms)_4]$ [bbimms = 1,3-bis(benzimidazol-1-ylmethyl)-2,4,6-trimethylbenzene] when we reacted the semi-rigid ligand bbimms with $HgCl_2$ which favors bent coordination geometry. The neutral molecular tube was generated by self-cyclization of four $[HgCl_2(bbimms)]$ subunits whose orientation alternates successively up and down (Figure 7, b), and the guest molecules DMSO or DMF played an important role in the formation and stabilization of the tubular structures. The interior cavity of the tube was approximately $4.6 \times 8.6 \times 16.8$ Å after consideration of the van der Waals radii. Furthermore, the neutral tubes were aligned to resemble a pipeline and that these pipelines were arranged into a three-dimensional columnar architecture.[36e]

## Concluding Remarks

In summary, well-shaped discrete molecular architectures are able to be constructed by using non-rigid ligands in contrast to the usually favored rigid ligands. Appropriate design and control of the donor groups and conformations of the semi-rigid or flexible ligands facilitate formation of relatively lower symmetric metallacyclic, prismatic and tubular structures in comparison to the higher symmetric polygonal or polyhedral structures. According to the distinguished nature of the non-rigid ligands and symmetry modification of metal ions, four assembly routes are available to direct formation of rectangular, prismatic and tubular architectures which are inherently related through the rotation symmetry. However, it should be noticed that the non-rigid ligands often display conformation freedom, for example, facile conversion between *cis* conformation and *trans* conformation of the ditopic semi-rigid ligands, which make it possible to generate coordination polymers instead of discrete molecular architectures. Therefore, vast effort is still needed to fully understand various subtle factors that influence the formation of closed molecular architectures as well as the shape stability and cavity size.

# High-Yield Synthesis of a New Layered High-Nuclearity Carbonyl Osmium-Rhodium Cluster Complex – Synthesis, Structural Characterization, and Electrochemistry of [PPN][$Os_9Rh_3(\mu\text{-}CO)_2(CO)_{26}$]

**Jasmine Po-Kwan Lau,[a] Yan-Juan Gu,[a] and Wing-Tak Wong*[a]**

**Keywords:** Osmium / Rhodium / High-nuclearity clusters / Electrochemistry

A direct and high-yield synthetic route for a novel dodecanuclear osmium-rhodium mixed-metal cluster is presented. The redox properties of the cluster were examined, and it was found that the anion behaves as an "electron reservoir".

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

The synthesis and isolation of the first heteronuclear carbonyl transition-metal complexes in the 1960s[1–3] had a great impact on the field of mixed-metal cluster chemistry. A large number of articles have appeared within the last 20 years that have reported the preparation and characterization of high-nuclearity mixed-metal clusters. The interest in these clusters is due to their fascinating metal core, potential application in catalysis,[4] and ability to act as an electron reservoir, and more recently, as valuable precursors to support nanocatalysts and nanosized metal particles.[5] To date, the majority of high-nuclearity mixed-metal clusters have been achieved by the use of redox coupling reactions between an anionic carbonyl compound and cationic metal electrophiles.[6–8] However, high-nuclearity Os-Rh mixed-metal clusters that have been achieved by a similar approach are rare.[9] We recently established a facile and reliable route for preparing such species in high yield by the simple thermolysis of a neutral Os-Rh cluster, [$Os_3Rh(\mu\text{-}H)_3(CO)_{12}$]. The high yields of the cluster allowed an electrochemical study of the complex and revealed the ability of the cluster to function as an "electron reservoir" that permits the uptake and release of electrons without significant cluster breakdown. We now report the synthesis, structural characterization, and electrochemical study of the novel high-nuclearity osmium-rhodium mixed-metal cluster [PPN][$Os_9Rh_3(\mu\text{-}CO)_2(CO)_{26}$] ([PPN]**1**). The metal framework in **1** is observed for the first time for an $M_{12}$ system.

## Results and Discussion

The high-nuclearity Os-Rh mixed-metal cluster anion **1** was isolated as a $[PPN]^+$ salt with a 60% yield from the thermolysis of a neutral Os-Rh cluster, [$Os_3Rh(\mu\text{-}H)_3(CO)_{12}$], in *n*-heptane for 2 h (see Scheme 1), together with a number of uncharacterized cluster species in very low quantity. The complex was characterized by spectroscopic methods and by a single-crystal X-ray diffraction study. The arrangement of the metal center of **1** can be described as two fused octahedra that share a common equatorial Rh–Rh edge. Two additional osmium atoms cap the faces of these octahedra in such a way that one adjacent triangular face is capped at the opposite ends of the fused bioctahedral structure (Figure 1). The Rh(1)–Rh(2) bond length [2.781(2) Å] is comparable to other apical-equatorial Rh–Rh distances observed within the compound and those bond lengths that have been observed for other trirhodium faces in osmium-rhodium mixed-metal clusters.[9] The structure of **1** contains 28 carbonyl ligands, and two of them are μ-bridging across the same apical-apical Rh–Os bond (Figure 2). The Rh(3)–Os(9) [2.632(8) Å] distance is slightly shorter than the average apical-equatorial Rh–Os bond [2.672(2) Å] of the cluster but much shorter than all other equatorial-equatorial Rh–Os distances in the molecule. A short Os–Os bond is observed between the apices of the fused octahedra. The Os(2)–Os(3) distance [2.626(1) Å] is shorter than the remaining Os–Os bonds, whose lengths range from 2.721(4) to 2.868(1) Å in the compound and are comparable to the normal average Os–Os distance in other osmium clusters.[10,11] To the best of our knowledge, the metal arrangement in complex **1** has not been observed in an $M_{12}$ system. Essentially, a similar framework structure is adopted by other homo- and heterometallic decanuclear clusters, such as [$Ru_8Pt_2(CO)_{23}(\mu_3\text{-}H)_2$],[12] [$Ru_{10}C_2(CO)_{24}$]$^{2-}$,[13] [$Ru_{10}C_2(\mu\text{-}\eta^2\text{:}\eta^2\text{-}C_3H_4)$]$^{2-}$,[14] [$Ga_{10}${Si-

$(SiMe_3)_3\}_6]$,[15] and $Os_{10}(CO)_{24}\{Au(PPh_2R)\}_4]$[10] (R = Ph or Me). Cluster **1** contains 31 short contacts, and has an overall electron count of 156. This electron count cannot be obtained by the application of any of the usual electron counting schemes.[16,17] This is not entirely unexpected, as it is common for rhodium to have a stable 16-electron configuration.

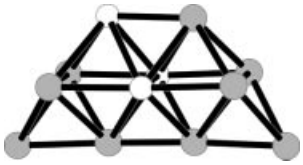

Figure 2. Metal core geometry of $[PPN][Os_9Rh_3(\mu\text{-}CO)_2(CO)_{26}]$ (**1**) (Os in grey and Rh in white).

To investigate the redox properties of this new mixed-metal cluster anion, a cyclic voltammetry of **1** in $CH_2Cl_2$ with *n*-tetrabutylammonium hexafluorophosphate (TBAHFP) as the supporting electrolyte at room temperature was carried out, the result of which is depicted in Figure 3. The electrochemical data are summarized in Table 1. Cluster **1** exhibits four successive reversible cathodic waves at $E_{pc}$ = –0.34, –0.72, –1.12, and –1.42 V, and two irreversible anodic waves at 0.71 and 0.80 V vs. $Ag/AgNO_3$, which is similar to that observed in the high-nuclearity osmium-palladium mixed-metal cluster $[PPN]_2[Os_{18}Pd_3(\mu\text{-}C)_2(CO)_{42}]$.[8] The four successive reversible cathodic waves reveal that the anionic charge of the cluster itself does not prevent it from accepting more electrons and releasing them reversibly. This suggests that cluster **1** can act as an electron reservoir, and has the ability to gain or lose electrons with-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

out significant decomposition. Controlled potential coulometry was performed at –0.53 V for **1**, indicating that each redox process consumes one electron per molecule. With regard to oxidation, two irreversible anodic waves were also observed, and this oxidation process is believed to lead to the breakdown of the cluster.

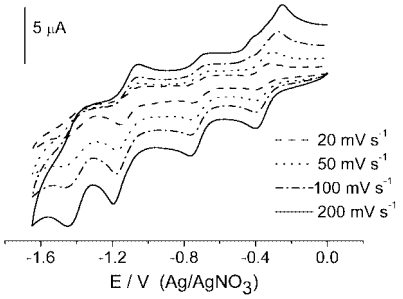

Figure 3. Cyclic voltammogram of [PPN][$Os_9Rh_3(\mu\text{-}CO)_2(CO)_{26}$] in $CH_2Cl_2$ containing 0.1 M $t$Bu$_4$NPF$_6$ in $CH_2Cl_2$; glass carbon electrode, platinum auxiliary electrode and Ag/$AgNO_3$ reference electrode; scan rate that varied from 20 to 200 mV s$^{-1}$.

Table 1. Electrochemical data[a] for cluster **1**.

| Reduction [V][b,c] | | Oxidation [V][b] | |
|---|---|---|---|
| $E_{pc1}$ | (–0.34) | $E_{pa1}$ | 0.71 |
| $E_{pc2}$ | (–0.72) | $E_{pa2}$ | 0.80 |
| $E_{pc3}$ | (–1.12) | | |
| $E_{pc4}$ | (–1.42) | | |

[a] Ca. $10^{-3}$ M cluster in 0.1 M $t$Bu$_4$NPF$_6$ in $CH_2Cl_2$ at 298 K, the working electrode was a glassy carbon electrode, the auxiliary electrode was a platinum electrode, and the reference electrode was Ag/$AgNO_3$ (0 V) under the same conditions, calibrated with ferroence. The scan rate was 100 mV s$^{-1}$. [b] $E_{pa}$ and $E_{pc}$ are the anodic and cathodic potential, respectively. [c] The values in parentheses are the $E_{1/2}$, half-wave potential values.

It is noteworthy that the average separation ($\Delta E_{av}$) between the formal electrode potentials of the consecutive redox couples observed in **1** is significantly smaller than those found in the dodecanuclear metal clusters that have been reported (see Table 2). An estimated value of $\Delta E_{av}$ for an $M_{12}$ cluster that is based on the nuclearity should be around 0.6 V.[24] The number of cluster valence electrons (CVE) found in **1** is 156 and is fewer than 158, as predicted by the Condensed Polyhedron Electrons (CPE) theory.[17] However, the observed CVE for other $M_{12}$ clusters that have been reported are all higher than the expected electron count using the CPE approach. The intrinsic electron deficiency of **1** may allow for the uptake of more electrons and a smaller $\Delta E_{av}$.

## Conclusions

The formation of a high-yield synthesis of high-nuclearity osmium-rhodium mixed-metal cluster by thermolysis of the neutral cluster [$Os_3Rh(\mu\text{-}H)_3(CO)_{12}$] has been developed. An unprecedented metal skeleton of this $M_{12}$ system is observed. The electrochemical studies revealed four reversible redox couples with unusually smaller separations for this cluster anion.

## Experimental Section

**Synthesis:** All manipulations were carried out under nitrogen with dry deoxygenated solvents. Thermolysis of [$Os_3Rh(\mu\text{-}H)_3(CO)_{12}$] (200 mg, 0.2 mmol) in $n$-heptane (50 mL) for 2 h led to a dark brown suspension upon stirring. The solution was then filtered to remove the black residue, and the filtrate was reduced under reduced pressure to 3 mL. An excess amount of [$N(PPh_3)_2Cl$] (110 mg, 0.5 mmol) in MeOH (3 mL) was added to the solution. TLC separation using $n$-hexane/$CH_2Cl_2$ (2:1, v/v) as an eluent afforded the [$Os_9Rh_3(\mu\text{-}CO)_2(CO)_{26}]^-$ salt (337 mg, 0.12 mmol, 60%) with an uncharacterized red brown complex in very small quantities. Black crystals of compound [PPN]**1** were obtained by slow concentration of an octane/$CH_2Cl_2$ solution mixture at –20 °C for 5–7 d in the presence of excess [PPN]$^+$ salts. $C_{64}H_{30}NO_{28}Os_9Rh_3$ (3281.45): calcd. C 22.99, H 0.90, N 0.42, P 1.85; found C 22.90, H 0.88, N 0.45, P 1.90. IR [$CH_2Cl_2$, ν(CO)]: $\tilde{\nu}$ = 2068 (vs), 2035 (vs), 2026 (m), 1610 (w) cm$^{-1}$. MS (FAB, +ve): 2804 (calcd. 2804). $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 7.50 (m, 24 H, Ph), 7.52 (m, 6 H, Ph) ppm.

**Crystallographic Data for 1:** [$C_{28}O_{28}Os_9Rh_3{\cdot}C_{36}H_{30}NP_2$]·0.5($CH_2Cl_2$), $M$ = 3385.86, triclinic, space group $P\bar{1}$ (#2), $a$ = 17.115(5), $b$ = 16.146(6), $c$ = 19.686(7) Å, $\alpha$ = 104.32(4), $\beta$ = 102.55(1), $\gamma$ = 99.07(1)°, $V$ = 3843(3) Å, $Z$ = 2, $D_{calcd.}$ = 2.926 g/cm$^3$, $T$ = 298 K, $F(000)$ = 3030.00, Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å), $\mu$(Mo-$K_\alpha$) = 155.8 cm$^{-1}$, crystal dimensions 0.25 × 0.30 × 0.35 mm. 9566 observed diffraction data [$I > 1.50\sigma(I)$] and $R_{int}$ = 0.055. The structure was solved by Patterson methods and expanded by using Fourier difference techniques,[18] and refined by full-matrix least-squares analysis on $F$ to $R$ = 0.056, $Rw$ = 0.058, and $\omega = 1/\sigma^2(F_o)$. All metal atoms were refined anisotropically and the other non-hydrogen atoms were refined isotropically. The hydrogen atoms were generated in their ideal positions and were included in the structure factor calculations using the riding mode. The osmium atoms Os(9) and Os(10) were found to be disordered in a 50:50 amount with the Rh(4) and Rh(3) atoms at the apices of the fused bioctahedra, respectively. Refinement converged with 50% occupancy of each atom type at each of the two sites. A highly disordered dichloromethane molecule was also present with 50% occupancy. All calculations were performed with a computer using the program package Crystal Structure.[19] CCDC-297120 contains the

# Synthesis and Structural Characterisation of Copper(II) 15-Metallacrown-5 Complexes with $Pb^{II}$, $Hg^{II}$, $Ag^{I}$, $Na^{I}$ and $Y^{III}$ Central Metal Ions

**Sabry Hamed Seda,[a] Jan Janczak,[b] and Jerzy Lisowski*[a]**

**Keywords:** Metallamacrocyles / Hydroxamic acids / Lead / Mercury / Copper / Crystal structure

The new copper(II) 15-metallacrown-5 complexes with the central metal ions $Pb^{II}$, $Hg^{II}$, $Ag^{I}$, $Na^{I}$ and $Y^{III}$, with the formula $[MCu_5L_5]X_n$ {$H_2L$ is 2-picolinehydroxamic acid or (*S*)-phenylalaninehydroxamic acid and $X^-$ is $NO_3^-$ or $Cl^-$}, have been synthesised and characterised by NMR and UV/Vis spectroscopy, electrospray mass spectrometry and elemental analysis. The $Pb^{II}$- and $Hg^{II}$ 15-metallacrown-5 complexes were obtained in the crystalline form as pyridine adducts $[PbCu_5(picha)_5(py)_6](NO_3)_2{\cdot}3(py)$ and $[HgCu_5(picha)_5(py)_7](NO_3)_2{\cdot}2(py)$ and their X-ray crystal structures were determined. In both complexes, each peripheral $Cu^{II}$ ion of the metallacrown is coordinated by one pyridine molecule bonded in the axial position. In the case of the $Pb^{II}$ derivative, one additional axial pyridine molecule is bound to the central metal ion, while in the case of the $Hg^{II}$ derivative, two axial pyridine ligands are bound to the central $Hg^{II}$ ion. The relative stability of the copper(II) 15-metallacrown-5 complexes with various central metal ions was determined on the basis of competition reactions. The relative preference of the 15-metallacrown-5 system for the central metal ion follows the series $Na^{I}$, $Ag^{I}$ < lanthanide(III), $Hg^{II}$ < $Pb^{II}$.

## Introduction

The bridging properties of aminohydroximate ligands are the basis for the formation of cyclic polynuclear complexes called metallacrowns,[1] which are inorganic analogues of crown ethers. In particular, the geometric requirements of the α-aminohydroximates, that form only five-membered chelate rings, result in a pentagonal arrangement of the 15-metallacrown-5 system (Figure 1), as observed in the interesting heteropolynuclear copper(II)–lanthanide(III) complexes[2–5] such as $[LnCu_5(picha)_5](NO_3)_3$ and $[LnCu_5(pheha)_5](NO_3)_3$, {where Ln is the lanthanide(III) ion, picha is the 2-picolinehydroxamic acid dianion and pheha is the (*S*)-phenylalaninehydroxamic acid dianion (Figure 2)} or analogous uranyl(VI) and calcium(II) complexes.[6] These complexes, which contain five copper(II) ions and which were discovered by the Pecoraro group, are assembled in the presence of an additional central metal ion, i.e. $Ln^{3+}$, $UO_2^{2+}$ or $Ca^{2+}$, and they correspond to complexed forms of crown ethers. In contrast, without the additional metal template, the same α-aminohydroxamic acids form the $[Cu_5L_4]X_2$ 12-metallacrown-4 complexes.[7,8] Analogous 15-metallacrown-5 lanthanide(III) complexes in which the peripheral $Cu^{II}$ ions are replaced by $Ni^{II}$ ions[9] or the α-aminohydroximate ligand is replaced by mandelohydroximate[10] (Figure 2) are also known. The high stability and preferred binding of $UO_2^{2+}$ over $Ca^{2+}$ by the copper(II) 15-metallacrown-5 complexes were studied in the context of the sequestering of the toxic uranyl ions and the biological importance of hydroxamic acids.[8a] The α-aminohydroxamic acids alone were also studied as possible sequestering agents for toxic lead(II) ions.[11]

metallacrown-5 complexes (Figure 1) with new central metal ions [M = $Pb^{II}$, $Hg^{II}$, $Ag^{I}$, $Na^{I}$ or $Y^{III}$, L = picha or pheha, X = $NO_3^-$ or $Cl^-$] and demonstrate the high stability of the 15-metallacrown-5 complexes of toxic lead(II) and mercury(II) metal ions.

## Results and Discussion

### X-ray Crystal Structure of the $[PbCu_5(picha)_5(py)_6](NO_3)_2 \cdot 3(py)$ Complex

The slow diffusion of diethyl ether into a pyridine solution of the $[PbCu_5(picha)_5](NO_3)_2 \cdot 3H_2O$ complex results in the formation of crystals of the pyridine adduct $[PbCu_5(picha)_5(py)_6](NO_3)_2 \cdot 3(py)$. The asymmetric unit of this complex contains the cationic complex $[PbCu_5(picha)_5(py)_6]^{2+}$ (Figure 3). The 15-metallacrown-5 system formed by five $Cu^{II}$ ions and five bridging 2-picolinehydroximate anions in this complex is less planar (the deviation of the atoms from the mean equatorial plane ranges from –1.061 Å for C43 to +0.804 Å for O41) relative to that in other copper(II) 15-metallacrown-5 complexes.[2–6] The buckling of the metallacrown most likely results from the relatively large size of the $Pb^{II}$ ion. Two of the 2-picolinehydroximate fragments are tilted with respect to the plane formed by the remaining three 2-picolinehydroximate ligands in such a way that the diameter of the ring formed by the five hydroximate oxygen atoms increases. The cavity radius of the metallacrown is 1.15 Å and matches well with the radius of the six-coordinate $Pb^{II}$ ion (1.19 Å). Each copper(II) ion is equatorially coordinated by two O atoms [the Cu–O distances range from 1.908 to 1.989(3) Å] and two N atoms [the Cu–N distances range from 1.941 to 2.030(3) Å] of the two neighbouring 2-picolinehydroximate ligands and one axial pyridine molecule [the Cu–$N_{py}$ distances range from 2.289 to 2.416(4) Å]. Thus, the complex has a pseudo fivefold symmetry. In this way, all five copper(II) ions exhibit identical coordination environments, in contrast to previously reported copper(II) 15-metallacrown-5 complexes,[2–6] which exhibit a variation in the axial donor sets of the copper(II) ions. The $Pb^{II}$ ion is coordinated in the centre of the metallacrown by five hydroximate oxygen atoms [the Pb–O distances range from 2.491 to 2.590(3) Å] and is additionally coordinated by one axial pyridine molecule with a Pb–$N_{py}$ bond length of 2.493(3) Å. Interestingly, this pyridine molecule and all five pyridine molecules coordinated to the $Cu^{II}$ ions are positioned on the same side of the macrocycle. Moreover, the pyridine-rich faces of the neighbouring complex cations related by an inversion centre are directed towards each other, which results in the formation of layers of pyridine molecules almost parallel to the (020) crystallographic plane (see Figure 4). In the unit cell, two of the three additional pyridine solvate molecules are located on the other side of the 15-metallacrown-5 core and one of the two is located almost perpendicularly to the core and is oriented with the N atom pointing towards the Cu4 atom [the Cu4···$N_{py}$ contact is 2.752(3) Å]. The third pyridine solvate molecule is located in the same plane as the coordinated pyridine molecules.

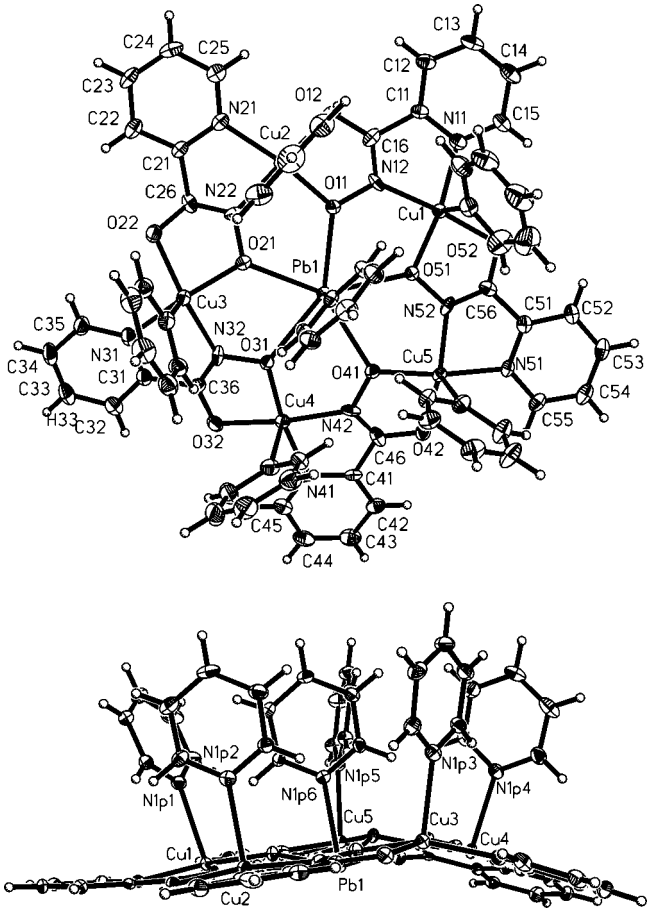

Figure 3. Top and side view of the $[PbCu_5(picha)_5(py)_6]^{2+}$ complex cation.

The $Pb^{II}$ ion adopts a pentagonal-pyramidal geometry, which is similar to that observed in a related nickel(II) 15-metallacrown-5 complex.[9] This geometry is relatively rare for lead(II) complexes.[12,13] The arrangement of the donor atoms around the $Pb^{II}$ ion is hemi-directed, in accord with the presence of the stereochemically active lone pair of electrons.[14] The $Pb^{II}$ ion is slightly displaced by 0.476(2) Å from the mean plane formed by the five hydroximate oxygen atoms in a direction away from the bound pyridine ligand. As a result of this displacement towards the open face, the $Pb^{II}$ ion adopts an umbrella-like structure.[12,13] The displacement of the $Pb^{II}$ ion towards the stereochemically active lone pair and the resulting distortion of the pentagonal pyramid is in accord with the VSEPR model, which predicts the privileged position of the lone pair.[15]

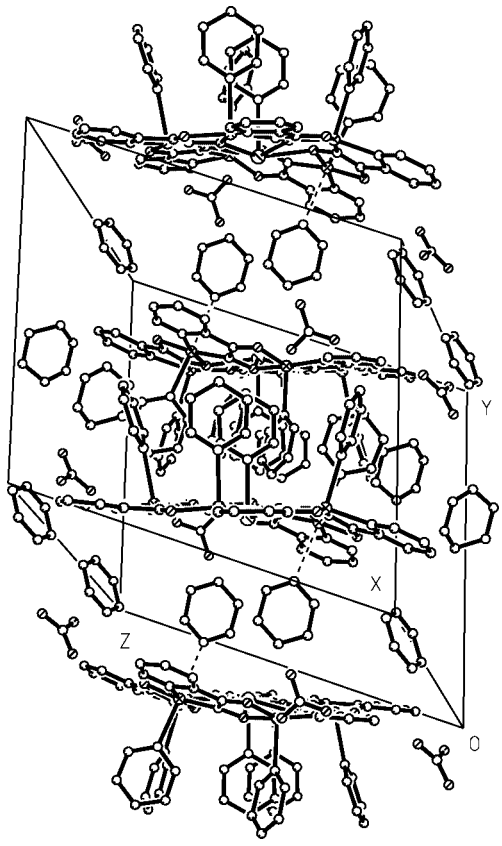

Figure 4. View of the crystal packing of $[PbCu_5(picha)_5(py)_6](NO_3)_2 \cdot 3(py)$ showing layers of pyridine molecules almost parallel to the (020) crystallographic plane.

### X-ray Crystal Structure of the $[HgCu_5(picha)_5(py)_7](NO_3)_2 \cdot 2(py)$ Complex

The slow diffusion of diethyl ether into a pyridine solution of the $[HgCu_5(picha)_5](NO_3)_2 \cdot 5H_2O$ complex also results in the formation of a pyridine adduct, $[HgCu_5(picha)_5(py)_7](NO_3)_2 \cdot 2(py)$. The asymmetric unit of this crystal contains the cationic complex $[HgCu_5(picha)_5(py)_7]^{2+}$ (Figure 5). The central $Hg^{II}$ ion is positioned almost exactly in the least-squares plane of the five oxygen donor atoms of the metallacrown [deviation from this plane is equal to 0.071(3) Å]. This ion is seven-coordinate – the five equatorial oxygen atoms of the metallacrown [the Hg–O distances range from 2.533 to 2.568(2) Å] and the two nitrogen atoms of the axially coordinated pyridine molecules [the two Hg–$N_{py}$ distances are equal to 2.175(3) and 2.182(3) Å] define a pentagonal-bipyramidal geometry. While several mercury(II) complexes of highly distorted pentagonal-bipyramidal geometry are known,[16] the discussed complex presents the first example of $Hg^{II}$ complexes that forms an almost regular pentagonal bipyramid with a fivefold symmetry (Supporting Information, Table S1). Each copper(II) ion in $[HgCu_5(picha)_5(py)_7]^{2+}$ is equatorially coordinated by two O atoms [the Cu–O distances range from 1.914 to 1.994(2) Å] and two N atoms [the Cu–N distances range from 1.928 to 2.043(3) Å] of the two neighbouring 2-picolinehydroximate ligands and one axial pyridine molecule [the Cu–$N_{py}$ distances range from 2.256 to 2.275(3) Å]. Similarly, as in the lead(II) complex discussed above, all the pyridine molecules axially coordinated to the $Cu^{II}$ ions are positioned on the same side of the metallacrown.

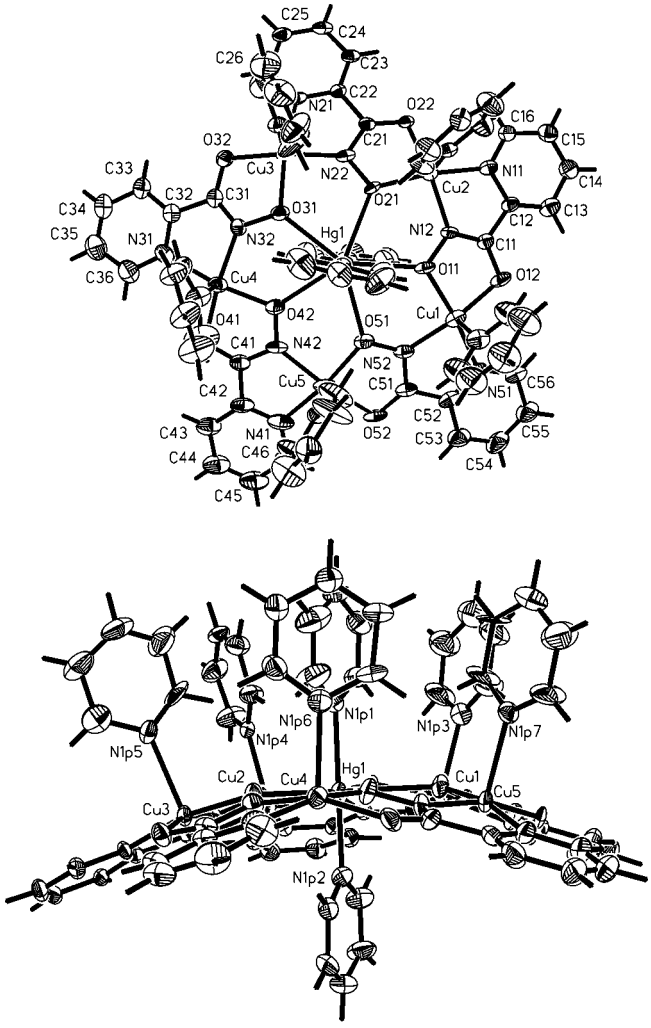

Figure 5. Top and side view of the $[HgCu_5(picha)_5(py)_7]^{2+}$ complex cation.

The deviation of the copper(II) 15-metallacrown-5 system from planarity in this complex is the largest for this class of compounds. The metallacrown adjusts itself to the size of the central $Hg^{II}$ ion by adopting a distinctive bowl shape. The cavity radius of the metallacrown further increases to 1.20 Å, which reflects the large effective size of the central mercury(II) ion. A search of the Cambridge Structural Database (Version 5.24) for Hg complexes containing a similar $N_2O_5$ donor set yields only one complex, bis[(μ2-trifluoroacetato-*O*,*O*,*O*′)-(trifluoroacetato-*O*,*O*′)pyridinemercury(II)] with a highly distorted pentagonal-bipyramidal geometry.[16a] The latter complex contains five equatorially coordinated oxygen atoms and two axially coordinated pyridine molecules with Hg–O distances that range from 2.55 to 2.87 Å and an average Hg–$N_{py}$ distance of 2.12 Å. These values, which are somewhat similar to those observed in $[HgCu_5(picha)_5(py)_7](NO_3)_2 \cdot 2(py)$, indi-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

cate that the effective "equatorial" radius of mercury(II) in this type of environment is substantially larger than the 1.02 and 1.14 Å reported for six- and eight-coordinate mercury(II) complexes, respectively.[17] Even longer bonds with equatorial donor atoms are found in mercury(II) complexes that have other donor sets and that exhibit a distorted pentagonal-bipyramidal geometry.[16] Thus, the seven-coordinate mercury(II) ion is large enough to push aside the aminohydroximate ligands and force the 15-metallacrown-5 system to adopt a bowl shape. The variation in the cavity radius reflects the flexibility of the copper(II) 15-metallacrown-5 ring in adjusting to the geometric requirements of the central metal ion.

In the unit cell, the pyridine solvate molecules are located in the hole between the cationic $[HgCu_5(picha)_5(py)_7]^{2+}$ complexes related by an inversion centre and translation (see Supporting Information, Figure S1). The two charge-compensating nitrate anions are also located in this hole. The pyridine-rich faces of the neighbouring complex cations related by an inversion centre form a layer of pyridine molecules almost parallel to the (230) crystallographic plane.

### Synthesis and Solution Characterization of the $[MCu_5L_5]X_n$ Complexes

The 15-metallacrown-5 complexes with the $Pb^{II}$, $Hg^{II}$, $Ag^{I}$, $Na^{I}$ and $Y^{III}$ central metal ions can be obtained in high yields in a straightforward synthesis based on the self assembly of α-aminohydroxamic acid, $Cu^{II}$ ions and the central metal ion in the presence of base. The NMR spectroscopic and ESI MS analyses of the crude reaction mixtures show that the 15-metallacrown-5 complex is the main product. In the case of the $Ag^{I}$ complex, the product isolated in the synthesis based on stoichiometric amounts of substrates exhibits small amounts of other complexes, and the use of excess $Ag^{I}$ ions was necessary for the isolation of the pure product. It is interesting to note the profound differences in product formation when NaOH or KOH was used in the reaction with α-aminohydroxamic acid and $Cu^{II}$ ions. While the smaller sodium cation templates the formation of the 15-metallacrown-5 ring, the potassium cation is too big to fit in the centre of this metallacrown, and the 12-metallacrown-4 complex with a central $Cu^{II}$ ion is therefore formed.[7]

The identities of the new copper(II) 15-metallacrown-5 complexes, $[NaCu_5(picha)_5](NO_3)$, $[AgCu_5(picha)_5](NO_3)$, $[PbCu_5(picha)_5](NO_3)_2$, $[PbCu_5(pheha)_5](NO_3)_2$, $[HgCu_5(picha)_5](NO_3)_2$ and $[YCu_5(pheha)_5]Cl_3$, are confirmed by positive mode ESI MS analysis in methanol/DMSO solutions. The spectra of the two lead(II) complexes exhibit peaks at $m/z$ = 1266 and 602 corresponding to the $\{[PbCu_5(picha)_5](NO_3)\}^+$ and $[PbCu_5(picha)_5]^{2+}$ species, respectively (Supporting Information, Figure S2), or a peak at $m/z$ = 707 corresponding to $[PbCu_5(pheha)_5]^{2+}$ (Supporting Information, Figure S3). The ESI-MS spectrum of the mercury(II) complex reveals peaks at $m/z$ = 1260 and 599 corresponding to $\{[HgCu_5(picha)_5](NO_3)\}^+$ and $[HgCu_5(picha)_5]^{2+}$, respectively, in addition to the signals of unidentified species that are formed by rearrangement of the starting complex in diluted solution. In the case of the yttrium(III) complex, signals at $m/z$ = 1368, 666 and 432 corresponding to the $\{[YCu_5(pheha)_5](Cl)_2\}^+$, $\{[YCu_5(pheha)_5](Cl)\}^{2+}$ and $[YCu_5(pheha)_5]^{3+}$ species, respectively, were observed in its spectrum, while only one signal is observed for both the silver(I) and sodium(I) 15-metallacrown-5 complexes; $m/z$ = 1107 for $[AgCu_5(picha)_5]^+$ and $m/z$ = 1021 for $[NaCu_5(picha)_5]^+$.

The positions of copper(II) d–d bands of the discussed 15-metallacrown complexes are sensitive to the type of central metal ion. This effect may reflect changes in axial ligation and/or in the degree of distortion from the ideal geometry (e.g. square pyramidal) of the copper(II) ions, which results from the slightly different buckling of the 15-metallacrown-5 system in each complex. The UV/Vis spectra of DMSO solutions of the $Na^{I}$, $Hg^{II}$ and $Pb^{II}$ complexes derived from picolinehydroxamic acid show bands at 558, 592 and 622 nm, respectively, and the spectra of the $Pb^{II}$ and $Yb^{III}$ complexes derived from (*S*)-phenylalaninehydroxamic acid exhibit d–d bands at 547 and 573 nm, respectively.

The $^1H$ NMR spectra of the $[D_6]$DMSO solutions of the 15-metallacrown-5 complexes derived from 2-picolinehydroxamic acid each exhibit four signals (Figure 6), while those of the derivatives of (*S*)-phenylalaninehydroxamic acid show six non-exchangeable signals (Supporting Information, Figure S4) in addition to two proton-exchangeable signals, in accord with the presence of diastereotopic $CH_2$ and $NH_2$ groups. The $^1H$ NMR signals can be tentatively assigned on the basis of linewidth analysis. In paramagnetic complexes with dominant dipolar and Curie relaxation mechanisms, the linewidths are inversely proportional to the sixth power of the proton–metal distance.[18] On this basis, the broadest and most-downfield-shifted $^1H$ NMR signals of the $[MCu_5(picha)_5](NO_3)_x$ complexes can be assigned to the protons at position 6 of the picoline ring, the two signals in the 20–40 ppm region correspond to those at positions 3 and 5 and the relatively narrow signals around 10 ppm correspond to those at position 4. In the case of the $Pb^{II}$ derivative, this assignment was confirmed by the observation of correlations between the signals for the protons at positions 3 and 4 and between the signals for those at positions 5 and 4 (in other cases, the nuclear relaxation was too fast to observe the expected COSY correlations). In the case of the $[MCu_5(pheha)_5]X_n$ complexes, the most-downfield-shifted $^1H$ NMR signals correspond to the protons at the α position, the next two signals correspond to those at the β positions, the three relatively narrow signals around 7 ppm are assigned to the protons of the phenyl ring and the two very broad upfield-shifted signals to the $NH_2$ protons. The two upfield-shifted signals disappear after addition of $D_2O$ because they correspond to exchangeable protons. The signals for the two diastereotopic β protons are well separated as expected for paramagnetic complexes. The $^1H$ NMR spectral patterns of the discussed $[MCu_5L_5]^{n+}$ complexes are very similar to those of the anal-

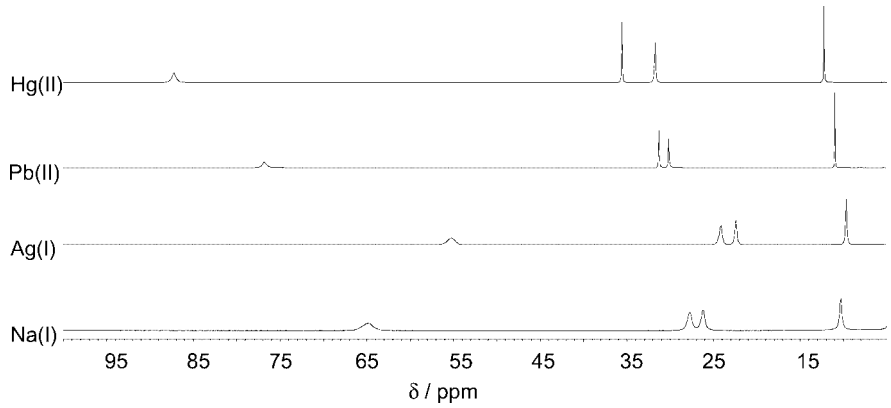

Figure 6. $^1$H NMR spectra (298 K) of [D$_6$]DMSO solutions of the [NaCu$_5$(picha)$_5$](NO$_3$), [AgCu$_5$(picha)$_5$](NO$_3$), [PbCu$_5$(picha)$_5$](NO$_3$)$_2$ and [HgCu$_5$(picha)$_5$](NO$_3$)$_2$ 15-metallacrown-5 complexes.

ogous $[MNi_5L_5]^{n+}$ and $[Cu_5L_4]^{2+}$ complexes,[7,9] which is in accord with the dominant contact contribution to the isotropic (paramagnetic) shifts of the aminohydroximate ligand. The upfield paramagnetic shifts of the $NH_2$ protons probably reflect sizeable dipolar contributions to the isotropic shift or spin polarisation effects,[18] which lead to a different sign of the contact shift of the $NH_2$ protons relative to those of other ligand protons.

The simple NMR spectra of the metallacrown complexes, in terms of the number of lines expected for a single α-aminohydroximate ligand, may arise as a result of two possibilities: (i) the presence of a single, pure complex of high symmetry with equivalent aminohydroximate ligands, or (ii) the presence of kinetically labile complexes of low symmetry or a mixture of labile complexes. In the latter case, the dissociation and rearrangement of the metallacrown complexes may lead to fast ligand exchange on the NMR time scale and observation of only one set of averaged signals. However, in the present case this situation can be excluded, since separate NMR signals for various α-aminohydroximate complexes are indeed observed for solutions of crude reaction mixtures or for the less-pure preparations of the discussed metallacrowns. Similarly, separate signals for the two ligand types are observed for the solutions containing mixtures of two 15-metallacrown-5 complexes with different central metal ions. Thus, the simplicity of the observed NMR spectra proves that only one complex with a high, effective fivefold symmetry is present in each case.

$^1$H NMR spectroscopy was used to compare the relative stabilities of the 15-metallacrown-5 complexes with various central metal ions. In the competition experiments, the additional metal salt was combined with the [D$_6$]DMSO solutions of the 15-metallacrown-5 complexes, and the $^1$H NMR spectra recorded over a period of time were used to monitor the exchange of the central metal ion. In the case of copper(II) 15-metallacrown-5 complexes with $Na^I$ or $Ag^I$ central metal ions, the addition of one equivalent of Pb(NO$_3$)$_2$ resulted in the disappearance of the $^1$H NMR signals corresponding to the starting complexes $[NaCu_5(picha)_5]^+$ or $[AgCu_5(picha)_5]^+$ and the appearance of new four signals at positions identical to those observed for [D$_6$]DMSO solution of [PbCu$_5$(picha)$_5$](NO$_3$)$_2$. The reaction was relatively fast (the transformation was completed after 15 min) and no intermediate was detected. Similarly, after 5 d at 323 K, complete conversion of the $Na^I$- or $Ag^I$ 15-metallacrown-5 complexes into $[LnCu_5(picha)_5]^{3+}$ (Ln = La, Sm) was observed after addition of one equivalent of the nitrate salt of a light lanthanide(III) ion (Figure 7, Supporting Information, Figure S5). The final spectra were identical to those of the independently synthesised $[LnCu_5(picha)_5]^{3+}$ complexes. In the same reaction with heavier lanthanide(III) ions (Ln = Sm, Yb), a small amount of the pentanuclear $[Cu_5(picha)_4]^{2+}$ 12-metallacrown-4 complex[7] was formed, which was detected in the final NMR spectra (Supporting Information, Figures S6 and S7). The slightly different behaviour of the heavy and light lanthanide(III) ions is related to the higher stability of the copper(II) 15-metallacrown-5 complex with the lighter lanthanide(III) ions.[7] The preference for the larger (lighter) lanthanide ions can be further confirmed by competition reactions between lanthanide(III) 15-metallacrown-5 derivatives and various lanthanide(III) salts. Addition of one equivalent of La(NO$_3$)$_3$·6H$_2$O or Sm(NO$_3$)$_3$·6H$_2$O to a DMSO solution of $[YbCu_5(picha)_5]^{3+}$ results in the gradual growth of a new signals corresponding to $[LaCu_5(picha)_5]^{3+}$ or $[SmCu_5(picha)_5]^{3+}$, respectively (Supporting Information, Figures S8 and S9). A partial conversion was obtained after the solution was heated for 55 d at 323 K (70% of the starting complex was converted in the case of $La^{III}$ and 63% in the case of $Sm^{III}$). The reverse reactions were not observed in analogous $^1$H NMR measurements. These observations indicate that the exchange of the lanthanide(III) ions is very slow, and equilibrium is not reached in these experiments. A similar situation was observed for the reaction of lanthanide(III) 15-metallacrown-5 complexes with the lead(II) nitrate. The partial (40–70%) conversion of the $[LnCu_5(picha)_5]^{3+}$ complex into $[PbCu_5(picha)_5]^{2+}$ was observed (Figure 8, Supporting Information, Figures S10–S12). Partial conversion of $[LnCu_5(picha)_5]^{3+}$ into the corresponding mercury(II) 15-metallacrown-5 complex, $[HgCu_5(picha)_5]^{2+}$, was also observed in the reaction with the mer-

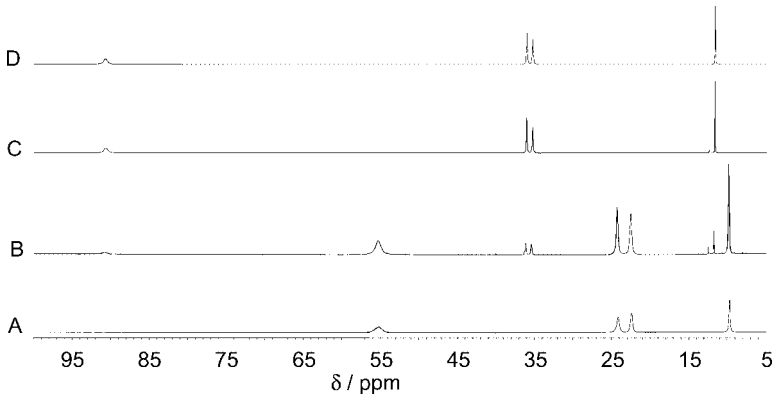

Figure 7. The $^1$H NMR spectra ([D$_6$]DMSO, 298 K) of: (A) the $[AgCu_5(picha)_5]^+$ complex, (B) $[AgCu_5(picha)_5]^+$ treated at 323 K with 1 equiv. $Sm(NO_3)_3{\cdot}6H_2O$ for 1 h, (C) for 5 d, (D) the $[SmCu_5(picha)_5]^{3+}$ complex.

cury(II) nitrate. In this case, however, a more complicated behaviour was observed – the subsequent decomposition of the resulting complex upon prolonged heating.

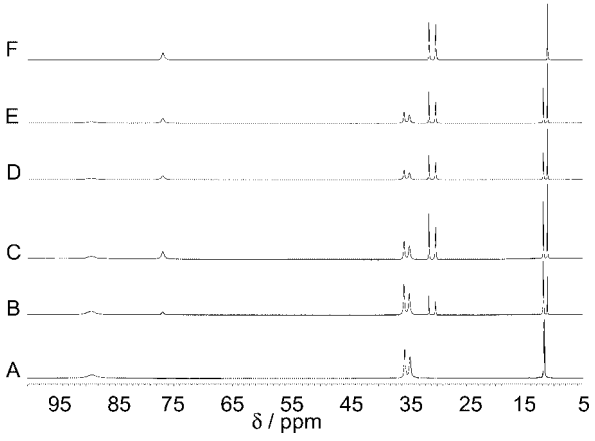

Figure 8. The $^1$H NMR spectra ([D$_6$]DMSO, 298 K) of: (A) the $[LaCu_5(picha)_5]^{3+}$ complex, (B) $[LaCu_5(picha)_5]^{3+}$ treated at 323 K with 1 equiv. $Pb(NO_3)_2$ for 1 d, (C) for one week, (D) for two weeks, (E) for one month, (F) the $[PbCu_5(picha)_5]^{2+}$ complex.

It should also be noted that the copper(II) 15-metallacrown-5 system is more stable than the copper(II) 12-metallacrown-4 system. The ring system of the 15-metallacrown-5 complex with the central $Pb^{II}$ or $Hg^{II}$ metal ion is not destroyed in pyridine solutions, while the 12-metallacrown-4 ring of $[Cu_5(picha)_4](NO_3)_2$ is destroyed by the competing pyridine ligand.[7] Further, the $[Cu_5(picha)_4]^{2+}$ complex is converted into $[MCu_5(picha)_5]^{n+}$ complexes after the addition of $Ag^I$, $Pb^{II}$ or $Hg^{II}$ nitrate, as indicated by $^1$H NMR spectra.

## Conclusions

We have shown that the copper(II) 15-metallacrown-5 system is well suited for the binding of a variety of relatively large metal ions in the centre of the metallacrown. In particular, the heavy metal ions lead(II) and mercury(II) form stable complexes of this type. In pyridine solution, these complexes form pyridine adducts, $[HgCu_5(picha)_5(py)_7](NO_3)_2$ and $[PbCu_5(picha)_5(py)_6](NO_3)_2$, in which the pyridine molecules are bound to the $Cu^{II}$ ions on the same side of the metallacrown. The 15-metallacrown-5 ring can adopt a buckled conformation in order to adjust to the size and coordination requirements of the central metal ion. The relative preference of the 15-metallacrown-5 system for the central metal ion follows the series $Na^I$, $Ag^I$ < lanthanide(III), $Hg^{II}$ < $Pb^{II}$. This series indicates that both electronic factors (preference for the metal ions that form strong bonds with the nitrogen and oxygen donor atoms) and geometric factors (preference for the larger metal ions) influence the stability of the formed complexes.

## Experimental Section

### Reagents and Materials

2-Picolinehydroxamic acid ($H_2$picha) and (*S*)-phenylalaninehydroxamic acid ($H_2$pheha) were prepared as reported previously.[4] All lanthanide(III) nitrates were obtained from Aldrich Chemical Co., $Cu(NO_3)_2{\cdot}3H_2O$, $Cu(CH_3COO)_2{\cdot}H_2O$, NaOH, $Pb(NO_3)_2$, $Hg(NO_3)_2{\cdot}H_2O$, pyridine and methanol (obtained from POCH) were of analytical grade and used without further purification.

### Synthesis

**$[NaCu_5(picha)_5](NO_3){\cdot}3H_2O$:** NaOH (0.095 g, 2.39 mmol) was added to a methanolic solution (25 mL) of 2-picolinehydroxamic acid (0.165 g, 1.19 mmol), and the resultant mixture was stirred for 10 min until a clear solution was obtained. A methanolic solution (10 mL) of $Cu(NO_3)_2{\cdot}3H_2O$ (1.19 mmol, 0.288 g) was added, and a brown precipitate, which appeared immediately, was separated. The product was recrystallised from methanol to give a deep brown complex $[NaCu_5(picha)_5](NO_3){\cdot}3H_2O$ (90 mg, 33% yield). $C_{30}H_{26}Cu_5N_{11}NaO_{16}$ (1137.31): calcd. C 31.70, H 2.30, N 13.56; found C 31.38, H 1.99, N 13.48%. $^1$H NMR (DMSO): $\delta$ = 9.90, 25.60, 27.42, 64.13 ppm; ($CD_3OD$): $\delta$ = 10.29, 26.19, 27.70, 64.82 ppm.

**$[AgCu_5(picha)_5](NO_3){\cdot}5H_2O$:** Solid NaOH (0.048 g, 1.19 mmol) was added to a solution of 2-picolinehydroxamic acid (0.165 g, 1.19 mmol) in methanol (25 mL), and the resultant clear solution was stirred for 10 min. $Cu(NO_3)_2{\cdot}3H_2O$ (0.144 g, 0.597 mmol) and solid $Ag(NO_3)$ (0.041 g, 0.238 mmol) were then added, and a brown precipitate started to appear. The solution mixture was stirred for 2 d. The obtained brown precipitate was filtered and dissolved in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

methanol again. Addition of a second portion of $Ag(NO_3)$ (0.02 g) to the methanol solution resulted in the formation of a brown-black precipitate, which was filtered and dried (81 mg 27% yield). $C_{30}H_{30}AgCu_5N_{11}O_{18}$ (1258.22): calcd. C 28.63, H 2.4, N 12.25; found C 28.49, H 2.38, N 12.35. $^1$H NMR (DMSO): $\delta$ = 9.66, 22.38, 24.11, 55.25 ppm.

**$[PbCu_5(picha)_5](NO_3)_2\cdot 3H_2O$:** 2-picolinehydroxamic acid (0.082 g, 0.60 mmol) was added to a methanolic solution (25 mL) of $Cu(CH_3COO)_2\cdot H_2O$ (0.120 g, 0.60 mmol), and the resultant deep brown solution was stirred for 10 min. A hot methanolic solution (10 mL) of $Pb(NO_3)_2$ (0.040 g, 0.12 mmol) was then added, and the green solution was left to stir overnight. The volume was reduced by a rotary evaporator, and the brown precipitate was filtered and dried (102 mg, 62% yield). $C_{30}H_{26}Cu_5N_{12}O_{19}Pb$ (1383.53): calcd. C 26.04, H 1.89, N 12.15; found C 26.17, H 1.72, N 12.19%. $^1$H NMR (DMSO): $\delta$ = 10.98, 31.15, 31.27, 76.79 ppm.

**$[PbCu_5(pheha)_5](NO_3)_2\cdot 5H_2O$:** $Cu(CH_3COO)_2\cdot H_2O$ (0.120 g, 0.60 mmol) was dissolved in methanol (25 mL), (*S*)-phenylalaninehydroxamic acid (0.107 g, 0.60 mmol) was added, and the mixture was stirred for 15 min. A hot methanolic solution (10 mL) of $Pb(NO_3)_2$ (0.040 g, 0.12 mmol) was then added, and the green solution was left to stir for 2 h. After evaporation of solvent, a brown precipitate was obtained (117 mg, 60% yield). $C_{45}H_{60}Cu_5N_{12}O_{21}Pb$ (1629.96): calcd. C 33.15, H 3.71, N 10.31; found C 32.96, H 3.60, N 10.31%. $^1$H NMR (DMSO): $\delta$ = 6.87, 7.00, 7.15, 7.90, 14.20, 21.52, –83.61, –98.96 ppm.

**$[HgCu_5(picha)_5](NO_3)_2\cdot 5H_2O$:** $Cu(CH_3COO)_2\cdot H_2O$ (0.120 g, 0.60 mmol) was dissolved in methanol (25 mL), 2-picolinehydroxamic acid (0.082 g, 0.60 mmol) was added, and the resultant solution was stirred for 15 min. A hot methanolic solution (10 mL) of $Hg(NO_3)_2$ (0.041 g, 0.12 mmol) was then added dropwise whilst stirring, and the resultant solution was heated at reflux overnight. The green-orange product that formed was filtered, washed with methanol and dried (91 mg, 54% yield). $C_{30}H_{30}Cu_5HgN_{12}O_{21}$ (1412.83): calcd. C 25.49, H 2.14, N 11.89; found C 25.65, H 1.76, N 11.55%. $^1$H NMR (DMSO): $\delta$ = 12.24, 31.74, 35.53, 87.25 ppm.

**$[YCu_5(pheha)_5]Cl_3\cdot 12H_2O$:** (*S*)-phenylalaninehydroxamic acid (0.107 g, 0.60 mmol) was added to a stirred solution of $Cu(CH_3COO)_2\cdot H_2O$ (0.120 g, 0.60 mmol) in $H_2O$ (25 mL). An aqueous solution (10 mL) of $YCl_3$ (0.033 g, 12 mmol) was added dropwise whilst stirring, and the colour of the mixture changed from green to deep blue. The mixture was left to stir overnight. Deep blue crystals of the complex were obtained (87 mg, 45% yield) upon slow evaporation of the solvent. $C_{45}H_{74}Cl_3Cu_5N_{10}O_{22}Y$ (1620.12): calcd. C 33.35, H 4.60, N 8.30; found C 33.06, H 4.60, N, 8.64%. $^1$H NMR ($CD_3OD$): $\delta$ = 7.05, 7.26, 7.34, 9.69, 16.64, 30.38 ppm.

**$[LnCu_5(picha)_5](NO_3)_3$ Complexes:** These were synthesised as described previously.[4,7]

### $^1$H NMR, ESI-MS and UV/Vis Measurements

The $^1$H NMR spectra were collected on a Bruker AMX 500 spectrometer. The spectra were calibrated by using solvent signals as reference. The gradient-COSY spectra were acquired with 256 × 1K data points and zero-filled to 1K×1K matrix. The positive-mode ESI-MS spectra were measured with a Finnigan MAT TSQ 700 triple stage quadrupole mass spectrometer equipped with an electrospray ionization (ESI) source and with a Micromass LCT (TOF) instrument. The UV/Vis absorption spectra were measured with a CARY 5 spectrophotometer. The elemental analyses were carried out on a Perkin–Elmer 2400 CHN elemental analyzer.

### X-ray Data Collection and Structure Determination

X-ray intensity data for both crystals were collected by using graphite monochromated Mo-$K_\alpha$ radiation on a four-circle κ-geometry KUMA KM-4 diffractometer with a two-dimensional area CCD detector at 100(2) K. The ω-scan technique with $\Delta\omega$ = 0.75° for each image was used for the data collection; 960 images for six different runs covering about 98% of the Ewald sphere were performed. Initially the lattice parameters were refined on about 150 reflections obtained from 40 images for eight runs with different orientations in the reciprocal space. Finally, the lattice parameters were refined by least-squares methods based on all the reflections with $I > 2\sigma(F^2)$. One image was used as a standard for monitoring

the stability of the crystals as well as for monitoring the data collection after every 40 images, and no correction on the relative intensity variation was necessary. Integration of the intensities and correction for Lorenz and polarisation effects were performed with a KUMA KM-4 CCD program system.[19] The face-indexed analytical absorption was calculated with the SHELXTL program.[20] The structures were solved by direct methods by using SHELXS of the SHELXL97 program.[21] The structures were refined with anisotropic thermal parameters for all non-hydrogen atoms. Difference Fourier maps gave electron density concentrations located approximately for all hydrogen atom positions; these positions were idealised (HFIX 43 for all H atoms of the pyridyl rings with isotropic thermal parameters of $1.2U_{eq}$ of the carbon atoms joined directly to the hydrogen atoms). Final difference Fourier maps showed no peaks of chemical significance. Details of the data collection parameters and final agreement factors are presented in Table 1. Selected bond lengths are listed in the Supporting Information, Table S1. CCDC-620938 and -620939 contains the supplementary crystallographic data for the $[PbCu_5(picha)_5(py)_6](NO_3)\cdot 3(py)$ and $[HgCu_5(picha)_5(py)_7](NO_3)\cdot 2(py)$ complexes, respectively. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

**Supporting Information** (see footnote on the first page of this article): Figure S1 – crystal packing of the $[HgCu_5(picha)_5(py)_7](NO_3)\cdot 2(py)$ complex, Figures S2 and S3 – ESI MS spectra of $Pb^{II}$ derivatives, Figures S4–S12 – NMR spectra, and Table S1 – selected geometrical parameters for the $[PbCu_5(picha)_5(py)_6](NO_3)\cdot 3(py)$ and $[HgCu_5(picha)_5(py)_7](NO_3)\cdot 2(py)$ complexes are presented.

# The Role of Equatorial and Axial Ligands in Promoting the Activity of Non-Heme Oxidoiron(IV) Catalysts in Alkane Hydroxylation

**Leonardo Bernasconi,*[a] Manuel J. Louwerse,[a] and Evert Jan Baerends*[a]**

**Keywords:** Density functional calculations / Fenton reaction / Alkanes / Hydroxylation / High-valent oxidoiron(IV) systems / Push effect

The key electronic structural feature of the $FeO^{2+}$ moiety, which determines its activity as an alkane hydroxylation catalyst, is the presence of low-lying acceptor orbitals, namely the $3\sigma^\star$ $3d_{z^2}$–$2p_z$ antibonding orbital. Both the energetic position of this orbital and the spin state of the system (which in turn also affects the $3\sigma^\star$ energy) depend on the surrounding ligands. We present results of density functional theory (DFT) calculations performed on a series of gas-phase complexes of composition $[FeO(H_2O)_n(L)_{5-n}]^{2+}$ ($n$ = 4, 1, 0) derived from the recently characterised aqueous $[FeO(H_2O)_5]^{2+}$ by substitution of ligand water molecules with L = $NH_3$, $CH_3CN$, $H_2S$ and $BF_3$. The calculations reveal that the high-spin (quintet) state is favoured by the weaker σ-donating equatorial ligands, which is consistent with the literature. The high-spin configuration is more reactive because of significant exchange stabilisation of the crucial $3\sigma^\star\uparrow$ orbital. Once the quintet state is formed by a judicious choice of *equatorial* ligands, the reactivity can be fine-tuned by modulating the energy of the $3\sigma^\star$ orbital by varying the nature of the *axial* ligand. A linear relation between the σ-donor properties of the axial ligand (estimated from the magnitude of the orbital interaction between the σ lone pair and the $3\sigma^\star$ orbital) and the activation barrier for the abstraction reaction is observed, and is related to a "push effect" of the σ donors that destabilises the $3\sigma^\star$ orbital. We propose that species with enhanced activation properties for hydrogen abstraction relative to $[FeO(H_2O)_5]^{2+}$ might be obtainable by either replacing the axial ligand with a σ donor weaker than $H_2O$ or by preventing ligands from coordinating to iron in an axial position.

## I. Introduction

The identification of high-valent transition-metal-ion intermediates in several enzymatic oxidation processes of biosynthetic and metabolic relevance[1–7] has been one of the key achievements in understanding mechanisms responsible for the in vivo activation and reduction of molecular oxygen. Among the most common cofactors of enzymes involved in oxidative processes, copper, manganese and iron, the latter is by far the most widespread.[8–14] Reactions mediated by iron-containing oxygenases have been studied for over 30 years,[15,16] and high-valent (oxido)$Fe^{IV}$ (ferryl) intermediates were recognised early in compounds I and II of catalases and peroxidases.[17–22] The highly reactive nature of these intermediates hampers their isolation as stable species, and spectroscopic methods, often along with theoretical studies, are thus important sources of information on their structure and mechanistic properties.

High-valent metal states have also been postulated in intermediates of various non-heme-iron–protein catalysed processes. Only recently, however, has the involvement of a ferryl species been conclusively proved, specifically in the catalytic cycle of the taurine/α-ketoglutarate dioxygenase (TauD) enzyme.[23–25] This compound has an S = 2 (quintet) ground state,[26] at variance with the S = 1 (triplet) state invariably observed in model porphyrin and non-porphyrin systems, a fact that has been related to the local geometry of the metal coordination environment.[27] A number of biomimetic polydentate non-heme ligands, such as 1,4,8,11-tetramethyl-1,4,8,11-tetraaza-cyclotetradecane (TMC)[28,29] and *N*,*N*-bis(2-pyridylmethyl)-*N*-bis(2-pyridyl)methylamine (N4Py),[30] capable of stabilising high-valent iron states have been synthesised and extensively studied since 2000.[31,32] Various ferryl complexes with room-temperature lifetimes that range from seconds to days have been generated and identified spectroscopically and, to date, three of them have been characterised crystallographically.[29,31,33,34]

An important issue is the presence and role of different spin states of oxidoiron complexes. The presence of different spin states is a key element in the work on two-state reactivity (mostly of $FeO^+$) by Schröder, Shaik, Schwarz and co-workers.[35–37] Various computational studies of S = 2 (oxido)$Fe^{IV}$ systems have appeared (e.g. refs.[38–42]). Schöneboom et al.[43] have applied DFT and various correlated ab initio methods to five-coordinate $C_{4v}$ $[FeO]^{2+}$ com-

plexes. In subsequent work,[44] Neese examined in detail the interplay between triplet and quintet states on the structure, energy and spectroscopic properties of $[FeO(NH_3)_5]^{2+}$ by using (hybrid) DFT and multireference configuration interaction methods. The main factor governing the relative stability of the triplet vs. quintet ground state in this simple system was found to be the strength of the equatorial ligand field. The triplet state was found to be lower in energy in the equilibrium geometry having a distance of $R(FeN_{eq})$ = 2.062 Å between the metal centre and the equatorial N atoms, whereas a lower-energy quintet state was found at larger distances [$R(FeN_{eq})$ = 2.203 Å]. Very little influence from the *axial* ligand on the triplet–quintet separation was observed. Furthermore, the length and strength of the $Fe^{IV}$–O bond was found to be similar for the two spin states. On the basis of DFT calculations, it has also been observed that an S = 1 → S = 2 spin transition would radically change the spectroscopic properties of a $[FeO(TMC)(X)]^{2+}$ species, yet leave the nature of the $Fe^{IV}O$ bond essentially unmodified.[42,45]

Although the S = 1 → S = 2 spin transition has but little effect on the stability of the $Fe^{IV}$–O bond, this phenomenon has important implications for the *catalytic activity* of $Fe^{IV}O$-containing species. In general, non-heme enzymes (typically S = 2) are more reactive than heme ones (typically S = 1). The fact that in non-heme iron enzymes the metal ion is in a high-spin state while heme enzymes as well as all known synthetic $Fe^{IV}O$ complexes (with the exception of $[FeO(H_2O)_5]^{2+}$) are low-spin[16] is explained by the *weaker ligand field* in the non-heme systems. Although it is well recognised that high-spin complexes are more reactive than the low-spin ones, a straightforward explanation seems to be lacking still; we will address this issue in the present work (cf. also ref.[46]).

Not only the equatorial ligands, but also the axial ligand *trans* to the oxido ligand affects the reactivity. A classical example of the influence of the axial ligand on the activity of metal centres in enzymes is the *push effect* in the dioxygen cleavage reaction catalysed by cytochrome P450,[47–50] to yield the elusive Compound I.[3,13,43,51–53] A strong electron donation from the thiolate ligand in the proximal site of heme was first proposed in 1976[47] to be solely responsible for the highly efficient O–O breaking ability of P450. Although experimental findings have provided some support for this hypothesis,[48,50] a complete model for the catalytic activity of P450 is currently still lacking,[54] and various additional factors (e.g. the presence of potassium ions or specific amino acid residues in the vicinity of the heme site, hydrogen bonds with a proximal cysteine ligand, involvement of a reductase enzyme promoting the electron transfer) may contribute to the regulation of its activity. Isolating and characterising the role of axial ligand effects in the catalytic activity may therefore provide insight into the relative importance of the different factors promoting reactions catalysed by FeO-containing enzymes.

In studying activation effects on hydrogen atom abstraction from weak C–H bonds induced by substitution of the *axial* NCMe with $CF_3COO^-$ in the synthetic S = 1 complex $[FeO(TMC)(NCMe)]^{2+}$, Rohde and Que[28] advanced the hypothesis that this ligand substitution may be able to induce a weakening of the ligand field and provide access to the more reactive S = 2 surface. This study of $[FeO(TMC)(CF_3COO)]^+$, a subsequent one devoted to similar non-heme complexes with anionic ligands, $[FeO(TMC)(NCS)]^+$ and $[FeO(TMC)(N_3)]^+$,[55] and the recent theoretical work of Kamachi et al.,[56] devoted to activation effects in the first step of the cyclohexane hydroxylation reaction induced by anionic ligands coordinated to an $Fe^{IV}O$ porphyrin π-cation radical, confirm the remarkable importance of axial ligands in modulating the activity of oxidoiron complexes in organic oxidations.

$[FeO(H_2O)_5]^{2+}$ has attracted considerable attention from a theoretical perspective, because of its controversial role in the chemistry of the Fenton reaction (oxidation by a mixture of ferrous salts and hydrogen peroxide). The important intermediate in this reaction is either a free hydroxyl radical, as proposed in the 1930s by Haber and Weiss,[57] or the ferryl ion, as proposed by Bray and Gorin.[58]. Ever since, the issue has been the subject of much debate: see the original work of Groves et al.[59,60] and for reviews refs.[15,61–63] and references cited therein. DFT calculations[38,64] and first-principles molecular dynamics[64–66] have shown that the formation of the ferryl ion is thermodynamically favourable in the gas phase and viable in aqueous solution at room temperature. Experimentally, $[FeO(H_2O)_5]^{2+}$ has been obtained by reaction of $[Fe(H_2O)_5]^{2+}$ with $O_3$ in acidic aqueous solution, and it has been found to be stable over a period of about 10 seconds.[67–69] To date, this is the only known synthetic S = 2 ferryl complex. Buda et al.[38,41] and Louwerse and Baerends[46] presented detailed analyses of the electronic structure of this complex and of the factors governing its reactivity in hydrogen abstraction from methane and methanol. The effect of solvation on reaction barriers was also studied.[46,70,71] The essential results of these studies is that the reactivity of $[FeO(H_2O)_5]^{2+}$ in hydrogen abstraction from a simple alkane or alcohol is a one-electron phenomenon involving the empty $3\sigma^*\uparrow$ orbital of $[FeO(H_2O)_5]^{2+}$, and that solvation affects the reactivity strongly by changing the energy of the latter orbital. The importance of the $3\sigma^*\uparrow$ orbital has also been recognised in the work of Decker et al.[72]

In the present work we analyse the effects of ligand substitution in simple gas-phase systems of composition $[FeO(H_2O)_n(L)_{5-n}]^{2+}$, with L = $NH_3$, $CH_3CN$, $H_2S$ and $BF_3$. As for the precursor species $[FeO(H_2O)_5]^{2+}$, in these systems the metal ion is surrounded by a distorted octahedral coordination environment of $C_{2v}$ symmetry, with four equatorial ligands in roughly planar geometry and one axial ligand in the *trans* position to the oxide ion (Figure 1). The aim of this study is to gauge the relative importance of axial vs. equatorial ligands in: (a) favouring either a low (S = 1) or high (S = 2) spin state; (b) influencing the ability of the system to abstract a hydrogen atom from a methane molecule. We also address the issue of the origin of the higher reactivity in S = 2 vs. S = 1 complexes in alkane hydroxylation.

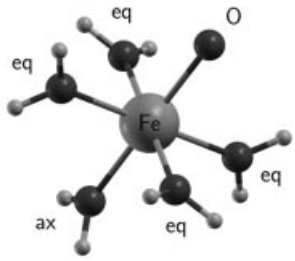

Figure 1. The structure of $[FeO(H_2O)_5]^{2+}$. Equatorial and axial ligands are indicated. O is the O(oxido) atom.

The paper is organised as follows. In Section II, details of the calculations are given. In Section IIIA, we study the role of equatorial and axial ligands in influencing the relative stabilities of high- and low-spin states of the compounds $[FeO(H_2O)_n(NH_3)_{5-n}]^{2+}$. In Section IIIB, we analyse the hydrogen atom transfer reaction from a methane molecule to each of the latter compounds (corresponding to the first step in $Fe^{IV}O$-catalysed aliphatic hydroxylation[15]). We verify the more reactive nature of high-spin complexes, which has experimentally often been observed. Here it is explained as being caused by the strong exchange stabilisation of the crucial $3\sigma^* \uparrow$ acceptor orbital in high-spin complexes with weak equatorial ligand fields. In Section IIIC, we study the manner in which the energy of the latter orbital can be modified by varying the nature of the axial ligand in (high-spin) compounds of composition $[FeO(H_2O)_4(L_{ax})]^{2+}$. The $3\sigma^* \uparrow$ orbital is pushed up by stronger σ donors at the axial coordination site, which leads to reduced reactivity. This effect in the high-spin complexes is opposite to the *push effect* that has been identified in the *low-spin* $Fe^{IV}O$ porphyrin π-cation radical. Our findings are summarised in Section IV. The general rules emerging from our study are, first, that weak-field equatorial ligands are needed to obtain the high-spin state, in order to enhance the good acceptor properties (electrophilic nature) of $[L_5FeO]^{2+}$ through stabilisation of the acceptor orbital, and second, that even higher efficiency of hydrogen atom transfer from methane than in reactions involving $[FeO(H_2O)_5]^{2+}$ might be achievable by occupying the axial coordination site with a weaker donor ligand (or even an electron acceptor), or by leaving it unoccupied and enforcing a square-planar equatorial coordination for iron.

## II. Computational Details

Calculations were performed by using ADF[73–75] with a QZ4P basis set for iron and a TZ2P basis set for all other atoms. All electrons were treated explicitly. Relativistic effects were included by using the Zero-Order Regular Approximation (ZORA).[76] In the majority of the calculations exchange-correlation effects were described at the BLYP[77,78] level of theory. Standard generalised gradient corrections (GGAs), as well as the local density approximation, are known to disfavour high-spin states in $Fe^{II}$ and $Fe^{III}$ complexes, as opposed to hybrid and some *meta*-GGA functionals.[79–81] For this reason, in determining the most stable spin state for the ground state of each of the complexes examined, we performed additional full geometry optimisation by using the OPBE functional, a combination of the OPTX[82] and the PBE[83] functionals. OPBE has been shown to yield spin state relative stabilities comparable to hybrid and *meta*-GGA prescriptions.[81,84] Convergence criteria for geometry optimisations were $5 \times 10^{-4}$ hartree in the total energy, $5 \times 10^{-3}$ hartree Å$^{-1}$ in the gradients, $5 \times 10^{-3}$ Å in bond lengths and 0.25° in bond and dihedral angles.

## III. Results and Discussion

### A. Ligand-Induced Spin Transition in $[FeO(H_2O)_n(NH_3)_{5-n}]^{2+}$

Detailed discussions of the electronic structure of $[FeO]^{2+}$ and of its "microsolvated" counterpart $[FeO(H_2O)_5]^{2+}$ (**1**) are given in refs.[38,41,46,72] The characteristic one-electron spectrum of $[FeO(H_2O)_5]^{2+}$ in its quintet ground state (Figure 2) shows significant stabilisation of the majority of ↑ spin orbitals, caused by the exchange field generated by four unpaired ↑ electrons. For the $d_{xy}\uparrow$ / $d_{xy}\downarrow$ pair, there are additional sources for the especially large gap (see below). Overlap of 3d and O(oxido) 2p orbitals leads to bonding/antibonding pairs of σ symmetry ($2\sigma$: $d_{z^2}+p_z$, doubly occupied; $3\sigma^*$: $d_{z^2}-p_z$, virtual) and π symmetry ($1\pi$: $d_{xz,yz}+p_{x,y}$, doubly occupied; $2\pi^*$: $d_{xz,yz}-p_{x,y}$, singly occupied). The d orbitals of δ symmetry, $d_{x^2-y^2}$ and $d_{xy}$, cannot mix by symmetry with O $2p_z$ orbitals, they are one hundred percent d (in $FeO^{2+}$) and Fe–O nonbonding. The $d_{xy}/d_{x^2-y^2}$ pair with ↑ spin (both singly occupied) are degenerate in bare $[FeO]^{2+}$, but the degeneracy is lifted in the $[FeO(H_2O)_5]^{2+}$ complex by antibonding interactions of the $d_{x^2-y^2}$ orbital with the σ lone pairs of the equatorial water molecules and by bonding interactions of the $d_{xy}$ with their π lone pairs.[41] These contributions bring about a difference in energy of 2.69 eV between the occupied orbitals $d_{xy}\uparrow$ and $d_{x^2-y^2}\uparrow$. The gap between the corresponding unoccupied orbitals $d_{xy}\downarrow$ and $d_{x^2-y^2}\downarrow$ is much smaller (1.13 eV),

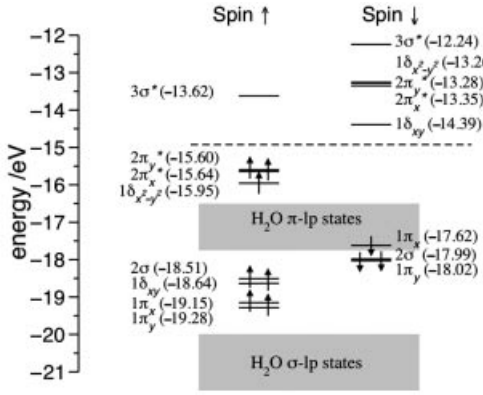

Figure 2. BLYP Kohn–Sham one-particle energies (in parentheses) of $[FeO(H_2O)_5]^{2+}$. The *z* axis is parallel to the Fe–O bond. Shaded areas represent the energy regions spanned by π ($1b_2$) and σ ($2a_1$) lone pairs of the water molecules. The dashed line separates occupied from virtual states (Cf. ref.[46]).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

since they are both above the water lone pairs and are both pushed up (only the $d_{xy}\downarrow$ less so by the weaker π interactions than the $d_{x^2-y^2}\downarrow$ by the stronger σ interactions). Nevertheless, the fact that $d_{xy}\uparrow$ is pushed down, on top of being stabilised by the exchange field of the excess ↑ spin electrons, and that the $d_{xy}\downarrow$ is pushed up, on top of being less stabilised by the exchange field, leads to the particularly large gap of 4.25 eV between this ↑/↓ pair. These orbital interactions with the water lone pairs also explain the different nodal structure of the two spin components of the $d_{xy}$ orbital (Figure 3): the $d_{xy}\uparrow$ component, which clearly exhibits the in-phase mixing with water π lone pairs and the $d_{xy}\downarrow$ component, which has out-of-phase mixing with those lone pairs.

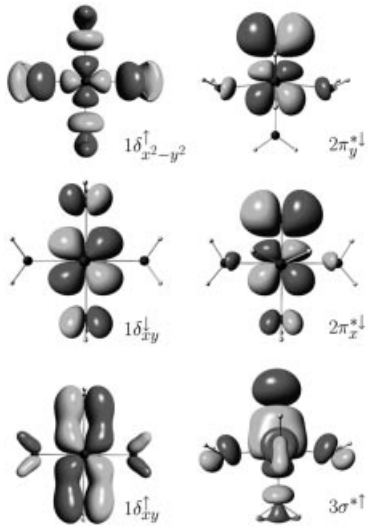

Figure 3. Selected Kohn–Sham orbitals of $[FeO(H_2O)_5]^{2+}$. Nonbonding $1\delta_{x^2-y^2}\uparrow$ and $1\delta_{xy}\downarrow$ orbitals are involved in the composition-induced transition from the quintet to the triplet ground state, in which they act as the donor and acceptor of one electron, respectively. Antibonding $2\pi_{x,y}^*\downarrow$ and $3\sigma^*\uparrow$ orbitals, which are empty in both spin states, regulate the attitude of the $Fe^{IV}O$ towards accepting electrons from a substrate and determine the reaction pathway in H-atom abstraction from a hydrocarbon. In the three plots on the left, the *z* axis [parallel to the Fe–O(oxido) bond] is perpendicular to the plane of the page, and the axial water molecule is not visible. In the plots on the right, the *z* axis is along the vertical and the axial ligand is in the lower part of each plot.

We consider now the substitution of the ligand water molecules with ammonia molecules to yield axially monosubstituted $[FeO(H_2O)_4(NH_3)]^{2+}$ (**1a**), equatorially substituted $[FeO(NH_3)_4(H_2O)]^{2+}$ (**1b**) and the fully ammoniated complex $[FeO(NH_3)_5]^{2+}$ (**1c**). The Kohn–Sham levels for these complexes are shown in Figure 4. The monosubstituted complex **1a** was found to possess a quintet ground state, albeit the difference in energy between quintet and triplet was found to decrease in comparison to the all-water complex **1** (Table 1). In accordance with ref.,[81] we found the BLYP functional to underestimate the absolute value of the quintet–triplet energy difference as compared to OPBE. The two did, however, yield a ground state with the same multiplicity in all complexes. For **1b** and **1c**, the triplet state appears to be preferred, although the difference in energy between the two spin states, particularly in the fully ammoniated system, is small. So, we find here that, in agreement with the results of ref.[44], the spin state of the complex is almost completely determined by the nature of the equatorial ligands: electron donating ligands in the equatorial position favour the low-spin triplet state.

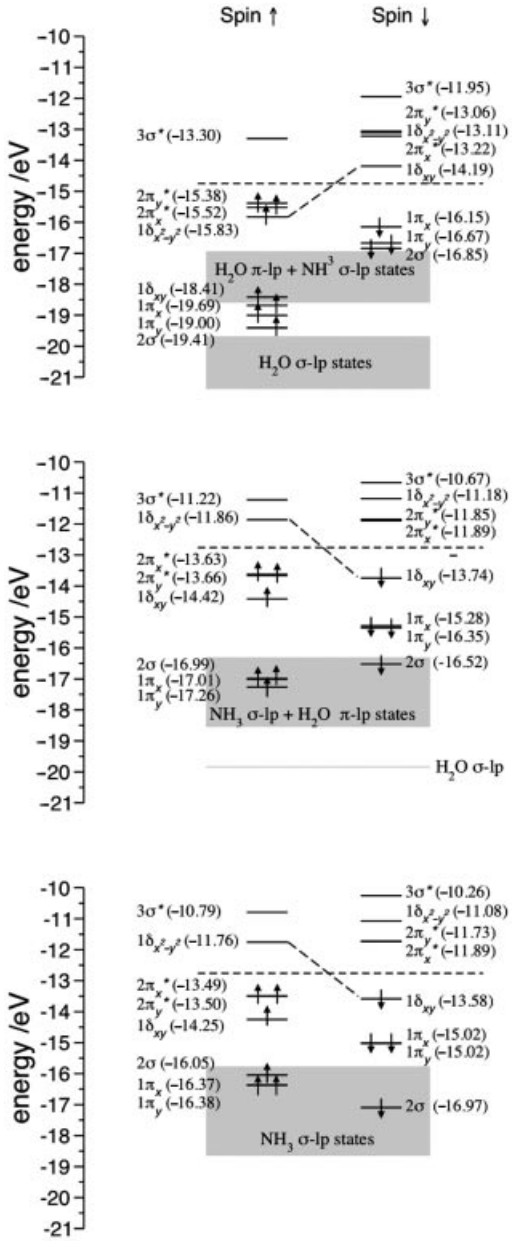

Figure 4. Kohn–Sham energy levels of axially (*top*), equatorially (*centre*) and fully $NH_3$-substituted $[FeO(H_2O)_n(NH_3)_{5-n}]^{2+}$ ($n$ = 4, 1, 0) complexes. The first system is in a quintet ground state, the second and third in a triplet. Oblique dashed lines indicate the energy difference between $1\delta_{x^2-y^2}\uparrow$ and $1\delta_{xy}\downarrow$ orbitals. See main text for details.

The reason is simple. Equatorial substitution selectively affects the energy of orbitals extending in the *xy* plane. Since the σ lone pair of $NH_3$ is more electron-donating than

the σ lone pair of $H_2O$, an orbital like $d_{x^2-y^2}$ with antibonding σ interactions with the ligands is strongly destabilised, and the $d_{x^2-y^2}\uparrow$ moves in the orbital spectrum close to the $3\sigma^*\uparrow$ orbital (Figure 5). It actually becomes so high-lying that it loses its electron to the empty, now lower-lying ↓ spin orbital $d_{xy}\downarrow$. It should be noted that the effect of equatorial $NH_3$ substitution is different for the $d_{xy}$ orbitals of ↑ and ↓ spin. The $d_{xy}\uparrow$ loses the pushing down effect of the higher-lying π lone pairs of the equatorial waters and moves up, like $d_{x^2-y^2}\uparrow$ did; the $d_{xy}\downarrow$ loses the pushing up effect of the lower-lying water π lone pairs and moves down, so that it even more readily accepts the electron of the destabilised $d_{x^2-y^2}\uparrow$ orbital. Electron transfer from $d_{x^2-y^2}\uparrow$ to $d_{xy}\downarrow$ entails a spin flip, with the effect that the stabilising exchange field for the ↑ spin orbitals becomes smaller, which provides an additional relative destabilisation of $d_{x^2-y^2}\uparrow$ with respect to $d_{xy}\downarrow$. This spin flip leaves only two unpaired ↑ spin electrons in the $2\pi^*$ orbitals, hence a triplet state. We note that finally the $d_{xy}\uparrow$ and $d_{xy}\downarrow$, which are both occupied, have now a much reduced gap (ca. 0.7 eV) relative to the initial gap of 4.2 eV. The remaining gap reflects the remaining exchange stabilisation of the two excess ↑ spins in the $2\pi^*$ orbitals. Since electron transfer from the $d_{x^2-y^2}\uparrow$ to the $d_{xy}\downarrow$ orbital occurs between orbitals with nonbonding Fe–O character, the stability of the $Fe^{IV}O$ bond is barely affected.[42,44,45] This is confirmed by the change in the $Fe^{IV}O$ bond length of no more than ≈0.02 Å as a function of composition and/or spin state (Table 2). The spin flip has, nevertheless, a crucial effect on the reactivity, because of the loss of (part of) the exchange stabilisation of the $3\sigma^*\uparrow$ orbital. The role of the $3\sigma^*\uparrow$ orbital in the reactivity is discussed in the following sections.

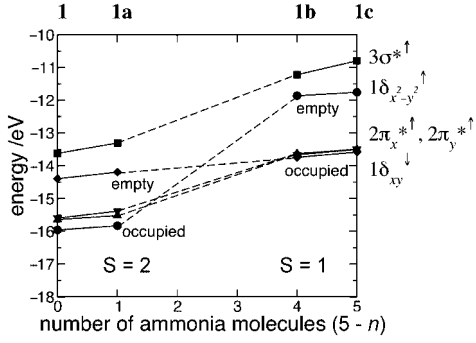

Figure 5. Energy of selected spin orbitals of $[FeO(H_2O)_n(NH_3)_{5-n}]^{2+}$ as a function of the number of ammonia molecules, 5–*n*, in the complex. Lines are guides for the eye.

Substitution of only the axial water molecule in **1** with ammonia has a very moderate destabilising effect (upshift of 0.1–0.3 eV) for all orbitals of π and δ symmetry (Figure 5), consistent with the fact that their wavefunctions have zero overlap with the σ lone pair of the axial $NH_3$. Replacement of the axial water molecule with ammonia does, however, more visibly affect orbitals with lobes along the *z* axis (the Fe–O bond axis) like 2σ, which is pushed down by the higher-lying $NH_3$ lone pair by ca. 1 eV, and the $3\sigma^*$ orbital, which is pushed up by ca. 0.3 eV. In fact, the overall orbital energy pattern is little affected by substitution of only the axial water molecule, and this substitution is not in itself able to induce a transition from high- to low-spin multiplicity, although a destabilisation of the S = 2 state vs. S = 1 is observed, possibly caused by small changes in the geometry of the equatorial ligand environment (Table 2). In either spin state, the effects of axial ligands on the energy

Table 2. Selected bond lengths [Å] in $[FeO(H_2O)_n(NH_3)_{5-n}]^{2+}$ (*n* = 5, 4, 1, 0) complexes. All geometries have been optimised in both high- and low-spin states. Subscripts ax and eq refer to ligands in axial and equatorial positions, respectively. For equatorial distances, averages over four values are reported.

of the 3σ* orbital (pushing up by stronger donors) will have a similar effect on the reactivity. This will be discussed in Section III C. Overall, the S = 2 → S = 1 spin conversion upon equatorial $NH_3$ substitution has the effect of raising the axial 3σ* ↑ orbital away from the vicinity of the Fermi energy. This fact will be shown to bear remarkable consequences on the electron-acceptor properties of the coordinated $[FeO]^{2+}$ group.

### B. Ligand Effects on Hydrogen Abstraction from Methane

Alkane hydroxylation by the $[Fe^{IV}O]^{2+}$ species follows a *rebound mechanism*.[15,59,60,70] First, one hydrogen atom is abstracted from the substrate to yield $[Fe^{III}OH]^{2+}$ and a carbon radical. The latter then collapses onto the hydroxy oxygen. It has been emphasised that the ability of $[Fe^{IV}O]^{2+}$ to promote hydrogen abstraction is directly connected to its electrophilic character: the FeO···HR bond is established by electron donation out of the RH bonding orbitals into a low-lying acceptor orbital on $[Fe^{IV}O]^{2+}$.[46,72] The empty 3σ* ↑ orbital lies 2 eV above the HOMO $2\pi_x$* ↑ and 0.3 eV below the next occupied $2\pi_x$* ↓ orbital, and it has a lobe extending on the oxygen side of the $Fe^{IV}O$ group (Figure 3). Its energy and shape thus make it an ideal acceptor for the electron of the incoming hydrogen atom. Its unusual stability, in spite of being an antibonding Fe $3d_{z^2}$–O $2p_z$ combination, originates (apart from the 2+ charge on $FeO^{2+}$ and the stabilising exchange field in particular in the high-spin state) from an in-phase overlap of O $2p_z$ with the equatorial torus of the Fe $3d_{z^2}$. This contribution attenuates the antibonding character of the orbital (cf. Figure 5 in ref.[46]). Analysis of the interaction between $[FeO(H_2O)_5]^{2+}$ and various substrate molecules ($CH_4$, $CH_3OH$, $H_2O$) has indeed shown that the 3σ* ↑ orbital plays a cardinal role in driving hydrogen abstractions in the gas phase, in aqueous solution and possibly in other media.[46] In all these cases, the abstraction reaction was found to follow an identical pattern, involving as first step the formation of a $[FeO(H_2O)_5]^{2+}$–substrate encounter complex. The bonding energy of the complex, ranging from 9 ($CH_4$) to 70 ($CH_3OH$) kJ mol$^{-1}$, reflects the amount of interaction between the donor orbital (HOMO) of the substrate and the 3σ* ↑ orbital of $[FeO(H_2O)_5]^{2+}$. In the case of methane, the in-phase combination of one of the $T_2$ molecular orbitals and the latter has 89% $T_2$ and 11% 3σ* ↑ character. This situation corresponds to a partial, if small, transfer of an electron from the donor to the acceptor. In the more tightly bound methanol complex, the mixing of donor and 3σ* ↑ in their bonding combination is 55–45%, indicating that the electron is almost equally shared between the donor orbital and the 3σ* ↑ orbital. In both the methane and methanol complexes, the donor orbital is essentially a C–H σ bond. Partial promotion of an electron to the 3σ* ↑ orbital thus results in a weakening of this bond. Since the overall reaction brings about the net transfer of one electron from the substrate to $[FeO(H_2O)_5]^{2+}$ via a concerted bond breaking (substrate–H) and bond formation (H–$OFe^{IV}$),[15] partial electron transfer in the reactants corresponds to a starting electronic structure more similar to the transition state, hence to a lower activation barrier. The stronger the electron-sharing interaction between the substrate molecule and $[FeO(H_2O)_5]^{2+}$ in the encounter complex, the more facile is then the abstraction of the hydrogen atom from the substrate.

We show in Figure 6 the abstraction barriers for the reaction of $CH_4$ with the axially, equatorially and fully ammoniated complexes **1a**, **1b**, **1c**. The energy of the 3σ* ↑ orbital is 0.32 (in **1a**), 2.4 (in **1b**) and 2.8 eV (in **1c**) higher than that in the nonammoniated complex **1** (Table 1). These complexes are representative of (a) an S = 2 system (the complex **1a**) with moderate 3σ* ↑ destabilisation (as compared to the all-water complex **1**), and (b) two S = 1 systems (the complexes **1b** and **1c**) with large and comparable 3σ* ↑ destabilisation. Reaction profiles were obtained by (unconstrained) preliminary optimisation of the encounter complex followed by constrained reduction of the O(oxido)–H distance. For each value of the constraint, a full geometry optimisation was carried out. The reaction barrier for hydrogen abstraction is defined here as the difference in total energy between the transition state (at the maximum of each curve) and the energy of the reactant complex. We computed barriers of 54, 111 and 103 kJ mol$^{-1}$ for **1a** + $CH_4$, **1b** + $CH_4$ and **1c** + $CH_4$, respectively. These should be compared to the value for the **1** + $CH_4$ abstraction reaction, 23 kJ mol$^{-1}$.[46] Overall, a decrease in the reaction rate is therefore observed in the sequence **1** > **1a** > **1b** ≈ **1c**.

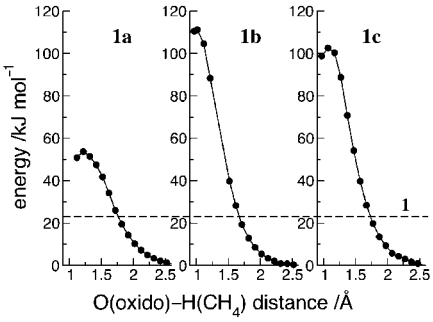

Figure 6. Energy barriers for C–H bond cleavage in axially (**1a**), equatorially (**1b**) and fully (**1c**) $NH_3$-substituted $[FeO(H_2O)_5]^{2+}$. The total energy of the $[FeO(H_2O)_n(NH_3)_{5-n}]^{2+} + CH_4$ complex is represented here as a function of the constrained O(oxido)–H distance. The energy of the reactant complex is taken as the zero point of the energy scale. The dashed line indicates the barrier height for $[FeO(H_2O)_5]^{2+}$ (**1**, see ref.[46]).

The transition to the triplet ground state as a result of equatorial substitution (i.e. going from **1** to **1b**) raises the height of the barrier roughly by a factor of four. Substitution of the axial water molecule, both in **1** and **1b** has, by contrast, only a moderate effect. This trend mirrors the moderate destabilisation of the 3σ* ↑ orbital, 0.3 eV (**1** → **1a**) and 0.4 eV (**1b** → **1c**), to be compared to the much larger effect of equatorial substitution and spin flip, e.g.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.5 eV for **1a** → **1c**. We do, however, observe that, although the destabilisation of the 3σ*↑ orbital is moderate in both **1** → **1a** and **1b** → **1c**, the latter substitution (axial ligand) results in a much larger increase in the reaction barrier. This is the only case in which no correlation is observed between 3σ*↑ energy and reaction barrier, and this indicates that in triplet compounds the reactivity is no longer *exclusively* determined by the 3σ*↑ orbital alone. The ability of the 3σ*↑ orbital to act as an electron accepting orbital (AO) depends in the first place on its energy relative to the donating orbital (DO) of the substrate. The energy of AO and the DO should be compared in the same conditions (geometry, overall charge, etc.) as in the starting reactant complex. A second factor contributing to the AO–DO interaction is the spatial distribution of the 3σ*↑ orbital. Since the electron transfer occurs at the oxygen side of the Fe–O group and the 3σ*↑ orbital arises from a combination of the Fe $3d_{z^2}$ and the $2p_z$ orbital of O(oxido), the large contribution from the latter (ca. 50%) results in enhanced in-phase overlap of 3σ*↑ with the DO.

For a given substrate, the variation of the energy of the 3σ*↑ orbital in the $[L_5FeO]^{2+}$ complex caused by ligand replacement or other environmental changes provides a qualitative index of reactivity. An upward shift of the 3σ*↑ orbital results in larger activation barriers. The changes that induce a rise in the orbital energy of 3σ*↑ lead to a concomitant reduction of the amplitude of the 3σ*↑ orbital at the oxido side. Axial substitution pushes the $3d_{z^2}$ up directly, and equatorial substitution does so indirectly by causing a spin flip and a weaker exchange field. The relative contributions of the Fe $3d_{z^2}$ to the AO 3σ*↑ therefore increase along the sequence **1** → **1a** → **1b** → **1c**, varying as 37%, 42%, 52%, 51%, and those of the O(oxido) $2p_z$ diminish in the sequence 48%, 30%, 25%, 23%, respectively. So there is a progressive localisation of the orbital on the metal centre and a consequent decrease in the ability to overlap with the DO on the O(oxido) side. Both factors, the higher orbital energy of the 3σ*↑ orbital and the decreasing amplitude at the oxido side, work in the same direction in increasing the activation barrier.

We observe that this model, using only the 3σ*↑ AO and the C–H bonding orbital as the DO, applies strictly only to those $FeO^{2+}$ complexes in which 3σ*↑ is the only important acceptor orbital. This only holds for a quintet ground state. The S = 2 → S = 1 transition not only destabilises 3σ*↑, decreasing its electron accepting ability, but it also opens an alternative electron-transfer channel through the now lower lying $2\pi_x$*↓ and $2\pi_y$*↓ orbitals (Figure 5, **1b** and **1c**). An incoming DO might then interact with the 3σ*↑ and $2\pi_{x,y}$*↓ orbitals simultaneously, leading to an Fe–O–H angle that is considerably smaller than the 180° we have observed in the quintet state.[46] The proximity of the empty $2\pi_{x,y}$*↓ orbitals even in the quintet state, will make the energy surface of the reactant complex, and probably also that of the transition state, rather flat with respect to the Fe–O–H angle.

### C. Axial Ligand Influence on Reactivity

We showed in the previous sections that: (1) the spin state of a complex $[FeO(L_{eq})_4(L_{ax})]^{2+}$ is determined by the nature of the equatorial ligands ($L_{eq}$) alone; (2) the quintet ground state is more reactive than the triplet in hydrogen abstractions; (3) the reactivity of the quintet ground state is driven by the transfer of an electron to a low-lying 3σ*↑ orbital; (4) the axial ligand ($L_{ax}$) regulates the reactivity of the complex by inducing relatively minor (few tenths of an eV) shifts in the energy of the 3σ*↑ orbital. Here we address the issue of how the last effect can be directed to tuning the reactivity of an $Fe^{IV}$–O complex in C–H bond cleavage.

We examined a series of simple systems $[FeO(H_2O)_5]^{2+}$, by substitution of either the axial or the equatorial ligand water molecules with $CH_3CN$ and $H_2S$, but carrying the same charge. Similar to the $[FeO(H_2O)_n(NH_3)_{5-n}]^{2+}$ complexes described above, a transition to a triplet ground state was observed for $L_{eq} = CH_3CN$, irrespective of the nature of $L_{ax}$. The situation is far less clear in the $H_2S$-substituted complexes, where differences in energy between the quintet and triplet states after equatorial substitution are within 0.02 eV. In both $CH_3CN$ and $H_2S$ complexes, however, replacement of only the axial ligand was not sufficient to favour the triplet over the quintet state, similar to $NH_3$ substitution, OPBE quintet–triplet energy differences being ≈0.4 and ≈0.2 eV in the $CH_3CN$ and $H_2S$ complexes respectively. In particular, we observed an overall change of no more than ≈0.2 eV in the energy difference between $1\delta_{xy}$↓ and $1\delta_{x^2-y^2}$↑ as a result of the replacement of the axial ligand (Table 3).

Replacement of the axial ligand in $[FeO(H_2O)_4(L_{ax})]^{2+}$ was found to decrease slightly the energy of the 3σ*↑ orbital in the case of $H_2S$ (–0.06 eV) and to increase it by 0.72 eV in the case of $CH_3CN$. The relative 3σ*↑ contri-

bution to the in-phase $3\sigma^* \uparrow -e_z$ orbital combination is very similar in the $H_2O$ and $H_2S$ complexes (11 and 10% respectively) as well as in the $CH_3CN$ and $NH_3$ complexes (both 7%). C–H cleavage reaction barriers vary according to the sequence $[FeO(H_2O)_4(H_2S)]^{2+} \approx [FeO(H_2O)_5]^{2+} < [FeO(H_2O)_4(CH_3CN)]^{2+} < [FeO(H_2O)_4(NH_3)]^{2+}$. This mirrors the total amount of $3\sigma^* \uparrow -e_z$ orbital interaction in the reactant complex and, to a lesser extent, the absolute energy of the $3\sigma^* \uparrow$ orbital. The initial $3\sigma^* \uparrow -e_z$ orbital interaction is a good index of reactivity, since in all complexes the transition state is characterised by an equal distribution of the electron between the DO and the AO (Table 4), which will be obtained more readily if the starting point is more strongly mixed. The overall height of the activation barrier is therefore correlated with the contribution of the $3\sigma^* \uparrow$ orbital to the $CH_4$–$[FeO(H_2O)_4(L_{ax})]^{2+}$ charge-transfer state; the larger this quantity the lower the activation energy.

Table 4. Percentage $3\sigma^* \uparrow$ character in the in-phase $3\sigma^* \uparrow -e_z$ overlap for methane complexes ($3\sigma^* \uparrow$ %) in the reactant complex (RC) and transition state (TS) geometries. | $[FeO(H_2O)_4(H_2S)]^{2+}$ | 10 | 49 | 1.94 | 25 |
| $[FeO(H_2O)_4(CH_3CN)]^{2+}$ | 7 | 49 | 3.06 | 41 |
| $[FeO(H_2O)_4(BF_3)]^{2+}$ | 25 | 54 | <1 | 7 |
| $[FeO(H_2O)_4(o)]^{2+}$ | 34 | 48 | 0 | 1 |

We have verified that a stronger σ-donating axial ligand decreases the ability of a $[FeO(H_2O)_4(L_{ax})]^{2+}$ complex to promote C–H bond breaking, and that a ligand with a σ-donating character comparable to that of water ($H_2S$) leaves it virtually unchanged.[85] It is therefore reasonable to expect that a ligand with no σ-donor character might be able to revert the trend in reactivity observed above and yield an even higher reactivity than that obtained with all-water ligands. For this reason we studied the compound $[FeO(H_2O)_4(BF_3)]^{2+}$, where as before the electron-deficient $BF_3$ ligand occupies the axial position. Although this species was found to be stable in the gas phase, we do not address here the issue of its stability either with respect to $[FeO(H_2O)_5]^{2+}$ or as a solvated species. The $BF_3$ molecule coordinates to the metal centre through one of the fluorine atoms with a Fe–F–B angle of 141.1°. The $3\sigma^* \uparrow$ orbital (Figure 7) exhibits a nodal structure analogous to the one observed in $[FeO(H_2O)_5]^{2+}$; one of the B–F bonding orbitals of $BF_3$ replaces the σ lone pair of $H_2O$, and its energy is 0.51 eV lower than that in the latter species. For this system, we computed a C–H dissociation barrier of only 7 kJ mol$^{-1}$, which is consistent with the large $3\sigma^* \uparrow$ stabilisation.

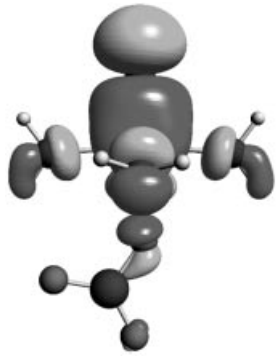

Figure 7. The $3\sigma^* \uparrow$ orbital in $[FeO(H_2O)_4(BF_3)]^{2+}$. The $BF_3$ molecule axially coordinated to $Fe^{IV}$ is in the lower portion of the figure. The orientation is as in Figure 3, right column. Note that the $C_3$ axis of the $BF_3$ ligand is not perpendicular to the $z$ axis, and one of the B–F bonds is roughly oriented toward the metal centre.

Finally, we consider a hypothetical $[FeO(H_2O)_4(o)]^{2+}$ complex in which the axial ligand is removed, and the O–Fe–O angles (where O stands for the oxygen atoms of the remaining ligands) are constrained to their values as in $[FeO(H_2O)_5]^{2+}$. Owing to the absence of an antibonding combination with orbitals of the axial ligand, the energy of the $3\sigma^* \uparrow$ orbital is further lowered relative to the $BF_3$ complex to 1.16 eV below its value in $[FeO(H_2O)_5]^{2+}$. The C–H bond cleavage occurs with virtually no barrier, the activation energy being lower than 1 kJ mol$^{-1}$. In the reactant complex, the DO of $CH_4$ carries a substantial $3\sigma^* \uparrow$ character (34%, vs. 53% $e_z$ character), which is roughly three times as much as that in the $[FeO(H_2O)_5]^{2+} + CH_4$ complex.

In Figure 8 we show activation barriers as a function of the percentage σ lone pair character of the axial ligand (or the $e_1$ orbital in the case of $BF_3$) in the $3\sigma^* \uparrow$ orbital. The latter quantity can be taken as measure of the overall "push" (or destabilisation) experienced by the $3\sigma^* \uparrow$ orbital because of the presence of a σ-donating ligand. For the S = 2 complexes considered in this work, this quantity varies from 0 (for $[FeO(H_2O)_4(o)]^{2+}$) to 4.95% (for $[FeO(H_2O)_4(NH_3)]^{2+}$), and the C–H activation barriers are shown here to depend on it linearly (with a correlation coefficient ≈0.98).

It is interesting to observe that Rohde and Que[28] have found that the axial NCMe ligand in $[FeO(TMC)(L_{ax})]^{2+}$ leads to lower reactivity than the axial carboxylate ligand $CF_3COO^-$. These are low-spin complexes because of equatorial nitrogen donor coordination by the TMC ligand, and the carboxylate substitution may, as suggested by the authors, lead to relative stabilisation of the high-spin S = 2 state, so that the latter becomes more easily accessible (possibly along the reaction path, in a two-state reactivity process). We do indeed find the difference between the S = 1 ground state and the S = 2 state in **1c** to be very small (BLYP) or vanishing (OPBE). However, we should note that the experimental observation corresponds to the expected effect of a weaker ligand field from the carboxylate than from the NCMe ligand, leading to reduced destabilisa-

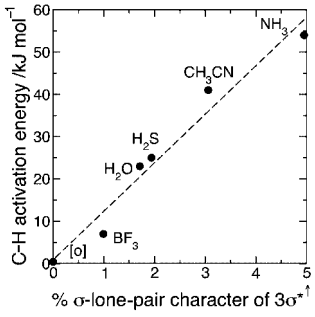

Figure 8. C–H bond-cleavage energy as a function of percentage σ lone pair contribution to the 3σ*↑ orbital in isolated $[FeO(H_2O)_4(L_{ax})]^{2+}$ complexes. The nature of $L_{ax}$ is indicated, and [o] represents the complex with removed axial ligand. The dashed line (with slope 11.47 kJ mol$^{-1}$ and intercept 0.89 kJ mol$^{-1}$) has been obtained by linear regression from the calculated values.

tion of the 3σ*↑ orbital. Overall, the activation effect observed in ref.[28] is therefore fully consistent with the molecular orbital model of reactivity described here.

## IV. Conclusions

We have highlighted the electronic structural features explaining the extraordinary reactivity of the $[Fe^{IV}O]^{2+}$ group in the oxidation of aliphatic C–H bonds: (a) a very low-lying acceptor orbital interacts with the C–H bonding orbital which acts as a donor; (b) in high-spin complexes, the energy of the 3σ*↑ acceptor orbital is lowered by the exchange field of the excess ↑ spin electrons, leading to enhanced reactivity.

The empty 3σ*↑ orbital ($3d_{z^2}$–$2p_z$) is the most important acceptor orbital, being low-lying and having a large amplitude at the oxido ligand. We have detailed that the non-bonding electrons in the dδ orbitals $3d_{x^2-y^2}$ and $3d_{xy}$ (perpendicular to the Fe–O axis) are not just spectator electrons. When a ligand-induced switching occurs from the unpaired spin electron configuration $(3d_{x^2-y^2}\uparrow)^1(3d_{xy}\uparrow)^1$ to the spin-paired configuration $(3d_{xy})^2$, the lowering of the spin multiplicity from S = 2 to S = 1 makes the exchange field of the unpaired spin up electrons considerably less stabilising, and the empty 3σ*↑ shifts up. It then less readily accepts electrons from the C–H bonding orbital, hence the low-spin state S = 1 will require a higher activation energy in the hydrogen abstraction step. The spin state is determined by the ligand environment, in particular by the equatorial ligand field acting on the $d_{x^2-y^2}$ orbital. We analysed a series of compounds of composition $[FeO(L_{eq})_4(L_{ax})]^{2+}$ derived from $[FeO(H_2O)_5]^{2+}$ (S = 2) by substitution of water with ligands with enhanced or decreased σ-donor capability. For all complexes, there are two possible ground states of different spin multiplicity (quintet or triplet) lying close in energy. The quintet ground state was found to be more stable for $[FeO(H_2O)_5]^{2+}$ and all the systems in which only the axial water molecule is replaced. The triplet ground state is favoured by the stronger σ-donating ligands (e.g. $L_{eq} = NH_3$). These ligands push the $3d_{x^2-y^2}\uparrow$ up, so that it becomes favourable for it to shed its electron into the originally empty $3d_{xy}\downarrow$, where it can pair up with the electron in the $3d_{xy}\uparrow$.

Whereas the equatorial ligands have the most important effect, determining the spin state, the *axial* ligand (*trans* to the oxido ligand) directly interacts with the crucial acceptor orbital 3σ*↑ and affects its energy and shape. Therefore, the catalytic properties can be fine-tuned by varying the σ-donor properties of the *axial* ligand alone. Changes in the orbital energy of ≈1 eV or less may result in variations of up to 100 kJ mol$^{-1}$ in the C–H bond cleavage activation barrier. We also proved that axial ligands with decreased σ-donor ability enhance the catalytic properties of $[FeO(H_2O)_5]^{2+}$-derived systems by decreasing the energy of the 3σ*↑ orbital and favouring its overlap with a suitable donor orbital of the substrate. We also proved the existence of a linear relation between the magnitude of the mixing between 3σ*↑ and the axial-ligand orbital responsible for its destabilisation. The effect of the *axial* ligand can be optimally tuned by modifying its σ-donor properties. In the absence of σ donation (as in the hypothetical $[FeO(H_2O)_4(o)]^{2+} + CH_4$ system), C–H bond cleavage occurs almost spontaneously.

In summary, the optimal electronic properties for C–H bond activation and hydroxylation require a high-spin state, which is favoured by equatorial ligands with a weak ligand field, such as $H_2O$. A weak axial ligand field is similarly favourable, once the high-spin state is stabilised by a suitable equatorial field. These findings are consistent with the high catalytic activity of non-heme enzymes with flexible ligand environments and oxygen donor ligands rather than nitrogen lone pairs, such as TauD. The 2-His 1-carboxylate facial triad in the active site of the latter system consists of an equatorial ligand set with one nitrogen donor; the other equatorial ligands are oxygen based (e.g. $H_2O$). The remaining histidine ligand coordinates the metal centre through a nitrogen donor in the axial site, a situation that is, according to our analysis, not optimal. A carboxylate ligand instead of a nitrogen donor in the axial position would in principle be more favourable, which is also in accordance with the results of ref.[28] The insights gained in this work may be helpful in devising catalytic species for homogeneous alkane hydroxylation with superior activation properties, as well as in understanding the mechanistic role of oxidation intermediates containing high-valent metal centres with $[FeO(H_2O)_5]^{2+}$-like coordination and supported by a protective framework, such as zeolites[86] and oxygenated EDTA–Fe complexes in aqueous solution.[87–89]

# Influence of the Polypyridyl (pp) Ligand Size on the DNA Binding Properties, Cytotoxicity and Cellular Uptake of Organoruthenium(II) Complexes of the Type $[(\eta^6\text{-}C_6Me_6)Ru(L)(pp)]^{n+}$ [L = Cl, $n$ = 1; L = $(NH_2)_2CS$, $n$ = 2]

**Sven Schäfer,[a] Ingo Ott,[b] Ronald Gust,[b] and William S. Sheldrick*[a]**

**Keywords:** Ruthenium / Iridium / DNA / Antitumour agents / Arene ligands

The DNA binding of polypyridyl (pp) ($\eta^6$-hexamethylbenzene)ruthenium(II) complexes of the type $[(\eta^6\text{-}C_6Me_6)RuCl(pp)](CF_3SO_3)$ (pp = phen, tap, dpq, dppz, dppn) **1**–**5** and $[(\eta^6\text{-}C_6Me_6)Ru\{(NH_2)_2CS\}(pp)](CF_3SO_3)_2$ (pp = dpq, dppz, dppn) **6**–**8** has been studied by UV/Vis spectroscopy, circular dichroism and viscosity measurements. Complexes **3**–**5**, **7** and **8** are potent cytotoxic agents towards the human cancer cell lines MCF-7 and HT-29. Stable intercalative binding into CT DNA is indicated for the dpq and dppz complexes by large increases $\Delta T_m$ of 12–25 °C in the DNA thermal denaturation temperature for $r$ = [complex]/[DNA] = 0.1. Large viscosity increases for DNA in the presence of **3** and **4** are also in accordance with this binding mode as are the pronounced hypochromic UV/Vis shifts for the $\pi$–$\pi^*$ transitions of the dppz ligands of **4** and **7** in the range 360–400 nm. A small $\Delta T_m$ value of 2 °C and effectively unchanged viscosity suggest that Ru–N (nucleobase) coordinative binding is thermodynamically preferred for the larger polypyridyl ligand of **5** under equilibrium conditions, as is also the case for the small ligands phen and tap in complexes **1** and **2**. CD spectra indicate that the B DNA conformation is essentially retained for interaction with the chloro complexes **1**–**5** but that very significant distortions occur for the thiourea complexes **6**–**8**. The in vitro cytotoxicities of the chloro complexes **3**–**5** are dependent on the size of the polypyridyl ligand with $IC_{50}$ values increasing in the order dppn < dppz < dpq: for instance $IC_{50}$ values of 11.1, 2.12, and 0.13 μM were determined for **3**–**5** towards MCF-7. These values correlate well with the cellular uptake efficiency which increases from 1.1 over 146.6 to 906.7 ng(Ru)/mg (protein) within the series **3**–**5**.

## Introduction

The intercalation of transition metal polypyridyl complexes into DNA has been a topic major bioinorganic interest in the past two decades and continues to receive much attention.[1–3] We have recently established that organometallic half-sandwich compounds of the types $[(\eta^5\text{-Cp*})Ir(amino\ acid\text{-}\kappa S)(dppz)]^{n+}$ ($n$ = 1–3, dppz = dipyrido[3,2-*a*:2′,3′-*c*]phenazine)[4–6] and $[(\eta^6\text{-arene})Ru(amino\ acid\text{-}\kappa S)(dppz)]^{n+}$ ($n$ = 1–3, arene = $C_6H_6$, $Me_3C_6H_3$, $C_6Me_6$),[7] with a thioether-coordinated methionine-containing amino acid or peptide, exhibit strong intercalative binding into DNA. In these complexes and in $[(\eta^5\text{-Cp*})Ru(dppz)(NO)](CF_3SO_3)_2$,[8] the magnitudes of the binding constants $K_b$ ($8.8\times10^4$ to $5.5\times10^6$ M$^{-1}$) are clearly dependent on the overall cation charge $n$ (1–3), i.e. on additional electrostatic interactions with the negatively charged phosphodiester backbone of DNA.

This finding is in accordance with the results of Sartorius and Schneider[9] for heterocyclic derivatives with positively charged ammonium groups in their side chains. These authors also found that the intercalation binding strength is essentially a function of the size of the aromatic system, independent of heteroatoms or the presence of local positive charges within such planar moieties. Sterical considerations suggest that such a simple size dependence will be unlikely for the side-on intercalation mode (Figure 1) established by 2D-NOESY[7] for the interaction of $[(\eta^6\text{-}C_6Me_6)Ru(Ac\text{-}met\text{-}OH\text{-}\kappa S)(dppz)]^{2+}$ (Ac-met-OH = *N*-acetyl-L-methionine) with the hexanucleotide $d(GTCGAC)_2$. Inspection of Figure 1 indicates, for instance, that increasing the surface area and length of the polypyridyl ligand by replacing dppz with dppn (benzo[*i*]dipyrido[3,2-*a*:2′,3′-*c*]phenazine) might favour this type of intercalation by enabling additional stacking with the adenine and cytosine bases of the left-hand strand. On the other hand, inevitable close non-bonding contacts between atoms of the additional six-membered ring of dppn and DNA riboses could prevent a suitable alignment of the polypyridyl ligand.

To establish whether there is, indeed, an optimum polypyridyl ligand (pp) for side-on intercalation of $(\eta^6\text{-}C_6Me_6)Ru^{II}$ complexes, we have now studied the DNA binding

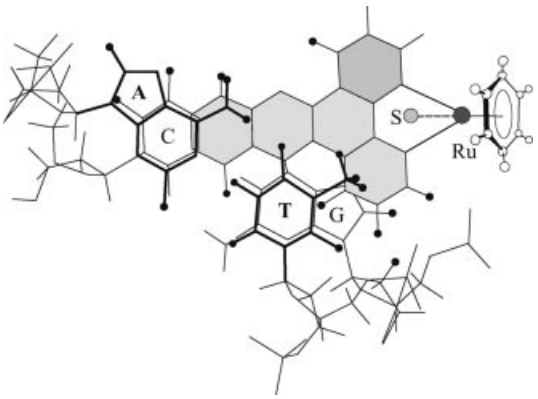

Figure 1. Schematic illustration of the side-on intercalation of [($\eta^6$-$C_6Me_6$)Ru(Ac-met-OH-κ*S*)(dppz)]$^{2+}$ into the $G_1T_2/C_6A_5$ sequence of the hexanucleotide d(GTCGAC)$_2$.[7]

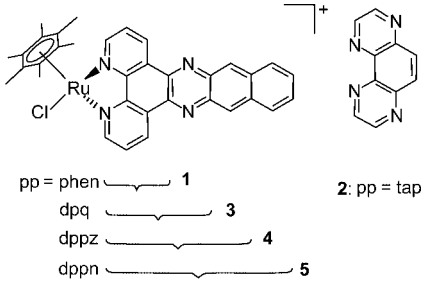
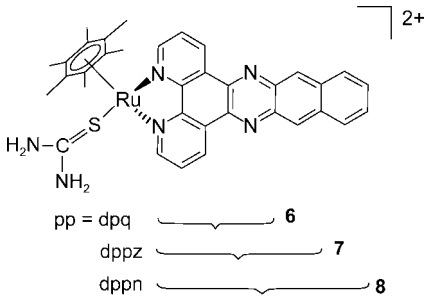
properties of compounds of the type [($\eta^6$-$C_6Me_6$)RuCl(pp)]-($CF_3SO_3$)$_2$ (**1**–**5**) with the diimine ligands phen (1,10-phenanthroline), tap (1,4,5,8-tetraazaphenanthrene), dpq (dipyrido[3,2-*f*:2′,3′-*h*]quinoxaline), dppz and dppn (Scheme 1). The preparation of [($\eta^6$-$C_6Me_6$)RuCl(phen)]Cl has recently been reported by Süss–Fink et al.,[10] who studied the hydrolytic potential of the corresponding dicationic aqua complex [($\eta^6$-$C_6Me_6$)Ru($H_2O$)(phen)]($BF_4$)$_2$ for transfer hydrogenation reactions in aqueous solution. Both dppz and dppn have been confirmed as intercalating ligands in their $Re^I$ complexes such as [*fac*-Re(CO)$_3$(pp)(pyridine)]($CF_3SO_3$),[11–13] which exhibit steric requirements similar to the half-sandwich polypyridyl ($\eta^6$-$C_6Me_6$)$Ru^{II}$ complexes. As polypyridyl ligand intercalation and chloride substitution by purine nucleobases might be expected to compete as possible DNA binding modes for complexes **1**–**5**, three thiourea complexes [($\eta^6$-$C_6Me_6$)Ru{($NH_2$)$_2$CS}(pp)] ($CF_3SO_3$)$_2$ (pp = dpq, dppz, dppn) **6**–**8** were also investigated (Scheme 2). The *trans*-sited thiourea ligands in the metallointercalator [Pt(bpy){($NH_2$)$_2$CS}$_2$]$Cl_2$ remain coordinated on DNA interaction and have been shown to play effectively no role in DNA binding.[14] As they are *cis*-sited relative to the polypyridyl ligands, additional N–H···O hydrogen bonding interactions to DNA could be possible for complexes **6**–**8**.



Scheme 1

Arene ruthenium(II) complexes have been shown to exhibit promising anticancer activity.[15,16] The first report appeared in 1990 when the amino acidato complex [($\eta^6$-$C_6H_6$)-RuCl(L-H-Pro-O-κ$^2$*N*,*O*)] (H-Pro-OH = L-proline) was found to be significantly active in vivo towards mouse P388 leukaemia cells (T/C = 125% for a dosis 0.68 mg kg$^{-1}$) but inactive in vitro towards L1210 cells.[17] The in vitro cytotoxic properties of [($\eta^6$-arene)$Ru^{II}$] complexes with phosphane,[16,21] sulfoxide[18–20] and chelating diamine or diimine ligands[15,22] have been investigated in recent years. Compounds of the latter type [($\eta^6$-arene)RuCl(LL′)]($PF_6$) (LL′ = diamine or diimine) with extended polycyclic arenes (e.g. tetrahydroanthracene) and LL′ = ethylenediamine are most active towards A2780 human ovarian cancer cells, whereas those with polar substituents on the arene or with aromatic diimine ligands such as bpy or phen, exhibit considerably reduced activity.[23] As DNA is considered to be a possible target for ($\eta^6$-arene)$Ru^{II}$ compounds,[15] we considered it to be of interest to also study the in vitro cytotoxity of complexes **3**–**5**, **7** and **8** with the extended polypyridyl ligands dpq, dppz and dppn, and to establish whether this can be correlated with the mode and strength of DNA binding and/or with cellular uptake. The human cell lines MCF-7 (breast cancer) and HT-29 (colon cancer) were selected for cytotoxicity studies.



Scheme 2

## Results and Discussion

### Synthesis of 1–8 and Structures of 1 and 3

The compounds of the type [($\eta^6$-$C_6Me_6$)RuCl(pp)]-($CF_3SO_3$) **1**–**5** (pp = phen, tap, dpq, dppz, dppn) were prepared by refluxing the solvent complex [($\eta^6$-$C_6Me_6$)-RuCl(acetone)$_2$] ($CF_3SO_3$) with the appropriate polypyridyl ligand (pp) in $CH_3OH/CH_2Cl_2$ for 2 h.

[($\eta^6$-$C_6Me_6$)RuCl(acetone)$_2$]$^+$ can be obtained in situ by addition of two equivalents of Ag($CF_3SO_3$) to a solution of the dimeric complex [{($C_6Me_6$)$RuCl_2$}$_2$] in acetone and subsequent filtration of the precipitated AgCl after stirring in the dark for 0.5 h. Following removal of the remaining chloride ligand by analogous treatment of complexes **3**–**5** with a second equivalent of Ag($CF_3SO_3$) in acetone, addition of thiourea to the resulting in situ complexes [($\eta^6$-$C_6Me_6$)Ru(acetone)(pp)]$^{2+}$ affords [($\eta^6$-$C_6Me_6$)Ru(pp)-{($NH_2$)$_2$CS}] ($CF_3SO_3$)$_2$ **6**–**8** (pp = dpq, dppz, dppn) after refluxing the reaction mixture for 2 h in $CH_3OH/CH_2Cl_2$. All the complexes were characterised by $^1$H and $^{13}$C NMR

and positive-ion LSIMS and gave satisfactory microanalyses. The structures of complexes **1** and **3** were determined by X-ray structural analysis (Table 1) and their respective cations are depicted in Figures 2 and 3. Complex **1** exhibits an interplanar angle of 54.1° between its benzene and polypyridyl ring systems, complex **2** a much larger angle of 75.2°. The individual $[(\eta^6\text{-}C_6Me_6)RuCl(pp)]^+$ cations pack with parallel polypyridyl ligands in their respective lattices.

## DNA Binding Studies

### *UV/Vis Absorption and Thermal Denaturation Studies for 1–8*

Following an incubation period of 5 min, UV/Vis spectra for the buffered solutions of **1**–**4**, **6** and **7** (pH 7.2, 10 mM phosphate) with CT DNA at $r = 0.1$ {$r$ = [complex]/[DNA] with DNA concentration in mol/L (nucleotide)} exhibit no

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

further significant changes, thereby indicating that achievement of equilibrium conditions is relatively rapid. A pronounced decrease in absorbance at about 364 and 383 nm and bathochromic shifts of about 5 nm are indicative of possible dppz intercalation into the biopolymer for complexes **4** and **7**. The time dependence of these changes is illustrated for the chloro complex **4** in part a of Figure 4.

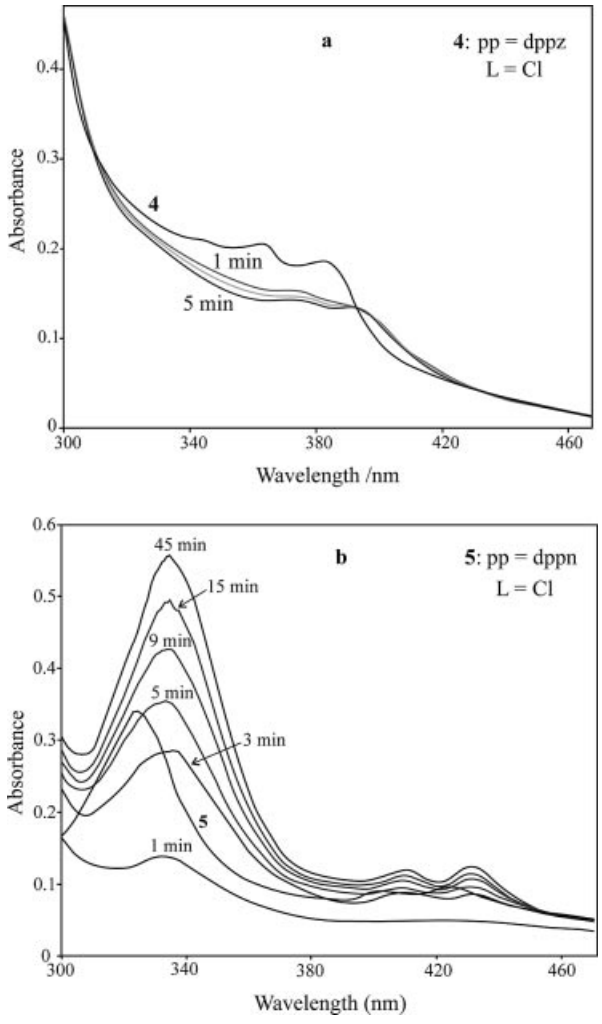

Figure 4. Time dependence of the UV/Vis spectra of complexes **4** and **5** (both 20 μM) in a 10 mM phosphate buffer (pH = 7.2) with CT DNA (200 μM). Times are given in minutes for individual curves.

Hypochromic shifts $\Delta A/A$ of respectively –28% and –16% at 364 nm are observed for **4** and **7** and indicate that the nature of the DNA interaction must be similar for both the dppz complexes. On mixing with CT DNA, the UV/Vis spectrum of the dppn complex **5** initially exhibits even more pronounced hypo- and bathochromic shifts for the spin-allowed π–π* transitions at about 327, 403 and 425 nm. Part b of Figure 4 depicts the $\Delta A/A$ value of –59% at 336 nm and the associated red shift of about 9 nm after 1 min. These initial spectral changes are followed by an increase in the absorbance values over the next 45 min to reach a maximum value of +63% at 336 nm. The original absorbance values of the complex are reached within 5 min after mixing. In similarity to complex **5** (Figure 4, b), significant decreases in $\Delta A/A$ are also observed for the dppn complex **8** at 327, 403 and 425 nm on initial mixing with DNA and these are followed by large increases with equilibrium being achieved within 15 min. The respective initial and final values of $\Delta A/A$ at the first maximum are –29% and +49%. No effective changes in absorption in the range 300–420 nm were recorded for the complexes **1** (pp = phen), **2** (pp = tap) and **3** (pp = dpq) on mixing with CT DNA. The UV/Vis spectra for all complex/[DNA] reaction mixtures exhibit no significant changes over a period of 36 h after equilibrium is achieved.

Thermal denaturation studies for CT DNA can provide simple a means of gauging the efficacy of polypyridyl intercalation for organometallic complexes[4–7] such as **1**–**8**, provided that electrostatic and hydrogen-bonding interactions with the biopolymer may be regarded as remaining effectively unchanged by pp ligand variation. The $\Delta T_m$ values listed in Table 2 for the monocations of **1**–**5** and the dications of **6**–**8** were recorded under equilibrium conditions in a phosphate buffer, (pH = 7.2) for $r = 0.1$ and are indicative of strong DNA intercalation for the dppz ligand of **4** ($\Delta T_m$ = 20 °C), and **7** ($\Delta T_m$ = 25 °C). In contrast, the DNA melting temperature remains effectively unchanged on treatment with complexes **1**, **2** and **5** [$\Delta T_m$ = 0 (phen), +2 (tap), +2 °C (dppn)]. A similar $\Delta T_m$ value of –2 °C has also been reported for $[(\eta^6\text{-}C_6H_6)RuCl(en)]^+$ (en = ethylenediamine),[22] which preferentially coordinates DNA guanine nucleobases at their endocyclic nitrogen atoms N7. The small $\Delta T_m$ value of only + 2 °C is more surprising for the larger dppn ligand with its much more extensive aromatic surface area, but in accordance with the previously discussed UV/Vis studies (Figure 4, b), which indicate an absence of dppn intercalation under equilibrium conditions. Relatively large increases in $T_m$ of 14° and 12 °C are, however, observed for the dpq complexes **3** and **6** respectively, suggesting that this polypyridyl ligand could also participate in intercalative DNA binding. The significant increase in $\Delta T_m$ for the dicationic complexes **7** and **8** [$\Delta T_m$ changes: +5 (dppz), +6 °C (dppn)] in comparison to the monocationic species **4** and **5** may be caused by the increased strength of the electrostatic interactions with the biopolymer but the possibility of N–H···X (X = O, N) hydrogen bonding involving the thiourea

Table 2. Melting temperature shifts $\Delta T_m$, for the interaction of complexes $[(\eta^6\text{-}C_6Me_6)Ru(L)(pp)]^{n+}$ ($n$ = 1, 2) **1**–**8** with CT DNA ($r = 0.1$) in a 10 mM phosphate buffer at pH = 7.2 after incubation for 60 min.

amino functions and DNA acceptor atoms X cannot be ruled out. Interestingly a small relative decrease in $\Delta T_m$ of –2 °C is observed for the dicationic dpq complex **6** in comparison to its chloro analogue **3**.

### *Circular Dichroism Studies for 1–8*

The high $\Delta T_m$ values recorded for the dppz complexes **4** and **7** in comparison to the dppn complexes **5** and **8** suggest that dppz may offer a close to optimum aromatic surface area for side-on intercalation into B DNA[7] (Figure 1) and that dppn may be too long and its surface area too extensive for effective DNA binding in this mode. Characteristic changes in the observed circular dichroism (CD) spectra of DNA provide a convenient means of monitoring conformational changes for the biopolymer.[7,24,25] As depicted in Figure 5, a negative band at 246 nm caused by the helical B conformation and a positive band at 275 nm due to base stacking are observed for CT DNA.[26] Addition of the phen and tap complexes **1** and **2** at a 1:10 complex/[DNA] molar ratio leads to only minor spectral changes, thereby indicating little distortion of the B helix following the formation of Ru–N bonds to DNA nucleobases. The spectra of Figure 5 and the CD spectra for the other complexes exhibited no significant changes during a period of 36 h following equilibrium achievement. Complex/[DNA] solutions remained clear and opalescence was not observed. The depicted spectra were all recorded after 24 h.

Although aromatic molecules often generate CD bands between 300 and 400 nm on interaction with DNA, the appearance of these signals is generally not of relevance for the assignment of the binding mode. This is because the observed induced circular dichroism is caused by a rigid orientation of the molecule with respect to the double helix and this can result from surface or groove binding in addition to intercalation. The dppz complexes **4** and **7** do, however, exhibit characteristic negative CD bands with molar elipticities [$\theta$] of $-4.1 \times 10^{-3}$ and $-1.9 \times 0^{-3}$ deg cm$^2$ mol$^{-1}$ at $\lambda$ = 300 nm (Figure 6) and we have previously established[6] that the appearance of such bands in the range 290–340 nm is, indeed characteristic for intercalating organometallic dppz complexes. The observed wavelength range corresponds with that of the broad π–π* absorption maximum at $\lambda_{max}$ = 280 nm of the complexes themselves. A small but significant increase in [$\theta$] for the positive CD band at 272 nm for **4** may be attributed to additional stabilisation of base stacking in the helix due to dppz intercalation. Whereas the molar ellipticity for the positive band at 268 nm is also similar for the analogous thiourea complex **7**, a dramatic decrease in the negative value of [$\theta$] for the band at 243 nm is apparent in the latter case. This implies a significant change in the original B helical conformation due possibly to both the twofold positive charge and the participation of thiourea amino functions in hydrogen bonding to the biopolymer.

The CD spectra for 1:10 mixtures of the dpq complexes **3** and **6** with CT DNA (Figure 7) also provide evidence for intercalation. When compared to the CD spectrum of CT DNA alone, a broadening and apparent splitting of the positive CD band are ascertainable for the **3**/DNA mixture and, to a lesser extent, the **6**/DNA mixture. As complexes **3** and **6** exhibit absorption maxima for spin-allowed MLCT π–π* transitions at $\lambda_{max}$ 261 and 284 nm, the appearance of the positive band in the range 270–295 nm could be due to a spectral overlap with a negative CD contribution due to intercalating dpq ligands. This interpretation would correlate with the large $\Delta T_m$ values of 14 and 12 °C registered for these dpq complexes. The decrease in the negative value of the molar ellipticity [$\theta$] for the band at 243 nm is less pronounced for **6** than for the analogous dppz complex **7**, but once again indicates that significant changes in the B DNA conformation must have taken place.

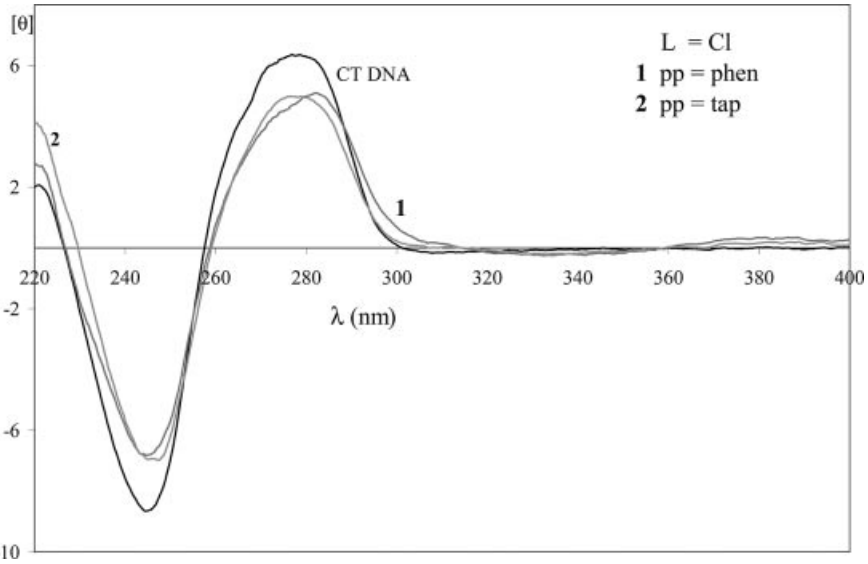

Figure 5. CD spectra of CT DNA and mixtures of **1** (pp = phen) and **2** (pp = tap) with CT DNA ($r$ = 0.1) in a 10 mM phosphate buffer (pH = 7.2) after 24 h incubation.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

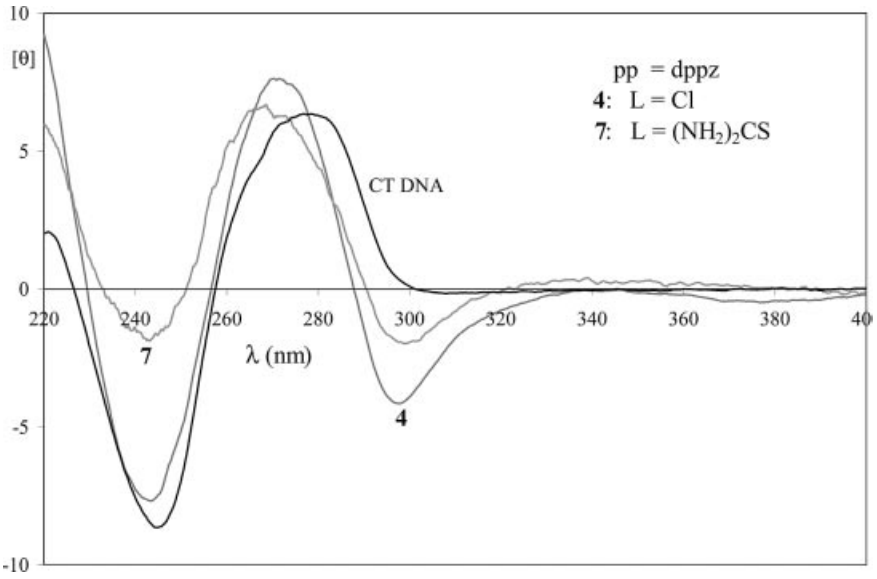

Figure 6. CD spectra of CT DNA and mixtures of **4** and **7** (pp = dppz) with CT DNA ($r$ = 0.1) in a 10 mM phosphate buffer (pH = 7.2) after 24 h incubation.

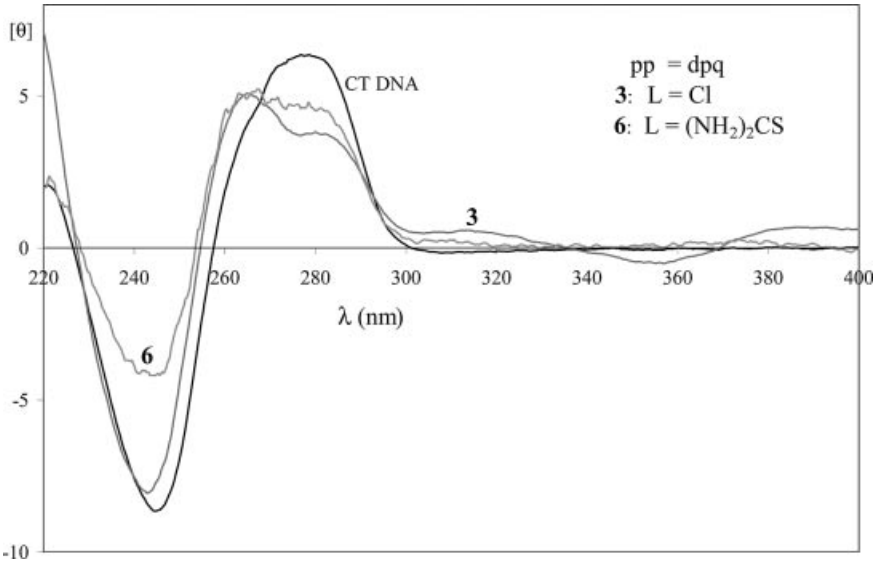

Figure 7. CD spectra of mixtures of **3** and **6** (pp = dpq) with CT DNA ($r$ = 0.1) in a 10 mM phosphate buffer (pH = 7.2) after 24 h incubation.

Both the large increase in $\Delta A/A$ of +63% at 327 nm and the minimal increase in the DNA melting temperature of +2 °C are in accordance with an absence of dppn intercalation for **5**/DNA mixtures under equilibrium conditions. The CD spectrum for such a mixture after 24 h incubation (Figure 8) is closely similar to those registered for the coordinatively bonded phen and tap complexes **1** and **2**. These observations contrast dramatically with other intercalation studies for transition metal complexes, which have established strong intercalative binding for this polypyridyl ligand.[11–13,27] For instance, a binding constant $K_b$ = $7.8 \times 10^4$ M$^{-1}$ and site size $s$ of 1.4 have very recently been determined for the complex [Ir(dppn)(ppy)$_2$] ($PF_6$) (Hppy = 2-phenylpyridine).[27] This $K_b$ value is significantly larger than that of $2.0 \times 10^4$ M$^{-1}$ ($s$ = 1.3) obtained for the analogous dppz complex, in accordance with similar findings for rhenium(I) complexes.[11–13] In agreement with the conclusions of Sartorius and Schneider,[9] it seems likely that an enhanced, presumably end-on intercalative binding affinity results from the larger planar surface area of the dppn ligand in comparison to dppz. Intercalative DNA binding has also recently been confirmed for the complexes [Ru(bpy)$_2$(ppip)]$^{2+}$ and [Ru(phen)$_2$(ppip)]$^{2+}$ [ppip = 2-(4′-phenoxyphenyl)imidazo[4,5-*f*][1,10]phenanthroline],[28] whose ppip ligand is even longer than dppn. The apparent lack of intercalation for **5** under equilibrium conditions must, therefore, be attributed to the preferred side-on mode of ($\eta^6$-arene)Ru$^{II}$ complexes.[7] It is possible that a kinetically favoured end-on intercalation may lead to the initial dramatic decrease in $\Delta A/A$ of –59% at 327 nm for the **5**/

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

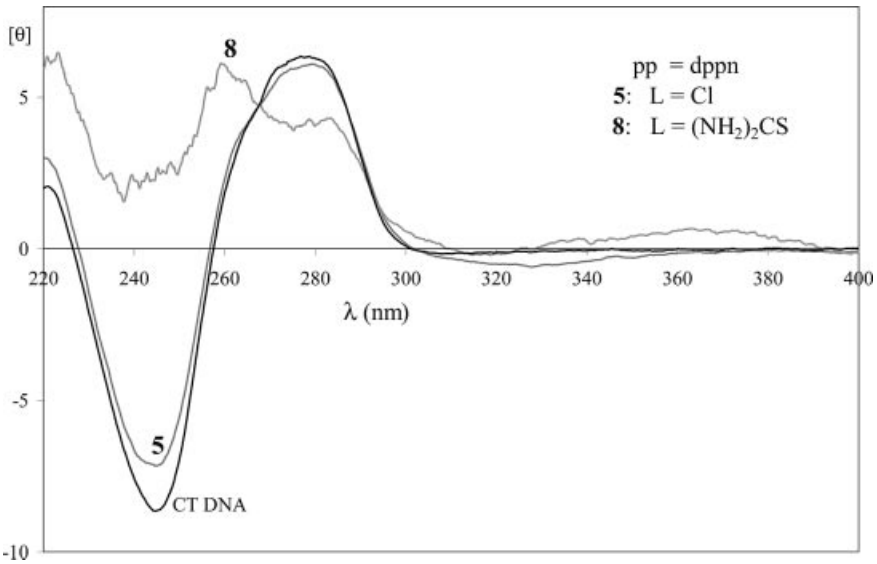

Figure 8. CD spectra of mixtures of **5** and **8** (pp = dppn) with CT DNA ($r$ = 0.1) in a 10 mM phosphate buffer (pH = 7.2) after 24 h incubation.

DNA mixture but that a subsequent rearrangement to a side-on mode with increased base overlap is no longer possible. Support for this line of reasoning is provided by the CD spectrum of the **8**/DNA mixture (Figure 8), for which the stability of the Ru–S (thiourea) bond will be expected to prevent a ligand-substitution reaction and resulting Ru–N (nucleobase) binding. The disappearance of the negative DNA CD band at about 246 nm on the addition of the non-coordinating thiourea complex **8** now implies, in contrast to **5**, DNA damage and complete loss of the original B-helix conformation.

### *Viscosity Measurements on 3–5*

Intercalation of aromatic ligands such as dppz between adjacent nucleobase pairs leads to a lengthening and stiffening of the double helix and these structural changes are reflected in an increase in DNA viscosity.[29,30] The CD spectra of mixtures of the chloro complexes **3**–**5** (pp = dpq, dppz, dppn) with CT DNA suggest that the B conformation of the double helix remains essentially unperturbed in each case, independent of whether the interaction is predominantly intercalative or coordinative. These systems were therefore selected for viscometric titrations and Figure 9 illustrates the dependence of the DNA viscosity on the logarithmic function $\ln(1+r)$ with $r$ = [complex]/[DNA] for complexes **3**–**5**. The slopes of +2.23 and +3.13 for **3** and **4** correlate well with the observed $\Delta T_m$ value of +14 and +20 °C and confirm DNA lengthening and thereby intercalation. In contrast, a small decrease in viscosity is observed for the dppn complex **5** in accordance with its small $\Delta T_m$ value of +2 °C and the positive $\Delta A/A$ values at equilibrium, which are in accordance with coordinative binding following substitution of the chloride ligand.

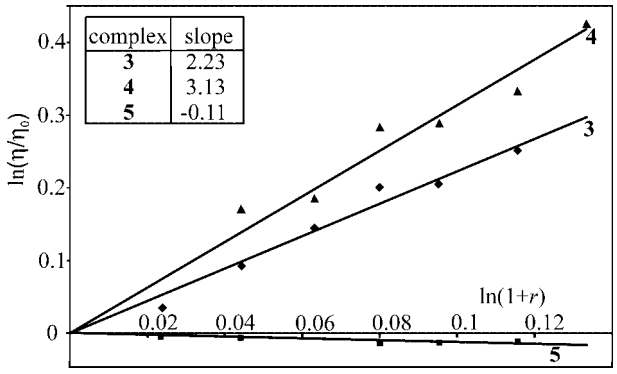

Figure 9. Viscometric titration of sonicated DNA with the complexes **3**–**5** (pp = dpq, dppz, dppn; X = Cl) in a 10 mM phosphate buffer (pH = 7.2): η = reduced viscosity of the DNA solution in the presence of a complex, $\eta_o$ = the reduced viscosity of the DNA solution without the complex, $r$ = [complex]/[DNA].

It is interesting to compare the DNA binding studies on **3**–**5** with our contrasting recent results for the analogous $(\eta^5\text{-}C_5Me_5)Ir^{III}$ complexes $[(\eta^5\text{-}C_5Me_5)IrCl(pp)](CF_3SO_3)$ (pp = dpq, dppz, dppn),[31] for which chloride substitution will be several orders of magnitude more rapid.[32] Whereas a very small increase is observed for the DNA viscosity (slope = +0.16) on mixing with the $(\eta^5\text{-}C_5Me_5)Ir^{III}$ dpq complex, significant decreases (slopes –1.63 and –1.42) occur for the dppz and dppn complexes. As the $\Delta T_m$ values of respectively +2, +7 and +2 °C are modest for the $(\eta^5\text{-}C_5Me_5)Ir^{III}$ complexes and the UV/Vis and CD spectra for their reaction mixtures with CT DNA also provide no evidence for intercalation, it is reasonable to conclude that coordinative Ir–N7 binding to the DNA purine bases must be predominant. The viscosity decreases for the dppz and dppn complexes may be due to kinking or bending of the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

double helix[33,34] caused by hydrophobic interactions with the DNA surface and associated polypyridyl stacking.

### DNA Binding Parameters for 4

Binding constants $K_b$ in the range $7.3 \times 10^5$ to $5.5 \times 10^6$ M$^{-1}$ have been determined for least-squares fits to UV/Vis titration data of complexes of the type $[(\eta^6\text{-}C_6Me_6)\text{-}Ru(dppz)(peptide\text{-}\kappa S)]^{n+}$ ($n$ = 2, 3) with CT DNA using the hypochromic absorption shifts at $\lambda_{max}$ = 364 nm and the non-cooperative non-specific binding model of Bard and Thorp.[35,36] The corresponding site sizes $s$ between 2.3 and 5.1 are in accordance with intercalative binding.[7] It is interesting to compare these parameters with those now obtained for the dppz complexes **4** and **7**. UV/Vis spectra were recorded for buffered 20 μM solutions of **4** and **7** at pH 7.2 following a 60 min incubation with increasing quantities of CT DNA (10–300 μM). An isosbestic point at 399 nm is in each case in accordance with a simple equilibrium distribution between DNA-bound and free $(\eta^6\text{-}C_6Me_6)Ru^{II}$ complex. Figure 10 depicts the least-squares fit to absorbance values recorded for complex **4** at 383 nm, which afforded a $K_b$ value of 2.0(5) $10^6$ M$^{-1}$ and a site size $s$ of 1.42(8). The analogous binding parameters for the thiourea complex **7** are 6(3) $10^6$ M$^{-1}$ for $K_b$ and 1.55(6) for s. These binding constants are much higher than those of $1.6 \times 10^5$ and $1.5 \times 10^5$ reported for the monocationic complex cations $[(\eta^6\text{-}C_6Me_6)\text{-}Ru(AcH_{-1}cysOH\text{-}\kappa S)(dppz)]^+$ and $[(\eta^6\text{-}C_6Me_6)Ru(HglyglyH_{-1}cysOH\text{-}\kappa S)(dppz)]^+$ (HcysOH = L-cysteine, HglyOH = glycine) but similar to those of $7.3 \times 10^5$–$5.5 \times 10^6$ M$^{-1}$ previously observed for complex di- and trications of this type (e.g. peptide = AcmetOH, $H_2$metOMe).[7] The DNA melting temperature increases of 10.4 and 9.4 °C are also much lower for the former monocationic species, whereas the typical $\Delta T_m$ values in the range 18.2–18.5 °C for the latter cations are close to that of 20 °C recorded for **4**. These findings suggest that aquation of the original chloride complex $[(\eta^6\text{-}C_6Me_6)RuCl(dppz)]^+$ may take place during the incubation period and that the intercalation data may correspond to the aqua dication $[(\eta^6\text{-}C_6Me_6)Ru(dppz)(H_2O)]^{2+}$. A similar line of reasoning applies to the dpq complex **3**, whose $\Delta T_m$ value of 14 °C is close to that of 12 °C recorded for the dications of **6**. The higher $K_b$ value for complex **7** in comparison to **4** may be due to additional hydrogen bonding involving the thiourea ligands.

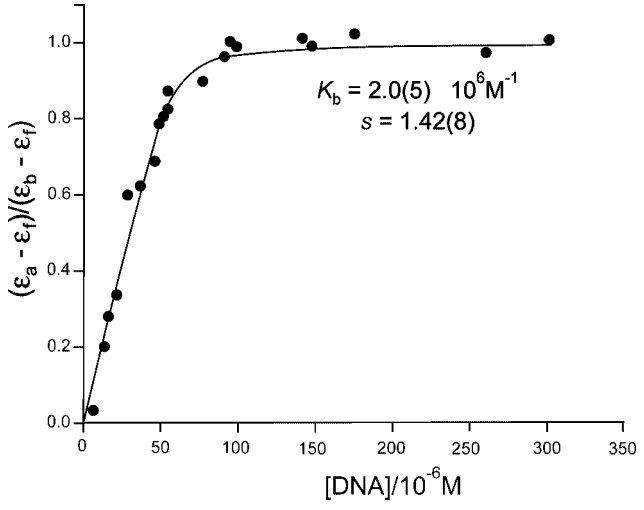

Figure 10. Best least-squares fit to the model of Bard and Thorp[34,35] for the UV/Vis titration data complex **4** with CT DNA.

### Cytotoxicity Studies

Table 3 lists the in vitro cytotoxicity of selected $[(\eta^6\text{-}C_6Me_6)Ru^{II}]$ and $[(\eta^5\text{-}C_5Me_5)Ir^{III}]$ complexes against selected human cancer cell lines MCF-7 (breast cancer) and HT-29 (colon cancer). It is apparent for the $[(\eta^6\text{-}C_6Me_6)\text{-}Ru^{II}]$ chloro complexes **3**–**5** that their cytotoxicity is directly correlated to the surface area of the polypyridyl ligand. The $IC_{50}$ values vary in the following order: dppn < dppz < dpq. A similar partial trend (dppn < dppz) can be discerned for the $IC_{50}$ values of the thiourea complexes **7** and **8** towards the HT-29 cell line and to a lesser extent towards MCF-7. Comparison of the observed cytotoxicities for the monocationic and dicationic dppn complexes **5** and **8** suggests that the overall cation charge may also play a role.

On taking our DNA binding studies into account, a number of ways may be proposed in which the polypyridyl ligand could influence the cytotoxicity of this class of compound:

(1) Extending the size of the polypyridyl ligand will confer lipophilic character to the complexes and thereby enhance their uptake into cells. A lower cation charge should likewise favour increased cellular uptake.

(2) Complex recognition and initial kinetically favoured intercalation into the DNA double helix will likewise be enhanced by an increase in the surface area and length of the polypyridyl ligand.

(3) When initial intercalation is followed by substitution of ligand L (or $H_2O$ if aquation has previously taken place), the size of the polypyridyl ligand may influence the degree of distortion of the B DNA conformation caused by coordinative M–N (nucleobase) binding (M = Ru, Ir) or by surface binding.

Inspection of Table 3 indicates that the MCF-7 $IC_{50}$ values for the dppz complexes $[(\eta^6\text{-}C_6Me_6)RuCl(dppz)]^+$ (**4**), $[(\eta^6\text{-}C_6Me_6)Ru(dppz)\{(H_2N)_2CS\}]^{2+}$ (**7**) and $[(\eta^5\text{-}C_5Me_5)\text{-}IrCl(dppz)]^+$ are effectively independent of the nature of the metal or the ligand L. Whereas both **4** and **7** exhibit stable side-on intercalative binding into DNA, relatively rapid Ir–N (nucleobase) coordination is observed for the $(\eta^5\text{-}C_5Me_5)\text{-}Ir^{III}$ complex following initial intercalation.[31] These observations suggest that cell uptake and kinetically favoured DNA intercalation as a rapid recognition process may play the key roles in determining the potency of such organometallic polypyridyl complexes. It is interesting to note, in this respect, that compounds of the type $[(\eta^6\text{-arene})RuCl(en)]^+$ containing polycyclic aromatic coligands have been found to be more potent than the analogous $\eta^6$-benzene or $\eta^6$-cymene complexes.[15,23] In striking contrast to such ($\eta^6$-ar-

[a] Towards the human cancer cell lines MCF-7 (breast cancer) and HT-29 (colon cancer); the values between brackets represent the standard errors.

ene)$Ru^{II}$ compounds, the $IC_{50}$ values for the polypyridyl complexes of Table 3 appear, however, to be independent of the lability of the M–L bond. The low $IC_{50}$ values for the complex $[(\eta^5\text{-}C_5Me_5)Ir\{(NMe_2)CS\}(dppn)](CF_3SO_3)_2$[31] in comparison to **8** may result from its increased lipophilicity owing to the presence of $(NMe_2)_2CS$ ligands rather than thiourea.

These structure–activity relations suggest that initial DNA recognition and intercalation[38] rather than kinetically controlled coordinative Ru–N(DNA) binding could be of central importance in determining the cytotoxicity of organometallic polypyridyl complexes. It is, therefore, of interest to compare our results with those recently obtained for other metallointercalators. Like the dppz complexes of Table 3, $[Pt(4\text{-}Bu\text{-}ppy)(dppz)](CF_3SO_3)$ is a potent cytotoxic agent and exhibits $IC_{50}$ values some 10 and 40 times lower than cisplatin towards the human cell lines KB-3–1 and KB-V1.[39] In contrast, the dirhodium(II) complexes *cis*-$[Rh_2(\mu\text{-}O_2CCH_3)_2(pp)(O_2CCH_3\text{-}\kappa O)(CH_3OH\text{-}\kappa O)]^+$ (pp = dppz,dppn) are about 4 to 7 times less cytotoxic towards Hs-27 human skin cells than the parent paddlewheel compound *cis*-$[Rh_2(\mu\text{-}O_2CCH_3)_4]$.[40,41] The structure-activity studies on these and other dirhodium complexes are of particular relevance for the present investigation because their $IC_{50}$ values were shown to be related to the lability of the equatorial ligands in the $Rh_2$ core rather than to the size of the polypyridyl ligand.

## Cellular Uptake

In order to evaluate the influence of the cellular uptake on the results of the cytotoxicity experiments we quantified the ruthenium concentration in tumour cells exposed to **3**–**5**, **7** and **8** by atomic absorption spectroscopy. On the basis of the data depicted in Figure 11, it can be concluded that the Ru uptake increases dramatically in the order dpq < dppz < dppn and is much higher for monocationic than for dicationic species with the same polypyridyl ligand, which is in good agreement with the results from the cytotoxicity studies. Accordingly, the highest uptakes of 906.7(1.5) and 1054.7(94.5) ng Ru/mg protein were observed for the monocationic dppn compound **5** with MCF-7 and HT-29 cells, respectively. The dicationic dppn complex **8** exhibited significantly lower cellular ruthenium levels, which were even lower than those found for the monocationic dppz complex **4**. Incubation with the dicationic dppz complex **7** led to decreased cellular ruthenium concentrations in comparison to dppn complex **8** and the monocationic dpq complex **3** was accumulated at the lowest levels with values of only 1.1(1.1) and 11.8(8.5) ng Ru/mg protein being recorded for the cell lines MCF-7 and HT-29. The increase in cellular uptake efficiency with increasing lipophilicity of the ligands is more pronounced for the monocationic series of complexes (**3** << **4** << **5**) than for the dicationic compounds (**7** < **8**). It is apparent that ligand hydrophobicity outweighs the influence of the number of positive charges.

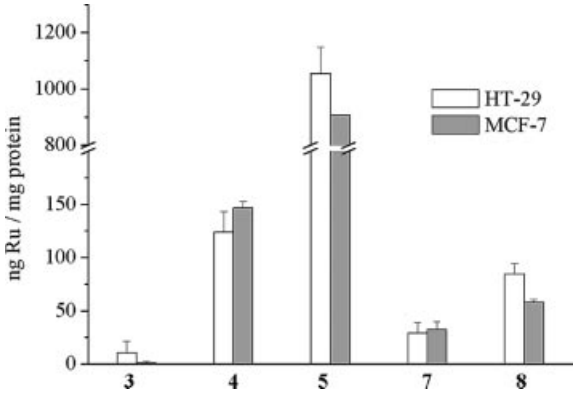

Figure 11. Cellular ruthenium levels in HT-29 and MCF-7 tumour cells after exposure to 10 μM of the complexes for 4 h ($n$ = 2). In some cases the error bars are hidden behind the columns.

The outstanding result is the extraordinarily high uptake of dppn complex **5** which is approximately one order of magnitude higher than the average uptake of the other Ru complexes. Interestingly, this is in good agreement with the significantly lower $IC_{50}$ values of **5** compared to **3**, **4**, **7** and

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the second dppn complex **8**. Additional experiments using only 1.0 μM instead of 10 μM solutions of **5** resulted in ruthenium levels [59.1(5.5) ng Ru/mg protein in MCF-7 and 74.5(10.2) ng Ru/mg protein in HT-29 cells] in the range observed for the other compounds at 10 μM. In contrast, the ruthenium content of the samples was found to be below the limit of detection on exposure to 1.0 μM solutions **3**, **4**, **7** and **8**. As compound **3** was barely detectable at 10 μM concentration a higher dosage for this compound was applied for sake of comparison. As expected 100 μM solutions of **3** afforded clearly detectable cellular ruthenium levels of 219.3(80.0) ng Ru/mg protein in MCF-7 and 287.9(43.1) ng Ru/mg protein in HT-29 cells.

Comparison of the cytotoxicity data of Table 3 and the cellular uptake data of Figure 11 indicates that the antiproliferative effects of the complexes were slightly more pronounced in MCF-7 cells than in HT-29 cells (with the exception of **8**) but that the cellular uptake was similar in both tumour cell types. On the basis of distinct cellular parameters (such as cell volume and cell protein content) of MCF-7[42] and HT-29[43] cells, the molar cellular ruthenium concentrations can be estimated from the observed ng/mg values. According to this procedure, 1.0 ng ruthenium per 1.0 mg cell protein correspond to a complex concentration of 1.1 μM in MCF-7 but to 2.0 μM in HT-29 cells. Therefore, the effective molar ruthenium concentrations are higher in HT-29 cells than in MCF-7 cells. Other differences between the two tumour cell types (e.g. the generally faster growth of HT-29 cells) or the intracellular distribution of the complexes will probably play an important role in determining the observed antiproliferative effects. MCF-7 cells are also more sensitive towards the platinum complex cisplatin than HT-29 cells. A decreased activity for cisplatin in colon cancer cells is an established fact, for which resistance phenomena have been made responsible.[44] The uptake of ruthenium indazole complexes such as *trans*-(Hind)[$RuCl_4$-$(ind)_2$] (ind = indazole), KP1019, into HT-29 cells has been reported.[45] In these experiments, a 30 min incubation with 100 μM of the agents resulted in up to 120–160 ng ruthenium being observed per $10^6$ cells. Based on the fact that 1.0 mg cell protein of HT-29 cells correspond to approximately $5.6 \times 10^6$ cells,[43] the values for the indazole complexes are within the same order of magnitude to those reported in this study, e.g. 188 ng Ru/$10^6$ cells for 10 μM concentrations of **5** or 51.4 ng Ru/$10^6$ cells for 100 μM concentrations of **3** in HT-29 cells. It is worth noting, however, that the uptake of **5** was recorded for a tenfold lower complex concentration in comparison to KP1019.

## Conclusions

We have demonstrated that the DNA binding of polypyridyl organoruthenium complexes of the types [($\eta^6$-$C_6Me_6$)-RuCl(pp)]($CF_3SO_3$) and [($\eta^6$-$C_6Me_6$)Ru{$(NH_2)_2CS$}(pp)]-($CF_3SO_3$)$_2$ is governed by both the size of the polypyridyl ligand and the lability of the Ru–L bond [L = Cl, $(NH_2)_2$-CS]. Whereas stable intercalative binding is observed for the dpq complexes **3**, **4** (L = Cl), **6** and **7** [L = $(NH_2)_2CS$], substitution of the chloride ligand leads to preferred Ru–N (DNA) coordinative binding for both smaller (**1**, phen; **2**, tap) and larger (**5**, dppn) polypyridyl ligands. The significant increase in $\Delta T_m$ and DNA viscosity on going from dpq in **3** to dppz in **4** suggest that the latter ligand may offer a close to optimum size for side-on intercalation. In contrast, the cytotoxicity of such compounds appears to be governed mainly by the size of the polypyridyl ligands with $IC_{50}$ values varying in the following order dppn < dppz < dpq. The cellular uptake increases in the order dpq < dppz < dppn and $n = 2 < n = 1$ ($n$ = cation charge) and is in good agreement with the observed $IC_{50}$ values. To the best of our knowledge [($\eta^5$-$C_5Me_5$)IrCl(dppz)]($CF_3SO_3$) and [($\eta^5$-$C_5Me_5$)Ir{$(NMe_2)_2CS$}(dppn)]($CF_3SO_3$)$_2$ are the first organoiridium(III) complexes with proven in vitro cytotoxicity towards cancer cell lines.

## Experimental Section

**General:** UV/Vis spectra were recorded with an Analytik Jena SPECORD 200 spectrometer and CD spectra with a Jasco J-715 instrument in the range 220–400 nm for 1:10 complex/[DNA] mixtures [complex = 20 μM, DNA concentration in M(nucleotide) = 200 μM] in a 10 mM phosphate buffer at pH 7.2. LSIMS spectra (LSIMS = liquid secondary ion mass spectrometry) were registered for the mass range $m/z < 3000$ with a Fisons VG Autospec employing a caesium ion gun (voltage 17 kV) and 3-nitrobenzyl alcohol as the liquid matrix. A Bruker DRX 400 was employed for the registration of $^1H$ and $^{13}C$ NMR spectra with chemical shifts reported as $\delta$ values relative to the signal of the deuterated solvent. $^{13}C$ NMR signals for the $CF_3SO_3$ anions of **1**–**8** were observed in the range $\delta$ = 121.8–122.8 ppm (q) and are not listed for individual complexes. Elemental analyses were performed on a Vario EL of Elementar Analysensysteme GmbH. $RuCl_3 \cdot xH_2O$ and $Ag(CF_3SO_3)$ was obtained from Chempur, 1,10-phenanthroline from J. T. Baker, hexamethylbenzene, thiourea and $(Me_2N)_2CS$ from Acros, and calf thymus DNA (CT DNA) from Sigma. The starting compounds [{($\eta^6$-$C_6Me_6$)RuCl(μ-Cl)}$_2$],[46] tap,[47] dpq,[48] dppz[49] and dppn[11] were prepared in accordance with literature procedures. All solvents were analytical reagents grade (J. T. Baker) and were dried and distilled before use. [($\eta^5$-$C_5Me_5$)IrCl(pp)]($CF_3SO_3$) (pp = phen, dppz) and [($\eta^5$-$C_5Me_5$)IrCl(en)]($CF_3SO_3$) were prepared described previously.[31,37]

**[($\eta^6$-$C_6Me_6$)RuCl(phen)]($CF_3SO_3$) (1):** Two equivalents of $Ag(CF_3SO_3)$ (25.7 mg, 0.1 mmol) were added to [{($C_6Me_6$)-$RuCl_2$}$_2$] (34.0 mg, 0.05 mmol) and stirred in the dark for 0.5 h in 10 mL acetone. Filtration of the resulting AgCl precipitate and subsequent solvent removal under vacuum afforded [($C_6Me_6$)Ru-Cl(acetone)$_2$]($CF_3SO_3$), which was stirred with the ligand phen (18.0 mg, 0.1 mmol) in $CH_3OH/CH_2Cl_2$ (1:1, 10 mL) at 55 °C for 2 h. Following volume reduction of the resulting clear solution to 2 mL and addition of $CH_3OH$ (3 mL), the product was precipitated with diethyl ether, washed and dried in vacuo. Yield: 62% (39 mg). $C_{25}H_{26}ClF_3N_2O_3RuS$ (628.1): calcd. C 47.8, H 4.2, N 4.4, S 5.1; found C 47.4, H 4.4, N 4.3, S 5.2. LSIMS: $m/z$ (%) = 593 (2) [M – Cl]$^+$, 479 (100) [M – OTf]$^+$, 444 (10) [M – Cl – OTf]$^+$. $^1H$ NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.33 (s, 18 H, C$H_3$ $C_6Me_6$), 8.16 (m, 2 H, phen), 8.23 (s, 2 H, phen), 8.80 (dd, 2 H, phen), 9.41 (dd, 2 H, phen) ppm. $^{13}C$ NMR ([D$_6$]DMSO): $\delta$ = 15.8 (C$CH_3$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$C_6Me_6$), 97.2 ($CCH_3$ $C_6Me_6$), 127.6, 128.8, 131.9, 139.7, 147.2, 154.8 (phen) ppm.

**[(η⁶-$C_6Me_6$)RuCl(tap)]($CF_3SO_3$) (2):** Preparation as for **1** with the ligand tap (18.2 mg, 0.1 mmol). Yield: 70% (44 mg). $C_{23}H_{26}ClF_3N_4O_3RuS$ (630.1): calcd. C 43.9, H 3.8, N 8.9, S 5.1; found C 43.6, H 3.8, N 8.9, S 5.1. LSIMS: *m/z* (%) = 631 (1) [M + H]$^+$, 595 (1) [M – Cl]$^+$, 481 (100) [M – OTf]$^+$, 446 (15) [M – Cl – OTf]$^+$. $^1$H NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.31 (s, 18 H, $CH_3C_6Me_6$), 8.61 (s, 2 H, tap), 9.45 (d, 2 H, tap), 9.51 (d, 2 H, tap) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 16.0 ($CCH_3$ $C_6Me_6$), 98.7 ($CCH_3$ $C_6Me_6$), 133.7, 146.9, 148.9, 150.9 (tap) ppm.

**[(η⁶-$C_6Me_6$)RuCl(dpq)]($CF_3SO_3$) (3):** Preparation as for **1** with the ligand dpq (23.2 mg, 0.1 mmol). Yield: 46% (31 mg). $C_{27}H_{26}ClF_3N_4O_3RuS$ (680.1): calcd. C 47.7, H 3.9, N 8.2, S 4.7; found C 47.3, H 3.9, N 8.2, S 4.4. LSIMS: *m/z* (%) = 635 (1) [M – Cl]$^+$, 531 (100) [M – OTf]$^+$, 496 (15) [M – Cl – OTf]$^+$. $^1$H NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.13 (s, 18 H, $CH_3$ $C_6Me_6$), 8.30 (m, 2 H, dpq), 9.33 (s, 2 H, dpq), 9.46 (d, 2 H, dpq), 9.61 (d, 2 H, dpq) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 15.2 ($CCH_3$ $C_6Me_6$), 95.5 ($CCH_3$ $C_6Me_6$), 127.6, 128.5, 134.7, 138.9, 146.7, 146.9, 155.0 (dpq) ppm.

**[(η⁶-$C_6Me_6$)RuCl(dppz)]($CF_3SO_3$) (4):** Preparation as for **1** with the ligand dppz (28.2 mg, 0.1 mmol). Yield: 45% (33 mg). $C_{31}H_{28}ClF_3N_4O_3RuS$ (730.2): calcd. C 51.0, H 3.9, N 7.7, S 4.4; found C 50.6, H 3.8, N 7.3, S 4.2. LSIMS: *m/z* (%) = 581 (100) [M – OTf]$^+$, 545 (15) [M – Cl – OTf]$^+$. $^1$H NMR (400 MHz, [D$_6$]-DMSO, 25 °C): $\delta$ = 2.18 (s, 18 H, $CH_3$ $C_6Me_6$), 8.19 (m, 2 H, dppz), 8.34 (m, 2 H, dppz) 8.49 (m, 2 H, dppz) 9.46 (dd, 2 H, dppz), 9.71 (dd, 2 H, dppz) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 17.0 ($CCH_3$ $C_6Me_6$), 97.4 ($CCH_3$ $C_6Me_6$), 128.9, 130.3, 130.5, 133.6, 136.1, 140.7, 143.0, 149.3, 156.2 (dppz) ppm.

**[(η⁶-$C_6Me_6$)RuCl(dppn)]($CF_3SO_3$) (5):** Preparation as for **1** with the ligand dppn (33.2 mg, 0.1 mmol). Yield: 74% (58 mg). $C_{35}H_{30}ClF_3N_4O_3RuS$ (780.2): calcd. C 53.9, H 3.9, N 7.2, S 4.1; found C 53.9, H 3.8, N 7.1, S 4.2. LSIMS: *m/z* (%) = 631 (100) [M – OTf]$^+$, 596 (10) [M – Cl – OTf]$^+$. $^1$H NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.14 (s, 18 H, $CH_3$ $C_6Me_6$), 7.73 (m, 2 H, dppn), 8.29 (m, 2 H, dppn), 8.39 (m, 2 H, dppn), 9.16 (s, 2 H, dppn), 9.40 (dd, 2 H, dppn), 9.64 (dd, 2 H, dppn) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 15.2 ($CCH_3$ $C_6Me_6$), 95.5 ($CCH_3$ $C_6Me_6$), 127.87, 127.89, 127.91, 128.5, 129.6, 134.5, 135.0, 137.8, 140.0, 148.8, 155.1 (dppn) ppm.

**[(η⁶-$C_6Me_6$)Ru(dpq){$(NH_2)_2CS$}]($CF_3SO_3$)$_2$ (6):** An equivalent of $Ag(CF_3SO_3)$ (25.7 mg, 0.1 mmol) was added to a solution of [{($C_6Me_6$)$RuCl_2$}$_2$] (34.0 mg, 0.05 mmol) in 10 mL acetone and stirred in the dark for 0.5 h. Filtration of the precipitate AgCl and subsequent solvent removal under vacuum afforded [($C_6Me_6$)Ru-Cl(acetone)$_2$] ($CF_3SO_3$), which was stirred with the ligand dpq (23 mg, 0.1 mmol) at 55 °C for 2 h. Following solvent removal, the resulting residue of complex 3 was dissolved in 10 mL acetone and treated with a further equivalent of $Ag(CF_3SO_3)$. After stirring in the dark for 0.5 h, filtration of AgCl and solvent removal, the remaining solid was dissolved in 10 mL of a 1:1 $CH_3OH/CH_2Cl_2$ mixture and treated with thiourea (7.6 mg, 0.1 mmol). The solution was then refluxed for 12 h and subsequently reduced in volume to 2 mL. Following addition of 2 mL of $CH_3OH$, the product was precipitated by addition of diethyl ether, washed and dried in vacuo. Yield: 44% (38 mg). $C_{29}H_{30}F_6N_6O_6RuS_3$ (869.8): calcd. C 40.0, H 3.5, N 9.7, S 11.1; found C 39.6, H 3.2, N 9.5, S 10.9. LSIMS: *m/z* (%) = 722 (4) [M – OTf]$^+$, 645 (45) [M – OTf – thiourea]$^+$. $^1$H NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.10 (s, 18 H, $CH_3$ $C_6Me_6$), 7.1 (br., 4 H, thiourea), 8.32 (m, 2 H, dpq), 9.24 (d, 2 H, dpq), 9.37 (s, 2 H, dpq), 9.61 (d, 2 H, dpq) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 15.4 ($CCH_3$ $C_6Me_6$), 97.7 ($CCH_3$ $C_6Me_6$), 128.4, 129.1, 134.9, 139.4, 147.0, 147.3, 156.0 (dpq), 174.4 (thiourea) ppm.

**[(η⁶-$C_6Me_6$)Ru(dppz){$(NH_2)_2CS$}]($CF_3SO_3$)$_2$ (7):** Preparation as for **6** with the ligand dppz (29.1 mg, 0.1 mmol). Yield: 63% (58 mg). $C_{33}H_{32}F_6N_6O_6RuS_3$ (919.9): calcd. C 43.1, H 3.5, N 9.1, S 10.5; found C 42.9, H 3.8, N 8.8, S 10.2. LSIMS: *m/z* (%) = 943 (2) [M + Na]$^+$, 771 (12) [M – OTf]$^+$, 695 (7) [M – OTf – thiourea]$^+$, 621 (10) [M – 2OTf]$^+$, 546 (35) [M – 2OTf – thiourea]$^+$. $^1$H NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.12 (s, 18 H, $CH_3$ $C_6Me_6$), 7.1 (br., 4 H, thiourea), 8.21 (m, 2 H, dppz), 8.32 (m, 2 H, dppz) ppm. 8.53 (m, 2 H, dppz), 9.23 (d, 2 H, dppz), 9.71 (d, 2 H, dppz). $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 15.7 ($CCH_3$), 97.8 ($CCH_3$), 128.6, 129.7, 129.8, 133.3, 135.2, 140.0, 142.2, 148.5, 156.1 (dppz), 174.4 (thiourea) ppm.

**[(η⁶-$C_6Me_6$)Ru(dppn)] {$(NH_2)_2CS$}($CF_3SO_3$)$_2$ (8):** Preparation as for **6** with the ligand dppn (32.0 mg, 0.1 mmol). Yield: 47% (46 mg). $C_{37}H_{34}F_6N_6O_6RuS_3$ (970.0): calcd. C 45.8, H 3.5, N 8.7, S 9.9; found C 46.2, H 3.3, N 8.5, S 10.1. LSIMS: *m/z* (%) = 821 (4) [M – OTf]$^+$, 744 (3) [M – 2OTf – thiourea]$^+$ [M – OTf – thiourea]$^+$ 596 (7). $^1$H NMR (400 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 2.13 (s, 18 H, $CH_3$ $C_6Me_6$), 7.2 (br., 4 H, thiourea), 7.82 (m, 2 H, dppn), 8.31 (m, 2 H, dppn), 8.48 (m, 2 H, dppn) 9.19 (m, 2 H, dppn), 9.25 (s, 2 H, dppn), 9.69 (m, 2 H, dppn) ppm. $^{13}$C NMR ([D$_6$]DMSO): $\delta$ = 15.7 ($CCH_3$), 97.8 ($CCH_3$), 128.3, 128.5, 128.8, 129.0, 130.1, 135.0, 135.3, 138.2, 141.1, 149.0, 156.1 (dppn) 174.4 (thiourea) ppm.

**X-ray Structural Analysis of 1 and 3:** Crystal and refinement data are summarised in Table 1. Intensity data were collected with an Oxford Diffraction Sapphire-CCD diffractometer at 293 K (**1**) and 109 K (**3**) using 1° $\omega$ scans and Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The data were corrected for absorption by the Gauss method and solved by direct methods with SHELX97. Refinement against $F^2$ was performed by SHELXL97[50] with anisotropic temperature factors for non-hydrogen atoms and protons at geometrically calculated positions as riding atoms.

CCDC-635848 to -635849 contain the supplementary crystallographic data for **1** and **3** and may be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; Fax: +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk.

**DNA Binding Studies of 1–8:** The thermal denaturation temperature $T_m$ of 1:10 complex/DNA mixtures [DNA concentration = M(nucleotide)] were determined in a 10 mM phosphate buffer at pH = 7.2. Melting curves were recorded at 2 °C steps for the wavelength 260 nm with an Analytik Jena SPECORD 200 spectrometer equipped with a Peltier temperature controller. $T_m$ values were calculated by determining the midpoints of melting curves from the first-order derivatives. The experimental $\Delta T_m$ values of Table 2 are estimated to be accurate within ±1 °C. Concentrations of CT DNA were determined spectrophotometrically using the molar extinction coefficient $\varepsilon_{260}$ = 6600 M$^{-1}$ cm$^{-1}$.[51]

All electronic absorption titrations were performed at 293 K. After sonication, buffered solutions of CT DNA gave a UV absorbance ration $A_{260}/A_{280}$ of ca. 1.90, indicating that the DNA was sufficiently free of proton.[52] 20 μM solutions of the individual metal complexes were treated with DNA over a range of molarities 20 to 300 μM (nucleotide). All UV/Vis spectra were measured after equilibration, i.e. no further change in the monitored absorbance. Titration curves were constructed from the fractional change in absorbance as a function of DNA concentration according to the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

model of Bard and Thorp[35,36] for non-cooperative non specific binding for one type of discrete DNA binding site.

Equation (1) was used to fit the absorption data by least-squares refinement of binding constants ($K_b$) and site sizes ($s$) with $b = 1 + K_bC_t + K_b$ [DNA]/2$s$, where $\varepsilon_a$ is the extinction coefficient of the complex in the absence of DNA, $\varepsilon_b$ the extinction coefficient of the complex when fully bound to DNA (i.e. no absorption change on further addition of DNA), $K_b$ the equilibrium constant in $M^{-1}$, $C_t$ the total metal complex concentration, [DNA] the DNA concentration in M(nucleotide) and $s$ the binding site size. Values of $\varepsilon_b$ were obtained by extrapolation from the $y$ intercept of plots of $\varepsilon_a/\varepsilon_f$ vs. 1/[DNA]. The $K_b$ and $s$ values of Table 2 are those for the best least-squares fits to the individual UV/Vis titration curves using the program ORIGIN 6.0.

$$(\varepsilon_a - \varepsilon_f)/(\varepsilon_b - \varepsilon_f) = (b - \{b^2 - 2K^2_bC_t[\text{DNA}]/s\}^{1/2})/2K_bC_t \quad (1)$$

**Viscosity Measurements:** Viscosities for complex/sonicated DNA mixtures were determined using a Cannon–Ubbelhode Semi-micro dilution viscometer (Series No 75, Cannon Instrument Co) held at a constant temperature of 25 °C in a water bath. The viscometer contained 2 mL of 0.4 mM sonicated DNA solution in a 10 mM phosphate buffer (pH = 7.2). 0.2 mM complex solutions also containing sonicated DNA at the same concentration as in the viscometer (0.4 mM) were added in increments of 100 μL from a micropipet. Solutions were passed through filters to remove particulate material prior to use. Reduced viscosities $\eta_O$ were calculated by literature methods[29] and plotted as $\ln(\eta/\eta_O)$ ($\eta_O$ = reduced viscosity of the DNA solution in the absence of complex) against $\ln(1+r)$ for rod-like DNA (approximately 600 base pairs).

**Cell Culture:** MCF-7 breast cancer and HT-29 human colon carcinoma cells were maintained in 10% (v/v) fetal calf serum containing cell culture medium (minimum essential medium eagle supplemented with 2.2 g $NaHCO_3$, 110 mg/L sodium pyruvate and 50 mg/L gentamicin sulfate adjusted to pH 7.4) at 37 °C: 5% $CO_2$ and passaged twice a week according to standard procedures.

**Cytotoxicity Measurements:** The antiproliferative effects of the compounds were determined following an established procedure.[53] In short, cells were suspended in cell culture medium (HT-29: 2850 cells/mL, MCF-7: 10000 cells/mL), and 100 μL aliquots thereof were plated in 96 well plates and incubated at 37 °C: 5% $CO_2$ for 48 h (HT-29) or 72 h (MCF-7). Stock solutions of the compounds in DMSO were freshly prepared and diluted with cell culture medium to the desired concentrations (final DMSO concentration: 0.1% v/v). The medium in the plates was replaced with medium containing the compounds in graded concentrations (six replicates). After further incubation for 72 h (HT-29) or 96 h (MCF-7) the cell biomass was determined by crystal violet staining and the $IC_{50}$ values were determined as those concentrations causing 50% inhibition of cell proliferation. Results were calculated from 2–3 independent experiments.

**Cellular Uptake:** For cellular uptake studies, cells were grown until at least 70% confluency in 175-$cm^2$ cell culture flasks. Stock solutions of the complexes in DMSO were freshly prepared and diluted with cell culture medium to the desired concentrations (final DMSO concentration: 0.1% v/v, final complex concentrations: 1.0 and 10 μM). The cell culture medium of the cell culture flasks was replaced with 10 mL of the cell culture medium solutions containing the compounds and the flasks were incubated at 37 °C:5% $CO_2$ for 4 h. The culture medium was removed, the cell layer washed with 10 mL PBS (phosphate buffered saline pH 7.4), treated with 2–3 mL trypsin solution (0.05% trypsin, 0.02% EDTA in PBS) and incubated for 2 min at 37 °C:5% $CO_2$ after removal of the trypsin solution. Cells were resuspended in 10 mL PBS and isolated by centrifugation (room temperature, 2000 g, 5 min). The cell pellets were resuspended in 1.0 mL twice distilled water, lysed by use of a sonotrode and appropriately diluted with twice distilled water. The ruthenium content of the samples was determined by AAS (see below) and the protein content by the Bradford method. Results were calculated as ng ruthenium per mg cellular protein from the data obtained in 2 independent experiments.

**AAS Measurements:** A Vario 6 graphite furnace atomic absorption spectrometer (AnalytikJena AG) was used for ruthenium quantification. Ru was detected at a wavelength of 349.9 nm with a bandpass of 1.2 nm. A deuterium lamp was used for background correction. Standards for calibration purposes were prepared as aqueous dilutions of a commercially available ruthenium standard stock solution [Acros, 1 mg/mL ruthenium in HCl (5%)]. To each 160 μL sample or standard solution 20 μL Triton X-100 (1%) and 40 μL HCl (1 N) were added. A volume of 25 μL thereof was injected into the graphite tubes. Drying, pyrolysis and atomization in the graphite furnace was performed according to the conditions listed in Table 4. The detection limit for the method was 4.8 μg Ru $L^{-1}$. The mean AUC (area under curve) absorptions of duplicate injections were used throughout the study.

Table 4. Graphite furnace program for AAS measurements.

# Mutual Influence of Spacer Length and Noncoordinating Anions on Thermal and Light-Induced Spin-Crossover Properties of Iron(II)–α,ω-Bis(tetrazol-1-yl)-alkane Coordination Polymers

**Alina Absmeier,[a,b] Matthias Bartel,[a,c] Chiara Carbonera,[b] Guy N. L. Jameson,[d] Franz Werner,[a] Michael Reissner,[e] Andrea Caneschi,[c] Jean-François Létard,[b] and Wolfgang Linert*[a]**

**Keywords:** Iron(II) / Magnetic properties / Coordination polymers / Photomagnetism / Spin crossover

The influence of noncoordinating anions is analysed in an extension of our systematic investigations into iron(II) spin-crossover coordination polymers. We present here ditetrazole complexes of iron(II) tetrafluoroborate where the two tetrazole moieties are separated by alkylene spacers. The number of carbon atoms in the spacer (*n*) was varied between *n* = 5–10, 12, and the complexes were compared with their $ClO_4^-$ analogues. Pronounced magnetic and magneto-optical differences were found in the comparison of the two series. A chain-type arrangement in the complexes' crystal structures is proposed with decreased interactions between iron centres as *n* increases, leading to more gradual spin transitions. When *n* = 5–7 the smaller tetrafluoroborate causes the spin transitions of the respective complexes to occur at higher temperatures than those of the equivalent perchlorate series. Both series exhibit a parity effect, but at *n* = 8 the parity effect reverses for tetrafluoroborate. With increasing *n*, however, iron–iron interactions seem to fade away and a limiting value of $T_{SC}$ = 160 K is approached by both series.

## Introduction

Interest in multifunctional spin-crossover (SC) compounds within more complicated structural frameworks has increased dramatically in recent years,[1–3] leading to the discovery of exciting magnetic and photomagnetic properties. These investigations have yielded 1D,[4–8] 2D[9] and 3D[10–15] coordination polymers using iron(II) as the SC species. Our group has focused its recent research efforts on ditetrazole ligands with varying length alkylene spacer groups between the coordinating tetrazole groups, hereafter referred to as *n*ditz (see Figure 1). Within this family, short spacers (two carbon atoms) lead to 1D chain networks,[4] whilst four carbon atoms lead to 3D networks.[16,17] To build these frameworks not only is the number of carbon atoms (*n*) in the bridging alkylene groups in the ditetrazole ligand important, but the noncoordinating anion is also important. Anions are also believed to influence the SC behaviour of coordination compounds, varying spin transition temperatures and cooperative effects associated with the sharpness and hysteresis of the transition.[7,18–22]

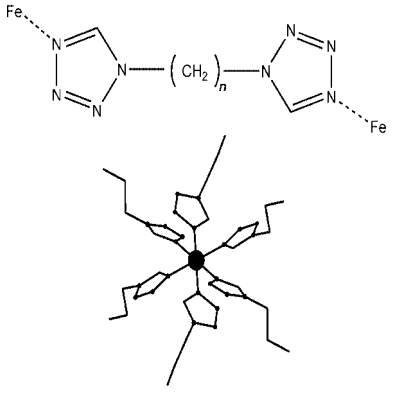

Figure 1. The ditetrazole ligand used and the octahedral geometry around iron(II).

In a previous investigation[23] we reported detailed magneto-optical data for a series (*n* = 4–9) using perchlorate as the anion, which showed an interesting dependence between the magneto-optical properties and the parity of the alky-

lene spacer. In order to compare and contrast the results obtained for the perchlorates,[23] we synthesised an analogous series ($n$ = 5–9) of complexes with the tetrafluoroborate anion and extended both series up to $n$ = 12. Tetrafluoroborate is known to be of similar size, geometry and chemical hardness to perchlorate. Indeed, the estimated ionic radii are 2.29 Å for $BF_4^-$ and 2.37 Å for $ClO_4^-$.[24] Furthermore, the polymers were identically prepared and this minimised differences. We did not want to change the structure of the complexes considerably by using bigger, softer and geometrically different anions such as $PF_6^-$ or $SbF_6^-$ because then a direct comparison would be unsound. We present here a comparison of the magneto-optical properties and provide tentative structural information based on comparative X-ray powder diffraction (XRPD) studies of the two series. As seen from preliminary inspections of X-ray patterns, $[Fe(4ditz)_3](BF_4)_2$ and $[Fe(4ditz)_3](ClO_4)_2$ adopt completely different structures when compared with the complexes with longer spacers and are therefore excluded from this report and will be presented in a separate paper. Taking into consideration the small decrease in diameter in going from $ClO_4^-$ to $BF_4^-$, the difference in properties are far greater than anticipated.

## Results and Discussion

### Powder Diffraction

As it was impossible to grow single crystals of the title materials, the microcrystalline samples were investigated by XRPD. The homologous series $[Fe(n\text{ditz})_3](X)_2\cdot EtOH$ ($n$ = 5–10, 12; X = $BF_4^-$, $ClO_4^-$) are characterised as follows (Figure 2): (i) The perchlorate compounds[23] show a higher degree of crystallinity compared with that of the tetrafluoroborates. (ii) The diffractograms are very similar in shape. (iii) The reflection with the longest d-spacing is the strongest and is shifted systematically to lower diffraction angles with increasing alkyl chain length. (iv) The reflections broaden with increasing $n$ and level off to background at $2\theta \approx 35°$, while the half-widths of the longest ones are more or less conserved. (v) All phases form very thin platelike microcrystallites with a thickness of a fraction of a micrometer.

Point (ii) lets us conclude that the phases exhibit more or less the same basic structure. The reflection broadening can be explained by size effects due to the extremely thin plates. As the largest crystallographic axis is usually the direction of the lowest crystal growth rate, the base plane of the microplates lies perpendicular to the longest cell axis. The reflection with the largest d-spacing, showing a steady shift as $n$ increases, can be regarded as this axis (possibly of higher order) that mirrors the increasing number of methylene groups in the ligands. Powder indexing of the phase $[Fe(5ditz)_3](BF_4)_2\cdot EtOH$, with the positions of the first 20 reflections determined using the DICVOL program,[25] yielded a preliminary solution in the monoclinic crystal system (pseudohexagonal): $a$ = 10.99, $b$ = 20.37, $c$ = 10.07 Å, $\alpha = \gamma = 90$, $\beta$ = 126.1°, $V$ = 1822 Å$^3$, $M_{20}$ = 13, which is in

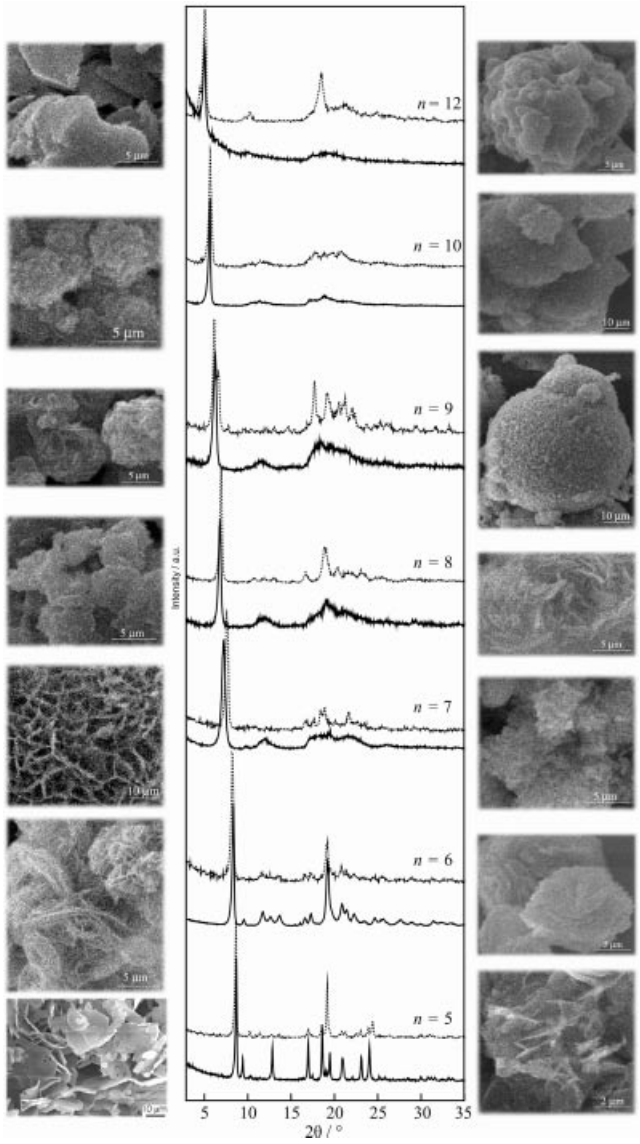

Figure 2. Comparison of the $[Fe(n\text{ditz})_3](BF_4)_2\cdot EtOH$ ($n$ = 5–10, 12; solid) series' X-ray powder patterns ($\lambda$ = Cu-$K_{\alpha 1,2}$) with those of the corresponding perchlorates (upper lines), flanked by the corresponding SEM images ($BF_4^-$ left, $ClO_4^-$ right).

accordance with a unit cell content of $Z$ = 2. This metric can be regarded as a distorted variant of the trigonal symmetry found for $[Fe(2ditz)_3](BF_4)_2$[4] with comparable lattice parameters: $a = b$ = 10.380(1), $c$ = 14.953(3) Å, $V$ = 1395.3(3) Å$^3$ [at 296(2) K, the shortened $c$ axis is caused by the ethylene spacer]. Therefore we tend to describe the pentylene- to dodecylene-ditetrazole complex series in a chain-type arrangement as well. The higher order complexes are suspected to crystallise in the triclinic system which, however, is not possible to confirm from the low-quality powder patterns. Calculating the unit cell volumes for the phases under investigation, assuming the monoclinic cell from earlier and setting the $b$ axis length to $d\times 2$ of the longest line (i.e., the 020 reflection), results in unit cell contents $Z$ ca. 2, which again is in accordance with the $[Fe(2ditz)_3](BF_4)_2$ complex. In Figure 3 an idealised tenta-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tive structural proposition is depicted. The ligands, linked together by iron(II), are stretched out and aligned parallel in a hexagonal close-packed manner with the counterions in between the chains. Increases in the alkylene spacer length will expand the unit cell in the crystallographic direction of the chains, leaving the other two untouched. Additionally, the voids between them become larger and are likely to be filled with presumably disordered and nonstoichiometric amounts of solvent molecules. As the interaction between the chains is weak [the Coulomb forces between the positively charged iron(II) and $BF_4^-$ will diminish with increasing *n*], stacking faults are favoured by longer spacers, and additional reflection broadening is likely to be observed.

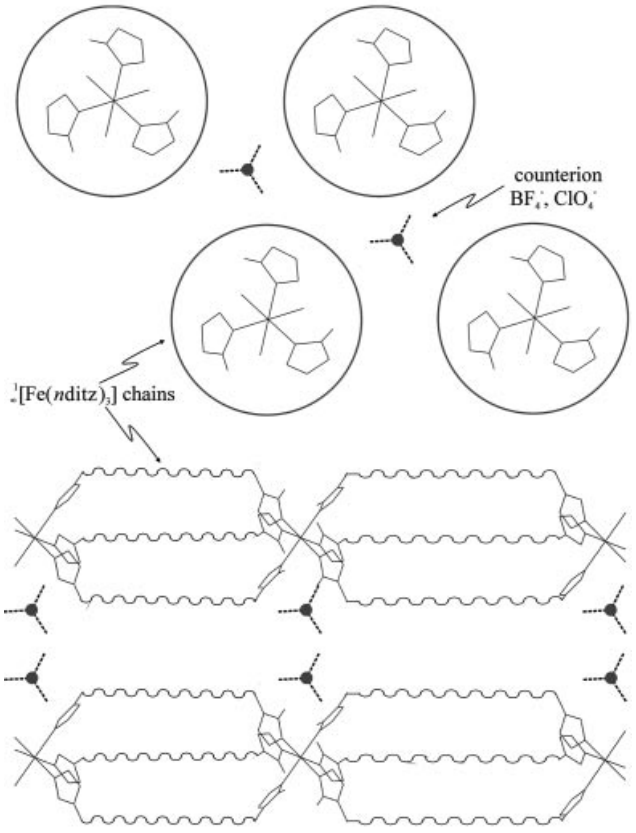

Figure 3. Tentative basic structural model of the $[Fe(nditz)_3](X)_2 \cdot EtOH$ ($n$ = 5–10, 12; X = $BF_4^-$, $ClO_4^-$) phases viewed along the $[Fe(nditz)_3]^{2+}$ chains (circled, top) and the perpendicular direction (bottom). The orientation and geometry of the complex is presumed arbitrarily.

## Optical Properties

As expected, all members of the series show a thermochromic effect associated with a spin transition, that is, from white in the HS state at room temperature to violet in the LS state at lower temperatures. The result of a typical temperature-dependent reflectivity experiment, which is a preliminary test for the LIESST (light-induced excited spin-state trapping) measurement (see below), is illustrated in Figure 4, using $[Fe(5ditz)_3](BF_4)_2$ as an example. No significant differences are found between the $BF_4^-$ and $ClO_4^-$ series. The spectra shown are measured within the range 450–900 nm at particular temperatures between 10 and 290 K and clearly show the presence of the expected d-d transitions of an octahedrally coordinated $Fe^{II}$ complex: the $^5T_2 \rightarrow {}^5E$ band at 830 nm when HS and the $^1A_1 \rightarrow {}^1T_1$ band at 570 nm when LS. The second LS transition, $^1A_1 \rightarrow {}^1T_2$, normally observable at 370 nm, is not within the range of the instrument. In addition, we recorded the change in intensity of both HS and LS bands as a function of temperature under constant light irradiation (see inset in Figure 4) by following changes in the reflectivity occurring at $(830 \pm 2.5)$ and $(550 \pm 2.5)$ nm.

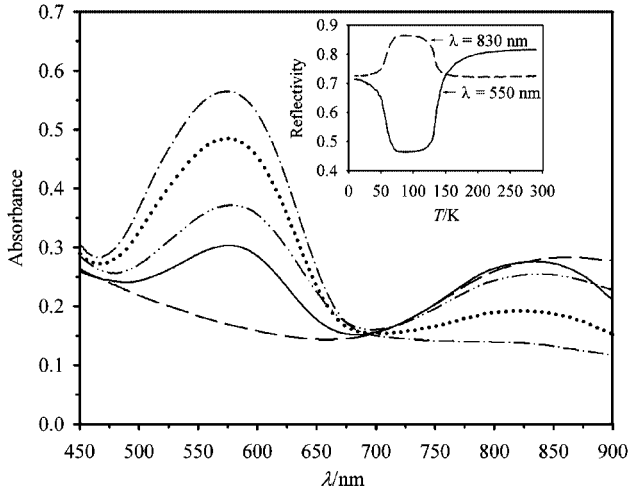

Figure 4. Reflectivity measurements of $[Fe(5ditz)_3](BF_4)_2$ as a function of temperature. Absorbance spectra at 280 K (– –), 140 K (– · · –), 80 K (– · –), 60 K (···) and 10 K (–) are shown. The inset reports the reflectivity followed at $(550 \pm 2.5)$ and $(830 \pm 2.5)$ nm.

For all compounds, at room temperature only the HS band is visible, whilst at 80 K only the LS transition is observable. Below 80 K, however, the reflectivity experiment demonstrates the existence of a photoinduced phenomenon at the surface. In fact, at low temperatures the sample was seen to bleach (see Figure 4 and inset), indicating the occurrence of a LS/HS photoconversion through the LIESST effect. For each compound, we calculated the amount of photobleached fraction (%Irr-Surface; reported in Table 1) relative to the value found at room temperature. However, similar to the previously published $ClO_4^-$ analogues,[23] the higher the $T_{SC}$, the lower the level of the light-induced LS/HS transformation as described by the inverse energy-gap law by Hauser[26] and the $T(LIESST)/T_{SC}$ relation introduced by Letard.[27] Magneto-optical parameters of $[Fe(nditz)_3](X)_2$ where $n$ = 10, 12 and X = $BF_4^-$, $ClO_4^-$ were not measured.

### Magnetic and Photomagnetic Properties

Susceptibility curves were measured between 10 and 300 K for all compounds, and the obtained curves depicting $\chi_M T$ versus $T$, where $\chi_M$ is the molar magnetic susceptibility and $T$ is the temperature, are shown in Figure 5. The temperature of the thermal spin transition, $T_{SC}$, estimated from the maximum in the first derivative of the $\chi_M T$ versus $T$ plot, is given in Table 1. Photomagnetic measurements were carried out as previously published,[23] and this procedure allowed the quantification of $T$(LIESST) (see Table 1), which is determined by the minimum of the $d(\chi_M T)/d(T)$ versus $T$ curve recorded during thermal-induced relaxation.[28] Figure 5 shows the photomagnetic behaviour, and Table 1 shows for each compound the percentage of photoconversion obtained by irradiation at 10 K relative to the magnetic value recorded at room temperature where a pure HS state is assumed (%Irr-Bulk).

All compounds {$[Fe(n\text{ditz})_3](X)_2$, $n$ = 5–10, 12; X = $BF_4^-$, $ClO_4^-$} undergo a complete spin transition between 100 and 220 K (see Figure 5, a–e) and reach a $\chi_M T$ product close to 3.3 $cm^3 \cdot K \cdot mol^{-1}$, in agreement with the theoretically expected value for HS $Fe^{II}$ compounds at room temperature.

At low temperatures in some of the curves, a residual magnetisation is observed yielding a $\chi_M T$ value up to 0.4 $cm^3 \cdot K \cdot mol^{-1}$, which might be caused by thermally inactive HS iron(II) or traces of iron(III). Comparison of the new magnetic data with the perchlorate data shows a similar trend for $n$ = 5–7. The SC curves themselves are all very similar with the $[Fe(5ditz)_3](BF_4)_2$ transition curve a little steeper. The temperatures of transition, $T_{SC}$, are all higher for $BF_4^-$ than for $ClO_4^-$. The %Irr-Surface and %Irr-Bulk values show a similar relationship with $n$ but the actual values are different, suggesting a similar relationship with parity. There is, however, a variation when $n$ is changed from 7 to 8. Here $T_{SC}$ of $[Fe(8ditz)_3](BF_4)_2$ is lower and the transition itself is a lot more gradual than its perchlorate analogue, while %Irr-Surface and %Irr-Bulk are significantly higher. This reversal of the parity dependence at this point suggests that the smaller $BF_4^-$ causes a change in the arrangement of the alkyl chains. By $n$ = 9, the transition is very gradual and almost exactly the same in both cases ($T_{SC}$ = 154 K for $BF_4^-$ and 155 K for $ClO_4^-$). The lowered $\chi_M T$ value at high temperature for the $BF_4^-$ complex is caused by LS $Fe^{II}$ or LS $Fe^{III}$ impurities. $[Fe(10ditz)_3](ClO_4)_2$ has a flatter magnetic curve than that of the $BF_4^-$ analogue but $T_{SC}$ is 10 K higher (see Figure 6). However by $n$ = 12, the transitions are remarkably similar again (see Figure 6). This might be because any further changes in the arrangement of the alkyl chains would now be insignificant with respect to the greater separation of the iron centres.

The larger iron–iron distances and disorder should lead to a concomitant decrease in cooperativity between iron centres until the transition can be described by a simple Boltzmann distribution. This behaviour is supported by the magnetic properties around the transition temperature. The slope at the inflection point of the transition curves ($T_{SC}$) is plotted in Figure 7. It can be seen that the spin transition curves become more gradual with increasing $n$ as expected. This lends further support to the suggestion that all compounds in the series produce a chain-type arrangement, as proposed in the XRPD section.

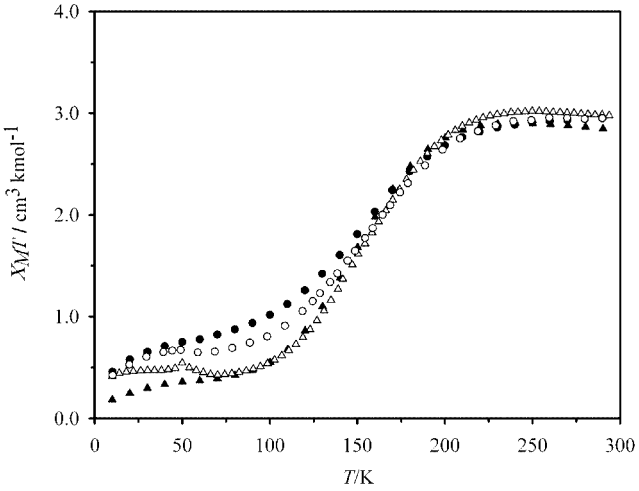

Figure 6. Temperature dependence of $\chi_M T$ for (a) $[Fe(10ditz)_3](BF_4)_2$ (▲) and $[Fe(10ditz)_3](ClO_4)_2$ (●) and b) $[Fe(12ditz)_3](BF_4)_2$ (Δ) and $[Fe(12ditz)_3](ClO_4)_2$ (○), in the heating mode. The existence of a small anomaly at around 50 K on the curves almost certainly corresponds to a remnant oxygen contamination.

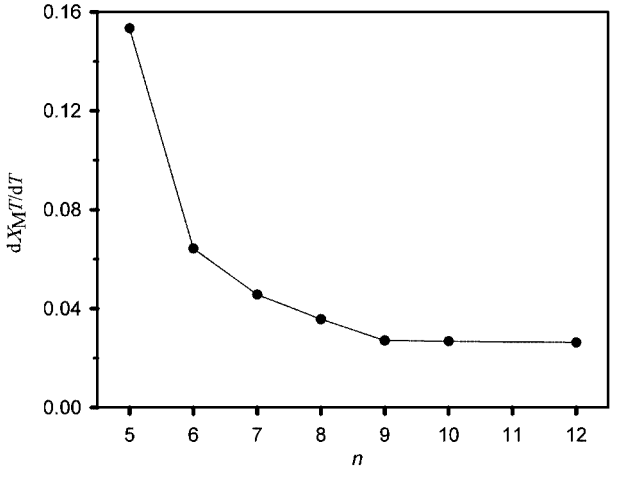

Figure 7. The slope of the $\chi_M T$ curves of the $BF_4^-$ series at the transition temperature ($T_{SC}$) for $n$ = 5–10, 12, in the heating mode. The line connecting the points has no physical meaning and is intended only as a guide.

## Conclusions

We present here a detailed study of a homologous series of iron(II) SC coordination polymers using $BF_4^-$ as the counteranion and compare this data with our previous study of closely related compounds[23] using the same ligands but with $ClO_4^-$ as the counteranion. By changing the anion to $BF_4^-$, we observed that the structure has changed slightly and thus altered the SC behaviour. As indicated by XRPD, the phases seem to adopt a 1D polymer by forming

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chains, arranged approximately in a hexagonal close-packed manner. The longer the alkylene spacer, the higher the disorder of the infinite 1D network as indicated by severe reflection broadening.

In Figure 8, $T_{SC}$ versus $n$ is shown for the $BF_4^-$ and the $ClO_4^-$ series. Both curves show a zigzag behaviour with decreasing amplitude, reaching a similar end point. Indeed, $[Fe(12ditz)_3](ClO_4)_2$ has a $T_{SC}$ = 159 K and $[Fe(12ditz)_3](BF_4)_2$ has a $T_{SC}$ = 156 K. This suggests that as the alkylene spacer is lengthened, $T_{SC}$ eventually reaches a limiting value of 160 K. It is, however, obvious that the tetrafluoroborates show a reversal in the parity effect as $n$ is increased from 7 to 8. This suggests that at this length the alkylene chains are differently arranged. In contrast, the perchlorates show a parity effect up to $n$ = 12[23] (see Figure 8).

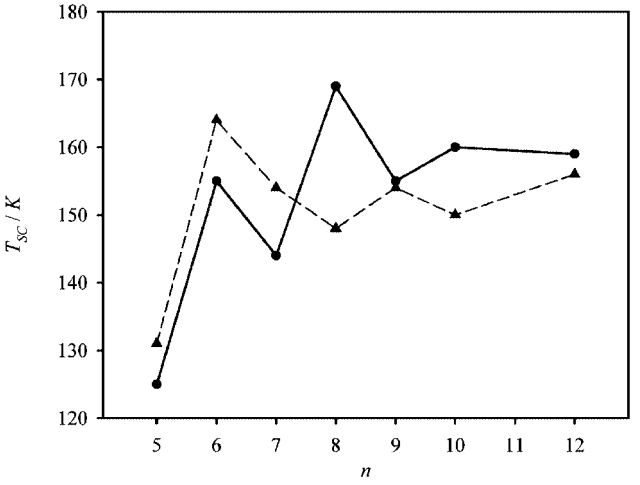

Figure 8. Comparison of $T_{SC}$ as a function of the number of carbon atoms ($n$) in the spacer of the ditetrazole ligands for the $BF_4^-$ (▲) and $ClO_4^-$ (●) series.

Chemical intuition would suggest more or less identical results for such similar noncoordinating anions like perchlorate and tetrafluoroborate. In spite of this, our investigations on these two related series clearly show that there is a anion dependence, especially in terms of their magneto-optical behaviour. Furthermore, the pronounced dependence of $T_{SC}$ upon the parity of the spacer length which was found in the perchlorate series is also found, with alterations, in the tetrafluoroborate over the whole series (see Figure 8). Eventually, however, both series reach the same limiting value of $T_{SC}$ at high $n$ when orientation is insignificant with respect to the separation of the iron centres. As far as we can derive from our studies, the choice of the ligand system represents the fundamental requirement to obtain a SC compound, but the impact of the noncoordinating anion seems to be of similar importance. With this in mind, the interest is now focused on complexes in which the interaction of anion and ligand leads to optimised systems where the spin transition and cooperativity can be systematically tuned to be used for future applications of new materials with interesting magneto-optical features.

## Experimental Section

**Chemicals and Standard Physical Characterisation:** Iron(II) tetrafluoroborate hexahydrate was obtained from Aldrich. All other chemicals were standard reagent grade and used as supplied. Elemental analyses (C, H and N) were performed in the laboratories of Dr. Roman Boca (Slovenská Vyská Scola Technicá v Bratislava, Chemitechothenologická Fakulta, Radlinského 9, 81237 Bratislava, Slovakia). Mid-range FTIR spectra of the compounds were recorded as KBr pellets within the range of 4400–450 $cm^{-1}$ using a Perkin–Elmer 16PC FTIR spectrometer. Pellets were obtained by pressing the powdered mixture of the samples in KBr in vacuo using a hydraulic press applying a pressure of 10000 $kg \cdot cm^{-2}$ for 5 min.

**Synthesis of the Complexes:** The general synthetic pathway and the synthesis of the ligands used [1,*n*-bis(tetrazol-1-yl)alkane; $n$ = 5–10, 12] has been previously reported.[17,23,29,30] Note that the 1,11-bis(tetrazol-1-yl)undecan has not yet been synthesised. The respective ligand (*n*ditz, 1 mmol) was dissolved in reagent grade ethanol ($n$ = 5–10, 12). While the solution cooled down to 40 °C, iron(II) tetrafluoroborate hexahydrate or iron(II) perchlorate hexahydrate (0.33 mmol) and a small amount of ascorbic acid to keep the iron as iron(II) were diluted in ethanol (5 mL). This solution was slowly added to the dissolved ligand, and the resulting mixture was stirred for 4 h. The precipitate was filtered off, and the obtained powder was dried with $P_2O_5$. It has so far proved impossible to grow single crystals by any of the standard methods including H-tube slow diffusion or slow cooling.

**Elemental Analyses and Mid-FTIR**

**$[Fe(5ditz)_3](BF_4)_2$:** Yield: 0.16 g (59%). $C_{21}H_{36}B_2F_8FeN_{24}$ (854.14): calcd. C 29.53, H 4.25, N 39.36; found C 29.30, H 4.18, N 37.66. Mid-FTIR: $\tilde{\nu}$ = 3146 (C–H stretching vibration, ν, of the aromatic tetrazole ring), 2949, 2933 and 2862 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1506, 1370 ($\nu_{N=N}$, $\nu_{C-N}$), 1183, 1109 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**$[Fe(6ditz)_3](BF_4)_2$:** Yield: 0.15 g (50%). $C_{24}H_{42}B_2F_8FeN_{24}$ (896.22): calcd. C 32.16, H 4.72, N 37.51; found C 31.41, H 4.78, N 36.15. Mid-FTIR: $\tilde{\nu}$ = 3148 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2938 and 2862 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1506, 1372 ($\nu_{N=N}$, $\nu_{C-N}$), 1182, 1102 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**$[Fe(7ditz)_3](BF_4)_2$:** Yield: 0.19 g (61%). $C_{27}H_{48}B_2F_8FeN_{24}$ (938.31): calcd. C 34.56, H 5.16, N 35.83; found C 34.00, H 5.18, N 35.72. Mid-FTIR: $\tilde{\nu}$ = 3147 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2940 and 2862 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1507, 1375 ($\nu_{N=N}$, $\nu_{C-N}$), 1173, 1108 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**$[Fe(8ditz)_3](BF_4)_2$:** Yield: 0.18 g (55%). $C_{30}H_{54}B_2F_8FeN_{24}$ (980.39): calcd. C 36.75, H 5.55, N 34.29; found C 36.84, H 5.58, N 33.63. Mid-FTIR: $\tilde{\nu}$ = 3148 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2936 and 2859 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1507, 1368 ($\nu_{N=N}$, $\nu_{C-N}$), 1183, 1102 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**$[Fe(9ditz)_3](BF_4)_2$:** Yield: 0.25 g (72%). $C_{33}H_{60}B_2F_8FeN_{24}$ (1022.47): calcd. C 38.77, H 5.91, N 32.88; found C 38.95, H 5.83, N 31.96. Mid-FTIR: $\tilde{\nu}$ = 3148 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2933 and 2857 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1507, 1375 ($\nu_{N=N}$, $\nu_{C-N}$), 1174, 1108 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**$[Fe(10ditz)_3](BF_4)_2$:** Yield: 0.24 g (69%). $C_{36}H_{66}B_2F_8FeN_{24}$ (1064.55): calcd. C 40.62, H 6.25, N 31.58; found C 40.83, H 6.03, N 31.41. Mid-FTIR: $\tilde{\nu}$ = 3145 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2929 and 2851 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1504, 1372 ($\nu_{N=N}$, $\nu_{C-N}$), 1177, 1098 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**$[Fe(12ditz)_3](BF_4)_2$:** Yield: 0.26 g (67%). $C_{42}H_{72}B_2F_8FeN_{24}$ (1148.71): calcd. C 44.15, H 6.35, N 29.42; found C 44.08, H 6.90, N 28.08. Mid-FTIR: $\tilde{\nu}$ = 3141 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2917 and 2852 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1501, 1383 ($\nu_{N=N}$, $\nu_{C-N}$), 1176, 1096 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**$[Fe(10ditz)_3](ClO_4)_2$:** Yield: 0.20 g (55%). $C_{36}H_{66}Cl_2FeN_{24}O_8$ (1089.84): calcd. C 39.68, H 6.10, N 30.85; found C 39.03, H 5.60, N 29.23. Mid-FTIR: $\tilde{\nu}$ = 3136 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2917 and 2850 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1508, 1383 ($\nu_{N=N}$, $\nu_{C-N}$), 1178, 1088 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**$[Fe(12ditz)_3](ClO_4)_2$:** Yield: 0.28 g (71%). $C_{42}H_{72}Cl_2FeN_{24}O_8$ (1167.94): calcd. C 43.19, H 6.21, N 28.78; found C 42.57, H 6.63, N 28.01. Mid-FTIR: $\tilde{\nu}$ = 3139 ($\nu_{C-H}$ of the aromatic tetrazole ring), 2922 and 2851 ($\nu_{C-H}$ of the aliphatic C–H in the butylene spacer), 1504, 1375 ($\nu_{N=N}$, $\nu_{C-N}$), 1175, 1094 ($\nu_{C=N}$, $\nu_{N-N}$, $\nu_{C-N}$) $cm^{-1}$.

**X-ray Powder Diffraction:** The samples were gently ground and placed on flat-plate single-crystal silicon sample holders by the slurry technique with cyclohexane (Merck, p.a.) as elutriating liquid. Powder patterns were recorded with a Philips X'Pert diffractometer in Bragg–Brentano geometry using Cu-$K_{\alpha 1,2}$ radiation.

**Reflectivity Measurements:** Reflectivity of the samples was investigated by using a custom-built reflectivity set-up equipped with a CVI spectrometer, which allowed the collection of both the reflectivity spectra within the range of 450–900 nm at a given temperature and the following of the temperature dependence of the signal at a selected wavelength (±2.5 nm) at 5–290 K. The experiment was performed directly using a thin layer of the powdered sample without any dispersion in a matrix.[31]

**Magnetic Susceptibility and Magneto-Optical Measurements:** Magnetic measurements were completed with two SQUID magnetometers: (i) SQUID Cryogenix S600 magnetometer with an applied field of 1 T and (ii) MPMS-55 Quantum Design SQUID magnetometer with an operating field of 2 T within the temperature range of 2–300 K and with a cooling/heating speed of 10 $K \cdot min^{-1}$ in the settle mode at atmospheric pressure. Further measurements were made with a 9 T-PPMS-system from Quantum Design VSM operating with a field of 1 T. All magnetic measurements were performed using powder samples weighing ca. 12 mg. The data were corrected for the magnetisation of the sample holder and for diamagnetic contributions, estimated from Pascal's constants.

The photomagnetic measurements were performed using a Spectra Physics Series 2025 $Kr^+$ laser ($\lambda$ = 532 nm) coupled by an optical fibre to the cavity of the SQUID magnetometer previously described in ref.[27] The laser light power at the sample was adjusted to 5 $mW \cdot cm^{-2}$. Bulk attenuation of light intensity was limited as much as possible by the preparation of a thin layer of compound. It is noteworthy that there was no change in the data due to sample heating upon laser irradiation. The weight of these thin layer samples (approximately 0.2 mg) was obtained by comparison of the measured thermal spin-crossover curve with another curve of a more accurately weighed sample of the same compound.

## Acknowledgments

The financial support of the Austrian Science Foundation, FWF project 19335-N17, the Italian Ministero dell'Università e della Ricerca through project FIRB RBNE033KMA, and the European Community for NE "MAGMAnet" NMP3-CT-2005-515767 projects is gratefully acknowledged. Furthermore, we want to thank the European Cooperation in the Field of Science and Technology (COST) for granting A. A. a "Short Term Scientific Mission" in Bordeaux D14 and D35. Additionally, M. B. carried out research in Florence within the Marie Curie Training site LAMM (MOL-MAG-MEST-CT-2004-504204). We wish to thank the Vienna University of Technology for funding under the "Innovatives Projekt NovMat". We also wish to thank Prof. K. Mereiter (TU Vienna) for the collection of the XRPD data, Dr. M. Grunert (University of Mainz) for producing $[Fe(12ditz)_3](BF_4)_2$, Prof. G. Hilscher (TU Vienna) for SQUID measurements on the same sample, Mrs. K. Poppenberger (TU Vienna) and Mr. Y. Hasegawa (Aoyama-Gakuin University) for the SEM measurements.

# Synthesis of Cycloruthenated Compounds as Potential Anticancer Agents

**Lida Leyva,[a] Claude Sirlin,*[a] Laura Rubio,[b] Cecilia Franco,[b] Ronan Le Lagadec,[b] John Spencer,[c] Pierre Bischoff,[d] Christian Gaiddon,[e] Jean-Philippe Loeffler,[e] and Michel Pfeffer*[a]**

**Keywords:** Bioinorganic chemistry / Ruthenium / Metallacycles / Antitumor agents

A library of 19 cycloruthenated derivatives is constructed by making use of the well-known cyclometalation reaction. Their geometries are modified in a straightforward manner by addition of either mono- or bidentate ligands, such as bipyridine, phenanthroline, 1,2-bis(diphenylphosphanyl)ethane, dimethylphenylphosphane, triphenylphosphane, and 1,3,5-triaza-7-phosphatricyclo[3.3.1.1]decane (PTA) ligands, to cationic cycloruthenated centers. The antitumor properties of the compounds thus obtained are investigated in order to compare them with recently reported ruthenium complexes and cisplatin. $IC_{50}$ values against mammalian cells (A-172, HCT-116, and RDM-4) are determined for the library compounds and some of them, such as those derived from orthoruthenated phenylpyridine and a bidentate N,N ligand, display activity of the same order of magnitude as cisplatin.

## Introduction

It is now well established that metal complexes can be considered as pharmaceuticals for therapeutic or diagnostic use.[1] Since the fortuitous discovery of their anticancer properties in the 1960s, platinum compounds have been recognized as very powerful anticancer drugs that have helped to revolutionize cancer therapy.[2] Consequently, cisplatin is currently one of the three most widely used drugs in chemotherapy and is highly effective in treating ovarian and testicular cancers. It also contributes to the treatment of many other cancers. Despite these facts, it presents two major disadvantages, namely its severe toxicity, especially nephrotoxicity, neurotoxicity, and emetogenesis, and its limited applicability to a narrow range of tumors as several tumors are naturally resistant or have developed resistance.[2c] In order to improve cancer therapies, new platinum and non-platinum containing entities such as metallocenes, titanium(IV) and gold(I) complexes, and gallium(III) salts have been considered as alternatives to cisplatin.[1b,1c]

In this respect, special attention has been paid to the application of ruthenium compounds in chemotherapy since such complexes are often able to display properties similar to those of platinum and iron in that they have analogous ligand-exchange abilities to platinum complexes and are less toxic than platinum, presumably because they can mimic iron in the course of binding to serum transferrin or albumin. Since rapidly dividing cells have a greater requirement for iron, these cells will increase the number of transferrin receptors at their surface, thereby sequestering more metal-loaded receptors. As the drug becomes targeted toward cancer cells, its toxicity should be reduced.[3] Some noticeable progress has been made recently whereby several teams have developed new organometallic or coordination complexes based on ruthenium(III) for this purpose.[4] Recently, $[ImH]^+[Ru(Im)(Me_2SO)Cl_4]^-$ (NAMI-A; Im = imidazole) and $[IndH]^+[Ru(Ind)_2Cl_4]^-$ (KP1019; Ind = 1*H*-indazole) have successfully completed phase I clinical trials as antimetastatic drugs[5] and have been shown to be precursors of $Ru^{II}$ complexes in vivo. Following on from these results a growing number of research groups have studied the biological activities of related ruthenium(II) complexes. Thus, Sadler et al. have found that some areneruthenium(II) complexes exhibit interesting in vitro and in vivo anticancer activities,[6] and Dyson et al. have studied related complexes and determined their antibiotic and antiviral activities.[7] Similarly, Reedijk et al. have established the high cytotoxicity of a series of bis(2-phenylazopyridine)ruthenium(II) complexes against A2780 human ovarian carcinoma cell lines.[8]

Some of us have recently reported that organometallic cycloruthenated compounds, such as those formed by the direct cyclometalation (involving a CH activation reaction)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

of a nitrogen-containing ligand, can interact with biological molecules. Indeed, these organometallic species can be used as very efficient mediators of electron transfer to or from oxidized or reduced active sites of redox enzymes.[9] We thus reasoned that these molecules might have potential anticancer applications, as was shown recently for related cyclopalladated or cycloplatinated complexes.[10] Given that most metal complexes that have been previously tested for antitumor activity contain ligands that are only weakly bound to the metal via a heteroatom (N, O, S) to metal coordination bond, it is very likely that at some point in the process these ligands can dissociate from the metal in an in vivo context. In contrast to previous work, we were interested in assessing the behavior towards tumor cells of related complexes in which a ligand is bound to a metal by strong covalent bonds such as, for instance, a C–M σ bond stabilized by intramolecular coordination of an heteroatom, a bonding scheme that is typical of cyclometalated compounds. We reasoned that these cyclometalated ligands might remain attached to the metal throughout the biological process, whereas more labile ligands such as halides or solvents can dissociate and enable DNA binding. These stable ligands may additionally impart useful physical properties to the organometallic moiety (fluorescence or phosphorescence for instance), thus enabling the metal and ligand to be traced in the cells and in vivo. Other reasons for studying compounds with monoanionic bidentate ligands strongly bound to the metal center include: (i) the complexes obtained with only neutral ligands will be monocationic whereas the corresponding compounds having a neutral bidentate chelate will lead to dicationic species under similar conditions, and (ii) the electronic behavior (electrophilicity or nucleophilicity) of the ruthenium center will be significantly modified as compared to that of $Ru^{II}$ complexes containing neutral bidentate ligands. This might shed light upon its mechanism of interaction with cell-based macromolecules such as DNA or proteins, for instance. Previous studies of the reactivity of cycloruthenated complexes towards various nucleophilic or electrophilic reagents[11] have shown that, depending on the reaction conditions, the metallacyclic unit of these compounds is rather inert and that the existence of the cycloruthenated ligand is able to stabilize the whole complex. We thus decided to evaluate the biological activity of some of these compounds and were delighted to observe that they indeed display interesting properties as antitumor agents in vitro.[12] In this paper we wish to disclose the synthesis and characterization together with some further biological results that we have established in this area with cycloruthenated compounds.

## Synthesis and Characterization of the Cycloruthenated Compounds

The library of organoruthenium compounds employed in this study is shown in Scheme 1. Most starting cycloruthenated materials were obtained by the well-known cyclometalation reaction involving a C–H bond activation at an early stage of the procedure. The cycloruthenation of *N*,*N*-dimethyl(phenylmethyl)amine and the 2-phenylpyridine ligands to afford the starting materials **1** and **2** has been described elsewhere.[13]

Complexes **3** and **4** were synthesized more than a decade ago by the same cyclometalation reaction, although a transmetalation reaction using orthomercuriated derivatives of *N*,*N*-dimethylbenzylamine and (*R*)- or (*S*)-*N*,*N*-dimethyl(1-phenylethyl)amine, respectively, have been shown to be more efficient for obtaining these chloride derivatives.[14]

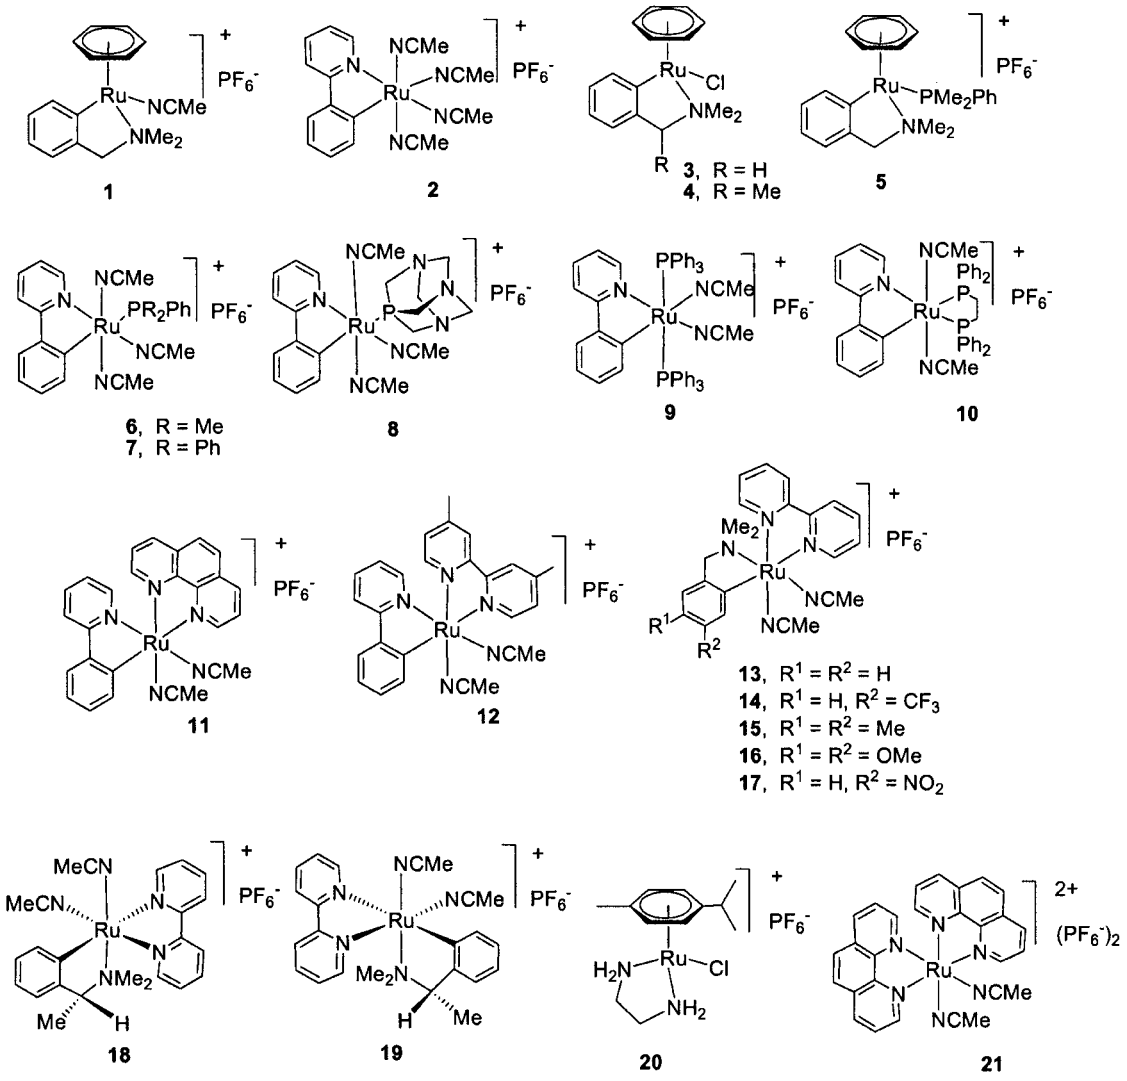
Compounds **5**–**8** were obtained by adding one equivalent of the required phosphane ligand {$PMe_2Ph$, $PPh_3$, or 1,3,5-triaza-7-phosphatricyclo[3.3.1.1]decane (PTA)[15]} at room temperature to solutions of **1** (to afford **5**) or **2** (to afford **6**, **7**, and **8**). Similar yields of product were obtained in dichloromethane, acetonitrile, and methanol.

The compounds were characterized by elemental analysis as well as by $^1H$ and $^{31}P$ NMR spectroscopy. Thus, a $^4J_{P,H}$ coupling constant was observed for the signal of the $\eta^6$-benzene ligand in **5**, thereby providing evidence for the *trans* geometry of the phosphane and the metalated arene. A chiral version of this compound has been reported previously along with its crystal structure.[16] The $^1H$ and $^{31}P$ NMR spectra of **6**, **7**, and **8** reveal that these compounds exist as only one regioisomer. The acetonitrile ligands gave rise to two signals in a 1:2 ratio and both of them show a $^5J_{P,H}$ coupling of 1.3–1.8 Hz. This clearly indicates the presence of two nonequivalent acetonitrile molecules located *trans* to each other at the ruthenium atom; the third one and the phosphane ligand are in the same plane as the orthoruthenated phenylpyridine unit. However, spectroscopic investigations were not helpful in determining the position of the phosphane ligand with respect to the C–N chelate in these complexes. The single-crystal X-ray diffraction analysis of **7** and **8** (see Figures 1 and 2, respectively, for ORTEP drawings of the cations) revealed that the geometry of the complexes was as predicted from the NMR spectroscopic data.

The identification of the atoms of the C–N chelate bound to Ru from the X-ray structure was, however, ambiguous, although the analysis of the lengths of the Ru–N bond of the Ru-NCMe units allowed us to establish unambiguously that the phosphorus atom is *trans* to the carbon atom of the chelate in both **7** and **8**. The Ru–N4 bond (2.029 Å) in **7** and Ru–N3 bond (2.024 Å) in **8** are typical of acetonitrile ligands bound to Ru *trans* to N, as can be verified from X-ray diffraction data of related compounds (see Table 1). Indeed, when the acetonitrile ligand is *trans* to C, the Ru–N distance is usually around 0.1 Å longer (see compounds **2** and **9**). Consequently, the phosphane ligands must be located *trans* to the carbon atom in **7** and **8**, and this fact is further highlighted by the longer Ru–P bonds [2.458(1) and 2.395(1) Å, respectively] than in any other $Ru^{II}$ complex studied in this paper [average: 2.367(1) Å]. This lengthening of the Ru–N and Ru–P bonds is expected for such bonds *trans* to a carbon atom, which is known to exert a larger *trans* influence than a nitrogen atom.[17]

As the positions *trans* to the carbon and *trans* to the nitrogen atom are identical here as far as their steric con-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 1.

straints are concerned, the location of the phosphanes is very likely to be the result of a larger *trans* effect[17] of the phenyl group of the C–N chelate bonded to Ru through a C–Ru σ bond as compared to that of the pyridine unit of the same chelate. This result is in line with what was found recently when bidentate bipyridine or phenanthroline ligands were coordinated to the same compound **2** (in **12** and **11**) and for which one nitrogen atom was also coordinated *trans* to the Ru–C bond. The position of the $PPh_3$ and the PTA ligands *trans* to the carbon atom was, however, not expected as there are plenty of examples in the literature of the coordination of phosphane ligands in similar cyclometalated compounds of palladium for which it has been shown that the phosphane is indeed very reluctant to coordinate to the palladium atom *trans* to the carbon atom.[20] It was thus not unreasonable to expect the phosphane ligands to be bound to Ru in any position except the one *trans* to C. Complexes **7** and **8** are likely to be formed under kinetic control.

When two equivalents of phosphane were added to **2** in refluxing acetonitrile and the mixture stirred for 24 h a different reaction took place as we observed the formation of **9** due to the substitution of two acetonitrile ligands on the ruthenium atom by two triphenylphosphanes. The positions occupied by these latter ligands seemed to be symmetrical as only one signal is observed for the two phosphorus atoms in the $^{31}P$ NMR spectrum. In contrast to the previous case, the signals of the acetonitrile protons did not display any $J_{H,P}$ coupling with the phosphorus atoms, thereby suggesting that these ligands are located *trans* to the N and the C atoms of the phenylpyridine chelate, respectively. The structure of **9** was ascertained by an X-ray diffraction study on a single crystal.[21] The results are displayed in Figure 3, which shows an ORTEP view of the cationic part of **9**. It is at once apparent that the two phosphane ligands are located in a mutual *trans* arrangement. The Ru–P, Ru–C, and Ru–N bond lengths are in the expected range for such bonds.

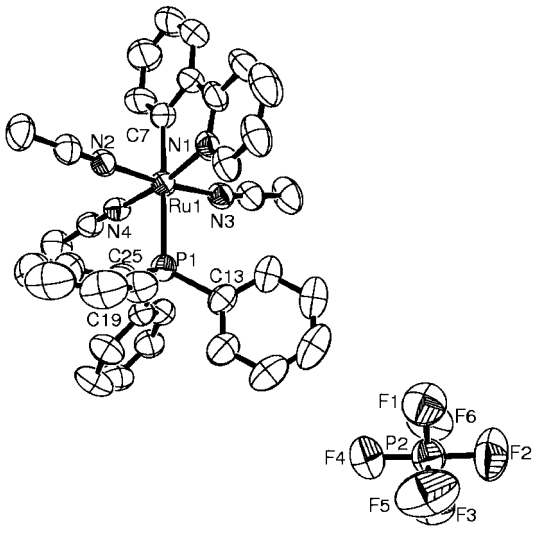

Figure 1. ORTEP view of compound **7**. Selected bond distances [Å] and angles [°]: Ru1–N2 2.009(3), Ru1–N(4) 2.026(3), Ru1–N3 2.039(3), Ru1–C7 2.049(4), Ru1–N1 2.088(3), Ru1–P1 2.458(1); N2–Ru1–N4 87.89(11), N2–Ru1–N3 172.84(11), N4–Ru1–N3 91.65(11), N2–Ru1–C7 87.63(12), N4–Ru1–C7 92.85(13), N3–Ru1–C7 85.26(12), N2–Ru1–N1 87.46(10), N4–Ru1–N1 171.53(11).

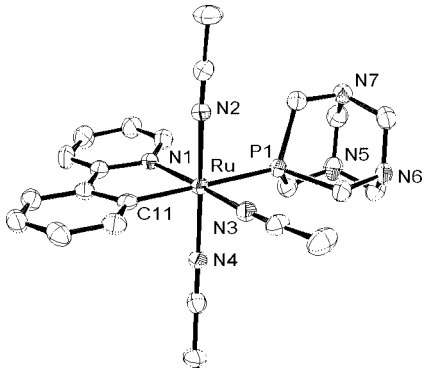

Figure 2. ORTEP view of the cation of **8**. Selected bond distances [Å] and angles [°]: Ru1–N2 2.013(2), Ru1–N4 2.022(2), Ru1–N3 2.024(2), Ru1–C11 2.068(3), Ru1–N1 2.087(2), Ru1–P1 2.395(1); N2–Ru1–N4 175.34(8), N2–Ru1–N3 88.70(8), N4–Ru1–N3 87.91(7), N2–Ru1–C11 90.75(8), N4–Ru1–C11 90.75(8), N3–Ru1–C11 95.46(9), N2–Ru1–N1 89.66(7), N4–Ru1–N1 93.41(7).

Adding one equivalent of 1,2-bis(diphenylphosphanyl)-ethane (dppe) to **2** in acetonitrile under the same conditions as for the synthesis of **9** afforded **10** in yields of up to 60%. Whereas the $^{31}P$ NMR spectrum of **10** shows an AB-type pattern for two nonequivalent phosphorus atoms ($^3J_{P,P}$ = 8 Hz), the signal of the acetonitrile protons is a singlet with no $J_{H,P}$ coupling visible. This situation clearly indicates that the acetonitrile ligands are located *trans* to each other. This was confirmed by the X-ray diffraction study of a single crystal of **10**, an ORTEP view of which is shown in Figure 4. We note that the Ru–C(8) and Ru–N(1) bond lengths are elongated by 5% (approx. 0.1 Å) relative to related compounds due to the large *trans* influence of the phosphorus atoms. The distances and angles of the other parts of the molecules are as expected.

Table 1. Ru–N bond lengths of Ru–NCMe units in various cycloruthenated complexes.

| | Ru–N [Å] | Atom or ligands *trans* to N | Ref. |

The remaining compounds of our library of cycloruthenated compounds (see Scheme 1) that do not contain a phosphane ligand (**11**–**19**) have either been described earlier (**11**[19] and **13**–**17**[18]) or were synthesized by following similar procedures (**12** as **11** and **18**, **19** as **13**) Compounds **18** and **19** are chiral versions of **13** with the two opposite

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

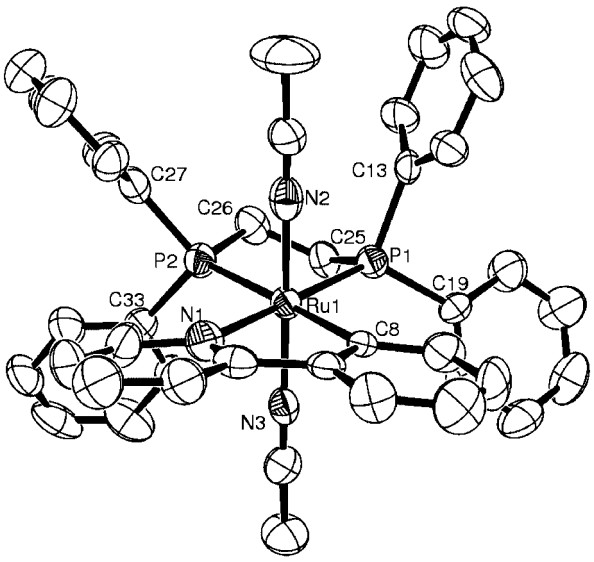

Figure 4. ORTEP view of the cationic part of compound **10**. Selected bond distances [Å] and angles [°]: Ru1–N3 2.001(6), Ru1–N2 2.001(6), Ru1–C8 2.096(6), Ru1–N1 2.118(5), Ru1–P1 2.343(2), Ru1–P2 2.373(2); N3–Ru1–N2 175.9(2), P1–Ru1–P2 83.08(6), C8–Ru1–N1 77.6(2), C8–Ru1–P1 100.42(17), N1–Ru1–P2 98.86(18).

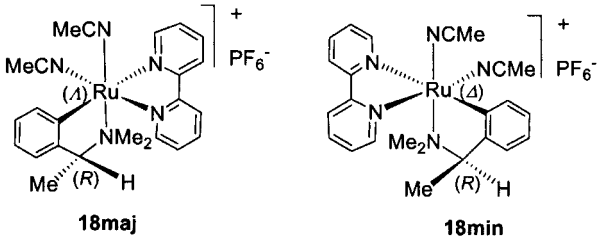
configurations at the benzylic fragment of the cycloruthenated ligand. The starting materials for the synthesis of **18** and **19**, namely $[(\eta^6\text{-}C_6H_6)Ru\{C_6H_4\text{-}2\text{-}(R)\text{-}CHMeNMe_2\}(NCMe)]PF_6$ and $[(\eta^6\text{-}C_6H_6)Ru\{C_6H_4\text{-}2\text{-}(S)\text{-}CHMeNMe_2\}(NCMe)]PF_6$ respectively, were obtained by a direct cyclometalation of the corresponding (*R*)- or (*S*)-1,1-*N*,*N*-dimethyl(phenylethyl)amine, respectively.[12] Due to the chirality at the ruthenium center these two complexes were a mixture of diastereomers with a diastereomeric excess (*de*) of 48% in favor of the ($R_C$,$S_{Ru}$) and ($S_C$,$R_{Ru}$) isomers rather than the ($R_C$,$R_{Ru}$) and ($S_C$,$S_{Ru}$) isomers, respectively.

We will only describe the synthesis and characterization of **18** from $[(\eta^6\text{-}C_6H_6)Ru\{C_6H_4\text{-}2\text{-}(R)\text{-}CHMeNMe_2\}(NCMe)]PF_6$ as **19** displays exactly the same behavior. The $\eta^6$-benzene ligand was removed by adding one equivalent of bipyridine in acetonitrile and stirring at room temperature for 12 h, which led to good yields of **18**. The $^1$H NMR spectra indicated that this complex also exists as diastereomers, with the *de* having dropped to 22%. Thus, **18** is a mixture of two diastereomers (**18maj** and **18min**).



Crystallization from $CH_2Cl_2/Et_2O$ afforded crystals that consisted mainly of the major isomer **18maj**, with a *de* value of 98.5% (note that the mother liquor from which these crystals were obtained now has a *de* = 0% as a result of the removal of part of the major diastereomer). Redissolution of this compound did not cause any change in its *de*, even after several days at room temperature. Moreover, the composition of the initial mixture of diastereomers in $CD_3CN$ did not vary with temperature in the range –40 to 55 °C. These data allowed us to conclude that these diastereomers, in contrast to their pseudo-tetrahedral counterpart $[(\eta^6\text{-}C_6H_6)Ru\{C_6H_4\text{-}2\text{-}(R)\text{-}CHMeNMe_2\}(NCMe)]PF_6$, are very likely to be rigid in solution such that their epimerization, if it takes place at all, should occur at much higher temperatures. An X-ray diffraction study was performed for each of the complexes. An ORTEP of **18**, together with some typical distances and angles, is given in Figure 5; the data for **19**, which are obviously identical to those of **18**, have been deposited.

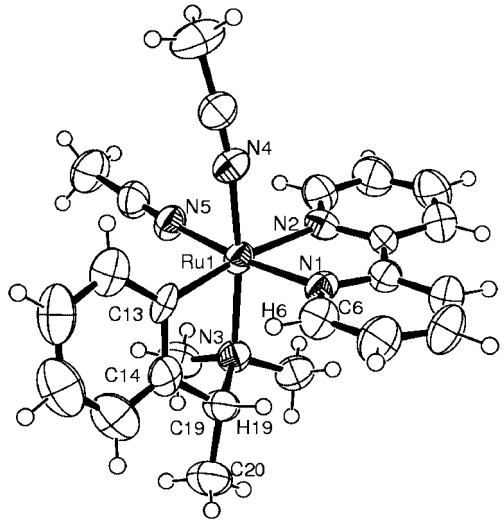


Figure 5. ORTEP view of the cationic part of compound **18**. Selected bond distances [Å] and angles [°]: Ru1–N3 2.175(5), Ru1–N4 2.018(5), Ru1–N5 2.001(5), Ru1–C13 2.027(6), Ru1–N1 2.057(5), Ru1–N2 2.148(5); N2–Ru1–N1 78.16(19), N2–Ru1–N3 96.69(18), N3–Ru1–C13 78.4(2), N4–Ru1–N5 84.5(2), N4–Ru1–N3 172.4(2).

It is immediately clear that the structure is similar to that of the *N*,*N*-dimethylbenzylamine derivatives as one of the bipyridine nitrogen atoms is linked to Ru *trans* to the C atom of the C–N chelate. The configuration at the ruthenium metal is such that the major diastereomer has a *lambda* (Λ)[22] configuration at the ruthenium atom associated with an *R* configuration at the carbon atom, whereas a *delta* (Δ) configuration was found for the other derivative which has an *S* configuration at the benzylic carbon atom. In order to verify that the crystal selected for the X-ray diffraction study was indeed the major isomer, we recorded its $^1$H NMR spectra. The 2D NOESY spectrum shows that there is an interaction between the benzylic proton and the *ortho* H [on C(6)] of the bipyridine [they are around 2.53 Å apart; see HC(19)···HC(6) in Figure 5]. This cannot be the case in the minor isomer as the C–N chelate must have rotated by 180° around the Ru–C bond, which places the benzylic proton away from the bipyridine one.

## Solubility and Stability of the Complexes

### Solubilities

Except for **8**, most of the cycloruthenated compounds are poorly soluble in pure water. For instance, complex **11** has a solubility in water of only 0.1 mM. However, all of them are sufficiently soluble in DMSO, MeCN, or alcohols (methanol, ethanol). The samples for in vitro tests were obtained from 50.0 mM solutions of the ruthenium complexes in pure DMSO or MeCN, which were then sequentially diluted with the required amount of cell culture media in order to obtain the solutions to be studied, whose concentration ranged from 0.2 to 50 μM. These solutions were assimilated to water solutions of our compounds. In marked contrast to the other compounds, **8** has a sufficiently high solubility in water (3.2 mM) that its characterization by $^1$H NMR spectroscopy in $D_2O$ proved possible. This latter study showed that the MeCN ligands are not displaced by water since a $^5J_{P,H}$ coupling was observed for the signals of the acetonitrile ligands.

As compound **11** gave some of the best results with respect to in vitro activity, we studied the behavior of solutions of this complex in water. Because of its insufficient aqueous solubility we could not follow the behavior of such solutions by NMR spectroscopy. Nevertheless, we found that the MeCN ligands were not displaced by $CD_3OD$ or [$D_6$]acetone.

### Stabilities

We initially verified that the UV/Vis spectrum of a $10^{-4}$ M solution of **11** in pure $CH_3CN$ did not change with time (after 48 h). This somewhat predictable result proved that the C–N chelate is not labile in this medium. The same spectrum and the same stability over a 24 h period were observed for $10^{-4}$ M solutions of **11** obtained from either a $CH_3CN$ solution or a DMSO solution of this compound to which water, buffered at pH 7, was added. This result highlighted the fact that the behavior of solutions of **11** in water is not dependent upon the solvent used to obtain their mother solutions. No changes were observed in the UV/Vis spectra when the pH of the solution was increased to 9 or when sodium chloride (150 mM) was added to the water solution at pH 7. Moreover, no significant changes were observed for any of these solutions after 48 h in the dark.

We also found that the stability of aqueous solutions of **11** changed dramatically when they were irradiated with an halogen lamp (approx. 150 W) for up to 20 minutes as we observed the disappearance of the absorptions at 400 and 450 nm together with the appearance of a new absorption at around 366 nm. Ryabov et al. have recently reported a related study of the behavior of a methanol solution of **11**, which they found to be photosensitive,[19] and they suggested that the MeCN ligand is substituted by methanol upon irradiation. It is very likely that our water solution of **11** behaves similarly to give an aquo species that is more prone to oxidation as we observed a UV/Vis spectrum that is very similar to that described in MeOH. We also checked that a solution used for in vitro tests irradiated as above had a lower antitumor activity than the nonirradiated one (see Table 2 below).

## Biological Effects

### In Vitro Cell Growth Inhibition

To evaluate the antitumor potential of the various ruthenium-derived compounds we analyzed their effect on cell proliferation. A-172 cells derived from a human glioblastoma were treated with different doses of complexes from our library or with cisplatin and the cells' viability was determined by measuring a specific cellular enzymatic activity of the remaining living cells after 48 h. We next studied the effect of these compounds on other cell lines derived from adenocarcinoma (HCT-116) and lymphoma (RDM-4) and evaluated their $IC_{50}$ values. The results obtained with the three different cell lines are summarized in Table 2.

Table 2. $IC_{50}$ [μM] values of the cycloruthenated complexes compared with those of reference compounds (cisplatin, **20**, and **21**) for three cell lines.

[a] The $IC_{50}$ values reported for this compound in ref.[12] are erroneous. [b] The $IC_{50}$ values obtained for solutions of **11** irradiated with visible light are about twice as high as those for solutions protected from light (the data given here are for solutions of **11** protected from light).

We first tested the complexes **3**–**5** that are structurally related to **20**,[6] which is known to inhibit the growth of A-2780 human ovarian cancer cells. The $IC_{50}$ values for **3** and **4** show that these species are inactive, whereas **5** displayed a good activity. According to the above classification, **20** displays a moderate $IC_{50}$ value of 5–20 μM with our cell lines.

In order to mimic the anticancer behavior of cisplatin we then turned our attention to ruthenium-containing species that have two mutually *cis* and potentially aquatable coordination sites for binding to DNA. We thus selected alternative cycloruthenated compounds containing from two to four MeCN ligands on Ru. Complex **2**, which has four acetonitrile ligands bound to the ruthenium atom, was found to be inactive. However, substitution of these MeCN ligands with either 2,2′-bipyridine (bipy), phenanthroline (phen), or phosphane or diphosphane ligands significantly improved its activity. This increased activity for the bipy or phen derivatives might be related to the fact that ruthenium complexes containing bipyridine or phenanthroline are known to be cytotoxic due to their potential for intercalation.[1g] Compounds **5**–**15** thus displayed good to medium activities, with the exception of **8**, which displayed a disappointingly low activity with two cell lines (see Table 2). This low activity is not correlated to the instability of the complex towards oxygen as we verified that only 15% of the compound is oxidized in water solution after 48 h [$^1$H and $^{31}$P NMR spectra indicated the presence of O=P($CH_2$-N-$CH_2$)$_3$[23]]. Note, however, that the two MeCN ligands do not have to be mutually *cis*, as **9** and **10**, which have two MeCN ligands that are *cis* and *trans* to each other, respectively, displayed similarly good activities

As this stage, we checked whether the presence of a Ru–C bond has a significant effect on the activity of such compounds. Indeed, we found that **21**,[24] which is structurally closely related to **11**, displayed no activity. We note, however, that **21** has a double positive charge on the Ru atom whereas **11** has only a single charge. The increased activity on going from **21** to **11** might thus be due to the presence of the Ru–C bond but also to a larger lipophilicity for **11** as compared to **21**.

The putative target of the cycloruthenated compounds is DNA, which is a chiral molecule. As a consequence we prepared and tested the two enantiomeric complexes **18** and **19**, which both consist of a mixture of diastereomers with a *de* of 98.5 (see above), in order to observe potential chiral recognition. Unfortunately, these two complexes were found to be only poorly active and no conclusion could be drawn.

We were also interested in examining the effect of the electronic properties of the metalated phenyl unit upon the activity. The trifluoromethyl-substituted compound **14** and the dimethyl-substituted complex **15** were found to be as efficient as **13**, whereas the dimethoxy and nitro derivatives (**16** and **17**, respectively) are less active. These data did not allow us to correlate the activity of the organoruthenium compounds to the electronic nature of the cyclometalated ligand.

### Induction of G1 Arrest and Apoptosis

To understand the effect of our compounds on cell growth we examined their effect on the cell cycle by FACS (Fluorescence Activated Cell Sorter) analysis. Treatment of RDM-4 cell lines with 15 μM of **6** or **11** (near to the approximate $IC_{50}$ value) led to a marked increase in the number of cells in the G0/G1 phase. On the other hand, treatment with 45 μM of **6** or **11** (total inhibiting concentration) led to the formation of hypodiploid particles that created an important sub-G1 phase. The number of cells accumulated in the sub-G1 phase was lower than 10% at 24 h, but exceeded 50% at 48 h and reached 60% at 72 h. These results show that cycloruthenated compounds are able to both induce a G1 cell-cycle arrest and DNA fragmentation, which suggests induction of apoptosis.

To further analyze the characteristics of cell death induced by cycloruthenated compounds we performed immunocytochemistry experiments to assess the status of the nucleus and the possible activation of caspase 3, a protease induced by, and involved in, the apoptotic process. A-172 cells were treated with cisplatin, **6**, or **11** for 24 or 48 h. After fixation, the cells were labeled with an antibody that recognizes the active fragment of caspase 3. The nuclei were stained with Hoechst colorant. The cells treated with cisplatin or cycloruthenated compounds showed nuclei alterations, such as fragmentation or condensation. Moreover, we observed that cycloruthenated compounds stimulate Bax protein levels, which suggests that these compounds induce apoptosis by a mitochondrial pathway.[12] However, it is possible that other apoptotic pathways involving Fas and/or caspase 8 might still operate.

## Conclusions

A series of cycloruthenated complexes, some of which have been synthesized and characterized for the first time here, have been tested for their biological activities. Some of these compounds induce cytostatic and cytotoxic effects on mammalian tumor cells at least as effectively as cisplatin. Taking into account all of the results we have not yet been able to determine the nature of the particular pharmacophore. Cellular studies have shown that several ruthenium-derived compounds lead to $G_1$ arrest and induce apoptosis in various tumor lines of glioblastoma, neuroblastoma, and lymphoma. Several investigations are currently underway to improve the potential use of these substances as a cancer treatment. These include the determination of their in vivo toxicity and efficiency and the evaluation of the DNA-drug interaction at the molecular level.

## Experimental Section

**Chemicals:** All reactions were performed in Schlenk tubes under argon. Further workup, chromatography over standardized alumina, and crystallization were also performed under argon. We note, however, that our compounds are stable in air as solids once isolated, whereas solutions are stable for up to 48 h. Solvents were dried and distilled under argon prior to use: diethyl ether and *n*-hexane over sodium/benzophenone, dichloromethane and acetonitrile over calcium hydride. Mass spectra were recorded with a JEOL JMS-SX102A instrument with *m*-nitrobenzyl alcohol as the matrix. $^1$H and $^{13}$C NMR spectra were recorded with FT-Bruker AC 300 and ARX 500 spectrometers operating at 300.13 and 500.14 MHz

for $^1H$ and 75.47 and 125.77 MHz for $^{13}C$, respectively. 2D COSY and $^1H/^{13}C$ HSQC sequences were used to help the assignments of the $^1H$ and $^{13}C$ spectra. The chemical shifts are referenced to the residual solvent peaks; chemical shifts ($\delta$) and coupling constants ($J$) are expressed in ppm and Hz, respectively. Elemental analyses were performed by the Service de Microanalyse de l'Institut de Chimie, Strasbourg (France); the presence of crystallization solvent in some compounds was ascertained by $^1H$ NMR spectroscopy.

**[Ru(η⁶-C₆H₆){2-(CH₂NMe₂-κ*N*)-C₆H₄-κ*C*¹}(PMe₂Ph)]PF₆ (5):** A yellow solution of complex **1** (0.08 g, 0.156 mmol) and $PMe_2Ph$ (0.023 mL, 0.162 mmol) was stirred in $CH_2Cl_2$ (10 mL) for 3 h at room temperature. The reaction mixture was concentrated in vacuo and washed with *n*-hexane. The yellow residue was dissolved in a minimum amount of $CH_2Cl_2$ (1 mL) and a yellow solid was precipitated by the addition of *n*-hexane (0.09 g, 95% yield). $C_{23}H_{23}F_6NP_2Ru\cdot 1/2CH_2Cl_2$ (632.91): calcd. data collected were processed to produce conventional intensity data with the SAINT plus program. The intensity data were corrected for Lorentz and polarization effects, no absorption correction was applied. The structures were solved by direct methods, completed by a subsequent difference Fourier synthesis map, and refined by full-matrix least-squares procedures on $F^2$. All non-hydrogen atoms were refined anisotropically. The crystal structures have solvents of crystallization, which were refined isotropically in two or three major contributors. In the case of compound **7**, the molecule of methanol was refined in three positions with major contributors. Hydrogen atoms could not be refined due to the high level of disorder. The $PF_6$ anions are in special positions and the fluorine atoms are distorted and were modeled and refined anisotropically in two major contributors. Hydrogen atom positions were calculated and included in the final cycle of refinement. All calculations were performed with the SHELXTL (6.10) program package.[25] CCDC-617638 to -617642 and CCDC-629738 (for **7**, **9**, **10**, **18**, **19**, and **8**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Center at http://www.ccdc.ac.uk.data/cif.

**Cell-Proliferation Assays:** The ruthenium samples for in vitro tests were obtained from 50.0 mM solutions of the ruthenium complexes in pure DMSO, which were then sequentially diluted with the required amount of cell culture media in order to obtain study solutions with a concentration ranging from 0.2 to 50 μM. A-172 and HCT-116 cells were obtained from American Type Cell Culture Collection. RDM-4, a murine T lymphoma, was obtained from Dr. D. Oth (Institut Armand Frappier, Laval des Rapides, Québec, Canada). Cells were grown in 96-well plates and treated at 70% confluence. The medium was removed after 48 h and MTT (0.5 mg mL$^{-1}$) in DMEM (Dulbecco's Modified Eagle Medium) was added for 1 h. The medium was removed again and 0.04% HCl in 2-propanol was added to solubilize the crystals. Absorption differences were quantified with an Elisa plate reader (Metertech USA) at 490–650 nm. The experiments were repeated between two and five times, and the mean deviation was determined by considering the extreme values found over all experiments.

**Cell-Cycle Analysis and Apoptosis Assays:** Hypodiploid DNA was measured as described according to Nicoletti.[26] Briefly, $10^6$ cells were centrifuged and fixed in 1 mL of cold 70% ethanol at 4 °C for one hour, washed once with PBS (Phosphate Buffered Saline) and EDTA (2 mM), and re-suspended in 1 mL of PBS containing 0.25 mg Rnase A, 2 mM EDTA and 0.1 mg of propidium iodide. Cells were analyzed after incubation at 37 °C for 30 min in the dark. The fluorescence of 10,000 cells was analyzed using a FACS scan flow cytometer and CellQuest software (Becton Dickinson, San José, CA).

## Acknowledgments

The Université Louis Pasteur and the Ministère de l'Education Nationale are thanked for a student fellowship (to L. L.), the Centre National de la Recherche Scientifique (CNRS), Institut National de la Santé et de la Recherche Médicale (INSERM), the Consejo Nacional de Ciencia y Tecnología (CONACYT) (project numbers 34293-E and 40135-Q), and the Agence Nationale de la Recherche (ANR-05-EMPB-019-01/02) are thanked for partial support of the work. We are grateful to Ms. B. Wieczoreck and K. Küpfer for their help in the synthesis and characterization of **11**. X-ray diffraction studies were performed by Dr. Simon Hernandez and Dr. Ruben Alfredo Toscano (UNA Mexico; compounds **7**, **9**, **10**, **18**, and **19**) and by Dr. A. de Cian (ULP Strasbourg, compound **8**).

# Ligand Exchange Processes on Solvated Lithium Cations: Complexation by Cryptands in Acetone as Solvent[‡]

Ewa Pasgreta,[a] Ralph Puchta,[a,b] Achim Zahl,[a] and Rudi van Eldik*[a]

**Keywords:** Lithium / Cryptands / Acetone / Exchange mechanism

Kinetic studies on $Li^+$ exchange between the cryptands C222 and C221 and acetone as solvent were performed as a function of ligand-to-metal ratio, temperature and pressure using $^7Li$ NMR spectroscopy. Temperature and pressure dependence measurements were performed in the presence of an excess of $Li^+$. The rate and activation parameters for the exchange process are: C222: $k_{298} = (1.7 \pm 0.5) \times 10^3$ $s^{-1}$, $\Delta H^{\#} = 24 \pm 1$ $kJ\,mol^{-1}$ and $\Delta S^{\#} = -105 \pm 4$ $J\,K^{-1}\,mol^{-1}$; C221: $k_{298} = 2.24 \pm 0.09$ $s^{-1}$, $\Delta H^{\#} = 29 \pm 2$ $kJ\,mol^{-1}$ and $\Delta S^{\#} = -141 \pm 5$ $J\,K^{-1}\,mol^{-1}$. The influence of pressure on the exchange rate is insignificant for both ligands, such that the activation volume is around zero within the experimental error limits. The reported activation parameters suggest that the exchange of $Li^+$ between solvated and chelated ions follows an associative interchange mechanism.

## Introduction

Following the work of Pedersen on two-dimensional crowns, Lehn and co-workers developed in the late 1960s a range of three-dimensional, polycyclic ligand systems which they named cryptands (Greek: *cryptos* = cave).[1] Until today this class of compounds has been intensively explored and extended in different directions[2] in terms of cavity size,[3,4] donor atoms,[5] and metalla-topomers.[6] Because cryptands readily form complexes with a wide range of metal ions and $NH_4^+$,[7] provided the ion involved is not too large to be contained in the macrocyclic cavity,[8] they find their application in various areas like catalysis, medicine, biomimetic research,[9,10] and as receptors[11] and electrides.[12] Studies on the complexes (cryptates) formed between alkali-metal ions and cryptands, have revealed a substantial understanding of the effects of metal-ion size and cryptand-cavity size on the structure, stability and lability of cryptates, and the mechanism of the cryptate complex-formation processes.[13,14] Such selective complexation has led to many biological and chemical studies.

Kinetic studies on macrocyclic complex-formation reactions with alkali cations not only result in important information on the rates and mechanisms of complex-formation reactions, but also lead to a better understanding of the high selectivity of these ligands toward different cations. The broad impact of such studies spans from the theory of complexation to cation transport through membranes, and makes the ability to control cation selectivity via tactical structural changes in the complexing agent of prime importance.[10] Polyoxo macrobicyclic diamines, represented by the structure in Figure 1, are able to form metal-ion complexes in which the metal ion is located in the cavity of the macromolecule and two nitrogen donors along with the oxygen donors participate in binding the metal cation. All complexes have a 1:1 stoichiometry with the metal ion positioned at the center of the ligand cavity.[13]

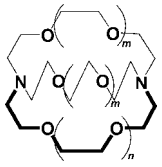

Figure 1. Chelate structures: C211: $m = 0$, $n = 1$; C221: $m = 1$, $n = 0$; C222: $m = 1$, $n = 1$.

In case of crown ethers and cryptands in non-aqueous solutions, the rates of complex-formation ($k_f$) with alkali-metal cations are in general diffusion-controlled and, consequently, the complexation selectivities are governed by the decomplexation rates ($k_d$).[15] These reactions have received significant attention, initially from Lehn and co-workers and more recently from Popov et al.[16,17] and Lincoln et al.[18] Many examples have been included in a series of review articles.[19,20] It has been reported that ligand structure and solvent properties have considerable effects on the reaction rates, activation parameters, and exchange mechanism

of cations between the solvated and complexed sites. We have now extended our earlier studies[21] on $Li^+$ exchange reactions to acetone as solvent.

Non-aqueous solvents and their mixtures combined with $Li^+$ are often used in secondary lithium batteries.[22] $Li^+$ in acetone is also known to catalyze Diels–Alder-reactions[23] and the ene reaction.[24] The behavior of $Li^+$-ions in different solvents is therefore an important research area.[25–27] A variety of studies on solutions of $Li^+$ in acetone have been mainly studied experimentally[26,28] and some theoretically,[29,30] as well as for solvent/acetone combinations[27] or chelator/acetone combinations.[27,31] In this contribution, we focus on acetone as a solvent and the competition between solvated and endohedral complexed $Li^+$, report kinetic parameters for the exchange of $Li^+$ between solvated and complexed states in acetone under ambient and elevated pressure conditions, and discuss the mechanistic implications.

## Results and Discussion

### Spectroscopic and Kinetic Observations

In preliminary experiments we investigated the $Li^+$ exchange in different solvents. In water and methanol the exchange process was too fast to be studied by $^7Li$ NMR (only a single signal was observed). The process became slower in acetonitrile, and in acetone two completely separated signals were observed at low temperature. We, therefore, investigated $Li^+$ exchange between the selected cryptands and acetone as solvent. A similar system was also investigated before by Popov et al.[17] Although they reported a significantly negative value for the activation entropy, they suggested the operation of a dissociative exchange mechanism. We realized that it would be worth to perform a reinvestigation of this system in acetone in order to clarify this apparent discrepancy, in particular by means of high pressure $^7Li$ NMR spectroscopy.

Initially, a series of $^7Li$ NMR measurements for the $Li^+$–cryptand system in acetone were performed. For each of the cryptands C222, C221 and C211, molar ratio dependent measurements were performed by variation of both the cryptand/$Li^+$ and $Li^+$/cryptand molar ratios. The results enabled us to observe the distribution of particular species on variation of the concentration ratio. Basically, two signals of varying intensity were observed in the $^7Li$ NMR spectra that refer to solvated $Li^+$ and $Li^+$ bound inside the cryptand cavity. In case of the smallest chelate C211, however, an additional signal appeared which can be ascribed to $Li^+$ bound outside the cryptand and being partially solvated. In the case of $Li(C211)^+$, the complex is very stable and almost no exchange takes place. A detailed study of the observed rate constant, $k_{obsd.}$, for the exchange of $Li^+$ as a function of temperature and pressure was therefore undertaken only for C221 and C222. The lithium exchange reaction between cryptand and acetone was studied for three solutions with different ligand-to-metal ratios in the presence of an excess of $Li^+$.

Three signals can be observed in Figure 2, viz. one coming from the reference ($\delta$ = 5.8 ppm) and the other two from the exchanging sites ($\delta$ = 9.0 ppm for solvated $Li^+$ and 6.6 ppm for complexed $Li^+$). At low temperature the signals are sharp and completely separated due to very slow or no exchange. Because the formation constant for $Li(C221)^+$ is very high,[13] the concentration of bound lithium equals the amount of cryptand added. At ca. 283 K, the signals start to broaden and the exchange process takes place. The linear temperature dependence for the temperature range in which exchange takes place can be seen in Figure 5. In the case of C222 (Figure 3), the exchange process is faster due to the larger cavity of the cryptand. The signals that refer to solvated and complexed Li cation (8.7 and 6.8 ppm, respectively at 223 K) coalescence at ca. 263 K and at high temperature (>313 K) only one sharp signal at 7.7 ppm was observed as a consequence of a very fast exchange process. An accurate temperature dependence for C222 over a large temperature range can be observed in Figure 6.

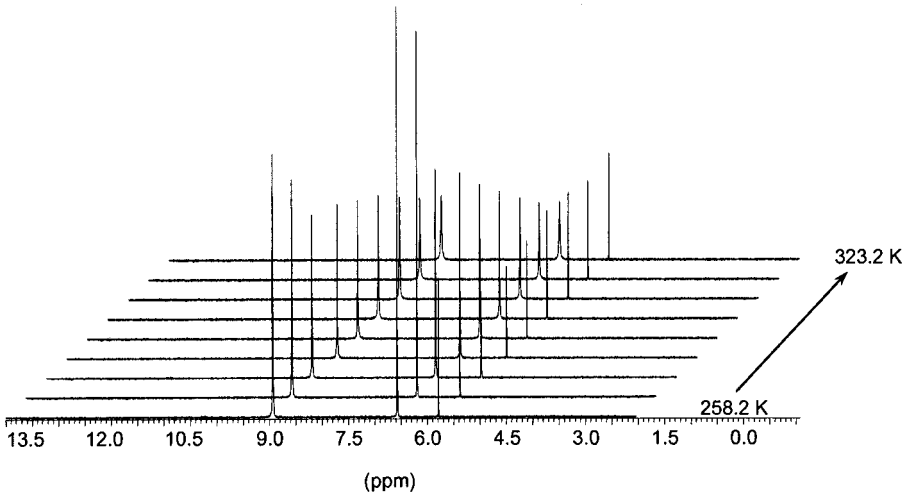

Figure 2. $^7Li$ NMR spectra recorded as a function of temperature for the mol ratio C221/$LiClO_4$ = 0.5.

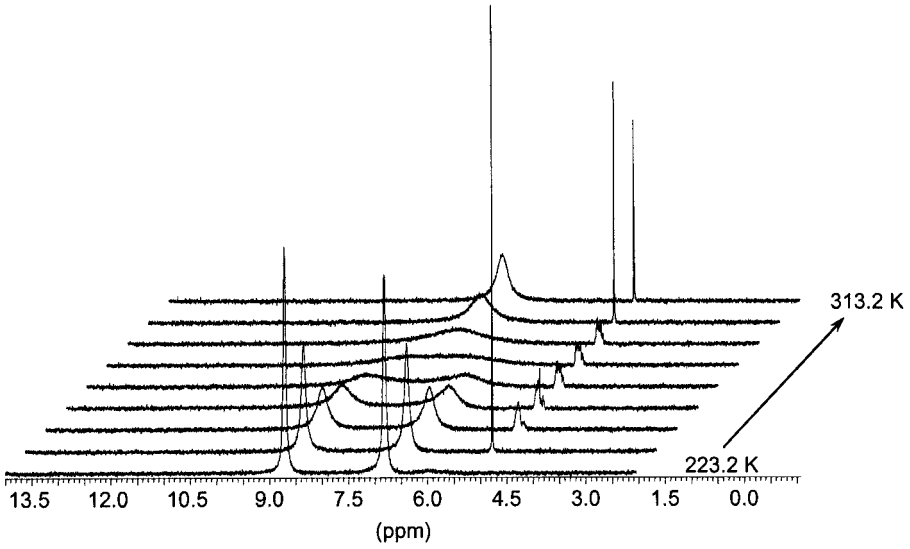

Figure 3. $^{7}$Li NMR spectra recorded as a function of temperature for the mol ratio C222/$LiClO_4$ = 0.5.

The rate of the exchange reaction increased not only with increasing cavity size of the cryptand but also with increasing concentration of the chelate, as can be recognized from the shape of the signals at 223 K in Figure 4 and from the values of $k_{obsd.}$ in Table 1 (see Figure 5 and Figure 6). A summary of the all the measured rate constants are given in Tables S1 and S2 (see Supporting Information).

| 0.75 | 6346 ± 254 | 29 ± 1 | –75 ± 2 |

## Suggested Exchange Mechanism

Two mechanisms should be considered for the decomplexation processes of cryptand–alkali-metal complexes: unimolecular (dissociative) and bimolecular (associative) cation exchange. The solvent plays a major role in the unimolecular mechanism and this mechanism is therefore favored in strong donor solvents.[20]

Lincoln et al.[18] investigated many similar systems where the $Li^+$ cation was exchanged between different cryptands or crown ethers and common solvents. In case of crown ethers and cryptands in non-aqueous solutions, the rates of formation ($k_c$) for their interaction with alkali-metal cations are generally diffusion controlled and, consequently, the complexation selectivities are governed by the decomplexation rates ($k_d$). They proposed the operation of a monomolecular mechanism for the decomplexation of $Li^+$ from the cryptand, notwithstanding the fact that decomplexation is characterized by very negative activation entropies.

According to Popov et al.,[17] there are two possible mechanisms that need to be considered for the exchange of $Li^+$ cation between the solvated and the complexed sites, viz. bimolecular (associative) (*I*) and unimolecular (dissociative) (back reaction in II) cation exchange processes, where S presents solvent and L the employed chelate.[17,32] (In this description we have added the terms "associative" and "dissociative" because this is implied by the mechanistic interpretation offered by the authors.)

$$*Li(S)^+ + Li(L)^+ \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} Li(S)^+ + *Li(L)^+ \quad (I)$$

$$Li(S)^- + L \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} Li(L)^+ + S \quad (II)$$

At equilibrium:

$k_1[*Li(S)][Li(L)] = k_{-1}[*Li(L)][Li(S)]$

$k_2[Li(S)][L] = k_{-2}[Li(L)][S]$

Therefore see Equations (1) and (2)

$$-\frac{d}{dt}[Li(S)] = k_{obsd.}[Li(S)] = k_1[Li(S)][Li(L)] + k_{-2}[Li(L)][S] \quad (1)$$

$$k_{obsd.} = k_1[Li(L)] + \frac{k_{-2}[Li(L)][S]}{[Li(S)]} \quad (2)$$

An alternative form of Equation (2) is Equation (3), which was used to fit the data in Figure 7 and Figure 9.

$$\frac{k_{obsd.}}{[Li(S)]} = k_1 + k_{-2}' \cdot \frac{1}{[Li(S)]} \quad (3)$$

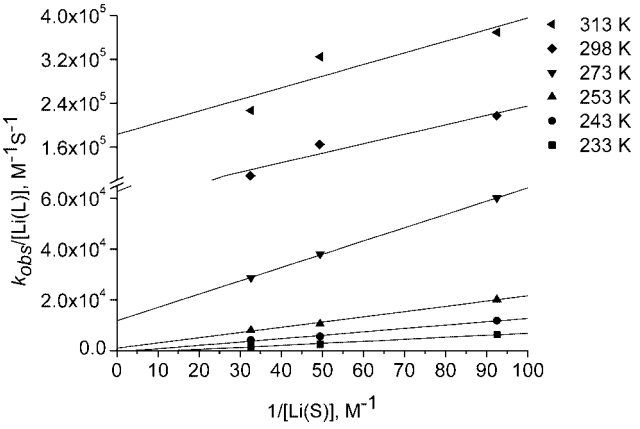

Figure 7. Plots of $k_{obsd.}$/[Li(L)] vs. 1/[Li(S)] for C222 as a function of temperature.

Plots of $k_{obsd.}$/[Li(L)] vs. 1/[Li(S)] were found to be linear with varying slopes ($k_{-2}' = k_{-2}$[S]) and intercepts ($k_1$) (see Figure 7 and Figure 8). The plots indicate that both path-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ways compete with each other and the competition is controlled by temperature and the nature of the cryptand. In the case of C222 (Figure 7), the plots at low temperature exhibit no meaning intercept, whereas the plots at high temperature exhibit very large intercepts. Thus the contribution from $k_1$ increases significantly with temperature. In the case of C221 (Figure 8), all the plots exhibit almost no intercept, such that the exchange process is mainly controlled by $k_{-2}$. The corresponding Eyring plots are shown in Figure 9 and Figure 10, respectively, and the thermal activation parameters are summarized in Table 2.

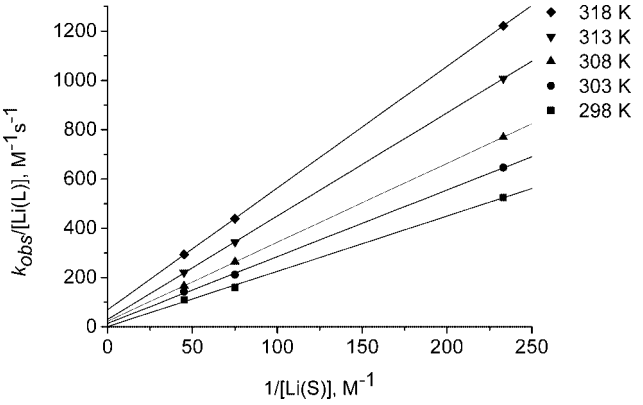

Figure 8. Plots of $k_{obsd.}$/[Li(L)] vs. 1/[Li(S)] for C221 as a function of temperature.

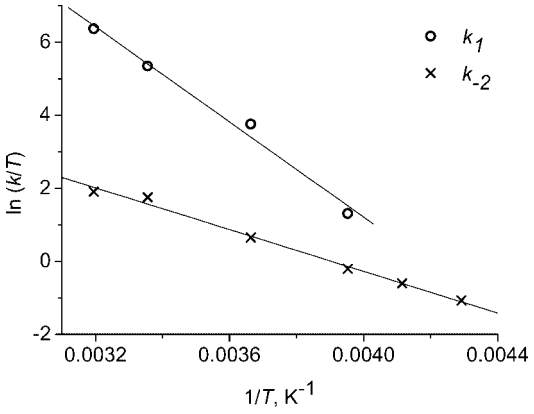

Figure 9. Eyring plots for $k_1$ and $k_{-2}$ as a function of temperature for C222.

The activation parameters derived from the temperature dependence of $k_1$ are rather inaccurate due to the large error limits of the intercepts and the reported activation entropy has no mechanistic meaning. On the basis of the values of $k_{-2}$ and the significantly negative activation entropies obtained for this pathway, the activation parameters support an associative type of exchange process. $k_{-2}$ for C222

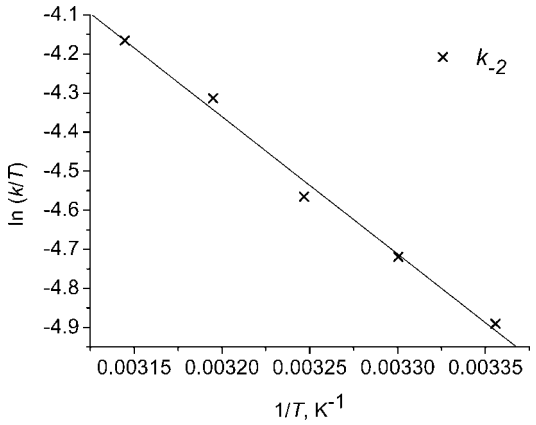

Figure 10. Eyring plot for $k_{-2}$ as a function of temperature for C221.

is almost three orders of magnitude larger than for C221. Furthermore, the activation parameters are very similar to those obtained directly from the values of $k_{obsd.}$ as a function of temperature. This would be in a good agreement with that postulated by Lincoln, who assumed that only the decomplexation process contributes to the observed reaction under the given experimental conditions. The negative activation entropies found for the decomplexation reactions of both C221 and C222 strongly suggest that attack of the solvent on the complexes $Li^+$ must play an important role in the decomplexation process, i.e. decomplexation follows an associative mechanism (see theoretical calculations).

The reported activation parameters are within the range of those reported by Popov et al. for closely related systems.[17] However, it should be pointed out that they used a different rate law than the one proposed by Shchori et al.[33] and the one used in the present study, which complicates a direct comparison of the reported activation parameters. Nevertheless, although they proposed another mechanism, the values of the activation parameters obtained from their study are very similar to ours, as shown in Table 3.

Table 3. Comparison of activation parameters.

| | $k_b$ [$s^{-1}$] | $\Delta H^{\#}$ [kJ $mol^{-1}$] | $\Delta S^{\#}$ [J $K^{-1}$ $mol^{-1}$] |
|---|---|---|---|
| Popov et al.[28] | 794 ± 42 | 20 ± 1 | –121 ± 3 |
| This work | 1724 ± 484 | 24 ± 1 | –105 ± 4 |

It is reasonable to expect that solvents such as acetonitrile, acetone and γ-butyrolactone, due to their similar properties as expected from their rather similar Gutmann donor numbers ($DN$ = 14.1, 17.0 and 18.0, respectively,[34]) should coordinate to $Li^+$ in a similar way and should have a similar influence on the exchange mechanism. This obser-

vation corresponds to that reported by Shamsipur et al.[35] for the exchange of $Li^+$ between C221 and acetonitrile/nitromethane mixtures. In all solvent mixtures used, $Li^+$ exchange was found to occur through an associative mechanism, as expected for weakly donor solvents (*DN* = 14.1 and 2.7 for acetonitrile and nitromethane, respectively).

### High Pressure $^7$Li NMR Measurements

Additional mechanistic information on the intimate nature of the exchange mechanism can in principle be obtained from the effect of pressure on the $Li^+$ exchange process.[36] A systematic pressure dependence study was performed to determine the volume of activation for the $Li^+$ exchange process for both chelates. Pressure-dependent NMR spectra were recorded for each sample over the pressure range of 0.1 to 150 MPa at 313.2 K. The higher temperature had to be chosen, because in the case of C221 the exchange process hardly occurs at room temperature, whereas in the case of C222 the signals are broad at room temperature due to coalescence and it was difficult to observe line broadening that resulted from increasing pressure. There are two signals to be seen in Figure 11: one for the solvated Li at 8.8 ppm and the one for Li complexed by C221 at 6.5 ppm. It can be observed that there is a very small difference in the shape of the NMR spectra recorded at various pressures. The same effect was observed for the second ligand, C222 (Figure 12), where only one signal appears due to the fast exchange. Its shape almost does not change with the varying pressure for any of the three samples. The rate constants calculated for each pressure were very similar within the experimental error limits and resulted in a practically zero value for $\Delta V^{\#}_{obsd.}$ for both ligands, which points to a concerted interchange type of exchange mechanism.[37] In terms of an interchange mechanism, bond formation and bond cleavage occur in a concerted fashion without the formation of a distinct intermediate of higher or lower coordination number. In addition, decomplexation will be accompanied by charge creation due to the release of $Li^+$, which in turn will lead to an increase in electrostriction which will offset the intrinsic volume changes.

### Theoretical Calculations

For the closely related γ-butyrolactone and $Li^+$/γ-butyrolactone high level ab initio studies were recently performed by Rey et al.[38] For acetone and $Li^+$/acetone only Hartree–Fock calculations were performed.[30] In our DFT calculations we found that the $Li^+$ cation coordinates to the carbonyl oxygen with an almost co-linear configuration relative to the carbon–oxygen bond, as for γ-butyrolactone. This configuration holds for clusters of up to four molecules and also in the solid phase, where a tetrahedral first solvation (coordination) sphere was found (see Table 4).[31]

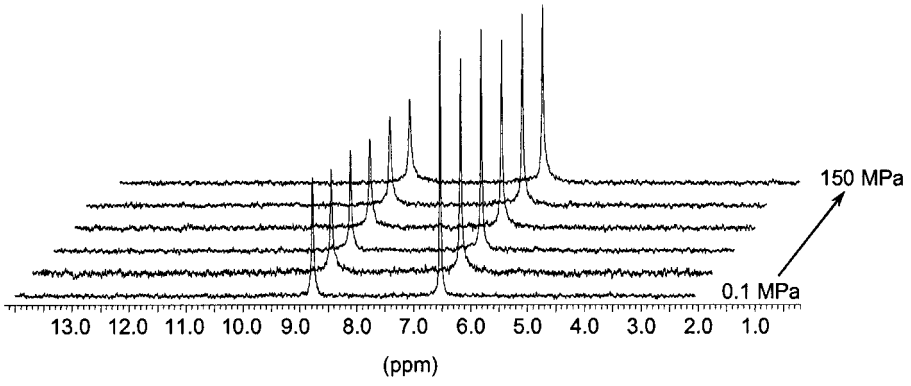

Figure 11. $^7$Li NMR spectra recorded as a function of pressure at 313.2 K for the mol ratio C221/$LiClO_4$ = 0.5.

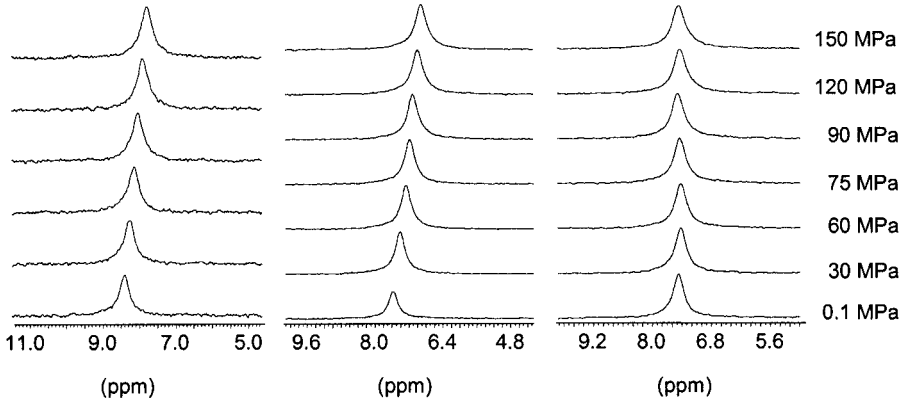

Figure 12. $^7$Li NMR spectra of C222 and $LiClO_4$ in acetone. Pressure dependence for the sample ratios C222/$LiClO_4$ = 0.25, 0.5, and 0.75, respectively, at 313.2 K.

Table 4. Calculated bond length for $Li^+$ solvated in acetone.

| Bond length [Å] | PG | B3LYP/D95Vp | B3LYP/6-311+G** |
|---|---|---|---|
| $[Li(acetone)]^+$ | $C_2$ | 1.77 | 1.75 |
| $[Li(acetone)_2]^+$ | $D_2$ | 1.81 | 1.79 |
| $[Li(acetone)_3]^+$ | $D_3$ | 1.88 | 1.86 |
| $[Li(acetone)_4]^+$ | $C_1$ | 1.96 (averaged) | 1.96 (averaged) |

Experimentally, a decrease in the cavity size of the cryptands hampers the exchange of $Li^+$ between the cryptand and the solvent. We were able to observe it in the case of γ-butyrolactone and again we can see it in the present case. The improved binding of $Li^+$ in a smaller cavity is visible from the structure and the following model reaction [Equation (4)] that describes the energy required for the dechelation process. Application of the CPCM solvent model strengthens this trend significantly (see Table 5).

$$[Li \subset Cryptand]^+ + 4\ solvent \rightarrow [Li(solvent)_4]^+ + Cryptand \quad (4)$$

Table 5. Dechelation energy, $E_{dechelation}$, for the reaction outlined in Equation (4).[a]

|---|---|---|---|
| $E_{dechelation}$ (DFT) [kcal/mol] | –8.6 | +2.0 | +3.0 |
| $E_{dechelation}$ (CPCM) [kcal/mol] | +5.4 | +13.6 | +20.4 |
| γ-Butyrolactone | C222 | C221 | C211 |
| $E_{dechelation}$ (DFT) [kcal/mol][21] | –16.8 | –11.6 | –5.3 |

[a] DFT: RB3LYP/D95Vp, CPCM: RB3LYP(CPCM)/D95Vp//RB3LYP/D95Vp.

In agreement with previous studies by Wipff et al.,[3] we also found only a limited flexibility for the investigated cryptands in our DFT calculations, therefore all cryptands were calculated within the highest possible symmetry (Table 5). We recently demonstrated that reaction (4) is a valuable tool to determine ion selectivity as a function of the ionic radii[39] and to examine cavity size of the cryptands as a variable.[21,40]

In agreement with the experimental kinetic data, the smaller cryptand binds $Li^+$ better and slows down its exchange rate (Table 2). On comparing the calculated Li–O and Li–N bond lengths of the three structures with the bond length in $[Li(OH_2)_4]^+$ and $[Li(NH_3)_4]^+$, the trend can easily be understood (see Table 6 and Figure 11). In C222, $Li^+$ is four-fold weakly coordinated in a trigonal-pyramidal shape by one Li–N and three Li–O interactions all clearly elongated (0.2 and 0.1 Å, respectively). The $Li^+$ cation in C221 is five-fold coordinated (distorted trigonal-bipyramidal structure) by one nitrogen and four oxygen bonds all extended by around 0.15 Å. The coordinating bonds in $[Li \subset C211]^+$ are even more extended, but the Li–O bonds form a somewhat distorted tetrahedral coordination sphere for the lithium monocation, while the stronger elongated Li–N bonds form a kind of second coordination sphere. Therefore, the lithium ion can formally adopt a six-coordinate state, which strongly supports the proposed associative character of the decomplexation process that involves binding of external solvent molecules as suggested by the very negative activation entropies. A comparison of the calculated and X-ray bond lengths shows a good agreement. A comparison between the calculated data for γ-butyrolactone and acetone shows the same trend for both solvents. $Li^+$ is better coordinated in the smaller cavities of the smaller cryptands, as expected.

To draw a conclusion on solvation abilities from a direct comparison of the dechelating energies in acetone and γ-butyrolactone, is risky. The calculated dechelating energies can not be considered as a proof of the rule of Madrakian et al., that there is an inverse relationship between the stability of the complexes and the solvating ability of the solvent.[31] The different values can be attributed to the different number of non-hydrogen atoms in both solvents. Acetone has only four non-hydrogen atoms, while γ-butyrolactone has six and can therefore stabilize charge much better.

## Conclusions

It can be concluded from the results of the present study that for the $Li^+$ exchange process between C222, C221 and acetone as solvent, two pathways, viz. bimolecular (associative) and unimolecular (dissociative) compete with each other. The pressure dependence of the exchange process suggests the operation of a pure interchange mechanism, whereas the negative activation entropy values favor an associative interchange process for the decomplexation reaction. The basic idea of an interchange process involves concerted bond formation and bond cleavage, which is in agreement with the consideration that acetone is a rather weak

Table 6. Calculated (RB3LYP/D95Vp) and X-ray bond lengths (in Å).

donor. The results are in good agreement with that expected on the basis of a systematic comparison with data reported in the literature for solvents of similar donor strength.

## Experimental Section

**General Procedures:** The preparation of test solutions was carried out under Ar or $N_2$ using standard Schlenk techniques, under an Ar in a glove box, or under vacuum. Lithium perchlorate (Aldrich, battery grade) was vacuum-dried at 120 °C for 48 h and then stored under dry nitrogen. The cryptands C222 (purchased from Fluka), C221 and C211 (purchased from Aldrich) were dried under vacuum for 48 h and stored under dry nitrogen. Acetone (Acros, extra dry, water < 50 ppm) was used as received. Solutions of $LiClO_4$, C222, C221 and C211 in acetone were prepared under dry nitrogen. For the $^7$Li NMR measurements the solutions were sealed in 5-mm NMR tubes under Ar. In order to study the kinetics of the exchange of $Li^+$ between C222 and C221 and acetone as solvent, three solutions of different concentration ratio were prepared for each system. The concentration of lithium perchlorate in each solution was kept constant at 0.04 M, whereas the concentration of ligand was varied between 0.01 M and 0.032 M. In this way the measurements were always performed in the presence of an excess of $Li^+$.

**$^7$Li NMR Spectroscopy:** Variable-temperature and variable-pressure Fourier transform $^7$Li NMR spectra were recorded at a frequency of 155 MHz with a Bruker Avance DRX 400WB spectrometer equipped with a superconducting BC-94/89 magnet system. Spinning tubes (5 mm) were used with a 1-mm o.d. melting point capillary inserted coaxially in the spinning tube and filled with an external reference solution (1 M $LiClO_4$ in acetonitrile). The temperature dependence measurements were performed over a wide as possible temperature range for each system. We did not use a temperature calibration by insertion of a capillary filled with methanol (low temperature calibration) or ethylene glycol (high temperature calibration) into the sample tube, as the corresponding signals of these solvents would disturb the NMR spectra in the region of interest. In such a case a temperature-calibrated NMR probe has to be used in order to determine the temperature of the sample accurately.

Methanol was used for the low-temperature calibration of the NMR probe, whereas ethylene glycol was used for high-temperature calibration. The actual sample temperature can be calculated from the chemical shift differences. If there is any difference between the sample temperature and the temperature detected by the thermocouple of the probe, the probe can be calibrated by using standard Bruker Topspin software.

A homemade high-pressure probe described in the literature[46] was used for the variable-pressure experiments which were conducted at a selected temperature and at ambient, 30, 60, 75, 90, 120 and

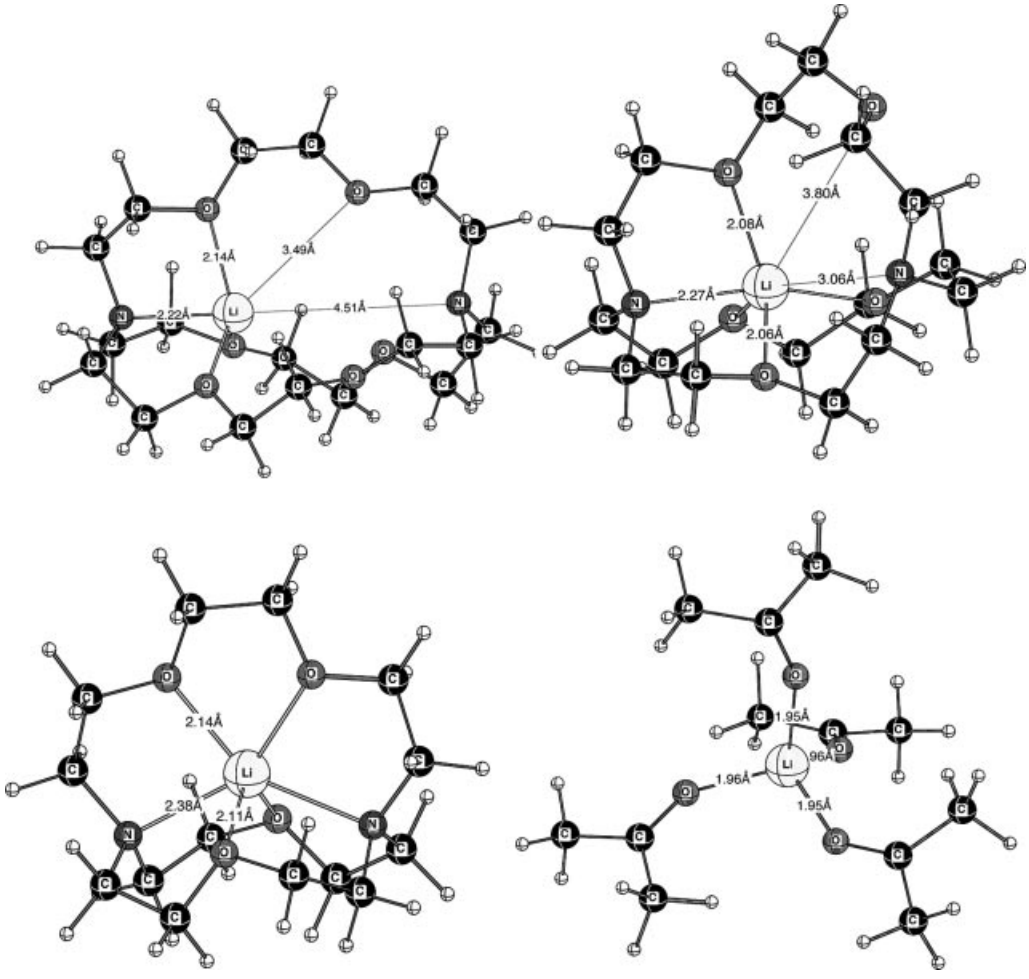

Figure 13. Optimized structures for $[Li \subset C222]^+$, $[Li \subset C221]^+$, $[Li \subset C211]^+$ and $[Li(acetone)_4]^+$.

150 MPa pressure. A standard 5-mm NMR tube cut to a length of 45 mm was used for the sample solution. The high-pressure NMR tube was sealed with a MACOR plug and an O-ring made of VITON. The plug and O-ring were shown to be stable in the employed solvent. The pressure was transmitted by the movable MACOR piston to the sample, and the temperature of the sample was controlled with a Pt-100 resistor. The probe itself was externally heated with a thermostatted circulating fluid that was pumped through a double helix that was cut into the outer surface of the autoclave. Because the sample is embedded in the high-pressure transmitting fluid that serves as a thermostating bath, a reliable temperature setting is guaranteed.

For a typical kinetic run, 0.8 mL of solution was transferred under Ar to a Wilmad screw-cap NMR tube equipped with a poly(tetrafluoroethylene) septum. All test samples were prepared in the same way.

**Programs:** The line widths of the NMR signals were obtained by fitting Lorentzian functions to the experimental spectra using the NMRICMA 2.7 program[47] for Matlab.[48] The adjustable parameters were the resonance frequency, intensity, line width and baseline. Complete line-shape analysis based on the Kubo–Sack formalism using modified Bloch equations[49] was also performed with NMRICMA 2.7 to extract rate constants from experimental spectra. The temperature and pressure dependent $^{7}$Li line widths and chemical shifts employed in the line shape analysis were extrapolated from low temperatures where no exchange-induced modification occurred.

**Quantum Chemical Calculations:** All structures were optimized with the B3LYP[50] and the basis set D95Vp,[51] or with 6-311+G** with no constrains other than symmetry, and confirmed to be minima by computation of vibrational frequencies. Relative energies were corrected for zero point vibrational energy differences (Figure 13). The D95V basis set, augmented with polarisation functions (D95Vp), was used.[52] If not otherwise mentioned, calculations were done without a solvent model. The influence of bulk solvent was probed using the CPCM[53] formalism and water as solvent, i.e., B3LYP(CPCM)/D95Vp//B3LYP/D95Vp. The Gaussian 03 suite of programs was used throughout.[54]

**Supporting Information** (see also the footnote on the first page of this article): Two tables with values of the observed rate constants ($k_{obs}$) calculated from the line shape analysis for the exchange of $Li^+$ between solvated and chelated sites for two cryptands.

## Acknowledgments

This work was supported by the European Commission Training and Mobility of Researchers Network (HPRN-CT-2000-19, "Solvation Dynamics and Ionic Mobility in Conventional and Polymer Solvents") and the Deutsche Forschungsgemeinschaft (SFB 583 on Redox-active Metal Complexes). We would like to thank Dr. Lothar Helm (EPFL Lausanne) for introducing E. P. to the software NMRICMA 2.7, Dr. Nico van Eikema Hommes for helpful discussions, Michael Galle for preliminary calculations, Prof. Tim Clark for hosting this work in the CCC and the Regionales Rechenzentrum Erlangen (RRZE) for a generous allotment of computer time.

# Facile Formation of Hexacyclic [$Al_3O_2Cl$] Aluminum and Alkoxide-Bridged Titanium Complexes: Reactions of $AlMe_3$ with [$Ti(L)Cl_2$] [L = 2,2′-Methylenebis(6-*tert*-butyl-4-methylphenolato)]

**Dao Zhang*[a]**

**Keywords:** Aluminum complexes / Titanium complexes / Trimethylaluminum

The titanium dichloride complex [(L)$TiCl_2$] [L = 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato)] (**1**) reacted with trimethylaluminum ($AlMe_3$) in a 1:2 ratio to give a trimetallic aluminum complex of the composition [(L)$(AlMe_2)_3(\mu$-Cl)] (**2**) with a symmetric six-membered ring [$Al_3(\mu_2$-O)$_2(\mu_2$-Cl)] and a four-coordinate aluminum center in the solid state. The reaction of 1 equiv. $AlMe_3$ gave [(L)TiMeCl] (**3**), which could absorb $O_2$ gas to afford the oxygen-insertion product [{(L)-$TiCl\}_2(\mu$-$OMe)_2$] (**4**) with a five-coordinate metal center. Upon reaction of $H_2L$ with $AlMe_3$, the binuclear, four-coordinate adduct [{(L)$AlMe\}_2$] (**5**) was formed. Complex **4** supported on $MgCl_2$ and activated with aluminum alkyls reveals high catalytic activity for ethylene polymerization to produce polymers with molecular weight distributions of ca. 3.1.

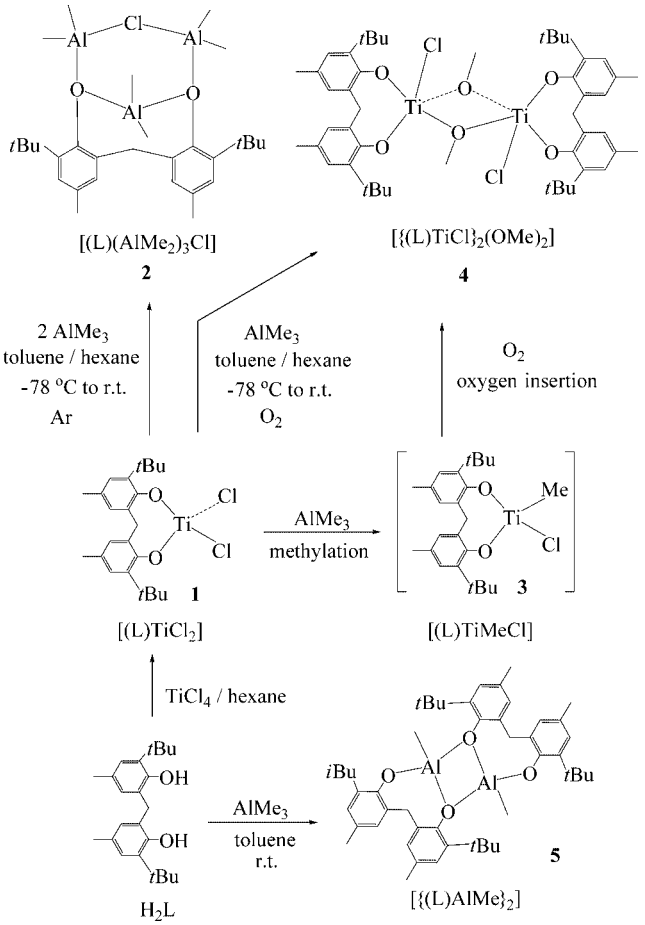
## Introduction

Reactions of organometal(IV) halides with alkyls of group 13 elements, especially those of aluminum, have attracted much interest because of their inherent fundamental chemistry as well as their potential applications. The methylation of a metallocene(IV) chloride is assumed to be the first step of activation of a polymerization catalyst and one of the first well-defined products is Tebbe's reagent, [$Cp_2Ti(\mu_2$-$CH_2)(\mu_2$-Cl)$AlMe_2$], derived from $Cp_2TiMe_2$ and $AlMe_3$.[1] Later, methyl nonmetallocene transition-metal complexes could be conveniently prepared with the Jordan amido/alkyl exchange protocol using $AlMe_3$, a technique primarily utilized with complexes of the metallocene type.[2] Several novel aluminum-containing clusters, [$(Cp^*M)_3Al_6$-$Me_8(CH)_5(CH_2)_2$] (M = Zr, Hf),[3] [($t$$Bu_3PN$)$Ti(\mu$-Me)$(\mu_4$-C)-$(AlMe_2)_2]_2$,[4] and [$Cp^*_4Y_4(\mu_2$-$CH_3)_2\{(CH_3)Al(\mu_2$-$CH_3)_2\}_4$-$(\mu_4$-$CH)_2$],[5] have been developed by the reactions of the corresponding metal complexes with $AlMe_3$ that could perform the abstraction of hydrogen from methyl groups. Nevertheless, such clusters, particularly those bearing two or more different metals, are very rare because of the limitations inherent in available synthetic methods. Moreover, a surprisingly facile transmetalation of the multidentate ligands from a transition metal such as zirconium or iron to aluminum was reported by using $AlR_3$ (R = Me or Et).[6,7]

As part of an ongoing project whose aim is to study the chemistry of olefin polymerization catalysis, some novel metal catalysts have been designed and successfully pre-



Scheme 1. Synthesis of aluminum and titanium complexes **2**–**5** using $AlMe_3$.

pared.[8] Our goal is to create highly active, single-site heterogeneous systems for the ethylene polymerization process. Some titanium complexes supported on $MgCl_2$, which is a widely used support in conventional Z–N catalysts, and activated with aluminum alkyls are highly effective ethylene polymerization catalysts.[9] Especially the interaction of titanium compounds with aluminum derivatives was of great interest to us for understanding the high activity of titanium aryloxides in the ethylene polymerization process.[10]

In the present report, we aim to present the synthesis and structures of an unexpected trimetallic, hexacyclic aluminum and alkoxide-bridged titanium complex by the reaction of trimethylaluminum with $[(L)TiCl]_2$ [(L) = 2,2′-methylenebis(6-*tert*-butyl-4-methylphenolato)] (**1**) (Scheme 1). To the best of our knowledge, such examples have never been demonstrated. Ethylene polymerization with an alkoxide-bridged titanium complex supported on $MgCl_2$ and activated with alkylaluminum compounds is also included.

## Results and Discussion

Reaction of $AlMe_3$ solved in toluene with **1** at a 2:1 molar ratio at room temp. leads to a color change from red to dark brown, and the air- and moisture-sensitive complex, $[(L)(AlMe_2)_3Cl]$ (**2**), is formed as dark green crystals and isolated by filtration in 31% yield after the reaction solution is cooled to –20 °C overnight. Compound **2** does not react further with $AlMe_3$, even not at 100 °C in [$D_8$]toluene, and is soluble and stable in benzene and toluene.

The $^1H$ (see Figure 1) and $^{13}C$ NMR spectra of **2** are in good agreement with the crystal structure obtained from X-ray diffraction techniques. The alkyl groups attached to the metal centers are not equivalent and are in the expected chemical shift ranges; both the $^1H$ and $^{13}C$ signals are shifted distinctly from the starting $AlMe_3$. $^1H$ NMR spectroscopic data for **2** reveals the presence of three different methyl ($AlMe_2$) environments at $\delta$ = –1.19, –0.52, and 0.17 ppm in [$D_6$]benzene ($\delta$ = –1.26, –0.57, and 0.12 ppm in [$D_8$]toluene) with integral intensity ratios of 3:6:9 (Figure 1). Also observed is one set of resonances for the L ligand. These observations suggest that compound **2** has the same structure in solution and in the solid state.

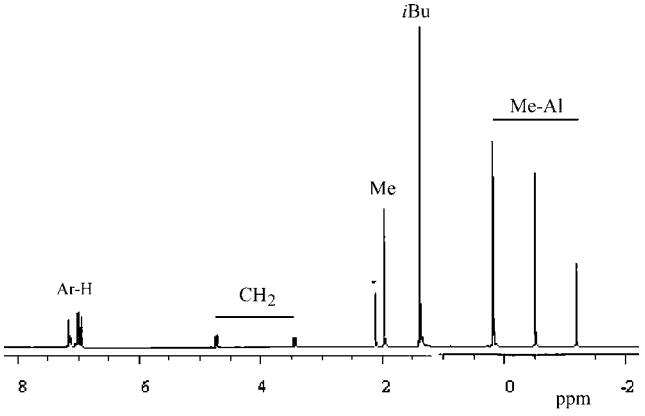

Figure 1. $^1H$ NMR spectra of **2** (containing toluene marked with *) in [$D_6$]benzene.

In the solid state, compound **2** forms unexpected trinuclear aluminum molecules in which there are no titanium atoms, indicating that transmetalation occurs (Figure 2 and Table 1). The central, nearly symmetrical, hexacyclic $[Al_3(\mu_2\text{-}O)_2(\mu_2\text{-}Cl)]$ is composed of three aluminum atoms, one bridging chlorine, and two bridging oxygen atoms [O(1), O(1A)] of the L ligand. This type of bridging has been rarely observed in phenolate aluminum compounds. Each aluminum atom is coordinated in a distorted tetrahedral fashion by oxygen [O(1), O(1A)] of the L ligands or chloride besides two methyl groups. The Al–O bond lengths are similar to those found in other structures of four-coordinate aluminum aryloxides.[11] The Al–Cl distance of 2.321(2) Å lies in the range of 2.2695(17)–2.3224(11) Å observed for other chlorine-bridged aluminum complexes with multidentate aryloxide ligands linked by three different spacers.[12]

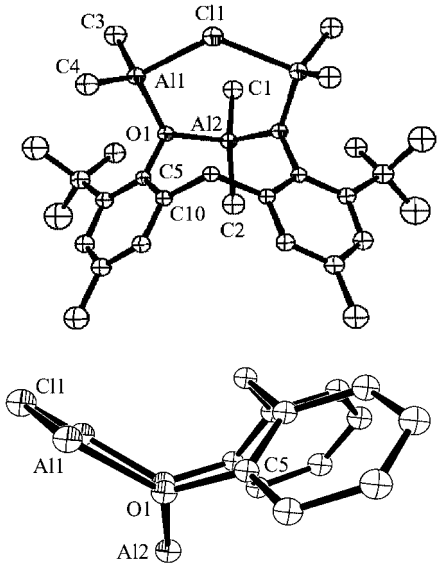

Figure 2. Molecular structure of **2**.

Table 1. Selected bond lengths [Å] and angles [°] for **2**.

| | | | |
|---|---|---|---|
| Cl(1)–Al(1) | 2.321(2) | Al(1)–O(1) | 1.855(5) |
| Al(1)–C(3) | 1.954(6) | Al(1)–C(4) | 1.935(8) |
| Al(2)–O(1) | 1.890(5) | Al(2)–C(1) | 1.929(7) |
| Al(2)–C(2) | 1.96(1) | O(1)–C(5) | 1.436(5) |
| C(5)–C(10) | 1.397(7) | C(10)–C(11) | 1.521(8) |
| O(1)–Al(1)–C(3) | 115.4(3) | O(1)–Al(1)–C(4) | 111.5(2) |
| O(1)–Al(1)–Cl(1) | 99.9(1) | C(3)–Al(1)–C(4) | 119.3(3) |
| C(3)–Al(1)–Cl(1) | 102.3(2) | C(4)–Al(1)–Cl(1) | 105.3(3) |
| O(1)–Al(2)–C(1) | 106.6(2) | O(1)–Al(2)–C(2) | 108.2(2) |
| C(1)–Al(2)–C(2) | 123.8(5) | C(5)–O(1)–Al(1) | 117.1(4) |
| C(5)–O(1)–Al(2) | 114.9(3) | Al(1)–O(1)–Al(2) | 126.6(2) |
| C(10)–C(5)–O(1) | 116.3(5) | C(11)–C(10)–C(5) | 123.4(4) |

However, treatment of **1** with precisely 1 equiv. $AlMe_3$ in [$D_6$]benzene in a J-Young tube under argon resulted in the formation of an unidentified mixture ($^1H$ NMR), and no [(L)TiMeCl] (**3**) could be isolated. Interestingly, the same reaction carried out under $O_2$ affords small amount of yellow, very thin, needle-like crystals of $\{[(L)TiCl]_2(\mu\text{-}OMe)_2\}$ (**4**). The formation of **4** clearly indicates the insertion of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dioxygen into "M–R" bonds of the resultant intermediate titanium complex **3**.[13] The presence of ν(Ti–Cl) frequencies at ca. 419 $cm^{-1}$ in the IR spectra of **4** indicates characteristic modes for terminally coordinated chlorine. The methoxy groups bridging the two titanium centers are equivalent, giving rise to one singlet at $\delta$ = 4.12 ppm in the $^1H$ NMR spectra. Also, one set of resonances due to the (L) ligand, slightly shifted from that detected for **1**, was observed.

The X-ray crystal structure of **4** (Figure 3 and Table 2) shows that the binuclear molecule contains a core of two internal aluminum atoms linked by oxygen atoms from the two OMe groups. The remaining two chlorine atoms are bonded terminally to the titanium atoms. Two boat-conformation L ligands are bonded similarly, having two oxygen atoms in the same titanium coordination sphere. The coordination sphere around the titanium center can be described as distorted square pyramidal, the oxygen atoms of the L ligand [O(1), O(2)] and of two bridging OMe groups [O(3), O(3A)] forming the equatorial plane, while the chlorine atom [Cl(1)] occupies the apical sites. As expected, the average Ti–μ-O (methoxo) distance of 1.962(2) Å is significantly longer than the terminal ones [av. 1.788(3) Å] but similar to those observed in $[(tritox)_2Ti_2(\mu\text{-}OMe)_2Me_2]$ [2.015(10) Å].[13a] The Ti–Cl distance of 2.2599(1) Å is shorter than that detected in [(tbmp)Ti ($\eta^5$-$C_5H_5$)Cl] [2.343(2)] and $Ti(tmbp)Cl_2$ [2.236(2) Å] (tmbp = 2,2′-thiobis(4-methyl-6-*tert*-butylphenoxo)[14] and is only surpassed by the values of 2.252(2) and 2.237(2) Å found in $[(tbop)_2Ti_3(OEt)_2Cl_6]$.[15]

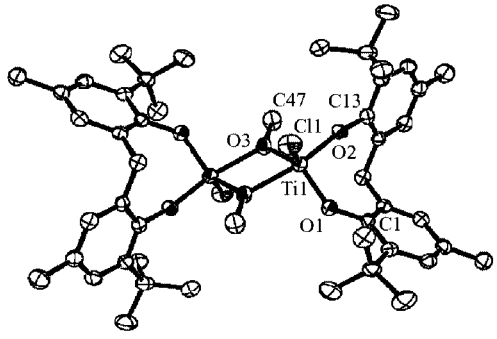

Figure 3. Molecular structure of **4**.

Table 2. Selected bond lengths [Å] and angles [°] for **4**.

| | | | |
|---|---|---|---|
| Ti(1)–Cl(1) | 2.259(1) | Ti(1)–O(1) | 1.805(2) |
| Ti(1)–O(2) | 1.776(2) | Ti(1)–O(3) | 1.962(2) |
| Cl(1)–Ti(1)–O(1) | 112.52(8) | Cl(1)–Ti(1)–O(2) | 98.95(9) |
| Cl(1)–Ti(1)–O(3) | 121.75(8) | O(1)–Ti(1)–O(2) | 98.0(1) |
| O(1)–Ti(1)–O(3) | 122.2(1) | O(2)–Ti(1)–O(3) | 92.1(1) |
| Cl(2)–Ti(2)–O(4) | 112.67(8) | C(1)–O(1)–Ti(1) | 140.9(2) |
| C(13)–O(2)–Ti(1) | 155.4(3) | C(47)–O(3)–Ti(1) | 129.6(2) |

The reaction of $H_2L$ and $AlMe_3$ in an equimolar ratio in toluene as well as in *n*-hexane leads to formation of the dimer $\{[(L)AlMe]_2\}$ (**5**) in good yield.[12d] There is no OH resonance in the $^1H$ NMR spectrum, indicating a loss of hydroxy protons. The methyl groups attached to the metal centers are equivalent and are in the expected chemical shift ranges; both the $^1H$ and $^{13}C$ signals are shifted slightly from the starting $AlMe_3$.

Crystals of **5** suitable for X-ray structure determination were obtained from hexane/toluene. The molecular structure of **5** is shown in Figure 4, and selected bond lengths and angles are listed in Table 3. Crystals of **5** comprise a centrosymmetric dimer with a planar $Ti_2O_2$ core. The titanium atoms in **4** have tetrahedral geometry. The two Al–O(aryloxo) distances of 1.693(1) and 1.856(1) Å are in the expected range for $Al^{III}$ complexes with facially coordinated bis(aryloxo) ligands. The Ti–C(methyl) distance of 1.941(3) Å is typical for $Ti_2O_2$ moieties and similar to those observed in $[(tritox)_2Ti_2(\mu\text{-}OMe)_2Me_2]$ [2.063(10) Å][13a] and $[(L)TiMe_2]$ [2.090(9) and 2.030(10) Å].[16]

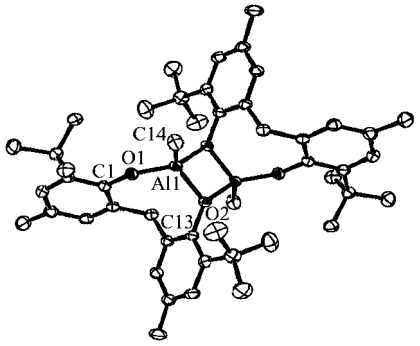

Figure 4. Molecular structure of **5**.

Table 3. Selected bond lengths [Å] and angles [°] for **5**.

| | | | |
|---|---|---|---|
| Al(1)–O(1) | 1.693(1) | Al(1)–O(2) | 1.856(1) |
| Al(1)–C(14) | 1.941(3) | O(1)–Al(1)–O(2) | 108.93(6) |
| O(1)–Al(1)–C(14) | 108.1(1) | O(2)–Al(1)–C(14) | 125.64(8) |
| C(1)–O(1)–Al(1) | 158.2(2) | C(13)–O(2)–Al(1) | 124.8(1) |

Titanium complex **4** was tested in an ethylene polymerization process. The catalyst was prepared in *n*-hexane by milling a slurry of $[MgCl_2(thf)_2]$ with **4** (the molar ratio is 10:1) and $AlEt_2Cl$ as the cocatalyst (see Exp. Sect.). Prior to the polymerization, ethylene was passed through the suspension of the catalyst. Then, MAO was added to the catalyst and dispersed in the prepolymer to form a highly active catalyst. Thus, the polymerization of ethylene was performed in a two-step process. The aim of the first step (very low Al:Ti molar ratio, normal pressure of monomer, very low rate of polymerization) was to prepare granules of polymer containing dispersed catalyst. These granules acted as a "microreactor" in the second step of polymerization with a high rate (Granular Reactor Technology). This method gave PE yields twice as high as those obtained with the one-stage activation process. The ethylene polymerization results and polymer characterization data are summarized in Table 4.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Table 4. Results of ethylene polymerization.[a]

| Entry | Complex | $T$ [°C] | Activity[b] | $M_w/M_n$ |
|---|---|---|---|---|
| 1 | **4** | 50 | 123 | 3.08 |
| 2 | **4** | 70 | 149 | 3.11 |
| 3[c] | **4** | 50 | 278 | n.d.[d] |
| 4 | $Cp_2TiCl_2$ | 50 | 108 | 2.94 |

[a] Polymerization conditions: MAO (Al:Ti = 4000) as the cocatalyst, ethylene pressure: $P_{gauge}$ = 70 psi, 0.5 h. [b] kg PE $g^{-1}$ Ti $h^{-1}$. [c] Ethylene pressure is $P_{gauge}$ = 100 psi. [d] Not determined.

For comparison of catalyst activities, titanocene dichloride ($Cp_2TiCl_2$) was used as a reference under the same conditions (Table 1, entry 4). It turned out that the catalysts based on complex **4** (entries 1–3) exhibited comparable catalytic activity (about 120 kg PE $g^{-1}$Ti $h^{-1}$) for ethylene polymerization. This is compared with the titanocene catalyst, and much less than that originally reported for [(tbmp)-$TiX_2$]/MAO (820 kg PE/g of Ti h for X = Cl and 677 kg PE/g of Ti h for X = O*i*Pr; 20 °C, 3 MPa, 1 μmmol catalyst)[17] and [$(tbop)_2Ti_3(OEt)_2Cl_6$]/MAO (353 kg PE/g of Ti h; 50 °C, 0.5 MPa, 1 μmmol catalyst)[15] systems. The molecular weights ($M_w$) of the polyethylene produced range from 9.18 to $11.97 \times 10^5$, and the molecular weight distributions ($M_w/M_n$) are narrower than those reported for ethylene polymerization with catalysts.[18,19] It would appear that, for polymerization of ethylene, activation of systems based on complex **4** affords a single well-defined active species. This indicates that the cocatalyst does not abstract the ligand L from the titanium center to the aluminum. The nature of the active center in the catalyst based on the L–titanium complexes is currently being investigated.

## Conclusions

In contrast to methylation of some organometal chlorides with $AlMe_3$, the unexpected transmetalation reaction of the corresponding titanium chloride complex **1** with $AlMe_3$ in a 1:2 ratio occurs with the generation of trialuminum complex **2** with a symmetrical, hexacyclic [$Al_3(\mu_2\text{-}O)_2$-($\mu_2$-Cl)] core. The reaction of **1** with $AlMe_3$ in an equimolar ratio affords the methoxy-bridged dimeric titanium chloride complex **4**, which suggests the formation of the monomethyl titanium complex **3** that easily absorbs $O_2$ to give an oxygen-insertion product. Treatment of $H_2$mbmp with $AlMe_3$ leads to the formation of the dimeric methyl titanium complex **5**. Complex **4** supported on $MgCl_2$ and activated with aluminum alkyls is highly effective as an ethylene polymerization catalyst. The narrow molecular weight distribution for this system suggests the operation of a well-defined, heterogeneous single-site catalyst.

## Experimental Section

**General Considerations:** All operations were carried out under a dry argon atmosphere, using standard Schlenk techniques. All of the solvents were distilled under dinitrogen from the appropriate drying agents prior to use. [$D_6$]Benzene and [$D_8$]toluene were distilled from K metal and degassed by three freeze-pump-thaw cycles prior to use. The $TiCl_4$, $AlMe_3$ solution (1.0 M in hexane), and MAO compounds were obtained from the Aldrich Chemical Co. and were used without further purification unless stated otherwise. 2,2′-Methylenebis(6-*tert*-butyl-4-methylphenol) [$H_2$(L)] and [Ti(L)-$Cl_2$] (**1**) were synthesized according to literature methods.[20] $^1$H and $^{13}$C NMR spectra were recorded with a JEOL Lambda-500 spectrometer. Chemical shifts are reported in parts per million. Elemental analyses were measured with Yanaco MT-6 and MSU-32 microanalyzers. Infrared spectra were recorded with a Perkin–Elmer 180 spectrophotometer in Nujol mulls.

**Synthesis of [(L)($AlMe_2$)$_3$($\mu$-Cl)] (2):** $AlMe_3$ (1.0 M $Me_3Al$, 0.82 mL in hexane, 0.82 mmol) was added to a toluene/hexane solution (10/40 mL) of Ti(L)$Cl_2$ (**1**) (188 mg, 0.41 mmol) at –78 °C. The mixture was slowly warmed to room temp., and the color of the solution changed from red to brown-yellow and finally dark brown. After the resulting solution was stirred for another 8 h, the blue precipitate was separated by filtration. The clear solution was cooled to –20 °C for about one week to afford **2** as dark green crystals in 31% yield (46 mg based on $AlMe_3$). $^1$H NMR (500 MHz, $C_6D_6$): $\delta$ = –1.19 (s, 3 H, $CH_3$-Al), –0.52 (s, 6 H, $CH_3$-Al), 0.17 (s, 9 H, $CH_3$-Al), 1.38 (s, 18 H, $C(CH_3)_3$), 1.97 (s, 6 H, $CH_3$), 2.11 (s, 3 H, toluene), 3.45 (d, $J_{H\text{-}H}$ = 13.65 Hz, $CH_2$), 4.73 (d, $J_{H\text{-}H}$ = 13.65 Hz, $CH_2$), 6.96 (s, 2 H, Ar), 7.00–7.13 (m, 5 H, toluene), 7.16 (s, 2 H, Ar) ppm. $^1$H NMR (500 MHz, $C_7D_8$): $\delta$ = –1.26 (s, 3 H, $CH_3$-Al), –0.57 (s, 6 H, $CH_3$-Al), 0.12 (s, 3 H, $CH_3$-Al), 0.13 (s, 6 H, $CH_3$-Al), 1.40 (s, 18 H, $C(CH_3)_3$), 2.01 (s, 6 H, $CH_3$), 2.14 (s, toluene), 3.38 (d, $J_{H\text{-}H}$ = 13.65 Hz, $CH_2$), 4.66 (d, $J_{H\text{-}H}$ = 13.65 Hz, $CH_2$), 6.94 –7.12 (m, H-Ar, toluene) ppm. $^{13}$C NMR (126 MHz, $C_6D_6$): $\delta$ = 147.35, 140.60, 137.84, 135.23, 134.69, 130.32, 129.28, 129.18, 128.51, 128.29, 128.10, 127.91, 125.64, 35.68, 34.48, 32.75, 21.36, 20.85, –2.85, –6.00, –7.42, –8.75 ppm. $C_{29}H_{48}Al_3ClO_2$ (545.09): calcd. C 63.90, H 8.88; found C 63.77, H 8.91.

**Synthesis of [{(L)TiCl}$_2$($\mu$-OMe)$_2$] (4):** $AlMe_3$ (1.0 equiv. $AlMe_3$, 1.64 mL in hexane, 1.64 mmol) was added to a toluene/hexane solution (10/40 mL) of [(L)$TiCl_2$] (**1**) (0.375 g, 0.82 mmol) at –78 °C. The mixture was slowly warmed to room temp., and the color of the solution changed from red to orange. After the resulting solution was stirred for another 8 h under a dioxygen atmosphere, the precipitate was separated by filtration. The clear solution was cooled to –35 °C for about one week to afford orange crystals in 21% yield. $^1$H NMR (500 MHz, $C_6D_6$): $\delta$ = 1.47 (s, 9 H, $CH_3$), 1.52 (s, 9 H, $CH_3$), 2.05 (s, 3 H, $CH_3$), 2.08 (s, 3 H, $CH_3$), 3.42 (d, $J_{H\text{-}H}$ = 14.0 Hz, $CH_2$), 3.95 (d, $J_{H\text{-}H}$ = 14.0 Hz, $CH_2$), 4.12 (s, 6 H), 6.87 (s, 1 H, Ar), 6.92 (s, 3 H, Ar), 6.70 (s, 2 H, Ar) ppm. $^{13}$C NMR (126 MHz, $C_6D_6$): $\delta$ = 161.73, 161.52 ($\Delta\delta$ = 0.208, O-$C_{Ar}$), 136.44, 136.37, 136.01, 135.28, 133.17, 133.06, 129.28, 129.02, 128.97, 128.51, 128.41, 128.30, 128.10, 127.91, 126.11, 126.08, 69.81, 64.56, 35.38, 35.22, 35.16, 34.65, 30.32, 30.21, 21.05, 21.01 ppm. $C_{48}H_{66}Cl_2O_6Ti_2$ (905.67): calcd. C 63.66, H 7.35; found C 63.91, H 7.42.

**Synthesis of {[(L)$AlMe]_2$} (5):** Complex **5** was prepared by using a modification of the technique used in ref.[12d]. $AlMe_3$ (1.0 equiv. $AlMe_3$, 1.5 mL in hexane, 1.5 mmol) was added to a toluene/hexane solution (10/15 mL) of $H_2$L (0.5 g, 1.5 mmol) at –78 °C. The mixture was slowly warmed to room temp. and a white solid appeared. After the resulting mixture was stirred for another 8 h, the precipitate was separated by filtration and washed with hexane to give 0.29 g of **5** as a white solid in 52% yield. $^1$H NMR (500 MHz, $C_6D_6$): $\delta$ = 0.144 (s, 3 H, Al-$CH_3$), 1.37 (s, 9 H, $CH_3$), 1.40 (s, 9 H, $CH_3$), 1.84 (s, 3 H, $CH_3$), 2.32 (s, 3 H, $CH_3$), 3.69 (d, $J_{H\text{-}H}$ = 12.95 Hz, $CH_2$), 4.69 (d, $J_{H\text{-}H}$ = 12.95 Hz, $CH_2$), 6.88 (s, 1 H, Ar),

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

7.04 (s, 1 H, Ar) ppm. $^{13}C$ NMR (126 MHz, $C_6D_6$): $\delta$ = 161.73, 161.52 ($\Delta\delta$ = 0.208, O-$C_{Ar}$), 136.44, 136.37, 136.01, 135.28, 133.17, 133.06, 129.28, 129.02, 128.97, 128.51, 128.41, 128.30, 128.10, 127.91, 126.11, 126.08, 69.81, 64.56, 35.38, 35.22, 35.16, 34.65, 30.32, 30.21, 21.05, 21.01 ppm. $C_{48}H_{66}Al_2O_4$ (761.00): calcd. C 75.76, H 8.74; found C 75.67, H 8.71.

**Ethylene Polymerization:** To a slurry of [$MgCl_2(thf)_2$] (10 mmol) in *n*-hexane milled under argon in a glass mill (250 mL capacity, with 20 balls) at room temp. for 10 h, were added the titanium compound **4** (1 mmol) and *n*-hexane (50 mL). After the mixture was milled for an additional 24 h, the sample of precatalyst suspension (containing 0.01 mmol of titanium) was activated with $AlEt_2Cl$ (the molar ratio Al:Ti is 150) for 15 min at 50 °C under argon. Prior to polymerization, ethylene was passed through the suspension of the catalyst (10 mL) in a Schlenk ampoule for 15 min at room temp. and normal pressure, and the prepolymer was obtained. Then, MAO was added to the catalyst and dispersed in the prepolymer to form a highly active catalyst. The polymerization of ethylene was carried out in *n*-hexane at 50 or 70 °C in a stainless steel reactor (1 L), equipped with a stirrer, at $P_{gauge}$ = 70 or 100 psi pressure. The polymerization was quenched with a solution of HCl (5% in methanol) and dried under vacuum. The molecular weight ($M_w$) and molecular weight distribution ($M_w/M_n$) of the polypropylenes were determined by GPC in 1,2,4-trichlorobenzene using standard polystyrenes as a reference.

**X-ray Crystal Structure Determination:** A suitable crystal was immersed in mineral oil and mounted on a nylon loop in a random orientation under a cold stream of dry nitrogen (Rigaku GNNP low-temperature device). Diffraction experiments were performed with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71070 Å) in a Rigaku CCD diffractometer. The data were collected in a hemisphere in 720 frames with 20–40-s exposure times (4.0° < 2$\theta$ < 45–55°). The data were processed by using CrystalClear (Rigaku) processing packages.[21] The structures were determined by routine heavy-atom and Fourier methods by using SHELXS 97[22] and refined by full-matrix least-squares with the non-hydrogen atoms with anisotropic and hydrogen with fixed isotropic thermal parameters of 0.07 Å by means of the SHELXL 97[23] program. The hydrogen atoms were partially located from difference electron-density maps, and the rest were fixed at predetermined positions. Scattering factors were from common sources.[24] Some details of data collection and refinement are given in Table 5.

Table 5. Summary of data collection and structure refinement details for **2**, **4**, and **5**.

| Compound | **2** | **4** | **5** |
|---|---|---|---|
| Formula | $C_{29}H_{48}Al_3ClO_2$ | $C_{56}H_{85}Cl_2O_6Ti_2$ | $C_{30}H_{39}AlO_2$ |
| $F_w$ | 545.09 | 1020.99 | 458.62 |
| Temp. [K] | 173 | 173 | 173 |
| Crystal system | monoclinic | monoclinic | triclinic |
| Space group | *Cm* (#8) | $P\bar{1}$ (#2) | $P\bar{1}$ (#2) |
| *a* [Å] | 11.677(8) | 9.787(3) | 9.209(3) |
| *b* [Å] | 20.261(11) | 12.689(4) | 11.613(3) |
| *c* [Å] | 9.214(6) | 25.294(8) | 14.466(5) |
| $\alpha$ [°] | 90 | 73.659(10) | 73.496(12) |
| $\beta$ [°] | 121.886(8) | 78.020(12) | 87.58(1) |
| $\gamma$ [°] | 90 | 76.319(12) | 66.038(10) |

# Preferred Phosphorus Ylide Formation Upon Alkylation of Lithiobis(diphenylphosphanyl)acetonitrile

**Leonie Braun,[a] Gerald Kehr,[a] Tobias Blömker,[a][‡] Roland Fröhlich,[a][‡] and Gerhard Erker*[a]**

*Dedicated to Professor Rolf Gleiter on the occasion of his 70th birthday*

**Keywords:** Chelates / Phosphane ligands / Carbanions / Ylides / Alkylation

Deprotonation of the readily available chelate phosphane bis(diphenylphosphanyl)acetonitrile (**6**) leads to stabilized carbanion system **7**. Lithiobis(diphenylphosphanyl)acetonitrile (**7**) features a unique thf-stabilized monomeric structure in the crystal form with a short cyanonitrogen–Li contact. Alkylation of **7** with *n*-alkyl bromides (R–Br, R = ethyl, *n*-propyl, *n*-butyl, *n*-hexyl) takes place selectively at one phosphorus atom to yield stabilized ylides **8a**–**d** (two examples characterized by X-ray diffraction). Treatment of **7** with the more reactive alkylation agents methyl iodide or benzyl bromide results in alkylation at both phosphorus atoms to give delocalized bis(phosphonium)ylides **9a**,**b** (both characterized by X-ray diffraction). Similarly, the reaction of **7** with 1,3-dibromopropane or 1,4-dibromobutane yields six- and seven-membered heterocyclic bis(phosphonium)ylides **10a**,**b**, respectively. The spectroscopic characterization and X-ray crystal structure analysis again indicate the presence of delocalized $Ph_2RP–C(CN)–PRPh_2$ substructures.

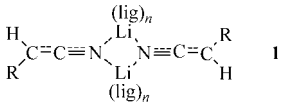
## Introduction

A variety of structural alternatives has been discussed for α-lithiated acetonitrile derivatives.[1] From a number of experimental studies complemented by spectroscopic and theoretical investigations it seemed clear that the majority of $RCHCN^-$ systems favored dimeric structures of type **1** in the solid state, which are characterized by the presence of a central $N_2Li_2$ four-membered heterocyclic arrangement (Figure 1).[2–6]



**1**

Figure 1. Preferred dimeric structures of lithiated acetonitrile derivatives.

We recently observed a monomeric structure of a lithiated acetonitrile example, namely lithiobis(diphenylphosphanyl)acetonitrile (**7**, see below).[7a] Phosphorus substituted ylides such as **2** or **3** are very interesting multifunctionalized organophosphorus compounds. Their structural and chemical features have attracted considerable interest.[7–10] Investigations in this field have led to the discovery of extended systems such as **4** or **5** (Figure 2).[8c,11–12]

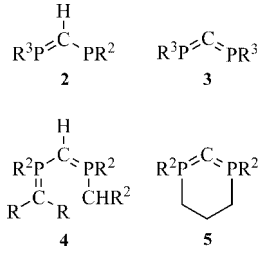


Figure 2. Examples of *P*-substituted phosphorus ylides.

We have now combined the chemistry of the $Li[(Ph_2P)_2CCN]$ system (**7**) with that of the P-stabilized ylides. This followed from a very typical reaction mode that is characteristic of **7**, namely its preferred alkylation at phosphorus upon treatment with a variety of alkyl halide electrophiles with the formation of new cyano-functionalized phosphorus ylides derived from the framework of **7**. A detailed description of some of this work is presented in this account.

## Results and Discussion

We previously showed that bis(diphenylphosphanyl)acetonitrile (**6**, dppmCN)[13] was readily obtained from the reaction of acetonitrile with chlorodiphenylphosphane in the

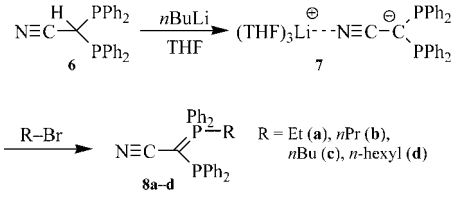
presence of a strong base. System **6** has served as a chelate ligand for metal complex formation. The in situ generated Pd(dppmCN) catalyst was shown to give very high activities in a Suzuki–Miyaura carbon–carbon coupling reaction.[14]

The deprotonation of dppmCN (**6**) was cleanly effected by treatment with *n*-butyllithium (Scheme 1).[7a] The resulting lithiobis(diphenylphosphanyl)acetonitrile product (**7**) was characterized by X-ray diffraction.[15–17] System **7** features a shortened C1–C2 [1.386(3) Å] bond and the C2–N linkage [1.162(3) Å] is lengthened relative to that reported for **6**[6] [cf. C1–C2 1.462(3) Å, C2–N 1.148(3) Å]. In **7**, the C1–P bonds are markedly shortened [1.784(2) Å, 1.775(2) Å] relative to the P1–C(Ar) bonds in **7** [1.835(2)–1.845(2) Å] and those reported in the literature for **6**[6] [1.874(2) Å, 1.895(2) Å]. These characteristic data indicate some electronic delocalization in **7**, including the pair of phosphorus groups. Most remarkably, system **7** is monomeric in the solid state – quite different from the preferred dimeric structures of its congeners **1** – with a N–Li contact of 1.957(4) Å. Figure 3 shows a view of the molecular structure of **7**.



Scheme 1.

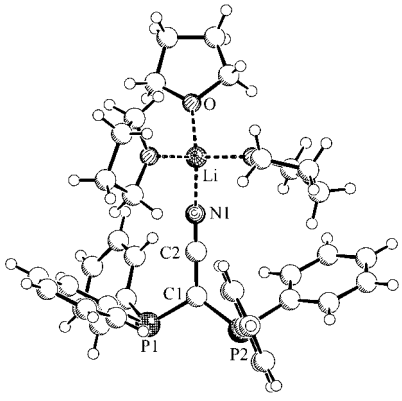


Figure 3. A view of the molecular structure of **7**.

Compound **7** is attacked by primary *n*-alkyl bromide electrophiles exclusively at one of the phosphorus atoms with clean formation of the respective ylide products (**8a**–**d**, R = ethyl, *n*-propyl, *n*-butyl, *n*-hexyl). Spectroscopically, the products are characterized by the observation of two very different $^{31}$P NMR spectroscopic phosphorus resonances. The ylidic phosphorus signal is shifted substantially to positive $\delta$ values relative to its neutral precursor **6** or its anionic precursor **7** (for details see Table 1). The central carbon atom C1 consequently features two very different $^{1}J_{P,C}$ coupling constants (e.g. **8a**: $\delta$ = 6.92 ppm, $^{1}J_{P,C}$ = 128.0, 28.9 Hz).

Table 1. Selected spectroscopic data of ylide products **8a**–**d**.[a]

| | **8a** ($C_2H_5$) | **8b** ($nC_3H_7$) | **8c** ($nC_4H_9$) | **8d** ($nC_6H_{13}$) |

[a] NMR spectra in $CD_2Cl_2$, $\delta$ [ppm], $J$ [Hz]; IR spectra in KBr, $\tilde{\nu}$ [$cm^{-1}$].

Compounds **8a**,**c** both exhibit very similar structures (Table 2). Therefore, only example **8c** (R = *n*-butyl) is described here in detail (Figure 4 and Table 2). Single crystals suitable for X-ray crystal structure analysis were obtained by the slow evaporation of solvent from a toluene/dichloromethane solution of functionalized ylide **8c**.

Table 2. Selected structural parameters of ylide products **8a**,**c**.[a]

| | **8a** (ethyl) | **8c** (*n*-butyl) |
|---|---|---|
| C2–N1 | 1.155(3) | 1.151(3) |
| C1–C2 | 1.409(3) | 1.412(3) |
| C1–P1 | 1.793(2) | 1.790(2) |
| C1–P2 | 1.728(2) | 1.721(2) |
| P1–C1–P2 | 121.0(1) | 118.8(1) |
| P1–C3 | 1.816(2) | 1.809(2) |

[a] Bond lengths [Å]; angles [°].

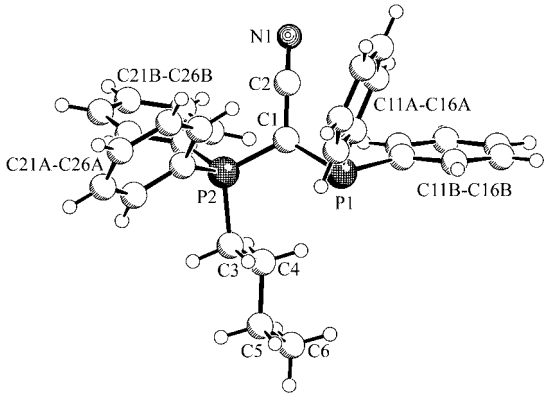

Figure 4. Molecular geometry of **8c**.

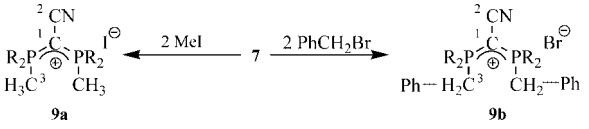
Compound **8c** features a central $sp^2$ hybridized planar tricoordinate ylidic carbon center (C1) to which a cyano substituent and a pair of differently substituted phosphorus atoms are bonded (Figure 4). The C1–C≡N unit is linear [angle C1–C2–N1 178.6(2)°]. Relative to the reference molecule bis(diphenylphosphanyl)acetonitrile (**6**), the C≡N bond in **8c** is slightly longer at 1.151(3) Å [cf. **6**: 1.148(2) Å] and the adjacent C1–C2 linkage is shorter [**8c**: 1.412(3) Å, cf. **6**: 1.462(2) Å], which indicates some conjugative stabilization of the adjacent ylide moiety [P2–C1: 1.721(2) Å]. Consequently, the remaining C1–P1 bond [1.790(2) Å] is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

markedly longer. The bond angles at C1 amount to 118.8(1)° (P1–C1–P2), 117.4(1)° (P2–C1–C2), and 121.5(1)° (P1–C1–C2) and the *n*-butyl substituent angle at P2 is 112.5(1)° [C1–P2–C3; P2–C3: 1.809(2) Å]. The remaining P–C aryl bond lengths at the tetracoordinate phosphorus atom P2 [P2–C21A: 1.812(2) Å, P2–21B: 1.810(2) Å] are slightly shorter relative to the P–C(aryl) bonds of its tricoordinate congener P1 [P1–C11A: 1.837(2) Å, P1–C11B: 1.835(2) Å].

The reaction of anion **7** takes a slightly different course when more reactive alkyl halide electrophiles are employed. Thus, treatment of **7** with methyl iodide results in the formation of a bisalkylated product (**9a**) (Scheme 2). In this case, a methyl group becomes attached at each phosphorus atom.[8c,11] Formally, the product may be regarded as a cyano-stabilized phosphorus ylide that is further stabilized by a newly formed phosphonium cation substituent. In reality, it appears that a delocalized bis(phosphonium)ylide is formed. In solution, this led to the observation of a single $^{31}$P NMR spectroscopic resonance at $\delta$ = 21.7 ppm and there is a single [P]–$CH_3$ $^1$H NMR spectroscopic signal at $\delta$ = 2.40 ppm.



Scheme 2.

The $^{13}$C NMR spectrum of **9a** features a binominal triplet resonance of the central carbon atom C1 at $\delta$ = 5.6 ppm with a $^1J_{P,C}$ = 117.1 Hz. The corresponding C≡N $^{13}$C NMR spectroscopic signal was located at $\delta$ = 119.4 ppm. Both the P–$CH_3$ and the P–$C_{ipso}$(aryl) $^{13}$C NMR spectroscopic signals ($\delta$ = 14.6 and 122.6 ppm) have a more complicated appearance due to nonfirst-order splitting of the respective $^{13}$C/$^{31}$P NMR spin systems (for further details see Table 3 and the Experimental Section).

Table 3. Selected spectroscopic data of compounds **9** and **10**.[a].

| | **9a** ($CH_3$) | **9b** ($CH_2$Ph) | **10a** $(CH_2)_3$ | **10b** $(CH_2)_4$ |

[a] NMR spectra in $CD_2Cl_2$, $\delta$ [ppm], *J* [Hz]; IR in KBr, $\tilde{\nu}$ [$cm^{-1}$]. [b] Tentative absolute assignment. [c] Singlet structure with $\nu_{1/2}$ ca. 2 Hz.

The reaction of **6** with benzyl bromide takes a similar course. We isolated doubly benzylated bis(phosphonium)ylide product **9b** from the reaction mixture in close to quantitative yield. Product **9b** exhibits similar spectroscopic features (Table 3). Both products **9a**,**b** were characterized by X-ray diffraction. Single crystals of **9a** were obtained by the slow evaporation of a saturated toluene/dichloromethane solution. Single crystals of **9b** were similarly obtained from dichloromethane.

Compound **9a** exhibits a delocalized bis(phosphonium)ylide-type structure with well separated cations and anions (Figure 5). In the crystal form, a chiral conformation is adopted. Nevertheless, the pair of C1–P1 and C1–P2 bonds is almost equal in length [1.734(4) Å, 1.751(4) Å]. The system features a distorted U-shaped conformation ranging from the aryl *ipso*-carbon C11B through P1, C1, and P2 to the methyl carbon atom C4 (Figure 5). The C1–C2(N) bond of **9a** is short [1.413(6) Å], which is a structural indication of CN stabilization of the central ylidic moiety. The conformation of the central section of the molecule is characterized by dihedral angles 104.3(3)° (C3–P1–C1–P2), –34.6(4)° (P1–C1–P2–C4), –80.2° (C3–P1–C1–C2), and 149.9° (C2–C1–P2–C4). The C1–C2–N1 unit is close to linear [178.7(5)°].

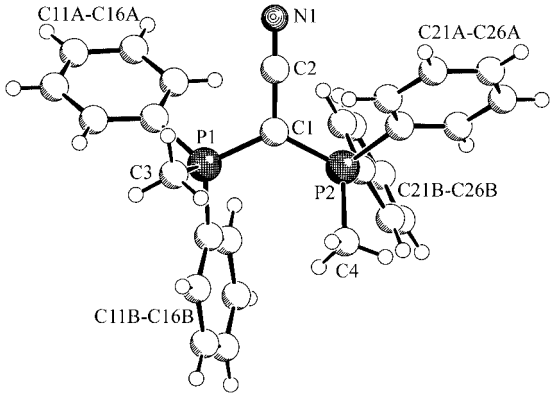

Figure 5. Molecular structure of **9a** (only the cation is depicted).

Compound **9b** features an overall structure that is similar to **9a**. Again, the P–C($sp^2$) bond lengths are similar to each other (Table 4) and both the C1–C2 and the adjacent C2–N1 bonds are rather short. Compound **9b** exhibits a slightly different conformation. The trio of aryl and alkyl substituents at the phosphorus atoms are arranged such that they are oriented close to the staggered position along the hypothetical P1···P2 axis. Both benzyl groups are pointing away from the core of molecule **9b** in this geometrical arrangement (Figure 6).

The reaction of anionic reagent **7** with 1,3-dibromopropane takes a similar course. Alkylation at both phosphorus atoms yields ylidic product **10a** (87%, isolated) (Scheme 3). The NMR spectra of **10a** point to a similar delocalized bis(phosphonium)ylide structure as it was found for **9a**,**b**. Compound **10a** features a single $^{31}$P NMR spectroscopic resonance at $\delta$ = 18.3 ppm and a single set of $^1$H/$^{13}$C NMR phenyl spectroscopic resonances (Table 3 and the Experimental Section). The bridging trimethylene unit appears to be symmetrical in solution, and in the $^1$H NMR spectrum it resonates as a 4 H multiplet at $\delta$ = 3.50 ppm ([P]–$CH_2$) and a 2 H signal at $\delta$ = 2.45 ppm (–$CH_2$–).

| P2–C1–C2 | 117.2(3) | 115.7(1) | 118.3(2) | 115.3(2) |

[a] Bond lengths [Å]; angles [°]. [b] P1–C11. [c] P2–C41 (Figure 6). [d] P2–C5 (Figure 7). [e] P2–C6 (see Figure 6).

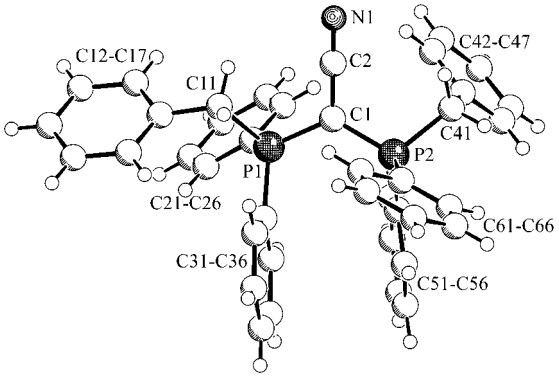

Figure 6. A projection of the molecular geometry of compound **9b** in the crystal form (only the cation is shown).

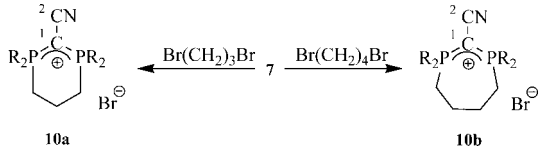

Scheme 3.

The corresponding $^{13}C$ NMR spectroscopic signals were observed at $\delta$ = 21.5 ppm (C3/C5) and $\delta$ = 17.0 ppm (t, $^3J_{P,C}$ = 6.0 Hz, C-4). As expected, the central ylidic carbon atom resonance shows up as a binominal triplet due to coupling with a pair of symmetry-equivalent phosphorus neighbors ($\delta$ = 3.2 ppm, $^1J_{P,C}$ = 103.8 Hz), and the adjacent nitrile carbon atom resonance appears at $\delta$ = 119.1 ppm (s, $\nu_{1/2}$ ca. 2 Hz).

The reaction of **7** with 1,4-dibromobutane proceeds analogously to yield product **10b** (73% isolated). Compound **10b** also seems to be a delocalized stabilized ylide. It features spectroscopic data similar to **10a** (Table 3).

Single crystals for X-ray crystal structure analyses of compounds **10a**,**b** were obtained by slow evaporation of the solvent from toluene/dichloromethane solutions. The structure of **10a** features a six-membered heterocycle (Figure 7). It contains a delocalized P1–C2–P2 unit with a pair of close-to-equal P–C bond lengths (Table 4). The corresponding C1–C2 bond length is in the typical range [1.410(4) Å] as is the adjacent C2–N1 linkage [1.157(4) Å]. The coordination geometry around the central ylidic carbon atom C1 is trigonal planar (for bond angles, see Table 4). The endocyclic saturated trimethylene unit of **10a** exhibits a typical staggered conformation.

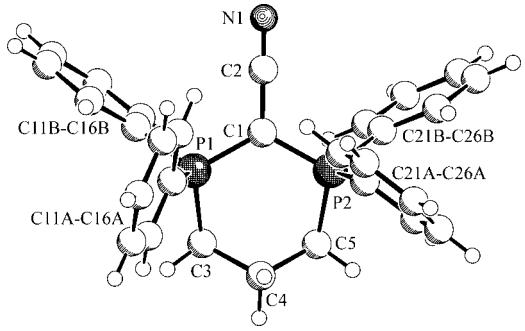

Figure 7. Molecular structure of **10a** (cation only).

The bonding parameters of the P1–C(CN)–P2 unit of seven-membered heterocyclic compound **10b** are similar to those of **10a**. In this case, the P1–C1 [1.748(2) Å] and P–C2 [1.745(2) Å] bonds are in fact almost identical in length as it is expected for a delocalized stabilized bis(phosphonium)-ylide structure. Again, the P–C(aryl) vectors are oriented close to the eclipsed conformation along the hypothetical P1···P2 connection and the P1–C3 [1.786(3) Å] and P2–C6 [1.801(3) Å] vectors are arranged close to parallel to each other. The remaining connecting tetramethylene unit of compound **10b** adopts an all-staggered conformation (Figure 8).

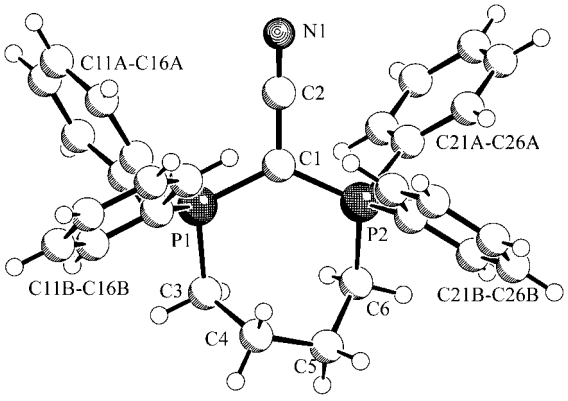

Figure 8. A view of the molecular structure of compound **10b** (cation only).

## Conclusions

We have shown that the chelate phosphane bis(diphenylphosphanyl)acetonitrile (dppmCN, **6**) is readily deprotonated by treatment with, for example, *n*-butyllithium to selectively yield monoanionic system **7**. Lithiobis(diphenylphosphanyl)acetonitrile (**7**) features a unique monomeric thf-stabilized structure in the crystal form that contains a delocalized P–C(CN)–P moiety and a short contact of the lithium cation to the nitrile nitrogen at the opposite end of the system. Nevertheless, the alkylation with a variety of alkyl ha-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

lide electrophiles very selectively takes place only at phosphorus. In each of the examples studied and described here, the –CN nitrogen atom as well as the "carbanionic" $P_2C1$ carbon center was left untouched by these reagents under the applied reaction conditions.[18] In some cases, selective alkylation at one of the two phosphorus centers was observed, which resulted in the formation of phosphorus ylides that are stabilized by the cyano substituent and the $–PR_2$ group at the ylidic carbon atom. Upon treatment with more strongly electrophilic reagents such as methyl iodide or benzyl bromide, twofold alkylation at phosphorus was observed, which led to the formation of apparently delocalized bis(phosphonium)ylide structures. Treatment of **7** with difunctional α,ω-dibromoalkanes led to analogous cyclic bis(phosphonium)ylide products. We assume that the subsequent P–C bond-forming step was favored because it took place intramolecularly. Now that such highly stabilized ylidic systems have become so easily available and their structure and spectroscopic features investigated and characterized, it will be interesting to learn their specific chemical properties and their potential synthetic use.

## Experimental Section

**General Information:** Most reactions were carried out under an inert atmosphere (argon) in Schlenk-type glassware or in a glove box. Solvents were dried and distilled under an atmosphere of argon prior to use. NMR spectra were recorded with Bruker AC 200 FT ($^1$H: 200 MHz, $^{13}$C: 50.3 MHz, $^{31}$P: 81 MHz), Varian Inova 500 ($^1$H: 499.8 MHz, $^{13}$C: 126 MHz), or Unity Plus 600 ($^1$H: 600 MHz, $^{13}$C: 151 MHz, $^{31}$P: 242.5 MHz) spectrometers. Most NMR assignments were supported by additional 2D experiments. The assignment of $J_{P,H}$ or $J_{P,C}$ was made by $^1$H{$^{31}$P} or $^{13}$C{$^1$H,$^{31}$P} NMR decoupling experiments. Melting points were determined with a DSC 2010 (TA-Instruments) apparatus. IR spectra were obtained with a Varian 3100 FT-IR (ECALIBUR Serie) spectrometer. MS (ESI) spectra were measured with a Micromass QuatroLC-Z mass spectrometer. GC was performed with a Hewlett Packard HP 6890 Series GC System. X-ray crystal structure data sets were collected with a Nonius KappaCCD diffractometer with Mo-radiation and equipped with a rotating anode generator. The following programs were used for data analysis: data collection, COLLECT;[19] data reduction, Denzo-SMN;[20] absorption correction, SORTAV[21] and Denzo;[22] structure solution, SHELXS-97;[23] structure refinement, SHELXL-97;[24] graphics, SCHAKAL.[25] CCDC-629968, -629969, and -631598 to -631602 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Preparation of Lithiobis(diphenylphosphanyl)acetonitrile (7):** Bis(diphenylphosphanyl)acetonitrile (3.26 g, 7.96 mmol) was dissolved in dry tetrahydrofuran (50 mL) and cooled to –78 °C. After the addition of *n*-butyllithium (1.6 M in hexane, 5.47 mL, 8.76 mmol), the reaction mixture was warmed to room temperature and stirred overnight. The solvent was removed in vacuo, and the residue was suspended in pentane (40 mL). The product was collected by filtration, washed with pentane (3 × 40 mL), and dried in vacuo (white solid, yield: 3.68 g, 73%). M.p. 144 °C (DSC). $^1$H NMR (600 MHz, $C_6D_6$/tdf, 298 K): $\delta$ = 7.40 (m, 8 H, *o*-Ph), 7.06 (m, 8 H, *m*-Ph), 6.99 (m, 4 H, *p*-Ph), 3.54 (br. s, 12 H, thf), 1.68 (br. s, 12 H, thf) ppm. $^{13}$C{$^1$H} NMR (151 MHz, $C_6D_6$/TDF, 298 K): $\delta$ = 147.2 (m, *i*-Ph), 133.1 (m, *o*-Ph), 129.4 (t, $^2J_{P,C}$ = 3.3 Hz, CN), 127.6 (m, *m*-Ph), 126.3 (s, *p*-Ph), 68.1 (m, thf), 26.3 (m, thf), 15.5 (t, $^2J_{P,C}$ = 13.5 Hz, C-1) ppm. $^{31}$P{$^1$H} NMR (81 MHz, $C_6D_6$/tdf, 298 K): $\delta$ = 2.7 (s) ppm. FTIR (KBr): $\tilde{\nu}$ = 3043, 2968, 2878, 2107, 2066, 1478, 1429, 1040, 744, 695, 560, 508 cm$^{-1}$. $C_{26}H_{20}LiNP_2$·3thf (631.66): calcd. C 72.26, H 7.02, N 2.22; found C 71.53, H 6.85, N 2.11. X-ray crystal structure analysis of **7**: formula $C_{26}H_{20}NP_2Li$·$(C_4H_8O)_3$, $M$ = 631.62, light yellow crystal 0.25 × 0.25 × 0.20 mm, $a$ = 9.658(1), $b$ = 18.516(1), $c$ = 19.627(1) Å, $\beta$ = 96.27(1)°, $V$ = 3488.9(4) Å$^3$, $\rho_{calcd.}$ = 1.202 g cm$^{-3}$, $\mu$ = 0.161 mm$^{-1}$, empirical absorption correction ($0.961 \le T \le 0.969$), $Z$ = 4, monoclinic, space group $P2_1/c$ (No. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\phi$ scans, 23326 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sin$\theta$)/$\lambda$] = 0.66 Å$^{-1}$, 8344 independent ($R_{int}$ = 0.059) and 5029 observed reflections [$I \ge 2\sigma(I)$], 410 refined parameters, $R$ = 0.057, $wR_2$ = 0.147, max. residual electron density 0.41 (–0.30) e Å$^{-3}$, hydrogen atoms calculated and refined as riding atoms.

**General Procedure for the Reaction of 7 with Alkyl Bromides:** Lithium cyanobis(diphenylphosphanyl)methanide·$(thf)_3$ (**7**, 1 equiv.) was dissolved in dry tetrahydrofuran (50 mL). After the addition of the respective alkyl halide (4 or 6 equiv.) the solution was stirred at room temperature overnight. The solvent was removed in vacuo, and the residue was suspended in dichloromethane (50 mL). The precipitate was filtered off and washed with dichloromethane (3 × 20 mL). The organic phases were combined, and the volatilities were removed in vacuo. The obtained crude product was suspended in pentane (40 mL), collected by filtration, washed with pentane, and then dried in vacuo.

**8a:** The reaction of **7** (0.50 g, 0.79 mmol) with bromoethane (0.35 g, 0.24 mL, 3.21 mmol) yielded **8a** as a white solid (0.24 g, 69%). M.p. 129 °C (DSC). $^1$H NMR (600 MHz, $CD_2Cl_2$, 298 K): $\delta$ = 7.67 (m, $^3J_{P-1,H}$ = 12.1 Hz, 4 H, *o*-Ph$^1$), 7.63 (m, $^5J_{P-1,H}$ = 1.8 Hz, 2 H, *p*-Ph$^1$), 7.52 (m, $^4J_{P-1,H}$ = 2.9 Hz, 4 H, *m*-Ph$^1$), 7.45 (m, $^3J_{P-2,H}$ = 7.8 Hz, 4 H, *o*-Ph$^2$), 7.32 (m, $^4J_{P-2,H}$ = 1.5 Hz, 4 H, *m*-Ph$^2$), 7.30 (m, 2 H, *p*-Ph$^2$), 2.71 (dq, $^2J_{P-1,H}$ = 12.2 Hz, $^3J_{H,H}$ = 7.4 Hz, $PCH_2$), 1.23 (td, $^3J_{P-1,H}$ = 18.4 Hz, $^3J_{H,H}$ = 7.4 Hz, $CH_3$) ppm. $^{13}$C{$^1$H} NMR (126 MHz, $CD_2Cl_2$, 298 K): $\delta$ = 141.1 (dd, $^1J_{P-2,C}$ = 8.5 Hz, $^3J_{P-1,C}$ = 7.2 Hz, *i*-Ph$^2$), 133.04 (dd, $^2J_{P-1,C}$ = 9.2 Hz, $^4J_{P-2,C}$ = 1.5 Hz, *o*-Ph$^1$), 133.03 (d, $^4J_{P-1,C}$ = 2.9 Hz, *p*-Ph$^1$), 132.7 (d, $^2J_{P-2,C}$ = 19.6 Hz, *o*-Ph$^2$), 129.4 (d, $^3J_{P-1,C}$ = 12.0 Hz, *m*-Ph$^1$), 128.5 (d, $^3J_{C,P-2}$ = 6.8 Hz, *m*-Ph$^2$), 128.2 (s, *p*-Ph$^2$), 127.0 (dd, $^1J_{P-1,C}$ = 86.7 Hz, $^2J_{P-1,C}$ = 2.6 Hz, *i*-Ph$^1$), 125.0 (dd, $^2J_{P-1,C}$ = 13.1 Hz, $^2J_{P-2,C}$ = 0.8 Hz, C≡N), 19.1 (dd, $^1J_{P-1,C}$ = 62.5 Hz, $^3J_{P-2,C}$ = 9.9 Hz, $CH_2$), 6.96 (dd, $^2J_{P-1,C}$ = 4.9 Hz, $^4J_{P-2,C}$ = 2.9 Hz, $CH_3$), 6.92 (dd, $^1J_{P-1,C}$ = 128.0 Hz, $^1J_{P-2,C}$ = 28.9 Hz, P=C) ppm. $^{31}$P{$^1$H} NMR (202 MHz, $CD_2Cl_2$, 298 K): $\delta$ = 29.3 (d, $^2J_{P-1,P-2}$ = 140.8 Hz, P-1), –19.2 (d, $^2J_{P-2,P-1}$ = 140.8 Hz, P-2) ppm. FTIR (KBr): $\tilde{\nu}$ = 3058, 2957, 2137, 1429, 1261, 1100, 1025, 800, 695, 564 cm$^{-1}$. MS (EI, 70 eV): $m/z$ (%) = 437.2 (72) $[M]^+$, 408.1 (100) $[M - CH_2CH_3]^+$, 360 (17) $[M - C_6H_5]^+$, 262.1 (16), 185.1 (23) $[M - C_{12}H_{10}P]^+$, 183.0 (29) $[C_{12}H_8P]^+$. $C_{28}H_{25}NP_2$ (437.46): calcd. C 76.88, H 5.76, N 3.20; found C 76.43, H 5.71, N 3.11. X-ray crystal structure analysis of **8a**: formula $C_{28}H_{25}NP_2$, $M$ = 437.43, colorless crystal 0.30 × 0.30 × 0.20 mm, $a$ = 9.602(1), $b$ = 15.189(1), $c$ = 15.789(1) Å, $\beta$ = 100.05(1)°, $V$ = 2267.4(3) Å$^3$, $\rho_{calcd.}$ = 1.281 g cm$^{-3}$, $\mu$ = 0.208 mm$^{-1}$, empirical absorption correction ($0.941 \le T \le 0.960$), $Z$ = 4, monoclinic, space group $P2_1/n$ (No. 14), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\phi$ scans, 15000 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sin$\theta$)/$\lambda$] = 0.67 Å$^{-1}$, 5441 independent ($R_{int}$ = 0.043) and 4049 observed reflections [$I \ge 2\sigma(I)$], 281 refined parameters, $R$ = 0.045, $wR_2$ = 0.112, max. residual electron density

# Dinuclear (Arene)ruthenium Complexes Containing a Chiral-at-Phosphorus Phosphanido Bridge

**Mathieu J.-L. Tschan,[a] Georg Süss-Fink,*[a] Frédéric Chérioux,[b] and Bruno Therrien[a]**

*Dedicated to Professor Hans-Ludwig Krauss on the occasion of his 80th birthday*

**Keywords:** Arene ligands / Ruthenium / Tethered complexes / P ligands / Hydride ligands

The unsaturated diruthenium cation $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2(\mu_2\text{-}H)_3]^+$ reacts with $PPh_2(CH_2)_3Ph$ to give the phosphanido complex $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ (**1**), which contains a stereogenic phosphorus atom in the bridge, and benzene. Heating of **1** in bromobenzene gives the first chiral-at-phosphorus diruthenium complex $[(\eta^6\text{-}C_6Me_6)Ru_2\{\mu_2\text{-}PPh(CH_2)_3\text{-}\eta^6\text{-}Ph\}(\mu_2\text{-}Br)_2]^+$ (**3**) due to the replacement of the *p*-cymene ligand by the phenyl group at the pendant arm and hydrido bridges by bromido bridges. The single-crystal X-ray structure analysis of [**3**][$BF_4$] reveals a racemic mixture of both enantiomers ($R_P$)-**3** and ($S_P$)-**3** in the crystal. Similarly, the reaction of $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2(\mu_2\text{-}H)_3]^+$ and the enantiopure phosphane (*R*)-$PPh_2(CH_2)_2CHMePh$ yields the complex $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMePh\}(\mu_2\text{-}H)_2]^+$ (**4**) as a mixture of diastereomers. An optically active mixture (*de* = 4 %) of phosphanido-bridged complexes $[(\eta^6\text{-}C_6Me_6)Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMe\text{-}\eta^6\text{-}Ph\}(\mu_2\text{-}Br)_2]^+$ (**6**), containing the ($R_C$,$S_P$) and ($R_C$,$R_P$) diastereomers, is obtained upon heating of **4** in bromobenzene. The molecular structure of [**6**][$BF_4$] reveals that the two diastereomers ($R_C$,$S_P$)-**6** and ($R_C$,$R_P$)-**6** exist as two conformers. The non-chiral-at-phosphorus analogues $[(\eta^6\text{-}C_6Me_6)_2Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ (**2**) and $[(\eta^6\text{-}C_6Me_6)_2Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMePh\}(\mu_2\text{-}H)_2]^+$ (**5**) have also been synthesized and structurally characterized by single-crystal X-ray structure analyses of [**2**][$BF_4$] and [**5**][$BF_4$].

## Introduction

(Arene)ruthenium complexes, in spite of their venerable history, have not lost their fascination thanks to their rich and diversified chemistry.[1] An increasing number of catalytic reactions involving (arene)ruthenium complexes, such as transfer hydrogenation reactions,[2] alkene metathesis[3] or Diels–Alder reactions,[4] have contributed to the steadily growing interest in these complexes, which owe their fertility and versatility mainly to the stability of the arene–ruthenium bond. The complete loss of the arene ligand can be an undesired side-reaction during a catalytic process, although the stability of the (arene)ruthenium moiety can be increased by arene ligands containing chelating substituents.[5] The synthesis of such (arene)ruthenium complexes can be achieved by intramolecular arene ligand exchange at the ruthenium atom, which works only if either an electron-poor arene ligand is replaced by an electron-rich one[6] or if the reaction can take advantage of the chelate effect.[5] Thus, examples of tethered (arene)ruthenium complexes containing oxygen,[7] phosphorus,[5,6,8] sulfur[9] and carbon or nitrogen[10] donor atoms have been reported.

Recently, we found that the unsaturated dinuclear cation $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ reacts with tertiary phosphanes such as $PPh_3$ and $PPhMe_2$ to give the phosphanido-bridged complexes $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PR_2)(\mu_2\text{-}H)_2]^+$ (R = Ph, Me) and benzene.[11] The reaction proceeds by P–C activation intermediates containing a bridging phenyl ligand, $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PR_2)(\mu_2\text{-}Ph)(\mu_2\text{-}H)]^+$ (R = Ph, Me), and the phenyl derivative is isolated as the tetrafluoroborate salt. This P–C bond-cleavage reaction occurs even in the case of trialkylphosphanes such as P*n*$Bu_3$ and P*n*$Oct_3$ to give the cations $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PR_2)(\mu_2\text{-}H)_2]^+$ (R = *n*Bu, *n*Oct) and the corresponding olefin and dihydrogen.[11] The diphenylphosphanido derivative $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PPh_2)(\mu_2\text{-}H)_2]^+$ turned out to be a highly selective catalyst for hydrogenation of carbon–carbon double bonds.[12]

The mixed dinuclear (arene)trihydridoruthenium complex $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2(\mu_2\text{-}H)_3]^+$, which we synthesized recently,[13] reacts with phosphanes in the same way as its symmetrical analogue, $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$, although, because of the asymmetry of the diruthenium backbone, the reaction with mixed phosphanes allows

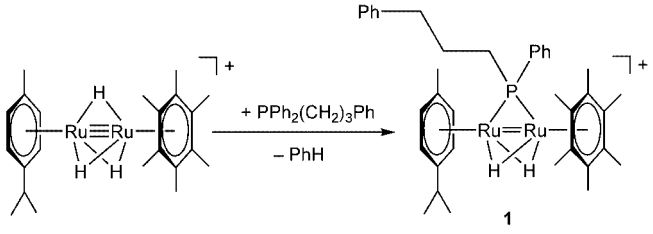
the synthesis of phosphanido-bridged diruthenium complexes that are chiral at the phosphorus atom. Moreover, the use of mixed phosphanes containing a phenyl substituent at the end of a pendant arm should give access to tethered P-chiral diruthenium complexes.

In this paper, we report the synthesis of the first tethered chiral-at-phosphorus diruthenium complex, $[(\eta^6\text{-}C_6Me_6)Ru_2\{\mu_2\text{-}PPh(CH_2)_3\text{-}\eta^6\text{-}Ph\}(\mu_2\text{-}Br)_2]^+$ (**3**), which was obtained as a racemic mixture by heating of $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ (**1**) in bromobenzene. The enantiopure phosphane (*R*)-$PPh_2(CH_2)_2$-CHMePh, reported by Zenneck et al.,[8c] gave an optically active mixture of the diastereomeric complexes ($R_C$,$S_P$)- and ($R_C$,$R_P$)-$[(\eta^6\text{-}C_6Me_6)Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMe\text{-}\eta^6\text{-}Ph\}(\mu_2\text{-}Br)_2]^+$ (**6**).

## Results and Discussion

The dinuclear trihydrido complex $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}i\text{PrMeC}_6H_4)Ru_2(\mu_2\text{-}H)_3]^+$ reacts with the mixed phosphane $PPh_2(CH_2)_3Ph$, which was recently reported by Wright et al.,[5] to give the phosphanido-bridged complex $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ (**1**; Scheme 1). The reaction was carried out at 55 °C in dichloromethane solution, and the yield of [**1**][$BF_4$] can be increased from 30% to 38% by performing the reaction under hydrogen pressure (3 bar). The reason for the use of hydrogen in this reaction is the conversion of the intermediate $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}Ph)(\mu_2\text{-}H)]^+$, which was observed by mass spectrometry in accordance with the fully characterized analogue $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}PPh_2)(\mu_2\text{-}Ph)(\mu_2\text{-}H)]^+$,[11] into **1** by reaction with $H_2$.



Scheme 1. Synthesis of $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ (**1**).

Complex **1** possesses a stereogenic phosphanido bridge and was obtained as a racemic mixture since the nucleophilic attack of the phosphane occurs at one of the two ruthenium atoms and none of the two P–$C_{(aryl)}$ bonds is preferentially cleaved. The two hydrido ligands in **1** are diastereotopic, as seen by the $^1$H NMR spectrum, which exhibits two doublets of doublets in the hydride region at $\delta$ = –14.65 (dd, $^2J_{H,H}$ = 2.8, $^2J_{H,P}$ = 28 Hz, 1 H) and –16.06 (dd, $^2J_{H,H}$ = 2.8, $^2J_{H,P}$ = 31 Hz, 1 H) ppm. The two enantiomers of **1** are shown in Figure 1.

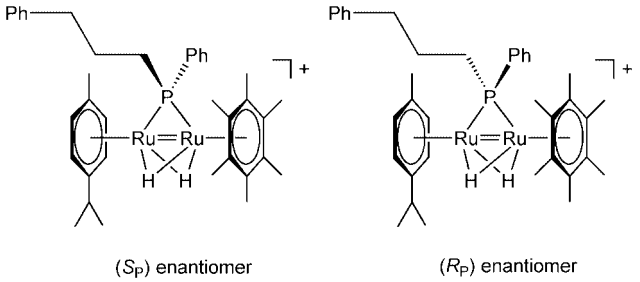


Figure 1. The two enantiomers of $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ (**1**).

As we failed to obtain crystals of [**1**][$BF_4$] suitable for X-ray structure analysis, we synthesized an achiral analogue of **1** containing two hexamethylbenzene ligands. The cation $[(\eta^6\text{-}C_6Me_6)_2Ru_2\{\mu_2\text{-}PPh(CH_2)_3Ph\}(\mu_2\text{-}H)_2]^+$ (**2**) is accessible in the same way as **1** from $PPh_2(CH_2)_3Ph$ and $[(\eta^6\text{-}C_6Me_6)_2Ru_2(\mu_2\text{-}H)_3]^+$ (Scheme 2). The reaction was carried out under the same conditions as for **1** ($CH_2Cl_2$, 55 °C, 3 bar $H_2$) and, in this case, the yield of the reaction was much higher (85%). Dark-red crystals of [**2**][$BF_4$] suitable

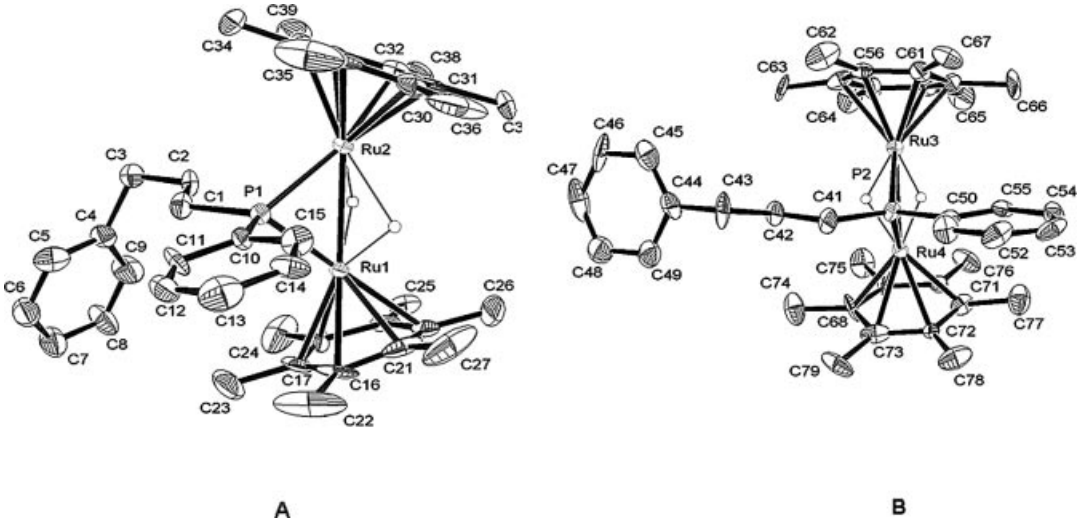

Figure 2. Molecular structure of the two independent molecules of cation **2** (anions, solvent molecules, and hydrogen atoms, except for the hydrido ligands, have been omitted for clarity).

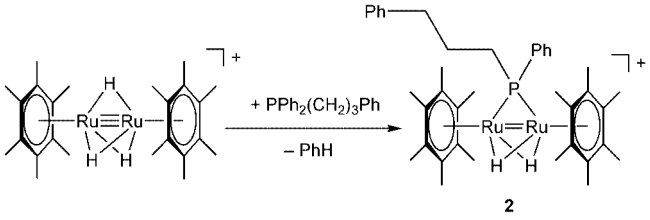
for X-ray structure analysis were obtained by slow diffusion of hexane into a concentrated dichloromethane solution of [**2**][$BF_4$]. The molecular structure of cation **2** is shown in Figure 2.



2

Scheme 2. Synthesis of [($\eta^6$-$C_6Me_6$)$_2$$Ru_2${$\mu_2$-PPh$(CH_2)_3$Ph}($\mu_2$-H)$_2$]$^+$ (**2**).

The single-crystal X-ray structure analysis for cation **2** reveals a PPh$(CH_2)_3$Ph moiety and two hydrido ligands bridging the two ruthenium atoms, with each ruthenium atom also being coordinated to an $\eta^6$-$C_6Me_6$ ligand. The Ru–Ru distances [2.670(2) and 2.767(2) Å] are similar to those expected for a ruthenium–ruthenium double bond. Two independent molecules are observed in the crystal structure of [**2**][$BF_4$], with the major difference between them being the conformation of the P$(CH_2)_3$Ph unit (see Figure 2). Thus, the C1–C2–C3–C4 torsion angle in molecule **A** is 170(3)° (*anti* conformation), while in molecule **B** the C41–C42–C43–C44 torsion angle is –69(2)° (*syn* conformation). These two molecules adopt a pairwise arrangement in the unit cell of [**2**][$BF_4$], as shown in Figure 3. The presence of a bridging PPh$(CH_2)_3$Ph ligand forces the arene moieties to adopt a tilted geometry. The two $C_6Me_6$ arene ligands are not parallel to each other, and the angles between the $C_6Me_6$ planes are 34.9(2)° and 34.4(4)° for molecules **A** and **B**, respectively.

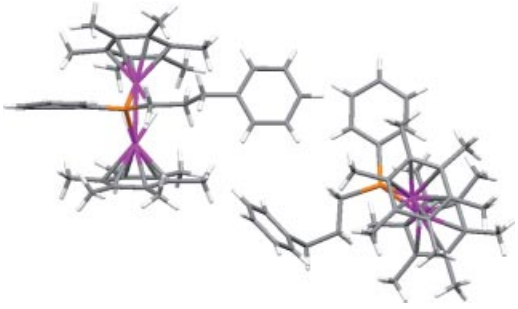


Figure 3. Pairwise arrangement of *anti*-**2** (molecule **A**) and *syn*-**2** (molecule **B**) in the unit cell of [**2**][$BF_4$].

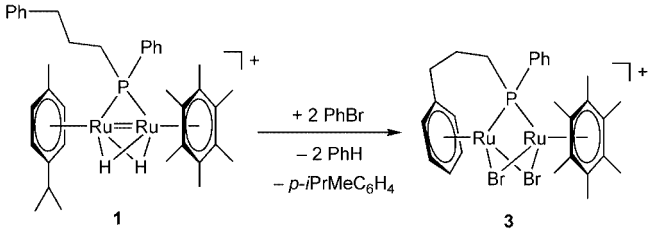
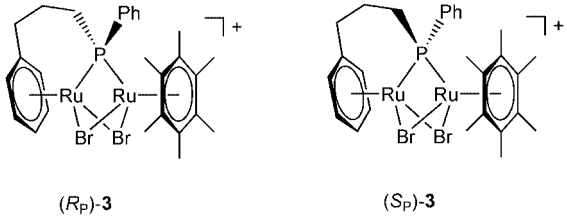
The arene exchange reaction between the *p*-cymene ligand and the phenyl substituent in the pendant arm of the phosphanido ligand in [($\eta^6$-$C_6Me_6$)($\eta^6$-*p*-*i*PrMe$C_6H_4$)-$Ru_2${$\mu_2$-PPh$(CH_2)_3$Ph}($\mu_2$-H)$_2$]$^+$ (**1**) is achieved by heating of [**1**][$BF_4$] at 150 °C in bromobenzene. The reaction leads to the dibromo complex [($\eta^6$-$C_6Me_6$)$Ru_2${$\mu_2$-PPh$(CH_2)_3$-$\eta^6$-Ph}($\mu_2$-Br)$_2$]$^+$ (**3**; Scheme 3), and the reaction requires more forcing conditions than in the case of [($\eta^6$-*p*-*i*PrMe$C_6H_4$)-$Ru${$PPh_2(CH_2)_3$Ph}$Cl_2$].[5] Replacement of the $C_6M_6$ ligand is not observed.



1 3

Scheme 3. Synthesis of [($\eta^6$-$C_6Me_6$)$Ru_2${$\mu_2$-PPh$(CH_2)_3$-$\eta^6$-Ph}($\mu_2$-Br)$_2$]$^+$ (**3**).

The surprising substitution of the two hydrido bridges in **1** by two bromido bridges in **3** that occurs during arene ligand exchange was confirmed by NMR monitoring: on comparing the $^1$H NMR spectra of [**1**][$BF_4$] and [**3**][$BF_4$] it becomes clear that both the *p*-cymene signals and the hydride signals have disappeared and that coordination of the $\eta^6$-$C_6H_5$ substituent of the pendant arm gives rise to three new signals at $\delta$ = 6.25 (m, 2 H, *H-ortho*), 5.43 (t, $^3J_{H,H}$ = 4.8 Hz, 1 H, *H-para*), and 5.04 (m, 2 H, *H-meta*) ppm. As expected, the three methylene groups in the ligand arm give rise to two signals each because the $CH_2$ protons are diastereotopic (Figure 4). In contrast to **1** and **2**, the $^4J_{P,H}$ coupling (1 Hz) for **3**, which gives rise to a doublet at $\delta$ = 1.94 ppm, is visible for the methyl protons of the $\eta^6$-$C_6Me_6$ ligand, presumably due to the almost parallel arrangement of the two $\eta^6$-arene ligands. A similar $^4J_{P,H}$ coupling has been observed in the mononuclear complexes [($\eta^6$-$C_6Me_6$)-Ru(CO)(P$Me_3$)Me]$^+$,[14] [($\eta^6$-$C_6Me_6$)Ru(P$R_3$)$Me_2$], and [($\eta^6$-$C_6Me_6$)Ru(P$R_3$)(OCO$CF_3$)Me] (P$R_3$ = P$Me_3$, P$Ph_3$, P$Me_2$Ph).[15] In accordance with the presence of two bromido ligands, the ESI mass spectrum of [**3**][$BF_4$] shows a parent peak at *m*/*z* = 752. The molecular structure of this complex was finally confirmed by single-crystal X-ray analysis.



($R_P$)-**3** ($S_P$)-**3**

Figure 4. The two enantiomers ($R_P$)-**3** and ($S_P$)-**3**.

Dark-orange crystals of [**3**][$BF_4$] suitable for an X-ray structure analysis were obtained by slow diffusion of diethyl ether into a concentrated acetone solution of [**3**][$BF_4$]. Two enantiomers are observed independently in the asymmetric unit of [**3**][$BF_4$] (see Figure 5).

The ruthenium atoms in [**3**][$BF_4$] are in a distorted octahedral geometry in which the two metal centers are bridged by a tethered phosphanido and two bromido ligands. The Ru–Br bond lengths [ranging from 2.552(1) to 2.586(1) Å] and Ru–Br–Ru angles [ranging from 82.16(4) to 82.90(4)°] are similar to those found in other dinuclear ($\eta^6$-arene)-ruthenium complexes bridged by bromine atoms, for example [$Ru_2$($\eta^6$-1,3,5-$C_6H_3Et_3$)$_2$($\mu_2$-Br)$_3$][$Re_2(CO)_6$($\mu_2$-Br)$_3$] and [$Ru_2$($\eta^6$-*p*-*i*PrMe$C_6H_4$)$_2$($\mu_2$-Br)$_3$][$Re_2(CO)_6$($\mu_2$-Br)$_3$].[16] The

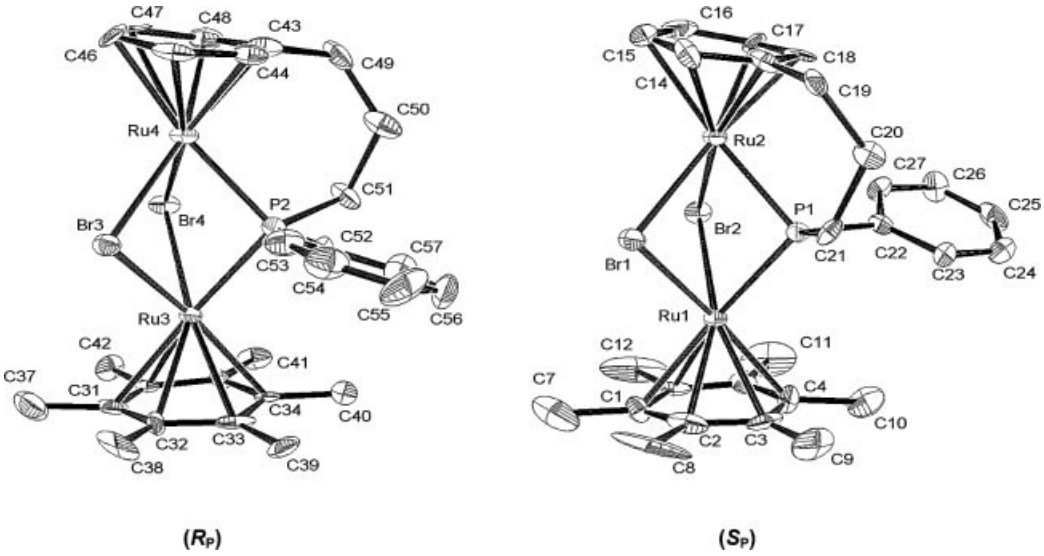

Figure 5. Molecular structure of the two independent enantiomers of cation **3** (anions and hydrogen atoms have been omitted for clarity).

Ru–Ru distances [3.3973(3) and 3.3764(3) Å] are well outside the range (2.28–2.95 Å) for a metal–metal single bond.[17] The phenyl rings of the η⁶-arene ligands are almost parallel, with an angle between the two planes of 8.8(7)° in ($R_P$)-**3** and 9.8(7)° in ($S_P$)-**3**. The *p*-cymene ligand in [**1**][$BF_4$] is replaced by the phenyl ring of the pendant arm of the phosphanido ligand upon formation of [**3**][$BF_4$], which gives rise to a six-membered metallacycle. Both enantiomers of **3** show a chair-like conformation for the six-membered metallacycles (see Figure 6).

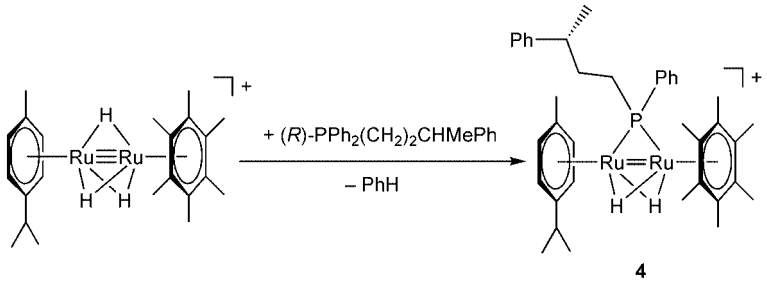
Figure 6. Capped-stick representation of the chair-like conformation observed in cations ($R_P$)-**3** and ($S_P$)-**3**.

In order to obtain a mixture of diastereomers instead of a racemic mixture of enantiomers we decided to treat [(η⁶-$C_6Me_6$)(η⁶-*p*-*i*PrMe$C_6H_4$)$Ru_2$(μ₂-H)₃]⁺ with the enantiopure phosphane (*R*)-$PPh_2(CH_2)_2$CHMePh, which contains a stereogenic carbon center and is similar to the achiral analogue $PPh_2(CH_2)_3$Ph. Given the fact that racemization of the stereogenic carbon atom in this ligand was not observed during the synthesis of [$RuCl_2${η¹-(*R*)-$PPh_2(CH_2)_2$-CHMe-η⁶-Ph}],[8c] we can assume that the ($R_C$) configuration of (*R*)-$PPh_2(CH_2)_2$CHMePh also does not change in the reaction with the dinuclear trihydrido complex.

The trihydrido complex [(η⁶-$C_6Me_6$)(η⁶-*p*-*i*PrMe$C_6H_4$)-$Ru_2$(μ₂-H)₃]⁺ reacts with the enantiopure phosphane (*R*)-$PPh_2(CH_2)_2$CHMePh to give the cation [(η⁶-$C_6Me_6$)(η⁶-*p*-*i*PrMe$C_6H_4$)$Ru_2${μ₂-(*R*)-PPh$(CH_2)_2$CHMePh}(μ₂-H)₂]⁺ (**4**), which was obtained as a mixture of the two diastereomers ($R_C$,$R_P$)-**4** and ($R_C$,$S_P$)-**4** (Scheme 4). The reaction was carried out in dichloromethane at 55 °C under hydrogen (3 bar). The yield of 38% is similar to that for the synthesis of **1**. Unfortunately, we were not able to separate the two diastereomers either by crystallization or by chromatography on silica gel.

As no X-ray quality crystals of [**4**][$BF_4$] could be obtained, we treated the enantiopure phosphane (*R*)-$PPh_2(CH_2)_2$CHMePh with the bis(hexamethylbenzene) analogue [(η⁶-$C_6Me_6$)$_2Ru_2$(μ₂-H)₃]⁺ to obtain [(η⁶-$C_6Me_6$)$_2$-$Ru_2${μ₂-(*R*)-PPh$(CH_2)_2$CHMePh}(μ₂-H)₂]⁺ (**5**; Scheme 5).

The dark-red crystals of [**5**][$BF_4$] obtained by slow diffusion of diethyl ether into a concentrated solution of



Scheme 4. Synthesis of [(η⁶-$C_6Me_6$)(η⁶-*p*-*i*PrMe$C_6H_4$)$Ru_2${μ₂-(*R*)-PPh$(CH_2)_2$CH-MePh}(μ₂-H)₂]⁺ (**4**).

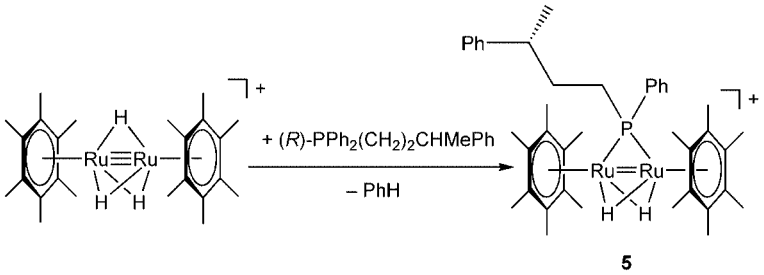

Scheme 5. Synthesis of $[(\eta^6\text{-}C_6Me_6)_2Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMePh\}(\mu_2\text{-}H)_2]^+$ (**5**).

[**5**][$BF_4$] in dichloromethane were found to be suitable for X-ray analysis. The molecular structure of cation **5** was confirmed by X-ray crystal structure analysis of its tetrafluoroborate salt (Figure 7).

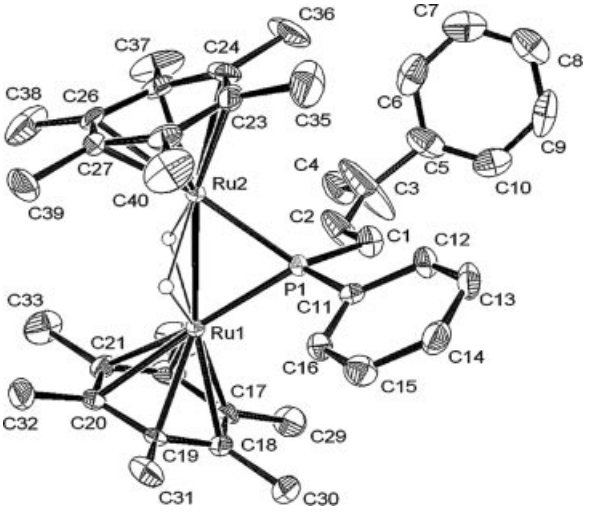

Figure 7. Molecular structure of cation **5** (anion and hydrogen atoms other than the hydrido ligands have been omitted for clarity).

The centrosymmetric space group $P2_1/c$ of [**5**][$BF_4$] suggests a racemic mixture of ($R_C$) and ($S_C$) enantiomers of **5** in the crystal. However, the stereogenic carbon atom (C3 in Figure 7) in **5** is highly disordered, as demonstrated by the exceptionally stretched ellipsoid along the C–H axis in the ORTEP plot (Figure 7), which may give rise to a centrosymmetric space group despite retention of the ($R_C$) configuration. The Ru–Ru distance [2.6346(8) Å] is similar to those observed in [**2**][$BF_4$] and remains within the range of a ruthenium–ruthenium double bond. As in [**2**][$BF_4$], the presence of a bridging phosphanido ligand forces the arene moieties to adopt a tilted geometry. The angle between the two $C_6Me_6$ planes is 38.8(2)°.

As the question of the enantiomeric purity of **5** could not be solved by X-ray crystallography because of the centrosymmetric space group ($P2_1/c$) and disorder problems, we used circular dichroism to find out whether or not the stereogenic carbon center in the side-chain has racemized during the synthesis of **5**, despite the known enantiostability of (*R*)-$PPh_2(CH_2)_2CHMePh$.[8c] Although the concentration-dependent CD signal at 350 nm (Figure 8) shows **5** to be optically active, which suggests that the stereogenic carbon center has (*R*) configuration, we cannot exclude partial racemization during the synthesis of this compound.

As in the case of **1**, the ligand exchange reaction between *p*-cymene and the phenyl substituent on the pendant arm

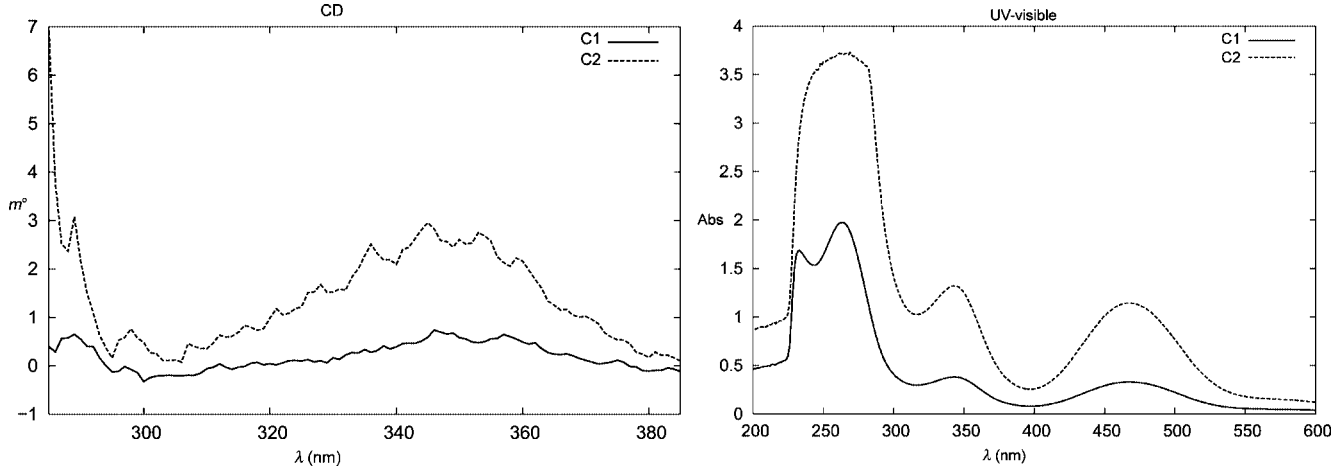

Figure 8. CD (left) and UV/Vis (right) spectra of [**5**][$BF_4$] recorded in $CH_2Cl_2$ at two different concentrations ($c_1 = 5.05 \times 10^{-4}$ M, $c_2 = 1.67 \times 10^{-3}$ M), $m° = 10^{-3}°$.

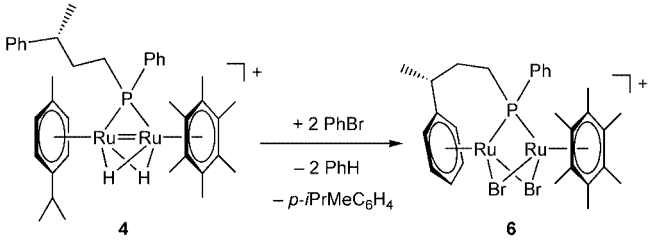
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

was achieved by heating of $[(\eta^6\text{-}C_6Me_6)(\eta^6\text{-}p\text{-}i\text{PrMeC}_6H_4)\text{-}Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMePh\}(\mu_2\text{-}H)_2]^+$ (**4**) at 150 °C in bromobenzene. This reaction also leads to the dibromido derivative $[(\eta^6\text{-}C_6Me_6)Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMe\text{-}\eta^6\text{-}Ph\}(\mu_2\text{-}Br)_2]^+$ (**6**; Scheme 6), which was obtained as a mixture of ($R_C$,$S_P$) and ($R_C$,$R_P$) diastereomers (Figure 9).



Scheme 6. Synthesis of $[(\eta^6\text{-}C_6Me_6)Ru_2\{\mu_2\text{-}(R)\text{-}PPh(CH_2)_2CHMe\text{-}\eta^6\text{-}Ph\}(\mu_2\text{-}Br)_2]^+$ (**6**).

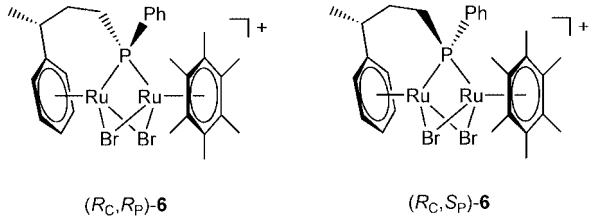


Figure 9. The two diastereomers ($R_C$,$R_P$)-**6** and ($R_C$,$S_P$)-**6**.

Single crystals suitable for an X-ray structure analysis were obtained by slow diffusion of diethyl ether into a concentrated acetone solution of [**6**][$BF_4$]. Examination of the structure with PLATON[18] revealed an ambiguity over the choice of the space group ($P1$ or $P\bar{1}$). Expecting a chiral molecule, resolution was performed in the noncentrosymmetric group $P1$. The structure was refined to convergence with a Flack parameter of 0.23(2). Both diastereomers, ($R_C$,$R_P$)-**6** and ($R_C$,$S_P$)-**6**, show the two ruthenium atoms to be in a distorted octahedral geometry in which the metal

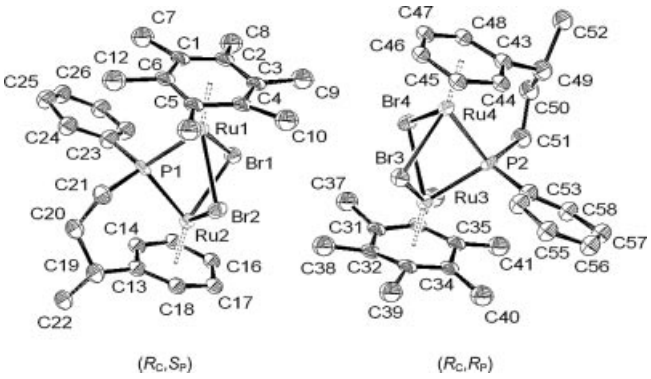

Figure 10. The molecular structure of the diastereomers of cation **6** (anions, solvent molecules, and hydrogen atoms have been omitted for clarity).

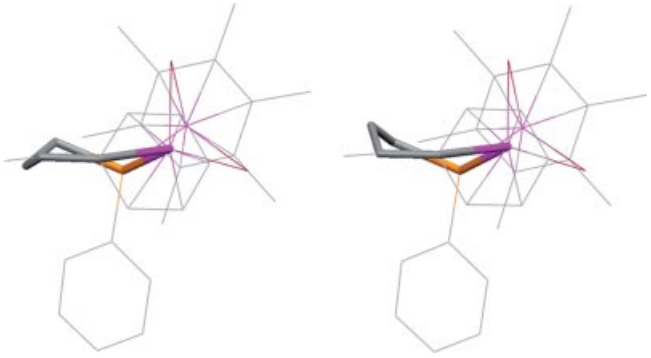

Figure 11. The chair-like (left) and half-twist-like (right) conformations in cation **6**.

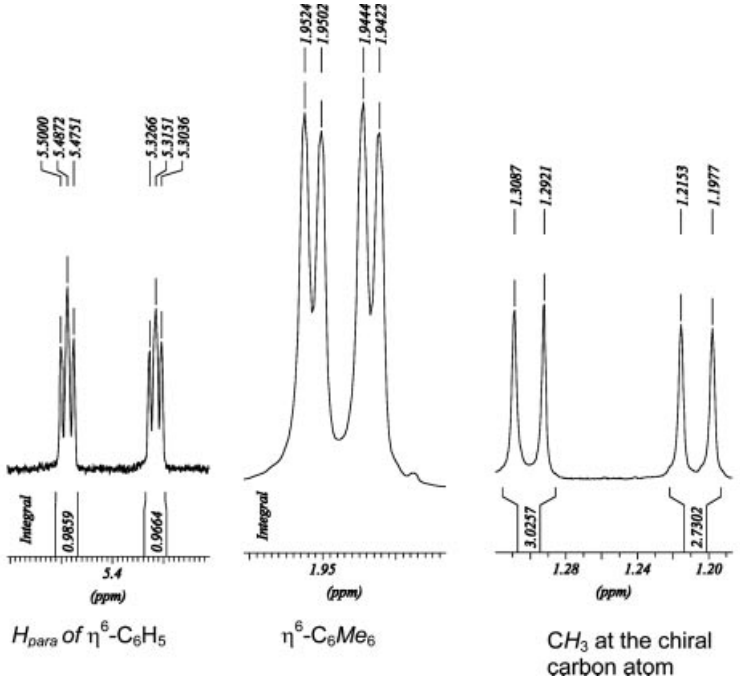

Figure 12. Selected $^1$H NMR signals ([$D_6$] acetone) of the diastereomeric mixture of [**6**][$BF_4$].

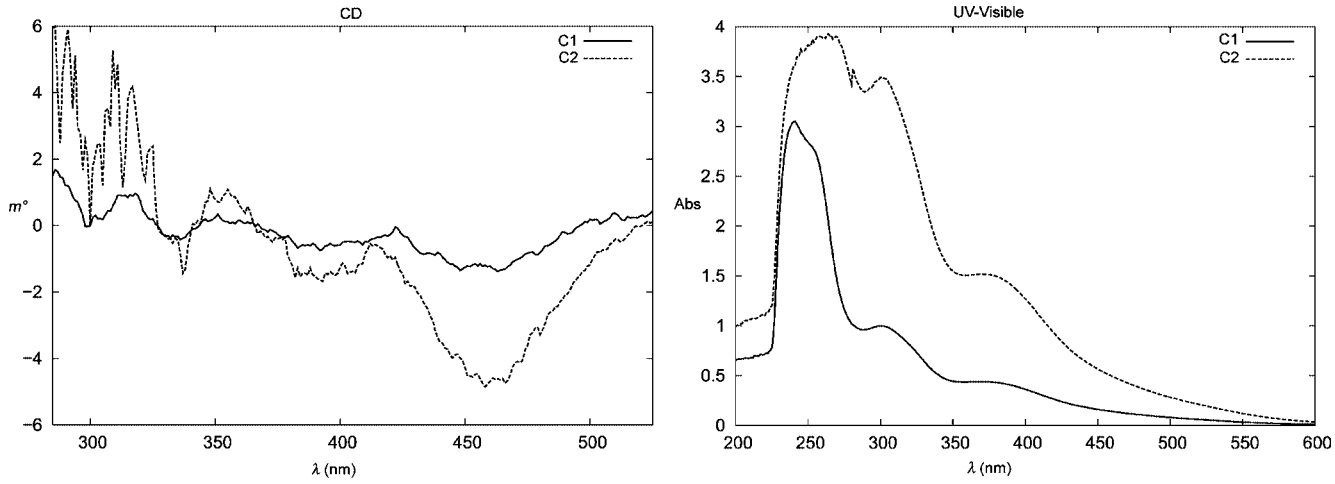

Figure 13. CD and UV/Vis spectra of [**6**][$BF_4$] at two different concentrations ($c_1 = 5.86 \times 10^{-4}$ M, $c_2 = 2.05 \times 10^{-3}$ M).

centers are bridged by a tethered phosphanido and two bromido ligands (Figure 10). The Ru–Br bond lengths (average 2.572 Å) and the Ru–Br–Ru angles (average 82.15°) are similar to those found in [**3**][$BF_4$]. Similarly, the Ru–Ru distances [identical at 3.380(2) Å] are similar to those observed in [**3**][$BF_4$]. The two $\eta^6$-arene ligands are almost parallel to each other in both molecules, with an angle between the two aromatic planes of 10.2(4)° for the ($R_C$,$S_P$) and 12.1(4)° for the ($R_C$,$R_P$) isomer. Replacement of the *p*-cymene ligand by a phenyl ring at the pendant arm of the phosphanido ligand in [**6**][$BF_4$] generates a six-membered metallacycle upon coordination. Surprisingly, two conformations are observed for the six-membered metallacycle, a chair-like ($R_C$,$S_P$) and a half-twist-like ($R_C$,$R_P$) conformation for the diastereomers of **6** (Figure 11).[19]

The two diastereomers ($R_C$,$S_P$)-**6** and ($R_C$,$R_P$)-**6** are distinguishable in the $^1$H NMR spectrum, which shows two doublets of almost equal intensity for the $\eta^6$-$C_6Me_6$ protons at $\delta$ = 1.95 and 1.94 ppm. As in **3**, the $^4J_{P,H}$ coupling (0.9 Hz) is also observable for the methyl protons of the $\eta^6$-$C_6Me_6$ ligand in **6** since the two arene ligands in this complex are almost parallel to each other. Accordingly, two signals are observed for the *para* protons of the $\eta^6$-$C_6H_5$ ligand [$\delta$ = 5.48 (t) and 5.31 ppm (t)] and for the methyl substituent at the stereogenic carbon atom [$\delta$ = 1.29 (d) and 1.20 (d) ppm]. The integration of the $^1$H NMR signals suggests that both diastereomers are present in almost equal quantities, with a slight excess of one (52:48; Figure 12). This diastereoselectivity (*de* = 4%) was confirmed by circular dichroism: The CD spectrum of [**6**][$BF_4$] in dichloromethane, recorded at two different concentrations, indeed shows a small concentration-dependent CD signal centered at 460 nm (Figure 13).

## Conclusions

We have synthesized several chiral-at-phosphorus phosphanidodiruthenium complexes and shown that an intramolecular ligand exchange between one arene ligand at the ruthenium atom and a phenyl substituent in the side-arm of the phosphanido bridge leads to chiral tethered derivatives. Introduction of a stereogenic carbon atom in the pendant arm of the phosphanido bridging ligand gives rise to the formation of diastereomeric complexes.

## Experimental Section

**General Remarks:** All manipulations were carried out under nitrogen using standard Schlenk techniques. All solvents were degassed with nitrogen prior to use. The silica gel (type G) used for preparative thin-layer chromatography was purchased from Macherey–Nagel GmbH. The phosphanes were synthesized according to previously described methods.[5,8c] The starting compounds [($\eta^6$-$C_6Me_6$)($\eta^6$-*p*-*i*PrMe$C_6H_4$)$Ru_2$($\mu_2$-H)$_3$][$BF_4$][13] and [($C_6Me_6$)$_2Ru_2$($\mu_2$-H)$_3$][$BF_4$][20] were synthesized according to previously described methods. Bromobenzene (puriss.) was purchased from Fluka, stored under nitrogen, and dried with molecular sieves (4 Å). Deuterated NMR solvents were purchased from Cambridge Isotope Laboratories, Inc. NMR spectra were recorded with a Bruker 400 MHz spectrometer. Mass spectra were recorded by Prof. Titus Jenny at the University of Fribourg. Microanalyses were carried out in the Laboratory of Pharmaceutical Chemistry at the University of Geneva.

**Synthesis of [($\eta^6$-$C_6Me_6$)($\eta^6$-*p*-*i*PrMe$C_6H_4$)$Ru_2${$\mu_2$-PPh($CH_2$)$_3$Ph}-($\mu_2$-H)$_2$][$BF_4$] [1][$BF_4$]:** [($\eta^6$-$C_6Me_6$)($\eta^6$-*p*-*i*PrMe$C_6H_4$)$Ru_2$($\mu_2$-H)$_3$]-[$BF_4$] (230 mg, 0.39 mmol) was dissolved in dichloromethane (250 mL) in a pressure Schlenk tube and the phosphane $PPh_2$-($CH_2$)$_3$Ph (178 mg, 0.58 mmol) was added. The solution was then flushed and pressurized with hydrogen (3 bar) and stirred at 55 °C under hydrogen pressure for 18 h. After cooling to room temperature, the solvent was evaporated to dryness and the brown product obtained was purified by preparative thin-layer chromatography on silica gel (acetone/dichloromethane, 1:10). The product was extracted from the silica with acetone from the brown band, and evaporation of the solvent gave the pure product (yield: 38%, 120 mg, 0.15 mmol). $^1$H NMR (400 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 7.32–7.20 (m, 8 H, *H*-Ph), 7.04 (m, 2 H, *H*-Ph), 6.03 (t, $^3J_{H,H}$ = 5 Hz, 2 H, *H*-Ar *p*-cymene), 5.72 (d, $^3J_{H,H}$ = 5.9 Hz, 1 H, *H*-Ar *p*-cymene), 5.65 (d, $^3J_{H,H}$ = 6.2 Hz, 1 H, *H*-Ar *p*-cymene), 2.73 (m, 2 H, PPhC$H_2$C$H_2$C$H_2$Ph), 2.57 (m, 3 H, *H*-*i*Pr, PPhC$H_2$C$H_2$C$H_2$Ph), 2.11 [s, 18 H, $C_6$(Me)$_6$], 2.02 (s, 3 H,

**Synthesis of [($\eta^6$-$C_6Me_6$)$_2$Ru$_2${$\mu_2$-PPh(CH$_2$)$_3$Ph}($\mu_2$-H)$_2$][BF$_4$] [2][BF$_4$]:** [($\eta^6$-$C_6Me_6$)$_2$Ru$_2$($\mu_2$-H)$_3$][BF$_4$] (150 mg, 0.24 mmol) was dissolved in dichloromethane (200 mL) in a pressure Schlenk tube and the phosphane $PPh_2(CH_2)_3Ph$ (93 mg, 0.30 mmol) was added. The solution was then flushed and pressurized with hydrogen (3 bar) and stirred at 55 °C under hydrogen pressure for 18 h. After cooling to room temperature, the solvent was evaporated to dryness and the brown product obtained was purified by preparative thin-layer chromatography on silica gel (acetone/dichloromethane, 1:10). The product was extracted with acetone from the brown band, and evaporation of the solvent gave the pure product (yield: 85%, 172 mg, 0.20 mmol). Crystals suitable for X-ray structure analysis were obtained by diffusion of diethyl ether into a concentrated dichloromethane solution of [**2**][BF$_4$]. $^1H$ NMR (400 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 7.38–7.20 (m, 8 H, *H*-Ph), 6.95 (m, 2 H, *H*-Ph), 2.78 (t, $^3J_{H,H}$ = 7.4 Hz, 2 H, $PPhCH_2CH_2CH_2Ph$), 2.55 (m, 2 H, $PPhCH_2CH_2CH_2Ph$), 2.17 [s, 18 H, $C_6(CH_3)_6$], 0.86 (m, 2 H, $PPhCH_2CH_2CH_2Ph$), –15.18 (dd, $^2J_{H,H}$ = 3, $^2J_{H,P}$ = 28 Hz, 1 H, hydride), –16.50 (dd, $^2J_{H,H}$ = 3, $^2J_{H,P}$ = 30 Hz, 1 H, hydride) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 142.4 (*C*-Ar), 132.1 (*C*-Ar), 132.0 (*C*-Ar), 128.9 (*C*-Ar), 128.8 (*C*-Ar), 128.0 (*C*-Ar), 127.9 (*C*-Ar), 126.3 (*C*-Ar), 96.9 [$C_6$(Me)$_6$], 36.7 (d, $J_{C,P}$ = 20 Hz, $CH_2$), 31.8 ($CH_2$), 31.52 (d, $J_{C,P}$ = 12 Hz, $CH_2$), 17.4 [$C_6(CH_3)_6$] ppm. $^{31}P\{^1H\}$ NMR (160 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 101.73 (s) ppm. MS (ESI): *m*/*z* 756 $[M + H]^+$. $C_{39}H_{56}BF_4PRu_2$ (844.78): calcd. C 55.45, H 6.68; found C 55.39, H 6.61.

**Synthesis of [($\eta^6$-$C_6Me_6$)Ru$_2${$\mu_2$-PPh(CH$_2$)$_3$-$\eta^6$-Ph}($\mu_2$-Br)$_2$][BF$_4$] [3][BF$_4$]:** [($\eta^6$-$C_6Me_6$)($\eta^6$-*p*-*i*PrMe$C_6H_4$)Ru$_2${$\mu_2$-PPh(CH$_2$)$_3$Ph}($\mu_2$-H)$_2$][BF$_4$] (120 mg, 0.15 mmol) was dissolved in bromobenzene (25 mL) that had been dried with molecular sieves (4 Å) and saturated with nitrogen prior to use. The solution was heated at 150 °C for 20 h. After cooling to room temperature, the solvent was evaporated to dryness in a trap-to-trap apparatus. The brown-red product obtained was purified by preparative thin-layer chromatography on silica gel (acetone/dichloromethane, 1:10). The product was extracted with acetone from the lowest major orange band ($R_f$ = 0.4). Evaporation of the solvent gave the pure product (yield: 30%, 38 mg, 0.045 mmol). Crystals suitable for X-ray structure analysis were obtained by slow diffusion of diethyl ether into a concentrated acetone solution of [**3**][BF$_4$]. $^1H$ NMR (400 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 7.96 (br., 2 H, P-*Ph*), 7.53 (m, 3 H, P-*Ph*), 6.25 (m, 2 H, *H-ortho* $\eta^6$-*Ph*), 5.43 (t, $^3J_{H,H}$ = 4.8 Hz, 1 H, *H-para* $\eta^6$-*Ph*), 5.04 (m, 2 H, *H-meta* $\eta^6$-*Ph*), 3.44 (m, 1 H, $CH_2$), 3.05 (td, $^3J_{H,H}$ = 3.7, $^2J_{H,H}$ = 15.3 Hz, 1 H, $CH_2$), 2.58 (m, 1 H, $CH_2$), 2.38 (m, 1 H, $CH_2$), 1.98 (m, 1 H, $CH_2$), 1.94 [d, $^4J_{P,H}$ = 1 Hz, 18 H, $C_6(CH_3)_6$], 1.40 (m, 1 H, $CH_2$) ppm. $^{13}C\{^1H\}$ NMR (100 MHz, [D$_6$]acetone, 25 °C): $\delta$ = 136.6 (P-*Ph*), 136.4 (P-*Ph*), 130.6 (P-*Ph*), 130.6 (P-*Ph*), 129.2 (P-*Ph*), 129.1 (P-*Ph*), 99.2 ($\eta^6$-*Ph*), 94.9 ($\eta^6$-*Ph*), 93.8 [$C_6(CH_3)_6$], 84.9 ($\eta^6$-*Ph*), 82.0 ($\eta^6$-*Ph*), 81.7 ($\eta^6$-*Ph*), 72.5 ($\eta^6$-*Ph*), 30.2 (d, $J_{C,P}$ = 33 Hz, $CH_2$), 24.5 (d, $J_{C,P}$ = 7 Hz, $CH_2$), 20.2 (d, $J_{C,P}$ = 16 Hz, $CH_2$), 15.3 [$C_6(CH_3)_6$] ppm. $^{31}P\{^1H\}$ NMR (160 MHz, [D$_6$]acetone, 25 °C): $\delta$ = –14.53 (s) ppm. **X-ray Crystallographic Study:** Crystals of [**2**][$BF_4$]·0.5$CH_2Cl_2$, [**3**][$BF_4$], [**5**][$BF_4$], and [**6**][$BF_4$]·$(CH_3)_2CO$ were mounted individually on a Stoe Image Plate Diffraction system equipped with a φ circle goniometer, using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data were collected in the φ range 0–200°, with increments of 1.2°, 1.5°, 1.0° and 1.0°, respectively, in the 2$\theta$ range from 2.0–26° ($D_{max}$–$D_{min}$ = 12.45–0.81 Å). The structures were solved by direct methods using the program SHELXS-97.[21] Refinement and all further calculations were carried out using SHELXL-97.[22] The H atoms were included in calculated positions and treated as riding atoms using the SHELXL default parameters in all cases. The non-H atoms were refined anisotropically, using weighted full-matrix least squares on $F^2$. Crystallographic details are summarized in Table 1. Figures 2, 5, 7, and 10 were drawn with ORTEP,[23] while Figures 3, 6, and 11 were produced with the program MERCURY.[24] CCDC-629980 ([**2**][$BF_4$]·0.5$CH_2Cl_2$), -629981 ([**3**][$BF_4$]), -629982 ([**5**][$BF_4$]), and -629983 {[**6**][$BF_4$]·$(CH_3)_2CO$} contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

Financial support from the Fond National Suisse de la Recherche Scientifique is gratefully acknowledged. The authors are also indebted to the Johnson Mathey Technology Centre for a loan of ruthenium trichloride hydrate and to Professor H. Stoeckli-Evans for free access to X-ray facilities.

# Coordinated 1,3-Diyne Diols as Organometallic Building Blocks for Large Macrocycles Containing Oxygen and Unsaturated Donor Units

**Louisa J. Hope-Weeks,*[a] Martin J. Mays,[b] and Gregory A. Solan*[c]**

**Keywords:** Macrocycles / Cobalt complexes / Oxygen / Alkynes / Nicholas reaction

The acid-catalysed reaction of [{$Co_2(CO)_6$(μ-η²-$HOCH_2C_2$-)}$_2$] (**1a**) with a range of alkyl diols has been examined as means of preparing large crown-type macrocycles (up to twenty eight-membered) containing at least one coordinated 1,3-diyne unit, multiple oxygen atoms and a variety of soft donor units. Thus, interaction of **1a** with $HOCH_2(CH_2)_nCH_2OH$, allows access to the monomeric cyclised complexes [{$Co_2(CO)_6$}$_2${*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2OCH_2(CH_2)_nCH_2O$}] (**3a**: $n = 2$, **3b**: $n = 3$, **3c**: $n = 4$) along with the dimeric cyclised species [{$Co_2(CO)_6$}$_2$-{*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2OCH_2(CH_2)_nCH_2O$}]$_2$ (**4a**: $n = 2$, **4b**: $n = 3$, **4c**: $n = 4$). Introduction of additional oxygen donor atoms into the macrocycle can be achieved by reaction of **1a** with the glycols, $HO(CH_2CH_2O)_nH$, to afford exclusively monomeric [{$Co_2(CO)_6$}$_2${*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2O(CH_2CH_2O)_n$}] (**5a**: $n = 3$, **5b**: $n = 4$). On the other hand, treatment of **1a** with the 1,3-diyne-linked alkyl diols, $HOCR_2C{\equiv}CC{\equiv}CCR_2OH$, furnishes the more rigid monomeric [{$Co_2(CO)_6$}$_2$-{*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2OCR_2C_2C_2CR_2O$}] [**6a**: R = H, **6b**: R = Me] and dimeric macrocycles [{$Co_2(CO)_6$}$_2$-{*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2OCR_2C_2C_2CR_2O$}]$_2$ [**7a**: R = H, **7b**: R = Me], whereas the use of the alkynyl- or aryl-linked alkyl diols, $HOCH_2(L)CH_2OH$, affords the unsymmetrical dimeric [{$Co_2(CO)_6$}$_2$-{*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2$}$_2$O{$OCH_2(L)CH_2O$}] [**8a**: L = –C≡C–, **8b**: L = 1,4-$C_6H_4$] and symmetrical dimeric species [{$Co_2(CO)_6$}$_2$-{*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2OCH_2(L)CH_2O$}]$_2$ [**9a**: L = –C≡C–, **9b**: L = 1,4-$C_6H_4$]. Also isolated as a by-product from all the above reactions is the self-dimerised macrocycle [{$Co_2(CO)_6$}$_2$-{*cyclo*-μ-η²:μ-η²-$CH_2C_2C_2CH_2O$}]$_2$ (**2**) which can itself be synthesised more directly by treating **1a** with catalytic quantities of $HBF_4{\cdot}OEt_2$. Single crystal X-ray diffraction studies have been performed on **2**, **3a**, **5a**, **7a**, **8a**, **8b** and **9a**.

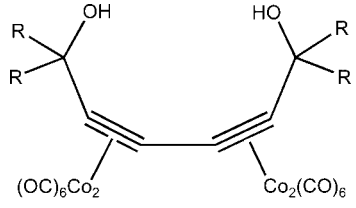
## Introduction

Recent years have seen a surge of interest in the application of the acid-catalysed Nicholas reaction (both intra- and intermolecular)[1] to promote the formation of both carbocyclic and heteroatom-containing medium to large ring systems.[1d,2–6,9–11] This can, in part, be attributed to the connection the resultant materials have to either natural products,[2,4] bio-inorganic hosts,[7] molecular sensors[7] or to nanomaterials.[8] With regard to intermolecular reactions, the reactivity of hexacarbonyldicobalt-coordinated monoyne diols, [{$Co_2(CO)_6$(μ-η²-$HOCR_2C{\equiv}CR_2OH$)}] (R = H, hydrocarbyl), towards a range of nucleophiles has been extensively investigated by Went and co-workers and allows access to a rich variety of medium to large macrocycles containing an assortment of donor functionalities.[3] On the other hand, the use of the more extended bis(hexacarbonyldicobalt)-coordinated diyne diols (and ethers) has received less attention with a few reports focusing on the reactivity of organo-linked diyne derivatives.[4–6] In our programme, we have found that the less flexible and conjugated 1,3-diyne diol, [{$Co_2(CO)_6$(μ-η²-$HOCH_2C_2$-)}$_2$] (**1a**, Figure 1), can also serve as a pre-organised building block for the assembly of ring systems including large thio- and mixed S,O-macrocycles.[9,10] Significantly, the use of the more bulky [{$Co_2(CO)_6$(μ-η²-$HOCMe_2C_2$-)}$_2$] (**1b**) inhibits an intermolecular reaction and instead generates a strained seven-membered ring carbocycle via an intramolecular pathway.[11]



R = H (**1a**), Me (**1b**)

Figure 1. Bis[$Co_2(CO)_6$]-coordinated diyne-diol **1**.

As an extension to our work in this area, we have been interested in employing the Nicholas reaction to generate crown-type macrocycles that can additionally incorporate soft donor groups such as 1,3-diynes, alkynes and aryls groups. To this end we have targeted a family of alkyl diols,

$HOCR_2$-linker-$CR_2OH$ (linker = alkyl, glycol, 1,3-diynyl, alkynyl, aryl; R = H, Me), as potential nucleophiles for the acid-catalysed reaction with the less sterically encumbered **1a**. Herein, we report full details of our findings from this study.

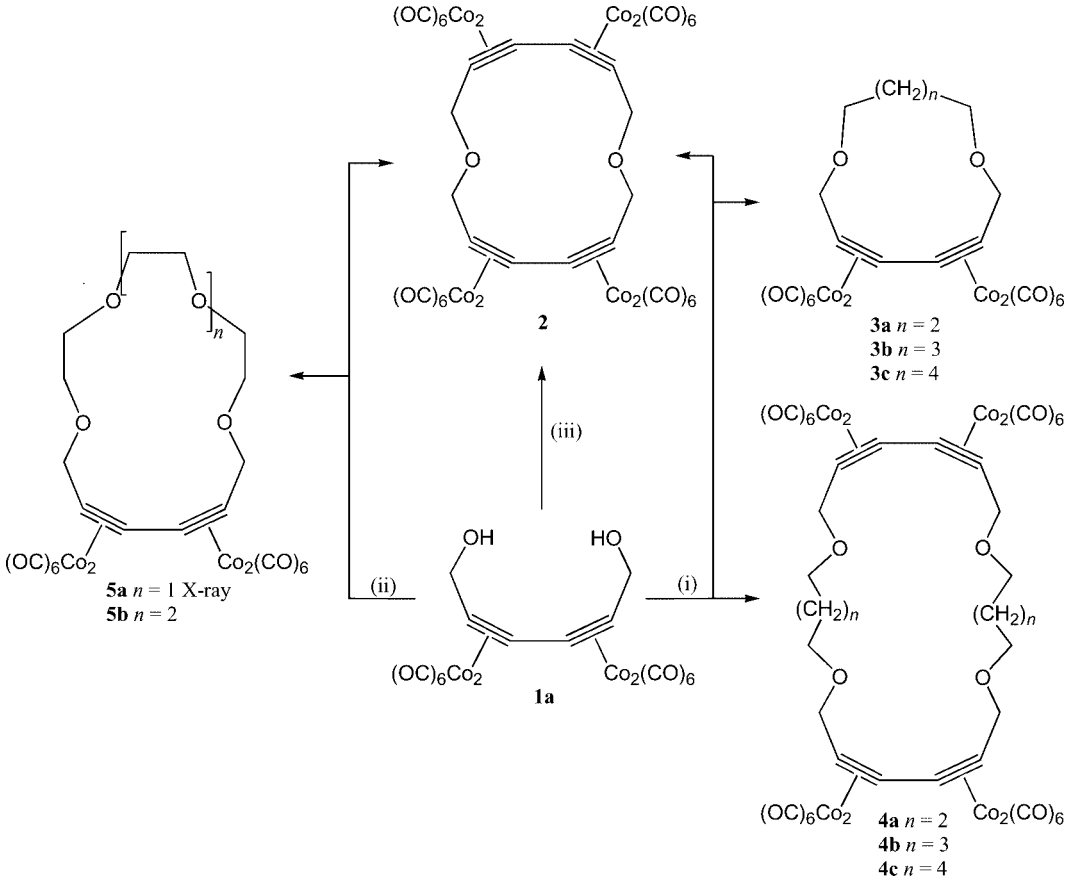
## Results and Discussion

### 1. Reactions of 1a with Alkyl Diols

The reaction of $[\{Co_2(CO)_6(\mu\text{-}\eta^2\text{-}HOCH_2C_2\text{-})\}_2]$ (**1a**) with one equivalent of $HOCH_2(CH_2)_nCH_2OH$ ($n$ = 2–4) in dichloromethane at –78 °C in the presence of $HBF_4{\cdot}OEt_2$ gave the self-dimerised product $[\{Co_2(CO)_6\}_2\{cyclo\text{-}\mu\text{-}\eta^2\text{:}\mu\text{-}\eta^2\text{-}CH_2C_2C_2CH_2O\}]_2$ (**2**), the monomeric cyclised complexes $[\{Co_2(CO)_6\}_2\{cyclo\text{-}\mu\text{-}\eta^2\text{:}\mu\text{-}\eta^2\text{-}CH_2C_2C_2CH_2OCH_2(CH_2)_nCH_2O\}]$ (**3a**: $n$ = 2, **3b**: $n$ = 3, **3c**: $n$ = 4) and the dimeric cyclised species $[\{Co_2(CO)_6\}_2\{cyclo\text{-}\mu\text{-}\eta^2\text{:}\mu\text{-}\eta^2\text{-}CH_2C_2C_2CH_2OCH_2(CH_2)_nCH_2O\}]_2$ (**4a**: $n$ = 2, **4b**: $n$ = 3, **4c**: $n$ = 4) in high combined yield (Scheme 1). Complex **2** can also be obtained by stirring **1a** in dichloromethane in the presence of $HBF_4{\cdot}OEt_2$. The complexes **2**–**4** have been characterised by FAB mass spectrometry and by $^1H$ and $^{13}C$ NMR and IR spectroscopy (see Table 1 and experimental section). Satisfactory microanalytical data were obtained for all complexes. In addition, the complexes **2** and **3a** have been the subject of single-crystal X-ray diffraction studies.

Suitable crystals of **2** and **3a** for the X-ray determination were grown from dichloromethane by slow diffusion of hexane at 0 °C. Perspective views of **2** and **3a** are depicted in Figures 2 and 3; selected bond lengths and angles are listed in Tables 2 and 3. The molecular structure of **2** contains a crystallographic centre of symmetry which lies at the midpoint of the C(18)–C(13A) and C(13)–C(18A) alkynic bonds. The structure itself is based on a fourteen-membered 1,8-dioxacyclotetradeca-3,5,10,12-tetrayne ring with the two diyne units each coordinated by two $Co_2(CO)_6$ units in an $\eta^2$:$\eta^2$ fashion. The $Co_2C_2$ cores adopt the expected tetrahedral arrangements with the bond parameters falling within the normal range.[12–14] Within each coordinated diyne unit the two $Co_2C_2$ units are disposed in a pseudo *cis* configuration [torsion angle C(16)–C(17)–C(18)–C(13A) 36.5°] with the C≡C–$CH_2$ *bend-back* angles[15] [C(15)–C(16)–C(17) 141.5(2), C(18A)–C(13)–C(14) 144.5(2)°] similar to those observed in related acyclic cobalt–alkyne complexes;[12,13] the mean C≡C–$CH_2$ angle is 141.31°.[16]

Complex **3a** crystallises with two discrete independent molecules (A and B in Table 3) within its asymmetric unit. The main difference between the two molecules is the presence of some disorder within the O(16)–C(17)–C(18)–C(19)



Scheme 1. Reagents and conditions; (i) $HOCH_2(CH_2)_nCH_2OH$, $HBF_4{\cdot}OEt_2$ (cat.), –78 °C, $CH_2Cl_2$; (ii) $HO(CH_2CH_2O)_nH$, $HBF_4{\cdot}OEt_2$ (cat.), –78 °C, $CH_2Cl_2$; (iii) $HBF_4{\cdot}OEt_2$ (cat.), –78 °C, $CH_2Cl_2$.

[a] $CH_2Cl_2$ solution, 0.5 mm NaCl cells. [b] $^1$H NMR chemical shifts in ppm relative to $SiMe_4$ ($\delta$ = 0.0 ppm), coupling constants in Hz in $CDCl_3$ at 293 K. [c] Calculated values shown in parentheses. [d] Calculated values include 0.5 hexane.

section of the ring in molecule A which is absent in B. The molecular structure consists of a twelve-membered 1,6-dioxacyclododeca-8,10-diyne macrocyclic ring with the diyne section coordinated by two $Co_2(CO)_6$ units and linked at each end by a $CH_2OCH_2CH_2CH_2CH_2OCH_2$ chain. The $Co_2C_2$ cores adopt the expected tetrahedral arrangements with the metal–metal bonds of each being located almost perpendicular to the corresponding alkyne vectors and their lengths falling in the expected ranges.[12–14] Inspection of the C≡C–C≡C torsion angle within the coordinated 1,3-diyne section of the macrocycle also reveals some differences between the independent molecules [torsion angle C(14)–C(13)–C(24)–C(23) 50.7° (molecule A), 44.2° (molecule B)] with the mean value ca. 11° larger than that in **2**. The *bend back* angles within and between molecules are similar [140.7(3), 140.2(3) (molecule A) vs. 138.6(3), 140.4(4)° (molecule B)] and as with **2** comparable with those found in related non-cyclic 1,3-diyne cobalt carbonyl complexes.[12,13]

The IR spectra of **2**–**4** reveal terminal carbonyl bands with patterns similar to that for **1a**[17] and to other bis(hexacarbonyldicobalt)-protected 1,3-diyne complexes.[13] In their FAB mass spectra, molecular ions are clearly visible along with fragmentation peaks corresponding to the loss of carbonyl groups from the corresponding molecular ion. In the $^1$H NMR spectra of **2**–**4**, the protons for the methylene groups adjacent to both an alkynic carbon atom and an oxygen atom are seen as singlets in the range $\delta$ = 4.57–4.93 while the aliphatic chain $CH_2$ groups in **3** and **4** are seen more upfield. Due to the high degree of symmetry as

well as the quadrupole broadening due to $^{59}$Co, the NMR spectroscopic data for monomeric **3** and its respective dimer **4** are virtually indistinguishable.

## 2. Reaction of 1a with Glycols

With the intent of introducing additional hard oxygen donor functionality into the macrocycle, the reaction of **1a** with two types of glycol was examined. Thus, treatment of **1a** with one equivalent of $HO(CH_2CH_2O)_nH$ ($n$ = 3, 4) in dichloromethane at –78 °C in the presence of $HBF_4{\cdot}OEt_2$ gave the monomeric cyclised complexes [$\{Co_2(CO)_6\}_2$-{*cyclo*-μ-η$^2$:μ-η$^2$-$CH_2C_2C_2CH_2O(CH_2CH_2O)_n$}] (**5a**: $n$ = 3, **5b**: $n$ = 4) in high yield (Scheme 1). As with the reactions of **1a** with $HO(CH_2)_nOH$ (vide supra), **2** was isolated as a minor by-product in each case. Both new complexes have been characterised by mass spectrometry and by $^1$H, $^{13}$C NMR and IR spectroscopy (see Table 1 and Experimental section). Satisfactory microanalytical data were obtained for both **5a** and **5b**. In addition, **5a** has been the subject of a single-crystal X-ray diffraction study.

Single crystals of **5a** suitable for the X-ray determination were grown from hexane by slow evaporation at 0 °C. A view of the structure is depicted in Figure 4; selected bond lengths and angles are given in Table 4. The structure consists of a sixteen-membered 1,4,7,10-tetraoxacyclohexadeca-12,14-diyne ring with the two methylene end groups of the coordinated $CH_2C{\equiv}C{-}C{\equiv}CCH_2$ moiety linked by a triethyleneglycol-derived tether. Within the $Co_2C_2$ tetrahedral cores there are no unusual structural features, with all bond lengths and angles falling in the expected ranges.[12–14] The relative disposition of the two $Co_2C_2$ fragments can be described as pseudo *cis* [torsion angle C(14)–C(15)–C(16)–C(17) 45.6°] while the two $CH_2$–C≡C *bend back* angles are comparable [C(13)–C(14)–C(15) 142.05(19) vs. C(16)–C(17)–C(18) 140.9(2)°]. An approximation of the cavity size can be made by studying the non-bonding oxygen–oxygen separations [O(13)···O(14) 2.916, O(13)···O(15) 4.730, O(13)···O(16) 5.240, O(14)···O(16) 4.800 Å] which can be compared to the non-bonding O–O separations of 4.362, 3.012 and 2.971 Å in 12-crown-4.[18]

The $^1$H NMR spectra of **5a** and **5b** are similar with the methylene protons on the $OCH_2$ groups adjacent to the alkynic carbons taking the form of a singlet at ca. 4.80 while the $OCH_2CH_2O$ protons are seen as multiplets in the range $\delta$ = 3.82–3.56. The $^{13}$C NMR spectra are also similar but differ with two resonances seen for the methylene carbons

in **5a** while four are present in **5b**. Confirmation of the monomeric nature of **5a** and **5b** is revealed in their FAB mass spectra with molecular ion peaks along with fragmentation peaks corresponding to the loss of carbonyl groups from the parent ion evident.

It is uncertain why an additional dimeric species is not formed in any of the reactions of **1a** with glycols in a manner similar to that seen for the reaction of **1a** with aliphatic diols (vide supra). It would seem likely that the presence of oxygen donors within the glycolic-based nucleophile could lead to a weak Co–O interaction in an intermediate (or transition state) which would favour monomeric ring closure. Indeed, such an Co–O interaction has previously been proposed to explain the high monomer to dimer ratio observed during the reaction of **1a** with dithioethers.[9b]

### 3. Reaction of 1a with Diynyl-, Alkynyl- or Aryl-Linked Alkyl Diols

In order to introduce a soft donor into the macrocycle we have also targeted the reactions of alkyl diols that contain alkynyl or aryl linking units. Accordingly, the reaction of **1a** with one equivalent of the 1,3-diyne-linked alkyl diols, $HOCR_2C{\equiv}CC{\equiv}CCR_2OH$, was initially examined and found to furnish, in addition to trace quantities of **2**, monomeric [$\{Co_2(CO)_6\}_2$-{*cyclo*-μ-$\eta^2$:μ-$\eta^2$-$CH_2C_2C_2CH_2OCR_2C_2C_2CR_2O$}] [**6a**: R = H, **6b**: R = Me] and dimeric macrocycles [$\{Co_2(CO)_6\}_2${*cyclo*-μ-$\eta^2$:μ-$\eta^2$-$CH_2C_2C_2CH_2OCR_2C_2C_2CR_2O$}]$_2$ [**7a** R = H, **7b** R = Me] in high combined yield (Scheme 2).

As with **3** and **4**, the similarity of the spectroscopic data for monomeric **6** with the corresponding dimeric **7** meant unequivocal identification by NMR and IR spectroscopy proved problematic (see Table 1). Nevertheless, the incorporation of the uncoordinated 1,3-diyne into the macrocycle could be confirmed by the presence of two different types of methylene protons in the $^1$H NMR spectra of **6a** and **7a**, while the equivalent methyl protons in **6b** and **7b** are seen as singlets (see Table 1). In the FAB mass spectra of **6** and **7**, however, the complexes could be readily distinguished, with molecular ion peaks corresponding to monomeric and dimeric species along with fragmentation peaks that match to the loss of twelve or twenty-four successive carbonyl groups, respectively.

In order to identify unambiguously the new complexes the structure of one such complex, **7a**, was determined by a single-crystal X-ray diffraction study. Suitable crystals for the study could be grown from dichloromethane by slow diffusion of hexane at 0 °C. Selected bond lengths and angles are given in Table 5 and a view of the molecular structure is depicted in Figure 5.

The molecular structure of **7a** sits on a crystallographic centre of symmetry which lies between the alkynic bonds C(13)–C(14A) and C(13A)–C(14). The structure confirms the molecule is comprised of four $Co_2(CO)_6$ units and is bridged by a twenty-eight-membered 1,8,15,22-tetraoxacycloicosaocta-3,5,10,12,17,19,24,26-octayne ring. The geometric parameters of the pseudo-tetrahedral $Co_2C_2$ cores are unexceptional. As expected the *bend back* angles for the non-coordinated diyne are close to one hundred and eighty degrees [C(18)–C(19)–C(20) 177.2(3), C(21)–C(22)–C(23) 173.4°] while the coordinated ones [C(15)–C(16)–C(17) 141.2(2), C(24)–C(13)–C(14A) 138.3(2)°] fall in a range similar to previously reported acyclic cobalt-bound diyne complexes.[12–14] The two uncoordinated diyne chains adopt a parallel relative conformation with the C(22) and C(22A) separation being 3.748 Å. Examination of the coordinated C≡C–C≡C torsion angles (40.2°) reveals the $Co_2C_2$ units to be disposed in a pseudo *cis* configuration.

The reaction of the shorter alkynyl- or aryl-linked alkyl diols, $HOCH_2(L)CH_2OH$ (L = –C≡C–, 1,4-$C_6H_4$) with **1a** has also been examined. Thus treatment of **1a** with one equivalent of $HOCH_2(L)CH_2OH$ (L = –C≡C–, 1,4-$C_6H_4$), in the presence of $HBF_4{\cdot}OEt_2$, affords the unsymmetrical dimeric [$\{Co_2(CO)_6\}_2${*cyclo*-μ-$\eta^2$:μ-$\eta^2$-$CH_2C_2C_2CH_2$}$_2$O-{$OCH_2(L)CH_2O$}] [**8a**: L = –C≡C–, **8b**: L = 1,4-$C_6H_4$] and symmetrical dimeric species [$\{Co_2(CO)_6\}_2${*cyclo*-μ-$\eta^2$:μ-$\eta^2$-$CH_2C_2C_2CH_2OCH_2(L)CH_2O$}]$_2$ [**9a**: L = –C≡C–, **9b**: L = 1,4-$C_6H_4$] in high combined yields (Scheme 2). Also isolated in trace quantities is the self-dimerised species **2** but there is no evidence for any monomeric species (cf. reactions of **1a** with diynyl-linked alkyl diols).

The FAB mass spectra of **8** and **9** give molecular ion peaks along with fragmentation peaks consistent with the proposed dimeric structures (see Table 1). In the IR spectra for **9** four terminal carbonyl bands are seen in a pattern similar to that observed for the other symmetrical monomeric (**3**, **5**, **6**) or dimeric (**2**, **4**, **7**) species prepared in this work. In the case of **8a** and **8b**, however, the terminal carbonyl regions are more complicated with greater than four bands evident and consistent with the dicobalt units now being in non-equivalent environments. The unsymmetrical nature of **8a** and **8b** is further supported by the $^1$H NMR spectra which show three singlets for the inequivalent methylene protons, this inequivalence also being reflected in the $^{13}$C NMR spectra with three singlets observed for the corresponding methylene carbon atoms.

[a] Atoms with suffix A are generated by symmetry ($-x + 1/2, -y + 1/2, -z$).

Confirmation of the proposed structural types was obtained from single-crystal X-ray diffraction studies that were performed on **8a**, **8b** and **9a**. Suitable crystals of each complex could be grown form dichloromethane solution by diffusion of hexane at 0 °C. Views of **8a**, **8b** and **9a** are shown in Figure 6, Figure 7 and Figure 8; selected bond lengths are angles are listed in Table 6, Table 7 and Table 8.

The molecular structure of **8a** sits on a crystallographic centre of symmetry which lies at the centre of O(13) and the mid-point of the C(21)···C(21A) and C(22)···C(22A) vectors within the phenyl ring; no such centre of symmetry is apparent in **8a**. The structures of **8a** and **8b** are similar and reveal nineteen- (**8a**) and twenty-one-membered (**8b**) macrocyclic rings with one methylene end-group in each $\{Co_2(CO)_6\}_2$(*cyclo*-μ-η$^2$:μ-η$^2$-$CH_2C_2C_2CH_2$) unit linked by an oxygen atom and the other by a $OCH_2C{\equiv}CH_2O$ (**8a**) or by a $OCH_2C_6H_4CH_2O$ (**8b**) moiety. The $Co_2C_2$ cores, as in related structures, adopt pseudo tetrahedral geometries with all bond lengths within the cores falling in the expected

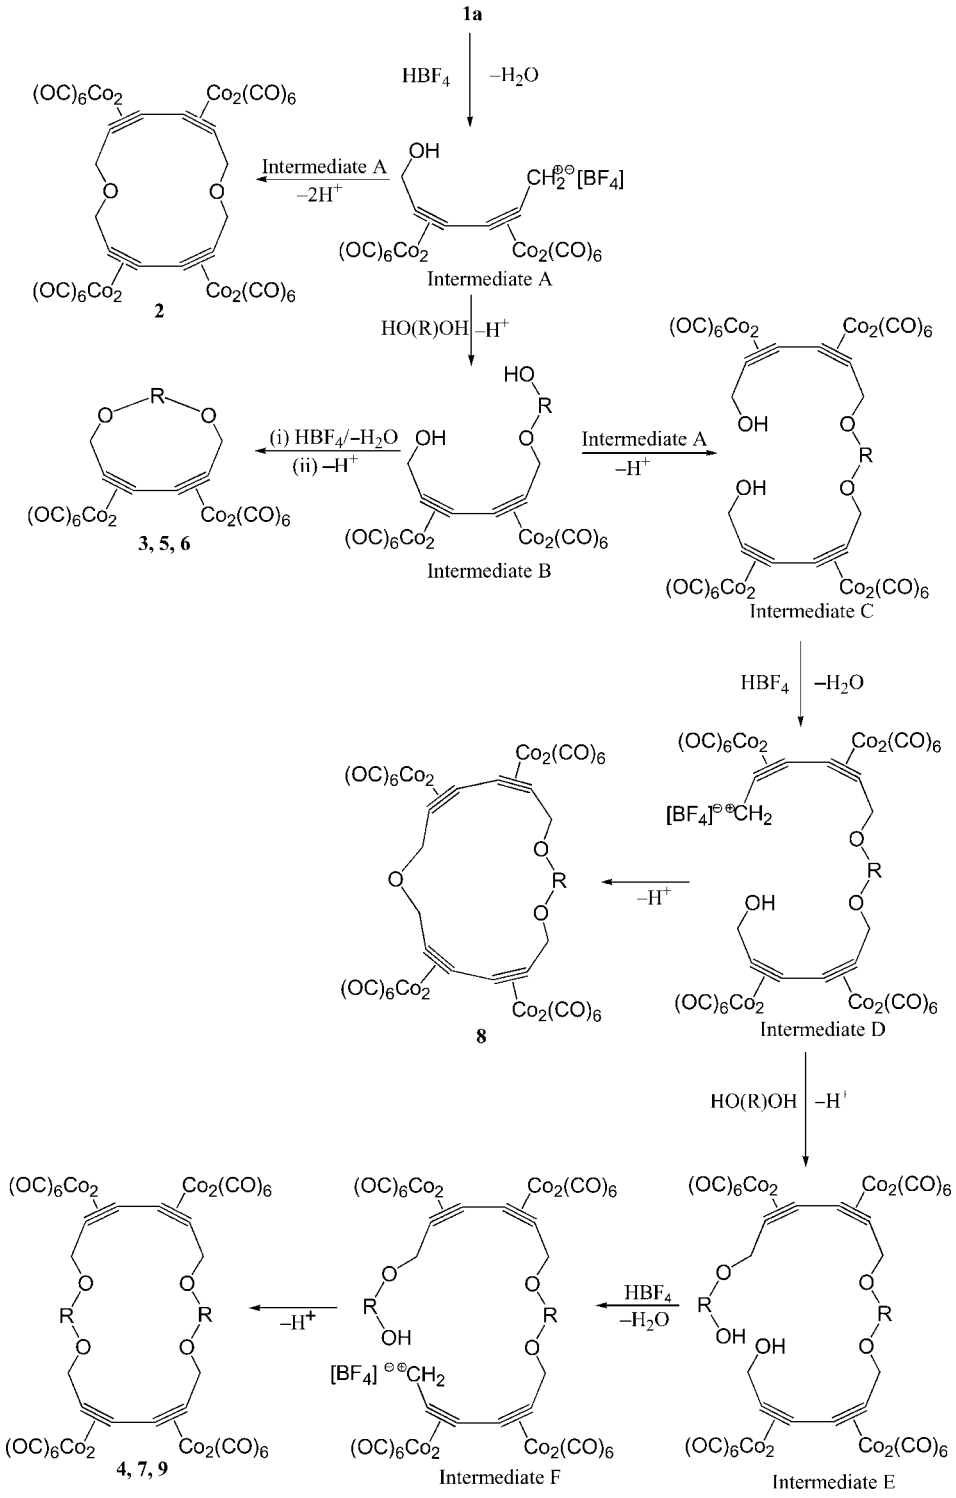
previous structures in this work the two $Co_2C_2$ units within each coordinated diyne are disposed in a pseudo *cis* configuration [torsion angle C(26)–C(27)–C(28)–C(29) 39.6°, C(32)–C(33)–C(34)–C(35) 46.0° (**8a**); C(14)–C(15)–C(16)–C(17) 47.8° (**8b**)].

As with **8b**, the molecular structure of **9a** sits on a crystallographic centre of symmetry which lies in this case between bonds C(13)–C(22A) and C(13A)–C(22). The structure comprises a twenty-four-membered 1,6,13,18-tetraoxacycloicosatetra-3,8,10,15,20,22-hexayne ring containing two uncoordinated alkyne moieties and two coordinated diyne groups. Within the $Co_2C_2$ tetrahedral cores there are no unusual features with all bond lengths and angles falling in the expected ranges.[12–14] In contrast to previous struc-



Scheme 3. Proposed pathway for the formation of **2**–**9** (R = linking unit).

tures determined in this work, the relative disposition of the two $Co_2C_2$ fragments on each diyne unit can be best described as pseudo *trans* [torsion angle C(13)–C(14)–C(15)–C(16) 101.7°] while the two $CH_2$–C≡C *bend back* angles are comparable [139.6(2) vs. 139.0(2)°].

The formation of the unsymmetrical complexes **8** was unexpected but could be used as some indirect evidence that the Nicholas reaction chemistry outlined here occurs via sequential functionalisation at the α carbon atoms and not by a dication (e.g., $[\{Co_2(CO)_6(\mu\text{-}\eta^2\text{-}CH_2C_2\text{-})\}_2]^{2+}$).[6d,17c,19] Indeed, we have shown elsewhere that a mono-functionalised derivative can be isolated on treatment of **1a** with PhSH which can in turn be converted to a di-functionalised derivative with the same or with a different thiol-based nucleophile.[20] With these observations in mind a possible pathway for the formation of the macrocyclic complexes **2**–**9** is shown in Scheme 3.

The initial step for all products proceeds by the formation of the propargylium monocation (intermediate A) when can then can either undergo nucleophilic attack with one end of the alkyl diol, HO(R)OH to form intermediate B or undergo self dimerisation to give **2**. Intermediate B can then follow one of two pathways; for complexes **3**, **5** and **6** the generation of the cationic species derived from B results in ring closure via an intramolecular reaction. The second pathway is for intermediate B to act as nucleophile and to react with A to form intermediate C. Intermediate C can then in turn follow, via cationic intermediate D, one of two pathways to afford unsymmetrical **8** or symmetrical **4**, **7** and **9**. It would seem likely that formation of **8** would be preferred with shorter chain R groups (i.e., $CH_2C{\equiv}CCH_2$ or $CH_2C_6H_4CH_2$) allowing closer proximity of the intramolecular reactive partners in D. Complexes **4**, **7** and **9** are formed when D elects to undergo intermolecular nucleophilic attack with HO(R)OH to give intermediate E. Ring closure is achieved by the intramolecular reaction resulting from generation of cationic intermediate F and nucleophilic attack by the remaining hydroxy group on the chain.

## 4. Conclusions

Our systematic study has showed that the alkyl diols, $HOCR_2$-linker-$CR_2OH$ (linker = alkyl, glycol, 1,3-diynyl, alkynyl, aryl; R = H, Me), can all act as effective nucleophiles on reaction with **1a** to generate crown-type macrocycles containing between and twelve and twenty eight atoms in high yields. In all cases the presence of trace quantities of the self-dimerised product **2** indicates a competitive reaction pathway that was not observed in our previous study of the reactions of thiol-based nucleophiles with **1a**.[9] The nature of the linker in the alkyl diol plays a key role in determining the monomer to dimer ratio, with monomeric **5** being uniquely favoured when **1a** is treated with glycols while with alkynyl- or aryl-linked alkyl diols solely the dimeric products **8**, **9** result; with alkyl- or 1,3-diyne-linked alkyl diols mixtures of both monomeric (**3**, **6**) and dimeric species (**4**, **7**) can be isolated. The identification of unsymmetrical dimeric species **8** when alkynyl- or aryl-linked alkyl diols nucleophiles are employed represents an unexpected observation.

## Experimental Section

**General Remarks:** Unless otherwise stated all experiments were carried out under dry, oxygen-free nitrogen, using standard Schlenk line techniques and solvents freshly distilled from appropriate drying agent.[21] NMR spectra were recorded in $CDCl_3$ with a Bruker DRX 400 spectrometer with TMS as an external standard for $^1H$ and $^{13}C$ spectra at ambient temperature. Infrared spectra were recorded in dichloromethane solution in 0.5-mm NaCl solution cells, with a Perkin–Elmer 1710 Fourier Transform Spectrometer. FAB (Fast atom bombardment) mass spectra were recorded with a Kratos MS 890 instrument using 3-nitrobenzyl alcohol as matrix. Elemental analyses were performed by the Microanalytical Department at the University of Cambridge. Preparative TLC was carried out on 1-mm silica plates prepared at the University of Cambridge. Column chromatography was performed on Kieselgel 60 (70–230 mesh ASTM). All products are listed in order of decreasing $R_f$. The reagents, 1,4-butanediol, 1,5-pentanediol, 1,6-hexanediol, triethylene glycol, tetraethylene glycol, tetrafluoroboric acid (54 wt.-% in diethyl ether), 1,4-benzenedimethanol, 2-butyne-1,4-diol, 2,4-hexadiyne-1,6-diol and 2,7-dimethyl-3,5-octadiyne-2,7-diol were obtained from Aldrich Chemical Co. and used without further purification. Complex $[\{Co_2(CO)_6(\mu\text{-}\eta^2\text{-}HOCH_2C_2\text{-})\}_2]$ (**1a**) was prepared by the literature method.[17]

**Reaction with $HOCH_2(CH_2)_2CH_2OH$:** Six drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HOCH_2(CH_2)_2CH_2OH$ (0.07 mL, 0.764 mmol) in dichloromethane (150 mL) at –78 °C. The solution was warmed to room temperature and after 6 h an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue taken up in hexane and the suspension filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.10 g, 10%) and **3a** (0.15 g, 28%). Further elution of the column with hexane/dichloromethane (6:1) yielded red crystalline **4a** (0.42 g, 39%). **Complex 2:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 199.4 (CO), 96.6 (C≡C), 72.4 ($OCH_2$) ppm. **Complex 3a:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 199.6 (CO), 92.6, 82.6 (C≡C), 72.3, 71.6 ($OCH_2$), 29.7 [$OCH_2(CH_2)_2CH_2O$] ppm. **Complex 4a:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 191.5, 189.8 (CO), 99.2 (C≡C), 71.3, 70.9 ($OCH_2$), 29.7, 26.8 [$OCH_2(CH_2)_2CH_2O$] ppm.

**Reaction with $HOCH_2(CH_2)_3CH_2OH$:** Six drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HOCH_2(CH_2)_3CH_2OH$ (0.08 mL, 0.763 mmol) in dichloromethane (150 mL) at –78 °C. The solution was warmed to room temperature and after 6 h an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue taken up in hexane and the suspension filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.05 g, 5%). Further elution of the column with hexane/dichloromethane (6:1) yielded red crystalline **3b** (0.15 g, 28%) and then with hexane/dichloromethane (4:1), orange crystalline **4b** (0.32 g, 29%). **Complex 3b:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ =

196.5 (CO), 98.8 (C≡C), 71.6, 69.8 ($OCH_2$), 26.7, 23.5 [$OCH_2(CH_2)_3CH_2O$] ppm. **Complex 4b:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 199.6 (CO), 94.3 (C≡C), 72.8, 71.4 ($OCH_2$), 24.3, 23.5 [$OCH_2(CH_2)_3CH_2O$] ppm.

**Reaction with $HOCH_2(CH_2)_4CH_2OH$:** Six drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HOCH_2(CH_2)_4CH_2OH$ (0.09 g, 0.762 mmol) in dichloromethane (150 mL) at –78 °C. The solution was warmed to room temperature and after 6 h an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue taken up in hexane and the suspension filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.10 g, 10%). Further elution of the column with hexane/dichloromethane (7:1) yielded red crystalline **3c** (0.31 g, 55%) and then with hexane/dichloromethane (4:1), orange crystalline **4c** (0.31 g, 28%). **Complex 3c:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): 198.9 (CO), 98.7 (C≡C), 71.3, 70.1 ($OCH_2$), 26.7 [$OCH_2(CH_2)_4CH_2O$]. **Complex 4c:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 198.9 (CO), 96.8 (C≡C), 74.2, 71.3 ($OCH_2$), 29.6, 25.9 [$OCH_2(CH_2)_4CH_2O$] ppm.

**Reaction with $HO(CH_2CH_2O)_3H$:** Four drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HO(CH_2CH_2O)_3H$ (0.10 mL, 0.749 mmol) in dichloromethane (150 mL) at –78 °C. The solution was warmed to room temperature and after 12 h an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue taken up in hexane and the suspension filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.05 g, 5%). Further elution of the column with dichloromethane yielded deep red crystalline **5a** (0.49 g, 83%). **Complex 5a:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 195.6 (CO), 101.2, 82.6 (C≡C), 72.4, 71.8 ($OCH_2$) ppm.

**Reaction with $HO(CH_2CH_2O)_4H$:** Four drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HO(CH_2CH_2O)_4H$ (0.13 mL, 0.753 mmol) in dichloromethane (150 mL) at –78 °C. The solution was warmed to room temperature and after 12 h an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue taken up in hexane and the suspension filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.10 g, 10%). Further elution of the column with dichloromethane afforded red crystalline **5b** (0.25 g, 40%). **Complex 5b:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 199.0 (CO), 98.8, 83.4 (C≡C), 72.0, 71.4, 71.0, 70.8 ($OCH_2$) ppm.

**Reaction with $HOCH_2C{\equiv}CC{\equiv}CCH_2OH$:** Six drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HOCH_2C{\equiv}CC{\equiv}CCH_2OH$ (0.080 g, 0.736 mmol) in dichloromethane (150 mL) at room temperature. After 16 h of stirring an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue taken up in hexane and the suspension filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.04 g, 4%). Further elution of the column with hexane/dichloromethane (3:1) gave deep red crystalline **6a** (0.18 g, 32%) and then with hexane/dichloromethane (2:1), deep red crystalline **7a** (0.18 g, 32%). **Complex 6a:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 194.3 (CO), 98.4, 91.2 (C≡C), 73.2, 71.2 ($OCH_2$) ppm. **Complex 7a:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 198.7 (CO), 101.2, 82.6 (C≡C), 74.6, 71.2 ($OCH_2$) ppm.

**Reaction with $HOC(Me)_2C{\equiv}CC{\equiv}CC(Me)_2OH$:** Six drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HOC(Me)_2C{\equiv}CC{\equiv}CC(Me)_2OH$ (0.081 g, 0.736 mmol) in dichloromethane (150 mL) at room temperature. After 16 h of stirring an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue taken up in hexane and the suspension filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.04 g, 4%). Further elution of the column with hexane/dichloromethane (4:1) gave red crystalline **6b** (0.16 g, 27%) and then with hexane/dichloromethane (2:1), orange crystalline **7b** (0.41 g, 34%). **Complex 6b:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 198.9 (CO), 96.4, 82.4 (C≡C), 72.6 [$OC(CH_3)_2$], 28.4 ($CH_3$) ppm. **Complex 7b:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 198.9 (CO), 98.6, 84.2 (C≡C), 72.5 [$OC(CH_3)_2$], 26.9 ($CH_3$) ppm.

**Reaction with $HOCH_2C{\equiv}CCH_2OH$:** Six drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HOCH_2C{\equiv}CCH_2OH$ (0.065 g, 0.755 mmol) in dichloromethane (150 mL) at room temperature. After 16 h of stirring an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue dissolved in hexane and the solution filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.04 g, 4%). Further elution of the column with hexane/dichloromethane (4:1) gave deep red crystalline **8a** (0.24 g, 23%) and then with hexane/dichloromethane (3:1), deep red crystalline **9a** (0.52 g, 48%). **Complex 8a:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 199.9 (CO), 104.2, 94.3, 89.6 (C≡C), 74.3, 72.4, 68.2 ($CH_2$) ppm. **Complex 9a:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 194.5 (CO), 94.2, 92.6 (C≡C), 74.8, 73.2 ($OCH_2$) ppm.

**Reaction with $HOCH_2(C_6H_4)CH_2OH$:** Six drops of $HBF_4{\cdot}OEt_2$ were added to a stirred solution of **1a** (0.50 g, 0.733 mmol) and $HOCH_2(C_6H_4)CH_2OH$ (0.11 g, 0.796 mmol) in dichloromethane (150 mL) at room temperature. After 16 h of stirring an excess of sodium hydrogen carbonate was added. All volatiles were removed on the rotary evaporator, the residue dissolved in hexane and the solution filtered through a plug of magnesium sulfate. The filtrate was adsorbed onto silica, the silica pumped dry and added to the top of a chromatography column. Elution with hexane/dichloromethane (8:1) afforded orange crystalline **2** (0.04 g, 4%). Further elution of the column with hexane/dichloromethane (4:1) yielded deep red crystalline **8b** (0.42 g, 40%) and then with hexane/dichloromethane (3:1), deep red crystalline **9b** (0.39 g, 34%). **Complex 8b:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 199.0 (CO), 137.7, 129.3 (Ph), 101.2, 97.9, 92.7 (C≡C), 73.7, 72.6, 71.7 ($OCH_2$) ppm. **Complex 9b:** $^{13}C\{^1H\}$ NMR ($CDCl_3$, 75 MHz): $\delta$ = 198.9 (CO), 137.6, 127.9 (Ph), 99.7, 92.7 (C≡C), 72.8, 70.6 ($OCH_2$) ppm.

**Crystallographic Studies:** Single crystal X-ray diffraction data for **2**, **3a**, **5a**, **7a**, **8a**, **8b** and **9a** were collected using a Nonius-Kappa CCD diffractometer, equipped with an Oxford Cryosystems cyrostream and employing Mo-$K_\alpha$ ($\lambda$ = 0.71073 Å) irradiation from a sealed tube X-ray source. Cell refinement, data collection and data

reduction were performed with the programs DENZO[22] and COLLECT[23] and multi-scan absorption corrections were applied to all intensity data with the program SORTAV.[24] All structures were solved and refined with the programs SHELXS97 and SHELXL97,[25] respectively. Hydrogen atoms were included in calculated positions (C–H = 0.96 Å) riding on the bonded atom with isotropic displacement parameters set to $1.5U_{eq}$(C) for methyl H atoms and $1.2U_{eq}$(C) for all other H atoms. Details of the data collection, refinement and crystal data are listed in Table 9.

CCDC-634737 (for **2**), -634738 (for **3a**), -634739 (for **5a**), -634740 (for **7a**), -63741 (for **8a**), -63743 (for **8b**) and -63742 (for **9a**) contain

# Platinum(II) Alkynyl Complexes Containing *N*- and *S*-Propargylated Ligands: Synthesis, Structures and Formation of $Pt^{II}/Ag^{I}$ Coordination Compounds

**Fabian Mohr,*[a,b] Aránzazu Mendía,*[b] and Mariano Laguna[c]**

**Keywords:** Platinum / Alkynes / Silver / Dimetallic / Coordination complexes

Alkylation of 2-hydroxypyridine, 2-pyridinethiol, 2-hydroxy-4-methylquinoline, phthalimide and pyrazole with propargyl bromide gave a series of alkynes in high yield. These alkynes were reacted with the chloroplatinum(II) compounds *trans*-$[PtCl_2(PPh_3)_2]$ and *cis*-$[PtCl_2(dppe)]$ to afford the respective *trans*- and *cis*-bis(alkynyl)platinum(II) complexes, which were characterised by spectroscopic analysis and by X-ray diffraction. The platinum(II) complexes containing the thiopyridyl- and pyrazolyl-substituted alkynes react with 1 or 2 equiv. of $[Ag(NO_3)(PPh_3)]$ to give dimetallic $Pt^{II}/Ag^{I}$ complexes.

## Introduction

Platinum(II) alkynyl complexes have been known for many years, but since the discovery of their luminescence and nonlinear optical (NLO) properties the field has experienced rapid growth.[1–5] Numerous platinum(II) alkynyl complexes have been synthesised by a variety of different routes and some complexes have been structurally characterised.[6,7] O-Propargylated compounds, in particular those derived from bisphenols, have been extensively used as C-donor ligands in the supramolecular assembly of gold(I) polymers, macrocycles and catenanes;[8–13] however, no examples of their use as ligands in other transition-metal complexes have been reported. Whereas the preparation, some organic transformations and applications of selected *N*-propargylated compounds have been published,[14–17] the organometallic chemistry of these species acting as C-donor ligands is a relatively unexplored field. Silver alkynyl complexes of various propargylamines have been used as alkyne transfer reagents in the synthesis of analogues of the opium derivative cotarnine.[18] Similarly, gold(I) phosphane complexes containing *N*-propargylphthalimide have been used to transfer the Au-phosphane moiety to tetra- and penta-iron clusters.[19] A series of alkynyl tin and silicon complexes containing C-coordinated *N*-propargylpyrazole have been prepared from the lithium salt.[20] Alkynyl complexes of mercury containing *N*-propargylated acridone are strongly fluorescent and have been used as sensitive sensors for the detection of organomercury compounds in water or biological systems.[21,22] *S*-Propargylated compounds are even less well-studied; their preparation and some organic chemistry of only a small number of compounds has been reported.[23,24] The only known example of a metal-containing derivative of an *S*-propargylated compound is the tin complex of propargylthiotriazole, which was patented as a fungicide.[25] In light of this lack of organometallic chemistry of *N*- and *S*-propargylated compounds, we wished to pursue our interest in metal alkynyl complexes[26–28] and the chemistry of platinum complexes with N,S-donor ligands[29] by preparing and structurally characterising some platinum(II) alkynyl complexes of various *N*- and *S*-propargylated compounds.

## Results and Discussion

The tautomerism of 2-hydroxypyridine has been studied both experimentally and computationally in great detail by various groups. Spectroscopic data indicates that the hydroxy form is the major tautomer in the gas phase.[30–32] In the solid state, however, the formation of hydrogen bonded dimers seems to favour the 2-pyridone tautomers.[33] Similarly, we found, by $^1H$ and $^{13}C$ NMR spectroscopy in acetone, that 2-hydroxypyridine and 2-pyridinethiol exist exclusively as the 2-pyridone and 2-pyridinethione tautomers, respectively. Upon reaction of these compounds with propargyl bromide in the presence of base in acetone, these two starting materials gave two different propargylated products. In the case of 2-hydroxypyridine, the *N*-propargylated product ($R^1CH_2C{\equiv}CH$) was obtained, whereas from 2-pyridinethiol the *S*-propargylated compound ($R^2CH_2C{\equiv}CH$)

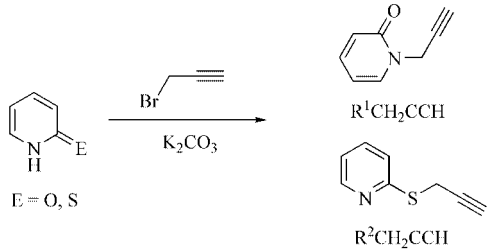
was isolated (Scheme 1). We calculated the relative energies of each of the four possible propargylated isomers using density functional theory (DFT) methods. In the case of 2-hydroxypyridine, the *N*-propargylated compound is 8.8 kcal/mol more stable than the O-propargylated tautomer. In contrast, for 2-pyridinethione the *S*-propargylated species is 2.5 kcal/mol more stable than the *N*-propargylated tautomer (Figure 1). These computational results are in agreement with our, and previously reported, experimental observations.[16,23] In addition to the two alkynes discussed above, the previously reported *N*-propargylated compounds derived from 2-hydroxy-4-methylquinoline,[14] phthalimide[17] and pyrazole[15] (designated as $R^nCH_2C{\equiv}CH$; $n$ = 3–5) were prepared similarly (Scheme 2). In our hands, the procedure using $K_2CO_3$ in acetone was much simpler in terms of work up (filtration and evaporation of acetone) than the previously described methods. *N*-Alkylation in $R^1CH_2CCH$ and $R^3CH_2CCH$ is evident from their NMR- (particularly $^{13}C$) and IR spectra. The methylene carbon signal in the $^{13}C$ NMR spectra of these two compounds is shifted by ca. 17 ppm downfield relative to that of the *S*-propargyl derivative $R^2CH_2CCH$. Similarly, although less pronounced, the $NCH_2$ proton signals of $R^1CH_2CCH$ and $R^3CH_2CCH$ are shifted ca. 2 ppm downfield relative to the $SCH_2$ resonance of $R^2CH_2CCH$, which is consistent with the difference in electronegativity of sulfur and nitrogen. Further evidence for *N*-propargylation is seen in the IR spectra of $R^1CH_2CCH$ and $R^3CH_2CCH$, which show strong C=O absorption bands.



Scheme 1.

These alkynes react with the dichloroplatinum(II) complexes *trans*-$[PtCl_2(PPh_3)_2]$ and *cis*-$[PtCl_2(dppe)]$ [dppe = $Ph_2P(CH_2)_2PPh_2$] in the presence of $Et_2NH$ and a catalytic amount of [CuI][34–36] to afford the air- and water-stable alkynyl platinum(II) complexes *trans*-$[Pt(C{\equiv}CCH_2R)_2(PPh_3)_2]$ ($R^1$ = **1**, $R^2$ = **3**, $R^3$ = **5**, $R^4$ = **7**, $R^5$ = **9**) and *cis*-$[Pt(C{\equiv}CCH_2R)_2(dppe)]$ ($R^1$ = **2**, $R^2$ = **4**, $R^3$ = **6**, $R^4$ = **8**, $R^5$ = **10**), respectively, in high yields (Scheme 3). Complexes **1**–**10** were characterised spectroscopically including $^1H$ and $^{31}P\{^1H\}$ NMR spectroscopy, mass spectrometry, IR spectroscopy and elemental analysis. The $^{31}P\{^1H\}$ NMR spectra of complexes **1**–**10** show sharp singlet resonances with Pt satellites having $J_{Pt-P}$ values of ca. 2600 and 2300 Hz for the *trans* and *cis* isomers, respectively, which indicates the presence of a single species in solution. In principle, there are two possible configurations of the R groups for all but complexes **7** and **8**, namely the *exo–exo* and *endo–exo* configurations as illustrated for complex **2** in Figure 2. The $^1H$

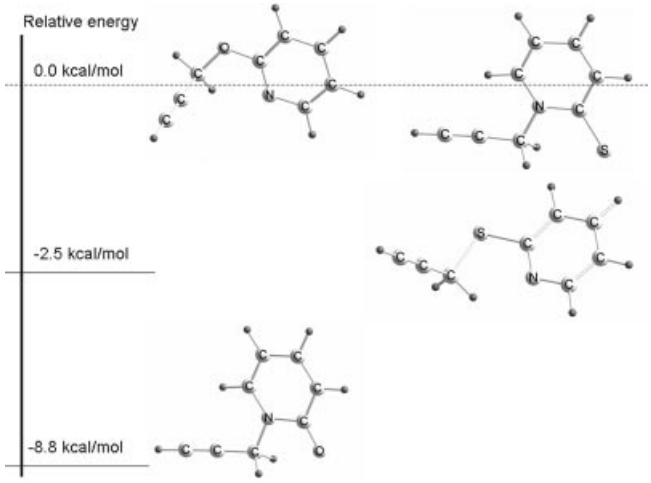


Figure 1. DFT optimised structures of the propargylated tautomers of 2-propargyloxypyridine and 2-propargylthiopyridine showing the energy differences between the two forms.

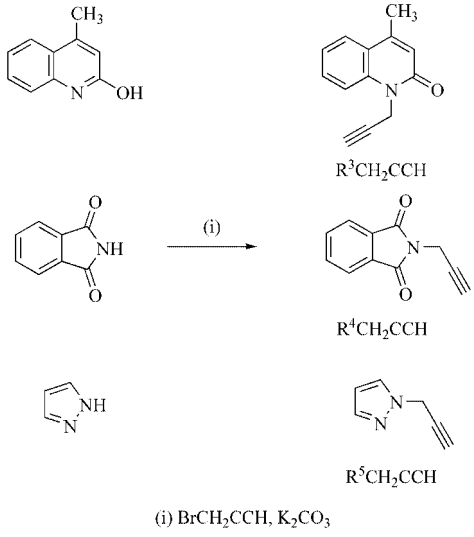

Scheme 2.

NMR spectrum of complex **2** in $CDCl_3$ at room temperature shows only one set of signals (doublets and triplets) for the R substituents, which indicates that rotation about the C–N bond is rapid in solution on the NMR timescale. Lowering the temperature to –80 °C has no effect on the appearance of the $^1H$ NMR spectrum, which suggests that any of the possible conformations rapidly interconvert in solution. In the solid-state structures, however, the *endo–exo* configuration is found. It is worth mentioning here that some of

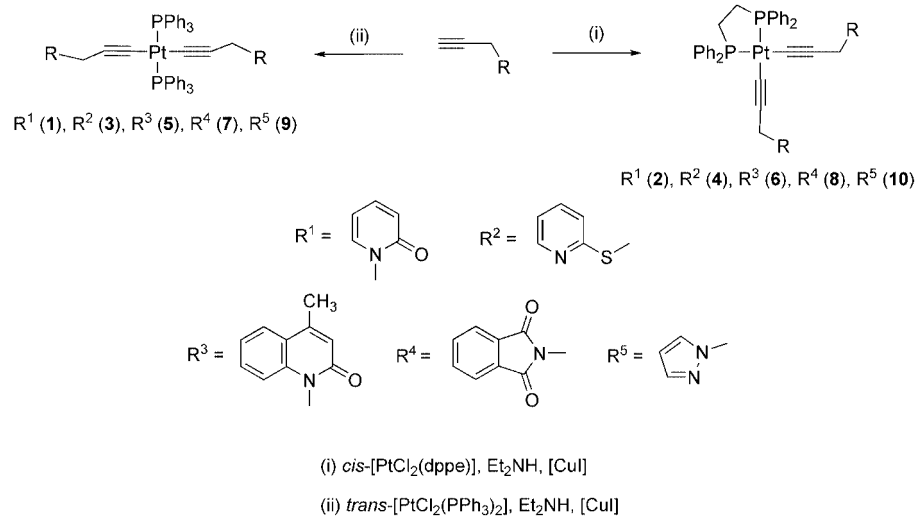

Scheme 3.

these complexes hold water tenaciously, as is evident from $H_2O$ signals in the $^1H$ NMR spectra and confirmed by elemental analysis. Even prolonged drying under high vacuum does not seem to remove this solvated water. The LSIMS mass spectra of all ten complexes show molecular ion peaks whose isotopic distributions match the expected patterns. The solid-state structures of the complexes *trans*-[Pt(C≡C$CH_2R^1$)$_2$($PPh_3$)$_2$] (**1**), *cis*-[Pt(C≡C$CH_2R^1$)$_2$(dppe)] (**2**), *trans*-[Pt(C≡C$CH_2R^3$)$_2$($PPh_3$)$_2$] (**5**), *trans*-[Pt(C≡C$CH_2R^5$)$_2$($PPh_3$)$_2$] (**9**) and *cis*-[Pt(C≡C$CH_2R^5$)$_2$(dppe)] (**10**) were determined by single-crystal X-ray diffraction. The molecular structure of **1** (Figure 3) consists of a platinum atom coordinated by two triphenylphosphane ligands and two acetylide molecules in a *trans* geometry. The coordination about the platinum atom is square planar, and the angle subtended at the Pt centre is 92.90(14)°. The Pt–C, Pt–P and C≡C bond lengths [1.998(5), 2.3163(12) and 1.201(7) Å, respectively] are very similar to those observed in other *trans*-bis(triphenylphosphane)platinum(II) acetylide complexes such as *trans*-[Pt(C≡C$C_6H_4$-4-$NH_2$)$_2$($PPh_3$)$_2$] [Pt–P = 2.310(1), Pt–C = 2.005(4) and C≡C = 1.206(6) Å][37] or *trans*-[Pt{C≡C$C_6H_4$-4-SC(O)Me}$_2$($PPh_3$)$_2$] [Pt–P = 2.3177(15), Pt–C = 2.027(6) and C≡C = 1.179(9) Å].[38] A unique feature of the solid-state structure of complex **1** is the presence of a hydrogen-bonding interaction between the alkyne ligand carbonyl group oxygen atom and a *meta* hydrogen of one of the $Ph_3P$ phenyl rings with a H···O=C distance of ca. 2.7 Å, a distance typically found in weak hydrogen-bonding interactions.[39] The molecular structure of *cis* complexes **2** (Figure 4) and **10** (Figure 5) consist of a distorted [P–Pt–C angle ca. 173°] square planar platinum centre to which one dppe unit and two C-bonded alkyne molecules are coordinated in a mutually *cis* arrangement. The Pt–C and Pt–P bond lengths (see Table 1) are similar to those of the *trans* derivative (see above) and also similar to other *cis* platinum alkynyl complexes including *cis*-[Pt(C≡CH)$_2$(dppe)] [Pt–C = 2.025(5), Pt–P = 2.2851(12) and C≡C = 1.164(8) Å][40] and *cis*-[Pt(C≡CC≡CH)$_2$(dppe)] [Pt–C = 2.20(1), Pt–P = 2.269(3) and C≡C = 1.218(6) Å].[41]

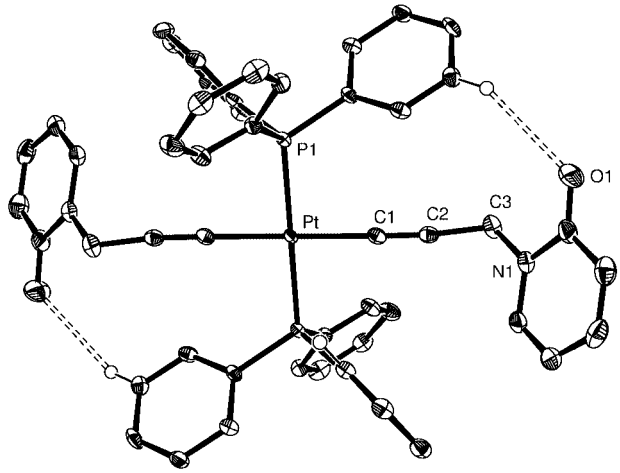

Figure 3. Molecular structure of *trans*-[Pt(C≡C$CH_2R^1$)$_2$($PPh_3$)$_2$] (**1**). Thermal ellipsoids show 50% probability levels. Hydrogen atoms (except those involved in H-bonding interactions) omitted for clarity.

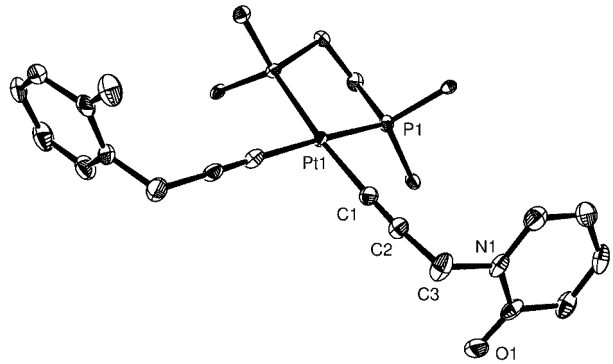

Figure 4. Molecular structure of *cis*-[Pt(C≡C$CH_2R^1$)$_2$(dppe)] (**2**). Thermal ellipsoids show 50% probability levels. Hydrogen atoms have been omitted for clarity and only the *ipso* carbon atoms of the phenyl groups are shown.

Table 1. Selected structural parameters for complexes **1**, **2**, **5**, **9** and **10**.

| | **1** | **2** | **5** | **9** | **10** |
|---|---|---|---|---|---|
| P–Pt–C angle [°] | 92.90(14) | 173.96(14) | 88.39(12) | 93.12(17) | 173.64(18), 174.7(2) |
| Pt–C [Å] | 1.998(5) | 2.018(5) | 2.013(4) | 2.006(6) | 2.046(8), 2.060(7) |
| Pt–P [Å] | 2.3163(14) | 2.2823(13) | 2.2872(13) | 2.2896(15) | 2.2802(18), 2.2807(17) |
| C≡C [Å] | 1.201(7) | 1.168(7) | 1.190(6) | 1.191(9) | 1.135(10), 1.114(9) |

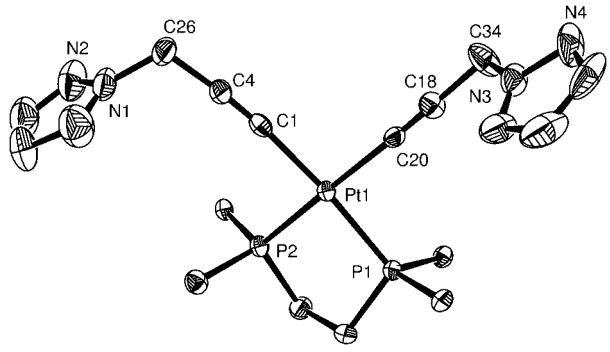

Figure 5. Molecular structure of *cis*-[Pt(C≡CCH$_2$R$^5$)$_2$(dppe)] (**10**). Thermal ellipsoids show 50% probability levels. Hydrogen atoms have been omitted for clarity and only the *ipso* carbon atoms of the phenyl groups are shown.

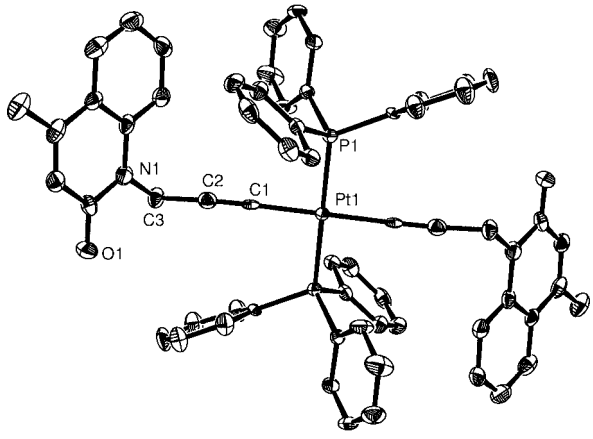

Figure 6. Molecular structure of *trans*-[Pt(C≡CCH$_2$R$^3$)$_2$(PPh$_3$)$_2$] (**5**). Thermal ellipsoids show 50% probability levels. Hydrogen atoms have been omitted for clarity.

As a consequence of the *trans* effect, the C≡C bond lengths in *cis* complexes **2** [1.1687(7) Å] and **10** [1.135(10) and 1.114(9) Å] are slightly shorter than those of the *trans* complexes. The other two *trans* complexes **5** (Figure 6) and **9** (Figure 7) are structurally very similar to complex **1**, although with slightly longer Pt–P distances. For comparison, important structural data for the *trans* and *cis* complexes is summarised in Table 1.

The platinum(II) complexes containing the alkynes R$^2$CH$_2$C≡CH and R$^5$CH$_2$C≡CH (**3**, **4**, **9** and **10**) possess an uncoordinated nitrogen atom which could allow theses compounds to act as organometallic ligands to give heterodimetallic species upon coordination to other metals. Indeed, *trans* complexes **3** and **9** react with 2 equiv. of [Ag-

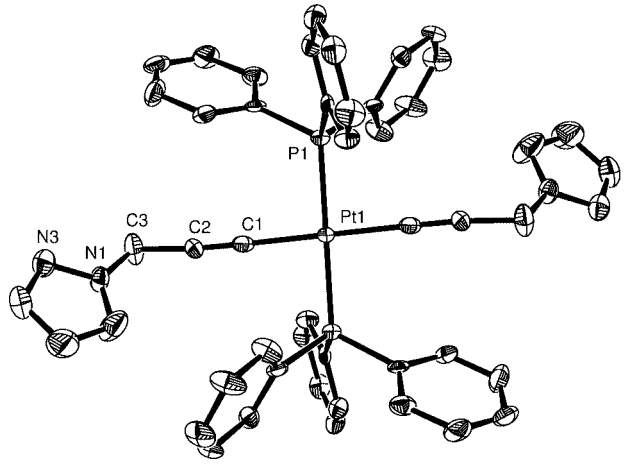

Figure 7. Molecular structure of *trans*-[Pt(C≡CCH$_2$R$^5$)$_2$(PPh$_3$)$_2$]·2CHCl$_3$ (**9**). Thermal ellipsoids show 50% probability levels. Hydrogen atoms and CHCl$_3$ of solvation have been omitted for clarity.

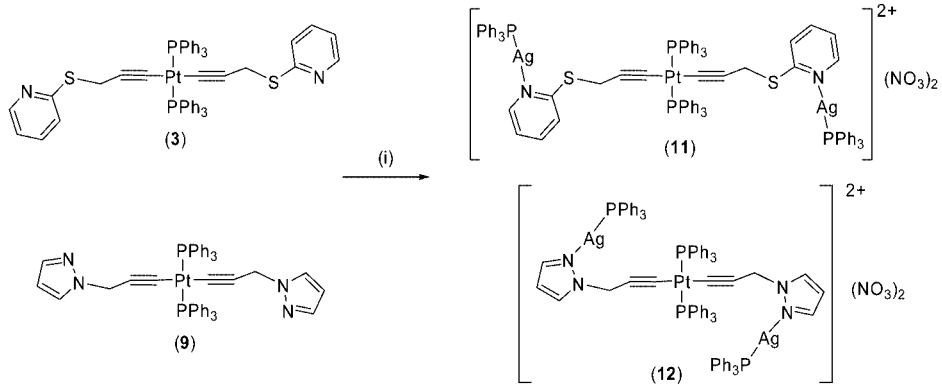

Scheme 4.

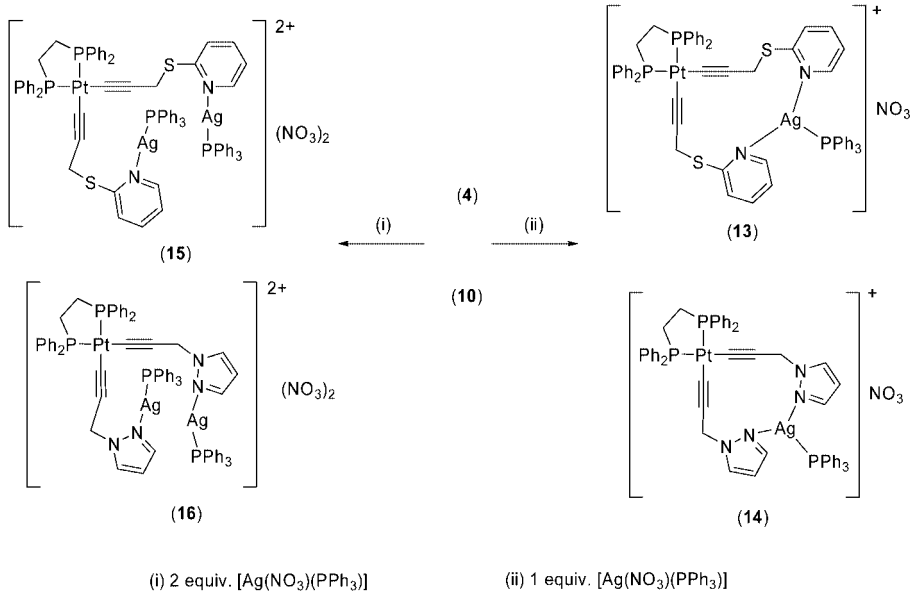
$(NO_3)(PPh_3)$] to give the cationic platinum(II)/silver(I) complexes *trans*-[Pt(C≡CCH$_2$R$^n$)$_2$($PPh_3$)$_2$($AgPPh_3$)$_2$]($NO_3$)$_2$ (*n* = 2, **11**; *n* = 5, **12**) (Scheme 4). The reaction of complexes **3** and **9** with only 1 equiv. of [Ag($NO_3$)$PPh_3$] gave mixtures of products which were not analysed further. NMR spectroscopic data of these mixtures seems to indicate the presence of both starting material (i.e. complex **3** or **9**) as well as dimetallic complexes **11** or **13**. Clearly, the *trans* geometry does not allow the system to bend in such a manner that a macrocyclic complex incorporating only one silver ion can be formed. Similarly, *cis* complexes **4** and **10** react with either 1 or 2 equiv. of the silver compound to give the heterodimetallic compounds *cis*-[Pt(C≡CCH$_2$R$^n$)$_2$(dppe)($AgPPh_3$)]$NO_3$ (*n* = 2, **13**; *n* = 5, **14**) or *cis*-[Pt(C≡CCH$_2$R$^n$)$_2$(dppe)($AgPPh_3$)$_2$]($NO_3$)$_2$ (*n* = 2, **15**; *n* = 5, **16**), respectively (Scheme 5). Complexes **11**–**16** were characterised spectroscopically; attempts to grow X-ray quality crystals so far have failed as the stability of these compounds in solution is limited. The $^{31}P\{^1H\}$ NMR spectra of complexes **11**–**16** consist of a singlet resonance with $^{195}Pt$ satellites due to the Pt–phosphane unit and, at room temperature, a very broad (almost invisible) signal for the Ag–$PPh_3$ moiety. At –80 °C, this broad signal is resolved into a pair of doublets arising from coupling of the phosphorus nucleus to both the $^{109}Ag$ and $^{107}Ag$ isotopomers (Figure 8). The $^{195}Pt$–$^{31}P$ coupling constants of dimetallic Pt/Ag macrocycles **13**–**14** are ca. 100 Hz larger than those of the "free-ligand" Pt complexes, consistent with a change of angle about the platinum centre



Scheme 5.

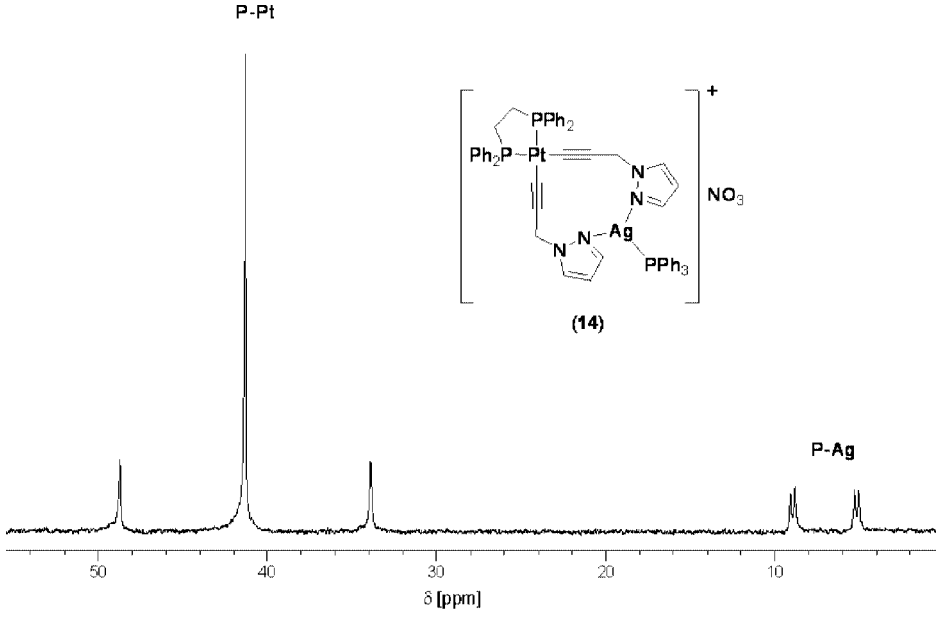


Figure 8. $^{31}P\{^1H\}$ NMR (162 MHz) spectrum of *cis*-[Pt(C≡CCH$_2$R$^5$)$_2$(dppe)($AgPPh_3$)]$NO_3$ (**14**) in $CD_2Cl_2$ at –80 °C.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

consistent with the expected "tweezer-motion" of the alkyne substituents to coordinate to the silver atom. The possibility that the silver ions are coordinated to the triple bond rather than the N atom can be disproved from the IR data; the C≡C stretching frequency of both the "free" and "coordinated" Pt complexes are almost identical. Complexes **11**–**16** represent examples of complexes in which an organometallic compound acts as metalloligand. Some examples of such metalloligands include the alkynyl gold(I) macrocycles and [2]catenanes containing pyridyl and bipyridyl backbones that are coordinated to a $Pt^{IV}$ centre,[42] the pyrazolyl- and pyridyl-substituted ferrocenes that are N-coordinated to various Au and Ag species,[43,44] the alkynyl-functionalised bis(pyrazolyl)methane derivatives containing Au/Pd and Pt/Pd[45] and various supramolecular assemblies based on the M–C≡C (4-$C_6H_4N$) (M = Pt, Ru) unit.[40,46–48]

## Conclusion

We have shown that various *N*- and *S*-propargylated compounds form platinum(II) alkynyl complexes in high yields and that these compounds can act as N-donor ligands to $Ag^{I}$ ions. In the case of *cis*-Pt complexes, dimetallic macrocycles are formed. Further work on the use of these organometallic ligands is currently in progress.

## Experimental Section

**General:** NMR spectra were recorded with a 400 MHz Varian Inova spectrometer. Chemical shifts are quoted relative to external TMS ($^1$H, $^{13}$C) or 85% $H_3PO_4$ ($^{31}$P). LSIMS mass spectra were measured with a Micromass Autospec spectrometer in positive ion mode by using NBA as matrix. IR spectra were recorded with a Nicolet Impact 410 instrument. Elemental analyses were obtained in-house by using a LECO CHNS-932 microanalyser. *N*-Propargyl-2-pyridone, 2-propargylthiopyridine, *N*-propargyl-4-methyl-2-quinolidone, *N*-propargylphthalimide and 2-propargylpyrazole were prepared by modified literature procedures.[14–17,23] Spectroscopic data of these alkynes is given here since only very few details have been previously reported. The $Pt^{II}$ phosphane complexes *trans*-[$PtCl_2(PPh_3)_2$] and *cis*-[$PtCl_2$(dppe)] were prepared by the reaction of [$PtCl_2(NCMe)_2$] with appropriate amounts of the phosphanes. The silver(I) complex [$Ag(NO_3)(PPh_3)$] was prepared by a literature procedure.[49] All other reagents and solvents were obtained commercially and used as received. DFT calculations were carried out with the PRIRODA software package incorporating relativistic Stevens, Basch, Krauss basis sets.[50,51] Geometries were fully optimised and the located minima were confirmed by the absence of imaginary frequencies.

**Preparation of the Alkynes:** A mixture of the appropriate NH or SH derivatives (2-pyridone, 2-hydroxy-4-methylquinoline, phthalimide and 2-pyridinethiol), $K_2CO_3$ (excess) and propargyl bromide (1.6 equiv.) was heated at reflux in acetone for ca. 8 h. The cooled mixture was filtered, and the filtrate was evaporated to dryness. The resulting crude products were purified by chromatography on silica gel using $CH_2Cl_2$ as eluent.

**Preparation of the [Pt(C≡CR)$_2$(P)] Complexes:** A mixture of the alkyne (0.228 mmol), [$PtCl_2$(P)] (0.098 mmol), [CuI] (5 mg) in $Et_2NH$ (5 mL) and EtOH (5 mL) was heated at reflux for ca. 1 h. The solid products were isolated by filtration, washed with $H_2O$, EtOH and $Et_2O$ and dried in vacuo.

***N*-Propargyl-2-pyridone (R$^1$CH$_2$C≡CH):** Yield: 2.10 g (75%), dark orange oil. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 2.27 (t, $J$ = 2.5 Hz, 1 H, ≡CH), 4.74 (d, $J$ = 2.5 Hz, 2 H, $NCH_2$), 6.22 (dt, $J$ = 6.6, 1.3 Hz, 1 H, H$^5$), 6.55 (dd, $J$ = 9.1, 0.8 Hz, 2 H, H$^3$), 7.33 (m, 1 H, H$^4$), 6.61 (ddd, $J$ = 6.8, 2.0, 0.5 Hz, 1 H, H$^6$) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 37.45 ($NCH_2$), 75.21 (C≡CH), 76.73 (C≡CH), 106.24 (C5), 120.32 (C3), 135.74 (C4), 139.68 (C6), 161.80 (C2) ppm.

***trans*-[Pt(C≡CR$^1$)$_2$(PPh$_3$)$_2$] (1):** Yield: 0.258 g (83%), pale brown solid. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 4.01 (t, $J$ = 1.8 Hz, 4 H, $NCH_2$), 5.61 (dt, $J$ = 6.8, 1.5 Hz, 2 H, H$^5$), 6.33 (ddd, $J$ = 8.8, 2.0, 0.5 Hz, 2 H, H$^3$), 6.88 (dd, $J$ = 6.8, 2.0 Hz, 2 H, H$^6$), 7.12 (dt, $J$ = 6.6, 2.0 Hz, 2 H, H$^4$), 7.31–7.44 (m, 18 H, *p*-, *m*-$Ph_3$P), 7.70–7.77 (m, 12 H, *o*-$Ph_3$P) ppm. $^{31}$P{$^1$H} NMR (162 MHz, $CDCl_3$): $\delta$ = 18.89 ($J_{Pt,P}$ = 2619 Hz) ppm. IR (KBr disk): $\tilde{\nu}$ = 2135 (C≡C), 1657 (C=O) cm$^{-1}$. FAB MS: $m/z$ = 984 [M + H]$^+$. $C_{52}H_{42}N_2O_2P_2Pt$ (983.9): calcd. C 63.48, H 4.30, N 2.85; found C 63.03, H 4.32, N 3.02. X-ray quality crystals were grown by slow diffusion of $Et_2O$ into a $CH_2Cl_2$ solution of the complex.

***cis*-[Pt(C≡CR$^1$)$_2$(dppe)] (2):** Yield: 0.242 g (75%), colourless solid. $^1$H NMR (400 MHz, $CDCl_3$): $\delta$ = 2.30–2.48 (m, 4 H, $PCH_2CH_2P$), 4.76 (t, $J$ = 6.6 Hz, 4 H, $NCH_2$), 5.81 (dt, $J$ = 6.6, 1.2 Hz, 2 H, H$^5$), 6.42 (d, $J$ = 8.6 Hz, 2 H, H$^3$), 7.19 (m, 2 H, H$^4$), 7.38–7.51 (m, 12 H, *p*-, *m*-$Ph_2$P), 7.80–7.88 (m, 8 H, *o*-$Ph_2$P), 7.89 (dd, $J$ = 7.0, 1.9 Hz, 2 H, H$^6$) ppm. $^{31}$P{$^1$H} NMR (162 MHz, $CDCl_3$): $\delta$ = 43.23 ($J_{Pt,P}$ = 2316 Hz) ppm. **X-ray Crystallography:** Crystals of complex **1** (colourless block, 0.09 × 0.12 × 0.21 mm), **2** (colourless block, 0.10 × 0.10 × 0.20 mm), **5** (yellow prism 0.10 × 0.20 × 0.20 mm), **9**·2CHCl$_3$ (colourless prism, 0.20 × 0.30 × 0.50 mm) and **10** (colourless prism, 0.60 × 0.10 × 0.10 mm) were mounted in oil on a glass fibre. Data was collected at 100 K (293 K for complex **10**) by using a Bruker Apex CCD diffractometer with graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data reduction and absorption corrections were applied by using SADABS.[52] The structures were solved by direct methods and refined to $F_o^2$ by using full-matrix least-squares.[53] All hydrogen atoms were placed in calculated positions and refined as riding on their respective carbon atoms. Crystallographic and refinement details are collected in Table 2.

CCDC-634848, -634849, -634850, -634851 and -634052 (for compounds **1**, **2**, **5**, **9** and **10**, respectively) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

## Acknowledgments

We wish to thank the Spanish Ministry for Education and Science, Junta de Castilla y León as well as the University of Burgos for generous financial support (grant numbers BQU2005-0899, BU033A06 and 112-541A-487.01). F. M. thanks the University of Burgos for a visiting fellowship.

# Substituent Effects on the Stereoelectronic and Chemical Properties of a Novel Phosphapalladacycle

Joseph Kok-Peng Ng,[a] Shuli Chen,[b] Geok-Kheng Tan,[a] and Pak-Hing Leung*[b]

**Keywords:** Palladium / Phosphane ligands / Chirality / NMR spectroscopy / Substituent effects

A novel phosphapalladacycle was prepared by direct cyclopalladation of the ligand (diphenylmethyl)diphenylphosphane (**2**). The corresponding μ-chloro five-membered phosphapalladacycle **3** was obtained by heating a toluene solution of **2** and $Pd(OAc)_2$ followed by chloride ion metathesis. An optical resolution procedure was then employed by separation of the (*S*)-prolinato derivatives **4** by fractional crystallization followed by treatment with dilute hydrochloric acid to yield both enantiopodes of the dimers **3** in the optically active forms. The current phosphapalladacycle was noted to display different properties with respect to the analogous phosphapalladacycle prepared from (diphenylmethyl)di-*tert*-butylphosphane. For instance, the phosphapalladacycle based on the (diphenylmethyl)di-*tert*-butylphosphane was shown to be conformationally rigid. In contrast, the analogous five-membered phosphapalladacycle of phosphane **2** was noted to exist in both the δ and λ conformations in the solid state, while a flattened conformation was observed in solution. In addition, the (diphenylmethyl)di-*tert*-butylphosphane-based phosphapalladacycle was noted to exhibit a much more improved regioselectivity towards ancillary ligands such as (*S*)-prolinate and triphenylphosphane than **2**. Furthermore, the μ-chloro dimer **3** of the current palladacycle was shown to be lacking in thermodynamic stability of the Pd–C bond that was noted for the *t*Bu analogue. In contrast, the Pd–C bonds of dimer **3** were immediately ruptured in the presence of concentrated HCl to give rise to the binuclear complex **5**, in which the phosphane was coordinated in the $\eta^1$-P coordination mode.

## Introduction

Metal complexes of phosphorus-based ligands have played central roles in organometallic and synthetic chemistry.[1] In particular, the chiral forms of these metal complexes have also continued to be invaluable as agents in catalytic asymmetric syntheses.[2] Suitable forms of these ligands may be transformed to give rise to palladacycles.[3–5] The latter (or cyclopalladated complexes) are a well-known class of compounds in organometallic chemistry, and they can be derived from ligands containing other heteroatom donors such as nitrogen and sulfur, apart from those of phosphorus. The syntheses and applications of many of these cyclopalladated complexes are currently being reported.[6] The properties of a ligand could be enhanced as a result of cyclopalladation. For instance, Lewis demonstrated that while a cyclopalladated triarylphosphite was effective as a catalyst for halogenating C=C bonds, the same task could not be accomplished by its non-cyclopalladated analogue.[7] Since then, the synthetic utilities of these systems as homogeneous catalysts were further illustrated.[3a–3j,5a–5e,8]

We have previously contributed to the field of palladacycle chemistry by the exploitation of chiral, nitrogen-based palladacycles for the syntheses of optically active phosphanes of various functionalities.[9] To further improve the synthetic efficiency of these invaluable phosphanes in terms of enhanced chemo-, regio-, diastereo- and enantioselectivities, it is essential to develop new variants of this palladacycle motif. Apart from modifying the organic framework of the cyclopalladated ligand,[8m,9d,9e] we have explored the possibility of replacing the original nitrogen atom with its phosphorus and arsenic congeners.[4] The work reported herein serves to describe the development and characteristics of a new phosphorus-based palladacycle that was prepared in the optically active form. The palladacycle was constructed from the ligand (diphenylmethyl)diphenylphosphane and reveals features that are characteristically different from that of the structurally analogous (diphenylmethyl)di-*tert*-butylphosphane.[10]

## Results and Discussion

### Synthesis of the Phosphapalladacycle in the Optically Active Form

The preparation of the prochiral phosphane **2** was based on the reported procedure that was applied to the synthesis

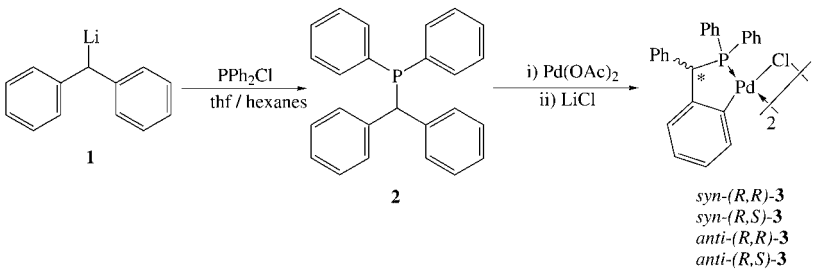

Scheme 1. Synthesis of compounds **2** and **3**.

of its *t*Bu analogue,[11] i.e. treatment of (diphenylmethyl)-lithium (**1**) with the corresponding chlorodiphenylphosphane (Scheme 1), which afforded the product as a white solid. Earlier attempts had failed to synthesize **2** by the more common methods of halide displacement from either (a) chlorodiphenylphosphane with a Grignard reagent or (b) an alkyl halide by using sodium diphenylphosphanide, which was found to be efficient for structurally analogous phosphanes.[4] The structure of compound **2** was confirmed by the doublet resonance of the α-CH proton in the $^1$H NMR spectrum ($CDCl_3$). This proton spin couples with the $^{31}$P nucleus with $^2J_{P,H}$ = 6.8 Hz. Importantly, this doublet resonance is crucial as an indicator of the successful merging of the diphenylmethyl and diphenylphosphanyl skeletons.

As illustrated in Scheme 1, treatment of the phosphane **2** with palladium(II) acetate followed by chloride ion metathesis led to the chloro-bridged dimeric complex **3** of the phosphapalladacycle. Complex **3** was thus isolated as air-stable pale yellow blocks in 61% yield. The dimer was detected by $^{31}$P NMR spectroscopy ($CDCl_3$) as a series of overlapping peaks at $\delta$ = 70.4–70.8 ppm at room temperature (300 K). However, upon cooling to 223 K, the resonance was reproduced as four resolved singlets at $\delta$ = 70.7, 70.8, 70.9 and 71.4 ppm. This supports the chiral and racemic nature of the phosphapalladacycle in solution, which is exemplified by the presence of the six equilibrating isomers, namely, the chiral *syn*- and *anti*-(*R*,*R*)/(*S*,*S*) and the achiral, *meso syn*- and *anti*-(*R*,*S*) isomers.

In the solid state, an X-ray diffraction study of **3** revealed that the complex was crystallized as the achiral, *meso-anti* isomer. The molecular structure is presented in Figure 1. The structure consists of a symmetrical plane that bisects the ClCl axis, each half of the dimer being the mirror image of the other. Moreover, the central four-membered {$Pd_2(\mu$-$Cl)_2$}cycle is flat, and its four atoms form a perfect plane. The stereogenic states of the two α-C atoms are manifested by the attachments of four different substituents. *ortho*-Palladation generates diastereotopicity on the two PPh rings. One of them is considered "axial", since its P1–$C_{ipso}$ bond subtends an angle of 18.5° with the normal to the m.c.pl. (mean coordination plane), while the value of 62.4° applies to the equivalent bond of the "equatorial" PPh ring.

Addition of the chiral ligand, (*S*)-prolinate, to the dimer **3** gave rise to a mixture of two pairs of diastereomeric derivatives **4** (Scheme 2). The presence of the two extra isomers was a consequence of geometric (*E*,*Z*) isomerism resulting from the nonsymmetrical nature of the (*S*)-prolinate. Four singlets were therefore present in the $^{31}$P NMR spectrum ($CDCl_3$). The racemic (and therefore chiral) nature of the phosphapalladacycle was emphasized by categorizing the four singlets into two pairs of resonances with overall equal intensities. These were observed at $\delta$ = 62.7, 71.0 and 64.4, 72.1 ppm with relative intensities of 4:9 and 3:10 correspondingly.

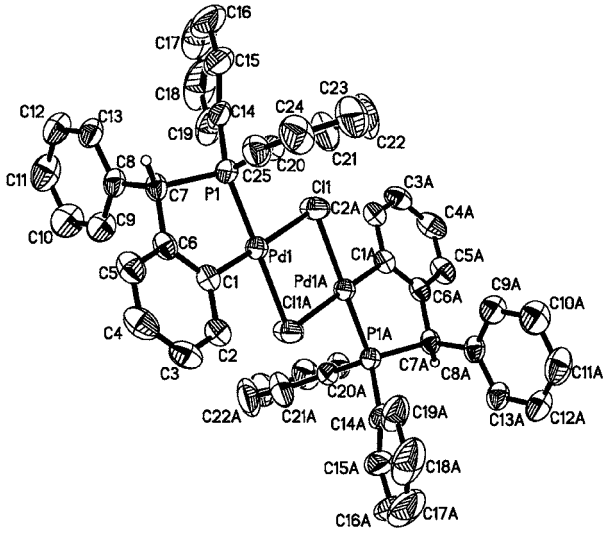

Figure 1. X-ray molecular structure of *meso*-**3**. Selected bond lengths [Å] and bond angles [°]: Pd1–C1, 2.017(3); Pd1–P1, 2.183(1); Pd1–Cl1, 2.441(1); Pd1–Cl1A, 2.407(1); C1–Pd1–P1, 79.43(8); C1–Pd1–Cl1, 174.43(8); C1–Pd1–Cl1A, 97.87(8); P1–Pd1–Cl1, 96.95(3); Cl1–Pd1–Cl1A, 97.87(8); Pd1–Cl1–Pd1A, 94.39(3).

The separation of the two enantiomeric forms of the phosphapalladacycle was then accomplished by the slow fractional crystallization of the mixture of four diastereomers from a solution of $CH_2Cl_2$/diethyl ether. The (*R*,*S*)- and (*S*,*S*)-**4** complexes were obtained sequentially in 59 and 77% yields. The absolute configurations of these derivatives were determined from their X-ray molecular structures. These are presented in Figure 2 and Figure 3 for (*R*,*S*)-**4** and (*S*,*S*)-**4** [as the (*Z*)-isomers], respectively, while the selected bond lengths and bond angles are presented in Table 1. Their absolute configurations were confirmed from

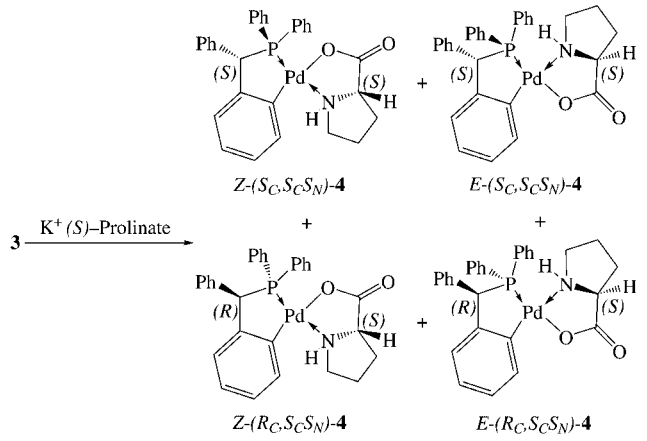

Scheme 2. Formation of (*S*)-prolinate derivatives **4**.

their respective Flack parameters of 0.02(3) and 0.04(4). Like the previously reported (*S*)-prolinate complexes, the secondary stereogenic nitrogen atom from the (*N*,*O*) chelate was noted to adopt the (*S*) configuration in both diastereomers.[9e,12] Both diastereomers are presented as the (*Z*) geometrical isomer and they are noted to have similar bond lengths and bond angles.

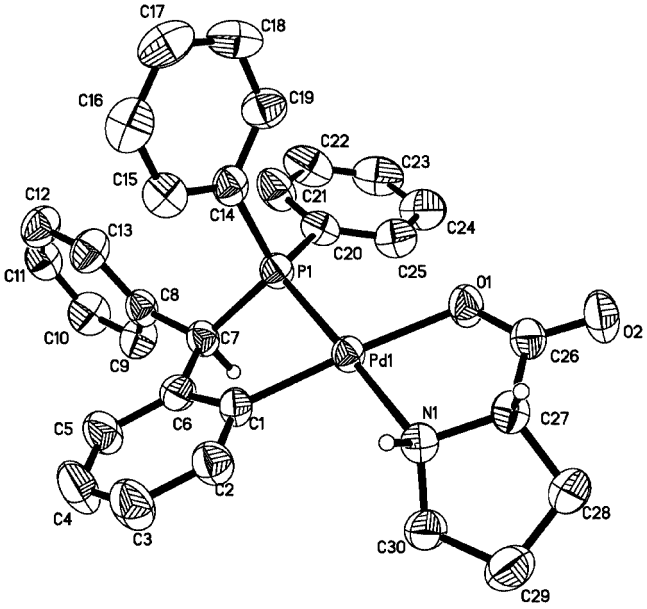

Figure 2. X-ray molecular structure of *Z*-($R_C$,$S_CS_N$)-**4**.

The two optical antipodes of the chloro dimer **3** were then readily obtained by mixing the respective (*S*)-prolinate derivatives **4** with 1 M HCl. Thus, (*R*,*R*)-**3** was isolated as a yellowish-green amorphous powder in quantitative yield (Scheme 3), with $[a]_D$ = –382° ($CH_2Cl_2$). Notably, such acid treatment did not lead to any loss of optical activity, as verified from the $^{31}P$ NMR spectroscopic data of the (*S*)-prolinate complexes **4**, obtained by a re-derivatization of the optically resolved forms of **3**. At room temperature (300 K), the $^{31}P\{^1H\}$ spectra ($CDCl_3$) of the optically resolved dimers **3** had an apparent broad singlet at $\delta$ = 70.8–70.9 ppm. The variable temperature (VT) $^{31}P\{^1H\}$ NMR spectra of (*R*,*R*)-**3**, summarized in Figure 4, indicate that the appearance of the NMR resonance signals is temperature-dependent, as an additional singlet emerges upon cooling. This resonance is shifted progressively downfield relative to the parent signal. The effect is completely reversible, so that warming the NMR sample causes the signal to coalesce with the latter, albeit rather weakly shifted upfield. The appearance of two sets of singlets indicates the existence of the *syn* and *anti* regioisomers that are possible within the dimeric nature of **3**. The fact that other signals originating from the achiral, *meso syn*- and *anti*-(*R*,*S*) iso-

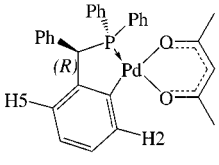
### Substituent Effects on Phosphapalladacycle Characteristics

While the palladacycle obtained from (diphenylmethyl)-di-*tert*-butylphosphane structurally resembles the current one (the two differ only in terms of the substituents on the phosphorus atom), the properties of the two systems were noticeably dissimilar. First, the replacement of the *t*Bu$_2$P with the Ph$_2$P group seems to evoke a conformational flexibility on the phosphapalladacycle ring. Comparison of the *meso*-**3**, (*R*,*S*)- and (*S*,*S*)-**4** molecular structures (Figure 1, Figure 2 and Figure 3) reveals the possibility of the ring to adopt either one of the two conformational states. This is because in *meso*-**3** and (*S*,*S*)-**4**, the phenyl substituent at the stereogenic α-C atom is noted to adopt the axial orientation, as indicated by the respective angles of 7.0 and 9.5° subtended by this substituent to the normal of the m.c.pl. On the other hand, this angle was found to be 96.8° (or 83.2° as the adjacent angle) for (*R*,*S*)-**4** and as such, the phenyl substituent at the α-C atom is considered equatorially disposed. The possibility of the α-C phenyl substituent to adopt two different orientations indicates a lack of crucial intrachelate steric interactions to enforce it to permanently adopt an axial orientation. The absence of such an interaction is due to the rotational ability of this substituent along the C7–C8 bond. Evidently, this could be supported by the diversification of the angle between the mean planes of this phenyl substituent and the palladated {C(1–6)} phenylene ring by 24.6° from 99.2° in *meso*-**3** to 74.6° in ($S_C S_C$)-**4**, despite the common axial disposition of their α-C phenyl substituents. It should be noted from the structure of ($R_C S_C$)-**4** that, when the substituent is equatorially disposed, the mean plane of this phenyl ring is almost perpendicular to that of the palladated phenylene ring, at 83.1°. When the α-C phenyl substituent is in this rotameric state, any unfavourable steric repulsion with the palladated ring may thus be effectively minimized. In support of this statement, the shortest distance between the two aromatic rings, i.e. that between the H5 and H13 protons, at 3.350 Å, may be mentioned. A separation of this magnitude for these two atoms far exceeds the sum of van der Waals radii for two hydrogen atoms (2.4 Å) and is considered too large to generate any kind of instability to the conformational state of the phosphapalladacycle ring when the α-C phenyl substituent is equatorially disposed. For comparison, a close interaction of this kind at 2.148–2.234 Å between the α-C proton and the nearest proton of the palladated naphthylene ring was found for the conformationally rigid *ortho*-palladated [1-(1′-naphthyl)ethyl]diphenylphosphane system.[4a] In other words, in the current phosphapalladacycle, the prevention of any unfavourable steric contacts between the two aromatic rings may be accomplished simply by the adoption of a suitable rotameric state for the equatorially disposed α-C phenyl substituent or by the alternate axial orientation of this substituent. In contrast, the solid state studies of the *t*Bu-based phosphapalladacycle (*S*)-**7** revealed an axial orientation of the α-C phenyl substituent.[10] The alternate equatorially disposed orientation of this substituent was prevented by the close interaction of this phenyl ring with the *t*Bu groups or the H5 atom of the palladated phenyl ring. Any form of steric relief that could be brought about by the adoption of a certain rotameric state of this phenyl ring seems remote, since it is surrounded by three groups in this conformational state.



(*R*)-**6**

The lack of conformational rigidity of the current –PPh$_2$ based phosphapalladacycle is not restricted to the solid state but extends to solution. This was observed in the 2D $^1$H-$^1$H NOESY NMR spectrum (Figure 5) of the β-dike-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tonate derivative, (*R*)-**6**, which was obtained as an amorphous powder, with $[\alpha]_{436} = -1123°$ ($CH_2Cl_2$), from the direct treatment of the dimer (*R*,*R*)-**3** with sodium acetylacetonate in acetone. From its $^1H$ NMR spectrum ($CDCl_3$), two visibly distinguished sets of *ortho*-, *meta*- and *para*-PPh protons appear, as the two PPh rings are diastereotopic. Assignment of the signals was made by a combination of $^1H\{^{31}P\}$, 2D $^1H$-$^1H$ COSY and NOESY NMR spectroscopic experiments. The four aromatic protons of the *ortho*-palladated ring form a spin system, as observed from the COSY data. The most upfield aromatic signal was assigned to the H5 proton, in recognition of its NOE contact (interaction C) with the α-CH proton. The latter spin couples with the adjacent $^{31}P$ nucleus and was presented as a simple doublet resonance ($^2J_{P,H}$ = 13.3 Hz). A rather unexpected long-range coupling with the $^{31}P$ nucleus was detected for the H2 proton, the corresponding coupling constant being a rather significant 4.0 Hz. The five aromatic protons of the α-C phenyl substituent are collectively represented as an extensively overlapping multiplet at $\delta$ = 7.00–7.05 ppm. The 2D $^1H$-$^1H$ NOESY NMR spectrum points to a rather flattened palladacycle ring in which each PPh ring was observed to distinctly interact through NOE with only either the methine proton or the phenyl ring at the stereogenic α-C centre (interactions A and D). Such a conformational picture may be satisfied by either one of the two Newman representations in Figure 6.

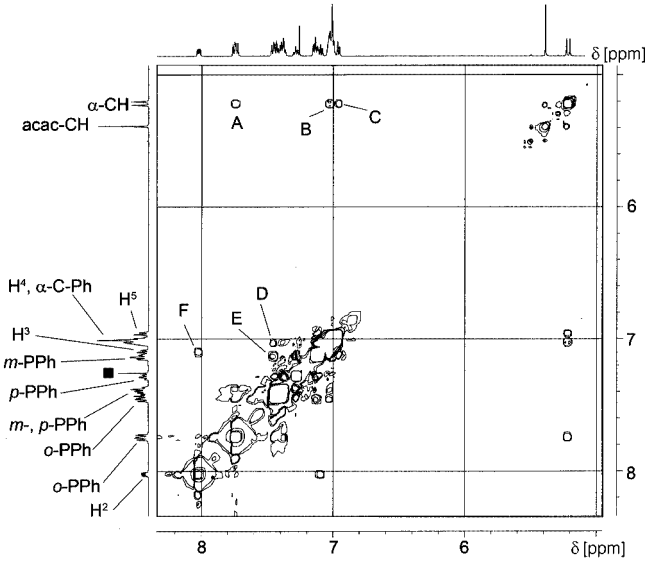


Figure 5. Expanded 2D $^1H$-$^1H$ NOESY NMR spectrum of (*R*)-**6** ($CDCl_3$). Selected NOE interactions: A: α-CH–*o*-PPh; B: α-CH–*o*-Ph of α-CPh; C: α-CH–H5; D: *o*-PPh–*o*-Ph of α-CPh; E: *o*-PPh–*m*-PPh; F: H2–H3. Solvent signal: ■, $CDCl_3$.

In contrast, the phosphapalladacycle ring of the $tBu_2P$ equivalent is conformationally rigid, on the basis of a similar 2D $^1H$-$^1H$ NOESY NMR study performed on the analogous β-diketonate complex **7** (whose preparation was reported earlier[10]) containing the (*S*) configuration at the α-C centre. The aromatic signals in its $^1H$ NMR spectrum may be divided into two separate sets of spin patterns accounting for a total of nine aromatic protons. One of these

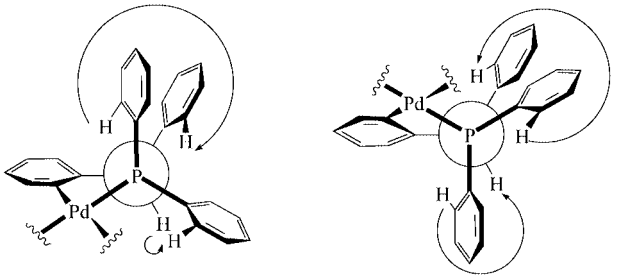

Figure 6. Newman projections for two possible flattened palladacycle conformations for complex (*R*)-**6**. Curved arrows depict NOE contacts.

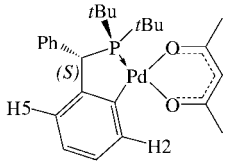

(*S*)-**7**

comprises the four protons (H2–H5) of the *ortho*-palladated phenylene ring, while the other set of signals is representative of the remaining five aromatic protons belonging to the α-C phenyl substituent. The most upfield aromatic signal was assigned the H5 proton on account of its NOE contact with the α-C methine proton from the 2D $^1H$-$^1H$ NOESY NMR spectrum (Figure 7 and Figure 8). Among the (H2–H5) set of aromatic protons, such an NOE interaction is only possible for this proton, given its closest proximity to the α-CH proton. The remaining three aromatic protons of the same set may next be unambiguously assigned by using the H5 proton as a starting point by considering either (i) the coupling information from the COSY data or (ii) the negative, off-diagonal, i.e. NOE signals among these protons from the NOESY NMR spectrum.

As an added peculiarity, the spectral pattern of the five aromatic protons of the α-C phenyl substituent corresponds to a rather complicated ABCDE spin system, in which both *ortho* protons are chemically nonequivalent on the NMR time scale, a characteristic that is also shared by the *meta* protons. The detection of an off-diagonal, opposite-phased EXSY signal (signal I, in Figure 8) between the two *ortho* protons in the 2-D $^1H$-$^1H$ NOESY NMR spectrum points to the exchangeability between these two protons, which may be provided by the rotational capability of the $C^{\alpha}$–$C^{i}$ bond of the phosphapalladacycle, but such capability must be rather restricted even in solution to allow a differentiation and hence signal-doubling of both *ortho* protons (as well as the *meta* protons).

In the expanded 2-D $^1H$-$^1H$ NOESY NMR spectrum (Figure 7), NOE contacts were observed between the α-CH protons and both sets of the *t*Bu substituents (interactions C and D). Moreover, similar interactions between the two *ortho* protons of the α-C phenyl substituent and only one of the two available *t*Bu substituents were noted (interactions A and B). Consequently, these NOE patterns, together with the absence of similar NOE contacts between the α-C

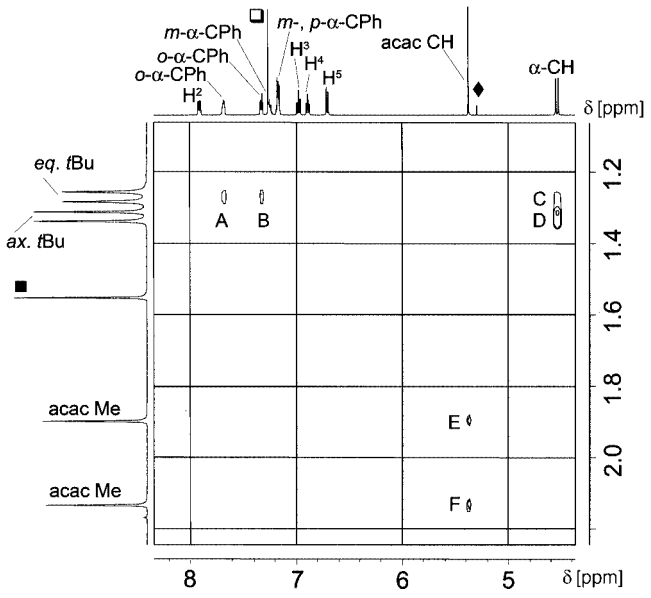

Figure 7. Expanded 2D $^1$H-$^1$H NOESY NMR spectrum of (*S*)-**7** ($CDCl_3$). Aliphatic–aromatic NOE interactions: A: equatorial *t*Bu–*o*-α-Ph; B: equatorial *t*Bu–*o*-α–Ph; C: equatorial *t*Bu–α–CH; D: axial *t*Bu–α–CH; E: acac CH–acac Me; F: acac CH–acac Me. Solvent signals: ■, $H_2O$, ♦, $CH_2Cl_2$, □, $CDCl_3$.

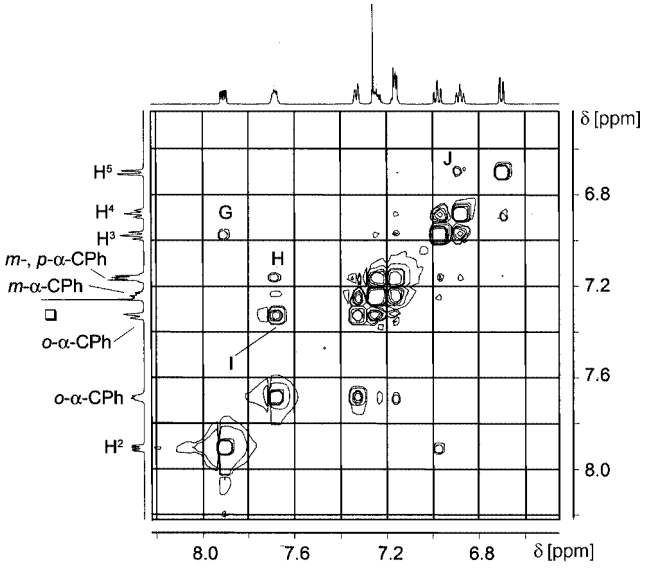

Figure 8. Expanded 2D $^1$H-$^1$H NOESY NMR spectrum of (*S*)-**7** ($CDCl_3$). Selected aromatic–aromatic NOE interactions: G: H2–H3; H: *o*-α-Ph–*m*-α-Ph; J: H4–H5. EXSY signal: I: *o*-α-Ph–*o*-α-Ph. Solvent signal: □, $CDCl_3$.

phenyl *ortho* protons and the remaining *t*Bu group (i.e. the axially disposed *t*Bu group; the other *t*Bu group must be the equatorially disposed one) must be known in support of the λ conformation and the rigid state of the phosphapalladacycle with (*S*) absolute configuration in solution. As a comparison, this set of NOE interactions is impossible for the case of the δ conformation for the same absolute (*S*) configuration at the α-C centre, as illustrated by the by the Sawhorse and Newman projections along the P–α-C bond in Figure 9.

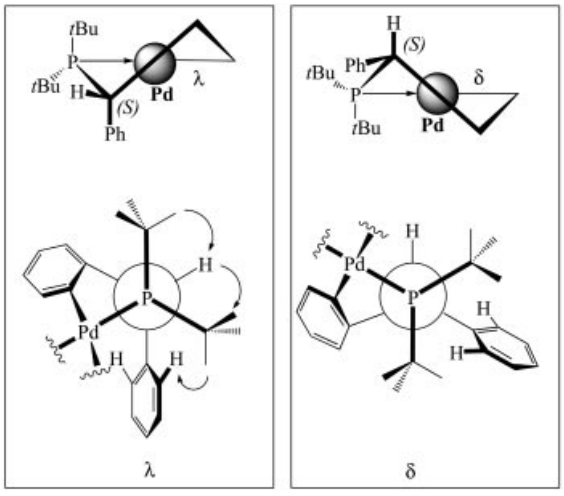

Figure 9. Sawhorse and Newman projections for the λ and δ conformations for complex (*S*)-**7** ($CDCl_3$). Curved arrows depict NOE contacts.

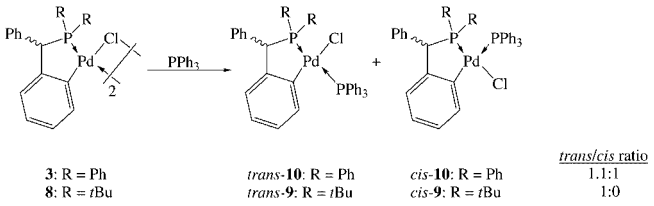
A mentionable observation among these aromatic signals is the presence of the long-range $^1$H–$^{31}$P spin-spin couplings for the H2 and H4 protons. A rather significant coupling constant of 3.9 Hz over four bonds was found for the former, while a coupling constant of 2.1 Hz over possibly five bonds was detected for the latter. Such a phenomenon is unusual, when similar couplings for the other two aromatic protons belonging to the same phenylene ring do not exist. A similar feature was also noted for the corresponding H2 proton in (*R*)-**6**.

The large steric bulk of the *t*Bu groups has resulted in a better regioselectivity with respect to the coordination of arriving ancillary ligands to the palladacycle. This was noted in the reaction of the chloro-bridged dimer **8** with (*S*)-prolinate, in which the strong degree of regioselectivity is evident from the product distribution of 99:1 and 98:2 (*E*/*Z*) for its (*S*,*S*) and (*R*,*S*) derivatives, correspondingly.[10] Furthermore, compound **8** reacted with triphenylphosphane to give the *trans* isomer (±)-**9** exclusively (Scheme 4). This is far superior with respect to the current phosphapalladacycle **3**, which generated a mixture of *cis* and *trans* isomers (±)-**10** in 1.1:1 ratio. Both geometrical isomers were readily distinguished from each other by a consideration of the $^2J_{P,P}$ coupling constants. These were determined to be 29.0 Hz for *cis*-**10** and were more pronounced at 418.1 and 390.6 Hz for *trans*-(±)-**10** and *trans*-(±)-**9**, respectively. For *trans*-(±)-**9**, only one set of signals was observed in its $^1$H NMR spectrum expectedly and the *trans*-(*P*, *P*) geometry was further inferred from the relatively high-field position of the phenylene aromatic proton at $\delta$ = 6.24 ppm. The best evidence for this geometry was provided by its molecular structure. The structure (with the accompanying numbering scheme) is presented in Figure 10. The chiral nature of the phosphapalladacycle is obvious from the stereogenic α-C atom, by the *ortho*-palladation of only one of the two available phenyl rings (i.e. the C1–C6 phenyl ring) on the phosphane moiety. Analysis of the extent of the tetrahedral distortion on the central Pd atom reveals that it is located in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a highly congested environment: the dihedral angle between the {P1–Pd1–C1} and {Cl1–Pd1–P2} planes has a large value of 23.0°. Such a large value is probably an indication of the need to relieve steric repulsion due to the presence of the phosphapalladacycle bulky *t*Bu substituents and the $PPh_3$ phenyl rings. The overcrowding around the central Pd atom was further demonstrated by the mean vertical displacement of 0.2483 Å from planarity of the five atoms of the m.c.pl.



Scheme 4. Formation of triphenylphosphane adducts (±)-**9** and (±)-**10**.

Notably, the current $Ph_2P$-based phosphapalladacycle also discloses a profound difference in the Pd–C bond reactivity. To recall, the Pd–C bond of the *t*$Bu_2P$ analogue was noted to be only kinetically unstable and the phosphapalladacycle ring opens and closes reversibly by Pd–C bond cleavage in refluxing acetone containing concentrated HCl.[10] This effect was attributed to the thermodynamic stability imparted to the palladacycle by the steric influence of the bulky *t*Bu substituents. In stark contrast to its *t*$Bu_2P$ analogue, the presence of a few drops of concentrated HCl in a $CDCl_3$ solution of the chloro dimer **3** led to a permanent ring opening of the phosphapalladacycle by cleavage of the Pd–C bond (Scheme 5). The transformation was immediate, as observed from the colour change from pale yellow to orange-red. The fact that the Pd–C bond cleavage of the current phosphapalladacycle was permanent was affirmed by the possibility to even isolate the binuclear product **5** from this procedure and perform an X-ray diffraction study. From Figure 11, the complex has an overall *anti* structure that reveals the occupation of both diagonally opposite terminal ends of the dimer by two additional chloride ligands. Moreover, the $\eta^1$-P type of coordination mode adopted by the phosphane ligand is apparent here. Unlike the *ortho*-palladated structure, however, the central four-membered $\{Pd_2(\mu\text{-}Cl)_2\}$cycle is not planar, since each Pd atom deviates from planarity by an angle of 6.45°. It is worth mentioning that the P–Pd bond has weakened as a result of palladacycle ring opening. This bond length has increased from 2.1832(7) Å in the *ortho*-palladated structure

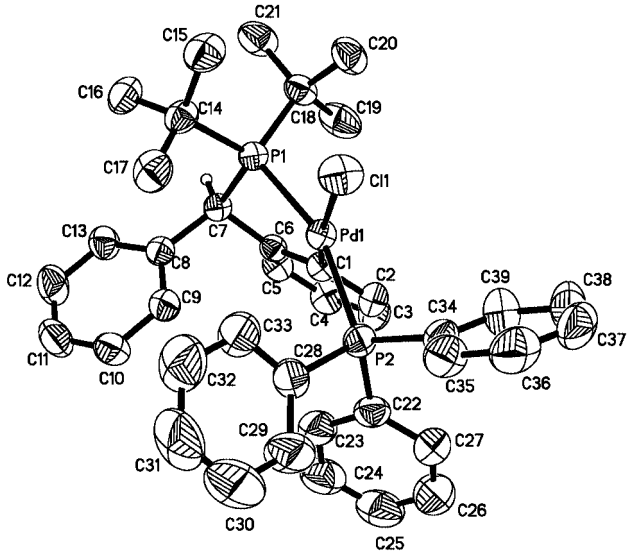


Figure 10. X-ray molecular structure of *trans*-(±)-**9**. **3** to 2.237(3) Å in the monodentate state. Thus, the possibility of stabilizing the P–Pd bond as a result of *ortho*-palladation is noteworthy. The P–C bond strengths have not varied significantly, however.

## Conclusions

The novel palladacycle based on the ligand (diphenylmethyl)diphenylphosphane was prepared in the optically active forms by optical resolution of its (*S*)-prolinate derivatives. This palladacycle was shown to display properties which were different from those of its bulkier analogue, the (diphenylmethyl)di-*tert*-butylphosphane-based palladacycle. First, the five-membered ring of the current palladacycle assumes both available conformations in solution and in the solid state. From solid-state X-ray structure studies, the conformational flexibility of this system was directly attributed to the absence of intrachelate interactions in either the λ or the δ conformations. Second, the bulkiness of the *t*Bu groups also brings about a more improved regioselectivity with respect to the coordination of ancillary triphenylphosphane and (*S*)-prolinate ligands for the latter palladacycle. Third, in the absence of such steric effects originating from the *t*Bu groups, the Pd–C bond of the former does not possess the type of thermodynamic stability that was observed for the latter. Currently, both palladacycles are being tested in various asymmetric applications.

## Experimental Section

**General:** Reactions involving air-sensitive compounds were performed under a positive pressure of argon. Routine $^1$H NMR spectra were recorded at 300 MHz or 500 MHz with a Bruker ACF 300 or Bruker AMX 500 NMR spectrometer. All the $^{31}$P{$^1$H} NMR spectra were recorded at 120 MHz or 202 MHz with a Bruker ACF 300 or Bruker AMX 500 NMR spectrometer. Unless stated otherwise, all NMR spectroscopic experiments were performed at room temperature (300 K). Melting points were determined with a Büchi melting point B-545 apparatus and are uncorrected. Optical rotations were measured on the specified solution in 1-dm or 0.1-dm cells at 25 °C with a Perkin–Elmer Model 341 polarimeter. Elemental analyses were performed by the Elemental Analysis Laboratory of the Department of Chemistry at the National University of Singapore.

**(Diphenylmethyl)diphenylphosphane (2):** A solution of (diphenylmethyl)lithium was prepared by syringing *n*-BuLi in hexanes (3.7 mL, 5.9 mmol, 1.6 M) into a thf solution (5 mL) of diphenylmethane (1.00 g, 5.94 mmol) and allowing the mixture to stir at room temperature for 3 h. The freshly prepared, intensely red solution of (diphenylmethyl)lithium was then added dropwise to an ice-chilled thf solution (5 mL) of chlorodiphenylphosphane (0.98 g, 4.46 mmol) with rapid stirring. The addition led to an immediate decolourization of the (diphenylmethyl)lithium reagent. When decolourization was no longer observed upon further addition of the (diphenylmethyl)lithium reagent, the addition was discontinued, the ice-bath was removed, and the mixture was allowed to stir at room temperature for a further 30 min. It was then concentrated to dryness, washed with freshly deoxygenated water (20 mL) and extracted with $CH_2Cl_2$ (3 × 50 mL). The organic extracts were combined, dried with $MgSO_4$ and filtered. The product was finally obtained as a white solid upon removal of solvents by distillation and further drying under reduced pressure. Yield: 1.54 g (98.0%). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 4.63 (d, $^2J_{P,H}$ = 6.8 Hz, 1 H, $Ph_2CH$), 7.03–7.26 (m, 20 H, aromatic protons) ppm. $^{31}$P{$^1$H} NMR (121 MHz, $CDCl_3$): $\delta$ = –3.2 (s) ppm.

**Di-μ-chlorobis{[(diphenylphosphanyl)(phenyl)methyl]phenyl-*C*$^2$,*P*}-dipalladium(II) (3):** The phosphane **2** (1.57 g, 4.46 mmol) and palladium(II) acetate (1.00 g, 4.46 mmol) were suspended in toluene (100 mL), and the reacting mixture was stirred at 50 °C for 2 h to give a deep reddish brown mixture with deposition of palladium black. The mixture was concentrated to dryness by using a rotary evaporator to yield a crude reddish-black residue. $^{31}$P{$^1$H} NMR (121 MHz, $CDCl_3$): $\delta$ = 68.4 (s) ppm. The residue was then suspended in acetone (15 mL), to which a solution of lithium chloride (0.50 g, 11.8 mmol) in acetone/methanol (1:3, v/v) was added. The mixture was then stirred for 90 min, concentrated to dryness and re-suspended in $CH_2Cl_2$. This suspension was filtered through a plug of Celite to yield an orange solution, which was further washed with water (40 mL). The organic extract was concentrated and chromatographed on a silica gel column from which the chloro dimer was eluted as a pale yellowish-green fraction by using $CH_2Cl_2$–hexanes (1:2, v/v). Crystallization from $CH_2Cl_2$/diethyl ether yielded pale yellow blocks; m.p. (decomp.) 232–236 °C. Yield: 1.36 g (61.3%). $C_{50}H_{40}Cl_2P_2Pd_2$ (986.52): calcd. C 60.9, H 4.1; found C 60.6, H 4.1. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 5.27 (d, $^2J_{P,H}$ = 13.6 Hz, 1 H, α-CH), 6.98–8.11 (br. overlapping m, 19 H, aromatic protons) ppm. $^{31}$P{$^1$H} NMR (121 MHz, $CDCl_3$): $\delta$ = 70.4, 70.6, 70.8 (br. overlapping s) ppm; (223 K) four sets of signals at $\delta$ = 70.7 (s), 70.8 (s), 70.9 (s) and 71.4 (s) ppm.

***sym*-Dichlorodi-μ-chlorobis[(diphenylmethyl)diphenylphosphane]dipalladium(II) (5):** To a $CH_2Cl_2$ solution (3 mL) of the racemic complex **3** (0.11 g, 0.12 mmol) was added an excess of conc. HCl (30 μL, 37% wt/wt, spec. gravity 1.19) with a micropipette. The mixture was allowed to stir vigorously for 1 h at room temperature, after which it was diluted with water (5 mL) and $CH_2Cl_2$ (20 mL). The orange-red organic layer was separated and was washed with water (2 × 5 mL) and dried with $MgSO_4$. The excess $CH_2Cl_2$ was removed, from which the product was obtained as fine orange-red crystals from $CH_2Cl_2$/hexanes exhibiting low solubility; m.p. (decomp.) 231–233 °C. Yield: 0.088 g (72.7%). $C_{50}H_{42}Cl_4P_2Pd_2$ (1059.44): calcd. C 56.7, H 4.0; found C 56.3, H 4.3. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 6.35 (d, $^2J_{P,H}$ = 15.6 Hz, 1 H, α-CH), 7.19–7.48 (m, 20 H, aromatic protons) ppm. $^{31}$P{$^1$H} NMR (121 MHz, $CDCl_3$): $\delta$ = 36.8 (s) ppm.

**Chloro{[(±)-(diphenylphosphanyl)(phenyl)methyl]phenyl-*C*$^2$,*P*}-(triphenylphosphane)palladium(II) [(±)-10]:** Triphenylphosphane (0.012 g, 0.045 mmol) was added to a $CH_2Cl_2$ solution (3 mL) of the dimer **3** (0.022 g, 0.022 mmol), and the mixture was stirred for 30 min, after which the pale yellow solution was concentrated in vacuo, and the product was obtained as pale yellow crystals in $CH_2Cl_2$/hexanes; m.p. 200–202 °C. Yield: 0.020 g (58.8%).

ness in vacuo to afford the (*R*,*R*)-**3** as a greenish-yellow powder (attempts to crystallize the product by using a variety of solvents have been unsuccessful thus far); m.p. (decomp.) 196–200 °C. $[\alpha]_D$ = –382°, $[\alpha]_{578}$ = –400°, $[\alpha]_{546}$ = –468°, $[\alpha]_{436}$ = –946° (*c* 0.5, $CH_2Cl_2$). Yield: 0.20 g (99.0%). $C_{50}H_{40}Cl_2P_2Pd_2$ (986.52): calcd. C 60.9, H 4.1; found C 61.2, H 4.0. $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 5.22 (d, $^2J_{P,H}$ = 13.7 Hz, 1 H, α-CH), 6.89–8.03 (br. overlapping m, 19 H, aromatic protons) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = 70.8 (s), (253 K) 2 sets of signals with relative intensities of 1: 0.65, $\delta$ = 70.8 (s), 71.1(s) ppm.

**(*S*,*S*)-di-μ-Chlorobis{[(diphenylphosphanyl)(phenyl)methyl]phenyl-*C*$^2$,*P*}dipalladium(II) [(*S*,*S*)-3]:** Dilute HCl (7 mL, 1 M) was added to a $CH_2Cl_2$ solution (10 mL) of the ($S_C$, $S_CS_N$)-**4** (0.1642 g, 0.287 mmol), and the resulting solution was vigorously stirred for 5 min at room temperature. The aqueous layer was separated, and the procedure was repeated once with the same amount of HCl. The organic layer was next removed, washed with water (2 × 10 mL), dried with $MgSO_4$ and the solvents evaporated to dryness in vacuo to afford the (*S*,*S*)-**3** as a greenish-yellow powder; m.p. (decomp.) 198–202 °C. $[\alpha]_D$ = +368°, $[\alpha]_{578}$ = +384°, $[\alpha]_{546}$ = +446°, $[\alpha]_{436}$ = +908° (*c* 0.5, $CH_2Cl_2$). Yield: 0.141 g (99.5%). $C_{50}H_{40}Cl_2P_2Pd_2$ (986.52): calcd. C 60.9, H 4.1; found C 60.9, H 3.9. $^1$H NMR ($CDCl_3$, 300 MHz): $\delta$ = 5.22 (d, $^2J_{P,H}$ = 13.7 Hz, 1 H, α-CH), 6.89–8.03 (br. overlapping m, 19 H, aromatic protons) ppm. $^{31}P\{^1H\}$ NMR (121 MHz, $CDCl_3$): $\delta$ = 70.9 (s) ppm.

**(*R*)-(Acetylacetonato-*O*,*O*′){1-[(diphenylphosphanyl)(phenyl)methyl]-phenyl-*C*$^2$,*P*}dipalladium(II) [(*R*)-6]:** To an acetone solution (3 mL) of the dimer (*R*,*R*)-**3** (0.139 g, 0.141 mmol) was added Na acac·$H_2O$ (0.040 g, 0.282 mmol), and the mixture was vigorously stirred at room temperature for 2 h until a white suspension was obtained. The suspension was filtered through a short plug of Celite, and the colourless solution was concentrated to dryness in vacuo to yield a white amorphous powder; m.p. 86–89 °C. $[\alpha]_{436}$ = –1123°, $[\alpha]_{365}$ = –2397° (*c* 0.7, $CH_2Cl_2$). Yield: 0.089 g (56.7%). $C_{30}H_{27}O_2PPd$ (556.92): calcd. C 64.7, H 4.9; found C 64.9, H 4.8. $^1$H NMR ($CDCl_3$, 500 MHz): $\delta$ = 1.84 (s, 3 H, acac-Me), 2.15 (s, 3 H, acac-Me), 5.22 (d, $^2J_{P,H}$ = 13.3 Hz, 1 H, α-CH), 5.39 (s, 1 H, acac-CH), 6.96 (dd, $^3J_{H,H}$ = 7.6 Hz, $^4J_{H,H}$ = 1.42 Hz, 1 H, 5-H), 7.00–7.05 (m, 6 H, 4-H, *o*-Ph, *m*-Ph, *p*-Ph protons of α-C-Ph substituent), 7.09 (m, 1 H, 3-H), 7.13 (m, 2 H, *m*-PPh), 7.29 (dtt, $^3J_{H,H}$ = 7.4 Hz, $^4J_{H,H}$ = 1.29Hz, $^5J_{P,H}$ = 2.1 Hz, 1 H, *p*-PPh), 7.45 (ddd, $^3J$(H,H) = 8.5, $^4J_{H,H}$ = 1.3, $^3J_{P,H}$ = 11.5 Hz, 2 H, *o*-PPh), 7.74 (dddd, $^3J_{H,H}$ = 8.0 Hz, $^4J_{H,H}$ = 1.8 Hz, $^4J_{H,H}$ = 1.3 Hz, $^3J_{P,H}$ = 11.2 Hz, 2 H, *o*-PPh), 8.02 (ddd, $^3J_{H,H}$ = 7.8 Hz, $^4J_{H,H}$ = 1.3 Hz, $J_{P,H}$ = 4.0 Hz, 1 H, 2-H) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$, 202 MHz): $\delta$ = 66.4 (s) ppm.

**Chloro{(±)-1-[(di-*tert*-butylphosphanyl)(phenyl)methyl]phenyl-*C*$^2$,*P*}(triphenylphosphane)palladium(II) [(±)-9]:** Triphenylphosphane (0.069 g, 0.262 mmol) was added to a $CH_2Cl_2$ solution of the corresponding chloro dimer **3** (0.108 g, 0.119 mmol), and the resulting mixture was allowed to stir for 16 h under a positive pressure of argon. The product was isolated as pale yellow blocks from $CH_2Cl_2$/hexanes upon slow crystallization; m.p. 216–217 °C. Yield: 0.145 g (85.3%). $C_{39}H_{43}ClP_2Pd$ (715.57): calcd. C 65.5, H 6.1; found C 65.4, H 6.1. $^1$H NMR ($CDCl_3$, 500 MHz): $\delta$ = 1.21 (d, $^3J_{P,H}$ = 12.8 Hz, 9 H, axial *t*Bu), 1.40 (d, $^3J_{P,H}$ = 13.1 Hz, 9 H, equatorial *t*Bu), 4.54 (dd, $^2J_{P,H}$ = 11.7 Hz, $^4J_{P,H}$ = 5.1 Hz, 1 H, α-CH), 6.24 (m, 1 H, 2-H), 6.64–6.71 (m, 2 H, 3-H, 4-H), 6.80 (dd, $^3J_{H,H}$ = 7.6 Hz, $^4J_{H,H}$ = 1.4 Hz, 1 H, 5-H), 6.94 (br. dd, $^3J_{H,H}$ = $^3J_{H,H}$ = 7.5 Hz, 1 H, *m*-α-Ph), 7.17 (m, 1 H, *p*-α-Ph), 7.24–7.40 (m, *m*-$PPh_3$, *p*-$PPh_3$, *o*-α-Ph, *m*-α-Ph, signals of free $PPh_3$), 7.70 (m, 6 H, *o*-$PPh_3$), 8.46 (br. d, $^3J_{H,H}$ = 7.8 Hz, 1 H, *o*-α-Ph) ppm. $^{31}P\{^1H\}$ NMR (202 MHz, $CDCl_3$): $\delta$ = –5.0 (*s*, free $PPh_3$), 24.8 (d, $^2J_{P,P}$ = 390.6 Hz, coordinated $PPh_3$), 100.5 (d, $^2J_{P,P}$ = 390.6 Hz, palladacycle P), four overlapping sets of signals at 111.8, 111.9, 112.1, 112.2 (s, signals of racemic dimer) ppm.

**X-ray Diffraction Studies of the Complexes *meso*-3, (*Z*)-($R_C$,$S_CS_N$)-4, (*Z*)-($S_C$, $S_CS_N$)-4, 5 and *trans*-(±)-9:** Crystal data for these five complexes and a summary of the crystallographic analyses are given in Table 2. Diffraction data were collected on a Siemens SMART CCD diffractometer with Mo-$K_\alpha$ radiation (graphite monochromator) by using $\omega$-scans. SADABS absorption corrections were applied, and refinements by full-matrix least-squares were based on SHELXL 93.[13] All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced at fixed distance from carbon atoms and were assigned fixed thermal parameters.

CCDC-634583 (for *meso*-**3**), -634584 [for (*Z*)-($R_C$,$S_CS_N$)-**4**], -634585 [for (*Z*)-($S_C$,$S_CS_N$)-**4**], -634586 (for **5**), and -634587 [for *trans*-(±)-**9**] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 2. Crystallographic data for complexes *meso*-**3**, *Z*-($R_C$,$S_CS_N$)-**4**, *Z*-($S_C$,$S_CS_N$)-**4**, **5** and *trans*-(±)-**9**.

**The EUChemSoc Societies have taken the significant step into the future by merging their traditional journals, to form two leading chemistry journals, the *European Journal of Inorganic Chemistry* and the *European Journal of Organic Chemistry.* Three further EUChemSoc Societies (Austria, Czech Republic and Sweden) are Associates of the two journals.**

## COVER PICTURE

**The cover picture shows** the electro-induced core interconversions in three dinuclear manganese tris(2-methylpyridyl)amine (tpa) complexes. The mono-(μ-oxo) mono-(μ-acetato) $[Mn_2^{III,III}(O)(O_2CCH_3)(tpa)_2]^{3+}$ and the bis-(μ-oxo) $[Mn_2^{IV,IV}(O)_2(tpa)_2]^{4+}$ complexes are selectively and quasi-quantitatively generated by sequential exhaustive electrochemical two-electron oxidations of the bis-(μ-acetato) $[Mn_2^{II,II}(O_2CCH_3)_2(tpa)_2]^{2+}$ complex. At each step one acetato bridge is substituted by an oxo bridge coming from the deprotonation of one residual water molecule in the solvent. The background picture shows some cyclic voltammograms recorded during this study. Details are discussed in the article by M.-N. Collomb et al. on p. 3179 ff. We thank Dr. Damien Jouvenot for the design of the cover picture.

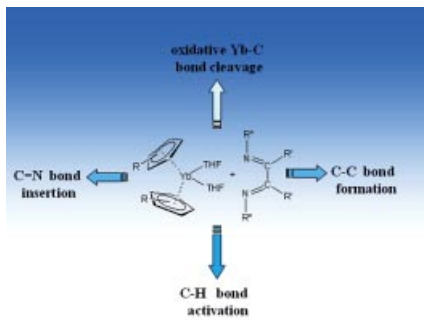
Reactions of Ytterbocenes with Diimines: Steric Manipulation of Reductive Reactivity

**Keywords:** Lanthanides / Diimines / Reductive reactivity / N,N ligands / Redox tautomerism



Reactions of ytterbocenes with diimines are found to be strongly influenced by the steric crowding in the coordination sphere of the metal atom and the coordination capacities of π-aromatic ligands. The reactions may occur with oxidation of the ytterbium atom as well as with retention of its oxidation state. C–C bond formation, C–H bond activation, C=N bond insertion, and oxidative Yb–C bond cleavage processes are documented.

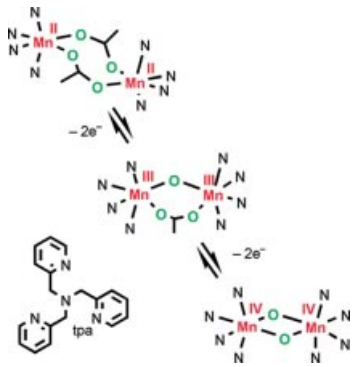
## Dinuclear Manganese Complexes



The electro-induced interconversion of the bis(μ-acetato) dinuclear manganese(II,II) complex $[Mn_2(O_2CCH_3)_2(tpa)_2]^{2+}$ into the corresponding mono-(μ-oxo) mono-(μ-acetato) $Mn_2^{III,III}$ and bis(μ-oxo) $Mn_2^{IV,IV}$ complexes has been investigated in $CH_3CN$. The isolation and characterization of the $Mn_2^{III,III}$ complex is also reported.

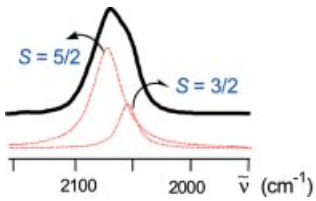
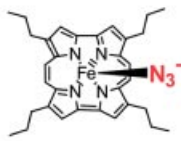
## Iron(III) Spin Crossover





Magnetic characterization of the azide complex of iron(III) porphycene indicates that this complex is in mixed $S = 5/2$, 3/2 states. The IR stretching band of the coordinating azide was found to split into the 2049- and 2066-$cm^{-1}$ bands, demonstrating that the two spin isomers are not quantum-mechanically admixed but in thermal equilibrium. The minimum lifetime of the spin isomers was estimated to be 0.3 ps.

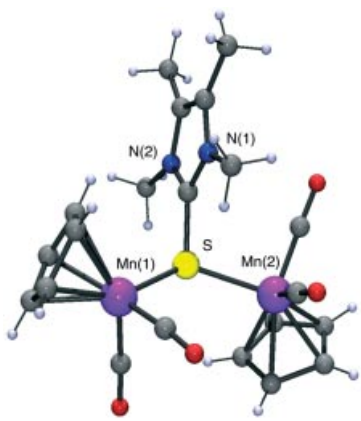
## Bridging Thione Ligands



Photolysis of $[CpMn(CO)_3]$ in the presence of 1,3,4,5-tetramethylimidazoline-2-thione produced a bridging thione complex, $[\{CpMn(CO)_2\}_2(\mu\text{-}SC_3N_2Me_4)]$, which has an unprecedented geometry featuring a pyramidal sulfur atom and long Mn···Mn distance. Photoreaction of $[M(CO)_6]$ with the thione yielded mononuclear complexes $[M(CO)_5(SC_3N_2Me_4)]$ (M = Mo, W).

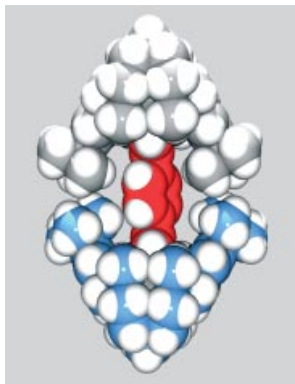
Tetranuclear Nickel Complexes Composed of Pairs of Dinuclear $LNi_2$ Fragments Linked by 4,4′-Bipyrazolyl, 1,4-Bis(4′-pyrazolyl)benzene, and 4,4′-Bipyridazine: Synthesis, Structures, and Magnetic Properties

**Keywords:** Macrocyclic ligands / Bipyrazolate ligands / Nickel / Polynuclear complexes / Magnetic properties



The ability of 4,4′-bipyrazolate type ligands to link dinuclear $LNi_2$ units has been examined. The formation of the $Ni_4$ complexes depends critically on the steric bulkiness of the supporting ligand L and the length of the organic spacer between the connecting heterocycles. The ability of the bipyrazolate moiety to transmit magnetic exchange interactions has also been examined.

## Quadrant Effects

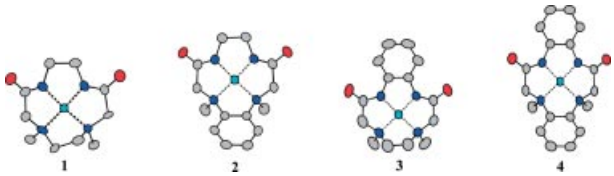
## $Ni^{II}/Ni^{III}$ Chemistry



This work shows the design and synthesis of four novel macrocyclic ligands and their square-planar $Ni^{II}$ complexes **1**−**4**. The attainable redox potential for $Ni^{II}$ complexes (>0.6 V vs. SCE) allowed us to oxidize them electrochemically or chemically to generate an unstable "green species" that show distinct features in the absorption spectrum and exhibit anisotropic EPR spectrum. These findings strongly point out that the unstable green species is a $Ni^{III}$ species.

# Reactions of Ytterbocenes with Diimines: Steric Manipulation of Reductive Reactivity

**Alexander A. Trifonov*[a]**

*Dedicated to Prof. G. A. Abakumov on the occasion of his 70th birthday*

**Keywords:** Lanthanides / Diimines / Reductive reactivity / N,N ligands / Redox tautomerism

This review is devoted to the investigation of reactions of ytterbocenes with diimines. These reactions are found to be strongly influenced by the steric crowding in the coordination sphere of the metal atom and the coordination capacities of π-aromatic ligands coordinated to the ytterbium. The reactions may occur with oxidation of the ytterbium atom as well as with retention of its oxidation state. C–C bond formation, C–H bond activation, C=N bond insertion, and oxidative Yb–C bond cleavage processes are documented for reactions of ytterbocenes with diimines. Steric overcrowding of the coordination sphere of the ytterbium atom can induce "extra" reducing ability of ytterbocenes and allow them to act not only as one- but also as two-electron reductants with respect to diimines.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Diimino ligands appeared in transition-metal chemistry in the late 1960s and have turned out to be a promising coordination environment able to provide unusual structures and unique reactivity.[1] The high catalytic activity of the diimino complexes of late transition metals in olefin polymerization has demonstrated the high potential of this ligand system in catalysis.[2] The permanent attention for diimines is mainly roused by the diversity of their redox and coordination properties. The lone electron pair at nitrogen atoms and the π electrons of the C=N bonds allow the diimine molecule to act both as a N-donor and as a π-electron donor ligand in a variety of coordination modes. The redox-active diimine molecule can coordinate metal atoms in high oxidation states as a neutral ligand[3] (Scheme 1, A), but also, due to its pronounced electron affinity (for example, the reduction potential of *t*BuN=CH–CH=N*t*Bu is $E^0_{SCE}$ = 1.822 V),[4] it can oxidize electropositive metals accepting one or two electrons, thus forming a radical anion (Scheme 1, B)[5] or dianion (Scheme 1, C).[6]

The diimine ligands were introduced into organolanthanide chemistry in the works of Cloke and Edelmann in the 1980s and allowed the synthesis of isolable lanthanide complexes.[7] The known compounds could be divided into two main groups based on the reduction state and the coordination mode of the diimino ligand. The first group is presented by homo- and hetero-ligated compounds containing the diimine radical anion coordinated to the lanthanide atom by two nitrogen atoms (Scheme 1, B).[7a–7f] The second group consists of complexes coordinated by the doubly reduced enediamido fragment 2σ:π-bonded to the central metal atom (Scheme 1, C).[7g,7h]

The redox-active character of diimines and the low energy of their π* orbitals[8] makes their complexes with lanthanide metals of two stable oxidation states promising ob-

*Alexander Trifonov was born in Gorky (Nizhny Novgorod), Russia in 1962. In 1979–1984 he studied chemistry at the State University of Gorky and in 1984 received his diploma degree. During his PhD studies he worked at the Institute of Organometallic Chemistry of Russian Academy of Sciences (Nizhny Novgorod) under the supervision of Prof. M. N. Bochkarev and in 1989 received his PhD. He did postdoctoral studies at the Technical University of Berlin (Prof. H. Schumann, 1991), Université de Paris-Sud (Prof. H. Kagan, 1993–1995), and Mainz University (Prof. J. Okuda, 1999–2000). After returning to the Institute of Organometallic Chemistry, he defended the second thesis in 2003 and in 2004 became head of the Laboratory of Coordination Chemistry. Since 2005 he has been a professor of chemistry of Nizhny Novgorod State University. His research interests lie in the area of the synthesis of organometallic and coordination compounds of rare earth metals and their application in homogeneous catalysis and material chemistry.*

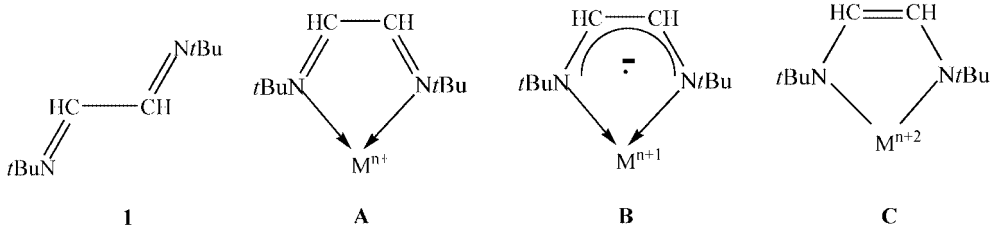


Scheme 1.

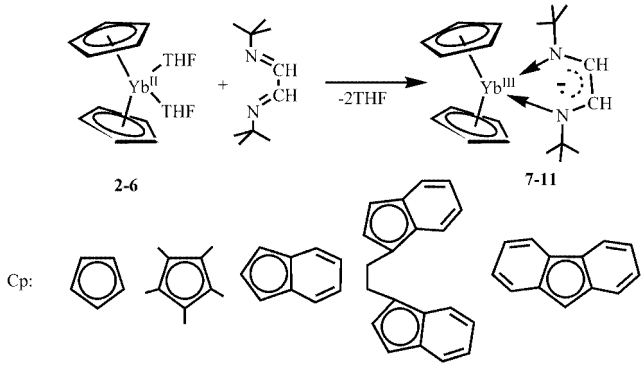
jects with respect to investigation of intramolecular metal–ligand electron transfers. Ytterbium seems to be the most advantageous candidate for this purpose due to a rather low $Yb^{II} \rightleftharpoons Yb^{III}$ transformation potential (for comparison, reduction potentials of $M^{III}/M^{II}$ in aqueous solution vs. SHE: Eu, –0.35; Yb, –1.15; Sm, –1.55 V).[9] Diamagnetism of the divalent ytterbium (electron configuration $Yb^{II}$ $4f^{14}$) complexes and moderate paramagnetism of its trivalent species (electron configuration $Yb^{III}$ $4f^{13}$, $\mu$ = 3.29–4.45 $\mu_B$)[10] makes NMR spectroscopy applicable for the investigation of ytterbium compounds in both oxidation states. On the other hand, noticeable differences in the magnetic properties of the $Yb^{II}$ and $Yb^{III}$ derivatives[10] allow easy estimation of the ytterbium atom oxidation state by means of magnetochemistry. Moreover, complexes of trivalent ytterbium emitting in the near-infrared region and containing conjugated diimino ligands which can act as sensitizers are of great interest because of potential applications in optoelectronic devices and medical diagnosis.[11] Compounds that undergo easy and reversible redox transformations by intramolecular electron transfer provoked by low-energy external excitations are of potential interest for the construction of molecular switches.

Complexes of trivalent ytterbium containing radical-anionic diimine ligands are promising models for investigation of metal–ligand bonding to provide a ground for a deeper understanding of the electronic structure of f-metal compounds and the contribution of f-electrons in a bonding interaction. The first tris(diazabutadiene) derivative of trivalent ytterbium ($t$BuNCHCHN$t$Bu)$_3$Yb containing three radical-anionic diimine ligands has demonstrated a complex temperature-dependent magnetic behavior which allowed us to suggest the existence of redox tautomerism.[7f] In order to gain insight into the nature of bonding in diimino complexes of f-elements, we focused on the synthesis of mixed-ligand $Yb^{III}$ compounds containing one paramagnetic ligand. The reactions of ytterbocenes with diimines were chosen as a synthetic approach to this class of compounds, and systematic investigation of these reactions has unexpectedly discovered a very rich and often unpredictable reactivity. The differences in reactivity as a function of steric crowding in the coordination sphere of the metal atom, coordination capacities of the π-aromatic ligands bound to ytterbium, and their tendency towards haptotropic rearrangements allow an expansion of ytterbocene reductive chemistry and the revelation of new types of reactions and complexes.

The review is mainly focused on the ytterbium derivatives since there is far less known about the diimine complexes of samarium and ytterbium. Work on this subject is being pursued at the moment.

## 2. Reactions Resulting in the Formation of Diimino Complexes $[Cp_2Yb^{III}(L^{\cdot-})]$ and $[Cp_2Yb^{II}(L^0)]$ (Cp = $C_5H_5$, $C_5MeH_4$, $C_5Me_5$, $C_9H_7$, $C_9H_6CH_2$, $C_{13}H_9$; L = RN=CH–CH=NR, bipy)

The *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene (**1**) was the first and remains the most widely employed diazabutadiene ligand in organolanthanide chemistry. Ytterbocenes $[Cp_2Yb(THF)_2]$ {Cp = $C_5H_5$ (**2**), $C_5Me_5$ (**3**), $C_9H_7$ (**4**), $C_9H_6CH_2$ (**5**), $C_{13}H_9$ (**6**)} reacted with **1** in a similar way, and the reactions afforded sandwich complexes of trivalent ytterbium containing the radical anion of diazabutadiene $[Cp_2Yb(t$BuNCHCHN$t$Bu$^{\cdot-})]$ {Cp = $C_5H_5$ (**7**),[12] $C_5Me_5$ (**8**),[13] $C_9H_7$ (**9**),[14] $C_9H_6CH_2$ (**10**),[14] $C_{13}H_9$ (**11**)[15]} (Scheme 2). It is worthy to note that **1** oxidized complex **2** at room temperature in THF solution, while compounds **3**–**6** did not react with **1** in THF. This is proven by the $^1$H NMR spectra of the reaction mixtures of **3**–**6** and **1** in [$D_8$]-thf which show superposition of the spectra of the diamagnetic $Yb^{II}$ complexes and of free diazabutadiene. In contrast, $^1$H NMR spectroscopy indicates paramagnetism of the product formed in the reaction of **2** and **1** in THF, thus giving evidence for the oxidation of the ytterbium atom to $Yb^{III}$ oxidation state. The reactions of complexes **3**–**6** with **1** occurred only in toluene media at 60 °C and resulted in the formation of the complexes **8**–**11** (Scheme 2).



Scheme 2.

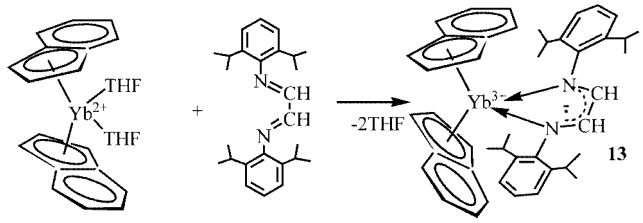
$$2(C_5H_5)_2YbCl(THF) + Na^+{}_2(t\text{BuNCHCHN}t\text{Bu}^{2-}) \xrightarrow{THF} (C_5H_5)_2Yb(t\text{BuNCHCHN}t\text{Bu}) + (C_5H_5)_2Yb(THF)_2 + 2NaCl$$

**7**

Scheme 3.

Complex **7** was also obtained by the metathesis reaction of equimolar amounts of $[(C_5H_5)_2YbCl(THF)]$ and $(t\text{BuNCHCHN}t\text{Bu}^{-})K^+$ (Scheme 3). An attempt to synthesize a dinuclear compound containing two $[(C_5H_5)_2Yb]$ moieties linked by a μ-bridging enediamido fragment by the reaction of a twofold molar excess of $[(C_5H_5)_2YbCl(THF)]$ with $Na^+{}_2(t\text{BuNCHCHN}t\text{Bu}^{2-})$ afforded a mixture of complex **7** and $[(C_5H_5)_2Yb(THF)_2]$ (Scheme 3).[12]

The bulkier 1,4-bis(2,6-diisopropylphenyl)-1,4-diaza-1,3-butadiene (**12**) also reacted with ytterbocenes $[(C_9H_7)_2Yb(THF)_2]$ and $[(C_5MeH_4)_2Yb(THF)_2]$ in toluene, affording the derivatives of trivalent ytterbium coordinated by the radical anion of diazadiene $[(C_9H_7)_2Yb(i\text{Pr}_2C_6H_3NCHCHNC_6H_3i\text{Pr}_2)]$ (**13**)[16] and $[(C_5MeH_4)_2Yb(i\text{Pr}_2C_6H_3NCHCHNC_6H_3i\text{Pr}_2)]$ (**14**), respectively (Scheme 4).[17]



Scheme 4.

The structures of complexes **7**–**10**, **13**, **14** have been determined by X-ray diffraction studies which revealed that in all compounds, the ytterbium atom is $\eta^5$-coordinated by the two "cyclopentadienyl" units and the two nitrogen atoms of the radical-anionic diazabutadiene ligand, and it adopts the geometry of a distorted tetrahedron (Figures 1, 2, 3, 4, 5, and 6).

The Yb–$Cp_{Centr.}$ distances in complexes **7**–**10**, **13**, **14** (Table 1) are shorter than those in the starting $Yb^{II}$ complexes.[18] The shortening of the Yb–$Cp_{Centr.}$ distances in complexes **7**–**10**, **13**, **14** compared with those in the starting ytterbocenes indicates the oxidation of the ytterbium atom from $Yb^{II}$ to $Yb^{III}$.[19] However, in all cases the magnitude of the shortening is considerably less than that expected on the basis of the difference in the ionic radii of $Yb^{II}$ and $Yb^{III}$ (0.155 Å) and obviously results from reciprocal repul-

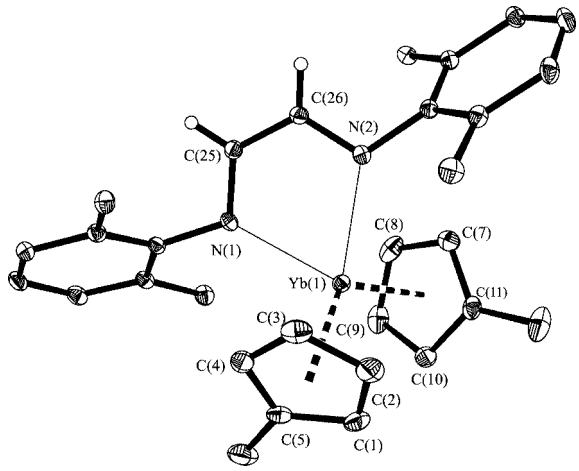

Figure 6. Molecular structure of complex $[(C_5MeH_4)_2Yb(i\text{Pr}_2\text{-}C_6H_3NCHCHNC_6H_3i\text{Pr}_2)]$ (**14**). The methyl carbon atoms of the *i*Pr groups are omitted.

sion of the π-aromatic ligands coordinated to the ytterbium atom and the diazabutadiene ligand. The Yb–$Cp_{Centr.}$ bond lengths observed in the related complexes **7**–**10** increase as a function of the bulkiness of the $\eta^5$-coordinated ligand and become the maximum for the pentamethylcyclopentadienyl ligand, reflecting its highest steric demand in the series of synthesized compounds. The same tendency is also observed for Yb–N bond lengths in complexes **7**–**10** (Table 1). Comparison of the bonding situation in complexes **9** and **13**, containing the same indenyl ligands but different diazadienes, shows that the replacement of the *tert*-butyl radical by bulkier 2,6-diisopropylphenyl in the diazadiene molecule results in noticeable lengthening of the Yb–N bonds. The bond lengths within the diazabutadiene ligand of compounds **7**–**10**, **13**, **14** indicate its radical-anionic character. An electron transfer from the ytterbium atom to the LUMO of the ligand is expected to cause delocalization of the charge over the whole conjugated NCCN fragment which involves changes in the bond lengths. Compared with the N=C and C–C bond lengths in the parent free diazadiene molecules,[20,21] the N=C bonds in the diazadiene ligands of complexes **7**–**10**, **13**, **14** are substantially elongated, while the C–C bonds are shortened and close to the values of aromatic C–C bonds.[22] The structural parameters of complexes **7**–**10**, **13**, **14** are in agreement with the trivalent oxidation state of the ytterbium atom and the radical-anionic character of the diazadiene ligand. Unexpectedly, the complexes **7**–**11**, **13**, **14** in the solid state as well as in toluene solutions are ESR silent in the temperature range 173 to 300 K. This fact is attributable either to a substantial broadening of the signal of the diazadiene radical anion in the field of the paramagnetic $Yb^{III}$ ion or to antiferromagnetic coupling of the spin carriers. The IR and UV/Vis spectra of complexes **7**–**11**, **13**, **14** identify the diazabutadiene ligand as a radical anion. The complexes **7**–**11**, **13**, **14** are paramagnetic with the values of the effective magnetic moments in the region 3.0–4.8 $\mu_B$ (300 K), giving evidence for the trivalent oxidation state of the ytterbium atom.[10]

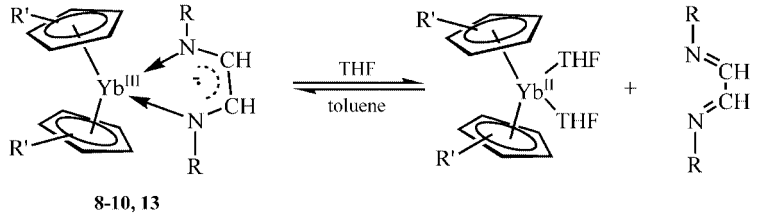
Magnetic measurements of crystalline samples of complexes **9**, **10**,[14] **13**,[16] **14**[17] in the temperature range 2–300 K show a similar shape of the plots of $1/\chi$ versus $T$ and $\mu$ versus $T$ with nonlinear dependence as a function of temperature. The effective magnetic moments of the complexes **9**, **10**, **13** increase from 1.50–1.60 $\mu_B$ at 2 K to 3.0–3.4 $\mu_B$ at 300 K. The values of the effective magnetic moments of **9**, **10**, **13** in benzene solution at 300 K, estimated according to the published procedure,[23] are in agreement with the data obtained for the crystalline samples by the SQUID method. Trivalent ytterbium is paramagnetic with an electron configuration of $4f^{13}$, and the expected magnetic moment of $Yb^{III}$ complexes is 3.8 $\mu_B$ at 5–30 K and 4.5 $\mu_B$ at 90–300 K.[24] For complexes containing noninteracting spins, their contribution to the molar magnetic susceptibility is additive. A $Yb^{III}$ complex additionally containing a radical anion, as is suggested for **9**, **10**, **13**, should show a magnetic moment of 4.2 $\mu_B$ in the temperature range of 5–30 K and 4.8 $\mu_B$ in the temperature range of 90–300 K, provided that the spins of the two unpaired electrons do not interact. However, the experimental values of the magnetic moments obtained for **9**, **10**, **13** are considerably lower than the expected values which can be caused either by redox tautomerism between paramagnetic [$(C_9H_7)_2Yb^{III}(L^{-})$] and diamagnetic [$(C_9H_7)_2Yb^{II}(L^0)$] molecules or by antiferromagnetic coupling of the two unpaired electrons in [$(C_9H_7)_2Yb^{III}(L^{-})$] (L = diazadiene). Antiferromagnetic coupling between trivalent rare earth ions and paramagnetic semiquinone ligands was found to be dominating for the series of complexes Ln(DTBSQ)$(HBPz_3)_2$ (Ln = Er, Tb, Dy, Yb; DTBSQ = 3,5-di-*tert*-butylsemiquinone; $HBPz_3$ = hydrotrispyrazolylborate).[25] Hatfield and co-workers have described a strong exchange coupling between the lanthanide ions and the phthalocyaninato ligand radical in bis(phthalocyaninato)lanthanide sandwich compounds ($Pc^{2-}$) $Ln^{III}(Pc^{1-})$ (Ln = Gd, Tb, Dy, Ho, Er, Tm, Yb, Lu). The value of the room-temperature magnetic moment for the trivalent ytterbium antiferromagnetically coupled with an organic radical anion was calculated as 3.46 $\mu_B$.[26] The value of the magnetic moment (4.06 $\mu_B$) observed at 300 K for complex **14** suggests that both ferro- and antiferromagnetic coupled states of $Yb^{3+}$ and the radical anion are present at room temperature. The analysis of the plots $1/\chi$ versus $T$ and $\mu$ versus $T$ suggests that an antiferromagnetic spin interaction is a plausible reason for the low magnetic moments, however the available data do not allow definite exclusion of the existence of redox tautomers for **9**, **10**, **13**, **14**.

Complexes **8**–**10**, **13** have demonstrated uncommon solvent-mediated intramolecular redox transformations in solutions.[13,14,16] Complexes **8**–**10**, **13** in the crystalline state as well as in nonsolvating solvents (aromatic or aliphatic hydrocarbons) exist as paramagnetic derivatives of trivalent ytterbium coordinated by the diazadiene radical anion [$(R)_2Yb^{III}(L^{-})$] (R = $C_5Me_5$, $C_9H_7$, $-CH_2C_9H_6$; L = diazadiene), while in solvating solvents (THF) these compounds are diamagnetic. $^1$H NMR, UV/Vis spectroscopy, and magnetic measurements proved the diamagnetism of complexes **8**–**10**, **13** in THF solutions and therefore the divalent oxidation state of the ytterbium atom. Moreover, recrystallization of complexes **8**–**10**, **13** from THF/hexane mixtures allowed the recovery of the parent ytterbocene in good yields. Dissolution of **8**–**10**, **13** in THF caused displacement of the radical-anionic diazadiene ligand by THF molecules. This process implies an electron transfer from the diazadiene radical anion to the ytterbium ion, resulting in the oxidation of the ligand to neutral diazadiene and reduction of $Yb^{III}$ to $Yb^{II}$ followed by substitution of the neutral diazadiene ligand by THF molecules (Scheme 5).[14,16]

One can suppose that steric repulsion of the bulky indenyl, pentamethylcyclopentadienyl, and diazadiene ligands is decisive for the examined reactions and the elongation and weakening of the Yb–N bonds in complexes **8**–**10**, **13**. Hence, the energy of the Coulomb interaction between the $[(R)_2Yb^{III}]^+$ cationic species and the radical anion of diazadiene is comparable with that of the coordination bonds between $R_2Yb^{II}$ and THF molecules, and as a result the diazadiene ligand redox substitution becomes feasible.

Unlike complexes **8**–**10**, **13**, compound [$Cp_2Yb$($t$BuNCHCHN$t$Bu)] (**7**) did not undergo a reductive substitution process and remained paramagnetic in THF solutions.[12] Such a distinction in solution redox behavior is

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



Scheme 5.

obviously caused by the structural difference of **7** and namely by the Yb–N bond lengths which are the shortest in the series of related compounds (Table 1). The shorter contact between cationic and anionic moieties in complex **7** should result in an increase in the energy of the Coulomb interaction, and the energy consumption for the reductive substitution of the diazadiene ligand can not be overcome by formation of coordination ytterbium–oxygen bonds. A similar behavior towards THF was described by Evans and co-workers for decamethylsamarocene complexes with aromatic polycyclic ligands.[27] However, unlike complexes **8**–**10**, **13**, the samarium derivatives can not be regenerated by removal of THF and addition of aromatic or aliphatic solvents.

Distinctions in the reductive reactivity of metallocene derivatives of divalent samarium and europium toward diimines from that of ytterbium compounds are defined by the $Ln^{II}/Ln^{III}$ transformation potentials characteristic for these elements. The reducing capacity of $Ln^{II}$ compounds increases in the triad Eu < Yb < Sm (for comparison, reduction potentials $M^{III}/M^{II}$ in aqueous solution vs. SHE: Eu, –0.35; Yb, –1.15; Sm, –1.55 V).[9a] Decamethylsamarocene easily reduced *N*,*N*′-di-*tert*-butyl-1,4-diazabutadiene, affording the derivative of trivalent samarium coordinated by the radical anion of diazadiene $(C_5Me_5)_2Sm^{III}$-(*t*BuNCHCHN*t*Bu$^{-\cdot}$) (**15**),[7c] whereas the reaction of the europium analogue $(C_5Me_5)_2Eu(Et_2O)$ resulted in the formation of the adduct with the neutral diazadiene ligand $(C_5Me_5)_2Eu^{II}$(*t*BuNCHCHN*t*Bu$^0$) (**16**).[28] On the other hand, the diazadiene $(C_6F_5)N{=}C(Me){-}C(Me){=}N(C_6F_5)$ possessing higher electron affinity oxidized $(C_5Me_5)_2Eu(Et_2O)$ in toluene solution at room temperature to the trivalent europium complex $(C_5Me_5)_2Eu^{III}\{C_6F_5NC(Me)C(Me)NC_6F_5^{-\cdot}\}$ (**17**) (Scheme 6).[28] The difference in the oxidation state of the europium atom in complexes **16** and **17** is undoubtedly proven by the metric parameters and magnetic measurements of the compounds.

Solvent-mediated reversible intramolecular redox reaction, analogous to that previously described for ytterbium compounds,[13,14,16] was reported for complex **17**.

The reactivity of metallocene-type complexes of trivalent lanthanides containing the radical anion of diazadiene is poorly investigated. Complexes **7**–**11**, **13** are inactive in olefin polymerization. Reaction of complex **7** with 9-fluorenone in a 1:1 molar ratio in THF was found to occur with oxidation of the diazadiene radical anion, abstraction of

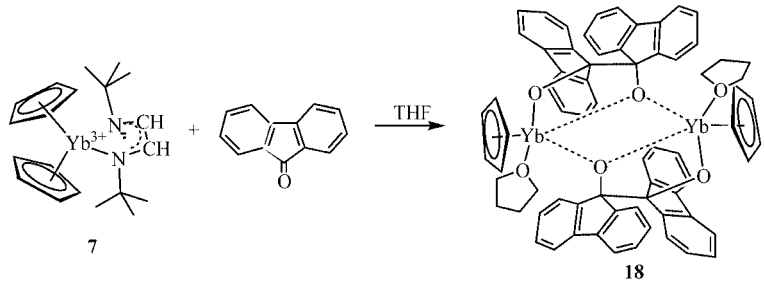

Scheme 7.

one cyclopentadienyl ring, pinakol condensation, and formation of the dimeric $Yb^{III}$ complex [CpYb($\mu^2$-$OC_{13}H_8$–$C_{13}H_8O$)(THF)]$_2$ (**18**) (Scheme 7).[13] An X-ray diffraction study of complex **18** has revealed that two [CpYb(THF)] moieties are linked by two 9,9-difluorenyldialcoxo ligands (Figure 7).

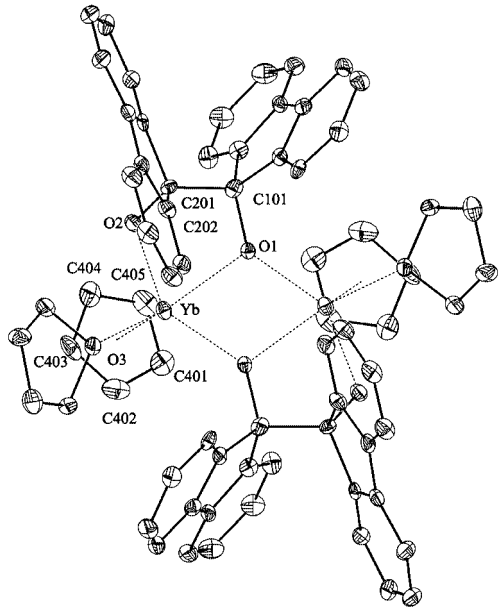

Figure 7. Molecular structure of complex [CpYb($\mu^2$-$OC_{13}H_8$–$C_{13}H_8O$)(THF)]$_2$ (**18**).

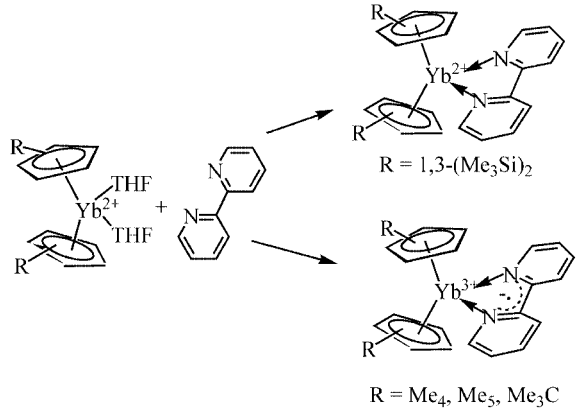
2,2′-Bipyridine (bipy), which has a virtually planar structure and contains a N=C–C=N fragment, can be considered as a diimine ligand. The reduction potential of bipy (–2.18 V)[29] is noticeably lower than that of 1,4-di-*tert*-butyl-1,4-diazabuta-1,3-diene (–1.822 V),[4] and bipyridine derivatives of ytterbium have promise from the standpoint of possible redox tautomeric transformations. Andersen and co-workers have investigated reactions of ytterbocenes bearing cyclopentadienyl ligands with different substituents [Cp′′$_2$Yb($Et_2O$)] {Cp′′ = $C_5Me_5$, $C_5Me_4H$, 1,3-$(Me_3C)_2$-$C_5H_3$, 1,3-$(Me_3Si)_2C_5H_3$} with 2,2′-bipyridine (bipy) and phenanthroline (phen), which afforded complexes [Cp′′$_2$Yb(L)] (L = bipy, phen).[30,31] The various ytterbocenes interacted differently with bipy and phenanthroline depending on the steric and electronic properties of the substituents on the cyclopentadienyl ligands, which also influence the extent of paramagnetism of the resultant compounds [Cp′′$_2$Yb(L)]. The electron-withdrawing $SiMe_3$ groups make the metal more electropositive thus stabilizing the $Yb^{II}$ oxidation state; the derived ytterbocene did not reduce bipy and phen, and the reactions afforded the adducts with neutral L [Cp′′$_2$$Yb^{II}$($L^0$)]. The ytterbocenes containing electron-donating alkyl groups (pentamethyl, tetramethyl, *t*Bu) on the cyclopentadienyl rings tend to reduce bipy and phen, affording paramagnetic $Yb^{III}$ complexes containing a bipy radical anion [Cp′′$_2$$Yb^{III}$($L^{-\cdot}$)] (Scheme 8).



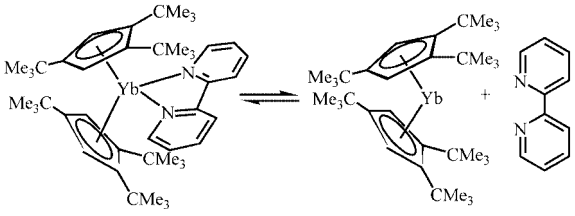
Scheme 8.

The measured magnetic moments of obtained complexes, which are less than those expected for complexes [Cp′′$_2$$Yb^{III}$($L^{-\cdot}$)] containing two noninteracting paramagnetic centers, are explained by electron exchange model for spin coupling between $Yb^{III}$ and the single unpaired electron in the anion radical $L^{-\cdot}$. The extent of paramagnetism of paramagnetic complexes [$(C_5Me_5)_2$Yb(bipy-X)] with 4,4′-disubstituted bipyridines (X = Me, $Me_3C$, OMe, Ph, $CO_2Me$, $CO_2Et$) was found to be dependent on the substituents on the bipyridine ligands. The values of $\chi$ and $\mu_{eff}$ at 400 K increase in the series OMe < H < $CO_2R$ (R = Me, Et) ≤ Ph and correlate with the electron-withdrawing properties of the substituents.[32]

Unusual for substituted ytterbocene bipyridine adducts, rapid exchange (on the NMR time scale) between the complex [{1,2,4-$(Me_3C)_3C_5H_2$}$_2$Yb(bipy)] and free 2,2′-bipyr-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

idine was observed in [$D_8$]toluene in a wide range of temperatures, thus indicating fluxional behavior in solution (Scheme 9).[31]



Scheme 9.

The electrochemical studies of complexes [$(C_5Me_5)_2$Yb(L)] (L = bipy, phen) have demonstrated that stabilization of their respective LUMOs of diimine ligands and destabilization of metal f-orbitals favors the spontaneous ground-state charge-transfer process. The spectroscopic data from the f-f transition region for [$(C_5Me_5)_2$Yb(L)] indicate that the f-orbital splitting in these compounds is not sensitive to the differences in the electronic structures of bipy and phen. The separation between the ligand-based oxidation wave ($L^{0/-}$) and the metal-based reduction wave ($Yb^{III/II}$) in the adducts [$(C_5Me_5)_2$Yb(L)] is 0.79 V for both bipy and phen derivatives. In the spectra of complexes [$(C_5Me_5)_2$Yb(L)] previously unreported, the near-IR bands have been assigned to ligand($\pi^*$)-to-metal(f-orbital) charge-transfer transitions. The Raman spectra give evidence of the radical-anionic nature of the diimine ligands in these complexes.[33]

The bis(indenyl) derivative [$(C_9H_7)_2$Yb(THF)$_2$] (**4**) reacted with bipy in THF at room temperature to yield the $Yb^{II}$ complex [$(C_9H_7)_2Yb^{II}(bipy^0)$] (**19**). This is consistent with the lower electron-donating ability of the indenyl ligand compared with that of the pentamethylcyclopentadienyl ligand that results in lower reducing capacity of complex **4**. Surprisingly despite the higher electron affinity of diazadiene **1**, it did not react with complex **4** in THF media, while the reaction with bipy immediately afforded compound **19** in good yield. Obviously that can be attributed to the higher steric demand of the ligand **1**. Magnetic measurement, $^1$H NMR, IR, and UV/Vis spectra of **19** indicate that the complex is a diamagnetic adduct with neutral bipy. The X-ray diffraction analysis of complex **19** has revealed that the crystals contain two crystallographically independent molecules. The Yb–C bond lengths indicate the divalent state of the ytterbium atom. The most essential difference of the two crystallographically independent molecules **19** are the dihedral angles between the planes of the pyridine rings: 11.2(8)° and 4.8(8)°.[16] The torsion angle between the planes of the pyridine rings serves as an indicator of the electronic state of the bipy ligand in the complex. This angle in free bipy and in complexes with the neutral bipy ligand is in the region 10–17°;[29,30] the electron transfer to the highest occupied molecular orbital of the bipy molecule leads to a change in its geometry, including its flattening due to partial double bonding between two C atoms at positions 2 and 2′. Hence, the presence of two crystallographically independent molecules, which differ in the geometric parameters of the bipy ligand, could be considered as evidence for the existence of redox isomers of **19**. However, the identity of the Yb–C bond lengths and the geometry of the bipy ligands in both molecules **19** rules out the existence of redox isomers. Apparently, the difference in the dihedral angles of the bipy ligands in two crystallographically independent molecules is associated not with the electronic state but with steric restrictions caused by the mutual arrangement of the indenyl and bipy ligands. Furthermore, in one of the molecules, the six-membered fragments of the indenyl ligands are located above each pyridine ring of the bipyridine ligand (Figure 8).

Therefore, an increase in the dihedral angle between the pyridine rings should result in close contacts between indenyl and bipy ligands and consequently in the increase in the energy of nonbonded repulsions.

## 3. Reactions Resulting in C–C Bond Formation

As mentioned earlier, the Yb–N bond lengths and the reversibility of the intramolecular metal–ligand electron transfer can be regulated by tuning the steric demand of the ligands coordinated to the ytterbium atom and the substituents at the nitrogen atoms of the diimine molecule. However, successive increase in the π-aromatic ligand size in the series $C_5MeH_4$, $C_9H_7$, $C_{13}H_9$ led (in the case of fluor-

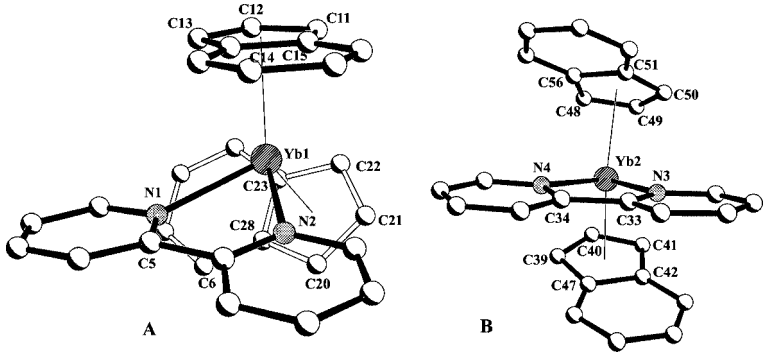


Figure 8. Two crystallographically independent molecules of complex [$(C_9H_7)_2Yb^{II}(bipy^0)$] (**19**).

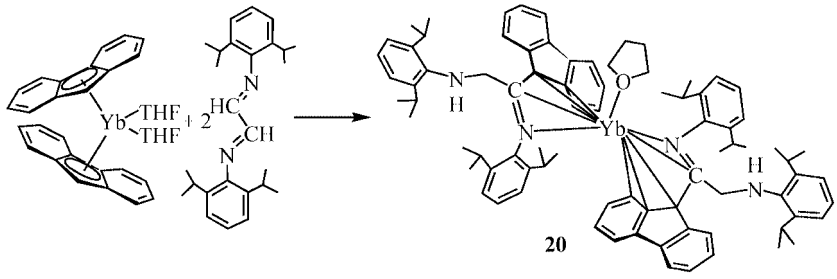

Scheme 10.

enyl) to a dramatic change in the pathway of the reaction of 1,4-bis(2,6-diisopropylphenyl)-1,4-diaza-1,3-butadiene (**12**) with a related ytterbocene. Unlike the previously mentioned reactions of ytterbocenes with diimines, the reaction of the bis(fluorenyl) complex $[(C_{13}H_9)_2Yb(THF)_2]$ with bulkier **12** under the same conditions did not occur with oxidation of the ytterbium atom but resulted in the formation of the unusual $Yb^{II}$ derivative $[Yb\{\eta^5\text{-}C_{13}H_8C(=N\text{–}C_6H_3iPr_2\text{-}2,6)CH_2NHC_6H_3iPr_2\text{-}2,6\}_2(THF)]$ (**20**) which was isolated in 80% yield (Scheme 10).[34]

The $Yb^{II}$ cation is $\eta^5$-coordinated by two novel monoanionic multifunctional ligands $\{C_{13}H_8C(=N\text{–}C_6H_3iPr_2\text{-}2,6)CH_2NHC_6H_3iPr_2\text{-}2,6\}^-$ arising from unprecedented coupling of the allylic carbon atom of the fluorenyl ligand with the imino carbon atom of the diazadiene **12** (Figure 9).

The C–C bond formation in **20** also implies migration of the two H atoms initially bonded to the coupled carbon atoms and acquisition of these hydrogen atoms by the second imino group which results in the hydrogenated $–CH_2–NH–$ fragment. In the course of the reaction, the coordination mode of the fluorenyl ligand to the Yb atom changes from the $\eta^5$-type in the starting complex $[(C_{13}H_9)_2Yb(THF)_2]$,[15] to a rather unusual $\eta^3$-type by one carbon atom of the five-membered ring and two carbon atoms of the six-membered ring. The $\eta^2$-coordination of the imino group to the Yb atom results in formation of the planer $\eta^5$-bonded heteropentadienyl frame. The bonding situation gives evidence of a delocalized π system in the heteropentadienyl fragment. The arrangement around the ytterbium atom in **20** determines the geometry of the heteropentadienyl bent sandwich complex.

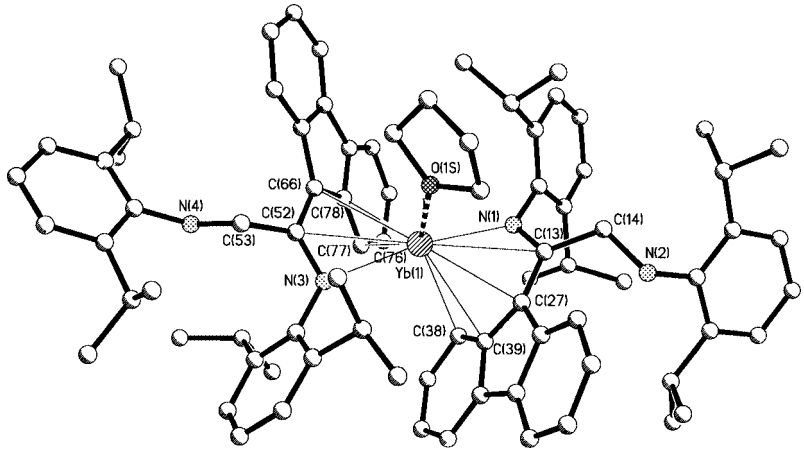

Figure 9. Molecular structure of complex $[Yb\{\eta^5\text{-}C_{13}H_8C(=N\text{–}C_6H_3iPr_2\text{-}2,6)CH_2NHC_6H_3iPr_2\text{-}2,6\}_2(THF)]$ (**20**).

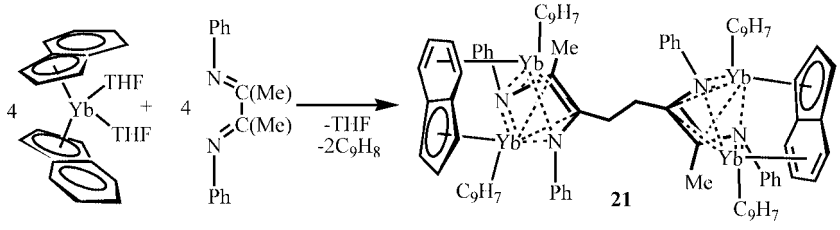

Scheme 11.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

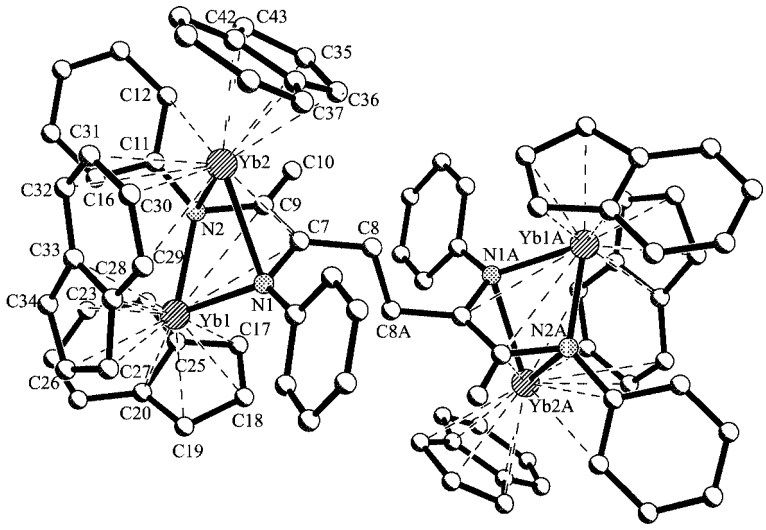

Figure 10. Molecular structure of complex $[Yb_2(\mu\text{-}\eta^5{:}\eta^4\text{-}C_9H_7)(\eta^5\text{-}C_9H_7)_2\{\mu\text{-}\eta^4{:}\eta^4\text{-}PhNC(CH_2)=C(Me)NPh\}]_2$ (**21**).

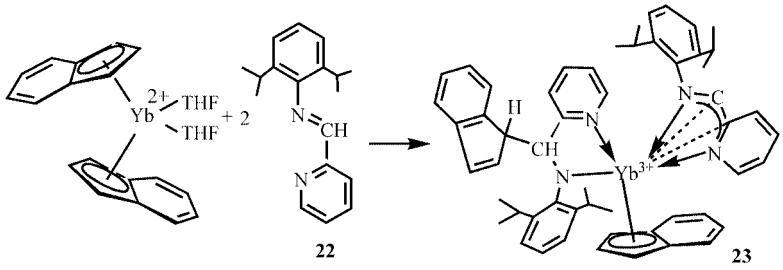
Another example of C–C bond formation was documented for the reaction of bis(indenyl)ytterbium complex $[(C_9H_7)_2Yb(THF)_2]$ with an equimolar amount of the diazabutadiene PhN=C(Me)–C(Me)=NPh. The reaction occurred with reductive diimine coupling and afforded the tetranuclear complex $[Yb_2(\mu\text{-}\eta^5{:}\eta^4\text{-}C_9H_7)(\eta^5\text{-}C_9H_7)_2\{\mu\text{-}\eta^4{:}\eta^4\text{-}PhNC(CH_2)=C(Me)NPh\}]_2$ (**21**) (Scheme 11).[35]

The reaction is accompanied by indene formation which obviously arises as a product of partial cleavage of Yb–indenyl bonds and hydrogen abstraction by the indenyl radical from a molecule of solvent or diimine. The molecule of **21** has a tetranuclear core which consists of two dinuclear units $[Yb_2(\mu\text{-}\eta^5{:}\eta^4\text{-}C_9H_7)(\eta^5\text{-}C_9H_7)_2\{\mu\text{-}\eta^4{:}\eta^4\text{-}PhNC(CH_2)=C(Me)NPh\}]$ connected by the $CH_2$–$CH_2$ bridge, as a result of hydrogen abstraction from one of the methyl radicals at the imino group of the diazadiene ligand and coupling of these methylene carbon atoms (Figure 10).

The dinuclear fragments are assembled due to unusual bridging $\mu\text{-}\eta^5{:}\eta^4$-coordination of the indenyl ligand and $\mu\text{-}\eta^4{:}\eta^4$-coordination of the diimine ligand. Each ytterbium atom in complex **20** is coordinated by two indenyl ligands but in different ways. One ytterbium atom of the dinuclear unit is $\eta^5$-bound with two cyclopentadienyl fragments of two indenyl ligands, while the second ytterbium atom is coordinated by the five- and six-membered rings in $\eta^5$- and $\eta^4$-fashion, respectively. Coordination of the six-membered ring leads to noticeable distortion of its planarity. Such $\mu$-bridging coordination of indenyl ligands is rather rare[36] and, to the best of our knowledge, has never been described for organolanthanides. The *ipso*- and *ortho*-carbon atoms of one of the phenyl rings of the diimine ligand are also involved in metal–ligand bonding through $\eta^2$-coordination to the ytterbium atom. The average Yb–C($C_5$-indenyl) and Yb–N bond lengths in **21** are somewhat different for the ytterbium atoms within a dinuclear unit. Complex **21** is paramagnetic with the experimental value of the effective magnetic moment 2.6 $\mu_B$ (293 K), which is intermediate between the average $\mu_{eff}$ value reported for $Yb^{III}$ derivatives and that of diamagnetic $Yb^{II}$ compounds.[10] Thus both the X-ray analysis data and magnetic measurements provide evidence that complex **21** is a mixed-valent compound containing both $Yb^{II}$ and $Yb^{III}$ atoms. The bonding situation within the NCCN fragment of **21** is consistent with a dianionic character of the diimino ligand. The double C–C bond of a doubly reduced enediamido moiety also participates in a dinuclear core formation, coordinating to both ytterbium atoms in $\eta^2$-fashion. The length of the carbon–carbon bond formed in the reaction is characteristic for ordinary C–C σ bonds.[22]



Scheme 12.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Iminopyridines containing a conjugated NCCN fragment might be considered as diimino ligands. Formation of a C–C bond resulted from N=C bond insertion into the Yb–($\eta^5$-$C_9H_7$) bond which was observed in the reaction of bis(indenyl) derivative [$(C_9H_7)_2Yb(THF)_2$] with a twofold molar excess of *N*-2,6-diisopropylphenylimino-2-pyridine (**22**) (THF, 20 °C), which led to formation of the $Yb^{III}$ complex [Yb($\eta^5$-$C_9H_7$){N(2,6-*i*$Pr_2C_6H_3$)CH($C_9H_7$)($C_5H_5N$)}-{$\eta^4$-2,6-*i*$Pr_2C_6H_3$NCH($C_5H_5N$)}] (**23**) (Scheme 12).[37]

Paramagnetism of complex **23** ($\mu_{eff}$ = 4.3 $\mu_B$, 293 K) indicates the trivalent oxidation state of the ytterbium atom.[10] Compound **23** is a half-sandwich complex in which the coordination sphere of the Yb atom is set up by an $\eta^5$-coordinated $C_9H_7$ anion, two nitrogen atoms of an amido-pyridinato ligand, and two nitrogen atoms of an iminopyridine radical anion (Figure 11).

The chelating amido-pyridinato ligand arises from insertion of the N=C bond of iminopyridine **22** into the Yb–($\eta^5$-$C_9H_7$) bond. This insertion results in Yb–$C_9H_7$ bond cleavage and formation of Yb–N and C–C bonds. To the best of our knowledge this is the sole example of such an insertion. The amido-pyridinato ligand is bound to the Yb atom by one covalent and one coordination bond. The bond angles about the methyne carbon atom of the amido-pyridinato ligand prove that, unlike the related carbon in the parent **22**, it adopts $sp^3$ hybridization. The geometric parameters within the planar NCCN fragment of the iminopyridine ligand in **22** give evidence of its reduced radical-anionic character. Formation of the amido-pyridinato ligand in complex **22** obviously implies rearrangement of the coordination fashion of one of the indenyl ligands in the $(C_9H_7)_2Yb$ fragment from $\eta^5$ to $\eta^1$ and subsequent insertion of the N=C bond of the iminopyridine molecule coordinated to the ytterbium atom into the Yb–$C_9H_7$ bond (Scheme 13).

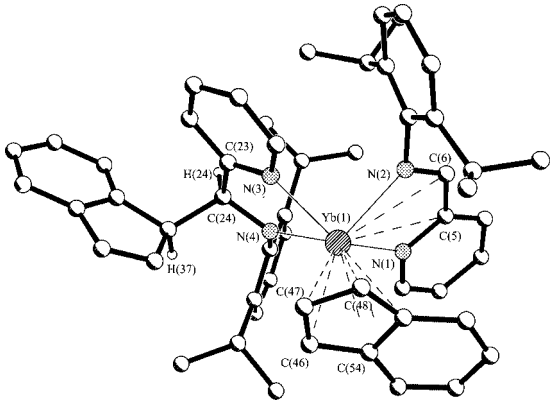


Figure 11. Molecular structure of complex [Yb($\eta^5$-$C_9H_7$){N(2,6-*i*$Pr_2C_6H_3$)CH($C_9H_7$)($C_5H_5N$)}{$\eta^4$-2,6-*i*$Pr_2C_6H_3$NCH($C_5H_5N$)}] (**23**).

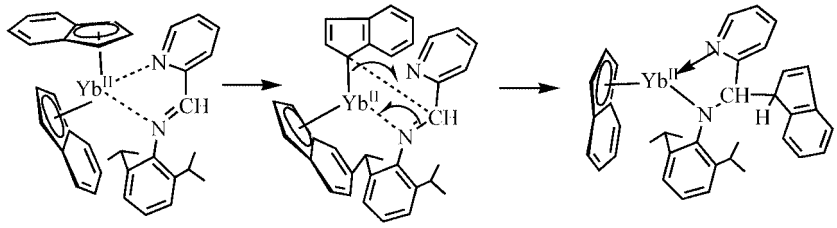
## 4. Reactions Resulting in C–H Bond Activation

In order to evaluate the influence of the steric and electronic properties of the diimine on the pathway of its reaction with ytterbocenes, the bis(fluorenyl) compound [$(C_{13}H_9)_2Yb(THF)_2$] was treated with the bulky diimine *i*$Pr_2C_6H_3$N=C(Me)C(Me)=N$C_6H_3$*i*$Pr_2$ (**23**) bearing two methyl substituents at the imino carbon atoms (in contrast to diimine **12**). It was found that replacement of the imino hydrogen atoms by two methyl radicals dramatically influenced the reaction pathway and led to formation of the novel half-sandwich $Yb^{II}$ derivative [Yb($\eta^5$-$C_{13}H_9$){2,6-*i*$Pr_2C_6H_3$–N=C($CH_3$)–C($CH_2$)=N–$C_6H_3$*i*$Pr_2$-2,6}(THF)] (**24**) (Scheme 14).[34]

The compound is diamagnetic, corresponding to the $Yb^{II}$ oxidation state. The coordination sphere of the ytterbium atom in **24** is set up by one fluorenyl ligand coordinated in $\eta^5$-fashion, two nitrogen atoms of the novel monoanionic ligand {2,6-*i*$Pr_2C_6H_3$–N=C($CH_3$)–C($CH_2$)=N–$C_6H_3$*i*$Pr_2$-2,6}$^-$ (resulting from proton abstraction from the methyl radical at the imino group of the parent diimine), and one THF molecule (Figure 12).

Unlike the geometry of the diimine radical anions in $Yb^{III}$ complexes exhibiting redistribution of the bond lengths characteristic of the delocalized NCCN π system, the geometry of the monoanionic ligand in **24** indicates a partial double bonding and delocalization of the negative charge only in the NCC fragment (Scheme 15).[34] Flat geometry of the methylene carbon atom (the sum of the bond angles is 359.8°) in this fragment and the C–C bond length give evidence for $sp^2$ hybridization of this carbon atom.

Concentration of the negative charge on the N atom of the $NCCH_2$ fragment results in shortening of the respective Yb–N bond and nonequivalence of the Yb–N bonds. Partial double C–C bonding in the $NCCH_2$ fragment becomes evident also from NMR spectra of **24** which indicate that the two methylene protons become diastereotopic. The geometry of the $NCCH_2$ fragment may be formally presented as the result of the existence and interconversion of two resonance forms of complex **24** (Scheme 15). Isolation of fluorene from the reaction in nearly quantitative yield



Scheme 13.

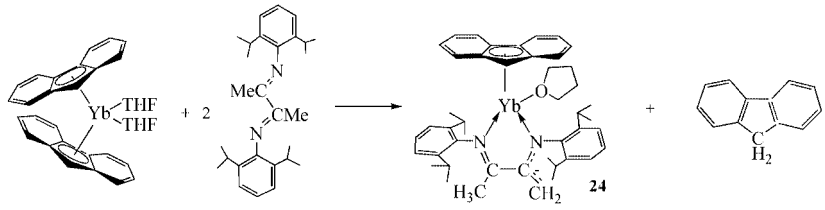

Scheme 14.

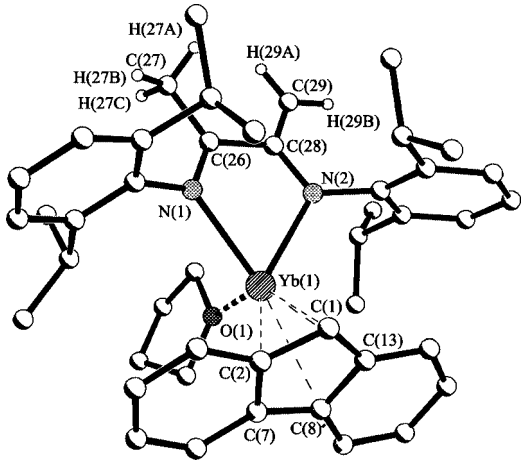

Figure 12. Molecular structure of complex [Yb(η$^5$-$C_{13}H_9$){2,6-*i*Pr$_2$C$_6$H$_3$–N=C(CH$_3$)–C(CH$_2$)=N–C$_6$H$_3$*i*Pr$_2$-2,6}(THF)] (**24**).

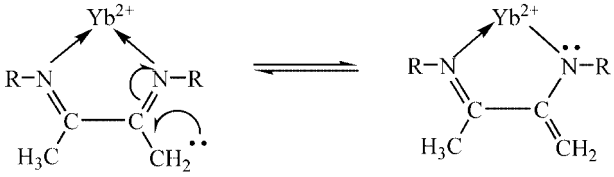


Scheme 15.

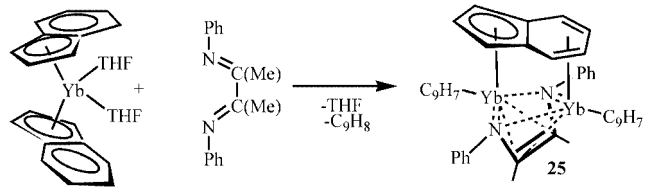
proves that the fluorenyl anion (or radical) is responsible for the proton abstraction from **23** and formation of the monoanionic diimino ligand.

The previously mentioned reaction of the formation of complex **21** (Scheme 11) also implies the stage of C–H bond activation. It is noteworthy that the substituents at the imino carbon atoms of the diimine molecule strongly influence their reactions with ytterbocenes. Thus the diimine *i*Pr$_2$C$_6$H$_3$N=CHCH=NC$_6$H$_3$*i*Pr$_2$ (**12**) easily oxidized complex [(C$_{13}$H$_9$)$_2$Yb(THF)$_2$], and the reaction afforded complex [(C$_9$H$_7$)$_2$Yb$^{III}$(*i*Pr$_2$C$_6$H$_3$NCHCHNC$_6$H$_3$*i*Pr$_2^{\cdot-}$)] (**13**),[16] while the analogue bearing two methyl groups at the imino carbon atoms *i*Pr$_2$C$_6$H$_3$N=C(Me)C(Me)=NC$_6$H$_3$*i*Pr$_2$ (**23**) did not react with the same ytterbocene even after continuous heating in toluene at 60 °C.[38]

## 5. Reactions Resulting in Yb–C Bond Cleavage

Yb–C bond cleavage was observed in several reactions of ytterbocenes with diazadienes and iminopyridines and was always accompanied by oxidation of the ytterbium atom to the trivalent state. This type of reactivity has never been documented for the reactions with bipy or phen.

The reaction of [(C$_9$H$_7$)$_2$Yb(THF)$_2$] with diimine PhN=C(Me)–C(Me)=NPh in equimolar amounts was mentioned to afford a tetranuclear mixed-valent ytterbium complex [Yb$_2$(μ-η$^5$:η$^4$-C$_9$H$_7$)(η$^5$-C$_9$H$_7$)$_2${μ-η$^4$:η$^4$-PhNC(CH$_2$)=C(Me)NPh}]$_2$ (**21**) that resulted from reductive diimine coupling. The same reaction in 1:2 molar ratio resulted in formation of the dinuclear mixed-valent complex [Yb$_2$(μ-η$^5$:η$^4$-C$_9$H$_7$)(η$^5$-C$_9$H$_7$)$_2${μ-η$^4$:η$^4$-PhNC(Me)=C(Me)NPh}] (**25**) (Scheme 16).[35] The reaction occurred with partial cleavage of the Yb–C bonds and was accompanied by indene formation.



Scheme 16.

Complex **25** is paramagnetic. The effective magnetic moment found for **25** ($\mu_{eff}$ = 2.7 $\mu_B$ at 293 K) is intermediate between the average $\mu_{eff}$ value reported for Yb$^{III}$ derivatives (4.3 $\mu_B$) and that of diamagnetic Yb$^{II}$ compounds[10] and provides evidence of different oxidation states of ytterbium atoms. Assembling of the dinuclear species of **25** becomes possible due to the unusual bridging μ-η$^5$:η$^4$-coordination of the indenyl ligand and μ-η$^4$:η$^4$-coordination of the doubly reduced diimine ligand (Figure 13).

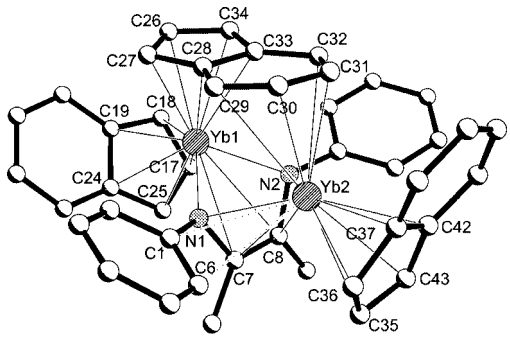


Figure 13. Molecular structure of complex [Yb$_2$(μ-η$^5$:η$^4$-C$_9$H$_7$)(η$^5$-C$_9$H$_7$)$_2${μ-η$^4$:η$^4$-PhNC(Me)=C(Me)NPh}] (**25**).

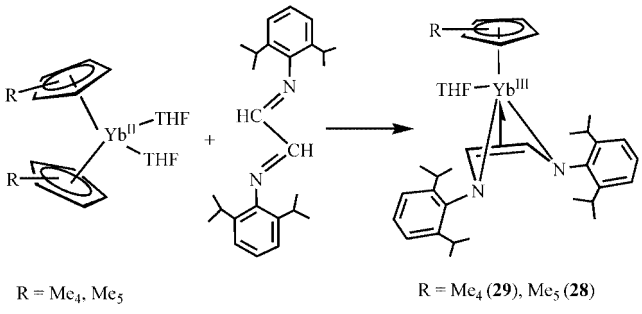
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Cleavage of the Yb–C bonds occurred in the reactions of ytterbocenes containing bulky cyclopentadienyl ligands $[Cp^*_2Yb(THF)_2]$ {$Cp^* = C_5Me_5$ (**26**), $C_5Me_4H$ (**27**)} with 1,4-bis(2,6-diisopropylphenyl)-1,4-diaza-1,3-butadiene (**12**). The reductive reactivity of ytterbocenes in their reactions with **12** has been found to be strongly dependent on steric crowding in the coordination sphere of the ytterbium atom. Unlike the previously described reaction of complex $[(C_5MeH_4)_2Yb(THF)_2]$ which resulted in formation of the $Yb^{III}$ derivative with the radical anion of diimine $[(C_5MeH_4)_2Yb(iPr_2C_6H_3NCHCHNC_6H_3iPr_2)]$ (**14**), interactions of ytterbocenes **26** and **27** containing bulkier polymethylated cyclopentadienyl ligands with **12** under similar conditions resulted in elimination of one Cp* ring, oxidation of the ytterbium atom, and formation of the mono(cyclopentadienyl) $Yb^{III}$ complex $[(Cp^*)Yb^{III}(iPr_2C_6H_3NCH{=}CHNC_6H_3iPr_2^{2-})(THF)]$ {$Cp^* = C_5Me_5$ (**28**), $C_5Me_4H$ (**29**)} (Scheme 17).[17]



Scheme 17.

Consequently, depending on the steric crowding in the coordination sphere of the metal atom, ytterbocenes can act as both one- and two-electron reductants in their reactions with diimines. Obviously, complexes $[Cp^*_2Yb(THF)_2]$ demonstrate sterically induced reductive reactivity,[39] and double reduction of **12** becomes possible due to oxidation of the $Yb^{II}$ to $Yb^{III}$ and oxidation of one Cp* anion.

In complexes **28** and **29** the coordination sphere of the $Yb^{III}$ is set up by a $\eta^5$-coordinated Cp* ligand, the dianion of diazabutadiene which is bonded in $\eta^4$-fashion, and one THF molecule (Figures 14 and 15).

The geometry of the planar NCCN fragment in **28** and **29** is consistent with a dianionic character of the diimino ligand. The bonding situation within the diimino ligand and its coordination mode in **28** and **29** is different from those observed for the radical-anionic ligand in **14**. The C=C bond of a doubly reduced enediamido moiety NCCN also participates in metal–ligand bonding and is coordinated to the ytterbium atom in $\eta^2$-fashion. The Yb–N bond lengths in **28** and **29** are remarkably shorter than those in compound **14**, thus indicating a different type of metal–ligand bonding which may be considered in these complexes as $2\sigma{:}\pi$.

The investigation of the magnetic properties of **28** has been performed in a wide range of temperatures. Complex **28** is a very attractive object for investigation of redox tautomeric transformations since both forms {$[(C_5Me_5)Yb^{III}(DAD^{2-})(THF)]$ and $[(C_5Me_5)Yb^{II}(DAD^{\cdot-})(THF)]$} (DAD = $iPr_2C_6H_3NCH{=}CHNC_6H_3iPr_2$) contain a single paramagnetic center, and spin antiferromagnetic coupling can be excluded. The magnetic moment of **28** at 300 K is 4.41 $\mu_B$ which is close to the calculated free $Yb^{III}$ ion value for a $^2F_{7/2}$ multiplet.[24c] The magnetic moment of **28** at 2 K of 2.03 $\mu_B$ is too low for $Yb^{III}$ and is more compatible with the magnetic moments observed for organic radical anions with $S = ½$ (1.73 $\mu_B$). The field dependence of the magnetization performed at 2 K for sample **28** was satisfactory fitted with the Brilloun function with $S = ½$. However, the value of the saturation magnetization at 50 kOe of 1.21 $\mu_B$ is slightly higher than the expected value for a free radical with $S = ½$ and $g = 2.0023$. Such magnetic behavior may be attributed to temperature-induced redox tautomeric transformations of two forms of complex **28** (Scheme 18).

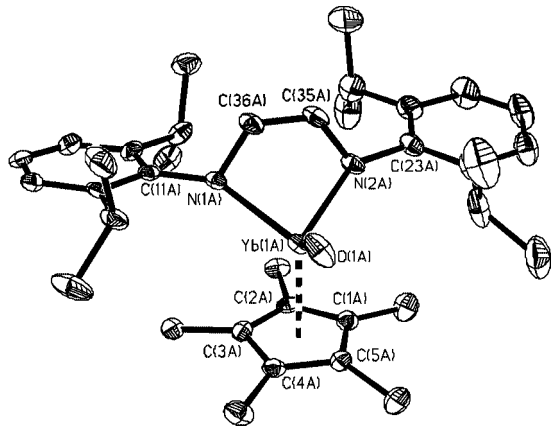


Figure 14. Molecular structure of complex $[(C_5Me_5)Yb^{III}(iPr_2C_6H_3NCH{=}CHNC_6H_3iPr_2^{2-})(THF)]$ (**28**). The methylene groups of the THF molecule are omitted.

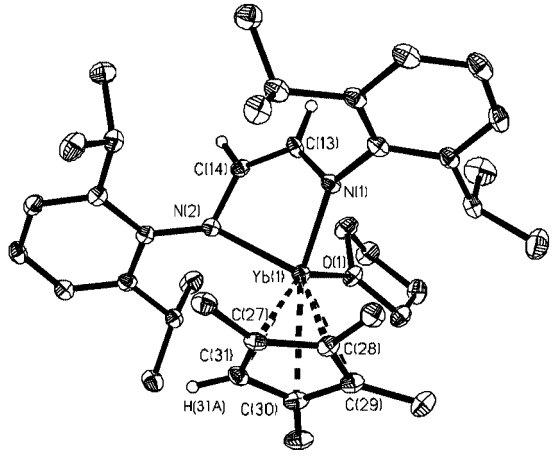

Figure 15. Molecular structure of complex $[(C_5Me_4H)Yb^{III}(iPr_2C_6H_3NCH{=}CHNC_6H_3iPr_2^{2-})(THF)]$ (**29**).

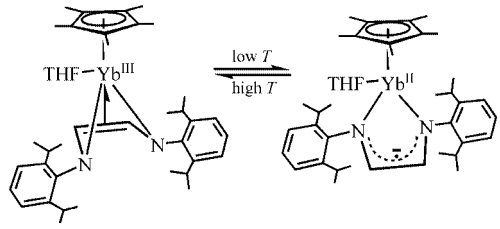

Scheme 18.

To the best of our knowledge, complexes **28** and **29** are the first examples of a terminal $\eta^4$-coordination mode of the diimine dianion to a lanthanide atom. In the organolanthanide complexes previously reported, dianionic diimino ligands adopted a μ-bridging coordination mode bonding two homo- or heterometallic centers (Scheme 19) in **30**, **31**,[7a,7g] **32**,[40] **33**.[41]

Replacement of the indenyl ligand by a bulkier fluorenyl analogue in a ytterbocene molecule switched the pathway of the reaction with *N*-(2,6-diisopropylphenyl)imino-2-pyridine (**22**) from C–C bond formation to Yb–C bond cleavage.[37] The reaction of the complex $[(C_{13}H_9)_2Yb(THF)_2]$ with **22** under similar conditions resulted in cleavage of all $\eta^5$-Yb–$C_{13}H_9$ bonds, oxidation of the Yb atom to the trivalent state, and formation of the tris(iminopyridine) compound $[\{2,6\text{-}i\text{Pr}_2C_6H_5NCH(C_5H_5N)^{-\bullet}\}_3Yb^{III}]$ (**34**) (Scheme 20).

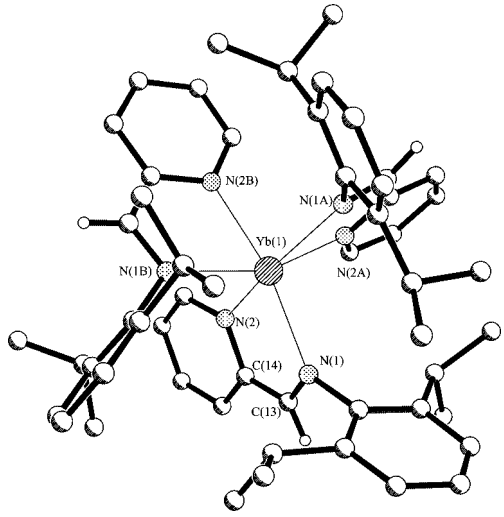

Figure 16. Molecular structure of complex $[\{2,6\text{-}i\text{Pr}_2C_6H_5\text{-}NCH(C_5H_5N)^{-\bullet}\}_3Yb^{III}]$ (**34**).

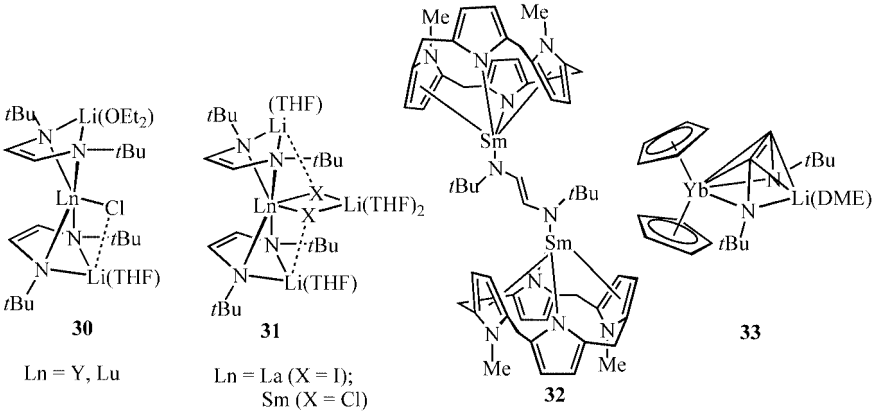
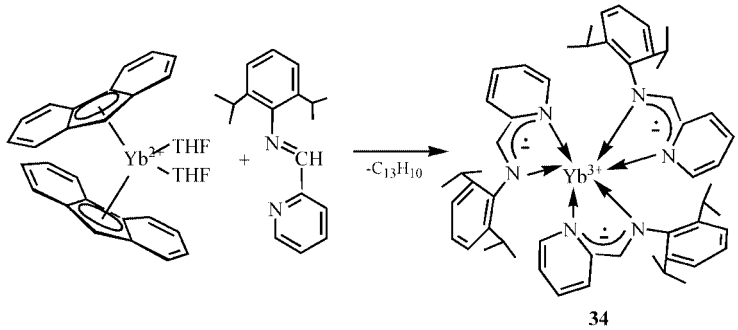


Scheme 19.



Scheme 20.

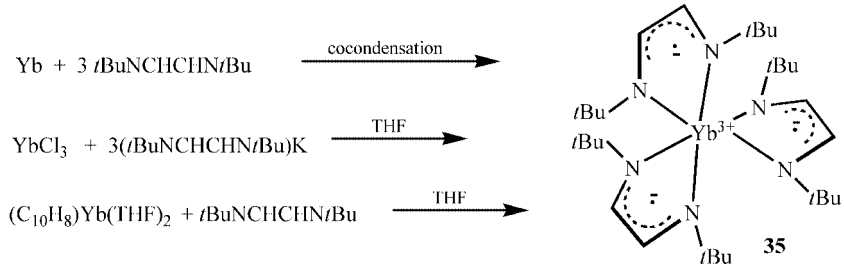
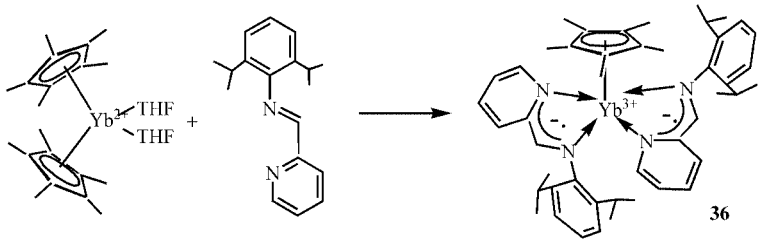


Scheme 21.



Scheme 22.

The magnetic moment of complex **34** (3.74 $\mu_B$, 293 K) gives evidence of the trivalent oxidation state of the ytterbium atom. The $Yb^{III}$ atom in **34** is coordinated by three chelating iminopyridine ligands bound by two nitrogen atoms (Figure 16).

The Yb–N bond lengths in **34** are comparable to the appropriate distances in $Yb^{III}$ complexes with radical-anionic diimine ligands. The bonding situation within the planar diimino fragment is consistent with the radical-anionic form of the iminopyridine ligand. Previously we synthesized a related tris(diazabutadiene) complex of trivalent ytterbium [(*t*BuNCHCHN*t*Bu)$_3$Yb] (**35**) in which the $Yb^{III}$ atom is coordinated by three radical anions of diazabutadiene (Scheme 21).[7f]

The nature as well as the coordination environment of the ytterbium atom in both complexes **34** and **35** is very similar; nevertheless, the value of the magnetic moment of **35** (5.78 $\mu_B$, 293 K) is much higher than that of **34** (3.74 $\mu_B$, 293 K). The low-temperature magnetic investigation of complex **35** suggested the existence of temperature-induced redox tautomeric transformations for this compound.[7f]

'Complex [$(C_5Me_5)_2Yb(THF)_2$] containing the pentamethylcyclopentadienyl ligand, which has the highest steric demand in the series of the studied compounds, reacted with *N*-2,6-diisopropylphenylimino-2-pyridine (**22**) in a different way. The reaction of [$(C_5Me_5)_2Yb(THF)_2$] with a twofold molar excess of **22** under similar conditions occurred with abstraction of one Cp* ring, oxidation of the ytterbium atom, and afforded a novel half-sandwich complex of trivalent ytterbium [$(C_5Me_5)Yb^{III}${2,6-*i*Pr$_2$C$_6$H$_3$NCH(C$_5$H$_5$N)$^{-\cdot}$}$_2$] (**36**) (Scheme 22).[37] The value of the magnetic moment of complex **36** (3.71 $\mu_B$, 293 K) is consistent with the trivalent oxidation state of the ytterbium atom.[10] In complex **36** the ytterbium atom is coordinated by one $C_5Me_5$ ligand in $\eta^5$-fashion and two iminopyridine radical anions. Both chelating iminopyridine radical anions in **36** are bound to the ytterbium atom through two coordination Yb–N bonds (Figure 17). Complex **36** is the first example of a half-sandwich lanthanide compound containing two radical-anionic ligands.

## 6. Conclusions

The pathway of reactions of ytterbocenes with diimines is strongly influenced by the steric crowding in the coordination sphere of the metal atom created by both π-aromatic ligands and substituents at the nitrogen atoms of the diimine molecule. Moreover, coordination capacities and a tendency of π-aromatic ligands coordinated to the ytterbium atom for haptotropic rearrangements ($\eta^5$–$\eta^3$–$\eta^1$) play a crucial role in the modification of the reactivity of ytterbocenes toward diimines. These reactions may occur with oxidation of the ytterbium atom as well as with retention of its oxidation state. C–C bond formation, C–H bond activation, C=N bond insertion, and oxidative Yb–C bond cleavage processes were documented for reactions of ytterbocenes with diimines. Steric overcrowding of the coordination sphere of the ytterbium atom can induce "extra" reducing ability of ytterbocenes and allow them to act not only as one- but also as two-electron reductants with respect to diimines. Fine tuning of the Yb–N bond length in complexes [$Cp_2Yb^{III}(L^{-\cdot})$] (L = diimine) by means of regulation of both steric and electronic properties of Cp and L ligands provides control of intramolecular metal–ligand electron transfer. Complexes [$Cp_2Yb^{III}(L^{-\cdot})$] and [$CpYb^{III}(L^{2-})$-(THF)] are promising objects for the investigation of spin

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coupling and temperature-induced redox tautomerism which provide a ground for exploring bonding models and electronic structure of compounds of f-transition metals.

# Electron Density and Bonding in Borates: An Experimental Study of Tetrabutylammonium Heptahydridohexaborate, $[(C_4H_9)_4N][B_6H_7]$

**Diana Förster,[a] Stephan Scheins,[a] Peter Luger,[a] Dieter Lentz,*[b] and Wilhelm Preetz[c]**

**Keywords:** Charge density / Borates / Topological analysis

An experimental study of a high-resolution X-ray data set of the *closo*-boranate $[B_6H_7]^-$ was performed. The charge density distribution and its topological properties were analyzed according to the "Atoms in Molecules" theory of R. W. Bader. The $[B_6H_7]^-$ anion forms an octahedral boron cage with one of the six faces capped by an additional proton. The unusual bonding situation of the threefold capping hydrogen atom is of special interest and is discussed in detail. Three new B–H bonds form, while the B–B bonds in the capped boron triangle vanish. The reactivity of the $[B_6H_7]^-$ anion is visualized by the electrostatic potential.

## Results and Discussion

The very stable $[B_nH_n]^{2-}$ anions form *closo* clusters with spherical aromaticity.[1,2] $[B_6H_6]^{2-}$, $[B_7H_7]^{2-}$, $[B_8H_8]^{2-}$ and $[B_{10}H_{10}]^{2-}$ can be protonated forming stable monoanions.[3,4] The structures of $[B_6H_7]^-$ and $[B_{10}H_{11}]^-$ have been determined by X-ray diffraction[3] and nonempirical calculations.[5–7] During our experimental charge density studies of compounds with multi-center two-electron bonds like $B_2H_6$[8] we became interested in the charge-density distribution $\rho(\mathbf{r})$ and its topological analysis of $[B_6H_6]^{2-}$ and $[B_6H_7]^-$.[9] Herein, we report on the results of a study based on a high-resolution low-temperature X-ray diffraction experiment of $[Bu_4N]^+[B_6H_7]^-$, where the $[B_6H_7]^-$ anion crystallizes with one tetrabutylammonium cation in the asymmetric unit. Figure 1 shows the structure of the $[B_6H_7]^-$ anion and its numbering scheme.[10]

A multipole refinement based on the Hansen–Coppens formalism[14] and a topological analysis were performed using the program package XD.[15] A known problem in X-ray structure solution and charge-density analysis is the determination of the position of the hydrogen atoms. Thus, in this study the terminal hydrogen atoms $H_{term}$ of the borate were fixed at neutron distances, taken from neutron diffraction data of decaborane.[16] Mebel et al. published a theoretical study of the structure and migrational non-rigidity of the $[B_6H_7]^-$ anion (Gaussian80, SCF/4-31G).[5] They found five stable states whose total energy levels are very close together. The global minimum has $C_{3v}$ symmetry. A geometry optimization of the title anion was performed (Gaussian98,[17] B3LYP/6-311G**), starting at experimental geometry which converged with a $C_s$ symmetry as depicted in Figure 2. Therefore, the anion packed with

$[Bu_4N]^+$ in $P2_1/n$ presents a local energy minimum. The B–$H_{term}$ distances obtained by ab initio calculations correspond exactly to neutron values of $B_{10}D_{14}$, while the theoretical optimized B–B distances differ only in the fourth decimal place from the experimental results of $[B_6H_7]^-$. Thus, it seemed to be justified to fix the bond lengths to the capping hydrogen atom, B–H7 to the corresponding values of the ab initio calculation (at 1.41 Å from B2 and B3, and 1.43 Å from B1, see Figure 2) for the multipole refinement.

The topological analysis of the charge density was carried out using the formalism of the theory of "atoms in molecules" (AIM) developed by Bader.[12,13] The values of the electron density $\rho_{bcp}$ and the Laplacian $\nabla^2\rho_{bcp}$ at the bond critical points (bcp) enable a quantitative description of the bonds. They are given in Table 1. The topological parameters of the capping bonds B–$H_{cap}$ and the region they influence reveal several interesting aspects.

Bond critical points can be found on all B–B contacts except those capped by the hydrogen atom. Thus, the capping of the triangular face results in the loss of three covalent bonds [distances B1–B2 1.867(1) Å, B2–B3 1.863(1) Å and B3–B1 1.874(1) Å], so that four-membered rings are formed by H7 and three boron atoms, e.g. B1–H7–B3–B4, characterized by ring critical points (rcp) located in the center. The experimentally derived bond topological properties are in very good agreement with the theoretical ones. For the B–B bonds the mean deviation for $\rho_{bcp}$ and $\nabla^2\rho_{bcp}$ between theory and experiment is 0.05(2) e Å$^{-3}$ and 0.5(3) e Å$^{-5}$, even for the ring critical points the deviation is small, 0.05(1) e Å$^{-3}$ and 0.17(2) e Å$^{-5}$. In case of the B–H bonds the differences between theory and experiment are slightly higher. For terminal B–$H_{term}$ bonds it is 0.05(3) e Å$^{-3}$ and 7.0(8) e Å$^{-5}$, while the capping B–$H_{cap}$ bonds differ by 0.10(2) e Å$^{-3}$ in $\rho_{bcp}$ and 1.6(8) e Å$^{-5}$ in the Laplacian values.

Figure 3 shows the contour line Laplacian diagram of the capped boron plane B1–B2–B3 (left) compared to the plane spanned by the atoms B4–B5–B6 (right). In contrast to the capped plane the uncapped one shows shared interaction on the B–B bonds, indicated by a charge concentration on the B–B bond path, bordered furthermore by the zero Laplace line (black). As a consequence of the missing bcp values, the coordination number of B1, B2 and B3 is 4, while B4, B5 and B6 are bonded to five neighboring atoms.

[a] av. is the average of the values in the column.

Figure 4 shows the bending of the bond paths which is most pronounced for the B–$H_{cap}$ bonds curved into the interior of the $B_6$ cage (see Figure 4, right). This results in longer bond-path lengths in comparison to the atomic distances, which is 0.002 Å for the B–B bonds and up to 0.2 Å for the B–$H_{cap}$ bonds.

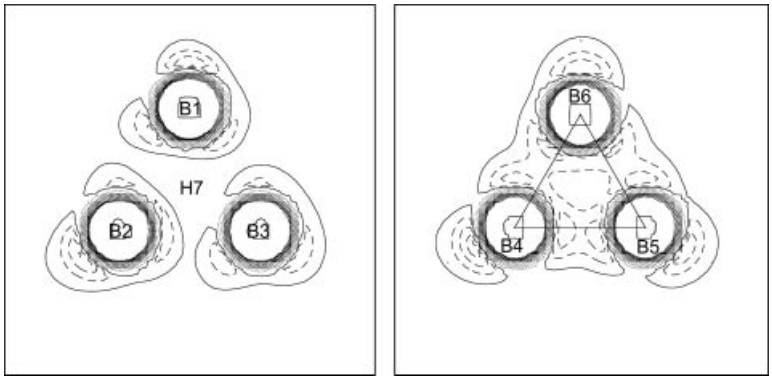

Figure 3. Contour line diagram of the Laplacian (dotted lines positive values, dashed lines negative, solid line zero Laplacian) of the capped B1–B2–B3 plane (left) and the uncapped B4–B5–B6 plane on the opposite side of the molecule (right).

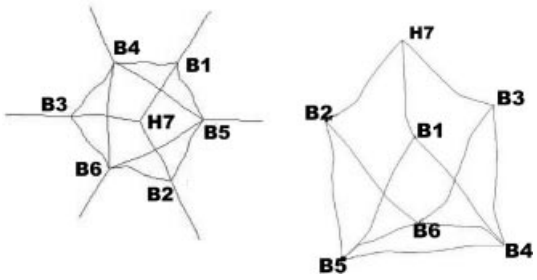

Figure 4. Bond paths of the title compound. Left: View from above the capped boron triangle, capping hydrogen atom in the center of the figure. Right: Side view, capping hydrogen atom on top of the figure.

The electrostatic potential (esp) was calculated by using the method of Su and Coppens[18] on the basis of experimental data. This calculation considers a $[B_6H_7]^-$ ion extracted from the crystal but still containing the polarization effects induced by intermolecular interactions. Figure 5 displays the electrostatic potential, mapped onto the isoelectron-density surface at $\rho(\mathbf{r}) = 0.5 e Å^{-3}$. The positive potential (red) is concentrated around the boron atoms and the negative potential around the terminal hydrogen atoms. There is a gradient of polarization between the hydrogen atoms. Thereby the terminal hydrogen atoms of the capped triangle are less polarized (green) than the hydrogen atoms on the opposite site of the molecule (blue). The remarkable effect of the capping H7 atom is also shown in the esp value. It shows a positive potential (red), indicating the reactivity of this hydrogen atom towards nucleophilic attack. $[B_6H_7]^-$ is very unstable and reacts in basic solution immediately by emitting a proton to form $[B_6H_6]^{2-}$.

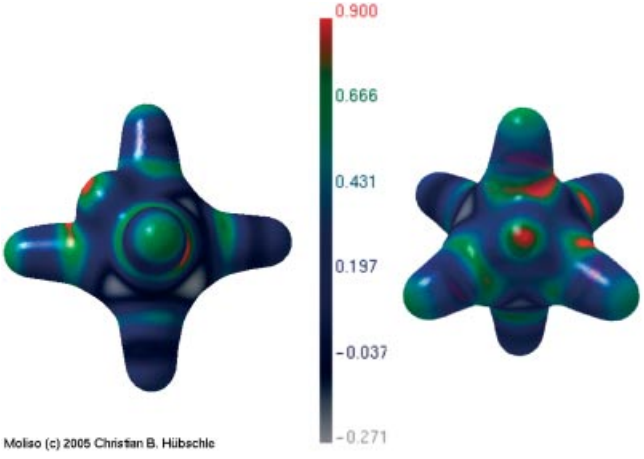

Figure 5. Electrostatic potential of the title compound; generated with the MolIso program.[19] Left: View from above the capped boron triangle, capping hydrogen atom in the center of the figure. Right: View from a terminal hydrogen atom of the non-capped triangle, capping hydrogen atom on top of the figure.

# Conformational Flexibility in a Carbobicyclic Diphosphinite Ligand

**Ian J. S. Fairlamb,*[a] Simona Tommasi,[a] Benjamin E. Moulton,[a] Wenxu Zheng,[b] Zhenyang Lin,[b] and Adrian C. Whitwood[a]**

**Keywords:** Ligands / Bite angle / Trans-spanning / Palladium / Binuclear complexes

An unsymmetrical bicyclo[3.2.0]heptanyl diphosphinite ligand, FLEXIphosO, shows flexible coordination modes to palladium centres. The X-ray crystal structure for [$Pd^0_2$-(P,P′)$_3$] has been determined which reveals that the bicyclic backbone of the FLEXIphosO ligand exists in an *exo*-envelope conformation. The change in conformation stands in stark contrast to that observed in mononuclear neutral and cationic palladium(II) complexes containing the FLEXIphosO ligand, where an *endo*-envelope is observed in solution and in the solid-state. Theoretical studies provide an insight into the relative stability of palladium(0) complexes containing the FLEXIphosO ligand. Another large spanning angle ligand, SPANphos, does not form a similar palladium(0) dimer complex under identical reaction conditions, highlighting the unusual behaviour of the FLEXIphosO ligand.

## Introduction

Bidentate phosphorus ligands are commonly used in coordination chemistry, synthesis and catalysis. The majority of these are rigid and on coordination to a transition metal possess a defined bite angle, a structural feature that is important in key steps in many transition metal-catalysed processes. The global complexity of the complete catalytic cycles of these reactions leads one to anticipate that bidentate ligands that can alter their bite angle could be beneficial to individual steps that are intrinsically different, e.g. oxidative addition and transmetallation, leading to an overall more efficient process. Although this proposition remains a significant challenge, it is evident that the identification of ligands that are capable of energetically accessible geometrical changes will be useful in addressing a key evolution in the design of efficient dynamic ligands. Ligands such as dioxop,[1] bisbi,[2] triptycene,[3] TRANSphos,[4] TRAP,[5] dppf,[6] xantphos,[7] and others[8] offer *cis* and *trans* coordination modes in square-planar complexes. SPANphos, a second generation variant of Xantphos developed by van Leeuwen and co-workers,[9] exhibits interesting catalytic properties in methanol carbonylation,[10] a facile *cis* to *trans* coordination mode switch, as well as the ability to form bimetallic complexes. Further additions to these ligand classes would be useful, particularly structures that utilise conformational changes imposed by a carbobicyclic skeleton – a potentially beneficial structural facet that has rarely been employed in ligand design strategies.[11] In this report we present evidence showing that the bicyclo[3.2.0]-heptanyl ligand **1**, B[3.2.0]DPO[12] renamed as FLEXIphosO[13] (Figure 1), can undergo a conformational change on coordination to $Pd^0$. Our previous studies[14] have established that **1** exhibits an exclusive *cis*-coordination mode in neutral and cationic $Pd^{II}$ and $Pt^{II}$ complexes, e.g. **2**–**4**, where

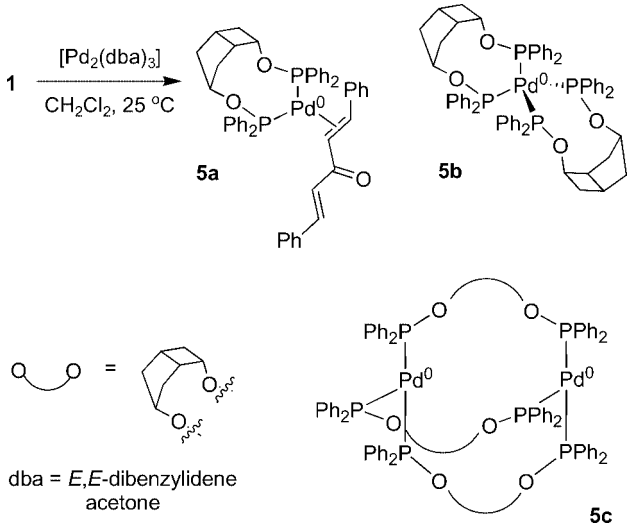
the ligand backbone possesses an *endo*-envelope conformation (**I**). Crucially, theoretical calculations support a conformational change from **I** to **II**, the latter an *exo*-envelope, for the stabilisation of cationic $[Pd^{II}(H)L_2]$ species, which are proposed key intermediates in 1,6-diene cycloisomerization reactions.[15] Direct experimental evidence for the existence of conformation **II** is presented in this communication.

## Results and Discussion

Generally, new bidentate ligands are often coordinated to $Pd^{II}$, $Pt^{II}$ and $Rh^{I}$, perhaps due to their ease of preparation, stability and purification. Low oxidation state metal complexes are less often prepared, e.g. $Pd^0$, leading us to investigate the complexation of **1** to $Pd^0$. The reaction of **1** with $[Pd_2(dba)_3]$ (**1**/Pd = 1:1) in $CD_2Cl_2$ at 25 °C affords one species as evidenced by $^{31}P$ NMR spectroscopy. Complexes **5a** (thermodynamic) and **5b** (kinetic) represent the most likely products. Two broad signals at {P1: $\delta$ = 108.1 and P2: $\delta$ = 109.8 (br. s); $\Delta\nu_{1/2}$ = 40 Hz} suggests **5a** as the product. The pseudo-molecular ion ($MH^+$ = *m*/*z* 837.1853; calculated 837.1873) was confirmed by APCI-ESI MS, exhibiting a correct isotopic distribution against calculated values for $C_{48}H_{45}O_3P_2Pd_1$. Repeats of this experiment resulted in the appearance of a minor species, possessing several phosphorus environments, as shown by $^{31}P$ NMR spectroscopy. The presence of excess **1** relative to Pd accounts for the formation of this species, confirmed by the reaction of ca. 3 equiv. of **1** with $[Pd_2(dba)_3]$, which affords this species as the major component[16] (Scheme 1). Two sharp singlets in the $^{31}P$ NMR spectrum are observed at $\delta$ = 108.8 and $\delta$ = 116.6, as well as two sets of multiplets, the first collected between $\delta$ = 107.7–110.1 and the second between $\delta$ = 112.4–115.6. The $^{31}P$ NMR spectrum appears to be complicated by ligand **1** being unsymmetrical. The two sharp singlets could be attributed to either **5b** or **5c**. However, the multiplets could only arise through consideration of the possible isomeric forms **5c** and **5cc** (Figure 2).



Scheme 1. Synthesis of $Pd^0$ complexes containing ligand **1**.

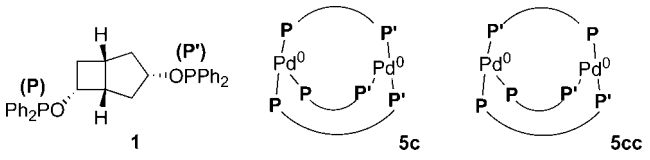


Figure 2. Isomeric forms of $[Pd_2(FLEXIphosO)_3]$ complex (**5c**/**5cc**).

Simulation of the $^{31}P$ NMR spectrum for this mixture of compounds using the gNMR package confirmed that the muliplets were attributable to an isomeric form **5cc**, e.g. a six-spin system (Figure 3). The large $^2J_{PP}$ couplings (about 100–127 Hz) and small chemical shift differences between the phosphorus substituents in each of the cyclobutyl and cyclopentyl rings leads to pronounced second order effects, complicating the appearance of the $^{31}P$ NMR spectrum (Table 1 and Figure 3). The phosphorus environments in **5cc** are inequivalent due to the phosphinite group in the cyclobutyl ring in fragment (Pd1–P,P′,P′) breaking the overall symmetry, which directly affects the spin-spin coupling pattern for the other fragment (Pd2–P,P,P′). The larger $^2J$(P,P′) couplings are observed in the (Pd1–P,P′,P′) fragment between P (environment D) and both P′ groups (environments B and C; 123.7 and 126.8 Hz, respectively). In

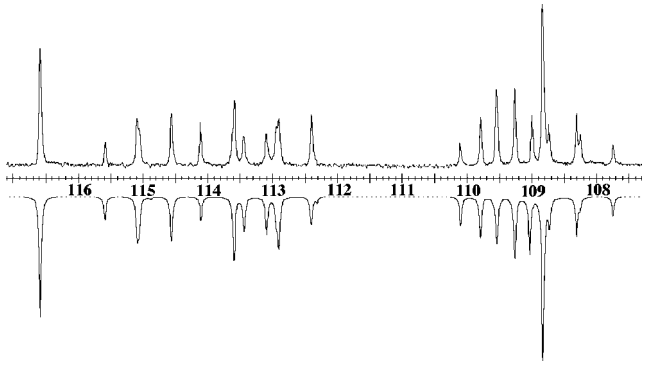

Figure 3. Experimental (upper) and simulated (lower) $^{31}P$ NMR spectra for **5c**/**5cc**.

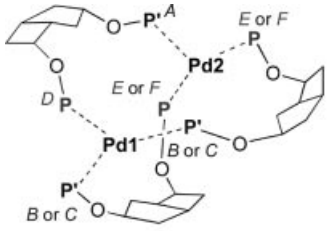
Table 1. Simulated $^{31}P$ NMR spectroscopic data for complex **5cc**.



| P environment | $\delta$ | $J_A$ | $J_B$ | $J_C$ | $J_D$ | $J_E$ |
|---|---|---|---|---|---|---|
| A | 109.3 | | | | | |
| B | 109.5 | 0 | | | | |
| C | 108.4 | 0 | 116.0 | | | |
| D | 113.6 | 0 | 123.7 | 126.8 | | |
| E | 112.9 | 107.8 | 0 | 0 | 0 | |
| F | 115.0 | 108.7 | 0 | 0 | 0 | 100.4 |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

contrast there is a smaller $^2J_{P',P'}$ coupling between B and C (is 116 Hz). Smaller couplings are seen in the (Pd2–P,P,P′) fragment, with P′ (environment A) coupling with both P groups (environments E and F; 107.8 and 108.7, respectively). As with the first fragment, the two similar phosphorus environments, in this case E and F, exhibit a $^2J_{P,P}$ coupling of 100.4 Hz. Isomer **5c** is much more straightforward, exhibiting only two singlets at $\delta$ = 108.8 and $\delta$ = 116.6, due to $C_{3v}$ symmetry. Attributing these singlets to **5b** has been ruled out on the basis that this species is undetected by APCI-ESI MS, whilst **5a** and **5c** are. It is interesting to note that [**5c**]$^+$ is produced as a stable ion on ionizing **5a** by this technique, highlighting the gas-phase stability of this species.

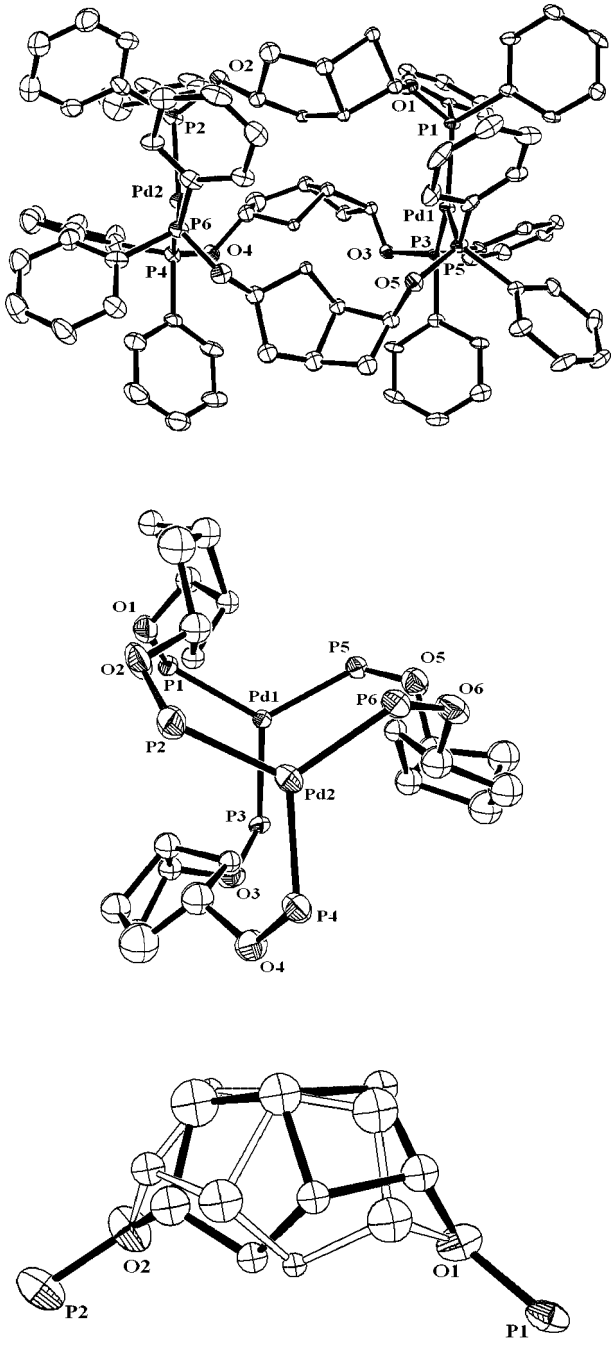


Figure 4. X-ray structure of complex **5c/5cc** (H atoms and $CH_2Cl_2$ omitted for clarity). Top structure: each ligand oriented in the same direction. Middle structure: phosphorus phenyl groups omitted. Bottom structure: showing the two orientations of the bicyclo[3.2.0]heptanyl structure in the ligand backbone. Selected bond lengths [Å] and angles [°]: O(1)–P(1) 1.632(6); O(2)–P(2) 1.624(6); O(3)–P(3) 1.641(6); O(4)–P(4) 1.637(6); O(5)–P(5) 1.631(6); O(6)–P(6) 1.618(6); P(1)–Pd(1) 2.294(2); P(2)–Pd(2) 2.284(2); P(3)–Pd(1) 2.295(2); P(4)–Pd(2) 2.284(2); P(5)–Pd(1) 2.289(2); P(6)–Pd(2) 2.275(2); P(5)–Pd(1)–P(1) 121.50(8); P(5)–Pd(1)–P(3) 119.89(8); P(1)–Pd(1)–P(3) 118.46(8); P(6)–Pd(2)–P(2) 117.98(9); P(6)–Pd(2)–P(4) 121.24(8); P(2)–Pd(2)–P(4) 120.08(9).

Layering a dichloromethane solution of the mixture of **5c** and **5cc**, under an inert atmosphere,[17] with diethyl ether (1:5, v/v) produced dark red crystals suitable for analysis by X-ray diffraction, which revealed the dimeric structure as a mixture of these isomeric forms (Figure 4).

The dimeric complex contains three bridging ligands and as ligand **1** is unsymmetrical it is found in two positions, which has been modelled with a 2:1 occupancy. The complex crystallizes with one molecule of dichloromethane. There is no evidence for a Pd–Pd bond in this structure and the total electron count for each metal is 16-electrons. The Pd(1)–Pd(2) distance is 7.191 Å. The average phosphorus–palladium bond length is slightly different for each Pd atom {Pd(1)–P 2.293(2) Å; Pd(2)–P 2.284(2) Å}, as is the average oxygen–phosphorus bond length around each Pd centre {O–P for Pd(1) 1.635(6); O–P for Pd(2) 1.626(6)}. The $PdP_3$ fragments are near eclipsed, and if one considers isomer **5c** possesses $C_{3v}$ symmetry.

Of particular interest is the observation that this complex is isostructural with $[Pd^0{}_2(dba)_3{\cdot}CH_2Cl_2]$.[18] In the latter complex, each $Pd^0$ centre is coordinated by three alkenes, with the dba acting as a bridging ligand {the Pd(1)–Pd(2) bond length is 3.194 Å in this complex}.[18c] The dimeric complex is a rare example of a phosphorus variant of this ubiquitous dimeric $Pd^0$ alkenyl complex. Two more closely related $[Pd^0{}_2(P,P)_3]$ complexes are known, where P,P = bis(diphenylphosphanyl)methane[19] and bis(diphenoxy)-*N*-methylphospazane.[20] In each of these complexes, the Pd···Pd bond length is 2.959(2) and 2.855(2), respectively. Moreover, these ligands possess small spanning angle ligands, whereas ligand **1** exhibits a much larger angle.

## Theoretical Studies

To study the geometric properties and relative stabilities of the species illustrated in Scheme 1, theoretical calculations were performed at the Becke3LYP level of DFT theory on the model complexes in which the phenyl groups were replaced by hydrogens.

As discussed above, the reaction of **1** with $[Pd_2(dba)_3]$ (**1**/Pd = 1:1) in $CH_2Cl_2$ affords **5a** initially. The absence of **5b** experimentally is intriguing. Bidentate phosphane ligands usually give this type of complex as the kinetic product.[21] To compare the relative stability of **5a** and **5b**, the reaction energy for Equation (1) was calculated.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

**5b** + dba → **5a** + FLEXIphosO (1)

The calculations reveal that the reaction energy $\Delta E$ is –0.5 kcal/mol. Once the phenyl groups are employed in the calculations, **5b** is expected to be even less favoured due to its relatively more congested structure. Experimentally an excess of dba may further tip the balance in favour of **5a**, more so than seen for other types of phosphanes. In the presence of a slight excess of ligand **1** relative to Pd, the reaction actually gives the dimeric complex **5c**; again **5b** is not formed. To study the relative stability of **5c**, the reaction energy for Equation (2) was calculated.

2 **5a** + FLEXIphosO (**1**) → **5c** + 2 dba (2)

The reaction energy $\Delta E$ was calculated to be –4.5 kcal/mol, confirming the experimental observation that the dimeric complex **5c** is the only species in the presence of a slight excess of **1** relative to Pd.

Since both the *endo*- and *exo*-envelope conformations for the free ligand are possible, it is interesting to assess how the stability of the complexes changes with the variation of the ligand's conformation. Both **5a** and **5b** shown in Scheme 1 have an *endo*-envelope conformation of ligand **1**. We were able to locate their conformational isomers **5a′** and **5b′** in which the ligand shows an *exo*-envelope conformation (Figure 5). **5a′** and **5b′** were found to be less stable by 2.7 and 4.8 kcal mol$^{-1}$ than **5a** and **5b**, respectively. **5c** has an *exo*-envelope conformation of the ligand. Crucially, its *endo*-envelope conformational isomer **5c′** does not correspond to a local minimum on the potential energy surface.

In a previous study on related complexes with ligand **1** containing a $Pd^{II}$ metal centre,[12] we found that when the ligand offers a *cis* coordination mode only the *endo*-envelope conformational isomer exists; when the ligand offers a *trans* coordination mode only the *exo*-envelope conformational isomer exists. In the $Pd^{II}$ complexes studied, the geometry around the metal centre is square-planarly-based and the P–Pd–P bite angles are forced to be close to either 90° or 180°.

The trigonal planar geometry of $Pd^0L_3$ complexes and the tetrahedral geometry of $Pd^0L_4$ complexes allows ligand **1** to show its binding flexibility since the P–Pd–P bite angles are no longer limited to those close to either 90° or 180°. Therefore, in the mononuclear $Pd^0$ complexes shown in Scheme 1, both the *endo*- and *exo*-envelope conformations of ligand **1** are local minima on the potential energy surface.

In the dimeric palladium complex **5c**, the long distance between the two phosphorus atoms in each of the three bridging ligands, a situation similar to that when ligand **1** offers a *trans* coordination mode in $Pd^{II}$ complexes, forces each ligand to adopt the *exo*-envelope conformation.

A final note is that in addition to **5c**, the calculations show that the dimeric complex can easily access the isomeric form **5cc** as shown in Figure 2, considering the (P,P′) structure of the ligand. The isomers **5c** and **5cc** share comparable stability. The difference in energy between **5c** and **5cc** is only 0.3 kcal/mol, implying that both **5c** and **5cc** coexist in solution, a finding supported by the $^{31}P$ NMR spectroscopic studies. In the calculated structures the distance between the two Pd atoms is 6.58 Å in **5c** and 6.60 Å in **5cc**.

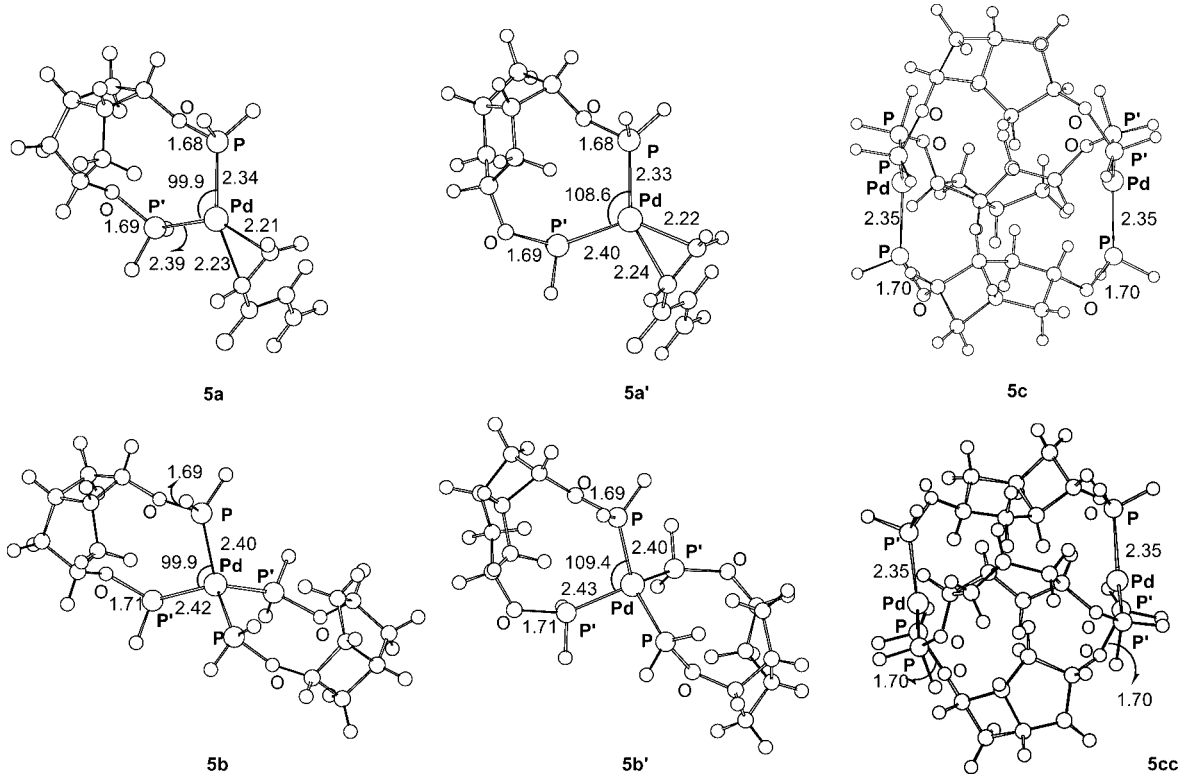

Figure 5. Calculated structures for the model $Pd^0$ complexes. The bond lengths are given in angstrom and the bond angles in degrees.

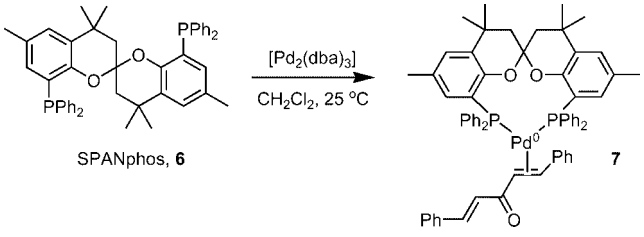
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

It is clear that there is no interaction between these two atoms. The long P–P′ distance (≈ 6.7 Å) in each ligand can only be accessed via the *exo* conformation. In the solid state, the phenyl groups cause significant lengthening (to 7.191 Å). All the P–O and Pd–P bonds in two isomers are about 1.70 and 2.35 Å respectively, which are longer than that found in the solid-state structure of **5c**.

We envisaged that other ligands possessing large bite angles would allow for the preparation of similar complexes. The reaction of SPANphos **6** with $[Pd_2(dba)_3]$ (**1**/Pd = 1:1) in $CD_2Cl_2$ at 25 °C was monitored by $^{31}P$ NMR spectroscopy which showed one very broad signal at $\delta$ = 22.7–24.8, characterized as [Pd(**6**)($\eta^2$-dba)] (**7**), the pseudo-molecular ion ($MH^+$ = *m*/*z* 1045.3135; calculated 1045.3125) was confirmed by APCI-ESI MS, exhibiting a correct isotopic distribution against calculated values for $C_{64}H_{61}O_3P_2Pd_1$ (Scheme 2). The same reaction with excess SPANphos (ca. 3 equiv.) affords once again this complex, in addition to free ligand ($\delta$ = –16.2 ppm). It is interesting to note that ligand **6** does form rhodium dimer complexes of the type $[Rh_2(\mu\text{-}Cl)_2(\mathbf{6})(CO)_2]$, where the ligand exhibits a conformational change in the bichroman backbone.[9a,10] Molecular models suggest that unfavourable steric factors may explain why $[Pd_2(\mathbf{6})_3]$ is not formed under similar conditions to ligand **1**.



Scheme 2. Synthesis of a $Pd^0$ complex containing SPANphos.

## Conclusions

In summary, the bicyclo[3.2.0]heptanyl ligand **1**, renamed as FLEXIphosO, shows flexible coordination modes[22] to transition metal centres. The influence of substituents on this bicyclic ring system is currently being assessed in our laboratories. We envisage that other carbobicyclic compounds will exhibit similar behaviour. Finally, conformational flexibility is a structural facet that could readily be exploited in transition metal–ligand catalyst design.

## Experimental Section

**NMR Experiments:** All reactions were conducted in a dry box ($O_2$ and $H_2O$ levels < 0.5 ppm). A typical experiment: $[Pd_2(dba)_3]$ (5 mg) was added to ligand **1** (1 equiv.) in $CD_2Cl_2$ (0.5 mL) at 25 ± 0.5 °C. The mixture was stirred for 0.5 h, and then filtered through Celite™ (pipette and glass wool used); the filtrate was analysed directly by NMR spectroscopy. The ratio of **1**/Pd and solvent was changed according to the details supplied in the main text. Similar experiments were performed for the SPANphos ligand **6**. It should be noted that all the phosphane–palladium–alkene complexes are air sensitive.

**Crystallography:** X-ray quality single crystals of **5c/5cc** were grown layering a $CH_2Cl_2$ solution containing the complex with diethyl ether (1:5, v/v) in a dry-box, which gave dark red crystals. The X-ray diffraction experiment was carried out on a Bruker Smart Apex diffractometer with Mo-$K_\alpha$ radiation ($\bar{\lambda}$ = 0.71073 Å) using a SMART CCD camera. The low temperature of the crystal was maintained with a Cryostream (Oxford Cryosystems) open-flow gas cryostat. The reflection intensities were corrected for absorption by a semi-empirical method based on the intensities of Laue equivalents and multiple measurements of identical reflections. The structures were solved by the Patterson and Fourier technique and refined by full-matrix least-squares against $F^2$ of all reflections, using SHELXTL software. The atoms of the bicyclo[3.2.0]heptanyl ring systems (x3) are disordered over two positions (50:50), as depicted in Figure 2. **Crystal data**: $C_{94}H_{92}Cl_2O_6P_6Pd_2$, $M$ = 1787.20, triclinic, $a$ = 12.1575(15), $b$ = 12.2884(16), $c$ = 32.357(4) Å, $U$ = 4184.9(9) Å$^3$, $\alpha$ = 81.132(3), $\beta$ = 79.892(3), $\gamma$ = 61.929(2), $T$ = 110(2) K, space group = $P\bar{1}$, $Z$ = 2, $\mu$(Mo–$K_a$) = 0.663 mm$^{-1}$, 15636 reflections measured, 8992 unique ($R_{int}$ = 0.0358) which were used in all calculations. Final $R1$ = 0.0627 and $wR(F^2)$ = 0.1595 (all data). CCDC-642869 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**APCI-ESI MS Experiments:** Bruker MicroTOF from Bruker Daltonics, Bremen, Germany. ESI was performed by injecting a 5 µl of the sample prepared in a dry-box (50 µg in $CH_2Cl_2$/MeOH; 95:5 v/v) into a stream of 200 µl/min methanol on a LC system Agilent 1200 (capillary 4500V; nebulizer 1.3 Bar; dry gas 8 L min$^{-1}$; dry temp. 180 °C).

**Theoretical Calculations:** Density functional theory calculations were performed at the B3LYP level using Gaussian 03.

**Supporting Information** (see also the footnote on the first page of this article): The $^{31}P$ NMR spectroscopic data for all the palladium complexes described in this paper. X-ray data for complex **5c/5cc** and the computational details and Cartesian coordinates for the calculated structures (depicted in Figure 5) are included.

## Acknowledgments

We are grateful to The Royal Society, Engineering and Physical Sciences Research Council (EPSRC) and Stylacats for funding and Astra-Zeneca for an unrestricted research award. Prof. P. van Leeuwen, Dr. Z. Freixa and Ms N. Goetz (ICIQ, Tarragona, Spain) are thanked for helpful discussions and providing SPANphos. Drs. J. M. Lynam and T. A. Dransfield have provided valuable assistance with gNMR and MS, respectively, and Dr. M. Bandini (Bologna, Italy) is thanked for supporting an exchange visit for S. T.

# Redox-Induced μ-Acetato and μ-Oxo Core Interconversions in Dinuclear Manganese Tris(2-methylpyridyl)amine (tpa) Complexes: Isolation and Characterization of $[Mn_2^{III}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)(tpa)_2]^{3+}$

**Marie-Noëlle Collomb,*[a] Claire Mantel,[a,b] Sophie Romain,[a] Carole Duboc,[b] Jean-Claude Leprêtre,[a] Jacques Pécaut,[c] and Alain Deronzier[a]**

**Keywords:** Manganese / Electrochemistry / N ligands / Bridging ligands

The electrochemical properties of the bis(μ-acetato) complex $[Mn_2^{II}(O_2CCH_3)_2(tpa)_2]^{2+}$ ($\mathbf{1}^{2+}$) [tpa = tris(2-methylpyridyl)-amine] in an organic medium ($CH_3CN$) have been studied. Two successive controlled potential oxidations of a solution of $\mathbf{1}^{2+}$ at 0.7 and 1.1 V vs. $Ag/Ag^+$ (10 mM) allow the selective and nearly quantitative formation of the mono-(μ-oxo) mono-(μ-acetato) complex $[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2]^{3+}$ ($\mathbf{2}^{3+}$) and the bis(μ-oxo) complex $[Mn_2^{IV}(O)_2(tpa)_2]^{4+}$ ($\mathbf{3}^{4+}$), respectively. These results show that each substitution of an acetate group by an oxo group is caused by an overall two-electron oxidation of the corresponding dimanganese complex. The associated electrochemical back transformations were also investigated. Complex $\mathbf{2}^{3+}$, which possesses a rare mono-(μ-oxo) mono-(μ-acetato) motif, has been isolated and characterized by X-ray crystallography. This complex crystallizes in the monoclinic system, space group $P2_1/n$ with $a$ = 11.9899(17), $b$ = 35.050(5), $c$ = 12.3952(18) Å, $\beta$ = 101.218(6)°, $Z$ = 4.

## Introduction

Much effort has been directed towards the chemistry of binuclear manganese complexes with oxo- and/or acetato-bridged cores due to their relevance to biological systems such as the manganese catalases (Mn Cat) and the oxygen-evolving complex (OEC) of photosystem II (PSII).[1–3] The active centers are a di- (MnCat) or a tetranuclear (OEC) manganese complex where oxidation states II, III, and IV are implicated during the enzymatic catalytic cycles. The MnCat switches between the $Mn_2^{II}$ and $Mn_2^{III}$ forms during the catalysis, and only these two oxidation states are able to catalyze the disproportionation of $H_2O_2$ at extremely high rates.[1] Recent structural characterizations[4–7] of the oxidized $Mn_2^{III}$ form reveal a Mn–Mn separation of 3.03 to 3.4 Å and that the two metal centers are triply bridged by a $\mu_{1,3}$-carboxylate group of a glutamate (or aspartate) residue and two oxygen atoms, possibly one oxo and one hydroxo. EXAFS studies suggest that the Mn–Mn separation is significantly longer in the reduced $Mn_2^{II}$ form of the enzyme (3.4 to 3.7 Å), such that both bridging oxygen atoms come from water and/or hydroxide.[8]

In contrast, the exact structure of the active center in PSII, as well as the mechanism of water oxidation, remain elusive.[2,9–15] During the catalytic cycle it is known that the tetranuclear manganese cluster in PSII cycles through five increasingly oxidized states, denoted as $S_0$–$S_4$. The most oxidized state, $S_4$, is unstable and relaxes back to $S_0$ with the release of $O_2$. On the basis of XAS and EPR data, it is generally accepted that the oxidation states in $S_1$ and $S_2$ are $Mn_2^{III}Mn_2^{IV}$ and $Mn^{III}Mn_3^{IV}$, respectively.[2,16] XAS studies have also provided evidence for the existence of Mn–(μ-O)$_2$–Mn (Mn–Mn distance of 2.7 Å) and Mn–(μ-O)–Mn (Mn–Mn distance of 3.3 Å) moieties in the tetramer,[17,18] while the recent crystal structures of PSII[19–23] suggest that the four metallic ions of the OEC are organized in a "3 + 1" fashion.

The oxidation state changes in both MnCat and PSII enzymes are accompanied by structural changes involving the groups bridging the Mn atoms. For example, the significant structural changes that occur during the $S_0 \rightarrow S_1$ and $S_2 \rightarrow S_3$ transitions in PSII have been identified as a deprotonation of a μ-hydroxo bridge and the formation of a third Mn–(μ-O)$_2$–Mn unit, respectively.[2,14] In addition, as suggested recently, the combination of bidentate carboxylate ligands and mono- or di-oxo bridges could enhance the stability of the cation arrangement and facilitate rearrangement of the μ-oxo bridges during the S-state cycle.[23]

μ-Acetato/μ-hydroxo or μ-oxo bridging ligand changes in relation to Mn oxidation have been reported for synthetic binuclear Mn complexes with multidentate ancillary N and/or O ligands.[24–34] Electrochemistry is a convenient way to investigate these kinds of redox-induced structural changes, and we have previously demonstrated the efficiency of the electrochemically induced core interconversion in an organic medium ($CH_3CN$) for the tris(μ-acetato) complex $[Mn_2^{II}(O_2CCH_3)_3(bpea)_2]^+$ [bpea = *N*,*N*-bis(2-methylpyridyl)ethylamine].[28,29] The mono-(μ-oxo) $[Mn_2^{III}(O)(O_2CCH_3)_2(bpea)_2]^{2+}$ and bis(μ-oxo) $[Mn_2^{IV}(O)_2(O_2CCH_3)(bpea)_2]^{3+}$ complexes have been selectively and quantitatively generated by an exhaustive electrochemical oxidation of $[Mn_2^{II}(O_2CCH_3)_3(bpea)_2]^+$. In order to evaluate the influence of the structure of the complex on the efficiency of the electrochemical process, we report here a similar study conducted with the bis(μ-acetato) complex $[Mn_2^{II}(O_2CCH_3)_2(tpa)_2]^{2+}$ ($\mathbf{1}^{2+}$) [tpa = tris(2-methylpyridyl)amine]. This latter complex contains tetradentate amino ligands instead of tridentate ones and only two acetate bridging ligands instead of three. The electrochemical synthesis of the mono-(μ-oxo) mono-(μ-acetato) complex $[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2]^{3+}$ ($\mathbf{2}^{3+}$) and the redox properties of the bis(μ-oxo) complex $[Mn_2^{III,IV}(O)_2(tpa)_2]^{3+}$ ($\mathbf{3}^{3+}$) are also reported. Complexes $\mathbf{1}(TCNQ)_2\cdot CH_3CN$, $\mathbf{3}(BPh_4)_2$, and $\mathbf{3}(S_2O_6)_{3/2}\cdot 7H_2O$[35–37] have been structurally and spectroscopically characterized previously, and the electrochemical properties of $\mathbf{3}^{3+}$ have been briefly studied in $CH_3CN$.[37,38] In contrast, complex $\mathbf{2}^{3+}$, which possesses a rare mono-(μ-oxo) mono-(μ-acetato) motif,[39–41] has not been isolated previously and we report here its characterization by X-ray crystallography.

## Results

### Synthesis and Crystal Structure of $[Mn_2^{III}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)(tpa)_2](PF_6)_3$ $[\mathbf{2}(PF_6)_3]$

This complex was obtained by preparative electrolysis of a concentrated solution of $\mathbf{1}^{2+}$ in $CH_3CN$ containing 0.1 M $Bu_4NPF_6$. Slow diffusion of diethyl ether into this solution leads to single crystals of $\mathbf{2}(PF_6)_3\cdot CH_3CN$ in good yield (see Experimental Section). The structure of this complex was determined by X-ray diffraction. Figure 1 shows the structure of the $[Mn_2^{III}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)(tpa)_2]^{3+}$ cation and the atom labelling scheme; Table 1 summarises important bond lengths and angles. Each manganese atom exhibits a highly distorted octahedral geometry and is bound by four nitrogen atoms from a single tpa ligand and two oxygen atoms, one from the bridging oxo group and the other from the bridging acetate.

The $\{Mn_2(O)(O_2CCH_3)\}^{3+}$ core of the complex yields a Mn···Mn distance of 3.253(3) Å. To the best of our knowledge, only four other crystallographically characterized complexes possess this type of core. In $[Mn_2^{III}(O)(O_2CCH_3)(bispicen)_2]^{3+}$ [bispicen = *N*,*N*′-bis(2-methylpyridyl)ethane-1,2-diamine] and $[Mn_2^{III}(O)(O_2CCH_3)(bispicMe_2en)_2]^{3+}$ [bispicMe$_2$en = *N*,*N*′-dimethyl-*N*,*N*′-bis(2-methylpyridyl)ethane-1,2-diamine],[39] the Mn···Mn distances are 3.276(3) and 3.292(14) Å, respectively, whereas in $[Mn_2^{III}(O)(O_2CCH_3)(tmima)_2]^{2+}$ [tmima = tris(1-methylimidazol-2-yl)methylamine][40] and $[Mn_2^{III}(O)(O_2CCH_3)(bpia)_2]^{3+}$ [bpia = bis(picolyl)(*N*-methylimidazol-2-yl)amine][41] the two manganese ions are separated by 3.250(1) and 3.2544(8) Å, respectively. Compared to the other crystallographically characterized dimanganese tpa complexes, the Mn···Mn distance in $\mathbf{2}^{3+}$ is significantly longer than those found in the bis(μ-oxo) complexes at the (III,III) and (III,IV) oxidation level [2.656(2) Å ($\mathbf{3}^{2+}$)[36] and 2.643(1) Å ($\mathbf{3}^{3+}$)[37]] and shorter than that in the bis(μ-acetato) complex [4.154(1) Å ($\mathbf{1}^{2+}$)].[35] A noticeable compression of the bond

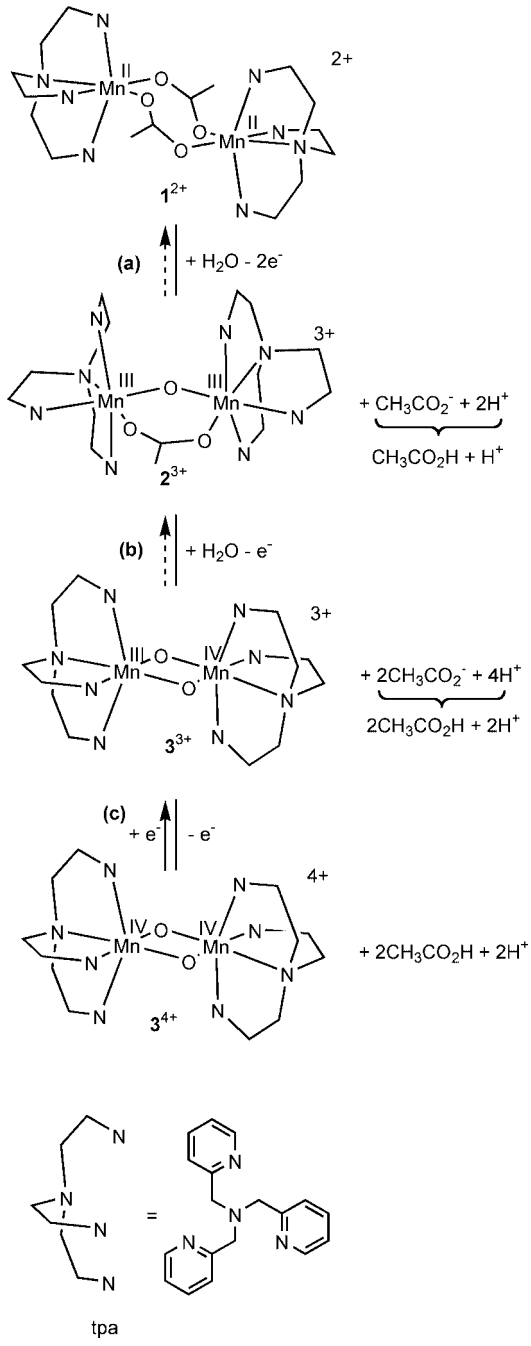
lengths along the $N_{pyridine}$(4 or 8)–Mn–$O_{oxo}$(3) axis is observed in $\mathbf{2}^{3+}$ due to the Jahn–Teller effect expected for a high-spin $d^4$ $Mn^{III}$ ion. Although this kind of distortion is rarely observed for a $Mn^{III}$ ion, a similar tetragonal compression occurs in the four other complexes with the same core.[39–41] The Mn–$O_{oxo}$–Mn angle of 131.82(3)° in $\mathbf{2}^{3+}$ is comparable to those found in the four other complexes (130.9° < Mn–$O_{oxo}$–Mn < 133°). The Mn–$O_{oxo}$ bond lengths of 1.778(2) and 1.786(2) Å and the Mn–$O_{acetate}$ distance of 1.987(3) Å in $\mathbf{2}^{3+}$ are consistent with the corresponding bond lengths reported for the parent complexes [1.784(3) < Mn–$O_{oxo}$ < 1.801(3) Å and 1.90(3) < Mn–$O_{carb}$ < 2.042(4) Å].[39–41] The Mn–$N_{pyridine}$(4 and 8) bonds [2.048(3) and 2.058(3) Å] *trans* to the oxo group are considerably shorter than the other Mn–$N_{pyridine}$ bond lengths due to the compression of the octahedron [Mn(1)–N(2) 2.163(3), Mn(1)–N(3) 2.194(3), Mn(2)–N(6) 2.193(3), Mn(2)–N(7) 2.201(3) Å]. The distortions from octahedral geometry observed around the Mn ions are also due to the spatially constrained nature of the tetradentate tpa ligand, as revealed by the values of the $N_{amine}$–Mn–$N_{pyridine}$ intraligand angles, which range between 75.38° and 90.22° (Table 1); the theoretical value is 90°.



Scheme 1. Electrochemical interconversions of dinuclear manganese tpa complexes.

## Electrochemistry

As we will see, the oxidation of $\mathbf{1}^{2+}$ in $CH_3CN$ is a fully irreversible process that leads first to the mono-(μ-oxo)/mono-(μ-acetato) complex $\mathbf{2}^{3+}$ and then the bis(μ-oxo) complex $\mathbf{3}^{4+}$ (Scheme 1). For a better understanding of the processes involved, the electrochemical behavior of $\mathbf{3}^{3+}$ is first presented, and then those of complexes $\mathbf{2}^{3+}$ and $\mathbf{1}^{2+}$. All the potentials are referenced to an Ag/0.01 M $AgNO_3$ reference electrode in $CH_3CN$ + 0.1 M $Bu_4NClO_4$. Potentials referred to this system can be converted to the ferrocene/ferrocenium couple by subtracting 87 mV, or to SCE or NHE by adding 298 or 548 mV, respectively.[42]

### *Electrochemical Behavior of $[Mn_2^{III,IV}(O)_2(tpa)_2](ClO_4)_3$ [$3(ClO_4)_3$]*

As previously observed by Suzuki et al.,[38] the cyclic voltammogram of a $CH_3CN$ solution of $\mathbf{3}^{3+}$ in the presence of 0.1 M $Bu_4NClO_4$ (Figure 2, A) displays a single reversible oxidation wave at $E^{3A}_{1/2}$ = 0.77 V ($E^{3A}_{pa}$ = 0.80 and $E^{3A}_{pc}$ = 0.74 V; $\Delta E_p$ = 60 mV) and one reversible reduction wave at $E^{3B}_{1/2}$ = –0.05 V ($E^{3B}_{pc}$ = –0.08 and $E^{3B}_{pa}$ = –0.02 V; $\Delta E_p$ = 60 mV) corresponding to Equations (1) and (2), respectively.

$$[Mn_2^{III,IV}(O)_2(tpa)_2]^{3+} \rightleftharpoons [Mn_2^{IV,IV}(O)_2(tpa)_2]^{4+} + e^- \quad (1)$$
$$\mathbf{3}^{3+} \qquad\qquad \mathbf{3}^{4+}$$

$$[Mn_2^{III,IV}(O)_2(tpa)_2]^{3+} + e^- \rightleftharpoons [Mn_2^{III,III}(O)_2(tpa)_2]^{2+} \quad (2)$$
$$\mathbf{3}^{3+} \qquad\qquad \mathbf{3}^{2+}$$

Exhaustive electrolyses of solutions of this complex confirm the excellent stability of the $Mn_2^{III,III}$ ($\mathbf{3}^{2+}$) and $Mn_2^{IV,IV}$ ($\mathbf{3}^{4+}$) species. Exhaustive reduction of a solution of $\mathbf{3}^{3+}$ at –0.2 V consumes one electron per molecule of complex and leads to the quasi-quantitative formation of the one-electron-reduced species $\mathbf{3}^{2+}$ (yield: 97%). The yield is calculated from the relative height of the two waves [Equation (2)] of the voltammograms at a rotating disc electrode before and after reduction (Figure 2, B).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

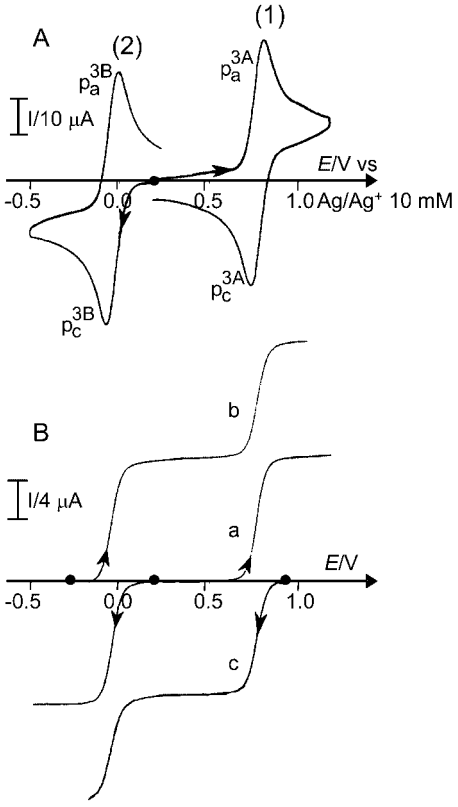


Figure 2. (A) Cyclic voltammograms at a Pt electrode (diameter: 5 mm) of a 0.72 mM solution of $\mathbf{3}^{3+}$ in $CH_3CN$ + 0.1 M $Bu_4NClO_4$; sweep rate: 100 mV s$^{-1}$; (B) voltamperograms at a Pt rotating disc electrode (diameter: 0.2 mm); rotation speed: 600 min$^{-1}$; sweep rate: 10 mV s$^{-1}$: (a) solution (A), (b) solution (A) after exhaustive reduction at –0.2 V (formation of $\mathbf{3}^{2+}$), and (c) after exhaustive oxidation of a solution of a 0.72 mM of $\mathbf{3}^{3+}$ in $CH_3CN$ + 0.1 M $Bu_4NBF_4$ at 0.9 V (formation of $\mathbf{3}^{4+}$). The numbers in parentheses correspond to the equation number in the text.

On the other hand, as previously reported,[38] exhaustive oxidation of a solution of $\mathbf{3}^{3+}$ at 0.9 V in $CH_3CN$ in the presence of 0.1 M $Bu_4NClO_4$ leads to the formation of a green precipitate corresponding to $\mathbf{3}^{4+}$. However, we were able to prevent the precipitation of $\mathbf{3}^{4+}$ by using $Bu_4NBF_4$ as supporting electrolyte instead of $Bu_4NClO_4$. This complex is formed in solution with a 95% yield after one electron has been consumed per molecule (Figure 2B). Figure 3 displays the absorption spectra of the different species in the visible region. The green (III,IV) complex $\mathbf{3}^{3+}$ (spectrum a) shows three bands in the visible region at 444 ($\varepsilon$ = 1490 M$^{-1}$ cm$^{-1}$), 560 (760), and 658 nm (620) and one band in the UV region at 258 nm (36850). The green (IV,IV) complex $\mathbf{3}^{4+}$ (spectrum c) exhibits three visible bands at 418, 534 and 642 nm. This spectrum is similar to that obtained by Suzuki et al.[38] after redissolution of the green precipitate of $[Mn_2^{IV,IV}(O)_2(tpa)_2](ClO_4)_4$ in $CH_3CN$ in the absence of supporting electrolyte [418 (6000), 534 (1032), and 642 nm (1084)]. The pale-yellow (III,III) complex (spectrum b) does not exhibit any well-resolved bands in the visible region.[36]

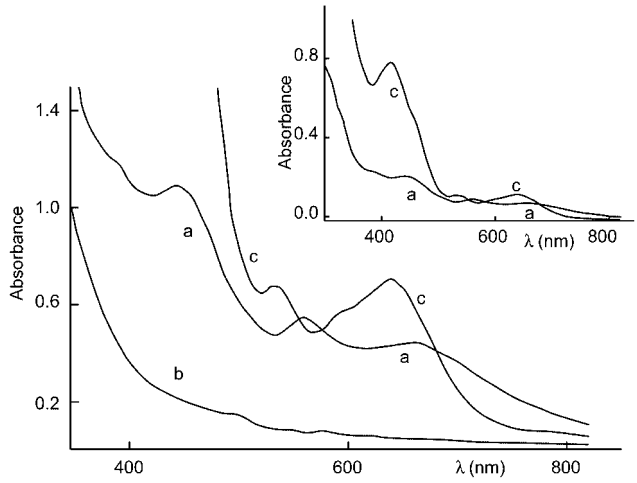

Figure 3. Visible absorption spectra of a 0.72 mM solution of $\mathbf{3}^{3+}$ in $CH_3CN$ + 0.1 M $Bu_4NClO_4$: (a) initial solution, (b) solution (a) after exhaustive reduction at –0.2 V, and (c) after exhaustive oxidation of a 0.72 mM solution of $\mathbf{3}^{3+}$ in $CH_3CN$ + 0.1 M $Bu_4NBF_4$ at 0.9 V; $l$ = 1 cm; inset: $l$ = 2 mm.

### *Electrochemical Behavior of $[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2](PF_6)_3\cdot CH_3CN$ [2(PF$_6$)$_3$·CH$_3$CN]*

Figure 4 shows the visible absorption spectrum of $\mathbf{2}^{3+}$. This pale purple/red complex exhibits two visible absorption bands at 494 ($\varepsilon$ = 520 M$^{-1}$ cm$^{-1}$) and 532 nm (440) corresponding to d-d transitions and a broad absorption band centerd at 720 nm (185). This spectrum is similar to those reported for other complexes possessing the same $\{Mn_2(O)(O_2CCH_3)\}^{3+}$ core.[39–41] The cyclic voltammogram of this complex in $CH_3CN$ containing 0.1 M $Bu_4NBF_4$ (scan rate of 100 mV s$^{-1}$) displays three waves at $E_{1/2}^{2A}$ = 0.95 V ($E_{pa}^{2A}$ = 1.00 and $E_{pc}^{2A}$ = 0.90 V; $\Delta E_p$ = 100 mV),

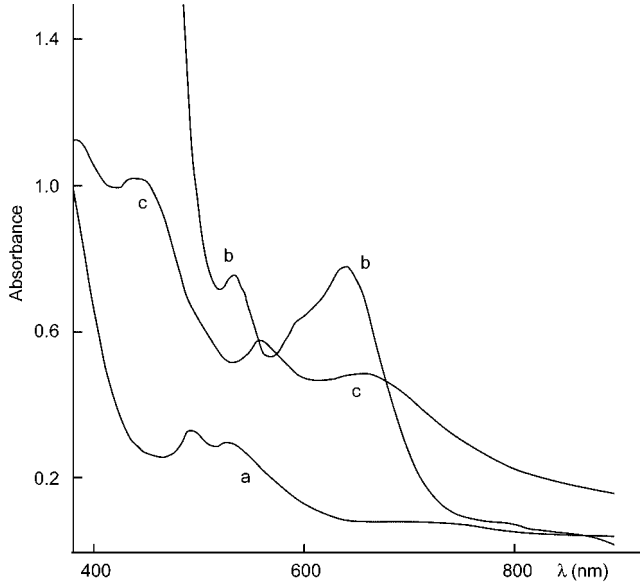

Figure 4. Visible absorption spectra of a 0.77 mM solution of $\mathbf{2}^{3+}$ in $CH_3CN$ + 0.1 M $Bu_4NBF_4$: (a) initial solution, (b) solution (a) after exhaustive oxidation at 1.15 V, and (c) solution (b) after exhaustive reduction at 0.6 V; $l$ = 1 cm.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$E_{1/2}^{2B}$ = 1.45 V ($E_{pa}^{2B}$ = 1.49 and $E_{pc}^{2B}$ = 1.41 V; $\Delta E_p$ = 80 mV); $E_{1/2}^{2C}$ = –0.07 V ($E_{pc}^{2C}$ = –0.12 and $E_{pa}^{2C}$ = –0.02 V; $\Delta E_p$ = 100 mV; Figure 5, A). The two oxidation waves are reversible and are attributed to the redox couples $Mn_2^{III,III/III,IV}$ and $Mn_2^{III,IV/IV,IV}$ [Equations (3) and (4), respectively].

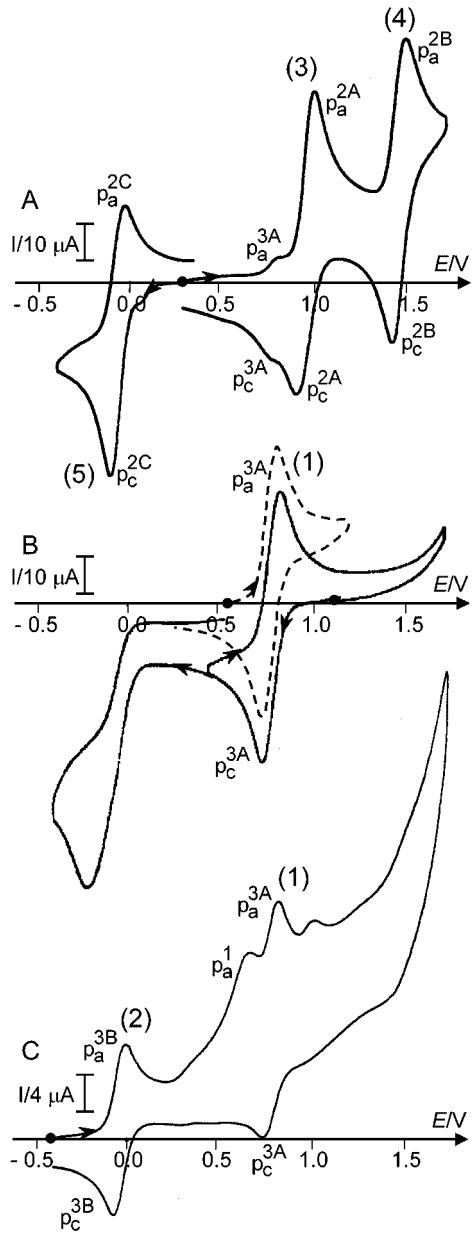

Figure 5. (A) Cyclic voltammograms at a Pt electrode (diameter: 5 mm) of a 0.77 mM solution of $\mathbf{2}^{3+}$ in $CH_3CN$ + 0.1 M $Bu_4NBF_4$; scan rate: 100 mV $s^{-1}$; (B) solution (A) after exhaustive oxidation at 1.15 V [curve (–), formation of $\mathbf{3}^{4+}$], then exhaustive reduction at 0.6 V [curve (----), formation of $\mathbf{3}^{3+}$], and (C) after exhaustive reduction of a 0.3 mM solution of $\mathbf{2}^{3+}$ at –0.4 V (formation of $\mathbf{1}^{2+}$ and $\mathbf{3}^{2+}$); scan rate: 100 mV $s^{-1}$. The numbers in parentheses correspond to the equation number in the text.

The reduction wave, which is only partially reversible at that scan rate, is associated with the redox states $Mn_2^{III,III/III,II}$ [Equation (5)].

$$[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2]^{3+} \rightleftharpoons [Mn_2^{III,IV}(O)(O_2CCH_3)(tpa)_2]^{4+} + e^- \quad (3)$$
$$\mathbf{2}^{3+} \qquad\qquad \mathbf{2}^{4+}$$

$$[Mn_2^{III,IV}(O)(O_2CCH_3)(tpa)_2]^{4+} \rightleftharpoons [Mn_2^{IV}(O)(O_2CCH_3)(tpa)_2]^{5+} + e^- \quad (4)$$
$$\mathbf{2}^{4+} \qquad\qquad \mathbf{2}^{5+}$$

$$[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2]^{3+} + e^- \rightleftharpoons [Mn_2^{III,II}(O)(O_2CCH_3)(tpa)_2]^{2+} \quad (5)$$
$$\mathbf{2}^{3+} \qquad\qquad \mathbf{2}^{2+}$$

The additional reversible wave with low intensity located at $E_{1/2}^{3A}$ = 0.77 V corresponds to an impurity of about 8% of the bis(μ-oxo) complex $\mathbf{3}^{3+}$ present in the sample (see below). None of the oxidized or reduced species of $\mathbf{2}^{3+}$ are stable over the timescale of a controlled potential electrolysis.

Exhaustive oxidation of a solution of $\mathbf{2}^{3+}$ at a potential of 1.15 V consumes about two electrons per molecule of complex and leads to the quasi-quantitative formation of the di-μ-oxo $Mn_2^{IV,IV}$ complex $\mathbf{3}^{4+}$. The formation of this complex is the result of the instability of the one-electron-oxidized form of $\mathbf{2}^{3+}$ $[Mn_2^{III,IV}(O)(O_2CCH_3)(tpa)_2]^{4+}$ [Equation (3)], which reacts with residual water in the solvent[25–29,43] to form the binuclear complex $\mathbf{3}^{3+}$ by substitution of one acetato bridge by an oxo bridge [Equation (6)].

$$[Mn_2^{III,IV}(O)(O_2CCH_3)(tpa)_2]^{4+} + H_2O \rightleftharpoons [Mn_2^{III,IV}(O)_2(tpa)_2]^{3+} + CH_3CO_2^- + 2\,H^+ \quad (6)$$
$$\mathbf{2}^{4+} \qquad\qquad \mathbf{3}^{3+}$$

However, since $\mathbf{3}^{3+}$ is more easily oxidizable than $\mathbf{2}^{3+}$ ($E_{1/2}^{3A}$ = 0.77 and $E_{1/2}^{2A}$ = 0.95 V, respectively), $\mathbf{3}^{3+}$ is oxidized to $\mathbf{3}^{4+}$ at the electrolysis potential used for the oxidation of $\mathbf{2}^{2+}$ [$E$ = 1.15 V; Equation (1)]. Equation (7) summarises the overall reaction.

$$[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2]^{3+} + H_2O \rightleftharpoons [Mn_2^{IV}(O)_2(tpa)_2]^{4+} + CH_3CO_2^- + 2\,H^+ + 2e^- \quad (7)$$
$$\mathbf{2}^{3+} \qquad\qquad \mathbf{3}^{4+}$$

It should be noted that if one of the two protons released is trapped by the acetate anion released, the other one does not interact with $\mathbf{3}^{4+}$ since the formation of this complex is quasi-quantitative, as estimated by electrochemistry and by visible absorption spectroscopy (Figure 4, spectrum b). The cyclic voltammogram obtained after oxidation (Figure 5, B) shows the one-electron reversible wave at $E_{1/2}^{3A}$ = 0.77 V which is typical of the electroactivity of $\mathbf{3}^{4+}$, $[Mn_2^{IV,IV}/$

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$Mn_2^{III,IV}$ couple; Equation (1)] and is followed by a second irreversible system at –0.21 V corresponding to the reduction of $\mathbf{3}^{3+}$. The irreversibility of this latter system is due to the presence of both acetate anions and protons released during the oxidation in solution [Equation (7)].

Indeed, under these particular conditions the reduction of the electrolyzed solution of $\mathbf{3}^{4+}$ at –0.4 V (three electrons consumed per initial molecule of $\mathbf{2}^{3+}$) does not lead selectively to the complex $\mathbf{3}^{2+}$ but to an equimolar mixture of complexes $\mathbf{3}^{2+}$ and $\mathbf{1}^{2+}$, as for the direct reduction of the initial solution of $\mathbf{2}^{3+}$ at this potential (see below). If the electrolyzed solution of $\mathbf{3}^{4+}$ is reduced at 0.6 V (consumption of about one electron per molecule of initial complex $\mathbf{2}^{3+}$), $\mathbf{3}^{3+}$ is obtained [Equation (1), Figure 5, B (dashed curve].

Exhaustive reduction of a solution of complex $\mathbf{2}^{3+}$ at a controlled potential of –0.4 V consumes one electron per molecule of complex. The resulting cyclic voltammogram (Figure 5, C) corresponds to the superimposition of the activity of complexes $\mathbf{3}^{2+}$ and $\mathbf{1}^{2+}$ (see below). The respective amount of both complexes was estimated from the height of the different waves at the rotating disc electrode and corresponds, for each complex, to half of the initial concentration of $\mathbf{2}^{3+}$. The reduction mechanism of $\mathbf{2}^{3+}$ involves the initial formation of the unstable species $\mathbf{2}^{2+}$ [Equation (5)] which undergoes a disproportionation reaction to give the stable final species $\mathbf{1}^{2+}$ and $\mathbf{3}^{2+}$ [Equation (8)].

$$[Mn_2^{II,III}(O)(O_2CCH_3)(tpa)_2]^{2+} \rightleftharpoons \underset{\mathbf{2}^{2+}}{} \quad (8)$$

$$\tfrac{1}{2}\,[Mn_2^{II}(O_2CCH_3)_2(tpa)_2]^{2+} + \tfrac{1}{2}\,[Mn_2^{III}(O)_2(tpa)_2]^{2+}$$
$$\mathbf{1}^{2+} \qquad\qquad \mathbf{3}^{2+}$$

Equation (9) summarises the overall process.

$$[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2]^{3+} + e^- \rightleftharpoons \underset{\mathbf{2}^{3+}}{} \quad (9)$$

$$\tfrac{1}{2}\,[Mn_2^{II}(O_2CCH_3)_2(tpa)_2]^{2+} + \tfrac{1}{2}\,[Mn_2^{III}(O)_2(tpa)_2]^{2+}$$
$$\mathbf{1}^{2+} \qquad\qquad \mathbf{3}^{2+}$$

The two oxidation waves of $\mathbf{2}^{3+}$ [Equations (3) and (4)] appear to be more reversible than those of $[Mn_2^{III}(O)(O_2CCH_3)_2(bpea)_2]^{2+}$ at the same scan rate.[29] This shows that the rate of formation of the bis(μ-oxo) complex $\mathbf{3}^{3+}$ is slower than that of $[Mn_2^{III,IV}(O)_2(O_2CCH_3)(bpea)_2]^{2+}$ due to the greater stability of $[Mn_2^{III,IV}(O)(O_2CCH_3)(tpa)_2]^{4+}$ compared to $[Mn_2^{III,IV}(O)(O_2CCH_3)_2(bpea)_2]^{3+}$.

### *Electrochemical Behavior of $[Mn_2^{II}(O_2CCH_3)_2(tpa)_2](PF_6)_2$ [1(PF$_6$)$_2$]*

The cyclic voltammogram of a solution of $\mathbf{1}^{2+}$ in $CH_3CN$ containing 0.1 M $Bu_4NBF_4$ displays a first irreversible oxidation peak at $E_{pa}^{1}$ = 0.70 V corresponding to the oxidation of the metallic centers of the complex (Figure 6, A). This oxidation leads to the formation of $\mathbf{2}^{3+}$, as evidenced by the presence of its two partially reversible oxidation waves at $E_{1/2}^{2A}$ = 0.95 and $E_{1/2}^{2B}$ = 1.45 V, which follow the irreversible oxidation peak at 0.70 V, and by the irreversible reduction peak at –0.04 V in the reverse scan. Complex $\mathbf{3}^{3+}$, which is formed during the oxidation of $\mathbf{2}^{3+}$ at $E_{pa}^{2A}$ = 1.0 V, is also detected in the cyclic voltammogram by the presence of its first reduction peak at $E_{pc}^{3A}$ = 0.73 V. This electro-induced transformation is faster than the oxidation of $\mathbf{2}^{3+}$ into $\mathbf{3}^{3+}$ since the oxidation peak of $\mathbf{1}^{2+}$ is fully irreversible even for higher scan rates of up to 500 mV s$^{-1}$.

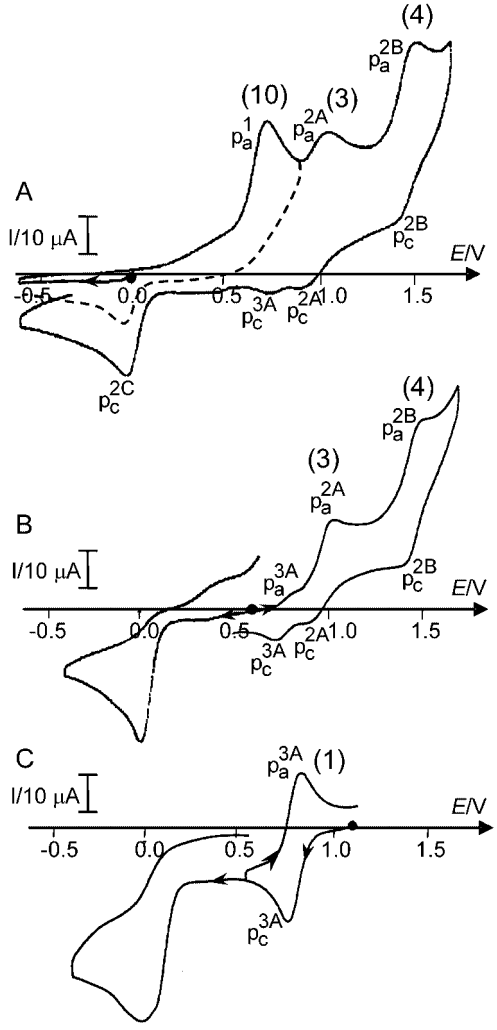

Figure 6. Cyclic voltammograms at a Pt electrode (diameter: 5 mm) of (A) a 0.45 mM solution of $\mathbf{1}^{2+}$ in $CH_3CN$ + 0.1 M of $Bu_4NClO_4$; (B) solution (A) after exhaustive oxidation at 0.7 V (formation of $\mathbf{2}^{3+}$), and (C) solution (B) after exhaustive oxidation at 1.10 V (formation of $\mathbf{3}^{4+}$); scan rate: 100 mV s$^{-1}$. The numbers in parentheses correspond to the equation number in the text.

As expected, exhaustive oxidation of a solution of $\mathbf{1}^{2+}$ at 0.7 V consumes two electrons per molecule of complex and leads mainly to the formation of $\mathbf{2}^{3+}$ (yield: 90%). The resulting cyclic voltammogram displays the typical activity of this complex (Figure 6, B). However, a small amount of $\mathbf{3}^{3+}$ is also formed during the oxidation process (about 8%), as

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

attested by the presence of its reversible oxidation wave at $E^{3A}_{1/2}$ = 0.77 V. This explains why the same amount of this complex is present in the sample of $\mathbf{2}^{3+}$ isolated from electrolyzed solutions.

The processes involved in the oxidation of $\mathbf{1}^{2+}$ are summarized in Equation (10) [Scheme 1(a)].

$$\underset{\mathbf{1}^{2+}}{[Mn_2^{II}(O_2CCH_3)_2(tpa)_2]^{2+}} + H_2O \rightleftharpoons \underset{\mathbf{2}^{3+}}{[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2]^{3+}} + CH_3CO_2^- + 2\,H^+ + 2\,e^- \quad (10)$$

As for the oxidation of $\mathbf{2}^{3+}$ into $\mathbf{3}^{4+}$ [Equation (7)], the oxidation of $\mathbf{1}^{2+}$ into $\mathbf{2}^{3+}$ leads to the dissociation of one acetate anion and the formation of an oxo bridge between the two manganese ions by deprotonation of a water molecule from the solvent.

Subsequent electrolysis at 1.10 V results in the quantitative formation of $\mathbf{3}^{4+}$ after the exchange of two additional electrons per molecule of the initial complex $\mathbf{1}^{2+}$ [Equation (7)] [Scheme 1 (b)]. The cyclic voltammogram of the resulting green solution (Figure 6, C), as well as the visible absorption spectrum, are typical of a solution of $\mathbf{3}^{4+}$. It should be noted that $\mathbf{3}^{4+}$ can be generated directly, with the same yield, by a four-electron oxidation of $\mathbf{1}^{2+}$ at 1.10 V [Equation (11); Scheme 1 (a–c)].

$$\underset{\mathbf{1}^{2+}}{[Mn_2^{II}(O_2CCH_3)_2(tpa)_2]^{2+}} + 2\,H_2O \rightleftharpoons \underset{\mathbf{3}^{4+}}{[Mn_2^{IV}(O)_2(tpa)_2]^{4+}} + 2\,CH_3CO_2^- + 4\,H^+ + 4\,e^- \quad (11)$$

The reaction in Equation (10) is an overall reversible process, therefore a controlled-potential reduction of the electrochemically generated solution of $\mathbf{2}^{3+}$ at –0.6 V completely restores the initial amount of $\mathbf{1}^{2+}$ [Scheme 1 (a)] after the consumption of two electrons per molecule of initial $\mathbf{1}^{2+}$. Likewise, the initial amount of $\mathbf{1}^{2+}$ can also be obtained by a controlled-potential reduction of the electrochemically generated solution of $\mathbf{3}^{4+}$ at –0.6 V [Equation (11); Scheme 1 (a–c)] after consumption of 3.8 electrons per molecule of $\mathbf{1}^{2+}$.

## Discussion and Conclusion

We have systematically investigated the redox properties of three different cores $\{Mn_2^{II}(\mu\text{-}O_2CCH_3)_2\}$, $\{Mn_2^{III}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)\}$, and $\{Mn_2^{III}(\mu\text{-}O)_2\}/\{Mn_2^{III,IV}(\mu\text{-}O)_2\}/\{Mn_2^{IV,IV}(\mu\text{-}O)_2\}$ with the same terminal ligand (tpa) and studied possible core interconversions between the various oxidation levels of manganese. Oxidation of the $\{Mn_2^{II}(\mu\text{-}O_2CCH_3)_2\}$ complex $\mathbf{1}^{2+}$ is fully irreversible and mainly leads to $\{Mn_2^{III}(\mu\text{-}O)(\mu\text{-}O_2CCH_3)\}$ ($\mathbf{2}^{3+}$). Further oxidation of $\mathbf{2}^{3+}$ yields the $\{Mn_2^{IV,IV}(\mu\text{-}O)_2\}$ complex $\mathbf{3}^{4+}$ quantitatively (Scheme 1). The rate of the electroinduced transformation of $\mathbf{1}^{2+}$ into $\mathbf{2}^{3+}$ is faster than that of $\mathbf{2}^{3+}$ into $\mathbf{3}^{4+}$, as shown by the shape of the cyclic voltammograms of $\mathbf{1}^{2+}$ and $\mathbf{2}^{3+}$, which attests to the greater instability of a $(\mu\text{-}O_2CCH_3)_2$ species at the $Mn_2^{II,III}$ oxidation level than that of a $(\mu\text{-}O)(\mu\text{-}O_2CCH_3)$ at the $Mn_2^{III,IV}$ oxidation level. In addition, $\mathbf{2}^{3+}$ and $\mathbf{3}^{4+}$ can be selectively generated owing to a good separation of the two two-electron oxidation waves [the oxidation potentials of $\mathbf{1}^{2+}$ and $\mathbf{2}^{3+}$ are 0.70 and 0.95 V vs. $Ag/Ag^+$ (10 mM), respectively]. The oxidation potential of $\mathbf{3}^{3+}$ (0.77 V) is located between the oxidation potentials of $\mathbf{1}^{2+}$ and $\mathbf{2}^{3+}$. These transformations ($\mathbf{1}^{2+}$ into $\mathbf{2}^{3+}$ and $\mathbf{2}^{3+}$ into $\mathbf{3}^{4+}$) are chemically reversible by reduction processes, although the two steps are not separated. Indeed, $\mathbf{1}^{2+}$ is directly and entirely regenerated by reduction of $\mathbf{3}^{4+}$ (or $\mathbf{3}^{3+}$). These core interconversions under oxidative and reductive conditions obviously occur concomitantly with protonation/deprotonation reactions at the bridging oxo groups.

We have also isolated and crystallographically characterized a new binuclear manganese complex in the tpa series ($\mathbf{2}^{3+}$), which shows that the (III,III) oxidation state in the tpa series is stable with two types of cores: a bis(μ-oxo) and a mono-(μ-oxo) mono-(μ-acetato). The difference in Mn···Mn separation across the four binuclear tpa compounds is 1.50 Å [$\{Mn_2^{II}(O_2CCH_3)_2\}$ 4.154(1), $\{Mn_2^{III}(O)(O_2CCH_3)\}$ 3.253, $\{Mn_2^{III}(O)_2\}$ 2.656(2), $\{Mn_2^{III,IV}(O)_2\}$ 2.643(1) Å].

These electrochemical and crystallographic results are in agreement with the hypothesis of the presence of one oxo bridge for the active site of MnCat in the $Mn_2^{III,III}$ oxidation state.

We are currently evaluating the ability of these tpa complexes to disproportionate hydrogen peroxide in order to compare their efficiencies to those of the parent bpea complexes. Indeed, although the electrochemical behavior of the bpea and tpa complexes are quite similar, the oxidation potentials of the bpea complexes are clearly lower (about 160–190 mV) than those of the tpa complexes owing to the presence of an additional acetate bridge, which has a more pronounced electron-donor character than that of pyridine. In addition, the rate of formation of the $Mn_2^{III,IV}$ complex $\mathbf{3}^{3+}$ by oxidation of the $Mn_2^{III,III}$ complex $\mathbf{2}^{3+}$ is slower than that of the tpa derivative. A different catalytic efficiency may therefore be expected for these two kinds of complexes.

## Experimental Section

**Materials:** Acetonitrile (Rathburn, HPLC grade) was used as received and stored under argon in a glovebox. Tetra-*n*-butylammonium perchlorate ($Bu_4NClO_4$), tetra-*n*-butylammonium tetrafluoroborate ($Bu_4NBF_4$), and tetra-*n*-butylammonium hexafluorophosphate ($Bu_4NPF_6$) were purchased from Fluka and used as received.

Tris(2-pyridylmethyl)amine (tpa) and the complex $\mathbf{3}(ClO_4)_3$ were synthesized according to previously described methods.[38]

**$[Mn_2^{II}(O_2CCH_3)_2(tpa)_2](PF_6)_2$ [$\mathbf{1}(PF_6)_2$]:** A solution of $MnSO_4{\cdot}H_2O$ (38.2 mg, 0.227 mmol) in water (5 mL) was added to

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

a solution of tpa (66 mg, 0.227 mmol) in methanol (5 mL). After 25 min of stirring, a solution of $NaCH_3CO_2$ (19 mg, 0.227 mmol) in water (1 mL) was added. The resulting colorless solution was stirred at room temperature for 15 min. After addition of solid $KPF_6$ (82.2 mg, 0.446 mmol) the solution was evaporated to dryness and the yellow-white residue redissolved in $CH_3CN$. The solution was filtered to remove insoluble white $K_2SO_4$ and the filtrate was then evaporated to dryness. The colorless residue obtained was then redissolved in dichloromethane and the resulting solution filtered to remove a white powder corresponding to excess $KPF_6$. The filtrate was then evaporated to dryness and a pale-yellow powder corresponding to **1**$(PF_6)_2$ was obtained. Yield: 150 mg (60%). These crystals analyzed satisfactorily as $[Mn_2^{II}(\mu\text{-}O_2CCH_3)_2(tpa)_2](PF_6)_2$. $C_{40}H_{42}F_{12}Mn_2N_8O_4P_2$ (1098.6): calcd. C 43.71, H 3.85, N 10.2; found C 43.66, H3.91, N 10.12. IR (KBr): $\tilde{\nu}$ = 3428 $cm^{-1}$ (m), 1605 (s), 1580 (s), 1505 (w), 1484 (m), 1444 (s), 1353 (w), 1294 (m), 1269 (w), 1158 (m), 1122 (w), 1100 (m), 1053 (m), 1017 (m), 840 (vs), 764 (s), 639 (m), 557 (s), 500 (w), 415 (w).

**$[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2](PF_6)_3$ [2$(PF_6)_3$]:** This complex was synthesized by an electrochemical procedure. Exhaustive oxidation of a 4.5 mM solution of **1**$(PF_6)_2$ in 12 mL of $CH_3CN$ containing 0.1 M $Bu_4NPF_6$ as supporting electrolyte at 0.80 V on a platinum plate led to formation of a red-purple solution corresponding to the complex $\mathbf{2}^{3+}$. Red-purple crystals of **2**$(PF_6)_3{\cdot}CH_3CN$ suitable for X-ray diffraction were grown after one day by slow vapor diffusion of diethyl ether into this solution. These were filtered, washed with $CH_2Cl_2$, and dried under air. Yield: 53.9 mg (85%). These crystals analyzed satisfactorily as **2**$(PF_6)_3$. $C_{38}H_{39}Mn_2N_8O_3P_3F_{18}$ (1200): calcd. C 37.93, H3.24, N 9.51; found C 38.00, H 3.25, N 9.33. IR (KBr): $\tilde{\nu}$ = 3445 $cm^{-1}$ (vs), 1609 (s), 1574 (w), 1531 (w), 1487 (w), 1445 (s), 1295 (m), 1163 (m), 1101 (m), 1063 (m), 1032 (m), 1023 (m), 839 (vs), 761 (m), 707 (m), 678 (m), 661 (m), 614 (m), 557 (s), 414 (w). UV/Vis ($CH_3CN$): $\lambda_{max}$ ($\varepsilon$) = 256 nm (20640 $M^{-1}cm^{-1}$), 289 (10910, sh), 380 (1160, sh), 494 (410), 532 (350), 720 (150).

**Spectroscopy:** Infrared spectra were recorded with a Perkin–Elmer Spectrum GX FTIR spectrometer. Electronic absorption spectra were recorded with a Cary 50 Varian spectrophotometer. Initial and electrolyzed solutions were transferred into a conventional cuvette cell in a glovebox. The cell was inserted into an optical translator connected to the spectrophotometer through a fiber optic system (Photonetics Spectrofip System). The optical fibers pass through the wall of the dry box via seals.

**Electrochemical Measurements:** All electrochemical measurements were run under argon in a dry glovebox at room temperature. Cyclic voltammetry (CV) and controlled potential electrolysis experiments were performed using an EG&G PAR model 173 potentiostat equipped with a PAR model universal programmer and a PAR model 179 digital coulometer. The electrolyte was a 0.1 M solution of $Bu_4NClO_4$, $Bu_4NBF_4$, or $Bu_4NPF_6$ in $CH_3CN$. A standard three-electrode electrochemical cell was used. Potentials were referred to an Ag/10 mM $AgNO_3$ reference electrode in $CH_3CN$ (+0.1 M $Bu_4NClO_4$). The working electrodes were 5-mm-diameter platinum disks polished with 2-μm diamond paste for cyclic voltammetry [$E_{pa}$: anodic peak potential; $E_{pc}$: cathodic peak potential; $E_{1/2} = (E_{pa} + E_{pc})/2$; $\Delta E_p = E_{pa} - E_{pc}$] and 2-mm-diameter disks for rotating disk electrode experiments (RDE). Exhaustive electrolyses were carried out with a 5 $cm^2$ platinum cylinder or a 10×10×4 $mm^3$ carbon felt electrode (RCV, 2000, 65 mg $cm^{-3}$, from Le Carbone Lorraine). The counter electrode was a Pt wire in $CH_3CN$ (+0.1 M $Bu_4NClO_4$, $Bu_4NBF_4$, or $Bu_4NPF_6$).

**Crystal-Structure Determination of 2$(PF_6)_3{\cdot}CH_3CN$:** A crystal of **2**$(PF_6)_3{\cdot}CH_3CN$ of dimensions 0.5×0.4×0.08 $mm^3$ was selected. Diffraction data were collected with a Bruker SMART diffractometer with Mo-$K_\alpha$ radiation. All calculations were performed using the SHELXTL computer program.[44] The structure was solved by direct methods and refined by full-matrix least-squares fits on $F^2$. The crystallographic data are summarized in Tables 1 and 2.

Table 2. Principal crystallographic data and parameters for $[Mn_2^{III}(O)(O_2CCH_3)(tpa)_2](PF_6)_3{\cdot}CH_3CN$ [**2**$(PF_6)_3{\cdot}CH_3CN$].

**Keywords:** Macrocyclic ligands / Iron / Electronic structure / Spin crossover / Azides / IR spectroscopy

The five-coordinate ferric azide complex of 2,7,12,17-tetrapropylporphyrcene [Fe(TPrPc)$N_3$] was characterized with proton NMR, electron paramagnetic resonance (EPR), Mössbauer, and IR techniques. The paramagnetic NMR showed the pyrrole-H signal that exhibits anomalous *anti*-Curie type of 1/$T$-dependence over a 310–190 K range. The EPR of the solid sample resolved a signal with $g$ = 5.42, 5.40, and 2.00 at 5 K. The quadrupole splitting parameter of the Mössbauer spectrum was 2.20 mm s$^{-1}$ at 290 K, and the magnetic moment was 4.70 $\mu_B$ at 290 K for the microcrystalline sample. These results suggest that [Fe(TPrPc)$N_3$] is not pure high-spin ($S$ = 5/2) but a spin mixture of the $S$ = 5/2, 3/2 states. The azide in [Fe(TPrPc)$N_3$] exhibited split IR bands ascribed to the two spin isomers at 2066 and 2049 cm$^{-1}$. The 2049-cm$^{-1}$ band, assigned to the $S$ = 3/2 species, was reversibly intensified with decreasing temperature. The IR results demonstrate that the $S$ = 3/2, 5/2 states are not quantum-mechanically admixed but in thermal equilibrium. The thermodynamic parameters associated with the spin equilibrium, $\Delta H$ = –3 990 cal mol$^{-1}$ and $\Delta S$ = –16.5 cal mol$^{-1}$ K$^{-1}$, were obtained from the NMR shift analysis, and the population of the $S$ = 3/2 isomer was calculated to be 0.19 at 293 K. A minimum lifetime of the two spin isomers was estimated to be 0.3 ps with IR.

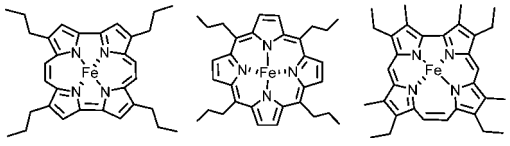
## Introduction

Understanding of hemoprotein function is aided by the elucidation of the structure of the prosthetic group. There is a general consensus that heme is not always rigid but flexible and can deform easily. Nonplanar heme deformation in a crowded protein matrix is suggested to be functionally important.[1] Porphyrin molecular shape can be artificially changed with organic synthesis by rearranging the tetrapyrrole array.[2] A typical example is 2,7,12,17-tetrapropylporphycene (TPrPc; Scheme 1), discovered by Vogel et al. in 1987.[3] The macrocycle consists of a rectangular tetrapyrrole, in marked contrast with the square porphyrin. The modified tetrapyrrole extensively alters the physicochemical properties of parent porphyrin. TPrPc exhibits characteristic light absorption spectra[2,3] and redox properties.[4]



Scheme 1. Structure of the Fe$^{III}$ complex of the porphyrinoids. The coordinating azide ion is omitted for clarity.

Among the exogenous heme ligands, azide ion ($N_3^-$) occupies a distinctive position to induce a thermal equilibrium between the high- ($S$ = 5/2) and low-spin ($S$ = 1/2) states in ferric hemoprotein.[5] The equilibrium was analyzed to monitor the heme–globin interactions.[6,7] The spin-state equilibrium of azide hemoprotein has been well reproduced with six-coordinate model hemes.[8–12] In contrast, the five-coordinate ferric heme [Fe(porphyrinato)$N_3$] is a typical high-spin complex.[10,11] The X-ray analysis for [Fe(TPP)-

$N_3$] (TPP, *meso*-tetraphenylporphyrinato) provided structural rationale for the high-spin state in five-coordinate azide heme.[11]

The coordination core in porphycene is contracted.[2,3] Recent spectroscopic investigations suggest that the narrower metallo cavity in porphycene affects the magnetic properties of the central iron(III) atom. The five-coordinate ferric chloride complex of porphycene, for instance, exhibits some intermediate-spin ($S$ = 3/2) character,[13,14] whereas the corresponding iron porphyrin is pure high-spin. In six-coordinate ferric porphycene with axial azide/imidazole, the high-spin population is lost, whereas the corresponding porphyrin is 15% high-spin.[6] The unique structure of the corrphycene molecule suggests that the azide complex of ferric iron porphycene [Fe(TPrPc)$N_3$] is likely to exhibit an unusual behavior. We found that [Fe(TPrPc)$N_3$] has magnetic properties, which are intermediate between the $S$ = 5/2 and 3/2 states, in marked contrast with the pure $S$ = 5/2 state of the corresponding iron porphyrins. Although the mixed-spin $S$ = 5/2, 3/2 compounds have been extensively elucidated with various physical methods,[15,16] there has apparently been no IR spectroscopic report for this system. We demonstrate here that IR spectroscopy, when applied to [Fe(TPrPc)$N_3$], discloses a novel picture of the spin admixing.

## Results

### $^1$H NMR and EPR

We recorded the $^1$H NMR of [Fe(TPrPc)$N_3$] to elucidate the magnetic anomaly inferred from the unique structure. Figure 1 shows the NMR spectrum recorded in $CD_2Cl_2$. The α-$CH_2$, β-$CH_2$, and γ-$CH_3$ signals of the *n*-propyl substituents were observed at 37.2, 33.6, 6.1, 6.0, and 3.6 ppm, respectively. The ethene-bridge proton was located at –11.6 ppm, and pyrrole-H was at $\delta$ = 19.1 ppm. The assignment is based on the peak intensity and iron–proton distance. The methylene doublets come from the magnetic anisotropy brought about by iron displacement from the porphycene plane (diastereotropic effect), and indicate the five-coordinate state.[17] The five-coordinate structure is supported from the pyrrole-H shift at $\delta$ = 19 ppm because the six-coordinate high-spin heme iron exhibits the pyrrole-H shift at about 65 ppm.[17] The 1/$T$ dependence of these signals is irregular. The protons in the propyl groups and ethene bridges do not follow the Curie law to exhibit curved plots. The Curie plots of the pyrrole-H are especially anomalous. The signal shifted to –30 ppm at 200 K beyond the diamagnetic region (Figure 1, part B). The behavior of the pyrrole-H closely resembles that of [Fe(TPP)$ClO_4$][18] and [Fe(TPrPc)X] (X = Cl, Br, I),[13] which are in the mixed-spin $S$ = 5/2, 3/2 state. The nonlinear Curie behaviors suggest that [Fe(TPrPc)$N_3$] is not pure high spin.

Figure 2 displays the EPR spectrum of solid [Fe(TPrPc)-$N_3$] at 5 K. The spectrum shows nearly axial-symmetric signals with $g$ = 5.42, 5.40, and 2.00. These $g$-values were determined from the theoretical simulation. The split $g_\perp$ signals are consistent with the lower symmetry of the porphycene. The $g_\perp$ = 5.42 is between $g_\perp$ = 6 and 4 for the typical $S$ = 5/2 and 3/2 species, respectively.[19,20] A similar spectrum with $g$ = 5.82, 5.78, and 2.00 was obtained in toluene at 5 K (result not shown). Another notable EPR observation is the considerable temperature dependence. The EPR

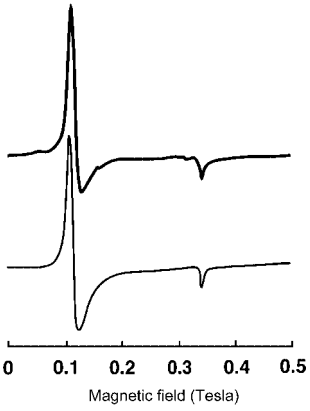

Figure 2. The EPR spectra of microcrystalline [Fe(TPrPc)$N_3$] at 5 K. The upper spectrum is the observed spectrum, and the lower is a simulation with $g$ = 5.42, 5.40, and 2.00.

spectrum broadened out above 10 K and no signals were detected at 77 K. This is in contrast with ordinary ferric high-spin heme with well-defined EPR signals at liquid nitrogen temperature.[20]

### Analysis of NMR Isotropic Shift

Unusual NMR behavior of the pyrrole-H signal (Figure 1) and the characteristic EPR (Figure 2) suggest a magnetic anomaly for [Fe(TPrPc)$N_3$]. The paramagnetic shift was analyzed on the basis of the two-spin model. The observed pyrrole-H shift $\delta$ consists of the diamagnetic and isotropic contributions.[17] A 9.6-ppm diamagnetic of the pyrrole-H shift was adopted from the metal-free TPrPc.[3] Then we obtain $\delta - 9.6 = a\delta_A + (1 - a)\delta_B$, where $\delta_A = A/T$ and $\delta_B = B/T$ are the isotropic shifts of the two paramagnetic components **A** and **B**. The constants $A$ and $B$ define, respectively, the slope of the straight lines in the Curie plots for **A** and **B**, and $a$ and $(1 - a)$ represent fractions of the two components. It follows that the isotropic shift is $\delta - 9.6 = a(A/T) + (1 - a)(B/T)$ and that the equilibrium constant is $K = [\mathbf{A}]/[\mathbf{B}] = a/(1 - a) = [A - T(\delta - 9.6)]/[T(\delta - 9.6) - B]$. The van't Hoff equation, $\ln K = -\Delta H/RT + \Delta S/R$, is modified for the NMR analysis into the following form:

$$\ln\frac{A-T(\delta-9.6)}{T(\delta-9.6)-B}=-\frac{\Delta H}{R}\frac{1}{T}+\frac{\Delta S}{R}$$

The pyrrole-H shift $\delta$ was analyzed by fitting the temperature profiles for [Fe(TPrPc)$N_3$] (Figure 1, part B) to the van't Hoff formalism. For this end, the parameters $A$ and $B$ were varied at $\delta = 10$ ppm $K^{-1}$ intervals in a realistic ($A$, $B$) = (40000 to 5000, –1500 to –50000) region, and an ($A$, $B$) set that gives rise to the best linear plots was looked for. The computer program that was originally used for the analysis of the thermochromism[21] and isotropic shift[22] of azide hemoprotein was employed. The best linear plot, with a correlation coefficient 0.99579, was obtained at ($A$, $B$) = (7940, –22660), corresponding to $\Delta H = -3990$ cal $mol^{-1}$ and $\Delta S = -16.5$ cal $mol^{-1}$ $K^{-1}$. From these thermodynamic values, an equilibrium constant $K = [\mathbf{A}]/[\mathbf{B}] = 19{:}81$ at 295 K and the midpoint of transition $T_c = \Delta H/\Delta S = 242$ K were determined. The solid curve for the pyrrole-H shift in Figure 1 represents the theoretical fit calculated with these parameters.

### Mössbauer

We examined the Mössbauer of [Fe(TPrPc)$N_3$] to ascertain further the anomalies inferred from the above NMR and EPR. The Mössbauer spectra of a powder sample are shown in Figure 3. The isomer shift $\delta_{Fe}$ is 0.19 mm $s^{-1}$ and quadrupole splitting $\Delta E_q$ is 2.20 mm $s^{-1}$ at 290 K. These values are temperature dependent, and gradually changed to $\delta_{Fe} = 0.26$ mm $s^{-1}$ and $\Delta E_q = 2.68$ mm $s^{-1}$ at 77 K.

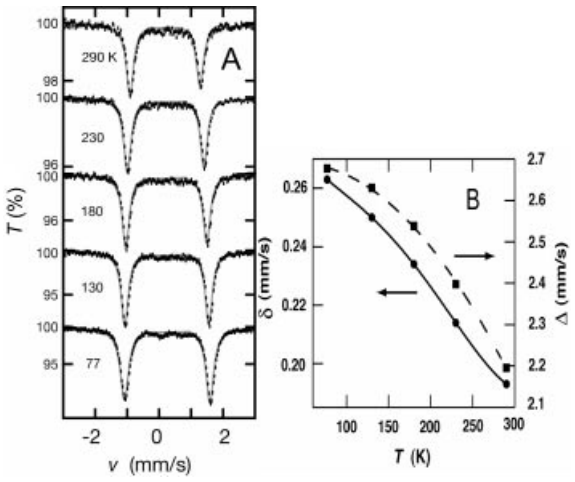

Figure 3. The solid-state Mössbauer spectra of [Fe(TPrPc)$N_3$]. (A) Observed spectra at the indicated temperatures. (B) Temperature dependence of quadrupole splitting $\Delta E_q$ and isomer shift $\delta_{Fe}$.

### Magnetic Susceptibility

The magnetic moment provides the direct and quantitative evaluation of the spin configuration of metal complexes. Figure 4 shows the magnetic susceptibility of microcrystalline [Fe(TPrPc)$N_3$] recorded over a 5–300 K range. The effective magnetic moment 4.80 $\mu_B$ at 290 K gradually fell down to 4.06 $\mu_B$ at 50 K. The values are intermediate between 5.92 and 3.87 $\mu_B$, expected for the pure $S = 5/2$ and 3/2 states, respectively.[5]

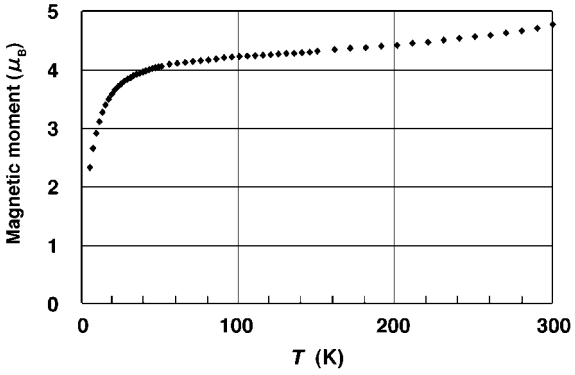

Figure 4. Temperature dependence of the effective magnetic moments of microcrystalline [Fe(TPrPc)$N_3$].

### IR Spectra

Several iron-bound ligands of heme exhibit sufficiently intense vibrational bands. The antisymmetric IR stretching band of the azide is observed around 2030 $cm^{-1}$.[6–9] Figure 5 compares the IR spectra of the azide in [Fe(TPrP)$N_3$], [Fe(corrphycenato)$N_3$], and [Fe(TPrPc)$N_3$]. In the spectra of the former two compounds, single bands with a half-height width $\Delta\nu_{1/2} = 18$ $cm^{-1}$ were observed at 2060 $cm^{-1}$. The spectral profile is in agreement with those observed for azide complexes of protohemin (2065 $cm^{-1}$, $\Delta\nu_{1/2} = 19$ $cm^{-1}$)[7,10] and another iron corrphycene (2058 $cm^{-1}$,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$\Delta\nu_{1/2}$ = 16 cm$^{-1}$).[23] The single IR bands for [Fe(TPrP)$N_3$] and [Fe(corrphycenato)$N_3$] suggest their pure high-spin ($S$ = 5/2) state. On the other hand, the azide band of porphycene [Fe(TPrPc)$N_3$] at 2062 cm$^{-1}$ is not symmetric and somewhat broader, with a shoulder around 2040 cm$^{-1}$ (Figure 5, part C). The curve analysis resolved two peaks at 2066 cm$^{-1}$ ($\Delta\nu_{1/2}$ = 28 cm$^{-1}$) and 2049 cm$^{-1}$ ($\Delta\nu_{1/2}$ = 18 cm$^{-1}$) with an integrated intensity ratio of $I_{2049}/I_{2066}$ = 24/76. The IR spectrum was temperature-dependent, the 2049-cm$^{-1}$ peak being notably intensified with an isosbestic point at 2055 cm$^{-1}$ upon cooling (Figure 6). The transition was fully reversible. We recorded the IR spectrum in the solid state to examine the consistency with EPR and Mössbauer spectra. Figure 7 shows the IR spectrum of [Fe(TPrPc)$N_3$] in solid state. The bands were also identified at 2027 cm$^{-1}$ ($\Delta\nu_{1/2}$ = 18 cm$^{-1}$) and 2012 cm$^{-1}$ ($\Delta\nu_{1/2}$ = 15 cm$^{-1}$) with $I_{2012}/I_{2027}$ = 26/74.

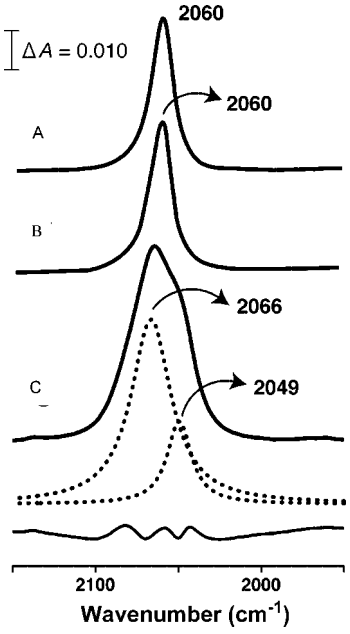

Figure 5. The IR absorption of iron-bound azide at 295 K. The iron concentration is about 2 mM in chloroform. (A) [Fe(TPrP)$N_3$], (B) [Fe(etiocorrphycenato)$N_3$], and (C) [Fe(TPrPc)$N_3$]. The broken curves in (C) are from Gaussian fitting. The half-height widths of the 2066- and 2049-cm$^{-1}$ bands are 29 and 18 cm$^{-1}$, respectively. The lowest curve in (C) is the residual.

## Discussion

### Magnetic Anomalies in [Fe(TPrPc)$N_3$]

[Fe(TPrPc)$N_3$] exhibits several magnetic anomalies. The pyrrole-H shift does not follow the Curie law (Figure 1). The NMR behavior parallels that reported for [Fe(TPP)-$ClO_4$][18] and [Fe(TPrPc)X] (X = Br, Cl, I).[13] The NMR similarity suggests that [Fe(TPrPc)$N_3$] is predominantly high-spin, with an appreciable intermediate-spin ($S$ = 3/2) character. The pyrrole-H shift of 19 ppm (Figure 1) supports the mixing of the $S$ = 3/2 state because the signal resonates at 48 and –30 ppm for the five-coordinate ferric porphyrin in the $S$ = 5/2 and $S$ = 3/2 states, respectively.[17,18] The strong upfield bias of this signal at lower temperature indicates the $S$ = 3/2 ground state. Mixing of the $S$ = 3/2 state in [Fe(TPrPc)$N_3$] is supported from the EPR spectrum with $g_\perp$ = 5.42 (Figure 2). The quadrupole splitting $\Delta E_q$ = 2.20 mm s$^{-1}$ at 290 K (Figure 3) is also intermediate between those of the typical $S$ = 5/2 ($\Delta E_q$ = 0.8 ± 0.2) and $S$ = 3/2 complexes ($\Delta E_q$ = 3.2 ± 0.3).[24] Quantitative support for the $S$ = 5/2, 3/2 assignment comes from the magnetic moment of 4.8–4.1 $\mu_B$ over a 300–20 K range. On the basis of these physical results, we assign a mixed $S$ = 5/2, 3/2 state to [Fe(TPrPc)$N_3$].

As the ranking of azide in the spectrochemical[25] and magnetochemical[19] series is comparable with halides, a pure $S$ = 5/2 state, which is ordinarily found in [Fe(porphyrinato)X] (X = halides), may be expected for [Fe(TPrPc)$N_3$] as well. Contrary to the expectation, [Fe(TPrPc)$N_3$] is not pure high-spin. We note similar deviation from the pure high-spin state in [Fe(TPrPc)X] (X = Cl, Br, I)[13] and the all-alkyl porphycene derivatives.[14] The X-ray analyses of free base TPrPc[3] and relevant iron(III) porphyrins[26–28] provide the structural account for the mixing of the $S$ = 3/2 state. Porphycene has a narrower coordination core.[3] The narrower metallo cavity in TPrPc results in a shorter Fe–N(pyrrole) bond and strengthens the equatorial ligand field of the iron. Under the circumstances, the $d_{x^2-y^2}$ orbital of high-spin iron is destabilized to induce the $S$ = 3/2 state. Thus, the mixed $S$ = 3/2 state in [Fe(TPrPc)$N_3$] is achieved with the synchronization of the core contraction[3,26–28] and a moderately small ligand-field splitting parameter of azide.[19,25]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

### IR Spectra

The most characteristic observation for [Fe(TPrPc)$N_3$] is the split IR bands of the coordinating azide (Figure 5, part C). This is in contrast with the single azide band in [Fe(TPrP)$N_3$] (2060 $cm^{-1}$; Figure 5, part A) or [Fe(proto-porphyrinato)$N_3$] (2064 $cm^{-1}$).[7,10] It may be possible, however, that the 2049-$cm^{-1}$ band in [Fe(TPrPc)$N_3$] is from a plausible contaminant, a di-azide species. Contamination with di-azide species is set aside because a bis-azide hemin displays the two IR bands at about 2035 and 2015 $cm^{-1}$.[12] In addition, the proton NMR spectrum of [Fe(TPrPc)$N_3$] (Figure 1) shows a single pyrrole-H peak at $\delta$ = 19 ppm to rule out the sample contamination. It is possible that the 2049-$cm^{-1}$ peak is from a trace amount of the sodium azide, which is NMR invisible, suspended in the chloroform. This possibility is eliminated because the IR band of sodium azide in chloroform is at 2170 $cm^{-1}$.[7] It might also be possible that the split IR bands in [Fe(TPrPc)$N_3$] come from an equilibrium between five-coordinate [Fe(TPrPc)$N_3$] and six-coordinate [Fe(TPrPc)$N_3$($H_2O$)], where the iron-bound water molecule comes from a trace amount of residual water in chloroform. This possibility is unlikely because a reference porphyrin [Fe(TPrP)$N_3$] (Figure 5, part A), measured in the same lot of chloroform, exhibits a single band. As porphycene has a rectangular molecule with a $C_2$ symmetry, one may claim that the two IR bands in [Fe(TPrPc)-$N_3$] arise from the rotational isomers of azide about the azide–iron bond. The possibility is also eliminated because [Fe(etiocorrphycenato)$N_3$] (Figure 5, part B) and [Fe{bis(ethoxycarbonyl)corrphycenato}$N_3$][23] exhibit single azide bands despite their trapezoidal molecular shape. The prospect of Fermi resonance[29] for the split azide bands may be neglected because no sharp signal occurred at 1024 $cm^{-1}$, and because the 2049-$cm^{-1}$ band is markedly intensified at lower temperature. Thus the two IR bands in [Fe(TPrPc)$N_3$] reflect a real magnetic anomaly of the iron.

Another notable observation is that the IR peak width is different between the 2049- ($\Delta\nu_{1/2}$ = 18 $cm^{-1}$) and 2066-$cm^{-1}$ ($\Delta\nu_{1/2}$ = 28 $cm^{-1}$) bands (Figure 5). The notably larger line width of the latter may reflect increased orientation variability of the azide about the iron–azide bond because the IR band width of iron-bound azide has been demonstrated to increase with increasing ligand fluctuation.[30] Consistent with this proposal, the IR bands of the solid [Fe(TPrPc)$N_3$] in Figure 7, that is, $\Delta\nu_{1/2}$ = 18 $cm^{-1}$ (2027 $cm^{-1}$) and 15 $cm^{-1}$ (2012 $cm^{-1}$), are narrower owing to a decreased ligand motion in the solid.

### Novel View Emerged from IR

It has been proposed for the ferric porphyrin with a mixed-spin $S$ = 5/2, 3/2 system that the two states are quantum-mechanically admixed through the spin-orbit coupling and that the admixed state has a new discrete ground state.[15,16] The spin mixing has been proposed to occur in hemoproteins like cytochrome $c'$ and horseradish peroxidase.[16] NMR, EPR, and Mössbauer results for the model compounds of cytochrome $c'$ are apparently consistent with the quantum mechanical model.[19,26–28] In the proton NMR of [Fe(TPP)$ClO_4$][18,19] and [Fe(TPrPc)X] (X = Cl, Br, I),[13] the single pyrrole-H peaks shift far-upfield at lower temperature. The EPR and Mössbauer do not exhibit the two signals from the spin isomers. Present NMR, EPR, and Mössbauer results for [Fe(TPrPc)$N_3$] parallel those reported for [Fe(TPP)$ClO_4$] and [Fe(TPcPc)X].[13,18,19]

IR, on the other hand, resolves two azide peaks for [Fe(TPrPc)$N_3$] (Figure 5, part C). This observation demonstrates that the $S$ = 5/2 and 3/2 states are not quantum-mechanically admixed but that they coexist separately. Based on the NMR, EPR, and Mössbauer results indicating dominance of the $S$ = 3/2 species at lower temperature, we assign the 2049-$cm^{-1}$ IR peak, which prevails at 216 K, to the $S$ = 3/2 isomer and the 2066-$cm^{-1}$ band to the $S$ = 5/2 isomer. Population of the $S$ = 3/2 species is estimated to be 0.21 at 20 °C on the assumption that the two magnetic isomers have closely similar extinction coefficients in the IR spectrum. The equilibrium is more quantitatively evaluated from the pyrrole-H shift in Figure 1. We now assign the **A** and **B** states assumed in the NMR analysis to the $S$ = 3/2 and $S$ = 5/2 states, respectively. Fractions of the $S$ = 3/2 isomer, calculated with the $\Delta H$ and $\Delta S$ for the NMR analysis, are 0.20 (293 K), 0.43 (254 K), and 0.72 (216 K). These values are in good agreement with 0.24 (293 K), 0.43 (254 K), and 0.61 (216 K) estimated from the solution IR (Figure 6). The IR spectrum of the solid in Figure 7 resolves two IR bands. Existence of the two spin isomers in the IR spectrum is consistent with the implication from EPR, Mössbauer, and magnetic susceptibility, which were measured for the solid sample (Figures 2–4).

We emphasize that IR resolves the two spin isomers of [Fe(TPrPc)$N_3$] while EPR, NMR, and Mössbauer do not. Why does IR alone discriminate the spin isomers? The conflict is explained by realizing the timescale of the applied spectroscopic methods. The approximate timescales of IR, EPR, NMR, and Mössbauer are $10^{-13}$, $10^{-4}$–$10^{-8}$, $10^{-1}$–$10^{-9}$, and $10^{-7}$ $s^{-1}$, respectively.[31] IR has excellent temporal resolution over EPR, NMR, and Mössbauer, which observe the time-averaged structures. Consequently, we can discern with IR the thermal spin-state equilibrium and the quantum mechanical mixing in the mixed $S$ = 5/2, 3/2 system. Increase of the 2049-$cm^{-1}$ peak and concomitant decrease of the 2066-$cm^{-1}$ band with decreasing temperature, accompanied with the 2054-$cm^{-1}$ isosbestic point (Figure 6), demonstrate that the $S$ = 5/2 and $S$ = 3/2 isomers are in a thermal equilibrium. This is in marked contrast with the claim that a homogeneous $S$ = 5/2, 3/2 state in the ferric heme iron is solely created by quantum mechanical spin-orbit coupling.[16]

A closely related coexistence of two spin isomers has been reported for ferric azide heme in a mixed $S$ = 5/2, 1/2 system where the two states are in a thermal equilibrium. IR distinguishes the $S$ = 5/2, 1/2 spin isomers of the azide hemes[9,10,21] and hemoproteins,[7,8] while NMR and EPR do not. Unfortunately, IR has been scarcely applied to the mixed $S$ = 5/2, 3/2 heme. Strong IR absorption of the iron-

bound azide in [Fe(TPrPc)$N_3$] provides a unique opportunity to make use of the vibration spectroscopy to the mixed $S$ = 5/2, 3/2 heme. IR resolves the $S$ = 5/2, 3/2 isomers, demonstrating that the $S$ = 3/2 and 5/2 states of [Fe(TPrPc)$N_3$] are not uniformly admixed but slowly interchanging on the IR timescale. From the peak separation of 17 $cm^{-1}$ and the relationship $\tau = 1/(2\pi\Delta\nu)$, where $\Delta\nu$ = (light velocity) × (peak separation),[31] we can estimate a minimum lifetime $\tau$ = 0.3 ps for the two magnetic isomers.

### Unified View of the Spin Mixing in Iron(III)

The ferric heme iron adopts either $S$ = 5/2, 3/2, or 1/2 state depending on the axial ligand and/or macrocycle conformation. Mixing of the three spin states is frequently observed. The thermal mixing of the $S$ = 5/2, 1/2 states or spin crossover of ferric hemes and hemoproteins has been established.[5–10] Recently, Nakamura et al. have found a novel type of spin crossover between the $S$ = 3/2 and 1/2 states for the saddle-shaped ferric porphyrins.[32–34] The deformed iron porphyrin is magnetically inhomogeneous with independent $S$ = 3/2 and 1/2 components in the mixed $S$ = 3/2, 1/2 system. An analogous thermal mixing of the $S$ = 3/2, 1/2 isomers has been reported for a non-heme complex of bis(*o*-iminobenzoquinonato)iron(III) by Chun et al.[35] Thus, the spin mixing in the $S$ = 5/2, 1/2 and $S$ = 3/2, 1/2 systems occurs through thermal spin crossover. Present IR analysis for [Fe(TPrPc)$N_3$] demonstrates that the $S$ = 5/2 and 3/2 states are not quantum-mechanically admixed but in a thermal equilibrium. This situation parallels those found in the $S$ = 5/2, 1/2[5–10] and $S$ = 3/2, 1/2[32–34] systems. The temperature-dependent changes of the EPR, NMR, and Mössbauer for [Fe(TPrPc)$N_3$] are thus interpreted to reflect the spin crossover. In view of the IR elucidation for [Fe(TPrPc)$N_3$], the quantum chemical admixing of the two ground states is unlikely for this complex. We therefore point out the possibility that the three types of magnetic mixing among the $S$ = 5/2, 3/2, and 1/2 states in ferric heme could be commonly described in terms of thermal spin crossover between the two magnetic isomers. The general distinction of the quantum-mechanical or thermal mixing of the spin states, however, is still to be established by further case-by-case analyses.

## Experimental Section

**TPrPc, [Fe(TPrPc)$N_3$], and Related Macrocycles:** 2,7,12,17-Tetrapropylporphycene (TPrPc) was prepared by the method of Vogel et al.[3] The ferric chloride complex [Fe(TPrPc)Cl][36] was purified with silica-gel column chromatography with chloroform/methanol (97:3, v/v) mixture. The [Fe(TPrPc)Cl] in benzene was vigorously mixed overnight with aqueous sodium azide (5 M)[7] overnight to furnish [Fe(TPrPc)$N_3$]. The sample was recrystallized from hexane/dichloromethane. $C_{32}H_{36}FeN_7$: calcd. C 66.90, H 6.31, N 16.89; found C 67.15, H 6.12, N 17.02. Formation of [Fe(TPrPc)$N_3$] was also confirmed with the $^1$H NMR spectrum where the hyperfine-shifted pyrrole-H signal ($\delta$ = 28.2 ppm in $CDCl_3$) of [Fe(TPrPc)Cl] was replaced with the new signal ($\delta$ = 24.3 ppm) from [Fe(TPrPc)$N_3$].

*meso*-Tetrapropylporphyrin (TPrP, Scheme 1) and the iron chloride [Fe(TPrP)Cl] were obtained according to the literature methods.[37,38] The azide complex [Fe(TPrP)$N_3$] was derived from the chloride compound after the ligand exchange as carried out for [Fe(TPrPc)$N_3$]; the sample was recrystallized from hexane/dichloromethane. Synthesis of [Fe(etiocorrphycenato)$N_3$] (Scheme 1) has been reported.[6]

**Spectroscopic Measurements:** $^1$H NMR spectra at 300 MHz were recorded with a JEOL LA300 with a temperature variation unit, and chemical shifts were referenced to tetramethylsilane. The X-band electron paramagnetic resonance (EPR) spectra were recorded with a Bruker E500 spectrometer equipped with an Oxford helium cryostat. IR spectra were obtained on a Nicolet Avatar spectrometer at a 2-$cm^{-1}$ resolution with a 50-μm cell, and apodized with a Happe–Genzel function. IR spectra at low temperature were obtained on a Digilab FTS-7000 spectrometer equipped with an Oxford cooling unit.[38] The IR spectrum of the solid material was recorded after evaporation of concentrated sample in dichloromethane over the $CaF_2$ disk. $^{57}$Fe Mössbauer spectra were measured on a Wissel–Mössbauer spectrometer system. The sample was kept in a gas-flow cryostat and $^{57}$Co(Rh) source was kept at room temperature. Isomer shifts $\delta_{Fe}$ were referenced to α-iron at room temperature. The solid-state magnetic susceptibilities were measured over a 5–300 K range at 1 T with a Quantum Design MPMS-7 SQUID magnetometer. The data were corrected for both the diamagnetism of the basket and molecule Pascal's constants.

# Syntheses and Structures of Molybdenum, Tungsten, and Manganese Complexes of a Cyclic Thiourea, $[M(CO)_5(SC_3N_2Me_4)]$ (M = Mo, W) and $[\{CpMn(CO)_2\}_2(\mu\text{-}SC_3N_2Me_4)]$

**Kazuya Saito,[a] Yasuro Kawano,*[a] and Mamoru Shimoi*[a]**

**Keywords:** Imidazolinethiones / Manganese / Molybdenum / Thioureas / Tungsten

Photolysis of $[CpMn(CO)_3]$ in the presence of 1,3,4,5-tetramethylimidazoline-2-thione, $SC_3N_2Me_4$ (**1**), produced a thione-bridged dinuclear complex, $[\{CpMn(CO)_2\}_2(\mu\text{-}SC_3N_2Me_4)]$ (**2**). Compound **2** shows unprecedented geometry of the Mn–S–Mn framework, featuring a pyramidal sulfur atom and long Mn···Mn distance. Photoreaction of $[M(CO)_6]$ (M = Mo, W) with **1** afforded mononuclear complexes $[M(CO)_5(SC_3N_2Me_4)]$ [M = Mo (**3**), W (**4**)]. In compounds **2**–**4**, the C–S bond of the thione ligand is stretched on coordination because of the polarization of the metal–ligand linkage. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

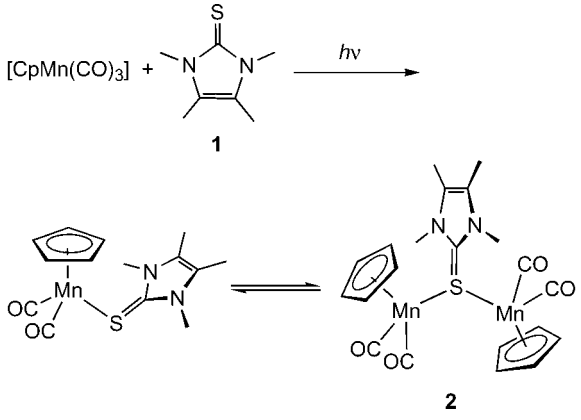
## Introduction

*N*-Heterocyclic carbenes (NHC) have proved to be excellent ligands in transition-metal complexes.[1–4] NHCs also form various adducts with *p*-block element fragments to give compounds with a formula of $E–C(NR)_2(CR')_2$, where E = $BX_3$, $AlX_3$, $GeI_2$, $SnCl_2$, $CH_2$, S, Se, and so forth.[4,5] The sulfur adducts, imidazolinethiones (cyclic thioureas), are employed as precursors of NHCs.[6] They are also components of tris(mercaptoimidazolyl)hydroborate ligands, which attract considerable attention because of their face-capping character and strong electron-donating ability, and are applied to enzyme models.[7] It is thus increasingly important to better understand the coordinating ability of imidazolinethiones. However, few examples of their transition-metal complexes have been reported.[8–10] In this paper, we describe the reaction of 1,3,4,5-tetramethylimidazoline-2-thione (**1**)[6] with $[CpMn(CO)_3]$, which produces a dinuclear complex that involves a rare bridging thione ligand, $[\{CpMn(CO)_2\}_2(\mu\text{-}SC_3N_2Me_4)]$ (**2**). The syntheses and structures of molybdenum and tungsten derivatives, $[M(CO)_5(SC_3N_2Me_4)]$ [M = Mo (**3**), W (**4**)], are also reported here.

## Results and Discussion

### Synthesis of a Thione-Bridged Dinuclear Manganese Complex $[\{CpMn(CO)_2\}_2(\mu\text{-}SC_3N_2Me_4)]$ (2)

Irradiation of $[CpMn(CO)_3]$ with **1** in a 2:1 ratio produced a red solution. Its $^1H$ NMR spectrum exhibited three singlet resonances at $\delta$ = 1.11, 3.13, and 4.41 ppm, and their relative intensity was 6:6:5. This suggests formation of a mononuclear thione complex, $[CpMn(CO)_2(SC_3N_2Me_4)]$. However, cooling the solution afforded a small amount of $[\{CpMn(CO)_2\}_2(\mu\text{-}SC_3N_2Me_4)]$ (**2**) as red needles. Probably, the thione ligand is labile in solution, and a $[CpMn(CO)_2]$ fragment generated is reversibly coordinated to the sulfur atom of another molecule of $[CpMn(CO)_2(SC_3N_2Me_4)]$ to provide the dimer **2**, which precipitates on cooling [Equation (1)]. Indeed, when crystals of **2** were dissolved in $[D_6]$-benzene, the solution showed the $^1H$ NMR spectrum of the monomer.



(1)

The molecular structure of **2** is displayed in Figure 1, and key geometrical parameters are given in Table 1. Two $[CpMn(CO)_2]$ moieties are bridged by the imidazolinethione ligand. The Mn(1)–S and Mn(2)–S bond lengths are 2.3343(15) and 2.3495(11) Å, respectively. These values are similar to those of $[Mn_2(\mu\text{-}SMe)_2(\mu\text{-}CO)(PMe_3)_2$-

$(CO)_4$] (av. 2.331 Å).[11] Cationic dinuclear manganese thiolates, [{(MeCp)Mn$(CO)_2$}$_2$(μ-SR)][$PF_6$] (**5**, R = *i*Pr, *t*Bu; MeCp = $\eta^5$-$MeC_5H_4$), have substantially shorter Mn–S bonds [2.242(2)–2.267(1) Å].[12] The Mn–S bonds of "inidene" complexes, [{CpMn$(CO)_2$}$_2${μ-S($C_6H_4$X)}][$PF_6$] (**6**, X = H, $NO_2$), are even shorter [2.177(3)–2.218(3) Å] because of their multiple bond character.[12,13]

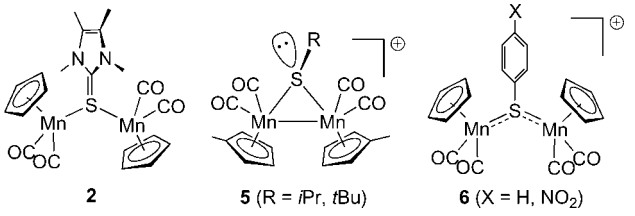
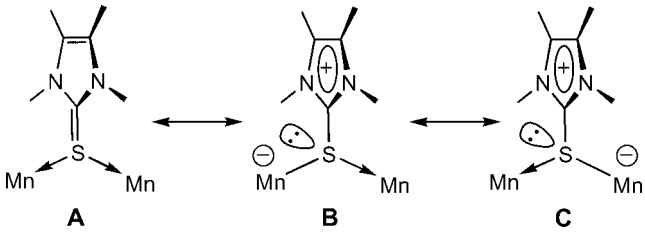
[a] CNT: the centroid of the cyclopentadinyl ring.

The bridging sulfur atom is pyramidalized. The sum of the bond angles around this atom is 343°, indicating the existence of a lone electron pair at the sulfur atom. The Mn(1)···Mn(2) interatomic distance is 4.1878(18) Å, and the Mn(1)–S–Mn(2) bond angle is 126.79(3)°. These indicate the absence of bonding interaction between the two metal atoms. Thus, the structure of **2** features a pyramidal sulfur atom and long Mn···Mn separation. This is an unprecedented geometry of the Mn–S–Mn framework (see Scheme 1). Thiolates **5** contain a pyramidal sulfur atom, but they have a Mn–Mn single bond.[12] The intermetallic bond length is 2.906(1) (R = *i*Pr) or 2.962(1) Å (R = *t*Bu). In contrast, the inidene complex **6** (X = $NO_2$) includes a planar sulfur atom and long Mn···Mn distance (4.032 and 4.046 Å; two independent molecules are present in the asymmetric unit).[12] Complex [$Mn_2$(μ-SMe)$_2$(μ-CO)-$(PMe_3)_2(CO)_4$] has pyramidal sulfur atoms and a Mn–Mn single bond (2.581 Å).[11]



Scheme 1.

The C–S bond of the imidazolinethione ligand is stretched on coordination to the manganese atoms. The C(15)–S bond length is 1.740(3) Å, which is significantly longer than that of free **1**, 1.690(2) Å.[14] This is probably due to the pronounced polarization of the metal–ligand linkage (canonical structures **B** and **C**, Scheme 2), which is induced by the capability to take positive charge into the imidazole ring of the thione ligand. Through this polarization, the C–S moiety carries a single bond character. The imidazole ring is almost perpendicular with respect to the Mn–Mn vector. This is also consistent with the canonical structures **B** and **C**. If the sulfur–manganese interaction was composed of coordination of the lone electron pair on $sp^2$-sulfur (Scheme 2, **A**), the imidazole ring would be expected to be nearly parallel to the Mn–Mn vector.



Scheme 2.

Creighton and co-workers have reported the reaction of an imidazolinethione with $CuCl_2$. During the reaction, $Cu^{II}$ is reduced to afford a dimeric $Cu^{I}$ complex **7** (Scheme 3), which contains bridging imidazolinethione ligands and a short Cu–Cu contact [2.914(1) Å].[15]

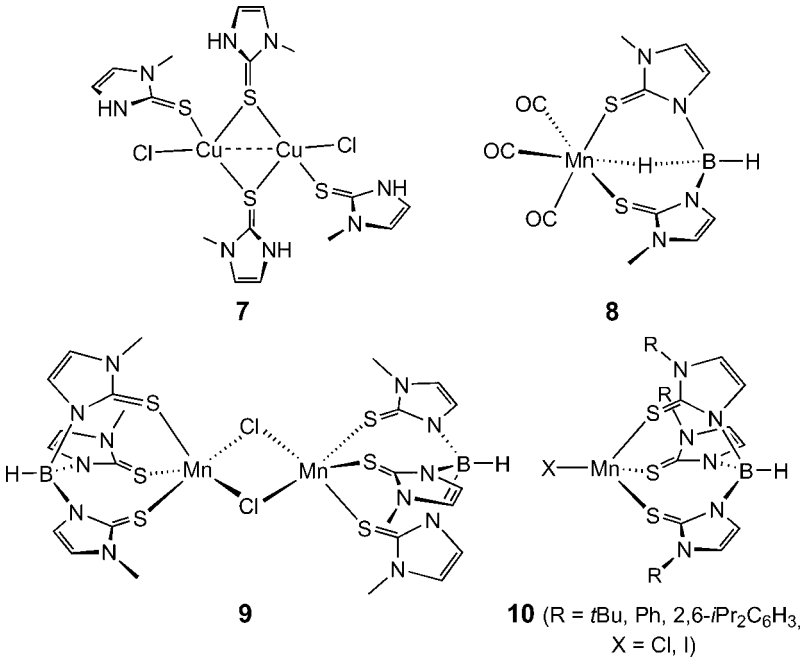


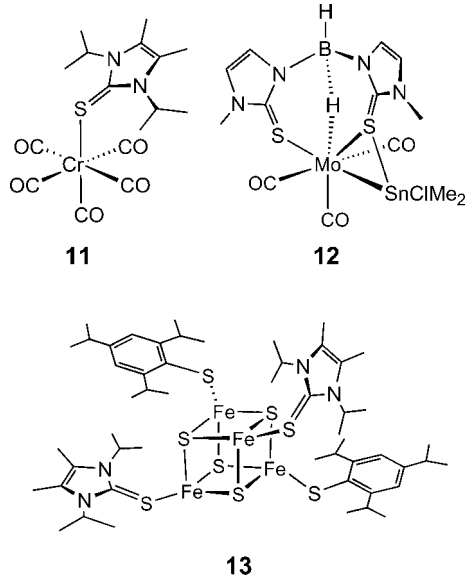
Scheme 3.

Several manganese complexes containing a bis- or tris-(mercaptoimidazolyl)hydroborate ligand have been reported (**8**–**10**, Scheme 3).[16,17] The crystal structures of **9** and **10** were determined, and it was shown that they had Mn–S bond lengths of 2.435(3)–2.569(8) Å and S–C bond lengths of 1.707(2)–1.721(2) Å.[17] Compound **2** has a shorter Mn–S bond and a longer C–S bond than **9** and **10**. Hence, the thione ligand polarizes very strongly in **2**, probably because the charge separation concentrates in one imidazolinethione unit.

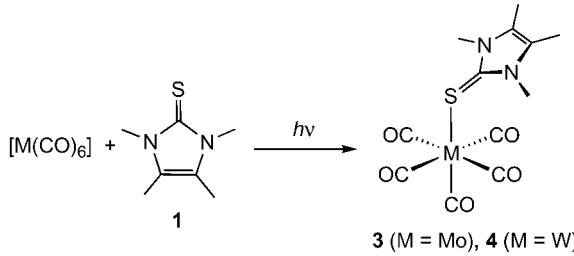
### Synthesis of Group 6 Metal Complexes $[M(CO)_5(SC_3N_2Me_4)]$ [M = Mo (3), W (4)]

Group 6 metal complexes of chalcogenoimidazolines have been synthesized by Kuhn and co-workers. Thione, selone, and tellone, $E{=}C(N\mathit{i}Pr)_2(CMe)_2$ (E = S, Se, Te), react with $[M(CO)_6]$ or $[M(CO)_5(thf)]$ to produce the corresponding mononuclear chalcogenoimidazoline complexes.[8] Chromium derivatives $[Cr(CO)_5\{E{=}C(N\mathit{i}Pr)_2(CMe)_2\}]$ (**11**, E = S, Se, Scheme 4) were crystallographically characterized. However, with regard to tetramethylimidazoline derivatives, only the tellone complex $[W(CO)_5\{TeC_3N_2Me_4\}]$ has been documented.[8] Does the use of sterically less demanding **1** influence the number of metal fragments in the product, as observed in the formation of **2**? To clarify this point, we carried out the reaction of **1** with $[M(CO)_6]$ (M = Mo, W) under photolytic conditions.

Photoreactions of $[M(CO)_6]$ with **1** proceeded smoothly and gave yellow solutions, from which the thione complexes $[M(CO)_5(SC_3N_2Me_4)]$ [M = Mo (**3**), W (**4**)] were isolated as analytically pure crystals [76% for **3** and 33% for **4**, Equation (2)]. No evidence for the formation of dimeric species was obtained.



Scheme 4.



(2)

Figures 2 and 3 display the crystal structures of compounds **3** and **4**. The important bond lengths and angles are listed in Tables 2 and 3. Although the molecular struc-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tures of **3** and **4** are quite similar, the two compounds are not isomorphous. Crystals of **3** contain two crystallographically independent molecules in the asymmetric unit. However, their structures are essentially the same. The two molecules of **3** are associated through π-stacking of the imidazole rings. The separation between the five-membered rings is 3.3–3.6 Å. In **3** and **4**, the $[M(CO)_5]$ unit is coordinated to the cyclic thione ligand through a M–S dative bond to form an octahedral geometry. As a whole, their structures are akin to Kuhn's complex **11**.[8] They also resemble that of a methyleneimidazoline complex, $[Mo(CO)_5(CH_2{=}C_3N_2Me_4)]$,[18] whose ligand, an ylidic olefine, is isoelectronic with **1**. The M–S bond lengths are 2.6084(11) Å and 2.6113(11) Å in **3**, and 2.6146(14) Å in **4**. In compound **12** (Scheme 4), one thione unit of the bis(mercaptoimidazolyl)dihydroborate bridges the molybdenum center and tin atom with a long Mo–S bond length of 2.631(3) Å. The interatomic distance between the molybdenum and sulfur of the other ("terminal") thione moiety is 2.51(2) Å.[19]

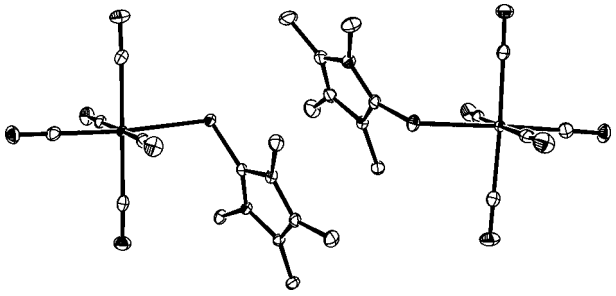


Figure 2. ORTEP drawing of $[Mo(CO)_5(SC_3N_2Me_4)]$ (**3**) (50% thermal ellipsoids). Hydrogen atoms have been omitted for clarity.

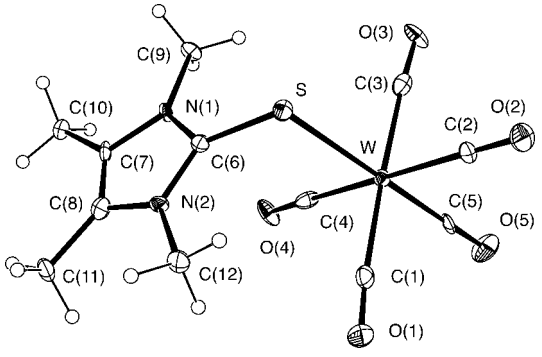

Figure 3. ORTEP drawing of $[W(CO)_5(SC_3N_2Me_4)]$ (**4**) (50% thermal ellipsoids).

The imidazolinethione ligand is connected to the central metal, directing the face of the heterocycle to the $[M(CO)_5]$ fragment. This is in sharp contrast to a chromium–thioacetone complex $[Cr(CO)_5(S{=}CMe_2)]$[20] and a mercury derivative $[HgCl_2(SC_3N_2H_4)_2]$,[21] in which the thione ligand directs the edge of the molecular plane to the metal. Such geometry of **3** and **4** suggests $sp^3$ hybridization of the sulfur atom caused by the greatly polarized M–S–C linkage (canonical structure **E**, Scheme 5). Indeed, the M–S–C bond angles are 108.31(7) and 109.40(7)° in **3**, and 103.29(16)° in **4**, which are close to the tetrahedral angle. As expected, the C=S bond is elongated. The C–S interatomic distances are 1.719(2) and 1.717(2) in **3** and 1.731(5) Å in **4** [that of free **1** is 1.690(2) Å].[14] Such phenomena are also found in **11**

Table 2. Selected bond lengths [Å] and angles [°] for $[Mo(CO)_5(S{=}C_3N_2Me_4)]$ (**3**).

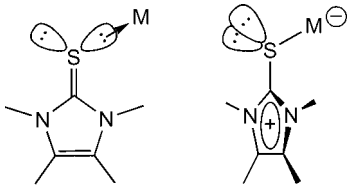
[the C–S bond length is 1.737(5) Å][8] and a rhodium complex [RhCl(cod)($SC_3N_2Me_4$)] [1.725(2) Å].[9] An iron–sulfur cluster **13** includes two imidazolinethione ligands, whose C–S bond lengths are 1.689(14) and 1.719(16), respectively.[10]



Scheme 5.

The strong donating ability of the thione ligand leads to enhancement of back-donation to the *trans* carbonyl ligand. The bond lengths between the metal and *trans*-carbonyl carbon atoms are 1.969(2) and 1.967(2) Å for **3**, and 1.966(5) Å for **4**. These are substantially shorter than the metal–*cis*-carbonyl bonds. The averages of the separations between the metal and *cis* carbonyls are 2.05 and 2.04 Å for **3** and **4**, respectively. In fact, the infrared spectra of **3** and **4** showed carbonyl stretching bands that are low-frequency shifted relative to $[M(CO)_6]$.

## Experimental Section

All manipulations were carried out under high vacuum or dry nitrogen. Reagent-grade hexane, THF, and toluene were distilled under nitrogen from sodium-benzophenone ketyl just before use. $[D_6]$-benzene was dried with potassium mirrors before use and transferred into NMR tubes under vacuum. $SC_3N_2Me_4$ (**1**) was prepared according to the literature.[6] $[Mo(CO)_6]$ (Strem), $[W(CO)_6]$ (Aldrich), and $[CpMn(CO)_3]$ (Strem) were used as purchased. $^1H$ and $^{13}C$ NMR spectra were recorded with a JEOL α-500 spectrometer. IR spectra were recorded with a JASCO FTIR-350 spectrometer. Mass spectra were measured with a JEOL JMS-S600H spectrometer.

**Syntheses of $[\{CpMn(CO)_2\}_2(\mu\text{-}SC_3N_2Me_4)]$ (2):** A solution of $[CpMn(CO)_3]$ (80 mg, 0.040 mmol) and **1** (31 mg, 0.020 mg) in hexane (4 mL) and THF (1 mL) mixture was irradiated with a 450-W medium-pressure Hg arc lamp for 1 h. Removal of volatiles, extraction of the residue with toluene, and cooling of the extract afforded **2** as red needles in small amounts. $^1H$ NMR (500 MHz, $[D_6]$benzene): $\delta$ = 1.11 (s, 6 H, CMe), 3.13 (s, 6 H, NMe), 4.41 (br., 5 H) ppm. This spectrum is consistent with a mononuclear complex, $[CpMn(CO)_2(SC_3N_2Me_4)]$.

**Syntheses of $[Mo(CO)_5(SC_3N_2Me_4)]$ (3):** A dichloromethane solution of $[Mo(CO)_6]$ (85 mg, 0.32 mmol) and **1** (46 mg, 0.30 mmol) was irradiated at 8 °C for 1 h with stirring using a 450-W medium pressure Hg lamp. The resulting yellow solution was concentrated to about 1 mL and diluted with hexane (4 mL). Cooling the solution to –25 °C provided **2** (90 mg, 0.23 mmol, 76%) as yellow-gray crystals. $^1H$ NMR (500 MHz, $[D_6]$benzene): $\delta$ = 1.09 (s, 6 H, CMe), 2.92 (s, 6 H, NMe) ppm. $^{13}C$ NMR (125 MHz, $[D_6]$benzene): $\delta$ = 7.96 (CMe), 31.9 (NMe), 122.6 (ring-C), 158.6 (C=S), 206.5, 213.7 (CO) ppm. IR (Nujol mull): $\tilde{\nu}$ = $\nu$(CO) 2066, 1987, 1912, 1872 $cm^{-1}$. MS (70 eV): $m/z$ (%) = 393 ($[M^+]$), 156 ($[SC_3N_2Me_4^+]$). $C_{12}H_{12}MoN_2O_5S$ (392.24): calcd. C 36.75, H 3.08, N 7.14; found C 36.59, H 3.10, N 6.96.

**Syntheses of $[W(CO)_5(SC_3N_2Me_4)]$ (4):** The synthesis of **4** was conducted in a similar manner to that of **3**. The yield of yellow crystals

**X-ray Crystal Structure Determination:** Crystals of **2**, **3**, and **4** (Table 4) were grown by cooling their solutions. Intensity data were collected with a Rigaku RAPID imaging plate diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). Data collection was carried out at –120 °C. Crystal data, data collection parameters, and convergence results are listed in Table 4.

Numerical absorption corrections were applied on the crystal shapes. The structures of all complexes were solved by the direct method and refined on $F^2$. All non-hydrogen atoms were located and refined applying anisotropic temperature factors. Coordinates of hydrogen atoms were idealized with the use of riding models. Calculations were performed using the program package SHELX 97.[22]

CCDC-634432 (for **2**), -634433 (for **3**), and -634434 (for **4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif

# The Role of *Escherichia coliform* in the Biomineralization of Calcium Oxalate Crystals

**Long Chen,[a] Yuhua Shen,*[a] Rong Jia,[b] Anjian Xie,*[a,c] Bei Huang,[b] Xiaobin Cheng,[b] Qingfeng Zhang,[a] and Ruiyong Guo[b]**

**Keywords:** Urolithiasis / *Escherichia coliform* / Calcium oxalate / Nucleation and growth / Biomineralization

The influence of the common bacterium *Escherichia coliform* (*E. coli*) on the nucleation and growth of calcium oxalate (CaOxa) in aqueous solution is studied in order to determine its role in the biomineralization of urinary stones. The results show that CaOxa crystals obtained in the presence of *E. coli* transform more quickly from calcium oxalate dihydrate (COD) into calcium oxalate monohydrate (COM), and they become even larger, than in the absence of the bacterium. On decreasing the concentration of chemical reagents, in other words increasing the ratio bacterium/CaOxa, except for the more rapid phase transition from COD to COM, the CaOxa particles obtained become larger and more regular with a hexagonal morphology. This suggests that *E. coli* accelerates the crystallization of COM, which is the most stable crystal phase of CaOxa and the major component of urinary stones. Transmission electron microscopy (TEM) images, electron diffraction (ED) patterns, and Fourier-transform IR (FTIR) spectra show that the biomineralization process of CaOxa crystals takes place both inside and outside the bacterium, which implies that it is induced by both intracellular biomolecules and the bioorganic secretions of the bacteria. Sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) data and UV/Vis spectra show that the proteins bound to the crystal surface with a molecular weight of around 26.5 kDa have tyrosine, tryptophan, or phenylalanine residues. The zeta potential and FTIR spectra are used to investigate the mineralization mechanism of CaOxa with *E. coli* and show that, the negatively charged biomolecules inside and outside the bacterium interact with $Ca^{2+}$ ions to provide nucleation sites and then act as modifiers to induce the nucleation, growth, and aggregation of COM crystals. Therefore, we infer that *E. coli* mineralizes calcium oxalate and plays a role in the formation of urinary stones.

## Introduction

Urolithiasis is a common disease affecting millions throughout the world that remains a serious health concern due to its severe symptoms, such as great pain and urinary-tract obstruction and infection. At present, stones are mainly treated by surgery or extracorporeal shock wave lithotripsy followed by prolonged antibiotic treatment and oral citrate, although these remedies are unsatisfactory because of a high rate of recurrence. No effective drugs or treatment methods for this stubborn disease are currently available, therefore many studies on the mechanism of stone formation have been performed in recent years in the search for such treatments and methods. A number of questions still remain, however, regarding the factors that promote and inhibit stone formation, some of which are somewhat controversial.[1]

A urinary stone is a product of abnormal biomineralization whose principal mineral component is calcium oxalate monohydrate (COM),[2,3] which is the thermodynamically most stable phase of CaOxa. The other two phases of CaOxa, namely calcium oxalate trihydrate (COT) and calcium oxalate dihydrate (COD), rarely form stones as they are unstable and are more easily excreted in the urine than COM. In these stones, inorganic crystals are always mixed with organic matrices such as lipids, carbohydrates, and proteinaceous materials, and studies have shown that, although these organic materials account for only about 2% of the total mass, they play a very important role in the stone-formation process.[4,5] To better understand the role of organic matrices in urinary stone formation, Langmuir monolayers,[6–12] vesicles,[13] biomolecules,[14] etc., have all been used to induce the nucleation and growth of COM crystals. Our groups have recently studied the crystal growth of CaOxa in a reverse microemulsion of *p*-octyl polyethylene glycol phenyl ether (OP)/isooctyl alcohol (IOA)/cyclohexane/water containing different kinds of amino acids, and found that the type of amino acid, the pH, and surfactant can all influence the formation of CaOxa

crystals.[15] We have also investigated crystal growth of CaOxa induced by octadecanoic acid/octadecylamine monolayers influenced by different concentrations of human serum albumin, and obtained different morphologies of CaOxa crystals with three kinds of phases.[16] We have also successfully inhibited the phase transition from COT to COM with 1,2-bis(*O*-aminophenoxy)ethane-*N*,*N*,*N*,*N*-tetraacetic acid.[16]

Some microorganisms, especially nanobacteria, have been reported to be involved in the formation of urinary stones. Nanobacteria are very tiny bacteria that range from 80–500 nm in size which have been isolated from renal stones[17,18] and have been shown to mineralize calcium and phosphate even under physiological conditions.[19,20] Cuerpo et al., for example, have found that when these bacteria are injected intravenously they accumulate in the kidney and produce apatite,[21,22] which suggests that the kidney is a preferred site for mineralization by these tiny bacteria, and Shiekh et al. have investigated the effects of intravenous administration of nanobacteria on the kidneys of Wistar rats and have found evidence for their inflammatory infiltration and accumulation in the cortex; in addition, small uniform renal calcification was seen on the surface of renal tubules.[23] These studies have therefore shown that nanobacteria may act as biomineralization centers for the initiation of kidney stones and play a contributory role in urolithiasis. Instead of promoting the formation of stone, oxalate-eating bacteria such as *Oxalobacter formigenes* can degrade oxalate and prevent the occurrence of CaOxa urolithiasis.[24,25]

The common bacterium *Escherichia coliform* (*E. coli*) is often found in urinary stones and it could damage the protective anti-adhesive GAG layer and cause crystal retention or alter urine composition in such a way that favors stone formation.[26,27] It has also been found that *E. coli* plays an important role in urinary-tract infections.[28] However, to date, there is no report of its true role in the biomineralization of urinary stones. In the present study, we report that *E. coli* can induce the nucleation, growth, and aggregation of CaOxa by biomolecules internally or externally and promote the formation of COM with a regular morphology, which suggests that it plays a contributory role in the biomineralization of urinary stones. This may help our further understanding of the stone-formation mechanism and lead to a method for the prevention and treatment of urolithiasis. In addition, it is also significant for the synthesis of inorganic materials with different morphologies.

## Results and Discussion

SEM images of CaOxa particles obtained after an aging time of 5 h in the absence and presence of *E. coli* are shown in Figure 1; the corresponding XRD patterns are shown in Figure 2. It can clearly be seen that the CaOxa particles obtained under these two conditions have different sizes and crystal phases. Without the bacterium, quasi-hexagonal or irregular CaOxa particles with an average diagonal of about 150 nm (shown in Figure 1a) are obtained. The corresponding XRD patterns (shown in Figure 2a) display diffraction peaks at 14.22°, 15.08°, 19.90°, 24.44°, 30.20°, 31.66°, and 32.02°, which can be indexed to the (*hkl*) indices (200), (211), and (411) of a COD phase (JCPDS card number 17-541), and the ($\bar{1}$01), (020), ($\bar{2}$02), and (121) indices of a COM phase (JCPDS card number 20-231), respectively. This indicates that the crystals obtained are a mixture of COM and COD. Figure 1b shows that hexagonal or rhombic particles with an average diagonal of about 300 nm are obtained in the presence of *E. coli* (0.5 wt.-%) that are larger than those formed without the bacterium. The XRD patterns (Figure 2b) show that they are all COM. These results imply that *E. coli* promotes the crystallization of COM and influences the size and morphology of the product.

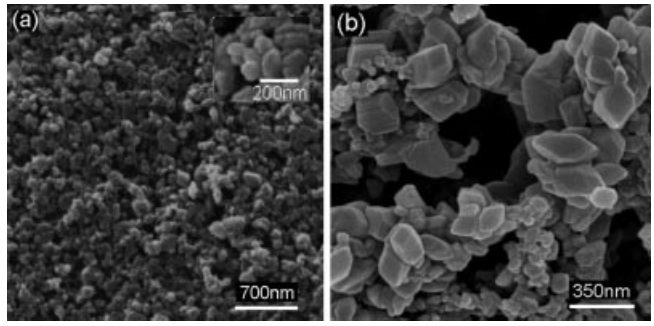

Figure 1. SEM images of CaOxa precipitates obtained in different systems after 5 h of reaction: (a) without *E. coli*, (b) with *E. coli* (0.5 wt.-%). The inset in (a) is a magnification.

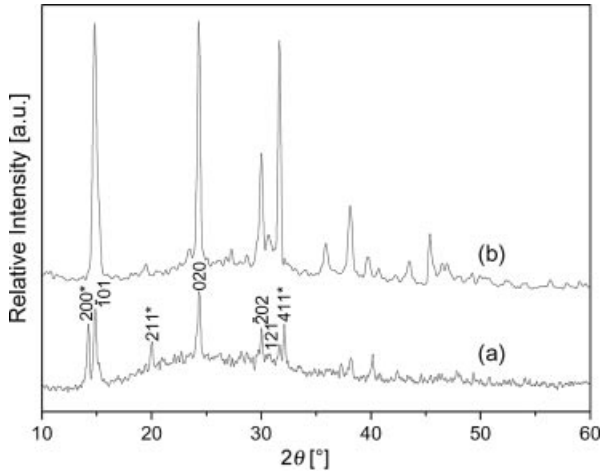

Figure 2. XRD patterns of CaOxa precipitates obtained in different systems after 5 h of reaction: (a) without *E. coli*, (b) with *E. coli* (0.5 wt.-%). The peaks of COD are labeled with an asterisk.

In order to investigate the influence of aging time and the ratio bacterium/chemical reagents on the formation of CaOxa, SEM images (Figure 3) and XRD patterns (Figure 4) of the products formed in two systems at different reaction times were recorded. At a CaOxa concentration of $2.5 \times 10^{-2}$ M the mass ratio bacteria/CaOxa is 1.56:1 (*E. coli*: 0.5 wt.-%) and the morphologies of CaOxa particles obtained transform from predominantly bipyramidal to predominantly hexagonal, although the sizes show no obvious

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

changes (range from 100–600 nm) after aging for between 5 min and 3 d (shown in Figure 3a–d). The corresponding XRD patterns show that the CaOxa obtained has two phases including COD and COM (shown in Figure 4a–d). If $I_D$ and $I_M$ are defined as the intensity of the characteristic diffraction peaks of COD (200) and COM ($\bar{1}01$), the percentage of COD in the mixture can be calculated from the equation $\%COD = I_D/(I_M + I_D)$.[29] With aging times of 5 min, 30 min, 3 h, and 3 d, the percentage of COD in the products is 55.6%, 52.7%, 26.5%, and 0.02%, respectively. This clearly shows that the amount of COD in the crystals decreases gradually and almost disappears with an increase of aging time, which suggests that thermodynamically unstable COD changed into stable COM with time.

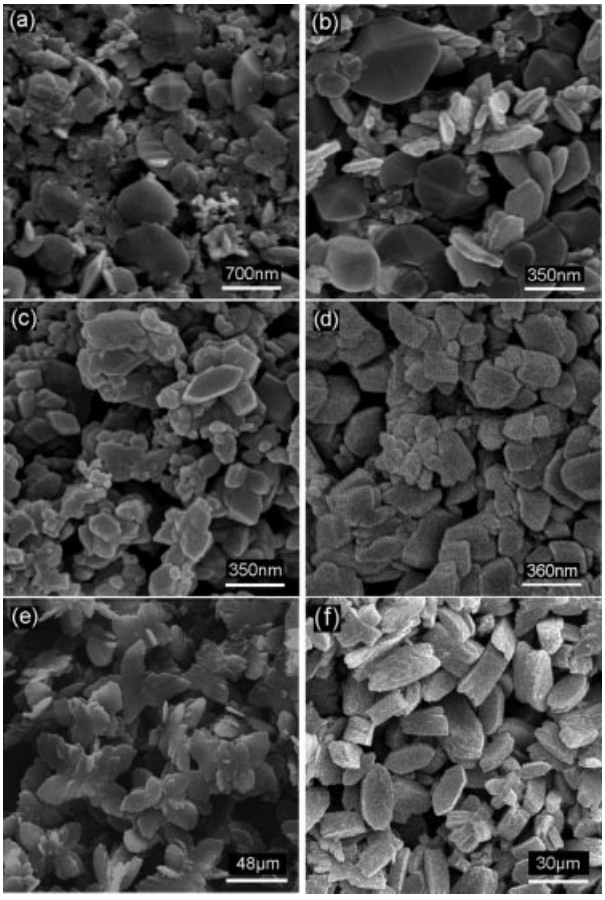

Figure 3. SEM images of CaOxa precipitates obtained in two systems at different reaction times: (a)–(d) concentration of CaOxa of $2.5 \times 10^{-2}$ M with aging times of 5 min, 30 min, 3 h, and 3 d, respectively, with 0.5 wt.-% *E. coli*; (e), (f) concentration of CaOxa of $2.5 \times 10^{-3}$ M and aging times of 3 h and 3 d, respectively, with 0.5 wt.-% *E. coli*.

Decreasing the concentration of CaOxa to $2.5 \times 10^{-3}$ M increased the mass ratio bacteria/CaOxa (15.6:1) and the sizes and morphologies of the CaOxa particles obtained also changed. It can be seen from Figure 3e, taken after 3 h, that flower-like CaOxa particles were obtained. Every "petal" of the "flower" is quasi-hexagonal with a mean diagonal of around 30 μm. The corresponding XRD patterns show that they are all COM crystals (Figure 4e). To the

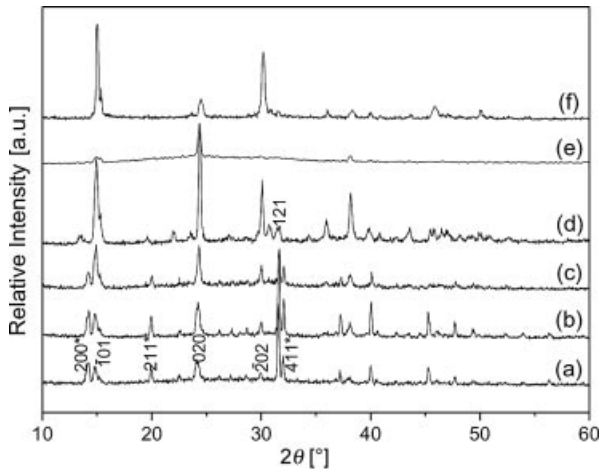

Figure 4. XRD patterns of CaOxa precipitates obtained in two systems at different reaction times: (a)–(d) concentration of CaOxa of $2.5 \times 10^{-2}$ M with aging times of 5 min, 30 min, 3 h, and 3 d, respectively, with 0.5 wt.-% *E. coli*; (e), (f) concentration of CaOxa of $2.5 \times 10^{-3}$ M and aging times of 3 h and 3 d, respectively, with 0.5 wt.-% *E. coli*. The peaks labeled with an asterisk correspond to COD.

best of our knowledge the general morphology of COM is hexagonal, therefore the "flowers" probably form due to the aggregation of several single hexagonal COM particles. This suggests that *E. coli* influences the growth and aggregation of CaOxa. When the aging time was increased to 3 d mainly hexagonal CaOxa particles with an average diagonal of around 30 μm were obtained (Figure 3f). Compared with those formed after 3 h, these particles are isolated with no apparent change in size. The XRD results show that they are also COM (Figure 4f), although the strongest diffraction peak is ($\bar{1}01$) instead of (020), which implies that the bacterium (*E. coli*) influences the crystallization process.

It can be seen from the above results that the CaOxa particles obtained become larger, more regular, and aggregate more easily with an increase in the bacteria/CaOxa ratio and that, at the same aging time (3 h), the phase transition from COD to COM is more rapid. This further suggests that *E. coli* accelerates the crystallization of COM and makes the particles become larger. Larger COM particles form urinary stones more easily because they are more difficult to excrete, therefore we can speculate that *E. coli* plays an important role in the biomineralization process of urinary stones. In addition, it can also be speculated from the above results that a higher concentration of CaOxa does not always result in a risk of urinary stones.

TEM images of the products obtained by drying the reacting solution containing $2.5 \times 10^{-3}$ M CaOxa and 0.5 wt.-% *E. coli* after aging for 12 h were recorded in order to explore the details of nucleation and growth of COM induced by *E. coli* (see Figure 5). It can clearly be seen that there are many uniform spindle-shaped particles in the CaOxa-centered area (Figure 5a), which were proved by their electron diffraction (ED) pattern (Figure 5c) to be COM crystals. When examined carefully, these crystals are found to be enclosed by light shells. We infer that the light

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

materials on the crystal surface are the bioorganic secretions of the bacterium. In addition, many light, rod-like bacteria (*E. coli*) can be seen in the bacteria-centered area (Figure 5b). The darker parts seen in the bodies of some bacteria were shown from their ED patterns (Figure 5d) to be COM crystals. This suggests that $Ca^{2+}$ and $C_2O_4^{2-}$ ions can enter into the cells of the bacteria and form COM crystals due to inducement by intracellular biomolecules. In other words, the bacteria can control the nucleation and growth of COM crystals in their interior. In order to confirm the TEM results, the FTIR spectrum of CaOxa crystals obtained from the solution after the same reaction time was determined (Figure 6). It can be seen from this spectrum that the symmetric and antisymmetric oxalate C=O stretching bands are located at 1618 and 1321 $cm^{-1}$, respectively. Very importantly, the band located at 1640 $cm^{-1}$ (amide I) shows that the CaOxa obtained contains *E. coli* proteins. The surface-bound proteins released from the COM crystals grown in the presence of *E. coli* were removed by treatment with NaOCl and analyzed by 10% sodium dodecyl sulfate polyacrylamide gel electrophoresis (SDS-PAGE) at pH = 8.2. The data show that the surface-bound proteins have a molecular weight of about 26.5 kDa (lane 2, Figure 7a). The UV/Vis spectrum of the surface-bound proteins is shown in Figure 7b. The peak at 210 nm was assigned to the strong absorption of the peptide bonds of the protein in the extract, which arises from an n–π* transition of the C=O group. The absorption at 280 nm is due to the π–π* transition of the tyrosine, tryptophan, or phenylalanine residues of the proteins. Two enzymes in urine, namely sialidase and urokinase, are thought to play a role in urolithiasis. Sialidase is responsible for the conversion of urinary mucosubstances into mineralizable matrix and urokinase regulates the urinary uromucoid concentration. du Toit et al.[30] have found that *E. coli* can inhibit urokinase and stimulate sialidase activity, which leads to the formation of a mineralizable stone matrix. They also suggested that *E. coli* might cause urolithiasis by producing matrix substances that increase crystal adherence to the epithelium.[31] The average concentration of *E. coli* in the urine of patients with a urinary tract infection or urolithiasis is about $10^6$ cells/mL,[32,33] which is very close to the experimental levels found by du Toit et al.[30] It can be speculated that the CaOxa surface-bound proteins with a molecular weight of about 26.5 kDa are probably the urokinase inhibitor and sialidase stimulator synthesized by *E. coli* during incubation.[30] Except for altering the excretion of the two enzymes, these proteins could also act as matrices for stone formation. Further investigations are in progress to determine the sequences of the proteins and the nature of the interaction of the proteins with the different crystallographic faces of CaOxa crystals. Taken together, these results suggest that the bacteria and their secretions participate in the crystallization of CaOxa, which means that *E. coli* can mineralize calcium and oxalate both intracellularly and with their bioorganic secretions. Previous studies have shown that nanobacteria can mineralize calcium and phosphate and act as crystallization centers during the formation of urinary stones,[21–23] therefore we speculate that *E. coli* probably also acts as a nucleus in the biomineralization of urinary stones.

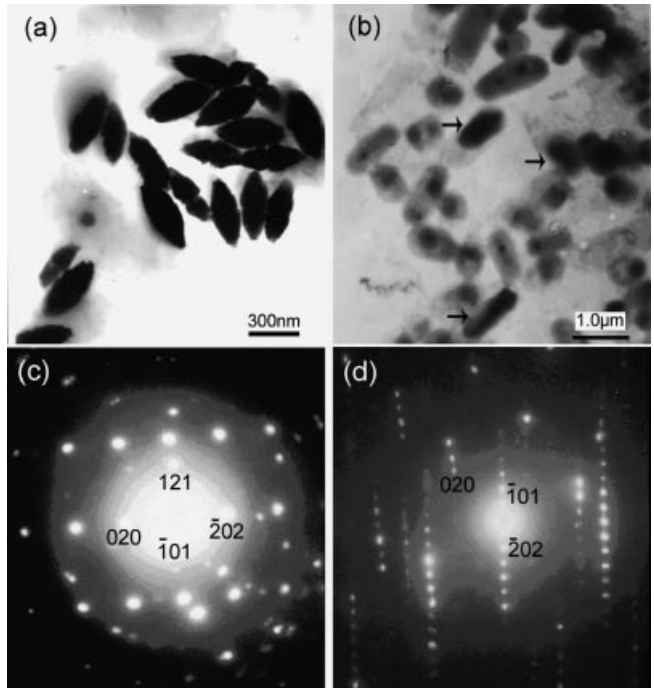

Figure 5. TEM images of the products obtained by drying the reaction solution containing $2.5 \times 10^{-3}$ M CaOxa and 0.5 wt.-% *E. coli* after aging for 12 h [(a): CaOxa-centered area; (b): bacteria-centered area] and electron-diffraction (ED) patterns of the crystals obtained [(c): CaOxa-centered area; (d): bacteria-centered area]. The arrows in (b) point to CaOxa crystals grown in cells of *E. coli*.

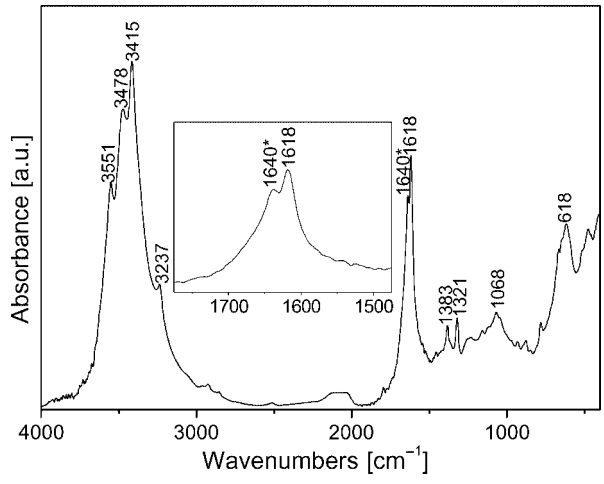

Figure 6. FTIR spectrum of CaOxa particles obtained from the reaction solution containing $2.5 \times 10^{-3}$ M CaOxa and 0.5 wt.-% *E. coli* after aging for12 h. The inset shows the magnification of the bands located at 1618 and 1640 $cm^{-1}$. The peak labeled with an asterisk is the amide I band of the *E. coli* proteins.

To the best of our knowledge, the cell walls of *E. coli* are composed of lipopolysaccharide and peptidoglycan, which is a polymer of glucide and protein with a polysaccharide structure, 30% of whose subunits (*N*-acetylglucosamines and *N*-acetylmuramic acids) interlace together to form a

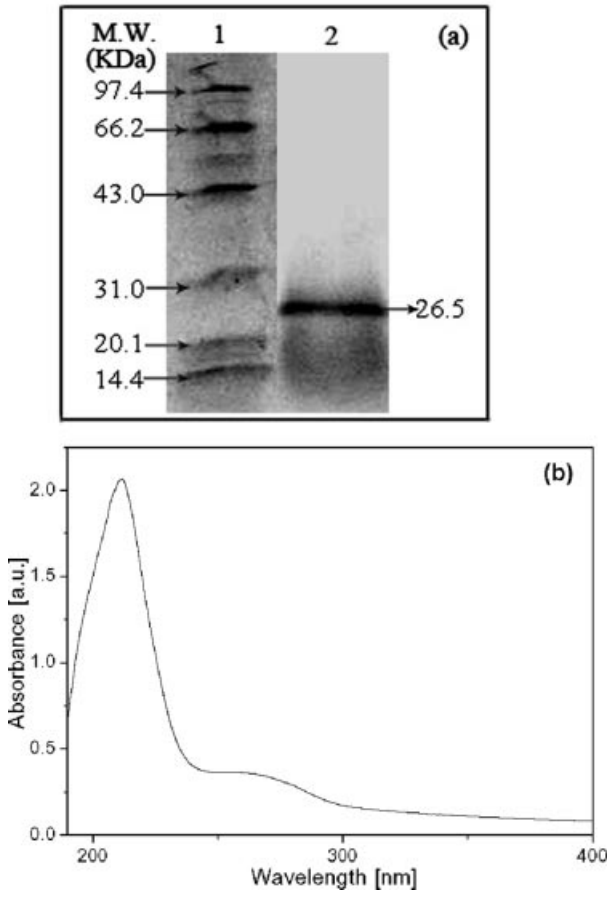

Figure 7. (a) SDS-PAGE data showing the proteins that were originally bound to the surface of the COM crystals grown in the presence of *E. coli*. Lane 1 shows standard protein molecular weight markers with the corresponding molecular weights, in kDa, indicated by arrows. Lane 2 corresponds to the protein bands in the *E. coli* secretions obtained by treatment of COM crystals grown in the presence of *E. coli* with NaOCl. (b) UV/Vis spectrum of the proteins obtained by treatment of COM crystals grown in the presence of *E. coli* with NaOCl.

relatively loose structure with many bare electronegative groups, which could attract and combine with $Ca^{2+}$ ions to provide nucleation sites. In addition, proteins and other biomolecules present in the cell could also interact with $Ca^{2+}$ ions. $C_2O_4^{2-}$ anions would then be attracted to the $Ca^{2+}$-enriched environment and the crystal nucleus of CaOxa would form. Growth of CaOxa crystals would then be controlled by the cell walls or the biomolecules in the bacterial cells.

Bacteria can produce many extracellular proteins such as enzymes, etc.;[34] therefore, we also studied the secretions of *E. coli* in detail by means of zeta potential and FTIR measurements to clarify the interaction between the bacteria and CaOxa. The zeta potential of *E. coli* secretions in aqueous solution shows a peak at about –137 mV (Figure 8), which implies that they are negatively charged and could therefore strongly attract and enrich $Ca^{2+}$ through electrostatic interactions to provide nucleation sites for CaOxa crystals.

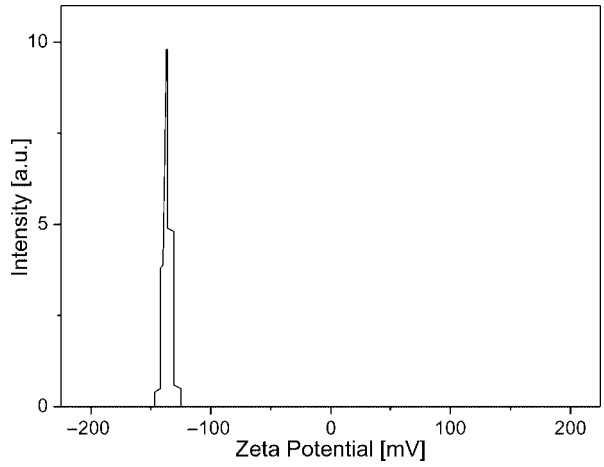

Figure 8. Zeta potential of the *E. coli* secretions in aqueous solution (*E. coli*: 0.5 wt.-%).

Figure 9 shows the FTIR spectra of *E. coli* and its secretions in the absence and presence of $CaCl_2$. Figure 9a clearly shows that their principal components are mainly proteins, and the main bands at 1640, 1543, and 1401 $cm^{-1}$ can be assigned to amide I ($\nu_{C=O}$), II ($\delta_{N-H}$), and III ($\nu_{C-N}$) absorptions, respectively. In the spectrum in Figure 9b, which was recorded in the presence of $Ca^{2+}$, the amide I band is shifted by 6 $cm^{-1}$ to lower frequencies and the amide II band has disappeared, which indicates that there are strong interactions between $Ca^{2+}$ ions and the proteins secreted by *E. coli*. In order to obtain more detailed information, the secondary structures of the proteins with and without $Ca^{2+}$ ions were studied by recording the second derivative followed by a curve fitting (shown in Figure 10a, b).[35] In the absence of $Ca^{2+}$ ions, the bands located at 1641, 1632, 1623, and 1614 $cm^{-1}$ were assigned to a β-sheet, that at 1677 $cm^{-1}$ to a β-turn, those at 1669 and 1661 $cm^{-1}$ to an α-helix, and that at 1652 $cm^{-1}$ to a random coil of a protein secondary structure. In the presence of $Ca^{2+}$ ions, however, the bands attributed to the β-sheet are found at 1690, 1641, 1631, 1622, 1613, and 1603 $cm^{-1}$, that for the β-turn at 1678 $cm^{-1}$, those for the α-helix at 1669 and 1662 $cm^{-1}$, and that for the random coil at 1653 $cm^{-1}$. The percentages of β-sheet, β-turn, α-helix and random coil of *E. coli* proteins in the absence and presence of $Ca^{2+}$ ions change from 53.5%, 14.2%, 13.4%, and 18.9% in the former case to 62.4%, 8.8%, 11.3%, and 17.5% in the latter. This indicates that, compared with that of the proteins, the percentage of β-sheet of protein-$Ca^{2+}$ compounds increases while the percentage of β-turn, α-helix, and random coil all significantly decreased, which suggests that the interaction between $Ca^{2+}$ and proteins makes the conformation of the proteins become more ordered. These ordered proteins could influence the nucleation, growth, and aggregation of CaOxa crystals.

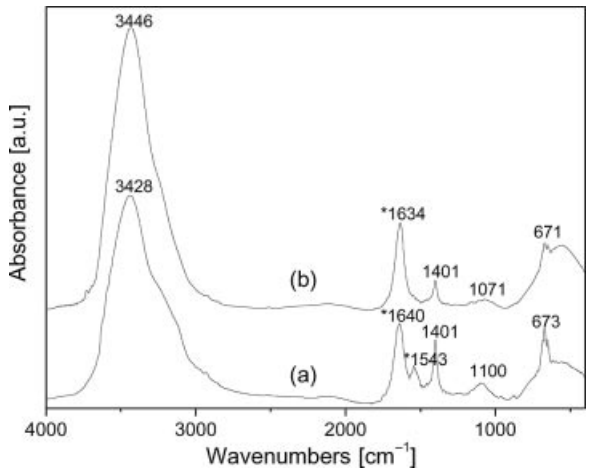

Figure 9. FTIR spectra of (a) *E. coli* aqueous solution (*E. coli*: 0.5 wt.-%) and (b) *E. coli*/$CaCl_2$ aqueous solution (*E. coli*: 0.5 wt.-%; $CaCl_2$: $5 \times 10^{-3}$ M). The amide I and II bands of the *E. coli* proteins are labeled with an asterisk.

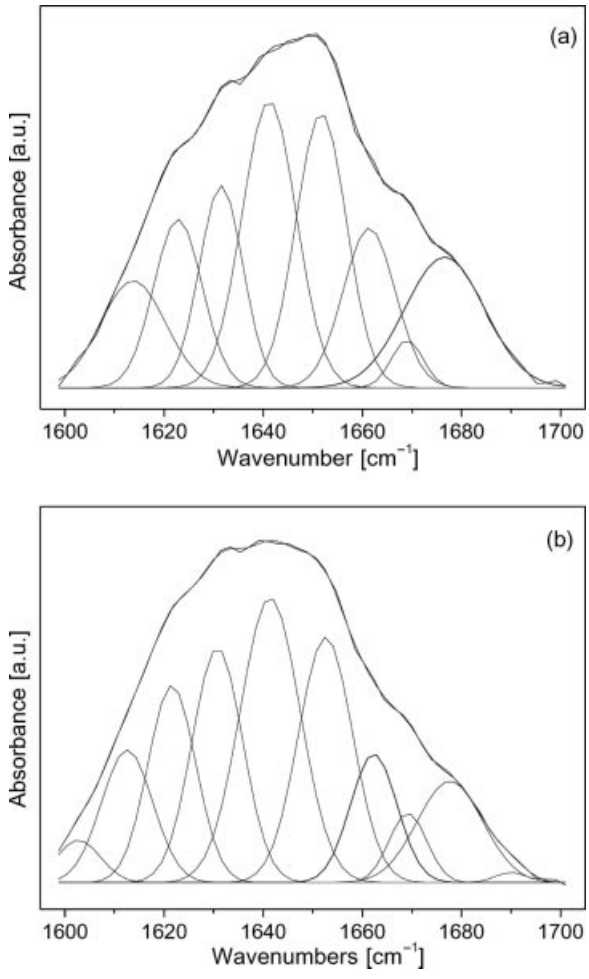

Figure 10. Second derivative and Gaussian curve fitting of the bands between 1600 and 1700 $cm^{-1}$ (amide I of proteins) for (a) *E. coli* proteins and (b) *E. coli* protein-$Ca^{2+}$ complexes.

According to the Gibbs–Thomson formula of classic nucleation theory,[36] the nucleation and growth of CaOxa induced by *E. coli* could be explained by thermodynamic Equation (1), where $J$ and $S$ are the nucleation rate and supersaturation, respectively, and A and B are constants.

$$J = A\exp[-B(\ln S)^{-2}] \quad (1)$$

We can see from this equation that the rate of nucleation increases with an increase of supersaturation. The interaction between *E. coli* proteins and $Ca^{2+}$ ions concentrates these ions around the negatively charged groups of the proteins, which results in an increased supersaturation of CaOxa in this region. As a result, the nucleation rate of CaOxa is increased and the electronegative and ordered proteins also direct the growth of the nucleus and promote the formation of COM crystals. The bacteria therefore accelerate the nucleation and growth of COM crystals.

The above results imply that the common bacterium *E. coli* could also induce the nucleation and growth of CaOxa crystals and accelerate the crystallization of COM when it infects the urinary tract, which means that *E. coli* plays an important role in biomineralization and promotes the formation of urinary stones.

## Conclusions

Investigation of the influence of *E. coli* on the nucleation and growth of CaOxa crystals in aqueous solution has shown that this bacterium accelerates the formation of COM crystals and makes the particles become larger. When the concentration of CaOxa is decreased, the ratio bacteria/CaOxa increases, the COM crystals obtained become more regular and larger, and the phase transition from COD to COM occurs more rapidly. TEM and FTIR results have shown that the nucleation and growth of CaOxa crystals are induced by intracellular biomolecules and bacterial secretions. SDS-PAGE data and UV/Vis spectroscopy have shown that the surface-bound proteins with a molecular weight of about 26.5 kDa contain tyrosine, tryptophan, or phenylalanine residues. The formation mechanism of CaOxa in the presence of *E. coli* has also been discussed. It is likely that the negatively charged *E. coli* proteins interact strongly with $Ca^{2+}$ ions and make the secondary structure of these proteins more ordered. These ordered proteins induce the nucleation and growth of CaOxa crystals. *E. coli* is therefore likely to play an important role in biomineralization and promote the formation of urinary stone.

## Experimental Section

**Materials and Instruments:** Chloroform, anhydrous ethanol, and acetone were all purchased from Shanghai Chemical Reagent Company (Shanghai, China) and were all analytically pure. Anhydrous calcium chloride, sodium hydroxide, hydrochloric acid, and sodium oxalate ($Na_2Oxa$) were obtained commercially and were also analytically pure. All the above reagents were used without further purification. Doubly distilled water was used in all experiments. Bacteria (*E. coli*) were cultivated on beef peptone culture medium after 48 h incubation at 37 °C in our laboratory. Fourier transform infrared

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

spectra were recorded with a Nicolet 870 instrument with a resolution of 4 $cm^{-1}$ in the wavenumber range from 400 to 4000 $cm^{-1}$ using the KBr pellet technique. X-ray diffraction patterns were recorded with a DX-2000 diffractometer using Cu-$K_\alpha$ radiation at a scan rate of 0.06° in $2\theta$ per second. Scanning electron microscopy was performed with a Hitachi X-650 instrument at an accelerating voltage of 20 kV. Transmission electron microscopy and selected-area electron diffraction studies of the CaOxa particles were carried out with a JEM model 100SX electron microscope from Japan Electron Co. at an accelerating voltage at 200 kV. A UV/Vis double beam spectrophotometer (Beijing Purkinje General Instrument Co., Ltd, China) and a zeta potentiometer (Malvern Instruments Limited) were also used.

**Methods:** In a typical experiment, the appropriate amount of *E. coli* was added to a $5\times10^{-2}$ or $5\times10^{-3}$ M aqueous solution of $CaCl_2$ (40 mL), and this solution was mixed with the same concentration and volume of an aqueous $Na_2Oxa$ solution. The reaction solution was airproofed and kept at a temperature of 35±1 °C for between 5 min and 72 h after stirring for 30 s. The concentration of *E. coli* in the reaction solution was kept constant at 0.5 wt.-% and the pH of the solution was adjusted to about 7.0. Control experiments were carried out under the same conditions without addition of bacteria. The size and the morphology of the precipitates obtained were examined by scanning electron microscopy (SEM), while their crystalline phases were examined by X-ray powder diffraction (XRD). The zeta potential of an aqueous *E. coli* (0.5 wt.-%) solution was measured to determine the nature of the charge of the bacterial secretions. A drop of an aqueous *E. coli* solution (*E. coli*: 0.5 wt.-%) with and without $CaCl_2$ ($CaCl_2$: $5\times10^{-3}$ M) was placed on a KBr crystal after aging for 1 h at a temperature of 35±1 °C and dried before recording the FTIR spectra to determine the composition of the *E. coli* secretion and the interaction between the *E. coli* secretion and $Ca^{2+}$ ions. A drop of reaction solution (*E. coli*: 0.5 wt.-%; CaOxa: $2.5\times10^{-3}$ M) was placed on a copper grid after aging for 12 h at a temperature of 35 ± 1 °C and dried before recording the TEM image and SAED patterns in order to investigate the influence of the bacterium on the growth of CaOxa crystals. The particles obtained by centrifuging the reaction solution (after aging for 12 h) were washed with doubly distilled water and dried for FTIR spectroscopic determination. To identify the proteins bound to the calcium oxalate crystals that are possibly responsible for the crystal shape and type control, the CaOxa crystals obtained in the presence of bacteria were washed thoroughly after aging for 72 h and then treated with 4% sodium hypochlorite (NaOCl) solution. The free proteins detached from the COM crystals in solution were separated by centrifugation and analyzed by 10% SDS-PAGE at pH = 8.2 and UV/Vis spectroscopy.

# Syntheses, Structures and Coordination Modes of Acetatopalladium(II) Complexes with 1,3-Bis(2-arylimino)isoindoline Ligands of Different Steric Influence

**Martin Bröring,*[a] Christian Kleeberg,[a] and Esther Cónsul Tejero[a]**

**Keywords:** Cyclometalation / Isoindoline ligands / Polynuclear complexes / Palladium / Coordination modes

Acetatopalladium(II) complexes of four different 1,3-bis(2-arylimino)isoindoline ligands (bai's) with different degrees of steric congestion have been prepared and were characterized by NMR and XRD with respect to nuclearity and coordination mode. In particular, the propensity for heteroaryl ring rotation and C–H activation has been investigated. Palladium(II) ions bind to bai ligands in different coordination modes, either as classical Werner-type *N*,*N*,*N* bonded complexes or—after pyridyl ring rotation and C–H activation—as carbometalated *C*,*N*,*N* chelates. In the latter case two (bai•)-Pd(OAc) subunits have been found to dimerize via two bridging Pd(OAc) moieties in the solid and in solution. These stable and electroneutral tetranuclear species are of low solubility in non-donor solvents, but break up into soluble dinuclear species of unknown composition upon the addition of DMSO, azide or cyanide. Attempts to activate C–C bonds by this strategy were not successful. Surprisingly, the exchange of the terminal pyridines by pyrimidines does not result in the formation of oligonuclear or oligomeric species. Besides the degree of steric hindrance, three more factors, solubility of the products, stoichiometry of metal precursor and charge compensation, have been identified to govern the outcome of the metalation of these bai ligands.

## Introduction

Palladacycles[1] constitute an important class of organometallic species. Despite their historical role in the development of organometallic chemistry,[2] cyclometallated palladium(II) compounds have found entry in many different fields like organic synthesis, catalysis, and material science.[3] In addition, many of the nowadays indispensable palladium-promoted organic transformations are considered to proceed via palladacyclic intermediates.[4]

1,3-Bis(2-arylimino)isoindolines (bai) are monoanionic, meridonal tridentate *N*,*N*,*N* ligands[5] that were first introduced in the 1950s.[6] Palladium(II) complexes of such bai ligands like **1** and others are known as classical coordination compounds,[7] and their catalytic capabilities in the hydrogenation of alkenes have been demonstrated.[8] In a recent study it was described that steric strain applied to the coordination unit of such classical (bai)Pd complexes by well-situated terminal methyl groups results in an intriguing reactivity, i.e. pyridine ring rotation and C–H activation of the heteroaromatic ligand, to yield the carbopalladated 1,3-bis(6-methylpyridyl-2-imino)isoindoline (6-Me-bpi*) species **2** (Figure 1).[9] This report tempted us to investigate the reactivity of palladium(II) ions on bai ligands of different steric influence and to compare their behaviour with a class of related meridonal-tridentate *N*,*N*,*N* ligands, the α,ω-dimethyltripyrrins,[10] that we had studied before. In a first attempt we were able to show, that the stoichiometry of the palladium precursor added to the bai ligand is responsible for the outcome of the reaction, i.e. the formation of a Werner-type or a cyclopalladated product, if the steric hindrance is equal for the N- and the C donor positions.[11] We have now extended the study to ligands with different degrees of intramolecular strain, and report here about the results of our work.

## Results and Discussion

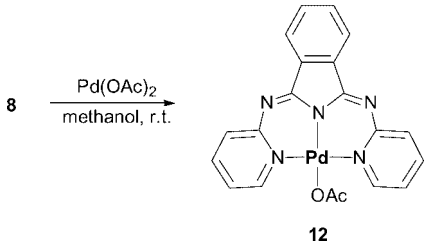
### Preparation of 1,3-Bis(2-arylimino)isoindolines H(bai) 8–11

The preparation of the 1,3-bis(2-arylimino)isoindolines H(bai) **8**–**11** used in this study is presented in Scheme 1. In general, symmetric H(bai) derivatives can be prepared by a method introduced by Siegl[5a)] upon treatment of phthalodinitrile **3** with a heteroarylamine $ArNH_2$ **4**–**7** and calcium chloride in 1-butanol (Scheme 1). **8** and **9** had been prepared by this approach before.[5a] The new compounds **10** and **11** form in yields of 62% and 7%, and were analyzed by elemental analyses and HRMS, respectively. The low yield was obtained for H(4-Me-bpmi) **11** after 7 d at reflux and is a result of the fair reactivity of aminopyrimidine **7**. Only one successful attempt for the preparation of H(bpmi) derivatives had been described in literature so far.[5j]

The interpretation of the spectroscopic properties of **10** and **11** is straightforward and proofs that the new derivatives behave very similar to other known H(bai) species.[5a)] The NMR spectra show $C_{2v}$ symmetric species in solution and are typically governed by the large number of signals arising from the different aromatic C–H groups. These congested spectra can easily be interpreted after separation in three subspectra. The signals of the methyl group protons typically appear between $\delta$ = 2 and 3 ppm (2.42 and 2.43 ppm for **10**, 2.58 ppm for **11**). The second subspectrum concerns the α- and β protons of the central $C_6H_4$ moiety, which lead to two multiplets for **10** and **11** at 8.05/7.65 and 8.10/7.68 ppm, respectively. The other signals at 7.46/6.86 ppm and 8.62/6.96 ppm belong to the C–H protons of the terminal heterocycles, i.e. the pyridines in **10** and the pyrimidines in **11**. A similar signal pattern is also found for all (bai)$Pd^{II}$(OAc) complexes in this study. For the free base ligands **10** and **11**, however, another broad signal indicating a NH function appears at $\delta$ = 12.3 and 13.3 ppm, respectively.

### Formation of Mono- and Tetranuclear Species 12 and 13 from H(bai) 8 and 9

The complex (bpi)Pd(OAc) **12** was prepared from 1,3-bis(pyridyl-2-imino)isoindoline H(bpi)[5a)] (**8**) and palladium acetate in methanol and precipitates from the reaction mixture as an orange, microcrystalline powder in a yield of 76% (Scheme 2). The constitution $C_{20}H_{15}N_5PdO_2$ was confirmed by combustion analysis and MALDI-MS.



Scheme 2. Preparation of (bpi)Pd(OAc) **12**.

$^1H$ and $^{13}C$ NMR spectra of **12** are in agreement with a compound of $C_2$ symmetry. The acetato ligand can be detected by characteristic signals for the methyl protons and for the carbon atoms at 2.15, 24.8 and 172.7 ppm, respectively. The assumed Werner-type *N*,*N*,*N* coordination of the palladium ion was established by a X-ray crystallographic analysis. A suitable crystal ($CH_2Cl_2$ solvate) grew from a dichloromethane solution at –40 °C. Selected bond lengths and angles are summarized in Table 1 (with Figure 2). Table 2 gives crystallographic details. The molecular structure of **12** is shown in Figure 3.

The molecular structure of **12** confirms the solution spectra and shows a palladium(II) ion coordinated to three nitrogen atoms N1, N2 and N3 of the bpi ligand at distances of 2.038(5), 1.946(5) and 2.037(5) Å. The fourth coordination site is occupied by the O1 donor atom of the acetate moiety in a distance of 2.034(3) Å. The central Pd–N2 bond is markedly shorter than the other two. Literature proposes

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

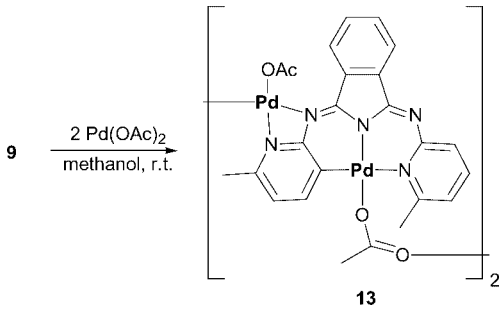
N3 and N2–Pd–O1 of 10.7° and 5.4°, respectively, from 180° reveal a non-planar coordination of the $d^8$ $Pd^{II}$ ion that obviously derives from steric interactions between the acetato donor O1 and the terminal protons at C1,18. With 2.208 and 2.212 Å the O1···H distances are found to undercut the van der Waals limit by up to 15.1%.[12] For **1** and **2** which contain the larger chlorido ligand instead of the acetate oxygen atom the N2–Pd–Cl angle is found steeper at 167.74 and 165.13°, respectively, but with a similar degree of X···H and/or X···$CH_3$ interaction of 16.3–20.2% below the van der Waals limit. The bpi ligand of **12** displays a non-planar, convex conformation with twists of the pyridyl and isoindole ring mean squares planes from the N1,N2,N3 plane of 10.82°, 14.42° and 4.34°, respectively. Similar twists are unknown for related tripyrrin complexes and allow bai ligands to better adapt to coordinative requirements by a higher degree of conformational flexibility.

The reaction of H(6-Me-bpi) **9** with two equivalents of palladium(II) acetate also proceeds under the slow formation of a solid precipitate. The product **13** that is obtained after filtration and excessive washing with methanol in 46% yield, however, shows a lower solubility and an entirely different constitution than (bpi)Pd(OAc) **12**. From mass spectra and combustion analytical data the presence of a tetranuclear dimer can be concluded. As will be shown by XRD and NMR studies the constitution of the product **13** is that of a carbopalladated tetranuclear dimer as displayed in Scheme 3. **13** forms very selectively even if less than the stoichiometric amount of palladium acetate is used, and it is reasonable to assume that the low solubility of the tetranuclear dimer efficiently supports the selective formation of the unexpected product. A similar behaviour has been observed with the 4,6-Me2-bpi derivative,[11] if two (or more) equivalents of palladium acetate are employed.



Scheme 3. Formation of [(6-Me-bpi*)$_2$Pd$_4$(OAc)$_4$] **13**.

A crystal of **13** suitable for a X-ray crystallographic analysis was obtained from a solution in chloroform by layering with *n*-hexane and diffusion at room temperature. **13** crystallizes as a solvate, presumably a dihydrate, in the monoclinic system, space group *C*2/*c*, with $Z = 8$. Due to the severe disorder the solvent was removed using the SQUEEZE command in PLATON. The molecular structure of **13** contains two identical monomeric subunits and is presented in Figure 4. Selected bond lengths and angles are given in Table 1. Table 2 summarizes crystallographic details.

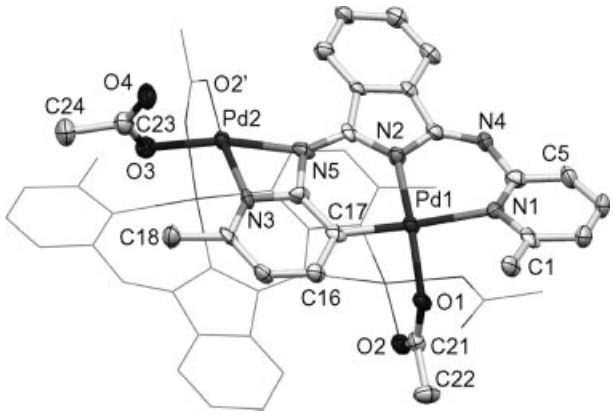


Figure 4. Molecular structure of (6-Me-bpi*)$_2$Pd$_4$(OAc)$_4$ **13** in the solid state (hydrogen atoms omitted for clarity; ellipsoids are set at the 50% probability level).

Complex **13** is a dimer of a palladium complex of a C-H activated 6-Me-bpi ligand, referred to as 6-Me-bpi*. The monomeric (6-Me-bpi*)Pd$_2$(OAc) subunits are doubly bridged by two bidentate acetato ligands which occupy one coordination site on each type of palladium ion, the central ion Pd1 and the peripheral ion Pd2, with Pd–O distances of 2.054(7) and 2.029(7) Å. Besides the acetate coordination the peripheral $Pd^{II}$ ion is bound to N3 and N5 in distances of 2.010(9) and 2.079(8) Å, respectively, and with a narrow N3–Pd2–N5 angle of 65.0(3)°. The fourth coordination site of the distorted square-planar Pd2 ion is saturated by a terminal acetate in a distance of 1.977(6) Å. The *C*,*N*,*N* coordination of the Pd1 atom of **13** is identical to the one recently reported for the mononuclear H[(6-Me-bpi*)PdCl] **2**.[9] Instead of a second palladium ion coordinated to N3 and N5, however, **2** contains a proton at N3 for charge balance. For this reason as well as for the geometrical differences of the bridging coordination modes of chlorido vs. acetato ligands precedent **2** lacks the ability for dimerization via intermolecular coordinative interactions and thus remains monomeric. With the exception of nuclearity, however, the metrics of **2** and **13** as determined by XRD are very similar.

The (6-Me-bpi*)Pd subunits of **13** are stacked above each other in an antiparallel orientation and in a distance of about 3.157 Å. The correlation (Pd–N1) > (Pd–N2) seen above for the Werner-type complex **12** is retained in **13**, and the *trans* influence of the C* donor opposite to N1 is clearly visible in the elongated Pd–N1 bond of 2.174(7) Å. The carbon atom C17 of the inverted pyridine moiety binds to Pd1 in a distance of 1.975(7) Å. The conformation of the 6-Me-bpi* ligand is convex as in **12** but unsymmetric in the predictable sense that the *N* bound pyridine ring with the methyl group close to the acetate O1 atom shows a large tilt of 18.82° while the *C* bonded pyridine ring with the methyl group turned away from the acetato ligand tilts only slightly by 9.78° with respect to the N1,N2,C* plane. The distances O1···H16 and O1···$CH_3$ of 2.362 and 2.764 Å are 9.2% and 18.7% below the van der Waals limit and therefore again in a range that appears typical for this class of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

compounds. With the exception of the remaining rotational freedom of the terminal acetates the tetranuclear and dimeric morphology of **13** is very rigid, so that the poor solubility of this compound can be rationalized from its structure.

The $^1$H NMR spectrum of **13** in $CD_2Cl_2$ shows a characteristic signal at $\delta$ = 5.51 ppm that was assigned to a proton situated at the C–H activated pyridyl residue (H5) by H,H COSY spectroscopy (see ESI, Figure S1). As the molecular structure of **13** reveals, this proton is situated directly above the aromatic $C_6H_4$ moiety of the isoindoline subunit of the symmetry equivalent monomer in a distance of about 3.3 Å. The high field shift observed for this signal is a consequence from the aromatic ring current of the benzene moiety, and H5 can thus be regarded a probe for the degree of aggregation. The $^1$H NMR spectra proof that the dimeric nature of **13** is not broken up in non-donor solvents like $CH_2Cl_2$ but largely resemble those found in the solid state. The XRD and NMR results of **13** resemble those observed before for a related 4,6-$Me_2$-bpi derivative.[11]

### Investigations of the Formation and Deaggregation of the Tetranuclear Species 13

While for **9** only the tetranuclear cage compound **13** could be isolated in substance, it was possible to isolate a Werner-type complex like **11** with the 4,6-$Me_2$-bpi ligand, depending on the stoichiometry of the metallation agent.[11] Obviously, the steric hindrance for C–H activation is higher for the 4,6-$Me_2$-bpi complex and leads to an increased kinetic stabilization of a mononuclear Werner-type species. In order to gain insight into the elemental steps of the formation of **13** the reaction between H(6-Me-bpi) **9** and two equivalents of $Pd(OAc)_2$ was carried out in deuterated methanol and investigated by $^1$H NMR spectroscopy. The mixture became turbid after a hour, and a spectrum was recorded which clearly showed the presence of two major and one minor species (Figure 5). One of the major as well as the minor species could be identified as the free base ligand H(6-Me-bpi) **9** and as a tetranuclear dimer similar to or identical with **13**, which seems to be present already in its saturation concentration. The remaining signals indicate the presence of a new, $C_2$ symmetric compound with a higher solubility, presumably the Werner-type complex (6-Me-bpi)Pd(OAc). Unfortunately all attempts to isolate this species failed, and **13** was obtained after work-up as the sole product. The study shows that the pyridine rotation and the C–H activation step occur *after* the initial metalation of **9**, and that the kinetic stability of the Werner-type intermediate (6-Me-bpi)Pd(OAc) in the presence of excess $Pd^{II}$ ions is not sufficient to prevent the concurring precipitation of **13**. With respect to the exclusive formation of the Werner-type compound from the unhindered ligand **8** this result supports the hypothesis of strain-induced C–H activation[9] and proofs the labilizing influence of steric strain on the kinetic stability of *N*,*N*,*N* bound species. Further insight into the C–H activation step and/or the pyridine ring inversion, however, could not be obtained. Especially the role of the solvent for the observed pyridin ring rotation/cyclometallation reaction remains unclear, since all attempts to metallate different bai ligands with palladium(II) acetate in solvents other than methanol yielded mixtures of several unassigned compounds.

A second set of $^1$H NMR spectroscopic experiments was devoted to the deaggregation of **13** and the possible determination of the structures of dinuclear fragments of **13**. The experiments were carried out using a) a donor solvent ([$D_6$]-DMSO), b) a donor anion in a donor solvent ($NaN_3$ in [$D_6$]DMSO), and c) a donor anion in a non-donor solvent ([$n$Bu$_4$N]CN in $CD_2Cl_2$; see ESI for selected details from $^1$H-NMR and H,H-COSY spectra obtained from these experiments).

If the $^1$H NMR spectrum of **13** is measured in [$D_6$]-DMSO a major compound with $C_s$ symmetry and without signals for aromatic C–H groups below a chemical shift of 6.9 ppm is detected, indicating a monomeric species in solution. In addition, a number of poorly resolved signals appear and indicate the presence of several side products. An

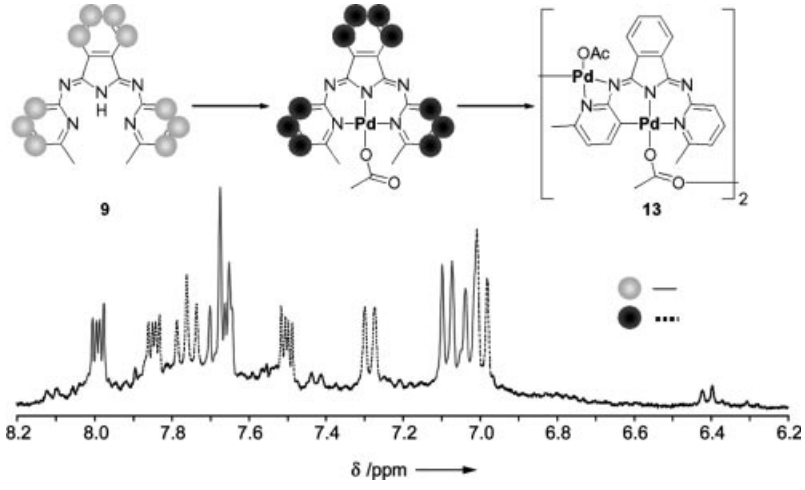

Figure 5. Details from the $^1$H NMR spectroscopic reaction control of the metalation of **9** (400 MHz, [D4]MeOH) and identification of the Werner-type monomeric species (6-Me-bpi)Pd(OAc).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

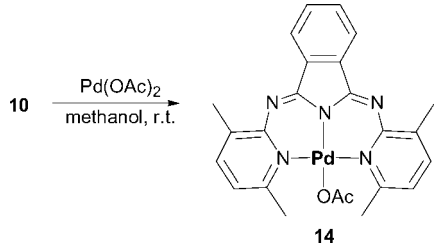
exact description of the molecular structure of the monomeric species, however, or a decision about whether one or two palladium ions are bound to the 6-Me-bpi* ligand, can not be given from the spectrum.

Upon the addition of excess sodium azide to the solution of **13** in [$D_6$]DMSO the spectrum clearifies and now displays the presence of one major and one minor compound which are both monomeric in nature and show both $C_s$ symmetry (presumably isomers). In addition only one singlet for an acetate species is present at $\delta$ = 1.64 ppm. This value is characteristic for a weakly bound acetate (e.g. NaOAc in [$D_6$]DMSO: 1.57 ppm) and suggests complete exchange for azido ligands.

A similar $^1$H NMR spectrum with a major and a minor form and a single signal for acetate protons at $\delta$ = 1.78 ppm was obtained from **13** in deuterated dichloromethane upon the addition of tetra-*n*-butylammonium cyanide. Directly after the addition a colour change from orange to yellow was observed. After several hours a yellow solid formed and precipitated from this solution. The solid is insoluble in most solvents, but is slowly taken up in pyridine with an intense yellow colour. The formation and reactivity of the insoluble final product may be explained by the polymerization of a dinuclear fragment [(6-Me-bpi*)$Pd_2$CN]$^+$ via μ-cyanido ligands.

### Metalation Behaviour of New bai Ligands H(bai) 10 and 11

The ease of C–H activation promoted by a simple steric stimulation as in **13** tempted us to use the same stimulus for a C–C activation reaction. Similar reactions have been studied before in pincer complexes with other noble metals like ruthenium, iridium and others.[13] Towards this goal the suitably substituted H(3,6-$Me_2$-bpi) **10** was designed and employed in the reaction with palladium acetate under standard conditions (Scheme 4). Even upon prolonged heating, however, only the Werner-type complex **14** was formed and could be isolated in 21% yield. Elemental analysis and mass spectra confirmed the constitution $C_{24}H_{23}N_5O_2Pd$ of **14**.



Scheme 4. Preparation of (3,6-$Me_2$-bpi)Pd(OAc) **14**.

The $C_2$ symmetry of the product can be derived from the proton and carbon NMR spectra. Support for the assignments was obtained by a X-ray crystallographic analysis. Two similar molecules **A** and **B** are present in the unit cell of which only the parameters of molecule **A** will be discussed. The molecular structure of **14A** is shown in Figure 6. Selected bond lengths and angles for both molecules are summarized in Table 1. Table 2 gives crystallographic details for the structure determination.

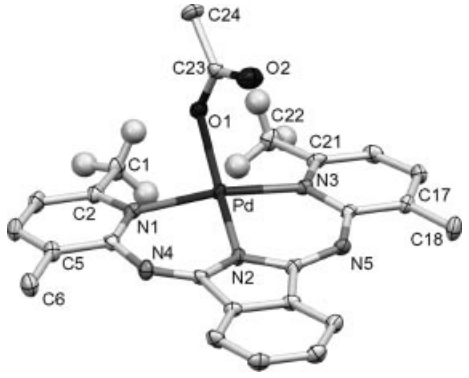


Figure 6. Molecular structure of (3,6-$Me_2$-bpi)Pd(OAc) **14** (molecule **A**) in the solid state (most hydrogen atoms omitted for clarity; ellipsoids are set at the 50% probability level).

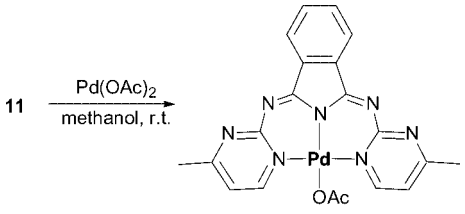
The result from the crystallographic analysis of **14** shows the expected distortion of the coordination sphere of the palladium(II) ion by non-linear N1–Pd–N3 and N2–Pd–O1 angles of 164.71° and 160.27°, respectively. These angles correspond to a pseudoplanar conformation of the 3,6-$Me_2$-bpi ligand[10b)] and indicate repulsive interactions between the terminal methyl groups of the bpi subunit and the O1 donor atom of the acetate group. Other than the bpi ligand in **12**, however, the 3,6-$Me_2$-bpi ligand of **14** shows no convex distortion but rather a conformation, in which the mean squares plane of the isoindole subunit is about 0.3–0.5 Å underneath the (almost) coplanar mean squares plane of both pyridyl moieties. This arrangement results in additional space for the acetate O1 donor atom which is located in distances of 2.792(6) and 2.845(6) Å, i.e. 17.9% and 16.3% below the van der Waals limit, from the terminal methyl groups. Very similar values of 16.0% and 18.1% have been obtained from the related mononuclear (4,6-$Me_2$-bpi)Pd(OAc) described earlier.[11] In both cases, an additional fraction of intramolecular strain is distributed to the Pd–N1 and Pd–N3 bonds as judged by their elongations of about 0.04 Å with respect to **12**. Obviously, the system contains sufficient resources to compensate for intramolecular strain, so that a process that requires a significantly larger activation energy than the C($sp^2$)–H activation is not sufficiently promoted by this approach.

Of particular interest was the question of why the C–H activation of **13** does not occur on the site of the peripheral $Pd^{II}$ ion and without pyridyl ring rotation. In particular it is unclear, whether the pyridyl rotation/C–H activation step is necessary for the coordination of a second palladium ion (as could be suggested from the inertness of **12** towards additional $Pd(OAc)_2$), or if the coordination of a second ion ($Pd^{II}$ for **13** and the 4,6-$Me_2$-bpi precedent, $H^+$ for **2**) to an initially formed kinetic product, i.e. the signals of a Werner-type *N*,*N*,*N*-bonded complex seen in the NMR experiment (Figure 5) or the isolated mononuclear 4,6-$Me_2$-bpi complex, assists in this process. To answer this question

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the bis(pyrimidyl) derivative **11** was designed. The kinetic *and* the thermodynamic product of the reaction of **11** with a first equivalent of $Pd(OAc)_2$ must be identical due to the inability of **11** to undergo a C–H activation process, and should already exhibit two heteroaryl termini with two methyl groups and two *N* donor atoms pointing outwards. Thus, as the final product, a di- or trinuclear complex or an aggregate thereof should be expected.

**11** was metalated under standard conditions and a new, yellow compound **15** separated from the reaction mixture (Scheme 5). Elemental analysis and mass spectra indicate the exclusive formation of a mononuclear compound. Surprisingly, neither a two- or threefold metalation nor a di- or oligomerization occurs despite the presence of excessive palladium acetate. $^1H$ and $^{13}C$ NMR spectroscopic data for **15** again suggests the formation of a $C_2$ symmetric species. Whether both methyl termini point in- or outwards could be clearified in favour of the latter scenario by a X-ray diffraction study.



**15**

Scheme 5. Preparation of (6-Me-bpmi)Pd(OAc) **15**.

Yellow needles of **15** suitable for the XRD investigation were obtained by diffusion of *n*-hexane into a $CHCl_3$ solution at room temperature. The molecular structure of **15** is shown in Figure 7. Selected bond lengths and angles are summarized in Table 1. Table 2 gives crystallographic details.

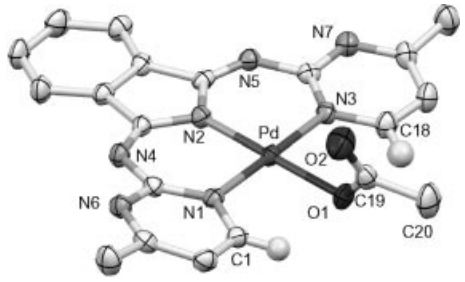


Figure 7. Molecular structure of (6-Me-bpmi)Pd(OAc) **15** in the solid state (most hydrogen atoms omitted for clarity; ellipsoids are set at the 50% probability level).

Complex **15** resides in the expected conformation for a mononuclear chelate, in that the methyl substituents of both pyrimidine rings point outwards. Other than for **12** the coordination environment of the $Pd^{II}$ ion of **15** is close to planar, and the N1–Pd–N3– and N2–Pd–O1–angles are almost linear with 178.81(10)° and 177.59(9)°, respectively. Related values in the (trpy)Pd series usually indicate a *helical* conformation of the organic chelate ligand.[10a,10b,10f,10g] For **15** a new conformation, the concave twist (with respect to the orientation of the acetate group; Figure 7), is observed. With angles between mean squares planes of the pyrimidine(N1) and pyrimidine(N3) subunits and the N1,N2,N3 plane of only 11.06(15)° and 3.36(15)°, respectively, the heterocycles are only slightly tilted away. The Pd–N (1.958(2)–2.060(2) Å] and Pd–O1 distances (2.033(2) Å] are intermediate to those observed for the bpi complexes **12** and **14**, and the typical shortness of the Pd–N2 bond is observed for **15**, too. **15** is thus another example for the structural diversity of bai complexes.

Two rationals may be considered for the exclusive formation of a mononuclear and monomeric species in the reaction of **11** with palladium acetate. First, the outwards pointing methyl groups might interfere with the coordination of a second equivalent of the metal carrier, and secondly, **15** is devoid of a ionic trigger. The first argument appears improbable due to the fact that the same steric encumbrance is present at the peripheral coordination site of the tetranuclear dimer **13**. For the second, more probable argument one has to consider that the monomeric and mononuclear species from **13**, $[(6\text{-Me-bpi*})Pd(OAc)]^-$, which is the formal *C* bonded analog of **15**, carries a negative charge that promotes the binding of another cation.

## Conclusions

In summary we have prepared a set of related (bai)-$Pd^{II}$(OAc) complexes and characterized them in solution and in the solid state with respect to their propensity for intramolecular C–H and C–C activation in dependence of intramolecular strain. In the majority of cases classical, though strained Werner type coordination compounds were found. Despite their constitution from $sp^2$ centres the bai ligands show a remarkable flexibility that allows to adapt smoothly to coordinative constraints and dissipates much of the strain energy to the ligand backbone. As a second coordination mode C–H activation has been observed in a tetranuclear dimer. This outcome of the metalation reaction appears feasible if the rotation of one pyridyl ring is sufficiently supported by the sterics. The comparative study with a pyrimidine derived ligand unraveled, that the binding of a second palladium(II) ion occurs most probably *after* the C–H activation step and becomes a favourable process mainly due to charge balance. Thus the second cation supports the selective formation of a cyclopalladated product mainly indirectly by the formation of a neutral dimer with a low solubility.

## Experimental Section

**General:** All reagents and solvents were purchased from commercial sources. Reagents were used as received. Solvents were dried by standard methods and stored under an argon atmosphere. NMR spectra were obtained on a Bruker ARX 300 or DRX 400 spectrometer in the solvents indicated below. Mass spectra were recorded on a VG Tribid or a Varian CH7 (EI, 70 eV), a Bruker Biflex IV (MALDI), a Qstar Pulsar i (HR-MALDI) or a Ionspec Ultima (ESI) instrument. *m*/*z* values are given for the most abun-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

dant isotopes only. UV/Vis spectra were measured on a Shimadzu UV1601PC in the range from 200–1100 nm. For X-ray crystallographic measurements an IPDS-I (Stoe) was used. All structures were solved using "*SHELXS*, Program for Crystal Structure Determination"[14] and refined with "*SHELXL*, Program for Crystal Structure Refinement".[15] The solvent in the structure of **13** was removed using the program SQUEEZE in PLATON.[16] CCDC-639805 to -639808 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

**Syntheses of 1,3-Bis(arylimino)isoindolines H(bai) 10 and 11. General Procedure:** Phthalodinitrile (**1**) (2.56 g, 20 mmol), heterocyclic amine **6** or 7 (50 mmol) and anhydrous calcium chloride (0.22 g, 2 mmol) are suspended in 1-butanol and heated to reflux for 44 h (**10**) or 168 h (**11**). The solvent is removed in vacuo to leave a yellowish residue. For **10** this solid is extracted with dichloromethane, filtered and recrystallized by the addition of *n*-hexane to leave a yellow solid. For **11** chromatography on silica with THF/pentane (1:3, then 2:1), followed by recrystallization from THF/pentane (1:1) produces a clean, yellow material.

**1,3-Bis(3,6-dimethyl-2-pyridylimino)isoindoline (10):** Yield 4.40 g (62%), m.p. 140–142 °C. $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 2.42 (s, 6 H, $CH_3$), 2.43 (s, 6 H, $CH_3$), 6.86 (d, $^3J$ = 7.6 Hz, 2 H, 5-$CH_{Py}$), 7.46 (d, $^3J$ = 7.6 Hz, 2 H, 4-$CH_{Py}$), 7.62–7.68 (m, 2 H, β-CH), 8.02–8.07 (m, 2 H, α-CH), 12.3 (s br, 1 H, NH) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 17.2, 24.1, 119.5, 122.2, 126.9, 131.5, 136.0, 139.2, 151.8, 154.2, 158.2 ppm. MS (EI): *m*/*z* = 355 [M$^+$], 249 ([M – $C_7H_8N$]$^+$), 235 ([M – $C_7H_8N_2$]$^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ = 237, 286, 384 nm. $C_{22}H_{21}N_5$ (355.436): calcd. C 74.34, H 5.96, N 19.70; found C 74.18, H 5.82, N 19.43.

**1,3-Bis(4-methyl-2-pyrimidinylimino)isoindoline (11):** Yield 0.50 g (7%), m.p. >200 °C. $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 2.58 (s, 6 H, $CH_3$), 6.96 (d, $^3J$ = 5.1 Hz, 2 H, 5-$CH_{Pm}$), 7.67–7.70 (m, 2 H, β-CH), 8.08–8.12 (m, 2 H, α-CH), 8.62 (d, $^3J$ = 5.1 Hz, 2 H, 4-$CH_{Pm}$), 13.3 (s br, 1 H, NH) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 24.3, 116.5, 123.1, 132.5, 135.8, 156.4, 157.5, 165.1, 168.8 ppm. HRMS (ESI) calcd. for $C_{18}H_{15}N_7Na$: 352.1281; obs. 352.1281, Δ = 0.0 mmu. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ = 265, 337, 350 nm.

**Syntheses of Acetatopalladium(II) Chelates 12–15. General Procedure:** H(bai) **8**–**11** (0.1 mmol) and palladium acetate (44.9 mg, 0.2 mmol) are suspended in methanol (3 mL) and stirred at ambient temperature under a blanket of argon for 16 h. A solid separates, which is collected by filtration and washed extensively with methanol to leave the product as a red to orange solid.

**(bpi)Pd(OAc) 12:** Yield 35.3 mg (76%), m.p. >200 °C. $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 2.15 (s, 3 H, OAc), 7.13 (t, $^3J$ = 6.3 Hz, 2 H, $CH_{Py}$), 7.55–7.98 (m, 4 H, $CH_{Py}$, α-CH), 7.58–7.63 (m, 4 H, $CH_{Py}$, β-CH), 8.89 (m, 2 H, $CH_{Py}$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 24.8, 120.4, 122.4, 127.5, 131.7, 138.3, 139.7, 148.4, 152.1, 145.0, 172.7 ppm. MS (MALDI): *m*/*z* = 404 [[M – OAc]$^+$]. UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ = 241, 330, 434, 463 nm. $C_{20}H_{15}N_5O_2Pd$ (463.79): calcd. C 51.79, H 3.26, N 15.10; found C 51.60, H 3.25, N 15.07.

**(6-Me-bpi*)$_2$Pd$_4$(OAc)$_4$ (13):** Yield 30.2 mg (46%), m.p. >200 °C. $^1$H NMR (400 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 1.33 (s, 3 H, $CH_3$), 1.98 (s, 3 H, $CH_3$), 2.30 (s, 3 H, $CH_3$), 3.04 (s, 3 H, $CH_3$), 5.51 (d, $^3J$ = 8.3 Hz, 1 H, 5-$CH_{Py}$), 7.10 (d, $^3J$ = 7.6 Hz, 1 H, $CH'_{Py}$), 7.15 (d, $^3J$ = 8.3 Hz, 1 H, 1 H, 4-$CH_{Py}$), 7.32 (m, 1 H, β/β′-CH), 7.43 (d, $^3J$ = 7.3 Hz, 1 H, $CH'_{Py}$), 7.51 (m, 1 H, β/β′-CH), 7.67 (d, $^3J$ = 8.0 Hz, 1 H, α/α′-CH), 7.76 (t, $^3J$ = 7.6 Hz, 1 H, 4-$CH'_{Py}$), 7.87 (d, $^3J$ = 7.3 Hz, 1 H, α/α′-CH) ppm. $^1$H NMR (300 MHz, [D$_6$]DMSO, 25 °C): $\delta$ = 1.78 (s, 2 H), 1.91 (s, 2 H), 1.99 (s, 2 H), 2.87 (s, 3 H, $CH_3$), 3.19 (s, 3 H, $CH_3$), 6.94 (d, $^3J$ = 6.6 Hz, 1 H, $CH_{Py}$), 7.14 (d, $^3J$ = 7.3 Hz, 1 H, $CH'_{Py}$), 7.38 (d, $^3J$ = 8.0 Hz, 1 H, $CH'_{Py}$), 7.68–7.76 (m, 2 H, β,β′-CH), 7.87 (t, $^3J$ = 6.5 Hz, 1 H, $CH'_{Py}$), 8.02 (d, $^3J$ = 7.3 Hz, 1 H, α/α′-CH), 8.13 (d, $^3J$ = 6.6 Hz, 1 H, $CH_{Py}$), 9.13 (d, $^3J$ = 6.6 Hz, 1 H, α/α′-CH), 11.94 (br.s, 1 H) ppm. $^{13}$C{$^1$H} NMR (100 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 19.3, 21.9, 25.4, 26.2, 116.6, 118.1, 121.9, 122.5, 123.8, 124.0, 128.4, 130.9, 134.2, 138.3, 144.4, 154.9, 160.0, 182.3; due to the low solubility of the compound the signals for two quarternary carbon atoms were not detected ppm. MS (MALDI): *m*/*z* = 1253 ([M – OAc]$^+$), 598 ([M/2 – OAc]$^+$), 432 ([(6-Me-bpi*)Pd]$^+$). UV/Vis ($CH_2Cl_2$): $\lambda_{max}$ = 237, 306, 359, 458, 489 nm. $C_{48}H_{42}N_{10}O_8Pd_4$ (1312.59): calcd. C 43.92, H 3.23, N 10.67; found C 43.70, H 3.43, N 10.53.

**(3,6-Me$_2$-bpi)Pd(OAc) (14):** Yield 10.9 mg (21%), m.p. >200 °C. $^1$H NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 1.76 (s, 3 H, OAc), 2.59 (s, 6 H, $CH_3$), 2.60 (s, 6 H, $CH_3$), 6.84 (d, $^3J$ = 7.6 Hz, 2 H, $CH_{Py}$), 7.51–7.56 (m, 2 H, β-CH), 7.57–7.92 (m, 2 H, α-CH), 7.59 (d, $^3J$ = 7.3 Hz, 2 H, $CH_{Py}$) ppm. $^{13}$C{$^1$H} NMR (75 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 17.8, 23.5, 26.8, 121.3, 122.2, 129.6, 130.9, 137.7, 140.2, 152.6, 154.7, 159.2, 176.7 ppm. # Tetranuclear Nickel Complexes Composed of Pairs of Dinuclear $LNi_2$ Fragments Linked by 4,4′-Bipyrazolyl, 1,4-Bis(4′-pyrazolyl)benzene, and 4,4′-Bipyridazine: Synthesis, Structures, and Magnetic Properties

**Vasile Lozan,[a] Pavlo Y. Solntsev,[b] Guido Leibeling,[c] Konstantin V. Domasevitch,*[b] and Berthold Kersting*[a]**

**Keywords:** Macrocyclic ligands / Bipyrazolate ligands / Nickel / Polynuclear complexes / Magnetic properties

The ability of the ligands 4,4′-bipyrazolyl ($H_2bpz$), 1,4-bis(4′-pyrazolyl)benzene ($H_2bpzb$), and 4,4′-bipyridazine (*bpdz*) to link two dioctahedral $LNi_2$ units has been examined. The following complexes were prepared: $[L^1Ni^{II}_2(Hbpz)][BPh_4]$ (**6**$[BPh_4]$), $[L^1Ni^{II}_2(bpdz)][ClO_4]_2$ (**7**$[ClO_4]_2$), $[(L^1Ni^{II}_2)_2(bpzb)][BPh_4]_2$ (**8**$[BPh_4]_2$), and $[(L^2Ni^{II}_2)_2(bpz)][BPh_4]_2$ (**9**$[BPh_4]_2$), where $(L^1)^{2-}$ and $(L^2)^{2-}$ represent macrocyclic hexaaza-dithiophenolate ligands. All complexes have been characterised by UV/Vis spectroscopy, IR spectroscopy, and X-ray crystallography. Whereas $(Hbpz)^-$ and *bpdz* in **6**$[BPh_4]_2$ and **7**$[ClO_4]_2$ act as bidentate ligands coordinating to only one $[LNi_2]^{2+}$ unit, in **8**$[BPh_4]_2$ and **9**$[BPh_4]_2$ the $(bpzb)^{2-}$ and $(bpz)^{2-}$ units are tetradentate linkers. This is qualitatively explained in terms of the absence or presence of steric repulsions between the *t*Bu groups of the supporting ligands and the length of the coligands. The structures of the tetranuclear complexes differ mainly in the distance between the center of the Ni···Ni axes of the isostructural $[LNi_2]$ units {14.040(1) Å in **8**$[BPh_4]_2$, 9.184(1) Å in **9**$[BPh_4]_2$}. The two $Ni_2$-pyrazolato planes in **9**$[BPh_4]_2$ are coplanar. An analysis of the temperature-dependent magnetic susceptibility data for **9**$[BPh_4]_2$ reveals the presence of weak ferromagnetic exchange interactions between the $Ni^{II}$ ions in the binuclear $[L^2Ni_2]$ subunits with values for the magnetic exchange constant $J_1$ of 23.97 $cm^{-1}$ ($\mathbf{H} = -2JS_1S_2$). The exchange coupling across the dipyrazolato bridge is less than 0.1 $cm^{-1}$, suggesting that no significant interdimer exchange coupling occurs in **9**$[BPh_4]_2$.

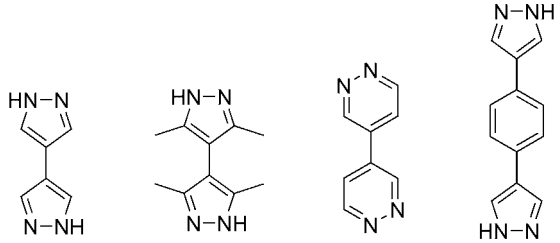
## Introduction

The coordination chemistry of the potentially quadridentate ligands 4,4′-bipyrazolyl ($H_2bpz$)[1,2] and its derivative 3,3′,5,5′-tetramethyl-4,4′-bipyrazolyl ($H_2Me_4bpz$)[3–6] has been studied in some detail, primarily due to their capability to form porous coordination polymers with potential uses as solid sorbents, ion exchangers or heterogeneous catalysts.[7–11] In this context, a large body of work has been carried out concerning the formation of polypyrazolate-based coordination networks with open framework structures.[12,13] It is surprising that such ligands have not yet been used in the construction of discrete polynuclear complexes. The oligonuclear $Pd_3$ and $Pd_4$ complexes reported by Yu et al. may serve as rather rare examples of this class of compounds.[14]



$H_2bpz$ $H_2Me_4bpz$ *bpdz* $H_2bpzb$

In previous work, we described a series of dinuclear transition-metal complexes of the macrocyclic $N_6S_2$ ligands $L^1$ and $L^2$ (Scheme 1).[15,16] These complexes have a rich coordination chemistry since the $[L^1M_2]^{2+}$ fragments are able to coordinate a large variety of coligands such as $Cl^-$,[15] $OH^-$,[17] $NO_2^-$, $NO_3^-$, $N_3^-$,[18] $BH_4^-$,[19] $ClO_4^-$, $ReO_4^-$, $SO_4^{2-}$, $MoO_4^{2-}$,[20] $MoO_3(OMe)^-$,[21] and various carboxylate anions.[16,22,23]

The magnetic properties of an isostructural series of bioctahedral $[L^1M^{II}_2(OAc)]^+$ complexes have also been reported.[24] In the $Mn^{II}_2$, $Fe^{II}_2$ and $Co^{II}_2$ complexes of this

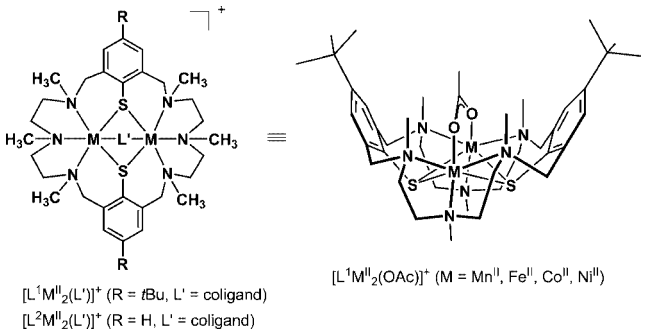


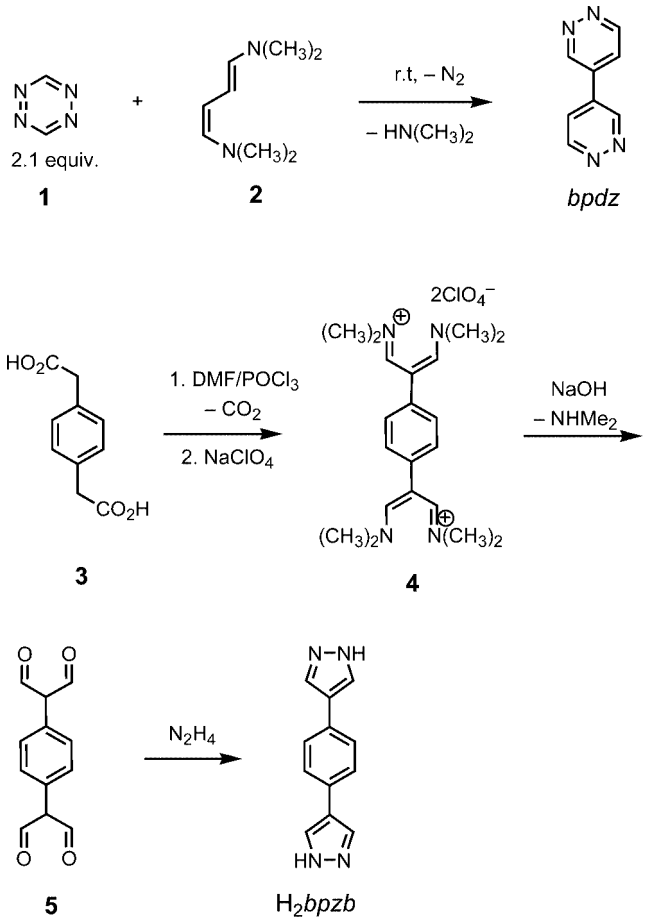
Scheme 1. Dinuclear complexes of the hexaaza-dithiophenolate ligands $(L^1)^{2-}$ and $(L^2)^{2-}$.

series intramolecular antiferromagnetic exchange interactions are present with $J$ values of –5.1, –10.6, and –2.0 $cm^{-1}$ ($\mathbf{H} = -2J\mathbf{S}_1\mathbf{S}_2$). For the corresponding $Ni^{II}_2$ complex, however, a ferromagnetic exchange interaction is observed ($J$ = +6.4 $cm^{-1}$). In view of the strong interest in the targeted design of molecular-based magnetic materials using high-spin molecules of higher nuclearity,[25–31] we have initiated a study on the synthesis of complexes in which pairs of exchange coupled $[L^1Ni_2]$ units are linked by 4,4′-bipyrazole ($H_2bpz$) and 1,4-bis(4-pyrazolyl)-benzene ($H_2bpzb$). The neutral ligand 4,4′-bipyridazine (*bpdz*) was also included in this study. We report herein the results of our investigation together with the single-crystal X-ray structure determination of the complexes $[L^1Ni^{II}_2(Hbpz)][BPh_4]$ (**6**[$BPh_4$]), $[L^1Ni^{II}_2(bpdz)][ClO_4]_2$ (**7**[$ClO_4$]$_2$), $[(L^1Ni^{II}_2)_2(bpzb)][BPh_4]_2$ (**8**[$BPh_4$]$_2$), and $[(L^2Ni^{II}_2)_2(bpz)][BPh_4]_2$ (**9**[$BPh_4$]$_2$). The results of temperature-dependent magnetic susceptibility measurements on $[(L^2Ni^{II}_2)_2(bpz)][BPh_4]_2$ (**9**[$BPh_4$]$_2$) are also described.

## Results and Discussion

### Synthesis of Ligands and Complexes

Of the N-heterocycles used in this study, only 4,4′-bipyrazolyl ($H_2bpz$) was reported previously.[1,2] Scheme 2 depicts the syntheses of the new compounds $H_2bpzb$ and *bpdz*. The Diels–Alder reaction of bright-red 1,2,4,5-tetrazine (**1**) with *cis*-/*trans*-1,4-bis(dimethylamino)butadiene (**2**) in a 2.1:1 ratio is accompanied by a vigorous evolution of dinitrogen and affords after thermal elimination of dimethylamine and recrystallization from methanol colourless 4,4′-bipyridazine (*bpdz*) in reasonable yields (39%). The route to $H_2bpzb$ began with a Vilsmeyer–Haack-type reaction of *p*-phenylenediacetic acid **3** with $POCl_3$/DMF to give the bis(trimethinium) salt **4**, which was isolated as its perchlorate salt.[32] Hydrolysis of **4** followed by treatment of the resulting tetraaldehyde **5** (not isolated) with hydrazine furnished the new dipyrazole derivative $H_2bpzb$ as thin white needles in good overall yield (78%). The new compounds were of sufficient purity for metal complex syntheses.



Scheme 2. Synthesis of the heterocycles $H_2bpzb$ and *bpdz*.

Attempts to link two $[L^1Ni_2]^{2+}$ units by a $(bpz)^{2-}$ dianion did not meet with any success. Treatment of $[L^1Ni_2Cl][ClO_4]$ with triethylammonium 4,4-bipyrazolate in methanol in varying molar ratios resulted always in the formation of the green 1:1 complex $[(L^1)Ni_2(Hbpz)][ClO_4]$ (**6**[$ClO_4$]), presumably as a result of the sterically demanding *tert*-butyl groups. Nickel complexes of the neutral *bpdz* ligand were found to be inaccessible from $[L^1Ni_2Cl][ClO_4]$. The substitution reaction succeeded only with the more labile perchlorato complex $[L^1Ni_2(ClO_4)][ClO_4]$, but again only 1:1 complexes formed. Thus, treatment of a dark green acetonitrile solution of $[L^1Ni_2(ClO_4)][ClO_4]$ with *bpdz* produced a brown-yellow solution, from which brown crystals of $[L^1Ni_2(bpdz)][ClO_4]_2$ (**7**[$ClO_4$]$_2$) could be isolated in 80% yield.

It was clear at this stage that tetranuclear $Ni_4$ complexes would only be accessible with longer bipyrazolyls or with less bulky $LNi_2$ precursor subunits. Indeed, reaction of $[L^1Ni_2Cl][ClO_4]$ with a 0.5 molar equivalent of $(bpzb)^{2-}$ (prepared in situ from $H_2bpzb$ and $NEt_3$) in methanol followed by addition of an exess of $LiClO_4$ and recrystallization from acetonitrile affords the green complex $[(L^1Ni_2)_2(bpzb)][ClO_4]_2$ (**8**[$ClO_4$]$_2$) in 76% yield. Similarly, reaction of $[L^2Ni_2Cl][ClO_4]$ with half a molar equivalent of $(bpz)^{2-}$ in methanol followed by addition of an excess of $LiClO_4$ fur-

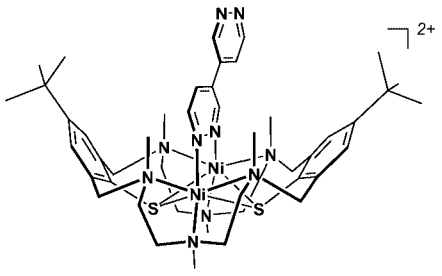
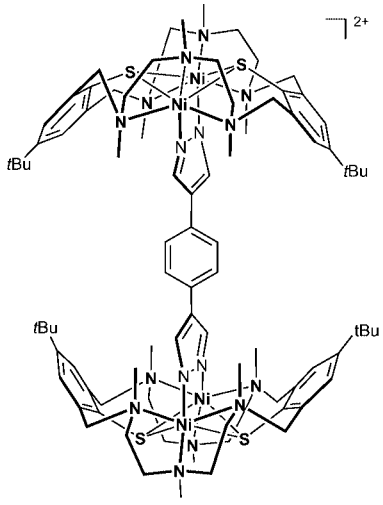
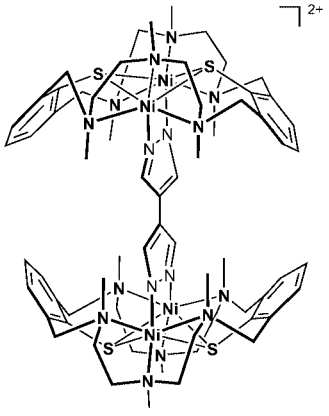
$[L^1Ni_2(Hbpz)]^+$ (**6**)



$[L^1Ni_2(bpdz)]^+$ (**7**)



$[(L^1Ni)_2(bpzb)]^{2+}$ (**8**)



$[(L^2Ni)_2(bpz)]^{2+}$ (**9**)

nished the tetranuclear species $[(L^2Ni_2)_2(bpz)][ClO_4]_2$ (**9**$[ClO_4]_2$) as a dark-green, air-stable solid. Complexes **8** and **9** were also isolated as tetraphenylborate salts.

All compounds gave satisfactory elemental analyses and were characterized by IR spectroscopy and UV/Vis spectroscopy, and compounds **6**$[BPh_4]\cdot 1.5MeCN$, **7**$[ClO_4]_2\cdot 3MeCN$, **8**$[BPh_4]_2\cdot 6MeCN\cdot 2H_2O$, and **9**$[BPh_4]_2\cdot 2CH_2Cl_2$ also by X-ray structure analysis.

## Characterization of the Complexes

### *Spectroscopic Characterization. IR and UV/Vis Spectroscopy*

The infrared spectra of all compounds display the bands expected for the macrocyclic ligands and counterions, but were not informative with respect to the conformations of the supporting or coligands. Only the band at 3385 $cm^{-1}$ in the IR spectrum of **6**$[BPh_4]$ can be attributed to the N–H stretching vibration of the protonated pyrazole moiety. The electronic absorption spectra of the nickel complexes have been recorded in the 300–1600 nm range in acetonitrile solution. The spectra of the pyrazolato complexes **6**, **8** and **9** display two weak absorption bands around 640 and 1190 nm typical of octahedral $Ni^{II}$ ($S = 1$) ions. The observed values closely compare with those of $[L^1Ni_2(pz)]^+$ (*pz* = pyrazolate)[18] indicative of $\mu_{1,2}$-bridging pyrazolate functions and pseudo-octahedral $N_4S_2$ coordination environments around the Ni atoms. The UV/Vis spectrum of the bipyridazine complex **7**$[ClO_4]$ is similar but not identical with that of **6**$[BPh_4]$, displaying two weak bands at 608 and 1100 nm. The corresponding absorptions in previously reported $[L^1Ni_2(pydz)]^{2+}$ (*pydz* = pyridazine)[18] were observed at 615 and 1095 nm. The slight differences in the position of the d-d transitions indicate that each complex retains its integrity in solution.

## X-ray Crystallography

Single-crystals of **6**$[BPh_4]\cdot 1.5MeCN$ were obtained by slow evaporation of a 1:1 acetonitrile/ethanol solution of **6**$[BPh_4]$. The crystal structure is composed of dinuclear $[L^1Ni_2(Hbpz)]^+$ cations, tetraphenylborate anions, and acetonitrile molecules of solvent of crystallization. An Ortep plot of the structure of complex **6** is depicted in Figure 1. Selected bond lengths and angles are summarized in Table 1. The bipyrazolato ligand acts only as a bidentate ligand towards one dinuclear $[L^1Ni^{II}_2]^{2+}$ unit through the ring atoms N(7) and N(8). The atoms N(9) and N(10) remain uncoordinated, but the hydrogen atom bonded to N(9) is involved in a hydrogen bonding interaction with an adjacent acetonitrile solvate molecule [N(9)···N(11)

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

2.975 Å]. The distance between the N atom of the acetonitrile and N(10) is 3.652 Å. The corresponding C–C, C–N, and N–N distances of the two five membered rings of the $(bpz)^{2-}$ dianion do not deviate significantly from each other; the largest difference being in the N–N bonds [N(7)–N(8) 1.384(2) Å, N(9)–N(10) 1.329(2) Å]. Note that the two heterocycles are not strictly coplanar. The dihedral angle between the two five-membered rings is 25.6°. The C(40)–C(42) bond is of length 1.472(2) Å indicative of a C–C single bond. The $[L^1Ni_2]^{2+}$ subunits in **6** and the compounds described below are structurally very similar, and the Ni–N and Ni–S distances lie within very narrow ranges (Table 1). The Ni···Ni distance is at 3.373(1) Å, which is nearly identical with that in $[L^1Ni_2(pz)][BPh_4]$ [3.389(1) Å].[18] Overall, this structure clearly shows that the bipyrazolate moiety cannot link two $[L^1Ni_2]^{2+}$ units. This can be attributed to the steric demand of the *t*Bu groups which hinder the formation of a tetranuclear complex. This assumption is nicely corroborated by the crystal structure determination of **9**$[BPh_4]_2$.

Figure 2 shows the structure of the dinuclear $Ni^{II}_2$ complex **7** in crystals of **7**$[ClO_4]_2$·3MeCN. Again, the 4,4′-bipyridazine ligand acts only as a bidentate group coordinating to only one bioctahedral $[L^1Ni_2]^{2+}$ entity through the ring nitrogen atoms N(7) and N(8). Metal complexes of 4,4′-bipyridazine have not been reported previously. The average $Ni–N_{pyridazine}$ bond length of 2.159(2) Å is significantly longer than the $Ni–N_{pyrazolate}$ distance in **6** [2.043(2) Å], implying that the neutral bipyridazine binds more weakly to the dinuclear $[L^1Ni_2]^{2+}$ fragment in **7** than

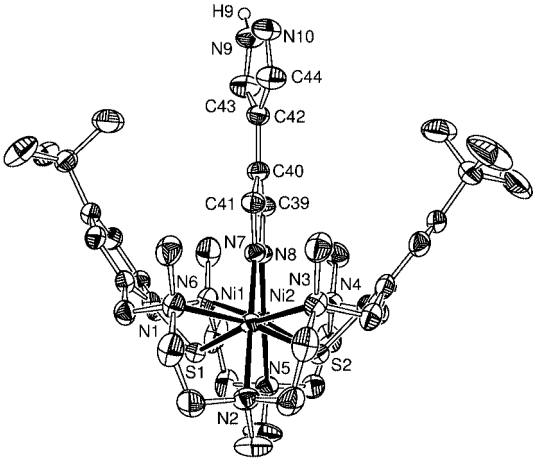


Figure 1. ORTEP representation of the structure of the $[L^1Ni^{II}_2(Hbpz)]^+$ cation in crystals of **6**$[BPh_4]$·1.5MeCN. Ellipsoids are represented at the 50% probability level. Hydrogen atoms except H(9) have been omitted for clarity.

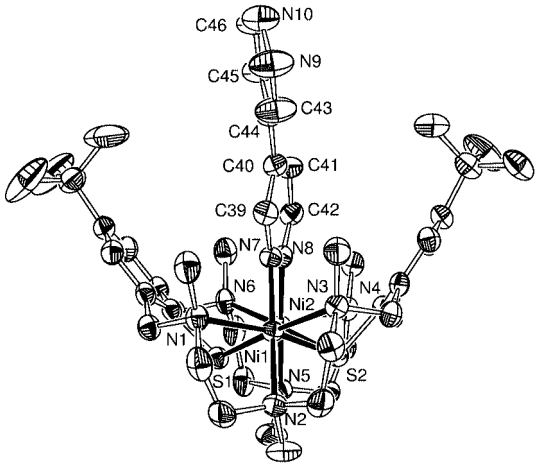

Figure 2. Structure of the $[L^1Ni^{II}_2(bpdz)]^{2+}$ dication in crystals of **7**$[ClO_4]_2$·3MeCN with thermal ellipsoids at the 50% probability level. Hydrogen atoms are omitted for reasons clarity.

does the charged pyrazolato ligand in **6**. A similar behaviour has been noted previously for $[L^1Ni_2(pydz)]^{2+}$ and $[L^1Ni_2(pz)]$.[18] As in **6**, the coordination of the pyridazine ring to the $Ni^{II}$ ions results in a slight elongation of the N–N bond length [N(7)–N(8) = 1.336(2) Å vs. N(9)–N(10) 1.366(2) Å]. Likewise, the two six-membered rings are also tilted by 25.2° with respect to each other. The Ni···Ni distance is at 3.401(1) Å.

Complex **8**$[BPh_4]_2$·6MeCN·$2H_2O$ crystallizes in the triclinic space group $P\bar{1}$ with six cocrystallized acetonitrile and two water molecules. The $[(L^1Ni_2)_2(bpzb)]^{2+}$ complex is centrosymmetric (Figure 3). Selected bond lengths and angles are summarized in Table 1. The structure of **8** unambiguously confirms the ability of the deprotonated 1,4-bis(4′-pyrazolyl)-benzene to link two $[L^1Ni^{II}_2]^{2+}$ units. The four six-coordinate Ni atoms are arranged in a rectangular fashion, the Ni···Ni distances being 3.349(1) Å [Ni(1)···Ni(2)] and 14.040(1) Å [Ni(1)···Ni(2′)], respectively. Note that the $Ni_2$pyrazolato planes are coplanar with each other, but that the central aromatic ring is slightly twisted out of this plane ($\tau$ = 23.8°). The metal–ligand bond lengths within the $[L^1Ni_2(pyrazolato)]^{2+}$ units reveal no anomalities and are very similar to those in **6** [Table 1]. There are no significant intermolecular interactions between the $Ni_4$ complexes. The shortest intermolecular Ni···Ni distance is at 7.806[1] Å.

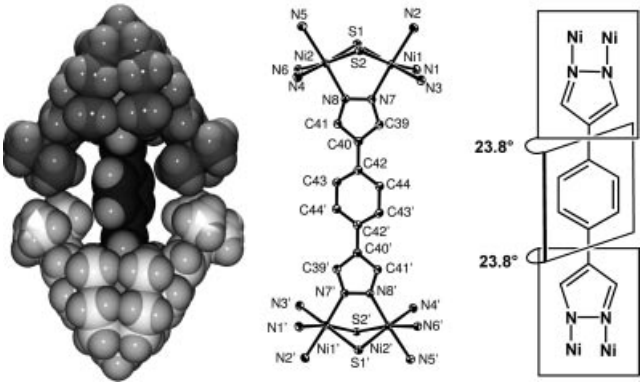

Figure 3. Left: Van der Waals plot of the $[(L^1Ni^{II}_2)_2(bpzb)]^{2+}$ dication in crystals of **8**$[BPh_4]_2$·6MeCN·$2H_2O$. Middle: ORTEP representation of the core structure of **8** with the atom labeling Scheme. Ellipsoids are represented at the 50% probability level. Symmetry code used to generate equivalent atoms: $1 - x$, $1 - y$, $1 - z$ (′). Right: Mutual orientation of the $Ni_2$pyrazolato planes in **8**.

Crystals of **9**$[BPh_4]_2$·$2CH_2Cl_2$ are triclinic, space group $P\bar{1}$. Ortep views of the structure of the dication **9** and the central core are provided in Figure 4. A selection of the most important bond lengths is given in Table 1. Again, **9** exhibits crystallographically imposed inversion symmetry. In striking contrast to **6**, the bipyrazolate moiety in **9** behaves as a tetradentate bridging ligand joining two binuclear $[L^2Ni_2]$ subunits, most likely as a consequence of the absence of the *tert*-butyl groups in $(L^2)^{2-}$. The bipyrazolate ligand assumes a planar conformation and the $Ni_2N_2$ planes are only slightly folded with respect to the bipyrazolato plane (folding angle: 165.4°). The Ni···Ni distance of 3.448(1) Å is the same as that in **6**. The distance *d* between the center of the Ni···Ni axes of the binuclear subunits amounts to 9.184(1) Å, which is significantly smaller than the corresponding distance in **8**. The bond lengths and angles around the Ni atoms within the $[L^2Ni_2]^{2+}$ unit reveal no unusual features. The average Ni–S, Ni–$N_{amine}$ and Ni–$N_{pyrazolato}$ distances are at 2.018(3), 2.291(3), and 2.517(1) Å, respectively. Virtually the same distances are seen in **6**. A large number of polymeric metal complexes containing bipyrazolato ligands have been structurally characterized;[2–7] to the best of our knowledge, **9** is the first discrete species of $(bpz)^{2-}$. Overall, this structure clearly shows that two bioctahedral $[L^2Ni_2]^{2+}$ units can be linked by bipyrazolate dianions.

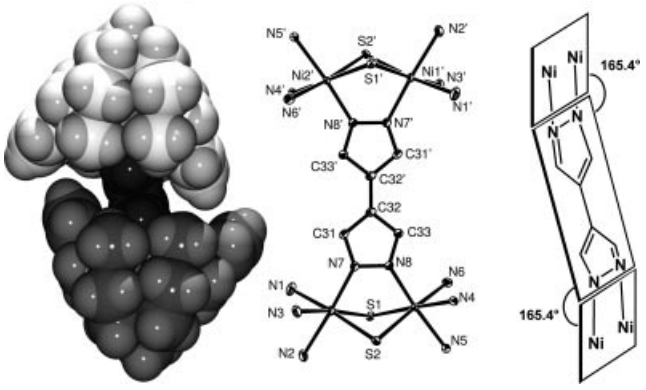

Figure 4. Left: van der Waals plot of the $[(L^2Ni^{II}_2)_2(\mu\text{-bipyrazolato})]^{2+}$ dication in crystals of **9**$[BPh_4]_2$·$2CH_2Cl_2$. Symmetry code used to generate equivalent atoms: $1 - x$, $2 - y$, $- z$ (′). Right: Tilting of the $Ni_2$pyrazolato planes in **9**.

## Magnetic Properties of 9$[BPh_4]_2$

To gain insight into the electronic structure of **9**$[BPh_4]_2$ variable-temperature magnetic susceptibility data were measured between 2.0 and 295 K by using a SQUID magnetometer in an applied external magnetic field of 0.2 T. Figure 5 shows a plot of the temperature dependence of the effective magnetic moment for **9**$[BPh_4]_2$. The effective magnetic moment increases from 6.75 $\mu_B$ at 295 K to a maximum value of 7.59 $\mu_B$ at 22 K. On lowering the temperature further the magnetic moment decreases to 6.97 $\mu_B$ at 2.0 K. Although the effective magnetic moment at 22 K is smaller than expected for the spin-only value of 9.84 $\mu_B$ for $S_T$ = 4 resulting from the ferromagnetic coupling of four $Ni^{II}$ ions ($S_i$ = 1, $g$ = 2.20), it is larger than the value of 6.22 $\mu_B$ calculated for four noninteracting $Ni^{II}$ ions. This behaviour indicates the presence of weak ferromagnetic exchange interactions between the $Ni^{II}$ ions in the binuclear subunits but negligible – if any – coupling across the bipyrazolate bridge. This is not surprising, considering the long distance between the nickel(II) ions.

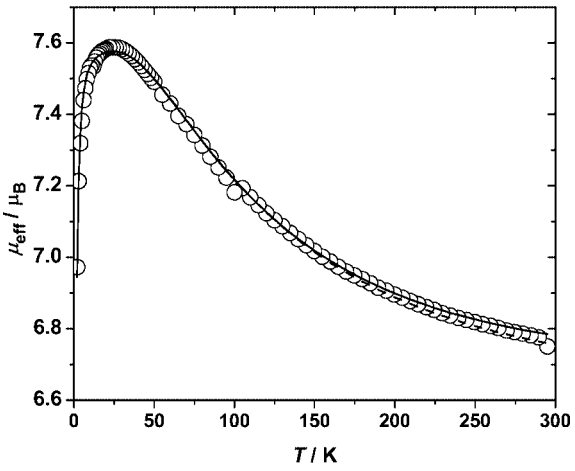

Figure 5. Temperature dependence of $\mu_{eff}$ (per tetranuclear complex) for **9**$[BPh_4]_2$. The full line represents the best theoretical fit to Equation (1). The dashed line represents the best fit to the dimer model in Equation (3).

The magnetic susceptibility data were fitted to Equation (1), where $\chi_{tetra}$ and $\chi_{mono}$ refer to the molar susceptibilities of a $Ni_4$ complex and a fraction $\rho$ of a mononuclear nickel(II) impurity with Curie constant $C = Ng^2\mu_B^2/3kT$.

$$\chi = \chi_{tetra}(1 - \rho) + 4\chi_{mono}\rho \quad (1)$$

The molar magnetic susceptibility $\chi_{tetra}$ was derived from the appropriate spin-Hamiltonian Equation (2) including the isotropic HDVV exchange, the single-ion zero-field splitting and the single-ion Zeeman interaction by a full-matrix diagonalization approach.

$$H = -2J_1(\hat{S}_1 \cdot \hat{S}_2 + \hat{S}_3 \cdot \hat{S}_4) - 2J_2(\hat{S}_1 \cdot \hat{S}_3 + \hat{S}_1 \cdot \hat{S}_4 + \hat{S}_2 \cdot \hat{S}_3 + \hat{S}_2 \cdot \hat{S}_4) + \sum_{i=1}^{4}[D_i(\hat{S}_{iz}^2 - \tfrac{1}{3}S_i(S_i+1)) + g_i\mu_B S_{i\tau}B_\tau] \ (\tau = x, y, z) \quad (2)$$

In this model $J_1$ represents the exchange interaction between the $Ni^{2+}$ ions within the dinuclear subunit, whereas $J_2$ describes the interaction across the bipyrazolate moiety. The $D$ and $g$ values were considered to be identical for all of the four $Ni^{2+}$ ions. Notice that D represents an effective zero-field splitting parameter, since in Equation (2) and Equation (4) the zero-field splitting tensors of all ions are assumed to be collinear. The least-squares fitting of the experimental data over the full temperature range led to $J_1$ = +24.0(1) $cm^{-1}$, $J_2$ = –0.001(5) $cm^{-1}$, $g$ = 2.19(1), $D$ = 4.8(2) $cm^{-1}$, and $\rho$ = 0.02(1)%. The inclusion of the $D$ parameter improves the low-temperature fit significantly, but it represents by no means an accurate value since temperature-dependent magnetic susceptibility measurements are not very appropriate for the determination of the sign and magnitude of $D$.[33,34] However, this analysis establishes clearly that magnetic exchange interactions via the dipyrazolate moiety are not significant ($J_2 < 0.1$ $cm^{-1}$) and that the magnetic properties of complex **9** are solely based on the exchange couplings in the binuclear $[L^2Ni_2(pyrazolate)]^+$ subunits. Therefore, we also tried to simulate the temperature dependence of the magnetic data by using an isotropic dimer model [Equation (3)] for two $Ni^{II}$ ($S$ = 1) ions based on the Hamiltonian in [Equation (4)].

$$\chi = 2[\chi_{dim}(1 - \rho) + 2\chi_{mono}\rho] \quad (3)$$

$$H = -2JS_1S_2 + \sum_{i=1}^{2}(D_i(\hat{S}_{zi}^2 - 1/3(S_i(S_i+1)) + g_i\mu_B S_{i\tau}B_\tau)) \ (\tau = x, y, z) \quad (4)$$

The magnetic data could be reproduced equally well by this approach (Figure 5), yielding $J_1$ = +24.14 $cm^{-1}$, $g$ = 2.19, $D$ = 4.85 $cm^{-1}$, and $\rho$ = 0.020%. Again, this analysis reveals a weak ferromagnetic coupling between the two $Ni^{II}$ ions. All of these values are in excellent agreement with those reported for other dinuclear nickel(II) complexes of $(L^1)^{2-}$ providing further support for the absence of significant interdimer exchange coupling in **9**$[BPh_4]_2$.[18,24]

It should be noted that there is much interest in the distance-dependence of superexchange interactions between paramagnetic transition metal ions bridged by extended organic spacer ligands. Thus, a large number of dicarboxylato-bridged copper(II) dimers with Cu···Cu separations of 5 to 15 Å have been prepared and their magnetic properties have been determined.[35–41] The magnetic exchange interactions decrease rapidly with increasing Cu···Cu separations and the experimentally determined $J$ values approach the values predicted by the Coffman–Buettner relation [$|J| \leq 1$ $cm^{-1}$ for $d$(M···M) $\geq$ 9 Å].[42] This finding also applies to other paramagnetic metal ions than Cu.[43] The observations made for the nickel(II) complexes presented herein are in good agreement with the reported trend. It is also worth mentioning that the coplanarity of the two $Ni_2$pyrazolato planes in **9** does not strengthen the magnetic exchange interactions via the bipyrazolate moiety.

## Conclusions

In summary, we presented the synthesis of two new heterocyclic $N_4$-ligands and the first members of a new class of tetranuclear nickel(II) complexes in which pairs of dinuclear $LNi_2$ fragments are united by $(bpz)^{2-}$ and $(bpzb)^{2-}$ groups. The isolation of the two dinuclear complexes **6** and **7** clearly show that the ease of formation of a tetranuclear cluster depends critically on two factors: (*i*) the length of the bridging coligand and (*ii*) the steric demand of the supporting ligand. If one pays attention to these two factors one can readily prepare higher nuclearity clusters such as **8** and **9**. These exist as stable and discrete complexes in solution and in the solid state as ascertained by various spectroscopic methods and X-ray crystallography. The $Ni_4$ complexes are well separated from each other in the solid state. The magnitude of the exchange interaction $J_2$ across the bipyrazolate was found to be less than 0.1 $cm^{-1}$, suggesting that no interdimer exchange coupling occurs in **9**. In this

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

sense the $LNi_2^{2+}$ fragments are ideally suited to screen novel extended bridging ligands for their ability to transmit magnetic exchange interactions between paramagnetic transitions metal ions.

## Experimental Section

**General Remarks:** Solvents and reagents were of reagent grade quality and used as received unless otherwise specified. The compounds 4,4′-bipyrazol,[2] $[L^1Ni^{II}_2Cl][ClO_4]$,[15] $[L^1Ni^{II}_2(ClO_4)][ClO_4]$,[20] and $[L^2Ni^{II}_2(Cl)][ClO_4]$[16] were prepared according to the literature procedures. Melting points were determined in capillaries and are uncorrected. IR spectra were measured on a Bruker VECTOR 22 FT-IR spectrophotometer as KBr pellets, electronic absorption spectra on a Jasco V-570 UV/Vis/near IR spectrophotometer. Elemental analysis were performed on a Vario EL analyzer (Elementaranalysensysteme GmbH). All metal complexes crystallize with solvent molecules (see crystal structures), but slowly lose their solvent molecules of crystallization upon standing in air. This is why the observed microanalytical data do not fit exactly with the calculated values (for the solvent-free compounds). Temperature-dependent magnetic susceptibility measurements on powdered solid samples were carried out on a SQUID magnetometer (MPMS Quantum Design) over the temperature range 2.0 –293 K. The magnetic field applied was 0.20 Tesla. The observed susceptibility data were corrected for underlying diamagnetism by using Pascal's constants.

***Safety Note: Caution!*** *Perchlorate salts of transition metal complexes are potentially hazardous and may explode. Only small quantities should be prepared and handled with great care.*

**4,4′-Bipyridazine (*bpdz*):** A solution of 12.31 g (0.15 mol) 1,2,4,5-tetrazine (**1**) in 150 mL of dry 1,4-dioxane was added dropwise for a period of 40 min to a stirred solution of 10.09 g (0.072 mol) of *cis-trans*-1,4-bis(dimethylamino)butadiene (**2**) in 60 mL of dry 1,4-dioxane. The immediate evolution of nitrogen gas and discoloration were accompanied with a pronounced exothermic effect. After the addition was completed, the red-brown reaction mixture was stirred at 80 °C for 4 h (elimination of dimethylamine) and then left overnight at room temp. The precipitate was filtered, washed with 5 mL $CH_2Cl_2$ and twice crystallized from methanol with charcoal yielding a pure product (4.44 g, 39%) as thin colorless needles. $^1$H NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 9.77 (s, 2 H, 3-CH), 9.37 (d, 2 H, 6-CH), 8.23 (dd, 2 H, 5-CH) ppm. $C_8H_6N_4$ (158.16): calcd. C 60.75, H 3.82, N 35.43; found C 60.44, H 3.89, N 35.17.

**1,4-Bis(4′-pyrazolyl)benzene. Intermediate 4:** 11.2 mL (0.12 mol) $POCl_3$ was added dropwise to 45 mL of dry DMF at 5–10 °C with constant stirring. The mixture was stirred for an additional hour at room temp. Then 3.88 g (20.0 mmol) solid *p*-phenylenediacetic acid (**3**) was added at once and the clear solution formed was stirred for 4 h at 90–95 °C and then at room temperature overnight. The resulting black mixture was poured on 100 g crushed ice. After decomposition of the excess Vilsmeyer reagent a saturated solution of 15.0 g $NaClO_4$ was added with stirring. The resulting nearly white crystalline deposit of the bis(trimethinium) diperchlorate (**4**[$ClO_4$]$_2$) was filtered and washed with two 15 mL portions of water. The yield was 8.21 g (79.5%). This compound was used in the next step without further purification. **Intermediate 5:** 8.22 g (15.6 mmol) of the perchlorate salt **4**[$ClO_4$]$_2$ were added to a warm solution of 3.45 g (86 mmol) NaOH in 20 mL water, and the mixture was heated with stirring for 7–8 min (bath temperature 90 °C) until total dissolution of the organic salt was observed. The yellow-colored mixture was cooled to room temp., diluted with 10 mL water and 10% HCl solution was added to pH = 5, leading to precipitation of the tetraaldehyde **5**. Then 5.0 mL hydrazine hydrate was added at once with stirring, which effects dissolution of **5** and after 15–20 min stirring at room temp. the dipyrazole $H_2$*bpzb* deposits as thin white needles. The mixture was left overnight and filtered to yield 3.22 g (98.5%) of the product. This compound was used for the preparation of the metal complexes without further purification.

**$[L^1Ni_2(H$*bpz*$)][ClO_4]$ (6[$ClO_4$]):** To a solution of $H_2$*bpz* (13.8 mg, 0.103 mmol) in methanol (30 mL) was added triethylamine (20 mg, 0.20 mmol). Complex $[L^1Ni_2Cl][ClO_4]$ (194 mg, 0.210 mmol) was added and the resulting yellow solution was stirred for 12 h. A solution of $LiClO_4 \cdot 3H_2O$ (160 mg, 1.00 mmol) in methanol (2 mL) was then added. After further stirring for 12 h, the green precipitate was filtered, washed with cold ethanol, and dried in air. Yield: 80 mg (76%). M.p. 363–365 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3394 (m), 2961 (s), 2867 (s), 1629 (w), 1463 (s), 1394 (w), 1363 (w), 1311 (w), 1265 (w), 1236 (w), 1203 (w), 1151 (m), 1078 [vs, $\nu_3(ClO_4^-)$], 1057 (s), 1041 (s), 1008 (w), 914 (m), 882 (w), 825 (m), 754 (w), 657 (w), 626 [m, $\nu_4(ClO_4^-)$], 563 (w), 535 (w), 492 (w), 461 (w), 418 (w). UV/Vis ($CH_3CN$): $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$ cm$^{-1}$) = 385 (1064), 634 (13), 1187 (24).

**$[L^1Ni_2(H$*bpz*$)][BPh_4]$ (6[$BPh_4$]):** To a solution of **6**[$ClO_4$] (102 mg, 0.100 mmol) in methanol (50 mL) was added a solution of $NaBPh_4$ (342 mg, 1.00 mmol) in methanol (50 mL). The reaction mixture was allowed to stir for 3 h. The green product was filtered, washed with ethanol, and dried in air to give 113 mg (91%) of **6**[$BPh_4$] as a green, air-stable, microcrystalline powder. M.p. 295–297 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3384 (m), 3123 (w), 3054 (m), 3032 (m), 2963 (s), 2858 (s), 1944 (w), 1877 (w), 1815 (w), 1764 (w), 1622 (w), 1580 (w), 1524 (w), 1462 (s), 1425 (m), 1393 (m), 1363 (m), 1309 (w), 1265 (m), 1235 (m), 1201 (w), 1169 (w), 1151 (w), 1126 (w), 1075 (m), 1040 (s), 1006 (w), 928 (w), 912 (m), 881 (w), 824 (m), 733 [s, $\nu(BPh_4^-)$], 704 [s, $\nu(BPh_4^-)$], 628 (m), 611 (m), 562 (w), 534 (w), 492 (w), 467 (w), 430 (w), 417 (w). UV/Vis ($CH_3CN$): $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$ cm$^{-1}$) = 382 (1037), 634 (14), 1182 (24). $C_{68}H_{89}BN_{10}Ni_2S_2$ (1238.83): calcd. C 65.93, H 7.24, N 11.31, S 5.18; found C 65.50, H 7.53, N 11.00, S 4.96. Single crystals of **6**[$BPh_4$]·1.5MeCN suitable for X-ray structure analysis were grown by slow evaporation of an ethanol/acetonitrile solution of **6**[$BPh_4$]. These crystals slowly lose the solvent molecules of solvent of crystallization at ambient temperature and become turbid.

**$[L^1Ni_2($*bpdz*$)][ClO_4]_2$ (7[$ClO_4$]$_2$):** To a solution of $[L^1Ni_2Cl][ClO_4]$ (92 mg, 0.10 mmol) in methanol (30 mL) was added solid Pb($ClO_4$)$_2$ (80 mg, 0.20 mmol). The color of the reaction mixture immediately turned from yellow to dark green. The reaction mixture was stirred for 5 min, filtered off from $PbCl_2$, and to the dark-green filtrate was added a solution of *bpdz* (7.9 mg, 0.050 mmol) in acetonitrile (5 mL) to give a brown-yellow solution. The solution was kept at room temperature for three days during which time brown crystals separated. These were isolated by filtration, washed with a little amount of cold methanol, and dried in air. Yield: 91 mg (80%). M.p. 297–298 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3433 (m), 2962 (s), 2868 (s), 2250 (w), 2017 (w), 1603 (w), 1581 (m), 1464 (s), 1395 (m), 1364 (m), 1310 (m), 1267 (m), 1235 (m), 1199 (w), 1094 [vs, $\nu_3(ClO_4^-)$], 912 (m), 887 (m), 850 (w), 824 (s), 755 (w), 688 (w), 669 (w), 624 [s, $\nu_4(ClO_4^-)$], 566 (w), 538 (w), 494 (w), 440 (w), 414 (w) cm$^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$/nm ($\varepsilon$/M$^{-1}$ cm$^{-1}$) = 608 (47), 1094 (51). $C_{46}H_{70}Cl_2N_{10}Ni_2O_8S_2$ (1143.53): calcd. C 48.31, H 6.17, N 12.25, S 5.61; found C 48.25, H 5.98, N 11.95, S 5.32. The crystals of **7**[$ClO_4$]$_2$·3MeCN used for an X-ray structure determination were picked from the mother liquor.

**[($L^1Ni_2$)$_2$(*bpzb*)][$ClO_4$]$_2$ (**8**[$ClO_4$]$_2$):** To a solution of $H_2$*bpzb* (21 mg, 0.10 mmol) in methanol (50 mL) and triethylamine (20 mg, 0.20 mmol) was added solid [$L^1Ni_2Cl$][$ClO_4$] (184 mg, 0.200 mmol). The mixture was stirred for 3 d during which time the colour of the suspension changed from yellow to green. A solution of $LiClO_4 \cdot 3H_2O$ (320 mg, 2.00 mmol) in methanol (10 mL) was added. After stirring for 1 d, the green precipitate was collected by filtration, washed several times with cold ethanol and dried in air. Yield: 150 mg (76%). M.p. 342–343 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3431 (s), 2962 (s), 2866 (s), 1630 (w), 1579 (w), 1462 (s), 1395 (w), 1363 (w), 1310 (w), 1266 (w), 1233 (m), 1201 (w), 1150 (m), 1121 (s), 1077 [vs, $\nu(ClO_4^-)$], 1057 (s), 1041 (s), 1000 (w), 956 (w), 928 (w), 913 (w), 881 (w), 826 (m), 807 (w), 754 (w), 625 [m, $\nu_4(ClO_4^-)$], 564 (w), 535 (w), 493 (w), 413 (w) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$/nm ($\varepsilon$/$M^{-1}cm^{-1}$) = 380 (4989), 627 (57), 1195 (132).

**[($L^1Ni_2$)$_2$(*bpzb*)][$BPh_4$]$_2$ (**8**[$BPh_4$]$_2$):** To a solution of **8**[$ClO_4$]$_2$ (198 mg, 0.100 mmol) in methanol (50 mL) was added a solution of $NaBPh_4$ (684 mg, 2.00 mmol) in methanol (10 mL). The reaction mixture was allowed to stir for 1 h, and the volume of the solution reduced in vacuo to about 30 mL. The green product was filtered, washed with ethanol and dried in air to give 189 mg (78%) of **8**[$BPh_4$]$_2$ as a green, air-stable, microcrystalline powder. M.p. 350–351 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3435 (s), 3054 (m), 3027 (m), 2963 (s), 2866 (s), 1636 (w), 1579 (w), 1480 (m), 1462 (s), 1395 (w), 1363 (w), 1310 (w), 1266 (w), 1233 (m), 1201 (w), 1169 (w), 1152 (w), 1122 (w), 1108 (w), 1076 (m), 1056 (m), 1042 (s), 1000 (w), 956 (w), 928 (w), 912 (w), 881 (w), 825 (s), 733 [s, $\nu(BPh_4^-)$], 704 [s, $\nu(BPh_4^-)$], 629 (w), 612 (m), 564 (w), 535 (w), 492 (w), 445 (w) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$/nm ($\varepsilon$/$M^{-1}cm^{-1}$) = 381 (4626), 631 (53), 1190 (112). $C_{136}H_{176}B_2N_{16}Ni_4S_4$ (2419.62): calcd. C 67.51, H 7.33, N 9.26, S 5.30; found C 66.92, H 7.39, N 9.15, S 4.82. Single crystals of **8**[$BPh_4$]·6MeCN·$2H_2O$ suitable for X-ray structure analysis were grown by slow evaporation of an ethanol/acetonitrile solution of **8**[$BPh_4$].

**[($L^2Ni_2$)$_2$(*bpz*)][$ClO_4$]$_2$ (**9**[$ClO_4$]$_2$):** To a solution of $H_2$*bpz* (13.4 mg, 0.100 mmol) in methanol (30 mL) was added triethylamine (20 mg, 0.20 mmol). Complex [$L^2Ni_2Cl$][$ClO_4$] (162 mg, 0.200 mmol) was slowly added resulting in the immediate formation of a green precipitate. After the addition was complete, further $LiClO_4 \cdot 3H_2O$ (320 mg, 2.00 mmol) dissolved in methanol (2 mL) was added, and stirring was continued for additional 12 h. The green product was collected by filtration, washed several times with cold methanol, and dried in air. Yield: 123 mg (73%). M.p. 340–341 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3521 (m), 2969 (s), 2855 (s), 2245 (w), 2017 (w), 1628 (w), 1587 (m), 1487 (s), 1454 (s), 1435 (s), 1396 (m), 1364 (w), 1350 (w), 1298 (m), 1268 (s), 1254 (m), 1200 (w), 1170 (m), 1095 [vs, $\nu_3(ClO_4^-)$], 1042 (s), 999 (m), 956 (w), 916 (s), 897 (w), 828 (s), 806 (m), 764 (s), 727 (w), 670 (m), 655 (w), 623 [s, $\nu_4(ClO_4^-)$], 566 (w), 537 (w), 489 (w), 462 (w), 433 (w), 412 (w) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$/nm ($\varepsilon$/$M^{-1}cm^{-1}$) = 294 (23213), 380 (3785), 635 (66), 1178 (91).

**[($L^2Ni_2$)$_2$(*bpz*)][$BPh_4$]$_2$ (**9**[$BPh_4$]$_2$):** To a warm solution of **9**[$ClO_4$]$_2$ (168 mg, 0.100 mmol) in methanol (50 mL) was added a solution of $NaBPh_4$ (342 mg, 1.00 mmol) in methanol (100 mL). The reaction mixture was allowed to stir for 3 h. The green microcrystalline precipitate was filtered, washed with ethanol and dried in air yielding 186 mg (88%) of **9**[$BPh_4$]$_2$ as a green powder. M.p. 335–336 °C (decomp.). IR (KBr): $\tilde{\nu}$ = 3523 (w), 3054 (m), 2984 (s), 2854 (s), 2247 (w), 1634 (w), 1586 (m), 1484 (m), 1463 (s), 1435 (s), 1396 (m), 1364 (m), 1350 (w), 1337 (w), 1297 (m), 1267 (s), 1255 (m), 1200 (w), 1169 (m), 1095 (s), 1075 (s), 1041 (s), 998 (m), 956 (m), 916 (s), 896 (m), 827 (s), 806 (m), 761 (s), 732 [s, $\nu(BPh_4^-)$], 704 [s, $\nu(BPh_4^-)$], 669 (m), 623 (s), 612 (m), 565 (w), 536 (w), 488 (w), 465 (w), 433 (w), 412 (w) $cm^{-1}$. UV/Vis ($CH_3CN$): $\lambda_{max}$/nm ($\varepsilon$/$M^{-1}cm^{-1}$) = 294 (27244), 376 (4504), 637 (63), 1183 (111). $C_{114}H_{140}B_2N_{16}Ni_4S_4$ (2119.09): calcd. C 64.61, H 6.66, N 10.58, S 6.05; found C 62.79, H 6.81, N 11.43, S 5.92. Single crystals of **9**[$BPh_4$]$_2$·$2CH_2Cl_2$ suitable for X-ray structure analysis were grown by recrystallization from dichloromethane.

**Collection and Reduction of X-ray Data:** Suitable single crystals of **6**[$BPh_4$]·1.5MeCN, **7**[$ClO_4$]$_2$·3MeCN, **8**[$BPh_4$]$_2$·6MeCN·$2H_2O$, and **9**[$BPh_4$]$_2$·$2CH_2Cl_2$ were selected and mounted on the tip of a glass fibre using perfluoropolyether oil. The data sets were collected at 213(2) K using a STOE IPDS-2T diffractometer. Graphite-mono-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) was used throughout. The data were processed with the program STOE X-AREA.[44] Selected details of the data collection and refinement are given in Table 2. The structures were solved by direct methods[45] and refined by full-matrix least-squares techniques on the basis of all data against $F^2$ using SHELXL-97.[46] PLATON was used to search for higher symmetry.[47] All non-hydrogen atoms were refined anisotropically. H atoms were placed at calculated positions and refined as riding atoms with isotropic displacement parameters.

Some of the solvate molecules in **6** and **7** were found to be disordered or only partially occupied. In the crystal structure of **6**$[BPh_4]_2$·1.5MeCN the occupancy factor of one MeCN was reduced to 0.5. In the crystal structure of **7**$[BPh_4]_2$·6MeCN·$2H_2O$ the water molecule was found to be disordered over two sites. The respective orientations were refined by using a split atom model to give site occupancy factors of 0.59(1) [O(1a)] and 0.41(1) [for O(1b)]. Water hydrogen atoms were not included in the refinement. Graphics were produced with Ortep3 for Windows.[48]

CCDC-641207 (for **2**), -641208 (for **3**), -641209 (for **4**), and -641210 (for **5**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre via www.ccdc.cam.ac/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Experimental and calculated magnetic values susceptibility data for **9**$[BPh_4]_2$.

## Acknowledgments

We sincerely thank the Deutsche Forschungsgemeinschaft (DFG) (priority program 1137 "Molecular Magnetism") for funding of this work. We are grateful to Prof. Dr. F. Meyer for providing facilities for magnetic susceptibility measurements.

# The Influence of Steric Pressure on the Structure of Homodimetallic Rhodium(I) and Iridium(I) Complexes Containing a Bis(bidentate) Phosphane Ligand

**Christian Bachmann,[a] Rene Gutmann,[a] Georg Czermak,[a] Alexander Dumfort,[a] Sylvia Eller,[a] Markus Fessler,[a] Holger Kopacka,[a] Karl-Hans Ongania,[b] and Peter Brüggeller*[a]**

**Keywords:** X-ray diffraction / Chelates / Phosphane ligands / Iridium / Rhodium

Fifteen novel homodimetallic $Rh^I$ and $Ir^I$ complexes containing the bis(bidentate) phosphane ligand *cis*,*trans*,*cis*-1,2,3,4-tetrakis(diphenylphosphanyl)cyclobutane (dppcb) were prepared and characterized by NMR spectroscopy ($^1H$, $^{13}C\{^1H\}$, $^{31}P\{^1H\}$), mass spectrometry, IR spectroscopy, elemental analyses and melting points. Furthermore, the solid-state structures of seven of these new compounds were fully determined by single-crystal X-ray diffraction analyses to study the influence of steric pressure. The precursor complex $[Rh_2(\eta^4\text{-cod})_2(dppcb)]X_2$ (**1**), $X^- = BF_4^-$, $PF_6^-$, $SbF_6^-$, completely characterized by its X-ray structure, smoothly reacts with mono- or bidentate ligands containing phosphorus or nitrogen donor atoms. Thus, monophosphanes and monophosphites produce compounds of the structure type $[Rh_2L_4(dppcb)](SbF_6)_2$ [L = $PMe_2Ph$, **2**; $PMePh_2$, **3**; $P(OMe)_3$, **5**; $P(OPh)_3$, **6**]. The X-ray structures of **3** and **6** show that $PMePh_2$ and $P(OPh)_3$ are capable of compensating steric interactions. The treatment of **1** with diphosphanes leads to the structure type $[Rh_2L_2(dppcb)](SbF_6)_2$ [L = bis(diphosphanyl)-methane, dppm, **7**; bis(diphenylphosphanyl)amine, dppam, **8**; 1,2-bis(diphenylphosphanyl)ethane, dppe, **9**; *cis*-1,2-bis(diphenylphosphanyl)ethene, *cis*-dppen, **10**]. The X-ray structures of **8**, **9** and **10** clearly indicate the onset of steric pressure as a consequence of mechanical coupling, which results in two different coordination moieties for homodimetallic species **9** and **10**. Under steric pressure, the quadrant effects of dppcb and dppe become comparable to $Rh^I$ complexes. The use of mono- or bidentate ligands containing nitrogen donor atoms leads to the compounds $[Rh_2(pyridine)_4(dppcb)](SbF_6)_2$ (**11**), $[Rh_2(2,2'\text{-bipyridine})_2(dppcb)](SbF_6)_2$ (**12**) and $[Rh_2(1,10\text{-phenanthroline})_2(dppcb)](SbF_6)_2$ (**13**). The crystal structures of **1** and the novel complex $[Ir_2(\eta^4\text{-cod})_2(dppcb)]X_2$ (**14**), $X^- = BF_4^-$, $SbF_6^-$, are isomorphous. However, it was only possible to produce restricted examples of derivatives of **14** owing to the reluctance of **14** to release cod. Thus, monophosphanes lead to the five-coordinate species $[Ir_2(\eta^4\text{-cod})_2(PMe_2Ph)_2(dppcb)](BF_4)_2$ (**15**), whereas the four-coordinate compound $[Ir_2(PMePh_2)_4(dppcb)](BF_4)_2$ (**16**) is formed by using the sterically more demanding ligand $PMePh_2$ instead of $PMe_2Ph$.

## Introduction

Only recently was it shown that the efficiency of catalysts containing bidentate or bis(bidentate) phosphanes is strongly determined by the flexibility of their backbones.[1–3] This influence of the backbone can be seen in different catalytic applications like the copolymerization of carbon monoxide and ethene,[1] the oxidative carbonylation of styrene[2] and the Schulz–Flory oligomerization of ethene.[3] The common feature of these different kinds of homogeneous catalysis is that square-planar complexes are thought to be responsible for the catalytic activity.[1–3] By contrast, it is well-known that in the case of hydroformylation the catalytically active species is a trigonal bipyramidal hydrido rhodium complex, which usually contains two phosphorus donor ligands.[4] Because the whole catalytic cycle for the hydroformylation reaction consists of five-coordinate species,[4] the enlargement in the coordination number relative to the above square planar catalysts certainly increases the steric pressure.[5]

In this context, steric pressure is defined as the sum of intramolecular steric interactions keeping the coordination geometry and/or conformation of a certain complex virtually intact.[5] This means that the onset of steric pressure enforcing intramolecular contact approaches also changes the quadrant effect[1–3] in square planar species because the quadrant diagrams usually depend on the spatial distributions of the phenyl groups present in bidentate or bis(bidentate) phosphanes (see below, Figure 3). A certain intramolecular steric pressure only allows distinct spatial distri-

butions of these phenyl rings and hence controls the quadrant effect. Thus, steric pressure is important to determine the structure of the resultant complexes and steers their catalytic activity by the quadrant effect.[1–3]

Therefore, in this work, the onset of steric pressure is studied in a series of X-ray structures of novel square planar homodimetallic $Rh^I$ species containing the bis(bidentate) phosphane *cis*,*trans*,*cis*-1,2,3,4-tetrakis(diphenylphosphanyl)cyclobutane (dppcb) prepared in our laboratory.[6] It seemed to us especially interesting to see if the rigidity of the backbone of dppcb is enough to provide the same usual quadrant effect,[1–3] which shows one axial and one equatorial phenyl group at each phosphorus centre, even under "steric pressure". In the case of dppcb, the onset of intramolecular steric interactions leads to excellent photochemical and photophysical properties of six-coordinate homodimetallic $Ru^{II}$ compounds.[7,8] However, in general, sterically congested five-coordinate complexes of $Rh^I$ are rare and/or unstable towards the loss of the fifth ligand.[9] In contrast, a typical situation for carbonylation catalysis is that starting square planar compounds lead to five-coordinate species.[9,10] Therefore, a subtle choice of the steric requirements of further ligands should make it possible to observe a change in the usual conformation of the cyclobutane backbone of dppcb also in square planar $Rh^I$ complexes, which would result in a different quadrant effect. This study should shed light on the question of whether there is sufficient flexibility in the ligand backbone of dppcb to allow easy access to all intermediates in the catalytic carbonylation cycle.[11]

## Results and Discussion

### Synthesis of Complexes

$[Rh_2(\eta^4\text{-cod})_2(dppcb)]X_2$ (**1**), $X^- = BF_4^-$, $PF_6^-$, $SbF_6^-$ (Figure 4), was prepared by a reported procedure for the in situ generation of a coordinatively unsaturated species $[Rh(\eta^4\text{-cod})(acetone)_2]X$ from the chlorido-bridged dirhodium complex $[RhCl(\eta^4\text{-cod})]_2$.[12] Treatment of $[Rh(\eta^4\text{-cod})(acetone)_2]X$ with dppcb leads to **1** in excellent yield. The use of different anions was necessary, as only the $BF_4^-$ salt yielded single crystals suitable for X-ray structure analysis, $PF_6^-$ is the only innocent counterion under the planned catalytic hydroformylation conditions, and only the $SbF_6^-$ form of **1** produced further derivatives in excellent yield. The exchange of these anions was carried out by utilizing the corresponding silver salt.[12]

The apparent simple cod substitution from **1** makes it a suitable precursor complex.[13] Thus, **1** smoothly reacts with the monophosphane $PMe_2Ph$ to give $[Rh_2(PMe_2Ph)_4(dppcb)](SbF_6)_2$ (**2**, see Figure 1). However, in the case of the sterically more demanding monophosphane $PMePh_2$, not only the main product (Figure 1) $[Rh_2(PMePh_2)_4(dppcb)](SbF_6)_2$ (**3**) was formed, but also the known homoleptic complex[12b] $[Rh(PMePh_2)_4](SbF_6)$ (**4**), which was produced in a side reaction and isolated in a pure form (Figure 1). The formation of homoleptic species depending on the steric demands of the involved ligands is typical for this kind of reaction.[13] However, the use of the sterically congested monophosphane $PPh_3$ and **1** leads to a fast equilibrium between the different compounds as evidenced from the resulting $^{31}P\{^1H\}$ NMR spectrum; no product could be isolated.

Figure 1. Structure types observed in Rh and Ir complexes.

Phosphanes can be sterically and electronically modified.[14] Because the propensity for incremental tuning is crucially important in catalysis,[14] we successfully extended the reaction sequence above to phosphites, diphosphanes and mono- and bidentate nitrogen ligands (see complexes **5**–**13** in Figures 1 and 2). Only this synthetic effort made it possible to obtain a series of X-ray structures containing increasingly sterically more-demanding ligands and to study their fine tuning of the conformation of dppcb. It was especially hoped that the onset of steric pressure could lead to different coordination units within these homodimetallic species.

In the case of $Ir^I$, the analogous reaction sequence leading to **1** was unsuccessful. However, as observed previously[15] for a comparable synthesis, it was possible to perform the direct reaction of dppcb with the chlorido-bridged

Figure 2. Structure types observed in Rh and Ir complexes.

diiridium complex $[IrCl(\eta^4\text{-cod})]_2$ and $[Ir_2Cl_2(\eta^4\text{-cod})_2$-(dppcb)] resulted in excellent yield. Subsequent treatment with AgX produced $[Ir_2(\eta^4\text{-cod})_2(dppcb)]X_2$ (**14**), $X^-$ = $BF_4^-$, $SbF_6^-$ (see Figure 1).[15]

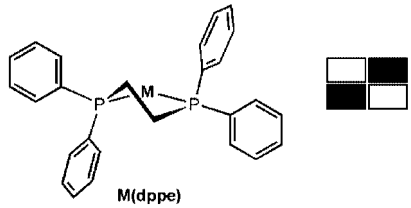
Analogous to **1**, only the $BF_4^-$ salt of **14** yielded single crystals that were suitable for X-ray structure analysis; the crystal structures of **1** and **14** are isomorphous. However, synthetic difficulties appeared when **14** was used as a precursor complex for further derivatives in its $BF_4^-$ as well as $SbF_6^-$ forms. Similar observations were made when other chelating ligands were treated with iridium precursor complexes and even under harsh conditions it was not possible to displace the remaining cod ligand; decomposition occurred instead.[11] This is in agreement with the higher degree of metal-to-cod bonding and back-bonding in the iridium complexes than in the rhodium complexes and hence with the greater stability of the Ir–cod compounds.[16] Because the ligand exchange reactions observed in $Rh^I$ and $Ir^I$ systems are likely to proceed by associative mechanisms,[13] **14** smoothly reacts with the monophosphane $PMe_2Ph$ to give the five-coordinate species $[Ir_2(\eta^4\text{-cod})_2(PMe_2Ph)_2$-$(dppcb)](BF_4)_2$ (**15**, see Figure 2). Pentacoordinated structures containing cod are well-known for $Ir^I$;[17] they are much more stable than the $Rh^I$ complexes (compare analogous complexes **2** and **15** in Figures 1 and 2).

However, the greater steric pressure of $PMePh_2$ leads to the displacement of cod in **14** and the four-coordinate compound $[Ir_2(PMePh_2)_4(dppcb)](BF_4)_2$ (**16**, Figure 1) is formed.

Interestingly, the substitutional lability of 1,5-cod versus triorganophosphane ligands does not play any role in the clean synthesis of **1** or **14**, though this lability is consistent with predictions that are based on hard–soft acid–base theory where the soft olefin ligand is replaced preferentially by a soft triorganophosphane donor.[18] However, as a consequence of the intrinsic problem of pentacoordination in the $Ir^I$ case it was not possible to obtain the same series of complexes as for those of $Rh^I$, which reflected increasing steric pressure.

## Comparison of the Quadrant Effects in Complexes of dppe and dppcb

Conformations and quadrant diagrams for M(dppe) and $M_2$(dppcb) complexes are shown in Figure 3.[19] The conformation adopted by the phenyl groups in dppe complexes is noticeably different from that for the dppcb ligand. In terms of the quadrant effect, the steric crowding provided by the phenyl groups is diagonally disposed with respect to the coordination plane in the dppe derivatives. By contrast, this steric crowding is usually concentrated on one side of the coordination plane in the dppcb complexes owing to spatial distributions of the phenyl substituents on the phosphorus donors so that the two axial phenyl rings are located on the same side of the coordination plane.[2,19] However, it is clear that the conformations shown in Figure 3 are only the borderline cases.



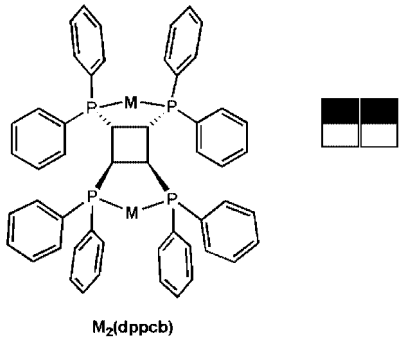


Figure 3. Quadrant effects in complexes of dppe and dppcb.

Especially for $M_2$(dppcb), a centrosymmetric structure is depicted where each coordination unit contains two axial and two equatorial phenyl groups. This conformation is typical for homodimetallic species of dppcb without steric pressure.[1–3,6,20] The distances of the *ipso* carbon atoms of the phenyl substituents from the coordination planes clearly define axial, equatorial and diagonal dispositions (see Figure 3). Thus, the influence of the onset of steric pressure on the idealized $M_2$(dppcb) conformation in Figure 3 can be directly measured.

### Isomorphous X-ray Structures of $[M_2(\eta^4\text{-cod})_2(dppcb)](BF_4)_2$ [M = Rh (1), Ir (14)]

It is well-known that the time-averaged preferred conformations of the five-membered metallarings in complexes of type **1** (see Figure 1) are dictated by the nature of the bidentate or bis(bidentate) phosphane ligand.[2] The X-ray structure of **1** (see Figure 4) clearly reveals that only the phenyl groups attached to P(2) show axial and equatorial spatial distributions with respect to the coordination plane.

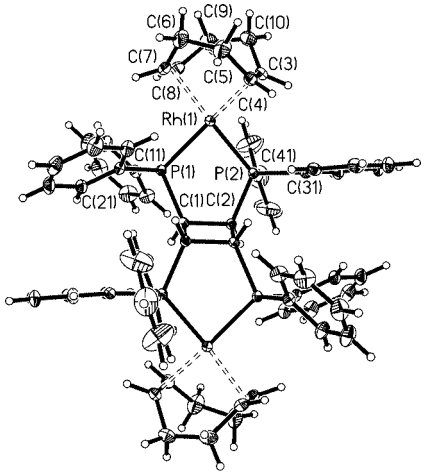

Figure 4. View of the cation of $[Rh_2(\eta^4\text{-cod})_2(dppcb)](BF_4)_2$ (**1**). The atom labelling scheme is shown.

The diagonal disposition of the phenyl substituents at P(1) is characteristic of dppe.[2,19,21] This difference is shown by the deviations of the four *ipso* carbon atoms C(11), C(21), C(31) and C(41) of –1.177(4), 1.650(4), 0.187(5) and –2.079(5) Å, respectively, from the coordination plane defined by the atoms Rh(1), P(1) and P(2) and the centres of gravity of the cod double bonds (see Figure 4).[22] The largest deviations for C(21) of 1.650(4) Å and for C(41) of –2.079(5) Å indicate that the diagonal quadrants are more hindered (see Figures 3 and 4). Obviously the steric pressure introduced by cod is already enough to change the usual quadrant effect of $M_2$(dppcb) in Figure 3. The atoms and centres of gravity ($C_g$) defining the coordination plane are tetrahedrally distorted, as shown by the deviations from this plane: Rh(1) 0.038(2) Å, P(1) 0.267(2) Å, P(2) –0.289(2) Å, $C_{g1}$ 0.284(3) Å, $C_{g2}$ –0.301(3) Å.

It was shown that short intramolecular contacts due to steric pressure in homodimetallic complexes of dppcb change their photochemical and photophysical properties.[7,8] In the case of **1**, this steric pressure is clearly responsible for the observed unusual quadrant effect. Thus, in **1** the shortest intramolecular contact between the phenyl rings along a *trans* axis of the cyclobutane ring is C(22)···H(46B) of 2.988 Å. Furthermore, the hydrogen atoms attached to the double bonds of cod (see Figure 4) also show pronounced intramolecular interactions with adjacent phenyl groups: H(3A)···H(42A) 2.980 Å, H(4A)···H(36A) 2.475 Å, H(7A)···H(22A) 2.764 Å, H(8A)···H(12A) 2.558 Å. As a consequence, the C=C bonds of the cod ring are not coordinated perpendicular to the P(1)–Rh(1)–P(2) plane and a dihedral angle of 22.5(1)° with the $C_{g1}$–Rh(1)–$C_{g2}$ plane occurs. In **1**, the distortion from an ideal square-planar coordination is larger than that in $[Rh(\eta^4\text{-cod})\{CH_2P(C_6H_4\text{-}SiMe_2CH_2CH_2C_6F_{13}\text{-}p)_2\}_2](BPh_4)$ with a corresponding dihedral angle of 13.1°,[21] though the steric crowding of the latter complex is considerable. A further indication of steric pressure in **1** is the significantly different Rh–C distances,[21,23] where selected bond lengths and angles of **1** and **14** are given in Table 1.

Table 1. Selected bond lengths [Å] and angles [°] for **1** and **14**.

| Compound **1** | | Compound **14** | |
|---|---|---|---|
| Rh(1)–P(1) | 2.2797(7) | Ir(1)–P(1) | 2.2775(13) |
| Rh(1)–P(2) | 2.2671(7) | Ir(1)–P(2) | 2.2815(13) |
| Rh(1)–C(3) | 2.264(3) | Ir(1)–C(3) | 2.192(6) |
| Rh(1)–C(4) | 2.227(3) | Ir(1)–C(4) | 2.242(6) |
| Rh(1)–C(7) | 2.276(3) | Ir(1)–C(7) | 2.200(5) |
| Rh(1)–C(8) | 2.234(3) | Ir(1)–C(8) | 2.225(6) |
| C(3)–C(4) | 1.368(5) | C(3)–C(4) | 1.360(11) |
| C(7)–C(8) | 1.361(6) | C(7)–C(8) | 1.396(9) |
| P(1)–Rh(1)–P(2) | 83.65(2) | P(1)–Ir(1)–P(2) | 84.45(4) |

However, these Rh–C distances are significantly shorter than in *cis*-$[Rh(\eta^4\text{-cod})\{Me_2Si(\mu\text{-}NtBu)_2PCH_2\}_2](BF_4)$ with an average Rh–C distance of 2.305(6) Å.[14] The latter long rhodium–carbon bonds were interpreted in terms of an increased steric repulsion between the bis(phosphane) and the cyclooctadiene moieties.[14] Obviously, in **1** the steric pressure is efficiently released by a suitable distortion of the square-planar coordination together with a suitable spatial distribution of the phenyl substituents leading to an unusual quadrant effect for homodimetallic species of dppcb.

The structures of **1** and **14** fulfill the criteria of the same ligands, the same coordination number and geometry, isomorphous crystal lattices and equal experimental conditions, and, therefore, allow an exact comparison of their geometric features.[24] The quadrant effect in **14**, given by the deviations of the four *ipso* carbon atoms C(11), C(21), C(31) and C(41) of –1.169(5), 1.647(5), 0.217(6) and –2.080(5) Å, respectively, from the coordination plane defined as above, is nearly identical to **1**. The same is true for the tetrahedral distortion of the coordination plane, as shown by the deviations from this plane: Ir(1) 0.032(2) Å, P(1) 0.272(2) Å, P(2) –0.289(2) Å, $C_{g1}$ 0.297(3) Å, $C_{g2}$ –0.311(3) Å and the resulting dihedral angle defined as above of 23.0(1)°. Also, the steric pressure of **14** is comparable to **1** (see above): C(22)···H(46B) 2.982 Å, H(3A)···H(42A) 2.908 Å, H(4A)···H(36A) 2.417 Å, H(7A)···H(22A) 2.729 Å, H(8A)···H(12A) 2.602 Å. However, the mean value of the significantly shorter Ir–C distances (see Table 1) of 2.196(4) Å in **14** is significantly shorter than the corresponding parameter of 2.231(2) Å in **1**. Analogously, the mean value of the significantly longer Ir–C distances of 2.234(4) Å is significantly shorter than the corresponding parameter of 2.270(2) Å in **1**.

Olefins such as cod are generally considered to be rather weakly binding ligands.[11] However, the possibility of a preorganization of the metal binding site leads to the formation of especially stable complexes and the olefin is not dis-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

placed in the catalytically active species.[11] It was shown above in the cases of **1** and **14** that a reorganization of dppcb, which results in the coordination of cod, produces a suitable quadrant effect and a tetrahedrally distorted coordination sphere that are responsible for the tighter binding of cod. As a consequence, the C=C bond lengths of cod are elongated in these complexes, which is normal for diene complexes of this type.[16] The mean values of the cod double bond lengths are 1.365(4) Å in **1** and 1.378(7) Å in **14**. Thus, the bond lengthening in the iridium complex is slightly more pronounced, which is in agreement with its higher degree of metal-to-ligand bonding and back-bonding.[16] This is in line with the significantly longer mean value of the M–centroid distances of 2.145(2) Å in **1** relative to the corresponding parameter of 2.105(4) Å in **14**. Though the M–cod *trans* influence is smaller than the M–C *trans* influence of organic groups,[25] the significantly longer M–centroid mean value in **1** produces a significantly shorter mean value of the M–P bond lengths of 2.2734(5) Å in **1** versus 2.2795(9) Å in **14**. The use of weakly bonded olefins as leaving groups is wide-spread for rhodium catalysts.[26] The M–C distances in **1** and **14** are located within the typical range of 2.1–2.3 Å.[15,17,18,27] However, the significantly longer mean value of the M–centroid distances in **1** than in **14** nicely corresponds to the fact that cod is easily displaced in the case of **1**, whereas difficulties appear using **14** as a precursor complex as a result of the five-coordinate species that still contains cod.

### X-ray Structures of $[Rh_2(PMePh_2)_4(dppcb)](SbF_6)_2$ (3), $[Rh(PMePh_2)_4](SbF_6)$ (4) and $[Rh_2\{P(OPh)_3\}_4(dppcb)](SbF_6)_2$ (6)

To confirm the observation that steric pressure changes the quadrant effect in homodimetallic species of dppcb such as **1** and **14**, a series of X-ray structures showing increasing steric pressure were analyzed. Figure 5 clearly shows that in **3** the phenyl rings at P(1) are diagonally disposed with respect to the coordination plane, whereas the phenyl groups attached to P(2) show axial and equatorial spatial distributions. This means that the quadrant effect in **3** is similar to **1** and **14** (compare with Figure 4). In all cases, this influence on the quadrant effect by conformational restraints can be referred to as mechanical coupling in analogy to the concept of molecular mechanics strain energy.[28] As in the field of molecular mechanics, mechanical coupling refers to the energy terms associated with bond stretches, bond angle bends, torsional deformations, van der Waals and electrostatic interactions.[28]

Obviously, the steric pressure imposed by cod in **1** and **14** is comparable to two $PMePh_2$ moieties in **3**. Thus, the deviations of the four *ipso* carbon atoms C(11), C(21), C(31) and C(41) from the coordination plane defined by the atoms Rh(1), P(1), P(2), P(3) and P(4) are –1.175(6), 1.534(5), 0.237(5) and –2.022(6) Å, respectively (see Figure 5). These deviations are almost identical to the corresponding parameters of **1** and **14** (see above), where the largest deviations for C(21) of 1.534(5) Å and for C(41) of –2.022(6) Å again indicate that the diagonal quadrants are more hindered. Also, in **3** the coordination plane is tetrahedrally distorted, as shown by the deviations from this plane: Rh(1) 0.008(1) Å, P(1) 0.303(1) Å, P(2) –0.305(1) Å, P(3) 0.261(1) Å, P(4) –0.267(1) Å.

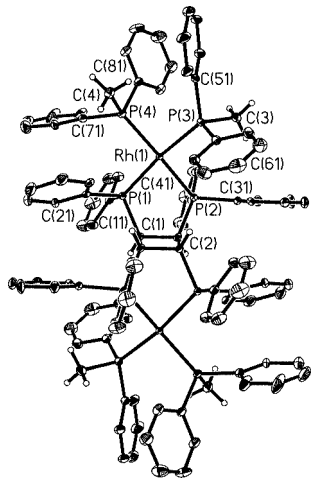

Figure 5. View of the cation of $[Rh_2(PMePh_2)_4(dppcb)](SbF_6)_2$ (**3**). The atom labelling scheme is shown. Hydrogen atoms attached to the phenyl rings are omitted for clarity.

Although alternative ligand conformations are undoubtedly accessible in solution, the solid-state structures presented in this work exhibit trends which are consistent with steric effects exerting an important influence on reactivity.[19] In the case of **3**, the occurrence of steric pressure leads to isolable side product **4**. The evidence of steric crowding in **3**, which is comparable to **1** and **14**, again stems from short intramolecular contact approaches. Thus, the shortest intramolecular contact between the phenyl rings along a *trans* axis of the cyclobutane ring is C(33)···H(22B) of 3.080 Å. The shortest intramolecular contact between the dppcb and $PMePh_2$ moieties is H(46A)···H(86A) of 2.449 Å and the shortest intramolecular contact between the $PMePh_2$ moieties is H(4B)···C(56) of 2.554 Å. As in the cases of **1** and **14**, the steric pressure in **3** is partly released by a dihedral angle of 20.7(1)° between the P(1)–Rh(1)–P(2) and P(3)–Rh(1)–P(4) planes.

The formation of homoleptic complexes such as **4** is typical for the reaction type leading to **3**.[13] In general, the amount of tetrahedral distortion in cations $[(phosphane)_4Rh]^+$ can be rationalized as a compromise between the preferred square planar arrangement of a $d^8$ transition-metal centre and the steric repulsion of the four $PR_2$ groups.[13] In Figure 6 this tetrahedral distortion can be clearly seen for **4**.

The crystal structure of **4** consists of two slightly different conformations and shows dihedral angles defined as above between *cis* P–Rh–P planes of 34.5(1)° and 31.2(1)°, respectively. The Rh–P bond lengths in the two conformations of **4** are significantly shorter than the Rh–$PMePh_2$ distances in **3** (see Table 2). This is in line with a better release of steric pressure in **4** than in **3**, where also the elec-

tronic bite angle effect of dppcb could play a part.[4] The Rh–P bond lengths of **4** are in between the average of the equatorial Rh–P bond lengths of 2.308 Å and the corresponding axial parameter of 2.337(2) Å in the distorted trigonal bipyramidal $[RhH(PMePh_2)_4]$.[29] Distortions of the square planar structure like in **4** for example, also in the case of chlorotris(triphenylphosphane)rhodium(I), are well-known.[18]

It was recognized that the quadrant effect in **1**, **3** and **14** is nearly identical and shows axial and equatorial phenyl rings attached to one phosphorus atom and diagonally disposed phenyl groups attached to the other. However, further enhancement in the steric pressure as a result of the introduction of $P(OPh)_3$ leads to a change in the quadrant effect in **6**. Thus, in **6** the deviations of the four *ipso* carbon atoms C(11), C(21), C(31) and C(41) from the coordination plane defined by the atoms Rh(1), P(1), P(2), P(3) and P(4) are 0.620(5), –1.945(5), 1.480(5) and –1.394(6) Å, respectively (see Figure 7). This means that in contrast to **1**, **3** and **14**, no typical equatorial phenyl ring is present in **6** and, rather, the spatial distributions of the phenyl substituents resemble pseudoequatorial, pseudoaxial and diagonal dispositions, respectively.[22] However, the largest deviations for C(21) of –1.945(5) Å and for C(31) of 1.480(5) Å are still in line with more hindered diagonal quadrants as in the cases **1**, **3** and **14** (see Figures 3 and 7). In **6**, the coordination plane is again tetrahedrally distorted, where the deviations from this plane are: Rh(1) 0.028(1) Å, P(1) –0.180(1) Å, P(2) 0.163(1) Å, P(3) –0.171(1) Å, P(4) 0.160(1) Å.

For comparable (diphosphane)rhodium compounds it was found that structures determined by X-ray methods in the solid state and structures characterizing the ensembles of molecules in solution are congruent within the limits of error.[30] This means that a change in the quadrant effect observed in the solid state is important for active catalysts derived from precatalysts such as **1**. Also, in **6** short intramolecular contact approaches are responsible for the observed conformation leading to a change in the quadrant effect compared with **1**, **3** and **14**. The shortest intramolecular contact between the phenyl rings along a *trans* axis of the cyclobutane ring is C(34)···H(26B) of 2.910 Å. The shortest intramolecular contact between the dppcb and $P(OPh)_3$ moieties is H(16A)···H(6BA) of 2.591 Å and the shortest intramolecular contact between the $P(OPh)_3$ moieties is H(1BA)···H(4BA) of 2.604 Å. However, the dihedral angle of 12.4(1)° between the P(1)–Rh(1)–P(2) and P(3)–Rh(1)–P(4) planes in **6** is significantly smaller than the corresponding parameters in **1**, **3** and **14**. This means that the steric pressure in **6** is better released by a change in the quadrant effect of dppcb than by a strong tetrahedral distortion of the coordination plane.

### X-ray Structures of $[Rh_2(dppam)_2(dppcb)](SbF_6)_2$ (8), $[Rh_2(dppe)_2(dppcb)](SbF_6)_2$ (9) and $[Rh_2(cis\text{-}dppen)_2(dppcb)](SbF_6)_2$ (10)

To the best of our knowledge, the X-ray structures of **8**–**10** are the first X-ray structural characterizations of rhodi-

um(I) complexes with two different chelating phosphanes. Of course, the difficulty in preparing and crystallizing these compounds stems from a further enhancement of steric pressure. As a consequence, dppcb could show the ability to form different coordination sites within homodimetallic species. This may have implications for their potential use as dimetallic catalysts, comparable to the ability of dimetallic systems with $M_2P_4$ units containing bis[{(diphenylphosphanyl)ethyl}phenylphosphanyl]methane to move between open and closed bridged forms.[25] Indeed, Figures 8, 9 and 10 clearly show that the stronger steric pressure in **9** and **10**, which contain 5–5–4–5–5-membered ring systems compared with **8** that contains a 4–5–4–5–4-membered ring system, produces two different coordination sites in **9** and **10**, respectively. As all X-ray structures presented in this study show no strong intermolecular contacts or no obvious packing effect, we may assume as a first approximation that the forces on the molecule in solution are of the same order of magnitude as those in the solid.[31] Though the crystallographic restraints are strong for structures **1**, **3**, **6**, **8** and **14** because of the presence of centres of symmetry in the middle of the cyclobutane rings, this means that centrosymmetric conformations are also available in solution for these structures. By contrast, it seems likely that **9** and **10** crystallizing in different space groups not only show noncentrosymmetric structures in the solid state, but also in solution.

Interestingly, the quadrant effect of dppcb in **8** is similar to **1**, **3** and **14**. Thus, the phenyl groups attached to one phosphorus atom show axial and equatorial spatial distributions, whereas a diagonal disposition occurs for the phenyl substituents of the other phosphorus atom (see Figure 8).

This is clearly reflected in the deviations of the four *ipso* carbon atoms C(11), C(21), C(31) and C(41) of –0.164(5), 1.912(5), 1.368(5) and –1.253(5) Å, respectively, from the coordination plane defined by the atoms Rh(1), P(1), P(2), P(3) and P(4). However, the largest deviations for C(21) of 1.912(5) Å and for C(31) of 1.368(5) Å concentrate the steric crowding now on one side of the coordination plane (see Figures 3 and 8). The atoms defining this least-squares plane are again tetrahedrally distorted, as shown by the deviations from this plane: Rh(1) 0.025(1) Å, P(1) 0.185(1) Å, P(2) –0.196(1) Å, P(3) 0.213(1) Å, P(4) –0.226(1) Å and the resulting dihedral angle defined as above of 16.9(1)°. Also, in this case short intramolecular contacts indicate steric crowding. The shortest contacts are 3.199 Å for H(22A)···

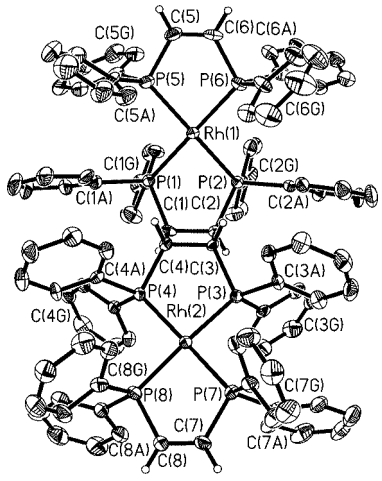

Figure 10. View of the cation of $[Rh_2(cis\text{-dppen})_2(dppcb)](SbF_6)_2$ (**10**). The atom labelling scheme is shown. Hydrogen atoms attached to the phenyl rings are omitted for clarity.

H(46B) along a *trans* axis of the cyclobutane ring and 2.540 Å for H(36A)···H(62A) between the dppcb and dppam moieties. However, the small four-membered chelate ring angle P(3)–Rh(1)–P(4) of only 69.90(4)° (see Table 3) moves the phenyl groups of dppam away from the rhodium centre, which reduces the overall steric pressure of **8**. In contrast to **9** and **10**, this could still allow a centrosymmetric conformation for **8**. Compound **8** shows only very weak hydrogen bonds between the located N–H hydrogen atoms of dppam and the $SbF_6^-$ counterions. This is nicely confirmed by the shorter N–H bond length of 0.74(4) Å (see Table 3) than in comparable complexes of dppam with strong hydrogen bonds (0.78–0.79 Å).[32] Furthermore, it is also in agreement with the values of **8** for $\nu$(N–H) and $\delta$(N–H) of 3330 and 1266 $cm^{-1}$, respectively.[33] It is well-known that π–π stacking of phenyl rings might play a role in tuning organometallic reactivity.[19] Though no crystallographic restraints influence the X-ray structures of **9** and **10**, these alignments of the phenyl groups can be seen in several cases in Figures 9 and 10.

Obviously, the steric pressure is so enormous in **9** and **10** that it is necessary to minimize steric tensions through this effect. This has dramatic consequences on the conformations of **9** and **10**. The envelope-foldings, defined as the angles between the least-squares planes through the chelating phosphorus and backbone carbon atoms of dppcb and through the chelating phosphorus atoms of dppcb and the rhodium atoms, are usually orientated towards the cyclobutane rings: 20.6(1)°, **1**; 30.7(1)°, **3**; 16.5(1)°, **6**; 31.8(1)°, **8**; 20.4(1)°, **14**. The same effect is present in **9** and **10** with regard to the Rh(1) atom: 38.1(2)°, **9**; 36.8(2)°, **10**. However, the analogous envelope-foldings for the Rh(2) centres in **9** and **10** are orientated away from the cyclobutane rings: 10.0(2)°, **9**; 11.8(2)°, **10**. This inverse envelope-folding is rare for homodimetallic species of dppcb and indicative of strong steric pressure.[7]

Indeed, the quadrant effects of dppcb become completely different for the two unequal coordination units of **9** and **10**, respectively (see Figures 9 and 10). In the cases of **9** and **10**, the phenyl rings attached to the phosphorus atoms of dppcb coordinating to the Rh(1) atoms show pseudoaxial and pseudoequatorial spatial distributions, as indicated by the deviations of the four *ipso* carbon atoms from the coordination planes defined as above: **9**, C(3A) –0.541(5) Å, C(3G) 1.653(5) Å, C(4A) –0.514(5) Å, C(4G) 1.670(5) Å; **10**, C(1A) –0.755(4) Å, C(1G) 1.619(4) Å, C(2A) –0.359(5) Å, C(2G) 1.786(5) Å. In both cases the steric crowding is concentrated on one side of the coordination plane as a result of the largest deviations for C(3G) of 1.653(5) Å and for C(4G) of 1.670(5) Å in the case of **9** and for C(1G) of 1.619(4) Å and for C(2G) of 1.786(5) Å in the case of **10** (see Figures 3, 9 and 10). In contrast, the phenyl substituents attached to the phosphorus atoms of dppcb coordinating to the Rh(2) centres unequivocally show diagonal dispositions, where the corresponding parameters are: **9**, C(7A) 1.599(5) Å, C(7G) –1.270(5) Å, C(8A) –1.373(5) Å, C(8G) 1.511(5) Å; **10**, C(3A) –1.116(5) Å, C(3G) 1.667(5) Å, C(4A) –1.446(4) Å, C(4G) 1.402(4) Å. The largest deviations corresponding to the Rh(2) centre in **9** for C(7A) of 1.599(5) Å and for C(8G) of 1.511(5) Å again concentrate the steric crowding on one side of the coordination plane (see Figures 3 and 9).

Interestingly, the analogous largest deviations in **10** for C(3G) of 1.667(5) Å and for C(4A) of –1.446(4) Å are in line with more hindered diagonal quadrants (see Figures 3 and 10). However, in **9** and **10** all deviations from the least-squares coordination planes are below 0.08 Å, as also indicated by the resulting small dihedral angles defined as above: **9**, at Rh(1) 3.3(2)°, at Rh(2) 1.8(2)°; **10**, at Rh(1) 7.4(2)°, at Rh(2) 5.0(2)°. Again, short intramolecular contacts are responsible for the observed unusual conformations. The shortest intramolecular contacts along a *trans* axis of the cyclobutane rings are 2.778 Å for C(4A)···H(7FA) in **9** and 2.916 Å for C(2A)···H(3HA) in **10**. Furthermore, the shortest intramolecular contacts are 2.310 Å for H(2HA)···H(3LA) between the dppcb and dppe moieties and 2.635 Å for H(6HA)···H(2FA) between the dppcb and *cis*-dppen moieties.

Obviously, the significantly larger five-membered chelate ring angles of dppe and *cis*-dppen in **9** and **10** relative to dppam in **8** (see Table 3) move the phenyl groups of dppe and *cis*-dppen towards the rhodium centres. This leads to overall steric pressures in **9** and **10**, which cannot be released within centrosymmetric conformations. Interestingly, though no crystallographic restraints are present, the cyclobutane rings of **9** and **10** are completely planar within statistical significance, which further confirms the similarity of the solid state to the solution structures, as discussed above. Both **9** and **10** show significantly different chelate angles of dppcb for the two unequal coordination units: **9**, 81.12(13)° and 86.63(13)°; **10**, 80.97(10)° and 86.35(10)° (see Table 3). This means that under steric pressure the chelate angles may also change, which is, beside the quadrant effect, another important feature for catalytic cycles.[19]

### Investigation of 1–3 and 5–16 in the Solution State

All compounds **1**–**3** and **5**–**16** show sharp doublets in the rhodium cases that are due to $^1J_{Rh,P}$ couplings and sharp single peaks in the iridium cases for the dppcb resonances in the $^{31}P\{^1H\}$ NMR spectra at ambient temperature. This indicates equivalent phosphorus atoms of dppcb for all complexes. Cooling the sample down to 178 K only leads to broadened signals. This behaviour is typical for dppcb conformations with planar cyclobutane rings,[34] in contrast to folded cyclobutane ring conformations.[6] Because planar cyclobutane rings were also observed in the X-ray structures of **1**, **3**, **6**, **8**, **9**, **10** and **14** independent of crystallographic constraints, this nicely confirms the fact that the solid-state and solution structures are identical. The structure types shown in Figures 1 and 2 are not only determined by these X-ray structures, but also their $^1J_{Rh,P}$ values of dppcb are consistent with the proposed *trans* influence series for $Rh^I$ species.[12a] Typically, nitrogen-containing ligands such as those in **11**–**13** exert a weak *trans* influence, which leads to $^1J_{Rh,P}$ parameters of 162–180 Hz. In **1** cod shows a stronger *trans* influence with $^1J_{Rh,P}$ of 154 Hz, which is characteristic of cod.[12b] In this series, the two ligand types with the highest *trans* influence, phosphanes and phosphites,[12a] produce $^1J_{Rh,P}$ values for dppcb of 129–137 Hz. A similar range of 121–135 Hz was observed for the corresponding $^1J_{Rh,P}$ parameters of the mono- and diphosphanes in **2**, **3** and **7**–**10**. The phosphites in **5** and **6** show larger $^1J_{Rh,P}$ values of 199 Hz and 234 Hz, respectively, which is also in agreement with earlier results.[12a] The range of $^2J_{P,P_{trans}}$ parameters of 234–267 Hz is typical for phosphanes, where also in this case the $^2J_{P,P_{trans}}$ values for phosphites of 364 Hz in **5** and 380 Hz in **6** are larger.[12a]

In **9** and **10**, the two different coordination units interchange with one another, with the asymmetric isomer being the more stable one. This leads to a coalescence of the $^{31}P\{^1H\}$ NMR signals for dppcb as well as for those of dppe and *cis*-dppen, which cannot be resolved at low temperatures. This effect is comparable to the conformational isomerisation of [(κ-$PMes_2CH_2CH(OH)CH_2$-κ-$PPh_2$]-Rh(η⁴-cod)]⁺, where $\delta$ and $\lambda$ isomers interchange with one another, with the $\lambda$ isomer being the more stable one.[30] In this complex, the mesityl groups at the $PMes_2$ entity behave as coupled rotors, their rotation is only possible in the transformation between the $\delta$ and $\lambda$ forms.[30] In an analogous manner, the phenyl groups at the $PPh_2$ entities in **9** and **10** behave as coupled rotors, their rotation is only possible in the transformation between pseudoaxial and pseudoequatorial spatial distributions and diagonal dispositions of the phenyl rings of dppcb (see Figures 9 and 10). This is clearly confirmed by the observed π–π stacking interactions in **9** and **10** and could be regarded as a "mechanical molecular machine".[30] These conformational properties will control the stereochemical result of reactions mediated by chelate compounds of dppcb.[35]

## Summary

The series of X-ray structures presented in this work indicates that steric pressure changes the quadrant effect. It clearly proves that the rigid cyclobutane backbone of dppcb does not play any role in determining the quadrant effect, if homodimetallic $Rh^I$ complexes of dppcb are under steric pressure. Depending on the kind and magnitude of steric pressure, both borderline cases typical for the M(dppe) and $M_2$(dppcb) quadrant effects in Figure 3 are observed. In consequence of which, dppcb and dppe show no differentiation between their distributions of equatorial–equatorial and equatorial–axial geometric isomers for the five-coordinate intermediates in the case of catalytic hydroformylation.[36] However, the regioselectivity of hydroformylation is governed by a complex web of electronic and steric effects that have so far defied unravelling.[19] Nevertheless, excellent progress was made in realizing when and how regioselectivity and enantioselectivity are controlled within a catalytic hydroformylation cycle.[37] Our work shows that it is not enough to study the quadrant effects of precatalysts such as **1**,[38] but it is also necessary to realize how the steric pressure varies during the catalytic cycle. Predictions solely based on X-ray structures of precatalysts such as **1** could be misleading. The occurrence of two different coordination units in **9** and **10** also seems to be of some importance for rhodium-catalysed tandem reactions.[39]

## Experimental Section

**Reagents and General Procedures:** The ligand dppcb was prepared as described earlier.[6] $[RhCl(\eta^4\text{-cod})]_2$, $[IrCl(\eta^4\text{-cod})]_2$, AgX ($X^-$ = $BF_4^-$, $PF_6^-$, $SbF_6^-$) and dry solvents of purissimum grade quality were obtained from Fluka. Mono- and diphosphanes, phosphites and nitrogen-containing ligands were purchased from Strem. A Schlenk apparatus and oxygen-free, dry Ar were used in the syntheses of all complexes. Solvents were degassed by several freeze–pump–thaw cycles prior to use. All reactions were carried out at ambient temperature.

**Instrumentation:** Fourier-mode $^1H$, $^{13}C\{^1H\}$ and $^{31}P\{^1H\}$ NMR spectra were obtained with a Bruker DPX-300 spectrometer (internal deuterium lock) at 298 K. Positive chemical shifts are downfield from the standards: TMS for the $^1H$ and $^{13}C\{^1H\}$ resonances and 85% $H_3PO_4$ for the $^{31}P\{^1H\}$ resonances. Owing to the restricted solubility of compounds **1**–**16**, the $^{13}C\{^1H\}$ NMR spectra in $CD_2Cl_2$ are rather insensitive to structural variations, where only the $^{13}C\{^1H\}$ NMR resonances of the phenyl rings are clearly resolved in the range 128–136 ppm as multiplets.

**$[Rh_2(\eta^4\text{-cod})_2(dppcb)]X_2$ (1), $X^- = BF_4^-$, $PF_6^-$, $SbF_6^-$:** $[RhCl(\eta^4\text{-cod})]_2$ (40 mg, 0.081 mmol) was dissolved in acetone (5 mL) and $AgBF_4$ (32 mg, 0.162 mmol) also dissolved in acetone (1 mL) was added with vigorous stirring. The reaction mixture was stirred for 3 h, and the formed AgCl was filtered off. To this solution, dppcb (64 mg, 0.081 mmol) was added with vigorous stirring. The dark orange solution was stirred for 15 min, and the solvent was then completely removed. The orange residue was washed with diethyl ether (5 mL) and dried in vacuo. Red crystals were recrystallized from $CH_2Cl_2$. Yield: 0.125 g (91%). M.p. 255 °C (dec.). $^1H$ NMR (300 MHz, $CD_2Cl_2$, 25 °C): $\delta$ = 6.5–8.0 (m, 40 H, Ph), 4.92 [s, 8 H,

absorption corrections were based on $\psi$ scans of nine reflections, respectively ($\chi$ = 78 to 102°, 360° scans in 10° steps in $\psi$).[42] All structure determination calculations were carried out with SHELXTL NT 5.10 including SHELXS-97[43] and SHELXL-97.[44] Final refinements on $F^2$ were carried out with anisotropic thermal parameters for all non-hydrogen atoms in all cases. For **8**, the protons attached to the nitrogen atom of dppam and the cyclobutane ring were located and isotropically refined with fixed $U$. All other hydrogen atoms were included using a riding model with isotropic $U$ values depending on the $U_{eq}$ of the adjacent carbon atoms. The $CH_2Cl_2$ solvent molecules in **1**, **3**, **6**, **9**, **10** and **14** are disordered. Tables 1, 2 and 3 contain selected bond lengths and bond angles of all eight structures.

CCDC-628190 to -628197 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/datarequest/cif.

## Acknowledgments

R. G., G. C. and A. D., and S. E., and M. F. thank the University of Innsbruck for post doctoral, PhD and diploma grants, respectively. This research was also financially supported by the Fonds zur Förderung der wissenschaftlichen Forschung, Vienna, Austria and the Tiroler Wissenschaftsfonds, Innsbruck, Austria. P. B. thanks Claudio Bianchini and Werner Oberhauser for helpful discussions.

# A Linear Ru-Tl-Ru Complex Obtained from Halide Abstraction: An Example of Metal-Dative Bonding

**Ian Bytheway,[a] Christopher S. Griffith,[a][‡] George A. Koutsantonis,*[a] Brian W. Skelton,[a] and Allan H. White[a]**

**Keywords:** Ruthenium / Thallium / AIM calculations / Metal–metal bond

The simple abstraction of chloride ion from $[RuCl(CO)_2(\eta\text{-}C_5H_5)]$ using $[TlBF_4]$ proved problematic, unexpectedly giving a new complex containing linear Ru–Tl–Ru. The complex, $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}Tl)(F\text{–}BF_2\text{–}F)]_\infty$, was polymeric, as determined by a single-crystal X-ray diffraction experiment, in which the thallium centres are bridged by the anions. In an effort to compare the nature of the Tl–Ru bonds, an additional complex was prepared by the reaction of $Tl^{3+}$ ions with $[Ru(CO)_2(\eta\text{-}C_5H_5)]^-$. The resulting neutral complex, $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_3(\mu\text{-}Tl)]$, was also structurally characterised. Quantum chemical calculations of $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}Tl)][BF_4]$ suggest that the Tl–Ru bond has ionic character with integrated atomic charges showing that the metal–metal bonding is best represented as $Ru^0$–$Tl^I$–$Ru^0$.

## Introduction

Interactions between closed-shell metals and their ions has spawned the field of "metallophilicity"[1–4] which is attracting increasing interest with respect to the photophysical properties of the resulting complexes.[5–8] Additionally there is an interest in the coordination chemistry of low-valent group 13, particularly those transition-metal complexes containing "naked" group 13 atoms as bridging ligands,[9] the thesis being that these atoms should display very strong π-acceptor properties.

In recent work, we have been pursuing the chemistry of the $Ru(CO)_2(\eta\text{-}C_5H_5)$ fragment in various guises[10–19] and have observed that protonation of $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}C{\equiv}C)]$ gave the unexpected trinuclear complex, $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_3(\mu\text{-}C{\equiv}C)]^+$.[16] This reaction was irreproducible, but the nature of the product suggested that a more rational and dependable route to its synthesis was the addition of the metal electrophile $[Ru(CO)_2(\eta\text{-}C_5H_5)(solvent)]^+$ to $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}C{\equiv}C)]$. The unusual chemistry encountered in the attempted syntheses of such *solvento* cations is described below.

## Results and Discussion

The synthesis of $[Ru(thf)(CO)_2(\eta\text{-}C_5H_5)](BF_4)$ (**1**) by chloride abstraction from the electron-poor complex, $[Ru(CO)_2(\eta\text{-}C_5H_5)Cl]$ (**2**), using $[AgBF_4]$ was attempted but the reaction, surprisingly, proved to be problematic. The precipitation of a grey/white material, presumably $[AgCl]_n$, was observed at reflux in thf and the reaction monitored by infrared spectroscopy for 12 h, beyond which the infrared spectrum of the reaction mixture changed minimally. Two new ν(CO) absorptions at 2019 and 2073 $cm^{-1}$ were observed along with those attributable to residual **2**. Recrystallisation of the reaction mixture gave material which appeared to correspond to **1**, contaminated (ca. 5%) with **2**. The analogous abstraction of the halide ions from $[Fe(CO)_2(\eta\text{-}C_5R_5)X]$ (R = H, Me; X = Cl, I) complexes by silver ion in donor solvents is well known, giving the corresponding *solvento* cation,[20–22] although the preparation of complex **1**, to the best of our knowledge, is unreported. Our attempts to use this material in further reactions proved unsuccessful.

The alternative halide-abstraction reagent, $[TlBF_4]$, was employed in the attempted removal of the chloride ion from **2**, but instead of the expected *solvento* cation the reaction gave a moderate yield of the 1D polymer, $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}Tl)(F\text{–}BF_2\text{–}F)]_\infty$ (**3**), the connectivity of which was determined by a single-crystal X-ray structural determination.

The FAB mass spectrum of complex **3** consisted of a base peak at *m*/*z* 651 corresponding to $[M]^+$. The $^1H$ NMR spectrum had the expected singlet resonance at $\delta$ = 5.54 ppm assigned to $Ru(\eta\text{-}C_5H_5)$, and is comparable to the resonance reported for the complex $[Ru(CO)_2(\eta\text{-}C_5H_5)(MeCN)][PF_6]$.[23] The $^{19}F$ NMR spectrum contains a single, broad resonance at $\delta$ = 151.72 ppm, which is inconsistent with the solid-state structure where two fluorine environments are observed suggesting that the polymeric

 InterScience © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structure arises from cation–anion contacts imposed to some extent by close packing contraints. The fluxional nature of the complex in solution is highlighted by the infrared spectrum where the three absorptions at 2024, 1999 and 1971 $cm^{-1}$ do not imply an exclusive, relative synclinal orientation of the two cyclopentadienyl ligands as defined by the solid-state structure. In spite of the apparent stability of **3** in the solid state, inconsistent microanalytical results were obtained.

Given the dearth of complexes with Ru–Tl complexes in the literature we decided to add to the examples extant with the reaction of $[Ru(CO)_2(\eta\text{-}C_5H_5)]^-$[24] and $TlCl_3{\cdot}4H_2O$ which gave $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}Tl)]$ (**4**) in moderate yield. The infrared spectrum of **4** contains three strong υ(CO) absorptions at 1998, 1972 and 1929 $cm^{-1}$, reminiscent of the infrared spectrum of $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}In)]$.[25] The FAB mass spectrum does not contain a molecular ion but resembles that for complex **3** with an ion assigned to $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(Tl)]^+$ at *m*/*z* 651. The $^1H$ NMR spectrum contains a doublet centred at $\delta$ = 4.69 ppm attributed to coupling of the $^{205}Tl$ nuclei to $Ru(\eta\text{-}C_5H_5)$ ($^3J_{TlH}$ = 7.9 Hz).

The complexes $[\{M(CO)_x(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}Tl)]$ (M = Cr, *x* = 3, **5**;[26] M = Mo, *x* = 3, **6**;[26,27] M = W, *x* = 3, **7**;[26] M = Fe, *x* = 2, **8**.[28]) are examples of complexes analogous to **4**, although the oxidation state of the thallium in these examples is formally $Tl^{III}$. Complex **6** has also been prepared from the reaction of $Tl(C_5H_5)$ and $Mo(CO)_6$.[27]

A similar $^2J_{TlH}$ coupling was not observed for complexes **3**, **6**[27] or the complexes $[TlR_2\{M(CO)_2(\eta\text{-}C_5H_5)\}]$ (R = Me, M = Mo; R = Me, M = W; R = Et, M = Mo).[29,30] However, Whitmire and co-workers[28] observed a $^3J_{TlH}$ coupling constant of 26 Hz for **8** and, in accord with these workers, the pair of doublets centered at $\delta$ = 85.1 and 202.7 ppm in the $^{13}C$ NMR spectrum of **4** is assigned to the coupling of the $^{205}Tl$ nuclei to $Ru(\eta\text{-}C_5H_5)$ ($^2J_{TlC}$ = 7.8 Hz) and Ru–CO ($^2J_{TlC}$ = 279.3 Hz). These assignments imply a single $\{Ru(CO)_2(\eta\text{-}C_5H_5)\}$ environment in solution which is inconsistent with the solid-state structures and suggests that the $(\eta\text{-}C_5H_5)$ environments are exchanging on the NMR time-scale.

The most relevant literature precedent for **3** is the anion produced in the reaction between $[RuBr(CO)_3(\eta^3\text{-}C_3H_5)]$ and Tl(*closo*-1,2-$Me_2$-3,1,2-$TlC_2B_9H_9$), viz. $Tl[\{Ru(CO)_2(\eta^5\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_9)\}_2(\mu\text{-}Tl)]$, which was isolated as the $[NEt_4]^+$ salt, **9**, after metathesis, along with a small amount of the neutral tricarbonyl, $[Ru(CO)_3(\eta^5\text{-}7,8\text{-}Me_2\text{-}7,8\text{-}C_2B_9H_9)]$.[31] Most notable in the difference between the compound reported here, **3**, and complex **9** is that the former contains the bridging Tl in a cation while the latter is more typically an anion. The bonding can be described as purely ionic, involving two anionic $Ru^{II}$ centres and the $Tl^+$ cation, as has been postulated for a number of transition-metal salts containing $Tl^+$.[31] However, in the light of what the authors considered as relatively short Ru–Tl bonds, it was suggested that a significant covalent interaction might be imparting stability, leading to short Ru–Tl distances in complex **9**, through filled 4d and empty 5p orbitals of suitable symmetry on Ru and the filled 6s and empty 6p orbitals on the thallium atom, based on assertions suggested for the bonding in $[Ir_2(\mu\text{-}Tl)\{\mu\text{-}(PPh_2CH_2)_2AsPh\}_2Cl(CO)_2]^+$.[32] We have explored the bonding in **3** in more detail using ab initio calculations and these will be discussed below.

### Solid State Structures of $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}Tl)(F\text{–}BF_2\text{–}F)]$ (3) and $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}Tl)]$ (4)

The results of the single-crystal structural determinations of complexes **3** and **4** are presented in Figure 1 and Figure 2 with interatomic parameters collected in Table 1 and details of the determinations in Table 5. Preliminary examination of the Tl–Ru bond lengths present in **3**, suggested they appeared to be very short when compared to the sum of the metallic radii of the two metals (3.03 Å).[33] In the complexes, $[\{Mn(CO)_2(\eta\text{-}C_5H_4R)\}_2(\mu\text{-}E)]$ (E = Ge, R = $CH_3$; E = Pb, R = H), this comparison of the bond lengths has been used as the prime indicator of multiple bond character between the main and transition-metal centres,[34–37] the most relevant example of this type of complex to **3** being $[\{Cr(CO)_5\}_2(\mu\text{-}Tl)]^-$.[38] Surprisingly, there exist only two crystallographically characterised complexes containing a Tl–Ru bond, the high nuclearity ruthenium carbido clus-

| Ru(3)–C(3*m*)–O(3*m*) | – | 178.6(9), 179(1) |

[a] Carbonyls C,O (*n* = 1–3) are attached to Ru(*n*) [*n* = 1, 2, (3)]; C,O [1, 2, (3)*m*] designate carbonyls *m* = 1, 2, (3) attached to Ru[1, 2, (3)].

The successful synthesis and structural determination of complex **4** gave another suitable complex containing Tl–Ru single bonds for comparison against that of **3** and as such will be discussed here. Complex **3** crystallises in the monoclinic centrosymmetric space group $P2_1/c$, a single formula unit, devoid of crystallographic symmetry, comprising the asymmetric unit of the structure. The structure of **3** comprises an essentially one-dimensional polymeric strand with a repeating unit consisting of one cation and one anion. The close contact of a fluorine atom from the tetrafluoroborate anion of the repeating unit and that of an adjacent repeating unit with the thallium atom of the cation [2.88(1), 2.92(1) Å] results in the observed polymeric structure. The anion B–F(1–4) are 1.38, 1.39, 1.32, 1.34(2) Å, suggesting a distinction between the interacting and non-interacting F–B distances, but that may be impacted by lack of libration correction. F(1)–B–F(2) and F(3)–B–F(4) are enlarged above the tetrahedral norm to 112(1), 120(2)°.

The cation comprises two $\{Ru(CO)_2(\eta\text{-}C_5H_5)\}$ groups coordinated to a central thallium atom such that the Ru–Tl–Ru vector is essentially linear [176.98(3) °]. The geometries about the two Ru atoms are unremarkable but the relative synclinal orientation of the fragments is intriguing given that this stereochemistry places the two cyclopentadienyl ligands at the intuitively unfavourable point of least separation. Presumably the steric requirements of the cations is such that this orientation offers the most favourable crystal packing situation as well as allowing the maximum intermolecular anion-cation contacts. The Tl–Ru bond lengths of 2.6298(7) Å [Ru(1)] and 2.6260(7) Å [Ru(2)] seem unusually "short" in comparison to the sum of the two metallic radii (3.05 Å).[33] However, a recent structural determination of a similar complex, $[\{Ru(CO)_2(\eta^5\text{-}7,8\text{-}C_2B_9H_9)\}_2(\mu\text{-}Tl)][NEt_4]$[31] gave a significantly shorter distance of 2.5994(4) Å. In this anionic complex the Ru–Tl–Ru vector is appreciably bent at 165.67(2)°.

The $Tl_3Ru$ complex **4** crystallises in the centrosymmetric space group $P\bar{1}$; a single molecule, devoid of crystallographic symmetry, together with one half of the toluene molecule of solvation, which lies disordered about a crystallographic inversion centre, comprises the asymmetric unit of the structure. The molecular structure of **4** is shown in Figure 2, together with the numbering scheme used; pertinent bond lengths and angles are presented in Table 1.

The determination shows that the complex consists of a central thallium atom surrounded by three $\{Ru(CO)_2(\eta\text{-}C_5H_5)\}$ groups. The geometry about the thallium atom is trigonal planar, as is evident from the sum of the three ∠ Ru–Tl–Ru being equal to 360°, with the thallium atom located only 0.012(1) Å out of the $Ru_3$ plane. The measured Tl–Ru bond lengths are 2.7327(8) [Ru(1)], 2.7198(8) [Ru(2)] and 2.7089(8) Å [Ru(3)], which are significantly elongated from those measured for **3** by ca. 0.09 Å and 0.133 Å for **9** but "short" compared to the sum of the metallic radii.[33] The large steric bulk of the $\{Ru(CO)_2(\eta\text{-}C_5H_5)\}$ groups appears to be accommodated around the central thallium atom by rotation about the Tl–Ru vectors resulting in two of the cyclopentadienyl ligands orientated on the same side of the $TlRu_3$ plane with the remaining cyclopentadienyl ligand in a relative anticlinal orientation. The overall arrangement of the $\{Ru(CO)_2(\eta\text{-}C_5H_5)\}$ groups is comparable to that observed in the solid-state structure of the triiron thallium complex **8**;[28] presumably the Tl–Ru bond rotations play some part in the solution process which results in the equivalence observed in the $^1H$ and $^{13}C$ NMR solution spectra. Similar rotation about the M–Ga vectors of $[\{M(CO)_3(\eta\text{-}C_5H_5)\}_3(\mu_3\text{-}Ga)]$ (M = Mo **5**,[40] W **6**[41]) has been discussed previously.[42] The (carborane)$Ru(CO)_2$ units in **9** are mutually twisted and seem to allow even closer approach of the Ru and Tl centres.

With these observations in mind, elongation of the Tl–Ru bond lengths for **4** with respect to **3** and **9** may only be consequent on the steric congestion about the thallium atom and not on the presence of any multiple bonding in complex **3**. This situation is a reminder that the assignment of multiple bonding in these and other systems, based purely on structural data, is fraught with uncertainty.

### Quantum Chemical Calculations of $[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}Tl)(F\text{–}BF_2\text{–}F)]_\infty$ (3)

In order to probe the nature of the bonding in **3**, quantum-chemical calculations were performed on $[\{Ru(CO)_2(Cp)\}_2Tl]^+$ at the geometry observed from the single-crystal X-ray structural determination of **3** to obtain the total charge density distribution, $\rho(r)$, for analysis using the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

theory of Atoms in Molecules (AIM).[43] To produce $\rho(r)$ amenable to study by AIM, all electron basis sets were used in conjuction with the Hartree–Fock method.

Within the theory of AIM, bonds are defined in terms of lines of maximum charge density connecting given nuclei, such that each line passes through a saddle point. The collection of these bond paths as well as other topological features of $\rho(r)$ is termed the molecular graph. For **3** the molecular graph is comprised of 2 Ru–Tl, 14 Ru–C, 4 C–O, 10 C–C and 10 C–H bond critical points. As predicted, ring critical points were located at the centre of each cyclopentadienyl ring and cage critical points located between each ruthenium and cyclopentadienyl ligand. The location of these bond critical points indicated that the utilised basis sets were adequate for the purpose of describing the total $\rho$ present within the solid-state structure of **3**. Bond critical point data are summarised in Table 2.

Table 2. Average values, in atomic units, of $\rho(r)$ and $\nabla^2\rho(r)$ at various bond critical points in **3**.

| Bond | $\rho(r)$ | $\nabla^2\rho(r)$ |
|---|---|---|
| Ru–Tl | 0.065 | 0.12 |
| Ru–C (CO) | 0.15 | 0.63 |
| Ru–C (Cp) | 0.079 | 0.22 |
| C–O | 0.45 | 0.56 |
| C–C | 0.27 | –0.91 |

Inspection of $\rho(r)$ at the ruthenium and thallium bond critical points shows these values are relatively small and possess positive Laplacians [$\nabla^2\rho(r)$], also evident from Figure 3 is the depletion of charge in the Ru–Tl internuclear regions, tending to indicate that the charges of the ruthenium and thallium nuclei are contracted and best described as "closed shell" or ionic.[43] The interatomic surface separating the ruthenium and thallium atoms is also shown.

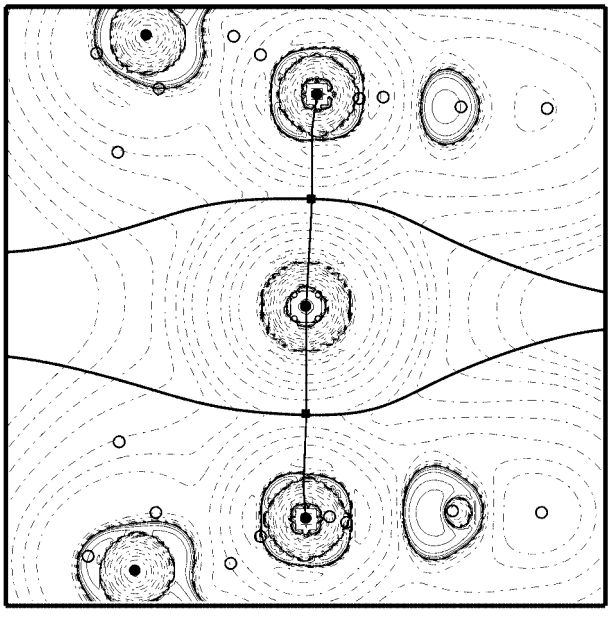

Figure 3. Plot of $\nabla^2\rho(r)$ for **3**, in a plane containing the metal nuclei. Full contours denote regions where charge is concentrated ($\nabla^2\rho(r) < 0$) and broken contours denote regions where charge is depleted ($\nabla^2\rho(r) > 0$). The bond paths joining the Ru and Tl nuclei are superimposed, and the bond critical point is denoted by the filled square. The interatomic surface separating Ru and Tl is also shown.

Similar depletion of charge in the internuclear region of a metal–metal bond has recently received experimental verification for the molecules $[Co_2(CO)_6(AsPh_3)_2]$[44] and $[Mn_2(CO)_{10}]$.[45]

Although the implied ionic nature of the Ru–Tl interaction suggested that multiple metal–metal bonding was absent in **3**, further clarification of the interaction by determination of the atomic populations for each metal nucleus was sought. Two separate methodologies were employed for these calculations:

1) integration of the calculated charge density within the zero-flux surface for each atom;[43]

2) use of the Natural Bond Orbital scheme (NBO).[46,47]

Atomic populations calculated by both methods are presented in Table 3 and support the initial calculations that the Ru–Tl bonding interaction is best described as ionic with no support for any metal–metal multiple bonding but there is substantial donation of electron density from the Ru atoms to the Tl centre. Importantly, the NBO analysis yields electron configurations of $6s^{1.5}\ 6p^{0.6}$ for thallium and $5s^{0.4}\ 4d^{7.4}$ for both ruthenium atoms. Thus, one can consider a dative interaction from the Ru to the Tl as a description of the bonding in **3**.

Table 3. Net atomic populations ($q$), calculated for both the experimental and optimised geometries of **3**.

| Method | All electrons | | B3LYP/LANL2DZ | |
|---|---|---|---|---|
| | Experimental geometry | | 0° | 180° |
| $q$ | Integrated | NBO | NBO | NBO |
| Tl | 1.32[a] | 0.74 | 1.03 | 1.03 |
| Ru | 0.16 | 0.16 | –0.25 | –0.25 |
| CO | –0.10 | 0.07 | 0.16 | 0.15 |
| Cp | –0.11 | –0.17 | –0.08 | –0.07 |

[a] This value obtained by difference from the other integrated populations.

The observed synclinal orientation of the {$Ru(CO)_2(\eta$-$C_5H_5)$} fragments in complex **3** was noted in the solid-state structure and so optimisation of this and the anticlinal stereochemistry was undertaken at the B3LYP/LANL2DZ level of theory. The calculated bond lengths and angles at these orientations were found to be closely similar to the experimental data (Table 4).

Surprisingly, the difference in energy of the two orientations was calculated at 5 kJ/mol, in favour of the anticlinal geometry, and one may have regarded that this orientation would be the most favoured based purely upon steric considerations. Observation of the synclinal stereochemistry in the solid-state structure, coupled with the rather small energy difference calculated between the syn- and anticlinal orientations, suggests that the stereochemistry may be purely a result of crystal packing effects or, perhaps, stabilisation by the tetrafluoroborate counter-anions. Additionally,

Table 4. Selected experimental and calculated bond lengths [Å] and angles (°) for **3**.

| | Experimental | Calculated geometry 0° | 180° |
|---|---|---|---|
| Bond length | | | |
| Tl–Ru | 2.6279 | 2.743 | 2.740 |
| Ru–C (CO) | 1.875 | 1.898 | 1.897 |
| Ru–C ($Cp_c$) | 1.885 | 2.001 | 2.000 |
| C–O | 1.135 | 1.178 | 1.178 |
| Bond angle | | | |
| Ru–Tl–Ru | 176.98 | 177.97 | 180.00 |
| Ru–C–O | 175.98 | 178.50 | 176.70 |
| Tl–Ru–C (CO) | 88.23 | 88.98 | 89.20 |
| Tl–Ru–C ($Cp_c$) | 120.0 | 121.80 | 120.98 |
| (CO) C–Ru–C (CO) | 92.40 | 92.80 | 92.84 |
| ($Cp_c$) C–Ru–C (CO) | 122.5 | 126.50 | 126.70 |

NBO charges obtained for both optimised geometries also suggest that thallium is unipositive (see Table 3).

The chemistry which results in the formation of **3** can represented by the following equation:

$$2[RuCl(CO)_2(\eta\text{-}C_5H_5)] + 4Tl(BF_4)_4 \rightarrow [\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu_2\text{-}Tl)][BF_4] + 2TlCl + Tl(BF_4)_3$$

The reaction presumably proceeds by oxidation of thallous ions to give formally zero-valent ruthenium that then combines with the available $Tl^+$ ions to give the products. However, this intrepretation is a little problematic given that it suggests that highly oxidising $Tl^{III}$ will co-exist with highly reduced ruthenium species.

## Conclusions

We have shown that so-called simple halide abstraction reactions can be problematic but some TlRu complexes are readily prepared by nucleophilic substitution of transition metal halides. Ab initio calculations have helped rationalise both the bonding within the linear Ru–Tl–Ru complex and the observation of solid state packing effects within the crystal structure of complex, **3**, and suggesting that the Tl atom is a significant acceptor of electron density in the linear Ru–Tl–Ru complex. Additionally, it is clear that bond lengths alone are no arbiter of multiple bonding

## Experimental Section

**General Remarks:** Manipulations of oxygen- and moisture-sensitive compounds were performed under high purity argon using standard Schlenk techniques or in a dry box (Miller Howe).

Infrared spectra were recorded with a Bio-Rad FTS 45 or 40 FTIR spectrometer. $^1H$ and $^{13}C$ NMR spectra were acquired with Varian Gemini 200 or Bruker ARX 500 spectrometers. $^{31}P$ NMR spectra were acquired with a Bruker ARX 500 spectrometer. $^1H$ and $^{13}C$ NMR spectra were referenced with respect to incompletely deuterated solvent signals. Mass spectra were obtained with a VG AutoSpec spectrometer employing a Fast Atom Bombardment (FAB) ionisation source in all samples unless otherwise specified. Elemental analyses were performed by The Research School of Chemistry Microanalytical Unit, Australian National University, ACT. *n*-Hexane and toluene were dried with sodium metal and distilled from sodium benzophenone ketyl under argon. Distilled solvents were stored over sodium or potassium mirrors until use.

**$[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_2(\mu\text{-}Tl)][BF_4]$(3):** A solution of $RuCl(CO)_2(\eta\text{-}C_5H_5)$ (100 mg, 0.388 mmol) and $TlBF_4$ (112 mg, 0.385 mmol) in tetrahydrofuran (30 mL) was heated at reflux (48 h) till the infrared absorption at 2023 $cm^{-1}$ became constant. The reaction mixture was filtered, the solution volume reduced (to ca. 20 mL), then added dropwise to diethyl ether (50 mL) to give a pale yellow precipitate. Recrystallisation ($CH_2Cl_2$/$Et_2O$) gave **3** (60 mg, 42%) as yellow rods. $C_{14}H_{10}BF_4O_4Ru_2Tl$ (735.56): calcd. C 21.85, H 1.37; found C 22.21, H 0.83. FABMS: *m*/*z* (%) = 651 (35) [$M^+$]. IR ($CH_2Cl_2$): $\tilde{\nu}$ = 2024 (m), 1999 (m), 1971 [m (CO)] $cm^{-1}$. $^1H$ NMR (500 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 5.54 [s, ($\eta$-$C_5H_5$)] ppm. $^{19}F$ NMR (470 MHz, [$D_6$]acetone, 25 °C): $\delta$ = 151.7 (s, $BF_4$) ppm.

**$[\{Ru(CO)_2(\eta\text{-}C_5H_5)\}_3(\mu\text{-}Tl)]$(4)·0.5$C_6H_5CH_3$:** A solution of freshly prepared $Na[Ru(CO)_2(\eta\text{-}C_5H_5)]$ (0.674 mmol) in tetrahydrofuran was added to a stirred solution of $TlCl_3$ (70 mg, 0.224 mmol) in tetrahydrofuran (15 mL), then heated at reflux (2 h). The solvent was removed in vacuo and the residues extracted with toluene (2 × 30 mL) to give a blood-red solution. Reduction of the solution volume (to ca. 50 mL) and addition of hexane gave red crystals of **4** at –35 °C (119 mg, 61%). IR ($C_7H_7$): $\tilde{\nu}$ = ν(CO) = 1998 m, 1972 (s), 1929 [m (CO)] $cm^{-1}$. $^1H$ NMR (200 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 4.69 [d, $^2J_{TlH}$ = 7.9 Hz, ($\eta$-$C_5H_5$)] ppm. $^{13}C$ NMR (50.3 MHz, [$D_6$]benzene, 25 °C): $\delta$ = 202.7 (d, $^2J_{TlC}$ = 279.3 Hz, Ru-CO), 85.1 [d, $J_{TlH}$ = 7.8 Hz, ($\eta$-$C_5H_5$)] ppm. FABMS: *m*/*z* (%) = 651 (35) [$M^+$ – {$Ru(CO)_2(\eta$-$C_5H_5)$}]. $C_{21}H_{15}O_6Ru_3Tl$ (871.24): calcd. C 28.95, H 1.74; found C 28.39, H 1.67.

**X-ray Crystallographic Study:** Full spheres of CCD area-detector diffractometer data were measured (Bruker AXS instrument, ω-scans, *T* ca. 300 K; monochromatic Mo-$K_\alpha$ radiation, $\lambda$ = 0.7107$_3$ Å) yielding $N_{t(otal)}$ reflections, these merging to *N* unique ($R_{int}$ quoted) after "empirical"/multiscan absorption correction (proprietary software). $N_o$ with $F > 4\sigma(F)$ were considered "observed"

Table 5. Crystallographic structure determinations of [{$Ru(CO)_2(\eta$-$C_5H_5)$}$_2$($\mu$-Tl)][$BF_4$] (**3**) and [{$Ru(CO)_2(\eta$-$C_5H_5)$}$_3$($\mu$-Tl)] (**4**).

and used in the full-matrix least-squares refinements, refining anisotropic thermal parameter forms for the non-hydrogen atoms ($x$, $y$, $z$, $U_{iso})_H$ being constrained at estimated values. Conventional residuals $R$, $R_w$ on $|F|$ are cited at convergence {reflection weights: $[\sigma^2(F) + 0.0004F^2]^{-1}$}. Neutral atom complex scattering factors were employed within the Xtal 3.7 program system.[48] Pertinent data are given in Table 5 and Figure 1 and Figure 2, the latter showing 20% probability amplitude displacement envelopes for the non-hydrogen atoms, hydrogen atoms having arbitrary radii of 0.1 Å.

CCDC-116532 and -116533 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Theoretical Calculations:** Ab initio calculations were performed with the Gaussian 94 software package.[49] The experimental geometry was used for the calculation of a Hartree–Fock all-electron wave function. The Huzinaga[50] basis sets with uncontracted outer d-shells were used for Ru [432211/4211/321] and Tl [4322211/422211/4211/3] while standard 3-21G basis sets[49] were used for C, O and H atoms. Optimized geometries were obtained using the B3LYP functional[51,52] as implemented in Gaussian 94[49,53] in conjunction with the LANL2DZ effective core potentials for Ru and Tl[54] and D95V all-electron basis sets[55] for C,O and H. The MORPHY98 program[56] was used to search for critical points in the total charge density[57] and to calculate integrated atomic populations.[58] Orbital occupancies and charges were also obtained using the natural bond orbital (NBO) program[46,47] implemented in Gaussian 94.

# Effect of Ligand Architecture on the Structure and Properties of Square-Planar Nickel(II) Complexes of Amide-Based Macrocycles

**Savita K. Sharma,[a] Shailesh Upreti,[b] and Rajeev Gupta*[a]**

**Keywords:** Nickel complexes / Macrocyclic ligands / Electrochemistry

The present work discusses the design and synthesis of four novel macrocyclic ligands and their $Ni^{II}$ complexes. All four ligands ($H_21^{EN}$, $H_22^{EN}$, $H_23^{OP}$, $H_24^{OP}$) are designed to provide an identical donor-environment composed of two deprotonated anionic amide-*N* coordination and two neutral amine-*N* coordination and an identical 12-membered macrocyclic ring around the nickel center. The $Ni^{II}$ complexes (**1**, **2**, **3**, and **4** of doubly deprotonated ligands $[1^{EN}]^{2-}$, $[2^{EN}]^{2-}$, $[3^{OP}]^{2-}$, and $[4^{OP}]^{2-}$, respectively) are prepared and thoroughly characterized. The coordination geometry around the $Ni^{II}$ center is square planar as determined by the single crystal structure analyses. The average $Ni–N_{amide}$ bond lengths are shorter by ca. 0.1 Å than the average $Ni–N_{amine}$ distances while the average $N_{amide}–Ni–N_{amide}$ angles are shorter by ca. 4° than the average $N_{amine}–Ni–N_{amine}$ angles. The $Ni^{II}$ ion is housed quite tightly within the aperture of the macrocycle as seen by the short Ni–N bond lengths and a very small displacement (0.11–0.17 Å) of the Ni center out of the $N_4$ basal plane. The detailed $^1H$ and $^{13}C$ NMR studies on the diamagnetic Ni–complexes reveal that the solid state conformation of the complexes **1**–**4** is retained in the solution. The $Ni^{III/II}$ potential is fairly positive (>0.6 V vs. SCE) for all four complexes, while the complexes with phenylene as part of the ligand also show the oxidation(s) of the ring(s) (>1.1 V vs. SCE). Coulometric measurements confirm both responses as $1e^-$ process. Electrochemical or chemical oxidation at the 1st potential results in the generation of an unstable "green species" that show distinct features in the absorption spectrum and exhibit anisotropic EPR spectrum. These findings strongly point out that the unstable green species is a $Ni^{III}$ species. The 2nd and/or 3rd oxidation is centered on the phenylene ring(s) and lead to an immediate decomposition.

## Introduction

The interest in the nickel coordination complexes supported with amide ligands has always attracted synthetic chemists due to many reasons. One of them is to stabilize nickel ions in high oxidation states to gain knowledge about such species in general and to further use them as oxidizing agents.[1] Secondly, the recent developments in spectroscopic and/or structural identification of the nickel species in the catalytic cycle of several enzymes, for example, [NiFe]-hydrogenases,[2] Ni-dependent superoxide dismutase,[3] acetyl-coenzyme A synthase[4] and Ni-tetrahydrocorphinoid cofactor ($F_{430}$) of methyl-coenzyme M reductase[5] has reignited the interests in the area of bioinorganic model studies of nickel ion. In fact, the identification of deprotonated carboxamido-*N* coordination in a number of Ni-enzymes has challenged the synthetic chemists to design the low-molecular weight models to understand the structure and function of the native enzymes. A latest case is the emergence of quite interesting synthetic systems to model the active site structure of Acetyl coenzyme A synthase/carbon monoxide dehydrogenase (ACS/CODH).[6] Also, $Ni^{II}$ in conjunction with oligopeptides has found to cause DNA cleavage in the presence of suitable oxidants; $Ni^{III}$ and/or $Ni^{IV}$ species have been postulated for this cleavage.[7] In this context, as well as in order to develop better oxidizing systems, emphasis should be to achieve a high oxidation state of the nickel ion. The redox properties of a nickel center can be fine-tuned by the use of strong donor groups in a constrained environment in conjunction with the incorporation of non-innocent ligand features that also participate in the redox properties.

Amide-based macrocyclic ligands possess interesting oligopeptide features of the biologically important moieties and serve as effective ligands for early and late transition metal ions.[8,9] Extensive research has been devoted in understanding the nickel coordination chemistry with amide-based azamacrocyclic ligands;[8] however, studies have mainly been limited to the solution generated species in most of the instances with structural information limited to handful examples. Such studies have primarily been targeted to understand the effective placement of the nickel ion within the aperture or the cavity of the macrocycle with

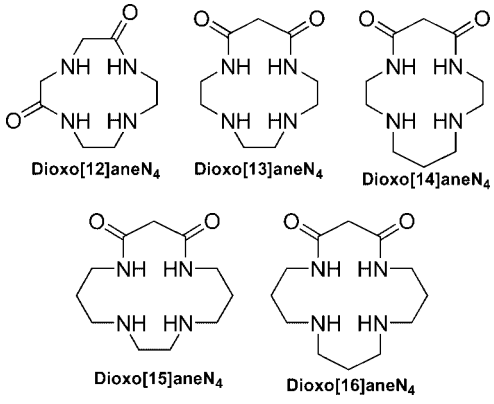
the emphasis on the 13-and 14-membered dioxotetraamines (see Scheme 1). The pioneering work of Kimura and Kodama[10] has resulted in a number of important conclusions, for example, 13-membered macrocycle, dioxo[13]-aneN$_4$ ideally house the low-spin Ni$^{II}$ ion tightly compared to the analogous 14-membered, dioxo[14]aneN$_4$ and 15-membered, dioxo[15]aneN$_4$ macrocycles. In continuation, they also show that the macrocyclic ring size (13...15-membered) has a profound effect on the redox potential of the Ni$^{II}$/Ni$^{III}$ couple. Lampeka and Gavrish[11,12] have further progressed this work and recently shown the crystal structures of the Ni$^{II}$ complexes with dioxo[13]aneN$_4$ and dioxo[14]aneN$_4$ ligands. Both Ni complexes, as anticipated earlier, are square planar and the solid-state structures have shown to be retained in solution by the proton NMR studies. In spite of the importance anticipated for the 12-membered macrocycles (such as small size of the macrocyclic aperture and tight chelation), surprisingly, the chemistry has not been explored. A possible explanation for the expansion of the chemistry of 13-membered or higher macrocycle is the readily accessibility of such ligands via the aminolysis reaction of malonic esters with variable polyamines.[8] Moreover, it was always anticipated that a tiny 12-membered macrocycle may not be able to accommodate a transition metal ion. In fact, Martell and co-workers[13] have shown few 2:1 sandwich metal complexes of a very similar amide ligand (1,4,7,10-tetraazacyclododecane-2,9-dione), where M$^{II}$ (M = Co, Ni, and Cu) ion is in between two ligands. This is to be noted, however, that these complexes were synthesized and isolated at neutral pH. These literature precedents have laid the foundation of our present work and we have commenced a systematic synthetic investigation to shed light on the effect of the ligand architecture imposed by the macrocyclic ligands on the properties of coordination complexes. Herein, we report the design and synthesis of four novel macrocyclic ligands and their coordination chemistry towards Ni$^{II}$ ion. These ligands have been designed to keep two important parameters identical; basic donor-environment around the nickel center, and the size of macrocycle which is 12-membered in all four cases. This is followed by the understanding of the effect of ligand planarity and non-innocent feature(s) on the structural, spectroscopic, and redox properties of the nickel center.

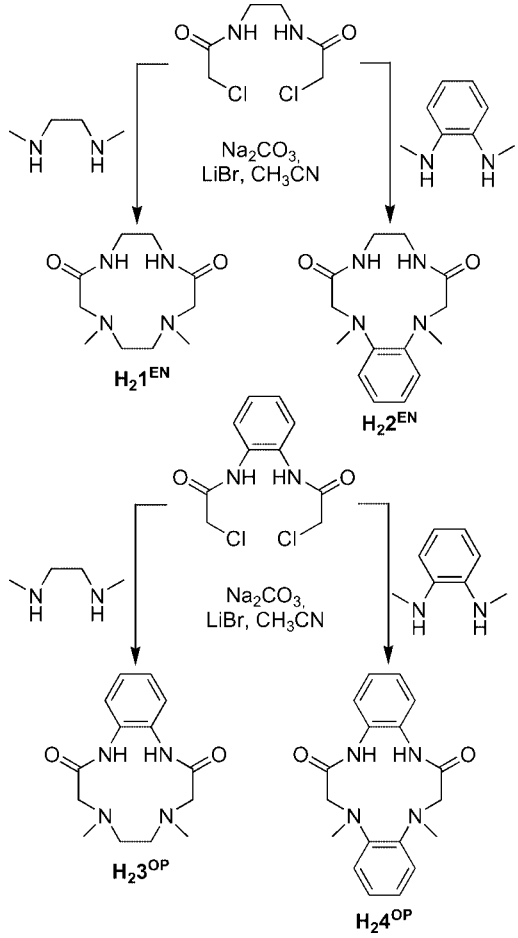


Scheme 1.

## Results and Discussion

### Ligand Design and Synthesis

The macrocyclic ligands ($H_21^{EN}$, $H_22^{EN}$, $H_23^{OP}$, and $H_24^{OP}$) are designed to simultaneously provide two amide and two amine coordinations to the metal center. Moreover, the ligands are intended to afford an identical primary coordination environment to the metal center. The only difference between these four ligands is the subtle alteration in the backbone of the ligands. For example, $H_22^{EN}$ differ from $H_21^{EN}$ by the involvement of one phenylene unit in the framework of the macrocycle, whereas $H_24^{OP}$ differ from $H_21^{EN}$ by the incorporation of two such units. These ligands are synthesized in two steps starting from the corresponding primary diamines (Scheme 2).



Scheme 2. Synthesis of ligands.

In the first step, the diamine is converted into the respective bis(chloroacetamide) by treating with two equiv. of chloroacetyl chloride.[14] In the next step, the bis(chloroacetamide) is treated with the corresponding secondary amine to afford the desired ligand. It is worth mentioning here that during the synthesis of these ligands, LiBr was used as a templating agent.[15] Interestingly, the synthetic attempts were unsuccessful without the addition of LiBr as templating agent. The utilization of a templating agent is well known in the literature for the synthesis of macrocyclic

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligands from simple crown-ethers to more complex molecules.[16] All new ligands are thoroughly characterized using various spectroscopic measurements and give satisfactory microanalysis results.

### Synthesis and Characterization of Metal Complexes

All $Ni^{II}$ complexes, **1**–**4**, were synthesized as follows: DMF solution of the respective ligand was first deprotonated with solid NaH under $N_2$ atmosphere followed by the addition of $NiCl_2$ as the metal source. The complex **1** can, however, be synthesized in better yield by treating the methanolic solution of the ligand $H_21^{EN}$ with 2 equiv. of NaOH followed by the addition of the $Ni(OAc)_2$ salt. Usual workup and recrystallization (vapor diffusion of diethyl ether to a MeCN solution of complexes) afforded highly crystalline material in moderate recrystallized yield (ca. 40%). All complexes are deep yellow to orange-yellow in color.

In the FTIR spectra, the absence of ν(N–H) stretching frequency confirms the deprotonated nature of the amide ligands. A bathochromic shift in the C=O stretching frequency was observed for all complexes compared to the free ligand and prove that the deprotonated N-amide group is coordinated to the Ni ion.[17] In addition, complex **2** also has water as solvent of crystallization which shows the ν(OH)[17] absorption in the region of 3300–3400 $cm^{-1}$ (cf. crystal structure). Solution conductivity data[18] confirm the non-electrolytic nature of all $Ni^{II}$ complexes, whereas the elemental analyses results authenticate the purity of the bulk samples. In the electrospray mass spectra, molecular ion peak corresponding to the complexes, **1**, **2**, **3**, and **4** were obtained at 285.05 (**1** + $H^+$), 333.27 (**2** + $H^+$), 333.05 (**3** + $H^+$), and 381.35 (**4** + $H^+$), respectively, and assert the integrity of the metal complexes in the solution.

### Crystal Structure Studies

All $Ni^{II}$ complexes have been structurally characterized and the molecular structures of the complexes are shown in Figures 1, 2, 3, and 4, while the important crystallographic

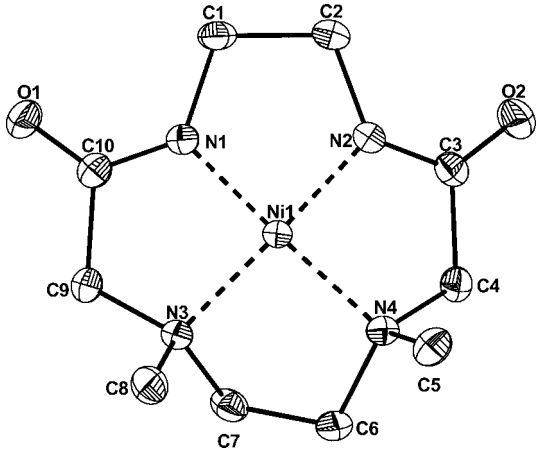


Figure 1. Molecular structure of complex **1** (thermal ellipsoid are drawn at 30% probability level). Hydrogen atoms, solvent molecule are omitted for clarity.

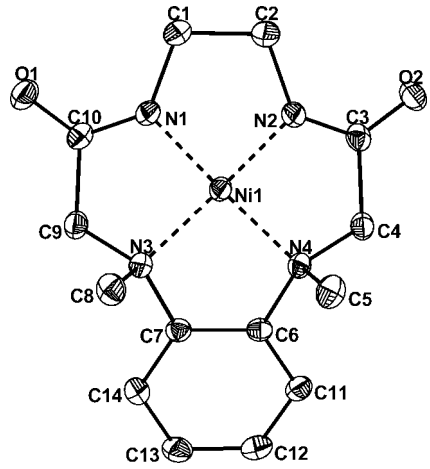

Figure 2. Molecular structure of complex **2** (thermal ellipsoid are drawn at 30% probability level). Hydrogen atoms, solvent molecule are omitted for clarity.

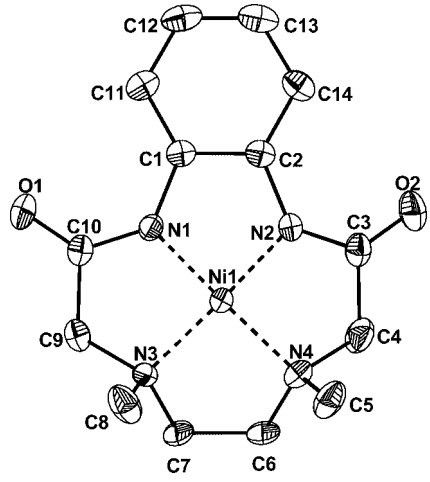

Figure 3. Molecular structure of complex **3** (thermal ellipsoid are drawn at 30% probability level). Hydrogen atoms are omitted for clarity. The atoms C6 and C7 were occupying two crystallographically independent positions and only the atoms with site occupancy factor of 0.8 are shown for clarity.

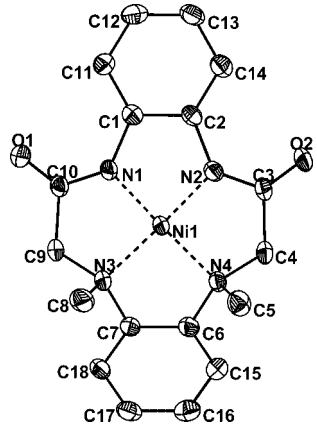

Figure 4. Molecular structure of complex **4** (thermal ellipsoid are drawn at 30% probability level). Hydrogen atoms are omitted for clarity.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and structural parameters are presented in Tables 1, 2 and S1 (for the latter see electronic supporting information). The coordination geometry around the $Ni^{II}$ center is square planar in all four complexes. The $Ni^{II}$ ion is simultaneously coordinated by two deprotonated amidic-*N* atoms and two tertiary amine-*N* atoms. In all four complexes $Ni^{II}$ ion is surrounded by four five-membered chelate rings. In all cases, the bond angles formed by the lateral chelate rings about the Ni center are close to the ideal value of 90° for a perfect square-planar complex; however, the bond angle involving two anionic $N_{amide}$ has a slightly smaller value of ca. 88° which is compensated by a little higher angle (ca. 92°) for the chelate ring involving two $N_{amine}$. The methyl groups on the tertiary nitrogen centers are located on one side of the plane in all cases. This is in contrast to a number of examples where relative position of the N–H or N–R groups results in the occurrence of the geometrical isomers.[11] The lateral 5-membered chelate rings [–C(O)–$CH_2$– fragment] in all complexes are adopting the envelope conformation.[11,19] Both carbon atoms in these rings are present on the same side of $N_{amide}$–Ni–$N_{amine}$ plane with larger displacement of the carbon atoms connected to the amine nitrogens ($sp^3$ centers).

For complex **1**, the average Ni–$N_{amide}$ bond length is ca. 1.81 Å, while the average Ni–$N_{amine}$ bond length is ca. 1.91 Å. The difference of 0.1 Å may be attributed to the anionic coordination from the deprotonated amidic nitrogens compared to the neutral amine nitrogen donors. The N(1)–Ni–N(2) bond angle of 87.40° is smaller than the N(3)–Ni–N(4) bond angle of 92.36°. The observed difference of ca. 5° between the two bond angles explains the tight chelate formation from the two anionic amidate nitrogens. The other two angles (ca. 89°) involving lateral five-membered rings are similar to each other. Another interesting feature of the structure is the orientation of the carbon centers of the –$CH_2CH_2$– fragments of the amine part of the macrocyclic ligand which is adapting *gauche* conformation.[11]

The average Ni–$N_{amide}$ and Ni–$N_{amine}$ distances at ca. 1.81 Å and 1.91 Å, respectively, for complex **2** are identical to **1**. The other distances and angles are comparable to that of **1**. However, the amine carbon centers emerging from the 1, 2-diaminobenzene are now planar as a result of the involvement of a rigid phenylene unit. Interestingly the carbon centers of the $–CH_2CH_2–$ fragments connected to the amide part of the macrocyclic ligand are now adopting a partial *gauche* conformation.[11] Moreover, the unit cell has a water molecule which is hydrogen bonded to the amide oxygen atoms from two different molecules of **2**. The consequence is the formation of a zig–zag chain with alternate arrangement of complex **2** and $H_2O$ (Figure S1).

The average bond lengths for **3** are simialr to that of **1** and **2**. The $–CH_2CH_2–$ fragment of the amine part is now adopting envelope conformation[11,19] in contrast to the gauche conformation of **1**. Moreover, the incorporation of the phenylene group as part of the macrocyclic backbone resulted in a more planar arrangement of the chelate involving two amidic nitrogens than in case of **1** and **2** (cf. Table S1).

In line with other three complexes, the bond lengths and angles for the complex **4** are also comparable. Interestingly, due to the involvement of the phenylene groups both from the amide part of the macrocyclic backbone as well as the amine part of the macrocyclic backbone, the attached carbon centers have become co-planar as can be seen by their respective angles. However, the molecule as a whole is non-planar and adopts a saucer shaped conformation (lateral view, Figure S2).

The average Ni–$N_{amide}$ bond lengths of the present complexes are shortest among the reported examples having a similar coordination environment.[10f,10g,11,12] For example, the average Ni–$N_{amide}$ bond lengths for the $Ni^{II}$ complexes of the ligands, dioxo[13]ane$N_4$ and dioxo[14]ane$N_4$ are 1.839 and 1.889 Å, respectively.[11] In fact, the average Ni–$N_{amide}$ bond lengths distance of the complexes reported in this work are 0.04–0.05 Å shorter than the mentioned examples. This is worth to mention here that the average Ni–$N_{amide}$ bond lengths of a $Ni^{III}$ complex of a tetraamide ligand of Collins[20] is ca. 1.84 Å which is 0.04 Å longer than our complexes.

The deviation of the $Ni^{II}$ ion from the coordination basal plane (defined by N1, N2, N3, and N4) is an indication of the optimal placement of the metal ion within the macrocyclic aperture. This out of $N_4$ basal plane displacement is maximum for the **1** (0.170 Å) and minimum for the **4** (0.110 Å) with other two complexes **2** and **3** have intermediate values. These numbers suggest that the $Ni^{2+}$ ion is most tightly and optimally placed in **4** (Table S1).

The angles between the various planes are presented in Table S1. In general, the plane involving $N_{amide}$ centers (N1 and N2) are comparatively planar due to the enhanced delocalization in the amidate fragment. The angle between the plane comprising both $N_{amide}$ (Ni1, N1, C1, C2, and N2) and the plane involving both $N_{amine}$ (Ni1, N4, C6, C7, and N3) is quite significant. This value varies from 23.62° to 28.70° in all four cases and explains the reason for a saucer-shaped structure of the complexes (lateral view, Figure S2). Similarly, the angle between planes involving lateral carbon centers varies from 30.27° for **3** to 40.29° for **1** and points out towards the envelope conformation.

### Absorption Spectral Studies

The absorption spectra of **1**–**4** complexes in MeCN are displayed in Figure 5. All complexes are deep yellow in color and their absorption spectra display distinct features for the four-coordinate square planar $Ni^{II}$ ion. Complexes **1**–**4**, display the $\lambda_{max}$ within a small range of 436 to 444 nm, thus indicating a similar electronic environment created by the ligand around the Ni ion. The observed similarity between the absorption features of complexes is also reflected in their very similar solid state crystal structures (vide supra) as well as NMR spectra (vide infra). High energy features are observed below 310 nm and could tentatively be assigned as intra-ligand transitions. The absorption spectral features of $Ni^{II}$ complexes of macrocyclic ligands have been subjected to detailed investigations to understand the ligand planarity and the placement of the Ni center in the cavity of the macrocycle.[8,10a,21] It has been suggested that the lower the $\lambda_{max}$ value for the $Ni^{II}$ complex better the fitting of the $Ni^{II}$ center inside the macrocyclic cavity. Comparing the $\lambda_{max}$ values of the $Ni^{II}$ complexes, it is clear that the complexes **1** and **2** differ marginally with each other, while the complexes **3** and **4** indicate an almost identical placement. These data indicate that in the solution state the $Ni^{II}$ ion is most optimally placed within the basal plane provided by the ligand framework in the following order: **1**, **2**, **3** ≈ **4**.

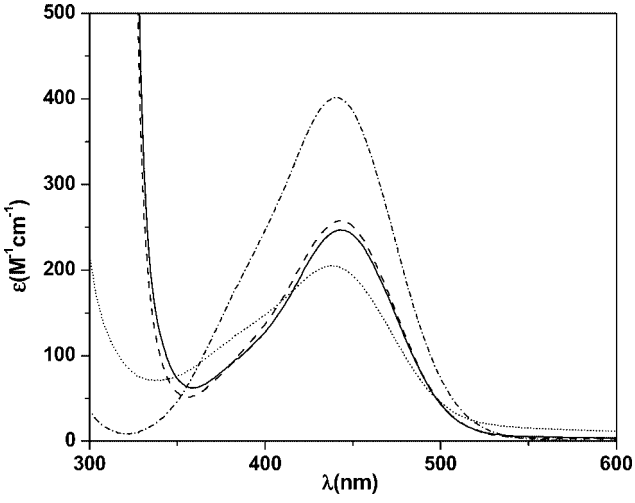

Figure 5. UV/Vis spectra of $Ni^{II}$ complexes in $CH_3CN$: complex **1** (-·-·-·-·), complex **2** (——), complex **3** (----), and complex **4** (·····).

In order to analyze the binding affinity of the axial ligands towards the present square planar $Ni^{II}$ complexes, **1**–**4** were titrated with few potential monodentate ligands [$Cl^–$, pyridine, 4-(dimethylamino)pyridine]. No change in the absorbance maximum was observed for any of the four complexes. This experiment rules out the binding affinity of

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

such ligands towards nickel complexes. For the similar reason, absorption spectra were also recorded in better coordinating solvent, for example, DMF, DMSO, and $H_2O$ (Figure S3, S4, and S5). The $\lambda_{max}$ was observed in a narrow range (430–444 nm) for all four complexes, thus again eliminates the possibility of the solvent coordination. A shoulder at ca. 380 nm was also noticed for all complexes; the intensity of this shoulder was found to vary with the solvent of study.

### Nuclear Magnetic Resonance Studies

To investigate the solution state structures of the nickel complexes, their $^1H$ and $^{13}C$ NMR spectroscopic studies were performed (Figures S6, S7, S8, S9 and Table 3, Table S2). $^1H$ NMR spectra of all complexes were recorded in [$D_6$]DMSO as well as in $CD_3CN$ and are very similar. All complexes, **1**–**4** are diamagnetic with $S = 0$ ground state as displayed by their diamagnetic NMR spectra. Assignments of the signals have been made through the consideration of the relative peak areas and comparison with free ligand spectrum. However, in the case of complex **1**, 2D {$^1H$-$^{13}C$} correlation spectrum was also performed to accurately assign various signals (Figure S10). The $^1H$ NMR spectra of all complexes are quite interesting and deserve special attention. The twisting of the $–CH_2CH_2–$ fragment (of the *N*,*N*′-dimethylethylenediamine part) results in the different chemical environment of the protons attached to these carbon centers. Two sets of H signals were observed as multiplets for complex **1** and **3** at 2.67 and 3.76; and 2.74 and 3.86 ppm, respectively (labeled as proton *a* and *c*, respectively). The $–CH_2CH_2–$ fragment of the deprotonated amide backbone was also twisted and resulted in the appearance of the multiplets at $\delta = 2.67$ and 3.21 ppm (labeled as proton *a* and *b*, respectively) for **1**, and 2.78 and 3.22 ppm for **2**, respectively. Coincidently, for complex **1**, one of the $–CH_2–$ group's proton signals (labeled as proton *a*) were observed at the same position suggesting a similar chemical environment. The most interesting aspect of the spectra of all complexes **1**–**4** is the observation of the AB-type coupling (or geminal coupling) between the protons attached to the $–C(O)CH_2–$ fragment.[11,12] The signals for the pair of protons from the $–C(O)CH_2–$ fragment (*d* and *e*) appear at $\delta = 3.07$ and 4.00 ppm for **1**, 3.70 and 4.15 for **2**, 3.12 and 4.13 ppm for **3**, and 3.89 and 4.43 ppm for **4**. The geminal coupling constant, $J(H^dH^e)$ for complexes **1** and **3** was 15.9 Hz, while a value of ca. 15.5 Hz was observed for **2** and **4**, respectively. The observation of the AB-type coupling in these complexes suggests the rigid nature of the macrocyclic ligands that places protons *d* and *e* in different chemical environment. In general, the $^1H$ NMR spectra of the transition metal complexes of azamacrocyclic ligands are complicated due to the "frozen" conformation of the chelate rings[11,12] and the spectra of **1**, **2**, **3**, and **4**

are no exception. Conformational rigidity of such systems results from the fact that the inversion of the chelate rings requires a change of the configuration of the coordinated amine nitrogen atom(s). The complex nature of the $^1$H NMR spectra of **1**–**4** is most likely arising due to the macrocyclic nature of the coordinated ligand. The inherent strain of the macrocyclic ligand have caused few of the carbon centers to be out of the plane as also observed in the crystal structure determination (vide supra).

In contrast to the proton NMR spectra, the $^{13}$C NMR spectra of **1**–**4** are quite straight forward (Table S2, Figure S9). Even though proton NMR spectra reflected the complexity arising due to the non-planarity of few carbon centers that resulted in the different chemical environment for the attached protons, the carbon NMR spectra were averaged out. A close similarity in the $^{13}$C chemical shifts of identical carbon centers was observed for all complexes. For example, the methyl C signals were observed in a close range of 47–52 ppm. Similarly, the chemical shift for the carbon centers of *N*,*N*′-dimethylethylenediamine part (labeled as *d*) were seen at $\delta \approx 60$ ppm for **1** and **3**.

There was no evidence of any paramagnetic species in the NMR spectra, which show that the Ni$^{II}$ complexes retain their square-planar geometry in solution. This observation also corroborate the identical conclusion drawn from the absorption spectral studies that the Ni$^{II}$ complexes of the present ligands do not bind various axial ligands [Cl$^-$, pyridine, 4-(dimethylamino)pyridine, or solvents, etc.].

## Electrochemical Studies

Cyclic voltammetric (CV) and controlled potential electrolysis (coulometric) studies were performed for all four Ni$^{II}$ samples to investigate the extent of stabilization of the Ni$^{III}$ state as well as the possible ligand oxidation.[22] In addition, the CV results will also help in understanding the accessibility of the higher oxidation states and the effect of the ligand architecture on the redox potential. The electrochemical data for complexes **1**–**4** are summarized in Table 4.

### *Electrochemistry in CH$_3$CN*

The 1$^{st}$ oxidation process for all complexes is displayed in Figure 6, while the complete oxidation range is shown for complex **4** (Figure 7). In $CH_3CN$, for 1$^{st}$ oxidation, each complex undergo 1e$^-$ oxidation in the potential range of 0.61–0.83 V (vs. SCE). The one electron nature of each redox response has been confirmed by the controlled potential electrolysis experiments. The peak-to-peak separation ($\Delta E_p$) for the 1$^{st}$ response, for complexes **1**–**4** are in the range of 60–100 mV and point out towards reversible to quasi-reversible nature of the responses (Table 4). For comparison, the redox potential for the complex, [Ni(dioxo[12]-aneN$_4$)] is 0.62 V[10b] (vs. SCE in $H_2O$) while Ni complexes of 13- and 14-analogues appear at higher potential (> 0.80 V, Table 4).[10b–10e,10g] No reduction wave was observed in the potential range studied (–2.0 V for $CH_3CN$ and –2.2 V for DMF vs. SCE).

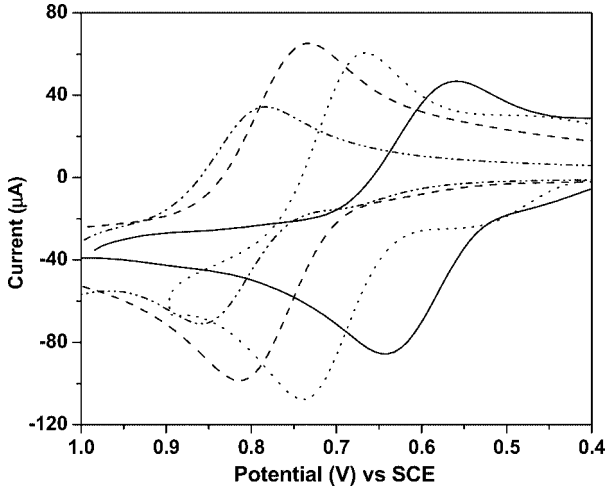

Figure 6. Cyclic voltammograms of Ni$^{II}$ complexes in $CH_3CN$: complex **1** (——), complex **2** (----), complex **3** (·····), and complex **4** (-·-·-·-·).

The complex **1** show only one oxidation response at 0.61 V ($\Delta E_p$ = 90 mV), as expected for the Ni$^{II}$ complex of a perfect innocent ligand. On the other hand, rest of the

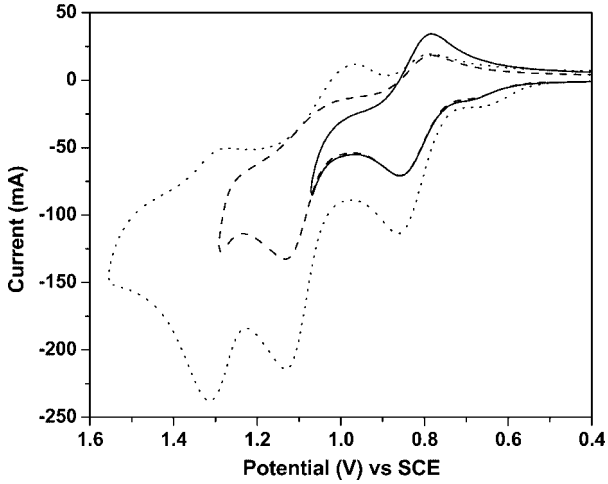

Figure 7. Cyclic voltammogram of complex **4** in $CH_3CN$.

complexes, **2**, **3**, and **4** display oxidation waves corresponding to both metal as well as the ligand oxidation(s). The extent of the non-innocent feature(s) increases in the following order: **1** > **2** ≈ **3** > **4**. The complex **2** display oxidation waves at 0.78 and 1.88 V ($E_{pa}$), which we assign as the $Ni^{III/II}$ response and irreversible ligand oxidation, respectively. The similar responses for the complex **3** were observed at 0.71 and 1.1 V ($E_{pa}$), respectively. For complex **3**, the occurrence of the ligand oxidation potential at much lower potential is most likely due to the involvement of the ring π–current in resonance with the nickel *d*-electrons. The complex **4** exhibits three oxidation peaks at 0.83 V, 1.13 ($E_{pa}$), and 1.32 ($E_{pa}$) V, while the 1st one is metal-centered, the other two processes are ligand-centered. It has been found that the ligands incorporating 1,2-diaminobenzene ring are susceptible to oxidation, generating a cation radical.[22c,23,24] Based on these literature reports we tentatively assign the redox processes observed at >1.1 V located on the ligand π-system.[24f,24g]

A comparison of the stepwise redox potential values of the $[Ni(Ligand)]^+/[Ni(Ligand)]$ ($E_1$) and $[Ni(Ligand)]^{2+}/[Ni(Ligand)]^+$ ($E_2$) couples for all four complexes, **1**–**4** allows the establishment of the nature of the singly, doubly, and in one case triply oxidized species along the present series of the complexes. The four different ligands used in the present study differ only by the placement of the amine and amide fragments within the ethylene or *o*-phenylene part that coordinate to the nickel ion. For example, the ligand $H_2\mathbf{1}^{EN}$ is an innocent one while the other three ligands have at least one non-innocent feature, either in the form of extended π-conjugated *o*-phenylenediamidate fragment or *N*,*N*′-dimethyl-*o*-phenylenediamine fragment. The significant shift in the $E_1$ potentials of complexes **1**–**4** toward more positive values according to $[\mathbf{1}^{EN}]^{2-} < [\mathbf{3}^{OP}]^{2-} < [\mathbf{2}^{EN}]^{2-} < [\mathbf{4}^{OP}]^{2-}$ clearly indicates that the 1st oxidation is metal-centered, leading to a $Ni^{III}$ species. The destabilization of the trivalent oxidation state by increasing the π-conjugated *o*-phenylene fragment(s) is attributed to the poor donor capacity of such ligands due to the delocalization of the negative charge on the deprotonated amide groups into the attached phenylene fragment.[25,26]

In contrast, the $E_2$ value for the second oxidation, for complexes and **3** and **4**, appear at ca. 1.1 V and does not vary upon changing the ligand. This situation is more consistent with ligand-centered oxidation at the *o*-benezenediamidate fragment, generating the $Ni^{III}$-*o*-benzosemiquinonediimine π-cation species.[25] The almost identical potential for $E_2$ (except for complex **2**) rules out metal-centered oxidation as that would have resulted in altered potential due to the ligand field effect. For complex **2**, an irreversible response was observed at a very high potential (ca. 1.9 V vs. SCE). We tentatively assign this response as the oxidation of the *o*-phenylene-*N*,*N*′-dimethyldiamine fragment. The reason for very high positive potential could be due to the non-conjugation of the $sp^3$-based fragment with Ni center. Interestingly, a 3rd potential ($E_3$) for the complex **4** was noticed as an irreversible process at ca. 1.3 V vs. SCE. We again assign this redox process based at the *N*,*N*′-dimethyl-*o*-phenylenediamine fragment. However, why this oxidation appears at a lower potential than the complex **2** is not clear to us.

### *Electrochemistry in DMF*

CV studies were also carried out in DMF to understand the effect of a more polar and better coordinating solvent. A comparative CV plot is shown in Figure 8 while the data are presented in Table 4. As can be seen from the Table 4, the $Ni^{III}/Ni^{II}$ potential are between the range of 0.53 V, lowest for complex **1**, and 0.78 V, highest for complex **4**. A similar trend has been observed before in $CH_3CN$. However, in general, the $Ni^{III}$ state is more stabilized by 40 mV for complex **3** to 110 mV for **2** in DMF than in MeCN. This investigation reveals that the $Ni^{III}$ state of the complexes is better stabilized due to the enhanced solvation, as the polarity of the solvent increased. Ligand-centered oxidation ($E_{pa}$) for complexes, **3** and **4** were observed at 1.13 and

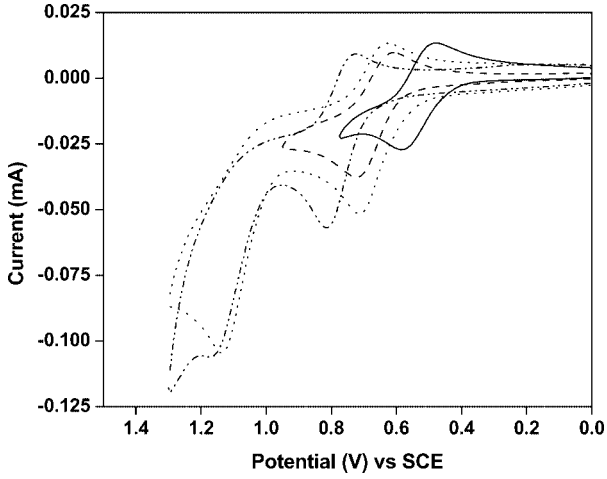

Figure 8. Cyclic voltammograms of $Ni^{II}$ complexes in DMF: complex **1** (——), complex **2** (----), complex **3** (·····), and complex **4** (-·-·-·-).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

1.20 V, respectively, as noted before in MeCN. The observed potentials are consistent with the oxidation of *o*-benzenediamidate fragment, generating the $Ni^{III}$-*o*-benzosemiquinonediimine π-cation species. Finally, the oxidation of the *N*,*N*′-dimethyl-*o*-phenylenediamine fragment was not observed within the solvent limit.

### *Electrochemical Oxidation and Spectroscopic Characterization of the Oxidized Species*

The singly oxidized forms of complexes, **1**–**4** were generated electrochemically in $CH_3CN$ solution and characterized by the absorption and EPR spectroscopy. The electrochemical oxidation of the solution containing the respective $Ni^{II}$ complex generated a metastable green to greenish-brown species which was stable enough to record the absorption (Figure 9) and the EPR spectra (Figure 10).

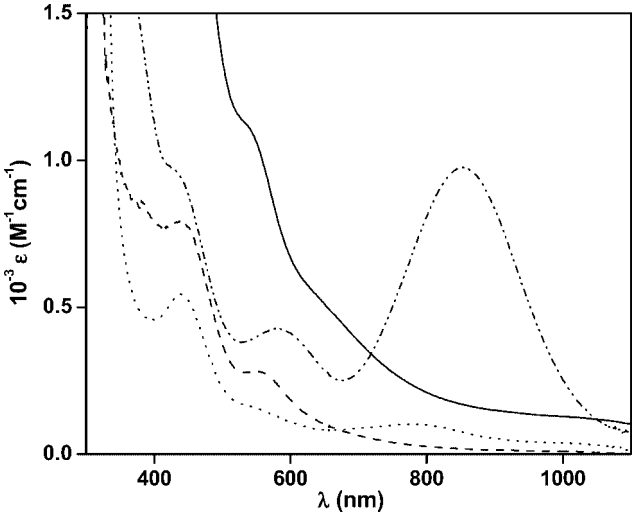

Figure 9. Absorption spectra of electrochemically generated $[\mathbf{1}^{Ox}]^+$, $[\mathbf{2}^{Ox}]^+$, $[\mathbf{3}^{Ox}]^+$, and $[\mathbf{4}^{Ox}]^+$ in $CH_3CN$: complex $[\mathbf{1}^{Ox}]^+$ (——), complex $[\mathbf{2}^{Ox}]^+$ (----), complex $[\mathbf{3}^{Ox}]^+$ (-·-·-·-), and complex $[\mathbf{4}^{Ox}]^+$ (·····).

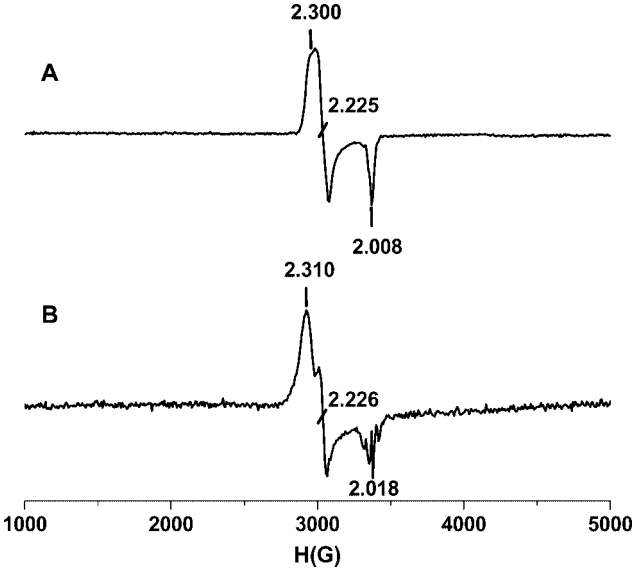

Figure 10. EPR spectra of electrochemically generated $[\mathbf{2}^{Ox}]^+$ (A) and $[\mathbf{3}^{Ox}]^+$ (B) species in $CH_3CN$ at 100 K.

The absorption spectra of these oxidized complexes have rich features and are dominated by a string of charge-transfer bands having ε values in the range of 200–1000 $M^{-1}cm^{-1}$. For complex **1**, the oxidized species $[\mathbf{1}^{Ox}]^+$ was generated after oxidizing the solution at 0.8 V vs. SCE and resulted in a brownish-green colored solution. This solution displays broad features at ca. 1000, ca. 660 and ca. 540 nm and justifies its brownish-green color. The $[\mathbf{2}^{Ox}]^+$ was generated after setting the potential at 0.95 V vs. SCE and produced a green solution with $\lambda_{max}$ at 555 and 437 nm. An intense deep green solution resulted when the complex **3** was oxidized at 0.90 V. Here, an exceptionally intense peak with $\lambda_{max}$ at 855 nm (ε ca. 1000 $M^{-1}cm^{-1}$) was noticed along with two weak features at 580 and ca. 430 nm. Qualitatively, this oxidized species was also the most stable one. We believe that the close proximity of the *o*-benzenediamidate fragment with the $Ni^{III}$ center has helped in the delocalization of the unpaired spin onto the ligand's π orbitals. This enhanced delocalization has resulted in the better stability of the green species as well as the occurrence of the intense and broad absorption features in the visible region. In contrast, a less stable pale-green species resulted after the oxidation at 1.0 V for complex **4**. For $[\mathbf{4}^{Ox}]^+$, the absorption features were observed at ca. 1020, 780, ca. 550, and 440 nm. By a purely qualitative comparison, the oxidized species $[\mathbf{2}^{Ox}]^+$ and $[\mathbf{4}^{Ox}]^+$ are more unstable than the other two species, $[\mathbf{1}^{Ox}]^+$ and $[\mathbf{3}^{Ox}]^+$. The most probable reason is that the incorporation of the non-planar *N*,*N*′-dimethyl-*o*-phenylenediamine fragment in the complexes, **2** and **4** (cf. crystal structures) may have increased the distortion at the nickel center and diminish the possibility of the delocalization of the unpaired spin accumulated on the $Ni^{III}$ ion.

The $Ni^{II}$ complexes of various macrocyclic ligands listed in Scheme 1 have also been reported for their ability to stabilize the $Ni^{III}$ state. The electrochemical or chemical oxidation of the aqueous solution resulted in the generation of a "brown" species that displays transitions in the UV region, 300–360 nm.[10b,10d,27,28] The nature of these transitions has been suggested to be charge transfer. A six-coordinate species has been suggested with solvent molecules serving as the axial ligands. Recently, Journaux and Garcia have reported a solution generated $Ni^{III}$ species of a tetradentate tetraamide ligand.[25c] For this systems, the $\lambda_{max}$ for the $Ni^{III}$ species was observed at 910 with a shoulder at 760 nm. The observed similarity between the $Ni^{III}$ species of Journaux and Garcia to that of our systems suggest a similar electronic chromophore.[25c]

The solution generated oxidized species, $[\mathbf{1}^{Ox}]^+$ – $[\mathbf{4}^{Ox}]^+$, display anisotropic signals in their X-band EPR spectra. The EPR spectra of the singly oxidized $Ni^{III}$ –complexes, $[\mathbf{2}^{Ox}]^+$ and $[\mathbf{3}^{Ox}]^+$ in the frozen $CH_3CN$ solution at 100 K are shown in Figure 10. The spectra consist of a rhombic signal characteristic of a four-coordinate square-planar $Ni^{III}$ (a $d^7$ low-spin system) with an $S = 1/2$ ground state. The individual *g* values for $[\mathbf{1}^{Ox}]^+$ and $[\mathbf{2}^{Ox}]^+$ are 2.360, 2.167, and 2.005 and 2.300, 2.225, and 2.008, while for the $[\mathbf{3}^{Ox}]^+$ and $[\mathbf{4}^{Ox}]^+$ are 2.310, 2.226, and 2.018, and 2.205, 2.188, and 2.006, respectively. The large rhombicity and the

high average $g$ values ($g_{avg} = (g_1 + g_2 + g_3)/3$; 2.177, 2.178, 2.185, and 2.133, for $[\mathbf{1^{Ox}}]^+$, $[\mathbf{2^{Ox}}]^+$, $[\mathbf{3^{Ox}}]^+$, $[\mathbf{4^{Ox}}]^+$, respectively) unambiguously indicates that the oxidation is located on the Ni center, thereby confirming the $Ni^{III}$ nature of the singly oxidized species.[25] In case ligand oxidation had occurred, the resulting cation-radical would likely to exhibit an isotropic EPR spectrum with g value close to the free electron value of 2.002.[25a,25b] Moreover, the presence of three distinct signals ($g_1$, $g_2$, and $g_3$) in the spectrum also rules out the existence of a 5-or 6-coordinate species in solution as that would give an axial signal with $g_\perp > g_\parallel$. In fact, the solution generated $Ni^{III}$ species of the dioxo[14]-ane$N_4$ ligand displays $g_\perp$ at 2.23 and $g_\parallel$ at 2.02 with $g_\perp > g_\parallel$.[28] These findings along with the absorption spectroscopic data strongly suggest that the present Ni complexes remain four-coordinated. The observation of the three different g values at 2.193, 2.080, and 2.006 for the $Ni^{III}$ species reported by the Journaux and Garcia, are quite similar to the present systems, thus again indicating a similar electronic structure. In fact, these authors have suggested that the unpaired electron occupies a π-type metal 3d orbital and thus attesting the metal-centered oxidation rather than the ligand-centered oxidation.[25c]

Our efforts to characterize the doubly oxidized species were unsuccessful owing to very unstable nature of the respective species. The electrochemical oxidation at the 2nd (for **2**, **3** and **4**) and 3rd potential (for **4** only) immediately lead to the decomposition of the transiently generated species. It is to be noted, however, that all these redox processes were $1e^-$ in nature as determined by the coulometry.

### Chemical Oxidation and Vindication of Electrochemical Findings

The accessible redox potentials (cf. Table 4) of the complexes **1**–**4** and the successful electrochemical generation of the singly oxidized forms, $[\mathbf{1^{Ox}}]^+$ – $[\mathbf{4^{Ox}}]^+$, prompted us to try chemical oxidation. A number of $1e^-$ oxidants were attempted (for example, $(NH_4)_2[Ce(NO_3)_6]$, $[NO]BF_4$, and AgOTf),[29] however, a mixture of species and decomposed products avoided the clear conversion, until a rather uncommon oxidant, $Cu(OTf)_2$ was used. The redox potential of the $Cu(OTf)_2$ in $CH_3CN$ is 0.8 V vs. SCE[29] and clearly seem to cause oxidation at the first oxidation potential of the complexes **1**–**4**. Indeed, addition of 1.2 equiv. of the $Cu(OTf)_2$ to a $CH_3CN$ solution of the respective $Ni^{II}$ complex, resulted in a clean $1e^-$ oxidation. The chemical oxidation of the solution containing the respective Ni complex generated a green to greenish-brown species as observed electrochemically before. The UV/Vis spectra of the chemically oxidized form were recorded and found to be identical as shown in Figure 9. EPR spectra of the oxidized species were not attempted due to the possible contamination from the unreacted $Cu(OTf)_2$.

## Conclusions

The presented work demonstrates the syntheses and characterization of four novel square-planar $Ni^{II}$ complexes with amide-amine-based macrocyclic ligands. The important findings of the present study are summarized as follows:

(1) To the best of our knowledge, for the first time a systematic investigation has been carried out to understand the structural, spectroscopic and redox properties of the $Ni^{II}$ ion in a set of 12-membered macrocyclic ligands.

(2) Crystal structures show a very tight binding of the Ni ion by the macrocyclic ligand in all four cases. Some of the Ni–$N_{amide}$ bond lengths are the shortest amongst the literature examples.

(3) The occurrence of the geminal coupling for few protons in the proton NMR spectra clearly depict the inherent strain present in the macrocycle of the $Ni^{II}$ complexes.

(4) The low-valent $Ni^{II}$ complexes are capable of undergoing one, two and in one case three $1e^-$ oxidations that are successively metal-and ligand-centered, as revealed by the trend observed in the formal redox potentials on changing the ligand along the present series of the complexes.

(5) The $Ni^{III}$ species were generated in solution both electrochemically and chemically [after oxidizing with $Cu(OTf)_2$] and shown to have rich spectroscopic features.

(6) The unstable $1e^-$ oxidized species are concluded to be $Ni^{III}$ species by the absorption spectra and their anisotropic EPR spectra typical for a $Ni^{III}$ ion in a square-planar geometry.

(7) The $2e^-$ and $3e^-$ oxidations, which are ligand-centered, lead to immediate decomposition, and prevented us to characterize this species.

## Experimental Section

**Materials and Reagents:** All reagents were obtained from commercial sources and used as received. *N*,*N*′-Dimethylformamide (DMF) was dried and distilled from 4-Å molecular sieves and stored over sieves. Acetonitrile (MeCN) was dried by distillation from anhydrous $CaH_2$. Diethyl ether was dried by refluxing over sodium metal wires under inert atmosphere. Tetrahydrofuran (THF) was dried by refluxing and distilling from sodium metal and benzophenone. Ethyl alcohol ($C_2H_5OH$) and methyl alcohol ($CH_3OH$) were distilled from magnesium ethoxide and magnesium methoxide, respectively. Chloroform ($CHCl_3$) and dichloromethane ($CH_2Cl_2$) were purified by washing with 5% aqueous sodium carbonate solution followed by water and finally dried with anhydrous $CaCl_2$, before a final reflux and distillation. Petroleum ether (boiling range: 60–80 °C) and hexanes (boiling range: 60–80 °C) were dried by refluxing and distilling over sodium metal wires. *N*,*N*′-bis(chloroacetyl)ethylenediamine and *N*,*N*′-bis(chloroacetyl)-*o*-phenylenediamine were prepared according to a published procedure.[14]

### Ligand Syntheses

**$H_2\mathbf{1}^{EN}$:** LiBr (0.8 g, 9 mmol), $Na_2CO_3$ (4.0 g, 40 mmol) and *N*,*N*′-bis(chloroacetyl)ethylenediamine (1.0 g, 5 mmol) were taken in MeCN (140 mL) and the mixture was refluxed with stirring for 1 h. To this was added *N*,*N*′-dimethylethylenediamine (0.4 g, 5 mmol) dissolved in MeCN (20 mL). The resulting mixture was refluxed whilst stirring for an additional 48 h. The mixture was cooled, filtered and the solvent was removed under reduced pressure to afford a semi-mass. The crude product was further purified by column

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chromatography using silica gel (100–200 mesh) with 10% MeOH/$CHCl_3$ ($R_f$ = 0.45). A white product was obtained after purification. Yield 0.15 g (16%). An analytically pure product (in ca. 75% yield) can also be obtained by recrystallizing the crude product by layering the $CHCl_3$ solution with the petroleum ether (boiling range: 60–80 °C). $C_{10}H_{20}N_4O_2$ (228.30): calcd. C 52.61, H 8.83, N 24.54; found C 52.95, H 8.82, N 24.34. M.p. 170–174 °C. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.38 (s, 6 H, $CH_3$), 2.50 (s, 4 H, $–CH_2CH_2–$), 2.96 [s, 4 H,$–CH_2C(O)$-], 3.48 (m, 4 H, $–CH_2CH_2–$), 7.2 [s (broad), 2 H, NH] ppm. FT-IR (KBr disk): $\tilde{\nu}$ = 3310, 2940, 2840, 2820, 2781, 1651 cm$^{-1}$. MS (EI$^+$, *m*/*z*): calcd. for $C_{10}H_{20}N_4O_2$ 228.30, found 228.58.

**$H_22^{EN}$:** This ligand was synthesized in a similar manner as that of $H_21^{EN}$ with following reagents: LiBr (0.51 g, 5.8 mmol), $Na_2CO_3$ (2.49 g, 23.52 mmol), *N*,*N*′-bis(chloroacetyl)ethylenediamine (0.63 g, 2.94 mmol), and *N*,*N*′-dimethyl-*o*-phenylenediamine (0.4 g, 2.94 mmol). The crude product was recrystallized by layering the $CHCl_3$ layer with hexanes. Yield 0.250 g (30%). $C_{14}H_{20}N_4O_2$ (277.34): calcd. C 60.85, H 7.30, N 20.28; found C 60.79, H 7.18, N 19.68. M.p. 164–165 °C. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.85 (s, 6 H, $CH_3$), 2.78 (s, 4 H, $–CH_2–CH_2–$), 3.56 [s, 4 H, $–CH_2–C(O)–$], 7.2–7.4 (m, 4 H, arom.), 9.5 [s (broad), 2 H, NH] ppm. FT-IR (KBr disk): $\tilde{\nu}$ = 3233, 3050, 2866, 1664 cm$^{-1}$. MS (EI$^+$, *m*/*z*): calcd. for $C_{14}H_{20}N_4O_2$ 277.34, found 277.344.

**$H_23^{OP}$:** This ligand was synthesized in a similar manner as that of $H_21^{EN}$. However, this time following reagents were used: LiBr (0.7 g, 8 mmol), $Na_2CO_3$ (4.0 g, 32 mmol), *N*,*N*′-bis(chloroacetyl)-*o*-phenylenediamine (1.0 g, 4 mmol), and *N*,*N*′-dimethylethylenediamine (0.4 g, 4 mmol). The crude product was recrystallized from $CHCl_3$ solution after layering with the petroleum ether (boiling range: 60–80 °C). Yield 0.90 g (95%). $C_{14}H_{20}N_4O_2$ (276.34): calcd. C 60.85, H 7.30, N 20.28; found C 60.49, H 7.42, N 20.61. M.p. 164–165 °C. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.45 (s, 6 H, $CH_3$), 2.64 (m, 4 H, $–CH_2–CH_2$), 3.16 [s, 4 H, $–CH_2C(O)–$], 7.21 (m, 2 H, arom.), 7.60 (m, 2 H, arom.), 9.48 [s (broad), 2 H, NH] ppm. FT-IR (KBr disk): $\tilde{\nu}$ = 3221, 2942, 2833, 1674 cm$^{-1}$. MS (EI$^+$, *m*/*z*): calcd. for $C_{14}H_{20}N_4O_2$ 276.34, found 276.38.

**$H_24^{OP}$:** Using the aforementioned procedure, the ligand $H_24^{OP}$, was synthesized with following reagents: LiBr (1.3 g, 14.8 mmol), $Na_2CO_3$ (6.3 g, 59 mmol), *N*,*N*′-bis(chloroacetyl)-*o*-phenylenediamine (1.93 g, 7.4 mmol), and *N*,*N*′-dimethyl-*o*-phenylenediamine (1.0 g, 7.4 mmol). The crude product was recrystallized from $CHCl_3$ solution after layering with the petroleum ether (boiling range: 60–80 °C) or hexanes. Yield 1.0 g (42%). $C_{18}H_{20}N_4O_2$ (324.38): calcd. C 66.65, H 6.21, N 17.27; found C 66.7, H 6.15, N 16.98. M.p. 178–184 °C. $^1$H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta$ = 2.95 (s, 6 H, $CH_3$), 3.72 [s, 4 H, $–CH_2C(O)$-], 7.12 (m, 4 H, arom.), 7.22 (m, 4 H, arom.), 7.52 [s (broad), 2 H, NH] ppm. FT-IR (KBr disk): $\tilde{\nu}$ = 3317, 3221, 2942, 2833, 1689 cm$^{-1}$. MS (EI$^+$, *m*/*z*): calcd. for $C_{18}H_{20}N_4O_2$ 324.38, found 324.60.

### Syntheses of Metal Complexes

**[$Ni^{II}(1^{EN})$] (1) Method A:** The ligand $H_21^{EN}$ (0.10 g, 0.44 mmol) was dissolved in DMF (10 mL) under magnetic stirring and solid NaH (0.023 g, 0.96 mmol) was added under nitrogen atmosphere. The resulting mixture was stirred until $H_2$ evolution was ceased. To this mixture was added a solution of $NiCl_2$ (0.057 g, 0.44 mmol) dissolved in DMF (5 mL). The resulting deep yellow solution was stirred for 3 h at room temperature. The solvent was evaporated under reduced pressure and the crude compound was isolated after washing with diethyl ether. The crude compound was dissolved in MeCN (15 mL) and passed through celite pad in a medium porosity frit. The filtrate was concentrated to 1/3$^{rd}$ of its original volume and the diffusion of diethyl ether resulted in deep yellow crystalline product in a day. The product was filtered and dried under vacuum. Yield 0.040 g (35%).

**Method B:** The ligand $H_21^{EN}$ (0.10 g, 0.439 mmol) was dissolved in MeOH (5 mL) and treated with solid NaOH (0.035 g, 0.88 mmol) under magnetic stirring. A solution of $Ni(OAc)_2$ dissolved in MeOH (6 mL) was added dropwise to the ligand solution. The resulting straw yellow solution was stirred for 2 h at room temperature. The solvent was removed under reduced pressure and the crude compound was isolated after washing with diethyl ether. The recrystallization was achieved by dissolving the crude compound in MeCN and diffusing diethyl ether. The highly crystalline deep yellow product was filtered, washed with diethyl ether and dried under vacuum. Yield 0.050 g (40%). $C_{10}H_{18.5}N_4O_{2.25}Ni$ (including $0.25H_2O$, 284.97): calcd. C 41.49, H 6.40, N 19.36; found C 41.56, H 6.39, N 19.03. FT-IR (KBr disk): $\tilde{\nu}$ = 3400, 2984, 2948, 2905, 2859, 2808, 1607 cm$^{-1}$. Conductivity ($CH_3CN$, ca. 1 mM solution, 298 K): $\Lambda_M$ = 2 $\Omega^{-1}$ cm$^2$ mol$^{-1}$. UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in $CH_3CN$): 230 sh (18200), 260 sh (6100), 436 (390). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in DMF): 440 (400). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in DMSO): 440 (570). UV/Vis [($\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in $H_2O$): 435 (140). MS (EI$^+$, *m*/*z*): calcd. for $C_{10}H_{18}N_4O_2Ni$ 284.08, found 285.05 (**1** + H$^+$). $^1$H NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 2.49 (s, 6 H, $–CH_3$), 2.67 (m, 4 H, $–CH_2–$), 3.07 (d, 2 H, $–CH_2C(O)–$), 3.21 (m, 2 H, $–CH_2–$), 3.76 (m, 2 H, $–CH_2–$), 4.00 (d, 2 H, $–CH_2C(O)–$) ppm. $^1$H NMR ($CD_3CN$, 300 MHz, 25 °C): $\delta$ = 2.45 (s, 6 H, $–CH_3$), 2.66 (m, 4 H, $–CH_2–$), 3.08 (d, 2 H, $–CH_2C(O)–$), 3.25 (m, 2 H, $–CH_2–$), 3.69 (m, 2 H, $–CH_2–$), 3.90 (d, 2 H, $–CH_2C(O)–$) ppm. $^{13}$C NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 48.21 ($–CH_3$), 49.07 ($–CH_2CH_2–$), 60.70 ($–CH_2CH_2–$), 69.66 ($–C(O)CH_2–$), 175.14 (C=O) ppm.

**[$Ni^{II}(2^{EN})$] (2):** This complex was synthesized following the method **A** (yield 45%) or **B** (yield 35%) for complex **1**. $C_{14}H_{19}N_4O_{2.5}Ni$ (including $0.5H_2O$, 333.01): calcd. C 46.70, H 5.83, N 15.56; found C 46.51, H 5.83, N 15.32. FT-IR (KBr disk): $\tilde{\nu}$ = 3400, 2935, 2866, 1598 cm$^{-1}$. Conductivity ($CH_3CN$, ca. 1 mM solution, 298 K): $\Lambda_M$ = 12 $\Omega^{-1}$ cm$^2$ mol$^{-1}$. UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in $CH_3CN$): 241 (7560), 440 (270). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in DMF): 440 (270). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in DMSO): 438 (200). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in $H_2O$): 430 (190). MS (EI$^+$, *m*/*z*): calcd. for $C_{14}H_{18}N_4O_2Ni$ 332.08, found 333.27 (**2** + H$^+$). $^1$H NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 2.78 (m, 2 H, $–CH_2–$), 2.87 (s, 6 H, $–CH_3$), 3.22 (m, 2 H, $–CH_2–$), 3.70 (d, 2 H, $–CH_2C(O)–$), 4.15 (d, 2 H, $–CH_2C(O)–$), 7.47 (m, 4 H, arom. H) ppm. $^1$H NMR ($CD_3CN$, 300 MHz, 25 °C): $\delta$ = 2.73 (m, 2 H, $–CH_2–$), 2.79 (s, 6 H, $–CH_3$), 3.23 (m, 2 H, $–CH_2–$), 3.58 (d, 2 H, $–CH_2C(O)–$), 4.13 (d, 2 H, $–CH_2C(O)–$), 7.26 (m, 2 H, arom. H), 7.36 (m, 2 H, arom. H) ppm. $^{13}$C NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 48.23 ($–CH_3$), 51.34 ($–CH_2CH_2–$), 70.03 ($–C(O)CH_2–$), 123.75 (Ar-h), 129.83 (Ar-g), 149.14 (Ar-f), 172.47 (C=O) ppm.

**[$Ni^{II}(3^{OP})$] (3):** A similar procedure as that of **1** was followed and the product was isolated as deep yellow blocks. Yield from method **A**: 42%. Yield from method **B**: 37%. $C_{14}H_{18}N_4O_2Ni$ (333.01): calcd. C 50.50, H 5.41, N 16.83; found C 50.53, H 5.33, N 16.62. FT-IR (KBr disk): $\tilde{\nu}$ = 2933, 1619, 1601 cm$^{-1}$. Conductivity ($CH_3CN$, ca. 1 mM solution, 298 K): $\Lambda_M$ = 10 $\Omega^{-1}$ cm$^2$ mol$^{-1}$. UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in $CH_3CN$): 271 (1300), 291 (11360), 444 (325). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in DMF): 292 (18200), 441 (370). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in DMSO): 441 (250). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$cm$^{-1}$)] (in $H_2O$): 437 (350). MS (EI$^+$, *m*/*z*): calcd. for $C_{14}H_{18}N_4O_2Ni$ 332.08, found 333.06 (**3** + H$^+$). $^1$H NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 2.52 (s, 6H $–CH_3$), 2.74 (m, 2

H, $-CH_2-$), 3.12 (d, 2 H, $-CH_2C(O)-$), 3.86 m, 2 H, $-CH_2-$), 4.13 (d, 2 H, $-CH_2C(O)-$), 6.54 (m, 2 H, Ar-g), 7.41 (m, 2 H, Ar-f) ppm. $^1$H NMR ($CD_3CN$, 300 MHz, 25 °C): $\delta$ = 2.64 (s, 6H $-CH_3$), 2.80 (m, 2 H, $-CH_2-$), 3.28 (d, 2 H, $-CH_2C(O)-$), 3.89 (m, 2 H, $-CH_2-$), 4.14 (d, 2 H, $-CH_2C(O)-$), 6.70 (m, 2 H, Ar-g), 7.56 (m, 2 H, Ar-f) ppm. $^{13}$C NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 47.68 ($-CH_3$), 59.72 ($-CH_2CH_2-$), 69.50 ($-C(O)CH_2-$), 119.15 (Ar-k), 120.30 (Ar-j), 142.36 (Ar-i), 171.60 (C=O) ppm.

**[Ni$^{II}$(4$^{OP}$)] (4):** This complex was also synthesized in an analogous method and the recrystallized product was isolated as orange-yellow crystals in 38% from method **A** and 30% from method **B**. $C_{18}H_{18}N_4O_2Ni$ (380.69): calcd. C 56.79, H 4.77, N 14.7; found C 56.78, H 4.85, N 14.63. FT-IR (KBr disk): $\tilde{\nu}$ = 3006, 2935, 1632 cm$^{-1}$. Conductivity ($CH_3CN$, ca. 1 mM solution, 298 K): $\Lambda_M$ = 2 $\Omega^{-1}$ cm$^2$ mol$^{-1}$. UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$ cm$^{-1}$)] (in $CH_3CN$): 265 (17000), 290 (13000), 443 (250). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$ cm$^{-1}$)] (in DMF): 291 (10600), 441 (200). UV/Vis [$\lambda_{max}$, nm ($\varepsilon$, M$^{-1}$ cm$^{-1}$)] (in DMSO): 441 (250). UV/Vis [$\lambda_{max}$, nm, qualitative (in $H_2O$)]: 438. MS (EI$^+$, *m*/*z*): calcd. for $C_{18}H_{18}N_4O_2Ni$ 380.08, found 381.35 (**4** + H$^+$). $^1$H NMR ($CD_3CN$, 300 MHz, 25 °C): $\delta$ = 3.00 (s, 6 H, $-CH_3$), 3.80 (d, 2 H, $-CH_2C(O)-$), 4.42 (d, 2 H, $-CH_2C(O)-$), 6.65 (m, 2 H, Ar-i), 7.30 (m, 2 H, Ar-h), 7.44 (m, 2 H, Ar-g), 7.62 (m, 2 H, Ar-f) ppm. $^1$H NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 3.01 (s, 6 H, $-CH_3$), 3.89 (d, 2 H, $-CH_2C(O)-$), 4.43 (d, 2 H, $-CH_2C(O)-$), 6.67 (m, 4 H, Ar-H), 7.55 (m, 4 H, Ar-H) ppm. $^1$H NMR ($CDCl_3$, 300 MHz, 25 °C): $\delta$ = 3.06 (s, 6 H, $-CH_3$), 3.86 (d, 2 H, $-CH_2C(O)-$), 4.51 (d, 2 H, $-CH_2C(O)-$), 6.85 (m, 2 H, Ar-i), 7.25 (m, 2 H, Ar-h), 7.49 (m, 2 H, Ar-g), 7.76 (m, 2 H, Ar-f) ppm. $^{13}$C NMR ([D$_6$]DMSO, 300 MHz, 25 °C): $\delta$ = 51.81 ($-CH_3$), 70.33 ($-C(O)CH_2-$), 119.41 (Ar-k), 121.09 (Ar-j), 123.59 (Ar-h), 129.94 (Ar-g), 142.46 (Ar-i), 148.81 (Ar-f), 170.63 (C=O) ppm.

**Physical Measurements:** The conductivity measurements were done in organic solvents using the digital conductivity bridge from Popular Traders, India (model number: PT-825). The elemental analysis data were obtained from Elementar Analysen Systeme GmbH Vario EL-III instrument. The NMR measurements were done using either Hitachi R-600 FT NMR (60 MHz) or an Avance Bruker (300 MHz) instrument. The infra-red spectra (either as KBr pellet or as a mull in mineral oil) were recorded using the Perkin–Elmer FTIR 2000 spectrometer. The absorption spectra were recorded using the Perkin–Elmer Lambda-25 spectrophotometer. The mass spectra were obtained on a Jeol SX102/DA-6000 instrument.

**Electrochemical Measurements:** Cyclic voltammetric experiments were performed by using a PAR model 370 electrochemistry system consisting of M-174A polarographic analyzer, M-175 universal programmer, and RE 0074 X-Y recorder or a CH instruments electrochemical analyzer (Model No. 600B Series). The cell contained a glassy carbon (PAR model G0021) or a Beckman Pt (M-39273) working electrode, a Pt wire auxiliary electrode, and a saturated calomel electrode (SCE) as reference electrode. A salt bridge (containing supporting electrolyte, tetra-*n*-butylammonium perchlorate (TBAP) dissolved in either MeCN or DMF) was used to connect the SCE with the electrochemistry solution.[30] For constant potential electrolysis experiments a Pt-mesh was used as the working electrode. The solutions were ca. 1 mM in complex and ca. 0.1 M in supporting electrolyte, tetra-*n*-butylammonium perchlorate (TBAP). Under our experimental conditions, the $E_{1/2}$ values (in Volts) for the couple Fc$^+$/Fc were 0.40 in MeCN vs. SCE.

**Crystal Structure Determination:** X-ray diffraction studies of crystal mounted on a capillary were carried out on a Bruker AXS SMART-APEX diffractometer with a CCD area detector ($K_\alpha$ radiation, $\lambda$ = 0.71073 Å, monochromator: graphite).[31] Frames were collected at $T$ = 293 as well as at $T$ = 100 K by $\omega$, $\phi$ and $2\theta$ rotation at 10 s per frame with SAINT.[32] The measured intensities were reduced to $F^2$ and corrected for absorption with SADABS.[33] Structure solution, refinement, and data output were carried out with the SHELXTL program.[33] Non-hydrogen atoms were refined anisotropically. All hydrogen atoms were placed in geometrically calculated positions by using a riding model. For complex **3**, disorder was observed for the C6 and C7 atoms of the amine fragment. These atoms (C6 and C7) were occupying two crystallographically independent positions which could be located from the additional residual electron density. The site occupancy factors were refined with the help of free variable PART instruction. Refinement of the site occupancy factors (SOFs) for the disordered atoms C6 and C7 gave the value 0.81 (2) this factor was thereafter fixed at 0.80. The occupancy factor of the other possible set of positions (C6D/C7D) was 0.20. A structure model based on a statistically disordered C atom improved the accuracy of C–C bonds of interest. H atoms have been omitted from the disordered part. Table 1 contains necessary crystallographic details.

CCDC-635113 to -635116 (for **1**–**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Crystal packing diagram of complex **2** (Figure S1); lateral view of the crystal structures of the complexes **1**, **2**, **3**, and **4** (Figure S2); absorption spectra for complexes **1**, **2**, **3**, and **4** recorded in DMF (Figure S3), DMSO (Figure S4), and $H_2O$ (Figure S5); $^1$H NMR spectra of complexes **1**, **2**, **3**, and **4** in [D$_3$]MeCN (Figure S6) and in [D$_6$]DMSO (Figure S7), $^1$H NMR spectra of complex **4** in $CDCl_3$ (Figure S8) and $^{13}$C NMR spectra of complexes **1**, **2**, **3**, and **4** in [D$_6$]DMSO (Figure S9); 2D {$^1$H-$^{13}$C} NMR spectrum of complex **1** (Figure S10); Plane and displacement parameters (Table S1); and $^{13}$C NMR spectroscopic data (Table S2).

## Acknowledgments

Authors (RG) thank the Department of Science and Technology (DST), New Delhi, India for the financial support, Professors R. Ramanan and A. K. Ganguli from Indian Institute of Technology, New Delhi, India for the crystallographic help, and DST-FIST funded single crystal diffraction facility at IIT-Delhi for data collection. We express our deepest gratitude to Professor R. Mukherjee and his research group at IIT - Kanpur for extending their laboratory facilities for the detailed electrochemical studies. Reviewer's suggestions during the revision stage were very helpful.

# Lanthanide Borohydride Complexes of Bulky Guanidinate Ligands $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Ln(\mu\text{-}BH_4)_2Li(THF)_2$ (Ln = Nd, Sm, Yb): Synthesis, Structure and Catalytic Activity in Lactide Polymerization

**Grigorii G. Skvortsov,[a] Marina V. Yakovenko,[a] Pascal M. Castro,[b] Georgy K. Fukin,[a] Anton V. Cherkasov,[a] Jean-François Carpentier,*[b] and Alexander A. Trifonov*[a]**

**Keywords:** Lanthanides / Borohydrides / Guanidinates / N ligands / Lactides / Polymerization

A series of new lanthanide borohydride complexes supported by bulky guanidinate ligands $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Ln(\mu\text{-}BH_4)_2Li(THF)_2$ [Ln = Nd (**1**), Sm (**2**), Yb (**3**)] was synthesized by the reaction of related tris(borohydride)s $Ln(BH_4)_3(THF)_2$ with a twofold molar excess of $[(Me_3Si)_2NC(N\text{-}Cy)_2]Li$ in toluene at 65 °C. The complexes were isolated after recrystallization from hexane in 66, 64, and 68 % yield, respectively. X-ray diffraction studies revealed that compounds **1**–**3** are heterodimetallic complexes that have two borohydride ligands μ-bridging the lanthanide and lithium atoms. Those compounds, especially neodymium complex **1**, act as monoinitiators for the ring-opening polymerization of racemic lactide, providing atactic polymers with a good degree of control, that is, controlled molecular weights and relatively narrow polydispersities ($1.09 < M_w/M_n < 1.77$), provided moderate substrate-to-initiator ratios are used.

## Introduction

Metallocene-type lanthanide borohydride complexes have been known for three decades;[1] nevertheless, this class of compounds still attracts considerable attention because of their structural diversity and high catalytic activity.[2] Monoanionic borohydride groups can perform both μ-bridging and terminal coordination modes that result in formation of dimeric[3,4] or monomeric organolanthanide complexes.[5–7] Depending on the central atom size and its coordination environment, borohydride anions can act in monomeric complexes as bi-[1,3,5,7,8] and tridentate[1,4,9,10] ligands. For dimeric complexes $\mu^3$:$\mu^2$-bridging coordination has been described.[4,11] A renewed interest in lanthanide borohydride complexes arose from communications on their catalytic activity in lactone,[12] lactide,[13] and methyl methacrylate[14] polymerizations. Also, some lanthanide sandwich and half-sandwich borohydrides have been used as precatalysts in two-component systems for ethylene,[9] styrene,[10a,10b] and isoprene[9,10a] polymerizations.

The stability, structures and reactivity of organic derivatives of lanthanides are known to be mainly determined by the electropositivity, Lewis acidity, and large ionic radii of these elements. These factors render organolanthanides highly sensitive to steric saturation of the metal coordination sphere and, therefore, design of the environment about the metal center is crucial. On the other hand, investigation of the influence of the ancillary ligation on the reactivity of Ln–C and Ln–H bonds may be rewarding, as it may serve as a useful tool for modification of catalytic activity of lanthanide hydrocarbyl and hydrido complexes. To date, lanthanide borohydride complexes are mainly presented by sandwich- and half-sandwich-type derivatives,[2] while compounds supported by non-cyclopentadienyl ligands still remain virtually unexplored. The yttrium borohydride complex $[Ph(NSiMe_3)_2]_2Y(BH_4)(THF)$ supported by amidinate ligands was reported by Teuben and co-workers.[15] Recently, synthesis of lanthanide borohydrides containing aryl oxide,[16] polydentate diamino-bis(phenoxide),[13] and diamide–diamine[14] ligands was described. In our continuing research we have shown that bulky guanidinate ligands provide a useful coordination environment, which allows the synthesis of isolable lanthanide hydrocarbyl[17,18] and hydrido[19,20] species. That is why we employed the guanidinate ligands for preparing lanthanide mono-[21a] and bis(borohydride)[21b] complexes. Later, Yuan and co-workers synthesized the mono(guanidinate) lanthanide borohydride complexes $[(Me_3Si)_2NC(N\text{-}Cy)_2]Ln(BH_4)_2(THF)_2$ (Ln = Er, Yb).[22] Herein we report on the synthesis, structure, and

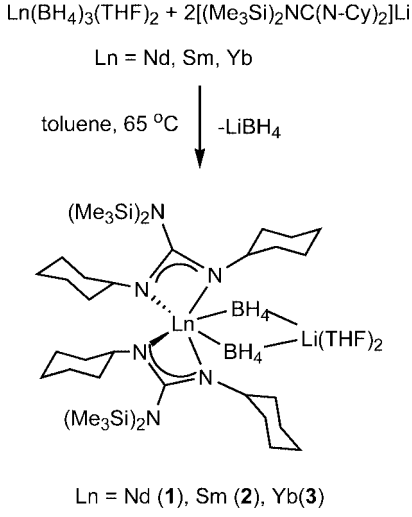
catalytic activity in lactide polymerization of heterodimetallic bis(guanidinate) borohydride complexes $\{(Me_3Si)_2NC(N\text{-}Cy)_2\}_2Ln(BH_4)_2Li(THF)_2$ (Ln = Nd, Sm, Yb).

## Results and Discussion

### Synthesis and Characterization of Lanthanide Bis(guanidinate) Borohydrides

Initially the metathesis reactions of lanthanide bis(guanidinate)chloride complexes $[\{(Me_3Si)_2NC(N\text{-}Cy)_2\}_2LnCl]_2$ (Ln = Nd, Sm) with $NaBH_4$ were investigated as a synthetic route to the related borohydrides. However, this method was found to be inefficient as the prolonged heating (48 h) of equimolar amounts of the starting reagents in THF at 65° did not allow preparation of the borohydride complexes in good yields. Increasing the amount of $NaBH_4$ (to a 1.5-fold molar excess) did not result in a higher product yield and considerable amounts (about 15–20%) of the starting chloride complexes $[\{(Me_3Si)_2NC(N\text{-}Cy)_2\}_2LnCl]_2$ were recovered in the reaction mixture. This hampered isolation and purification of the borohydride complexes. Moreover, the reaction of $[\{(Me_3Si)_2NC(N\text{-}iPr)_2\}_2SmCl]_2$ with $NaBH_4$ was found to occur with redistribution of guanidinate ligands and formation of the bis(borohydride) derivative $\{(Me_3Si)_2NC(N\text{-}iPr)_2\}Sm(BH_4)_2(DME)$.[21a] During the past decade, several reports[10–14,16] on the successful conversions of lanthanide tris(borohydrides) $Ln(BH_4)_3(THF)_n$[23–25] into new derivatives by reactions with anionic reagents have appeared. This prompted us to use $Ln(BH_4)_3(THF)_n$ complexes as starting reagents for preparation of related bis(guanidinate) borohydrides.

The reactions of $Ln(BH_4)_3(THF)_2$ (Ln = Nd, Sm, Yb) with a twofold molar excess of the lithium guanidinate $[(Me_3Si)_2NC(N\text{-}Cy)_2]Li$, obtained in situ from the amide $(Me_3Si)_2NLi(Et_2O)$ and 1,3-dicyclohexylcarbodiimide, were carried out in toluene at 65 °C (Scheme 1).



Scheme 1.

Filtration of the reaction mixture, evaporation of toluene, subsequent recrystallization of the solid residue from hexane, and drying in vacuo at room temperature afforded complexes $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Ln(\mu\text{-}BH_4)_2Li(THF)_2$ [Ln = Nd (**1**), Sm (**2**), Yb (**3**)] in 66, 64, and 68% yield, respectively. Complex **1** was isolated as blue, **2** yellow and **3** orange crystalline solids. Complexes **1**–**3** are highly air- and moisture-sensitive. Nevertheless, in an inert atmosphere, they can be stored for weeks without decomposition at room temperature. They are readily soluble in hydrocarbon solvents, which hampers their isolation by recrystallization and decreases the yields. The IR spectra of complexes **1**–**3** show, in the region 2000–2500 $cm^{-1}$, four strong absorptions diagnostic of $\mu^3$- and $\mu^2$-bridging borohydride ligands.[4,5] The $^1H$ and $^{13}C$ NMR spectra of the slightly paramagnetic complex **2** in [D$_6$]benzene at 20 °C show the expected sets of resonances for the guanidinate ligand and the coordinated THF. The borohydride group appears in the $^1H$ NMR spectrum as a broad singlet at $\delta$ = –1.34 ppm. The $^7Li$ and $^{11}B$ NMR spectra contain sole singlets at $\delta$ = 0.03 and 49.04 ppm, respectively.

Crystals suitable for single-crystal X-ray diffraction studies of **1**–**3** were obtained from hexane solutions by slow evaporation of the solvent at room temperature and were isolated as the hexane solvates $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Ln(\mu\text{-}BH_4)_2Li(THF)_2\cdot(C_6H_{14})_{0.5}$. The X-ray crystal structure investigations revealed that complexes **1**–**3** have similar structures. The molecular structure of **3** is depicted in Figure 1; the crystal and structural refinement data, and selected bond lengths and angles for **1**–**3** are listed in Tables 1 and 2, respectively. The molecular structure (Figure 1) shows that compounds **1**–**3** are heterodimetallic complexes containing one residual $LiBH_4$ per $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Ln(BH_4)$ unit in which the lanthanide and the lithium atoms are connected by two μ-bridging $BH_4$ groups. The coordination sphere of the lanthanide atoms in complexes **1**–**3** is set up by four nitrogen atoms of two guanidinate ligands and by two borohydride anions. The lithium atom is further coordinated by two THF molecules.

Despite the fact that both borohydride groups in complexes **1**–**3** are μ-bridging, their coordination modes are different: one group is tridentate with respect to the lanthanide atom and bidentate with respect to the lithium, while the second one is $\mu\text{-}\eta^2\text{:}\eta^2$-bridging in complexes **1** and **2**, but $\mu\text{-}\eta^2\text{:}\eta^1$-bridging in complex **3** (Figure 2).

The Ln–H and Li–H distances fall in the ranges 2.42(2)–2.56(2) and 1.89(2)–2.29(2) Å in complex **1**, 2.36(2)–2.53(2) and 1.88(2)–2.30(2) Å in **2**, and 2.29(2)–2.47(2) and 1.92(2)–2.13(2) Å in **3**, respectively. It should be noted that the interatomic Li(1)···H(2A) distance in **3** [2.91(2) Å] is noticeably longer than the other Li–H distances in **1**–**3** [1.89(2)–2.29(2) Å]. Obviously, the difference of the coordination modes of borohydride groups in complex **3** is caused by steric factors, which is consistent with the smallest ionic radius of ytterbium in the series of the prepared lanthanide compounds.[26] The difference in the coordination mode of the borohydride moieties to the lanthanide atom does not strongly affect the Ln–B distances: in all three complexes

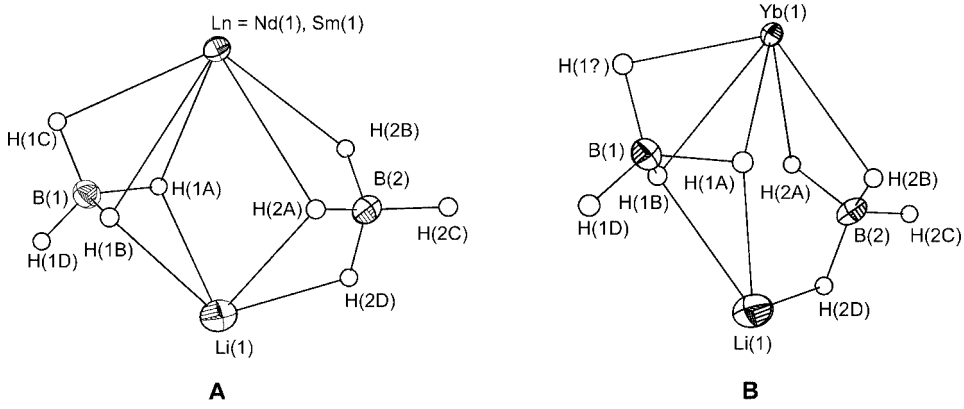

Figure 2. The coordination modes of borohydride groups in complexes $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Ln(\mu\text{-}BH_4)_2Li(THF)_2$ (A, **1**, **2**; B, **3**).

Yb. The Ln–B distances for bridging borohydride groups in complexes **1**–**3** are expectedly longer than those in complexes with terminal $BH_4$ groups[6,8,10,21] and comparable to the values reported for related dimeric compounds.[11,14] The N–C distances in the guanidinate ligands of **1**–**3** differ only slightly between each other (Table 2), which reflects the electron delocalization within the anionic NCN units. Shortening of the Ln–N, Ln–B, and Ln···Li distances in complexes **1**–**3** should lead to an increase of nonvalent interactions in the coordination sphere of the Ln atoms. Calculations[30] of the steric saturation degree about the Ln atoms have shown that the total metal atom shielding increases in the series of complexes **1** [86.6(2)%], **2** [87.8(2)%], and **3** [91.3(2)%] and reflects the steric crowding in the coordination sphere of the metal centers. The value of the dihedral angle between the N(1)C(1)N(2) and N(4)C(20)N(5) planes in **3** [78.1(1)°] is noticeably smaller than the analogous parameters in complexes **1** [79.7(1)°] and **2** [79.7(1)°], thus providing evidence for the strongest nonvalent interactions in the coordination sphere of the Yb atom.

### Ring-Opening Polymerization of *rac*-Lactide and (*S*,*S*)-Lactide

There is considerable interest in the controlled ring-opening polymerization (ROP) of lactides (LAs) by well-defined metal initiators because of the biodegradable and biocompatible nature of polylactides (PLAs) and their potential commercial applications.[31–34] Bonnet, Mountford et al. have studied the ROP of racemic (*S*,*S*/*R*,*R*)- and (*S*,*S*)-lactide with monoborohydride rare earth complexes (Y, Sm, Nd) supported by diamino-bis(phenolate) ligands.[13] These systems feature moderate activity and enable the formation of heterotactic-enriched (up to 87% $P_r$) or isotactic PLAs, with relatively narrow molecular-weight distributions ($M_w/M_n$ = 1.3–1.7), though the molecular weights were lower than expected, because of chain transfer reactions. Arnold and co-workers have investigated the ROP of lactide with monoguanidinate–lanthanum complexes having two reactive phenolate ligands.[35] The PLAs obtained had relatively broad molecular-weight distributions ($M_w/M_n$ = 1.5–2.0)

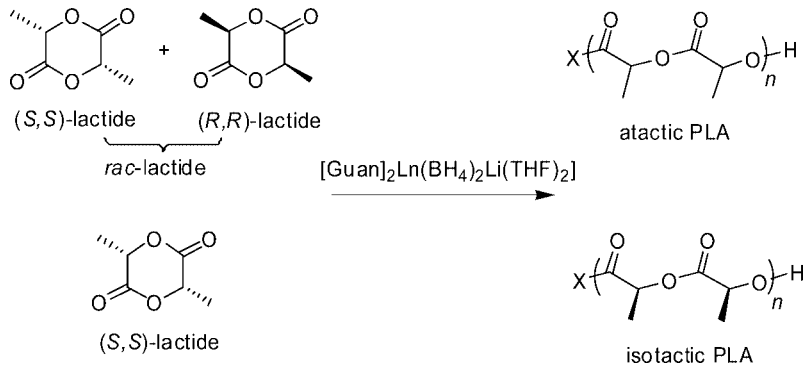
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and no control over the stereochemistry of the polymer was observed. Interestingly, the molecular weights increased linearly with a monomer-to-metal ratio up to 500, but dramatically decreased for higher [LA]/[La] ratios, an observation indicative of a high degree of chain transfer, ascribed to the presence of two phenoxide groups per metal center.

Complexes **1**–**3** have been evaluated in the ROP of *rac*- and (*S*,*S*)-lactide (Scheme 2). A blank experiment using $LiBH_4$ showed this compound is not active for the ROP of *rac*-lactide under the conditions used. This observation is in line with previous observations in the ROP of cyclic esters (ε-caprolactone) and carbonates (TMC) (S. Guillaume, personal communication), and discards the possibility that ROP is initiated by $LiBH_4$ arising from dissociation of complexes **1**–**3**.

Representative results are summarized in Table 3. Complexes **1**–**3** are moderately active under mild conditions, allowing conversion of 100–400 equiv. of lactide in 10–1000 min at room temperature in either toluene or THF solutions at [LA] = 0.5 mol/L. Kinetic monitoring revealed, however, that activities of the complexes are dramatically affected by the nature of the metal center and polymerization solvent. With the three complexes investigated, the reactions proceeded much faster in an apolar, noncoordinating solvent such as toluene than in THF. It is assumed that the latter solvent, because of its high affinity for oxophilic metals such as lanthanides, competes with the lactide monomer in the coordination onto the metal center, thus accounting for the longer completion times. A similar detrimental effect of THF on the rate of ROP reactions promoted by group 3 metal complexes is often observed.[36] Nevertheless, it is noteworthy that Bonnet, Mountford et al. have observed an opposite trend for the ROP of lactides with diamino-bis(phenolate)-lanthanide borohydride complexes; that is, polymerization rates are higher in THF than in toluene.[13] For both series of reactions carried out in toluene and in THF with complexes **1**–**3**, the observed decreasing order of activity was Nd >> Yb > Sm. There is, therefore, no direct correlation of the polymerization activity with ionic radii of the lanthanide centers, and this observation rather points out that more subtle parameters should be taken into account.

All the PLAs produced from *rac*-lactide with the initiators **1**–**3** show atactic microstructures, as determined by NMR analysis.[37–39] Contrary to our previous observations with [amino-ether-bis(phenolate)]-lanthanide amido systems,[13,37] decreasing the temperature down to –20 °C and changing the solvent (toluene vs. THF) resulted in no en-



Scheme 2.

hancement of stereoselectivity. Polymerization of (*S*,*S*)-lactide by **2** (entry 11) or **1** resulted in pure isotactic PLA; the decoupled $^1$H NMR spectrum of the polymer showed one sharp resonance for the methine region. This observation supports the lack of base-promoted epimerization of lactide or PLA and argues against an anionic polymerization mechanism being operative.[40,41]

Experiments aimed at investigating the degree of control of polymerizations were carried out. All the PLAs obtained with borohydride complexes **1**–**3** showed monomodal GPC traces with polydispersity values in the range $M_w/M_n$ = 1.09–2.99. In general, quite narrow molecular-weight distributions ($1.09 < M_w/M_n < 1.50$) were observed for polymerizations carried out in toluene and for monomer-to-metal ratios ≤200, indicative of a single-site character under these conditions. For the three initiators, the number-average molecular mass ($M_n$) values increase monotonously, though not linearly, with the monomer-to-metal ratio. An important issue with complexes **1**–**3** is to assess if they act as mono- or di-initiators; that is, if only one or both borohydride groups initiate a polymer chain. The corrected experimental number-average molecular mass ($M_n$) values of PLAs produced with **1** are in most cases close to the theoretical ones, calculated on the assumption that a single $HBH_3$ group initiates the polymerization, that is a single PLA chain is produced per metal center (entries 1–4). For PLAs produced by **2** and **3**, the experimental $M_n$ values approximately matched the calculated ones on the latter principle, but only if the monomer-to-metal ratio was low. For [LA]/[Sm] = 400 and [LA]/[Yb] > 200, the molecular weight distributions were large, which hampers meaningful comparisons of $M_n$ values. Thus, system **1** features overall a better control of polymerizations than complexes **2** and **3** do. This observation corroborates the aforementioned difference in activity between **1**, and **2** and **3**, and suggests that the former and latter complexes may have different initiation processes.

The $^1$H NMR spectra in $CDCl_3$ of relatively low-molecular-weight samples of PLA (e.g., entry 6) all show the quartet characteristic of the C*H*(Me)OH terminal group at $\delta$ = 4.33 ppm. The latter group is formed after hydrolysis of the metal–alkoxide bond, an observation that is indicative of a classical coordination/insertion mechanism with an initial ring-opening through acyl–oxygen bond cleavage.[42–45] It has been recently reported by Guillaume and co-workers that, in the ROP of ε-caprolactone with lanthanide borohydride complexes, the [$HBH_3$] functionality acts as both an initiating group and a reducing agent, yielding α,ω-telechelic poly(ε-caprolactone) diols by reduction of the aldehyde formed after the insertion of the first monomer into the metal–hydride bond.[12,46,47] A similar result was asserted about the ROP of *rac*- and (*S*,*S*)-lactide with diamino-bis(phenolate)-lanthanide borohydride initiators, yielding α,ω-telechelic PLA diols, however without supporting this statement with experimental data.[13] In our case, the presence of a second alcohol function at the other extremity of the polymer chain could not be established unambiguously; additional resonances were observed, which include a doublet of doublet at $\delta$ = 5.50 ppm and two doublets/quartets at $\delta$ = 4.15 and 4.45 ppm, which could correspond to C$H_2$OH end-groups; but their lower than expected intensity and diversity suggest incomplete and/or multiple processes (see Supporting Information; see footnote on the first page of this article).

## Conclusions

Bulky guanidinate ligands provide a suitable coordination environment that allows synthesis of isolable monomeric borohydride derivatives $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Ln(\mu\text{-}BH_4)_2Li(THF)_2$ (Ln = Nd, Sm, Yb) in reasonable yields. The complexes, especially neodymium complex **1**, act as monoinitiators for the ring-opening polymerization of racemic lactide, providing atactic polymers with a certain degree of control, that is, controlled molecular weights and relatively narrow polydispersities, provided moderate substrate-to-initiator ratios are used.

## Experimental Section

**General Conditions:** All experiments were performed in evacuated tubes, using standard Schlenk techniques, with rigorous exclusion of traces of moisture and air. After drying over KOH, THF was purified by distillation from sodium/benzophenone ketyl, and hexane and toluene were dried by distillation from sodium/triglyme and benzophenone ketyl prior to use. [$D_6$]benzene was dried with sodium and condensed in vacuo into the NMR tubes prior to use. *N*,*N*′-Dicyclohexylcarbodiimide was purchased from Acros. Anhydrous $LnCl_3$,[48] and $(Me_3Si)_2NLi(Et_2O)$[49] were prepared according to literature procedures. All other commercially available chemicals were used after the appropriate purification.

**Instruments and Measurements:** NMR spectra were recorded with a Bruker DPX 200 spectrometer ($^1$H, 200 MHz; $^{13}$C, 50 MHz; $^{11}$B, 64.2 MHz; $^7$Li, 77.7 MHz). Chemical shifts for $^1$H and $^{13}$C spectra were referenced internally using the residual solvent resonances and are reported relative to TMS. IR spectra were recorded as Nujol mulls with a Specord M80 instrument. Lanthanide metal analysis was carried out by complexometric titration and the C,H elemental analysis by the microanalytical laboratory of IOMC. Size exclusion chromatography (SEC) of PLAs was performed in THF at 20 °C using a Waters SIS HPLC pump, a Waters 410 refractometer, a DAD-UV detector, and Waters styragel columns (HR2, HR3, HR4, HR5E) or PL-GEL Mixte B and 100A columns. The number average molecular masses ($M_n$) and polydispersity index ($M_w/M_n$) of the resultant polymers were calculated with reference to a polystyrene calibration. $M_n$ values were corrected with a Mark-Houwink factor of 0.58 to account for the difference in hydrodynamic volumes between polystyrene and polylactide (PLA).[50,51] The microstructure of PLAs was measured by homodecoupling $^1$H NMR spectroscopy at 20 °C in $CDCl_3$ on a Bruker AC-500 spectrometer.[37]

**Synthesis of $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Nd(\mu\text{-}BH_4)_2Li(THF)_2$ (1):** CyN=C=NCy (0.52 g, 2.52 mmol) was added to a solution of $(Me_3Si)_2NLi(Et_2O)$ (0.61 g, 2.52 mmol) in toluene (30 mL) at 20 °C and after 45 min stirring $Nd(BH_4)_3(THF)_2$ (0.43 g, 1.26 mmol) was added. The reaction mixture was stirred and heated at 65 °C for a further 12 h. The reaction mixture was filtered off and from the clear solution the solvent was evaporated in vacuo. The remaining

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

solid was extracted with hexane (2 × 20 mL). After filtration of the hexane extracts, the resulting solution was slowly concentrated under vacuum at room temperature. The blue crystalline solid formed overnight was washed with cold hexane and dried in vacuo at room temperature for 40 min, yielding **1** (0.88 g, 66%) as a blue crystalline solid. $C_{46}H_{104}B_2LiN_6NdO_2Si_4$ (1057.7): calcd. C 52.23, H 9.83, Nd 13.63; found C 52.00, H 9.41, Nd 13.23. **Synthesis of $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Sm(\mu\text{-}BH_4)_2Li(THF)_2$ (2):** Complex **2** was synthesized following the standard procedure described for **1** starting from $(Me_3Si)_2NLi(Et_2O)$ (0.58 g, 2.42 mmol), CyN=C=NCy (0.50 g, 2.42 mmol), and $Sm(BH_4)_3(THF)_2$ (0.40 g, 1.21 mmol) in toluene (30 mL). Complex **2** was isolated as a yellow crystalline solid (0.83 g, 64%). $C_{46}H_{104}B_2LiN_6O_2Si_4Sm$ (1063.9): calcd. C 51.93, H 9.77, Sm 14.13; found C 51.55, H 9.34, Sm 14.26. $^1H$ NMR (200 MHz, [D$_6$]benzene ): $\delta$ = –1.34 (br. s, 8 H, B$H_4$), 0.28, 0.35 [both s, together 36 H, Si(C$H_3$)$_3$], 1.32–1.94 (br. m, 48 H, C$H_2$ Cy, β-C$H_2$, THF), 2.83 (br. m, 4 H, C$H$ Cy), 3.56 (br. s, 8 H, α-C$H_2$, THF) ppm. $^7Li$ NMR (77.7 MHz, [D$_6$]benzene ): $\delta$ = 0.03 ppm. $^{11}B$ NMR (64.2 MHz, [D$_6$]benzene): $\delta$ = 49.04 ppm. $^{13}C\{^1H\}$ NMR (50 MHz, [D$_6$]benzene): $\delta$ = 4.2 [(NSi$CH_3$)$_2$], 25.4 (β-$CH_2$, THF), 22.0, 25.7, 26.3, 31.9, 36.7 ($CH_2$, Cy), 53.3 ($CH$, Cy), 68.3 (α-$CH_2$, THF), 208.6 ($CN_3$) ppm. IR (Nujol, KBr): $\tilde{\nu}$ = 2658 (m), 2419 (s), 2396 (s), 2244 (s), 2204 (s), 1638 (s), 1600 (m), 1405 (s), 1355 (s), 1300 (s), 1187 (m), 1175 (m), 1136 (m), 1071 (m), 1057 (s), 1004 (s), 943 (s), 841 (s), 676 (m) $cm^{-1}$.

**Synthesis of $[(Me_3Si)_2NC(N\text{-}Cy)_2]_2Yb(\mu\text{-}BH_4)_2Li(THF)_2$ (3):** Complex **3** was synthesized following the standard procedure described for **1** starting from $(Me_3Si)_2NLi(Et_2O)$ (0.89 g, 3.73 mmol), CyN=C=NCy (0.77 g, 3.73 mmol), and $Yb(BH_4)_3(THF)_2$ (0.67 g, 1.86 mmol) in toluene (30 mL). Complex **3** was isolated as an orange crystalline solid (1.37 g, 68%). $C_{46}H_{104}B_2LiN_6O_2Si_4Yb$ (1086.5): calcd. C 50.85, H 9.57, Yb 15.92; found C 50.39, H 9.21, Yb 16.06. IR (Nujol, KBr): $\tilde{\nu}$ = 2661 (m), 2431 (s), 2296 (s), 2246 (s), 2200 (s), 1634 (s), 1600 (m), 1405 (s), 1358 (s), 1304 (s), 1249 (s), 1190 (s), 1136 (m), 1073 (m), 1050 (s), 1002 (s), 944 (s), 842 (s), 678 (m) $cm^{-1}$.

**General Procedure for Lactide Polymerization:** In the glovebox, a Schlenk flask was charged with a solution of the metal initiator (typically 0.019 mmol, about 10 mg) in toluene (0.2 mL) or THF (0.2 mL). A solution of the monomer [*rac*-LA, (*S*,*S*)-LA; previously recrystallized twice from dry toluene and then sublimed under vacuum at 50 °C] was added rapidly to this solution in the appropriate ratio in toluene or THF (3.0 mL). The mixture was immediately stirred with a magnetic stir bar at room temperature. Aliquots were periodically removed with a pipette for monitoring the monomer conversion by $^1H$ NMR spectroscopy. After completion or the desired time, the reaction was quenched with acidic methanol (0.5 mL of a 1.2 M HCl solution), and the polymer was precipitated with excess methanol (100 mL). The polymer was then dried under vacuum to constant weight.

**X-ray Crystallographic Study:** The crystal data and details of data collection are given in Table 1. X-ray data were collected on a SMART APEX diffractometer (graphite-monochromated Mo-$K_\alpha$ radiation, $\lambda$ = 0.71073 Å, $\phi$-$\omega$-scan technique) at –100 °C. The intensity data were integrated in the SAINT program.[52] SADABS[53] was used to perform area-detector scaling and absorption corrections. The structures were solved by direct methods and were refined on $F^2$ using all reflections with SHELXTL.[54] All non-hydrogen atoms were refined anisotropically. The hydrogen atoms in **1** and **2** were found from the Fourier syntheses of electron density except the H atoms of THF ligands and solvate hexane molecules. The H atoms of $BH_4$ groups in **3** were found from the Fourier syntheses of electron density whereas the remaining hydrogen atoms were placed in calculated positions. The H atoms in **1**–**3**, found from the differential syntheses of electron density, were refined isotropically, whereas all other hydrogen atoms were refined in the "riding model".

CCDC-634981 (for **1**), -634982 (for **2**), and -634983 (for **3**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**Supporting Information** (see also the footnote on the first page of this article): Details of the $^1H$ NMR spectrum and GPC trace of a PLA sample.

# (Phthalocyaninato)copper(II) Complexes Fused with Different Numbers of 15-Crown-5 Moieties – Synthesis, Spectroscopy, Supramolecular Structures, and the Effects of Substituent Number and Molecular Symmetry

**Ning Sheng,[a] Yuexing Zhang,[a] Hui Xu,[a] Meng Bao,[b] Xuan Sun,*[a] and Jianzhuang Jiang*[a]**

**Keywords:** Phthalocyanines / Crown ether / Supramolecular chemistry / Molecular symmetry

Symmetrical (phthalocyaninato)copper(II) complexes Cu(Pc′) [Pc′ = Pc(15C5), Pc(opp-15C5)$_2$, Pc(adj-15C5)$_2$, Pc(15C5)$_3$; Pc = unsubstituted phthalocyaninate, Pc(15C5) = 2,3-(15-crown-5)phthalocyaninate, Pc(opp-15C5)$_2$ = 2,3,16,17-bis(15-crown-5)phthalocyaninate, Pc(adj-15C5)$_2$ = 2,3,9,10-bis(15-crown-5)phthalocyaninate, Pc(15C5)$_3$ = 2,3,9,10,16,17-tris(15-crown-5)phthalocyaninate] (**2**–**5**) have been prepared by the reaction of corresponding heteroleptic bis(phthalocyaninato)europium complexes Eu(Pc)(Pc′) [Pc′ = Pc(15C5), Pc(opp-15C5)$_2$, Pc(adj-15C5)$_2$, Pc(15C5)$_3$, Pc(15C5)$_4$; Pc = unsubstituted phthalocyaninate] with Cu(OAc)$_2$ in dry dmf at 100 °C. For the purpose of comparative studies, the symmetrical counterparts CuPc (**1**) and CuPc(15C5)$_4$ [Pc(15C5)$_4$ = 2,3,9,10,16,17,24,25-tetrakis(15-crown-5)phthalocyaninate] (**7**) have also been prepared. These monomeric complexes have been characterized by spectroscopic methods in addition to elemental analysis. Having a series of closely related phthalocyanines with a different number and/or disposition of 15-crown-5 groups at the peripheral positions, the effects of 15-crown-5 substituent number and molecular symmetry on the electronic absorption spectra, infra-red (IR) spectra, and supramolecular structure formation induced by $K^+$ ions have been investigated. Systematic studies on the formation of dimeric supramolecular structures of the series of monomers **2**–**6** reveal and confirm the previously proposed two-step three-stage process of $K^+$-induced dimerization of phthalocyanines with three or four 15-crown-5 moieties.

## Introduction

The design and preparation of supramolecular structures have attracted significant research interest due to their great potential applications in materials science and molecular electronics. Phthalocyanines have been an important class of molecular materials since their first synthesis early in the last century.[1] Crown ethers have also found wide application in molecular electronic devices due to their remarkable recognition and metal-binding properties.[2] The combination of these two functional subunits for the purpose of constructing novel supramolecular structures with novel multi-functional properties has stimulated wide research interest since the 1980s.[3]

The first trial in this direction was the preparation of CuPc(15C5)$_4$ in 1986 by three independent research groups.[3] Subsequently, these crown ether substituted metal-free or metallo-phthalocyanines have been studied for their dimerization in a two-step three-stage process in the presence of potassium ions in a mixed solvent of chloroform and methanol.[4] Since then, significant efforts have been put into adding different numbers of 15-crown-5 voids onto the phthalocyanine skeleton through asymmetric σ-bonded substitution of the peripheral protons. However, most probably because of the absence of a suitable effective separation method for the mono-, bis-, tris-, and tetrakis(15-crown-5)-substituted phthalocyanine compounds, which each have a high and similar polarity, only a few tris(15-crown-5)-substituted phthalocyanine analogues have been isolated.[5] The main target of the present work is to introduce different numbers of 15-crown-5 groups, from one to four, at different peripheral positions of the phthalocyanine ligand of (phthalocyaninato)copper complexes, and then systematically study their spectroscopic and dimeric supramolecular structure formation characteristics.

It is worth pointing out that the effects of lowering the molecular symmetry of phthalocyanine molecules on the spectra have not yet been fully exploited. Most of the studies so far have focused on the spectral properties of phthalocyanine analogues with reduced molecular symmetry because of their lower π-system symmetry than $D_{4h}$,[6] which are obviously significantly affected by the change in the size of the π-system.

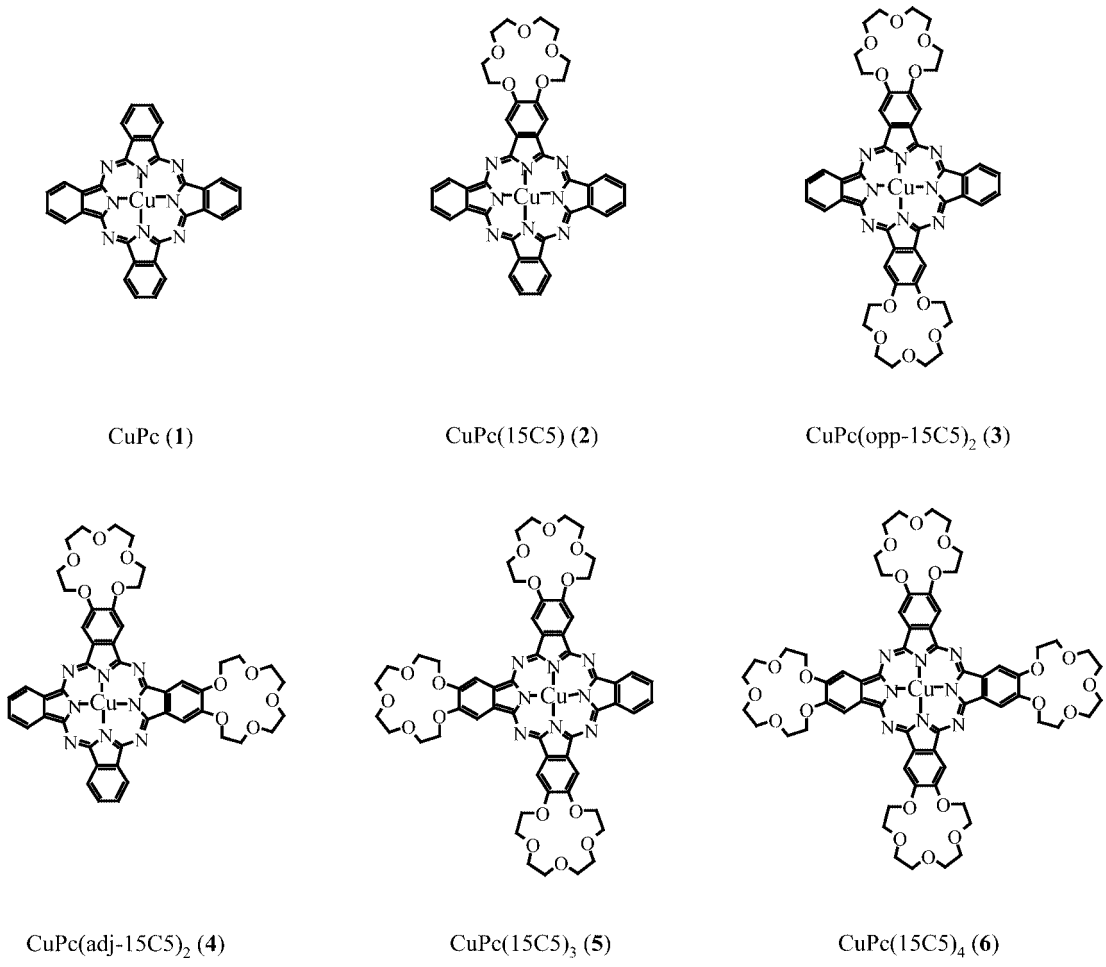

Figure 1. Schematic molecular structures of (phthalocyaninato)copper complexes fused with different numbers of 15-crown-5 moieties.

In this paper, we report the synthesis of a series of unsymmetrical (phthalocyaninato)copper(II) complexes, namely CuPc(15C5) (**2**), CuPc(opp-15C5)$_2$ (**3**), CuPc(adj-15C5)$_2$ (**4**), and CuPc(15C5)$_3$ (**5**) as well as symmetrical CuPc (**1**) and CuPc(15C5)$_4$ (**6**) with zero, one, two, three, and four 15-crown-5 voids attached at different positions of the phthalocyanine ring (Figure 1). Their spectroscopic properties have also been comparatively studied, trying to reveal the effects of lowering the molecular symmetry of phthalocyanines. It is worth mentioning that in spite of the very recent efforts on the heteroleptic bis(phthalocyaninato)europium complexes Eu(Pc)(Pc′) [Pc′ = Pc(15C5), Pc(opp-15C5)$_2$, Pc(adj-15C5)$_2$, Pc(15C5)$_3$, Pc(15C5)$_4$],[7] these effects could not be clearly revealed due to the attenuation and/or covering of such effects by strong π-π interactions in the double-decker molecules, which predominantly control their spectral properties.

## Results and Discussion

### Synthesis

Two synthetic pathways have been reported so far to prepare unsymmetrical monomeric phthalocyanine analogues. The first method involves a mixed cyclization of two phthalonitrile (or isoindole) precursors in the presence of a metal salt or organic base.[8] As can easily be expected, the separation of a series of closely related and isomeric phthalocyanines obtained in this way has been a great challenge for chemists. As a result, except for the two whole series of phthalocyanine analogues, whose π-system itself has a lower symmetry than $D_{4h}$, reported by Kenny and Tian,[6a,9] respectively, from the reaction between a tetraazaporphyrin precursor and a phthalocyanine precursor and between a phthalocyanine precursor and a naphthalocyanine precursor, unsymmetrical phthalocyanine derivatives whose π-system itself still maintains the $D_{4h}$ symmetry prepared and isolated with this method as a whole series are still very rare, limited to MPc[(R)$_n$(OCH$_2$CH$_2$OCH$_2$CH$_2$OCH$_2$CH$_2$OCH$_3$)$_{8-n}$] (M = 2H), to the best of our knowledge.[10] The second pathway involves the ring-expansion reaction of subphthalocyanine. Treatment of a new dinitrile in the isoindole form with a subphthalocyanine led to the formation of phthalocyanine analogues with a 3:1 ratio of the two dinitriles. This method, again, is not practical for the present case. In this work, we employed a novel methodology using heteroleptic bis(phthalocyaninato) rare earth complexes Eu(Pc)(Pc′) [Pc′ = Pc(15C5), Pc(opp-15C5)$_2$, Pc(adj-

Table 1. Analytical and mass spectrometric data for (phthalocyaninato)copper complexes **2**–**7**.[a]

| Compound | $[M]^+$ ($m/z$)[b] | Analysis | | |
|---|---|---|---|---|
| | | C | H | N |
| CuPc(15C5) (**2**) | 765.3 (765.2) | [c] | [c] | [c] |
| CuPc(opp-15C5)$_2$·2CH$_3$OH (**3**) | 955.4 (955.2) | 58.48 (58.85) | 5.11 (5.14) | 10.38 (10.98) |
| CuPc(adj-15C5)$_2$·2CH$_3$OH (**4**) | 955.5 (955.2) | 58.84 (58.85) | 5.22 (5.14) | 10.29 (10.98) |
| CuPc(15C5)$_3$·2CHCl$_3$ (**5**) | 1145.7 (1145.3) | 50.71 (50.28) | 4.15 (4.30) | 8.20 (8.20) |

[a] Calculated values given in parentheses. [b] By MALDI-TOF mass spectrometry. [c] Satisfactory elemental analysis data is not obtained for this compound.

15C5)$_2$, Pc(15C5)$_3$, Pc(15C5)$_4$] as the starting material. Reaction with a large excess of copper acetate in dry dmf at 100 °C for 1.5 h provides two different kinds of (phthalocyaninato)copper compounds Cu(Pc) and CuPc(15C5)$_n$ ($n$ = 1–4) (**2**–**6**) in relatively good yields. Fortunately, all the 15-crown-5-substituted (phthalocyaninato)copper complexes **3**–**6**, except for **2**, could be relatively easily separated and purified from its unsubstituted analogue CuPc (**1**) by simple filtration followed by general neutral alumina column chromatography, due to the presence of 15-crown-5 moieties on the phthalocyanine ring of compounds **3**–**6**. It is worth noting that the symmetrical compound CuPc(15C5)$_4$ (**6**) together with CuPc (**1**) was actually obtained from the simple tetramerization of 4,5-dicyanobenzo-15-crown-5 or unsubstituted dicyanobenzene, in the presence of copper acetate.

Because of the low solubility of CuPc(15C5) (**2**), similar to that of CuPc, complex **2** could not be isolated from the reaction between Eu(Pc)[Pc(15C5)] and Cu(OAc)$_2$. This compound, however, was actually prepared by the reaction between Cu(OAc)$_2$ and metal-free H$_2$Pc(15C5), the latter of which was prepared and separated from mixed ring tetramerization of dicyanobenzene and 4,5-dicyanobenzo-15-crown-5.

All the newly prepared (phthalocyaninto)copper(II) complexes **2**–**5** gave satisfactory elemental analysis results as given in Table 1. They were further characterized by spectroscopic methods. The MALDI-TOF spectra of all these compounds showed the molecular ion $[M]^+$ signals with correct isotopic pattern (Table 1).

### Electronic Absorption Spectra

The electronic absorption spectra of the series of (phthalocyaninato)copper complexes **1**–**6** were recorded in CHCl$_3$ and the data are summarized in Table 2. Figure 2 compares the UV/Vis spectra in the range of 300–900 nm of the whole series of compounds. All the absorption spectra show a typical broad Soret band at 340–343 nm, involving a couple of electronic transitions dealing with the third occupied HOMO and the first LUMO. The Q bands for these compounds are observed in the range of 666–677 nm, with two vibrational shoulders at 602–611 and 637–648 nm. In addition, a weak band at 411–435 nm is also observed. Except for the Soret band, both the absorption positions of the Q band and the weak band at 411–435 nm show dependence on the number of 15-crown-5 substituents. The Q band shifts gradually and slightly to the red and the weak band at 411–435 nm to the blue upon an increase in the number of 15-crown-5 substituents. Apart from the absorption position, the appearance of the electronic spectra is also sensitive to the number of 15-crown-5 substituents. For example, the weak band in the range of 411–435 nm for 15-crown-5-containing (phthalocyaninato)copper complexes **2**–**6**, which is absent in the unsubstituted CuPc (**1**), gradually increases in intensity and moves to the higher energy side coinciding with the increase in the number of 15-crown-5 groups from **2** to **6**. This result clearly reveals the origin of this absorption which is associated with the 15-crown-5 substituents. In combination with the fact that a similar band was observed for all the 15-crown-5-substituted monomeric phthalocyanines[3] and even the alkoxy-substituted phthalocyanine derivatives,[11] this absorption can be attributed to the n→π* transitions arising from the oxygen lone pairs of electrons. This assignment is further confirmed by our recent calculation results on the electronic absorption spectra of nonperipherally tetraalkoxy-substituted (phthalocyaninato)lead complexes.[12] It is also noteworthy that for the isomeric complexes **3** and **4**, a very slight shift is still observed for some of the absorption bands, indicating that the electronic absorption properties are also more or less dependent on the substituent positions.

Table 2. Electronic absorption data for (phthalocyaninato)copper complexes **1**–**6** in CHCl$_3$.

| Compound | $\lambda_{max}$ [nm] (log ε) | | | | |

As shown in Figure 2, except for the weak n→π* transition band at ca. 420 nm, all the unsymmetrical (phthalocyaninato)copper(II) complexes **2**–**5** display very similar absorption features, which also resemble their symmetrical counterparts **1** and **6**. This observation reveals that the effect of lowering the molecular symmetry of phthalocyanines only through asymmetric σ-bonded substitution of the peripheral protons is too small to be reflected in their electronic absorption spectra. Phthalocyanines with diminished molecular symmetry through asymmetric σ-bonded substitution of the nonperipheral protons are expected to provide more information in this regard.

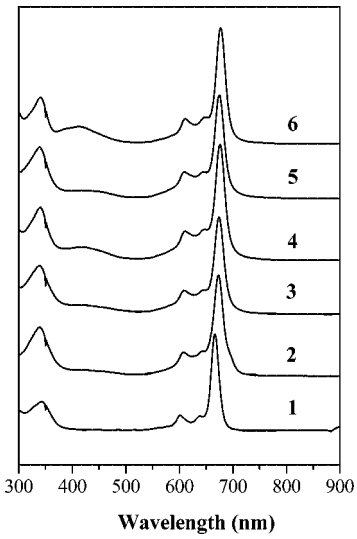

Figure 2. The electronic absorption spectra of CuPc (**1**), CuPc(15C5) (**2**), CuPc(opp-15C5)$_2$ (**3**), CuPc(adj-15C5)$_2$ (**4**), CuPc(15C5)$_3$ (**5**), and CuPc(15C5)$_4$ (**6**) in $CHCl_3$.

## IR Spectra

Because of the interest in the sandwich-type (tetrapyrrole)metal complexes related to their potential applications in molecular electronics and magnetism, we have focused our attention on the synthesis and structures of a series of (na)phthalocyaninato and/or porphyrinato rare earth complexes in the past decade.[13–16] IR spectroscopic characteristics of (na)phthalocyanine in these sandwich-type complexes have also been systematically studied for the purpose of investigating the intrinsic properties of these phthalocyanine compounds.[17–19] However, except for the early efforts paid to the metal-free and metalo-phthalocyanines without peripheral substituents and the recent work on the calculated spectra of several phthalocyanine compounds employing the DFT method, systematic investigation of the IR spectroscopy of monomeric phthalocyanine compounds seems not to have been conducted to date. Our compounds in the present work are therefore expected to give representative data for the series of peripherally substituted (phthalocyaninato)metal complexes.

As clearly shown in Figure S1 and Table S1 (Supporting Information), the presence of one, two, three, and four 15-crown-5 moieties on the peripheral positions of the phthalocyanine ring in the molecules of compounds **2**, **3** and **4**, **5**, and **6** increases the number of IR-active modes. The common absorptions for the 15-crown-5-substituted complexes **2**–**6** observed at 2954–2958, 2921–2924, 2871–2872, 2851–2856, 1280–1287, and 1045–1047 $cm^{-1}$, which are absent in the spectrum of unsubstituted CuPc (**1**), are attributed to the asymmetric and symmetric C–H stretching vibrations and C–O–C stretching vibrations of the 15-crown-5 groups, respectively. Nevertheless, the intensity of all these absorptions has been found to increase along with the number of 15-crown-5 moieties from **2** to **6**.

It is also worth noting that despite of several additional peaks observed for CuPc(15C5)$_4$ (**6**) compared with CuPc (**1**), the characteristic pattern of the IR spectrum of CuPc(15C5)$_4$ (**6**) still remains simple, somewhat simpler than those of **2**–**5**, revealing the relatively higher molecular symmetry of the former compound. The static molecular geometry of CuPc (**1**) and CuPc(15C5)$_4$ (**6**) suggests a $D_{4h}$ point group for their molecule, while **2**, **3**, **4**, and **5**, have a $C_{2v}$, $D_{2h}$, $C_{2v}$, and $C_{2v}$ point group, respectively. This is clearly revealed by the larger number of vibrational modes observed in the IR spectra of **2**–**5** compared with those of either CuPc (**1**) or CuPc(15C5)$_4$ (**6**) (Figure S1 and Table S1; Supporting Information). The difference in the characteristic pattern of IR spectra between the isomers **3** and **4** is clearly due to their different molecular symmetry.

## Formation of Dimeric Phthalocyanine Supramolecular Structures

The $K^+$-induced cofacial dimer formation of monomeric phthalocyanine derivatives substituted with three or four 15-crown-5 voids, in particular CuPc(15C5)$_4$, has been well studied by Kobayashi and co-workers.[4a,5] On the basis of corresponding results, a two-step three-stage process was proposed for cofacial dimer formation of monomeric phthalocyanine derivatives. In the present study, the formation process of $K^+$-induced dimeric supramolecular structures of 15-crown-5-substituted (phthalocyaninato)metal complexes, *in a two-step three-stage process*, has been clearly revealed and confirmed by studying the formation processes of (phthalocyaninato)copper complexes in $CHCl_3$ mixed with a trace amount of MeOH due to the availability of the series of mono-, bis-, tris-, and tetrakis(15-crown-5)-substituted (phthalocyaninato)copper complexes, in particular CuPc(15C5) (**2**), CuPc(adj-15C5)$_2$ (**4**), CuPc(15C5)$_3$ (**5**), and CuPc(15C5)$_4$ (**6**).

Figure 3 compares the systematic changes in absorption spectra of CuPc(15C5) (**2**), CuPc(adj-15C5)$_2$ (**4**), CuPc(15C5)$_3$ (**5**), and CuPc(15C5)$_4$ (**6**) in $CHCl_3$ upon titration with KOAc in $CHCl_3$/MeOH (9:1, v/v) and the final spectra obtained when [$CH_3COOK$]/[compound] = 3.0 for all these compounds are listed in Figure S2 (Supporting Information). It can be seen that after adding $K^+$ ions, the intense Q-band at 673 nm for **2** does not take a blue shift but gradually attenuates in intensity. Moreover, no new peak appears in this Q-band region. These results indicate the formation of linear (or noncofacial) dimeric supramolecular structure [CuPc(15C5)]$(K^+)_1$[CuPc(15C5)][(**2**)$(K^+)_1$-(**2**)]. This is also true for the formation of linear (or noncofacial) dimeric supramolecular structure [CuPc(adj-15C5)$_2$]-$(K^+)_2$[CuPc(adj-15C5)$_2$] [(**4**)$(K^+)_2$(**4**)] when $K^+$ ions are added to a solution of the (phthalocyaninato)copper compound with two 15-crown-5 moieties at the adjacent peripheral positions according to the experimental results shown in Figure 3 and Figure S2 (Supporting Information).

However, significant change in the electronic absorption spectrum takes place after $K^+$ ions are added to the solution of compound **5**, see Figure 3 and Figure S2 (Supporting Information). Along with the decrease of the Q-band

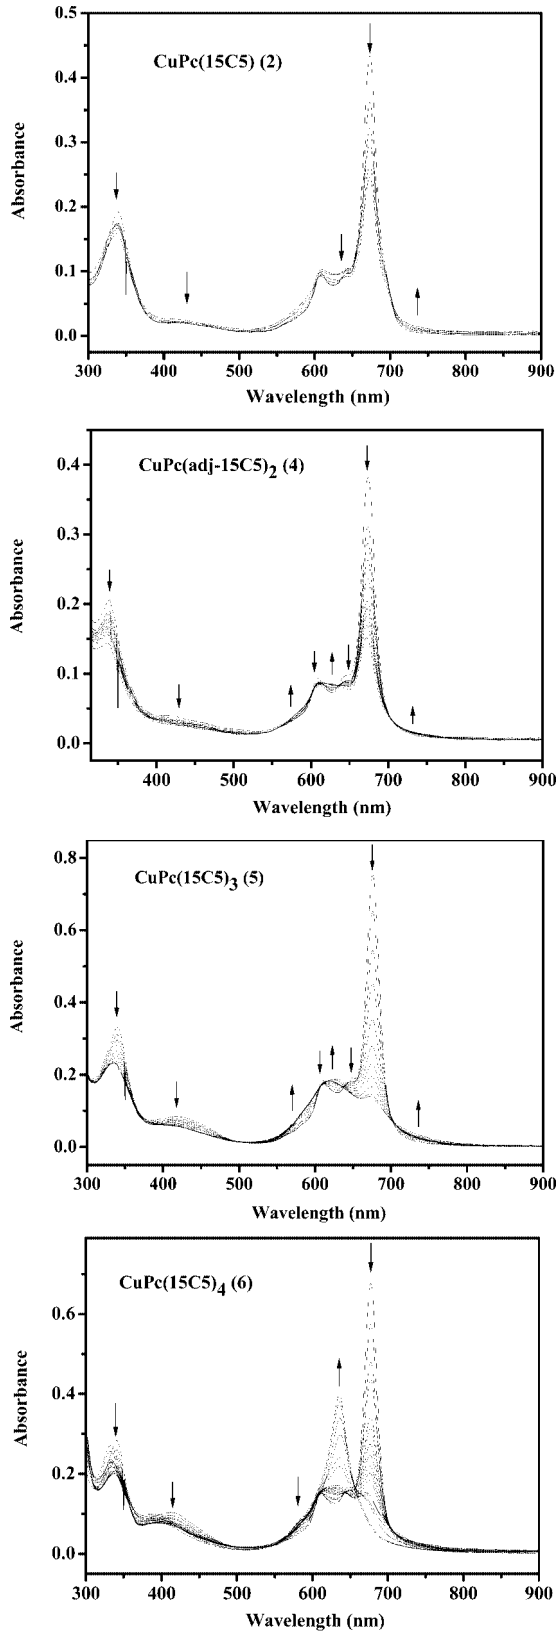

Figure 3. Changes in absorption spectra of CuPc(15C5) (**2**), CuPc(adj-15C5)$_2$ (**4**), CuPc(15C5)$_3$ (**5**), and CuPc(15C5)$_4$ (**6**) in $CHCl_3$ upon titration with KOAc in $CHCl_3$/MeOH (9:1, v/v). Arrows indicate the direction of the spectral changes. The final spectra were obtained when [$CH_3COOK$]/[compound] = 3.0 (for **2**, **4**–**6**).

of **5** at 676 nm, a new band appears at 624 nm due to the formation of cofacial dimeric supramolecule [CuPc(15C5)$_3$]($K^+$)$_3$[CuPc(15C5)$_3$] [(**5**)($K^+$)$_3$(**5**)]. This is in line with the results found during the formation of $K^+$-induced cofacial dimerization of phthalocyanine analogues with three 15-crown-5 voids.[4a,5] It is worth noting that the Soret band at 341 nm for **5** also shifts to the shorter wavelength (335 nm) with addition of $K^+$. In line with the previous reports,[4a,5] cofacial dimeric supramolecular structure [CuPc(15C5)$_4$]($K^+$)$_4$[CuPc(15C5)$_4$] [(**6**)($K^+$)$_4$(**6**)] is formed with addition of $K^+$.

It is noteworthy that a similar result to that of **5** was observed for compound **3** (Figures S2 and S3; Supporting Information). When no changes occur anymore upon addition of excess $K^+$ ions, the electronic absorption spectrum can be ascribed to the cofacial dimeric supramolecular structure [CuPc(opp-15C5)$_2$]($K^+$)$_2$[CuPc(opp-15C5)$_2$] [(**3**)($K^+$)$_2$(**3**)].

As a result, it has been found that $K^+$-induced cofacial dimerization of phthalocyanines with three or four 15-crown-5 voids, for instance compound **5** or **6**, should proceed in the following manner: two monomeric 15-crown-5-substituted phthalocyanine molecules combine with the first $K^+$ cation to form a linear dimer, which then combines with the second $K^+$ cation to form a linear or cofacial dimer, and finally transforms into a stable cofacial dimer when the third and/or fourth $K^+$ cation(s) are combined. In other words, $K^+$-induced cofacial dimerization of phthalocyanines with three or four 15-crown-5 voids should proceed according to the following three stages:[4a,5] (1) The first involves the formation of a linear (or noncofacial) dimer at a [$K^+$]/[MPc(15C5)$_4$] value of 0–0.5; (2) the second in the region of $0.5 \leq [K^+]/[MPc(15C5)_4] \leq 1.5$ involves the transition from the linear (or noncofacial) dimer to the cofacial dimer when the second and third $K^+$ cations are combined; (3) the third involves the complete formation of a cofacial dimer at $[K^+]/[MPc(15C5)_4] \geq 1.5$.

In addition, to monitor the cofacial supramolecular formation for compounds **5** and **3**, the changes in absorption of the so-called monomer band (at 676 nm) and the dimer band (at 592 nm) for **5** (Tables 2 and 3), and monomer band (at 675 nm) and the dimer band (at 593 nm) for **3**, were recorded as a function of [$K^+$]/[**5**] and [$K^+$]/[**3**], respectively. As shown in Figure 4 and Figure S4 (Supporting Information), the concomitant change of the two characteristic bands indicates that upon addition of $K^+$ ions, monomer **5** or **3** is converted exclusively to the dimeric supramolecular

Table 3. Electronic absorption data for the supramolecular dimers (SD) formed from the 15-crown-5-substituted (phthalocyaninato)-copper complexes **2**–**6** in $CHCl_3$ upon titration with KOAc in $CHCl_3$/MeOH (9:1, v/v).

| Compound | $\lambda_{max}$ [nm] (log ε) | | | | |
|---|---|---|---|---|---|
| SD2 | 338 (4.45) | | 610 (4.19) | 643 (4.20) | 673 (4.61) |
| SD3 | 333 (4.45) | | 615 (4.31) | | 673 (4.22) |
| SD4 | 335 (4.37) | | 623 (4.18) | | 672 (4.36) |
| SD5 | 335 (4.44) | | 624 (4.33) | | 671 (4.22) |
| SD6 | 334 (4.41) | 389 (3.98) | 637 (4.53) | | |

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

structure. The formation process is similar to that of $MPc(15C5)_4$ (M = $H_2$, Zn, Co, Ni, Cu) in $CHCl_3$. However, probably due to the low solubility of these compounds including complexes **4** and **2**, about a threefold amount of $K^+$ ions (i.e. $[K^+]/[\mathbf{5}$ or $\mathbf{3}] \approx 3$) is required to reach a steady state (Figure 4 and Figure S4; Supporting Information), instead of the value of 2 observed for other reported monomeric phthalocyanine counterparts.[4a,5]

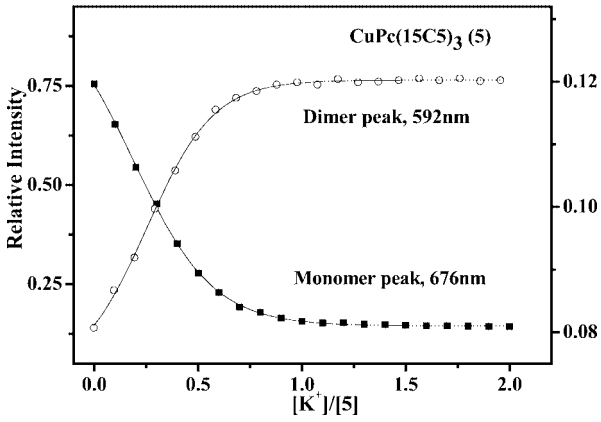

Figure 4. Variation of the absorbance 676 and 592 nm during titration of **5** in $CHCl_3$ with KOAc in $CHCl_3$/MeOH (9:1). The curve going up with $[K^+]$ represents the change at the dimer peak and should be referred to the right-hand axis, while that going down is the change at the monomer peak and should be referred to the left-hand axis.

Equation (1) shows the equilibrium between monomer **5** or **3** (upon addition of $K^+$ ions) and the corresponding dimer. According to the method described by West and Pearce,[20] the monomer and dimer concentrations could be calculated from the spectral changes during titration, and their relationship be depicted as shown in Figure 5 and Figure S5 (Supporting Information) for the present systems. The region with a slope of ca. 2.0 indicates the dimerization occurs in this region. For these present systems, this includes the data point of $[K^+]/[\mathbf{5}$ or $\mathbf{3}] = 0.5$. When $[K^+]/[\mathbf{5}$ or $\mathbf{3}] > 3$, the slope of the plot approaches zero.

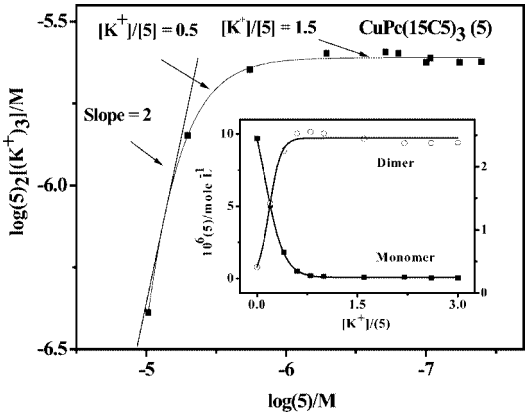

Figure 5. Plots of log[**5**] vs. log[(**5**)$(K^+)_3$(**5**)] for $CuPc(15C5)_3$ (**5**) in $CHCl_3$/MeOH. The inset shows the dependence of monomer and dimer concentrations on $[K^+]/[\mathbf{5}]$.

$$n\ K^+ + 2\ CuPc(15C5)_n \overset{K}{\leftrightarrow} dimer{\cdot}K^+_n \quad (1)$$

It is worth pointing out that for all the crown ether substituted (phthalocyaninato)copper compounds, namely CuPc(15C5) (**2**), $CuPc(opp\text{-}15C5)_2$ (**3**), $CuPc(adj\text{-}15C5)_2$ (**4**), $CuPc(15C5)_3$ (**5**), and $CuPc(15C5)_4$ (**6**), when two $CuPc(15C5)_n$ units bind one $K^+$ cation and start to form the dimer in the first stage, the monomer–dimer conversion proceeds with a very high formation constant, $K = 3.0 \times 10^{10}$ to $7.0 \times 10^{10}$ L$^2$ mol$^{-2}$ with $n = 1$ for Equation (1).[4a]

## Conclusions

We have prepared a series of unsymmetrical (phthalocyaninato)copper(II) complexes **2**–**5**, containing different numbers and positions of 15-crown-5 substituents, from the reaction of corresponding heteroleptic bis(phthalocyaninato)europium complexes Eu(Pc)(Pc′) with $Cu(OAc)_2{\cdot}nH_2O$. It has been found that all the unsymmetrical compounds **2**–**5** and the symmetrical analogues **1** and **6** display very similar absorption features, indicating that the electronic absorption spectra of these compounds are not sensitive enough to show the change in the molecular symmetry due to unsymmetrical substitution of 15-crown-5 moieties, which however can be clearly reflected by their IR spectra. Systematic studies over the formation of dimeric supramolecular structures of the series of monomers **2**–**6** clearly reveal and confirm the previously proposed two-step three-stage process of phthalocyanines with three or four 15-crown-5 moieties in $CHCl_3$ with trace amounts of MeOH in the presence of $K^+$.

## Experimental Section

**General Remarks:** 1,8-Diazabicyclo[5.4.0]undec-7-ene (dbu) and dicyanobenzene were purchased from Aldrich. *n*-Pentanol and *N*,*N*-dimethylformamide (dmf) were freshly distilled from Na and $CaH_2$, respectively, under nitrogen. Column chromatography was carried out on neutral alumina (SCRC, 200–300 mesh) with the indicated eluents. All other reagents and solvents were used as received. 4,5-Dicyanobenzo-15-crown-5,[4,21] Eu(Pc)(Pc′) [Pc′ = Pc(15C5), $Pc(opp\text{-}15C5)_2$, $Pc(adj\text{-}15C5)_2$, $Pc(15C5)_3$, $Pc(15C5)_4$],[7] CuPc (**1**),[22] and $CuPc(15C5)_4$ (**6**)[4] were prepared according to published procedures. $^1$H NMR spectra were recorded with a Bruker DPX 300 spectrometer (300 MHz) in [$D_6$]dmso. Spectra were referenced internally by using the residual solvent resonance ($\delta$ = 2.49 for [$D_6$]-dmso) relative to $SiMe_4$. Electronic absorption spectra were recorded with a Hitachi U-4100 spectrophotometer. MALDI-TOF mass spectra were measured with a Bruker BIFLEX III ultra-high resolution mass spectrometer with α-cyano-4-hydroxycinnamic acid as matrix. Elemental analyses were performed by the Institute of Chemistry, Chinese Academy of Sciences.

**Preparation of $H_2Pc(15C5)$:** According to a literature method,[23] a mixture of dicyanobenzene (76.8 mg, 0.60 mmol), 4,5-dicya-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

nobenzo-15-crown-5 (31.8 mg, 0.10 mmol), and an excess amount of lithium (2.8 mg, 0.40 mmol) in *n*-pentanol (3 mL) was heated to reflux under nitrogen for 2 h. After cooling to room temperature, the resulting green solution was poured into methanol (100 mL) containing a few drops of concentrated HCl. The precipitate was collected by filtration and chromatographed on an alumina column using $CHCl_3$/MeOH (99:1) as the eluent. After eluting the first band containing unsubstituted metal-free $H_2Pc$, the second green band containing the target compound $H_2Pc(15C5)$ was developed which was collected and the solvent removed in a rotary evaporator. Repeated chromatography followed by recrystallization from $CHCl_3$ and MeOH gave pure $H_2Pc(15C5)$ as a blue powder (12 mg, 16%). MS: calcd. for $C_{40}H_{32}N_8O_5$ $[M]^+$ 704.2; found for $H_2Pc(15C5)$ 704.8.

**Preparation of CuPc(15C5) (2):** A mixture of $H_2Pc(15C5)$ (12 mg, 0.017 mmol) and $Cu(OAc)_2$ (15 mg, 0.08 mmol) in dry dmf (3 mL) was heated to 100 °C for 1.5 h under a slow stream of nitrogen. After cooling to room temperature, MeOH (30 mL) was poured into the resulting blue solution. The precipitate was collected by filtration and chromatographed on an alumina column using $CH_2Cl_2$/MeOH (99.5:0.5) as the eluent. The blue band containing the target compound CuPc(15C5) was then collected. Repeated chromatography followed by recrystallization from $CH_2Cl_2$ and MeOH gave pure CuPc(15C5) as a blue powder (8 mg, 60%). It is worth noting that a satisfactory elemental analysis result could not be obtained for this compound even after repeated purification by column chromatography and recrystallization due to its limited solubility in common organic solvent.

**Preparation of CuPc(opp-15C5)$_2$ (3), CuPc(adj-15C5)$_2$ (4), and CuPc(15C5)$_3$ (5):** A mixture of Eu(Pc)(Pc′) [Pc′ = $Pc(opp\text{-}15C5)_2$, $Pc(adj\text{-}15C5)_2$, $Pc(15C5)_3$] (20 mg) and a large excess amount of $Cu(OAc)_2$ (15 mg, 0.08 mmol) in dry dmf (3 mL) was heated to 100 °C for 1.5 h under a slow stream of nitrogen. After cooling to room temperature, MeOH (30 mL) was poured into the resulting blue solution. The precipitate collected by filtration was then dissolved in $CHCl_3$. After removing the undissolved CuPc by filtration, the resulting product was then chromatographed on an alumina column using $CH_2Cl_2$/MeOH (98.5:1.5 for **3** and **4**, 98:2 for **5**) as the eluent. The blue band containing the target compound $CuPc(15C5)_n$ ($n$ = 2–4) (**3**–**5**) was then collected. Repeated chromatography followed by recrystallization from $CHCl_3$ and MeOH gave pure $CuPc(15C5)_n$ as green powders. Yield: $CuPc(opp\text{-}15C5)_2$ (**3**) (8 mg, 56%), $CuPc(adj\text{-}15C5)_2$ (**4**) (7 mg, 53%), and $CuPc(15C5)_3$ (**5**) (10 mg, 61%).

**Supporting Information** (see footnote on the first page of this article)(see also the footnote on the first page of this article): IR spectra of (phthalocyaninato)copper complexes **1**–**6** in the region of 400–1800 $cm^{-1}$. UV/Vis absorption spectra of monomers **2**–**5** and corresponding dimers in $CHCl_3$ and in $CHCl_3$/MeOH (9:1, v/v), respectively; changes in absorption spectrum of $CuPc(opp\text{-}15C5)_2$ (**3**) in $CHCl_3$ upon titration with KOAc in $CHCl_3$/MeOH (9:1, v/v); variation of the absorbance at 675 and 593 nm during titration of **3** in $CHCl_3$ with KOAc in $CHCl_3$/MeOH (9:1); plots of log[**3**] vs. log[(**3**)$(K^+)_2$(**3**)] for $CuPc(opp\text{-}15C5)_2$ (**3**) in $CHCl_3$/MeOH; characteristic IR bands ($cm^{-1}$) of (phthalocyaninato)copper complexes **1**–**6** with 2 $cm^{-1}$ resolution.

# Pentadentate Ligands for the 1:1 Coordination of Lanthanide(III) Salts

**Markus Albrecht,*[a] Sebastian Mirtschin,[a] Olga Osetska,[a] Sabrina Dehn,[a] Dieter Enders,[a] Roland Fröhlich,[b] Tanja Pape,[c] and Ekkehardt F. Hahn[c]**

*Dedicated to Professor Dr. H.-J. Gais on the occasion of his 65th birthday*

**Keywords:** Hydrazone / Lanthanides / Coordination compounds / Chelating ligands / Helical compounds

Three hydrazone type ligands, namely **2**-H, **3**, and **4**, which were designed to form 1:1 complexes with lanthanoid(III) ions, are presented. Although the tetradentate ligand **2**$^-$ leads to an interesting complex [(**2**)(**2**-H)$YCl_2$] with yttrium(III), a more general principle for the coordination of the metal ions by hydrazone-type ligands can be found with ligand **3**, where 1:1 complexes are obtained with an effective coordination of the metal salts by the ligand. The stable dimer [{(**3**)$Nd(CF_3SO_3)$}$_2$(μ-$CF_3SO_3$)$_3$]$CF_3SO_3$ was characterized by X-ray structure determination. Depending on the size of the metal ion, additional co-ligands can also be bound to the metal centers. This is observed in the molecular structures of [(**3**)$Pr(NO_3)_2(MeOH)_2$]$(NO_3)$, [(**3**)$NdCl_2$(MeOH)(EtOH)]Cl, [(**3**)$ErCl_2$(MeOH)]Cl, and [(**3**)$LuCl_2$]Cl. The solid-state molecular structures of **4** and **4**·HCl show the helicating ability of this ligand upon metal coordination. The corresponding lanthanide complexes of **4** are characterized by standard techniques such as NMR and CD spectroscopy and mass spectrometry.

## Introduction

Lanthanide chemistry has become more and more important in recent years due to the special properties of these metal ions. Their use in lighting devices, their magnetic properties, their unique redox chemistry, and their application in catalysis and diagnostics make them an attractive target of current research,[1] with the main focus being on solid-phase materials and organometallic chemistry.[2] Coordination chemistry is mainly based on the development of new imaging agents and sensors.[3] However, this field offers an easy entry to prepare stable, well-defined molecular species and to introduce special properties with the ligand.

Coordination compounds of the lanthanides are frequently used as catalysts, as impressively demonstrated by the work of Shibasaki,[4] Kobayashi,[5] and others,[6] although often the catalytically active complexes are not isolated but are only generated in solution.

Herein we present a general study of the preparation of a series of lanthanide(III) complexes with pentadentate ligands in order to obtain Lewis acidic compounds. The introduction of chirality at the ligands offers the opportunity to prepare enantiomerically pure complexes with ligands wrapping around the metal in a helical fashion.[7]

## Results and Discussion

### Studies with 8-Hydroxyquinoline Derivatives

We recently described the formation and molecular structures of a series of lanthanide(III) complexes with the semicarbazone ligand **1**-H.[8,9] In order to get enantiomerically pure coordination compounds the semicarbazone moiety is now substituted by the SAMP hydrazone to give ligand **2**-H, which can be prepared in a simple condensation reaction of SAMP[10] with 8-hydroxyquinoline 2-carbaldehyde in 94% yield (Scheme 1).[11]

Compound **2**-H is a tetradentate ligand like **1**-H with the difference that the strongly donating carbonyl unit is substituted by a more weakly donating ether moiety and that the chelating N,O unit in the side chain is elongated by one atom. In addition, the chiral information at the hydrazone leads to a helical twisting in **2**-H, while **1**-H usually adopts a planar conformation.

Treatment of **2**-H with a series of lanthanide(III) salts under different conditions did not lead to well-defined complexes, and only the reaction of **2**-H with $YCl_3$ in methanol in the presence of potassium carbonate gave a red powder, which exhibits in its $^1$H NMR spectrum two different sets

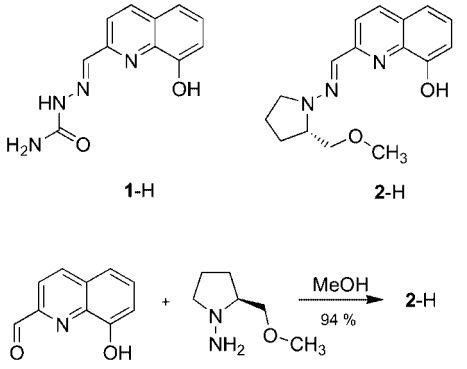

Scheme 1. Semicarbazone ligands **1**-H and **2**-H.

of signals for two unsymmetrically bound $\mathbf{2}^-$ ligands. The ESI mass spectrum reveals the peak of $[(\mathbf{2})_2Y]^+$ at *m*/*z* 657.

X-ray quality crystals were obtained from a $CH_3CN/CHCl_3$ solution of the complex. The X-ray diffraction analysis shows that the two ligands are coordinated in different ways, with one binding in a tetradentate and the other a monodentate fashion. The latter binds to the metal through the phenolate oxygen atom and is additionally fixed by hydrogen bonding of the protonated quinoline to the phenolate of the tetracoordinate ligand. This bridging hydrogen atom can be observed by $^1H$ NMR spectroscopy at $\delta = 15.80$ ppm in $CDCl_3$ solution. In addition, two chloride atoms bind to yttrium(III) in mutually *trans* position. The molecular structure of $[(\mathbf{2})(\mathbf{2}\text{-H})YCl_2]$ is shown in Figure 1.

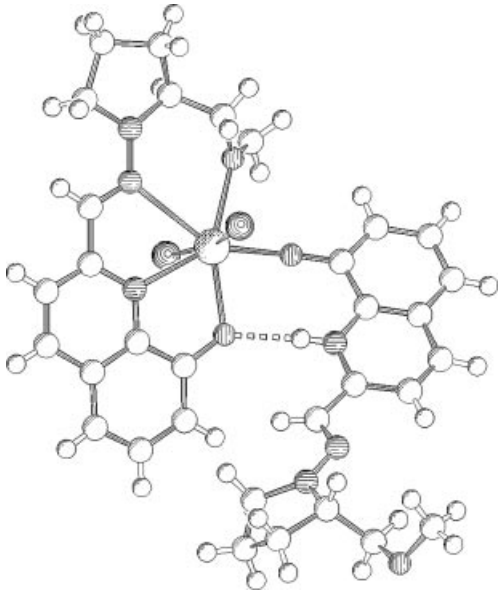

Figure 1. Molecular structure of $[(\mathbf{2})(\mathbf{2}\text{-H})YCl_2]$ as found in the crystal.

Based on those preliminary results, which show that ligand **2**-H is not ideal for the effective coordination of lanthanide(III) ions, the new pentadentate ligands **3** and **4** were developed.[12] Compound **4** (Figure 2) is a helicating ligand[13] with the potential to wrap around a single lanthanide(III) center to form a single-stranded helix.[14]

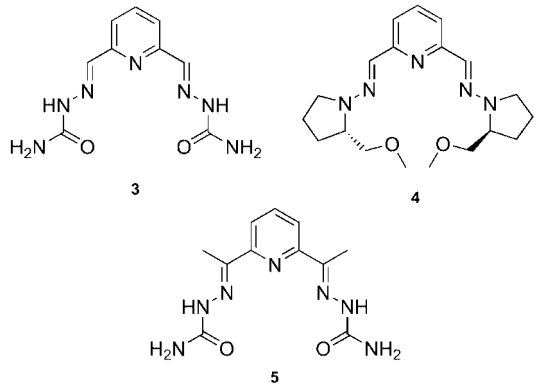

Figure 2. Pentadentate ligands **3**–**5**.

While we were investigating the coordination chemistry of ligands **3** and **4**, a publication by Palenik on the lanthanide(III) coordination chemistry of the related ligand **5** appeared concerning various lanthanide(III) coordination compounds $[(\mathbf{5})LnX_n]$. As expected, **5** provides a planar pentacoordinate platform.[15a]

## Preparation of Ligands 3 and 4 and the Solid-State Structures of 4 and 4·HCl

Ligands **3** and **4** were synthesized by a simple imine-type condensation of the easy to prepare 2,6-pyridinedicarbaldehyde with either semicarbazide hydrochloride or SAMP [(*S*)-1-amino-2-(methoxymethyl)pyrrolidine] in methanol. Ligand **3** was obtained in 72% yield as its bis-HCl adduct, while **4** was isolated as the unprotonated species in 78% yield. Both compounds were characterized by standard procedures.

We were able to obtain X-ray quality crystals of the chiral compound **4** as well as of its mono-HCl adduct **4**·HCl (Figure 3). In both compounds the external imine bonds show an *s-trans* conformation at the pyridine nitrogen. The methoxymethyl substituents at the pyrrolidine units are located at the "back side" of the molecules. One of the substituents is placed above the plane of the molecule while the other is pointing downwards, which means that the symmetry of the molecule is close to $C_2$.

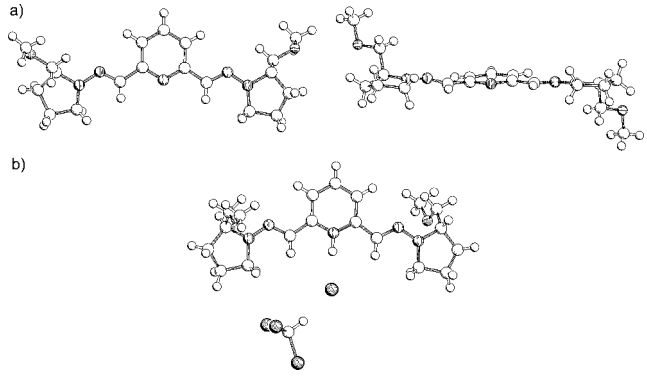

Figure 3. Molecular structures of compounds **4**; a) top and side view, b) **4**·HCl.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The conformations of **4** in its free as well as in its protonated form are very similar. However, the additional proton of **4**·HCl is located at the pyridine nitrogen atom with the chloride atom in close contact with this positively charged unit. In addition, one molecule of chloroform co-crystallizes with its hydrogen atom pointing towards the halide anion.

In order to form coordination compounds ligand **4** has to undergo a conformational change of the $C_{pyridine}$–$C_{imine}$ bonds involving a 180° rotation. This provides a pocket that is ideal for metal binding in a tri- or pentadentate fashion.

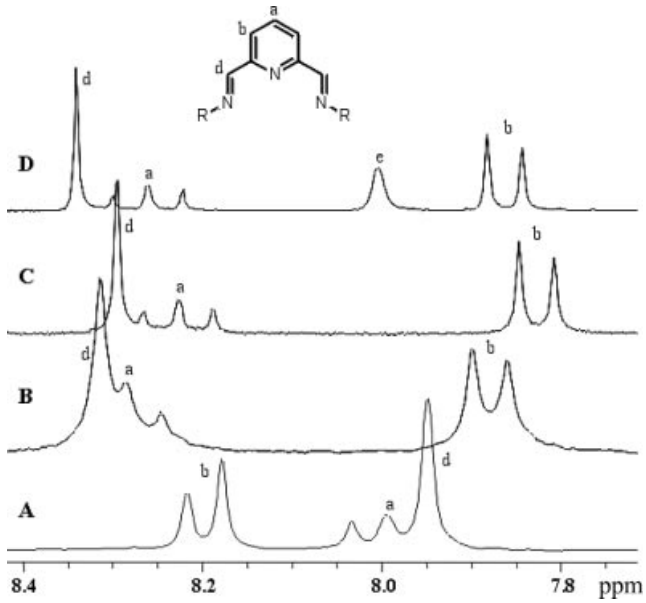

Figure 4. Portions of the $^1$H NMR spectra of **3** in [$D_6$]DMSO (A) and [(**3**)La][$CF_3SO_3$]$_3$ (B), [(**3**)La][Cl]$_3$ (C), and [(**3**)Lu][$NO_3$]$_3$ (D) in [$D_4$]MeOH. The assignment of ligand signals is presented in the inset (e = $NH_{hydrazone}$).

### Coordination Chemistry of Ligand 3 with Lanthanide(III) Ions

Complexes of ligand **3** with lanthanides were prepared by addition of lanthanide(III) salts to a suspension of **3** in either methanol or acetonitrile. Characterization of the complexes was done by mass spectrometry and, where possible, by elemental analysis. Coordination compounds of the diamagnetic meta ions yttrium(III), lanthanum(III), and lutetium(III) were also characterized by NMR spectroscopy (Table 1).

Table 1 lists some results of mass spectrometric investigations of the coordination compounds of ligand **3** with lanthanides. In all cases 1:1 complexes between the ligands and the metals are observed, although with neodymium(III) triflate a dimeric 2:2 species is found in addition to the monomer. In some cases displacement of the anion by hydroxide or methoxide from the solvent matrix occurs.

Representative portions of the $^1$H NMR spectra of complexes of **3** with diamagnetic lanthanum(III) and lutetium(III) ions in [$D_4$]MeOH are depicted in Figure 4. Unfortunately, the free ligand **3** is not soluble in this solvent therefore the spectrum of the ligand was recorded in [$D_6$]-DMSO.

Due to the different solvents the spectra of the ligand and the complexes cannot be compared directly. However, a remarkable shift difference can be detected for the hydrazone CH=N proton. Thus, in the ligand (in [$D_6$]DMSO) its resonance is observed at $\delta$ = 7.95 ppm while in the complexes (in $CD_3OD$) shifts of $\delta$ = 8.32 [La($CF_3SO_3$)], 8.30 (LaCl), and 8.38 ppm [Lu($NO_3$)] are found. In addition, significant low-field shifts are observed for the proton in the 4-position and high-field shifts for the protons in the 3- and 5-positions of the pyridine ring of **3**. The shift differences between coordinated and free ligands are due to the conformational changes that occur in **3** upon coordination to the metal, and the differences in the NMR spectra of complexes with different anions indicate that at least some of the anions are still coordinated to the metals in solution.

We were able to obtain X-ray quality crystals of several coordination compounds of ligand **3** with different lanthanide salts and the complexes of the larger lanthanides $Pr^{III}$ and $Nd^{III}$ as well as of the smaller lanthanides $Er^{III}$ and $Lu^{III}$ were structurally characterized (Table 2).

### *[(3)Pr(NO$_3$)$_2$(CH$_3$OH)$_2$]NO$_3$·CH$_3$OH*

X-ray quality crystals of the complex of **3** with praseodymium(III) nitrate were obtained from methanol solution. Two different views of the molecular structure of the cation [(**3**)Pr(NO$_3$)$_2$(CH$_3$OH)$_2$]$^+$ are presented in Figure 5 and selected bond lengths and angles are listed in Table 2. Compound **3** acts as a pentadentate ligand that coordinates to the praseodymium ion through the pyridine and two "imine" nitrogen atoms of the semicarbazone as well as through the two carbonyl oxygen atoms. The coordinated ligand is not planar but possesses a slight helical twisting. In addition, two bidentate nitrate anions binding to the metal above and below the plane of the "(**3**)Pr" platform. The third nitrate anion does not coordinate to the metal center. This leaves additional sites in the front of the complex, where two molecules of methanol are coordinated to the metal. The coordination number for Pr$^{III}$ is therefore eleven. The coordination of two nitrate anions to the metal center presents a remarkable difference to the structures obtained by Palenik et al. for their complexes of ligand **5**,[15b] where only one nitrate as well as numerous water molecules bind to the metals.

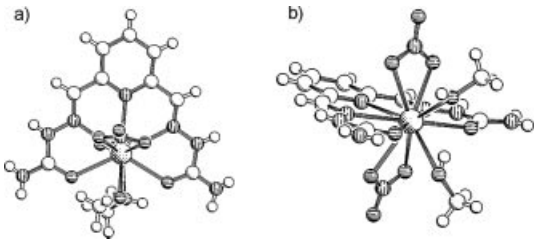

Figure 5. Top (a) and side view (b) of the cation [(**3**)Pr(NO$_3$)$_2$(CH$_3$OH)$_2$]$^+$ as observed in the solid state.

### *[{(3)Nd(CF$_3$SO$_3$)}$_2$(μ-CF$_3$SO$_3$)$_3$]CF$_3$SO$_3$·2CH$_3$CN·(CH$_3$CH$_2$)$_2$O*

Crystals of neodymium(III) triflate were obtained from acetonitrile/diethyl ether solution. The molecular structure of the cation [{(**3**)Nd(CF$_3$SO$_3$)}$_2$(μ-CF$_3$SO$_3$)$_3$]$^+$ in the crystal is depicted in Figure 6 and representative bond length and angles are listed in Table 2.

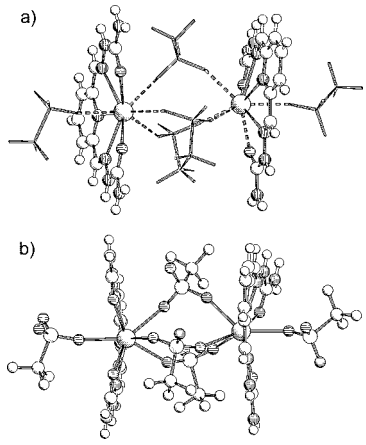

Figure 6. Two different views of the cation [{(**3**)Nd(CF$_3$SO$_3$)}$_2$(μ-CF$_3$SO$_3$)$_3$]$^+$ as observed in the solid state. The triflate anions in a) are indicated by lines.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The cation $[\{(\mathbf{3})Nd(CF_3SO_3)\}_2(\mu\text{-}CF_3SO_3)_3]^+$ adopts a dimeric structure with two "(**3**)Nd(OTf)" moieties connected by three bridging triflate anions. The bridging triflates each coordinate through two different oxygen atoms to the different metals, while the terminal triflates act only as monodentate ligands. The two ligands **3** are orientated in an *anti* fashion within a planar arrangement. However, the steric bulk of the three bridging anions forces the metal ions out of the plane of the pentacoordinate ligands. The remaining triflate anion does not interact with the metal center but is incorporated within the crystal lattice. This dimer possesses an unusual stability as positive-ion ESI mass spectrometry showed its presence even in methanol solution. The corresponding peak of the dimer $[(\mathbf{3})_2Nd_2(F_3CSO_3)_5]^+$ is detected at *m*/*z* 1531 along with the monomer $[(\mathbf{3})Nd(F_3CSO_3)_2]^+$ at *m*/*z* 691.

### *[(3)NdCl$_2$(CH$_3$OH){(CH$_3$CH$_2$)$_2$O}]Cl*

The complex of neodymium(III) chloride with **3** was crystallized from methanol/ethanol solution. Figure 7 presents the solid-state structure of $[(\mathbf{3})NdCl_2(CH_3OH)\{(CH_3CH_2)_2O\}]^+$.

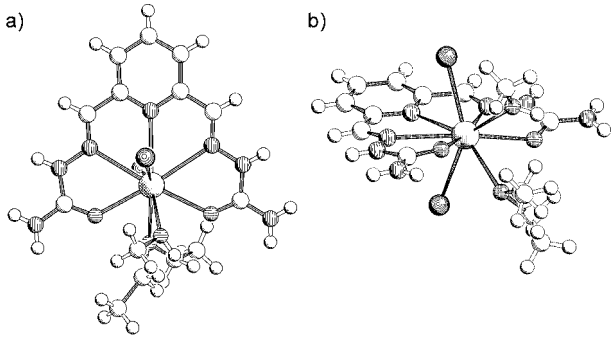

Figure 7. Two different views of the cation $[(\mathbf{3})NdCl_2(CH_3OH)\{(CH_3CH_2)_2O\}]^+$ as observed in the solid state.

Ligand **3** coordinates to the metal center in an almost planar fashion with the chloride atoms sitting above and below the plane of the ligand. In addition, one methanol molecule and one molecule of diethyl ether coordinate at the front of the complex. Due to the high coordination number and the steric bulk of the co-ligands, the Nd–N bonds are longer than those in the dimer $[\{(\mathbf{3})Nd(CF_3SO_3)\}_2(\mu\text{-}CF_3SO_3)_3]^+$ (see Table 2).

### *[(3)ErCl$_2$(CH$_3$OH)]Cl*

Crystals of the erbium complex of ligand **3** were obtained from methanol. Figure 8 (a) shows a top view of the structure of the cation $[(\mathbf{3})ErCl_2(CH_3OH)]^+$ where the almost planar coordination of the ligand is clear. However, the side view (Figure 8 b) reveals a slight helical twisting. This is caused by an asymmetric coordination of further ligands; one chloride anion from the top and chloride and methanol from the bottom. The steric bulk of the methanol forces the ligand to deviate from planarity and additionally leads to a nonplanar Cl–Er–Cl arrangement with an angle of 150.92°. In the crystal, the third chloride ion is found close to the NH units of the semicarbazones.

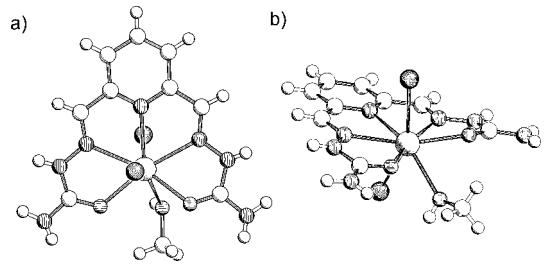

Figure 8. Two different views of the cation $[(\mathbf{3})ErCl_2(CH_3OH)]^+$ as observed in the solid state.

### *[(3)LuCl$_2$]Cl*

X-ray quality crystals of $[(\mathbf{3})LuCl_2]Cl$ were obtained by diffusion of diethyl ether into a solution of the complex in acetonitrile/methanol. The solid-state structure of the cation $[(\mathbf{3})LuCl_2]^+$ is shown in Figure 9.

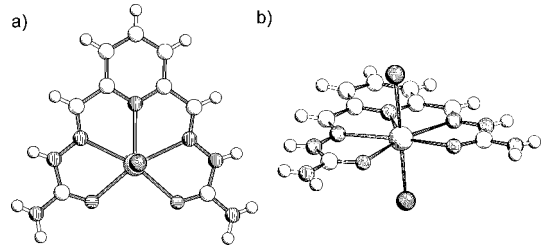

Figure 9. Two different views of the cation $[(\mathbf{3})LuCl_2]^+$ as observed in the solid state.

In principle it is related to the corresponding cation $[(\mathbf{3})ErCl_2(CH_3OH)]^+$ described above. Due to the smaller size of lutetium(III) than erbium(III), however, a lower coordination number of seven is adopted, which means that no methanol is bound to the metal in the lutetium complex. This results in some structural differences between $[(\mathbf{3})LuCl_2]^+$ and $[(\mathbf{3})ErCl_2(CH_3OH)]^+$. Thus, the chloride atoms are now bound in a more symmetric fashion leading to a nearly planar Cl–Lu–Cl arrangement of 177.14°. Consequently, the ligand adopts a close to planar geometry with no significant helical distortion.

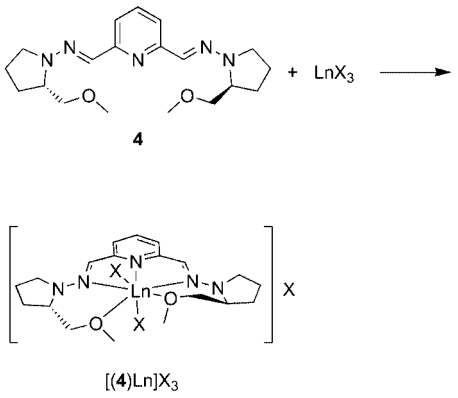
The results of the above X-ray structural investigations show that ligand **3** acts as a pentadentate ligand for the complexation of lanthanide(III) ions. Due to the different sizes of the different metal ions, varying numbers of co-ligands are bound to the metal centers. In order to adjust to the different metals, the ligand has to adopt a more open (for larger ions) or a more closed (for smaller ions) tweezer-type arrangement. This is demonstrated by a decrease of the distance between the two terminal $NH_2$ groups of **3** depending on the size of the metals. This N–N distance is 8.998 Å for Pr, 8.783 Å for the Nd monomer, 8.134/8.230 Å for the Nd dimer, 7.983 Å for Er, and 7.842 Å for Lu.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Following the series of structures with chloride anions, it is clear that the $[(\mathbf{3})MCl_2]^+$ cation is only observed for the small lutetium(III) ion, whereas for the larger erbium(III) ion the metal center is not coordinatively saturated and an additional solvent molecule is bound in the front of the complex. The still larger neodymium(III) ion even provides space for two such solvent molecules, which means that the complexes of the larger cations would be the best candidates to test their ability to act as Lewis acid catalysts.

### Coordination Chemistry of the Chiral Ligand 4 with Lanthanide(III) Ions

Coordination compounds of lanthanides with the chiral ligand **4** were synthesized in analogy to the preparation of complexes with the semicarbazone ligand **3**. Thus, the corresponding lanthanide(III) salt in methanol or acetonitrile was added to a solution of the ligand **4** in methanol or acetonitrile. The mixture was stirred for 16–72 h and the solvent was then removed in vacuo to yield orange-yellow to red compounds (Scheme 2).



Scheme 2. Formation of lanthanide(III) complexes of ligand **4**. The coordination at the metal is proposed based on the described results obtained with ligand **3** and the NMR spectroscopic and mass spectrometric observations. Ln = La, Pr, Nd, Sm, Er, Yb, Lu, and Y; X = Cl, $NO_3$, and triflate.

We could not obtain X-ray quality crystals of the complexes with ligand **4**, although we were able to characterize them by NMR spectroscopy, mass spectrometry, and, in several cases, by elemental analysis. The $^1$H NMR spectrum of ligand **4** (A) is compared with the corresponding spectra of representative complexes in Figure 10. The spectra of the diamagnetic lutetium (B) and the paramagnetic ytterbium complex (C) are shown, the latter of which reveals a nicely resolved NMR spectrum with some line broadening due to the presence of the paramagnetic metal ion.

Similarly to the coordination compounds with ligand **3**, complexes of **4** exhibit a low-field shift for the proton in the 4-position of the pyridine and a high-field shift for those in the 3- and 5-positions relative to the signals of free ligand (in $[D_3]$acetonitrile). However, in contrast to complexes of **3**, the signal for the CH=N "imine" proton is observed at higher field. This is probably due to the different nature of the two hydrazone-type substituents of **3** and **4**, which leads to different electronic influences on the CH=N proton upon metal coordination. In addition, ligand **4** adopts a helical conformation upon complexation while **3** is more or less planar.

A strong influence of the anions on the NMR spectra is found for these complexes, as shown in Figure 11 for the $^1$H NMR spectrum of the lutetium(III) complexes of **4** in $[D_3]$acetonitrile. The "imine" proton only shifts to higher field if anions are present that coordinate in a bidentate fashion [triflate (A) or nitrate (C)]. In the presence of chloride a shift of this ligand signal to lower field occurs upon complexation to lutetium (B). The differences in the chemical shifts of the imine, 3- and 5-pyridine protons, and of the proton in the 4-position show that the anions are still coordinated to the lutetium in solution.

As representative examples of the mass spectrometric investigations, the molar peaks, including the isotopic patterns, of the cations $[(\mathbf{4})ErX_2]^+$ (X = triflate, chloride, nitrate) are presented in Figure 12. The depicted spectra were obtained by using the positive-ion LDI-TOF technique. The observed patterns correspond to the calculated ones. Similar spectra are observed for most of the prepared coor-

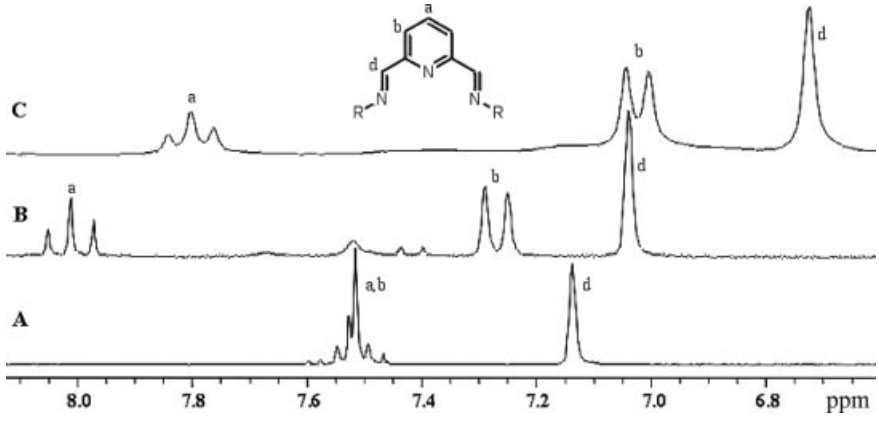


Figure 10. Portions of the $^1$H NMR spectra of **4** (A), $[(\mathbf{4})Lu][F_3CSO_3]_3$ (B), and $[(\mathbf{4})Yb][F_3CSO_3]_3$ (C) in $[D_3]$acetonitrile. The assignment of the protons to the pyridine and the imine moiety is indicated.

[a] Not prepared.

We also performed CD spectroscopic studies with ligand **4** and selected complexes of this ligand with lanthanides. The spectra of the complexes in dichloromethane reveal essentially the same features and therefore only the spectrum of [(**4**)Er(Cl)$_3$] is described as a representative example. Very similar UV spectra are observed for ligand **4** and [(**4**)Er-

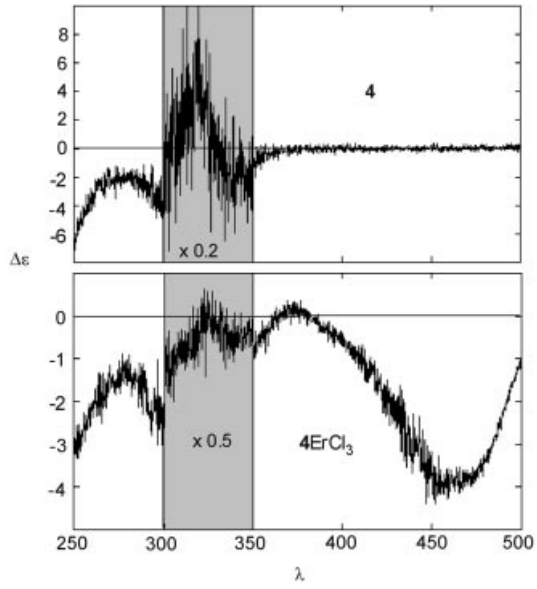

Figure 13. CD spectra of **4** (top) and [(**4**)Er(Cl)$_3$] (bottom) in dichloromethane. Note that measurement of the spectrum between 300 and 350 nm (grey) was problematic due to the high optical density of the sample in this region. The measurements in this region therefore had to be performed at lower concentrations.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$(Cl)_3$], both of which show an intense transition at 320 nm. CD spectra proved difficult to record in the region of this band due to the high optical density of the sample (Figure 13).

The most intriguing difference between the CD spectra of **4** and [(**4**)$ErCl_3$] is the presence of a strong band with a negative Cotton effect at 400–500 nm. This becomes dominant in the CD spectrum due to the chirality that is induced around the metal center.

## Conclusions

We have presented a structural work on the coordination chemistry of the pentadentate bis-semicarbazone pyridine ligand **3**. The ligand provides a planar coordination platform and effectively binds lanthanide(III) salts (chlorides, nitrates, or triflates). Small lanthanide(III) ions preferably form cationic complexes $[(\mathbf{3})LnX_2]^+$. One or more additional co-ligands, which are often are not the remaining third counteranions but solvent molecules, bind to the metal center in the case of the bigger ions. This latter finding gives some hint as to how complexes related to those of ligand **4** should be designed to obtain effective Lewis acid catalysts: (i) a pentadentate ligand must exhibit poorer donor ability than **3** in order to enhance Lewis acidity, (ii) the "side arms" of the ligand have to be more labile coordinating units, and (iii) chirality should be introduced.

Following those three requirements we prepared the helicating ligand **4** and showed that it can form 1:1 complexes with lanthanide(III) salts. Further studies will be directed towards the use of complexes of **4** with lanthanides as Lewis acid catalysts.

## Experimental Section

**General:** NMR spectra were recorded with a Bruker AC 200, AMX 400, or a Varian Inova 400 or Mercury 300 spectrometer. FT-IR spectra were recorded by the diffuse reflection technique (KBr) with a Bruker Vector 22 or Perkin–Elmer PE-1760 FT spectrometer. Mass spectra were recorded with a Finnigan MAT MS 90, LCQ Deca XP Plus, Bruker Reflex IV, or Micromass Quattro LC-Z mass spectrometer. Elemental analyses were obtained with a Heraeus CHN-O-Rapid analyzer or a Vario EL III CHNS. Melting points: Büchi B-540 (uncorrected). Lanthanide chlorides, triflates, and nitrates were prepared as described before.[16]

**X-ray Crystallography:** Data sets were collected with Nonius KappaCCD and Bruker APEX CCD diffractometers, both equipped with rotating anode generators. Programs used: data collection: COLLECT (Nonius B.V., 1998) and SMART (Bruker AXS, 2000); data reduction: Denzo-SMN[17] and SAINT (BrukerAXS, 2000); absorption correction: SORTAV,[18] Denzo,[19] and SADABS (Bruker AXS, 2000); structure solution: SHELXS-97;[20] structure refinement: SHELXL-97 (G. M. Sheldrick, University of Göttingen, 1997); graphics: SCHAKAL (E. Keller, University of Freiburg, 1997).

CCDC-631745 to -631752 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

**2-H:** A mixture of 8-hydroxyquinoline-2-carbaldehyde (1 equiv., 0.052 g, 0.3 mmol) and SAMP (1.1 equiv., 0.043 g, 0.33 mmol) in methanol was stirred overnight at room temp. The solvent was then distilled off and the crude residue was washed with diethyl ether and dried in vacuo. The product was obtained in 94% yield (0.08 g, 0.28 mmol) as a yellow oil. $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 7.98 (m, 2 H), 7.33 (d, $J$ = 7.4 Hz, 1 H), 7.30 (d, $J$ = 7.4 Hz, 1 H), 7.23 (dd, $J$ = 8.2, 1.5 Hz, 1 H), 7.11 (dd, $J$ = 7.4, 1.5 Hz, 1 H), 3.83 (m, 1 H), 3.68 (dd, $J$ = 9.4, 3.7 Hz, 1 H), 3.55 (dd, $J$ = 9.4, 6.7 Hz, 1 H), 3.46 (m, 1 H), 3.40 (s, 3 H), 3.21 (m, 1 H), 2.00 (m, 4 H) ppm. $^{13}$C NMR ($CDCl_3$): $\delta$ = 154.62 (C), 151.80 (C), 137.70 (C), 135.49 (CH), 130.89 (CH), 127.27 (C), 126.40 (CH), 117.97 (CH), 117.74 (CH), 109.98 (CH), 74.33 ($CH_2$), 62.89 (CH), 59.34 ($CH_3$), 48.36 ($CH_2$), 26.99 ($CH_2$), 22.29 ($CH_2$) ppm. Positive-ion ESI MS: $m/z$ 286.2 $[M + H]^+$.

**[(2)(2-H)$YCl_2$]:** The ligand **2**-H (2 equiv., 0.04 g, 0.14 mmol) and $YCl_3$ (1 equiv., 0.021 g, 0.07 mmol) were stirred overnight in MeOH (10 mL) in the presence of $K_2CO_3$ as a base (1.9 equiv., 0.01 g, 0.072 mmol) at room temp. The solvent was then removed and the residue dried in vacuo. Extraction with $CH_2Cl_2$ gave a red powder in quantitative yield (0.053 g, 0.07 mmol). $^1$H NMR (300 MHz, $CDCl_3$): $\delta$ = 15.80 (br., 1 H), 8.18 (d, $J$ = 8.4 Hz, 1 H), 8.09 (d, $J$ = 8.4 Hz, 1 H), 7.55 (m, 1 H), 7.63 (d, $J$ = 7.9 Hz, 1 H), 7.4–7.2 (m, 6 H), 6.92 (d, $J$ = 8.2 Hz, 1 H), 6.69 (d, $J$ = 7.4 Hz, 1 H), 5.23 (d, $J$ = 9.1 Hz, 1 H), 4.94 (d, $J$ = 6.2 Hz, 1 H), 4.06 (m, 1 H), 3.99 (s, 2 H), 3.85 (m, 2 H), 3.70 (s, 3 H), 3.56 (m, 3 H), 3.41 (s, 3 H), 2.31 (m, 1 H), 2.03 (m, 6 H), 1.71 (m, 2 H), 1.61 (m, 2 H) ppm. Positive-ion ESI MS: $m/z$ 657.4 $[M - HCl - Cl]^+$. IR (KBr): $\tilde{\nu}$ = 3851, 3745, 3406, 2929, 2873, 2361, 2338, 1629, 1586, 1527, 1456, 1389, 1323, 1235, 1099, 848, 744, 677, 598 $cm^{-1}$. $C_{32}H_{37}Cl_2N_6O_4Y{\cdot}H_2O{\cdot}CH_3OH$: calcd. C 50.84, H 5.56, N 10.78; found C 51.06, H 5.45, N 11.01.

X-ray quality crystals of [(**2**)(**2**-H)$YCl_2$] were obtained by slow evaporation of a concentrated $CH_3CN/CHCl_3$ solution. X-ray crystal structure analysis for [(**2**)(**2**-H)$YCl_2$]: formula $C_{32}H_{37}Cl_2N_6O_4Y$, $M$ = 729.49, orange crystal $0.10 \times 0.06 \times 0.05$ $mm^3$, $a$ = 15.660(1), $b$ = 12.582(1), $c$ = 17.051(1) Å, $\beta$ = 104.64(1)°, $V$ = 3250.6(4) $Å^3$, $\rho_{calc}$ = 1.491 $g cm^{-3}$, $\mu$ = 2.005 $mm^{-1}$, empirical absorption correction ($0.825 \leq T \leq 0.906$), $Z$ = 4, monoclinic, space group $P2_1$ (no. 4), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\phi$ scans, 12952 reflections collected ($\pm h$, $\pm k$, $\pm l$), $[(\sin\theta)/\lambda]$ = 0.54 $Å^{-1}$, 7864 independent ($R_{int}$ = 0.081) and 5566 observed reflections [$I \geq 2\sigma(I)$], 815 refined parameters, $R$ = 0.066, $wR_2$ = 0.113, Flack parameter –0.004(11), max. residual electron density 0.43 (–0.45) e $Å^{-3}$. The hydrogen atom at nitrogen was found from difference Fourier calculations. The others were calculated and refined as riding on their parent atoms. Due to crystal size the analysis is of limited accuracy.

**2,2′-[Pyridine-2,6-diylbis(methan-1-yl-1-ylidene)]bis(hydrazinecarboxamide) (3):** Semicarbazone hydrochloride (670 mg, 6.0 mmol) was dissolved in 40 mL of methanol and pyridine-2,5-dicarbaldehyde (400 mg, 2.9 mmol) in 15 mL of methanol was added. The yellow precipitate that formed over 70 h was collected, washed with cold methanol, and dried in vacuo to give a yellow solid. Yield: 666 mg (2.1 mmol, 72%). M.p. 214.8 °C (dec.). $^1$H NMR (400 MHz, [D$_6$]DMSO): $\delta$ = 10.88 (s, 2 H), 8.23 (d, $J$ = 7.9 Hz, 2 H, b), 8.04 (t, $J$ = 7.9 Hz, 1 H), 7.99 (s, 2 H), 6.76 (br. s, 2 H) ppm. $^{13}$C NMR (50 MHz, [D$_6$]DMSO): $\delta$ = 156.2, 151.2, 139.3, 136.1, 120.1 ppm. IR (KBr): $\tilde{\nu}$ = 3779, 3705, 3632, 3411, 2974, 2381, 2275, 1815, 1717, 1587, 1513, 1430, 1343, 1294, 1229, 1178, 1074, 933, 817, 725, 634, 559, 486 $cm^{-1}$. MS (pos. MALDI-TOF, DHB): $m/z$ 272.0 (26) $[M + Na]^+$, 250.0 (100) $[M + H]^+$. $C_9H_{11}N_7O_2{\cdot}2HCl{\cdot}H_2O$: calcd. C 31.78, H 4.44, N 28.82; found C 31.70, H 4.60, N 27.96.

**(2*S*,2′*S*)-*N*,*N*′-[Pyridine-2,6-diylbis(methan-1-yl-1-ylidene)]bis[2-(methoxymethyl)pyrrolidin-1-amine] (4):** Pyridine-2,6-dicarbaldehyde (1.00 g, 7.4 mmol) in 10 mL of methanol was slowly added to a solution of SAMP (2.00 g, 15.4 mmol) in 4 mL of methanol and, after stirring overnight, the solvent was removed in vacuo. The crude product was recrystallized from hot pentane by cooling to 6 °C. Yield: 2.07 g (5.8 mmol, 78%) of a colorless solid. M.p. 77.8 °C. $^1$H NMR (400 MHz, $CD_3CN$): $\delta$ = 7.54 (t, $J$ = 6.0 Hz, 1 H), 7.51 (d, $J$ = 6.0 Hz, 2 H), 7.14 (s, 2 H), 3.69 (quint, $J$ = 4.0 Hz, 2 H), 3.60 (dd, $J$ = 7.6, 4.0 Hz, 2 H), 3.47 (dd, $J$ = 9.6, 6.9 Hz, 2 H), 3.41 (dt, $J$ = 6.9, 4.0 Hz, 2 H), 3.33 (s, 6 H), 3.13 (dt, $J$ = 9.6, 7.6 Hz, 2 H), 2.08–1.77 (m, 8 H) ppm. $^{13}$C NMR (100 MHz, $CD_3CN$): $\delta$ = 156.9, 137.1, 132.2, 116.2, 75.3, 63.9, 59.4, 49.4, 27.8, 23.0 ppm. IR (KBr): $\tilde{\nu}$ = 3851, 3745, 3678, 3621, 2361, 1836, 1649, 1547, 1459, 1107, 669 cm$^{-1}$. MS (EI-DIP, 70 eV): *m*/*z* (%) 359.1 (66) [M$^+$], 314.1 (45), 246 (100), 219 (59), 201 (47). $C_{19}H_{29}N_5O_2$: calcd. C 63.48, H 8.13, N 19.48; found C 63.21, H 8.00, N 19.08.

**X-ray Crystal Structure Analysis for 4:** $C_{19}H_{27}N_5O_2$, $M$ = 357.46, colorless crystal 0.49 × 0.28 × 0.17 mm$^3$, $a$ = 7.8706(15), $b$ = 12.524(2), $c$ = 20.475(4) Å, $V$ = 2018.2(7) Å$^3$, $\rho_{calc}$ = 1.176 g cm$^{-3}$, $\mu$ = 0.079 mm$^{-1}$, empirical absorption correction (0.962 ≤ $T$ ≤ 0.987), $Z$ = 4, orthorhombic, space group $P2_12_12_1$ (no. 19), $\lambda$ = 0.71073 Å, $T$ = 233 K, $\omega$ and $\phi$ scans, 16268 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sin$\theta$)/$\lambda$] = 0.60 Å$^{-1}$, 3549 independent ($R_{int}$ = 0.038) and 2835 observed reflections [$I \geq 2\sigma(I)$], 237 refined parameters, $R$ = 0.065, $wR_2$ = 0.185, Flack parameter 3(3), max. residual electron density 0.38 (–0.20) e Å$^{-3}$; hydrogen atoms were calculated and refined as riding.

**X-ray Crystal Structure Analysis for 4·HCl·CHCl$_3$:** $C_{20}H_{31}Cl_4N_5O_2$, $M$ = 515.30, colorless crystal 0.22 × 0.20 × 0.15 mm$^3$, $a$ = 5.601(1), $b$ = 17.230(1), $c$ = 13.217(4) Å, $\beta$ = 93.41(1)°, $V$ = 1273.3(3) Å$^3$, $\rho_{calc}$ = 1.344 g cm$^{-3}$, $\mu$ = 0.491 mm$^{-1}$, empirical absorption correction (0.902 ≤ $T$ ≤ 0.930), $Z$ = 4, monoclinic, space group $P2_1$ (no. 4), $\lambda$ = 0.71073 Å, $T$ = 198 K, $\omega$ and $\phi$ scans, 10536 reflections collected ($\pm h$, $\pm k$, $\pm l$), [(sin$\theta$)/$\lambda$] = 0.66 Å$^{-1}$, 5622 independent ($R_{int}$ = 0.051) and 4225 observed reflections [$I \geq 2\sigma(I)$], 286 refined parameters, $R$ = 0.045, $wR_2$ = 0.109, Flack parameter 0.02(5), max. residual electron density 0.38 (–0.20) e Å$^{-3}$. The hydrogen atom at nitrogen was observed in the difference Fourier calculations; the others were calculated and refined as riding.

**General Procedure for the Preparation of Metal Complexes:** A solution of the lanthanoid(III) salt (approx. 0.1 mmol) in methanol or acetonitrile was added to the ligand (**3** or **4**) in either methanol, acetonitrile, or nitromethane and the mixture was stirred overnight. The solvent was then removed in vacuo and the residue dried in vacuo. In the case of complexations with ligand **3** in acetonitrile, the mixture was filtered prior to work up.

**[(3)YCl$_3$]:** The reaction was performed in methanol. Yield: 70.7 mg (0.12 mmol, quant.), colorless solid. $^1$H NMR (200 MHz, $CD_3OD$): $\delta$ = 8.30 (t, $J$ = 8.0 Hz, 1 H), 8.27 (s, 2 H), 7.88 (d, $J$ = 8.0 Hz, 2 H) ppm. IR (KBr): $\tilde{\nu}$ = 3381, 3220, 1670, 1543, 1388, 1175 cm$^{-1}$. MS (pos. ESI, $CH_3OH$): *m*/*z* 407.9 (18) [(**3**)YCl$_2$]$^+$, 399.7 (100) [(**3**)Y(CH$_3$O)$_2$]$^+$. $C_9H_{11}Cl_3N_7O_2Y\cdot 7H_2O$: calcd. C 18.94, H 4.42, N 17.18; found C 18.49, H 3.82, N 16.63.

**[(3)Y(NO$_3$)$_3$]:** This complex was prepared in acetonitrile. Yield: 75.4 mg (0.12 mmol, quant.), pale-yellow solid. $^1$H NMR (200 MHz, $CD_3OD$): $\delta$ = 8.31 (t, $J$ = 7.9 Hz, 1 H), 8.29 (s, 2 H), 7.90 (d, $J$ = 7.9 Hz, 2 H) ppm. IR (KBr): $\tilde{\nu}$ = 3422, 1670, 1559, 1386, 1167 cm$^{-1}$. MS (pos. ## COVER PICTURE

**The cover picture shows** how aminoguanidine may behave as either a monodentate or bidentate ligand in square-planar complexes of platinum or palladium. In each case, the coordinating ligands can participate in extensive hydrogen-bonding networks. Details are discussed in the article by D. J. Aitken, J. Kozelka et al. on p. 3327ff.

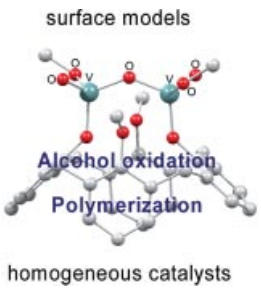
## MICROREVIEW

### Oxovanadium Calixarenes

**C. Limberg* ..... 3303–3314**

Calixarene-Based Oxovanadium Complexes as Molecular Models for Catalytically Active Surface Species and Homogeneous Catalysts

**Keywords:** Vanadium / Oxo complexes / Models / Calixarenes / Catalysis



Oxovanadium calixarene complexes can be regarded as models for active surface species on vanadium oxide based heterogeneous catalysts, and their investigation thus contributes to a more comprehensive understanding of the effective mechanisms. In addition, they are interesting as homogeneous catalysts, for instance for aerobic alcohol oxidation and olefin polymerization.

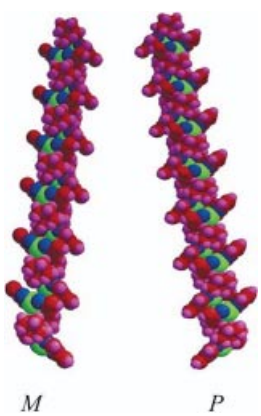
## SHORT COMMUNICATIONS

### Supramolecular Helical Assemblies

**X.-F. Shan, L.-Z. Wu,* X.-Y. Liu, L.-P. Zhang, C.-H. Tung ..... 3315–3319**

C–H···$Ni^{II}$ Interaction-Driven Homochiral *M* and *P* Helices of Neutral (*R,R*)- and (*S,S*)-Bis(pyrrol-2-ylmethyleneamino)-cyclohexane $Ni^{II}$ Complexes

**Keywords:** Nickel(II) complexes / C–H···$Ni^{II}$ interactions / Helical structures



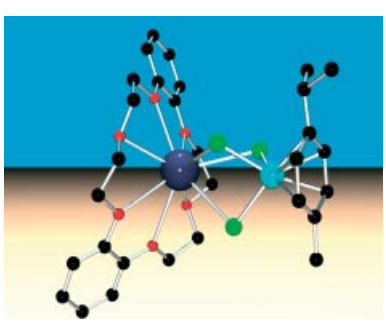
Reaction of (*R,R*)- and (*S,S*)-bis(pyrrol-2-ylmethyleneamino)cyclohexane with $Ni^{II}(OAc)_2 \cdot 4H_2O$ afforded enantiomeric nickel(II) Schiff-base complexes. Rare C–H···$Ni^{II}$ interactions were found to be responsible for the facile formation of the homochiral *M* and *P* helices of the neutral, chiral, mononuclear complexes in crystal lattices.

### Heterodimetallic Dinuclear Complexes

**C. A. Vock, R. Scopelliti, P. J. Dyson* ..... 3320–3322**

Synthesis and Crystallographic Characterisation of the Heterodimetallic Complex [(Dibenzo-18-crown-6)K($\mu$-Cl)$_3$Ru($\eta^6$-*p*-cymene)]

**Keywords:** Heterometallic complexes / Bridging ligands / Ruthenium / Crown compounds / X-ray crystallography



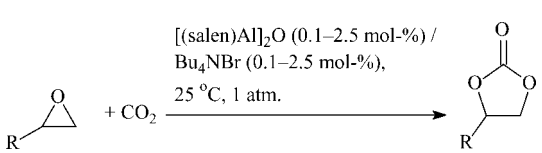
The first example of a triple-chlorido-bridged heterodimetallic dinuclear complex comprising an ($\eta^6$-arene)$Ru^{II}$ fragment and a Group 1 metal crown ether fragment is presented. The solid-state structure was determined by X-ray crystallography. NMR investigations indicate the presence of a dynamic equilibrium in solution.

### Carbon Dioxide Fixation

**J. Meléndez, M. North,* R. Pasquale ..... 3323–3326**

Synthesis of Cyclic Carbonates from Atmospheric Pressure Carbon Dioxide Using Exceptionally Active Aluminium(salen) Complexes as Catalysts

**Keywords:** Carbon dioxide fixation / Aluminium / Schiff bases / Epoxides / Catalysis



Dimetallic aluminium(salen) complexes show exceptionally high catalytic activity for the synthesis of cyclic carbonates from terminal epoxides at ambient temperature and pressure. The process has the potential to contribute towards decreasing atmospheric carbon dioxide emissions from the burning of fossil fuels.

# FULL PAPERS

## Aminoguanidine Coordination Modes

Aminoguanidine forms monodentate and bidentate complexes with $Pt^{II}$ and $Pd^{II}$. A series of N4-bound monodentate and N1,N4-bound chelate complexes was synthesized and characterized by solution NMR and by X-ray crystallography. In the solid state, hydrogen-bonding networks were observed; all four nitrogens of the Amgu ligand are able to behave as hydrogen atom donors.

Platinum(II) and Palladium(II) Complexes with *N*-Aminoguanidine

**Keywords:** Platinum / Palladium / N ligands / Coordination modes

## Gas-Phase Fragmentation

Electrospray ionization is used for the investigation vanadium(V) complexes of maleic and succinic acid. The fragmentation patterns of the mass-selected ions inter alia reveal a hitherto unrecognized connection between succinato and maleato complexes, which may be relevant in the context of vanadium-oxide-mediated formation of maleic acid upon partial oxidation of $C_4$-hydrocarbons.

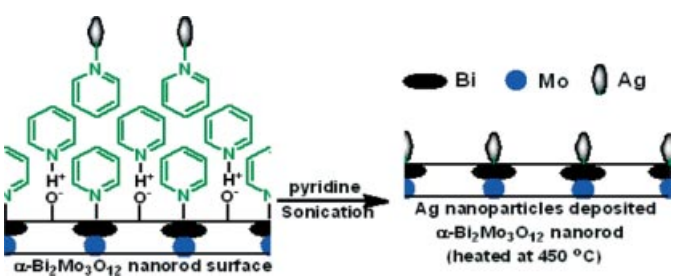
## Hybrid Nanocomposites



Silver nanoparticles with an average size of about 10 nm were uniformly deposited on the surface of $\alpha$-$Bi_2Mo_3O_{12}$ nanorods by using power ultrasound. Pyridine as a medium assisted the deposition process of the Ag nanoparticles, whereas Bi was observed to be the preferred binding site on the surface of the nanorods.

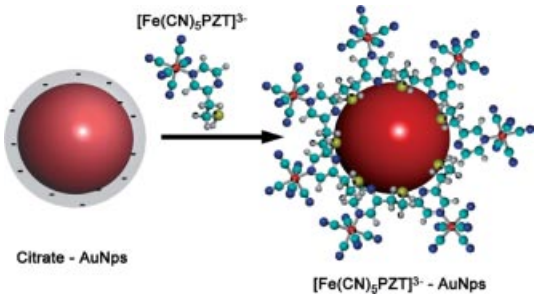
## Metal Nanoparticles

**S. H. Toma, J. A. Bonacin, K. Araki, H. E. Toma* ..... 3356–3364**

Controlled Stabilization and Flocculation of Gold Nanoparticles by Means of 2-Pyrazin-2-ylethanethiol and Pentacyanidoferrate(II) Complexes

**Keywords:** Aggregation / Colloids / Semiempirical calculations / Raman spectroscopy / UV/Vis spectroscopy / Charge transfer



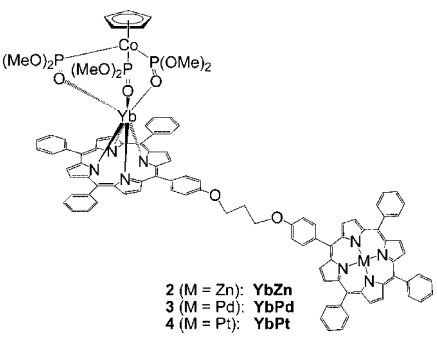
Coordination of pentacyanidoferrates and 2-pyrazin-2-ylethanethiol exerts a strong influence on the flocculation of gold nanoparticles, giving rise to contrasting SERS effects.

## Heterodimetallic Bisporphyrins

**F.-L. Jiang, W.-K. Wong,* X.-J. Zhu, G.-J. Zhou, W.-Y. Wong, P.-L. Wu, H.-L. Tam, K.-W. Cheah, C. Ye, Y. Liu* ..... 3365–3374**

Synthesis, Characterization, and Photophysical Properties of Some Heterodimetallic Bisporphyrins of Ytterbium and Transition Metals – Enhancement and Lifetime Extension of $Yb^{3+}$ Emission by Transition-Metal Porphyrin Sensitization

**Keywords:** Lanthanides / Optical limiting / Photoluminescence / Porphyrins / Transition metals



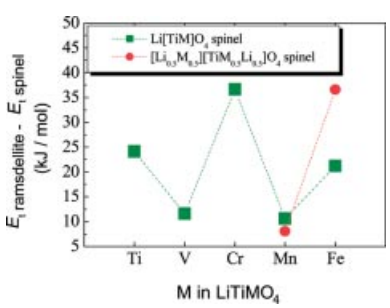
A series of heterodimetallic bisporphyrins of ytterbium and transition metals (**YbZn**, **YbPd**, and **YbPt**) have been synthesized and fully characterized. Their near-infrared photophysical studies show that the transition-metal porphyrinate unit enhances the $Yb^{III}$ emission and the $Yb^{III}$ lifetimes of **YbPd** and **YbPt** are extended because of sensitization of the $^3$Pd(TPP)* and $^3$Pt(TPP)* cores, respectively. The two-photon absorption and optical limiting properties of these mixed-metal complexes have also been investigated.

## Ramsdellites for Lithium Batteries

**A. Kuhn, P. Díaz-Carrasco, M. E. Arroyo y de Dompablo,* F. García-Alvarado* ..... 3375–3384**

On the Synthesis of Ramsdellite $LiTiMO_4$ (M = Ti, V, Cr, Mn, Fe): An Experimental and Computational Study of the Spinel–Ramsdellite Transformation

**Keywords:** Titanates / Phase transitions / Ab initio calculations / Solid-state reactions / Electrochemistry



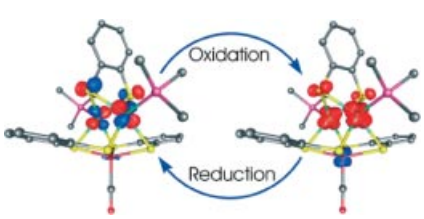
The $LiTiMO_4$ (spinel) ↔ $LiTiMO_4$ (ramsdellite) transformation is investigated by a combination of computational and experimental techniques for M = Ti, V, Cr, Mn, and Fe in order to understand the characteristics of this transformation.

## [NiFe] Hydrogenase Model Complex

**F. Lauderbach, R. Prakash,* A. W. Götz,* M. Munoz, F. W. Heinemann, U. Nickel, B. A. Hess, D. Sellmann ..... 3385–3393**

Alternative Synthesis, Density Functional Calculations and Proton Reactivity Study of a Trinuclear [NiFe] Hydrogenase Model Compound

**Keywords:** Constant potential coulometry / Density functional calculations / Iron / Nickel / NiFe hydrogenases / S ligands

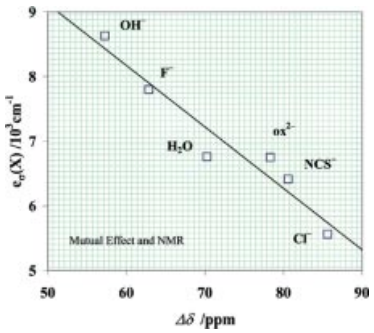


Reversible oxidation of a trinuclear [NiFe] hydrogenase model compound (see picture) can be employed electrochemically for the reduction of protons to dihydrogen at a mild reduction potential. Density functional theory calculations give an insight into the redox process. The trinuclear compound can be synthesized from simple metal salts without use of any precursor complexes.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

## Ligand Effects

The effect of the co-ligand (X) on the $^2H$ NMR chemical shift difference ($\Delta\delta$) for *trans*-$[CrX_2([D_4]3,2,3\text{-tet})]^{n+}$ and *cis*-α-$[CrX_2([D_4]trien)]^{n+}$ is found to correlate well with the reported $e_\sigma(X)$ values of these co-ligands, thereby demonstrating the first example of the co-ligand effect or a mutual influence of ligands associated with variation of the Cr−N and Cr−X bonds in *cis*- and *trans*-$[CrX_2N_4]$-type complexes.



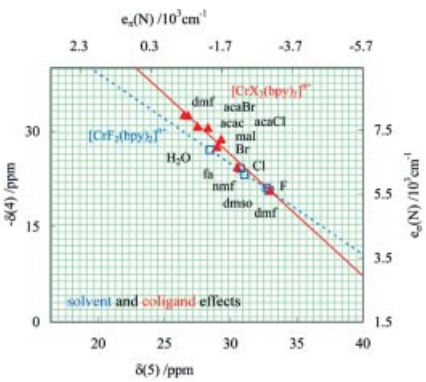
**Y. Yamaguchi-Terasaki, T. Fujihara, S. Kaizaki* ..... 3394−3399**

Mutual Influences of Ligands as Revealed by $^2H$ NMR Shifts and the Angular Overlap Model Parameters: *trans*- and *cis*-$[CrX_2(N)_4]$-Type Complexes with Aliphatic Amine Ligands

**Keywords:** Chromium complexes / Ligand effects / N ligands / NMR spectroscopy / Angular overlap model parameters

## Ligand Effects

The dependence of the $^2H$ NMR shifts of *cis*-$[CrX_2([D_4]bpy)_2]^{n+}$ and *fac*-$[CrX_3([D_{12}]tpa)]^{n+}$ on the co-ligands X allows the ordering of the AOM parameter for monodentate and/or didentate ligands, from which the ranking of the two-dimensional spectrochemical series for $Cl^-$ and $Br^-$ is found to differ from that in the aliphatic amine complexes. This change is explained in terms of the hard/soft acid/base (HSAB) concept.



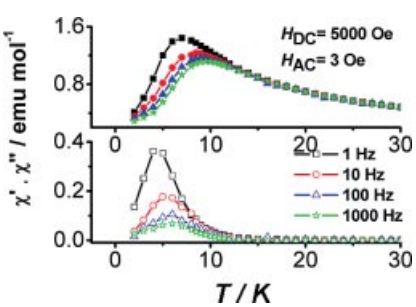
**Y. Terasaki, T. Fujihara, S. Kaizaki* ..... 3400−3404**

Mutual Influences of Ligands as Revealed by the $^2H$ NMR Chemical Shifts and the Angular Overlap Model Parameters: *cis*-$[CrX_2(N)_4]$ and *fac*-$[CrX_3(N)_3]$-Type Complexes with Aromatic Amines

**Keywords:** Chromium complexes / Ligand effects / N ligands / NMR spectroscopy / Angular overlap model parameters

## Molecular Magnetism

A new lanthanide citrate $[Dy(citrate)(H_2O)]_n$ (**1**) was hydrothermally synthesized and structurally characterized. The structure of **1** exhibits a 2D layer structure. The photoluminescence spectrum shows blue luminescence in the solid state at room temperature. Owing to the special frustration structure, unusual magnetic relaxation was found in compound **1**.



**F.-Y. Li, L. Xu,* G.-G. Gao, L.-H. Fan, B. Bi ..... 3405−3409**

Unusual Magnetic Behavior of a 2D Citrate-Bridged Dysprosium(III) Coordination Polymer

**Keywords:** Lanthanides / Coordination chemistry / Magnetic properties / Hydrothermal synthesis

## Lanthanide−Organic Frameworks

Three novel LnOFs $[Ln(pza)(OH)(H_2O)]_n$ (Ln = Y, Er and Yb) with helical chains and 2D $(4^3)_2(4^6,6^6,8^3)$ topology were obtained by hydrothermal synthesis. The upconversion properties resulting from two-photon excitation of Y: Er, Yb codoped coordination polymer and the magnetic properties of the Er and Yb complexes are investigated.

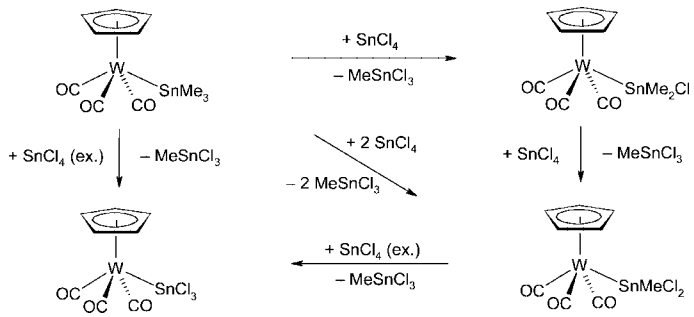
## Organotin Complexes

**H. Braunschweig,* H. Bera, B. Geibel, R. Dörfler, D. Götz, F. Seeler, T. Kupfer, K. Radacki ..... 3416–3424**

Synthesis of Half-Sandwich Tungsten Chlorogermyl and Chlorostannyl Complexes

**Keywords:** Half-sandwich complexes / Tungsten complexes / Germanes / Stannanes / Stannylcyclopentadienes



A chlorination system is established, which enables a controlled and successive chlorination of a trimethylstannyl tungsten complex to the trichlorostannyl derivative via the isolable mono- and double-chlorinated compounds by use of $SnCl_4$. In addition, we proved that alkali salt elimination has to be regarded as a straightforward route to synthesize a range of diorgano chlorogermyl and chlorostannyl tungsten complexes of the general formula $[(\eta^5\text{-}C_5R'_5)L(OC)_2W(ER_2Cl)]$ (R′ = H, Me; L = CO, $PPh_3$; E = Ge, Sn; R = Me, Bu).

## Nitrosyl Complexes

**S. Maji, C. Chatterjee, S. M. Mobin, G. K. Lahiri* ..... 3425–3434**

Synthesis and Spectro-electrochemical Aspects of $[Ru^{II}(trpy)(pdt)(X)]^{n+}$ (trpy = 2,2′:6′,2″-Terpyridine, pdt = 5,6-Diphenyl-3-pyridyl-*as*-triazine, X = $Cl^-$, $CH_3CN$, $NO_2^-$, $NO^+$, $NO^{\cdot}$) – Electrophilicity of $\{Ru^{II}\text{–}NO^+\}$ and Photolability of $\{Ru^{II}\text{–}NO^{\cdot}\}$

**Keywords:** Ruthenium / Nitrosyl complex / Spectroscopy / Electrochemistry / Reactivity

Moderately electrophilic nitrosyl ($\nu NO^+$ = 1944 $cm^{-1}$) in $\mathbf{4}^{3+}$ transforms to the corresponding nitro species in $CH_3CN$ under alkaline conditions with a pseudo-first-order rate constant ($k$/s) of $4.13 \times 10^{-4}$ at 298 K and on exposure of light $\mathbf{4}^{2+}$ undergoes slow photocleavage of the $Ru^{II}\text{–}NO\cdot$ bond in $CH_3CN$ with a $k_{NO}$ of $4.4 \times 10^{-3}$ $min^{-1}$ ($t_{1/2} \approx 157$ min).

# Calixarene-Based Oxovanadium Complexes as Molecular Models for Catalytically Active Surface Species and Homogeneous Catalysts

**Christian Limberg*[a]**

**Keywords:** Vanadium / Oxo complexes / Models / Calixarenes / Catalysis

There are several reasons that make the combination of calixarenes with oxovanadium moieties attractive. Calixarenes are capable of simulating the surfaces of oxide bulk materials and supports, and on the other hand, supported vanadium oxides are an important class of heterogeneous catalysts, whose reactivity is still discussed controversially with respect to the effective mechanisms. Oxovanadium calixarene complexes can thus represent molecular models whose investigation in the homogeneous phase can shed some light into surface processes. This review describes the recent achievements in the synthesis of oxovanadium calixarene, thiacalixarene, and oxacalixarene complexes and the investigation of their reactivity. It has been shown that they represent active catalysts for the oxidation of alcohols and the polymerization/copolymerization of olefins.

(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## 1. Introduction

Heterogeneous catalysts play an important role in the chemical and pharmaceutical industry where 90% of all compounds produced require at least one *catalytic* step during their synthesis.[1] While in comparison to homogeneous catalysts the employment of heterogeneous catalysts has certain advantages with respect to product separation, stability (for instance at higher temperatures), and technical issues,[1] the unequivocal identification of their surface constitution and active sites poses problems. These properties are best studied by a combination of physical and chemical methods such as IR, Raman, Mössbauer, and solid-state NMR spectroscopy as well as EXAFS, XANES, and XPS.[2] However, these techniques involve bulk measurements, and their sensitivity is often inadequate for obtaining accurate data from the various sites that are present on the surface in low concentration.[3] Furthermore, even if the active sites are known, the clarification of mechanistic questions is far more difficult for heterogeneous catalysts than for homogeneous catalysts, as in situ studies on surfaces under catalytic conditions require methods far from routine. Naturally, the results of such investigations as well as hypotheses derived from kinetic investigations and isotopic enrichment studies provide a stimulus for the synthesis of molecular models: these can be investigated in the homogeneous phase and may serve to support or defeat mechanistic proposals, thus offering hope that heterogeneous catalysts can be designed rationally. In addition, such models can in turn prove themselves as novel homogeneous catalysts, independently of the heterogeneous process that led to their synthesis.

One important class of heterogeneous catalysts consists of metal oxides on inert supports which are employed, for instance, to mediate oxidations with $O_2$ as well as other processes like polymerizations.[4] The construction of molecular models for oxometal (the terms "oxo" and "chloro" are used as ligand names throughout this Microreview as in the original articles) surface sites requires ligands that are capable of mimicking the oxide environments surrounding oxometal moieties on oxide supports or in bulk materials,

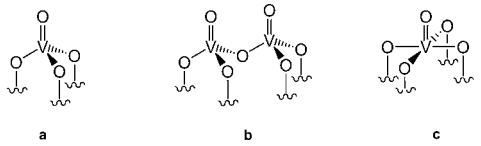
*Christian Limberg was born in 1965 in Essen and studied chemistry from 1985 to 1990 in Bochum. He earned his doctorate with Professor A. Haas in 1992 and concluded his postdoctoral work together with Professor A. J. Downs at Oxford University with a further Ph. D. thesis and Inauguration (D. Phil.). In 1995 he then joined the research group of Professor G. Huttner in Heidelberg to start his Habilitation work, which was finished in 1999. Having received a Heisenberg scholarship, he stayed in Heidelberg until 2001, when he moved to the TU Munich to lead the Inorganic Chemistry chair on behalf of Professor Herrmann. In 2002 he accepted an offer to become full professor at the Humboldt-University of Berlin, where he is currently Dean of the Faculty I for Mathematics and Natural Sciences. The author of this contribution is mainly concerned with oxometal complexes and their reactivity under synthetic and mechanistic viewpoints. He received the ADUC prize for Habilitanden and was further awarded a Karl-Winnacker-Stipendium, the academy prize of the Academy of Science in Göttingen, as well as the Carl-Duisberg-Gedächtnispreis of the GDCh.*

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

and in this context in particular, two ligand systems have established themselves: silsesquioxanes[3,5a–5d] and calixarenes.[5e,5f] This review focuses on the most recent research concerning oxovanadium calixarene complexes that were synthesized in order to model supported vanadium catalysts, finding applications for instance in the oxidative dehydrogenation (ODH)[6] of light alkanes and methanol. Various surface species have been found to be active during the heterogeneous processes in one way or the other, and hence these structural motifs represent an inspiration for attempts to mimic them in molecular compounds.



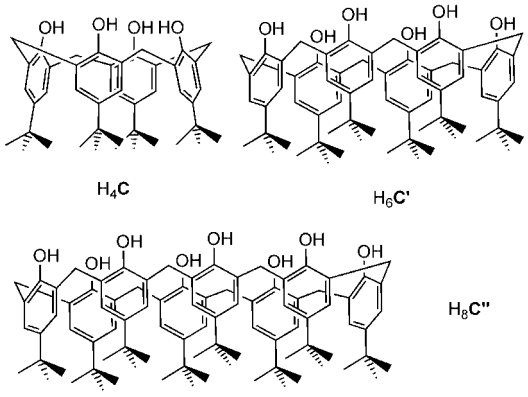
On the other hand, silica-supported vanadium materials have proved to be efficient as heterogeneous catalysts for olefin polymerization,[7a–7d] and oxovanadium complexes with multipodal ligands were shown to catalyze such polymerizations homogeneously.[7e] It follows that oxovanadium calixarene complexes were also investigated in this respect.

The results of studies on both aspects are discussed below.

## 2. Synthesis of Oxovanadium Calixarene Complexes and Their Properties

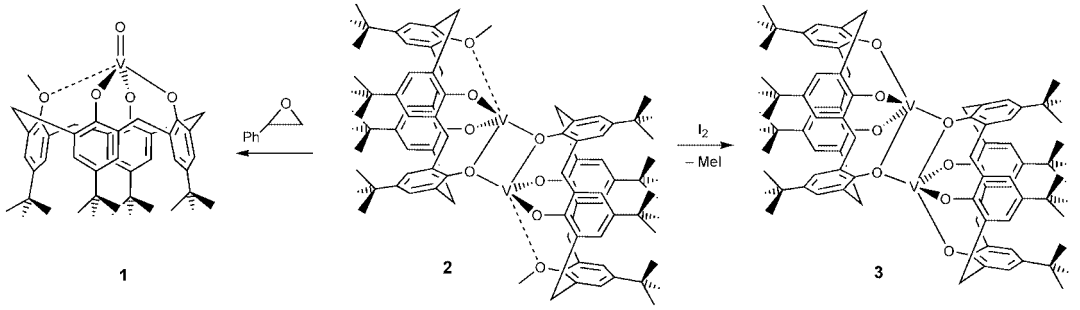
### 2.1. Complexes with "Classical" Calixarene Ligands

In addition to silsesquioxane ligands, calixarene ligands such as $H_4$**C**, $H_6$**C**′, and $H_8$**C**′′ have recommended themselves for the simulation of oxide surfaces in recent years.[5e,5f] While $H_4$**C** yields a tetrapodal ligand after deprotonation, $H_3$**C**$^{\mathbf{R}}$ (a derivative of $H_4$**C** where one of the phenolic protons is replaced by an alkyl group R) leads to a tripodal ligand. Employing $H_4$**C** and $H_3$**C**$^{\mathbf{R}}$ thus enables modelling the embedding of a transition metal ion in the midst of three and four oxygen atoms of an oxide surface (for instance a support), respectively. On the other hand, ligands like [**C**′]$^{6-}$ or a calix[8]arene with eight phenolate units ([**C**′′]$^{8-}$) provide more extended platforms of oxygen atoms, where polynuclear moieties can arrange themselves, too.



Until recently, oxovanadium complexes of calix[4]arenes (**C**$^{4-}$) were not known, and the literature on the coordination of oxovanadium units by other calixarene-based ligands was scarce, too: one complex with a ligand derived from $H_4$**C** by monomethylation of a phenolic function, **C**$^{\mathbf{Me}}$**V**$^{\mathbf{V}}$=O (**1**), (see Scheme 1) had been reported[8] as well as a few others containing calix[3]-, calix[6]-, and calix[8]arene ligands, which, however, were either not characterized structurally or contained vanadium centers that were not exclusively ligated by O donor atoms.[9,8]

Whereas these examples all involve $V^V$, naturally, there is also interest in reduced complexes that could model reduced species formed after oxidation reactions on surfaces, and in this context $V^{IV}$ and $V^{III}$ are important. The chemistry of a vanadium(III) center complexed by calix[4]arene has been investigated by C. Floriani et al.[8] Metalation of $H_3$**C**$^{\mathbf{Me}}$ with [$VMes_3$·thf] led to the collapse of the coordinatively unsaturated $V^{III}$-$d^2$ fragment **C**$^{\mathbf{Me}}$**V**$^{\mathbf{III}}$ to the dimer [{μ-**C**$^{\mathbf{Me}}$}V]$_2$ (**2**). In addition to reactions with *t*BuNC, PhCN, pyridine, and 4,4′-bipyridine, the one-electron oxidation with $I_2$, which led to the $V^{IV}$ complex [{μ-**C**}V]$_2$ (**3**), was investigated. A two-electron oxidation of the $V^{III}$-$d^2$ system to the oxovanadium(V) derivative **C**$^{\mathbf{Me}}$**V**$^{\mathbf{V}}$=O (**1**), has been achieved by using styrene oxide. Very recently, Redshaw et al.[10] published synthetic methods that lead to a complex **3**$^{\mathbf{AN}}$, which is closely related to **3**: **3**$^{\mathbf{AN}}$ differs from **3** (Scheme 1) in that it additionally contains two metal-bound acetonitrile molecules within the two calyx cavities, which results in pseudo-octahedral coordination spheres for the vanadium atoms, and it can be obtained by starting from $H_4$**C** upon treatment with [V(N*p*-tolyl)-



Scheme 1.

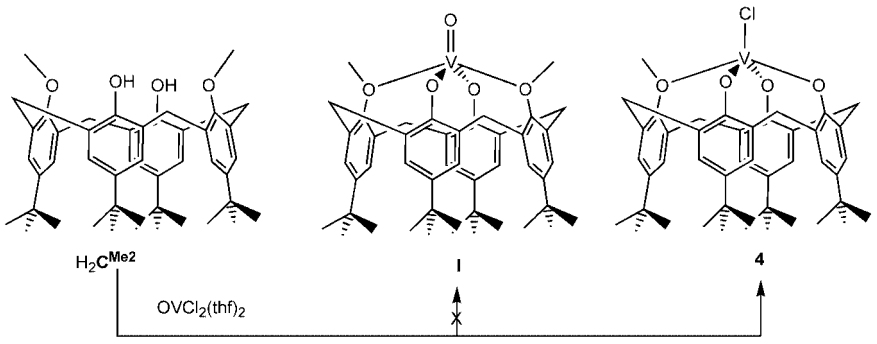


Scheme 2.

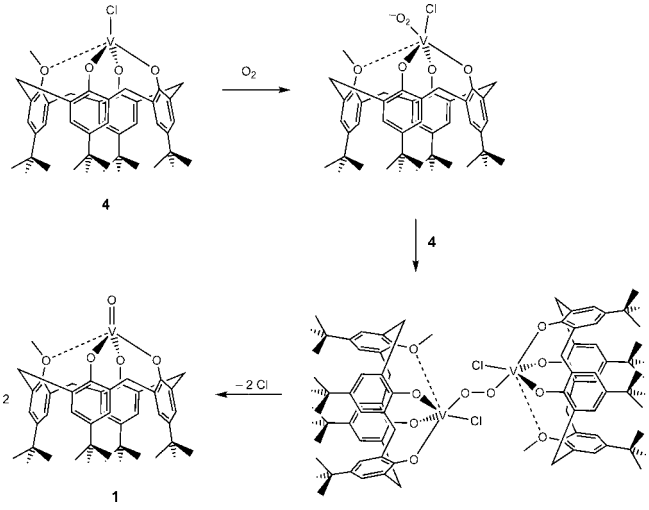
($O$*n*Pr)$_3$] or [$VCl_3$(thf)$_3$] followed by recrystallization from acetonitrile. Moreover, it was found that **1** is also accessible by the use of $H_3\mathbf{C}^{\mathbf{Me}}$ and [VO($O$*n*Pr)$_3$].[10]

We set out to investigate the chemistry of $V^{IV}$ on an oxo surface modeled by calixarene ligands in order to study possible reoxidation reactions. Accordingly, we treated [$VOCl_2$(thf)$_2$] with dimethylated $H_4\mathbf{C}$ and $H_2\mathbf{C}^{\mathbf{Me2}}$, in order to synthesize a complex **I** as depicted in Scheme 2. A pure product was obtained in good yield, whose characterization, however, showed that the expected complex **I** had not been formed, but a compound that had been previously suggested by Floriani et al.[11] as the product of the reaction between the complex $\mathbf{C}^{\mathbf{Me2}}\mathbf{V}^{\mathbf{III}}$-Cl and iodine on the basis of an elemental analysis and decomposition studies: $\mathbf{C}^{\mathbf{Me}}\mathbf{V}^{\mathbf{IV}}$-Cl (**4**).[12] The preparation of **4** by the route shown in Scheme 2 allowed its full characterization, and its crystal structure could be determined, too (very recently it has also been identified as the product of the reaction between $H_3\mathbf{C}^{\mathbf{Me}}$ and [RN=$VCl_3$]).[13] Compound **4** was found to be sensitive to both water and $O_2$.

Hydrolysis leads to $H_3\mathbf{C}^{\mathbf{Me}}$ as well as unidentified oxovanadium halides. The reaction with oxygen astonishingly leads to **1**, which crystallizes isotypically with **4**, so that both compounds can be present side by side (cocrystallized) within the same crystal. Naturally, the question arose as to how **1** is formed from **4** and dioxygen. Most likely, the initiating step consists of an end-on addition of $O_2$ to the Lewis acidic $V^{IV}$ center to form a $V^{IV}Cl(\eta^1\text{-}O{=}O)$ unit. Subsequently, an electron can be expected to flow from the vanadium center to the oxygen ligand so that a vanadium(V)superoxide moiety is produced (Scheme 3).

The next step should represent a reaction with a second molecule of **4** to give a peroxide unit. To generate **1**, the O–O bond then has to be cleaved homolytically, but since the V centers are already in their highest oxidation states, a V=O bond can only form if an additional electron is provided, and at the same time the chloride ligands have to leave the molecule. How these subsequent steps proceed remains unclear; they result in chloride and organic decomposition products. This type of reactivity is not restricted to **4**: replacement of chloride by triphenylsiloxide followed by exposure to $O_2$ leads to the same results.[12]

We next turned our attention to the synthesis and reactivity of oxovanadium(V) complexes. Would a complex like



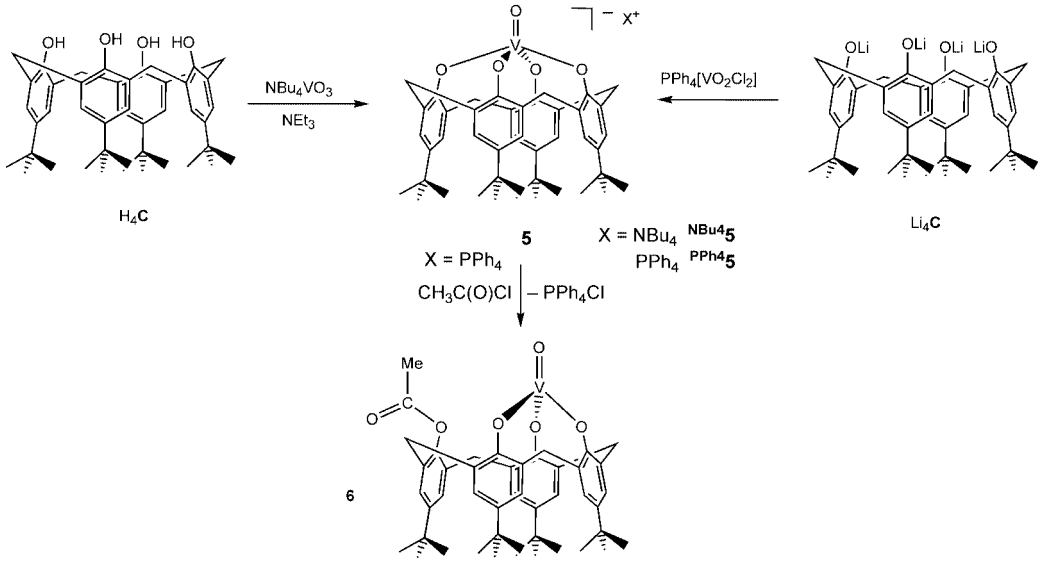
Scheme 3.

**1** behave as a functional model for oxovanadium sites on surfaces, that is, would it show any oxidation chemistry? How would an additional charge alter the situation, and would polynuclear species behave differently? In order to address these questions, systematic studies on the preparation of calixarene oxovanadium complexes with varying nuclearity and charge were performed. This was followed by an investigation of their reactivity and potential as structural or functional models for active sites on surfaces.[14,15]

In order to obtain a complex containing an $O{=}V^{3+}$ unit embedded in a tetragonal oxo coordination environment, tetrabutylammonium metavanadate was treated with $H_4\mathbf{C}$ in the presence of $NEt_3$, and indeed the envisioned complex, $NBu_4[\mathbf{C}V{=}O]$ ($^{\mathbf{NBu4}}\mathbf{5}$) (Scheme 4) formed in good yields.[14] Alternatively, the complex anion **5** can be synthesized starting from the lithium salt $Li_4\mathbf{C}$ that can be obtained by treatment of $H_4\mathbf{C}$ with lithium naphthalenide: The corresponding reaction with tetraphenylphosphonium dichlorodioxovanadate $PPh_4[VO_2Cl_2]$ leads to the elimination of LiCl (and apparently also $Li_2O$), yielding $PPh_4[\mathbf{C}V{=}O]$ ($^{\mathbf{PPh4}}\mathbf{5}$) (Scheme 4).[14]

According to a crystal structure analysis, the V=O group in **5** is surrounded symmetrically by an $O_4$ donor set as expected, and **5** therefore represents the first model for such a situation on an oxide support.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



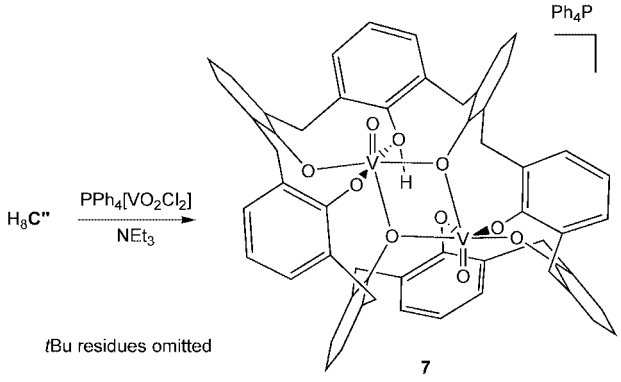
Scheme 4.

For comparative reactivity studies it seemed desirable to also investigate a neutral calixarene oxovanadium(V) complex. As mentioned, there is one complex known, **1**, which, however, is difficult to isolate in larger quantities and in a pure state free from $V^{IV}$ impurities by the reactions shown in Scheme 1 and Scheme 3. Hence, we contemplated the synthesis of a more easily accessible derivative. Indeed, starting from $^{PPh4}$**5** such a neutral complex can be obtained in a clean and facile synthesis: addition of $CH_3C(O)Cl$ leads to the precipitation of $PPh_4Cl$ and formation of $\mathbf{C}^{OAc}V^{V}$=O (**6**) (see Scheme 4).[14]

Whereas the coordination geometry around V in **1** – due to the fact that the methoxy group binds at a longer distance to V, too (compare Scheme 1) – has to be described most appropriately as distorted trigonal bipyramidal, the vanadium center in **6** is coordinated tetrahedrally; there is no interaction with the O atom of the acetyl unit, and **6** can thus be regarded as a model for a species **a**.

We next turned our attention to the synthesis of compounds containing two oxovanadium units to also allow a comparison of the reactivities of dinuclear and mononuclear complexes. Accordingly, higher calixarenes were employed as starting materials, as these offer room for more than one vanadium center. First of all, $H_8$**C**′′ was chosen to be treated with $PPh_4[VO_2Cl_2]$ in the presence of $Et_3N$ as a base. The resulting product was fully characterized, and a single-crystal X-ray analysis revealed the structure (Scheme 5) and constitution of $PPh_4[HC''V_2O_2]$ (**7**).[14]

It turned out that a salt containing the anion of **7** in combination with a different cation had been reported before by Pedersen and co-workers[16] as the product of the conversion of $VO(OiPr)_3$ with $H_8$**C**′′ in the presence of (*R*)-(+)-1-(1-naphthyl)ethylamine. A single-crystal X-ray diffraction study had not been performed, but the constitution was suggested correctly on the basis of a structure determination for a similar titanium complex. The formation of **7** must have proceeded by reaction of OH functions with V–



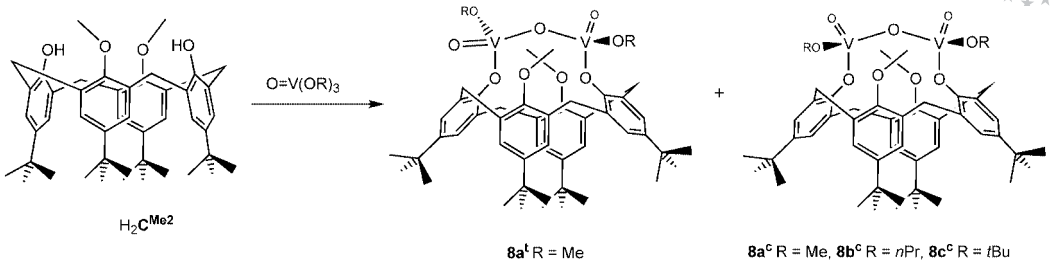
Scheme 5.

Cl and V=O groups under elimination of HCl and water, so that two – at first independent – $O=V^{3+}$ units are initially coordinated by four aryloxo ligands each, as in **5**. However, two facts prohibit a description of **7** as a dinuclear version of **5**: First of all, one of the phenol functions in $H_8$**C**′′ is *not* deprotonated (i.e. a coordinated alcohol function results), so that **7** contains only a monoanion, and secondly, the arene band folds in a way that allows two of the phenoxy functions to adopt a bridging binding mode, such that the two vanadium atoms are located in pseudo-octahedral environments.

Having accessed a dinuclear, singly charged oxovanadium complex, we also pursued the synthesis of a corresponding neutral complex, ideally containing V–O–V units. Heating a mixture of $H_2\mathbf{C}^{Me2}$ with $[VO(OCH_3)_3]$ in acetonitrile solution at reflux led to such a compound, [$\mathbf{C}^{Me2}$-[O=V(OMe)]$_2$μ-O] (**8a**), which also represents the first dinuclear calix[4]arene complex in general (see Scheme 6).[14]

The two phenoxy functions in $\mathbf{C}^{Me2}$ bind two V=O units that are connected by a bridging oxo ligand. The residual coordination sphere is completed for each V center by

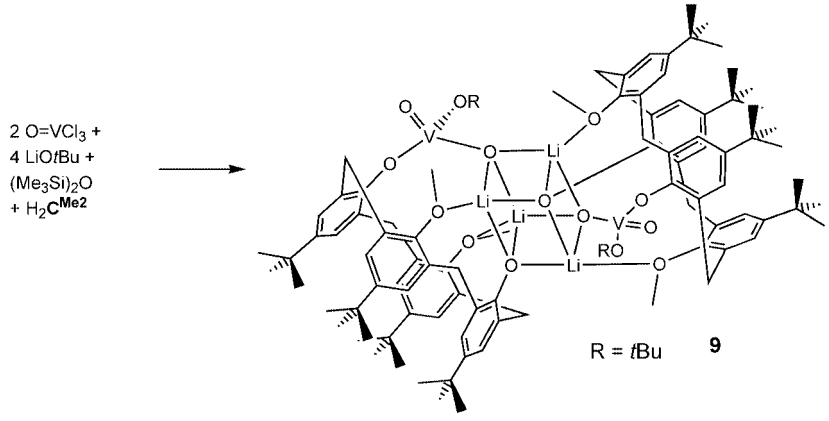
 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 



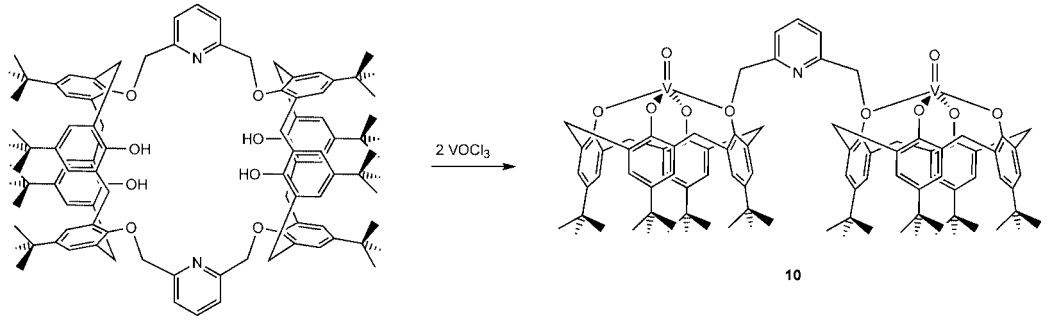
Scheme 6.

methoxy ligands, which can either be located *cis* or *trans* to each other (a mixture of isomers is obtained), i.e. the geometries around the V atoms can be assigned as tetrahedral. At the same time and independently, Redshaw and co-workers reported the analogous syntheses of the corresponding *n*-propyl and *tert*-butyl derivatives **8b**$^{c}$ and **8c**$^{c}$.[10] The origin of the μ-O bridge is still unclear. Whereas in alkoxide chemistry there is sufficient precedence for the formation of oxo ligands by ether elimination, Redshaw and co-workers contemplated a fortuitous hydrolysis reaction of the vanadyl esters prior to the reaction with $H_2C^{Me2}$. Envisioning that a more rational route might involve the initial formation of a chloro alkoxide complex of the form $[VOCl(OtBu)_2]$ to which an oxo bridge could be introduced by reaction with $(Me_3Si)_2O$ before the addition to $H_2C^{Me2}$, a corresponding investigation was carried out: After reaction of $[VOCl_3]$ with a twofold excess of LiO*t*Bu, first $(Me_3Si)_2O$ and then $H_2C^{Me2}$ were added to the resulting mixture in order to obtain **8c**$^{c}$. However, $[\{C^{Me2}V(OtBu)(O)\}_2Li_4O_4]$ (**9**) was isolated instead, where a $Li_4O_4$ cubane-type core is trapped between two oxovanadium calix[4]arene units (Scheme 7).[10]

With the aim of preparing a different type of dinuclear oxovanadium calix[4]arene complex, a special type of ligand was employed where two calix[4]arene units are linked by two lutidene moieties. Reaction with $[VOCl_3]$ in refluxing toluene led to the loss of one of these linkers and to the formation of the bimetallic complex **10** (Scheme 8). As in the mononuclear "version" **1**, each vanadium atom here adopts a trigonal bipyramidal geometry, for which both vanadyl groups are oriented in the same direction with respect to the lutidene bridge.[10]



Scheme 7.



Scheme 8.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

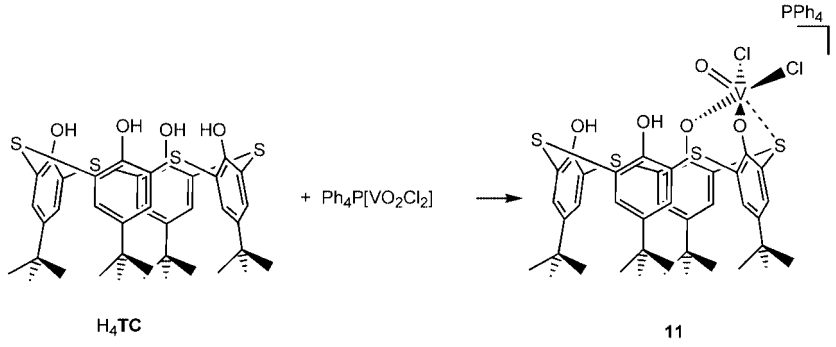
### 2.2. Complexes with Thiacalixarene Ligands

Compared with that of the related *p-tert*-butylcalix[4]-arene, the chemistry of thiacalixarenes is still in its infancy, as the synthesis of thiacalixarenes and their sulfinyl and sulfonyl derivatives has been known only since the late 1990's.[17] Recent publications provide evidence that the thioether units can take part in metal ion coordination, which leads to a stronger interaction with transition metals relative to calixarenes.[18] As such interactions can be anticipated to lead to significant chemical differences, it seemed interesting to also prepare oxovanadium thiacalix[4]arene complexes in order to compare their reactivities with those of the corresponding complexes based on the "classical" calixarenes. First, a reaction of *p-tert*-butyltetrathiacalix[4]-arene ($H_4$**TC**) with $Ph_4P[VO_2Cl_2]$ was carried out in the absence of an external base; this led to $PPh_4[(H_2$**TC**$)VOCl_2]$ (**11**), as demonstrated by single-crystal X-ray crystallography, elemental analysis, and IR and NMR spectroscopy (Scheme 9).[15]

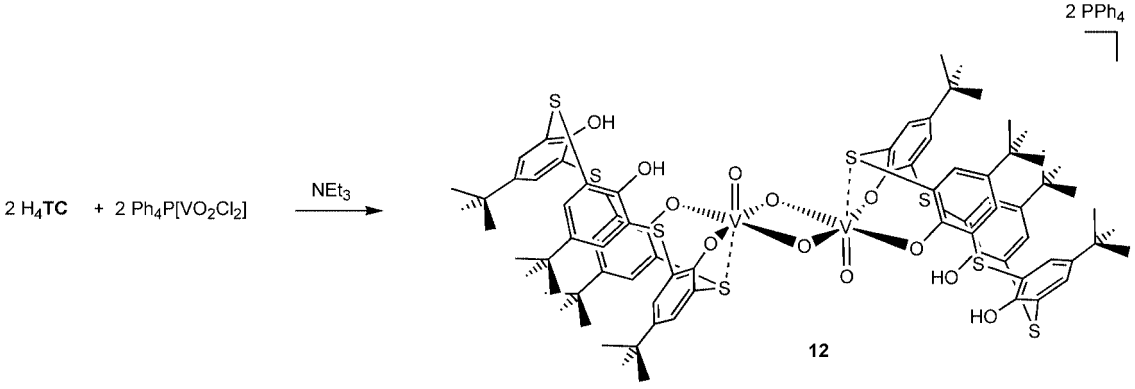
In **11** a vanadyl unit is positioned somewhat above the plane defined by the O atoms belonging to the two calixarene phenolate functions and the two terminal chloride ligands. The coordination sphere of V is completed by one of the thioether functions belonging to the ligand: The distance to the closest S atom is significantly shorter than the sum of the van der Waals radii of vanadium and sulfur, indicating a coordinative interaction.

The formation of **11** must have proceeded by addition of two OH functions to one of the V=O groups belonging to the starting material with elimination of water. Accordingly, in the absence of an external base, the protons of $H_4$**TC** are acidic enough to attack one of the nucleophilic oxygen atoms of $[VO_2Cl_2]^-$, as in the case of the "normal" calixarenes. However, they are not acidic enough to further induce intramolecular HCl elimination: the anion of **11** formally still contains two equivalents of HCl, whose elimination would lead to the thia analog of **5**. The fact that such a complex is not formed spontaneously may to some extent be a result of the coordinative support of the sulfur atom at the vanadium center. On the other hand, the formation of **5** – as mentioned before – required the addition of a base at least as strong as $NEt_3$. Therefore, the reaction in Scheme 9 was repeated in the presence of $NEt_3$, which led to the precipitation of a red solid. After purification and crystallization, this solid was identified as $(PPh_4)_2$-$[H_2$**TC**$V(O)(\mu\text{-}O)]_2$ (**12**) with the aid of X-ray crystal structure determination, elemental analysis, and IR and NMR spectroscopy (Scheme 10).[15]

In the molecular structure of the anion of **12**, two O=V groups are linked by two bridging oxo ligands in a way that positions the terminal O ligands in an *anti* fashion, and a noncrystallographic mirror plane runs through them. Furthermore, each vanadium center coordinates a calixarene ligand in a cone conformation through two phenolate



Scheme 9.



Scheme 10.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

functions and again also through interaction with a thioether function.

### 2.3. Complexes with Oxacalixarene Ligands

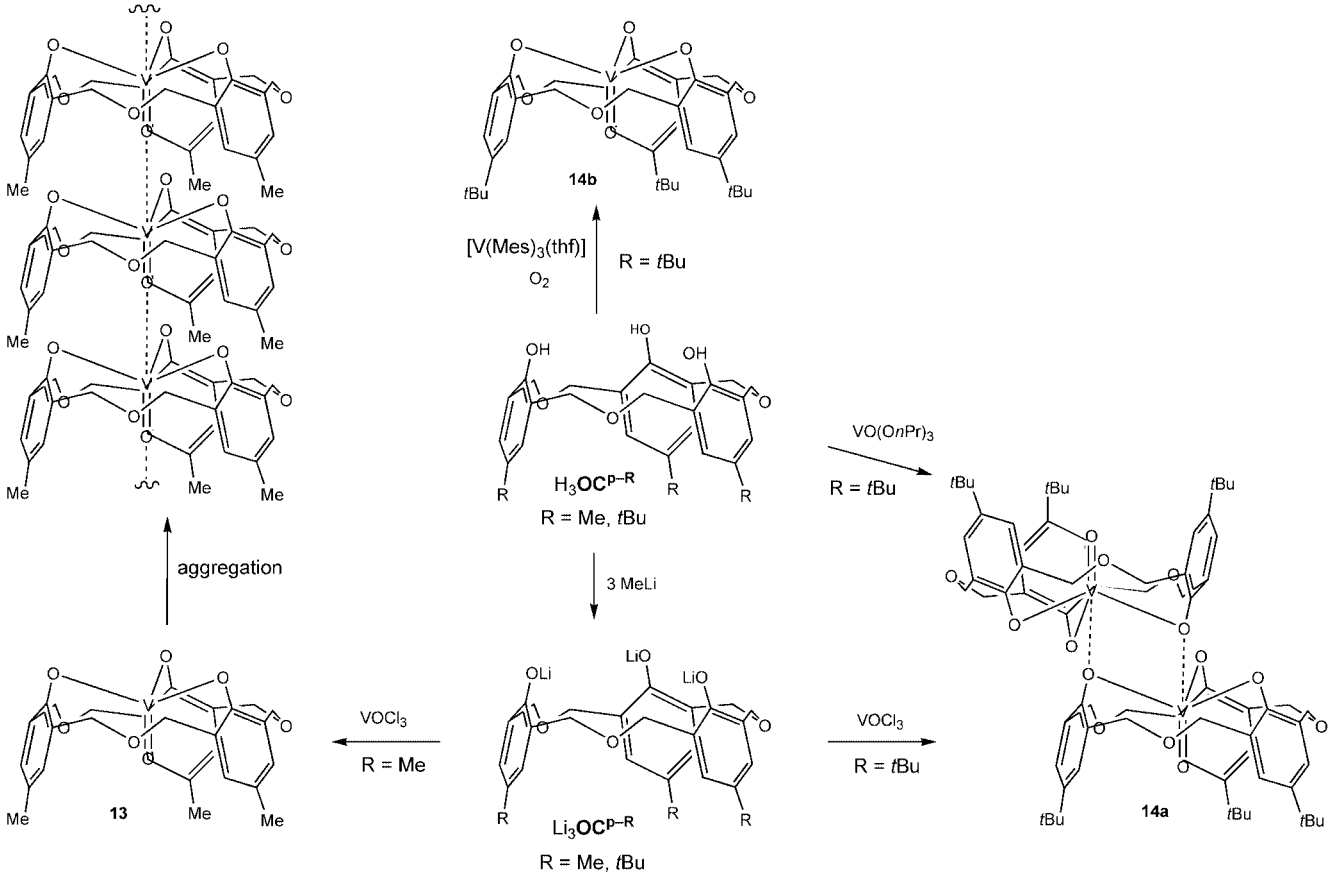
In 1997, Hampton et al. treated lithiated *p*-methylhexahomotrioxacalix[3]arene, $H_3OC^{p\text{-}Me}$, with [$VOCl_3$], in order to prepare linear chain polymers, and obtained a compound of the expected stoichiometry, [$OC^{p\text{-}Me}V{=}O$] (**13**).[9b] On the basis of spectroscopic data obtained for solutions of **13**, a structure in which the vanadyl group is positioned within the calyx (Scheme 11) was proposed, even though the corresponding "oxo-out" structure could not be ruled out. A fibrous solid precipitated from such solutions after several days, and the spectroscopic data obtained for this solid indicated that an asymmetric μ-oxo-bridged linear chain polymer had formed. Unfortunately, single crystals suitable for an X-ray diffraction study could not be grown for any of the forms of **13**.

Recently, the *p-tert*-butyl derivative of **13** was prepared by treating the corresponding calix[3]arene $H_3OC^{p\text{-}Bu}$ with [$VO(OnPr)_3$] or by treating $Li_3OC^{p\text{-}Bu}$ with [$VOCl_3$].[10] A single-crystal X-ray analysis showed that the resulting complex **14a** (Scheme 11) is monomeric with a trigonal pyramidal coordination of the vanadium atom. In the solid state, there are only very weak intermolecular interactions between the vanadium center of one molecule and a phenoxy function of another molecule. This gives rise to a pair of molecules that lie face to face over an inversion center, which contrasts the identification of a polymeric structure for **13**. Interestingly, the reaction of [$VMes_3$·thf] with $H_3OC^{p\text{-}Bu}$ followed by treatment with $O_2$ provided a complex that could be identified as a discretely monomeric molecule **14b** by means of X-ray diffraction after crystallization of the compound.[10]

## 3. Catalytic Activity

### 3.1. Evaluation of the Potential of the Compounds as Functional Models for ODH

As outlined in the introduction, the most prominent conversions that can be carried out by using vanadia on oxide supports as heterogeneous catalysts are the ODH of methanol and alkanes. Naturally, molecular models such as those described here will prove to be unreactive in contact with alkanes, as the rate-determining step of ODH is the first C–H bond cleavage, which has a large activation barrier (which means that heterogeneous catalysis at elevated temperatures is required for the reaction to take place). However, methanol and higher alcohols are less inert as substrates, so that their reactions can also be investigated with molecular compounds in the liquid phase. Any information derived from such studies might contribute to a



Scheme 11.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

more comprehensive understanding of methanol oxidation at vanadia catalysts, and they might as well provide ideas for the (probably) more complex ODH of alkanes.

In order to test the compounds described above for reactivity in relation to ODH and to establish their suitability as models, we therefore decided to investigate the oxidation of a palette of various alcohols to the corresponding carbonyl compounds with $O_2$ as the reagent.[14,15] Of course there are numerous methods to oxidize alcohols with organic or inorganic reagents,[19] which, however, are often stoichiometric and/or lead to toxic waste products. Hence, at present, the performance of catalytic oxidations with $O_2$ is still an attractive topic, and a lot of research has been devoted to it in the past.[19] Certainly, the background of the study presented here – as mentioned – was an inquiry as to whether oxovanadium calixarene and thiacalixarene complexes could represent not only structural but also functional models for the heterogeneously catalyzed ODH, and we did not have the aim of finding an improved catalyst for the aerobic oxidation of alcohols. Nevertheless, the latter aspect was borne in mind as a potential, beneficial part of the investigation.

As we consider the $V^V$ compounds **5**–**8**, **11**, and **12** as functional models, they are expected to contain functional moieties already, i.e. the first step of a possible catalytic cycle should consist of a reaction with the chosen alcohol (vide infra). After a potential oxidation reaction, $O_2$ could serve to regenerate the active species. As a reference, a system was chosen that has been recently shown to efficiently catalyze the aerobic oxidation of 1-phenyl-1-propargyl alcohol,[20] $OV(acac)_2$. This system probably belongs to the category of complexes that activate $O_2$ first. Figure 1 combines the list of alcohols chosen and the complexes tested with the turnover frequencies (TOFs) measured at 80 °C in the presence of molecular sieves to remove the water generated during the ODH.

For none of the nonactivated aliphatic alcohols was any activity observed by employing the catalysts depicted. When focusing on the complexes with the classical calixarene ligands first, the following picture emerged on employment of 1-phenyl-1-propargylic alcohol and fluorenol: the mononuclear complexes **5** and **6** only led to low conversions. However, the dinuclear complexes and the reference system led to much higher TOFs between 7.7 and 43 $h^{-1}$. With a TOF of 43 $h^{-1}$, the activity of **7** for the oxidation of fluorenol was even almost twice as high as that of $OV(acac)_2$.[14]

Subsequent studies even showed that the singly charged mononuclear complex **5** is completely inert under various conditions also towards other substrates, whereas the two dinuclear complexes were also capable of oxidizing a nonfunctionalized hydrocarbon such as 9,10-dihydroanthracene, although the TOFs are much lower in than those for the alcohol oxidations. The oxidation products were identified as 10.0% (1.0%) anthracene, 13.0% (1.5%) 10*H*-anthracene-9-one, and 7% (1.5%) 9,10-dihydroanthracene-

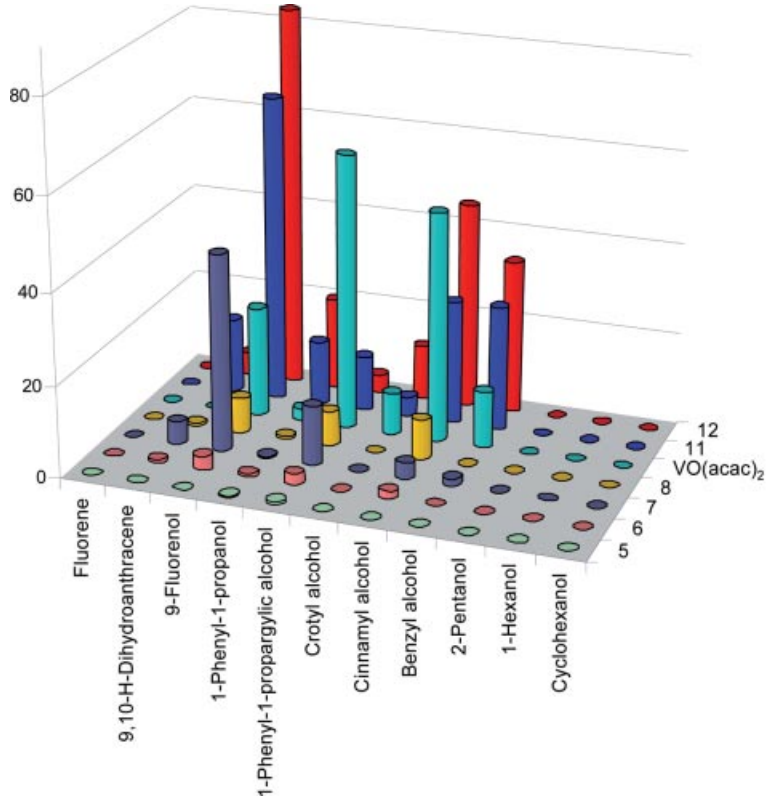


Figure 1. Substrate oxidation with $O_2$ catalyzed by complexes **5**–**8**, **11**, and **12**. The numbers refer to TOFs ($h^{-1}$), calculated per V center present.[15]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

9,10-diol (the percentage values specify the yield of oxidation product obtained by employing **7** (**8**) [1 mol-%] within 3 h with respect to the alcohol employed).

Turning our attention now to the thiacalixarene complexes, it can be noted that **11** and **12** are significantly more active than **5**–**8**,[15] and **12** catalyzes the oxidation of benzyl alcohol (33.6 $h^{-1}$) and crotyl alcohol (12.0 $h^{-1}$) even more efficiently than the reference system. The outstanding behavior of **12** fits the observation that dinuclear complexes are more active than the corresponding mononuclear ones, as was already evident during the investigation of the classical calixarenes.[14] In fact, **12** is more active than **11** for all alcohols except for one: 1-phenyl-1-propargyl alcohol. At the same time, this is the only case where **11** and **12** are less active than **7** and **8**, so that something seems to be special about the reactivity of this alcohol in combination with the thiacalixarene complexes. In contrast, the TOF observed for the oxidation of fluorenol catalyzed by **12** (83.4 $h^{-1}$) is twice as high as that observed for **7** (43.0 $h^{-1}$), and **11** is also very active (67.0 $h^{-1}$), whereas the two mononuclear calixarene complexes **5** and **6** – as mentioned previously – show hardly any activity. With reference to 9,10-dihydroanthracene, it becomes evident that, of all complexes investigated, **11** performs best (13.0 $h^{-1}$), whereas **12** is three times more active than **8** but only half as active as **7**. With fluorene, whose C–H bonds are somewhat (ca. 23 kJ/mol) stronger, as the substrate, none of the compounds employed showed any activity.

Having identified **11** and **12** as the most active catalysts, we subjected them to studies concerning mechanistic questions. Hence, the effects of the individual reagents and reaction conditions were analyzed, and it was found that heating dissolved **11** to 80 °C in the absence of alcohol and $O_2$ leads to the thia analog of **5**, $PPh_4$[(**TC**)V=O] (**15**) (Scheme 12).

This indicates that, whenever **11** is employed as a catalyst for conversions at 80 °C, **15** will be the active species being generated from **11** in situ by a double intramolecular HCl elimination. Compound **15** then reacts with convertible alcohols, as indicated by a further color change, and most likely this leads to the carbonyl compounds. $O_2$ is then needed to reoxidize the V center, which apparently yields **15** again. So far we were not able to identify any of the intermediates occurring in the catalytic cycle involving **15** in contact with alcohols. However, we were more successful in the case of **12**: Treating **12** with two equivalents of fluorenol at 80 °C in the absence of $O_2$ led to a light green solution from which $(PPh_4)_2$[{$H_2$**TC**V(O)}$_2$(μ-OH)(μ-$OC_{13}H_9$)] (**16**) could be isolated in good yields.[15] Compound **16** can be derived from **12** by formally replacing one of the two divalent μ-O ligands in **12** by one μ-OH and one μ-fluorenolate ligand, and in consequence both vanadium atoms are then in the oxidation state +IV. How is **16** formed? Scheme 13 shows a possible catalytic cycle involving **16**.

It is not clear whether a prebinding of the alcohol is necessary for the oxidation step, but if this were the case, it most likely occurs at one of the V centers through a replacement of the weakly bound, "soft" thioether donor belonging to the calixarene ligand as shown in Scheme 13. The next steps might consist of a dehydrogenation (possibly in the form of two consecutive H atom abstractions) leading to fluorenone and a complex with two hydroxo bridges. To get from there to **16** a replacement of one of the two hydroxo bridges by an alcoholate ligand with elimination of water has to occur, a step that should be sufficiently fast at 80 °C, especially in the presence of molecular sieves that constantly remove the water out of the equilibrium. By the mechanism in Scheme 13, one equivalent of fluorenone should be formed simultaneously with **16**, and indeed this could be detected. $O_2$ can then oxidize **16** to give a second equivalent of fluorenone and the starting material **12**, and this was independently shown to proceed already at room temp.; the process involves four electrons and two protons, which, in combination with $O_2$, lead to one equivalent of water and the $O^{2-}$ ligand necessary to regenerate **12**.

Hence, this catalytic cycle for the oxidation of fluorenol with $O_2$ mediated by **12** is plausible, and it additionally even seems to be conferrable to the oxidations of other alcohols: After analogous treatment of **12** with benzyl alcohol, **17**, the derivative corresponding to **16**, (Scheme 13) was isolated. It is interesting to note that oxidation chemistry preferably takes place at the bridging oxo functions and not at the terminal oxo ligands present. This in turn means that the conclusion drawn for the functioning of **12** can not be valid as such for the other calixarene-based catalysts (**5**–**8** and **11**/**15**), since each of those has its individual features

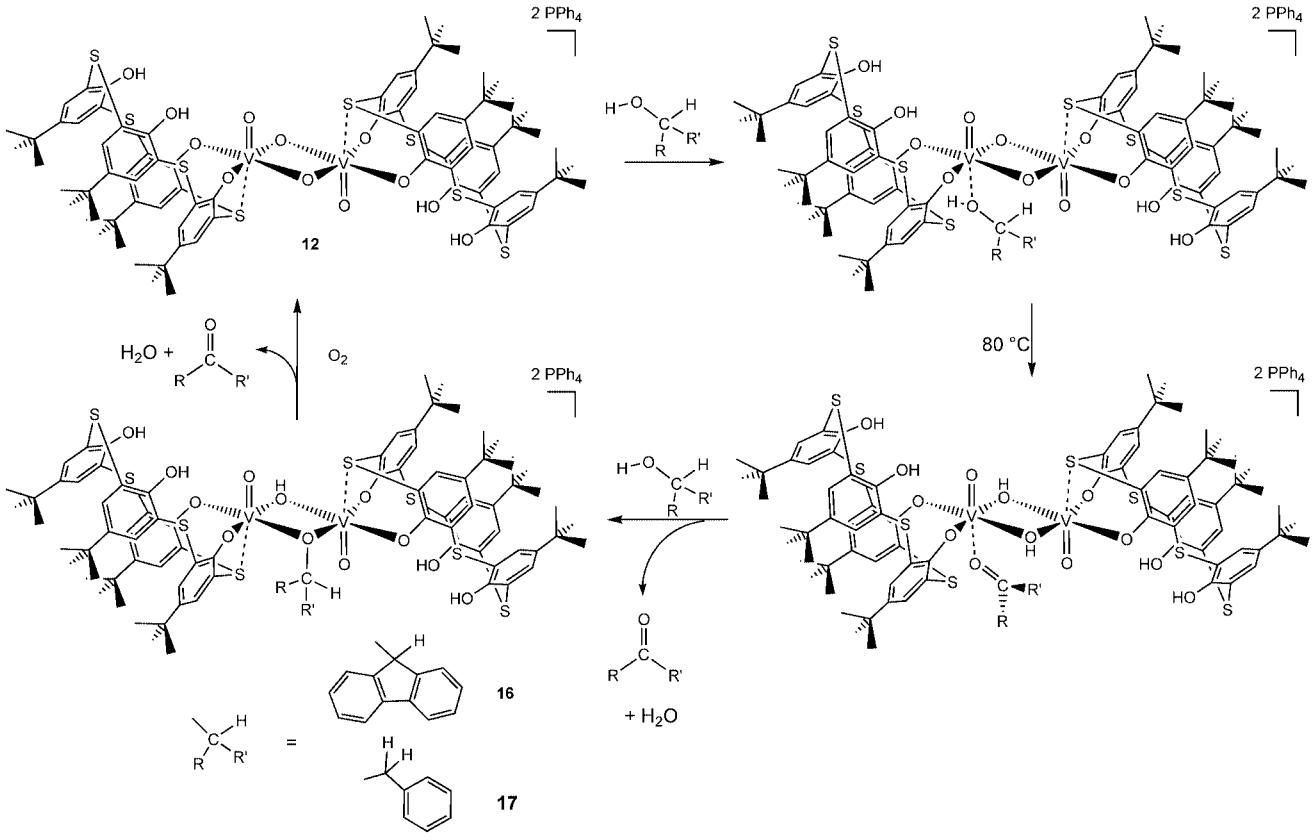

Scheme 13.

and none of them contains a bis(μ-oxo) unit. However, the mechanism in Scheme 13 exemplifies why it might be advantageous for a catalyst to contain two V centers, putting across the observation that dinuclear catalysts are more effective: all oxidation equivalents of $O_2$ are consumed within one cycle, and the vanadium centers only have to switch oxidation states between +V and +IV, whereas the functioning of mononuclear catalysts requires a change between +V and +III. This finding could, in principle, apply to the ODH of alcohols by surface sites, too, i.e. dinuclear sites containing bridging oxo functions should be more active than mononuclear ones. It will be interesting to follow up this working hypothesis in the future.

### 3.2. Olefin Polymerization

With the background described above in the Introduction, a number of the above-mentioned compounds were screened as potential catalysts for the polymerization of ethylene and for ethylene/propylene copolymerization in the presence of a number of organoaluminum cocatalysts as for instance MAO, and dimethylaluminum chloride (DMAC); the effect of the presence of the reactivating substance ethyl trichloroacetate (ETA) was tested, too.[10]

Among the oxovanadium calixarene compounds tested as catalysts, **1**, **3**$^{AN}$, **8b**$^{c}$, **9**, **10**, and **14**, **14** in combination with DMAC/ETA displayed the highest activity for ethylene polymerization [up to 130,000 g mmol$^{-1}$ h$^{-1}$ bar$^{-1}$ at 80 °C, yielding ultra-high-molecular-weight (>5,500,000) linear polyethylene], and ethylene/propylene copolymerization (up to 10,000 g mmol$^{-1}$ h$^{-1}$ bar$^{-1}$ at 25 °C) with about 14.5 mol-% propylene incorporation. These activities are amongst the highest reported to date for nonmetallocene systems.[21] An additional advantageous property of **14** is its stability to prolonged exposure to air. If other organoaluminum cocatalysts are employed such as MAO, much poorer catalytic activities are observed. In comparison to the oxacalix[3]arene complex **14** calix[4]arene-based procatalysts are at best an order of magnitude less active. Hence, the variation from oxa(-$CH_2OCH_2$-)- to methylene (-$CH_2$-)-bridged calixarenes as ancillary ligands leads to clear differences in catalytic performance for α-olefin polymerization systems. Although the nature of the active species formed upon addition of excess DMAC remains uncertain, the reasons are thought to be both steric and electronic in nature and relate to the ease with which the macrocycle can be disconnected from the vanadium center.[10] The shape and size of the oxacalix[3]arene ligand (and associated cavity) is very different from that of the calix[4]arene ligand, and this clearly leads, for instance, to different binding modes (exo vs. endo) for the V=O group: in oxacalixarene complexes this unit is located in the cavity, and this renders the vanadium somewhat exposed, whereas in vanadyl calix[4]arene complexes an exo orientation is observed. The depths of each type of cavity are also very different.[10]

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

Among the vanadyl calix[4]arene complexes investigated, those containing two vanadium centers (**8b**$^{c}$ and **10**) exhibit the highest activities, which may be the result of cooperative effects between the vanadium centers upon formation of the active species.

## 4. Conclusions and Outlook

Taken together, all the findings described in 3.1. may have implications on the discussion of which kind of species are active in oxidative dehydrogenation with vanadia catalysts, as they suggest an increase of activity through the cooperative behavior of two metal centers. However, a larger number of complexes has to be synthesized, and more detailed mechanistic investigations have to be performed to support this hypothesis.

With regard to the mechanism suggested for catalyst **12**, it seems interesting to investigate the kind of reactivity that forms the basis for the activity of mononuclear complexes: the identity of the products generated after addition of the alcohols to **15** at 80 °C or the other mononuclear complexes remains unclear, as we were so far not able to identify any of these potential intermediates. A further question concerns the reasons for the better performance of the thiacalixarene complexes relative to **5**–**8**. A striking result is the high activity observed for **15** (which is identical with the one ascribed to **11**), whereas the calixarene analog **5** is absolutely inert. The rate-determining step (probably the alcohol conversion) seems to be accelerated by the interaction of the thioether functions with the vanadium centers. More detailed and extensive studies might provide some insight in the future.

Interestingly, the results of the investigations concerning the catalytic activity for olefin polymerization (section 3.2) seem to suggest the same general trends as in the alcohol oxidation: the heterocalixarenes (here oxacalixarenes) are more active, and dinuclear complexes display higher activities than mononuclear compounds. It will be interesting to examine the reasons in the future and to investigate other open questions concerning the exact role played by DMAC, which is still far from clear. Success in the identification of the active species in these vanadium-based systems would be a major step forward in the current understanding and provide information vital to the future design of new vanadium-based catalytic systems.

# C–H···Ni$^{II}$ Interaction-Driven Homochiral *M* and *P* Helices of Neutral (*R*,*R*)- and (*S*,*S*)-Bis(pyrrol-2-ylmethyleneamino)cyclohexane Ni$^{II}$ Complexes

**Xu-Feng Shan,[a] Li-Zhu Wu,*[a] Xian-Yu Liu,[a] Li-Ping Zhang,[a] and Chen-Ho Tung[a]**

**Keywords:** Nickel(II) complexes / C–H···Ni$^{II}$ interactions / Helical structures

Reaction of (*R*,*R*)- and (*S*,*S*)-bis(pyrrol-2-ylmethyleneamino)-cyclohexane with Ni$^{II}$(OAc)$_2$·4H$_2$O afforded enantiomeric nickel(II) Schiff-base complexes (*R*,*R*)-**1** and (*S*,*S*)-**1**, respectively. Rare C–H···Ni$^{II}$ interactions were found to be responsible for the facile formation of homochiral *M* and *P* helices of the neutral, chiral, mononuclear complexes in crystal lattices. (© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

Inspired by biology and driven by applications in material science, chemists have made tremendous efforts in building helical arrays that play important roles across the whole spectrum of science and technology.[1–2] A large number of supramolecular helical architectures of coordination compounds have been constructed over the years.[2–6] It is known that the size and structure of the helix can be altered by subtle manipulation of the intermolecular interactions, such as hydrogen bonding, π–π stacking, and electrostatic and van der Waals forces.[1–6] Although C–H···M (M: metal) interaction was initially postulated in the literature,[7] its significance in self-assembling processes has not been realized until recently.[8] Ma and coworkers[8a] described in 2004 that the weak intermolecular C–H···Cu hydrogen bond plays a crucial role in constructing the network polymer of bis(pyrrol-2-ylmethyleneamine) ligands with Cu$^{II}$. Earlier work by Alyea et al.[8b] revealed that pairs of *cis*-[PdCl$_2$(TPA)$_2$] (TPA = 1,3,5-triaza-7-phosphaadamantane) molecules are linked about inversion centers by intermolecular C–H···Pd hydrogen interactions, where water molecules link these dimers via O–H···N hydrogen bonds to form infinite chains that extends in the *c* direction in the crystal lattice.

In this communication, we report homochiral supramolecular left-handed (*M*) and right-handed (*P*) helices, which are derived from chiral neutral mononuclear (*R*,*R*)- and (*S*,*S*)-bis(pyrrol-2-ylmethyleneamino)cyclohexane nickel(II) complexes, (*R*,*R*)-**1** and (*S*,*S*)-**1**, respectively. The use of pyrrol-2-yl Schiff base avoids counterion coordination,[3c,8a] and thereby achieves exclusive coordination of the tetradentate ligand to nickel(II) center. X-ray crystal structural analysis reveals that (*R*,*R*)-**1** and (*S*,*S*)-**1** self-assemble via the intermolecular C–H···Ni$^{II}$ interaction and the chirality of mononuclear nickel(II) complexes of (*R*,*R*)-**1** and (*S*,*S*)-**1** extends over the whole supramolecular structure. Although the chiral Schiff complexes are known to construct supramolecular helical structures,[3–7] to the best of our knowledge, the homochiral helix solely driven by the rare C–H···M interaction in neutral mononuclear metal complex has not yet been reported.

## Results and Discussion

The optically pure ligands of (*R*,*R*)- and (*S*,*S*)-bis(pyrrol-2-ylmethyleneamino)cyclohexane were prepared by condensation of (*R*,*R*)-1,2-diaminocyclohexane mono-(+)-tartrate salt and (*S*,*S*)-1,2-diaminocyclohexane with 2-pyrrolealdehyde, respectively.[9] Under the base conditions, the two enantiomeric ligands were further reacted with Ni$^{II}$(OAc)$_2$·4H$_2$O at room temperature to afford neutral mononuclear complexes (*R*,*R*)-**1** and (*S*,*S*)-**1** with yields of 93 and 92%, respectively (Scheme 1). For comparison, racemic complex **1**[9b] was also synthesized.

Figure 1 shows the UV/Vis absorption and circular dichromism (CD) spectra of neutral complexes (*R*,*R*)-**1** and (*S*,*S*)-**1**. It was noted that the optically pure enantiomers of (*R*,*R*)-**1** {$[\alpha]_D^{20}$ = –3832 (*c* = 0.0033, $CH_2Cl_2$)} and (*S*,*S*)-**1** {$[\alpha]_D^{20}$ = +3833 (*c* = 0.0032, $CH_2Cl_2$)} show near mirror image behaviors in the circular dichroism (CD) spectra, while the absorption spectra are not distinguishable from each other. Correlated with the observed CD spectra, the absolute configuration of (*R*,*R*)-**1** and (*S*,*S*)-**1** can be subsequently assigned to Δ and Λ, respectively, in terms of the definition of IUPAC nomenclature[10a] and the reference method.[10b–10c]

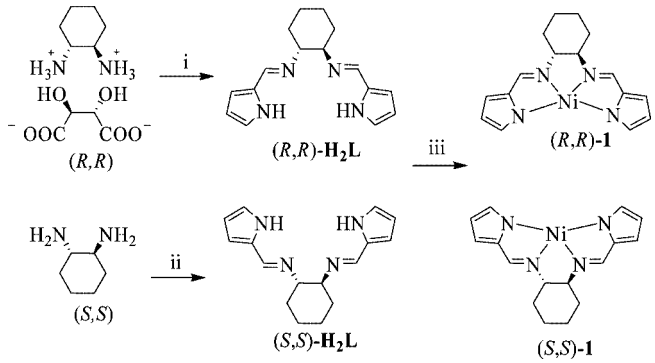

Scheme 1. Synthesis of (*R*,*R*)-**1** and (*S*,*S*)-**1** complexes. Reaction conditions: i) $K_2CO_3$, 2-pyrrolealdehyde, 80 °C, 4 h, water/ethanol (2:1); ii) 2-pyrrolealdehyde, reflux, 12 h, ethanol; iii) $Ni^{II}(OAc)_2 \cdot 4H_2O$, KOH, r.t., 2 h, methanol.

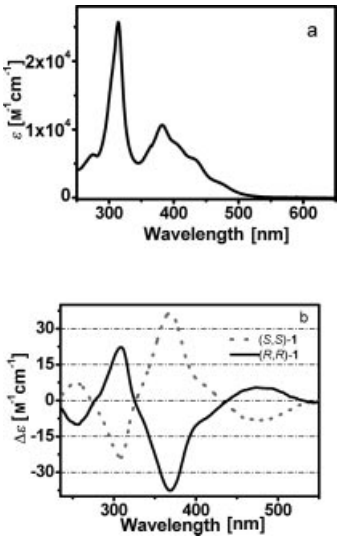

Figure 1. The absorption spectrum (a) and circular dichroism spectrum (b) of (*R*,*R*)-**1** ($4.43 \times 10^{-5}$ M) and (*S*,*S*)-**1** ($3.68 \times 10^{-5}$ M) in acetonitrile solution at room temperature.

Single crystals of (*R*,*R*)-**1**, (*S*,*S*)-**1**, and **1** were obtained by slow evaporation of a $CH_2Cl_2$/methanol solution. Red single crystals of these three complexes as needles were used for data collection with the use of a Bruker Smart 1000 X-ray diffractometer with Mo-$K_\alpha$ radiation. The crystals of (*R*,*R*)-**1** and (*S*,*S*)-**1** belong to the monoclinic crystal system and $P2_1$ space group, while **1** is the monoclinic crystal system and $P2_1/c$ space group. The crystallographic data for (*R*,*R*)-**1** and (*S*,*S*)-**1**, as well as **1** were listed in Table 2. Figure 2 shows the two neutral mononuclear (*R*,*R*)-**1** and (*S*,*S*)-**1** complexes. Each $Ni^{II}$ center is four-coordinate to four N atoms from pyrrol-2-yl-cyclohexenediamine Schiff-base unit. The length of the $Ni^{II}$–N bond is in the range of 1.844–1.890 Å. The dative $Ni^{II}$–N(imine) bond lengths (1.844–1.867 Å) are comparable to those of other similar $Ni^{II}$–N bonds (1.843–1.895 Å) in the literature,[9b] but are shorter than those of the $Ni^{II}$–N(pyrrole) (1.877–1.890 Å). The conformation of *trans*-1,2-cyclohexyldiamine leads to a twisted conformation, where the cyclohexyl ring is in a stable chair conformation and the two pyrrol-2-yl units of same ligand adopt a *cis* conformation with dihedral angles of 18° (Ni1–N1–N2 and Ni1–N4–N3) in (*R*,*R*)-**1** and 18.3° (Ni1–N1–N2 and Ni1–N4–N3) in (*S*,*S*)-**1**, respectively. The dihedral angles in (*R*,*R*)-**1** and (*S*,*S*)-**1** implied that the $Ni^{II}$ center has a small deviation from the square-planar coordination geometry. Evidently, the configuration of (*R*,*R*)-**1** and (*S*,*S*)-**1** can be definitely evaluated as Δ and Λ with respect to the $C_2$-axis, which is consistent with their assignments on the basis of CD spectra.

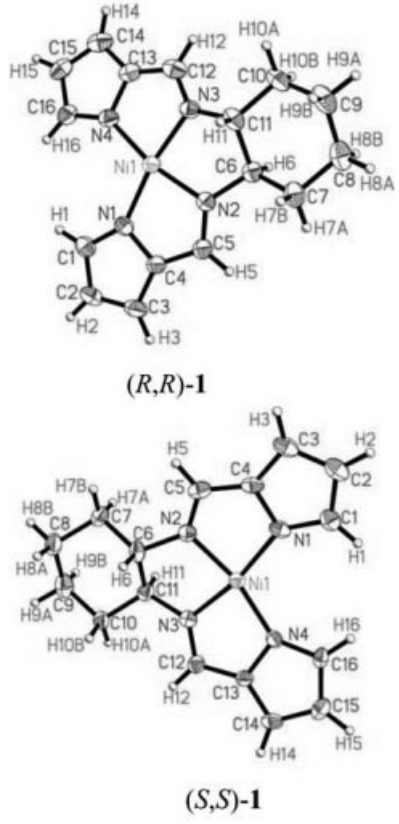

Figure 2. Crystal structures of (*R*,*R*)-**1** and (*S*,*S*)-**1** with atom numbering.

A noticeable feature of (*R*,*R*)-**1** and (*S*,*S*)-**1** lies in the weak intermolecular C–H···$Ni^{II}$ interactions in the molecular packing (Figure 3). As in the case of (*R*,*R*)-**1**, each ligand uses its hydrogen atoms to bind the nickel(II) center of the others. Because the two pyrrol-2-yldiamine units of the same ligand adopt a *cis* conformation and the C–N-(imine) bonds in the rigid *trans*-1,2-cyclohexyl moiety are arranged reciprocally, the unit cell contains three different intermolecular C–H···$Ni^{II}$ interactions in the crystal of (*R*,*R*)-**1**. As sketched in Figure 3, each molecule of (*R*,*R*)-**1** is stacking with two adjacent molecules via the intermolecular C–H···$Ni^{II}$ interactions. Table 1gives the structural parameters related to the C–H···$Ni^{II}$ interactions in (*R*,*R*)-**1** and (*S*,*S*)-**1**. The $Ni^{II}$···H distance is similar to that recently observed by Pal. et al., who demonstrated the presence of intramolecular apical C–H···$Ni^{II}$ interactions in square-planar nickel(II) complexes with dianionic tridentate ligands and 2-phenylimidazole.[11] The intermolecular contacts of 3.002 Å at C43A–H43A···Ni1A, 3.025 Å at

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

C6A–H6A···Ni3A, and 3.127 Å at C7A–H7BA···Ni3B with the C–H···Ni$^{II}$ angle of 141.1°, 166.9°, and 141.5°, respectively, lead to the formation of helical assemblies with different pitches in the helix. Two sets, four complex fragments form one helix with a screw-pitch of 17.242 Å. The intermolecular metal···metal contacts are found to be 5.989 Å (Ni3A–Ni1A) and 8.621 Å (Ni1A–Ni3B), respectively. Obviously, the turn required to generate a perfect periodic self-assembly of (*R*,*R*)-**1** in a helical fashion is induced by the chirality of the building block coupled with the weak intermolecular C–H···Ni$^{II}$ interactions. An *M* handedness can be clearly assigned to complexes (*R*,*R*)-**1** when viewed along the *b* axis. At the molecular level, this local chirality translates throughout the crystal into the formation of only left-handed (*M*) helix at the supramolecular level. The path of the helix can be easily traced by following the C–H···Ni$^{II}$ interactions counterclockwise around the screw axis of the helix. A similar self-assembly pattern exists in the crystal packing of (*S*,*S*)-**1**. The only difference is the opposite direction presented in which the intermolecular C–H···Ni$^{II}$ interactions show a clockwise turn around the screw axis to give a right-handed (*P*) helix. A comparison of the two space-filling models evidences the near mirror image behavior of the (*R*,*R*)-**1** and (*S*,*S*)-**1** helices (Figure 3), indicating they are enantiomeric from a supramolecular point of view.

To provide more evidence for the unique intermolecular C–H···Ni$^{II}$ interaction, the self-assembly manner presented in racemic complex **1** was also investigated. Apparently, the situation is quite different from that in (*R*,*R*)-**1** and (*S*,*S*)-**1**. Two molecules of (*R*,*R*)-**1** and (*S*,*S*)-**1** interact with each other in one unit cell via intermolecular C–H···Ni$^{II}$ interactions (Figure 4). However, one H atom from the pyrrole

Table 1. Parameters for C–H···Ni$^{II}$ intermolecular interactions in three Ni$^{II}$ complexes.

ring rather than from the 1,2-cyclohexyl unit in one molecule is bound to the Ni center of the other. Since the intermolecular C–H···$Ni^{II}$ distance of 2.884 Å at C11D–H11D···Ni1B and 2.884 Å at C11B–H11B···Ni1D in complex **1** are appreciably shorter than those of either (*R*,*R*)-**1** or (*S*,*S*)-**1**, homochiral *M* and *P* helices were not observed in the crystal packing of **1**. Alternatively, the racemic unit cell of complex **1** is assembled to display a picture that is far from that observed for the (*R*,*R*)-**1** and (*S*,*S*)-**1** helices.

## Conclusions

We demonstrated that the rare C–H···$Ni^{II}$ interaction is responsible for controlling self-assembly of neutral, chiral, mononuclear complexes of (*R*,*R*)-**1** and (*S*,*S*)-**1**, leading to the formation of *M* and *P* helices of (*R*,*R*)-**1** and (*S*,*S*)-**1** in crystal lattices. Extending the scope of the intriguing complexes and exploring their applications are ongoing in our laboratory.

## Experimental Section

All synthetic regents were of analytical grade and used as received. The solvents used for spectroscopic measurements were purified according to the literature method.[12] Melting points were determined with a Yanaco MP-500 micro-melting point apparatus. NMR spectra were recorded with a Bruker Avance dpx 400 MHz instrument using TMS as an internal standard. Mass spectra were obtained with Bruker APEX II spectrometers. Elemental analyses were performed with a FLASH EA1112 elemental analyzer. The UV/Vis absorption spectra of these compounds were recorded using a Shimadzu 1601 spectrophotometer. The circular dichroism (CD) spectra were measured with a JASCO J-810 spectropolarimeter. The values of specific rotation were measured with a Perkin–Elmer 341LC polarimeter.

**(*R*,*R*)-Bis(pyrrol-2-ylmethyleneamino)cyclohexane [(*R*,*R*)-$H_2$L]:** A 100-mL two-necked flask equipped with a magnetic stirrer, a reflux condenser, and an addition funnel was charged with (*R*,*R*)-1,2-diaminocyclohexane mono-(+)-tartrate salt (2.64 g), $K_2CO_3$ (2.79 g) and distilled water/ethanol (2:1, 60 mL). The mixture was heated to 80°C, and then 2-formylpyrrole (1.9 g) in ethanol (10 mL) was added slowly over 20 min. The yellow solution was heated at reflux for 2 h before distilled water (20 mL) was added. The solution was placed in an ice bath for 4 h to afford a white solid, which was collected by vacuum filtration, washed with water, and dried under vacuum. The product was further recrystallized from ethanol to give optically pure (*R*,*R*)-**$H_2$L**. Yield: 2.2 g, 78%. M.p. 204 °C (dec.). $[\alpha]_D^{20}$ = –1041 (*c* = 0.0023, $CH_3OH$). $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.36–1.79 (m, 8 H), 3.01–3.05 (m, 2 H), 6.17 (dd, *J* = 2.5, 2.7 Hz, 2 H), 6.36 (d, *J* = 2.5 Hz, 2 H); 6.81 (s, 2 H), 7.77 (s, 2 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 24.92, 34.34, 72.87, 109.69, 114.55, 122.01, 130.66, 152.32 ppm. MS (EI): *m*/*z* = 268. $C_{16}H_{20}N_4 \cdot H_2O$ (286.4): calcd. C 67.11, H 7.74, N 19.56; found C 66.96, H 7.75, N 19.40.

**(*S*,*S*)-Bis(pyrrol-2-ylmethyleneamino)cyclohexane [(*S*,*S*)-$H_2$L]:** 2-Formylpyrrole (6 mmol) and (*S*,*S*)-1,2-diaminocyclohexane (3 mmol) were dissolved in ethanol (35 mL). The yellow solution was heated at reflux for 12 h under an atmosphere of argon. The solvent was removed by evaporation. The residue was further recrystallized from 95% ethanol to give optically pure (*S*,*S*)-**$H_2$L**. Yield: 0.58 g, 68%. M.p. 206 °C (dec.). $[\alpha]_D^{20}$ = +1040 (*c* = 0.0021, $CH_3OH$). $^1$H NMR (400 MHz, $CDCl_3$, 25 °C): $\delta$ = 1.36–1.79 (m, 8 H), 3.01–3.05 (m, 2 H), 6.17 (dd, *J* = 2.5, 2.7 Hz, 2 H), 6.36 (d, *J* = 2.5 Hz, 2 H); 6.81 (s, 2 H), 7.77 (s, 2 H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 24.93, 34.33, 72.88, 109.68, 114.57, 122.02, 130.66, 152.30 ppm. MS (EI): *m*/*z* = 268. $C_{16}H_{20}N_4 \cdot H_2O$ (286.4): calcd. C 67.11, H 7.74, N 19.56; found C 66.98, H 7.73, N 19.42.

**(*R*,*R*)-Bis(pyrrol-2-ylmethyleneamino)cyclohexane Nickel(II) Complex [(*R*,*R*)-1]:** A mixture of optically pure (*R*,*R*)-**$H_2$L** (1 mmol) and $Ni^{II}(OAc)_2 \cdot 4H_2O$ (1.1 mmol) in methanol (30 mL) was stirred for 10 min at r.t. With the addition of KOH (2 mmol) in methanol (10 mL), the mixture was stirred for another 2 h accompanying the formation of a precipitate, which was collected by suction filtration followed by washing with distilled water and methanol. Recrystallization from dichloromethane/methanol produced the expected red crystals. Yield: 301 mg, 93%. M.p. 272 °C (dec.). $[\alpha]_D^{20}$ = –3832 (*c* = 0.0033, $CH_2Cl_2$). $^1$H NMR (400 MHz, $CDCl_3$, 25°C): $\delta$ = 1.27–1.29 (m, 4 H, $CH_2$), 1.80–1.81 (br. s, 2 H, $CH_2$), 2.19–2.20 (br. s, 2 H, $CH_2$), 3.41–3.42 (br. s, 2 H, CH), 6.12 (dd, *J* = 3.6, 3.4 Hz, 2 H, pyrrole-βH), 6.58 (d, *J* = 3.6 Hz, 2 H, pyrrole-γH), 6.80 (s, 2 H, pyrrole-αH), 7.17 (s, 2 H, imine-H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 24.1, 28.0, 70.4, 111.3, 116.3, 136.0, 142.9, 154.0 ppm. HRMS (FAB): calcd. for $C_{16}H_{18}N_4Ni$ $[M + H]^+$ 324.0878; found 324.0877. $C_{16}H_{18}N_4Ni$ (324.1): calcd. C 59.12, H 5.58, N 17.24; found C 58.94, H 5.58, N 17.28.

**(*S*,*S*)-Bis(pyrrol-2-ylmethyleneamino)cyclohexane Nickel(II) Complex [(*S*,*S*)-1]:** The synthetic procedure was similar to that of (*R*,*R*)-**1** except for optically pure (*S*,*S*)-**$H_2$L** was used. Yield: 298 mg, 92%. M.p. 268 °C (dec.). $[\alpha]_D^{20}$ = +3833 (*c* = 0.0032, $CH_2Cl_2$). $^1$H NMR (400 MHz, $CDCl_3$, 25°C): $\delta$ = 1.27–1.29 (m, 4 H, $CH_2$); 1.80–1.81 (br. s, 2 H, $CH_2$), 2.19–2.20 (br. s, 2 H, $CH_2$), 3.41–3.42 (br. s, 2 H, CH), 6.12 (dd, *J* = 3.6, 3.5 Hz, 2 H, pyrrole-βH), 6.57 (d, *J* = 3.6 Hz, 2 H, pyrrole-γH), 6.80 (s, 2 H, pyrrole-αH), 7.17 (s, 2 H, imine-H) ppm. $^{13}$C NMR (100 MHz, $CDCl_3$): $\delta$ = 24.1, 27.9, 70.5, 111.3, 116.2, 135.6, 143.0, 154.2 ppm. HRMS (FAB): calcd. for $C_{16}H_{18}N_4Ni$ $[M + H]^+$ 324.0878; found 324.0870. $C_{16}H_{18}N_4Ni$ (324.1): calcd. C 59.12, H 5.58, N 17.24; found C 58.94, H 5.48, N 17.30.

**X-ray Crystallographic Studies:** Crystals suitable for X-ray analysis were obtained by slow evaporation of a saturated solution of dichloromethane/methanol. Accurate unit cell parameters were determined by least-squares fit of 2$\theta$ values, measured for 200 strong reflections, and intensity data sets were measured with a Bruker Smart 1000 CCD diffractometer with Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å) at 294 K. The intensities were corrected for Lorentz and polarization effects. All structures were analyzed by direct methods. The non-hydrogen atoms were located in successive difference Fourier synthesis. The final refinement was performed by full-matrix least-squares methods with anisotropic thermal parameters for non-hydrogen atoms on $F^2$ (SHELXL-97).[13] The hydrogen atoms were added theoretically and treated as riding on the concerted atoms. Crystallographic data and experimental details for structure analyses are summarized in Table 2. CCDC-638806, -638807, and -638808 [for (*R*,*R*)-**1**, (*S*,*S*)-**1**, and **1**, respectively] contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis and Crystallographic Characterisation of the Heterodimetallic Complex [(Dibenzo-18-crown-6)K(μ-Cl)$_3$Ru(η$^6$-*p*-cymene)]

**Carsten A. Vock,[a] Rosario Scopelliti,[a] and Paul J. Dyson*[a]**

**Keywords:** Heterometallic complexes / Bridging ligands / Ruthenium / Crown compounds / X-ray crystallography

The triple-chlorido-bridged heterodimetallic dinuclear complex [(dibenzo-18-crown-6)K(μ-Cl)$_3$Ru(η$^6$-*p*-cymene)] containing an (η$^6$-arene)Ru$^{II}$ fragment and a Group 1 metal crown ether fragment was synthesized and characterized by spectroscopy and X-ray crystallography. The solid-state structure clearly reveals the presence of the triple-chlorido-bridged dinuclear complex, whereas NMR investigations in different deuteriated solvents reveal the presence of an essentially 1:1 mixture of **1** and starting materials, indicating the presence of a dynamic equilibrium.

## Introduction

Dinuclear homometallic cationic ruthenium(II) complexes of the general type [(η$^6$-arene)Ru(μ-Cl$_3$)(η$^6$-arene)]$^+$ were first described in the early 1970s by Bennett and Smith.[1] Subsequently, these compounds were explored in more detail by Stephenson et al.,[2] with an emphasis on synthetic and electrochemical aspects. A series of crystallographic analyses[3] in combination with theoretical investigations,[4] have also been reported, and applications in hydrogen transfer reactions were reported.[5]

In recent years, dimetallic complexes involving the (η$^6$-arene)Ru$^{II}$ fragment and another transition metal fragment have been widely explored, and impressive applications in catalysis have been observed. For example, the metathesis catalysts Ru(=CHR)Cl$_2$(PCy$_3$)$_2$ (R = CHCPh$_2$ or Ph), react quantitatively with the bridged dimers [M(η$^6$-*p*-cymene)Cl$_2$]$_2$ (M = Ru or Os) to form dimetallic complexes in which the two metal centres are bridged by two chlorido ligands;[6] the resulting dimetallic complexes were found to have higher activities than the mononuclear complexes. Moreover, dimetallic complexes, in which two metal fragments are connected by three halogenido bridges also exhibit interesting properties. Their potential as precursors in catalytic reactions has been demonstrated in Oppenauer-type oxidation reactions of alcohols[7] and for atom-transfer radical reactions.[8] The dimetallic precursors are composed of two transition metal fragments; prominent examples for metal combinations in these heterodimetallic complexes are Ru–Rh[7] and Ru–Ir.[7c,9] However, to the best of our knowledge, halogenido-bridged dimetallic complexes, in which one metal fragment is ruthenium and the other is a main group metal, have not been reported. Herein, we describe the synthesis and characterisation of the first triple-chlorido-bridged Ru$^{II}$–alkali metal heterodimetallic dinuclear complex (Scheme 1).

## Results and Discussion

Treatment of [Ru(η$^6$-*p*-cymene)Cl$_2$]$_2$ with a slight excess of [(dibenzo-18-crown-6)K][Cl] (freshly prepared from dibenzo-18-crown-6 and KCl in MeOH/H$_2$O) in CH$_2$Cl$_2$ at room temperature and subsequent precipitation by addition of ethyl acetate and slow evaporation of CH$_2$Cl$_2$ in vacuo afforded [(dibenzo-18-crown-6)K(μ-Cl)$_3$Ru(η$^6$-*p*-cymene)]·EtOAc (**1**·EtOAc) in moderate yield as orange-brown solid. NMR studies in CD$_2$Cl$_2$ revealed the presence of a mixture of essentially equal amounts of a new species and starting material [Ru(η$^6$-*p*-cymene)Cl$_2$]$_2$, indicating a dynamic equilibrium in solution, as recently described for the salt [Ph$_4$P][Ru(η$^6$-*p*-cymene)Cl$_3$].[10] However, for the system described herein, the equilibrium is not strongly dependent on the solvent, since measurements in CDCl$_3$ and C$_6$D$_6$ lead only to marginal changes in the starting material/product ratio. In comparison, for [Ph$_4$P][Ru(η$^6$-*p*-cymene)Cl$_3$],[10] changing the solvent from CD$_2$Cl$_2$ to CDCl$_3$ led to an al-

most complete shift of the equilibrium towards the starting material.

Crystallization by layering a $CH_2Cl_2$ solution of the obtained material with ethyl acetate and storage at 4 °C for several days yielded orange crystals of **1**·EtOAc that were suitable for X-ray analysis. An ORTEP plot of the structure is depicted in Figure 1. Crystal data and data of the structure refinement are presented in Table 1. Compound **1** crystallizes as discrete molecules in space group $P2_1/n$. The coordination around the Ru$^{II}$ centre is defined by an η$^6$-*p*-cymene ligand [Ru–centroid 1.653(3) Å] and by three chlorido bridges [Ru–Cl$_{av}$, 2.437(2) Å]. The potassium ion lies in the middle of the crown ether and is displaced by 1.216 Å towards the chlorido ligands and the Ru ion [Ru···K, 4.066(2) Å]. The potassium ion completes its ninefold coordination with the three bridging chlorido ligands [K–Cl$_{av}$, 3.232(2) Å], these distances being slightly longer than those found in solid KCl [3.146 Å].[11] The K–O distances within the crown ether show a wide range of values [2.938(4)–3.127(4) Å] and, compared to those found in a similar molecule,[12] clearly bear out the reduced flexibility of this ligand with respect to the classical 18-crown-6. The solvent molecule lies in the large cavity formed by the crown ether, and it shows short K···C interactions [3.555(8) Å; K···H$_{Me}$, 3.07 Å]. Some weak CH···O hydrogen bonds are observed between the complex and the ethyl acetate of a neighbouring asymmetric unit.

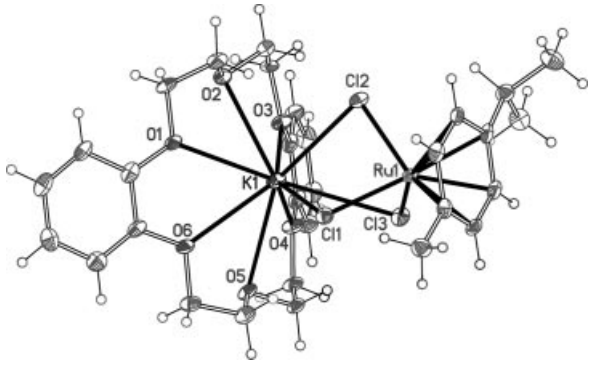

Figure 1. ORTEP representation of **1**·EtOAc; EtOAc solvent has been omitted for clarity; thermal ellipsoids are drawn at the 50% probability level. Selected bond lengths [Å] and angles [°]: Ru1–Cl1 2.4334(15), Ru1–Cl2 2.4302(14), Ru1–Cl3 2.4460(14), K1–Cl1 3.2350(19), K1–Cl2 3.2268(18), K1–Cl3 3.2342(18), K1–O1 3.099(4), K1–O2 2.952(4), K1–O3 2.952(4), K1–O4 2.938(4), K1–O5 2.943(4), K1–O6 3.127(4); Cl2–Ru1–Cl1 86.40(5), Cl1–Ru1–Cl3 87.11(5), Cl2–Ru1–Cl3 87.51(5), O2–K1–O1 101.41(10), O1–K1–O6 49.52(9), O1–K1–Cl2 97.70(8), O1–K1–Cl3 150.38(8).

(Arene)ruthenium(II) compounds are playing an increasingly important role in organometallic chemistry,[13] and as far as we are aware the structural motif of the (arene)ruthenium(II) compound described herein is unique. The structure demonstrates that under certain conditions Group 1 metal ions can interact with the (arene)ruthenium(II) unit. The implications of such an observation are potentially far-reaching as the Noyori-type transfer hydrogenation catalysts based on the (arene)ruthenium(II) unit are activated in the presence of KOH.[14] It has previously been shown that attaching a crown ether to the arene ring in these catalysts influences the rate of the reaction depending on the nature of the ion, viz. $Na^+$, $K^+$ or $Cs^+$.[15] (Arene)ruthenium(II) compounds have also been immobilised in materials which contain Group 1 ions, such as clays,[16] and again, interactions between the two units could be present. (Arene)ruthenium(II) complexes are also being increasingly evaluated in medicinal applications,[17] and again, in a physiological environment interactions with ions such as $Na^+$ or $K^+$ could prove to be important, activating the compounds towards reaction with biomolecular targets.

Table 1. Crystallographic parameters for **1**·EtOAc.

| | **1**·EtOAc |
|---|---|

## Experimental Section

**Synthesis and Spectroscopic Characterization:** [RuCl$_2$(η$^6$-*p*-cymene)]$_2$ was synthesized according to a literature protocol.[18] All other reagents and solvents were obtained from commercial sources and used without further purification. $^1$H and $^{13}$C NMR spectra were recorded with a Bruker 400 MHz spectrometer at room temperature in $CD_2Cl_2$. NMR spectra were referenced to internal solvents as follows: $\delta(CH_2Cl_2, {}^1H)$ = 5.35 and $\delta(CD_2Cl_2, {}^{13}C)$ = 53.45. Elemental analyses were conducted at the EPFL.

**Synthesis of [(Dibenzo-18-crown-6)K(μ-Cl)$_3$Ru(η$^6$-*p*-cymene)]·EtOAc (1·EtOAc):** To a solution of KCl (49.0 mg, 0.657 mmol, 2.12 equiv.) in $H_2O$ (1 mL) and MeOH (10 mL), dibenzo-18-crown-6 (237 mg, 0.658 mmol, 2.12 equiv.) was added, and the resulting mixture was stirred at room temperature for 75 min. The solvent was removed in vacuo. The white solid residue was dissolved in

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

$CH_2Cl_2$ (10 mL), [Ru($\eta^6$-*p*-cymene)$Cl_2$]$_2$ (190 mg, 0.310 mmol) was added, and the mixture was stirred at room temperature for 1 h. The solution was filtered, and the residue was washed with $CH_2Cl_2$ (2 × 5 mL). EtOAc (30 mL) was added to the combined filtrates, and $CH_2Cl_2$ was removed in vacuo. After standing at room temperature overnight, the formed voluminous precipitate was filtered, washed with EtOAc (2 × 10 mL) and dried in vacuo, affording **1** as an orange-brown solid (271 mg, 0.327 mmol, 53%). Crystals of the solvated compound **1**·EtOAc suitable for X-ray analysis were obtained by layering a $CH_2Cl_2$ solution of the obtained product with EtOAc and storing at 4 °C for several days. $^1$H NMR (400 MHz, $CD_2Cl_2$): $\delta$ = 1.29 [d, $J$ = 7.0 Hz, 6 H, 1-CH(C$H_3$)$_2$], 2.14 (s, 3 H, 4-C$H_3$), 2.99 [sept, $J$ = 7.0 Hz, 1 H, 1-C$H$(CH$_3$)$_2$], 4.05 (br. t, $J$ = 4.2 Hz, 8 H, 4 × OC$H_2$CH$_2$OC$_6$H$_4$ of dibenzo-18-crown-6), 4.17 (br. t, $J$ = 4.2 Hz, 8 H, 4 × OCH$_2$C$H_2$OC$_6$H$_4$ of dibenzo-18-crown-6), 5.12 (d, $J$ = 5.8 Hz, 2 H, 2-H, 6-H), 5.35–5.37 (m, 2 H, 3-H, 5-H), 6.91 (m$_c$, 8 H, 2 × OC$_6$$H_4$O). $^{13}$C NMR (101 MHz, $CD_2Cl_2$): $\delta$ = 18.47 (4-*C*H$_3$), 21.98 [1-CH(*C*H$_3$)$_2$], 30.76 [1-*C*H(CH$_3$)$_2$], 67.26 (4 × O*C*H$_2$CH$_2$OC$_6$H$_4$ of dibenzo-18-crown-6), 69.05 (4 × OCH$_2$-*C*H$_2$OC$_6$H$_4$ of dibenzo-18-crown-6), 79.17 (C-2, C-6), 81.84 (C-3, C-5), 96.30 (C-4), 100.9 (C-1), 111.7 (4 × *ortho*-C of dibenzo-18-crown-6), 120.9 (4 × *meta*-C of dibenzo-18-crown-6), 147.8 (4 × *C*O of dibenzo-18-crown-6). $C_{30}H_{38}Cl_3KO_6Ru$·1.5 EtOAc (873.30): calcd. C 49.51, H 5.77; found C 49.87, H 5.43.

**Crystallography:** Diffraction data for **1** were measured with a Bruker-Nonius kappa diffractometer equipped with an APEX II CCD using Mo-$K_\alpha$ radiation. Data were reduced by EvalCCD[19] and then corrected for absorption by a semiempirical method.[20] The structure was solved by direct methods,[21] and refined using full-matrix least squares on $F^2$ with all non-H atoms anisotropically defined. Hydrogen atoms were placed in calculated positions using the "riding model". Structure solution, refinement, geometrical calculations and geometrical representations were carried out with SHELXTL.[22] CCDC-643569 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

# Synthesis of Cyclic Carbonates from Atmospheric Pressure Carbon Dioxide Using Exceptionally Active Aluminium(salen) Complexes as Catalysts

**Jaisiel Meléndez,[a] Michael North,*[a] and Riccardo Pasquale[a]**

**Keywords:** Carbon dioxide fixation / Aluminium / Schiff bases / Epoxides / Catalysis

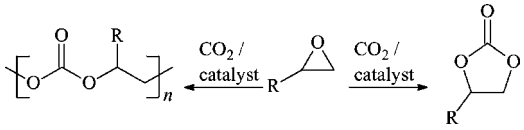
Dimetallic aluminium(salen) complexes show exceptionally high catalytic activity for the synthesis of cyclic carbonates from terminal epoxides at ambient temperature and pressure. The process has the potential to contribute towards decreasing atmospheric carbon dioxide emissions from the burning of fossil fuels.
(© Wiley-VCH Verlag GmbH & Co. KGaA, 69451 Weinheim, Germany, 2007)

## Introduction

One of the main scientific challenges facing the human race in the 21st century is controlling global warming due to increasing levels of atmospheric carbon dioxide.[1] In the long term, it may be possible to move entirely to renewable, or non-carbon-based fuels; however, for the foreseeable future, annual consumption of fossil fuels is predicted to continue to increase markedly with a corresponding rise in atmospheric carbon dioxide levels.[2] The only solution currently being considered to this problem is "carbon capture and storage" which involves concentrating and compressing carbon dioxide and then storing it in disused oil/gas wells or under the ocean.[3] However, it is far from certain that long-term containment is feasible given the volatile nature of carbon dioxide.

An alternative solution to the problem would be to convert the carbon dioxide at source (taking advantage of the relatively high concentration of carbon dioxide in for example the exhaust stream of a fossil fuel power station) into a chemical for which there is a significant commercial demand.[1,3,4] In order to be feasible, any such procedure would have to occur at atmospheric pressure and near ambient temperature; otherwise the energy required to operate the process will generate more carbon dioxide than is remediated. Unfortunately, the low chemical reactivity of carbon dioxide severely restricts the range of chemical reactions which might be feasible.

One unusually facile reaction of carbon dioxide is its insertion into epoxides to generate cyclic carbonates or a polycarbonate[5–7] as shown in Scheme 1. Ethylene, propylene and butylene carbonates are manufactured commercially and it has been estimated that cyclic carbonates and products derived from them could reduce atmospheric carbon dioxide emissions by up to 120 million tons per year if the economics of the process could be improved.[3] The epoxide co-reactants required for the chemistry shown in Scheme 1 are readily available by the catalytic epoxidation of alkenes, a process which can be achieved using hydrogen peroxide as a green oxidant,[8] and the alkenes can be obtained from waste plastics or biological sources. A large number of homogeneous and heterogeneous catalysts have been reported to induce the reaction between epoxides and carbon dioxide.[7,9] However, almost all of these require elevated reaction temperatures and/or high pressures of carbon dioxide; often the reaction is conducted in supercritical carbon dioxide.



Scheme 1. Synthesis of polymeric or cyclic carbonates from $CO_2$ and epoxides.

Notable amongst the catalysts which have been employed to synthesise cyclic carbonates are metal(salen) complexes[6,10] derived from aluminium,[11] nickel,[11a] copper,[11a,12] zinc,[11a,12] magnesium,[11a] cobalt,[11a,12–14] chromium,[11a,15] or tin.[16] In previous work from our group,[17] we have demonstrated that dimetallic salen complexes display much higher catalytic activity than their monometallic counterparts in asymmetric cyanohydrin synthesis because the two metal ions can each activate one of the two components of the reaction. Polycarbonate and cyclic carbonate synthesis using chromium(salen) complexes are known to be bimolecular,[15] therefore, we reasoned that a suitable dimetallic salen complex might display significantly improved catalytic activity in the reaction between carbon dioxide and epoxides. Here we report the successful accomplish-

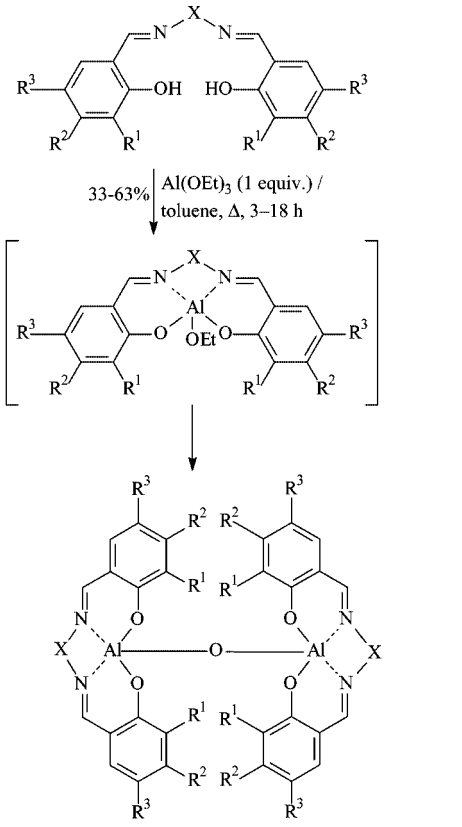
ment of this concept through the development of a dimetallic aluminium(salen) complex which will catalyse the insertion of carbon dioxide into epoxides at atmospheric pressure and ambient temperature.

## Results and Discussion

We selected aluminium as the metal of choice due to its low environmental impact and previous use in cyclic carbonate synthesis, albeit at elevated pressures of carbon dioxide (at least 6 atm).[11] Thus, treatment of a salen ligand with aluminium triethoxide in toluene gave complexes **1a**–**h** as yellow or orange solids in 33–63% yields as shown in Scheme 2. The μ-O atom in complexes **1a**–**h** could be derived from adventitious moisture, by decomposition of ethanol formed during the reaction, and/or from the ethoxy group. Complexes **1a** and **1c** have previously been prepared by a different route[18,19] and used to catalyse asymmetric Michael additions.[19] The X-ray structure of complexes **1c**[20] and **1d**[21] have previously been reported, and the mass spectra of compounds **1a**–**h** confirmed their dimetallic structures (see Supporting Information).

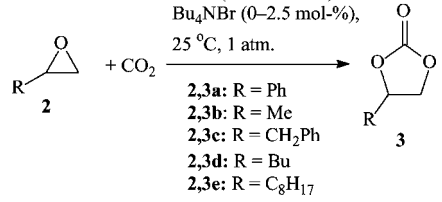
Complexes **1a**–**h** were tested for their ability to catalyse the formation of carbonate **3a** from racemic styrene oxide (**2a**) and carbon dioxide under solvent-free conditions as shown in Scheme 3, and the results are summarised in Table 1. In the absence of a co-catalyst, no reaction occurred, even at 5 atm pressure and elevated temperature (Table 1, Entries 1 and 2). This is in line with previous work using aluminium(salen)-derived catalysts where reaction only occurred in the presence of a tetrabutylammonium halide,[11a–11d] DMAP[11e,11f] or *N*-methylimidazole[11e] co-catalyst. The combination of complex **1a** and tetrabutylammonium bromide was found to display extremely high catalytic activity (Table 1, Entries 4–11). This combination of catalysts displayed unprecedented catalytic activity at 1 atm carbon dioxide pressure and room temperature. Tetrabutylammonium chloride and iodide were also investigated as co-catalysts, but were found to be less effective than the use of tetrabutylammonium bromide. The only previous reports of synthetic studies[11c,13c] on the preparation of cyclic carbonates at ambient temperature required carbon dioxide pressures of 6–15 atm[14,22] or reaction times of up to 7 d.[23] That the observed catalysis was not due solely to the tetrabutylammonium bromide co-catalyst was demonstrated by a reaction run in the absence of an aluminium(salen) complex (Table 1, Entry 3). Although use of just 1.0 mol-% of catalyst **1a** gave a good conversion after 24 h (Table 1, Entry 10), use of 2.5 mol-% was adopted as standard in subsequent studies as this allowed good conversions (62% with 57% isolated yield) to be achieved after just 3 h (Table 1, Entry 8).

Attempts to increase the reactivity of the catalyst by varying the substituents on the aromatic rings or the diamine of the salen ligand were not successful as none of catalysts **1b**–**h** were significantly more active than complex **1a** (Table 1, Entries 12–18). The trend in reactivity appears



**1a**: X = (1*R*,2*R*)-cyclohexyl; $R^1 = R^3 = t$Bu; $R^2$ = H
**1b**: X = (1*R*,2*R*)-cyclohexyl; $R^1 = t$Bu; $R^2$ = H; $R^3 = NO_2$
**1c**: X = $(CH_2)_2$; $R^1 = R^3 = t$Bu; $R^2$ = H
**1d**: X = 1,2-$C_6H_4$; $R^1 = R^3 = t$Bu; $R^2$ = H
**1e**: X = (1*R*,2*R*)-cyclohexyl; $R^1 = R^3$ = H; $R^2$ = OMe
**1f**: X = (1*R*,2*R*)-cyclohexyl; $R^1 = R^2 = R^3$ = H
**1g**: X = (1*R*,2*R*)-cyclohexyl; $R^1 = t$Bu; $R^2 = R^3$ = H
**1h**: X = (1*R*,2*R*)-cyclohexyl; $R^1 = t$Bu; $R^2$ = H; $R^3$ = OMe

Scheme 2. Synthesis of catalysts **1a**–**h**.



Scheme 3. Synthesis of cyclic carbonates **3** using complexes **1a**–**h**.

to be related to the solubility of the catalyst in styrene oxide rather than to any steric or electronic factors, as the highest catalytic activity was observed with the most hydrophobic complexes, and complexes **1d** and **1f** which gave the lowest conversions (Table 1, Entries 14 and 16) did not fully dissolve during the reaction.

Cyclic carbonates derived from other monosubstituted epoxides could also be obtained from the combination of complex **1a** and tetrabutylammonium bromide (Scheme 3), as detailed in Table 2. Propylene oxide was a particularly reactive substrate, and only 1 mol-% of catalyst was necessary to convert it into propylene carbonate in good yield,

[a] Conversions are based on $^1H$ NMR analysis of the reaction mixture.

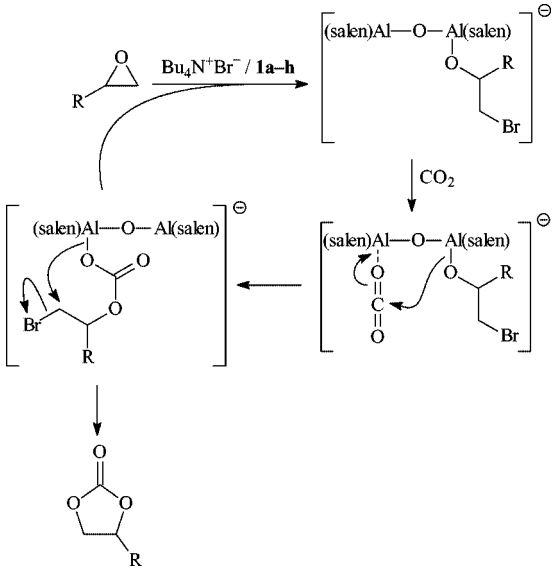
even at 0 °C (Table 2; Entries 1–3). The other monosubstituted epoxides studied were converted into the corresponding carbonates in good to high yield using the standard conditions developed above (Table 2, Entries 4–7), but use of lower amounts of catalyst/co-catalyst seriously reduced the yields in these cases. Disubstituted epoxides were much less reactive with *trans*-stilbene oxide giving just 8% of the corresponding cyclic carbonate after a reaction time of 48 h, whilst cyclohexene oxide and 2-phenylpropylene oxide failed to give any cyclic carbonate under these conditions. No polycarbonate was detected in any reaction catalysed by complexes **1a**–**h** with any of substrates **2a**–**e**, indicating that these complexes display a high selectivity for cyclic carbonate rather than polycarbonate formation.

Table 2. Synthesis of carbonates **3b**–**e** using catalyst **1a**.

| Entry[a] | Epoxide | **1a**/$Bu_4NBr$ [mol-%] | Time [h] | Yield [%][c] |
|---|---|---|---|---|
| 1[b] | **2b** (R = Me) | 2.5 + 2.5 | 3 | 77 |
| 2[b] | **2b** (R = Me) | 1 + 1 | 3 | 40 |
| 3[b] | **2b** (R = Me) | 1 + 1 | 24 | 63 |
| 4 | **2c** (R = $CH_2Ph$) | 2.5 + 2.5 | 3 | 44 |
| 5 | **2c** (R = $CH_2Ph$) | 2.5 + 2.5 | 24 | 99 |
| 6 | **2d** (R = Bu) | 2.5 + 2.5 | 3 | 87 |
| 7 | **2e** (R = $C_8H_{17}$) | 2.5 + 2.5 | 3 | 64 |

[a] All reactions were conducted in the absence of solvent at 1 atm pressure of carbon dioxide and at 25 °C, unless otherwise stated. [b] Reaction at 0 °C. [c] Yield of isolated product obtained after chromatographic purification. Conversions (based on $^1H$ NMR analysis of the reaction mixture) are also given in the Supporting Information.

The exceptional catalytic activity of the catalysts **1a**–**h** is consistent with a mechanism in which both aluminium ions of the complex play a role in activating the components of the reaction as shown in Scheme 4. Thus, ring-opening of the epoxide by bromide results in an aluminium-bound alkoxide. Coordination of carbon dioxide to the second aluminium ion, followed by intramolecular transfer of the alkoxide onto the coordinated carbon dioxide gives an aluminium carbonate which can cyclize to form the cyclic carbonate product and regenerate both catalysts. Work is currently underway to study the kinetics of this process and to detect reaction intermediates to confirm this mechanistic hypothesis.



Scheme 4. Possible mechanism to explain the catalytic activity of complexes **1a**–**h**.

## Conclusions

The dimetallic aluminium(salen) complexes **1a**–**h** display exceptionally high catalytic activity for the conversion of terminal epoxides into cyclic carbonates at room temperature and 1 atm pressure.

# Platinum(II) and Palladium(II) Complexes with *N*-Aminoguanidine

David J. Aitken,*[a] Alberto Albinati,[b] Arnaud Gautier,[a] Henri-Philippe Husson,[c] Georges Morgant,[d] Dung Nguyen-Huy,[d] Jiří Kozelka,*[e] Pascale Lemoine,[f] Sandrine Ongeri,[c] Silvia Rizzato,[b] and Bernard Viossat[f]

**Keywords:** Platinum / Palladium / N ligands / Coordination modes

*N*-Aminoguanidine (Amgu) was examined for its behaviour as a ligand for platinum(II) and palladium(II). Protonated $AmguH^+$ can coordinate platinum as a monodentate ligand bound via the N4 amino group. Deprotonated, electrically neutral Amgu forms chelate complexes with both $Pt^{II}$ and $Pd^{II}$; in these complexes Amgu is coordinated to the metal by the N4 amino group and the deprotonated N1 imino group, forming a five-membered ring. $K[PtCl_3(dmso)]$ reacted with Amgu·HCl to yield a chelate complex with N1 bound *trans* to S, suggesting that an exchange between the N1 and N4 binding sites followed the primary nucleophilic attack of N4 on platinum. Whereas reactions between $K_2PdCl_4$ and Amgu·HCl were rapid and straightforward, $K_2PtCl_4$ was easily reduced to metallic platinum by Amgu·HCl, especially in stoichiometric conditions. Solution NMR and X-ray crystallographic characterization is presented for five new complexes: *trans*-$[PtCl_2(AmguH\text{-}N4)_2]Cl_2\cdot 2^1/_2H_2O$ (**3**), *trans*-$[Pt(Amgu\text{-}N1,N4)_2](NO_3)_2$ (**4**), $[PtCl(Amgu\text{-}N1,N4)(dmso)]Cl\cdot 2H_2O$ (**5**), $[PdCl_2(AmguH\text{-}N1,N4)]$ (**6**), and *trans*-$[Pd(Amgu\text{-}N1,N4)_2]Cl_2$ (**7**).

## Introduction

Cisplatin (*cis*-$[PtCl_2(NH_3)_2]$; cisplatyl®; platinol®; Figure 1) is one of the most successful drugs used currently in cancer chemotherapy.[1,2] Despite numerous efforts to synthesize analogues which would cause less severe side effects, have improved activity profiles, and/or allow the resistance to cisplatin to be circumvented, only three cisplatin analogues have been admitted for clinical use to date, carboplatin,[3] oxaliplatin,[4] and nedaplatin,[5] although none of them has brought about a real breakthrough in cancer chemotherapy. The particular features of the parent drug cisplatin, which distinguish it from its analogues, are its unique hydrogen-bonding capacity and its small size.[6] In this respect, aminoguanidine (Amgu; Figure 1) is an interesting potential bidentate ligand for replacement of the two $NH_3$ ligands, since it is only slightly bulkier and has six N–H bonds oriented in a manner different to those of cisplatin, thus offering a different pattern of strong hydrogen bonds. Amgu is in fact a molecule of considerable biological importance in its own right,[7–9] and its structure has been incorporated into a wide variety of organic compounds displaying diverse pharmacological activities.[10–15] Amgu is a

dibasic compound, which is unstable in the free state; the guanidinium centre has the higher proton affinity (protonation on N1) but a dicationic species (second protonation on N4) is also known.[16–18]

The coordination chemistry of Amgu has been described for a few transition metals. In one of the earliest studies, Thiele[19] described a complex salt of copper with the formula $[(CN_4H_5)_2Cu](HNO_3)_2$, which was later confirmed as the double chelate $[Cu(Amgu)_2](NO_3)_2$.[20,21] Similar square-planar chelate structures have been attributed to complexes of nickel(II).[21,22] Dirhodium(II) tetracarboxylate complexes of general formula $Rh_2(RCOO)_4(Amgu)(H_2O)$ where R = H, $CH_3$ or $C_2H_5$ have been described, in which the presence of a C=N→Rh bond was deduced; no evidence for the coordination of a second nitrogen function was found, although a bridging role for the Amgu ligand was not entirely ruled out.[23] In 1985, the preparation of a platinum(II) complex of Amgu having promising biological activity was reported in a patent.[24] Presumably on the basis of analogy with other diamino ligands, it was assumed that a chelate structure was obtained; no characterisation of the material was described, however.

In order to gain insight into the behaviour of Amgu as a ligand for $Pt^{II}$, particularly with a view to establishing a basis for new antitumour candidates, we undertook an investigation of the synthesis of several $Pt^{II}$-aminoguanidine complexes, and also of related $Pd^{II}$ complexes for comparison.

## Results and Discussion

### Platinum Complexes

In our first experiments, we reacted equimolar amounts of Amgu·HCl and $K_2PtCl_4$ in aqueous solution at ambient temperature for 15 h, according to the patent procedure.[24] In contrast to the literature report, no solid product appeared during this time; instead, small amounts of a black deposit (presumably reduced platinum) appeared on the walls of the reaction vessel. The remaining solution was evaporated and the residue was examined by NMR spectroscopy. Integration of $^1H$ NMR signals of a $[D_7]$dmf solution showed the presence of seven protons, which suggested that the Amgu ligand was protonated. The $^{195}Pt$ NMR spectrum showed one major signal at $\delta$ = –1997 ppm, corresponding to an $NCl_3$ ligand set for square planar platinum(II) species.[25] Minor peaks at $\delta$ = –1631, –2128 and –2218 ppm correspond to $Cl_4$ and two $N_2Cl_2$ ligand sets, respectively. We suspect that one of the latter two constituents was the anticipated chelate structure **2**, but the major species appeared to be a monodentate zwitterionic compound **1** (Scheme 1). N4 is the only nitrogen of Amgu having a lone-pair available to coordinate platinum when N1 of the guanidinium centre is protonated.

Attempts to adapt the reaction conditions in order to obtain chelate **2** met with failure. Neutralization of an aqueous Amgu·HCl solution with one equivalent of KOH immediately prior to addition of one equivalent of $K_2PtCl_4$ simply increased the production of the black deposit. Treatment of an aqueous Amgu·HCl solution with $AgNO_3$ immediately produced a white precipitate of AgCl which was removed by filtration, leaving a solution of Amgu·$HNO_3$. Addition of $K_2PtCl_4$ to Amgu·$HNO_3$ solution (or to Amgu·$HNO_3$ solution + one equivalent of KOH) produced an intractable solution containing the usual black deposit. Treating $K_2PtCl_4$ with two or four equivalents of $AgNO_3$ to replace chloride ions followed by addition of one equivalent of Amgu·$HNO_3$ solution (with or without one equivalent of KOH) gave similar results.

These unsuccessful attempts to isolate a single-chelate ligand complex such as **2** prompted us to investigate the possibility of forming a bis-chelate. In an initial effort, treatment of $K_2PtCl_4$ with two equivalents of Amgu·HCl lead once again to extensive black deposit formation over a 15 h reaction period. However, when an aqueous solution of $K_2PtCl_4$ was treated with 5 equiv. of Amgu·HCl and the solvent was evaporated under reduced pressure over a period of several hours, a yellow crystalline product was formed. Its NMR spectroscopic data in $[D_7]$dmf solution (8 identical N1 and N2 guanidinium protons at $\delta$ = 8.27 and a single $^{195}Pt$ signal at $\delta$ = –2277) and microanalytical data were consistent with the formula *trans*-$[PtCl_2(AmguH\text{-}N4)_2]Cl_2$ (**3**) (Scheme 1); the structure was confirmed by X-ray crystallographic analysis (Figure 2).

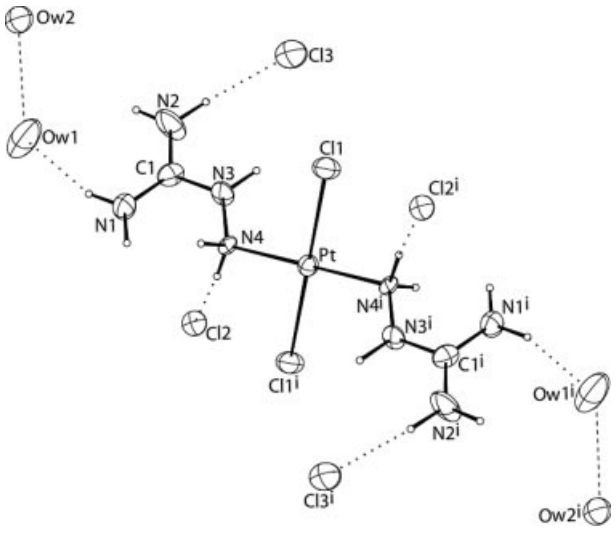

Figure 2. CAMERON plot (50% thermal probability ellipsoids) of the crystal structure of **3**. Selected bond lengths [Å] and angles [°]: Pt–Cl1 2.295(3), Pt–N4 2.064(7), C1–N1 1.295(13), C1–N2 1.283(13), C1–N3 1.350(13), N4–N3 1.389(11), Cl1–Pt–N4 90.8(2), Cl1–Pt–N4i 89.2(2), N1–C1–N2 121.9(10), N1–C1–N3 121.6(9), N2–C1–N3 116.4(10).

In the crystal, the structure is centrosymmetric, so that only half of the molecule is independent, with two Amgu molecules acting as monodentate ligands, coordinating to platinum through the hydrazine-type nitrogen N4, whose geometry and hydrogen atom count clearly indicate $sp^3$ hybridization. Two chlorine atoms complete the inner ligand sphere with a *trans*-geometry, and two chloride ions and 2.5 water molecules per unit cell are located in the crystal. The Pt atom lies on a centre of symmetry. The N1 and N2 atoms of Amgu each bear two hydrogens; one of the N1 hydrogens participates in a hydrogen bond with a water molecule. Hydrogen bonds with chloride counterions are also observed for one hydrogen on each atom N2 and N4. Distances and angles at the platinum centre have usual values, while distances and angles of the Amgu moiety are comparable to those observed for uncomplexed Amgu cations in the solid state.[16,26–28] Distances C1–N1, C1–N2 and C1–N3 have approximately equal values, as should be expected for a delocalized guanidinium system. The Amgu ligand is approximately planar (maximum deviation from the least-squares-plane defined by the atoms C1, N1, N2, N3, and N4 is 0.039(2) Å for N3), confirming that nitrogen N3 is $sp^2$ hybridized. On the other hand, the overall structure of **3** is not planar; the angle between the platinum coordination plane and the mean ligand plane (N1–C1–N2–N3–N4) is 147.4°.

In an effort to make the Amgu ligands of complex **3** behave as chelates, a sample of **3** was treated with 4 equiv. of silver nitrate to precipitate all halide, then with 2 equiv. of base. This induced the slow appearance of colourless crystals, which were identified as *trans*-$[Pt(Amgu)_2](NO_3)_2$ (**4**; Scheme 1) by X-ray diffraction analysis, as shown in Figure 3.

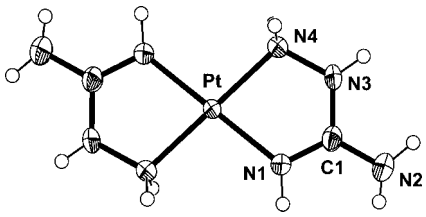

Figure 3. ORTEP plot (50% thermal probability ellipsoids) of the crystal structure of **4**; nitrate counterions are omitted. Selected bond lengths [Å] and angles [°]: Pt–N1 1.996(6), Pt–N4 2.031(6), N1–C1 1.305(10), C1–N2 1.331(10), C1–N3 1.348(10), N4–N3 1.434(9), N1–Pt–N4 80.0(2), C1–N1–Pt 116.2(5), N1–C1–N2 125.8(8), N1–C1–N3 117.0(6), C1–N3–N4 116.6(5), N3–N4–Pt 110.1(4), N2–C1–N3 116.8(7).

The structure consists of centrosymmetric square planar $[Pt(Amgu)_2]^{2+}$ cations and nitrate counterions; the Pt atom lies on a centre of symmetry. The coordination sphere of the Pt atom is formed by two *trans*-oriented bidentate Amgu ligands coordinated through the terminal hydrazine N4 atom and the imine N1 atom, each of which forms a planar five-membered chelate ring with the metal centre (maximum deviation from the $PtN_4$ least-squares plane: 0.04 Å). The small bite angle of Amgu constrains the endocyclic N1–Pt–N4 angle to 80.0(2)° which is slightly less than the angle of 83.1(1)° found for the bis(ethylenediamine) complex $[Pt(en)_2]^{2+}$.[29] The Amgu moiety of **4** is nearly planar (torsion angle N2–C1–N3–N4 4.6°). Distances C1–N1, C1–N2 and C1–N3 are again of approximately equal values, and are comparable with those for protonated uncomplexed ligand.[16,26–28] There is no localised double bond, and the positions of the H atoms and the planarity of the ligand suggest an $sp^2$ hybridisation for all atoms except N4, which remains $sp^3$-hybridised.

The packing of the Pt units gives rise to infinite stacks of square-planar complexes (correlated by a *c* glide plane) with a Pt–Pt separation of 3.332(1) Å. The molecular packing is stabilized by hydrogen-bonding interactions between the cationic complex and the oxygen atoms of nitrate (N–O in the range 2.90–3.28 Å), generating a complex supramolecular three-dimensional network in which all the nitrate oxygens and the N-bonded hydrogens of the ligands are involved (Figure 4). This network demonstrates the hydrogen-bond forming potential of platinum-chelated Amgu.

The unsuccessful attempts to prepare a mono-Amgu complex from $K_2PtCl_4$ prompted us to investigate alternative platinum(II) starting materials. We have previously found $K[PtCl_3(dmso)]$[30] to be more convenient than $K_2PtCl_4$ for the formation of binuclear platinum(II) complexes with rigid diamine ligands.[31,32] Furthermore, $K[PtCl_3(dmso)]$ successfully provided a chelate complex with Gly-His where reaction of this ligand with $K_2PtCl_4$ failed.[33] In the event, when a slight molar excess of Amgu·HCl was added to a solution of $K[PtCl_3(dmso)]$ in water, a solid product began forming after only 90 min. A satisfactory 73% yield of a single chelate complex was obtained; its composition was suggested as [PtCl(Amgu)(dmso)]Cl (**5**) from analytical and spectro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

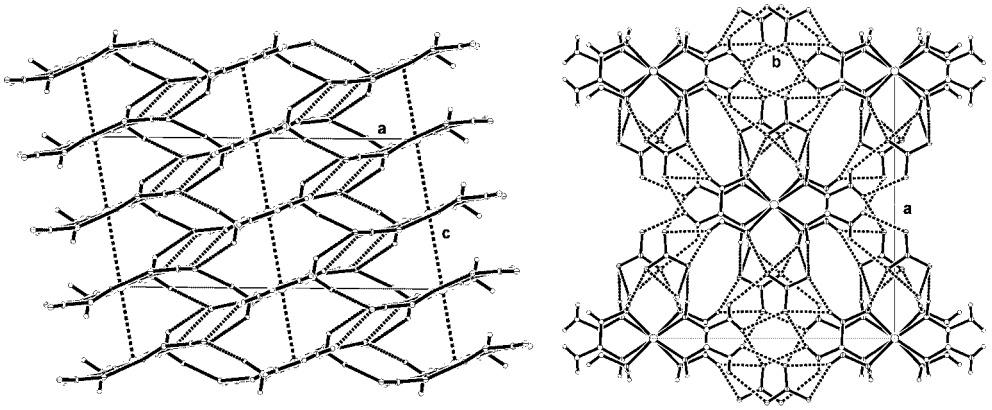

Figure 4. Views along the b (left) and c (right) crystallographic axes of the molecular packing of **4**. The selection criteria for hydrogen bonds (depicted as thin dotted lines) were: $d$(N···O) < R(N) + R(O) + 0.50, $d$(H···O) < R(H) + R(O) –0.12, N–H···O > 100.0°.

scopic data (in particular $^1$H NMR signal integrations and a single $^{195}$Pt NMR signal at $\delta$ = –3134 ppm) and was confirmed by X-ray diffraction (Figure 5).

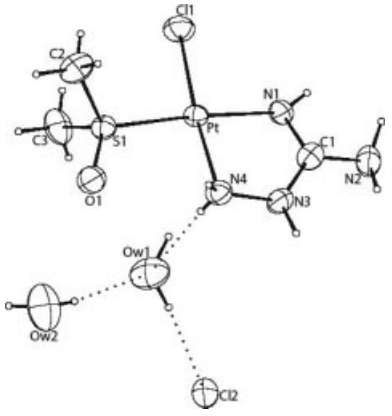

Figure 5. CAMERON plot (50% thermal probability ellipsoids) of the crystal structure of **5**. Selected bond lengths [Å] and angles [°]: Pt–Cl1 2.298(1), Pt–S1 2.208(1), Pt–N1 1.990(4), Pt–N4 2.034(4), C1–N1 1.312(6), C1–N2 1.340(6), C1–N3 1.338(7), N3–N4 1.443(6), N1–Pt–N4 80.6(2), Pt–N1–C1 115.2(3), N1–C1–N2 124.5(5), N1–C1–N3 117.4(4). N2–C1–N3 118.0(5), C1–N3–N4 117.0(4), N3–N4–Pt 109.1(3), Cl1–Pt–N1 93.9(1), Cl1–Pt–S1 92.81(6), S1–Pt–N4 92.8(1).

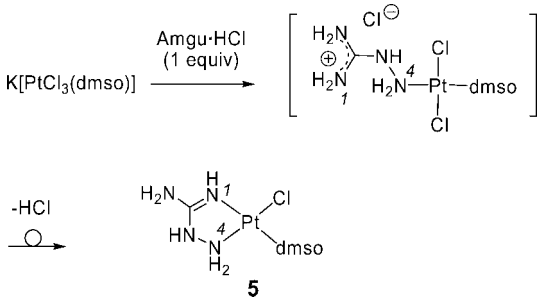
Distances and angles at the platinum centre have typical values. Comparison of the Pt–N1 and Pt–N4 bond lengths for **4** with those observed for **5** reveals no indication for any significahe least-squares-plane of 0.050(2) Å for N4. The crystal packing of this complex involves several hydrogen bonds, in particular N4–H4B···Ow1 [2.996(7) Å, 167°].

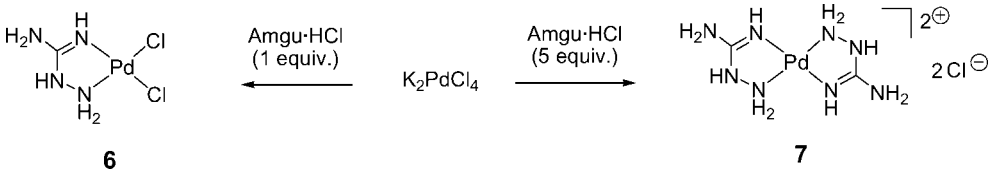
When $[PtCl_3(dmso)]^-$ reacts with $AmguH^+$, the first nucleophilic substitution is expected to occur *trans* to the dmso ligand,[30,34] yielding *trans*-$[PtCl_2$(AmguH-*N4*)-(dmso)$]^+$. Deprotonation (aided by the acidifying effect that N4-coordination to platinum is expected to exert on the N3 imonium group) and chelation would produce the isomer of $[PtCl$(Amgu-*N1*,*N4*)(dmso)$]^+$ with N4 bound *trans* to dmso. The fact that in crystals of complex **5** the N4 atom is coordinated *trans* to $Cl^-$ suggests that a rearrangement has occurred following the first N4 attack, producing the thermodynamically more stable isomer (Scheme 2).



Scheme 2.

## Palladium Complexes

The stoichiometric reaction between $K_2PdCl_4$ and Amgu·HCl proceeded smoothly, in contrast to that with $K_2PtCl_4$, yielding $[PdCl_2$(AmguH-*N1*,*N4*)] (**6**), without any sign of reduction of $Pd^{II}$ (Scheme 3). This difference can be attributed to the standard oxidation potentials for the $M^0$/$M^{II}$ couples which are more negative for platinum than for palladium[35] and to the $10^3$ times faster substitution reaction rates of $Pd^{II}$ compared to $Pt^{II}$.[36] The structure of **6** (Figure 6), indicated by solution state NMR spectroscopic data, was confirmed by X-ray crystallographic analysis. The



Scheme 3.

square planar palladium(II) centre presents usual bond lengths and angles, while the chelating ligand, coordinated through N1 and N4, is virtually planar (torsion angle N1–C1–N3–N4 2°). It is noteworthy that there was no need to liberate the Amgu ligand in its free base form in order to obtain complex **6**; indeed, repeating the reaction in the presence of 1 equiv. of NaOH led to a lower isolated yield (72%) of compound **6**.

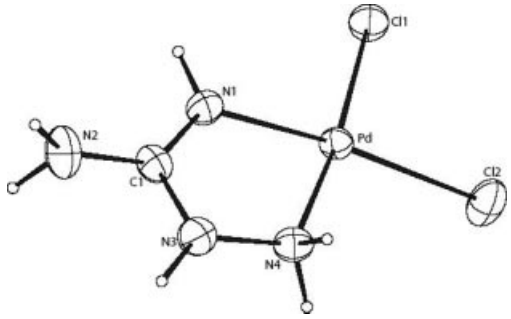

Figure 6. CAMERON plot (50% thermal probability ellipsoids) of the crystal structure of **6**; selected bond lengths [Å] and angles [°]: Pd–Cl1 2.303(2), Pd–Cl2 2.322(2), Pd–N1 1.968(6), Pd–N4 2.019(5), C1–N1 1.307(8), C1–N2 1.339(9), C1–N3 1.347(9), N3–N4 1.407(8), Cl1–Pd–Cl2 93.86(6), Cl1–Pd–N1 92.7(2), Cl2–Pd–N4 92.5(2), N1–Pd–N4 81.0(2), N1–C1–N2 123.7(7), N1–C1–N3 117.9(6), N3–C1–N2 118.3(6).

Treatment of $K_2PdCl_4$ with 5 equiv. of Amgu·HCl in aqueous solution followed by evaporation of the solvent over a period of several hours gave a good yield of *trans*-[Pd(Amgu-*N1*,*N4*)$_2$]Cl$_2$ (**7**) (Scheme 3). Once again, the prerequisite loss of one proton for coordination of N1 proceeded even in the acidic solution; the final pH of the reaction mixture was 1.5. The bis-chelate structure of **7** was confirmed by X-ray crystallographic analysis (Figure 7). The planar palladium(II) centre is centrosymmetric, bearing two Amgu ligands chelated through N1 and N4 in a *trans* fashion. The ligand is again almost planar (torsion angle N1–C1–N3–N4 5°) and the overall structure of the metal complex is very similar to that of **4**. Two chloride ions are located in the crystal packing and are involved in two hydrogen bonds with the complex.

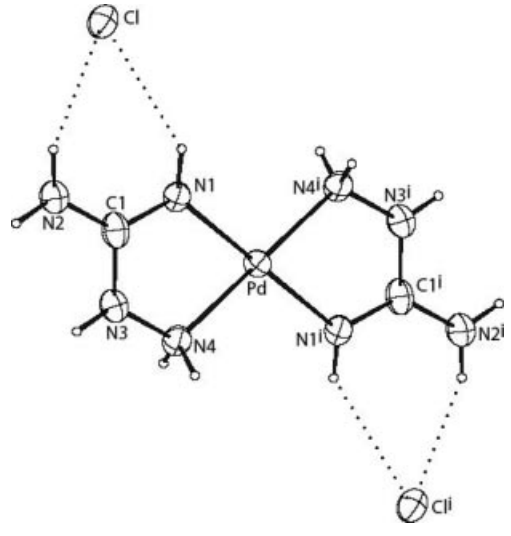

Figure 7. CAMERON plot (50% thermal probability ellipsoids) of the crystal structure of **7**. Selected bond lengths [Å] and angles [°]: Pd–N1 1.977(7), Pd–N4 2.029(7), C1–N1 1.303(11), C1–N2 1.341(12), C1–N3 1.358(11), N3–N4 1.401(9), H1···Cl 3.436(8), H21···Cl 3.288(9), N1–Pd–N4 80.6(3), Pd–N1–C1 115.2(6), N1–C1–N3 117.2(8), N2–C1–N3 116.8(9). N1–C1–N2 125.9(9), C1–N3–N4 116.9(7), N3–N4–Pd 109.7(5), N1–H1···Cl 142, N2–H21···Cl 151.

## Conclusions

*N*-Aminoguanidine has been shown to be a chelator of platinum(II) and palladium(II), coordinating the metal through the hydrazine-type amino N4 group and the imino groupN1. Reaction between K[PtCl$_3$(dmso)] and Amgu·HCl yielded the mono-chelate [PtCl(Amgu-*N1*,*N4*)(dmso)]$^+$ (**5**) in which the N4 atom of Amgu is bound *trans* to Cl$^-$, whereas the initial coordination is expected to place N4 *trans* to dmso. Thus, the activation barrier for breakage of the Pt–N4 bond *trans* to Pt–S does not seem to be high, and the thermodynamically more stable isomer is obtained. For the Pd$^{II}$ complexes, kinetic lability and formation of the thermodynamically more stable isomers was expected in any case.

Amgu is also a reducing agent, and in some cases reactions with Pt$^{II}$ complexes led to reduction to Pt$^0$, whereas the analogous Pd$^{II}$ complex underwent a clean ligand-substitution reaction under the same conditions. K[PtCl$_3$(dmso)] proved to be a starting material less susceptible to reduction by Amgu than $K_2PtCl_4$. Protonated AmguH$^+$ has a single coordination site, the hydrazine-type amino group N4, and we have characterized one platinum complex with two AmguH$^+$ ligands bound in a *trans*-configuration (complex **3**).

The solid-state structures of the compounds studied here show a variety of hydrogen bonding networks. All four nitrogens of the Amgu ligand are able to behave as hydrogen atom donors, suggesting that platinum complexes of this ligand may warrant further investigation for their interactions with DNA. Hydrogen bonding between platinum spectator ligands and DNA are thought to play a role in stabilizing particular conformers in guanine···guanine crosslinks[37] and it has been hypothesized that they may be important for antitumour activity.[38,39]

## Experimental Section

**General Remarks:** Melting points were determined on a Thermovar apparatus and are uncorrected. Electrospray mass spectra were obtained using a Thomson quadrupole instrument equipped with an Analytica atmospheric pressure source. IR spectra were recorded from samples dispersed as nujol mulls between KBr plates on a Perkin–Elmer 1600 Fourier Transform instrument. NMR spectra were recorded on a Bruker AC-300 instrument ($^1$H: 300.13 MHz; $^{13}$C{$^1$H}: 75.43 MHz) and a Bruker ARX-250 instrument ($^{195}$Pt: 53.63 MHz) using standard pulse sequences. Chemical shifts ($\delta$) are given in ppm and are quoted relative to TMS or $Na_2PtCl_6$. Elemental analyses were carried out by Laboratoire de Microanalyse, Insti-

tut de Chimie des Substances Naturelles du CNRS, Gif-sur-Yvette, France. Water was doubly distilled and organic solvents were purified by standard procedures before use. Aminoguanidine hydrochloride, potassium tetrachloroplatinate and potassium tetrachloropalladate were obtained commercially and used without further purification. The salt $K[PtCl_3(dmso)]$ was prepared via the literature procedure.[30]

**$K[PtCl_3(AmguH)]$ (1):** Amgu·HCl (55 mg, 0.5 mmol) was added to a solution of $K_2PtCl_4$ (207 mg, 0.5 mmol) in water (1 mL), and the mixture was stirred at room temp. for 12 h. A dark deposit was removed by filtration and the filtrate was evaporated to leave an amorphous brown residue (220 mg). This sample showed: $^1$H NMR ([D$_7$]dmf): $\delta$ = 7.44 (s, 2 H), 7.95 (s, 2 H), 8.45 (s, 1 H), 8.99 (s, 2 H) ppm. $^{13}C\{^1H\}$ NMR ([D$_7$]dmf): $\delta$ = 157.9 ppm. $^{195}$Pt NMR ([D$_7$]dmf): $\delta$ = –1631 (minor), –1997 (major), –2128 (minor), –2218 (minor) ppm.

***trans*-$[PtCl_2(AmguH\text{-}N4)_2]Cl_2\cdot 2^1/_2H_2O$ (3):** Amgu·HCl (220 mg, 2.0 mmol) was added to a solution of $K_2PtCl_4$ (166 mg, 0.4 mmol) in water (2 mL). The mixture was stirred at room temp. for 15 min, during which time the pH dropped to 2.7, and was then placed in a vacuum desiccator (10 Torr) in the presence of active silica gel and left at room temp. for 15 h. The slow evaporation of water left yellow crystals which were washed successively with water, ethanol, ether, then dried under vacuum (0.5 Torr) to give a first crop of compound **3** (39 mg). The combined washings were evaporated to leave more yellow crystals which were washed with water, ethanol and ether, as before, to give a second crop of compound **3** (62 mg). Combined yield: 52%. M.p. 140 °C. ESMS: $m/z$ = 208 $[M]^{2+}$. IR: $\tilde{\nu}$ = 3379 (NH), 3329 (NH), 3134 (NH), 1674 (C=N), 1607 (NH) cm$^{-1}$. $^1$H NMR ([D$_7$]dmf): $\delta$ = 8.27 (s, 8 H), 8.54 (s, 4 H), 9.31 (s, 2 H) ppm. $^{13}C\{^1H\}$ NMR ([D$_7$]dmf): $\delta$ = 158.7 ppm. $^{195}$Pt NMR ([D$_7$]dmf): $\delta$ = –2277 ppm. $C_2H_{14}Cl_4N_8Pt\cdot 2^1/_2H_2O$ (532.2): calcd. C 4.51, H 3.60, N 21.06, Cl 26.64; found C 4.86, H 3.31, N 20.66, Cl 26.66.

***trans*-$[Pt(Amgu\text{-}N1,N4)_2](NO_3)_2$ (4):** Complex **3** (15 mg; 0.029 mmol) and 4 equiv. $AgNO_3$ (19.7 mg) in 0.5 mL $D_2O$ were stirred at ambient temperature for 3 d. The precipitate was filtered off, the filtrate was treated with 6 μL of 1 N NaOH (ca. 2 equiv.), and the solution placed in an NMR tube. A $^{195}$Pt NMR spectrum recorded overnight did not show any peaks but it the tube colorless crystals appeared. The crystals were identified as $[Pt(Amgu)_2](NO_3)_2$ by means of a structure analysis using X-ray diffractometry.

**$PtCl(Amgu\text{-}N1,N4)(dmso)]Cl\cdot 2H_2O$ (5):** Amgu·HCl (46 mg, 0.42 mmol) was added to a solution of $K[PtCl_3(dmso)]$ (160 mg, 0.38 mmol) in water (1.2 mL). The mixture was stirred at room temp. for 90 min, during which time few crystals started to precipitate. The mixture was then placed in a vacuum desiccator (10 Torr) over $CaCl_2$ and left until one third of the volume remained. The solid residue was filtered, washed with water, then dried under vacuum (0.5 Torr). Compound **5** was thus obtained as yellow-white crystals. Yield: 117 mg, 73%. M.p. 192 °C (dec.). ESMS: $m/z$ = 383 [M – Cl]. IR: $\tilde{\nu}$ = 1635 (C=N), 1553 (NH), 1126 (S=O), 1023 (S=O) cm$^{-1}$. $^1$H NMR ([D$_7$]dmf): $\delta$ = 3.62 (s, 6 H), 6.68 (s, 1 H), 7.16 (s, 2 H), 9.38 (s, 2 H), 10.00 (s, 2 H) ppm. $^{13}C\{^1H\}$ NMR ([D$_7$]dmf): $\delta$ = 43.3, 167.8 ppm. $^{195}$Pt NMR ([D$_7$]dmf): $\delta$ = –3134 ppm. $C_3H_{12}Cl_2N_4OPtS\cdot 2H_2O$: calcd. C 7.93, H 3.55, N 12.33, S 7.06; found C 7.62, H 3.29, N 11.89, S 7.48.

**$[PdCl_2(AmguH\text{-}N1,N4)]$ (6):** Amgu·HCl (55 mg, 0.5 mmol) was added to a solution of $K_2PdCl_4$ (163 mg, 0.5 mmol) in water (2.5 mL). The mixture was stirred at room temp. for 15 min, during which time a precipitate formed. This solid was isolated by filtration and washed with ethanol then ether, and dried under vacuum (0.5 Torr). Compound **6** was thus obtained as brownish-red crystals. Yield: 102 mg, 82%. M.p. 188–190 °C (dec.). IR: $\tilde{\nu}$ = 3423 (NH), 3338 (NH), 3186 (NH), 3106 (NH), 1620 (C=N), 1580 (NH) cm$^{-1}$. $^1$H NMR ([D$_7$]dmf): $\delta$ = 5.06 (s, 1 H), 6.44 (s, 2 H), 7.77 (s, 2 H), 8.59 (s, 1 H) ppm. $^{13}C\{^1H\}$ NMR ([D$_7$]dmf): $\delta$ = 166.1 ppm. $CH_6Cl_2N_4Pd$ (251.4): calcd. C 4.78, H 2.41, N 22.28, Cl 28.20; found C 4.51, H 2.51, N 22.32, Cl 28.16.

***trans*-$[Pd(Amgu\text{-}N1,N4)_2]Cl_2$ (7):** Amgu·HCl (276 mg, 2.5 mmol) was added to a solution of $K_2PdCl_4$ (163 mg, 0.5 mmol) in water (2.5 mL). The mixture was stirred at room temp. for 15 min, during which time the pH dropped to 1.5 and a precipitate formed. The mixture was then placed in a vacuum desiccator (10 Torr) in the presence of active silica gel and left at room temp. for 5 h. The solid residue was washed with a methanol/water mixture (9:1), then dried under vacuum (0.5 Torr). Compound **7** was thus obtained as yellow crystals. Yield: 146 mg, 89%. M.p. 200 °C (dec.). ESMS: $m/z$ = 127 $[M]^{2+}$. IR: $\tilde{\nu}$ = 3392 (NH), 3332 (NH), 3106 (NH), 1639 (C=N), 1560 (NH) cm$^{-1}$. $^1$H NMR ([D$_6$]dmso): $\delta$ = 5.20 (s, 2 H), 6.51 (s, 4 H), 7.93 (s, 4 H), 8.66 (s, 2 H) ppm. $^{13}C\{^1H\}$ NMR ([D$_6$]-dmso): $\delta$ = 165.5 ppm. $C_2H_{12}Cl_2N_8Pd$ (325.5): calcd. C 7.38, H 3.72, N 34.43, Cl 21.78; found C 7.89, H 3.38, N 33.82, Cl 22.86.

**X-ray Crystallographic Studies:** For compounds **3**, **5**, **6** and **7**, diffraction intensity data were collected at $T$ = 292 K using CAD4 Express Enraf–Nonius software[40] with a CAD4 diffractometer equipped with a graphite monochromator [Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å)], and data reduction using RC93.[41] All data were corrected for Lorentz-polarisation effects and empirical absorption correction using DIFABS[42] was applied. The structure was solved by direct methods using SIR-92[43] and refined by least-squares methods on $F$ using CRYSTALS,[44] except in the case of compound **5**, for which the structure was refined by least-squares methods on $F^2$ using SHELXL-97[45] incorporated in the WinGX package.[46] Hydrogen atoms were placed geometrically after each cycle with isotropic parameters constrained to be 1.2 times the $U_{eq}$ of the carrier atoms. Molecules were drawn using CAMERON.[47]

For compound **4**, despite the screening of a large number of crystals, we were unable to find crystals for which the conventional auto-indexing routine of the SMART programme[48] could find a plausible unit cell. Nonetheless, data collection was performed at $T$ = 293 K on a SMART-CCD Bruker diffractometer [Mo-$K_\alpha$ radiation ($\lambda$ = 0.7107 Å)] using the $\omega$-scan method, in the range $2° < \theta < 25°$. Many reflections showed a splitting typical of twin crystals; therefore a twin analysis with the program GEMINI[49] was attempted using about 800 of the collected reflections. This analysis revealed a multiple twinning with at least two different crystal components. It was possible to obtain a substantial number of pure reflections, from the larger of the two identified domains, which allowed the resolution of the structure by traditional Patterson methods. Data from the second component were also integrated, but due to the much worse internal agreement, were neglected. The space group was determined from the systematic absences, while the cell constants were refined with the data reduction software SAINT.[50] The collected intensities were corrected for Lorentz and polarization factors and empirically for absorption using the SADABS program.[51] The structure was refined by full-matrix least-squares on $F^2$ using SHELX-97[52] using anisotropic thermal parameters for all atoms except hydrogens. The hydrogen atoms were located, during the last stage of refinement, in the difference Fourier maps. The molecule was drawn using ORTEP.[53] The search for hydrogen bonds in the packing was carried out using PLATON.[54]

Crystal data, data collection parameters and convergence results are listed in Table 1.

# Gas-Phase Fragmentation Behavior of Vanadium(V) Complexes Containing One Molecule of a $C_4$-Dicarboxylic Acid

**Malgorzata Kaczorowska,[a] Helmut Schwarz,[a] and Detlef Schröder*[b]**

**Keywords:** Carboxylato complexes / Vanadium / Electrospray ionization / Maleic anhydride / Mass spectrometry

Complexes of vanadium(V) with $C_4$-dicarboxylic acids, i.e. maleic, fumaric, and succinic acid, are investigated by means of electrospray ionization (ESI) mass spectrometry. Under soft conditions of ionization, ESI of a diluted solution of $OV(OC_2H_5)_3$ in methanol gives rise to complexes, which are best described by the general formula $[(XCOO)_2VO(C,H_4,O)]^+$ (X = CH, $CH_2$), where the solvent employed delivers the $(C,H_4,O)$ unit, whose components are either attached to vanadium as an intact methanol ligand or are distributed over the other atoms. In the complexes containing maleic or succinic acid, the acids appear to act as chelating ligands with coordination of the vanadium center by two oxygen atoms from two different carboxylic groups. In contrast, the *trans*-configuration in fumaric acid prevents the formation of similar chelate complexes. The fragmentation reactions of the complexes are studied by collision-induced dissociation and labeling experiments. For the vanadium(V) complex derived from maleic acid, a preferential elimination of $CO_2$ is observed, followed by combined losses of $CO_2$, CO, and $C_2H_2$ or alternatively an intact $C_4H_2O_3$ unit, which most likely corresponds to maleic anhydride. Instead, evaporation of water followed by loss of carbon monoxide predominates for the corresponding $V^V$ cation generated in the presence of succinic acid. Due to the fact that the loss of water involves the central methylene groups of succinic acid, a connection to the vanadium-oxide-mediated formation of maleic acid upon partial oxidation of $C_4$-hydrocarbons is proposed.

## Introduction

Transition metals and their oxides play important roles as catalysts exhibiting high selectivities and activities in many processes[1] and therefore are widely used in chemical and petrochemical industries since more than a century. Among the transition-metal oxides, a particularly important class of catalysts are vanadium oxides, which are employed in several selective oxidations and also act as an important support material in numerous technical applications.[2–7]

One of the most complex selective oxidation reactions is the conversion of *n*-butane to maleic anhydride on the surface of vanadyl-pyrophosphate oxide (VPO).[8–10] In this reaction, eight hydrogen atoms are abstracted from the reactant and three oxygen atoms are added to eventually afford maleic anhydride as a product.[11] Although the reaction has been extensively studied during recent years, the mechanistic knowledge is still limited, mainly because of the complexity of the oxidation as well as the fact that none of the potential reaction intermediates, such as butenes or furane, have been observed among the reaction products under standard industrial conditions.[12] Based on studies of reaction kinetics[13,14] and on the observation of intermediates under non-standard conditions,[13,15] the oxidation of *n*-butane to maleic anhydride has been proposed to proceed via two independent pathways.[16] The first is referred to as the olefinic route, which involves a consecutive conversion of *n*-butane to butene and then to butadiene, followed by oxygenation of butadiene to form furane and the subsequent conversion of furane into maleic anhydride.[9] For the olefinic route, the intermediate products were proposed to easily desorb from the oxidic surface of the catalyst. In contrast, on the basis of kinetic data Zhang-Lin et al.[13,14] concluded that the main pathway for the formation of maleic anhydride from *n*-butane proceeds via metal-alkoxide species as key intermediates, which are able to maintain σ-bonds between the organic components and vanadium species present on the catalyst ("alkoxide route"). In this reaction sequence, the intermediate products do not leave the surface until completion of the reaction.[17] Despite numerous studies aimed at gaining insight into the mechanisms, it is still not settled which route is preferred. Further, based on isotopic labeling studies, Chen and Munson[18] presented direct evidence that the conversion of *n*-butane into maleic anhydride on VPO catalysts proceeds via two different mechanistic scenarios. Supported by NMR spectroscopic data, they suggested that both routes may occur simulta-

neously to produce maleic acid, before conversion to the final product maleic anhydride is achieved. Using $^{13}C$ NMR, Chen and Munson recently proposed a single-site organometallic mechanism for the selective oxidation of *n*-butane on VPO catalysts.[19] According to their conclusions, activated butane forms a chelating configuration on the surface of the catalyst by coordination of C(1) and C(4) of butane to vanadium species. The chelating configuration is kept during the reaction sequence until maleic anhydride is formed. The reaction model proposed by Chen and Munson can also account for a number of other previous observations, such as the formation of ethylene as a side product, for example. Control of the formation of side products during the production of maleic anhydride is a non-trivial problem. Various species are formed in different processes and both the presence and ratios of side products and intermediates depend on many factors, for example, the ratio of V/P in the VPO catalysts and the presence of gaseous oxygen.[18] In particular, the formation of maleic anhydride is further associated with partial combustion leading to the formation of carbon oxides. In fact, the variety of intermediates and side products conceivable during the formation of maleic anhydride and their possible reactions with surface species render the complete understanding of the catalytic process rather difficult.

Information about mechanistic aspects in heterogeneous catalysis has been derived mainly from in-situ characterization of the catalysts and from observations of related processes which occur in solution or at liquid-solid or gas-solid interfaces. Recently, gas-phase studies of mass-selected cluster ions have been introduced as a complementary method for gaining information about the elementary steps of such reactions.[20–22]

In this respect, vanadium(V) complexes are of interest because they may be formed as transients in alkane oxidation on vanadium oxides in general and in particular because they have been shown to be involved in the oxidation of *n*-butane to maleic anhydride.[9,23] While most previous gas-phase studies on this topic have addressed the oxidation of hydrocarbons by gaseous vanadium-oxide ions,[21,24–29] here, we approach the problem from the side of the putative products. Accordingly, we investigate the generation and the behavior of vanadium(V) complexes containing one molecule of either maleic acid, fumaric acid, or succinic acid, which contain the $C_4$ skeleton of *n*-butane. The investigation of the dissociation behavior of these complexes may in turn add to the understanding of the processes which occur during the production of maleic anhydride. The ions of interest were produced using electrospray ionization (ESI) mass spectrometry,[30] a technique which permits transfer of ionic complexes into the gas phase directly from solution, with a variable degree of desolvation or fragmentation. Accordingly, ESI has been used for the analysis of inorganic and organometallic systems,[31–33] also including vanadium-oxide clusters.[9,25,26,28,30]

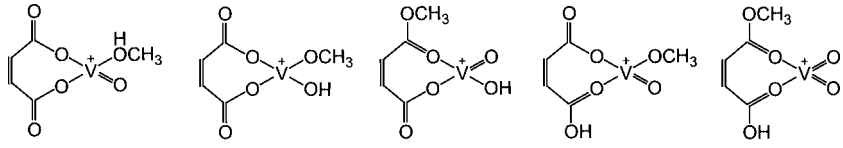
## Results

Electrospray ionization of $OV(OC_2H_5)_3$ dissolved in methanol together with a small amount of maleic acid or succinic acid inter alia leads to the formation of vanadium(V) complexes which formally include a $VO^+$ unit originating from the metal precursor, one (doubly deprotonated) unit of the diacid, and one solvent molecule, i.e. formally corresponding to $[(XCOO)_2VO(C,H_4,O)]^+$ with X = CH or $CH_2$ and the $(C,H_4,O)$ unit stemming from the solvent. The precise connectivity of the complexes is unknown, however; specifically, it is not certain, how the $(C,H_4,O)$ unit is distributed over the rest of the molecule. The first task is accordingly to investigate the types of ionic complexes formed. Given the components of the solutions used in ESI, structures **1**–**5** appear plausible for the case of maleic acid (Scheme 1); note that in addition to structures **1**–**5**, various related arrangements are conceivable (e.g. interchange of coordination from the carbonyl to the ester oxygen atoms).

Before addressing the ion structures, we note that the abundances of the $[(XCOO)_2VO(C,H_4,O)]^+$ complexes strongly depend on the concentrations of $OV(OC_2H_5)_3$ as well as the acids. If the concentration of acid is too high, the positive ion mass spectra are dominated by proton-bound oligomers of the acid itself, such as $[((CHCOOH)_2)_2H]^+$ ($m/z$ = 233) and $[((CHCOOH)_2)_3H]^+$ ($m/z$ = 349) in the case of maleic acid (X = CH). Vice versa, the yields of the desired mononuclear carboxylato-vanadium(V) complexes are also poor when the concentration of triethoxovanadate(V) is too large, due to the formation of polynuclear metal complexes.

### Complexes of Vanadium(V) with Maleic Acid

Under soft ionization conditions, ESI of a triethoxovanadate(V) solution in methanol with a trace of maleic acid provides an abundant signal at $m/z$ = 213 which can be attributed to the above mentioned $[(XCOO)_2VO(C,H_4,O)]^+$ species. According to the structural proposals shown in Scheme 1, the vanadium(V) center is connected with maleic acid through oxygen atoms from both carboxy groups,



Scheme 1.

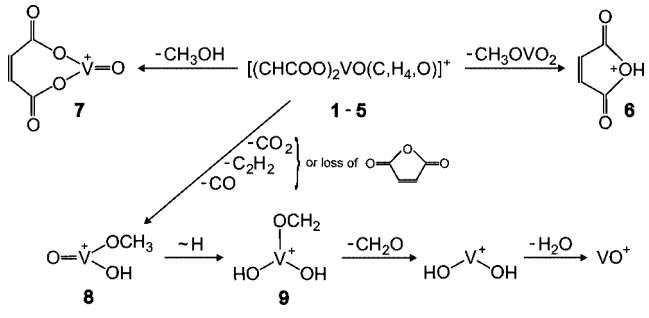
Table 1. Neutral losses (given as mass differences, $\Delta m$) observed upon CID of the mass-selected cations with $m/z$ = 213 and 217 generated by ESI of $OV(OC_2H_5)_3$ and maleic acid in $CH_3OH$ and $CD_3OD$, respectively. Data are given relative to the base peak (100) of the CID products at $E_{lab}$ = 5 eV.

| $\Delta m$ | –18 | –20 | –30 | –32 | –36 | –44 | –58 | –62 | –74 | –76 | –98 | –114 | –117 | –128 | –130 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| $m/z$ 213 | 20 | | 5 | 13 | | 100 | 11 | | 19 | | 50 | 2 | | 6 | |
| $m/z$ 217 | | 9 | | 4 | 10 | 100 | | 15 | | 20 | 60 | | 5 | | 3 |

thereby forming a chelating configuration. The coordination shell is filled by an oxo- and a methanol ligand in the case of structure **1**, a hydroxy- and a methoxy group in structure **2**, an oxo- and a hydroxo group with the methyl group forming an ester with one carboxy unit, i.e. a complex of the singly deprotonated monomethyl ester of maleic acid with a $V(O)(OH)^+$ unit (structure **3**), the reverse arrangement of H and $CH_3$ in structure **4**, and finally H and $CH_3$ are both connected with oxygen atoms of the acid with two oxo ligands at vanadium, structure **5**. In all structures considered, the vanadium is coordinated by four oxygen atoms, and thus **1**–**5** only differ by the location of the hydrogen atom and the methyl group of the $(C,H_4,O)$ unit.

The CID spectrum of the mass-selected ion with $m/z$ = 213 produced upon ESI of a methanolic solution of triethoxovanadate(V) and maleic acid is dominated by the expulsion of neutral $CO_2$ ($\Delta m$ = –44, Table 1). The next intense signal, corresponding to $\Delta m$ = –98, can be assigned to a combined loss of $CO_2$, CO, and $C_2H_2$, suggesting a complete disintegration of the maleic acid attached as a ligand. Alternatively, this dissociation may involve the elimination of maleic anhydride as an intact $C_4H_2O_3$ entity. The latter conjecture is supported by the formation of protonated maleic anhydride (**6**) upon dissociation of the ion with $m/z$ = 213 ($\Delta m$ = –114, Scheme 2). As a result of the formal loss of neutral $C_4H_2O_3$, the cationic fragment ion $[OV(OH)(OCH_3)]^+$ is proposed to be formed (structure **8** in Scheme 2). This ion undergoes subsequent isomerization via hydrogen migration from the methoxo ligand to the oxo group (**8** → **9**) followed by elimination of $CH_2O$ (thus, $\Delta m$ = –128 in total) to yield the dihydroxo vanadium-cation $V(OH)_2^+$, which can then expel water to finally afford the diatomic cation $VO^+$.[34] Minor dissociation pathways correspond to the expulsions of water ($\Delta m$ = –18), formaldehyde ($\Delta m$ = –30), methanol ($\Delta m$ = –32), and the combined losses of methanol and acetylene ($\Delta m$ = –58).



Scheme 2.

If deuterated methanol is used as a solvent, the mass of the precursor ion shifts to $m/z$ = 217, and CID of this species shows a similar fragmentation pattern. The most notable shifts of the mass differences upon ion fragmentation are those expected for the reactions in which neutral methanol or its fragments, such as formaldehyde, are lost. In contrast, the mass difference $\Delta m$ = –98 remains unchanged, consistent with the suggested formation of maleic anhydride without participation of the $(C,H_4,O)$ unit.

With regard to the ion structures **1**–**5**, there are a few, indirect arguments in favor of the presence of isomers **2** and/or **4**. (i) For a methoxo ligand directly attached to a metal core, such as in structures **2** and **4**, there is ample evidence of prevailing redox reactions via β-hydrogen migrations which then provide neutral formaldehyde as a fragment ($\Delta m$ = –30),[35–37] even including cationic catecholatovandadium(V) methoxides closely related to structure **2**.[38] Further, the loss of methanol ($\Delta m$ = –32) can easily occur from **2** and **4** after hydrogen migration to form isomer **1** followed by dissociation. (ii) While consideration of structures **2** and/or **4** provide an explanation for the minor losses of formaldehyde and methanol, respectively, the prevailing decarboxylation upon CID implies the presence of a carboxylato group from which $CO_2$ can be lost easily, which can occur for isomers **1**–**4** bearing carboxylato ligands.[39–42] (iii) Structurally indicative are the competing losses of neutral $CH_3OVO_2$ and neutral $C_4H_2O_3$, which only differ by the location of the proton in the ionic product. Assuming the smallest amount of rearrangement prior to fragmentation, this is consistent with the presence of structures **1**, **2**, and **4**; in case of structure **4**, the loss of neutral methoxovanadium dioxide $CH_3OVO_2$ ($\Delta m$ = –114) to afford protonated maleic anhydride can proceed from without any further hydrogen migrations prior to dissociation. (iv) Structures **3** and **5** derived from the monomethylester of maleic acid appear less likely, because the CID spectrum of the ion with $m/z$ = 213 independently prepared from a solution of $OV(OC_2H_5)_3$ and the monomethyl ester in methanol is dominated by loss of methanol and, in particular, decarboxylation is only a very minor process. (v) Last but not least, structure **1** with a presumably loosely bound methanol unit appears less likely because predominating loss of $CH_3OH$ would be expected upon CID, which is not the case in the experiment. As a general note of caution we add, however, that the assignment of the ion structure is further complicated by the fact that proton migrations may allow for a facile interconversion between the various isomers. Strictly speaking, no unambiguously distinction between isomers **1**–**5** can be made based on the CID experiments, and par-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ticularly the presence of a mixture of ion structures cannot be ruled out. Nevertheless, the CID data reported in Table 1 can be explained by the mechanism depicted in Scheme 2, which is also fully consistent with the labeling data. Further, the loss of methanol is suggested to afford the oxo complex **7**, whose CID spectrum has been recorded independently and is dominated by an expulsion of CO ($\Delta m$ = –28) with minor pathways corresponding to losses of $CO_2$ ($\Delta m$ = –44), two molecules of CO ($\Delta m$ = –56), and maleic anhydride (or $CO_2$, CO, and $C_2H_2$, both $\Delta m$ = –98) to afford bare $VO_2^+$.

Notably, a mixture of $OV(OC_2H_5)_3$ and fumaric acid does not form a corresponding ion with $m/z$ = 213 under ESI conditions, no matter which concentrations of the precursors were used. Specifically, the ESI solutions were prepared by mixing of 0.5 mL of methanolic triethoxovanadate solution (0.5 μL triethoxovanadate in 10 mL methanol) with 0.5 mL of a solution of fumaric acid in methanol (different concentrations from 0.05 to 1 g of fumaric acid in 10 mL methanol were applied). As the same mixing ratios were used successfully in the cases of maleic and succinic acid, we conclude that the *trans*-configuration of fumaric acid prevents the formation of chelate rings with the cationic vanadium core.

### Complexes of Vanadium(V) with Succinic Acid

Similar to the case of maleic acid, ESI of a dilute methanolic solution of succinic acid and triethoxovanadate(V) affords a monocationic complex with $m/z$ = 215, which, by analogy, we attribute to one of the vanadium(V) species **10**–**14** shown in Scheme 3; again, a more definitive assignment cannot be made on the basis of the CID spectra.

The CID spectrum of the mass-selected complex with $m/z$ = 215 (Table 2) is dominated by eliminations of water ($\Delta m$ = –18), methanol ($\Delta m$ = –32), as well as a combined loss of CO and $H_2O$ ($\Delta m$ = –46). Minor dissociation pathways correspond to combined eliminations of $CO_2$ and $H_2O$ ($\Delta m$ = –62), $CO_2$, $H_2O$, and CO ($\Delta m$ = –90), as well as $CO_2$, CO, and $C_2H_4$ ($\Delta m$ = –100); again, the latter fragmentation can also be due to the loss of an intact unit, i.e. succinic anhydride in this case. As a result of these minor dissociation processes, the cation $[OV(OH)(OCH_3)]^+$ is formed which already was observed in the case of the complex with maleic acid (structure **8** in Scheme 2) and which undergoes a subsequent loss of $CH_2O$ (thus, $\Delta m$ = –130 in total). Also similar to the complex derived from maleic acid, an expulsion of $CH_3OVO_2$ concomitant with formation of protonated succinic anhydride is observed as a minor channel ($\Delta m$ = –114).

Table 2. Neutral losses (gives as mass differences, $\Delta m$) observed upon of CID of the mass-selected cations [**A** = $(CH_2COO)_2VO(C,H_4,O)]^+$, **B** = $[(CD_2COO)_2VO(C,H_4,O)]^+$, and **C** = $[(CH_2COO)_2VO(C,D_4,O)]^+$ generated by ESI of $OV(OC_2H_5)_3$ and succinic acid in methanol using either unlabeled reagents or [2,2,3,3-$D_4$]-succinic acid and $CD_3OD$, respectively. Data are given relative to the base peak (100) of the CID products at $E_{lab}$ = 5 eV.

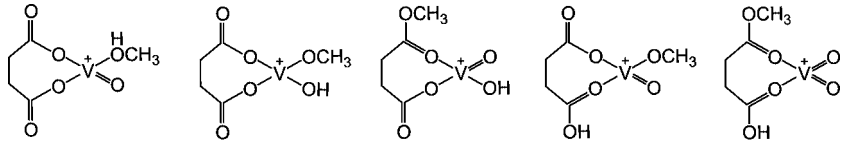
| –163 | | | 27 |
| –164 | | | 17 |

The experimentally observed mass difference $\Delta m$ = –46 can be assigned to the expulsion of CO and $H_2O$, but it may also correspond to the loss of an ethanol molecule formed from the triethoxovanadate precursor. Hence, an additional labeling experiment was performed using $(CD_2COOH)_2$ as the acidic component. From methanolic solution of a mixture of triethoxovanadate(V) and $(CD_2COOH)_2$, the corresponding cation $[(CD_2COO)_2VO(C,H_4,O)]^+$, $m/z$ = 219, is generated under soft ESI condi-

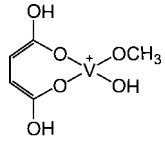


Scheme 3.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

tions. The CID spectrum of mass-selected $m/z$ = 219 shows a mass difference of $\Delta m$ = –48 as the base peak (Table 2), which can thus be only assigned to a combined expulsion of CO and $D_2O$. The mass difference of $\Delta m$ = –47 is accordingly attributed to a combined elimination of CO and HDO. The CID spectrum of $[(CD_2COO)_2VO(C,H_4,O)]^+$ is further characterized by expulsions of HDO ($\Delta m$ = –19), $D_2O$ ($\Delta m$ = –20), methanol ($\Delta m$ = –32), respectively, as well as the combined losses of $CO_2$ and $D_2O$ ($\Delta m$ = –64), $CO_2$ and HDO ($\Delta m$ = –63), $CO_2$, CO, and $C_2HD_3$ ($\Delta m$ = –103), as well as $CO_2$, CO, and $C_2D_4$ ($\Delta m$ = –104). Once more, the combined losses of carbon oxides and ethylene may also be assigned to the expulsion of an intact acid anhydride. In addition to the expulsions of $H_2O$ ($\Delta m$ = –18) and HDO ($\Delta m$ = –19), the CID spectra of the mass-selected ion $[(CH_2COO)_2VO(C,D_4,O)]^+$ generated from $CD_3OD$ solution reveal preferential combined eliminations of CO and $H_2O$ ($\Delta m$ = –46) as well as CO and HDO ($\Delta m$ = –47).

In comparison, the fragmentations of the complexes derived from maleic and succinic acid are closely related to each other. In both cases, the CID spectra are characterized by the eliminations of identical or very similar neutral fragments. In fact, the mechanism proposed in Scheme 2 can describe the dissociation reactions observed in both cases. The main difference is that for the complex derived from maleic acid the major fragmentations are associated with an expulsion of $CO_2$ ($\Delta m$ = –44) and the elimination of $C_4H_2O_3$ ($\Delta m$ = –98), whereas for the complex generated using succinic acid the most abundant fragmentations correspond to the elimination of water ($\Delta m$ = –18) and the combined loss of $H_2O$ and CO ($\Delta m$ = –46). We note in passing that the pronounced loss of water from the complexes derived from succinic acid might be associated to contributions of enol forms as reaction intermediates, e.g. structure **15** (Scheme 4).



**15**

Scheme 4.

### Complexes of Vanadium (V) with Acetic Acid

ESI of triethoxovanadate dissolved in methanol with up to 20% of acetic acid leads to the formation of various complexes containing vanadium as well as acetic acid. For comparison with the complexes derived from the diacids discussed above, we focus on the vanadium(V) complex containing a vanadyl cation, two (deprotonated) molecules of acetic acid, and one methanol unit, i.e. formally $[(CH_3COO)_2V(O)(C,H_4,O)]^+$ ($m/z$ = 217). Upon CID of the mass-selected complex with $m/z$ = 217, the main process corresponds to the expulsion of neutral acetic acid ($\Delta m$ = –60). Minor dissociation pathways are associated with the expulsion of water ($\Delta m$ = –18), methanol ($\Delta m$ = –32), and a combined loss of water and acetic acid ($\Delta m$ = –78). Like for all vanadium(V) complexes studied here, the formation of $VO^+$ ($\Delta m$ = –150) as a terminal fragment is observed at larger collision energies.[43] In marked contrast to the complexes derived from maleic and succinic acid, however, no losses of carbon oxides are observed. Hence, consistent with the results obtained in the case of fumaric acid, the ability of maleic as well as succinic acid to form a chelating coordination to the vanadium center gives rise to a unique reactivity pattern. The fact that we can observe the complex with acetic acid, while the corresponding experiments with fumaric acid were not successful may be attributed to the experimental circumstances. Thus, due to the reasonable volatility of acetic acid, larger quantities of this compound can be added to the solution used in ESI and also gas-phase reactions occurring during the spray process may enhance formation of loosely bound ion/molecule complexes,[44] e.g. the tautomeric structure $[(CH_3COOH)(CH_3COO)V(O)(OCH_3)]^+$ with an intact acetic acid ligand.

### Mechanistic Implications

Most of the results reported here follow general expectations. Thus, among the major dissociation pathways for the $V^V$ cations derived from maleic as well as succinic acid are routes leading to the formation of carbon oxides. Similar decarbonylations as well as decarboxylations of carboxylic acids are known ever since the beginning of organic chemistry, e.g. the Kolbe synthesis. Further, the apparent losses of the maleic and succinic anhydride as intact neutral fragments from the respective complexes is consistent with the way of ion generation, but does not provide further insight with regard to the production of maleic anhydride from butane.

Nevertheless, there is one specific aspect in the fragmentation patterns of the ion derived from succinic acid which deserves particular attention with respect to oxidation catalysis. Specifically, loss of water is found as the most abundant process upon low-energy CID of complex $[(CH_2COO)_2VO(C,H_4,O)]^+$. Deuterium labeling in both ions, $[(CD_2COO)_2VO(C,H_4,O)]^+$ and $[(CH_2COO)_2VO(C,D_4,O)]^+$, demonstrates that the majority of the neutral water molecules lost incorporate H(D) atoms from the methylene groups of succinic acid, in that loss of $D_2O$ ($\Delta m$ = –20) prevails for $[(CD_2COO)_2VO(C,H_4,O)]^+$, whereas expulsion of $H_2O$ ($\Delta m$ = –18) predominates in the case of $[(CH_2COO)_2VO(C,D_4,O)]^+$ (Table 2). This finding implies that the central C–C bond undergoes dehydrogenation, thereby suggesting a possible connection from succinic to maleic acid in vanadium-mediated oxidations of hydrocarbons; an example for an illustration of this perspective is shown in Scheme 5 for the isomer **13** proposed to be involved for the ion formed upon ESI of the solution contained succinic acid, whose dehydration would lead from the $V^V$ species **13** to the $V^{III}$ complex **16**.

Scheme 5.

In a more general perspective of the butane oxidation to maleic anhydride, the obvious importance of chelating coordination by maleic as well as succinic acid supports the formation of surface-bound intermediates in the course of the oxidation reaction. Thus, the suggested alkoxide route or related pathways, which involve the formation of reaction intermediates covalently bound to vanadium surface species, find some analogy in the gas-phase chemistry of these systems.

## Conclusions

Electrospray ionization mass spectrometry is applied for the generation of dicarboxylato-vanadium(V) complexes derived from maleic and succinic acid, respectively. The results suggest that acids which are capable of forming a chelate ligand bring about an efficient coordination with a vanadium(V) center under ESI conditions. Upon collision-induced dissociation of the $V^V$ complexes, the expulsion of $CO_2$ is favored for the complexes derived from maleic acid, whereas a combined evaporation of $H_2O$ and CO is preferred for the corresponding complexes formed from succinic acid. Interestingly, the dehydration observed in the latter case provides a connection between succinic and maleic acid, which has not been considered so far in mechanistic considerations regarding the partial oxidation of $C_4$ hydrocarbons to maleic anhydride on vanadia-based catalysts.

## Experimental Section

The experiments were performed using a VG BIO-Q mass spectrometer of QHQ configuration (Q: quadrupole, H: hexapole) equipped with an electrospray ionization source.[45] The vanadium(V) complexes of interest were generated by ESI of dilute solutions of $OV(OC_2H_5)_3$ and the appropriate acids in methanol (or $CD_3OD$). The solutions were introduced into the ESI source via a silica capillary using a syringe pump at a flow rate of 5 μL/min and a source temperature of 80 °C with nitrogen as nebulizing and drying gas. All data were collected and averaged over at least 20 scans. Collision-induced dissociation experiments were performed with Q1 mass-selected ions using xenon as a collision gas in the hexapole at a pressure of ca. $2 \times 10^{-4}$ mbar and collision energies from $E_{lab}$ = 0–30 eV, while analyzing the ionic products by scanning Q2.

Although many different cations of rather broad stoichiometric compositions are formed from the solutions studied by ESI, we were interested only in complexes containing a single vanadium(V) and one molecule of the corresponding diacid. The number of ligands of the solvated cations is crucially dependent on the cone voltage of the ESI source.[45–48] All vanadium(V) complexes presented here are formed under comparably soft conditions of ionization, i.e. at cone voltages between 20 and 40 V, where multiply ligated ions predominate; at cone voltages above 80 V, diatomic $VO^+$ prevails for all mixtures studied.[43]

# Synthesis and Characterization of Silver-Nanoparticle-Deposited α-$Bi_2Mo_3O_{12}$ Nanorods

**Anil Vithal Ghule,[a] Kalyani Ghule,[a] Shin-Hwa Tzing,[a] and Yong-Chien Ling*[a]**

**Keywords:** Nanoparticles / Ultrasound / Deposition / Nanorods / Surface analysis / Electron microscopy

Silver (Ag) nanoparticles with an average size of ca. 10 nm were uniformly deposited on the surface of α-$Bi_2Mo_3O_{12}$ nanorods by using an ultrasound sonication method. Ultrasonic irradiation of preformed α-$Bi_2Mo_3O_{12}$ spherical nanoparticles (ca. 200 nm) in pyridine resulted in α-$Bi_2Mo_3O_{12}$ nanorods (ca. 100 nm diameter). Further, sonication of the mixture of α-$Bi_2Mo_3O_{12}$ nanorods and $Ag_2O$ in pyridine yielded a nanocomposite of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles and pyridine. Calcination of the nanocomposite at 450 °C afforded pyridine-free α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles. A plausible mechanism is proposed. The crystallized Ag nanoparticles are uniformly deposited on the surface, with bismuth (Bi) as the preferential binding site, as revealed by time-of-flight secondary ion mass spectrometry (TOF-SIMS). Structural, compositional and morphological characterization of the products is carried out by using transmission electron microscopy, energy-dispersive X-ray analysis, scanning electron microscopy, thermogravimetric analysis, X-ray diffraction, X-ray photoelectron spectroscopy and TOF-SIMS.

## Introduction

Since last decade, the science and technology of nanomaterials has created immense interest in their potential technological applications. This has inspired the synthesis of nanomaterials of various shapes and sizes including nanoparticles, nanotubes, nanorods, nanoribbons, nanowires, nanospheres, nanocrystals, nanoflasks and so on, composed of metals, metal oxides, organic, inorganic and bioinorganic compounds, and their hybrid composites.[1] The category of hybrid nanocomposites in general has broadened significantly to encompass a large variety of systems and is a fast-growing area of research. Layered inorganic compounds have been studied for a considerable time as candidates for the generation of nanohybrids. This area is enjoying a resurgence of interest and activity as a result of the exceptional properties that can be realized from these nanocomposites. Because inorganic layered materials exist in great variety with a well-defined ordered intralamellar space, they serve as hosts accessible to guest species and yield interesting hybrid nanocomposites. Significant efforts are focused on the ability to obtain control of the nanoscale structures by judiciously engineering the host–guest interactions through innovative synthetic approaches. This has enabled the synthesis of nanocomposites with a broad range of properties. The properties of nanocomposites depend not only on the properties of their individual parents, but also on their morphology and interfacial characteristics. As the remarkable properties of conventional composites are mainly due to interface interactions, any system that is subjected to critical analysis is of interest. Although selected classes of these composites may be amenable to direct structural characterization by standard crystallographic methods, an important issue in this area is the limited availability of structural and morphological details. Furthermore, nanocomposites also offer the possibility to combine diverse properties, which is impossible within a single material; thus, they promise new applications in many fields.

Bismuth, molybdenum and their oxides have been explored with great interest for technological applications.[2] However, very little attention was focused on binary oxides, despite their wide applicability. Bismuth molybdates (α-$Bi_2Mo_3O_{12}$, β-$Bi_2Mo_2O_9$ and γ-$Bi_2MoO_6$) are popular and widely explored catalysts of commercial importance.[3] Furthermore, bismuth–molybdenum-based oxides have also found applications as pure oxide ionic conductors,[4] as optical[5] and acousto–optical materials,[6] as photoconductors in thin films,[7] and as gas sensors in breath-analyzer devices.[8] Modification of the surface properties plays an important role in the behaviour of these compounds; thus, increased effort has been made to modify their surfaces to create new classes of compounds with different properties.[9]

Ag dispersed on metal oxides is gaining popularity as a catalyst.[10] Moreover, Ag has low hardness and wear resistance, and thus it is often alloyed with other metals to improve its properties.[11] For example, Ag–Bi alloys have gained importance as they find applications in electronics, lead-free soldering, radiotechnics and in the production of

 InterScience © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

coatings exposed to severe conditions, for example, friction under high pressure.[12] The use of Ag films as a buffer layer for the preparation of Bi-2212 tapes on Ni, Ni–Cr, stainless steel and Hastelloy substrates has also been exploited with great interest.[13] Thus, by banking on the information that Ag has a good interaction with Bi, Ag was selected for deposition on α-$Bi_2Mo_3O_{12}$ nanorods in this work. It was also of interest to investigate the mode of interaction and preferred binding site of Ag on the surface of the α-$Bi_2Mo_3O_{12}$ nanorods, which would provide useful information for the design of novel composite materials with improved properties.

Various methods, including wet chemistry techniques, colloid reduction chemical routes, inverse micelle and surfactant utilization, electrochemical and electroless plating, sol-gel and spray pyrolysis etc., have been employed to modify or coat the substrates with noble metals, and complicated apparatus are usually required. In contrast, sonochemistry is a simple alternative technique, which has been exploited extensively to coat nanoparticles and prepare a variety of metal nanoparticles and oxide nanorods.[14,15] Herein, we use a simple ultrasound method[16,17] to deposit Ag nanoparticles on the surface of α-$Bi_2Mo_3O_{12}$ nanorods. To the best of our knowledge, this is the first report of this procedure.

## Results and Discussion

Sonochemistry is gaining importance for its simplicity in the synthesis of nanomaterials and coating nanoparticles on substrates.[18] Power ultrasound effecting chemical changes by cavitation phenomena that involves the formation, growth and implosive collapse of bubbles in liquid, is exploited in this technique.[17] Synthesis of metal nanoparticles by using ultrasound techniques is well reported.[14] Furthermore, sonication of the precursor nanoparticles in the presence of an inorganic support such as α-$Bi_2Mo_3O_{12}$ nanorods provides a means of trapping the nanoparticles by chemical affinity to produce heterogeneous catalysts. Herein it is exploited to deposit Ag nanoparticles on the surface of α-$Bi_2Mo_3O_{12}$ nanorods by using pyridine as a medium.

The motivation for the use of pyridine in this work comes from the extensive studies conducted on pyridine intercalation with bismuth molybdate as substrates, where mostly hydrated forms were used as starting material.[19–21] The use of the hydrated form of bismuth molybdate adds to the controversy and thus the anhydrous form is used in this work, the details of which are discussed elsewhere.[16,22] Moreover, no change in the composition of the substrates was reported or observed by us with the use of pyridine.[16,22] In contrast, sonication of α-$Bi_2Mo_3O_{12}$ in water and $NH_4OH$ (pH of 8) results in the formation of $MoO_3$ nanorods and nanoribbons instead of the formation of α-$Bi_2Mo_3O_{12}$ nanorods. This is confirmed by transmission electron microscopy (TEM) images, energy dispersive X-ray analysis (EDS) spectra and selected area electron diffraction (SAED) patterns (data not shown).[16] This supports the importance of pyridine in α-$Bi_2Mo_3O_{12}$ nanorod formation. Furthermore, it was observed that the intercalation and adsorption of pyridine on the surface of α-$Bi_2Mo_3O_{12}$ nanorods helps to retain its phase without degradation to form mixed phases.[16] Extensive reports on the adsorption of pyridine on metal surfaces also exist,[23] which provides active sites for chemical manipulation of the surfaces. This N-containing aromatic compound has generated particular interest because of its useful physical and chemical properties that are derived from the lone pair of electrons on the N atom. Pyridine molecules are adsorbed on the surface predominantly through metal–N dative bonding and to oxygen as pyridinium or pyridinium oxide.[16,24] The pyridine molecules orient themselves perpendicular to the surface and parallel to each other.

### Electron Microscopy

Scanning electron microscopy (SEM) and TEM are used for morphological characterization of Ag-nanoparticle-deposited α-$Bi_2Mo_3O_{12}$ nanorods and also to investigate the nature of the adherence of the particles to the surface. The SEM and TEM micrographs of Ag nanoparticles that are deposited on α-$Bi_2Mo_3O_{12}$ nanorods obtained after sonication for 60 min are shown in Figure 1a and b, respectively. The Ag nanoparticles, which are about 10 nm in size, deposit uniformly on the surface of α-$Bi_2Mo_3O_{12}$ nanorods as shown in Figure 1b. The inset of Figure 1b shows a TEM image of Ag nanoparticles (ca. 10 nm size) obtained on sonication of $Ag_2O$ in pyridine for 60 min. Figure 1c shows a high-resolution TEM micrograph of a Ag nanoparticle. Crystallinity of the Ag nanoparticles is confirmed by the lattice fringes and lattice spacing, which are characteristic of Ag. The lattice spacing is noted to be 0.235 nm for the (111) plane and is in agreement with earlier reports.[25] To further confirm the crystallinity of the Ag nanoparticles, SAED patterns and EDS spectra were also recorded. The SAED pattern of a single Ag nanoparticle is shown in the inset of Figure 1c. It shows diffused rings with *d* spacing 0.235 [111], 0.144 [220], 0.118 [222] and 0.091 [420], which is characteristic of FCC silver metal and in agreement with the International Center for Diffraction Data file #03-0931. For better comparison, EDS spectra from (i) α-$Bi_2Mo_3O_{12}$ nanorods, (ii) α-$Bi_2Mo_3O_{12}$ nanorods coated with Ag nanoparticles and (iii) a single Ag nanoparticle are recorded as shown in Figure 1d. The presence of silver, bismuth, molybdenum, oxygen and copper is confirmed from the α-$Bi_2Mo_3O_{12}$ nanorods that contain deposited Ag nanoparticles [Figure 1d, spectrum (ii)], whereas the EDS spectrum procured from a single Ag nanoparticle shows the exclusive presence of Ag [Figure 1d, spectrum (iii)].

Experiments with an increased sonication time (90 and 120 min) were also conducted and showed aggregation of Ag nanoparticles possibly because of forced excess collapse of Ag nanoparticles with increased sonication time. The representative TEM micrograph of Ag nanoparticles aggre-

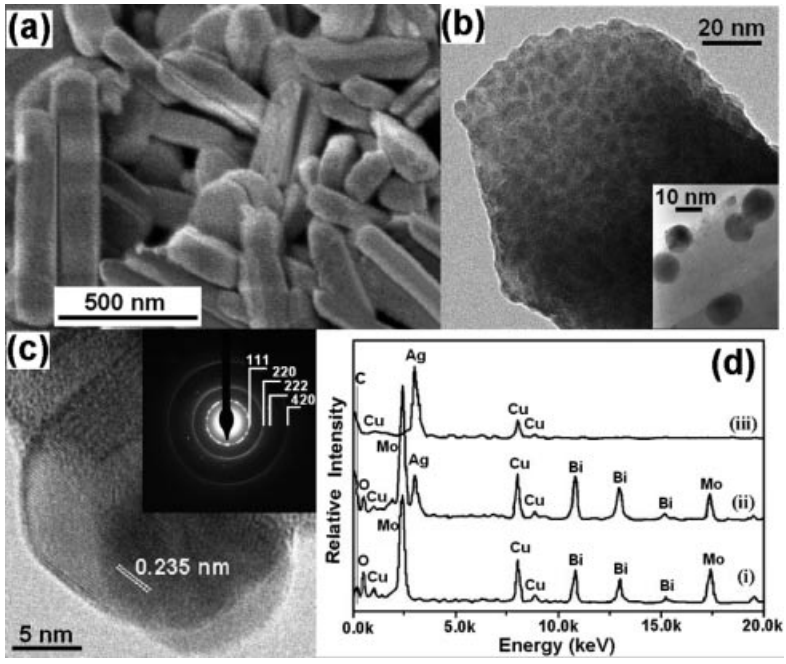

Figure 1. (a) SEM and (b) TEM micrographs of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles obtained after sonication for 60 min. Inset shows Ag nanoparticles (ca. 10 nm) obtained from sonication of $Ag_2O$ in pyridine for 60 min. (c) HRTEM image of a single Ag nanoparticle, indicating the size of ca. 10 nm and showing lattice fringes characteristic of metallic Ag. The inset is the characteristic SAED pattern obtained from the Ag nanoparticle. (d) Representative energy-dispersive X-ray analysis spectra (EDS) of (i) α-$Bi_2Mo_3O_{12}$ nanorods, (ii) α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles showing the presence of Bi, Mo, Ag and O and (iii) a single Ag nanoparticle.

gated on α-$Bi_2Mo_3O_{12}$ nanorods obtained after sonication for 120 min is shown in Figure 2a. When the amount of $Ag_2O$ is varied (200 and 300 mg) with the use of the same amount of α-$Bi_2Mo_3O_{12}$ nanorods (2 g) and a sonication time of 60 min, the number of deposited Ag nanoparticles increased. Figure 2b shows a representative TEM micrograph of one end (tip) of Ag nanoparticles deposited α-$Bi_2Mo_3O_{12}$ nanorods obtained from the use of 300 mg of $Ag_2O$ and a sonication time of 60 min. The Ag nanoparticles appear to be localized in close vicinity with minimal aggregation; however, the particle size is observed to be same (ca. 10 nm) unlike that observed after an increased sonication time (Figure 2a). It appears that subsequently deposited Ag nanoparticles are directed to the voids of the previously deposited nanoparticles (inset in Figure 2b) as a result of pyridine being adsorbed on the surface. It is also observed that the number of free Ag nanoparticles in the product increases with increased amounts of $Ag_2O$. Figure 2c shows a TEM image of randomly deposited $Ag_2O$ nanoparticles on the surface of α-$Bi_2Mo_3O_{12}$ nanorods obtained from vigorous stirring of the mixture of $Ag_2O$ and α-$Bi_2Mo_3O_{12}$ nanorods at 40 °C for 60 min. The size of the deposited and free nanoparticles in the product is larger and the particles are confirmed to be of $Ag_2O$. The XRD pattern obtained from the product shows characteristic peaks at $2\theta$ = 32.85°, 38.10°, 55.01° and 65.57°, which can be indexed to [111], [200], [220] and [311] reflection lines, respectively, of $Ag_2O$ particles (JCPDS 75-1532). Additionally, chains of large $Ag_2O$ particles are also observed in the

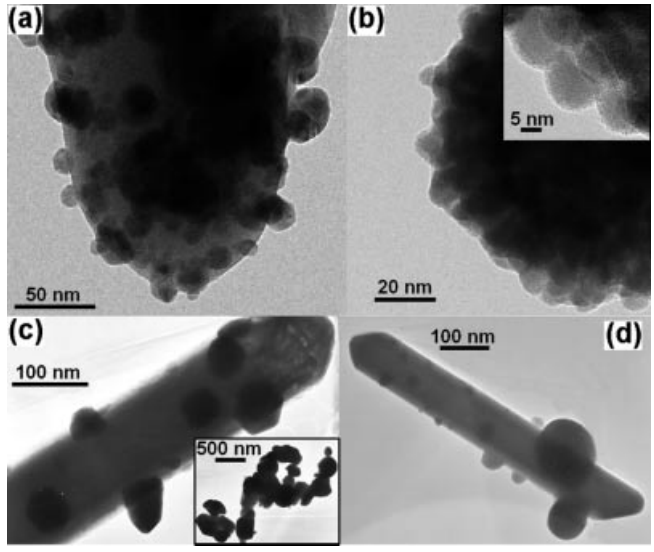

Figure 2. (a) Aggregation and growth of Ag nanoparticles with increased sonication time (120 min; after calcination to 450 °C). (b) TEM micrograph of the tip of a α-$Bi_2Mo_3O_{12}$ nanorod with deposited Ag nanoparticles, showing the nature of deposition and morphology of deposited Ag nanoparticles when 300 mg of $Ag_2O$ was used. Inset shows an HRTEM image. (c) TEM image of randomly deposited $Ag_2O$ nanoparticles on α-$Bi_2Mo_3O_{12}$ nanorods obtained after stirring the mixture of $Ag_2O$ and α-$Bi_2Mo_3O_{12}$ nanorods in pyridine at 40 °C. Inset shows TEM image of a chain of large $Ag_2O$ nanoparticles observed in the product. (d) Representative TEM micrograph of a nanorod obtained on heating the homogenized mixture of $Ag_2O$ and α-$Bi_2Mo_3O_{12}$ nanorods at a controlled rate of 5 °C $min^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

product, as shown in the inset in Figure 2c. These might be due to the fusion of free $Ag_2O$ particles during the calcination process. In contrast, when a homogenized mixture of $Ag_2O$ and α-$Bi_2Mo_3O_{12}$ nanorods is heated to 450 °C in the absence of pyridine and at a controlled heating rate of 5 °C min$^{-1}$, very few $Ag_2O$ particles of varying size are seen bound to the surface of the nanorods, as shown in Figure 2d. Furthermore, the XRD pattern (Figure 4e) obtained from the product shows a change in composition and the pattern is observed to be in good agreement with that of $AgBi(MoO_4)_2$ (JCPDS 32-0999).

### Thermal Analysis

TG-DTG thermograms recorded in the temperature range from 30 to 500 °C with a heating rate of 5 °C min$^{-1}$ in a flow of air at 20 mL min$^{-1}$ using pyridine-intercalated α-$Bi_2Mo_3O_{12}$ nanorods are shown in Figure 3a and 3a′and those of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles are shown in Figure 3b and b′. The TG thermogram (Figure 3a) recorded from pyridine-intercalated α-$Bi_2Mo_3O_{12}$ nanorods shows a weight loss of 5% and can be attributed to the loss of pyridine. The respective DTG thermogram (Figure 3a′), which is derivative of the TG thermogram, shows dips at 187, 245 and 314 °C, which indicates that the weight loss takes place in three steps. The deintercalation process extends up to 400 °C and no further weight loss is observed at higher temperatures. The TG thermogram (Figure 3b) recorded from α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles shows a weight loss of 8.8% due to loss of pyridine. The desorption and deintercalation process extends up to 450 °C, slightly higher than that observed in the earlier thermogram, which might be due to the deposited silver nanoparticles. Moreover, the observed weight loss is also higher and can be attributed to the loss of pyridine adsorbed on Ag nanoparticles in addition to loss of pyridine intercalated in α-$Bi_2Mo_3O_{12}$ nanorods. The respective DTG thermogram (Figure 3b′) shows a sharp dip at 90.1 °C and can be attributed to desorption of pyridine adsorbed on Ag nanoparticles. The two broad dips at 209 and 314 °C might be due to slow elongated deintercalation of pyridine from the product because of the deposited Ag nanoparticles on the surface.

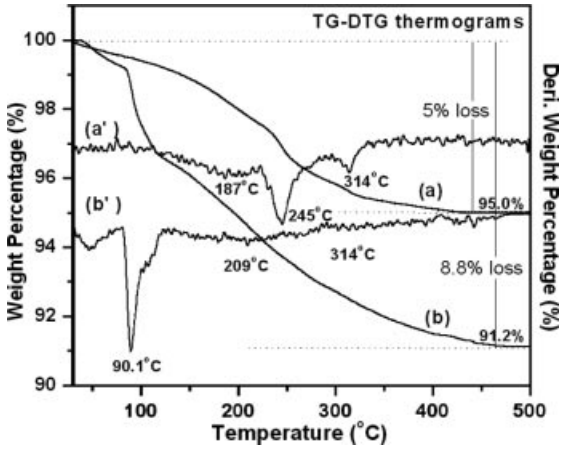

Figure 3. (a) TG thermogram obtained from pyridine-intercalated α-$Bi_2Mo_3O_{12}$ nanorods and (a′) its DTG thermogram. (b) TG thermogram obtained from α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles obtained after sonication for 60 min with 100 mg $Ag_2O$ and (b′) its DTG thermogram.

### X-ray Diffraction

The XRD patterns of the product and intermediates are shown in Figure 4. Representative XRD patterns of $Bi_2Mo_3O_{12}\cdot 5H_2O$ shown in Figure 4a can be indexed to a monoclinic cell with lattice parameters of $a$ = 6.334, $b$ = 11.593, $c$ = 5.777 Å and $\beta$ = 113.166° (JCPDS 41-0361), even though the formula is given to be $Bi_2Mo_3O_{12}\cdot 4.75H_2O$. The XRD pattern is also observed to be in close agreement with that reported by Barnes et al.,[21] even though they claimed the correct formula to be $BiMo_2O_7OH\cdot 2H_2O$. However, our EDS analysis is in accordance with the expected Bi/Mo ratio of 2:3 and also the TG analysis shows weight loss corresponding to five molecules of water.[26] The XRD pattern obtained from spherical nanoparticles of α-$Bi_2Mo_3O_{12}$ phase as shown in Figure 4b is in close agreement with that reported by Li and Cheng[27] and in a literature report (JCPDS 70-1396). The crystal structure of α-$Bi_2Mo_3O_{12}$ phase (scheelite structure) is reported to be monoclinic, trigonal-bipyramidal or distorted tetrahedral with space group $P2_1/c$ and cell parameters $a$ = 7.685, $b$ = 11.491 and $c$ = 11.929 Å and characteristic edge $\beta$ = 115.40°. The XRD pattern of pyridine-intercalated α-$Bi_2Mo_3O_{12}$ nanorods is shown in Figure 4c. It exhibits some similarities with that of pure α-$Bi_2Mo_3O_{12}$ phase (Figure 4b) owing to the use of α-$Bi_2Mo_3O_{12}$ as the starting material for pyridine intercalation. The peaks observed at lower $2\theta$ values are indicative of an increased interlayer region due to pyridine intercalation similar to that reported earlier.[19,21] The peaks appear to be broad, probably because of the reduced particle size and intercalation of pyridine. To the best of our knowledge, the reference database file (JCPDS) does not exist, as most of the researchers used the hydrated form of $Bi_2Mo_3O_{12}$ for pyridine intercalation studies, as discussed in an earlier report.[16] The XRD pattern of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles (Figure 4d) is different from its counterpart in the sense that it shows characteristic peaks at $2\theta$ = 38.04°, 44.22° and 64.36° that could be indexed to [111], [200] and [220] reflection lines, respectively, of FCC Ag particle (JCPDS 04-0783). Traces of less intense peaks indicative of cubic $Ag_2O$ (JCPDS 75-1532) are also observed and can be attributed to the surface oxidation of Ag nanoparticles. The XRD pattern obtained from slow controlled heating of a homogenized mixture of α-$Bi_2Mo_3O_{12}$ nanorods and $Ag_2O$ is shown in Figure 4e. The pattern is in good agreement with that reported for $AgBi(MoO_4)_2$ (JCPDS 32-0999) and different from that observed for α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles. This indicates a change in composition during solid-state reaction as a result of diffusion of Ag atoms, which

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

alter the composition during the heating process. It is interesting to note that the α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles (Figure 4d) do not show diffusion of Ag or change in composition. This might be due to intercalated pyridine preventing the diffusion of Ag, as diffusion and deintercalation processes are expected to occur at the same time during heating.

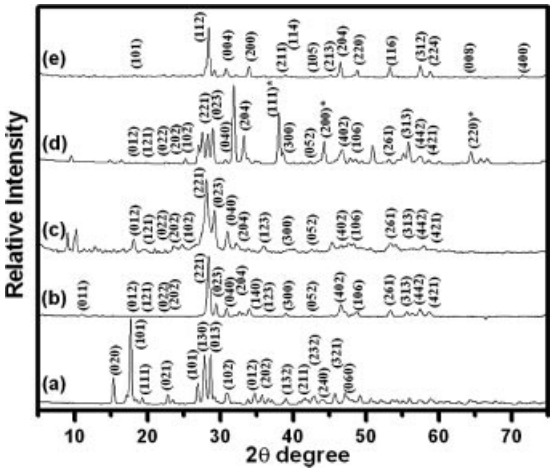

Figure 4. XRD spectra of (a) $Bi_2Mo_3O_{12}·5H_2O$, (b) α-$Bi_2Mo_3O_{12}$, (c) pyridine-intercalated α-$Bi_2Mo_3O_{12}$ nanorods, (d) α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles obtained after sonication for 60 min with 100 mg $Ag_2O$ and (e) product obtained from heating the homogenized mixture of $Ag_2O$ and α-$Bi_2Mo_3O_{12}$ nanorods.

### X-ray Photoelectron Spectroscopy

An XPS surface scan spectrum of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles is shown in Figure 5. It shows characteristic peaks for $Mo3d_{5/2}$ (233 eV), $Mo3d_{3/2}$ (235.8 eV), $Bi4f_{7/2}$ (160 eV) and $Bi4f_{5/2}$ (165 eV). XPS analysis did not detect any modification in the atomic ratio or Mo oxidation state of the Ag-nanoparticle-deposited α-$Bi_2Mo_3O_{12}$ nanorods compared to those of α-$Bi_2Mo_3O_{12}$. However, a considerable shift in the $Bi4f_{5/2}$ peak is observed, probably because of the change in oxidation state of Bi. It is well known that there is a strong interaction between Bi and Ag, and thus, it is expected that the deposited Ag nanoparticles would prefer Bi sites rather than Mo for binding on the surface. Reports on the presence of stable Ag–Bi alloys support our speculation.[12,13] To further confirm this possibility, TOF-SIMS analysis and TOF-SIMS imaging were also conducted.

### TOF-SIMS

Figure 6 shows a positive TOF-SIMS spectrum of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles. A typical TOF-SIMS spectrum in positive-ion mode shows the presence of characteristic ions of $^{98}Mo^+$ ($m/z$ = 98), $MoO^+$ ($m/z$ = 114), $^{209}Bi^+$ ($m/z$ = 209), $^{107}Ag^+$ ($m/z$ = 107) and $^{109}Ag^+$ ($m/z$ = 109) supporting the deposition of Ag nanoparticles on the surface of α-$Bi_2Mo_3O_{12}$ phase nanorods. Additionally, ions corresponding to $Na^+$ and $K^+$ as trace impurities were also observed. The absence of ions corresponding to pyridine indicates the complete removal of pyridine on heating at 450 °C. The high-intensity peaks $^{107}Ag^+$ and $^{109}Ag^+$ confirm the major composition of Ag nanoparticles deposited on the surface of α-$Bi_2Mo_3O_{12}$ nanorods. No more information with regards to the site or nature of binding of the Ag nanoparticles could be extracted and thus TOF-SIMS imaging is also performed.

To investigate the dispersion and binding site of Ag nanoparticles on the surface of α-$Bi_2Mo_3O_{12}$ nanorods, secondary-ion images characteristic of Bi, Mo and Ag were obtained. Figure 7 shows secondary-ion images of individual elemental components (a) $^{209}Bi^+$, (b) $^{98}Mo^+$, (c) $^{107}Ag^+$ and (d) $^{109}Ag^+$ obtained from Ag-nanoparticle-deposited α-$Bi_2Mo_3O_{12}$ nanorods that were sonicated for 60 min. The two-component total-ion images of $^{209}Bi^+$ and $^{107}Ag^+$ (Figure 7e), and $^{98}Mo^+$ and $^{109}Ag^+$ (Figure 7f) were also recorded for comparison. The bright spots in the image indicate the presence of characteristic metal species. Homogen-

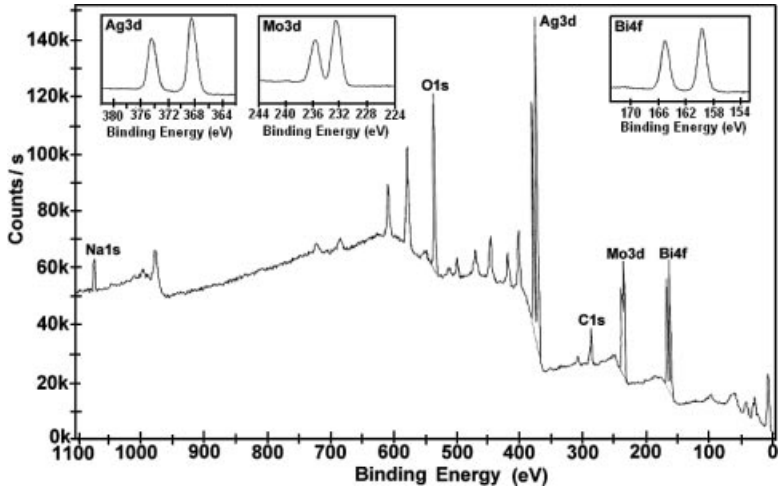

Figure 5. XPS spectrum measured on α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

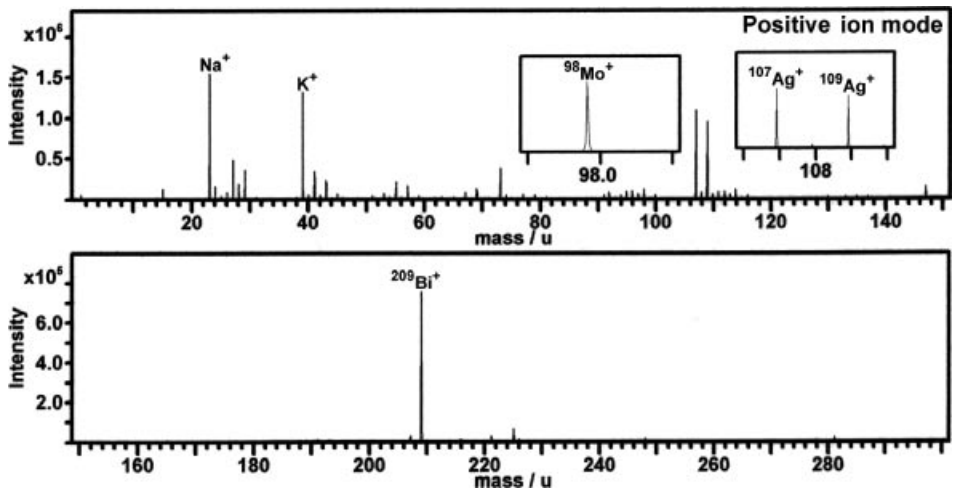

Figure 6. TOF-SIMS spectra of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles in positive-ion detection mode.

eous distribution of Bi and Mo is observed (Figure 7a and b). However, the ion images of $^{107}Ag^+$ and $^{109}Ag^+$ show significant overlap with $^{209}Bi^+$, as depicted from the bright spots in the pattern of Figure 7a, b, d and e. In other words, the image pattern characteristic of Bi and that of Ag are similar. This supports our speculation that Bi might be the preferred site for deposition of Ag nanoparticles on the surface of α-$Bi_2Mo_3O_{12}$ nanorods. The fact that the Ag nanoparticles are dispersed on the surface suggests that Bi is localized on the α-$Bi_2Mo_3O_{12}$ nanorods, maintaining the compositional structure of the nanorods.

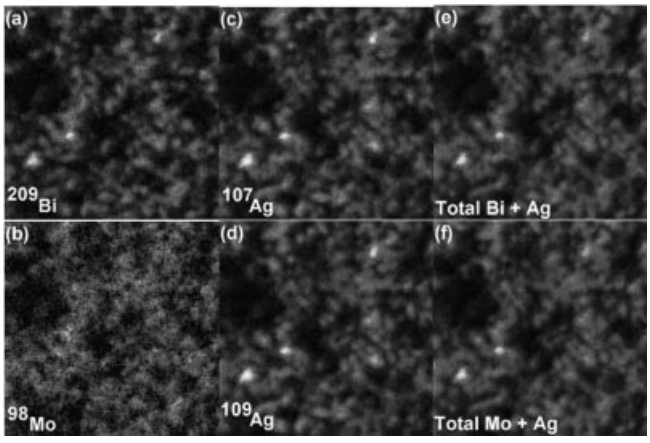

Figure 7. TOF-SIMS images of characteristic elements: (a) $^{209}Bi^+$, (b) $^{98}Mo^+$, (c) $^{107}Ag^+$ and (d) $^{109}Ag^+$ from α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles. Two-component total-ion images of (e) $^{209}Bi^+$ and $^{107}Ag^+$ and (f) $^{98}Mo^+$ and $^{109}Ag^+$.

## Proposed Mechanism

Sonication of $Ag_2O$ in pyridine results in the formation of Ag nanoparticles of about 10 nm (inset in Figure 1b) and subsequently pyridine is adsorbed on the surface. Similarly, synthesis and crystal growth of uniform Ag nanoplates and ring-like gold nanocrystals in *N*,*N*-dimethylformamide solution were reported by using the sonochemical route.[28] The pyridine-adsorbed Ag nanoparticles eventually align in the vicinity of pyridine-adsorbed α-$Bi_2Mo_3O_{12}$ nanorods through π stacking interactions of surface-adsorbed pyridine. The adsorption and intercalation of pyridine is confirmed by thermogravimetric analysis. Further, with the implosive collapse of bubbles in the liquid due to ultrasonic irradiation, the Ag nanoparticles deposit on the surface of the α-$Bi_2Mo_3O_{12}$ nanorods and form a Ag-nanoparticle-deposited α-$Bi_2Mo_3O_{12}$ nanorod and pyridine nanocomposite. The uniform deposition of Ag nanoparticles on the surface might be due to the presence of adsorbed pyridine on the Ag nanoparticles, which would prevent aggregation.

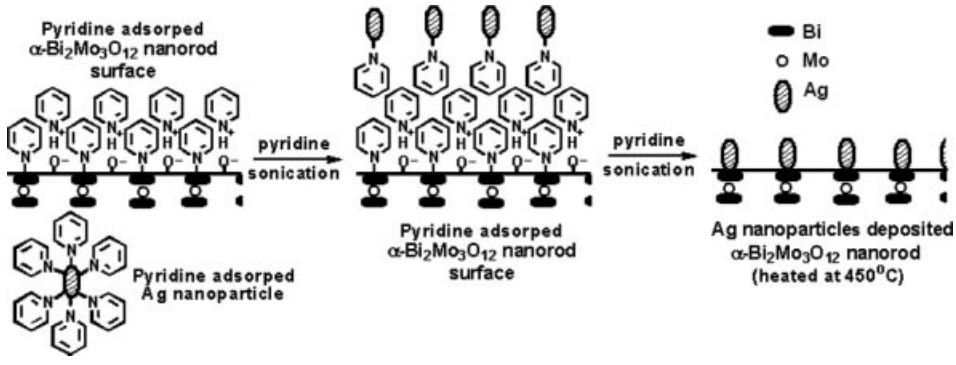

Figure 8. Schematic diagram for the proposed mechanism producing α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

With the use of increased amounts of $Ag_2O$, the deposition of Ag nanoparticles was found to increase; the particles were localized in close vicinity to each other on the surface of the α-$Bi_2Mo_3O_{12}$ nanorods, with less aggregation, and the particles maintained their size. The particles seem to deposit in the voids of the Ag nanoparticles instead of collapsing on the previously deposited Ag nanoparticles, probably because of surface-adsorbed pyridine. However, it was observed that an increased sonication time forces the collapse of the Ag nanoparticles and the formation of aggregates of Ag nanoparticles on the surface. Further, calcination of the nanocomposite at 450 °C results in pyridine-free, Ag-nanoparticle-deposited α-$Bi_2Mo_3O_{12}$ nanorods. A schematic diagram of the proposed mechanism is shown in Figure 8.

## Conclusions

Silver nanoparticles are uniformly deposited on the surface of α-$Bi_2Mo_3O_{12}$ nanorods by using a simple ultrasonication method. The Ag nanoparticles disperse well in pyridine and bind to the surface of nanorods under the influence of the liquid bubbles generated by ultrasound in the pyridine medium, forming a nanocomposite of α-$Bi_2Mo_3O_{12}$ nanorods with deposited Ag nanoparticles, and pyridine. Adsorption and intercalation of pyridine prevents aggregation and diffusion of Ag nanoparticles. By heating the sample at 450 °C, the formation of a pyridine-free nanocomposite with deposited crystalline Ag nanoparticles is observed. Thorough characterization using TEM, SAED, EDS, XRD, XPS and TOF-SIMS was carried out to confirm the presence of crystalline Ag nanoparticles. Additionally, the use of TOF-SIMS imaging could provide information with regards to the possible binding site of the Ag nanoparticles on the surface of the α-$Bi_2Mo_3O_{12}$ nanorods. These Ag-nanoparticle-deposited α-$Bi_2Mo_3O_{12}$ nanorods might find applications in catalysis.

## Experimental Section

$Bi_2O_3$ (Aldrich, 99%), $Na_2MoO_4{\cdot}2H_2O$ (Riedel-de Haën, 99%), $Ag_2O$ (Showa, 98%) and pyridine (Fluka, >99%) were purchased and used without further purification.

Large spherical nanoparticles of α-$Bi_2Mo_3O_{12}$ (ca. 200 nm size) were prepared as discussed in our earlier report.[16,26] The resultant α-$Bi_2Mo_3O_{12}$ product (2 g in each experiment) was further treated with an excess of pyridine (10 mL), and sonicated at 30–40 °C by using a fixed power sonicator (L&R Ultrasonics, Quantrex 140, 150 W, 45 kHz) under a nitrogen atmosphere for 60 min to produce α-$Bi_2Mo_3O_{12}$ nanorods (ca. 100 nm diameter). The excess pyridine was vacuum evaporated, followed by an acetone wash and dried at 60 °C. Compositional and morphological characterization of nanorods was performed thereafter. Thermal treatment (calcination) of the nanocomposite at 450 °C removed the residual pyridine and afforded pyridine-free nanorods of α-$Bi_2Mo_3O_{12}$. The morphological features of the nanorods thus obtained did not vary from those of the intercalated product, similar to those observed in our earlier report.[16] The deposition of Ag nanoparticles on the surface of α-$Bi_2Mo_3O_{12}$ nanorods was conducted by sonicating the mixture of $Ag_2O$ (100 mg) and α-$Bi_2Mo_3O_{12}$ nanorods (2 g) in the presence of pyridine for 60 min. Alternatively, the same results were obtained when α-$Bi_2Mo_3O_{12}$ nanorods formed after sonication in pyridine (from α-$Bi_2Mo_3O_{12}$ nanoparticles) were subsequently treated with $Ag_2O$ (100 mg) and further sonicated for 60 min. The $Ag_2O$ used was free of trace amounts of elemental silver. Experiments with an increased sonication time (60, 90 and 120 min) and the use of different amounts of $Ag_2O$ (100, 200 and 300 mg) were also conducted. Prior to characterization, the final product was washed, dried and calcinated by using the same protocol as mentioned earlier. Furthermore, to prove the effect of ultrasound in uniform deposition of Ag nanoparticles on α-$Bi_2Mo_3O_{12}$ nanorods, a contrast experiment involving controlled heating (5 °C min$^{-1}$) of a homogenized mixture of pyridine-free α-$Bi_2Mo_3O_{12}$ nanorods (2 g) and $Ag_2O$ (100 mg) was conducted. The mixture was heated to 450 °C and cooled naturally. An additional experiment involving vigorous stirring of a mixture of α-$Bi_2Mo_3O_{12}$ nanorods (2 g) and $Ag_2O$ (100 mg) in pyridine (10 mL) at 40 °C for 60 min in nitrogen was also conducted.

A thermogravimetric analyzer (Perkin–Elmer TGA6) was used to record the thermograms in the temperature range 30–500 °C with a heating rate of 5 °C min$^{-1}$ in a flow of air at 20 mL min$^{-1}$. Morphological characterization was performed using a transmission electron microscope (TEM) (Philips, Tecnai 20) working at 200 kV accelerating voltage. A drop of sample suspension, which had been previously dispersed in methanol by ultrasonication, was placed on the Cu microgrid coated with lacey carbon film and dried before microscopy study. Elemental composition was obtained by energy-dispersive X-ray analysis (EDS) (Philips, Tecnai 20). Scanning electron microscope (SEM) (Hitachi-S4700, Noran Instruments) was also employed. The samples in powder form were dispersed on the carbon tape mounted on the sample holder and an epitaxial thin film of platinum was coated (plasma coating technique) on the sample surface to avoid surface charging problems. The X-ray diffraction (XRD) patterns were obtained using Material Analysis and Characterization (MAC) advanced powder X-ray diffractometer (using Cu-$K_\alpha$ = 1.54056 Å radiation) and scanning in the $2\theta$ range between 5° and 100° at a rate of 0.25° min$^{-1}$. An X-ray photoelectron spectrometer (Thermo VG Scientific) with monochromatized Al-$K_\alpha$ X-ray (1486.6 eV) source and a spherical capacitor analyzer with multichannel detector was used for surface composition study. The samples were pressed into pellets and mounted on a standard sample holder using conductive carbon tape. The vacuum in the analysis chamber was maintained at $10^{-9}$ Torr. A total of 10–30 scans were collected from the spot size of 400 μm, with an energy step of 1 eV and pass energy of 100 eV. A detailed surface composition of metal deposits was obtained by analysis of Ag3d, Mo3d, Bi4f, O1s and C1s peaks.

TOF-SIMS (ION-TOF; Munich, Germany) measurements in positive-ion mode were performed for the analysis of α-$Bi_2Mo_3O_{12}$ nanorods and Ag-nanoparticle-deposited α-$Bi_2Mo_3O_{12}$ nanorods. The samples were pressed onto the carbon tape supported on a clean Si wafer. Excess particles were removed by blowing with compressed air such that the layer thickness was minimal, but large enough to prevent exposure of the carbon tape. The primary-ion source was a pulsed $^{69}Ga^+$ source (pulsing current 2.5 pA, and a pulse width of 30 ns) operated at 15 keV with postacceleration of 10 kV. An analysis area of 100 × 100 μm, data acquisition time of 200 s and charge compensation by applying low-energy electrons (ca. 30 eV) from a pulsed flood gun were used for the measurements. The pressure of the main chamber was kept between $10^{-8}$ and $10^{-9}$ Torr. The best resolution obtained was $m/\Delta m$ = 8000.

Calibration of the mass spectra was based on peaks such as $H^+$ (1.007 *m*/*z*), $CH_3^+$ (15.024 *m*/*z*), $C_2H_5^+$ (29.044 *m*/*z*), $Mo^+$ (97.908 *m*/*z*), $^{107}Ag^+$ (106.907 *m*/*z*), $^{109}Ag^+$ (108.906 *m*/*z*) and $Bi^+$ (208.983 *m*/*z*), and the peak areas were normalized to the most intense peak in the spectrum. The generated data were processed using inbuilt IonSpec and Ionimage software.

# Influence of the Synthetic Pathway on the Properties of Oxygen-Deficient Manganese-Related Perovskites

José M. Alonso,[a,b] Raquel Cortés-Gil,[a,c] Luisa Ruiz-González,[c] José M. González-Calbet,*,[a,c] Antonio Hernando,[a,d] María Vallet-Regí,[a,e] María E. Dávila,[b] and María C. Asensio[b,f]

**Keywords:** Mixed-valent compounds / Perovskite phases / Magnetic properties / X-ray absorption near-edge spectroscopy (XANES) / Topotactic reaction

Thermogravimetry, X-ray and electron diffraction and high resolution electron microscopy show that the reduction process from perovskite $La_{0.5}Ca_{0.5}MnO_3$ to brownmillerite $La_{0.5}Ca_{0.5}MnO_{2.5}$ is a reversible topotactic process. Two series of monophasic $La_{0.5}Ca_{0.5}MnO_{3-\delta}$ oxygen-deficient perovskites were stabilized in the $0 \leq \delta \leq 0.12$ range, either from reduction of $La_{0.5}Ca_{0.5}MnO_3$ or oxidation of $La_{0.5}Ca_{0.5}MnO_{2.5}$. Soft X-ray absorption spectroscopy shows that Mn oxidation states differ as a function of the synthetic pathway. Temperature dependence of the magnetization as a function of anionic vacancies concentration at constant doping level are reported together with the evolution of high-resolution O K-edge and Mn L-edge spectra. Our results show dramatic changes in the magnetic behaviour due to the stabilization of different Mn oxidation states.

## Introduction

The influence of cationic substitution and anionic vacancies on the magnetic and conducting properties of transition-metal oxides is a subject of high scientific and technological interest. The main objective of most of these studies is to get a precise understanding of the nominal composition, microstructure and electronic properties of intriguing and complex materials, as in the case of manganese-related perovskites. These materials exhibit a wide range of unusual magnetic properties, which can be modified by changing the doping level due to the long-established ability of the manganese ion to develop several oxidation states. This essential property could be directly related to the number of unpaired electrons in the 3d orbitals, as well as to the magnetic moment associated with each of the Mn ions present in the compound.

Particularly interesting in the $La_{1-x}Ca_xMnO_3$ system is the $La_{0.5}Ca_{0.5}MnO_3$ material, which shows a remarkable coexistence of ferromagnetism and charge ordered (CO) phase.[1–4] At this state, the 1:1 arrangement of octahedrally coordinated $Mn^{3+}$ and $Mn^{4+}$ leads to charge and orbital order at low temperature. However, some authors disagree with this general description.[5–8]

From a magnetic point of view, CO represents the limit between ferromagnetic (FM) metallic (M) and antiferromagnetic (AF) insulator (I) behaviour.[9,10] The shift towards one behaviour or the other is obtained by varying the $Mn^{4+}/Mn^{3+}$ ratio. Thus, when such a ratio verifies $0.20 < Mn^{4+}/Mn^{3+} < 1$, the system is FM-M, whereas values of $Mn^{4+}/Mn^{3+} \geq 1$ give rise to an AF-I system. To modify the concentration of doped holes ($Mn^{4+}$ ions), it suffices to change the $x$ value. However, introducing anionic vacancies can also modify this ratio. Actually, for a small concentration of anionic vacancies, the FM fraction in $La_{0.5}Ca_{0.5}MnO_{3-\delta}$ increases as the CO fraction decreases; this effect yields a net FM behaviour, related in turn to the decrease in the $Mn^{4+}/Mn^{3+}$ ratio.[11,12] Despite experimental effort, a clear relationship between the CO state in $La_{0.5}Ca_{0.5}MnO_{3-\delta}$ and the valence d-configuration of the Mn ions is still missing.

In a previous paper,[13] it was shown that the reduction process of $La_{0.5}Ca_{0.5}Mn^{4+}{}_{0.5}Mn^{3+}{}_{0.5}O_{3-\delta}$ down to an oxy-

gen deficiency $\delta = 0.5$ gave rise to a new oxide with the composition $La_{0.5}Ca_{0.5}MnO_{2.5}$, isostructural to $Sr_2Fe_2O_5$.[14] This reduction process is a topotactic one since the perovskite framework is kept as the oxygen content decreases, that is, the reduction pathway involves ordering of the anionic vacancies through the tetrahedra formation leading to the basic sequence ···OT··· (O = octahedron and T = tetrahedron) of the brownmillerite structure. Different topotactic processes have been already described for other Mn-related perovskite oxides. A well-known example is the case of $CaMnO_3$ which is transformed into $CaMnO_{2.5}$ through the formation of squared pyramids.[15] Another example is the reduction process of $LaMnO_3$ to $LaMnO_{2.75}$ which involves tetrahedra formation.[16] Moreover in $La_{0.5}Ca_{0.5}MnO_{2.5}$, Mn shows an average oxidation state of 2.5 which, according to the structural data,[13] could fit to contents of 75% of $Mn^{2+}$ and 25% of $Mn^{4+}$. Taking this into account, the reduction process $La_{0.5}Ca_{0.5}Mn^{4+}_{0.5}Mn^{3+}_{0.5}O_3 \rightarrow La_{0.5}Ca_{0.5}Mn^{4+}_{0.25}Mn^{2+}_{0.75}O_{2.5}$ obviously involves the coexistence of $Mn^{4+}$, $Mn^{3+}$ and $Mn^{2+}$ for certain oxygen contents. Although rather unusual, the coexistence of a single metallic cation in three different oxidation states within a mixed oxide has been suggested by some authors in $Ln_{1-x}A_xMnO_3$ systems, as a consequence of the $Mn^{3+}$ disproportion.[17] Moreover, such behaviour was previously observed in the oxygen-deficient perovskite $CaLaMgMnO_{6-\delta}$[18] and also in the solid solution goethite-groutite $\alpha$-$Mn_xFe_{1-x}OOH$.[19] In order to confirm this assertion for $La_{0.5}Ca_{0.5}MnO_{2.5}$, which is basic to understanding the magnetic behaviour, further experimental evidence of the manganese oxidation state is clearly needed.

In this sense, it is well known that one of the most useful tools in the study of the atom-resolved unoccupied electronic structure of multi-element compounds is X-ray absorption fine structure spectroscopy. By tuning the photon energy to the threshold of a specific element, the shape of the absorption spectrum by its X-ray absorption near-edge spectroscopy (XANES) gives the electronic structure projected onto this particular site. This projection is usually strongly influenced by the hybridization between the states of different atoms, for complex multicomponent compounds. Because of the site- and symmetry-selective character of XANES, a simultaneous Mn L-edge and O K-edge study can give information about the manganese oxidation state and slight structural changes induced by cationic doping and anionic vacancies. This XANES ability has been previously illustrated by numerous studies on doped manganites.[20–23]

In this work, the Mn oxidation states and the magnetic properties of several $La_{0.5}Ca_{0.5}MnO_{3-\delta}$ materials as a function of the synthetic pathway were studied. In this sense, we prepared samples with the same oxygen content through two different methods: (i) reduction of $La_{0.5}Ca_{0.5}MnO_3$ and (ii) oxidation of $La_{0.5}Ca_{0.5}MnO_{2.5}$. The evolution of high-resolution O K-edge and Mn L-edge X-ray absorption spectroscopy as a function of anionic vacancies concentration at constant doping level is reported.

## Results and Discussion

The powder XRD pattern corresponding to the $La_{0.5}Ca_{0.5}MnO_3$ ($A_{3.00}$) sample is in agreement with a perovskite-like orthorhombic structure[1] [$a$ = 0.5407(2), $b$ = 0.7629(2) and $c$ = 0.5401(2) nm] with space group (SG) *Pnma*. A different situation is observed for the reduced sample, $La_{0.5}Ca_{0.5}MnO_{2.5}$ ($R_{2.50}$), which can be indexed on the basis of a brownmillerite unit cell[14] with parameters $a$ = 0.5361(3), $b$ = 1.6463(9) and $c$ = 0.5340(3) nm (SG *Ibm*2) as a consequence of ordering of anionic vacancies. This structure can be described as an alternating sequence of octahedral and tetrahedral layers along the $b$ direction of the perovskite subcell (Figure 1). The SAED and HREM study is in agreement with this model. Figure 2 shows a SAED pattern and its corresponding HREM image along [10$\bar{1}$] zone axis. An image calculation was performed taking into account the given unit cell and the atomic parameters characteristic of the brownmillerite structure.[13] A good agreement between experimental and calculated image (Figure 2, c) is observed. The charge balance in $La_{0.5}Ca_{0.5}MnO_{2.5}$ corresponds to a Mn average oxidation state of 2.50, which would fit to 50% of $Mn^{3+}$ and 50% of $Mn^{2+}$. This is an unexpected situation since it would involve a smaller $b$ parameter than the experimental one.[13] Considering the ionic radius[24] and the oxygen content, a more plausible situation would be 75% of $Mn^{2+}$ and 25% of $Mn^{4+}$, although obviously an experimental measurement of the oxidation states is required.

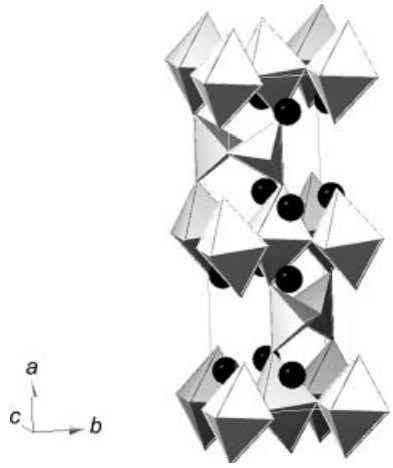

Figure 1. Brownmillerite structural model showing the alternating sequence of octahedral and tetrahedral layers along the $b$ direction.

In order to determine the oxidation state of Mn in these materials, a detailed XANES study was performed. XANES spectra were treated quantitatively by using a factorial analysis taking into account the reference compounds spectra. This method was based on the modelling of the experimental spectra by means of a linear combination of reference spectra. The first step was to analyse well-defined patterns for the different oxidation states that Mn can adopt. In this sense, three different manganese compounds, $MnO_2$, $LaMnO_3$ and $MnCO_3$, exhibiting the three characteristic oxidation states $Mn^{4+}$, $Mn^{3+}$ and $Mn^{2+}$, respec-

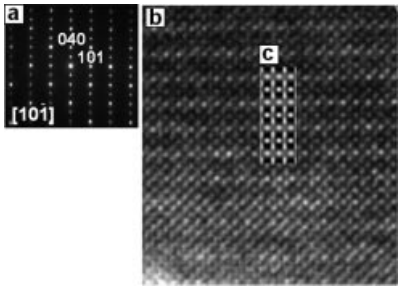

Figure 2. (a) SAED diffraction pattern along [10$\bar{1}$] zone axis; (b) HREM image; (c) calculated image taking into account the brownmillerite atomic positions.

tively, were used. Note that a perovskite-related compound $LaMnO_3$ was chosen as $Mn^{3+}$ standard, while an oxide and a carbonate were selected for $Mn^{4+}$ and $Mn^{2+}$, respectively. This was done because manganese perovskite-related phases only containing $Mn^{4+}$ or $Mn^{2+}$ have not been stabilized in the $La_{1-x}Ca_xMnO_3$ system. In fact, $CaMnO_3$ is always slightly deficient ($CaMnO_{3-\delta}$), leading to a small fraction of $Mn^{3+}$. In this sense, $MnO_2$ was used for $Mn^{4+}$. However, MnO was not used as the standard for $Mn^{2+}$ because $Mn_3O_4$ impurities were detected by magnetic measurements, and thus $MnCO_3$ was considered more appropriate. In addition, we compared these data with already published standards of $Mn^{4+}$[25] and $Mn^{2+}$.[26]

The spectra in Figure 3 (a–c) show the Mn L-edge of the three different manganese compounds. For $MnO_2$ and $LaMnO_3$, the Mn L-edge spectra (Figure 3, parts a and b, respectively) present two main maxima, at 643 and 653 eV, which are accompanied by fine modulation. In fact, the first maximum of the $MnO_2$ spectrum shows a shoulder around 640 eV. Similar features are observed for the Mn L-edge spectrum of $LaMnO_3$. For $Mn^{2+}$, the main feature is a well-defined maximum at 641.2 eV accompanied by two small peaks at 640.5 and 642.7 eV. More pronounced differences are observed in the O K-edge spectra in the 528–538 eV range (Figure 4). Actually, $Mn^{4+}$ shows two peaks: a more intense peak located at 529 eV and a second peak at 531.8 eV. For $Mn^{3+}$, the spectrum shows two broad maxima accompanied by fine modulation, whereas the $Mn^{2+}$ shows only a peak located at 533.5 eV. Once the characteristic energies of $Mn^{4+}$, $Mn^{3+}$ and $Mn^{2+}$ have been established, the XANES spectra of the manganese materials can be more easily interpreted. Parts d and e in Figure 3 show the Mn L-edge XANES spectra of $A_{3.00}$ and $R_{2.50}$ samples, respectively. For $A_{3.00}$, two main peaks and a shoulder (around 641 eV) appear, as observed in $MnO_2$ and $LaMnO_3$, suggesting the presence of both $Mn^{3+}$ and $Mn^{4+}$. $R_{2.50}$ exhibits similar features but the shoulder is transformed into a clear peak around 641 eV, which could be related to the presence of $Mn^{2+}$. In order to get more reliable information, the O K-edge spectra were studied (Figure 4, d and e). For $A_{3.00}$, the spectrum shows a profile characteristic of the coexistence of $Mn^{3+}$ and $Mn^{4+}$, in agreement with the O K-edge of the reference materials. The spectrum corresponding to $R_{2.50}$ (Figure 4, e) shows a clear peak at around 533 eV which, in agreement with the O K-edge of the reference, is related to $Mn^{2+}$. Moreover, two more peaks appear at 529 and 536 eV indicating the presence of $Mn^{4+}$ and $Mn^{3+}$, respectively. The data set of O K-edge and Mn L-edge of $A_{3.00}$ and $R_{2.50}$ XANES spectra were quantitatively treated, taking into account the reference compounds spectra, as depicted in Table 1. The ensemble of these results shows the coexistence of $Mn^{2+}$, $Mn^{3+}$ and $Mn^{4+}$ in $La_{0.5}Ca_{0.5}MnO_{2.5}$, obtained through the topotactic reduction process $A_{3.00} \rightarrow R_{2.50}$.

| $A_{3.00}$ | 50.00 | 50.00 | 0 |
| $R_{2.50}$ | 12.50 | 25.00 | 62.50 |

The oxidation process $R_{2.50} \rightarrow A_{3.00}$ is again a topotactic one involving the transformation of brownmillerite to perovskite.[27] At this point, in order to ascertain whether or not samples with the same composition comprise the same oxidation states, the oxidation mechanism was studied, since different pathways would involve different oxidation states and properties.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

The influence of the anionic vacancies concentration in the crystalline structure and magnetotransport properties of samples obtained by reduction of the $La_{0.5}Ca_{0.5}MnO_3$ material has already been studied by several authors.[11–13] It has been shown that for a small concentration of anionic vacancies the CO state disappears whereas the ferromagnetic character is preserved. In particular, according to Trukhanov et al.,[12] the anionic vacancies originated in the reduction process are randomly distributed and the orthorhombic symmetry of the starting material remains up to $\delta$ = 0.25 ppm. However, when samples are obtained by oxidation of $R_{2.50}$, monophasic materials are only obtained, under the synthetic conditions described in ref.,[25] for $\delta <$ 0.15. For this reason, the comparative study of $R_y$ and $O_y$ materials was limited to the $0 \leq \delta \leq 0.12$ range.

All $R_y$ and $O_y$ materials show very similar X-ray diffraction patterns, which can be indexed on the basis of an orthorhombic symmetry and space group *Pnma*. All samples were characterized by SAED and HREM. Electron diffraction patterns did not show superstructure spots, suggesting that anionic vacancies in both $R_y$ and $O_y$ samples are randomly distributed in the $0 \leq \delta \leq 0.12$ range.

As in the starting materials, a detailed XANES study was performed. Figure 5 (a) shows the Mn L-edge XANES spectra of $R_y$ samples. Taking into account the described reference patterns, spectra peaks suggest the presence of $Mn^{3+}$ and $Mn^{4+}$. The spectra corresponding to the O K-edge (Figure 5, b) show maxima around 529 and 536 eV characteristic of $Mn^{3+}$ and $Mn^{4+}$, respectively. Therefore, the reduction pathway $A_{3.00} \rightarrow R_{2.88}$ only involves the coexistence of both $Mn^{4+}$ and $Mn^{3+}$. Figure 6 (a and b) show the Mn L-edge and O K-edge characteristics, respectively, of the oxidized samples. The presence of $Mn^{3+}$ and $Mn^{4+}$ is observed in Mn L-edge while an additional peak around 533 eV, suggesting $Mn^{2+}$, appears at the O K-edge. The quantification led to the results shown in Table 2, which confirm the presence of $Mn^{3+}$ and $Mn^{4+}$ in the R series while the three oxidation states $Mn^{2+}$, $Mn^{3+}$ and $Mn^{4+}$ coexist in the O series of samples. This table summarizes the fact that both topotactic reactions, $A_{3.00} \rightarrow R_{2.50}$ and $R_{2.50} \rightarrow A_{3.00}$, in the $0 \leq \delta \leq 0.12$ compositional range, occur through different pathways, that is, comprising different oxidation states. It is then clear that materials exhibiting the same composition but different electronic environment for Mn ions were stabilized. This should influence the properties, producing dramatic effects on the magnetic behaviour of these manganites.

| Sample $y$ | $R_y$ % Mn (XANES) | | | $O_y$ % Mn (XANES) | | |
|---|---|---|---|---|---|---|
| | $Mn^{4+}$ | $Mn^{3+}$ | $Mn^{2+}$ | $Mn^{4+}$ | $Mn^{3+}$ | $Mn^{2+}$ |
| 2.95 | 40.00 | 60.00 | 0.00 | 40.00 | 55.00 | 5.00 |
| 2.93 | 38.00 | 62.00 | 0.00 | 39.00 | 54.00 | 7.00 |
| 2.88 | 30.00 | 70.00 | 0.00 | 32.00 | 56.00 | 12.00 |

Figure 7 shows the temperature dependence of magnetization for $A_{3.00}$ and $R_y$ samples. In agreement with previous results,[1,2,13] the fully oxidized $A_{3.00}$ sample shows a first transition from paramagnetic (PM) to almost FM at $T_C \approx 250$ K and a second transition at lower temperature to an AF state associated with CO of the charge carriers ($T_{CO} \approx 190$ K). At low temperature, a magnetization value of 0.25 $\mu_B$/u.f. is still obtained since a 10% FM phase is observed despite the material being chemically homogeneous.[3,28] The reduction process of $A_{3.00}$ material involves the transformation of octahedra into square pyramids, inducing a rapid increase in the magnetization at low tem-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

perature: 0.69 $\mu_B$/u.f at 80 K for $R_{2.95}$. This fact is due to a partial breaking of the CO state which leads to a rapid increase in the FM fraction. A higher anionic vacancies concentration leads to a decrease in the magnetization for $R_{2.93}$ and $R_{2.88}$ samples. Similar behaviour was reported by Trukhanov et al.[12] where a maximum magnetization value was obtained for $y = 2.96$ and a minimum value for $y = 2.80$. This fact suggests that a high concentration of the anionic vacancies breaks the FM ordering due to a decrease in the $Mn^{4+}/Mn^{3+}$ ratio and so allows the possibility of double exchange. In fact, when anionic vacancies content is increased to $\delta = 0.50$, the ferromagnetic interactions disappear as can be observed in the variation of the magnetization curve versus applied magnetic field (Figure 8).

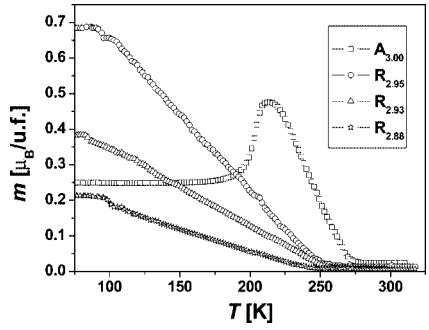

Figure 7. Magnetization vs. temperature corresponding to $R_y$ samples.

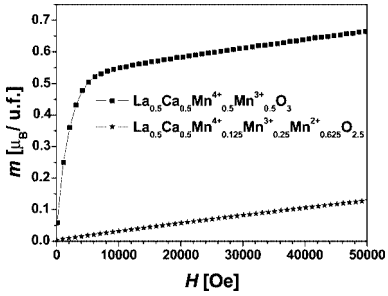

Figure 8. Magnetization vs. applied magnetic field at 5 K.

The magnetic behaviour of $O_y$ materials (Figure 9) is different from that shown by $R_y$ samples despite both composition and structure being identical. These oxidized samples show a first PM-FM transition: the magnetization value being higher for the $O_{2.95}$ sample. At 205 K, this sample shows again, although less markedly, the FM-AF transition associated with the CO observed in $A_{3.00}$. In fact, from 150 K, the magnetization corresponding to $O_{2.95}$ is lower than that observed for $O_{2.93}$, probably due to the presence of a higher number of AF regions in CO state, as a consequence of the lower $Mn^{2+}$ content. The lowest oxygen-content sample, $O_{2.88}$, shows the highest 0.64 $\mu_B$/u.f. magnetization value, which could be related to the absence of CO region in this composition. From the structural point of view,[29] the oxidation process leads to isolated rows of tetrahedrally coordinated $Mn^{2+}$, randomly distributed in an octahedrally coordinated $Mn^{3+}$–$Mn^{4+}$ matrix, which accounts for the double exchange and, as a consequence, for FM behaviour. This situation is different from the one observed in the reduced sample of the same composition and can be explained taking into account structural considerations as well as the corresponding oxidation states. In this sense, for $O_{2.88}$ the FM ordering is locally broken due to the anionic vacancies concentrated around $Mn^{2+}$, whereas for $R_{2.88}$ it is associated with the vacancies around $Mn^{3+}$. In this last case, the number of Mn ions accompanied by a vacant is double than that in $O_{2.88}$ and, therefore, is also twice the number of positions where the double exchange is broken, leading to a lower magnetization value.

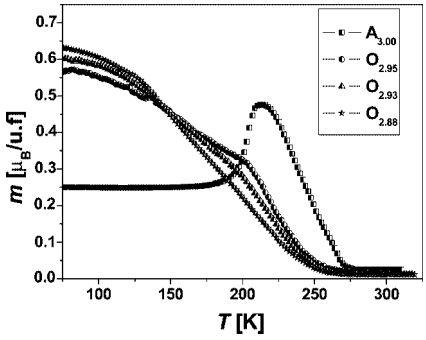

Figure 9. Magnetization vs. temperature corresponding to $O_y$ samples.

## Conclusions

The described results clearly show that the synthetic conditions play an important role in the stabilization of Mn oxidation state in perovskite-related materials. Numerous papers[11–13] have been devoted to studying the influence of an oxygen content change on the magnetic properties of these manganites. Up to now, it has been considered that the introduction of anionic vacancies only affects the $Mn^{4+}/Mn^{3+}$ ratio. We have shown that, as a function of the synthetic pathway, $Mn^{2+}$ can also be stabilized, leading to materials with Mn in three oxidation states.

## Experimental Section

Two materials with the composition $La_{0.5}Ca_{0.5}MnO_3$ ($A_{3.00}$) and $La_{0.5}Ca_{0.5}MnO_{2.5}$ ($R_{2.50}$) were initially prepared. The starting material, $A_{3.00}$, was prepared by solid-state reaction of stoichiometric amounts of $La_2O_3$, $CaCO_3$ and $MnO_2$ at 1400 °C in air for 110 h. $La_{0.5}Ca_{0.5}MnO_{2.5}$ was obtained under controlled reduction of the $La_{0.5}Ca_{0.5}MnO_3$ sample. The reduction process was performed in a CAHN D-200 electrobalance, equipped with a furnace and a two-channel register, by heating the starting material at 630 °C under $H_2$ (200 mbar) and He (300 mbar) at 6 °C min$^{-1}$. Once a desired weight loss was attained, the sample was annealed at 630 °C, under He, for 24 h to facilitate a more homogeneous distribution of anionic vacancies. The oxygen content can be determined within $\pm 10^{-3}$ for a sample of total mass about 100 mg. Oxygen content

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

(as determined in this reduction process) and cationic composition of both materials (as determined by atomic absorption, plasma source emission spectroscopy and electron probe microanalysis) are in agreement with the nominal composition.

On the other hand, two series of samples $La_{0.5}Ca_{0.5}MnO_{3-\delta}$ were prepared by two different synthetic routes: (i) samples $R_y$, obtained by reduction of $La_{0.5}Ca_{0.5}MnO_3$ and (ii) samples $O_y$, after oxidation of $La_{0.5}Ca_{0.5}MnO_{2.5}$ until reaching, in both cases, the desired oxygen content $y$ ($y = 3 - \delta$). Reduced $R_{2.95}$, $R_{2.93}$ and $R_{2.88}$ samples were obtained from $A_{3.00}$ under $H_2$ (200 mbar) and He (300 mbar) around 450 °C, whereas oxidized $O_{2.95}$, $O_{2.93}$ and $O_{2.88}$ materials were obtained from $R_{2.50}$ under $O_2$ (100 mbar) and He (400 mbar) around 170 °C. Both series were synthesized in an electrobalance allowing rigorous control of the oxygen content.

Powder X-ray diffraction (XRD) was performed by using a Philips X'Pert diffractometer with Cu-$K_\alpha$ radiation. Selected area electron diffraction (SAED) was performed by using a JEOL 2000FX electron microscope fitted with a double tilting goniometer stage (±45°), and high resolution electron microscopy (HREM) was carried out with a JEOL 3000FEG electron microscope fitted with an Oxford LINK EDS analyser. The sample was ultrasonically dispersed in 1-butanol and then transferred to holey carbon-coated copper grids. Magnetic properties were obtained using a LDJ vibrating sample and Quantum Design SQUID magnetometers in the temperature range 5 to 350 K under applied fields up to 5 T. Magnetic measurements versus temperature (5–350 K) were performed under field cool conditions in a 1000 Oe applied magnetic field. Magnetization measurements versus magnetic field (0–5 T) were carried out at 5 K.

Both Mn L-edge and O K-edge XANES measurements were performed using the PGM monochromator of the SU8 undulator-beamline at LURE. The spectra were collected in the total electron yield mode measuring the sample current. The energy resolution at the O K-edge and Mn L-edge X-ray absorption edge, around 530 and 643 eV was better than 0.5 and 0.6 eV, respectively. The surface sensibility of the XANES total yield technique was evaluated for these particular samples, recording the same absorption spectra by using the photoelectron effect. In this case, the detector was the photoelectron current recorded at the analyser. As the excited electrons should leave the solid to be collected at the vacuum, this recording mode is particularly sensible to the surface. A close comparison of XANES spectra recorded by both methods, evidences that surface effects can be ignored. The base pressure in the experimental chamber was in the low $10^{-10}$ mbar range. The samples were scraped in situ with a diamond file to remove surface contamination. Before every experiment, the samples were refreshed in order to avoid the formation of any stable carbonate. High level of sample cleanliness was guaranteed by synchrotron radiation core level photoemission continuous checking throughout the experiment. In particular, the evolution of the shape and intensity of the O K-edge and C K-edge core levels were monitored before and after the absorption measurements. As the valence band states near the Fermi level have shown to be very sensitive to external agents and spurious contamination, this kinetic energy range was monitored for all investigated samples.

# Controlled Stabilization and Flocculation of Gold Nanoparticles by Means of 2-Pyrazin-2-ylethanethiol and Pentacyanidoferrate(II) Complexes

**Sergio H. Toma,[a] Juliano A. Bonacin,[a] Koiti Araki,[a] and Henrique E. Toma*[a]**

**Keywords:** Aggregation / Colloids / Semi-empirical calculations / Raman spectroscopy / UV/Vis spectroscopy / Charge transfer

2-Pyrazin-2-ylethanethiol (PZT) interacts with gold nanoparticles (AuNps) and pentacyanidoferrates, providing a suitable bridging ligand for the exploitation of the coordination chemistry involved in the stabilization of the colloidal solutions and in the controlled formation of aggregates in the presence of dimethyl sulfoxide. The electronic and vibrational spectra of the molecules have been investigated and discussed based on DFT and ZINDO/S theoretical calculations. The PZT-modified AuNps exhibit strong SERS, coherent with the electromagnetic enhancement mechanism. In contrast, the charge-transfer mechanism seems to predominate in the Raman spectra of the $[Fe(CN)_5PZT]^{3-}$-modified gold nanoparticles.

## Introduction

Gold nanoparticles (AuNps) exhibit interesting properties associated with the surface plasmons, allowing a wide range of applications in chemistry, biology, and nanotechnology.[1–4] Most applications require their stabilization as a colloidal solution by means of surface modification with electrically charged species, such as citrate ions, or by using long-chain alkane thiols and detergents.[1–3,5,6] Another method is based on the coordination chemistry analogy between the gold nanoparticles and the transition-metal complexes. According to this approach, the stabilization of the gold nanoparticles can be conveniently performed by means of multifunctional bridging ligands, such as those containing thiol groups, capable of simultaneously binding transition-metal ions and the gold surface atoms.[7] The attractive point of this approach is the possibility of exploiting the controlled charge stabilization promoted by the metal complexes, while incorporating their characteristics and properties into the modified nanoparticles.

Pentacyanidoferrate(II) ions are unique candidates for this purpose, because of their high ionic charges, and suitable kinetic and thermodynamic behavior. Such species have been extensively used to probe the binding affinity of specific donor atoms towards iron ions.[8] This is justified, since the cyanido ligands in the $[Fe(CN)_5]^{3-}$ group are substitution-inert, leaving only one coordinating site for interacting with a specific donor atom of a multifunctional ligand (L).[8,9] On the other hand, the chemical properties of the products, $[Fe(CN)_5L]^{3-}$, are strongly dependent on the nature of L. For instance, pentacyanidoferrate(II) ions show a high affinity for N-heterocycles, amino acids and S-containing ligands, such as sulfoxides, thioethers, and thioamides.[8–16] Interestingly, the affinity of the pentacyanidoferrate(II) ions for thiol groups is relatively small,[7] in contrast to their high affinity for strong π-acceptor ligands, such as pyrazine.[8] Therefore, by using the 2-pyrazin-2-ylethanethiol (PZT) ligand, a preferential binding of the $[Fe(CN)_5]^{3-}$ complex to the pyrazine moiety is expected, leaving the SH group available for interaction with the gold nanoparticles, as illustrated in Figure 1.

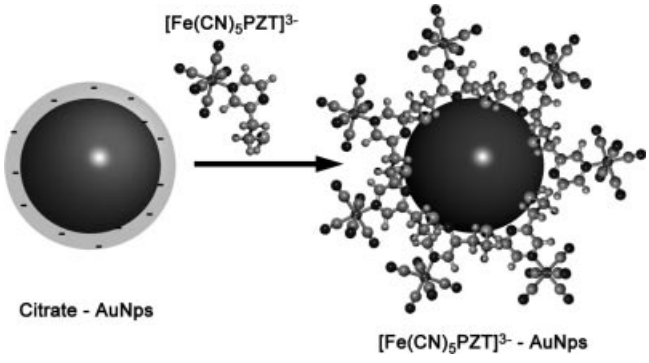

Figure 1. Representation of a gold nanoparticle stabilized with $[Fe(CN)_5PZT]^{3-}$ complexes.

In the presence of dimethyl sulfoxide (dmso) in excess, the pentacyanidoferrate(II) complexes undergo complete ligand exchange, yielding the very stable, colorless $[Fe(CN)_5(dmso)]^{3-}$ complex.[10] In this way, the electrostatic stabilization of the pentacyanidoferrate(II)-modified gold nanoparticles can be removed in the presence of dmso, providing an interesting way of controlling the flocculation of the gold nanoparticles. Because of the many interesting aspects in-

[a] Instituto de Química, Universidade de São Paulo, Caixa Postal 26077, CEP 05513-970 São Paulo, SP, Brazil

 InterScience © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

volved, we carried out a detailed investigation of this system, focusing especially on the coordination chemistry of pentacyanidoferrates and on the flocculation behavior of the gold nanoparticles, including their characterization based on surface-enhanced Raman scattering (SERS).

## Results and Discussion

The electronic configuration of the $[Fe(CN)_5PZT]^{3-}$ complex is typically low-spin, as a consequence of the strong ligand-field strength of the cyanido ligands. The UV/Vis spectrum exhibits two characteristic strong absorption bands at $\lambda_{max}$ = 266 and 461 nm (log $\varepsilon$ = 3.68), ascribed to PZT intraligand π-π* transition, and to metal-to-ligand charge transfer transition, i.e., $d\pi(Fe^{II})\rightarrow p\pi^*(PZT)$, respectively, by analogy with the literature.[8]

The $^1H$ NMR spectrum of the pentacyanidoferrate(II) complex in $^2H_2O$ exhibits the characteristic downfield shift of the signals of the adjacent aromatic protons (*α*) of the N-heterocycles coordinated to the $Fe(CN)_5^{3-}$ moiety, changing from δ = 8.41 to 9.03 ppm for $H^{2'}$ and from δ = 8.41 to 8.93 ppm for the $H^2$ signal in respect of the free ligand. This behavior follows the spectroscopic trends for monomeric pentacyanidoferrate(II) complexes, as shown in Figure 2, in which the downfield shift increases from 4-methylpyridine ($\Delta\delta^1H$ = 0.40 ppm) ≈ pyridine ($\Delta\delta^1H$ = 0.33 ppm) < isonicotinamide ($\Delta\delta^1H$ = 0.40 ppm) < pyrazine ($\Delta\delta^1H$ = 0.50 ppm) < *N*-methylpyrazinium ion ($\Delta\delta^1H$ = 0.80 ppm). For the PZT α-proton signals, downfield shifts of $\Delta\delta^1H^{2'}$ = 0.62 ppm and $\Delta\delta^1H^2$ = 0.52 ppm were observed, which are close to that expected from the spectrochemical series ($E_{TE}$ = 21.7 kK). The PZT β-aromatic proton signal underwent an upfield shift from δ = 8.34 to 8.14 ppm.

The observed behavior of the aromatic protons in pentacyanidoferrate(II) N-heterocyclic complexes involves main contributions from the $d\pi\rightarrow p\pi$ back-bonding to the heterocyclic ligand and the opposing inductive effect, whereas for the α-protons the magnetic anisotropy due to the electron looping at the CN axis bond is most relevant.[17] Curiously, the thiol proton signal exhibits a pronounced change in the chemical shift with respect to that of the free PZT ligand, i.e., from δ = 1.43 ($^2H_2O$) or 1.46 ($C^2HCl_3$) to 3.33 ppm in the pentacyanidoferrate(II) complex. This effect can be ascribed to the magnetic anisotropy of the cyanido ligands, producing a deshielding effect on the nuclei located perpendicular to this triple bond. As the thiol proton lies in a deshielding region, a large downfield shift is observed. Another evidence of the magnetic anisotropy of the cyanido ligands is reflected in the shape of the thiol proton peak. In fact, in $^2H_2O$, the S–H signal of the free PZT ligand appears as a broad coalescent peak at $\delta$ = 1.43 ppm. After coordination to the pentacyanidoferrate(II) complex, this peak became rather narrow, at $\delta$ = 3.33 ppm, exhibiting a strong spin-decoupling effect, removing the triplet feature observed in aprotic solvents.

Cyclic voltammetry (CV) and differential pulse voltammetry (DPV) for $[Fe(CN)_5PZT]^{3-}$ exhibited only a single redox process at 0.55 V (SHE), $E_{pa} - E_{pc}$ = 60 mV, showing no evidence of formation of dinuclear or any other species in solution. The $E_{1/2}$ is in good agreement with the analogous $[Fe(CN)_5pz]^{3-}$ (pz = pyrazine) species (0.55 V vs. SCE).[8]

### Solvatochromic Behavior

Cyanidoiron complexes exhibit strong solvent effects influencing their chemical reactivity and solvatochromic behavior.[18–22] Such solvent effects arise from specific donor–acceptor interactions of the solvent molecules with the available nonbonding electron pairs of the cyanido ligands. For this reason, the observed solvatochromism is best correlated with the acceptor number[23] (AN) of the solvents. In Figure 3 the normalized spectra of $[Fe(CN)_5PZT]^{3-}$ in the different solvents are shown.

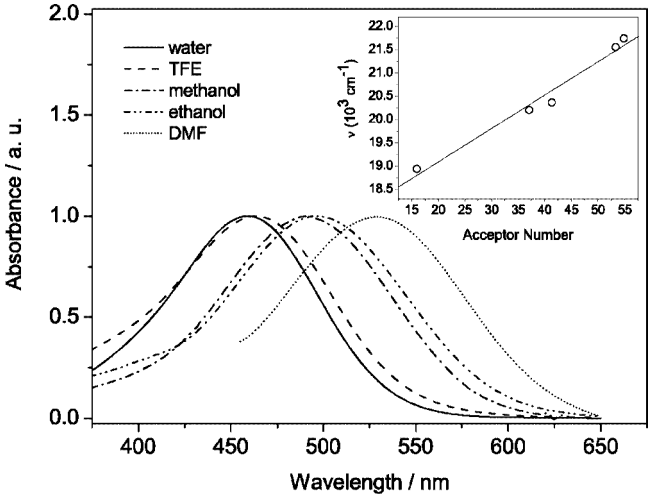

Figure 3. Normalized spectra of the $[Fe(CN)_5PZT]^{3-}$ complex in several solvents, as a function of the acceptor number: (——) water (AN = 54.8), (– – –) trifluoroethanol (TFE) (AN = 53.3), (– · – · –) methanol (AN = 41.3), (– ·· – ·· –) ethanol (AN = 37.1), (···) DMF (AN = 16.0). Inset: Correlation between the MLCT band energies of the $[Fe(CN)_5PZT]^{3-}$ complex and the AN parameter of the solvents (water, trifluoroethanol, methanol, ethanol, DMF).

As expected, the energy of the charge-transfer band shows a strong dependence with the solvent acceptor number.[20–22] Solvents displaying high AN values are able to interact with the nitrogen electron pair on the cyanido ligands, removing part of σ-electron density, while increasing the dπ→pπ* back-bonding contribution. This leads to the stabilization of the occupied metal dπ orbitals, thus increasing the energies of the MLCT bands, as expressed by the equation:[20]

$$\nu_s = \nu_0 + a(AN)$$

where $\nu_s$ is the experimental wavenumber and $\nu_0$ corresponds to the extrapolated value at AN = 0 (Figure 3, inset). The parameter $a$ measures the sensitivity of the charge-transfer band to the solvent acceptor properties. For the $[Fe(CN)_5PZT]^{3-}$ complex, $\nu_0$ = 17660 cm$^{-1}$, and $a$ = 72 cm$^{-1}$.

### Theoretical Simulation of the Electronic Spectrum

The DFT-optimized geometry for the $[Fe(CN)_5PZT]^{3-}$ ion is consistent with an octahedral configuration, with four equatorial Fe–C and C≡N bonds of 1.982 and 1.178 Å, respectively. The corresponding axial bond lengths were 1.970 and 1.176 Å, respectively, reflecting the *trans*-influence of the dπ→pπ* interactions from the Fe–PZT moiety. On the basis of the DFT-optimized geometry, ZINDO/S calculations were carried out, simulating the electronic spectrum of the $[Fe(CN)_5PZT]^{3-}$ ion, with the MLCT band at 17827 cm$^{-1}$ displaying an oscillator strength of 0.496. This theoretical value refers to a vacuum calculation, and differs significantly from the experimental value of 21700 cm$^{-1}$ in aqueous solution, coinciding, however, with the extrapolated value at AN = 0 ($\nu_0$ = 17660 cm$^{-1}$).[20] This observation is quite relevant, justifying a careful investigation of the solvatochromic effects, prior to the theoretical simulation of the electronic spectra.

According to the theoretical calculations, the observed MLCT transition involves the HOMO→LUMO (MOs 52→53) excitation. The composition of the HOMO and LUMO levels is shown in Table 1. The HOMO level (MO-52) is mainly composed of the metal dπ orbitals (68%), as illustrated in Figure 4, while the LUMO (MO-53) has the largest contribution from the PZT π* orbitals (Figure 4, B).

Table 1. MOs' percent composition obtained from ZINDO/S calculations.

| | HOMO | LUMO |
|---|---|---|
| MO | 52 | 53 |
| Energy [eV] | 1.8834 | 7.1168 |
| % Fe | 68.36[a] | 13.45[b] |
| % CN | 14.56 | 28.55 |
| % PZT | 17.08 | 58.00 |

[a] d($xz$): 39.25%, d($yz$): 29.06%, d($xy$): 0.02%, d($z^2$): 0.02%, d($x^2$–$y^2$): 0.01%. [b] d($xz$): 7.64%, d($yz$): 5.80%, d($xy$): 0.01%, d($z^2$): 0.00%, d($x^2$–$y^2$): 0.00%.

### Vibrational Study of PZT and $[Fe(CN)_5PZT]^{3-}$

In Figure 5 is shown the FT-IR spectra of the PZT ligand and its corresponding pentacyanidoferrate(II) complex. The IR spectrum of PZT exhibits the characteristic high-energy frequencies associated with the C–H stretching modes of the $–CH_2–CH_2–$ group, and a broad band at 2540 cm$^{-1}$ related to the S–H stretching vibration. In the pentacyanidoferrate(II) complex, the FT-IR spectrum presents two characteristic bands at ca. 2050 and 570 cm$^{-1}$ associated with the vibrational modes of the C≡N and Fe–CN bonds. The S–H stretching mode can also be detected in the FTIR spectra, shifting from 2540 to 2470 cm$^{-1}$ upon the N-coordination to the pentacyanidoferrate complex,

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

corroborating the observed influence on the S–H group in the NMR spectrum.

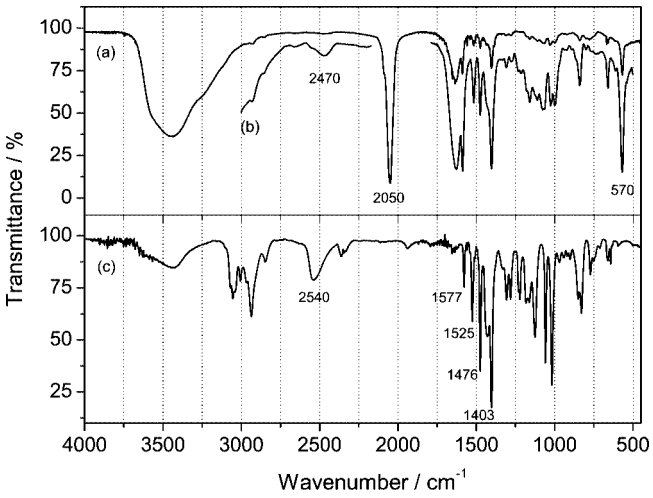

Figure 5. IR spectra of $Na_3[Fe(CN)_5PZT]\cdot 3H_2O$ in KBr pellets: (a) diluted and (b) three times more concentrated, (c) IR spectrum of pure liquid PZT.

The Raman spectrum of the PZT ligand is dominated by two intense bands at 1058 and 1018 $cm^{-1}$ ascribed to the vibrational modes of the $–CH_2–CH_2–$ and pyrazine moieties, respectively.

The complete assignment of the PZT and $Na_3[Fe(CN)_5$-PZT]$\cdot 3H_2O$ vibrational frequencies was carried out based on the theoretical calculations, as shown in Tables 2 and 3.

### Interaction of Gold Nanoparticles with PZT

The colloidal solutions of citrate-stabilized gold nanoparticles (average size 20 nm) exhibit a characteristic red-wine color ascribed to the optical interaction with the surface plasmons, as accounted for by the Mie theory.[24] The spectral variation of the gold nanoparticles in the presence of PZT ($1 \times 10^{-5}$ mol $dm^{-3}$) can be seen in Figure 6. After the addition of PZT to the gold nanoparticles solution, the intensity of the plasmon absorption band at 520 nm decreases in parallel with the rise of a new band above 600 nm. As this band becomes more intense, there is a bathochromic shift to 660 nm. Such optical changes can be

Table 2. Assignment of calculated wavenumber [$cm^{-1}$] to experimental bands in the FT-IR and Raman of PZT.

ascribed to the aggregation of the gold nanoparticles, arising from the mutual interference of the plasmon levels in neighboring nanoparticles.[1] The intensity of the 660 nm band reaches a maximum, after which there is a gradual decay and shift to about 700 nm, due to the precipitation process.

A contrasting behavior is observed for the $[Fe(CN)_5PZT]^{3-}$-modified AuNps. In Figure 7 the spectra of the AuNps upon addition of $[Fe(CN)_5PZT]^{3-}$ ($1 \times 10^{-5}$ mol dm$^{-3}$) is shown. The characteristic MLCT band at 460 nm for the $[Fe(CN)_5PZT]^{3-}$ complex can be observed as a shoulder of the plasmon resonance band at 520 nm, exhibiting only a small decrease in intensity after the binding and replacement of the citrate shell of the gold nanoparticles. In this case, a stable colloidal solution is obtained, which can be stored for many days, under argon, without any evidence of the plasmon coupling band above 600 nm, associated with flocculation.

### SERS Effect on PZT-AuNps and $Na_3[Fe(CN)_5PZT]$-AuNps

Because of the expected occurrence of SERS, the aggregated PZT-AuNps in aqueous media were also studied by Raman spectroscopy. Typical spectra can be seen in Figure 8, in comparison with the normal Raman spectra of the PZT ligand (pure form).

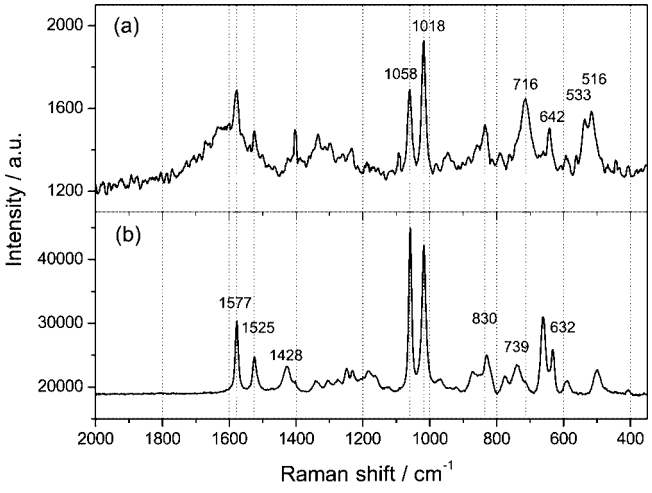

Figure 8. SERS spectrum of the PZT-AuNps ([PZT] = $1 \times 10^{-5}$ mol dm$^{-3}$) (a) and Raman spectrum of the PZT in pure liquid form (b).

Considering the very low concentrations ([PZT] = $10^{-5}$ mol dm$^{-3}$) employed in the measurements, the strong (SERS) intensification of the PZT vibrational peaks becomes quite evident in Figure 8. It is known that the SERS effect can involve either electromagnetic (EM)[25] or charge transfer (CT)[26] mechanisms. In the EM model, the Raman enhancement is attributed to the excitation of the surface plasmon polaritons by the exciting wavelength, as described by the Mie formalism.[24] This mechanism is typically observed in the case of plasmon resonance involving physically adsorbed molecules.[27] Usually, SERS of particles smaller than the exciting wavelength are a function of the radius and refractive index, and the maximum enhancement is observed when the molecules are as close as possible to the surface and the incident and scattered waves are perpendicular to the scattering plane.

In the case of chemically adsorbed molecules, a charge-transfer mechanism becomes plausible. Generally, it involves the transfer of an electron from the Fermi level of the metal atom to an unoccupied molecular orbital of the adsorbate or vice versa, but the evidence of this particular type of excitation has been mainly obtained from electrochemical experiments. It should be noted that SERS can be observed even for chemically adsorbed molecules without charge-transfer resonance.[27] When charge-transfer resonance and surface-enhanced resonance Raman scattering are involved, the mechanism is referred to as SERRS (Surface Enhanced Resonance Raman Scattering). One of the first reports on the SERRS mechanism dealt with the $[\{Fe(CN)_5\}_2(\mu\text{-bipy})]^{6-}$ complex adsorbed on a silver electrode.[28] Although a direct spectroscopic evidence has not been obtained in this case, it is important to notice that outer-sphere charge-transfer excitation in pentacyanidoferrate(II) complexes have already been reported in the literature,[29,30] as well as in $TiO_2$ films containing anchored $[Fe(CN)_5L]^{n-}$ species.[31]

In the case of the PZT-AuNps, the aggregation phenomenon in aqueous solution leads to the selective enhancement of the vibrational modes associated with the PZT ligand, involving both the pyrazine ring and thioalkane moieties. It is interesting to note that the relative intensity of the peaks at 1058 and 1018 cm$^{-1}$ associated with ethanethiol and pyrazine vibrational modes, respectively, is inverted in relation to the normal Raman spectrum of the PZT species. The peaks at ca. 738 and 500 cm$^{-1}$, ascribed to C–S stretching and–$CH_2$–$CH_2$– vibrational modes undergo strong enhancement, shifting to 716 and 516 cm$^{-1}$, respectively. This is in agreement with the electromagnetic mechanism, since such groups are in close proximity to the gold surface due to the thiol binding.

The Raman spectrum of the pentacyanidoiron-stabilized AuNps shows a strong enhancement of the vibrational modes, exhibiting a rather contrasting profile in relation to the normal spectrum of the isolated complex, as can be observed in Figure 9.

The 659 cm$^{-1}$ peak ascribed to the C–S stretching mode exhibits the greatest enhancement, shifting to 700 cm$^{-1}$. The original peaks at 1590, 1159, 1076, and 1034 cm$^{-1}$ in the normal spectra practically vanish and some new peaks arise in this region. This result suggests a different origin for the SERS effect in the $[Fe(CN)_5PZT]^{3-}$-stabilized AuNps, in comparison with the PZT-AuNps aggregates. The enhancement of the new bands seems to be associated with the electronic character of the excited state, and the occurrence of a charge-transfer mechanism can be plausible in this case. The puzzling point, however, is that there is no plasmon coupling band above 600 nm, as in the case of the PZT-AuNps. Presumably, an interfacial charge-transfer excitation is involved, as in the preceding example involving

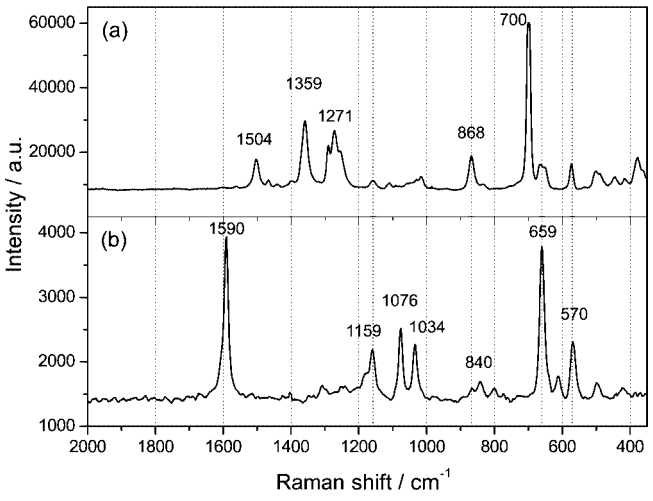

Figure 9. SERS spectrum of the complex $Na_3[Fe(CN)_5PZT]$ at $10^{-5}$ mol dm$^{-3}$ stabilizing AuNps (a) and Raman spectrum of the iron complex at 1 mol dm$^{-3}$ in aqueous solution (b).

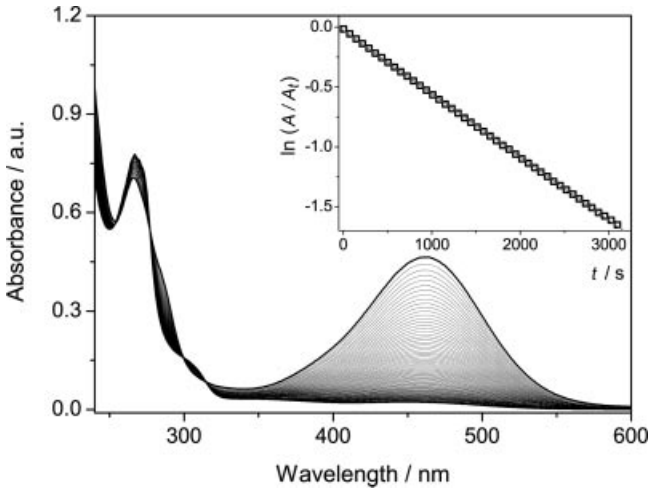

Figure 10. UV/Vis spectra of $1 \times 10^{-4}$ mol dm$^{-3}$ $[Fe(CN)_5PZT]^{3-}$ in the presence of 0.5 mol dm$^{-3}$ dmso. Inset: first-order kinetic plot, where $k_{obs} = 5.2 \times 10^{-4}$ s$^{-1}$ with 99.9% correlation.

cyanidoiron complexes, from the literature.[28] In addition, it has been shown that many chromophore-functionalized gold nanoparticles[32] undergo complete quenching of emission, from such interfacial charge transfer effects. At the present time, the SERS phenomenon and their many variations are not yet completely understood,[27] and the unusual behavior of the $[Fe(CN)_5PZT]^{3-}$-stabilized AuNps will be subject of a future, detailed investigation.

### Dissociation Kinetics of $[Fe(CN)_5PZT]^{3-}$ and Controlled Aggregation of the Modified Gold Nanoparticles

The dissociation kinetics of the $[Fe(CN)_5PZT]^{3-}$ complex was studied in the presence of a large excess of dimethyl sulfoxide as the attacking ligand. The resulting $[Fe(CN)_5dmso]^{3-}$ complex is quite stable, and does not absorb in the visible region.[10] Therefore, the dissociation reaction can be conveniently monitored by the disappearance of the MLCT band at 461 nm.

The substitution kinetics of the PZT ligand by dmso, in large excess (0.5 mol dm$^{-3}$), proceeded according to first-order kinetics, as shown in Figure 10 (inset). It should be noted that ligand substitution in aromatic N-heterocycle pentacyanidoferrates(II) complexes occurs by a dissociative mechanism,[8–13] as expressed by the equations:

$$[Fe(CN)_5pzt]^{3-} \underset{k_{-PZT}}{\overset{k_{PZT}}{\rightleftharpoons}} [Fe(CN)_5]^{3-} + pzt$$

$$[Fe(CN)_5]^{3-} + H_2O \underset{k_1}{\overset{k_{-1}}{\rightleftharpoons}} [Fe(CN)_5H_2O]^{3-}$$

$$[Fe(CN)_5]^{3-} + dmso \xrightarrow{k_{dmso}} [Fe(CN)_5dmso]^{3-}$$

$$k_{obs} = \frac{k_{-PZT}\, k_{dmso}\, [dmso]}{k_{PZT}\, [PZT] + k_{dmso}[dmso]}$$

As previously shown,[8] under pseudo-first-order conditions, and assuming steady-state hypothesis for the $[Fe(CN)_5]^{3-}$ intermediate, the observed rate constants are given by:

In the presence of a large excess of dmso, $k_{dmso}[dmso] >> k_{PZT}[PZT]$, and the observed rate constant coincides with the limiting dissociation rate constant for the $[Fe(CN)_5PZT]^{3-}$ complex, i.e., $k_{obs} = k_{-PZT}$.

The same pattern was also observed (Figure 11) for the $[Fe(CN)_5PZT]^{3-}$-stabilized gold nanoparticles in the presence of dmso (0.5 mol dm$^{-3}$). As observed for the free complex, the reaction with dmso leads to an exponential decrease of the MLCT band at ca. 460 nm (Figure 11, inset), with a kinetic dissociation constant of $6.2 \times 10^{-4}$ s$^{-1}$. This value is comparable to $5.2 \times 10^{-4}$ s$^{-1}$ obtained for the free complex.

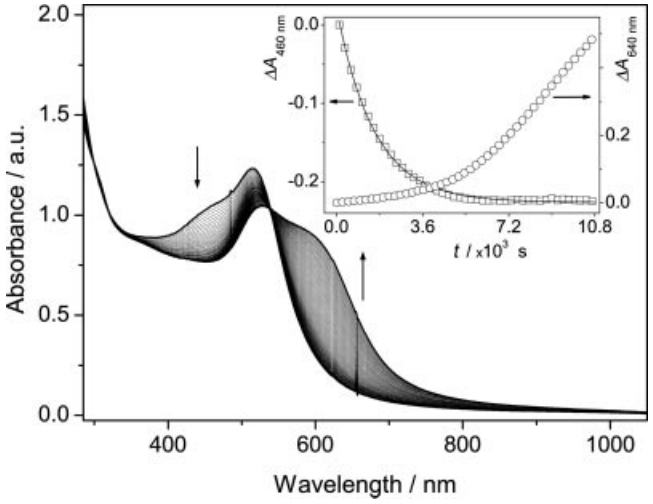

Figure 11. UV/Vis spectra and dissociation kinetics of the $[Fe(CN)_5PZT]^{3-}$-stabilized gold nanoparticles after addition of 0.5 mol dm$^{-3}$ dmso. Inset: Decrease of absorbance at 460 (□, left) and 640 nm (○, right). The solid line is a pseudo-first-order behavior fit at 460 nm, where $k_{obs} = 6.2 \times 10^{-4}$ s$^{-1}$ with 99.8% of correlation.

It should be noted that the dissociation of the pentacyanidoferrate(II) complex from the AuNps surface removes the electrostatic stabilization of the nanoparticles. Therefore, as

[a] The complexes are listed in decreasing order of reduction potential. [b] In mV (SHE). [c] Estimated values based on assumed value of the pyrazine: $k_f^{II}$ = 380 mol$^{-1}$ s$^{-1}$.

expected, the ligand-substitution reaction is followed by the flocculation of the resulting PZT-AuNps, leading to an increase of the absorbance at 640 nm, i.e.:

$[Fe(CN)_5PZT]$-AuNps + dmso → $[Fe(CN)_5dmso]^{3-}$ + PZT-AuNps

PZT-AuNps → flocculation

From the kinetics and electrochemical parameters obtained in this work, it is possible to estimate the equilibrium constants for $[Fe(CN)_5PZT]^{3-}$ and to compare with related systems, as shown in Table 4. The results are rather consistent, indicating that the characteristic properties of the pentacyanidoferrate(II) complexes are preserved after their binding to the gold nanoparticles.

## Conclusions

Gold nanoparticles and pentacyanidoferrates can be successfully combined by means of a suitable bridging ligand such as 2-pyrazin-2-ylethanethiol, allowing the exploitation of the coordination chemistry involved, especially, the stabilization of the colloidal solutions and the controlled formation of aggregates in the presence of a strong ligand, such as dimethyl sulfoxide. The modified gold nanoparticles exhibit a strong SERS effect. The results are coherent with the enhancement by the electromagnetic mechanism for the PZT-modified gold nanoparticles, while the charge-transfer mechanism seems to predominate in the case of the $[Fe(CN)_5PZT]^{3-}$-modified gold nanoparticles. The reported strategy, based on a typical coordination chemistry approach, can be extended to the generation of functional, self-assembled nanoparticle films, of great relevance in molecular devices.

## Experimental Section

**Materials:** All solvents and reactants used in this work were of analytical grade and used as supplied. $HAuCl_4{\cdot}3H_2O$, trisodium citrate hydrate, and 2-pyrazin-2-ylethanethiol (PZT), were purchased from Aldrich. $Na_3[Fe(CN)_5NH_3]{\cdot}3H_2O$ was prepared from sodium nitroprusside, $Na_3[Fe(CN)_5NO]{\cdot}2H_2O$ (Carlos Erba), according to the usual procedure.[34] All aqueous solutions were prepared using MilliQ water (18.2 MΩ cm). Citrate-stabilized gold nanoparticles (AuNps) were prepared according to the Turkevitch[35] method as described previously.[7] The concentration of gold nanoparticles suspension used in the experiments was calculated as $10^{-9}$ mol dm$^{-3}$, assuming a total conversion of $AuCl_4^-$ ions into colloidal nanoparticles of 20 nm average size, as previously measured by MEV and STM on HOPG substrate. The calculated area per particle was $1.26\times10^{-15}$ m$^2$, yielding a total surface area of 0.756 m$^2$ dm$^{-3}$. $Na_3[Fe(CN)_5PZT]{\cdot}3H_2O$ was prepared by adapting the procedures described by Toma et al.[8–14] $Na_3[Fe(CN)_5NH_3]{\cdot}3H_2O$ (0.326 g or 1.0 mmol) was mixed with a tenfold excess of 2-pyrazin-2-ylethanethiol (1.40 g or 10.0 mmol) in 10 mL of water, and the mixture magnetically stirred at room temperature under argon for 30 min. The product precipitated by addition of ethanol, and was collected on a glass filter, washed with cold ethanol and dried under vacuum. Yield: 84%. $Na_3[Fe(CN)_5PZT]{\cdot}3H_2O$: $C_{11}H_{14}FeN_7Na_3SO_3$ (449.15): calcd. C 30.4, H 3.24, N 19.3; found C 30.3, H 3.35, N 19.3. $^1$H NMR (300 MHz, $^2H_2O$): $\delta$ = 9.03 (s, 1 H, H$^{2'}$), 8.93 (m, 1 H, H$^2$), 8.13 (m, 1 H, H$^3$), 3.06 (m, 2 H, H$^5$), 2.90 (m, 2 H, H$^6$), 3.33 (s, 1 H, SH) ppm. For comparison purposes: PZT: $^1$H NMR (300 MHz, $^2H_2O$): $\delta$ = 8.41 (m, 2 H, H$^2$ and H$^{2'}$), 8.35 (m, 1 H, H$^3$), 2.99 (t, $J$ = 6.9 Hz, 2 H, H$^5$), (t, $J$ = 6.9 Hz, 2 H, H$^6$), 1.43 (shoulder, SH) ppm. PZT: $^1$H NMR (300 MHz, $C^2HCl_3$): $\delta$ = 8.535 (m, $J'$ = 2.7 Hz, $J''$ = 1.5 Hz, 1 H, H$^2$), (d, $J$ = 1.5 Hz, 1 H, H$^{2'}$), (d, $J$ = 2.7 Hz, 1 H, H$^3$), 3.132 (t, $J$ = 6.9 Hz, 2 H, H$^5$), 2.978 (m, $J'$ = 6.9 Hz, $J''$ = 1 Hz, 2 H, H$^6$), 1.46 (t, $J$ = 8.2 Hz, 1 H, SH) ppm. CV for $Na_3[Fe(CN)_5PZT]{\cdot}3H_2O$: $E_{1/2}$ = +0.55 V (SCE). For comparison purposes: $[Fe(CN)_5pz]^{3-}$ (where pz = pyrazine): $E_{1/2}$ = +0.55 V (SCE).[8]

**Physical Measurements:** NMR spectra were recorded with a Varian 300 MHz (INOVA 1) spectrometer using $1\times10^{-2}$ mol dm$^{-3}$ solutions. All peaks were related to tetramethylsilane (TMS). Cyclic and differential pulse voltammetry measurements were carried out with an Autolab PGSTAT 30 potentiostat/galvanostat with a conventional three-electrode cell constituted by a carbon glass disk working electrode (0.196 cm$^2$), a coiled platinum wire as the counter electrode, and an Ag/AgCl (KCl 0.1 mol dm$^{-3}$) reference electrode. The electrolyte employed was 0.1 mol dm$^{-3}$ KCl in water containing 1 mmol dm$^{-3}$ of the iron complex. UV/Vis spectra and kinetics experiments were recorded with a Hewlett Packard model HP-8453 diode-array spectrophotometer with a thermostatted cell holder. FT-IR spectra were recorded with a Shimadzu model FTIR 8300 spectrophotometer. Raman measurements were performed using an InPhotote portable instrument equipped with Raman probe optical fiber and a 300-mW (785 nm) diode laser (resolution of 6 cm$^{-1}$ and 350–2000 cm$^{-1}$ spectral range). Typically, an accumulation time of 120 s was employed to obtain the Raman spectra. For the free PZT and $Na_3[Fe(CN)_5PZT]{\cdot}3H_2O$ complex, the Raman spectra were recorded from pure sample and 1 mol dm$^{-3}$ aqueous solution, respectively. SERS measurements were performed using $1\times10^{-5}$ mol dm$^{-3}$ aqueous solutions. The dissoci-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ation kinetics of $[Fe(CN)_5PZT]^{3-}$ were studied in the presence of a large excess of dimethyl sulfoxide (dmso), at $25.0 \pm 0.1$ °C and 0.1 mol dm$^{-3}$ LiCl. The disappearance of the MLCT band of the $[Fe(CN)_5PZT]^{3-}$ species at 461 nm, was monitored under pseudo-first-order conditions, and the observed rate constants, $k_{obs}$, were obtained by linear fitting of $\ln(A_\infty/A_t)$ vs. time. For the evaluation of the dissociation kinetic constants of the gold nanoparticles stabilized with the iron complex, the changes of optical density at 460 nm were plotted vs. time, yielding a single exponential curve. The kinetic constant was obtained by a simplex fitting of this curve, according to the equation $y = y_0 + A\exp(-kt)$.

**Theoretical Calculations:** The DFT method was employed for geometry optimization, using GAMESS[36] software running on a PC cluster. Becke's three-parameter hybrid functional[37] with the LYP correlation functional[38] (B3LYP) was employed with a 6-31G(d,p) basis set for all atoms. Semi-empirical calculations were performed using the HYPERCHEM software package.[39] Theoretical calculations of the electronic spectrum were carried out using ZINDO/S,[40] employing a convergence criterion of $10^{-7}$ kcal mol$^{-1}$ for SCF and single CI excitations, using an active space of 40 frontier molecular orbitals (20 highest occupied and 20 lowest unoccupied MOs). The harmonic vibrational frequencies and intensities were calculated at this same level of theory, based on the analytical evaluation of second derivatives of energy as a function of atomic coordinates. Raman intensities were simulated by the numerical differentiation procedure of Komornicki and others,[41,42] applying an intensity of $2 \times 10^{-3}$ a.u. for the electric field.

# Synthesis, Characterization, and Photophysical Properties of Some Heterodimetallic Bisporphyrins of Ytterbium and Transition Metals – Enhancement and Lifetime Extension of $Yb^{3+}$ Emission by Transition-Metal Porphyrin Sensitization

**Feng-Lei Jiang,[a,b] Wai-Kwok Wong,*[b,c] Xun-Jin Zhu,[b] Gui-Jiang Zhou,[b] Wai-Yeung Wong,[b,c] Po-Lam Wu,[c,d] Hoi-Lam Tam,[c,d] Kok-Wai Cheah,[c,d] Cheng Ye,[e] and Yi Liu*[a]**

**Keywords:** Lanthanides / Optical limiting / Photoluminescence / Porphyrins / Transition metals

A series of d-f heterodimetallic bisporphyrin complexes (**YbZn**, **YbPd**, and **YbPt**), in which a $Yb^{III}$ porphyrinate moiety is linked to a transition-metal porphyrinate moiety by a flexible three-carbon chain, were synthesized. They were fully characterized by high-resolution mass spectrometry, $^1H$ and $^{31}P$ NMR spectroscopy, electronic absorption, and fluorescence methods. Variable-temperature near-infrared photoluminescence studies showed that the transition-metal porphyrinate moiety would enhance the ytterbium(III) emission centered at about 998 nm and extend its emission lifetime. **YbPd** and **YbPt** showed large two-photon absorption cross-section values because of the interaction between the porphyrin units, which caused a loss of centrosymmetry. Optical limiting investigation demonstrated that [Yb(TPP)($L_{OMe}$)] and **YbPt** have comparable performance to $C_{60}$ by virtue of their heavy-metal effect. Our results indicate that these bisporphyrin dimetallic complexes will find valuable applications in the field of nonlinear optics.

## Introduction

In the late 1970s, bisporphyrins with four linkages each on the *meso* position[1a] and β position[1b] were reported. Later on, bisporphyrins and their metal complexes were synthesized to study the photoinduced energy transfer from porphyrin to $O_2$.[2] Bisporphyrins are basically divided into two classes by virtue of their conformations: cofacial (mostly linked on the *ortho* position of the *meso*-phenyl group of porphyrin macrocycles) and linear (mostly linked on the *para* position of the *meso*-phenyl group of porphyrin macrocycles). Other than the linkage at the *meso*-phenyl group, there are bisporphyrins with linkages at the β position of the pyrrole unit as well.[3] Bisporphyrins with various kinds of linkages and different central metal ions have attracted much attention because of their potential application in host–guest chemistry,[4] chemical sensing,[5] supramolecular chirogenesis,[6] catalytic photooxidation,[7] molecular switches,[8] photoinduced energy transfer,[9] two-photon absorption,[10] etc. Linear bisporphyrins were mainly investigated on the energy transfer from one porphyrin unit to the other one by varying the rigid linkages, such as the phenylene and alkyne units.[11]

Trivalent lanthanide ions continue to attract considerable interest because of their unique optical properties such as line-like emission bands and relatively long luminescence lifetimes.[12] However, while it was recently reported that $Sm^{2+}$ complexes can be directly excited because the transitions are allowed,[13a] it is generally difficult to excite lanthanide ions directly because of the forbidden nature of their electronic transitions.[13] In order to overcome this problem, lanthanide ions are usually excited by the energy transferred from organic chromophores, which can encapsulate the lanthanide ions. Porphyrin can act as an antenna for photoluminescence (PL) in light of its highly conjugated system, which absorbs strongly in the UV/Vis region. Ytterbium(III) complexes, which emit in the near-infrared (NIR) region centered at about 998 nm, where biological tissues and fluids are relatively transparent, are promising probes

for fluoroimmunoassays. We have shown that porphyrinato ligands could act as antennae and sensitize NIR emission of $Nd^{3+}$, $Er^{3+}$, and $Yb^{3+}$ ions.[14] Recently, there has been considerable interest in extending the lifetimes of $Nd^{III}$, $Er^{III}$, and $Yb^{III}$. Transition-metal ions with long lifetimes, such as $Cr^{III}$, $Ru^{II}$, and $Pt^{II}$, were inserted into d-f heterodimetallic complexes and found to serve as sensitizers for lanthanide ions.[15–17] The best result of lifetime extension was observed for the CrLn (Ln = Nd, Yb) complex,[15] which showed that $Cr^{III}\rightarrow Ln^{III}$ intramolecular energy transfer could extend the lifetimes of lanthanide ions from the microsecond to millisecond timescale at 10 K. However, the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

ligands only absorbed light in the high-energy region at 247 and 334 nm. To this end, we want to develop a strategy to extend the lanthanide lifetime by using sensitizers that absorb strongly in the UV/Vis region, such as metalloporphyrins of transition metals. To the best of our knowledge, there is no report in the literature on the synthesis of bisporphyrin complexes containing a lanthanide and a d-block transition metal. Herein, we report the synthesis, and photophysical and optical limiting properties of several bisporphyrin complexes, in which a $Yb^{III}$ porphyrinate moiety is linked to a transition-metal porphyrinate moiety by a flexible three-carbon chain.

## Results and Discussion

### Synthesis

Ytterbium(III) bisporphyrinate complexes **YbFb** (**1**), **YbZn** (**2**), **YbPd** (**3**), and **YbPt** (**4**) were prepared as shown in Scheme 1. When 5-(*p*-hydroxyphenyl)-10,15,20-triphenylporphyrin (*p*-OH-$TPPH_2$) was treated with excess $Yb[N(SiMe_3)_2]_3{\cdot}[LiCl(THF)_3]_x$ under nitrogen in refluxing toluene for 12 h followed by the addition of excess $Na\{(\eta^5\text{-}C_5H_5)Co[P(=O)(OMe)_2]_3\}$ ($NaL_{OMe}$) to the reaction mixture at room temperature (room temp.), workup gave purple air-stable crystals of [Yb(*p*-OH-TPP)($L_{OMe}$)] in 84% yield. The complex [Yb(*p*-OH-TPP)($L_{OMe}$)] was quite stable towards moisture and could be purified by column chromatography on silica gel. In the presence of $K_2CO_3$, reaction of *p*-OH-$TPPH_2$ with excess 1,3-dibromopropane in dry DMF under nitrogen at room temp. overnight gave 5-[*p*-(3-bromopropoxy)phenyl]-10,15,20-triphenylporphyrin (*p*-$BrC_3O$-$TPPH_2$) in 94% yield. The interaction of [Yb(*p*-OH-TPP)($L_{OMe}$)] with *p*-$BrC_3O$-$TPPH_2$, in the presence of $K_2CO_3$ in dry DMF at 60 °C overnight, gave the porphyrin complex **YbFb** (**1**), in which a porphyrin free base is appended to the $Yb^{III}$ porphyrinate complex by a flexible linkage, $-OCH_2CH_2CH_2O-$, in 58% yield. **YbFb** could also be prepared by the reaction of *p*-OH-$H_2$TPP with [Yb(*p*-$BrC_3O$-TPP)($L_{OMe}$)], which was synthesized by the reaction of [Yb(*p*-OH-TPP)($L_{OMe}$)] with 1,3-dibromopropane in the presence of $K_2CO_3$. All the above porphyrin free bases and Yb porphyrinate complexes were fully characterized by $^1H$ and $^{31}P$ (if applicable) NMR, MS, and UV/Vis spectroscopy. The solid-state structure of [Yb(*p*-$BrC_3O$-TPP)($L_{OMe}$)] (Figure 1), ascertained by X-ray crystallography, is very similar to that of [Yb(TMPP)($L_{OEt}$)].[14c] Crystal structure analysis revealed that the Yb ion is seven-coordinate, surrounded by four N atoms of the porphyrinate dianion and three O atoms of the three phosphito groups. The Yb–N and Yb–O distances are in the ranges 2.343(6)–2.367(5) and 2.260(7)–2.281(7) Å, respectively. The bond lengths and bond angles are almost the same as those in [Yb(TMPP)($L_{OEt}$)].[14c]

When **YbFb** was treated with $M(OAc)_2{\cdot}2H_2O$ (M = Zn, Pd) in a refluxing $CHCl_3$/MeOH (1:1, v/v) mixture for 24 h, **YbZn** (**2**) and **YbPd** (**3**) were obtained in 83% and 88% yields, respectively; and with $PtCl_2(PhCN)_2$ in refluxing PhCN, **YbPt** (**4**) was obtained in 60% yield. Complexes **1**–**4** are thermally and air-stable and can be purified by column chromatography. The four bisporphyrins were fully characterized by mass spectrometry, $^1H$ and $^{31}P$ (if applicable) NMR, and UV/Vis spectroscopy. The MALDI-TOF mass spectra of complexes **1**–**4** exhibit the $[M + 1]^+$ peaks at *m*/*z* = 1924.4353, 1988.3409, 2028.3187, and 2117.3801, respectively, which deviate less than 5 ppm from the theoretical values of 1924.4363, 1988.3490, 2028.3251, and 2117.3859, respectively, and their isotopic distribution patterns match

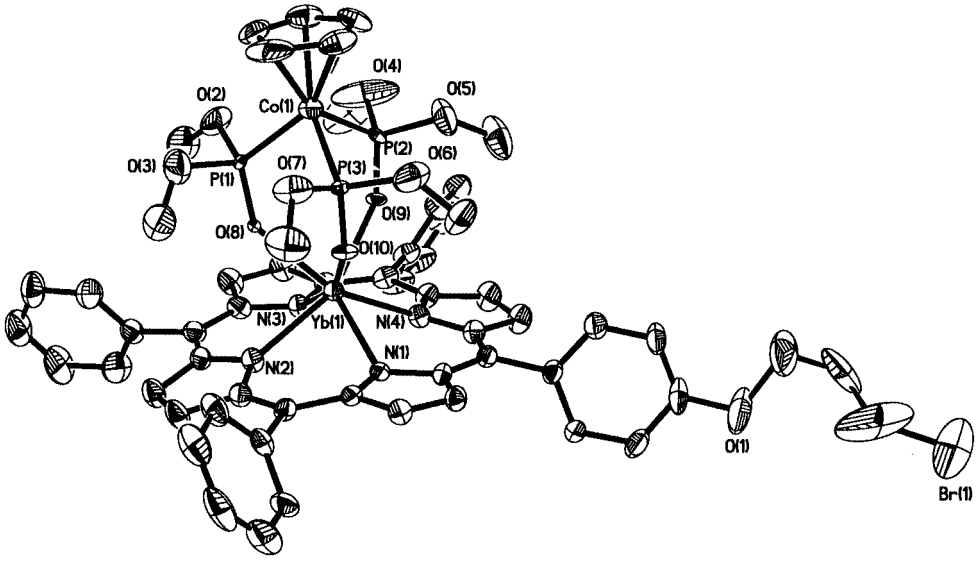

Figure 1. Perspective drawing of [Yb(*p*-$BrC_3O$-TPP)($L_{OMe}$)]. Hydrogen atoms were omitted for clarity. Selected bond lengths [Å] and bond angles [°]: N(1)–Yb(1) 2.367(5), N(2)–Yb(1) 2.350(6), N(3)–Yb(1) 2.343(6), N(4)–Yb(1) 2.350(5), O(8)–Yb(1) 2.260(7), O(9)–Yb(1) 2.280(7), O(10)–Yb(1) 2.281(7); O(8)–Yb(1)–O(9) 76.4(3), O(8)–Yb(1)–O(10) 78.9(3), O(9)–Yb(1)–O(10) 80.7(3), N(3)–Yb(1)–N(2) 77.99(19), N(3)–Yb(1)–N(4) 75.51(19), N(2)–Yb(1)–N(4) 122.5(2), N(3)–Yb(1)–N(1) 121.9(2), N(2)–Yb(1)–N(1) 76.17(18), N(4)–Yb(1)–N(1) 76.23(17).

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the theoretical distribution. The $^1$H NMR spectrum (in $CDCl_3$) of **1** shows a singlet at $\delta$ = –2.64 ppm for the inner NH groups of the porphyrin free base moiety. This peak is absent in the $^1$H NMR spectra of dyads **2**–**4**, which indicates that the transition metals are coordinated to the four nitrogen atoms of the appended porphyrin free base. The $^1$H NMR spectra of the four dyads exhibit single peaks at $\delta$ = –4.52 ppm for the five cyclopentadienyl protons, quartets at $\delta \approx$ 3.34 ppm for the –$OCH_2CH_2CH_2O$– protons, and two triplets at $\delta \approx$ 5.20 and 5.64 ppm for the –$OCH_2CH_2CH_2O$– protons. The $^{31}P\{^1H\}$ NMR spectra (vs. 85% $H_3PO_4$) of **1**–**4** show single peaks at $\delta$ = 69.2, 69.2, 69.2, and 69.0 ppm, respectively, for the phosphito groups of the anionic $L_{OMe}^-$ ligand.

## Photophysical Properties

The photophysical properties of the four dyads **1**–**4** have been examined and the data are summarized in Table 1. The absorption spectrum of each of the four dyads **1**–**4** is the sum of the absorption spectra of the two separate porphyrinate moieties, [Yb(TPP)($L_{OMe}$)] and [M(TPP)] (M = $H_2$, Zn, Pd or Pt). Figure 2 shows the absorption spectra of [Yb(TPP)($L_{OMe}$)], [Pt(TPP)], and **4** (**YbPt**) in toluene at room temp. The room-temperature solution electronic absorption, excitation, and emission spectra of **1**–**4** in the UV/Vis region are characteristic of intraligand transitions of normal porphyrinate complexes. The absorption bands (Soret and Q bands) and emission peaks in the visible region are typical of the intraligand $\pi \rightarrow \pi^*$ transitions of the porphyrinato ligand. The visible emissions, which have a decay time ($\tau$) of about 3.79–9.17 ns and quantum yields ($\Phi_{em}$) of $(1.1–9.1) \times 10^{-2}$, can be assigned to the $S_1 \rightarrow S_0$ ligand-centered singlet ($^1$LC) fluorescence. The photoluminescence intensity of the four dyads strongly increases at 77 K and other than for **YbFb**, which exhibits no bathochromicity, the emission peaks of the dyads are redshifted by about 10 nm as compared with their emission bands at room temp. Lifetime measurements at 77 K showed that unlike dyads **YbFb** and **YbZn**, which exhibit only $^1$LC fluorescence at 652 ($\tau$ = 12.96 ns) and 611 ($\tau$ = 3.88 ns) nm, respectively, dyads **YbPd** and **YbPt** also exhibit phosphorescence at 693 ($\tau$ = 950 μs) and 660 ($\tau$ = 100 μs) nm, which almost coincides with the ligand-centered triplet ($^3$LC) emission of [Pd(TPP)] and [Pt(TPP)] complexes, respectively, and could be assigned to the $^3$LC emission of the [M(TPP)] moiety of the dyads. Figure 3 shows the solution excitation and emission spectra of dyad **YbPd** and the [Pd(TPP)] complex in the visible region at both room temp. and 77 K. The lowest $^3$LC state of the [Yb(TPP)($L_{OMe}$)] moiety of the dyads can be identified by measuring the emission spectrum and decay time of the [Gd(TPP)($L_{OMe}$)] complex.[18–21] This is possible because the metal-centered (MC) electronic levels of $Gd^{3+}$ are known to be located at 31000 $cm^{-1}$, typically well above the LC electronic levels of the aromatic ligands.[22] Therefore, ligand-to-metal energy transfer and the consequent MC luminescence cannot be observed. The time-resolved spectrum of the [Gd(TPP)($L_{OMe}$)] complex at 77 K shows that the LC long-lived phosphorescence is detected at 792 nm ($\tau$ = 136 μs).[23]

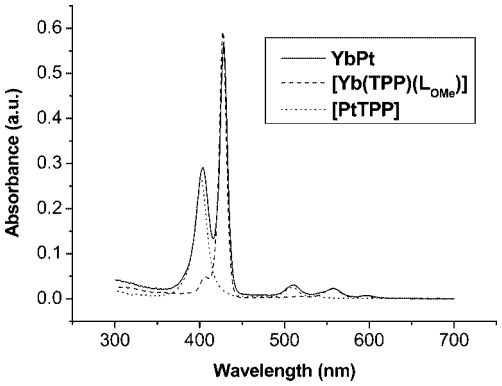

Figure 2. Absorption spectra of **YbPt**, [Yb(TPP)($L_{OMe}$)], and [Pt(TPP)].

Table 1. Photophysical data of **YbFb**, **YbZn**, **YbPd**, and **YbPt** in toluene.[a]

| Compound | Absorption $\lambda_{max}$ (log $\varepsilon$) [nm ($dm^3 mol^{-1} cm^{-1}$)] | Excitation $\lambda_{exc}$ [nm] | Emission at 298 K $\lambda_{em}$ [nm] ($\tau$, $\Phi_{em} \times 10^2$)[b–d] | Emission at 77 K $\lambda_{em}$ [nm] ($\tau$) |
|---|---|---|---|---|
| **YbFb** | 428 (5.86), 517 (4.34), 556 (4.48) 595 (4.06), 646 (3.71) | 419 | 652 (9.02 ns, 9.1), 717 998 (30 μs) | 652 (12.96 ns), 717 998 (30 μs) |
| **YbZn** | 427 (5.95), 557 (4.61), 595 (4.12) | 422 | 601, 651 (3.79 ns, 1.1) 998 (30 μs) | 611 (3.88 ns), 670 998 (30 μs) |
| **YbPd** | 428 (5.81), 524 (4.51), 557 (4.43) 596 (3.92) | 420 | 654 (9.17 ns, 1.6), 721 998 (40 μs) | 648, 693 (950 μs), 772 998 (40 μs) |
| **YbPt** | 403 (5.46), 428 (5.75), 511 (4.49) 558 (4.36), 596 (3.88) | 420 | 652 (8.72 ns, 2.0), 716 998 (30 μs) | 660 (100 μs), 726 998 (70 μs) |
| [Yb(TPP)($L_{OMe}$)] | 428 (5.79), 558 (4.40), 597 (3.85) | 419 | 652 (6.93 ns), 718 998 (30 μs) | 652 (9.15 ns), 718 998 (30 μs) |
| [Gd(TPP)($L_{OMe}$)] | 428 (5.86), 559 (4.35), 597 (3.76) | 420 | 656 (9.92 ns), 720 | 650 (12.71 ns), 792 (136 μs) |
| [Pd(TPP)] | 416, 524 | 420 | 610, 652, 715 | 698 (1340 μs) |
| [Pt(TPP)] | 402, 509, 540 | 403 | 662 | 660 (120 μs) |

[a] Measurements were carried out at a concentration of $1 \times 10^{-6}$ M in toluene. [b] The quantum yield standard used in this study was tetraphenylporphyrin ($H_2$TPP) in anhydrous benzene in air ($\Phi_F$ = 0.11 at 298 K). Quantum yields were calculated using standard methods. [c] Near-infrared (NIR) photoluminescence measurements were carried out in toluene at a concentration of $1 \times 10^{-6}$ M excited at 514 nm. [d] The wavelength of the laser for lifetime measurement was 337 nm.

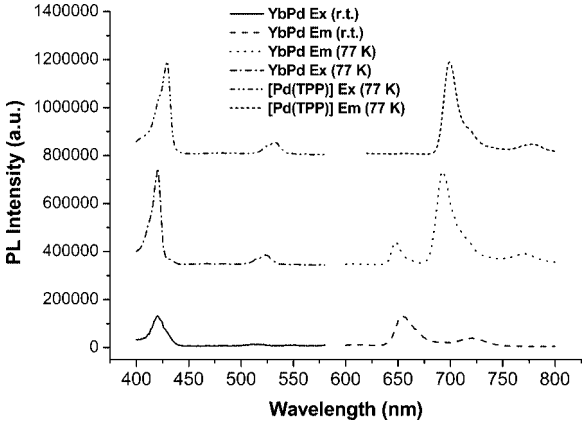

Figure 3. Excitation and emission spectra of **YbPd** and [Pd(TPP)] at 77 K and room temperature.

Other than the visible emission, dyads **1**–**4** also exhibit $Yb^{3+}$ ion emission in the NIR region. The emissions at 998 nm can be assigned to the $^2F_{5/2}\rightarrow{}^2F_{7/2}$ transition of $Yb^{3+}$. These NIR emissions are very similar to those reported for $Yb^{III}$ monoporphyrinate complexes, and the lifetime values are in good agreement with the literature values.[24,25] The $Yb^{3+}$ luminescence lifetimes at room temp. lie within 30–40 μs for the four dyads and are much longer than the lifetime of the porphyrinate emission. Figure 4 shows the visible and NIR emission and the excitation spectra of **YbPd** in toluene. The excitation spectrum of **YbPd** monitored at 998 nm is identical to that monitored at 654 nm, and its excitation bands at 526, 560, and 602 nm almost coincide with its visible absorption bands at 524, 557, and 596 nm. This clearly shows that both the visible and NIR emissions originate from the $\pi\rightarrow\pi^*$ transitions of the porphyrinate antenna, and excitation of porphyrin is the photophysical pathway leading to the observable NIR luminescence. A comparison of the NIR luminescence intensity of the dyads with that of the [Yb(TPP)($L_{OMe}$)] complex at room temp. shows that the relative intensity increases in the order of [Yb(TPP)($L_{OMe}$)] (1.0) < **YbZn** (1.8) < **YbPd** (4.0) < **YbPt** (5.0) (Figure 5). This suggests that

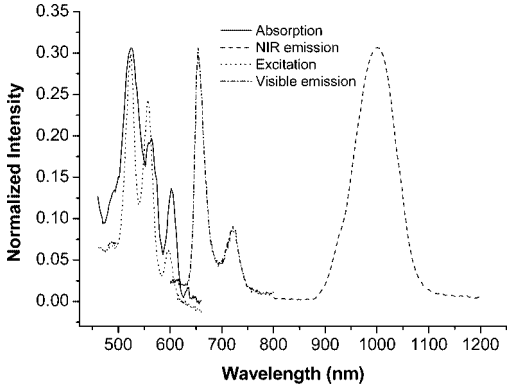

Figure 4. Room-temperature absorption, NIR emission (excited at 514 nm) and excitation (monitored at 998 nm) spectra of **YbPd** in toluene.

the [M(TPP)] (M = Zn, Pd and Pt) moiety, which contributes to the enhancement of NIR emission, transfers its energy to the $Yb^{3+}$ ion. Fluorescence studies at room temp. further support the above donor-acceptor-based hypothesis. The visible fluorescence intensity of the **YbPd** dyad is much weaker than that of the [Pd(TPP)] complex (Figure 6). This indicates that the [Pd(TPP)] moiety (donor) of the **YbPd** dyad is quenched by the [Yb(TPP)($L_{OMe}$)] moiety, probably by the transfer of the $^1$LC energy to the $Yb^{3+}$ ion center (acceptor).

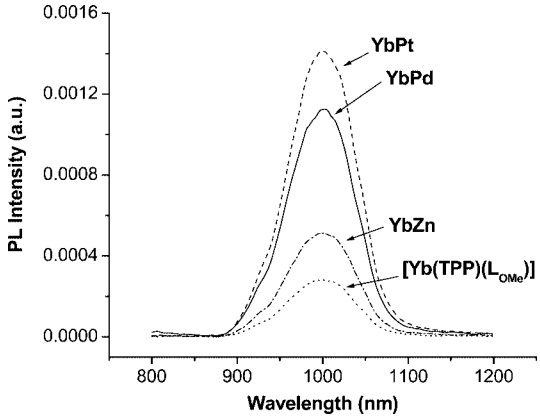

Figure 5. Near-infrared photoluminescence spectra excited at 514 nm at the same concentration in toluene.

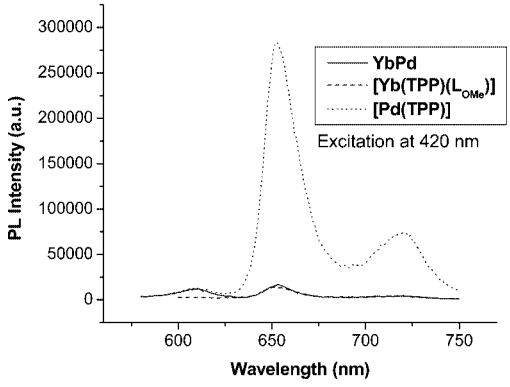

Figure 6. Emission spectra of **YbPd**, [Yb(TPP)($L_{OMe}$)], and [Pd(TPP)] at the same concentration at room temperature.

Optical absorption of the $^1$M(TPP) unit leads to an $S_0\rightarrow S_1$ transition to the singlet excited state $^1$M(TPP)*, followed by a fluorescent emission or intersystem crossing to the triplet excited state $^3$M(TPP)*, which results in the phosphorescent emission and nonradiative deactivation with rate constants $k_r$ and $k_{nr}$, respectively. The energy of the $^3$M(TPP)* excited state can be transferred to $(Yb^{3+})$* with rate constant $k_{ET}$ so that the $Yb^{III}$ NIR emission is enhanced and the lifetime extended (Figure 7). At 77 K, the $Yb^{3+}$ luminescence lifetime of dyads **YbFb** and **YbZn** remains unchanged (30 μs) and is the same as that of [Yb(TPP)($L_{OMe}$)], whereas that of **YbPd** and **YbPt** is extended from 30 to 40 and 70 μs, respectively. This may be

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

due to the presence of a very intense, long-lived $^3$M(TPP)* state in **YbPd** ($\lambda$ = 693 nm, $\tau$ = 950 μs) and **YbPt** ($\lambda$ = 660 nm, $\tau$ = 100 μs), which sensitizes and prolongs the lifetime of the $Yb^{3+}$ luminescence. Such a long-lived $^3$M(TPP)* state is absent in **YbFb** and **YbZn**. The better extension of the $Yb^{III}$ lifetime of **YbPt** than **YbPd** clearly shows that the efficiency of energy transfer by the triplet excited state is better in the former than in the latter.

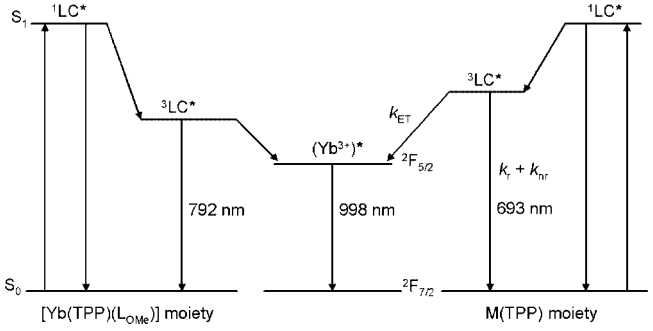

Figure 7. Scheme for the energy transfer from the transition-metal porphyrin unit {[Pd(TPP)] for example} to the Yb porphyrin unit (LC = ligand center). $k_{ET}$ is the rate constant for energy transfer; $k_r$ is the rate constant for radiative deactivation; $k_{nr}$ is the rate constant for nonradiative deactivation. $k_r + k_{nr} = \tau_0^{-1}$ and $k_r + k_{nr} + k_{ET} = \tau^{-1}$.

$H_2$TPP and [Zn(TPP)] are strongly fluorescent while [Pd(TPP)] and [Pt(TPP)] are strongly phosphorescent.[26] Brookfield et al.[27] investigated the energy transfer in Zn-metal-free porphyrin dimers and found that the Zn porphyrin unit transfers singlet-state excitation energy to the free-base porphyrin unit. For the bisporphyrins here, dipole–dipole energy transfer is the dominant mechanism. Here, the $Yb^{III}$ ion is sensitized by two species: one is the porphyrin chromophore, which is coordinated to it; the other is the triplet excited state of the transition-metal porphyrinate unit, which enhances its NIR luminescence. Because the lifetimes of **YbPd** at 693 nm and **YbPt** at 660 nm at 77 K are mainly contributed by the triplet excited state $^3$M(TPP)* lifetimes of the [Pd(TPP)] and [Pt(TPP)] moiety, respectively, the rate constants for the energy transfer from the [M(TPP)] chromophores to the $Yb^{3+}$ ion, $k_{ET}$, can be calculated from Equation (1), where $\tau$ and $\tau_0$ are the lifetimes of the donor-acceptor dyad (**YbPd** and **YbPt**) and the donor chromophore [M(TPP)] (M = Pd and Pt), respectively.

$$k_{ET} = \left(\frac{1}{\tau} - \frac{1}{\tau_0}\right) \quad (1)$$

As a result, $k_{ET}$ for **YbPd** and **YbPt** is 306 and 1667 $s^{-1}$, respectively. Comparing the $k_{ET}$ values, triplet excited state energy transfer of **YbPt** is much faster than that of **YbPd**.

## Two-Photon Absorption

Porphyrin derivatives have attracted increasing attention because of their two-photon absorption (TPA) properties, which could be applied in many research fields, such as 3D microfabrication,[28] photodynamic therapy[29] and optical limiting.[30] The TPA efficacy, which is evaluated by the TPA cross-section value, $\sigma^{(2)}$, is defined as the excitation obtained by the simultaneous absorption of two photons at a longer wavelength followed by the emission at a shorter wavelength (Figure 8). Because of the low quantum yield of porphyrin, the nonlinear transmittance method was used to determine $\sigma^{(2)}$. In this paper, $\sigma^{(2)}$ was measured at 800 nm with 100-fs pulses by an open-aperture *Z*-scan method. Porphyrin is supposed to be excited to the singlet excited state by simultaneously absorbing two photons at 800 nm. It can then emit photons at 650 nm or relax to the triplet excited state through intersystem crossing; thereafter energy could

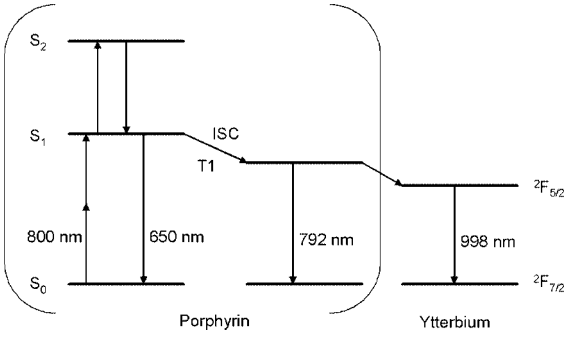

Figure 8. Scheme for the two-photon absorption of Yb porphyrinate complexes.

Table 2. TPA cross-section $\sigma^{(2)}$ (GM) values.[a]

| Compound | Concentration [mol $L^{-1}$] | $\beta$ [cm $GW^{-1}$] | Cross section $\sigma$[b] [GM] |
|---|---|---|---|
| YbFb | $2.5 \times 10^{-4}$ | 0.00061 | 101 |
| YbZn | $2.5 \times 10^{-4}$ | too weak | too weak |
| YbPd | $2.5 \times 10^{-4}$ | 0.00088 | 145 |
| YbPt | $2.5 \times 10^{-4}$ | 0.00147 | 247 |
| [Yb(TPP)($L_{OMe}$)] | $2.5 \times 10^{-4}$ | too weak | too weak |
| $H_2$TPP | $1 \times 10^{-3}$ | 0.00068 | 28 |
| [Zn(TPP)] | $1 \times 10^{-3}$ | 0.00036 | 15 |
| [Pd(TPP)] | $1 \times 10^{-3}$ | 0.00060 | 25 |
| [Pt(TPP)] | $1 \times 10^{-3}$ | 0.00067 | 28 |

[a] The TPA measurements were carried out at an excitation wavelength of 800 nm. [b] 1 GM = $10^{-50}$ $cm^4 \cdot s$ $photon^{-1}$.

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

be transferred to the $Yb^{III}$ ion, which emits at 998 nm. While the $\sigma^{(2)}$ value is wavelength-dependent, it is 28 GM for $H_2TPP$ at 800 nm in this work (cf. the reported value of 15 GM at 780 nm).[31] [Yb(TPP)($L_{OMe}$)] has a very low $\sigma^{(2)}$ value, whereas the dyads **YbFb**, **YbPd**, and **YbPt** have four to eight times larger $\sigma^{(2)}$ values than the corresponding transition-metal porphyrin [M(TPP)] monomers (Table 2).

### Optical Limiting Properties

Optical limiters are typically those dyes with nonlinear optical properties in which the light transmittance will decrease sharply under high light flux so that they can protect sensors from high optical power. Optical limiting (OL) effect can be explained by a mechanism known as reverse saturable absorption (RSA)[32] (see Supporting Information). Until now, indium tetra-*tert*-butylphthalocyanine chloride (InClPc) has been considered to be one of the best optical limiters.[33] Among many different kinds of OL materials, porphyrins continue to attract considerable attention because the structure-property relationships can be investigated easily through structural modification by changing the central metal center, ligand substituents etc. In general, porphyrins exhibit strong excited-state absorptions and long-lived triplet excited states.[30] In addition, they allow high transmission in the visible region because their ground-state absorptions are mainly confined to a few narrow regions (Soret and Q bands). Recently, the optical limiting properties of metalloporphyrins have been examined.[34] Herein, we studied the OL effect of our porphyrin dyads with the *Z*-scan technique[35] at 532 nm. The transmittances for **YbPd**, **YbZn**, **YbPt**, and [Yb(TPP)($L_{OMe}$)] decrease to 55%, 54%, 44%, and 40%, respectively, of their original linear transmission (Figure 9). The OL performance of [Yb(TPP)($L_{OMe}$)] and **4** is comparable to the benchmark material $C_{60}$.

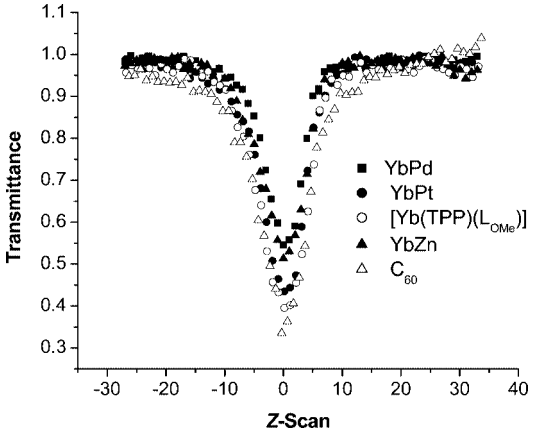

Figure 9. Open-aperture *Z*-scans at 532 nm for optical limiting measurements at a linear transmittance of 85%.

## Conclusions

We have prepared and characterized a series of d-f heterodimetallic bisporphyrin complexes, in which a $Yb^{III}$ porphyrinate moiety was linked to a transition-metal porphyrinate moiety by a flexible three-carbon chain. Upon excitation at 514 nm, the four dyads gave NIR emission centered at 998 nm, with the emission intensity increasing in the order of **YbZn** < **YbPd** < **YbPt**. Photophysical studies showed that the transition-metal porphyrinate moiety sensitized NIR emission and enhanced the $Yb^{III}$ emission intensity and lifetime. Two-photon absorption (TPA) measurements at 800 nm showed that, except for **YbZn**, the bisporphyrins had much larger TPA cross-section values, $\sigma^{(2)}$, than those of [Yb(TPP)($L_{OMe}$)] and [M(TPP)] (M = $H_2$, Zn, Pd, and Pt) complexes. The optical limiting (OP) measurements at 532 nm showed that the OL property was enhanced in the order of **YbPd** < **YbZn** < **YbPt** < [Yb(TPP)($L_{OMe}$)], and the OL performance of [Yb(TPP)($L_{OMe}$)] and **YbPt** is comparable to that of $C_{60}$.

## Experimental Section

**General:** All reactions were carried out in dry nitrogen. Solvents were dried by standard procedures, distilled, and deaerated prior to use. All chemicals used were obtained from Aldrich Chemical Company. $PtCl_2(PhCN)_2$,[36] $Yb[N(SiMe_3)_2]_3$·[$LiCl(THF)_3$]$_x$,[14d] and [Yb(TPP)($L_{OMe}$)][14c] were prepared according to literature methods. Electronic absorption spectra in the UV/Vis region were recorded with a Varian Cary 100 UV/Vis spectrophotometer, steady-state visible fluorescence and PL excitation spectra were recorded with a Photon Technology International (PTI) Alphascan spectrofluorimeter, and visible decay spectra with a pico-$N_2$ laser system (PTI TimeMaster) using $\lambda_{exc}$ = 337 nm. NIR emission was detected by a liquid-nitrogen-cooled InSb IR detector (EG & G) with a preamplifier and recorded by a lock-in amplifier system as the third harmonics. Quantum yields of the visible emissions were computed according to the literature method[37] using tetraphenylporphyrin ($H_2TPP$) as the reference standard ($\Phi$ = 0.11 at 419 nm in benzene in air). NMR spectra were recorded with a Varian Unity Inova 400 MHz spectrometer. $^1H$ NMR chemical shifts were referenced to internal deuteriated chloroform and then recalculated to TMS ($\delta$ = 0.00 ppm) and those from the $^{31}P\{^1H\}$ NMR spectra to external 85% $H_3PO_4$. High- and low-resolution mass spectra, reported as *m*/*z*, were obtained with an Autoflex Bruker MALDI-TOF system and a Finnigan MAT SSQ710 mass spectrometer, respectively. Elemental analyses carried out at the Department of Chemistry, Shanxi University, P. R. China.

**Two-Photon Absorption Measurement:** The two-photon absorption spectra were measured at 800 nm by using the open-aperture *Z*-scan method with 100-fs pulses with a peak power of 276 GW cm$^{-2}$ from an optical parametric amplifier operating at a 1-kHz repetition rate generated from a Ti:sapphire regenerative amplifier system. The laser beam was split into two parts by a beam splitter. One was monitored by a photodiode (D1) as the incident intensity reference, and the other (D2) was detected for the transmitted intensity. After passing through a lens with *f* = 20 cm, the laser beam was focused and passed through a quartz cell. The position of the sample cell was moved along the laser-beam direction (*z* axis) by a computer-controlled translatable table, so the local power density within the sample cell would be changed under the constant incident intensity laser power level. Finally, the transmitted intensity from the sample cell was detected by the photodiode (D2). The photodiode (D2) was connected to the computer, so each transmitted intensity would be taken over 100 times iteration by the

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

computer. Assuming a Gaussian beam profile, the nonlinear absorption coefficient $\beta$ can be obtained by curve fitting to the observed open-aperture traces with Equation (2), where $\alpha_0$ is the linear absorption coefficient, $l$ is the sample length, and $z_0$ is the diffraction length of the incident beam.

$$T(z) = 1 - \frac{\beta I_0 (1 - e^{-\alpha_0 l})}{2a_0(1 + (z/z_0)^2)} \quad (2)$$

After obtaining the nonlinear absorption coefficient $\beta$, the TPA cross-section $\sigma^{(2)}$ of one solute molecule (in units of 1 GM = $10^{-50}$ cm$^4$ s photon$^{-1}$) can be determined by using Equation (3), where $N_A$ is the Avogadro constant, $d$ is the concentration of the TPA compound in solution, $h$ is the Planck constant, and $v$ is the frequency of the incident laser beam.

$$\sigma^{(2)} = \frac{1000\beta h v}{N_A d} \quad (3)$$

**Optical Limiting Measurement:** The investigation of optical limiting properties was performed with a Q-switched Nd:YAG laser at the repetition of 10 Hz. The arrangement of the system is shown in the Supporting Information. The laser was frequency-doubled with an output wavelength of 532 nm with 10-ns pulse width for Gaussian mode by a frequency double crystal (FDC). Then the laser beam was split into two beams by a beam splitter (BS). One was used as the reference beam, which was received by a detector ($D_1$), and the other was for the sample measurement and was focused with a lens ($L_1$, $f$ = 20 cm). After transmitting the light beam through the sample (S), it entered another detector ($D_2$). The sample to be measured was moved along a rail to change the incidence irradiance on it. The incident and transmitted energies were detected simultaneously by the two detectors $D_1$ and $D_2$ (LPE-1A) individually. The solution samples were measured in a 1-mm quartz cell.

**Preparation of Porphyrin Free Bases**

**5-(*p*-Hydroxyphenyl)-10,15,20-triphenylporphyrin (*p*-OH-TPPH$_2$):** This compound was prepared according to a modified literature method.[14b] A solution of benzaldehyde (18.29 mL, 180 mmol) and *p*-hydroxybenzaldehyde (7.32 g, 60 mmol) in propionic acid (700 mL) was heated to 130 °C. Then freshly distilled pyrrole (16.65 mL, 240 mmol) in propionic acid (50 mL) was added slowly to the solution over a period of 0.5 h. The reaction mixture was heated to reflux for another 0.5 h and then cooled to room temp. Then the volume of the reaction mixture was reduced to about half of its original volume under reduced pressure, and methanol (300 mL) was added to the concentrated solution. The resultant solution was kept in a refrigerator overnight. Filtration gave about 4.5 g of crude product, which was redissolved in a minimum amount of chloroform and chromatographed on a silica gel column with dichloromethane as eluent. The second band gave the desired *p*-OH-TPPH$_2$. Yield: 1.9 g (5%). FAB-MS: 631 [M + H]$^+$. $^1$H NMR ($CDCl_3$): $\delta$ = –2.78 (s, 2 H), 4.14 (s, 1 H), 7.19 (m, 2 H), 7.74 (m, 9 H), 8.05 (m, 2 H), 8.21 (m, 6 H), 8.85 (m, 8 H) ppm. UV/Vis (toluene): $\lambda_{max}$ (log $\varepsilon$) = 419 (5.48), 515 (4.20), 550 (3.88), 592 (3.64), 651 (3.71 dm$^3$ mol$^{-1}$ cm$^{-1}$) nm.

**5-[*p*-(3-Bromopropoxy)phenyl]-10,15,20-triphenylporphyrin (*p*-BrC$_3$O-TPPH$_2$):** This compound was prepared according to a modified literature method.[14b] 1,3-Dibromopropane (2 mL, 800 μL, 7.9 mmol) was added to a suspension of *p*-OH-TPPH$_2$ (0.50 g, 0.8 mmol) and anhydrous $K_2CO_3$ in dry DMF (20 mL). The mixture was stirred at room temp., and the progress of the reaction was monitored by TLC. After 24 h, dichloromethane (20 mL) was added to the reaction mixture, which was then washed with water (6 × 20 mL) until all of the DMF and potassium carbonate were removed. The organic phase was dried with sodium sulfate, filtered and the solvents were evaporated to dryness in vacuo. The residue was redissolved in a chloroform/hexane mixture (1:1, v/v) and chromatographed on a silica gel column using chloroform/hexane (5:1, v/v) as eluent. The first band gave the product *p*-BrC$_3$O-TPPH$_2$. Yield: 560 mg (94%). FAB-MS: 752 [M + H]$^+$. $^1$H NMR ($CDCl_3$): $\delta$ = –2.77 (s, 2 H), 2.50 (m, 2 H), 3.77 (q, 2 H), 4.38 (q, 2 H), 7.28 (m, 2 H), 7.74 (m, 9 H), 8.12 (m, 2 H), 8.21 (m, 6 H), 8.86 (m, 8 H) ppm. UV/Vis (toluene): $\lambda_{max}$ (log $\varepsilon$) = 420 (5.43), 515 (4.07), 550 (3.74), 594 (3.50), 650 (3.44 dm$^3$ mol$^{-1}$ cm$^{-1}$) nm.

**Preparation of Yb Porphyrinate Complexes**

**[Yb(*p*-OH-TPP)(L$_{OMe}$)]:** This compound was prepared according to a modification of the literature method.[14c] After *p*-OH-TPPH$_2$ (518 mg, 0.82 mmol) had been treated with excess Yb[N(SiMe$_3$)$_2$]$_3$·[LiCl(THF)$_3$]$_x$ (0.16 mol L$^{-1}$, 10 mL) under nitrogen in refluxing toluene for 12 h, the mixture was cooled down to room temp., followed by the addition of excess NaL$_{OMe}$. The reaction mixture was concentrated under reduced pressure to remove toluene and purified by column chromatography on silica to give purple crystals of [Yb(*p*-OH-TPP)(L$_{OMe}$)] after recrystallization. Yield: 863 mg (84%). MALDI-TOF MS: calcd. for [M$^+$] 1253.1549, found 1253.1516. $^1$H NMR ($CDCl_3$): $\delta$ = –4.62 (s, 5 H), 6.98 (s, 18 H), 8.13 (s, 1 H), 8.57–8.76 (br., 8 H), 9.36–9.42 (br., 3 H), 9.93 (br., 1 H), 10.56 (br., 3 H), 15.29 (br., 8 H), 16.56 (br., 1 H), 16.85 (br., 3 H) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 69.2 ppm. UV/Vis (toluene): $\lambda_{max}$ (log $\varepsilon$) = 429 (5.80), 558 (4.37), 599 (3.82 dm$^3$ mol$^{-1}$ cm$^{-1}$) nm.

**[Yb(*p*-BrC$_3$O-TPP)(L$_{OMe}$)]:** [Yb(*p*-OH-TPP)(L$_{OMe}$)] (100 mg, 0.08 mmol) was stirred in dry DMF (10 mL) in the presence of anhydrous potassium carbonate (300 mg) for 20 min, followed by addition of 10 equiv. of 1,3-dibromopropane. The reaction mixture was stirred overnight, and dichloromethane (20 mL) was then added. The mixture was washed with deionized water (3 × 20 mL) until all the DMF was washed away. The solution was dried with anhydrous sodium sulfate, and the residue upon concentration was purified by column chromatography on silica with dichloromethane as eluent. The first band gave [Yb(*p*-BrC$_3$O-TPP)(L$_{OMe}$)]. Yield: 90 mg (82%). MALDI-TOF MS: calcd. for [M + H]$^+$ 1374.1178, found 1374.1234. $^1$H NMR ($CDCl_3$): $\delta$ = –4.54 (s, 5 H), 3.25 (q, 2 H), 4.53 (t, 2 H), 5.38 (t, 2 H), 6.62 (s, 18 H), 8.38 (br., 1 H), 8.90–9.02 (br., 7 H), 9.64 (m, 3 H), 10.24 (br., 1 H), 10.80 (br., 3 H), 15.62 (br., 8 H), 16.87–17.18 (br., 4 H) ppm. $^{31}$P{$^1$H} NMR ($CDCl_3$): $\delta$ = 68.2 ppm. UV/Vis (toluene): $\lambda_{max}$ (log $\varepsilon$) = 429 (5.68), 558 (4.26), 598 (3.77 dm$^3$ mol$^{-1}$ cm$^{-1}$) nm.

**Preparation of Yb Bisporphyrin Complexes**

**YbFb:** *p*-BrC$_3$O-TPPH$_2$ (200 mg, 0.27 mmol) was added to a suspension of [Yb(*p*-OH-TPP)(L$_{OMe}$)] (358 mg, 0.29 mmol) in dry DMF (10 mL) in the presence of anhydrous potassium carbonate. The resultant mixture was stirred at 60 °C overnight and cooled to room temp. Dichloromethane (10 mL) was added to the reaction mixture, which was then washed with water (6 × 10 mL) until all of the DMF and potassium carbonate was removed. The organic phase was dried with sodium sulfate, filtered, and the solvents were evaporated to dryness in vacuo. The residue was redissolved in chloroform/hexane (1:1, v/v) and chromatographed on a silica gel column using chloroform/hexane (5:1, v/v) as eluent to give **YbFb** from the first band. Yield: 318 mg (58%). MALDI-TOF MS: calcd. for [M + H]$^+$ 1924.4363, found 1924.4353. IR (KBr): $\tilde{\nu}$ = 3446 (s),

2939 (w), 1701 (w), 1652 (w), 1600 (w), 1511 (m), 1472 (m), 1438 (w), 1240 (m), 1175 (m), 1141 (s), 1035 (m), 1007 (m), 799 (s), 775 (m), 727 (s), 702 (m), 620 (w), 587 (m) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = –4.52 (s, 5 H), –2.64 (s, 2 H), 3.34 (q, 2 H), 5.20 (t, 2 H), 5.64 (t, 2 H), 6.34 (s, 18 H), 7.20–7.83 (m, 11 H), 8.24–8.30 (m, 6 H), 8.47 (d, 2 H), 8.65–8.73 (br., 8 H), 8.89 (s, 4 H), 9.00 (d, 2 H), 9.19 (d, 2 H), 9.36 (br., 3 H), 10.15 (br., 1 H), 10.52 (br., 3 H), 15.22 (br., 8 H), 16.60–16.78 (br., 4 H) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 69.2 ppm. **YbFb** could also be prepared by the reaction of [Yb(*p*-$BrC_3O$-TPP)($L_{OMe}$)] with *p*-OH-$TPPH_2$. [Yb(*p*-$BrC_3O$-TPP)($L_{OMe}$)] (100 mg, 0.073 mmol) was added to a suspension of *p*-OH-$TPPH_2$ (70 mg, 0.11 mmol) in dry DMF (10 mL) in the presence of anhydrous potassium carbonate (300 mg). Then the resultant mixture was stirred at 60 °C overnight and cooled to room temp. Dichloromethane (10 mL) was added to the reaction mixture, which was then washed with water (6 × 10 mL) until all of the DMF and potassium carbonate were removed. The organic phase was dried with sodium sulfate, filtered, and the solvents were evaporated to dryness in vacuo. The residue was redissolved in chloroform/hexane (1:1, v/v) and chromatographed on a silica gel column using chloroform/hexane (5:1, v/v) as eluent to give **YbFb** from the first band. Yield: 84 mg (60%). $C_{102}H_{85}CoN_8O_{11}P_3Yb{\cdot}CHCl_3{\cdot}1.5C_7H_8{\cdot}2H_2O$ (2217.32): calcd. C 61.48, H 4.64, N 5.05; found C 61.55, H 4.59, N 4.96.

**YbZn and YbPd: YbFb** (100 mg, 0.052 mmol) was treated with $Zn(OAc)_2$ hydrate (300 mg, 1.37 mmol) or $Pd(OAc)_2$ hydrate (550 mg, 2.45 mmol) in a refluxing solution mixture of chloroform/methanol (1:1, v/v) (20 mL) for 24 h. Then chloroform and methanol were removed in a rotary evaporator. The resulting solid was dissolved in chloroform and chromatographed on a silica gel column using chloroform/hexane (5:1, v/v) as eluent. The second band gave **YbZn** (86 mg, 83%) or **YbPd** (93 mg, 88%) in good yields. **YbZn:** MALDI-TOF MS: calcd. for $[M + H]^+$ 1988.3490, found 1988.3409. IR (KBr): $\tilde{\nu}$ = 3449 (s), 2939 (w), 1711 (s), 1600 (w), 1513 (m), 1480 (m), 1436 (w), 1359 (m), 1333 (w), 1225 (m), 1174 (w), 1140 (s), 1097 (w), 1064 (w), 1034 (m), 997 (s), 837 (w), 797 (m), 752 (m), 725 (m), 702 (m), 654 (w), 620 (w), 588 (w), 531 (w) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = –4.54 (s, 5 H), 3.34 (q, 2 H), 5.21 (t, 3 H), 5.62 (t, 3 H), 6.33 (s, 18 H), 7.76–7.83 (m, 11 H), 8.24–8.31 (m, 6 H), 8.48 (d, 2 H), 8.65–8.73 (br., 8 H), 8.98 (s, 4 H), 9.11 (d, 2 H), 9.30 (d, 2 H), 8.34–8.39 (br., 3 H), 10.13 (br., 1 H), 10.51 (br., 3 H), 15.23 (br., 8 H), 16.78 (br., 4 H) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 69.2 ppm. $C_{102}H_{83}CoN_8O_{11}P_3YbZn{\cdot}CHCl_3{\cdot}1.5C_7H_8{\cdot}H_2O$ (2262.68): calcd. C 60.25, H 4.36, N 4.95; found C 60.30, H 4.41, N 4.93. **YbPd:** MALDI-TOF MS: calcd. for $[M + H]^+$ 2028.3251, found 2028.3187. IR (KBr): $\tilde{\nu}$ = 3445 (s), 2939 (w), 1710 (s), 1599 (m), 1510 (m), 1474 (m), 1440 (m), 1354 (m), 1238 (m), 1140 (s), 1009 (s), 798 (m), 752 (m), 725 (m), 704 (m), 587 (m) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = –4.54 (s, 5 H), 3.30 (q, 2 H), 5.14 (t, 2 H), 5.60 (t, 2 H), 6.34 (s, 18 H), 7.77 (m, 11 H), 8.23 (m, 6 H), 8.40 (d, 2 H), 8.73 (br., 8 H), 8.87 (s, 4 H), 8.97 (d, 2 H), 9.15 (d, 2 H), 9.37 (br., 3 H), 10.12 (br., 1 H), 10.52 (br., 3 H), 15.24 (br., 8 H), 16.79 (br., 4 H) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 69.2 ppm. $C_{102}H_{83}CoN_8O_{11}P_3PdYb{\cdot}CHCl_3{\cdot}C_7H_8{\cdot}H_2O$ (2257.64): calcd. C 58.52, H 4.20, N 4.96; found C 58.51, H 4.18, N 4.88.

**YbPt:** After **YbFb** (100 mg, 0.052 mmol) had been treated with $PtCl_2(PhCN)_2$ (125 mg, 0.26 mmol) in refluxing benzonitrile (5 mL) for 24 h, the solvent was removed under reduced pressure. The resulting solid was dissolved in a minimum amount of dichloromethane and chromatographed on a silica gel column using dichloromethane as eluent. The second band gave **YbPt** in 60% yield (66 mg). MALDI-TOF MS: calcd. for $[M + H]^+$ 2117.3859, found 2117.3801. IR (KBr): $\tilde{\nu}$ = 3434 (s), 2925 (m), 1602 (m), 1510 (w), 1444 (w), 1359 (w), 1325 (w), 1240 (m), 1175 (m), 1142 (s), 1014 (s), 796 (m), 753 (m), 726 (m), 704 (m), 588 (m) $cm^{-1}$. $^1H$ NMR ($CDCl_3$): $\delta$ = –4.53 (s, 5 H), 3.36 (q, 2 H), 5.22 (t, 2 H), 5.67 (t, 2 H), 6.35 (s, 18 H), 7.74–7.82 (m, 11 H), 8.21 (m, 6 H), 8.41 (d, 2 H), 8.55–8.75 (br., 8 H), 8.80 (s, 4 H), 8.91 (d, 2 H), 9.10 (d, 2 H), 9.38 (br., 3 H), 10.14 (br., 1 H), 10.52 (br., 3 H), 15.25 (br., 8 H), 16.81 (br., 4 H) ppm. $^{31}P\{^1H\}$ NMR ($CDCl_3$): $\delta$ = 69.0 ppm. $C_{102}H_{83}CoN_8O_{11}P_3PtYb{\cdot}CHCl_3{\cdot}1.5C_7H_8$ (2374.36): calcd. C 57.41, H 4.08, N 4.72; found C 57.57, H 4.02, N 5.08.

**X-ray Crystallography:** Pertinent crystallographic data and other experimental details are summarized in Table 3. Crystals of [Yb(*p*-$BrC_3O$-TPP)($L_{OMe}$)]·$2CHCl_3$ suitable for X-ray diffraction studies were grown by slow concentration of a chloroform/methanol solution of the complex in air. The crystals were wrapped in epoxy glue to prevent them from losing solvent, and mounted on a thin glass fiber. Intensity data were collected at 293 K with a Bruker Axs SMART 100 CCD area-detector diffractometer using graphite-monochromated Mo-$K_\alpha$ radiation ($\lambda$ = 0.71073 Å). The collected frames were processed with the software SAINT,[38] and an absorption correction was applied (SADABS)[39] to the collected reflections. The space group of the crystal was determined from the systematic absences and Laue symmetry checks and confirmed by successful refinement of the structure. The structure was solved by direct methods (SHELXTL)[40] and refined against $F^2$ by full-matrix least-squares analyses. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were generated in their idealized positions and allowed to ride on their respective parent carbon atoms. CCDC-635196 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif.

Table 3. Crystallographic data for [Yb(*p*-$BrC_3O$-TPP)($L_{OMe}$)]·$2CHCl_3$.

| | |
|---|---|
| Empirical formula | $C_{60}H_{58}BrCl_6CoN_4O_{10}P_3Yb$ |
| Formula mass | 1612.59 |
| Color and habit | purple block |
| Crystal size [mm] | 0.30 × 0.25 × 0.21 |
| Crystal system | monoclinic |
| Space group | $P2_1/c$ |
| $a$ [Å] | 13.2139(6) |
| $b$ [Å] | 43.627(2) |
| $c$ [Å] | 12.3255(6) |
| $\alpha$ [°] | 90 |
| $\beta$ [°] | 109.3310(10) |
| $\gamma$ [°] | 90 |
| $V$ [Å$^3$] | 6704.9(6) |
| $Z$ | 4 |
| $D_{calcd.}$ [g cm$^{-3}$] | 1.598 |
| Absorption coefficient [mm$^{-1}$] | 2.597 |
| $F(000)$ | 3220 |
| $\theta$ range [°] | 1.87–25.00 |
| Reflections collected | 32118 |
| Independent reflections | 11531 ($R_{int}$ = 0.0429) |
| Observed reflections [$I > 2.0\sigma(I)$] | 8698 |
| Goodness of fit on $F^2$ | 1.098 |
| Final $R$ indices [$I > 2\sigma(I)$] | $R_1$ = 0.0785, $wR_2$ = 0.1807 |
| $R$ indices (all data) | $R_1$ = 0.1063, $wR_2$ = 0.1955 |

**Supporting Information** (see footnote on the first page of this article): $^1H$ NMR and COSY spectra of [Yb(TPP)($L_{OMe}$)], the optical limiting (OL) mechanism and experimental setup for OL.

# On the Synthesis of Ramsdellite $LiTiMO_4$ (M = Ti, V, Cr, Mn, Fe): An Experimental and Computational Study of the Spinel–Ramsdellite Transformation

**Alois Kuhn,[a] Pilar Díaz-Carrasco,[a] María Elena Arroyo y de Dompablo,*[b] and Flaviano García-Alvarado*[a]**

**Keywords:** Titanates / Phase transitions / Ab initio calculations / Solid-state reactions / Electrochemistry

The $LiTiMO_4$ (spinel) ↔ $LiTiMO_4$ (ramsdellite) transformation has been investigated by combining computational and experimental techniques, for M = Ti, V, Cr, Mn, and Fe, in order to understand the characteristics of this transformation and the influence of the metal M on the relative stability of the ramsdellite polymorph. The calculations predict that all the aforementioned $LiTiMO_4$ spinels are thermodynamically stable with respect to the ramsdellite polymorph, with the calculated enthalpy variation of the transformation being less than 40 $kJ\,mol^{-1}$. In the case of normal spinels $[Li]_t[TiM]_oO_4$ we estimated a transformation temperature in the range 900–1600 °C, whereas the polymorphic transformation for inverse spinels $[Li_{0.5}M_{0.5}]_t[TiM_{0.5}Li_{0.5}]_oO_4$ is accompanied by a lower entropy gain, hence a much higher temperature would be needed to overcome the enthalpy of the transformation. The transformation is thus entropically controlled. Accordingly, experimental results show that normal $[Li]_t[TiM]_oO_4$ spinels (M = Ti, V, Cr) readily transform into ramsdellites at temperatures between 900 and 1400 °C, whereas this transition is hindered for spinels $LiTiMO_4$ (M = Fe, Mn), which possess a high degree of inversion. Based on a possible mechanism for the transformation, we infer that the impossibility of transforming the Mn and Fe inverse-spinels into their ramsdellite forms is also due to the high energy barriers that must be overcome during the transformation. The obtained $LiTiMO_4$ (M = Ti, V, and Cr) ramsdellites, which contain $Ti^{IV}$ and $M^{III}$, display a twofold electrochemical application, namely that one lithium ion per formula unit can be inserted into these compounds at about 1.4 V vs. Li (reduction of $Ti^{IV}$ to $Ti^{III}$). The oxidation of $M^{III}$ ions to $M^{IV}$ enables lithium deinsertion from $LiTiMO_4$ (M = Ti, V, and Cr) at potentials of 1.9 V (M = Ti), 3.1 V (M = V), and 4.2 (M = Cr) vs. Li.

## Introduction

Electrode materials for rechargeable lithium batteries are based on transition metal inorganic frameworks that can reversibly intercalate large amounts of lithium ions. The application of such materials as positive or negative electrodes depends on the potential at which lithium ions are intercalated − potentials above 3 V and below 1 V vs. Li are desirable for the positive and the negative electrode, respectively. In terms of lithium battery applications, titanates with the ramsdellite structure are of considerable interest because this structure enables fast and reversible insertion of a good quantity of lithium ions. A schematic representation of the ramsdellite structure is depicted in part a of Figure 1. It is built up by $[TiO]_6$ octahedra that form double edge-sharing chains running along [001]. These chains are interconnected through corners in the *ab* plane. Lithium ions partially occupy some crystallographic sites located in the $1 \times 2$ tunnels running parallel to the *c* axis.[1,2] The presence of unoccupied Li sites in these channels in ramsdellite $Li_2Ti_3O_7$ allows for a further lithium uptake of up to 2.24 Li ions, which means that $Li_2Ti_3O_7$ would deliver a specific capacity of 240 $Ah\,kg^{-1}$ as an electrode in a lithium cell.[3] The high temperature polymorph of spinel $LiTi_2O_4$ also presents the ramsdellite structural type. Hereafter the spinel polymorph will be denoted as $LiTi_2O_4$(S) while the ramsdellite polymorph will be denoted as $LiTi_2O_4$(R). The latter has recently been proposed as a new electrode material for lithium batteries.[4–6] $LiTi_2O_4$(R) is nominally formulated as $LiTi^{3+}Ti^{4+}O_4$, therefore lithium intercalation into this material proceeds only up to a maximum of one Li per formula unit (specific capacity of 160 $Ah\,kg^{-1}$), in other words complete reduction of the $Ti^{4+}$ ions. The reversible reduction of $Ti^{4+}$ ions in both $Li_2Ti_3O_7$ and $LiTi_2O_4$ occurs at 1.4 V vs. the lithium electrode.

The presence of $Ti^{3+}$, which can be oxidised, in $LiTi_2O_4$(R) permits the deintercalation of a maximum of one Li per formula unit. Indeed, the extraction of lithium from

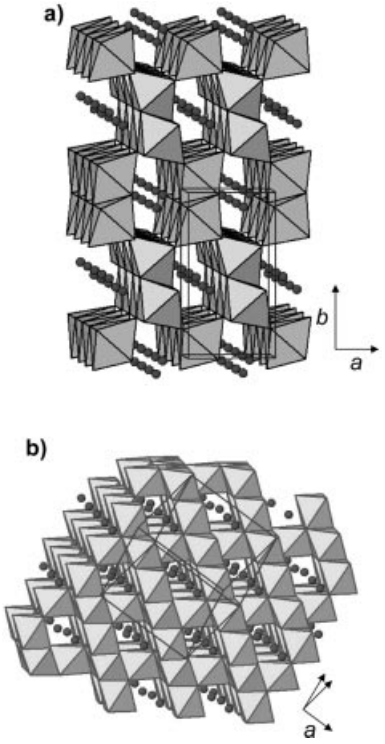

Figure 1. Schematic representation of a) the ramsdellite structure of $Li_2Ti_3O_7$ and b) the spinel structure of $LiTi_2O_4$. In both cases circles correspond to lithium ions and octahedra represent $TiO_6$ coordination.

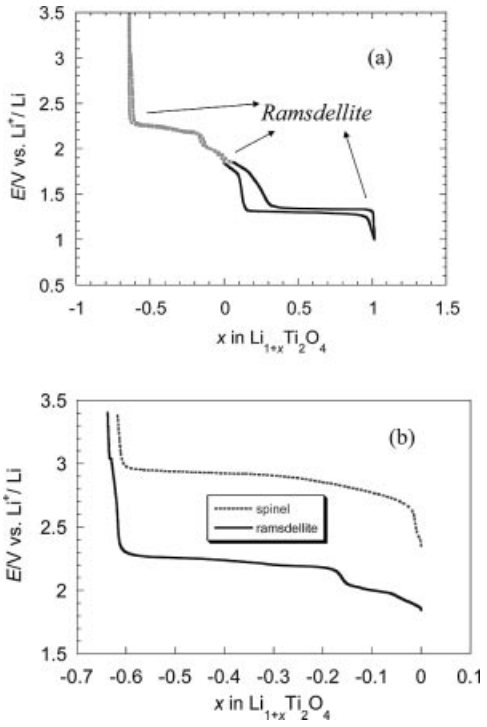

Figure 2. (a) Voltage vs. composition curve of a $LiTi_2O_4$ (ramsdellite)//Li cell started on discharge (continuous line) and started on charge (dashed line). (b) Voltage vs. composition curve of a $LiTi_2O_4$//Li cell started on charge showing the behavior of the two different polymorphs [ramsdellite (continuous line) and spinel (dashed line)].

$LiTi_2O_4$ at room temperature by both chemical and electrochemical methods has been reported as a route to the ramsdellite polymorph of $TiO_2$.[4,7] Thus, the coexistence of $Ti^{3+}$ and $Ti^{4+}$ in $LiTi_2O_4$ allows for the deinsertion of one lithium ion (oxidation of $Ti^{3+}$) and the insertion of one lithium ion (reduction of $Ti^{4+}$). Figure 2 (a) shows a typical voltage composition plot obtained when a Li//$LiTi_2O_4$(R) cell is cycled between either 1.8 and 1 V (continuous line) or 1.8 and 3.5 V (dashed line), which correspond to the intercalation of lithium into $LiTi_2O_4$(R) and de-intercalation of lithium from $LiTi_2O_4$(R), respectively. Both processes are reversible. The flat intercalation and de-intercalation regions are characteristic of two-phase domains, as indicated in previous works[4,5] and confirmed by in situ XRD studies using synchrotron radiation.[8] At the end of the intercalation (1 V) and de-intercalation curves (3.5 V), two different ramsdellites with formulae $Li_2Ti_2O_4$ and $TiO_2$, respectively, exist. In other words, the intermediate $Li_xTi_2O_4$ composition located at the plateaux actually corresponds to mixtures of the two ramsdellite extremes ($x$ = 0, 1, or 2) in different ratios.

The main advantage of ramsdellites as an electrode material for rechargeable lithium batteries is the high reversibility of the intercalation process. It has been demonstrated that electrochemically inserted $Li_{2+x}Ti_3O_7$ compounds retain the ramsdellite framework for large amounts of lithium ($x \approx 2.24$). The small changes in the basic ramsdellite cell parameters during the intercalation process, also known as zero-strain behavior, are likely to be the origin of the good capacity retention with cycling.[3] The formation of $Li_2Ti_2O_4$(R)/$TiO_2$(R) upon reduction/oxidation of $LiTi_2O_4$ is also accompanied by very small volume changes. Bearing in mind the good reversibility and high capacity of ramsdellites, we have been working on the synthesis and characterization of novel $LiTi_{2-y}M_yO_4$ ramsdellites obtained by substitution of the trivalent Ti by other ions. The oxidation of $Ti^{3+}$ in $LiTi_2O_4$ occurs at about 1.9 V and it is therefore desirable to increase this potential to the 3–4 V range, as the $V^{3+}/V^{4+}$, $Fe^{3+}/Fe^{4+}$, $Mn^{3+}/Mn^{4+}$, and $Cr^{3+}/Cr^{4+}$ redox couples are known to be operative at such high voltages vs. Li.

Although $LiTi_2O_4$ can be prepared in the ramsdellite structure, its stable form at room temperature is spinel-like. Transformation of $LiTi_2O_4$(S) into $LiTi_2O_4$(R) occurs at 925 °C.[9,10] On the other hand, spinels with the formula $LiTiMO_4$ (M = Ti, V, Cr, Mn, and Fe) are known to exist. With the aim of preparing the novel ramsdellites $LiTiMO_4$ (M = V, Cr, Mn, and Fe), in this work we will try to induce the spinel–ramsdellite phase transformation by thermal treatment in a reaction that can be written as:

$$LiTiMO_4(S) \leftrightarrow LiTiMO_4(R) \quad (1)$$

The relative thermodynamic stability of polymorphs can be explored by first-principles methods, a good example of which is the investigation of Reed et al.[11] dealing with the stability of layered $Li_{0.5}MO_2$ with respect to its transformation into spinel $LiM_2O_4$ (M is a transition metal). In this

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

work we have performed a computational study on the stability of ramsdellite with respect to the spinel form to assess whether the transformation of spinel $LiTiMO_4$ (M = V, Cr, Mn and Fe) to ramsdellite is feasible from a thermodynamic point of view. Based on these predictions we have attempted to synthesize the new ramsdellites $LiTiMO_4$ (M = V, Cr, Mn and Fe) starting from the spinel-like polymorphs. A preliminary structural characterization is also presented for those ramsdellites that have been obtained. Finally, although full electrochemical studies of individual ramsdellites are described elsewhere,[12–14] the general electrochemical behavior of the novel ramsdellites is also included here for completeness.

## Results and Discussion

### Computational Analysis of the $LiTiMO_4$(S) ↔ $LiTiMO_4$(R) Transformation

Computing the energy of a periodic electronic structure requires a cation-ordering scheme to be imposed on the simulated unit cell. The unit cell of $LiTiMO_4$(S) contains eight formula units and shows cubic symmetry (space group *Fd3m*) with a lattice parameter *a* of about 8.2 Å. In this cell we have imposed the simplest order in which Ti and M atoms alternate in the octahedral sites of the spinel along two main crystallographic directions. By doing so, the *Fd3m* symmetry is broken and the new cell must be redefined in the *Imma* space group. The lattice parameters of the ordered structure are $a = a_o/\sqrt{2}$, $b = a_o/\sqrt{2}$, and $c = a_o$, where $a_o$ denotes the lattice parameter of the cubic spinel ($a_o \approx 8.2$ Å). Hence, the unit cell of the ordered spinel (space group *Imma*) is related to that of the cubic spinel (space group *Fd3m*) by a 45° rotation around the *c* axis. In the case of the ramsdellite compounds, M and Ti ions alternate along the [010] direction in the ordered cell used for the calculations in such a way that chains of either M or Ti edge-sharing octahedra run parallel to the [001] axis.

Tables 1 and 2 list the optimized values of the lattice parameters for spinel and ramsdellite $LiTiMO_4$ (M = Ti, V, Cr, Mn and Fe) obtained in this ab initio study. It should be noted that all the transition metal ions occupy octahedral sites in the computed spinel cell. However, experimental results indicate that in the case of M = Cr, Mn and Fe some transition metal ions are located in the tetrahedral sites.[15–18] Note that in the first part of this computational study we have not considered the degree of inversion. In view of the data in Tables 1 and 2, it can be concluded that, generally speaking, the calculation method allows a correct prediction of the cell parameters, with differences of around 2–4% that are typical for state-of-the-art approximations to density functional theory in transition metal oxides. It is well documented that the generalized gradient approximation (GGA) method has a tendency to overestimate the equilibrium volume.

Table 1. Calculated and experimental lattice parameters of spinels $LiTiMO_4$ (M = Ti, V, Cr, Mn, and Fe). The parameters are given for a cell of *Imma* symmetry (four $LiTiMO_4$ formula units per cell) that was used for the calculations (see text). Experimental data are given in parentheses.

[a] Error between calculated and experimental data.

In the last year first-principles calculations have been widely use to accurately predict the lithium intercalation voltage of a large variety of electrode materials (see, for instance, refs.[23–25]). The average lithium de-intercalation voltages of $LiTi_2O_4$ for both ramsdellite and spinel structural types have also been computed in this work as some of them are known experimentally and their comparison may be a convenient way of validating the calculations. Since the insertion reaction is written as Equation (2) the open-circuit average voltage for the lithium insertion pro-

cess can be obtained as explained by Aydinol et al.[24] from a total energy difference expression [see Equation (3); $E_{total}$ refers to the total energy per formula unit] if entropy and volumetric effects are ignored.

$$Ti_2O_4 + Li \leftrightarrow LiTi_2O_4 \quad (2)$$

$$V_a = E_{total(Ti_2O_4)} + E_{total(Li)} - E_{total(LiTi_2O_4)} \quad (3)$$

Calculations predict an average lithium insertion voltage of 1.86 V for $TiO_2$(R), which is about 0.3 V below the experimental results presented in Figure 2 (b). Such voltage underestimations are usually reported in the literature for transition metal oxides in the GGA implementation (see, for instance, refs.[24,26]). Regarding the spinel, the calculated potential is 3 V, which is in good agreement with the experimental data (see Figure 2, b).

The relative thermodynamic stability of both spinel and ramsdellite $LiMTiO_4$ can be inferred from the difference between their calculated total energies. The results obtained for M = Ti, V, Cr, Mn, and Fe are summarized in Figure 3 for normal (squares) and inverse spinels (circles). The spinel structure is energetically more stable than the ramsdellite form in all cases. To produce a phase transformation between the polymorphs the free-energy variation of Equation (1) should be zero:

$$\Delta G_r = \Delta E_r + P\Delta V_r - T\Delta S_r \quad (4)$$

In this equation $E_r$ is the reaction energy, whose calculated values are given in Figure 3, and the term $P\Delta V_r$ can be obtained from the calculated volume data summarized in Tables 1 and 2. At ambient pressure the $P\Delta V_r$ term has a small value of the order of $10^{-4}$ kJ mol$^{-1}$, and is therefore negligible compared to the energy of the reaction ($E_r$ is of the order of $10^1$ kJ mol$^{-1}$). Obviously, the transformation is an endothermic reaction ($\Delta H_r = \Delta E_r + P\Delta V_r$, $\Delta H_r \approx \Delta E_r$). Even if the polymorphic transformation has a positive reaction enthalpy, it might occur if a large positive entropy accompanies the transformation reaction. In this case, the transformation would become favorable at high temperature ($\Delta H_r = T\Delta S_r$). This is indeed found experimentally in the case of M = Ti, since it is well known that the spinel is the low-temperature polymorph and that the transformation to ramsdellite requires heating at 925 °C and final quenching to room temperature. Computational results indicate that the enthalpy of transformation between spinel and ramsdellite $LiTi_2O_4$ is about 24.14 kJ mol$^{-1}$. The free-energy difference between polymorphs at the transition temperature is zero, therefore the enthalpy variation of the reaction is equal to the $T\Delta S_r$ term. First-principles investigations do not provide information about the entropy term, which makes it impossible to predict the transition temperature. However, the entropy term can be approximated for the $LiTi_2O_4$(S)–$LiTi_2O_4$(R) transformation, which occurs at a temperature of 925 °C. Thus, taking into account the calculated value of the enthalpy (24.14 kJ mol$^{-1}$), the entropy value for this transformation is 20.13 J mol$^{-1}$ K$^{-1}$. To estimate the temperature needed for the remaining $LiMTiO_4$ spinels we can assume that the entropy variation between the normal spinel and the ramsdellite forms is similar for any M.

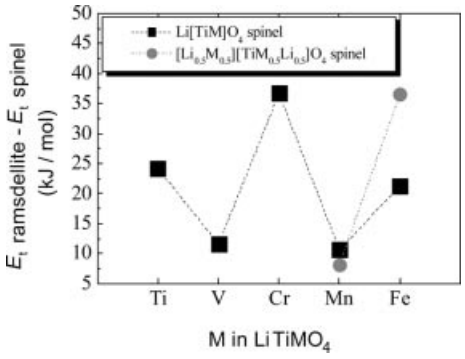

Figure 3. Calculated total energy difference between the ramsdellite and spinel polymorphs for $LiTiMO_4$ (M = Ti, V, Cr, Mn, and Fe). Two configurations, namely the normal cationic distribution $[Li]_t[TiM]_oO_4$ (squares) and the inverse $[Li_{0.5}M_{0.5}]_t[TiM_{0.5}Li_{0.5}]_oO_4$ configuration (circles), were computed for the spinel structure.

The energy difference between the Fe-substituted ramsdellite and the normal spinel (21 kJ mol$^{-1}$) is close to that of the $LiTi_2O_4$ system, therefore calculations suggest that $LiTiFeO_4$(R) could be stabilized by similar thermal treatment (considering $\Delta S$ to be 0.02 kJ mol$^{-1}$ K$^{-1}$). In light of this entropy value, the phase transformation for M = V and Mn would occur at lower temperatures, at around 300 °C. The spinel-ramsdellite transformation in the Cr system seems to be the most unfavorable since it presents the largest energy difference (36.6 kJ mol$^{-1}$). This suggests that the transformation would occur at higher temperatures, around 1550 °C.

So far we have discussed the results considering the normal spinel structure $Li_2(Ti_2M_2)_oO_8$, where all the M ions occupy octahedral sites. However, neutron diffraction measurements have shown that Li and Ti ions show a partial inverted distribution in $LiMnTiO_4$ over the tetrahedral and octahedral sites, although a more recent study has suggested that the Mn ion is disordered between these sites.[18] The same situation occurs in $LiFeTiO_4$ with Li and Fe ions.[17,22] The corresponding formulae – $[Li_{0.66}Ti_{0.34}]_{8a}[Li_{0.34}MnTi_{0.66}]_{16d}O_4$ and $[Li_{0.47}Fe_{0.53}]_{8a}[Li_{0.53}Fe_{0.47}Ti]_{16d}O_4$ – suggest inversion degrees of 34% and 53%, respectively. To account for this degree of inversion, in a second stage we have computed the total energy of the spinels $[Li_{0.5}M_{0.5}]_t[Ti_1M_{0.5}Li_{0.5}]_oO_4$ (M = Fe and Mn). In the case of Fe the inverse spinel is 15.8 kJ mol$^{-1}$ more stable than the normal spinel, hence the energy difference between ramsdellite and spinel forms increases by the same amount to 36.5 kJ mol$^{-1}$, which is the same energy difference found in the Cr system (see Figure 3). The enthalpic stabilization of the inverse spinel with respect to the normal configuration is rooted in the tetrahedral-site preference of $Fe^{3+}$ (although small). In addition, the configurational entropy also

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

minimizes the free energy of the inverse spinel with respect to the normal spinel. Navrotsky et al.,[27] amongst others, have reported that the configurational entropy in spinels depends on the degree of inversion, and is 11.3 and 14.6 $J\,mol^{-1}\,K^{-1}$ larger for the inverse spinels $B(AB)O_4$ and $A_{0.5}B_{0.5}(A_{0.5}B_{1.5})O_4$, respectively, than for the normal spinel $A(B_2)O_4$. Hence, the inverse spinel↔ramsdellite transformation is accompanied by a lower entropy gain than the normal spinel↔ramsdellite transformation. The entropy of the inverse-spinel↔ramsdellite transformation can be roughly approximated as follows:

$LiTiMO_4$ (normal spinel) ↔ $LiTiMO_4$ (ramsdellite)
$\Delta S \approx 0.02\ kJ\,mol^{-1}\,K^{-1}$

$LiTiMO_4$ (normal spinel) ↔ $[Li_{0.5}M_{0.5}]_t[TiM_{0.5}Li_{0.5}]_oO_4$ (inverse spinel)
$\Delta S \approx 0.015\ kJ\,mol^{-1}\,K^{-1}$[27]

$[Li_{0.5}M_{0.5}]_t[TiM_{0.5}Li_{0.5}]_oO_4$ (inverse spinel) ↔ $LiTiMO_4$ (ramsdellite)
$\Delta S \approx 0.005\ kJ\,mol^{-1}\,K^{-1}$

The estimated entropy variation of the inverse spinel–ramsdellite transformation is 0.005 $kJ\,mol^{-1}\,K^{-1}$, while the calculated enthalpy for the Fe system is 36.5 $kJ\,mol^{-1}$ (Figure 3). With these data, the transformation would occur at about 7000 °C, which is significantly higher than the value of 900 °C estimated for the normal spinel–ramsdellite transformation. These results therefore suggest that the spinel↔ramsdellite transformation is entropically controlled.

The Mn inverse spinel is calculated to be 3 $kJ\,mol^{-1}$ *less* stable than its normal configuration. This apparent disagreement with experiment does not come as a surprise, however, as $Mn^{3+}$ has a large octahedral-site preference and the inverse $Mn^{3+}$ spinels are not enthalpically stabilized. Considering entropic factors, the disorder of cations in the octahedral/tetrahedral sites in the inverse spinels supposes a gain of mixing entropy which, together with the gain of configurational entropy mentioned above, allows to overcome the small energy of 3 $kJ\,mol^{-1}$ at high temperature (DFT refers to zero Kelvin). Therefore the inability of DFT to accurately predict the inversion in Mn spinels is likely rooted in the fact that these spinels are stabilized by entropic factors (configurational and mixing entropy), which cannot be taken into account by first-principles methods. Furthermore, the possibility of valence changes when $Mn^{3+}$ migrates to tetrahedral sites[11,28] also complicates the picture. Concerning the temperature of the $[Li_{0.5}Mn_{0.5}]_t$-$[TiMn_{0.5}Li_{0.5}]_oO_4$ inverse spinel↔ramsdellite transformation, the estimated entropy of 0.005 $kJ\,mol^{-1}\,K^{-1}$ suggests that a temperature of 1327 °C will be needed to produce such a transformation.

As this works aims to prepare novel ramsdellites $LiM^{III}Ti^{IV}O_4$, it is important to determine the oxidation state of M and Ti in the fully relaxed structures of the calculated $LiTiMO_4$ ramsdellites. An approximate oxidation state for Ti and M in the studied compounds can be obtained by integrating the net electron spin density over a radius sphere around each transition metal ion.[11,29] Some of the results are shown in Figure 4 for $LiTi_2O_4$(R) and the substituted ramsdellites with Cr and Mn. The net spin density increases steeply when integrated through the *d*-states of the metal ion up to 1 Å, then a plateau is observed because the charge density of the oxygen ions does not contribute to the spin density. The net spin around Ti ions in $LiTi_2O_4$(R) suggests that the oxidation state of both titanium ions is +3.5, in agreement with the metallic behavior reported previously.[7,30] On the contrary, titanium is present in the substituted ramsdellites $LiTiCrO_4$ and $LiTiMnO_4$ as a diamagnetic tetravalent ion ($Ti^{4+}$), while both Cr and Mn are in the trivalent state, with three ($t_{2g}^3$) and four ($t_{2g}^3\ e_g^1$) unpaired electrons, respectively. Similar results are obtained for the $LiTiVO_4$ and $LiTiFeO_4$ spinels.

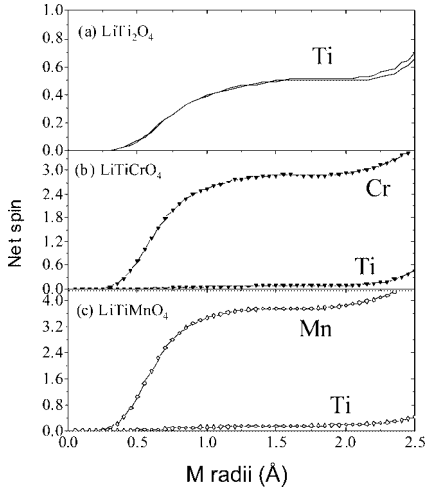

Figure 4. Integral of the net spin density for the calculated $LiTiMO_4$ ramsdellites with M = Ti (a), Cr (b), and Mn (c).

## Experimental Study of the $LiTiMO_4$(S) ↔ $LiTiMO_4$(R) Transformation

The computational data suggest that the normal spinel↔ramsdellite transformation could be achieved at temperatures below 1600 °C, whereas the inverse spinel↔ramsdellite transformation is entropically hindered. We therefore attempted to induce the spinel↔ramsdellite transformation for the $LiTiMO_4$ spinels (M = V, Cr, Mn and Fe) as described in the Methodology section. For comparison purposes we also carried out the transformation of $LiTi_2O_4$.

Transformation of $LiTi_2O_4$ was achieved at 950 °C, in agreement with previously reported results.[9,10] A slightly higher temperature (1050 °C) was required for $LiTiVO_4$ since mixtures of spinel and ramsdellite are obtained at lower temperature. The corresponding X-ray diffraction pattern and Rietveld refinement of the new ramsdellite with composition $LiTiVO_4$ are shown in Figure 5 ($R_{wp}$ = 0.062; $R_p$ = 0.048; $R_B$ = 0.088, $\chi^2$ = 1.38). The cell parameters are given in Table 2. The structural model is that corresponding to $LiTi_2O_4$(R) with Ti and V disordered in the octahedral positions. The light lithium ions could not be located from the X-ray data, therefore they were modeled as occupying

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

the same position as in $LiTi_2O_4$. The lithium parameters were therefore held constant at the start of the refinement, assuming an ideal occupancy of 0.5.

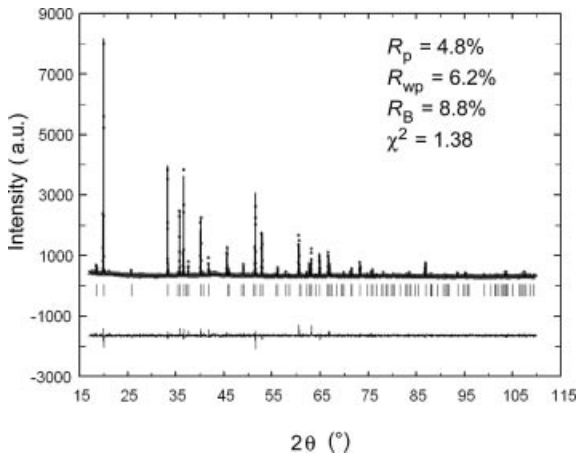

Figure 5. Rietveld refinement plot (experimental, calculated, and difference curve) for ramsdellite $LiTiVO_4$ in the space group *Pbnm* and with $a$ = 5.0090(8), $b$ = 9.5570(1), $c$ = 2.94242(3) Å.

The computational data indicate that the enthalpy of the transformation reaction is lower for V than for Ti. As discussed above, assuming that the entropy change is similar, the transformation temperature should be lower for V than for Ti, which is not what we found experimentally. We note that kinetics may be the origin of this mismatch between estimated and experimental transition temperatures.

The transformation from spinel to ramsdellite for the Cr system occurs over a rather wide temperature range. Transformation begins at around 900 °C but is not complete until about 1250 °C. The evolution of the ratio of each polymorph with temperature was followed by means of high temperature X-ray diffraction. The results are shown in Figure 6. It can be seen that the spinel continuously transforms to ramsdellite following the typical behavior of a two-phase transformation, and a new pure ramsdellite phase is obtained at 1250 °C. The corresponding XRD pattern is similar to that shown in Figure 5 and Rietveld refinement was performed using the same structural model as above ($R_{wp}$ = 0.183; $R_p$ = 0.138; $R_B$ = 0.079, $\chi^2$ = 3.9). The lattice parameters of this new ramsdellite are also given in Table 2. The difference in the temperature needed to obtain $LiTi_2O_4$(R) and $LiTiCrO_4$(R) seems to be related, at least partially, to the larger energy difference calculated between spinel and ramsdellite for $LiTiCrO_4$ in comparison to $LiTi_2O_4$ (see above).

A quite different behavior was found for the Mn and Fe cases. Treatment at temperatures ranging from 925 to 1400 °C produced either no transformation or mixtures of several phases without any evidence of a ramsdellite phase. It therefore seems that the high-temperature polymorph cannot be stabilized for these two cases. This is obviously expected from the computational results, which indicate that the inverse spinel↔ramsdellite transformation is entropically hindered.

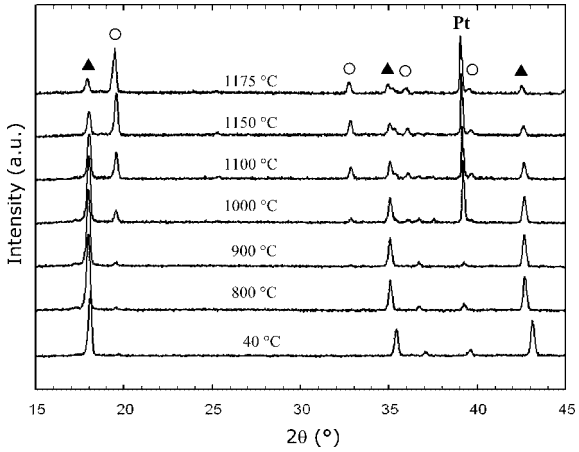

Figure 6. Temperature-resolved in situ X-ray diagrams of the spinel to ramsdellite transition of $LiTiCrO_4$ between 40 and 1175 °C. ▲ spinel reflections, ○ ramsdellite reflections.

We will now consider the possible mechanism for the spinel–ramsdellite transformation. A mechanism for this transformation can be proposed based on the model proposed by Thackeray and co-workers for the process occurring in ramsdellite-like γ-$MnO_2$.[31,32] A schematic representation is depicted in Figure 7 and can be described in two stages, as follows. The spinel structure initially responds (Figure 7, a) with a cooperative displacement of one quarter of the titanium ions (see arrows on filled octahedra) and half of the lithium ions (see arrows on filled circles). Displacement of the metals is followed by a shear operation of the spinel blocks perpendicular to the (111) spinel direction (dashed arrows in Figure 7, a). A second shear operation in the same direction (dashed arrows in Figure 7, b) produces the hexagonal packed $(Ti_2)O_4$ framework of $LiTi_2O_4$(R) that is shown in Figure 7 (c). It is evident that a relatively high energy is needed to displace the titanium ions from the octahedral sites of the spinel structure to interstitial octahedral sites. The use of high temperatures assists the diffusion of the titanium and lithium cations and rearrangement of the oxygen ions from cubic close packing in the spinel structure to hexagonal packing in the ramsdellite structure. This structural transformation does not, in principle, affect either the tetrahedral coordination of Li or the octahedral coordination of Ti, but it does affect the structural connection between the polyhedra. Thus, while Li ions in the spinel structure are located in the vicinity of titanium ions in vertex-shared octahedra, in the ramsdellite structure the Li ions are located in the vicinity of titanium ions that reside in neighboring face-sharing octahedra. This produces an increase in the electrostatic interaction between face-sharing Li and Ti polyhedra, which means that the phase transformation should be favored for spinels with a normal cationic distribution (the normal spinel structure), whereas an inversion of the cationic distribution, especially of highly charged transition metals in the tetrahedral sites, will destabilize the ramsdellite structure due to electrostatic repulsion

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

between metal ions in face-sharing polyhedra. Thus, kinetic factors might also hinder the inverse spinel↔ramsdellite transformation.

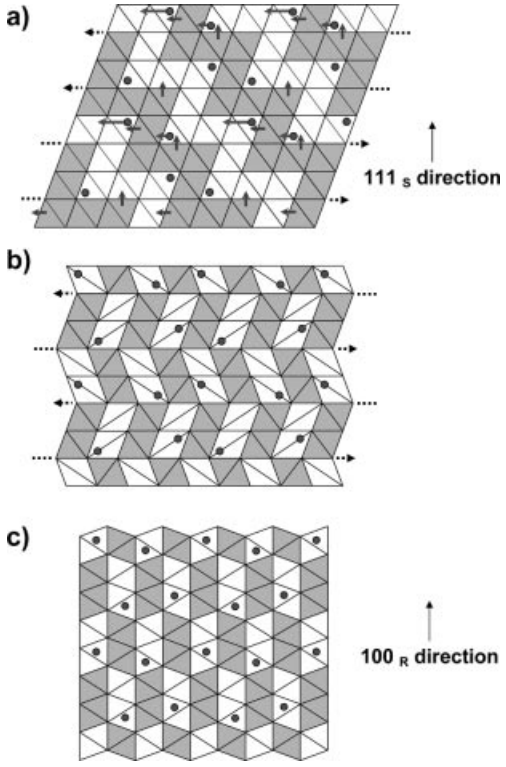

Figure 7. Proposed schematic representation for the spinel $LiTiMO_4$ to ramsdellite $LiTiMO_4$ transformation based on refs.[31,32] Filled octahedra: $(M,Ti)O_6$; small circles: $Li^+$ ions.

In agreement with this $LiTi_2O_4$(S) and $LiTiVO_4$(S),[19] which are normal spinels, transform readily into the corresponding ramsdellites. $LiTiCrO_4$(S) has been reported by several authors to adopt a normal spinel structure (space group *Fd3m*) with all Li ions at the (tetrahedral) 8a site and a random distribution of Ti and Cr over the (octahedral) 16d site, corresponding to the formulation $[Li]_t[Ti,Cr]_oO_4$,[20,33–36] although a slight inversion (12%) in cationic site distribution regarding Li and Ti has been found by neutron diffraction experiments.[15] This, in addition to the higher enthalpy calculated for the transformation, would account for a more hindered phase transition and mean that the full transformation requires a much higher temperature than in the case of Ti or V. The situation is different for Mn and Fe, however, which present an important degree of inversion, with the proposed cationic distributions being $[Li_{0.66}Ti_{0.34}]_{8a}[Li_{0.34}MnTi_{0.66}]_{16d}O_4$[16,18] and $[Li_{0.47}Fe_{0.53}]_{8a}[Li_{0.53}Fe_{0.47}Ti]_{16d}$.[17,22] We have already discussed that the spinel↔ramsdellite transformation is entropically controlled therefore, in view of the proposed mechanism, the phase transition for the Mn and Fe systems will also be impeded due to enhanced electrostatic repulsions between higher valent cations in neighboring face-sharing polyhedra. The transformation into ramsdellite in these cases must therefore be linked to a more reconstructive mechanism in which all lithium ions would remain in the tetrahedral position and all higher valent transition metals would occupy the octahedral position.

### Electrochemistry of the Novel $LiTiVO_4$ and $LiTiCrO_4$ Ramsdellites

The electrochemical behavior of $LiTiVO_4$(R) and $LiTiCrO_4$(R) can be fully interpreted assuming the replacement of $Ti^{3+}$ in $LiTi_2O_4$ by $V^{3+}$ and $Cr^{3+}$, respectively. Such a hypothesis is in good agreement with the computational results, and has been confirmed by magnetic susceptibility measurements, as reported elsewhere.[13,14,30]

As expected, no significant differences were found for the three ramsdellites $LiTiMO_4$ (M = Ti, V, and Cr) regarding intercalation of lithium (reduction). The same voltage profile is observed down to 1 V, with the plateau characteristic of reduction of $Ti^{4+}$ to $Ti^{3+}$ at about 1.4 V (see part a in Figure 2, continuous line). This result can be explained in terms of the occurrence of the same reaction in all three cases, namely

$$LiTi^{4+}M^{3+}O_4(R) + xLi \rightarrow Li_{1+x}\ Ti^{4+}{}_{1-x}Ti^{3+}{}_x\ M^{3+}{}_xO_4(R);\ x < 1 \quad (5)$$

Figure 8 shows the first charge of a Li//$LiTiMO_4$(R) cell for M = Ti, V, and Cr. Any differences in polarization and quantity of lithium extracted are mainly due to the different electrical conductivity that is expected for the different ramsdellites. The oxidative reaction can be written as

$$LiTi^{4+}M^{3+}O_4(R) \rightarrow Li_{1-x}Ti^{4+}M^{3+}{}_{1-x}M^{4+}{}_xO_4(R) + xLi;\ x < 1 \quad (6)$$

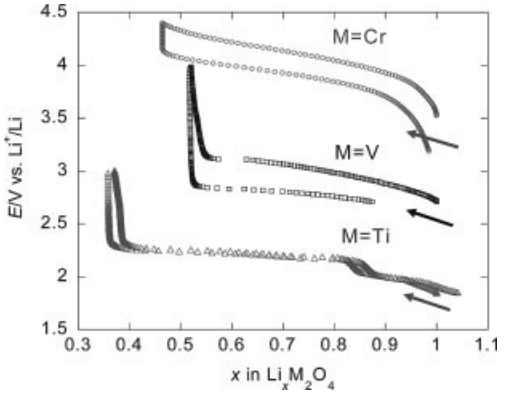

Figure 8. Typical voltage composition plot obtained from galvanostatic experiments (0.1 $mA\,cm^{-2}$) on cells $LiTiMO_4$//Li. Data were recorded by starting the cells first on oxidation followed by reduction down to the initial open circuit voltage.

For M = Ti this process occurs at an average voltage of 1.9 V, as reported previously.[4,5,8] When $Ti^{3+}$ is replaced by $V^{3+}$ the average oxidation voltage increases to 3.1 V, which is characteristic of $V^{III}$ oxidation. The oxidation voltage for $LiTiCrO_4$(R) is shifted to an average voltage of 4.2 V, which is in agreement with the value observed for the $Cr^{4+}/Cr^{3+}$ redox couple in related systems.[37,38] Since the average oxidative voltage of $LiTi_2O_4$ has increased by more than 1 and 2 V for $LiTiVO_4$ and $LiTiCrO_4$, respectively, the electro-

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

chemical performance of a lithium cell made from either $LiTiVO_4$(R) or $LiTiCrO_4$(R) as the positive electrode is much better. The maximum quantity of lithium that can be de-intercalated is expected to be constant as it is limited by the content of lithium and $M^{3+}$ (one ion per formula unit), therefore the maximum theoretical capacity of $LiTiVO_4$(R) or $LiTiCrO_4$(R) is around 160 $mAh\,g^{-1}$, as in $LiTi_2O_4$. However, the higher oxidation voltage of $LiTiVO_4$ and $LiTiCrO_4$ results in a significant increase of the specific energy delivered by the electrode material of 50% and 100%, respectively.

To sum up the electrochemical performance, it is interesting to note that the new ramsdellites described herein present two different processes at very different voltages that correspond to the oxidation of $V^{3+}$ and $Cr^{3+}$ at high voltage and the reduction of $Ti^{4+}$ at low voltage. The application of these materials in lithium batteries as high voltage cathodes might make use of the former process, while if a low voltage anode material is desired the low voltage process could be used. More detailed studies on performances, mainly regarding cyclability, will be published elsewhere,[13,14] while the influence of the $Ti^{3+}/M^{3+}$ ratio on performance is now under investigation.

## Conclusions

As part of our search for novel materials with potential interest as electrodes in lithium batteries, we have reported the preparation of novel $LiTiMO_4$ ramsdellites by inducing a temperature-driven transformation in the corresponding spinel-like forms and have combined computational and experimental techniques to study this $LiTiMO_4$ (spinel) ↔ $LiTiMO_4$ (ramsdellite) transformation.

The computational study performed on the compounds $LiTiMO_4$ (M = Ti, V, Cr, Mn, and Fe) indicates that the spinel form is enthalpically more stable than the corresponding ramsdellite. However, in agreement with the order of the total energy differences (below 40 $kJ\,mol^{-1}$ per formula unit), the spinels can be transformed into their corresponding ramsdellites by thermal treatment. While it is possible to compute the enthalpy of the transformation, it is impossible to predict the temperature at which it will occur. The reasons for these limitations are: (i) first-principle methods refer to zero Kelvin, (ii) calculations are performed for perfectly ordered structures while, experimentally, M and Ti ions randomly occupy the octahedral sites of the ramsdellite/spinel structure. Hence no information about the entropy that accompanies the transformation can be obtained from first principles. The entropy of the transformation has been approximated here from values of temperatures and entropies available in the literature. The estimated temperatures for the $LiTiMO_4$(S) ↔ $LiTiMO_4$(R) transformation are lower than 1600 °C for all the metals studied, hence this transformation is feasible from a thermodynamic point of view. Since the experimental findings showed that the transition metal ions can move to the tetrahedral sites, in a second step we have estimated the temperature of the $LiTiMO_4$(inverse spinel) ↔ $LiTiMO_4$(R) transformation. Our data support that this transformation is entropically hindered.

Experimental results have shown that thermal treatment of spinels $LiTiMO_4$ induces a phase transformation to the ramsdellite-like polymorph for M = Ti, V, and Cr. Indeed, the new ramsdellites $LiTiMO_4$ (M = V and Cr) have been isolated and characterized. Such a transformation could not be detected in the explored temperature range ($T \leq$ 1400 °C) for Fe- and Mn-containing spinels. Therefore the experimental results corroborate that the degree of inversion of the spinel has an influence on the transformation: the transformation only occurs if the starting spinel has a normal cationic distribution while it does not for the inverse spinel. The former situation is found for M = Ti and V, and even for Cr with only a slight degree of inversion, whereas the second situation is found for M = Mn and Fe. We have proposed a mechanism for the transformation in which strong cationic repulsions exist along the transformation pathway in the case of inverse spinels. Thus, in light of the experimental and computational results we can conclude that the impossibility of transforming the Mn and Fe inverse-spinel into their ramsdellite forms is due to at least two reasons, firstly that the transformation is entropically hindered and secondly that there are kinetic limitations due the high energetic barriers that should be overcome during the transformation. At present we cannot say whether the entropy or the kinetic impediment is the main limiting factor of this transformation.

The substituted $LiTiMO_4$ (M = Ti, V and Cr) compounds contain $Ti^{4+}$ and $M^{3+}$, both of which are ions that are electrochemically active in a lithium cell on reduction ($Ti^{4+}/Ti^{3+}$ couple) or oxidation ($M^{3+}/M^{4+}$ couple). In all the prepared $LiTiMO_4$ ramsdellites the reduction of $Ti^{4+}$ occurs at a similar voltage (1.4 V vs. lithium electrode) and develops the same capacity (160 $Ah\,kg^{-1}$). On the other hand, the measured oxidation potentials of the $M^{3+}$ ions in $LiTiMO_4$ range from around 2 V for $LiTi_2O_4$, to about 3 V for $LiTiVO_4$ and 4 V for $LiTiCrO_4$, with the two latter cases being particularly interesting. The high voltage observed when $LiTiMO_4$(R) (M = V, Cr) are oxidized may allow further development of new high-energy positive-electrode materials for rechargeable lithium batteries.

Taking into account the promising electrochemical performances of $LiTiMO_4$(R), the possible relationship between the transformation of the spinels and the inversion factor may be considered as a guide in the search for new electrode materials for rechargeable lithium batteries based on the ramsdellite structure.

## Methodology

### Computational

The total energy of $LiTiMO_4$ (M = Ti, V, Cr, Mn and Fe) was calculated using the Vienna ab initio Simulation Package (VASP).[39] The exchange-correlation energy was approximated in the generalized gradient approximation (GGA), using ultra-soft

 © 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim 

pseudopotentials. A plane-wave basis set with a kinetic energy cutoff of 500 eV was used. The reciprocal space sampling was done with *k*-point grids of $4\times4\times4$. Relaxation was allowed and the final energies of the optimized geometries were recalculated so as to correct for changes in basis during relaxation. All the calculations are spin-polarized. Calculations were initialized considering a ferromagnetic ordering of ions for normal spinels $Li(TiM)_oO_4$ and ramsdellites. In the case of inverse spinels $[Li_{0.5}M_{0.5}]_t$-$[TiM_{0.5}Li_{0.5}]_oO_4$ antiferromagnetic interactions between ions in the tetrahedral and octahedral sites were considered.

**Experimental**

The synthesis of ramsdellite $LiTiMO_4$ (M = Ti, V, Cr, Mn, and Fe) was attempted by heating the corresponding spinel-like compounds in the hope of achieving the polymorphic transformation. Different temperatures above 900 °C were used until either full transformation to ramsdellite or decomposition of the corresponding spinel was detected. The spinels were prepared by a ceramic procedure. Thus, in order to minimize loss of lithium oxide, a mixture of $Li_2CO_3$ and $TiO_2$ in a 1:1 ratio was fired at 700 °C for 24 h to produce $Li_2TiO_3$. The carbonate-free product was mixed with stoichiometric amounts of $TiO_2$ and $M_2O_3$ (M = Cr, Mn, or Fe) and heated at different temperatures. For M = Ti and V, handling and mixing of the air-sensitive reagents $V_2O_3$ and $Ti_2O_3$ was done under argon in a dry glove box (water content < 1 ppm). Mixtures were pressed, wrapped in copper foil, and placed into a quartz ampoule, which was vacuum-sealed and fired. In all cases a typical treatment consisted of heating for 24 h followed by quenching to room temperature.

A preliminary structural characterization was made by means of powder X-ray diffraction with a Bruker D8 high-resolution X-ray powder diffractometer using monochromatic Cu-$K_{\alpha1}$ ($\lambda$ = 1.5406 Å) radiation produced with a germanium primary monochromator. The diffractometer was equipped with an MBraun PSD-50M position sensitive detector (PSD). For the case of samples containing either trivalent V or Ti the XRD patterns were collected in transmission mode using glass capillaries of 0.5-mm diameter, which were filled inside a glove box. Diffraction patterns were analyzed using the FullProf program.[40] X-ray diffraction experiments at high temperature were performed in the case of $LiTiCrO_4$ with a Siemens D5000 diffractometer working in reflection mode (Cu-$K_{\alpha1}$ radiation) equipped with a Bühler HDKS1 high-temperature chamber. Diffraction patterns at temperatures ranging from 800 to 1200 °C were collected in a selected $2\theta$ range (15–45°).

Electrochemical experiments were performed in Swagelok cells with the following configuration: Li|$LiPF_6$ (1 M) in EC (ethylene carbonate) + DMC (dimethyl carbonate) (2:1) host material + carbon black + binder. Positive electrodes were fabricated as pellets 8 mm in diameter from a mixture consisting of 75–85% (w/w) $LiTiMO_4$ (M = Ti, Cr, V), 20–10% (w/w) carbon black, and 5% (w/w) Kynarflex® (kindly provided by Elf-Atochem). A disk of lithium metal was used as the negative and reference electrode. Commercial Selectipur LP31® (Merck) electrolyte solution for lithium batteries was used. Cells were cycled under galvanostatic conditions at a current density of 0.1 $mA\,cm^{-2}$.

# Alternative Synthesis, Density Functional Calculations and Proton Reactivity Study of a Trinuclear [NiFe] Hydrogenase Model Compound

**Frank Lauderbach,[a] Raju Prakash,*[a][‡] Andreas W. Götz,*[b][‡‡] Marcela Munoz,[b] Frank W. Heinemann,[a] Ulrich Nickel,[b] Bernd A. Hess,[c][†] and Dieter Sellmann[a][†]**

**Keywords:** Constant potential coulometry / Density functional calculations / Iron / Nickel / NiFe hydrogenases / S ligands

The trinuclear complex [('$S_2$')\{Ni($PMe_3$)\}$_2$Fe(CO)('$S_2$')$_2$] (**1**) {'$S_2$'$^{2-}$ = 1,2-benzenedithiolate(2–)} has been reported as a structural as well as functional model for [NiFe] hydrogenases since it contains key structural features of the [NiFe] hydrogenase active site, and is oxidized by protons to give [**1**]$^+$ and $H_2$. Complex **1** formed as an unexpected product from the reaction of [Fe(CO)$_2$('$S_3$')]$_2$ {'$S_3$'$^{2-}$ = bis(2-mercaptophenyl) sulfide(2–)} and [Ni($PMe_3$)$_2$('$S_2$')]. Both the iron and nickel centers of **1** are chelated by '$S_2$' donors, but not with any '$S_3$' ligand. In order to understand this reaction, the new precursor [Fe(CO)$_2$($^{si}S_3$)]$_2$ (**2**) {$^{si}S_3^{2-}$ = bis(2-mercapto-3-trimethylsilylphenyl) sulfide(2–)} was synthesized. Compound **2** readily loses its CO ligand to give [Fe(CO)($^{si}S_3$)]$_2$ (**3**), which consists of two 16 valence electron fragments and could be isolated in the solid state. Conversion of **3** to **2** is feasible with gentle bubbling of CO gas for about 2 min. Treatment of **2** with [Ni($PMe_3$)$_2$('$S_2$')] resulted exclusively in the formation of complex **1**, which confirms that all three '$S_2$' ligands in **1** originate from [Ni($PMe_3$)$_2$('$S_2$')]. Therefore, an alternative synthesis of **1**, which does not involve any '$S_3$' ligand, has been developed. Density functional theory (DFT) calculations suggest that the oxidation states of the metal centers are $Fe^{II}$ and $Ni^{II}$ and do not change upon oxidation of **1** to [**1**]$^+$. The unpaired electron in [**1**]$^+$ is located to a large extent on the nickel atoms and the adjacent thiolate donor functions. The charge, however, is distributed over the whole cluster, main parts residing on the '$S_2$' ligands. Preliminary constant potential coulometric measurements indicate that **1** mediates the reduction of protons to dihydrogen at a mild potential (–0.48 V vs. NHE). Based upon these experimental and theoretical results, plausible mechanisms for this reduction are briefly discussed.

## Introduction

Hydrogenases comprise a fundamental group of bacterial enzymes that catalyze the reversible interconversion of protons and molecular hydrogen. Thus, they play a key role in molecular bioenergetics.[1] In recent years, interest in hydrogenases has intensified due to their environmental and industrial potential in the context of the development of a pollution-free and sustainable hydrogen economy.[2] Hydrogenases can be divided into two main groups based on the type of metal containing active sites, namely, [NiFe][3] and [Fe]-only[4] hydrogenases. [NiFe] hydrogenases represent the major class among hydrogenases, consisting of a dinuclear nickel–iron active site (Figure 1).

Numerous spectroscopic,[5] structural,[3,6] and theoretical[7] studies on various enzymes have provided further insight into the structure and function of the active sites of [NiFe] hydrogenases. Despite these efforts, the exact nature of the catalytic cycle and the exact oxidation state of nickel during the catalytic cycle remain uncertain. This has prompted the synthesis of a number of low-molecular weight di- and oligonuclear heterometallic complex analogues to the active site of the [NiFe] enzymes.[8,9] Studies on such compounds can lead to a better understanding of the properties of the active site and can shed light on the catalytic reaction that takes place in the enzyme. The advantage of such models is that they are low-molecular

weight compounds and therefore are often more easily isolated and examined by various physicochemical methods than the macromolecular enzyme itself. In addition, electronic and steric modifications can be generated by adjusting the ligand environment.

Recently, two [NiFe] model complexes $[Fe(CO)_2(CN)_2(\mu\text{-}SCH_2CH_2CH_2S)Ni(S_2CNR_2)]$ [R = Et and -$(CH_2)_5$-] were synthesized which up to now resemble the structural features of hydrogenases most closely.[10] However, in practice, none of the reported sulfur-bridged [NiFe] model complexes shows any hydrogenase-like reactivity.

We have previously reported on the sulfur-bridged trinuclear complex [('$S_2$')\{$Ni(PMe_3)$\}$_2$Fe(CO)('$S_2$')$_2$] (**1**) {'$S_2$'$^{2-}$ = 1,2-benzenedithiolate(2–)}, which stoichiometrically reduces protons to dihydrogen and in turn gets oxidized to [('$S_2$')\{$Ni(PMe_3)$\}$_2$Fe(CO)('$S_2$')$_2$]$^+$ ([**1**]$^+$).[11] The reversible conversion of **1**/[**1**]$^+$ was also achieved with ferrocenium salt and $NBu_4BH_4$, respectively. Moreover, the structural parameters (bond lengths and angles) of **1** and [**1**]$^+$ are nearly identical. This structural rigidity during the redox reaction indicates a low reorganization barrier and therefore favors a rapid electron transfer.[12] This result is insofar highly interesting as many oxidoreductases undergo redox reactions which are accompanied only by marginal structural changes. These intriguing facts inspired us to investigate the properties of **1** in greater detail. Herein, we describe the exact formation pathway and a novel straightforward synthetic route of **1**. Density functional Theory (DFT) calculations reveal important insights into the oxidation reaction of **1** to [**1**]$^+$. In addition, we report preliminary coulometric studies which employed **1** as an electrocatalyst for the reduction of protons to dihydrogen at a low reduction potential.
